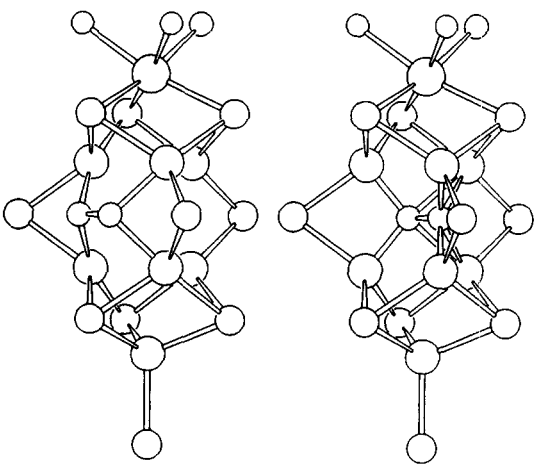
functional theory. The calculations by Dance were performed on an FeFe-model other than the FeMoco. Machado and Davidson [19] investigated *ab initio* results of dinitrogen side-on and end-on coordination to one, two and four iron centers of some iron–sulfur cofactor models. Although the above calculations have provided valuable ideas about this complex problem of dinitrogen binding, there are some details which need to be investigated in much more comprehensive ways. First, models used in calculations must well characterize the FeMoco. The replacement of the residues on the Mo atom and the anchor Fe atom by simple groups such as H atoms would have a large effect on results, as pointed out by Stavrev and Zerner [20] based on the INDO calculations of oxidized rubredoxin. Secondly, dinitrogen binding would be considered as a moving process of dinitrogen approaching to the FeMoco while some geometrical changes may occur, such as the fluctuation of the skeleton of the FeMoco and the flapping of the bridging sulfur atoms. During the process, many intermediates of the complex of dinitrogen with the FeMoco can be generated as the possible dinitrogen binding mode. A rational binding model must be selected from these intermediates by comparison of some factors such as the net charge on dinitrogen, the N—N bond order and the barrier for forming the complex of dinitrogen with the FeMoco. In addition, the geometric space maintained for the entry of protons and the exit of ammonia also is an important factor.

In this paper, quantum chemical calculations are performed on the processes of dinitrogen approaching in several manners to the FeMoco. The results will suggest an alternative dinitrogen binding mode. The mechanism for the protonation of dinitrogen also is discussed based upon the selected binding mode.

GEOMETRICAL CONSIDERATION AND CALCULATIONAL DETAILS

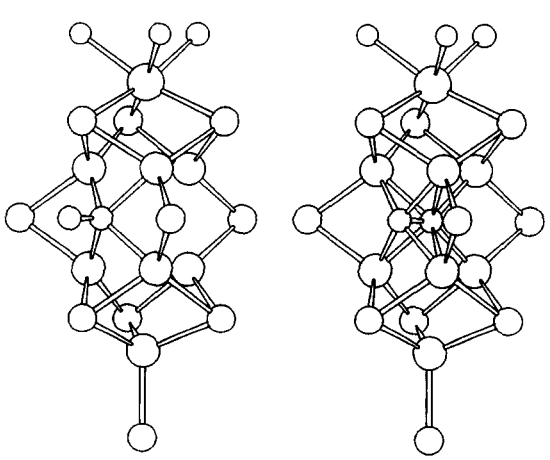
The model for the FeMoco used in our calculations is chosen as **1** of stoichiometry $[MoFe_7S_9(:N(CH)_2NHCH)(—OCH_2COO—)(—SCH_3)]$, which involves all ligand groups directly ligating to the metal atoms. These terminal ligand groups are coordinately saturated by hydrogen atoms, after removing the outer residues. The terminal ligands on the Mo atom are chosen by replacement of homocitrate with a simple group (—OCH_2COO—) and by replacement of the imidazole of His-442 with a simple imidazole (:$N(CH)_2NHCH$), the later providing two electrons to bond to Mo. The ligand on the anchor Fe atom is SCH_3. This calculation model guarantees that the metal–ligand bonding of the FeMoco keeps unchanged. In addition, the 193 valence electrons of this model, may fit in with the $S = 3/2$ spin state [21, 22] of the isolated FeMoco in its semireduced (or the "native") state. The interatomic distances are chosen according to Table 1 to be: 2.65 Å (Fe—Fe), 2.70 Å (Fe—Mo), 2.30 Å (Fe—S), 2.40 Å (Mo—S), 2.20 Å (Mo—O), and 2.20 Å (Mo—N). For dinitrogen, the N—N bond length is chosen to be 1.1 Å. Besides, the Fe—N distances thought to present direct interaction between Fe and N are chosen to be 1.9 Å to 2.0 Å, values being close to the sum of the valence radii of Fe and N.

1



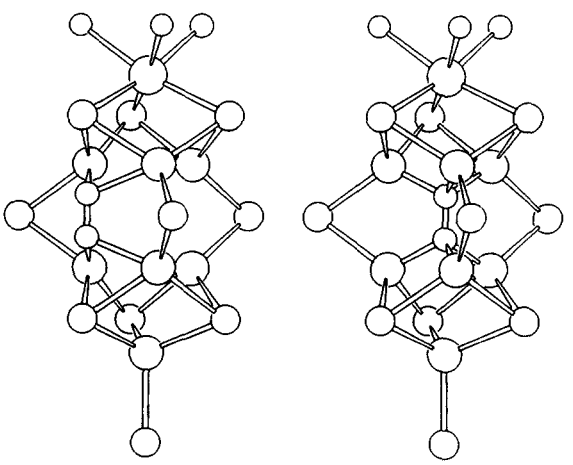
Up to now, there is no direct experimental evidence to indicate where the active sites are. If molybdenum is at the active site, the structure for the FeMoco does not yet help us define its function [23]. In addition, mono-atom site hardly provides effective activation according to our preliminary calculations as well as the reported calculated results [15]. On the other hand, the suggestion of the iron sites [24] was reformulated based upon firmer chemical evidence [25,26]. The multicentric binding fashion provided by the Fe_6 prism can transfer more charge to dinitrogen and effectively activate it. Therefore, it focus our attention on the Fe_6 prism which center (or the cavity), three Fe_4 surfaces (or the windows), and one Fe_2 gap caused by release of one bridging sulfur atom, can serve as active sites. The possible binding modes contain three types: the center-site modes (**3, 5, 7, 8, 9, 10, 11, 12, 14** and **16**), the face-site modes (**2, 4,** and **6**) and the bridge-site modes (**13** and **14**).

Dinitrogen can utilize the end-on or/and side-on fashions to bind to these active sites. It is certainly possible that a variety of different binding modes are utilized by the intermediates generated during dinitrogen moving toward the FeMoco. To describe the moving of dinitrogen, we define a coordinate frame (see **1**, the dotted lines) with the origin located at the geometrical center of the FeMoco, the z axis pointing to the Mo atom and the x axis pointing to one of the three bridging sulfur atoms. Six schemes expressing the moving of dinitrogen are considered below.



Scheme **I** (**2** → **3**): Along the negative x axis, dinitrogen moves toward the FeMoco. If dinitrogen is in the end-on fashion (or dinitrogen being vertical to the Fe_4 square surface), the first nitrogen atom begins to interact with the four atoms while the second nitrogen atom does not direct interaction with the FeMoco. This results in mode **2**. The 3.8 Å distance between two diagonal Fe atoms of the Fe_4 window is large enough to allow the inserting of dinitrogen in the end-on fashion. When the first nitrogen enters the cavity and goes near the geometrical center, the second nitrogen atom still stays out of the Fe_4 surface. We have mode **3**, where four Fe—N distances correlative to the outer nitrogen atom are about 1.9 Å and the six ones correlative to the centric nitrogen atom are about 2.0 Å.

Scheme **II** (**4** → **5**): Along the negative x axis, dinitrogen moves in a horizontal side-on fashion (or the bond axis of dinitrogen being parallel to the Fe_4 face but orthogonal with the z axis). As each nitrogen atom begins to interact with two of the four iron atoms, we obtain mode **4**. If dinitrogen can penetrate through the Fe_4 window which is considerably small to the dinitrogen in the side-on fashion, and enter the Fe_6 cavity, we arrive at mode **5**.

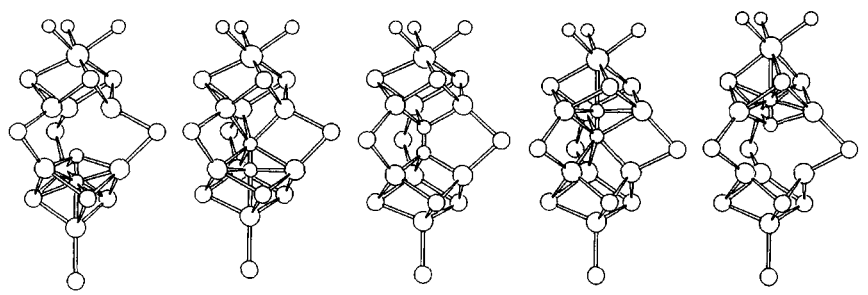


Scheme **III** (**6** → **7**): It is similar to Scheme **II**, but dinitrogen being in a vertical side-on fashion (or the bond axis of dinitrogen being parallel to both the Fe_4 face and the z axis). We have mode **6** and mode **7**.

Scheme II

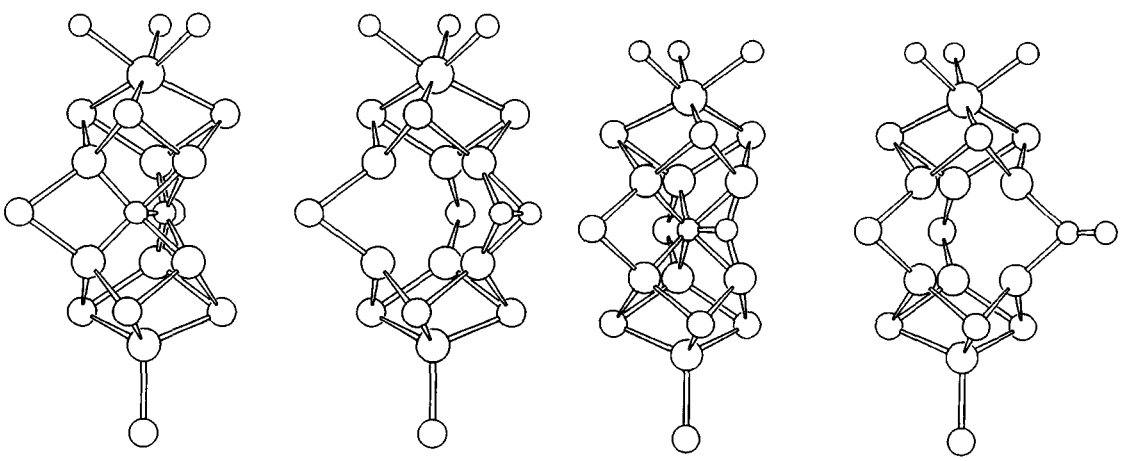
Scheme I

Scheme III



The latter is just the mode proposed by Chan, Kim, and Rees [3]. However, the Fe_6 cavity is too small for dinitrogen binding in mode **7**. The Fe_6 prism must increase its Fe—Fe edges up to 3.0 Å.

Scheme **IV** (**10** ← **9** ← **8** → **11** → **12**): Mode **8** is like mode **7**, but has a larger Fe_6 cavity of 3.0 Å Fe—Fe edges which can satisfy the demand of 2.0 Å Fe—N distances [3,15]. When dinitrogen drops down to and into the Fe_4S_3 cluster, we have two binding modes. One is mode **9** in which the first nitrogen atom is on the Fe_3 trigonal face of the Fe_4S_3 cluster, while the Fe—Fe distances are expanded to 3.4 Å. Another one is mode **10** in which dinitrogen inserts its half in the Fe_4S_3 bag while the Fe—Fe distances recover a little to 3.3 Å. Similarly, we have modes **11** and **12** as dinitrogen jumps up to and into the $MoFe_3S_3$ cluster. At each step, other atoms will change their sites according to the interatomic distances described previously.



Scheme **V** (**14** ← **13**): Dinitrogen approaches the FeMoco in a horizontal side-on fashion along the positive x axis (contrary to Scheme **II**), while the bridging sulfur atom has been released to generate a Fe_2 gap which can grasp dinitrogen. When each nitrogen atom has interaction with the two Fe atoms, we have mode **13**, which is just Orme-Johnson's first mode [27] and supported by the EHMO calculations by Deng and Hoffmann [15]. If the Fe_2 gap enlarges enough to swallow dinitrogen, we have mode **14** in which dinitrogen lays in the center of the Fe_6 cavity like in mode **5**.

Scheme **VI** (**16** ← **15**): Along the positive x axis, dinitrogen moves in the end-on fashion to approach the Fe_2 gap. When the first nitrogen atom begins to interact with the two Fe atoms of the Fe_2 gap, we have mode **15**. As dinitrogen enters the cavity, we have mode **16** in which dinitrogen also lays in the center of the cavity.

About 50 configuration points are calculated during each process of dinitrogen moving toward the FeMoco. The calculations are divided into two steps. First, for comparing the possible binding modes involved in the above six schemes, the geometry of the FeMoco keeps unchanged for six schemes. Secondly, for further analysis of binding process, the fluctuation of the FeMoco skeleton and the lengthening of N—N bond are taken into account. Although DFT calculation [17] and *ab initio* calculation [18] have been

Scheme IV

Scheme V

Scheme VI

performed on some individual structures to model the complex of dinitrogen with FeMoco, such a laborious problem as the above described process of dinitrogen moving toward the FeMoco is not easy to calculate at a high level. Therefore we employ the semi-empirical CNDO method [28], by which calculations of a series of continuous geometrical configurations are believable because the energy differences computed from the values in CNDO calculations may be compared directly with the results computed from jobs using other methods [29].

POSSIBLE DINITROGEN BINDING MODES

A rational binding mode should be consistent with the following criteria: (1) a lower barrier of the total energy for forming the complex of dinitrogen with the FeMoco; (2) a negative net charge on dinitrogen; (3) A significant weakening of the triple bond of dinitrogen; (4) enough spacious sites for the entry of the protons and for the exit of the product ammonia.

For each scheme described above for expressing dinitrogen binding, we examine the variations of three important quantities: (1) the N—N bond order, (2) the net charge on dinitrogen, and (3) the relative values of the total energy (in atomic unit, au) of the system consisting of dinitrogen and the FeMoco. The three quantities for each scheme are expressed by three curves in order from the top to the bottom of the left vertical axis in each sub-figure of Fig. 1, where the FeMoco keeps its original electron number and the $S = 3/2$ spin state [23,24]. In Fig. 1, the horizontal axis for sub-figures (a), (b), (c), (e), and (f) is the x axis, but the z axis for sub-figure (d). The vertical dotted lines in each sub-figure indicate where exist explicit Fe—N interaction of about 1.9–2.0 Å Fe—N distance, and correspond to possible binding modes which numbers (Nos.) are also marked on the tops of the dotted lines.

Figure 1(a) expresses Scheme **I**. When dinitrogen stays far away (the left of Fig. 1(a)) from the FeMoco, it almost has no interaction with the FeMoco, and keeps the triple bond (the Wiberg bond order is 3.0) and the zero net charge. When it approaches the Fe Moco and begins to bind to the Fe_4 surface, mode **2** is formed around the point of $x = -1.2$ in the horizontal axis, where dinitrogen has the negative net charge of -0.6 and the N—N bond order of 1.7. When dinitrogen inserts its half in the Fe_6 prism to form mode **3** which is indicated by a dotted line at the point $x = 0$ of the horizontal axis, the negative net charge accumulates to about -1.4 and the N—N bond order further decreases to 1.0. In mode **3**, it is obvious that much charge has been transferred to dinitrogen from the metal centers of the FeMoco, and dinitrogen has already been activated greatly. There is no explicit barrier in the smooth energy curve which shows the possibility of dinitrogen inserting. Orme-Johnson's second dinitrogen binding mode [30] is somewhat like mode **3**. The complete entry of dinitrogen into the cavity in Orme-Johnson's second mode requires a light expansion of the Fe_6 frame. Our calculation on this expansion, shows that it is possible with respect to the total energy. However, this entry does not bring further weakening of the bond order of dinitrogen, and is not helpful to the subsequent process of dinitrogen reduction which is associated to the entry of protons and the exit of ammonia. In mode **3**, one nitrogen atom keeps out of the Fe_4 surface, thus granting large space for the addition of protons. The further calculation of local geometry optimization shows that the N—N bond length in mode **3** can be elongated to near 1.5 Å, it just being the length of N—N single bond.

Figure 1(b) expresses Scheme **II**, by which dinitrogen attaches to the Fe_4 surface in the horizontal side-on fashion. Mode **4** is indicated by the dotted line at about $x = -1.9$ in the horizontal axis, where the correlative N—N bond order is 1.7 and the net charge on dinitrogen is -0.7. When going near the Fe_4 face, dinitrogen will be much activated. Mode **4** is the binding mode suggested by Dance [17]. A higher barrier for the entry of dinitrogen in the side-on fashion, shows the difficulty of the formation of mode **5** in this scheme. In view of the different path, mode **5** may be regarded as a derivative of mode **3** when dinitrogen rotates an angle of 30 and the nitrogen atom in the cavity moves out of another Fe_4 surface. Our further calculation shows that this rotation is not difficult in energy, as long as the N—N bond length is stretched gradually during the rotation.

Figure 1(c) expresses Scheme **III** by which dinitrogen attaches to the Fe_4 surface in the vertical side-on fashion. Mode **6** is indicated by the dotted line at the point $x = -1.9$ of the horizontal axis, in which the net charge on N_2 is -0.7 and the N—N bond order is 1.5. Both mode **6** and mode **4** which are similar, have not made dinitrogen sufficiently activated. Mode **7** is just the binding mode proposed by Chan, Kim and Rees [3], which requires the entry of dinitrogen. However this entry is inhibited by a higher barrier which arises from the restriction of the smaller Fe_4 window to the entry of the dinitrogen in side-on fashion. This binding mode **7** can be expressed better as mode **8** below, which has an enlarged Fe_6 cavity with Fe—Fe distances of 3.0 Å, geometrically allowing the standing of dinitrogen in the center.

Figure 1(d) expresses Scheme **IV** by which dinitrogen in the cavity of the prism is artificially moved down to the Fe_4S_3 cluster to form modes **9** and **10** (the left of Fig. 1(d)), and up to the $MoFe_3S_3$ cluster to form modes **11** and **12** (the right of Fig. 1(d)). Mode **8** (the center of Fig. 1(d)) is preferable to other correlative modes **9**, **10**, **11** and **12**, for it has the smaller N—N bond order of 1.1, larger negative net charge of -1.5, and the lower energy. Here, it must be pointed out that the five modes are generated after the entry of dinitrogen in the vertical side-on fashion into the Fe_6 cavity, which is inhibited by a barrier shown

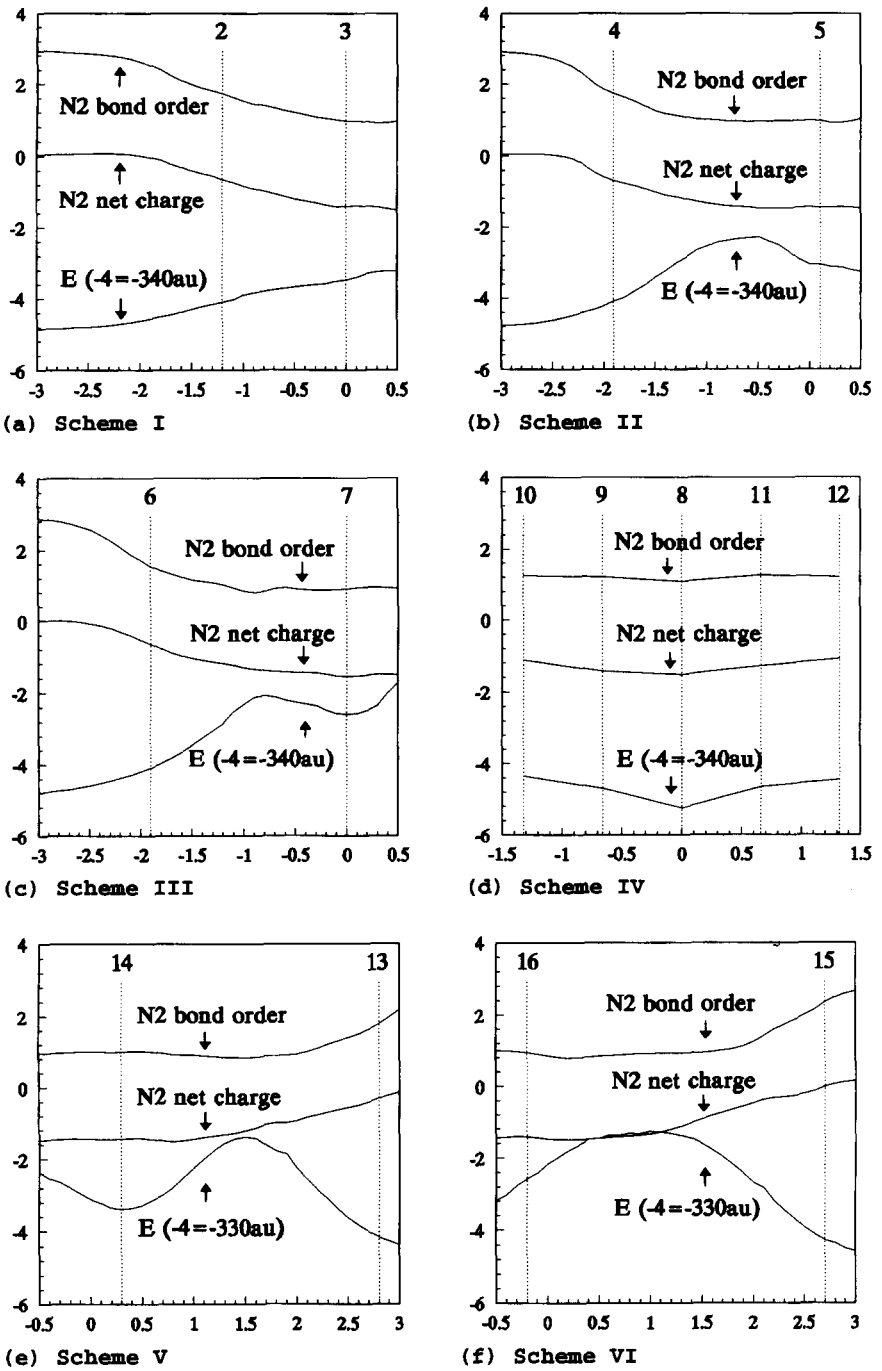


Fig. 1. Variation of the N—N bond order, the net charge on dinitrogen, and the relative value of the total energy (in au), during the process of dinitrogen approaching and binding to the FeMoco according to the six schemes. The dotted lines indicate the positions of possible binding modes.

in Fig. 1(c). In addition, there are not enough spaces in the five modes for the protonation. Therefore, we think that the five modes are not good binding modes.

The fixation of dinitrogen perhaps relates to the release of a bridging sulfur atom. One reason for this suggestion is that the release of the bridging sulfur provides a Fe_2 gap to grasp dinitrogen. Figure 1(e) shows the process (i.e., Scheme V) that dinitrogen in side-on fashion approaches to the gap and enters the cavity. The dotted line at the point $x = 2.8$ of the horizontal axis, expresses mode **13** where the N—N bond order is about 1.8 and the net charge is -0.3. Figure 1(f) expresses a similar process (i.e., Scheme **VI**), in which dinitrogen is in the end-on fashion. The dotted line indicates mode **15,** where the N—N bond order is about 2.4 and the net charge is almost zero.

Both Scheme V and **VI** encounter a high barrier which inhibits the entry of dinitrogen into the cavity. The two central modes **14** and **16** indeed may be regarded the derivatives of modes **5** and **3**, respectively, when losing a bridging sulfur.

In both modes **13** and **15**, the interactions between metal atoms and dinitrogen are not strong. Therefore, the dinitrogen in both mode **13** and mode **15** will be easily replaced by a stronger substrate such as C_2H_4. However, C_2H_4 cannot affect the dinitrogen reduction at the FeMoco site [31]. This evidence suggests that dinitrogen binding prefers a stronger binding mode such as the dinitrogen-inserting mode **3** or the central modes. Therefore, modes **13** and **15** are not good binding modes. Certainly, there are some other possible binding modes, such as that one of dinitrogen bridging over the Fe_2 gap in the vertical side-on fashion. These binding modes including one-metal-center modes, however, cannot sufficiently activate dinitrogen, and are disregarded here.

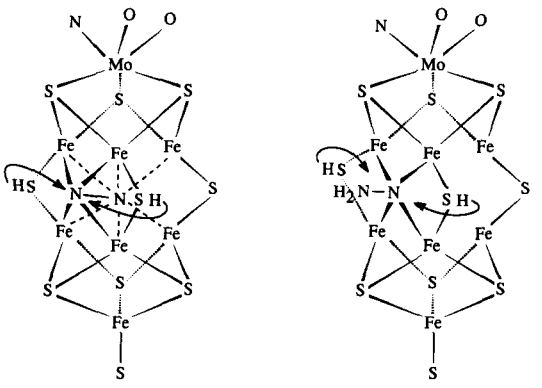
Table 2 lists the calculated results of typical binding modes. It can be seen that the N—N bond orders in mode **3** and the center-site modes **5, 8, 14** and **16,** are smaller than those in face-site modes **4** and **6,** and also smaller than those in bridging-site modes **13** and **15**. However, the barrier for forming each central binding mode is high, but smooth for mode **3**. This means that dinitrogen can insert in or/and enters into the cavity only through the Fe_4 window and only in the end-on fashion. Therefore, we suggest that mode **3** could best express dinitrogen binding. Other central modes such as **5, 14,** and **16** may be regarded as derivatives of mode **3**.

The six schemes expressed in Fig. 1 correlate to the $S = 3/2$ spin state of the semi-reduced FeMoco. However, the characteristic $S = 3/2$ EPR signal will be lost when one electron transferred from the Fe-protein to the MoFe-protein ends up on the FeMoco [24,32]. There are two distinct viewpoints [23] about which state dinitrogen should bind to. One is that N_2 and possibly other substrates can only bind after the MoFe protein has been reduced by more than one electron. The other is that substrates should bind to the $S = 3/2$ state of isolated FeMoco. To check if mode **3** is or not still the preferable binding mode in each state of the FeMoco, we have calculated eight sets of figures each involving six schemes. The eight cases correlate to four redox states, i.e. the original semi-reduced state and its three reduced states by one, two and three electrons, respectively, while each redox state may have two spin states. We make laborious calculations in order to remedy the defect of the CNDO method when treating systems with significant spin problems. There are some differences between the results of calculations of the eight cases. For example, the total energy decreases with the reduction of the FeMoco. However, comprehensive analysis of the four criteria described above for a rational binding mode, still suggests that mode **3** is the best candidate. Furthermore, to investigate the effect of the variation of interatomic distances, we have also performed the same calculation jobs on larger FeMoco skeletons with larger interatomic distances. Although some significant changes are encountered with the total energy, the net charge and the N—N bond order for individual binding mode, mode **3** still is preferable to other modes.

In conclusion, mode **3** is the best dinitrogen binding mode. As a derivative of mode **3,** mode **5** is a possible mode, in which the lengthened N—N bond allows two nitrogen atoms located at sites just out of the centers of two Fe_4 faces respectively. This arrangement of nitrogen atoms retains larger space for protonation. In addition, mode **4** is also possible because the two nitrogen atoms can easily grasp protons transferred by bridging sulfur atoms, as pointed out by Dance [18]. Certainly, the activation of dinitrogen in mode **4** is not sufficient as in modes **3** and **5**.

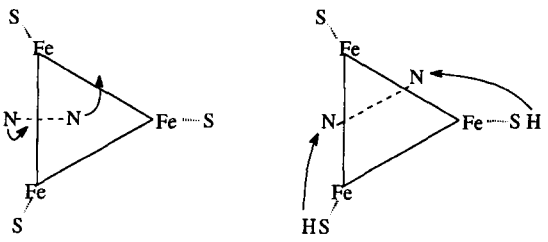
Table 2. The net charge and the Wiberg bond order of dinitrogen binding to the FeMoco in typical binding modes

Mode	Net charge on N_2	N—N bond order
2	−0.6	1.7
3	−1.4	1.0
4	−0.7	1.6
5	−1.4	1.0
6	−0.7	1.5
8	−1.5	1.1
9	−1.4	1.2
10	−1.1	1.3
11	−1.3	1.3
12	−1.1	1.2
13	−0.3	1.8
14	−1.4	1.0
15	0.0	2.4
16	−1.4	1.0



MECHANISM FOR THE PROTONATION OF DINITROGEN

Dinitrogen reduction at the FeMoco site mainly consists of two processes. One is the binding of dinitrogen and the transfer of electrons. The other is the transfer of protons and the release of product NH_3. Certainly, the two processes could be fulfilled in a parallel manner. This suggests that electrons could be transferred both before the transfer of protons and during the protonation of dinitrogen. In the first process, dinitrogen approaches and binds to the FeMoco, meanwhile charge is transferred from the metal centers of the FeMoco to dinitrogen, and dinitrogen is activated with the significant weakening of the N—N bond. Based on the calculations provided in the previous sections, we have determined the best dinitrogen binding mode, i.e., mode **3**. To check the transfer of electrons, let us cut the FeMoco model into



three parts, i.e., the $MoFe_3S_3$ cluster including ligands on Mo atom, three bridging sulfur atoms, and the Fe_4S_3 cluster including the ligand on the anchor Fe atom. The distribution of the charge in mode **3** is, -1.4 on dinitrogen, 1.6 on the $MoFe_3S_3$ cluster, -1.2 on three bridging S atoms and 1.0 on the Fe_4S_3 cluster. This result makes clear the transfer of charge from the metal centers of the FeMoco to dinitrogen. In the second process, protons are transferred from surrounding proteins to dinitrogen, possibly through the bridging sulfur atoms which have hydrogen-bond interaction with surrounding residues. Dance [18] has analyzed the details of proton transfer *via* the wing sulfurs, and proposed a mechanism for the protonation of dinitrogen binding to the Fe_4 face as in mode **4**. Here, we propose two alternative mechanisms for the protonation of dinitrogen at the FeMoco site, based upon the just selected dinitrogen binding mode **3**.

One mechanism for the protonation of dinitrogen is shown in Scheme **VII** which contains two steps. The first step (see **17**) is the transfer of protons from the bridging sulfur atoms to the nitrogen atom exposed out of the Fe_4 surface. Then the nitrogen atom which has caught two protons, will try to go away from the Fe_4 face both for weakening of N—Fe interactions by formation of N—H bonds and for the tension of the bent hydrogen bond N—H···S. Sequentially, the moving of the outer nitrogen atom could bring the inner nitrogen atom to exit the 4Fe window, because there still exists a weak interaction between two nitrogen atoms although the adding of two protons has further decreased the N—N bond order (but the N—N bond order still keeps a smaller value near 0.7). Thus, this process reaches an intermediate state (see mode **18**), in which H_2N—N is in the end-on fashion to binding the Fe_4 face. The bridging sulfur atoms which have just passed two protons to the outer nitrogen atom, will flap toward the surrounding residue (e.g. Arg-96 according to Ree's structure [1–3,18] to grasp other protons, and continuously transfer them to nitrogen atoms. The second step of the protonation of dinitrogen, is the adding of other protons to H_2N—N, probably in two ways. One way is from [H_2N—N : (Fe_4 face)] to [H_3N+HN : (Fe_4 face)] and finally to [$2NH_3$ + FeMoco]. Another way is from [H_2N—N : (Fe_4 face)] to [H_2N—H_2N···(Fe_4 face)] and finally to [$2NH_3$ + FeMoco]. It can be noted that in the second way the intermediate H_2NNH_2 could release. However, H_2NNH_2 has not been experimentally observed in nitrogenase yet. Therefore, the first way seems more plausible.

Another possible mechanism for the protonation of dinitrogen is shown in Scheme **VIII**. As previously discussed, mode **5** can be derived from mode **3** when dinitrogen rotates an angle of about 30°. This transformation is shown as **19** which is the bird's-eye view of the FeMoco in mode **3**, but only keeping the top Fe_3 triangle and three bridging sulfurs for the sake of clarity. This rotation is feasible in energy when the

Scheme VII

Scheme VIII

N—N bond length slightly increases. After this rotation, each nitrogen atom is located almost at the center of a Fe_4 face, see **20**. Then the bridging sulfurs repeatedly transfer protons to dinitrogen until two NH_3 form and release.

(Received 20 March 1996; accepted 18 June 1996)

Abstract—The solubility studies in the $Al(OR)_3$-$M(OR)_4 \cdot ROH$-ROH (R = Pr^i) systems at 20°C revealed the existence of the only complex, $Al_2M(OR)_{10}$, [M = Hf(**I**), Zr(**II**)]. The literature data on the existence of the $AlM(OR)_7$ species were disproved. According to the results of the single crystal X-ray diffraction study of **I**, its molecule has a two-fold symmetry axis and involves two peripheral tetrahedrally coordinated Al atoms, each of their coordination tetrahedra sharing one common edge with the coordination octahedron of the central Hf atom, $[(RO)_2Al(\mu\text{-}OR)_2]_2Hf(OR)_2$. The mean planes of almost planar $[AlO_2Hf]$ cycles form the dihedral angle of 82° with each other. Mass-spectra of **I** and **II** show two fragmentation pathways, *viz.*: (1) the elimination of the ether molecule accompanied by the formation of oxo groups, and (2) the $Al(OR)_3$ molecule abstraction producing the $AlM(OR)_6^+$ ions. According to the X-ray powder diffraction data crystals of **I** and **II** are isostructural. The influence of the oligomeric Zr and Hf oxoalkoxides, formed as a result of partial thermolysis of $M(OR)_4 \cdot ROH$, on the processes of formation of complexes with $Al(OR)_3$ has been elucidated. The non-crystalline solid $Al_2Hf(OEt)_{10}$ was isolated from ethanol solution, its mass-spectral fragmentation being analogous to that of **I** and **II**. Copyright © 1996 Elsevier Science Ltd

Keywords: aluminium alkoxozirconates; -hafnates; single-crystal X-ray diffraction; mass-spectral study; physico-chemical analysis.

The alkoxy-derived Al_2O_3 and MO_2 (M = Zr, Hf) based materials find extensive applications in the production of optical, refractory materials and solid electrolytes. The existence of aluminium alkoxozirconates and alkoxohafnates of two compositions, $Al_2M(OR)_{10}$ and $[AlM(OR)_7]_2$ ‡ has been reported in the earlier literature [1–4]. Later on the physico-chemical analysis of the $Al(OR)_3$-$Zr(OR)_4 \cdot ROH$-ROH system led to the conclusion, that in this system only one complex, *viz.*, $AlZr(OR)_7$, actually exists [5].

The present paper reports the results of the studies of composition of aluminium alkoxohafnates and alkoxozirconates by means of physico-chemical analysis, single crystal X-ray diffraction, and mass spectrometry.

EXPERIMENTAL

Drying of ROH (R = Pr^i, Et) was carried out by the prolonged refluxing over crystalline $Al(OPr^i)_3$ or $Ca(OEt)_2$ respectively and subsequent distillation. $Al(OR)_3$ (R = Pr^i, Et) was prepared by reaction of the metal with absolute ROH, complexes $M(OR)_4 \cdot ROH$ (M = Zr, Hf; R = Pr^i) and $Hf(OEt)_4$ were synthesized by anodic oxidation of the metal in the alcohol in the presence of LiCl [6].

Zr and Hf in the presence of Al were determined by complexonometric titration in acidic medium (pH = 1–2) using xylenol orange for indication (the solution colour changed from pink to yellow). The

‡ In this case and further on in the text R = Pr^i.

Al content was calculated from the difference after determination of the sum of all oxides, obtained after calcination of the solutions or solid phases at 800°C.

Synthesis of aluminium alkoxohafnate and -zirconate

Reactions were carried out by 1–2 h refluxing of the mixture of the solutions of crystalline $Al(OR)_3$ and $Hf(OR)_4 \cdot ROH$ in ROH taken in the ratio of 2:1. The concentration of the initial solutions after complete dissolution of the components amounted to 8–10% with respect to the sum of both alkoxides. It is noteworthy that simple cooling of the hot initial solutions containing both alkoxides without the refluxing resulted in the crystallization of the starting material $Hf(OR)_4 \cdot ROH$ solvate. The precipitation of a fine crystalline sample of $Al_2Hf(OR)_{10}$ (**I**) from reaction solutions obtained after partial removal of the solvent (up to the concentration of 40–50%) begins after about 3 days. After complete evaporation of the solvent the yellowish liquids are formed which become solid after standing for about a month. The recrystallization of the fine powder of **I** from the alcohol produced the single crystals suitable for X-ray diffraction study (yield ~50%). Found: Al 6.5; Hf 21.1; C 43.3; H 8.5. Calc. for $Al_2Hf(OR)_{10}$: Al 6.6; Hf 21.7; C 43.8; H 8.5%.

It should be also mentioned that large crystals of **I** were isolated along with the fine crystalline powder of $Hf(OR)_4 \cdot ROH$ (according to the X-ray powder diffraction data) from the reaction mixture in those cases, where the starting solutions were taken in Al:Hf = 1:1 ratio. Crystals of **I** melt at 57–62°C.

When carrying out the synthesis of alkoxozirconate of the 2:1 composition under the conditions described above for the synthesis of **I**, the crystallization of the fine crystalline powder from the 40–50% solutions was observed only after 7–10 days (yield ~30%). Found: Al 7.5; Zr 12.5; C 48.4; H 9.5. Calc. for $Al_2Zr(OR)_{10}$: Al 7.3; Zr 12.4; C 48.9; H 9.5%.

Attempts to use the solutions with higher concentrations has led to the solidification of the entire reaction mixture and no crystalline phase could be isolated. Further efforts to obtain the bimetallic complex by recrystallization of the solidified mass yielded only the well-formed crystalline product, which, according to the X-ray powder diffraction data, represented $Al(OR)_3$.

In order to determine the composition of zirconium and hafnium isopropoxides after their refluxing in isopropanol, the special experiments were carried out. Thus, after refluxing of the 6% solution of $Zr(OR)_4 \cdot ROH$ in ROH for 1 h the crystallization of monosolvate was observed, and the concentration of the mother liquor proved to be significantly higher than the equilibrium values for 20°C (3.3% $Zr(OR)_4$ rather than 1.7% [6]). The refluxing of 3–4% solution is accompanied by even more profound destruction, so that the concentration of the mother liquor over the 1:1 sample turns out to be as high as 10% (after evaporation of the solvent *in vacuo*). The melting of these samples occurs in a rather wide temperature range of 100–128°C (according to [6] m.p. of $Zr(OR)_4 \cdot ROH$ is equal to 138–141°C). The results are analogous to those observed for the desolvation of Zr and Hf isopropoxides, which occurs at higher temperatures and results in the formation of $M_3O(OR)_{10}$ and $Zr_4O(OR)_{14}$ oxoisopropoxides [6].

The reaction of "$Hf(OEt)_4$" with $Al(OEt)_3$ was carried out under the same conditions as the synthesis of complexes **I** and **II**. A few crystals of hafnium ethoxoaluminate (**III**) were in some cases precipitated from the viscous solution obtained by evaporation of the solvent from reaction mixture *in vacuo*. Found: Al 7.3; Hf 25.9; C 35.7; H 7.6. Calc. for $Al_2Hf(OEt)_{10}$: Al 7.9; Hf 26.1; C 35.2; H 7.3%.

Study of the solubility diagrams

The solubility in the $Al(OR)_3$-$M(OR)_4 \cdot ROH$-ROH systems were studied by the analytical method at 20°C. Solubilities of **I** and **II** were determined by saturation of alcohol with the corresponding crystalline complexes. The euthonics were obtained after agitation of alcohol with two solid phases: $Al(OPr^i)_3$ and **I** (or **II**) and $M(OPr^i)_4 \cdot Pr^iOH$ with **I** (or **II**), respectively.

In each of the binary systems, $M(OR)_4 \cdot ROH$-ROH (M = Hf, Zr), there exists the only solid phase, *viz.* monosolvate, which shows rather low solubility (1.9% and 1.5% for M = Hf and Zr, respectively) [6]. The solubility of $Al(OR)_3$ (with m.p. of 140°C) in the alcohol is equal to 4.3% at 20°C [7]. Figure 1 shows that **I** and **II** are congruently soluble and may be crystallized from a sufficiently broad region on both sides of the 2:1 section. It has already been mentioned that **I** also precipitates from the solutions with 1:1 component ratio. It should be particularly emphasized that in many cases in these systems supersaturated solutions are formed, which have concentrations significantly higher than those corresponding to the equilibrium values and yet do not yield the crystalline phase even after standing for several days.

The crystallization region of **II** is sufficiently large. The solubility values are substantially higher than those reported in [5] (Tables 1 and 2).

X-ray diffraction study

$C_{30}H_{70}Al_2HfO_{10}$, M = 823.31, monoclinic, space group $C2/c$, at 293° $a = 23.311(5)$, $b = 11.176(2)$, $c = 17.372(4)$ Å, $\beta = 104.94(3)°$, $V = 4373(2)$ Å^3, $Z = 4$, $D_c = 1.251$ g cm^{-3}, $D_{exp} = 1.249$ g cm^{-3}. X-ray diffraction experiment was carried out with a Siemens P3/PC diffractometer ($T = 293$ K, graphite-monochromated Mo-$K\alpha$ radiation, $\lambda = 0.71073$ Å $\theta/2\theta$ scan technique, no absorption correction was applied, μ(Mo-Kα) = 24.67 cm^{-1}, $\theta = 2$–29°). The structure

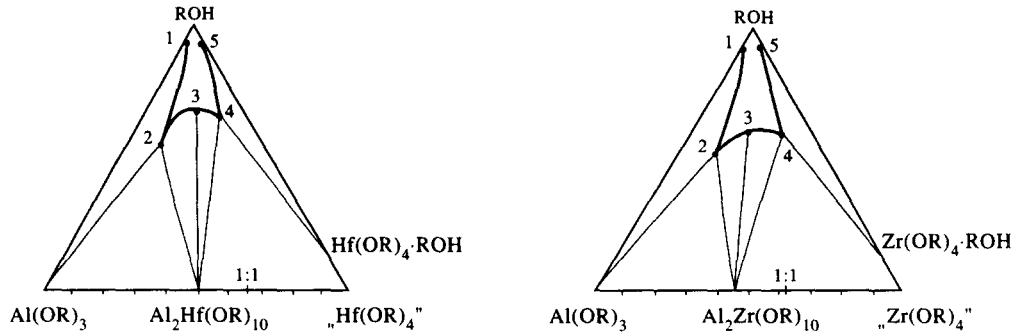

Fig. 1. Solubility in the $Al(OR)_3$-$M(OR)_4 \cdot ROH$-ROH systems at 20°C (mass. %).

was solved by direct methods and refined by the full-matrix least-squares technique in the anisotropic approximation. All H atoms were placed in geometrically calculated positions and included in the refinement using the riding model approximation with the $U_{iso}(H) = 1.2U_{eq}(C)$ for the methyne and $U_{iso}(H) = 1.5U_{eq}(C)$ for methyl groups, where the $U_{eq}(C)$ is the equivalent isotropic temperature factor of the carbon atom bonded to the corresponding H atom. Final discrepancy factors are: $R1 = 0.0500$ (on F for 4057 reflections with $I > 2\sigma(I)$), $wR2 = 0.1458$ (on F^2 for all 5810 reflections used in the refinement of 195 parameters). All calculations were carried out on IBM PC with the help of SHELXTL PLUS 5 (gamma version) program. Atomic coordinates are available from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, U.K.

Mass-spectra were measured using an AEI MS-30 mass-spectrometer, the temperature of the injected sample was 150°C, ionization potential was 70 eV, the masses of the ions involving the ^{180}Hf, ^{90}Zr and ^{12}C isotopes are listed.

RESULTS AND DISCUSSION

It is noteworthy that the mere simultaneous presence of two alkoxides in the solution does not provide sufficient condition for their chemical interaction. Complex formation actually occurs only in the course of the prolonged refluxing of the solutions. It was established that this process, as well as the desolvation of $[M(OR)_4(ROH)]_2$ in the absence of the solvent [6], is accompanied by the partial thermolysis of the components.

One may suggest that it is actually the presence of the oxo group in Zr and Hf alkoxides, which makes possible the formation of bimetallic isopropoxide complexes. We have already come across the similar phenomena earlier, when studying the chemistry of

5	—	1.5	$Zr(OR)_4 \cdot ROH$

polymeric $M(OR)_2$ (M = Co, Ni, Cr, Fe). These alkoxides react with Al, Nb and other alkoxide species only in the presence of traces of water, i.e. only after oxo groups are introduced into the coordination sphere of metal atom [8,9]. Another process, which is known to be a source of oxo groups in alkoxide molecules, thus promoting the formation of complexes, is the oxidation by traces of oxygen, occurring, for instance, for alkaline and alkaline-earth alkoxides. Such oxidation process is especially well documented in case of the reaction between Ba and Ti alkoxides [10].

The present work provides additional evidence for the role of the presence of the traces of oxo groups in the process of complex formation. It does not exclude, however, the possibility of crystallization of bimetallic alkoxides, without oxo groups from such solutions. Along with the complexes **I** and **II** we have observed the crystallization of such complexes in the course of the synthesis of $LaNb_2(OR)_{13}\cdot 2ROH$ [8] and $Ba_2Zr(OR)_8\cdot 5ROH$ [11]. The yields in all cases were far from being quantitative, as the mother liquors in both cases were known to contain oxo groups, either within the $La_5O(OR)_{13}$ component (in case of the lanthanum–niobium system) or as a result of $Ba(OR)_2$ oxidation (in case of barium–zirconium complex). The composition of the bimetallic complexes, which are formed eventually, *viz.*, the presence or absence of the oxo groups in such complexes, is determined in each particular case by the energy of crystal lattice. Therefore, on carrying out the synthesis of bimetallic alkoxides, one should pay special attention to the possibly full separation of the crystalline phase from the mother liquors, as the oxo complexes are frequently accumulated in one of the phases. Otherwise, it may well happen that it would be impossible to have definite data on the individual character and composition of bimetallic complexes. Thus, the difficulties with crystallization of complexes **II** and its incomplete separation from the liquid phase resulted in incorrect determination of its composition as 1:1 [5].

The single-crystal X-ray diffraction study has shown that the crystal of **I** is built of trinuclear molecules (Fig. 2, Table 3) which have the structure, first suggested by Mehrotra [3]. The molecule occupies a special position on the two-fold axis, which passes through the Hf atom and involves the central coordination octahedron $[Hf(OR)_6]$ sharing common edges with each of the two peripheral coordination tetrahedra $[Al(OR)_4]$. The metal–oxygen core of the complex **I** is analogous to that of the trinuclear aluminium isopropoxochloride derivative, $Al_3Cl_5(OPr^i)_4$ [12] (the latter is believed to be structurally related to trimeric aluminium isopropoxide, $[Al(OPr^i)_3]_3$), the only difference being the higher coordination number of the central atom in case of six-coordinated Hf rather than five-coordinated aluminium. Molecule **I** also shows some structural similarity with tetranuclear alkoxides $[Al(OPr^i)_3]_4$ [13, 14] and

Atoms labelled by letter A are generated from the reference atoms by the $-x, y, -z+1/2$ symmetry transformation.

$Er[Al(OR)_4]_3$ [15], which, in contrast to **I**, involve three, rather than two, peripheral $[Al(OR)_4]$ groups. Although compound **I** has two *cis*-terminal OR groups at the central Hf atom instead of the third four-membered cycle, two $[HfO_2Al]$ cycles, which are present in the structure are geometrically close to those observed in the tetranuclear complexes. In particular the mean planes of two almost planar $[HfO_2Al]$ cycles in **I** form the dihedral angle of 82° with each other, which is quite close to values of the corresponding dihedral angles in the structure of $[Al(OR)_3]_4$.

The angular distortions of the Hf coordination octahedron and the Al tetrahedra are naturally due to the formation of the four-membered rings and are manifested in the significant decrease of the endocyclic bond angles [O(1)—Hf(1)—O(2), 67.9(2)° and O(1)—Al(1)—O(2), 83.5(2)°] and the simultaneous increase of most of those bond angles which are not involved in any cycles [O(1)—Hf(1)—O(3), 100.7(2); O(1)—Hf(1)—O(3A), 92.4(2); O(3)—Hf(1)—O(3A), 100.8(3)° and O(1)—Al(1)—O(4), 109.1(2); O(1)—Al(1)—O(5), 112.4(4); O(2)—Al(1)—O(4), 114.3(2); O(2)—Al(1)—O(5), 112.2(3), O(4)—Al(1)—O(5), 118.7(4)°]. The bridging as well as the terminal Hf—O bond lengths in **I** [Hf(1)—O(1) 2.140(4), Hf(1)—O(2) 2.213(3) Å and Hf(1)—O(3) 1.913(4) Å] do not differ from the distances observed for the corresponding Zr(Hf)—OR bonds in the $[M(OR)_4(ROH)]_2$ solvates [16]. The increased bond order of the terminal Hf—O bonds is reflected in the widening of the corresponding HfOC bond angles, which is even more pronounced in complex **I** [Hf(1)—O(3)—C(7) 177.4(7)°] than in the $Hf(OR)_4 \cdot ROH$ structure, wherein the relevant HfOC angles span the range of 167.3–177.6°. The regular increase of the O—C bond lengths and simultaneous decrease of the HfÔC bond angles are observed in molecule **I** on going from terminal [O(3)—C(7) 1.377(9) Å] to bridging OR groups [O(1)—C(1) 1.454(8), O(2)—C(4) 1.450(6) Å, Hf(1)—Ô(1)—C(1) 126.3(5), Hf(1)—Ô(2)—C(4) 127.9(4)°].

Analogous geometrical differences are found in the coordination environment of the Al atoms. The Al—O and C—O bond lengths both terminal [Al(1)—O(4) 1.689(5), O(4)—C(10) 1.379(9) Å and

Al(1)—O(5) 1.667(6), O(5)—C(13) 1.288(12) Å*] and bridging [Al(1)—O(1) 1.803(5) and Al(1)—O(2) 1.787(4) Å], as well as the terminal and bridging AlOC bond angles [Al(1)—Ô(4)—C(10) 138.5(6), Al(1)—Ô(5)—C(13) 160.19(12)° and Al(1)—Ô(1)—C(1) 128.7(5), Al(1)—Ô(2)—C(4) 129.8(4)° respectively] are quite close to those observed earlier in the structures of $[Al(OR)_3]_4$ [13] and $Al_3(OR)_4Cl_5$ [12]. The sums of the bond angles at the bridging oxygen atoms are approximately equal to 360°, which indicates that these atoms are evidently sp^2-hybridized.

The results of the indexing of the powder diffraction pattern of **I** and **II** using the unit cell parameters, found in the single-crystal X-ray study of **I** (*vide infra*), are listed in Table 4.

Solubility studies of the $Al(OR)_3$-$M(OR)_4 \cdot ROH$-ROH (M = Hf, Zr) systems at 20°C (Fig. 1, Tables 1 and 2) lead to the conclusion that in each case there exists the only one complex, *viz.* complex $Al_2M(O\text{-}Pr^i)_{10}$ (M = Hf(**I**), Zr(**II**)) with the 2:1 composition. Both complexes are sufficiently stable and crystallize in a broad range of concentrations on both sides of the 2:1 section. According to the mass-spectroscopic data, these complexes are also present in the vapour phase (Fig. 3, Table 5). Mass-spectroscopic study of **I** and **II** shows that the complexes exhibit two main fragmentation pathways on electron impact, *viz.*, (1) the consecutive elimination of OR, R_2O and CH_2 groups; and (2) the abstraction of $Al(OR)_3$ with the formation of $AlM(OR)_7$ and subsequent fragmentation of the latter, proceeding similarly to the decomposition of molecule **I** to **II**.

Table 5. Mass spectra of $Al_2M(OR)_{10}$, M = Hf (**I**) and Zr (**II**)[a]

475	5	—	—	$Al_2MO_2(OR)_3(OMe)^+$
459	3.5	369	—	$AlMO(OR)_4^+$
401	2	311	37	$Al_2MO_3(OR)_2^+$

[a]Along with the listed ions in both mass-spectra the ions corresponding to the products of the $[Al(OR)_3]_n$ (n = 3, 4) fragmentation are present: 757 $[Al_4(OR)_{11}^+]$, 553 $[Al_3(OR)_8^+]$, 349 $[Al_2(OR)_5^+]$.

In the X-ray powder diffraction pattern for the samples of "$AlZr(OR)_7$" only those diffraction lines which may be attributed to complex **II** were present; the same is, by the way, true for the hafnium derivatives. It may be, therefore, assumed that the excess of the zirconium alkoxide is found in the sample in the form of amorphous thermolysis product $Zr(OR)_4 \cdot ROH$ [6] (this fact may account for the variations of the solubility values of the samples having the 1:1 composition).

The mass-spectrum of the "$AlZr(OR)_7$" samples, reported earlier [5] may find more natural interpretation in the assumption of the presence of both complex **II** and the $Zr(OR)_4 \cdot ROH$ solvate in these samples. It may, therefore, be concluded that alkoxozirconates and -hafnates of the 1:1 composition do not exist.

The study of the interaction of Al and Hf ethoxides is of particular interest, taking into account, that in this case both components contain oxo groups. Thus, according to the preliminary results of the X-ray diffraction study the $Hf(OEt)_4$ samples contain the $[Hf_3O(OEt)_{10}(EtOH)]_2$ species [18]. The reaction of complex formation with polymer aluminium ethoxide

*The Al—O bond lengths in the almost regular tetrahedron in the structure of $[C_6H_{11}NH_3]^+[Al(OR)_4]^-$ are equal to 1.73–1.76 Å [17].

419	10	$Al_2HfO_3(OEt)_3^+$
403	5	$AlHfO(OEt)_4^+$
345	10	$Al_2HfO_4(OEt)^+$

[a]The ions corresponding to the fragmentation of $[Al(OEt)_3]_n$ (973 $[Al_6(OEt)_{18}^+]$, 779 $[Al_5(OEt)_{14}CH_2^+]$, 691 $[Al_5(OEt)_{12}O^+]$, 529 $[Al_4(OEt)_9O^+]$, 442 $[Al_3(OEt)_8^+]$, 323 $[Al_2(OEt)_6^+]$) and "hafnium ethoxide" ions (956 $[Hf_3O(OEt)_9^+]$, 817 $[Hf_3O_3(OEt)_5^+]$) are also present.

proceeds only after prolonged refluxing with the solution of "$Hf(OEt)_4$" in ethanol, which probably increases the concentration of oxo ligands. Nevertheless, it is possible to isolate from the concentrated solutions (in rather low yields) the crystals of $Al_2Hf(OEt)_{10}$ (**III**). Mass-spectrum of **III**, and that of the foam-like sample, formed after evaporation of the solvent from the 2 : 1 aluminium and hafnium ethoxide solution *in vacuo*, turned out to be identical and their fragmentation scheme (Table 6) was similar to that of **I** and **II**. It means, therefore, that molecules of **III** exist also in the vapour phase, and the ions of the $Al_2HfO_n(OR)_{9-n}^+$ type (n = 1–4) are formed only in the process of the elimination of ether from **III**.

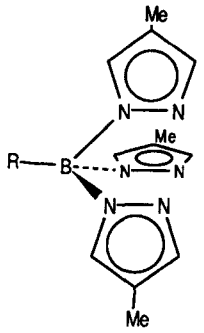
(Received 15 May 1996; accepted 13 June 1996)

Abstract—A series of new metal complexes of general formula $M[Tp^{\#}]_2$ (where $Tp^{\#}$ = hydridotris(4-methyl-1*H*-pyrazol-1-yl)borate (Tp^{4Me}) or tetrakis(4-methyl-1*H*-pyrazol-1-yl)borate ($pzTp^{4Me}$) and M = Mn, Fe, Co, Ni, Cu, Zn, Cd) were synthesized from the appropriate metal chloride and $KTp^{\#}$ in aqueous solution. These compounds are air-stable solids, sparingly soluble in most organic solvents; they have been characterized by elemental analysis, conductivity and molecular weight measurements, IR, UV, visible spectra and, in the case of diamagnetic compounds, also with ^1H and ^{13}C NMR spectra. The X-ray crystal structure of bis[hydridotris(4-methyl-1*H*-pyrazol-1-yl)borate]zinc(II) · $CHCl_3$ has been determined. The metal is six-coordinate in a distorted octahedral geometry. The N—Zn—N intraligand bond angles range from 84.3(1) to 86.3(1)°. The Zn—N distances vary from 2.114(3) to 2.205(4) Å. The geometry around the B atoms is tetrahedral. The angles N—B—N range from 106.8(3) to 111.0(3)°, the B—N bond distances vary from 1.528(6) to 1.564(5) Å. Comparison is made with some related compounds. Copyright © 1996 Elsevier Science Ltd



Keywords: polypyrazolylborates; X-ray; UV–visible; IR; metal(II) derivatives; NMR.

The poly(1*H*-pyrazolyl)borate donors $[H_nB(pz)_{4-n}]$ $[Tp^{\#}]$ ($n \leqslant 2$) constitute an important and versatile family of ligands. It is possible to change easily their electronic and steric features and prepare coordination compounds characterized by different stoichiometries and geometries [1]. The donors $[H_nB(pz)_{4-n}]^-$ can generally act as bidentate ($n = 0$ or 2) or tridentate ligands ($n = 0$ or 1). In the latter coordination mode they are particularly interesting: for example it is possible to synthesize simple models for active sites of bio-organic macromolecules such as enzymes [2–4]. Moreover, this class of compounds is useful in this study of the electronic spin-state transitions induced by pressure [5] or temperature [6]. Most of the research into the coordination chemistry of tris- and tetrakis(pyrazolyl)borates has been focused on the first-row transition metals [1, 7, 8]. The data obtained from spectroscopic techniques [8] and from the X-ray crystal structures of $M(Tp^{\#})_2$ with Tp [9], Tp* [10], or Tp^{3Me} [11], have conveyed direct information on structural parameters of the slightly distorted octahedral complexes.†

Here we report the synthesis of the anionic polydentate chelating ligands, hydridotris(4-methyl-1*H*-pyrazol-1-yl)borate (Tp^{4Me}) and tetrakis(4-methyl-1*H*-pyrazol-1-yl)borate ($pzTp^{4Me}$) (Fig. 1), obtained by heating KBH_4 in the corresponding molten pyrazole. Through careful temperature control it was possible to stop at the tri-substitution stage or to continue until tetra-substitution of the hydrogens with pyrazole moieties. The potassium salts are water soluble and their hydrolytic stability increases with increasing substitution of B-bonded hydrides by pyrazolate groups. These monoanionic N-donors have been chosen in

* Author to whom correspondence should be addressed.

† The ligand abbreviations are according to Trofimenko (refs [1,8]) and the symbol $Tp^{\#}$ stands for any pyrazolylborate.

R = H or 4-Methypyrazole

Fig. 1. Ligands used in this work.

view of the fact that, differently from the 3- or 3,5-substituted parent ligands, they offer the 3-position free from steric hindrance. The presence of a methyl group in the 4-position increases the donating ability of the donors.

The coordination chemistry of these ligands towards transition metal M^{2+} ions (M = Mn, Fe, Co, Ni, Cu, Zn, Cd), is described and the tridentate chelating character of tris(pyrazolyl)borates in the solid state is conclusively demonstrated from the X-ray crystal structure determination of $Zn[Tp^{4Me}]_2 \cdot CHCl_3$.

RESULTS AND DISCUSSION

Coordination compounds derived from the anionic $[Tp^{4Me}]$ or $[pzTp^{4Me}]$, and divalent first-row transition or group 12 metal ions can be readily prepared by metathesis reaction:

$$MX_2 + 2KTp^{\#} \xrightarrow{H_2O} M[Tp^{\#}]_2 + 2KX$$
1–14

M = Mn, Co, Ni, Zn or Cd, X = Cl;
M = Fe or Cu, $X_2 = SO_4$;
$Tp^{\#} = Tp^{4Me}$ or $pzTp^{4Me}$.

The analytical data of derivates **1–14** are given in Table 1. Most of the $M[Tp^{\#}]_2$ derivatives gradually decompose on heating, without melting: this behavior

[a] Tp^{4Me} is hydridotris(4-methyl-1*H*-pyrazol-1-yl)borate, $C_{12}H_{16}BN_6$, and $pzTp^{4Me}$ is tetrakis(4-methyl-1*H*-pyrazol-1-yl)borate, $C_{16}H_{20}BN_8$.

[b] Calculated values in parentheses.

[c] Molar conductivity in CH_2Cl_2 solution ($ohm^{-1}\ cm^2\ mol^{-1}$) at room temperature, the molar concentration $\times 10^{-3}$.

has been previously observed also in other poly(pyrazolyl)borato derivatives [12].

Compounds **1–14** are sparingly soluble in polar solvents such as acetone or methanol, and soluble in DMSO and chlorinated solvents, from which they may be suitably recrystallized. The solubility of compounds **8–14** is generally lower than that of compounds **1–7**. The $M[pzTp^{4Me}]_2$ have the same colours as their $M[Tp^{4Me}]_2$ counterparts, except in the case of the iron derivatives $Fe[Tp^{4Me}]_2$ and $Fe[pzTp^{4Me}]_2$, which are violet and red, respectively. Conductivity measurements carried out in dichloromethane solution indicate that all the derivates are non-electrolytes in this solvent. Molecular weight determinations have shown also that compounds **1–14** are not dissociated in chloroform: for example the ratio between the vaporimetric and the calculated molecular weight is 0.90 (=441/491) for **6** and 0.92 (=577/624) for **13**.

IR data

Selected infrared data of $M[Tp^{4Me}]_2$ and $M[pzTp^{4Me}]_2$ derivatives are reported in Table 2. In the spectra of $M[Tp^{4Me}]_2$ we have observed a ν(B—H) absorption in the region 2400–2500 cm^{-1}: it is found at higher frequencies shifted with respect to the potassium ligand salt (a similar behaviour likely due to solid state effects, has been previously found in other poly(pyrazolyl)borato derivatives [13]) and it is generally split into two components.

Over 3000 cm^{-1} we have found weak absorptions, assigned to heterocyclic ν(C—H) vibrations. The spectra of **1–14** exhibit in the 1500–1600 cm^{-1} region strong or medium bands due to the "breathing" of the pyrazole rings. Finally, the medium intensity absorption at *ca* 1410 cm^{-1} in $M[Tp^{4Me}]_2$ and at *ca* 1420 cm^{-1} in $M[pzTp^{4Me}]_2$ derivatives can be tentatively assigned to ν(B—N) stretch [14]. It has not been possible to assign with certainty the metal–ligand absorptions in the far-IR region because of the presence of several overlapped ligand bands.

NMR data

The ^1H and ^{13}C NMR spectra have been performed in the case of zinc and cadmium derivatives (Table 3). The NMR spectra of **6** and **7** suggest that the three pyrazolyl rings are equivalent over the temperature range of 220–300 K, in accordance with the presence of tridentate ligands. However we cannot exclude the possibility of lower coordination numbers in solution, due to a fluxional behaviour similar to those previously observed in related Tp and Tp* complexes [15, 16]. The pyrazole ring exchange may be very rapid, as observed for MeHg(Tp) [17], which doesn't allow the direct observation of signal splitting even at −90°C.

Consequently the determination of the coordination mode of the donor in solution is not possible.

The ^{13}C NMR spectrum of $Cd[Tp^{4Me}]_2$ exhibits an interesting feature: we observed at room temperature the coupling constant (21 Hz) between $^{111,113}Cd$ and C(3). This coupling is of the same order of magnitude of that previously observed (14 Hz) in the spectrum of $Cd[Tp^*]_2$ at 263 K [18]. In the spectra of cadmium derivatives a slightly deshielding of the H(3) and C(3) nuclei with respect to those of zinc derivatives is detected, thus indicating a likely stronger donation of the ligand in the former compounds.

In the spectra of derivatives **13** and **14** we observed at room temperature only one set of signals. Cooling the samples to −50°C an initial splitting of the signals appeared, whereas at −80°C the splitting was complete, two different sets of signals, in 3 : 1 intensity ratio, being detected. This suggests that in the frame of an octahedral structure, one pyrazole ring is different from the other three, but also that at room temperature a fluxional behavior, which makes all pyrazoles indistinguishable, is operating in solution. As previously indicated for derivatives of (pzTp), the exchange rate of pyrazoles is fast compared with the NMR time scale, at room temperature.

UV–visible data

The UV-visible spectra of derivatives **1–14** have been carried out in chloroform solutions. The position of absorption maxima and the extinction coefficients are given in Table 4.

All the complexes exhibit a very intense band at *ca* 240 nm, which corresponds to pyrazolic intraligand transition. Moreover at the limit of the UV part of the spectra (at *ca* 290 nm) and in the visible region (at *ca* 340 nm) some absorptions of medium intensity are often detected, which should be attributed to "metal to ligand charge transfer" (MLCT) [9a]: the relatively high extinction coefficient may be a conclusive proof for this attribution.

In the spectrum of nickel(II) derivative **4** we observed a weak absorption at 354 nm, (ε = 35), typical of *d–d* transitions.

In the spectra of iron(II) derivatives **2** and **9** we observed three absorptions between 290 and 490 nm, due to MLCT transitions. Moreover an additional absorption at *ca* 580 nm was found, which could be tentatively assigned to $^1T_{1g}(^1I) \leftarrow {}^1A_{1g}$ transition, on the basis of previous reports on low and high spin iron d^6 six-coordinated complexes [9b].

In the spectra of copper(II) derivatives **5** and **12** a weak broad band at 592 nm was detected, which may be assigned to $^2T_{2g} \leftarrow {}^1E_g$ transition in skewed octahedral $Cu(N\text{-donor})_6$ complexes [19]. The broadening and the splitting of the absorption is caused by the trigonal component of the field, spin-orbital coupling and Jahn-Teller distortion, in accordance with that previously indicated for distorted octahedral $Cu(Tp^{\#})_2$ complexes, structurally investigated [9f,h]. The apparent octahedral splitting parameter Δ, neglecting Jahn–Teller effects, is ~16,000 cm^{-1}, thus indicating

a relatively strong ligand field, similar to those caused by the donors (Tp) and (pzTp) [9a]. As indicated by Jesson [9a] the extinction coefficient (ε) increases *ca* 60 cm^{-1} with the substitution of the hydrido group with a pyrazole molecule. A similar trend is found in the spectra of iron derivatives **2** and **9** for the MLCT absorption (342 nm), where ε increase from 6900 in $Fe[Tp^{4Me}]_2$ to 11400 cm^{-1} in $Fe[pzTp^{4Me}]_2$.

X-ray crystal structure of $Zn[Tp^{4Me}]_2 \cdot CHCl_3$

The molecular structures of the two independent molecules of $Zn[Tp^{4Me}]_2 \cdot CHCl_3$ is shown in Fig. 2 together with its numbering scheme [20]. The molecules exhibit crystallographic symmetry -1 because the Zn atoms occupy special positions *a* (0, 0, 0) and *h* (1/2, 1/2, 1/2).

Since the differences among chemically equivalent interatomic distances and angles in the molecules have only relative meaning, their average values are given in Table 5, whereas the individual values in the coordination sphere are listed in Table 6. The individual distances and angles in the ligands are available as Supplementary Material.

The packing of the complex molecules in the crystal leaves space for the chloroform molecules. The

[a] All values calculated according to A. Domenicano, A. Vaciago and C. A. Coulson, *Acta Crystal.*, **B3**, 1975, 221.

octahedral N—Zn—N intraligand bond angles range from 84.3(1) to 86.3(1)° [weighted average 85.2(3)°], whereas the interligand corresponding angles range from 93.7(1) to 95.7(1)° [weighted average 94.8(3)°]. These values are comparable with those found in the bis[hydridotris(1-pyrazolyl-N^2)borato]zinc(II) [21].

In the pyrazole rings without a free lone pair, the following pattern for the angles is observed: Zn—N(2)—C(3) > Zn—N(2)—N(1) [weighted average 135.6(9) > 119.1(4)°], N(2)—N(1)—C(5) > N(1)—N(2)—C(3) [weighted average 110.7(4) > 105.1(9)°] and N(2)—C(3)—C(4) > C(4)—C(5)—N(1) [weighted average 111.3(9) > 107.9(5)°], consistent with the empirical rules concerning the bond angles in pyrazoles [22]. A similar trend was observed in [HB—(μ-pz)$_3$—Cu(PPh$_3$)] [23].

The weighted average N···N intraligand distance of 2.902(3) Å is shorter than the average interligand N···N distance of 3.15(2) Å. The least-squares planes of the pyrazole rings suggest the following probability that the rings are non-planar: $P > 99\%$ for N(1A)—C(5A), N(1C)—C(5C), N(1D)—C(5D), and N(1E)—C(5E), $P = 81.5\%$ for N(1B)—C(5B), $P = 53.9\%$ for N(1F)—C(5F); maximum out-of-plane displacements (Å): C(5A) −0.019(4), C(5C) −0.010(5), C(3D) 0.020(5) and C(3E) −0.012(4).

The steric demands of ligands were recognized as important in determining the stability of complexes, in ligand competition and exchange [24]. It is of value to calculate effective cone angles of ligands from the crystallographic structural data. The effective cone angles of the ligand HB(4-Mepz)$_3$ were calculated assuming the midpoint of three Zn—N vectors as the cone axes and the Zn atoms as the cone vertexes. The angle between the cone axes and the vector which touches the van der Waals radii of the hydrogen atoms closest to Zn (r = 1.17 Å for H) for each end of the tridentate ligand is: 102.4° for H(3A), 103.8° for H(3B) and 105.8° for H(3C) and 102.4° for H(3D), 111.6 for H(3E) and 104.1° for H(3F). These angles correspond to a total average value θ: 208.0° for Zn(1) ligand and 212.0° for Zn(2) ligand. These values are consistent with the value 212.2° found in the parent ligand [HB-(μ-pz)$_3$] [23].

Table 6. Selected interatomic distances (Å) and bond angles (°) with e.s.d.s in parentheses of $Zn[Tp^{4Me}]_2 \cdot CHCl_3$

Zn(1)—N(2A)	2.185(4)	Zn(2)—N(2D)	2.205(4)
Zn(1)—N(2B)	2.117(3)	Zn(2)—N(2E)	2.114(3)
Zn(1)—N(2C)	2.119(3)	Zn(2)—N(2F)	2.116(4)
N(2A)—Zn(1)—N(2B)	85.5(1)	N(2D)—Zn(2)—N(2E)	84.3(1)
N(2A)—Zn(1)—N(2C)	84.8(1)	N(2D)—Zn(2)—N(2F)	84.4(1)
N(2B)—Zn(1)—N(2C)	86.3(1)	N(2E)—Zn(2)—N(2F)	85.2(1)
N(2A)—Zn(1)—N(2B′)	94.5(1)	N(2D)—Zn(2)—N(2E′)	95.7(1)
N(2A)—Zn(1)—N(2C′)	95.2(1)	N(2D)—Zn(2)—N(2F′)	95.6(1)
N(2B)—Zn(1)—N(2C′)	93.7(1)	N(2E)—Zn(2)—N(2F′)	94.8(1)

The geometry around the B atom is tetrahedral. The B–N bond distances vary from 1.528(6) to 1.564(5) Å, with weighted average 1.547(6) Å. The angles N—B—N range from 106.8(3) to 111.0(3)° with weighted average 108.7(7)°.

The B(1)···Zn(1) and B(2)···Zn(2) distances are 3.183(5) and 3.237(6) (weighted average 3.20(3) Å) comparable with the values found in $Zn[HB(pz)_3]_2$ [21].

Bond distances and angles within the solvent molecule $CHCl_3$ and: C(1)—Cl(1) 1.728(7), C(1)—Cl(2) 1.771(7) and C(1)—Cl(3) 1.769(5) Å; Cl(1)—C(1)—Cl(2) 109.2(4), Cl(1)—C(1)—Cl(3) 110.9(3) and Cl(2)—C(1)—Cl(3) 106.9(3)° respectively.

In Table 7, selected bond distances and angles of $Zn[Tp^{4Me}]_2$ are compared with the values reported for other six-coordinate octahedral $M[Tp^{\#}]_2$-type compounds [9, 16, 21, 25–33]. Several general patterns emerge; for example for M—N bond distance is nearly equal to the sum of Shannon's ionic radii [34] and increases when alkyl groups are in the 3-position of the heterocyclic rings of the ligand, near to coordination sites. We also observed the mean M—N value increases on going from the metals of the (n) to those of ($n+1$) period.

According to Shannon and Prewitt [35], two very different Fe—N distances are found in the case of low ($Fe[Tp]_2$) and high-spin ($Fe[Tp^*]_2$) derivatives respectively. Between all the derivatives the shortest M—N distance is found in $Fe[Tp]_2$ whereas the longest is found in the $Pb[Tp^{\#}]_2$ derivatives, where, if the lone pair is also stereochemically inactive, the structure is a trigonally distorted octahedron due to strong interligand steric effects.

Only in the $Cu[Tp^{\#}]_2$ derivatives did we observe three different sets of Cu—N distances. The structure can be described as an elongated rhombic octahedron. The marked distortion could be ascribed to the Jahn–Teller effect.

The average N—M—N bite angles range from 73.2 in $Pb[Tp]_2$ to 91.2 in $Fe[Tp^{3Me}]_2$. It is worth noting that N—M—N values decrease with increasing of the M—N distances, i.e. the mean N—M–N value decreases on going from the metal of the (n) to those of ($n+1$) period.

In the case of Mg, Ca, Co, Ni, Cu, Zn, Cd and Pb derivatives we observed that the presence of an alkyl group in the 3-, 4- and 5-position of the heterocyclic ring doesn't seem to produce relevant effects on the molecular parameters reported in Table 8. Only in the case of the iron derivatives the steric hindrance exerted by a Me group in 3 position is the decisive factor to determine the stability of high-spin states and consequently the lengthening of the Fe—N bonds and the opening of the N—Fe—N bites.

EXPERIMENTAL

General laboratory equipment

Concentration was always carried out under reduced pressure (water aspirator). The samples were dried *in vacuo* till constant weight (20°C, *ca* 0.1 Torr). Carbon, hydrogen, and nitrogen analyses were carried out with a Fisons Instruments 1108 CHNS-O Elemental analyzer. Molecular weight determinations were performed with a Knauer membrane osmometer. Infrared spectra were recorded from 4000 to 200 cm^{-1} on a Perkin–Elmer 2000 System Series FTIR instrument. ^1H- and ^{13}C-NMR spectra were recorded on a Varian VXR-300 spectrometer operating at room temperature (300 MHz for ^1H, 75 MHz for ^{13}C). The conductances of solutions were measured with a Crison CDTM 522 conductimeter at room temperature.

Synthesis of the donors

Potassium[hydridotris(4-methyl-1H-pyrazol-1-yl) borate]. Potassium borohydride (2.7 g, 0.05 mol) and 4-methyl-pyrazole (16.4 g, 0.20 mol) were gradually heated under stirring in a 1-litre flask at temperature not exceeding 190°C. Potassium borohydride dissolved slowly with evolution of hydrogen. After 60 h the melt was poured dropwise into 300 cm^3 of stirred hot xylene. Upon cooling, a solid precipitated and, after repeated washings in *n*-heptane/diethy ether (2 : 1

methanol (10 cm^3, 1 : 1 v/v) and dried under reduced pressure. The crude product was recrystallized with $CHCl_3$ and shown to be compound **6**. Compounds **1–5** and **7–14** were prepared similarly.

X-ray analysis

A needle-shaped colourless crystal of $Zn[Tp^{4Me}]_2$, **6**, with dimension $1.05 \times 0.21 \times 0.17$ mm was selected for the X-ray analysis and mounted on the Enraf-Nonius CAD4 diffractometer with graphite-monochromated Cu-K_α radiation of the Centro Grandi Strumenti dell'Università, Pavia, Italy.

The SEARCH program was used to obtain 25 reflections, from which approximate cell dimensions were derived by the INDEX program. Accurate lattice parameters were obtained by least-squares refinement of these reflections.

The triclinic cell quoted was confirmed by the TRACER program [36]. The $\omega/2\theta$ scan technique was used to collect the intensities. Three standard reflections were measured every 300 min and showed small random deviations within the limits of statistical fluctuation. The intensities were corrected for Lorentz and polarization factors; an empirical absorption correction [37] with minimum and maximum absorption factors of 0.5589 and 0.9942 was applied. The structure factors were put on an absolute scale [38] and an overall isotropic thermal factor of 5.651 Å^2 was obtained thereby.

Table 8 lists crystal data, data-collection parameters and details of structure refinement.

4499 reflections having $I > 3\sigma(I)$ were considered observed and used in the structure analysis.

Structure determination and refinement

The structure was obtained by Patterson and Fourier methods. A difference Fourier synthesis phased on the two Zn atoms revealed the positions of all the non-hydrogen atoms of the complex molecules. Residual electronic density, observed on successive difference-Fourier syntheses is due to the crystallization solvent $CHCl_3$. The positions of the hydrogen atoms were calculated from the geometry of the compound and checked in a final difference-Fourier map. The final least-squares anisotropic refinement included the hydrogen atoms in fixed positions with the equivalent isotropic thermal parameters of their bonded atoms. In the early refinement stages the observed reflections were given unit weight. The maximum ratio of the parameter shift to the e.s.d. in the final refinement cycle was 0.01. The largest residual peaks on the final difference-Fourer map were 0.432 and −0.303 e Å^{-3} both close to the Zn(2) atom. No extinction correction was applied.

All calculations were carried out with the Enraf-Nonius SDP crystallographic computing package [39] and with local programs.

Supplementary material available

Tables of atomic positional parameters of all atoms, anisotropic thermal parameters, bond distances and bond angles involving non-hydrogen atoms and hydrogen atoms, planarity of molecular regions and a listing of observed and calculated structure factors (total of 45 pages).

(Received 25 April 1996; accepted 5 June 1996)

Abstract—The new compound acetato *meso*-tetra(4-methoxyphenylporphyrinato)thallium(III), Tl(tmpp)(OAc), has been synthesized and its molecular structure determined by X-ray analysis. The displacement of the thallium atom from the porphyrin mean plane was 0.808 Å. The geometry around the thallium centre of the Tl(tmpp)(OAc) molecule has Tl—O(1) = 2.29(1) and Tl—O(2) = 2.48(1) and average Tl—Np = 2.211(8)Å. An asymmetric-bidentate acetato group is coordinated to the thallium(III) atom. The free energy of activation $\Delta G^{\ddagger}_{224}$ for the acetato group of Tl(tmpp)(OAc) in CD_2Cl_2 solvent undergoing intramolecular exchange has been derived to be 48.4 kJ mol^{-1} through ^1H NMR temperature-dependent measurements. In the intermediate exchange region, neither the carbonyl nor methyl signals of the acetate ligand for Tl(tmpp)(OAc) in CD_2Cl_2 solvent in ^{13}C NMR spectra was found at 20°C. In the slow exchange region, the methyl and carbonyl carbons of the acetato group are separately located at 17.7 ppm [with ^3J(Tl—^{13}C) coupling constant 275 Hz] and 173.9 ppm [with ^2J(Tl—^{13}C) coupling constant 230 Hz], respectively, for the Tl(tmpp)(OAc) in CD_2Cl_2 at −90°C. The ^{13}C resonance of the axial cyano ligand in the title compound cyano *meso*-tetra(4-methoxyphenylporphyrinato)thallium(III), Tl(tmpp)(CN), was observed at 139.9 ppm (20°C) [with ^1J(^{205}Tl—^{13}C) coupling constant 5287.3 Hz and ^1J(^{203}Tl—^{13}C) coupling constant 5238.0 Hz]. This indicates that the cyano group is, as cyanide type, axially coordinated to the Tl atom in Tl(tmpp)(CN).

Keywords: crystal structure; thallium porphyrins; NMR analysis; asymmetric-bidentate ligand; intra- and intermolecular exchange; acetate.

The molecular structure and dynamical NMR studies of acetato *meso*-tetraphenylporphyrinatothallium (III), Tl(tpp)(OAc) [1–3], and acetato *meso*-tetra(4-pyridyl)porphyrinatothallium(III), Tl(tpyp)(OAc) [4, 5], have been reported by ourselves and others. It turned out that the acetato ligand exchange for Tl(tpyp)(OAc) in CD_2Cl_2 solvent was intermolecular [4, 5], whereas the exchange for Tl(tpp)(OAc) in the same solvent was intramolecular [1, 2]. The driving force for the intermolecular exchange might be due to hydrogen bonding between Tl(tpyp)(OAc) and HOAc. When the tpp or tpyp was replaced by tmpp, the new complex, acetato *meso*-tetra(4-methoxyphenyl) porphyrinatothallium(III), Tl(tmpp)(OAc) was obtained. The acetato exchange of Tl(tpyp)(OAc) and

* Author to whom correspondence should be addressed.

Tl(tpp)(OAc) in CD_2Cl_2 encouraged us to investigate similar exchange of Tl(tmpp)(OAc) in the same solvent by a dynamical NMR method.

Previously, Senge *et al.* [6] reported the X-ray crystallographic characterization of cyano *meso*-tetra(4 - methoxypheyl)porphyrinatothallium(III), Tl(tmpp)(CN) and Coutsolelos *et al.* [7] reported the crystal structure of isocyano *meso*-tetraphenylporphyrinatothallium(III), Tl(tpp)(NC). However, they were not able unambiguously to solve the dichotomy of isocyanide versus cyanide binding to the thallium centre on the basis of the crystalographic data for Tl(tmpp)(CN) [6] and Tl(tpp)(NC) [7]. As described in our previous papers, with a pulse delay of 3.5 s (i.e. longer than 3.0 s), the ^{13}C signal of CN instead of bonding to Tl(tpp)(NC) [7] but bonding to cyano *meso*-tetraphenylporphyrinatothallium(III), Tl(tpp)(CN) [8], [or cyano *meso*-tetra(4-pyridyl)porphyrinatothallium(III), Tl(tpyp)(CN), [9] appears as two pairs of doublets at 139.2 ppm with $^1J(^{205}Tl—C) = 5394$ Hz and $^1J(^{203}Tl—C) = 5344$ Hz [or at 137.7 ppm with $^1J(^{205}Tl—C) = 5852$ Hz and $^1J(^{203}Tl—C) = 5795$ Hz].

In this paper, the synthesis, its NMR spectroscopic studies, and the molecular structure of the crystalline Tl(tmpp)(OAc) by X-ray analysis are reported. The long pulse delay technique was used to observe the ^{13}C resonance of the cyano ligand of Tl(tmpp)(CN) and resolve the ambiguous binding for both types.

EXPERIMENTAL

Crystallography

Crystal Data and other information for Tl(tmpp)(OAc)·$1CH_2Cl_2$ (or $C_{51}H_{41}Cl_2N_4O_6Tl$) are given in Table 1. Measurements were made on a Siemens R3m/V diffractometer using monochromatized Mo-K_α radiation ($\lambda = 0.71073$ Å) *via* the $\theta-2\theta$ scan technique. Semi-empirical absorption corrections were applied. The range of transmission factors was 0.416–1.000. The structure was solved by direct methods (SHELXTL PLUS) and refined by full-matrix least-squares. All non-hydrogen atoms were refined with anisotropic thermal parameters, whereas all hydrogen atoms were calculated using a riding model and included in the structure factor calculations. Selected bond distances and angles are given in Table 2.

NMR spectra

Proton and ^{13}C NMR spectra were recorded at 400.13 and 100.61 MHz, respectively, on a Bruker AM-400 spectrometer in CD_2Cl_2 (or $CDCl_3$) locked on solvent deuterium, and referenced to the solvent peak. The temperature of the spectrometer probe was calibrated by the shift difference of methanol resonance in the ^1H NMR spectrum. Solid-state ^{13}C CP/MAS NMR spectra were recorded at 20°C at 50.33 MHz on a Bruker MSL-200 solid-state NMR spectrometer. Dry nitrogen gas was used to drive MAS rates of 3.6 Hz.

Preparation of Tl(tmpp)(OAc)

Free base (tmpp); 146.1 mg, 0.19 mmoles, from Aldrich) and $Tl(OAc)_3$ (236.4 mg, 0.62 mmoles) were refluxed for 5 h in 20 cm^3 of acetic acid containing sodium acetate 70.9 mg. After cooling, water (150 cm^3) was added, and the solid collected and dried by suction. The filter cake was dissolved with CH_2Cl_2 and collected by vacuum filtration. Recrystallization from CH_2Cl_2–hexane gave violet crystals (181 mg, 91.4%). The crystals were grown by diffusion of ether vapour into a $CHCl_3$ solution. It was dissolved in CD_2Cl_2 for ^1H and ^{13}C NMR measurement (shown in Tables 3 and 4).

Preparation of Tl(tmpp)Cl

Tl(tmpp)(OAc) (101.1 mg, 0.101 mmoles) was passed down an alumina column (10 g, neutral, activity I). The major purple band eluting with chloro-

form was collected and concentrated. The crystalline product obtained was purple (91.5 mg, 94.7%). It was dissolved in CD_2Cl_2 for NMR measurement at 20°C (shown in Tables 3 and 4).

Preparation of Tl(tmpp)(CN)

The compound Tl(tmpp)Cl (370 mg, 0.387 mmoles) was dissolved in $CHCl_3$ (20 cm^3). After the addition of a solution of NaCN (189.67 mg) in dry methanol (15 cm^3), the mixture was stirred for 3 days at room temperature [9], then extracted with distilled water thrice (50 × 3 cm^3). The purple crystals, Tl(tmpp)(CN), (333 mg, 90.8%) were collected by vacuum filtration and dried. It was dissolved in $CDCl_3$ for ^1H (Table 3) and ^{13}C (Table 4) NMR measurement at 20°C.

RESULTS AND DISCUSSION

Molecular structure of Tl(tmpp)(OAc)

The skeletal framework of the Tl(tmpp)(OAc) molecule is illustrated in Fig. 1. It reveals the six-coordination of the thallium atom with the four nitrogen atoms (N_p) of the porphyrinato group and the asymmetric-bidentate OAc^- ligand, the bond distances are: Tl—O(1) = 2.29(1), Tl—O(2) = 2.48(1), O(1)—C(21) = 1.19(2), O(2)—C(21) = 1.21(2), C(21)—C(22) = 1.49(2) Å and the mean Tl—N_p = 2.211(8) Å. The thallium atom lies 0.741

[a]Chemical shifts in ppm relative to the centre line of CD_2Cl_2 at 53.2 ppm or to the centre line of $CDCl_3$ at 77.0 ppm. Values in parentheses beneath are $J(Tl—^{13}C)$ coupling constants in Hz.

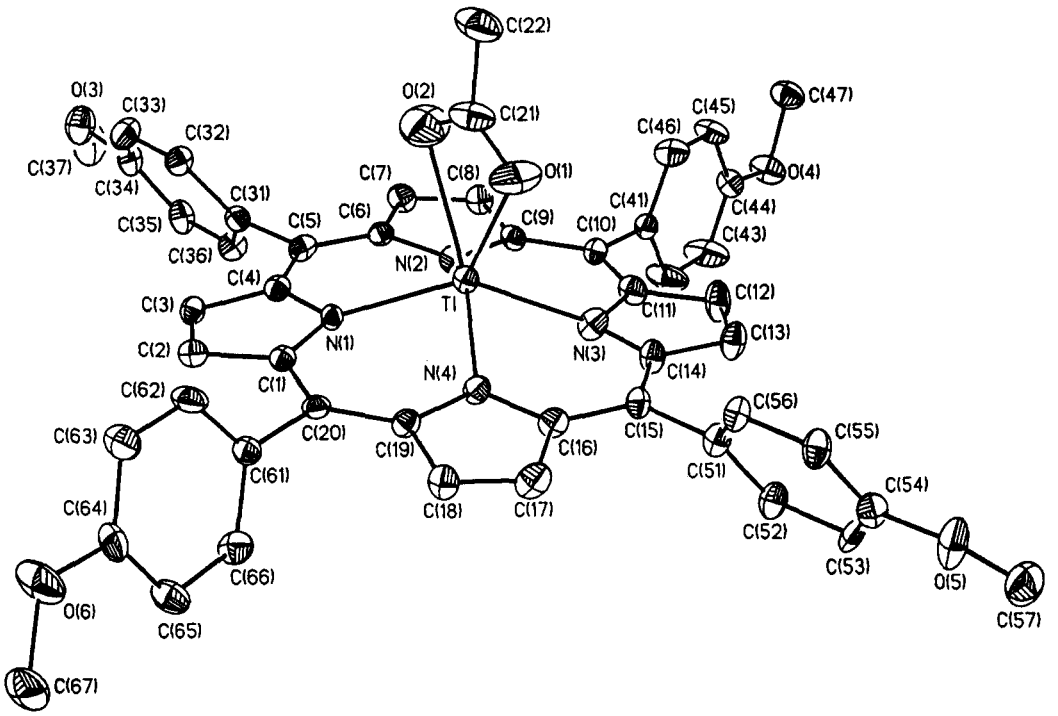
and 0.808 Å from the four porphyrin nitrogens (N_p) and the 24-atom porphyrin plane ($C_{20}N_4$), respectively, and the O(1)—Tl—O(2) bond angle is 51.2(4)°. The dihedral angles between the mean plane of the porphyrin skeleton and the mean planes of four phenyl groups are 59.6° [C(31)], 96.8° [C(41)], 59.5° [C(51)], and 110.4° [C(61)].

Hoard and co-workers [10] have calculated that the radial strain in the core of a metalloporphyrin is minimized for a "radius of the central hole" of about 2.01 Å. The radius of core size (i.e. C_t—N, the distance from the geometrical centre of the mean plane of the 24-atom core to the porphyrinato-core N atoms) of Tl(tmpp)(OAc) is 2.084 Å, which is larger than 2.01 Å. The Tl^{III} atom is bonded in a highly expanded porphyrinato core ($C_{20}N_4$) in Tl(tmpp)(OAc) and the porphyrin ($C_{20}N_4$ and Tl) can be viewed as dome shaped. Figure 2 shows the displacement (in Å) of each atom of the porphyrin ($C_{20}N_4$ and Tl) from the porphyrin mean plane ($C_{20}N_4$). The average out-of-plane displacements of the thallium, nitrogen (N_p), C_α, C_{meso}, and C_β atom are 0.81, 0.07, 0.02, 0.02, and −0.06 Å, respectively (shown in Fig. 2). This structure shows marked "doming" with atoms approximately in descending planes thallium, N_p, Cα, C_{meso}, C_β. The difference between the displacement of the metal centre from the mean plane of the four pyrrole nitrogens ($4N_p$) and the mean plane of the $C_{20}N_4$ porphyrin skeleton has been used to describe the degree of doming. The net doming is ~ 0.07 Å (≈ 0.808–0.741).

Dynamical NMR of Tl(tmpp)(OAc) *in* CD_2Cl_2

When a 0.02 M solution of Tl(tmpp)(OAc) in CD_2Cl_2 (Fig. 3) was cooled, the methyl proton signal, a single peak at 20°C (δ = 0.01 ppm) first broadened (temperature of coalescence, T_c = −49°C) and then split into two peaks with a separation of 14.2 Hz. The process is completely reversible, and the results measured at 400 MHz confirm the separation as a coupling $^4J(Tl—H)$ rather than a chemical-shift difference. This process is treated as a two-site intramolecular exchange [11], a comparison of observed and computed spectra yields $\Delta G^*_{224} = 48.4$ kJ/mol. ^{13}C NMR data for Tl(tmpp)(OAc) at 20 and −85°C is shown in Table 4. At −85°C, the rate of intramolecular exchange of OAc^- for Tl(tmpp)(OAc) in CD_2Cl_2 is 5.8 Hz. This exchange rate is slow comparable with the coupling frequency $Tl—^{13}C$, i.e. 253 ± 23 Hz. The methyl and carbonyl carbons of the acetato group are observed at 17.7 ppm [with $^3J(Tl—^{13}C) = 275$ Hz] and 173.9 ppm [with $^2J(Tl—^{13}C) = 230$ Hz], respectively. At 20°C, the intramolecular exchange rate of the acetato ligand is comparable with the coupling frequency of $Tl—^{13}C$. In this intermediate exchange region, the signals are broadened beyond detection. Hence, no signal of the axial ^{13}C has been found at 20°C.

Tl(tmpp)(OAc) does not hydrolyze in CD_2Cl_2.



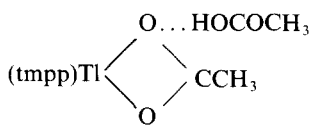


Fig. 1. Molecular configuration and atoms labelling scheme for Tl(tmpp)(OAc)·$1CH_2Cl_2$. Hydrogen atoms and solvent [C(71)H_2Cl(1)Cl(2)] are omitted for clarity.

Hence, the exchange of OAc^- for Tl(tmpp)(OAc) in CD_2Cl_2 solvent is intramolecular. If ~ 0.05 cm^3 of acetic acid (HOAc) is intentionally added to the solution of Tl(tmpp)(OAc) in CD_2Cl_2, the OAc^- exchange switches from intramolecular to intermolecular. At −90°C, the singlet peak with population 99% at 2.03 ppm corresponds to added HOAc and the other singlet peak with population 1% at −0.09 ppm is due to Tl(tmpp)(OAc). These two sets of peaks arise from the slow exchange of OAc^- between Tl(tmpp)(OAc) and HOAc. The slow exchange limit should be at temperature below −90°C. At 20°C, the sharp singlet at 1.99 ppm is due to the fast exchange of OAc^- between two compounds. This result indicates that two stages occur. The first stage is possibly a hydrogen bonding between Tl(tmpp)(OAc) and HOAc:

The other stage is a reversible intermolecular OAc^- exchange between Tl(tmpp)(OAc) and HOAc. The key step for the occurrence of intermolecular OAc^- exchange is the existence of HOAc externally added.

Solid-state ^{13}C *NMR data for* Tl(tmpp)(OAc)

Solid-state ^{13}C CP/MAS data of crystalline Tl(tmpp)(OAc) at 20°C are shown in Table 4. Eight major resonances with the methyl carbon at δ = 16.9, carbonyl carbon at δ = 173.9, *p*-O-CH_3 at δ = 55.8. *meta* carbon ($C_{3,5}$) at δ = 109.9, *meso* carbon (C_m) at δ = 122.4, $C_{1,2,6,\beta}$ at δ = 132.9, α carbon (C_α) at δ = 150.6, and *para* carbon (C_4) at δ = 158.9 ppm were observed. Both the ^{13}C chemical shift and thallium–carbon coupling constant data for the crystalline are consistent with the low-temperature solution data of Tl(tmpp)(OAc) in CD_2Cl_2 at −90°C. This provides evidence that the acetate is asymmetric-bidentate chelating to the thallium atom in CD_2Cl_2 at −90°C. As the temperature increases from −90 to 20°C, it becomes dynamical symmetric bidentate (or symmetrically pseudo-chelating) [2,12], and the acetate exchange is fast on the ^1H NMR time-scale at this temperature. This explains how the methyl protons of the apical acetate ligand were observed at 20°C as a sharp singlet at δ = 0.01 ppm, with no evidence of coupling of the thallium nuclei with the acetate group.

The intermolecular exchange of the OAc^- group is rapid for Tl(tmpp)(OAc) in CD_2Cl_2 at 20°C, whereas the rotation of the anisole group along C_1—C_{meso} bond is slow at the same temperature on the NMR time-scale. It is supported either by the assignment of 135.7, 136.3 ppm to $C_{2,6}$ carbons and 112.6, 112.5 ppm due to the $C_{3,5}$ carbons (shown in Table 4) or by the assignment of 8.22, 8.05 ppm to $H_{2,6}$ protons and 7.33, 7.28 ppm due to the $H_{3,5}$ protons (shown in Table 3) for Tl(tmpp)(OAc) at 20°C. Likewise, inequivalent *o*-H and *m*-H protons at 20°C are observed for

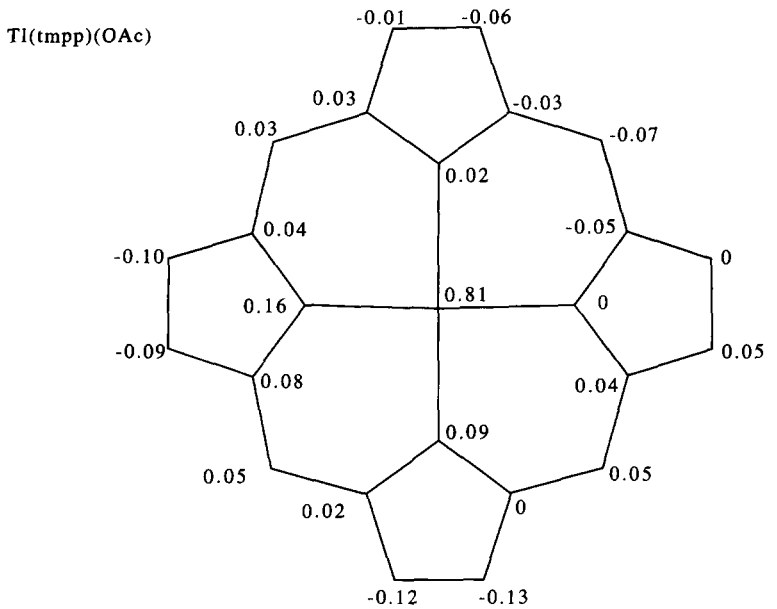

Fig. 2. Formal diagram for the porphyrin core ($C_{20}N_4$ and Tl) of Tl(tmpp)(OAc) in which each atom symbol is replaced by a number showing the displacement (in unit of Å) of that atom from the mean plane of the porphyrin ($C_{20}N_4$).

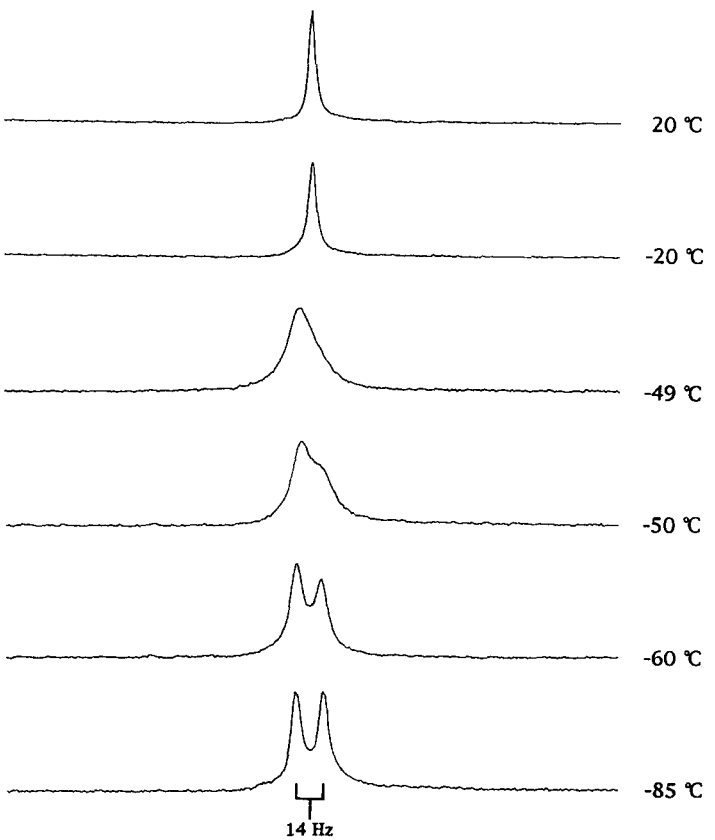

Fig. 3. 400.13 MHz ^{1}H NMR spectra for the axial acetato protons of Tl(tmpp)(OAc) in CH_2Cl_2 at various temperatures.

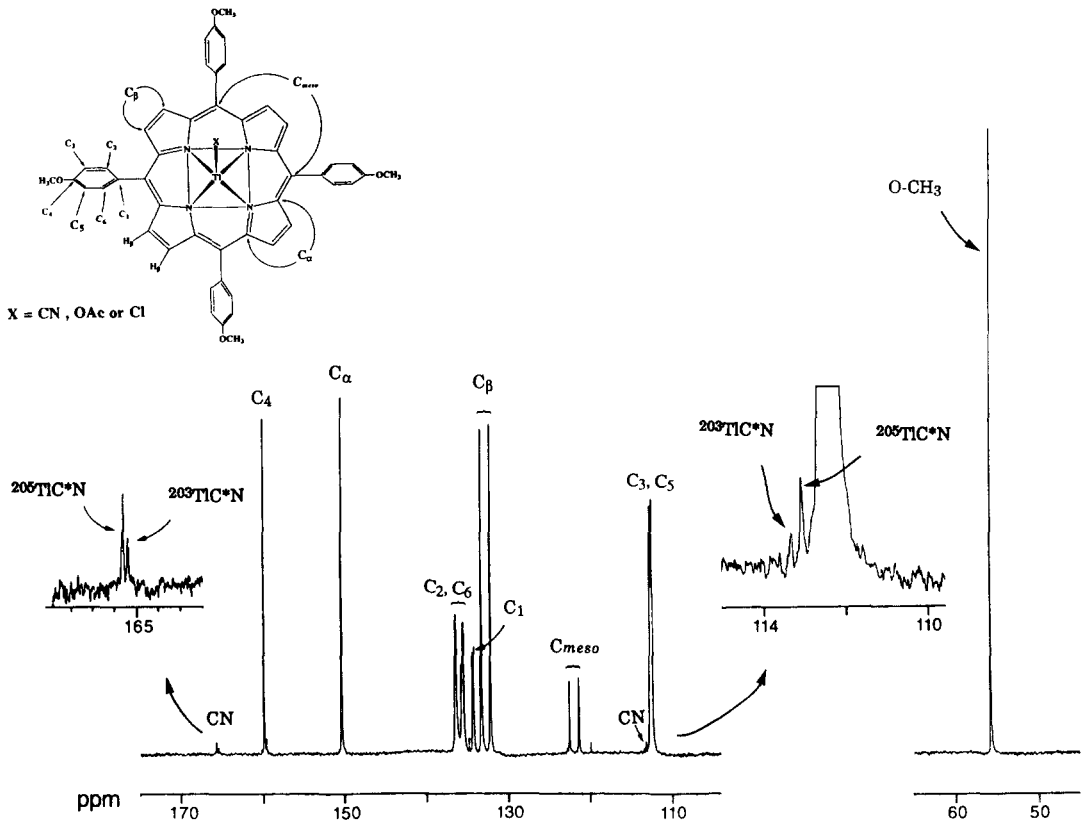

Fig. 4. 100.61 MHz ^{13}C Broad band NMR spectrum of Tl(tmpp)(CN) in $CDCl_3$ at 20°C with a pulse delay of 3.5 s.

Tl(tmpp)(OAc), Tl(tmpp)Cl and Tl(tmpp)(CN) (shown in Table 3) while the literature data appear to show average values at room temperature [6].

^{13}C *NMR for* Tl(tmpp)(CN) in solution

Figure 4 shows the representative broad band ^{13}C spectrum of Tl(tmpp)(CN) in $CDCl_3$ solvent at 20°C with a pulse delay of 3.5 s. The ^{13}C signal of CN bonded to Tl(tmpp)(CN) appears as two pairs of doublets at 165.57 and 113.02 ppm and 165.33 and 113.27 ppm for the outer and inner pairs, respectively. The outer pair arises from $^{205}Tl—^{13}C$ coupling (5287.3 Hz) and the inner one from $^1J(^{203}Tl—^{13}C)$ (5238.0 Hz). This is confirmed by noting that $^1J(^{205}Tl—^{13}C)/^1J(^{203}Tl—^{13}C) = 1.0094$, which is quite close to the theoretical value calculated from $\gamma(^{205}Tl)/\gamma(^{203}Tl) = 1.0098$. The ^{13}C chemical shifts of axial CN are upfield shift about 29.2 ppm from 168.5 ppm (obtained on saturated aqueous solution of the KCN salts) [13] to 139.3 ppm. The value of $^1J(^{203,205}Tl—^{13}C)$ obtained from Tl(tmpp)(CN) are agreeable to those obtained {5852[$^1J(^{205}Tl—^{13}C)$], 5795 [$^1J(^{203}Tl—^{13}C)$]} from Tl(tpyp)(CN) [9] and {5394[$^1J(^{205}Tl—^{13}C)$], 5344 [$^1J(^{203}Tl—^{13}C)$]} from Tl(tpp)(CN) [8].

Preparation, crystal structure, magnetic and EPR properties of a heptacoordinated manganese(II) chain of $[Mn(bipy)(H_2O)(TBD)]_n$ (H_2TBD = *trans*-2-butene diacid, bipy = 2,2′-bipyridine)

(Received 10 April 1996; accepted 5 June 1996)

Abstract—An infinite zigzag chain manganese(II) complex $[Mn(bipy)(H_2O)TBD)]_n$ (bipy = 2,2′-bipyridine; H_2TBD = trans-2-butene diacid) has been prepared and characterized by single-crystal X-ray diffraction, and magnetic measurements. The structure was solved by direct methods and refined by least-squares methods to $R(Rw)$ values of 0.031 (0.042). Each TBD is bound to two manganese(II) ions through carboxylate oxygens, affording the manganese(II) ions bridged by TBD group to yield a infinite chain running along the a axis. The intrachain Mn···Mn separation is 9.05 Å, while the shortest interchain Mn···Mn distance is 5.86 Å. The manganese(II) ion displays a distorted pentagonal bipyramid coordination by virtue of a bidentate bipyridine, two carboxylate groups of two TBD and a H_2O molecule. The variable temperature magnetic susceptibility of the title complex in the temperature range 3.3–302 K has been interpreted in terms of Heisenberg chain model with a molecular field, the values obtained for J, g and zJ' being: 0.58 cm^{-1}, 2.01, and −0.09 cm^{-1}, respectively, indicating weakly antiferromagnetic intra- and interchain exchange interactions. The x-band EPR spectrum of the complex exhibits a six-line manganese hyperfine pattern centered at $g = 2.001$, $A = 94.5$ G, together with five "forbidden" hyperfine doublets. Keywords: manganese complexes; chain complexes; crystal structures; magnetism; trans-2-butene diacid; z,z′-bipyridine.

The study of magnetic exchange interaction through extended bridging ligands has been of major interest in the field of molecular magnetism in the past few years [1]. In consideration of this reason, a number of homo- and(or) heteronuclear one-dimensional chain manganese(II) complex polymers [2–7] has been designed and synthesized, and magnetic exchange interactions of these complexes have been revealed by single crystal X-ray and magnetic analyses. However, to our knowledge, no polymeric manganese(II) complexes bridged by TBD (dianion of *trans*-2-butene diacid) ligands has been reported up to now. In the present paper we describe the preparation, crystal structure and magnetic and EPR properties of an infinite chain manganese(II) complex with bridging TBD ligand, $[Mn(bipy)(H_2O)(TBD)]_n$. This complex is also the first example of a heptacoordinated manganese(II) compound in an infinite zigzag chain.

EXPERIMENTAL

Preparations

All reagents were reagent grade and used as received. The piperidinium salt of *trans*-2-butene

diacid was prepared in the similar method to piperidinium salt of terephthalic acid [8].

$[Mn(bipy)H_2O)\ (TBD)]_n$. A methanolic solution (30 cm^3) of 2,2′-bipyridine (2.0 mmol) and piperidinium salt of *trans*-2-butene diacid (2.0 mmol) was slowly added to the solution (30 cm^3) of manganese(II) perchlorate hexahydrate (2.0 mmol) in the same solvent with continuous stirring. The light yellow powder separated during the addition was obtained by filtration. Yellow rhombohedra of the title complex suitable for X-ray analysis were obtained in a 65% yield after 2 weeks by slow evaporation of the mother-liquor at room temperature. Found: C, 49.4; H, 3.6; N, 8.2; Mn, 16.4. Calc. for $C_{14}H_{12}N_2O_5Mn$: C, 48.9; H, 3.5; N, 8.2; Mn, 16.0%.

Physical measurements

Magnetic measurements on powder samples were carried out with a CF-1 type extracting sample magnetometer in the temperature range 3.3–302 K, and corrections for the diamagnetism of the title complex was estimated from Pascal's constants to be -175.0×10^{-6} cm^3/mol. The X-band EPR spectrum was recorded with a Bruker ER 200D-SRC spectrometer in MeOH/DMF solution at 110 K, employing X-band radiation and cylindrical cavity with 100 KHz magnetic field modulation. Calibrations of the microwave frequency were performed with an EIP 845A microwave frequency counter.

X-ray crystallography

Diffraction data were collected at 293(1) K on a Rigaku AFC7R four-circle diffractometer with graphite monochromated Mo-K_α radiation (λ = 0.71069 Å) and a 12 kW rotating anode generator. Details of the crystallographic data collection and structure refinement are listed in Table 1. The cell parameters were determined from least-squares refinement of the setting angles of 22 reflections in the range $23.45 < 2\theta < 26.67°$. A total of 2769 reflections were collected using the ω-2θ scan technique to a maximum 2θ value of 50.0°. The intensities of three representative reflections were measured after every 200 reflections. Over the course of data collection, the standards decreased by −0.5%. A linear correction factor was applied to the data to account for this phenomenon. The linear absorption coefficient, μ, for Mo-K_α radiation is 9.4 cm^{-1}. An empirical absorption correction based on azimuthal scans of several reflections was applied which results in transmission factors ranging from 0.67 to 1.00. The data was corrected for Lorentz and polarization effects. The structure was solved by direct methods and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically, while hydrogen atoms were refined isotropically. The final cycle of full-matrix least-squares refinement was based on 1874 observed reflections ($I > 3.00\sigma(I)$) and 248 variable parameters and converged with unweighted and weighted agreement factor of $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.031$, $Rw = [\Sigma w(|F_o| - |F_c|)^2/\Sigma F_o^2]^{1/2} = 0.043$. The standard deviation of an observation of unit weight was 1.46. The maximum and minimum peaks on the final difference Fourier map corresponded to 0.28 and −0.32 $eÅ^{-3}$, respectively. All calculations were performed using the TEXSAN crystallographic software package of Molecular Structure Corporation.

RESULT AND DISCUSSION

Structure description

Selected bond lengths and angles are listed in Table 2. The structure of the title complex consists of infinite zigzag chains of $[Mn(bipy)\ (H_2O)\ (TBD)]_n$ (Figs 1 and 2). One of the independent structure units is shown in Fig. 1 together with the atom-numbering scheme. The TBD (dianion of *trans*-2-butene diacid) group acts as a tetrakis (monodentate) ligand which is bound on each side to one manganese(II) ion through the carboxylate oxygens in a *syn* configuration yielding a chain which runs parallel to the *a* axis of the orthorhombic cell, as shown in Fig. 2. The intrachain Mn···Mn separation is 9.05 Å, while the shortest interchain Mn···Mn distance is 5.86 Å. These infinite zig-zig chains are cross-linked by O—H···O hydrogen bonds, involving water O(5) with symmetry related O(2*) and O(3*) (* denotes the symmetry

operation x, $1/2-y$, $z+1/2$), as shown in Fig. 2. The hydrogen-bonding parameters are listed in Table 2.

Every Mn^{II} ion is heptacoordinate and possesses an N_2O_5 ligand environment by virtue of four oxygen atoms of two TBD ligands, two nitrogen atoms of one bipyridine and one oxygen atom of a coordinated water molecule. The manganese(II) ion displays a distorted pentagonal bipyramid with the approximate equatorial plane defined by O(1), O(2), O(3), O(4) and N(2) atoms and the Mn(II) ion is 0.046 Å out of this plane. The Mn—O average length is 2.285 Å, which is slightly longer than those of hexacoordinate Mn^{II} complex, and the Mn—N average distance (2.275 Å) is similar to those in reported manganese(II) complexes [9,10]. The bond angles of O(1)—Mn—O(2) [55.66(7)°] and O(3)—Mn—O(4) [56.49(6)°] in the equatorial plane deviate from 72°, which are restricted by the four-membered chelate rings. Similarly the large deviation from the idealized orthogonal geometry is found at the Mn atom in the five-membered Mn—N(1)—C(9)—C(10)—N(2) chelate ring [71.70(8)°] as expected due to the small bite distance of the bipyridine ligand [6,11]. The all carbon and nitrogen atoms of the bipy ligand are coplanar with deviations from the mean plane not greater than ±0.06 Å.

Magnetic and EPR properties

The temperature dependence of the molar magnetic susceptibility and magnetic moment per 1 Mn ion unit of the title complex in the form of χ_M *vs* T (μ_{eff} *vs* T) is shown in Fig. 3(a, b). the effective magnetic moment at 302.51 K is 5.95 B.M. which is in accord with the spin-only moment (5.92 B.M.) in the absence of any exchange interaction for Mn^{II} ions. Upon cooling, the value of μ_{eff} remains unchanged down to about 52 K (5.93 B.M.), then it decreases very slowly from 5.91 B.M. at 47 K to 5.74 B.M. at 15.45 K, below 15 K it decreases rapidly to 3.59 B.M. at 3.32 K, thus showing the presence of a very weakly intrachain antiferromagnetic exchange interaction. The decrease of the μ_{eff} below 15 K may be attributed to an interchain antiferromagnetic interaction and/or a zero-field splitting of the Mn^{II} ion.

Owing to the large spin of Mn^{II}, the data in the low-dimensional regime may be fitted with the expression calculated by Fisher for a classical-spin Heisenberg chain [12,13], scaled to a real spin $S = 1/2$:

$$\chi_M = [2Ng^2\mu_{B2}S(S+1)/3kT] \times (1-U)/(1+U) \quad (1)$$

where $U = -\coth K + 1/K$, $K = J(S+1)/kT$, and the exchange Hamiltonian is written as $H = -JS_iS_j$.

A molecular field correction [14,15] was added to account for the actual nature of the compound. Thus the expression for the magnetic susceptibility of the title complex becomes:

$$\chi_M = \chi_M/[1-2zJ'\chi_M/Ng^2\mu_B^2]. \quad (2)$$

Using eq. (2), a very close agreement with experiment is obtained with $J = -0.58$ cm^{-1}, $g = 2.01$, $zJ' = -0.09$ cm^{-1} and $R = 1.35 \times 10^{-3}$ [$R = \Sigma(\chi_{calc} - \chi_{obs})^2/\Sigma(\chi_{obs})^2$]. The magnetic susceptibility calculated by using the fit parameters is shown as the solid line in Fig. 3(a).

The weakly magnetic exchange interaction through bridging TBD ligands with a large intramolecular Mn···Mn separation (*ca* 9.05 Å) is consistent with those of other Mn^{II} and Co^{II} complexes bridged by terephthalate or isophthalate ligands ($J = -1.04 \rightarrow$

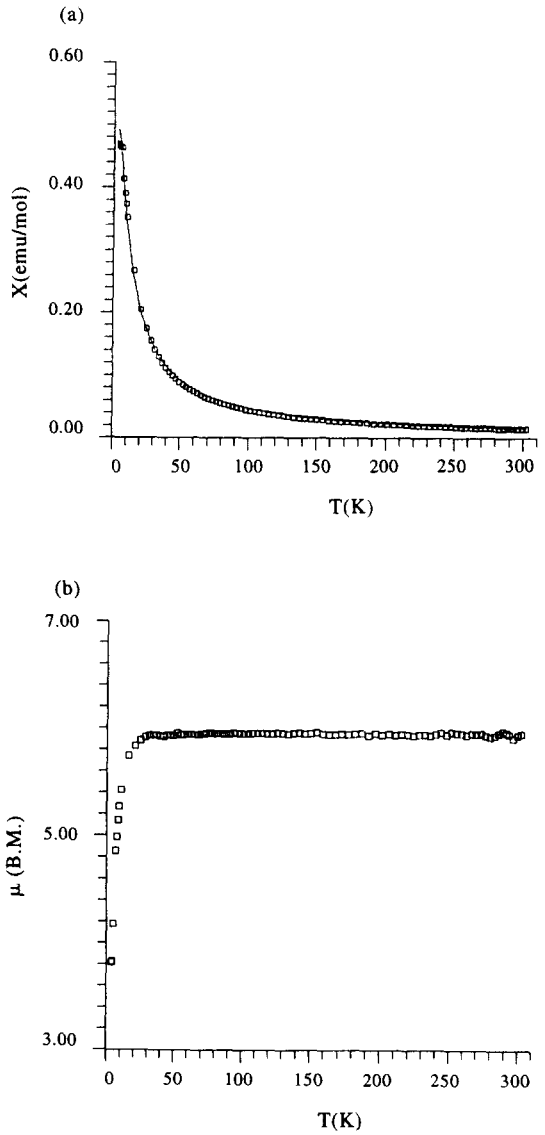

Fig. 3. (a) The Plot of $X-T$ for the title complex. The solid line represents best fit of data according to eq. (2). (b) Plot of μ_{eff} *vs* T for the title complex.

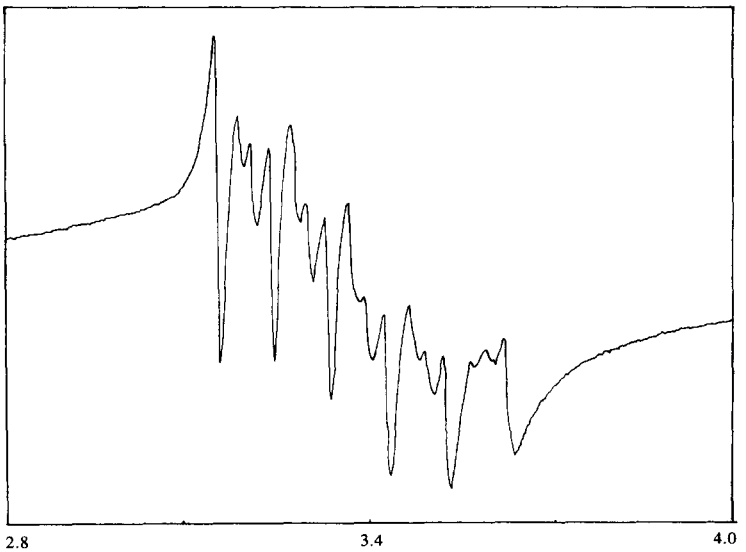

Fig. 4. X-band EPR spectrum for the title complex.

0.53 cm^{-1}) [16–19]. Despite the weakness of the exchange interaction, the fact that the magnetic data can be described without considering other factors as single-ion zero-field splitting and/or the local anisotropy or Mn^{II} ion, suggests that their effects are negligible as can be seen in other case [11].

The X-band EPR spectrum was measured in dilute frozen MeOH/DMF solution at 110 K. The spectrum (Fig. 4) exhibits a six-line manganese hyperfine pattern centered at $g = 2.001$, $A = 94.5$ G, which is that expected of an odd unpaired electron system ($S = 5/2$), $m_s = \pm 5/2, \pm 3/2, \pm 1/2$; and $I = 5/2$, $m_I = \pm 5/2, \pm 3/2, \pm 1/2$) with the g, A tensors isotropic, resulting from "allowed" transitions ($\Delta m_s = \pm 1$, $\Delta_I = 0$) [11,20]. Besides, between every adjacent pair of the "allowed" six hyperfine lines of the $g \sim 2$ resonance there is a pair of relatively weak "forbidden" ($\Delta m_s = \pm 1$, $\Delta m_I = \pm 1$) transitions [21, 22]. The average separation of the "forbidden" hyperfine doublets in the spectrum is 23.25 G.

(Received 23 February 1996; accepted 5 June 1996)

Abstract—The crystal structure of the β-$(NiL_2)Br_2$ (L = S-methylisothiosemicarbazide, $C_2H_7N_3S$) complex was solved on the basis of X-ray diffraction data. It was established that the central Ni^{II} atom has a square-planar coordination, with the four nitrogen atoms of two chelate ligands. In the case of $[NiL_2]X_2$ (X = Br, I) the crystallographic data for the Ni—N bond length, together with the experimentally obtained values for frequencies of electronic *d–d* transitions represented the basis for the calculation of the ionization potentials H_{dd}, constants of partial population of *s* and *p*, as well as the charge *q* of the Ni^{II} ion in these complexes. In addition, the energies of the electronic *d* levels of Ni^{II} were calculated and the most probable MO scheme has been constructed. Published by Elsevier Science Ltd

Keywords: transition metal complexes; square-planar Ni^{II}; crystal structure; electronic spectra; orbital energy; MO scheme.

This work represents a continuation of our experimental and theoretical studies of Ni^{II} complexes with different ligands [1,2]. The synthesis of the investigated complexes of the formula $[NiL_2]X_2$ (L = S-methylisothiosemicarbazide, X = Br, I) has been reported earlier [3], as well as the structure of the $[NiL_2]I_2$ complex [4]. In the case of the $[NiL_2]Br_2$ complexes two crystal modifications: triclinic (α) and orthorhombic (β) were established. The crystal and molecular structure of α-$[NiL_2]Br_2$ has been reported elsewhere [5], whereas the structure of β-$[NiL_2]Br_2$ complex is the subject of the present work. Also, the calculation of the energies of the Ni^{II} electronic states and the most probable MO scheme are presented.

EXPERIMENTAL

Physical measurements

The crystal structure was solved from three-dimensional intensity data collected on an Enraf-Nonius CAD-4 diffractometer using Mo-K_α radiation (λ = 0.071069 nm), monochromatized with a graphite crystal and the ω-2θ scan mode. Of the 956 unique reflections recorded in the range $3 \leqslant 2\theta \leqslant 50°$, 730 reflections with $F_o \geqslant 4\sigma$ (F_o) were included in the crystal structure analysis ($0 \leqslant h \leqslant 4, 0 \leqslant k \leqslant 23$, $0 \leqslant l \leqslant 14$) and refinement (9 atoms, 73 parameters), $w = 1.5799/\sigma^2(F_o)$. No absorption correction was applied. All calculations were carried out using SHELX-76 program [6].

The crystal data are: orthorhombic, *P*bnm,

S—C(1)—N(2)	114.8(5)	116.0(12)	113.9(11)

$a = 0.4399(3)$, $b = 1.9663(4)$, $c = 1.5293(4)$ nm, $V = 1.3228(2)$ nm^3, $Z = 4$, $D_0 = 2.21$ g cm^{-3}, $D_c = 2.25$ g cm^{-3}.

The positions of Br and Ni atoms were determined from the three-dimensional Patterson function; the coordinates of the other atoms were found from electron density maps. Both Ni and Br atoms occupy special positions of the *P*bnm space group, the remaining atoms are located in general position. The structure was refined anisotropically by the least-squares routine to an R value of 0.059 (R_w was 0.052). Hydrogen atoms have not been located. Bond distances and angles are given in Table 1.

Reflectance spectra were measured in the 10,000–45,000 cm^{-1} range at room temperature using a monochromator SPM-2 (Veb Zeiss, Jena) with a R-45/0 type reflection cell. MgO was used as "white" standard.

CALCULATION OF THE ENERGIES OF Ni^{II} ELECTRONIC STATES

Spectral investigations [7] have afforded experimental values of the electronic *d–d*, intraligand (IL) and charge-transfer (CT) transitions (Table 2). These values represented the basis for calculation of the energies of molecular orbitals of the investigated complexes.

The energies of electronic states b_{1g}, a_{1g}, b_{2g} and e_g of the d level of square-planar Ni^{II} complexes were calculated by solving the secular equation [8]:

$$|H_{ij} - WG_{ij}| = 0$$

where G_{ij} represents the group overlap integral, and H_{ij} is the exchange integral which can be expressed in terms of Coulomb integral H_{jj} and group overlap integral G_{ij} as:

$$H_{ij} = F\left(\frac{H_{ii} + H_{jj}}{2}\right)G_{ij}.$$

The group overlap integrals can be calculated on the basis of the two-atom overlap integral, S, taken from the tables [9], and they represent a function of the parameters p and τ:

$$p = \frac{1}{2}(\mu_A + \mu_B)\frac{R}{R_0}, \quad \tau = \frac{\mu_A - \mu_B}{\mu_A + \mu_B}$$

where R_0 represents the first Bohr radius, and μ_A and μ_B (the index A stands for the N atoms of the surroundings, and B is referred to the Ni^{II} atom) are the exponents of the radial part of the Slater wave functions [10]. On the basis of the solved crystal structures, the parameter p was calculated taking an average value for the Ni—N bond distance $\bar{R}_{Ni-N} = 1.898$, 1.907 and 1.889 Å for [NiL$_2$]I$_2$, α-[NiL$_2$]Br$_2$ and β-[NiL$_2$]Br$_2$, respectively. The values of parameters p and τ thus obtained, as well as the two-atom overlap integrals, are presented in Table 3.

The group overlap integrals, calculated on the basis of the two-atom overlap integrals are presented in

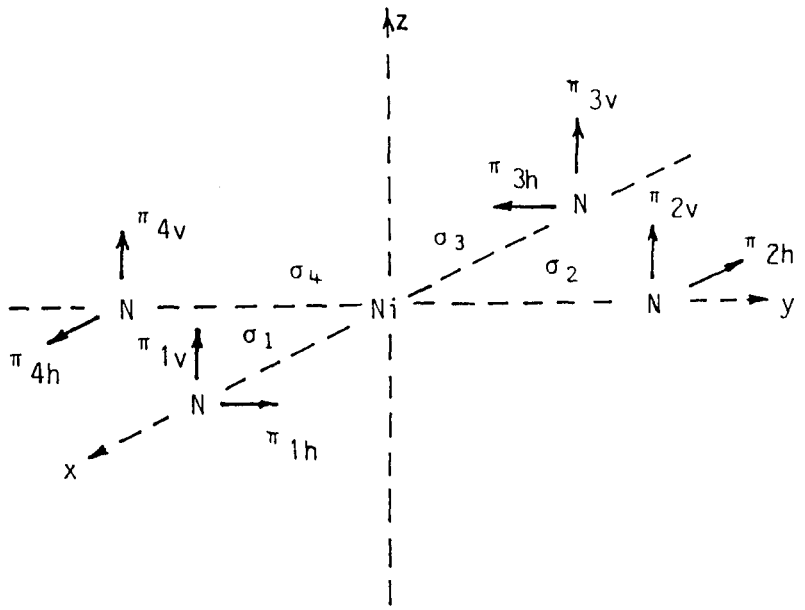

Fig. 1. Coordinate system for σ- and π-molecular orbitals for square planar Ni^{II} complexes.

Table 4, whereas in Fig. 1 is presented the coordinate system of square-planar Ni^{II} complexes.

The Coulomb integral H_{jj} was approximated by the ionization potential of the N atoms of the Ni^{II} surroundings, and $H_{ii} = H_{dd}$ was calculated on the basis of the relation:

$$H_{dd} = \mathrm{d(VSIE)} = (1-s-p)(\mathrm{dVSIE}: d^n) + s(\mathrm{dVSIE}: d^{n-1}s) + p(\mathrm{dVSIE}: d^{n-1}p)$$

where VSIE stands for the valence state ionization energies [10]. On the basis of this procedure we calculated the matrix elements $H_{ij}(b_{1g})$, $H_{ij}(b_{2g})$, $H_{ij}(a_{1g})$ and $H_{ij}(e_g)$, as well as the energies of the corresponding d-levels of Ni^{II} presented in Table 5. The experimental values of the frequencies of d–d transitions (Table 2) enabled the calculation of the constants of partial population of s and p, as well as of q for Ni^{II} in the investigated complexes. By a reverse iterative calculation, the more exact values of ionization energies H_{dd}, i.e. of the electronic energies of the d levels, were calculated. The process was repeated until the calculated values agreed with the experimental ones within the limits of experimental errors.

DISCUSSION

Crystal structure of β-[NiL$_2$]Br$_2$ complex

The crystal structure consists of the centrosymmetric complex cation of the type $[NiL_2]^{2+}$ and

bromine anions, where L is S-methylisothiosemicarbazide bonded to the Ni ion as a chelate *via* two N atoms, from both the amine and hydrazine groups. The complex cation is formed by two S-methylisothiosemicarbazide moieties in a *trans* position, planarly coordinated to the Ni atom (Fig. 2). This can also be inferred from the diamagnetic behaviour of the complex [7]. The *imido* form of the S-methylthiosemicarbazide ligand, which is a characteristic for the majority of the S-alkyl derivatives of thiosemicarbazides and thiosemicarbazones [11], has also been confirmed. The electronic charge density is well localised along the N(1)—C(1)—N(2) fragment as indicated by the values of the bond distances C(1)—N(1) and C(1)—N(2). The similar bond distances in the same fragment were also found in related structures of bis(S-methylthiosemicarbazide) nickel(II)iodide [4]. Bond distances and angles of the β-$[NiL_2]Br_2$ are given in Table 1 and compared with corresponding values of similar compounds α-$[NiL_2]Br_2$ and $[NiL_2]I_2$ [4,5]. The Ni–N bond distances are similar to those found in the similar planar complexes with the same ligand [4,5]. No Ni—Ni bonding interactions were observed and the Ni atom did not exhibit the tendency of assuming an octahedral surrounding. The complex cations are also well separated from the bromine anions, and none of the distances are shorter than 0.365 nm.

The energies of Ni^{II} *electronic states*

The orbitals of the metal atom participating in the formation of σ-bonding MO in the square-planar Ni^{II} complexes are $3d_{z^2}$, $3d_{x^2-y^2}$, $4s$, $4p_x$ and $4p_y$. As the contribution of the atomic orbitals to the formation of molecular orbitals is proportional to the atomic orbital overlap, which is expressed by the value of the group overlap integral, it is evident from Table 4 that the contribution of the $3d_{x^2-y^2}$ orbital to σ molecular orbitals is much greater than that of the d_{z^2} orbital.

The a_{2u} π molecular orbital is formed by overlapping of the Ni^{II} orbital with four π_v ligand orbitals of the N-surroundings, (Fig. 1) giving the so-called "ring" π^b orbital, which stabilizes the square-planar coordination of the metal ion in these complexes. The ionization potential of the N atoms of the ligand is $\simeq 13.2$ eV (106×10^3 cm^{-1}), and the energies $e_g(\pi^*)$, $a_{1g}(\sigma^*)$ of the d levels of Ni^{II} are $\simeq 12.4$ eV and 12.2 eV, respectively. Since the $a_{2u}(\pi^*)$ level is stabilized by the empty $4p_z$ metal orbital, and if $3d_{xy}$, $3d_{yz}$, $3d_{yz}$ and $3d_{z^2}$ are weakly antibonding, the bands at 30.8×10^3 and 34.0×10^3 cm^{-1} can be ascribed to charge-transfer transitions of the metal-ligand type, between the d-orbital of the Ni^{II} and the π^* orbital of the N atom. The experimentally obtained energy difference of 41.2×10^3 cm^{-1} corresponds to the transition between the ligand $a_{2u}(\pi^b)$ and $a_{2u}(\pi^*)$ levels, which is in agreement with the results of our calculations. The results obtained by calculating the energies of the molecular orbitals (Table 5) show that the distance between the $b_{1g}(\sigma^*)$ and $b_{2g}(\pi^*)$ levels is greater than the difference between the $b_{2g}(\pi^*)$ and $a_{1g}(\sigma^*)$ levels, and much greater than the distance of the $a_{1g}(\sigma^*)$ and $e_g(\pi^*)$ levels. This indicates that $d_{x^2-y^2}$ orbital, which has the highest energy with respect to all other d-orbitals, takes part in formation of four dsp^2 hybrid orbitals, which are then involved in bonding with ligand N-atoms [12].

The values obtained for the energies of the corresponding MO's are in agreement with the square-planar coordination of the four N atoms of the first coordination sphere, as well as with the crystallographic data about the Ni—Cl and Ni—Br bond length, which exclude the possibility of formation of a distorted octrahedron. The calculated MO energies are fully consistent with the experimental data obtained from electronic spectra, giving the exact difference between the one-electron molecular orbital levels, and resulting in the most probably MO scheme presented in Figure 3.

Degradative oxidation of D-ribono-1,4-lactone by Cr^{VI} in perchloric acid

S. Signorella, S. Garcia and L. F. Sala*

Area Inorgánica, Facultad de Ciencias Bioquímicas y Farmacéuticas (UNR), Suipacha 531, 2000 Rosario, Argentina

(Received 16 January 1996; accepted 5 June 1996)

Abstract—The oxidation of D-ribono-1,4-lactone by Cr^{VI} yielded D-erythronic acid, erythrose, carbon dioxide and Cr^{III} as final products when a 15-fold or higher excess of sugar over Cr^{VI} was used. The kinetics of the redox processes involving the Cr^{VI}/Cr^{III} couple were determined and a mechanism is proposed. The complete rate law for the Cr^{VI} oxidation reaction is expressed by: $-d[Cr^{VI}]/dt = \{a[S]+b[S][H^+]+c[H^+]^3\}\ [Cr^{VI}]_T$, where $a = 3.09\times10^{-3}\ M^{-1}\ s^{-1}$, $b = 4.98\times10^{-2}\ M^{-2}\ s^{-1}$, $c = 1.07\times10^{-3}\ M^{-3}\ s^{-1}$ and S refers to the total reductant concentration, at 60°C. Cr^{V} is formed in a fast step by reaction of the CO_2^- radical and Cr^{VI}, and Cr^{V} reacts with the organic substrate faster than Cr^{VI} does. The EPR spectra show that the intermediate Cr^{V} complex (g = 1.978) is formed and decays by a first-order process. Copyright © 1996 Elsevier Science Ltd

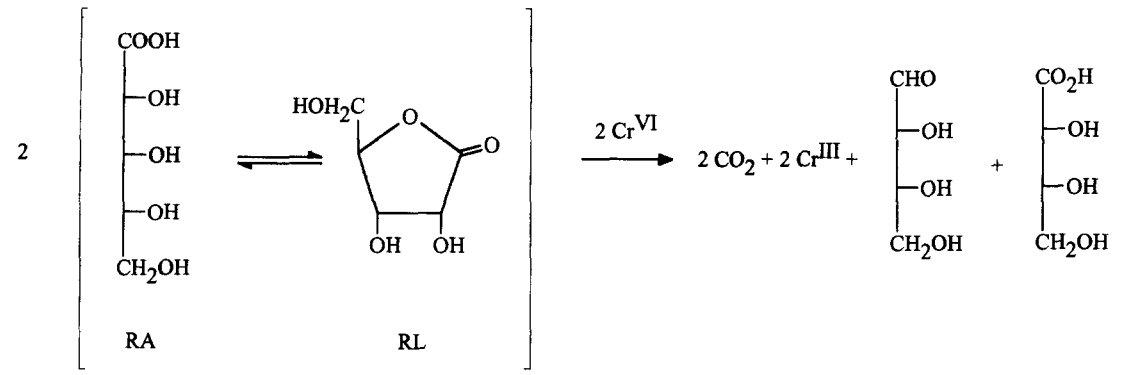
Keywords: ribonolactone; chromium; oxidation; kinetics; mechanism; Cr^{V}; Cr^{VI}.

Hexavalent chromium, in many different compounds, is a well established carcinogen and mutagen [1–4]. There is, therefore, appreciable interest in determining the mode of action of chromium species derived from initial uptake of Cr^{VI} compounds [5]. Ligands that possess two oxygen atoms able to form five-membered rings about the metal atom, such as 1,2-diols and α-hydroxyacids are reported to stabilize Cr^{V} intermediates after further interaction with biological reductants [6–10]. For this reason, some sugars, or their derivatives, may play an important role in the chemistry of Cr^{VI}. Aldonic acids (or their lactones) have been found as metabolic intermediates in animals, plants and microorganisms, as products of the action of microorganisms on carbohydrates and as constituents of acidic polysaccharides [11].

As part of a general project dealing with the interaction of carbohydrates and transition metal ions, we have studied the reaction of Cr^{VI} with low molecular weight model reductants [12–20].

Chromic oxidation of α-hydroxyacids has been extensively studied [12,21–26]. These oxidations may yield products coming from either C—C [12, 23–26] or C—H, [22,26] depending on the particular molecular characteristics, through mechanisms involving either two-electron or three-electron initial oxidation of substrate by Cr^{VI}. Polyhydroxyacids offer additional binding sites to form the chromic ester precursor of the slow electron-transfer steps and might help to elucidate stereoelectronic effects affecting the reaction course [26]. In this paper we report the results obtained in our investigation of the chromic oxidation of D-ribono-1,4-lactone (RL) (Scheme I) in perchloric acid.

EXPERIMENTAL



Materials

D-Ribono-1,4-lactone (sigma grade), potassium dichromate (Cicarelli c.a), perchloric acid (P.A. Merck), acrylonitrile (Aldrich grade) and sodium perchlorate (Sigma grade) were used without further purification.

Spectrophotometric measurements

Kinetic measurements were made at 350 nm by monitoring the absorbance changes on a Guilford Response II spectrophotometer with fully thermostated cell compartments. Pseudo-first-order rate constants, determined from the slope of ln(Abs) *vs*

Scheme I.

time, were deduced from multiple determinations and were within ±5% of each other. In most experiments the concentration of Cr^{VI} was kept constant at 7.75 10^{-4} M while the RL was varied from 0.0116 to 0.062 M. Mixtures of sodium perchlorate and perchloric acid were used to maintain a constant ionic strength of 1.0 M.

Disappearance of Cr^{VI} was followed until at least 80% conversion. Reactant solutions were previously thermostated and transferred into a cell of 1 cm path length immediately after mixing. Experiments were performed at 60°C unless otherwise mentioned.

The acid : lactone proportion of the reductant in the starting solution was calculated by optical rotation measurements at given hydrogen ion concentrations [27]. Table 1 shows the composition of the substrate solution at different perchloric acid concentrations. Ribonic acid (RA) is the major form in solution over the whole acid concentration range (0.2–1.0 M $HClO_4$), and as expected, the lactone proportion increases with increasing [$HClO_4$]. In order to confirm that no cooxidation process occurs at the primary hydroxy group, RL was methylated at C-5OH to yield the 5-O-methyl-D-ribono-1,4-lactone (MRL) [29]. The chromic oxidation of MRL and RL affords the same k_{obs} values, under the same reaction conditions.

Product analysis

Under conditions employed in the kinetic measurements (ratios of RL over Cr^{VI} from 15/1 to 80/1) qualitative identification of D-erythronic acid (EA) and erythrose as the reaction products was carried out by paper chromatography. EA and erythrose were identified against authentic samples using *n*-butanol/acetic acid/water (4 : 1 : 5) as eluent. Paper chromatograms were visualized by two kinds of development reagents: a three-stage dip of silver nitrate, sodium hydroxide and sodium thiosulfate [30] and *p*-anisidine reagent [31]. Under these conditions, carbon dioxide was detected and the quantitative determination of this gas afforded 1 mole of CO_2 per mole of Cr^{VI}.

Test for free radicals

A solution of potassium dichromate (1.16×10^{-3} M) in 1 cm^3 of 0.5 M $HClO_4$ was added to a mixture of 1.16×10^{-3} M RL in 0.5 M $HClO_4$ (2 cm^3) and acrylonitrile (0.5 cm^3) at 20°C. After 20 min a white precipitate of a polymer slowly appeared. Blank experiments in the absence of organic substrate or

oxidant agent did not show formation of any such precipitate.

EPR measurements

EPR spectra were recorded with a Bruker spectrometer model ER-200. Spectra were acquired at a frequency of *ca* 9.8 GHz with a center field of 3500 G, a swept width of 100–1000 G and variable modulation amplitude. The cavity and sample tube were kept at 25°C. Initial Cr^{VI} concentration in all the EPR measurements was 7.75×10^{-4} M.

RESULTS AND DISCUSSION

Over the whole range of perchloric acid concentrations used in the kinetic measurements, spectrophotometric studies showed that the reaction of RL and Cr^{VI} resulted in an absorbance band at 350 nm and a shoulder at 420–500 nm characteristic of the $Cr_2O_7^{2-}$ ion. It is known that Cr^V species, usually formed in these oxidation reactions, absorb at 350 nm and may superimpose Cr^{VI} absorbance yielding the wrong interpretation of spectrophotometric absorbance decay values [22]. However, if Cr^V reacts faster than Cr^{VI} and exists in solution in a sufficiently small concentration, changes in absorbance at 350 nm essentially reflect changes in Cr^{VI} concentration. We observed deviations from first-order decay over very short time periods and we calculated pseudo-first-order rate constants from the slopes of the linear part of the ln(Abs) *vs* time curves; a good criterion only if Cr^V decays faster than Cr^{VI}. The relative values of the Cr^{VI} *vs* Cr^V oxidation rates constants obtained from the Cr^V EPR signal intensities during the reaction course (discussed below) demonstrate this is the case for the present reaction.

Unlike that observed for the chromic oxidation of gluconic acid [16], in the present case, Cr^V was not detected spectrophotometrically at 750 nm under conditions used in the kinetic experiments. Fortunately, it could be easily detected by EPR measurements. The reaction of Cr^{VI} with excess RL generates an EPR spectrum dominated by a single detectable sharp signal at $g_{iso} = 1.978$ (Fig. 1 inset (a)), typical of five-coordinate oxochromate(V) complexes [32,33]. The Cr^V signal grows and decays with time to yield the broad Cr^{III} signal ($g_{iso} = 1.981$) as the ultimate fate of chromium in this reaction (Fig. 1 inset (b)). Figure 1 shows a curve for peak-to-peak heights of Cr^V EPR signal *vs* time obtained on a reacting solution. Values of the rates of disappearance of Cr^{VI} (k_6) and Cr^V (k_5), respectively, may be calculated by eq. (1) [12,16], which fits well the experimentally observed Cr^V intermediate growth and decay curve in Fig. 1.

$$h = Ak_6\{\exp(-k_5t) - \exp(-2k_6t)\}/(2k_6 - k_5). \quad (1)$$

It has been shown that any rate profiles dealing with the build up and decay of an intermediate by first order processes can be described by a pair of solutions having the same numerical values for the rate constants, but with the order of the assignment reversed [34]. For conditions stated in Fig. 1, $k_6 = 8.35 \times 10^{-5}\ s^{-1}$ and $k_5 = 0.00768\ s^{-1}$ and the time of maximum Cr^V concentration, $T_{max} \approx 8.5$ min. We have chosen this assignment for the rate constant values and not the reverse one, for several reasons. In the EPR measurements, the temperature is lower than that used in the spectrophotometric experiments. Since the redox rates increase when the temperature rises, k_6 obtained from EPR data (at 25°C) should be lower than values obtained from the spectrophotometric measurements at 60°C (a value of 0.00768 exceeds all the k_{obs} values in Table 3). Besides, we have evaluated $k_{obs}(2k_6)$ spectrophotometrically at 25°C under conditions used in the EPR experiments, and we have reproduced the $k_{obs}(2k_6)$ value (the value obtained by this technique, for conditions in Fig. 1, is: $1.84 \times 10^{-4}\ s^{-1}$). Thus, the fact that k_5 is 91 times higher than k_6 justifies our initial assumption that changes in absorbance at 350 nm essentially reflect changes in Cr^{VI} concentration.

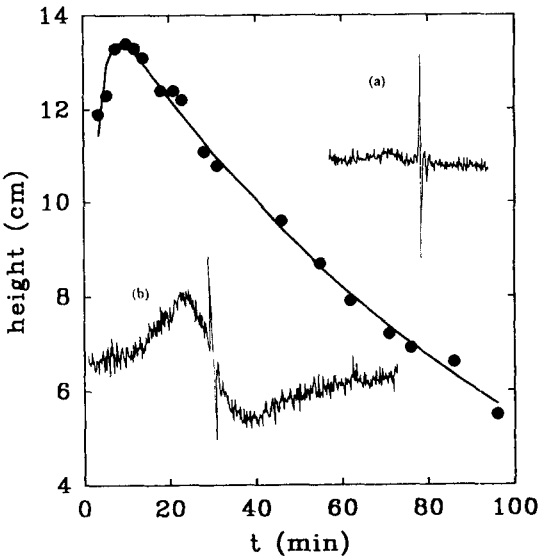

Fig. 1. Peak-to-peak heights of Cr^V EPR signals *vs* time [*S*] = 0.039 M; $[Cr^{VI}]_0 = 7.75 \times 10^{-4}$ M; $[HClO_4] = 1$ M; $T = 25$°C. Inset: (a) Cr^V EPR signal recorded at $t = 5$ min; (b) superimposition of Cr^V and Cr^{III} EPR signals as Cr^{III} builds up during the run ($t = 35$ min).

In order to verify the dependence of rate upon Cr^{VI}, pseudo-first order rate constants were calculated at various $[Cr^{VI}]_0$ ($4–26 \times 10^{-4}$ M) but at constant temperature, [RL], $[H^+]$ and ionic strength (Table 2). The rate constant was found to increase with increasing $[Cr^{VI}]_0$. However, values of $k_{obs}[Cr^{VI}]_0/[Cr_2O_7^{2-}]$ at various $[Cr^{VI}]_0$ were found to be constant, meaning that the dimeric species, *viz.* $Cr_2O_7^{2-}$, is the effective oxidant. The equilibrium $HCrO_4^-/Cr_2O_7^{2-}$ ($K = 76$) [35] was used to calculate $[Cr_2O_7^{2-}]$, neglecting the

Table 2. Effect of oxidant on the oxidation of ribonolactone. [RL] = 0.08 M; $[HClO_4]$ = 1 M; T = 35°C

$10^4[Cr^{VI}]_0$/M	$10^3 k_{obs}[Cr^{VI}]_0/[Cr_2O_7^{2-}]$

26	13.7

subsidiary equilibrium $HCrO_4^-/CrO_4^{2-}$ because of the high $[HClO_4]$ employed.

Table 3 summarizes values of k_{obs} for various concentrations of RL at fixed concentrations of perchloric acid. Plots of k_{obs} *vs* [RL+RA] ([*S*]) (Fig. 2) gave straight lines with a positive intercept from which values of k_1 and k_2 were determined (Table 4). Dependence of k_1 and k_2 with $[HClO_4]$ is shown in Fig. 3 and may be expressed by:

$$k_1 = a + b[H^+], \quad (2)$$

$$k_2 = c[H^+]^3, \quad (3)$$

where $a = 3.09 \times 10^{-3}$ M^{-1} s^{-1}, $b = 4.98 \times 10^{-2}$ M^{-2} s^{-1}, $c = 1.07 \times 10^{-3}$ M^{-3} s^{-1}.

The complete rate law is then given by:

$$-d[Cr^{VI}]/dt = k_{obs}[Cr^{VI}]_T = (k_1[S] + k_2)[Cr^{VI}]_T =$$

$$\{(a + b[H^+])[S] + c[H^+]^3\}[Cr^{VI}]_T, \quad (4)$$

where [*S*] refers to the total organic substrate concentration: RL+RA.

experimental kinetic law well, is proposed in Scheme II.

In this mechanism we have assumed that the open carboxylic acid is the reactive form of the organic substrate. This assumption is based on previous findings showing the enhanced ability of hydroxyacids to bind Cr^{VI} and Cr^{V} [21–26]. In any case, a possible mechanism involving the lactone may not be discarded. However, if the lactone was the reactive form of the organic reductant, coordination of Cr^{VI} should be favored at the pair of *syn* hydroxyl groups of the molecule, C(2)—OH and C(3)—OH [36]. The intermediate complex formed in this way might be present in the equilibrium mixture but should not be a direct precursor of the slow redox steps. Opening of the lactone ring and rearrangement should be required for the slow electron-transfer steps to take place within a complex with the carboxylate bound to Cr^{VI}.

Thus, the first step of the proposed mechanism may be interpreted as the formation of a monochelate with RA acting as a bidendate ligand bound to Cr^{VI} at C(1)—O and C(2)—O to yield the anionic species $[(RA)(O)_2(OH_2)CrOCrO_3]^{2-}$ (A^{2-}). This intermediate, or its monoprotonated form (AH^-), may decompose to the products in the presence of a second RA molecule, whereas the diprotonated form (AH_2) yields the products through an acid catalyzed step. We propose here that redox paths involving either the anionic or neutral complexes, are three-electron steps, just as observed for the chromic oxidation of mandelic acid [23], and Cr^{III} is formed with the oxidation products.

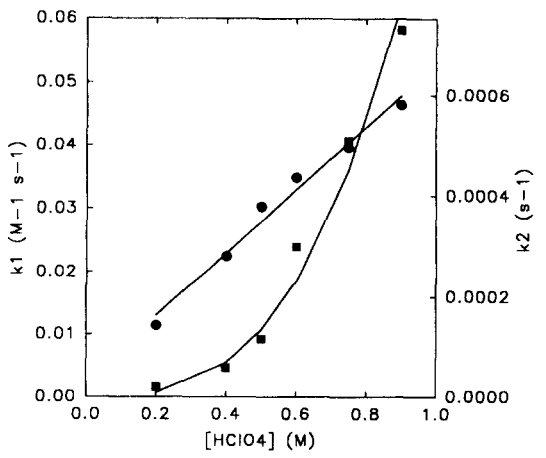

Fig. 3. Effect of acidity on k_1 and k_2.

If A^{2-}, AH^- and AH_2 are formed in rapid equilibria, the rate law corresponding to this mechanism may be expressed as:

$$v = -d[Cr^{VI}]/dt$$
$$= \{k_1K_1[RA]^2 + k_2K_2K_1[RA]^2[H^+] + k_3K_3K_2K_1[H^+]^3[RA]\}[Cr_2O_7^{2-}]. \quad (5)$$

Since

$$[Cr^{VI}]_T = [Cr_2O_7^{2-}]\{1 + 1/K_d + K_1[RA] + K_1K_2[RA][H^+] + K_1K_2K_3[H^+]^2[RA]\}. \quad (6)$$

Replacing $[Cr_2O_7^{2-}]$ in eq. (6)

$$v = \{k_1K_1[RA]^2 + k_2K_2K_1[RA]^2[H^+] + k_3K_3K_2K_1[H^+]^3[RA][Cr^{VI}]_T\} \times \{1 + 1/K_d + K_1[RA] + K_1K_2[RA][H^+] + K_1K_2K_3[H^+]^2[RA]\}^{-1}. \quad (7)$$

If $K_1[RA]$ is the largest term in the denominator (a reasonable assumption since K_1 corresponds to a complex formation constant while K_2 and K_3 are protonation ones), eq. (7) will be simplified to the experimentally observed form:

$$v = \{k_1[RA] + k_2K_2[RA][H^+] + k_3K_3K_2[H^+]^3\}[Cr^{VI}]_T. \quad (8)$$

Equation (8) may be expressed as a function of the total organic substrate concentration:

$$v = \{(k_1[S] + k_2K_2[S][H^+])K_h/(1 + K_h) + k_3K_3K_2[H^+]^3\}[Cr^{VI}]_T. \quad (9)$$

Polymerization after addition of acrylonitrile supports the formation of $^{\cdot}CO_2^-$ radicals. These radicals formed in the slow steps may react with Cr^{VI} to yield Cr^{V} and carbon dioxide:

$$^{\cdot}CO_2^- + Cr^{VI} \overset{fast}{\rightarrow} CO_2 + Cr^{V}. \quad (10)$$

Finally, Cr^{V} may react with excess substrate to yield erythrose, carbon dioxide and Cr^{III} in a two-electron step:

$$Cr^{V} + RA \overset{fast}{\rightarrow} CH_2OH(CHOH)_2CHO + CO_2 + Cr^{III}. \quad (11)$$

CONCLUSIONS

The present results indicate that the oxidation of RA occurs by a Cr^{VI}/Cr^{III} three-electron path yielding erythronic acid and the $^{\cdot}CO_2^-$ radical; followed by a $Cr^{VI}/Cr^{V}/Cr^{III}$ one-electron/two-electron path, leading to erythrose and carbon dioxide. This mechanistic proposal fits the experimental kinetics well and explains the products detected after the reaction completion, when an excess of sugar acid over Cr^{VI} is used. The present results are consistent with those obtained for a number of reported α-hydroxy acids chromic oxidations [12,23–26]. However, a reactant structure/cleaved bond type relation may not be easily rationalized upon comparison with other polyhydroxy acids. In the case of gluconic acid, C2—H break occurs through a two-electron transfer process [16] and the α-keto-acid is the only reaction product. On the other hand, galactonic acid yields lyxonic acid and carbon dioxide as products [37]. It seems reasonable to suggest that the relative C2, C3, C4 configuration influences the reaction course. Thus, the C2, C3, C4 *ribo* configuration behaves as the *arbino* (in galactonic acid) but different from the *xylo* (in gluconic acid). Even when any conclusive explanation may not be given at present, we think that after studying the chromic oxidation of a number of sugar acids of the same carbon-chain length it will be possible to find correlations between the structure of the reactants and the type of bond cleavage.

Abstract—The sequential substitution of two $Fe(CO)_3$ groups in $[(\mu\text{-H})_2Fe_3(\mu_3\text{-Se})(CO)_9]$ with isolobal fragments $CpW(CO)_2$ (the first stage) and $CpMo(CO)_2$ (the second stage) has been shown to result in the title heterotrimetal cluster $[FeMoW(\mu_3\text{-Se})(CO)_7Cp_2]$. Its structure and the structure of its $[FeW_2(\mu_3\text{-Se})(CO)_7Cp_2]$ analog obtained previously have been determined by X-ray analysis. Copyright © 1996 Elsevier Science Ltd

Keywords: iron; molybdenum; selenium; tungsten; heterometallic clusters; synthesis; crystal and molcular structure.

The directed synthesis of heterometal clusters containing three or more different transition metals is one of the most interesting and important, but complicated problems of modern cluster chemistry [2]. One approach to this problem is the sequential metal substitution in homometal clusters and their heteronuclear derivatives. For example, in the last two decades many heterotrimetal complexes were obtained when the compounds $[(\mu\text{-H})_2Fe_3(\mu_3\text{-S})(CO)_9]$ and $[FeCo_2(\mu_3\text{-S})(CO)_9]$ were used as the starting reagents [2–4]. In this work an analogous approach has been shown to be useful for the parent selenide iron cluster $[(\mu\text{-H})_2Fe_3(\mu_3\text{-Se})(CO)_9]$ (**I**).

EXPERIMENTAL

The reaction of $[(\mu\text{-H})Fe_2W(\mu_3\text{-Se})(CO)_8Cp]$ (**II**) with $[CpMo(CO)_3]_2$ was carried out under argon; the other manipulations were performed in the air. All solvents were distilled from appropriate drying agents. The IR spectra were recorded on the Bruker IFS85 spectrometer. The NMR spectra were recorded on Bruker SXP-4-100 (^1H at 90 MHz) and CXP-300 (^{77}Se at 57.3 MHz) spectrometers. The chemical shift of ^{77}Se (positive downfield) was referenced to the saturated water solution of H_2SeO_3 as an external standard and counted relative to dimethylselenide [1]. Complexes **II** and $[FeW_2(\mu_3\text{-Se})(CO)_7Cp_2]$ (**III**) were obtained by a slight modification of the method recently described [1].

Synthesis of 1,1,2,2,3,3,3-heptacarbonyl-1,2-bis-(η^5-cyclopentadienyl)-(1,2,3,μ_3-selenido)-triangulo-tungsten-molybdenum-iron

Compound **I** (0.12 g, 0.18 mmol) and $[CpMo(CO)_3]_2$ (0.17 g, 0.35 mmol) in *m*-xylene (5 cm^3) were refluxed for 8 h and the volatiles then removed *in vacuo*. The solid residue was extracted with several portions of $CHCl_3$ and concentrated *in vacuo*. The mixture of soluble products thus obtained was separated by TLC on "Silufol" plates (hexane–benzene in a 3:2 ratio). Four major fractions were collected:

(4) The dark red fraction: trace amounts of **III**.

X-ray structure determination

The structures of **III** and **V** were determined by X-Ray analysis. Single crystals were prepared by the slow diffusion of pentane into toluene solutions of these compounds (Table 1). Absorption corrections were applied using the integration method on crystal shape. The structures were solved by direct methods ("SHELXS-86") [6] and refined by the full-matrix least squares method on F^2 using all independent reflections ("SHELXL-93") [7]. Hydrogen atoms were refined in the rigid body approximation (C—H distance is 0.96 Å). It has been found that in the structure of **V**, Mo and W positions were not located and both M(1) and M(2) contain a Mo/W mixture. After a final refinement M(1) and M(2) was found to be 34.3(5)% W+65.7(5)% Mo and 65.7(5)% W+34.3(5)% Mo, respectively. Atomic coordinates and thermal parameters are deposited in the Cambridge Crystallographic Database. Molecules of **III** and **V** are shown in Figs 1 and 2 with selected bond distances in the captions. Crystal packing is shown in Fig. 3.

RESULTS AND DISCUSSION

Synthesis and spectroscopy

Cluster **I** was recently shown to react with the dineric complexes $[CpM(CO)_3]_2$ (M = Mo, W) in *m*-xylene at the boiling point of the solvent resulting in metal substituted derivatives formation. [1,5] Now we have found that the first-step tungsten substituted produce **II** can be used to obtain the heterotrimetal cluster **V** in an analogous manner (Scheme 1).

III, **V** and **IV** can be considered as a series of clusters obtained by the sequential substitution of the group $CpW(CO)_2$ with $CpMo(CO)_2$. Their IR spectra ($CHCl_3$ solution) are very similar, but there are some differences in the peak locations and the intensity ratio.

The ^{77}Se NMR spectra of those complexes show signals for μ_3-Se. It is interesting that their chemical

(I) **(II)** **(V)**

Scheme 1.

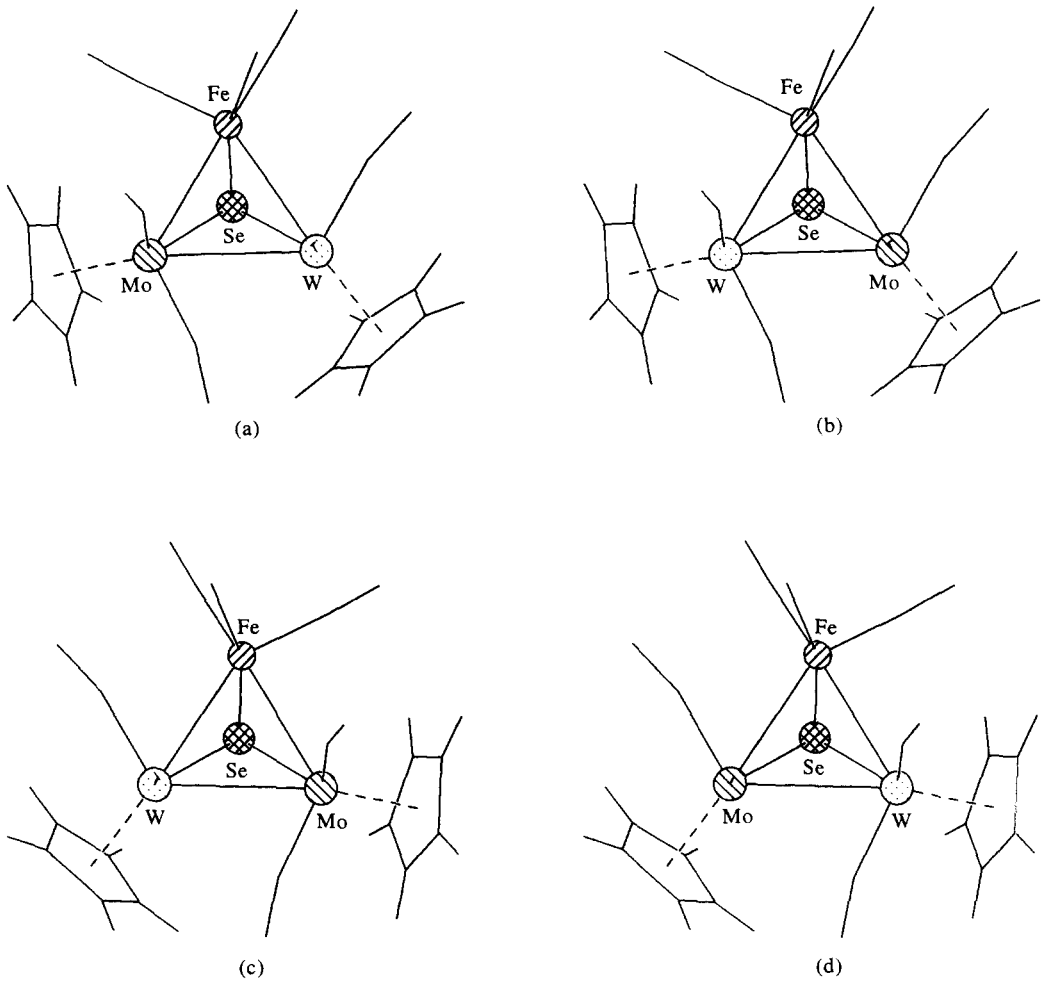

Fig. 4. Four isomers of cluster **V** occurring in the crystalline state shown in a common orientation: μ_3-Se atom is situated over the FeM(1)M(2) plane. Isomers **a** and **b** (as well as **c** and **d**) occupy a common crystallographic position giving a Mo/W disorder.

shifts are additively increased in the row: **III** ($\delta = -51$ ppm) [1], **V** ($\delta = 183$ ppm) and **IV** ($\delta = 421$ ppm)* [5]. In each step the $\Delta\delta$ values are nearly equal: 234 and 238 ppm, respectively.

The ^{1}H NMR spectrum of **V** contains two singlet signals for protons of two Cp ligands bonded to W and Mo. Their chemical shifts (see Experimental Section) are approximately the same as those in the cases of **III** [5.31 ppm] [1] and **IV** [5.28 ppm] [5].

Crystal and molecular structures of **III** *and* **V**

X-Ray structural analysis has shown **III** and **V** to be isostructural. They are also isostructural to one of the two known polymorphous modifications of [$FeMo_2$ (μ_3-Se) $(CO)_7Cp_2$] (**IV**) [8], but differ in the crystal packing from the other one [5]. Also the structures of two analogous sulfide clusters [FeW_2 (μ_3-S) $(CO)_7Cp_2$] (**VI**) [9] and [$FeMo_2$ (μ_3-S) $(CO)_7$ (η^5-$CH_3C_5H_4)_2$] (**VII**) [10] are known.

From our point of view the most interesting feature of **III, IV, VI** and **VII** is an unexpected chirality of their molecules in the crystalline state resulting from the ligands disposition asymmetry: these clusters have pseudo mirror symmetry within the tetrahedral FeM_2 (μ_3-X) core and at the same time have no symmetry in the ligand arrangement (Fig. 1). The latter fact causes the formation of two optical isomers related by crystallographic symmetry operations: the inversion and glide reflection (Fig. 4).

In the case of **V** the situation is more interesting: in addition to a ligand disposition asymmetry the tetrahedral FeMoW(μ_3-X) core has no symmetry elements. Therefore, in theory, **V** would exist in the crystalline state as a mixture of four isomers resulting from the combination of these two chirality types (Fig. 4). Molybdenum and tungsten atoms have been determined to be statistically distributed in the M(1) and (2) positions (Fig. 2). Based on the ^{77}Se NMR and IR spectra

* All ^{77}Se NMR spectra were recorded for CH_2Cl_2 solutions of clusters.

of **V** and the result of chromatography separation results (see previous sections), we can conclude that **V** is an individual compound but not a mixture of **III** and **IV**. Therefore, X-ray data can be interpreted in the following manner: all four isomers of **V** occur in a crystal as the statistically distributed blocks of enantiomer pairs **V(a,c)** and **V(b,d)** (see Figs 3 and 4) in a 34.3 : 65.7 ratio. This occurs because Mo and W are closely related in size. The bond distances in **III** and **V** are very close. The M(1)—M(2) bond in **V** is slightly longer than W(1)—W(2) that in **III** due to the presence of the Mo atoms in M positions. In **III** as well as in **V**, the M—Se distances are virtually equal for M(1) and M(2).

CONCLUSION

The method which we have used to obtain clusters **II**–**V** is based on the cooperative degradation of both reaction partners at a high temperature resulting in a new cluster core formation. It is not predictable *a priori* and requires an experimental testing for each new object. In this work this approach has been shown to have some success in the case of the selenide iron carbonyl clusters as well as in the case of a number of parent compounds containing other μ_3-coordinated non-transition elements [2,3].

(Received 8 February 1996; accepted 22 May 1996)

Abstract—The title compound, $[(DMNP)_4SiW_{12}O_{40} \cdot 2DMF]$ (DMNP = 4-dimethylamino-1-methylpyridylammonium; DMF = N,N-dimethyl formamide) has been synthesized from $(TBA)_4SiW_{12}O_{40}$ (TBA- = tetrabutylammonium) and DMNP iodide in acetonitrile. The compound crystallized in $P2_1/n$ space group from DMF solution, and was characterized by elemental analysis, XPS study, IR, ESR and electronic spectra. X-ray structure analysis confirmed the presence of the Keggin structure of $SiW_{12}O_{40}^{4-}$. The sites of four oxygen atoms bonded to Si atom are disordered over 8 possible locations in each anion in the crystal, which increases the symmetry of the polyanion. The bond distances of Si—O and W=O are 1.636(5)–1.655(5) and 1.632–1.726 Å, respectively. Copyright © 1996 Elsevier Science Ltd

Keywords: X-ray structure; charge-transfer; Keggin structure; DMNP; donor; acceptor.

The design and synthesis of new magnetic molecular materials based on charge-transfer (CT) compounds has been developed rapidly in recent years [1–3]. These materials are made up of organic donors such as tetrathiafulvalene (TTF) and its derivatives and inorganic acceptors derived from the polyoxometalates whose structures are made by association of MO_6 (M = Mo, W) octahedra [4,5]. These polyanions present a field of interest because of their reversible high electron-acceptor capabilities such as the Keggin structure $[(XM_{12}O_{40})^{n-}$, M = W, Mo; X = P, Si, Ge ...] and Dawson structure $[(X_2M_{18}O_{62})^{n-}$, M = W, Mo; X = P, Si, As ...], which also keep their gross structures [6]. We focus our investigations on polyanions having the Keggin structure. This paper deals with the preparation and characterization of a CT compound obtained from the reaction with DMNP and the tetrabutyl ammonium salt of $SiW_{12}O_{40}^{4-}$.

EXPERIMENTAL

Materials

All chemicals were procured commercially and used without subsequent purification. The polyoxometalate $(TBA)_4SiW_{12}O_{40}$ was synthesized according to the procedure described earlier [7]. The DMNP iodide was prepared by the literature method.

Synthesis of $(DMNP)_4SiW_{12}O_{40} \cdot 2DMF$

In 50 cm^3 acetonitrile solution, $(TBA)_4SiW_{12}O_{40}$ (0.3 mmol, 1.15 g) and the DMNP iodide (1.2 mmol, 0.422 g) were mixed and refluxed for 2 h. After cooling to room temperature, the yellow precipitates were filtered by suction and washed several times by acetonitrile. Yield: 0.98 g, 95%. The yellow crystals of the title complex were obtained by recrystallization in

DMF. Found: C, 12.5; H, 1.6; N, 3.8. Calc. for $C_{38}H_{66}N_{10}O_{42}SiW_{12}$: C, 12.8; H, 1.8; N, 3.9%.

Measurements

Elemental analysis was performed on a Perkin-Elmer 240C analytical Instrument. The IR spectrum was recorded on a Nicolet FT-IR 170SX spectrophotometer with KBr pellet. The XPS was performed on a VG ESCALAB MK-II. The low temperature powder ESR spectrum was obtained on a Bruker 2000D-SRC spectrometer.

Crystallography

Data collection. A prismatic crystal of size $0.22 \times 0.28 \times 0.30$ mm was used for data collection on Siemens P4/PC diffractometer with graphite monochromated Mo—K_α ($\lambda = 0.71073$ Å) radiation using ω scan type with variable scan speed of 4.0–29.30° min^{-1}. Three standard reflections were measured every 100 reflections. No absorption correction was made. From a total of 12,767 reflections measured for $4.0 \leqslant 2\theta \leqslant 50.0°$ ($-16 \leqslant h \leqslant 16$, $-24 \leqslant k \leqslant 24$, $-18 \leqslant l \leqslant 0$), 7144 were independent and 3638 reflections were considered observed using the criteria $F > 6.0\sigma(F)$.

Structure solution and refinement. The structure was solved by direct methods using Siemens SHELXTL P4/PC and refined by full-matrix least-squares. All non-hydrogen atoms were refined anisotropically. All the hydrogen atoms were refined using the riding model with fixed isotropic thermal parameter U. The final reliability factors were $R = 0.072$, $R_w = 0.0962$. The weighting scheme is $w = 1/[\sigma^2(F) + 0.0055F^2]$. All computations were performed on an IBM compatible 486/DX2 personal computer. The high R value is due to the poor crystal and disorder of the anion. The crystal data are summarized in Table 1. The final atomic coordinates and thermal parameters, together with observed and calculated structure factors, have been deposited as supplementary material with the Editor, from whom copies are available on request.

RESULTS AND DISCUSSION

IR spectrum

The IR data of the title compound and $(TBA)_4SiW_{12}O_{40}$ are shown in Table 2. It can be seen that the related vibration bands of the polyoxometalate remain almost unchanged in the title complex, ν(W—Od) from 967.6 to 969 cm^{-1}, ν(Si—Oa) 919 cm^{-1} [unchanged], ν(W—Ob—W) 884 to 883 cm^{-1}, and ν(W—Oc—W) 792 to 791 cm^{-1} [7]. This suggests that the interaction between organic donor and polyoxoanion is very weak, which can be verified by UV spectra in DMF solution that has only one strong absorption near 290 nm and no charge-transfer band appears.

UV spectra

Figure 1 compares the UV spectra of the title compound and $(TBA)_4SiW_{12}O_{40}$ in DMF solution. The only one strong absorption band appeared at 290 nm which is a characterization band of $SiW_{12}O_{40}^{4-}$ polyanion [4]. The spectra indicates that the organic cation is a weak donor, and the $SiW_{12}O_{40}^{4-}$ is a weak acceptor. The interactions between the polyoxometalate and DMNP are very weak, and the title complex is almost entirely dissociated in solution [6]. This result agrees with the IR spectra.

ESR spectra

The low temperature ESR spectra of the title compound irradiated by Hg lamp for 1 h is displayed in Fig. 2. The appearance of the Mo^V signal is because small amounts of molybdenum (from the raw materials, about 0.005%) are always contained in the polytungstate. They behave as selective electron traps under reducing conditions. The signal of $g_\parallel = 1.912$, $g_\perp = 1.933$, is ascribed to Mo^V [4]. The ESR signal of polytungstosilicate was not observed in the spectra, which may be due to the fact that the signal from the 12-tungstate blues rapidly decreased in intensity without broadening significantly and were unobservable as the temperature was raised [8].

XPS study

The XPS data of related compounds for W_{4f}, Si_{2p}, and O_{1s} are shown in Table 3. The yellow title compound turned into grey-blue in the course of being irradiated under the 500 W Hg lamp. From Table 3, it can be seen that the XPS data of W_{4f}, Si_{2p} and O_{1s} in the title compound are 35.6, 101.9 and 530.7 eV, respectively. The core electron binding energies are higher, 0.3, 0.4 and 0.3 eV respectively than those in $(TBA)_4SiW_{12}O_{40}$. The related binding energies of irradiated compound are higher at 0.6, 0.2 and 0.5 eV than those in the unirradiated title compound. The above results are not consistent with the earlier reports [9,10], but similar to the compounds of TTF and its derivatives [11]. Further work is being carried out on this case.

Structural studies

Selected bond distances and bond angles are listed in Tables 4 and 5, respectively. The diagram rep-

Scheme 1.

resentation of the cation DMNP is given in Scheme 1. The view of the molecule and polyoxoanion structure of the title compound and its atomic numbering are shown in Fig. 3. A stereoview of the packing diagram viewed down the *Y* axis is given in Fig. 4. The X-ray

analysis of the complex indicates the presence of the Keggin structure for the polyoxometalate. The silicon atom is in the centre of the polyanion and the four oxygen atoms of the SiO_4 tetrahedron are disordered. Every oxygen atom has two equal sites, O(7) and O(7A), O(8) and O(8A), O(7′) and O(7′A), O(8′) and O(8′A). The relevant Si—O bond lengths are 1.655(5), 1.635(5), 1.644(6) and 1.649(5) Å, respectively. The bond distances of the polyoxometalate are in the range of 1.632(6)–1.731(4) Å for the terminal oxygen, 1.726(3)–2.082(5) Å for the bridging oxygens, and 2.289(5)–2.482(6) Å for the oxygens of the SiO_4 group. The shortest bond distances of W—O in the anion is W(1)—O(1) 1.632(6) Å, and the longest W—O bond length W(5)—O(8) is 2.482(6) Å, which indicate the severe distortion of the WO_6 octahedra in the polyanion. The bond lengths and angles relating to the organic cation are normal and are not discussed further. In the crystal structure, the large spherical polyoxometalate anions and DMNP cations form an interval layer arrangement along the [010] direction. The DMNP cations act as interstitial species at specific sites. The part of positive charge in the organic donor is closer to the polyoxoanion. The organic cation has two kinds of arrangement in the unit cell. One type has a compact parallel alignment in the form of head-to-head and tail-to-tail. The other four cations located on both sides of the polyoxoanion formed an overlapping head-to-head arrangement, respectively. Planes of the two kinds of cations have certain dihedral angles. The shortest contact distances between the cation and polyoxoanion are O(6)—C(6) 3.11 Å and O(2)—C(6) 3.37 Å, which suggest that the interaction may occur in the organic donor and inorganic acceptor.

(Received 7 May 1996; accepted 20 May 1996)

Abstract—The reaction of $[Cp'TaCl_4]$ ($Cp' = C_5H_4Me$) with $KPPh_2(dioxane)_2$ (1 : 1) in diethyl ether at room temperature gave the phosphanido-bridged tantalum(III) complex $[Cp'Ta(\mu\text{-}PPh_2)(PPh_2)]_2$ (**1**)$\cdot C_7H_8$ as black crystals. $[Cp'TaCl_4]$ reacted with 2,4,6-triisopropylphenylphosphine with formation of the adduct $[Cp'TaCl_4\{PH_2(2,4,6\text{-}Pr^i_3C_6H_2)\}]$ (**2**). Attempts to eliminate HCl from **2** with DBU (DBU = 1,8-diazabicyclo-[5,4,0]-undec-7-ene) gave the phosphinidene-bridged tantalum(IV) complex $[Cp'TaCl\{\mu\text{-}P(2,4,6\text{-}Pr^i_3C_6H_2)\}]_2$ (**3**)$\cdot C_7H_8$. It was shown independently that DBU acts as a base and as a reducing agent. **1**–**3** were characterized spectroscopically (IR, MS, NMR) as well as by crystal structure determinations. Copyright © 1996 Elsevier Science Ltd

Keywords: methylcyclopentadienyl tantalum complexes; phosphide ligand; phosphanido ligand; phosphinidene ligand.

Organometallic dialkyl- and diarylphosphanido complexes of early transition metals have been studied intensively, while complexes derived from functionalised phosphines which exhibit a reactive phosphorus-ligand bond have been largely neglected [1]. It was recently shown that Zr [2] and Mo [3] complexes react with primary phosphines or alkali metal phosphanides to yield a wide variety of products, whose formation depends on the nature of the organic substituents on phosphorus and the transition metal. The zirconocene derivatives with functionalised phosphorus-based ligands exhibit remarkable reactivity; thus, substitution of the P-based ligand by polar or protic reagents, and insertion of multiply-bonded inorganic or organic systems into the metal–phosphorus bond are observed [2]. The latter yields novel functionalised phosphorus ligands in the coordination sphere of the transition metal that are not available by other routes.

We have now extended our work on zirconocene [2] and molybdenum [3] chemistry to cyclopentadienyl tantalum complexes to investigate the influence of the nature of the transition metal on the reactivity observed in reactions with primary phosphines and alkali metal phosphanides. While the P—Si or P—H bond in zirconium complexes is generally less reactive

† Dedicated to Professor Hans Georg von Schnering, on the occasion of his 65th birthday.

§ Author to whom correspondence should be addressed.

[2], we expect this bond to be more reactive when the P ligand is coordinated to a group 5 or 6 metal; thus, modification of the ligand should be possible.

To date, only a few phosphanido derivatives of organometallic [4] and inorganic [5,6] tantalum compounds and two stable terminal phosphinidene complexes [6,7] have been described in the literature, although potential starting materials such as cyclopentadienyl-substituted tantalum halides, alkyls, hydrides or carbonyls [8] are accessible, as are inorganic tantalum halides [9].

We now report the synthesis of a tantalum phosphanido complex $[Cp'Ta(\mu\text{-}PPh_2)(PPh_2)]_2$ (**1**) ($Cp' = C_5H_4Me$), as well as the preparation of the first organometallic tantalum complex with a *primary* phosphine ligand $[Cp'TaCl_4\{PH_2(2,4,6\text{-}Pr^i_3C_6H_2)\}]$ (**2**). The latter can be utilised as starting material for the synthesis of the tantalum phosphinidene complex $[Cp'TaCl\{\mu\text{-}P(2,4,6\text{-}Pr^i_3C_6H_2)\}]_2$ (**3**).

RESULTS AND DISCUSSION

Synthesis and properties of $[Cp'Ta(\mu\text{-}PPh_2)(PPh_2)]_2$ (**1**)$\cdot C_7H_8$

Phosphanido complexes of tantalum are rare. Thus, $[Cp_2TaH_2(PPh_2)]$ was mentioned as an intermediate in the formation of the diphosphene complex $[Cp_2TaH(\eta^2\text{-}P_2Ph_2)]$ in 1989 [4a], but it was only in 1995 that its synthesis and spectroscopic details were reported [4c]. Another monophosphanido complex, $[Cp^*TaMe(\eta^2\text{-}C_2H_4)(PPh_2)]$ ($Cp^* = C_5Me_5$), which is accessible from $[Cp^*TaMe_2(\eta^2\text{-}C_2H_4)]$ and $PHPh_2$, was reported in 1993 [4b]. Hydrogenation of this complex in the presence of $PHPh_2$ gives the tris-phosphanido complex $[Cp^*TaH(PPh_2)_3]$. Both complexes exhibit fluxional behaviour at room temperature [4b].

Our attempts to utilise the salt elimination reaction as a synthetic approach to tantalum(V) phosphanido complexes were thwarted due to the high reducing potential of alkali metal phosphanides. Thus, the reaction of $[Cp'TaCl_4]$ with $KPPh_2(dioxane)_2$ (1 : 1) in ether afforded after work up black, rhombic crystals of $[Cp'Ta(\mu\text{-}PPh_2)(PPh_2)]_2$ (**1**)$\cdot C_7H_8$, which could be handled in air for a short time without decomposition. Similar to the reaction of cyclopentadienyl-substituted molybdenum(V) complexes with $KPPh_2(dioxane)_2$ [10], both reduction of the Ta^V starting material to Ta^{III} (formally $[Cp'TaCl_2]$; comparable Ta^{III} complexes $[Cp^RTaCl_2]$ with $Cp^R = C_5H_5$, C_5Me_5, C_5Me_4Et have been obtained by controlled reduction of $[Cp^RTaCl_4]$) [11] and substitution of the chloro ligands by PPh_2 are observed. Surprisingly, $[Cp^*NbCl_4]$ reacted with $LiPPh_2$ at low temperature to give only the substitution product $[Cp^*NbCl_3(PPh_2)]$, which was characterised by IR and ^1H NMR spectroscopy [12]. However, when a fourfold excess of lithium phosphanide was employed, only reduction products were observed [12].

In the mass spectrum of **1**, a signal for toluene is observed at *ca* 140°C, and at *ca* 290°C the molecular ion peak is observed at $m/z = 1260$, as well as signals for fragments arising from loss of Cp′ ligands and phenyl groups.

No signals due to **1** are observed in the ^1H and ^{31}P NMR spectrum, suggesting the presence of a paramagnetic species.

Synthesis and properties of $[Cp'TaCl_4\{PH_2(2,4,6\text{-}Pr^i_3C_6H_2)\}]$ (**2**) *and* $[Cp'TaCl\{\mu\text{-}P(2,4,6\text{-}Pr^i_3C_6H_2)\}]_2$ (**3**)

When equimolar amounts of $PH_2(2,4,6\text{-}Pr^i_3C_6H_2)$ are added to a toluene solution of $[Cp'TaCl_4]$, a colour change from yellow to orange indicates the formation of the adduct $[Cp'TaCl_4\{PH_2(2,4,6\text{-}Pr^i_3C_6H_2)\}]$ (**2**), which can be isolated as yellow crystals.

The Lewis acidity of tantalum(V) and niobium(V) complexes has been extensively studied and a large number of adducts of $[Cp^RMCl_4]$ with ethers, amines, nitriles, and isonitriles has been reported [13]. Up to now, only a few phosphine complexes of cyclopentadienyl tantalum (or niobium) tetrachloride are known, all of which possess *tertiary* phosphine ligands. While $[CpMCl_4(PMe_3)]$ (M = Nb, Ta) [13d, 14] and $[CpNbCl_4(PEt_3)]$ [14] were earlier reported to be unstable, it was shown only recently that stable adducts can be obtained provided there is *no excess* of phosphine present. Thus, the complexes $[Cp^*NbCl_4(L)]$ ($L = PMe_3$, PMe_2Ph, $PMePh_2$), $[Cp^*NbCl_3(Me)(PMe_2Ph)]$ and $[\{Cp^*NbCl_4\}_2(\mu\text{-dmpe})]$ (dmpe = $Me_2PCH_2CH_2PMe_2$) are accessible in high yield [12], as are the phosphine adducts $[CpNbCl_4(L)]$ ($L = PMe_3$, PMe_2Ph, $PMePh_2$) [15]. With excess phosphine, these complexes are readily reduced to niobium(IV) compounds, with PMe_3 being the best reducing agent (formation of $PMe_3H^+Cl^-$) [12, 15]. With **2**, no reaction is observed with excess phosphine.

In the NMR spectra, $[Cp'TaCl_4\{PH_2(2,4,6\text{-}Pr^i_3C_6H_2)\}]$ (**2**) exhibits dynamic behaviour which we attribute to rotation about the Ta—P bond. Thus, at room temperature only broad signals are observed for the PH_2 group in the ^1H and ^{31}P NMR spectra. Below 290 K a triplet is observed in the proton-coupled ^{31}P NMR spectrum [$\Delta G^‡$ (288 K) = 67 ± 2 kJ mol^{-1} [16]. Similarly, the dynamic behaviour of $[Cp^*TaMe(\eta^2\text{-}C_2H_4)(PPh_2)]$ was attributed to restricted rotation about the Ta—P bond [$\Delta G^‡ = 48 \pm 1.3$ kJ mol^{-1}] [4b]. Inversion barriers of terminal phosphanido groups lie in the same range (e.g., 48–60 kJ mol^{-1} for Nb, Re, Fe, and W complexes [17].

As expected on coordination to a transition metal, the signal of the phosphine ligand is shifted to low field compared to the free phosphine (−158.2 ppm, J(PH) 203 Hz) [18b, 18c] by 122.5 ppm, and the P—H coupling constant increases by 158 Hz. Accordingly,

a low-field shift of the P—H signal by 2.80 ppm is observed in the proton NMR spectrum. Similarly, low-field shifts are observed for the resonances of the *ortho*-Pr^i groups of the aromatic ligand (free phosphine: 1.19 CH*Me*$_2$, 3.41 C*H*Me$_2$ [18], coordinated: 1.29 and 3.90, respectively), while the differences in the chemical shifts of the *para*-Pr^i ligand and the *meta*-H atoms of the phenyl ligand are less pronounced. Comparable effects are observed in the ^{31}P NMR spectra of LiPH(2,4,6-Pr$^i_3$C$_6$H$_2$) (−165 ppm, *J*(PH) 166 Hz) [19] and the corresponding phosphanido complex [Cp$'_2$Zr(Cl){PH(2,4,6-Pr$^i_3$C$_6$H$_2$)}] (−4.6 ppm, *J*(PH) 230 Hz) [19]. For most tantalum and niobium complexes with tertiary phosphine ligands, no ^{31}P NMR data have been reported. However, for those complexes for which data are available, e.g. [Cp*NbCl$_3$(X)(PMe$_2$Ph)] (X = Cl: 2 ppm, X = Me: −1.9 ppm) [12], [CpNbCl$_4$(L)] (L = PMe$_3$: 5 ppm, L = PMe$_2$Ph: 12 ppm, L = PMePh$_2$: 17 ppm) [15] and the cationic complex [Cp$_2$TaH$_2$(PHPh$_2$)]$^+$ (0.2 ppm, *J*(PH) 389 Hz) [4c], broad signals and a low-field shift compared to the free phosphines (PMe$_3$: −62 ppm, PMe$_2$Ph: −46 ppm, PMePh$_2$: −26 ppm, PHPh$_2$: −41.1 ppm, ^{1}*J*(PH) 214.3 Hz) [20] are also observed; however, here the difference is less pronounced.

In the ^{1}H NMR spectrum of **2** and **3**, the signals of the Cp′ ligand are shifted to high field by up to 1 ppm compared to [Cp′TaCl$_4$] [21]. In **2**, the *ipso*-C atom of the triisopropylphenyl ligand (152.2 ppm, *J*(PC) 28 Hz) exhibits the expected chemical shift [18c], however, the PC coupling constant is smaller than in the free phosphine (*J*(PC) 57.2 Hz) [18c] and in [Cp*TaMe(η^2-C$_2$H$_4$)(PPh$_2$)] (145.9 ppm, *J*(PC) 41 Hz) [4b].

No molecular ion peak is observed in the mass spectrum of **2**. Only signals for [Cp′TaCl$_4$] and PH$_2$(2,4,6-Pr$^i_3$C$_6$H$_2$) as well as fragmentation products thereof are observed.

The phosphinidene-bridged tantalum(IV) complex [Cp′TaCl{μ-P(2,4,6-Pr$^i_3$C$_6$H$_2$)}]$_2$ (**3**) is obtained on reacting **2** with DBU (1:2 or 1:3) in *ca* 55% yield. Also, when [Cp′TaCl$_4$] is reacted *in situ* with PH$_2$(2,4,6-Pr$^i_3$C$_6$H$_2$) and DBU (1:1:1), only **3** can be isolated, in low yield (*ca* 10–15%). The formation of an intermediate phosphanido complex was not observed. While no reaction of **2** was observed with excess phosphine, we were able to show that [Cp′TaCl$_4$] is reduced by equimolar amounts of DBU to give a paramagnetic Ta^{IV} species (Experimental Section). Thus, in the reaction between [Cp′TaCl$_4$], PH$_2$(2,4,6-Pr$^i_3$C$_6$H$_2$) and DBU, the amine is the reducing agent even in the absence of primary phosphine. Similarly, [MCl$_5$] (M = Nb, Ta) have been reported to be reduced to M^{IV} by aliphatic [22] and aromatic [23] amines. Surprisingly, in the reaction of [Cp*TaCl$_4$] with aniline the adduct [Cp*TaCl$_4$(NH$_2$Ph)] is formed [24]. This adduct also reacts with base (LiNEt$_2$) undergoing elimination of HCl (without reduction) and formation of the Ta^V imido complex [Cp*TaCl$_2$(NPh)] [24].

Stable terminal phosphinidene complexes of inorganic tantalum derivatives, [(SiMe$_3$NCH$_2$CH$_2$)$_3$NTa=PR] (R = Ph, Cy, Bu^t) [7] (yellow) and [(Bu$^t_3$SiO)$_3$Ta=PPh] [6] (red), have been reported, in addition to those known for Mo [25], W [26] and Zr [27]. [(SiMe$_3$NCH$_2$CH$_2$)$_3$NTa=PR] [175.1 (R = Cy) and 227.3 ppm (R = Bu^t)] [7] and [(Bu$^t_3$SiO)$_3$Ta=PPh] [6] (334.6 ppm) have ^{31}P chemical shifts which indicate the presence of a linear MPR unit (bent MPR unit: 660 to 800 ppm [25]), for **3**, a ^{31}P chemical shift of 391.5 ppm is observed. Also, the deshielding effect on coordination to a transition metal is even more pronounced in **3**. Thus, all resonances of the triisopropylphenyl ligand are shifted to low field by 0.1 to 0.5 ppm in the ^{1}H NMR spectrum.

In the mass spectrum, the molecular ion peak of **3** (*m/z* 1060) as well as a signal for the monomeric compound (*m/z* 530) and fragmentation products of the Cp′TaCl and P(2,4,6-Pr$^i_3$C$_6$H$_2$) fragment are observed.

Molecular structures of [Cp′Ta(μ-PPh$_2$)(PPh$_2$)]$_2$(**1**)·C$_7$H$_8$, [Cp′TaCl$_4$\{PH$_2$(2,4,6-Pr$^i_3$C$_6$H$_2$)\}] (**2**) *and* [Cp′TaCl{μ-P(2,4,6-Pr$^i_3$C$_6$H$_2$)}]$_2$ (**3**)·C$_7$H$_8$

Single crystals of **1** were obtained by covering a saturated toluene solution with a layer of n-heptane. The compound crystallises in the triclinic space group $P\bar{1}$ and has one formula unit per unit cell (Table 1, Table 4). The unit cell also contains a disordered toluene molecule without bonding interactions. Single crystals of **2** are obtained as yellow needles on cooling a saturated pentane solution to 5 C. **2** crystallises in the triclinic space group $P\bar{1}$ and has two formula units per unit cell (Table 2, Table 4). **3** is obtained as dark red cubes on cooling a saturated toluene/pentane solution to −20 C. The compound crystallises in the monoclinic space group $P2_1/n$ with two formula units per unit cell (Table 3, Table 4). The unit cell also contains two disordered toluene molecules without bonding interactions.

The pronounced tendency of low-valent Ta^{III} and Ta^{IV} complexes to form binuclear complexes is also exhibited in the molecular structures of **1** and **3**. Both consist of centrosymmetric dimeric molecules in which Ta atoms are bound by two bridging phosphanido (PPh$_2$, **1**) or phosphinidene [P(2,4,6-Pr$^i_3$C$_6$H$_2$), **3**] groups. In **1** each Ta atom also bears a terminal PPh$_2$ ligand (Fig. 1), in **3** there are terminal chloro ligands (Fig. 2). In both complexes, a Cp′ group completes the coordination of the Ta atom. The centrum of the Ta$_2$P$_2$ rings in **1** and **3** coincides with a crystallographic inversion centre [**1**: 0, 1/2, 0 (c), **3**: 0, 0, 1/2 (b)].

The four-membered metallacycles Ta(1)—P(2)—Ta(1)′—P(2)′ (**1**) and Ta—P—Ta′—P′ (**3**) are planar. The bond lengths and angles of the central Ta$_2$P$_2$ ring in **1** [Ta(1)—P(2)$_{br}$ 2.458(2), 2.486(2) Å;

attributed to the high steric demand of the bridging PPh_2 ligands. In **3**, The Ta—Ta bond length of 3.100(3) Å is comparable to that observed in **1**. As **3** exhibits diamagnetic behaviour, the presence of a Ta—Ta single bond must be assumed. A comparable value of 3.165 Å is observed for a Ta—Ta bond in $[TaCl_3(SMe_2)(\mu\text{-SPh})]_2$ [33].

The Ta(1)—P(1) bond length of the terminal phosphanido ligand in **1** of 2.390(2) Å is only slightly shorter than that in $[TaH(PPh_2)_2(dmpe)]$ [Ta—P 2.430(6) and 2.404(6) Å] [5]. In both compounds, the P atom of the terminal phosphanido group is trigonal-planar (sum of bond angles *ca* 360°), indicating that the PPh_2 group is acting as a three-electron donor. In contrast, an increase in the Ta—P bond length and a pyramidal geometry of the P atom are observed when the phosphanido ligand acts as a one-electron donor (e.g., $[Cp_2TaH_2(PPh_2)]$, Ta—P 2.595(3) Å) [4c].

In **3**, the Ta—P bond lengths of the bridging phosphinidene ligand are comparable to that observed for the terminal phosphanido group in **1**. The dependence of the Ta—P bond length on the substituents and geometrical arrangement at phosphorus is demonstrated in the following complexes: Thus, the Ta—P double bond in $[(SiMe_3NCH_2CH_2)_3NTa{=}PCy]$ [7] of 2.145(7) Å (TaPC is linear) is much shorter than that observed for $[(Bu^t_3SiO)_3Ta{=}PPh]$ [6] (2.317(4) Å, Ta—P—C 110.2(4)°, bent TaPC). However, all these distances are shorter than the sum of the covalent radii of Ta and P (2.44 Å) [34].

The Ta—Cl bond length in **3** [2.350(2) Å] is shorter

than those in octahedral Ta derivatives (e.g., $[TaCl_2(\mu\text{-}Cl)(\mu\text{-dmpm})]_2$, dmpm = $Me_2PCH_2PMe_2$, Ta—Cl (terminal) 2.435(7), 2.457(6) Å [35], *trans*-$[CpTaCl_2(CO)(PMe_2Ph)_2]$, Ta—Cl 2.518(4), 2.539(4) Å [13d], $[Cp^*TaCl_3(PMe_3)]$, Ta—Cl 2.395(3) to 2.416(3) Å [11b], *cis*-$[Cp^*TaCl_2(CO)_2(PMe_3)]$, Ta—Cl 2.504(2), 2.512(2) Å [11b]), indicating a less pronounced *trans* effect of the bridging phosphorus ligand.

$[Cp'TaCl_4\{PH_2(2,4,6\text{-}Pr^i_3C_6H_2)\}]$ (**2**) (Figs 3 and 4) is the first phosphine adduct of $[Cp'TaCl_4]$ to be crystallographically characterised. A niobium complex, $[CpNbCl_4(PMePh_2)]$ [15], an amine complex, $[Cp^*TaCl_4(NH_2Ph)]$ [24], and an isocyanide complex $[Cp^*TaCl_4(CN\text{-}2,6\text{-}Me_2C_6H_3)]$ [24] which are structurally related, have been reported.

In **2**, the Ta atom has a pseudo-octahedral geometry, with the phosphine ligand located *trans* to the Cp′ ligand and the four chlorine ligands bent away from the Cp′ ligand [Cl(4)—Ta(1)—Cl(1) 88.07(10), Cl(4)—Ta(1)—Cl(3) 86.50(8), Cl(1)—Ta(1)—Cl(2) 86.07(9), Cl(3)—Ta(1)—Cl(2) 86.10(7)]. The Ta atom is shifted towards the Cp′ ligands and lies 0.58 Å above the plane defined by the four chlorine ligands, which is parallel to the plane defined by the Cp′ ring.

The Ta—Cl bond lengths [Ta(1)—Cl(1) 2.402(2), Ta(1)—Cl(2) 2.417(2), Ta(1)—Cl(3) 2.416(2), Ta(1)—Cl(4) 2.386(2)] are comparable to those observed in related compounds [e.g. $Cp^*TaCl_3(PMe_3)$], Ta—Cl 2.395(3) to 2.416(3) Å] [11b], while an increase in bond length is observed due to a strong *trans* effect in *cis*-$[Cp^*TaCl_2(CO)_2(PMe_3)]$ [Ta—Cl 2.504(2), 2.512(2) Å] [11b].

While the Ta—P bond lengths of phosphine adducts are in the range 2.59–2.67 Å [11b,13,14, 35–38], **2** exhibits a rather long Ta(1)—P(1) bond length of 2.710(2) Å, which is possibly due to the steric influence of the chlorine ligands or the *trans* effect of the Cp′ ligand. In the structurally related complexes $[CpNbCl_4(PMePh_2)]$ [Nb—P 2.7844(9) Å] [15] and

Table 4. Crystal data and structure refinement for $[Cp'Ta(\mu\text{-}PPh_2)(PPh_2)]_2$ (**1**)·C_7H_8, $[Cp'TaCl_4\{PH_2(2,4,6\text{-}Pr^i_3C_6H_2)\}]$ (**2**), and $[Cp'TaCl\{\mu\text{-}P(2,4,6\text{-}Pr^i_3C_6H_2)\}]_2$ (**3**)·C_7H_8

[a] Located on the Ta—Ta vector.

$[Cp^*TaCl_2(CO)_2(PMe_3)]$ [Ta—P 2.707(2) Å] [11b], in which the phosphine ligand is in a position *trans* to the cyclopentadienyl ligand, lengthening of the metal–P bond was also observed.

EXPERIMENTAL

All experiments were carried out under purified dry nitrogen (for **1**) or argon (for **2** and **3**). Solvents were dried and freshly distilled under nitrogen or argon. For **1**: the IR spectrum was recorded on a Perkin-Elmer 883 in the range 200–4000 cm^{-1}; MS: Varian MAT 711 (EI, 70 eV, source temperature 180°C). For **2** and **3**, the IR spectra were recorded on a FT spectrometer System 2000 (Perkin-Elmer) in the range 200–4000 cm^{-1}; NMR spectra with an AVANCE DRX 400 spectrometer (Bruker), ^{1}H NMR: internal standard solvent (e.g., benzene, toluene), ^{31}P NMR: external standard 85% H_3PO_4; MS: with a Sektorfeldgerät AMD 402 (AMD Intectra GmbH) (EI, 70 EV). The EPR spectrum was recorded with a Bruker ESP 300E. The melting points were determined in sealed capillaries under nitrogen or argon and are uncorrected. $[Cp'TaCl_4]$ [13b], $KPPh_2(dioxane)_2$ [39], and $PH_2(2,4,6\text{-}Pr^i_3C_6H_2)$ [18] were prepared by literature procedures.

Synthesis of $[Cp'Ta(\mu\text{-}PPh_2)(PPh_2)]_2$ (**1**)·C_7H_8

$[Cp'TaCl_4]$ (0.50 g, 1.24 mmol) and $KPPh_2(dioxane)_2$ (0.49 g, 1.24 mmol) were placed in a Schlenk tube. 20 cm^3 of ether was added at room temperature. A brown solution was obtained. The solvent was removed to dryness and the residue extracted with toluene. After filtering, the solution was covered with a layer of n-heptane. After several days at room temperature black rhombic crystals of **1** were obtained: *ca* 40 mg (20% based on $KPPh_2(dioxane)_2$), m.p. 167°C. EI-MS (70 eV), m/z (%): 1260 (28.4) [$M^+ = [Cp'Ta(\mu\text{-}PPh_2)(PPh_2)]_2^+$], 1181 (12.0) [(M-Cp′)$^+$], 1104 (19.4) [(M-2Cp′)$^+ = [Ta(\mu\text{-}PPh_2)(PPh_2)]_2^+$], 1026(5.7) [(M-Ph-2Cp′)$^+$], 998 (5.8) [(M-2Ph-2Cp′)$^+$], 920 (4.3) [(M-3Ph-2Cp′)$^+$], 552 (3.9) [$(Ta(PPh_2)_2)^+$], and fragmentation products thereof. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3056 m, 2957 w, 2920 w, 2850 w, 2350 w, 2322 vw, 1954 vw, 1879 vw, 1804 vw, 1750 vw, 1610 vw, 1578 m, 1474 m, 1429 m, 1379 m, 1300 m, 1266 m, 1177 m, 1154 w, 1127 w, 1081 w, 1063 w, 1026 m, 997 w, 890 vw, 865 w, 843 w, 800 m, 737 s, 696 vs, 560 vw, 512 s, 484 m, 452 m, 425 m, 308 w.

Synthesis of $[Cp'TaCl_4\{PH_2(2,4,6\text{-}Pr^i_3C_6H_2)\}]$ (**2**)

$[Cp'TaCl_4]$ (1.95 g, 4.88 mmol) was suspended in 30 cm^3 toluene and with stirring $PH_2(2,4,6$-

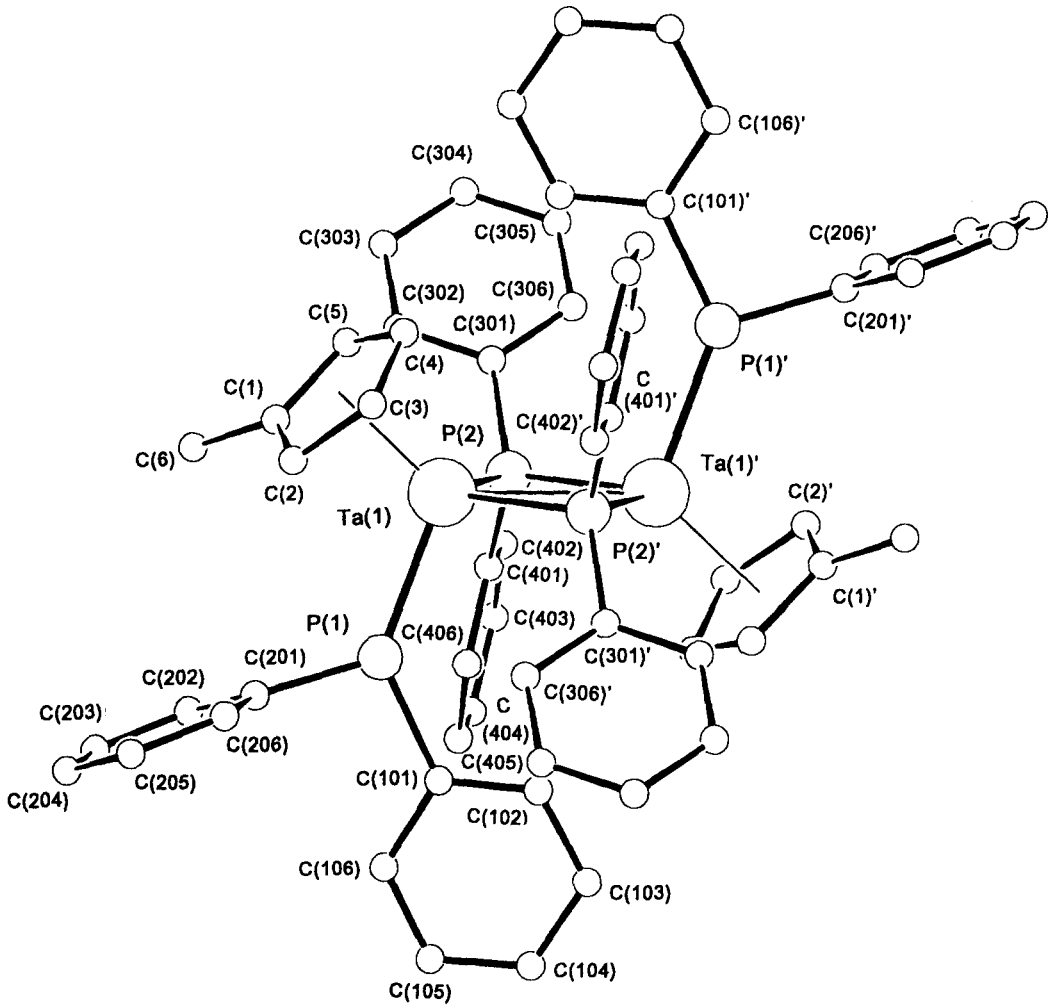

Fig. 1. Molecular structure of $[Cp'Ta(\mu\text{-}PPh_2)(PPh_2)]_2$ (**1**) showing the atom numbering scheme employed (SCHAKAL plot) [43]. Hydrogen atoms are omitted for clarity.

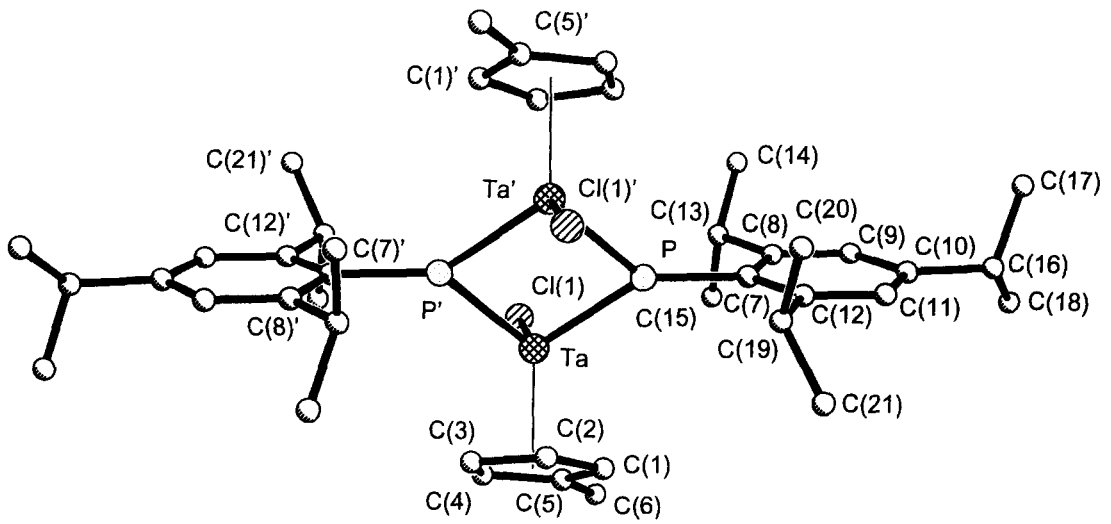

Fig. 2. Molecular structure of $[Cp'TaCl\{\mu\text{-}P(2,4,6\text{-}Pr^i_3C_6H_2)\}]_2$ (**3**) showing the atom numbering scheme employed (SHELXTL PLUS; XP) [41]. Hydrogen atoms are omitted for clarity.

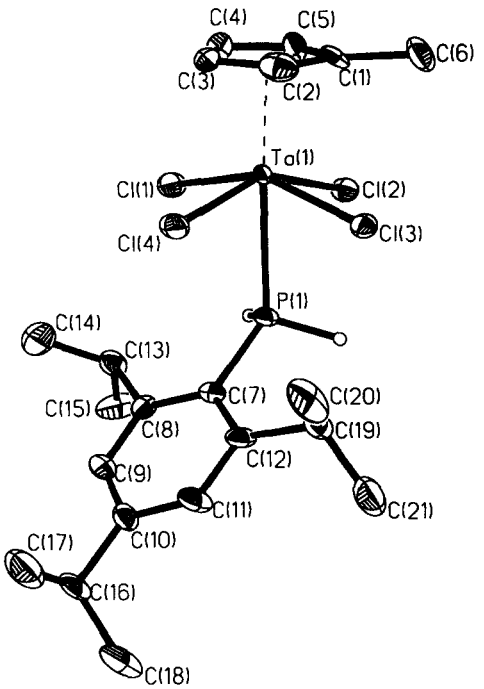

Fig. 3. Molecular structure of [Cp′TaCl$_4${PH$_2$(2,4,6-Pr$^i_3$C$_6$H$_2$)}] (**2**) showing the atom numbering scheme employed (ORTEP plot, 50% probability, SHELXTL PLUS; XP) [41]. Hydrogen atoms (other than P—H) are omitted for clarity.

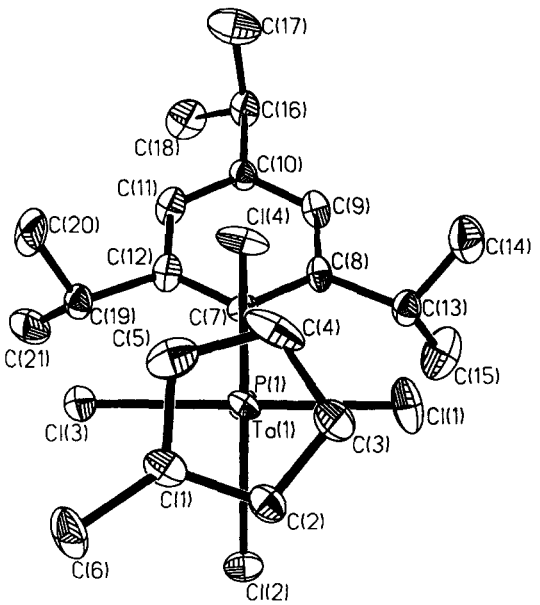

Fig. 4. View along the Ta—P bond axis of [Cp′TaCl$_4${PH$_2$(2,4,6-Pr$^i_3$C$_6$H$_2$)}] (**2**) (ORTEP plot, 50% probability, SHELXTL PLUS; XP) [41]. Hydrogen atoms are omitted for clarity.

Pr$^i_3$C$_6$H$_2$) (1.15 g, 4.88 mmol) was added with a syringe. The reaction is exothermic and a clear orange solution is obtained. The solution was stirred overnight. Then the solvent was removed to dryness and the residue extracted with pentane. Cooling to 5°C afforded yellow needles of **2**: 2.8 g (90%). The product is only slightly air sensitive but is hydrolysed rapidly. **2** is soluble in CH_2Cl_2 and $CHCl_3$ without decomposition. M.p. 147°C.

^{1}H NMR (400 MHz; C_7D_8; 298 K, ppm): 1.12 [d, ^3J(HH) 6.8 Hz, 6 H, 4-(*Me*$_2$CH)C$_6$H$_2$], 1.29 [d, ^3J(HH) 6.5 Hz, 12 H, 2,6-(*Me*$_2$CH)$_2$C$_6$H$_2$], 2.09 (s, br, 3H, C$_5$H$_4$*Me*), 2.68 [sept, ^3J(HH) 6.8 Hz, 1 H, 4-(Me$_2$C*H*)C$_6$H$_2$], 3.90 [broad with fine structure, 2 H, 2,6-(Me$_2$C*H*)$_2$C$_6$H$_2$], 5.69 (s, br 2 H, C$_5$*H*$_4$Me), *ca* 5.8 [br, 1 H, P*H*$_2${2,4,6-(Me$_2$CH)$_3$C$_6$H$_2$}], 6.23 (s, 2H, C$_5$*H*$_4$Me), *ca* 6.7 [br, 1 H, P*H*$_2${2,4,6-(Me$_2$CH)$_3$C$_6$H$_2$}], 7.12 [s, 2 H, 2,4,6-(Me$_2$CH)$_3$C$_6$*H*$_2$]. ^{1}H NMR (400 MHz; toluene-d_8; 263 K, ppm): all signals broaden apart from the broad signals at *ca* 5.8 and 6.7 ppm; the broad P—H resonances are observed as sharp singlets at 6.10 and 6.99 ppm [J(PH) 357 Hz] at low temperature. ^{31}P NMR (C_7D_8, ppm): (a) 300 K, *ca* −36, broad, $\nu_{1/2}$ *ca* 800 Hz, (b) T < 290 K, −35.7 t [^1J(PH) 360.9 Hz]. ^{13}C NMR (C_7D_8 298 K, ppm): 16.1 (C$_5$H$_4$*Me*); 24.4, 24.9 [2,4,6-(*Me*$_2$CH)$_3$C$_6$H$_2$]; 34.3, 35.1 [2,4,6-(Me$_2$*C*H)$_3$C$_6$H$_2$]; 121.1, 122.5, 135.1 (*C*$_5$H$_4$Me); 152.2 (d, J(PC) 28 Hz, C$_{ipso}$-PH$_2$), other signals for 2,4,6-(Me$_2$CH)$_3$*C*$_6$H$_2$ are obscured by those of toluene. EI-MS (70 eV): no molecular ion peak is observed. Only signals for [Cp′TaCl$_4$] and PH$_2$(2,4,6-Pr$^i_3$C$_6$H$_2$) as well as fragmentation products thereof are observed, *m/z* (%): 402 (100) ([Cp′TaCl$_4$]$^+$), 236 (35) [PH$_2$(2,4,6-Pr$^i_3$C$_6$H$_2$)$^+$], 204 (90) [(2,4,6-Pr$^i_3$C$_6$H$_2$)$^+$], 79 (25) [(Cp′)$^+$], 43 (30) [(Pr^i)$^+$]. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 3113 s, 2926 m, 2866 m, 1600 m, 1561 sh, 1498 m, 1459 m, 1424 m, 1382 m, 1361 m, 1170 sh, 1105 m, 1080 m, 1048 m, 938 s, 869 m, 746 m, 414 sh. Found: C 39.1; H 5.3; Cl 22.4. Calc. for $C_{21}H_{32}Cl_4PTa$ (638.2): C 39.5; H 5.1; Cl 22.2%.

Synthesis of [Cp′TaCl{μ-P(2,4,6-Pr$^i_3$C$_6$H$_2$)}]$_2$ (**3**)·C$_7$H$_8$

With stirring, DBU (0.96 g, 6.29 mmol, 1 cm^3) was added with a syringe to a yellow solution of [Cp′TaCl$_4${PH$_2$(2,4,6-Pr$^i_3$C$_6$H$_2$)}] (**2**) (2.0 g, 3.14 mmol) in 30 cm^3 toluene. A colour change to red-brown was observed. The solution was stirred at r.t. for 2 h. Then the solvent was removed to dryness and the residue dissolved in 20 cm^3 pentane/2 cm^3 toluene giving a red-brown solution. Cooling to −20 C yielded dark red cubic crystals of **3**·C$_7$H$_8$. **3** is soluble in CH_2Cl_2 and $CHCl_3$ without decomposition. The product is only slightly air sensitive but hydrolysed rapidly. The crystals were ground and the resulting powder dried *in vacuo* to remove the included toluene. Yield: 0.91 g (55%). M.p. 268°C. ^{1}H NMR (400 MHz, C_6D_6, 298 K, ppm): 1.28 [d, ^3J(HH) 5.6 Hz, 24 H, 2,6-(*Me*$_2$CH)$_2$C$_6$H$_2$], 1.51 [d, ^3J(HH) 6.6 Hz, 12 H, 4-(*Me*$_2$CH)C$_6$H$_2$], 1.96 (s, 6 H, C$_5$H$_4$*Me*), 3.27 [sept, ^3J(HH) 6.6 Hz, 2 H, 4-(Me$_2$C*H*)C$_6$H$_2$], 3.93 [broad

with fine structure, 4 H, 2,6-$(Me_2CH)_2C_6H_2$], 5.24 (s, br, 4 H, C_5H_4Me), 5.91 (s, br, 4 H, C_5H_4Me), 7.36 [s, 4 H, 2,4,6-$(Me_2CH)_3C_6H_2$]. ^{31}P NMR (C_6D_6, ppm): 391.5, s. EI-MS (70 eV, *m/z* (%)): 1060 (100) [M^+ = [Cp′TaCl{μ-P(2,4,6-$Pr^i_3C_6H_2$)}]$_2^+$], 530 (1.0) [Cp′TaCl{μ-P(2,4,6-$Pr^i_3C_6H_2$)}$^+$], 204 (60) [(2,4,6-$Pr^i_3C_6H_2$)$^+$], 79 (20) [(Cp′)$^+$], 43 (40) [(Pr^i)$^+$], as well as fragmentation products thereof. IR (KBr, cm^{-1}): $\tilde{\nu}$ = 2958 s, 2924 m, 2865 m, 1596 m, 1490 sh, 1459 m, 1419 m, 1379 m, 1359 m, 1313 m, 1262 m, 1099 m, 1031 m, 936 sh, 876 m, 805 s, 753 sh, 506 sh. Found: C, 47.1; H, 5.8. Calc. for $C_{42}H_{60}Cl_2P_2Ta_2$ (1059.7): C, 47.6, H, 5.7%.

Reaction of [Cp′$TaCl_4$] *with DBU*

DBU (0.8 g, 5.0 mmol) was added with a syringe to a stirred yellow suspension of [Cp′$TaCl_4$] (2.0 g, 5.0 mmol) in 30 cm^3 toluene. A colour change to red-brown was observed. The solution was stirred at r.t. for 5 h. Then the solvent was removed to dryness and the residue was washed with 20 cm^3 pentane and dissolved in 30 cm^3 CH_2Cl_2. An EPR spectrum of the CH_2Cl_2 solution showed the 8-line spectrum expected for a paramagnetic tantalum compound (Ta: $I = 7/2$).

Data collection and structure refinement for [Cp′Ta(μ-PPh_2)(PPh_2)]$_2$ (**1**)·C_7H_8, [Cp′$TaCl_4$ {PH_2(2,4,6-$Pr^i_3C_6H_2$)}] (**2**), *and* [Cp′TaCl{μ-P(2,4,6-$Pr^i_3C_6H_2$)}]$_2$ (**3**)·C_7H_8

Data (Mo-K_α = 0.71069 Å) were collected with a Stoe STADI 4 diffractometer (for **1** and **3**) and with a Siemens CCD (SMART) (for **2**). 25 reflections (2Θ range: 2–25°) (**1**) or 80 reflections (2θ range: 28–40°) (**3**) were used for determination of the unit cell parameters; for **2**, 1930 reflections (2θ range: 12–25°) were used for refinement of the unit cell parameters. Absorption correction: psi-scans. The structures were solved by direct methods (**1**, **3**: SHELXS-86 [40], **2**: SHELXTL PLUS [41]) and subsequent difference Fourier syntheses and refined by full-matrix least-squares on F^2 (**1**, **3**: SHELXL-93 [42], **2**: SHELXTL PLUS [41]). Restrictions for **1**: Ta, P and C atoms anisotropic, H atoms isotropic in calculated positions. One molecule of toluene (disordered, only C atoms located and refined isotropically) per formula unit of **1** is present in the unit cell. Restrictions for **2**: Ta, P, Cl and C atoms anisotropic, H atoms isotropic in calculated positions. Restrictions for **3**: Ta, P, Cl and C atoms anisotropic, H atoms isotropic in calculated positions. One molecule of toluene (disordered, only C atoms located and refined isotropically) per formula unit of **3** is present in the unit cell. A summary of data collection parameters is given in Table 4. Anisotropic atomic parameters and full lists of bond lengths and angles have been deposited as supplementary material with the Cambridge Crystallographic Data Centre.

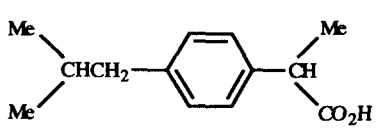
Synthesis and characterization of copper–ibuprofenate complexes with 2,2′-bipyridine and 1,10-phenanthrolines and their hydrolytic activities in phosphate diester cleavage

A. Latif Abuhijleh



Department of Chemistry, Birzeit University, P.O. Box 14, West Bank—via Israel

(Received 6 February 1996; accepted 29 April 1996)

Abstract—A synthetic investigation of copper(II) ibuprofenate (Ibup) addition compounds with 2,2′-bipyridine (bpy), 1,10-phenanthroline (phen) and 2,9-dimethyl-1,10-phenanthroline (dmph) has led to the isolation of dinuclear adducts of the forms $[Cu(Ibup)_2(bpy)]_2 \cdot 4H_2O$ (**1**) and $[Cu(Ibup)_2(phen)]_2$ (**2**) and a mononuclear adduct $Cu(Ibup)_2(dmph)$ (**3**). Spectroscopic data for adducts **1** and **2** are consistent with a dinuclear structure with two CuN_2O_2+O chromophors. Each copper is coordinated with two ibuprofenate bridges, a terminal diimine molecule and a monodentate ibuprofenate group complete five-coordination at each metal atom. Spectroscopic data for adduct **3** are consistent with a mononuclear structure having a very distorted square-pyramidal CuN_2O_2+O chromophore. The Cu^{II} atom is coordinated to two nitrogen atoms from a chelating dmph ligand, two carboxylic oxygens of a bidentate ibuprofenate ion and an oxygen atom of a monodentate carboxylic group of a second ibuprofenate ion. The reduction of adduct (**3**) by ascorbic acid produced stable red copper(I) complex of the form $[Cu(dmph)_2]$ (Ibup) (**4**). Spectral data of this adduct indicated that the cation has distorted tetrahedral geometry about the copper atom. The effect of **1** and **2** on the rate of hydrolysis of bis(*p*-nitrophenyl) phosphate (BNPP) have been examined in aqueous methanol solution at 70°C and pH 7.4. Copyright © 1996 Elsevier Science Ltd

Keywords: copper complexes; ibuprofen; diimines; hydrolysis; phosphate.

It has been suggested that copper(II) complexes of anti-inflammatory drugs are often more active and desirable drugs than the parent ligands themselves [1]. Ibuprofen [2-(4-isobutylphenyl)propionic acid], [Scheme 1] is a non-steroidal anti-inflammatory drug and has been used for many years in the treatment of inflammatory diseases. Physical studies of copper(II) ibuprofenate [2] have shown that it contains dinuclear units with bridging carboxylates, similar to the familiar copper acetate and many other copper(II) carboxylates [3]. It is well known that many copper(II) carboxylates form dinuclear adducts with basic ligands [3,4]; however, with certain bases many copper(II) carboxylates also form mononuclear adducts [3b,4–8]. Several studies from our laboratories and others have been designed to investigate the factors which influence the adoption of either dinuclear or mononuclear complexes for copper(II) carboxylate adducts [3a,4–10]. In general, it has been found that by increasing the acidity of the alkyl (or aryl) carboxylate ligands, such as through halogenation of alkyl groups and/or by increasing the basicity of the other ligands, the tendency towards formation of mononuclear complexes increases [2b,4–10].

Scheme 1.

Our interest in copper(II) carboxylate complexes with nitrogen-donor ligands evolves from their biological implications [1,4,7,11]. As an example, the imidazole and carboxylate groups are the ligating moieties found in proteins and in many naturally occurring mixed-ligand complexes [12]. In addition, mononuclear and dinuclear copper(II) carboxylates and their nitrogen-donor adducts have been found

to have a variety of pharmacological effects, such as antitumour [1,13], superoxide dismutase [14], catecholase [4,7], cytotoxicity and antiviral activities [11]. Chelators such as 2,2′-bipyridine and 1,10-phenanthroline have potential antitumour activity and their activity may be increased through their chelation to the copper ion [15]. A complex between the chelating agent 1,10-phenanthroline and copper(II) is able to induce the degradation of DNA in the presence of reducing agents[16] and 2,2′-bipyridine complexes of copper(II) have been used as non-enzymatic catalysts for the hydrolytic cleavage of phosphodiester backbone of DNA and RNA [17,18]. There has been interest in developing metal complexes which can promote hydrolysis of phosphate esters as model systems for metallo-phosphatase enzymes and as catalysts for the detoxification of man-made phosphorus(V) toxins of some pesticides and chemical weapons [17,18]. In addition, the development of new artificial photosynthetic assemblies capable of harvesting solar energy is of great interest in inorganic photochemistry [19]. Cuprous diimine chromophores have received considerable attention since these chromophores display metal-to-ligand charge transfer (MLCT) bands in the visible region [20]. Recently, light excitation into these bands leads to room-temperature emission in argon dichloromethane solution and the photo-driven energy transfer from cuprous phenanthroline derivatives has been demonstrated [21]. As part of an ongoing investigation into the biological and photochemical activities of copper compounds, this article reports the synthesis and spectroscopic characterization of ternary complexes of copper(II) ibuprofenate with 2,2′-bipyridine, 1,10-phenanthroline and 2,9-dimethyl-1,10-phenanthroline and examines the activities of the first two complexes for the hydrolysis of bis(*p*-nitrophenyl)phosphate. In addition, the reduction of copper(II) ibuprofenate adduct of 2,9-dimethyl-1,10-phenanthroline to bis(2,9-dimethyl-1,10-phenanthroline) copper(I) ibuprofenate is also reported.

EXPERIMENTAL

Materials

2,2′-Bipyridine (bpy), 1,10-phenanthroline(phen) and 2,9-dimethyl-1,10-phenanthroline (dmph) were purchased from Aldrich; sodium bis(*p*-nitrophenyl)phosphate (BNPP) and biological buffer HEPES [N-(2-hydroxyethyl) piperazine-N′-ethanesulfonic acid] were from Sigma and used without further purification. Tetrakis(μ-ibuprofenato) dicopper(II), $[Cu_2(Ibup)_4]$ (Ibup = ibuprofenate ion), was prepared as described previously [2b] and recrystallized from anhydrous diethylether: dichloromethane (1 : 1).

Preparation of complexes

$[Cu(Ibup)_2(bpy)]_2 \cdot 4H_2O$ (**1**). A solution of 2,2′-biypridine (0.164 g, 1.05 mmol) in methanol (50 cm^3) was added to Cu_2 $(Ibup)_4$ (0.496, 0.524 mmol). The mixture was stirred at room temperature for 2 h. The blue solution was filtered and left in the hood to evaporate. The bluish-green precipitate that formed was recrystallized from chloroform and air dried. Yield 0.58 g (83%). Found: C 65.0; H, 7.0; N, 4.1. Calc. for $C_{72}H_{92}N_4O_{12}Cu_2$: C, 64.9; H, 6.9; N, 4.2%.

$[Cu(Ibup)_2(phen)]_2$ (**2**). A solution of 1,10-phenanthroline (0.133 g, 0.68 mmol) in methanol (50 cm^3) was added to $Cu_2(Ibup)_2$ (0.319 g, 0.337 mmol). The mixture was stirred at room temperature for 2 h. The bluish-green solution was filtered and left in the hood to evaporate. The sky-blue precipitate that formed was recrystallized from chloroform and air dried. Yield 0.38 g (86%). Found: C 70.0; H, 6.6; N, 4.2. Calc. for $C_{76}H_{84}N_4O_8Cu_2$: C, 69.8; H, 6.4; N, 4.3%.

$Cu(Ibup)_2(dmph)$ (**3**). A solution of 2,9-dimethyl-1,10-phenanthroline (0.176 g, 0.845 mmol) in methanol (50 cm^3) was added to $Cu_2(Ibup)_4$ (0.398 g, 0.420 mmol). The solution was protected from the light and stirred at room temperature for 3 h. The green solution was filtered and left in the hood to evaporate. The green precipitate that formed was recrystallized from chloroform and air dried. Yield 0.37 g (65%). Found: C, 70.1; H, 6.9; N, 4.0. Calc. for $C_{40}H_{46}N_2O_4Cu$: C, 70.4; H, 6.8; N, 4.1%.

$[Cu(dmph)_2]Ibup$ (**4**). Solid ascorbic acid (0.053 g, 0.30 mmol) was added to the green solution of **3** (0.2 g, 0.29 mmol) in acetonitrile (15 cm^3). The red solution which formed was stirred for 15 min, filtered and left in the hood to evaporate. The red oily product was dissolved in dichloromethane (20 cm^3) and filtered. The red filtrate was concentrated by slow evaporation to *ca* 2 cm^3 then anhydrous diethylether was added to the solution with stirring until the red precipitate formed. The complex was filtered under reduced pressure, washed several times with anhydrous diethyether and dried *in vacuo*. Yield 0.045 g (45%). Found: C, 71.2; H, 6.1; N, 8.4. Calc. for $C_{41}H_{41}N_4O_2Cu$: C, 71.9; H, 6.0; N, 8.2%.

Physical measurements

Elemental analyses for C, H and N were performed by Galbraith Laboratories, Knoxville, Tennessee, U.S.A. Room-temperature (298 K) magnetic susceptibility measurements of powdered and solution samples were determined as described previously [4,6]. Electronic data of dichloromethane solutions were obtained with a Bausch and Lomb Spectronic 2000. IR spectra of Nujol or hexachlorobutadiene mulls sealed between polyethylene sheets were obtained in the 4000–200 cm^{-1} region with a Perkin–Elmer model 843 IR spectrophotometer. X-band ESR spectra of polycrystalline material and of methanol/toluene solu-

tions were obtained at room temperature and 77 K with an ESPIT-330 Vol. 501 spectrometer. Diphenylpicrylhydrazide (DPPH, $g = 2.0036$) was used as the calibrating field marker. A Varian 360A-60MHz spectrometer was used to obtain NMR spectra and chemical shifts were referenced to $SiMe_4$.

Kinetics

All kinetic studies were performed at 70°C and pH 7.4 with temperature compensation probe. The Sigma biological buffer HEPES (5 mmol dm^{-3}) was used to maintain a constant pH at 7.4. The pH of the buffer solutions was adjusted with NaOH or HNO_3 and checked at 70°C. Kinetic measurements were performed with the use of Bausch and Lomb 2000 UV–vis spectrophotometer equipped with a thermostated cell compartment.

The hydrolysis of sodium bis(*p*-nitrophenyl) phosphate (BNPP) by copper(II) complexes was monitored spectrophotometrically by following the production of *p*-nitrophenolate at 400 nm ($\varepsilon = 14\,000$ M^{-1} cm^{-1}, pH = 7.4) [17a]. The reactions were carried out under pseudo-first-order conditions with an excess copper(II) complex over BNPP concentrations. In a typical kinetic experiment, 1.5 cm^3 (2×10^{-3} M) of copper(II) complex dissolved in methanol and 1.5 cm^3 (1×10^{-4} M) of BNPP dissolved in HEPES buffer (pH 7.4) were combined in a 1 cm quartz cell and the absorbance changes at 400 nm were recorded at 70°C against the reference cell under identical conditions, except copper(II) complex was omitted. The final concentrations in the cell were (1×10^{-3} M) copper(II) complex and (5×10^{-5} M) BNPP.

First-order rate constants, k_{obs} (s^{-1}), were calculated from the slope of the linear plots of absorbance against time by converting to concentration units and dividing by the initial BNPP concentration. All experiments were run in triplicate and the first-order rate constants represent the average of these experiments.

RESULTS AND DISCUSSION

Magnetic and spectroscopic characterization

The ESR parameters, g and A, for frozen solutions and solid-state spectra of complexes studied are given in Table 1. The room-temperature ESR spectra of solid state samples of **1, 2** and **3** are anisotropic and contain $g_\parallel$ and $g_\perp$ components. Two of the four copper(II) hyperfine components in the $g_\parallel$ region for complex **3** are partially resolved. These spectra are of axial type ($g_\parallel > g_\perp > 2.040$), suggesting for all compounds $d_{x^2-y^2}$ (or d_{xy}) ground state, characteristic of a square-planar, square-based pyramidal or octahedral stereochemistry [22].

Frozen-solution ESR spectra of complexes **1** and **2** in 3.0 kG region exhibit a resolved structure with $g_\parallel > g_\perp$ (Table 1) and a representative frozen solution spectrum is that of **1** shown in Fig. 1. In addition to the hyperfine structure of copper(II) in the $g_\parallel$ region, the $g_\perp$ regions of these spectra exhibit ^{14}N-super-hyperfine structure consisting of five lines. This structure is attributed to the presence of two nitrogen atoms in the plane of the copper(II) ion. The spectral parameters for the complexes are comparable to those previously reported complexes that have square-based CuN_2O_2 of tetragonally elongated CuN_2O_2+O or $CuN_2O_2+O_2$ chromophore, including those reported for copper(II) carboxylates with α,α'-diimine [4–7, 23]. In these complexes the copper(II) ion is bonded to two unidentate nitrogen donors (e.g. imidazoles) or one bidentate chelate α,α'-diimine ligand and one oxygen atom from each of the two carboxylate anions. The second oxygen atom of each carboxylate ligand is in a weakly pseudo-axial position [5,7,9,11,24].

In addition to the above signals expected for $\Delta M_s = 1$ allowed transition of magnetic dilute copper(II) complexes $S = \frac{1}{2}$, the ESR spectra for complexes **1** and **2** in the full ESR region show another three weak signals at about 1200, 2230 and 3830 G and a representative spectrum is that of **2** shown in Fig. 2(a). These signals are attributed to the spin-

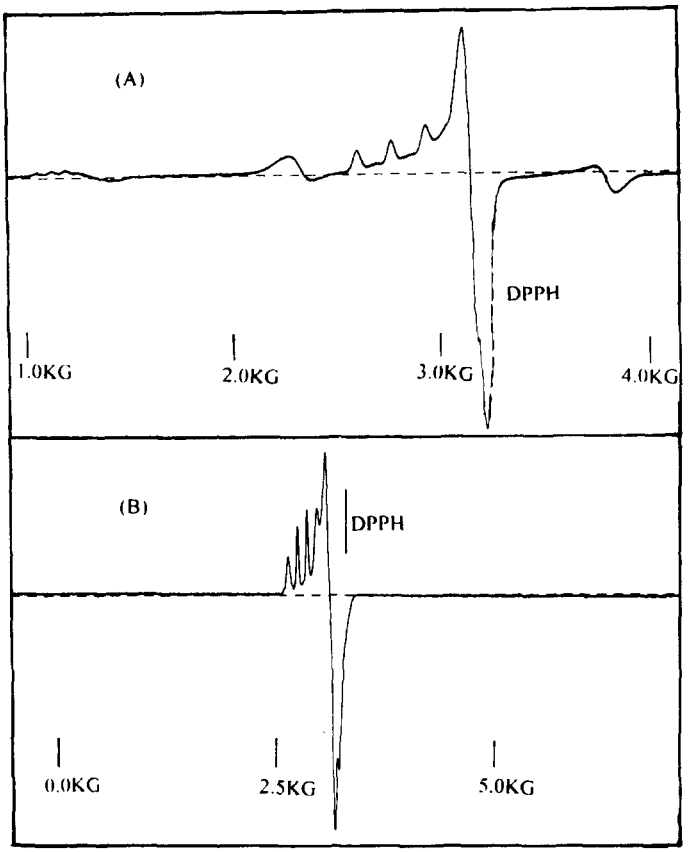
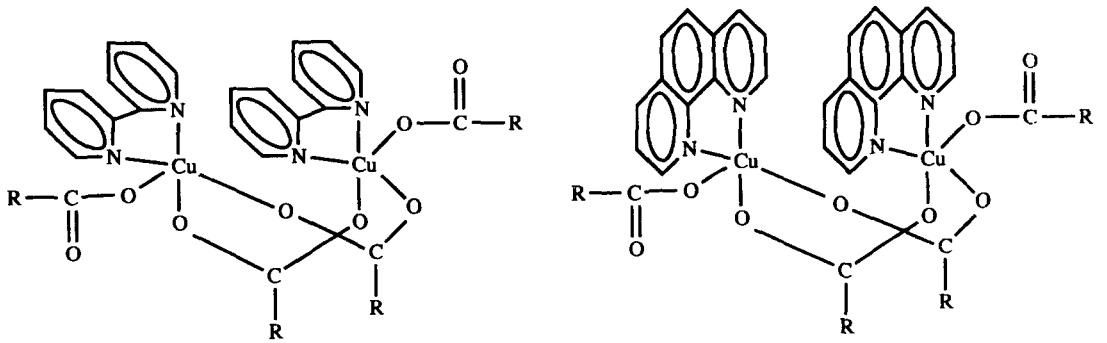
triplet state with $S = 1$. The signals at 2230 and 3830 G are devoid of any hyperfine structure, they are assigned to the $\Delta M_s = 1$ transitions Hxy_1 and Hxy_2 [24a]. The weak signal at 1200 G showed a resolved seven-line hyperfine structure ($A = 100 \times 10^{-4}$ cm^{-1}) and is attributed to the half-field $\Delta M_s = 2$ forbidden transition in dinuclear copper(II) complexes [25]. The positions and the assignment of these signals are comparable with those found for dicopper(II) complexes having an acetate ion-bridged ligand [25] and with those reported recently for ternary dinuclear copper(II) complexes of 4-aminobenzoic acid with 4,7-disubstituted phenanthrolines [26]. In these complexes each copper atom is coordinated with two 4-aminobenzoate bridges, a terminal diimine molecule and the fifth coordination position is occupied by a water molecule. In addition, the hyperfine coupling constant observed, 100×10^{-4} cm^{-1}, is about one half of that of mononuclear copper(II) units of axial symmetry (Table 1) and is comparable to those of the spin-triplet states of magnetically coupled dicopper(II,II) complexes [25,27]. Based on these ESR spectral properties along with other spectral data, dinuclear structure are proposed for these complexes of the type $[Cu(Ibup)_2(diimine)]_2$ (diimine = bpy or phen) in the solid state and the dinuclearity of these complexes is, at least partially, preserved in methanolic solutions with the monomeric units being bridged by two ibuprofenato ligands. In addition, spectral parameters for complexes **1** and **2** are comparable to those of previously reported for other dinuclear copper(II) carboxylates with diimines [26,28], such as $[Cu(4\text{-aminobenzoate})_2(H_2O)(phen)]_2(NO_3)_2$ [26] and $[Cu(acetate)_2(OClO_3)(bpy)]_2$ [28]. X-ray analysis of these complexes showed that the geometry at each copper(II) atom is distorted square-pyramidal. The basal coordination sites are occupied by the nitrogen atoms of a chelating diimine and two oxygen atoms of bridging carboxylates and the apical position is occupied by an oxygen atom of a monodentate ligand (water or perchlorato group). The dinuclear structure is stabilized by diimine–diimine stacking interactions. The structure of complex **1** or **2** (Scheme 2) can be described in the same manner, except ibuprofenato groups replaced both the bridging 4-aminobenzoato or acetato groups and the terminal monodentate ligands (water or perchlorato group).

The frozen-solution ESR spectrum of complex **3** [Fig. 2(b)] is clearly of rhombic type (Table 1), suggesting a distortion from square symmetry in solution. No signals due to a triplet state were observed in the spectrum of this compound, which is consistent with its mononuclear structure. The lowest g value (2.035) lies between the values obtainable in rhombic spectra for distorted square-based pyramidal or for distorted trigonal-bipyramidal geometry [22]. The structure deviation from square symmetry is attributed to the presence of methyl groups in the 2 and 9 positions on the phenanthroline moiety, close to the coordinated nitrogens to copper(II). In addition, the absence of the ^{14}N superhyperfine splitting may be attributed to the deviation from square symmetry. The ESR and other spectral parameters for complex **3** (Scheme 3) are comparable to those of ternary mononuclear copper(II) complexes of 2,5-dimethoxycinnamic acid or 3,5-disubstituted salicylates and 2,9-dimethyl-1,10-phennthroline [11, 23]. The crystal structure of the ternary complex of 2,5-dimethoxycinnamic acid have





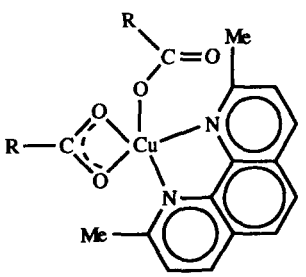


Fig. 2. Frozen-solution ESR spectra of compound (a) **2** and (b) **3**.

RCOO = ibuprofenate anion

Scheme 2.

RCOO = ibuprofenate anion

Scheme 3.

been determined [23]. The copper(II) ion in this complex is five-coordinated and complexes by two nitrogen atoms from 2,9-dimethyl-1,10-phenanthroline, two carboxylic oxygens of a bidentate cinnamic acid and one oxygen atom of a monodentate carboxyl group of a second cinnamic acid molecule. The geometry of the complex has been described as a very distorted square pyramid or trigonal bipyramid.

Inspection of the ESR parameters (Table 1) shows that $A_{\perp}$ values for complexes **1** and **2** are greater than $A_{\parallel}$ for complex **3**, while $g_{\parallel}$ values in the former complexes are smaller. These results are consistent with the presence of a stronger equatorial ligand-field in complexes **1** and **2** with an in-plane CuN_2O_2 chro-

mophore, compared with complex **3** with a very distorted an in-plane CuN_2O_2 chromophore.

The magnetic moments and electronic and IR spectral data are summarized in Table 2. Complexes **1** and **2** exhibit magnetic moments values at room temperature a little lower than normally found in magnetically dilute copper(II) ion complexes, as found in complex **3**. This is attributed to the presence of weak antiferromagnetic coupling in complexes **1** and **2**, which are proposed to have dinuclear structure as shown from spectral data. Facilities to carry out detailed magnetic properties with temperature variation were not available to us. However, it is worth noting that dinuclear copper(II) complexes with doubly bridged carboxylate groups, including those of 2,2′-bipyridine as a secondary ligand, are known to be weakly antiferromagnetically coupled [26–30]. Their $-2J$ values are much less than those found in the familiar tetracarboxylato-ligand complexes of the type $Cu_2(O_2CR)_4L_2$. This decrease has been attributed [30] to the decrease in the number of bridging carboxylato groups by which the superexchange interaction is mediated [26–30].

The electronic spectra for complexes **1** and **2** obtained in CH_2Cl_2 solutions exhibit one very broad absorption band near 675 nm and shoulder near 400 nm (Table 2). The broad band is assigned to the copper(II) *d–d* transitions. The position of this band fall within the range expected for a distorted-tetragonal copper(II) environment with an in-plane CuN_2O_2 chromophore [4–7], including those reported for copper(II) carboxylates with α,α^--diimine [11, 23, 27, 28]. The shoulder near 400 nm is assigned to the charge-transfer band, as expected when π–π interactions between aromatic system are present [36].

The electronic spectrum of complex **3** in CH_2Cl_2 solution exhibits a very broad *d–d* band at 820 nm, similar to that seen for mononuclear copper(II) carboxylates with 2,9-dimethyl-1,10-phenanthroline [11, 23]. The copper(II) ion is five-coordinated, contains the CuN_2O_2+O chromophore and complexes by a chelating 2,9-dimethyl-1,10-phanenthroline, one bidentate and one monodentate carboxylate groups. The low energy of the *d–d* electronic transitions is due to the presence of a pronounced distortion from planar symmetry in this complex and it is consistent with the ESR spectral data.

In the solid-state IR spectra, complexes **1** and **2** possess similar spectra for the ν_{as}(COO) and ν_s(COO) bands (Table 2), supporting similar structures. Two ν_{as}(COO) and two ν_s(COO) are observed, indicating the presence of two types of ibuprofenate groups. The bands at 1610 and 1395–1380 cm^{-1} with large separation, $\Delta\nu$ [ν_{as}(COO) − ν_s(COO)] value of 230–215 cm^{-1}, are assigned to the stretching modes of the monodentate carboxyl group. The positions and separation between them are comparable to those associated with a monodentate coordination of carboxylate group [31]. The bands at 1595 and *ca* 1420–1415 cm^{-1} with $\Delta\nu$ value of 175–180 cm^{-1} are assigned to the "bridging" bidentate carboxylate ligand. The positions and separation between these frequencies are similar to those associated with classical carboxylate bridges (Cu—O—C—O—Cu), including those of $Cu_2(Ibup)_4$ [2, 8, 31]. These IR spectral results are consistent with the proposed structures of these complexes in which two ibuprofenate are bridging two copper atoms and one ibuprofenate is coordinated as a monodentate ligand to each copper atom. In addition to bands of carboxyl groups in complex **1**, bands due to water molecules were observed at 3530–3460 cm^{-1}. When this complex was heated at 110°C for *ca* 10–15 min these bands only disappeared from the IR spectra, while the rest of the spectrum retained its features. This observation indicated that water molecules in this complex are not coordinated, but are present as lattice molecules which were lost on heating.

Solid-state IR spectra for complex **3** exhibit two ν_{as}(COO) and two ν_s(COO) stretching bands (Table 2), indicating the presence of two types of ibuprofenate ligands. The 1610 and 1380 cm^{-1} ($\Delta\nu$ = 230 cm^{-1}) pair observed in the solid-state are assigned to the carboxylate group that acts as a monodentate ligand and the 1600 and 1410 cm^{-1} ($\Delta\nu$ = 190 cm^{-1}) pair are assigned to the other carboxylate that acts as

asymmetric bidentate ligand [31]. These results are consistent with the proposed mononuclear structure containing CuN_2O_2+O chromophore, as discussed in the above spectral properties.

In conclusion, all physical measurements carried out in this study suggest that complexes **1** and **2** have essentially identical dinuclear structures of the type $[Cu(Ibup)_2(diimine)]_2$, in which a dinuclear structure results from the bridging of two ibuprofenate molecules by bidentate carboxylic groups (Scheme 2). In these adducts intermolecular stacking which is usually connected with π–π interactions between the diimine ligands (bpy or phen) may be important in determining the dinuclear structure. The steric hindrance caused by the presence of methyl groups in the 2 and 9 positions on the diimine (dmph) aromatic rings close to the coordination sites, which resulted in a pronounced distortion in the sphere of coordination, complex **3**, precludes the possibility of obtaining an intermolecular stack between diimine ligands and then obtaining the dinuclear structure; instead only mononuclear complex of the type $Cu(Ibup)_2(dmph)$ was obtained (Scheme 3).

Complex **4**, bis(2,9-dimethyl-1,10-phenanthroline) copper(I) ibuprofenate, which was obtained by the reduction of complex **3** was identified by UV–vis, IR and NMR spectral data, in addition to its elemental analyses. Its electronic spectrum obtained in CH_2Cl_2 solution exhibited the metal-to-ligand charge-transfer (MLCT) at 456 nm ($\varepsilon = 6400\ M^{-1}\ cm^{-1}$). The position of this band and its molar absorptivity are comparable with those previously reported for the $Cu(dmph)_2^+$ cation [20, 32]. Examination of the ^1H NMR spectrum, especially the methyl groups of the ligand (dmph), showed an upfield change in the chemical shift of the six proton at *ca* 2.4 ppm compared with those of the free ligand at *ca* 2.8 ppm. This shift was ascribed to an aromatic ring current effect [32] exhibited by cations of the type $[(2,9\text{-dialkyl-1,10-phenanthroline})_2Cu]^+$. The structure of these cations are known to have the distorted tetrahedral geometry about the copper atom [20,32]. The other protons of dmph ligand were not resolved, but relatively broad signals were observed between 7 and 9 ppm. An IR spectrum of the complex revealed peaks of coordinated dmph ligands at 1635, 1505, 1362, 855, 730 and 550 cm^{-1} and peaks of the carboxyl group of ibuprofenate ion at 1585 and 1380 cm^{-1}. The positions of these peaks are comparable with those recently reported for $CuCl(dmph)_2$ [32a] and $(dmph)_2$ Cu(butyrate) [32b]. Collectively, these spectral data suggest that complex **4** has structure of the type $[(dmph)_2Cu](Ibup)$ (Scheme 4).

RCOO = ibuprofenate anion

Scheme 4.

Hydrolysis of BNPP

Since the hydrolysed product *p*-nitrophenolate anion shows a characteristic band at 400 nm ($\varepsilon = 14\,000\ M^{-1}\ cm^{-1}$, at pH 7.4) [17a], the hydrolysis of BNPP [bis(*p*-nitrophenyl)phosphate] by copper(II) complexes **1** and **2** can be easily followed spectrophotometrically. The change in absorbance at 400 nm versus time of the reaction with complexes **1** and **2** was obtained and the pseudo-first-order rate constants, k_{obs}, for the two complexes were found to be $1.0\times10^{-5}\ s^{-1}$ and $0.7\times10^{-5}\ s^{-1}$, respectively. These values showed rate enhancement of *ca* 3.6×10^3 and 2.6×10^3 in the presence of 1 mM of complex **1** or **2**, respectively, compared with the rate constant of the uncatalysed reaction (k_{unc}) of *ca* $2.75\times10^{-9}\ s^{-1}$ at 70°C and pH 7.4 [17d]. It was not possible to obtain kinetic data for complex **3** due to its reduction to copper(I) diimine adduct at 70°C in aqueous methanol solution. This was judged by the disappearance of the copper(II) *d*–*d* transition band at 820 nm and the appearance of an intense metal-to-ligand charge-transfer band at 456 nm characteristic of the copper(I) diimine adduct, **4**.

BNPP has been used as a model for hydrolytic cleavage of the phosphodiester backbone of DNA and RNA [18a,b]. Several possible mechanisms for the hydrolysis of phosphate diesters, including BNPP, by transition-metal complexes have been proposed [17, 18]. In these mechanisms the metal ions supply electrophilic acceptor sites for the phosphodiester's P—O^- followed by an external nucleophilic (H_2O or OH^-) attack or an intramolecular metal hydroxide attack at P=O, which then facilitates the hydrolysis of *p*-nitrophenolate groups. In addition, cooperation between metal ions and carboxyl groups of the ibuprofenate ions which may make a nucleophilic attack at phosphodiester cannot be ruled out in the hydrolysis of BNPP in the presence of complex **1** or **2**. Detailed kinetic studies and the potential application of these new complexes in the hydrolysis of biological phosphoric ester is being investigated.

Studies on the formation and decomposition of copper(III) and nickel(III) complexes with macrocyclic ligands containing amide groups

Fuping Kou, Shourong Zhu,* Huakuan Lin, Keqin Ma and Yunti Chen

Department of Chemistry, Nankai University, Tianjin 300071, P. R. China

(Received 23 February 1996; accepted 26 April 1996)

Abstract—The spectral characteristics of 13- and 14-membered C-functionalized macrocyclic dioxotetraamine and the corresponding saturated polyamine copper(II), copper(III) and nickel(III) complexes have been studied. It was shown that C-functionalized substituents, although not coordinating to the metal ion, have significant effects on the spectral properties of their M^{III} complexes. As for copper(II) complexes, substituents increase the in-plane ligand field and decrease the wavelength of the *d–d* absorption of their complexes. Substituents increase the π-CT wavelength and decrease the absorption coefficients. Rate constants and activation parameters for the oxidation of Cu^{II} complexes by peroxodisulfate and decomposition reactions of copper(III) complexes in aqueous solution were also measured. Activation parameters were shown to be dependent on ligand structure. Copyright © 1996 Elsevier Science Ltd

Keywords: macrocyclic dioxotetraamine; copper(III) complex; nickel(III) complex; formation; decomposition; kinetics.

Square-planar saturated and unsaturated N_4 ligands have been well demonstrated to stabilize various oxidation states of enclosed iron [1], cobalt [2,3] or nickel [4,5] in aprotic solvents. The redox properties are determined by various structural parameters: a large ring, the presence of alkyl side chains to interfere with axial solvation or unsaturation of N donors for the lower valence states, while the absence of these factors or the presence of negative charge on N donors stabilizes higher oxidation states. Another efficient ligand factor facilitating higher oxidation states of metal ions in aqueous solutions was discovered in oligopeptide complexes of Cu^{II} [6] and Ni^{II} [7], where anionic imide N donors reduce the electrode potentials for M^{III}/M^{II} couples. Highly deprotonated peptide complexes have extremely low potentials [8]. It is postulated that oxidative cleavage of peptides by air in the presence of Cu^{II} or Ni^{II} involves M^{III}-peptide complexes as intermediates. The stabilization of high-oxidation states of 3*d* transition metal ions, in particular Cu^{III}, is of great current interest. This is due to the fact that such compounds can serve as models for some enzymes such as galactose oxidase [9] and may be used as effective oxidants and redox catalysts [10]. However, it is necessary to bear in mind that thermodynamic stabilization of the high oxidation state (i.e. lowering $M^{III}L/M^{II}L$ couple potential) prevents its use as an effective oxidant. More attractive in this sense would be compounds possessing high redox potentials along with high kinetic stability.

Among copper(II) stabilizing ligands, macroscopic tri- and tetrapeptides have been most widely studied [10]. The data obtained show that an increase in the number of deprotonated amide groups in the macrocycles cause a thermodynamic stabilization of copper(III). On the other hand, saturated tetraaza macrocycles containing only secondary amine donors do not stabilize copper(III), but are good nickel(III)-stabilizing ligands [11]. From this point of view, macrocyclic ligands containing both secondary amines and amide groups are of interest. Recently, we have developed a simple and versatile method for the synthesis of C-functionalized macrocyclic dioxotetraamine [12] that produce appropriate ligand fields and steric environments so as to reproduce certain essential redox functions that occur in natural metal-containing enzymes. On the basis of our pre-

vious studies [13–17], copper and nickel complexes with macrocyclic dioxotetraamine ligand I_1–I_4 were chosen to investigate the effects of ligand structure on their spectral properties, formation and decomposition kinetics of Cu^{III} and Ni^{III} complex (Fig. 1).

EXPERIMENTAL

Reagents

All chemicals and solvents used in the synthesis and determination were of reagent grade and were used without further purification.

Synthesis

All reagents used were of analytical grade. L_1–L_4 were prepared according to the new method recently developed by us [12]. The corresponding saturated polyamine macrocycles were prepared by B_2H_6 reduction of dioxotetraamine [16].

Apparatus and instruments

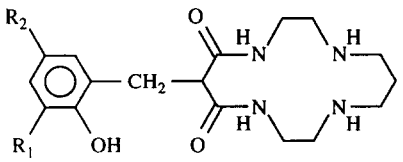
Cyclic voltammetry was used to determine the electrode potentials E of a series of the present M^{II}-macrocycle complexes in a similar fashion as before [12]. A PARC model 273 electrochemical apparatus was used. The working electrode used was glassy carbon. Platinum was used as an auxiliary electrode. Saturated calomel was used as reference electrode. Voltammograms were obtained in 0.5 mol dm^{-3} Na_2SO_4 solution at 25°C and a scan rate of 100 mV s^{-1} for metal complexes (3×10^{-3} mol dm^{-3}). Complex solutions were prepared by mixing equimolar quantities of the ligand and copper(II)/nickel(II) sulfate. The E values (V versus SCE) were obtained from an average of three independent solution measurements and have a reproducibility of 5 mV. As a supporting electrolyte, we have consistently used 0.5 mol dm^{-3} sodium sulfate. The separation of the anodic and cathodic peaks was 70–110 mV and the peak current ratios were near unity. These features are indicative of quasi-reversible electrochemical behaviour and, therefore, the midpoint between the oxidation peak and the reduction peak was taken as the electrode potential E for M^{III}/M^{II} couples. All of the E values thus obtained were summarized in Table 1.

Kinetic measurements

Kinetic measurements were carried out spectrophotometrically in a thermostatted (±0.1°C) quartz cell (1 cm) using a Shimadzu UV–Vis 160A spectrophotometry. Extinction coefficient ε were determined by oxidation of the complex (5×10^{-4} mol dm^{-3}) in $K_2S_2O_8$ (0.1 mol dm^{-3}). Solutions of reagents were thermostatted before measurement for *ca* 15 min. Solutions of $K_2S_2O_8$ were prepared immediately before use. The formation of copper(III) and nickel(III) complexes and their disappearance was followed at their absorption maximum (−410 nm), where absorption of the initial copper(II) complexes is negligible. All measurements unless otherwise stated were carried out at ionic strength $I = 0.1$ M $NaClO_4$. The $K_2S_2O_8$ concentration was 2.0×10^{-3} mol dm^{-3}. The complex concentration was 3×10^{-3}–1.0×10^{-4} mol dm^{-3}. pH values were adjusted to 6–7 with NaOH. All solutions were prepared with twice distilled water.

RESULTS AND DISCUSSION

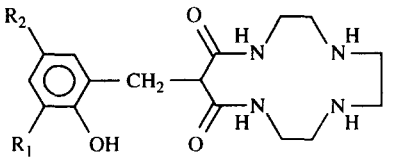
Reaction of dioxotetraamine macrocycles with transition metal ions proceeds according to the following equations to yield positively charged and neutral complexes [12b]:



$$M^{2+} + L = MH_{-1}L^{+} + H^{+} \quad (1)$$

$$M^{2+} + L = MH_{-2}L + 2H^{+}. \quad (2)$$

The mechanism of this reaction includes coordination of the metal ion to secondary amine nitrogen atoms and a subsequent deprotonation of amide groups. It must be noted that, unlike in previous reports, two amido groups are different, that is, when coordinated to the metal ion, especially copper(II), the amido hydrogen does not dissociate simultaneously [13]. As shown in the reaction equation, the equilibrium strongly depends on pH; at pH 4.8, the positively charged $[CuH_{-1}L]^{+}$ has a maximum value about 15%, when pH rise to 5.5 or higher, all metal ions existed in the form of $MH_{-2}L$ (Fig. 2). In the present kinetic study, the initial pH of the complex is 6–7, in which range $MH_{-1}L$ does not exist. Since phenolic oxygen does not coordinate to copper(II), substituents have little effect on properties of their M^{II} complexes. However, there are some differences between the complex with and without substituents. Table 1 summarizes some spectral data and Cu^{II}/Cu^{III} half-wave potentials.



The position of the *d–d* absorption band in the electronic spectra is typical of square-planar complexes. The data presented show that the absorption maxima shifted to short wavelength with the introduction of a substituent. The greater *d–d* transition energy of complexes with substituents indicate the evidence that they have greater in-plane ligand field strength. To our knowledge, these complexes have the greatest in-plane ligand field strength.

It is well known that the most suitable macrocycles for Cu^{II} ions are 14-membered ligands. Apparently, in complexes with 13-membered ligands, the coordination polyhedron of the metal ion has some distortion from planarity and this distortion decreases the in-plane ligand field strength, thus the wavelength of the copper(II) complexes are larger than corresponding 14-membered ligands. Due to this distor-

tion, the absorption coefficient increased. All oxidation processes of the complexes in aqueous solution are quasi-reversible. Substituents increase the Cu^{II}/Cu^{III} potential of the complex. Lower $E_{1/2}$ values for complexes with 13-membered ligands compared with 14-membered ones are due to a better fit of the 13-membered ring to the copper(III) ion. However, substituents decrease the Ni^{II}/Ni^{III} potential. This is quite different from that in copper(II) complexes and indicates that there must be some interaction between substituents and Ni^{II} or Ni^{III} ions because d^7-Ni^{III} tends to form a distorted octrahedral complex; the phenol substitute interacts and stabilizes the Ni^{III} complex, thus decreasing the Ni^{III}/Ni^{II} potentials. For 13-membered macrocyclic dioxotetraamine, it is the strong ligand field that stabilizes copper(III) efficiently. However, macrocyclic polyamine, especially 14-membered macrocyclic polyamine, stabilizes nickel(III) effectively. Substituents in macrocyclic polyamines can further stabilize the Ni^{III} state.

Due to the low Cu^{II}/Cu^{III} potential, one expects that macrocyclic dioxotetraamine copper(II) can easily by oxidized. When the macrocyclic dioxotetraamine copper(II) complex was oxidized chemically or electrochemically, brown copper(III) complexes were formed. Their charge-transfer absorption bands have been reported. In our study, potassium peroxodisulfate was used as an oxidant, since both potassium peroxodisulfate and its reduction products do not absorb in the visible and the near-UV region and its reactions with copper(II) complexes are slow enough to study them by conventional spectrophotometric techniques.

After addition of oxidant to a solution of the copper(II) complexes, an intense new absorption band appears in the near UV and visible spectral region (Fig. 3).

Both in ligands and complexes there are no absorptions in the 380–440 nm region in our experimental conditions. When free ligands were oxidized by potassium peroxodisulfate, no absorption in this region was observed even in a longer time interval (1 h). Hay [18] attributed this band to be a *d–d* transition, while Lampeka [19] reported it to be a CT band. We assign the 380–440 nm absorption to be an L–M CT band of the copper(III) complex, because of its large absorption coefficient. This M^{III} CT band does not change in 0.1 mol dm^{-3} $HClO_4$. Absorption maxima and extinction coefficients were summarized in Table 2.

We can see from Table 2 that, as in copper(II) complexes, the absorption maximum varies with the substituents. Compared with L_9 complexes, the presence of substituents leads to a substantial intensity decrease and wavelength increase. This indicates that a significant π-interaction of the phenol substituent

with the central M^{III} ion may exist, in agreement with Lampeka [19]. However, some different structure macrocyclic dioxotetraamine copper(III) complexes have a similar absorption maximum [20] (350 nm), such as L_{11} (300 nm), L_{10} and L_{12} (300 nm) [19], L_{14} (365 nm) [21], L_{15} (Ni^{III} complex, 370 nm) [22], L_{13}, L_{16} and L_{17} (350 nm) [18], L_{18} (355 nm) [20], and L_{19} (395 nm) [21]. Both λ_{max} and the absorption coefficient of the present C-functionalized copper(III) complexes are similar to the tripeptide copper(III) and nickel(III) complexes [23]. Unlike in acid solution, all the M^{III} complexes decomposed quickly in strong alkaline solution. This further supports the view that the absorption at 350–450 nm is caused by M^{III} complexes [22,23].

Oxidation kinetics

Despite the availability of a large number of papers concerning the properties of copper(III) and nickel(III) complexes, kinetic investigations of copper(II) or nickel(II) on corresponding M^{III} states are few. Only the oxidation of some peptide complexes by $IrCl_8^{2-}$ and several cross reactions between peptide complexes appear to have been studied [24,25]. Figure 4 shows spectral changes occurring during oxidation of a C-functionalized macrocyclic dioxotetraamine copper(II) complex by peroxodisulfate. From Fig. 4 we can see that the reaction processes are characteristic of consecutive reaction. In fact, the absorption increase at 410 nm is contributed to the copper(III) complex formation. While the decrease indicates the decomposition of the copper(II) complex.

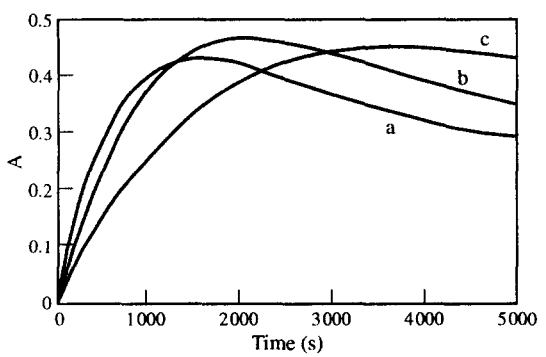

Fig. 4. Spectroscopic changes at 410 mm during oxidation of $Cu^{II}L$.

Rate constants for the oxidation were calculated from the initially linear regions of kinetic curves using the calculated ε values for the copper(III) and nickel(III) complexes. The M^{III} complexes formation rate was found to be first-order in both reagents. That is:

$$d[Cu^{III}L]/dt = k_{obs}[Cu^{II}L][S_2O_8^{2-}].$$

The observed second-order rate constants of Cu^{II} and Ni^{II} complexes are summarized in Tables 3 and 4.

Comparison of k_{obs} and $E_{1/2}$ values shows that complexes of 13-membered ligands having lower redox potentials will oxidize more slowly. Substituents

decrease the redox rate considerably, which may be due to the fact that the steric hindrance of the substituents decreased the stability of the intermediate complexes because the phenol substituent covered the metal ions [13].

In accordance with the literature results [11, 19], the following scheme can be used to describe the oxidation mechanism:

$$M^{II}L + S_2O_8^{2-} \overset{K}{\rightleftharpoons} [M^{II}L \cdot S_2O_8]^{2-}$$

$$[M^{II}L \cdot S_2O_8]^{2-} \overset{k}{\rightarrow} M^{III}L^{+} + SO_4^{2-} + SO_4^{-}$$

$$M^{II}L + SO_4^{-} \overset{\text{fast}}{\rightarrow} M^{III}L^{+} + SO_4^{2-}.$$

The first step is a fast pre-equilibrium process; an outer-sphere intermediate complex was formed between oxidant and reductant. The second step is the activation and electron-transfer step, which is the rate-determining step. The free radical is active and is quickly reduced as shown in step 3. After oxidation, $BaCl_2$ solution was added to the mixture and a white precipitate formed, which indicated that $S_2O_8^{2-}$ was reduced to SO_4^{2-}.

According to the mechanism, we have:

$$d[M^{III}L^{+}]/dt = kK[M^{II}L][S_2O_8]^{2-},$$

therefore, $k_{obs} = kK$.

In the formation of the outer-sphere intermediate complex, there is no bonding formation, i.e. the enthalpy is small in the formation of the intermediate complex.

Using Eyring's formula, the activation parameters of the rate-determining step were obtained (Table 5).

From Tables 5 and 6 we can see that, for complexes with 13-membered ligands, the values of $\Delta H_m^{\ddagger}$ are considerably higher than those for complexes with 14-membered analogues, while the difference of $\Delta S_m^{\ddagger}$ values are small. This reflects different stereochemistry in both types of complexes.

The data presented may lead us to ascertain the effect of the substituents on activation parameters. It is the large $\Delta H_m^{\ddagger}$ value of complexes with substituents that greatly reduced their oxidation rates. On comparison with 13-membered copper(II) complexes, k_{obs} of 14-membered copper(II) complexes are larger because of their small $\Delta H_m^{\ddagger}$ value. In our opinion, the reason is that 14-membered macrocycles are best fitted to the copper(II) ion, the strong coordinative interactions exerted by the 14-membered macrocyclic dioxotetraamine ligand raising the energy of the antibonding level (essentially metallic in character) from which the electron is abstracted, thus decreases the $\Delta H_m^{\ddagger}$ values. While 13-membered macrocyclics most readily fit the nickel(II) ion [26], therefore, their oxidation rates are larger than 14-membered analogues. Electron-giving substituents increase the level of the highest occupying orbitals of the metal ions, thus k_{obs} values were increased compared with the electron-withdrawing substituent.

Decomposition of copper(III) *and nickel*(III) *complexes*

Copper(III) and nickel(III) complexes formed in the oxidation reactions are not stable enough and decompose via intramolecular redox reaction. Our experiments have shown that the decompositions are first-order in copper(III) or nickel(III) complexes:

$$-d[M^{III}L^{+}]/dt = k_d[M^{III}L^{+}].$$

Since the decomposition reactions are slow, rate constants for the oxidation were calculated from the initially linear regions of kinetic curves. The starting point was chosen 5–10 min. after the absorption maximum to ensure all the copper(II) complexes were oxidized. Rate constants and activation parameters for the decomposition of M^{III} complexes are summarized in Table 7.

Analysis of the data presented in Table 7 shows little effect of ring size on decomposition rate constants and activation parameters of copper(III) complexes, but the effect of the substituents is more pronounced. Electron-withdrawing substituents not only decrease the oxidation rate of copper(II) complexes, but also decrease the decomposition rate of copper(III) complexes. The introduction of substituents greatly increased the kinetic stability of copper(III) complexes. The half-lives of Cu^{III} complexes of macrocyclic-dioxotetraamine at 25°C are 2.5 to 5 h, while Ni^{III} complexes have half-lives of 4–18 h.

Nickel(III) complexes of macrocyclic dioxotetraamines are thermodynamically unstable,

Table 7. Rate constants and activation parameters for decomposition of M^{III} complexes

Complex	k_d ($s^{-1} \times 10^5$) 15°C	25°C	35°C	$\Delta H_m^{\ddagger}$ (kJ mol^{-1})	$\Delta S_m^{\ddagger}$ (J mol^{-1} K^{-1})
$Cu^{III}L_1$	7.00	11.7	16.8	28.3	−226
$Cu^{III}L_5$	6.34	10.1	13.5	25.5	−236
$Cu^{III}L_7$	4.79	7.04	11.7	32.6	−218
$Cu^{III}L_8$	3.51	5.41	8.06	30.2	−229
$Cu^{III}L_9$		21		61	−111
$Ni^{III}L_1$	1.93	2.94	4.95	30.2	−230
$Ni^{III}L_3$	1.51	2.22	3.40	27.5	−242
$Ni^{III}L_4$	1.13	1.57	1.99	18.5	−122
$Ni^{III}L_5$	2.95	6.81	14.7	56.8	−134
$Ni^{III}L_9$	7.21	14.5	27.5	47.0	−161

however, they do have considerable kinetic stability. As in the case of copper(III) complexes, substituents, especially electron-withdrawing substituents, increase the kinetic stability of Ni^{III} complexes. Substituted polyamine Ni^{III} complexes even have no noticeable spectral change over 1 week.

Decomposition of the M^{III} complex was very slow compared with the oxidation process: in 0.1 mol dm^3 $K_2S_2O_8$ solution the decomposition rate was even less than 1% of the oxidation rate, according to formula $28\ \beta = K^{K/(1-K)}$, where β is the mole ratio of the M^{III} complex and K is the ratio of decomposition and formation rate of the M^{III} complex, 95% or higher M^{III} complex existed in the absorption maxima, therefore, we can easily determine the absorption coefficient by the oxidation of M^{II} complex in 0.1 mol dm^{-3} $K_2S_2O_8$ solution.

In conclusion, our study shows that though phenols do not coordinate to M^{II}, they do affect the spectral characteristics and M^{II}/M^{III} potentials. Substituents increasing the in-plane ligand field can increase redox potentials, but decrease the oxidation rate of their M^{II} complexes and decomposition rates of their M^{III} complexes.

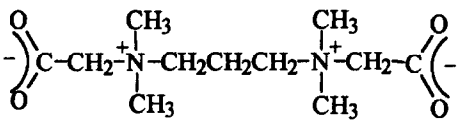
(Received 28 June 1996; accepted 17 July 1996)

Abstract—Four novel two-dimensional lanthanide(III) coordination polymers of two flexible double betaines with different numbers of methylene groups bridging two quaternary nitrogen atoms, namely $[\{Nd(L^2)_2(H_2O)_2\}_n][ClO_4]_{3n}$ (**1**), $[\{Nd(L^2)_2(H_2O)_2\}_n][ClO_4]_{3n}\cdot nH_2O$ (**2**), $[\{Er(L^1)_2(H_2O)_2\}_n][ClO_4]_{3n}\cdot nH_2O$ (**3**) and $[\{Er(L^2)_2(H_2O)\}_n][ClO_4]_{3n}\cdot nH_2O$ (**4**) [L^1 = *N,N′*-dicarboxymethyl-*N,N,N′,N′*-tetramethyl-1,3-propanediammonium: $^-O_2CCH_2N^+Me_2—(CH_2)_3—N^+Me_2CH_2CO_2^-$; L^2 = *N,N′*-dicarboxymethyl-*N,N,N′,N′*-tetramethyl-1,4-butanediammonium: $^-O_2CCH_2N^+Me_2—(CH_2)_4—N^+Me_2CH_2CO_2^-$], have been prepared and characterized by X-ray crystallography. Each complex contains a centrosymmetric paddle-wheel-like dimeric subunit in which each pair of adjacent metal atoms is bridged by four *syn–syn* μ-carboxylato-*O,O′* groups that are oriented nearly perpendicular to each other about the metal–metal axis. The dimeric subunits are extended into a polymeric chain through the linkage of each metal centre to carboxylato groups of an adjacent dimer. Such infinite chains are extended into a plane wave-like layer structure by cross-linkage of the molecular skeletons of double betaine ligands. The neodymium(III) atom is (**1**) is surrounded, in a distorted monocapped square-antiprismatic geometry, by seven carboxylato oxygen atoms and two aqua ligands, and the carboxylato groups are involved in three different coordination modes: the common bidentate bridging, unidentate and unusual tridentate bridging. In (**2**), (**3**) and (**4**), the lanthanide(III) atom exhibits eight coordination in a distorted square antiprism, and the carboxylato groups in the dimeric subunits adopt the common unidentate and bidentate bridging modes. In addition, the uncommon bidentate chelate mode of carboxylato groups also occurs in (**4**). Copyright © 1996 Elsevier Science Ltd

Keywords: betaine; carboxylate; neodymium; erbium; lanthanide; coordination polymer.



There has been considerable interest in the coordination chemistry of lanthanide complexes with carboxylato ligands owing to their potential application as luminescent probes in systems of biological relevance [1], particularly as resonance contrasting agents [2,3]. Of the numerous lanthanide complexes that have been widely studied [4–7], most have been found to possess a variety of dimeric or infinite chain structures in which the carboxylate groups act as bridges between metal atoms, and the number of bridging carboxylato groups varies in different complexes. In the case of the acetate ligand, the cerium(III) complex adopts a linear polymeric structure with respective pairs of metal atoms bridged by three acetato groups [8], whereas the holmium(III) complex takes a dimeric form in which the lanthanide atoms are bridged by only two carboxylate groups [9]. The neodymium(III) (methylthio)acetate complex has nine-coordinate lanthanide atoms that are bridged in pairs by two or four carboxylato ligands into a linear polymeric chain [10]. In ytterium(III) (methylthio)acetate, which takes a linear polymeric form, adjacent metal atoms are linked by only one carboxylato group [11]. In contrast, lanthanide carboxylates with a two-dimensional polymeric network

† Author to whom correspondence should be addressed.

are rare, although the formate has been found to exhibit a layered structure [12].

Our recent studies have demonstrated that betaine ($Me_3N^+CH_2CO_2^-$; IUPAC name, trimethylammoniumacetate) and its derivatives, considered as structural analogues of the corresponding carboxylate anions, are useful in the preparation of carboxylate complexes of transition metals [13–17]. Furthermore, by virtue of their overall charge neutrality, betaine compounds have been used to prepare metal complexes with new structural features compared with the common metal carboxylates [18–22]. In previous studies we have obtained two-dimensional crystalline mercury(II) chloride adducts, as well as silver and sodium coordination polymers with layer-type or three-dimensional networks by using a series of flexible double betaines with an adipic acid skeleton, or different polymethylene bridges between the quaternary nitrogen atoms [23–27]. Lanthanide complexes of betaine and its derivatives are much less well known, although several examples have been reported recently [28]. In this paper, we describe the preparation and characterization of four new neodymium(III) and erbium(III) complexes containing two-dimensional frameworks constructed from two flexible dicarboxylate-like double betaines with different numbers of methylene groups linking two quaternary nitrogen atoms, namely $[\{Nd(L^1)_2(H_2O)_2\}_n][ClO_4]_{3n}$ (**1**), $[\{Nd(L^2)_2(H_2O)_2\}_n][ClO_4]_{3n} \cdot nH_2O$ (**2**), $[\{Er(L^1)_2(H_2O)_2\}_n][ClO_4]_{3n} \cdot nH_2O$ (**3**) and $[\{Er(L^2)_2(H_2O)\}_n][ClO_4]_{3n} \cdot nH_2O$ (**4**) [L^1 = *N*,*N*′-dicarboxymethyl-*N*,*N*,*N*′,*N*′-tetramethyl-1,3-propanediammonium: $^-O_2CCH_2N^+Me_2$—$(CH_2)_3$—$N^+Me_2CH_2CO_2^-$; L^2 = *N*,*N*′-dicarboxylmethyl-*N*,*N*,*N*′,*N*′-tetramethyl-1,4-butanediammonium: $^-O_2CCH_2N^+Me_2$—$(CH_2)_4$—$N^+Me_2CH_2CO_2^-$].

Structural formulas of L^1 and L^2

EXPERIMENTAL

The flexible double betaines L^1 and L^2 were synthesized as described previously [27]. The C, H and N microanalyses were carried out on a Perkin–Elmer 240 elemental analyser. Infrared spectra were recorded from KBr pellets in the range of 4000–400 cm^{-1} on a Perkin–Elmer 1600 FT-IR spectrometer.

Synthesis of $[\{Nd(L^1)_2(H_2O)_2\}_n][ClO_4]_{3n}$ (**1**)

Perchloric acid (2 N) was added slowly to an aqueous suspension (10 cm^3) of neodymium oxide (Nd_2O_3; 0.084 g, 0.25 mmol) with stirring at *ca* 60°C. The resulting clear solution of neodymium(III) perchlorate (0.5 mmol) was mixed with an aqueous solution (5 cm^3) of L^1 (0.26 g, 1.0 mmol). After stirring at *ca* 60°C for a few minutes, a clear solution was obtained by filtration. Storage of the solution in a desiccator charged with drierite for a few days yielded pink prismatic crystals. Found: C, 27.1; H, 5.1; N, 5.6. Calc. for $C_{22}H_{48}N_4O_{22}Cl_3Nd$: C, 27.2; H, 4.9; N, 5.8%. IR: 3433s, 3011w, 2978w, 2078w, 1661m, 1622vs, 1478m, 1406s, 1328m, 1272w, 1144s, 1117s, 983w, 939w, 906m, 717m, 628m and 546w cm^{-1}.

Synthesis of $[\{Nd(L^2)_2(H_2O)_2\}_n][ClO_4]_{3n} \cdot nH_2O$ (**2**)

To an aqueous solution (10 cm^3 of neodymium(III) perchlorate (0.5 mmol) was added a solution of L^2 (0.274 g, 1.0 mmol) in water (5 cm^3) with stirring at *ca* 60°C for a few minutes. After filtration, pink block-like crystals were obtained by diffusing ethanol into the aqueous solution. Found: C, 28.6; H, 5.2; N, 5.5. Calc. for $C_{24}H_{54}N_4O_{23}Cl_3Nd$: C, 28.3; H, 5.3; N, 5.5%. IR: 3435s, 3065w, 2967w, 2075w, 1613vs, 1488m, 1405m, 1341m, 1145s, 1118s, 1080s, 1009w, 938w, 894m, 715m, 628m and 552w cm^{-1}.

Synthesis of $[\{Er(L^1)_2(H_2O)_2\}_n][ClO_4]_{3n} \cdot nH_2O$ (**3**)

The aqueous solution (10 cm^3) of erbium(III) perchlorate (0.5 mmol) prepared in a similar manner to that above was mixed with a solution of L^1 (260 mg, 1.0 mmol) in water (5 cm^3) with stirring at *ca* 60°C for a few minutes. The solution was filtered, and ethanol was diffused into the resulting solution for a week to yield pink crystals. Found: C, 26.5; H, 5.1; N, 5.4. Calc. for $C_{22}H_{48}N_4O_{22}Cl_3Er$: C, 26.1; H, 4.9; N, 5.5%. IR: 3424s, 3011w, 2978w, 2020w, 1635s, 1613s, 1482m, 1406s, 1355m, 1275w, 1145s, 1118s, 1080s, 982w, 938w, 900m, 709w, 628w and 541w cm^{-1}.

Synthesis of $[\{Er(L^2)_2(H_2O)\}_n][ClO_4]_{3n} \cdot nH_2O$ (**4**)

To an aqueous solution (10 cm^3) of erbium(III) perchlorate (0.5 mmol) was added L^2 (274 mg, 1.0 mmol) in water (5 cm^3) with stirring under heating.

After filtration pink prismatic crystals were obtained by diffusing ethanol into the aqueous solution. Found: C, 28.3; H, 5.1; N, 5.5. Calc. for $C_{24}H_{52}H_4O_{22}Cl_3Er$: C, 28.2; H, 5.1; N, 5.5%. IR: 3446s, 3065w, 2967w, 2031w, 1607s, 1482m, 1411s, 1346m, 1139s, 1118s, 932w, 894m, 726m, 622m and 562w cm^{-1}.

CAUTION. Metal perchlorate salts containing organic ligands are potentially explosive and should be handled with great care.

Crystal structure determinations

Information concerning crystallographic data and structure refinement of the four complexes is summarized in Table 1. Raw intensities of complexes **1, 3** and **4** were collected at 293 K on a MSC/Rigaku RAXIS-IIC imaging plate system with a rotating anode Mo-K_α X-ray source ($\lambda = 0.71073$ Å, 50 kV, 150 mA) [29], and corrected for absorption using the ABSCOR program [30]. Raw intensities of complex **2** were collected on a Siemens R3m/V diffractometer in the variable ω-scan mode [31] using Mo-K_α radiation ($\lambda = 0.71073$ Å) at 293 K. Unit-cell parameters were calculated from least-squares fitting of 2θ angles for 25 reflections. Crystal stability was monitored by recording three check reflections at intervals of 150 data measurements, and no significant variation was detected. The raw data were processed with a learnt-profile procedure [32], and empirical absorption corrections based on ψ-scan data were also applied.

All calculations were performed on a PC 486 computer with the SHELXTL-PC program package [33]. Each crystal structure was solved with the Patterson superposition method. The non-hydrogen atoms were refined anisotropically, except for the oxygen atoms of the slightly disordered perchlorate groups in complexes **1–4,** which were subjected to interatomic distance constraints of Cl—O 1.42 ± 0.01 Å and O···O 2.31 ± 0.02 Å and refined isotropically. All the hydrogen atoms were generated geometrically (C—H = 0.96 Å), assigned fixed isotropic thermal parameters and included in the structure factor calculations. Analytical expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated [34]. Selected bond lengths and angles are given in Table 2.

Additional material deposited at the Cambridge Crystallographic Data Centre comprises atom coordinates, thermal parameters and remaining bond lengths and angles.

RESULTS AND DISCUSSION

Crystal structure of $[\{Nd(L^1)_2(H_2O)_2\}_n][ClO_4]_{3n}$ (**1**)

Complex **1** comprises discrete perchlorate anions and a two-dimensional cationic polymeric layer containing tetrakis(carboxylato-*O*,*O*′)-bridged centrosymmetric dimeric subunits. As illustrated in Fig. 1a, four carboxylato groups from respective L^1 ligands link a pair of neodymium(III) atoms in the *O*,*O*′-bridging mode to generate a paddle-wheel-like centrosymmetric [Nd_2(carboxylato-*O*,*O*′)$_4$] dimer. The Nd···Nd separation [4.243(3) Å] is significantly shorter than that [4.315 Å] in $[\{Nd(ClCH_2CO_2)_3\}_3(H_2O)_5]_n$ [7]. Each neodymium atom is coordinated by seven carboxylato oxygen atoms from L^1 ligands and two aqua ligands in a nine-coordinate environment. The carboxylato groups are involved in three different coordination modes: a common bidentate bridging mode in the *syn–syn* configuration [C(1)—O(1)—Nd(1), 139.4(3) and C(1)—O(2)—Nd(1a) 137.6(3)°], a unidentate mode [C(11c)—O(3c)—Nd(1), 145.7(3) and C(22b)—O(7b)—Nd(1), 142.4(3)°], as well as an unusual tridentate bridging coordination mode [C(12)—O(6)—Nd(1), 99.8(3), C(12)—O(5)—Nd(1), 88.5(2) and C(12)—O(5)—Nd(1a), 160.4(3)°] in which the Nd(1)—O(5) distance [2.772(3) Å] is much longer than those of Nd(1)—O(6) [2.554(3) Å] and Nd(1a)—O(5) [2.424(3) Å] bonds. This latter coordination mode involves both *syn–syn* and *syn–anti* bridging and is rarely encountered in betaine lanthanide complexes with two- and three-dimensional polymeric networks, although the bridging tridentate carboxylato group is known in chloroacetate lanthanide complexes, which adopt infinite chain structures [7]. The coordination geometry about the neodymium atom may be described as a distorted NdO_9 monocapped, square antiprism as shown in Fig. 2a. One square face comprises four carboxylato oxygen atoms [O(1), O(5a), O(2a) and O(6)] with large mean deviation (0.117 Å) from the least-squares plane, whereas the other face as defined by two carboxylato oxygen atoms [O(3b) and O(7c)] and two aqua oxygen atoms [O(1w) and O(2w)] having a mean deviation of 0.041 Å from the least-squares plane. The dihedral angle between the square faces is *ca* 6.7°. The Nd—O distances vary from 2.407(3) to 2.772(3) Å, among which the shortest one is associated with the unidentate bridging carboxylato oxygen atom, and the longest one with the tridentate bridging carboxylato oxygen atom.

The molecular backbone of each of the two independent, flexible, double betaine ligands is extended to achieve a longer separation between its two quaternary nitrogen atoms. The conformation of the double betaine is similar to that in its hydrated form [27], but different from that in its mercury adduct, in which the symmetry of the molecular backbone of L^1 has a C_2-axis at the middle methylene carbon atom [24]. A perspective view of complex **1** is shown in Fig. 1b, where the dimeric subunits are extended into a polymeric chain running along the *c*-direction. Such chains are further cross-linked by the molecular skeleton of the double betaine ligand, thereby extending the structure into a plane wave-like layer corresponding to the plane [200]. The crystal structure is built up by a packing of these layers such that the perchlorate groups (one of which exhibits orientational disorder and forms an acceptor hydrogen bond [O(2w)···O(9) 2.875(7) Å] with one coordinated aqua oxygen atom [O(2w)]) are accommodated in the interlayer regions.

Crystal structure of $[\{Nd(L^2)_2(H_2O)_2\}_n][ClO_4]_{3n} \cdot nH_2O$ (**2**)

There are one complete and two half molecules of L^2 in the asymmetric unit of complex **2**. The resulting dimeric moiety is similar to that in complex **1**, being also a paddle-wheel-like structure based on tetrakis(carboxylato-*O*,*O*′) bridging (Fig. 3a). However, the neodymium(III) atom is coordinated by six carboxylato oxygen atoms from L^2 ligands and two aqua ligands in an eight-coordinate environment, being different from that of complex **1**. As shown in Fig. 2b, the coordination geometry about the neodymium atom in complex **2** may be described as a square antiprism with Nd—O distances in the range of 2.390(5) to 2.583(4) Å. The upper square face consists of two carboxylato oxygen atoms [O(3b) and O(5)] and two aqua oxygen atoms [O(1w) and O(2w)] with negligible mean deviation (0.005 Å) from the least-squares plane. The lower face is defined by oxygen atoms [O(1), O(7), O(2a) and O(8a)] from four carboxylato groups of L^2 ligands with a mean deviation of 0.078 Å from the least-squares plane. The dihedral angle between the square face is *ca* 3.4°.

Unlike complex **1**, in which the carboxylato groups exhibit three different coordination modes (unidentate, bidentate bridging and tridentate bridging), the carboxylato groups in complex **2** functions only in the unidentate [C(12c)—O(3c)—Nd(1a), 142.4(3) and C(13)—O(5)—Nd(1), 140.4(3)°] and bidentate bridging modes [C(1)—O(1)—Nd(1), 166.9(3), C(1)—O(2)—Nd(1a), 107.9(4), C(19)—O(7)—Nd(1), 138.9(3) and C(19)—O(8)—Nd(1a), 141.6(3)°]. Coexistence of uni- and bidentate modes has been found in some dimeric lanthanide carboxylates [28]. The Nd···Nd separation [4.376(3) Å] is comparable to that in $[\{Nd(ClCH_2CO_2)_3\}_3(H_2O)_5]_n$ [7] but is significantly longer than that in complex **1**. It is noteworthy that the conformations of the independent double betaine ligands are different: two ligands each have an inversion centre located between the two middle methylene carbons, being similar to that in its hydrated form [27] but different from that in its mercury adduct, in which the molecular backbone of L^2 has a C_2-axis [24], but the other ligand has no crystallographically imposed symmetry. A perspective view of complex **2** (Fig. 3b) shows that col-

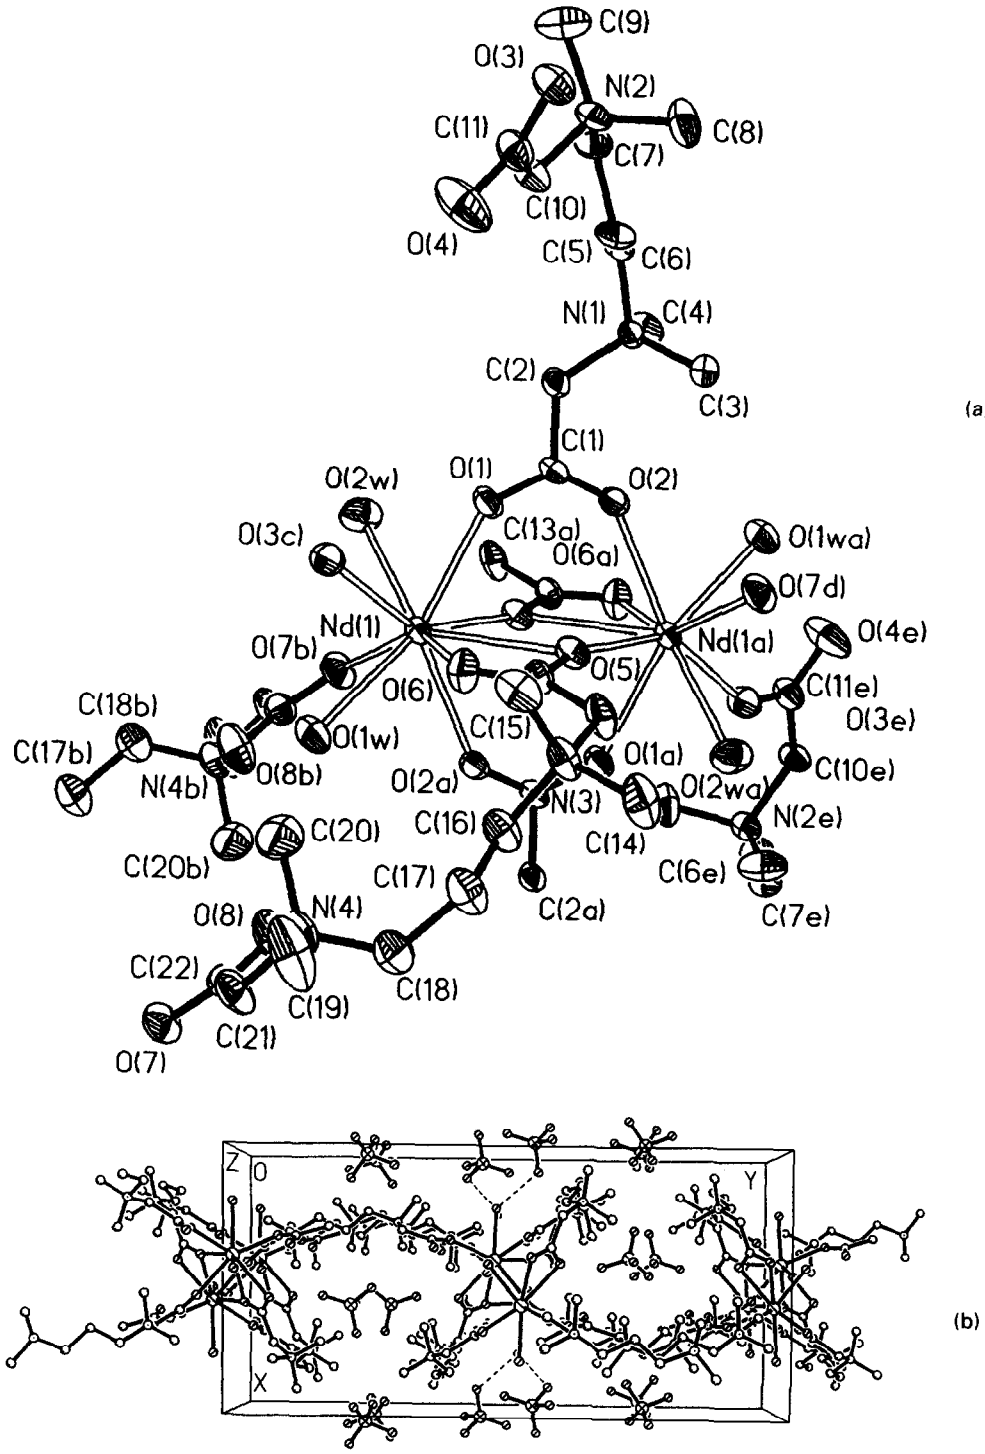

Fig. 1. (a) Structural skeleton of the asymmetric unit (35% thermal ellipsoid) of $[\{Nd(L^1)_2(H_2O)_2\}_n][ClO_4]_{3n}$ (**1**) with atom labelling. (b) Packing drawing showing the plane wave-like layer structure corresponding to [200] in the crystal structure of **1**.

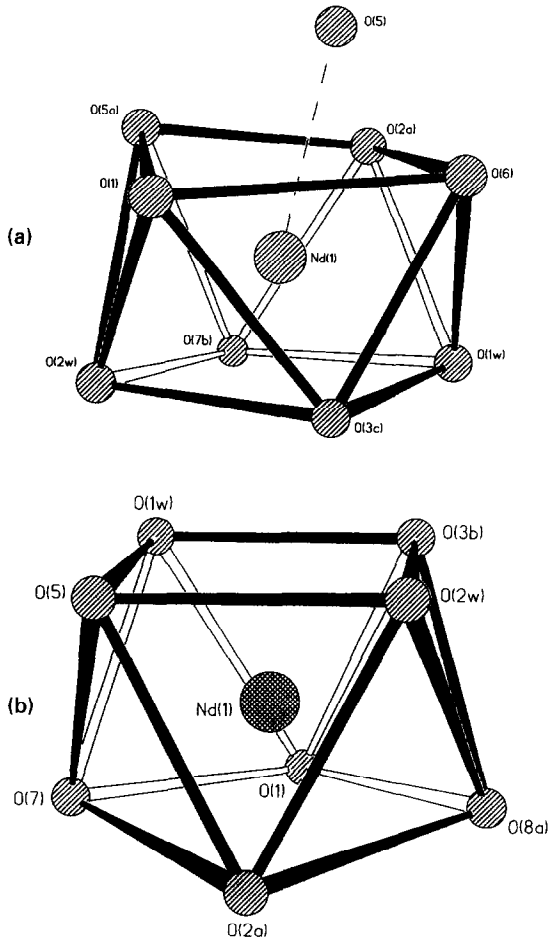

Fig. 2. Perspective view showing the coordination polyhedron about (a) the neodymium(III) atom in **1** and (b) the neodymium(III) and erbium(III) atoms in **2**, **3** and **4**.

umns of paddle-wheel-like dimeric subunits [Nd_2(carboxylato-*O*,*O*′)$_4$] stacked parallel to the *a* direction are cross linked by the double betaine skeletons to generate a two-dimensional polymeric network corresponding to the [01$\bar{1}$] plane. The perchlorate groups, one of which forms an acceptor hydrogen bond [O(1w)···O(14), 2.880(7) Å] with an aqua ligand oxygen atom [O(1w)], occupy the interlayer regions. The lattice water molecule [O(3w)] forms a hydrogen bond [O(3w)···O(2w), 2.815 Å] with the other aqua oxygen atom [O(2w)].

Crystal structure of [{Er(L^1)$_2$(H$_2$O)$_2$}$_n$][ClO$_4$]$_{3n}$·nH$_2$O (**3**)

Complex **3** comprises discrete perchlorate anions and a two-dimensional cationic polymeric layer containing tetrakis (*μ*-carboxylato-*O*,*O*′)-bridged centrosymmetric dimeric subunits (Fig. 4a). In the dimeric subunit, four carboxylato groups from respective L^1 ligands oriented nearly perpendicular to each other about the Er···Er direction bridge the metal centers in a *syn–syn* manner to yield a paddle-wheel-like [Er_2(carboxylato-*O*,*O*′)$_4$] dimer. The Er(1)···Er(1a) separation is 4.423(4) Å, and the erbium(III) atom in the present complex is coordinated by eight oxygen atoms from four bidentate L^1, two monodentate L^1 and two aqua ligands in a square-antiprismatic environment. One square face consists of two carboxylato oxygen atoms [O(1) and O(5)] and two aqua oxygen atoms [O(1w) and O(2w)] with a mean deviation 0.0704 Å from the least-squares plane. The other face is defined by oxygen atoms [O(3b), O(4c), O(7d) and O(8e)] from four carboxylato groups of L^1 ligands with a mean deviation 0.0249 Å from the least-squares plane. The dihedral angle between the square faces is *ca* 2.5°.

The Er—O distances lie between 2.264(4) and 2.470(3) Å, which are comparable to those found for other related erbium(III) complexes [6,35]. The carboxylato ligands around the erbium atom not only act in the bidentate bridging mode [C(11c)—O(3c)—Er(1a), 139.3(3), C(11c)—O(4c)—Er(1), 143.9(3), C(22d)—O(7d)—Er(1), 119.3(3) and C(22d)—O(8d)—Er(1a), 168.6(3)°], but also in the unidentate mode [C(1)—O(1)—Er(1), 147.1(3) and C(12)—O(5)—Er(1), 158.2(4)°], being similar to that in complex **2**. The extended conformation of the flexible double betaine skeleton is similar to that in complex **1**. Intramolecular hydrogen bonds [O(2)···O(2w) 2.719(7) and O(6)···O(2w) 2.909(7) Å] between the uncoordinated oxygen atoms [O(2) and O(6)] of the two unidentate carboxylato groups and one of the aqua ligands [O(2w)] are formed (Fig. 4a). A perspective view of complex **3** is given in Fig. 4b, showing a wavy polymeric layer network corresponding to the plane [100]. The crystal structure is built up by a packing of these infinite layers such that the interlayer interactions are mainly of the van der Waal's type. The perchlorate groups, having no contact with the metal ions, are packed between the layers.

Crystal structure of [{Er(L^2)$_2$(H$_2$O)}$_n$][ClO$_4$]$_{3n}$·nH$_2$O (**4**)

Complex **4** is a coordination polymer featuring a centrosymmetric tetrakis(carboxylato-*O*,*O*′)-bridged dimer similar to those of **1**–**3**. The Er···Er separation [4.492(3) Å] in the dimer is comparable to that in complex **3**. As shown in Fig. 5a, the erbium atom is coordinated by seven carboxylato oxygen atoms from L^2 ligands and one aqua oxygen atom in a square-antiprismatic geometry similar to that in complexes **2** and **3**, with Er—O bond distances lying in the range of 2.266(4) to 2.488(4) Å. The mean deviations of the sets of oxygen atoms [O(3c), O(4d), O(5), O(6a) and O(1), O(2), O(7b), O(1w)] from their least-squares planes are 0.001 and 0.099 Å, respectively. The dihedral angle between the least-squares planes is *ca* 4.5°.

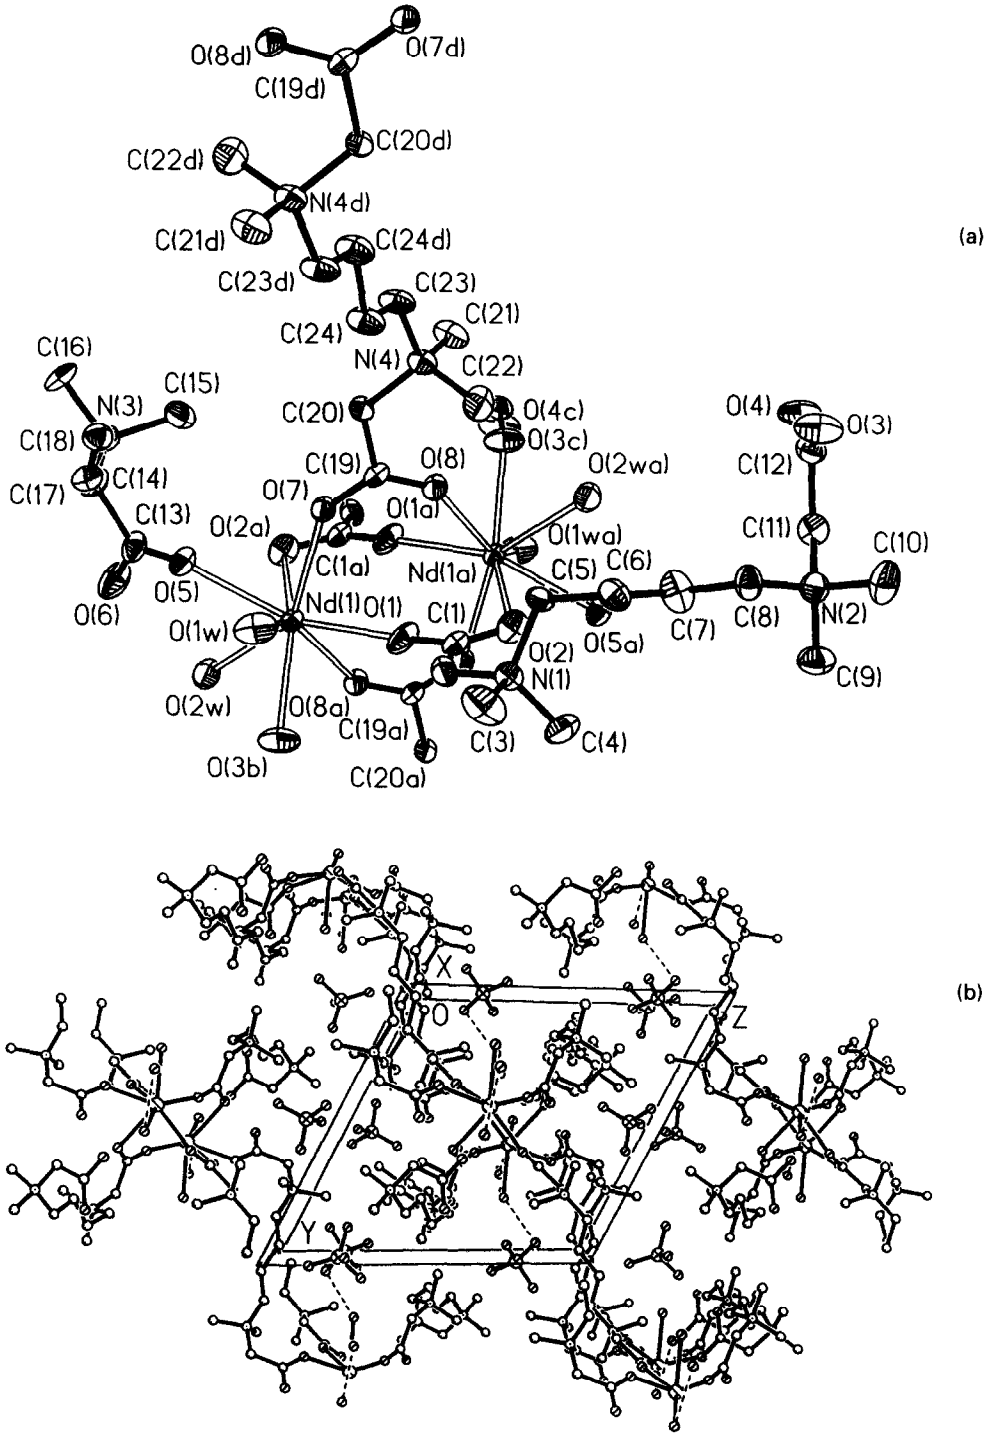

Fig. 3. (a) Structural skeleton of the asymmetric unit (35% thermal ellipsoid) of $[\{Nd(L^2)_2(H_2O)_2\}_n][ClO_4]_{3n} \cdot nH_2O$ (**2**) with atom labelling. (b) Packing drawing showing the plane wave-like layer structure corresponding to [01$\bar{1}$] in the crystal structure of **2**.

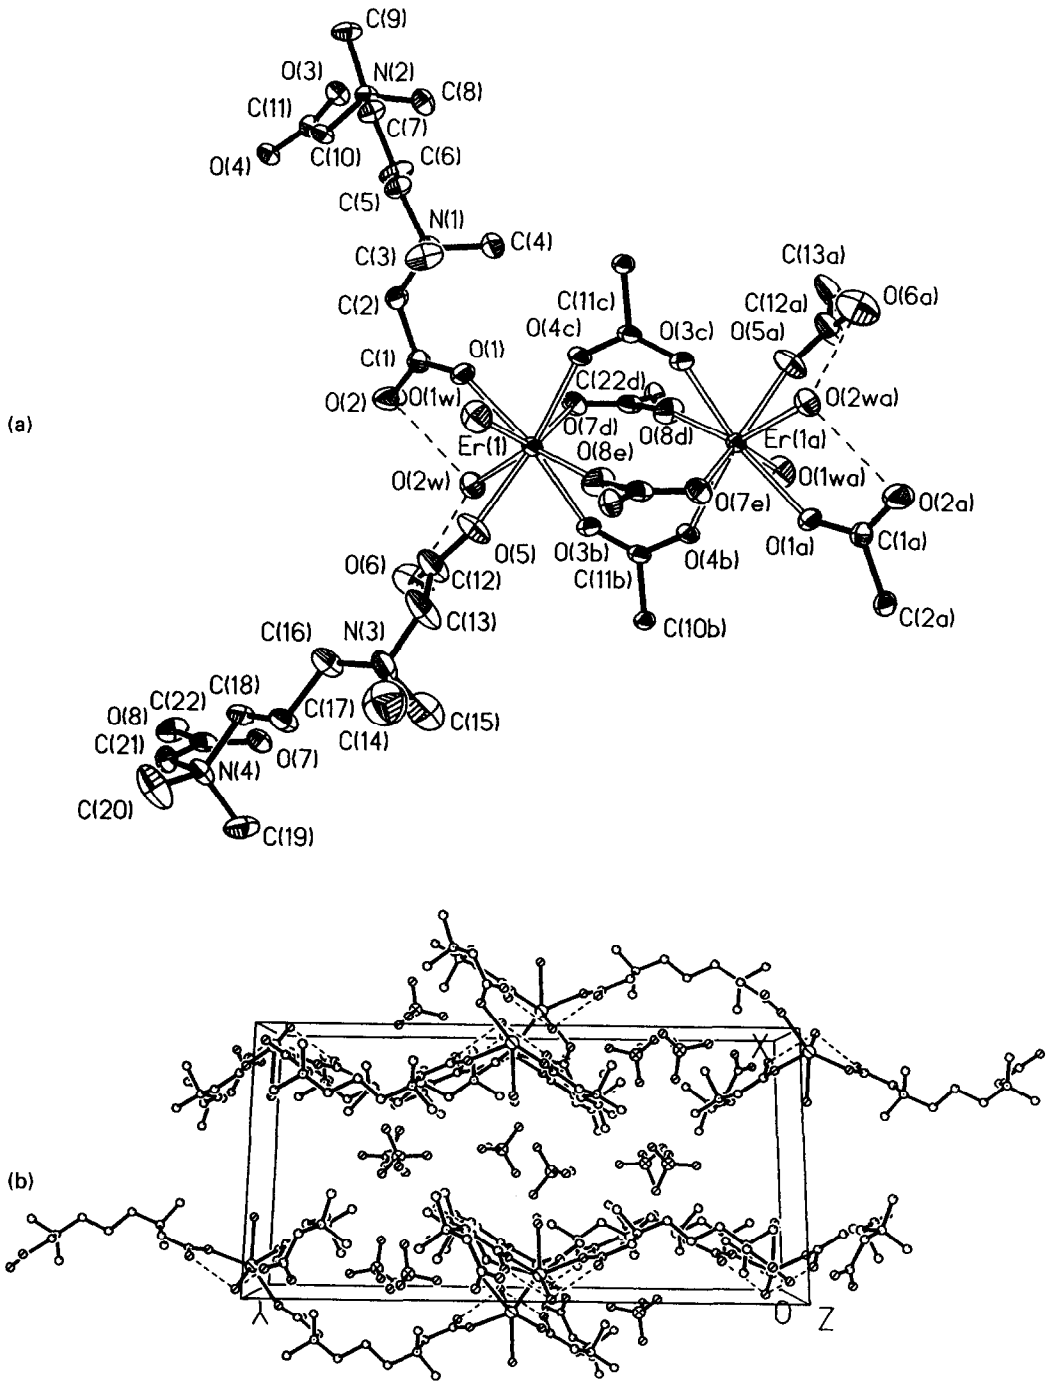

Fig. 4. (a) Structural skeleton of the asymmetric unit (35% thermal ellipsoid) of $[\{Er(L^1)_2(H_2O)_2\}_n][ClO_4]_{3n}\cdot nH_2O$ (**3**) with atom labelling. (b) Packing drawing showing the plane wave-like layer structure corresponding to [200] in the crystal structure of **3**.

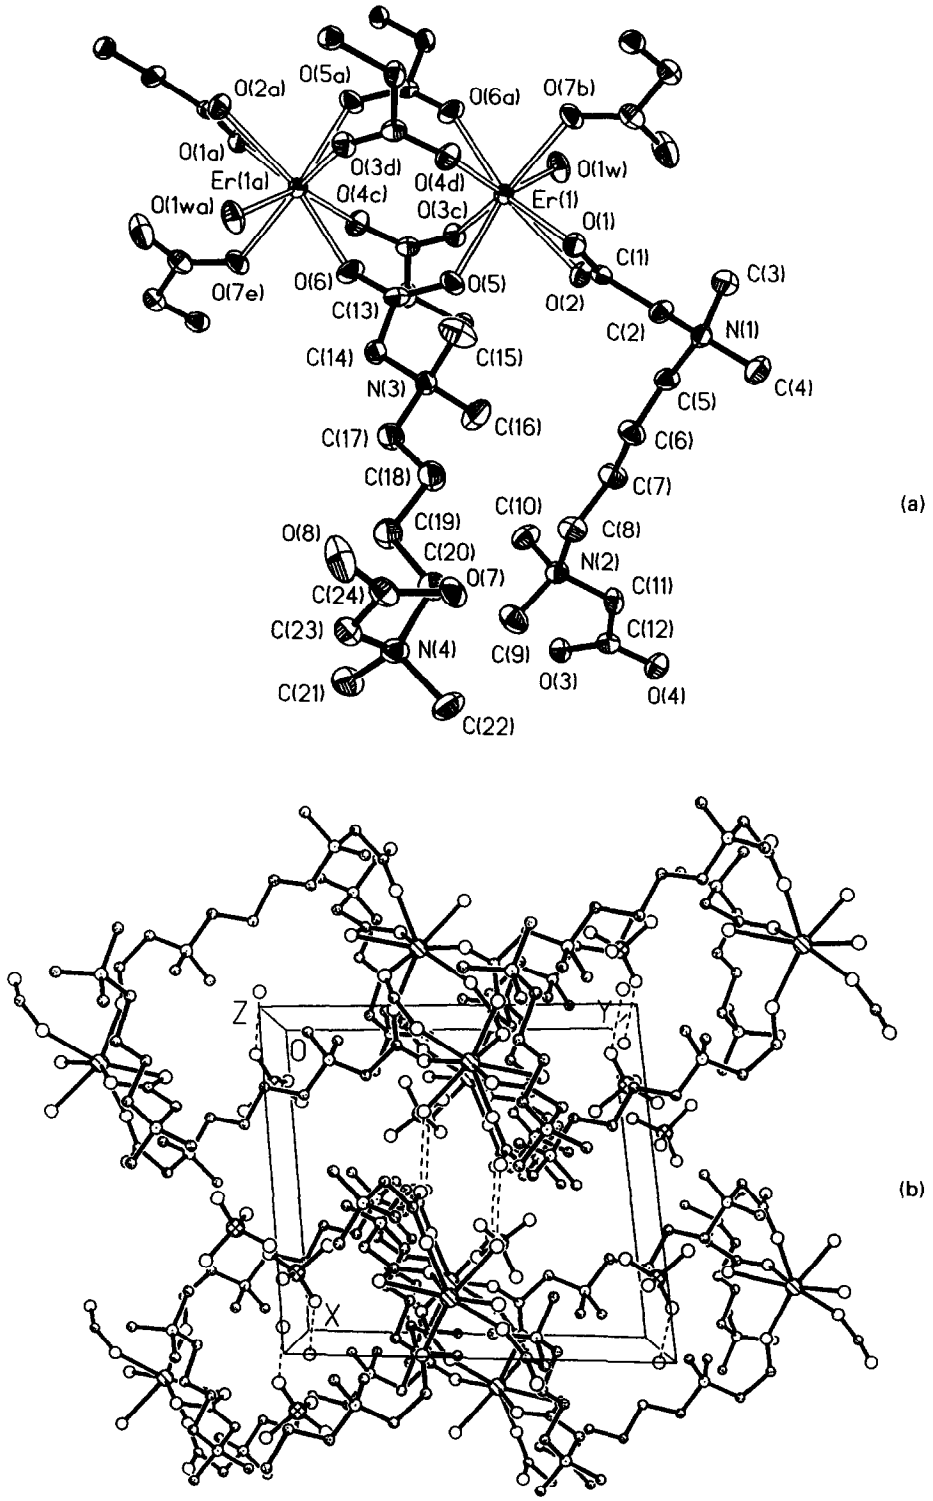

Fig. 5. (a) Structural skeleton of the asymmetric unit (35% thermal ellipsoid) of $[\{Er(L^2)_2(H_2O)\}_n][ClO_4]_{3n} \cdot nH_2O$ (**4**) with atom labelling. (b) Packing drawing showing the plane wave-like layer structure corresponding to [100] in the crystal structure of **4**.

Unlike complex **3**, in which the carboxylato groups act only in the unidentate and bridging bidentate coordination modes, the carboxylato groups of L^2 in complex **4** show three coordination modes: the common bridging bidentate [C(12c)—O(3c)—Er(1), 148.4(3); C(12c)—O(4c)—Er(1a), 135.3(3); C(13)—O(5)—Er(1), 134.4(4) and C(13)—O(6)—Er(1a), 152.7(3)°], unidentate [C(24b)—O(7b)—Er(1), 128.8(3)°], as well as bidentate chelate modes [C(1)—O(1)—Er(1) 90.1(3) and C(1)—O(2)—Er(1) 93.3(3)°]. The bidentate chelate mode is uncommon in polymeric lanthanide carboxylates, although some monomeric lanthanide carboxylate complexes are known to exhibit this type of ligand coordination [36,37]. The coexistence of the above types of coordination modes of carboxylato groups in complex **4** is rare among lanthanide carboxylates. The conformation of each of the two independent double betaines L^2 is different from that in complex **2**, and also different from that in its hydrated form and mercury adduct, in which the symmetry of the molecular backbone of L^2 has an inversion centre [24,27] at the midpoint between the two middle methylene carbons (Fig. 6). As shown in Fig. 5b, the wave-like, two-dimensional polymeric network in the crystal structure of complex **4** corresponds to the [100] plane. The aqua ligand [O(1w)] about the erbium atom in one layer forms an intermolecular hydrogen bond [O(1w)···O(8), 2.726(7) Å] with one of the uncoordinated unidentate carboxylato oxygen atoms from an adjacent layer, and *vice versa*, so that each neighbouring pair of layers are linked by such hydrogen bonds. An anionic perchlorate group, which exhibits orientational disorder and forms an acceptor hydrogen bond [O(2w)···O(11′), 2.912(7) Å] with the aqua ligand O(2w), is stacked inside the resulting partially open channels. The remaining perchlorate groups occupy the interlayer regions.

CONCLUSIONS

The present study has demonstrated that two-dimensional coordination polymeric networks can be generated from neodymium(III) and erbium(III) perchlorates with flexible double betaines. The resulting four complexes in the present study are all based on the cross-linkage of tetrakis(carboxylato)-bridged dimers with a paddle-wheel-like structure by the double betaine molecular backbones. Variation of the number of methylene units linking the two positively charged quaternary nitrogen atoms in the double betaine skeleton, the particular lanthanide(III) species employed, as well as the presence or absence of lattice water molecules, results in different skeletal configurations and carboxylate coordination modes of the flexible betaine ligands, and consequently the coordination geometries adopted by the lanthanide(III) atoms.

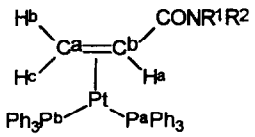
Abstract—Reaction of [Pt(C_2H_4)(PPh_3)$_2$] with a range of alkenes gave the complexes [Pt(alkene)(PPh_3)$_2$]. Complexes of alkenes bearing electron-withdrawing ligands were, predictably, more stable than those of electron-rich alkenes. The complexes were characterized by multinuclear (^{1}H, ^{13}C, ^{31}P and ^{195}Pt) NMR spectroscopy and the structures of the derivatives of *trans*-PhCH=CHCHO and *trans*-PhCH=CHCOMe were established by X-ray diffraction studies. The complexes reacted with PCy_3 to give [Pt(alkene)(PCy_3)(PPh_3)], usually as a mixture of regioisomers. Copyright © 1996 Elsevier Science Ltd

Keywords: platinum(0); alkene complexes; NMR spectroscopy; X-ray crystallography.

We have been interested for some time in the substitution chemistry of platinum(0), and have shown that the reaction of [Pt(C_2H_4)(PPh_3)$_2$] with bulky phosphines at low temperature results in substitution of the phosphine rather than the ethene [1]. A number of platinum alkene complexes have been prepared by displacement of ethene by another alkene. The reactions are clean, as the only by-product is gaseous ethene which is easily removed [2]. Alkene complexes isolated by this method include derivatives of ketenes [3], cumulenes [4], allenes [5], $C_2H_{4-n}X_n$ (X = CN or COOMe, n = 0–4 [6], styrene [7], strained cycloalkenes [8], Dewar benzenes [9], cyclooctene [10] and others [11]. The reaction of [Pt(C_2H_4)(DIOP)] with chiral alkenes has been used to indicate the enantiometric purity of the alkene [12], and alkynes have also been shown to displace ethene [13]. We have recently reported the preparation and characterization of a range of complexes in which the added alkene is a propenoate or a 2-methylpropenoate ester [14], and we now extend this to more varied alkenes.

RESULTS AND DISCUSSION



Reaction of alkenes with [Pt(C_2H_4)(PPh_3)$_2$]

Addition of a wide range of alkenes [15] to a toluene solution of [Pt(C_2H_4)(PPh_3)$_2$] resulted in clean conversion to the complexes **1–7**, which were generally isolated by reduction of the volume of toluene and precipitation with light petroleum (b.p. 30–40°C) to give white or cream powders. Analytically pure material was obtained in this way in several cases. However, the complexes decomposed when attempts were made to recrystallize them. The yields were generally good, except for **2a**, which was rather unstable and decomposed completely in solution at room temperature in less than 1 h. Since bonding in these complexes is dominated by metal to ligand back-bonding, we would expect that complexes of electron-rich alkenes would be less stable than those of alkenes bearing electron-withdrawing groups.

the labelling convention used. The presence of electron-withdrawing substituents on the alkenes causes a decrease in the coupling constant $^1J(Pt–P_a)$ and an increase in $^1J(Pt–P_b)$ relative to $[Pt(C_2H_4)(PPh_3)_2]$. This follows the trend previously established for the propenoates, and may be attributed to the *trans* influence of the electron-withdrawing group. The substitution of an α-methyl group on the double bond (compare complexes **6a**, and **6b**, and **7a** and **7b**) causes an increase in $^1J(Pt–P_a)$ and a decrease in $^1J(Pt–P_b)$. The methyl group is an inductive donor, and might be expected to weaken the Pt–P bond *trans* to it; hence $^1J(Pt–P_b)$ is decreased.

For complexes **1a–c**, $^1J(Pt–P_a)$ increases with substitution at nitrogen, but the effect is small. This parallels the results with propenoate ester complexes; we can postulate that as the alkene becomes more hindered, bonding to it is weakened and there is a concomitant increase in the strength of the platinum–phosphorus bonds [16].

Complexes of alkenes bearing electron-donating groups, **2**, show a decrease in both phosphorus–platinum coupling constants relative to $[Pt(C_2H_4)(PPh_3)_2]$, whilst $^2J(PP)$ increases to 50–52 Hz. The complex of *trans*-PhCH=CHPh gave data comparable with the ethene complex. In the less symmetrical styrene derivative, however, the α-phenyl substitution decreases the value of $^1J(Pt–P_b)$ by approximately 40 Hz; the phenyl might appear to be acting as a donor of electron density into the platinum–phosphorus bond *trans* to it. However, it is more likely that the phenyl substituent has an effect on the position of the

$\{Pt(PPh_3)_2\}$ moiety relative to the carbon–carbon double bond. The steric bulk of the phenyl group could cause slippage of the platinum towards the less hindered terminus, which would have the same effect on the observed coupling constant.

^{195}Pt *NMR spectra* (Table 2)

In platinum NMR spectroscopy chemical shifts are relatively insensitive to small changes in molecular structure, but they are indicative of the oxidation state of platinum [17]. The chemical shifts of compounds **1–7** confirm that they are platinum(0) complexes. The appearance of each spectrum is a doublet of doublets, since coupling to the two phosphorus atoms is distinct in each case (Fig. 1).

^{13}C *NMR spectra* (Table 3)

The alkene carbons in the complexes resonate at higher fields than in the free alkenes (upfield shift *ca* 80 ppm), as is common in metal alkene complexes [18]. A typical spectrum is shown in Fig. 2. The notation for the labelling of the carbon atoms is shown in structures **1–7**.

The effect of a methyl substituent on the double bond is to change the chemical shift of the carbon atom to which it is bonded, C_b. Thus, in the free alkene the shift moves downfield; δ for C_b in $CH_2{=}CHCHO$ is 138.6, whereas for $CH_2{=}C(Me)CHO$ it is 145.6. In the complexes this effect is accentuated. An α-phenyl substituent causes a downfield shift of the resonance of the carbon atom to which it is bonded by 20 ppm relative to a proton. For example, in **6a** $\delta(C_a) = 39.8$ whereas for **5c** $\delta(C_a) = 60.7$.

Each carbon atom has one large (*ca* 24–30 Hz) and one small (*ca* 3–7 Hz) coupling constant associated with the two phosphorus atoms. The large coupling constant is assumed to be that associated with the pseudo *trans* phosphorus atom. These are significantly smaller than those reported for highly strained and pyramidalized alkenes, but are comparable with that in $[Pt(C_2H_4)(PPh_3)_2]$ [9]. As the signals were relatively weak, ^{195}Pt satellites could be identified only in one complex, that of PhCH=CHCOPh, **5a**, *viz.* $^1J(Pt—C_b) = 149$ Hz. This is smaller than the coupling found in $[Pt(C_2H_4)(PPh_3)_2]$ [$^1J(PtC) = 194$ Hz]. This may suggest that the steric hindrance in **5a** results in a longer Pt—C distance, and hence a smaller coupling constant, but more examples would be needed for a definitive answer. An α-methyl or an α-phenyl group

increases $^2J(C_aP_a)$ and decreases $^2J(C_bP_b)$. No significant effect was found on $^2J(C_aP_b)$ or $^2J(C_bP_a)$. We suggest that this is a result of the fact that the α substituent causes some slippage of the platinum towards the less hindered end of the double bond.

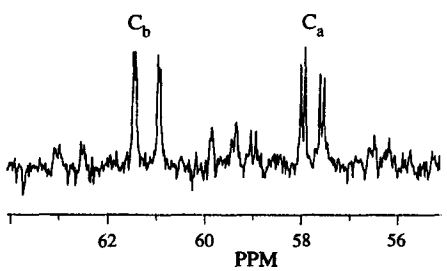

Fig. 2. Alkene region of the ^{13}C NMR spectrum of [Pt(*trans*-PhCH=CHCOPh)(PPh_3)$_2$], **5a**.

^{1}H *NMR spectra* (Tables 4 and 5)

The chemical shift of the protons attached to the carbon–carbon double bond is moved upfield by 3–4 ppm up on coordination, as is typical for this type of complex [20]. An expansion of the alkene region of the spectrum of **6a** is shown in Fig. 3; this illustrates the complexity of the assignments. The coupling constants were determined by ^{1}H {^{31}P} decoupling experiments followed by simulation using PANIC [21], but even this did not allow complete assignment in every case (the spectra of **1a, 1b, 2a, 2b, 6a** and **7a** were not assigned).

The interproton coupling is very different from that in the free alkenes. Both *trans* and *cis* couplings are reduced and the geminal coupling is increased. These data are all consistent with the lowering of the carbon–carbon bond order in the complex. For each proton

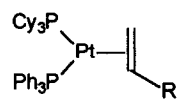
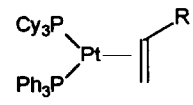
[a] Data for the uncomplexed alkenes.



there is a large coupling to one phosphorous atom, and a smaller one to the other. The ^3J(PH) couplings are similar to those in related complexes. For example, in [Pt{MeOCH=C(CN)$_2$}(PPh$_3$)$_2$] $^3J(HP_a)$ = 6.9 Hz and $^3J(HP_b)$ = 3.6 Hz [22]. As it is known which phosphorus has the larger coupling to each proton (from the decoupling experiments) and we know which phosphorus was decoupled, we can tell which phosphorus was which. The significance of the coupling of the alkene protons to ^{195}Pt was not analysed in detail, but varied between 38 and 66 Hz. $^2J(Pt–H_a)$ is typically 60–66 Hz.

Structure of [Pt(*trans*-PhCH=CHCHO)(PPh$_3$)$_2$], **5c**



A number of platinum(0) complexes of the type [Pt(alkene)(PPh$_3$)$_2$] have been characterized crystallographically including those for which the alkene was *trans*-4-$O_2NC_6H_4CH$=CHC_6H_4-4-NO_2 [23], *trans*-Ph(CN)C=C(CN)Ph [24], $(NC)_2C$=$C(CN)_2$ [25], $(MeO_2C)_2C$=$CHCO_2Me$ [26], Cl_2C=CCl_2 [27], *trans*-NCCH=CHCN [28] and **8** [29]. The geometry of these complexes is characterized by a trigonal planar arrangement of the ligands with the alkene in the plane of the triangle. There is a non-zero angle between the PtP_2 and PtC_2 planes.

8

9a

9b

Crystals of **5c** were grown by slow evaporation of a perdeuterotoluene solution. The molecular structure is shown in Fig. 4, and selected bond lengths and angles are given in Table 6. The Pt—P bond lengths [2.252(3), 2.272(4) Å] are slightly shorter than those in [Pt{$(MeO_2C)_2C$=$CHCO_2Me$}(PPh$_3$)$_2$] [26] [2.283(4), 2.286(3) Å], reflecting lower steric hindrance, but the carbon–carbon bond length of the bound alkene [1.43(1) Å versus 1.44(2) Å] is essentially identical. The P—Pt—P bond angle [113.5(1)°] is larger than is usually found in this type of complex. For example P—Pt—P is 100.6(2)° in [Pt(Cl_2C=CCl_2)(PPh$_3$)$_2$] [27], 104.4(2)° in [Pt(*trans*-NCCH=CHCN)(PPh$_3$)$_2$] [30] and 103.90(3)° in [Pt{*trans*-Ph(CN)C=C(CN)Ph}(PPh$_3$)$_2$] [24]. The reason for this unusually high value is not immediately apparent, except that

the Pt—P bond lengths are short in comparison with related complexes, so that the bond angle is opened to minimize steric repulsions. The angle between the PtC_2 and PtP_2 planes is 5(3)°, in the expected range.

Structure of $[Pt(trans\text{-}PhCH{=}CHCOMe)(PPh_3)_2]$, **5b**

Crystals of **5b** were grown by evaporation of a per-deuterotoluene solution. The structure is shown in Fig. 5, and selected bond lengths and angles are given in Table 7. The structure is quite similar to that of **5c**. The Pt—P bond lengths are a little longer, as are the Pt—C bond distances, and the P—Pt—P angle has been closed to 109.87(3)°. These changes all reflect the increased steric demand of the alkene. Strain is also alleviated by twisting the PtC_2 and PtP_2 planes relative to each other; the dihedral angle in this case is 12.2(4)°.

In the complex of PhCH=CHCHO there is little or no slippage [31] of the platinum away from the midpoint of the carbon–carbon double bond. However, in **5b** the platinum has slipped towards the less hindered end of the bond [Pt—C_a = 2.124(3) Å, Pt—C_b = 2.139(4) Å]. The reason is unclear, since study of a model reveals no severe interactions on moving the platinum to the midpoint of the double bond.

Reactions of the complexes with PCy_3

It was known that reaction of $[Pt(C_2H_4)(PPh_3)_2]$ with bulky phosphines at low temperature gave $[Pt(C_2H_4)(PPh_3(PR_3)]$, and that, of these complexes,

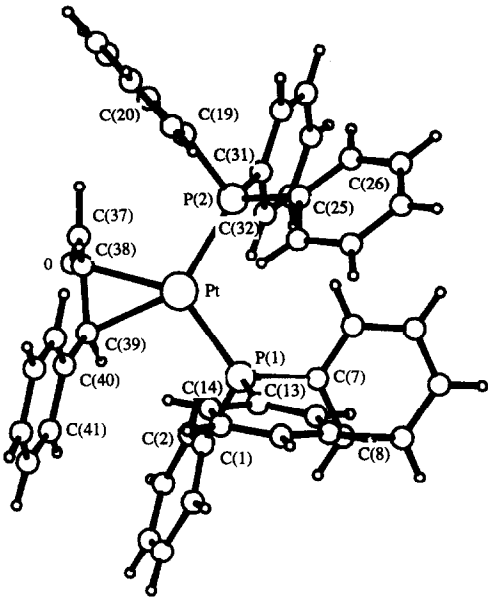

Fig. 4. Structure of [Pt(*trans*-PhCH=CHCHO)(PPh_3)$_2$], **5c**.

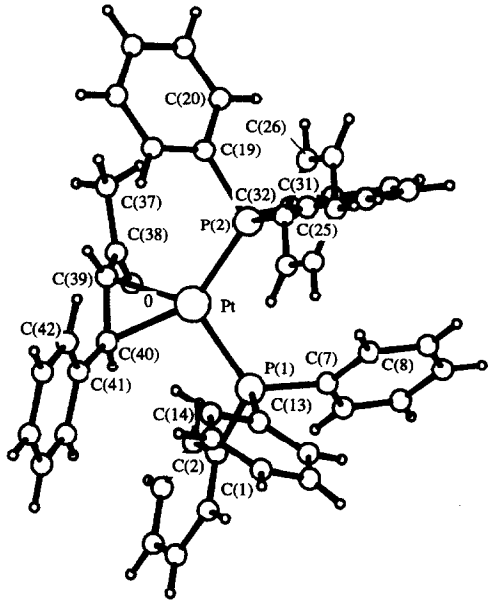

Fig. 5. Structure of [Pt(*trans*-PhCH=CHCOMe)(PPh_3)$_2$], **5b**.

the one with PCy_3 was the most stable. PCy_3 has a large cone angle [32], and since it is appreciably more basic than PPh_3, the chemical shift is sufficiently different from that for PPh_3 that the ^{31}P NMR spectra should be readily interpreted. PCy_3 was therefore added to complexes **1**–**7** at −50°C. The ^{31}P NMR spectra of the products show one or more AB quartets, and the reaction appears to go to completion in most cases, although some of the products were very insoluble. The same reaction products were obtained by addition of the relevant alkene to [Pt(C_2H_4)(PCy_3)(PPh_3)], formed *in situ*. In each case there are two possible regioisomers, which are shown as **9a** and **9b** for a monosubstituted alkene complex. The reaction mixture was stored at −20°C for 1–2 weeks and any equilibration monitored by ^{31}P NMR spectroscopy.

Details of the complexes formed and the ratios between the regioisomers are given in Table 8. In some cases (**1a, 4b, 5c,** minor isomers from **5d, 6b**) complete data were not obtained owing to the low solubility of the complexes. The reaction of **2a** was unsuccessful because of decomposition; this was not surprising as this was much the least stable of the complexes prepared. Complex **7b** did not appear to react. The complexes of CH_2=CHCONH$_2$, *trans*-PhCH=CHCHO, HC≡CCH$_2$OH and CH_2=CHCHO gave a single regioisomer on reaction with PCy_3, and the complex of PhCH=CHPh gave a single product because of its symmetry. It seems that the selective production of a single regioisomer is confined to complexes of ligands with low steric demand. This suggests that only in these complexes is there no barrier to PCy_3, the bulkier and more basic ligand, taking up the electronically favourable site.

Equilibration studies on alkene complexes

In order to gain some insight into the relative stabilities of the complexes, the displacement of one alkene by another was followed by ^{31}P NMR spectroscopy. One molar equivalent of a second alkene was added at −50°C to [Pt(alkene)(PPh_3)$_2$] prepared *in situ*. The resulting solution was warmed slowly in the NMR probe, and the ^{31}P NMR spectrum recorded. The solu-

[a] The date for the major complex is given first in each case.
[b] Not determined owing to low solubility.

tion was then kept at 25°C and the ^{31}P NMR spectrum recorded at intervals until no further change was observed. It was shown that it did not matter in which order the reaction was carried out; the same ratio of final products was obtained. The spectra for a typical experiment involving the reaction of [Pt(*trans*-PhCH=CHCOMe)(PPh_3)$_2$] with CH_2=$CHCO_2$Me are shown in Fig. 6. Some of the data obtained are shown in Table 9. This allowed us to construct a stability series for the platinum(0) alkene complexes as follows:

CH_2=CHCN ~ CH_2=CHCHO > CH_2=$CHCO_2$

CH_2Ph > CH_2=$CHCO_2$Me > CH_2=$CHCO_2$Bu^t >

HC≡CCH_2OH ~ CH_2=C(Me)CN ~

CH_2=C(Me)CHO > *trans*-PhCH=CHCHO >

trans-PhCH=CHCOCH=CHPh >

CH_2=$CHCONH_2$ > CH_2=CHCONMePh >

trans-PhCH=CHCOMe > *trans*-PhCH=CHCOPh :

CH_2=C(Me)COOR > CH_2=$CHCH_2OH$ >

CH_2=CHPh > *trans*-PhCH=CHPh >

CH_2=CHOCOMe

It can be clearly seen that two factors are important.

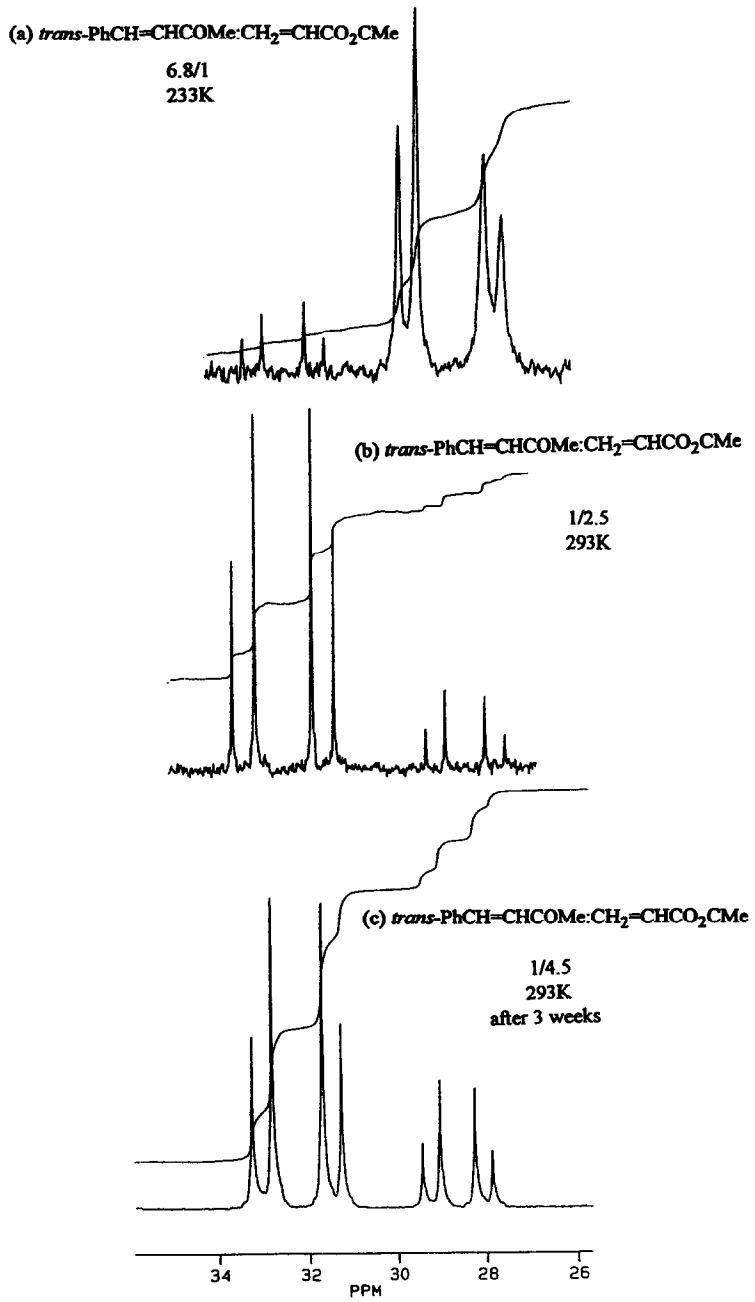

Fig. 6. ^{31}P NMR spectra of the products of the reactions between [Pt(*trans*-PhCH=CHCOMe)(PPh_3)$_2$] **5b**, and CH_2=$CHCO_2Me$.

The most stable complexes are those bearing alkenes with the most electron-withdrawing groups; thus CH_2=CHCHO > CH_2=$CHCO_2Me$ > CH_2=$CHCONH_2$ > CH_2=$CHCH_2OH$. However, steric factors are also important. The substitution of an α-methyl group contributes to both effects, and the phenyl group is even bulkier. Bulky groups tend to cause twisting of the alkene, which decreases orbital overlap. The results described here have parallels in the work of Tolman [33]. He determined the equilibrium constants for the reaction of [Ni(alkene){$P(OC_6H_4$-2-Me)$_3$}$_2$] with 38 alkenes. He concluded that the most important contribution to bonding was back-bonding from the metal into the π^* orbital of the alkene, and that steric effects were less significant than electronic ones.

CONCLUSIONS

Spectroscopic parameters for complexes **1**–**7** may be rationalized in terms of steric and electronic effects. The bonding to the metal is strongest, and the com-

plexes are most stable, when the alkene bears electron-withdrawing groups, and has a low steric demand; the major component of the bonding is back-donation from platinum(0) to the π^* orbital of the alkene. When PCy_3 is reacted with **1–7** two regioisomers are generally formed, but a few complexes, usually of unhindered alkenes, gave a single regioisomer.

EXPERIMENTAL

All preparations were carried out under nitrogen using standard Schlenk line techniques. Solvents were dried, distilled and degassed prior to use. NMR spectra were recorded using a Bruker ACP250 FT spectrometer operating at 250 (^{1}H), 62.82 (^{13}C), 101.20 (^{31}P) or 53.78 MHz (^{195}Pt). Chemical shifts are reported relative to external TMS (^{1}H, ^{13}C), 85% H_3PO_4 (^{31}P) or $Na_2[PtCl_6]$ (^{195}Pt). Microanalyses were performed using a Perkin–Elmer 400 CHN analyser. Melting points were determined using a Stuart melting point apparatus and are uncorrected.

Synthesis of cis-$[Pt(PPh_3)_2Cl_2]$

The synthesis was carried out as described by Gillard and Pilbrow with 87% yield [34].

Synthesis of $[Pt(C_2H_4)(PPh_3)_2]$

The synthesis was carried out as described by Nagel with 90% yield [35].

Synthesis of complexes of the type $[Pt(alkene)(PPh_3)_2]$

In a typical synthesis $[Pt(C_2H_4)(PPh_3)_2]$ (0.1483 g, 19.8 mmol) was placed in a Schlenk line and dissolved in dry degassed toluene (3 cm^3). The alkene (1 : 1 molar ratio with platinum) was added to the solution, which was then stirred for 2 h. After cooling to 0°C, light petroleum (b.p. 30–40°C, 10 cm^3) was added and the complex was precipitated. The precipitate was collected by filtration under nitrogen, washed (light petroleum, b.p. 30–40°C, 10 cm^3) and dried *in vacuo*.

In many cases analytically pure material was obtained in this way. However, recrystallization proved difficult as all the complexes deteriorated slowly in solution. Details of the preparations and the microanalytical data (where available) are given in Table 10.

Structure of [Pt(*trans*-PhCH=CHCHO)(PPh_3)$_2$], **5c**

Data were collected using a crystal grown by slow evaporation from perdeuterotoluene, *ca* $0.15 \times 0.15 \times 0.10$ mm^3 on an Enraf–Nonius CAD4 diffractometer operating in the θ–2θ mode with $\Delta\theta = (0.8 + 0.35 \tan\theta)$ and a maximum scan time of 1 min, monochromated Mo-K_α radiation, $\lambda = 0.71069$ Å, $\mu = 39.9$ cm^{-1}. Unit-cell parameters were obtained from a least-square fit of 25 reflections, $7.3 < \theta < 10.4°$. A total of 3635 independent reflections were measured for $2 < \theta < 25°$ and h 0–39, k 0–15, l 0–13. 2236 observed reflections with $|F^2| > 3\sigma(F^2)$, $\sigma(F^2) = \{\sigma^2(I) + (0.04I)^2\}^{1/2}/Lp$ were used in the refinement. Two reference reflections were remeasured every 60 min and showed a maximum deviation of 0.2%. Lorentz and polarization corrections and absorption correction by DIFABS [36] (max. 1.12, min. 0.92) were applied. The structure was solved by routine heavy-atom methods and non-hydrogen atoms refined anisotropically by full-matrix least squares. The phenyl hydrogen atoms were fixed at calculated positions ($B_{iso} = 1.4B_{eq}$ for parent atom) and the other hydrogen atoms were freely refined. The absolute structure was determined by refinement of a $\Delta F''$ multiplier. The weighting scheme was $w = 1/\sigma^2(F)$, $\Sigma w(|F_o|-|F_c|)^2$ minimized, and the final residuals were $R = 0.031$, $wR = 0.037$. $C_{45}H_{38}OP_2Pt$, $M_w = 851.8$, orthorhombic, $Pna2_1$ (No. 33), $a = 24.513(3)$, $b = 13.292(2)$, $c = 11.227(4)$ Å, $V = 3657.8$ Å^3, $Z = 4$, $D_x = 1.55$ g cm^{-3}, $F(000) = 1696$, 453 variables, $S = 1.24$, $\Delta/\sigma_{max}0.05$, $\Delta\rho_{max,min} = +0.81, -0.83$ eÅ^3.

Structure of [Pt(*trans*-PhCH=CHCOMe)(PPh_3)$_2$], **5b**

Data were collected using a crystal grown by slow evaporation from perdeuterotoluene, *ca* $0.35 \times 0.25 \times 0.20$ mm^3 on an Enraf–Nonius CAD4 diffractometer operating in the θ–2θ mode with $\Delta\theta = (0.8 + 0.35 \tan\theta)$ and a maximum scan time of 1 min, monochromated Mo-K_α radiation, $\lambda = 0.71069$ Å, $\mu = 38.8$ cm^{-1}. Unit-cell parameters were obtained from least squares fit of 25 reflections, $7.3 < \theta < 10.3°$. A total of 6616 independent reflections were measured for $2 < \theta < 25°$ and h 0–11, k −15 to 15, l −19 to 19. 5926 observed reflections with $|F^2| > 3\sigma(F^2)$, $\sigma(F^2) = \{\sigma^2(I) + (0.04I)^2\}^{1/2}/Lp$ were used in the refinement. Two reference reflections were remeasured every 60 min and showed a maximum deviation of 0.7%. Lorentz and polarization corrections and absorption correction by DIFABS [36] (max 1.19, min 0.89) were applied. The structure was solved by routine heavy-atom methods and non-

[a] All the complexes decompose on melting, hence the long melting ranges.

hydrogen atoms refined anisotropically by full-matrix least squares. The phenyl hydrogen atoms were fixed at calculated positions ($B_{iso} = 1.3B_{eq}$ for parent atom) and the other hydrogen atoms were freely refined. The weighting scheme was $w = 1/\sigma^2(F)$, $\Sigma w|F_o|-|F_c|)^2$ minimized, and the final residuals were $R = 0.019$, $wR = 0.026$. $C_{46}H_{40}OP_2Pt$, $M_w = 865.9$, triclinic, $P\bar{1}$, $a = 9.667(1)$, $b = 12.859(2)$, $c = 16.571(3)$ Å, $\alpha = 76.62(1)$, $\beta = 84.13(1)°$, $\gamma = 70.04(1)°$, $V = 1883.0$ Å^3, $Z = 2$, $D_x = 1.53$ g cm^{-3}, $F(000) = 864$, Δ/σ_{max} 0.4, $\Delta\rho_{max,min} = +0.85, -0.83$ eÅ^3.

Reactions of complexes **1–7** *with* PCy_3

The complexes **1–7** were formed *in situ* by addition of the relevant alkene (1 : 1 molar ratio) to a dry, degassed solution of $[Pt(C_2H_4)(PPh_3)_2]$ in $C_6D_5CD_3$ (0.5 cm^3) in an NMR tube. The tube was then cooled to −70°C and a solution of PCy_3 (1 : 1 molar ratio with platinum) in $C_6D_5CD_3$ (0.5 cm^3) was added. The NMR tube was shaken carefully and the ^{31}P NMR spectrum recorded at −70 and −50°C, and then allowed to equilibrate at 5°C over 2–3 weeks.

Crystal and molecular structure of cyclo-tetrakis[μ-oxo-bis(2,2,6,6-tetramethylheptan-3,5-dionate)titanium(IV)] pentane adduct

Sergei I. Troyanov* and Oleg Yu. Gorbenko

Moscow State University, Chemistry Department, Vorobjevy Gory, 119899 Moscow, Russia

(Received 1 April 1996; accepted 17 July 1996)

Abstract—The X-ray crystal structure of titanium(IV) oxo-bis-2,2,6,6-tetramethylheptan-3,5-dionate, pentane (1 : 1) adduct has been determined. The tetrameric molecule of $[TiO(thd)_2]_4$ contains a nearly planar $(Ti—O)_4$ ring with two Ti atoms on a twofold axis. Compared with the dimeric titanium oxo-bis-(acetylacetonate), another type of TiO_6 octahedral connection takes place, namely through vertices instead of edges. Copyright © 1996 Elsevier Science Ltd

Keywords: β-diketonates; titanium; crystal structure.

Various volatile titanium compounds, firstly alkoxides, have been used as precursors for CVD of ferroelectrics like $(Ba,Sr)TiO_3$ and $PbZr_{1-x}Ti_xO_3$. Besides high volatility, important characteristics of the precursors are their thermal and hydrolytic stability, decomposition mechanism and by-products. It has been shown that $(Ba,Sr)TiO_3$ thin films, prepared by liquid source CVD using $TiO(thd)_2$ (thd = 2,2,6,6-tetramethylheptan-3,5-dionate) instead of the more volatile $Ti(OPr^i)_4$ and $Ti(OPr^i)_2(thd)_2$, demonstrated better step coverage and improved electrical properties [1,2]. The thermal properties of $TiO(thd)_2$ have been reported [3,4].

The molecular structure of $TiO(thd)_2$, which could be useful for understanding its properties, has not been reported so far. The analogous acetylacetonate (=acac) derivative, $TiO(acac)_2$, is known to be dimeric [5].

EXPERIMENTAL

Synthesis

Titanium oxo-β-diketonates can be prepared by the hydrolysis of bis(alkoxy)bis(β-diketonate)titanium(IV) [6] or dihalobis(β-diketonate)titanium(IV) [7] and by oxidation of tris(β-diketonate) titanium(III) [3,8]. With excess β-diketone some titanium(IV) alkoxides convert to titanium oxo-β-diketonates [9].

Preliminary study had shown that $Ti(OPr^i)_2(thd)_2$ is rather stable to hydrolysis, in accordance with the considerations in ref. [10]: no mass change was observed for a 1 g sample held in air for 6 h. Under the same conditions $Ti(OPr^i)_2(acac)_2$ was completely converted to $TiO(acac)_2$ in 2 h. More severe conditions should be used to hydrolyse $Ti(OPr^i)_2(thd)_2$. To our knowledge the compound is not inclined to ether elimination, at least up to 150°C. Thus, we believe that the procedure described below resulted from hydrolysis rather than from an elimination reaction.

About 1 g of $Ti(OPr^i)_2(thd)_2$ was dissolved in the minimal quantity of acetone containing traces of water at room temperature. The solution was heated to boiling point for a few minutes. After slow cooling fine, plate-like crystals were formed, which were separated by decantation and recrystallized from pentane.

Crystal structure determination

The selected crystal with approximate dimensions $0.2 \times 0.2 \times 0.3$ mm^3 was sealed in a Lindemann glass capillary. The data were collected at room temperature on an Enraf–Nonius CAD-4 diffractometer

(Mo-K_α radiation, graphite monochromator, θ–2θ scan method, $\theta_{max} = 24°$). The crystallographic calculations were performed using the SHELXS-86 and SHELXL-93 program packages [1]. The structure was solved using a combination of direct and Fourier methods and refined by the full-matrix least-squares technique with anistropic thermal parameters for all non-hydrogen atoms.

The tert-butyl groups have been found to be strongly disordered between two positions around their pseudo-threefold axes. After refinement the occupancies of the more abundant configurations have been found to be in the range 0.56–0.83. The positions of the hydrogen atoms were calculated using a riding model and included in the structure factor calculation. Crystal data and structure refinement parameters for $[TiO(thd)_2]_4 \cdot C_5H_{12}$ are given in Table 1. Selected bond lengths are summarized in Table 2 and selected angles in Table 3. Atomic coordinates, bond lengths and distances and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.

Powder diffraction measurement (θ–2θ scan) was performed with a DRON-3M diffractometer using Co-K_α radiation in the 2θ range 6–50°. The experimental and calculated diffraction patterns (see Supplementary data) agree satisfactorily, indicating a formation of only one solid phase.

RESULTS AND DISCUSSION

The tetrameric molecule of $[TiO(thd)_2]_4$ with two Ti atoms [Ti(2) and Ti(3)] lying on a crystallographic two-fold axis is shown in Fig. 1. The pentane molecules, strongly disordered in the $[TiO(thd)_2]_4 \cdot C_5H_{12}$ structure, are trapped in the holes between tetrameric molecules near the centre of inversion at coordinates (0.25, 0.25, 0). No chemical bonding to $[TiO(thd)_2]_4$ takes place.

Four Ti atoms lie in a plane forming a square. Two independent Ti—Ti distances are equal 3.598 Å. The μ-oxo atoms are nearly in the same plane, but they are shifted out from the square sides. Similar tetranuclear $(Ti—O)_4$ rings have been found in $[Cp'TiX(\mu\text{-}O)]_4$ derivatives, where $Cp' = C_5H_{5-n}Me_n$; $n = 0, 1, 4, 5$; X = Cl, Br [12–14]. In the Br complex [12], there is a planar (but not square) Ti—O arrangement with Ti—O 1.80–1.82 Å, and the O—Ti—O angle of 103–106. In most other structures, the Ti—O distances are 1.78–1.82 Å with O—Ti—O angles in the range 103–105°.

In the $[TiO(thd)_2]_4$ molecule each titanium atom has a distorted octahedral coordination. Three pairs of Ti—O bonds are present: the short Ti—O bonds

Symmetry transformation code (′): $-x, y, \frac{1}{2}-z$.

in nearly linear Ti—O—Ti bridges (*ca* 1.81 Å), the long Ti—O bonds with oxygen, *trans* to μ-O (*ca* 2.12 Å) and the Ti—O bonds of the intermediate length with O, *cis* to μ-O (*ca* 1.96 Å). This last value is close to the Ti—O distances in rutile (1.944 and 1.988 Å) [15]. Variations in O—Ti—O angles in the TiO_6 octahedra follow the change of bond lengths (Table 3): the angle between short Ti—O bonds is *ca* 100°, that between long bonds is *ca* 80°, deviations from 90°C being equal in magnitude. Thus, the strong *trans* influence is clearly observed in the plane of the $(Ti—O)_4$ ring. Similar pairs of bonds were found in $[TiO(acac)_2]_2$, with bond lengths 1.83, 1.97 and 2.06 Å, respectively.

Owing to the rigidity of the β-diketonate ligand only one coordination mode is possible: with one oxygen atom in the *cis* position to μ-O and another one in the *trans* position. The latter is out of the $(Ti—O)_4$ ring plane by more than 0.25 Å. The Ti—O(*cis*) bond is nearly orthogonal to the Ti—O bond with μ-O, which is in the *trans* position to another oxygen of the same β-diketonate ligand; for example, O(1)—Ti(1)—O(10) $\approx$ O(2)—Ti(1)—O(7) $\approx 90°$. Corresponding angles in dimeric $[TiO(acac)_2]_2$ are more distorted (*ca* 93°). This is probably owing to the difference in the oxygen bridges: Ti—O—Ti angle *ca* 170° in $[TiO(thd)_2]_4$ and *ca* 97° in $[TiO(acac)_2]_2$. The TiO_6 octahedra are connected by edges in the latter compound and by vertices in the former. Such behaviour is not surprising taking into account that *tert*-butyl groups occupy more space than methyl groups, thus some steric hindrance would occur in the case of edge connection.

Recently, the structure of $[TiO(acac)_2]_2[SiO(OBu^t)_2]_2$ has been reported [16]. It is very similar to that of $[TiO(thd)_2]_4$. The bond lengths and angles in the TiO_6 octahedra are close: for instance the Ti—O distance in the bridge is 1.80 Å, and the O—Ti—O angles in the chelate rings are *ca* 83°. The eight-membered titanosiloxane cycle is also nearly planar:

One could expect that such a molecular structure could be a template for special oxide phases formed

by decomposition of the precursors. For instance, the $(Ti—O)_4$ ring can easily support the formation of the (TiO_2) plane of the perovskite structure of $(Ba,Sr)TiO_3$.

Supramolecular self-organization in methyl(diphenylphosphinothioato)mercury(II), [HgMe{S(O)PPh$_2$}], a polymer containing $Hg_2O_2P_2S_2$ eight-membered rings interconnected through secondary Hg···O bonds

José S. Casas,* Alfonso Castiñeiras, Ionel Haiduc,*† Agustín Sánchez, José Sordo and Ezequiel M. Vázquez-López

Departamento de Química Inorgánica, Facultade de Farmacia, Universidade de Santiago de Compostela, E-15706 Santiago de Compostela, Galicia, Spain

(Received 19 January 1995; accepted 17 July 1996)

Abstract—Methyl- and phenylmercury(II) diphenylphosphinothioates [HgR{S(O)PPh$_2$}] (R = Me and Ph) were synthesized. In [HgMe{S(O)PPh$_2$}] the mercury atom is coordinated to the methyl carbon atom and to the ligand sulfur atom. Intermolecular Hg···O interactions form a supramolecular ribbon structure along the *b*-axis. The IR and NMR (^{1}H, ^{13}C, ^{31}P and ^{199}Hg) spectra of the two compounds are discussed. Copyright © 1996 Elsevier Science Ltd

Keywords: supramolecular chemistry; methylmercury(II); phenylmercury(II); phosphinothioates; X-ray structure; multinuclear NMR.

Organometallic derivatives of oxo and thio phosphorus acids are frequently supramolecular compounds, in which the molecular units are associated through secondary and/or dative bonds. This association is due to the tendency of the metal in the organometallic coordination centre to increase its coordination number, and to the ability of the oxo and thio organophosphorus moieties to act as bridging ligands. From supramolecular chemistry being defined as "the chemistry of molecular assemblies and of intermolecular bond", dealing with "organized entities that result from the association of two or more chemical species held together by intermolecular forces" [1], it follows that the structures of the type reported here can be described as "supramolecular".

Among the organophosphorus anions which serve as ligands, the phosphinothioates (monothiophosphinates), R_2POS^-, are particularly interesting, due to their ambident character and to the simultaneous presence in the molecule of soft donor (sulfur) and hard donor (oxygen) sites. This may have interesting structural consequences. It has been shown previously that organometallic derivatives of these anionic ligands are associated into supramolecular, polymeric structures. Examples include [SbPh$_2${O(S)PPh$_2$}]$_n$ [2], [SnMe$_3${O(S)PMe$_2$}]$_n$ [3], [SnMe$_2${O(S)PPh$_2$}$_2$]$_n$ [4] and [TlMe$_2${O(S)PPh$_2$}]$_n$ [5]. Supramolecular structures are also found in phosphorodithioates (dithiophosphates), phosphinodithioates (dithiophosphinates), dithioarseniates and other functional organometallic derivatives [6].

The formation of supramolecular structures involves a process of self-organization, which goes beyond the simple packing of molecules in the crystal lattice. In addition to the primary bonds which connect the ligand to the organometallic coordination centre, such structures may contain intramolecular and intermolecular secondary bonds, that are defined by interatomic distances intermediate between the sum of covalent radii and the sum of van der Waals radii [7]. The former usually lead to cyclizations and

the latter connect the building units into supramolecular structures.

We now report the supramolecular structure of methyl(diphenylphosphinothioato)mercury(II), $[HgMe\{S(O)PPh_2\}]_n$, as determined by X-ray diffraction. The probably isostructural phenylmercury derivative, $[HgPh\{S(O)PPh_2\}]$, was also prepared.

EXPERIMENTAL

Diphenylphosphinothioic acid, $Ph_2P(S)OH$, was prepared according to a literature method [8]. Methylmercury(II) hydroxide and phenylmercury(II) acetate (Ventron) were used as received. The instruments used for spectroscopic characterization were as described earlier [9–11].

Preparation of $[HgMe\{S(O)PPh_2\}]_n$

Diphenylphosphinothioic acid (0.234 g, 1 mmol), dissolved in 20 cm^3 ethanol, was mixed with a solution of 0.233 g (1 mmol) methylmercury(II) hydroxide in water at room temperature, and stirred for 2 h. A white crystalline substance deposited after concentrating the solution. The solid was filtered, washed with heptane and dried. Yield: 0.331 g (73.8%), m.p. 137–138°C (with decomposition). Found: C, 34.3; H, 3.0; S, 7.8. $C_{13}H_{13}OPSHg$ requires: C, 34.8; H, 2.9; S, 7.1%. IR spectrum (cm^{-1}, KBr pellets): $\nu(P\cdots O)$ = 1163 vs, $\nu(P—S)$ = 696s.

Preparation of $[HgPh\{S(O)PPh_2\}]$

A solution containing 0.674 g (2 mmol) phenylmercury(II) acetate in 30 cm^3 ethanol was mixed with a solution containing 0.468 g (2 mmol) of diphenylphosphinothioic acid in 25 cm^3 ethanol, and allowed to stand without stirring. After *ca* 10 min, a white crystalline precipitate (long needles) deposited. That was filtered, washed with heptane and dried. Yield: 0.733 g (75.7%), m.p. 181–183°C (with decomposition). Found: C, 42.9; H, 3.0; S, 6.7. $C_{18}H_{15}OPSHg$ requires: C, 42.3; H, 3.0; S, 6.3%. IR spectrum (cm^{-1}, KBr pellets): $\nu(P\cdots O)$ = 1169vs, $\nu(P—S)$ = 698s.

Crystal structure determination of $[HgMe\{S(O)PPh_2\}]$

Collection and reduction of X-ray data. A colourless prismatic crystal of approximate dimensions $0.02 \times 0.2 \times 0.4$ mm^3 was analysed in a CAD4 Enraf–Nonius diffractometer, at room temperature (293 K), using Mo-K_α ($\lambda = 0.71073$ Å) graphite monochromated radiation.

Crystal data. $C_{13}H_{13}OPSHg$, $M = 448.88$, monoclinic, space group $C2/c$ (no. 15), $a = 26.339(2)$, $b = 6.177(1)$, $c = 17.702(5)$ Å, $\beta = 96.118(1)°$ and $V = 2863.7(9)$ $Å^3$, $Z = 8$, $D_{calc} = 2.082$ g cm^{-3}, $F(000) = 1680$, $\mu = 10.988$ mm^{-1}.

The ω–2θ scan technique was used in the range 3–30°. Cell parameters were refined by a least-square procedure on the setting angles of 25 reflections ($6.5 \leqslant \theta \leqslant 13.6°$). Corrections were applied for Lorentz and polarization effects and for absorption [12]. A total of 4275 reflections were collected, of which 4144 were unique ($R_{int} = 0.0254$) and of these 3227 with $I > 2\sigma(I)$ were used for refinement.

The structure was solved by direct methods [13] and refined by a full-matrix least square procedure based on F^2 [14]. Non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were included in the model at geometrically calculated positions [14]. The final R (on F) was 0.0356, R_w (on F^2) 0.0895 and goodness of fit was 1.078 for all observed reflections.

Further details of the crystal structure determination have been deposited with the Editor and the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The structure of methyl(diphenylphosphinothioato)mercury(II) consists of dimers, connected into an infinite ribbon running along the *b*-axis of the crystal. An ORTEP [15] drawing of the dimer, with the atom numbering scheme, is shown in Fig. 1 and that of the polymeric ribbon in Fig. 2. Selected interatomic distances and bond angles are given in Table 1.

The structure of the dimeric unit

In the monomeric $[HgMe\{S(O)PPh_2\}]$ moiety, the mercury atom forms the primary bonds with the methyl group [Hg—C(1) = 2.073(6) Å], and with the sulfur atom of the thiophosphorus ligand [Hg—S = 2.391(2) Å]. The phosphorus–oxygen bonds seem to retain a certain degree of double bond character [P—O = 1.489(4) Å] [5]. The phosphorus–sulfur bond is a single bond [P—S = 2.047(2) Å] [5]. The two primary bonds are basically co-linear [S—Hg—C = 177.3(2)°].

Monomeric units are joined in pairs through mercury–oxygen secondary interactions [$Hg\cdots O^{ii}$ = 2.897(4) Å, ii = $-x$, $-y+1$, $-z+2$, thereby forming an eight-membered ring of chair conformation (see Fig. 1)].

The transannular $Hg\cdots O$ distances are longer than the sum of the Van der Waals radii (3.23 Å) [16] and they suggest no secondary interaction.

The conformation of the eight-membered ring is clearly described by the bond angles S—P—O = 115.7(2)° (angle at phosphorus larger than tetrahedral) and Hg—S—P = 100.24(7)°. Other significant angles are $S—Hg\cdots O^{ii}$ = 91.96(9)°. Torsion angles are listed in Table 2.

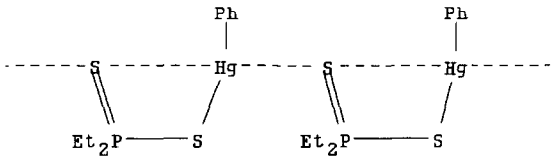
Hg	O^{ii}	P^{ii}	S^{ii}	−162.15(0.84)

Supramolecular association



The dimers are further connected into a supramolecular ribbon structure (SCHAKAL [17] drawing is shown in Fig. 2) through additional Hg···O secondary interactions [Hg···O^{i} = 2.831(3) Å, i = $x, y-1, z$] slightly shorter than the Hg···O secondary bonds leading to the formation of the dimeric units. In the ribbon, eight-membered $Hg_2O_2P_2S_2$ rings alternate with four-membered Hg_2O_2 rings; the latter consist only of Hg···O secondary bonds. Figure 3 shows the Hg_2O_2 units as planar, and with the P—S bond (part of the eight-membered ring). Only the *ipso* carbons of the phenyl groups are shown, for clarity. When viewed along the *b*-axis, the mercury atoms are delineated in two parallel rows and the building units are in the eclipsed arrangement (Fig. 4). It can be seen that, within the ribbon, which is enveloped on the outside of the phenyl and methyl groups, there are channels delimited by the mercury, oxygen sulfur and phosphorus atoms.

If the secondary bonds are considered, the coordination geometry around the metal atom can be described as ψ-trigonal bipyramidal (distorted), with the sulfur atom and methyl group in axial positions and two Hg···O secondary interactions in equatorial positions; the distortion comes mostly from the O···Hg···O angles [O^{i}···Hg···O^{ii} = 95.61(9)°].

Comparison with other structures

In organoantimony [2] and organotin [3,4] phosphinothioate(monothiophosphinate) compounds, the metal–ligand primary bond is to oxygen (Sb—O, Sn—O), whereas in the organothallium compound [$TlMe_2\{S(O)PPh_2\}$] [5] the primary bond is through sulfur although, in this case, there are also a strong dative intermolecular O → Tl bond. According with the "softer" character of the mercury atom, in the compound discussed here the primary bond is Hg—S.

An interesting comparison can be made with other organomercury derivatives of dithiophosphorus ligands (phosphorodithioates and phosphinodithioates). Thus, both [$HgMe(S_2PPh_2)$] [9] and [$HgPh\{S_2P(OEt)_2\}$] [10] are discrete cyclic dimers, in which an eight-membered $Hg_2S_4P_2$ ring is formed through Hg···S intermolecular secondary interactions (*cf.* Hg—S = 2.379 Å and Hg···S = 3.152 Å in the phenyl derivative, and Hg—S = 2.383 Å and Hg···S = 3.323 Å in the ethoxy derivative). Unlike these, the compound [$HgPh(S_2PEt_2)$] [11] is a polymer (**1**) formed through Hg···S secondary bonds (3.183 Å) between four-membered chelate rings, which contain both primary (Hg—S = 2.375 Å) and secondary intermolecular (Hg···S = 3.182 Å) bonds.

			$C_p = 128.40$	—			

[a] δ in ppm and J in Hz; s = singlet.
[b] Other signals are obscured by those of the ligand.

The compound described here are cyclic dimers connected by secondary Hg···O bonds (Fig. 2).

It is also worth mentioning that the structural diversity of inorganic mercury(II) [18] and organomercury(II) compounds of mono- and dithiophosphorus ligands, derived from a change in the peripheral organic groups, either at the metal or at phosphorus. This suggests that structural investigations of related derivatives is worthwhile and further work along these lines is in progress in our laboratory.

Spectroscopic studies

The similar values of the IR ν(P—S) and ν(P═O) bands (see Experimental section) suggest a similar coordination mode of the ligand in the two organomercury complexes.

Table 3 lists the relevant NMR data obtained in $CDCl_3$ for both compounds. The phosphorus is more shielded than in the dimethylthallium derivative [5] in accordance with the different behaviour of the ligand. It is interesting to note the presence of $^{31}P—^{199}Hg$ coupling satellites with a $^2J(^{31}P—^{199}Hg)$ value similar to that described for $[Hg(SCN)_2(SPBu_3)_2]$ [19]. This coupling is usually not observed in monoorganomercury(II) dithiophosphinates and dithiophosphates [9–11], suggesting a lower lability for the monothiophosphinato ligands [20]. The $\delta(^{13}C(R—Hg))$ and $^nJ(^{13}C—^{199}Hg)$ values are similar and in the phenylmercury derivative the $\delta(^{199}Hg)$ value is intermediate between those found in organomercuric dithiophosphinates and dithiophosphates [9–11].

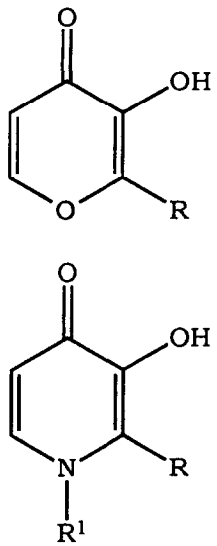
(Received 28 June 1996; accepted 12 July 1996)

Abstract—The synthesis and characterization of several new bis-ligand-oxo-vanadium(IV) complexes containing 1,2-substituted-3-hydroxy-4-pyridinonates or ethylmaltolate (3-hydroxy-2-ethyl-pyranonate) are reported. Structures are proposed based on EXAFS data. Copyright © 1996 Elsevier Science Ltd



Keywords: vanadium(IV) complexes; pyranonate and pyridinonate complexes; EXAFS; UV–vis spectra.

Since the seventies, vanadium has been associated with insulin and its role in the body [1]. Control of glucose levels in plasma has been achieved, *in vitro* and *in vivo*, by means of vanadium administration in the form of inorganic salts [2]. However, as these compounds are poorly absorbed, the required high doses have been associated with undesirable side effects. In order to achieve better absorption and so reduce the doses of the element, it seemed appropriate to administer it in the form of an organic matrix. The synthesis of a potential insulin substitute, bis(maltolato)oxovanadium(IV) [$VO(ma)_2$, BMOV], was reported in 1992 by Orvig and co-workers [3]; its structure and properties have since been fully documented [4]. This compound was administered to diabetic rats and the studies demonstrated that BMOV is effective, at a lower dose than inorganic vanadium salts, in regulating glucose levels in the plasma [5]. It lowered cholesterol and triglyceride levels and ameliorated the cardiac disfunction normally observed in diabetic patients [6]. It exhibited no significant toxic effects on hepatic and kidney functions [7].

Maltol (3-hydroxy-2-methyl-4-pyranone) (**1a**) is a permitted food additive, used in the baking industry. It, or ethyl maltol (**1b**), reacts with primary amines to yield 3-hydroxy-2-methyl(ethyl)-4-pyridinones (**2a–h**). This class of ligands has recognized pharmaceutical importance, in iron and aluminium oral chelation therapy [8] and in the administration of gallium and indium isotopes in radiodiagnosis and radiotherapy [9]. Pyridinone ligands are not only good chelators of M^{III} and M^{II} metal ions, but also permit modulation of the hydrophilic/lipophilic balance (HLB), of ligands and of complexes, by changing the substituent on the ring nitrogen atom. Such a possibility of tailoring the HLB is of paramount importance for substances to be used *in vivo*, as this parameter is crucial for the transport properties of ligands and complexes across biological membranes.

We now report the synthesis and characterization of oxovanadium(IV) (vanadyl) complexes VOL_2, in which the ligands L are anions of the 3-hydroxy-4-pyranone (**1b**) and of the 3-hydroxy-4-pyridinones (**2a–h**) (Fig. 1); the synthesis and solution chemistry of the analogous complex of **1a** have been described earlier [4]. The new complexes have been characterized by elemental analysis and mass spectrometry, and structurally by vibrational, electronic

and electron spin resonance (ESR) spectroscopy, and by EXAFS.

EXPERIMENTAL

The oxovanadium(IV) complexes were synthesized by adding the stoichiometric amounts of vanadyl sulfate and the pyranone or pyridinone ligand in water, adjusting the pH to 5, and refluxing the mixture for about 1 h. The blue–grey solids that formed were filtered while the solution was still warm, washed with cold water or, for complexes of the more hydrophobic ligands, with methanol–water, and dried over phosphorus pentoxide. Elemental analyses were performed at the Microanalytical Laboratory of the University of Manchester; thermogravimetric analysis was carried out on a TA3000 instrument; mass spectra were obtained on a Kratos Concept instrument (fast atom bombardment and electron impact modes).

Vibrational spectra were obtained in potassium bromide discs on a Mattson 5000 FTIR spectrometer. Reflectance electronic spectra were recorded in the range 300–1200 nm at room temperature on a Shimadzu UV-3101PC spectrometer, using barium sulfate as reference material. X-band ESR spectra were recorded in solution at room temperature and at 77 K on a Bruker ESP300E spectrometer using diphenylpicrylhydrazyl as reference. The solutions for ESR were prepared under anaerobic conditions in 1 : 1 chloroform–toluene mixtures.

EXAFS experiments were performed in the region of the vanadium K-edge using station 7.1 at the Synchrotron Radiation Source, Daresbury, U.K. The beam energy was 2 GeV and a typical average stored ring current was 150 mA in multibunch mode and brilliance configuration. Data were acquired in the EXAFS transmission mode with argon-filled ion chambers using an Si(111) monochromator with 50% harmonic rejection. The data analysis was performed using the Daresbury EXAFS suite of programs.

RESULTS AND DISCUSSION

In exploratory experiments, the compounds were prepared either by adjusting the pH of the solution to 9, as described for the bis(maltolato) oxovanadium(IV) complex [3], or by adjusting the pH of the solution to 5, as described for other oxovanadium(IV) complexes with bidentate oxygen ligands [10]. The latter conditions were chosen, as the resulting products gave better elemental analyses.

Mass spectra show the expected peaks for the complexes VOL_2 and for fragments VOL and L. The results relating to the most intense peak, together with the results of elemental analyses (CHN), are shown in Table 1 for the 10 compounds prepared. It is clear that all compounds must contain five-coordinate vanadium except for complex **2a**, in which a water molecule appears to be bound in the sixth coordination position (also see below, in the EXAFS section). Thermogravimetric analyses are consistent with **2a** being a monohydrate; the remaining complexes are anhydrous.

The IR spectra exhibit in the range 1600–1440 cm^{-1} a set of four bands characteristic of pyranones or pyridinones [11]. Upon coordination, the band characteristic of the O—H stretching vibration is lost, as expected, but the band characteristic of the V=O vibration remains well defined and appears, for all the compounds, within the range 965–993 cm^{-1} (Table

1), thus confirming the stability of the +4 oxidation state in the solid state.

Comparison of solution and reflectance electronic spectra of several of our complexes persuaded us to concentrate on the latter. Figure 2 shows some typical reflectance spectra. The solution spectra suffered from the disadvantage that it often proved difficult or impossible to locate the weakest band in the visible region, and from the complication of the introduction of solvation effects at too early a stage in the investigation. Reflectance electronic spectra exhibit for all compounds four bands in the visible region, which appear in the following ranges: 393–417, 528–549, 609–651 and 700–784 nm. Spectra of **1a**, **2c** and **2f** are shown in Fig. 2; the data for all compounds are summarized in Table 1. The optical spectra of vanadyl complexes are normally interpreted in terms of the energy level scheme derived originally by Ballhausen and Gray from a molecular orbital study for a square-pyramidal structure of C_{4v} symmetry [12], with the z-axis taken as the vanadium–oxygen double bond and the x- and y-axes along the equatorial bonds. In this scheme b_2 $(d_{xy}) < e(d_{xz}, d_{yz}) < b_1(d_{x^2-y^2}) < a_1$ (d_{z^2}), and three electronic transitions are predicted, and indeed normally observed, for vanadyl complexes. However, some complexes exhibit four bands, and it is then assumed that the $^2E(xy, yz)$ state is split in low symmetry. The three- or four-band patterns observed in optical spectra of vanadyl complexes and the assignment of the electronic transitions have been discussed and interpreted not only in terms of symmetry but also of stereochemistry and size of chelate ring [10, 13–17]. Furthermore, for vanadyl complexes for which *cis–trans* isomerism is possible, and for which the chelate rings are five-membered, the four-band pattern has been associated with the *trans* isomer, the three-band pattern with the *cis*. Using α-hydroxycarboxylates as examples, the *cis*-tartrate exhibits three bands, the *trans*-tartrate four, with the same pattern for lactate, glycolate and diphenylglycolate complexes [10,18].

The bis(pyranonato) and bis(pyridinonato) oxovanadium(IV) complexes described here have electronic spectra with four bands, and as the transition energies are very similar to those reported for the α-hydroxycarboxylato complexes, the assignment developed for these latter complexes will be used: $\Delta E_{xy} < \Delta E_{xz} < \Delta E_{x^2-y^2} < \Delta E_{z^2}$ (or CT) [16]. This analogy can be extended further to postulate that our solid products consist of the *trans* isomer in each case. This is consistent with the recently reported crystal structure of $VO(ma)_2$, which shows the vanadium to be five-coordinate with distorted square-pyramidal geometry (the vanadium atom lies 0.07 Å above the equatorial plane defined by the donor oxygen atoms) and the two maltolate ligands *trans* to each other [4]. Also, for $VO(ma)_2$ the three low-energy bands appear at 534, 609 and 703 nm, in reasonable accordance with those reported in chloroform (where the authors implied four bands but quoted only three λ_{max} values, 549, 602 and 752 nm) [10]. These λ_{max} values are very different from those in strongly coordinating solvents such as pyridine (476, 610, 769 and 847 nm) [10] or water (three bands only reported, at 441, 625 and 860 nm) [4].

For series of closely related ligands, as here, it is to be expected that differences in donor strength should arise from σ donating power, and so the stretching

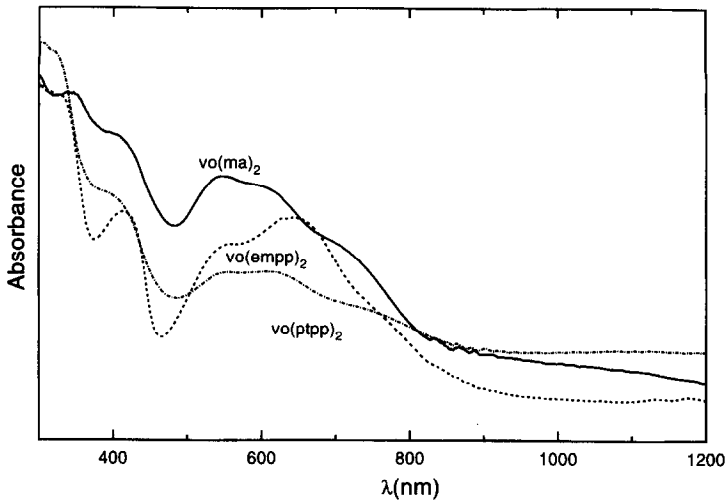

Fig. 2. Diffuse reflectance spectra of the complexes $VO(ma)_2$, $VO(empp)_2$ and $VO(ptpp)_2$.

frequency of the V=O bond can be a measure of its strength. A decrease in stretching frequency has been interpreted as resulting from an increase in electron donation to vanadium, thereby making it less able to accept charge from the oxygen, thus reducing the bond order. For the five-coordinate complexes [i.e. excluding results for the hydrated complex, $VO(mpp)_2H_2O$] values of ν(V=O) correlate with expected stabilities, with the lowest value for the most strongly bonding ligand (**2b**) and the highest for the least strongly bonding (**1a**). Furthermore, a reasonable linear correlation is observed between the energy (E cm^{-1}) of the $(xy) \rightarrow (z^2)$ or $(xy) \rightarrow (x^2-y^2)$ transitions and ν(V=O) for the five-coordinate bis(pyridinonato)oxovanadium(IV) complexes.

ESR spectra were obtained, in chloroform–toluene solutions, at room temperature and at 77 K. At both temperatures they are well resolved and typical of a d^1 electron configuration ($S = 1/2$). At ambient temperature the isotropic spectra exhibit eight well-defined lines resulting from the hyperfine interaction of the unpaired electron with the vanadium nucleus (^{51}V, $I = 7/2$). The frozen solution spectra are similar for all the compounds, exhibiting strong anisotropy. It is possible to distinguish in the low-field and high-field regions lines representative of the parallel splitting due to the hyperfine interaction of the unpaired electron with the vandium nucleus (^{51}V, $I = 7/2$) and a central region where different sets of lines corresponding to the x and y components of the hyperfine interaction are superimposed. According to the optical spectra, and bearing in mind the low symmetry of our compounds, rhombic spectra are to be expected. Table 2 summarizes the values of g_{iso} and A_{iso}, obtained directly from the spectra at ambient temperature by averaging the separation of the $-mI$ to $+mI$ transitions, as well as $g_\parallel$ and $A_\parallel$, obtained directly from frozen solution spectra. The ESR parameters are practically invariant for all the compounds and are indicative of similar metal–ligand covalency.

In order to gain insight into the local structure of the synthesized complexes, EXAFS experiments were carried out, since it proved impossible to grow crystals of sufficient quality for single-crystal X-ray diffractometry.* The vanadium–oxygen bond distances obtained are given in Table 3, which also includes data for $VO(ma)_2$ determined by X-ray diffraction for comparison. Both EXAFS and X-ray diffraction show two oxygen atoms at 3.7 Å from each vanadium, which are the nearest neighbours in adjacent layers. A detailed report and analysis of our EXAFS results will be published elsewhere [19]. The results confirm

[b] X-ray diffraction data: V=O = 1.596 Å; VO = 1.971, 1.998, 1.958, 2.204 Å.

that all the compounds are five-coordinate, with the exception of **2a**, for which a bound water molecule was detected at 2.3 Å from the vanadium in the sixth coordination position. The other bond lengths are similar for all the compounds and are indicative of the presence of five oxygen atoms coordinated to the vanadium: the vanadyl-oxygen at 1.59–1.16 Å, the four other oxygens at 1.94–1.95 Å. These results are as expected, both in relation to the structure of $VO(ma)_2$ and to the corresponding distances in $VO(acac)_2$ and $VO(bzac)_2$, which, from single-crystal X-ray diffraction, are between 1.56 and 1.61 Å and between 1.95 and 1.99 Å, respectively [20].

The EXAFS results we have obtained for $VO(ma)_2$ are in very good agreement with the X-ray diffraction data. We believe that the information obtained from the absorption technique is of great importance, as it permits the accurate establishment of structure in the vicinity of the metal in circumstances where single-crystal X-ray diffraction is not possible. In the present context, this means that we can obtain structural information on related complexes containing long hydrocarbon chain substituents in the pyridinone ligands, and on these complexes in solution; in other words, we shall be able to probe solvation of this group of complexes in a range of solvent media.

Table 3 indicates that the vanadium–oxygen bond lengths do not vary significantly between the various pyridinone complexes, thus showing that the local structure around the metal centre is not appreciably modified by changing the substituents on the ring nitrogen atom. This indicates that the HLB of these complexes can be tuned without altering the structure around the metal centre. Indeed, all our structural and spectroscopic data suggest that inclusion of substituents on the ring nitrogen does not significantly affect such properties of these complexes.

(Received 25 June 1996; accepted 12 July 1996)

Abstract—The title compound was prepared from 1-methyl-2(3H)-imidazolinethione and triphenyltin(IV) hydroxide, and its crystal structure was determined by X-ray diffraction. The crystal consists of discrete molecules with the tin atom coordinated to one carbon atom of each of the three phenyl groups and to the sulfur atom of the deprotonated ligand. An Sn—N interaction [2.920(3) Å] slightly distorts the tin coordination geometry from that of a perfect tetrahedron. NMR spectroscopy was used to study the hydrolysis of this compound in $CDCl_3$. Copyright © 1996 Elsevier Science Ltd

Keywords: tin; X-ray structure; NMR; triphenyltin complex.

Increasing industrial use of organotin compounds containing an Sn—S bond, especially as stabilizers of polyvinyl chlorides [1], and recognition of the importance of this bond for the biological properties of organotin compounds [2], have together spurred on the study of thiolates of tin. An interesting class of such compounds comprises those of general formula $SnR_3(SR')$, where R′ contains a donor atom (D) capable of forming a secondary bond with the tin atom. The coordination polyhedra of these compounds are thus intermediate between tetrahedra and trigonal bipyramids, the degree of distortion of the former towards the latter depending on the strength of the Sn—D bond.

In a previous paper [3] we reported the preparation and structural characterization of triphenyl(5-mercapto-1-phenyl-1,2,3,4-tetrazolato)tin(IV), [$SnPh_3$(MPT)], which has both an Sn—S bond of normal length and an Sn—N bond length of 3.275(3) Å (shorter than the sum of the van der Waals radii of tin and nitrogen, but too long to substantially distort the tetrahedral tin environment). We now describe the synthesis and structure of [$SnPh_3$(mimt)] (Hmimt = 1-methyl-2(3H)-imidazolinethione), another compound in which the presence of a nitrogen atom contiguous to a C—S bond leads to the possible formation of a four membered Sn—S—C—N ring. In [$SnPh_3$(mimt)], the Sn—N bond [2.920(3) Å] is shorter than in [$SnPh_3$(MPT)], with the result that this bond affects the coordination polyhedron of the tin atom. The temperature dependence of a hydrolytic equilibrium detected in the NMR spectra of solutions of this compound in $CDCl_3$ is also described.

EXPERIMENTAL

1-Methyl-2(3H)-imidazolinethione (Aldrich) and triphenyltin(IV) hydroxide (Aldrich) were used as supplied.

Preparation of [$SnPh_3$(mimt)]

Triphenyltin(IV) hydroxide (0.288 g, 0.79 mmol) and 1-methyl-2(3H)-imidazolinethione (0.100 g, 0.88 mmol) were suspended in 60 cm^3 of benzene (**caution**) in a 100 cm^3 round-bottomed flask fitted with a condenser and a Dean-Stark moisture trap. The reaction mixture was refluxed for 22 h, filtered and the clear filtrate concentrated to dryness, yielding an oil which afforded a crystalline solid, isolated and identified as

* Author to whom correspondence should be addressed.

[$SnPh_3$(mimt)], m.p. 94°C. Found: C, 56.7; H, 4.2; N, 6.2; S, 6.4. Calc. for $C_{22}H_{20}N_2SSn$: C, 56.9; H, 4.3; N 6.0; S, 6.9%. When the clear filtrate of the synthesis was slowly concentrated without reaching dryness, it afforded initially a crystalline solid, which was identified as the ligand (Hmimt).

Physico-chemical measurements

Analytical data were obtained with a Carlo-Erba 1108 apparatus. Melting points were determined in a Büchi apparatus. NMR spectra of samples as 0.1 M solutions in $CDCl_3$ were recorded in a Bruker AMX 500 spectrometer operating at 500.14 MHz (^1H; 5 mm o.d. NMR tube) or 125.76 MHz (^{13}C; 5 mm o.d. NMR tube) and at 186.50 MHz (^{119}Sn; 5 mm o.d. sealed tubes); the internal lock and reference to tetramethylsilane was provided by $CDCl_3$ for the ^1H (7.26 ppm) and ^{13}C (77.0 ppm) spectra, and by tetramethyltin for the ^{119}Sn spectra.

Crystal structure determination of [$SnPh_3$(mimt)]

Crystals suitable for X-ray diffraction studies were selected from the first batch of the synthesis. No further purification was necessary.

Crystal data. $C_{22}H_{20}N_2SSn$, $M = 463.17$, monoclinic, space group $P2_1/c$, $a = 11.362(1)$, $b = 9.808(1)$, $c = 19.111(2)$ Å, $\beta = 105.44(1)°$, $V = 2052.9(6)$ Å^3, $Z = 4$, $D_x = 1.449$ g cm^{-3}, $F(000) = 928$.

Intensity data for a colourless prismatic crystal ($0.35 \times 0.35 \times 0.40$ mm^3) were obtained at room temperature (293 K) in an Enraf–Nonius CAD4 diffractometer using graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å). The ω–2θ scan technique was used to measure the intensities of 6552 reflections up to a maximum Bragg angle of 30°. Cell parameters were obtained by a least-squares procedure from the setting angles of 25 reflections ($8.3 \leqslant \theta \leqslant 11.9°$) [4]. No decomposition of the crystal occurred during data collection. Corrections were applied for Lorentz and polarization effects and for absorption ($\mu = 1.35$ mm^{-1}) [5]. Of the 6552 reflections collected, 5988 were unique ($R_{int} = 0.035$); of these, 3905 satisfied the $I \geqslant 3.0\ \sigma(I)$ criterion of observability and were used in the subsequent analysis.

The structure was solved by Patterson and Fourier methods [6] and was refined on F by a full-matrix least-squares procedure [4] using anisotropic displacement parameters for non-hydrogen atoms. Hydrogen atoms were located from difference Fourier syntheses and refined with isotropic B_{eq} values fixed at 4.0 Å^2. The weighting scheme $w = 1/\sigma^2(F)$ was used. Refinement proceeded smoothly to convergence with a maximum of Δ/σ 0.02 ($R = 0.035$, $R_w = 0.034$) and goodness-of-fit = 1.38 for 296 variables. A correction for extinction was made in the last cycle of refinement [7]. The secondary extinction coefficient refined to $g = 1.587 \times 10^{-8}$ $\{F_c = F_c/[1 + g(F_c)^2 Lp]\}$. Analysis of variance showed no special features, and the maximum and minimum residual electron density peaks in the final difference map were +0.89 and −0.77 e Å^{-3}, respectively.

Atomic scattering factors and anomalous dispersion corrections for all atoms were taken from *International Tables for X-ray Crystallography* [8].

RESULTS AND DISCUSSION

Description of the structure of [$SnPh_3$(mimt)]

In Fig. 1, an ORTEP drawing [9] shows the structure of [$SnPh_3$(mimt)] and the atomic numbering scheme used. Table 1 lists interatomic distances and angles.

The crystal consists of discrete molecules in which the tin atom is coordinated to the sulfur atom of the mimt ligand and to the one carbon atom of each of the three phenyl groups. The Sn—S bond length lies towards the lower end of the range recently reported for triphenyltin thiolates (2.405–2.481 Å) [10–12], close to the sum of the covalent radii of tin and sulfur (2.42 Å) [13]. The Sn—C bond distances are within the range 2.12–2.18 Å reported for triphenyltin compounds [10]. The Sn—S distance and the orientation of the mimt ligand [the torsion angle Sn—S—C(2)—N(1) is 163.4(3)°] places N(3) at 2.920(3) Å from the tin atom. This distance, longer than the sum of the covalent radii of tin and nitrogen (2.15 Å), but shorter than the sum of the van der Waals radii (3.75 Å) [13], lies towards the upper end of the range (2.601–3.057 Å) reported for [$SnPh_3$(L)] complexes, in which L coordinates to the tin *via* sulfur and nitrogen atoms [10–12] and is also longish compared with intramolecular Sn—N distances in other tin compounds [14].

Around the tin atom, the angles C(21)—Sn—C(31) and S—Sn—C(31) are wider and S—Sn—C(11) and C(11)—Sn—C(21) are narrower than the ideal tetrahedral angle. By contrast, in [$SnPh_3$(SPh)] [15] there is only minimal distortion of the tetrahedral environment (C—Sn—C = 112.1°). Since mimt and SPh would be expected to exert similar steric effects, this difference may be attributed to the Sn—N(3) interaction in [$SnPh_3$(mimt)]. Although this might suggest description of the tin environment in [$SnPh_3$(mimt)] as a *cis*-trigonal bipyramid with N(3) and C(11) in the apical positions and sulfur, C(21) and C(31) in the equatorial positions, this bipyramid is extremely distorted: the tin atom lies 0.539 Å out of the S—C(21)—C(31) equatorial plane, the sum of the equatorial angles is only 342.8° and the axial Sn—C bond length is close to the equatorial ones. In contrast, pentacoordinate tin complexes containing a five-membered Sn—S—C—C—N ring have only very slightly distorted trigonal bipyramids [10,11]. Thus, the environment of tin in [$SnPh_3$(mimt)] is best described as a distorted tetrahedron. Similarly distorted tin

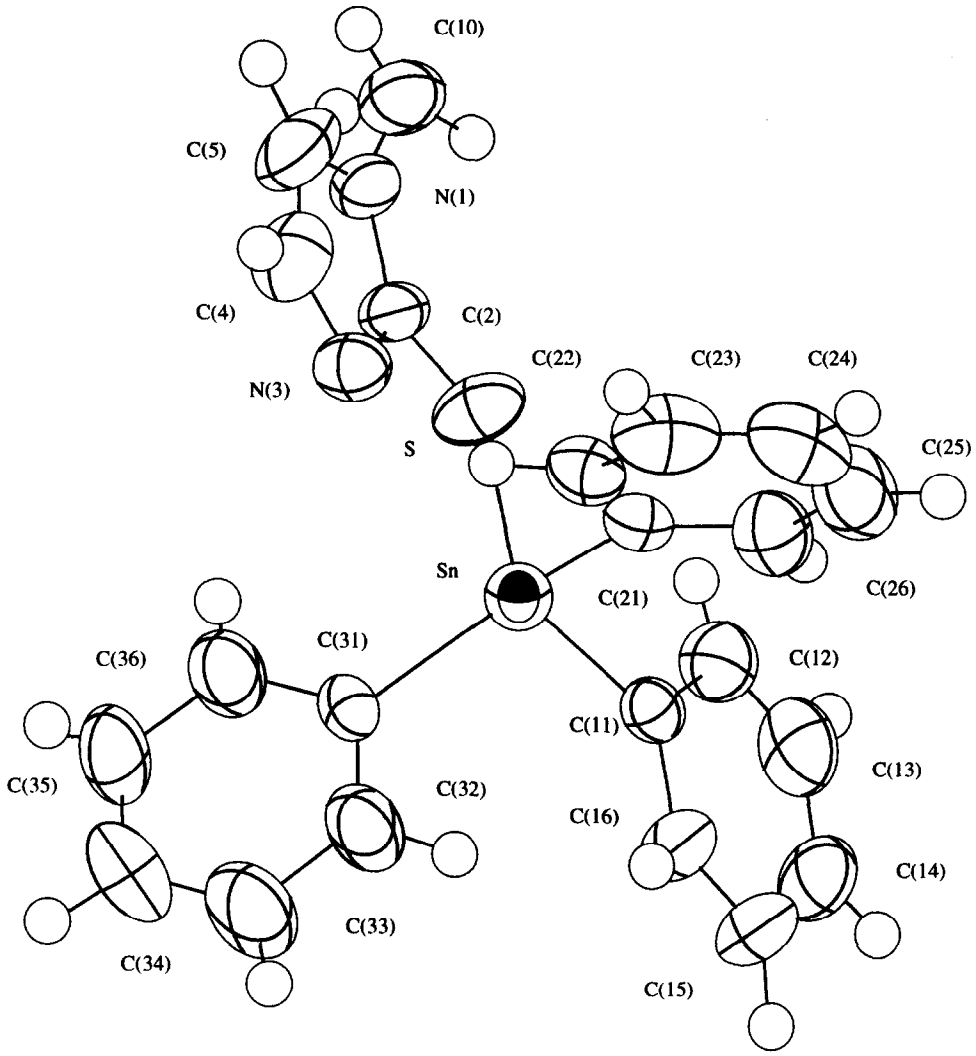

Fig. 1. Perspective view of $[SnPh_3(mimt)]$ showing the atom numbering scheme and the coordination geometry about the tin atom.

coordination polyhedra have been described for triphenyltin *o*-quinolinylthiolate [Sn—S, 2.42(1) Å; Sn—N, 2.836(3) Å] [11] and for triphenyltin pyrimidine-2-thionate [Sn—S, 2.442(3) Å; Sn—N, 2.88(5) Å] [12], which also contain a four-membered Sn—S—C—N ring.

The bond lengths of mimt in $[SnPh_3(mimt)]$ are very similar to those found previously in complexes in which this ligand is S, N-bridged ($[\{Cu(mimt)\}_4]$ [16] and $[GaMe_2(mimt)]_2$ [17]). The angle S—C(2)—N(3) is narrower in the tin complex, and N(3)—C(2)—N(1) is wider; however, and as expected, the greatest difference concerns the M—S—C angle, which is much wider in the complexes of copper [106.8(2)°] and gallium [100.97(9)°] than in $[SnPh_3(mimt)]$ [91.8(1)°], probably due to the disposition of mimt in copper and gallium complexes to form tetramers and dimers, respectively. The M—S—C angle in $[SnPh_3(mimt)]$ is also narrower than the 95.5(7)° found in [HgMe(mimt)] [18] (in which mimt is S-monodentate), possibly due to the Sn—N(3) interaction in the tin complex. High e.s.d. values preclude comparison of bond distances in both compounds.

NMR spectra

Table 2 lists ^1H and ^{13}C chemical shifts for the free ligand Hmimt and the complex $[SnPh_3(mimt)]$. The ^1H NMR spectrum of the complex contains two broad signals at 7.39 and 7.68 ppm attributable to the $SnPh_3$ moiety and the signals of the mimt ligand, slightly shielded with respect to Hmimt. The presence of a

[a] b = broad, d = doublet, m = multiplet, s = singlet, vb = very broad. δ in ppm. J in Hz.
[b] Very weak, broad singlet at $\approx$ 11 ppm.
[c] Not observed.
Numbering scheme:

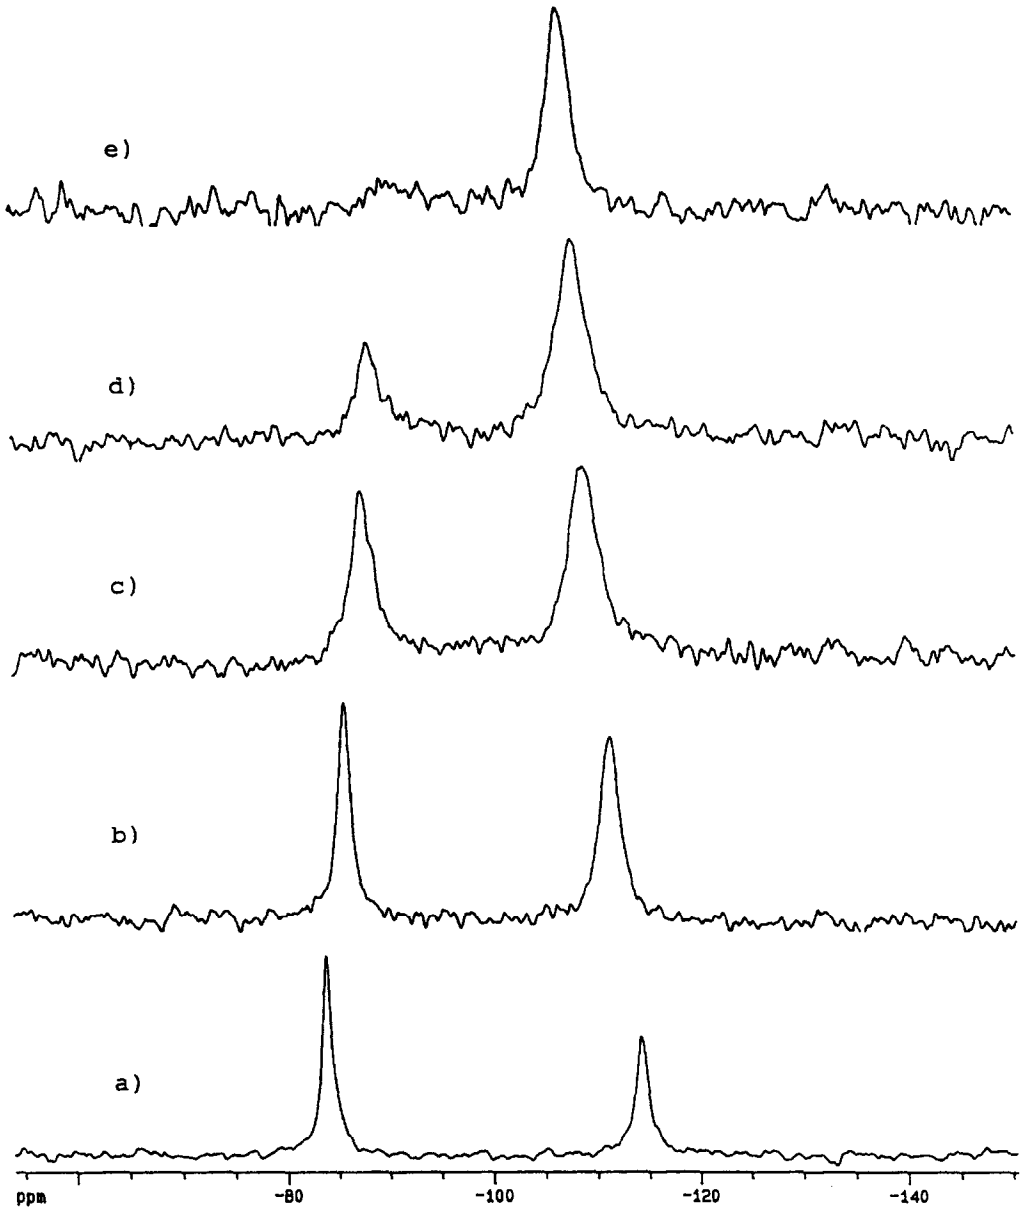

Fig. 2. ^{119}Sn NMR spectra of [$SnPh_3$(mimt)] at 280 K (a), 300 K (b), 320 K (c), 330 K (d) and 340 K (e).

very weak, broad singlet at $\approx$ 11 ppm attributable to N(3)H, together with the liberation of free Hmimt ligand in the synthesis if water is present in the reaction (see Experimental section), suggested the occurrence of a hydrolytic equilibrium:

$$[SnPh_3(mimt)] + H_2O = SnPh_3OH + Hmimt \quad (1)$$

Since no other signals due to the individual or complexed species were observed in the ^{1}H or ^{13}C spectra of the complex {the main feature in the latter spectrum is the shift of the signal of C(2) to higher field upon complexation, as expected for a process involving deprotonation of N(3) and a partial evolution of the thione form at C(2) into a thiolate form [3]}, equilibrium (1) must be fast at room temperature on the ^{1}H and ^{13}C NMR timescales. In the ^{119}Sn spectrum, however, signals due to both $SnPh_3OH$ (−85.8 ppm) and [$SnPh_3$(mimt)] (−111.2 ppm) were detected. Furthermore, addition of a few drops of water to the NMR sample increased the intensity of the $SnPh_3OH$ signal without changing its position, thus confirming the existence of equilibrium (1) by showing it to have been displaced to the right.

The influence of temperature on the above equilibrium was investigated using ^{119}Sn NMR spectroscopy in the range 280–340 K (Fig. 2). At 280 K, $SnPh_3OH$ and [$SnPh_3$(mimt)] gave signals at −83.8 and −114.3 ppm, respectively. Increasing the tem-

perature caused the $SnPh_3OH$ signal to move upfield and to decrease in intensity, while the [$SnPh_3$(mimt)] signal moved downfield and increased in intensity. At 340 K, a single signal attributed to [$SnPh_3$(mimt)] was observed at −106.5 ppm, the equilibrium (1) at this temperature being displaced towards complex formation even when H_2O is present. Note that upon varying the temperature, the position of the ^{119}Sn NMR signal of the complex remained in the narrow range −114.6 to −106.5 ppm, which is towards the upper end of the usual range for a tetracoordinate tin atom in a triphenyltin compound in $CDCl_3$ [19].

State Key Laboratory of Structural Chemistry, Fujian Institute of Research on Structure of Matter, Chinese Academy of Sciences, Fuzhou, Fujian 350002, P.R. China

(Received 25 June 1996; accepted 12 July 1996)

Abstract—The heterobimetallic complexes (dppe)$PdMS_4$ [dppe = $(CH_2PPh_2)_2$, M = W, Mo] have been synthesized by the reaction of (dppe)$PdCl_2$ and $(NH_4)_2MS_4$ in CH_2Cl_2–CH_3CN solvent, and characterized by elemental analysis, UV–vis and IR spectroscopies. The structure of (dppe)$PdWS_4$ has been determined by single-crystal X-ray analysis. The Pd—W distance is 2.89 Å, the average distance of the W—S bridge is 2.23 Å, and that of terminal W—S is 2.14 Å. Copyright © 1996 Elsevier Science Ltd

Keywords: heterobimetallic; palladium; tetrathiometallate; synthesis; structure.

Transition metal sulfido complexes have stimulated profound research interest due to their solid-state properties, applications in catalysis and structural similarity to the cluster core of metal–sulfur metalloenzymes [1]. The tetrathiometallate anions, WS_4^{2-} and MoS_4^{2-}, which are useful and versatile reagents, play a key role in some biological processes [2, 3]. Many types of compound which are interesting from the standpoint of structural chemistry are formed with the aid of doubly, triply and quasi-quadruply bridging tetrathiometallate ligands. The MoS_4^{2-} anion has been claimed to be the most effective antagonist of copper metabolism [4]. There has been extensive research on WS_4^{2-}/$Cu(Ag^I)$ and MoS_4^{2-}/$Cu(Ag^I)$ complexes [5], which has shown a rich structural variation.

Recently, a series of heterometallic sulfido complexes with $\{MWS_4M'\}$ and $\{MMoS_4M'\}$ cores (M = Ag, Cu; M′ = Cu, Fe) were synthesized by the unit construction method in our laboratory [6]. However, heterometallic sulfido complexes derived from MS_4^{2-} (M = W, Mo) with palladium metal are rare [7]. Herein, we report the syntheses of two heterometallic sulfido complexes [(dppe)$PdWS_4$] (**I**) and [(dppe)$PdMoS_4$) (**II**) and the structure of **I**.

EXPERIMENTAL

All solvents were A.R. grade. $(NH_4)_2WS_4$, $(NH_4)_2MoS_4$ [8] and (dppe)$PdCl_2$ [9] were synthesized according to the literature methods. Elemental analyses were carried out by the Elemental Analysis laboratories of our institute. UV–vis spectra were obtained on a Schimadzu UV-3000 spectrophotometer. IR spectra were recorded on a Perkin–Elmer 750 spectrometer as KBr discs.

Syntheses

Preparation of [(dppe)$PdWS_4$] (**I**). (dppe)$PdCl_2$ (0.40 g, 0.70 mmol) and $(NH_4)_2WS_4$ (0.35 g, 1.00 mmol) were added to 20 cm^3 of a mixed solution of CH_2Cl_2 and CH_3CN (1 : 1 v/v), and the mixture was stirred for 1 day at ambient temperature. After filtering, the product was washed with CH_2Cl_2, distilled H_2O, EtOH and Et_2O, respectively. The yellow product was dried in air (yield: 88%). Single yellow crystals were obtained by diffusing ethyl ether into DMF solution. Found: C, 38.4; H, 2.7. Calc. for $C_{26}H_{24}P_2PdWS_4$: C, 38.2; H, 3.0%. IR (KBr): 1583, 1483(m), 1435(s), 717(s), 530(s), 497(s), 482(s), 441(m) cm^{-1}.

Preparation of [(dppe)$PdMoS_4$] (**II**). The method was similar to that for **I**; (dppe)$PdCl_2$ (0.40 g, 0.70

X-ray structure determination of [(dppe)PdWS$_4$] (I)

A crystal of *ca* $0.50\times0.14\times0.08$ mm^3 was used for the structure determination. Some experimental conditions are reported in Table 1. Data were collected on an Enraf–Noniuns CAD4 diffractometer using Mo-K_α radiation ($\lambda = 0.71073$ Å) *via* the ω–2θ scan technique at *ca* 296 K. A total of 5301 reflections for I were collected, of which 4962 were unique. The data were corrected for Lorentz and polarization factors and for absorption using empirical scan data and DIFABS [10]. The maximum and minimum absorption corrections were 1.0829 and 0.8757, respectively, with an average value of 0.9780.

The structure was solved by using the Patterson heavy atom method, which revealed the heavy atoms. The remaining atoms were located in successive difference Fourier syntheses. The structure was refined using a full-matrix least-squares technique. All non-hydrogen atoms were refined with anisotropic thermal parameters, whereas all hydrogen atoms were calculated using a riding model and included in the structure factor calculation. The 2730 reflections with $I \geqslant 3\sigma(I)$ were considered to be observed and used in the refinement. All calculations were performed on a Compaq computer using. MolEN/PC [11].

RESULTS AND DISCUSSION

Because the chloride ligands are good leaving groups in the palladium complex (dppe)PdCl$_2$, they are easily displaced by a strong nucleophilic group, especially a bidentate ligand, like MS_4^{2-} (M = W, Mo). The resulting products were obtained according to the following equation:

$$(dppe)PdCl_2 + (NH_4)_2MS_4 \longrightarrow (dppe)PdMS_4 + 2NH_4Cl \quad (M = W, Mo).$$

The products have poor solubility in common solvents, and slight solubility in DMF, DMSO and CH_3NO_2.

The band maxima and their intensities in the UV–vis spectra of I and II are summarized in Table 2; the recorded spectra of I and II are given in Fig. 1. λ_1 and λ_2 of these spectra belong to the π–π^* transition of the dppe ligand. The λ_3 values of I and II, assigned to the charge transition of S_t—M, are similar to those of MS_4^{2-} (M = W, Mo) [12].

The crystal of compound I is a neutral compound consisting of a distorted tetrahedral WS_4 unit with a palladium atom and two sulfur atom bridges (Fig. 2).

Table 2. Band maxima λ_{max} (in nm), extinction coefficients ε_{mol} (dm^3 cm^{-1} mol^{-1}) in UV–vis spectra of I and II (in DMF)

those for (dppe)$PdCl_2$ [14]. The W—S—Pd angles (78.0° average) are 2.0° larger and the W—Pd distance (2.89 Å) is 0.08 Å longer than those in [[(allyl)$Pd]_2WS_4$] (76.0° and 2.81 Å average, respectively). The terminal W—S distances (2.14 Å average) are shorter than in $(NH_4)_2WS_4$ (2.17 Å) [15], but the W—S bridge distances (2.23 Å average) are slightly longer than those in [[(allyl)$Pd]_2WS_4$] (2.21 Å) [13].

Copper(II)–diethylenetriamine complexes with monodentate N-donor ligands: crystal and molecular structure of diethylenetriamine 2-cyanoguanidine copper(II) nitrate

Michael J. Begley, Peter Hubberstey* and Jo Stroud

Department of Chemistry, Nottingham University, Nottingham NG7 2RD, U.K.

(Received 18 June 1996; accepted 8 July 1996)

Abstract—Mixed ligand copper(II) complexes, $[Cu(dien)(cnge)X_2 \cdot nH_2O]$ ($X = NO_3^-$, NO_2^- or $0.5SO_4^{2-}$), containing diethylenetriamine (dien) and cyanoguanidine (cnge), have been prepared and characterized. Similar complexes, $[Cu(dien)(ImH)X_2 \cdot nH_2O]$ ($X = Cl^-$, NO_3^-, NO_2^- or $0.5SO_4^{2-}$), containing diethylenetriamine (dien) and imidazole (ImH), were prepared for comparison. Under identical reaction conditions, the corresponding pyridine complexes could not be isolated, the copper(II)–dien complexes, $[Cu(dien)X_2 \cdot nH_2O]$ ($X = Br^-$, Cl^-, NO_3^-, NO_2^- or $0.5SO_4^{2-}$) being formed. The structure of $[Cu(dien)(cnge)(ONO_2)_2]$ (**5**) has been determined by single-crystal X-ray diffraction methods. It comprises discrete molecular units based on a tetragonally elongated octahedral copper(II) coordination sphere with equatorially bound dien (average Cu---N = 2.004 Å) and cnge (Cu---N = 1.945 Å) and axially bound nitrate (Cu---O = 2.517, 2.567 Å). Marked shifts ($\sim 25\ cm^{-1}$) to higher frequency in the ν_{as}(NCN) band of cnge on coordination to copper(II) in **5** and related complexes are shown to be consistent with strongly bound cnge, as evidenced by short Cu—N distances and near linear CuNC bond angles. FAB-MS studies gave comparable patterns for all complexes, inferring structural types similar to that for $[Cu(dien)(cnge)(ONO_2)_2]$. Copyright © 1996 Elsevier Science Ltd

Keywords: copper(II); diethylenetriamine; 2-cyanoguanidine.

2-Cyanoguanidine (cnge) readily coordinates later transition metals [1–8], complexes with copper(I) [1], copper(II) [2–6] and cadmium(II) [7] having been structurally characterized. In the absence of multidentate ligands, copper(II) normally binds two *trans*-located cnge ligands [2,3]; in the presence of bidentate chelating 2,2′-bipyridine (bipy), it coordinates two *cis*-located cnge ligands [4]. In the presence of tridentate chelating 1-(2-aminoethyl)biguanide (aebg), copper(II) binds a single cnge ligand [5]. In all cases, the cnge molecules occupy equatorial positions of the tetragonally elongated copper(II) (d^9) coordination sphere; the only example of axially located cnge occurs in the unique tetrakis(acetato) bridged dinuclear copper(II) complex [6]. We now describe the coordination of cnge to copper(II) in a complex containing the tridentate chelating ligand, diethylenetriamine [bis(2-aminoethyl)amine, 3-azapentane-1,5-diamine, dien].

Although mixed ligand complexes of copper(II) containing dien have been known for many years [9–11], structural data are limited. Of those which have been structurally characterized, very few contain dien and a monodentate ligand [10]; the majority contain dien and a bidentate ligand [11]. The latter adopt five-coordinate distorted square pyramidal geometries, with dien located equatorially and the bidentate ligand occupying one equatorial and one axial position; anions are not coordinated [11]. The former adopt six-coordinate tetragonally elongated octahedral geometries, with both ligands located equatorially and anions weakly bound axially [10]. Surprisingly, analogous pentamethyldiethylenetriamine (Me_5dien) complexes all adopt five-coordinate square pyramidal geometries [12,13]. Those with Me_5dien and a bidentate ligand are structurally analogous to the corresponding dien complexes [12]; those with Me_5dien and a monodentate ligand bind a

third ligand (either solvent or anion) in the axial position [13].

RESULTS AND DISCUSSION

Mixed ligand copper(II) complexes, containing dien and either imidazole (ImH), 2-cyanoguanidine (cnge) or pyridine (py), were targeted. Anions varied from bromide through chloride, nitrate and nitrite to sulfate. The general synthetic route comprised treatment of an aqueous solution of the copper(II) salt with an aqueous solution containing dien and the appropriate monodentate N-donor ligand. Of the 15 possible mixed ligand products only seven formed; they are listed in Table 1. Imidazole was the most effective monodentate ligand, forming complexes **1–4** with all anions except bromide; cnge formed complexes **5–7** with the oxoanions, but not the halides, and pyridine did not form any complexes. The products of the other eight systems were the simple copper(II)–dien complexes (**8–12**), which were also produced in the absence of the monodentate ligand. Of the 12 products, only eight (**1, 2, 4, 5, 7–10**) could be satisfactorily characterized by analytical and spectroscopic methods; the other four (**3, 6, 11, 12**) were so deliquescent that quantitative analysis was not attempted. Vibrational spectroscopy was used, however, to confirm the presence of dien, monodentate ligand and anion, as appropriate. Analytical and spectroscopic data are collated in Table 1. UV–vis spectra of all products were similar, comprising a single broad band with λ_{max} close to 660 nm. They had magnetic moments close to 1.7 B.M., typical of mononuclear copper(II) d^9 systems. Fast atomic bombardment mass spectroscopy (FAB-MS) studies of all 12 products, plus $Cu(Me_5dien)(cnge)(NO_3)_2$ (**13**), were undertaken. Although the parent ions were not observed, the fragmentation and combination patterns were consistent with the proposed product identities.

X-ray crystal structure of $[Cu(dien)(cnge)(ONO_2)_2]$ (**5**)

After recrystallization, $[Cu(dien)(ImH)Cl_2 \cdot 2H_2O]$ (**1**), $[Cu(dien)(ImH)(NO_3)_2 \cdot H_2O]$ (**2**) and $[Cu(dien)(cnge)(NO_3)_2]$ (**5**) gave good quality crystals. However, structural analysis was only pursued for **5**, the structure of the imidazole (ImH) and 1-ethylimidazole (EtImH) complexes, $[Cu(dien)(L)(OClO_3)_2]$ [L = ImH (**14**) or EtImH (**15**)] having been determined previously [10]. The molecular structure of **5** is shown in Fig. 1; selected interatomic distances and angles are given in Table 2. It comprises discrete molecular units based on a tetragonally elongated octahedral copper(II) coordination sphere, typical of Jahn–Teller distorted d^9 $[(d_{z^2})^2 (d_{x^2-y^2})^1]$ systems, with strongly bonded N-donor ligands in the equatorial sites and weakly bonded

nitrates in the axial sites. The analogous ImH and EtImH complexes are very similar, with equatorially located dien and imidazole molecules and axially located perchlorate anions. Pertinent structural data for the copper(II) coordination spheres of all three complexes are compared in Table 3. The most significant difference lies in the copper to anion distances, those to perchlorate being somewhat longer than those to nitrate. It is also interesting to note that the Cu—N distances increase in the sequence, cnge (1.945

The cnge molecule bonds to the copper(II) ion in an equatorial position. As for other examples of cnge coordinated to copper(II) [2–6], its geometry (Table 2) does not differ significantly from that for free cnge [14]. Although effectively planar [maximum deviation from the least squares mean plane = 0.047 Å, C(12)], the cnge molecule is twisted out of the plane formed by the four ligating nitrogen atoms (dihedral angle = 36.1°). The latter is slightly distorted, the *trans*-located terminal dien nitrogens lying above the mean plane [N(21), 0.073 Å; N(27), 0.072 Å] and the pivotal dien nitrogen and cnge nitrile nitrogen lying below the mean plane [N(24), −0.079 Å; N(11), −0.066 Å]. The copper atom lies 0.077 Å below the mean plane, between the pivotal dien and cnge nitrogens [N(11)—Cu—N(24) 179.4(2)]. The nitrate anions are planar and subtend dihedral angles of 20.0° [$N(1)O_3^-$] and 67.4° [$N(2)O_3^-$] with the N_4 plane.

The monodentate coordination of the nitrate anions in **5** differs from that of the nitrate anions in [Cu(dien)(NO_3)](NO_3) (**16**) [15] and [Cu(dien)$_2$]$(NO_3)_2$ (**17**) [16]. In **16**, one nitrate acts as a bidentate bridging ligand and the other is non-coordinated, as are both nitrates in **17**. The distorted trigonal bipyramidal copper(II) coordination sphere in **16** is completed by a single tridentate chelating dien molecule [15]. The copper(II) in **17** is surrounded by two tridentate chelating dien ligands, its six-coordinate geometry, the relatively rare, compressed tetragonally distorted octahedron, the alternative Jahn–Teller distorted d^9 [$(d_{x^2-y^2})^2 (d_{z^2})^1$] system, being dictated by the steric requirements of the dien ligand [16]. The differing strength of nitrate binding in **5** and **17** can be traced to the copper(II) coordination geometry. Whereas the nitrate anions bind weakly in the axial positions of the tetragonally elongated octahedron in **5** (Cu···O = 2.52, 2.57 Å), it is much more strongly coordinated in the bridging equatorial positions of the distorted trigonal bipyramid in **16** (Cu···O = 2.12, 2.29 Å). Nitrate binding in **16** is enhanced by secondary interactions, giving a pseudo-bidentate chelating coordination for both copper–nitrate contacts (Cu···O = 2.58, 2.89 Å) and hence a pseudo-seven-fold coordination geometry.

The molecules of **5** are held in place in the crystal predominantly by hydrogen bonding interactions between the cnge amino moieties and the nitrate anions. Hydrogen bond contacts also occur between terminal dien amino groups and the nitrate anions. These interactions are shown in Fig. 2 and structural details for all possible hydrogen bond contacts are collected in Table 4.

A marked increase in the frequency of the doublet assigned to ν_{as}(NCN) [17] is observed on coordination of cnge in [Cu(dien)(cnge)$(ONO_2)_2$] (Table 1). This change is typical of coordinated cnge, as shown by comparison with data for the five previously structurally characterized copper(II)–cnge complexes (Table 5). Only one complex, [$(\mu$-OAc$)_4${Cu(cnge)}$_2$], does not exhibit such a change in ν_{as}(NCN). Although the marked shifts in ν_{as}(NCN) cannot be related to trends in the geometry of the ligating nitrile moiety of the cnge molecule, they do appear to be sensitive to the cnge coordination geometry and the strength of the Cu---N coordinate bond. Marked increases in ν_{as}(NCN) are consistent with short Cu···N distances and near linear Cu—N—C bond angles, presumed indicative of strongly bound cnge. Virtually no change in ν_{as}(NCN) occurs for [$(\mu$-OAc$)_4${Cu(cnge)}$_2$], which has the longest Cu---N distance and smallest Cu—N—C angle (Table 5). Thus despite the increasing database on copper(II)–cnge complexes, ν_{as}(NCN) can only be used as a crude indicator of the strength of cnge bonding.

Although coordination of cnge in Cu(dien)(cnge)$(SO_4)\cdot 3H_2O$ (**7**) results in an increase in ν_{as}(NCN) similar to that observed in **5**, a decrease in ν_{as}(NCN) is observed for Cu(dien)(cnge)$(NO_2)_2\cdot nH_2O$ (**6**) (Table 1). Hence, similar coordination geometries may be inferred for **5** and **7**, but not **6**. As **6** is the first copper(II)–cnge complex for which a decrease has been observed and we have not been able to obtain a pure crystalline sample, an assessment of its structural chemistry is not possible.

Mass spectrometric studies of copper(II)–dien complexes

FAB-MS studies of copper(II)–dien complexes have been particularly valuable, the spectra following a consistent pattern. The fragmentation and combination patterns for $Cu(dien)X_2$ and $Cu(dien)LX_2$ (L = ImH or cnge; X = Br, Cl, NO_3 or NO_2) complexes are summarized in Schemes 1 and 2, respectively. The ions (minimum *m/z* values) observed for individual complexes are collated in Table 6. In neither case is the parent ion observed. In the absence of a mondentate N-donor ligand (Scheme 1), however, loss of X^- gives the observed $[Cu^{II}(dien)X]^+$ cation, which either loses X to form $[Cu^{I}(dien)]^+$ or combines with $[Cu^{II}(dien)X_2]$ or $[Cu^{I}X]$ moieties to form species which consecutively lose up to two HX fragments. For complexes containing a monodentate N-donor ligand (Scheme 2), a similar behaviour pattern emerges, loss of X^- giving $[Cu^{II}(dien)LX]^+$, which either loses L to form $[Cu^{I}(dien)X]^+$ or combines with $[Cu^{II}(dien)X_2]$ or $[Cu^{I}X]$ moieties to form species which exhibit HX loss. The formation of $[Cu^{I}(dien)X]^+$, which could also arise from $Cu(dien)LX_2$ *via* $Cu(dien)X_2$ by sequential loss of L and X^-, leads to those ions observed in the spectra of $Cu(dien)X_2$ (Scheme 1).

The spectra for the sulfates (Schemes 1 and 2; Table 6) are analogous to those for the complexes containing singly charged ions, the only significant difference involving the formation of the pivotal ions, addition of H^+ giving $[Cu^{II}(dien)(SO_4H)]^+$ (Scheme 1) and

Scheme 1.

Scheme 2.

$[Cu^{II}(dien)L(SO_4H)]^+$ (Scheme 2), which behave as $[Cu^{II}(dien)X]^+$ and $[Cu^{II}(dien)LX]^+$, HSO_4^- being the singly charged X^- anion.

EXPERIMENTAL

Elemental analysis, mass spectrometry, IR and UV–vis spectroscopy and magnetic measurements were used to characterize all products, except for the highly deliquescent nitrites and sulfates, which were studied using spectroscopic methods only; pertinent data are collated in Table 1. Carbon, nitrogen and hydrogen analyses (microanalysis) and copper analyses (atomic absorption spectroscopy) and mass spectral data acquisition were carried out in the University of Nottingham Chemistry Department by Mr T. J. Spencer, Mr M. Guyler and Mr T. Hollingworth, respectively. IR spectra were obtained as KBr pressed pellets on either a Perkin–Elmer PE983G or PE 1600 series FTIR spectrophotometer and UV–vis spectra on either a Perkin–Elmer Lambda 5 or Unicam UV2-100 spectrometer.

Copper(II) nitrite was prepared *in situ* by treatment of $CuSO_4 \cdot 5H_2O$ with $Ba(NO_2)_2$. The other copper(II) salts [$CuBr_2$, $CuCl_2 \cdot 2H_2O$, $Cu(NO_3)_2 \cdot 3H_2O$, $CuSO_4 \cdot 5H_2O$] were obtained from Aldrich Chemical Company Ltd and recrystallized from deionized water prior to use. The N-donor ligands, dien, ImH, cnge and py, were obtained from Aldrich Chemical Company Ltd and used without further purification.

Preparation of bromide salts

An aqueous solution (50 cm^3) of $CuBr_2$ (4.00 g, 17.9 mmol) was added to an aqueous solution (50 cm^3) containing either dien (1.93 g, 18.0 mmol) alone or dien (1.39 g, 18.0 mmol) with either ImH (1.24 g, 18.2 mmol), cnge (1.50 g, 17.8 mmol) or py (1.43 g, 18.1 mmol). The resulting blue solution was heated to 90°C

[a] For these ions read Me_5dien for dien.

for 30 min, before the solvent volume was reduced to yield a blue gum. For all four experiments, washing with ethanol gave a dark blue solid, which after recrystallization from aqueous ethanol was found to be $Cu(dien)Br_2$ (4.95 g, 15.2 mmol, 85%).

Preparation of chloride salts

An aqueous solution (60 cm^3) of $CuCl_2 \cdot 2H_2O$ (5.00 g, 29.3 mmol) was added to an aqueous solution (60 cm^3) containing either dien (3.10 g, 28.9 mmol) alone or dien (3.10 g, 28.9 mmol) with either ImH (1.95 g, 28.6 mmol), cnge (2.45 g, 29.1 mmol) or py (2.30 g, 29.1 mmol). The resulting blue solution was heated to 90°C for 30 min, solvent volume was reduced and ethanol added to yield a blue solid. Recrystallization from aqueous ethanol gave $Cu(dien)Cl_2$ (4.90 g, 20.6 mmol, 71%) or $Cu(dien)(ImH)Cl_2 \cdot 2H_2O$ (5.05 g, 14.8 mmol, 52%).

Preparation of nitrate salts

An aqueous solution (60 cm^3) of $Cu(NO_3)_2 \cdot 3H_2O$ (5.00 g, 20.7 mmol) was added to an aqueous solution (60 cm^3) containing either dien (2.22 g, 20.7 mmol) alone or dien (2.22 g, 20.7 mmol) with either ImH (1.40 g, 20.6 mmol), cnge (1.75 g, 20.8 mmol) or py (1.65 g, 20.9 mmol). The resulting blue solution was heated to 90°C for 30 min, solvent volume reduced, ethanol added and the mixture left at 5°C for 16 h. All four experiments gave blue solids, which after recrystallization from aqueous ethanol analysed for $Cu(dien)(NO_3)_2$ (4.20 g, 14.5 mmol, 70%), $Cu(dien)(ImH)(NO_3)_2 \cdot H_2O$ (6.25 g, 16.6 mmol, 80%), $Cu(dien)(cnge)(NO_3)_2$ (5.95 g, 15.8 mmol, 77%) and $Cu(dien)(NO_3)_2 \cdot H_2O$ (3.65 g, 11.8 mmol, 57%), respectively.

Preparation of nitrite salts

An aqueous solution (30 cm^3) of $CuSO_4 \cdot 5H_2O$ (3.26 g, 13.1 mmol) was added to an aqueous solution (30 cm^3) of $Ba(NO_2)_2$ (3.00 g, 13.1 mmol). A white precipitate of $BaSO_4$, which formed immediately, was filtered off to leave a lime green solution, which was then added to an aqueous solution (40 cm^3) containing dien (1.35 g, 12.6 mmol) alone or dien (1.35 g, 12.6 mmol) with either ImH (0.86 g, 12.6 mmol), cnge (1.05 g, 12.5 mmol) or py (1.00 g, 12.6 mmol). The resulting blue solution was heated to 90°C for 30 min, solvent volume reduced, ethanol added and the mixture left at 5°C for 16 h. In none of the experiments did precipitation occur. Other diverse solvent combinations (H_2O–Pr^iOH, MeCN–Et_2O, MeCN–toluene) were tried but without success. A solid product could only be obtained by removal of all solvent *in vacuo*.

Preparation of sulfate salts

An aqueous solution (60 cm^3) of $CuSO_4 \cdot 5H_2O$ (8.00 g, 32.0 mmol) was added to an aqueous solution (60 cm^3) containing either dien (3.45 g, 32.2 mmol) alone or dien (3.45 g, 32.2 mmol) with either ImH (2.15 g, 31.6 mmol), cnge (2.69 g, 32.0 mmol) or py (2.55 g, 32.2 mmol). The resulting blue solution was heated to 90°C for 30 min, solvent volume reduced, ethanol added and the mixture left at 5°C for 16 h. In the presence of ImH or cnge, highly deliquescent blue solids analysing for $Cu(dien)(ImH)(SO_4) \cdot 2H_2O$ (6.10 g, 16.6 mmol, 53%) and $Cu(dien)(cnge)(SO_4) \cdot 3H_2O$ (6.45 g, 16.1 mmol, 50%) were recovered. In the presence of py or with dien alone, precipitation did not occur. As for the nitrites, various solvent combinations (H_2O–Pr^iOH, MeCN–Et_2O, MeCN–toluene) were tried but without success. A solid product could only be obtained by removal of all solvent *in vacuo*.

X-ray crystallography

Oscillation and Weissenberg photographs revealed preliminary cell parameters for selected crystals of **5** (triclinic) mounted in Lindemann tubes under dry nitrogen. X-ray diffraction data for the refinement of cell parameters and structure determination were collected using a Hilger and Watts Y290 four-circle diffractometer.

Crystal data. $C_6H_{17}CuN_9O_6$, M = 374.80, triclinic, space group $P\bar{1}$, $a = 7.949(3)$, $b = 10.217(4)$, $c = 10.351(4)$ Å, $\alpha = 66.08(5)°$, $\beta = 75.39(5)°$, $\gamma = 85.45(5)°$, $U = 743.36$ Å^3, $Z = 2$, $F(000) = 386$, D_m (bromoform/hexane) = 1.68 g cm^{-3}, $D_c = 1.67$ g cm^{-3}, Mo-K_α radiation, $\lambda = 0.71073$ Å, $\mu_{calc} = 15.15$ cm^{-1}, crystal dimensions $0.08 \times 0.20 \times 0.25$ mm^3.

One unique set of data (2199 reflections; index ranges $-9 < h < 9$, $-10 < k < 12$, $0 < l < 12$) was collected at 298 K in the range $1 < \theta < 25°$ (scan mode: ω–2θ) using graphite monochromated Mo-K_α radiation. Standard reflections were constant throughout the course of the data collection, indicating that the crystals were stable. Data were corrected for Lorentz and polarization effects; absorption corrections were not applied.

The positions of the copper atoms were determined by identifying the copper–copper $2x$, $2y$, $2z$ vector in the Patterson map (CRYSTALS [18]). The positions of the remaining atoms were obtained by Fourier difference syntheses. All atoms were refined with anisotropic displacement parameters with the exception of the hydrogen atoms, which were refined isotropically. Full least squares matrix refinement (CRYSTALS [18]) against F values [2199 data with $I > 3\sigma(I)$] with unit weights converged to $R = 0.040$ and $R_w = 0.042$ for 257 parameters in space group $P\bar{1}$; residual $\Delta\rho_{min} = -0.513$, $\Delta\rho_{max} = 0.619$, $(\Delta/\sigma)_{max} = 0.065$.

Atomic coordinates, thermal parameters, a complete list of interatomic distances and angles, and observed and calculated structure factors have been deposited with the Editor as supplementary material.

(Received 24 May 1996; accepted 8 July 1996)

Abstract—A series of new acyclic platinum(II) and palladium(II) 5,5′-bis-amide substituted 2,2′-bipyridyl receptors have been synthesized and single-crystal structural investigations of two receptors are described. Proton NMR anion binding studies reveal that these neutral receptors recognize chloride anions in dimethyl sulfoxide solution. Copyright © 1996 Elsevier Science Ltd

Keywords: anion; recognition; platinum; palladium; bipyridyl; chloride.

The molecular recognition [1] and sensing [2] of anionic species is a rapidly expanding area of host–guest chemistry. A variety of positively charged and neutral electron-deficient abiotic receptor molecules have been synthesized and shown in some cases to selectively recognize anions [3, 4]. As part of a research programme aimed at designing new optical and electrochemical sensory reagents for anions [2], we have recently reported new classes of anion receptor that contain positively charged organometallic and coordination transition metal Lewis acidic binding sites in combination with amide N—H groups [5,6]. For example, spectral and electrochemical recognition of anions has been demonstrated by ruthenium(II) 4,4′- and 5,5′-bis-disubstituted bipyridyl derivatives [7,8]. In an effort to investigate the effect of charge of the Lewis acidic centre upon the anion recognition process, we describe here the preparation and anion complexation ability of new neutral platinum(II) and palladium(II) bipyridyl receptors.

RESULTS AND DISCUSSION

Anion receptor syntheses

The preparation of the 5,5′-bis-amide substituted 2,2′-bipyridyl ligands has been described previously (Fig. 1) [8]. Attempts were made to coordinate the ligands L^1, L^2, L^3 and L^4 to platinum(II) using $K_2[PtCl_4]$ (Scheme 1). The literature procedures for the preparation of such complexes are usually made in water [9]. However, all the ligands demonstrated an extreme hydrophobicity. Consequently, ligand L^1 was dissolved in methanol (using the preparation of $Pt(phen)Cl_2$ as a precedent [10]), to which was added the platinum precursor $K_2[PtCl_4]$ in aqueous acetonitrile, with stirring for several hours. The product $Pt(L^1)Cl_2$ was isolated following removal of the solvent and recrystallized from methanol as a yellow solid in 70% yield. Ligands L^{2-4} proved insoluble in methanol, so warm DMSO was used as the reaction solvent. After several hours of heating with $K_2[PtCl_4]$ the solvent was removed by vacuum distillation, and the products $Pt(L^{2-4})Cl_2$ were obtained as yellow solids.

The analogous palladium complexes $Pd(L^{1,3,4})Cl_2$ were prepared similarly using $K_2[PdCl_4]$ in good yields as yellow–brown solids. Unfortunately, extreme insolubility problems with the palladium complex product of L^2 prevented its characterization.

It is noteworthy that with the platinum complexes the addition of water caused a dramatic colour change from yellow to bright red. This colour change has also been observed under extreme conditions with Pt(bipy)Cl_2, and typically is derived from refluxing [Pt(bi-

Scheme 1.

$py)(NH_3)_2]^{2+}$ in hydrochloric acid to give the red form [11,12]. There is substantial evidence that the yellow and red complexes are monomeric structures and so it has been postulated that the colour change is due to differing spatial arrangements in the crystal structure. Since the amide functionalized complexes readily change colour on the addition of water, this could be attributed to hydrogen bonding to water by the complexes, forcing the crystal structure to rearrange in some manner. Unfortunately, the poor solubility of the complexes prevented a solution investigation into this phenomenon using electronic spectroscopy.

Structural studies

$Pt(L^2)Cl_2$. Crystals of complex $Pt(L^2)Cl_2$ suitable for X-ray structural analysis were obtained as yellow needles by dissolving in warm DMSO and subsequent slow evaporation over 9 months. The structure is shown in Fig. 2, together with the atomic numbering scheme. The platinum complex has crystallographic C_2 symmetry and there is a DMSO solvent molecule per complex, with a hydrogen bond between the amide nitrogen atom N(12) and the oxygen atom in the solvent DMSO [N(12)···O(1S) $(-x,-y,1-z)$ 2.838

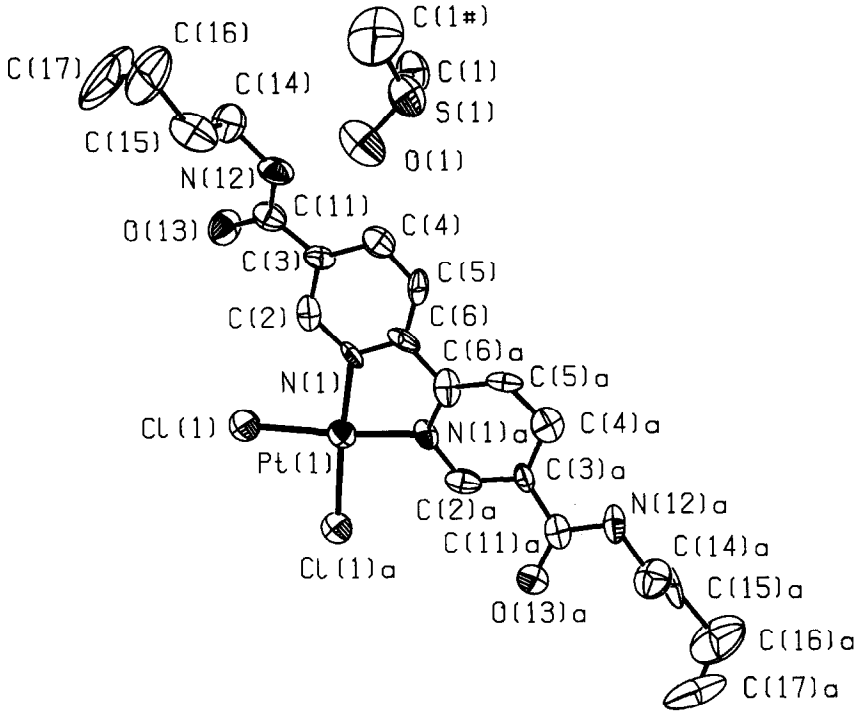

Fig. 2. Thermal motion ellipsoid plot of $Pt(L^2)Cl_2$, with ellipsoids drawn at the 30% probability level.

Å]. The bond lengths and angles for the bipyridyl platinum fragments are in good agreement with those for $Pt(bipy)Cl_2$ (both the red and yellow forms) [12] (Table 1). It was observed that the bond distances between the platinum centre and the ligated atoms were slightly smaller than with $Pt(bipy)Cl_2$ [12]. This is probably due to the electron-withdrawing effect of the new amide functionalized ligand, causing better d–π^* back bonding, and consequently shorter bond lengths are observed and the reduced electron density on the platinum centre facilitates stronger bonding to the chloride ligands.

The molecules are planar and stack in a staggered array of overlapping units, as shown in Fig. 3a and b. The structure does not, however, demonstrate the configuration of either the yellow or the red isomorph of $Pt(bipy)Cl_2$, with the Pt—Pt distance being comparatively much larger (6.695 Å) [12]. The individual units lie in line with each other as in the red form, but the two platinum atoms do not sit directly over each other. It is presumed that on the addition of water, a rearrangement can occur which brings the two platinum centres closer together, by virtue of a change in the hydrogen bonding arrangement, giving the distinct colour change observed.

$Pd(L^1)Cl_2$. Crystals of complex $Pd(L^1)Cl_2$ suitable for X-ray structure analysis were obtained as yellow needles by dissolving in warm DMSO and subsequent

slow evaporation over 6 months. The structure is shown in Fig. 4, together with the atomic numbering scheme. The units themselves indicate that the bond lengths and distances are similar to those of Pd(bipy)Cl_2 [13], with changes in the metal-to-ligand bond distances again associated with the additional electron-withdrawing nature of the amide groups (Table 2).

These planar molecules also pack closely in a linear stack (Fig. 5a, b); however, in this case the packing is more similar to the literature (compare the Pd—Pd distances in Table 2) [13], where the packing is isomorphic with the yellow form of Pt(bipy)Cl_2. There is no solvent in this structure and two types of hydrogen bond link the individual units together in a two-dimensional lattice. One is formed between an amide

nitrogen [N(23)] atom and an adjacent chloride [Cl(2)] ligand lying in the plane [N(23)—Cl(2) $(0.5-x,-y,0.5+z)$ 3.321 Å]. The other is formed from the amide nitrogen [N(33)] atom and an amide oxygen [O(22)] atom in the molecule directly above the stack [N(33)—O(32) $(0.5+x,y,0.5-z)$ 2.907 Å]. In order to achieve this hydrogen bond, there are two differences in the conformation of the ligand in the palladium complex relative to the platinum complex, where both carbonyl groups are positioned on the same side as each other and on the same side as the metal atom. By contrast, in the palladium complex, while one carbonyl group is on the metal side, the other is rotated around to point away from the metal so that it can participate in hydrogen bonding. In addition, this atom is severely twisted out of the plane of the pyridine ring to which it is attached, thus the C(11)—C(10)—C(31)—N(33) torsion angle is 37.1° compared to the more expected angle for C(2)—C(3)—C(21)—N(23) of −2.1° (Table 3).

Proton NMR anion coordination studies

The addition of tetrabutylammonium chloride to DMSO-d_6 solutions of the neutral platinum and palladium(II) bipyridyl receptors resulted in significant downfield perturbations of the 4,4′-bipyridyl and especially the amide protons (Table 4). Typically, an amide proton shift of $\Delta\delta = 0.1$ ppm was observed after the addition of two equivalents of the chloride salt. As noted previously, these results suggest that favourable amide CONH---Cl^- hydrogen bonding is a crucial contributing factor to the overall anion complexation process. Disappointingly, precipitation problems with the $ML^{2,3}$ Cl_2 (M = Pt, Pd) receptors precluded complete titration curves being obtained. However, stability constants for 1:1 receptor:chloride anion stoichiometry were determined from the titration data of the other receptors using the least squares curve fitting program EQNMR [14], and the results are summarized in Table 4. Within experimental error all four neutral platinum(II) and palladium(II) receptors complex the chloride anion with similar magnitudes of stability constant, suggesting neither the nature of the metal nor the alkyl or aryl

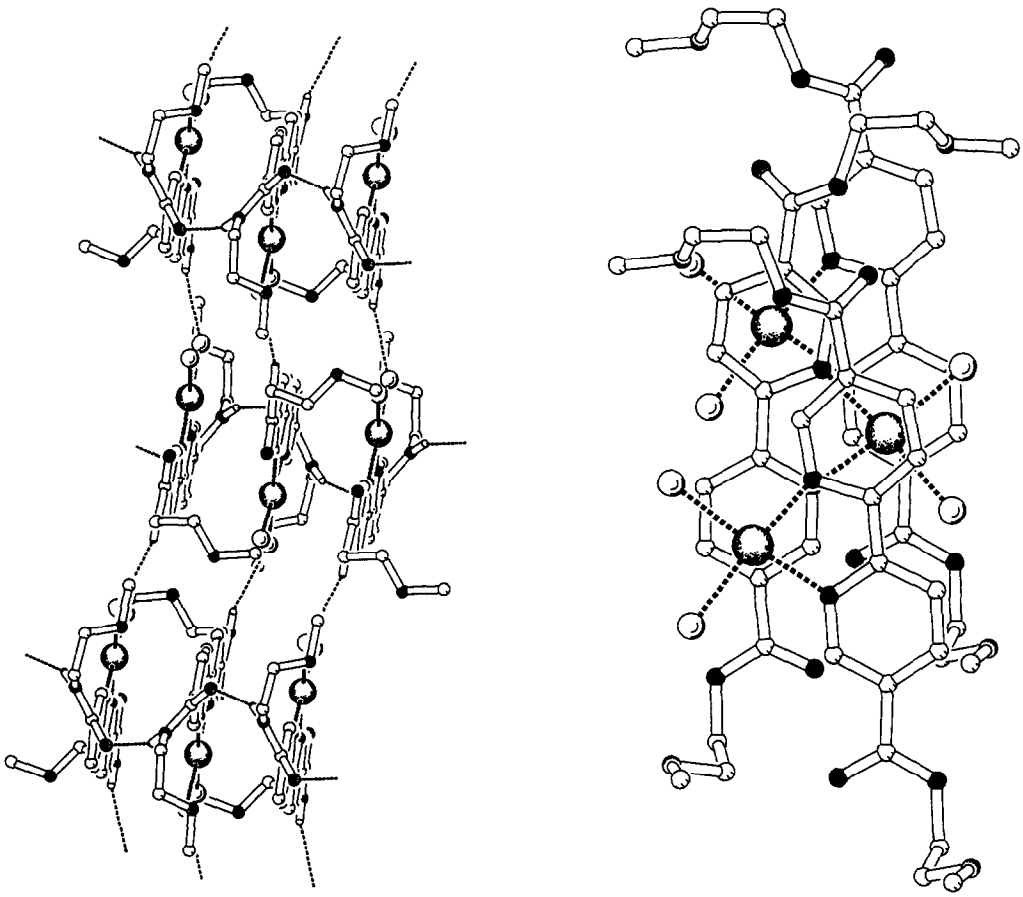

Fig. 5. PLUTON straw plot of the structure of $Pd(L^1)Cl_2$, illustrating the two-dimensional array of the molecules, held together by intermolecular hydrogen bonding.

substituent greatly influences the strength of halide anion binding. Interestingly, charged ruthenium(II) 5,5′-bis-amide-substituted 2,2′-bipyridyl receptor analogues [8] exhibited only slightly larger magnitudes of stability constant with chloride in DMSO, of typical value 45 $dm^3\ mol^{-1}$, implying that the charged or neutral character of the transition metal bipyridyl coordinated Lewis acid centre is not critical to the inclusive thermodynamic stability of anion binding in these systems.

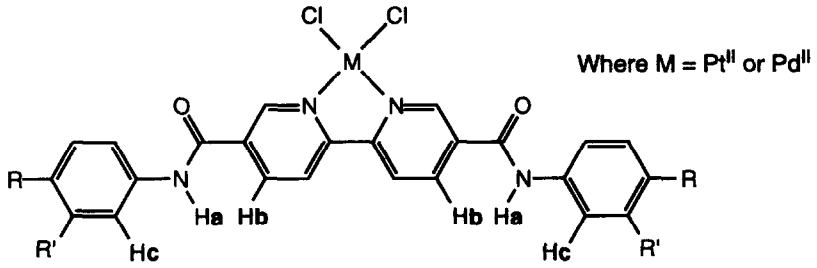
CONCLUSIONS



New acyclic neutral platinum(II) and palladium(II) 5,5′-bis-amide-substituted 2,2′-bipyridyl receptors have been prepared and the single-crystal structures of two receptors determined. Proton NMR chloride anion binding studies in deuteriated DMSO solution reveal that these neutral receptors complex the halide anion *via* favourable amide CO—NH---Cl^- hydrogen bonding interactions. Stability constant evaluations suggest the strength of halide anion binding is largely independent of the nature of the d^8 metal or the alkyl/aryl amide-linked substituent.

EXPERIMENTAL

Instrumentation

NMR spectra were recorded on a Bruker AM300 instrument using the solvent deuterium signal as an

internal reference. Mass spectrometry was performed by the analytical services at Kodak Ltd, Harrow. Elemental analyses were performed at the Inorganic Chemistry Laboratory, University of Oxford. Unless stated to the contrary, commercial grade chemicals were used without further purification.

The preparation of the ligands have been described previously [8].

Synthesis

Platinum(II) (5,5′-*bis*(*methoxyethylamido*)-2,2′-*bipyridine*) *dichloride* (PtL^1Cl_2). Ligand L^1 (36 mg, 0.101 mmol) was dissolved in methanol (20 cm^3) with gentle heating, to which was added $K_2[PtCl_4]$ (47 mg, 0.114 mmol) in 50% aqueous acetonitrile (20 cm^3). The reaction mixture was stirred for 4.5 h and filtered. The solvent was removed from the filtrate giving a yellow residue, and the product was isolated after recrystallization from methanol. Yield 44 mg, 70%. ^{1}H NMR (DMSO): δ 3.29 (4H, m, $NHCH_2CH_2$), 3.32 (6H, s, OCH_3), 3.50 (4H, m, CH_2CH_2O), 8.75 (2H, d, $J = 8.4$ Hz, bipyC*H*^{4}), 8.79 (2H, d, $J = 8.5$ Hz, bipyC*H*^{3}), 9.15 (2H, bt, N*H*), 9.88 (2H, s, bipy C*H*^{6}). Found: C, 34.9; H, 3.7; N, 7.7. Calc. for $C_{18}H_{22}N_4O_4Cl_2Pt$: C, 34.6; H, 3.6; N, 8.0%. FAB-MS: $[MH]^+$ 625, $[M-Cl]^+$ 589.

Platinum(II) (5,5′-*bis*(*butylamido*)-2,2′-*bipyridine*) *dichloride* (PtL^2Cl_2). Ligand L^2 (46 mg, 0.130 mmol) and $K_2[PtCl_4]$ (85 mg, 0.205 mmol) were mixed in DMSO (20 cm^3) and heated at 60°C for 1 h. Following additional stirring for 22 h at room temperature, the solvent was removed at reduced pressure at approx. 60°C to give a yellow solid. The residue was ground up, stirred in water (50 cm^3) for 2 h, filtered and dried *in vacuo*, giving a red solid which went yellow on drying. Yield 51 mg, 63%. ^{1}H NMR (DMSO): δ 0.91 (6H, t, $J = 7.2$ Hz, CH_2CH_3), 1.33 (4H, m, $CH_2CH_2CH_3$), 1.54 (4H, m, $CH_2CH_2CH_2$), 2.37 (4H, m, $NHCH_2CH_2$), 8.75 (4H, s, bipyC*H*^{3} and bipyC*H*^{4}), 9.01 (2H, t, $J = 5.3$ Hz, N*H*), 9.87 (2H, d, $J = 2.0$ Hz, bipyC*H*^{6}). Found: C, 37.8; H, 4.1; N, 8.3. Calc. for $C_{20}H_{26}N_4O_2Cl_2Pt \cdot 2H_2O$: C, 38.7; H, 4.2; N, 9.0%. FAB-MS: $[MH]^+$ 620, $[M-Cl]^+$ 579.

Platinum(II) (5,5′-*bis*(3,4-*dimethoxyphenylamido*)-2,2′-*bipyridine*) *dichloride* (PtL^3Cl_2). Using ligand L^3, an analogous synthetic procedure was used as in the preparation of $Pt(L^2)Cl_2$. Yield 78%. ^{1}H NMR (DMSO): δ 3.76 (6H, s, OCH_3), 3.78 (6H, s, OCH_3), 6.98 (2H, d, $J = 9.3$ Hz, ArC*H*^{5}), 7.33 (2H, d, $J = 8.2$ Hz, ArC*H*^{6}), 7.45 (2H, s, ArC*H*^{2}), 8.84 (2H, d, $J = 9.8$ Hz, bipyC*H*^{4}), 8.94 (2H, d, $J = 7.8$ Hz, bipyC*H*^{3}), 9.96 (2H, s, bipyC*H*^{6}), 10.68 (2H, s, N*H*). Found: C, 42.2; H, 3.1; N, 6.8. Calc. for $C_{28}H_{26}N_4O_6Cl_2Pt$: C, 43.1; H, 3.4; N, 7.2%. FAB-MS: $[MH]^+$ 780, $[M-Cl]^+$ 744.

Platinum(II) (5,5′-*bis*(4-*hydroxyphenylamido*)-2,2′-*bipyridine*) *dichloride* (PdL^4Cl_2). Using ligand L^4, an analogous synthetic procedure was used as in the preparation of $Pt(L^1)Cl_2$. Yield 68%. ^{1}H NMR (DMSO): δ 6.78 (4H, d, $J = 8.3$ Hz, PhC*H*^{2}), 7.55 (4H, d, $J = 8.2$ Hz, PhC*H*^{3}), 8.82 (2H, d, $J = 8.2$ Hz, bipyC*H*^{4}), 8.92 (2H, d, $J = 8.0$ Hz, bipyC*H*^{3}), 9.41 (2H, s, bipyC*H*^{6}), 9.92 (2H, s, O*H*), 10.59 (2H, s, N*H*). Found: C, 39.5; H, 2.8; N, 6.9. Calc. for $C_{24}H_{18}N_4O_4Cl_2Pt \cdot 2H_2O$: C, 39.6; H, 3.0; N, 7.7%.

Palladium(II) (5,5′-*bis*(*methoxyethylamido*)-2,2′-*bipyridine*) *dichloride* (PdL^1Cl_2). Using ligand L^1, an analogous synthetic procedure was used as in the preparation of $Pt(L^1)Cl_2$. Yield 89%. ^{1}H NMR (DMSO):

δ 3.28 (4H, m, $NHCH_2CH_2$), 3.34 (6H, s, OCH_3), 3.49 (4H, m, CH_2CH_2O), 8.74 (2H, d, $J = 8.4$ Hz, bipyCH^4), 8.76 (2H, d, $J = 8.4$ Hz, bipyCH^3), 9.12 (2H, bt, NH), 9.50 (2H, s, bipyCH^6). Found: C, 40.2; H, 3.8; N, 10.5. Calc. for $C_{18}H_{22}N_4O_4Cl_2Pd$: C, 40.4; H, 4.1; N, 10.5%. FAB-MS: $[MH]^+$ 535, $[M-Cl]^+$ 501, $[MH-2Cl]^+$ 460.

Palladium(II) (5,5′-*bis*(3,4-*dimethoxyphenylamido*)-2,2′-*bipyridine*) *dichloride* (PdL^2Cl_2). Using ligand L^3, an analogous synthetic procedure was used as in the preparation of $Pt(L^2)Cl_2$, giving a brown solid. Yield 68%. ^{1}H NMR (DMSO): δ 3.77 (6H, s, OCH_3), 3.79 (6H, s, OCH_3), 7.00 (2H, bd, ArCH^5), 7.35 (2H, bd, Hz, ArCH^6), 7.47 (2H, s, ArCH^2), 8.8–8.9 (4H, m, bipyCH^4 and bipyCH^3), 9.62 (2H, s, bipyCH^6), 10.68 (2H, s, NH). Found: C, 44.7; H, 3.4; N, 7.1. Calc. for $C_{28}H_{26}N_4O_6Cl_2Pd$: C, 48.6; H, 3.8; N, 8.1%.

Palladium(II) (5,5′-*bis*(4-*hydroxyphenylamido*)-2,2′-*bipyridine*) *dichloride* (PdL^4Cl_2). Using ligand L^4, an analogous synthetic procedure was used as in the preparation of $Pt(L^2)Cl_2$. Yield 67%. ^{1}H NMR (DMSO): δ 6.78 (4H, d, $J = 8.4$ Hz, PhCH^2), 7.54 (4H, d, $J = 8.4$ Hz, PhCH^3), 8.82 (2H, d, $J = 8.2$ Hz, bipyCH^4), 8.87 (2H, d, $J = 8.1$ Hz, bipyCH^3), 9.41 (2H, s, bipyCH^6), 9.53 (2H, s, OH), 10.57 (2H, s, NH). Found: C, 46.0; H, 3.0; N, 8.7. Calc. for $C_{24}H_{18}N_4O_4Cl_2Pd \cdot H_2O$: C, 46.4; H, 3.2; N, 9.0%.

Crystal structure analysis

Crystal data are given in Table 5, together with refinement details. Data for both crystals were collected with Mo-K_α radiation using the MARresearch Image Plate System. The crystals were positioned at 75 mm from the Image Plate. Ninety-five frames were measured at 2° intervals with a counting time of 2 min. Data analysis was carried out with the XDS program [15]. Both structures were solved using heavy atom methods with the SHELX86 program [16]. In both structures the non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen

atoms were included in geometric positions and were given thermal parameters equivalent to 1.2 times that of the atom to which they were bonded. Both structures were refined using SHELXL [17]. All calculations were carried out on a Silicon Graphics R4000 Workstation at the University of Reading. Unfortunately, in the structure refinement of $Pt(L2)Cl_2$, C(4) and C(5) could not be refined with positive definite thermal parameters, presumably because of some slight disorder, and were given isotropic thermal parameters. Diagrams were prepared using PLATON [18] and PLUTON [19].

(Received 18 June 1996; accepted 4 July 1996)

Abstract—A new complex of copper(II) azide with pyrazinic acid, of general formula KCu_2(pyrazinato)$(N_3)_4$ has been synthesized and characterized by spectroscopic and crystallographic methods. The structure of the complex consists of a new dinuclear complex anion $[Cu_2(N_3)_6]^{2-}$, potassium cations and neutral polymeric complex [Cu(pyrazinato)(N_3)]. Each distorted square-planar copper centre [Cu(1)] in the complex anion is coordinated to four nitrogen atoms from two terminal and two μ-(1,1) bridging azido ligands [Cu—N distances 1.940(6)–2.011(5) Å]. In the polymeric complex, each copper atom, Cu(2), is coordinated to N(41) of a terminal azido group and N(61), N(62) and O(31) from pyrazinato anions to form infinite, "neutral" chains of polyhedra with orientations along [010]. The potassium cations are located in broad channels which are a consequence of stacking of the copper complexes. The IR spectrum confirms the presence of different asymmetric azido ligands. The absorption frequencies of diagnostic values are given and discussed. The electronic spectrum displays three absorption bands associated with N_3^-—Cu^{II} charge transfer transitions. The EPR spectrum of the solid complex suggests an axial structure with non-coupled copper(II) atoms. Copyright © 1996 Elsevier Science Ltd

Keywords: copper(II) azide; pyrazinic acid; complex; spectra; structure.

It has long been accepted [1–4] that picolinic acid, also known as 2-pyridinecarboxylic acid, chelates divalent metal ions to form a five-membered ring through the ligation of the picolinate anion, which serves as a *N,O*-bidentate ligand. The picolinate anion also acts as a *N,O,O'*-tridentate chelating bridging ligand as found in the structure of [Cu(picolinato)$_2$]·2(H_2O) [5]. Recently we established that the picolinate anion can act as a *N,O,O*,-tridentate ligand as in [Mn(picolinato)$(N_3)(H_2O)]_n$ [6], and as a *N,O,O,O'*-tetradentate ligand as found in the structure of $[Cu(picolinato)Cl]_n$ [7] or $[Cd(picolinato)X]_n$ (X = N_3 or NCS) [8]. Both coordinative interactions to transition metal centres and ionic interaction to alkali metals, have been observed in the crystal structures of $[NaCu(picolinato)_2(N_3)(H_2O)_2]_n$ [9] and $[MCu(picolinato)(N_3)_2]_n$ (M = Na or K) [10]. Thus, the picolinato anion is a versatile ligand that can bind metal ions in a variety of bonding modes.

Pyrazine and pyrazine-2-carboxylic acid, also called pyrazinic acid (hereafter abbreviated as H-pyz) combine the coordinating properties of the pyridine-2-carboxylic acid with the fact that the pyrazine moiety may act as a bridge and thus aid the formation of polymeric derivatives [11]. Pyrazinic acid is, therefore, expected to be at least as versatile as the azide ion, a ligand which can bind metal ions in a different matter [12–18]. Combination of these two versatile ligands with copper(II) ion was anticipated to yield interesting

results. The present work constitutes part of our continuing study of metal pseudo-halides containing substituted pyridine ligands [19,20].

EXPERIMENTAL

Pyrazinic acid was obtained from Aldrich and other chemicals were of analytical grade quality.

Preparation of KCu_2(pyrazinato)$(N_3)_4$ *complex*

Copper(II) nitrate trihydrate (0.48 g, *ca* 2 mmol) dissolved in ethanol (10 cm^3) and pyrazinic acid (0.26 g, *ca* 2 mmol) in water/ethanol (30 cm^3) were mixed together. To this mixture an aqueous solution (5 cm^3) of KN_3 (0.34 g, *ca* 4 mmol) was added dropwise until a deep green solution was obtained. If a green precipitate formed after several minutes, the mixture was filtered off. In order to obtain suitable crystals, two drops of the azide solution were added to the green filtrate and the solution was left undisturbed for several weeks. Olive-green crystals of the complex were deposited along with an unidentified blue crystalline material. Found: C, 13.3; H, 0.8; N, 43.2; Cu, 28.0; K, 8.0. Calc. for KCu_2(pyrazinato)$(N_3)_4$: C, 13.1; H, 0.7; N, 42.9; Cu, 27.8; K, 8.6%.

X-ray crystallography

For the X-ray structure determination a prism-shaped single crystal was used (Enraf–Nonius, CAD4, graphite-monochromatized Mo-K_α radiation). Data were collected at 295 K (ω–θ scans, variable scan width and scan time) and processed in the usual way. Crystallographic data and processing parameters are given in Table 1.

The Mo1EN program package was used for structure solution and subsequent refinement [21]. Anisotropic displacement parameters were applied only to the non-hydrogen atoms in full-matrix least-squares refinements. The occupation factors of the three split positions of the disordered potassium atoms were adjusted by taking into account the corresponding electron density maxima obtained from Fourier maps. Selected bond distances and bond angles are given in Table 2. Positional parameters, anisotropic displacement parameters, hydrogen atom coordinates, a full list of bond lengths and angles have been deposited at the Cambridge Crystallographic Data Centre.

Physical measurements

The procedures and instruments used for other measurements were as described previously [22].

RESULTS AND DISCUSSION

The interaction of copper(II) ion and pyrazinic acid in the presence of potassium azide afforded an olive green-complex of empirical formula KCu_2(pyrazinato)$(N_3)_4$, along with an unidentified blue crystalline compound.

The structure of the title complex, **1**, consists of a packing of $[Cu_2(N_3)_6]^{2-}$ anions, potassium cations and a polymeric neutral complex [Cu(pyrazinato)$(N_3)]_n$ (Figs 1 and 2). Each copper centre, Cu(1), in the dinuclear complex anion is coordinated by four nitrogen atoms; two nitrogens from two terminal azido groups at Cu—N distances of 1.940(6) and 1.979(5) Å and two nitrogen atoms from two μ-(1,1) bridging azido ligands [Cu—N = 1.997(6) and 2.011(5) Å]. The coordination environment about each copper atom may be described as distorted square planar. This complex anion is the first to have been isolated and structurally characterized in the case of copper(II) azido complexes. The Cu—Cu separation within the dinuclear complex anion is 3.126(2) Å. The Cu—Cu distances in copper(II) azido complexes fall in the range 3.78 in $CuL'(N_3)_3$ [L = (2-aminoethyl)pyridine] [23] to 3.08 Å in $[Cu(N_3)_2]_n$ [24], which has infinite chains of planar $Cu(N_3)_2$ units. The terminal azido ligands are asymmetric [N(11)—N(12) = 1.216(8), N(12)—N(13) = 1.141(9) and N(21)—N(22) = 1.213(9) and N(22)—N(23) = 1.141(11) Å] with $\Delta d = 0.075$ and 0.072 Å, respectively [Δd is the difference between the two N—N distances within an azide group]. The μ-(1,1) azido ligands, on the other hand, are less asym-

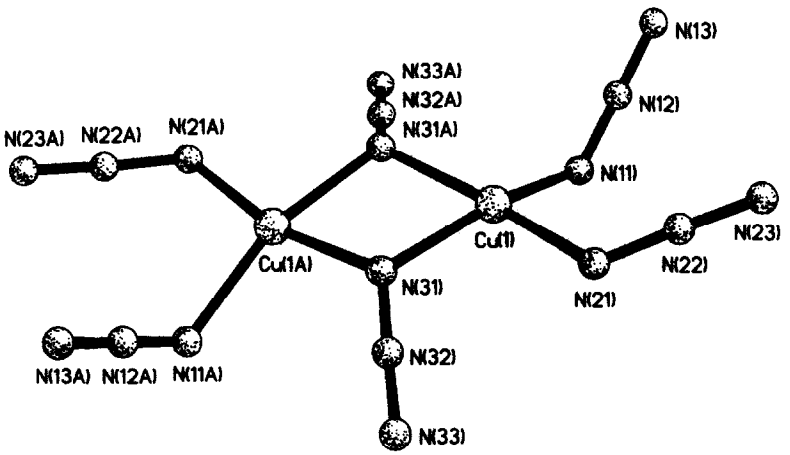

Fig. 1. The molecular geometry and atom-numbering scheme of the binuclear $[Cu_2(N_3)_6]^{2-}$ anion.

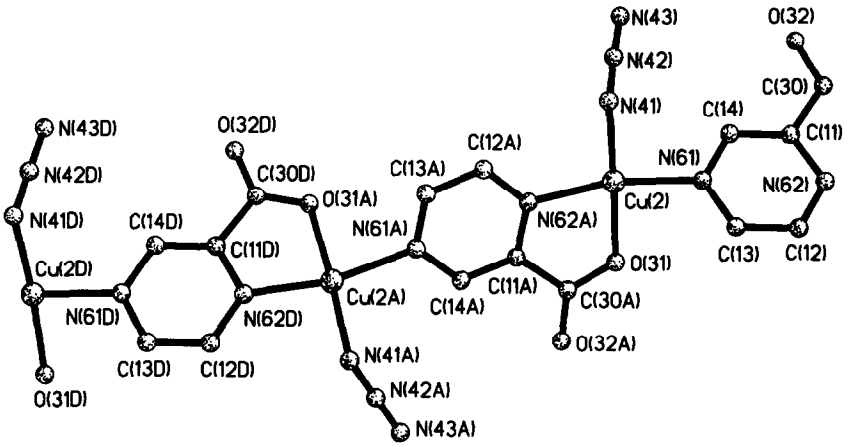

Fig. 2. the molecular geometry and atom-numbering scheme of the polymeric complex [Cu(pyrazinato)(N_3)]$_n$. The chains of polyhedra are oriented along [010].

metric than the terminal azido ligands [N(31)—N(32) = 1.194(8) and N(32)—N(33) = 1.152(10) Å; Δd = 0.042 Å]. In both cases, however, the long N—N distance is that between the central nitrogen atom and the nitrogen atom bonded to the copper atom, as found in the structures of other copper(II) azido complexes [25]. Both types of azido ligand are linear within experimental error (Table 2).

A dinuclear azido complex anion of the type $[M_2(N_3)_6]^{2-}$ has previously been reported only for M = Pd [26]. In the palladium anion, the azido ligands of both types are significantly asymmetric and the M—N—N angles are larger than the corresponding values in the present anion; reported values are: N_α—N_β = 1.239(14), N_β—N_γ = 1.142(17) Å, Δd = 0.097 Å (terminal); N_α—N_β = 1.205(18), N_β—N_γ = 1.139(16) Å, Δd = 0.066 Å; (μ-1,1); Pd—N—N = 127.6(13) and 120.6(14)°.

In the neutral complex, each copper atom [Cu(2)] is also four-coordinated to N(41) of a terminal azido ligand at a Cu—N distance of 1.943(5) Å, N(61) and N(62) of two pyrazinato anions [Cu—N = 2.022(4) and 2.010(4) Å], and an oxygen atom O(31) at Cu—O bond length of 1.954(5) Å. The pyrazinato anion, therefore, acts as an *N,N',O*-tridentate ligand bridging two metal centres [angle N(61)—Cu—N(62a) = 166.3(2)°] *via* both nitrogen atoms to form infinite, "neutral" chains of polyhedra (Figs 2 and 3). The five-membered chelate ring deviates 0.019 Å from planarity. The Cu—N(pyz) distances are comparable with corresponding values found in the structures of [MCu(picolinato)$(N_3)_2$]$_n$ [Cu—N(pic) = 2.012(5) Å for M = Na, 2, and 2.003(3) Å for M = K, **3**] [10], but significantly longer than Cu—N(pic) = 1.961(3) Å found in the structure of [NaCu(picolinato)$_2(N_3)(H_2O)_2]_n$, **4** [9]. The Cu—O(pyz) bond length, on the other hand, is significantly shorter than corresponding values [Cu—O(pic) = 1.997(5) and 1.990(3) Å] in **2** and **3**, respectively, but agrees very well those [1.951(3) and 1.944(3) Å] found in the structure of **4**. The terminal azide group is linear and asymmetric, as found in the above anion.

Both anionic and neutral copper complexes are arranged in sheets of polyhedra with orientation normal to [001] (Fig. 3). The potassium cations are located in broad channels. These channels are a consequence of stacking of the copper polyhedra. The location of the potassium ion is split into three different positions; i.e. K(11), K(12) and K(13) with occupation factors of 0.45, 0.40 and 0.15, respectively. K(11) and K(12) are arranged within 1.5 Å in the same height as the sheets of $[Cu_2(N_3)_6]^{2-}$ whereas K(13) is almost within the height of the chains of Cu(2) polyhedra.

The structure of the present complex differs from that of the polymeric [NaMn(pyrazinato)$(N_3)_2(H_2O)_2]_n$, complex **5**, which also contains two azido groups and a single pyrazinato anion [27]. Complex **5** crystallizes with two aqua ligands and the pyrazinato anion functions only as a chelating *N,O*-bidentate ligand, as compared with the tridentate anion in the present structure. Complex **5** features octahedrally coordinated manganese and sodium atoms, μ-1,1,3 bridging azido ligands, bridging and terminally bonded aqua molecules and heterodinuclear units, Na—$\mu(N_3)\mu(OH_2)$—Mn.

The IR spectrum of free pyrazinic acid exhibits the following absorption bands: (cm^{-1}, v = very, w = weak, m = medium, s = strong, br = broad); 1725vs, br [ν(C=O)], 1316vs [ν(C—O)], 1020s, 825m, 789s, 705m, 410m (pyrazine vibrations) [28]. The spectrum of the complex, on the other hand, shows a substantial shift to lower wavenumber of the ν_{as}(CO_2^-) which appears at 1684 cm^{-1}, and increase of the $\nu_s(CO_2^-)$ to 1384 cm^{-1}. This large separation between the two ν(C—O) indicates a monodentate coordination to the metal atoms as found for many metal complexes of carboxylic acids [29–32]. Vibrations related to the pyrazine moiety are shifted to higher wavenumbers and appear at 1050m, 855m,

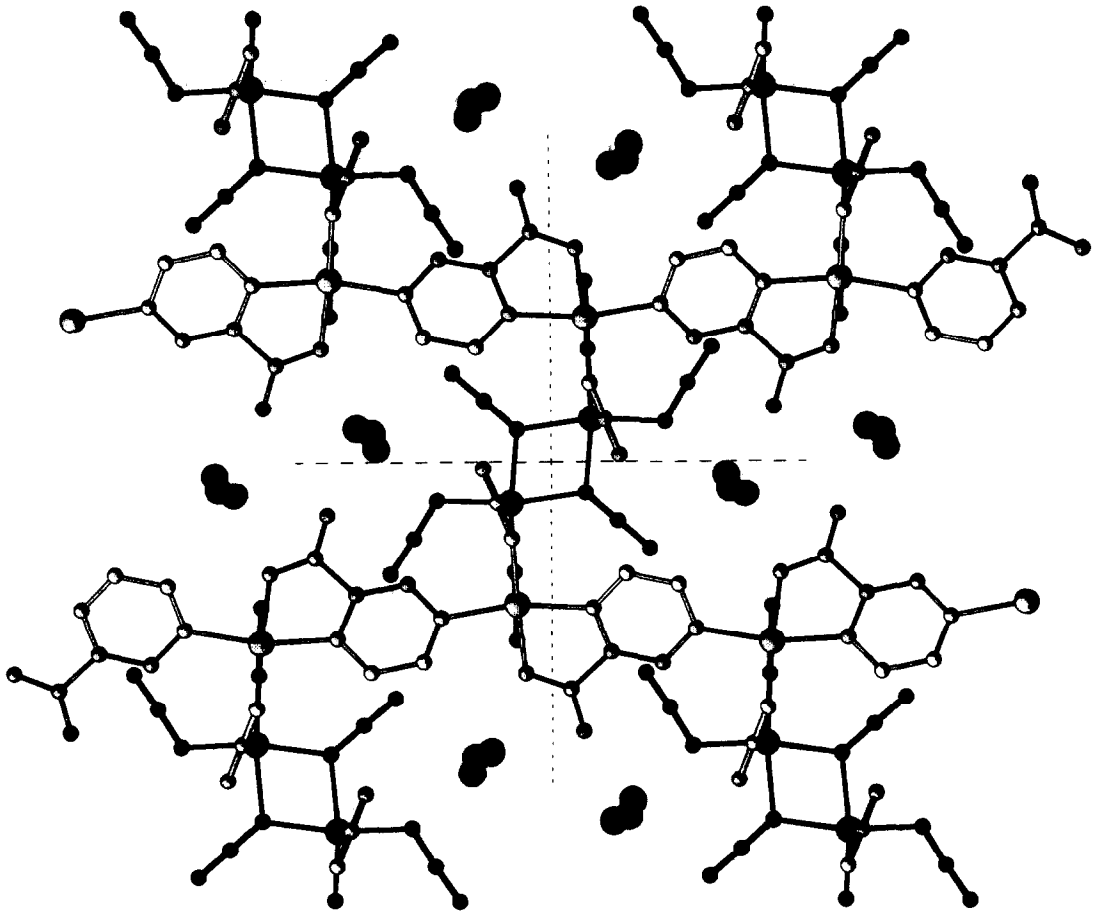

Fig. 3. Packing of KCu_2(pyrazinato)$(N_3)_4$ viewed along the *c*-axis of the unit cell. The binuclear $[Cu_2(N_3)_6]^{2-}$ anions (dark) and linear chains of polymeric $[Cu(pyrazinato)(N_3)]_n$ molecules (light) form alternating sheets normal to [001]. Disordered potassium ions (isolated spheres) are located in broad channels oriented along [001].

815m, 725m and 430w. While these results are indicative of the coordination of the pyrazine moiety it could not be distinguish whether one or both nitrogen atoms are coordinated.

The IR spectrum of the present complex also shows at least three bands of different intensities at 2128vs, 2055s and 2010m, associated with the $\nu_{as}(N_3)$ mode. The crystal structure determination reveals that the complex contains four independent azido groups with different Δd values, and hence four absorption bands are expected owing to the asymmetric stretching vibrations of these azides. In fact, the Δd values for two pairs of these azides are very close; 0.075 and 0.072 Å for N(11)—N(12)—N(13) and N(21)—N(22)—N(23) and 0.042 and 0.050 Å for N(31)—N(32)—N(33) and N(41)—N(42)—N(43). These values suggest the possibility that the corresponding four vibrations may appear as two superimposed bands. However, according to the relationship between Δd and $\nu_{as}(N_3)$ given by Agrell [33], the observed Δd values suggest the higher and lower frequency bands should appear near 2080 and 2040 cm^{-1}, respectively. In contrast, the higher and lower frequency bands appear in the spectrum at 2128 and 2010 cm^{-1}, respectively. It is possible that the coincidence of the vibrations related to the two azides with Δds of 0.075 and 0.072 Å leads to some kind of resonance or configuration interaction, which in turn leads to the appearance of two bands at 2128 and 2055 cm^{-1}, instead of just one band at approx. 2080 cm^{-1}. The same may be true for the other two ν_{as} vibrations leading to two bands at 2055 and 2010 cm^{-1} rather than one at *ca* 2045 cm^{-1}. In the region 1350–1250 cm^{-1}, where the symmetric stretch mode of the azide usually appears, we could not locate any related band owing to the strong absorption of the ligand itself.

The electronic spectrum of the solid complex (Fig. 4) exhibits its *d–d* transition as a very broad band centred around 14,400 cm^{-1} as found for four- and six-coordinated copper(II) complexes [34,35]. The spectrum also exhibits two very strong broad bands centred around 27,500 and 22,440 cm^{-1}. These bands are a result of $N_3^- \rightarrow Cu^{II}$ charge transfer transitions. For terminal copper(II) azide monomers one feature is reported, Π_σ^{nb}-to-copper(II) charge transfer, whereas two bands are observed for μ-1,3 or μ-1,1

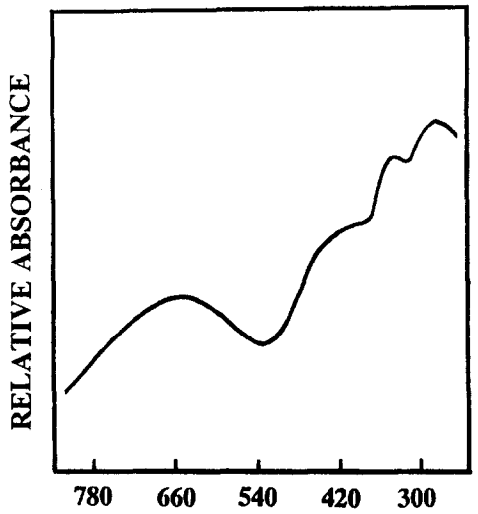

Fig. 4. Reflectance spectrum of solid KCu_2(pyrazinato)$(N_3)_4$.

dimers [36]. The present complex contains both types of azide ligands, hence three CT bands are expected. In fact, the lower energy CT band is so broad that it covers the range 27,000–19,500 cm^{-1}.

The powder EPR spectrum of the title solid complex measured at room temperature is of the axial type, with $g_{\|} = 2.233$ and $g_{\perp} = 2.061$. The G value of 3.82 calculated as the ratio of $(g_{\|}-2)/(g_{\perp}-2)$, is a little lower than 4, suggesting some exchange coupling between bridged copper atoms in this complex. The spectrum, however, displays no absorption in the lower field region.

(Received 17 April 1996; accepted 2 July 1996)

Abstract—The title complexes have been obtained from reaction of ammonium tetrathiotungstate and silver nitrate in the presence of lanthanide nitrate in DMF and CH_3CN. The one-dimensional polymeric cluster anionic structure can be viewed as square-type $[W_4Ag_4S_{16}]^{4-}$ fragments bridged by Ag^+ cations. The valence and dimensions of the lanthanide-coordinated cations play significant roles in the assembly reaction of ammonium tetrathiotungstate and silver nitrate. In addition, the IR and Raman spectra are discussed. Copyright © 1996 Elsevier Science Ltd

Keywords: chalcogenide; clusters; tungsten–silver compounds; polymeric tungsten–silver–sulfur compounds; structure; lanthanide compounds.

Thiometalates and their related multi-metal sulfides have been extensively researched. Many reports have shown the considerable variety of structures of such complexes and their role in the chemistry of life processes [1]. In addition, polymeric transition metal chalcogenides have attracted much attention owing to their useful properties derived directly from their structural peculiarities [2].

In the M/Ag/S system (M = Mo, W), many discrete, and a few polymeric, M—Ag—S cluster complexes have been obtained, such as: $[(PPh_3)_2AgS_2MS_2Ag(PPh_3)\cdot 0.8CH_2Cl_2]$ (linear) [3], $[Et_4N][(PPh_3)_2AgS_3MOCu(CN)]$ (butterfly-type) [4], $[Ag_6S_6M_2(SCMe_3)_2(O)_2(PPh_3)_4]$ (double-cubane-like) [5], $[(PPh_3)_4Ag_4W_2S_8]$ (cage) [6], $[AgWS_4\cdot HNEt_3\cdot DMF]_n$ [7] and $[AgMS_4\cdot 4\text{-}MePyH]_n$ [8] (M = Mo, W). Recently, the assembly reaction system of tetrathiotungstate and silver nitrate has been explored in our laboratory, and the polymeric complex $[WS_4Ag\cdot NH_3C(CH_2OH)_3\cdot H_2O]_n$ (double-chain) [9] with a novel polymeric cluster configuration has been isolated. Herein, the detailed synthesis, characterization and structure of the title complexes $[W_4Ag_5S_{16}\cdot Ln(DMF)_8]_n$ [10], which are also derived from the assembly system of tetrathiotungstate and silver nitrate, are reported.

EXPERIMENTAL

All operations were performed at room temperature in air. $(NH_4)_2WS_4$ was synthesized according to the literature [11]. Other chemicals were used as purchased. Elemental analyses were performed by the Elemental Analysis Laboratories of our institute. IR and Raman spectra were recorded on a Nicolet Magna 750 FT-IR spectrometer and a Nicolet 910 FT-Raman laser spectrometer, respectively.

Preparation of $[W_4Ag_5S_{16}]_n\cdot n[Ln(DMF)_8]$

To a solution of $(NH_4)_2WS_4$ (0.70 g, 2 mmol) in DMF (5 cm^3) was added a solution of $AgNO_3$ (0.68

* Author to whom correspondence should be addressed.

g, 4 mmol), $Ln(NO_3)_3 \cdot 6H_2O$ (1 mmol) and *p*-nitroaniline (0.28 g, 2 mmol) in CH_3CN (15 cm^3). The dark precipitate was filtered off, and 0.30 g of red crystals were obtained from allowing the red filtrate to stand in air for one day.

Found: C, 11.9; H, 2.2; N, 4.7. Calc. for $[W_4Ag_5S_{16}][Nd(DMF)_8]$: C, 11.5; H, 2.2; N, 4.5%. IR (KBr pellet, cm^{-1}): 1647, 677, 496, 472, 461, 455, 442, 426 and 413. Raman (diluted with KBr, cm^{-1}): W—S, 498, 472, 466, 445 and 430; Ag—S, 259 and $\delta(WS_4)$, 191 and 171.

Found: C, 11.3; H, 2.3; N, 4.6. Calc. for $[W_4Ag_5S_{16}][Pr(DMF)_8]$: C, 11.5; H, 2.3; N, 4.5%. IR (KBr pellet, cm^{-1}): 1647, 677, 496, 472, 461, 455, 442, 426 and 413.

Found: C, 11.8; H, 2.2; N, 4.6. Calc. for $[W_4Ag_5S_{16}][La(DMF)_8]$: C, 11.5, H, 2.3; N, 4.5%. IR (KBr pellet, cm^{-1}): 1647, 675, 496, 472, 461, 455, 442, 426 and 413.

Crystal structure determination

Crystals of $[W_4Ag_5S_{16}]_n \cdot n[Nd(DMF)_8]$ were selected and mounted on glass fibres for the single-crystal X-ray diffraction experiment. The crystallographic and experimental data are given in Table 1. Diffraction data were collected on a Rigaku AFC-5R diffractometer using Mo-K_α radiation ($\lambda = 0.71069$ Å) at room temperature. Cell constants and orientation matrices were obtained from least squares by using the setting angles of 20 reflections in the range $12 < 2\theta < 50°$. Intensities were corrected for polarization and Lorentz factors and for absorption by using empirical ψ-scan data and the method of Walker and Stuart (DIFABS) [12].

The structures were solved by direct methods using MULTAN, and the positions of two heavy atoms were obtained from the *E*-map. The remaining non-hydrogen atoms were located from a difference Fourier map. No attempt was made to locate hydrogen atoms. Metal and sulfur atoms were refined anisotropically. The refinement of the structure was performed by full-matrix least-squares techniques using the MolEN program package [13]. All calculations were carried out on a Compaq Prolinea 4/50 computer. Atomic scattering factors were taken from ref. [14].

The cell dimensions for $[W_4Ag_5S_{16}]_n \cdot n[La(DMF)_8]$ were also determined and the values are $a = 16.162(7)$, $b = 16.354(9)$, $c = 12.621(5)$ Å, $\alpha = 94.24(4)$, $\beta = 94.57(4)$, $\gamma = 100.37(4)°$ and $V = 3258(3)$ Å^3.

RESULTS AND DISCUSSION

Synthesis of $[W_4Ag_5S_{16}]_n \cdot n[Ln(DMF)_8]$

Equation (1) shows the reaction of WS_4^{2-} anions and Ag^+ cations in the presence of Ln^{3+} cations.

$$WS_4^{2-} + Ag^+ \xrightarrow{Ln^{3+}} [(W_4Ag_5S_{16})^{3-}]_n. \quad (1)$$

In the syntheses of the title complexes, the trivalent Ln^{3+} cations were added in the reaction solution. These cations are oxygen and nitrogen philic and do not react with WS_4^{2-} moieties. However, through charge- and other interactions they can influence the assembly of WS_4^{2-} and Ag^+, and induce the formation of $[(W_4Ag_5S_{16})^{3-}]_n$ with the trinegative $(W_4Ag_5S_{16})^{3-}$ cluster anion fragments as cyclic units. In addition, Ln^{3+} cations are readily coordinated by oxygen atoms of DMF groups, and form large tripositive ions $[Ln(DMF)_8]^{3+}$. These mononuclear metal-coordinated ions $[Ln(DMF)_8]^{3+}$ occupy the interstices between the polymeric cluster anions $[(W_4Ag_5S_{16})^{3-}]_n$ in the crystalline product.

Description of the structure

Selected bond lengths and angles are listed in Tables 2 and 3, respectively. The structure of a portion of the

a: $(x, y, 1+z)$; b: $(x, y, z-1)$.

anion is shown in Fig. 1. This linear polymeric anion can be viewed as octanuclear cyclic cluster fragments, $[W_4Ag_4S_{16}]^{4-}$, bridged by Ag^+ cations. In the $[W_4Ag_4S_{16}]^{4-}$ fragment, the W atoms are arrayed in an approximate square; and the Ag atoms lie nearly along the edges of the square, between the W atoms. A similar square-type configuration has been shown in the reported cluster complex $[Et_4N]_4[W_4Cu_4S_{12}O_4]$ [15].

In the anion, the tungsten atoms retain their tetrahedral coordination geometry as in isolated WS_4^{2-} ions, but in two slightly different coordination environments; namely, one coordinated by one terminal sulfur atom, two μ_2-S atoms and one μ_3-S atom, and the other by two μ_2-S and two μ_3-S atoms. Compared with that of tungsten atoms, the coordination geometry of the silver atoms with two μ_2-S and two μ_3-S atoms is largely distorted from tetrahedral; the S—Ag—S angles range from 91.2 to 127.7°, similar to those reported in $[AgWS_4 \cdot 4\text{-MePyH}]_n$ (93.5–133.1°) [8] $[WS_4Ag \cdot NH_3C(CH_2OH)_3 \cdot H_2O]_n$ (92.1–126.7°) [9].

With three kinds of sulfur atoms in the anion, namely, terminal sulfur atoms, μ_2-S atoms and μ_3-S atoms, the W—S bond lengths range from 2.123 to 2.268 Å. The mean W—S_t, W—(μ_2-S) and W—(μ_3-S) bond lengths are 2.128, 2.190 and 2.248 Å, respectively. In comparison, the W—S_t bond length is 2.177 Å in isolated WS_4^{2-} ions [1a], and the W—S_t, W—(μ_2-S) and W—(μ_3-S) bond lengths are 2.144(3), 2.217(2) and 2.242(3) Å, respectively, in $[WS_4Ag_3(PPh_3)_3(S_2P(OCH_2CH_3)_2)]$ [16]. The average Ag—S bond length is 2.542 Å, which is comparable with those in other polymeric complexes (see Table 4). The average W—Ag distance of 2.964 Å is shorter than the values observed in $[(PPh_3)_3Ag_2WS_4 \cdot 0.8CH_2Cl_2]$ (2.971 Å) [3], $[WS_4Ag \cdot NH_3C(CH_2OH)_3 \cdot H_2O]_n$ (2.980 Å) [9], $[AgWS_4 \cdot HNEt_3 \cdot DMF]_n$ (2.983 Å) [7] and in $[WS_4Ag_3(PPh_3)_3(S_2P(OCH_2CH_3)_2)]$ (3.080 Å) [16], but longer than those in polymeric linear-chain complexes $[AgWS_4 \cdot 4\text{-MePyH}]_n$ (2.949 Å) [8] and $[WS_4Ag \cdot NH_3C(CH_2OH)_3 \cdot 2DMF]_n$ (2.931 Å) [9]. Comparison of the main bond lengths and angles of some polymeric W—Ag—S complexes is shown in Table 4.

In general, Ln atoms tend to attain high coordination numbers. Figure 2 shows that the Nd atoms is surrounded by eight DMF molecules. The average Nd—O bond length is 2.43 Å and the O—Nd—O coordination angles range from 70.4 to 144.8°.

The packing diagram of the unit cell viewed down the c-axis is shown in Fig. 3. The linear anionic $[(W_4Ag_5S_{16})^{3-}]_n$ cluster chains run parallel to the crys-

IR and Raman spectra

IR spectra of the title complexes are very similar. The strongest absorption band at 1647 cm^{-1} in each IR spectrum can be undoubtedly attributed to the C=O stretching vibration. In principle, W—S characteristic vibration absorption bands appear in the 400–500 cm^{-1} area. The complicated absorption peaks in this area of each spectrum suggest that there are many kinds of sulfur atoms in the complex. This is consistent with the results of the X-ray single-crystal diffraction. The crystal structure determination shows that three kinds of sulfur atoms exist in these complexes (terminal atoms, μ_2-S atoms and μ_3-S atoms).

Only the polymeric complex $[W_4Ag_5S_{16}]_n \cdot n[Nd(DMF)_8]$ was characterized by Raman spectroscopy. Compared with the IR spectrum, the Raman spectrum is simpler. The strongest absorption band at 1647 cm^{-1} in the IR spectrum disappears in the Raman spectrum because of prohib-

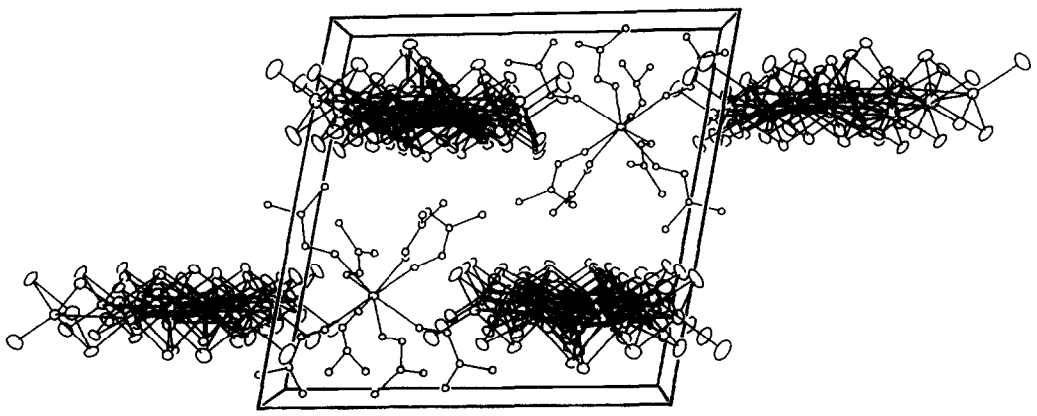

Fig. 3. Packing diagram of the unit cell viewed down the *c*-axis.

ition of the transition. In the 400–500 cm^{-1} area, the Raman spectrum also displays complicated bands of W—S vibration similar to those in the IR spectrum. The bands at 259 and 191 (and 171 cm^{-1}) can be assigned to ν_s(Ag—S) and $\delta(WS_4)$, respectively [17].

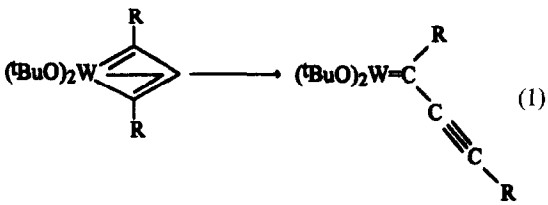
Further studies of the reactions involving ethyne and $M_2(OBu^t)_6$, where M = Mo and W. Polyacetylene formation versus formation of ethyne adducts and C—C coupled products



Malcolm H. Chisholm,* David M. Hoffman, Jill McCandless Northius and John C. Huffman

Department of Chemistry and Molecular Structure Center, Indiana University, Bloomington, IN 47405, U.S.A.

(Received 6 June 1996; accepted 1 July 1996)

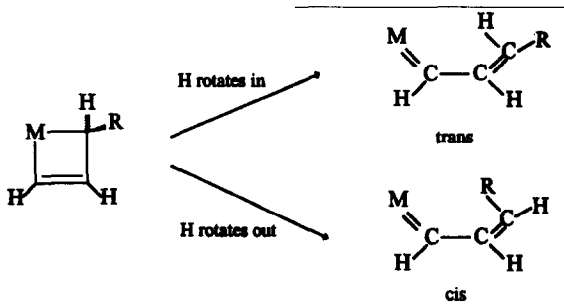
Abstract—$M_2(OBu^t)_6$ compounds in hydrocarbon solvents react with ethyne to give a mixture of *cis*- and *trans*-polyacetylene and ethyne- and μ-C_4H_4 adducts of $M_2(OBu^t)_6$ by competing pathways. The degree of ethyne polymerization is shown to *decrease* with increasing concentration of $M_2(OBu^t)_6$, to increase with increasing volumes of solvent for constant concentration and to be greater for M = Mo than for M = W. The kinetically labile complex $Mo_2(OBu^t)_6(\mu\text{-}C_2H_2)$, originally reported by Strutz and Schrock [*Organometallics* 1984, **4**, 1600], has been trapped by the addition of pyridine and 4-methylpyridine at −20°C and the structure of the latter compound determined by a single crystal X-ray study. There is a pseudo-tetrahedral Mo_2C_2 core, Mo—Mo = 2.645(1) Å, C—C = 1.39(1) Å and Mo—C = 2.092(7) Å (ave.), supported by a single OR bridge. Each metal atom has a pseudo-trigonal bipyramidal geometry. In the presence of an excess of ethyne, $Mo_2(OBu^t)_6$ yields a mixture of compounds, two of which are proposed to be isomers of formula $Mo_2(OBu^t)_6(\mu\text{-}C_4H_4)$. Addition of CO to a hydrocarbon solution of the latter gives $Mo_2(OBu^t)_6(\mu\text{-}C_4H_4)(CO)$ which is shown to be structurally related to its tungsten analogue by a single crystal X-ray determination. [ν(CO) = 1908 (M = Mo) and 1883 cm^{-1} (M = W).] The isolated compounds show no activity towards ethyne polymerization which is proposed to occur by way of a carbene/alkylidene mechanism. Consistent with this proposal is the finding that $Mo_2(OBu^t)_6$, which is unreactive towards norbornene, can be activated towards norbornene polymerization by the addition of ethyne (5 equiv.). Copyright © 1996 Elsevier Science Ltd

The polymerization of acetylenes by metal carbene complexes was first proposed and demonstrated by Katz and Lee [1]. Subsequently Schrock and co-workers [2] reported alkyne polymerization in alkyne metathesis systems and studied this process by well-defined alkylidene complexes. Alkynes are known to react with $W_2(OBu^t)_6$ to give $(Bu^tO)_3W{\equiv}CR$ complexes, which are alkyne metathesis catalysts [3], and, in related reactions involving $W_2(OR)_6$ compounds, alkyne polymerization has been observed [4]. Terminal acetylenes are also known to react to give deprotiometallacycles [5] and in the reaction between $W_2(OBu^t)_6$ and $Bu^tC{\equiv}CH$, the deprotiometallacyclic complex $W(OBu^t)_2(C_3Bu^t_2)$ was found to initiate the fast polymerization of alkynes [6]. In the latter reaction ring opening according to Eq. (1) may account for generation of the alkylidene ligand responsible for the initiation of alkyne polymerization.

(1)

$Mo_2(OBu^t)_6$ has been shown to react with alkynes to give alkylidynes in only a few instances [7] whereas $Mo_2(OR)_6$ compounds, where R = Pr^i and CH_2Bu^t, have been shown to effect cyclotrimerization to benzene [8]. Knox *et al.* [9] have also documented oligomerization of alkynes at a dinuclear centre [9] but

* Author to whom correspondence should be addressed.



to our knowledge no example of catalytic polymerization by a dinuclear centre has been documented. We return here to a study of the reactions between $M_2(OBu^t)_6$ compounds and ethyne, which are known to give polyacetylene and the kinetically labile complexes $Mo_2(OBu^t)_6(\mu\text{-}C_2H_2)$ [7] and $W_2(OBu^t)_6(\mu\text{-}C_2H_2)$, the latter having been trapped as a pyridine adduct and shown to exist in equilibrium with a methylidyne complex, as given by Eq. (2) [10]. In the presence of excess ethyne

$$W_2(OBu^t)_6(\mu\text{-}C_2H_2)(py) \rightleftharpoons 2[(Bu^tO)_3W{\equiv}CH]^+py \quad (2)$$

$W_2(OBu^t)_6(\mu\text{-}C_4H_4)$ was also detected and spectroscopically characterized [11]. We address the question of what role, if any, do dinuclear species derived from ethyne play in the polymerization of ethyne, and we characterize the previously elusive $\mu\text{-}C_2H_2$ and $\mu\text{-}C_4H_4$ adducts of $Mo_2(OBu^t)_6$ by trapping with pyridine and carbon monoxide, respectively.

RESULTS AND DISCUSSION

Black, shiny metallic looking polyacetylene formed upon exposure of C_2H_2 to hydrocarbon solutions of $M_2(OBu^t)_6$ compounds (M = Mo and W). These films were collected by filtration and dried *in vacuo*. In all instances we observed IR bands at 802 and 1013 cm^{-1} indicative of a mixture of *cis*- and *trans*-polyacetylene [12]. Polymerization of ethyne by a metal–carbene/alkylidene intermediate would be expected to proceed through a metallacyclobutene [13] which could open to give both *cis* and *trans* stereochemistry about the C—C double bond as shown in Eq. 3.

(3)

However, the observed stereochemistry does not rule out alternative mechanisms of polymerization such as Ziegler–Natta polymerization by way of a *cis*-migratory insertion involving a metal–vinyl (alkenyl), because the activation energy for *cis* to *trans* isomerization could be provided by the preparation of a Nujol mull or KBr pellet owing to local heating effects. [The *cis*-to-*trans* isomerization has a relatively low activation barrier, *ca* 17 kcal mol^{-1}] [14].

In an attempt to distinguish between a possible carbene/alkylidene mechanism and Ziegler–Natta type polymerization we investigated the reaction between $Mo_2(OBu^t)_6$ and norbornene. No reaction occurred between this strained olefin and $Mo_2(OBu^t)_6$ in hydrocarbon solvents at room temperature. However, addition of norbornene to hydrocarbon solutions of $Mo_2(OBu^t)_6$ followed by 5 equiv. of ethyne produced a rapid polymerization of norbornene. It is well known that metal–carbene/alkylidene complexes can affect the ring opening polymerization methathesis (ROMP) of norbornene [15] and, in our case, work-up of the polymer derived in the above reaction revealed the same ^1H and $^{13}C\{^1H\}$ NMR data as that reported by the polymer when formed from an authentic alkylidene catalyst precursor [16].

An estimation of the catalytic activity of the system with respect to ethyne polymerization was undertaken as follows.

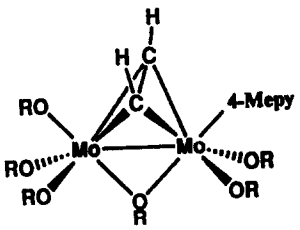
(a) Polymerization of ethyne by $Mo_2(OBu^t)_6$ was first conducted in hexane as solvent with varying concentrations of catalysts and solution volumes: 1.59×10^{-4} M (40 mg/5 cm^3); 1.59×10^{-3} M (40 mg/50 cm^3) and 0.79×10^{-3} M (40 mg/100 cm^3), yielding consumption of 50, 71 and 117 monomer equivalents, respectively. From this result it is apparent that the system is not very catalytically active. Because PA (PA = polyacetylene) is virtually insoluble in hexane it is reasonable to speculate that the catalyst died as the metal catalyst was incorporated with the PA. Thus, in this interpretation, the increase in volume of the solution allowed for a greater degree of polymerization before all the molybdenum-containing catalyst was precipitated from solution.

(b) The catalyst concentration was changed by keeping the solvent volume constant (along with all other factors) and changing the amount of solute. For $Mo_2(OBu^t)_6$ concentrations of 1.27×10^{-5}, 2.43×10^{-3} and 4.44×10^{-3} M in 15 cm^3 of hexane the monomer equivalents of ethyne consumed were 157, 91 and 39, respectively.

From (a) and (b) we conclude that active catalyst is *not* $Mo_2(OBu^t)_6$, but rather some species derived from its decomposition.

Similar experiments were carried out in toluene as solvent and similar results were obtained, although the monomer equivalents of ethyne consumed were

somewhat larger (by *ca* 40%), presumably because PA is slightly more soluble in toluene than hexane.



Polymerization of propyne was also carried out in hexane employing $Mo_2(OBu^t)_6$ as catalyst precursor; in this case, 5.29×10^{-3} M (50 mg/15 cm^3), 2.66×10^{-3} M (50 mg/30 cm^3) and 1.98×10^{-3} M (50 mg/40 cm^3) solutions consumed, respectively, 68, 167 and 300 equivalents of propyne.

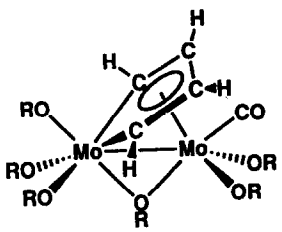
The catalytic activity of $Mo_2(OBu^t)_6$ and $W_2(OBu^t)_6$ were also compared under otherwise identical conditions and $Mo_2(OBu^t)_6$ solutions were found to be more active by a factor of two. This is an interesting observation since ethyne and $W_2(OBu^t)_6$ are known to produce the methylidyne species $(Bu^tO)_3W{\equiv}CH$ and alkylidynes are readily converted to alkylidenes with relatively mild protio sources such as those present on silica surfaces [17]. In addition, Freudenberger and Schrock [18] have shown that $(Bu^tO)_3W{\equiv}CBu^t$ reacts with various Brønstead acids, HX, to give $X_2(Bu^tO)_2W{=}CH(Bu^t)$ compounds, where X = PhO, Cl and RCOO.

Detection and characterization of organometallic compounds formed upon the addition of ethyne to hydrocarbon solutions of $Mo_2(OBu^t)_6$

Addition of $^{13}C_2H_2$ to $Mo_2(OBu^t)_6$ in toluene-d_8 was studied by ^{13}C and ^1H NMR spectroscopy. At -80 to -60°C only free $^{13}C_2H_2$ and $Mo_2(OBu^t)_6$ were detected by NMR spectroscopy, but the formation of PA was seen as a fine black film on the walls of the NMR tube at these temperatures. At -40 to -20°C, $Mo_2(OBu^t)_6(\mu\text{-}^{13}C_2H_2)$ was observed [$\delta(^{13}C)$ 127.2] in addition to free acetylene and $Mo_2(OBu^t)_6$. As the temperature was raised two other sets of ^{13}C signals were observed which are assignable to the metallacyclic species $Mo_2(OBu^t)_6(\mu\text{-}C_4H_4)$ (see later). The fact that the latter did not form until 0°C and that the ethyne adduct formed between -40 and -20°C led us to believe that the ethyne adduct could be independently synthesized and indeed this was achieved.

The addition of an excess of ethyne to a hydrocarbon solution of $Mo_2(OBu^t)_6$ in the presence of pyridine leads to the formation of $Mo_2(OBu^t)_6(py)(\mu\text{-}C_2H_2)$, which is isolated as a dark green crystalline solid. This compound is spectroscopically analogous to the tungsten congener, giving rise to four OBu^t signals in the low-temperature ^1H NMR spectrum in the integral ratio 1 : 1 : 2 : 2. The compound is thermally unstable in solution above 0°C, where $Mo_2(OBu^t)_6$ is formed along with free pyridine and some PA. Solutions containing $[Mo_2(OBu^t)_6(py)(\mu\text{-}^{13}C_2H_2)]$ and $[Mo_2(OBu^t)_6(py)(\mu\text{-}C_2D_2)]$ provided no evidence for the formation of a $Mo_2(\mu\text{-}H^{13}CCD)$-containing species [10]. Thus, in contrast to the tungsten analogue, there is no evidence that $Mo_2(OBu^t)_6(\mu\text{-}C_2H_2)$ is in equilibrium with the methylidyne complex $(Bu^tO)_3Mo{\equiv}CH$. From reactions between $Mo_2(OBu^t)_6$ and ethyne in the presence of 4-methylpyridine (4-Mepy) a green crystalline compound $[Mo_2(OBu^t)_6(4\text{-Mepy})(\mu\text{-}C_2H_2)]$ was isolated. The 4-Mepy adduct has been characterized crystallography (see later); the structure is shown schematically in **I**. It is akin to the previously reported tungsten compound $W_2(OBu^t)_6(py)(\mu\text{-}C_2H_2)$ [10].

I



The addition of ethyne-$^{13}C_2H_2$ (in excess) to a toluene-d_8 solution of $Mo_2(OBu^t)_6$ at room temperature leads to a mixture of products, including PA as a dark precipitate, $Mo_2(OBu^t)_6(\mu\text{-}C_2H_2)$[$\delta(^{13}C)$ 127.2, $^1J_{C-H}$=190 Hz] and ^1H-coupled ^{13}C resonances at δ 209.8 and 115.3 and at δ 179.8 and 124.6. Each of the signals is a multiplet that is one-half of an AA′XX′ spin system.

It should be emphasized that there are resonances owing to two AA′XX′ spin systems corresponding to a, roughly, 60 : 40 product mixture. It seems likely that one is akin to that of the μ-C_4H_4 groups previously seen in $[Mo_2(OCH_2Bu^t)_6(\mu\text{-}C_4H_4)(py)]$ and $[W_2(OPr^i)_6(\mu\text{-}C_4H_4)(\eta^2\text{-}C_2H_2)]$ and proposed for $W_2(OBu^t)_6(\mu\text{-}C_4H_4)$ [11]. The nature of the other μ-C_4H_4 group remains a mystery. It could be only σ bonded to one metal, or it could bridge the two metal atoms in a symmetrical perpendicular manner akin to that reported by Green and Mountford [19] for $Cp'_2W_2Cl_4(C_4Me_4)$.

Upon addition of carbon monoxide to the $Mo_2(OBu^t)_4(C_4H_4)$ compounds a red-orange solution of $Mo_2(OBu^t)_6(\mu\text{-}C_4H_4)(CO)]$ is formed. This compound is also accessible (and best prepared) from the reaction between $Mo_2(OBu^t)_6(\mu\text{-}C_2H_2)(py)]$ and an excess of ethyne followed by addition of carbon monoxide. Similarly addition of carbon monoxide to $W_2(O^tBu)_6(\mu\text{-}C_4H_4)$ formed *in situ* from the reaction between $Mo_2(OBu^t)_6(\mu\text{-}C_2H_2)(py)$ and an excess of ethyne, followed by addition of carbon monoxide. Similarly, addition of carbon monoxide to $W_2(OBu^t)_6(\mu\text{-}C_4H_4)$ formed *in situ* from the reaction between $W_2(OBu^t)_6$ and an excess of ethyne in hydrocarbon solutions, yielded $W_2(OBu^t)_6(\mu\text{-}C_4H_4)(CO)$. The compounds adopt a common structure, depicted by **II** and described in more detail below. The value of ν(CO) is 1908 for M = Mo and 1883 cm^{-1} for M = W, indicating greater M d_π to CO π^* back-bonding for the 3rd row element, W compared with the 2nd row Mo.

Solid-state and molecular structure of [$Mo_2(OBu^t)_6$(4-Mepy)(μ-C_2H_2)]

A summary of the crystal data is given in Table 1. Selected bond distances and bond angles are given in Tables 2 and 3, respectively. An ORTEP drawing of the molecule is shown in Fig. 1, along with the central $Mo_2O_6C_2N$ core giving the atom-numbering scheme used in the tables. If the μ-C_2 moiety is considered to occupy a single coordination site then the geometry may be described as a fusing of two trigonal bipyramids along a common equatorial (μ-C_2) and axial (μ-OR) edge. The Mo—Mo distance of 2.645(1) Å is consistent with a M—M single bond and the C—C distance of 1.39(1) Å is longer than that in ethylene,

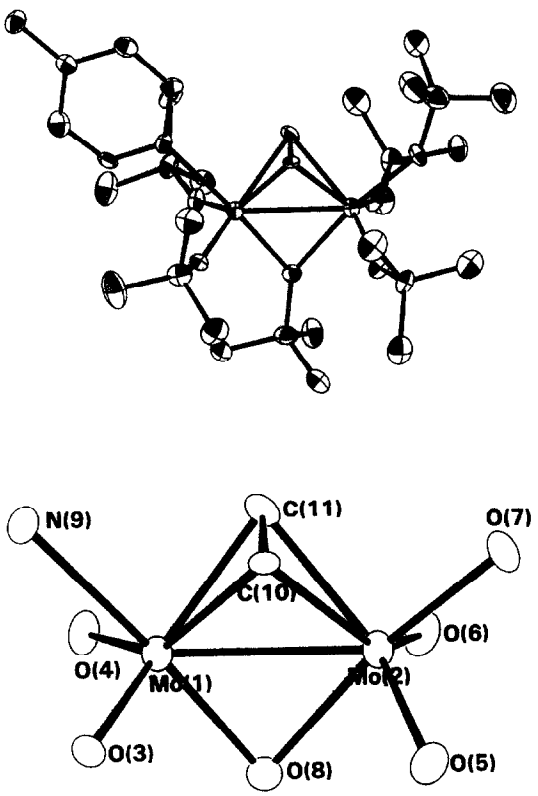

Fig. 1. An ORTEP drawing of the $Mo_2(OBu^t)_6$(4-Mepy)(μ-C_2H_2) molecule and the numbering scheme of its $Mo_2O_6NC_2$ core.

1.34 Å, and acetylene, 1.21 Å, collectively indicating that the central moiety can be viewed as a dimetallatetrahedrane [10]. The metric parameters differ little from those for the tungsten analogue: W—W = 2.665(1), W—C = 2.11(2) (ave) and C—C = 1.441(14) Å [10].

$M_2(OBu^t)_6(\mu\text{-}C_4H_4)(CO)$. A summary of the crystal data is given in Table 1 for the two compounds (M=Mo and W) and a comparison of bond distances and bond angles is given in Tables 4 and 5. An ORTEP drawing of the molybdenum compound is given in Fig. 2, together with a ball-and-stick diagram showing the central $Mo_2(O)_6C_4(CO)$ core.

The two molecules are remarkably similar. In each, one metal atom has a pseudo-octahedral geometry, forming four bonds to oxygen and two to carbon. The M—O(7) distances are asymmetric, with M(1)—O(7) being notably shorter. In a formal sense M(1) could be viewed as M(6+) and M(2) as a d^4 M(2+) centre being bonded datively to μ-OR, two terminal alkoxides, a terminal carbonyl and a butadiene ligand

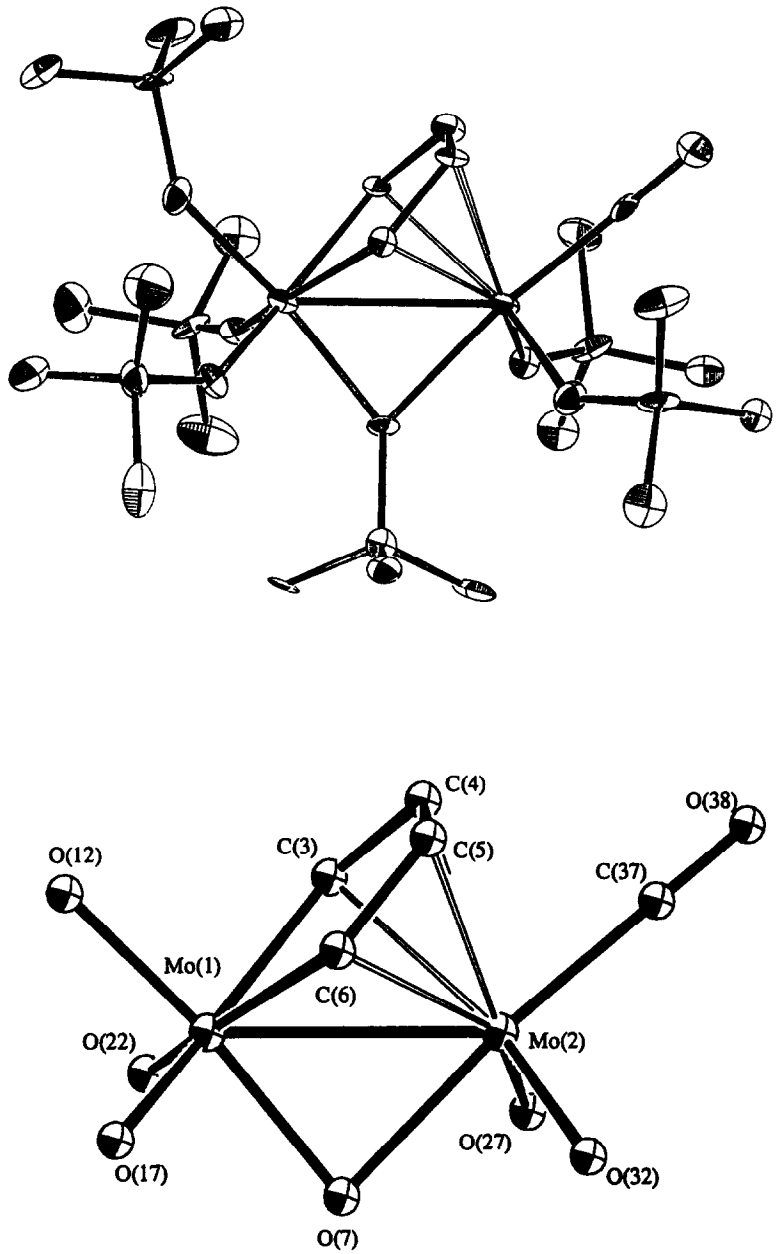

Fig. 2. An ORTEP drawing of the $Mo_2(OBu^t)_6(\mu\text{-}C_4H_4)(CO)$ molecule giving the atom-numbering scheme used for the central skeleton.

[C(3)—C(4)—C(5)—C(6)]. Since M(1) is contained in the C(3)—C(4)—C(5)—C(6) plane, one can also view the bridge as a metallacyclopentadiene. The structure is closely related to that of $Mo_2(OCH_2Bu^t)_6(py)(\mu\text{-}C_4H_4)$ [20], but with a CO ligand in place of pyridine.

Investigation of the role of $Mo_2(OBu^t)_6(\mu\text{-}C_2H_2)$ *and* $Mo_2(OBu^t)_6(\mu\text{-}C_4H_4)$ *in ethyne polymerization*

$Mo_2(OBu^t)_6(\mu\text{-}C_2H_2)$ and $Mo_2(OBu^t)_6(\mu\text{-}C_4H_4)$ are not thermally stable at room temperature. The dimolybdenum ethyne complex liberated ethyne, which was polymerized to PA, and reformed $Mo_2(OBu^t)_6$. At low temperatures, below $-20°C$, polymerization of added ethyne proceeded without the detectable involvement of the complexes. At these low temperatures, when labelled ethyne was added no labels were incorporated into the Mo_2-containing complexes. Previously, we showed that $Mo_2(OPr^i)_6(py)_2(\mu\text{-}C_2H_2)$ and $Mo_2(OCH_2Bu^t)_6(py)(\mu\text{-}C_4H_4)$ were not involved in alkyne polymerization but only in alkyne cyclotrimerization to given benzene [8]. In the present case we find no evidence for the formation of benzene and no evidence for participation in ethyne polymerization.

CONCLUSIONS

Careful synthetic studies have allowed us to prepare and characterize the previously elusive $Mo_2(\mu\text{-}C_2H_2)$- and $Mo_2(\mu\text{-}C_4H_4)$-containing compounds supported by six tert-butoxide ligands. Although ethyne is polymerized by solutions containing $Mo_2(OBu^t)_6$, the aforementioned compounds are not involved in the catalytic cycle. It seems likely that only a small impurity in solutions of $Mo_2(OBu^t)_6$ is responsible for ethyne polymerization and that this process may well involve the metal–carbene polymerization mechanism. The evidence in favour of a metal-mediated carbene mechanism is based on the observation that, whereas hydrocarbon solutions of $Mo_2(OBu^t)_6$ and norbornene do not react, the addition of ethyne produces a catalytically active system for polymerization of norbornene, and the NMR spectra for the polymer are identical to those for polymer produced by a well-defined metal–carbene catalyst precursor [16].

EXPERIMENTAL

All reactions were carried out under dry, oxygen-free N_2 employing standard Schlenk and glove-box techniques. Solvents were dried and freed from oxygen by distillation under N_2 over either sodium benzophenone ketal (hexane, toluene, benzene) or from CaH_2 (CH_2Cl_2). Freshly distilled solvents were stored under nitrogen over 3 Å molecular sieves. Reagent grade methanol was stored over molecular sieves and degassed to remove oxygen. The preparations of $Mo_2(OBu^t)_6$ [20] and $W_2(OBu^t)_6$ [21] have been described previously. Ethyne was purified by passing the gas through a cold trap at −78°C.

^1H, $^{13}C\{^1H\}$, proton-coupled ^{13}C and variable temperature NMR spectra were obtained on a Varian XL300 spectrometer. The ^1H spectra are referenced to protio impurities in commercial benzene-d_6, toluene-d_8 and dichloromethane-d_2. Infrared spectra were recorded as KBr pellets. Elemental analyses were performed by Oneida Research Services, Inc.

Preparation of $Mo_2(OBu^t)_6(py)(\mu\text{-}C_2H_2)$

$Mo_2(OBu^t)_6$ (1.365 g, 2.174 mmol) was taken up in hexane/pyridine (50 cm^3/5 cm^3). The resulting orange solution was then cooled to −196°C by immersion in a liquid nitrogen bath. With the use of a calibrated gas manifold, acetylene was added (2.826 mmol, 2.3 equiv.). The mixture was warmed to −20°C. The solution colour changed from yellow to dark green after stirring for 4 h at −20°C. The resulting green solution was concentrated to approximately one-half its original volume. The concentrated solution, when placed in the freezer overnight, yielded a dark green crystalline solid. The solution was removed *via* cannula and the resulting solid dried *in vacuo* (890 mg, 1.196 mmol) (55% yield). Elemental analyses were not obtained owing to the thermal instability of the compound. ^1H NMR (C_6D_6, 25°C), δ 8.56 (br m, 2H, py), 6.94 (br m, 1H, py), 6.65 (br m, 2H, py), 6.00 (s, 2H, C_2H_2), 1.46 (s, 54H, $OC(CH_3)_3$). ^1H NMR ($C_6D_5CD_3$, −60°C): δ 8.85 (br, py), 8.58 (br, py), 8.28 (br, py), 6.54 (br, py), 6.30 (br, 2H, C_2H_2), 6.18 (br, py), 2.18 (s, 9H, $OC(CH_3)_3$), 1.89 (s, 9H, $OC(CH_3)_3$), 1.71 (s, 18H, $OC(CH_3)_3$), 1.14 (s, 18H, $OC(CH_3)_3$). ^{13}C NMR (C_6D_6, 25°C): δ 127.2 (s, J_{C-H} = 190 Hz, C_2H_2), 82.0 (s, $OC(CH_3)_3$), 32.3 (q, J_{CH} = 130 Hz, $OC(CH_3)_3$).

Synthesis of $Mo_2(OBu^t)_6(\mu\text{-}C_4H_4)(CO)$

$Mo_2(OBu^t)_6(\mu\text{-}C_2H_2)(py)$, synthesized as above (151 mg, 0.205 mmol) was dissolved in hexane (30 cm^3). The resulting brown solution was frozen with the use of liquid nitrogen, and the flask evacuated. By using standard gas line techniques the flask was exposed to acetylene (0.247 mmol, 1.2 equiv.). Warming of this solution to room temperature for 1 h gave no noticeable colour change. The solution was again frozen in liquid nitrogen and the flask evacuated. Carbon monoxide (0.342 mmol, 1.7 equiv.) was added to the system with the use of a calibrated gas syringe. Again, the solution was warmed to room temperature. While warming, the solution changed from an emerald green to an orange-red colour. The colour change took place approximately 15 min after the solution was at, or near, room temperature. A noticeable precipitate (polyacetylene by analysis), also formed. To remove the polyacetylene, the solution was filtered with a medium filter frit giving a clear orange-red solution. Reducing the volume of the solution by one-half afforded red crystals after several days at −20°C. ^1H NMR (C_6D_6, 25°C): δ 7.53 (m, 2H, C_4H_4), 5.85 (m, 2H, C_4H_4), 1.99 (s, 9H, $OC(CH_3)_3$), 1.53 (s, 18H, $OC(CH_3)_3$), 1.44 (s, 9H, $OC(CH_3)_3$), 1.27 (s, 18H, $OC(CH_3)_3$). ^{13}C NMR (C_6D_6, 25°C): δ 243.2 (s, CO), 182.8 (s, C_α-sigma bound), 106.9 (s, C_β-π bound). IR (KBr, cm^{-1}): 2971m, 1908m (CO), 135m, 1171s, 949s.

Preparation of $W_2(OBu^t)_6(\mu\text{-}C_4H_4)(CO)$

This was prepared by the addition of an excess of acetylene to a hydrocarbon solution of $W_2(OBu^t)_6$, followed by the addition of CO. Crystals for the X-ray study were obtained by crystallization from a concentrated solution of hexane after removing PA by filtering through a fine frit.

Single-crystal X-ray studies

The general operating procedures used have been described previously [22].

Preparation and structure of $Mo_2(OBu^t)_6(4\text{-Mepy})(\mu\text{-}C_2H_2)$

The sample was prepared in an analogous manner to that described for $Mo_2(OBu^t)_6(py)(\mu\text{-}C_2H_2)$ but

employing 4-methylpyridine in place of pyridine. The crystals were grown slowly at −20°C from a 4:1 hexane/4-methylpyridine mixture. A brown crystal of dimensions $0.20 \times 0.30 \times 0.30$ mm^3 was mounted in a nitrogen-filled glove-bag by using silicone grease and was transferred to a goniostat. The sample was cooled to −175°C for characterization and data collection.

The structure was solved by the usual combination of direct methods (MULTAN78) and Fourier techniques. The Mo atom positions were obtained from an initial *E*-map and the remainder of the non-hydrogen atoms were found in subsequent iterations of least-squares refinement and difference Fourier calculations. After partial refinement of the non-hydrogen atoms, a difference Fourier revealed many, but not all, hydrogen atoms. All hydrogen atom positions were therefore calculated by using idealized geometries [d(C—H) = 0.95 Å].

Structure of $Mo_2(OBu^t)_6(\mu\text{-}C_4H_4)(CO)$

A suitable sample was transferred to the goniostat and cooled to −170°C for data collection.

The structure was solved by the usual combination of direct methods (MULTAN78) and Fourier techniques. The positions of the Mo atoms were determined from an E-map. The remaining non-hydrogen atoms were obtained from subsequent iterations of least-squares refinement and difference Fourier calculations. In the final cycles of refinement, four atoms with poorly behaved anisotropic thermal parameters were refined isotropically and all other non-hydrogen atoms were refined with anisotropic thermal parameters.

Structure of $W_2(OBu^t)_6(\mu\text{-}C_4H_4)(CO)$

A large, well-formed crystal was cleaved to obtain a nearly equidimensional cube and transferred to the goniostat using standard inert atmosphere handling techniques. The crystal was then cooled to −160°C for characterization and data collection.

Owing to a rather long b axis (*ca* 42 Å!), a short scan width was required. Experimentation revealed that a scan width of 0.8° resolved the peaks with little difficulty; fortunately, the crystal diffracted nearly perfectly, allowing the narrow scan width.

The two tungsten atoms were located by direct methods (MULTAN78) and all other non-hydrogen atoms were present in a difference Fourier phased on the two metal atoms. Hydrogen atoms were clearly visible in a difference Fourier phased on the refined non-hydrogen atoms, and were included in the final cycles of refinement (anisotropic thermal parameters for W, O and C; isotropic for H). A final difference Fourier map was featureless, with the largest peaks (1.2 and 1.1 e Å^3) lying adjacent to the two tungsten atoms. Ψ scans of several reflections were flat, so no absorption correction was deemed necessary.

Representative polymerization reactions

$Mo_2(OBu^t)_6$+HCCH. By using standard gas line techniques a hexane solution (40 cm^3) of $Mo_2(OBu^t)_6$ (50 mg, 0.79 mmol) at room temperature was exposed to 1 atm. of ethyne. The initial pale orange solution darkened and a dark precipitate formed. After 10–15 min the uptake of acetylene ceased (4.02 mmol, 50.3 equiv.). The solution was stirred for an additional hour before filtering through a medium porosity frit. The resulting precipitate was insoluble in all common solvents. The filtrate, analysed by NMR spectroscopy, appeared to contain three products.

Precipitate-polyacetylene: IR (KBr, cm^{-1}): 3030w, 2980s, 1645m, 1401m, 1262m, 1102m, 1013s (*trans*), 803m (*cis*).

Filtrate (when $^{13}C_2H_2$ was used): ^{1}H NMR (C_6H_6, 25°C): δ 6.32 (m), 5.64 (m), 4.21 (br, s), 3.18 (s), 2.67 (br, s), 1.88 (s), 1.73 (s), 1.57 (s), 1.52 (s), 1.47 (s), 1.40 (s), 1.04 (s). $^{13}C\{^1H\}$ NMR (C_6D_6, 25°C): δ 209.8 (m, AA′XX′), 179.3 (m, AA′XX′), 127.2 (s), 124.6 (m, AA′XX′), 115.2 (m, AA′XX′).

$Mo_2(OBu^t)_6$+CH_3CCH. Either hexane or toluene solutions (40 cm^3) of $Mo_2(OBu^t)_6$ (50 mg, 0.080 mmol) were exposed to 1 atm. propyne (CH_3CCH) by using a calibrated gas line. The orange solution darkened and after 10–15 min a dark precipitate formed. Continual exposure (90 minutes total) to approximately 1 atm. propyne resulted in a total propyne uptake of 24.2 mmol, 303 equiv. of hexane and 28.1 mmol, 351.3 equiv. of toluene. The solution was stirred for an additional 1 h before the volatile components were removed *in vacuo* leaving an oily red solid. A Katz and Lee procedure for work-up was followed [1]. The solid was extracted with CH_2Cl_2 (30 cm^3) giving a deep cherry red solution which was passed through a frit before precipitating the red polypropyne with MeOH (30 cm^3). [If worked-up in the presence of air the polymer is yellow.] ^{1}H NMR (CD_2Cl_2, 25°C): δ 6.8 (br s, 1H, CH), 1.8 (br s, 3H, CH_3). ^{13}C NMR (CD_2Cl_2, 25°C): δ 132.0 (br s), 22.6 (br s). IR (KBr, cm^{-1}): 2967s, 1717m, 1684m, 1652m, 1632m, 1443s, 1377s, 1252m, 1159m, 1066s, 1024s (*trans*), 874m (*cis*), 808m.

Synthesis of poly(norbornene). By using standard gas line techniques a toluene solution (15 cm^3) of $Mo_2(OBu^t)_6$ (42 mg, 0.067 mmol) was exposed to C_2H_2 (0.34 mmol, 5.1 equiv.). After 0.5 h this solution was black and polyacetylene had precipitated. A toluene solution (10 cm^3) of norbornene (598 mg, 6.36 mmol, 95 equiv.) was transferred *via* cannula to the black solution. The resulting mixture was stirred at room temperature for 24 h during which time a colour change from black to purple occurred. ^{1}H NMR (C_6D_6, 25°C): δ 5.50 (s), 5.36 (s), 2.91 (br s), 2.50 (br s), 2.04 (br s), 1.83 (br s), 1.47 (br s), 1.23 (br m). ^{13}C-$\{^1H\}$ NMR (C_6D_6, 25°C): δ 134.3 (s), 134.2 (s), 133.7 (2), 133.5 (s), 133.3 (s), 43.9 (s), 43.6 (s), 39.1 (s), 38.8 (s), 33.3 (s), 32.8 (s), 32.6 (s).

$Mo_2(OBu^t)_6$+$^{13}C_2H_2$. A hexane solution (10 cm^3)

of $Mo_2(OBu^t)_6$ (84 mg, 0.133 mmol) was exposed, using standard gas line techniques, to $^{13}C_2H_2$ (0.266 mmol, 2.0 equiv.). Warming the solution to room temperature gave a dark solution. Half of this solution was transferred to another flask where the volatile components were removed. The ^{13}C-$\{^1H\}$ NMR spectrum of the dark oil was obtained and the data are listed below as Sample A. To the other half of the solution was added, by using gas line techniques, ^{13}CO (0.133 mmol, > 1 equiv.). While warming this solution to room temperature a colour change through emerald green to red-black occurred. The volatile components were removed and the resulting oil was characterized by ^{13}C-$\{^1H\}$ spectroscopy; listed as Sample B. ^{13}C-$\{^1H\}$ NMR (C_6D_6, 25°C): Sample A: δ (C_4H_4) 209.8 (m, AA′XX′), 179.5 (m, AA′XX′), 124.7 (m, AA′XX′), 115.2 (m, AA′XX′), 127.2 (s, μ-C_2H_2); Sample B: δ (CO) 243.4 (s), (C_4H_4) 208.9 (m, AA′XX′), 182.7 (m, AA′XX′), 115.2 (m, AA′XX′), 106.9 (m, AA′XX′), 127.1 (s, μ-C_2H_2).

$Mo_2(OBu^t)_6 + {}^{13}C_2H_2$ *followed by addition of* $^{13}C_2H_2$. A hexane solution (10 cm^3) of $Mo_2(OBu^t)_6$ (60 mg, 0.095 mmol) was exposed to $^{13}C_2H_2$ (0.190 mmol, 2.0 equiv.). The solution was stirred at room temperature for 0.5 h. The solution was then exposed to $^{12}C_2H_2$ (uptake 13.6 equiv. based on Mo). The dark solution was filtered with a medium filter frit to remove the polyacteylene that had formed. The ^{13}C-$\{^1H\}$ NMR spectrum of the filtrate shows that the ^{13}C label remains with the ethyne adduct and the metallacyclic species. ^{13}C-$\{^1H\}$ NMR (C_6D_6, 25°): δ 209.8 (m, AA′XX), 179.6 (m, AA′XX′), 127.4 (m, AA′XX′), 115.2 (m, AA′XX′), 127.2 (s).

Kinetics and equilibria of the ternary complex formation of nitrilotriacetatoferrate(III) with 2,2′-bipyridyl in aqueous solutions

Sanjoy Kumar Bhattacharyya and Rupendranath Banerjee*

Department of Chemistry, Jadavpur University, Calcutta-700032, India

(Received 3 April 1996; accepted 1 July 1996)

Abstract—In the pH range 2.7–3.7, $[Fe(nta)(H_2O)_2]$ (**1**) reacted with $Hbipy^+$ and bipy to form the ternary complex, [Fe(nta)(bipy)] (**2**), which was also formed in the reaction between $[Fe(nta)(H_2O)(OH)]^-$ and $Hbipy^+$. The equilibrium constant determined spectrophotometrically agreed well with the kinetically determined value. Rate constants and corresponding activation parameters have been evaluated for different pathways leading to compound **2** and its dissociation. Bond dissociation appears to be important in the transition state. The greater thermodynamic stability of [Fe(nta)(benzohydroxamate)]$^-$ (**3**) than **2** is a consequence of a much greater rate of dissociation of compound **2** than of compound **3**; formation rate constants for compounds **2** and **3** are similar. Copyright © 1996 Elsevier Science Ltd

Keywords: kinetics; equilibrium; ternary complex; nitrilotriacetate; iron(III); 2,2′-bipyridyl.

Ternary complexes of $[Fe(nta)(H_2O)_2]$ (**1**, H_3nta = nitrilotriacetic acid) have a proven role in iron binding to transferrin [1,2] and in strongly enhancing the antimicrobial action of ciprofloxacin [3]. Thus, several ternary complexes with **1** have been prepared and their biological activity described [4]. The binary complex **1** is itself an analogue for the active centre in pyrocatechase [5], but **1** induces tissue damage in rats in the presence of H_2O_2 [6].

The kinetics and equilibria of formation and dissociation of ternary complexes formed with **1** are therefore interesting subjects for investigation. To our knowledge, only one such kinetic study has been reported [7] and no equilibrium study has appeared so far on the complexation of N donor ligands to **1**. This is somewhat surprising because substitution at $Fe^{3+}(aq)$ and $Fe(OH)^{2+}(aq)$ centres has been the subject of much kinetic investigation [8], which has been valuable in the emergence of general mechanistic patterns for substitution at these two aqua ions.

EXPERIMENTAL

Materials

All reagents used were of analytical grade and all solutions were in distilled water, redistilled from alkaline permanganate in an all-glass apparatus. The iron(III) nitrate solutions (*ca* 0.02 mol dm^{-3}) were prepared by dissolving $Fe(NO_3)_3 \cdot 9H_2O$ (Merck) in dilute HNO_3 (*ca* 0.05 mol dm^{-3}). Higher concentrations of Fe^{III} were avoided to eliminate dimeric Fe^{III} species. Iron(III) was first precipitated as $Fe_2O_3 \cdot xH_2O$ with dilute NH_3, thoroughly washed and then dissolved with 1 : 1 HCl. For standardization, the Fe^{III} solution thus produced was reduced with tin(II) chloride followed by oxidation with $K_2Cr_2O_7$ as usual [9]. Iron(III) was also quantified by complexometric titration with EDTA solution using variamine B as indicator [9]. The two results agreed within $\pm 1\%$.

Aqueous solutions of **1** were prepared from a mixture of equal volumes (100 dm^3) of equimolar (0.02 mol dm^{-3}) solutions of Fe^{III} and H_3nta; the pH being adjusted to 3.0 with dilute KOH. Under these conditions **1** is formed quantitatively and it is reasonably

stable against thermal and photochemical decompositions [10–13].

Solutions of KNO_3 (BDH) were standardized with a cation exchange resin in H^+-form. Melting points of the supplied ligands 2,2′-bipyridyl (Merck) and H_3nta (Koch-light, England) agreed within ±1°C with the literature values, and were used as received.

Physical measurements and kinetics

Rate measurements were performed on a Hi-Tech SF-5A stopped-flow spectrophotometer coupled to a data acquisition system [7]. The mixing chamber of the instrument was thermostatted. Rate constants were measured under pseudo first-order conditions and the corresponding $\ln(A_e - A)$ *vs* time (t) plots were linear for at least 90% attainment of the equilibrium. The reported rate constants (k_0) were calculated with a standard least-squares program and are mean values from at least five kinetic runs.

UV–vis spectra were recorded on a Carl–Zeiss Jena (VSU-2P) spectrophotometer. This, and the stopped-flow machine, were used to measure the equilibrium optical density, A_e.

The uncertainties of the reported kinetic and equilibrium parameters are the standard deviations obtained from the scattering of the points on the least-squares lines. All pH values were measured on a Systronics (335) instrument having combined electrodes calibrated with standard solutions as described earlier [14].

Perchlorate media were avoided because $[Hbipy]^+[ClO_4^-]$ has very limited solubility in such a media below pH 4.5.

RESULTS AND DISCUSSION

Solutions of **1** give, upon addition of bipy, a sufficient increase in absorption at 400 nm (Fig. 1), the lower limit of wavelengths sensed by our stopped-flow apparatus. At this wavelength absorbances of equilibrated reaction mixtures showed the presence of complex formation equilibrium (1):

$$[Fe(nta)(H_2O)_2] + Hbipy^+ \overset{K_1}{\rightleftharpoons} [Fe(nta)(bipy)] + H^+ \quad (1)$$

(1) **(2)**

At 400 nm only **1** and **2** absorb. Equation (2) can, therefore, be obtained:

$$\frac{C_{Fe}[H^+](K_h + [H^+])^{-1}}{(A_e - A_0)} = \frac{1 + K_H[H^+]}{K_1 K_H C_{bipy} \Delta\varepsilon} + \frac{1}{\Delta\varepsilon} \quad (2)$$

where A is the absorbance, K_H is the protonation constant of bipy, K_h is the first hydrolysis equilibrium constant of **1** [see Eq. (3)], $\Delta\varepsilon$ is the difference in the

$$[Fe(nta)(H_2O)_2] \overset{k_h}{\rightleftharpoons} [Fe(nta)(H_2O)(OH)]^- + H^+ \quad (3)$$

$$Hbipy^+ \overset{K_a}{\rightleftharpoons} bipy + H^+ \quad (4)$$

$$[Fe(nta)(H_2O)_2] + Hbipy^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [Fe(nta)(bipy)] + H^+ \quad (1a)$$

$$[Fe(nta)(H_2O)(OH)]^- + Hbipy^+ \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} [Fe(nta)(bipy)] + 2H_2O \quad (5)$$

$$[Fe(nta)(H_2O)_2] + bipy \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} [Fe(nta)(bipy)] + 2H_2O \quad (6)$$

$$[Fe(nta)(H_2O)(OH)]^- + bipy \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} [Fe(nta)(bipy)] + OH^- \quad (7)$$

Scheme 1.

molar absorptivity between **2** and **1** and C_{Fe} and C_{bipy} are the total metal and total ligand concentrations. The linearity of plots of the left-hand side of Eq. (2) as a function of $(1+K_H[H^+])/C_{bipy}$ (Fig. 2) confirms the validity of the stoichiometry reported in Eq. (1). Therefore, no protonated and/or hydrolysed complexes are formed under the present conditions. This was further verified from an ion-exchange experiment. A mixture of **1** and bipy equilibrated under kinetic conditions was eluted consecutively through a Dowex 50 W × 8 cation exchanger bed in K^+-form and an Amberlite IRA 400 anion exchanger bed in NO_3^--form. The total amount of iron initially charged passed out unabsorbed, indicating the absence of any ionic species of iron at analytically significant concentrations.

The K_1 and ε values for the ternary complex, **2**, obtained from Fig. 2 are 0.025 and 554 mol^{-1} dm^3 cm^{-1} at 25°C and $I = 0.1$ mol dm^{-3} (KNO_3).

Table 1 reports the k_0 data. The nature of the dependence of k_0 on different reaction conditions (see later) suggests the kinetics shown in Scheme 1.

For the present experimental conditions, Eq. (8) can be obtained from Scheme 1.

$$k_0 = k_f C_{bipy} + k_r \quad (8)$$

where

$$k_f = \left(k_1[H^+] + k_2 K_h + k_3 K_a + \frac{k_4 K_h K_a}{[H^+]} \right) (K_a + [H^+])^{-1} \quad (9)$$

and

$$k_r = k_{-1}[H^+] + k_{-2} + k_{-3} + \frac{k_{-4} K_w}{[H^+]}. \quad (10)$$

Plots of k_0 against C_{bipy} at different fixed acidities were linear with significant intercept k_r and slope k_f. Figure 3 shows the excellent linear dependence of k_f $(K_a + [H^+])$ on $[H^+]$. The k_r *vs* $[H^+]$ plot (Fig. 3) is also excellent straight line with significant intercepts. Linearity such as that shown in Fig. 3 suggests that

[a] mol^{-1} dm^3 s^{-1}.
[b] s^{-1}.

the active path could be as given in Eqs (1a), (5) and (6) and that path (7) is kinetically insignificant, probably owing to the small value for the quotient $K_aK_h[H^+]^{-1}$ under the experimental conditions used. k_1 and $(k_2K_h+k_3K_a)$ were evaluated from the slopes and intercepts, respectively, of Fig. 3A. Similarly, Fig. 3B gave k_{-1} as its slope and $(k_{-2}+k_{-3})$ as its intercept. These kinetic parameters are collected in Table 2 along with the activation parameters corresponding to k_1 and k_{-1}.

The equilibrium quotient K_1 for equilibrium 1 is equal to $k_1/k_{-1} = 0.027$ at 25°C, $I = 0.1$ mol dm^{-3} (KNO_3). This kinetically evaluated K_1 agrees with our equilibrium measurements ($K_1 = 0.025$) and lends support to the proposed mechanism. Once K_1 is known, the equilibrium constants for reaction (5) ($K_2 = K_1/K_h = 2700$ mol^{-1} dm^3) and for reaction (6) ($K_3 = K_1/K_a = 765$ mol^{-1} dm^3) may also be evaluated.

Das *et al.* [7] have studied the reaction of **1** with benzohydroxamic acid (Hbha) and found

$$[Fe(nta)(H_2O)_2] + Hbha \underset{k'_{-1}}{\overset{k'_1}{\rightleftharpoons}} [Fe(nta)(bha)]^- + H^+ \quad (11)$$

$k'_1 = 18.3$ mol^{-1} dm^3 s^{-1} ($\Delta H^{\neq} = 42.3$ kJ mol^{-1}, $\Delta S^{\neq} = -80$ J K^{-1} mol^{-1}) and $k'_{-1} = 168$ mol^{-1} dm^3 s^{-1} ($\Delta H^{\neq} = 41.3$ kJ mol^{-1}, $\Delta S^{\neq} = -65$ J K^{-1} mol^{-1}) at 25°C. The equilibrium constant K'_1 for reaction (11) is 0.108.

Within the range of experimental error the activation parameters for the k'_1 path [Eq. (11)] are the same as those for the k_1 path (Table 2). The value for k'_1 is also quite close to k_1, inspite of the wide difference in the nature of the entering ligands, *viz.* bha and bipy. This proximity in kinetic parameters for two widely different entering ligands strongly suggests an interchange mechanism, where Fe^{III}—OH_2 bond dissociation is more important than bond formation.

The presence of strong donors in the coordination

sphere of Fe^{III} induces dissociative activation. A well-known case in point is the observation that the reaction of $Fe(H_2O)_6^{3+}$ mostly follows an I_a pathway, while that of $Fe(H_2O)_5(OH)^{2+}$ prefers I_d. Such effects of donor ligands are also manifested in the replacement of H_2O from $[Fe(edta)(H_2O)]^-$ by S^{IV} [15]; the reaction proceeding through an I_d pathway. Similar situations were also found [16–18] in the formation of different ternary complexes with $[M(nta)(H_2O)_2]^-$ [$M = Ni^{II}$, Co^{II}, Mn^{II}].

Attachment of the strong σ-donor ligand nta to the Fe^{III} centre in **1** definitely weakens the remaining Fe^{III}—OH_2 bonds and thus favours a dissociative mechanism. Such bond weakening is probably reflected in the low $\Delta H^{\neq}$ value for the k_1 and k'_1 paths compared with $\Delta H^{\neq}$ (64 kJ mol^{-1}) for water exchange in Fe^{3+} [8b]. Unfortunately, no information is available on the water exchange rate for **1** and so its comparison with k_1 is not possible. Rate constant and activation parameters for the reverse pathways k_{-1} and k'_{-1} are widely different, indicating their dependence on the nature of the replaceable ligand and thus suggesting that bond dissociation is primarily important in the reverse reactions as well.

Dissociation of bipy from **2** is almost 10 times faster than the dissociation of bha from **3**. This is most likely a manifestation of stronger Fe^{III}—O bonds than Fe^{III}—N bonds [19,20], and the well-known affinity of Fe^{III} for hydroxamic acids. The lower stability of the bipyridyl complex **2** ($K_1 = 0.025$) compared with the bha complex **3** is therefore a consequence of the much higher rate of dissociation for **2**; the formation rate constant for **2** is close to that for **3**.

(Received 20 April 1996; accepted 28 June 1996)

Abstract—A series of N(4)-substituted thiosemicarbazones of isatin were synthesized and their copper(II) complexes prepared from copper(II) chloride. X-ray crystal structures of two of the thiosemicarbazones, isatin 3-(hexamethylenimylthiosemicarbazone) and isatin 3-(N(4)-ethylthiosemicarbazone), have been solved and are compared with a previously published structure of isatin 3-(N(4)-*p*-tolythiosemicarbazone). The coordination chemistry of the copper(II) complexes of these and other isatin thiosemicarbazones is reported and discussed.

Keywords: isatin; thiosemicarbazone; copper(II).

The 3-thiosemicarbazones of isatin have been of interest since 1-methylisatin-3-thiosemicarbazone (Marboran™) was found to be active in the treatment of smallpox 40 years ago [1–3]. Although substitution at the N(4) position (Fig. 1) of the thiosemicarbazone moiety was found to reduce anti-smallpox activity, substitution of two butyl groups at the N(4) position yields a compound with demonstrated activity against ectromelia (a vaccina virus unaffected by Marboran™) and also against type 2 polio, which is an enterovirus and quite unrelated to the vaccina family [4].

It has been suggested that thiosemicarbazone drugs may act to inhibit viruses by binding to copper ions, which are constituents of the virus [4]. Others have prepared and partially characterized metal complexes of N(4)-2-pyridyl ITSC [5], N(4)-phenyl ITSC [6], N(4)-ethyl ITSC [7] and N(4)-dimethyl ITSC [8]. These previously prepared complexes were of different stoichiometry to those described here, a result of the different preparative conditions.

Here, we present spectroscopic data on the ITSCs substituted at the N(4) position with one and two methyl, ethyl or propyl groups and with cyclic hydrocarbon groups which result in piperidine or hexamethylenimine rings, and their complexes prepared from copper chloride. We also include crystal structures of the isatin 3-(hexamethyleniminylthiosemicarbazone) (H_2Ishexim) and isatin 3-(N(4)-ethylthiosemicarbazone) (H_2Is4E).

EXPERIMENTAL

The thiosemicarbazones were prepared by reaction of equimolar amounts of the appropriate N(4)-substituted thiosemicarbazide, either purchased from Aldrich [N(4)-methyl- and N(4)-ethylthiosemicarbazide] or synthesized following the procedure developed by Holmberg and Psilanderhielm [9] and modified by Scovill [10], with isatin (Aldrich, 98%) at room temperature in absolute ethanol with a catalytic amount of conc. H_2SO_4. The products precipitated as yellow powders in 15 min to an hour, and were collected by suction filtration and washed with cold absolute ethanol.

Complexes were prepared by dissolving equimolar amounts of anhydrous copper(II) chloride and the

* Author to whom correspondence should be addressed.

desired ITSC in warm absolute ethanol. The resulting mixture was then refluxed for 1 h. Solids were collected by suction filtration and rinsed with EtOH and Et_2O to apparent dryness.

The NMR spectra were recorded in DMSO-d_6 with a Varian Gemini 2000 300 MHz spectrometer. Infrared and electronic spectra were recorded with Perkin–Elmer 783 and 330 spectrophotometers, respectively, and EPR spectra were recorded in the solid state and in DMSO solution in an insert Dewar with a Varian E104 spectrometer. The EPR spectra were calibrated with DPPH.

The X-ray crystal structures of H_2Ishexim and H_2Is4E were solved at room temperature using a Siemens P4 diffractometer. Yellow crystals of both compounds were grown by slow evaporation at 35°C of a DMSO/EtOH solution, and a pure DMSO solution, respectively. Complete crystallographic experimental parameters are given in Table 1. Lattice parameters were obtained from 25 reflections with $7.25 \leqslant 2\theta \leqslant 25.98°$ (H_2Ishexim) and $8.61 \leqslant 2\theta \leqslant 28.98°$ (H_2Is4E). Crystal stability was monitored using three standard reflections every 97 reflections, for both crystals. Intensity data corrections were made for background, Lorentz and polarization effects. The structures were solved by direct methods, and refined by full-matrix least-squares techniques using the Siemens SHELEXTL-Plus (PC version) [11] program. The absolute conformation of H_2Is4E was established by the method of Rogers ($\eta = 1.0(1)$) [12]. Anisotropic temperature factors were used for all non-H atoms. Hydrogen atoms attached to carbon were included using a riding model, except for the atoms N(1)—H and N(3)—H, which were located on a difference Fourier map at an advanced stage of refinement and then had their coordinates further refined. All H atoms were constrained and assigned fixed isotropic temperature factors; $U = 0.06$ Å^2, $\Sigma\omega(F_o - F_c)^2$ minimized, $\omega = [\sigma^2(F_o) + g(F_o)^2]^{-1}$, with final $g = 0.0005$ (where g is a "fudge factor" refined each cycle to prevent unrealistic weight). Residual electron density was between -0.34 and $+0.55$ eÅ^{-3} (H_2Ishexim) and -0.35 and $+0.29$ eÅ^{-3} (H_2Is4E). Scattering factors were taken from ref. [13].

RESULTS AND DISCUSSION

Perspective views of H_2Ishexim and H_2Is4E are presented in Fig. 1. Table 1 shows a summary of crystal data and X-ray analysis information for both compounds, and relevant bond distances and angles are listed in Table 2. A complete listing of bond distances and angles is included in the supplementary material. Despite repeated and varied efforts we have been unable to obtain a diffraction-quality single crystal of a copper(II) complex of any of the isatin thiosemicarbazones discussed.

Carbon atoms C(13) and C(14) of H_2Ishexim were found to be disordered with occupancy factors of 0.5586 and 0.4414 for C(13) and C(13a); 0.5698 and 0.4302 for C(14) and C(14a), respectively.

The six- and five-membered rings of the isatin moiety are very nearly planar. The dihedral angles between the mean planes of both rings are only 2.1 and 0.5° in H_2Ishexim and H_2Is4E, respectively, but the angle between the best least-squares plane describing the entire isatin moiety and that for the thiosemicarbazone (TSC) moiety [N(2)—N(3)—C(10)—S(1)—N(4)] is 18.1°(H_2Ishexim) and 10.77°(H_2Is4E), a significant deviation from planarity.

In H_2Ishexim, this deviation might be expected to be owing to a solid-state effect, but examination of the packing diagram revealed no significant intermolecular interaction. It therefore appears to be intrinsic and may be caused by overlap of lone pairs of electrons on S and N(2) that would occur if these moieties were coplanar. The hexamethylenimine ring (hexim) lies partly within the thiosemicarbazone plane, atoms N(4) and C(11) being in the plane; the remainder of the carbon atoms in the ring are angled out of the plane, similar to other TSCs with this functional group [14]. Interestingly, the oxygen atom lies above the plane of the isatin moiety of H_2Ishexim by 0.018(4) Å. This deviation is a consequence of being involved in hydrogen bonding with the N(3)—H atom which is attached to the TSC moiety and therefore lies above the plane of the isatin function.

In contrast, the packing diagram for H_2Is4E shows a possible interaction between sulfur and the N(4)—H

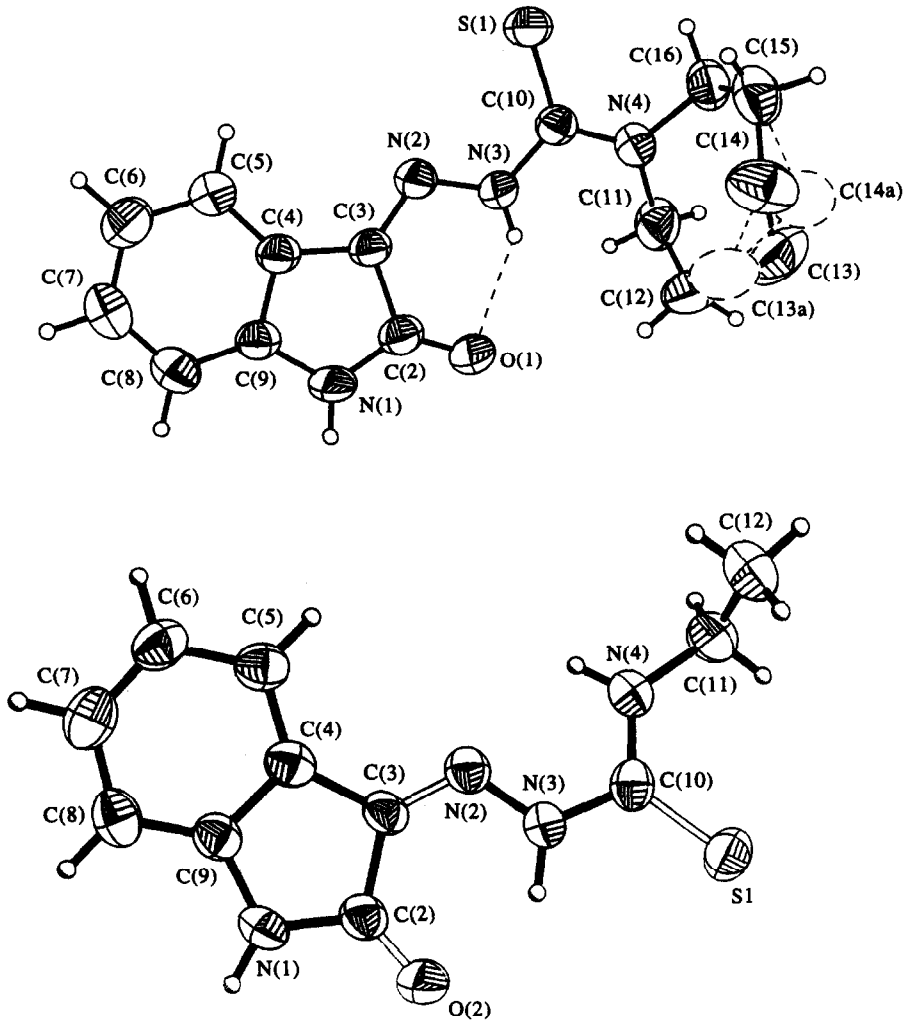

Fig. 1. Ortep diagrams of H_2Ishexim and H_2Is4E from X-ray data.

of a neighbouring molecule. This distance is 2.81(6) Å, which is comparable to the 2.77 Å distance observed in the related (to the point of crystallizing in the same space group) thiosemicarbazone HFo4M [14]. This indicates considerable interaction between the molecules and may therefore account for the deviation of the sulfur from the mean plane of the molecule.

In both structures, the thiosemicarbazone moiety is *Z* about the C(3)=N(2) double bond as a consequence of hydrogen bonding between N(3)—H and O(2). H_2Ishexim is also *Z* about the N(3)—C(10) bond. This latter *Z* conformation is thought to be owing to the lesser overlap of the lone pair of electrons on N(2) with an eclipsing sulfur atom than would be the case with an eclipsing hexim ring. The configuration about the N(3)—C(10) bond in H_2Is4E is *E*, the same as that found in the previously published isatin 3-(N(4)-paratoluylthiosemicarbazone) (H_2Is4pT) [15]. This conformation is brought about by a five-membered ring formed by H-bonding between N(4)—H and N(2). Although five-membered H-bonding rings are generally less favourable than the six-membered rings, the presence of such a hydrogen bond is supported by the inversion of configuration relative to H_2Ishexim, which lacks an N(4)—H atom. The reported structure of H_2Is4pT did not include refined coordinates for N(4)—H which might have helped substantiate the presence of hydrogen bonding. A comparison of bond distances and angles (Table 2) across the TSC and isatin moieties shows the only significant difference between the three molecules to lie in the extent to which the sulfur atom is deflected away from N(2). In H_2Ishexim, the *Z* configuration about the N(3)—C(10) bond places the sulfur in a position where its lone pairs overlap the lone pair on N(2). This results in a greater N(3)—C(10)—S(1) angle than is seen in H_2Is4E and H_2Is4pT, where the *E* configuration about this bond prevents interaction between sulfur and N(2).

H_2Ishexim, H_2Is4E and the other ITSCs of this study were identified by their ^{1}H and ^{13}C NMR spectra (Table 3). In the ^{1}H spectra, we assign the signal at δ 11.0–11.2 to N(1)—H based on the position of this peak in the spectrum of the parent isatin molecule. This assignment differs from earlier work [7] on the N(4)-ethyl compound in which this peak was ascribed to the N(3)-H; however, our assignment of the peak at δ 12.5–13.5 as the N(3)-H is supported both by its location at lower field (indicative of an intramolecularly hydrogen-bonded proton) and by the greater dependency of its position on the nature of the N(4) substituent. Further support for our assignment of the δ 13.12 peak as intramolecularly hydrogen bonded N(3)-H is found in a comparison of spectra of H_2Ispip recorded in DMSO-d_6 and $CDCl_3$.

A 0.8–1.0 ppm difference in the chemical shift of the N(3)-H (hydrogen bonded to the isatin oxygen) was observed with the N(4) dialkyl- and cycloalkyl-substituted compounds having the lower field chemical shift. It is likely that this difference in chemical shift lies in the configuration about the N(3)—C(10) bond. In the presence of bulky dialkyl or azacyclo functions at N(4), overlap of these groups and the lone pair at N(2) would be minimized by adoption of a *Z* configuration about the N(3)—C(10) bond (lone pair and S on the same side). For the N(4)-monoalkyl TSC this interaction would be minimized, and the formation of N(4)—H···N(2) intramolecular hydrogen bonds facilitated, by adoption of an *E* configuration.

No previous reports of ^{13}C spectra for these TSCs exist; however, a report of both ^{1}H and ^{13}C spectra of isatin [16] gives the amide C(2) at δ 159.4 and the ketonic C(3) at δ 184.4, respectively. Upon formation of the TSC, the ketonic (now azomethine) carbon signal is at significantly higher field (i.e. δ 131.5–134.8), the exact position being dependent on the nature of the N(4) substituent. A difference in the spectra of mono- and di-/cycloalkyl TSCs is also seen in the chemical shift of C(3) where the former appears 2–3 ppm further upfield (*ca* 134.5) than the latter (*ca* 131.5). The amide carbon {C(2)} resonance changes only slightly, moving upfield by *ca* 3 ppm.

Partial elemental analyses of the copper(II) complexes showed all to be of acceptable purity (Table 4). Magnetic moments for all complexes were close to the spin-only value of μ_{eff} = 1.7 B.M.

Table 3. ^{1}H and ^{13}C NMR data for isatin thiosemicarbazones

Compound	N(1)-*H*	N(3)-*H*	N(4)-*H*	*C*(2)	*C*(3)	*C*(9)	*C*(10)

H_2Is4P	11.19	12.56	9.26	162.85	131.80	142.43	177.29
H_2IsDP	11.24	13.56		162.91	134.83	141.65	177.99
H_2Ispip[d]	11.269	13.121		162.69	133.57	141.80	178.64
H_2Ishexim	11.258	13.504		162.85	134.81	141.70	178.47

[a] N(1)-H appears to hydrogen bond to the DMSO as suggested by the shifts for H_2Ispip in *d*.

[b] This assignment is based on the discussion in *d* and is contrary to the assignment in ref. [8].

[c] Based on the spectrum of H_2IsDH and the assignment in ref. [8], the N(4)-H hydrogen of H_2Is4E is intramolecularly hydrogen bonded to N(2), in agreement with the solid-state result. Similar behaviour is suggested for H_2Is4M and H_2Is4P.

[d] When H_2Ispip was recorded in $CDCl_3$, the signal at δ 11.269 was found at δ 8.154, but the signal at δ 13.12 did not change. This suggests that the δ 13 signal is N(3)-H and is intramolecularly hydrogen bonded, whereas the signal at δ 11.2 (DMSO) and δ 8.15 ppm is N(1)-H and hydrogen bonds in DMSO solution.

The vibrational spectra of the isatin TSCs (Table 5) show little difference between the members of the series. Upon formation of the copper(II) complexes, the anticipated changes in frequency of those vibrations involved in donation to the metal, and the difference between the neutral and monoanionic ligands, are plainly visible. The frequency of the ν(C=O) vibration shifts to lower energy by *ca* 30 cm^{-1} upon complexation as the anionic ligand. This is in keeping with a transfer of charge from the oxygen to the copper(II) centre and the corresponding decrease of the bond order in the carbonyl bond. In contrast, the frequency of ν(C=O) for the complexes of the neutral ligand, $[Cu(H_2Is4E)Cl_2]$ and $[Cu(H_2Is4P)Cl_2]$, remains relatively unchanged, suggesting little or no charge donation from oxygen to copper in these complexes. This observation is mirrored in the ν(C—S) vibration (i.e. thioamide IV), which also decreases in frequency by *ca* 70 cm^{-1} upon formation of the anionic ligand and is reduced only slightly in the neutral ligand. The apparent non-coordination of oxygen in the neutral complexes suggests that the TSC moiety coordinates in a bidentate fashion through N and S. There is no significant difference in the vibrational frequencies of the copper–ligand bonds throughout the series. In keeping with the stoichiometry of the compounds, two peaks (presumably symmetric and antisymmetric stretches) are found for ν(Cu—Cl) in $[Cu(H_2Is4E)Cl_2]$ and $[Cu(H_2Is4P)Cl_2]$. For the remainder of the complexes, the changes in frequency of the carbonyl, imine and thiocarbonyl bonds and the appearance of bands assignable to ν(Cu—O), ν(Cu—N), ν(Cu—S) and ν(Cu–Cl) in the spectra of the complexes strongly support the proposed structure of an anionic, tridentate chelating thiosemicarbazone with one chloride ligand completing the coordination sphere around copper.

[a] Obscured by N(4)-H.

[b] The spectra for [Cu(HIsDP)Cl], [Cu(HIspip)Cl], and [Cu(HIshexim)Cl] have a peak at *ca* 3275 cm^{-1} which seems unlikely to be ν{N(1)H}. This peak might be more reasonably assigned as ν{N(3)H} suggesting that the bulkier TSCs lose N(1)H, whereas the lighter TSCs lose N(3)H upon complexation with the copper. However, C=O and C=S IR bands and other spectral data do not show significant differences between complexes with bulky and less bulky substituents at N(4) to support this suggestion.

plexes (Table 6) show a strong π–π^* band in the ligand at *ca* 36,000 cm^{-1} (not shown in Table 6) which is obscured in the spectra of the complexes. The TSC moiety n—π^* band at 27,500–29,500 cm^{-1} is generally lower in energy in the anionic ligand complexes than in the uncomplexed TSCs, whereas the energy of the band increases slightly in the coordinated neutral ligand. This is consistent with the loss of N(3)H and the resultant formation of the conjugated TSC moiety for the anionic ligand. The low energy of the *d–d* transition in the neutral complexes suggests either coordination of an additional molecule in an axial position or tetrahedral distortion of the coordination sphere. This band in the complex [Cu(HIs4M)Cl] is found at higher than expected energy (15,150 cm^{-1}). The remaining complexes in the series have *d–d* bands around 14,000 cm^{-1}, suggesting a more distorted environment around copper owing to their bulkier N(4) substituents.

The solid-state EPR spectra (Table 7) also provide information about the coordination environment around copper(II) in these complexes. A previous EPR study [17] involving the 4-methylpiperidine N(1) Mannich base of isatin thiosemicarbazone (no substitution at the N(4) position) coordinated to copper(II) showed an isotropic powder spectrum. In contrast, only one of the present compounds has an isotropic spectrum [Cu(HIsDE)Cl], while all others gave approximately axial spectra. The spectrum for [Cu(HIsDE)Cl] is two orders of magnitude weaker than the spectra for the other complexes in this study, suggesting considerable internuclear interaction (i.e. binuclear or polynuclear).

EPR data for the neutral ligand complexes have higher values for both $g_\parallel$ and $g_\perp$ resulting in higher

values of g_{av}. The largest shift occurs for $g_{\parallel}$ which is *ca* 2.23 at both room and liquid nitrogen temperatures. This suggests a 4+1 or 4+2 coordination geometry for both [Cu(H_2Is4E)Cl_2] and [Cu(H_2Is 4P)Cl_2] in which the two chloro ligands of the complex are coordinated in the plane and chlorine(s) or sulfur(s) from the equatorial sphere of a neighbouring molecule occupy an axial position, resulting in either a paired or chain structure in the solid state. The complexes with anionic tridentate ligands are all thought to be planar with no significant axial interaction resulting in low values of $g_{\parallel}$ (and $g_{\perp}$). Some spectral variation occurs within this series of complexes, some having high $g_{\parallel}$ values ([Cu(HIs DM)Cl]) and some low $g_{\parallel}$ values ([Cu(HIs4M)Cl]), and most display some rhombic distortion. Higher values of $g_{\parallel}$ in these complexes are related to increased axial interaction(s).

Application of a combination of UV–vis adsorption and EPR spectral data permits the calculation of covalency parameters, $k_{\parallel}$ and $k_{\perp}$, for two of the complexes [18]. A value for either of 0.73 indicates minimal π-bond contribution, while smaller values indicate greater π-bonding. The values of $k_{\parallel}$ and $k_{\perp}$ for [Cu(HIs4M)Cl] are 0.66 and 0.69, and for [Cu(HIspip) Cl] they are 0.60 and 0.72, respectively. The low values of $k_{\parallel}$ suggest a marked amount of π bonding in the square-planar environment of each of these complexes, whereas the π contribution to axial bonding is much smaller. This is expected given that copper has filled π-bonding orbitals, but sulfur and chlorine (empty *d*) and nitrogen (π^*) have a limited π-acceptor capacity.

Supplementary material—Atomic coordinates, packing diagrams, complete listings of bond distances and angles and structure factors have been deposited at the Cambridge Crystallographic Data Centre.

(Received 11 March 1996; accepted 26 June 1996)

Abstract—The crystal and molecular structure of [ammonia–silver(I)-2-(4-chlorobenzoyl)benzoate], $[(NH_3)\cdot Ag(C_{14}H_8ClO_3)]$, has been solved by X-ray diffraction techniques. The carboxylate is bound to the silver in two modes, a linear two-coordinate silver (68%) and an asymmetrically chelated three-coordinate silver (32%). An unusually short Ag—N bond, 2.098(2) Å, is observed for the two-coordinate silver. Based on the structure of the $[(NH_3)\cdot Ag(C_{14}H_8ClO_3)]$ complex, and the similarities in the IR and thermal properties, the ammine free $[Ag(C_{14}H_8ClO_3)]$ complex starting material is proposed to have the normal eight-membered silver carboxylate structure. Copyright © 1996 Elsevier Science Ltd

Keywords: silver; carboxylate; ammine.

In our continuing effort to develop further understanding of silver carboxylate chemistry [1] the silver complex of 2-(4-chlorobenzoyl)benzoic acid, (CBBA) was investigated. The marginal solubility of the AgCBBA complex, however, prohibited preparation of X-ray quality crystals.

Silver carboxylates are known to be poorly soluble in common organic solvents [2], the main exception to this rule seems to be the halogenated hydrocarbon derivatives [3]. Pyridine has been reported as a co-solvent (with ethanol) for the recrystallization of silver carboxylates having long alkyl chains [4]. While this observation has been confirmed the crystals obtained by this technique have been found to be poorly formed on a molecular level [1e]. The poor quality of the crystals can be attributed to the slow diffusion of equilibrium-released pyridine; thus, alternative routes to the preparation of high quality crystals would have great utility. Silver carboxylates have been successfully recrystallized from aqueous ammonia without incorporation of the ammine into the complex [5] although ammine has since been found to be incorporated into the silver coordination sphere in some structures [6]. In recrystallizing AgCBBA from ammonia we have found that the ammine is incorporated into the silver's coordination sphere. This report summarizes the properties of two silver CBBA complexes, $[(NH_3)\cdot AgCBBA]$, including characterization of its molecular structure and the ammine-free [AgCBBA] complex. Based on the structure of the $[(NH_3)\cdot AgCBBA]$ complex, the ammine-free complex is proposed to have a silver coordination sphere analogous to known silver carboxylate structures [7].

EXPERIMENTAL

Instrumentation

Differential scanning calorimetry, (DSC) and thermal gravimetric analysis, (TGA) were carried out on a TA Instruments 2100 thermal analyser with a dual

* Author to whom correspondence should be addressed.

sample DSC (model 910) and a TGA (model 951). The heating rate for the DSC and TGA was 5°C min^{-1}, under a nitrogen purge of approximately 50 cm^3 min^{-1}. FTIR spectra were obtained on a BOMEM-MB 102 FTIR spectrometer as a Nujol paste between KBr plates (some samples run in KBr without Nujol appeared to form free carboxylic acid, owing to halide exchange).

X-ray data collection, structure determination and refinement

The space group of the transparent single crystal of the title compound was determined to be the centric $P2_1/c$. Two positions were readily apparent for the silver atom: they were refined to occupancy factors of 68% (Ag) and 32% (Ag′) in alternate least-squares cycles. The geometrically constrained hydrogen atoms were placed in calculated positions and allowed to ride on the bonded atom with $B = 1.2 \times U_{eqv}(C)$. The ammine hydrogen atoms were included as a rigid group with rotational freedom at the bonded nitrogen atom [$B = 1.2 \times U_{eqv}(N)$]. Two sets of these hydrogen atoms were included, one with 68% occupancy and one with 32% occupancy corresponding to the silver disorder. Refinement of non-hydrogen atoms was carried out with anisotropic temperature factors. Crystal data and structure refinement data and selected bond distances and angles are given in Tables 1 and 2.

Preparation of compounds

[AgCBBA]. 2-(4-Chlorobenzoyl)benzoic acid (2.80 g, 11.0 mmol, Aldrich Chemical Co.) and sodium hydroxide (0.40 g, 10 mmol) were dissolved in water (100 cm^3). A slight solid was removed by filtration and silver nitrate, (1.70 g, 10.0 mmol) in water (10 cm^3) was added. After 15 min of stirring the white solid was filtered, dispersed in an equal volume of water, filtered and allowed to dry in the dark. Found: C, 45.5; H, 2.1. Calc. for $C_{14}H_8ClO_3Ag$: C, 45.8; H, 2.2%.

[$(H_3N)\cdot$AgCBBA]. Silver-2-(4-chlorobenzoyl)benzoate (0.30 g, 0.81 mmol) was dispersed in ethanol (10 cm^3) and sufficient 30% aqueous NH_3 added to obtain a clear solution. The vessel was closed with a septum and vented, to allow slow NH_3 loss, with a #16 gauge needle. Standing in the dark for one week resulted in the formation of large, colourless cubic crystals. The solution was decanted and the air- and light-stable crystals allowed to dry. Found: C, 43.3; H, 2.9; N, 3.7. Calc. for $C_{14}H_{11}NClO_3Ag$: C, 43.7; H, 2.9; N, 3.6%.

RESULTS AND DISCUSSION

While silver carboxylates are well known to exhibit eight-membered ring structures [7], the *o*-benzoyl car-

bonyl of the CBBA ligand is in a position to coordinate with the silver in the eight-membered ring. The $[(NH_3)\cdot AgCBBA]$ complex resulting from recrystallization of AgCBBA from ammonia could form three quite different structures.

1. Axially coordinated NH_3 in which the eight-membered silver carboxylate ring is maintained, analogous to $[Ag_2(C_9H_8NO_3)_2(H_2O)_2]\cdot 2H_2O$ [5c].
2. Monomeric silver which is chelated by one carboxylate, analogous to the known $[AgSt(PPh_3)_2]$ complex [1b].
3. Polymeric silver carboxylate in which the silver is coordinated by an imine (resulting from NH_3 reaction with the *o*-benzoyl carbonyl) from an adjacent ligand.

All three structures would give the same elemental analysis and would be difficult to characterize by normal techniques such as IR and MS. We have determined the actual structure, by X-ray diffraction techniques, of the $[(NH_3)\cdot AgCBBA]$ complex to be a form of 2 : the two unique structures are shown in Fig. 1. The solid-state packing diagram is shown in Fig. 2.

Description of the $[(NH_3)\cdot AgCBBA]$ *structure*

Two different silver environments appear in the $[(NH_3)\cdot AgCBBA]$ complex; two-coordinate silver at 68% occupancy and three-coordinate silver at 32% occupancy. The carboxylate and the ammine are positionally unchanged in either configuration in the structure.

The two different types of silver coordination are clearly illustrated by the fact that one silver is approximately linearly coordinated by the carboxylate and the other is chelated. The two-coordinate silver exhibits a Ag—O bond [2.180(2) Å] that is slightly short compared to known silver carboxylates, which are normally 2.2–2.4 Å [7]. This distance is consistent, however, with the silver's low coordination number. The three-coordinate silver is asymmetrically chelated by the carboxylate, the Ag′—O bonds are 2.309(2) [O(2)] and 2.468(2) Å [O(1)]. The shorter bond length is quite normal for a stable Ag—O bond, and the longer bond is not unusual [7].

The two-coordinate silver in the $[(NH_3)\cdot AgCBBA]$ complex exhibits an unusually short Ag—N bond, [2.098(2) Å] which is substantially shorter than other silver complexes containing nitrogen ligands [1,5c,8]. The second Ag—N bond [2.169(2) Å], associated with the three-coordinate silver, is in the expected range for normal Ag—N bonds. The only $Ag—N_{ammine}$ bond distances reported in a carboxylate complex are 2.158(5) and 2.154(5) Å [6]. Simple $[Ag(NH_3)_2]^+$ complexes, on the other hand, exhibit shorter $Ag—N_{ammine}$ bond lengths of 2.11–2.18 Å [9].

As far as other potential bonding interactions within the $[(NH_3)\cdot AgCBBA]$ complex are concerned, such as those from the *o*-benzoyl oxygen which is in a position to coordinate with the silver, the *o*-benzoyl oxygen can be seen clearly to be uninvolved in silver complexation. The closest $Ag\cdots O_{benzoyl}$ contact distance is found to be 3.8 Å. In addition, the silver–chlorine separations, 3.516 (Ag···Cl) and 3.605 Å (Ag′···Cl), between adjacent ligands in the solid state, are not within the van der Waal's radii of the two atoms (3.5 Å). Bond distances for $Ag—Cl_{organic}$ systems fall in the range 2.626(3)–3.000(3) Å [10], although significant interactions have been reported for Ag···Cl as long as 3.160 Å [11].

IR spectra of $[(NH_3)\cdot AgCBBA]$ *and* [AgCBBA]

The IR spectrum (Table 3) suggests that the ammine is present as the NH_3 ligand and not the imine. The IR spectrum is not definitive, however, since imines exhibit NH stretches in this same region, although the number of imine stretches are usually fewer [12] than the four observed for the

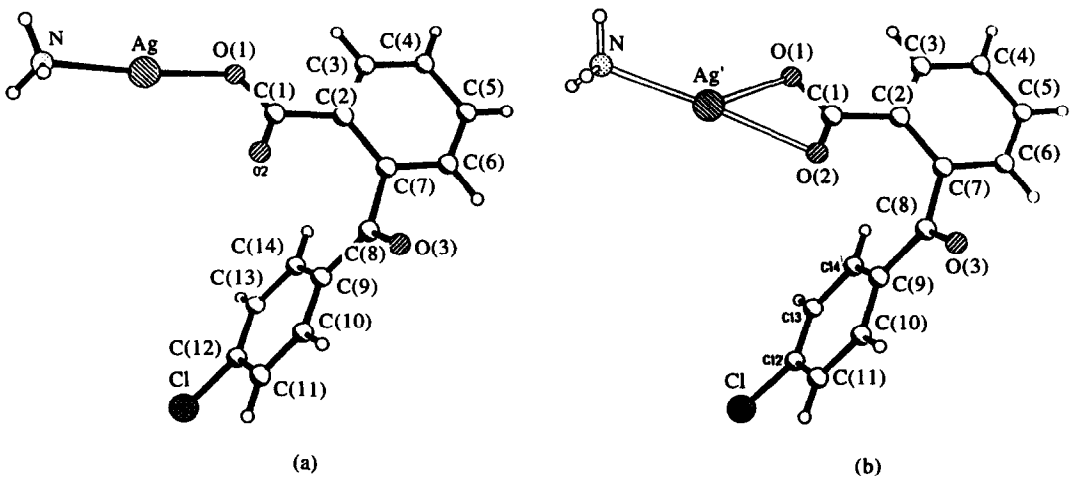

Fig. 1. Molecular structure of $[(NH_3)\cdot AgCBBA]$: (a) 68% occupancy; (b) 32% occupancy.

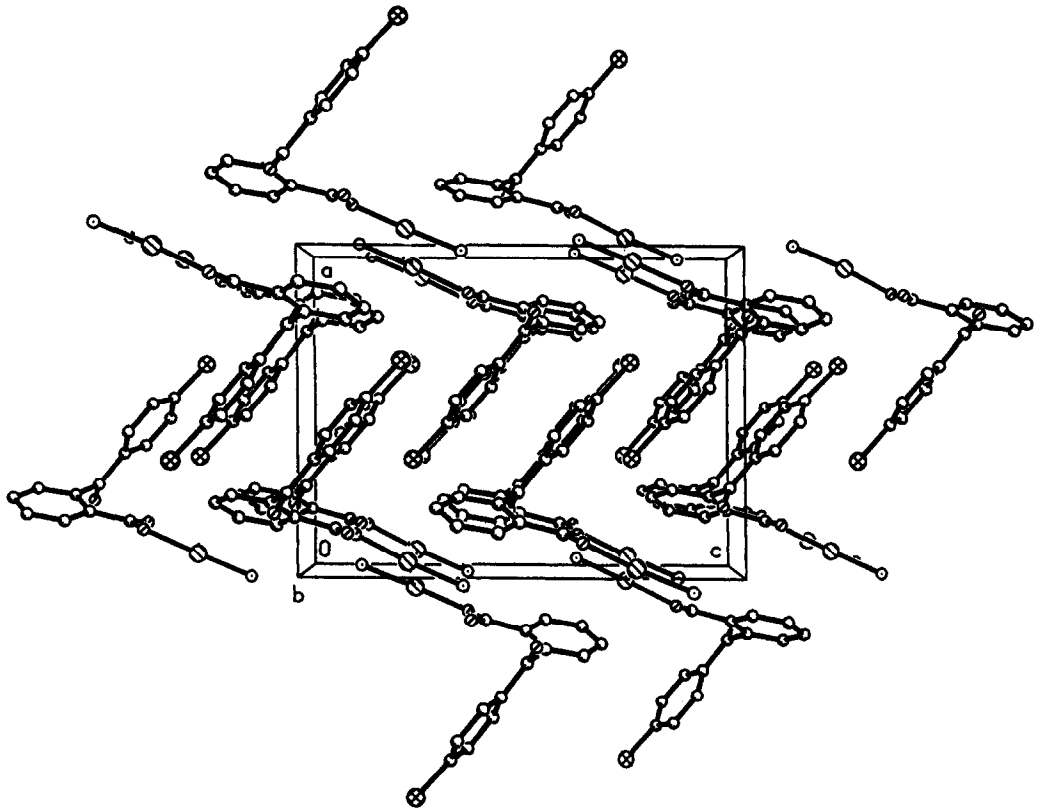

Fig. 2. Solid-state packing diagram of [(NH_3) · AgCBBA].

Table 3. Selected IR stretches (cm^{-1}) for [(NH_3) · AgCBBA] and [AgCBBA]

Complex	$\nu(NH_3)$	$\nu(C{=}O_{benzoyl})$	$\nu_{asym}(CO_2^-)$	$\nu_{sym}(CO_2^-)$
CBBA	—	1677	1682	—
[(NH_3) · AgCBBA]	3331, 3241, 3238, 3182	1661	1581, 1556	1377
[AgCBBA]	—	1657	1576, 1547	1382
$[Ag(NH_3)_2]_2SO_4$ [13]	3320, 3230, 3150	—	—	—

[$(NH_3$)AgCBBA] complex. On the other hand, the NH_3 stretches are quite similar to those reported for $[Ag(NH_3)_2]SO_4$ [13]. In addition, the weak absorptions seen in the spectrum of the [(NH_3) · AgCBBA] complex, but not in that of the ammine-free [AgCBBA] complex, in the 1600–1650 cm^{-1} region are most likely the δ (HNH) bands of NH_3. In addition, the NH_3 bands in the 3180–3330 cm^{-1} region are lost upon heating (see TGA results).

The *o*-benzoyl carbonyl stretch is in the same position for both [(NH_3) · AgCBBA] and [AgCBBA] complexes. Since the benzoyl carbonyl is not coordinated in the [(NH_3) · AgCBBA] complex, it may be concluded that this group is uncoordinated in the [AgCBBA] complex as well. The carboxylate carbonyl stretches in both complexes are very similar but not identical.

Thermal analysis of [(NH_3) · AgCBBA] *and* [AgCBBA] *complexes*

The thermal phase changes in the DSC of the [(NH_3) · AgCBBA] and [AgCBBA] complexes are the same, with the exception of the additional endothermic decomposition observed in the [(NH_3) · AgCBBA] complex centred at 186°C. Decomposition is confirmed in the TGA, (Fig. 3) by the observation of a weight loss at this temperature which is equivalent to one mole of NH_3 (6.1% = 23

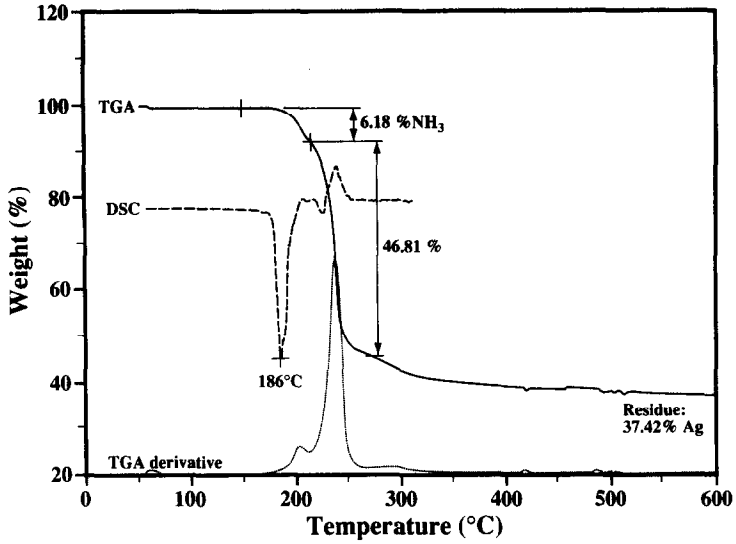

Fig. 3. DSC and TGA of [(NH_3) · AgCBBA].

amu), taking into account some convoluting of the NH_3 with subsequent weight losses. In addition, the IR spectrum of the [(NH_3) · AgCBBA] complex taken after cooling from heating past the first thermal transition (cooled from 200°C) clearly shows the loss of *ca* 100% of the ammine.

The TGAs of both complexes above 200°C are virtually superimposable, including the main decomposition in both cases (centred at *ca* 240°C) which is equivalent to *ca* 185 amu, and suggest a very similar species. Unfortunately, this latter mass does not readily correlate to identifiable fragments. Convoluted decomposition is not surprising in the case of [(NH_3) · AgCBBA] since the sample is still black at 600°C and the theoretical weight for residual Ag° is 28.3% (compared with the observed 37.4%), but the silvery residue in the ammine-free [AgCBBA] case should be 29.5%, which is quite close to the observed 30.3%.

Acknowledgements—We are grateful to R. Gould and C. Spicer (3M Analytical & Properties Research Laboratory) who obtained the IR spectra.

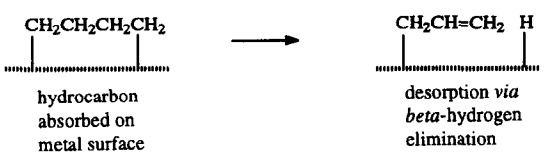
Reactivity studies on some η^1-alkenyl complexes of iron

Leoné Hermans and Selwyn F. Mapolie*

Department of Chemistry, University of the Western Cape, Bellville, 7535, South Africa

(Received 17 May 1996; accepted 13 June 1996)

Abstract—The η^1-alkenyl complexes $[\eta^5\text{-}C_5H_5(CO)_2Fe(CH_2)_nCH{=}CH_2]$ (n = 2 and 3) have been prepared by the reaction of $Na[\eta^5\text{-}C_5H_5(CO)_2Fe]$ with 4-bromo-1-butene and 5-bromo-1-pentene respectively. The reactivity of the σ-olefin complexes in hydrogenation, hydroboration and hydroformylation reactions are reported as are reactions with Lewis acids such as $TiCl_4$ and the electrophile HCl. Copyright © 1996 Elsevier Science Ltd



Keywords: iron-alkenyl; σ-olefins; iron-butenyl; iron-pentenyl; reactivity; functionalised-alkyls.

η^1-Alkenyl complexes are compounds in which an alkene ligand is bonded to a metal centre *via* a M—C σ bond. This class of compounds has the general formula shown below:

$L_nM{-}(CH_2)_y$ ⟋⟍

(L_nM = metal and its associated ligands)

With the exception of the allyl complexes [1,2] i.e. compounds where $y = 1$ in the above structure, not many examples of these complexes have been reported in the literature. This is quite surprising since these η^1-alkenyl complexes have often been implicated as potential model compounds for intermediates in a number of catalytic cycles involving transition metals as catalysts. Thus, for example, they could be models for hydrocarbons absorbed onto a catalytic metal surface in a process such as the Fischer–Tropsch reaction. In particular, they could represent hydrocarbon fragments at the stage at which desorption of these organic fragments from the catalyst surface occurs *via* β-hydrogen elimination.

Again with the exception of the allyl complexes, there is a great paucity of information with regard to the reactivity of these compounds. Very little indeed has been reported on the reactivity of the longer-chain alkenyl compounds of iron in particular. We have encountered only two reports [3,4] in which the iron–butenyl compound is briefly mentioned. It is in light of this that we embarked on our investigation of the reactivity of some iron complexes of the type $Cp(CO)_2Fe(CH_2)_nCH{=}CH_2$ ($Cp = \eta^5\text{-}C_5H_5$). We now report on some of these results.

EXPERIMENTAL

All reactions were performed under dry nitrogen using standard Schlenk tube techniques to manipulate air-sensitive compounds. $[CpFe(CO)_2]_2$, purchased from Strem Chemicals and the n-bromo-1-alkenes, purchased from Aldrich, were used without further purification. $HRh(CO)(PPh_3)_3$ [5] and $ClRh(PPh_3)_3$ [6] were prepared *via* literature methods. Tetrahydrofuran and hexane were distilled from sodium/benzophenone ketyl under nitrogen. Dichloromethane was dried by refluxing over P_2O_5 and distilling under nitrogen.

Infrared spectra were recorded on a Perkin–Elmer, Paragon 1000 FT-IR spectrophotometer and NMR spectra on a Varian EM 390 or a Varian VXR 200 spectrometer operating at 90 MHz and 200 MHz respectively. Tetramethylsilane was used as an internal standard (δ 0.00 ppm) for ^1H spectra while ^{13}C signals were measured relative to $CHCl_3$. Mass

* Author to whom correspondence should be addressed.

spectra were recorded on a V.G. Micromass 16F spectrometer operating at 70 eV and using an accelerating voltage of 4 kV. Microanalyses were performed by the microanalytical laboratory at the University of Cape Town.

Preparation of $Cp(CO)_2Fe(CH_2)_nCH{=}CH_2$, $n = 2$ *and* 3, *i.e. compounds* **1** *and* **2**

A solution of $[CpFe(CO)_2]_2$ (1 g, 2.83 mmol) in tetrahydrofuran (20 cm^3) was stirred over a sodium amalgam (0.2 g Na in 3 cm^3 Hg) for 2 h at room temperature. The resulting solution of $Na[CpFe(CO)_2]$ (5.68 mmol) was transferred using a syringe to a Schlenk tube, and the *n*-bromo-1-alkene, $CH_2{=}CH(CH_2)_nBr$, ($n = 2$ or 3) (5.86 mmol) was added dropwise with stirring. The resulting green-brown reaction mixture was stirred for 2 h at room temperature. The solvent was removed to give a green residue which was extracted with CH_2Cl_2 (2×30 cm^3) and filtered. The filtrate was evaporated on a rotary evaporator resulting in a yellow-brown oily residue. This was dissolved in a minimum of hexane and the solution chromatographed on an alumina column (10×2.5 cm). A yellow band was eluted with hexane and removal of the solvent gave the η^1-alkenyl compound as a yellow oil. The crude oil was purified by low temperature (-78°C) recrystallisation from hexane. Thus the crude oil was dissolved in a minimum of hexane in a Schlenk tube under nitrogen and the resulting yellow solution cooled to -78°C. This result in the formation of a yellow solid. The supernatant liquid was removed using a syringe and the yellow solid washed with ice-cold hexane (2×10 cm^3). The washings were also syringed off. On allowing the solid to warm up to room temperature, it melted giving a yellow-brown oil. This was then dried under reduced pressure. Yields and characterization data are given in Table 1.

Hydrogenation of $Cp(CO)_2Fe(CH_2)_nCH{=}CH_2$, $n = 2$ *and* 3

$ClRh(PPh_3)_3$ (0.02 g, 0.022 mmol) was dissolved in dichloromethane (2 cm^3). Hydrogen gas was bubbled through the solution for 30 min in order to activate the catalyst. A solution of the iron–alkene complex (0.64 mmol) dissolved in dichloromethane (5 cm^3), was added to the catalyst solution. The resulting mixture was allowed to stir under hydrogen for 2 h at room temperature after which the solvent was removed under reduced pressure. This resulted in the formation of a yellow-brown oil. The residue was dissolved in a minimum of hexane and then chromatographed on an alumina column (5×2.5 cm). A pale yellow band was eluted with pure hexane and gave a yellow-orange oil on removal of the solvent. Recrystallisation from hexane at -78°C gave a bright yellow solid which melts to a yellow-brown oil on warming to room temperature. The product was identified as the corresponding iron alkyl compound **3** or **4**, yields 60% and 54% respectively.

Oxidative hydroboration of the iron–alkenyl complexes

The oxidative hydroboration of the iron–butenyl compound **1**, is described to illustrate the procedure used for the iron alkenyl compounds in general. **1** (0.22 g, 0.90 mmol) was dissolved in THF (3 cm^3) in a Schlenk tube under nitrogen. The solution was cooled to 0°C and BH_3 (0.9 cm^3 of 1 M solution in THF) was added dropwise. The solution changes colour from yellow to dark greenish-yellow. The mixture was allowed to warm up to room temperature and then stirred for a further 1.5 h at this temperature. Water (2 drops) was added followed by 3 M NaOH (0.60 cm^3). The dark green-brown solution was treated dropwise with 30% H_2O_2 (0.20 cm^3). This results in the reaction mixture changing colour to light yellow. The resulting mixture was then refluxed for 1 h after which it was allowed to cool to room temperature. Any undissolved salts were filtered off. The filtrate was dried over $MgSO_4$. The mixture was filtered and the solvent removed, leaving a yellow-brown oil. The residue was redissolved in a minimum of CH_2Cl_2 and the solution chromatographed on an alumina column (2.5×2 cm). Elution with CH_2Cl_2 results in a two yellow bands *viz.* a pale yellow band moving with the solvent front and a second, more intense yellow band moving much slower. The first band was identified as the starting material, while the second band was found to be the hydroboration-oxidation product **5**, in 70% yield.

The hydroboration of **2** was carried out in a similar manner yielding compound **6** as product in 64% yield.

Hydroformylation of compounds **1** *and* **2**

The method for the hydroformylation of the iron–pentenyl compound **2** is described here but the procedure has also been applied with equal success to the iron–butenyl compound **1**.

The hydroformylation catalyst, $HRh(CO)(PPh_3)_3$ (0.063 g, 0.04 mmol) was dissolved in THF (5 cm^3) in a Schlenk tube. Synthesis gas ($CO : H_2$; 1 : 1) was bubbled through the solution for 10 min. A solution of **2** (0.33 g, 1.30 mmol) in THF (4 cm^3) was added to the catalyst solution and the mixture refluxed for 3.5 h under an atmosphere of syngas. The yellow reaction mixture turns dark brown during this period. After cooling to room temperature, the solvent was removed on a rotary evaporator leaving a brown oil. This was dissolved in a minimum of hexane and the solution chromatographed on an alumina column (2.5×5 cm), made up in hexane. Three components were observed, the first of which was eluted with pure hexane. Removal of the solvent results in a pale yellow oil which was identified as unreacted starting material

(32%). The second dark yellow band was eluted using a 1 : 1 hexane–dichloromethane mixture. On removing the solvent, a yellow-brown oil was obtained. This was identified as the aldehyde compound **8** (42% yield). The last yellow fraction was eluted with pure dichloromethane. Removal of the solvent resulted in a pale yellow oil which was found to be the ω-hydroxyhexyl species **9** (18% yield).

The corresponding iron–butenyl compound **1**, undergoes a similar reaction to yield **6** and **7** as the major products in 22 and 48% yields, respectively.

Reaction of **1** *with* $TiCl_4$

Compound **1** (0.2 g, 0.86 mmol) was dissolved in hexane (5 cm^3). To this was added dropwise a solution of $TiCl_4$ (0.15 cm^3, 1.37 mmol) in hexane (5 cm^3). The solution changes colour from bright yellow to dark brown almost immediately. The mixture was allowed to stir at room temperature for 1.5 h. During this time, the reaction mixture goes darker with a black precipitate forming. Methanol (2 cm^3) was added to the reaction mixture with rapid stirring which was continued for a further 15 min at room temperature. The solvent was removed from the reaction mixture leaving a dark brown oily residue. The oil was dissolved in a small amount of dichloromethane and the resulting solution chromatographed on an alumina column (2.5 × 5 cm) made up with dichloromethane. Elution with dichloromethane gave an orange-yellow band which on removal of the solvent from the eluent, yielded an orange-yellow solid. This was identified as the metallocycle **10** (60%, yield). A second yellow band yielded a small amount of a pale yellow solid which showed no ν(CO) bands in its IR spectrum. A third faint yellow band could not be eluted from the column.

Reaction of iron–alkenyl compounds with HCl

The reaction of **1** with HCl is outlined below; but again this procedure can be extended to compound **2**.

1 (0.15 g, 0.65 mmol) was dissolved in dry hexane (5 cm^3) at −20°C. Anhydrous HCl gas was bubbled through the solution for 1 h at this temperature. During this time the solution goes orange-red with an oily substance being deposited on the walls of the reaction flask. The solvent together with the excess HCl was removed *in vacuo*, resulting in an orange-red sticky residue. This was dissolved in a minimum of dichloromethane and the solution filtered by gravity. Hexane was carefully layered onto the filtrate until the mixture went cloudy. Cooling the mixture to −5°C resulted in the formation of a brick-red precipitate which was filtered off and identified as $CpFe(CO)_2Cl$ (90% yield).

A similar reaction using compound **2** as starting material resulted in the same product in 84% yield.

RESULTS AND DISCUSSION

The iron–butenyl compound **1** and the iron–pentenyl species **2** were isolated as yellow-brown oils from the reaction of $Na[CpFe(CO)_2]$ with 4-bromo-1-butene and 5-bromo-1-pentene, respectively.

$$Na[CpFe(CO)_2] + CH_2{=}CH(CH_2)_nCH_2Br \rightarrow Cp(CO)_2FeCH_2(CH_2)_nCH{=}CH_2 \quad (1)$$

1 $n = 1$
2 $n = 2$

Compounds **1** and **2** are both air and light sensitive. The decomposition of the compounds is further accelerated in solution, especially in the presence of air. They can however be stored for several weeks if kept at −20°C and in the absence of air and light. Both compounds were characterized by IR, ^1H and ^{13}C NMR spectroscopy as well as by elemental analysis. The characterization data are given in full in Table 1.

The IR spectra of the compounds in the ν(CO) region resemble those of the corresponding alkyl compounds with the general formula, $CpFe(CO)_2R$ (R = alkyl), showing two sharp bands at 1999 and 1949 cm^{-1}. The examination of the ^1H NMR spectra of both compounds clearly show the characteristic olefinic protons being present around δ 4.90 and δ 5.80 ppm.

Reactivity of the iron–alkenyl complexes

Most of the reactions described below were carried out on both the butenyl and the pentenyl compounds.

(*a*) *Catalytic hydrogenation of* **1** *and* **2**. It is well known that unsaturated hydrocarbons such as alkenes and alkynes undergo facile hydrogenation in the presence of Wilkinson's catalyst [6,7]. We thus considered it feasible that the iron–alkenyl compounds would also undergo a similar reaction. Under the relatively mild conditions employed one would expect that the Fe—C bond to remain intact and not to be susceptible to reductive elimination in the presence of hydrogen. We find that this is indeed the case. We observe that even refluxing the reaction mixture at temperatures between 40 and 50°C, results only in the hydrogenation of the pendant alkene functional group. The Fe—C bond is not affected under these conditions. The hydrogenation process results in the complete conversion of the iron–alkenyl compounds to the corresponding alkyl compounds, **3** and **4**. The latter were characterized by comparing their characterization data with those of authentic samples prepared using methods reported in the literature [8,9].

[a] Calculated values in parentheses; [b] Neat film between NaCl plates; [c] $CDCl_3$ as solvent unless otherwise stated; [d] Prepared by the hydroboration of the Fp-butenyl compound (Fp = C_5 $H_5Fe(CO)_2$); [e] Prepared by the hydroboration of the Fp-pentenyl compound; [f] Prepared *via* hydroformylation of the Fp-pentenyl compound; *Data not obtained.

As stated earlier, under the reaction conditions employed no iron–carbon bond cleavage occurs. This is confirmed by the fact that the expected cleavage product, $CpFe(CO)_2H$ is not detected during the reaction. There is also no sign of the dimer, $[CpFe(CO)_2]_2$ which would be an indication of the presence of the hydride since the latter has the tendency to decompose to the dimer in the presence of air.

(*b*) *Hydroboration-oxidation reactions.* Olefinic hydrocarbons readily undergo hydroboration to produce organoborane species which can be oxidized to 1° alcohols. Both the iron–butenyl and iron–pentenyl compounds undergo facile hydroboration followed by *in situ* oxidation to produce a ω-hydroxyalkyl compound of this type, $Cp(CO)_2Fe(CH_2)_yCH_2OH$ where $y = 3$ and 4.

$$\begin{array}{l} Cp(CO)_2FeCH_2(CH_2)_nCH{=}CH_2 \xrightarrow{\text{(i)}} \\ \quad \mathbf{1}\ \ n = 1 \\ \quad \mathbf{2}\ \ n = 2 \end{array}$$

$$\xrightarrow[\text{(iii)}]{\text{(ii)}} Cp(CO)_2Fe(CH_2)_yCH_2OH$$

$$\begin{array}{l} \mathbf{5}\ \ y = 3 \\ \mathbf{6}\ \ y = 4 \end{array}$$

(i) $BH_3 \cdot THF$ (ii) H_2O_2 (iii) NaOH (3)

The intermediate borane compounds were not isolated but were oxidized *in situ*. There are thus no characterization details available for these compounds. The ω-hydroxyalkyls were however fully characterized and these details are outlined in Table 1. The IR spectra of both compounds show two strong bands in the ν(CO) region and are at positions similar to those of the starting iron–alkenyl compounds. This is an indication that the metal environment remains unaffected during the reaction. The full range IR spectra (4000–600 cm^{-1}) of both **5** and **6**, show a strong band around 3350 cm^{-1} which can be assigned to the O—H stretching frequency of the hydroxy functionalised alkyl species. The spectra also show the absence of any C=C stretching frequency around 1630 cm^{-1} which is present in the parent alkenyl species. This clearly indicates that unsaturation is no longer present in the hydrocarbon chain of the products.

Only the mass spectrum of compound **6** shows a molecular ion, whereas that of **5** shows the highest mass peak representing the species M^+—CO. In both cases there appear to be two fragmentation patterns. The one involves initially the sequential loss of the terminal carbonyl groups from the parent ion followed by the loss of the hydroxy group of the alcohol functionality. This is then followed by the elimination of the hydrocarbon chain. The second fragmentation route again involves the initial loss of the terminal CO groups. However, in this case the hydroxy group is only eliminated after the loss of the aliphatic chain.

Table 2. Mass spectral data for the compounds $Cp(CO)_2Fe—(CH_2)_yCH_2OH$, **5** and **6**

Ion[a]	Relative peak intensities 5[b]	6[c]
M	—	2
M—CO	06	7
M—2CO	30	25
M—2CO—OH	08	04
M—2CO—H_2O	16	26
M—2CO—OH—$C_{1/2n}H_n$	14	—
M—2CO—OH—C_nH_{2n}	61	100
M—2CO—OH—C_nH_{2n}—Cp	42	15
M—2CO—C_nH_{2n}	100	96
M—2CO—Cp	22	33
M—2CO—Cp—OH	03	05
M—2CO—Cp—H_2O	51	23
M—2CO—Cp—H_2	02	05
M—2CO—Cp—$C_{1/2n}H_n$	03	—
M—2CO—Cp—C_nH_{2n}	02	05

[a] M = $Cp(CO)_2Fe(CH_2)_yCH_2OH$, Cp = η^5-C_5H_5; all ions have a single positive charge, ion refers to suggested assignment.

[b] Peak intensities relative to $m/z = 138$.

[c] Peak intensities relative to $m/z = 121$.

The full assignment of the various peaks in the mass spectra is given in Table 2.

(*c*) *Hydroformylation of compounds* **1** *and* **2.** The compound $HRh(CO)(PPh_3)_3$ is a well known hydroformylation catalyst and has been used to promote the hydroformylation of normal alkenes at room temperature and ambient pressure [10, 11]. It is for this reason that we employed this compound in the attempted hydroformylation of the metal–alkenyl compounds. The iron–alkenyl compounds were subjected to hydroformylation at atmospheric pressure at both 25°C and at 70°C. Both **1** and **2** undergo hydroformylation to some extent in each case a mixture of the hydroxy functionalised and aldehydic functionalised iron alkyl compounds were isolated together with some unreacted starting material.

$$\begin{array}{l} CpFe(CO)_2FeCH_2(CH_2)_nCH{=}CH_2 \\ \quad \mathbf{1}\ \ n = 1 \\ \quad \mathbf{2}\ \ n = 2 \end{array}$$

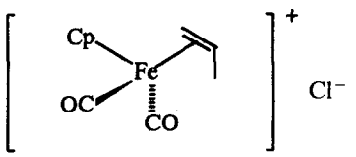
$$\xrightarrow[\text{THF}]{H_2/CO} Cp(CO)_2FeCH_2(CH_2)_{n+1}CH_2CHO$$

$$\begin{array}{l} \mathbf{7}\ \ n = 1 \\ \mathbf{8}\ \ n = 2 \end{array} \qquad (4)$$

$$+$$

$$\begin{array}{l} Cp(CO)_2FeCH_2(CH_2)_{n+1}CH_2CH_2OH \\ \mathbf{6}\ \ n = 1 \\ \mathbf{9}\ \ n = 2 \end{array}$$

Both the aldehyde and the alcohol are obtained



irrespective of the temperature at which the reaction is performed at room temperature or at 70°C. However, the selectivity to the alcohol is increased when the reaction is allowed to proceed at the higher temperature. This is in line with what normally occurs in the case of the hydroformylation of conventional alkenes. We also detect small amounts of the hydrogenation product i.e. the iron–alkyl species but this is less than 10% in both cases. The products obtained in these reactions are all new and the characterization details are given in Table 1. The alcohol obtained using compound **1** as starting material is the same as the compound obtained when **2** is subjected to oxidative hydroboration. The stability of alcohol **8** appears to be lower than the homologous compound **6,** decomposing rapidly when in solution and in the absence of nitrogen. Both the alcohols and the aldehydes were isolated as yellow-brown oils.

The aldehydes obtained in these reactions are also not very stable in solution. It can be stored for only short periods (a couple of days), even at −20°C and in the absence of air.

Reaction of compounds **1** *and* **2** *with* HCl

Green and Nagy [1], have shown that the iron–alkyl compound, $Cp(CO)_2Fe—CH_2CH=CH_2$, undergoes a facile reaction with mineral acids such as HCl to produce a cationic complex in which the allyl group undergoes rearrangement to be bonded in a η^2 fashion as shown below.

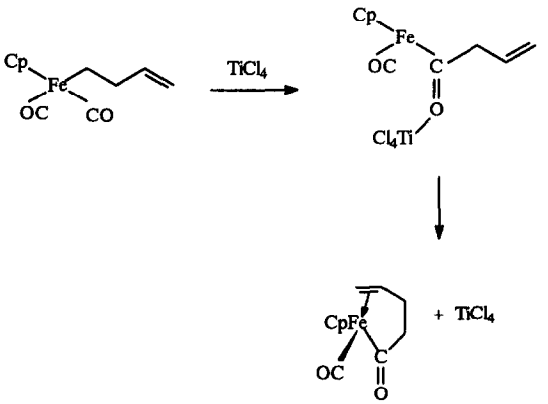
$$Cp(CO)_2Fe—CH_2CH=CH_2 \xrightarrow{HCl}$$

(5)

We attempted similar reactions with the homologous iron–butenyl and iron–pentenyl complexes to investigate whether related cationic species as above would be obtained. In our hands, we found that the longer chain alkenyl compounds to not yield the η^2 cationic species, but rather undergo iron–carbon bond cleavage to produce $CpFe(CO)_2Cl$ and the chloroalkene.

$$Cp(CO)_2FeCH_2(CH_2)_nCH=CH_2 \xrightarrow[20°C]{HCl}$$

1 $n = 1$
2 $n = 2$



$$CpFe(CO)_2Cl + ClCH_2(CH_2)_nCH=CH_2 \qquad (6)$$

The above cleavage reactions occur even under mild conditions such as low temperatures of −20°C. The organometallic product of the reaction was identified by comparing its IR and ^1H NMR spectra with that of an authentic sample [12]. The organic products were identified by GC analysis of the reaction mixture.

In both reactions we observed no evidence for electrophilic interactions between HCl and the double bond of the pendant alkene ligand.

Reaction of **1** *with* $TiCl_4$

The reactivity of the iron–butenyl compound with a Lewis acid such as $TiCl_4$ was investigated. The rationale behind this reaction was to attempt the coordination of the pendant alkene to the titanium centre. This unfortunately did not occur; instead the $TiCl_4$ acted as a Lewis acid promoter of alkyl migration leading to a coordinatively unsaturated iron centre (see below). This unsaturated species undergoes intramolecular cyclization in which the pendant alkene moiety coordinates to the iron centre in a η^2 fashion. The species isolated from this reaction has previously been isolated and characterized by Green and Smith [3] as a decomposition product of the iron–butenyl compound.

We observe a similar reaction if $AlCl_3$ is employed instead of $TiCl_4$ supporting our contention that the conversion to the cyclic acyl species is promoted by a Lewis acid. In the case of the pentenyl compound, we do not observe the formation of an analogous cyclic compound, instead the only product isolated is $CpFe(CO)_2Cl$.

CONCLUSION

The iron–alkenyl compounds have proved to be valuable starting materials to new functionalised alkyl complexes of iron. They have thus successfully been employed to produce iron–borane compounds as well as new hydroxy and aldehydic functionalised complexes. We are at present investigating the reactivity as well as the thermal properties of these new functionalised iron alkyls.

COMMUNICATION

Esterolytic activity of metal complexes of 2,6-diacetylpyridine dioxime

Paola Gómez Tagle and Anatoly K. Yatsimirsky*

Facultad de Química, Universidad Nacional Autónoma de México (UNAM), México D.F., 04510 México

(Received 10 May 1996; accepted 17 July 1996)

Abstract—The rate constants of the cleavage of 4-nitrophenyl acetate ($4\text{-}O_2NC_6H_4O_2CCH_3$) by the complexes of 2,6-diacetylpyridine dioxime with Ni^{II}, Hg^{II}, Zn^{II}, Pb^{II}, Mn^{II} and Cd^{II} range from 2 to *ca* 6000 times higher than that of the free ligand under the same conditions. Complexation of the oxime ligand with Co^{II} and Cu^{II} does not affect the reaction rate. The complex with Cd^{II} operates in a catalytic regime with respect to the oxime ligand. The activities of the complexes with different metals, excluding Co^{II}, correlate with those of metallocarboxypeptidases towards an ester substrate. Copyright © 1996 Elsevier Science Ltd

Keywords: ester hydrolysis; oxime; metal complexes; catalysis.

Catalytic properties of metal-substituted hydrolytic metalloenzymes were studied with the aim of clarifying the role of the metal centre in substrate activation [1]. The interpretation of such results is not straightforward, however, and a similar study with a model system would help to find a reasonable approach. In this communication we report the esterolytic activity of a series of metal complexes of 2,6-diacetylpyridine dioxime (H_2dapd). We chose this ligand for three reasons. Firstly, because earlier, the esterolysis by the zinc(II) [2,3] and palladium(II) [4] coordinated oxime group was studied as a mimic of acyl transfer enzyme mechanism. Secondly, because it usually forms tridentate complexes with the fourth position occupied by a solvent molecule or a counter ion [5], thus repeating a coordination motif typical of many zinc enzymes [6]. Finally, because it should form more stable metal complexes than the previously employed bidentate 2-pyridinealdoxime [2], allowing study of a wide series of metal cations in neutral and weakly basic aqueous solutions without concomitant cation hydrolysis and/or precipitation of hydroxides.

H_2dapd was synthesized from 2,6-diacetylpyridine (Aldrich) and hydroxylamine *via* a modified procedure of ref. [5c]. 4-Nitrophenyl acetate (NPA, Aldrich) was purified by recrystallization from acetic acid–ethyl acetate. The reaction course was monitored by the appearance of 4-nitrophenolate anion using a Hewlett–Packard 8452A diode array spectrophotometer equipped with a thermostatted cell holder. Owing to the low solubility of H_2dapd all solutions contained 24% (v/v) ethanol. Stock solutions of NPA were prepared in dry acetonitrile. Kinetic measurements normally used 4×10^{-5} mol dm^{-3} NPA and varied concentrations of metal salts and H_2dapd in 0.01 mol dm^{-3} BisTris or borate buffer solutions (used at appropriate pH intervals) with ionic strength 0.1 mol dm^{-3} (NaCl) at 25°C. The pseudo-first-order rate constants (k_{obs}) were calculated by the integral method, or, for slow reactions, from initial rates.

Kinetics of the cleavage of NPA by free H_2dapd was first order in both NPA and H_2dapd, the second-order rate constant being directly proportional to the OH^- concentration in pH range 7.92–9.94. Spectrophotometric titration of H_2dapd revealed the values $pK_{a1}^{LH} = 11.15$ and $pK_{a2}^{LH} = 11.74$ (no statistical

(Received 14 June 1996; accepted 31 July 1996)

Abstract—Centrosymmetric $[(\mu\text{-}Me_2Sn)_2(\mu\text{-}IMe_2Sn)_2(\mu\text{-}OEt)_2(\mu_3\text{-}O_2)]$ (**3**), obtained from 1,2:5,6-di-*O*-isopropylidene-3-*C*-iododimethylstannyl-α-D-allofuranoside on solvolysis in aqueous EtOH, has a ladder structure, made up of three fused Sn_2O_2 rings. There are two pairs of distinct five-coordinate tin centres in **3**. The ethoxide ligands bridge the two distinct Sn centres essentially symmetrically [Sn(1)—O(2) and Sn(2)—O(2) = 2.171(6) and 2.178(6) Å]. In centrosymmetric, solid $[(\mu\text{-}Me_2Sn)_2\{\mu\text{-}(PrCO_2)Me_2Sn\}_2(\mu\text{-}PrCO_2)_2(\mu_3\text{-}O)_2]$ (**4**) obtained from Me_2SnCl_2 and $CH_3CH_2CH_2CO_2H$ in H_2O, there are also two distinct tin sites. The Sn(1) atoms are bonded to 2 C and 4 O atoms, with tin–oxygen bond lengths between 2.027(6) and 2.712(8) Å. The immediate coordination sphere of Sn(2) consists of 2 C and 3 O [Sn(2)—O bond lengths between 2.020(5) and 2.216(11) Å]; there are also intramolecular, Sn(2)—O(5) [2.990(12)], and intermolecular, Sn(2)—O(5^{ii}) [3.109(11) Å] contacts. The core of the structure of **4** is a five rung ladder, made up of Sn_2O_2 rings, with additionally two side rings, composed of Sn_2O_3C units. Copyright © 1996 Elsevier Science Ltd

Keywords: organotin; crystal structure; carboxylate; organotin oxycarboxylate.

The Sn_2O_2 planar ring is a commonly found structural feature in organotin oxides and related compounds. In a search through the Cambridge Crystallographic Data Base (in Spring, 1996) over 130 compounds had been listed having this fragment. About 40 of these compounds were of the dimeric tetraorganodistannoxane type, $[(\mu\text{-}R_2Sn)_2(\mu\text{-}XR_2Sn)_2(\mu\text{-}Y)_2(\mu_3\text{-}O)_2]$ (**1**; X and Y = univalent anions).[1,2] For compounds (**1**, X = OH, Cl or NCS; Y = OH or Cl), the solid-state structure is the ladder structure [1b,1f, 3], illustrated in Fig. 1. For compounds in which X and Y are chelating anions, e.g. as in (**1**, X = Y = carboxylate), the structures are modified as a consequence of the bidentate nature of these ligands [1a, c]; for (**1**, X = Y = O_2CR) different structural motifs have been identified [2], one frequently found is that shown in Fig. 2.

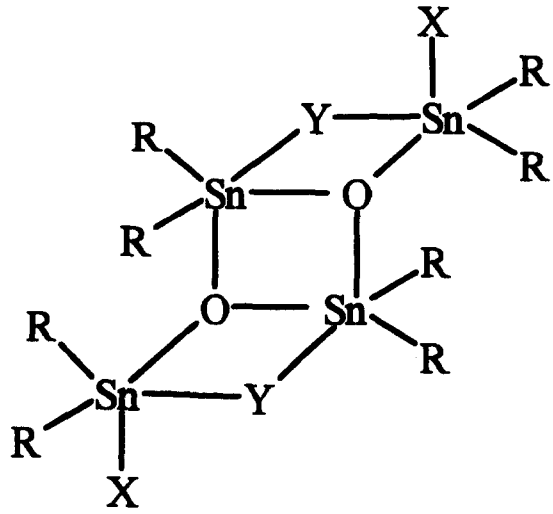

Fig. 1.

The oxyhalides are generally obtained by partial hydrolysis of diorganotin dihalides [4]. We have found that the stannylated carbohydrate 3-(iododimethylstannyl)-1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**2**) undergoes solvolysis in 95% ethanol to provide $[(\mu\text{-}Me_2Sn)_2(\mu\text{-}IMe_2Sn)_2\ (\mu\text{-}OEt)_2(\mu_3\text{-}O)_2]$ (**3**). Compound **3** is the first reported compound of type **1** to contain iodide and ethoxide groups. We now report the structure (and stability) of **3**. The

* Author to whom correspondence should be addressed.

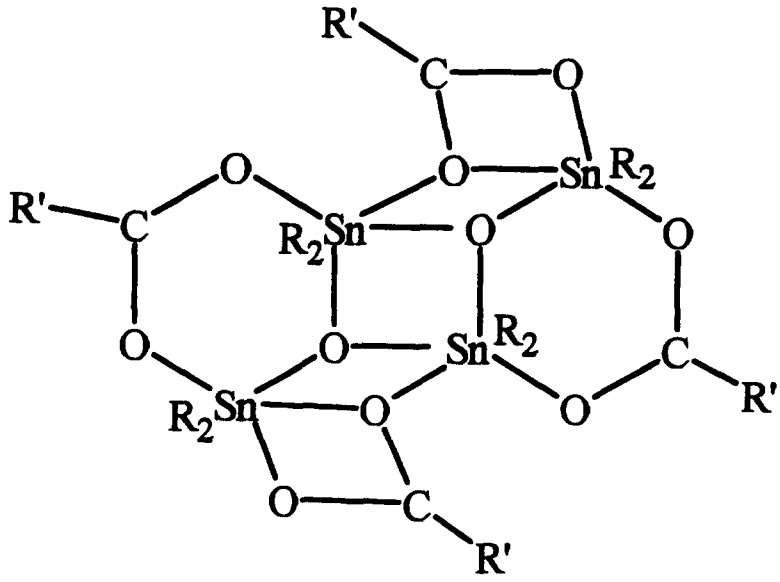

Fig. 2.

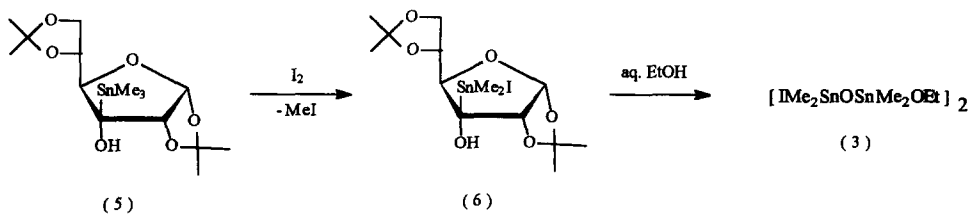


crystal structure of $[(\mu\text{-}Me_2Sn)_2\{\mu\text{-}(PrCO_2)Me_2Sn\}_2(\mu\text{-}PrCO_2)_2(\mu_3\text{-}O)_2]$ (**4**) has also been determined: **4** was obtained from the reaction of Me_2SnCl_2 and butanoic acid in water.

RESULTS AND DISCUSSION

Compound 3

Reaction of the stannylated carbohydrate **5** with equimolar I_2 in CCl_4 had been previously reported to produce **6** as the major tin-containing product; Me_3SnI was also obtained as a minor product [5]. Characterization of **6** was simply achieved from the NMR spectra data. Attempts to obtain a pure crystalline sample of **6** failed. Removal of all volatiles from the reaction mixture from **5** and I_2 and subsequent crystallisation of the resulting solid residue from 95% ethanol led to the isolation of crystalline **3**; the structure of solid **3**, a formal dimer of $[IMe_2Sn OSnMe_2OEt]$, was confirmed by X-ray diffraction (see later). Compound **3** is only sparingly soluble in $CDCl_3$ solution and only poorly resolved NMR spectra, e.g. without Sn—C coupling constants, were obtained. However, it was possible to detect from the ^1H and ^{13}C NMR spectra that two species (probably either different aggregates or stereoisomers) were present in $CDCl_3$ solution. For the OCH_2CH_3 units, there were two sets of δ^1H values [1.10 and 3.58 ppm (major compound) and 1.24 and 3.72 ppm (minor compound)], and two sets of $\delta^{13}C$ values [12.3 and 57.4 (major species) and 14.0 and 58.4 (minor species)]. In the ^1H NMR spectrum, three signals assignable to Me_2Sn groups were detected: these were at 0.96, 0.98 and 1.15 ppm, in the approximate ratio 6 : 1 : 5. It was possible to resolve these δ^1H values to give 0.96 and 1.15 ppm for the distinct Me_2Sn units of a major species and values of 0.98 and 1.15 ppm for those of a minor species. The ^{13}C NMR spectrum showed considerable complexity in the region 8–20 ppm, with $\delta^{13}C$ values of 8.1, 8.4, 9.4, 9.8, 18.1 and 19.7 ppm values. No compound of type **1**, having alkoxy groups, has been previously reported; aryloxy-containing compounds, $[(\mu\text{-}R_2Sn)_2(\mu\text{-}ArOR_2Sn)_2(\mu\text{-}OAr)_2(\mu_3\text{-}O)_2]$, however, have been prepared [3a] from $[R_2SnO]_n$ and ArOH. The $\delta^1H(Me_2Sn)$ values for $[(\mu\text{-}Me_2Sn)_2(\mu\text{-}ArOMe_2Sn)_2(\mu\text{-}Me_2Sn)_2(\mu\text{-}OAr)_2(\mu_3\text{-}O)_2]$ were 1.02 and 0.84 ppm (Ar = Ph) and 0.89 and 0.77 ppm (Ar = C_6H_4OMe-*p*); $\delta^{13}C(Me_2Sn)$ values were 2.4 and 4.5 ppm (Ar = Ph) and 5.2 and 7.2 ppm (Ar = C_6H_4OMe-*o*).

Compound **3** is considered to result from solvolytic cleavage of the tin–carbohydrate bond of **6**, on attempted recrystallization. The identification of the

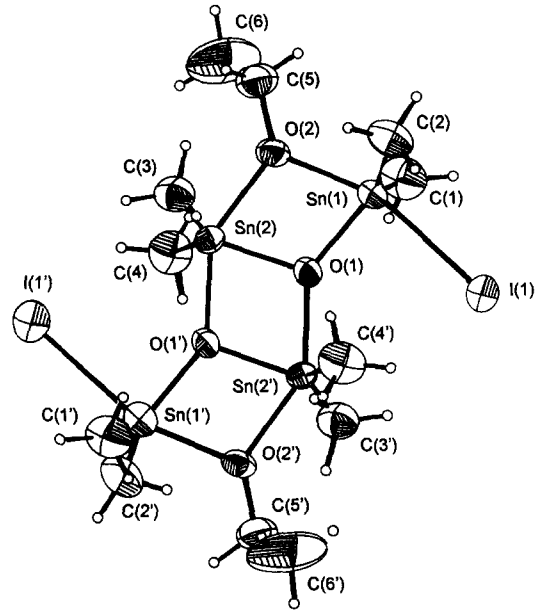
(5) (6) (3)

resulting sugar species was not attempted. Compound **3** itself is also unstable to hydrolysis. As shown by NMR spectra, **6** on storage in air or on further crystallizations from 95% EtOH loses ethoxide units with the formation of $[(\mu\text{-}Me_2Sn)_2(\mu\text{-}IMe_2Sn)_2(\mu\text{-}OH)_2(\mu_3\text{-}O)_2]$ [$\delta^1H(Me_2Sn)$ = 0.99 and 1.15 ppm].

A number of halodialkylstannyl-saccharide derivatives has also been found to be unstable on storage in moist air or on attempted recrystallization from protic solvents. Compound **3**, the first such "decomposition" product to be characterized, may well be representative of these hydrolysis products. Earlier we had reported [6] that the trimethylstannyl-saccharide 1,2:5,6-di-*O*-isopropylidene-3-*O*-[(trimethylstannyl)-methyl]-α-D-glucofuranose (**7**) on storage in air underwent decomposition to Me_3SnO_2CH, Eq. (1). The type of dealkylation and other transformations of the triorganostannyl-carbohydrates in aqueous/aerial environments are of significance when considering their biological activities.

Crystal structure of **3**. As a consequence of the complex solution NMR spectra of **3**, it was decided to undertaken an X-ray diffraction study. The crystal of **3** used in the X-ray diffraction study was obtained directly from the crystallization of the total solid residue isolated on evaporation of the reaction mixture from **5** and I_2 in $CHCl_3$ solution. The atom arrangements for **3** are shown in Figure 3; bond lengths and angles are listed in Table 1. The ethoxide groups, but not the iodides, act as bridging units. The ladder structure of centrosymmetric **3** possesses two distinct Sn sites: each Sn centre is five-coordinate. Sn(1) is bonded to two C, I and to two O and has a distorted trigonal bipyramidal geometry and EtO and I ligands in the axial sites: I—Sn(1)—O = 160.88(14)°. The sum of the equatorial angles about Sn(1) is 359.9(12)°. The Sn(1)—I(1) bond is appreciably longer [2.9458(14) Å] than the single Sn—I bond lengths found in tetrahedral organotin iodides (2.69–2.729 Å)[7]. The Sn(1)—O bond lengths are 2.014(5) and 2.171(6) Å.

A greater distortion from a trigonal bipyramidal geometry is found for Sn(2), which is bonded to two C and to three O atoms. The angles at tin range from 72.8(2) to 147.0(2)°, the largest angle [O(1')—Sn(2)—O(2), symmetry operation; (i) $1-x$, $-y$, $2-z$], being the quasi-axial angle. The sum of the equatorial angles about Sn(2) is 362.8(11)°. The Sn(2)—O bond lengths are in the range 2.051(5)–2.178(6) Å. The central $Sn(2)_2O_2$ ring has O—Sn—O and Sn—O—Sn bond angles of 74.2(2) and 105.8(2)°, respectively. The very near planar arrangement of the tin, iodide and oxygen atoms in **3** can be seen in Fig. 4, the carbon atoms being the only major atoms significantly out of the plane.



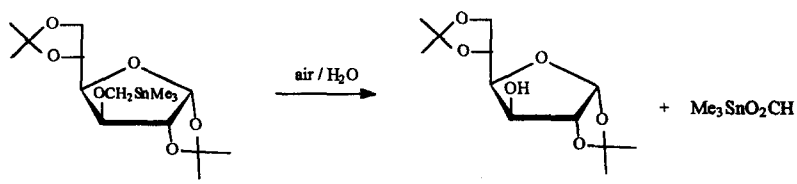


Fig. 3. Atom arrangements for **3**; ellipsoids are drawn at 40%.

The structure of the compound, $[(\mu\text{-}Bu_2Sn)_2[\mu\text{-}(o\text{-}MeOC_6H_4OBu_2Sn)\}_2$ $(\mu\text{-}o\text{-}MeOC_6H_4O)_2(\mu_3\text{-}O)_2]$ has also been reported [3a], this compound, which contains both bridging and nonbridging aroxy ligands, has a similar structure to that of **3**, with the nonbridging aroxy groups replacing the iodide units in **3**.

Compound **4**

Compound **4** was required for a study on the encapsulation and release of organotin species from controlled-release systems, based on metal carboxylate glasses [8]. It was prepared from Me_2SnCl_2 and butanoic acid in H_2O. Compound **4** is a further example of a compound with the general formula $[(R_2Sn)_4(R'CO_2)_4(O)_2]$. The NMR spectra of **4** in $CDCl_3$ solution indicated only a single species, with two different Me_2Sn sites. Figure 5 shows the atom arrangements for **4** in the solid state for a crystal

Symmetry operations: (i) $1-x, -y, 2-z$.

grown from MeOH solution; it has the general type of structure shown in Fig. 2. Selected bond lengths and angles are listed in Table 2.

Many of the previously reported [2] $[(R_2Sn)_4(R'CO_2)_4(O)_2]$ compounds, as the one here, have triclinic unit cells. The tetra-tin molecule **4** is centrosymmetric and contains two distinct tin atoms. The Sn(1) atom is bonded to two carbon and to four oxygen atoms, the longest Sn—O bond is that to O(4^{i}) [Sn(1)—O(4^{i}) = 2.712(8) Å, symmetry operation, (i) $1-x, 1-y, 1-z$], while the others are between 2.027(6) and 2.296(10) Å. The immediate coordination sphere of Sn(2) consists of two C and three O atoms, with Sn(2)—O bond lengths of 2.020(5) to 2.216(11) Å. There are, in addition, an intra-dimer contact, Sn(2)—O(5) [2.990(12) Å], and an inter-dimer contact, Sn(2)—O(5^{ii}) [3.109(11) Å, symmetry operation (ii), $1-x, 1-y, -z$]. Although these are clearly much weaker interactions, these are considered to be significant. There are two pairs of carboxylate groups: one is bidentate and bridges Sn(1) and Sn(2), while the other is chelated to Sn(2) atom and is bonded to Sn(1), within the molecule, and also is linked to a Sn(2) centre of an adjacent molecule. There are reports of other $[(Me_2Sn)_4(RCO_2)_4(O)_2]$ (e.g. R = CF_3 and CH_2Cl) having weak molecule–molecule

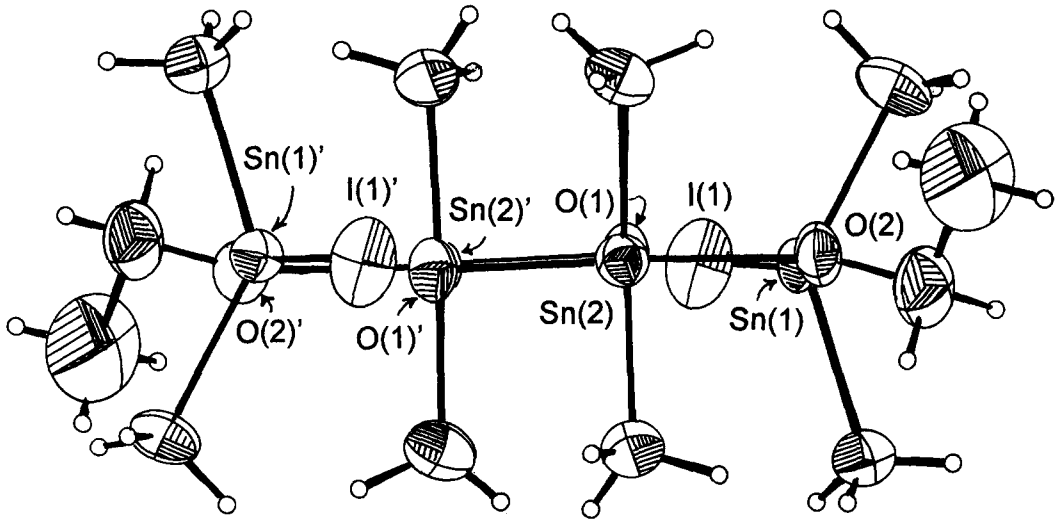

Fig. 4. View of the near planar arrangement of Sn, I and O atoms in **3**.

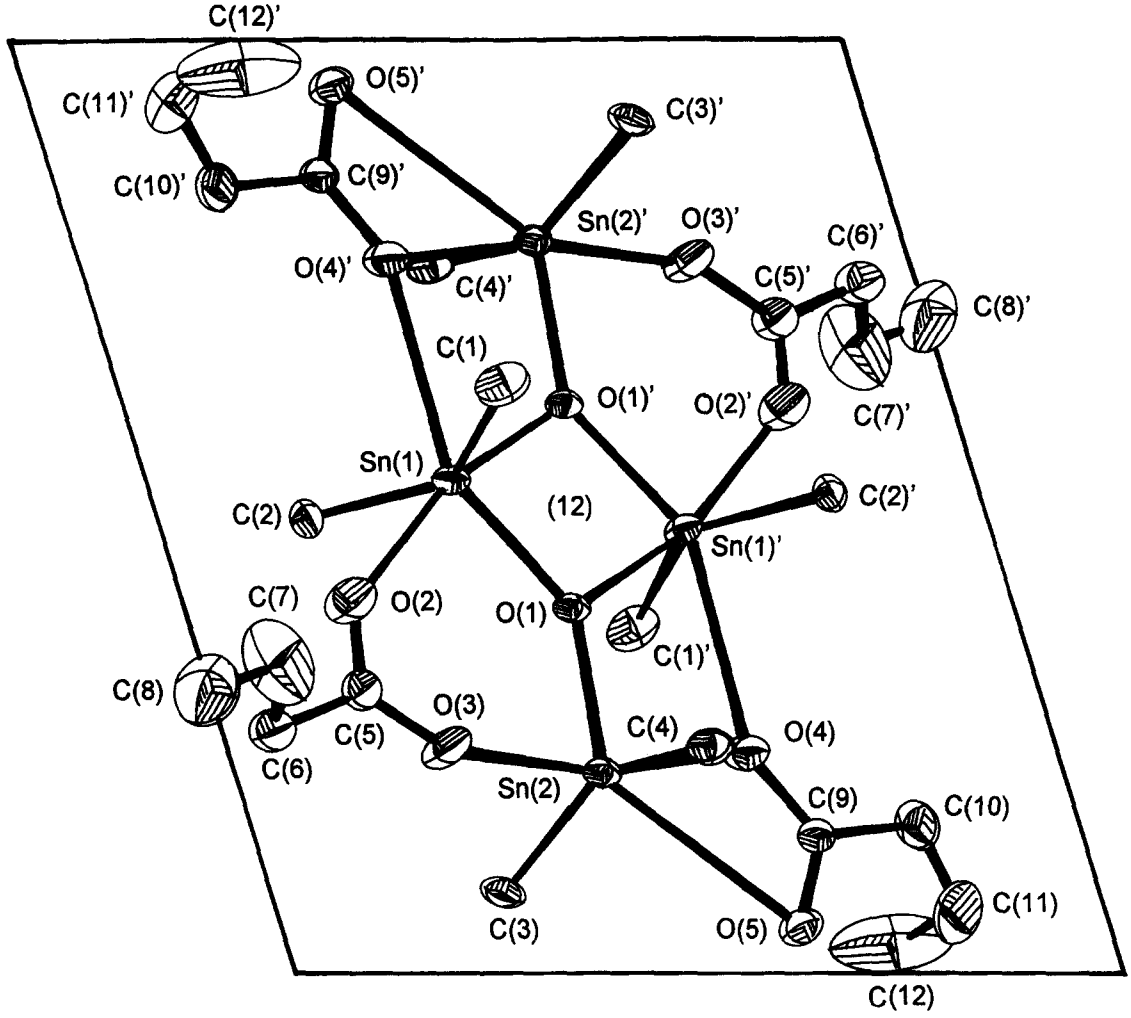

Fig. 5. The cell of **4** showing atom labels and 40% probability ellipsoids. The direction of view is along *b* (down into the page) and *x* and *z* as shown are the projections of *b* and *c*. H atoms have been omitted for clarity.

links with Sn—O connections between 3.0 and 3.2 Å [9]. Such interactions connect the tetra-nuclear molecules into chains running parallel to *c*. A stronger inter-molecule Sn—O interaction [2.56(1) Å] was reported [10] for the less symmetric $[(Me_2Sn)_4(AcO)_4(O)_2]$. The angles in the central Sn_2O_2 ring in **4** are 76.8(3) and 103.2(3)°.

The geometry of the molecule as a whole can be discussed in terms of displacements from the plane defined by the four tin atoms. The Sn/O nucleus of the molecule is remarkedly planar with out-of-plane distances for O(1), O(2), O(3), O(4) and O(5) of 0.003(6), 0.089(16), −0.104(15), 0.028(9) and 0.027(12) Å, respectively. For the tin–methyl carbon atoms, C(1), C(2), C(3) and C(4), the corresponding distances are −1.981(19), 1.989(14), 1.986(14) and −2.015(14) Å. A feature of **4** is the very high thermal parameters exhibited at room temperature; this is especially pronounced for the terminal carbons of the carboxylate units.

EXPERIMENTAL

Solution NMR spectra were obtained on a Bruker 250 MHz instrument and IR spectra on Philips Analytical PU 9800 FTIR and Nicolet 205 FTIR instruments. The X-ray diffraction data for 3 were collected by the EPSRC service, based at the University of Wales, Cardiff and that for **4** on a Nicolet P3 diffractometer.

Preparation of **3**

To a solution of 1,2 : 5,6-di-*O*-isopropylidene-3-*C*-trimethylstannyl-α-D-allofuranose [5] (0.588 g, 13.9×10^{-4} mol) in $CHCl_3$ (10 cm^3) was added I_2 (0.305 g, 13.9×10^{-4} mol). The reaction mixture was maintained at room temperature until the solution was decolourized (36 h). All volatiles were removed *in vacuo* and the solid residue was recrystallized from

ethanol. Colourless crystals of **3** (0.10 g) were obtained; compound **3** decomposed on heating. Found: C, 15.2; H, 3.8. Calc. For $C_{12}H_{34}I_2O_4Sn_4$: C, 14.8; H, 3.5%.

^{1}H NMR (250 MHz, $CDCl_3$): *major species* δ: 0.96 [s, 6H, $J(^{119,117}Sn—^1H)$ = *ca* 80 Hz, Me_2Sn], 1.10 [t, 6H, J = 7.3 Hz, CH_2CH_3], 1.15 [s, 6H, $J(^{119,117}Sn—^1H)$ = *ca* 80 Hz, Me_2Sn], 3.58[q, 4H, J = 7.3 Hz, CH_2CH_3].

minor species δ: 0.98 [s, 6H, $J(^{119,117}Sn—^1H)$ = *ca* 80 Hz, Me_2Sn], 1.15 [s, 6H, $J(^{119,117}Sn—^1H)$ = *ca* 80 Hz, Me_2Sn], 1.24 [t, 6H, J = 7.3 Hz, CH_2CH_3], 3.72 [br, 4H, CH_2CH_3].

^{13}C NMR (62.9 MHz, $CDCl_3$) δ: 8.0, 8.4, 9.5, 9.8, 12.3, 14.0, 18.3, 19.7, 57.7, 58.4.

Preparation of **4**

Dimethyltin dichloride (3.27 g, 0.0149 mol) in CH_2Cl_2 (100 cm^3) was shaken with sodium butanoate (3.28 g, 0.030 mol) in H_2O (50 cm^3) at room temperature for 12 h. The organic fraction was collected, washed with water and dried over $MgSO_4$. The solvent was removed under reduced pressure to leave an oil, which slowly crystallized. The product was recrystallized from MeOH; m.p. 161–162°C. Found: C, 29.9; H, 5.3. Calc.: C, 29.6; H, 5.3%.

^{1}H NMR ($CDCl_3$, 250 MHz); δ 0.77 [s, 6H, $J(^{119,117}Sn—H)$ = 84 Hz, Me_2Sn], 0.79 [s, 6H, $J(^{119,117}Sn—H)$ = 84 Hz, Me_2Sn], 0.93 (t, 3H, J = 7.3 Hz, $MeCH_2$), 1.61 (quintet, 2H, J = 7.3 Hz, $MeCH_2CH_2$), 2.16 (t, 2H, J = 7.3 Hz, CH_2CO).

^{13}C NMR ($CDCl_3$, 62.9 MHz): δ 6.3 [$J(^{119}Sn—^{13}C)$ = 755 Hz, $J(^{117}Sn—^{13}C)$ = 721 Hz, Me_2Sn], 8.6 [$J(^{119}Sn—^{13}C)$ 796 Hz, $J(^{117}Sn—^{13}C)$ = 761 Hz, Me_2Sn], 13.8 [$MeCH_2$ CH_2CO_2], 19.0 [$MeCH_2CH_2CO_2$], 38.1 [$MeCH_2$ CH_2CO_2], 180.1 [CO].

^{119}Sn NMR ($CDCl_3$, 93.3 MHz) δ: −175.5, 187.5.

Crystal structure determination of **3**

A colourless crystal was obtained from 95% ethanol solution. The unit cell and intensity data were col-

lected on a Delft Instruments FAST diffractometer using the routines ENDEX, REFINE and MADONL in the MADNES software [11] and processed using ABSMAD [12], detailed procedures have been described [13]. The structure was elucidated [14] with SIR92 and refined [15] with SHELXL93. A correction for absorption was made [16] with DIFABS. The non-H atoms were refined with anisotropic temperature factors and H atoms were refined to ride on their attached carbon atoms with isotropic temperatures 1.2° greater than their hosts. The molecular plot was obtained [17] using ZORTEP. Crystal data and structure refinement details are listed in Table 3.

Crystal structure determination of **4**

A colourless crystal was grown from MeOH solution. Data were collected on a Nicolet P3 diffractometer with Mo-K_α radiation; data collection used ω scan rates of 1.0 ($Ip < 150$) to 29.3 ($Ip > 2500$)° min^{-1}, where Ip was the prescan intensity. Scan width was 0.6° ω. Background counts were taken at $\pm 1.0°$ in ω from the Bragg angle of each reflection. Cell refinement was carried out using P3 diffractometer software [18]. Data reduction employed the program RDNIC [19]. Absorption correction utilised an empirical method based on psi scans [20]. The structure was solved by the heavy atom method, followed by successive Fourier and difference syntheses and refined by full-matrix least-squares. All non-H were refined anisotropically. The H-atoms were placed in calculated positions with C—H = 0.95 Å and refined upon the C to which they were attached with common group $U_{iso's}$ for each of Sn—methyl—H, alkyl methylene—H and alkyl methyl—H [refined values 0.23(2), 0.29(4) and 0.32(5), respectively]. All of the atoms in this structure display remarkedly high thermal vibration amplitudes. This is particularly so for the terminal atoms of the carboxylate anions which are clearly suffering from considerable disorder. All computations were performed on the SUN

SPARCserver (UNIX operating system) of the Computing Centre of the University of Aberdeen. Structure solution and refinement involved [21] SHELXS86 and SHELX76 [22], respectively. Molecular graphics utilized the ORTEX program [23] and the software used [24] for publication was XPUB. Crystal data and structure refinement details are listed in Table 3.

(Received 24 May 1996; accepted 31 July 1996)

Abstract—The copper(II)–glycine–thiocyanate ion system, which has been studied, afforded a new 1:1:1 complex which crystallized with an additional water molecule. The IR spectrum of the solid complex suggests an aquo ligand, a bridging thiocyanato ligand and a *N,O*-bidentate chelating glycinato ligand. Room-temperature magnetic moment, electronic spectra and ESR spectra suggested a tetragonally distorted octahedral structure for the complex $[Cu(glycinato)(NCS)(H_2O)]_n$, which was confirmed by X-ray crystallography. The complex contains $\mu(N,S)$-thiocyanato ligands and an aqua molecule. The glycinato anion chelates a copper atom *via* its N and O atoms. The second O atom of the glycinato group links another Cu atom at a long distance of 2.908(5) Å, giving rise to *N,O,O*-tridentate chelating bridging glycinato ligand. The structure of the complex is further consolidated by hydrogen bonds of the type O—H···O between aqua molecules and carboxylate O atoms. The thermal decomposition of the complex was investigated under nitrogen. Copyright © 1996 Elsevier Science Ltd

Keywords: glycinato; thiocyanato; copper(II) complex; crystal structure.

Binding of small ligand molecules to copper proteins has been widely employed as a method to obtain structural or mechanistic information on the metal sites [1]. For instance, the azide ion has been used in binding studies on amine oxidases [2], superoxide dismutase [3], galactose oxidase [4], laccase [5] and ascorbate oxidase [6]. Casella *et al.* have initiated a systematic investigation of the binding of azide and thiocyanate ions to a series of copper(II) complexes with ligands containing nitrogen and oxygen donor atoms which can be considered as mimics of the potential ligands of type 2 and 3 copper centers in the proteins [7,8]. In such cases binding of anions such as azide, thiocyanate and bromide to copper(II) is generally accompanied by the appearance of LMCT transitions in the visible or near-UV region and produce changes in the EPR spectra that may be potentially very useful for empirical correlations between spectra and structure.

X-ray analysis indicates that in $[M(gly)_2]\cdot nH_2O$, where M = Ni, Zn or Cd, n = 2 or 1 and gly = glycino anion, the two glycino anions coordinate *via* their N and O atoms to the metal by forming a *trans*-square planar structure [9,10]. Furthermore, it has been shown that the oxygens of the carbonyl groups that are not coordinated to the metal are hydrogen bonded either to the amino group of the neighboring molecule or to water of crystallization, or they are bounded weakly to the metal of the neighboring complex.

Recently we established that a substitution of one of the two picolinate anions in the parent [M(picolinato)$_2$] complex by other anion, such as Cl^-, NCS^- or N_3^-, leads to new mode of bonding of the picolinato anion [11–13]. As binding of pseudohalide ions to copper(II)–amino acid systems have not yet been

* Author to whom correspondence should be addressed.

investigated, we studied the binding of the thiocyanate anion to copper(II)–glycine complex in order to appraise the influence of these anions on the mode of bonding of each other. This system afforded a new polymeric 1 : 1 : 1 thiocyanato–copper(II)–glycinato complex which crystallizes with one water molecule. The synthesis and structural properties of this complex as elucidated by spectroscopic and X-ray crystallographic methods are reported here

EXPERIMENTAL

Glycine was obtained from Aldrich and the other chemicals were of analytical grade quality.

Preparation of the complexes

Cu(glycinato)$_2 \cdot H_2O$. This complex was prepared [14, 15] by mixing a solution of copper(II) nitrate trihydrate dissolved in acetone with an aqueous solution of glycine in 1 : 2 molar ratio. The mixture was stirred, heated for several minutes and allowed to stand until blue crystals were isolated. Found: C, 20.6; H, 4.5; N, 12.6; Cu, 27.9. Calc.: C, 20.9; H, 4.4; N, 12.2; Cu, 27.7%.

[Cu(glycinato)(NCS)$(H_2O)]_n$ (**1**). $Cu(NO_3)_2 \cdot 3H_2O$ (1.2 g, 5 mmol) dissolved in distilled water (20 cm^3) was mixed with glycine (0.75 g, 10 mmol) dissolved in water (20 cm^3). To this mixture, NaNCS (0.24 g, 3 mmol) dissolved in water (3 cm^3) was added dropwise. The final mixture should be filtered if some white precipitate is formed and the filtrate allowed to stand over several days until blue (green tinted) colored crystals are produced. Found: C, 16.7; H, 3.0; N, 13.2; S, 15.6; Cu, 29.5. Calc.: C, 16.9; H, 2.8; N, 13.1; S, 15.0; Cu, 29.7%.

Physical measurements

Procedures and instruments used for other physical measurements are as described previously [16].

X-ray crystallography

A modified STOE four-circle diffractometer was used for single-crystal X-ray measurements. Orientation matrix and lattice parameters were obtained by least-squares refinement of the diffraction data from 45 reflections in the 2θ range 10–29°. Data were collected at 298(1) K using graphite crystal-monochromatized Mo-K_α radiation ($\lambda = 0.71069$ Å) and the ω-scan technique. The intensities were corrected for Lorentz and polarisation effects and for absorption [17]. Crystallographic data are given in Table 1.

The structure was solved by Patterson superposition methods and subsequent Fourier analyses. Anisotropic displacement parameters were applied to the non-hydrogen atoms in full-matrix least-squares refinements. Hydrogen-atom positions were obtained from ΔF maps and included in the final refinement cycles by use of geometrical constraints. The programs DIFABS [17], SHELX-76 [18], SHELXS-86 [19], PLATON [29] and THE XRAY SYSTEM [21] were used for computations. Analytical expressions of neutral-atom scattering factors were employed and anomalous dispersion corrections were incorporated [22]. Selected bond distances and bond angles are given in Table 2. Positional parameters, anisotropic displacement parameters, hydrogen-atom coordinates, a full list of bond lengths and angles and observed and calculated structure factors have been deposited with the Editor as supplementary material.

RESULTS AND DISCUSSION

When thiocyanate was added to an aqueous solution of bis(thiocyanato)copper(II) complex no change of the blue color occurred whatever the amount of added thiocyanate. This is in contrast to what we have observed [23] in the case of the addition of the azide ion to the same system. In the latter case a new absorption band occurred at 354 nm. Addition of thiocyanate to an aqueous solution of a mixture of copper(II) ions and glycine in 1 : 2 molar ratio, however, was accompanied by a new absorption band at 339 nm. The electronic absorption spectrum of Cu(gly-

cinato)$_2 \cdot H_2O$ complex in water exhibited a single absorption band at 637.5 nm, whereas that of a mixture of copper(II) ions and glycine (1 : 2 molar ratio) showed the corresponding band at 732 nm. Thus, the complexes that exist in both cases are different. This result was confirmed by measuring the EPR spectra of both solutions. These spectra differ in number and positions of the EPR lines. Thus, while the thiocyanate does not bind the bis(glycinato) complex of copper(II), it interacts with the complex formed by mixing copper(II) ions and glycine.

Mixing of copper(II) ions, glycine and thiocyanate anions in a molar ratio of 1 : 2 : 1 in aqueous solution, however, afforded a green-colored solution from which a blue copper(II) complex of the empirical formula Cu(glycinato)(NCS)(H_2O) deposited. This complex is insoluble in water, alcohol, chloroform, carbon tetrachloride and acetone, but soluble in DMF and DMSO giving rise to nonconducting solutions. This result is an indication of the polymeric nature of the complex.

The principal structural features of the [Cu(glycinato)(NCS)(H_2O)] complex are illustrated in Fig. 1. The stereochemistry about each six-coordinated copper center is best described as a tetragonal bipyramid (4+2). The glycinato anion chelates a copper atom, Cu(1), *via* its amino nitrogen atom, N(2) [Cu—N = 2.015(5) Å], and a carboxylate oxygen atom, O(1) [Cu—O = 1.954(5) Å], to form a five-membered ring. The Cu(1) atom is further coordinated by a second oxygen atom, O(2c), of the carboxylate group of another glycinato anion at a Cu—O distance of 2.908(5) Å. Thus, the glycinato anion behaves as a *N,O,O*-tridentate chelating bridging ligand in the present complex. Each metal atom is further linked by an oxygen atom of an aquo molecule

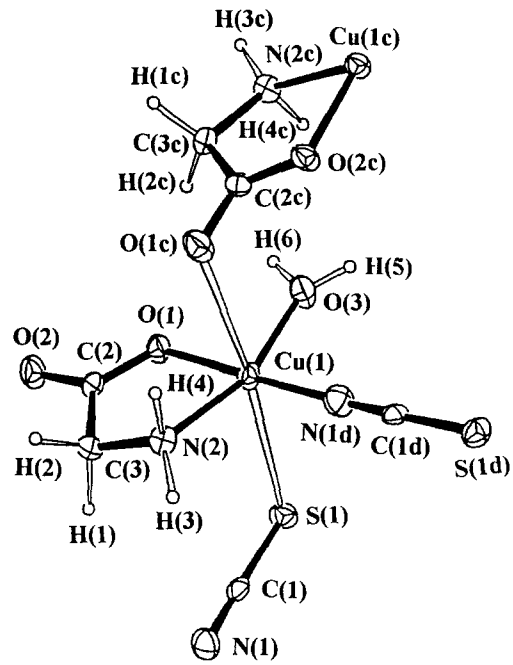

Fig. 1. Molecular geometry and atom labeling scheme of $Cu(C_2H_4O_2N)(NCS)(H_2O)$. Symmetry code according to Table 2.

[Cu—O = 1.945(6) Å]. The thiocyanato groups are functioning in the $\mu(N,S)$ fashion to bridge each copper atom with its nearest copper neighbor [Cu—NCS and Cu—SCN distances are 1.905(7) Å and 2.894(2) Å, respectively], forming a three-dimensional network structure. The C—S bond length of 1.628(6) Å found in the present complex is very close, whereas the N—C distance of 1.165(9) Å is larger than corresponding values [1.646(4) Å for C—S and 1.148(6) Å for N—C] found in [Cd(picolinato)(NCS)]$_n$-containing $\mu(N,S)$ thiocyanato ligands [13]. The N—C bond length is much larger than the corresponding value [1.140(11) Å] found in the [Mn(H-quin)(quin)(NCS)$(H_2O)_2$] complex (H-quin is quinaldic acid) with terminal nitrogen-bonded thiocyanato ligands [24]. The thiocyanato ligand in the present structure is linear [$\angle$NCS = 178.5(6)°]. Intermolecular hydrogen bonds of the type O—H $\cdots$ O between the aquo molecules and the oxygen atoms of the carboxylate groups (Fig. 2, and Table 2) consolidate the structure of the present complex.

The structure of the title complex may be compared with that of [Cd(picolinato)(NCS)]$_n$ [13], which also exhibits $\mu(N,S)$-thiocyanato ligands and six-coordinated metal centers. In the cadmium complex the picolinato anion is coordinated *via* N(1) and O(1) to Cd(1), forming a chelating five-membered ring. O(1) and O(2) are further coordinated to another cadmium center, Cd(1c) (see Fig. 3, ref. [13]), forming an additional chelating four-membered ring. As a consequence the cadmium atoms and O(1) atoms of the picolinate anions form the backbone of a zigzag chain structure oriented along the short *b* axis of the monoclinic unit cell. The picolinato anion in the cadmium complex functions as a *N,O,O,O'*-tetradentate chelating bridging ligand.

The IR spectrum of the solid complex (**1**) shows a very broad band in the range 3500–2200 cm^{-1}, due to νO—H $\cdots$ O [25], between aqua molecules and COO$^-$ groups of glycinato ligands. The absorption vibrations due to the bonded NH_2 group appear as strong bands at 3300 and 3260 cm^{-1}, similar to those for

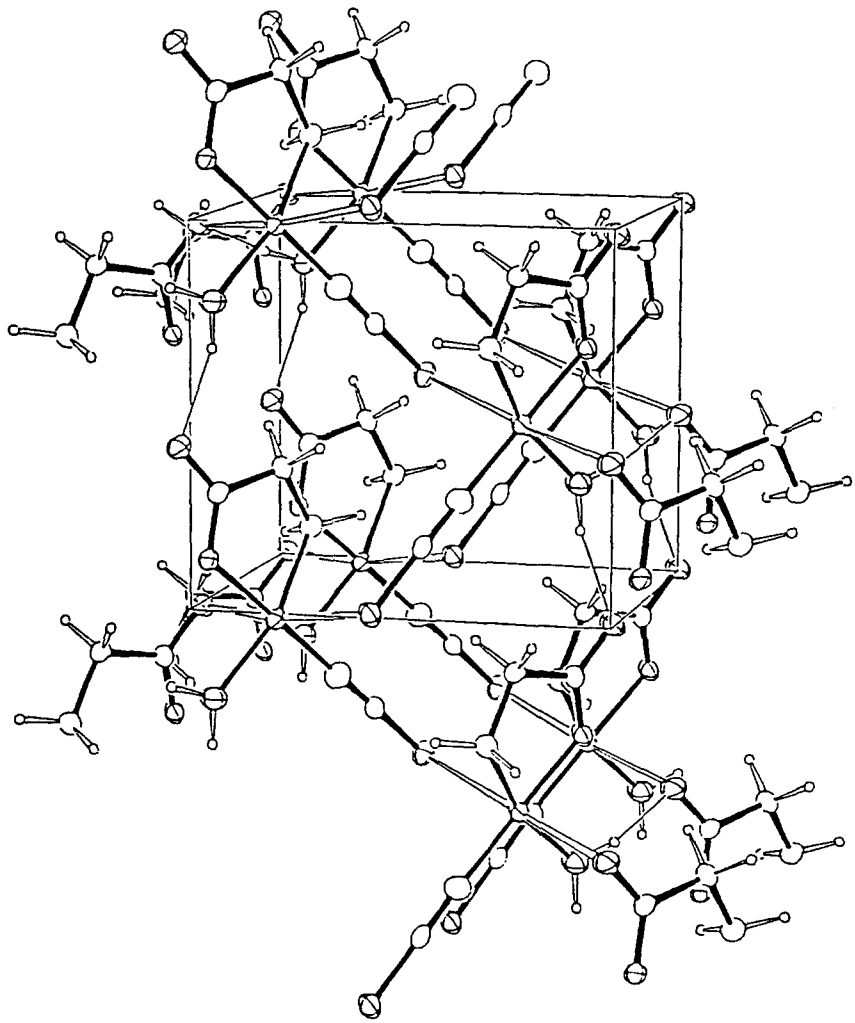

Fig. 2. Unit-cell plot (stereo) of Cu($C_2H_4O_2N$)(NCS)(H_2O), viewed along the *a* axis of the unit cell. Hydrogen bonds are indicated by thin lines.

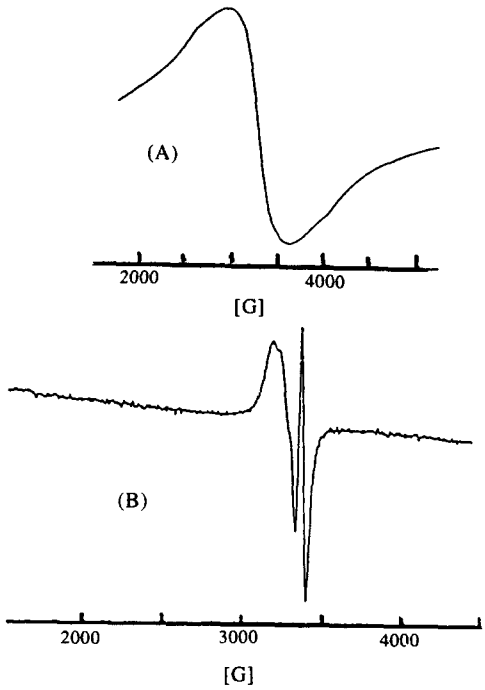

Fig. 3. ESR spectra of $Cu(C_2H_4O_2N)(NCS)(H_2O)$ complex: (a) polycrystalline powder and (b) DMSO saturated solution.

$Cu(gly)_2 \cdot H_2O$. The carbonyl stretching absorption band [ν(C=O)] appears at 1653 cm^{-1}, whereas ν(C—O) appears at 1401 cm^{-1} compared with the corresponding bands (1593 and 1392 cm^{-1}, respectively) in the spectrum of $[Cu(gly)_2]$ [26]. We tentatively assigned the following frequencies [27]: the band at 532 cm^{-1} due to [$\rho_w(H_2O)$], at 462 cm^{-1} to [δNCS + ν(Cu—OH_2)] and at 422 cm^{-1} to [ν(Cu—N(gly))].

The IR spectrum of complex **1** shows a very strong band at 2100 cm^{-1} due to the ν(C—N) mode, in addition to two medium bands at 809 and 770 cm^{-1} related to ν(C—S). Bridging *N,S*-thiocyanato groups are expected to exhibit two ν(C—N) bands above and below 2100 cm^{-1} as well as two ν(C—S) bands [28–32]. While the appearance of two ν(C—S) bands is consistent with the X-ray structural results of the complex, the band at 2100 cm^{-1} is on the borderline between N- and S-bonded thiocyanato ligands. The appearance of a single ν(C—N) absorption band in the IR spectrum, however, is not unusual and has been observed for many μ(*N,S*)-thiocyanato complexes [13, 33,34].

The room-temperature magnetic moment of 1.82 B.M. found for complex **1** is consistent with magnetically dilute tetragonal copper(II) systems, show-

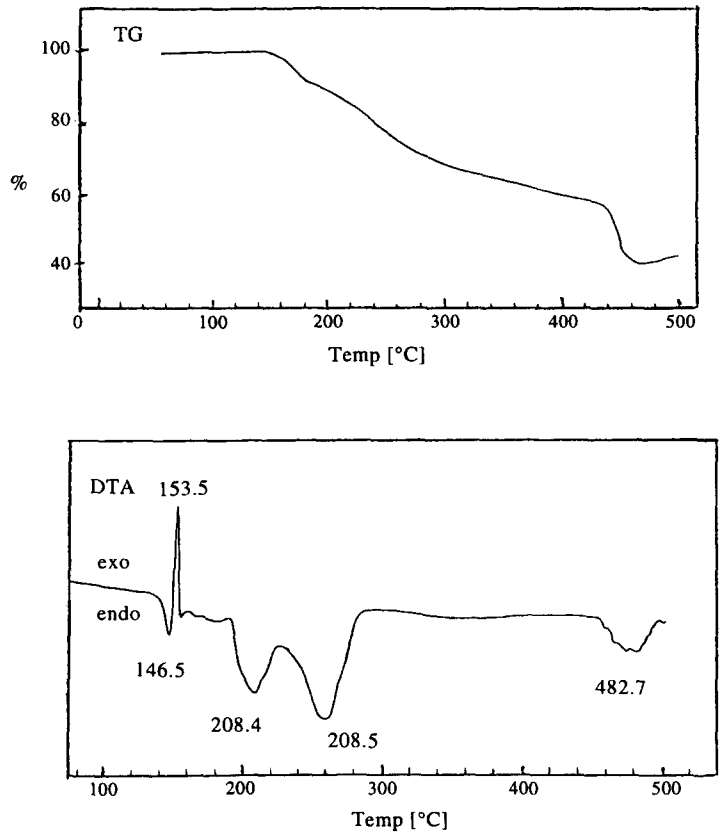

Fig. 4. Thermal decomposition of $[Cu(C_2H_4O_2N)(NCS)(H_2O)]$.

ing an orbitally nondegenerate groundstate [35]. The electronic absorption spectrum of the title complex as a solid mulled in Nujol displays a broad *d–d* band centered around 641 nm, which is consistent with a tetragonal, octahedral geometry around copper(II) [36]. The spectrum of a saturated DMSO solution of complex **1** shows the *d–d* band at 754 nm; a position which is suggestive of five-coordination geometry of copper(II) [37,38]. Thus, complex **1** does not maintain its solid-state structure in DMSO solution. This may be achieved by breaking the long Cu—O bond of 2.908 Å value in DMSO solvent.

The ESR spectrum of a polycrystalline powder of the title complex at room temperature is of one *g*-value type with a *g* value of 2.146 (Fig. 3). As reported for other complexes of Cu^{II} [39], a grossly misaligned set of tetragonal axes seems to be a more plausible explanation. As a result of the poor dissolution of this complex, its ESR spectrum in DMSO displays a poor resolution of the four hyperfine lines of uncoupled copper(II) as can be seen from Fig. 3.

The thermal decomposition of [Cu(glycenato)(NCS)$(H_2O)]_n$ is represented in Fig. 4. The first step of the thermal decomposition consists of a dehydration at 146°C [loss of weight (%); experimental 8.5 and theoretical 8.4]. The DTA curve [Fig. 4(b)] starts this step with a narrow endotherm (melting endotherm), immediately followed by an exotherm. This may be interpreted as a rearrangement of the amorphous system in the crystalline phase. The following, well-separated step 2 for the dehydrated compound does not reflect a simple one-stage process and the DTA curve shows two endotherms. The experimental loss of weight of 34.65%, however, indicates that $C_2H_4NO_2$ is released (theoretical 34.66%) in the second step. A reductive [Cu^{II}–Cu^{I}] degradation is completed at *ca* 440°C in dynamic nitrogen atmosphere. A polymer residue of the empirical formula $[Cu(SCN)]_n$ is indicated by the calculated weight loss of the complex. The weight loss of 16.84% in the temperature range 440–500°C (T_{max} = 482.6°C, Fig. 4) may indicate the release of sulfur (calc. 15.0%) with the formation of another polymer residue $[Cu(CN)]_n$. This suggestion was borne in mind because of the fact that the thermal decomposition of $K[Cu_2(CN)_3] \cdot H_2O$ and $[(CH_3)_2(C_6H_5)S][Cu_2(CN)_3]$ [40] ended with the formation of CuCN at 420 and 470°C, respectively.

(Received 5 July 1996; accepted 24 July 1996)

Abstract—In the novel centrosymmetric dinuclear manganese(II) complex $[\{Mn(bpy)_2(p\text{-}Me_2N^+C_5H_4NCH_2CO_2^-)\}_2](ClO_4)_4$, the bridging betaine ligand functions in an abnormal non-planar *skew–skew* mode, with both Mn^{II} atoms lying on the same side of the mean plane of each bridging carboxylato group. The intramolecular metal–metal separation in the dinuclear cation agrees well with those in the range 4.64–4.79 Å found for known doubly carboxylato-bridged manganese(II) complexes. Copyright © 1996 Elsevier Science Ltd

Keywords: dinuclear manganese(II) complex; betaine; 4-dimethylaminopyridinioacetate; carboxylate; bridging ligand.

There has been considerable interest in the coordination chemistry of manganese complexes with carboxylato ligands, owing to the fact that there is an increased recognition of the role of this metal in biological systems [1–3]. Dinuclear manganese(II) complexes are of special interest, since such systems are known to exist at the active centres of some manganese-containing enzymes [4]. Recently, dinuclear units with one to three carboxylato bridges were suggested to be plausible structures of the dinuclear sites in Mn catalases [5,6].

Our recent studies have demonstrated that betaine ($Me_3N^+CH_2CO_2^-$; IUPAC name: trimethylammonioacetate) and its derivatives, considered as structural analogues of the corresponding carboxylate anions, are useful in the preparation of soluble carboxylate-like complexes of transition metals [7–11]. The crystal structures of manganese(II) carboxylates have been widely studied, and polymeric structures generally predominate [12,13]. Several dinuclear manganese(II) carboxylates containing one to three carboxylate bridges that are stabilized by the incorporation of bidentate terminal ligands such as 2,2′-bipyridine have been reported [14–19]. Among these, the bridging carboxylato group exhibits the common bidentate coplanar *syn–syn* mode in $[Mn_2(bpy)_4(ta)](ClO_4)_2$ (ta = terephthalate dianion) [14] and the coplanar *syn–anti* bridging mode in $[\{Mn(bpy)_2(H_2O)\}_2(Me_3N^+CH_2CO_2^-)](ClO_4)_4\cdot 2H_2O$ [15]. The non-planar *skew–skew* bridging mode of the carboxylato group was previously found in the manganese(II) complexes $[\{Mn(Me_3N^+CH_2CO_2^-)_3\}_n]\cdot(MnCl_4)_n$ [20], $[Mn(tpa)(\mu\text{-}OAc)]_2(TCNQ)_2\cdot 2CH_3CN$ and $[Mn(tpa)(TCNQ)(CH_3OH)](TCNQ)_2\cdot CH_3CN$ (tpa = tris(2-pyridylmethyl)amine, TCNQ = tetracyanoquinodimethane) [21], $[Mn_2(L)_2(\mu\text{-}OAc)_2](ClO_4)_2$ [L = *N*,*N*′-dimethyl-*N*,*N*′-bis(2-pyridylmethyl)ethane-1,2-diamine] [22], as well as the iron(II) complex $[Fe_2(tpa)(\mu\text{-}OAc)_2](BPh_4)_2$, in which the coordination geometry of the iron atom is similar to that of the corresponding manganese ion [23]. In these complexes two metal centres lie on different sides of the mean plane of each bridging carboxylate. We now report the synthesis and single-crystal X-ray analysis of a novel dinuclear manganese(II) complex with 4-dimethylaminopyridinioacetate and 2,2′-bipyridine (bpy), namely $[\{Mn(bpy)_2(p\text{-}Me_2N^+C_5H_4NCH_2CO_2^-)\}_2](ClO_4)_4$ (**1**), in which the two metal ions are bridged by a pair of *skew–skew* car-

boxylato groups but lie on the same side of the mean plane of each bridging ligand.

EXPERIMENTAL

4-Dimethylaminopyridinioacetate was synthesized by the reaction of 4-dimethylaminopyridine with ethylchloroacetate as described previously [24]. C, H, N microanalyses were carried out on a Perkin–Elmer 240 elemental analyser. Infrared spectra were recorded from KBr pellets in the range of 4000–400 cm^{-1} on a Perkin–Elmer 600 FT-IR spectrometer.

Synthesis

To an aqueous solution (10 cm^3) of 4-dimethylaminopyridinioacetate (180 mg, 1.0 mmol) was added $MnCl_2 \cdot 4H_2O$ (98 mg, 0.5 mmol) with stirring for 10 min at 60°C. Then bpy (78 mg, 0.5 mmol) and $NaClO_4 \cdot H_2O$ (144 mg, 1.0 mmol) were added and the mixture was stirred for 20 min. After filtration the resulting solution was allowed to stand in air for a few days, from which yellow block crystals deposited. The yield was 86 mg (*ca* 46% based on Mn) of **1**. Found: C, 46.3; H, 3.4; N, 11.2. Calc. for $C_{29}H_{28}N_6O_{10}Cl_2Mn$: C, 46.7; H, 3.8; N, 11.3%. IR data (cm^{-1}): 3423s, 3092m, 3060m, 1654vs, 1622m, 1595s, 1568s, 1472m, 1435s, 1381s, 1306m, 1211m, 1178m, 1141vs, 1111vs, 1082vs, 1013m, 943w, 906w, 821w, 772s, 730m, 687w, 623s, 548w.

CAUTION! Perchlorate salts of metal complexes with organic ligands are potentially explosive. Only a small amount of compound should be prepared, and it must be handled with caution.

X-ray data collection and structure refinement

A selected single crystal of **1** was used to collect X-ray data at 292 K on a MSC/Rigaku RAXIS-IIC imaging plate system with a rotating anode X-ray generator (Mo-K_α, $\lambda = 0.71073$ Å, 50 kV, 150 mA) [25] and corrected for absorption using the REQAB program [26]. Crystallographic data are summarized in Table 1.

All computations were performed on a PC-486 computer with the SHELXTL-PLUS program package [27]. The direct method yielded the positions of all non-hydrogen atoms, and the hydrogen atoms of the betaine ligands were generated geometrically (C—H = 0.96 Å) and allowed to ride on their respective parent carbon atoms. The final refinement cycles were performed by full-matrix least squares with anisotropic thermal parameters for all non-hydrogen atoms and assigned isotropic thermal parameters for hydrogen atoms. Analytic expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated [28].

Selected bond lengths and angles are given in Table 2 and lists of the remaining bond lengths and angles, hydrogen atom coordinates and anisotropic thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

The crystal structure of complex **1** consists of a packing of discrete dinuclear cations and perchlorate anions. As illustrated in Fig. 1, a pair of symmetry-related manganese(II) atoms, separated by a non-bonding distance of 4.874(2) Å, are bridged by two carboxylato groups into a centrosymmetric eight-membered metallacyclic ring. Each manganese(II) atom in the resulting dinuclear cation has a distorted octahedral coordination geometry comprising two carboxylato oxygen atoms [O(1) and O(2a)] from two betaine ligands which occupy *cis* positions, and four nitrogen atoms [N(3), N(4), N(5) and N(6)] from a pair of chelate bpy groups; the most distorted angles of the octahedron are the bite angles of the chelate bpy ligands [72.8(1)–73.4(1)°]. The Mn—N(bpy) bond lengths lie in the range 2.229(1)–2.266(1) Å and are significantly longer than those of Mn—O(carboxylate) (average 2.108 Å). These bond distances are in agreement with literature values for both bpy- and carboxylato-containing manganese(II) complexes [14, 15, 29]. The best equatorial plane is defined by atoms O(1), N(3), N(5) and N(6) [the largest deviation from the mean plane is 0.040 Å for N(6)] and

Symmetry codes: (a) $2-x, -y, 1-z$.

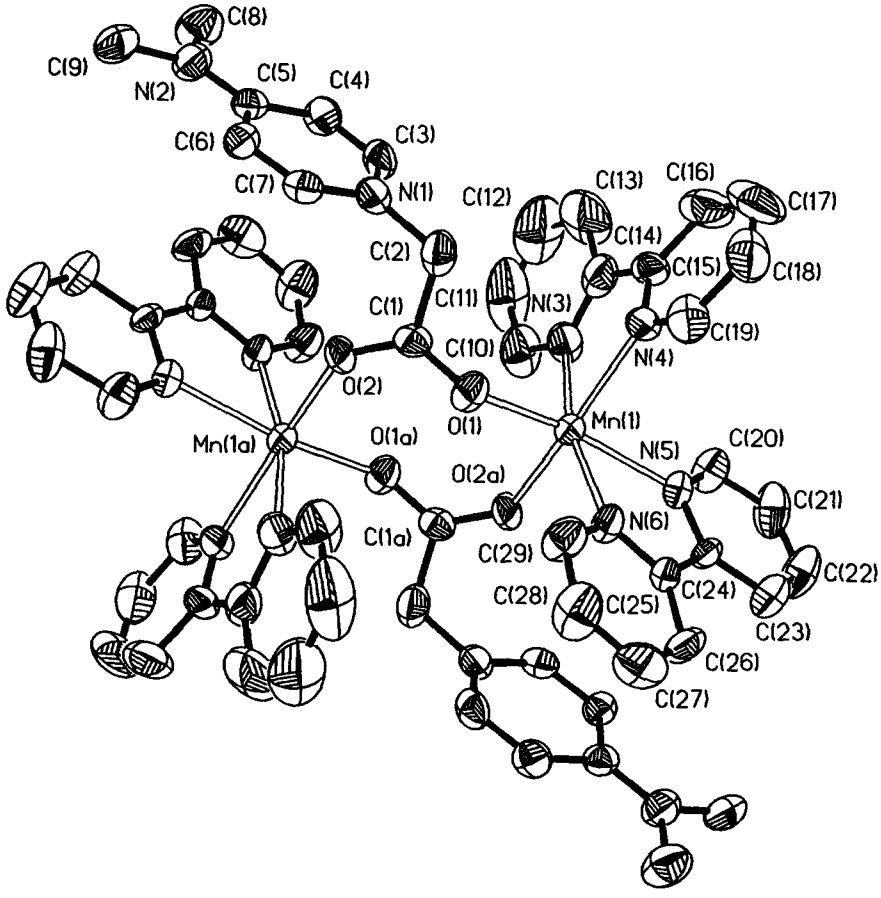

Fig. 1. ORTEP drawing (35% thermal ellipsoids) of the dinuclear $[\{Mn(bpy)_2(p\text{-}Me_2NC_5H_4NCH_2CO_2)\}_2]^{2+}$ cation in **1**. Symmetry code is given in Table 1.

the manganese atom is displaced 0.061 Å out of this plane towards atom O(2a).

The most interesting structural feature in complex **1** is that the carboxylato group of the betaine ligand bridges the Mn^{II} atoms in an abnormal non-planar *skew–skew* (e) mode, which differs from the coplanar *syn–syn* (a), *syn–anti* (b) and *anti–anti* (c) bridging modes commonly occurring in metal carboxylates [13], as well as the unusual non-planar *syn–skew* (d) mode found in $[Cd_3(C_5H_4N^+CH_2CO_2^-)_4Cl_6]$ [30] (see Fig. 2). The O(2) atom coordinates Mn(1a) in an out-of-plane fashion with a torsion angle Mn(1a)—O(2)—C(1)—C(2) = 152.3(2)°, and the Mn(1)—O(1) bond is rotated out of the plane of the carboxylato group by an even greater extent [torsion angle Mn(1)—O(1)—C(1)—C(2) = −72.5(2)°]. The Mn(1) and Mn(1a) atoms thus lie on the same side of the mean plane containing the carboxylato group of the bridging betaine ligand. This non-planar *skew–skew* coordination mode (e) is therefore different from mode (f) as found in the above-mentioned Mn^{II} and Fe^{II} complexes [20–23]. The intramolecular metal–metal separation in the present dinuclear cation agrees well with those in the range 4.64–4.79 Å found for known doubly carboxylato-bridged manganese(II) complexes [14, 29c, 31]. In contrast, the metal–metal distance is considerably longer than those [4.03–4.44 Å] reported for triply μ-carboxylato-bridged manganese(II) complexes [18, 32, 33] and much shorter than those [5.60–5.67 Å] found for singly carboxylato-bridged manganese(II) complexes [15,34], implying that the metal–metal separation in the $(\mu$-carboxylato$)_n$ bridged systems may be controlled by varying the number of such bridges, as well as their coordination modes.

The carboxylato group in the molecular skeleton of the betaine ligand deviates from being perpendicular to the dimethylaminopyridinium moity, the dihedral angle between the plane containing atoms O(1), O(2), C(1), C(2) (mean deviation 0.007 Å) and the plane containing atoms N(1), C(3), C(4), C(5), N(2), C(6), C(7), C(8), C(9) (mean deviation 0.025 Å) being 74.2°. The conformation of the betaine ligand is thus similar to that in its hydrochloride form (dihedral angle 60.7°), but different from that in its hydrate form (dihedral angle 96.3°), in which the molecular skeleton of the betaine ligand possesses approximate C_s symmetry [24].

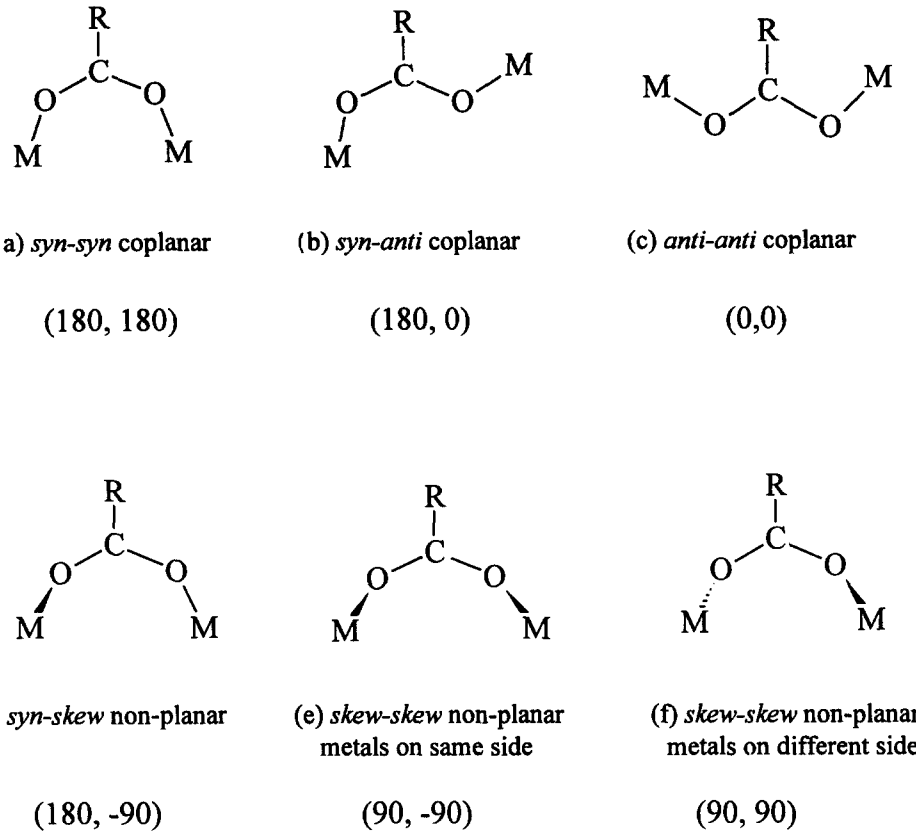

Fig. 2. Six idealized bridging modes of carboxylate and betaine ligands in their metal complexes. Enclosed in parentheses are the representative numerical values of the pair of R—C—O—M torsion angles (°) for each type of geometry.

(Received 15 May 1996; accepted 30 July 1996)

Abstract—The salen complex CuL and the corresponding tetrahydrosalen complex Cu[H_4]L were investigated by ESR spectroscopy and molecular orbital calculations [H_2L = *N*,*N*′-bis(3-*tert*-butyl-5-methylsalicylidene)-2,3-diamino-2,3-dimethylbutane; H_2[H_4]L = *N*,*N*′-bis(2-hydroxy-3-*tert*-butyl-5-methylbenzyl)-2,3-diamino-2,3-dimethylbutane]. X-ray structure determination of CuL confirmed a slightly distorted planar geometry of the CuN_2O_2 coordination core. The ESR spectra of CuL at both 77 K and room temperature revealed that very well resolved lines cannot be attributed to the interaction with copper nuclear spin and ^{14}N donor nuclei alone. Computer simulation showed that in addition to copper hyperfine (g_{iso} = 2.094, $|A^{Cu}(iso)|$ = 270 MHz, room temperature) and nitrogen superhyperfine structure [$|A^{N}(iso)|$ = 46 MHz] a distant interaction with two equivalent protons is also present [$|A^{H}(iso)|$ = 23 MHz]. These protons are attached to the carbon atoms adjacent to ^{14}N nuclei. In contrast the number of lines in the spectrum of the hydrogenated analogue Cu[H_4]L is greatly reduced. At room temperature only a quintet with considerable smaller nitrogen shf constant [$|A^{N}(iso)|$] = 25 MHz is observed. Thus, both factors planarity and conjugation, are essential for the observation of distant hydrogen shf splitting in CuL. The ESR findings are in good agreement with calculated spin densities by QR-INDO/1 method. Copyright © 1996 Elsevier Science Ltd

Keywords: copper salen complexes; effect of hydrogenation; crystal structure; superhyperfine splitting; EPR; MO calculations.

In order to emulate the biological activity of proteins [1], various model metal complexes containing Schiff base ligands have been prepared and in some cases dioxygen activation and its relevance in oxidative catalysis investigated [2]. These studies on model systems indicate that the key attributes for a metalloprotein to carry out a specific biological function are the environment around the metal center and conformational flexibility. For example, the flexibility of the ethylene diamine backbone in salen [3] plays a crucial role in the dioxygen activation. Most of the studies were carried out with the tetradentate Schiff base ligand salen, while tetrahydrosalens have rarely been studied with the exception of the hydrogenation product of nonsubstituted salen. The coordination chemistry of this ligand with nickel [4,5], zinc [4,5], cobalt [5,6], molybdenum [7,8], copper [5,9], and iron

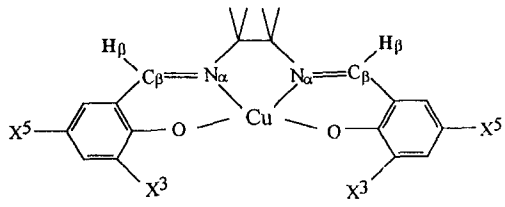
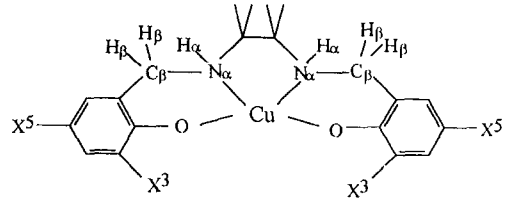
[10] has been reported as well as dinuclear complexes [6, 10a, 11]. More recently a trinuclear cobalt [12] complex was prepared and characterized.



We have recently reported on metal-catalysed oxidative dehydrogenation of the C—N bond in coordinated tetrahydrosalens [13, 14]. Comparing the ligand properties of salen and tetrahydrosalen, one expects both an increased *N*-basicity and greater conformational flexibility as a consequence of C=N bond hydrogenation. The loss of conjugation in coordinated tetrahydrosalens might generate interesting electronic and magnetic properties of such complexes, reflected in absence of weak *distant* magnetic interactions. The aim of this short contribution is to present a comparative study of electronic and *distant* magnetic interactions on the substituted salen and tetrahydrosalen copper(II) complexes depicted in Fig. 1.

RESULTS AND DISCUSSION

From the crystal structure analysis for the molecule **1** the chromophore is of the *cis*-$\{CuN_2O_2\}$ type with distances Cu—N = 1.932(3) and Cu—O = 1.890(2) Å, respectively (Fig. 2). The planar arrangement of the chromophore is somewhat distorted, which follows from the O—Cu—O, O—Cu—N and N—Cu—N angles deviating from 90 and 180°, slightly (Tables 1 and 2).



The ESR spectrum of **1** in frozen toluene solution is shown in Fig. 3. It corresponds to an axially symmetric species with $g_{\parallel} = 2.191$ and $g_{\perp} = 2.040$ and detailed analysis shows that the very well resolved high-field perpendicular band of the spectrum cannot be attributed to the interaction with the copper nuclear spin ($I^{Cu} = 3/2$) and ^{14}N ($I^N = 1$) donor nuclei alone. Computer simulation [15, 16] showed that, in addition to copper hyperfine and nitrogen shf structure, a *distant* interaction with two equivalent protons is also present. These protons are attached to the carbon atoms adjacent to ^{14}N nuclei (depicted in Fig. 1). In addition, an "overshoot line" resulting from the angular spectral dependence of the copper hyperfine lines in perpendicular region is observed. In order to obtain exact values for both the hydrogen as well as nitrogen shf constants, room-temperature spectra were taken (Fig. 4). The isotropic spectrum, $g_{iso} = 2.094$, $|A^{Cu}(iso)| = 270$ MHz, shows m_I-dependent linewidth with clearly defined superhyperfine structure on the high-field line. Two equivalent nitrogen nuclei should give five lines which are further split into triplets by the interaction with two equivalent protons giving a 15 line spectrum. This interpretation gives a good match between the theoretical and the second derivative experimental spectrum, for which $|A^N(iso)| = 46$ MHz and $|A^H(iso)| = 23$ MHz were found. These values and those for the solid-state spectrum are in a good agreement with the monocrystal study of Maki and McGarvey [17a] as well as with ENDOR [17b] study on copper(II) bis-salicylaldehyde-imine 1 : 200 diluted in the corresponding nickel chelate.

In contrast the number of lines in the spectrum of the hydrogenated analog **2** is greatly reduced. Again the solution spectrum shows m_I-dependent linewidth with discernable hyperfine structure on the high-field line, however, in this case only a quintet with a considerable smaller nitrogen shf constant $|A^N(iso)| = 25$ MHz is observed, which is also confirmed in the low-temperature study (spectrum not shown). All spectral parameters are summarized in Table 3.

Space group	$C222_1$ (no. 20)
a (Å)	10.211(5)
b (Å)	23.979(11)
c (Å)	11.715(4)
V (Å^3)	2868.4(11)
Z	4
d_{calc} (g cm^{-3})	1.219
μ(Mo-K_α) (cm^{-1})	7.40
Temperature (°C)	25(2)
$R(F_o)^a$	0.0394
$R_w(F_o)^{b,c}$	0.1101
S (Goodness-of-fit)^d	1.128^d

[a] $R(F_o) = \Sigma(|F_o - F_c|)/\Sigma|F_c|$.

[b] $R_w(F_o) = \Sigma w^{1/2}|F_o - F_c|/\Sigma w^{1/2}|F_c|$.

[c] $w = 1[\sigma^2(F_0^2) + (0.0468P)^2 + 2.11P]$, where $P = (F_0^2 + 2F_c^2)/3$ with $\sigma(F_0^2)$ from computing statistics.

[d] $S = \{\Sigma[w(F_o - F_c)^2]/(n-p)\}^{1/2}$, where n is the number of observed reflections and p is the number of parameters refined.

An increase in $g_\parallel$ value and decrease in $|A_\parallel|$ for **2** can be attributed to an increased positive charge on a donor set as concluded by Peisach and Blumberg (P-B diagram) [18]. This is further reflected by a significant reduction in the nitrogen shf splitting constant 25 MHz, compared with 46 MHz for the non-hydrogenated complex. The decrease in nitrogen shf splitting for the hydrogenated analog is what may be expected for isotropic coupling of Cu^{II} to a sp^3 nitrogen versus a sp^2 nitrogen (i.e. less s-character). The shift to smaller $g_\parallel$ values in **1** indicates increased delocalization of the unpaired spin density away from the copper nucleus and may also be interpreted in terms of increased covalency of the metal–ligand bond.

The ratio of $g_\parallel/|A_\parallel|$ is a good measure of degree of tetrahedral distortion [19]. The value of this ratio for **1** is 105 cm, which correlates well with the square-planar arrangement around the copper center, the corresponding value of 112 cm for **2** reveals a slight tetrahedral distortion. Thus, the results of low-temperature frozen solution study are in good agreement with X-ray analysis, indicating that inert toluene does not affect the planarity of copper surroundings. Since the X-ray data for **2** are not available at present, the Ni counterpart data recently reported can be used [20]. The X-ray analysis revealed that the NiO_2N_2 plane does in fact show a slight tetrahedral distortion and that the two benzene rings are bent slightly upwards and downwards, respectively. Also Ni—O (1.866 and 1.850 Å) and Ni—N (1.930 and 1.890 Å) distances differ a little more. Assuming similar X-ray data for **2**, a good match between the X-ray and ESR conclusions may be derived.

In spite of the fact that we are aware of relative validity of calculated spin densities and their comparison against shf constants, particularly for a set of two compounds, we have carried out MO calculations within the INDO method (Table 4). They show that for both **1** and **2** the spin density is delocalized within the molecular plane over the chromophore: the donor nitrogen and oxygen atoms bear 0.047 and 0.050 spin density, respectively. This finding is quite typical for planar Cu^{II} complexes with Schiff-base type ligands. What is rather atypical is the nonvanishing spin density on the hydrogen atoms H_β approaching a value of 0.006. Such a value is manifestated in the ESR

spectra: the superhyperfine splitting can be observed even from a rather *distant* hydrogen atom. Comparison of the QR-INDO/1 and INDO/2 (not presented) values show that both sets of data lead to the same conclusion. It should be noted that the donor oxygen atoms and C_β atoms also bear some spin density. Since these atoms have zero nuclear spin, the effect of these spin densities is not seen in shf splitting of the ESR spectra. Thus, the only ESR active spin densities are those on the Cu, N and H atoms. The relatively high spin density on the H_α and H_β in the case of **1** is a consequence of the practically planar rearrangement of the respective hydrogen atoms. In the case of the hydrogenated analog **2** the spin density at the H_α and H_β atom is so low (these hydrogens are situated out of the planar rearrangement) that additional superhyperfine splitting in the ESR spectra is not observed.

EXPERIMENTAL

Preparation

The synthesis of the ligands H_2L and $H_2[H_4]L$ and preparation of the complexes CuL (**1**) and $Cu[H_4]L$ (**2**) was described earlier [13].

ESR spectroscopy

The ESR spectra were recorded on a Bruker SRC-200 D spectrometer operating at X-band. Spectral simulations were performed using computer programs described elsewhere [15,16].

X-ray structure determination

For X-ray diffraction a suitable specimen of **1** of dimensions $0.22 \times 0.22 \times 0.62$ mm (0.030 mm^3) was mounted on a STOE-STADI4 diffractometer with graphite-monochromatized Mo-K_α radiation. The final lattice constants (Table 1) were determined from the 2θ values of 56 reflections in the range 45–55°. The intensities of 2730 reflections ($-14 < h < 14$,

$-33 < k < 33$, $-16 < l < 16$) were measured in the interval $1.70 < \theta < 30°$. Independent reflections: 2581 ($R_{int} = 0.0121$). Reflections used with $F > 4.0\sigma(F)$: 2087. An empirical absorption correction was carried out. The structure was solved by the Patterson method and refined by full-matrix weighted least-squares techniques [21,22]. The *U*s for all the hydrogen atoms were fixed and isotropic. The final difference map was featureless with the highest peak of 0.48 and −0.36 e $Å^{-3}$, respectively.

Molecular orbital calculations

The MO calculations were performed within the approximate INDO (Intermediate Neglect of Differential Overlap) method. Two variants of the method have been applied; (i) standard INDO/2 extended to transition metals [23–26]. (ii) the nonempirical quasi-relativistic INDO/1 [27–29]. All 77 atoms in **1** were considered and the basis set consisted of 187 valence orbitals. The hydrogenated counterpart **2** was taken in geometry determined for a nickel analog [20]. UHF spin densities have been projected in order to eliminate the higher spin multiplicity components.

Supplementary material available. Atomic coordinates, thermal parameters and complete bond length and angles for complex **1** have been deposited with the Editor as supplementary data. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

(Received 25 April 1996; accepted 24 July 1996)

Abstract—The addition of $[Fe(CN)_6]^{4-}$ to $[Cu(tren)]^{2+}$ [tren = tris(2-aminoethyl)amine] gives a polynuclear complex of formula $[(tren)Cu(NC)Fe(CN)_4(CN)Cu(tren)]\cdot 12H_2O$, which has been characterized by spectroscopic techniques and single crystal X-ray analysis. The asymmetric unit comprises half a molecule and the iron atom is at the centre of symmetry. The $[Cu(tren)]^{2+}$ and $[Fe(CN)_6]^{4-}$ ions are linked together through cyanide bridges. Of the six CN^- groups around the iron atom, four are not bonded to copper atoms, but only interact through hydrogen bonds with the water molecules present in the lattice, the remaining two coordinate to copper atoms of adjacent $[Cu(tren)]^{2+}$ moieties, leading to a non-linear Fe—C≡N—Cu chain. The presence of six water molecules per asymmetric unit of the complex gives rise to an extensive hydrogen-bonded system. Infrared and electronic spectral results are discussed and related to the crystal structure. Copyright © 1996 Elsevier Science Ltd

Keywords: crystal structure; polynuclear complex; ferrocyanide; tris(2-aminoethyl)amine; copper(II) complex; characterization.

Interaction of ferrocyanide with copper proteins may lead to electron transfer between the two metals, the copper ion(s) being reduced. It is believed that outer-sphere charge-transfer (CT) complexes are formed during the process, and the binding in such complexes is suggested to occur *via* electrostatic interactions and hydrogen bonding. However, direct information on this process is not available [1]. In some cases, such as ferrocyanide with bovine superoxide dismutase and copper-substituted carbon anhydes [2,3], formation of CT complexes without electron exchange takes place. In the hope of throwing some light on the actual binding model of ferrocyanide, both with the copper enzymes and with copper complexes, we chose to study the copper(II) complex with tris(2-aminoethyl)amine, which commonly serves as a model for copper proteins and enzymes [4,5], to form the polynuclear complex $Cu^{(II)}$–$Fe^{(II)}$–$Cu^{(II)}$ and we report the single crystal structure.

EXPERIMENTAL

Materials

All chemicals were reagent grade and used without further purification. $[Cu(tren)][ClO_4]_2$ was synthesized according to the procedure described earlier [6].

CAUTION! Although no problems were encountered in this work, perchlorate salts containing

* Author to whom correspondence should be addressed.

† *Present address*: Institute of Food and Fermentation of Jiang Su, Nanjing, P.R. China.

organic ligands are potentially explosive. They should be prepared in small quantities and handled with care.

Preparation of the complex

A mixture of $[Cu(tren)][ClO_4]_2$ (0.82 g, 2 mmol) and $K_4[Fe(CN)_6]\cdot 3H_2O$ (1 mmol, 0.37 g) in water (10 cm^3) was stirred for 1 h. Dark green precipitates were formed after filtering off and slowly evaporating the water solution in air. Found: C, 25.2; H, 5.6; N, 22.6. Calc. for $C_{18}H_{36}N_{14}Cu_2Fe\cdot 12H_2O$: C, 25.5; H, 5.9; N, 23.1%.

Physical measurement

Elemental analyses were performed on a Perkin–Elmer 240C analytical instrument. IR spectra were recorded on a Nicolet 170SX FT spectrophotometer with KBr pellets in the range from 4000–500 cm^{-1}. The far-IR spectra (500–100 cm^{-1}) were recorded as Nujol mulls between polyethylene sheets. Electronic reflectance and solution (water) spectra were recorded on a Shimadzu 240 and 3100 spectrophotometers, respectively. Powder ESR spectra were measured at 100 K using a Bruker 200-D SRC spectrometer.

Crystallographic data collection and structure determination

The relevant crystal data and structural parameters are summarized in Table 1. The intensities were collected at 294 K on a Riguka RAXIS IIC imaging-plate diffractometer using Mo-K_α radiation ($\lambda = 0.71073$ Å) from a rotating-anode generator operating at 50 kV and 90 mA ($2\theta_{max} = 55.2°$); 60 oscillation frames in the range of 0 ~ 180°, exposure 8 min per frame for the complex [7].

The structure was solved by direct methods. All non-hydrogen atoms were refined anisotropically by full-matrix least squares. Hydrogen atoms of the ligand and the solvent molecules were placed in their calculated positions with C—H 0.96 Å, assigned fixed isotropic thermal parameters and allowed to ride on their respective parent atoms. The contributions of these hydrogen atoms were included in the structure factor calculations.

All computations were carried out on a PC-486 using the SHELXTL-PLUS program package [8]. Analytical expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated [9]. Bond distances and angles are listed in Table 2.

Additional material deposited at the Cambridge Crystallographic Data Centre comprises atom coordinates and thermal parameters.

RESULTS AND DISCUSSION

IR spectrum

The principal IR-active bands of the title complex fall in the regions 3100–3500 and 2000–2100 cm^{-1}, the first being characteristic of ν(O—H) and ν(N—H), the second of ν (C≡N). In the first interval, the band at 3450 cm^{-1} and a shoulder at 3500 cm^{-1} are assigned to the stretching vibrations of water molecules. The bands at 3338, 3277 and 3146 cm^{-1} are some of the expected NH_2 stretching vibrations of the tren ligand [10]. For the ν(C≡N) mode of $[Fe(CN)_6]^{4-}$ two main bond systems of comparable intensity are observed: one at 2058 cm^{-1} is assigned to the intermetallic C—N stretching [11], and another at 2041 cm^{-1} is assigned to terminal stretching modes. The two bands are derived from the T_{1u} species of ferrocyanide in the O_h point group by lowering of the symmetry [12]. The Cu—N (NH_2 of tren) stretching modes are at 422 and 472 cm^{-1}. The weak but sharp band at 534 cm^{-1} can be assigned to the Cu—N stretching mode of the imino nitrogen [13], while the band at 273 cm^{-1} might be assigned to the Cu—N stretching relative to CN^- group, and bands at 421 and 442 cm^{-1} might be due to the Fe—C stretching mode [14]. All of these indicate that the complex not only contains the ferrocyanide moiety, but also the copper(II) moiety with the CN^- group coordinated to it, as well as water molecules.

Electronic spectra and ESR spectrum

The solid reflectance electronic spectrum (Fig. 1) shows a band at 18,400 cm^{-1} and a shoulder at *ca*

Symmetry code: a $(1-x, 1-y, 1-z)$; b $(-x, 1-y, 1-z)$; c $(-x, 0.5+y, 1.5-z)$; d $(1-x, -0.5+y, 1.5-z)$; e $(1-x, 0.5+y, 1.5z)$.

14,600 cm^{-1}, the former can be assigned to the metal to metal charge transfer transition (MMCT) (15), and the latter to a *d–d* transition of the Cu^{II} moiety. However, the broadness and overlapping characteristics of the spectrum prevented us from obtaining further information about the coordination geometry

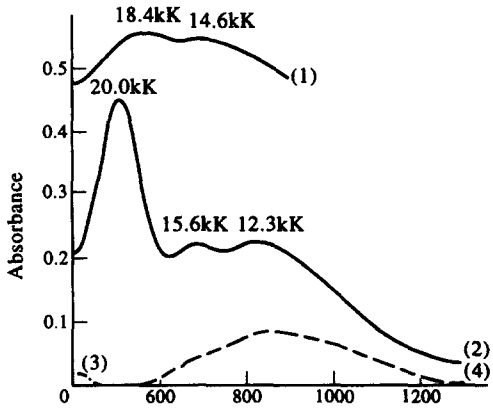

Fig. 1. The electronic reflectance (1) and absorption in water (2) of the title complex (——), comparing with the absorption in water for $K_4Fe(CN)_6 \cdot 3H_2O$(3) (-·--·-) and [Cu (tren)][ClO$_4$]$_2$ (4) (- - -).

of the copper(II) atoms. The solution electronic spectrum (Fig. 1) of the complex exhibits three well-separated bands at 20,000 (980), 15,600 (700) and 12,300 cm^{-1} (710 dm^{-3} mol^{-1} cm^{-1}). The band at 20,000 cm^{-1} is ascribed to a MMCT transition, the other two bands are assigned to *d–d* transitions of the copper(II) moiety, the equal intensity of the two bands indicated that the coordination geometry of Cu^{II} might be a *cis* octahedron or a geometry intermediate between the square pyramidal and trigonal bipyramidal topolgies [16,17]. However, discarding the tail of the MMCT band, it might be expected that the intensity of the band at *ca* 15,600 cm^{-1} will be lowered, and thus we can suggest that the coordination geometry of the copper(II) is square pyramidal with considerable trigonal bipyramidal distortion. This suggestion is also supported by the solid-state ESR spectrum at 100 K which has the $g_{\parallel} = 2.107$, $A_{\parallel} = 3.2 \times 10^{-3}$, $g_{\perp} = 2.077$ and $A_{\perp} = 5.7 \times 10^{-3}$.

Description of the structure of the complex

The stereochemistry of the complex is shown in Fig. 2. The structure consists of a neutral [(tren) Cu(NC)Fe(CN)$_4$(CN)Cu(tren)] unit as a separate

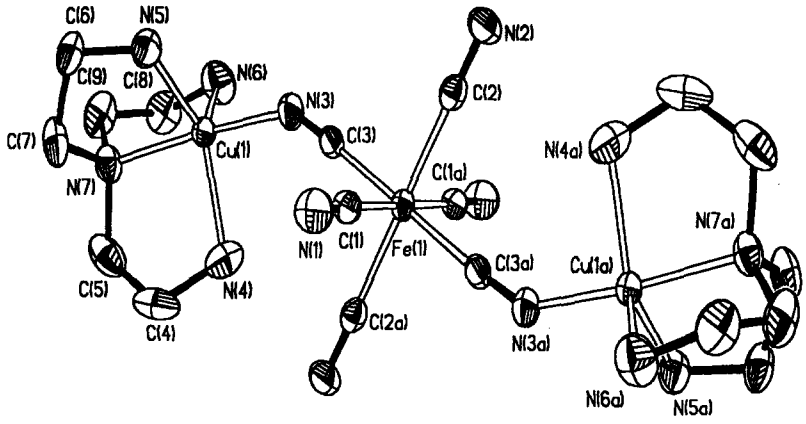

Fig. 2. Molecular structure and atom numbering of the complex.

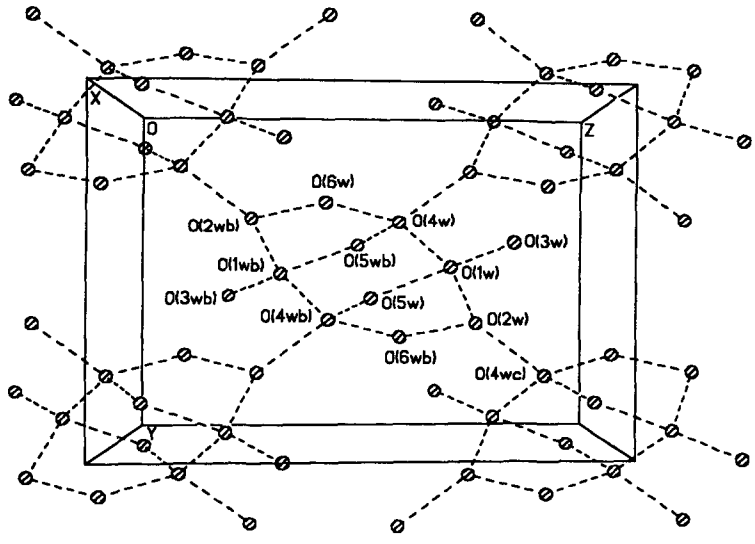

Fig. 3. Hydrogen bonding scheme for the water molecules in the molecular packing.

trinuclear complex. Within the polynuclear complex, the iron atom of the hexacyanoferrate ion occupies the centre of symmetry, and four of the six CN^- groups, namely C(1)≡N(1) and C(2)≡N(2), as well as the centrosymmetrically related ones, are bonded to iron and to water molecules. The other two cyanide ligands around iron reveal their amibdentate and bridging nature, forming bonds with the copper atoms of the nearest $[Cu(tren)]^{2+}$ ions and giving rise to non-linear Fe—C≡N—Cu sequences, with the Cu—N≡C bond angle of *ca* 144.1°. An intermediate geometry between regular, square-based pyramidal and trigonal bipyramidal around each copper atom is thus present, as suggested by the spectroscopy, and the geometrical parameter [18] $\tau = 0.48$ also indicates that there is some shift towards square pyramidal, as expected. This structure is quite different from the general mononuclear [17,19,20] and binuclear [21, 22] copper(II) complexes with the tren as ligand, which always give an almost regular trigonal bipyramidal arrangement around the copper(II), with τ close to 1.0, owing to the rigid C_{3v} structure of the tren ligand. In the basal plane the copper atom is coordinated by two primary amine nitrogen atoms, N(4), N(5), and the tertiary amine nitrogen atom, N(7), of the tren, and the nitrogen atom, N(2), belonging to the cyanide group, whereas, the other primary amine nitrogen atom of tren, N(6), is in an apical position of the square pyramid. The bond lengths and angles within each $[Fe(CN)_6]^{4-}$ and $[Cu(tren)]^{2+}$ unit do not differ significantly from values reported previously [6,20,23,24]

A two-dimensional network (Fig. 3) of the water molecules, connected by hydrogen bonds and in groups of six for each asymmetric unit of the polynuclear complex, is present in the lattice. Four of the

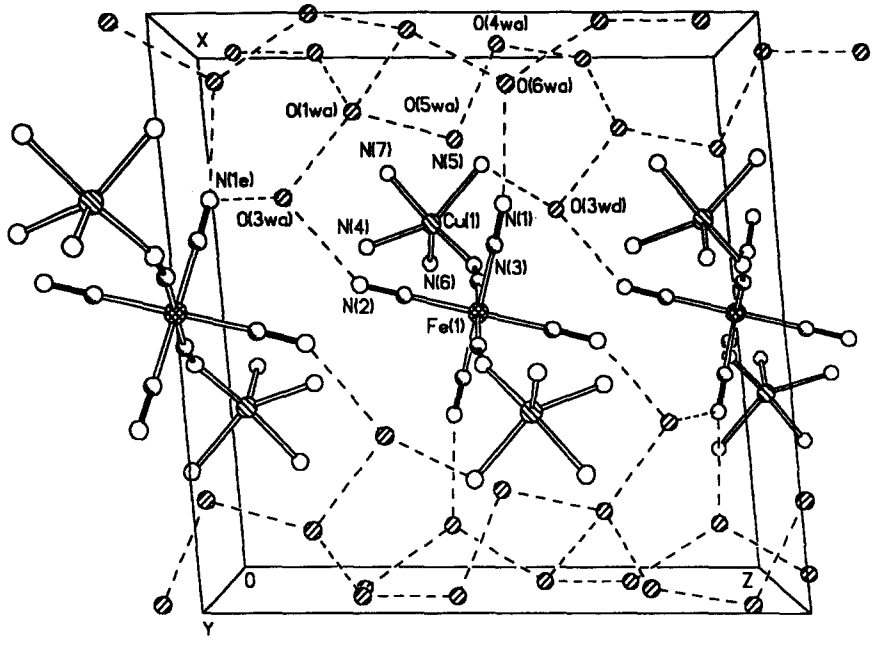

Fig. 4. Hydrogen bonding scheme in the molecular packing. Carbon atoms of the $[Cu(tren)]^{2+}$ moiety were omitted for clarity.

six water molecules, O(1w), O(2w), O(4w), O(6w), are connected together to form a main chain, the remaining two, O(5w) and O(3w), are connected to the chain through hydrogen bonds to water molecule O(1w). The main chain, together with the centrosymmetrically related ones, connect together to form the eight-membered ring. The rings are connected *via* hydrogen bonds $O(2w)\cdots O(4wc)$ $(-x, 0.5+y, 1.5-z)$ to form a two-dimensional network. This develops along the *a*-axis of the cell, and is associated with each of the separate polynuclear units through an extensive hydrogen-bond system involving some of the nitrogens of the hexacyanoferrate moiety, to form the three-dimensional networks shown in Fig. 4. Of the six water molecules, only two of them, O(3w) and O(6w), form hydrogen bonds to the nitrogen of the terminal CN^- group. Of the three primary amine nitrogen atoms, only one, N(5), forms a hydrogen bond to the water molecule. The intermolecular contacts of those water molecules and nitrogen atoms are listed in Table 2. No other intermolecular contacts are less than 3.15 Å.

(Received 20 March 1996; accepted 24 July 1996)

Abstract—A new binuclear cadmium(II) macrocyclic complex has been synthesized by [2+2] Schiff-base condensation of tris(3-aminopropyl)amine with sodium 2,6-diformyl-4-methoxylphenolate in the presence of $Cd(ClO_4)_2 \cdot 6H_2O$. The crystal structure, spectral characterization and molar conductivity show that two cadmium(II) ions were bridged by two μ_2-phenoxy oxygen atoms. Each cadmium(II) is located in a trigonal prismatic coordination environment (N_4O_2). Copyright © 1996 Published by Elsevier Science Ltd

Keywords: cadmium(II); binuclear complex; macrocycle; oxygen bridge; crystal structure; trigonal prism.

Pilkington and Robson [1] obtained a new kind of macrocyclic ligand for the first time by the template condensation of 2,6-diformyl-4-methylphenol with diamines. The ligands contain strong donors, namely, phenoxy oxygen atoms as well as amine nitrogen atoms, therefore they are excellent for catalysis and biological simulation [2,3] because of their special coordination ability with transition metal ions. The polyaza macrocyclic ligands also have these properties and have attracted much attention [4–6]. Cadmium is an environmental pollutant which inhibits RNA polymerase activity *in vivo* [7,8] and reacts readily with proteins and other biological molecules, and so the macrocyclic chemistry of cadmium has been developed recently [9]. Although many studies have been made on cadmium(II) macrocyclic complexes [10–12], only a few crystal structures have been reported, and most were found to be mononuclear complexes [13–17]. In this paper we report the synthesis, characterization and X-ray crystal structure of a new η-oxo-bridged binuclear cadmium(II) complex of a 28-membered macrocyclic complex with pendant arms (Fig. 1). To our knowledge, only a few of these kinds of structures have hitherto been reported.

EXPERIMENTAL

Materials

2,6-Diformyl-4-methoxylphenol (dmop) was prepared using the method described in the literature [18]. Sodium 2,6-diformyl-4-methoxylphenolate (sdmop) was obtained by mixing equimolar amounts of dmop and NaOH in ethanol. Tris(3-aminopropyl)amine was prepared by a modified literature method [19] with a purity of over 99%. All starting materials were of chemical purity.

Physical measurements

Solution electrical conductivity was measured by a BDS-A numerical conductometer (Jiangsu, China) with solution concentrations of *ca* 10^{-4} mol dm^{-3} in acetonitrile. IR spectra were measured as KBr discs

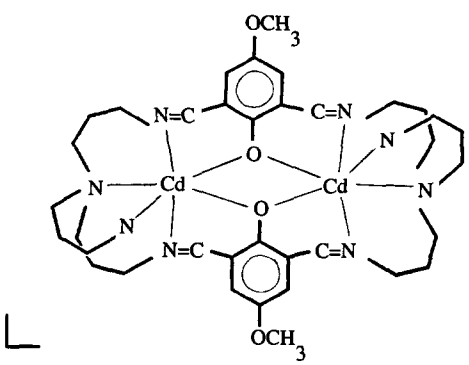

Fig. 1. The structure of the binuclear complex cation $[Cd_2(H_{-2}L)]^{2+}$.

using a Nicolet 5DX FT-IR spectrophotometer. Electronic spectra were recorded on Shimadazu UV-240 spectrophotometer.

Preparation of the complex $[Cd_2(H_{-2}L)](ClO_4)_2 \cdot 0.5CH_3OH$

To a stirred solution of sodium 2,6-diformyl-4-methoxyphenolate (0.101 g, 0.5 mmol) and $Cd(ClO_4)_2 \cdot 6H_2O$ (0.261 g, 0.625 mmol) in absolute methanol (30 cm^3) was added dropwise a solution of tris(3-aminopropyl)amine (0.094 g, 0.5 mmol) in absolute methanol (15 cm^3) at 0°C. After stirring for 2 h at 35°C, yellowish microcrystals were precipitated and filtered off, washed with methanol and dried *in vacuo* (yield 45%). Found: C, 40.2; H, 5.5; N, 10.5; Cd, 19.9. Calc. for $C_{36.5}H_{56}N_8O_{12.5}Cd_2Cl_2$; C, 39.8; H, 5.1; N, 10.2; Cd, 20.4%. IR (KBr, cm^{-1}): 3400 br, ν(OH)(CH_3OH); 3354s, $\nu_{as}(NH_2)$; 3300s, $\nu_s(NH_2)$; 1641s, ν(C=N); 1544s, ν(Ar—O); 1102 (ClO_4^-). UV–vis (λ_{max} nm, CH_3CN); 270 (9763 mol^{-1} dm^3 cm^{-1}); 430 (10078). Λ_M (CH_3CN, 279 K): 236 S cm^2 mol^{-1}. The yellowish crystals of $[Cd_2(H_{-2}L)](ClO_4)_2 \cdot 5CH_3OH$ suitable for X-ray structure determination were obtained by slow evaporation of the mother liquor at ambient temperature.

CAUTION. Perchlorate salts of metal complexes with organic ligands are potentially explosive. Only small amounts of material should be prepared, and these should be handled with caution. The complex described in this report has, so far, been found to be safe when used in small quantities.

X-ray crystal structure determination of $[Cd_2(H_{-2}L)](ClO_4)_2 \cdot 5CH_3OH$

Crystal data. $C_{36.5}H_{56}N_8O_{12.5}Cd_2Cl_2$, $M = 1102.65$, yellowish crystal, dimensions $0.9 \times 0.9 \times 0.45$ mm^3, triclinic, space group P_{-1}(#2), $a = 10.455(6)$, $b = 11.451(4)$, $c = 20.130(6)$ Å, $\alpha = 105.75(3)$, $\beta = 82.84(3)$, $\gamma = 97.21(3)°$, $V = 2291(2)$ $Å^3$, $F(000) = 1122$, $Z = 2$, $D_c = 1.60$ g cm^{-3}, $T = 296$ K, $\mu = 11.06$ cm^{-1}.

Data collection and refinement. A single crystal was mounted on a glass fibre. The crystal data were collected on an Enraf–Nonius CAD4 four-circle diffractometer with graphite-monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å) using an ω–2θ scan mode with ω scan width $0.95 + 0.350 \tan\theta$, scan rate 5.49° min^{-1}. A total of 8067 independent reflections were collected in the range $2 < 2\theta < 50°$, of which 6421 reflections with $I > 3\sigma(I)$ were used in the structure determination and refinement, after L_p corrections. The structure was solved by the MITHRIL direct method. The remaining non-hydrogen atoms were located from a difference Fourier map. Hydrogen atoms were introduced in calculated positions but not refined. The final least-squares cycle gave $R = 0.052$, $R_w = 0.064 (w = 1/\sigma^2(F_0))$. The maximum and minimum residuals had values of 0.63 and −0.89 $eÅ^{-3}$, respectively. All calculations were performed on a MICRO VAX-3100 computer using the programs contained in the TEXSAN [20].

RESULTS AND DISCUSSION

Characterization of the complex

In the infrared spectrum a strong peak appears at 1641 cm^{-1} corresponding to the stretching vibration of imino C=N bonds. The symmetric and asymmetric stretching frequencies (3300 and 3354 cm^{-1}) for NH_2 groups are also present, but no strong peaks at 1650–1700 cm^{-1} for the carbonyl groups. This means that two NH_2 groups and carbonyl groups have been condensed into C=N bonds, whilst another NH_2 group is unchanged. A broad band at *ca* 3400 cm^{-1}, characteristic of the OH group of CH_3OH, showed that CH_3OH molecules exist in the crystalline complex, in agreement with the elemental analysis. The strong peak at 1102 cm^{-1} without splitting showed that ClO_4^- did not take part in coordination with Cd^{II} ions. This is also confirmed by the molar conductivity of the complex ($\Lambda_M = 236$ S cm^2 mol^{-1}) which is attributable to a 2:1 electrolyte. Two intense absorptions in the electronic spectrum of the complex are designated to π–π^* transitions of the K band of the benzene rings and of C=N groups.

Description of the structure of $[Cd_2(H_{-2}L)](ClO_4)_2 \cdot 0.5CH_3OH$

A perspective view of the cation $[Cd_2(H_{-2}L)]^{2+}$ and a packing diagram are displayed in Figs 2 and 3, respectively. Selected bond distances and bond angles are given in Tables 1 and 2, respectively.

Figure 3 shows that each unit cell contains two complex associations, each consisting of one molecule of the macrocyclic complex cation $[Cd_2(H_{-2}L)]^{2+}$, two perchlorate anions and half of a methanol solvent

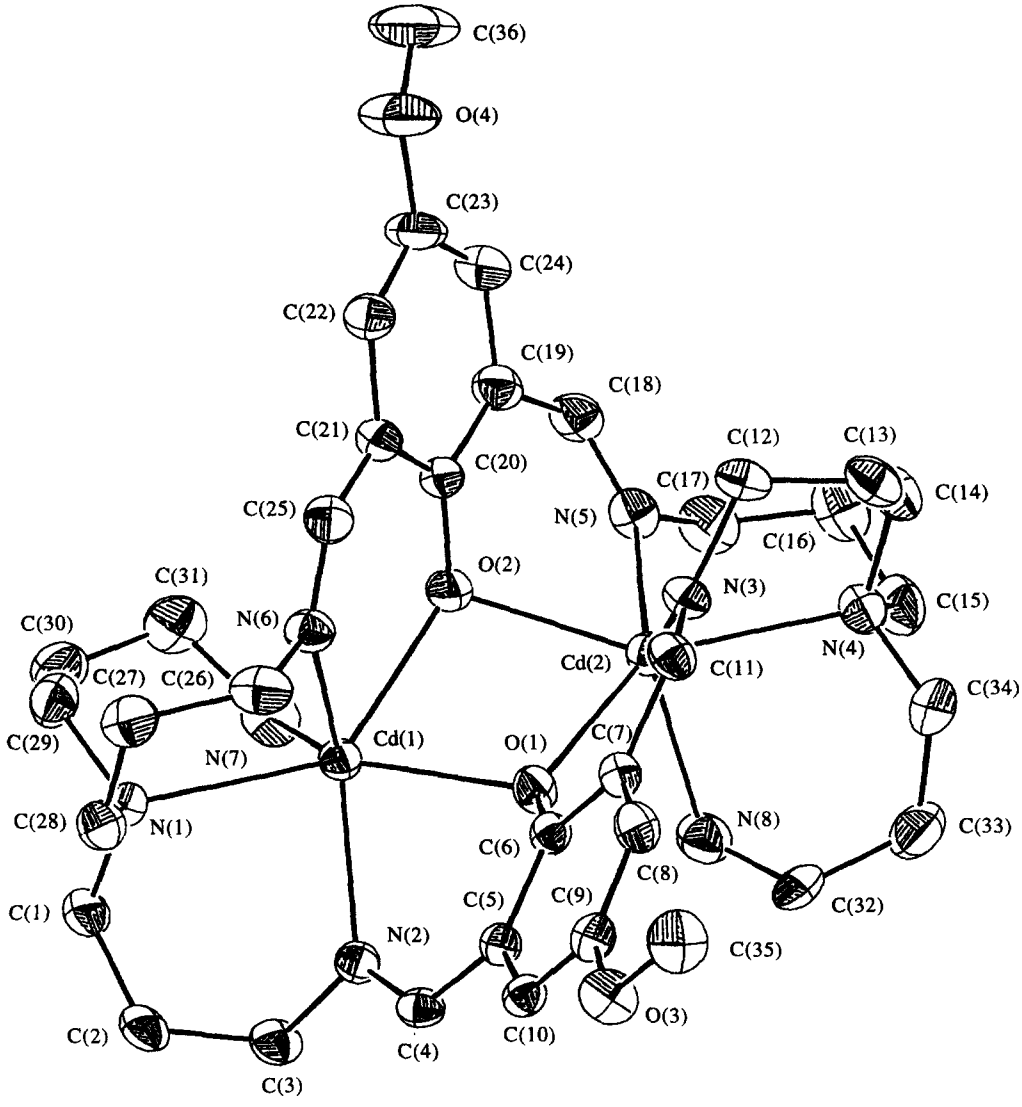

Fig. 2. A perspective view of the cation $[Cd(H_{-2}L)]^{2+}$.

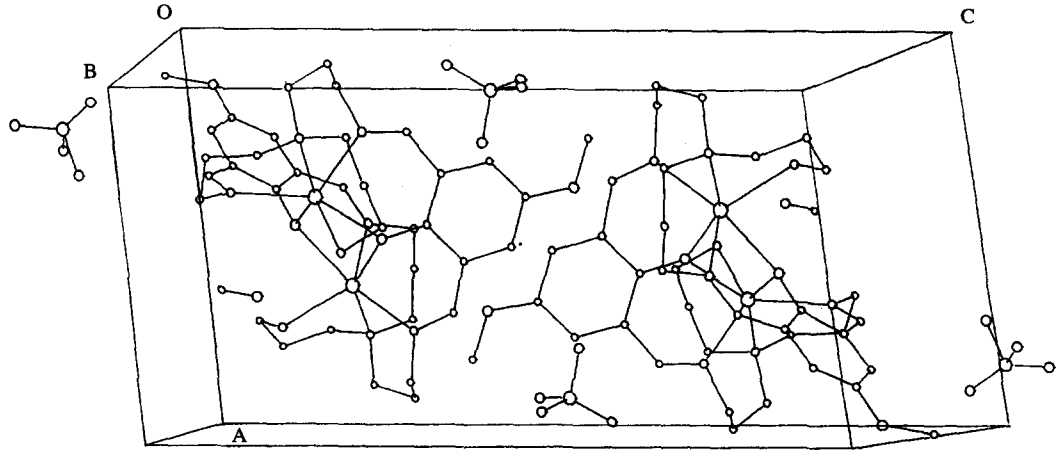

Fig. 3. A packing diagram of the complex $[Cd_2(H_{-2}L)](ClO_4)_2 \cdot 0.5CH_3OH$.

Table 1. Selected bond distances (Å)

Cd(1)—N(7)	2.294(6)	Cd(2)—N(3)	2.295(5)

molecule. The methanol and perchlorate anions are disordered over two interpenetrating sites. It can be seen from Fig. 2 that in the cation of the complex each Cd^{II} ion is enclosed within the polyaza macrocycle and coordinated by one bridgehead nitrogen atom, two imino nitrogen atoms, one amine nitrogen atom of the pendant arms and two oxygen atoms of phenoxy groups. Each Cd^{II} is located in a trigonal prismatic N_4O_2 coordination environment with coordination number of six. For the Cd(1) centre, the phenoxy oxygens O(1), O(2) and the amino nitrogen N(6) forms one trigonal face, the Cd(1) deviates downwards by 1.5181 Å from the face. The amino nitrogen atoms N(2), N(7) and the bridgehead nitrogen N(1) form another trigonal face, the Cd(1) deviates upwards by 1.2522 Å from the face. The dihedral angle between the two faces is 11.13°. For the Cd(2) centre, the phenoxy oxygens O(1), O(2) and amino nitrogen N(3) form one trigonal face and the Cd(2) deviates upwards by 1.4849 Å from the face. The amino nitrogens N(4), N(5) and the bridgehead nitrogen N(8) form another trigonal face and the Cd(2) deviates downwards by 1.2423 Å from the face. The dihedral angle between the two faces is 12.74°C. The dihedral angle between the plane consisting of Cd(1), O(1), Cd(2) and the plane consisting of Cd(1), O(2), Cd(2) is 151.00°. The phenoxy oxygens O(1) and O(2) bridge the two Cd^{II} ions. The bond distances of Cd(1)—N(imino) and Cd(2)—N(imino) are approximately equal, being in the range 2.294–2.311 Å. These Cd—N bond distances are shorter than the standard bond distance of 233 ± 0.005 Å [20]. This means that these imino groups have strong coordination ability towards Cd^{II}. Conversely, the two bond distances Cd(1)—N(1), Cd(2)—N(4) are 2.455 and 2.483 Å, respectively, implying weak interaction between the Cd^{II} ions and the bridgehead nitrogen atoms.

However, in the cadmium cryptate synthesized by condensation of tris(2-aminoethyl)amine with 2,6-diformyl-4-methylphenol [21], the corresponding bond distance of Cd—N(bridgehead) 2.787 Å, was larger than that reported in this paper. The long Cd(1)···Cd(2) distance (3.689 Å) indicates that there is no interaction between the two metal atoms. The bond distances Cd(1)—O(1), Cd(2)—O(2), Cd(2)—O(1) and Cd(2)—I(2) are 2.282, 2.350, 2.318 and 2.328 Å, respectively, being close to those reported by Drew *et al.* [21], also implying that Cd(1) is similar to Cd(2) in coordination environment but slightly different to Cd(2) in degree of distortion. An analogous complex $[Cu_2L'(OH)](ClO_4)_3$ which was synthesized by [2+2] Schiff-base condensation of tris(2-aminoethyl)amine with isophthalic aldehyde in the presence of $Cu(ClO_4)_2 \cdot 6H_2O$ is unstable [22]. In our complex, however, the flexibility of the carbon chain strengthened the coordination ability of the bridgehead nitrogen atoms, and the phenoxy oxygen atoms bridging the two Cd^{II} atoms enhanced the stability of the complex as well as forming the six-membered chelate rings and so stabilizing the structure of the complex.

Structure of [2-(aminomethyl)pyridine]silver(I) nitrate and EPR studies of its oxidation product*

G. Swarnabala and M. V. Rajasekharan†

School of Chemistry, University of Hyderabad, Hyderabad 500 046, India

(Received 8 January 1996; accepted 24 July 1996)

Abstract—Reaction of $AgNO_3$ with excess 2-(aminomethyl)pyridine (amp) in water led to the crystallization of Ag(amp)NO_3 (**1**). Nearly linear coordination of silver(I) by pyridine-N and amino-N from two different amp molecules results in a polymeric chain structure of **1**. The packing is stabilized by ring–ring stacking interactions between two inversion-related polymer chains. Oxidation of **1** with $(NH_4)_2S_2O_8$ resulted in an orange solution from which a magnetically dilute Ag^{II} complex was crystallized by the addition of NH_4PF_6. It gave a well-resolved EPR spectrum and is formulated as silver(II) picolinate co-crystallized with NH_4PF_6.
Copyright © 1996 Elsevier Science Ltd

Keywords: polymeric coordination compound; silver(I); silver(II); EPR.

2-(Aminomethyl)pyridine (amp), being a flexible ligand, can either form chelates or act as a bridging ligand. While several examples are known for tris-chelates with this ligand [1–4], there is only one example [5] for the bridging mode, namely, the polymeric $[Rh_2(OAc)_4(amp)]_n$ complex. Solution studies [6,7] indicated the formation of several Ag^I-containing species such as $[AgHL]^+$, $[AgL]^+$, $[Ag_2L_2]^{2+}$, $[AgL_2]^+$ and $[Ag_2L]^{2+}$ where L = amp. As part of our continuing interest in the complexes of Ag with N-heterocyclic ligands [8,9], we have now investigated Ag(amp)NO_3 (**1**) which has a polymeric structure analogous to that of Ag(pz)NO_3 [10] (where pz = pyrazine). Reaction of **1** with $(NH_4)_2S_2O_8$ resulted in the oxidation of Ag^I to Ag^{II}, as well as the conversion of the $—CH_2NH_2$ group to carboxylate. The EPR of the oxidation product is also presented.

EXPERIMENTAL

All chemicals were of reagent grade. Amp and 2-picolinic acid (picH) were purchased from Fluka. IR (KBr disks) and UV–vis spectra were recorded on Perkin–Elmer 1310 and Lambda-3B spectrometers, respectively. C, H, N analyses were performed using a Perkin–Elmer 240C analyser. Silver was estimated gravimetrically [11]. EPR spectra were measured using a Jeol-FE-3X spectrometer.

Synthesis

Ag(amp)NO_3. To a solution of $AgNO_3$ (0.169 g, 1.00 mmol) in water (2 cm^3), amp (0.20 cm^3, 1.9 mmol) was added. The resulting clear solution was allowed to evaporate slowly in a desiccator. Colourless rod-shaped, thick crystals of Ag(amp)NO_3 (**1**) deposited after two days which were washed with water and methanol and dried. Yield: 0.185 g (0.665 mmol) 66.5%, based on $AgNO_3$. Found: C, 26.3; H, 3.1; N, 15.0; Ag, 37.4. Calc. for $C_6H_8N_3O_3Ag$: C, 25.9; H, 2.9; N, 15.1; Ag, 38.8%. IR data (KBr): 3267b, 1763s, 1595s, 1388b, 1151s, 997s, 825s, 760s, 611m cm^{-1}.

X-ray crystallography

Single-crystal data were collected on an Enraf–Nonius CAD-4 diffractometer using graphite-monochromated Mo-K_α radiation. Unit-cell parameters are based on 25 accurately centred reflections. An empirical absorption correction based on ψ-plot [12] was applied to the intensity data. There was no significant crystal decay. Crystallographic data are given in Table 1. The structure was solved by a combination of heavy

atom and direct methods using SHELXS-86 [13] and refined over F^2 using SHELXL-93 [14]. The non-hydrogen atoms were refined anisotropically. The hydrogen atoms were located by geometrical considerations. The ring H atoms and CH_2 H atoms were allowed to ride upon the C atoms to which they were attached. The positional parameters of amine H atoms were refined, but restrained with respect to the adjacent CH_2 and Ag. The three common H atom thermal parameters (for ring, amine and CH_2) were refined isotropically. Refinement* converged with $wR_2 = 0.0973$, $R_1 = 0.0320$ [$I > 2\sigma(I)$] for 742 reflections; the goodness-of-fit (S) was = 1.208. The final difference map showed a residual electron density of 0.771 eÅ^{-3}. Molecular diagrams were obtained using the ORTEP program [18].

RESULTS AND DISCUSSION

Synthesis

Two types of crystals were obtained when amp was added to an aqueous solution of $AgNO_3$, in 1 : 1 and 2 : 1 proportions. The crystals reported here were obtained from the latter solution. It has been observed that the polymeric material is being formed only in the presence of excess ligand. The yield quoted is based on the first crop of pure crystals. The polymer has been synthesized several times by this method and checked by IR, and C, H, N analyses. The C, H, N analyses and the IR of the flake-like crystals formed in the former synthesis, using a 1 : 1 ratio, do not agree with that of the polymer. These crystals are being investigated further.

Structure

The structure is made up of a one-dimensional polymeric chain. Figure 1 shows the molecular structure of the repeating unit of the polymer while Fig. 2 shows the packing of the polymer chains in the unit cell. The coordination around the Ag atom is approximately linear [N(1)—Ag—N(2) = 164.9(2)°], and the Ag atom is bound by N atoms of pyridine and amine from two different ligands. The two oxygens of the nitrate ion are weakly bonded to Ag at a distance of 2.72(3) Å[Ag—O(1)]. These distances are outside the range of 2.3–2.6 Å usually expected for a weak Ag—O interaction. Nevertheless, the presence of these oxygens seems to be partly responsible for the deviation of the coordination from linearity. The structure is analogous to that of Ag(pz)NO_3 [10] where the silver atom is perturbed by distant nitrate oxygens [Ag—O = 2.72(2)–2.94(2) Å] leading to even greater deviation from linearity [N—Ag—N = 159.3(9)°]. The Ag—N(pyridine) and Ag—N(amine) distances are comparable to those observed in other Ag^I complexes with these types of ligands [9,10,19]. The two inversion-related polymeric chains lie nearly along the a-axis. The packing is stabilized by ring–ring stacking interactions (Fig. 2). The nitrogen atoms of the two pyridine rings are *anti* to each other. The shortest interplanar distance is 3.213(1) Å [C(5)···N(1)].

Oxidation of Ag(amp)NO_3 (1)

When $(NH_4)_2S_2O_8$ was added to a saturated solution of **1** at 4°C, the colour of the solution slowly changed to pink, from which pink, needle-shaped crystals (**2**) separated in a few hours. When NH_4PF_6

*Since systematic absences do not distinguish between $Pna2_1$ and its centrosymmetric counterpart, *Pnma*, structure solution and refinements were performed in both space groups. Both refinements converged readily (maximum shift/e.s.d. less than 0.01 for both), provided the starting coordinates are obtained from Fourier maps calculated in the respective space groups. (However, singularities result if refinement is attempted in *Pnma* with parameters refined in $Pna2_1$ or vice versa.) The residuals (R_1) are 0.030 for $Pna2_1$ and 0.032 for *Pnma*. One disadvantage of refining in $Pna2_1$ was that the z-coordinates were found to show significantly higher (about four times) standard deviations ($\sigma(z)$) compared to $\sigma(x, y)$. A survey of the recent literature [15] showed that such a discrepancy is often seen for nearly planar molecules in the $Pna2_1$ space group, and it probably has to do with correlations in the refinement process owing to the presence of pseudo symmetry (mirror plane). In the present case, even though intensity statistics and the Hamilton test [16] are in favour of the non-centrosymmetric space group, as pointed out by Marsh [17] as well as by a referee such tests are not definitive, especially for structures with heavy atoms. Since the geometrical parameters are identical in both space groups within one standard deviation, and there is no disorder in either refinement, the data in the more symmetric space group (*Pnma*) are presented here, while the $Pna2_1$ data are available from the corresponding author on request.

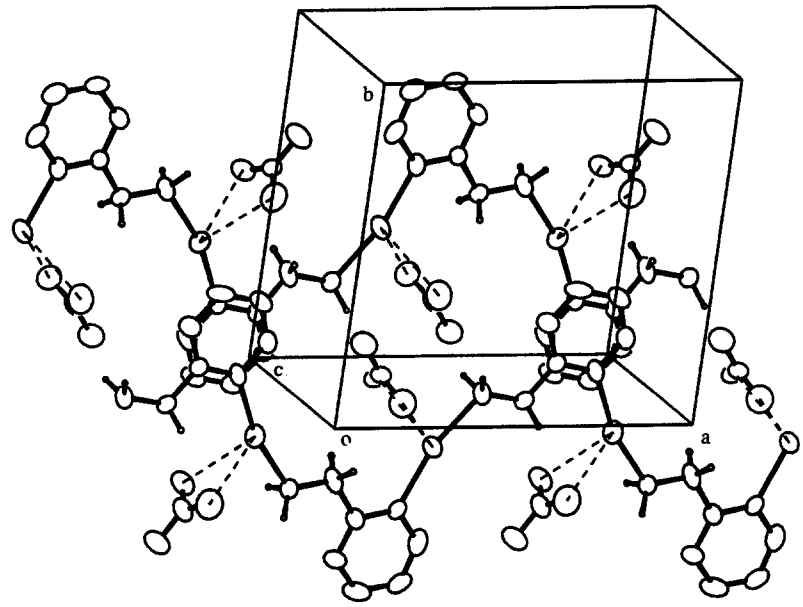

Fig. 2. The packing of polymer chains in the crystal illustrating the stacking of the pyridine rings of the ligand. The weak interactions of the nitrate oxygens with the silver ion are indicated by broken lines.

was added to the mother liquor a light pink precipitate (**3**) was formed. The rest of the solution, when kept in the refrigerator (4°C) for several days, deposited some pink crystals (**4**).

Owing to the instability of **3** and **4** when removed from mother liquor, definitive analytical data could not be obtained. The pink solution has electronic absorption bands at 19.6 and 27.8 kK. These may be assigned to *d–d* and LMCT transitions, respectively, of an Ag^{II} species [8,20]. The IR spectrum of **2**, as well as of **3**, shows a strong peak at 1690 cm^{-1} (typical for COO—) which is absent in **1**. Closer examination revealed that the IR spectrum of **2** matches that of the previously reported [20] $Ag(pic)_2$. These observations imply that our experimental conditions lead to the conversion of the aminomethyl side chain to carboxylate, as well as oxidation of Ag^{I} to Ag^{II}. Silver(I)-catalysed oxidation in the presence of persulfate, of amine to aldehyde, and aldehyde to carboxylate have been noted before [21]. It was further observed that the treatment of $Ag(pic)\cdot H_2O$, prepared using a reported procedure [22], with $(NH_4)_2S_2O_8$ followed by NH_4PF_6 leads to the precipitation of an unstable pink crystalline product identical in properties to **3**. All these observations lead to the conclusion that the Ag^{II} species resulting from the $S_2O_8^{2-}$ oxidation of $Ag(amp)NO_3$ is $Ag(pic)_2$.

The unique feature of **3** is that it gives a well-resolved EPR spectrum showing hyperfine splitting from $^{107,108}Ag$ ($I = 1/2$) and superhyperfine from two ^{14}N ($I = 1$) nuclei (Fig. 3b). However, a typical magnetically concentrated spectrum with $g_\parallel = 2.191$ and $g_\perp = 2.059$, was obtained for **2** (Fig. 3a). The computer simulation of the spectrum of **3** (Fig. 3c), using a previously described program [8], led to the following parameters: $g_\parallel = 2.184$, $g_\perp = 2.054$, $A_\parallel(Ag) = 45.8 \times 10^{-4}$ cm^{-1}, $A_\perp(Ag) = 18.0 \times 10^{-4}$ cm^{-1}, $A(N) = 25.7 \times 10^{-4}$ cm^{-1}, $B(N) = 15.3 \times 10^{-4}$ cm^{-1}. The nitrogen superhyperfine interaction was modelled assuming the tensors to be equivalent and axial with the Ag—N bond direction as the symmetry axis. For a square-planar coordination, $A_\parallel(Ag)$ is in the (x,y)-planes of the nitrogen tensors. The components of the ligand tensors along the principal direction of the Ag tensor, namely $A_\parallel(N)$ and $A_\perp(N)$ are then equal to $B(N)$ and $(1/\sqrt{2})\,(A^2+B^2)^{1/2}$, respectively. The observation of eight lines in the parallel region and six lines in the perpendicular region implies the following relation between the Ag and N hyperfine components: $A_\parallel(Ag) \cong 3A_\parallel(N)$ and $A_\perp(Ag) \cong A_\perp(N)$. The EPR spectrum showing coupling with only two N atoms, conforms with formulation of the paramagnetic species as $Ag(pic)_2$.

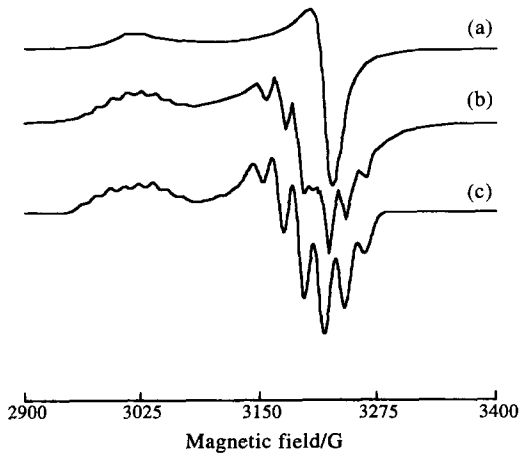

Fig. 3. EPR spectra (X-band, 300 K) of polycrystalline samples: (a) **2**, (b) **3** and (c) computer simulation of (b).

Well-resolved EPR spectra having similar parameters were observed previously [8] for Ag (dmbp) NO_3^+ and $Ag(dmp)NO_3^+$, where dmbp = 6,6′-dimethyl-2,2′-bipyridine and dmp = 2,9-dimethyl-1,10-phenanthroline, when the Ag^{II} species were precipitated by the addition of NH_4PF_6. Comparing with these two systems and other previously reported [23] Ag^{II} species, the EPR parameters of **3** also imply 35–50% delocalization of the odd electron. Detailed characterization of these magnetically dilute materials is hampered by the difficulty in obtaining stable crystals. However, IR spectra reveal the presence of NH_4^+ and PF_6^- ions, as well as strong features from the organic ligand. Since the observation of resolved EPR spectra require magnetic dilution at the molecular level, the compounds may be double salts or clathrate hydrates.

Unlike dmbp [9a] and dmp [9b], which form monochelates with $AgNO_3$, having a 3+1 (nearly) planar coordination at Ag, amp forms a polymeric complex having linear coordination with practically no involvement of the NO_3^- in the coordination sphere. The flexibility of the aminomethyl side chain and the stabilization of the crystal structure by stacking interactions between adjacent polymeric chains are responsible for this difference. Stacking interaction between aromatic rings makes an important contribution to the packing of dmbp and dmp complexes as well [9].

All three complexes, $Ag(L)NO_3$ (L = dmbp, dmp, amp), when treated with $S_2O_8^{2-}$ followed by NH_4PF_6 yielded magnetically dilute Ag^{II} species. This is puzzling because, based on EPR and IR, as well as confirmation by independent preparation, $Ag(amp)NO_3$ produces the neutral $Ag(pic)_2$ species, while $Ag(L)NO_3$ (L = dmbp, dmp) gave [8] $Ag(L)NO_3^+$. While the formation of double salts with NH_4PF_6 is plausible for the latter (as implied by analytical data), a host–guest complex between $Ag(pic)_2$ and NH_4PF_6*

*NH_4PF_6 has an NaCl-type lattice [24]. Size considerations preclude both substitutional and interstitial doping of the Ag^{II} species in NH_4PF_6. Formation of a clathrate phase upon crystallization from aqueous medium containing Ag^{II} species having appropriate size and shape may possibly account for the magnetically dilute EPR spectra. While the structures of hydrates of NH_4PF_6 are not available, $HPF_6\cdot 6H_2O$ does have a clathrate structure [24c].

is more likely for the former. It is noteworthy that $Ag(bpy)_2^{2+}$ (bpy = 2,2′-bipyridine) and $Ag(py)_4^{2+}$ (py = pyridine) do not yield magnetically dilute EPR spectra when crystallized with NH_4PF_6. Further studies using different paramagnetic species and other PF_6^- salts are in progress.

(Received 15 May 1996; accepted 22 July 1996)

Abstract—Ruthenium(II) complexes with general formula $[RuCl_3(NO)(P–P)]$ were obtained in the solid state, where $P–P = PPh_2(CH_2)_nPPh_2$ ($n = 1–3$) and $PPh_2\text{-}CH = CH\text{-}PPh_2$. The ^{31}P NMR spectra of these compounds measured in CH_2Cl_2 showed only singlets, consistent with a *fac* configuration containing two equivalent phosphorus atoms. However the X-ray diffraction data show that the $[RuCl_3(NO)\{PPh_2(CH_2)_3PPh_2\}]$ complex crystallizes in a *mer* configuration, where one of the phosphorus atoms is *trans* to the NO group, in a slightly distorted octahedral geometry. Keywords: ruthenium; nitrosyl; complexes; biphosphines; X-ray structure; isomerism.

The nitrosyl ligand has been shown to exist in both linear and bent forms corresponding to three-electron and one-electron donors, respectively. Crystallographic and spectroscopic studies have been used to distinguish between these two geometries in mononuclear nitrosyl complexes [1–6]. There is some evidence that bulky ligands present in ruthenium nitrosyl complexes govern the intramolecular geometry of these species [7–9]. Thus, bulky ligands in the ruthenium complexes bend away from the nitrosyl group towards less sterically crowded sites in order to relieve the strain caused by these coordinating molecules. In the complex $[OsCl_3(NH_3)(PPh_3)_2]$ [8], which contains an ammine ligand, less bulky than the nitrosyl, the phosphines bend towards the NH_3 by a small amount (0.3°) compared with $[RuCl_3(NO)(P\text{-}Ph_2Me)]$, where the phosphine bends away from the NO by a greater amount (4.1°) [9]. In this paper we report the preparation and characterization of ruthenium(II) complexes with general formula $[RuCl_3(NO)(P–P)]$, where P–P is one of the following diphosphine ligands: bis(diphenylphosphino)methane (dppm), 1,2-bis(diphenylphosphino)ethane (dppe), 1,3-bis(diphenylphosphino)propane (dppp), 1,2-bis (diphenylphosphino)ethylene (dppen), and the X-ray structure of the complex $[RuCl_3(NO)(dppp)]$. Our aim was mainly to provide information about the structure of this complex in solution and in the solid state, and to investigate the ability of coordinated NO^+ to cause a *trans* strengthening effect in $\{Ru^{II}–NO^+\}$-type complexes containing strong π acceptor ligands.

EXPERIMENTAL

Measurements

The infrared spectra of the complexes were measured from powder samples diluted in CsI on an FT-IR Bomem-Michelson 102 spectrometer in the 4000–200 cm^{-1} region. The ^{31}P $\{^1H\}$ spectra were recorded in CH_2Cl_2 on a Bruker 400 MHz spectrometer, with H_3PO_4 (85%) as the internal reference.

Synthesis

The $[RuCl_3(NO)\{PPh_2(CH_2)_nPPh_2\}]$ complexes were synthesized from $[RuCl_3(NO)]$, which was prepared by passing a stream of NO through a solution of commercial ruthenium chloride (Degussa S.A.) in dichloromethane until the solution became red, followed by evaporation to dryness. The dried solid obtained was kept in a vacuum desiccator for at least 3 days before use. The NO was generated by reaction of dilute nitric acid (*ca* 33%) over copper metal. The NO gas was dried by passing it through a column containing anhydrous $CaCl_2$. A typical synthesis of the $[RuCl_3(NO)\{PPh_2(CH_2)_nPPh_2\}]$ complexes was done by refluxing for about 4 h the deoxygenated methanolic solution (5 cm^3) of $[RuCl_3NO]$ (0.1 g, 0.42 mmol) and the corresponding diphosphine (0.42 mmol). In all cases solids were precipitated, which were filtered off and well washed with diethyl ether (yield: *ca* 80%).

$[RuCl_3(NO)dppen]$ (**4**). Yellow microcrystalline powder. Found: C, 49.7; H, 3.6; N, 2.2. Calc. for $C_{26}H_{22}Cl_3NOP_2Ru$: C, 49.3; H, 3.5; N, 2.2%. IR: ν(NO) 1875, ν(Ru—Cl) 330 and 283 cm^{-1}. ^{31}P-$\{^1H\}$ NMR: δ 54.10.

Crystal structure of **3**

Suitable crystals of complex **3** were grown by slow evaporation of a dichloromethane/diethyl ether solution. A single crystal was used for data collection and cell parameter determination on an Enraf–Nonius CAD-4 diffractometer, with graphite-monochromated Mo-K_α radiation at room temperature (T = 298 K). Unit-cell parameters were obtained by least squares from the setting angles of 25 reflections. Intensity data were collected in the ω scan mode up to θ_{max} = 26.32°, with scan rates between 3.3 and 16.5° min^{-1}. The intensity of three standard reflections were essentially constant during the measurement. Data were corrected for Lorentz polarization and absorption effects using the empirical Psi Scan method [10]. The structure was solved using the SIR method [11] and difference Fourier techniques. In the final cycles of least-squares refinement, all non-hydrogen atoms were treated anisotropically. All hydrogen atoms were assumed in their calculated position by the geometry of the ligand atom and included in the least-squares calculation with a fixed isotropic temperature factor (6.0 $Å^2$). The function minimized was $\Sigma w(|F_0| - |F_c|)^2$, where $w^{-1} = \sigma^2(F_0)$. Scattering factors for non-hydrogen atoms were taken from Cromer and Mann [12] with corrections for anomalous dispersion from Cromer and Liberman [13], and for hydrogen atoms from Stewart *et al.* [14].

All the calculations were performed with the system Mo1EN [10]. The data collection and experimental details are summarized in Table 1. The relevant interatomic bond lengths and angles are listed in Table 2.

RESULTS AND DISCUSSION

In all the diphosphine complexes studied in this work, the ν(NO) in the infrared spectra were close to 1870 cm^{-1}, indicating that they were indeed of the $\{Ru^{II}—NO^{+}\}$ type [1,2].

The $^{31}P-\{^{1}H\}$ NMR data mentioned in the experimental section show that these complexes present only a singlet, suggesting that in all cases the phosphorus atoms are *trans* to the chlorines. However, the crystal structure of the $[RuCl_3(NO)(dppp)]$ complex (Fig. 1) shows that the NO group is *trans* to a phosphorus atom, suggesting that this compound can be found as a *fac* isomer in solution and prefers, probably because of steric effects, to be crystallized as a *mer* isomer.

The ν(NO) in the IR spectrum obtained from crystals of the $[RuCl_3(NO)(dppp)]$ complex is at 1841 cm^{-1}, different from the 1875 cm^{-1} found for the sample prepared from powder of the same complex. Considering that the chlorine is a better donor than the phosphorus atom, in this case the back-bonding Ru → NO should be more intense for the structure where the NO is *trans* to the chlorine (*fac* isomer) and the ν(NO) should be expected to shift to a lower energy, which was not observed experimentally. In this case the shift of 34 cm^{-1} observed in the IR spectra

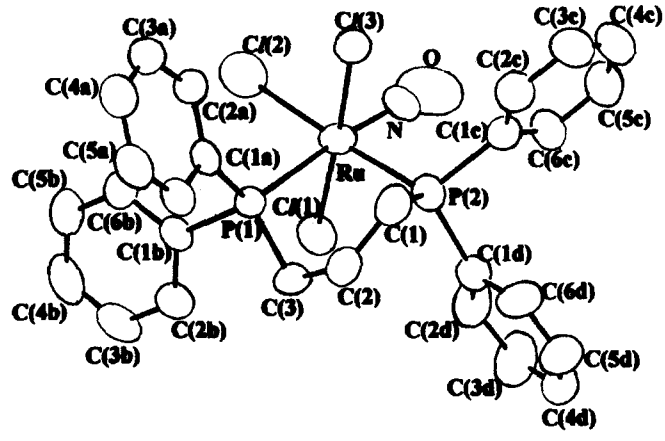

Fig. 1. Molecular structure and crystallographic numbering scheme for $[RuCl_3(NO)\{PPh_2(CH_2)_3PPh_2\}]$.

of the samples probably is not due to electronic effects, but is the consequence of steric effects. Thus, when the nitrosyl group is close to three chlorine atoms (*mer* isomer) for steric reasons it becames less linear, compared with the NO species which is only close to two chlorine atoms (*fac* isomer), and in this case the ν(NO) shifts to a lower energy [7]. For the crystal sample the IR spectra shows $\nu_{Ru\text{-}Cl}$ at 336 and 311 cm^{-1}.

It is interesting to point out that the isomerization process from the *mer* to the *fac* isomer was observed through $^{31}P\text{-}\{^1H\}$ experiments. In this case the $^{31}P\text{-}\{^1H\}$ spectra (A) of a fresh solution prepared with crystals of the $[RuCl_3(NO)(dppp)]$ in CH_2Cl_2 shows two doublets ($\delta = 10.13$ and $\delta = 0.27$, $J_{P\text{-}P} = 48.6$ Hz) as expected for the *mer* isomer. The intensity of these two doublets decreased with time and the singlet at $\delta = 14.17$, which belongs to the *fac* isomer, appeared (B) and at the end of this isomerization process only this isomer was present in the solution (C) (Fig. 2).

In the structure of the $[RuCl_3(NO)(dppp)]$ *mer* isomer (Fig. 1), three mutually perpendicular coordination planes are well defined and their angles are of a slightly distorted octahedron. Their angles are close to 90°. In this complex the Ru atom is displaced 0.099 Å towards the NO group, out of the best plane consisting of the three chlorines and the P(2) phosphorus atom. For the analogous series of *mer*-$[RuX_3(NO)(en)]$ complexes, where X = Cl, Br, I, these values were found to be 0.176(2), 0.1518(7) and 0.106(2) Å, respectively [16]. These distortions were attributed to the steric hindrance between the bulky Ru—NO bond orbital and the halogen. The distortion is decreased in the order Cl, Br, I because the bigger the halogen is the longer is the Ru—X length [average Ru—X lengths are 2.36, 2.50, 2.71 Å for X = Cl, Br and I, respectively]. This rationalization seems to be reasonable in order to explain the smaller value of the distortion (0.099 Å) found for the $[RuCl_3(NO)(dppp)]$ complex compared with those found for the halogen complexes $[RuX_3(NO)(en)]$, considering that the diphosphine is bulkier than the en ligand. This effect becomes evident when the average Ru—Cl distance in $[RuCl_3(NO)(en)]$ and $[RuCl_3(NO)(dppp)]$ are found to be essentially the same (*ca* 2.37 Å), but the Ru—N(2) and Ru—P(2), 2.092(9) [16] and 2.436(2) Å, respectively, are substantially different. In the case of $[RuCl_3(NO)(dppp)]$ the average interatomic distance between the nitrogen atom of the NO and the chlorine ligands is 3.07 Å, identical to that found in the *mer*-$[RuCl_3(NO)(en)]$ complex [16]. The identical distances found in these two complexes can be rationalized if we consider that, although the diphosphine ligand is bulkier than the en ligand, this effect is compensated for by the longer Ru—P(2) distance.

The observed Ru—N—O bond angle [172.0(6)°] is smaller than those found for $[RuX_3(NO)(en)]$ [16] [174.1(7), 176.9(5) and 179.4(2)° for X = Cl, Br and I, respectively]. This effect is attributed to the repulsion between the extensive molecular orbital of the NO ligand and the phenyl rings bonded to the P(2) atom of the diphosphine. The same effect is reflected in the angle P(1)—Ru—N, which is smaller than 180° [169.8(2)°], and in the angles Cl(3)—Ru—P(2) [82.13(5)°] and Cl(1)—Ru—P(2) [98.32(6)°]. The bulky NO molecular orbitals show influence even in the Cl(2)—Ru—P(1) and the Cl(2)—Ru—N angles. As can be seen in Table 2 these angles are equal to 86.41(5) and 93.0(2)°, respectively, which can be explained by considering that the NO molecular orbital pushes Cl(2) towards the P(1) atom. The Ru—P(1) and Ru—P(2) distances of 2.460(1) and 2.436(2) Å, respectively (see Table 2) are near to the expected values, which usually fall in the range 2.41–2.44 Å [17], and in this case the *trans* strengthening effect in the $[RuCl_3(NO)(dppp)]$ complex was not observed. It is likely that the essentially linear nitrosyl group does not achieve strong bonding (particularly through Ru—NO π back-bonding) when *trans* to phosphorus, which is not a very good donor atom [18]. Indeed, this crystal structure shows the oxygen atom of the NO group with a high thermal parameter, indicating some flexibility for the orientation of the nitrosyl with respect to the Ru—N bond. The distance Ru—N is longer [1.880(4) Å] when NO is *trans* to the phosphine, as in our complex, than when it is *trans* to bromine [1.787(9) Å] or *trans* to oxygen from the ethylsulfoxide [1.72(1) Å] as in $[RuBr_3(NO)(Pr^n_2S)_2]$ and $[RuBr_3(NO)(Et_2S)(Et_2SO)]$ complexes, respectively [19]. The Ru—N distance of 1.880(4) Å is a little larger than the expected metal–nitrogen double bond distance of 1.75(3) Å in ruthenium and osmium complexes that contain linear nitrosyl ligands [7]. The N—O distance [0.906(7) Å] is close to those found for the bis(dipropyl)sulfide [1.047(26) Å] and for the sulfide/sulfoxide [1.09(1) Å] complexes mentioned above [19].

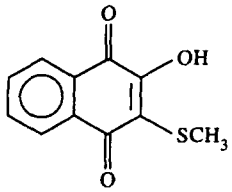
(Received 29 March 1996; accepted 19 July 1996)

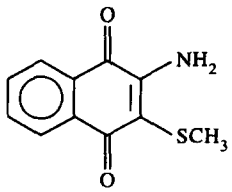
Abstract—The electron transfer complexes of general type $[M(L^1)_2]$, $[M(L^2)_2]$ and $[M(L^3)_2]$ with M = Ni^{II}, Cu^{II}, Pd^{II} and VO^{II} ions have been investigated using 2-hydroxy-3-methylmercaptan-1,4-naphthoquinone (HL^1), 2-amino-3-methylmercaptan-1,4-naphthoquinone (HL^2) and 2, 3-diamino-1,4-naphthoquinone (HL^3) as ligands. Polarographic results confirmed that some the these neutral compounds underwent reversible or quasi-reversible one-electron reduction processes, and the reduction potentials for the $[M(L^1)_2]$ and $[M(L^3)_2]$ complexes were lower than those of the corresponding $[M(L^2)_2]$ complexes. EPR spectra of the prepared compounds, except the $[Pd(L^2)_2]$ complex, show that they are paramagnetic and some of them behave as free radicals stabilized through the cation. An attempt to correlate spectroscopic and redox parameters has been made. Copyright © 1996 Elsevier Science Ltd

Keywords: spectroscopy; electrochemical; napthoquinone; complexes.



Transition metal charge transfer complexes have been the subject of a considerable amount of research over the past twenty years, and several reviews dealing with the unusual chemical and physical properties of these complexes have been published [1–5]. One of the most interesting properties of these compounds is their ability to undergo facile electron-transfer reactions, and the structural and spectroscopic changes that accompany these reactions have attracted much attention. As a result of these studies, it has been concluded that the accessibility of a range of oxidation states of the complex is the result of the accessibility of a number of formal oxidation states for the ligand, and that the electron density in the metal orbitals does not change significantly as the oxidation state is changed [3,5–6]. On the other hand, the observations indicate that it should be possible to stabilize new magnetic states in a planar geometry with appropriate extended π-system ligands containing *ortho* donor atoms in the nitrogen and oxygen families.

The easy isolation and characterization of the neutral naphthoquinonic complexes suggests reasonable stabilities associated with their electronic arrangements and raises the possibility that they can be reducible to mono- and/or dinegative anions. The data from this work referring to charge transfer complexes of the general types $[M—O_2S_2]$, $[M—N_2S_2]$ and $[M—N_4]$ used 1,4-naphthoquinonic derivatives as ligands. The following ligands were used: 2-hydroxy-3-mercaptomethyl-1,4-naphthoquinone (HL^1), 2-amino-3-mercaptomethyl-1,4-naphthoquinone (HL^2) and 2,3-diamino-1,4-naphthoquinone (HL^3). The ligands investigated have the structures shown.



EXPERIMENTAL

All operations leading to the formation of the complexes and isolation of the final product were carried out using degassed solutions and solvents and under nitrogen that had been freed from oxygen. The general method to obtain the complexes consists of adding,

HL_1

HL_2

HL_3

under continuous stirring, to an ethanolic solution of metal(II) chloride salts or vanadyl sulfate, a ligand solution in a 40% aqueous solution of tetrabutylammonium hydroxide. The formation of the complex compound takes place immediately. Stirring was continued for 2 h, at room temperature, and then the fine crystallized precipitate was filtered and dried *in vacuo*. The ligands were prepared following published methods [7] and wherever possible reagents of analytical grade were used without further purification. All solvents were dried following published methods.

EPR measurements were carried out at room temperature by means of an X-band spectrometer employing 100 kHz modulation of the magnetic field and operating at 9060 Mhz and using a Mn^{II} standard ($g_3 = 2.03584$, $g_4 = 1.98040$, $H_3 = 3179.5$ and $H_4 = 3268.5$ G). The polarographic measurements were obtained with an Orion KTS device. The half-wave potentials were measured at room temperature using the calomel reference electrode and the dropping mercury measuring electrode. Solutions of the complexes (1×10^{-3} mol dm^{-3}) were used and the supporting electrolyte was a 0.1 M solution of tetra-n-butylammonium perchlorate. The electronic spectra were recorded with a Zeiss–Jena VSU-1 spectrophotometer using spectral grade solvents. The IR spectra were run on a Zeiss–Jena UR-10 spectrophotometer, using anhydrous KBr pellets.

RESULTS AND DISCUSSION

Analytical data and molar conductivities, which establish the formulaes $[M(L^1)_2]$, $[M(L^2)_2]$ and $[M(L^3)_2]$, are given in Table 1. The results show that the ligands coordinate to metal ions with a molar ratio of 2:1. In dimethylformamide, the conductivity of the complexes ranges between 11.4 and 55 cm^2 mol^{-1} ohm^{-1}, which is in good agreement with their non-electrolyte character [8]. The minimum value that would allow characterization as a 1:1 electrolyte is 65 cm^2 mol^{-1} ohm^{-1} in this solvent. All the compounds are stable in air.

IR spectra

The IR spectra of the ligands in the region 4000–400 cm^{-1} show significant bands at 1650–1670 and 1575–1590 cm^{-1} as expected for C=O and C=C stretching vibrational modes. They are also characterized by two medium bands at 835–865 and 755–785 cm^{-1}, which are assigned to the C—H out-of-plane deformations of the naphthoquinonic ring. The observed characteristic absorption frequencies at 3380 (HL^1), 680 (HL^1 and HL^2), 3240 and 3380 (HL^2 and HL^3) cm^{-1} were assigned respectively, to the O—H and S—CH_3 vibrations and the symmetric and antisymmetric N—H vibrations of the ammino group.

The IR spectra of the coordination compounds obviously changed compared with those of the corresponding ligands. Modification or disappearance of the absorption band owing to the vibration of the O—H bond in the spectra of the $[M(L^1)_2]$ complexes proves that the coordination takes place through the oxygen atoms. In the same way, the characteristic absorption bands produced by the amino groups in the spectra of the $[M(L^2)_2]$ and $[M(L^3)_2]$ complexes disappeared and a new characteristic absorption band owing to N—H vibrations of the imino group was observed in the 3280–3320 cm^{-1} region. These results show that the HL^1 and HL^2 ligands are deprotonated and coordinate with metal ions to form neutral coordination compounds through the negative oxygen and imino ions of the hydroxyl and amino groups, respectively. The HL^3 ligand would participate in the formation of complexes in mono- or dianion forms, but, considering the composition data, it is inferred that HL^3 behaves as a bidentate monoanion. Furthermore, these ligands have a delocalized π orbital system which permits their participation in redox processes and they are able to coordinate to the central metal ion under the semiquinonic or quinonic forms.

EPR spectra

The metal complexes synthesized with ligands HL^1–HL^3 gave unusually strong EPR spectra, some of them with a good hyperfine resolution (Table 2). The non-isotropic values of the tensors were determined in all cases on polycrystalline powder samples at room temperature. Some of the isotropic g values in solution have already been published [9].

The species, NiL_2, of whatever ligand type, are para-

magnetic, which is not consistent with the presence of a deprotonated ligand system containing planar nickel(II). The signals obtained, are, however, proof of the semiquinonic character of the ligands. The signals support the definition proposed by Holm and co-workers [10] for these complexes as free radicals stabilized through the cation in which the unpaired electron is delocalized over the ligands, and to some extent over the central ion.

The $[Ni(L^1)_2]$ complex presents a hyperfine structure that is split into five hyperfine components with the intensity ratio 1:4:6:4:1, probably owing to interaction with four equivalent protons of the ligand. The $[Ni(L^2)_2]$ compound has a spectrum consisting of three components. It is suggested that two components ($g_\parallel, g_\perp$) originate in the splitting of the unpaired electron in the axial symmetry field of the complex, while the third component is the result of the donor–acceptor interaction between the ligands and the central ion ($g_3 = 2.0025$). The $[Ni(L^3)_2]$ complex has a signal with pronounced asymmetry and third-order anisotropy, indicating a distortion from square-planar configuration.

Both parallel and perpendicular features of ^{63}Cu are clearly resolved in polycrystalline powder samples of Cu^{II} complexes at room temperature. The $g_\parallel$ and $g_\perp$ values deviate considerably from the free spin value, and the trend $g_\parallel > g_\perp > 2.0023$ observed in the copper(II) complexes shows that the unpaired electron is in the $d_{x^2-y^2}$ orbital of the copper(II) ion [11]. A lower value of the total width for $[Cu(L^2)_2]$ and $[Cu(L^3)_2]$ compared with that of the $[Cu(L^1)_2]$ complex is indicative of more covalency in the in-plane σ bonding character of the former complexes [9].

The EPR of the palladium complexes show that $[Pd(L^2)_2]$ is diamagnetic while $[Pd(L^3)_2]$ presents a highly intense, symmetric and sharp signal (Fig. 1) with a g value of 2.0009 and total width of 18.26 G, suggesting the presence of a free radical stabilized through the cation. However, the observed paramagnetism may also be due to the strong donor–acceptor interaction observed in charge transfer complexes.

At room temperature the EPR spectrum of $[VO(L^1)_2]$ shows eight hyperfine lines characteristic of the vanadium nucleus ($I = \frac{7}{2}$). The oxovanadium com-

Fig. 1. EPR spectrum (X-band) at room temperature of $[Pd(L^3)_2]$ powder.

plex is likely to possess a tetragonal pyramidal structure [12] which is the basic type of coordination known for many oxovanadium compounds with a local C_{2v} symmetry [13]. The single unpaired electron is expected to be located in A_1 orbital which mainly consists of the vanadium $3d_{x^2-y^2}$ orbital [14,15]. The narrowing of the spectrum in the case of the $[VO(L^3)_2]$ complex and its poorer resolution indicate an increase in the covalent character of the metal–ligand bond. In this case the EPR signal consists of a single, extremely narrow line, characteristic of the donor–acceptor interactions present in typical charge transfer complexes.

Electronic spectra

In order to clarify the mode of bonding, the electronic spectra of the free ligands and metal chelates were studied and assigned on the basis of a careful comparison of the latter with the free ligands. In the spectra of the naphthoquinonic ligands, the aromatic bands at 47,200–35,700 cm^{-1} are attributed to naphthoquinone $\pi \rightarrow \pi^*$ transitions. The bands at 33,300–29,000 cm^{-1} are assigned to $n \rightarrow \pi^*$ transitions together with single bands detected at 21,000, 20,400 and 18,200 cm^{-1} for HL^1, HL^2 and HL^3 ligands, respectively. The electronic spectra of the complexes are summarized in Table 3. The electronic spectral data for the nickel(II) complexes are characterized by single *d–d* bands at 24,500 cm^{-1} for $[Ni(L^1)_2]$ in acetonitrile, 12,500 cm^{-1} for $[Ni(L^2)_2]$ and 20,200 cm^{-1} for $[Ni(L^3)_2]$ in acetone, which could be due to $d_{xy} \rightarrow D_{x^2-y^2}$ transitions in square-planar complexes.

The electronic spectra of the copper(II) complexes, $[Cu(L^1)_2]$ and $[Cu(L^2)_2]$ in acetonitrile exhibited three bands appearing at 12,500–13,500, 14,100–15,100 and 15,300–16,400 cm^{-1}, the positions of which were similar to those reported for square-planar or distorted tetrahedral geometries [16–18]. Tetrahedral complexes of Cu^{II} are rare owing to the Jahn–Teller effect and hence a square-planar geometry for these Cu^{II} derivatives can be suggested. The bands may reasonably be assigned, considering C_{4v} symmetry, as $^2B_{1g} \rightarrow {}^2A_{1g}$, $^2B_{1g} \rightarrow {}^2B_{2g}$, and $^2B_{1g} \rightarrow {}^2E_g$ transitions, respectively, which may be a result of the splitting of the ^2D state of the free ion in the four-coordinate state. The electronic spectrum of the $[Cu(L^3)_2]$ complex in 1:1 MeOH-dichloromethane solution contains a single band at 14,200 cm^{-1} which falls in the borderline region for square planar and tetrahedral types, indicating distortion from tetrahedral towards square-planar symmetry [19].

The electronic spectra of the palladium complexes, $[Pd(L^2)_2]$, in acetonitrile, and $[Pd(L^3)_2]$ in acetone, are consistent with a D_{4h} square–planar geometry [20], the *d–d* absorption bands at 15,800–16,000 and 18,500–21,200 cm^{-1} have been assigned to $^1A_{1g} \rightarrow {}^1B_{1g}$ and $^1A_{1g} \rightarrow {}^1E_g$ transitions, respectively.

The electronic spectra of the oxovanadium(IV) complexes have been studied very intensively, since it is the easiest of the d^1 systems to use experimentally. Unfortunately, the interpretation of the spectra has been complicated by the deviation of the complexes from regular octahedral or square-pyramidal stereochemistries. Only a single band at 16,100 cm^{-1} was detected for the oxovanadium(IV) complex and a second band is probably obscured by the strong charge transfer band observed at 25,400 cm^{-1}. These spectral features are comparable with those of various oxovanadium(IV) complexes already reported [12, 21]. We propose a C_{4v} symmetry for our five-coordinated oxovanadium(IV) complex.

Polarographic results

Polarographic measurements in acetonitrile have revealed several waves corresponding to reversible or quasi-reversible reductions of the complex species, and most of these present easily measurable and reproducible polarograms. A summary of polarographic potentials for complexes of HL^1, HL^2 and HL^3 is given in Table 3. The polarographic results indicate evidence for the existence of monoanions and dianions in solutions, but pure samples of these reduction processes were not isolated. The polarographic reduction of the complexes proceeds in two or three monoelectronic steps, some of them being reversible or quasi-reversible. The first wave was assigned to the reduction of the neutral complex species to the monoanionic species. The second wave was assigned to the reduction of the monoanionic species to the dianionic species. The third wave appears from $E_{1/2} = -0.87$ to -1.43 V and was assigned to the reduction of the naphthoquinone ring. The stability of the dianion

relative to the monoanion and the stability of the monoanion relative to neutral species is greater for the $[M(L^2)_2]$ complexes than for the corresponding $[M(L^1)_2]$ and $[M(L^3)_2]$ complexes. The most significant result that emerges from consideration of these potentials is their variation as the ligand is changed, for complexes of the same metal and charge type. For every metal investigated so far, the differences between the potentials for the $[M(L^3)_2]$ complexes and those for the $[M(L^2)_2]$ complexes are in the vicinity of 0.6 V. In contrast, the potentials for the monoanion of any one ligand with the entire series of metals cover a much smaller range. The conclusion appears to be that the ligand is assuming a commanding role in the ease of reduction and must participate somehow in the electron transfer process.

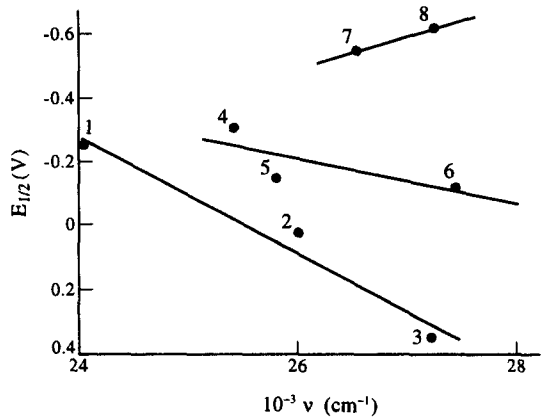

Fig. 2. Linear correlation between half-wave reduction potential and MLCT band energy. Numbers are as follows: 1, $[Cu(L^3)_2]$; 2, $[Pd(L^3)_2]$; 3, $[Ni(L^3)_2]$; 4, $[VO(L^1)_2]$; 5, $[Cu(L^1)_2]$; 6, $[Ni(L^1)_2]$; 7, $[Cu(L^2)_2]$; 8, $[Pd(L^2)_2]$.

Correlations between spectroscopic and electrochemical results

Square-planar complexes in which the ligands have a π electron system will have both π bonding and π^* antibonding ligand orbitals, and charge transfer (CT) bands of lowest energy are expected to involve transitions from the highest occupied metal orbitals (HOMOs) and the most stable (lowest) unoccupied ligand molecular orbital (LUMO). The detected charge transfer transitions can be seen in Table 3. A good approach to estimate the energies of the metal ligand charge transfer transitions from electrochemical data or *vice versa* [22] has been the correlation observed between the low energy electronic transition and the first potential reduction of the metal complex involved. The basis of such correlations lies in the fact that the same orbitals are involved in both the MLCT transition and in the electrochemical process. When the first reduction potential for the $[complex]^0/[complex]^{-1}$ couple and the lowest energy absorption band of the complexes were plotted a good relationship was obtained for each ligand with different metal ions (Fig. 2). The MLCT assignment of the lowest energy transitions in the metal complexes was thus established.

In Fig. 3 a range of A_T values, the total width of the EPR spectral band, are displayed as a function of the isotropic *g* factor for some of the charge transfer complexes. It can be appreciated that a smooth correlation was obtained since the extent of

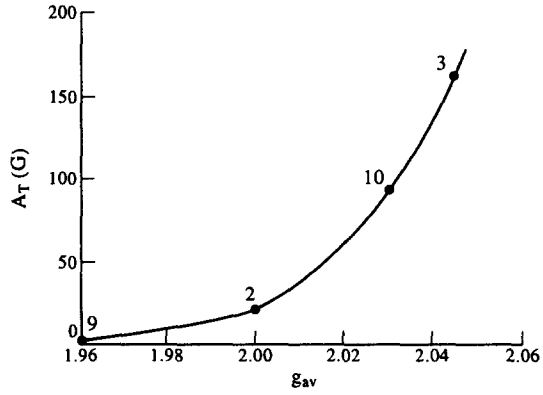

Fig. 3. Variation of the total width of the EPR spectrum with the g_{av} values. Numbers 2 and 3 as in Fig. 2; 9, $[VO(L^3)_2]$; 10, $[Ni(L^2)_2]$.

delocalization of the unpaired electron from the metal atom increases along the curve, moving towards $g = 2.0023$ as A_T falls. Deviations from the curve arise for the $[Cu(L^2)_2]$, $[Cu(L^3)_2]$ and $[Ni(L^1)_2]$ complexes and this is likely to be owing to the fact that they do not have full D_{4h} symmetry. These complexes might present distorted square-planar symmetry with third-order anisotropy.

On the other hand, the covalent character of the metal–ligand bonding would relate to the reduction potential of the metal ions having d^1 or d^9 electronic configurations. They present strong, well-resolved EPR spectra as a result of the interaction of the electron with the central metal ion. The higher the charge delocalization, the higher the covalent character of the metal–ligand bond and the ease of separation of an electron from the HOMO increases, so that the reduction potential increases. From Table 3 it can be appreciated that the total width, A_T, of the EPR spectra decreases along the series $[Cu(L^1)_2] > [VO(L^1)_2] > [Cu(L^2)_2]$, as the first reduction potential increases.

(Received 24 May 1996; accepted 17 July 1996)

Abstract—The crystal structure of $[Cu(mep)_2Cl](BF_4)$ [mep = 4-methoxy-2-(5-methoxy-3-methyl-1*H*-pyrazol-1-yl)-6-methylpyrimidine] has been determined by X-ray diffraction. The crystal structure is built up of $[Cu(mep)_2Cl]^+$ cations and BF_4^- anions. The structure of the cation involves a five-coordinated CuN_4Cl chromophore, with a stereochemistry near to a compressed trigonal bypyramid (TBP) but with a significant degree of distortion towards the square pyramidal (SP) topology. The EPR spectrum is indicative of a mixed $d_{z^2}/d_{x^2-y^2}$ ground state for the copper(II) ions, in agreement with the structural data. Copyright © 1996 Elsevier Science Ltd

Keywords: copper(II) complexes; stereochemistry; five-coordination; distortion; EPR; bidentate ligand.

As a part of our studies on the coordination behaviour of the pyrazole, pyrimidine and related nitrogen-containing heterocyclic derivatives, we have previously reported [1–6] the preparation and characterization of several complexes of divalent 3*d* ions with mepirizole [4-methoxy-2-(5-methoxy-3-methyl-1*H*-pyrazol-1-yl)-6-methylpyrimidine; hereafter, mep] a biologically active pyrimidine–pyrazole derivative. All structural studies show that mepirizole behaves as a bidentate ligand through two nitrogen atoms, one from each ring, with significant steric hindrance in the formation of metal complexes. Here we report the crystal structure and electronic properties of a new five-coordinated mepirizole-containing copper(II) complex, $[Cu(mep)_2Cl](BF_4)$. The stereochemistry of this compound is compared with those reported for related $[Cu(N\sim N)_2Cl]$ entities (where N∼N represents a N-donor bidentate ligand), which have been the focus of crystallographic and spectroscopic studies [7–9].

EXPERIMENTAL

Preparation of the complex

A solution of $NaBF_4$ (1 mmol) in water (25 cm^3) was added with stirring to a mixture of an ethanolic solution of mepirizole (1 mmol in 25 cm^3) and an aqueous solution of copper(II) chloride (0.5 mmol in 20 cm^3). The resulting green solution was left at room temperature and within 72 h a fine crystalline solid formed. This was filtered off, washed with a water/ethanol mixture, dried and stored over silica gel. By slow evaporation of the mother liquor at room temperature prismatic green crystals appeared, which were separated by filtration, washed and dried. Found: C, 40.8; Cl 5.4; N 17.2; Cu 9.6. Calc. for

$C_{22}H_{28}BClCuF_4N_8O_4$: C, 40.4; Cl, 5.4; N 17.1; Cu 9.7%.

Physical measurements

The IR spectrum (KBr pellets) was recorded on a Pye Unicam SP 2000 spectrophotometer. The diffuse reflectance spectrum was obtained using a Perkin–Elmer Lambda 9 UV/VIS/IR spectrophotometer. Polycrystalline powder EPR spectra were recorded at room temperature on Bruker ER 200D (X-band) and ESP-300 (Q-band) spectrometers.

Crystal structure

A green prismatic crystal of the complex with approximate dimensions ($0.2 \times 0.3 \times 0.4$ mm^3) was mounted on an Enraf–Nonius CAD-4 diffractometer. Intensity data and the 25 reflections for the unit cell determination (least-squares fit with $7 < \theta < 15°$) were measured at room temperature using graphite-monochromated Mo K_α radiation. The $\omega/2\theta$ scan technique was used, with variable speed, width $(0.8 + 0.35 \tan\theta)°$ in ω, and θ limits $1 < \theta < 26°$. No intensity decay was detected. From the 5570 independent reflections 4021 with $I > 2\sigma(I)$ were considered observed. Empirical absorption correction was made using Ψ-scan (max. and min. transmission factors 1.00 and 0.89).

The structure was solved by direct methods using the program SIR92 [10]. All non-hydrogen atoms were refined anisotropically by least squares on F_o using the XRAY76 System [11]. The hydrogen atoms were included as isotropic fixed contributors (370 refined parameters). In the final stages an empirical weighting scheme was chosen as to give no trends in $\langle w\Delta^2 F\rangle$ *vs* $\langle F_o\rangle$ and *vs* $\langle \sin\theta/\lambda\rangle$ using the program PESOS [12]. The final ΔF map showed a maximum peak of 0.38 e Å^{-3}.

All calculations were done with a VAX6410 computer and the atomic scattering factors and anomalous dispersion corrections were taken from ref. [13]. Other relevant parameters for the crystal structure analysis are listed in Table 1.

RESULTS AND DISCUSSION

Description of crystal structure

The crystal structure of the title compound is built up of $[Cu(mep)_2Cl]^+$ cations and BF_4^- anions. Figure 1 shows a perspective view of the $[Cu(mep)_2Cl]^+$ entity with the atomic-numbering scheme. Selected bond distances and angles are listed in Table 2.

The structure of the cation involves a five-coordinated CuN_4Cl chromophore, with no evidence for even semi-coordination of the BF_4 groups. In short, the stereochemistry of the coordination polyhedron can be viewed as near to a compressed trigonal bypiramid (TBP), similar to those reported [8,9] for several $[Cu(N\sim N)_2Cl]^+$ cations. Such a stereochemistry for five-coordinated copper(II) systems is slightly stabilized if significant steric hindrance is present [14]. There are two molecules per unit cell, but both copper(II) ions are in crystallographically equivalent sites with their trigonal axes parallel.

Two nitrogen atoms (one of each mepirizole molecule) and the chlorine atom define the equatorial plane, whereas the other two coordinated nitrogen atoms occupy the axial positions. The Cu—N_{ax} bond distances [mean value 2.001(5) Å] are not significantly different and are *ca* 0.13 Å shorter than the two equatorial ones [mean value of 2.135(4) Å]. On the other hand, the Cu—Cl bond length [2.264(2) Å] is longer than Cu—N distances consistent with the larger size of the chlorine atom. Furthermore, this copper–chlorine bond distance is significantly greater than that previously found [2] in $Cu(mep)Cl_2$ (2.19 Å), where distorted tetrahedral CuN_2Cl_2 chromophores are present.

The in-plane bond angles are far from the value of 120° corresponding to a regular TBP stereochemistry. In particular, the N_{eq}—Cu—N_{eq} angle [100.6(2)°] is appreciably lower than the ideal value, clearly indicating the distortion of the coordination polyhedron. We have quantified this distortion—from an ideal TBP geometry towards a square pyramidal (SP) one—by applying the method of Muetterties and Guggenberger [15] using the analytical formula proposed by Galy *et al.* [16]. The dihedral angles and the deviation (Δ) for both TBP and SP ideal geometries and the $[Cu(mep)_2Cl]^+$ cation are given in Table 3. The value of $\Delta = 0.22$ clearly indicates the predominance of the TBP form but with a significant degree of distortion towards the SP topology.

In addition, we have also used the τ parameter as defined by Addison *et al.* [17] to quantify the degree of distortion of the polyhedron. This is a simpler parameter but it affords similar qualitative results. So, for the title compound, $\tau = 0.67$ ($\tau = 1$ for a regular

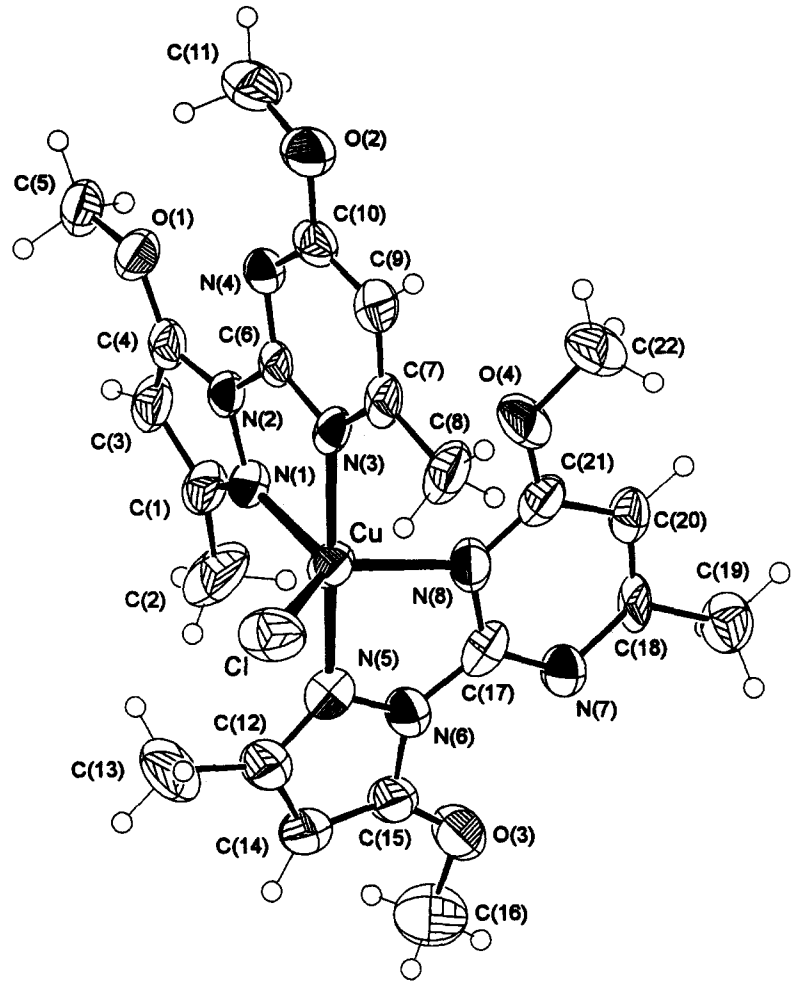

Fig. 1. Perspective view of the $[Cu(mep)_2Cl]^+$ cation showing the atom labelling.

TBP stereochemistry and $\tau = 0$ for a SP one), thus supporting the above conclusions.

Hathaway and co-workers [8] have studied the correlation between several molecular parameters for a series of five-coordinated $[Cu(bipy)_2Cl]^+$ cations that contain distorted trigonal bipyramidal CuN_4Cl chromophores. They pointed out that the in-plane bond lengths and angles vary systematically in the CuN_4Cl polyhedra. We have now reconsidered some of these correlations, including the title compound and others five-coordinated $[Cu(N\sim N)_2Cl]^+$ cations, using the τ parameter as a criterion for the degree of distortion. The graphic representation of the N_{eq}—Cu—N_{eq} angle versus τ is shown in Fig. 2a. If the compound $[Cu(bpy)_2Cl][CuCl_2]$ [18] (where the chlorine atom is involved in a bridging role to the copper atom in the anion $CuCl_2^-$) is omitted, a reasonable correlation is obtained, with the N_{eq}—Cu—N_{eq} angle increasing as τ increases.

With regard to the bond distances, it must be

Table 2. Bond lengths (Å) and angles (°) for the copper coordination sphere

Table 3. Dihedral angles (°) and distortion (Δ) of the coordination polyhedron for $[Cu(mep)_2Cl]BF_4$ compared with the ideal trigonal bipyramid (TBP) and regular square pyramid (SP) geometries

Dihedral angle	TBP	$[Cu(mep)_2Cl]^+$	SP
δa_1	101.5	90.8	121.8
δa_3	101.5	98.1	121.8
δa_4	101.5	112.0	121.8
δa_6	101.5	103.1	121.8
δa_2	101.5	84.1	73.9
δa_5	101.5	111.1	73.9
δe_1	53.1	67.0	73.9
δe_2	53.1	53.2	73.9
δe_3	53.1	48.7	0
Δ	0	0.22	1

stressed that the Cu—N_{ax} lengths are practically insensitive to the degree of distortion, whereas the Cu—N_{eq} distances vary with τ, but no explicit correlation can be established. So, only the Cu—Cl bond distance exhibits a roughly regular correlation with τ. A plot of d(Cu—Cl) against τ is showed in Fig. 2b. Again, with the exception of $[Cu(bipy)_2Cl][CuCl_2]$, an agreeable correlation is obtained, with d(Cu—Cl) decreasing with the degree of distortion.

In relation to the mepirizole molecules, the more striking feature is that they exhibit different conformations (hereafter noted as **A** and **B** conformations). In fact, to date only in the tris complex $[Cu(mep)_3](PF_6)_2$ has the **B** conformation been observed [6]. The two conformations are essentially related through rotation around the central C—N bond between the pyrimidinic and pyrazolic nuclei.

A *B*

Conformational analysis according to the rigid approximation in the MMX program [19] affords an energy barrier for this rotation of *ca* 50 kJ mol^{-1}. Thus, if significant steric restrictions are present they can stabilize the two conformers.

In other respects, there are no unusual bond distances or angles in the mepirizole molecules. In both molecules **A** and **B** the individual pyrimidine and pyrazole rings are planar (deviation from planarity ranging from 0.01 to 0.03 Å), with dihedral angles between both nuclei of 12.0° for the **A** molecule and 5.6° for the **B** molecule, clearly indicating significant torsions.

Finally the bite parameter defined by $b = 2d_0/(d_1+d_2)$ (where d_0 is the non-bonding distance between the two donor atoms, and d_1 and d_2 are the distances of these atoms to the metal centre) is $b = 1.27$ for molecule **A** and $b = 1.25$ for molecule **B**. The former compares well with the mean value of 1.29(2) for bidentate mepirizole molecules with conformation **A**. On the other hand, the **B** molecule exhibits a lower b value as occurs in the tris complex $[Cu(mep)_3](PF_6)_2$ ($b = 1.20$).

The BF_4^- anions exhibit a near-regular tetrahedral structure, with a mean B—F distance of 1.37(1) Å and a mean F—B—F angle of 109.5(7)°. The shortest Cu—F distance is 5.82 Å, in agreement with non-coordination of the tetrafluoroborate groups.

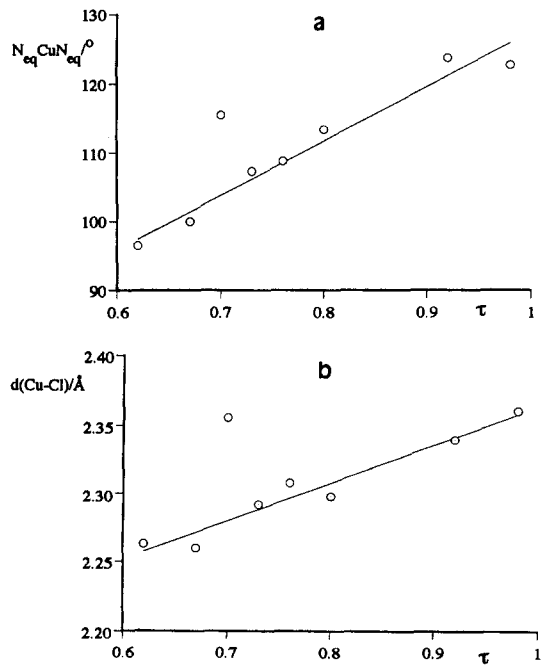

Fig. 2. (a) Correlation between the N_{eq}—Cu—N_{eq} angle and the τ parameter; (b) correlation between the Cu—Cl bond distance and the τ parameter (see text).

Vibrational and electronic spectra

The IR spectrum of the title compound shows a large number of absorption bands in the range 1700–1100 cm^{-1}, assigned to different vibrational modes of the mepirizole molecule. In addition, a strong band is observed at *ca* 1060 cm^{-1}, consistent with the presence of non-coordinated BF_4^- groups with T_d symmetry [20]. Finally, the absorption observed in the low

energy region at *ca* 390 cm^{-1} is assigned to Cu—Cl stretching vibrations [21].

The electronic reflectance spectrum of the compound studied exhibits a very broad structure in the visible region centred at 15,100 cm^{-1}. Taking into account the topology of the CuN_4Cl chromophores it may be assumed that the unresolved *d–d* band arises from overlap of the $(d_{xz}, d_{yz})\rightarrow d_{z^2}$ and $(d_{x^2-y^2}, d_{xy})\rightarrow d_{z^2}$ transitions in a point group symmetry close to C_{2v}. These observations compare well with those reported for similar CuN_4Cl chromophores [8].

EPR spectroscopy

The room-temperature X-band EPR powder spectrum of the title compound is clearly orthorhombic, although it was not fully resolved owing to the width of the signals, and leads to approximate *g* values of 2.03, 2.12 and 2.25. In the Q-band spectrum, the three lines are clearly defined giving more accurate *g* values of 2.017, 2.121 and 2.250 ($g_{average} = 2.129$). These values are very similar to those found in the complexes $Cu(terpy)X_2$ (X = Br, I, NCS) [22] which contain pentacoordinate CuN_3X_2 chromophores having a coordination geometry close to C_{2v}, and $[Cu(bipy)_2(NH_3)](BF_4)_2$ with CuN_5 chromophores intermediate between the ideal square pyramidal (C_{4v}) and trigonal bipyramidal (D_{3h}) [23]. In our compound, we can roughly consider that the local geometry of the CuN_4Cl entities is close to C_{2v} with the CuCl direction defining the twofold axis. Following the vibrational model proposed by Reinen and Atanasov [14], the ground-state wave function of a five-coordinated copper(II) complex can be expressed as follows:

$$\varphi_g = (1+c^2)^{-1/2}[d_{z^2} + c\, d_{x^2-y^2}].$$

The mixing coefficient *c* is zero for the trigonal bipyramid (d_{z^2} ground state) and is $1/\sqrt{3}$ for the square pyramid ($d_{z^2-y^2}$ ground state). The corresponding expressions for the *g* values are:

$$g_z = g_0 + 8[c^2/(1+c^2)]u_z$$

$$g_y = g_0 + 2[c^2/(1+c^2)][1-\sqrt{3}/c]^2 u_y$$

$$g_x = g_0 + 2[c^2/(1+c^2)][1+\sqrt{3}/c]^2 u_x$$

where u_i are the orbital contributions. Taking u_i as 0.032 ($g_{average} = g_0 + 4u_i$), the experimental *g* values can be reproduced nicely with *c* values of 0.33(3), very close to the value of 1/3 expected for a C_{2v} geometry, thus implying a ground state for the Cu(II) ions between d_{z^2} (TBP) and $d_{x^2-y^2}$ (SP). Hence, there is a full agreement between the structural and spectroscopic results.

Abstract—The non-linear optical (NLO) properties of two distorted cage clusters $\{WAg_3S_3[S_2P(OCH_2CH_3)_2]\}(S)(Ph_3P)_3$ (**1**) and $\{MoAg_3S_3[S_2P(OCH_2CH_3)_2]\}(S)(Ph_3P)_3$ (**2**) were studied. Both NLO absorption and refraction were observed with **1** and **2**, third-order effects were detected with $\alpha_2 = 6 \times 10^{-10}$ mW^{-1} for **1** and $\alpha_2 = 8 \times 10^{-10}$ mW^{-1} for **2**. NLO refraction was also found on **1** and **2**, with $n_2 = 1 \times 10^{-16}$ m^2 W^{-1} for **2**. The non-linearity of these two clusters was compared with some related NLO materials. Copyright © 1996 Elsevier Science Ltd

Keywords: optical non-linearity; cluster compound; tungsten; molybdenum; silver; incomplete cubane-like.

Traditionally, non-linear optical (NLO) research has been largely focused on semiconductors, conjugated polymers and discrete organic molecules [1,2]. Recently, studies on these clusters have been expanded to include their non-linear optical (NLO) properties. A series of studies on structure and NLO properties of Mo(W)–S(O)–Cu(Ag) clusters has been undertaken in the search for better NLO materials [3–8]. The butterfly-shaped clusters $[MOS_3Cu_2(PPh_3)x]$ (M = Mo, W; x = 3, 4) exhibit strong NLO refractive effect (self-focusing) [7], but their nest-shaped derivatives, $(n\text{-}Bu_4N)_2[MoOS_3Cu_3BrCl_2]$ and $(n\text{-}Bu_4N)_2[MoOS_3Cu_3(NCS)_3]$, behave quite differently. The self-focusing effect observed in this family of butterfly-shaped clusters is replaced by a self-focusing effect in the family of the nest-shaped clusters [5,6]. Here, we report a study on two novel distorted cubic cage-shaped inorganic clusters $\{MAg_3S_3[S_2P(OCH_2CH_3)_2]\}(S)(Ph_3P)_3$ [M = W(**1**), Mo(**2**)]. From a structural point of view, these two clusters can be considered as closed derivatives of the nest-shaped clusters. We discuss their structures, electronic spectra and NLO absorptive and refractive properties.

EXPERIMENTAL

Synthesis

Clusters **1** and **2** were prepared and characterized using published methods [9,10].

Synthesis of cluster **1**. $\{WAg_2S_4\}(Ph_3P)_3$ (0.6 g, 0.46 mmol) and $AgS_2P(OCH_2CH_3)$ (0.134 g, 0.46 mmol) were reacted in CH_2Cl_2 (40 cm^3) for about 3 h and then filtered. The orange filtrate was mixed with Pr^{i}OH (20 cm^3) and Et_2O (20 cm^3). Orange crystals (0.35 g) were obtained by cooling the filtrate at 5–10°C for several days.

Synthesis of cluster **2**. The synthesis was similar to that of cluster **1**, using $\{MoAg_2S_4\}(Ph_3P)_3$ instead of $\{WAg_2S_4\}(Ph_3P)_3$.

Optical measurements

Acetonitrile solutions of 5.2×10^{-4} g cm^{-3} of **1** and 2.6×10^{-4} g cm^{-3} of **2** were placed in 1 mm quartz

* Author to whom correspondence should be addressed.

cuvettes for optical measurements. Their non-linear absorption and non-linear refraction were measured with a linearly polarized laser light ($\lambda = 532$ nm; pulse width = 7 ns) generated from a Q-switched and frequency-doubled Nd-YAG laser. The spatial profiles of the optical pulses were nearly Gaussian. The laser beam was focused with a 25 cm focal-length focusing mirror. The radius of the beam waist was measured to 40 ± 5 μm (half-width at $1/e^2$ maximum). The incident and transmitted pulse energy were measured simultaneously by two Laser Precision detectors (RjP-735 energy probes) which were linked to the computer by an IEEE interface. The non-linear optical properties of the samples were manifested by moving the samples along the axis of the incident beam (Z-direction) with respect to the focal points [11]. An aperture of radius 0.5 mm was placed in front of a detector that was positioned behind the sample to assist the measurement of the self-defocusing effect of the sample.

RESULTS AND DISCUSSION

Molecular structure

Clusters **1** and **2** have the same molecular configuration, as shown in Fig. 1. The core $\{WAg_3S_3\}$ of cluster **1** is an incomplete cubane-like one, which is completed by three Ag atoms, and the terdentate WS_4^{2-}. Three PPh_3 ligands are terminally attached to the three Ag atoms, respectively. One sulfur of the bridging $S_2P(OCH_2CH_3)_2^{2-}$ is linked to a Ag atom and the other bridges the other two Ag atoms. In cluster **2** the W atoms are replaced by Mo.

Linear and non-linear optical properties

The electronic spectra were measured and absorption maxima were observed at 405 and 250 mm for **1** and at 256 nm for **2**. Both NLO absorption and NLO refraction were observed with **1** and **2**.

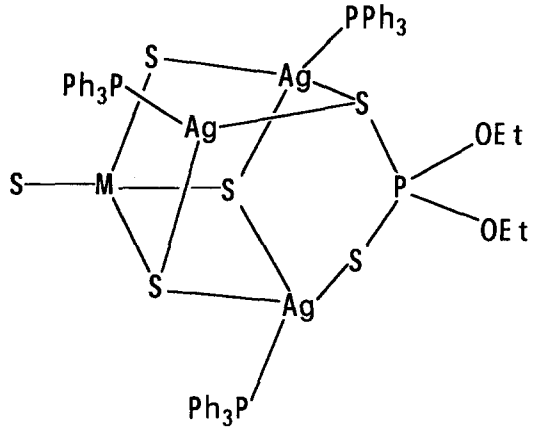

Fig. 1. The molecular configuration of **1** (M = W) and **2** (M = Mo).

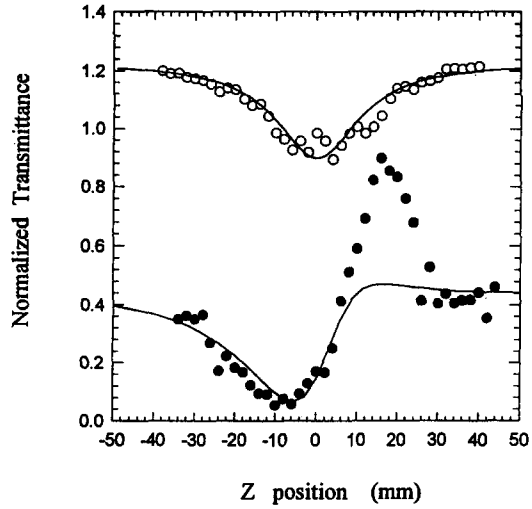

Fig. 2. Z-scan data for **1**. Observed under an open aperture configuration; upper solid curve: theoretical curve based on Eq. (1). Filled circles: Z-scan data observed under a closed aperture configuration divided by those obtained under the open aperture configuration to filter out the influence of NLO absorption. Lower solid curve: a theoretical curve obtained from Eq. (2). Cluster concentrations are 5.2×10^{-4} g cm^{-3} for **1** and 2.6×10^{-4} g cm^{-3} for **2**.

The NLO properties of **1** and **2** were revealed using a Z-scan technique [11]. Their non-linear absorptive properties are depicted by the open circles in Figs 2 and 3 while their non-linear refractive properties are

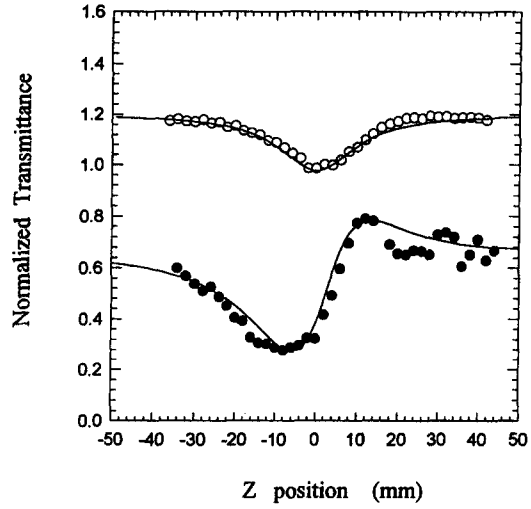

Fig. 3. Z-scan data for **2**. Observed under an open aperture configuration; upper solid curve: theoretical curve based on Eq. (1). Filled circles: Z-scan data observed under a closed aperture configuration divided by those obtained under the open aperture configuration to filter out the influence of NLO absorption. Lower solid curve: a theoretical curve obtained from Eq. (2). Cluster concentrations are 5.2×10^{-4} g cm^{-3} for **1** and 2.6×10^{-4} g cm^{-3} for **2**.

depicted by the filled circles in the figures. The solid curves in the figures are generated theoretically using Eqs (1) and (2):

$$T(z) = \frac{1}{\sqrt{\pi q(z)}} \int_{-\infty}^{+\infty} \ln[1+q(z)]e^{-\tau^2}\,d\tau \qquad (1)$$

$$T(z,s) = \frac{\int_{-\infty}^{+\infty} P_T(t)\,dt}{S\int_{-\infty}^{+\infty} P_i(t)\,dt} \qquad (2)$$

Equation (1) describes the typical and pure absorptive behaviour of a hypothetical third-order NLO process. The function $q(z)$ is defined by

$$q(r) = \int_0^{\infty}\int_0^{\infty} \alpha_2 I_i(r,t,z) L_{eff} r\,dr\,dt$$

where α_2 is the non-linear absorption coefficient of the cluster at 532 nm; $L_{eff} = [1-\exp(-\alpha_0 L)]/\alpha_0$, with α_0 being the linear absorption coefficient of the cluster and L being the sample thickness (1 mm in this study); $I_i(r,t,z) = \{I_0/[1+(z/z_0)^2]\}\exp[-2(r/\omega_0)^2-(t/t_0)^2]$ is the incident irradiance with $z_0 = \pi\omega_0^2/\lambda$ and $\omega^2 = \omega_0^2[1+(z/z_0)^2]$, where I_0 is the peak irradiance at focus, r is the radial coordinate, t is the time, t_0 is the pulse width, ω_0 is the spot radius of the laser beam at focus (40 μm in this study) and λ is the wavelength of the laser (532 nm). The peak irradiance used in the experiments are 85 MW cm^{-2} for **1** and 99 MW cm^{-2} for **2**.

It is obvious that the theoretical curves of the third-order NLO absorption reproduce well the general pattern of the observed experimental data (open circles). This suggests an effectively third-order characteristic for the experimentally detected NLO effects. The best fits of Eq. (1) to the open circles of Figs 2 and 3 give $\alpha_2 = 6\times10^{-10}$ m W^{-1} for **1** and $\alpha_2 = 8\times10^{-10}$ m W^{-1} for **2**.

Equation (2) describes the transmittance change detected behind a pinhole (0.5 mm radius) when both NLO absorptive and NLO refractive properties are considered.

$$P_i(t) = (1/2)I_0\pi\omega_0^2\exp[-(t/t_0)^2]$$

and

$$P_T(z,t) = \varepsilon_0 c n_0 \pi \int_0^{r_a} |E_a(r,t,z)|^2 r\,dr,$$

where ε_0 and c are the permittivity and speed of light in vacuum and n_0 is the linear refractive index of the sample. At the aperture, the electric component of the optical field is given by

$$E_a(r,t,z) = \{[2\pi/i\lambda(1-z)]\exp[i\pi r^2/\lambda(1-z)]\} \times \int_0^{\infty} \{r'E(r',t,z)J_0(2\pi r'r/\lambda(1-z)) \times \exp(i\pi r'^2/\lambda(1-z))\}dr'$$

in which 1 is the distance between the aperture and the focus,

$$E(r',t,z) = [2\sqrt{I(r',t,z)}/\varepsilon_0 c n_0] \times \exp\{(kn_2/\alpha_2)\ln[1+q(r',t,z)]\}$$

and $J_0(x)$ is the zeroth-order Bessel's function.

In the lower plots of Figs 2 and 3, the valley–peak pattern of the detected transmission behind the aperture indicates that the sign of the NLO refraction is positive, i.e. the materials have self-focusing capability. It is noted that the theoretical curves calculated from Eq. (2) can reproduce the qualitative trend of the experimental data represented by the filled circles in Figs 2 and 3, but significant deviation exists between the theoretical and experimental data for **1**. Since all of the even-order NLO effects are zero owing to the presence of a macroscopic inversion centre in the solutions, it seems plausible that higher odd-order NLO processes (such as fifth-order processes) are making significant contributions to the observed NLO refraction of **1**.

A control experiment shows that neither the photo damage of the quartz cells containing the solutions of **1** and **2**, nor the bubble formation in the solutions owing to local heating occurs to any detectable extent under the conditions used in this study. From the best

Table 1. Optical parameters of selected NLO chromophores

2	2.6×10^{-4} g cm^{-3}	532	8×10^{-10}	1×10^{-16}	This work

fit of Eq. (2) to the filled circles of Fig. 3, one obtains a value of $n_2 = 1 \times 10^{-16}$ m^2 W^{-1} for **2**.

To put the optical non-linearities of the clusters **1** and **2** in a proper perspective with reference to other known third-order NLO materials, these effective α_2 and n_2 values are listed in Table 1 along with the reported α_2 and n_2 values of related inorganics clusters and a few best-performing semiconductors and organic polymers. Most of the well-performing third-order NLO materials reported in the literature are solid materials (e.g. semiconductors and conjugated polymers). These are neat materials. One notices from Table 1 that impressive optical non-linearity is achieved with much-diluted inorganic clusters. Since both α_2 and n_2 values are expected to be proportional to the concentration of the NLO chromophore, superior NLO performance can be expected if the solubilities of the inorganic clusters can be improved significantly. Currently, the upper limit of the concentration of these clusters, which are close to the concentrations quoted in Table 1, are set by their log solubility in common organic solvents.

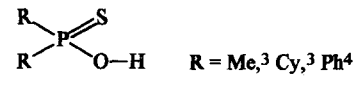
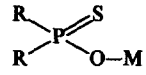
(Received 7 May 1996; accepted 15 July 1996)



Abstract—Diorganomonothiophosphinato–triphenylmetal(IV) derivatives, $Ph_3M(OSPR_2)$ (M = Ge, Sn, Pb; R = Me, Et, Ph), were prepared and investigated. The IR and multinuclear (^1H, ^{13}C, ^{31}P) NMR spectra are discussed in relation to the M—O and/or M—S bonding of the ambident $OSPR_2^-$ ligand. The crystal and molecular structures of $Ph_3Ge[O(S)PPh_2]$ (**1**) and $[Ph_2Sn\{O(S)PPh_2\}(\mu\text{-}OH)]_2$ (**2**) were determined by X-ray diffractometry. The asymmetric unit for $Ph_3Ge[O(S)PPh_2]$ contains two independent molecules. The monothiophosphinato group is bonded to germanium only through oxygen (av. Ge—O 1.826, Ge···S 3.892 Å), leading to a tetrahedral coordination around the germanium atom. The crystal of $[Ph_2Sn\{O(S)PPh_2\}(\mu\text{-}OH)]_2$ consists of dimeric units built up through Sn—O—Sn bridges involving the oxygen atom of the hydroxy groups. The monothiophosphinato group is again monodentate [Sn(1)—O(1) 2.089(3), Sn(1)···S(1) (non-bonding) 4.164 Å] and the coordination geometry around tin is trigonal bipyramidal, with the O(1) atom of the phosphorous ligand and the O(2′) atom of a bridging hydroxy group in axial positions. Copyright © 1996 Elsevier Science Ltd

Keywords: monothiophosphinato ligand; organogermanium(IV); organotin(IV); organolead(IV) compounds.



In contrast to the large amount of research work concerned with metal derivatives of dithiophosphorus ligands [1,2], there are comparatively few investigations of the related monothiophosphinates. In the free acids (**a**) the presence of O—H groups was established by X-ray diffractometry. The corresponding $[R_2PSO]^-$ anion is an ambident nucleophile and can exhibit primary coordination through either oxygen (**b**) or sulfur (**c**), depending on the "hard/soft" acid character of the metallic centre.

Thus, X-ray diffraction studies show that in $N(CH_2CH_2O)_3SiO(S)PPh_2$ [5] or $Me_3Sb[O(S)PPh_2]_2$ [6] the diphenylmonothiophosphinato ligand is attached to the metal only through oxygen, while in the gold complex $[(C_6F_5)_2Au\{S(O)PPh_2\}(CH_2PPh_2Me)$ [7] it is linked only through the sulfur atom. Moreover, this type of ligand not only could exhibit monometallic monoconnective (monodentate) coordination, but also could act in a monometallic biconnective (bidentate) fashion or in various bridging patterns (bi-

e

f

metallic biconnective or triconnective, trimetallic tetraconnective). Thus, anisobidentate coordination with primary bonds to oxygen (**d**) or to sulfur (**e**), or isobidentate coordination (**f**), is, in principle, possible. Secondary bonds [M···S in (**d**) and M···O in (**e**)] are longer than covalent bond lengths but shorter than van der Waals interatomic distances. Generally, with borderline Lewis acids, both oxygen and sulfur atoms of the $[R_2PSO]^-$ unit are involved in the coordination to the metallic centre (Table 1), as established by single-crystal X-ray diffraction studies. When such compounds are dissolved the crystal lattice is generally destroyed and the weak intra- or intermolecular chalcogen–metal interactions observed in the solid state are probably broken. In this case the magnitude of the ^{31}P NMR chemical shift is indicative of the coordination pattern of the $[R_2PSO]^-$ ligand, i.e. monodentate coordination with primary bonds through the oxygen or the sulfur atom, or a biconnective pattern involving both chalcogen atoms.

We now report the synthesis and spectroscopic characterization of triphenylmetal(IV) diorganomonothiophosphinates, $Ph_3M[OSPR_2]$ (M = Ge, Sn, Pb; R = Me, Et, Ph), and the crystal and molecular structures of $Ph_3Ge[O(S)PPh_2]$ and $[Ph_2Sn\{O(S)PPh_2\}(\mu\text{-}OH)]_2$.

EXPERIMENTAL

The starting materials were prepared according to literature methods: Ph_3GeCl [14], $Na[OSPMe_2]\cdot 1.5H_2O$, $Na[OSPEt_2]\cdot 3H_2O$[15], and $NH_4[OSPPh_2]$ [6,16]. Ph_3ECl (E = Sn, Pb) were commercial products. $Ph_3Sn[OSPEt_2]$ and $Ph_3Sn[OSPPh_2]$ were prepared as previously described [8,9]. Infrared spectra were run in the range 4000–400 cm^{-1} on a Perkin–Elmer 283B spectrometer, as KBr disks. ^1H, ^{13}C and ^{31}P NMR spectra were recorded on a Varian Gemini 300S instrument operating at 299.5, 75.4 and 121.4 MHz, respectively. The chemical shifts are reported in ppm relative to TMS and 85% H_3PO_4, respectively.

Preparation of the title compounds, $Ph_3M[OSPR_2]$ (Table 2)

A reaction mixture containing triphenylmetal chloride, Ph_3MCl, and the corresponding sodium or ammonium diorganomonothiophosphinate, $M^I[OSPR_2]\cdot nH_2O$ (excess was used for R = Me, Et) in 50 cm^3 organic solvent was stirred at room temperature for 8 h. The insoluble solid (the resulting M^ICl and the excess starting materials) was filtered off, the clear filtrate was dried over anhydrous Na_2SO_4 and then the solvent was evaporated to dryness in a rotary evaporator. The remaining solid product was recrystallized from organic solvents. When oily products were obtained (M = Ge, R = Me, Et), treatment with n-hexane led to the title compounds as white solids.

Crystal structure determinations

Colourless block crystals of $Ph_3Ge[O(S)PPh_2]$ (**1**) and $[Ph_2Sn\{O(S)PPh_2\}(\mu\text{-}OH)]_2$ (**2**) were mounted on glass fibres and sealed with epoxy glue. Data were collected on a Rigaku AFC6S diffractometer with graphite-monochromated Mo-K_α radiation, operating at 50 kV and 35 mA. Cell constants and an orientation matrix for data collection, obtained from 24 carefully centred reflections in the range $8.56 < 2\theta < 11.50°$ for **1** and $8.40 < 2\theta < 14.58°$ for **2** corresponded to a monoclinic and triclinic cell, respectively, whose dimensions are given in Table 3. The systematic absences ($h0l$, $l = 2n+1$; $0k0$, $k = 2n+1$) were observed for **1**. Based on statistical analyses of intensity distributions and the successful solution and refinement of the structure, the space group was determined to be $P-1$ for **2**.

The data were collected at a temperature of 23 ± 1°C using the ω–2θ scan technique to a maximum of 2θ value of 50.0°. The ω scans of several intense reflections, made prior to data collection, had an average width at half-height of 0.29° for compound **1** and 0.35° for **2**, with a take-off angle of 6.0°. Scans of $(1.37+0.30\tan\theta)°$ for **1** and $(1.68+0.30\tan\theta)°$ for **2**

[h] Intermolecular interaction.

were made at a speed of 32.0° min^{-1} (in ω). The weak reflections [$I < 10.0\sigma(I)$] were rescanned (maximum of four rescans) and the counts were accumulated to assure good counting statistics. Stationary background counts were recorded on each side of the reflection. The ratio of peak counting time to background counting time was 2:1. The diameter of the incident beam collimator was 1.0 mm, and the crystal to detector distance was 285.0 mm.

Of the 10,281 reflections for compound **1** and 4277 for **2** that were collected, 9971 and 4047, respectively, were unique (R_{int} = 0.153 and 0.061). The intensities of three representative reflections that were measured after every 150 reflections remained constant throughout data collection, indicating crystal and electronic stability (no decay correction was applied).

The linear absorption coefficient for Mo-K_α is 12.84 cm^{-1} for compound **1** and 12.88 cm^{-1} for **2**. An empirical absorption correction, based on azimuthal scans of several reflections was applied which resulted in transmission factors ranging from 0.76 to 1.00 for **1** and 0.64 to 1.00 for **2**. The data were corrected for Lorentz and polarization effects.

The structures were solved by direct methods [17]. The non-hydrogen atoms, other than carbon, were refined anisotropically. The hydrogen atom attached to oxygen in compound **2** was found from the Fourier map and its position then fixed. The hydrogen atoms attached to carbon were included in their idealized positions with C—H set at 0.95 Å. Their isotropic thermal parameters were set at 1.2 times that of the atom to which they were attached. The final cycle of full-matrix least-squares refinement [18] was based on 2677 observed reflections for **1** and 2967 for **2** [$I > 3.00\sigma(I)$] and 314 variable parameters for **1** and 262 for **2**.

The standard deviations of an observation of unit weight [19] were 1.97 and 1.53 for compounds **1** and

2, respectively. The weighting scheme was based on counting statistics and included a factor ($p = 0.004$ for **1** and 0.003 for **2**) to downweight the intense reflections. Plots of $\Sigma w(|F_o|-|F_c|)^2$ versus $|F_0|$, reflection order in data collection, $\sin\theta/\lambda$ and various classes of indices showed no unusual trends. The maximum and minimum peaks on the final difference Fourier map corresponded to 0.41 and -0.40 for **1** and 0.67 and -0.53 eÅ^{-3} for **2**.

Neutral-atom scattering factors were taken from Cromer and Waber [20]. Anomalous dispersion effects were included in F_c [21]; the values for Δf and $\Delta f'$ were those of Creagh and McAuley [22]. All calculations were performed using the TEXSAN [23] crystallographic software package.

Additional material available from the Cambridge Crystallographic Data Center comprises the final atomic coordinates of the non-hydrogen atoms, H-atom coordinates, thermal parameters and all of the bond lengths and angles. Structure factor tables are available from the authors.

RESULTS AND DISCUSSION

The title compounds were prepared as colourless, crystalline solids, by reacting the sodium or

ammonium salts of the diorganomonothiophosphinate with the appropriate triphenylmetal(IV) chloride, in chloroform or benzene, according to Eq. (1):

$$Ph_3MCl + M^I[OSPR_2]\cdot nH_2O \rightarrow Ph_3M[OSPR_2] + M^ICl + nH_2O$$

$$M = Ge, Sn, Pb; \quad M^I = Na; \quad R = Me, Et$$

$$M^I = NH_4; \quad R = Ph \qquad (1)$$

The triphenylgermanium(IV) and triphenyltin(IV) derivatives are stable compounds and can be stored in the solid state in the absence of air and moisture for months. An old sample of $Ph_3Sn[O(S)PPh_2]$ stored for years in a sealed flask showed no sign of decomposition as proved by NMR analysis. In contrast, the triphenyllead(IV) monothiophosphinates are quite unstable. Thus, for R = Me and Et, the solid compounds become grey in about 24 h.

In solution, however, the stability of the title tin and lead compounds is lower. Thus, a $CHCl_3$ solution of $Ph_3Pb[OSPPh_2]$ kept in the refrigerator turned orange and a red solid product deposited within days. Attempts to grow crystals of $Ph_3Sn[OSPR_2]$ for X-ray diffractometry investigations have failed, and only for R = Ph were some crystals separated that proved (NMR data, X-ray diffractometry) to be the unexpected hydroxo-bridged diphenyltin(IV) dimer, $[Ph_2Sn\{O(S)PPh_2\}(\mu\text{-}OH)]_2$. Indeed the magnitude of $^3J_{SnH}$ [^{1}H NMR ($CDCl_3$): δ 7.3 (m, P-C_6H_5, Sn-C_6H_5, *−meta+para*), 7.66 (dd, $^3J_{HH}$ 7.7, $^4J_{HH}$ 1.2, $^3J_{SnH}$ 85.9 Hz, Sn-C_6H_5, *−ortho*), 7.80 (ddd, $^3J_{HH}$ 7.6, $^4J_{HH}$ 1.4, $^3J_{PH}$ 13.5 Hz, P-C_6H_5, *−ortho*)] and of $^2J_{SnC}$ and $^3J_{SnC}$ [^{13}C NMR ($CDCl_3$): δ 127.96 (d, $^3J_{PC}$ 12.8 Hz, P-C_m), 128.79 (s, $^3J_{SnC}$ 94.9 Hz, Sn-C_m), 130.43 (s, P-C_p), 130.67 (s, Sn-C_p), 130.75 (d, $^2J_{PC}$ 11.0 Hz, P-C_0), 135.84 (s, $^2J_{SnC}$ 65.0 Hz, Sn-C_0). 138.48 (d, $^1J_{PC}$ 106.7 Hz, P-C_i)], 139.19 (s, Sn-C_i) are consistent with the presence of only two phenyl groups attached to tin (*cf.* ^{13}C NMR data for PH_2SnCl_2 ;$^2J_{SnC}$ 63, $^3J_{SnC}$ 90Hz, and for Ph_3SnCl: $^2J_{SnC}$ 49, $^3J_{SnC}$ 68 Hz) [24]. Moreover, the ^{31}P resonance of the hydroxo-bridged diphenyltin(IV) derivative was found to be surrounded by satellites due to phosphorous–tin coupling [^{31}P NMR ($CDCl_3$): δ 68.1 (s, $^2J_{PSn}$ 126.0 Hz)], a pattern that was not observed for the $Ph_3Sn[OSPR_2]$ compounds. The same hydroxobridged derivative was obtained upon attempted monocrystal growth of $Ph_2Sn[OSPPh_2]_2$, described previously [9]. This is in line with a previous report that bis(diorganomonothiophosphinato)diorganotin(IV) derivatives, $R_2Sn[OSP(OR')_2]_2$, are sensitive to atmospheric moisture and a monothiophosphinato group is readily hydrolysed to give $[R_2Sn\{O(S)P(OR')_2\}(\mu\text{-}OH)]_2$ or $[R_2Sn\{O(S)P(OR')_2\})_2O]_2$, depending on the nature of the R groups on the tin or phosphorous atoms [25, 26]. In our case the same compound was formed both by hydrolytic splitting of a phenyl group from $Ph_3Sn[OSPPh_2]$ or a monothiophosphinato group from $Ph_2Sn[OSPPh_2]_2$. Crystal samples of both origins were subjected to complete X-ray diffraction analysis in two different, independent laboratories (by J.E.D. and F.C.) and the results were practically identical. The data reported here are for the sample obtained from $Ph_3Sn[OSPPh_2]$ (J.E.D.'s laboratory).

The compounds were investigated by IR and multinuclear NMR spectroscopy and the crystal and molecular structure of $Ph_3Ge[O(S)PPh_2]$ and $[Ph_2Sn\{O(S)PPh_2\}(\mu\text{-}OH)]_2$ were determined by X-ray diffractometry.

Infrared spectra

The analysis of the infrared spectra was focused on the ν(PO) and ν(PS) stretching vibrations that proved to be a useful tool in establishing the coordination pattern of the monothiophosphinato ligand. The IR data for the present compounds are listed in Table 4, and compared with data for the corresponding O- and S-alkyl esters of the monothiophosphinic acids and their sodium or ammonium salts.

The infrared spectra of the O—R′ esters, $R_2P(S)OR'$, exhibit medium to very strong absorption bands in the regions of 1040–990 cm^{-1} and 590–580 cm^{-1} (R = Me, Et) or 630 cm^{-1} (R = Ph) which were assigned to single bond P—O(R) and double bond P=S stretching vibrations. For the S—R′ esters, $R_2P(O)SR'$, the absorption bands corresponding to the double bond P=O and single bond P—S(R) stretching vibrations are shifted, as expected, to higher (1200–1180 cm^{-1}) and lower [520–510 cm^{-1} (R = Me, Et) or 570 cm^{-1} (R = Ph)] wavenumbers, respectively. The infrared spectra of the sodium or ammonium salts exhibit absorption bands at intermediate values between those observed for the O—R′ and S—R′ esters, corresponding to a delocalization of the π electrons over the PSO fragment.

All triphenylgermanium(IV) derivatives exhibit medium to strong bonds at about 906 and 660–620 cm^{-1} which clearly indicate the coordination of the monothiophosphinato ligand only through the oxygen atom. Therefore, it is reasonable to propose a monomeric structure (**g**) for $Ph_3Ge[O(S)PR_2]$ in the solid state. In contrast, for triphenyltin(IV) and -lead(IV) analogues the positions of the bands assigned to the phosphorus–oxygen and phosphorous–sulfur stretching vibrations (Table 4) suggest bidentate behaviour of the monothiophosphinato ligand, i.e. coordination through both oxygen and sulfur atoms, thus leading to an increase of the coordination number of the central metal atom from four to five. As a result either monomeric **h** or polymeric **i** structures might be considered for $\{Ph_3M[OSPR_2]\}_n$ (M = Sn, Pb) in the solid state. In this case, on the basis of infrared data it is impossible to distinguish between isobidentate and anisobidentate coordination, and to assign a primary coordination of

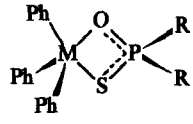
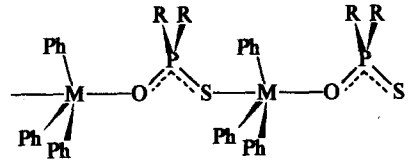
the monothiophosphinato ligand through oxygen or sulfur respectively. Single-crystal X-ray diffractometry investigations have confirmed a structure of type **g** for $Ph_3Ge[O(S)PPh_2]$(see below) and of type **i** for the $\{Me_3Sn[OSPMe_2]\}_n$ analogue [10].



NMR spectra

All of the triphenylmetal(IV) derivatives were investigated in solution by multinuclear NMR spectroscopy. Their ^1H NMR spectra (Table 5) exhibit two sets of resonances corresponding to the organic groups attached to phosphorous and metal atoms, respectively. For the protons of the diorganomonothiophosphinato ligands only one resonance with the expected splitting pattern owing to the proton–proton and phosphorous–proton couplings was observed for the P-C*H*$_3$ (doublet), P-C*H*$_2$-C*H*$_3$ (doublet of triplets), P-C*H*$_2$-CH$_3$ (doublet of quartets), P-C_6H_5 (*ortho*-H, doublet of multiplets), respectively. This indicates the equivalence of the organic groups attached to the same phosphorous atom on the NMR time-scale. The phenyl groups attached to the metal atom exhibit two multiplet resonances for the *ortho* and *meta*+*para* protons. In the case of Ph_3Sn^{IV} and Ph_3Pb^{IV} derivatives the resonance of the *ortho* protons is surrounded by satellites caused by the tin–proton and lead–proton couplings, with the expected magnitude of the ^3J(SnH) (*ca*, 60 Hz) and $^3J(^{207}PbH)$ (*ca* 105 Hz) coupling constants.



The ^{13}C NMR spectra (Table 6) show the expected downfield resonances for the carbon atoms of the phenyl groups attached to the metal. For the tin and lead derivatives the signals for the *ortho* and *meta* carbons are surrounded by satellites due to the metal–carbon couplings, with a magnitude of the ^2J(MC)

[a] Resonances for M—Ph and P—Ph overlapped.

and $^3J(MC)$ corresponding to a triphenylmetal moiety. No resonances suggesting the presence of a Ph_2Sn derivative were observed in the spectrum of $Ph_3Sn[OSPPh_2]$. Regardless of the nature of the metal atom in the Ph_3M moiety, the ^{13}C NMR spectra show only one set of signals for each carbon atom of the $OSPR_2$ ligand, thus indicating the equivalence of the organic groups attached to the same phosphorous atom on the NMR time-scale. These resonances exhibit the expected doublet pattern caused by the phosphorous–carbon couplings.

For all (diorganomonothiophosphinato)triphenylmetal(IV) the ^{31}P NMR spectra are seen as singlets. The magnitude of ^{31}P chemical shift of diorganomonothiophosphinic acid derivatives can be used to distinguish between the $R_2P(=S)O$—, $R_2P(=O)S$— or $[R_2PSO]$ structure of the coordinated ligands. Thus, the resonance for the S ester is shifted about 40–60 ppm to higher field, as expected, compared with the signal observed for the free acid (which contains an O—H group) and its O—Me ester, for the same R group attached to phosphorous. The resonances for the corresponding sodium or ammonium salts have intermediate values between these two extremes. A comparison of the ^{31}P chemical shifts of the Ph_3M derivatives with those of the free acids, their O— and S—Me esters and their sodium or ammonium salts is given in Table 7 and reveals interesting results. Thus, for all Ph_3Ge^{IV} derivatives the ^{31}P chemical shift is of the same magnitude as observed for the corresponding free acid or its O—Me ester. This behaviour is consistent with monodentate coordination of the monothiophosphinato moiety only through its oxygen atom, structure **g** found in the solid state for $Ph_3Ge[O(S)PPh_2]$ and indicated by the IR spectra, being also preserved in solution.

For the Ph_3M^{IV} (M = Sn, Pb) derivatives, with one exception, the ^{31}P chemical shift has an intermediate magnitude between those observed for the O— and S—Me esters of the corresponding monothiophosphinic acid. Taking into account the presence of only one set of ^1H and ^{13}C resonances, respectively,

[a] In $CDCl_3$.
[b] In CD_3OD.
[c] $\delta = 62.4$ in CD_3OD [32].
[d] In CD_3COCD_3.
[e] $\delta = 67.7$ in CD_3COCD_3 [32].

for both organic groups attached to phosphorous, this suggests that the ligand coordinates to the metallic centre through both chalcogen atoms and has fluxional behaviour in solution according to the following scheme:

In contrast, for M = Pb, R = Ph the ^{31}P chemical shift displays a value of δ 48.1, which compares very well with that of the S—Me ester, $Ph_2P(=O)SMe$ (*cf.* δ 42.8). This indicates that the structural formulation of this compound in solution should be $Ph_3PbS(O)PPh_2$, with a monodentate ligand attached to lead only through the sulfur atom.

On the basis of the above data we conclude that ^{31}P NMR can distinguish not only between the monodentate and bidentate coordination pattern of the monothiophosphinato ligands, but also between the $R_2P(=S)O$— or $R_2P(=O)S$— nature in the former situation. In addition, these data confirm the versatility of the monothiophosphinato ligand, i.e. its capacity to coordinate through oxygen to a "hard" metallic centre, to involve both chalcogen atoms, or to coordinate only through the sulphur atoms to a "soft" metallic centre.

Crystal and molecular structure of $Ph_3Ge[O(S)PPh_2]$

The solid state structure of $Ph_3Ge[O(S)PPh_2]$ was determined by single-crystal X-ray diffractometry. The asymmetric unit contains two, very similar, independent monomeric molecules, which are separated by normal van der Waals distances. Selected bond distances and angles for both molecules **1a** and **1b** are listed in Table 8, but in the subsequent discussion we will refer only to molecule **1a** (Fig. 1) (the same considerations can be used to describe molecule **1b**).

The monothiophosphinato ligand is coordinated through the oxygen atom in a clearly monodentate pattern. The phosphorous–oxygen and phosphorous–sulphur bond distances are characteristic for single P—O [1.563(7) Å] and double P=S [1.931(5) Å] bonds [*cf.* 1.582(2) and 1.956(1) Å in the free $Ph_2P(S)OH$ acid, [35] or 1.60(2) and 1.936(6) Å in its O—Me ester, $Ph_2P(S)OMe$ [36]. The tetrahedral geometry around the phosphorous atoms in both ligands is distorted with an O(1)—P(1)—S(1) angle [116.7(3)°] of the same magnitude as in the free $Ph_2P(S)OH$ acid [O—P—S 115.4(1)°] [35].

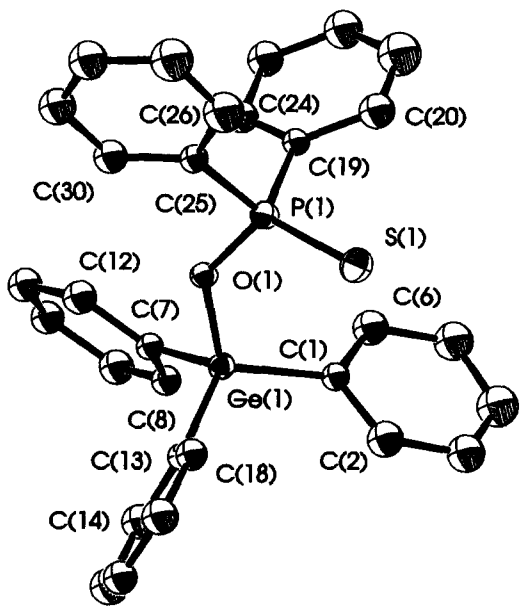

Fig. 1. ORTEP plot of the molecule $Ph_3Ge[O(S)PPh_2]$ (**1a**).

The Ge(1)—O(1) bond length is slightly longer [1.825(7) Å] than in $(Ph_3Ge)_2O$ [average 1.77(5) Å] [37], and close to the sum of the covalent radii of Ge and O, Σ_{cov}(Ge, O) = 1.95 [38]. The Ge(1)—O(1)—P(1) angle of 132.2(5)° is slightly less than the Ge—O—Ge angle of 135.7(7)° in $(Ph_3Ge)_2O$ [37]. The relative position of the sulfur atom double bonded to phosphorous with respect to the germanium atom is similar to that observed in the dithiophosphinato analogues, $Ph_3Ge[S(S)PR_2]$ (R = Me, Ph) [39], i.e. the monothiophosphorus ligand is twisted to bring the non-bonded sulfur atom much closer to the germanium atom, thus leading to a *syn* conformation of the Ge—O—P=S fragment. This situation contrasts to that observed in the dithiophosphinato derivative, $Ph_3GeS(S)P(OMe)_2$, for which the non-bonded sulfur atom is twisted as far as possible from the germanium atom (Ge···S 5.253 Å) [40]. The magnitude of the germanium-sulfur distances [Ge(1)···S(1) 3.843(4) and Ge(2)···S(2) 3.940(4) Å in molecules **1a** and **1b**, respectively] is in the range of van der Waals distances and too large to suggest any significant secondary interaction between these atoms.

The distortion from tetrahedral angles around Ge is not large but all C—Ge—C angles are greater than those for all tetrahedral angles (Table 8). In each independent molecule two O—Ge—C angles are well below all tetrahedral angles, while the third one is of the same value as the C—Ge—C angles. In comparison, the tetrahedral distortion is slightly less for the two germanium centres in $(Ph_3Ge)_2O$ [37], with the average C—Ge—C angle still larger than that for all tetrahedral angles at 111.4°, but only one O—Ge—C

angle in each half of the molecule significantly less, at 101.9(7) and 103.5(7)°. The above is essentially as expected from Bent's rule [41], which seems to operate well for germanium compounds; according to this rule "more electronegative substituents 'prefer' hybrid orbitals having less *s* character, and more electropositive substituents 'prefer' those having more *s* character". Alteratively, the distortion of the tetrahedral coordination polyhedron at germanium might be owing to the spatial requirements of the phenyl groups attached to germanium and of the non-bonded sulfur atom.

Crystal and molecular structure of $[Ph_2Sn\{O(S)PPh_2\}(\mu\text{-}OH)]_2$

The solid state structure of $[Ph_2Sn\{O(S)PPh_2\}(\mu\text{-}OH)]_2$ was also determined by single-crystal X-ray diffractometry. Selected bond distances and angles are listed in Table 9. Figure 2 shows the ORTEP view of the molecular structure, with the atom-numbering scheme.

The monothiophosphinato ligand is monodentate and linked to tin through the oxygen atom. The tin–sulfur interatomic distance is 4.164 Å, significantly longer than the sum of van der Waals radii of the corresponding atoms, $\Sigma_{vdW}(Sn, S) = 4.0$ Å [38]. As a result, each tin atom is five coordinated, in a distorted trigonal bipyramidal geometry (Fig. 3). The axial positions are occupied by the O(1) atom of the monothiophosphinato ligand and the O(2′) hydroxo oxygen

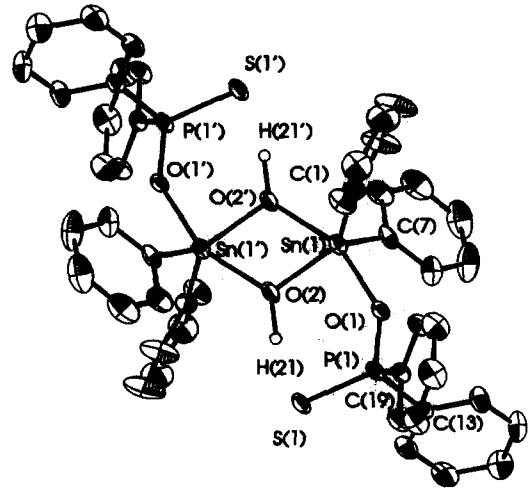

Fig. 2. ORTEP plot of the molecule $[Ph_2Sn\{O(S)PPh_2\}(\mu\text{-}OH)]_2$ (**2**) (the atoms are drawn with 30% probability ellipsoids and hydrogen atoms are omitted for clarity).

of the other molecular unit of the dimer, with an O(1)—Sn(1)—O(2′) angle of 156.76°, which reflects the distortion of the coordination polyhedron. The equatorial bond angles at tin range between 117.0 and 121.8°, and the O(2)Sn(1)C(1)C(7) system is basically planar [the deviations from the best equatorial plane are: Sn(1) −0.079, O(2) 0.028, C(1) 0.025, C(7) 0.026 Å]. The four-membered Sn_2O_2 ring is planar. The O(1)P(1)S(1) and O(1′)P(1′)S(1′) fragments are almost coplanar with the Sn_2O_2 system, being sym-

[a] Symmetry equivalent position $(1-x, 1-y, -z)$ is denoted by prime.
[b] Non-bonding distance.

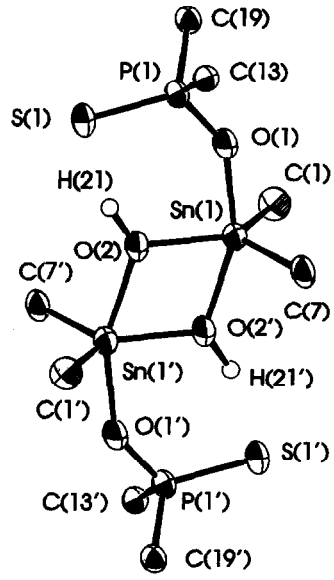

Fig. 3. ORTEP plot of the core of the molecule $[Ph_2Sn\{O(S)PPh_2\}(\mu\text{-}OH)]_2$ (**2**) showing the trigonal bipyramidal coordination around tin (the atoms are drawn with 50% probability ellipsoids and the phenyl rings, except for the carbon atoms attached to tin and phosphorous, are omitted for clarity).

metrically displaced on each side of the Sn_2O_2 plane [the deviations from the best Sn(1)O(2)Sn(1')O(2') plane are: O(1) −0.057, P(1) −0.028, S(1) −0.028 Å]. The equatorial planes at both tin atoms are almost perpendicular to the Sn_2O_2 ring ($OSnC_2/Sn_2O_2$ dihedral angle 88.6°).

The monodentate character of the ligand is supported by the phosphorus–chalcogen distances [P(1)—O(1) 1.548(3), P(1)—S(1) 1.972(2) Å; for comparison see the above discussion of the molecular structure of the germanium compound]. The hydrogen bond interactions between the sulfur and hydroxo oxygen atoms within each molecular unit might account for the slightly longer phosphorus–sulfur bond distance. A similar hydrogen bond interaction was observed for the monothiophosphinato analogue, $[Ph_2Sn\{O(S)OPh_2\}(\mu\text{-}OH)]_2$ [25], where the sulfur and hydroxo oxygen atoms within each molecular unit are brought together at 3.121 Å, compared with 3.050 Å in the present compound.

(Received 8 February 1996; accepted 15 July 1996)

Abstract—The reaction of diglycolic acid $O(CH_2COOH)_2$ with $Cu(NO_3)_2 \cdot 2H_2O$ and hydrated gadolinium nitrate at pH 7 produced a novel Ln–Cu mixed metal complex: $[Gd_2Cu_3\{O(CH_2COO)_2\}_6 \cdot 9H_2O]$, which was characterized by elemental analysis, IR spectrum and X-ray crystallography. In the complex, the Gd^{3+} ions and the Cu^{2+} ions are connected by the carboxylate groups of the ligand molecules, thus resulting in the formation of the complicated network structure. Copyright © 1996 Elsevier Science Ltd

Keywords: synthesis; crystal structure; rare earth copper complex; carboxylate acid.

The synthesis of polynuclear mixed copper–lanthanide complexes is of interest for several reasons [1–4]. These complexes are important in understanding the nature of the magnetic exchange interactions between lanthanide and transition metal ions, and they can possibly be used as magnetic materials [2, 3], and high temperature superconductors [5]. The structural chemistry of these compounds has also attracted our attention, most Ln–Cu complexes with Schiff-bases are polynuclear, such as $LnCu_2$, $LnCu_3$, Ln_2Cu_2, Ln_2Cu_4 [2,3,6]. The Ln–Cu complexes with pyridinioacetate have the octadecanuclear Ln_6Cu_{12}, in which the lanthanide ions form an octahedron with twelve Cu^{2+} ions occupying the edges of the octahedron and one ClO_4^- anion encapsulated in the centre [7]. The complex with the highest nuclearity reported so far contains a core of $[La_8Cu_{12}(OH)_{24}]$. It was synthesized through a metallomacrocycle route [8]. The lanthanide complexes with Cu(pba) form the so-called "ladder" structure, which differs slightly along the "lanthanide contraction" [9]. We deemed that the multidentate polycarboxylate acids would be good ligands for the preparation of the Ln–Cu mixed metal complexes since the metal ions can be bridged by the bidentate carboxylate groups. We selected the diglycolic acid as the ligand and successfully prepared the novel Gd–Cu title complex, and here we report its preparation and crystal structure.

EXPERIMENTAL

Preparation

$Cu(NO_3)_2 \cdot 2H_2O$ (1.5 mmol) and hydrated lanthanide nitrate (1 mmol) were dissolved in water (10 cm^3) and mixed with stirring. Diglycolic acid (3 mmol) was dissolved in another 10 cm^3 water and the pH was adjusted to 7.0 with $NH_3 \cdot H_2O$. These two solutions were then mixed with vigorous stirring, the green precipitates formed were filtered off and the clear solution was allowed to evaporate at room temperature, where upon prismatic green–blue crystals were isolated after several days. Found: C, 20.1; H, 3.1; Cu, 13.3; Gd, 21.3. Calc. C, 19.7; H, 2.9; Cu, 13.1; Gd, 21.5%. IR studies indicated that ν_{COO} (1724, 1419 cm^{-1}) of the free ligand were shifted to 1604 and 1425 cm^{-1}, proving the bidentate complexation of the carboxylate groups. Upon complexation, ν_{COC} of 1149 cm^{-1} for the free ligand was shifted to 1114 cm^{-1}. These results

are in good agreement with the structure determined by X-ray diffraction.

Data collection, structural determination and refinement

Data collection was performed on an Enraf–Nonius CAD4 diffractometer with graphite-monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å) operating at 298 K using ω–2θ scan methods. Data were corrected for Lorentz and polarization factors, and an empirical absorption correction applied based on the ψ scan technique.

From the systematic absences and statistical results, the space group was uniquely determined to be *P6/mcc* (#192). The structure was solved by direct methods, which revealed the coordinates of the Gd atom ($\frac{2}{3}, \frac{1}{3}, \frac{1}{4}$) and those of the Cu atom ($\frac{1}{2}, 0, \frac{1}{2}$). All remaining non-hydrogen atoms were located from subsequent difference Fourier syntheses. All non-hydrogen atoms except O(5) were refined by full-matrix least-squares procedures with anisotropic thermal parameters. The O(5) atom, with coordinates (0.195, 0.266, 0.500) and a peak height of 6.2 eÅ^3, which represents the free water molecule, was refined isotropically with its occupancy of $\frac{1}{4}$ according to the results from the occupancy refinement. All calculations were performed on a COMPAQ Prolinea 4/50 computer using the Molen program package [10] and published scattering factors [11].

A summary of data collection, structure determination and refinement is presented in Table 1.

RESULTS AND DISCUSSION

Selected bond lengths and angles for the complex are listed in Table 2. The coordination polyhedra for the Gd^{3+} and Cu^{2+} ions are shown in Fig. 1. The Gd^{3+} ion is nine coordinated by three ether oxygen atoms and six carboxylato oxygen atoms from three ligand molecules. The Gd—O(ether) and Gd—

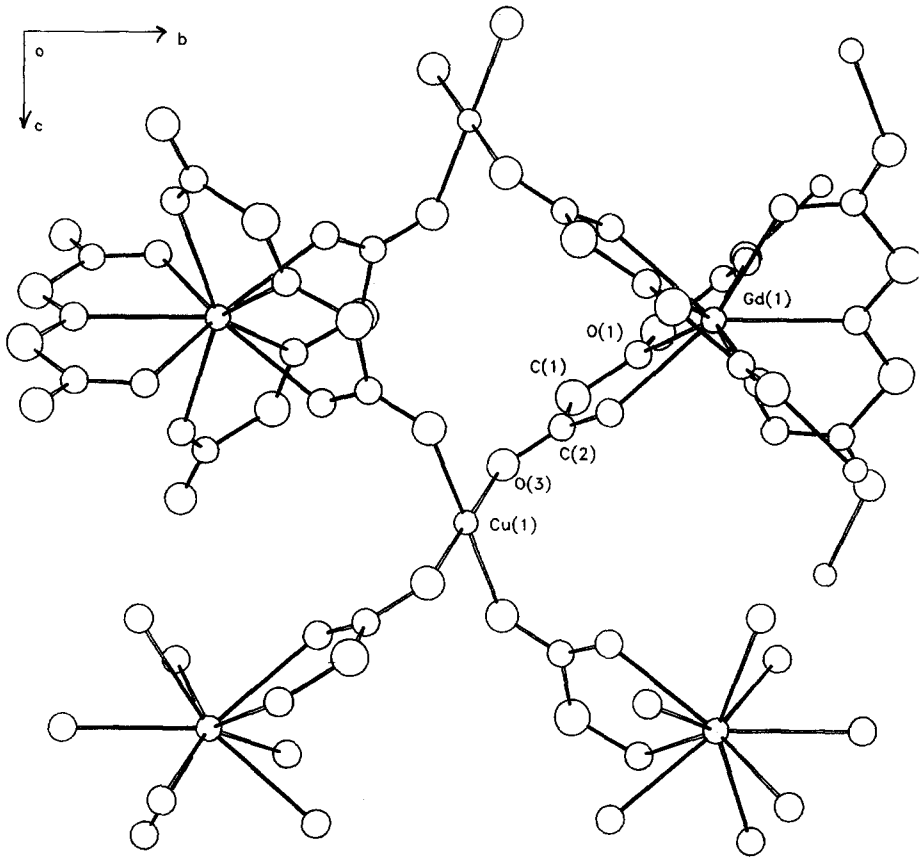

Fig. 2. Crystal structure of $Gd_2Cu_3(O(CH_2COO)_2)_6$ with atomic labelling along the (100) plane.

$O(COO^-)$ distances are 2.522(2) and 2.448(2) Å, respectively (Table 2). From these bond lengths we can see that the coordination ability of carboxylato group is much stronger than that of the ether oxygen atom. There coordination geometry of the gadolinium ion can be best described as a tricapped trigonal prism; the six carboxylato oxygen atoms form a trigonal prism with three ether oxygen atoms as capping atoms (Fig. 1a). The copper ion is four coordinated to four carboxylato oxygen atoms with a Cu—O bond length of 1.956(3) Å. There are also two weak Cu—$O(H_2O)$ bonds, with Cu—O separations of 2.519(4) Å. The O—Cu—O (oxygen atoms from the COO^- groups) bond angles are 180.0(2), 91.0(1) and 89.0(1)°, respectively. Thus, the Cu^{2+} ion has a slightly distorted square-planar coordination geometry. With

the two weak bonds, the geometry of the copper ion in the complex can best be described as distorted octahedral with the two axial bonds greatly elongated (Fig. 1b), resulting from the "Jahn–Teller effect".

The structure of the complex is shown in Fig. 2. The lanthanide ions and the copper ions are connected by the carboxylate groups. Each carboxylate group is bidentate, so every ligand molecule is pentadentate, being bonded to one lanthanide ion and two copper ions. This kind of connection results in the formation of a complicated three-dimensional network structure. The shortest Gd—Gd, Gd—Cu and Cu—Cu distances are 7.345(0), 5.706(0) and 7.345(0) Å, respectively.

Besides bonding weakly to the copper ions, the water molecules also form hydrogen bonds. The separations O(2)···O(4c), O(3)···O(4i) and O(5)···O(4j) (symmetry codes: c: $1-y, 1-x, \frac{1}{2}-z$; i: $1-x, -y, z$; j: $y, -x+y, z$) are 2.795(6), 3.007(7) and 2.78(3) Å, respectively, demonstrating the presence of hydrogen bonds.

(Received 25 June 1996; accepted 12 July 1996)

Abstract—The X-ray diffraction study of the crystals deposited from the solution obtained by the reaction of magnesium with methanol allowed the formulation of the product as $Mg(OMe)_2 \cdot 3.5MeOH$ (**I**). Its structure is built of the residues of four types, namely cubane $[Mg_4(\mu_3\text{-}OR)_4(OR)_4(ROH)_8]$ neutral molecules, $[Mg_4(\mu_3\text{-}OR)_4(OR)_2(ROH)_{10}]^{2+}$ cations, $[(RO)_2H]^-$ anions (R = Me) and eight crystallographically independent non-coordinated solvating methanol molecules. All residues are linked into a three-dimensional framework by means of a complicated hydrogen-bonding system. The crystal structure provides the basis for discussion of the possible mechanism of desolvation of **I**. Copyright © 1996 Elsevier Science Ltd

Keywords: magnesium methoxide; methanol solvate; structure; cubane.

Magnesium, as well as the alkaline-earth metal alkoxides, have been extensively studied due to the possibility of their application in the synthesis of inorganic materials, in particular the perovskite-type mixed oxide phases. Special attention has recently been paid to the II group metal alkoxides with bulky branched alkoxy groups, preventing the possible oligomerization and thus producing species which may potentially act as precursors in MOCVD processes. The studies of the structure and properties of the derivatives of the simplest alkoxy homologues, the so-called "ionic" alkoxides, soluble in polar solvents and employed as starting solutions for the sol–gel processes, are much less numerous. A few years ago we reported [1] the structure of the solvate formerly known as "$Ca(OEt)_2 \cdot 2EtOH$", prepared by the prolonged refluxing of ethanol solutions of calcium ethoxide. The solvate was proved to be the $Ca_6O_2(OEt)_8 \cdot 14EtOH$ oxocomplex, built of two $[Ca_4O_4]$ cubanes sharing a common $[Ca_2(oxo\text{-}O)_2]$ face.

Here we report the structure of magnesium methoxide solvate, which readily deposits on cooling from the freshly prepared solutions obtained by the reaction of magnesium with absolute MeOH. Two possible compositions of this solvate, namely $Mg(OR)_2 \cdot 3ROH$ [2] and $Mg(OR)_2 \cdot 4ROH$ [3] (R = Me) were suggested. The tensimetric study of the $Mg(OR)_2$ (solid)–ROH (vapour) system has led to the conclusion that the composition of the solvate is close to 1:4 [4]. Crystals of $Mg(OMe)_2 \cdot 3.5MeOH$ (**I**) easily lose the solvent in a dry atmosphere at 20°C; on heating above 39°C under mother liquor they decompose, yielding a powder whose composition is close to that of the monosolvate. The analogous product precipitates from the methanol solutions at temperatures higher than 40°C and again partially dissolves on cooling. On heating of the monosolvate *in vacuo* up to 50–70°C the non-solvated $Mg(OR)_2$ is formed [4].

EXPERIMENTAL

The reaction of magnesium with absolute MeOH occurs at room temperature. In order to avoid boiling of the alcohol, the metal is introduced into the solution in small portions. Otherwise, the solution quickly becomes opaque and immediately yields the monosolvate precipitate. On further cooling or evaporation

* Author to whom correspondence should be addressed.

of the solvent at 20°C, the transparent rhomboid or rectangular plates of $Mg(OR)_2 \cdot 3.5ROH$ (**I**) are deposited. Their composition, determined by X-ray diffraction, is in good agreement with the results of elemental analysis. Found: Mg, 12.2, 12.0. Calc.: Mg, 12.1%.

The crystallo-optical properties of the crystals are as follows. Crystals are biaxial, $\angle 2V \sim 90°$, the extinction is direct or slanting ($< 31°$); the elongation direction is positive and the optical sign is positive, $n'_g = 1.447$, $n'_p = 1.444$.

X-ray diffraction study

$C_{44}H_{160}Mg_8O_{44}$, $M = 1588.20$, orthorhombic, space group *Aba*2, at 188 K, $a = 23.60(1)$, $b = 24.331(8)$, $c = 31.954(9)$ Å, $V = 18{,}348(11)$ Å^{-3}, $Z = 8$, $D_c = 1.15$ g cm^{-3}. The X-ray diffraction experiment was carried out with a Syntex $P2_1$ diffractometer ($T = 188$ K, Mo-K_α radiation, θ–2θ scan technique, $\theta \leqslant 24°$, $\mu = 10.42$ cm^{-1}; no absorption correction was applied). The structure was solved by direct methods and refined by the full-matrix least-squares techniques in the anisotropic approximation. All methyl hydrogen atoms were placed in the geometrically calculated positions and included in the refinement using the riding model approximation with $U_{iso}(H) = 1.5U_{eq}(C)$, where $U_{eq}(C)$ is the equivalent isotropic temperature factor of the corresponding methyl carbon atom. The hydroxyl hydrogen atoms were not located. The determination of the absolute structure was impossible due to the lack of sufficiently strong anomalous scatterers. Final discrepancy factors are: $R_1 = 0.0885$ [on F for 3564 unique reflections with $I \geqslant 2\sigma(I)$], $R_{w2} = 0.2966$ (on F^2 for all 7253 reflections used in the refinement of 865 parameters). All calculations were carried out on an IBM PC with the help of the SHELXTL PLUS 5 program (gamma version). Bond lengths and angles are given in Tables 1 and 2. Atomic coordinates are available from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, U.K.

[a] For labelling of the symmetry-derived atoms, see the caption to Fig. 2.

RESULTS AND DISCUSSION

The crystal of the solvate of magnesium methoxide with methanol (**I**) is built of the residues belonging to four types, namely $[Mg_4(\mu_3\text{-}OMe)_4(OMe)_2(MeOH)_{10}]^{2+}$ cations (Ct), $[(MeO)_2H]^-$ anions, $[Mg_4(\mu_3\text{-}OMe)_4(OMe)_4(MeOH)_8]$ neutral molecules (NM) and non-coordinated solvating MeOH molecules linked together into an infinite three-dimensional hydrogen-bonding framework (Figs 1–3). Therefore, complex **I** should be formulated as $[Mg_4(OR)_6(ROH)_{10}]^{2+}[(RO)_2H]_2^- \cdot [Mg_4(OR)_8(ROH)_8] \cdot 8ROH$. Tetranuclear NM and Ct have the cubane $[Mg_4O_4]$ cage, with the magnesium and methoxide oxygen atoms occupying the alternating vertices. Each magnesium atom has a coordination octahedron formed by three μ_3-OR groups and three oxygen atoms of the terminal OR groups and solvating ROH molecules. The latter were identified taking into account the longer Mg—O(R)H as compared to Mg—OR distances, their participation in the intramolecular ROH···OR hydrogen bonds, and the general pattern of the hydrogen-bonding system in the structure. It turns out that two of the three terminal ligands at each magnesium atom belong to ROH, whereas the third terminal ligand corresponds to the OR group, the overall ROH : OR(terminal) ratio in

[a] For labelling of the symmetry-derived atoms, see the caption to Fig. 2.

NM thus becoming equal to 8:4. The number of coordinated ROH molecules in Ct is higher, as only two of their four magnesium atoms have terminal OR groups and the overall ROH : OR(terminal) ratio becomes equal to 10 : 2. The Mg—μ_3-OR and terminal Mg—O(R)H bond lengths are almost equal (2.05–2.14 and 2.08–2.15 Å, respectively), whereas the terminal bonds involving the OR groups are noticeably shorter (2.01–2.09 Å; see Table 1). The distortion of the cubane cages is similar in both cases and is clearly manifested in the decrease of the OMgO angle and corresponding increase of the MgOMg angle (78.4–85.5° and 92.9–101.4°, respectively).

It is noteworthy that $[Ba(OBu^t)_2(Bu^tOH)_2]_4$ has a quite similar structure, each barium atom bearing two terminal Bu^tOH molecules as well as one terminal OBu^t group [5]. However, the intramolecular hydrogen bonds in this barium complex are formed between those terminal ligands which are bonded to the same barium atom, in contrast to NM in **I**, wherein such hydrogen-bonds link the terminal ligands at different magnesium atoms, thus bridging four of the six $[Mg_2O_2]$ faces of the cubane $[Mg_4O_4]$ cage.

Both crystallographically independent cations Ct1 and Ct2 in structure **I** occupy special positions on the two-fold axis; Ct1 involves Mg(5) and Mg(6) as well as the symmetry related Mg(5A) and Mg(6A) atoms, whereas Ct2 involves the Mg(7), Mg(8) and Mg(7A) and Mg(8A) atoms. Two pairs of oxygen atoms in each cation participate in intracationic ROH ···OR bonds, which correspond to the short O(61)···O(61A) and O(53)···O(53A) in Ct1 and O(71)···O(82) and O(71A)···O(82A) contacts in Ct2. This is probably due to different functions of these hydrogen-bonds relative to the two-fold axis, which ultimately determine the crystallographic uniqueness of each of the two cations Ct1 and Ct2. It is noteworthy that the pairs of oxygen atoms involved in the intracationic hydrogen bonds do not take part in the interionic hydrogen-bonding. At the same time, in contrast with the oxygen atoms of the cations, four of these eight oxygen atoms of NM, which

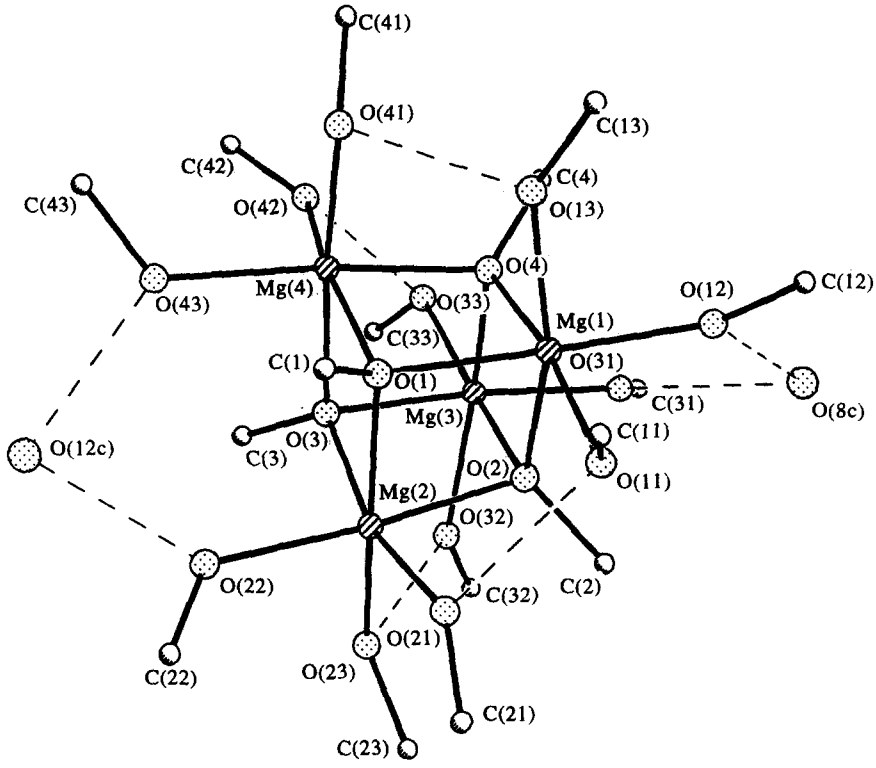

Fig. 1. Structure of the neutral molecule $[Mg_4(\mu_3\text{-}OMe)_4(OMe)_4(MeOH)_8]$ in the crystal of **I**. The O···O contacts corresponding to the intra- and intermolecular hydrogen bonds are shown as dashed lines.

form the intramolecular bonds O(11)···O(21), O(23)···O(32), O(33)···O(42) and O(41)···O(13), are involved in the intermolecular hydrogen bonds with the ROH molecules as well [O(11)···O(3c), O(23)···O(11c), O(33)···O(1c) and O(41)···O(9c)] (Fig. 3). One may therefore assume that this fact may lead to the weakening of the intramolecular hydrogen bonds in NM, which is reflected in the noticeably longer O···O distances in NM (2.49–2.59 Å) as compared to that in Ct1 [2.38(2) and 2.47(2) Å] and Ct2 [2.43(1) Å]. These values of the O···O distances allow us to assign the observed hydrogen bonds in **I** to the category of strong hydrogen bonds (O···O 2.4–2.7 Å) according to the classification suggested in Ref. [6].

All oxygen atoms in **I** participate in hydrogen-bonding, the OH groups acting both as donors and acceptors with the exception of those oxygen atoms and OH groups which are involved in the intracationic hydrogen bonds. NM, on one hand, and Ct1 and Ct2

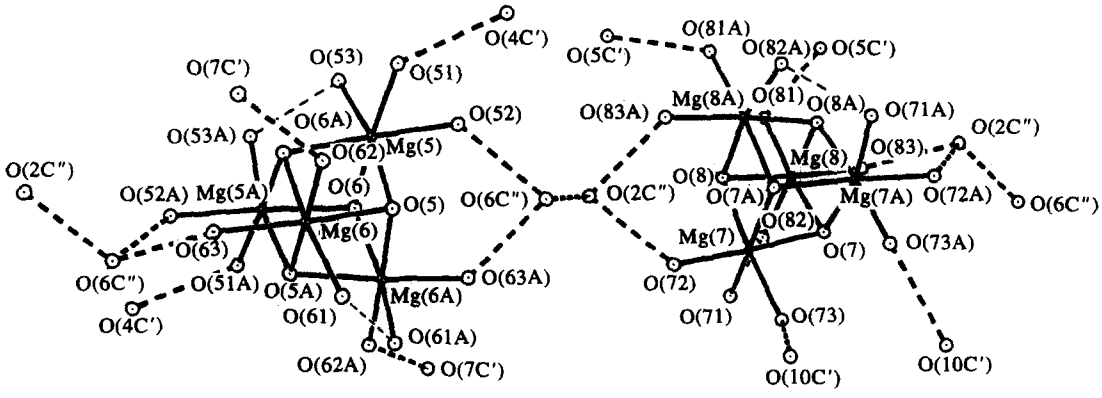

Fig. 2. The fragment of the ···Ct1···Ct2··· chain in the structure of **I**. The atoms related to the reference atoms of the Ct1 and Ct2 cations by the $x, -y, z$ and $1-x, y, z$ symmetry operations, respectively, are designated by the letter A in the atom label. The apostrophe and quotation marks indicate the participation of the oxygen atoms of the solvating molecules in the hydrogen bond links between and within the chains, respectively.

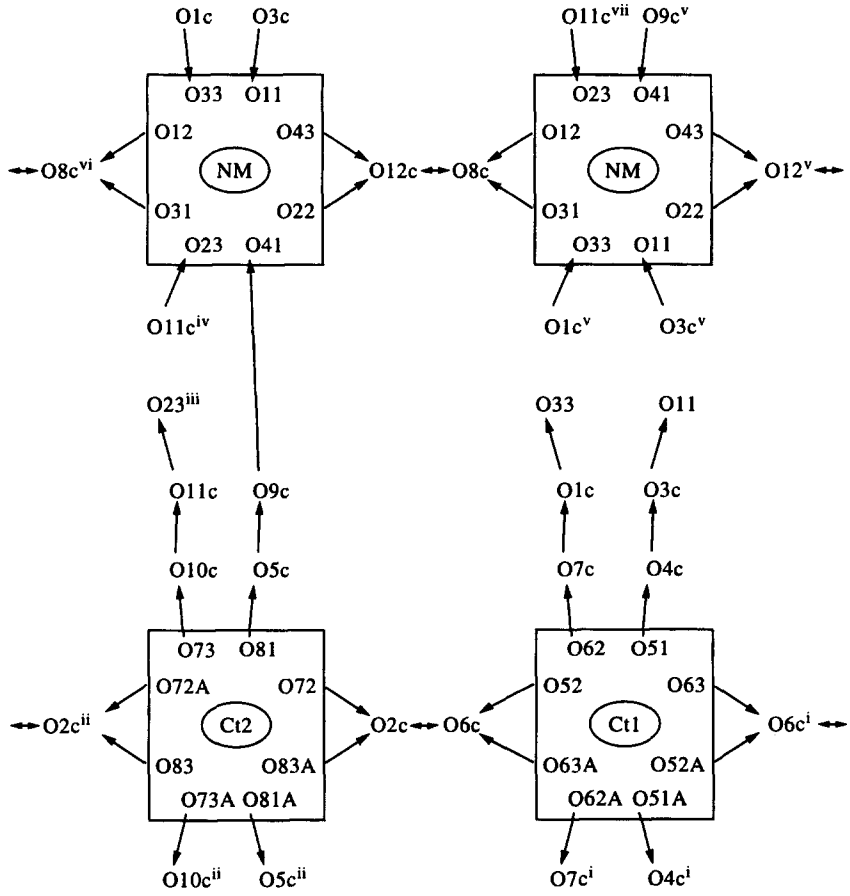

Fig. 3. The general scheme of hydrogen-bonding pattern in the structure of **I**. The arrows indicate the directions of the hydrogen bonds O—H → O. The superscripts are used for designating the oxygen atoms involved in various residues of the structure and derived from the reference atoms by means of the following symmetry operations: (i) $-x, -y, z$; (ii) $1-x, -y, z$; (iii) $1-x, 0.5-y, z-0.5$; (iv) $1-x, 0.5-y, 0.5+z$; (v) $x-0.5, 0.5-y, z$; (vi) $0.5+x, 0.5-y, z$; (vii) $0.5-x, y, 0.5+z$.

on the other, are engaged in two different infinite chains ···NM···NM··· and ···Ct1···Ct2···, both of which stretch along the *a*-axis (Fig. 2 shows a fragment of the cationic chain). The NM and Ct residues within both chains are linked *via* the $[(RO)_2H]^-$ anions each of which consists of one OR group and one solvating alcohol molecule, the O(8c)···O(12c) and O(2c)···O(6c) distances in the two crystallographically independent anions being equal to 2.423(15) and 2.419(15) Å, respectively. The ···NM···NM··· and ···Ct1···Ct2··· chains are connected with each other through the solvating ROH molecules. The general scheme of hydrogen-bonding in **I** is given in Fig. 3; the O···O distances corresponding to the hydrogen bonds are listed in Table 3. It may be seen in Fig. 3 that the solvating ROH molecules form tightly bound pairs which act as links between the ···NM···NM··· and ···Ct1···Ct2··· chains, thus producing the infinite three-dimensional hydrogen-bonding framework in the crystal of **I**.

The cubane $[M_4O_4]$ cage found in **I** presents one of the two main structural patterns known for tetranuclear mono- or bimetallic alkoxides or oxoalkoxides. Such a cage is formed by fusion of two four-membered $[M_2O_2]$ rings along all four Mg—O edges and involves the tetrahedral array of metal atoms, whereas the alternative structural pattern involves the planar array of the metal atoms. The cubane-shaped complexes are formed by the above mentioned calcium oxoethoxide [1], as well as by a number of molecular aggregates, namely $[MOBu^t]$, where M = K, Rb, Cs [7], $[NaO\text{-}CH(CF_3)_2]_4$ [8], $[MOSiMe_3]_4$ (M = Li to Cs) [7] and $[Ti(OR)_4]$, where R = Me or $SiPh_3$ [9, 10]. In all cases the cubane cage exhibits the same geometric distortions as those observed in the structure of **I**, i.e. the increase of the bond angles at the oxygen atoms and simultaneous decrease of the bond angles at the metal atoms. It is noteworthy that the minimal angular distortions of the cubane cage were observed for the derivatives of the alkaline metals. The cubane alkoxide molecules were proved to be much more stable than tetranuclear alkoxides with the alternative structure, e.g. titanium complexes $[Ti(OMe)_4]$ [11]; many cubanes were proved to exist in the vapour as well as

[a] For labelling of the symmetry-derived atoms, see the caption to Fig. 3.

in the solid phase [7, 8]. It is also remarkable that the $[Mg_4(OR)_6(ROH)_{10}]^{2+}$ cations found in the structure of I most probably exist in solution. This conclusion may be drawn from the fact that the crystals of methoxochlorides $[Mg_4(\mu_3\text{-}OR)_4(OR)_2(ROH)_{10}]Cl_2$ [12] with the same cation were isolated as one of the products of the reaction of I with $MgCl_2$ in ROH.

In conclusion we can try to use the information obtained from the crystal structure of I in order to gain some insight into the process of its desolvation. The isotherms of dissociation vapour pressure (Fig. 4) show that the equilibrium process takes place in the range of compositions from 1 : 3.5 up to approximately 1 : 1. At temperatures of 40–50°C the irreversible destruction of I starts for the compositions of 1 : 2 and 1 : 1.5, and is completed when the composition reaches 1 : 0.75. Further desolvation leads to the formation of the phases of variable composition and no longer represents the equilibrium process.

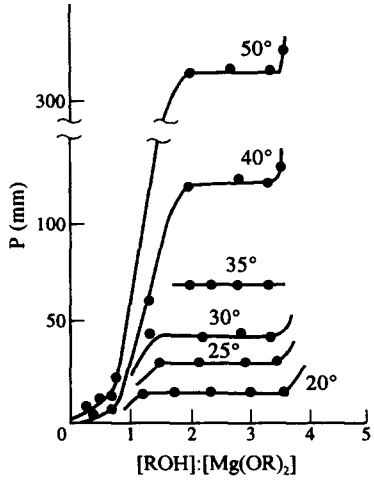

Fig. 4. The isotherms of the dissociation vapour pressure in the $Mg(OMe)_2$–MeOH system.

On degradation of I up to the composition of $Mg(OR)_2 \cdot 0.75ROH$, 2.75 M of ROH per 1 M of $Mg(OR)_2$ are lost. As was mentioned above, in the structures of the NM and Ct cubanes there exist ROH molecules which are bound more tightly than the others due to intramolecular hydrogen bonds; there are four such tightly bound molecules in NM and two such molecules in Ct. If we assume that these tightly bound molecules are the last to be eliminated in the desolvation process, we may suggest the existence of an intermediate with the composition $Mg(OR)_2 \cdot 0.75ROH$, which is in good agreement with the results of the tensimetry study. It is noteworthy that up to this composition the isolated cubane aggregates are retained in the intermediate complexes and, therefore, the desolvation process still remains reversible. The desolvation most probably begins with the elimination of eight solvating ROH molecules, thus producing the species of the overall composition $[Mg_8(OR)_{14}(ROH)_{18}]^{2+}[(RO)_2H]_2^-$, i.e. "$Mg(OR)_2 \cdot 2.5ROH$". Thereafter, the destruction of the anion occurs and the formation of the product consisting of the neutral cubanes, $Mg_4(OR)_8(ROH)_8$, i.e. "$Mg(OR)_2 \cdot 2ROH$", may be anticipated. Ultimately, the ROH molecules, which do not participate in hydrogen-bonding, are eliminated. Thus, after elimination of 22 ROH molecules from the starting $[Mg_4(OR)_6(ROH)_{10}]^{2+}[(RO)_2H]_2^-[Mg_4(OR)_8(ROH)_8] \cdot 8ROH$ compound, neutral molecules of $[Mg_4(OR)_8(ROH)_3]$ are formed. The magnesium atoms' coordination numbers in these molecules cannot attain the normal value of six and would remain equal to four or five, which provokes the aggregation of cubane cages, accompanied by the formation of stable polymeric structure and the increase of the coordination numbers of metal atoms. Indeed, the samples corresponding to the 1 : 1 to 1 : 0.75 compositions are amorphous and insoluble in alcohol. Their desolvation proceeds at temperatures $\geqslant$ 50°C and is

accompanied by partial thermolysis, which normally occurs at lower temperatures for methoxides than for their higher homologues. Therefore, the alkoxide with the "$Mg(OR)_2$" composition should contain oxo bridges, and the above-mentioned calcium ethoxide [1] may be considered as an example of such a species.

The X-ray powder diffraction pattern of $Mg(OR)_2$ shows diffuse reflections, which may be indexed on the basis of the hexagonal unit cell reported for the alkaline-earth methoxides, belonging to the CdI_2 structural type [4,13]. One can therefore suggest the formation of $[Mg(OR)_2]_\infty$ orthogonal to the six-fold symmetry axis. However, most of the $Mg(OR)_2$ sample consist of the amorphous phase, which is reflected, in particular, in the considerable difference (up to 40%) between the experimental and calculated density values [4]. It is noteworthy that the calcium, strontium and barium methoxides, which are also formed as a result of the destruction of the corresponding $M(OR)_2 \cdot 4ROH$ solvates, yield samples with significantly higher degrees of crystallinity, so that the corresponding experimental/calculated density ratio is in the range of 96–98% [4].

Note added in proof

After this manuscript was submitted for publication, we became acquainted with the paper by H. Thoms, M. Epple, H. Viebrock and A. Reller (*J. Mater. Chem.*, 1995, vol. 5, p. 589) wherein the crystal structure of the $Mg(OMe)_2 \cdot 2(MeOH)$ solvate is reported. The striking similarity of the unit cell dimensions and the closeness of the symmetries of both crystals make us believe that one and the same compound was in fact studied in both cases. The elemental analysis reported by H. Thoms *et al.* and the corresponding disolvate formulation would not have differed significantly for the 3.5-solvate and may have easily been affected by the instability of the product, which readily loses the solvating methanol molecules.

(Received 25 June 1996; accepted 12 July 1996)

Abstract—The zinc(II) and palladium(II) complexes of 16-ethyl-5,6,7,8,9,14-hexahydrodibenzo [*b*,*i*][1,4,8,11]tetraazacyclotetradecine (HL^1) and 5,14-dihydro-7,16-diethyldibenzo[*b*,*i*][1,4,8,11]tetraazacyclotetradecine (H_2L^2) have been synthesized and their spectroscopic data determined. The absorption bands of ML^1X (M = Zn, Pd; X = Cl, NCS, ClO_4) observed in the 20,400–23,900 cm^{-1} region were attributable to $\pi \rightarrow \pi^*$ and charge transfer transitions. Those bands for the three palladium(II) complexes (PdL^1X) are similar to each other in various solvents, but the bands of ZnL^1X are slightly different from one another. The ^{13}C NMR signals for $NiL^1(ClO_4)$ and $PdL^1(ClO_4)$ are similar to each other, but the C(15) and C(17) carbon signals for $ZnL^1(ClO_4)$ exhibit downfield shifts upon metal coordination. Judging from the molar conductances for the complexes, $ZnL^1(ClO_4)$ and PdL^1X (X = Cl, NCS, ClO_4) are 1:1 electrolytes in acetonitrile and nitromethane, but ZnL^1Cl and ZnL^1 (NCS) are non-electrolytes. The treatment of PdL^1X (X = Cl, NCS, ClO_4) in methanol solution with an excess of base in air gave (7-ethyldibenzo [*b*,*i*][1,4,8,11]tetraazacyclotetradecinato)palladium(II) (PdL^3). Keywords: dibenzotetraazaannulene; macrocycle; zinc complex; palladium complex; NMR spectrum; absorption spectrum.

Our recent research has been concerned with structural and spectroscopic properties of tetraazamacrocyclic complexes. Although much attention has been paid to the chemistry of transition-metal complexes with dibenzotetraaza[14]annulene macrocycles [1], there have been only a few studies of zinc and palladium complexes and/or a conjugated π-electron system [2]. Recently, we have synthesized (16-ethyl-5,6,7,8-tetrahydro-9*H*-dibenzo[*b*,*i*][1,4,8,11] tetraazacyclotetradecinato) nickel(II) complexes with eight types of counteranions [3]. Furthermore, we have reported the counteranion effect of their nickel(II) complexes.

In the present work, we have synthesized zinc(II) and palladium(II) complexes of 16-ethyl-5,6,7,8,9,14-hexahydrodibenzo[*b*,*i*][1,4,8,11]tetraazacyclotetradecine (HL^1) having three types of counteranions. The palladium(II) complexes of HL^1 in methanol are oxidized by the addition of excess base, and lead to (7-ethyldibenzo[*b*,*i*][1,4,8,11]tetraazacyclotetradecinato)-palladium(II) (PdL^3). We also prepared the zinc(II) and palladium(II) complexes of 5,14-dihydro-7,16-diethyldibenzo[*b*,*i*][1,4,8,11]tetraazacyclotetradecine (H_2L^2) following the procedure of NiL^2 [4]. We have characterized the spectral properties of ZiL^1X, PdL^1X, ZnL^2, PdL^2 and PdL^3 (X = Cl, NCS and ClO_4).

EXPERIMENTAL

Physical measurements

UV and visible spectra covering the 12,500–50,000 cm^{-1} region were recorded on a Shimadzu UV 200S

* Author to whom correspondence should be addressed.

double beam spectrophotometer at room temperature. IR spectra in the range of 400–4000 cm^{-1} were recorded on a Jeol JIR-5500 FT-IR spectrophotometer and a Hitachi 260-30 spectrophotometer at room temperature as Nujol mulls and using the potassium bromide disc method. ^1H and ^{13}C NMR measurements were recorded using a Jeol JNM-FX 60 spectrometer. The NMR spectra were obtained in $CDCl_3$, DMSO-d_6 and DMF-d_7. Chemical shifts are given in ppm relative to tetramethylsilane as an internal reference. Conductivity measurements were performed with acetonitrile and DMF solutions of the complexes kept at 25.0 ± 0.1°C using a Coolnics Thermo-Bath (model CTE-310). Conductivities were measured with a TOA Electronics Ltd CM-20E. FAB mass spectra (in a matrix of neat glycerin) for ZnL^1X and PdL^1X (X = Cl, NCS and ClO_4) and EI mass spectra (at 70 eV) for ZnL^2, PdL^2, NiL^3 and PdL^3 were obtained on a Jeol JMS-DX 300 gas chromatograph mass spectrometer. Argon was employed as the fast-atom beam. Melting points were determined with a Yanaco MP-S3 micro melting point apparatus (hot-plate type).

Preparation of macrocycles and their complexes

16-*Ethyl*-5,6,7,8,9,14-*hexahydrodibenzo*[*b*,*i*]-[1,4,8,11]*tetraazacyclotetradecine* (HL^1). The synthetic procedures for HL^1 and its nickel(II) complexes have been reported previously [3].

(16-*Ethyl*-5,6,7,8-*tetrahydro-9H-dibenzo*[*b*,*i*]-[1,4,8,11]*tetraazacyclotetradecinato*)*zinc*(II) *chloride* (ZnL^1Cl). A mixture of HL^1 (0.160 g, 0.50 mmol), zinc(II) chloride (0.082 g, 0.60 mmol) and methanol (30 cm^3) was heated at 50°C for 1 h with stirring. Water (30 cm^3) and ammonium chloride (1.0 g, 0.019 mol) were added to the reaction mixture. A precipitate was isolated by filtration and washed with water to give 154 mg (73%) of yellow needles, m.p. 140°C (dec.). IR KBr: 1609, 1461, 1310, 1283, 748 cm^{-1}. MS *m*/*z* (relative intensity): 383 (100), 384 (38.3), 385 (65.6), 386 (32.3), 387 (44.1). UV (acetonitrile): λ_{max} 472 (21,300), 271 (17,500), 246sh (18,700) nm.

(16-*Ethyl*-5,6,7,8-*tetrahydro-9H-dibenzo*[*b*,*i*]-[1,4,8,11]*tetraazacyclotetradecinato*)*zinc*(*II*) *isothiocyanate* (ZnL^1NCS). A mixture of HL^1 (0.160 g, 0.50 mmol), zinc(II) acetate dihydrate (0.132 g, 0.60 mmol) and methanol (30 cm^3) was heated at 50°C for 1 h with stirring. Water (60 cm^3) and ammonium thiocyanate (2.0 g, 0.026 mol) were added to the reaction mixture. A precipitate was separated by filtration and washed with water to give 215 mg (97%) of yellow needles, m.p. 155°C (dec.). IR (KBr): 3150 (N—H), 2074 (NCS), 1609, 1461, 1308, 1280, 751 cm^{-1}. MS *m*/*z* (relative intensity): 383 (100), 384 (39.4), 385 (63.1), 386 (33.1), 387 (42.1). UV (acetonitrile): λ_{max} 470 (23,200), 270 (17,500), 253 (17,200) nm.

(16-*Ethyl*-5,6,7,8-*tetrahydro-9H-dibenzo*[*b*,*i*]-[1,4,8,11]*tetraazacyclotetradecinato*)*zinc*(II) *perchlorate* (ZnL^1ClO_4). A mixture of HL^1 (0.160 g, 0.50 mmol), zinc(II) perchlorate (0.159 g, 0.60 mmol) and methanol (30 cm^3) was heated at 50°C for 1 h with stirring. Water (60 cm^3) and ammonium perchlorate (3.0 g, 0.026 mol) was added to the reaction mixture. A precipitate was recovered by filtration and washed with water to give 168 mg (69%) of yellow needles, m.p. 128°C (dec.). IR (KBr): 3252 (N—H), 1593, 1455, 1308, 1283, 1120–1040 (Cl—O), 748, 622 (Cl—O) cm^{-1}. MS *m*/*z* (relative intensity): 383 (100), 384 (37.4), 385 (64.3), 386 (30.4), 387 (42.0). UV (acetonitrile): λ_{max} 468 (21,300), 270 (17,400) nm.

(16-*Ethyl*-5,6,7,8-*tetrahydro-9H-dibenzo*[*b*,*i*]-[1,4,8,11]*tetraazacyclotetradecinato*)*palladium*(II) *chloride* (PdL^1Cl). A mixture of HL^1 (0.160 g, 0.50 mmol), palladium(II) acetate (0.150 g, 0.67 mmol) and methanol (60 cm^3) was treated at 20°C for 2 h with stirring while nitrogen was continuously bubbled through it. The reaction mixture was filtered and water (100 cm^3) and ammonium chloride (2.0 g, 0.037 mol) were added to the filtrate. A precipitate was separated by filtration and washed with water to give 219 mg (95%) of yellow needles, m.p. 247°C (dec.). IR (KBr): 1588, 1443, 1320, 1280, 1233, 742 cm^{-1}. MS *m*/*z* (relative intensity): 423 (41.3), 424 (79.9), 425 (100), 426 (32.9), 427 (83.3), 428 (27.3), 429 (38.7). UV (acetonitrile): λ_{max} 487 (21,900), 463 (16,000), 265 (16,500), 233 (18,500) nm.

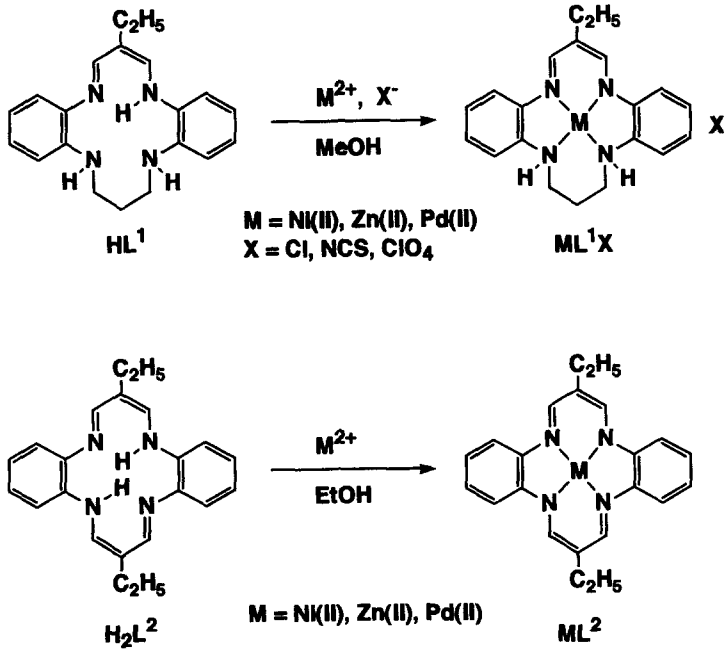
(16-*Ethyl*-5,6,7,8-*tetrahydro-9H-dibenzo*[*b*,*i*]-[1,4,8,11]*tetraazacyclotetradecinato*)*palladium*(II) *isothiocyanate* (PdL^1NCS). This was prepared from HL^1 (0.160 g, 0.50 mmol), palladium(II) acetate (0.150 g, 0.67 mmol), methanol (60 cm^3), water (100 cm^3) and ammonium thiocyanate (2.0 g, 0.026 mol) following the above procedure, and was recovered by filtration to obtain 232 mg (96%) of brown–yellow plates, m.p. 257°C (dec.). IR (KBr): 3055 (N—H), 2050 (NCS), 1590, 1440, 1319, 1278, 1234, 745 cm^{-1}. MS *m*/*z* (relative intensity): 423 (37.7), 424 (80.4), 425 (100), 426 (33.6), 427 (82.9), 428 (24.3), 429 (37.9). UV (acetonitrile): λ_{max} 487 (22,000), 464sh (17,000), 266 (17,200), 234 (20,500) nm.

(16-*Ethyl*-5,6,7,8-*tetrahydro-9H-dibenzo*[*b*,*i*]-[1,4,8,11]*tetraazacyclotetradecinato*)*palladium*(II) *perchlorate* (PdL^1ClO_4). This complex was prepared from HL^1 (0.160 g, 0.50 mmol), palladium(II) acetate (0.150 g, 0.67 mmol), methanol (60 cm^3), water (100 cm^3) and ammonium perchlorate (3.0 g, 0.026 mol) following the above procedure, and was isolated by filtration to yield 242 mg (92%) of brown–yellow needles, m.p. 279°C (dec.). IR (KBr): 3210 (N—H), 1588, 1440, 1315, 1265, 1231, 1120–1040 (Cl—O), 740, 620 (Cl—O) cm^{-1}. MS *m*/*z* (relative intensity): 423 (41.2), 424 (80.6), 425 (100), 426 (34.0), 427 (77.9), 428 (25.5), 429 (45.3). UV (acetonitrile): λ_{max} 487 (20,300), 464 (16,100), 264 (12,100), 232 (15,100) nm.

5,14-*Dihydro*-7,16-*diethyldibenzo*[*b*,*i*][1,4,8,11]-*tetraazacyclotetradecine* (H_2L^2). The synthetic procedure for H_2L^2 and its nickel(II) complex have been described previously [4].

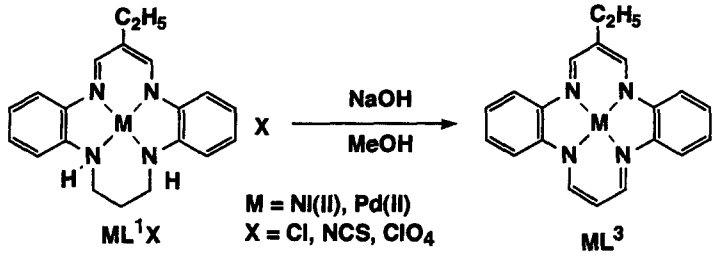
(7,16-*Diethyldibenzo*[*b*,*i*][1,4,8,11]*tetraazacyclotetradecinato*)*zinc*(II) (ZnL^2). A mixture of H_2L^2 (0.172 g, 0.50 mmol), zinc(II) acetate dihydrate (0.154 g, 0.70 mmol), sodium acetate trihydrate (0.150 g, 1.10 mmol) and ethanol (60 cm^3) was refluxed for 20 h with stirring while nitrogen was continuously bubbled through it. The product was collected and washed with ethanol to give 146 mg (72%) of brown needles, m.p. 243°C (dec.). IR (KBr): 1580, 1470, 1376, 1332, 1208, 734 cm^{-1}. MS *m*/*z* (relative intensity): 391 (100), 392 (27.9), 393 (60.8), 394 (22.7), 395 (36.3), 404 (17.3), 405 (8.5), 406 (71.5), 407 (22.0), 408 (43.2), 409 (16.9), 410 (25.9), 411 (6.4); UV (DMF): λ_{max} 504 (18,100), 486sh (17,200), 420 (69,000), 402sh (41,700), 291 (28,300) nm.

(7,16)-*Diethyldibenzo*[*b*,*i*][1,4,8,11]*tetraazacyclotetradecinato*)*palladium*(II) (PdL^2). A mixture of H_2L^2 (0.344 g, 1.00 mmol), palladium(II) sodium chloride trihydrate (0.350 g, 1.00 mmol) and DMF (25 cm^3) was refluxed for 1 h with stirring while nitrogen was continuously bubbled through it. Palladium(II) sodium chloride trihydrate (0.150 g, 0.43 mmol) was added to the reaction mixture, which was further refluxed for 1 h and filtered to remove the inorganic residue. Upon cooling the filtrate with an ice water bath, the product was separated and washed several times with methanol (10 cm^3) to give 186 mg (41%) of dark brown plates, m.p. 217°C (dec.). IR (KBr): 1595, 1470, 1443, 1338, 1228, 740 cm^{-1}. MS *m*/*z* (relative intensity): 431 (12.1), 432 (26.9), 433 (38.0), 434 (12.9), 435 (28.7), 436 (10.7), 437 (13.7), 446 (77.1), 448 (100), 449 (24.9), 450 (82.3), 451 (21.2), 452 (37.0), 453 (9.3). UV (DMF): λ_{max} 498 (16,700), 476 (14,800), 438 (29,900), 346 (5650), 274 (22,000) nm.



(16-*Ethyldibenzo*[*b*,*i*][1,4,8,11]*tetraazacyclotetradecinato*)*palladium*(II) (PdL^3). A mixture of PdL^2Cl (0.100 g, 0.22 mmol), sodium hydroxide (0.10 g, 2.5 mmol) and methanol (100 cm^3) was heated at 40°C for 6 h with stirring. Upon cooling the reaction mixture with an ice water bath, the crystalline solid was recovered by filtration and washed several times with methanol (10 cm^3) to give 50 mg (55%) of dark brown microcrystals, m.p. 262°C (dec.). IR (KBr): 1573, 1442, 1328, 732 cm^{-1}. MS *m*/*z* (relative intensity): 403 (36.0), 404 (79.1), 405 (100), 406 (24.9), 407 (84.6), 408 (21.7), 409 (39.1), 417 (20.3), 418 (47.1), 419 (60.8), 420 (82.1), 421 (23.9), 422 (66.3), 423 (16.6), 424 (25.4). UV (acetonitrile): λ_{max} 476 (13,300), 454 (12,400), 427 (32,500), 308 (4280), 268 (13,900) mm.

(16-*Ethyldibenzo*[*b*,*i*][1,4,8,11]*tetraazacyclotetradecinato*)*nickel*(II) (NiL^3). A mixture of methanol (100 cm^3), NiL^1Cl (0.100 g, 0.24 mmol) and sodium hydroxide (0.10 g, 2.5 mmol) was reacted as described above for 6 h to yield 73 mg (80%) of reddish violet needles, m.p. 244°C (dec.). IR (KBr): 1598, 1471, 1336, 1257, 739 cm^{-1}. MS *m*/*z* (relative intensity): 357 (100), 358 (23.8), 359 (41.2), 360 (11.1), 372 (81.0), 373 (21.3), 374 (32.1), 375 (9.0), 376 (6.1). UV (acetonitrile): λ_{max} 510 (7350), 470 (7370), 429 (59,400), 307 (15,700), 272 (19,900) nm.



RESULTS AND DISCUSSION

Preparation and properties of the metal complexes

The reaction of macrocycle HL^1 and/or H_2L^2 with zinc(II) and/or palladium(II) salts gave the cor-

Scheme 1.

Scheme 2.

responding zinc(II) and/or palladium(II) complexes (ML^1X, ML^2: M = Zn, Pd, X = Cl, NCS, ClO_4) in good yield. PdL^1X and NiL^1X in methanol are oxidized by the addition of base and by molecular oxygen, and then PdL^3 and NiL^3 are obtained [3,5]. On the other hand, ZnL^1X are recovered unchanged in methanol solution following the above procedure. The analytical data of the zinc(II), palladium(II) and nickel(II) complexes are listed in Table 1. Elemental analyses of these crystalline samples were in fair agreement with the compositions of these compounds.

Electronic spectra

The electronic absorption spectra covering the 15,000–40,000 cm^{-1} range in acetonitrile are shown in Fig. 1 for HL^1, $PdL^1(ClO_4)$ and PdL^3. The intense absorption bands for $PdL^1(ClO_4)$ observed in the 20,500–21,600 cm^{-1} region are reasonably attributed to $\pi \rightarrow \pi^*$ transitions within a ligand molecule and charge transfer transitions from metal to ligand, since the molar extinction coefficients are much larger than those normally assigned to ligand-field transitions.

Table 1. Analytical data for the complexes

Complex	Empirical formula	Elemental analyses Calc./Found (%) C	H	N
ZnL^1Cl	$C_{20}H_{23}N_4ZnCl$	57.2	5.5	13.3
		56.9	5.7	13.3
$ZnL^1(NCS)$	$C_{21}H_{23}N_5ZnS$	57.0	5.2	15.8
		57.1	5.4	15.6
$ZnL^1(ClO_4)$	$C_{20}H_{23}N_4ZnClO_4$	49.6	4.8	11.6
		49.3	5.1	11.6

		64.1	5.2	14.8
PdL^3	$C_{20}H_{18}N_4Pd$	57.1	4.3	13.3
		56.9	4.4	13.3
ZnL^2	$C_{22}H_{22}N_4Zn$	64.8	5.4	13.7
		65.1	5.5	13.8
PdL^2	$C_{22}H_{22}N_4Pd$	58.9	4.9	12.5
		58.9	5.2	12.6

Those bands for the three palladium(II) complexes (PdL^1X; X = Cl, NCS, ClO_4) are similar to each other, and are not influenced by any anion [3]. The ligand-field bands were not assigned for the present complexes, because all the ligand-field bands were obscured by the $\pi \rightarrow \pi^*$ and charge transfer transition bands of high intensity. The spectral behaviour is consistent with the square-planar coordination and is similar to that observed for tetraaza[14]annulene metal(II) complexes [1g, 4].

The electronic absorption spectra for $ZnL^1(ClO_4)$ and ZnL^2 are shown in Fig. 2. The intense absorption bands for ZnL^1X (X = Cl, NCS, ClO_4) observed in the 21,100–21,400 cm^{-1} range slightly differ from one another. The difference of these bands is observed in various solvents, such as ethyl acetate, chloroform, acetonitrile, DMF, *etc.* Namely, the absorption bands are affected by the counteranion and the solvent. This fact may show that the coordination structures of the zinc(II) complexes assume distorted square-planar and/or pentacoordinated configurations because of their ability to take the tetrahedral coordination of zinc(II).

General features of the spectra for ML^2 and ML^3 (M = Zn, Pd and Ni) are similar to each other. A pair of weaker bands (ε = 7000–18,000) are observed in the 19,600–22,000 cm^{-1} region, and the extremely intense absorption bands (ε = 30,000–69,000) observed in the 22,800–23,800 cm^{-1} range are assigned to the so-called Soret-type transition, as estimated for metal porphyrins [6]. Since the nickel(II) and palladium(II) complexes do not indicate any significant absorption below *ca* 19,000 cm^{-1}, they may be square-planar coordinations.

Molar conductivity

The molar conductances for zinc(II) and palladium(II) complexes are listed in Table 2, together with those for nickel(II) complexes. $ZnL^1(ClO_4)$ and PdL^1X (X = Cl, NCS, ClO_4) are 1 : 1 electrolytes in acetonitrile and nitromethane, but ZnL^1Cl and $ZnL^1(NCS)$ are non-electrolytes [7]. $NiL^1(ClO_4)$ $ZnL^1(ClO_4)$ and $PdL^1(ClO_4)$ are 1 : 1 electrolytes and

[c] For *ca* 10^{-4} mol dm^{-3} solutions.

are tetracoordinated complexes in acetonitrile and nitromethane solutions. Therefore, it is noted that the perchlorate anions of $ML^1(ClO_4)$ (M = Ni, Zn, Pd) ionize in these solvents. ZnL^1Cl, $ZnL^1(NCS)$ and NiL^1Cl become pentacoordinated complexes by taking up a chloride and/or an isothiocyanate anion in the axial state. On the other hand, the chloride and isothiocyanate anions of $NiL^1(NCS)$, PdL^1Cl and $PdL^1(NCS)$ ionize. These facts show that ML^1X (M = Ni, Zn, Pd; X = Cl, NCS) tend to increase coordination from four to five in the following order: Zn > Ni > Pd. This is ascribed to the characteristics of the metal(II) cations.

NMR spectra

The ^1H and ^{13}C NMR data of the zinc(II), palladium(II) and nickel(II) complexes are collected in Tables 3 and 4, respectively. The pattern of all ^1H NMR signals of ZnL^1X and PdL^1X (X = Cl, NCS and ClO_4) is similar to that of NiL^1X [3]. It is found

that the metal-free macrocycle (HL^1) releases an H^a-amine proton upon metal coordination and the metal ions are chelated by four nitrogens of the ligand in the nickel(II) complexes. The H^c-methine proton signals of PdL^1X are observed at higher field than those of HL^1, whereas those of ZnL^1X are observed at lower fields. This indicates that the coordination structures of PdL^1X and ZnL^1X are different. The ^{13}C NMR spectra were used to distinguish clearly NiL^1X, PdL^1X and ZnL^1X. That is to say the aromatic C(15) and C(17) signals for $NiL^1(ClO_4)$ and $PdL^1(ClO_4)$ are observed at slightly higher field (0.4, 3.0 ppm) than that for HL^1, but that of $ZnL^1(ClO_4)$ is observed at lower field (8.2 ppm). The C(19) and C(22) signals for the former are shifted to lower field than for the latter. In the nickel(II) and palladium(II) complexes with analogous ligands, 5,14-dihydro-7,16-diethyl-(*Z*)-dipyrido[*b*,*i*][1,4,8,11]tetraazacyclotetradecine [4c],5,14-dihydro-6,8,15,17-tetramethyldibenzo[*b*,*i*]-[1,4,8,11]tetraazacyclotetradecine [8] and 3,3′-(1,2-phenylenediimino)diacrolein [9], the C(15) and C(17) peaks exhibit upfield shifts (0–7 ppm) upon metal coordination, and the C(19) and C(22) peaks reveal downfield shifts (6–10 ppm). These facts show that the coordination structures of $NiL^1(ClO_4)$ and $PdL^1(ClO_4)$ are similar to each other and assume a square-planar configuration, while $ZnL^1(ClO_4)$ may have a distorted square-planar and/or a pentacoordinated structure. The bridged aliphatic ring C(6) and C(8) signals for $NiL^1(ClO_4)$, $ZnL^1(ClO_4)$ and $PdL^1(ClO_4)$ indicate lower field shifts on metal coordination. This is due to the electron-withdrawing effect of the metal cations.

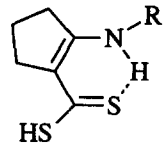
[b]Department of Chemistry, Bengal Engineering College (Deemed University), Shibpur, Howrah 711 103, India

(Received 30 April 1996; accepted 8 July 1996)

Abstract—Ruthenium(II) complexes $[Ru(R\text{-}acda)_2(PPh_3)_2]$ (**1a–e**), $[Ru(R\text{-}acda)(bpy)_2](ClO_4)$(**2a–d**), $[Ru(R\text{-}acda)(phen)_2](ClO_4)$(**2e–g**), $[Ru(R_2\text{-}dtc)(bpy)_2](ClO_4)$(**3a, b**) and $[Ru(R_2\text{-}dtc)(phen)_2](ClO_4)$(**3c, d**) (where R-acdaH = 2-alkylamino-1-cyclopentene-1-dithicarboxylic acid, R_2-dtcNa = sodium *N,N'*-dialkyl dithiocarbamate, bpy = 2,2′-bipyridine and phen = 1,10-phenanthroline) have been synthesized and characterized. The ^1H NMR spectra of the phosphine complexes (**1a–e**) show that, with the increase in the chain length of the alkyl group of R-acda$^-$, the N-alkylamino proton becomes more deshielded and is accompanied by a shift of the NH stretching frequency ν(NH) to lower energy. A linear relationship is obtained between the chemical shift δ(NH) and ν(NH). All the complexes exhibit absorption bands due to $d\pi \rightarrow \pi^*$ (bpy, phen or PPh_3), $d\pi \rightarrow \pi^*$ (R-acda$^-$ or R_2-dtc$^-$) charge transfer transitions and $\pi \rightarrow \pi^*$ intraligand transition. Complexes **1a–e** undergo two irreversible oxidations, $Ru^{II} \rightarrow Ru^{III}$ and $Ru^{III} \rightarrow Ru^{IV}$, while the other complexes (**2, 3**) exhibit one reversible (Ru^{II}/Ru^{III}) and one irreversible ($Ru^{III} \rightarrow Ru^{IV}$) oxidation process. Copyright © 1996 Elsevier Science Ltd

Keywords: Ru^{II} complexes; mixed-ligand Ru^{II} complexes; dithiocarboxylates of Ru^{II}; dithiocarbamates of Ru^{II}; thioacid ligands; electrochemistry of Ru^{II}.



Mononuclear ruthenium(II) polypyridine complexes have been the focus of attention because of their unique chemical stability and interesting redox properties [1–5]. However, the chemistry of mixed-ligand mononuclear ruthenium(II) complexes containing polypyridine and dithiocarboxylates or dithiocarbamates has not been studied much. Herein, we report the synthesis, characterization and electrochemical behaviour of a series of monomeric mixed-ligand ruthenium(II) complexes (**1a–e, 2a–g, 3a–d**) derived from the (S, S$^-$) donor ligands HL [1–5], NaL [6, 7] and using PPh_3, 2,2′-bipyridine and 1,10-phenanthroline as co-ligands.

EXPERIMENTAL

Physical measurements

IR spectra were recorded on a Perkin–Elmer 783 spectrophotometer using KBr discs and electronic spectra on a Shimadzu UV-160 spectrophotometer. The electrochemical data were obtained with a BAS 100B electrochemistry system. A three-electrode assembly (BAS) comprising a platinum working electrode, a platinum auxilliary electrode and an Ag–AgCl reference electrode was used. The concentration of the supporting electrolyte tetraethylammonium perchlorate (TEAP) was maintained at 0.1 mol dm^{-3}. ^1H NMR spectra were obtained in $CDCl_3$ solutions on a 270 MHz Bruker WH 270 spectrometer using $Si(CH_3)_4$ ($\delta H = 0$) as the internal standard. Carbon,

hydrogen and nitrogen analyses were carried out on a Perkin–Elmer 240C elemental analyser.

Materials

All reagents and solvents were purchased from chemical sources and used as received. 2-Alkylamino-1-cyclopentene-1-dithiocarboxylic acids were prepared by reported methods [6,7]. $Ru(bpy)_2Cl_2$, $Ru(phen)_2Cl_2$ and $Ru(PPh_3)_3Cl_2$ were prepared by the published methods [8,9]. Silver perchlorate was prepared from silver carbonate and perchloric acid, and recrystallized from benzene [10].

CAUTION! Silver perchlorate and the other perchlorate salts described below are potentially explosive. Although $AgClO_4$ was recrystallized in gram quantities without any difficulty, **extreme caution should be exercised in handling this material.**

Preparation of the complexes

All the reactions were carried out under nitrogen using dry solvents.

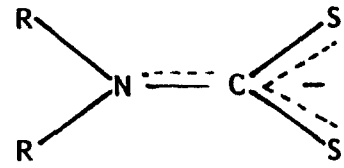
General procedure for the synthesis of the complexes $[Ru(R\text{-}acda)_2(PPh_3)_2]$ (**1a–e**). A typical procedure for the preparation of **1a** is given below.

$[Ru(H\text{-}acda)_2(PPh_3)_2]$(**1a**). To a stirred suspension of $Ru(PPh_3)_3Cl_2$(0.96 g, 1 mmol) in C_6H_6 (25 cm^3) was added a C_6H_6 solution (10 cm^3) of H-acdaH (0.32 g, 2.0 mmol). The mixture was stirred at room temperature for 5 h, during which time a clear solution was obtained. The solution was concentrated on a rotary evaporator to a small volume (*ca* 5 cm^3) and added dropwise to 50 cm^3 vigorously stirred petroleum ether (b.p. 40–60°C). The product precipitated was collected by filtration and purified by column chromatography using neutral alumina and C_6H_6 as the eluant; yield 0.75 g (80%).

General method for the preparation of $[Ru(A\text{-}A)_2(L^{1-4,6,7})](ClO_4)$ (A-A = bpy *or* phen) *complexes.* $[Ru(Me\text{-}acda)(bpy)_2](ClO_4)$ (**2b**). A stirred suspension of $[Ru(bpy)_2Cl_2]\cdot 2H_2O$ (0.26 g, 0.5 mmol) in EtOH (40 cm^3) was treated with $AgClO_4$ (0.21 g, 1 mmol) and filtered after 2 h to remove the AgCl precipitated. To the filtrate was added Me-acdaH (0.08 g, 0.5 mmol) dissolved in EtOH (10 cm^3). The solution was stirred at room temperature for 10 h, during which time the product deposited as microcrystals. These were collected by filtration and recrystallized from EtOH; yield 0.25 g (75%).

In the case of complexes **3a–d** the sodium salts of dialkyldithiocarbamates were used instead of Me-acdaH.

RESULTS AND DISCUSSION



The synthetic routes involved in the formation of the phosphine complexes (**1a–e**) and polypyridine complexes (**2a–g, 3a–d**) are given by Eqs (1) and (2), respectively:

$$Ru(PPh_3)_3Cl_2 \xrightarrow[C_6H_6]{\text{R-acdaH}} [Ru(\text{R-acda})_2(PPh_3)_2]$$

$$[Ru(bpy)_2Cl_2/Ru(phen)_2Cl_2] \xrightarrow[\text{(ii) R-acdaH/Na[R}_2\text{dtc]}]{\text{(i) AgClO}_4\text{, EtOH}} \textbf{(1a–e)} \quad (1)$$

$$[Ru(\text{R-acda/R}_2\text{-dtc})\langle(bpy)_2/(phen)_2\rangle](ClO_4) \quad \textbf{(2a–g, 3a–d)} \quad (2)$$

All the complexes have been isolated in good yield and their microanalytical data (Table 1) confirm the composition given. The IR spectra of the phosphine complexes exhibit three NH stretching frequencies between 3400 and 3200 cm^{-1} for **1a**, while for complexes **1b–e** only a single ν(NH) vibration is observed. Significantly, the ν(NH) frequencies of these compounds, 3250 (**1b**), 3240 (**1c**), 3230 (**1d**) and 3220 (**1e**) cm^{-1}, are progressively shifted to lower energy with the increase in size of the alkyl group R of R-acda$^-$. Complexes **1a–e** show a characteristic sharp band at about 820 cm^{-1} which has previously been assigned to $\nu_{as}(CS_2^-)$ [6,11–13]. Three diagnostic IR bands for the dithiocarbamate complexes **3a–d** are observed due to ν(C---N), $\nu_{as}(CS_2^-)$ and $\nu_s(CS_2^-)$ vibrations of the delocalized ligand moiety at about

1500, 1280 and 780 cm^{-1}, respectively [10]. Although the ν(CN) frequency of these complexes at 1500 cm^{-1} is almost independent of the substituents, it is shifted to a higher energy relative to those of the free ligands (*ca* 1480 cm^{-1}) due to the increased double bond character upon coordination to the metal centre [14,15]. All the perchlorate complexes show a broad band at about 1100 cm^{-1} and a sharp band at 620 cm^{-1}, indicating the presence of free ClO_4^- anion.

The UV–vis spectra data of the complexes are given in Table 2. All the phosphine complexes (**1a–e**) have similar spectra, exhibiting three bands. The lowest energy band observed at 460 nm may be attributed to a $d\pi \rightarrow \pi^*$ (PPh_3) metal-to-ligand charge transfer (MLCT) transition. The next highest energy band, observed at about 380 nm, is also an MLCT $d\pi \rightarrow \pi^*$ (R-acda$^-$) transition [16,17]. The intra-ligand transition occurs at about 330 nm.

Complexes **2a–g** also exhibit two MLCT bands at 490 and 350 nm, and an intra-ligand transition at 330 nm, of which the 490 nm band is assignable to a $d\pi \rightarrow \pi^*$ (bpy or phen) transition and the band at 350 nm to a $d\pi \rightarrow \pi^*$ (R-acda$^-$) transition. It may be mentioned that the MLCT transition of $[Ru(bpy)_3](ClO_4)_2$ occurring at 452 nm [18] is displaced to lower energies on substituting bpy with one or two ligands [19]. In the case of complexes **3a–d** the two MLCT bands are shifted to relatively higher wavelengths, 515 and 460 nm.

The ^{1}H NMR spectral data of the phosphine–R-acdaH complexes (**1a–e**) are given in Table 3. The spectrum of complex **1b** shows two overlapping but discernible singlets at 2.85 and 2.87 ppm for the methyl

1d	0.77–0.96 (m, 6H, 9-CH_3), 1.25–1.36 (m, 4H, 8-CH_2), 1.40–1.52 (m, 4H, 7-CH_2), 1.57–1.70 (m, 4H, 4-CH_2), 2.43–2.57 [m, 8H, (3, 5)-CH_2], 3.09–3.16 (m, 4H, 6-CH_2], 7.00–7.05 (m, 12H, *m*-Ph), 7.12–7.17 (m, 6H, *p*-Ph), 7.28–7.39 (m, 12H, *o*-Ph), 8.46–8.50 (m, 2H, NH)
1e	1.17–1.52 [m, 10H, (7–11)-CH_2], 1.58–1.82 (m, 4H, 4-CH_2), 2.45–2.64 [m, 8H, (3, 5)-CH_2], 3.24–3.25 (m, 2H, 6-CH), 6.99–7.05 (m, 12H, *m*-Ph), 7.11–7.16 (m, 4H, *p*-Ph), 7.30–7.36 (m, 12H, *o*-Ph), 8.64 (br, 2H, NH)

group of Me-acda, indicating the presence of two structural isomers. The occurrence of the two isomers can be rationalized by taking into consideration the restricted rotation of the N-methyl group of Me-acda in the delocalized structure **1** [6]. From the almost identical heights of the two peaks it may be concluded that the two isomers are present in a 1 : 1 ratio. In the case of **1c**, a broad multiplet due to the —CH_2— group of the N-ethyl moiety of Et-acda is observed between 3.13 and 3.22 ppm. Although a quartet is expected for a single isomer, the broad multiplet again indicates the presence of two isomers.

I

Another interesting aspect of the NMR spectra is that, with the increase in chain length of the alkyl group (cyclohexyl derivative included) in complexes **1b–e**, the chemical shift due to the NH proton increases. In other words, the NH proton becomes more deshielded as the substituent R of R-acda$^-$ is changed in the order Me, Et, Bu and cyclohexyl. Furthermore, with the increase in chain length of the alkyl group of R-acda$^-$, the NH stretching frequency is also shifted to a lower energy. Indeed, a linear correlation is obtained in a ν(NH) *vs* δ(NH) plot (Fig. 1). This observation indicates that along the series **1b–e**, a gradual change of the N—H bond distance probably occurs. However, in the absence of crystallographic results, it is not possible to ascertain the cause of such variation. It is important to note that the observed effect contradicts the trend expected purely on the basis of inductive influence of the alkyl groups. We note that Cole-Hamilton and Stephenson have reported the stereochemical features of $[Ru(PR_3)_2(S_2CNMe_2)_2]$ complexes [20].

The redox properties of the complexes were studied by cyclic voltammetry and differential pulse voltammetry, and the results are given in Table 4. The cyclic voltammograms of the phosphine complexes (**1a–e**) are consistent with two stepwise irreversible metal-centred oxidations, as shown in Eqs (3) and (4).

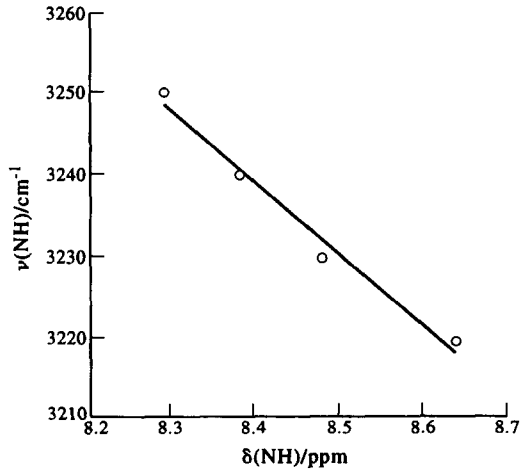

Fig. 1. Plot of chemical shift δ(NH) *vs* the stretching frequency ν(NH) of the phosphine complexes **1b–e**.

Table 4. Electrochemical data for the complexes

Complex	$E^1_{1/2}$(V)	ΔE_p (mV)	E^1_{pa}(V)	E^2_{pa}(V)
1a			0.26	0.72
1b			0.22	0.67
1c			0.24	0.67
1d			0.24	0.69
1e			0.23	0.69
2a	0.49	65		1.25
2b	0.45	64		1.15
2c	0.46	65		1.26
2d	0.45	63		1.26
2e	0.49	64		1.28
2f	0.45	64		1.20
2g	0.45	65		1.20
3a	0.56	60		1.60
3b	0.53	61		1.59
3c	0.55	63		1.57
3d	0.53	61		1.57

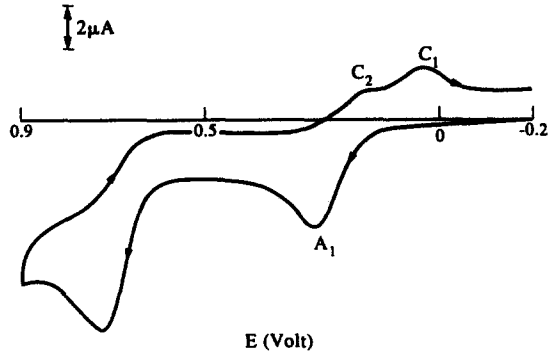

Fig. 2. Cyclic voltammogram of **1a** in CH_3CN with a platinum electrode at a scan rate of 100 mV s^{-1}. Concentration of the complex: 1.0×10^{-3} mol dm^{-3}; concentration of supporting electrolyte, $[Et_4N](ClO_4)$: 0.1 mol dm^{-3}.

$$[Ru^{II}(R\text{-acda})_2(PPh_3)_2]^0 \xrightarrow{E^1_{pa}} [Ru^{III}(R\text{-acda})_2(PPh_3)_2]^+ \quad (3)$$

$$[Ru^{III}(R\text{-acda})_2(PPh_3)_2]^+ \xrightarrow{E^2_{pa}} [Ru^{IV}(R\text{-acda})_2(PPh_3)_2]^{2+} \quad (4)$$

The E^1_{pa} and E^2_{pa} values of **1a** and **1b** are 0.26 and 0.72 V, and 0.21 and 0.67 V, respectively, indicating that the oxidation of **1a** is relatively somewhat more difficult than that of **1b**. This observation is in agreement with the greater electron-releasing ability of the methyl group in **1b** as compared to the hydrogen atom in **1a**. A similar trend is also observed for the oxidation of $R^{III} \rightarrow R^{IV}$ (E^2_{pa}). E^1_{pa} values for all substituted complexes (**1b–e**) lie in the narrow range of 0.21–0.24 V.

Recently, Chakravorty and co-workers have made extensive studies on the reactivities of ruthenium(II) complexes with S,S^- donor ligands containing phosphine and its derivatives, and have observed that the preferred geometries of these complexes are *cis* for ruthenium(II) and *trans* for ruthenium(III) [21–23]. They have demonstrated that at a lower temperature, *cis*-Ru^{II} oxidizes to *cis*-Ru^{III}, which, being unstable, isomerizes to stable *trans*-Ru^{III}. In the reverse scan, *trans*-Ru^{III} is reduced to *trans*-Ru^{II}, which is also unstable and isomerizes to *cis*-Ru^{II} [21–24].

The cyclic voltammogram of **1a** (Fig. 2) shows an indication of isomerism even at room temperature. As may be noted, the anodic peak $A_{(1)}$ has two components in the return sweep, $C_{(1)}$ and $C_{(2)}$, of which $C_{(1)}$ may be considered as due to *trans*-Ru^{II}, which then isomerizes to the more stable *cis*-Ru^{II}, which is indicated by $C_{(2)}$. Clearly, the isomerization rate is slow on the cyclic voltammetric time scale (100 mV s^{-1}).

Cyclic voltammograms of the mixed-ligand complexes (**2a–g**) exhibit reversible and irreversible metal-centred oxidation processes and two reversible reductions of bpy or phen. Thus, while the Ru^{II}/Ru^{III} couple is reversible, the conversion of $Ru^{III} \rightarrow Ru^{IV}$ takes place irreversibly. The criteria of reversibility were checked by observing the constancy of peak separation ($E_{pa} - E_{pa} = 60$–65 mV) and the ratio of peak heights ($i_{pa}/i_{pc} \approx 1$) with the variation of scan rates (50–500 mV s^{-1}). It may be noted that the $E^1_{1/2}$ value of **2a** (0.49 V) is again somewhat higher than the other alkyl derivatives **2b–d** (0.45 V); the latter compounds show practically no dependence on the substituents.

The reduction of bpy and phen in all the complexes occurs in two steps according to Eqs (5) and (6), typically at about −1.50 and −1.80 V:

$$[Ru(R\text{-acda})(bpy)_2]^+ + e \rightleftharpoons [Ru(R\text{-acda}(bpy)(bpy^{\cdot-})] \quad (5)$$

$$[Ru(R\text{-acda})(bpy)(bpy^{\cdot-})] + e \rightleftharpoons [Ru(R\text{-acda})(bpy^{\cdot-})_2] \quad (6)$$

Inasmuch as each bpy or phen can accept two electrons in this lowest unoccupied molecular orbital [25, 26], one should expect to observe four such reduction steps in the series **2a–g** and **3a–d**. The observation of only two couples up to −2.0 V was limited by the cut-off potential of the supporting electrolyte (TEAP) in acetonitrile.

Complexes **3a–d**, similar to **2a–g**, undergo reversible and irreversible meter-centred oxidation processes. The reduction behaviours of bpy or phen in these compounds are very similar to the preceding series. The $E^1_{1/2}$ values of **3a–d** (0.52–0.56 V) show a small substitutional effect.

A comparison of the electrochemical data for Ru^{II}/Ru^{III} in the three series of compounds (Table 4) reveals that the phosphine–R–acda$^-$ complexes (series **1**) are most easily oxidized relative to those of series **2** and **3**. The most important factor that contributes to the easier oxidation of the compounds of series **1** is

that they are uncharged, while those belonging to series **2** and **3** are monocationic. Another important difference lies in the number of (S,S^-) ligands attached, which is two for series **1** and one for series **2** and **3**. Between series **2** and **3,** the greater stability of ruthenium(II) in series **3** can be attributed to greater σ-donor capacity of the dithiocarbamate ligands relative to R-acda$^-$.

COMMUNICATION

The first observation of a Th^{3+} ion in aqueous solution

Thomas M. Klapötke* and Axel Schulz

Department of Chemistry, University of Glasgow, Glasgow G12 8QQ, U.K.

(Received 5 July 1996; accepted 12 July 1996)

Abstract—The reaction of $ThCl_4$ and HN_3 aqueous solution yielded the $Th^{3+}(aq)$ ion which was identified by its absorption (UV–vis, 200–1300 nm) and ESR spectra. In the high energy region of the electronic spectrum just below 650 nm, a significant and constant signal occurs until 420 nm (maximum at 460 nm), which sees the onset of a very intense, broad band with maxima at *ca* 332 (shoulder), 190 and below 185 nm. The ESR spectrum of a frozen solution revealed a very broad signal and a main g value of 2.19. Copyright © 1996 Elsevier Science Ltd

Keywords: thorium chemistry; hydrazoic acid; azides; ESR spectra; electronic spectra.

Recently the electronic structure of f^1 complexes of the early actinide elements (An = Pa, U, Np) has been studied experimentally and theoretically using non-relativistic and relativistic calculations of the optical transition energies of AnX_6^{q-} complexes [1,2]. Examples of actinide f^1 complexes include the tetrahedral borohydride compounds $[Pa(BH_4)_4]$ and $[Pa(BH_3CH_3)_4]$ [3], $[Pa(\eta^8\text{-}C_8H_8)_2]$ [4] and $[U(\eta^5\text{-}C_5H_5)_3NPh]$ [5], and the isoelectronic octahedral hexahalide complexes $[PaX_6]^{2-}$ (X = F, Cl, Br, I), $[UX_6]^-$ (X = F, Cl, Br) and NpF_6 [6, 7]. Thorium(III) complexes are very rare but intensely coloured organometallic systems such as blue $[\{Th(\eta^5\text{-}C_5H_3)(SiMe_3)_2\}_3]$ [8], violet $[Th(\eta^5\text{-}C_5H_5)_3]$ [9], green $[Th(\eta^5\text{-}C_5H_4Me)_3]$ [10] or brown $[Th(\eta^5\text{-}C_5H_5)_2Cl]$ [9] have been reported. In this communication we report the first observation and identification of a Th^{3+} ion in aqueous solution. As far as we are aware, there are no previous reports on a Th^{3+} ion and it is well-known textbook knowledge that: (i) "the oxidation state III is the only oxidation state which, with the possible exceptions of Th and Pa, is displayed by all actinides" [11a] and (ii) "Th^{3+} and Pa^{3+} do not exist in aqueous solution] [11b]. (N.B. For organometallic examples compare with refs [8–10].)

We have previously studied the chemistry and bonding of covalent azides and recently extended our studies to hydrazoic acid, HN_3 [12a–c]. The instability of Th^{3+} in aqueous solution can be attributed to the fact that it is rapidly oxidized by air and it reduces water with evolution of H_2 [11a]. The most recent value recommended for the system Th^{4+}/Th^{3+} is $E^0 = -3.0$ V [13a] (the earlier recommendation was -3.7 V) [13b]. On the other hand, the reduction potential of HN_3 is more negative than that of any other reducing agent in acidic aqueous solution [Eq. (1)] [11a]. The ΔE^0 value for a reaction according to Eq. (2) can be estimated to $\Delta E^0(2) = +0.54$ V and the reaction is therefore thermodynamically allowed [14]:

$$1.5N_2 + H^+(aq) + e^- \rightarrow HN_3(aq)$$

$$E^0 = -3.54 \text{ V (pH 3.5, 25°C) [15]} \quad (1)$$

$$Th^{4+} + HN_3 \rightarrow Th^{3+} + 1.5N_2 + H^+ \quad (2)$$

A solution of Th^{3+} was prepared from aqueous solutions of $ThCl_4$ and HN_3 [16a]. A solution of $ThCl_4$ (2.76 g, 7.38 mmol) in 10 cm^3 water ($c = 0.74$ mol l^{-1}) was added to 15 cm^3 of a fresh stirred, solution of HN_3 ($c = 2.0$ mol l^{-1}) under nitrogen. An amber solution of Th^{3+} was obtained immediately ($c = 0.3$ mol

l^{-1} [16b]; pH *ca* 3.5 [*cf.* $pK_a(HN_3)$ 4.77] [11a]; characterization see below) with evolution of N_2. The aqueous Th^{3+} solution in hydrazoic acid is stable for more than 1 h before Th^{3+} is slowly oxidized by water to form an insoluble, white, gel-like precipitate of thorium oxide hydroxide [17,18].

Recently, it has been shown that for f^1 complexes most of the $f \rightarrow f$ transitions are orbitally forbidden (N.B. the labels "$f \rightarrow f$" and "$f \rightarrow d$" refer to the predominant atomic orbital (AO) character of the molecular orbitals (MOs) involved in the transition) and are therefore observed experimentally as very weak, or are nonexistent [2]. Other transitions are permitted in their own right, and consequently $f \rightarrow d$ and certain charge-transfer bands will have much greater oscillator strengths and will obscure the weaker $f \rightarrow f$ peaks should they occur in the same energy range [2]. Figure 1 shows the higher energy transitions (200–1300 nm) for Th^{3+} [19]. As expected, the spectrum is very similar to the spectrum reported for the f^1 system $[Et_4N]_2[PaBr_6]$ [1] (*cf.* also ref. [20a,b] and for NpF_6 ref. [20c]). There are no well-defined $f \rightarrow f$ transitions below 1300 nm. At just below 650 nm, a significant and constant signal occurs until 420 nm (maximum at 460 nm), which sees the onset of a very intense, broad band with maxima at *ca* 332 (shoulder), 190 and below 185 nm. Since $5f \rightarrow 6d$ and metal $\rightarrow$ ligand charge transfers are allowed transitions, which are usually rather broad and occur in the UV region, the broad band centred at 460 nm as well as the intense absorptions at 332, 190 and below 185 nm can be assigned to such transitions. A number of small shoulders on the main peak occur over the energy range 270–190 nm, but these cannot be justifiably ascribed to well-defined electronic absorptions. Although it is clearly possible that $f \rightarrow f$ transitions occur in this range, there is no means by which they can be assigned with confidence to features in the experimental spectrum (Fig. 1). It should be mentioned, however, that it cannot be completely ruled out that the single electron in Th^{3+}

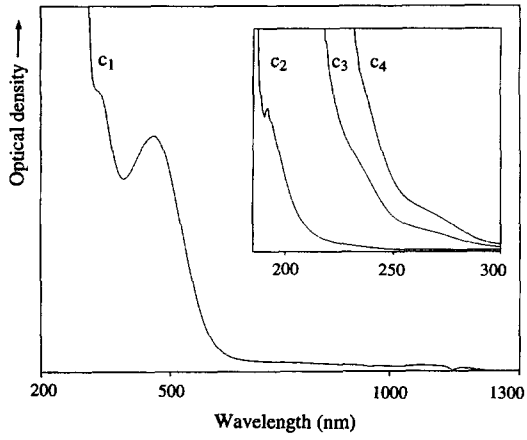

Fig. 1. Room temperature optical spectrum of Th^{3+} in HN_3 solution ($c_1 = 0.3$ mol l^{-1} [16b], $c_2 = 0.01$ mol l^{-1}, $c_3 = 5 \times 10^{-3}$ mol l^{-1}, $c_4 = 2 \times 10^{-4}$ mol l^{-1}) [21].

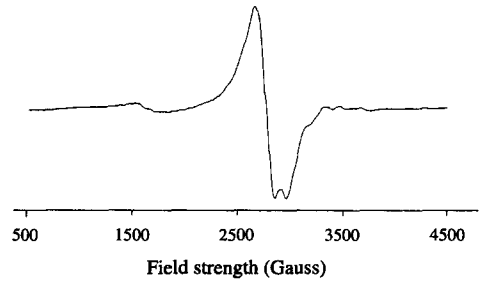

Fig. 2. ESR spectrum of a frozen solution of $[Th(H_2O)_x(N_3)_y(Cl)_z]^{(3+)-(y+z)}$ ($x+y+z=9$, *cf.* the CN of La^{3+} in aqueous solution is 9) [11a, 23].

(aq) is a $6d$ rather than a $5f$ electron. In Th^{3+} (g), the $6d$ level lies 9200 cm^{-1} above $5f$, but in the aqueous ion the d orbitals will be stabilized by the ligand field [13b,17]. In this interpretation, the band at 460 nm could be assigned to a d–d transition equal to the ligand field stabilization energy (*cf.* ref. [1]).

The ESR spectrum of a frozen solution (Fig. 2) shows a very broad signal, very similar in shape to that of the f^1 system $UCl_5 \cdot SOCl_2$ [22]. The observed main g value of 2.19 compares with those found for other f^1 systems [6]. The overall shape of the spectrum may well correspond to a system with axial symmetry. However, further experimental and especially theoretical studies have to be carried out to assign the different anisotropic g values with confidence.

Acknowledgements—We thank the University of Glasgow for financial support of this work. We are especially indebted to Dr K. J. Taylor for recording the ESR spectrum.

BOOK REVIEWS

Metal Complexes in Aqueous Solutions, by A. E. Martell and R. D. Hancock, 253 pp., Plenum, New York, 1996, $59.50, ISBN 0-306-45248.

If you are one of those chemists who is suspicious of numerical data and trusts only in the formation of crystals, you will learn a lot from this book. The measurement of formation constants often baffles outsiders. Complicated equilibria are described, even more complicated computer programs are run, and some numbers emerge into the light of publication, there to slumber peacefully for evermore. This book shows it need not be like that. We now have this integrated account of the whole subject of the thermodynamics of metal complexes in aqueous solution. It reads coherently and rationalizes the subject in a way that will teach experts and novices alike more than most other books in this area.

The authors have essentially expanded and modernized their 1989 *Chemical Review* article. The first three substantial chapters present an orderly development of why some ligand–metal complexes are more stable than others. Steric effects, enthalpy and entropy contributions, ligand field effects, hardness and softness, chelate effects and inductive effects are introduced when appropriate, and data are summarized with numerous clear structural diagrams and graphs. Some complex structures have been redrawn by the authors from literature data, giving a homogeneous style to the diagrams' appearance and often improving on the pictures provided by the original crystallographers.

The rational argument as to what effect generates what result is presented most persuasively by a series of examples. Just when you think one trend is safely established, another set of complexes is produced that bucks that trend, but the new anomaly can then be explained by some other development. Sceptics may think this all sounds rather like special pleading. After all, every complex has its own peculiarities, and nobody expects simple rules to apply in complicated situations. There is little discussion of kinetics, or of ligand synthesis, and many of the examples come from the authors' own research, with some other active groups being less frequently cited. Nevertheless, the whole story is very effective, and readers will find here an excellent rationalization of why chemists should select particular ligands to react with particular metals, and not select other combinations.

The second half of the book uses the principles already developed to design appropriate complexes for medicinal and radiopharmaceutical applications of metal complexes and to rationalize selected aspects of metallobiochemistry. The layout of these chapters is that of a review ordered by metals rather than ligands, and it is noticeable that various biological constraints now enter the argument. There is a certain amount of jargon, so that you will need to know what a myocardial pervasion agent is, and there is a rather elementary discussion of general technetium chemistry which could have been taken for granted. However, the principles the authors developed earlier allow us to see why, for example, hydroxide ions are bound to zinc effectively in carbonic anhydrase when the binding is much weaker in ordinary aqueous solutions. There are also five effective pages on magnetic resonance imaging. This would be a good introduction to the field for novices, but this section in particular is bound to be obsolete soon, whereas the principles of ligand design will remain valuable for a very long time to come.

The last chapter is a clear account of how to measure stability constants. Expert readers will probably know this already, and the topic is covered for novices elsewhere, but this account is certainly very clear.

There are a few minor mistakes, like the representation of pyridine as C_6H_5N (p. 34), and the assertion on p. 1 that there is a glossary for technical terms in the Appendix (there is neither a Glossary nor an Appendix). The index is really terrible, even by the standards of chemistry books. For one thing it is too brief, and the selection of entries is perverse. Successive entries feature Desferriferrioxamine (that is what we used to call desferrioxamine), DFO (an abbreviation of the previous entry), ΔH^0, ΔS^0 and Dibenzo-30-crown-10. I wonder when chemistry publishers will realize that indexes are supposed to be helpful rather than entertaining.

Energetics of Organometallic Species, edited by J. A. Martinho Simões, NATO ASI Series: Series C: Mathematical and Physical Sciences, Vol. 367. xii+442 pp. Kluwer Academic Publishers, Dordrecht 1992. Price: not stated. ISBN 0-7923-1707-6.

The days are long gone when organometallic compounds of the transition metals were automatically regarded as "unstable", now we know a bit more about thermodynamic and kinetic stability. But how strong are the bonds? This volume, a collection of 20 papers by participants at a 1991 Study Institute, sets out to answer this.

It is a measure of the sophistication attained nowadays that a large majority of papers are not concerned with either classical combustion or solution methods, although one of these latter is an important study of f-block thermochemistry (T. J. Marks). Instead, use is made of equilibrium methods, kinetic methods; short-lived species are studied by voltammetry. Mass spectra and other methods are employed in the gas phase. How do gas phase and solution data relate? Two papers show us. Concepts such as bond enthalpy transferability are explored (J. A. Connor). Quantitative theoretical calculations are reported. The overall impression is that this is a diverse and increasingly sophisticated field. Much of this material has by now been published in the learned journals. The benefits of such a meeting are obviously to those who attend the Institute, but also subsequently to the non-specialists who read these proceedings and obtain an overall view under one cover, a state-of-the-art snapshot, not easily obtained by reading the literature.

(Received 30 July 1996; accepted 16 August 1996)

Abstract—Compound $Nb_2(\mu_2\text{-}Se_2)_2(Te_2I_6)_2$ was obtained in high yield by high-temperature reaction (500 C) of the dinuclear cluster complex $Nb_2(\mu_2\text{-}Se_2)_2I_4$ with Te and I_2 in a 1:4:4 ratio. The structure of $Nb_2Se_4Te_4I_{12}$ has been determined by single-crystal X-ray diffraction. It is characterized by the presence of isolated molecules of $[Nb_2(\mu_2\text{-}Se_2)_2(Te_2I_6)_2]$. The inner skeleton is formed by a dinuclear $[Nb_2(\mu_2\text{-}Se_2)_2]^{4+}$ fragment with a Nb—Nb distance of 2.926(2) Å; the Se—Se distances are 2.310(2) and 2.311(2) Å. Each Nb atom is ligated (formally) by $Te_2I_6^{2-}$ ligands. The terminal Te—I distances in the $Te_2I_6^{2-}$ ligands range from 2.735(2) to 2.786(2) Å. The bridging Te—I distances are rather long, ranging from 3.175(1) to 3.261(2) Å. Copyright © 1997 Elsevier Science Ltd

Keywords: crystal structure; niobium complexes; selenium complexes; tellurium complexes.

The coordination chemistry of tellurium(II) halides and halotellurate(II) inorganic ligands is relatively undeveloped [1–3]. A limited number of complexes has been obtained recently and structurally characterized. The first example, a $Nb_2Te_8I_{12}$ complex, was described by Leist and Tremel in 1993 [4]. The structure of the compound was characterized by the presence of two $Te_2I_6^{2-}$ ligands coordinated to a $Nb_2(\mu_2\text{-}Te_2)_2^{4+}$ centre. TeI_3^- ligands coordinated to a triangular cluster fragment $[Mo_3(\mu_3\text{-}Te)(\mu_2\text{-}Te_2)_3]^{4+}$ were found for the first time in the structure of $Mo_3Te_{10}I_{10}$ [5]. In 1996 Strähle and co-workers described the tetrahedral $[Re_4(\mu_3\text{-}Te)_4(TeBr_2)_4Br_8]$ cluster complex [6]. This compound contains neutral $TeBr_2$ ligands. All of these compounds were obtained by direct combination of the elements. Hexanuclear Re_6 tellurohalide cluster complexes, $Re_6Te_6Cl_6(TeCl_2)_2$ and $[Re_6Te_8(TeBr_2)_6]Br_2$, have been obtained by reaction of rhenium halides with Te [7].

Our recent efforts have focused on the development of a high-temperature technique to synthesize tellurohalide cluster complexes by extrusion reactions from cluster chalcogenides or halochalcogenides of the transition elements. A new $[Re_6Te_8(TeI_2)_6]I_2$ complex has been prepared by the reaction of the octahedral cluster complex $[Re_6Te_8](Te_7)_{0.6}$ with I_2 [8].

Here we report the synthesis and crystal structure determination of $[Nb_2Se_4Te_4I_{12}]$ formally containing $Te_2I_6^{2-}$ ligands coordinated to niobium atoms of the $Nb_2(\mu_2\text{-}Se_2)_2^{4+}$ cluster fragment.

RESULTS AND DISCUSSION

The compound $[Nb_2Se_4Te_4I_{12}]$ was obtained in quantitative yield by the high-temperature reaction of the dinuclear cluster compound $Nb_2Se_4I_4$ with tellurium and iodine, according to Eq. (1).

$$Nb_2Se_4I_4 + 4Te + 4I_2 \rightarrow Nb_2Se_4Te_4I_{12} \qquad (1)$$

The initial compound, $[Nb_2(\mu_2\text{-}Se_2)_2]I_{8.2}$, has a polymeric layer structure [9,10]. High-temperature reaction with tellurium and iodine leads to the formation of isolated molecules of $[Nb_2(\mu_2\text{-}Se_2)_2(Te_2I_6)_2]$ (extrusion reaction [11]).

The structure of $[Nb_2Se_4Te_4I_{12}]$ has been determined by single-crystal X-ray diffraction. The complex has a central $Nb_2(\mu_2\text{-}Se_2)_2^{4+}$ core, in which the coordination of diselenium ligands resembles acetylene-type $\eta^2:\eta^2$:

* Author to whom correspondence should be addressed.

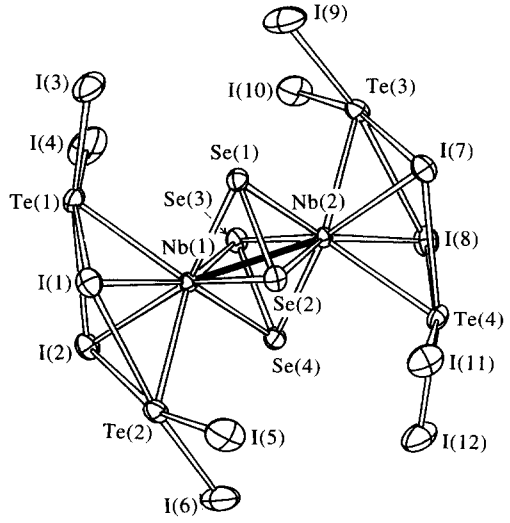

Fig. 1. ORTEP drawing of the $[Nb_2Se_4Te_4I_{12}]$ molecule. Thermal ellipsoids are drawn at the 50% probability level.

μ_2 coordination (Fig. 1). The Se_2 ligands coordinate almost symmetrically, with Nb—Se distances ranging from 2.602(2) to 2.614(2) Å. The Se—Se distances at 2.310(2) and 2.311(2) Å are similar to the corresponding values found in $Nb_2Se_4I_4$ [10]. The Nb—Nb distance of 2.926(2) Å is somewhat longer than the Nb—Nb distance in niobium metal (2.858 Å) and is comparable with the Nb—Nb distances in related Nb^{IV} compounds in which Nb—Nb single bonds are present [12].

The bond lengths and angles of the $Te_2I_6^{2-}$ ligands coordinated to the niobium atoms in $Nb_2(\mu_2\text{-}Se_2)_2(Te_2I_6)_2$ and $Nb_2(\mu_2\text{-}Te_2)_2(Te_2I_6)_2$ [4] are significantly different from those in the free $Te_2I_6^{2-}$ anion. In the planar anion, $Te_2I_6^{2-}$, the four-membered Te_2I_2 ring system is strongly asymmetric, with bridging Te—I bond lengths of 3.061 and 3.215 Å [3]. The corresponding distances for the compound $[Nb_2(\mu_2\text{-}Se_2)_2(Te_2I_6)_2]$ are appreciably longer and range from 3.212(2) to 3.257(2) Å and from 3.175(2) to 3.261(2) Å for $Te_2I_6^{2-}$ ligands coordinated to Nb(1) and Nb(2) atoms, respectively. (For the compound $Nb_2(\mu_2\text{-}Te_2)_2(Te_2I_6)_2$ the bridging Te—I distances are also rather long and span 3.167(1)–3.217(1) Å [4].) Moreover, the terminal Te—I bond lengths of the compound $Nb_2(\mu_2\text{-}Se_2)_2(Te_2I_6)_2$ are up to about 0.12 Å shorter than the corresponding value previously determined for the free $Te_2I_6^{2-}$ anion [3]. On the other hand the terminal Te—I distances (average 2.75 Å) are similar to the corresponding value, 2.76 Å, found in the octahedral cluster complex $[Re_6Te_8(TeI_2)_6]I_2$, with neutral TeI_2 ligands [8]. Therefore, we have some grounds to suppose that the structure of the compound $[Nb_2(\mu_2\text{-}Se_2)_2(Te_2I_6)_2]$ is half way between that of the $[(Nb^{4+})_2(\mu_2\text{-}Se_2^{2-})_2(Te_2I_6^{2-})_2]$ (complex with halochalcogenate ligands $Te_2I_6^{2-}$) and $[(Nb^{4+})_2(\mu_2\text{-}Se_2^{2-})_2(TeI_2)_4(I^-)_4]$ (complex with TeI_2 neutral ligands) extreme formulations.

The structure of $Nb_2Se_4Te_4I_{12}$ has two short intermolecular iodine–iodine distances, which are 3.552(2) Å for I(10)—I(10′) and 3.656(2) Å for I(5)—I(11′). These distances compare favourably with those found in polyiodide structures [13]. These interactions make a chain of molecules along the [212] direction as shown in Fig. 2. Other intermolecular distances are longer than 3.8 Å.

EXPERIMENTAL

Preparation of $Nb_2Se_4Te_4I_{12}$

The compound $Nb_2Se_4I_4$ was prepared by the literature method [10]. A mixture of $Nb_2Se_4I_4$ (2.0185 g,

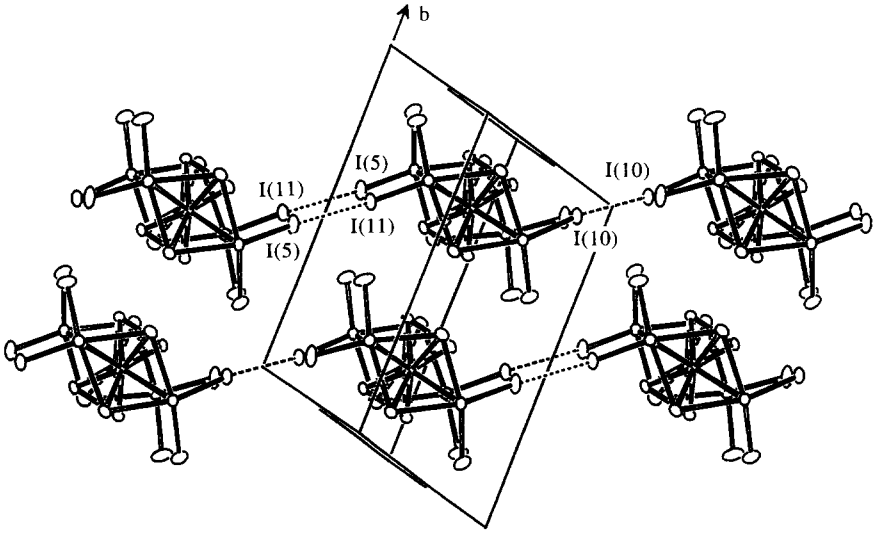

Fig. 2. ORTEP drawing of the crystal structure of $[Nb_2Se_4Te_4I_{12}]$ projected on a [101] plane showing intermolecular interactions. The horizontal direction is [212]. Thermal ellipsoids are drawn at the 50% probability level.

2.00 mmol), Te (1.0208 g, 8.00 mmol) and I_2 (2.0431 g, 8.05 mmol) was heated (500°C, 72 h) in an evacuated, fused silica tube. The tube was cooled at 10°C h^{-1} to promote crystal growth. Excess of iodine was evaporated *in vacuo* at 60°C, allowing the isolation of well-formed crystals of $Nb_2Se_4Te_4I_{12}$. Yield: 5.06 g (99%). Found: Nb, 7.3. Calc. for $I_{12}Nb_2Se_4Te_4$: Nb, 7.3%.

In order to ensure product homogeneity, the X-ray powder diffraction pattern of the product was obtained and found to be identical with that calculated from the single-crystal data.

The electrical conductivity, σ, of $Nb_2Se_4Te_4I_{12}$ crystals at room temperature was measured by a four-point contact method: $\sigma = 1 \times 10^{-11}$ ohm^{-1} cm^{-1}.

Crystal structure determination of $Nb_2Se_4Te_4I_{12}$

X-ray data were measured at 295 K on a Rigaku AFC-7R diffractometer with graphite-monochromated Mo-K_α radiation ($\lambda = 0.7107$ Å) using the 2θ–ω scan mode and an empirical absorption correction was applied (relative transmission factor: 0.502–0.994). A slight decay (3.3% in intensity) was detected during the data collection and the data were linearly corrected for the decay. The structure was solved by direct methods (SHELXS86) [14] and all atoms were refined anisotropically using the full-matrix least-squares analysis (ANYBLK) [15]. An extinction correction was made following Zachariasen's method [16], and the extinction parameter τT was refined to be 1.54×10^{-7}.

Crystal data and refinement results for $Nb_2Se_4Te_4I_{12}$ are given in Table 1. Selected interatomic distances and angles are given in Table 2.

Sulfur–hydrogen bond activation of thiols by the fragment CpFe(dppe)$^+$: cyclopentadienyl iron(III) thiolate complexes

C. Díaz

Departamento de Química, Facultad de Ciencias, Universidad de Chile, Casilla 653—Santiago, Chile

(Received 29 July 1996; accepted 16 August 1996)

Abstract—Oxidative addition of thiols RSH, R = CH_3, $CH_2CH_2CH_3$, $CH_2C_6H_5$, $C(CH_3)_3$ and C_6H_4Br, by the complex [CpFe(dppe)I] afforded the oxidized thiolate complexes [CpFe(dppe)-SR]PF_6. The reaction of [CpFe(dppe)I] with $HSC_6H_4NH_2$ produces the diamagnetic [CpFe(dppe)$HSC_6H_4NH_2$]PF_6 instead of the expected thiolate product. The reaction of the dithiol $HS(CH_2)_4SH$ with the same iron fragment, gives the binuclear complex [CpFe(dppe)-$S(CH_2)_2$S-CpFe(dppe)][PF_6]$_2$. The formation of the thiol-containing complexes as intermediates in the activation of the S—H bonds is discussed. Copyright © 1997 Elsevier Science Ltd

Keywords: thiol activation; sulfur–hydrogen bond; thiolate complexes; non-sulfur complexes; non III-thiolate complexes.

The hydrodesulfurization process is an essential step in the effective utilization of crude oil and high sulfur coal [1]. The elimination of organosulfur compounds from these hydrocarbon feedstock mixtures are processes catalysed by a variety of metal and organometallic compounds [2]. A fundamental step in the interaction between a catalyst and sulfur-containing substrates, such as hydrogen sulfide or thiols, is the oxidative addition of S—H bonds to the metal centres [3]. Activation of the S—H bond generally occurs with organometallic fragments in low oxidation states [3, 4]. In the majority of cases the activation is promoted by some drastic conditions, i.e. temperature [5] or UV radiation [6].

Previously we have reported the activation of the S—S bond in dithioethers by the electron-rich fragment CpFe(dppe)$^-$, to give the iron–thiolate complexes [CpFe(dppe)-SR]PF_6 [7]. Now we report the mild oxidative addition of thiols to the fragment CpFe(dppe)$^+$, to give the paramagnetic complexes [CpFe(dppe)-SR]PF_6.

RESULTS AND DISCUSSION

CpFe(dppe)I reacted with the thiols RSH to give the blue paramagnetic [CpFe(dppe)-SR]PF_6 complexes according to Eq. (1)

$$\text{CpFe(dppe)I} + \text{RSH} \xrightarrow[\text{CH}_3\text{OH}]{\text{NH}_4\text{PF}_6} \text{[CpFe(dppe)-SR]PF}_6 \qquad (1)$$

where R = CH_3 (**1**), $CH_2CH_2CH_3$ (**2**), $CH_2C_6H_5$ (**3**), C_6H_5 (**4**), t-$C(CH_3)_3$ (**5**) or C_6H_4Br (**6**). The complexes **1–4** have been previously obtained by oxidative addition of the corresponding dithioethers RSSR to the fragment CpFedppe$^+$ [7]. The new complexes **5** and **6** were characterized by elemental analysis and IR and UV–vis spectroscroptic methods.

The IR spectra (see Table 1) of **5** and **6** exhibit the typical absorption bands of the CpFe(dppe)$^+$ moiety [8]. Absorption bands were observed at 3060, ν(C—H), 1435, ν(C—C) and 1098 cm^{-1} δ (C—H), characteristic of an η^5-bonded cyclopentadienyl group. An intense band around 700 cm^{-1} assigned to the δ (C—H) out-of-plane vibration of the phenyl group of dppe, was also observed. The $\nu(PF_6)$ vibration of complexes **5** and **6** was observed normally at 840 cm^{-1} [8, 9].

The characteristic blue colour exhibited by the complexes is associated with their paramagnetic nature [7]. The lowest absorption bands observed around 450 and 590 nm are assigned to a *d–d* transition [7]. The spectrum of **5** is shown in Fig. 1.

On the other hand the reaction of CpFe(dppe)I with

Table 1. Selected spectroscopic data for the thiolate and thiol complexes

Complex	IR (KBr) (cm^{-1})			Visible λ max (CH_2Cl_2) (nm)	
	C_5H_5[a]	dppe[b]	$\nu(PF_6)$		
5	1098	700	846	457	587
6	1095	698	841	456	590
7[c]	1094	696	842	420	
8	1097	699	847	429	593

[a] (C—H) bending, in-plane vibration.
[b] (C—H) bending, out-of-plane vibration.
[c] ^1H NMR: δ 7.7–7.5 (m, C_6H_5), 4.5 (s, C_5H_5), 2.76 (m, CH_2—CH_2—). ^{31}P NMR: δ 90 (s, dppe), −143 (s, PF_6).

$NH_2C_6H_4SH$ afforded the diamagnetic [CpFe(dppe)($HSC_6H_4NH_2$)]PF_6 (**7**) instead of the expected iron–thiolate oxidized complex. The compound was obtained as a yellow-green oil which

$$CpFe(dppe)I + HS\text{-}C_6H_4\text{-}NH_2 \xrightarrow[CH_3OH]{NH_4PF_6} [CpFe(dppe)(HS\text{-}C_6H_4NH_2)]PF_6 \quad (2)$$

was characterized by IR, ^1H, ^{31}P NMR and UV–vis spectroscopic methods. The IR spectrum showed the typical bands of the CpFe(dppe) moiety [8] (see Table 1).

The ν(S—H) and ν(NH) bands were observed at 2558 and 3461, 3376 cm^{-1}, respectively. Comparing the IR spectra of the free 4-aminothiophenol with the coordinated ligand, the major changes are observed for the ν(S—H) band which suggests an S-coordination to the metal. In the free ligand ν(S—H) appears as a broad band around 2500 (owing to the association) while in the complex a narrow band was observed. More detailed studies in solution are precluded because of the low intensity exhibited by the ν(SH) band in solution [6a].

The ^{31}P NMR spectrum of **7** exhibits the signal for dppe at δ 90, a value typical of cationic [CpFe[dppe)L]$^+$ complexes with L = sulfur donor atom [9,10]. The PF_6 septuplet was observed at δ −143. The ^1H NMR spectrum exhibited the multiplet of C_6H_5 protons of dppe in the range δ 7.0–7.5 and the signal for the CH_2 protons was observed at δ 2.76, also as a multiplet. The C_5H_5 proton signal appeared at δ 4.5. All these values are typical of [CpFe(dppe)L]PF_6 complexes [9,10].

The UV–vis spectrum showed the absorption maximum around 420 nm, characteristic of [CpFe(dppe)L]$^+$ complexes where L is a neutral donor ligand [9,11]. The position of this maximum suggests S coordination rather than N coordination; amine complexes CpFe(dppe)NR_3^+ absorb around 500 nm [12].

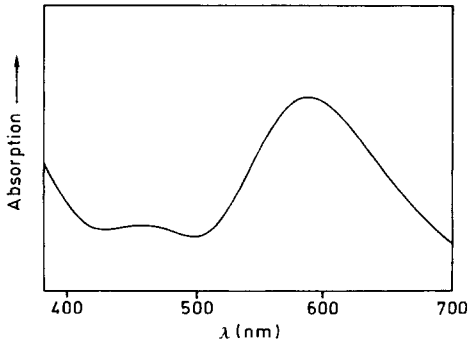

Fig. 1. UV–vis absorption spectrum of [CpFe(dppe)-S-Bu^t]PF_6 in CH_2Cl_2 solution at room temperature.

Reaction of $HS(CH_2)_2SH$ *with* CpFe(dppe)I

Reaction of $HS(CH_2)_2SH$ with CpFe(dppe)I afforded the binuclear product [CpFe(dppe)-S$(CH_2)_2$-S-CpFe(dppe)]$(PF_6)_2$ according to Eq. (3)

$$2CpFe(dppe)I + HS(CH_2)_2SH \xrightarrow[CH_3OH]{NH_4PF_6} [CpFe(dppe)\text{-}S\text{-}(CH_2)_2\text{-}S\text{-}CpFe(dppe)](PF_6)_2 \quad (3)$$

8

Complex **8** was characterized by elemental analysis as well as IR and UV–vis spectroscopic methods.

As observed for the monothiolate complexes, the IR spectrum of **8** exhibits the characteristic bands of the CpFe(dppe)$^+$ moiety [8]. As expected, the ν(S—H) band is absent. The $\nu(PF_6)$ band was observed in the normal range (see Table 1).

Compound **8** which was obtained as a blue solid, exhibited similar absorptions in the UV–vis spectrum to those of the monothiolate complexes **1**–**4**. Data are given in Table 1.

Coordination versus S—H *bond cleavage in thiols*

As suggested for the activation of dithioethers by the fragment CpFe(dppe)$^+$ [7], the activation of the S–H bond in thiols appears to occur through an intermediate involving the sulfur molecule coordinated to the metal fragment (see Fig. 2).

This assumption is supported by molecular orbital calculations [13] which indicate a favourable HOMO [CpFe(dppe)$^+$]–LUMO [RSH] back bonding interaction as shown in Fig. 3. The enhancement of the electron density of the LUMO of the thiol, which has a S—H, S—C antibonding character, produces a weak S—H bond. Thus the isolation of the complex [CpFe(dppe)$HSC_6H_4NH_2$]$^+$, probably coordinated to the metal *via* the sulfur atom, affords additional evidence for the activation mechanism.

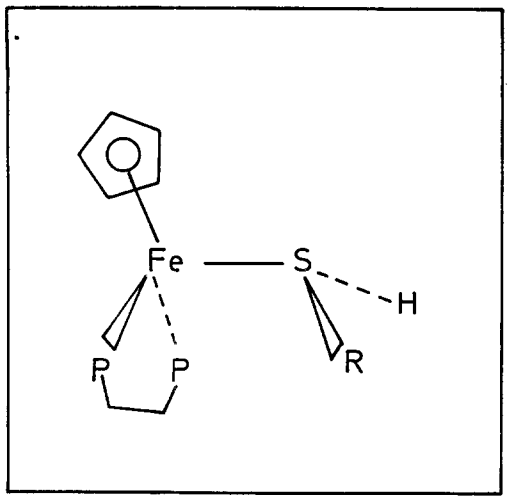

Fig. 2. Possible intermediate involved in the activation of thiols.

EXPERIMENTAL

Infrared spectra were recorded on a Perkin–Elmer FT-IR 2000 spectrophotometer. NMR spectra were recorded on a Bruker AMX 300 instrument. Chemical shifts are given relative to TMS (^{1}H) or 85% H_3PO_4 (^{31}P proton decoupled) with the shift reference being positive. Visible absorption spectra were measured on a Varian DMS-90 spectrophotometer in 1-cm curvettes. Elemental analyses were performed with a Perkin–Elmer 240 microanalyser.

All reactions were carried out under N_2 using standard Schlenk techniques. Solvents were purified using standard procedures. Thiols (Aldrich) were used without additional purification. CpFe(dppe)I was prepared using previously reported methods [10].

Reaction of thiols with CpFe(dppe)I

The complex CpFe(dppe)I (0.14 g, 0.2 mmol) was placed in a Schlenk vessel with the calculated amount

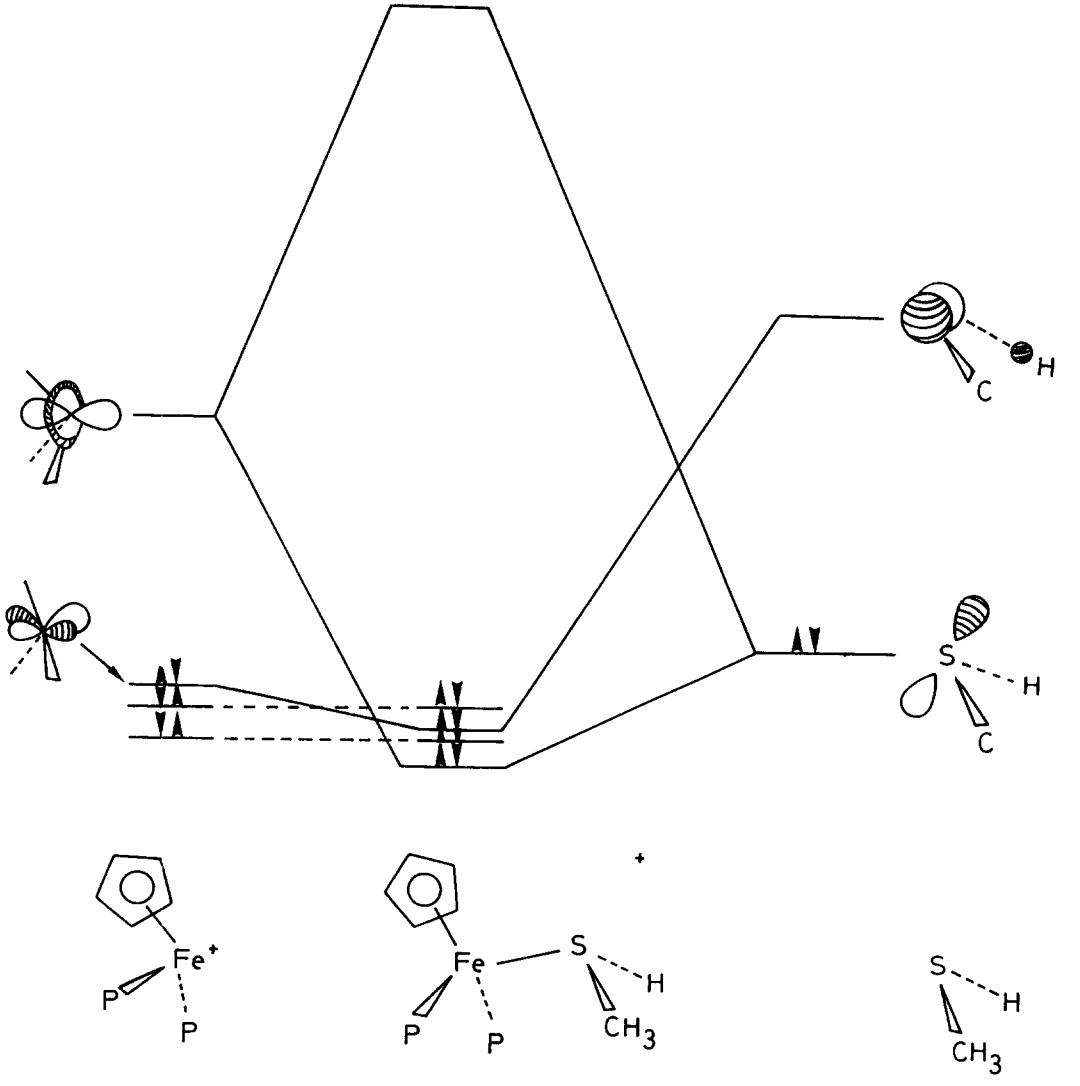

Fig. 3. Simplified molecular orbital diagram for [CpFe(dppe)HSR]$^+$. Possible geometries of the complexes adapted from refs [6a] and [14].

of thiol, RSH (R = CH_3, $CH_2CH_2CH_3$, $CH_2C_6H_5$ and C_6H_5) in the molar ratio 1 : 1 and in the presence of NH_4PF_6. A total of 20 cm^3 of CH_3OH was added and the reaction mixture was stirred for 12 h. After this, the solution, initially black, changed to blue. The solvent was removed *in vacuo* and the solid residue was extracted with CH_2Cl_2. The solutions were filtered through Celite and the solvent was partially evaporated *in vacuo*. Upon addition of a 1 : 10 mixture of n-hexane/diethyl ether the product, a dark blue powder, precipitated and was washed twice with the same solvent mixture. Identification of the products was by comparison of their IR and UV–vis spectra with those of an authentic sample [7].

For the reaction with methanethiol, the mercaptan was bubbled through the solution of [CpFe(dppe)I] in the presence of NH_4PF_6.

[CpFe(dppe)-S-Bu^t]PF_6 (**5**). The complex CpFe(dppe)I (0.14 g, 0.2 mmol) and $(CH_3)_3C$—SH (0.13 cm^3, 1.15 mmol) in the presence of NH_4PF_6 (0.21 g, 1.28 mmol) were stirred for 16 h in CH_3OH (20 cm^3). The solution changed from black to blue after 1 h. The solvent was removed *in vacuo* and the solid extracted with CH_2Cl_2, and then filtered through Celite. The solvent was partially evaporated at reduced pressure and a 1 : 10 mixture of n-hexane/diethyl ether was added. The blue–green powder precipitated was washed twice with the same solvent mixture and dried *in vacuo*. Yield 0.1 g (61%). Found: C, 55.6; H, 5.5. Calc. for $C_{35}H_{38}F_6SP_3Fe$: C, 55.8; H, 5.0%.

[CpFe(dppe)-S-C_6H_4Br]PF (**6**). CpFe(dppe)I (0.14 g, 0.2 mmol) and HSC_6H_4Br (0.061 g, 0.32 mmol) were stirred in the presence of NH_4PF_6 (0.24 g, 0.15 mmol) for 18 h at room temperature in CH_3OH. Separation and purification procedures similar to that for (**5**) afforded a black–blue powder. Yield 0.12 g, (65%). Found: C, 53.2; H, 3.4. Calc. for $C_{37}H_{33}F_6SP_3BrFe$: C, 52.1; H, 3.9%.

[CpFe(dppe)$HSC_6H_4NH_2$]PF_6 (**7**). CpFe(dppe)I (0.14 g, 0.2 mmol) and HS-C_6H_4-NH_2 (0.054 g, 0.43 mmol) in the presence of NH_4PF_6 (0.2 g, 0.6 mmol) and using CH_3OH as solvent were stirred for 20 h at room temperature. After this the solution changed from black to yellow–green. The solvent was removed *in vacuo* and the solid residue extracted with CH_2Cl_2 and filtered through Celite. Elimination of the solvent to dryness affords an oil which could not be converted to a solid in spite of various attempts with several solvents. The dark yellow product was identified spectroscopically: ^1H and ^{31}P NMR data are shown in Table 1. IR(film): 3461s, 3376vs, 3215m, 3055m, 3030m, 2924m, 2558w, 1889w, 1623vs, 1623vs, 1493vs, 1431m, 1289vs, 1177m, 1094s, 1007w, 842vs, 745m, 696s.

[CpFe(dppe)-S$(CH_2)_2$S-CpFe(dppe)]$PF_6)_2$ (**8**). CpFe(dppe)I (0.2 g, 0.31 mmol) and $HS(CH_2)_2SH$ (0.02 cm^3, 0.208 g, 1.7 mmol) were stirred in the presence of NH_4PF_6 (0.29 g, 1.7 mmol) using CH_3OH as solvent (30 cm^3) at room temperature. After 5 min the solution changed from black to blue. The solution was stirred additionally for a further 5 h, and the solvent removed *in vacuo*. The solid residue was extracted with CH_2Cl_2 and filtered through Celite. The solution was concentrated to *ca* 10 cm^3 and then a mixture of 1 : 10 ether/n-hexane was added. The black-blue solid precipitated was washed twice with the same mixture and dried *in vacuo*. Yield 0.18 g (81%). Found: C, 53.8; H, 4.6. Calc. for $C_{66}H_{66}F_{12}P_6S_2Fe_2$: C, 54.7; H, 4.5%.

Platinum(II) and palladium(II) complexes of tetrakis(pyrazolyl)cyclotriphosphazenes

K. R. Justin Thomas,[a]*† V. Chandrasekhar,[a] Piero Zanello[b] and Franco Laschi[b]

[a]Department of Chemistry, Indian Institute of Technology, Kanpur-208 016, India

[b]Departimento di Chimica dell' Universitá di Siena, Pian dei Mantellini 44, 53100 Siena, Italy

(Received 28 June 1996; accepted 16 August 1996)

Abstract—Reactions of tetrakis(pyrazolyl)cyclotriphosphazene derivatives, *gem*-$N_3P_3Ph_2Pz_4$ (**2**) and *gem*-$N_3P_3Ph_2(dmpz)_4$ (**4**), with $PdCl_2(PhCN)_2$ or $PtCl_2(PhCN)_2$ afforded complexes of the type MCl_2L (L = **2** or **4**). The detailed spectroscopic (proton, ^{13}C and ^{31}P NMR) investigations revealed that in these complexes the phosphazenes act as bidentate N_2-donor ligands *via* the two geminal pyrazolyl pyridinic nitrogen atoms, thus forming six-membered chelate rings. The platinum derivative $N_3P_3Ph_2Pz_4 \cdot PtCl_2$ (**6**) reacted further with $CuCl_2$ to yield a new heterobimetallic derivative, $N_3P_3Ph_2Pz_4 \cdot PtCl_2 \cdot CuCl_2$ (**9**). The EPR spectra of **9** indicated a distorted five-coordinate geometry around copper. The electrochemistry of **9** is also reported. Copyright © 1997 Elsevier Science Ltd

Keywords: cyclotriphosphazene ligand; pyrazole; platinum(II); palladium(II); copper(II) complexes; NMR.

Interest in the donor groups attached to cyclophosphazenes and their transition metal complexes arises from the fact that such small molecules can function as structural and functional models for their linear high molecular weight polymer analogs, which should exhibit unusual physical and chemical properties [1]. Ever since the pyrazolylcyclotriphosphazenes were introduced by Paddock and coworkers [2] into coordination chemistry, several novel pyrazolyl-substituted cyclotriphosphazene derivatives have been examined as ligands for transition metals [3–8]. Depending on the nature of the substituents other than pyrazolyl groups and the metals, four different modes of interaction between the pyrazolylcyclotriphosphazene and transition metals are observed (Fig. 1). In general they coordinate to the metal through the exocyclic pyrazolyl and the phosphazene skeletal nitrogens. The hexakis- and tetrakis(pyrazolyl)cyclotriphosphazenes $N_3P_3(dmpz)_6$ and $N_3P_3Ph_2(dmpz)_4$ form five-coordinate complexes with copper(II) and nickel(II) halides [3–5], in which the metal is bound to the ligand *via* two nongeminal pyr-

azolyl and one cyclotriphosphazene ring nitrogen. However, with platinum(II) and palladium(II) chlorides they produced mainly four-coordinate complexes with the N_2 donor set derived from two geminal pyrazolyl nitrogens [2,8]. The nongeminal coordination leads to five-membered chelate rings, while in the geminal (N_2) mode the complexes possess six-membered chelates with the boat conformation. In the geminal pattern the ring phosphazene nitrogen involvement in coordination is scarce and is identified only with certain group VI metal carbonyl complexes [9].

The interaction of the cyclophosphazene skeletal nitrogen with the transition metal is of σ-type and is generally weak. It was believed that the basicity of the cyclotriphosphazene ligand and the coordination number of the metals are the important factors affecting the ligating response of a particular pyrazolylcyclotriphosphazene. The basicity of a cyclophosphazene ligand may be affected by changing substituents other than donor groups with electron-rich moieties and/or by modifying the substituents on the exocyclic donor groups. To unravel the basicity factor we have synthesized a new ligand $N_3P_3Ph_2Pz_4$ (**2**), which contains four simple pyrazolyl groups as donors. The difference between **2** and $N_3P_3Ph_2(dmpz)_4$ (**4**) is the presence or absence of methyl substituents at the pyrazole nucleus and the basicity of **2** would be comparatively low. Our aim here is to compare the electronic and steric effects in the spectral and electrochemical properties of the complexes. We describe here in particular the mononuclear Pt^{II} and Pd^{II} chloride complexes of **2** and a heterobimetallic compound with Pt and Cu metal centers and an attempt is also made to compare with the related systems known in the literature.

Hdpctp: hexakis(3,5-dimethyl-1-pyrazolyl)cyclotriphosphazene, tdpctp: 2,2-diphenyl-4,4,6,6-tetrakis (3,5-dimethyl-1-pyrazolyl)cyclotriphosphazene, tpctp: 2,2-diphenyl-4,4,6,6-tetrakis (1-pyrazolyl) cyclotriphosphazene, dmpzH: 3,5-dimethylpyrazole, PzH: pyrazole.

Materials

The platinum and palladium precursors used in this study were obtained by known literature methods [10]. $N_3P_3[NH(CH_2)_3NH]Cl_4$, $N_3P_3Ph_2Cl_4$ and $N_3P_3Ph_2(dmpz)_4$ synthesized by adopting the reported procedures [11, 12, 4]. Solvents dichloromethane, benzene, hexane and acetonitrile were distilled from P_2O_5 and stored over molecular sieves.

Synthesis of the ligand **2**

A solution of $N_3P_3Ph_2Cl_4$ (4.31 g, 10 mmol) dissolved in benzene (50 cm^3) was added to a stirred mixture of pyrazole (2.72 g, 40 mmol) and triethylamine (6.06 g, 60 mmol) at 25°C. The reaction mixture was heated under reflux for 2 days, cooled and the precipitated triethylamine hydrochloride salt was filtered off. From the filtrate the solvent was stripped off *in vacuo*, leaving a residue. The residue was thoroughly washed with water (3×20 cm^3) and ether (3×20 cm^3) and subsequently dried *in vacuo*. A colorless solid obtained was crystallized from a 1 : 1 mixture of hexane and dichloromethane (4.18 g, Yield: 75%). M.p.: 219°C. Found: C, 51.6; H, 3.9; N, 27.8. Calc. for $C_{24}H_{22}N_{11}P_3$: C, 51.7; 3.9; N, 27.6%. IR (cm^{-1}): 1470 m, ν(C=N); 1280 vs; 1220 vs, br; 1165 vs, br, ν(P=N).

Synthesis of **3**

The title compound was obtained in 60% yield by using a very similar procedure that of above except that $N_3P_3Ph_2Cl_2$ was substituted by $N_3P_3[NH(CH_2)_3NH]Cl_4$ M.p.: 216°C.

Synthesis of the complexes

The complexes **5–8** were essentially made by following a same procedure. A general description is as follows: The ligand (1 mmol) and the metal precursor (1 mmol) were taken in benzene (20 cm^3) and heated to reflux for 2–4 h. The palladium complexes **5** and **7** were isolated as insoluble residues from the reaction mixture, while the platinum complexes **6** and **8** required the evaporation of the solvent followed by precipitation from diethyl ether. The solids obtained were crystallized from dichloromethane/benzene or hexane mixtures. The physical and analytical data presented in Table 1.

Synthesis of **9**

To a stirred solution of **6** (0.1646 g) dissolved in dichloromethane (20 cm^3) was added anhydrous $CuCl_2$ (0.030 g). The turbid mixture was stirred for 6 h. The light green precipitate formed was separated by filtration and dried *in vacuo*. Yield: 0.182 g (95%).

Physical measurements

IR spectra were recorded on a Perkin–Elmer 1320 spectrophotometer. The samples were prepared as potassium bromide pellets and the wavenumber was calibrated using polystyrene as calibrant. ^1H and ^{13}C NMR spectra were obtained on a Bruker spectrometer operating at 400 MHz and chemical shifts are reported with reference to internal tetramethylsilane. ^{31}P NMR

Table 1. Physical data for the complexes[a]

Compound	Color	Melting point (°dec.)	Elemental Analyses Found (Calc.) C	H	N
5	Orange	140	39.2[38.7]	3.0[3.3]	21.0[20.8]
6[b]	Yellow	134	42.1[42.2]	3.3[3.4]	16.4[16.25]
7	Orange	238	45.4[45.1]	4.5[4.7]	18.2[17.9]
8	Light yellow	125	41.1[41.2]	4.1[3.85]	16.5[16.2]
9[c]	Light green	120	30.1[30.2]	2.3[2.5]	16.1[16.0]

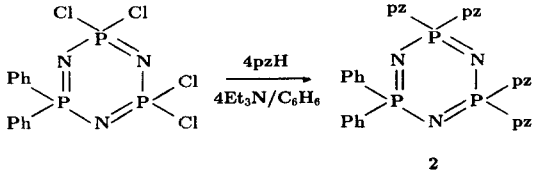
[a] The formulae of the complexes **4**–**9** are $N_3P_3Ph_2Pz_4 \cdot PdCl_2$, $N_3P_3Ph_2Pz_4 \cdot PtCl_2$, $N_3P_3Ph_2(dmpz)_4 \cdot PdCl_2$, $N_3P_3Ph_2(dmpz)_4 \cdot PtCl_2$ and $N_3P_3Ph_2Pz_4 \cdot PtCl_2 \cdot CuCl_2$.

[b] Includes half a molecule of benzene.

[c] Cu: 6.6[6.45].

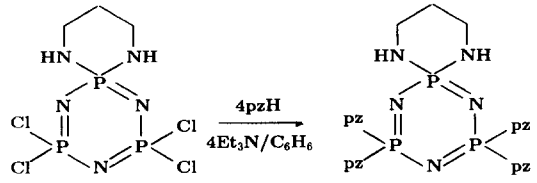
spectra were recorded on a Bruker spectrometer operating at 164.5 MHz. Phosphorus chemical shifts are reported with reference to external 85% H_3PO_4; upfield shifts are negative. Electrochemical measurements were performed with a BAS 100A electrochemical analyser [13]. The three-electrode cell consisted of a glassy-carbon working electrode, a platinum wire as a counter electrode and reference electrode saturated calomel electrode. All potential values are referred to the saturated calomel electrode. Under the present experimental conditions the one-electron oxidation of ferrocene occurs at +0.38 V.

RESULTS AND DISCUSSION



Synthesis

The geminal tetrakis(pyrazolyl)cyclotriphosphazene, $N_3P_3Ph_2pz_4$ (**2**), is obtained from the reaction of *gem*-$N_3P_3Ph_2Cl_4$ with pyrazole in the presence of triethylamine in refluxing benzene. Similarly, **3** is accessed by a facile nucleophilic substitution reaction of *spiro*-$N_3P_3[NH(CH_2)_3NH]Cl_4$ with pyrazole (Scheme 1). The phosphazenes **2** and **3** are obtained in relatively good yields. The pyrazolylcyclotriphosphazenes have been characterized by multinuclear NMR and IR spectroscopy and by C, H and N elemental analyses.



The reaction of **2** and $N_3P_3Ph_2(dmpz)_4$ (**4**) with $PdCl_2(NCPh)_2$ or $PtCl_2(NCPh)_2$ in benzene give the complexes of the general formula $[MCl_2 \cdot L]$, where L = **2**; M = Pd (**5**) or Pt (**6**) and L = **4**; M = Pd (**7**) or Pt (**8**), in good yields. The complexes are highly soluble in common halogenated solvents, such as dichloromethane, chloroform, etc. In these complexes the two geminal pyrazolyl pyridinic nitrogen atoms are involved in coordination. The coordinating ability of these "metallo-ligands" has been illustrated by the preparation of a heterobimetallic compound $2 \cdot PtCl_2 \cdot CuCl_2$ (**9**). All the complexes have been characterized by elemental analysis and multinuclear NMR spectroscopy. Electrochemical and ESR spectral studies have been performed on the heterobimetallic derivative **9**.

NMR spectroscopy

The ^1H NMR spectra of **2** and **3** show that the four pyrazolyl groups are equivalent. They exhibit three

Scheme 2.

different signals due to the 4-C, 5-C and 3-C protons of pyrazole nucleus at *ca* 6.2, 7.7 and 7.9 ppm, respectively (Fig. 2). The unresolved multiplet at *ca* 6.2 ppm is assigned to the 4-C protons. Recent studies on the polypyrazolyl borates and their complexes indicate that the 3-C protons resonate at lower fields than that of 5-C [12,13]. Considering the criterion to be compatible with the case for these pyrazolylphosphazenes also, we attribute the doublet in the downfield region to the 3-C protons and the other doublet at *ca* 7.7 ppm to the 5-C protons. In addition, the pyrazolylcyclotriphosphazenes **2** and **3** show features due to the phenyl and 1,3-diaminopropane moieties, respectively. The proton NMR spectrum of **2** shows a cluster of signals in the region 7.21–7.81 ppm for the phenyl groups, while that of **3** exhibits a multiplet at 1.67, a triplet at 3.35 and a broad signal at 4.86 ppm due to the $—CH_2—$, $—NCH_2—$ and the —NH— protons, respectively, of the 1,3-diamino propane *spiro* loop. After coordination to palladium (in complexes **5** and **7**) all the four pyrazolyl groups become nonequivalent and give rise to approximately four sets of signals at room temperature (Figs 3 and 4, Table 2). This is surprising to compare with the results reported by other authors who observe that the palladium derivatives of polypyrazolyl borate [14]

or pyrazolylphosphazenes [8] are fluxional in nature at room temperature.

This observation stimulated us to reinvestigate the spectra of the palladium complex **7**, derived from tdpctp, which was earlier reported by Paddock and Gallicano [2]. They have observed only three signals for 3- and 5-methyl protons. Interestingly, the spectra recorded at 400 MHz shows seven signals in the ratio $\alpha:\alpha:\beta:\alpha:\beta:\alpha:2\beta$ (Fig. 4). The observation of nonequivalent pyrazolyl groups are well explained by considering the two possible isomers for these complexes (Fig. 5). In isomer **A** the uncoordinated pyrazolyl groups are away from the metal center and constitute a stereochemically equivalent set. However, in isomer **B** the uncoordinated pyrazolyl groups are stereochemically nonequivalent. These differences, due to the spatial arrangement of pyrazolyl groups lead to a multitude of signals. Similar and somewhat less pronounced effects have been noticed in the ^{13}C NMR spectra of the compounds also (Table 3).

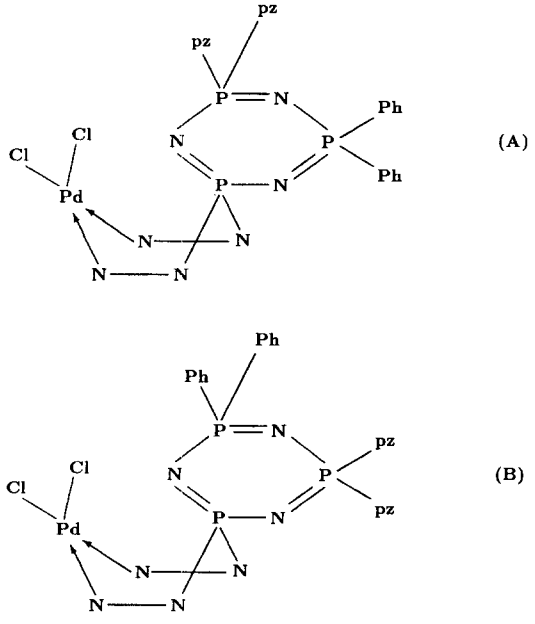

Fig. 5. Isomeric structures of the complexes with geminal N_2 coordination.

The ^{31}P NMR spectra of **2** and **3** display a AX_2 pattern with a doublet at −1.99 and 1.15 and a triplet at 24.10 and 14.58, respectively. The upfield doublet is readily assigned to the Ppz_2 groups by comparison with the value for $N_3P_3(dmpz)_4$ and **4**. The two bond coupling observed for Ppz_2 and PPh_2 or P_{spiro} centers in **2** and **3** are larger than that observed for PCl_2 and PPh_2 or P_{spiro} groups in their parent compounds $N_3P_3[NH(CH_2)_3NH]Cl_4$ [12] and $N_3P_3Ph_2Cl_4$ [15], respectively. The chemical shift of a particular phosphorus atom depends on several factors, such as the nature of the substituents (steric and electronegatively), extent of π-bonding with the substituents, bond angles at phosphorus, etc. The substituents on the adjacent phosphorus may also influence the chemical shift of the phosphorus nucleus under consideration [18]. It is clearly evident from Table 4 that the bulkiness of the pyrazolyl substituent is responsible for the drastic upfield shift when compared with the other aminocyclotriphosphazenes. A slight down-field shift for the Ppz_2 group in **3** may be attributed to the electronic effect exerted by the electron rich *spiro* loop.

The ^{31}P NMR spectra of palladium complexes **5** and **7** show an ABX pattern (see Table 4). The two ppz_2 phosphorus nuclei which are equivalent in **1** and **4** have become nonequivalent and the phosphorus bearing the coordinated pyrazole are shielded and phosphorus nucleus associated with the uncoordinated pyrazolyl groups are slightly deshielded. The PPh_2 phosphorus nuclei in the palladium complexes are also deshielded. The platinum complexes show only two broad signals at room temperature, suggestive of fluxional motions in solution. However, the nature of the dynamic processes are not clear at this stage.

EPR spectroscopy

The EPR spectrum of **9** recorded at room temperature as polycrystalline powder sample was isotropic and do not exhibit any metal or ligand splitting features. However, in solution it displayed informative spectra. Figure 6(b) shows the X-band EPR spectrum of tpctp·$PtCl_2$·$CuCl_2$ in acetonitrile solution recorded at 100 K. The well resolved lineshape is indicative of a $S = 1/2$ paramagnetic species in an axial symmetry ($g_\parallel > g_\perp$) with hyperfine resolution in the parallel region; a poorly but informative resolution of nine superhyperfine lines is also detectable in the perpendicular region. The overall lineshape is accounted for by magnetic coupling of the $S = 1/2$ unpaired electron with the copper nucleus ($I = 3/2$); the minor superhyperfine multiplet is attributable to the electron spin interaction with four nitrogen nuclei ($I = 1$; theoretical intensity of ratio = 1 : 5 : 10 : 14 : 19 : 14 : 10 : 5 : 1). The second derivative analysis affords a better resolution of the absorption pattern and gives the experimental values of the $A_\perp$(N) superhyperfine coupling constant. The poor resolution of the spectrum in the perpendicular region and corresponding linewidth are consistent with the non-equivalence of the four coordinating nitrogen nuclei, as confirmed by computer simulation. This further supports the proposed tetragonal arrangement [19] of the copper environment with the three nitrogens originating from two geminal pyrazolyl groups and one acetonitrile molecule lying in the equatorial plane (higher $A_\perp$(N)) and the fourth of the cyclo-

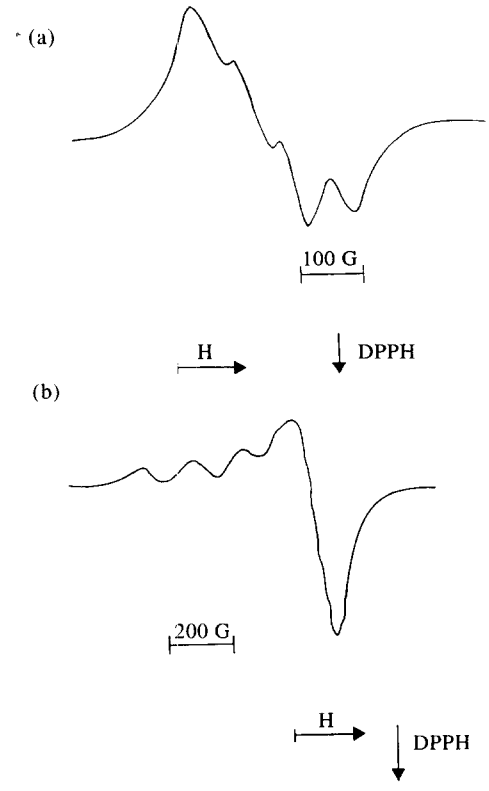

Fig. 6. EPR spectra of **9** (a) at room temperature (298 K) and (b) at 100 K in acetonitrile solution.

triphosphazene nitrogen occupying an apical position. The $A_{\parallel}$ values suggest that the equatorial plane is more tetrahedrally distorted [20]. The involvement of acetonitrile is further supported by the fact that when the spectrum was recorded in DMF the super hyperfine splitting collapsed. The parameters of the simulated spectrum are:

$g_{\parallel} = 2.270$	$g_{\perp} = 2.059$
$g_{av} = 1/3(g_{\parallel}+2g_{\perp}) = 2.130$	
$A_{\parallel} = 148.0$ G	$A_{\perp} = 10.0$ G
$A_{av} = 1/3(A_{\parallel}+2A_{\perp}) = 56.0$ G	
$A_{\parallel}(3N) = 4.0$ G	$A_{\perp}(3N) = 13.8$ G
$A_{\parallel}(N) = 3.7$ G	$A_{\perp}(N) = 12.7$ G.

Figure 6(a) shows the room-temperature X-band EPR spectrum of **9** in acetonitrile solution. Both the first and the second derivative spectra are poorly resolved and do not exhibit superhyperfine resolution. The relevant isotropic parameters ($g_{iso} = 2.132$; $A_{iso} = 58.3$ G) well fit the low temperature (100 K) ones. It must be noted that no absorption attributable to paramenetic platinum centered species have been detected neither in the original complex nor in solution from exhaustive electrolysis.

Electrochemistry

The unusual EPR spectral observations of the complex tpctp·$PtCl_2$·$CuCl_2$ prompted us to investigate the electrochemical behavior of it. The redox pattern exhibited by the heterodimetal complex is intriguing. As illustrated in Fig. 7, in acetonitrile solution it undergoes three subsequent cathodic steps at peaks A, B and C, respectively. Controlled potential coulometric tests served to elucidate overall reduction path. The catho-anodic peak system A/G ($E^{\circ} = +0.46$ V) proved to involve a chemically reversible electron transfer, in that controlled potential electrolysis ($E_w = 0.0$ V) consumes one electron per molecule. Concommitantly the initially EPR-active (see the previous section), yellow–green solution turns colorless and EPR silent. Such a final solution exhibits a cyclic voltammetric profile quite complementary to that illustrated in Fig. 7(c). Subsequent exhaustive one-electron reduction at the second cathodic step ($E_w = -1.0$ V) causes deposition of copper metal on the microelectrode surface. The resulting solution displays only the reduction process C, which we confidently assign to the reduction of the platinum(II) center, in analogy with the results on the platinum complexes of tpctp and tdpctp, which exhibit an irreversible Pt^{II}/Pt^{0} reduction at very negative potential values (in the range from -1.5 V to -1.6 V). Upon reoxidation of the electrodeposited copper metal

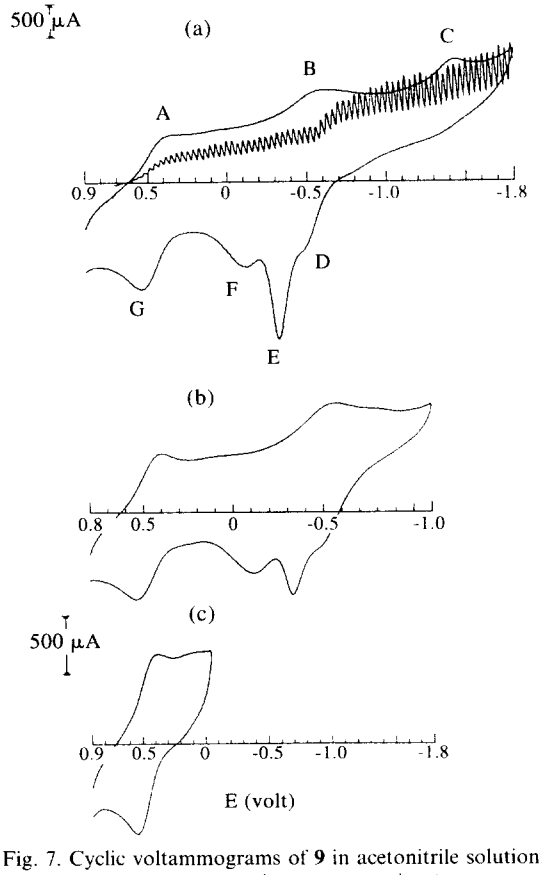

Fig. 7. Cyclic voltammograms of **9** in acetonitrile solution. Scan rates: (a), (c) 0.2 V s^{-1}; (b) 0.1 V s^{-1}. Direct current voltammetric scan rate: (a) 0.01 V s^{-1}.

($E_w = +0.6$ V), the solution restores the original voltammetric response shown in Fig. 7. In summary, the overall redox propensity of complex tpctp · $PtCl_2$ · $CuCl_2$ is so schematizable:

$$[LCu^{II}Pt^{II}] \underset{-e(G)}{\overset{+e(A)}{\rightleftharpoons}} [LCu^{I}Pt^{II}]^- \underset{-e(D)}{\overset{+e(B)}{\rightleftharpoons}} [LCu^{0}Pt^{II}]^{2-}$$

$$\downarrow$$

$$Cu^0 + [Pt^{II}L]^{2-}$$

$$-e\downarrow(E) \qquad (C)\downarrow +2e$$

$$Cu^I + [Pt^0L]^{4-}$$

$$-e\downarrow \qquad (F)\downarrow$$

$$Cu^{II} \qquad \text{degradation}$$

Finally a few further points deserve comment. (i) The thermodynamically easy access to the $Cu^IPt^{II}L$ (L = ligand) congener is quite rare [21], particularly when compared with the corresponding complex hdpctp · $CuCl_2$ · $PtCl_2$, which under the same experimental conditions undergoes the $[Cu^{II}Pt^{II}L]/[Cu^0Pt^{II}L]^{2-}$ reduction process through a single-stepped irreversible process ($E_p = -0.55$ V), without any stabilization of the intermediate mixed-valent species [22]. This is likely attributable to the electronic factors arising from the substitution of two pyrazolyl groups for two electron-withdrawing phenyl groups and removal of methyl groups from 3- and 5-positions of pyrazole ring, which makes easier the addition of electrons. (ii) The analysis of the peak system A/G with scan rates varying from 0.02 to 2 V s^{-1} shows that the peak-to-peak separation progressively increases from 140 to 315 mV. This high departure from the constant values of 59 mV expected for an electrochemically reversible one-electron transfer denotes that a considerable geometrical strain accompanies the $[Cu^{II}Pt^{II}L]/[Cu^0Pt^{II}L]^{2-}$ redox change [21].

CONCLUSION

The new pyrazolylcyclophazene ligand **1** reacts in a facile manner with the platinum and palladium salts to give the corresponding mononuclear complexes. The possibility of using these complexes as ligands for the assembly of heterobimetallic compounds has been demonstrated for the platinum complex **6**. It is also interesting to note that the absence of methyl groups in the pyrazolyl nucleus affects mainly the electrochemical property of the heterobimetallic derivative. However, the final conclusion on the role of substituents on pyrazolyl and cyclophosphazene moieties awaits more elaborate studies with more sensitive metals such as copper, cobalt, etc., and various suitably modified pyrazolylcyclotriphosphazenes. Work in this direction is in progress at our laboratories.

(Received 25 June 1996; accepted 16 August 1996)

Abstract—The reaction of copper(II) acetate with ethyl(2-benzothiazolyl)aminoformate (HL) gave red crystals of $[Cu_2L_4]_2$ (**1**). When complex **1** was treated with pyridine (Py) in chloroform/toluene, red crystals of $CuL_2(Py)_2$ (**2**), were deposited. Both complexes have been characterized by single-crystal X-ray diffraction methods, showing that the binuclear complex **1** has the copper atoms each located in a four-coordinate square-planar geometry of N_4, with two independent molecules in an asymmetric unit. The average bond distances of Cu—N(amine) and Cu—N(bta) (bta = benzothiazoyl) are 1.98 and 2.07 Å, respectively. Complex **2** is mononuclear with the Cu atom also in a square plane. The bond distances of Cu—N(py) and Cu—N(amine) are 2.011(4) and 1.997(4)Å, respectively. Copyright © 1997 Elsevier Science Ltd

Keywords: crystal structure; Cu^{II} complexes; syntheses; pyridine complex; amine complexes; ethyl(2-benzothiazolyl)aminoformate.

Amide-containing ligands have long invoked the interest of coordination chemists and biochemists, because of their biological significance [1]. It is believed that the coordination of amide to metal ions could provide simple models for more complex enzymes [2]. In recent years, the literature has reported many studies on the coordination behaviour of amide oxygen or deprotonated nitrogen to metal ions [3]. Amino acids are the basic units of proteins whose importance in living cells has been known for a long time. Amino acid esters can be hydrolysed directly into amino acids. In most cases, the biological activities associated with a given compound are often traceable to the coordination behaviour of the metals present in the biosystem. Thus, inspired by these facts, we have synthesized a new ligand, ethyl(2-benzothiazolyl)aminoformate (Fig. 1), and obtained two copper complexes **1** and **2**. In this paper, we report the characterization including the X-ray crystal structures, of **1** and **2**.

EXPERIMENTAL

Ethyl(2-benzothiazolyl)aminoformate (HL)

The ligand HL was prepared by the reaction of 2-aminobenzothiazole (1.50 g, 0.01 mol) with ethyl-

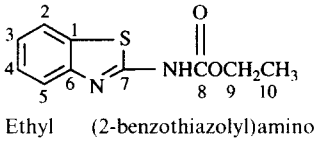

Fig. 1. Ethyl (2-benzothiazolyl)amino formate ($C_{10}H_{10}O_2N_2S$).

* Authors to whom correspondence should be addressed.

chloroformate (1.09 g, 0.01 mol) in boiling ethylacetate for 3–4 h by the method described in the literature [4]. Yield, 1.81 g (70%). M.p. 202–203°C. Found: C, 54.2; H, 4.4; N, 12.5; S, 14.6. Calc. for $C_{10}H_{10}O_2N_2S$: C, 54.1; H, 4.5; N, 12.6; S, 14.4%. ^{1}H NMR (DMSO-d_6): δ(NH) 12.03 (s, 1H, NH); δ(CH) 7.26–7.96 (m, 4H, aromatic ring); δ(CH) 4.23–4.27 (q, 2H, OCH_2); δ(CH) 1.26–1.30 (t, 3H, CH_3), ^{13}C NMR (DMSO-d_6) 159.93 $\delta(C_7)$, 154.26 (C_8), 149.50 (C_1), 131.82 (C_6), 120.45–126.21 (C_2–C_5), 62.14 (C_9), 14.56 (C_{10}).

Synthesis of complex **1** $[(Cu_2L_4)_2]$

To a boiling anhydrous ethanol solution (30 cm^3) containing HL (0.31 g, 1.40 mmol) was added $Cu(CH_3COO)_2 \cdot H_2O$ (0.14 g, 0.70 mmol). The mixture was refluxed for 2–3 h then cooled to room temperature, whereupon the solid precipitated was isolated by filtration, washed repeatedly with anhydrous ethanol and methanol and dried in a vacuum desiccator over anhydrous $CaCl_2$. Recrystallization from $CHCl_3/Et_2O$ gave red crystals of **1**. Yield, 0.36 g (79%). Found: C, 47.5; H, 3.8; N, 10.8; S, 12.4. Calc. for $C_{20}H_{18}O_4N_4S_2Cu$: C, 47.4; H, 3.6; N, 11.1; S, 12.6%.

Synthesis of complex **2** $[CuL_2(Py)_2]$

Complex **1** (0.2 g) was dissolved in a mixed chloroform/toluene/pyridine (2 : 2 : 1, v/v/v; 30 cm^3) solvent. After slow evaporation of this red solution at room temperature in air over a period of several days (the volume of the solution was reduced to about 5 cm^3), red crystals of **2** were obtained, which were filtered and dried in air. Yield, 0.08 g (40%). Found: C, 54.2; H, 4.3; N, 12.8; S, 9.5. Calc. for $C_{30}H_{28}O_4N_6S_2Cu$: C, 54.2; H, 4.2: N, 12.6; S, 9.6%.

Physical measurements

Elemental analyses (C, H, N) were performed on a Carlo–Erba 1106 elemental analyser. IR spectral data were recorded on a Magna 750 spectrometer. NMR (^{1}H and ^{13}C) spectra were collected on an AM 500 spectrometer in DMSO-d_6 solution.

X-ray diffraction analysis

A summary of data collection, crystallographic data and details of the structure refinement is listed in Table 1. For both complexes, the structures were solved by direct methods, refinements were carried out by full-matrix least-squares cycles and the hydrogen atoms were included in structural calculations but not refined. Some non-hydrogen atoms were refined anisotropically, while the rest were refined isotropically. All the calculations were performed using the TEXSAN crystallographic software package from the Molecular Structure Corporation.

RESULTS AND DISCUSSION

Complex **1** $[Cu_2L_4]_2$

Views of the molecular structures of the $Cu_{1,2}$ and $Cu_{3,4}$ units in complex **1** are shown in Fig. 2a, b, respectively, and the packing arrangement is given in Fig. 3. Selected atomic distances and bond angles are listed in Table 2.

The asymmetric unit contains two crystallographically independent molecules, each consisting of two four-coordinate copper(II) centres. The anionic L group acts as a bidentate ligand and coordinates to the central copper atoms with nitrogen atoms from the benzothiazoyl (bta) group and the amino group, respectively. Each of the copper atoms is in a distorted square plane composed of the N donor atoms from the four L groups, with two from the bta and two from the amino groups.

As shown in Table 2, the Cu—N(amino) distances range from 1.95(2) to 2.01(2) Å (mean 1.98 Å) and the Cu—N(bta) distances range from 1.98(2) to 2.07(2) Å (mean 2.01 Å) and are comparable with those found in related complexes [5–7]. It is noticed that the average Cu—Cu distance of 2.559 Å is shorter than the Cu—Cu van der Waals distance of 2.86 Å and much closer to that of 2.56 Å in metallic Cu [8], indicating the existence of a bonding interaction for Cu—Cu in complex **1**. This Cu—Cu distance is longer than that in $[Cu_2(NPhCPhNPh)_4]$ [9] which has a similar structure where the bridging NPhCPhNPh ligands result in an even shorter Cu—Cu distance of 2.45 Å.

The nitrogen atoms from the amino and bta groups coordinate to the Cu atoms in the *trans* form, with angles N_{bta}—Cu—N_{amino} of 89.7° (mean), N_{bta}—Cu—N_{bta} of 166.7° (mean) and N_{amino}—Cu—N_{amino} of 174.3° (mean). Inside the five-membered chelate rings [Cu—Cu—N_{amino}—C—N_{bta}], the Cu—N_{bta}—C angle ranges from 120(1) to 125(1)° (mean 123°), Cu—N(amino)—C ranges from 115(1) to 121(1)° (mean 118.5°), N_{bta}—Cu—Cu ranges from 82.5(5) to 85.1(5)° (mean 83.4°) and N_{amino}—Cu—Cu ranges from 84.9(5) to 88.8(5)° (mean 87.0°).

As shown in the structure, there are four chelate rings with each pair of Cu atoms in an independent molecule, and the average dihedral angle between each pair of *cis*-coordinated chelate rings is 87.7°, nearly perpendicular to each other. In addition, the average dihedral angle between each pair of *trans*-coordinated chelate rings is 1.08°, nearly parallel to each other.

Complex **2** $[CuL_2(Py)_2]$

The structure of complex *2* is illustrated in Fig. 4, and its packing arrangement is shown in Fig. 5. Selected bond distances and bond angles are also given in

Table 2. The copper(II) atom is in a four-coordinate square-planar geometry, in which either of the two L groups provides one nitrogen donor atom from the dehydrogenated amino group, and the other coordinated atoms are from the two nitrogen atoms contributed by two pyridine molecules. Unlike the structure of complex **1**, the benzothiazolyl nitrogen of the L group in **2** does not bind to the Cu^{II} ion. The Cu—N(1) bond distance is 2.011(4) Å, which agrees well with the bond distance for Cu—$N_{pyridine}$ elsewhere [10]. The bond Cu—N(2) of 1.997(4) Å is within the range of the corresponding bond found in complex **1**. The other bond distances in the ligand do not change much relative to those in complex **1**. This can be explained by the fact that the benzothiazolyl nitrogen atom coordinates to Cu^{II} only with its non-bonding electron pairs. The bond angle N(2)—Cu—N(1) of 90.4(1)° indicates that the square-planar geometry of Cu is quite exact. The angle C(6)—N(2)—Cu of 108.0(3)° is smaller than the corresponding one in complex **1** (average of 120°), where the angle is expanded for bridging.

The formation of the complexes can be depicted in Scheme 1 where the binuclear complex **1** dissociates into the mononuclear complex **2** in pyridine by dissociation of the N_{bta}—Cu bond.

This can be readily explained based on two facts. (i) The coordination ability of pyridine to copper is

stronger than that of N_{bta}, which can be seen from the atomic distances for N_{bta}—Cu (average 2.01 Å) and N_{py}—Cu [1.997(4) Å]. (ii) The binuclear complex **1** is asymmetric and more sterically congested, while the mononuclear complex **2** is symmetric and more stable thermodynamically.

IR spectra

The IR spectra of complexes **1** and **2** are very similar to each other because of their similar bond distances. In the IR spectra, ν(NH) is found at *ca* 3178 and 3140 cm^{-1} for the free ligand HL, but is absent in the complexes, indicating that the amino group has coordinated to the Cu^{II} ion through release of the hydrogen atom. The ν(C—O) at *ca* 1722 cm^{-1} for the free ligand is found to shift to lower frequency at *ca* 1686 cm^{-1} in the complexes. The Amide-II absorption band for HL appears at 1564 cm^{-1}, which is shifted to a higher frequency, 1573 cm^{-1}, in the complexes. This fact could be interpreted by back donation involving electron transfer in the direction copper→amide [11]. In addition, the absorption bands at *ca* 405 and 389 cm^{-1} are ascribed to ν(Cu—N_{amino}), and 366 cm^{-1} to ν(Cu—N_{bta}) [11].

Mixed valence complexes incorporating Ru^{III} and Fe^{II}: synthesis, characterization, kinetics and physico-chemical studies

Amitava Das* and H. C. Bajaj*

Central Salt and Marine Chemicals Research Institute, Bhavnagar 364002, India

(Received 14 June 1996; accepted 16 August 1996)

Abstract—A set of new mixed valence complexes of the type $Na_3[(edtaH)Ru^{III}LFe^{II}(CN)_5]$, where L = pyz, bp, dmbp, etybp or tmbp, has been synthesized and characterized by physico-chemical methods. The kinetics of formation of these binuclear complexes were studied using a stopped-flow spectrophotometer. Electrochemical studies for these complexes show only a weak metal–metal interaction in the ground state. All these complexes, except the one incorporating tmbp, gave an MMCT band in the region $900 < \lambda < 1000$ nm and belong to the Robin–Day class II type. Copyright © 1997 Elsevier Science Ltd

Keywords: synthesis; ruthenium; binuclear complexes; kinetics; mixed-valence.

The measurement of intramolecular rather than intermolecular electron transfer offers distinct advantages for investigating the detailed mechanism of electron transfer reactions [1]. In order to investigate the electron transfer in mixed valance systems, the study of binuclear metal complexes, in which the two redox active centres are linked by an unsaturated bridging ligand, have become increasingly popular [2]. The most widely studied mixed valence binuclear system is the Creutz–Taube ion, the theoretical study of which has contributed considerably to our understanding of electron transfer theory [3]. One of the most popular bridging ligands is 4,4′-bipyridyl and its derivatives [4]. A number of mixed valence homo- and heterobinuclear complexes has been synthesized using these bridging ligands to enable examination of metal–metal interactions and electron transfer processes across the molecular bridge, and also to determine the effects of length of the "molecular wire" on these [5].

The chemistry of polyaminopolycarboxylate complexes of ruthenium(III/II) is of continued interest owing to their biochemical importance [6] and catalytic ability [7] in oxidation and reduction reactions. $K[Ru^{III}(edtaH)Cl]$ is known to exist as Ru(edtaH)(H_2O) in aqueous solution [8,9] and to react with pyridine or substituted pyridine to form the corresponding pyridyl derivative through a facile aqua substitution path [8a,10]. To date, examples are scanty [10b] where the remarkable lability of the aqua ligand has been utilized for the design and synthesis of binuclear complexes. $Na_3[Fe(CN)_5(H_2O)]$ is known to react with N-heterocyclic ligands though a facile aqua substitution path [11]. We have taken advantage of these two aqua substitution reactions to synthesize a set of mixed valence heterobinuclear complexes of the type $Na_3[Ru(edtaH)LFe(CN)_5]$, where L = pyrazine (pyz), 4,4′bipyridyl (bp), 3,3-dimethyl-4,4′-bipyridyl (dmpb), *trans*-1,2-bis-4-pyridylethylene (etybp) and trimethyl bis-4-bipyridyl (tmbp) (Fig. 1). In this paper, we report the kinetics of the formation of the five mixed valence binuclear complexes **VI–X** using mononuclear complexes, **I–V** as ligands, their synthesis, characterization and physico-chemical studies. The mononuclear complex **I** was reported earlier by Matsubara and Creutz [8a] in aqueous solution. Synthesis and characterization of the mononuclear complex **I**, [Ru(edtaH)(Pyz)], along with complexes **II–V** are also included.

procedures [12,13]. Pyrazine (pyz), 4,4′-bipyridyl (bp), *trans*-1,2-bis(4-pyridyl)ethylene (etybp) and 1,3-bis(4-pyridyl)propane (tmbp) were used as received from Aldrich. 3,3′-Dimethyl-4,4′-bipyridyl (dmpb) was synthesized following a known method [14]. Solvents were purified and dried before use by standard methods and double distilled water was used. $[Bu_4N]ClO_4$ was used as background electrolyte for electrochemical studies.

Physical measurements

Microanalysis (C, H, N) were carried out with a Carlo–Erba elemental analyser. Absorption spectra were recorded on a Shimadzu UV 3101 PC spectrophotometer. IR spectra were recorded on a Carl–Zeiss specord M80 spectrometer as KBr pellets. EPR studies were carried out using a Bruker 300X spectrometer either at room temperature or at 77 K using a Dewar insert in the sample chamber. Electrochemical experiments were performed by using Princeton Applied Research (PAR 273A) electrochemical instruments. A conventional three electrode cell assembly was used. Saturated calomel electrode as reference and Pt as working electrode were used for this purpose. pH measurements were carried out with Digisun pH meter. For spectrophotometric and cyclic voltammetric studies of binuclear complexes, freshly prepared solutions were used throughout.

Kinetic studies

Kinetic studies were performed on a High-Tech SF51 stopped-flow spectrophotometer. The measurements were carried out by following the absorbance increase in the wavelength region 380–550 nm [the MLCT band for the $Fe(CN)_5$ unit upon coordination to the remote N atom of L in the Ru(edtaH)L unit] or at λ_{max} for the MMCT band for complexes **VI–IX**. In all instances pseudo first-order conditions were maintained {excess $[Ru(edta)L^-]$} and the corresponding first-order plots were linear for at least 2–3 half-lives of the reaction. Rate constant data are represented as an average of triplicate runs and are reproducible within $\pm 4\%$. pH for the kinetic solutions was maintained using acetic acid–acetate buffer and the ionic strength of the solution was maintained with KCl solution.

Synthesis

$Ru(edtaH)(L)\cdot 2H_2O$, *where* L = pyz, bp, dmbp, etybp *or* tmbp. $K[Ru(edtaH)Cl]\cdot 2H_2O$ (260 mg; 0.4 mM) was dissolved in warm water (5 cm^3), to which 4 mM of L (pyz, 320 mg; bp, 624 mg; dmbp, 736 mg; etybp, 728 mg; tmbp, 792 mg) dissolved in *ca* 5–10 cm^3 of ethanol was added and stirred at *ca* 50°C for 15 min. Then the volume was reduced to *ca* 5 cm^3, to which excess acetone was added and cooled to *ca* 5°C. The desired compound was precipitated, filtered off and washed thoroughly with methanol and acetone to remove excess L. Further purification involved recrystallization from water–methanol mixture and drying *in vacuo* (yield, 80–85%). Elemental analysis data (see Table 1) for these mononuclear complexes (**I–V**) agree well with the proposed formulation.

$Na_3[Ru(edtaH)LFe(CN)_5\cdot 3H_2O$, *where* L = pyz, bp, dmbp, etybp *or* tmbp. All binuclear complexes were synthesized by reaction of 0.4 mM Ru(edtaH)L with 0.4 mM (102 mg) of $Na_3[Fe(CN)_5(NH_3)]\cdot 3H_2O$ at room temperature in water (10 cm^3). The reaction mixture was stirred for 20 min and then concentrated at room temperature *in vacuo* to *ca* 3 cm^3. The desired binuclear complexes (**VI–X**) were precipitated on addition of cooled (5°C) and excess methanol and were allowed to stand for 1 h. Precipitate was filtered and washed with 8 : 2 (v/v) methanol/water mixture. Complexes **VI–X** were further purified by recrystallization from a water/methanol mixture (7 : 3; v/v) (yield 75–80%). Analytical data for complexes **VI–X** are given in Table 1 and are in good agreement with the proposed formulation.

RESULTS AND DISCUSSION

K[Ru(edtaH)Cl] hydrolysed [8,9] rapidly in aqueous solution to give $Ru(edtaH)(H_2O)$, which reacts with N-heterocyclic ligands through rapid aqua substitution pathway to yield mononuclear complexes (**I–**

V). For synthesis of these mononuclear complexes, a large excess of L (five-fold equimolar excess) was used to avoid the possibility of the formation of homobinuclear complexes [10b]. $[Fe(CN)_5(H_2O)]^{3-}$ is also known to react with N-donor heterocyclic ligands through substitution of the aqua molecule within the stopped-flow time-scale [11]. We have utilized these two specific reactions to synthesize the binuclear complexes **VI–X** (Fig. 1). IR spectra of all the complexes (Table 1) exhibit a sharp band at around 1735 cm^{-1} for the uncoordinated —COOH group, and a broad band at 1645 cm^{-1} for the coordinated $—COO^-$ group [10]. Bands at 1600 cm^{-1} and 1460 cm^{-1} appear owing to the stretching and bending of C=C and C=N, respectively, of the coordinated pyrazine or derivatives of the 4,4′-bipyridyl. The binuclear complexes (**VI–X**) also exhibit bands at around 2060 cm^{-1}, which are assigned to the —C≡N stretching of the $Fe(CN)_5^{3-}$ fragment [15]. All these complexes (**I–X**) exhibit a broad absorption band at around 3400 cm^{-1} owing to the H_2O molecule, present as water of crystallization.

The stability of the binuclear complexes (**VI–IX**) in aqueous solution at room temperature was monitored spectrophotometrically at the metal to metal charge transfer (MMCT) band (*vide infra*) and were found to be stable within the time-scale for EPR, electrochemical and spectrophotometric studies. However, decrease in the intensity at the MMCT band, i.e. decomposition of the mixed valence binuclear complex, was observed on prolonged storage of the aqueous solution.

Kinetic studies

Preliminary experiments showed that the aqueous solution of $Ru(edta)L^-$ (L = pyz, bp, dmbp, etybp or tmbp) and $Fe(CN)_5H_2O^{3-}$ on mixing, yielded binuclear complexes of the type $[(edta)Ru^{III}LFe^{II}(CN)_5]^{4-}$ within the stopped-flow time-scale. The kinetics of the formation of the binuclear complexes **VI–X** [Eq. (1)] were studied using mononuclear complexes, $Ru(edta)L^-$, as the incoming ligand under pseudo first-order conditions at pH = 5.0, where $Ru(edta)L^-$ and $Fe(CN)_5H_2O^{3-}$ are the only reactive species. The uncoordinated N atom on the remove side of L in $Ru(edta)L^-$ reacts with $Fe(CN)_5H_2O^{3-}$ through an aqua substitution path and a new MLCT band for Fe—L coordination develops in the visible region (*vide infra*). An additional, relatively intense, MMCT band appears at $900 < \lambda < 1000$ nm (*vide infra*) for complexes **VI–IX**. Reactions were studied at these two different wavelengths and k_{obs} were found to be same. A plot of k_{obs} *vs* $[Re(edta)L^-]$ gives a straight line with a small intercept, which signifies a reverse aquation reaction [Eq (2)]. Representative plots for reactions of $Fe(CN)_5H_2O^{3-}$ with $Ru(edta)(bp)^-$ and $Ru(edta)(etybp)^-$ are presented in Fig. 2. Rates for the formation (k_f) and aquation reactions (k_r) were obtained from the slope and intercept of the plot k_{obs} *vs* $[Ru(edta)L^-]$, respectively, and are summarized in Table 2 along with K ($=k_f/k_r$). These rate data are comparable with the related aqua substitution reaction [2b,9] in $Fe^{II}(CN)_5(H_2O)$ by N-heterocyclic ligands of the type $\{(NH_3)ML^{n+}\}$, where

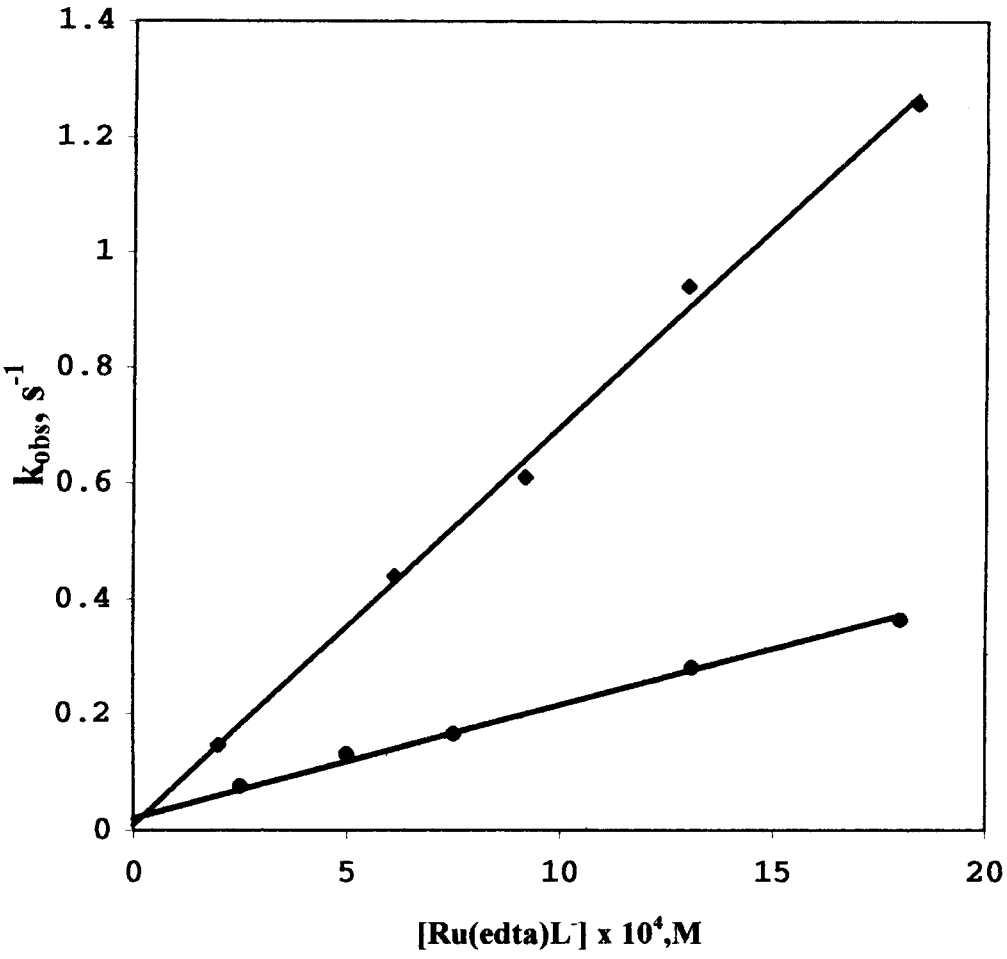

Fig. 2. Dependence of k_{obs} on [Ru(edta)L^-] for the reaction of $Fe(CN)_5H_2O^{3-}$ with Ru(edta)(bp)$^-$ (●) and Ru(edta)(etybp)$^-$ (◆): [$Fe(CN)_5H_2O^{3+}$] = 1.35×10^{-5} M; pH = 5.0 (acetic acid–acetate buffer, 0.2 M); ionic strength = 0.5 M (KCl); T = 25±0.1°C.

Table 2. Summary of rate parameters reaction (1)[a]

L	k_f ($M^{-1}s^{-1}$)	k_r (10^3) (s^{-1})	K (10^{-4}) (M^{-1})
pyz	150±10	2±0.6	7.5
bp	175±15	20±20	0.87
dmpb	146±10	35±10	0.42
etybp	684±35	9±5	7.6
tmbp	154±10	154±20	0.1

[a] At pH = 5.0, acetic acid–acetate buffer, T = 25.0±0.1°C; μ = 0.5 M (KCl).

M = Ru, Rh, Co. For tmbp, two pyridyl units are separated by a standard —CH_2—CH_2—CH_2— group and behaves more like 4-picoline, and is less effective as a π-acid ligand in stabilizing Fe^{II} owing to lower $\pi_M \rightarrow \pi_{py}$ back bonding which is reflected in higher value for k_r, compared with others (Table 2). Presumably, extended conjugation in etybp is responsible for more efficient $\pi_M \rightarrow \pi_{py}$ back bonding in complex **IX** and is reflected in higher k_f and relatively low k_r values. The steric constraint associated with the methyl groups in dmpb prevents the two pyridine ring from adopting the coplanar conformation necessary for good delocalization, hence the degree of conjugation is lower for dmbp and is reflected in slightly higher k_r value (Table 2). Thus it is interesting that the increasing stability of the binuclear complexes follows the order that would be expected on the basis of increasing back-bonding interaction. However, the important effect of ligand basicity has not been assessed.

$$Fe(CN)_5H_2O^{3-} + Ru(edta)L^- \underset{k_r}{\overset{k_f}{\rightleftharpoons}} [(edta)Ru^{III}LFe^{II}(CN)_5]^{4-} + H_2O \quad (1)$$

$$k_{obs} = k_f[Ru(edta)L^-] + k_r \quad (2)$$

EPR spectroscopy

All mononuclear and binuclear complexes (**I–X**) were found to be EPR active and exhibited broad

spectra at room temperature, while at 77 K [water/glycerol; 1:3 (v/v)] characteristic spectra were observed as reported for other complexes of Ru^{III} (edta) with π-acid ligands [10b,16]. Respective g_x, g_y and g_z values for the complexes are 2.61, 2.3 and 1.91. Comparison of the EPR spectra for mono- and binuclear complexes reveals that presence of a diamagnetic Fe^{II} centre does not have any influence on the nature of the EPR spectra for the Ru^{III} centre in the binuclear complexes **VI–X**.

Cyclic voltammetry

Cyclic voltammetric studies of complex **I–X** were carried out in water and the results are summarized in Table 3. The $E_{1/2}$ values for the $Ru^{II/III}$ couple for the mononuclear complex **I** (L = pyz) is comparable to that reported earlier [17]. Other mononuclear complexes, **II–V** have $E_{1/2}$ values comparable with that of the Ru^{III}(edta)Py^- complex [8a]. The ΔE ($E_{pa} - E_{pc}$) values for Ru^{II-III} couples are *ca* 140 mV, while those for the $Fe^{II/III}$ couple are *ca* 90 mV. Under identical experimental condition, the value of ΔE for the $Fe^{II/III}$ couple in $K_4Fe(CN)_6$ is 75 mV. The higher ΔE value for the $Ru^{II/III}$ couple signifies its quasi-reversible nature. Comparison of $E_{1/2}$ values for the mononuclear components [18] (Table 3) with those for the binuclear complexes **VI–X** (Table 3) reveals a little shift in the $E_{1/2}$ values of the individual component in binuclear complexes and thus there exists only a very weak electrochemical interaction between the two metal centres, linked by a hydrocarbon bridge, in the ground state.

UV-vis spectra

The ruthenium(III) centres in Ru(edta)pyridine-type complexes are known to be very weak σ donors and generally do not have any appreciable and characteristic absorption in the visible region [9,10], whereas the Fe^{II} centre in $[Fe(CN)_5Py]^{3-}$-type complexes, being a good π donor, is expected to have a strong MLCT band in the visible region. Thus, in the binuclear complexes, spectra in the visible region are dominated by the Fe^{II} to Py MLCT band (Table 1). The MLCT band for the Fe^{II} centre in complexes **VI–IX** appears almost in the same region as in the $[Fe(CN)_5Py]^{3-}$-type complexes. However, spectra in the UV region for complexes **VI–X** are dominated by the strong $n \rightarrow \pi^*$ transition of the coordinated edta group, which is intense enough to mask the expected $\pi \rightarrow \pi^*$ transition for the bipyridyl ligands, L. For complex **X**, the electronic spectrum is essentially the sum of the spectrum of the two monomeric units, [Ru(edtaH)tmbp] and $[Fe(CN)_5tmbp]^{3-}$. This is expected as the two π systems of the bridging ligand are separated by a saturated —CH_2—CH_2—CH_2— linkage and thus behave as a non-interacting chromophore. While all the other binuclear complexes (**VI–IX**) exhibit an additional relatively intense absorption band in the range $1000 > \lambda_{max} > 900$ nm, with $\varepsilon \sim 2.2\text{–}2.7 \times 10^3$ M^{-1} cm^{-1}, which disappear either on oxidation of the Fe^{II} by oxone or on reduction of the Ru^{III} centre by ascorbic acid in complexes **VI–IX**. Thus, the band in the near infrared region for complexes **VI–IX** is assigned as the metal to metal charge transfer absorption (MMCT) band [Eq. (3)]. ε Values observed for the MMCT band of the binuclear complexes **VI–IX** are comparable with those reported for similar mixed valence heterobinuclear complexes [10,15b] $[Ru^{III}(edtaH)NCFe^{II}(CN)_5]^{4-}$ and $[Ru^{III}(NH_3)_5CNFe^{II}(CN)_5]^-$. The MMCT band in mixed valence complexes provides information about the extent of electronic coupling between the metal centres and the rate of electron transfer from one metal centre to the other [1b,19–21].

$$[(edtaH)Ru^{III}\text{–}L\text{–}Fe^{II}(CN)_5]^{3-} \overset{E_{op}}{\underset{E_{th}}{\rightleftarrows}} [(edtaH)Ru^{II}\text{–}L\text{–}Fe^{II}(CN)_5]^{3-} \quad (3)$$

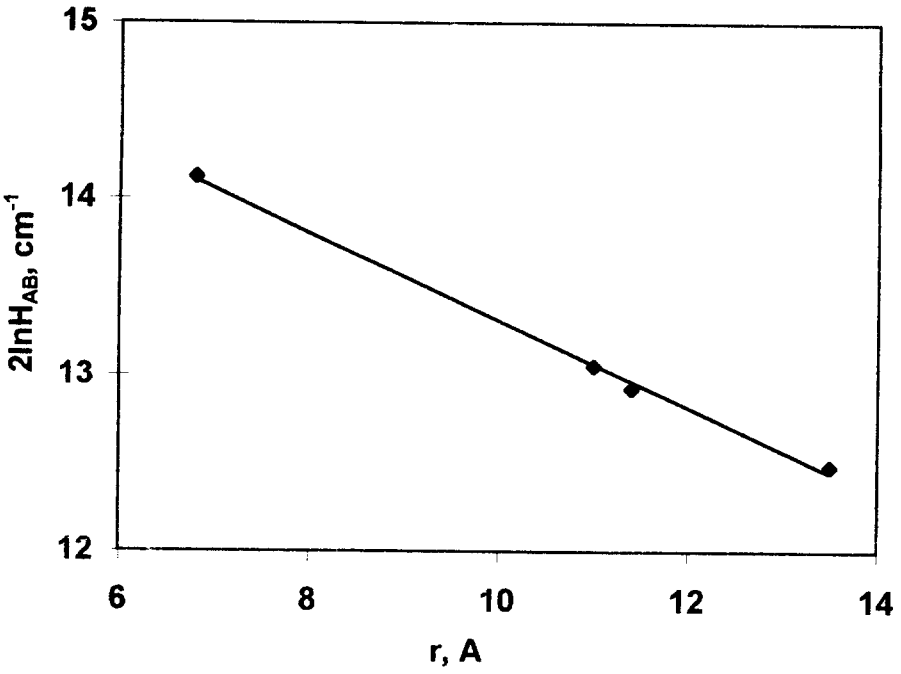

Fig. 3. Logarithmic plot of the square of the electronic coupling elements H_{AB} vs. metal to metal distance, r, in Na_3 [(edtaH)Ru^{III}–L–Fe^{II} $(CN)_5$] complexes; L : 1, pyz; 2, bp; 3, dmbp; 4, etybp.

(ν), molar absorbance at λ_{MMCT} (ε) and full width at the half maxima ($\Delta\nu_{1/2}$) for the intervalence charge transfer band (MMCT) for complexes **VI–IX** are presented in Table 4. Assuming a Gaussian band shape, a lower limit for the bandwidth ($\Delta\nu_{1/2}$) at room temperature can be calculated from Eq. (4) and the values are presented in Table 4.

$$\Delta\nu_{1/2} = (2310\nu_{max})^{1/2} \quad (4)$$

$\Delta\nu_{1/2}$ is related to the oscillator strength, f by Eq. (5) and f can also be expressed [1b,22] in terms of α (degree of mixing) and r (the metal–metal separation distance) (Eq. (6)].

$$f = 4.6 \times 10^{-9}\, \varepsilon_{max}\Delta\nu_{1/2} \quad (5)$$

$$f = 1.085 \times 10^{-5}\, \nu_{max}(\alpha r)^2 \quad (6)$$

Thus

Table 4. Mixed valence data for Na_3[(edtaH)Ru^{III}–L– Fe^{II} $(CN)_5$]

L Parameters	pyz	bp	dmbp	etybp
ν_{max} (cm^{-1})	10,917	10,718	10,163	10,030
$\Delta\nu_{1/2}$ (cm^{-1}) (calc.)	5020	4976	4845	4813
$\Delta\nu_{1/2}$ (cm^{-1})(expt)	5400	5200	5100	5000
α^2	0.01138	0.0041	0.004	0.0026
H_{AB} (cm^{-1})	1164	683	640	513

$$\alpha^2 = 4.24 \times 10^{-4}\varepsilon\Delta\nu_{1/2}/\nu_{max}r^2 \quad (7)$$

and

$$H_{AB} = \nu_{max}\alpha, \quad (8)$$

where α^2 is the measure of the ground state delocalization in the mixed valence complex and H_{AB} is the measure of electronic coupling. Values for α^2 and H_{AB}, calculated using Eqs. (4)–(8) are also summarized in Table 4. It is apparent that an increase in bridge length (metal–metal distances for pz, bp, dmbp and etybp are 6.8, 11, 11.4 and 13.5 Å, respectively) attenuates the communication between the metal centres. The delocalization parameter α^2 is in the order of 0.01 or less corresponding to an electron delocalization of only $< 1\%$. This is further consolidated by the lower, theoretically obtained, value for $\Delta\nu_{1/2}$ compared with the observed $\Delta\nu_{1/2}$ values [11b,23] for complexes **VI–IX**. Thus all these mixed valence complexes belongs to Robin–Day class II valence trapped system [1b,h,i,3a,24]. The plot of $2\ln H_{AB}$ *vs* r gives a straight line (Fig. 3) with $\beta = 0.25$ Å^{-1}, which reveals the measure of attenuation of the electronic overlap of donor and acceptor with the bridge [1e,23] and is close to that reported for polyene-bridged ruthenium amine complexes (0.22 Å^{-1}) [1e]. While for the complex **X**, there exists an interrupted π-system and thus no orbital pathway is available for metal–metal interaction. This is an example of a Robin–Day class I system [3a]. The decrease of electronic interaction with increase in the metal–metal distance has also been predicted theoretically [25]. As delocalization

from Fe^{II} to Ru^{III} is small [21,26] in complexes **VI–IX**, E_{th} can be given by Eq (9)

$$E_{th} = E_{op}/4 - H_{AB} \quad (9)$$

Thus, for reaction (1), assuming $T\Delta S \approx 0$ [26], the thermal electron transfer rate constant, k_{th}, can be expressed by

$$k_{th} = \nu_{et} \exp[-(\Delta G^*/RT)] \approx \nu_{et} \exp[-(E_{th}/RT)] \quad (10)$$

where ν_{et} is the electron hopping frequency and can be estimated [26] roughly ($\approx 10^{14}\ s^{-1}$ for **VI** and $\approx 10^{13}$ for complexes **VII–IX**) from the relation $\nu_{et} \approx 4H_{AB}/h$, [$h$ = Planck's constant] and this allows us to predict approximate values of k_{th} ($\approx 10^{10}$ for complex **VI** and $\approx 10^{9}\ s^{-1}$ for complexes **VII–IX**). Values obtained for k_{th} for complexes **VI–IX** are close to that reported for other related mixed valence binuclear complexes [21]. Moreover, the experimentally obtained value for k_{th} for the related mixed valence complex, $[(NH_3)_5Ru^{III}(NC)Fe^{II}(CN)_5]^-$ is $8 \times 10^{11}\ s^{-1}$ i.e. one/two orders of magnitude higher than that predicted for complexes **VI–IX**, which is a realistic one if the increased metal–metal distances are considered for these complexes.

A survey of terminal chalcogenido complexes of the transition metals: trends in their distribution and the variation of their M=E bond lengths

Tina M. Trnka and Gerard Parkin*

Department of Chemistry, Columbia University, New York, NY 10027, USA

(Received 25 June 1996; accepted 12 August 1996)

Abstract—The distribution of structurally characterized terminal chalcogenido complexes as a function of both the chalcogen and transition metal has been surveyed with the aid of the Cambridge Structural Database. The majority of these complexes are concentrated along the vanadium–molybdenum–rhenium diagonal with oxo derivatives being the most prevalent. Terminal chalcogenido derivatives of the early and late transition metals, and terminal tellurido complexes of all the transition metals, are particularly rare. Trends in the variation of metal–chalcogenido bond lengths are also described. Copyright © 1997 Elsevier Science Ltd

Keywords: metal; chalcogen; oxo; sulfido; selenido; tellurido.

Transition metal complexes with metal–ligand multiple bonds have attracted considerable attention over recent years [1]. The majority of these complexes feature multiple bonds to carbon, nitrogen and oxygen, with relatively few examples involving multiple bonding to their heavier congeners. In this regard, the chalcogens (E = O, S, Se, Te, Po) [2] are distinct from other groups of elements, since they represent the first group of non-metals for which all of the non-radioactive members (i.e. with the exclusion of Po) are known to form multiple bonds to the transition metals [3]. For this reason, it is timely to survey transition metal terminal chalcogenido complexes, and in this article we describe current trends in their distribution and the variation of the M=E bond lengths. The present study covers all transition metal terminal chalcogenido complexes, and, as such, is intended to complement Mayer's 1988 review concerned exclusively with oxo derivatives [4].

RESULTS AND DISCUSSION

We have surveyed the distribution of terminal chalcogenido complexes as a function of both the transition metal and chalcogen by using the Cambridge Structural Database (Version 5.11, April 1996). At the outset, it must be recognized that a survey of this type necessarily excludes complexes that have not been structurally characterized. However, since X-ray diffraction is often required to authenticate the presence of a terminal [M=E] moiety for the heavier chalcogens (S, Se, Te) [5], it is reasonable to consider that the distribution of structurally characterized complexes reflects their actual distribution. In contrast, the identification of terminal oxo complexes does not rely so heavily upon X-ray diffraction; for example, the terminal oxo moiety is frequently recognized by characteristic IR absorptions in the range *ca* 750–1100 cm^{-1} [1,6]. Consequently, the actual number of terminal oxo complexes may be significantly underestimated by surveying a structural database, a fact that should be considered when evaluating trends in distribution.

Distribution of terminal chalcogenido complexes

The distribution of structurally characterized terminal chalcogenido complexes of the transition metals is summarized in Table 1 and described below as a function of both the chalcogen and the transition metal.

Distribution as a function of the chalcogen. The occurrence of terminal chalcogenido complexes as a

* Author to whom correspondence should be addressed.

function of the chalcogen is illustrated in Fig. 1 [7], from which it is evident that their occurrence diminishes rapidly in the sequence O ≫ S > Se > Te. Furthermore, since the total number of oxo complexes is considerably greater than the number of structurally characterized examples, the difference between the actual distributions of oxo complexes and their heavier counterparts is in reality much more pronounced than is illustrated. In fact, the terminal metal–oxo moiety is the most common class of transition metal–ligand multiple bond [1,4], and studies on these complexes dominate those of their sulfido, selenido and tellurido counterparts [5,8,9]. Such a trend is in accord with the commonly observed preference for the heavier main group elements to form single rather than multiple bonds [5,10], but it must be recognized that the distribution also reflects other factors. For example, the oxidising nature of the atmosphere must be a consideration when rationalizing the abundance of terminal oxo complexes, while the scarcity of terminal tellurido complexes may simple be attributed to less research effort into the chemistry of tellurium compared with its lighter congeners [7].

Distribution as a function of the transition metal. The distribution of terminal chalcogenido complexes as a function of the transition metal is illustrated in Figs

2–8, from which it is apparent that their occurrence varies markedly with the location of the metal in the Periodic Table. The distribution as a function of Group is illustrated in Fig. 2, which indicates a rather peaked profile reaching a maximum with the Group 6 metals (Cr, Mo, W). The frequency of terminal chalcogenido complexes falls off quite dramatically on both sides of Group 6; indeed, there are no structurally characterized terminal chalcogenido complexes of either the Group 3 (Sc, Y, La) or Group 10 (Ni, Pd, Pt) transition metals. Moreover, there is only one such complex of the Group 9 metals, namely the iridium–oxo complex $(2,4,6\text{-}Me_3C_6H_2)_3IrO$ [11].

The lack of terminal oxo complexes for the late transition metals has already been noted by Mayer [12], who rationalized that their scarcity is a consequence of the necessarily high *d* electron count on late transition metal centers [13]. Specifically, π antibonding interactions resulting from the overlap of filled π orbitals on the oxo ligand with the filled d_π metal orbitals (so-called "filled–filled" repulsions [14]) destabilize a terminal metal–oxo interaction with respect to a bridged structure. Such an explanation, however, is clearly not applicable to the early transition metals (e.g. Sc, Y, La, Ti, Zr, Hf). For these elements, it is likely that the presence of a highly electrophilic metal center results in M=O moieties that are exceptionally reactive towards a variety of possible degradation reactions. For example, the zirconium–oxo complex, $Cp^*_2Zr(O)(NC_5H_5)$, reacts instantaneously with water to give the hydroxide derivative, $Cp^*_2Zr(OH)_2$ [6], whereas its tungsten counterpart, Cp^*_2WO, is stable with respect to $Cp^*_2W(OH)_2$ [15].

Concerning their distribution as a function of the transition series, the greatest number of structurally characterized terminal chalcogenido complexes are known for the second transition series, as illustrated in Fig. 3. However, rather than interpreting this as an indication of enhanced stability of their multiple bonds, it is more likely that the larger number of terminal chalcogenido complexes for the second versus third transition series is merely a consequence of more research effort being placed on the elements of the former series [16].

The distribution of terminal chalcogenido moieties

---

[a] The search of the Cambridge Structural Database (CSD) (Version 5.11, April 1996) was performed for the doubly bonded M=E moiety (where M = Groups 3–10 transition metals), restricting the coordination number of E to 1 and using the "insist-on-coordinates" and "insist-perfect-match" parameters in order to help eliminate inaccurate data. As a result of these constraints, not all complexes that have been structurally characterized may be retrieved in a particular search. For each transition metal, the number of terminal chalcogenido complexes is listed in the first line, with the mean M=E bond length (in Å) listed below. The number following the mean bond length in brackets indicates the sample standard deviation, while a number in parentheses indicates the esd for a single measurement.

[b] The titanium complex $[Et_4N][TiCl_4(S)]$ was excluded since the Ti—S interaction does not comprise a multiple bond. See: Müller, U. and Krug, V., *Angew. Chem., Int. Ed. Engl.* 1988, **27,** 293.

[c] Although no molecular terminal iron–oxo complexes were retrieved from the CSD search, the structure of the ferrate derivative K_2FeO_4, with a bond length of 1.67[1] Å, has been determined (see: Hoppe, M. L., Schlemper, E. O. and Murmann, R. K., *Acta. Cryst.* 1982, **B38,** 2237). Also, the X-ray structure of a complex proposed to be an iron(IV)–oxo–porphyrin complex has been cited in footnote 28 of Schappacher, M., Weiss, R., Montiel-Montoya, R. and Trautwein, A., *J. Am. Chem. Soc.* 1985, **107,** 3736. However, the sample was contaminated with an Fe^{III} bromide derivative, so that the derived Fe=O bond length [1.604(19) Å] should be regarded with caution (see: Parkin, G., *Chem. Rev.* 1993, **93,** 887). In addition to the above complexes that have been studied by X-ray diffraction, EXAFS studies on horseradish peroxidase and model compounds indicate Fe—O bond lengths in the range of 1.60–1.65 Å (see: Penner-Hahn, J. E., Eble, K. S., McMurry, T. J., Renner, M., Balch, A. L., Groves, J. T., Dawson, J. H. and Hodgson, K. O., *J. Am. Chem. Soc.* 1986, **108,** 7819 and Penner-Hahn, J. E., McMurry, T. J., Renner, M., Latos-Grazynsky, L., Eble, K. S., Davis, I. M., Balch, A. L., Groves, J. T., Dawson, J. H. and Hodgson, K. O., *J. Biol. Chem.* 1983, **258,** 12761.

[d] The CSD search did not retrieve the following anionic zirconium–oxo complexes which contain four-membered $[M_2O_2]$ rings (M = Li, K) owing to interaction of the oxo ligand with the counterion: $[\{\eta^5\text{-}\eta^1\text{-}\eta^5\text{-}\eta^1\text{-}Et_8C_4(C_4H_2N)_3(C_5H_3N)Zr=O\}_2(\mu\text{-}K)_2]$, with $d(Zr=O) = 1.813(2)$ Å, Jacoby, D., Floriani, C., Chiesi-Villa, A. and Rizzoli, C., *J. Am. Chem. Soc.* 1993, **115,** 7025; $[\{\eta^5\text{-}\eta^1\text{-}\eta^5\text{-}\eta^1\text{-}Et_8C_4(C_4H_2N)_3(3\text{-}EtC_5H_2N)Zr=O\}_2(\mu\text{-}K)_2]$, with $d(Zr=O) = 1.804(2)$ Å, Jacoby, D., Isoz, S., Floriani, C., Chiesi-Villa, A. and Rizzoli, C., *J. Am. Chem. Soc.* 1995, **117,** 2793; $[\{\eta^1\text{-}\eta^1\text{-}\eta^5\text{-}\eta^1\text{-}Et_7C_4(C_4H_2N)_3(CH_2CH_2C_5H_2N)Zr=O\}_2(\mu-Li)_2]$ with $d(Zr=O) = 1.838(7)$ Å, Jacoby, D., Isoz, S., Floriani, C., Chiesi-Villa, A. and Rizzoli, C., *J. Am. Chem. Soc.* 1995, **117,** 2805.

[e] The number of molybdenum–chalcogenido complexes and the Mo=E bond lengths include the complexes $Mo(PMe_3)_4(E)_2$ [S, 2.54(1) Å; Se, 2.381(1) Å; Te, 2.597(1) Å] (see: ref. [21]) and $[(3,5\text{-}Me_2C_6H_3)NBu^t]_3Mo=E$ [O, 1.706(2) Å; S, 2.168(1) Å; Se, 2.312(1) Å; Te, 2.535(1) Å] (C. C. Cummins, personal communication) which were not listed in Version 5.11 of the CSD.

[f] The number of hafnium–tellurido complexes and the mean Hf=Te bond length includes $[(Me_3Si)_3SiTe]_2Hf(Te)(dmpe)_2$ [2.637(2) Å] which was not listed in Version 5.11 of the CSD. See: Gerlach, C. P., Christou, V. and Arnold, J., *Inorg. Chem.* 1996, **35,** 2758.

[g] The value of 1.720[30] Å for Ta=O is different to that listed in the Cambridge Structural Database; it is the average value for two structure determinations of $Cp^*_2Ta(O)H$. See: Parkin, G., van Asselt, A., Leahy, D. J., Whinnery, L., Hua, N. G., Quan, R. W., Henling, L. M., Schaefer, W. P., Santarsiero, B. D. and Bercaw, J. E., *Inorg. Chem.* 1992, **31,** 82.

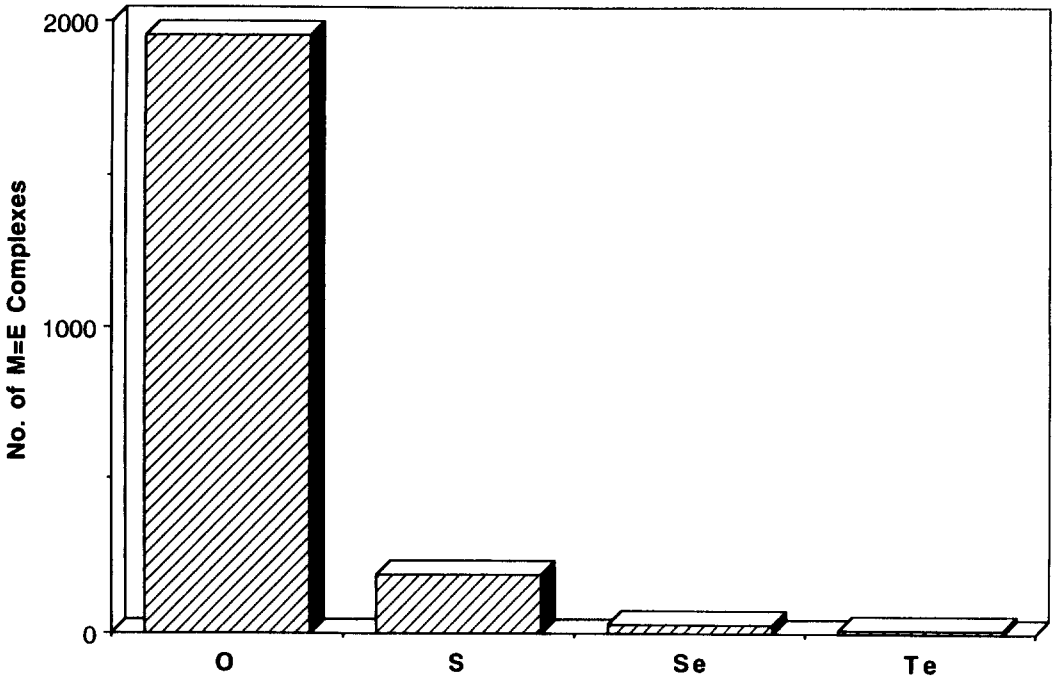

Fig. 1. Structurally characterized terminal chalcogenido complexes as a function of the chalcogen.

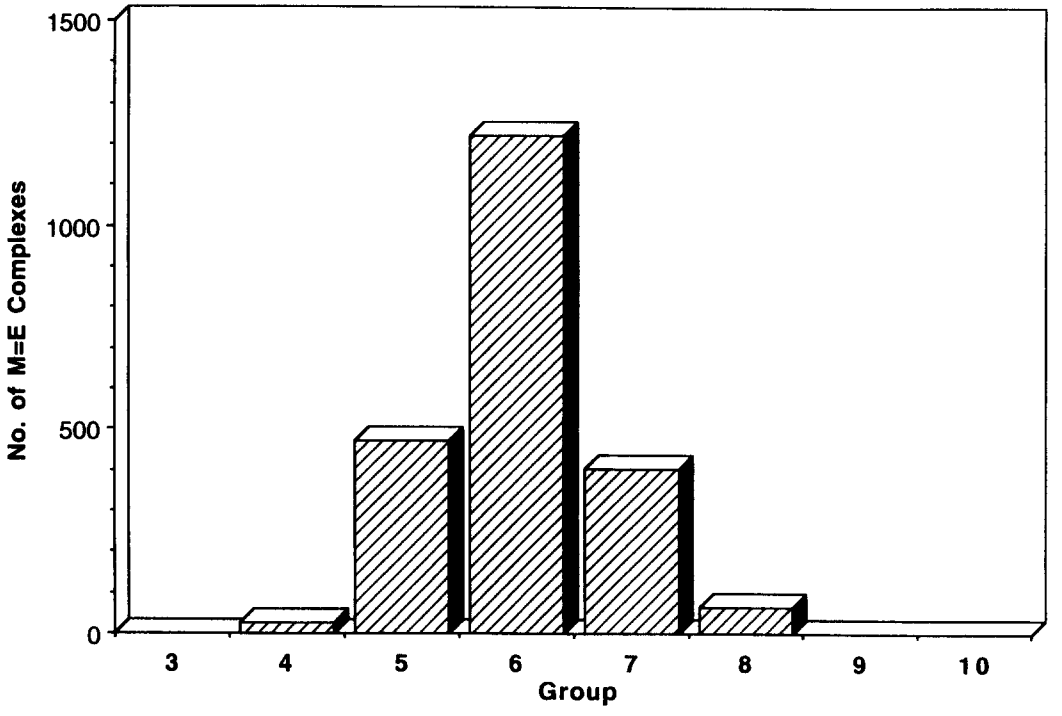

Fig. 2. Structurally characterized terminal chalcogenido complexes as a function of periodic group.

for each transition metal is illustrated in Fig. 4. Focusing attention on the Groups 5–7 metals, it is apparent that upon progressing from the first to the second to the third transition series, the peak in the distribution shifts from earlier to later transition metals. Thus, the element with the largest number of structurally characterized terminal chalcogenido complexes is vanadium (Group 5) in the first transition series, molybdenum (Group 6) in the second series, and rhenium (Group 7) in the third transition series. Not surprisingly, since metal–oxo complexes belong to the most common class of metal–ligand multiple bond, such a

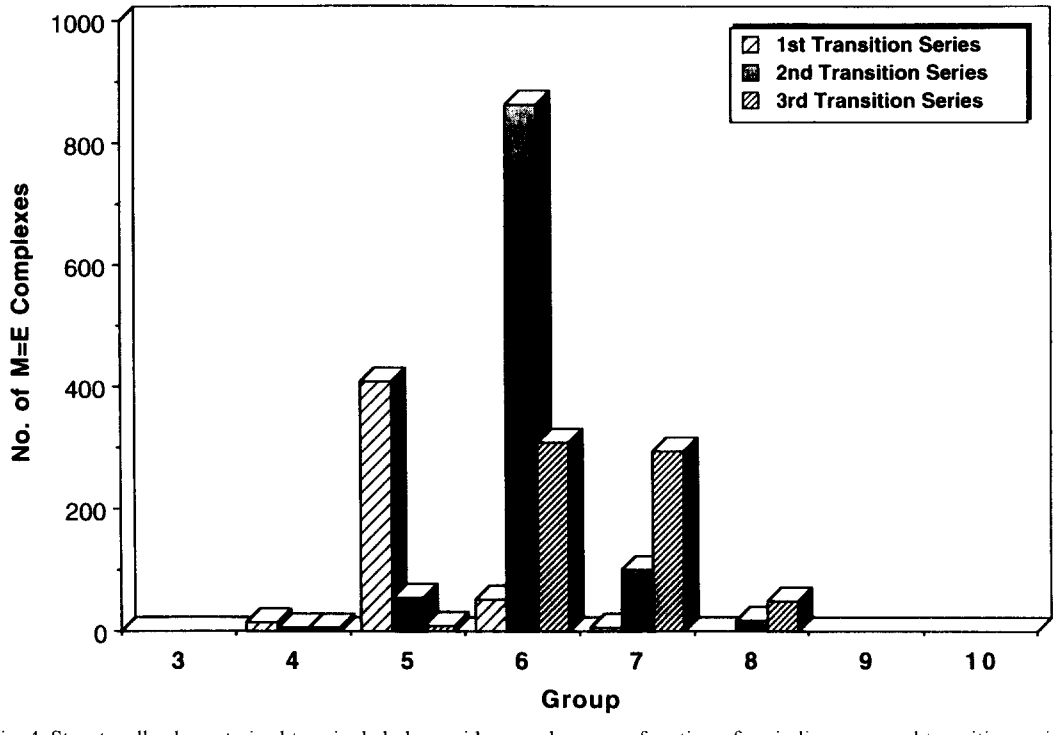

Fig. 4. Structurally characterized terminal chalcogenido complexes as a function of periodic group and transition series.

trend closely parallels that described for metal–ligand multiple bonds in general, for which the majority of complexes are concentrated on the vanadium–molybdenum–rhenium diagonal [1].

Finally, the distribution of terminal chalcogenido complexes for each individual transition metal as a function of the chalcogen is illustrated in Figs 5–8, with Fig. 8 emphasizing the distributions for com-

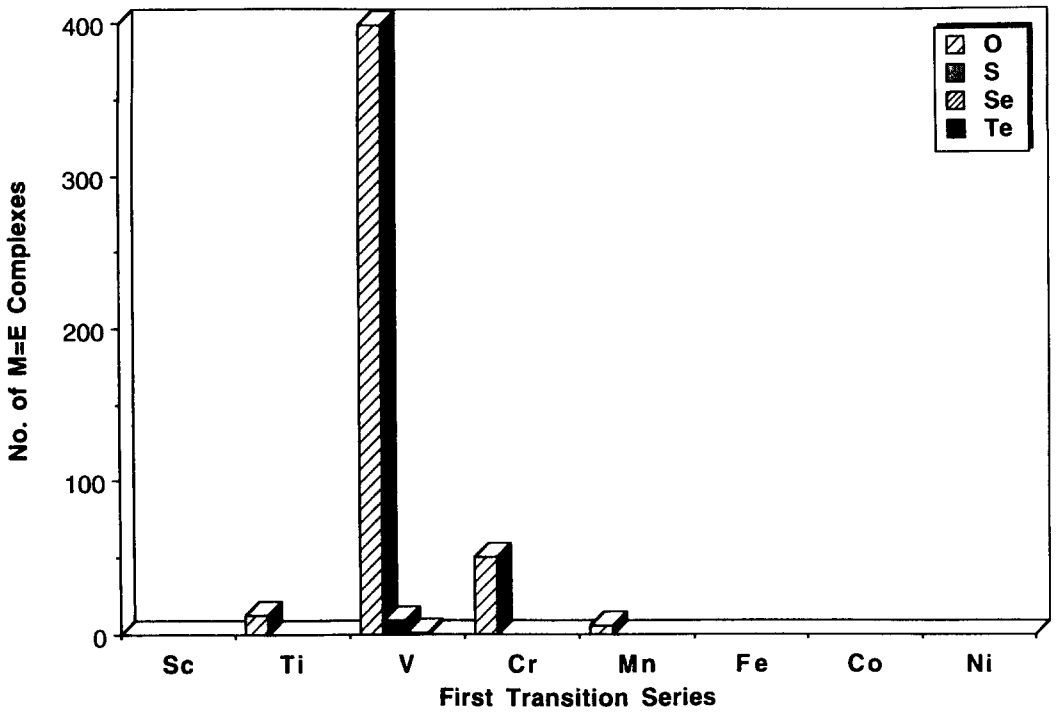

Fig. 5. Structurally characterized terminal chalcogenido complexes of the 1st transition series.

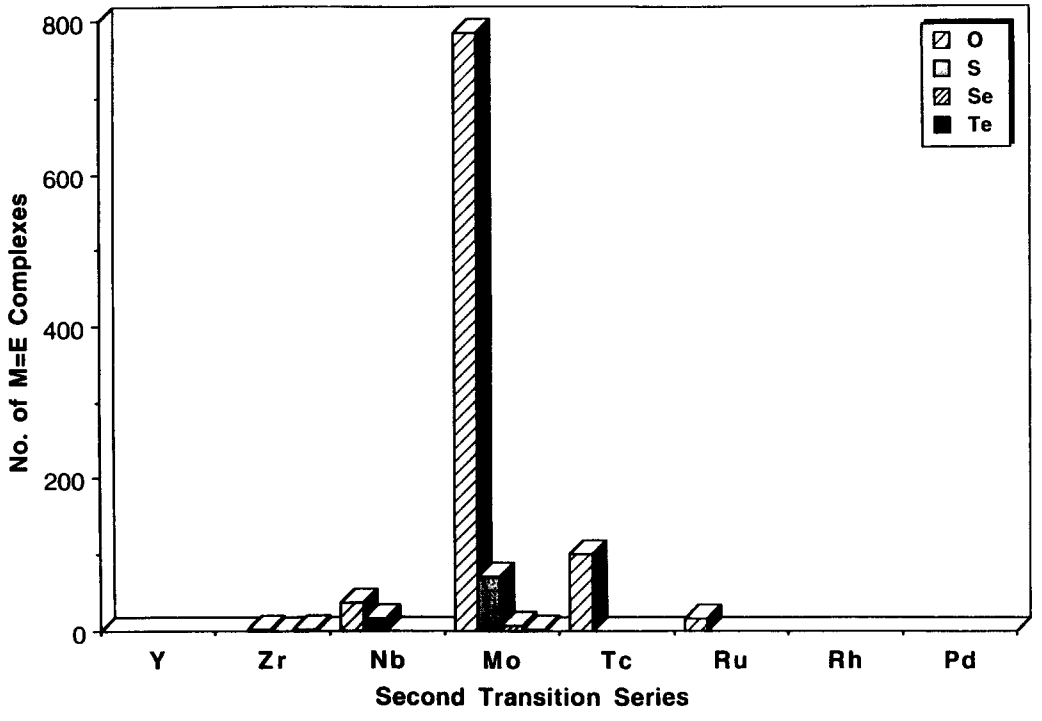

Fig. 6. Structurally characterized terminal chalcogenido complexes of the 2nd transition series.

plexes with low abundance. For each transition metal where a significant number (>20) of terminal chalcogenido complexes have been structurally characterized, the number of terminal oxo complexes outweighs that of the other derivatives, as would be expected from the trend shown in Fig. 1. Coupled with the fact that the occurrence of terminal chalcogenido complexes decreases rapidly with the early and late metals, it is no surprise that terminal selenido and tellurido complexes are particularly scarce for these

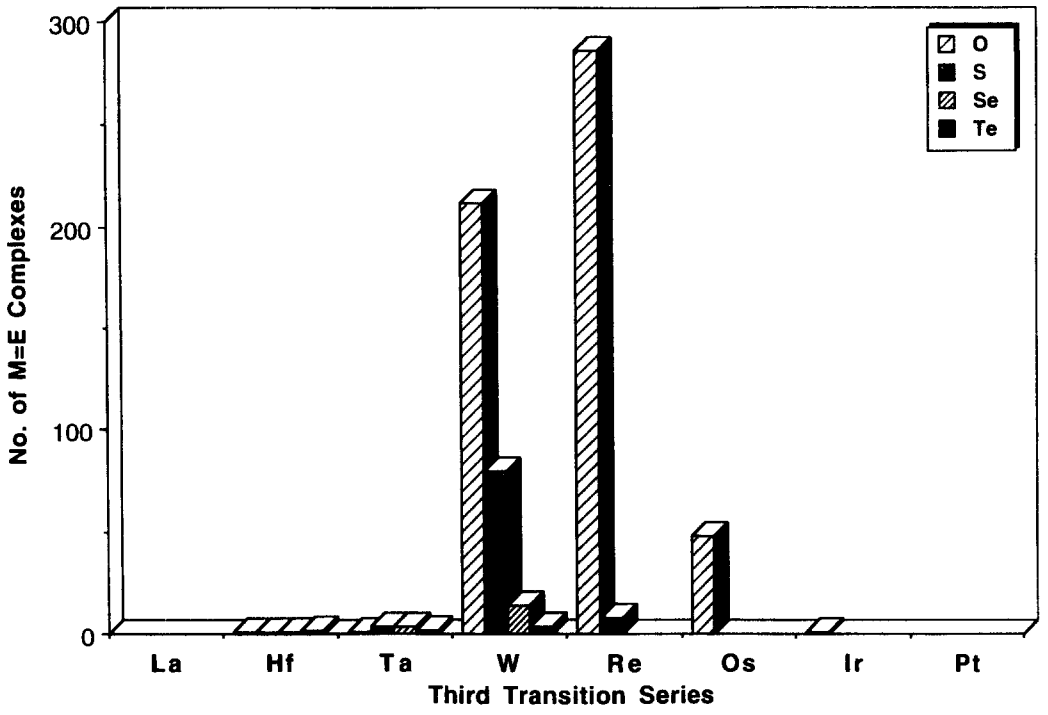

Fig. 7. Structurally characterized terminal chalcogenido complexes of the 3rd transition series.

elements. For example, we are not aware of any simple molecular terminal selenido or tellurido complexes of Cr, Mn, Tc, Re, Fe, Ru, Os and Ir, though each is known to form terminal oxo complexes. Consequently, the syntheses of terminal chalcogenido complexes at the extremes of these distributions represent a challenging goal for the synthetic chemist.

Variation of M=E bond lengths in terminal chalcogenido complexes

The distribution of M=E bond lengths for each of the transition metals has also been analyzed with the aid of the Cambridge Structural Database, and the mean d(M=E) bond lengths for all structurally characterized terminal chalcogenido complexes of the transition metals are summarized in Table 1 [17]. As an illustration, the bond length distributions for tungsten, one of the elements that forms terminal chalcogenido complexes with all of the chalcogens, are presented in Figs 9–11. Inspection of Figs 9 and 10 indicates that the distributions for W=O and W=S bond lengths are reasonably narrow, although there are clearly some outliers. For example, the average W=S bond length of 2.54(1) Å in $[W_4S_8(H_2NCH_2CH_2NH_2)_4]S$ [18] is approximately 0.4 Å longer than the mean (2.150 Å) of all terminal tungsten sulfido complexes (Fig. 10); furthermore, it is longer than the mean W—S single bond length (2.390 Å) of complexes listed in the Cambridge Structural Database [19]. In fact, the terminal sulfido bond length in $[W_4S_8(H_2NCH_2CH_2NH_2)_4]S$ is so long that it is comparable to the mean tungsten–tellurido bond length (2.546 Å). The anomalous W=S bond length in $[W_4S_8(H_2NCH_2CH_2NH_2)_4]S$ thus raises the issue of whether or not the complex actually contains a multiply bonded terminal sulfido ligand. Another example is provided by $Mo(dppe)_2(O)(S)$, with a Mo=S bond length of 2.415(7) Å [20], significantly longer than the mean value of 2.154 Å for all other terminal molybdenum–sulfido complexes. A possible explanation for the anomalous bond length was suggested [21] to be a consequence of the X-ray structure having been performed on a crystal of composition $(dppe)_2Mo(O)(S)\cdot SO_2\cdot H_2SO_4\cdot PhCH_3\cdot EtOH$ [20]; thus, in view of the proposed presence of H_2SO_4, it is possible that the sulfido ligand is actually protonated, i.e. $[(dppe)_2Mo(O)(SH)]^+$, so that the derived Mo—S bond length is that of a single bond, not that of a double bond [22]. Moreover, the anomalous Mo=O bond lengths for the *cis-mer*-$MoOCl_2(PR_3)_3$ complexes listed in Mayer's review [4,23], so-called "distortional" or "bond-stretch" isomers [24,25], are now recognized to be an artifact due to compositional disorder [26]. Thus, in the instances where a substantial body of data is available, it is prudent to scrutinize bond lengths that deviate significantly from the mean, for the true interpretation (e.g. correct atom/ligand assignment or problems with contamination) may not be so straightforward.

Mayer has previously noted that M=O bond lengths are generally insensitive to both coordination

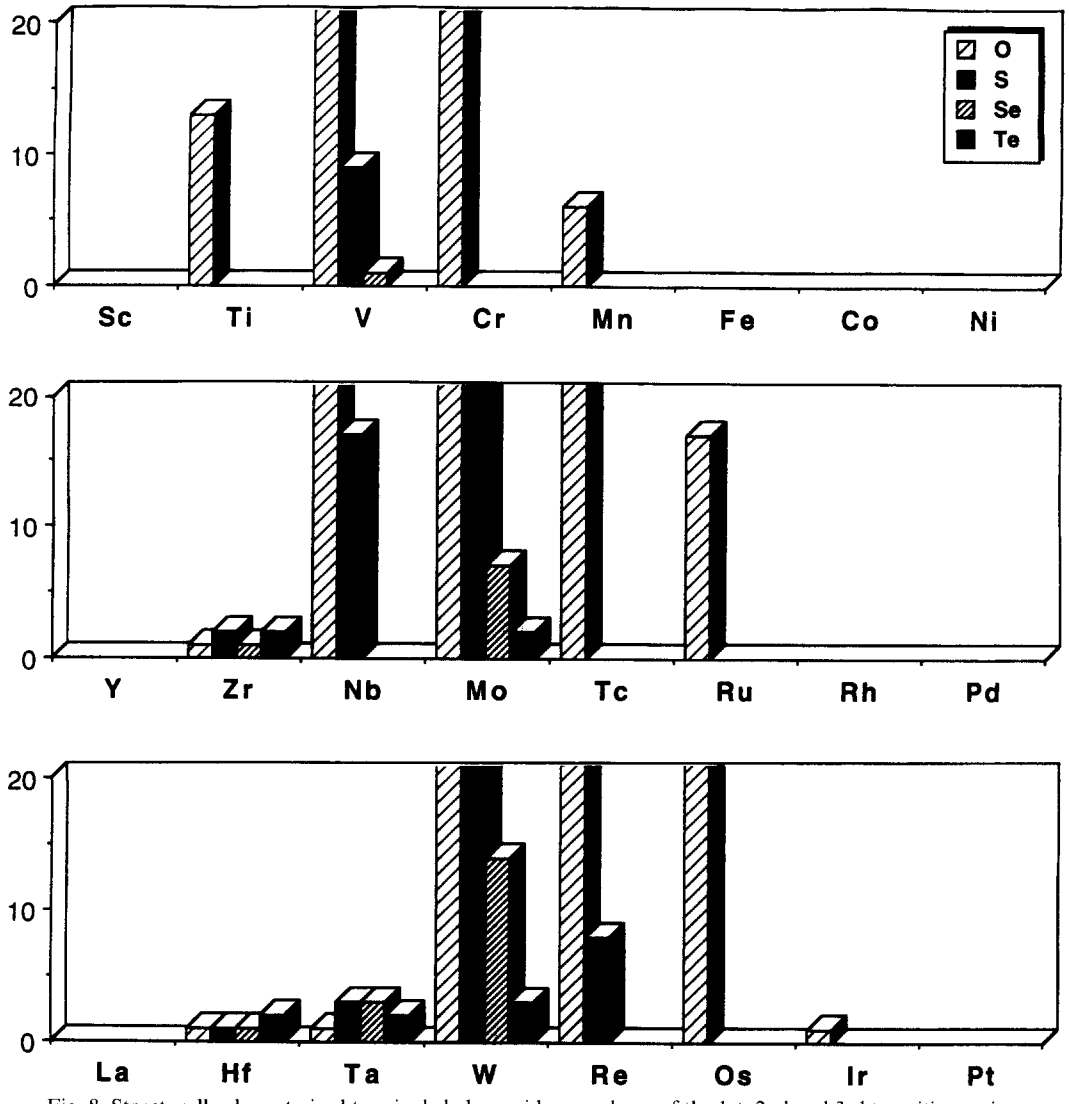

Fig. 8. Structurally characterized terminal chalcogenido complexes of the 1st, 2nd and 3rd transition series.

number and oxidation state of the metal [4,27]. Nevertheless, for a closely related series of complexes, the M=E bond length would be expected to correlate with bond order, which may vary between one and three, as illustrated by the resonance structures:

$$\overset{+}{M}\text{—}\overset{-}{E} \leftrightarrow M{=}E \leftrightarrow \overset{-}{M}{\equiv}\overset{+}{E}$$

Such a trend is aptly illustrated for the tungsten sulfido and selenido complexes listed in Table 2 [28]. Thus, a progressive decrease in bond length is observed as the formal bond order increases from 2 in the 18-electron complexes $W(PMe_3)_2(L)_2(E)_2$ and $W(PMe_4)_4(Se)H_2$, to 2.5 in the "16"-electron complexes $W(PMe_3)_2(E)_2(\eta^2\text{-OCHR})$, and to 3 in the "12"-electron complexes $W(E)X_4$ (E = S, Se; X = F, Cl, Br). Likewise, Mayer has rationalized that the long ruthenium–oxo bond lengths in d^4 octahedral ruthenium–oxo complexes is a consequence of reduced bond order [4]. Specifically, rather than possessing a $\overset{-}{Ru}{\equiv}\overset{+}{O}$ triple bond, the formal ruthenium–oxo bond order is restricted to 2 in 18-electron d^4 octahedral complexes of the type $[Ru(O)L_4X]^+$ [29], owing to the occupation of metal–oxygen π^* orbitals. Thus, such complexes exhibit ruthenium–oxo bond lengths at the long end of the distribution illustrated in Fig. 12. Further variations in M=E bond length are described in the following sections as a function of both the chalcogen and transition metal.

Variation in M=E bond length as a function of the chalcogen. Examination of Table 1 reveals that only five of the transition elements (Zr, Hf, Ta, Mo and W) are known to form terminal chalcogenido complexes with all of the non-radioactive chalcogens. The variation in mean M=E bond length for each of these transition metals is represented graphically in Fig. 13, which, for comparison, also includes the variation of the double bond covalent radii of the chalcogens. Thus, the change in M=E bond length as a function

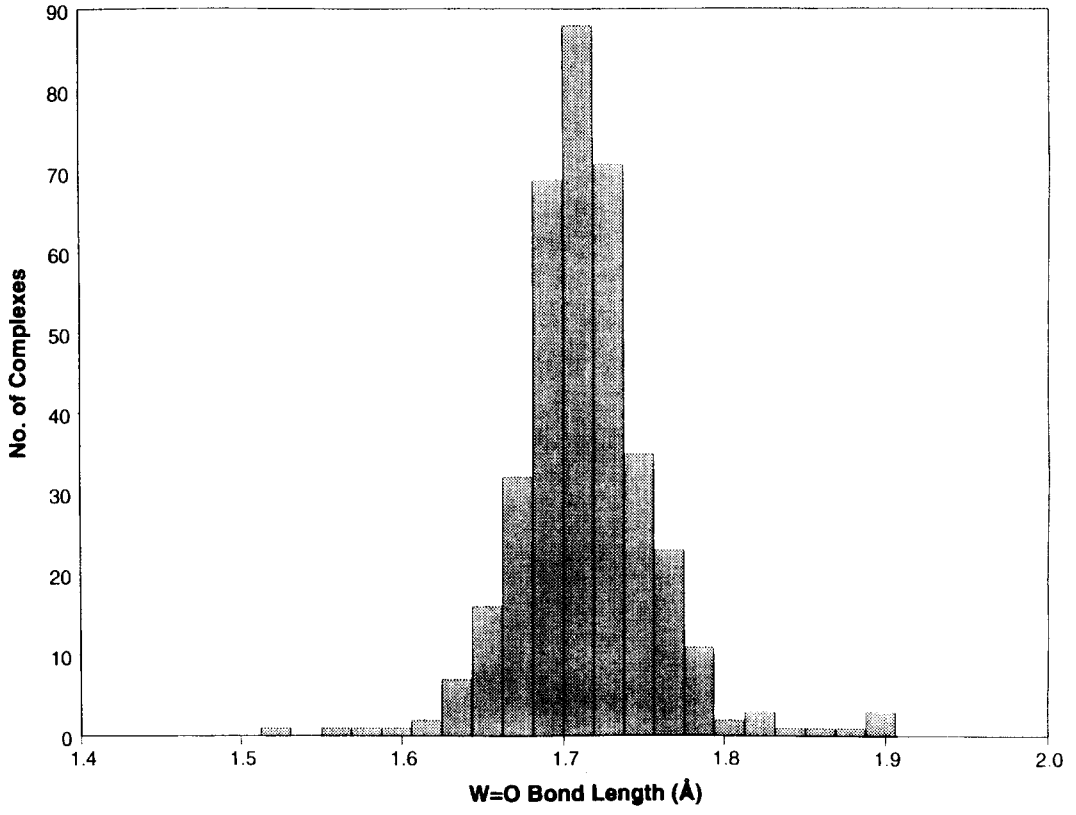

Fig. 9. Distribution of W=O bond lengths in tungsten–oxo complexes.

Table 2. Variation of W=E bond length with bond order

	Bond order	S	Se	Ref.
$W(PMe_3)_4(E)H_2$	2		2.445(2)	28
$W(PMe_3)_4(E)_2$	2	2.253[3]	2.380[1]	28
$W(PMe_3)_2(CNBu^t)_2(E)_2$	2	2.248(2)	2.375(2)	28
$W(PMe_3)_2(E)_2(\eta^2\text{-OCHPh})$	2.5	2.186[2]	2.317[4]	28
$W(E)F_4$	3	2.104(7)	2.226(7)	35
$W(E)Cl_4$	3	2.086(6)	2.203(4)	35
$W(E)Br_4$	3	2.109(11)	2.220(22)	35

of the chalcogen is similar for each of the transition metals and correlates reasonably well with the change in double bond covalent radii. However, upon closer inspection of the data summarized in Table 3 and Fig. 14, it is evident that the difference in M=O and M=Te bond lengths for a given transition metal (0.83–0.89 Å) is consistently greater than the difference in double bond covalent radii of oxygen and tellurium (0.72 Å). For the case of zirconium, the discrepancy has been attributed to the particularly large increase of 0.52 Å in bond length between the oxo and sulfido derivatives, compared with the difference of 0.39 Å in covalent radii of oxygen and sulfur [30]. In comparison, the increments in bond lengths between the sulfido, selenido and tellurido derivatives are close to those predicted by the differences in covalent radii of the chalcogens. Thus, the metal–oxo bond lengths are anomalously short, an observation that has been rationalized in terms of the resonance structure [Zr—O] for $(\eta^5\text{-}C_5Me_4Et)_2Zr(O)(NC_5H_5)$ [30], with bond shortening attributed to an ionic component [31]. Since the heavier chalcogens are both less electronegative and larger than oxygen, the corresponding zirconium–chalcogenido interactions would be subject to less ionic shortening,

Cundari has recently carried out computational

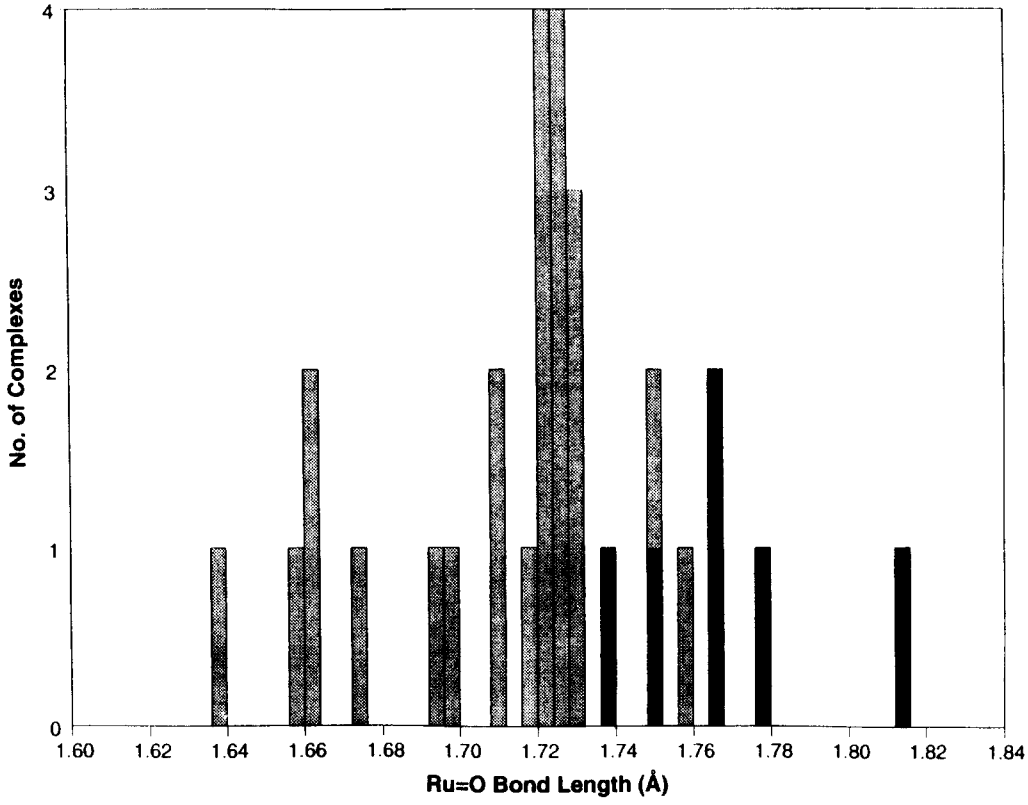

Fig. 12. Distribution of Ru=O bond lengths in ruthenium–oxo complexes, with the solid bars representing d^4 complexes.

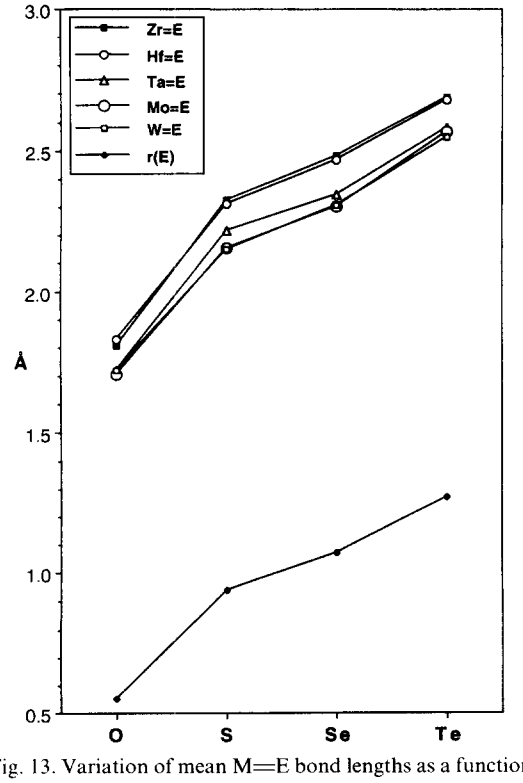

Fig. 13. Variation of mean M=E bond lengths as a function of the chalcogen.

studies on a comprehensive series of terminal chalcogenido complexes [32]. Significantly, the computational results are in excellent agreement with the experimental data. For example, computational studies on the hypothetical species $[Cp_2Zr{=}E]$ (E=O, S, Se, Te) demonstrated that, compared with the other derivatives, the oxo species shows a significant contribution from a singly bonded Zr—O structure, with the π bonds localized on the oxo ligand. Such a result is consistent with the proposed resonance structure $[\overset{+}{Z}r{-}\overset{-}{O}]$ for the zirconium–oxo complex $(\eta^5\text{-}C_5Me_4Et)_2Zr(O)(NC_5H_5)$ [30]. Furthermore, Cundari's calculations also predict the trend in which the difference in metal–oxo and metal–sulfido bond lengths decreases in going from the Group 4 to Group 6 transition metals (see Table 3 and Fig. 14). However, in view of the errors inherently associated with measuring the differences in mean bond lengths for limited datasets, further structural studies are warranted to establish the generality of these apparent trends.

Variation in M=E bond length as a function of the metal. In view of the paucity of heavier terminal chalcogenido complexes for all of the transition metals, it is only possible to illustrate the variation in M=E bond length as a function of the metal for the oxo derivatives. Thus, the variation of M=O bond lengths is shown in Fig. 15, which also includes the metallic radii of the transition metals [33] for purposes of comparison. Figure 15 also includes data for Zr, Hf and

Table 3. Comparison of M=E bond length increments with respect to the M=O derivative

	r_{db}(E)/Å[a]	$[r_{db}(E)-r_{db}(O)]$/Å	d(M=E) − d(M=O)/Å[b]				
			Zr	Hf	Ta	Mo	W
O	0.55	0	0	0	0	0	0
S	0.94	0.39	0.52	0.49	0.50	0.45	0.43
Se	1.07	0.52	0.67	0.64	0.62	0.60	0.59
Te	1.27	0.72	0.89	0.85	0.86	0.86	0.83

[a] r_{db}(E) is the double bond covalent radii of the chalcogens. Data taken from Pauling, L., *The Nature of the Chemical Bond*, 3rd edn. Cornell University Press, Ithaca, 1960, p. 224, with the exception of r_{db}(O) which was taken from Jolly, W. L., *Modern Inorganic Chemistry*, McGraw-Hill, New York, 1984, p. 53.

[b] See Table 1 for individual d(M=E) values.

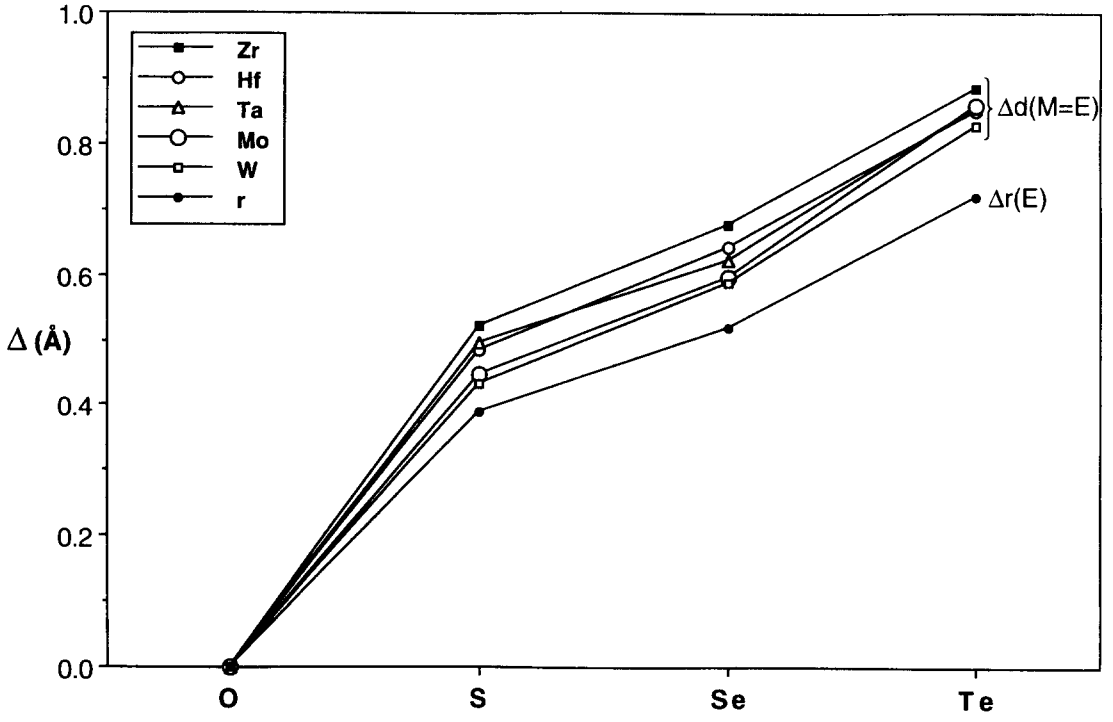

Fig. 14. Incremental changes relative to oxygen of (i) d(M=E) and (ii) r_{db}(E). Δd(M=E) = d(M=E) − d(M=O); Δr(E) = r_{db}(E) − r_{db}(O).

Ir which were not known to form terminal oxo complexes prior to 1988 when the last review on this topic was published [4]. Overall, there is a general decrease in mean M=O bond length upon crossing a period, with the largest incremental change for the earlier metals. With the exception of Mn and Fe (for which the available data is minimal), such a trend correlates reasonably well with the variation in covalent radii of the transition metals.

CONCLUDING REMARKS

The present paper has attempted to provide an account of the distribution of terminal chalcogenido complexes of the transition metals. Thus, at present, the majority of such complexes are oxo derivatives along the vanadium–molybdenum–rhenium diagonal. Particularly rare are terminal chalcogenido derivatives of the early and late transition metals, while terminal tellurido complexes are scarce for all the transition metals. While it would not be wise to correlate the distribution of terminal chalcogenido complexes with their stability in an absolute sense, it seems reasonable to consider that their distribution may indeed be a reflection of their intrinsic reactivity. For example, the zirconium–oxo complex $Cp^*_2Zr(O)(NC_5H_5)$ has been shown to be highly reactive, even with substrates such as H_2 [6]. Likewise, the terminal tellurido complex $W(PMe_3)_4(Te)_2$ exhibits a reductive coupling reaction with Bu^tNC to give the ditellurido complex

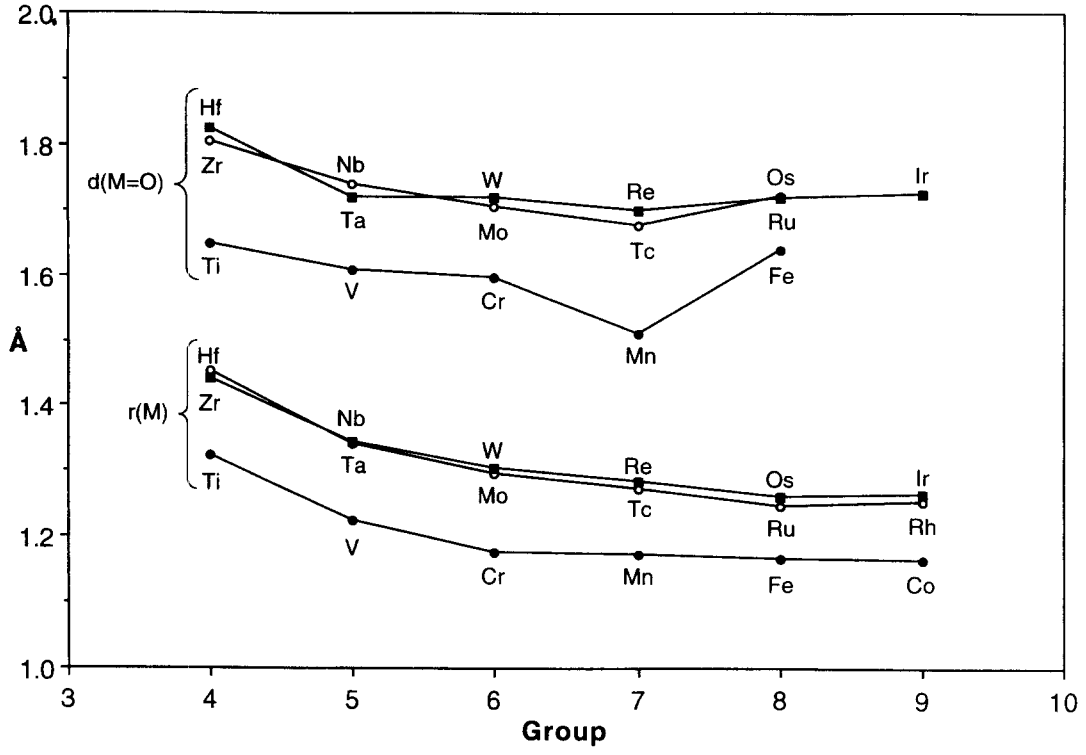

Fig. 15. Variation of mean M=O bond lengths as a function of the metal.

$W(PMe_3)(CNBu^t)_4(\eta^2\text{-}Te_2)$, a reaction that is unprecedented for the sulfido and selenido analogues [28]. Interestingly, both $Cp^*_2Zr(O)(NC_5H_5)$ and $W(PMe_3)_4(Te)_2$ represent classes of molecules (terminal zirconium–oxo and terminal–tellurido complexes) that were not known in 1988, when the classic text *Metal–Ligand Multiple Bonds* by Nugent and Mayer was published [1]. It is, therefore, likely that the most exciting future developments in the chemistry of terminal chalcogenido complexes will derive from the syntheses of presently unknown functionalities ranging from Sc=O to Ir=Te.

2. There is some controversy as to whether or not oxygen should be considered a chalcogen. The term chalcogen appears to have developed directly from the words "chalkosphäre" and "chalkophile", coined in the earlier part of this century by Goldschmidt, a geochemist [2a,b]. Goldschmidt used "chalkosphäre" to describe a region of the earth that is rich in metal oxides and sulfides, i.e. ores, while "chalkophile" was used to describe elements found in this region (e.g. Fe, Cu, Zn). Since these names derived from the Greek word "chalkos" (χαλκοσ) meaning copper, a literal translation of chalcogen is "copper-former". However, Jensen has rationalized that since "chalkos" may also be interpreted as copper alloy or ore, and since copper is not the only element considered to be a "chalkophile", a more pertinent interpretation of the term chalcogen is "ore-former" [2c]. Consequently, oxygen is appropriately considered to be a chalcogen, a term that has, in fact, been approved by IUPAC as the collective name for the group 16 elements: O, S, Se, Te, Po [2d]. 3. For example, only the first three members of the pnictogens are known to form isolable complexes with multiple bonds to transition metals, with $Bu^t_3SiO)_3Ta = EPh$ (E = N, P, As) being the first series of such complexes [3a]. The terminal stibido complexes, $[(CO)_4M{\equiv}Sb]^-$ (M = Cr, Mo, W) and $[(CO)_3Fe{\equiv}Sb]^-$, however, have been generated in the gas phase [3b]. (a) Bonanno, J. B., Wolczanski, P. 16. A crude estimate of the relative number of studies on elements of the second and third transition series may be obtained by examining the number of papers that cite these elements themselves either in the title or abstract. For example, using the names of the elements as keywords, there are *ca* 25% more listings in the Science Citation Index (1982–1996) for the elements of the second transition series than for the third transition series.
17. As described in the text, the metal–chalcogenido interactions are a composite of three resonance structures with formal single $[\overset{+}{M}—\overset{-}{E}]$, double $[\overset{-}{M}=\overset{+}{E}]$, and triple $[\overset{-}{M}\equiv\overset{+}{E}]$ bonds. For simplicity, however, in this paper we use the representation [M=E] to refer generally to any terminal chalcogenido moiety, regardless of bond order.

Spectrophotometry and voltammetry of cobalt triethanolamine complexes in aqueous solutions in the absence and presence of oxygen

Sophia Teller,[a] Yizhak Marcus[a]* and Yaakov Tur'Yan[b]

[a]Department of Inorganic and Analytical Chemistry, The Hebrew University of Jerusalem, Jerusalem 91904, Israel

(Received 3 April 1996; accepted 12 August 1996)

Abstract—The absorption spectra of solutions of Co^{II} and Co^{III} in the presence of triethanolamine (TEA) are reported. For the former complexes there is no evidence for chelation, but a bischelate is formed with the latter. Saturation of Co^{II}–TEA solutions with oxygen yields more than one new, dioxygen-containing, species that age slowly. The oxygen may be partly removed by bubbling nitrogen through the solutions. The electroreduction of cobalt–triethanolamine complexes in aqueous solutions in the presence of oxygen was followed voltammetrically on a stationary Pt disk electrode. Strong catalytic enhancement of the electroreduction current of oxygen involved with the complex was achieved. A mechanism for the formation of the electrochemically active species, involving OH- and O_2-bridged dimeric species of both Co^{II} and Co^{III}, was suggested. A pseudo first order was established for the reversible reaction of this complex formation. Relevant rate and equilibrium constants were obtained. Copyright © 1997 Elsevier Science Ltd

Keywords: oxygen; cobalt(II); cobalt(III); triethanolamine; spectra; electroreduction.

Complexed cobalt ions are known to catalyse the electroreduction of oxygen in aqueous solutions by forming coordination species with dioxygen. Most studies have been made with amine chelating ligands containing at least two nitrogen atoms (except for complexes with ammonia) forming well-characterized chelates [1, 2]. The formation, stability, properties and structure of the μ-peroxo and μ-superoxo complexes formed by such chelates with dioxygen have been reviewed [3–5]. Triethanolamine (TEA) as a ligand is an exception to this generalization, apparently not forming chelates (see below), although it permits well-catalysed electroreduction of oxygen, as is described in this paper. On the whole, aminoalcohol complexes of transition metals have not been studied extensively [6–9], in spite of the potential technological applications [7,8]. For instance, the catalase activity of cobalt–TEA complexes for the decomposition of hydrogen peroxide is higher than for some other cobalt–amine systems. The relative values are 50 for monoethanolamine, 140 for diethanolamine, 23–489 for ethylenediamine, 29–3350 for ammonia and as high as 24560 for TEA [10]. This is a result of coordination sites at the cobalt atom not being occupied by the TEA and available for the H_2O_2. TEA is, in a sense, unique among amine ligands in that, although it is potentially quadridentate (one N and three O donor atoms), it is reluctant to form chelates with metal ions in aqueous solutions, as is manifested by the known stability constants [6, 9] for complexes with TEA. For cobalt(II) ions this is illustrated by the following values of $\log K_1$ of the tripodant complexes with nitrilotriacetate (NTA) [11], $N(CH_2CO_2^-)_3$: 10.4, tris(2-aminoethyl)amine (tren) [12], $N(CH_2CH_2NH_2)_3$: 12.4, and triethanolamine (TEA) [13], $N(CH_2CH_2OH)_3$: 2.3.

The single species $CoTEA^{2+}$, with a stability constant $\log K_1 = 1.73$, was suggested [14] in a 0.5 M KNO_3 medium, whereas two species: $CoTEA^{2+}$, $\log K_1 = 2.70$, and $CoTEA_2^{2+}$, $\log K_2 = 1.65$ in a 0.43 M ethanolammonium nitrate medium were reported

* Author to whom correspondence should be addressed.

[15], in both cases at 25°C. The latter work appears to overestimate the tendency of Co^{II} to complex with triethanolamine, in view of the much lower $\bar{n}$ (mean ligand number) shown by this metal ion compared with that of, for example, Ni^{II}, with $\log K_1 \approx 2.9$ [6]. A more recent study [13] again reports only a single complex, $CoTEA^{2+}$ with $\log K_1 = 2.25$ in a 0.1 m $NaNO_3$ medium at 25°C.

An important feature of the chemistry of cobalt(II) ions in solution is their ready oxidation by molecular oxygen in the presence of a variety of complexing ligands, in particular those with hydrogen donor atoms. Owing to the instability of intermediates, the action of oxygen normally yields a binuclear peroxo species of cobalt(III) [1,2], but the initial step may well involve coordination of O_2 [3–5]. The activation of oxygen by transition metal complexes proceeds by the coordination interaction alone, without the need for external energy.

Whereas the spectra of the Ni^{II}–TEA species have been reported [6], this is not the case for the Co^{II} species, nor of the Co^{III} one. The octahedral hexaaquocobalt(II) ions, $Co(H_2O)_6^{2+}$, with cubic symmetry, have the ^4F level split into three, with the lowest one degenerate, $^4T_1$ ($t_{2g}^6 e_g^1$). The resulting weak bands peak at *ca* 1250 nm (*ca* 8000 cm^{-1}, $^4\Gamma_5$), 880 nm (11,300 cm^{-1}, $^2\Gamma_3$) and 625 nm (16,000 cm^{-1}, $^4\Gamma_3$), with $\varepsilon \leqslant 0.2$ M^{-1} cm^{-1}, whereas the stronger, still Laporte-forbidden bands, peak at 514 nm (19,400 cm^{-1}, $^4\Gamma_4$), $\varepsilon = 4.55$ M^{-1} cm^{-1}, and at 464 nm (21,550 cm^{-1}, $^4\Gamma_4$), $\varepsilon = 2.6$ M^{-1} cm^{-1} [16,17]. Nominally, octahedral cobalt(II) species with symmetry lower than a perfect cubic have enhanced absorptivities, as is the case, for instance, in ethanolic solutions [18] and as is shown here in aqueous TEA solutions. Replacement of the six oxygen donor atoms of the hexaaquocobalt(II) ion with six nitrogen atoms, as in the hexaamino or trisethylenediamino complexes leads to shifts of the main peaks to the red, as well as enhancement of the absorptivities [18].

The hexaaquocobalt(III) ion is unstable in aqueous solutions, oxidizing the solvent ($E^\circ[Co^{III}Co^{II}] = 1.841$ V at −5°C in a 6.5 M $NaClO_4$ medium [19], $E^\circ[Co^{III}Co^{II}] = 1.93 \pm 0.03$ V at 25°C) [20]. Still, the low-spin $Co(H_2O)_6^{3+}$ ion can be found in crystals of $CsCo(SO_4)_2 \cdot 12H_2O$ [20,21], and has been assigned two bands, peaking at 606 nm (16,500 cm^{-1}, $^1\Gamma_4$) and 405 nm (24,700 cm^{-1}, $^1\Gamma_5$) [17, 21]. Cobalt(III) in aqueous solutions is stabilized by complexation and the hexaamino and trisethylenediamino complexes, among others, have been well characterized. There are strong shifts to the blue, with $Co(en)_3^{3+}$ having peaks at 467 nm (21,400 cm^{-1}, $^1\Gamma_4$), $\varepsilon = 86$ M^{-1} cm^{-1}, and 338 nm (29,600 cm^{-1}, $^1\Gamma_5$), $\varepsilon = 80$ M^{-1} cm^{-1}, as well as a low intensity band at 730 nm (13,700 cm^{-1}, $^3\Gamma_4$), $\varepsilon = 0.3$ M^{-1} cm^{-1} [22].

The present paper examines the electrochemical and spectrophotometric behaviour of cobalt ions in solutions containing triethanolamine in the absence of oxygen and in its presence. In the former case only Co^{II} species are found, whereas in the latter both these (with coordinated oxygen) and Co^{III} species (again with coordinated oxygen) are found. Species responsible for the observed spectra and kinetics of reduction are suggested. The considerable enhancement of the rate of electroreduction of oxygen in these solutions at an inert cathode can be employed both as an analytical tool for oxygen in water and for fuel cells, where the cathode reaction is often rate limiting.

RESULTS

A solution containing 0.05 M cobalt(II) and 1.0 M TEA shows a much enhanced absorptivity relative to the hexaaquocobalt(II) species (Fig. 1), with the maxima shifted towards the red. The spectrum can be resolved into three bands with maxima ($\bar{\nu}/cm^{-1}$, ε/M^{-1} cm^{-1}) at 464 (21,550, 10.2), 534 (18,730, 21.8) and 555 nm (18,020, 2.5). At the concentrations employed and with the reported stability constants [13, 14], practically all the Co^{II} is converted to the monoligated complex. Its non-symmetrical structure explains the enhancement with respect to the spectrum of $Co(H_2O)_6^{+2}$, and the presence of one nitrogen donor atom instead of oxygen explains the red shift.

The absorption spectrum of a solution containing 0.05 M cobalt(III), obtained by anodic oxidation in 1.0 M TEA, 3.0 M sodium nitrate and in the absence of oxygen, is shown in Fig. 2. It has two main absorption peaks ($\bar{\nu}/cm^{-1}$, ε/M^{-1} cm^{-1}), at 348 (28,740, 68) and 527 nm (18,980, 27) and these are compared with those of $Co(H_2O)_6^{3+}$ and $Co(en)_3^{3+}$. The positions of the absorption maxima of the hexaaquocobalt(III) cations are indicated, but the molar absorptivity has not been reported [21, 23]. A blue shift of the two main peaks of the TEA-complexed cobalt(III) with respect of the hexaaquo ion is noted, but not as far as the shift of the trisethylenediamino complex [22]. The peak of the TEA complex of cobalt(III) at 527 nm, however, is sufficiently close to the position of the peak of the TEA–cobalt(II) complex, 534 nm, so that from the spectrum alone it is impossible to conclude that the anodic oxidation was complete. Polarographic reduction data [24] on the solution, see below, lend support to the observed peak in Fig. 2 at 527 nm being a result of the cobalt(III)–TEA complex. There is also some light absorption in the 730 nm region in the cobalt(III)–TEA solutions, which is some 5–10 times larger than in the tris-ethylenediamino complex, but the molar absorptivity could not be determined accurately owing to its low value, so it is not shown in Fig. 2.

When oxygen was bubbled through solutions containing cobalt(II) and TEA, absorption spectra were obtained similar in some respects to that of cobalt(III) complexed by TEA, but differing in others; typical spectra are shown in Fig. 3. The spectra evolved with time (up to a few days), depended on the pH of the solution and obeyed Beer's law only up to *ca* 0.1 M

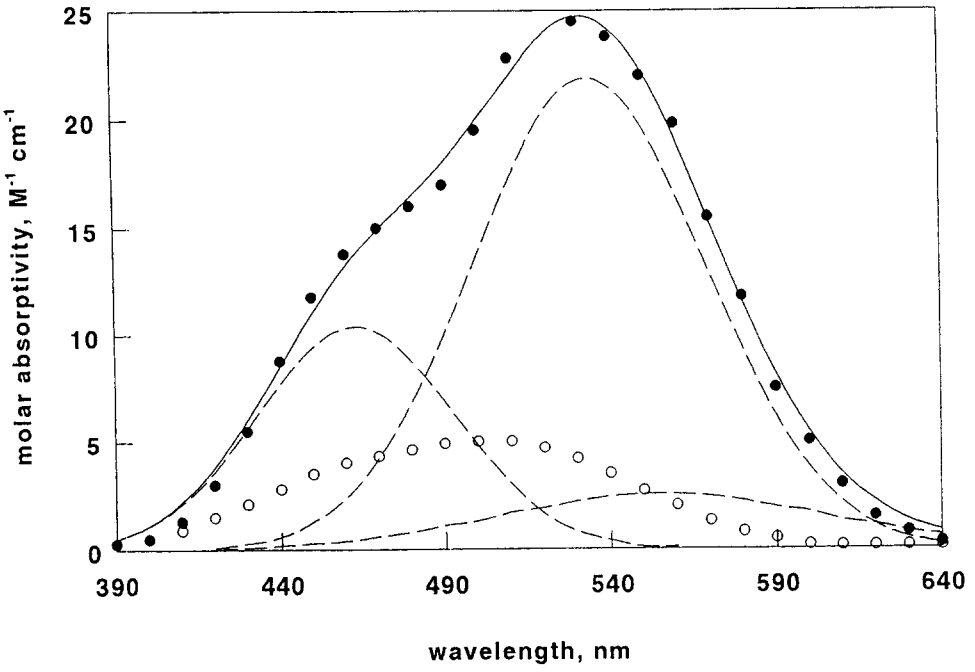

Fig. 1. The absorption spectra of cobalt(II) solutions: —, the observed $CoTEA(H_2O)_x^{2+}$ spectrum; ---, the component bands of this complex; ●, the spectrum calculated from these bands; ○, $Co(H_2O)_6^{2+}$ [11].

The absorption spectra of cobalt(III) solutions: —, the observed $CoTEA(H_2O)_x^{3+}$ spectrum; ———, the spectrum of $Co(en)_3^{3+}$ [17], the absorptivity of the long wavelength part (630–800 nm) having been magnified a hundred fold; ---, the reflectance spectrum of $Co(H_2O)_6^{3+}$ in crystalline $CsCo(SO_4)_2 \cdot 12H_2O$ (arbitrary absorptivities) [21].

cobalt salt (in 1 M TEA) immediately after the preparation of the solution. After *ca* 1 h, however, Beer's law was obeyed up to 0.2 M cobalt, and only when the concentration was increased to 0.5 M (so that there were only 2 TEA molecules per cobalt ion) was there a sharp break in the curve (Fig. 4).

at pH ≈ 9.5 showed a shoulder ($\bar{\nu}/cm^{-1}$, $\varepsilon/M^{-1}\,cm^{-1}$) at 333 nm (30,030, 68), and peaks at 353 (28,330, 83), 460 (21,740, 23), 525 (19,050, 52) and 717 nm (13,950, 21). Ageing of the solutions for 48 h caused a slight (0.2 units) decrease in pH when 0.5 M TEA was the ligand, no change at 1.0 M, and a slight increase in pH (0.2 units) with 2.0 M ligand. The spectra, however, were quite similar.

At pH ≥ 10, however, a band ($\bar{\nu}/cm^{-1}$, $\varepsilon/M^{-1}\,cm^{-1}$) at 267 (37,450, 83) grows in, the 333 nm shoulder becomes a band at 323 (30,960, 165) which shifts with time (within the first 30 min) to 351 nm (28,490 cm^{-1})

and increases in intensity, to $\varepsilon = 250\ M^{-1}\ cm^{-1}$. The 525 and 717 nm bands do not increase in intensity appreciably with time. The 460 nm band, however, is not observed at pH > 10. Further ageing of the solutions, after bubbling of oxygen was discontinued, caused further increases in the intensity of the 320–350 nm bands. If nitrogen is bubbled through the solutions the peak heights decrease appreciably, although the spectrum does not revert to that of Co^{II} in TEA.

Preliminary studies showed that the optimal composition of the solutions for the electroreduction of the cobalt/oxygen was 0.8–1.2 mol dm^{-3} TEA at pH of 9.5–12. In such solutions the catalytic effect for the oxygen electroreduction was most pronounced.

The electroreduction polarization curve of molecular oxygen in the absence of cobalt ions was measured in aerated aqueous 1 mol dm^{-3} TEA + 3 mol dm^{-3} $NaNO_3$ (Fig. 5, curve 2). The limiting current was 1.7 times lower than the corresponding current in aerated aqueous 0.1 mol dm^{-3} KCl (Fig. 5, curve 1), owing to the salting-out effect of the concentrated $NaNO_3$. In the absence of oxygen, in an inert atmosphere (N_2), the current was further decreased (Fig. 5, curve 3). In such freshly prepared, oxygen-free solutions the electroreduction current did not depend on the cobalt(II) concentration in the range 0.002–0.1 mol dm^{-3} (Fig. 5, curve 3). This means that the cobalt(II) triethanolamine complexes are not electroreduced in the given potential range.

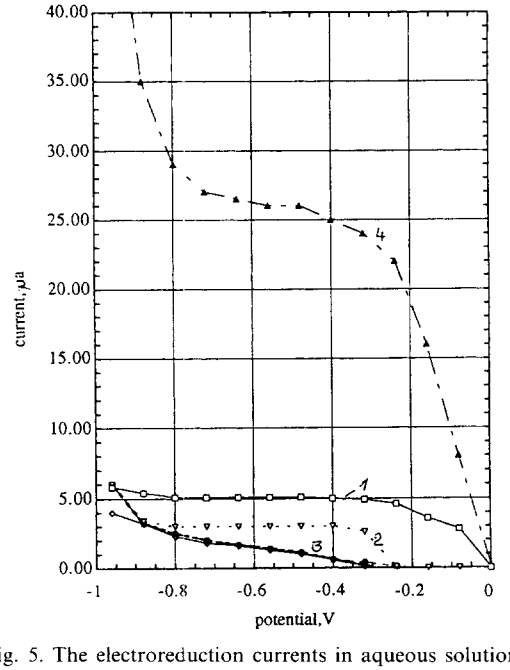

Fig. 5. The electroreduction currents in aqueous solutions containing: (1) 0.1 mol dm^{-3} KCl; (2) 1.0 mol dm^{-3} TEA + 3.0 mol dm^{-3} $NaNO_3$; (3) de-aerated (by N_2) 1.0 mol dm^{-3} TEA + 3.0 mol dm^{-3} $NaNO_3$ without and with 0.002 to 0.1 mol dm^{-3} $Co(NO_3)_2$; (4) as for curve (2) with 0.05 mol dm^{-3} $Co(NO_3)_2$ after bubbling air for 1 h at pH = 11.

When air was bubbled through the solutions to saturation the cobalt(II)–TEA complexes coordinated the oxygen readily, as the spectral results described above show. The electroreduction current increased many-fold (Fig. 5, curve 4, and Fig. 6) and depended on the bubbling time (Fig. 6). The formal redox potential shifted towards more positive values (*cf.* curves 2 and 4 in Fig. 5).

These observations coincide with the noted higher absorbance at 328 nm (Fig. 7) as well as at 267 nm (Fig. 3). The light absorption intensity of the 267 and 328 nm peaks depends not only on the concentration of the cobalt, but also on the rate and duration of the bubbling of air (Fig. 7). On the other hand, the 525 nm peak is a result of cobalt(II)–TEA complexes only.

The absorption of oxygen by the cobalt(II)–TEA complexes is slow (Fig. 6), the half-time being of the order of 0.5 h with equilibrium being substantially achieved in 3–4 h. Figures 6 and 8 show this for the limiting reduction current i_l at −0.40 V and the absorbance A at 333 nm, respectively. The equilibrium values of these quantities, i_{l_e} and A_e were obtained by extrapolation of the curves to *ca* 3 h. At longer times, ageing of the system takes place, leading to new species. During the first 3 h, however, the oxygen absorption reaction is completely reversible, and when nitrogen is bubbled after the saturation by air, oxygen evolution is observed.

DISCUSSION

Triethanolamine (TEA) is a unique ligand for Co^{II}, Co^{III} and $Co^{II,III}$–O_2 complexes in the sense that it has only one nitrogen donor atom but several oxygen donor atoms available for chelation in principle. In this respect it is similar to nitrilotriacetic acid (NTA), with the disadvantage that it is not charged at high pH values. The complex formed by TEA with Co^{II} is therefore fairly weak, although at the ligand concentrations employed in the present study practically all the cobalt is in the form of $CoTEA(H_2O)_x^{2+}$, in view of the reported stability constants [13–15]. That chelation may not take place in this complex can also be deduced from the similarity of K_1 for TEA and ammonia [13,25]. No data on the absorption spectrum of the corresponding $Co(NH_3)(H_2O)_x^{2+}$ species could be found. Only scant data are available for the spectrum of the mono-nitrilotriacetate chelate of cobalt(II) [26], which has one nitrogen and three oxygen donor atoms as has TEA, but the maximum of its absorption band appears to be at 510 nm ($\varepsilon \sim 21\ M^{-1}\ cm^{-1}$). This should be compared with the most intense component of the cobalt(II)–TEA complex, found here at 534 nm ($\varepsilon = 21.8\ M^{-1}\ cm^{-1}$, Fig. 1), which is more red shifted with respect to the hexaaquo complex that has perfect octahedral symmetry. The lower symmetry of the $CoTEA(H_2)_x^{2+}$ species causes removal of the degeneracy of the $^4T_1$ ground state level, and this explains the appearance of three bands, at 18,020,

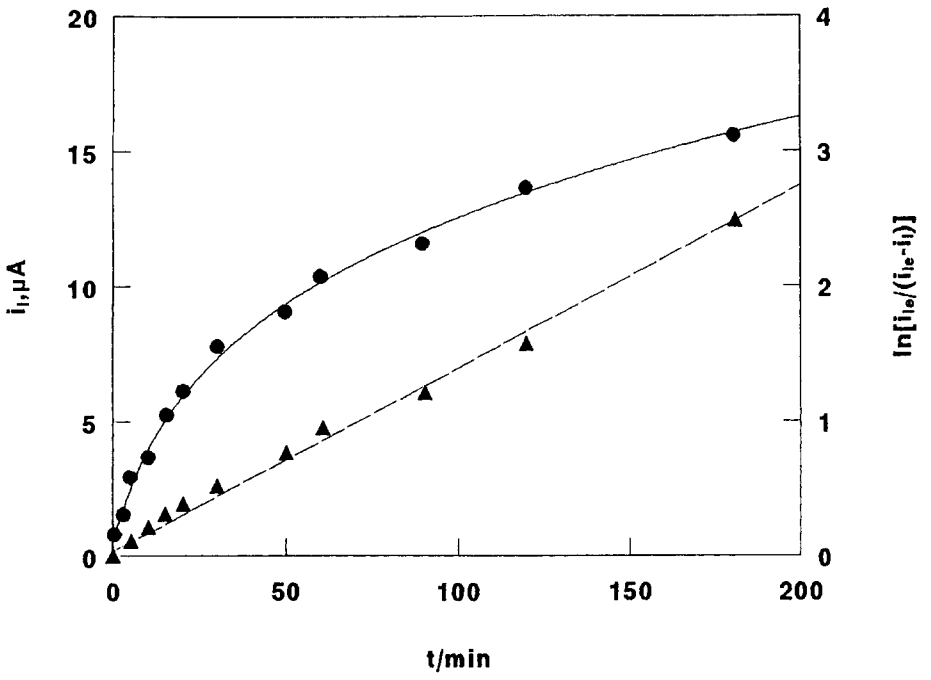

Fig. 6. The limiting currents i_r (●, left-hand ordinate) and the function $\ln [i_{re}/(i_{re} - i_r)]$ (▲, right-hand ordinate) in solutions containing 1.0 mol dm^{-3} TEA + 3.0 mol dm^{-3} $NaNO_3$ + 0.050 mol dm^{-3} $Co(NO_3)_2$ at pH = 9.6 as a function of time, t.

18,730 and 21,550 cm^{-1}, instead of the two, at 19,400 and 21,550 cm^{-1}, of $Co(H_2O)_6^{2+}$.

Cobalt(III) complexes with ligands having nitrogen and oxygen donor atoms are well known, but most have at least four nitrogen atoms in their octahedral coordination sphere (e.g. four ammonia or two ethylenediamine molecules, the other positions being occupied by water molecules). The apparent stability found here (Fig. 2) of a species with TEA ligands has not been observed previously. There being a 20-fold excess of TEA over Co^{III} in the solutions, and with the expected higher stability of the Co^{III} complexes with respect to the Co^{II} ones, it is conceivable that the species having the spectrum shown in Fig. 2 is $Co(TEA)_2(H_2O)_2^{3+}$ or $Co(TEA)_2^{3+}$, with each TEA ligand contributing one, respectively, two oxygen atoms towards chelation of the cobalt. Even so, the species have only two nitrogen atoms in the coordination shell. The appearance of just two bands, as is found in $Co(en)_6^{3+}$ (Fig. 2) or $Co(NH_3)_6^{3+}$, with maxima ($\bar{\nu}$/cm^{-1}, ε/M^{-1} cm^{-1}) at 339 (29,500, 55) and 475 nm (21,050, 60) [27], respectively, although with different molar absorptivities, indicates high symmetry for the species formed. The bands are assigned to the $^1A_{1g}$ to $^1T_{1g}$ and $^3T_{2g}$ transitions [20]. More bands are found for species with lower symmetry (e.g. $Co(NH_3)_5F^{2+}$ or $Co(NH_3)_4Cl_2^+$) [27], hence the presumed TEA species appears to be the more symmetric one of those assumed to be present. The spectrum of this species is quite different from the binuclear, dioxygen bridged Co^{III} complexes $L_5CoOOCoL_5$ or $L_4Co(O_2,OH)CoL_4$ formed with ligands having several nitrogen donor atoms, e.g. tren, in the presence of oxygen [28].

When oxygen is bubbled through alkaline cobalt salt solutions oxidation to cobalt(III) and/or formation of Co^{II}–ligand–dioxygen and/or Co^{III}–ligand–dioxygen complexes takes place, the latter being mononuclear and/or dinuclear [1,29]. Since so many species can be formed, and owing to the changes in the spectra with ageing, it is impossible to specify which ones are formed in the presence of TEA as the ligand. The spectra shown in Fig. 3, compared with that of the Co^{III}–TEA complex species in Fig. 2, do rule out the simple oxidation from Co^{II}–TEA to Co^{III}–TEA. The presence of oxygen in the species is thus established. The decrease of the absorbance when nitrogen is bubbled through the solutions shows, however, that some of the oxygen bound to the cobalt can be removed, but the remaining species is neither the Co^{II}–TEA nor the Co^{III}–TEA complex (Figs 1 and 2). Therefore, more than one dioxygen species must have been formed in the aged solutions.

The observed spectrophotometric (Figs 1–4) and electrochemical (Figs 6 and 7) data require a complicated mechanism for their explanation. Similar mechanisms have been invoked in the past for explaining kinetic and other results with ligands containing more than one nitrogen donor atom, such as tren and en [30,31]. However, the suggested mechanism must also explain the enhanced reactivity of the TEA-containing species (towards electroreduction and removal of some of the oxygen) compared with the relative inertness of species with ligands having more than

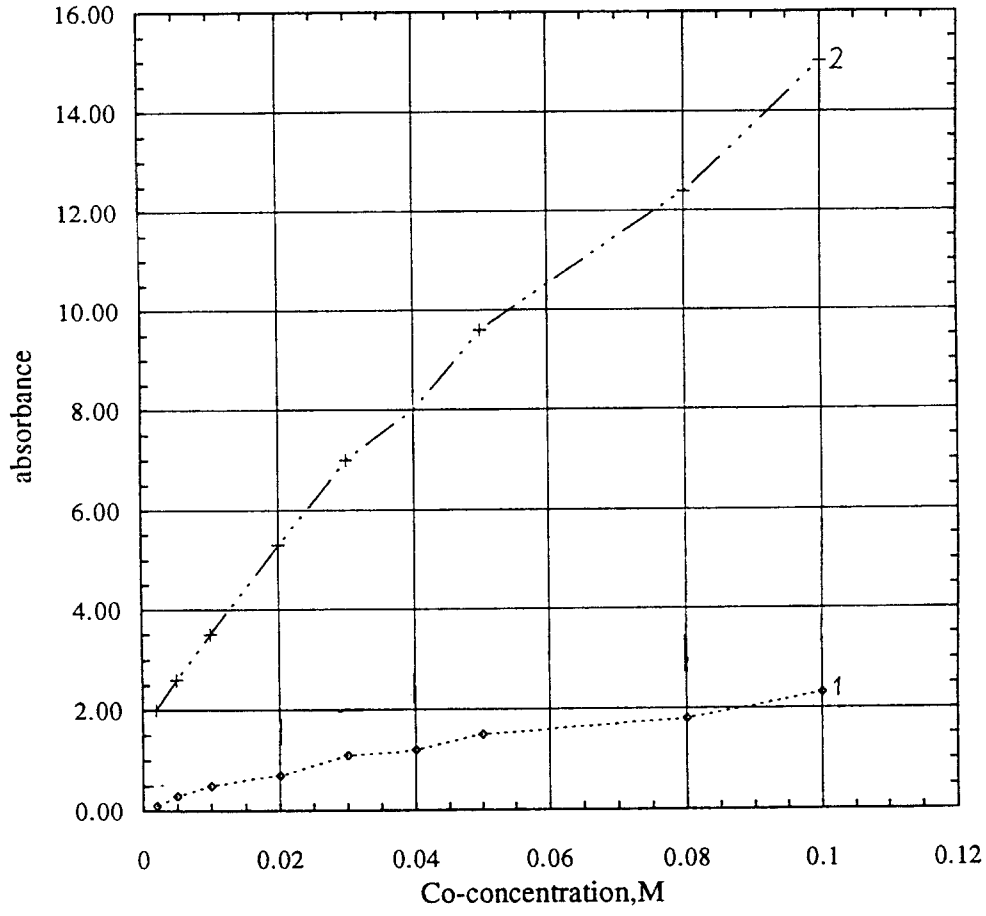

Fig. 7. Dependence of light absorbance at 328 nm on the cobalt concentration in 1.0 mol dm^{-3} TEA + 3.0 mol dm^{-3} $NaNO_3$ solutions: (1) exposed to a N_2 atmosphere for 3 h; (2) prepared similarly but after bubbling of air through the solution for 15 min.

one nitrogen donor atom. At the elevated pH values employed (9.5–12) deprotonation of the $CoTEA(H_2O)_x^{2+}$ complex ($x = 3$ or 4) is assumed to take place with simultaneous dimerization:

$$2CoTEA(H_2O)_x^{2+} + OH^- \rightleftarrows [(H_2O)_yTEACo\text{–}OH\text{–}CoTEA(H_2O)_y]^{3+} \quad (1)$$

The species on the right-hand side is designated $Co^{II,II}$ in short. On the basis of the stability constant of the Co^{II}–TEA complexes [13], the equilibrium of reaction (1) can be taken to lie considerably to the right, so that:

$$[Co(II,II)]_0 = c_{Co}^0/2 \quad (2)$$

where $[Co(II,II)]_0$ and c_{Co}^0 are the initial complexed and total (0.05 mol dm^{-3}) cobalt(II) concentrations, respectively.

The resulting species has such a distance between cobalt atoms that they can accommodate a coordinated oxygen molecule [1,2], in a reversible and slow reaction:

$$[(H_2O)_yTEACo\text{–}OH\text{–}CoTEA(H_2O)_y]^{3+} + O_2 \rightleftarrows [(H_2O)_yTEACo(\overset{OH}{\underset{O_2}{\diamond}})CoTEA(H_2O)_y]^{3+} \quad (3)$$

Subsequently and rapidly, an internal redox reaction takes place and an electron is transferred from one of the cobalt atoms to the oxygen molecule to produce Co^{III} and a superoxide ligand, rapidly reaching equilibrium:

$$[(H_2O)_yTEACo(II)(\overset{OH}{\underset{O_2}{\diamond}})Co(II)TEA(H_2O)_y]^{3+} \rightleftarrows [(H_2O)_yTEACo(II)(\overset{OH}{\underset{O_2^-}{\diamond}})Co(III)TEA(H_2O)_z]^{3+} + (y-z)H_2O \quad (4)$$

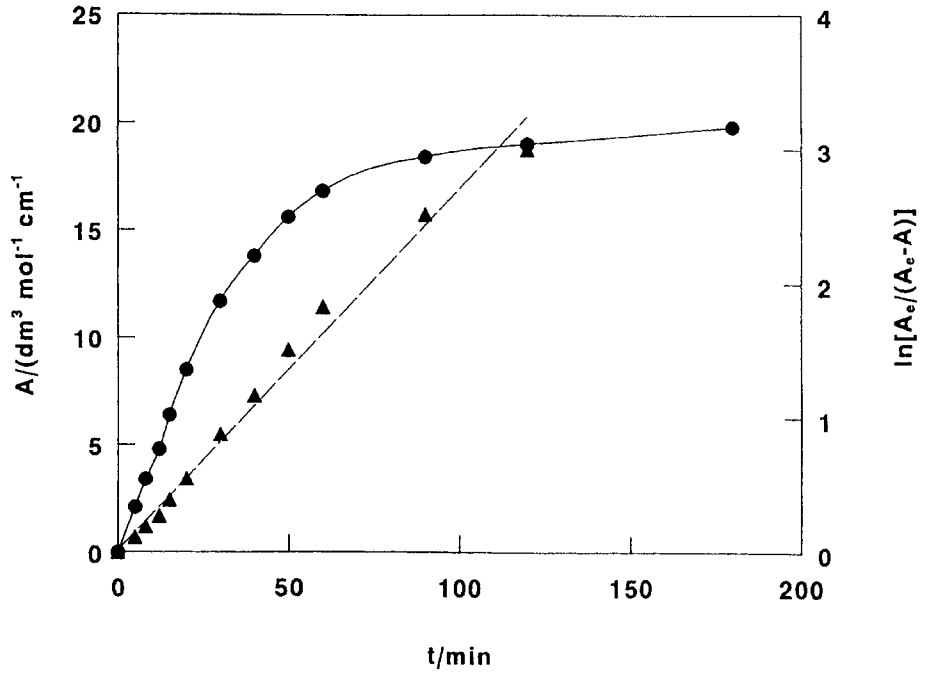

Fig. 8. The absorbance A at 330 nm (●, left-hand ordinate) and the function $\ln[A_e/(A_e-A)]$ (▲, right-hand ordinate) in solutions as in Fig. 6 as a function of time, t.

The species on the right-hand side is designated Co^{II,III,O_2^-} in short. Such a mechanism is suggested following studies of ethanolamine- and ethylenediamine-ligated complexes of cobalt binding with molecular oxygen [32–34]. It is noteworthy that the observed molar absorptivities (all $\varepsilon \leqslant 1000$ M^{-1} cm^{-1}) are considerably lower than those obtained for species with two Co^{III} centres, e.g. [31] $trenCo^{III}$ (μ-O_2,μ-OH)Co^{III})tren (with $\varepsilon > 6000$ M^{-1} cm^{-1}) [31]. The observed slow ageing reaction can be described by the overall scheme, combining reactions (1), (3) and (4):

$$Co^{II/II} + O_2 \underset{k_{-1}}{\overset{k_{+1}}{\rightleftharpoons}} Co^{II,III,O_2^-} \qquad (5)$$

At a constant concentration of oxygen in the solution, produced by bubbling air to saturation at a given temperature, the kinetics of the reversible reaction (5) are described by the pseudo first-order expression:

$$d[Co(II,III,O_2^-)]/dt = k_{+1}[Co(II,II)] - k_{-1}[Co(II,III,O_2^-)] \qquad (6)$$

The fact that at the potentials of this voltammetric study the $Co^{II,II}$ complex is electrochemically inactive (Fig. 5) was taken into account. The much enhanced electroreduction current of oxygen in the presence of the cobalt–TEA complex is therefore caused by the reduction of the $Co(II,III,O_2^-)$ complex:

$$Co(II,III,O_2^-) + 4e^- + 2H_2O \rightarrow Co(II,II) + 4OH^- \qquad (7)$$

Since the rate constant k_{+1} is relatively low (see below), the regeneration of the $Co(II,III,O_2^-)$ species according to reaction (3) on the electrode surface during reduction can be practically ignored. Therefore, the limiting current i_ℓ is diffusion controlled and:

$$i_\ell = k[Co(II,III,O_2^-)] \qquad (8)$$

On the basis of Eqs (2), (6) and (8) and that $[Co(II,II,O_2)] \ll [Co(II,III,O_2^-)]$, the kinetic equation for reaction (5) is:

$$\ln[i_{\ell e}/(i_{\ell e} - i_\ell)] = k_{+1}(i) \cdot c_{Co^0} \cdot t/2 \cdot [Co(II,III,O_2^-)]_e \qquad (9)$$

(see Fig. 8), where the subscript "e" designates the equilibrium condition. The values of $[Co(II,III,O_2^-)]_e$ is obtained from:

$$[Co(II,III,O_2^-)]_e = (i_{\ell e}/i_\ell{}^0)c_{O_2} \qquad (10)$$

where $i_\ell{}^0$ is the limiting current at $t = 0$. The solubility of oxygen in water at 25°C and 0.101 Mpa pressure is 1.274×10^{-3} mol dm^{-3} [27], so that air saturation of water should produce a concentration of 20.9% of this value (2.67×10^{-4} mol dm^{-3}) in view of the partial pressure of oxygen in air. Salting out by the 3 mol dm^{-3} sodium nitrate should decrease this concentration by $10^{3.0 \times 0.124}$ to $c_{O_2} = 1.13 \times 10^{-4}$ mol dm^{-3}, 0.124 being the Setchenow coefficient [35]. At the temperature of our experiments this concentration should be 2–4% higher, but this difference is ignored here. Hence, with the limiting currents $i_{\ell e}$ and $i_\ell{}^0$ read from

Fig. 2 and Eq. (10), $[Co(II,III,O_2^-)]_e = 2.3 \times 10^{-3}$ mol dm^{-3}. A large amount of oxygen is, thus, "stored" in the $Co(II,III,O_2^-)$ complex and is amenable to electroreduction.

Similarly, the absorbance data at 333 nm shown in Fig. 6 follow the expression:

$$\ln[A_e/(A_e - A)] = k_{+1}(A)c_{Co^0} \cdot t/2 \cdot [Co(II,III,O_2^-)]_e \quad (11)$$

where A is the absorbance of the $Co(II,III,O_2^-)$ species. The linear dependencies of $\ln[A_e/(A_e - A)]$, according to Eq. (11) (Fig. 6), and of $\ln[i_{/e}/(i_{/e} - i_/)]$, according to Eq. (9) (Fig. 8), on t require the values of $k_{+1}(A)$ and $k_{+1}(i)$ to be the same if the reducible species and absorbing species are the same. Within the imprecision of the measurements this is the case, the values being 2.4×10^{-3} min^{-1} and 1.4×10^{-3} min^{-1}, respectively.

The equilibrium constant of reaction (3) is:

$$K = [Co(II,III,O_2^-)]_e/[Co(II,II)]_e c_{O_2}$$

$$= [Co(II,III,O_2^-)]_e/\{c_{Co^0}/2 - [Co(II,III,O_2^-)]_e\}c_{O_2}$$

$$= 8.6 \times 10^2 \text{ dm}^3 \text{ mol}^{-1} \quad (12)$$

The rate constant for the reverse of reaction (4) is then $k_{-1} = k_{+1}/K \cdot c_{O_2} \approx 1.9 \times 10^{-3}/8.6 \times 10^2 \cdot 1.13 \times 10^{-4} = 1.9 \times 10^{-2}$ min^{-1} if the average of the voltammetrically and spectrophotometrically obtained forward rate constants is used.

The mechanism considered above is seen to be able to describe the kinetics and catalytic electroreduction current of oxygen in the cobalt(II)–TEA–O_2 system.

EXPERIMENTAL

The inorganic reagents used were of analytical grade: cobalt(II) chloride, nitrate and sulfate, sodium hydroxide and nitrate, and potassium chloride; and pure triethanolamine (Fluka, 99%) and triply distilled and deionized water were employed.

The spectra were measured on a Perkin–Elmer Lambda 5 spectrophotometer at ambient temperatures (23 ± 2°C). Owing to high absorptivities of some of the solutions, 1, 2, 5 and 10 mm light-path-length cells were used according to need. The wavelength range 240–800 nm was scanned. When nitrate solutions were used, the reference cell contained exactly the same concentration of nitrate in order to avoid complications from its charge transfer band.

Solutions containing cobalt(II) and TEA in the absence of oxygen were prepared in a glove-bag under nitrogen and the optical cells were stoppered tightly to avoid air oxidation. Solutions of cobalt(III) in the presence of TEA were made by anodic oxidation at a platinum electrode in the optical cell with a salt bridge to the cathode compartment, again in a glove-bag under nitrogen. This was done in order to avoid oxidizing reagents (such as air or hydrogen peroxide) that might leave oxygen in the solutions to form a complex with the cobalt.

Oxygenated solutions were prepared by bubbling air through them to saturation. In some cases, subsequent bubbling of nitrogen was used in order to (partly) decompose the dioxygen-containing complexes.

The electroreduction of cobalt ions in aqueous triethanolamine (TEA) solutions in the absence and presence of oxygen was studied voltammetrically and the bulk processes taking place were controlled spectrophotometrically. The pH of the solutions was controlled by a pH-meter with a glass electrode to ±0.01 units. The temperature was controlled at 23.0 ± 0.5°C by water flowing in the jacket of the cell from a Haake E-12 thermostat. Voltammetric measurements were made with a Polarecord E-261 instrument equipped with a stationary Pt disk electrode in an unstirred solution, except for comparative voltammograms (Fig. 5), when the solution was stirred with a magnetic stirrer. The reference electrode was Ag/AgCl/1 M KCl. The applied potential was varied at a rate of 5 mV s^{-1} and its interval was +0.2 to −1.0 V. The reproducibility of the electrode surface was checked by measurement of the current–voltage response for electroreduction of oxygen in 0.1 mol dm^{-3} KCl. As supporting electrolyte 3 mol dm^{-3} $NaNO_3$ was generally used.

(Received 18 June 1996; accepted 8 August 1996)

Abstract—The compounds $[(\eta^3\text{-}HB(N_2C_3H_3)_3]_3M$ of scandium, yttrium, lanthanum and of the trivalent lanthanides from cerium to lutetium (with the exception of promethium) have been synthesized by the reaction of MCl_3 with $K[HB(N_2C_3H_3)_3]$ in tetrahydrofuran or in water. The crystal and molecular structures of the Pr and Nd compounds were determined by single-crystal X-ray diffraction. The crystal structure corresponds to the structure of the praseodymium trichloride ($LaCl_3$-type). The Pr^{3+} is nine-coordinate to the N atoms of the three Tp ligands. One N atom of each of the three Tp ligands and the Pr ion are almost coplanar with a Pr—N distance of 278.3 pm, while all other six N atoms are at a distance of 260.9 pm in a tricapped trigonal prismatic arrangement. The M—N distances in the Nd compound are 280.4 (3 ×) and 259.9 (6 ×) pm. IR spectroscopic studies have shown that the metal ion in the $LnTp_3$ compounds from La to Dy is nine-coordinate, while in the compounds of the heavier lanthanides from Ho to Lu, of Sc, and Y, the central ion is eight-coordinate.

Keywords: lanthanide-trispyrazolyl borates; IR; NMR spectroscopy; magnetic susceptibility; structures.

Lanthanide trichlorides react with the [HB(pyrazol-1-yl)$_3$] ligand (=Tp^-)‡ to complexes of the type Tp_2LnCl, Tp_2LnL, Tp_3Ln^{III} and to several heteroleptic eight-coordinate complexes with oxybidentate ligands, such as oxalate, benzoate, tropolonate, β-diketonate, dipivalomethanido, trifluoroacetyl, etc. [1–6]. The crystal and molecular structure of several mixed lanthanide-complexes containing the Tp ligand have been investigated. Most of the compounds have a distorted square-antiprismatic geometry [3]. The structures of $Tp_2Y(H_2O)Cl$ [2] or $Tp_2Nd(H_2O)Cl$ [3], for example, show an eight-coordinate molecule with a *cis*-position of the water and chloride ligands. The divalent Sm in $(Tp^{t\text{-}But,Me})SmI(THF)$ is five-coordinate in a distorted trigonal-bipyramidal geometry with a N atom and the O atom of the tetrahydrofuran molecule occupying the axial sites [7]. The corresponding Yb

compound also has been described [9]. Recently, six-coordinate complexes of the divalent lanthanides Sm, Eu and Yb with Tp^{Me_2} as the ligand were synthesized and investigated [10].

From the $LnTp_3$ series, nevertheless, prepared in aqueous solutions [11], only the crystal and molecular structure of the ytterbium compound has been determined by single-crystal X-ray diffraction so far [12]. In this compound the Yb is not, as expected nine-, but eight-coordinate, one of the three Tp ligands being bidentate, with a bicapped-trigonal prismatic coordination geometry [12].

After we had synthesized and investigated compounds of the type $Tp^{Me_2}MCl_2$ (M = Pr, Nd, Yb and Pu), which are dimeric [13], and compounds of the type Tp_2LnCl [14], we were interested in the synthesis of the Tp_3Ln class of the lighter lanthanides and/or of the lighter actinides in order to obtain single crystals and to investigate the coordination of the central 4*f*-ion for comparing and discussing their molecular structure with the known structure of the ytterbium compound [12]. In this contribution we present the synthesis and coordination of pure $[HB(N_2C_3H_3)_3]_3M$ compounds of Sc^{3+}, Y^{3+}, La^{3+} and some trivalent lanthanide ions.

EXPERIMENTAL

Materials

All chemicals were reagent grade. The chlorides used were prepared by dissolving the sesquioxides in hydrochloric acid. Anhydrous chlorides were obtained by chlorination of the sesquioxides with a Cl_2/CCl_4/argon stream at temperatures up to the melting point of the corresponding chloride.

Physical and analytical methods

IR spectra were obtained on a Perkin–Elmer 2000-FT-IR spectrometer. Solid-state UV–NIR spectra of the compounds embedded in potassium bromide or teflon [15] as matrix were taken on a Perkin–Elmer Lambda 9 spectrometer. Metal analysis was made by gravimetric measurement of the sesquioxide after oxidation of the compound and/or by AAS.

Magnetic susceptibilities of polycrystalline samples were measured with a Faraday-type magnetic balance with magnets with Henry-type pole caps (Bruker-Analytische Messtechnik) and an electrical microbalance (Sartorius type 4102) at eight different external magnetic fields from 190 to 15,000 kOe [16]. Mass spectra were obtained with a Finnigan MAT 4500 equipment.

^1H and ^{13}C NMR spectra in solution (mostly CD_2Cl_2, 99% D, Merck) were recorded on Bruker AC 250 or 200 spectrometers. TMS was used as internal standard. Paramagnetic shifts Δ^{iso} of the pyrazolyl ring protons were referred to an average of the respective signals of the diamagnetic Lu complex (3-H : 7.2 ppm ; 4-H : 6.0 ppm ; 5-H : 6.5 ppm).

Synthesis of the MTp_3 *compounds*

The general preparation method used for the synthesis of the $LnTp_3$ compounds was the reaction of the anhydrous metal trichlorides with a stoichiometric molar amount of KTp in tetrahydrofuran or the reaction of the trichlorides with a slight molar excess of KTp in water as first reported by Bagnall *et al.* [11]. In the first method a mixture of the anhydrous $LnCl_3$ in THF with a slight excess of KTp was heated under reflux for 2 days. After elimination of the solvent *in vacuo*, the solid residue was extracted with THF, benzene or toluene for several days. The extracted dried $LnTp_3$ was heated *in vacuo* to remove the solvent. When THF was used as extractant, the compound contained traces of KCl. Sublimation of the polycrystalline compound at 300–330°C (10 Torr Ar) gave a microcrystalline, chloride-free compound.

In the second method MCl_3- or $M(NO_3)_3$-hydrate was used as starting material. The metal salt was dissolved in distilled water, the solution filtered for elimination of oxychlorides or hydrolysed salt and an excess of KTp added with stirring. After centrifugation, KTp was added to the clear decantate and the procedure repeated in the case that new MTp_3 is formed. Due to the low solubility of the $LnTp_3$ compounds and the good solubility of KTp and KCl in water, the crude products can be purified easily by washing them with distilled water with stirring, followed by centrifugation and drying in a desiccator with P_2O_5. Reaction conditions, yields and metal analysis for all compounds are listed in Table 1.

Separation of lanthanides by solvent extraction

A 1 : 1 molar mixture of $LaCl_3$ and $YbCl_3$ in distilled water was treated with KTp and the mixed compound $(La_{0.5}Yb_{0.5})Tp_3$ was isolated, purified and characterized by metal analysis and IR spectroscopy. Samples of 2–3 mg of the compound were extracted with 5 cm^3 of different solvents (rigorous shaking at room temperature for 10 hours). After centrifugation and filtration (250 nm filter) the La and Yb ions were determined in the filtrates. The concentrations (g dm^{-3}) of $YbTp_3$ and boron in the used solvents were : toluene : 0.389 (B : 0.016) ; CH_2Cl_2 : 0.563 (B : 0.020) ; THF : 0.586 (B : 0.021), while the concentration of La in all solvents was found to be lower than 1 ppm (5 mg $LaTp_3$ per dm^3). In all solvents $YbTp_3$ has been quantitatively extracted with a separation factor of 50–100.

‡ The abbreviation Tp used in this paper is that proposed by Dr S. Trofimenko, see Reference [1]. The authors appreciate the helpful suggestions of Dr Trofimenko.

Collection and analysis of X-ray data

Single crystals of the Pr compound were obtained by sublimation of polycrystalline Tp_2PrCl [14] or $PrTp_3$ in a glass tube sealed under low pressure of *ca* 10 Torr argon, at 300–310°C. The single crystals of the pale-green coloured compound were formed in the colder zone of the oven (*ca* 220°C) in a yield higher than 45%. Single crystals of the neodymium compound were obtained by prolonged extraction (several weeks) of the polycrystalline $NdTp_3$ with benzene. Attempts to grow single crystals of other compounds using different experimental methods failed [17].

The single crystals were mounted in quartz capillaries and transferred to an Siemens-Stoe AED II- and/or to a Enraf–Nonius CAD4 four-circle X-ray diffractometer. The unit-cell parameters were determined from 20–25 reflections in the region $4.5 < 2\theta < 22.0°$. The models were refined by using the SHELXTL PLUS program package [18] or with the Enraf–Nonius SDP program with a Microvax II computer [18]. Hydrogen atoms were included as fixed contributions in idealized positions. Structures were solved by standard Patterson, Fourier or direct-methods procedures. Atomic scattering factors were taken from the International tables for X-ray Crystallography [19]. A summary of the structure data, data collection and refinement are given in Table 2.

RESULTS AND DISCUSSION

Reaction of MCl_3 (M = Sc, Y, La, Lanthanide) with $K[HB(N_2C_3H_3)_3]$ (=KTp) in solution resulted in the spontaneous formation of MTp_3 compounds, which were insoluble in water. Through the tridentate ligand Tp the coordination sphere of the central ion is saturated and all of the synthesized compounds are stable in air when they are in crystalline form.

The colour of the compounds corresponds to that of the trichlorides, but it is somewhat brighter, due to the lower concentration of the trivalent ion compared with the corresponding concentration in the chloride. The compounds of the heavier lanthanides (Tb–Lu) are moderately soluble in toluene and more soluble in polar solvents, especially in those with electron-donor character, while the compounds of the lighter lanthanides (La to Gd) are practically insoluble. Thus, the heavier lanthanides can be easily separated from the lighter lanthanides in mixed $LnTp_3$ compounds by solvent extraction.

Although in the compounds of the second class the Ln^{3+} ion is eight-coordinate, the Ho–Lu compounds do not interact with Lewis bases, as nitriles, isonitriles, etc., to give isolable adducts.

All compounds can be sublimed *in vacuo* at temperatures above 180°C. Mass spectrometric investigations of the Pr compound show the molecular

peak ($m/z = 780.00$, $I_{rel} = 1\%$). The strongest peak ($I_{rel} = 100\%$) corresponds to the species $PrTp_2^+$ (m/z = calc. 0.566.97, exp.: 568.5; I_{rel}: 26.0, 567.2, $I_{rel} = 100$; 566.3, $I_{rel} = 59.7$). Further main fragments were $Pr[HB(N_2C_3H_3)_3][N_2HC_3H_3]$ ($m/z = 421.0$, $I_{rel} = 63.7\%$), $Pr[HB(N_2C_3H_3)_3]_2[HB(N_2HC_3H_3)_2]$ ($m/z = 712.8$, $I_{rel} = 6.60\%$), $Pr(N_2C_3H_3)_2$ ($m/z = 275.04$, $I_{rel} = 15.0\%$). The double ionized molecular peak ($m/z = 390.0$) occurs with $I_{rel} = 5\%$. The fragmentation pattern of the mass spectrum demonstrates the tendency of the compound to moieties with a seven-coordinate central ion. This is reflected by the highest intensity of $PrTp_2^+$, which was recently established experimentally through the crystallographic characterization of several seven-coordinate triflate complexes of the type $LnTp_2^{Me_2}(OTf)$ [8].

IR spectroscopic investigations

The IR spectra of the $LnTp_3$ compounds show two different structures. In the compounds of the lanthanides from La to Dy the central ion is nine-coordinate. All compounds of this class are isostructural and have the structure of $PrTp_3$ ($LaCl_3$-type), which is discussed later in this paper. The compounds of the heavier lanthanides from Ho to Lu and of Sc and Y, with small ionic radii, show a different structure. In this class of compounds, the central ion is eight-coordinate, as in the case of $YbTp_3$ [12]. For the dysprosium complex, there is evidence that both structural types coexist in the sublimed crystalline material. While the bulky microcrystalline compound obtained by sublimation *in vacuo* is nine-coordinate (crystal habitus prismatic), small crystals of plateform, which crystallize orthorhombic (eight-coordinate), can be observed under the microscope. Although the size of the hexagonal crystals was not suitable for a full crystallographic analysis, the elementary cell and its dimensions have shown that the compound exhibits a hexagonal structure. The crystal structure of the eight-coordinate orthorhombic

compound was indubitably elucidated [17]. The eight Dy—N distances are: 259.0, 253.9, 253.3, 250.1, 248.6, 248.0, 246.3 and 240.4 pm. There is no doubt that $DyTp_3$ is dimorphic. Both structures have been identified by IR-spectroscopy in the far-IR region (Table 3).

The structural change which results from the contraction in ionic radius across the lanthanide series occurs in the region of $DyTp_3$ and $HoTp_3$. From the crystallographic investigations it can be assumed that the critical ionic size for the structural change is 89 to 91 pm.

The two classes of the MTp_3 compounds exhibit a B—H stretch vibration in two different regions. The nine-coordinate compounds of the first class show a B—H vibration at 2440–2447 cm^{-1}, while the B—H vibration of the members of the second class is shifted to higher energies and occurs at 2457–2458 cm^{-1} (Table 1). In both classes of compounds the B—H frequency is shifted to higher energies relatively to the corresponding main absorption band in KTp (2437 cm^{-1}). Through the bonding of the Tp anion to the metal ion, *via* the three nitrogen atoms of the pyrazole rings, the B atom becomes more electropositive, thus the B—H bond is stronger and the corresponding frequency of the B—H bond is shifted to higher energies.

There are two further regions in the IR spectra, where the two compound groups show a distinct difference in number and positions of the absorption bands: (a) in the region 800–650 cm^{-1} (Fig. 1). The nine-coordinate compounds exhibit six absorption bands at *ca* 780, 770, 750, 739, 724 and 672 cm^{-1}. The eight-coordinate compounds show only four absorption bands at 782, 759, 724 and 670 cm^{-1}. (b) The second difference between the two compound classes is in the far-IR region below 400 cm^{-1}, where the characteristic skeleton vibrations of the molecule appear (Fig. 2). The absorption bands in this region reflect the molecular symmetry of the compound and can give quick information on the coordination of the central ion, as it has been shown earlier in the case of organometallic complexes of the actinide and lanthanide ions [20].

The M—N stretching absorptions appear between 150 and 288 cm^{-1}. The complexes of the second group (Ho–Lu, Sc, and Y) exhibit new absorptions at 272 and 282 cm^{-1} and three absorption bands in the 202–245 cm^{-1} IR region, whose positions correspond to the absorptions of KTp (Table 3). Obviously the latter absorption bands are due to the eight-coordinate central ion and have their origin in the uncoordinated pyrazolyl ring of one Tp anion, as the compounds of the lighter lanthanides La–Dy do not exhibit absorption bands in the 200–250 cm^{-1} region. The three absorptions at 320, 334 and 337–335 cm^{-1} can be undoubtedly assigned as ligand modes, because they appear in all $M^{III}Tp_3$ compounds, in KTp, and in the thorium, uranium and neptunium complexes of the type Tp_2AnX_2, with X = Cl, Br [14]. Although no group-theoretical analysis of the low-frequency IR absorption bands of Tp metal complexes is available, our suggestions are supported by the results of Hutchinson, Hoffbauer and Takemoto, who have used

the metal-isotope substitution method on Tp complexes of the light transition metals Fe, Co, Ni, Cu and Zn for the assignment of the low-frequency IR absorptions [21].

The crystal and molecular structure of MTp_3

The crystal structure of MTp_3 of the lighter lanthanides consists of discrete molecules in which the metal ion is nine-coordinate and displays tricapped trigonal prismatic geometry. The crystal lattice of the $PrTp_3$-type compounds has the same hexagonal structure ($LaCl_3$-type) as in the case of the trichlorides of the lighter lanthanides [22]. An ORTEP view with atom labeling and the coordination polyhedron of the hexagonal $LnTp_3$ compounds is shown in Fig. 3 and selected bond lengths are given in Table 4. Table 5 summarizes selected bond angles of the compounds.

The coordination polyhedron (Fig. 3) formed by the nine nitrogen atoms of the three Tp ligands about the lanthanide ion is an almost ideal tricapped trigonal prism. The six metal–apical N(3) bonds are exactly the same by symmetry (260.9 pm in the praseodymium and 259.9 pm in the neodymium compound), while the three equatorial N(1) atoms lie in the same plane with the central ion in a Ln–N(1) distance of 278.3 pm in the Pr and of 280.4 pm in the Nd compound. A D_{3h} site symmetry for the central can be stated.

Electronic absorption spectra

The almost identical magnetic behaviour of the two isostructural compounds $PrCl_3$ and $PrTp_3$ within the investigated temperature region between 1 and 330 K (see below) is certainly an experimental evidence for a comparable crystal field strength in the two compounds. In fact, the electronic absorption spectra of the two compounds are quite similar. Figure 4 shows the absorption spectra of the two isostructural compounds in the region 400–650 nm.

As can be seen from Fig. 4, the centres of gravity of the absorption bands for the ^3P, ^1J and ^1D terms of the two compounds have quite similar energies: $^3P_{1,2}$: 22,237 ($PrTp_3$) and 22,222 cm^{-1} ($PrCl_3$); $^1J_6$: 21,124 ($PrTp_3$) and 21,061 cm^{-1} ($PrCl_3$); $^3P_0$: 20,492 ($PrTp_3$) and 20,424 cm^{-1} ($PrCl_3$); $^1D_2$: 16,794 ($PrTp_3$) and 16,756 cm^{-1} ($PrCl_3$). The better resolution in the spectrum of $PrTp_3$ in Fig. 5 is due to the fact, that the sample in this case was prepared from powdered single

crystals, while the $PrCl_3$ sample was a powdered polycrystalline compound, obtained from anhydrous $PrCl_3$ fused in a HCl stream.

As in the case of $PrTp_3$ the electronic absorption spectra of all $LnTp_3$ compounds are quite similar to those of the trichlorides.

Magnetic susceptibility of $PrTp_3$

The same structure of $PrCl_3$ and $PrTp_3$ is reflected in the magnetic susceptibilities of the two compounds, which are almost identical (Fig. 5).

Both compounds obey the Curie–Weiss law with the same Θ constant of -23 (± 0.5) K. The magnetic moment of both compounds at room temperature is quite close to the moment of $3.62\mu_B$, calculated for the free Pr^{3+} ion ($4f^2$) with $g_j = 4/5$. The ground state of the two compounds very likely is the same.

NMR spectra

The aim of the NMR study was to elucidate the molecular structure of the MTp_3 complexes in solution and compare them with the solid-state structures. However, it turned out that the solubility of the complexes of the lighter lanthanides (La–Gd) in not too polar solvents, where decomposition reactions can be excluded, is too low to obtain meaningful spectra.

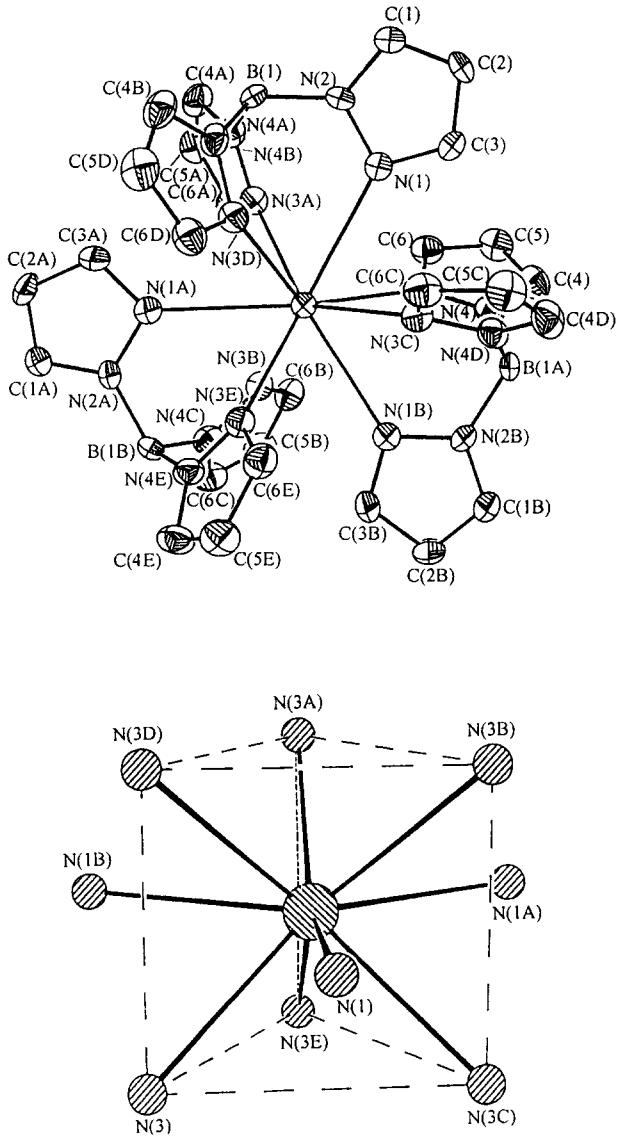

Fig. 3. ORTEP view of the molecular structure (top) and the coordination polyhedron of $LnTp_3$ (bottom); Ln = Pr, Nd.

Solution spectra could be obtained only for the complexes with M = Sc, Y and Tb–Yb.

The diamagnetic complexes MTp_3 (M = Lu, Sc, Y)

^1H and ^{13}C NMR spectra of $LuTp_3$ have been published by Stainer and Takats [23]. Assignment of the fairly complex ^1H spectrum (13 multiplets) was then only partially possible on the basis of the multiplicity of the signals (doublet of a doublet for the 3- and 5-protons, triplet for the 4-proton on each pyrazolyl ring). We have improved the assignment by two-dimensional ^1H-^1H Cosy spectra: of the 18 signals to be expected in the eight-coordinated structural case, 13 are resolved, so five overlap with others. From the Cosy spectrum (Fig. 6) it can definitely be deduced which three signals belong to the same ring. However, it is still not possible to assign the individual rings, e.g. the bidentate one.

The ^1H spectra of $ScTp_3$ and YTp_3 are practically identical with the spectrum of $LuTp_3$.

The same is true for the ^{13}C spectra, which consist of three groups of six lines each, from the C-4 carbons (centred at 104 ppm from TMS) and the C-3 and C-5 carbons (between 134 and 144 ppm).

The paramagnetic complexes (Ln = Tb, Dy, Ho, Er, Tm)

The ^1H spectra of the five complexes all show the expected 18 signals corresponding to the pyrazolyl rings; the broad signals of the three B—H protons,

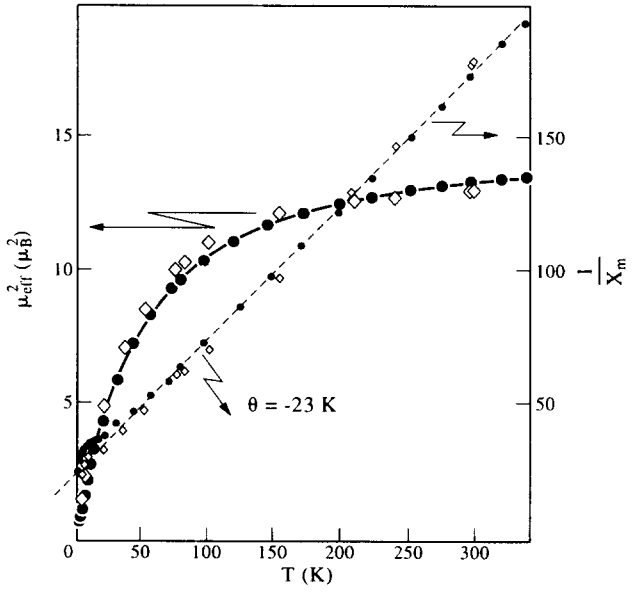

Fig. 5. Squared magnetic moment (left ordinate) and reciprocal molar susceptibility (right ordinate) of $PrTp_3$ (full symbols) and $PrCl_3$ (open symbols).

however, can be identified with certainty only in rare cases. If the assignment of the spectrum of the Yb complex [23] is taken as a basis, the spectra of the other complexes can also be assigned accordingly, with more or less certainty. Of course, the differing magnitude and sign of the magnetic anisotropy factors D_1 and D_2 in the equation for the dipolar shift [eq. (1)]:

$$\Delta^{dip} = D_1 \frac{(3\cos^2 \vartheta - 1)}{r^3} + D_2 \frac{\sin^2 \vartheta \cos^2 \omega}{r^3} \quad (1)$$

give rise to large shift variations, even if the geometry factors are considered to be constant (r, ϑ and ω are the polar coordinates of the respective nucleus with respect to the magnetic axis).

In Fig. 7 these variations are shown for several

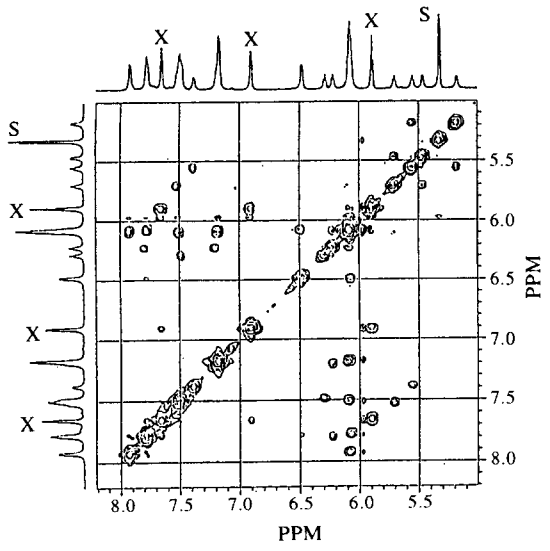

Fig. 6. Two-dimensional ^{1}H-^{1}H cosy spectrum of $LuTp_3$ in CD_2Cl_2 at 200 MHz (S = solvent, x = impurity, possibly of KTp, as the signals of pure KTp appear at 6.28, 6.49 and 7.62 ppm).

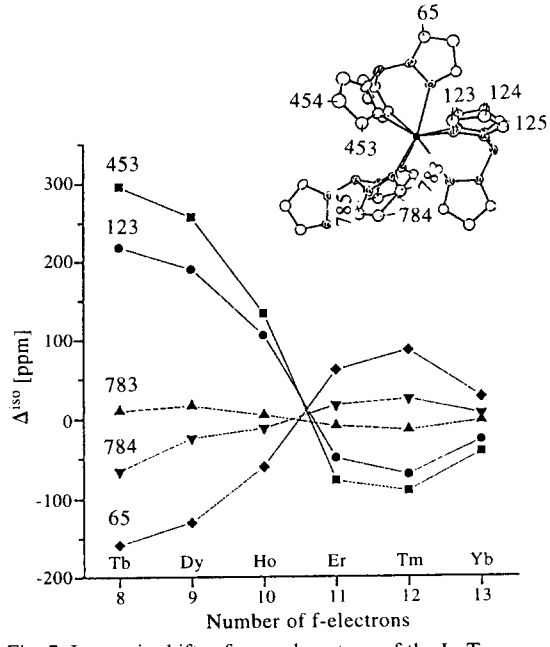

Fig. 7. Isotropic shifts of several protons of the $LnTp_3$ complexes (Ln = Tb–Yb); the numbers are the labels for the pyrazolyl ring protons according to [23].

protons whose assignment seems certain. The assignment labels were chosen according to Stainer and Takats [23], where the two-digit numbers 33, 34, 35, etc., refer to the three rings whose nuclei have intensity one and the three-digit numbers 123, 124, 125, etc., to the nuclei of two equivalent rings (intensity two). The last digit always refers to the ring position of the respective nucleus (see upper part of Fig. 7).

Tb causes the largest shifts: the H signals of $TbTp_3$ cover the range −190 (low field) to 288 ppm. The change of sign between Ho and Er is a phenomenon well known from other lanthanide complexes [24]. The spectrum most similar to that of the Yb complex and therefore easiest to assign is that of $TmTp_3$ (Fig. 8).

The signals of all 18 protons assigned by Stainer and Takats [23] appear in the same order with appropriate intensities. Except for the stronger anisotropy, the geometry factors seem to be almost identical to those in the Yb complex. The only uncertainty is the signal at 142.8 pm which should correspond to the B—H proton H3 (106.5 ppm in the Yb complex) but seems to have a too narrow line width for such a proton. The ratio $\Delta^{iso}(Tm)/\Delta^{iso}(Yb)$ for corresponding protons ranges between two and three or, in other words, the magnetic anisotropy of $TmTp_3$ is roughly two to three times as large as that of $YbTp_3$.

Quite similar to the spectrum of $TmTp_3$ is that of $ErTp_3$; we deduce therefrom that its structure essentially is still unchanged, resulting in nearly identical geometry factors of the various protons. The magnetic anisotropy of $ErTp_3$ is smaller than that of $TmTp_3$ by *ca* 15% (see Fig. 7).

The signal pattern observed in the spectra of $YbTp_3$, $TmTp_3$ and $ErTp_3$ is still retained in the ^{1}H spectra of the Ho, Dy and Tb complexes, but, apart from the fact that the magnetic anisotropy has changed its sign and is much larger than for the forementioned complexes (by a factor of about three for $TbTp_3$ compared with $TmTp_3$), assignments cannot be achieved with certainty for all signals. As an example, the spectrum of $DyTp_3$ is shown in Fig. 9.

Although assignment labels for all 18 non-equivalent protons are given, some of them must be considered tentative (especially in the region 35 to −21 ppm). Obviously, slight changes in the structure have been taken place, but there is no indication that the coordination number has changed from 8 to 9. In that case a much more profound change in the spectrum would have taken place. In the ideal case, when the highly symmetric X-ray structure of the solid phase is retained in solution, a pattern of three lines with intensity one and three lines with intensity two would result for the ring protons.

^{13}C *NMR*

The ^{13}C spectra which were recorded for the $LnTp_3$ compounds with Ln = Tb–Tm showed not nearly as good a signal-to-noise ratio than the spectrum of $YbTp_3$. This may be caused by a reduced solubility. Except for $ErTp_3$, where the line pattern resembles that of $YbTp_3$ fairly well, only part of the 18 signals to be expected could be identified. The anisotropy term in the shifts of $ErTp_3$ is approximately twice as large as for the Yb complex, in accordance with the ^{1}H case.

The NMR results of the Tb, Dy and Ho complexes

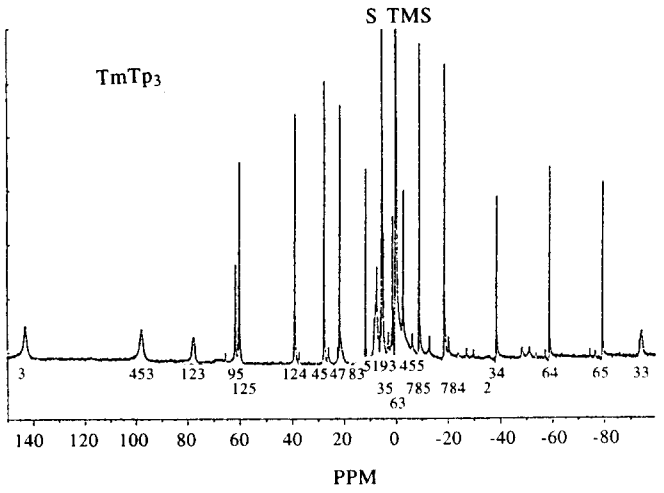

Fig. 8. ^{1}H NMR spectrum of $TmTp_3$ in CD_2Cl_2 at 300 K (250 MHz); assignments of the signals according to the spectrum of $YbTp_3$ [23].

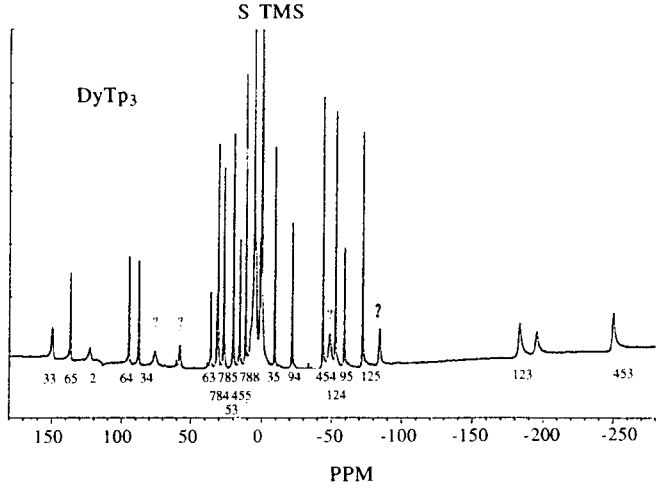

Fig. 9. ^{1}H NMR spectrum of $DyTp_3$ in CD_2Cl_2 at 300 K (250 MHz); assignment of the signals as in Fig. 8.

in solution seem to contradict the other measurements in the solid state reported above, where a change of the coordination number from 9 to 8 appears to take place between Ho and Dy. Two explanations for this discrepancy are possible:

(a) either the coordination number for the three complexes is different in the solid state (9) and in solution (8);
(b) or these complexes appear in dimorphic form (hexagonal and orthorhombic) in the solid state, as has been proven for $DyTp_3$. Only one of them (the orthorhombic form with eight-fold coordination) is soluble in CD_2Cl_2 and exhibits the spectrum of the more or less distorted structure of $YbTp_3$, whereas the other (hexagonal) insoluble form with nine-fold coordination is undetected by NMR.

Acknowledgements—We thank Mr W. Roth, ITC-CPV, for the MS investigations and Mr B. Fueger, WAK-GmbH Karlsruhe, for metal analysis of several compounds. Thanks are also due to Dr G. Schilling (University of Heidelberg) for recording some of the spectra, especially of the ^{1}H-^{1}H Cosy type. The authors are grateful to Professor H. H. Eysel, National Research Council, Winnipeg, Manitoba, Canada, for helpful discussions on the IR spectra.

Kinetics of iron removal from monoferric and cobalt-labelled monoferric transferrins by ethylenediaminetetra(methylenephosphonic acid) and ethylenediaminetetraacetic acid

Wesley R. Harris* and Gang Bao

Department of Chemistry, University of Missouri-St. Louis, St. Louis, MO 63121, USA

(Received 4 March 1996; accepted 7 August 1996)

Abstract—The rates at which ferric ion is removed from the two metal binding sites of the serum iron transport protein transferrin by ethylenediaminetetra(methylenephosphonic acid) (EDTP) and ethylenediaminetetraacetic acid (EDTA) have been evaluated. Solutions were buffered at pH 7.4 by 0.1 M *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid and maintained at 25°C. Pseudo first-order rate constants as a function of ligand concentration were measured for iron removal from diferric transferrin, from N- and C-terminal monoferric transferrin and from monoferric transferrins which had been labelled at the vacant site with kinetically inert cobalt(III). The data on iron removal from the cobalt-labelled monoferric transferrins provide accurate estimates of the rate constants for iron removal from diferric transferrin. A significant negative cooperativity is observed, in which occupancy of the C-terminal site slows the rate of iron release from the N-terminal site. Iron release from most of the transferrin complexes shows a combination of saturation and first-order kinetics which are interpreted in terms of parallel pathways for iron removal. The addition of 100 mM perchlorate to the samples accelerates iron removal through both pathways for the C-terminal site, but sharply decreases the rate of iron removal from the N-terminal site. The implications of these new results with respect to proposed mechanisms of iron release from transferrin are discussed. Copyright © 1997 Elsevier Science Ltd

Keywords: transferrin; monoferric transferrin; kinetics; phosphonic acids.

Serum transferrin (Tf) is the protein responsible for the transport of iron through the blood between sites of uptake, utilization and storage [1–4]. The protein consists of a single polypeptide chain, but it folds into a bilobal tertiary structure with a single high-affinity iron binding site located within each lobe [5,6]. The two sites are structurally very similar. Each ferric ion is six coordinate, ligated by the phenolic groups of two tyrosine residues, the imidazole side chain of a histidine residue, the carboxylate group of an aspartate residue and a bidentate carbonate anion [7–9]. This exogenous carbonate ligand is referred to as the synergistic anion, as it, or some suitable substitute, is required for strong metal binding to the protein.

Transferrin is a potential target for therapeutic chelating agents designed to treat the iron overload that accompanies long-term transfusion therapy for genetic diseases such as β-thalassaemia. A considerable amount of effort has been devoted to the elucidation of the mechanism of the exchange of iron between transferrin and low molecular weight chelating agents. Although several mechanisms have been proposed [10–14], the iron release process is still not well understood. Iron removal by some ligands follows simple saturation kinetics with respect to the ligand concentration [10,15,16]. In a few cases, iron removal has followed simple first-order kinetics with respect to the ligand [14,17], and in several cases the kinetics show a combination of saturation and linear dependence on the ligand [11,12,14,17–20].

Crystal structures of transferrin [5,8] and the closely related protein lactoferrin [6,9] have shown that the iron binding sites sit in a narrow cleft in the protein. When iron is removed to form apoTf, there is a major conformational change in which this cleft opens much wider [7,21]. This change, or possibly some intermediate step along the pathway of the overall con-

* Author to whom correspondence should be addressed.

formational change, is probably involved in regulating the rate of iron removal from the protein. It is also clear that the iron release process is strongly influenced by the binding of anions such as Cl^- or ClO_4^- from the solution [11–13,15,18,19,22–26]. In the case of charged ligands such as pyrophosphate, the chelating agent being used to remove the iron from the protein may also function as an allosteric anion [11,12,15].

We have previously reported on iron release by pyrophosphate and a series of aminophosphonic acids [14,17,20,24,27]. In all cases, the apparent first-order rate constant for iron removal shows a complex dependence on the ligand concentration, which appears to represent a combination of saturation and first-order kinetics. This paper extends these studies to include the kinetics of iron removal from both forms of monoferric transferrin by ethylenediaminetetra(methylenephosphonic acid) (EDTP). The expected complex ligand dependence is observed only at the C-terminal site. In addition, there is a surprising degree of negative cooperativity associated with iron release from the N-terminal site. The effect of sodium perchlorate on the iron removal kinetics has also been measured, and the data are discussed in terms of the current proposed mechanisms for iron removal.

EXPERIMENTAL

Materials

Human serum transferrin was purchased from Calbiochem and purified as previously described [28]. Simple monoferric transferrins and cobalt-labelled monoferric transferrins were prepared and purified as described previously [28]. Ethylenediaminetetra (methylenephosphonic acid) (EDTP) was purchased from TCI America in Portland, OR, and used as received.

Methods

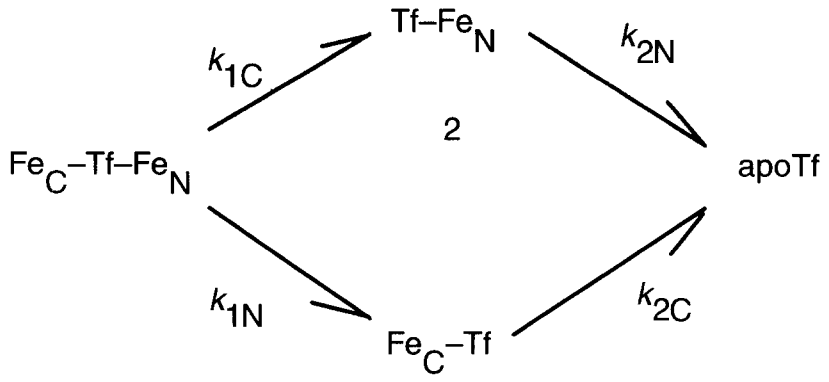
Iron removal reactions were run in 0.1 M *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid (HEPES) at pH 7.4. The reaction was followed by monitoring the decrease in the transferrin iron–phenolate charge transfer band at 465 nm with a Hewlett–Packard model 8452A diode array UV–vis spectrophotometer. The spectrophotometer was equipped with a six-position cell holder connected to an external constant temperature water bath to keep the cuvettes at 25°C during the iron removal reaction.

Rate constants were calculated using either the kinetics routines provided by Hewlett–Packard for the HP Chemstation computer or custom-written programmes based on the general non-linear least squares program ORGLS [29]. All iron removal reactions were run with a large excess of ligand over ferric transferrin and were treated as pseudo first-order, irreversible reactions. For kinetic studies on monoferric transferrins, the absorbance *vs.* time data were fit to Eq. (1)

$$A_t = (A_0 - A_\infty)\, e^{-k_{obs}t} + A_\infty \qquad (1)$$

where A_0, A_∞ and A_t are the absorbances at zero time, infinite time, and any intermediate time t during the reaction, and k_{obs} is the apparent first-order rate constant for a specified concentration of EDTP. For reactions that went to completion, A_0, A_∞ and k_{obs} were all treated as adjustable parameters, and data out to three or four half-lives were included in the calculation. In situations where iron removal did not go to completion, the value for A_∞ was fixed based on the values observed at higher ligand concentrations. The value for k_{obs} was calculated from the initial data collected before the back reaction of iron donation from EDTP to apoTf became a significant factor.

Iron removal from diferric transferrin was also followed by urea–polyacrylamide gel electrophoresis. The electrophoresis method was basically that originally reported by Makey and Seal [30] with the modifications described by Bali and Harris [28]. Gels were run using a BioRad Protean TM-11 16 cm vertical slab gel assembly with a BioRad Model 500/200 power supply. Gels were dried and scanned using a BioRad Model 620 Video densitometer. Peak areas were determined using the BioRad 1D software. In the kinetic studies, diferric transferrin was reacted with 100 mM EDTP. Sequential aliquots were removed from the reaction mixture, frozen in liquid nitrogen to stop further reaction, and later analysed by gel electrophoresis.



RESULTS

Because transferrin has two metal binding sites, there are four microscopic rate constants for iron removal from diferric transferrin as shown below. The subscript for each rate constant indicates the site from which iron is being removed (C-terminal or N-terminal) and whether it is the first or second iron to be removed from the transferrin molecule.

Based on Scheme 1, the exact function for absorbance *vs.* time during iron release from diferric transferrin is

$$A_t - A_\infty = (\varepsilon_C + \varepsilon_N) C_0\, e^{-(k_{1N}+k_{1C})t} + \left[\frac{\varepsilon_C C_0 k_{1N}}{k_{1N}+k_{1C}-k_{2C}}\left(e^{-k_{2C}t} - e^{-(k_{1N}+k_{1C})t}\right)\right] + \left[\frac{\varepsilon_N C_0 k_{1C}}{k_{1N}+k_{1C}-k_{2N}}\left(e^{-k_{2N}t} - e^{-(k_{1N}+k_{1C})t}\right)\right] \qquad (2)$$

where ε_C and ε_N are the molar extinction coefficients for ferric ion bound at each of the two binding sites,

Scheme 1.

and C_0 is the initial concentration of diferric transferrin [25]. Even though the two metal binding sites are about 40 Å apart [6], the occupancy of one site can affect the rate of iron removal at the other site [4,16,17,20,22], so one cannot routinely simplify the equation by assuming that $k_{1C} = k_{2C}$ or that $k_{1N} = k_{2N}$. Unfortunately, it can be extremely difficult to calculate reliable values for k_{1C}, k_{1N}, k_{2C} and k_{2N} from a four-parameter fit of absorbance *vs* time data on diferric transferrin to Eq. (2) [17,20]. Thus we have emphasized studies on purified N-terminal and C-terminal monoferric transferrins. This allows us to calculate values for k_{2N} and k_{2C} as a simple first-order process using Eq. (1).

Iron removal from monoferric transferrins

Pseudo first-order rate constants for the removal of ferric ion from both C-terminal and N-terminal monoferric transferrin have been measured at a series of EDTP concentrations. Plots of k_{obs} *vs* [EDTP] are shown in Fig. 1. These plots resemble saturation kinetics. However, it appears that the rate constant for iron removal from the C-terminal site continues to increase at high ligand concentrations. This more complex ligand dependence has been observed for several other ligands [11,14,17–20], and can be described empirically by the equation

$$k_{obs} = \frac{k'[L]}{1+k''[L]} + k'''[L] \qquad (3)$$

The data for both monoferric transferrins have been fit to Eq. (3) using k' and k'' only (two-parameter fit) and using k', k'' and k''' (three-parameter fit). The results for both two- and three-parameter fits are shown in Fig. 1. Each fit is characterized by an *R*-factor, R_x, where x denotes whether R corresponds to a two- or three-parameter fit. Since the addition of a third adjustable parameter should always improve the fit, the ratio of R_2/R_3 should always be greater than 1. One can test whether the improvement in the fit associated with the third adjustable parameter is statistically significant by comparing the ratio of R_2/R_3 with the test statistic

$$R_{b,n-p,\alpha} = \left(\frac{b}{n-p}F_{b,n-p,\alpha}+1\right)^{1/2} \qquad (4)$$

where p is the maximum number of parameters varied, b is the number of constants held fixed in the more restrictive two-parameter fit, n is the number of observations included in the fitting and α is the desired level of confidence [31]. One may conclude that the value of k''' makes a significant improvement in the fit of k_{obs} *vs* [EDTP] when the *R*-factor ratio exceeds $R_{b,n-p,\alpha}$.

This *R*-factor test has been applied to the data for both C- and N-terminal monoferric transferrin. For N-terminal monoferric transferrin, there is no significant improvement produced by including k''' in the calculation. Thus the N-terminal system follows simple saturation kinetics, and an excellent fit is obtained by setting k''' to zero and using only k' and k'' as adjustable parameters. However, for C-terminal monoferric transferrin, one obtains a significantly better fit with three parameters ($\alpha = 0.005$). Thus the C-terminal site shows complex kinetics that cannot be described as either first-order or saturation.

Equation (3) is an empirical description of the ligand dependence. The possible mechanisms that might explain this behaviour have been the subject of considerable debate [11,13–15,17–20,22]. We interpret the complex ligand dependence of k_{obs} in terms of two parallel pathways for iron removal, one which follows saturation kinetics and one which is simple first-order in ligand. In this model the parameter k'' describes the approach to saturation and has the units of an equilibrium constant. The ratio of k'/k'' gives k_{max}, the maximum rate constant for iron removal through the saturation pathway. The parameter k''' is the rate constant for the first-order pathway. Values of k_{max}, k'' and k''' for iron removal from the monoferric transferrins by EDTP are listed in Table 1.

To compare the behaviour of aminophosphonic acids *vs* aminocarboxylic acids, a more limited set of kinetic data were also collected for iron removal from

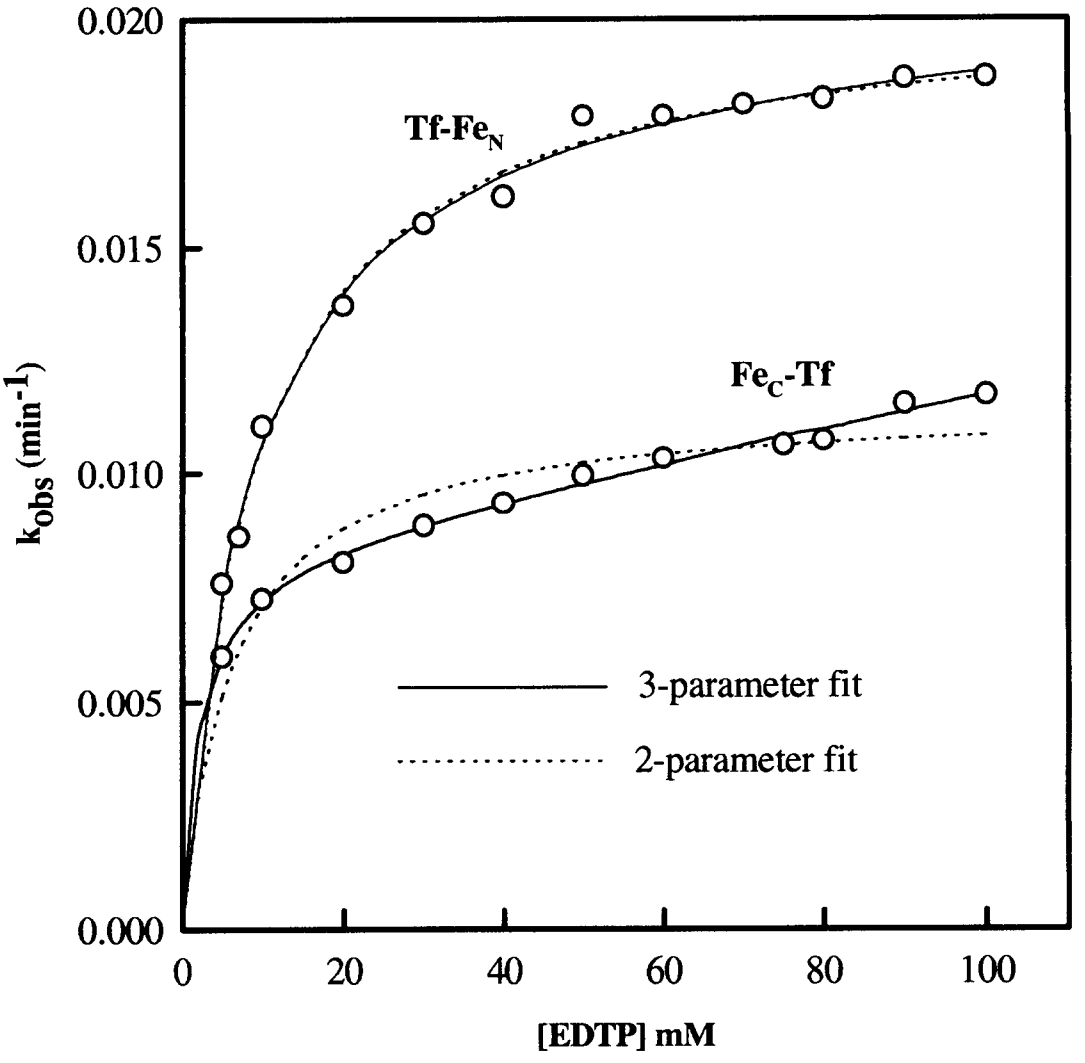


Fig. 1. Apparent first-order rate constants for iron removal from C- and N-terminal monoferric transferrins as a function of the concentration of EDTP. All solutions were buffered at pH 7.4 by 0.1 M HEPES and maintained at 25°C. The lines represent fits of the data to Eq. (3) using either k' and k'' only (two-parameter fit) or k', k'' and k''' (three-parameter fit).

Table 1. Kinetic parameters for iron removal from transferrins by EDTP and EDTA

Sample	$10^3\,k_{max}$ (min^{-1})	k'' (M^{-1})	$10^3\,k'''$ (M^{-1} min^{-1})
Without added perchlorate			
Fe$_C$–Tf + EDTP	8.3 ± 1.6	480 ± 70	36.0 ± 0.3
Fe$_C$–Tf–Co$_N$ + EDTP	11.4 ± 1.8	72 ± 9	0
Fe$_C$–Tf + EDTA	6.4 ± 1.6	118 ± 26	114 ± 6
Tf–Fe$_N$ + EDTP	20.4 ± 1.2	110 ± 5	0
Co$_C$–Tf–Fe$_N$ + EDTP	4.8 ± 1.7	210 ± 70	11.3 ± 4.9
Tf–Fe$_N$ + EDTA	24.9 ± 2.3	370 ± 30	27 ± 5
With 100 *mM* $NaClO_4$			
Fe$_C$–Tf + EDTP	40.7 ± 3.1	59 ± 4	148 ± 9
Tf–Fe$_N$ + EDTP	1.2 ± 0.7	73 ± 33	0

both forms of monoferric transferrin by EDTA. These data are plotted in Fig. 2. *R*-factor ratio tests indicate that three-parameter fits are appropriate for both sites, although the first-order component is much more prominent for the C-terminal site. Values for k_{max}, k'' and k''' are listed in Table 1.

Iron removal from cobalt-labelled monoferric transferrins

To assess the degree of cooperativity between the two transferrin binding sites, one needs to compare k_{1N} with k_{2N} and k_{1C} with k_{2C}. However, it can be difficult to calculate k_{1C} and k_{1N} simultaneously from data on iron removal from diferric transferrin. Thus we have developed the method of labelling one of the binding sites with the kinetically inert cobalt(III) ion [14,17,20]. This allows us to measure the rate of iron removal from one site while the other remains filled with a kinetically inert trivalent metal ion. The resulting rate constants are presented as estimates of k_{1C} and k_{1N} for diferric transferrin.

Both forms of monoferric transferrin have been labelled at the vacant binding site with cobalt(III) to give Fe_C–Tf–Co_N and Co_C–Tf–Fe_N. Dicobalt transferrin was also prepared. Preliminary studies on the reaction of dicobalt transferrin with EDTP showed that there was no significant removal of the kinetically inert cobalt(III) ion over the time period of the iron removal reactions. This is consistent with the recent report that the half-life for removal of Co^{3+} from transferrin by PP_i is over 20 h even at pH 6.5 [32].

Iron removal from Fe_C–Tf–Co_N by EDTP behaved as a simple pseudo first-order process described by Eq. (1). However, iron removal from Co_C–Tf–Fe_N unexpectedly showed two kinetic phases. There was a very rapid initial phase, which accounted for about 20% of the total absorbance change, followed by a larger, slower absorbance change. The first phase was

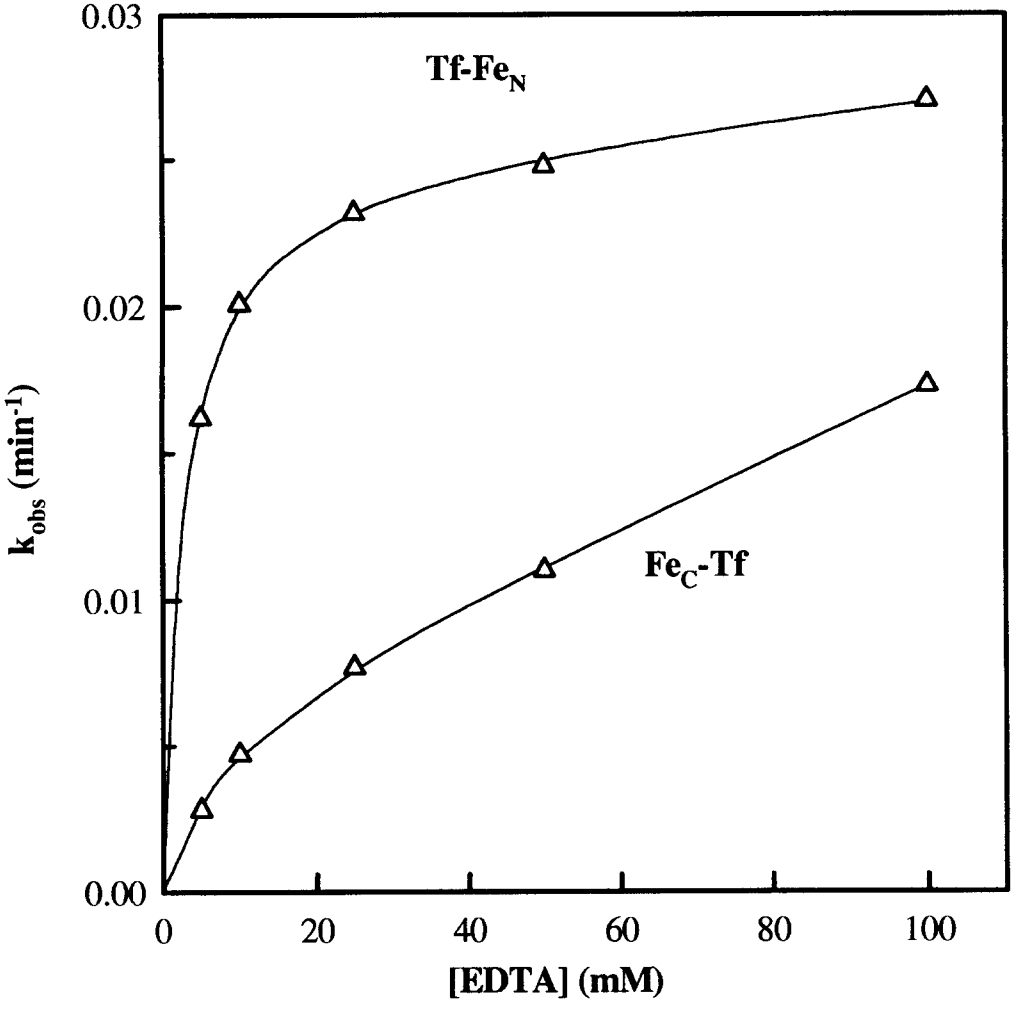

Fig. 2. Apparent first-order rate constants for iron removal from C- and N-terminal monoferric transferrins as a function of the concentration of EDTA. All solutions were buffered at pH 7.4 by 0.1 M HEPES and maintained at 25°C.

much more rapid than iron release from unlabelled monoferric transferrin, and the amplitude of the second phase coincided with the absorbance change expected for the iron removal reaction. Therefore, the rate constant for iron removal was calculated from the slow reaction phase. The origin of the initial faster phase is still not understood.

Rate constants for iron removal from the cobalt-labelled monoferric transferrins as a function of the EDTP concentration are presented in Fig. 3. The data have been treated by both two- and three-parameter fits. The *R*-factor ratio tests indicate that three parameters are required to fit the data for Co_C–Tf–Fe_N, but that iron removal from Fe_C–Tf–Co_N can be described by only two parameters. The resulting values for k_{max}, k'' and k''' are listed in Table 1. Adding cobalt to the N-terminal site has very little effect on the overall rate of iron removal from the C-terminal site. A small increase in k_{max} is offset by a decrease in k'''. In contrast, the addition of cobalt to the C-terminal site results in a sharp drop in the k_{max} for iron removal from the N-terminal site by EDTP. This type of negative cooperativity has not been observed in the previous studies on cobalt-labelled monoferric transferrins [14,17,20].

Iron removal from diferric transferrin

Two types of studies on iron removal from diferric transferrin were conducted to test the validity of using cobalt-labelled monoferric transferrins as a simple tool for measuring accurate values for k_{1C} and k_{1N}. In one set of experiments, iron removal was followed by electrophoresis. This method has the critical advantage that it can easily resolve diferric transferrin from monoferric and apotransferrin [30]. Thus, unlike the case with visible spectrophotometry, which only measures total iron removal, electrophoresis can directly follow the changes in the concentration of diferric transferrin.

The rate of disappearance of diferric transferrin is

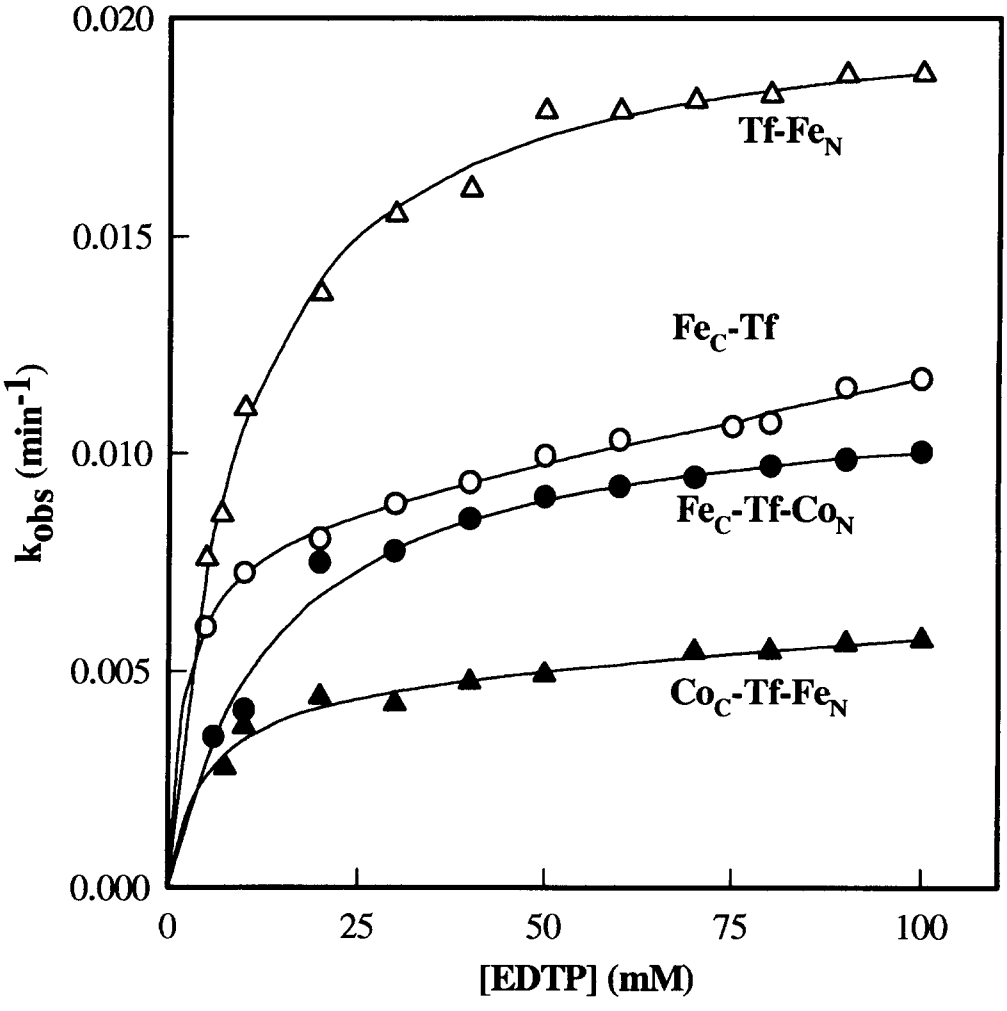

Fig. 3. Apparent first-order rate constants for iron removal from monoferric and cobalt-labelled monoferric transferrins as a function of the concentration of EDTP. All solutions were buffered at pH 7.4 by 0.1 M HEPES and maintained at 25°C.

first-order in diferric transferrin with an observed rate constant equal to the sum of $k_{1C}+k_{1N}$ [25,28]. The densitometry peak areas for diferric transferrin during iron removal by 100 mM EDTP were fit to a first-order equation to obtain $k_{obs} = 0.017 \pm 0.001$ min^{-1}. The sum of the k_{1C} and k_{1N} values for 100 mM EDTP from the spectrophotometric data on the cobalt-labelled monoferric transferrin is 0.016 ± 0.003 min^{-1}. Thus there is excellent agreement with the electrophoresis data on diferric transferrin and the spectrophotometric data on cobalt-labelled monoferric transferrins.

In a second set of experiments, iron removal from diferric transferrin by EDTP was followed spectrophotometrically for a series of EDTP concentrations from 10 to 100 mM. These data were analysed by several different computational methods. One method was to fit the data to Eq. (2) using all four site-specific rate constants as adjustable parameters. However, the parameters fluctuated widely during refinement, and the resulting values of k_{2C} and k_{2N} did not agree with the results on the purified monoferric transferrins. Even when k_{2C} and k_{2N} were both fixed at values determined for the monoferric transferrins, it was not possible to get a smooth, simultaneous refinement of k_{1C} and k_{1N}.

Since we were primarily interested in confirming that k_{1N} is smaller than k_{2N}, a third calculation was run in which k_{2C} and k_{2N} were fixed at the values for monoferric transferrin, k_{1C} was fixed at the value determined from studies on Fe_C–Tf–Co_N, and the data on differic transferrin were fit to Eq. (2) using only k_{1N} and A_∞ as adjustable parameters. Over the range of 20–100 mM EDTP, there was very good agreement between the values of k_{1N} calculated from data on diferric transferrin and from data on cobalt-labelled N-terminal monoferric transferrin. Below 20 mM EDTP, it became difficult to deal with the problem of incomplete iron removal from diferric transferrin. Nevertheless, the agreement between two sets of k_{1N} values confirms that the cobalt-labelled monoferric transferrins provide very good models for the kinetic behaviour of diferric transferrin, and that occupancy of the C-terminal site results in slower iron release from the N-terminal site by EDTP.

Owing to its complexity, Eq. (2) is often reduced to the two exponential Eq. (5)

$$(A - A_\infty) = C_0\varepsilon\left(\left(2 - \frac{m_1}{(m_1 - m_2)}\right)e^{-m_1 t} + \left(\frac{m_1}{m_1 - m_2}\right)e^{-m_2 t}\right) \quad (5)$$

where C_0 is the initial concentration of diferric transferrin, ε is the molar extinction coefficient of diferric transferrin and the rate constants are related back to Scheme 1 by the equations $m_1 = k_{1C}+k_{1N}$ and $m_2 = k_{2C} = k_{2N}$ [5,16,25]. The spectrophotometric data on iron removal from diferric transferrin by EDTP have been fit to Eq. (5) using m_1, m_2, C_0 and A_∞ as adjustable parameters. Equation (5) gives an excellent fit of the absorbance *vs* time data, and the resulting values of both m_1 and m_2 show simple saturation kinetics. However, the results are not consistent with the results on the monoferric transferrins. The value of m_2, which should approximate the average of k_{2C} and k_{2N}, levels off at only *ca* 0.006 min^{-1}, which is smaller than either k_{2C} (*ca* 0.010 min^{-1}) or k_{2N} (*ca* 0.018 min^{-1}). Conversely, the value of m_1 levels off at *ca* 0.022 min^{-1} and is greater than the sum of the k_{1C} and k_{1N} values determined from the cobalt-labelled monoferric transferrins.

Salt effects on iron removal

The ligand dependence of the apparent first-order rate constant for iron removal by EDTP has been measured in 0.1 M HEPES buffer which also contained 100 mM $NaClO_4$. At each ligand concentration, the reaction follows first-order kinetics. The apparent first-order rate constant is plotted as a function of the ligand concentration in Fig. 4 for both forms of monoferric transferrin. The presence of 100 mM perchlorate dramatically increases the rate of iron release from the C-terminal binding site. There is a highly significant improvement in the three-parameter fit for the C-terminal data. Thus the faster rate can be attributed to both an increase in k_{max} from 0.00824 to 0.0407 min^{-1} as well as an increase in k''' from 0.036 to 0.148 min^{-1}. These two factors combine to give an overall five-fold increase in the rate of iron removal by 100 mM EDTP. Perchlorate has a much different effect on iron release from the N-terminal binding site. There is a very sharp decrease in k_{max} from 0.020 min^{-1} to only 0.0012 min^{-1}. There is no first-order term either with or without perchlorate.

DISCUSSION

The rates of iron release by EDTP are generally similar to those reported previously for PP_i and other aminophosphonic acids [14,17,20]. However, the first-order component of the ligand dependence curves is less prominent for EDTP than for the related ligands nitrilotris(methlenephosphonic acid) (NTP) or diethylenetriaminepenta(methylenephosphonic acid) (DTPP). The value of k''' can be set to zero for iron removal from Tf–Fe_N and Fe_C–Tf–Co_N. Although the addition of k''' provides a statistically significant improvement in the fit for Co_C–Tf–Fe_N, the chemical significance of this added parameter is doubtful. The standard deviations for k'' and k''' are quite high, and the saturation pathway is still the dominant route of iron removal. The first-order pathway is most important for iron removal from Fe_C–Tf. In this case the improvement in the fit associated with the addition of k''' is highly significant, and the resulting value of k''' is well defined with a small standard deviation.

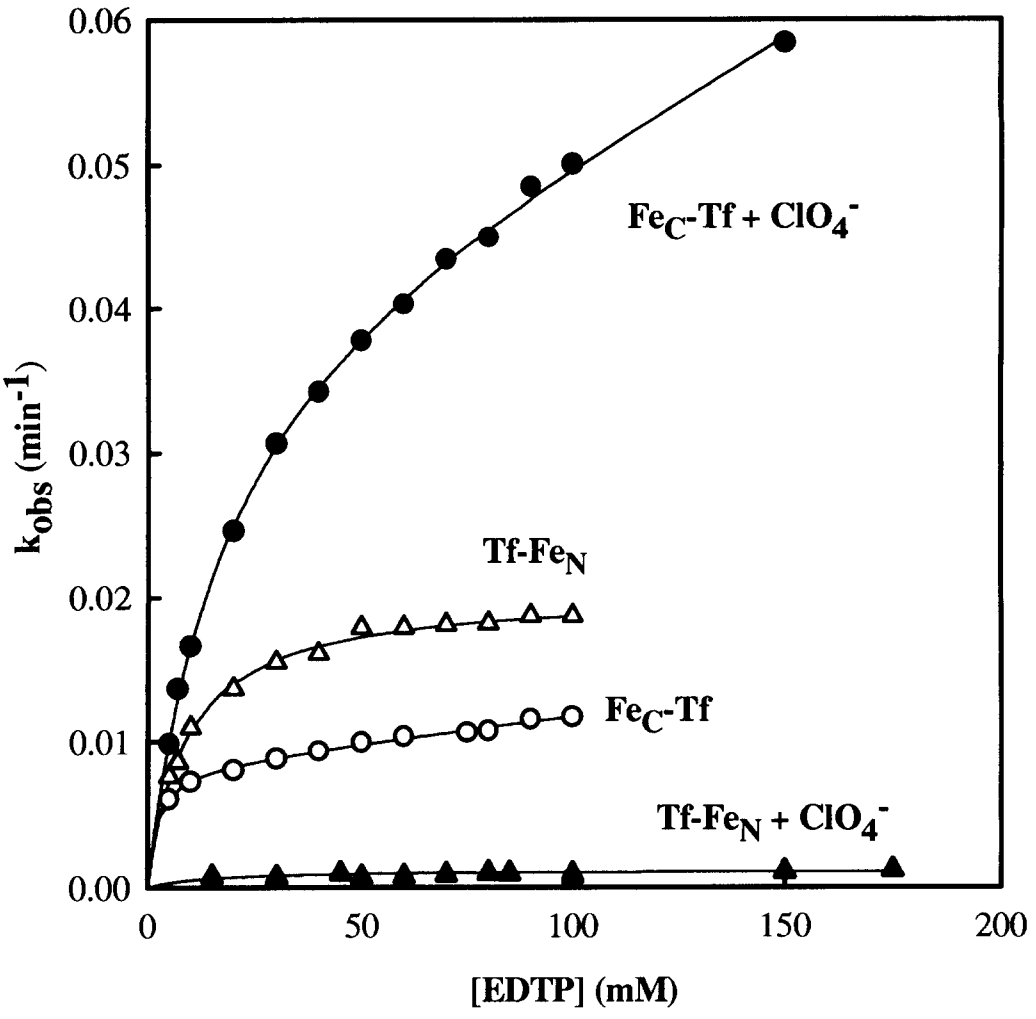

Fig. 4. The effect of $NaClO_4$ on the rates of iron removal from both forms of monoferric transferrin. Open symbols show apparent first-order rate constants in the absence of perchlorate, while closed symbols show the rate constants measured in the presence of 100 mM $NaClO_4$. All solutions were buffered at pH 7.4 by 0.1 M HEPES and maintained at 25°C.

In recent studies with both forms of monoferric transferrin, iron removal by the aminocarboxylates NTA and DTPA followed simple first-order kinetics with respect to the ligand concentration [14,17]. Iron removal from diferric transferrin by EDTA had been studied earlier and appeared to follow either saturation or complex kinetics [25]. In repeating the experiments on iron removal by EDTA using monoferric transferrins, we suspected that this apparent discrepancy between EDTA and the other aminocarboxylates reflected the difficulties of getting reliable two-exponential fits for diferric transferrin. Thus we expected that the monoferric transferrins would show simple first-order kinetics with EDTA as they had with NTA and DTPA. However, the results on the monoferric transferrins are in fact very similar to the earlier results on diferric transferrin [23,25]. It is quite clear that neither site follows simple first-order kinetics. It is not at all clear why EDTA behaves so differently from NTA and DTPA.

Cooperativity. In previous studies on iron removal by PP_i [20], NTP [17] and DTPP [14], cobalt-labelling has shown either no effect or a small positive cooperativity. This study on EDTP is the first example of significant negative cooperativity, in which cobalt-labelling of the C-terminal site substantially retards the rate of iron release from the N-terminal site. This is almost entirely owing to a sharp decrease in k_{max} from 0.020 to 0.0012 min^{-1}.

While the cooperativity effects in iron removal from the two transferrin binding sites tend to be rather modest, they are important in relation to attempts to simplify the fitting of the data on iron release from diferric transferrin. If there were no cooperativity between the two binding sites, then Eq. (2) would reduce to a simple two-exponential equation

$$A_t = (A_0 - A_\infty)(0.5\,e^{-k_C t} - +0.5\,e^{-k_N t}) + A_\infty \quad (6)$$

where k_C and k_N are the rate constants for the indi-

vidual binding sites. This equation was used with apparent success to fit the absorbance data on iron removal from diferric transferrin by high concentrations of EDTP and NTP [33]. However, Bali and Harris [20] showed that even though Eq. (6) gave an excellent fit to the experimental data on iron removal from diferric transferrin by PP_i, there were serious inconsistencies between the resulting rate constants for diferric transferrin and the rate constants measured for iron removal from the purified monoferric transferrins.

Equation (5) is also a two-exponential fit of the absorbance data, where it is assumed that k_{2C} and k_{2N} are similar to each other, and that each is much smaller than the sum of $k_{1C}+k_{1N}$ [25]. This equation is more flexible than Eq. (6), allowing for different pre-exponential terms and for cooperativity between the two sites. However, even these less restrictive assumptions are not valid for iron removal by EDTP. The values of k_{2C} and k_{2N} differ by almost a factor of 2, and the sum of $k_{1C}+k_{1N}$ is approximately equal to the average of k_{2C} and k_{2N}. Nevertheless, Eq. (5) still gives an excellent fit to the absorbance data reported here on iron removal from diferric transferrin by EDTP. The only indication that anything is wrong is the fact that the values of m_1 and m_2 are inconsistent with the results on the purified monoferric transferrins.

Similar discrepancies between m_1 and m_2 and corresponding data on monoferric transferrins have been reported for iron removal by NTP [17]. The critical point to be made here is not that Eq. (5) is necessarily invalid for all ligands, but that the quality of the fit of absorbance *vs* time is not a good criterion for judging the validity of the calculated values of m_1 and m_2. Thus one must be cautious in accepting results on iron removal from diferric transferrin based on two-exponential fits unless some corroborating data from monoferric transferrins is available.

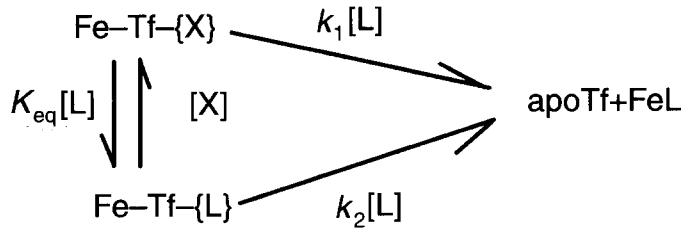
Mechanisms for iron release. Iron removal from the N-terminal binding site by EDTP follows simple saturation kinetics. Similar results have been observed for LICAMS [16], AHA [10], mimosine [15] and tiron [15]. Such results are consistent with a rate-limiting conformational change during iron removal as first proposed by Cowart *et al.* [10]. This simple conformational change mechanism is shown below.

$$\text{Fe–CO}_3\text{–Tf} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{Fe–CO}_3\text{–Tf*} \qquad (7)$$

$$\text{Fe–CO}_3\text{–Tf*} + \text{L} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \text{L–Fe–CO}_3\text{–Tf*} \qquad (8)$$

$$\text{L–Fe–CO}_3\text{–Tf*} \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} \text{HCO}_3\text{–Tf*} + \text{Fe–L} \qquad (9)$$

$$\text{apoTf*} + \text{HCO}_3 \overset{K_C}{\rightleftharpoons} \text{HCO}_3\text{–Tf*} \qquad (10)$$



The asterisk is used to denote an "open", reactive form of the protein. At high ligand concentration, the forward reaction in Eq. (7) becomes rate limiting. Since this step does not involve the ligand, one observes saturation kinetics with respect to the free ligand concentration.

Kretchmar and Raymond [13] have shown that the rates of iron removal by LICAMS extrapolate essentially to zero at zero ionic strength, and they have proposed that a critical anion binding site on the protein must be occupied in order for iron removal to occur. This site is often referred to as the *ki*netically *s*ignificant *a*nion *b*inding (KISAB) site [12,19]. This nomenclature serves to distinguish clearly this site from the binding of the synergistic bicarbonate anion. In the absence of added salts, the KISAB site is presumably filled by an anion from the buffer or by an anionic ligand. Although the KISAB site has not been structurally characterized, it has been suggested, based on the transferrin crystal structure, that it may involve cationic amino acid side chains that project into the interdomain cleft near the metal binding site [7,9].

There have been several reports that the addition of perchlorate accelerates iron release from the C-terminal binding site, but retards the rate of iron release from the N-terminal binding site [11,12,18,19,23,24]. The present study shows that the addition of perchlorate produces a sharp decrease in k_{max} for the saturation pathway of Tf–Fe_N from 0.020 to 0.0012 min^{-1}. The value of k''' for the N-terminal site is zero with or without perchlorate. Thus one cannot regard occupancy of the KISAB site as a simple on/off switch between native and modified forms of the protein, since replacing an anion from the buffer with perchlorate alters the value of k_{max} of the modified form. These results are essentially consistent with the kinetic model of Bertini *et al.* [11], which contains two saturation pathways linked by an anion binding equilibrium. It is also noteworthy that with EDTP, the binding of a cobalt ion at the C-terminal site produces much the same shift from one saturation process to a second, much slower saturation pathway.

Iron removal from Fe_C–Tf by EDTP shows a complex combination of saturation and first-order kinetics. As Fig. 4 shows, perchlorate accelerates both the saturation and the first-order components of iron release. There is an increase in k_{max} for the saturation pathway from 0.0083 to 0.0407 min^{-1}, as well as an increase in the first-order rate constant k''' from 0.036 to 0.148 min^{-1}. These results are consistent with the existence of two independent pathways for iron release, one that shows saturation kinetics and one that is first order in ligand, each of which can be affected by added anions. Such a mechanism is flexible enough to explain the salt effects and to accommodate the observations that some ligands, such as LICAMS and AHA, follow simple saturation kinetics [10,16], while other ligands, such as NTA and DTPA, follow simple first-order kinetics [14,17].

We have suggested that the first-order pathway is related to a disruption of the binding of the synergistic

Scheme 2.

bicarbonate anion by an anionic functional group of the ligand. It is well known that many different ligands (e.g. NTA, EDTA and oxalate) can form weak Fe–L–Tf ternary complexes [34,35], which would be expected to dissociate quickly into FeL and apoTf. Recent studies on the R124K and R124S mutants of the transferrin N-terminal half-molecule have confirmed that modification of the binding site arginine residue significantly accelerates iron removal by pyrophosphate, although iron removal from R124K continues to follow saturation kinetics with respect to pyrophosphate [26].

Recent crystallographic data indicate a degree of structural flexibility in the binding of the synergistic anion. In dicupric transferrin the carbonate anion in the C-terminal site is bidentate, while the anion in the N-terminal site is only monodentate [36]. Thus it is also possible that the first-order pathway might involve a direct attack of the ligand on the metal and a shift in the mode of coordination of the anion from bidentate to monodentate. One potential weakness of these hypotheses for the first-order pathway is that to avoid the rate limitations of the conformational change, one must accept that ligands have direct access to the iron even in the closed form of the Fe–CO_3–Tf complex.

Another mechanism for iron removal has been proposed, which consists of two first-order processes linked by the pre-equilibrium binding of an anion to the KISAB site [12,18,19], as shown in Scheme 2, where the { } brackets are used to denote the KISAB anion binding site. At low ligand concentration, the KISAB site is presumably occupied by an inorganic anion (X) from the buffer or from added salts [13]. As the ligand concentration increases, the ligand competes with the original anion for occupancy of the KISAB site. The appearance of complex ligand dependence curves is attributed to the conversion of Fe–Tf–{X}, with a faster first-order rate constant for iron removal, to Fe–Tf–{L}, with a slower first-order rate constant, i.e. k_2 must be smaller than k_1.

Since k_2 reflects the rate of iron release when the KISAB site is occupied by the ligand, this mechanism requires that for a given chelating agent, k_2 must be independent of any added anion. Egan *et al.* [12] evaluated the effect of several anions on iron removal from the C-terminal site at a series of PP_i concentrations, and found that, as predicted, these anions had no effect on k_2. The rate constant k_2 from Scheme 2 is mathematically equivalent to k''' in Eq. (3). Thus it is significant that the results reported here on EDTP show that the addition of perchlorate results in a very substantial increase in k''' from 0.036 to 0.148 min^{-1}. This indicates that the observation made by Egan *et al.* [12] that the slope of the linear portion of complex kinetic ligand dependence curves is unaffected by added anions, may be true for PP_i but it cannot be accepted as a general statement for other ligands. In addition, it is difficult to account for systems that show simple saturation kinetics as a combination of two first-order pathways. We believe that the only way to account for the range of kinetic behaviours observed with different ligands is to allow for two independent pathways, one which shows saturation kinetics and the other of which is first-order in ligand. The results of this study require that this model be expanded to allow for the binding of anions to a KISAB site. This anion binding can affect both pathways and may either accelerate or retard the rates of iron removal.

(Received 23 July 1996; accepted 6 August 1996)

Abstract—Interaction of $[M(NBu^t)(NHBu^t)(H_2NBu^t)Cl_2]_2$, M = Nb, Ta, with five equiv. of Bu^tNHLi gave $\{[M(NBu^t)_3(NHBu^t)]Li_2\}_2$, M = Nb (**2a**), M = Ta (**2b**), which showed the presence of three different *tert*-butylimido groups and resisted further metallation. Interaction of MCl_5, M = Nb, Ta, with 1-amino-2,2,6,6-tetramethylpiperidine, $C_9H_{18}NNH_2$, in the presence of Me_3SiCl–Et_3N gave $(Et_3NH)[M(C_9H_{18}N_2)_2Cl_4]$, M = Nb (**3a**), M = Ta (**3b**). A similar interaction with NH_4VO_3 gave low yields of $[(C_9H_{18}N_2)_2(OSiMe_3)_2V(\mu\text{-}O)V(O)(OSiMe_3)_2]$ (**4**). The X-ray crystal structures of (**2a**), (**3b**) and (**4**) have been determined. Copyright © 1997 Elsevier Science Ltd

Keywords: imido complexes; isodiazene complexes; vanadium; niobium; tantalum; crystal structures.

Anionic homoleptic *tert*-butylimido complexes $M(NBu^t)_4Li_2$, M = Mo, W [1a], Cr [1b], $Re(NBu^t)_4Li(tmed)$ [1c] and $Mn(NBu^t)_4Li_2(dme)_2$ [1d] were prepared by deprotonation of the complexes $M(NBu^t)_2(NHBu^t)_2$, M = Cr, Mo, W, $Re(NBu^t)_3(NHBu^t)$ and interaction of $Mn(NBu^t)_3Cl$ with $LiNHBu^t$ under specific conditions. This paper describes attempts to prepare homoleptic *tert*-butylimido complexes of niobium and tantalum.

Isodiazene complexes of tungsten and rhenium using the bulky hydrazine, 1-amino-2,2,6,6-tetramethylpiperidine, have been structurally characterized [2]. The extension of this chemistry to group 5 metals is also described.

RESULTS AND DISCUSSION

tert-*Butylimido complexes*

From the range of known *tert*-butylimido complexes of niobium and tantalum [3], $[M(NBu^t)(NHBu^t)(H_2NBu^t)Cl_2]_2$, M = Nb (**1a**), M = Ta (**1b**), seemed to be good starting materials for the synthesis of imido-amido complexes, which in turn could be deprotonated to anionic imido complexes by strongly basic alkyl lithiums. Interaction of **1a** or **1b** with 6 equiv. of $LiNHBu^t$ in diethyl ether gave, after work-up, oils, the ^1H NMR of which consisted of one broad and one sharp *tert*-butyl peaks in approximate ratio 3:1. Although a plausible formulation for these oils is $M(NBu^t)$ e.g. $(NHBu^t)_3$ (M = Nb, Ta), which is supported by their reactivity with $LiNHBu^t$ (see below), no attempt at further characterization was undertaken. Interaction of the dimers **1a** or **1b** with 10 equiv. of Bu^tNHLi in ether gave, after work-up, good yields of $\{[M(NBu^t)_3(NHBu^t)]Li_2\}_2$ M = Nb (**2a**); M = Ta (**2b**), as colourless, extremely air-sensitive prisms. Compounds **2a** and **2b** could also be obtained, but in lower yields, by reactions of the above mentioned oils with 3 equiv. of Bu^tNHLi. It is worth noting that neither higher $(Bu^tNHLi):\mathbf{1}$ ratios, nor interaction of **2a** or **2b** with Bu^nLi or MeLi, resulted in deprotonation of the remaining *tert*-butylamido group. An analogous situation was observed by Wigley [4] who reported the preparation of $[Li(thf)_2][M(Nmes)_3(NHmes)]$ M = Nb, Ta, mes = 2,4,6-trimethylphenyl.

* Author to whom correspondence should be addressed.

The crystal structure of **2a** has been determined by X-ray diffraction and is shown in Fig. 1; selected bond lengths and angles are in Table 1. There are two crystallographically independent centrosymmetric dimers in each of which two $Nb(NBu^t)_3(NHBu^t)$ units are linked by N···Li···N bridges. The four lithium cations of each dimer exhibit positional disorder and fractionally occupy six sites in the form of a cyclohexane-type ring (Fig. 1). A similar situation was observed in the related dimer $[W_2(NBu^t)_8Li_4]$ [5]. In the present case the amido function is presumed to be contained within the bridging system, since the terminal ligand is a normal, linear 6e *tert*-butylimido. The two imido groups on each niobium which are involved in the bridging are bent, presumably as a result both of the lithium coordination and the over availability of π-electrons for an 18e niobium count. Whilst there may be some disorder of the three bridged ligands, linked to the disorder of the lithiums, it would seem that the amide predominantly occupies the N(n4) site, which has the longest bond and the smallest Nb—N—C angle. The amide protons were not, however, located on a difference map. The lithium cations can formally be considered as four-coordinate. Three sites are occupied by nitrogen atoms with Li···N interactions ranging between 1.92(3) and 2.20(3) Å, and the fourth site taken up by an "agostic" interaction with a methyl group, with Li···C distances ranging from 2.50(2) to 2.66(2) Å.

Compounds **2a** and **2b** show identical spectroscopic (IR, NMR) behaviour. The ν(N—H) in the IR is at 3175 cm^{-1}, while in the ^1H NMR spectrum there are four inequivalent *tert*-butyl groups in the ratio 1 : 1 : 1 : 1. These are assigned to one linear *tert*-butylimido, one *tert*-butylamido and two *tert*-butylimido groups associated with lithium atoms. The chemical inequivalence of these four groups is consistent with an arrangement in which one lithium atom is bridging two imido groups, while the other is bridging one imido and one amido groups. Each lithium site connects the two NbN_4 tetrahedra by association with three nitrogen atoms, therefore, each cation is bound to two bridging imido nitrogen atoms and one amido nitrogen atom. This is further supported by the presence of two inequivalent lithium environments in the ^7Li NMR spectrum.

Compounds **2a** and **2b** reacted with C_6H_5SeBr in petroleum to give low yields of oily products which were characterized by EI mass spectra as $(Bu^tN)M(NHBu^t)(Bu^tNSePh)_2$, M = Nb, Ta, but crystalline compounds could not be obtained. Similar compounds have been obtained by interaction of $W(NBu^t)_4Li_2$ with C_6H_5SCl [6].

Isodiazene complexes

In a previous paper [2] we reported on the interaction of 1-amino-2,2,6,6-tetramethylpiperidine with tungsten and rhenium oxo-complexes to obtain com-

pounds which, on the grounds of structural data and oxidation state arguments, were classified as isodiazene complexes rather than hydrazido (2^-) species. Extension of this chemistry to group 5 metals led to isolation of anionic complexes $(Et_3NH)[M(N_2C_9H_{18})_2Cl_4]$ (**3a**), M = Nb; (**3b**) M = Ta. They were prepared in satisfactory yields in benzene from MCl_5 (M = Nb, Ta) in the presence of Et_3N/Me_3SiCl, which is thought to form *in situ* trimethylsilylhydrazine. They were crystallized from toluene as toluene solvates, which prevented informative and reproducible combustion analyses due to solvent loss.

The structure of **3b** was determined by X-ray crystallography and is shown in Fig. 2; selected bond lengths and angles are in Table 2. The tantalum centre has distorted octahedral geometry with *cis*-$C_9H_{18}N_2$ groups. Close intermolecular contacts are found between the octahedral face defined by Cl(2), Cl(3) and Cl(4) and the triethylammonium cation [N(3)···Cl distances range between 3.40(1) and 3.46(1) Å]. The Ta—N—N unit is nearly linear [176.5(5) and 176.4(5)°], while the *exo* nitrogen atoms N(11) and N(21) are planar [angle sum 357.5(2) and 357.2(2)°, respectively]. Their planes are approximately aligned with the meridional planes of the octahedron [i.e. plane of N(11) with that defined by N(1), Ta, Cl(1), Cl(3) and of N(21) with that defined by N(2), Ta, Cl(1) and Cl(3)]. There are two types of Ta—Cl distances, the longest being *trans* to the N ligands, indicative of a certain degree of *trans* influence exerted by the $C_9H_{18}N_2$ group. The Ta—N distances [1.865(7) and 1.882(6) Å] and the N—N distances [1.283(9) and 1.259(8) Å] are both within the range between single and double bonds. Thus, metrical data of the Ta—N—N moiety strongly support the presence of extensive π-interaction delocalized over the metal and nitrogen atoms. Various resonance forms have been invoked to describe the bonding in compounds of type MN_2R_4 [2], e.g.

$$M \leftarrow N^- {=}^+ NR_2 \quad M^- — \ddot{N} {=}^+ NR_2$$

$$M{=}\ddot{N}—\ddot{N}R_2 \quad M^- {\equiv}^+ N—NR_2$$

making the unambiguous assignment of formal metal oxidation states difficult. The two extreme models of hydrazido (2^-) and isodiazene (0) have been encountered in the literature [2]. In the present case an isodiazene formulation is preferred, since it gives a realistic oxidation state of (III) for the tantalum. In support of this is the observation of Ta—Cl(1) and Ta—Cl(3) distances [2.451(2) and 2.472(2) Å], which are longer than those reported for the tantalum(V) compounds [7] [2.317(2)–2.362(2) Å].

The diamagnetism of **3b** may be ascribed to pairing of the two *d*-electrons occupying the lowest energy single orbital resulting from π-perturbation because of the isodiazene ligands.

The identical ^1H NMR spectra of **3a** and **3b** suggest that they are isostructural.

Interaction of NH_4VO_3 with $H_2NNC_9H_{18}$ in neat Me_3SiCl/Et_3N (see Experimental) gave crystals of $[(C_9H_{18}N_2)_2(OSiMe_3)_2V(\mu\text{-}O)V(O)(OSiMe_3)_2]$ (**4**). This could not be obtained free of siloxanes even after repeated recrystallizations from petroleum.

The structure was unequivocally determined by X-ray crystallography and is shown in Fig. 3; selected bond lengths and angles are in Table 3. It is an asymmetric oxo-bridged dimer. The coordination geometry at V(1) can be best described as trigonal bypyramidal; the axial sites are occupied by one $C_9H_{18}N_2$ ligand and the bridging oxo atom, while an additional $C_9H_{18}N_2$ and two $OSiMe_3$ groups are in the equatorial position [coordination angles: N(1)—V(1)—O(1) = 171.97(11)°, the angles in the equatorial plane range between 117.68(12) and 120.22(11)°]. The coord-

ination geometry at V(2) is distorted tetrahedral comprising two $OSiMe_3$ groups, one terminal oxo and one bridging oxo atoms. The metrical data for the V—N—N moiety on V(1) observed here, e.g. short N—N [1.285(3)–1.245(4) Å], V—N [1.725(2)–1.781(3) Å] bonds and planar *exo*-nitrogen atoms [angle sums 356.6 and 359.9° around N(11) and N(21), respectively], resemble those already discussed above for **3b**, again pointing to an isodiazene as the best description of the nitrogen ligand. Of particular interest is the almost linear highly asymmetric oxo-bridge. In this V(2)—O(1) [1.650(2) Å] is only slightly longer than the terminal V(2)—O(6) [1.616(2) Å] and is in contrast with the long V(1)—O(1) bond [2.175(2) Å], the latter indicating weakening of the bond between V(1) and the bridging oxygen O(1). An explanation of this asymmetry could be found in the different electronic environment of the vanadium atoms: V(1), formally a V^{III} centre, is π-electron rich and, therefore, is not involved in any π-type interactions with the oxo-group. V(2) is more π-acidic, resulting in strong vanadium–oxygen bonds. The slight difference in V—$OSiMe_3$ distances between the two metal centres underlines the nature of siloxides as "spectator" ligands.

The same compound could be obtained when using $VOCl_3$, V_2O_5 or $VOCl_2(OSiMe_3)$ instead of NH_4VO_3, although purification was even more difficult. Replacement of the last oxo group from the vanadium proved impossible even after prolonged reaction times.

EXPERIMENTAL

Analyses were by the Imperial College microanalytical laboratory. All operations were carried out under purified Ar or N_2, or in a Vacuum Atmospheres

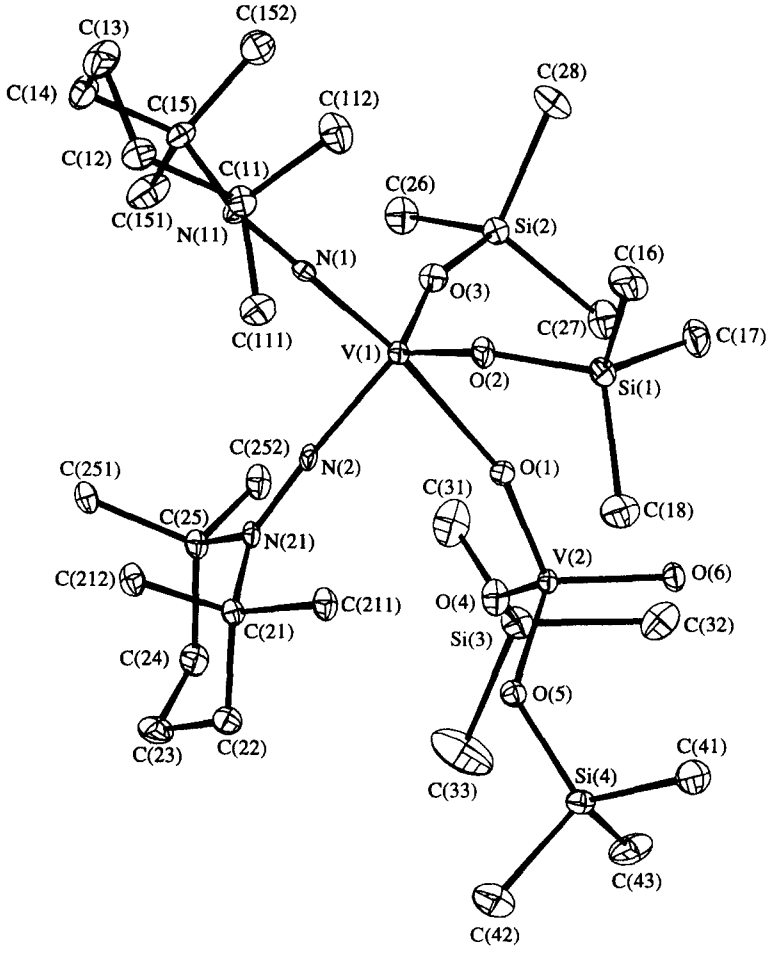

Fig. 3. The structure of $[(C_9H_{18}N_2)_2(OSiMe_3)_2V(\mu\text{-}O)V(O)(OSiMe_3)_2]$ (**4**).

glove-box. All solvents were degassed and distilled before use.

NMR data were obtained using a JEOL EX-270 or Bruker Avance DRX-300 spectrometer operating at 270 or 300 MHz (^1H), respectively, and referenced to the residual proton impurity in the solvent (δ 7.15 C_6D_6). Mass spectra were obtained on a VG-7070E or VG Autospec spectrometers.

Commercial chemicals were from Aldrich and Avocado Chemicals.

The following starting materials were prepared according to literature procedures: $[Nb(NBu^t)(HNBu^t)(H_2NBu^t)Cl_2]_2$ [8], $[Ta(NBu^t)(NHBu^t)(H_2NBu^t)Cl_2]_2$ [8] $H_2NNC_9H_{18}$ [9]. Bu^tNHLi was obtained by interaction of Bu^nLi with Bu^tNH_2 in hexanes. The petroleum used throughout had a boiling point of 40–60°C.

Dilithiumtris(tert-*butylimido*)(tert-*butylamido*) *niobate*(**2a**)

To a solution of $[(Bu^tN)Nb(HNBu^t)(H_2NBu^t)Cl_2]_2$ (0.76 g, 1 mmol) at −78°C in Et_2O (*ca* 50 cm^3) was added a suspension of Bu^tNHLi [0.79 g, 10 mmol in Et_2O (30 cm^3)]. The mixture was allowed to warm to room temperature and stirred overnight. Evaporation of volatiles under reduced pressure, extraction of residue with hot petroleum (5×30 cm^3), filtration and concentration of filtrate to *ca* 30 cm^3 and standing at room temperature overnight gave colourless prisms. Yield 0.55 g 70%; m.p. > 230°C (decomposition). X-ray quality crystals were obtained by slow cooling solutions in toluene. [Found (calc.): C, 49.2 (49.1); H, 9.4 (9.4); N, 15.0 (14.3)%]. NMR (C_6D_6): ^1H: δ 2.6 (s, br, 1H, N*H*CMe$_3$), 1.83, 1.62, 1.59 (s, 9H each, NC*Me*$_3$), 1.47 (s, 9H, NHC*Me*$_3$). ^7Li: δ 2.5 and 2.0.

Dilithiumtris(tert-*butylimido*)(tert-*butylamido*) *tantalate*(**2b**)

As for **2a**, but from $[(Bu^tN)Ta(HNBu^t)(H_2NBu^t)Cl_2]_2$ (0.94 g, 1 mmol) and Bu^tNHLi (0.79 g, 10 mmol). Yield 0.69 g, 75%; m.p. > 230°C (decomposition). [Found (calc.): C, 39.8 (40.0); H, 7.5 (7.7); N, 11.6 (11.7)%]. NMR (C_6D_6) ^1H: δ 2.6 (s, br, 1H, N*H*CMe$_3$), 1.73, 1.49, 1.47 (s, 9H each, NC*Me*$_3$), 1.37 (s, 9H, NHC*Me*$_3$). ^7Li: δ 2.5 and 2.0.

(Triethylammonium)[tetrachlorobis(2,2,6,6-tetramethylpiperid-1-ylnitrene)tantalate(III) (**3b**) *and niobate(III)* (**3a**)

To $TaCl_5$ (0.3 g, 0.84 mmol) in benzene (10 cm^3) was added sequentially Et_3N (0.58 g, 4.2 mmol), 1-amino-2,2,6,6-tetramethylpiperidine (0.32 g, 2.1 mmol) then Me_3SiCl (0.53 g, 4.2 mmol). The mixture was stirred and refluxed under N_2 overnight. After cooling and removal of all volatiles *in vacuo*, the residue was washed with petroleum (20 cm^3) and extracted with toluene (2×30 cm^3). After filtration, reduction of volume of toluene to *ca* 15 cm^3 and cooling to $-20°C$, orange–red crystals were obtained. Yield 0.36–0.48 g, 60–70%. Recrystallization from toluene yielded crystals of X-ray quality. The crystals decomposed on drying *in vacuo* due to facile removal of toluene. Consequently, no satisfactory analytical results were obtained. ^1H NMR of various samples showed the presence of toluene to varying concentrations. NMR (C_6D_6) ^1H: δ 9.42 (s, br, 1H, Et_3NH), 2.56 [pseudoquartet, br, 6H $(CH_3CH_2)_3NH$], 1.85 (s, 12H, $Me_4C_5H_6$), 1.77 (s, 12H, $Me_4C_5H_6$), 1.33 (m, 12H, $Me_4C_5H_6$), 0.78 (t, br, 9H, $(CH_3CH_2)_3NH$].

The corresponding niobium compound could be prepared in the same way with or without the presence of C_6H_6. However, toluene was lost more readily from the final crystalline material. NMR (C_6D_6) ^1H: δ 9.42 (s, br, 1H, Et_3NH), 2.56 [pseudoquartet, br, 6H $(CH_3CH_2)_3NH$], 1.85 (s, 12H, $Me_4C_5H_6$), 1.77 (s, 12H, $Me_4C_5H_6$), 1.33 (m, 12H, $Me_4C_5H_6$), 0.78 [t, br, 9H, $(CH_3CH_2)_3NH$].

[Bis(2,2,6,6-tetramethylpiperid-1-ylnitrene)bis(trimethylsiloxo)]vanadium(μ-oxo)[bis(trimethylsiloxo)oxo]vanadium (**4**)

This compound could be prepared using any of the following starting materials, $VOCl_3$, NH_4VO_3, V_2O_5, $VOCl_2(OSiMe_3)$ [prepared from $VOCl_3$ using $(Me_3Si)_2O$ in the presence of Et_3N and Me_3SiCl] without benzene as solvent. NH_4VO_3 gave the cleanest product. To NH_4VO_3 (0.6 g, 6 mmol) was added sequentially with stirring, Et_3N (8 g, 25 mmol), 1-amino-2,2,6,6-tetramethylpiperidine (2.3 g, 15 mmol) then Me_3SiCl (8 cm^3, 25 mmol) and the mixture refluxed overnight. After cooling the volatiles were removed under vacuum and the dark residue was extracted with petroleum (2×50 cm^3). After concentration of extracts *in vacuo* to *ca* 5 cm^3 and cooling to $-30°C$, dark violet crystals were obtained. X-ray quality crystals were obtained after recrystallization from petroleum. Yield: 0.25 g, 20–30%. Repeated recrystallization from petroleum did not yield crystals of analytical purity due to contamination by silicon-containing oils and starting piperidine, as proved by NMR. NMR (C_6D_6) ^1H: δ 1.47 (s, 12H, $Me_4C_5H_6$), 1.01, 0.89, 0.86, 0.82 (each s, 6H, $Me_4C_5H_6$), 0.35 (s, 18H, $OSiMe_3$), 0.28 (s, 18H, $OSiMe_3$).

X-ray crystallography

X-ray data for compounds **2a**, **3b** and **4** were collected at low temperature (see Table 4) using a FAST TV area detector diffractometer with Mo-K_α radiation ($\lambda = 0.71069$ Å), as previously described [10]. The structures were solved *via* direct methods procedures of SHELXS-86 [11], and refined by full-matrix least-squares on F_0^2, using the program SHELXL-93 [12]. All unique data used were corrected for Lorentz polarization factors and for absorption using the program DIFABS [13], with maximum and minimum correction factors listed in Table 4. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms of **2a** and **3b** were

included in idealised positions. Due to the uncertainties in positioning, hydrogen atoms on the Bu^t methyl groups of **1** associated with the Li interactions were omitted. The methylene protons of **4** were experimentally located whilst the methyl hydrogen atoms were placed in calculated positions. The solvent of crystallization, toluene, within the lattice of **3b** was shown to exhibit positional disorder. The carbon atoms were refined in split sites with partial occupancy factors and consequently hydrogen atoms were ignored in the refinement. All crystal data and refinement details are summarized in Table 4.

Additional material available from the Cambridge Crystallographic Data Centre comprises fractional atomic co-ordinates, thermal parameters and remaining bond lengths and angles.

(Received 28 June 1996; accepted 6 August 1996)

Abstract—Room-temperature reactions of asymmetric phosphines, (Ph)(DCA)(R)P (R = Et_2N—, Bu^n_2N—) with S_4N_4 in acetonitrile afforded phosphiniminocyclotrithiazenes, (Ph)(DCA)(R)P=N—S_3N_3 (R = Et_2N—, **I**; Bu^n_2N—, **II**) in modest yields (*ca* 50%). The heterocycles have been characterized by spectroscopic [IR, UV–vis, NMR (^1H and ^{31}P) and mass] and single crystal X-ray diffraction methods. Strikingly, the angle at P—N(4)—S(1) is 135° in **I**, the largest observed so far and is 119.3° in **II**. This is also accompanied by the shortest exocyclic S(1)—N(4) bond length of 1.537 Å observed in the case of **I**. In the unit cell of **II**, two types of molecules with slightly differing degree of deviation of the tricoordinate sulfur (0.664 and 0.673 Å from the mean plane [N(1)—S(2)—N(2)—S(3)—N(3)] are observed. Copyright © 1997 Elsevier Science Ltd

Keywords: asymmetric phosphines; phosphiniminocyclotrithiazenes; synthesis; spectra; X-ray structure.

Recently, we have prepared a large variety of phosphiniminocyclotrithiazenes, →P=N—S_3N_3, which are stable examples of monosubstituted 8π-electron "—S_3N_3" ring systems. We have since then undertaken detailed investigations to evaluate the influence if any, of the changing substituents on phosphorus on the stability, properties, structure and chemical behaviour of this type of inorganic heterocyclic compounds. Exploiting the steric protection offered by the dicyclohexylamino group (DCA), we have recently prepared several such compounds namely (Ph)(DCA)(R)PN—S_3N_3, where "R" is a *cyclic amino* group, and characterized them structurally [2,3].

In this paper, we report the preparation and characterization of (i) the asymmetric phosphines, (Ph)(DCA)(R)P, (ii) (Ph)(DCA)(R)PN—S_3N_3, where "R" is an *acyclic amino* group [(a) diethylamino and (b) di-*n*-butylamino group] and (iii) single crystal X-ray structure determination of the heterocycles.

EXPERIMENTAL

General procedures and materials

All the reactions and subsequent work-up were performed under dry N_2 gas. Solvents C_6H_6, *n*-C_6H_{14}, CH_3CN and CH_2Cl_2 were purified as per prescribed procedures [4] before use. S_4N_4 prepared by the literature method [5] was recrystallized from toluene before use. $PhPCl_2$ (Fluka), dicyclohexylamine (E. Merck), diethylamine (Ranbaxy) and di-*n*-butylamine (Fluka) were used as received.

Spectral facilities and operations made use of for the characterization of compounds are the same as described elsewhere [6].

Preparation of the phosphines (Ph)(DCA)(R)P [R = (i) Et_2N—; (ii) Bu^n_2N—]

The intermediate, "(Ph)(DCA)PCl", was produced by employing the reported procedure and was subsequently converted to (Ph)(DCA)(Et_2N)P and (Ph)(DCA)(Bu^n_2N)P by its stoichiometric reaction (1 : 2) with the corresponding amines following the same procedure [7]. Their characterization data is given in Table 1.

Preparation of (Ph)(DCA)(R)P=N—S_3N_3 [R = (i) Et_2N—; (ii) Bu^n_2N—]

S_4N_4 and the corresponding phosphine taken in 1 : 2 molar ratio were reacted as per the previously reported procedure [8] to isolate the corresponding →P=N—S_3N_3 derivatives as red precipitates. They were recrystallized using CH_2Cl_2–CH_3CN mixture (3 : 1) at 0°C. Table 1 lists their characterization data.

X-ray crystallographic analyses

Single crystals of **I** and **II** suitable for X-ray analyses were grown from a mixture of dichloromethane and acetonitrile (3 : 1, v/v) at 0°C. The crystal data and experimental conditions are summarized in Table 2. The crystals were glued at their sharpest points on to glass fibre. The cell constants were obtained by least-squares refinement employing 25 carefully chosen reflections in the range $8 \leqslant \theta \leqslant 12°$. All the data were collected on an Enraf–Nonius CAD-4 diffractometer using Mo-K_α radiation ($\lambda = 0.71073$ Å) at 293 K and were corrected for Lorentz and polarization effects. The reflections were measured using the ω–2θ scan technique. Numerical absorption corrections were made using an in-built software of the diffractometer.

The structure was solved by direct methods using the SHELXS-86 [9] program and refined by full-matrix least-squares using the program SHELXL-93 [10]. All the hydrogen atoms could be located from the difference electron-density maps during the refinement. All the non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms with isotropic temperature parameter. The quantity minimized was $\Sigma w(F_o^2 - F_c^2)^2$, where $w = 1/[\sigma(F_o^2 + aP^2 + bP]$, $P = [F_o^2 + 2F_c^2]/3$, and a and b are refinable parameters. All the atomic scattering factors were those incorporated in SHELXL-93.

Table 1. Characterization data for (Ph)(DCA)(R)P = N—S_3N_3[a,b] [R = Et_2N—, (**I**); Bu^n_2N—, (**II**)] and (Ph)(DCA)(R)P [R = Et_2N—, (**III**); Bu^n_2N—, (**IV**)

RESULTS AND DISCUSSION

The phosphines, (Ph)(DCA)(R)P [R = (i) diethylamino; (ii) di-n-butylamino], similar to other tertiary phosphines such as $(C_6H_5)_3P$ [11], $(C_5H_{10}N)_3P$ [8] and $(C_6H_5)_2(C_5H_{10}N)P$ [12] react smoothly with S_4N_4 to give the corresponding phosphiniminocyclotrithiazenes, (Ph)(DCA)(Et_2N)PN—S_3N_3 (**I**) and (Ph)(DCA)(Bu^n_2N)PN—S_3N_3 (**II**) as stable red crystal-line solids.

The electronic spectra of compounds **I** and **II** show, besides the two characteristic absorptions of the cyclotrithiazene ring (—S_3N_3) [13,14], an additional absorption at 290 nm, as in the case of tertiary aminophosphines [8]. The phosphorus chemical shifts in **I** and **II** are considerably more shielded compared with the corresponding phosphines **III** and **IV**, a situation also found in the case of all the aminophosphines reported so far [8,12].

X-ray crystal structures of **I** *and* **II**

The ORTEP plots, packing diagrams and selected bond length, bond angle data for **I** and **II** are shown in Figs 1–4 and Tables 3 and 4, respectively. Compounds **I** and **II** can be regarded as very similar except for the ethyl groups of **I** replaced with *n*-butyl groups in the other. Interestingly, the structural difference between the two, first became evident from the observed difference in their crystal system, space group and the volume of the unit cell. In accordance with the previous observation, the tricoordianate sulphur, S(1) in **I** and **II** is substantially deviated from the approximate mean plane, N(1)—S(2)—N(2)—S(3)—N(3), of the heterocycle. It is 0.701 Å for **I**, the

maximum observed so far and is found to be 0.664 and 0.673 Å for **II**, indicating that the compound **II** has two distinguishable types of molecules in the unit cell. Another strikingly different structural feature between **I** and **II** is that the angle at exocyclic nitrogen, P—N(4)—S(1), is significantly widened in **I** (135.0 *vs* 119.3°). This variation may be attributed to the stereochemical difference of the two chosen acyclic amino groups. This is further supported by the fact that the non-bonded P—S(1) distance is found to be *ca* 2.9 and 2.7 Å for **I** and **II** respectively. These values are sufficiently low compared with their van der Waals contact (3.65 Å), which indicates significant bonding interaction between "P" and "S(1)" in these compounds [8,15]. One of the angles at the tetrahedral phosphorus is distinctly larger than the rest in both **I** and **II**. While the dicy-

clohexylamino group determines this angle in **I** (120°), the acyclic amino group, namely the di-*n*-butylamino moiety, contributes to the observed angle in the other (*ca* 117°), which clearly demonstrates the steric influence of the groups on phosphorus on the structure.

Although the exocyclic P—N(4) bond length is practically the same for both **I** and **II**, the adjoining N—S bond [N(4)—S(1)] is considerably shorter in **I** (1.537 *vs* 1.569 Å). The reason for the observed N(4)—S(1) bond length of 1.537 Å, much shorter than a typical N—S double bond (1.55 Å [16]), though it remains unclear, is suggestive of its interaction with both the endocyclic S—N bonds and the adjoining P—N bond. The trend in the endocyclic bond variation in **I** and **II** is found to be similar as in the reported cases [8,15].

The cyclohexyl groups of "DCA" are found to be in an approximately chair conformation and the cyclotrithiazene ring is found to be in a half-chair conformation in both cases.

Conclusion

The introduction of acyclic amino groups, namely, diethylamino and di-*n*-butylamino moieties for "R" in (Ph)(DCA)(R)PN—S_3N_3 derivatives bring subtle, but noticeable differences in their structures, as revealed by X-ray crystallography.

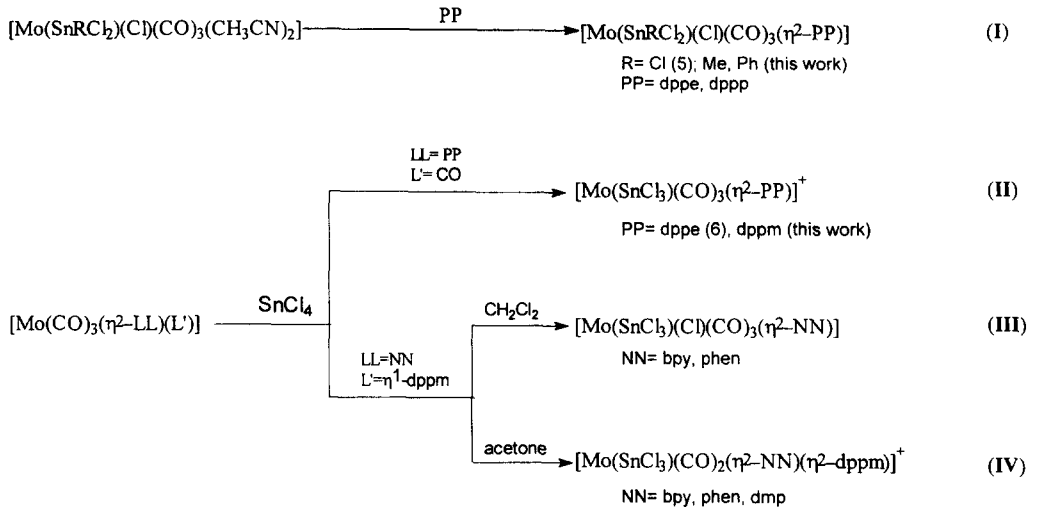
(Received 18 July 1996; accepted 2 August 1996)

Abstract—Two different routes have been studied to produce heterobimetallic Mo–Sn compounds containing bidentate PP-donor ligands. The first, involving the reaction of $[Mo(SnRCl_2)(Cl)(CO)_3(CH_3CN)_2]$ (R = Me, Ph) with PP-donor ligands [PP = 1,2-bis(diphenylphosphine)ethane, dppe; 1,3-bis(diphenylphosphine)propane, dppp] always gave rise to neutral seven-coordinate complexes of the type $[Mo(SnRCl_2)(Cl)(CO)_3(\eta^2\text{-PP})]$ (**I**). On the other band, three types of compounds were isolated from reactions of $[Mo(CO)_3(\eta^2\text{-LL})(L')]$ [LL = PP- or NN-donor ligand, PP = bis(diphenylphosphine)methane (dppm), NN = 2,2′-bipyridine (bpy), 1,10-phenanthroline (phen), 2,9-dimethyl-1,10-phenanthroline (dmp); L′ = CO or η^1-dppm] with $SnCl_4$ used as second synthetic route. So, the cationic six-coordinate complex $[Mo(SnCl_3)(CO)_3(\eta^2\text{-dppm})]^+$ (**II**) and neutral or cationic seven-coordinate complexes $[Mo(SnCl_3)(Cl)(CO)_3(\eta^2\text{-NN})]$ (**III**) and $[Mo(SnCl_3)(CO)_2(\eta^2\text{-NN})(\eta^2\text{-dppm})]^+$ (**IV**) are obtained depending on the solvent and the nature of the ligands. Copyright © 1997 Elsevier Science Ltd

Keywords: heterobimetallic Mo–Sn complexes; bidentate PP-donor ligands; cationic and neutral Mo–Sn compounds.



Seven-coordinate Mo complexes of the type $[Mo(X)_2(CO)_3(L)_2]$ (X = Cl, Br; L = PPh_3, $AsPh_3$) have been shown to exhibit important catalytic activity involving the dissociation of the L ligands as the rate determining step of that behaviour [1–3].

These precedents have encouraged research into related heterobimetallic compounds in which cooperative effects between dissimilar metals are also important from the point of view of their catalytic activity.

From previous results we now propose two potential synthetic routes in order to produce new seven-coordinate Mo–Sn compounds. The first consists of the displacement of acetonitrile ligands from $[Mo(SnRCl_2)(Cl)(CO)_3(CH_3CN)_2]$ (R = Cl, Me, Ph) by monodentate or bidentate P-donor ligands. Alternatively the oxidative addition of tin(IV) organohalides to $[Mo(CO)_3(\eta^2\text{-LL})(L')]$ (LL = NN- or PP-donor ligand; L′ = CO or monodentate P-donor ligand) is used as the second way to yield the desired species.

Some of these reactions have already been described. So, in a previous work [4] we have established that seven-coordinate complexes of the type $[Mo(L)(Cl)(CO)(CH_3CN)(PR'_3)]$, $[Mo(\mu\text{-Cl})(L)(CO)(PR'_3)]_2$ or $[Mo(L)(Cl)(CH_3COCH_3)_2(PR'_3)]$ [L = $(SnRCl_2)(CO)_2$, R = Me, Ph; R′ = 4-XC_6H_4, X = CH_3O, CH_3, H, F, Cl] are produced by reaction of $[Mo(SnRCl_2)(Cl)(CO)_3(CH_3CN)_2]$ with PR'_3 depending on several factors. The displacement of the two acetonitrile ligands in related complexes (R = Cl) by PP-donor ligands has also been established [5].

* Author to whom correspondence should be addressed.

Scheme 1.

Following these precedents we were interested to extend the above studies by using PP-donor ligands with different chain lengths.

So, the reactivity of $[Mo(SnRCl_2)(Cl)(CO)_3(CH_3CN)_2]$ (R = Me, Ph) towards 1,2-bis(diphenylphosphine)ethane(dppe) and 1,3-bis(diphenylphosphine)propane(dppp) is described in this work.

On the other hand, the reaction of complexes of the type $[Mo(CO)_3(\eta^2\text{-LL})(L')]$ (LL = bidentate NN- or PP-donor ligand; L′ = CO or monodentate P-donor ligand) with haloderivatives of Sn(IV) gave rise to tricarbonyl or dicarbonyl heterobimetallic complexes depending on the lability of the CO ligands towards to the other ligands [6–8]. Then, we think that $[Mo(CO)_3(\eta^2\text{-NN})(\eta^1\text{-dppm})]$ or $[Mo(CO)_3(\eta^2\text{-dppm})(CO)]$ [dppm = bis(diphenylphosphine)methane] should be appropriate starting compounds to react with tin(IV) derivatives in order to analyse the coordinative competence between CO and a P-donor atom of the dppm ligand, free in the former and coordinated in the latter, respectively.

On the above basis we also describe in this work the reactivity of $[Mo(CO)_3(\eta^2\text{-LL})(L')]$ [LL = 2,2′-bipyridine(bpy), 1,10-phenanthroline(phen), 2,9-dimethyl-1,10-phenanthroline(dmp), L′ = η^1-dppm; LL = dppm, L′ = CO] with $SnCl_4$.

RESULTS AND DISCUSSION

Scheme 1 summarizes the results of the reactions studied as well as the four types of heterobimetallic complexes (**I–IV**) isolated. Some literature results are included for comparative purposes.

Compounds of type I: Reactions of $[Mo(SnRCl_2)(Cl)(CO)_3(CH_3CN)_2]$ (R = Me, Ph) *with dppe and dppp* (**1–4**)

The reactions of $[Mo(SnRCl_2)(Cl)(CO)_3(CH_3CN)_2]$ (R = Me, Ph) with PP-donor ligands (dppe and dppp) in dichloromethane gave rise to the seven-coordinate complexes $[Mo(SnRCl_2)(Cl)(CO)_3(\eta^2\text{-PP})]$ (R = Me, Ph; PP = dppe, dppp; **1–4**), which were fully characterized by analytical and spectroscopic techniques (Table 1).

In these reactions the bidentate PP-donor ligands caused the elimination of the two acetonitrile molecules from the starting compounds, which were not displaced by two P-donor ligands of the type PR'_3 (R′ = 4-XC_6H_4; X = CH_3O, CH_3, H, F, Cl) [4]. A similar reaction had already been observed with dppm as the ligand [5]. Therefore, the different size or the steric characteristics of the PP-donor ligand does not modify the course of the reaction to produce seven-coordinate complexes **1–4**.

The IR spectra of **1–4** in the solid state show three bands in the carbonyl stretching region (Table 1), which suggests a *fac* distribution of the three carbonyl groups [9]. No absorptions in the $\nu(C{\equiv}N)$ region (2400–2200 cm^{-1}) are observed indicating the full substitution of the CH_3CN ligands.

The ^{31}P NMR spectra of **1–4** show signals in the range of coordinated phosphorus ligands, as deduced by the values of the coordination chemical shifts [$\Delta\delta(^{31}P)$], see Table 1. In all cases, with the exception of $[Mo(SnMeCl_2)(Cl)(CO)_3(\eta^2\text{-dppe})]$ (**1**), the presence of a single signal is consistent with an equivalence of the coordinate phosphorus atoms of the PP-donor ligand. The main feature comes from comparing the chelate ring size with the $\Delta\delta(^{31}P)$ values. So, com-

Table 1. Analytical and spectroscopic data of $[Mo(SnRCl_2)(Cl)(CO)_3(\eta^2\text{-PP})]$ (R = Me, Ph; PP = dppe, dppp) (**1–4**)

pounds with the dppe ligand show a substantially larger degree of deshielding than those with dppp. This fact, which could be related with the value of the P—M—P angle of the five- or six-membered rings produced in each type of compounds, had already been observed in other examples [10–12]. The higher P—M—P angle in the six-membered rings (compounds **2** and **4**) than in the five-membered rings (compounds **1** and **3**) appears to produce a less-favoured orbital overlap between the metal and the phosphorus atoms and consequently a higher shielding of them.

Compounds type II–IV: Reactions of $[Mo(CO)_3(\eta^2\text{-LL})(L')]$ (LL = *bpy, phen, dmp,* $L' = \eta^1$-*dppm*; LL = *dppm*, L′ = CO) *with* $SnCl_4$ (**5–11**)

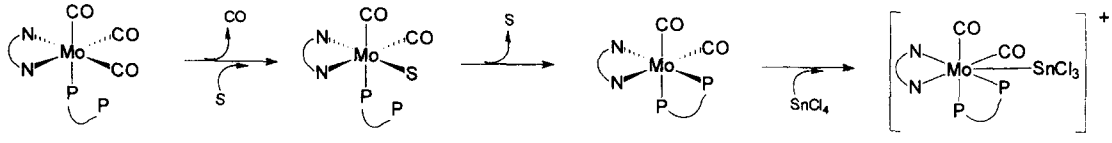
In the second part of this study we discuss the reactivity of complexes $[Mo(CO)_3(\eta^2\text{-LL})(L')]$ with $SnCl_4$. Bidentate LL ligands were NN- or PP-donor (NN = bpy, phen, dmp; PP = dppm) and monodentate L′ ligands were η^1-dppm or CO, respectively. Table 2 lists the analytical, conductivity and spectroscopic (IR and NMR) data of the new complexes (**5, 8–11**).

When LL = dppm and L′ = CO, the $[Mo(CO)_3(\eta^2\text{-dppm})]$ group was bonded to a $SnCl_3$ group giving rise to the cationic complex $[Mo(SnCl_3)(CO)_3(\eta^2\text{-dppm})]^+$, which was isolated as the salt of $[SnCl_5]^-$ (compound type **II**). The analytical, conductivity and spectroscopic data (Table 2) are consistent with a formulation as $[Mo(SnCl_3)(CO)_3(\eta^2\text{-dppm})][SnCl_5]\cdot(CH_3CH_2)_2O$ (**5**). The IR spectrum in the solid state shows in the carbonyl stretching region three bands (two strong and the other broad) at 1965, 1940 and 1870 cm^{-1}, typical of a *fac*-distribution [4]. In the lower region, a broad band centred at 365 cm^{-1} is consistent with the presence of different Sn—Cl bonds in the complex.

In the above reaction we consider the insertion of the $[Mo(CO)_3(\eta^2\text{-dppm})]$ fragment into a Sn—Cl bond of $SnCl_4$, followed by the dissociation of the Cl ligand bonded to the Mo atom. This chloride atom should be bonded to a second $SnCl_4$ molecule producing the counterpart anion $[SnCl_5]^-$, in agreement with the proposed formulation. The isolated complex shows a low stability in solution, but in freshly prepared solutions it behaves as 1 : 1 electrolyte. The stereochemistry of this complex is related with that observed in other seven-coordinate Mo–Sn complexes [6].

On the other hand, new types of compounds (**III** and **IV**) are formed when LL = η^2-NN (NN = bpy, phen, dmp) and L′ = η^1-dppm in the starting compounds (Scheme 1).

From the experimental results we deduce that the reaction course depends on the solvent used and on the NN-donor ligand.



So, in dichloromethane the elimination of the PP-donor ligand occurs and consequently the 16 e^- intermediate $[Mo(CO)_3(\eta^2\text{-NN})]$ (NN = bpy, phen) fragment is inserted into a Sn—Cl bond of $SnCl_4$ yielding type **III** compounds $[Mo(SnCl_3)(Cl)(CO)_3(\eta^2\text{-NN})]$ (NN = bpy, **6**; phen, **7**), which have already previously been described [13]. The analogous complex $[Mo(SnCl_3)(Cl)(CO)_3(\eta^2\text{-dmp})]$ (**8**) was not obtained by this route, but it is produced by reaction of $[Mo(CO)_4(\eta^2\text{-dmp})]$ with $SnCl_4$ in dichloromethane (Table 2).

By contrast if the reaction was carried out in a coordinating solvent such as acetone, the dppm ligand

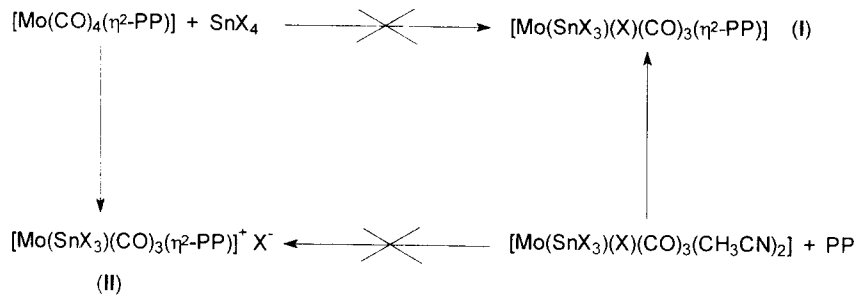
Scheme 2.



was coordinated in a bidentate fashion with the corresponding displacement of CO. A mechanism as depicted in Scheme 2 is proposed to explain the observed behaviour. The suggested intermediates $[Mo(CO)_2(\eta^2\text{-NN})(\eta^2\text{-dppm})]$ (NN = bpy, phen) are coordinatively and electronically saturated, therefore, only one $SnCl_3$ group is oxidatively added to produce the cationic seven-coordinate species $[Mo(SnCl_3)(CO)_2(\eta^2\text{-NN})(\eta^2\text{-dppm})]^+$ (type **IV**), which were isolated as salts of $[SnCl_5]^-$ (NN = bpy, **9**; phen, **10**; Table 2).

The same type of complex $[Mo(SnCl_3)(CO)_2(\eta^2\text{-dmp})(\eta^2\text{-dppm})][SnCl_5]$ (**11**) was formed by reaction of $[Mo(CO)_3(\eta^2\text{-dmp})(\eta^1\text{-dppm})]$ with $SnCl_4$ in dichloromethane at room temperature (Table 2). By contrast in acetone that complex is recovered as a side product together decomposition products.

The IR spectra of **9–11** in the solid state show two strong carbonyl bands centred at 1950 and 1890 cm^{-1}, typical of a *cis*-dicarbonyl disposition [14–15]. The ^{31}P NMR spectra in $CDCl_3$ solution of **9–11** show a single signal in the region of coordinate phosphine (Table 2), suggesting the presence of two equivalent phosphorus atoms. Complexes **9–11** show a low stability in solution, but they behave as 1 : 1 electrolytes in freshly prepared solutions.

The analytical, conductivity and spectroscopic data are consistent with the formulation $[Mo(SnCl_3)(CO)_2(\eta^2\text{-NN})(\eta^2\text{-dppm})][SnCl_3]\cdot(CH_3CH_2)_2O$ (NN = bpy, phen, dmp) for the new complexes. The $(CH_3CH_2)_2O$ molecule could be occupying the sixth position of coordination at the tin atom vacant on the $[SnCl_5]^-$ group. This fact is related with those observed in other relevant compounds containing Mo—Sn bonds [6].

In the light of the results of this work, the obtention of seven-coordinate Mo–Sn complexes is determined by the route of the preparation, independent of the nature of the PP-donor ligand used. As an illustrative

Scheme 3.

example. Scheme 3 shows this fact for type **I** and **II** complexes.

EXPERIMENTAL

General

All reactions were carried out under oxygen-free dinitrogen by standard Schlenk techniques. Commercial solvents were dried and degassed prior to use. $[Mo(SnRCl_2)(Cl)(CO)_3(CH_3CN)_2]$ (R = Me, Ph), $[Mo(CO)_3(\eta^2\text{-NN})(\eta^1\text{-dppm})]$ (NN = bpy, phen, dmp) and $[Mo(CO)_4(\eta^2\text{-dppm})]$ were prepared according to previously described methods [9,11,16] $SnCl_4$ was distilled prior to use. Other commercial reagents were used as supplied.

Elemental analyses for carbon, hydrogen and nitrogen were carried out by the Microanalytical Service of the Autónoma University of Madrid. IR spectra were recorded on Nicolet 5DX FT-IR or Perkin-Elmer 1300 spectometers. ^1H and ^{31}P NMR spectra were recorded on a Varian XL-300 spectrometer at room temperature in $CDCl_3$ solutions, operated at 299.95 MHz for ^1H and 121.42 MHz for ^{31}P (shifts are relative to internal tetramethylsylane and external 85% phosphoric acid, respectively). Conductance measurements were performed on freshly acetone solutions at room temperature with a Philips PW9526 conductivity bridge and a Philips PW9550/60 conductivity cell.

Reactions

Preparation of $[Mo(SnRCl_2)(Cl)(CO)_3(\eta^2\text{-PP})]$ (R = Me, Ph; PP = *dppe*, *dppp*) (**1–4**). To a solution of $[Mo(SnRCl_2)(Cl)(CO)_3(CH_3CN)_2]$ (0.7 mmol) in dichloromethane or acetone (15 cm^3) was added a stoichometric amount of the PP-donor ligand (0.7 mmol). The mixture was stirred under a slight stream of nitrogen for 2 h. Then the solvent was partially reduced and cold diethyl ether added. The solid formed was filtered off, washed with cold diethyl ether and dried *in vacuo*. The new complexes are air-sensitive solids and they are soluble in common polar solvents.

Preparation of $[Mo(SnCl_3)(CO)_3(\eta^2\text{-dppm})][SnCl_5]\cdot Et_2O$ (**5**). To a solution of $[Mo(CO)_4(\eta^2\text{-dppm})]$ (0.5 mmol) in acetone (20 cm^3) was added 3 drops of $SnCl_4$. The solution was stirred at 45°C for 4 h. Then the solvent was removed under reduced pressure, giving rise to an orange–brown oil which was treated with cold diethyl ether. The yellow solid formed was filtered off and dried *in vacuo*. The complex is very unstable even when stored under nitrogen in the dark and at low temperature. It is soluble in polar solvents but its solutions quickly decompose.

Preparation of $[Mo(SnCl_3)(Cl)(CO)_3(\eta^2\text{-NN})]$ (NN = *bpy*, *phen*) (**6**, **7**). To a solution of $[Mo(CO)_3(\eta^2\text{-NN})(\eta^1\text{-dppm})]$ (0.5 mmol) in dichloromethane (20 cm^3) was added 4 drops of $SnCl_4$. A change of the solution colour to yellow was immediately observed and after 5 min a yellow–orange solid precipitated. The mixture was stirred for 1 h and then the solid was filtered off, washed with cold diethyl ether and dried *in vacuo*.

Preparation of $[Mo(SnCl_3)(Cl)(CO)_3(\eta^2\text{-dmp})]\cdot CH_2Cl_2$ (**8**). $SnCl_4$ (4 drops) was added to a suspension of $[Mo(CO)_4(\eta^2\text{-dmp})]$ (0.5 mmol) in dichloromethane (15 cm^3) causing an immediate colour change to yellow–orange. The solution was stirred for 30 min and the solvent was then removed to dryness, and the orange oil formed treated with cold diethyl ether. The yellow–orange solid obtained was filtered off and dried *in vacuo*.

Preparation of $[Mo(SnCl_3)(CO)_2(\eta^2\text{-NN})(\eta^2\text{-dppm})][SnCl_5]\cdot Et_2O$ (NN = *bpy*, *phen*) (**9**, **10**). To a solution of $[Mo(CO)_3(\eta^2\text{-NN})(\eta^1\text{-dppm})]$ (0.5 mmol) in acetone (10 cm^3) was added an excess of $SnCl_4$ (4 drops). The solution quickly changed colour to red and later to yellow. The solution was stirred for 6 h and then cold diethyl ether added. The yellow–orange solid formed was filtered off, washed with cold diethyl ether and dried *in vacuo*. The new complexes are air-sensitive solids, which are soluble in polar solvents, but they show a low stability albeit enough to obtain good NMR spectra.

Preparation of $[Mo(SnCl_3)(CO)_2(\eta^2\text{-dmp})(\eta^2\text{-dppm})][SnCl_5]\cdot Et_2O$ (**11**). $SnCl_4$ (4 drops) was added to a solution of $[Mo(CO)_3(\eta^2\text{-dmp})(\eta^1\text{-dppm})]$ (0.5 mmol) in dichloromethane (20 cm^3). The solution colour quickly changed from violet to yellow. After 30

min of stirring, cold diethyl ether was added and then the orange solid formed was filtered off, washed with cold diethyl ether and dried *in vacuo*. The new complex shows the same behaviour as the related species **9–10**.

(Received 18 July 1996; accepted 2 August 1996)

Abstract—The new complexes $[M(CO)_4(R_2P(S)P(S)R_2)]$, **1A–1D, 2A–2D,** (**1A**, M = Mo, R = Me; **1B**, M = Mo, R = Et; **1C**, M = Mo, R = Pr-n; **1D**, M = Mo, R = Bu-n; **2A**, M = W, R = Me; **2B**; M = W, R = Et; **2C**, M = W, R = Pr-n; **2D**, M = W, R = Bu-n) have been prepared either by the photochemical reaction of $M(CO)_6$ with $R_2P(S)P(S)R_2$, or by thermal displacement of coordinated norbornadiene in $C_7H_8Mo(CO)_4$ with $R_2P(S)P(S)R_2$, to give the complexes $[M(CO)_4(R_2P(S)P(S)R_2)]$. The complexes have been characterized by elemental analysis, IR and ^{31}P-[^1H]-NMR spectroscopy and FAB-Mass spectrometry; the spectroscopic studies suggest a *cis*-chelate bidentate coordination of the ligand. Copyright © 1997 Elsevier Science Ltd

Keywords: phosphorus; sulfur; diphosphine disulfide; molybdenum carbonyl; tungsten carbonyl; photochemistry.

Since preparation of the first tetraalkyldiphosphine disulfide complexes in 1965 [1,2], such compounds have continued to attract attention in part because of the different possible coordination geometries which the ligand may adopt. In most cases the ligand is presumed to adopt the expected *cis*-chelate bidentate coordination, although in certain cases, e.g. $[CuCl{\cdot}Me_4P_2S_2]_2$ [3], the ligand, while retaining a chelating bidentate structure, adopts the *gauche* conformation. In the copper(II) complex $[CuCl_2{\cdot}Me_4P_2S_2]_m$ [4] the ligands retain the *trans* structure seen for the uncoordinated molecule and act in a bridging bidentate manner to give an infinite polymer in which $CuCl_2$ groups are connected by $Me_4P_2S_2$ molecules to form long —Cu—S—P—P—S—Cu—S—P—P—S— chains. It is possible for the ligand to adopt a monodentate coordination such as in $[Au(PPh_3)(Et_4P_2S_2)][PF_6]$, where a single sulfur atom coordinates to the gold centre [5]. In certain reactions fragmentations of the dialkyldiphosphine disulfide has been observed. This certainly occurs when a number of square-planar platinum complexes react with $Et_4P_2S_2$. A single crystal X-ray diffraction study of $[Pt(SPEt_2)P(OC_6H_5)_3]_2$, formed in this way [6], shows that the core of the molecule consists of a Pt—Pt moiety and to Et_2PS units in which each Pt atom is bonded to the P atom of one Et_2PS unit and to the S atom of the other equivalent unit. In another intriguing reaction $Cp^*_2Yb(OEt_2)$($Cp^* = \eta$-C_5Me_5) reacts with $Me_4P_2S_2$ to yield $Cp^*Yb(Me_2PS_2)$ as the only metal-containing products [7]. This last reaction illustrates an interesting rearrangement of the dialkyldiphosphine disulfide to a dialkyldithiophosphine ligand.

We have recently discovered a photochemical reaction of the above type in which $Mm_2(CO)_{10}$ and $Me_4P_2S_2$ react to form the dimethyldithiophosphinate derivative $Me_2PS_2Mn(CO)_4$ [8]. Some years ago it was found that the mononuclear metal carbonyl $Fe(CO)_5$ reacts photochemically with $Me_4P_2S_2$ to cleave the P—P bond and form the complex $[(CO)_3Fe(Me_2PS)]_2$, in which each sulfur atom bridges the two Fe centres [9]. In this paper we report that, in contrast to the last

* Author to whom correspondence should be addressed.

two mentioned reactions, simple tetraalkyldiphosphine disulfide complexes of $M(CO)_4$(M = Mo or W) fragments may be prepared by straightforward thermal and photochemical reactions. The complexes are characterized by elemental analysis backed up by FAB mass spectrometry, IR and ^{31}P NMR spectroscopy. The spectroscopic studies, moreover, suggest that the ligands adopt the usual *cis*-chelate bidentate structure.

EXPERIMENTAL

All preparations were carried out under dry nitrogen by using Schlenk techniques. All the solvents used in synthesis were deoxygenated. The elemental analyses were carried out using a Perkin–Elmer 240B microanalyser by Medac Ltd at Brunel University. IR spectra were recorded on samples in KBr discs at the University of Reading using a Perkin–Elmer 1720-X Fourier Transform Spectrophotometer. NMR spectra were recorded on $(CD_3)_2CO$ solutions at the University of Reading using a Jeol JNM-EX 400FT spectrometer. FAB-Mass spectra were recorded at the EPSRC Mass Spectrometry Center at University College, Swansea, on a VG Autospec instrument using caesium ion bombardment at 25 kV of the sample dissolved in 3-nitrobenzyl alcohol. UV irridiations were performed with a medium-pressure 400 W Medium Pressure Mercury Lamp through a quartz-walled immersion wall reactor.

Norbornadiene (nbd), tetrahydrofuran, benzene, hexane, pentane, dichloromethane, acetone and diethylether were purchased from Merck; $Mo(CO)_6$ and $W(CO)_6$ from Aldrich. These reagents were used as supplied. The tetraalkyldiphosphine disulfides [10, 11] and $C_7H_8Mo(CO)_4$ [12] were prepared by literature methods.

The complexes **1A–1D** and **2A–2D** (**1A**, M = Mo, R = Me; **1B**, M = Mo, R = Et; **1C**, M = Mo, R = Pr-n; **1D**, M = Mo, R = Bu-n; **2A**, M = W, R = Me; **2B**, M = W, R = Et; **2C**, M = W, R = Pr-n; **2D**, M = W, R = Bu-n) were prepared by the photochemical reactions of $R_2P(S)P(S)R_2$ and $M(CO)_6$. Yields were typically in the range 50–70%. Complexes **1A–1D** were also prepared by the thermal reaction of $C_7H_8Mo(CO)_4$ with $R_2P(S)P(S)R_2$ in typically >60% yield. The following two procedures exemplify the synthetic methods adopted.

Method A. $Mo(CO)_6$ (0.264 g, 1 mmol) and $Me_2P(S)P(S)Me_2$ (0.186 g, 1 mmol) were dissolved in benzene (100 cm^3 reactions utilising the Et, Pr-n and Bu-n derivatives were performed in *n*-pentane) and the solution mixture irradiated in a UV cell for 1 h. During the irridiation a bright-yellow precipitate was formed. The yellow solid was filtered, washed with pure solvent and dried *in vacuo*. to give yellow microcrystals (0.24 g, 61% yield).

Method B. A solution of $C_7H_8Mo(CO)_4$ (0.12 g, 0.4 mmol, in 10 cm^3 of warm *n*-hexane) was treated with $Me_2P(S)P(S)Me_2$ (0.07 g, 0.4 mmol in 10 cm^3 of CH_2Cl_2). A bright yellow precipitate formed immediately which was filtered, washed with pentane and dried *in vacuo* to give yellow microcrystals (0.12 g, 76% yield).

456(7) [M^+-3CO]; 428(5) [M^+-4CO]; 242(100) [$Et_4P_2S_2^+$]; 121(70) [Et_2PS^+]. **2C** (RMM = 596): 596(10) [M^+]; 568(25) [M^+-CO]; 540(50) [M^+-2CO]; 512(20) [M^+-3CO]; 484 (75) [M^+-4CO]; 298(95) [$Pr_4P_2S_2^+$]; 149(100) [Pr_2PS^+]. **2D** (RMM = 652); 652 (10)[M^+]; 624(15) [M^+-CO]; 596(25) [M^+-2CO]: 540(35) [M^+-4CO]; 354(100) [$Bu_4P_2S_2^+$]; 177(18) [Bu_2Ps^+].

The photogeneration of the 16-electron fragments $M(CO)_5$ from $M(CO)_6$ (M = Mo or W) and their reaction with available donors to form $M(CO_5)L$ species have been extensively studied. When L is a ligand capable of chelating bidentate coordination rapid continuation to the $M(CO)_4L$ product may occur [16]. The photochemical reactions of $M(CO)_6$ with $R_2P(S)P(S)R_2$ proceed in this expected manner to yield the hitherto unknown series of complexes **1A–1D** and **2A–2D**. Likewise, thermal reactions of the $nbdMo(CO)_4$ complex (nbd = C_7H_8) with $R_2P(S)P(S)R_2$ proceed in an entirely expected manner by displacement of the nbd ligand to give the monometallic complexes **1A–1D**.

1 M = Mo
2 M = W
A R = Me
B R = Et
C R = *n*-Pr
D R = *n*-Bu

The IR spectra data for **1A–2D** show a decrease in ν_{as}(PS) on coordination. In the free ligand the IR active mode ν_{as}(PS) is at 567 cm^{-1} for tetramethyl diphosphine disulfide [13]. On coordination, two bands are observed: *ca* 590 [ν_{sym}(PS)] and *ca* 550 cm^{-1} [ν_{as}(PS)]. As expected four bands arising from ν(CO) vibrations are seen for each complex which presumably have *local* C_{2v} symmetry of the $M(CO)_4$ unit.

The ^{31}P-[^1H]-NMR spectra of $(CD_3)_2CO$ solutions of the complexes show one signal corresponding to the phosphorus atoms of the coordinated ligands. The δ_P values of the coordinated ligands are higher than those of free ligands. Only one signal is observed in accord with the symmetry of the complexes [17]. The FAB-mass spectra show fragmentation *via* successive loss of CO groups and fragmentation of the organic ligands.

The IR spectroscopic results are in accord with a *cis*-chelating bidentate coordination of the ligand [2]. The ^{31}P NMR data show that the P atoms of the $R_4P_2S_2$ ligands are somewhat deshielded with respect to the free ligand. The ν(CO) modes of **1A–2D** move to low wavenumber when compared with the starting $M(CO)_6$ molecules. These data suggest, as expected, that the $R_4P_2S_2$ ligand is acting principally as a σ-donor.

Acknowledgements—We thank BP (Turkey) for the provision of photochemical apparatus. We thank UK EPSRC for allocation of time at the Mass Spectrometry Service at University College, Swansea. We thank the British Council for financial support of O.S.S. and F.S. We are grateful to Mr P. Heath for obtaining the NMR data.

(Received 12 July 1996; accepted 2 August 1996)

Abstract—Two β-ketoiminato complexes of zirconium, di[bis-trifluoroacetylacetone-ethylenediiminato]zirconium $Zr(enTFA_2)_2$ (**1**), and di[bis-trifluoroacetylacetone-trimethylenediiminato]zirconium, $Zr(trimenTFA_2)_2$ (**2**), have been obtained in high yield from the reaction of $ZrCl_4$ and the sodium salt of the corresponding Schiff base. The compounds have been characterized by elemental analysis, NMR, mass spectrometry and X-ray structure determination. The coordination geometry around the zirconium atom is a dodecahedron in **1** and a square antiprism in **2**. The increase of the aliphatic bridging chain of the ligand does not produce significant changes in the Zr—O_{av} bond distances [2.101(2) in **1** and 2.086(4) Å in **2**] while the Zr—N_{av} bond distances are lengthened [2.432(4) in **1** and 2.491(5) Å in **2**]. Keywords: zirconium; crystal structure; ketoimine ligands.

Tetradentate Schiff-base complexes of transition and main-group elements are well known and detailed studies have been reported on their synthesis and chemico-physical properties [1–4]. Moreover, due to the enhanced thermal stability of β-ketoiminato (or β-ketodiiminato) complexes with respect to the β-diketonates, their potential application in gas-chromatography for qualitative and quantitative metal analyses has been envisaged [5,6]. The recent development of MOCVD (metal organic chemical vapour deposition) technique for metal and metal oxides deposition and the related research aimed to find new metal precursors (thermally stable, air-stable, volatile and easy to handle) led to the "rediscovery" of some known classes of compounds such as alkoxides, diketonates and amides [7,8]. Among them β-ketoiminates and fluorinated β-ketoiminates of Cu^{I} and Cu^{II} and of Ni^{II} have been successfully used as precursors for copper and nickel deposition [9–11] and barium β-ketoiminate for $BaPbO_3$ MOCVD [12]. Such complexes, thermally stable and volatile, are interesting because, with respect to β-diketonates, an additional site, i.e. the imine nitrogen, can be exploited for tailoring their reactivity and their volatility. Few examples are reported on the synthesis and the crystal structure of complexes formed from $ZrCl_4$ with Schiff-base ligands [13–14]. In particular, studies on zirconium β-ketodiiminate are limited to the partially substituted Zr(β-ketodiiminate)Cl_2 [15]. Looking for suitable precursors for ZrO_2 chemical vapour deposition and having in mind the above reported results, we have synthesized and fully characterized two new zirconium compounds, namely di[bis-trifluoroacetylacetone-ethylenediiminato]zirconium, $Zr(enTFA_2)_2$, and di[bis-trifluoroacetylacetone-trimethylenediiminato]zirconium, $Zr(trimenTFA_2)_2$. Studies on their chemical-physical properties as well as their structural determination are reported and discussed.

EXPERIMENTAL

Synthesis of the complexes

Trifluoroacetylacetone (Htfac, Aldrich) was distilled prior to use. Ethylendiamine and 1,3-propanediamine were dried over potassium hydroxide and redistilled before use. Benzene, ethanol and n-hexane were dried and purified by standard

* Author to whom correspondence should be addressed.

procedures. ^1H and ^{13}C NMR spectra were recorded on a Bruker AC 200 spectrometer (solvent: C_6D_6 or $CDCl_3$, chemical shifts relative to TMS). Mass spectrometric measurements were performed on a VG ZAB 2F mass spectrometer (*EI* = 70 eV).

Tetradentate β-ketoimines. Both bis-trifluoroacetylacetone-ethylenediimine [H_2(enTFA$_2$)] and bis-trifluoroacetylacetone-trimethylenediimine [H_2(trimenTFA$_2$)] were synthesized according to the literature [1]. In particular, they were prepared by adding the diamine to an ethanolic solution of Htfac (Aldrich) at 0°C. After the addition, the mixture was allowed to warm up and refluxed for 3 h. Both the ketoamines (white, crystalline solids) are obtained by crystallization from water with a yield of *ca* 40%. Their purity was checked by elemental analysis, NMR, IR and mass spectroscopy.

Na *derivatives.* Na$_2$(enTFA$_2$) and Na$_2$(trimenTFA$_2$) were prepared by reaction of metallic sodium with the respective ketoimine in benzene at room temperature in dry-boxes [N_2 atmosphere, O_2 and H_2O < 2 ppm]. After 12 h excess sodium was eliminated by filtration and the natrium salt, obtained by evaporating the solvent, was characterized by ^1H NMR. Na$_2$(enTFA$_2$), ^1H NMR spectrum (C_6D_6): δ (ppm) 1.51 (s, 6H, CH_3), 5.28 (2, 2H, *CH*), 3.19 (s, 4H, N—CH_2); Na$_2$(trimenTFA$_2$), ^1H NMR spectrum (C_6D_6): δ (ppm) 1.49 (s, 6H, CH_3), 5.26 (s, 2H, *CH*), 3.02 (m, 4H, N—CH_2), 1.92 (m, 2H, CH_2).

Zr(enTFA$_2$)$_2$. A benzene solution of Na$_2$(enTFA$_2$) (3 g, 4 mmol) was added to $ZrCl_4$ (466 mg, 2 mmol) suspended in benzene. The mixture was refluxed for 3 h, NaCl was filtered and by crystallization from benzene and *n*-hexane, colourless, air-stable crystals of Zr(enTFA$_2$)$_2$ were obtained (decomposition starts at 170°C followed by melting at 220°C). Yield with respect to $ZrCl_4$: 80%. Found C, 37.8; H, 3.4; N, 7.0. Calc. for [$ZrN_4O_4C_{24}H_{24}F_{12}$]: C, 38.3; H, 3.2; N, 7.4%. ^1H NMR spectrum (C_6D_6): δ (ppm) 1.42 (s, 12H, CH_3), 5.38 (s, 4H, *CH*), 3.60 (s, 8H, N—CH_2); ^{13}C NMR spectrum ($CDCl_3$): δ (ppm) 22.47 (q, CH_3), 100.18 (d, *CH*), 51.04 (t, N—CH_2), 119.92 (q, CF_3, $^1J_{C-F}$ = 280 Hz), 154.42 (q, *CO*, $^2J_{C-F}$ = 33 Hz), 164.97 (s, *CN*).

Zr(trimenTFA$_2$)$_2$. $ZrCl_4$ (233 mg, 1 mmol) was slowly added, at room temperature, to a benzene solution of Na$_2$(trimenTFA$_2$) (692 mg, 2 mmol). After 3 h the mixture was filtered from NaCl, the solvent removed under vacuum and the white residue washed with *n*-hexane. By crystallization of the residue from a mixture of benzene/*n*-hexane, white air-stable crystals of Zr(trimenTFA$_2$)$_2$ were recovered. Yields with respect to $ZrCl_4$: 81%. It decomposes without melting at 210–220°C. Found: C, 40.0; H, 3.6; N, 7.0. Calc. for [$ZrN_4O_4C_{26}H_{28}F_{12}$]: C, 40.0; H, 3.6; N, 7.2%. ^1H NMR spectrum ($CDCl_3$): δ (ppm) 1.60 (s, 12H, CH_3), 4.97 (s, 4H, *CH*), 3.31 (m, 8H, N—CH_2), 1.96 (m, 4H, —CH_2—); ^{13}C NMR spectrum ($CDCl_3$): δ (ppm) 22.31 (q, CH_3), 102.55 (d, *CH*), 46.97 (t, N—CH_2), 26.24 (t, —CH_2—), 119.99 (q, CF_3, $^1J_{C-F}$ = 281 Hz), 153.87 (q, *CO*, $^2J_{C-F}$ = 36 Hz), 166.72 (s, *CN*).

X-ray measurements and structure determination

Crystal data, collected reflections and parameters of the final refinement for [Zr(enTFA$_2$)$_2$] and [Zr(trimenTFA$_2$)$_2$] are reported in Table 1. Reflections were collected using a Philips PW1100 diffractometer [16] with graphite-monochromated Mo-K_α radiation. The orientation matrix and cell dimensions were determined by least-squares refinement of the angular positions of 30 reflections. Data were collected at room temperature. Two standard reflections were monitored every 200 reflections and no significant decay was observed during data collection. The intensity data were corrected for Lorentz–Polarization effects and for absorption, as described by North *et al.* [17]. The structure was solved by heavy-atom methods [18]. All non-H atoms were located in the subsequent Fourier maps. The structures were refined by full-matrix least-squares using anisotropic temperature factors for all non-hydrogen atoms. The hydrogen atoms were introduced at calculated positions in their described geometries and during refinement were allowed to ride on the attached carbon atoms with fixed isotropic thermal parameters (1.2 U_{eq} of the parent carbon atom). Structure refinement and final geometrical calculations were carried out with SHELXL-93 [19] and PARST [20] programs, drawings were produced using ORTEP-II [21]. The significant bond lengths for the two compounds are reported in Table 2.

RESULTS AND DISCUSSION

The Schiff-base complexes were not straightforwardly prepared from H_2(enTFA$_2$) or H_2(trimenTFA$_2$) and $ZrCl_4$, but the sodium salt of the ligand was employed in order to better control the stoichiometry of the reaction. The complete replacement of the protic hydrogens and substitution with Na can be easily checked by NMR analysis, i.e. the signal of the enolic O—H proton disappears. The reaction of $ZrCl_4$ with the sodium salts gives **1** and **2** in high yield (80%). The new compounds are air-stable and easily crystallizable. Moreover, differently from other Schiff-base complexes, they are quite soluble in organic solvents and this allowed a complete spectroscopic characterization by ^{13}C and ^1H NMR.

The crystal structure of [Zr(enTFA$_2$)$_2$] consists of well separated molecules. An ORTEP view is shown in Fig. 1. The coordination polyhedron around Zr is a dodecahedron. The molecule possesses a two-fold crystallographic symmetry passing through the zirconium and half way of each ethylenic chain. The two independent six-membered chelation rings have the half-chair conformation and are twisted to form a dihedral angle of 61.0(2)°, while in the same ligand are approximately planar. The five-membered chelation

C—F(av.)	1.33(1)	1.30(1)

ring has again a half-chair conformation. The Zr—O distances are significantly shorter than the Zr—N distances [Zr—O_{av} 2.101(2)and Zr—N_{av} 2.432(3) Å] and follow the trend found in other zirconium β-ketoiminato derivatives such as $[Zr(acen)Cl_2(THF)]$ [15] and $[Zr(acen)Cl_2]$ [15] (acen = bis-acetylacetoneethylendiiminate). However, in these mono-acen derivatives of lower coordination numbers, seven and six, respectively, the Zr—O and Zr—N bond distances are shorter as expected and the difference between Zr—O_{av} and Zr—N_{av} is 0.264 and 0.245 Å, respectively, while in the bis ($enTFA_2$) derivative it is 0.331 Å. Increasing the length of the bridging aliphatic chain of the ligand of one member, the resulting $[Zr(trimenTFA_2)_2]$ derivative does not possess in the solid state any imposed crystallographic symmetry and the coordination polyhedron is a square antiprism where the two squares O(1), N(1), O(4), N(4) and O(2), N(2), O(3), N(3) are formed by the chelating hexaatomic ring belonging in both cases alternatively to each of the two "$trimenTFA_2$" ligands, as shown in Fig. 2; the twist angle between the two squares is about 43°. Also in this case the half-chair conformation is maintained and the two moieties in the same ligand are less planar with respect to the ethylene derivative, the dihedral angle being *ca* 8° in both ($trimenTFA_2$) ligands.

The two hexaatomic rings formed with the propylene chain have a twisted conformation. The increased length of the aliphatic chain which should induce more flexibility to the ($trimenTFA_2$) ligand allows shorter Zr—O bond distances [Zr—O $2.086(4)_{av}$ *vs* 2.101(2) Å in the ($enTFA_2$) derivative], but unexpectedly the Zr—N_{av} [2.491(5) Å] length is significantly longer than Zr—N_{av} [2.432(4) Å] in the ($enTFA_2$) derivative; the change in the coordination polyhedron from dodecahedron to a square antiprism could be responsible for this lengthening, influencing the weaker Zr—N bonds.

The major ions in the mass spectra of complexes **1** and **2** are reported in Table 3. Molecular ions are detectable for both compounds and are the most abundant species in the case of **2**. Analogously to fluorinated β-diketone chelates, loss of radical species ($F^{\cdot}$, $CF_3^{\cdot}$) takes place from the molecular ions and loss of neutral species (CF_2) from the (M^+-Ligand) ion [22]. Cleavage of the ligand corresponding to the N—C bond in **1** and C—C of the bridging chain in **2** leave analogous metal-containing fragments of **1** (*m/z* 598) and **2** (*m/z* 612):

The ligand undergoes cleavage of the remaining nitrogen–carbon bond leading to the analogous species:

(*m/z* 572 for **1** and 585 for **2**). For **1** the peak corresponding to a symmetrical cleavage of the ligand is also present (M^+-L/2, *m/z* 585).

The main feature of both spectra is the presence of very intense peaks corresponding to species obtained by loss of one ligand and F rearrangement with the formation of a Zr—F bond [(M^+-Ligand + F) = *m/z* 440, 100% for **1**; *m/z* 452, 88% for **2**]. The migration of fluorine to the metal has already been noticed in the mass spectra of several fluorinated compounds, such as fluoroalkoxides of zirconium [23] and β-diketonates of different metals [22], and thermodynamic and kinetic explanations of such processes have been reported. In this case thermodynamics play a major role since the compounds **1** and **2** do not present intramolecular F···Zr interactions, which could provide a kinetic route to Zr···F, nor in the solid state, as demonstrated by X-ray analysis and presumable neither in the gas phase. Since the results obtained in the mass spectrometer by electron ionization generally give some clues about the preferential thermal decomposition pathways, the formation of ZrF_4 in CVD experiments using **1** and **2** must be taken into account; in fact, as the fluorides are thermodynamically more stable than oxides many

reported fluorinated systems thermally decompose giving metal fluorides instead of metal oxides [23–25].

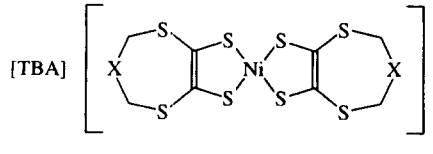
(Received 12 July 1996; accepted 2 August 1996)

Abstract—The complexes $[P(C_6H_5)_4][M(diod)_2]$ [where M = Ni, Pd, Cu or Au (**2a, b, c, d**)] have been prepared and characterized spectroscopically, electrochemically and by X-ray structure determination for **2c**. Preparation of **2d** involved isolation of an intermediate complex with only one diod ligand. The Ni complex **2a** forms semi-conducting charge transfer complexes with TTF and BEDT-TTF. Copyright © 1997 Elsevier Science Ltd

Keywords: dithiolene; crystal structure; charge-transfer salt.

Metal bis-1,2-dithiolene complexes have been widely studied due to potential applications as molecular conductors [1,2], the observation of large third order optical non-linearities [3] and the occurrence of unusual magnetic properties [4,5] in salts of these compounds. In order to extend the range of such compounds available for study, we recently prepared and structurally characterized TBA[Ni(diod)$_2$] (diod = 1,4-dithia-6-oxa-2,3-dithiolate, Fig. 1) from which a charge-transfer complex with BEDT-TTF was prepared [6]. We have also reported preliminary studies on analogous Cu and Au complexes [7]. These complexes have a structure related to that of the organic donor molecule OTT [bis(2-oxatrimethylenedithio)tetrathiafulvalene or BOBMT-TTF] [8], which has been shown to be capable of forming conducting charge transfer salts.



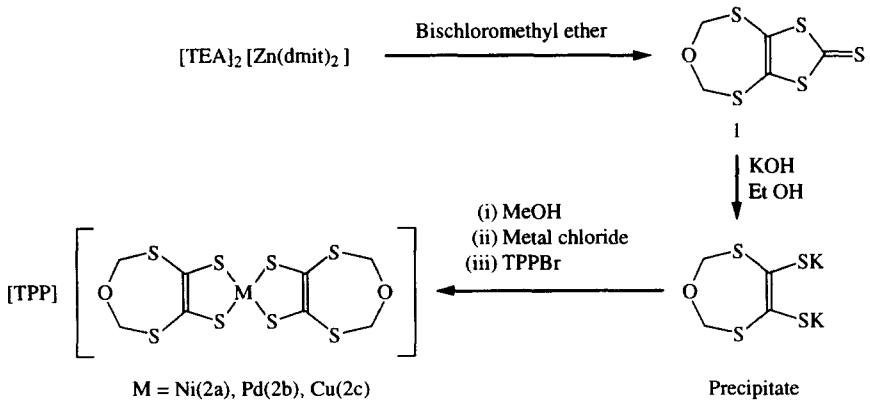


Fig. 1. X = O, TBA[Ni(diod)$_2$]; X = S, TBA[Ni(dtdt)$_2$].

We now report an improved synthesis of these compounds which has led to the isolation of TPP salts of Ni, Pd, Cu and Au complexes (**2a, b, c, d**) of the diod ligand and their spectroscopic and electrochemical characterization together with an X-ray structure determination of the Copper salt **2c**.

RESULTS AND DISCUSSION

The preparation of the complexes [TPP][M(diod)$_2$] (where M = Ni, Pd, Cu) is outlined in Scheme 1. The thione **1** was readily prepared by reaction of $[TEA]_2[Zn(dmit)_2]$ (dmit = 1,3-dithiol-2-thione-4,5-dithiolate), a convenient source of the $C_3S_5^{2-}$ unit, with bischloromethyl ether. The dipotassium salt of the ligand precursor was prepared by reaction of the thione **1** with KOH in warm ethanol and was obtained as a yellow precipitate which could be isolated. The potassium salt was allowed to react in methanol with the appropriate metal chloride and finally [TPP]Br was added to give a precipitate of the product. This procedure is analogous to that used by Kato *et al.* for the preparation of the analogous complex with a terminal sulfur rather than oxygen atom (Fig. 1) [9].

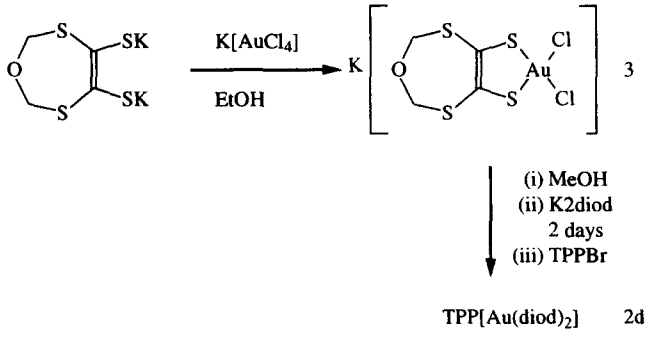

Scheme 1.

The analogous gold complex was not obtained by the above scheme due to formation of a brown precipitate after reaction of the ligand precursor with $K[AuCl_4]$. This product was believed to be $K[Au(diod)Cl_2]$ by analogy with the complex $K[Au(dtdt)Cl_2]$, which was isolated in a related study [10]. It was not possible to purify the product by recrystallization due to the almost complete lack of solubility, however, elemental analysis of the brown precipitate **3** was not inconsistent with this formula. Further evidence for the structure of **3** was obtained by the successful reaction of **3** with a further portion of K_2diod over 2 days in methanol to give the gold bis diod salt **2d** after addition of [TPP]Br (Scheme 2).

The synthesis of **2a, b, c, d** contrasts with the method used previously for the preparation of TBA[Ni(diod)$_2$] [6], in which the thione **1** was deprotected with refluxing NaOEt/EtOH and the soluble sodium salt formed reacted *in situ* with the metal chloride. This method was found to be unreliable over many repetitions as a mixture of products were often obtained which proved difficult to separate. It is believed that side products arose from the further degradation of the thione to $C_2S_4^{4-}$ fragments, which could bridge between metal centres to give rise to dimeric or polymeric products. This was supported by elemental analyses which showed a higher sulfur content and lower carbon content than that expected for the monomeric species and consistent with monoanionic salts of bridged species. In addition, an indication of interacting metal centres was detected electrochemically. The formation of the dipotassium salt of the ligand as a precipitate in the method described here, however, avoids the possibility of further degradation in solution.

The structure of $[PPh_4][Cu(diod)_2]$ (**2c**) was determined by single-crystal X-ray diffraction and consists of $[PPh_4]^+$ cations and $[Cu(diod)_2]^-$ anions held together by Van der Waals forces (Fig. 2). The shortest inter-ionic contact involving non-hydrogen atoms is 3.347 Å [O(1)$\cdots$C(8) at $1+y, z$], which indicates fairly close packing of the cationic and anionic species in the crystal. The anions are arranged in more or less parallel layers, but they are separated by the $[PPh_4]^+$ cations in a way that excludes any possibility of stacking interactions between them. The tetraphenylphosphonium cation is sited on a crystallographic two-fold axis with bond lengths and angles expected for this type of species. One of the angles at P(1) [C(5)—P(1)—C(5′)], however, is considerably narrowed compared with the others [104.5(3) *vs* 109.2(3)–111.1(2)°] probably as a result of packing requirements.

The $[Cu(diod)_2]^-$ moiety (Fig. 3) is centro-

symmetric with the Cu atom showing an exactly planar configuration. The unique Cu—S distances, 2.1800(13) and 2.1874(11) Å, are the same within experimental error. The *trans* angles are 180° by symmetry, whilst the *cis* angles show slight deviations (1.16°) from 90.0°, which may be attributed to the requirement of the bite angle of the chelating diod ligand. Similar angular distortions were also observed in the square planar $[Ni(diod)_2]^-$ anion in $[NBu_4][Ni(diod)_2]$ [6] and also in the complexes $[Ni(S_2C_2S_2R_2)_2]$ (R = butyl or hexyl) [11], $[Ni\{S_2C_2S_2(RR')\}_2]$ (R = Ph, R′ = Bu; R = Ph, R′ = cyclopentylmethyl) [12] and $[Ni(S_2C_2S_2(CH_2)_2C{=}CH_2)_2]$ [13]. Other geometrical parameters of the central $CuS_4C_4S_4$ core are typical for this class of compound [14]. The C—C bond length in

the chelate ring [1.331(5) Å] is comparable with those in other similar species and indicative of the delocalized nature of the bonding. The S(1)S(2)C(1)C(2) fragment of the diod ligand is planar within 0.009 Å, with the Cu(1), S(3) and S(4) atoms lying, respectively, −0.381, −0.071 and 0.014 Å away from this plane. As observed in $[NBu_4][Ni(diod)_2]$ [6], the seven-membered C_4OS_2 ring in the present case also has a chair conformation, with fold angles of 61.2 and 65.9° along the S(3)···S(4) and C(3)···C(4) lines, respectively. A similar conformation of the seven-membered C_5S_2 ring was also observed in $[Ni(dpdt)_2]$ [13], but in this case the two-fold angles above were nearly equal at 62.7 and 61.9° (see Tables 1 and 2).

The electrochemical properties of **2a, b, c, d** were studied by cyclic voltammetry against SCE in acetonitrile and the results are presented in Table 3.

The values obtained for the nickel complex **2a** are in agreement with those previously observed for the related TBA salt and show a 1−/0 couple similar to that of other metal dithiolene complexes with a proven ability to form molecular metals [6]. The separation between the 1−/0 and 2−/1− couples however, is large and indicates a poorer ability to delocalize charge than $[Ni(dmit)_2]^{x-}$. These observations are reflected in the inability to prepare molecular conductors with $[Ni(diod)_2]^{x-}$ as the sole conducting component, although the use of this complex as a counter ion for TTF or BEDT-TTF has shown greater utility towards the preparation of conducting solids. The palladium complex **2b** shows a similar reversible 1−/0 couple to **2a,** but differs in that the reduction to a dianionic state occurs irreversibly, again presumably reflecting the reduced ability of the diod ligand to delocalize charge. Compared with dmit therefore, the dianionic diod complex with Pd is destabilized such that no analogue of the isolable salts of $[Pd(dmit)_2]^{2-}$ is available.

The results obtained for the Cu and Au complexes **2c, d** reflect the double occupation of the HOMO for the monoanions of these complexes, which cause reduction to be disfavoured as it involves introduction of an electron into a higher energy molecular orbital. The Cu complex **2c** therefore, showed reduction at −1.4 V with an associated oxidation whose position and peak height was dependant on sweep rate, suggesting that this process would be chemically reversible if a high enough sweep rate could be attained. For the gold complex **2d,** no reduction was observed up to −1.5 V. The oxidation observed for **2d** occurred at +0.64 V and was irreversible. A recent study [15] has demonstrated that the oxidation process in related gold dithiolene complexes can become reversible at high sweep rates (50–2000 V s^{-1}). This, however, could not be investigated for **2d** due to instrumental limitations.

The UV–vis and near IR spectra of complexes **2a, b, c, d** were recorded in methylene chloride solution and results are presented in Table 4. The nickel complex **2a** shows an intense absorption at 950 nm typical for this class of compound and consistent with the results previously observed for the related TBA salt. The Pd complex **2b,** which also has a singly occupied HOMO displays a low energy band at 1200 nm. The large difference in the values observed for **2a** and **2b** indicates the strong influence of the central metal on the frontier orbitals of the complex. This is expected if the ligand is strongly electron-withdrawing and this may reflect the presence of the electron-withdrawing oxygen atom in the diod ligand. The Cu and Au analogues, however, possess an additional valence elec-

tron and, therefore, have a fully occupied HOMO and cannot exhibit a low-energy excitation. These observations are consistent with the electrochemical behaviour of these species.

The copper complex **2c** shows a visible colour change from green to red upon dissolution in methylene chloride and comparison of the solid-state reflectance and solution spectra showed additional broad bands at 1350 and 650 nm in the solid state. As the crystal structure of this complex indicates no significant intermolecular interactions, it appears that the colour change arises from some intramolecular rearrangement. It has been previously observed that in the complex [*N*-ethyl pyridinium][Cu(dmit)$_2$] the dihedral angle between the ligand planes is 57.3° around the central metal in the solid state structure [16]. This suggests that copper complexes are able to adopt a tetrahedral arrangement of the sulfur donor atoms in solution and that the colour change in **2c** may be associated with a change from tetrahedral to square-planar geometry.

In the IR spectrum of **2a,** a band was observed at 1386 cm^{-1} corresponding to a weakened C=C bond. For **2b, c, d,** this band could not be unambiguously

assigned due to the presence of broad bands in this region associated with the TPP cation. C—S bond stretching was observed for complexes **2a, b, c, d** at around 1040 cm^{-1} and at around 905 cm^{-1}. The gold complex **3** showed bands at 1399 and 1048 cm^{-1}, consistent with the presence of a diod ligand in the proposed structure.

Electrochemical crystallization of the TPP, TBA and TMA salts of the nickel complexes were attempted in order to obtain partially oxidized salts of this complex with TPP, TMA or TBA present as counterion. These studies, however, seemed only to lead to isolation of the neutral complex $[Ni(diod)_2]$, which has also been previously prepared by reaction of **2a** with I_2 [6]. Electrocrystallizations were also attempted in the presence of TTF and BEDT-TTF in order to obtain charge-transfer complexes involving these organic donors. Highly conducting solid-state products were obtained from these experiments which appeared from elemental analysis data to have a composition approximate to that of neutral $[Ni(diod)_2]$, but clearly contained some other component as the conductivity was several orders of magnitude higher (Table 5). We postulate that these products contain a small ratio of the organic donor to the nickel complex although it is not possible to ascertain the true stoichiometry in the absence of better quality crystals which could lead to structural data.

Conclusions

A series of monanionic metal complex salts of the ligand diod have been prepared and characterized, including a crystal structure of the copper complex. Preparation of the gold complex involved isolation of an intermediate which appeared to contain only one diod ligand and may have potential as a precursor towards the preparation of asymmetric metal dithiolene containing complexes. Conducting charge-transfer complexes have been prepared from TTF or BEDT-TTF with $[Ni(diod)_2]^{x-}$, but a detailed understanding could not be obtained due to lack of high quality crystals.

EXPERIMENTAL

Bischloromethyl ether [17], $TEA_2[Zn(dmit)_2]$ [18] and thione [6] were prepared by previously described methods. $NiCl_2 \cdot 6H_2O$, $PdCl_2(NCPh)_2$, $CuCl_2$ and $K[AuCl_4]$ were used as purchased without further purification. Ethanol was distilled from Mg/I_2 prior to use and stored over molecular sieve. IR spectra of samples pressed as KBr discs were recorded on a Perkin–Elmer 1600 series FTIR spectrometer. Near IR, UV–vis and reflectance spectra were recorded on a Beckman DK-2A instrument. Electrocrystallization experiments were carried out by methods analogous to those described previously [6].

$[BEDT\text{-}TTF]_x[Ni(diod)_2]$	3×10^{-1}

Preparation of $TPP[M(diod)_2]$ **(2a, b, c)**

(i) **2a**: The thione **1** (1.078 g, 4.49 mmol) was stirred in dry ethanol (50 cm^3) with KOH (2.0 g, 36 mmol) for 2 h in a water bath at 45–50°C. A pale yellow precipitate was formed which was filtered off under nitrogen and washed with ethanol. The salt was dried *in vacuo* and dissolved in dry methanol (20 cm^3). $NiCl_2 \cdot 6H_2O$ (0.309 g, 1.30 mmol) dissolved in dry methanol (20 cm^3) was added and stirring continued for 16 h at room temperature under nitrogen. Air was bubbled through the solution for 20 min and the mixture filtered to remove a pale yellow residue. TPPBr (2.524 g, 6.02 mmol) dissolved in methanol was added to the filtrate dropwise with stirring. The brown precipitate formed was filtered off, washed with methanol and dried in air. The product was recrystallized by dissolving in acetone, filtering to remove any undissolved solid, addition of IPA and reduction of the volume until the solution became cloudy. The crystalline product was allowed to form over 2 h, filtered off, washed with IPA and dried in air. Yield = 0.37 g, 0.47 mmol, 36%. Found: N, 0.0; C, 46.9; H, 3.5; S, 32.4. Requires: N, 0.0; C, 46.6; H, 2.4% S, 31.1. IR: ν_{max}/cm^{-1} 3433, 1480, 1434, 1386, 1305, 1184, 1107, 1038.

(ii) **2b,c**: These were formed by a procedure identical to that for **2a** but substituting $NiCl_2 \cdot 6H_2O$ for $PdCl_2(NCPh)_2$ and $CuCl_2$, respectively.

2b: Yield = 5%. Found: N, 0.1; C, 46.0; H, 2.6; S, 24.9. Requires: N, 0.0; C, 45.9; H, 3.3; S, 30.6%. IR: ν_{max}/cm^{-1} 3446, 2361, 1702, 1482, 1436, 1301, 1108, 1043, 996, 972, 906.

2c: Yield = 7%. Found: N, 0.0; C, 48.1; H, 3.1; S, 31.8. Requires: N, 0.0; C, 48.3; H, 3.5; S, 32.2%. IR: ν_{max}/cm^{-1} 1481, 1434, 1305, 1108, 1035, 904.

Preparation of **3**

The thione **1** (0.411 g, 1.71 mmol) and KOH (0.856 g, 15.26 mmol) were dissolved in dry ethanol (20 cm^3) and stirred under nitrogen at 45°C for 2.5 h. A pale yellow precipitate was formed and filtered off under nitrogen. The yellow solid was stirred in methanol (20 cm^3) under nitrogen along with $K[AuCl_4]$ (0.20 g, 0.52 mmol) and stirred overnight. A dark brown solid was formed which was filtered off and washed with methanol. Found: N, 0.0; C, 7.3; H, 0.5; S, 24.2. Requires:

N, 0.0; C, 9.5; H, 0.8; S, 25.5%. IR: ν_{max}/cm^{-1} 1399, 1048.

Preparation of **2d**

The thione **1** (0.20 g) and KOH (0.41 g) were reacted in dry ethanol over 2.5 h and the resultant yellow precipitate filtered off, washed with ethanol and dried under nitrogen. This solid was dissolved in dry methanol (50 cm^3) and reacted with **3** over 2 days at 50°C under nitrogen then filtered to remove any undissolved solid. To the filtrate was added TPPBr (0.813 g) in dry methanol (20 cm^3) dropwise with stirring forming a yellow/brown precipitate. This was filtered off, washed with methanol and dried in air. Yield = 0.113 g, 0.12 mmol, 24%. Found: N, 0.0; C, 40.7; H, 2.9; S, 28.7. Requires: N, 0.0; C, 41.4; H, 3.0; S, 27.6%. IR: ν_{max}/cm^{-1} 3448, 1638, 1548, 1484, 1436, 1382, 1304, 1108, 1037, 905, 723, 688, 618.

X-ray structure determination of $[PPh_4][Cu(diod)_2]$

All crystallographic measurements were made at 298(2) K on a Delft Instruments FAST TV area detector diffractometer positioned at the window of a rotating anode generator using Mo-K_α radiation ($\lambda = 0.71069$ Å) by following procedures described elsewhere [19]. The structure was solved by Patterson methods (SHELXS86) [20] and difference syntheses, and refined on F^2 by full-matrix least-squares (SHELXL93) [21] using all unique data corrected for Lorentz and polarization factors and also for absorption effects (DIFABS) [22]. The non-hydrogen atoms were refined anisotropically, the hydrogen atoms were included in calculated positions (riding model) with U_{iso} tied to the U_{eq} of the parent carbons. Sources of scattering factors as in reference [21]. The diagrams were drawn with SNOOPI [23]. The calculations were done on a Pentium P5-90 personal computer. Important bond lengths and angles are given in Table 1, and the crystal data and details of data collection and structure refinement are presented in Table 2. The atomic coordinates, thermal parameters, full lists of bond lengths and angles, and structure factor tables have been deposited with the Editor as supplementary material.

(Received 12 July 1996; accepted 1 August 1996)

Abstract—A novel chain complex containing chromium(III) and alkali metal, namely, [Cr(salen)$(NCS)_2K \cdot H_2O$] [salen^{2-} = *N*,*N*′-ethylenebis(salicyldiminato)] was prepared and its crystal structure was determined by X-ray diffraction technique. Each chromium atom is six-coordinated with the tetradentate ligand salen^{2-} in the equatorial plane and two NCS ligands in the axial positions *via* the N atoms. The bond lengths of the Cr atom with the coordinating atoms are comparable with other Cr^{III} Schiff base complexes. Each K atom is also six-coordinated with five oxygen atoms and a sulfur atom. The bond lengths of K—O fall into the range of potassium complexes of cyclic polyethers. There are two kinds of bridging modes: water molecules link two K atoms and phenolato groups in the Schiff base ligand and NCS anions link Cr and K atoms, resulting in a chain running in the direction parallel to the a-axis. Copyright © 1997 Elsevier Science Ltd

Keywords: chromium(III); potassium; crystal structure; heterometallic complex; one-dimensional chain.

One-dimensional coordination polymers of metal complexes have been intensely studied for nearly 30 years as materials with unusual properties [1–4]. Molecular-based ferromagnets, synthetic metallic conductors, non-linear optical materials and ferroelectrics represent several applications of low-dimensional coordination polymers. Many efforts have been made to prepare this kind of complex. It remains a continuing challenge for the experimental chemists to assemble molecules. In this study we attempted to obtain a complex [Cr(salen)$(NCS)_2$]$^-$ [salen^{2-} = *N*,*N*′-ethylenebis(salicyldiminato)], since the two thiocyanato ligands in it may act as bridging ligands. So, the complex may act as a precursor of one-dimensional polymers, especially heterometallic one-dimensional polymers. To our surprise, the structure determination revealed the title complex [Cr(salen)$(NCS)_2K \cdot H_2O$] to be a one-dimensional chromium–potassium heterobimetallic polymer. This kind of complex is still rare so far [5].

EXPERIMENTAL

Preparations

All the chemicals were analytical grade and used without further purification. [Cr(salen)$(H_2O)_2$]NO_3 was prepared according to the literature methods [6].

Synthesis of [Cr(salen)$(NCS)_2K \cdot H_2O$]. To a methanol solution (20 cm^3) of [Cr(salen)$(H_2O)_2$]NO_3 (2 mmol) was added a methanol solution (5 cm^3) of KSCN (8 mmol, molar ratio: 1:4) and the resultant mixture was refluxed for 4 h with stirring. Some insoluble solid appeared when cooled to room temperature. After filtration, the filtrate was allowed to stand for several days. Reddish-brown single crystals suitable for X-ray analysis were obtained. Found: C, 43.5; H, 2.9; N, 11.3. Calc. for $C_{18}H_{16}CrN_4O_3S_2K$: C, 44.0; H, 3.3; N, 11.4%.

Physical measurements

Elemental analyses were performed at the Analysis and Measurement Center of Nanjing University. The

FT-IR spectra were recorded in the 4000–400 cm^{-1} region using KBr pellets on a Nicolet 170 SX FTIR spectrometer.

X-ray structure determination

The crystal selected for X-ray diffraction was a reddish-brown parallelepiped of dimensions $0.5 \times 0.25 \times 0.18$ mm^3. Raw intensities were collected on a four-circle CAD4 diffractometer with Mo-K_α radiation at room temperature (27°C). The scan mode was ω-scan with a fixed speed of 3 s per reflection. The accurate unit-cell parameters were determined from automatic centring of 25 reflections ($1.90 \leqslant \theta \leqslant 24.98°$) and refined by least-squares methods. The crystallographic data, conditions retained for the intensity collection and some features of structure refinement are listed in Table 1.

7279 reflections were collected in the range $-10 \leqslant h \leqslant 10$, $0 \leqslant k \leqslant 15$, $-22 \leqslant l \leqslant 22$, and 3736 reflections were assumed as observed by applying the condition $I > 2\sigma(I)$. Absorption corrections based on 3 rather weak reflections were performed by means of the psi-scan technique. The structures were solved by

the Patterson method using SHELXS-86 [7]. All H atoms (except one on H_2O) were located from the difference map. All non-H atoms were subjected to anisotropic refinements. Crystallographic computations were performed using the SHELXL-93 package [8] on a 486 PC computer. Selected bond lengths and angles are given in Table 2.

Additional material available from the Cambridge Crystallographic Data Center comprises H-atom coordinates, and remaining bond lengths and angles.

RESULTS AND DISCUSSION

Description of the structure

Figure 1 illustrates the geometry and labelling of the cell unit. The Cr atom is six-coordinate with the tetradentate ligand salen^{2-} in the equatorial plane and two NCS ligands in the axial positions *via* the N atoms. The bond distances Cr—O(1) [1.948(2)], Cr—O(2) [1.937(2)], Cr—N(1) [2.006(3)] and Cr—N(2) [2.002(3) Å] are close to those in other Cr^{III} complexes $[Cr(salen)(H_2O)_2]^+Cl^-$ [9] and $[Bu_4N][\{Cr(salen)CN\}_2CN]$ [10], in which Cr—N(imine) is *ca* 2.00 Å and Cr—O(phenolato) is *ca* 1.94 Å. The bond lengths of Cr—N(3) and Cr—N(4) are 2.015(3) and 2.020(3) Å, respectively. Similar distances were also seen in $[\{Cr(tmpa)(NCS)\}_2O]^{2+}$ [Cr—N (NCS) = 2.004(3) Å] [11]. The bond angles of O(1)—Cr—N(2) and O(2)—Cr—N(1) are 171.83(11) and 173.37(11)°, respectively, showing the Cr atom slightly out of the equatorial plane. The bond angle ∠NCS is *ca* 177°, indicating a linear NCS group, but the bond angle of C(17)—N(3)—Cr (163.9°) is smaller than that of C(18)—N(4)—Cr [172.4(3)°].

The K atom is coordinated by five oxygen atoms and a sulfur atom (Fig. 2). The oxygen atoms originate from two water molecules and the others from different phenolato groups of salen ligands in the complex anions. The bond distances of K—O are in the range 2.7–2.9 Å and are comparable with the K—O distances of 2.70–3.09 Å in potassium complexes of cyclic polyethers [12–14]. The bond length of K—S (from the SCN anion) is 3.334(2) Å, close to those K—S bond distances (3.20–3.35 Å) in the potassium dithiocarboxylate complex $[S_2CphCS_2]2K \cdot 2H_2O$ [15] and the potassium monothiocarboxylates complex $[SOCNHNHCOS]2K \cdot 2H_2O$ [16]. The distances of K—C(17)2, K—N(3)2 and K—C(1)2 are 3.528(2), 3.228(4) and 3.291(3) Å, respectively, suggesting some weak interaction may operate among them. Two further points merit attention. One is that the water molecules in the crystal act as bridging ligands linking two K atoms. The other is that the phenolato groups in the Schiff base ligand and the NCS anions bridge the K atoms and Cr atoms. As a result, a chain including the Cr^{III} and K atoms forms running in the direction parallel to the *a*-axis.

IR spectra

The IR spectra of the complex display a strong absorption at 2045 cm^{-1}. It is the characteristic C=N stretch for an N-coordinated thiocyanate ion. This is consistent with the results of X-ray analysis. IR spectra also show a strong absorption band at *ca* 1623 cm^{-1} which is assigned to a C=N stretching mode in the Schiff base. Comparing with the free H_2salen ligand (1635 cm^{-1}) the absorption band is slightly red-shifted.

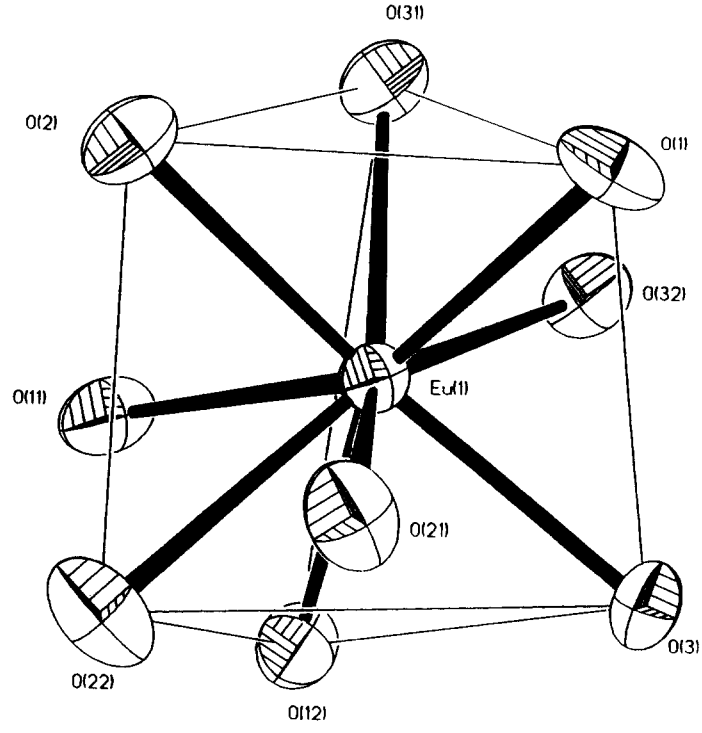

Fig. 2. The coordination around each Eu^{III}.

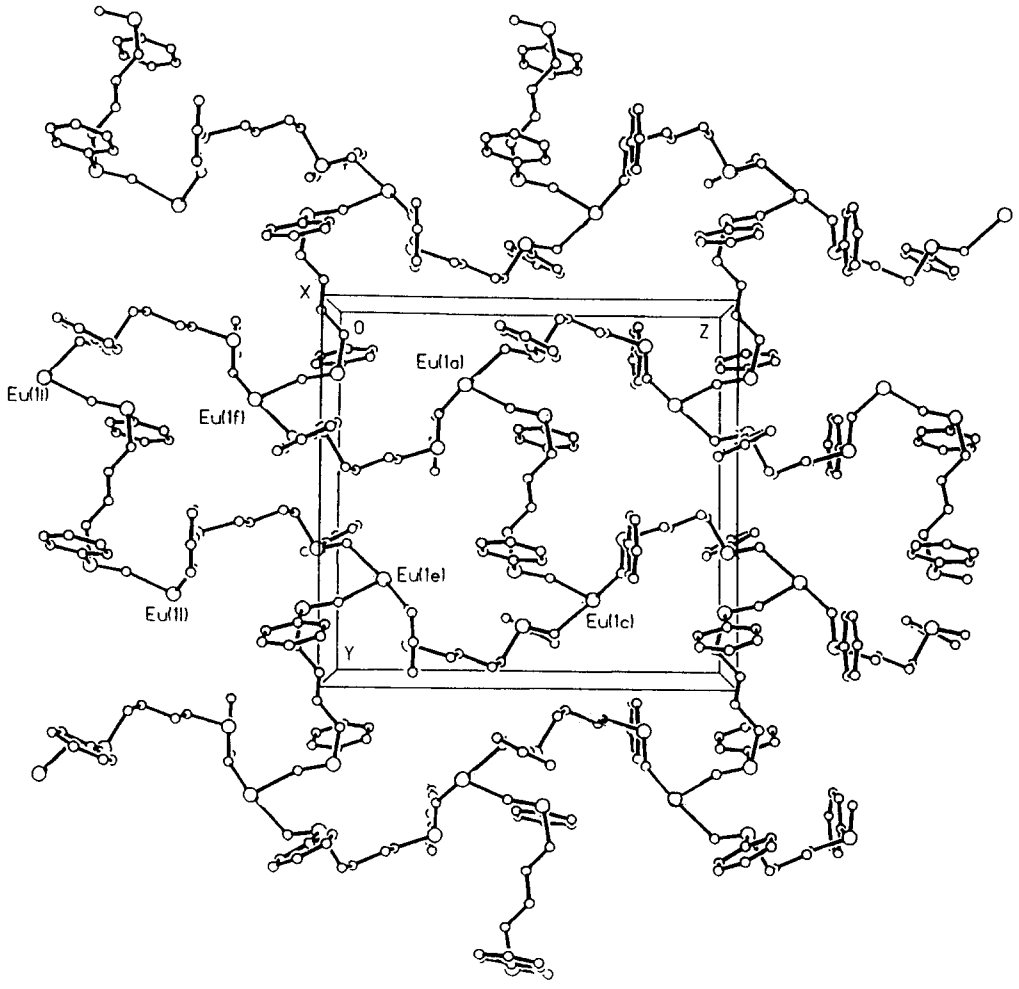

Fig. 3. Part of one of the sheet of linked 54-membered macrocycles in the structure of the complex (nitrate ions are not shown).

sheet (Fig. 3) in the y and z directions. The linkages between macrocycles are through one edge to form a chain of macrocycles extending along the z direction and bridged ligands along the y direction.

Molecular conductance and IR spectrum

The molar conductance value of the title complex in methanol is ~ 0 s mol^{-1} cm^2, which indicates the complex behaves as a nonelectrolyte.

The IR spectrum of the complex indicated that the bphsb binds metal ions through the oxygen atoms of sulfoxide moieties. The S=O bond stretching frequencies of the complex (988 cm^{-1}) are lower than the corresponding one in the free ligand (1040 cm^{-1}). IR data also indicate the presence of bidentate nitrate group [C_{2v}: $\nu_1(A_1)$ 1496, $\nu_4(B_1)$ 1290, $\nu_2(A_1)$ 1028, $\nu_3(A_1)$ 818, $\nu_5(B_1)$ 740 and $\nu_2+\nu_5$ 1765, $\nu_2+\nu_6$ 1725 cm^{-1}] [10]. Therefore, IR spectrum and molar conductance suggest that all nitrate ions are coordinated bidentately and the ligand bphsb acts as a neutral bidentate. These results are consistent with crystal structure analysis.

Absorption, excitation and emission spectra

The absorption spectrum of a methanol solution of the complex at room temperature shows three absorption bands: n–π^* band of the S=O group (213 nm) and two bands of the π–π^* transition (238, 270 nm).

The excitation spectrum at 610 nm emission presents a wide excitation band at 280–340 nm (absorption band of ligand) and some sharp bands in the range 360–500 nm (absorption bands of Eu^{3+}).

The emission spectrum of the complex shows a typical f–f transition of the $^5D_0$ state to ^7F_J stark levels of

(Received 5 July 1996; accepted 1 August 1996)

Abstract—A polynuclear europium(III) complex of the formula $[Eu(bphsb)_{1.5}(NO_3)_3]_n$ [bphsb = 1.4-bis(phenylsulfinyl)butane] has been prepared and its structure and luminescent properties have been determined by X-ray diffraction and spectral measurements. The structure consists of Eu^{III} ions bridged by bidentate bphsb ligands and coordinated by NO_3^- groups to make a polynuclear neutral complex. The europium ion is nine-coordinated and the geometry around the Eu^{III} is that of a distorted tricapped trigonal prism. The polynuclear complex has a framework structure with 54-membered macrocyclic rings, each containing six europium ions. The complex exhibits sensitized luminescence that originates from $^5D_0$ state to ^7F_J Stark levels. Copyright © 1997 Elsevier Science Ltd

Keywords: polynuclear europium(III) complex; framework structure; luminescent properties.

Polynuclear Ln^{III} complexes are important as novel light-conversion moleculear devices with potential application as probes and labels for a variety of chemical and biological systems [1–3]. Some polynuclear lanthanide complexes have been reported [4–5], but there is little information on lanthanide complexes with a framework structure [6]. During our studies on the coordinating ability of disulfoxide, we found 1,4-bis(phenylsulfinyl)butane (bphsb) was a good bridging ligand to generate polymers with unusual structures. To our knowledge, the bphsh ligand produces the first example of polynuclear complex with framework structure in the reported disulfoxide lanthanide complexes [7–8]. In this paper, we present the synthesis, structure and photophysical properties on the new polynuclear europium complex of bis(phenylsulfinyl)butane $[Eu(bphsb)_{1.5}(NO_3)_3]_n$, which is a new class of supramolecular compound.

ligand(bphsb)

Scheme 1. ligand(bphsb)

EXPERIMENTAL

Synthesis of polynuclear complex $[Eu(bphsb)_{1.5}(NO_3)_3]_n$

Hydrated eropium nitrate (0.5 mmol) in anhydrous methanol (5 cm^3) was dehydrated by the addition of triethylorthoformate (3 cm^3). The mixture solution was added dropwise to anhydrous methanol solution (4 cm^3) of ligand (bphsb, 1.5 mmol). The mixture was stirred at 70–80°C for 6 h. A small precipitate was filtered and the filtrate was allowed to evaporate slowly at room temperature; after a week, colorless single crystals were obtained. Found: Eu, 18.82. Calc. for $C_{24}H_{27}N_3O_{12}S_3Eu$: Eu, 19.1%.

Physical measurements

The IR spectrum of the complex in the 4000–400 cm^{-1} range (as KBr pellets) was recorded on a WHF-

* Author to whom correspondence should be addressed.

30 model spectrometer. Conductivity of the complex in the methanol solution (10^{-3} mol dm^{-3}) was measured at room temperature using a DDS-11A conductometer. Electronic spectrum of the methanol solution of the complex was recorded in the 190–325 nm range on a Shimadzu UV-240 spectrophotometer. Luminescence spectrum of the complex was recorded on a F111 AI Fluorolog-2 spectrofluorometer at room temperature.

Crystal structure determination and refinement

The data were collected using an Enraf–Nonius CAD4 diffractometer with Mo-K_α graphite-monochromated radiation ($\lambda = 0.071073$ nm) by using the ω–2θ scan method. A total of 4613 reflections were measured and 3303 observed reflections [$I > 3\sigma(I)$] used for the structure solution and refinement. The structure was solved by direct methods (MULTAN82). The final refinement by the full-matrix least-squares method with anisotropic thermal parameters for non-hydrogen atoms and gave the final unweighted and weighted agreement factors 0.039 and 0.05, respectively. All the calculation were carried out on a PDP11/44 computer using a SDP-PLUS computer program system.

The crystal data and additional details are as follows: $C_{24}H_{27}N_3O_{12}S_3Eu$: monoclinic, space group $P2_1/c$ $a = 1.0686(3)$, $b = 1.6365(6)$, $c = 1.7590(3)$ nm: $\beta = 91.28(3)^\circ$, $V = 3.075(2)$ nm^3, $M = 797.65$, $D_x = 1.723$ Mg m^{-3}, $\mu = 2.298$ mm^{-1}, $F(000) = 1596$, $Z = 4$.

RESULTS AND DISCUSSION

Description of the structure

Selected bond distances (nm) and angles (°) for the complex are listed in Table 1. Fig. 1. shows the structure and labeling scheme of the title complex.

The X-ray analysis of the title complex reveals the stoichiometry to be $[Eu(bphsb)_{1.5}(NO_3)_3]_n$. The europium(III) ion is nine-coordinated and is bound to one oxygen atom of each of three bphsb ligands and to three bidentate nitrates in a distorted tricapped trigonal prism configuration (Fig. 2). The Eu—O distances fall in two distinct groups with those to the bphsb oxygen atoms in the range: 0.2326(4)–0.2348(4) nm and those to the nitrate groups in the range: 0.2455(4)–0.2512(5) nm. The average Eu—O bond length is 0.2443(9) nm, a little smaller than the sum of the ionic radius of 0.247 nm (nine-coordinated Eu^{3+} 0.112 and O^{2-} 0.135 nm) [9]. This fact shows that the Eu—O bonds have some covalent character.

In the title complex, the bphsb ligands serve to bridge the adjacent metal centres forming a polynuclear structure with a macrocyclic array (Fig. 3). The resulting structure comprises 54-membered macrocyclic rings, each containing six europium atoms. Adjacent rings are in a "parquet-like" pattern to form a two-dimensional

Eu^{3+} (Fig. 4). The $^5D_0$–$^7F_0$ transition is weaker. There are two main transitions to $^7F_1$ level (585.5, 590.5 nm) and the transition to the $^7F_2$ level is comprised of three main bands (612.0, 616.0, 625.5 nm). The observed $^5D_0$–$^7F_4$ transition is split into three bands (688.0, 683.0, 698.5 nm). Overall the emission spectrum points to Eu^{III} ions having chemical and structural environment with a lower symmetry (not higher than C_3) [11].

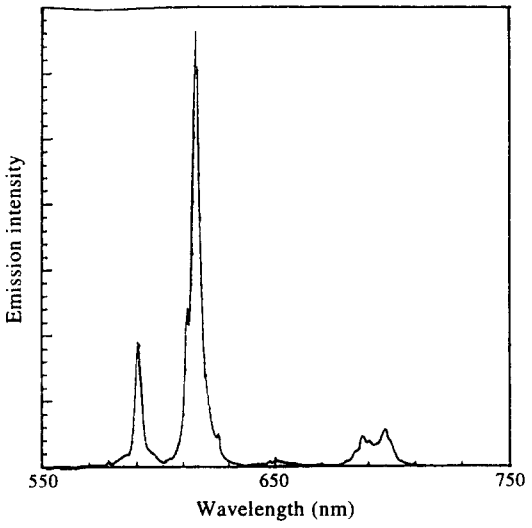

Fig. 4. The luminescent spectrum of the complex (room temperature, ED: 399 nm).

(Received 5 July 1996; accepted 1 August 1996)

Abstract—Thermal treatment of $Ce_2(OPr^i)_8(Pr^iOH)_2$ yielded $Ce_4(\mu_4\text{-}O)(OPr^i)_{14}$ by desolvation under mild conditions. The tetranuclear oxoalkoxide has been characterized by elemental analysis, FT-IR, ^1H NMR and X-ray diffraction. The structure is described as $[Ce_4(\mu_4\text{-}O)(\mu_3\text{-}OPr^i)_2(\mu\text{-}OPr^i)_4(OPr^i)_8]$. The $Ce_4(\mu_4\text{-}O)$ core corresponds to a distorted flattened tetrahedron, with two hexa- and two hepta-coordinated metals. The Ce—O bond lengths spread over the range 2.03(2) to 2.54(1) Å and follow the order Ce—OR < Ce—μOR < Ceμ_3—OR. Copyright © 1997 Elsevier Science Ltd

Keywords: cerium; oxoalkoxides; desolvation.

Despite the implication of cerium in a variety of advanced materials such as high T_c superconductors, γ-scintillators, solid electrolytes or catalysts, only a few molecular precursors are available [1]. They are essentially represented by a dimeric isopropoxide solvate $Ce_2(OPr^i)_8(Pr^iOH)_2$ having a structure similar to that of the other tetravalent metals (zirconium, hafnium, tin) [2] and by a monomeric butoxide $Ce(OBu^t)_4(THF)_2$ [3]. While the latter has been reported to convert to $Ce_3O(OBu^t)_{10}$ in toluene solutions over 2 days at room temperature the isopropoxide was considered to be stable up to *ca* 200°C [4]. While the photoreduction of $Ce_2(OPr^i)_8(Pr^iOH)_2$ led to the mixed valency Ce^{III}–Ce^{IV} cluster $Ce_4O(OPr^i)_{13}(Pr^iOH)$ [5], no further indication on its thermal stability was provided. A non-solvated isopropoxide, $[Ce(OPr^i)_4]_m$, has been reported but without further characterization [4].

Studies of the reactivity of $Ce_2(OPr^i)_8(Pr^iOH)_2$ required us to reinvestigate its thermal stability, both in the solid state and in solution. We report herein these investigations which afforded a tetranuclear Ce^{IV} oxo cluster, $Ce_4O(OPr^i)_{14}$, characterized by single crystal X-ray diffraction.

EXPERIMENTAL

All manipulations were carried out under argon using Schlenk tubes and vacuum-line techniques. Solvents were purified by standard methods. $Ce_2(OPr^i)_8(Pr^iOH)_2$ was prepared as reported in the literature [2]. IR spectra were obtained as Nujol mulls on an IRFS 45 Bruker spectrometer, NMR spectra were registered with an AC-200 Bruker spectrometer. Analyses were performed at the Centre de microanalyses du CNRS.

Synthesis of $Ce_4(\mu_4\text{-}O)(OPr^i)_{14}$

$Ce_2(OPr^i)_8(Pr^iOH)_2$ (2 g, 2.3 mmol) was heated in the solid state for about 15 min (70°C/10^{-3} mm Hg). The yellow solid became pasty and was dissolved in

* Author to whom correspondence should be addressed.

DME-Pr^{i}OH (2/3 in volume). Orange crystals of $Ce_4O(OPr^i)_{14}$ (0.7 g, 43%) and $Ce_2(OPr^i)_8(Pr^iOH)_2$ were separated by crystallization at $-10°C$. The oxo species is soluble in common solvents including isopropanol and hexane. M.p. 145°C, decomposition at 170°C.

Analysis found: C, 37.5; 6.9 calc. for $C_{42}H_{98}O_{15}Ce_4$: C, 35.9; H, 7.0%. IR (cm^{-1}): 1456s, 1377s, 1359sh, 1328m, 1159sh, 1135s, 1125sh, 986s, 973m, 952m, 936m, 827sh, 557sh, 520m, 504w, 490w, 448m, 412w, 395w (νCe—O); ^1H NMR (C_7D_8, 25°C): 5.4m (1H, CH); 1.37d ($J = 6.5$ Hz, 6H, Me); ^1H NMR (C_7D_8, $-70°C$): 5.80, 5.32, 5.15m 3:2:2, CH); 1.8–1.7, 1.5–1.4 (overlapping of doublets, 18H, $J = 6.5$ Hz, 24H, Me).

The same compound was obtained by refluxing $Ce_2(OPr^i)_8(Pr^iOH)_2$ in toluene for *ca* 1.5 h. The yellow solution turns orange immediately. Yield ~ 25%.

Crystal structure determination of $Ce_4(\mu_4\text{-}O)(OPr^i)_{14}$

Intensity data were collected at $-100°C$ on an Enraf–Nonius CAD-4 diffractometer, using Mo-K_α radiation. Unit-cell dimensions with estimated standard deviations were obtained from least-squares refinements of the setting angles of 25 well-centered reflections. Two standard reflections were monitored periodically, they showed no change during data collection. Crystallographic data and other information are summarized in Table 1. Corrections were made for Lorentz and polarization effects. Empirical absorption corrections (Difabs) [6] and extinction correction were applied.

Computations were performed by using the PC version of CRYSTALS [7]. Atomic form factors for neutral Ce, O and C were taken from reference [8]. Real and imaginary parts of anomalous dispersion were taken into account. The structure was solved by direct methods (SHELXS-86) [9] and successive Fourier maps. Two crystallographically independent molecules are found in the unit cell. All atoms were anisotropically refined. Refinements were carried out in five blocks by minimizing the function $\Sigma w(|F_o|-|F_c|)^2$, where F_o and F_c are the observed and calculated structure factors. Models reached convergence with $R = \Sigma(|F_o|-|F_c|)/\Sigma wF_o$ and $Rw = [\Sigma w(|F_o|-|F_c|)^2/\Sigma w(F_o)^2]^{1/2}$ having the values listed in Table 1. The weighting scheme was unity. The structure was drawn using the program Cameron [10].

Tables of atomic coordinates, anisotropic temperature factors, non-essential bond lengths and angles have been deposited at the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Our initial investigations of the reactivity of the cerium isopropoxide solvate **1** were hampered by a poor reproducibility [11]. These observations prompted us to reconsider the basic characteristics of this starting material and especially its stability. While information on its photosensitivity has been provided [4], the compound has been considered as reasonably stable thermally.

Thermal stability of $Ce_2(OPr^i)_8(Pr^iOH)_2$

The transformation of **1** in the solid state is actually observed after a period of heating as short as 15 min at 50–70°C *in vacuo*. The yellow crystals of **1** became pasty while their FT-IR spectrum accounts for the disappearance of the absorption band of the νOH vibration at 3170 cm^{-1} and the appearance of absorption bands characteristic of disopropylether (1120, 945, 920, 840, 805 cm^{-1}). Recrystallization in DME/Pr^{i}OH gave orange crystals of a compound, (**2**), identified by X-ray diffraction as $Ce_4O(OPr^i)_{14}$ in ~ 43% yield.

An orange colour developed also by heating **1** in refluxing toluene and in the dark. The oxoalkoxide **2** was, however, obtained in lower yield (~20%) and the transformation is slower than in the solid state. Longer reaction times did not improve the yield of **2**, either in solution or in the solid state, but led to the formation of other species. A yellow compound **3**, characterized in the FT-IR by νCe—O absorption bands at 561, 525, 512 and 495 cm^{-1} is for instance obtained by heating **1** for 1–4 h at 70°C.

Molecular structure of $Ce_4(\mu_4O)(OPr^i)_{14}$

X-ray diffraction studies established that compound **2** is actually a tetranuclear oxo species, of the formula $[Ce_4(\mu_4\text{-}O)(\mu_3\text{-}OPr^i)_2(\mu\text{-}OPr^i)_4(OPr^i)_8]$. Two independent molecules **2a** and **2b** are found in the unit cell. The molecular structure of one of these molecules is depicted in Fig. 1. Pertinent bond lengths and angles are collected in Table 2. The M_4O_{15} core is based on a distorted tetrahedral framework assembled around a μ_4-oxo ligand. The metals are further connected *via* doubly bridging alkoxide ligands. The coordination sphere of each cerium atom is completed with two terminal OR, thus providing coordination numbers of six for two metals and coordination number seven for two others. The surrounding of the oxo ligand O(1) is severely distorted with angles varying from 97.3(4) to 154.0(5)°. Similar distortions of the μ_4-oxo ligand have been observed for $Ce_4(\mu_4\text{-}O)(OPr^i)_{13}(Pr^iOH)$, which has a butterfly core [4], $Al_4(\mu_4\text{-}O)(\mu\text{-}OPr^i)_5[H(OPr^i)_2]Cl_4$ [12] and for $Pb_2Ti_2(\mu_4\text{-}O)(OPr^i)_{10}$ [13] for instance. Despite the distorted surrounding around the oxo ligand, the tetrahedron is quite regular for isomer **2a** [Ce···Ce distances spread over the range 3.485(2)–3.888(2) Å], while for isomer **2b** one non-bonding Ce···Ce distance, Ce(53)—Ce(54) expands to 4.377(1) Å, thus illustrating the main difference between the two independent molecules. The Ce···Ce distances are slightly longer than for the

initial dimer **1** (3.473 Å). The Ce—O bond lengths range from 2.02(1) to 2.57(1) Å, the order of variation being Ce—OR < Ce—μ-OR < Ce—μ_3-OR. The distortion of the oxo ligand is also illustrated by the difference in the Ce μ_4-O distances, mean value 2.23(1) Å for the six-coordinated metals Ce(3) and Ce(4) and 2.50(1) Å for the hepta-coordinated metals. The various Ce—O bond distances are in agreement with the values from the literature [2,14], and as expected they are slightly longer for the seven-coordinated metals. The latter have a monocapped trigonal prism stereochemistry. No short contact between the various molecules is detected. The Ce—O—C angles of the terminal isopropoxide ligands are large: (171.5° average for the six-coordinate metals, 162.6° average for the hepta-coordinated ones), as usually observed for lanthanides and early transition metals.

The formation of the tetranuclear species **2** results from the assembly of the two desolvated $Ce_2(OPr^i)_8$ dimeric units as shown in Fig. 2. This assembly proceeds with the elimination of diisopropylether as evidenced by FT-IR. The initial dimeric species, **1**, can be seen as two octahedra having a common edge. The coordinative insaturation due to the loss of one isopropanol molecule can be filled by the sharing of a face between the two octahedra. Elimination of the second solvated isopropanol molecule and junction of two dinuclear units along edges with subsequent elimination of isopropylether results in the formation of the M_4O_{15} framework. Formally, the condensation of Ce_2 units into Ce_4 ones corresponds to the transformation of two terminal OR groups into doubly bridging ones and of two doubly bridging ones into μ_3-ones, thus allowing two metal centers to be heptacoordinated.

The ^{1}H NMR spectra of **2** in $CDCl_3$ or deuterated toluene show only one type of isopropoxide ligands at 25°C, thus suggesting fluxionality. At −70°C, three types of magnetically non-equivalent OPr^i groups are observed at 5.80, 5.15 and 5.32 ppm (integration ratio 6:4:4). According to the solid-state structure, four resonances in an integration ration 2:4:4:4 are expected for the CH groups. The NMR spectra of **2** are independent of the dilution and thus account for the presence of a single molecular species. The NMR data suggest that the tetranuclear solid state structure of **2** is retained in solution, the μ-OPr^i and μ_3-OPr^i groups being still in dynamic exchange at −70°C, while the exchange between the terminal isopropoxide ligands borne by the six- and seven-coordinated

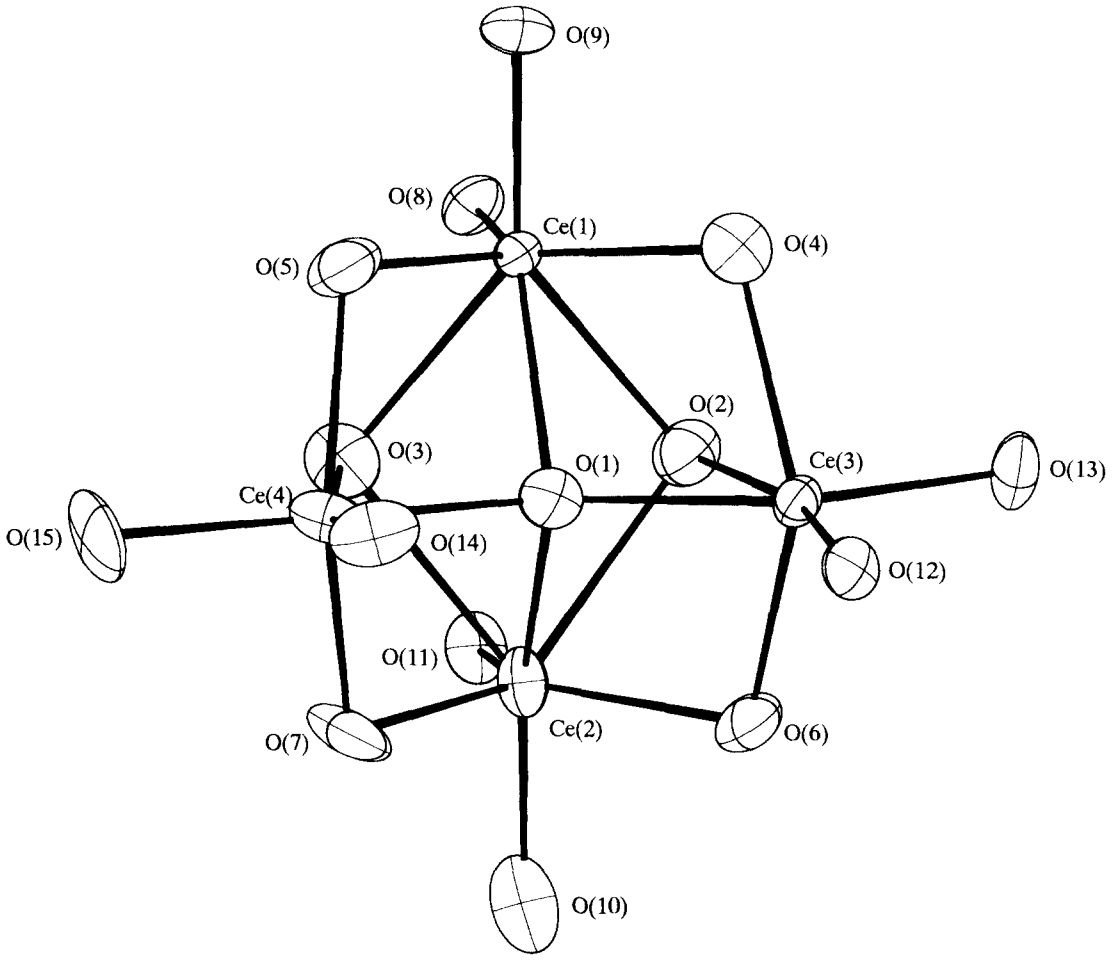

Fig. 1. CAMERON view of the Ce_4O_{15} core of the $Ce_4O(OPr^i)_{14}$ cluster.

cerium atoms is frozen out. At higher temperatures, coalescence between the two multiplets attributed to the terminal OR groups is observed, giving for instance at -30°C, a spectrum composed of two signals at 5.8 and 5.2 ppm corresponding to the bridging and terminal methine groups.

Oxoisopropoxides and more generally oxoalkoxides are a common feature in lanthanide alkoxide chemistry as a means to reach high coordination numbers [5] for the metals and thus stable species. The chemistry of structurally characterized Ce^{IV} oxoalkoxides has been limited to $Ce_3(\mu_3\text{-}O)(\mu\text{-}OBu^t)_3(OBu^t)_6$ obtained by decomposition of $Ce(OBu^t)_4(THF)_2$ or of $NaCe_2(OBu^t)_9$ [3]. Although a quite rich oxo chemistry has been observed for Ce^{IV} isopropoxides [11], no evidence could be obtained so far for a trinuclear $Ce_3O(OPr^i)_{10}$ moiety.

Oxoalkoxides derived from tetravalent metal alkoxides are essentially represented by the solvates $Sn_3(\mu_3\text{-}O)(\mu\text{-}OBu^t)_3(OBu^t)_7(Bu^tOH)_2$, resulting from the hydrolysis of $Sn(OBu^t)_4$ [15], and $[Hf_3(\mu_3\text{-}O)(\mu\text{-}OEt)_4(OEt)_6(EtOH)]_2$ [16], the latter corresponding to the compound formulated in the literature as $Hf(OEt)_4$. Unsolvated trinuclear oxoalkoxides based on large M^{IV} transition metals correspond to $[M_3(\mu_3\text{-}O)_3\text{-}OR)(\mu\text{-}OR)_3(OR)_6]$ M = Ce [3], Mo, W [17], U [18], Th). Hexa-coordination of the metals appears as a common feature. The $Zr_3O(OPr^i)_{10}$ moiety, which has been observed in mass spectrometry [19], has been stabilized in the $[PbZr_3O(OPr^i)_{10}(OAc)_2]$ mixed-metal species [20]. It is interesting to observe that these trinuclear units are generally derived from monomeric starting materials. The formation of $Ce_4O(OPr^i)_{14}$ rather than $Ce_3O(OPr^i)_{10}$ suggests that the dinuclear species **1** displays quite good stability with respect to dissociation into mononuclear fragments.

These studies establish that oxoalkoxides can be generated quite easily by desolvation reactions. Microhydrolysis experiments of **1** in toluene with an hydrolysis ratio $h = 0.5$ ($h =$ moles H_2O/ moles **1**) did not give access to **2** but afforded compound **3**. These observations are consistent with the fact that aggregates of higher nuclearity are generally obtained by hydrolysis [21] and in the absence of ancillary ligands such as β-diketones [1] or cyclopentadienyls [22], which can act as polymerization lockers. The overall results from thermal decomposition and microhydrolysis experiments indicate that cerium^{IV}

(Received 28 June 1996; accepted 30 July 1996)

Abstract—The complexation equilibria of (2-thiazolin-2-yl)hydrazine hydrochloride (TzHyHCl) with cobalt(II) have been studied in aqueous solution at 298 K and 0.1 M ionic strength in $NaClO_4$. The formation constants were determined and discussed in terms of the characteristics of the ligand. The compound $[Co(TzHy)_3]Cl_3 \cdot 2H_2O$ has been isolated and characterized by IR, UV–vis–NIR diffuse reflectance and thermal measurements, and its crystal and molecular structure determined by X-ray analysis. In this compound the complex cation shows a distorted octahedral geometry with the cobalt atom coordinated to three terminal hydrazine nitrogen atoms [average Co—N = 1.973 Å] and three thiazoline nitrogen atoms [average Co—N = 1.900 Å]. Angles N—Co—N for adjacent nitrogen donors are comprised between 94.9 and 82.8°. According to the position of the ligands, the complex can be described as a *facial* isomer. A hydrogen bond scheme is present in the structure interlinking TzHy ligands, water molecules and chloride ions. Copyright © 1997 Elsevier Science Ltd

Keywords: cobalt complexes; crystal structure; hydrazine; potentiometric study; thiazoline.

As part of our program on the coordination chemistry of (2-thiazolin-2-yl)hydrazine hydrochloride (TzHy HCl), we have reported its coordination behaviour and equilibria study with nickel(II) [1], zinc(II) and cadmium(II) [2] in aqueous solution. Likewise, the solid phases obtained by the reaction between the ligand and the aforementioned divalent cations have been characterized by elemental analysis and X-ray diffraction.

In the present paper we have set out to elucidate the behaviour of TzHyHCl with cobalt(II) ion in aqueous solution and we report the synthesis and characterization of the solid phase $[Co(TzHy)_3]Cl_3 \cdot 2H_2O$.

EXPERIMENTAL

Reagents

The ligand (2-thiazolin-2-yl)hydrazine hydrochloride (TzHyHCl) was prepared according to a reported procedure [3], taking into account published modifications [4] and recrystallized from methanol.

Cobalt(II) stock solutions were prepared in double distilled freshly boiled water from its chloride and their concentrations were determined as usually [5]. Sodium hydroxide stock solutions were prepared by dilution of a concentrated solution of sodium hydroxide, according to Kolthoff *et al* [6]. These solutions were kept under CO_2-free atmosphere and standardized by titration against potassium hydrogen phthalate. All working solutions were prepared at

0.1 M ionic strength adjusted with sodium perchlorate. All the remaining chemicals used were commercial, analytical grade reagents.

Preparation of $[Co(TzHy)_3]Cl_3 \cdot 2H_2O$

The Co^{III} complex was isolated as follows: a freshly prepared aqueous solution of cobalt(II) chloride was added to an aqueous solution of TzHyHCl and the pH of the whole solution was then adjusted, by dropwise addition of NaOH, at appropriate pH according with the titration curves. By means of liquid–vapor diffusion of ethanol over this solution, red crystals were isolated, filtered off by suction, washed with ethanol, air-dried and stored in a desiccator containing silica gel. Found: C, 19.9; H, 4.4; N, 22.7; S, 18.1; Co, 9.9. Calc. for $C_9H_{25}Cl_3N_9S_3Co$: C, 19.6; H, 4.6; N, 22.8; S, 17.4; Co, 10.7%.

Instrumental procedures

Chemical analysis of carbon, hydrogen, nitrogen and sulfur were performed by means of microanalytical methods using a Perkin–Elmer 240C microanalyser. The metal content was estimated by thermogravimetry as Co_3O_4. A UV–vis–NIR reflectance spectrum of the complex in the 200–1200 nm range was obtained from a pellet of the sample, using a Shimadzu UV-3101PC spectrophotometer and $BaSO_4$ as a reference. IR spectra were recorded on a Perkin–Elmer FT-IR 1720 spectrophotometer, from KBr pellets in the 4000–400 cm^{-1} range and on a Perkin–Elmer FT-IR 1700X spectrophotometer, from polyethylene pellets in the 400–150 cm^{-1} range. A thermal study was carried out on a Mettler TA-4000 system, provided with a Mettler TG-50 thermobalance and a DSC-20 differential scanning calorimeter. The TG curve was obtained on heating a sample of the solid in a dynamic pure air atmosphere (200 cm^3 min^{-1}) in the 35–900°C temperature range, whereas the DSC plot was recorded under a static air atmosphere in the temperature range between 35 and 600°C. In both cases a heating rate of 10°C min^{-1} and samples varying in weight from 3 to 13 mg were utilized. The procedures and apparatus used for potentiometric measurements were described in detail previously [1]. Briefly, measurements were made at 25 ± 0.1°C and 0.1 M ($NaClO_4$) ionic strength. The electrode system was calibrated in terms of hydrogen ion concentration by performing strong acid *vs* strong base titrations [7]. The concentration of ligand in the experimental solutions was always 2×10^{-3} mol dm^{-3} and successive 1:1, 2:1 and 3:1 ligand-to-metal ratios were investigated. The numerical analysis of all the experimental e.m.f. data were carried out with the computer program SUPERQUAD [8]. All calculations were performed on an IBM RS/6000 computer (Computer Centre, University of Extramadura). X-ray powder diffraction was obtained through a Philips PW-1700 diffractometer using Cu-K_α radiation.

Crystal structure determination

Crystal data, data collection and refinement details for $[Co(TzHy)_3]Cl_3 \cdot 2H_2O$ are given in Table 1. Examination of three standard reflections, monitored after 97 scans, showed no sign of crystal deterioration. The data were corrected for Lorentz and polarization effects, and were also corrected for absorption effects using an empirical method based on azimuthal scan data. The structure was solved by direct methods and subsequent Fourier differences using the SHELXTL-IRIS program [9] and refined by full-matrix least-squares. The H atoms were located from a differential Fourier synthesis and included in the calculation with estimated isotropic displacement parameters without refinement (riding model). All calculations were performed with a Silicon Graphics Iris Indigo XS24.

Thermal parameters, atom coordinates and a listing of observed and calculated structure factors have been deposited with the Editor, from whom copies are available on request.

RESULTS AND DISCUSSION

Potentiometric studies

The final stoichiometries and formation constants of the complexes formed were determined by means of the computer program SUPERQUAD [8] to identify that which, according to χ^2, best fitted the experimental data. The titration curves were treated either as a single set or as separate entities without significant variation in the formation constants. Only experimental points in which variations in the degree of formation of the complexes occurred were processed in the last refinement. The chemical models yielding the best fits between the measured and calculated titration curves, together with the refined formation constants and statistical parameters (SIGMA and χ^2), are compiled in Table 2. The formation constants for the hydrolysis products produced by the reaction of the cobalt(II) with water [10] were included in the chemical modelling. In addition, it has been established and also incorporated models of dissociation processes of the ligand in which the possible existence of neutral [(TzHy)] and protonated [$(TzHyH)^+$] species were considered. It was verified that all the proposed species [denoted as $M_p(TzHy)_qH_r$] existed in significant concentrations over a reasonable range data.

It can be seen that while in the titration curve with a relation ligand : metal 1 : 1 the model chosen, formed by the apparently simple model of 110, resulted in a satisfactory numerical and graphical fitting, in the titrations with a relation ligand : metal 2 : 1 and 3 : 1 the existing experimental evidence was sufficient to determine with accuracy that 133 complex is present. In addition, in the titration curve 2 : 1 the combination of this species and 121 gave the best findings.

Study of the $[Co(TzHy)_3]Cl_3 \cdot 2H_2O$ *complex*

The analytical results agree with the molecular formula $C_9H_{25}Cl_3N_9S_3Co$ for the red Co^{III} complex.

The structure of $[Co(TzHy)_3]Cl_3 \cdot 2H_2O$ is built up by $[Co(TzHy)_3]^{3+}$ cations, chloride anions and water molecules of crystallization. Figure 1 shows the molecular structure of the cation complex. Selected bond lengths, angles and hydrogen-bond parameters are listed in Table 3.

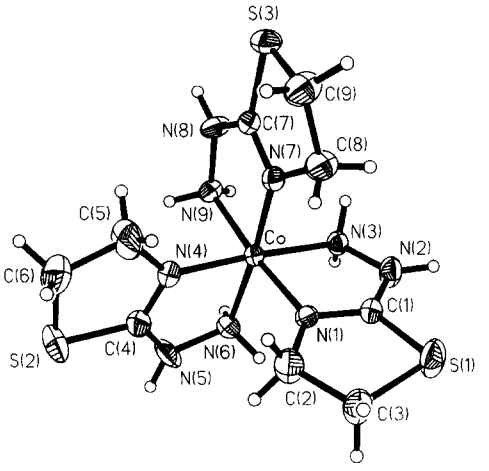

Fig. 1. Molecular structure of the $[Co(TzHy)_3]^{3+}$ cation, showing the atom-numbering scheme. The thermal ellipsoids are drawn at a 50% level.

Table 2. Formation constants (log β) at 25°C and $I = 0.1$ mol dm^{-3}

System	Species[a]	logβ	χ^2	Σ
$TzHyH^+/Co^{2+}$ (1/1)	$[Co(TzHy)]$	2.42(1)	10.29	2.4

$TzHy^+/Co^{2+}$ (3/1)	$[Co(TzHy)_3H_3]$	28.93(1)	12.00	2.8

[a]Changes are omitted for the sake of clarity.

The coordination geometry around the cobalt atom is a distorted octahedron with bidentate TzHy ligands coordinated through thiazolinic nitrogens and terminal hydrazine nitrogens. According to the position of the ligands, the complex can be described as a *facial* isomer. Thus, the whole molecule exhibits pseudo-C_3 symmetry with the C_3 axis passing through the centres of the faces defined by N(1), N(4), N(7) and N(3), N(6), N(9).

In similar form to that observed in other complexes containing the TzHy ligand [1,2], and for analogous reasons, the Co—N(thiazoline) distances [average 1.900 Å] are appreciably shorter than the Co—N (hydrazine) distances [average 1.973 Å].

The chelate rings are essentially planar, with maximum deviation for N(3) (0.086 Å).

Bond lengths and angles in the ligands are similar and comparable with those observed in TzHyHCl [1] and the complexes with Ni^{II}, Zn^{II} and Cd^{II} [1, 2], and indicate that the organic moiety preserves the thiazoline–hydrazine form. However, it should be pointed out that the three thiazoline rings show different conformations. Thus, the values of the puckering parameters, calculated according to Cremer and Pople [11], are:

Ring A
[S(1)—C(1)—N(1)—C(2)—C(3)] $q_2 = 0.152$ Å $\phi_2 = 150.0$

Ring B
[S(2)—C(4)—N(4)—C(5)—C(6)] $q_2 = 0.011$ Å $\phi_2 = 90.0$

Ring C
[S(3)—C(7)—N(7)—C(8)—C(9)] $q_2 = 0.268$ Å $\phi_2 = 134.6$

These values indicate that ring A shows a conformation near to envelope with the apex at C(3).

This atom is 0.233 Å out of the plant formed by S(1)—C(1)—N(1)—C(2) [maximum mean-plane deviation for N(1) = 0.008 Å]. Ring B is planar, with maximum mean-plane deviation for N(4) (0.007 Å). Ring C is puckered most and shows an intermediate form between envelope and half-chair conformations, with C(8) and C(9) deviating 0.151 and 0.298 Å above and below, respectively, the S(3)—C(7)—N(7) plane.

The crystal structure is stabilized by a very extensive hydrogen bond network in which hydrazinic nitrogen atoms act as donors, chloride anions act as acceptors and oxygen atoms of water of crystallization act as donors and acceptors. A view showing this network is given in Fig. 2.

The diffuse reflectance spectrum exhibits one band at 11,800 cm^{-1} and one triplet at 14,400, 14,900 and 16,000 cm^{-1}, all of low intensity, and two more intense bands at 19,650 and 26,750 cm^{-1}. These bands may be assigned as $^1A_{1g} \rightarrow {}^3T_{1g}$; $^1A_{1g} \rightarrow {}^3T_{2g}$; $^1A_{1g} \rightarrow {}^1T_{1g}$ and $^1A_{1g} \rightarrow {}^1T_{2g}$ transitions, respectively, in an idealized O_h symmetry. The position of the observed spectral bands permits to calculate the ligand field parameters, 10 Dq, B and C, using the following known relationships [12]:

$$E(^3T_{1g} \leftarrow {}^1A_{1g}) = 10\,Dq - 3C \quad (1)$$

$$E(^3T_{2g} \leftarrow {}^1A_{1g}) = 10\,Dq + 8B - 3C \quad (2)$$

$$E(^1T_{1g} \leftarrow {}^1A_{1g}) = 10\,Dq - C \quad (3)$$

$$E(^1T_{2g} \leftarrow {}^1A_{1g}) = 10\,Dq + 16B - C \quad (4)$$

in which, for the application of (2), the mean of the observed triplet has been considered. The calculated values of the ligand field parameters 10 Dq (~23,800 cm^{-1}), B (~430 cm^{-1}) and C (~4000 cm^{-1}) are consistent with the presence of a chromophore group $[Co^{III}N_6]$ [13].

The IR spectrum in the 4000–400 cm^{-1} region shows the presence of characteristic bands due to the thiazoline ring at 1630 (W_1), 970 (W_2), 880 (W_3), 800 (W_4), 680 (W_5), 615 (W_6), 560 (W_8), 480 (W_7) and 425 cm^{-1} (Γ_1) [14]. Moreover, other relevant bands are registered at 3505 and 3415 (ν_{H_2O}), 3160–3090 (ν_{NH_2},

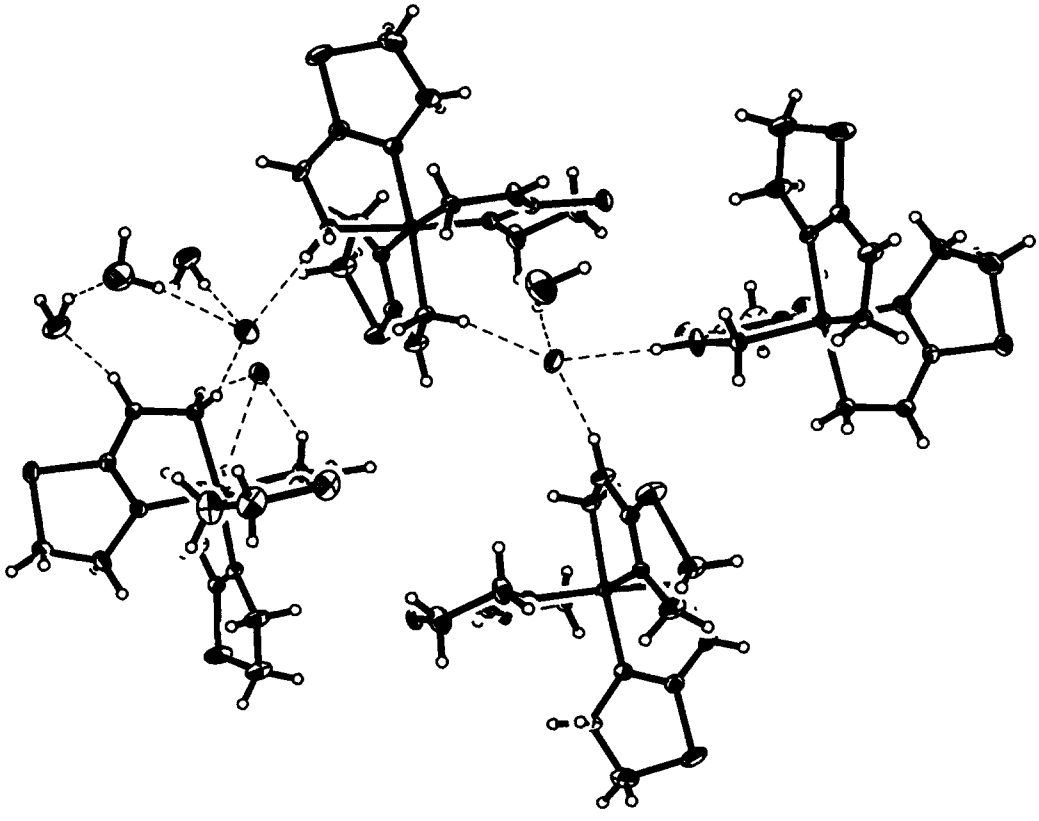

Fig. 2. View of the hydrogen-bond network of $[Co(TzHy)_3]Cl_3 \cdot 2H_2O$.

ν_{NH}), and 1040 cm^{-1} ($\nu_{N\ N}$). It is worth noting the absence of the bands observed at 2820 and 2790 cm^{-1} in the spectrum of TzHyHCl and assigned to ν_{NH^+} [15], which is according to the fact that the ligand acts in a deprotonated form.

The low-frequency region shows four bands assignable to Co–ligand stretching vibrations, concordantly with the pseudo-C_3 symmetry of the complex cation. In other complexes containing this ligand it is observed that $\nu_{M\text{-}N(hydrazine)}$ vibrations occur at upper frequencies than $\nu_{M\ N(thiazoline)}$ vibrations [15]. For that, the bands observed at 382 and 368 cm^{-1} are tentatively attributed to $\nu_{M\ N(hydrazine)}$, while the bands at 310 and 268 cm^{-1} could be assigned to $\nu_{M\ N(thiazoline)}$.

The study of thermal data obtained for $[Co(TzHy)_3]Cl_3 \cdot 2H_2O$ reveals that the decomposition takes place in three steps. In the first the complex becomes totally dehydrated in the 50–125°C range; at the last temperature the weight loss found (8.3%) could be assigned to moisture ($\sim$1.8%) and to the loss of two H_2O molecules (6.5%). This step is associated with an endothermic effect in the DSC plot (ΔH = 448 J g^{-1}). The anhydrous complex is stable up to 200°C. From this temperature onwards the decomposition starts with an intense effect of weight loss, in two overlapping steps ending at 430°C and corresponding to the pyrolytic degradation of the sample. These steps are reflected in the DSC plot by exothermic effects. At temperatures above this latter effect, combustion of the remaining sample takes place, finally giving Co_3O_4 that was characterized by IR spectroscopy and X-ray powder diffraction.

(Received 28 May 1996; accepted 30 July 1996)

Abstract—The preparation and characterization by means of IR and electronic spectroscopies, magnetic measurements and molecular structure by X-ray diffraction of a single-crystal are reported for a monomeric oxovanadium(V) complex: $[V^{V}O(5Cl\text{-}OHA\text{-}SHZ)(OCH_2CH_3)]$, where (5Cl-OHA-SHZ) is the dianionic tridentate ONO donor ligand 5-chloro-*o*-hydroxyacetophenone-salicylhydrazide. The vanadium atom is essentially five coordinate. Three ONO donor atoms of the (5Cl-OHA-SHZ) ligand and an oxygen atom from an alkoxide group form a distorted square-pyramidal geometry around the metal center. The basal coordination plane is formed by three donor atoms ONO (a phenolic oxygen, an imine nitrogen and an enolic oxygen) from the ligand and an oxygen atom from the alkoxide group. This structure is compared with the corresponding copper (II) complex with the same ligand. Copyright © 1997 Elsevier Science Ltd

Keywords: oxovanadium; alkoxo complex; *o*-hydroxyacetophenone; salicylhydrazide; monomeric complex; five-coordinate complex.

Within the general field of molecular recognition the selectivity of metal ions to binding by appropriate donor atoms of a receptor or ligand is important [1]. The metal cations are often viewed as hard spheres and the recognition is simply based on charge and size considerations [2]. This model works well for most metal cations, including transition metal cations, such as Cu^{II} and Ni^{II}, but for metal oxo cations, such as VO^{2+}, VO_2^+, UO_2^{2+}, the latter considerations are not satisfactory. In this case the ligands should include aspects which recognize the metal oxo moiety on the basis of geometrical properties (Stereognostic coordination chemistry [2]). Taking into account these considerations, a ligand that incorporates groups that can bind strongly to the equatorial positions of a square-based pyramid, for example, can be a candidate to form stable complexes with oxovanadium cations.

Also vanadium is receiving considerable attention as a biologically important metal due to the existence of vanadoenzymes [3,4]. Thus, work with model complexes to mimic the phenolate oxygen of tyrosine [5], so that alkoxide coordination may result from deprotonated serine or threonine residues [3] have been studied. In this paper we describe the synthesis, spectroscopic properties and the single-crystal X-ray structure of $[V^{V}O(5Cl\text{-}OHA\text{-}SHZ)(OCH_2CH_3)]$ com-

plex, where 5Cl-OHA-SHZ(5-chloro-*o*-hydroxyacetophenone-salicylhydrazide) is a dianionic tridentate ligand, which presents the ONO donor atoms (with a phenolate oxygen) that can bind strongly to the equatorial positions around the metal. This ligand forms a complex with Cu^{II} where the stereochemistry around the metal ion is distorted square planar incorporating an oxygen atom from a DMF solvent molecule in the fourth position [6]. We have also attempted the preparation of a complex of VO^{2+} with this ligand, but we have only been able to prepare a stable, mononuclear pentavalent vanadium complex. The pentavalent oxidation state rather than the tetravalent state is physiologically active [7], although the oxidation state within organisms seems to be highly variable [8].

EXPERIMENTAL

Synthesis of the compound

All chemicals were reagent grade and used as supplied. Salicylhydrazide and 5-chloro-2-hydroxyacetophenone were prepared following methods previously described [9,10]. 5Cl-OHA-SHZ was prepared by the procedure described in reference [6].

[$V^{V}O$(5Cl-OHA-SHZ)(OCH_2CH_3)]. To a magnetically stirred hot ethanolic solution (300 cm^3) of Schiff base 5Cl-OHA-SHZ (0.61 g, 2 mmol) was added an aqueous solution of $VOSO_4 \cdot 5H_2O$ (0.52 g, 2 mmol). The resulting green solution after 15 min turned reddish-brown and was then refluxed for 3 h. Evaporation of the solvent at room temperature yielded after several days a crystalline reddish-brown product, which was recrystallized twice from ethanol. The separated reddish-brown crystals, filtered off and air-dried, are slightly soluble in water and soluble in most common polar and nonpolar organic solvents. These crystals are stable up to 215°C, where decomposition begins to take place without melting. Found: C, 49.2; H, 3.9; N, 6.8; V, 12.2. $VOClC_{15}H_{12}N_2O_3 \cdot C_2H_5O$ requires: C, 48.9; H, 3.8; N, 6.7; V, 12.2%.

If it is recrystallized from methylene chloride the reddish-brown compound forms a green solution from which a green powder is precipitated. The redissolution of this latter compound in ethanol gave the initially prepared reddish-brown crystals of [$V^{V}O$(5Cl-OHA-SHZ)(OCH_2CH_3)] after several days.

Chemical analyses of C, H and N were performed on a Carlo Erba microanalyser. Vanadium was determined by thermogravimetric analysis, after decomposition and ignition of the sample to V_2O_5.

Physical measurements

Thermal analyses were carried out on a Perkin–Elmer TGS-1 thermobalance. Electronic spectra of the solid compound were run on a Beckman DU-2 spectrophotometer after dilution of the sample in $BaSO_4$, in the 400–1000 nm spectral range. IR spectra were recorded on a Nicolet 5PCFT spectrophotometer, using KBr as support, in the 4000–250 cm^{-1} spectral range. The magnetic susceptibility was measured on a Faraday type microbalance and the EPR spectra were recorded on a X-band Bruker spectrometer.

X-ray crystallography

Table 1 summarises crystal data, data collection and structure determination. Positions of the remaining non hydrogen atoms and the C_2H_5O group were located from the subsequent Fourier synthesis. The C(17) atom of the CH_3 group on C_2H_5O shows a statistical disorder which could be identified through a Fourier difference synthesis. The disorder problem was handled by refining the two carbon sites [C(171) and C(172)] with isotropic thermal parameters. In the final stages of the structure refinement, a Fourier difference synthesis revealed the locations of the hydrogen atoms except for the C_2H_5O group, which were subsequently refined with isotropic thermal parameters.

Additional material available from the Cambridge Crystallographic Data Centre comprises atom coordinates, thermal parameters, bond lengths and angles, torsion angles and least-squares mean planes.

RESULTS AND DISCUSSION

Molecular structure of [$V^{V}O$(5-Cl-OHA-SHZ)(OCH_2CH_3)]

Selected bond lengths and angles for this compound are shown in Table 2. An ORTEP [13] drawing of the structure including the atomic numbering scheme is given in Fig. 1. The asymmetric unit consists of a discrete molecule of the complex. The coordination around the vanadium can be described as distorted square pyramidal. The basal plane is made up by the phenolic oxygen O(1), [V(1)—O(1) = 1.856(4) Å], the enolic oxygen O(3), [V(1)—O(3) = 1.912(3) Å], the imine nitrogen N(2) [V(1)—N(2) = 2.136(3) Å] from the 5Cl-OHA-SHZ ligand and O(2) [V(1)—O(2) = 1.757(3) Å] from the deprotonated alkoxide oxygen. These values are in the range seen for other vanadium Schiff base complexes [3]. The 5Cl-OHA-SHZ acts as a tridente dianion ligand, presenting in the complex contiguous five and six-membered chelate rings as in the copper(II) complex [6]. If we compare these bond lengths with those found for copper(II) complex [6], [Cu(5Cl-OHA-SHZ)DMF], we observe that the largest difference corresponds to the imine nitrogen–copper distance [1.933(3) Å]. This is probably due to the presence of the terminal oxo ligand O(4) that produces a *cis* lengthening of the vanadium–nitrogen bond. There is

no significant distortion toward trigonal bipyramidal geometry, as demonstrated by the *trans*-O(3)—V(1)—O(1) and N(2)—V(1)—O(2) angles, 143.4(1) and 161.1(1)°, respectively. The same angles for the copper(II) complex [6] are 175.7(2) and 173.9(2)°, respectively, the coordination around the copper being essentially planar. The apical position is occupied by the terminal oxo group O(4), being the V(1)—O(4) distance 1.577(3)Å; this short distance (indicating a V=O strong double-bond character) is found in five-coordinate [2,3] and octahedral complexes [14] of vanadium(IV) and (V). The vanadium atom is displaced toward the apical oxo ligand O(4) by 0.402(1) Å from the best least-squares plane defined by O(1), O(3), N(2) and O(2). This deviation is between the values found for complexes [2, 3, 14] of vanadium(IV) and (V). The V(1)—N(2)—N(1)—C(9)—O(3) and V(1)—N(2)—C(7)—C(6)—C(1)—O(1) chelate rings do not deviate significantly from planarity, the dihedral angle formed by both planes being 162.5(1)°.

The shortest intermolecular contact was found for

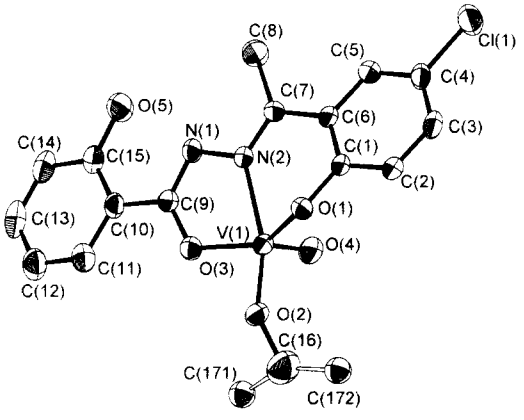

Fig. 1. ORTEP drawing and atom-numbering scheme for [$V^{V}O$(5Cl-OHA-SHZ)(OCH_2CH_3)] (50% probability ellipsoids, H atoms excluded)

V(1)—O(1′) 2.660(3) Å $(-x+1/2, -y+1/2-z)$. Through this phenolic oxygen, dimeric units as is found in vanadium(V) and (IV) complexes [3,14] could be formed.

The complex has a VO^{3+} core and the initial oxidation of VO^{2+} is due to aerobic conditions during the preparation of the complex. The change in color in a solution of methylene chloride from reddish-brown to green indicates a reduction to a vanadium(IV) complex. Unfortunately, we have not had success in preparing the dimer complex as well as isolating crystals of the green solution. The interconversion in solution of monomer–dimers, such as V^{IV}/V^{V} oxidative processes by dioxygen, are described in references [3,15], but not V^{V}/V^{IV} reductive processes in a nonpolar solvent such as CH_2Cl_2 as described in this paper.

The HO(5) atom is bonded to the N(1) atom in an intramolecular hydrogen bond 2.617(6) Å, the angle being 153.5(6) . One weak intramolecular hydrogen interaction is found between the C(11) atom and O(3), 2.785(6) Å, the angle being 101.2(3) .

Magnetic, EPR, electronic and IR spectroscopic measurements

The complex is diamagnetic, although a small amount of vanadium(IV) contaminant was detected only between 4.2 and 10 K with both EPR (a weak spectrum of eight-line pattern of a monomeric species ^{51}V, $I = 7/2$, 99.96% abundant) and magnetic susceptibility studies. Above 10 K the compound exhibits diamagnetic behavior.

The diffuse reflectance spectrum of the reddish-brown compound shows ligand–metal charge transfer (LMCT) bands at 405 and between 500 and 700 (weak) nm. These weak LMTC bands in this latter spectral region may be due to the existence of paramagnetic excited states of low energy [16].

The IR spectrum of the free ligand shows two strong bands at 3264 and 1630 cm^{-1}, which are assigned to ν(=N—H) and ν(>C=O) absorptions, respectively. In the complex these bands are not observed as a consequence of the coordination of the (=N—H)amide group through deprotonation and the enolization of the (>C=O) group. The bands appearing between 2500 and 3000 cm^{-1}, which are observed in both the free ligand and the complex spectra, although with lower intensity in the latter, which are associated with the presence of intramolecular hydrogen bonding OH ... N, already described. One band at 1602 cm^{-1} in the complex spectrum (not observed in the free ligand) is assigned to stretching frequency of the (>C=N—) [7].

Finally, the strong bands at 985 and 952 cm^{-1} which appear only in the complex spectrum are attributed

to V=O stretching frequencies. The splitting of the V=O band may be due to unit-cell group splitting or a crystal-packing effect [17].

A structural change between the complexes of praseodymium and neodymium nitrates with (*Z*)-2,3-diphenyl-1,4,7,10,13-pentaoxacyclopentadec-2-ene(stilbeno-15-crown-5): synthesis and structures of $[Pr(NO_3)_3$ (stilbeno-15-crown-5)] and $[Nd(NO_3)_3(EO_5)]$ (EO_5 = tetraethyleneglycol)

(Received 28 May 1996; accepted 30 July 1996)

Abstract—A structural change in $Ln(NO_3)_3 \cdot nH_2O$ complexes with stilbeno-15-crown-5 occurs between Ln = Pr and Ln = Nd. The unstable $Nd(NO_3)_3 \cdot L$ (L = stilbeno-15-crown-5) can react with formic acid to form stable $Nd(NO_3)_3 \cdot EO_5$. Under the same conditions the stable $Pr(NO_3)_3 \cdot L$ cannot be transformed into $Pr(NO_3)_3 \cdot EO_5$. X-ray crystallographic examinations of these two complexes have been carried out. There are two independent $Pr(NO_3)_3 \cdot L$ monomers in one asymmetric unit; in each the coordination number is 11. The tetraethyleneglycol ligand wraps around the neodymium(III) ion in $Nd(NO_3)_3 \cdot EO_5$ and all the three nitrate groups are bidentate. The coordination number is also 11. Copyright © 1997 Elsevier Science Ltd

Keywords: praseodymium nitrate; neodymium nitrate; stilbeno-15-crown-5; tetraethyleneglycol; synthesis; structural change.

The coordination power of the crown ethers depends on the number of donor atoms, the cavity diameter and the substituents. The crystal structures of $Ln(NO_3)_3 \cdot 12C4$ have revealed that 12-crown-4 can be coordinated directly to most of the lanthanide ions effectively, even though hydrated lanthanide nitrates are used as starting material [1,2]. 15-Crown-5, however, can only be coordinated directly to lighter lanthanide ions (La–Eu) [1], for the heavier lanthanide ions (Gd–Lu), second-sphere hydrogen-bonded complexes are obtained owing to the decreasing ionic radii [3,4]. (2-Methyl-1,3-xylyl)-15-crown-5 cannot be coordinated directly to all the lanthanide ions [1,5] due to the existence of the substituent.

Recently, we have reported the synthesis and properties of the solid complexes of stilbeno-15-crown-5 with lanthanide nitrates in anhydrous medium [6]. We found that only lighter lanthanide nitrate complexes (La–Nd) could be obtained and the yields changed from 75% for the praseodymium complex to 16% for the neodymium complex. In order to find out the reason of this change, we prepared the single crystals of these two complexes and the structural investigation shows some interesting results.

EXPERIMENTAL

Reagents

Hydrated lanthanide nitrates were prepared by dissolving the corresponding oxides (Anala R) in 50% nitric acid. The ligand was prepared by the literature method [7]. All other chemicals were AnalaR grade. The complexes were prepared according to the method described in a previous paper [6].

Preparation

Single crystals of the praseodymium complex were obtained by dissolving the powdered solid complex in acetonitrile and leaving the solution in a desiccator over $CaCl_2$ at room temperature. After about 10 days, the crystals used for the X-ray experiment formed from the solution. Found: C, 38.7; H, 3.9; N, 7.3; Pr, 19.2%. Calc. for $C_{23}H_{27.5}PrN_{3.5}O_{14}$: C, 38.5; H, 3.8; N, 6.8; Pr, 19.6%.

Single crystals of the neodymium complex could not be obtained under the above preparation condition.

In order to obtain the single crystals of the neodymium complex, triethylorthoformate was added to the solution of $Nd(NO_3)_3 \cdot L$ in acetonitrile. The mixture was refluxed for 1 h and then filtered. The filtrate was cooled to room temperature and left in a desiccator over $CaCl_2$. After about 1 month, the crystals used for the X-ray experiment formed from the solution. Found: C, 18.7; H, 3.5; N, 7.9; Nd, 27.2%. Calc. for $C_8H_{18}NdN_3O_{14}$: C, 18.3; H, 3.4; N, 8.0; Nd, 27.5%.

We prepared the single crystals of the praseodymium complex using the same method as preparing the single crystals of the neodymium complex. The analytical data indicates that the composition of the crystals of the praseodymium complex is also $Pr(NO_3)_3 \cdot L$.

X-ray crystallography of $[Pr(NO_3)_3 \cdot L] \cdot 0.5CH_3CN$

Crystal data. $2[C_{22}H_{26}PrN_3O_{14}] \cdot CH_3CN$, $M = 1434.8$, monoclinic, space group $P2_1/a$, $a = 16.132(3)$, $b = 15.635(3)$, $c = 22.781(4)$ Å, $\beta = 94.82(1)^\circ$, $U = 5725(2)$ Å^3, $D_c = 1.66$ g cm^{-3}, $Z = 4$, $\lambda(\text{Mo-}K_\alpha) = 0.71073$ Å, $F(000) = 1968$.

Data collection. X-ray diffraction intensities were collected at 298 K from crystals of dimensions $0.28 \times 0.52 \times 0.52$ mm on an R3M/E four-circle X-ray diffractometer with graphite-monochromatized Mo-K_α radiation, using the $\theta/2\theta$ scan technique, scan rate 8° min^{-1}. Negligible change in the intensities of three standards monitored during the data collection indicated no crystal decomposition. Some 9566 independent reflections were collected in the range $2 \leqslant 2\theta \leqslant 48^\circ$ (h from 0 to 20, k from 0 to 19, l from -28 to 28). Of these, 7308 reflections with $I \geqslant 1.5\sigma(I)$ were used in the structure determination and refinement. The intensities were corrected for Lorentz–polarization effects and for empirical absorption.

Structure solution and refinement. The structure was solved by the Patterson method and subsequent difference-Fourier techniques, and refined by full-matrix least-squares methods with anisotropic thermal factors for all non-hydrogen atoms; the crown ether hydrogen atoms were placed in calculated positions. All calculations were performed by using the SHELXTL system of computer programs. The final values $R = 0.0516$ $(R = \Sigma \| F_o | - | F_c \| / \Sigma | F_o |)$, $R_w = 0.0479$ $(R_w = \Sigma \| F_o | - | F_c \| w^{1/2} / \Sigma | F_o | w^{1/2})$, with $w = [\sigma^2 | F_o | + 0.0001 | F_o |^2]^{-1} \times [1 - \exp\{-5 (\sin\theta/\lambda)\}]$ were obtained.

X-ray crystallography of $[Nd(NO_3)_3 \cdot EO_5]$

Crystal data. ($C_8H_{18}NdN_3O_{14}$, $M = 524.24$, monoclinic, space group $P2_1/n$, $a = 8.143(1)$, $b = 16.806(3)$, $c = 12.739(3)$ Å^3, $\beta = 101.01(1)^0$, U = 1711(1) Å^3, $D_c = 2.03$ g cm^{-3}, $Z = 4$, $\lambda(\text{Mo-}K_\alpha) = 0.71073$ Å, $\mu(\text{Mo-}K_\alpha) = 31.46$ cm^{-1}, $F(000) = 1028$.

Data collection. X-ray diffraction intensities were collected at 298 K from crystals of dimensions $0.20 \times 0.20 \times 0.32$ mm on an R3M/E four-circle X-ray diffractometer with graphite-monochromatized MoK_α radiation, by using the $\theta/2\theta$ scan technique, scan rate 8° min^{-1}. Negligible change in the intensities of three standards monitored during the data collection indicated no crystal decomposition. Some 2524 independent reflections were collected in the range $1 \leqslant 2\theta \leqslant 45^\circ$ (h from 0 to 9, k from 0 to 19, l from -14 to 14). Of these, 2018 reflections with $I \geqslant 1.5\sigma(I)$ were used in the structure determination and refinement. The intensities were corrected for Lorentz–polarization effects and for empirical absorption.

Structure solution and refinement. The structure solution and refinement were determined as described above for $[Pr(NO_3)_3 \cdot L] \cdot 0.5CH_3CN$. The final values $R = 0.0295$ and $R_w = 0.0248$ were obtained. The weighting scheme employed converged at $w = [\sigma^2 | F_o | + 0.0001 | F_o |^2]^{-1} \times [1 - \exp\{-5(\sin\theta/\lambda)\}]$.

RESULTS AND DISCUSSION

The selected bond lengths and bond angles for $Pr(NO_3)_3 \cdot L$ are given in Tables 1 and 2, respectively. Figure 1 shows the molecular structures of the Pr(1) and Pr(2) monomers in $Pr(NO_3)_3 \cdot L$. Figure 2 illustrates the molecular packing arrangement in the unit cell.

As with $[La(NO_3)_3 \cdot L]$ [6], the structure analysis shows there are two independent $Pr(NO_3)_3 \cdot L$ monomers in one asymmetric unit and the structures of these two monomers are similar. In each of the $Pr(NO_3)_3 \cdot L$ nonomers, the praseodymium(III) is 11-coordinated, being bonded to five crown ether oxygen atoms on one side and six oxygen atoms of three bidentate nitrate groups on the other side. The bond

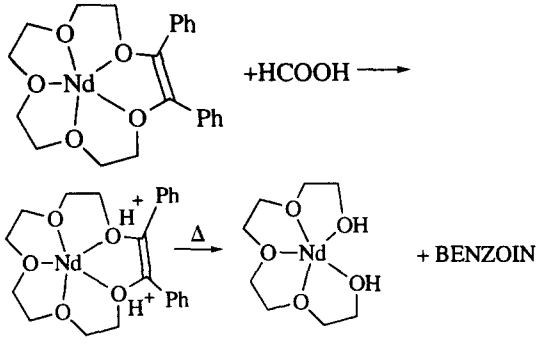

Table 1. Selected bond lengths (Å) for the Pr(1) and Pr(2) monomers

Pr(1)—O(1)	2.727(5)	Pr(2)—O(15)	2.261(4)

Pr(1)—O(6)	2.554(5)	Pr(2)—O(20)	2.544(5)
Pr(1)—O(7)	2.591(5)	Pr(2)—O(21)	2.521(5)
Pr(1)—O(9)	2.535(6)	Pr(2)—O(23)	2.602(5)
Pr(1)—O(10)	2.543(5)	Pr(2)—O(24)	2.530(6)
Pr(1)—O(12)	2.581(6)	Pr(2)—O(26)	2.515(6)
Pr(1)—O(13)	2.552(6)	Pr(1)—O(27)	2.645(6)

lengths lie in the ranges: Pr(1)—O(crown), 2.618(5)–2.727(5) [average 2.668(5)]; Pr(2)—O(crown), 2.583(5)–2.822(5) Å [average 2.679(5) Å]; Pr(1)—O(nitrate), 2.535(6)–2.591(5) [average 2.559(6) Å]; Pr(2)—O(nitrate), 2.515(6)–2.645(6) Å [average 2.556(6) Å]. From Table 1 it can be found that the Pr(1)—O(1) and Pr(2)—O(19) distances are significantly longer than other Pr—O(crown) distances. The reason is that the existence of the stibene group makes the flexibility of the crown ether become lower. The ligand is difficult to adopt to folded conformation to make O(1) and O(19) coordinate effectively to the praseodymium(III) ion. The shorter Pr(2)—O(15) and Pr(2)—O(16) distances suggested that the Pr(2) ion lies nearer the border of the crown ether than the Pr(1) ion. This arrangement makes the interaction of the Pr(1) and Pr(2) ions in the asymmetric unit decrease and the asymmetric unit becomes more stable.

Comparing the average Pr—O bond lengths with the corresponding average La—O bond lengths [6] [La(1)—O(crown) = 2.695(6), La(2)—O(crown) = 2.697(5), La(1)—O(nitrate) = 2.600(7), La(2)—O(nitrate) = 2.599(6) Å], it can be found that the Pr—O bond lengths are shorter than the La—O bond lengths due to the smaller Pr^{III} ionic radius. The decrease of Ln—O(nitrate) [La(1)—O–Pr(1)—O = 0.041 Å] is close to the expected decrease of La^{III} and Pr^{III} ionic radius [8] (0.05 Å, coordination number 11). However, the decrease of Ln—O(crown) [La(1)—O–Pr(1)—O = 0.027, La(2)—O–Pr(2)—O = 0.018 Å] is much smaller than the expected decrease of La^{III} and Pr^{III} ionic radius. This is also due to the rigidity of the stilbene group; the ligand cannot coordinate effectively to the praseodymium(III) ion. To the neodymium(III) ion with smaller ionic radius, a more folded conformation is needed in order to achieve the correct Nd—O distance. However, the more folded conformation makes the tensile force of the ligand in the complex become larger. The ligand is more difficult to be coordinated effectively to the neodymium(III) ion compared with the praseodymium(III) ion. So the neodymium complex can be obtained only with 16% yield and this complex is unstable owing to the larger tensile force in the complex. When triethylorthoformate is added to the solution of neodymium complex in acetonitrile at refluxing conditions, the following reactions occur:

$$HC(OC_2H_5)_3 + H_2O \text{ (trace in acetonitrile)} \longrightarrow HCOOH + C_2H_5OH \quad (1)$$

(2)

The stilbene group is dissociated from the crown ether by the action of acid catalyst and the flexible chain (EO_5) which can be coordinated effectively to the neodymium (III) ion is produced. $Nd(NO_3)_3 \cdot L$ is decomposed to stable $Nd(NO_3)_3 \cdot EO_5$. At the same condition, the stable $Pr(NO_3)_3 \cdot L$ complex cannot be transformed into $Pr(NO_3)_3 \cdot EO_5$. This transformation is testified by the results of elemental analysis and the crystal structure determination of neodymium complex.

Figure 3 shows the molecular structure of $Nd(NO_3)_3 \cdot EO_5$. Figure 4 illustrates the molecular packing arrangement in the unit cell. The selected bond lengths and bond angles are given in Tables 3 and 4, respectively.

As shown in Fig. 3, the 11-coordinate Nd^{3+} ion is coordinated to five oxygen atoms of EO_5 and six oxygen atoms of three bidentate nitrate groups. The five O(ligand) atoms form with one O(nitrate) [O(6)] atom a quasi regular hexagon around the metal ion in which the six O—Nd—O angles are comprised in a very small range of values (59.5–62.0°). The neodymium(III) ion and the above six oxygen atoms are coplanar. The two bidentate nitrates are coordinated axially above and below this plane, while the third nitrate is bonded to the Nd^{III} ion through the open side of the ligand chain. This coordination pattern is similar to that of $La(NO_3)_3 \cdot EO_5$ complex[9] and very different from that of another $Nd(NO_3)_3 \cdot EO_5$ complex reported by Hirashima *et al.*, in which the nitrate ion bonded through the open side of the ligand is monodentate. [10]

Five Nd—O(nitrate) distances lie in the range 2.551(4)–2.595(4) Å and average 2.620(4) Å, while the Nd—O(6) distance in which the oxygen atom is involved in the plane is considerably longer [2.859(4) Å]. A similar situation occurs for other 11-coordinate

complexes of lanthanum(III) [6,9,11], cerium(III) [12] and europium(III) [13], in which one or two Ln—O(nitrate) bond lengths are significantly longer. The five Nd—O(ligand) distances [mean 2.620(4) Å] are of two types: the two terminal Nd—O(alcohol) distances [mean 2.537(4) Å] are significantly shorter than the three Nd—O(ether) ones [mean 2.675(4) Å]. This pattern is much different from that found in the structure of $Pr(NO_3)_3 \cdot L$, in which the Pr(1)—O(1) and Pr(2)—O(19) distances are significantly longer than other Pr—O(ether) ones.

Comparing the mean Nd—O(ligand) and Nd—O(nitrate) distances with the corresponding Ln—O distances listed in Table 5, it can be found that the mean Nd—O(ligand) of 11-coordinated $Nd(NO_3)_3 \cdot EO_5$ is the shortest in all the complexes. It is even shorter than those of 10-coordinated $Nd(NO_3)_3 \cdot EO_5$ and 11-coordinated $Eu(NO_3)_3 \cdot 15C5$. On the contrary, the mean Nd—O(nitrate) distance of 11-coordinated $Nd(NO_3)_3 \cdot EO_5$ is significantly longer than other Ln—O(nitrate) complexes. This exception indicates the property of $Nd(NO_3)_3 \cdot EO_5$ decomposed from the $Nd(NO_3)_3 \cdot L$ is much different from that prepared from the $Nd(NO_3)_3 \cdot nH_2O$ and EO_5.

Conclusions

A structural change in $Ln(NO_3)_3 \cdot nH_2O$ complexes with stilbeno-15-crown-5 occurs between Ln = Pr and Ln = Nd. With Ln = Nd the unstable $Nd(NO_3)_3 \cdot L$ tends to become stable $Nd(NO_3)_3 \cdot EO_5$ in the presence of acid catalyst (triethylorthoformate) and this transformation is due to the rigidity of the ligand and the decrease of lanthanide ionic radius. The large tensile force owing to the folded conformation of the ligand during the complexation makes the complex becomes

(Received 24 May 1996; accepted 30 July 1996)

Abstract—The kinetics of the complex formation between $Pd(H_2O)_4^{2+}$ and glutathione was investigated in the presence of sodium dodecyl sulfate in the acidity range from 2 M $HClO_4$ to pH 5. Acceleration (from 2 M $HClO_4$ to pH 3.5) and retardation ($3.5 < pH < 5$) of the complex formation in the presence of anionic micelles was observed compared with the kinetic data in aqueous solution. These effects were explained by the electrostatic interaction of the reacting species with negatively charged micellar surface and their effective concentration and/or separation in the vicinity of micellar surface. Copyright © 1997 Elsevier Science Ltd

Keywords: palladium (II); glutathione; sodium dodecyl sulfate; stopped-flow; complex formation; micellar catalysis.

Glutathione (L-glutamyl-L-cysteinyl glycine, GSH) is a naturally occuring tripeptide containing a thioether group (see Scheme 1). GSH is a biological reducing agent in thiol-dependent enzyme reactions, recently reported to have anticancer activity [1].

GSH ($2.12 < pH < 3.53$)

Scheme 1.

Although complexes of Cr^{III} [2], Fe^{II} and Fe^{III} [3], and Zn^{II}, Cd^{II}, Hg^{II}, Pb^{II}, Co^{II}, Ni^{II} and Pd^{II} [4] with GSH have been synthesized and characterized, only a few studies have been published concerning the kinetics of the complex formation. So far, kinetics of the reactions of several Pt antitumor agents with GSH have been reported [5], as well as thiol exchange reaction between bis(thio)selenide of penicillamine and GSH [6].

In the present paper the influence of the anionic surfactant sodium dodecyl sulfate (SDS) on the rate of the complex formation between $Pd(H_2O)_4^{2+}$ and GSH in aqueous solution was studied. The mechanism of this reaction is already well understood in solutions containing no surfactant, in the broad acidity range from 2 M $HClO_4$ to pH 5 [7]. The effects of micellar systems on chemical reactions have been studied extensively, especially for organic reactions [8]. On the other hand, only a few studies have been done on inorganic reactions. Electron-transfer reactions involving metal complexes [9] and the complex formation of Ni^{II}, Mn^{II} and Pd^{II} with organic ligands have been investigated [10–15]. These studies are important not only from the viewpoint of inorganic reaction mechanisms, but also from biochemical aspects, i.e. as models of electron-transfer and ligand-exchange reactions on the surface of a biomembrane or at the interface of a globular protein.

EXPERIMENTAL

All reagents were commercial products of the highest purity available. The standard solution of 1×10^{-3} M $Pd(H_2O)_4^{2+}$ was prepared as described elsewhere

* Author to whom correspondence should be addressed.

[16]. The acidity of the solution was adjusted by addition of either NaOH ($2 < pH < 5$) or $HClO_4$ ($pH < 2$). The ionic strength was kept constant by the addition of $NaClO_4$ ($I = 0.1$), except for the measurements performed in concentrated perchloric acid. The acidity of the concentrated $HClO_4$ was characterized by the Hammet acidity function, H_0.

The absorption spectra were recorded on a Perkin–Elmer Lambda 5 UV–vis spectrophotometer. For the stopped-flow experiments, the universal rapid kinetic accessory HI-TECH model SFA 12 was fitted to a spectrophotometer. All the other reagents (surfactant, acid or inert salt) were added to the ligand and metal ion solutions at least 20 min prior to mixing. The kinetic experiments were performed by mixing equal volumes of GSH and $Pd(H_2O)_4^{2+}$ solutions at 25 ± 0.1°C. The rate of the complex formation was followed by monitoring the increase of the optical absorbance at 265 nm. All kinetic measurements were reproducible within the limits of error of $\pm 5\%$. The quoted values are the averages of at least five runs under identical experimental conditions.

The measurements of the relative light scattering intensity were performed using a Chomatix KMX-6 low-angle laser photometer operating at 633 nm. The optical purification of all solutions and solvent was carried out in the usual manner.

Absorption spectra of solutions containing (d) 2×10^{-5} M $Pd(H_2O)_4^{2+}$ and (e) 2×10^{-5} M GSH.

RESULTS AND DISCUSSION

Absorption spectra and stoichiometry of the Pd^{II}*–GSH complex in the presence of anionic micelles*

The complex formation between $Pd(H_2O)_4^{2+}$ and GSH in the presence of 1×10^{-2} M SDS was investigated in the acidity range from 2 M $HClO_4$ to pH 5. The absorption spectra of the solution containing equal concentration of $Pd(H_2O)_4^{2+}$ and GSH and 1×10^{-2} M SDS at different acidities are shown in Fig. 1. Clear isosbestic points were not observed indicating the existence of more than two absorbing species in the solution. The Pd^{II}–GSH complex in the presence of anionic micelles has the absorption maximum at 265 nm and the shoulders at 320 and 400 nm. For comparison, absorption spectra of the reacting species ($Pd(H_2O)_4^{2+}$ and GSH) are also given in Fig. 1.

The stoichiometry of the complex (Pd^{II}:GSH = 1:2) in the presence of 1×10^{-2} M SDS was determined at different acidities (2 M $HClO_4$, pH 1, 3 and 5) by continuous variation of the ratio between initial concentrations of $Pd(H_2O)_4^{2+}$ and GSH. Also, the absorption spectra at the constant $Pd(H_2O)_4^{2+}$/GSH ratio were followed as a function of the acidity. The absorption spectra indicated that the metal chelate structure was not affected by the change of acidity. The slight shift of the position of the absorption maximum is most likely due to the presence of different ionic forms of the ligand at different acidities ($pK_1 = 2.12$, $pK_2 = 3.53$) [17]. Similar effects were also noticed in the reactions of $Pd(H_2O)_4^{2+}$ and $PdCl_2$ with *S*-carboxymethyl-L-cysteine in aqueous [18] and micellar solutions [15].

The kinetics of complex formation between $Pd(H_2O)_4^{2+}$ *and GSH in the presence of SDS*

The kinetics of the complex formation between $Pd(H_2O)_4^{2+}$ and GSH in the presence of micelle forming surfactant SDS was followed in the acidity range from 2 M $HClO_4$ to pH 5. Under pseudo-first-order conditions (GSH $\gg$ Pd^{II}) the experimentally determined rate constants (k_{obs}) followed the simple rate expression:

$$k_{obs} = k_f C_{GSH} + k_r, \qquad (1)$$

where k_f and k_r are the forward and reverse pH-dependent rate constants, respectively. The collected values of k_{obs} as a function of C_{GSH} at constant acidity (see Table 1) indicated the absence of a measurable reverse reaction in the investigated range of acidity.

The pH dependence of k_f in the absence and in the presence of 1×10^{-2} M SDS is shown in Fig. 2. The presence of micelles has a two-fold effect on the rate of complex formation: (a) the complex formation is accelerated in the presence of micelles in the acidity range from 2 M $HClO_4$ to pH 3.5; (b) the complex formation is retarded in the pH range from 3.5 to

Table 1. Experimental rate constants (k_{obs}) of complex formation between GSH and $Pd(H_2O)_4^{2+}$ (2×10^{-5} M) as a function of the GSH concentration in the presence of 1×10^{-2} M SDS at different acidities

$C_{GSH} \times 10^5$	k_{obs} (s^{-1})					
pH	1	2	4	10	15	20
−0.8	0.020	0.039	0.095	0.198	0.350	0.470

5, compared with the kinetic results obtained in the absence of SDS. It should be noticed that the pH value at which rates of complex formation in the absence and in the presence of SDS are equal coincide with the pK_2 of GSH.

Acceleration of the complex formation between Pd^{II} and GSH in the acidity range from 2 M $HClO_4$ to pH 3.5 can be explained as a result of the increased concentration of reagent molecules in the vicinity of the anionic micelles (see Fig. 2). The anionic micelles provide a dispersed negatively charged surface in solution. As a consequence, the positively charged $Pd(H_2O)_4^{2+}$ ions will partition out the bulk aqueous phase into the surface region of the micelles. The estimated binding constants for bivalent ions are in the range from 1.2×10^3 to 2.5×10^3 M^{-1} [19] and almost all the $Pd(H_2O)_4^{2+}$ ions are on the micellar surface. Also, the process of concentration of two times protonated (from 2 M $HClO_4$ to pH 2.12) and zwitter ion ligand species with net positive charge equal to one ($2.12 < pH < 3.53$), in the vicinity of anionic micellar surface, is an electrostatically favorable process. The net effect is an overal increase in the concentration of reacting species in the vicinity of the micellar surface and the complex formation is faster compared with the reaction in the absence of surfactant.

In the pH range from 3.5 to 5 complex formation between Pd^{II} and GSH in the presence of 1×10^{-2} M SDS was slower compared with the kinetic results in aqueous solutions (see Fig. 2). This can be explained as a consequence of the effective separation of the reacting species in the presence of anionic micelles. In this pH range both carboxylic groups of the hydrophilic ligand GSH are deprotonated and the ligand species exist as a zwitter ion with the net charge equal to zero. Although the net charge of the ligand is equal to zero in this pH range, due to the electrostatic repulsion between negatively charged micellar surface and negatively charged terminal carboxylic groups, the ligand is located solely in the bulk aqueous phase. Therefore, in the presence of anionic micelles the reacting species are effectively separated and the complex formation is slowed down. Similar effects of acceleration/retardation have been observed for the Pd^{II}/MONO-PACA [1,8-dihydroxy-2-(pyrazol-5-ylazo)naphthalene-3,6-disulfonic acid] and Pd^{II}/$SCMCH_2$ (*S*-carboxymethyl-L-cysteine) systems [14, 15].

Although the influence of SDS on the rate of complex formation between Pd^{II} and GSH is very small, the kinetic measurements can be used for the precise detection of the surfactant concentration at which the micelle formation occurs, which is generally considered to be the critical micellization concentration (CMC) of the surfactant. Typical dependencies of the rate constants (k_{obs}) on the concentration of SDS, at different acidities, are shown in Fig. 3. The increase and/or decrease of the rate constant indicates the first appearance of micelles or pre-micellar aggregates. The CMC values, at different acidities, were also determined by measuring the relative light scattering inten-

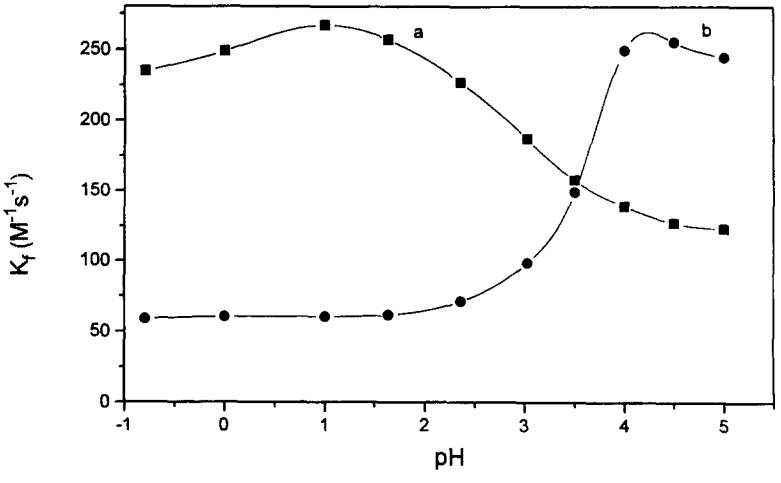

Fig. 2. pH profile of the forward rate constant (k_f) for the formation of the $Pd(H_2O)_4^{2+}$-GSH complex (a) in the presence and (b) in the absence of 1×10^{-2} M SDS at 298 K.

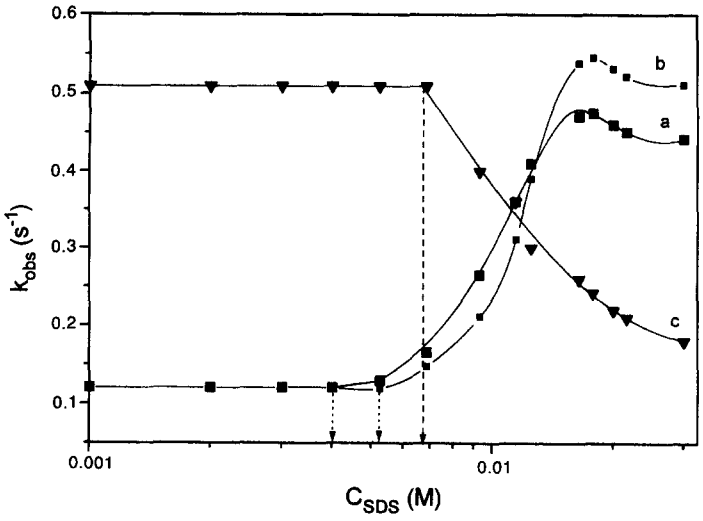

Fig. 3. Experimental rate constants (k_{obs}) of complex formation between 2×10^{-5} M $Pd(H_2O)_4^{2+}$ and 2×10^{-4} M GSH as a function of the SDS concentration at different acidities: (a) 2 M $HClO_4$; (b) pH 1; (c) pH 3; (d) pH 4.5. Temperature: 298 K.

sity as a function of the surfactant concentration. The agreement between the CMC values determined from light scattering and kinetic measurements was found. It should be noticed that the obtained CMC values (around 7×10^{-3}, 5×10^{-3} and 4×10^{-3} at pH 4.5 and 1, and in 2 M $HClO_4$, respectively) are smaller than the reported CMC value at zero ionic strength (7.75×10^{-3} M). This effect can be explained by the well-known fact that the addition of acids lowers the CMC of surfactants [20].

(Received 25 April 1996; accepted 30 July 1996)

Abstract—The condensed phase and matrix isolation IR and Raman spectra of antimony tribromide are reported. The solid-state spectrum comprises bands assignable to both molecular $SbBr_3$ and ionic $SbBr_6^-$ species. The frequency shifts and mode sequence in the melt spectrum indicate strong dipole–dipole interactions. The matrix isolation spectra show bands of monomeric $SbBr_3$ and of its centrosymmetric dimer, but no features of cooperative interactions. A "bond fluctuation" explanation, previously forwarded for antimony trichloride, is considered to be further substantiated by the present findings. Copyright © 1997 Elsevier Science Ltd

Keywords: $SbBr_3$; Raman; FIR/IR; matrix isolation; bond fluctuation; melt.

In a recent Raman spectroscopic investigation [1] of crystalline antimony trichloride the observed spectra were interpreted in terms of a "bond fluctuation", indicating a transition between the molecular and ionic forms, formally described by

$$2SbCl_3 \rightleftharpoons Sb^+ + SbCl_6^-.$$

This suggestion was based upon the fact that the number of the observed bands exceeded that expected for the monomeric molecular $SbCl_3$ and on coincidences of the recorded bands with modes of the ionic $SbCl_6^-$ species.

The phenomenon of molecular to ionic transition in the solid state is far less common than the parallel heterolytic dissociation of molecules to ions in polar solvents. In the absence of host environmental stabilization of the ionic products, the molecular to ionic transformation must then be interpreted in terms of a change in charge distribution, either intramolecularly or, more likely, intermolecularly, made feasible by bulk stabilization. Studies on the transition of molecular dinitrogen tetroxide to ionic nitrosonium nitrates investigated the intermolecularity, temperature and order/disorder dependence of the process in thin cryogenically deposited films [2]. Another well investigated system, showing both ionic and molecular solid forms, is phosphorus pentachloride [3], which can be deposited as either molecular PCl_5 or ionic $PCl_4^+ + PCl_6^-$.

The purpose of the present investigation is to study the vibrational spectrum of solid antimony tribromide in the solid [4–6] in comparison with that of the melt and of its matrix isolated species, to establish band assignments and to learn whether a molecular to ionic transition may also be proposed for this substance.

EXPERIMENTAL

Antimony tribromide used was prepared by synthesis from the elements with the bromine dissolved in CS_2 [7]. The crude product was refined by repeated distillations over metallic antimony and collected directly into glass tubes, which were then sealed. Inert gas techniques were used to avoid contamination and to exclude moisture and oxygen. Purity was checked thermo-analytically by establishing the melting point to be 96°C, in accordance with the literature value [7].

Room-temperature Raman spectra, excited by a Spectra Physics model 165 krypton ion laser, were recorded on a Coderg PH1 spectrometer. The Raman scattering was observed perpendicular to the incident beam. The spectrometer and modified sample compartment were described previously [8,9]. Low-temperature and matrix isolation Raman spectra were excited by either krypton ion or argon ion Spectra Physics model 164/5 lasers and recorded on a Spex 1401 double monochromator equipped with a Third Monochromator (TTM) filter in tandem to reduce scattered light. Samples were produced by co-deposition of vapor and rare gas beams onto a gold plated oxygen-free copper (OFHC) plate cooled by closed cycle Air Products CS202A helium refrigerator.

Low-temperature infrared and matrix isolation IR spectra were recorded on a Bruker 113v FT-IR spectrometer using the helium refrigerator and the reflection–absorption method. Far-IR (FIR) room-temperature spectra were obtained from $SbBr_3$/paraffin oil grindings on a modified Beckman FS interferometer interfaced to a Kontron KAP 1000 computer.

RESULTS

The vibrational spectra of crystalline and molten antimony tribromide are shown in Figs 1 and 2, respectively, and those of matrix isolated $SbBr_3$ in Figs 3 and 4. Table 1 summarizes the observed Raman and FIR frequencies of solid antimony tribromide with their proposed assignment in comparison to literature data. The Raman frequencies of molten $SbBr_3$ are given in Table 2, the FIR frequencies of the matrix isolated $SbBr_3$ species in Table 3 and the matrix isolation Raman frequencies in Table 4.

DISCUSSION

Crystalline antimony tribromide

In crystalline antimony tribromide (α-$SbBr_3$, $P2_12_12_1$, $Z = 4$; β-$SbBr_3$, *Pnma*, $Z = 4$) [11], pyramidal $SbBr_3$ molecules of C_{3v} symmetry are stacked one on top of the other. Therefore, an $SbBr_3$ molecule vibrational spectrum may be expected. Such a spectrum is indeed observed for gaseous and dissolved antimony tribromide [4,10], but the observed condensed state spectra show additional bands as listed in Tables 1 and 2. The assignments of the fundamentals of crystalline antimony tribromide cannot, therefore, be based on distinct $SbBr_3$ molecules only. The spectrum of crystalline antimony tribromide is analogous to that of antimony trichloride and will be interpreted in similar terms.

The interpretation of the solid-state $SbBr_3$ spectrum may be approached from the crystal field, ionic and "bond fluctuation" points of view.

As pointed out for crystalline $SbCl_3$ [1], which is isotypic to $SbBr_3$ [11], site or factor group splitting could not provide a satisfactory interpretation for the observed spectra. Therefore, these same arguments should be valid for crystalline antimony tribromide and its vibrational spectrum.

An ionic interpretation would involve a process of auto-dissociation to form distinct cations and anions. Such ions are encountered in the formation of PCl_4^+ and PCl_6^- in phosphorus pentachloride [3,12] or in the transition of dinitrogen tetroxide into nitrosonium NO^+ and nitrate NO_3^- ions [2]. In the present case, no bands assignable to either $SbBr_2^+$ or $SbBr^{2+}$ have been observed, nor has there been spectral evidence for the existence of the known bromoantimonate(III)

anions $SbBr_5^{2-}$, $SbBr_6^{3-}$, $Sb_2Br_7^-$ and $Sb_2Br_9^{3-}$ [6,13–20].

Only the "bond fluctuation" approach, involving an intermolecular charge delocalization and a transient existence of Sb^I and Sb^VBr_6 units in the lattice, may then provide a suitable interpretation of the spectrum, involving molecular $SbBr_3$ and ionic $SbBr_6^-$ species. The case for terming the phenomenon as "bond fluctuation" is even stronger for $SbBr_3$ than for $SbCl_3$. The vibrational modes of octahedral $SbBr_6^-$ ions [16,21,22] are not seen in the spectrum, in contrast to $SbCl_6^-$ modes in solid $SbCl_3$, which were observed in the spectrum of the solid [1]. In considering the $SbBr_3$ crystal structure (Fig. 5), a prismatic coordination of Sb is present in both the α- and β-modifications. Such a prismatic unit might be involved in a "bond fluctuation" in accordance with a formal equilibrium

$$2SbBr_3 \rightleftharpoons Sb^+ + SbBr_6^- \quad \text{(prism)}.$$

Such an $SbBr_6^-$ prism, of D_{3h} symmetry, existing due to this equilibrium, spans the following vibrational fundamentals [22]

$$\Gamma_{vib}(SbBr_6^- \text{ prism}/D_{3h}) = 2A_1'(R) + 3E'(R, IR) + A_1'' + 2A_2''(IR) + 2E''(IR),$$

with $A_1' + E' + A_2'' + E''$ being mostly stretching modes and $A_1' + 2E' + A_2'' + E''$, which are mostly bending frequencies. The assignment of the spectrum bands of crystalline antimony tribromide in Fig. 1, as given

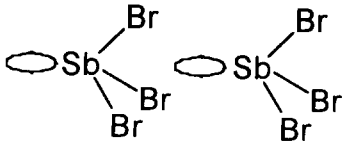
in Table 1, is then based on a superposition of the vibrational modes of $SbBr_3$ molecules and $SbBr_6^-$ prisms.

The interpretation of the solid-state $SbBr_3$ vibrational spectrum, suggested here, involving the "bond fluctuation" approach is consistent with the spectral observation. Further substantiation of this interpretation may be expected from high-pressure low-temperature investigations.



Molten antimony tribromide

The physical properties of $SbBr_3$ [23] favor a molecular melt with relatively strong intermolecular interactions. The Raman spectrum (Fig. 2, Table 2) of the antimony tribromide melt indeed exhibits no features indicating the existence of ionic species. Pyramidal $SbBr_3$ molecules, being of C_{3v} symmetry, span the vibrational modes [22]

$$\Gamma_{vib}(SbBr_3, C_{3v}) = 2A_1(R, IR) + 2E(R, IR),$$

with $A_1 + E$ contributions from both stretching and bending internal coordinates. Comparing the melt Raman spectrum with that of antimony tribromide in the gas phase or in solution, where the existence of isolated $SbBr_3$ molecules was confirmed [4,10], one notices a marked red shift of the stretching mode frequencies and a reversal in their order—$\nu_3(E) > \nu_1(A_1)$ for the melt compared with a $\nu_1(A_1) > \nu_3(E)$ sequence for isolated molecules. The fact that this reversal is observed in the melt, but in the more densely packed solid, where intermolecular interactions may be expected to be more evident, the normal sequence is retained, is taken as additional support for the interpretation of the spectrum of the latter, which is based on the existence of separated $SbBr_3$ entities.

The strong temperature dependence of the melt frequency values (Table 2) is indicative of a decrease in intermolecular dipole–dipole interactions with temperature increase. Due to these interactions the melt may be considered to be composed of aggregates, illustrated for the simplest case of two molecules as:

For such an arrangement, the repulsion between the bromide ion electron pairs with the Sb lone pair would cause an increase of the bond–bond angle in the melt and be responsible for the change of frequency sequence, discussed above, by bringing it closer to that of planar C_{3v} molecules and the frequency sequence characterizing them [24].

In this conjecture it is also instructive to compare the frequency sequences of antimony tribromide with those of other molecules of C_{3v} symmetry: NH_3 and PCl_3 present cases of $\nu_1(A_1) > \nu_3(E)$ and $\nu_3(E) > \nu_1(A_1)$, respectively [10,22,25], and in both the transition to condensed phase is accompanied with a red shift in frequencies. However, in both this shift is considerably larger for the E stretching mode than for the A_1 stretch. In PCl_3 $\Delta\nu_3(E)$ gas/liquid = 20 cm^{-1}, whereas $\Delta\nu_1(A_1) = 4$ cm^{-1}. In contrast, for $SbBr_3$ the corresponding values found are $\Delta\nu_3(E)$ gas/melt = 6 cm^{-1} and $\Delta\nu_1(A_1) = 32\,cm^{-1}$. It is reasonable that for molecular arrangement similar to that suggested, the concerted motion in the symmetric mode will be the more affected ones. As pointed out in the previous section, such an arrangement, promoting cooperative concerted vibrational motions, is also the basis for the assumption of the "bond fluctuation" stipulated there.

Matrix isolated antimony tribromide

The "bond fluctuation" model proposed above to explain the coexistence of molecular and ionic forms in a solid formed from a clearly molecular vapor relies on strong intermolecular interactions between the $SbBr_3$ species in condensed phase antimony tribromide. The major aim in studying the matrix isolation spectra of $SbBr_3$ species is then to corroborate this claim by recording spectra in a phase which, although condensed, provides for the separation of the molecules of interest. The nature of the molecular to ionic transition in thin films of dinitrogen tetroxide was established to be intermolecular on the basis of similar experiments [26].

In comparing the 20 K Raman spectra of matrix isolated $SbBr_3$ with that of solid antimony tribromide at the same temperature, it becomes immediately obvious that the 91.3 cm^{-1} band of the solid has no corresponding feature in the matrix isolation spectrum. However, this band does have its analog in the 170 cm^{-1} Raman band of solid antimony trichloride [1].

The matrix isolation IR and Raman spectra of antimony tribromide comprise more bands than expected for isolated monomeric $SbBr_3$ species. The assignment of the monomer bands in Tables 3 and 4 follows the accepted assignment for the gaseous molecule [10]. The existence of dimeric species of bridged structure in dihalide and trihalide matrix isolation spectra is well established and dimeric antimony bromide species would be the first to form along the monomers. The suggested assignment of the nonmonomeric bands is to these species. Three possible structures for the dimer are (Fig. 6)

(a) An Al_2Cl_6 analogous structure without any sterical activity of the lone pairs (D_{2h} symmetry), the vibrational modes spanning the symmetry species

$$\Gamma_{vib}(Sb_2Br_6/D_{2h}) = 4A_g(R) + 2B_{1g}(R) + 2B_{2g}(R) + B_{3g}(R) + A_{1u} + 3B_{1u}(IR) + 2B_{2u}(IR) + 3B_{3u}(IR)$$

with $A_g + B_{1g} + B_{2u} + B_{3u}$ contributions of the terminal bond stretches and $A_g + B_{2g} + B_{1u} + B_{3u}$ contributions of the bridging bond stretches.

(b) A *cis*-arrangement of the lone pairs (C_{2v} symmetry), the vibrational modes spanning the symmetry species

$$\Gamma_{vib}(Sb_2Br_6/C_{2v}) = 6A_1(R, IR) + 4A_2(R) + 4B_1(R, IR) + 4B_2(R, IR)$$

with $A_1 + A_2 + B_1 + B_2$ contributions from both the terminal and bridging stretches.

(c) A *trans*-arrangement of the lone pairs (C_{2h} symmetry), the vibrational modes spanning the symmetry species

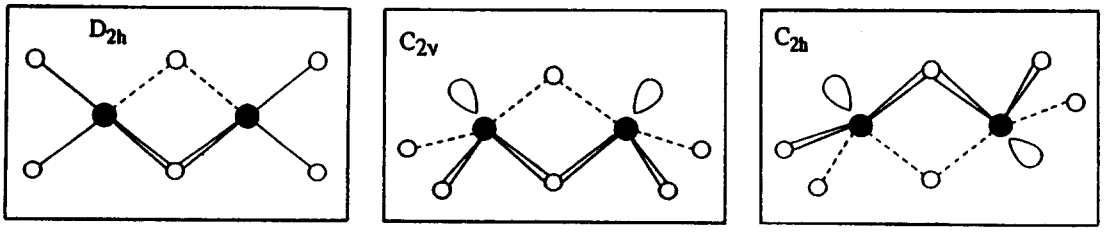


Fig. 6. Structures of Sb_2Br_6 species; (a) Al_2Cl_6 analog (D_{2h}), (b) *cis*-lone pair arrangement (C_{2v}), and (c) *trans*-lone pair arrangement (C_{2h}).

$$\Gamma_{vib}(Sb_2Br_6/C_{2h}) = 5A_g(R) + 4B_g(R) + 4A_u(IR) + 5B_u(IR)$$

with $A_g + B_g + A_u + B_u$ contributions from both the terminal and bridging stretches.

In $SbBr_3$ matrix isolation Raman spectrum only one weak sharp band at 231.6 cm^{-1} is discernible on top of a much broader feature, which is most probably due to the symmetric stretching mode of the outer nonbridging Sb—Br bonds. The fact that this band does not coincide with any of the observed IR bands confirms that the dimer is of centrosymmetric symmetry. Based on the stereochemical activity of the Sb^{III} lone pairs and their preferred *trans*-positions in Sb^{III} halogenocomplexes [27], it is concluded that the *trans*-Sb_2Br_6 species with C_{2h} symmetry is more likely. The broader background is caused by higher oligomeric and polymeric species, present in the matrix due to the experimental necessity to resort to higher concentration of guest molecules matrix isolation Raman experiments as compared to analogous IR investigation. While this preference of C_{2h} over a C_{2v} symmetry for these species cannot be considered to be fully conclusive, it would be compatible with the intermolecular interactions suggested here for the neat condensed phases. The other assignments, forwarded in Tables 3 and 4, are then in accordance with a C_{3v} symmetry of the monomer and the C_{2h} structure for the dimer.

CONCLUSIONS

We have reported the condensed phase and matrix isolation IR and Raman spectra of antimony tribromide. The solid-state spectrum exhibits both ionic and molecular features attributed to a "bond fluctuation". The strong intermolecular interactions evidenced by the frequency shifts and mode sequence in the spectrum of the melt are considered to be in support of this assumption. Additional support is found in the matrix isolation spectra where the bands due to cooperative interactions are absent, but features due to a centrosymmetric bridged dimer may be found.

(Received 23 February 1996; accepted 30 July 1996)

Abstract—Complexes of rhodium and iridium of the types MX_3L, $MX(CO)_2L$ and $MX_3(CO)L$ (X = halide) containing multidentate *N*-heterocycles (L), 2,6-bis(benzimidazolyl)pyridine ($bBzlH_2py$) and 2,6-bis(*N*-methylbenzimidazolyl)pyridine ($bBzlMe_2py$) have been prepared and characterized by IR, electronic and ^1H and ^{13}C NMR spectral data. $RhX(CO)_2L$, on treatment with alcoholic solvents or DMF undergoes reversible decarbonylation to produce $RhXL \cdot 2H_2O$. Passage of NO or O_2 through the carbonyl suspended in hot 2-methoxyethanol releases CO_2. Copyright © 1997 Elsevier Science Ltd

Keywords: rhodium; iridium; multidentate *N*-heterocycles; carbon monoxide; 2,6-bis(benzimidazolyl) pyridine; 2,6-bis(*N*-methylbenzimidazolyl)pyridine.

Development of new multidentate *N*-heterocycles, which produce organised supramolecules upon coordination to metal ions is of interest in the recent past [1]. They are quite promising in the design of stable light conversion devices and in the production of triple stranded helicates [2]. Further a wide variety of complexes associated with *N*-donor ligands are being actively considered for their catalytic activity [3]. We have been investigating metal complexes containing *N*-heterocycles as they are of potential relevance in such studies. Here, we describe the syntheses and characterization of complexes of rhodium and iridium containing polydentate benzimidazole derivatives (**I**), 2,6-bis(benzimidazolyl/*N*-methylbenzimidazolyl) pyridine ($bBzlH_2py$/$bBzlMe_2py$).

EXPERIMENTAL

Hydrated rhodium trichloride and sodium hexahaloiridates were obtained from Arora Matthey, India and Johnson Matthey, England. Hydrated rhodium tribromide and rhodium(III) perchlorate were prepared as described elsewhere [4]. Polydentate *N*-heterocycles-2,6-bis(benzimidazolyl)pyridine and its *N*-methylated derivative were prepared according to literature methods [5–7]. The IR (nujol mull and KBr) and electronic (Nujol mull and DMF solution) spectra were recorded on Carl–Zeiss SPECORD 75-IR and Hitachi 150-20 spectrophotometers, respectively. The ^1H and ^{13}C NMR spectra in DMSO-d_6 were recorded at ambient temperatures on Bruker 270 and 400 MHz spectrometers with TMS as the internal reference. Conductivity measurements were carried out using a Toshniwal conductivity bridge type CL 01.02.

Preparation of the complexes

$RhX_3(bBzlH_2py/bBzlMe_2py)$ (X = Cl, Br *or* I). An ethanolic solution (10 cm^3) of rhodium trichloride/bromide (1 mmol) was treated with the *N*-heterocycle (1 mmol) dissolved in ethanol (10 cm^3) and the mixture was refluxed on a steam bath for 4 h during which yellow or orange solid separated. It was washed with alcohol and dried *in vacuo*.

Metathesis reaction of the chloro complex in ethanol with 15-fold excess of sodium iodide gave the iodo complex as a brown solid. Yield: 80–90%.

$[Rh(bBzlH_2py)_2(OClO_3)](ClO_4)_2$ *and* $[Rh(bBzlMe_2py)](ClO_4)_3$. The perchlorate complexes were prepared using the procedure described above by taking rhodium perchlorate and the heterocycle in the mole ratio 1 : 2. Yield: 65%.

$IrX_3(bBzlH_2py/bBzlMe_2py)$ (X = Cl *or* Br). The complexes were prepared in the same way (preceding method) starting from sodium hexahalo iridate(IV) using 2-methoxy ethanol as the solvent. Yield: 55–60%.

$RhX(CO)_2L \cdot nH_2O$ (X = Cl *or* Br, L = $bBzlH_2py$, n = 1.5; X = Cl, L = $bBzlMe_2py$, n = 1). CO was bubbled through an ethanolic solution (10 cm^3) of hydrated rhodium trihalide (1 mmol) at refluxing temperature until it turned yellow. To this was added the *N*-heterocycle (1 mmol) in ethanol (10 cm^3) and the passage of CO was continued for about half an hour when an amorphous green solid separated. The solid was washed with ether and dried *in vacuo*. Yield: 60–70%.

$Rh(bBzlH_2py)(CO)_2(OClO_3)$ *and* $[Rh(bBzlMe_2py)(CO)_2]ClO_4$. The complexes were prepared starting from the carbonylated rhodium perchlorate solution using the procedure described above. Yield: 60%.

$[RhX_2(CO)(bBzlH_2py)]X$ (X = Cl *or* Br). $RhX(CO)_2(bBzlH_2py) \cdot 1.5H_2O$ (1 mmol) was suspended in CCl_4 (10 cm^3) and to this was added the corresponding halogen in CCl_4 (2 mmol) followed by ethanol (5 cm^3). The mixture was stirred, when the green dicarbonyl gradually dissolved simultaneously precipitating yellow/orange solid. It was washed with CCl_4 followed by ether and dried *in vacuo*. Yield: 60%.

$IrX(CO)_2(bBzlH_2py) \cdot nH_2O$ (X = Cl, n = 1; X = Br, n = 1.5). CO was bubbled through sodium hexahalo iridate (1 mmol) in 2-methoxy ethanol (10 cm^3) at refluxing temperature until the solution turned yellow. The solution was cooled to room temperature and the *N*-heterocycle (1 mmol) dissolved in 10 cm^3 of 2-methoxyethanol was added and the passage of CO was continued for 2 h. The solvent was evaporated under CO atmosphere to nearly 5 cm^3 and cooled to ice temperature when a green or red solid separated. It was washed with ether and dried *in vacuo*. Yield: 55%.

RESULTS AND DISCUSSION

Reaction of rhodium trihalide or sodium hexahalo iridate with the *N*-heterocycle, $bBzlH_2py/bBzlMe_2py$ (**I**) in 1 : 1 mole ratio in alcohol/2-methoxyethanol produced yellow, orange and red complexes whose elemental analyses correspond to the formula MX_3L (M = Rh or Ir, X = Cl or Br, L = $bBzlH_2py$ or $bBzlMe_2py$). In the case of rhodium, the iodo analogs are prepared by stirring a mixture of rhodium trichloride with 15-fold excess of sodium iodide and the *N*-heterocycle in 1 : 1 mole ratio in methanol. The complexes are insoluble in common organic solvents, but dissolve in DMF in which they behave as non-electrolytes. The complexes containing $bBzlMe_2py$ are sparingly soluble in DMF.

Rhodium(III) perchlorate reacts with $bBzlH_2py$ and $bBzlMe_2py$ in the mole ratio 1 : 2 in methanol refluxing temperature to give yellow crystalline solids. The elemental analyses of the complexes correspond to the formula $RhL_2(ClO_4)_3$. While the $bBzlH_2py$ complex behaves as a 1 : 2 electrolyte in MeCN or DMF, the $bBzlMe_2py$ analog is a 1 : 3 electrolyte in the same solvents. However, the former displayed 1 : 3 electrolytic behavior in DMSO. Some physical properties and analytical data of the complexes are listed in Table 1.

Treatment of a carbonylated solution of rhodium trihalide/perchlorate with the multidentate *N*-heterocycles produced green solids of the composition $MX(CO)_2L \cdot nH_2O$ (M = Rh, X = Cl or Br, *n* = 1.5, L = $bBzlH_2py$; X = ClO_4, *n* = 0, L = $bBzlH_2py$ or $bBzlMe_2py$; X = Cl, *n* = 1, L = $bBzlMe_2py$). The halocarbonyl complexes are also obtained by the (i) carbonylation of RhX_3L in DMF (ii) halobridge cleavage of the carbonyl dimers, $[RhX(CO)_2]_2$ (X = Cl or Br) with the *N*-heterocycle. The bromocarbonyl complex containing $bBzlMe_2py$ is obtained in a low state of purity. Carbonylation reactions with sodium hexahalo iridate and the *N*-heterocycle yielded green/orange solids of the composition $IrX(CO)_2(bBzlH_2py)$. The $bBzlMe_2py$ analogs are yet to be properly characterized.

The chloro- and bromocarbonyl complexes of rhodium are diamagnetic and undergo decarbonylation on treatment with solvents like alcohol, 2-methoxy ethanol and DMF to produce yellow solids whose elemental analyses correspond to the formula $RhX(L) \cdot 2H_2O$. Carbonylation of the latter suspended in the same solvents produced the parent carbonyls. Further the passage of NO or O_2 through alcoholic (2-methoxy or 2-ethoxy ethanol) suspension of $RhX(CO)_2L$ or $RhXL \cdot 2H_2O$ around 100°C produced carbon dioxide. Thus, these complexes seem to be good candidates for the design of three-way catalysts for automobile exhaust emissions. This is in view of the fact that among platinum group metals, rhodium has displayed the best catalytic activity [8]. This work is being pursued.

The dicarbonyl $RhX(CO)_2(bBzlH_2py) \cdot 1.5H_2O$ (X = Cl or Br) on oxidative addition with the corresponding halogen in CCl_4 undergoes the loss of a CO ligand and affords yellow or orange products of the formula $[RhX_2(CO)(bBzlH_2py)]X$. Such an oxidative addition reaction did not proceed in the case of $RhCl(CO)_2(bBzlMe_2py) \cdot H_2O$.

The Nujol mull IR spectra of the complexes are similar to those of the uncoordinated *N*-heterocycles, except for the minor shifts in the positions of the

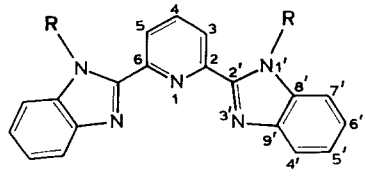
peaks. The spectra of $MX_3(bBzlH_2py)$ exhibited a ν_{NH} band in the range 3150–3180 cm^{-1}, indicating the coordination of the heterocycle through the tertiary nitrogens. This is further supported by the shift of the $\nu_{C=N}$ band by 20 cm^{-1} to lower/higher wave-number in the complexed species. A band at 1412 cm^{-1} noticed in the spectra of $MX_3(bBzlMe_2py)$ complexes is assigned to the N—Me stretch [7,9].

The IR spectra of the complexes $RhL_2(ClO_4)_3$, in addition to the peaks due to *N*-heterocycle, displayed bands due to perchlorate groups around 1100 (ν_3) and 620 cm^{-1} (ν_4). In the spectrum of $Rh(bBzlH_2py)_2(ClO_4)_3$, the former band is split (1083, 1010 cm^{-1}), implying the coordination of at least one of the perchlorates. This is supported by 1:2 electrolytic behavior of the complex in MeCN/DMF. In the case of $Rh(bBzlMe_2py)_2(ClO_4)_3$, both the IR spectral and conductivity data indicate the ionic nature of the perchlorates [10].



The IR spectra of Rh^I halocarbonyl complexes in KBr displayed a split peak at 1990 and 2030 cm^{-1} due to ν_{CO} and the intensities of the two peaks have been found to fluctuate with different preparations despite the elemental analysis being satisfactory. The IR spectra of $Rh(CO)_2(bBzlH_2py)(ClO_4)$ (ν_{CO}, 2047, 1987 cm^{-1}) and its $bBzlMe_2py$ analog (ν_{CO}, 1973 cm^{-1}), in addition to ν_{CO} peaks, displayed bands characteristic of coordinated (1113, 1110, 627 cm^{-1}) and ionic (1093, 627 cm^{-1}) perchlorates, respectively. The KBr pellet spectra of the monocarbonyls $[RhX_2(CO)(bBzlH_2py)]X$ (X = Cl or Br) exhibited two peaks, one around 2060 cm^{-1} and the other at 2100 cm^{-1} due to ν_{CO}, suggesting the presence of isomeric forms. For the chloro complex, the former band is more intense than the latter, whereas for the bromo analog the intensities of the two peaks varied with different preparations. The dicarbonyl complex of iridium $IrX(CO)_2(bBzlH_2py)$ (X = Cl or Br) displayed a strong IR peak around 2000 cm^{-1}, indicating a *trans* disposition of the carbonyl groups.

The ^1H NMR spectra of $bBzlH_2py$ and $bBzlMe_2py$ in DMSO-d_6 exhibited resonances due to phenylene and pyridine ring protons (Table 2) and the assignments are in consonance with those reported by Addison and coworkers [11]. The spectra of the complexes illustrated both positive and negative coordination induced shifts (c.i.s = $\delta_{complex}$-δ_{ligand}), the appreciable one being for H-4′. The resonance due

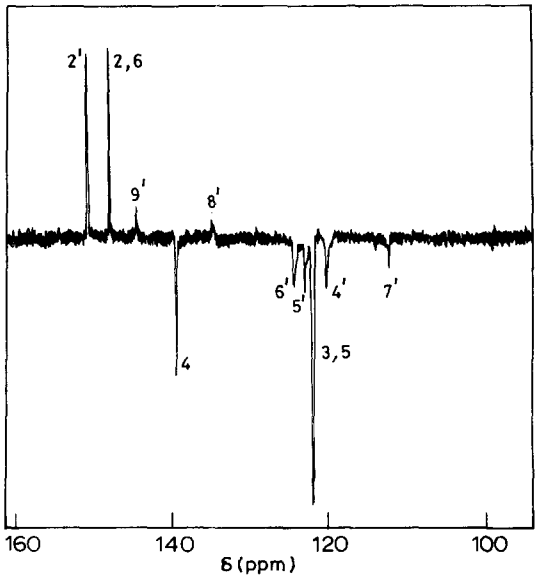

Fig. 1. ^{13}C SEFT NMR spectrum of $bBzlH_2py$

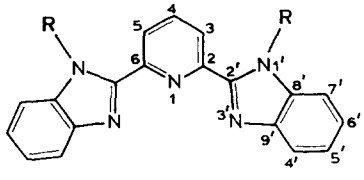
to the imine proton observed in the range 7–16 is concentration dependant. In the spectra of some of the complexes, the imine proton resonance is not observed, and probably it is too broad owing to rapid exchange with water protons present in the solvent. For the cationic complexes $[Rh(bBzlH_2py)_2(OClO_3)](ClO_4)_2$ and $[Rh(bBzlMe_2py)_2](ClO_4)_3$ only one set of proton resonances have been observed implying the magnetic equivalence of the corresponding protons in both the coordinated *N*-heterocycles. In the former complex, it is likely that the coordinated perchlorate becomes displaced by the uncoordinated N atom of the heterocycle. The spectra revealed c.i.s. and H-4′ has experienced a shielding effect.



The ^{13}C NMR spectra of the uncoordinated *N*-heterocycles in DMSO-d_6 displayed 10 resonances as against eight signals reported by Addison and coworkers [11], and the assignments are given in Table 3. An additional resonance at δ 32.5 is observed for the N—Me group of $bBzlMe_2py$. According to the earlier report on $bBzlMe_2py$, the phenylene carbons 7′ and 4′ are magnetically equivalent, so also are the quaternary carbons 8′ and 9′. Thus, two resonances, one at δ 115.72 for C-7′,4′ and another at δ 139.23 for C-8′,9′, have been reported [11]. A similar finding has been made for $bBzlMe_2py$. Surprisingly in the present investigation, the four carbons 7′, 4′, 8′ and 9′ are seen to be magnetically nonequivalent in the same solvent and thus four resonances at δ 112.1, 119.9, 134.5 and 144.2, respectively, have been observed (Fig. 1). On complexation, the carbons have displayed both positive and negative c.i.s. The resonances have been identified by Spin Echo Fourier Transformation experiments (Fig. 2).

The electronic spectra of MX_3L (L = $bBzlH_2py$ or $bBzlMe_2py$, X = Cl, Br or I for M = Rh and X = Cl or Br for M = Ir), $RhL_2(ClO_4)_3$ (L = $BzlH_2py$ or $bBzlMe_2py$) and $RhX_3(CO)(bBzlH_2py)$ (X = Cl or Br) complexes in Nujol mull have exhibited an intense band in the range 400–450 nm and is assigned to metal-to-ligand charge transfer transition. Two more

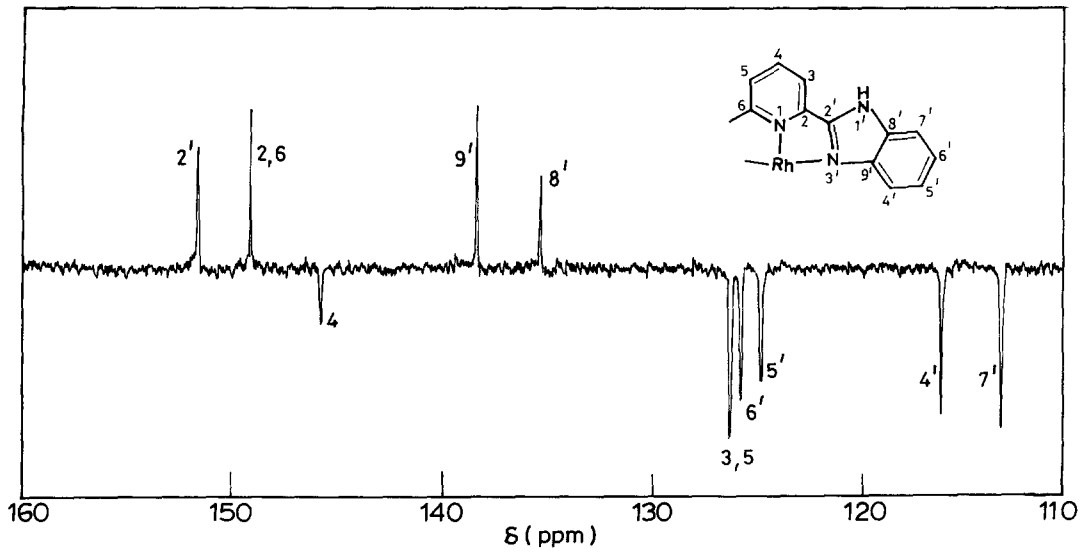

Fig. 2. ^{13}C SEFT NMR spectrum of $[Rh(bBzlH_2py)_2](ClO_4)_3$

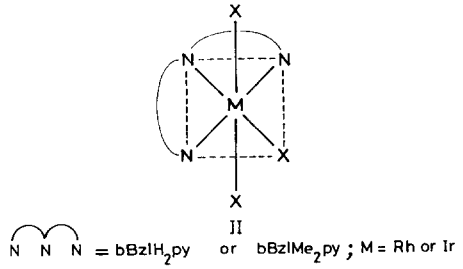
peaks are observed around 500 (weak) and 550 nm (very weak) and are respectively assigned to the $^1A_{1g} \rightarrow {}^1T_{1g}$ and $^1A_{1g} \rightarrow {}^3T_{2g}$ transition of an octahedral low-spin d^6 system [12,13]. The $^1A_{1g} \rightarrow {}^1T_{2g}$ transition is probably obscured in the M → L charge transfer band. The electronic spectra of $MX_3(bBzlH_2py)$, $RhL_2(ClO_4)_3$ and $[RhX_2(CO)(bBzlH_2py)]X$ complexes in DMF are compiled in Table 4. In the case of carbonyl complexes of rhodium(I) and iridium(I) the metal ions have strong reducing character and hence their *d–d* transitions are probably obscured in the intense metal-to-ligand charge-transfer band in the range 400–450 nm [13].

Stereochemistry



The *N*-heterocycles (L) are planar and each would function as chelating tridentate *via* the tertiary nitrogens. Hence, MX_3L complexes possess an octahedral meridional structure **II**. For the complex $[Rh(bBzlMe_2py)_2](ClO_4)_3$ an octahedral structure **III**, wherein each of the planar *N*-heterocycle would function as tridentate, is proposed, the two heterocycles' planes being mutually perpendicular [14]. In the case of $[Rh(bBzlH_2py)_2(OClO_3)](ClO_4)_2$ the solid-state IR spectrum indicated the presence of coordinated and ionic perchlorate and hence structure **IV** for the

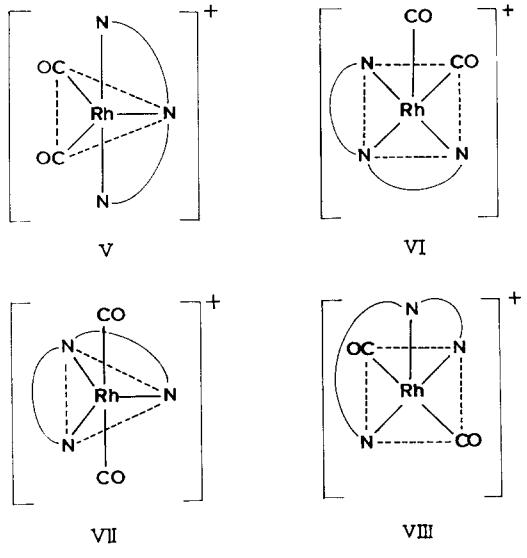
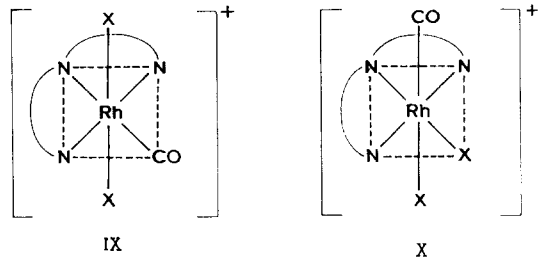
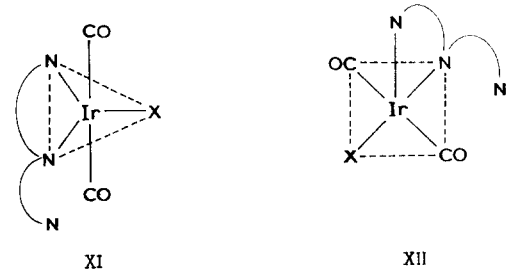
$[Rh(CO)Br_2(bBzlH_2py)]Br$	329(26634), 344(25899), 366(20629), 424(3738)
$IrCl_3(bBzlH_2py)$	315(37960), 331(44060), 343(42910), 364(31740), 430(5647), 514(1091), 565(503).
$IrBr_3(bBzlH_2py)$	333(51810), 439(7980), 515(614), 571(288).
$bBzlMe_2py$	306(51495), 323(61747).
$[Rh(bBzlMe_2py)_2](ClO_4)_3$	326(41724), 368(31517), 401(14879), 421(10310), 441(2569), 484(65), 516(53), 577(15).



[a] ε values are in parentheses.

complex, wherein one of the *N*-heterocycles is tridentate and the other is bidentate with a pendant nitrogen. Such varied coordination behavior for the multidentate *N*-heterocycles have been observed in $[Cu(bBzlMe_2py)_2]ClO_4 \cdot 2H_2O$ [14], $[Co(bBzlH_2py)_2(OClO_3)]ClO_4$ and $[Co(bBzlMe_2py)_2](ClO_4)_2$ [7,15].





The halo/perchlorate dicarbonyl complexes of rhodium(I) are expected to be five-coordinate with the *N*-heterocycle behaving as chelating tridentate. Five-coordinate complexes of rhodium(I) generally conceive trigonal-bipyramidal (tbp) or square-pyramidal (sp) (**V**–**VIII**) configuration [16].

For the complex $[Rh(CO)_2(bBzlMe_2py)]ClO_4$ the 1 : 1 electrolytic behavior in nitrobenzene and a single ν_{CO} peak in the IR region suggest trans disposition of the carbonyls and hence structure **VII** or **VIII** for the cation. The trihalo carbonyl cations may be proposed to have configuration **IX** or **X**, wherein the *N*-heterocycle would serve as a chelating tridentate ligand. Here again it is likely that the complexes exhibit isomerism as the intensities of the two ν_{CO} peaks varied with different preparations.

The halodicarbonyls $[IrX(CO)_2(bBzlH_2py)]$ exhibit a single ν_{CO} peak and hence five-coordinate square pyramidal/trigonal bipyramidal *trans*-COs structures (**XI** or **XII**) with the *N*-heterocycle as chelating bidentate are proposed.

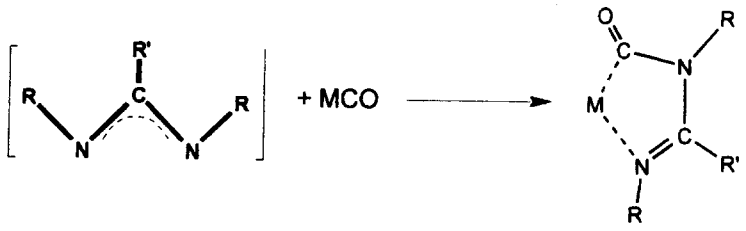
(Received 15 July 1996; accepted 25 July 1996)

Abstract—The purpose of this report is to call attention to the wide range of reactions that an amidine or amidinium may undergo in the presence of reduced metal ions, other than simple ligation of the metal ions. Crystal structures of five examples are presented. In (η-dmpm)Cl_2Ta(μ-NTol)(μ-η^2-HC=NTol)(μ-dmpm)TaCl(η^2-DTolF) (**I**), both fragments from a C—N bond cleavage of the di-*p*-tolylformamidinate anion, $DTolF^-$, namely tolylimido and tolylformimidoyl groups, are found forming bridges between the metal atoms. An amido group is also found in $TaCl_2$(NPh)(DPhF)(HDPhF) (**II**), in which a six-coordinated tantalum atom is surrounded also by two chlorine atoms, a chelating diphenylformamidinate, $DPhF^-$ and a neutral HDPhF molecule. A new neutral chelating ligand forms during the synthesis of $CoCl_2$(PhNCHNPhCHNPh) (**III**), in which the divalent cobalt atom is in a pseudo-tetrahedral environment. The six-membered metallocycle formed by the Co—N—C—N—C—N atoms is essentially planar. Reaction of K with crude $Ta_2(\mu_2$-η^4-$B_2H_6)(\mu$-$DTolF)_4$ produces [(B_2H_5)N(Tol)C(H)N(Tol)]Ta(μ_2-NTol)$_2$(μ_2-DTolF)$_2$Ta[(Tol)NC(H)N(Tol)B_2H_5]·$2Et_2O$ (**IV**), in which a ditantalum unit is bridged by two DTolF and two tolylimido groups. A new ligand formed by fusion of a $B_2H_5^-$ unit to a $DTolF^-$ anion chelates to each of the metal atoms. In the crystals, 50% of the B_2H_5 moieties are BH_3 groups. Coupling of two DPhF anions is observed in PhNC(H)N(Ph)C(H)(NPh)$_2$Ta(DPhF)$_3$·Et_2O (**V**). The new dianion chelates the metal center, to which three other DPhF groups are attached giving an eight-coordinated compound. Copyright © 1997 Elsevier Science Ltd



Keywords: tantalum and cobalt compounds; amidinate cleavage; coupling; borohydride insertion; crystal structure.

Amidinate anions of the type $[RNC(R')NR]^-$ have been widely used as ligands in coordination chemistry [1], where they are usually found intact in monodentate [2] and chelating [3] bonding modes, but also forming bridges between metal atoms [4]. It is in the latter field that many efforts have concentrated in the last few years [5]. Today more elements are known to form metal–metal bonded compounds with amidinate bridges than with the classical carboxylates or any other stereoelectronically similar type of ligand.

Up to now there have been few accounts of reactions in which an amidinate ligand reacted in the presence of a metal ion to lose its identity, either by adding another molecule or by losing some of its atoms to give a different ligand. The best studied reaction is the formation of carbamoyl complexes by insertion of a metal carbonyl into the amidinate ligand [6].

Kilner and collaborators have also studied the orthometalation of several compounds including

* Authors to whom correspondence should be addressed.

those of Pd and Pt with aryl amidinates [7]. Reports have appeared in which the amidinates are severed during the reaction to give imido-containing metal species [8]. Two reactions are also known in which benzonitrile has been a part of the reaction. In one case lithium benzamidinate was reacted with $Pt(PhCN)_2Cl_2$ to give $[Pt\{HNC(Ph)NC(Ph)NH\}_2]$, in which a different chelating mononegative anionic ligand was formed [9]. In the other case thermolysis of $C_6H_5C(NSiMe_3)_2Ti(OPri)_3$ promoted the elimination of C_6H_5CN to form an amide-containing species, namely $(SiMe_3)_2NTi(OPri)_3$ [10].

In this paper we show that the presence of metal species can modify the integrity of the amidinate moiety and thus lead to the subsequent isolation of many interesting but serendipitously obtained products. Most of the compounds were obtained in small yields as byproducts and a few crystals presented minor crystallographic problems such as slight twinning. Some of the structures were initially treated as oddities, but the continued appearance of transformed formamidinates has revealed a pattern of reactivity which can no longer be ignored. Consequently, we are reporting the structures of five compounds containing modified formamidinate species, with the intention of alerting others who may work with these useful ligands to the many unanticipated ways in which they can react.

EXPERIMENTAL

All operations were carried out under an argon atmosphere using standard Schlenk or dry-box techniques. Solvents were purified by conventional methods and distilled under nitrogen from Na/K. Tantalum(V) chloride (resublimed 99.99%) was obtained from Strem. Other chemicals, including HDPhF and $LiBH_4$ were purchased from Aldrich and were used as received. $CoCl_2(HDPhF)_2$ [2b] and $Ta_2(\mu_2\text{-}\eta^4\text{-}B_2H_6)(DTolF)_4$ [11] were prepared according to published procedures. Slightly modified literature procedures were used to synthesize HDTolF [12] and $Ta_2Cl_6(SMe_2)_3$ [13]. Potassium graphite (KC_8) was prepared by heating at 180°C a mixture of potassium metal and graphite with a potassium to carbon mole ratio of 1 : 8 [14].

Preparations

$(\eta\text{-dmpm})Cl_2Ta(\mu\text{-NTol})(\mu\text{-}\eta^2\text{-HC=NTol})(\mu\text{-dmpm})\ TaCl(\eta^2\text{-DTolF})$ (**I**). To a mixture of $Ta_2Cl_6(SMe_2)_3$ (0.38 g, 0.5 mmol) and LiDTolF (1.0 mmol) in toluene (15 cm^3) THF (1 cm^3) was added zinc powder (0.10 g, 1.5 mmol) and dmpm (0.18 cm^3, 1.1 mmol). The solution turned green upon addition of dmpm ligand. The mixture was allowed to react over a period of 4 h in a sonicator and then filtered. Crystals of compound **I** were obtained upon slow diffusion of hexanes (20 cm^3) into the filtrate. Yield 0.25 g, 21%.

$TaCl_2(NPh)(DPhF)(HDPhF)$ (**II**). $TaCl_5$ (1.46 g, 4.1 mmol) and $LiBH_4$ (0.29 g, 13.3 mmol) were mixed in toluene (20 cm^3) and heated to 105°C for 24 h. A dark solid formed. After distillation of most of the toluene, THF (20 cm^3) was added at room temperature. An exothermic reaction was observed. The brown suspension was stirred for 15 min and then cooled to −78°C. Then a solution of LiDPhF (8.2 mmol) in 15 cm^3 THF was transferred to the cold suspension, the mixture was slowly warmed to room temperature and stirred for 4 h. The solvent was removed *in vacuo* and the solid was extracted with benzene (30 cm^3)/hexane (5 cm^3). The solution was filtered through 3 cm Celite. Crystals of $Ta(NPh)(DPhF)_3$ were obtained after layering the solution with hexanes [8b].

To the remaining solid was added toluene (20 cm^3). The red–brown slurry was stirred for 2 h at 90°C. After cooling to room temperature, it was filtered through 3 cm Celite. The filtrate was then reduced to a volume of 15 cm^3 and layered with hexanes (20 cm^3). Red crystals of compound **II** were produced after slow diffusion of hexanes into the toluene solution. Yield 0.46 g, 15%.

$CoCl_2(PhNCHNPhCHNPh)$ (**III**). To a toluene solution of $CoCl_2(HDPhF)_2$ (0.40 g, 0.77 mmol) at −78°C was added 1.5 cm^3 of methyllithium (1.0 M in THF/cumene). After bubbling of methane ceased, the reaction mixture was warmed to room temperature. The solvent was then evaporated under vacuum and the residue was redissolved in a mixture of 10 cm^3 CH_2Cl_2/CH_3CN (1 : 1). Then, an acetonitrile solution of $NOBF_4$ (0.09 g, 0.77 mmol) was added by cannula and the mixture stirred for 1 h. The solvent was evaporated *in vacuo* and CH_2Cl_2 (10 cm^3) was added. After filtration, the solution was layered with hexanes to

produce large, blue needle-like crystals of **III**. Yield 0.035 g, 15%.

$[(B_2H_5)N(Tol)C(H)N(Tol)]Ta(\mu_2\text{-}NTol)_2(\mu_2\text{-}DTolF)_2Ta[(Tol)NC(H)N(Tol)B_2H_5]\cdot 2Et_2O$ (**IV**). To a solution of crude $Ta_2(\mu_2\text{-}\eta^4\text{-}B_2H_6)(DTolF)_4$ (0.80 g, 0.5 mmol) containing about 0.05 mmol of LiDTolF in toluene (30 cm^3) was added potassium metal (0.16 g, 4 mmol). The mixture was refluxed for 30 min and then stirred overnight at room temperature. After filtration the solvent was stripped off under reduced pressure and the solid obtained was extracted with diethyl ether (30 cm^3). A green–brown solution was obtained. After filtration it was placed in a freezer for 2 weeks. Crystals of **IV** suitable for single crystal X-ray analysis were obtained. Yield 0.10 g, 12%.

$PhNC(H)N(Ph)C(H)(NPh)_2Ta(DPhF)_3\cdot Et_2O$ (**V**). To a slurry of $TaCl_5$ (0.54 g, 1.51 mmol) and potassium graphite (0.62 g, 4.6 mmol) in THF (20 cm^3) was added LiDPhF (3 mmol) in THF (15 cm^3) at −30 C. After stirring for 4 h, the solvent was removed by syringe and the remaining dark green solid was dried *in vacuo*. It was extracted with ether (30 cm^3). The green–brown solution obtained after filtration was placed in a freezer for 2 weeks. The color of the solution changed to brown and brown crystals of compound **V** were obtained. Yield 0.095 g, 5%. The solid which remained after the extraction was then treated with 20 cm^3 toluene from which $Ta(DPhF)_4$ was isolated after layering with hexanes [8b].

X-ray structure determinations

Geometric and intensity data for compounds **I, II, III** and **V** were gathered at −60°C with an Enraf–Nonius FAST area detector system, utilizing the program MADNES [15]. Detailed procedures have previously been described [16]. Data for **IV** were collected on a Rigaku AFC5R diffractometer equipped with a Cu rotating anode.

Unit-cell indexing for **I, II, III** and **V** were performed on 50 reflections taken from three 10° ω rotations in the range $0 \leqslant \omega \leqslant 120°$ and unit-cell refinement used 250 reflections in the range $18 \leqslant 2\theta \leqslant 42°$. In each case, the cell dimensions and Laue group were confirmed by axial images. Unit-cell refinement for **IV** utilized 25 high-angle reflections. All data were corrected for Lorentz and polarization effects. An empirical absorption correction based on six ψ-scans was applied for **IV**. For compounds **I** and **V**, the program SORTAV was used to correct for absorption [17]. Data from the FAST diffractometer were processed into SHELX format using the program ABSURD [18]. Data for **IV** were processed using the TEXSAN package [19].

In all structures, the positions of the heavy atoms were found in direct methods E-maps produced by the software solution portion of SHELXTL [20]. Subsequent cycles of least-squares refinement followed by difference-Fourier syntheses revealed the positions of the remaining non-hydrogen atoms. For purposes of structure-factor calculations, hydrogen atoms were usually placed in idealized positions. In some cases, hydrogen atoms were located in difference Fourier maps and then refined isotropically. The positions of the two hydrogen atoms that bridge atoms Ta and B(1) in compound **IV** and the hydrogen atom that attaches to C(3) in compound **V** were obtained following this procedure.

In compound **I**, the two highest residuals of 1.3 and 1.9 e A^{-3} in the final difference Fourier map were found very close to the tantalum atoms. The highest peaks (1.3 and 1.4 e A^{-3}, respectively) in compounds **II** and **V** were 1.5 and 1.0 Å, respectively, from phenyl carbon atoms. The remainder of the final difference maps in these compounds were featureless.

Atom B(2) in compound **IV** was best refined anisotropically with an occupancy factor of 50%. This result indicates the existence of a mixture of $H_3BB(H)_2DTolF^-$ and hydrogen-substituted $HB(H)_2DTolF^-$ ligands. The terminal hydrogen atom in the $HB(H)_2DTolF^-$ moiety was refined with fixed coordinates at half occupancy. The refined model also includes two disordered molecules of diethyl ether either on a two-fold axis (56%) or a general position (44%).

Other details of data collection and refinement are given in Table 1. Selected bond distances and angles for compound **I** are given in Table 2 and a comparison with other coordinated formimidoyl and isocyanide ligands is presented in Table 3. For compounds **II–V**, selected bond distances and angles are found in Tables 4–7, respectively. Other crystallographic data are given as supplementary material.

RESULTS AND DISCUSSION

$(\eta\text{-dmpm})Cl_2Ta(\mu\text{-NTol})((\mu\text{-}\eta^2\text{-HC}{=}\text{NTol})(\mu\text{-dmpm})TaCl(\eta^2\text{-DTolF})$ (**I**)

The reduction of $Ta_2(\mu\text{-}SMe_2)_3Cl_6$ with Zn metal in the presence of bis(dimethylphosphino)methane (dmpm) and LiDTolF yields **I**, the structure of which is shown in Fig. 1. The dinuclear molecule is unsymmetric with six- and seven-coordinated tantalum atoms and has a long metal to metal separation of 2.948(1) Å. The dmpm ligands show two very different modes of bonding: one of them bridges the metal atoms in the usual way [21], while the other acts as a monodentate ligand, a mode which is not common but has also been observed in the solid state for dppm in $[Mo_2Cp_2(\mu\text{-}\eta\text{-}CNBu^t)(\eta\text{-}PPh_2CH_2PPh_2)(CO)_3$ [22] and in solution for dmpe compounds such as $Ru(\eta^2\text{-dmpe})(\eta^1\text{-dmpe})(CNPh)_2$ [23]. The most notable feature of **I** is the reduction and cleavage of a formamidine ligand which gives rise to bridging tolylimide and tolylformimidoyl fragments:

[a] There are two crystallographically independent molecules.

$$[Tol{-}N{-}C(H){-}N{-}Tol]^- \xrightarrow{\text{reduction}} Tol{-}N^{2-} + Tol{-}N{=}C(H)^{\cdot}.$$

The formimidoyl anions must also be present in the reaction from which compound **III** is isolated (*vide infra*).

Since we did not locate the hydrogen atom from our structural study there is of course the possibility that such a fragment could be formulated as an isocyanide. Table 3 shows the structural parameters for some representative compounds in which the formimidoyl and isocyanide fragments bridge metal atoms in a comparable way to that found in **I** [24, 25]. The M—C—N and C—N—R angles are within narrow ranges of 165–174 and 130–137° for the isocyanide compounds, while they are significantly smaller for the formimidoyl compounds. The C—N—R angles of 125(2)° found in **I** are essentially the same as those of the latter. The M—C—N angles are very close to those found in the dinuclear compounds but deviate from those found in trinuclear compounds, as expected.

$TaCl_2(NPh)(DPhF)(HDPhF)$ (II)

From a high temperature reaction of $TaCl_5$ with $LiBH_4$ in the presence of $DPhF^-$, crystals of $Ta(DPhF)_3(NPh)$ and **II** are isolated [8b]. The oxidation state of the metal atom remains unaffected but a formamidinate group is reduced to phenylimide anion, which binds to the tantalum atom in a nearly linear manner as shown in Fig. 2. The Ta—N(5)—C(51) bond angle is 173.6(6)°. As expected, the shortest Ta—N bond distance of 1.778(7) Å corresponds to the $Ta{-}N_{(imide)}$ bond [26], while the longest [2.351(7) Å] is to the corresponding *trans* nitrogen atom which belongs to a chelating formamidine group. The other coordination sites of the six-coordinated molecule (**II**), are occupied by two *cis* Cl atoms and the nitrogen atom of a neutral formamidine molecule. The latter

[a] Atoms labeled with an "A" are symmetry generated by a two-fold axis.

coordination mode has been observed in several compounds, examples of which are those of the divalent metal chloride, such as $MCl_2(amidine)_2$ for M = Fe, Co, Ni and Pt [2]. The ligand dimensions are comparable to those studied before.

$CoCl_2(PhNCHNPhCHNPh)$ (III)

If a reaction mixture containing $CoCl_2(HDPhF)_2$ and methyllithium, which is known to produce $Co_2(DPhF)_4$ and LiCl [27], is reacted with $NOBF_4$ in a mixture of CH_3CN and CH_2Cl_2, then compound **III** is isolated. The crystal structure of the blue compound contains a pseudotetrahedral cobalt atom as shown in Fig. 3. A two-fold axis bisects the Cl—Co—Cl angle and extends along the Co—N(2) vector. The neutral chelating N-[(phenylimino)methyl]methanimidamide ligand obtained can be thought of as formed from the reaction of a formamidine ligand and a phenylformimidoyl fragment from a ruptured formamidinate ligand (see discussion on compound **I**):

$$[PhN—C(H)—NPh]^- + HC{=}NPh^- \xrightarrow{\text{oxidation}} PhNC(H)N(Ph)C(H)NPh.$$

The six-membered metallocycle is planar as found in

[a] Atoms labeled with an "A" are generated by an inversion center.

two other compounds known for the benzyl substituted ligand, namely Cu(acetate)$_2$(BzN(CH)N(Bz)C(H)NBz) [28] and [Hg(BzNC(H)N(Bz)C(H)NBz)$_2$][Hg(C$_2$F$_3$O$_2$)$_4$] [29] and also in the hydrogen-substituted Cu(HNC(H)N(H)C(H)NH)$_2$(ClO$_4$)$_2$ compound [30]. The pattern of shorter bond distances between C(1)—N(1) and longer distance between C(1)—N(2) [1.283(5) and 1.382(5) Å, respectively] is essentially the same in the three compounds. Other compounds containing a planar M—N—C—N—C—N metallocycle or variations thereof are known [31]. However, variations in the nature of the substituents and the charge of the ligand do not allow a meaningful comparison of the molecular dimensions. The Co—N bond distances in **III** are very slightly shorter than those found in CoCl$_2$(HDTolF)$_2$ and CoCl$_2$(HDPhF)$_2$ as are the Co—Cl bond distances [2].

$[(B_2H_5)N(Tol)C(H)N(Tol)]Ta(\mu_2\text{-}NTol)_2(\mu_2\text{-}DTolF)_2Ta[(Tol)NC(H)N(Tol)B_2H_5]\cdot 2Et_2O$ (**IV**)

Reaction of potassium metal with crude $Ta_2(\mu_2\text{-}\eta^4\text{-}B_2H_6)(DTolF)_4$ produces compound **IV**. Fig. 4 shows the molecular structure. The dinuclear molecule possesses a crystallographically imposed inversion center. Two DTolF groups form bridges between the metal atoms which are separated by a distance of 2.6608(7) Å, which is consistent with the presence of a single bond. Two tolylimido groups also bridge the metal atoms. At opposite ends of the ditantalum unit a new type of ligand appears. It is formed by the insertion reaction of a $B_2H_5^-$ molecule into a DTolF group. This reaction is probably similar to the insertion reaction of metal carbonyls into amidinate groups to form carbamoyl units [6] or the reaction of BH_3 and diazaphosphates [32]. The refinement of the crystallographic data indicated that 50% of the molecules in the crystal are the product of insertion of a BH_3 group instead, in which case the third hydrogen atom resides where B(2) is shown in Fig. 5.

As expected, the Ta—N$_{(imide)}$ bond length of 1.976(3) Å found in **IV** is significantly shorter than the other three crystallographically independent Ta—N distances. The B(1)—N(2) distance of 1.535(6) Å compares well with those of other boron–nitrogen-containing species such as polypyrazolylborates [33]. The B(1)—B(2) separation of 1.58(1) Å is slightly shorter than those found in $Ta_2(\mu_2, \eta^4\text{-}B_2H_6)(DArF)_4$, Ar = phenyl and tolyl [1.72(2) and 1.68(2) Å, respectively] [11]. The reason for this shortening is likely to

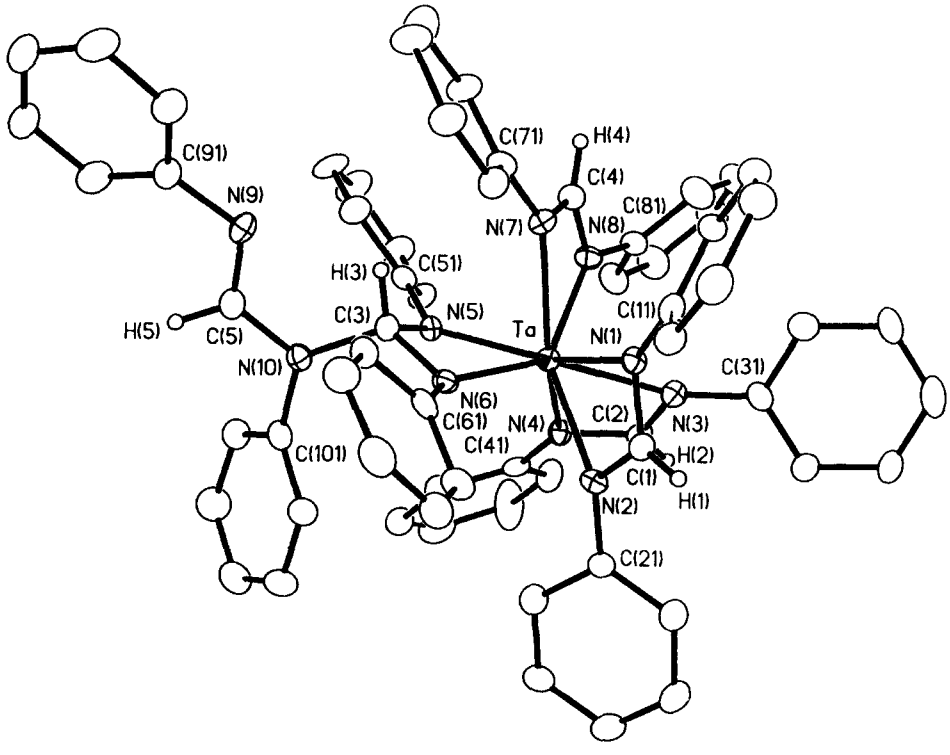

Fig. 6. A drawing of the molecular structure of **V**. Non-hydrogen atoms are represented by their 30% probability ellipsoids.

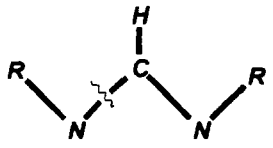
dianion that acts essentially as a diamide. The Ta—N distances to the dianion are shorter (0.12 to 0.22 Å) than those found in Ta—$N_{(DPhF)}$.

Figure 7 is a thermal ellipsoid drawing of the condensed ligand and shows some of the relevant interatomic dimensions. C(3) is clearly an sp^3 hybridized atom with long C—N bond lengths while C(5) is sp^2 hybridized. The C(5)—N(9) separation of 1.287(9) Å is typical for a C—N double bond.



Summary

In the development of the field of metal to metal bonds, carboxylates have played an important role. The ability of amidinates to stabilize a variety of oxidation states throughout the transition series allows the formation of compounds for which no carboxylate analogs are known, as well as analogs of known carboxylate compounds.

As more reactions have been carried out with elements which require more drastic conditions to obtain an oxidation state which might give bonds between the metal atoms, the reactive nature of the amidinate ligand has become more and more evident.

Figure 8 summarizes reactions in which amidinate ligands are modified in the presence of metal-containing species. Examples have been observed of coupling of small molecules such as CO and $B_2H_5^-$ or BH_3 (derived from $B_2H_6^{2-}$ and BH_4^-, respectively) which give rise to N—C and N—B bond formation. Phenylnitrile may be inserted into the amidine or removed from a benzamidine. Classical orthometalation reactions are also known for aryl substituted amidines. An unusual reaction in which two amidinate ligands couple is evidenced by **V**.

Other reactions require cleavage of a formamidine carbon–nitrogen bond which gives imido and formimidoyl fragments.

Both of those entities are present as such in **I**. The imido group frequently finds its way to the metal center to form either M=N—R or $M_2(\mu$-NR) moieties, while the formimidoyl anion may form bonds to the metal atoms as in **I** and **II** or insert into a formamidine anion as in **III** to give a new neutral chelating ligand. Cleavage of carbon–nitrogen bonds has precedent in the coordination chemistry of tantalum [34].

In addition to the unorthodox reaction products reported here, we have also observed an attack on a methyl carbon atom of a chelated acetylacetonate group to produce the anion PhN(H)C(H)C(H)C(O)C(H)C(O)(CH_3) [35]. In still another reaction there is an insertion of two carbon atoms of an acetone molecule between the imido and formimidoyl fragments [36]. Both of these reactions are being studied further and full reports will appear later.

Note added in Proof—Recent evidence found in our laboratory strongly suggests that compound **I** is an isocyanide complex. The presence of arylformimidoyl groups has been established unambiguously in other tantalum complexes (F. A. Cotton, L. M. Daniels, C. A. Murillo and X. Wang, *Inorg. Chem.*, submitted).

Abstract—Two Zintl anions which contain the [tris(ethylenediamine)-zinc]$^{2+}$ cation have been synthesized and structurally characterized by single-crystal X-ray diffraction. When a constant current of 1 mA is applied between a $ZnTe_{10}$ alloy cathode and a Ni plate anode, in a saturated solution of tetrapropylammonium bromide in ethylenediamine, a deep red–purple solution is generated around the cathode as polyanions are generated. After a few days, small, black crystals formed, which were identified by single crystal X-ray diffraction as $[Zn(N_2C_2H_8)_3][Te_3] \cdot 0.5(N_2C_2H_8)$ (**1**). The 1 : 1 : 1 stoichiometric reaction of the Zintl phase K_4SnTe_4 with $ZnCl_2$ in the presence of $(C_2H_5)_4NBr$ in ethylenediamine at 100°C for 1 day in a sealed evacuated quartz tube gave crystals of $[Zn(N_2C_2H_8)_3]_2[Sn_2Te_6] \cdot (en)$ (**2**). The structures of **1** and **2** consist of discrete anions which are surrounded in the solid state by the tris(ethylenediamine)-zinc cations. Copyright © 1997 Elsevier Science Ltd

Keywords: Zintl anion; crystal structure; zinc; tellurium; tin; electrochemical synthesis.

The chemistry of polytelluride complexes has become an increasingly active area of research [1]. This is partially due to the emerging uses of tellurides in industrial settings where they have found application as small-band gap semiconductors, in the preparation of photovoltaic materials and in IR detection devices [2]. There also exists a number of synthetic methodologies available to prepare these types of compounds, which not only circumvent the hazards associated with toxic substances such as H_2Te, but also produce a variety of new and interesting materials. By far, the most commonly used methods are those of the high temperature fusion of the elements [3] and the solvent extraction of alloy phases [4], although other less commonly used techniques such as the treatment of binary alloys with potassium (or other alkali metals) [4a], reactions carried out in molten salts [1d], solventothermal techniques [5] and chemical transport reactions [6] have been employed. We have also recently developed a novel electrochemical synthetic method which allows for the room-temperature generation of Zintl anion clusters from the cathodic dissolution of tellurium alloy electrodes [7]. This electrochemical method has been quite successful for generation of new polychalcogenides and has produced such species as $[Sb_9Te_6]^{3-}$ [8a], $[Sb_4Te_4]^{4-}$ [8a], $[Sb_2Te_5]^{4-}$ [8b], $[Sb_6Te_9]^{4-}$ [8b], $[Sn_2Te_3]^{2}$ [8c], $[Sn_2Te_6]^{4-}$ [8c], $[Au_3Te_4]^{3-}$ [8d], $[GaTe_2] \cdot (en)_2^{-1}$ [8e], $[In_2Te_4]^{2-}$ [8f], $[As_2Te_5]^{2-}$ [8g], $[Hg_3Te_7] \cdot (0.5en)^{4-}$ [8h] and $[Te_{12}]^{2-}$ [8i]. All of these techniques have produced an abundance of new and interesting molecular species, one-dimensional chain materials, layered compounds and even extended three-dimensional solid state structures. They have all been extremely successful as routes to the isolation of stable, solid derivatives of the homo- and heteropolyatomic anions of the heavier main group and

post-transition metals, and have helped to increase our understanding of the bonding modes and chemistry of these species.

In this paper we describe the synthesis and single-crystal X-ray structures of two polytellurides $[Zn(N_2C_2H_8)_3][Te_3]\cdot 0.5(N_2C_2H_8)$ (**1**) and $[Zn(N_2C_2H_8)_3]_2[Sn_2Te_6]\cdot(en)$ (**2**), with zinc-containing counter cations. The structures of both compounds **1** and **2** consist of discrete anions, which are surrounded in the solid state by the tris(ethylenediamine)-zinc cations.

EXPERIMENTAL

General techniques

All reactions and manipulations were performed with the careful exclusion of air and water under a high-purity He or Ar atmosphere. Ethylenediamine (Aldrich) was purified before use first by distillation from CaH_2 followed by multiple distillations from a red solution of K_4Sn_9. The electrochemical cells and quartz tube vessels were dried in an oven at 200°C for at least 2 h prior to use.

Preparation of $[Zn(N_2C_2H_8)_3][Te_3]\cdot 0.5(en)$ (**1**)

The synthesis of compound **1** was performed in a three-compartment, liquid-junction, air-tight electrochemical cell equipped with a Ni plate counter electrode in a saturated ethylenediamine (en) solution of tetrapropylammonium bromide (TPABr) as previously described [7], using a cathode of nominal composition $ZnTe_{10}$. The reaction was run at constant current using an external power supply which was connected to the leads of the cathode and anode and set to run at the maximum current allowed, 1 mA. Application of 1 mA of current resulted in the production of a dark purple stream of anions which surrounded the cathode and then slowly sank to the bottom of the cathode chamber. After approximately 4 days, small black crystals were found growing throughout the cathode chamber and were isolated in 38% yield [9].

Preparation of $[Zn(N_2C_2H_8)_3]_2[Sn_2Te_6]\cdot(en)$ (**2**)

The synthesis of compound **2** was accomplished by the reaction of the Zintl phase K_4SnTe_4 (0.10 g, 0.127 mmol) with $ZnCl_2$ (0.0173 g, 0.127 mmol) and $(C_2H_5)_4NBr$ (0.0267 g, 0.127 mmol) in ethylenediamine (1 cm^3) in a sealed quartz ampoule held at 100°C for 1 day. The K_4SnTe_4 was prepared by the high-temperature fusion reaction of KSn (2.00 g, 0.013 mol) and Te (1.62 g, 0.013 mol) in a quartz vessel under a constant pressure of argon (the KSn alloy was prepared by carefully reacting potassium metal with tin metal in a similar process). This rather violent reaction produces the congruently melting K_4SnTe_4 phase [10] and a tin plug which can be removed from the melt on grinding and recycled into the next reaction. Crystals of $[Zn(N_2C_2H_8)_3]_2[Sn_2Te_6]\cdot(en)$ (**2**) were isolated in approximately 40% yield [11]. The reaction also produces excess Te metal, which is required by the stoichiometry of the reaction and is observed as dark gray powder in the reaction vessel.

Since compound **2** does not contain the $(C_2H_5)_4N^+$ cation, attempts to grow crystals of **2** were tried in the absence of this cation. These reactions typically resulted in the formation of compound **2**, but with an overall decrease in the yield of the product. The role of the $(C_4H_5)_4NBr$ in the reaction process is not understood at this time.

X-ray diffraction analyses

$[Zn(N_2C_2H_8)_3][Te_3]\cdot 0.5(en)$ (**1**). A black block-shaped crystal of approximate dimensions $0.10\times 0.15\times 0.20$ mm was sealed into a glass capillary under an inert atmosphere of helium. X-ray intensity data were collected on a Rigaku AFC7R automatic four-cycle diffractometer equipped with Mo-K_α radiation and an RU300 18 kW rotating anode generator. Cell constants and an orientation matrix for data collection were obtained from the setting angles of 24 carefully centered reflections in the range $20.76 \leqslant 2\theta \leqslant 26.30°$ and corresponded to a primitive monoclinic cell with the unit cell dimensions given in Table 1. The systematic absences of $h0l$: $h+l \neq 2n$ and $0k0$: $k \neq 2n$ uniquely determined the space group to be $P2_1/n$ (no. 14).

The data collection consisted of scans of $(1.05+0.35\tan\theta)°$ in the range $5 \leqslant 2\theta \leqslant 50.1°$, which were made using the ω–2θ scan technique at a speed of 16.0° min^{-1} (in omega). The weak reflections $[I < 20\sigma(I)]$ were rescanned a maximum of four times and the counts were accumulated to ensure good counting statistics. The intensities of three standard reflections were measured after every 150 reflections and, over the course of data collection, decreased in intensity by 8.1%. A linear correction factor was supplied to the data to account for this phenomenon. An empirical absorption correction using the program DIFABS [12] was also applied in the final stages of refinement and resulted in transmission factors ranging from 0.88 to 1.00. The data were also corrected for Lorentz and polarization effects.

The structure was solved by direct methods [13] and refined by F by full-matrix least-squares using the *teXsan* crystallographic software package of Molecular Structure Corporation [14]. All of the non-hydrogen atoms in the structure were refined with anisotropic displacement coefficients. Hydrogen atoms were included in the final model, but were not refined. The final least-squares refinement was based on 1383 observed reflections $[I > 3.0\sigma(I)]$ and 163

variable parameters and converged with $R(R_w) = 0.029(0.028)$, with GOF = 1.54 and $\rho(\max) = 0.58$ e Å^{-3}, $\rho(\min) = -0.46$ e Å^{-3}. Further details of the X-ray structural analysis of **1** are given in Table 1.

$[Zn(N_2C_2H_8)_3]_2Sn_2Te_6\cdot(en)$ (**2**). A black prism-shaped crystal of approximate dimensions $0.20\times0.15\times0.30$ mm was sealed into a glass capillary tube under an inert atmosphere of helium. X-ray intensity data were collected on a Rigaku AFC7R automatic four-circle diffractometer equipped with Mo-K_α radiation and an RU300 18 kW rotating anode generator. Cell constants and an orientation matrix for data collection were obtained from the setting angles of 25 carefully centered reflections in the range $20.04 \leqslant 2\theta \leqslant 30.26°$ and corresponded to a primitive monoclinic cell with the unit cell dimensions given in Table 1. The systematic absences of $h0l$: $h+l \neq 2n$ and $0k0$: $k \neq 2n$ uniquely determined the space group to be $P2_1/n$ (no. 14).

The data collection consisted of scans of $(1.37+0.35\tan\theta)°$ in the range $5 \leqslant 2\theta \leqslant 50.1°$, which were made using the ω–2θ scan technique at a speed of 32° min^{-1} (in omega). The weak reflections [$I < 20\sigma(I)$] were rescanned a maximum of four times and the counts were accumulated to ensure good counting statistics. The intensities of three standard reflections were measured after every 150 reflections and, over the course of data collection, decreased in intensity by 0.4%. A linear correction factor was applied to the data to account for this phenomenon. An empirical absorption correction using the program DIFABS [12] was also applied in the final stages of refinement and resulted in transmission factors ranging from 0.89 to 1.00. The data were also corrected for Lorentz and polarization effects.

The structure was solved by direct methods [15] and refined on F by full-matrix least-squares using the *teXsan* crystallographic software package of Molecular Structure Corporation [14]. All of the non-hydrogen atoms in the structure were refined with anisotropic displacement coefficients. Hydrogen atoms were included in the final model, but were not refined. The final least-squares refinement was based on 3002 unique reflections [$I > 3.0\sigma(I)$] and 172 variable parameters and converged with $R(R_w) = 0.036(0.044)$. Further details of the X-ray structural analysis of **2** are given in Table 1.

RESULTS AND DISCUSSION

Two Zintl anions which contain the [tris (ethylenediamine)-zinc]$^{2+}$ cation have been synthesized, one by electrochemical methods and the other by the reaction of K_4SnTe_4 and $ZnCl_2$ in ethylenediamine in a sealed tube at 100°C. Electrochemical dissolution of a $ZnTe_{10}$ cathode in a saturated solution of tetrapropylammonium bromide in ethylenediamine formed a very dark purple solution from which crystals of $[Zn(N_2C_2H_8)_3][Te_3]\cdot 0.5(N_2C_2H_8)$ (**1**) were obtained. The polytelluride **1** recrystallizes as black, block-shaped crystals which contain one Te_3^{2-} anion, one [tris(ethylenediamine)-zinc]$^{2+}$ cation and half a molecule of ethylenediamine in the crystal lattice, per formula unit. The structure of the cation and anion

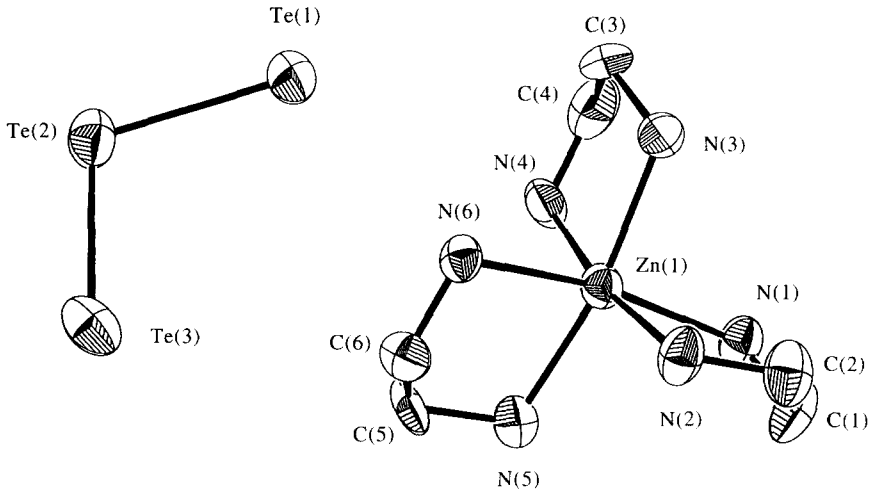

Fig. 1. The structure of $[Zn(N_2C_2H_8)_3][Te_3]\cdot 0.5(en)$ (**1**), showing the atomic numbering scheme and 50% probability ellipsoids. Selected bond distances and angles appear in Table 4.

of **1** are shown in Fig. 1. The Te_3^{2-} anion in **1** consists of three tellurium atoms which are connected by two Te—Te bonds. The anion has a bent structure with a Te—Te—Te angle of 105.24(5)° and Te—Te bond distances of 2.708(1) and 2.720(1) Å, which are similar to the 2.692(5)–2.805(3) Å range of distances and the 100.06–113.1(2)° range of angles found in other tritellurides [16].

A view of the unit cell of **1** down the *a* axis is shown in Fig. 2. This view shows the discrete Te_3^{2-} anions surrounded in the solid state by tris(ethylenediamine)-zinc cations and isolated ethylenediamine molecules. The ethylenediamine molecules of solvation are sufficiently far from the Te_3^{2-} anions, with the closest interaction being 3.68(1) Å, to rule out any interaction between the two, and can therefore be considered as simply solvates of crystallization.

The Zn^{2+} cations in both **1** and **2** are six-coordinate,

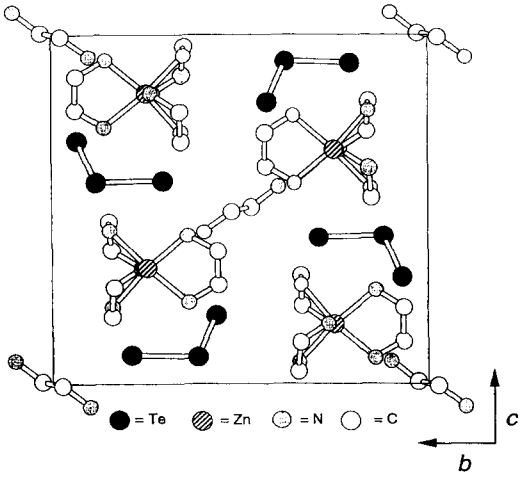

Fig. 2. Unit-cell view of the structure of $[Zn(N_2C_2H_8)_3][Te_3]\cdot 0.5(en)$ (**1**) down the crystallographic *a* axis.

with the Zn atom bonded to three bidentate ethylenediamine ligands. The structure of the [tris(ethylenediamine)-zinc]$^{2+}$ cation from compound **1** is shown in Fig. 1. The geometry around the Zn atoms is that of a slightly distorted octahedron with the N—Zn—N angles ranging from 79.8(4) to 96.4(3)° in **1** and 75.9(4) to 99.2(6)° in **2**.

The structure of compound **1** is most closely related to the structure of $[Ba(en)_3]Te_3$ [16], which also contains Te_3^{2-} anions. However, in the barium-containing structure, the coordination of the three ethylenediamine molecules about the barium is severely distorted by interactions between the Te_3^{2-} anion and the barium atom. This interaction causes the barium atom to be formally ten-coordinate, being bonded to three ethylenediamine molecules, three Te atoms from the Te_3^{2-} unit and one Te atom from an adjacent Te_3^{2-} moiety. This interaction is not seen between the Zn and Te atoms in **1**. This is most likely due, in part, to the large size of Ba^{2+} (effective ionic radius of 1.35 Å) [17] *vs* Zn^{2+} (effective ionic radius of 0.74 Å) [17] and therefore the ability of the barium atom to achieve a higher coordination number than zinc. The Te_3^{2-} anion has also been structurally characterized in K_2Te_3 [18], Rb_2Te_3 [19], Cs_2Te_3 [19], $BaTe_3$ [20] $[Ba(en)_{4.5}]Te_3$ [16] and $[K(2,2,2,\text{-crypt})]_2Te_3\cdot en$ [21], but never before with non-alkali or alkaline earth cations. Furthermore, the previously known Te_3^{2-} compounds were synthesized using more traditional thermal and extraction techniques, rather than using electrochemical methods. Selected bond distances and angles for compound **1** appear in Table 2.

Single crystals of the compound $[Zn(N_2C_2H_8)_3]_2Sn_2Te_6\cdot(en)$ (**2**) were prepared by the reaction of K_4SnTe_4 with $ZnCl_2$ and $(C_2H_5)_4NBr$ in ethylenediamine at 100°C. Compound **2** crystallizes as black prisms which contain the $Sn_2Te_6^{4-}$ anion, tris(ethylenediamine)-zinc cation, and one ethylenediamine molecule of crystallization per formula unit. The $Sn_6Te_6^{4-}$ anion con-

		Sn(1)—Te(2)—Sn(1*)	85.53(3)

sists of an essentially planar Sn_2Te_2 four-membered ring with four terminal Sn—Te bonds (Fig. 3). It can be described as two tetrahedral $SnTe_4$ units, which share an edge to form the $Sn_2Te_6^{4-}$ moiety. The $Sn_2Te_6^{4-}$ anion sits on an inversion center and although it is required to have only this crystallographic center of inversion, has effective *mmm* symmetry making it isostructural to diborane (B_2H_6). The $Sn_2Te_6^{4-}$ anion has been synthesized previously as the tetramethylammonium salt (by the methanol/$(CH_3)_4N^+$ extraction of the K_4SnTe_4Zintl phase) [10], the tetraethylammonium salt [by the reaction of Li_2Te, Te, $LiBH_4$ and $SnCl_2$ in DMF followed by extraction with a solution of $(C_2H_5)_4NCl$ in CH_3CN) [22], and in an electrochemical process involving the cathodic dissolution of a $SnTe_2$ alloy electrode in a saturated ethylenediamine solution of RbI and $(C_2H_5)_4NI$ [8c]. In all cases, the structure of the $Sn_2Te_6^{4-}$ anion retains its structural similarity to diborane.

The charge of 4− on the $Sn_2Te_6^{4-}$ anion is established by the presence of one crystallographically independent tris(ethylenediamine)-zinc^{2+} cation per $SnTe_3$ structural moiety in the asymmetric unit. In the structure of the anion, terminal Te atoms Te(1), Te(1*), Te(2) and Te(2*) each have only one bond and therefore can be considered to have a formal charge of −1. The two internal Te atoms [Te(2) and Te(2*)] are each two-coordinate and, as such, are neutral. This leads to an oxidation state of IV for the Sn atoms, which is expected for Sn in this tetrahedral environment.

The $Sn_2Te_6^{4-}$ anion has two sets of Sn—Te bond distances. The $Sn—Te_{terminal}$ bond distances are 2.6817(9) and 2.6830(9) Å. The $Sn—Te_{bridging}$ bond distances are significantly longer at 2.7865(9) and 2.789(1) Å. The Sn—Sn transannular non-bonded distance is 3.786 Å and that of the Te—Te bonded distance is 4.093 Å. These bond distances are essentially identical to those observed in the other two structurally characterized $Sn_2Te_6^{4-}$ anions.

A unit cell picture of the structure of $[Zn(N_2C_2H_8)_3]_2Sn_2Te_6\cdot(en)$ (**2**) is shown in Fig. 4. As can be seen from this figure, the compound consists

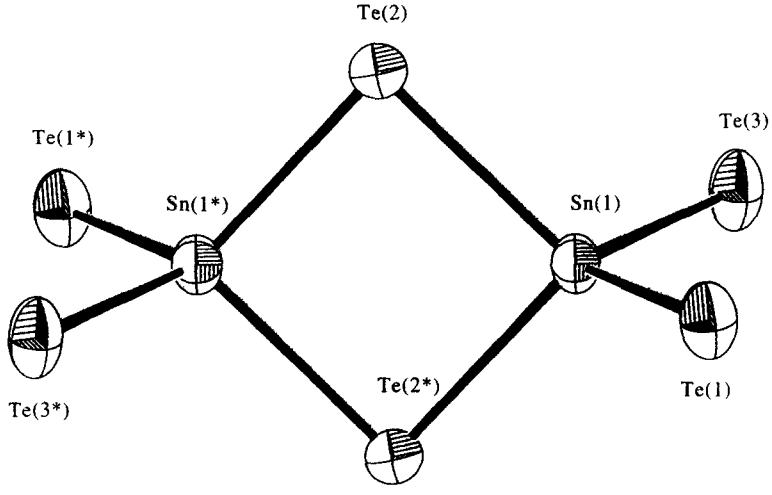

Fig. 3. The structure of the $[Sn_2Te_6]^{4-}$ anion showing the atomic numbering scheme and 50% probability thermal ellipsoids. Bond distances and angles for this anion appear in Table 4.

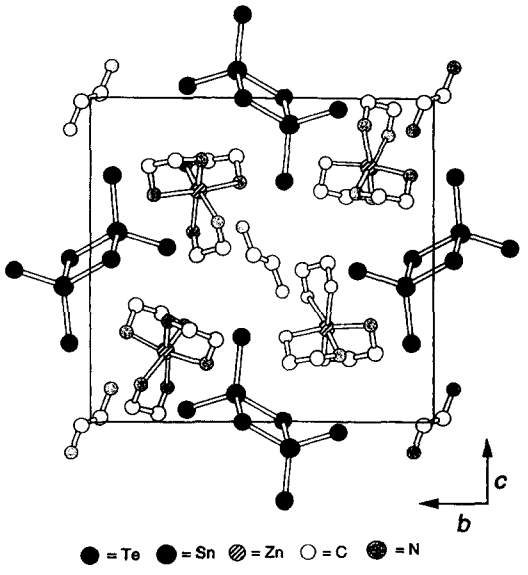

Fig. 4. Unit-cell view of the structure of $[Zn(N_2C_2H_8)_3]_2[Sn_2Te_6]\cdot(en)$ (**2**), down the crystallographic *a* axis.

of completely isolated $Sn_2Te_6^{4-}$ anions surrounded in the solid state by tris(ethylenediamine)-zinc cations and isolated ethylenediamine molecules. The ethylenediamine molecules in the structure are sufficiently distant from the Te atoms (closest N—Te bond distance = 3.881 Å) to preclude the possibility of any hydrogen bonding interactions. As in the crystal structure of **1**, they are present merely as solvates of crystallization.

Both the sulfur and selenium analogs to the $Sn_2Te_6^{4-}$ anion are known and have been prepared by methods involving the methanolothermal reactions of the alkali metal carbonates and the metal disulfides (or diselenides) [23]. All derivatives contain the edge-shared SnX_4 tetrahedra and display approximate *mmm* crystallographic symmetry. Selected bond distances and angles for compound **2** appear in Table 2.

In conclusion, two polychalcogenide Zintl anions containing the tris(ethylenediamine)-$zinc^{2+}$ cation have been synthesized by two entirely different processes, and both in reasonably good yield. The elctrochemical process is still relatively new and continues to yield new and interesting Zintl anions from a variety of main group systems. The second, a more traditional route to the synthesis of Zintl anions, has once again demonstrated its versatility by the synthesis of $[Zn(N_2C_2H_8)_3]_2Sn_2Te_6\cdot(en)$ (**2**).

Supplementary material

Complete tables of experimental crystallographic details, atomic coordinates, bond distances and angles, anisotropic displacement parameters and calculated and observed structure factors for **1** (9 pages) and **2** (10 pages) are available from author R.C.H.

9. Compound **1** was isolated in 38% yield based on 0.389 g (0.290 mmol) of $ZnTe_{10}$ electrode dissolved after 7 days, which gave rise to 0.074 g (0.112 mmol) of $[Zn(N_2C_2H_8)_3][Te_3]\cdot 0.5(N_2C_2H_8)$ crystals that were collected from the cathode chamber. The yield was based on moles of Zn. Electrochemical Yield = moles product/moles e^- passed = 12%. The deep purple color of the solution suggests that some fraction of the polyanions produced are soluble and remain in solution. Qualitative microprobe analysis (Princeton Gamma Technology EDS detector on a Hitachi S-2700 SEM) confirmed the crystals contained Zn and Te in approximately 1 : 3 ratio.

Studies on dinuclear metal complexes of macrocyclic ligands with varying chelate ring size

Chepuri. R. K. Rao and P. S. Zacharias*

School of Chemistry, University of Hyderabad, Hyderabad 500 046, India

(Received 28 June 1996; accepted 24 July 1996)

Abstract—Dinuclear $Cu^{(II)}$, $Ni^{(II)}$ and $Co^{(II)}$ complexes of macrocyclic Schiff-base ligands of 2,6-diformyl-4-methylphenol with α,ω-diamines have been synthesized and characterized. The effect of chelate ring size and saturation of azomethine groups of these ligands on stability, structure and electrochemical properties of the metal complexes has been investigated. Catalytic activity of the metal complexes in the oxidation reaction of 3,5-di-tert-butylcatechol to 3,5-di-tert-butylquinone by molecular oxygen is reported. Copyright © 1997 Elsevier Science Ltd

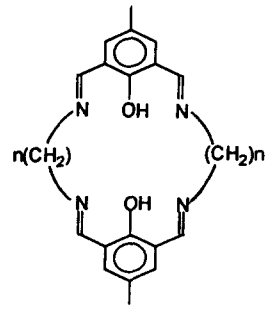
Keywords: macrocycle; Robson ligand; chelate ring; conproportion; antiferromagnetism; mixed valence.

Dinuclear complexes with two metal ions in close proximity show interesting magnetic, catalytic and electron transfer properties. Efforts to synthesize ligands capable of generating such dinuclear complexes have resulted in a large number of dinucleating ligands [1]. One such ligand system is obtained from [2+2] condensation of 2,6-diformyl-4-methylphenol with 1,3-diaminopropane [2]. The dinucleating ability of this ligand system stems from the readiness of phenol to deprotonate and bridge two metal ions in close proximity. Similar macrocyles, called "Robson-type ligands" have been used for studies on homo-, hetero- and mixed-valent [2–4] dinuclear complexes of 3*d* metal ions.

During our efforts to synthesize and study such systems, we have prepared and characterized a number of dinuclear $Cu^{(II)}$, $Ni^{(II)}$ and $Co^{(II/III)}$ metal complexes of unreduced ligands H_2L^1–H_2L^3 and reduced ligands H_2L^4–H_2L^6 (Fig. 1). These ligands have varying chelate ring sizes. The effect of ring size and the saturation of the azomethine groups on stability, structure, electrochemical and catalytic properties of these complexes has been investigated, and the results are presented and discussed here.

EXPERIMENTAL

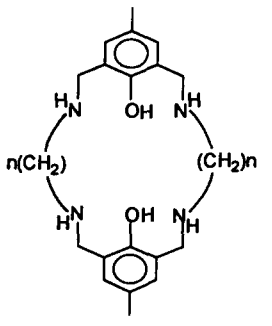
All amines were distilled prior to use. The solvents methanol and ethanol were purified by standard methods [5–8]. Spectroscopic grade *N*,*N*-dimethylformamide (DMF) and, acetonitrile (SD fine chemicals) were used for spectral and electrochemical studies. Metal(II) perchlorates were prepared by treating perchloric acid with the relevant carbonates. CAUTION! All perchlorates are explosion prone and must be handled with care.



Synthesis of ligands and metal complexes

2,6-Diformyl-4-methylphenol was prepared according to the procedure given by Gagne *et al.* [3]. The reduced ligands H_2L^4–H_2L^6 were prepared by the procedure reported by Mandal and Nag [9]. All complexes derived from the ligands H_2L^1–H_2L^3 were prepared by the procedure adopted by Robson *et al.* [2] and complexes derived from reduce ligands H_2L^4–H_2L^6 were prepared by the procedure given by Mandal and co-workers [10,11].

Preparation of $Cu_2L(ClO_4)_2$ *complexes* [L = L^1–L^3, **(1)**–**(3)**]



1,2-Diaminoethane (0.180 g, 3 mmol) dissolved in methanol (10 cm^3) was added to a solution of copper perchlorate (0.74 g, 2 mmol) in methanol (25 cm^3). 2,6-Diformyl-4-methylphenol (0.328 g, 2 mmol) in methanol (25 cm^3) was added while hot and the result-

Fig. 1. Structure of ligands and metal complexes.

ing, mixture was refluxed for 7 h with stirring. The green precipitate $[Cu_2L^1(ClO_4)_2]$ (**1**) was filtered and washed with water. This was recrystallized from a 1 : 1 methanol/water mixture. The complexes $Cu_2L^2(ClO_4)_2$ and $Cu_2L^3(ClO_4)_2$, (**2**) and (**3**), were prepared by similar methods.

Preparation of $Cu_2L'(ClO_4)_2$ *complexes* [L′ = L^4–L^6, (**4**)–(**6**)]

To the ligand H_2L^5 (0.41 g, 1 mmol) dissolved in methanol (10 cm^3) was added an aqueous (10 cm^3) solution of NaOH (0.08 g, 2 mmol). $Cu(ClO_4)_2 \cdot 6H_2O$ (0.74 g, 2 mmol) dissolved in water (10 cm^3) was added and the resulting mixture was refluxed for 3 h. The deep green crystals of **5** formed when cooled to room temperature were filtered and recrystallized from methanol. A similar procedure was adopted for the preparation of complexes **4** and **6** derived from the ligands H_2L^4 and H_2L^6. The resulting green products were recrystallized from methanol.

Preparation of $Ni_2L(ClO_4)_2$ *complexes* [L = L^1–L^3, (**7**)–(**9**)]

The nickel(II) complexes, $Ni_2L^1(ClO_4)_2$ (**7**), $Ni_2L^2(ClO_4)_2$ (**8**) and $Ni_2L^3(ClO_4)_2$ (**9**) were prepared by methods similar to those for corresponding copper(II) complexes. These complexes are orange and yellow in colour.

Preparation of $Ni_2L'(ClO_4)_2$ *complexes* [L′ = L^4–L^6, (**10**)–(**12**)]

To a methanol solution (15 cm^3) of the ligand H_2L^5 (0.41 g, 1 mmol), $Ni(ClO_4)_2 \cdot 6H_2O$ (0.731 g, 2 mmol) and triethylamine (0.3 cm^3, 98%) were added and

refluxed for 1 h. The resulting wine-red solution, on concentration over $CaCl_2$ afforded a pink crystalline compound, $Ni_2L^5(ClO_4)_2$ (**11**). This was filtered and recrystallized from methanol by diffusion of diethyl ether [11]. The complexes derived from H_2L^4 (**10**) and H_2L^6 (**12**) were pink and green, respectively, and were recrystallized from methanol and diethyl ether.

Preparation of cobalt(II/III) *complexes*

The cobalt complexes of unreduced ligands H_2L^1–H_2L^3 (**13–15**) and reduced ligands H_2L^4–H_2L^6 (**16–18**) were prepared by the same procedure as described for the preparation of $Cu_2L(ClO_4)_2$ (L = L′–L^3) and $Ni_2L'(ClO_4)_2$ (L′ = L^4–L^6) complexes, respectively, but under dry nitrogen.

Physical measurements

The C, H, N elemental analyses were performed on a Perkin–Elmer 240C elemental analyser. Conductivity measurements were done on a CM-82T Elico conductivity meter at 25°C in DMF at solution concentrations of *ca* 1×10^{-3} mol dm^{-3}. Infrared spectra were recorded as KBr pellets on a Perkin–Elmer 1310 spectrometer in the region 4000–600 cm^{-1}. Electronic spectra were recorded on a Perkin–Elmer Lamda 3B UV–vis and Cary 17D spectrophotometer. Proton NMR spectra were recorded on a Jeol JEL 980B JNM-FX–100 FT NMR spectrometer in $CDCl_3$ with tetramethylsilane (TMS) as internal standard. Magnetic susceptibility measurements were carried out by the Faraday technique on a Cahn magnetic susceptibility system equipped with a model 4600 adjustable gap electromagnet and Cahn 1000 electrobalance. $Hg[Co(SCN)_4]$ was used as standard. The resultant susceptibilities were corrected for diamagnetism. Cyclic voltammograms were recorded on a PAR electrochemistry system consisting of a model 174A polarographic analyser, a model 175 universal programmer and an RE 0074 X-Y recorder. A model 374 three-electrode cell system, consisting of a Metrohm E410 hanging mercury drop electrode (HMDE), BAS MF2013 Platinum or glassy carbon electrode as working electrodes, PAR model 9331 saturated calomel electrode (SCE) as reference electrode and Pt wire as auxiliary electrode were used. The experiments were carried out for 1×10^{-3} M solutions of the complexes under nitrogen using tetraethyl- or tetrabutylammonium perchlorates (TEAP or TBAP, 0.1 M) as supporting electrolytes at room temperature.

Catalysis experiments were carried out on a Shimadzu UV 200S double-beam, spectrophotometer in methanol using 3,5-di-t-butylcatechol (3,5-DTBC) as substrate. A methanol solution of 3,5-DTBC (1×10^{-3} M) and the respective copper(II), nickel(II) or cobalt(II/III) complexes (0.02×10^{-3} M) in a 10 cm^3 standard flask was kept under nitrogen. The characteristic absorbance band of 3,5-di-t-butylquinone (3,5-DTBQ) at 400 nm (ε/mol^{-1} dm^3 cm^{-1} = 1900 in methanol [12]) was taken as a measure of quinone formation. Absorbance was measured at regular intervals after exposing the solution to air.

RESULTS AND DISCUSSION

The ligands H_2L^1–H_2L^3 shown in Fig. 1 were generated *in situ* in the presence of metal perchlorates following the template synthesis procedure [2]. Complexes of these ligands exhibit characteristic IR bands at 1640 cm^{-1} due to —HC=N— and at 1100 and 620 cm^{-1} due to perchlorate ions. The reduced ligands H_2L^4–H_2L^6 are white crystalline compounds and are obtained in low yields. They are characterized by analytical, IR and NMR techniques. IR spectra of these ligands do not show the band at 1640 cm^{-1} indicating complete reduction of —HC=N— to —NH—CH_2—. In addition they show sharp bands at *ca* 3200 and 1600 cm^{-1} assignable to the ν_{NH} and δ_{NH} modes of the secondary amino group of the ligand. A broad band at *ca* 3500 cm^{-1} assigned to the ν_{OH} mode of phenol. The electronic absorption spectra of these ligands in DMF show two absorptions at *ca* 289 and 265 nm in the UV region. The $\pi \rightarrow \pi^*$ transition of azomethine (—HC=N—) group at *ca* 340 nm is absent.

Copper(II) *complexes*

Synthetic details of the complexes are given in the experimental section. The complex **1** is reported in the literature as the chloride salt [13], while complex **2** is known as the perchlorate salt [14], complex **1** is recrystallized from 50% aqueous methanol. Complex **2** is recrystallized from water and complex **3** is thoroughly washed with hot methanol to obtain pure compounds. The complexes of the ligands H_2L^4–H_2L^6 are green in colour and are recrystallized from methanol [15]. The purity of all these complexes was checked by C, H, N elemental analysis and the data are collected in Table 1. The complexes have the composition $[Cu_2L^n(ClO_4)_2]$ (n = 1–6) and the structure is shown in Fig. 1.

The positions of the characteristic peaks in the IR spectra and their assignments based on comparison to the related complexes [2] are presented in Table 2. Conversion of the aldehyde groups onto Schiff-base derivatives is indicated by the absence of the aldehyde HC=O stretching band at 1680 cm^{-1} and the appearance of a strong band at 1640 cm^{-1} assignable to the —HC=N— group. The complexes **1**, **3** and **4–6** exhibit a band centred between 3450 and 3500 cm^{-1} originating from ν_{OH} of water present. The ν_{NH} and δ_{NH} absorptions originating from the ligands are seen at *ca* 3200 and 1600 cm^{-1}, respectively. IR spectra show ν_3 and ν_4 absorptions of perchlorate ion at 1100 and 630 cm^{-1}, respectively. The band at 1100 cm^{-1}

Table 1. Analytical data of complexes

Complex	Analysis % (calculated) C	H	N
1·H_2O	37.0 (36.8)	3.5 (3.4)	7.7 (7.8)

18·2MeOH	41.1 (41.0)	5.7 (5.6)	7.0 (6.8)

for these complexes is broad, indicating possible coordination of perchlorate ion in the solid state [16].

The μ_{eff} at room temperature for complexes **1**–**3** are 1.10, 0.77 and 1.34 B.M., respectively (Table 2). The reported magnetic moment of the known complex **2**, is 0.46 B.M. [14]. The experimental difficulty of measuring the susceptibilities of weakly paramagnetic, spin-coupled systems led to variations in the values reported by various groups. For example, the complex $[Cu_2L(X)_2]$ (X = Cl^-, ClO_4^-) is reported to exhibit μ_{eff} values of 0.47 [14], 0.6 [4] and 0.74 B.M. [17] at room temperature. The μ_{eff} values of the present complexes are less than the spin-only value for one unpaired electron and indicate antiferromagnetic interactions between the copper(II) centres. Antiferromagnetic interaction has already been established in complex **2** [14]. The μ_{eff} for complexes **4**–**6** fall in the range of 0.8–1.1 B.M. and suggest antiferromagnetic interaction in these complexes also.

Electronic spectra. The electronic spectra of the complexes are recorded in DMF and the data are collected in Table 2. The complexes exhibit one high intensity band in the range 360–420 nm in the UV region and another in the visible region 545–770 nm. The high intensity band in the UV region may be owing to a combination of a $\pi \rightarrow \pi^*$ transition of HC=N— and ligand to metal charge transfer transitions. The charge transfer may be from the *p* orbital of coordinated phenolic oxygen to the vacant *d* orbitals of copper(II). Similar charge transfer bands have been observed in several oxo-bridged copper(II) complexes [18]. In comparison with electronic spectral data of complexes of similar ligands [2,3,14,19–21],

[a] In DMF.
[b] At room temperature.
[c] Diamagnetic.
[d] Insoluble.

the complex **1**, which has a ligand field band at 545 nm, could be square pyramidal. This geometry is achieved by the coordination of one perchlorate group each to the copper(II) atoms in a *trans* axial fashion in the solid state. The IR spectrum of this complex indicates coordinated perchlorate groups. Complex **2** is shown to have a distorted octahedral structure in the solid state [14] by the coordination of two perchlorate groups. The electronic spectrum of complex **2** in DMF shows two overlapping bands at *ca* 770 and 640 nm. Complex **3** has a band at 670 nm, which lies in between the band positions of the square pyramidal complex **1** and octahedral complex **2**. The IR spectrum of this complex shows a coordinated perchlorate group and analytical data indicate the presence of two water molecules. The red shift of the absorption band of **3** with respect to **1**, and the blue shift with respect to **2**, may arise through weak coordination of a water molecule to each copper centre, thereby providing an octahedral geometry wherein one of the axial positions is occupied by a coordinated water molecule and the other by a perchlorate group. The conductivity experiments show that these complexes are 1 : 2 electrolytes [22]. The two coordinated perchlorate groups of the complexes have been replaced by solvent DMF molecules in solution.

The ligand H_4L^5 is reported to form a copper(II) complex of composition $[Cu_2L^5(H_2O)_2](ClO_4)_2$ with square pyramidal geometry [23], with an electronic band at 574 nm. This complex is green and has a magnetic moment of 0.5 B.M. Complexes **4–6** are green in colour and exhibit *d–d* bands in the range 580–610 nm. Since IR spectra indicate perchlorate coordination, these complexes are suggested to possess a square-pyramidal structure with axial coordination of perchlorate ions to the copper(II) centres. The conductivity experiments for these complexes show that they are 1 : 2 electrolytes and indicate replacement of perchlorate groups in solution by solvent DMF molecules.

Electrochemistry. Redox properties of complexes **1**, **2** and **4–6** have been investigated in DMSO solvent using a glassy carbon electrode. Cyclic voltammograms of representative complexes **2** and **6** are shown in Fig. 2. The complexes undergo stepwise reductions at two different potentials. This is similar to the behaviour observed for related complexes [17]. The two redox couples are seen at *ca* −0.49, −1.07 V for complex **1**, and at *ca* −0.34, −0.76 V for **2** with reference to the SCE. Complex **3** gave only ill-defined peaks. A comparison of the first one-electron reduction potential for the two complexes indicates that the electron transfer is more facile in complex **2**. Ligand flexibility associated with the butylene bridge may be responsible for this. Such an effect has been noticed previously [14]. The ΔE_p values of the two redox couples are, 120 and 80 mV for complex **1** and 80 and 120 mV for complex **2**. These values show that redox couples involve quasi-reversible one-electron processes. The proposed mechanism involves $Cu^{II}/Cu^{II} \rightarrow Cu^{I}/Cu^{II}$ and $Cu^{I}/Cu^{II} \rightarrow Cu^{I}/Cu^{I}$ stepwise reductions. The stability of mixed-valence Cu^{I}/Cu^{II} complex intermediate expressed by the conproportionation constant, K_{con}, for the equilibrium

$$[Cu^{II}/Cu^{II}] + [Cu^{I}/Cu^{I}] \overset{K_{con}}{\rightleftharpoons} 2[Cu^{I}/Cu^{II}]$$

is given by $K_{con} = \exp(nF(\Delta E)/RT)$ where $\Delta E = E^1_{1/2} - E^2_{1/2}$. The larger the separation between the potentials of the couple (ΔE), the greater the stability of the mixed-valence species with respect to conproportionation. The K_{con} values have been estimated for the complexes. The higher value of K_{con} (6.5×10^9) for **1** compared with **2** (1.3×10^7) indicates that the intermediate species, Cu^{II}/Cu^{I} is more stable for complex **1**. The electrochemical data are given in Table 3.

The complexes **4–6** behaved in a similar way. The CV data are collected in Table 3. These complexes undergo stepwise one-electron reductions. Comparison of $E^1_{1/2}$ values of the complexes show that the first electron addition is facile for complex **6**. This trend is observed for the copper(II) complexes **1** and **2** (unreduced forms of **4** and **6**) and is also known from the literature [24]. Comparison of $E^1_{1/2}$ values shows a negative shift for complexes **4** and **6**. This indicates that Cu^{I} states are destabilized when the ligands are saturated. This may result from the ability of the unsaturated macrocycle to accept electrons from copper(I) through the antibonding orbital of C=N linkages, whereas the saturated macrocycle acts solely as an electron donor [15,25].

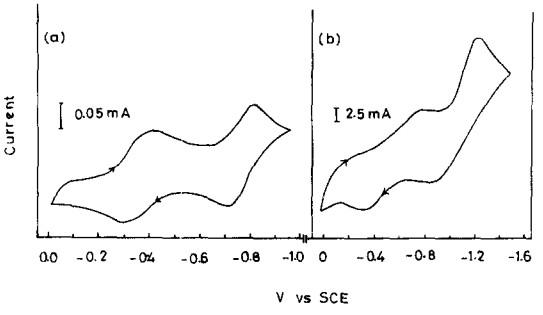

Fig. 2. Cyclic voltammograms of copper(II) complexes **2** (a) and **6** (b). The scan rate is 100 mV s^{-1}.

Nickel(II) complexes

The nickel(II) complexes **7–9** are obtained as orange and yellow solids. Complexes **10** and **11** are pink and complex **12** is green. These complexes are recrystallized from their methanol solutions by diffusion of diethyl ether. The analytical data for the complexes are collected in Table 1. Complexes **7–9** and **10** have the composition $[Ni_2L^n]^{2+}$, while the other complexes have the composition $[Ni_2L^n(MeOH)_2(ClO_4)_2]$. The structure of the complexes is shown in Fig. 1.

IR spectral data for the complexes are collected in

Table 3. Electrochemical data of copper(II) complexes

Complex	Cu^{II}/Cu^{II}–Cu^{II}/Cu^{I} $E^1_{1/2}$ (V)	ΔE_p (mV)	Cu^{II}/Cu^{I}–Cu^{I}/Cu^{I} $E^2_{1/2}$ (V)	ΔE_p (mV)	K_{con}
1	−0.490	120	−1.07	80	6.5×10^9
2	−0.34-	80	−0.760	120	1.3×10^7
4	−0.590	380	−1.150	200	2.96×10^9
5	−0.710	120	−1.060	100	8.3×10^5
6	−0.500	380	−0.950	200	4.09×10^7

Table 2. Broad bands are observed at *ca* 3400 cm^{-1} for complexes **7**–**9** indicative of lattice water and intense bands at *ca* 1640 cm^{-1} owing to HC=N— groups. The ν_3 absorption of the perchlorate group at *ca* 1100 cm^{-1} is seen as a sharp band and indicates the non-coordinated nature of the group, while the ν_4 absorption is seen at 630 cm^{-1}. The conductivity measurements in DMF show that the complexes behave as 1 : 2 electrolytes [22]. The conductivity data are collected in Table 2. All the complexes are diamagnetic which suggests a square-planar geometry. The IR spectra of complexes **11** and **12** exhibit a broad band centred at 3400 cm^{-1} indicating the presence of water or methanol. The C, H, N analytical data show two and three methanol molecules, respectively, are present in these complexes. The ν_3 band ofClO_4^- in complexes **11** and **12** at 1100 cm^{-1} is broad and indicates coordination to the metal centres. The ν_4 band is seen at 620 cm^{-1}. The ν_{NH} and δ_{NH} of the —NH— group are seen at *ca* 3200 and 1600 cm^{-1}, respectively, for complexes **10**–**12**. Conductivity experiments on these complexes show that they are 1 : 2 electrolytes.

Electronic spectra. The electronic spectra of the complexes **7** and **8** were measured in DMF solvent. Complex **9** is insoluble. The spectral data are collected in Table 2. The complexes show two high intensity bands in the range 360–410 nm in the UV region and one band in the 470–570 nm in the visible region.

The nickel(II) ion with a d^8 electronic configuration has a tendency to form four-coordinate, diamagnetic, planar complexes, especially with stronger ligands or where steric hindrance restricts higher coordination numbers. Such complexes exhibit a single *d*–*d* band in the range 400–550 nm and are often orange, yellow or red. The one *d*–*d* band in the diamagnetic, square-planar nickel(II) complexes is assigned to the $^1A_1(F) \rightarrow {}^1B_1$ transition [26,27]. The two high intensity bands at *ca* 370 and 400 nm for complexes **7** and **8** in the UV region can be interpreted as the intraligand $\pi \rightarrow \pi^*$ transition of the azomethine group and charge transfer from ligand to metal; similarly to the copper(II) complexes. It is noteworthy that the nickel(II) complex analogous to **7** with chloride as anion, $Ni_2L^1Cl_2 \cdot 3H_2O$, is also planar with a similar electronic spectrum [13].

Electronic spectra of the complexes **10**–**12** were measured in DMF and the data are collected in Table 2. The known complex **11** $[Ni_2L^5(CH_3OH)_2(ClO_4)_2]$, with distorted octahedral geometry exhibits electronic bands at 1160, 810, 750, 495, 375 nm. These bands are assigned to transitions from $^3B_{1g}$ to ^3E_g, $^3B_{2g}$, $^3A_{2g}$, ^3E_g, $^3A_{2g}$ and/or $^3E_g(P)$ in a tetragonally distorted octahedral field [11]. Complex **12** exhibits bands at 885, 770, 486 and 360 nm similar to complex **11**. Thus, this complex should also have a tetragonally distorted octahedral structure. This geometry is achieved by coordination of both methanol and perchlorate ions to each of the nickel centres. However, complex **10** exhibits bands at 1040 and 482 nm in DMF in the visible region, which is different from that of **11** and **12**. It has been established that [28] squeezing the macrocycle H_2L^5 by replacing one of the diaminopropane lateral chains [—NH—$(CH_2)_3$—NH—] with a diaminoethane chain [—NH—$(CH_2)_2$—NH—], generated a dinickel complex with one octahedral and one square-planar nickel centre. Since complex **10** has only diaminoethane as a bridging unit on both sides, two square-planar nickel(II) centres can be expected for this complex. The room temperature magnetic moment values for complexes **10**–**12** are given in Table 2. The μ_{eff} values for complexes **11** and **12** are in the range 3.1–3.31 B.M. and fall in the range usually observed for octahedral nickel(II) complexes and are comparable to related systems [11,28]. However, complex **10** is also paramagnetic, with a low μ_{eff} value (1.65 B.M. per nickel) at room temperature, which is contrary to the diamagnetism expected for square-planar complexes. This may be caused by the possible intermolecular interaction of nickel atoms with phenolic oxygens of other molecules in the solid state. Similar types of interactions have been reported in *N*,*N*′-polymethylenebis(salycilaldimine)nickel(II) complexes with a μ_{eff} value of 1.6 B.M. and electronic bands at 600 and 1000 nm [29].

Cobalt(II/III) *complexes*

The cobalt(II) complexes, **13** and **16,** are highly unstable and are obtained as black cobalt(III) complexes, while the other cobalt(II) complexes are stable and are brown in colour. Complexes **13–18** were recrystallized from methanol solutions by diffusion of diethyl ether. The cobalt(II) complexes have the general composition $[Co_2L''(ClO_4)_2]$. The general structure of the complexes is shown in Fig. 1.

IR spectra of these complexes indicate the presence of water or methanol as the ν_{OH} absorption is seen as a broad band at *ca* 3400 cm^{-1}. Sharp, intense bands are seen at 1640 cm^{-1} for complexes **13–15** and are assigned to —HC=N— groups. The analytical data in Table 1 suggest that two water molecules are present in the complexes. The broad bands centred at *ca* 1100 cm^{-1} are assignable to the ν_3 mode of the perchlorate group. The ν_4 absorption is seen as a sharp band at 630 cm^{-1}. The bands at *ca* 3200 and 1600 cm^{-1} are assigned to the ν_{NH} and δ_{NH} modes of the —NH— group.

Room temperature magnetic moments for complexes **13–18** are collected in Table 2. The cobalt(III) complex (**13**) is diamagnetic and presumably six-coordinated. The μ_{eff} values for **14** and **15** fall in the range expected for pseudo-tetrahedral or five-coordinate geometries. For complexes **14** and **15** a tetrahedral arrangement may not be favoured owing to the dinuclear nature of these complexes. An analogous dicobalt(II) complex [2] $[Co_2LCl_2]$ ($n = 3$, unreduced ligand), possesses a square-pyramidal geometry with a μ_{eff} value of 4.61 B.M. The μ_{eff} values for complexes **14** and **15** are 4.67 and 4.62 B.M., respectively. Square-pyramidal geometry appears to be reasonable for these complexes with two perchlorate groups coordinating to the two cobalt(II) ions [2, 27]. Room temperature magnetic moments for complexes **16–18** are given in Table 2. The cobalt(III) complex **16** is diamagnetic [30]. The other complexes, **17** and **18** exhibit μ_{eff} values in the range 4.7–4.8 B.M. per metal atom. The magnetic moment for high-spin, five-coordinate cobalt(II) complexes falls in the range 4.5–4.8 B.M. Thus, a square-pyramidal geometry with two perchlorate groups coordinating to each cobalt(II) ion is a distinct possibility [2] the conductivity measurements in DMF show that these complexes are 1 : 2 electrolytes (Table 2). This indicates that the perchlorate groups are replaced by solvent DMF molecules in solution.

Electronic spectra. The electronic spectra of these complexes were recorded in DMF and the data are collected in Table 2. The complexes show one high intensity band at *ca* 400 nm in the UV region and no bands are observed in the visible region. Because of intense UV bands tailing into the visible region, the *d–d* bands might have been masked. Dinuclear cobalt(II) systems have been reported where *d–d* bands are masked by such high intensity UV bands [31]. Therefore, electronic spectra in the visible region have not been effective in differentiating between square pyramidal or octahedral geometry for these complexes. The cobalt(III) complex **16** shows one band at 600 nm assignable to the $^1A_{1g} \rightarrow {}^1E_g$ transition, as expected for low-spin, six-coordinated cobalt(III) complexes [32]. The other complexes do not show any bands in the visible region.

Catalytic properties

It has been shown that magnetically interacting dinuclear complexes are catalytically active for the oxidation of two-electron donors such as 3,5-di-t-butylcatechol (3,5-DTBC) and ascorbic acid [33, 34]. The proposed pathway for the electron transfer between ascorbic acid and the dinuclear copper(II) complex involves a steric match between the donor and acceptor [33] and subsequent transfer of an electron, forming a Cu^I intermediate species. The formation of Cu^I species is generally evidenced by the disappearance of *d–d* bands in the visible absorption spectra. Although the complete mechanism of the catalytic process involved in oxidation of 3,5-DTBC is not yet established, it probably involves a 1 : 1 adduct between the complex and DTBC which requires a metal–metal distance of *ca* 3–4 Å. This adduct reacts with dioxygen to form the starting complex and 3,5-DTBQ.

The copper(II), nickel(II) and cobalt(II/III) complexes were examined for catalytic activity in the oxidation of 3,5-DTBC by molecular oxygen to the quinone, DTBQ. This is monitored by measurement of the 400 nm (ε/mol^{-1} dm^3 cm^{-1} = 1900 in methanol) [12] absorption band characteristic of 3,5-DTBQ. Catalytic activity is checked for a 50 : 1 molar ratio of catechol to the complex, except for the cobalt(III) complexes **13** and **16** for which it is 100 : 1. The results are summarized in Table 4. The reactions between ascorbic acid and the copper(II) complexes were also examined. These complexes failed to react with the acid.

The experiments on copper(II) complexes show that complexes with unreduced ligands (H_2L^1–H_2L^3) are more active than those with reduced ligands (H_2L^4–H_2L^6). The time-dependent growth of 3,5-DTBQ catalysed by copper(II) complex **4** is shown in Fig. 3 (a). The nickel(II) complexes are less active. The cobalt(III) complexes are found to be good catalysts. The Co^{III} complex **13** converts 97% in 3 h. Figure 3 (b) shows the time-dependent growth of 3,5-DTBQ catalysed by complex **13**. The other complex, **16,** converts 95% of 3,5-DTBC in 6 h. The catalytic efficiency of the complexes decreases in the order $Co^{III} > Co^{II} > Cu^{II} > Ni^{II}$.

(Received 17 April 1996; accepted 24 July 1996)

Abstract—Various dithiocarbamates of As^{III}, Sb^{III} and Bi^{III} with diethyldithiocarbamic acid (dedtc), *N*-methylaminoethanoldithiocarbamic acid (nmedtc) and *N*,*N*′-iminodiethanoldithiocarbamic acid were subjected to cyclic voltammetric reduction studies with a glassy carbon working electrode. One-electron reduction processes occurs around −1.0 V for As and Sb complexes and around −0.5 V for Bi complexes which are completely irreversible. Attachment of the polar ends of the molecule is indicated by the pre- and post-reduction adsorption processes. As the number of $—CH_2CH_2OH$ groups increases, the peak currents increase. In the case of Bi complexes, the reduction process tends to become reversible. In addition, the larger peak current associated with the third response indicates the possible reduction of $Bi(dtc)_2(DMF)_n$.

In all the complexes the dtc^- ion was lost from $M(dtc)_3^-$ species, with oxidization around +0.6 V in the reverse scans. The crystal structures of $As(deadtc)_3$ (**1**), $Sb(deadtc)_3$ (**2**) and $Bi(deadtc)_3$ (**3**) were determined by single crystal X-ray analysis.

The coordination polyhedron in $As(deadtc)_3$ is a distorted trigonal antiprism, with three strong (2.33–2.35 Å) and three weak (2.82–2.86 Å) As—S bonds. $Sb(deadtc)_3$ has a coordination polyhedron which can be described as a distorted pentagonal pyramid. One of the Sb—S bonds is very short (2.46 Å) and differences between others are not significant owing to the larger size of antimony compared with arsenic. The stereochemical requirement of the lone pair on Sb has a more pronounced effect in disturbing the neighbouring atoms than that observed in the corresponding As compounds. The binuclear $Bi_2(deadtc)_6$ complex is centrosymmetric, two bidentate ligands being bridged in such a way that each sulfur atom is simultaneously bonded to both metal ions. The resulting coordination polyhedron can be described as a distorted square antiprism. The asymmetry in the M—S (M = As, Sb, Bi) bonds is a consequence of the stereochemical requirement for the ligand and the lone pair of electrons on the metals. This is supported by the valence bond sums (VBS) calculated for the complexes. Copyright © 1997 Elsevier Science Ltd

Keywords: crystal structures; electronic effects; alkyl substituents; dithiocarbamates; cyclic voltammetry.

Group VA elements, such as As, Sb and Bi, provide interesting variations in their reactivities related to the gradual increase in metallic character down the group [1]. Various compounds of these elements were extensively used as medicines in the treatment of syphilis, kala-azar, elephantiasis and yaws but their use has been discouraged because of their toxicity [2,3]. A recent discovery that colloidal bismuth subcitrate (CBS) was useful in treating peptic ulcers has increased interest in the chemistry of these elements [4–6], as has the use of these elements in high-temperature superconductors [7,8].

Recently, a few studies on dithiocarbamato complexes of As, Sb and Bi have been reported [9–13]. As a continuation of our interest in sulfur-containing ligands [14–16], we report here the synthesis and cyclic voltammetric studies of various $M(dtc)_3$ complexes [M = As^{III}, Sb^{III}, Bi^{III}; dtc = *N,N'*-diethyldithiocarbamate (dedtc), *N*-methylaminoethanoldithiocarbamate (nmedtc), *N,N'*-iminodiethanoldithiocarbamate (deadtc)] along with the X-ray crystal structures of $As(deadtc)_3$, $Sb(deadtc)_3$ and $Bi(deadtc)_3$.

EXPERIMENTAL

Materials

$AsCl_3$, Sb_2O_3, $BiONO_3$ and *N,N'*-iminodiethanol, *N*-methylaminoethanol, *N,N'*-diethylamine from BDH/E-Merck were used as received.

N,N'-Imminodiethanoldithiocarbamic acid (0.03 mol) was prepared from 2.8 cm^3 of *N,N'*-iminodiethanol and 1.8 cm^3 of carbon disulfide in methanol under cold conditions (5°C).

Tris(N,N'-*iminodiethanoldithiocarbamato*)*arsenic* (III), $As(deadtc)_3$

A freshly prepared yellow dithiocarbamic acid solution (0.03 mol) was added to arsenic chloride (0.8 cm^3, 0.01 mol) in methanol (10 cm^3) with continuous stirring. The white dithiocarbamato complex separated out on neutralization of the excess acid by passing ammonia. Yield 60%, m.p. 107–110°C. Crystals suitable for X-ray analysis were obtained from methanol.

Tris(N,N'-*iminodiethanoldithiocarbamato*)*antimony* (III), $Sb(deadtc)_3$

Antimony trioxide Sb_2O_3, (1.5 g, 0.05 mol) was dissolved in concentrated HCl solution (5 cm^3) and the volume of the solution was reduced to 50% by boiling. After cooling the freshly prepared *N,N'*-iminodiethanoldithiocarbamic acid solution (0.03 mol) was added with continuous stirring. The resulting pale yellow solution gave a pale yellow complex after passing ammonia gas. Yield 70%, m.p. 130–132°C. Suitable crystals for X-ray analysis were obtained from a methanolic solution of the compound.

Tris(N,N'-*iminodiethanoldithiocarbamato*)*bismuth* (III), $Bi(deadtc)_3$

Bismuth oxynitrate $BiONO_3$ (2.9 g, 0.01 mol) was dissolved in concentrated HCl solution (5 cm^3) and the volume of the solution was reduced to 50% by Patterson and Fourier methods, alternated with cycles of least-squares refinement of the atomic parameters. Hydrogen atoms were located on the Fourier difference maps but were generally introduced in the calculated positions with fixed C—H distances and isotropic temperature factors (C—H = 1.08 Å, U_{iso} = 0.08 $Å^2$). It was not possible to locate the H atoms of the terminal OH groups in the Bi compound because of the partial disorder in the chains. Anisotropy was introduced for all non-hydrogen atoms. Refinement of scale factor and positional and thermal parameters was performed, minimizing the function $\Sigma w(\Delta F)^2$ with $w = 1$. At convergence, the largest parameter shift among the refined parameters of the non-hydrogen atoms was 0.2 times the standard deviation. No significant residuals of electron density were observed in the final electron density maps. Scattering factors for the atoms were supplied internally by the SHELX program system [17]. Crystal and intensity data for compounds **1**, **2** and **3** are reported in Table 1. Bond distances and angles are reported in Tables 2–5. Diagrams of the molecular structures of **1**, **2** and **3** are shown in Figs 1–3, respectively. Atomic coordinates and anisotropic thermal parameters for non-hydrogen atoms are available as supplementary material.

RESULTS AND DISCUSSION

Electrochemical reduction of $M(dtc)_3$ *complexes*

CV studies on the dithiocarbamato complexes of As, Sb and Bi are sparse. Data obtained in the present study are given in Table 6. Typical voltammograms are shown in Fig. 4. All the dithiocarbamato complexes, $M(dtc)_3$, showed three responses which are completely irreversible in the case of As and Sb. For the Bi complexes, the response around −0.5 V tends to become reversible.

Under identical experimental conditions $AsCl_3$ and $BiCl_3$ showed a single response during the reduction process at −0.82 and −0.70 V, respectively. However, the same could not be proved for $BiCl_3$ because of its high insolubility. The appearance of more CV responses for the $M(dtc)_3$ complexes is a result of the inherent property of the glassy carbon electrode used. Glassy carbon can have the functional groups adsorbed on the surface, leading to chemically modified pathways.

C(12)—N(3)—C(14)	118.9(9)		

Surface attachment of the polar ends of the compounds has already been encountered [18,19]. Of the three responses, those around −1.0 V for As and Sb and those around −0.5 V for Bi are owing to one-electron metal-based reductions. The peak currents associated with this set of responses were relatively larger than those associated with the other two responses.

Other weaker responses lie in the ranges 0 to −0.4

V and −1.5 to −2.4 V. For the less negative response (0 to −0.4 V) the maximum peak current was only 70 μA. This is probably owing to the attachment of polar ends of the molecule to the glassy carbon electrode. Data in Table 6 show that there is a significant linearity in the peak currents for the first response, in the order: $M(dedtc)_3 < M(nmedtc)_3 < M(deadtc)_3$. A large number of polar —CH_2CH_2OH groups increases the peak current. The reduced species $M(dtc)_3^-$ is highly unstable and could not be detected as observed earlier for other species [20]. Often, as an alternative to the stabilization of $M(dtc)_3^-$ species, dissociation takes place to give rise to dtc^-:

$$M(dtc)_3^- \rightarrow M(dtc)_2 + dtc^-.$$

Subsequently, dtc^- gets oxidised to disulfide [20, 21]. All $M(dtc)_3$ complexes showed three oxidation responses in the reverse scans: +0.60, +0.65 and +0.55 V for $dedtc^-$, $nmedtc^-$, and $deadtc^-$, respectively. The oxidation response appeared even if the potential scan was stopped after the second reduction responses in the complexes.

The third CV responses in the potential range −1.5 to −2.4 are of moderate peak currents. Variation in peak currents with respect to the number of —CH_2CH_2OH groups attached is regular for $As(dtc)_3$ complexes. Coulometry and controlled potential electrolysis gave no conclusive evidence of any conceivable species. Therefore, the third response should be attributed to the stabilization of $M(dtc)_2$ species on the electrode surface or to a second electron addition process on the solvated species $M(dtc)_2(DMF)_n$ [21]:

$$M(dtc)_2(DMF)_n + e^- \rightarrow M(dtc)_2(DMF)_n^-.$$

Stabilization of $M(dtc)_2$ on the electrode surface appears to be reasonable for As and Sb complexes. For the Bi analogues, the peak currents of the third responses are comparable to the second responses, therefore, the electron addition to the solvated species appears to be favoured.

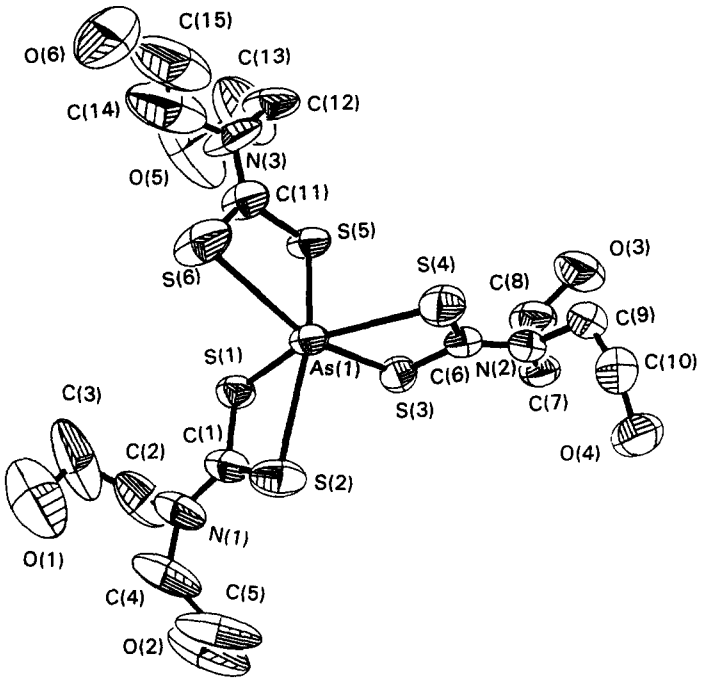

Fig. 1. ORTEP plot of As(deadtc)$_3$ (**1**) showing the labelling scheme.

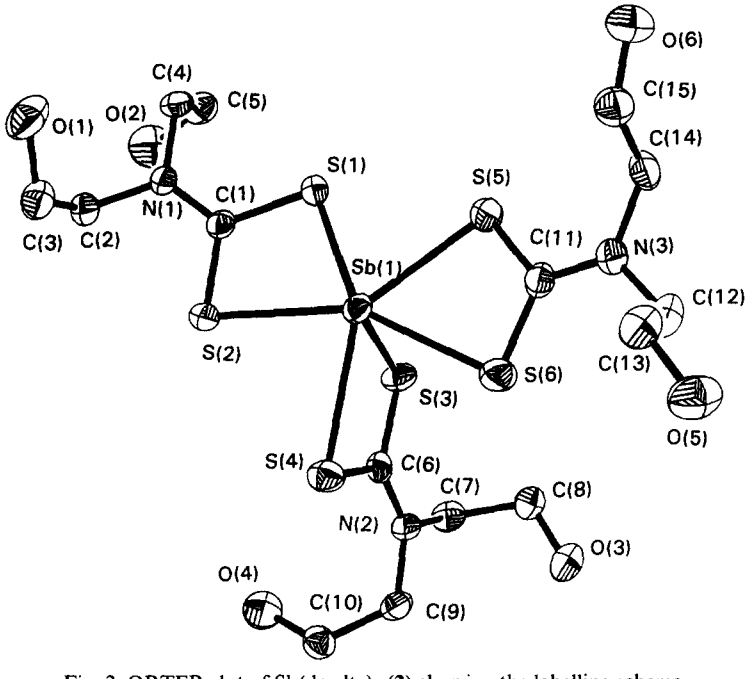

Fig. 2. ORTEP plot of Sb(deadtc)$_3$ (**2**) showing the labelling scheme.

In conclusion, the bismuth compound shows a lesser negative reduction potential compared with the other two complexes. The presence of polar —CH_2CH_2OH groups on the dithiocarbamate ligands increased the tendency to become stabilized on the glassy carbon electrode.

X-ray crystal structures

The structure of As(deadtc)$_3$ is shown in Fig. 1. The bidentate ligands are chelated to the As atom forming a polyhedron which can be described as a distorted trigonal antiprism. There are three short As—S bonds

and three long As—S bonds. All the three short bonds [mean As—S = 2.34(2) Å] indicate a strong "S" coordination while the other set corresponds to a weak interaction [mean As—S = 2.84(2) Å]. It is noticeable that in all ligands the C—S bond associated with the strong As—S bond is significantly longer [mean 1.77(9) Å] than that [mean 1.68(7) Å] associated with the weak As—S bond, showing clearly the localization of the double bonds. A remarkable feature concerns the N—C—S angles. Of the two sets of N—C—S angles [*viz.*, mean 123.9(7) Å and 118.2(7) Å] the larger value is as expected owing to the mutual repulsion between the double bond and the adjacent electronegative "N" atom. The strong As—S bonds are nearly at right angles to one another.

A schematic diagram of the coordination polyhedron showing the two trigonal faces of the antiprism is depicted in Figure 5. The plane defined by S(1), S(3) and S(5), which are the strongly coordinated sulfur atoms, is essentially parallel to that defined by S(2), S(4) and S(6) (the two planes are inclined by 2.2°) and As is displaced by 1.38 and 0.96 Å, respectively,

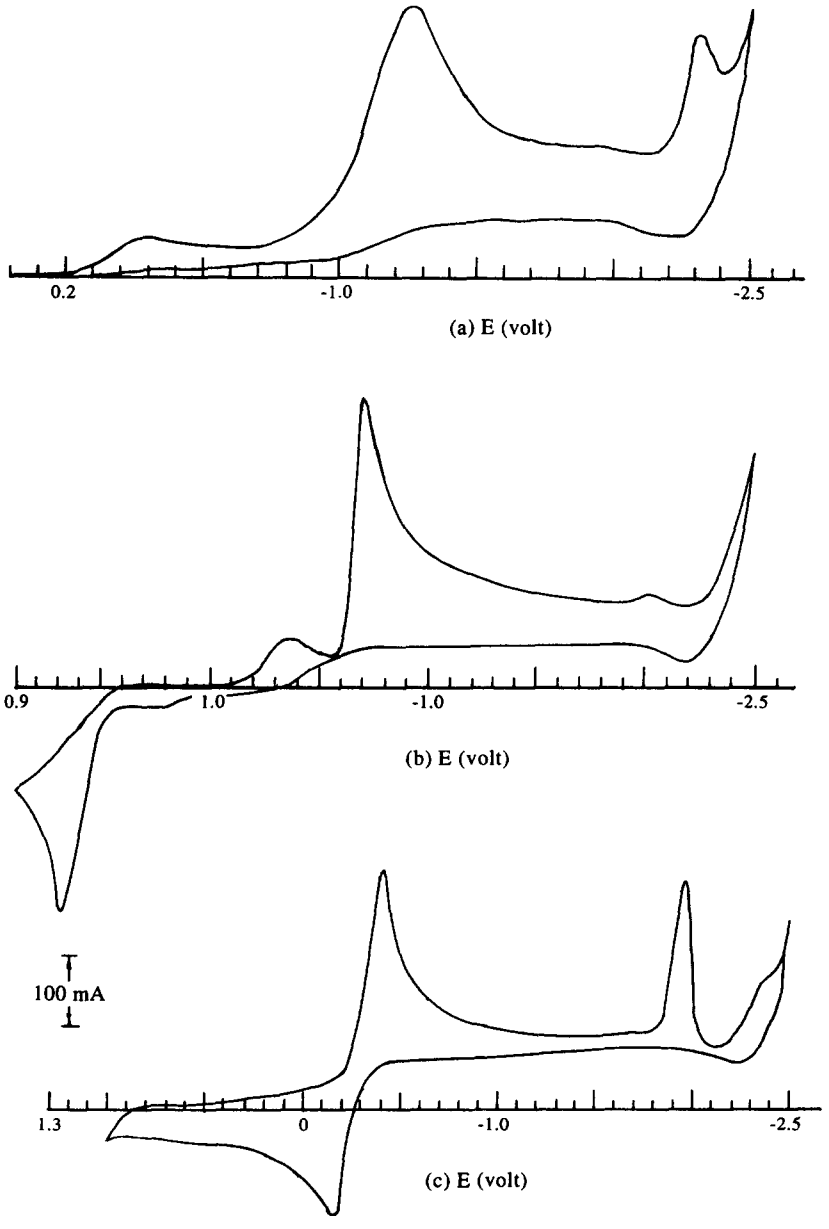

Fig. 4. Typical voltammograms of (a) $As(deadtc)_3$, (b) $Sb(nmedtc)_3$ and (c) $Bi(deadtc)_3$.

from the planes. Complexes of As^{III}, Sb^{III} and Bi^{III} with polydentate ligands occupying six coordination sites have been found to have a stereochemically active lone pair [22–25]. Of the two sets of S—As—S angles in the two trigonal prisms (Fig. 6), the large angle is 111.8(1)°, and this widening allows the lone pair to occupy the space.

The thioureide C—N bond [mean 1.33(1) Å] is comparable to that observed in the diethyldithiocarbamate analogue [11]. The presence of the electron-withdrawing $—CH_2CH_2OH$ group does not influence the thioureide distance significantly. However, the thioureide C—N bond is significantly shorter than the adjacent typical C—N single bond [mean 1.47(3) Å] indicating a partial double bond character as found earlier [15]. Two terminal C—C—O angles, C(12)—C(13)—O(5) and C(14)—C(15)—O(6) are 134(2) and 121(1)°, respectively. This is likely to be a result of the requirements of the terminal —OH groups and also the requirements of the lone pair on the arsenic atom.

The structure of $Sb(deadtc)_3$ is shown in Fig. 2 along with the numbering scheme. The coordination polyhedron can be described as a distorted pentagonal pyramid with S(3) as the apex. The relatively large size of the antimony, in addition to the establishment of metallic character by way of true coordinative interaction with the sulfurs of the deadtc, is responsible for comparable Sb—S bonds [10,12,13]. In the case of the arsenic analogue, the interaction is of a more covalent

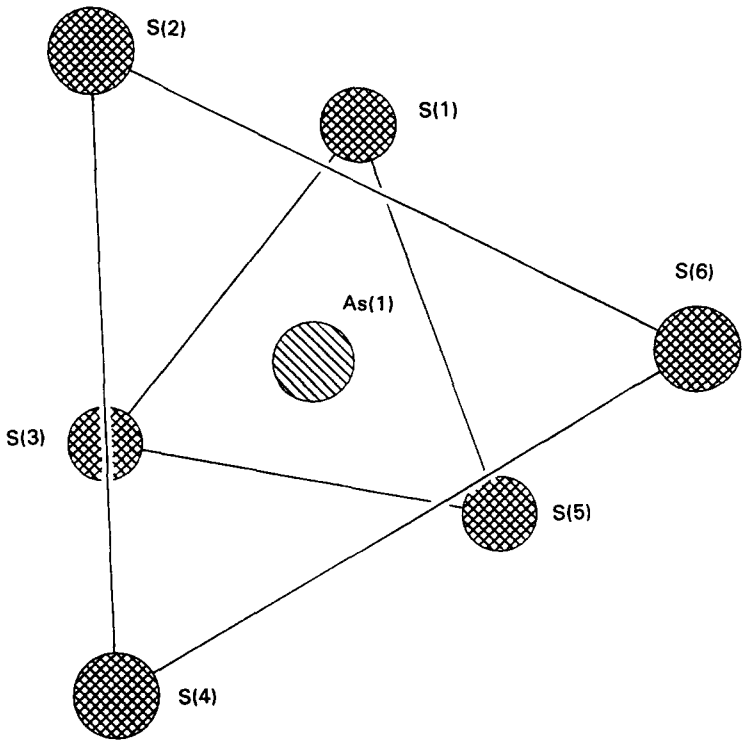

Fig. 5. A schematic diagram of the coordination polyhedron in $As(deadtc)_3$ showing the two trigonal faces of the antiprism.

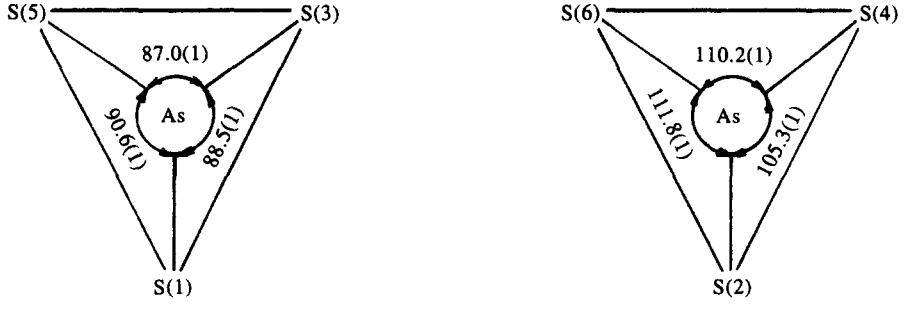

Fig. 6. Two sets of S—As—S angles in the two trigonal prisms of $As(deadtc)_3$.

nature leading to a trigonal antiprismatic polyhedron [9,11]. The strongest of all the Sb—S bonds is the apical Sb—S(3) bond with a bond distance of 2.46(2) Å. It is noteworthy that in the ligand where the two Sb—S bonds are similar, such as Sb—S(1) and Sb—S(2), the two C—S bonds are also roughly equivalent; while they are different when the difference between the Sb—S bonds is more pronounced, such as for Sb—S(5) and Sb—S(6). The difference becomes more significant in the third ligand where Sb—S(4) is the longest bond and Sb—S(3) is the shortest. In this context, the terminal C—C—O angles must also be considered. Of the six C—C—O angles, the C(9)—C(10)—O(4) angle is 128(1)°. Larger perturbations observed in the third ligand are likely to be a result of the position of the stereochemically active lone pair across S(2), S(4) [25]. The N—C—S angles are approximately equal in two ligands, while they differ significantly (122.7° *vs* 118.4°) in the third ligand, where the double bond character is more localized [on C(6)—S(4)]. The average thioureide C—N distance is 1.332(7) Å, which compares well with the value found in the diethyl analogue [10].

The molecular structure of $Bi_2(deadtc)_6$ is shown in Fig. 3. Two independent centrosymmetric molecules of the compound are present in the structure so that the asymmetric unit is formed by one half of both molecules, and a total of four molecules comprise the unit cell. In any case, although independent from a crystallographical point of view, all molecules have the same structure with comparable values for bond lengths and angles. Two of the six bidentate ligands are bridged in such a way that each sulfur atom is simultaneously bonded to both metal ions. As a result,

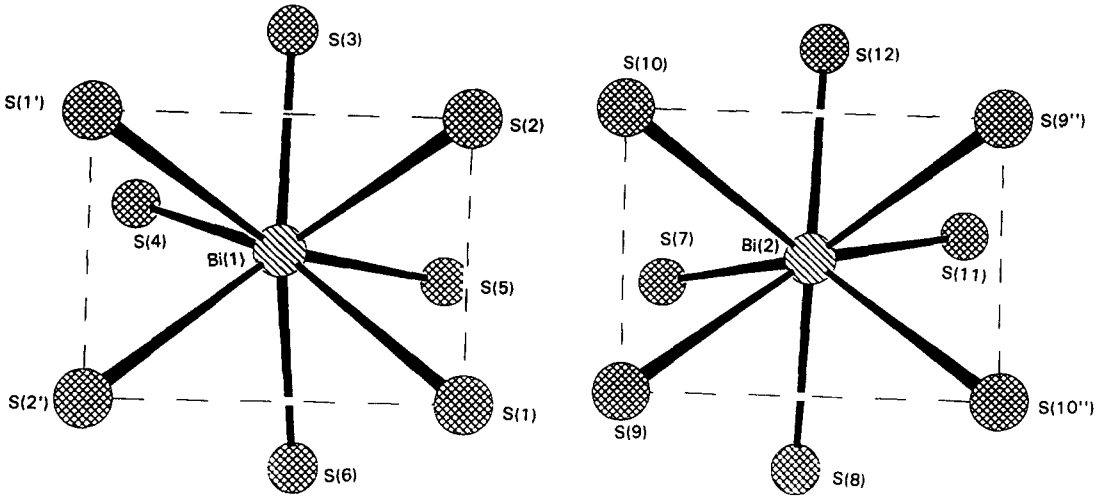

Fig. 7. Square antiprismatic environment of sulfurs around bismuth in $Bi_2(deadtc)_6$.

the metal is eight-coordinate in a coordination polyhedron that can be described as a distorted square antiprism (Fig. 7). Two sets of Bi—S distances are observed; mean Bi—S = 2.775(7) and 3.117(9) Å, and similarly two sets of S—Bi—S angles: 64.4(2) and 76.9(2)°. The two faces of the polyhedron are quasi parallel, with dihedral angles of 5.3 and 1.2°. The Bi atoms in the two molecules are displaced by 1.47 Å from the faces formed by the non-bridging S atoms, and by 1.94 and 1.90 Å from those of the bridging atoms. Inspection of bond lengths clearly shows that non-bridging S atoms form coordination bonds that are at least 0.35 Å shorter than those of the bridging S atoms. All Bi—S bond distances are generally longer than the sum of the corresponding covalent or atomic radii. In addition, one of the two Bi—S bonds of each non-bridging ligand is always significantly shorter than the other, whereas no systematic differences are found for the bridging ligands. Comparison of the structural parameters of $Bi_2(deadtc)_4$ with those of the diethyl analogue [10] clearly differentiates the characteristic dimer observed in the former.

In all three complexes, O···O non-bonded distances are observed of the order of 2.66 Å, indicating extensive intermolecular hydrogen bonding involving the alkyl chain. However, high esds associated with bond parameters and large thermal motions of the terminal oxygen atoms of the ligand molecules preclude detailed analysis. This is not surprising because the structure is strongly dominated by heavy As, Sb and Bi ions.

The formation of a complex of any metal ion with a multidentate ligand represents a compromise between steric interactions in the ligand and the steric and electronic requirements of the metal [3]. In particular, the anisobidenticity observed in the As, Sb and Bi dithiocarbamato complexes seems to be a consequence of the steric and electronic requirements. However, the valence bond sum (VBS) of the complexes [26, 27] determined from the bond valence parameters [28] accounts for the valence of the central ion irrespective of the number of bonds and the strength of interaction. In the present case, VBS-0B turns out to be 2.86, 2.99 and 3.11 for $As(deadtc)_3$, $Sb(deadtc)_3$ and $Bi(deadtc)_3$, respectively, and this clearly shows that charge neutralization is accomplished at the expense of anisobidenticity, In this study the valence bond sum should, theoretically, be equivalent to "3", in order to neutralize the charge on the central ion. The number of bonds attached to the metal and the variations in bond lengths observed in the complexes are only molecular adjustments to satisfy the requirements mentioned above. However, for all the complexes examined here, the VBS turns out to be close to 3, as expected, although the coordination polyhedra are different. The VBSs calculated for the As, Sb and Bi complexes are as shown in Table 7.

The VBS has been proposed to equal the valence or charge on an atom or ion and is calculated by summing $\exp[(r_c - r_o)/B]$ for each bond to the atom or ion in question, where r_c is a constant for a particular bond type, r_o is the observed bond length and B is a constant (taken as 0.37). The bond valence method has recently had considerable success in predicting and interpreting bond lengths in ionic solids.

Table 7. Valence bond sums for the complexes

Complex	R_{ij}[a]	VBS-OB[b]	VBS-BA[c]
$As(deadtc)_3$	2.272	2.86	3.12
$Sb(deadtc)_3$	2.474	2.99	3.18
$Bi(deadtc)_3$	2.570	3.11	3.27

(Received 28 May 1996; accepted 15 July 1996)

Abstract—Various routes to praseodymium alkoxides have been investigated. Compounds such as $Pr_5O(OR)_{13}$ [$R = Pr^i$ (**1**), Am^t], $[Pr_4O_2(ONp)_8]_m$ (Np = neopentyl), $[Pr(OC_2H_4NMe_2)_3]_3$ were obtained by reaction of praseodymium turnings with the corresponding alcohols. Alcoholysis reactions of the bis-trimethylsilylamide afforded $[Pr_4O(ONp)_{10}]_m$, $[Pr_4O_2(ONp)_8]_m$, $Pr_3(OR)_9(ROH)_2$ [$R = Bu^t$, Am^t] and $[Pr_4O_2(OC_2H_4OMe)_8]_m$ (**2a**), the latter derivatives illustrating the trend for the formation of oxo species. The compounds were characterized by elemental analysis, FT-IR and NMR. Their reactivity has been investigated, the mixed-metal species $Pr_4TiO(OPr^i)_{14}$ and $Y_4PrO(OPr^i)_{13}$ were obtained. Ligand exchange reactions afforded $[Pr_4O_2(OR)_3(OR')_5]_m$ species ($R = Pr^i$, $R' = C_2H_4NMe_2$' $R = SiMe_3$, $R' = Pr^i$) and $[Pr(OC_2H_4NMe_2)(thd)_2]_2$. X-ray structure analysis of the adduct obtained by reaction of $[Pr_4O_2(OC_2H_4OMe)_8]_m$ with trimethylphosphine oxide reveals a centrosymmetric framework $[Pr_4(\mu_4\text{-}O)_2(\mu_3,\eta^2\text{-}OR)_2(\mu,\eta^2\text{-}OR)_4(\mu,\eta^1\text{-}OR)(OR)(OPMe_3)]_2$ (**2b**) of eight octa-coordinated praseodymium atoms, assembled by tetrahedral and square-planar oxo ligands. The M—O bond lengths spread over the range 2.246(6)–2.762(6) Å and to follow the order Pr—OR (terminal) < μ,η^2-Pr—OR < μ_3,η^2-Pr—OR < Pr—O(ether). The $Y_4PrO(OPr^i)_{13}$ species corresponds to a pentanuclear oxo aggregate similar to that of the parent homometallic species. Copyright © 1997 Elsevier Science Ltd

Keywords: alkoxides; praseodymium; lanthanides; sol–gel; MOCVD; mixed-metal alkoxides.

The alkoxide chemistry of the lanthanides remains confined to a few elements. Regarding praseodymium, only the tris-isopropoxide [1] and a methoxyethoxide derivative resulting from C—O bond cleavage of DME [2] have been mentioned for many years. Fluoroalkoxides $\{Pr[OCMe(CF_3)_2]_3(NH_3)_2\}_2$, $\{Pr[OCMe(CF_3)_2]_3\}_3$ [3], the aryloxide $[Pr(O\text{-}C_6H_2(CH_2NMe_2)_3\text{-}2,4,6]_3(H_2O)_2$ [4] and the mixed-metal species $[PrAl_2Cl(OPr^i)_8(Pr^iOH)]_2$ [5] and [Pr Cu(bdmmpH)(bdmmp)(μ-OH)(hfacac)$_3$] (bdmmpH = 2,6-bis[dimethylamino)-methyl-4-methylphenol, hfacacH = hexfluoroacetylacetone) [5b] have been structurally characterized recently. Praseodymium oxide, Pr_6O_{11}, is used as an additive in varistors [6] and in $PrBa_2Cu_3O_x$, an insulating material [7] which might be associated with high temperature superconductors of comparable lattice parameters such as $YBa_2Cu_3O_{7-x}$ in order to form heterostructures, or, in $Pr_{1.85}Ce_{0.15}CuO_{4-x}$, the only superconducting material based on praseodymium reported so far [8].

Various routes, such as direct attack of the metal,

alcoholysis of the bis-trimethylsilylamide and alcohol exchange reactions, were investigated in order to expand the range of praseodymium oxide precursors. We report here the synthesis of $Pr_5O(OR)_{13}$ (R = Pr^i, Am^i), $[Pr_3(OR)_9(ROH)_2]$ (R = Bu^t, Am^t) and $[Pr_3(OC_2H_4NMe_2)_9]$. The high tendency of the formation of oxo species is illustrated by the formation of $[Pr_4O(ON_p)_{10}]_m$, $[Pr_4O_2(ONp)_8]_m$ and $[Pr_8(\mu_4\text{-}O)_4(OC_2H_4OMe)_{16}(OPMe_3)]_2$, the latter having been structurally characterized. Stabilization of the isopropoxide derivative has been achieved through the formation of mixed-metal species, $[Pr_4TiO(OPr^i)_{14}]$ and $[PrY_4O(OPr^i)_{13}]$. $[Pr_4O_2(OR)_3(OR')_5]_m$ and $[Pr(OC_2H_4NMe_2)(thd)_2]_2$ were obtained by ligand exchange reactions. The various compounds have been characterized by elemental analysis, FT-IR, NMR and molecular weight data.

EXPERIMENTAL

Synthesis and characterization were carried out routinely under argon using Schlenk tubes and vacuum line techniques. Solvents were dried using standard procedures. Alcohols were dried over molecular sieves or $Al(OPr^i)_3$ and distilled. Me_3SiOH [9] and $Pr[N(SiMe_3)_2]_3$ [10] were obtained according to the literature. IR spectra were obtained as Nujol mulls on an FT-IR45S Bruker spectrometer. NMR spectra were registered on an AC-200 Bruker spectrometer. Molecular weight data were obtained by the Signer method [11]. TGA data were obtained with a Setaram system using a heating rate of 5°C min^{-1}. Analytical data were obtained from the Centre de Microanalyses du CNRS. Analytical and FT-IR data of the various homometallic compounds are summarized in Table 1.

Reaction between praseodymium chips and alcohols

Synthesis of $Pr_5O(OR)_{13}$ [R = Pr^i (**1**), Am^i]. A toluene : Pr^iOH (1 : 1) solution (250 cm^3) was added to praseodymium chips (12.05 g, 85.5 mmol). After refluxing for 1 h, 10 mg of catalyst [$HgCl_2$: $Hg(OAc)_2$, 1 : 1] were added and refluxing was maintained for 48 h. The hot reaction mixture was filtered over a Celite pad. The filtrate was cooled to −35°C. Yellow–green crystals of $Pr_5O(OPr^i)_{13}$ (**1**) were isolated by filtration and dried *in vacuo* (24.4 g, 90%).

The same procedure using isoamyl alcohol gives $Pr_5O(OAm^i)_{13}$ (85%).

Synthesis of $[Pr_4O_2(ONp)_8]$ *and* $[Pr(OC_2H_4NMe_2)_3]_3$. The same reactions using neopentyl alcohol or 2,2-dimethylaminoethanol gave $[Pr_4O_2(ONp)_8]_m$ (65%) and $[Pr(OC_2H_4NMe_2)_3]_3$ (96%), respectively. M.W. (C_6H_6) = 1180 (calc. 1214.72).

$Pr_5O(OAm^i)_{13}$ and $[Pr(OC_2H_4NMe_2)_3]_3$ are soluble in common organic solvents, including petroleum ether. $Pr_5O(OPr^i)_{13}$ is, like other $Ln_5O(OPr^i)_{13}$ derivatives (Ln = Y, La, Nd, Sm, Gd), soluble in toluene when freshly prepared, but its solubility decreases on ageing.

Alcoholysis of $Pr[N(SiMe_3)_2]_3$

Synthesis of $Pr_3(OR)_9(ROH)_2$ (R = Bu^t, Am^t). A solution of Bu^tOH (0.8 g, 10.8 mmol) in toluene (20 cm^3) was added dropwise to a solution of $Pr[N(SiMe_3)_2]_3$ (1.5 g, 2.4 mmol) in toluene (40 cm^3) at 0°C. The reaction was slightly exothermic and the reaction mixture was stirred for 12 h. After filtration, concentration and cooling at −20°C, green crystals analysing as $Pr_3(OBu^t)_9(Bu^tOH)_2$ (0.6 g, 62%) were obtained.

A similar procedure applied to $Pr[N(SiMe_3)_2]_3$ (1.5 g, 2.4 mmol) in toluene (40 cm^3) and 0.9 g (10.8 mmol) of tert-amyl alcohol in toluene (20 cm^3) offered $Pr_3(OAm^t)_9(Am^tOH)_2$ (0.75 g, 69%).

Synthesis of $[Pr_4O(ONp)_{10}]_m$ *and* $[Pr_4O_2(ONp)_9]_m$. The preceeding procedure applied to $Pr[N(SiMe_3)_2]_3$ (1.5 g, 2.4 mmol) in toluene (40 cm^3) and neopentyl alcohol (0.83 g, 9.4 mmol) in toluene (20 cm^3) afforded $Pr_4O(ONp)_{10}$ (0.37 g, 42%) as the first crop of crystals and $Pr_4O_2(ONp)_8$ (0.18 g, 23%) as the second crop after 4 days at −30°C.

$Pr_3(OR)_9(ROH)_2$ (R = Bu^t,Am^t), $[Pr_4O(ONp)_{10}]_m$ and $[Pr_4O_2(ONp)_8]_m$ are soluble in toluene and THF but insoluble in hexane.

Alcohol interchange reactions of $Pr_5O(OPr^i)_{13}$

Synthesis of $[Pr_4O_2(OC_2H_4OMe)_8]_m$ (**2a**). 2-Methoxyethanol (0.37 cm^3, 4.7 mmol) was added to a suspension of $Pr_5O(OPr^i)$ (467 mg, 0.314 mmol) in petroleum ether (15 cm^3). After dissolution, precipitation was observed. Addition of THF (10 cm^3) gave a homogeneous solution, which gave crystals of $Pr_4O_2(OC_2H_4OMe)_8$ (0.3 g, 64%) on cooling to −30°C. The compound is poorly soluble in common organic solvents, even polar ones such as THF, but it is more soluble in 2-methoxyethanol.

The same compound was obtained by reacting Pr chips with 2-methoxyethanol in refluxing toluene but its isolation as crystals required several recrystallizations in diethyl ether, thus leading to a low yield.

Synthesis of $[Pr_4O_2(OPr^i)_3(OC_2H_4NMe_2)_5]_m$ *and* $[Pr_4O_2(OPr^i)_5(OSiMe_3)_3]_m$. $Me_2NC_2H_4OH$ (1.26 g, 15.6 mmol) was added to a suspension of $Pr_5O(OPr^i)_{13}$ (2.8 g, 1.9 mmol) in toluene (30 cm^3). Complete dissolution was observed over 45 min. Evaporation to dryness left a light green powder of formula $[Pr_4O_2(OPr^i)_3(OC_2H_4NMe_2)_5]_m$ (3.4 g, 98%).

The same procedure using a solution of freshly prepared Me_3SiOH (5.9 g, 65 mmol) diethyl ether (10 cm^3) and applied to a suspension of $Pr_5O(OPr^i)_{13}$ (2.8 g, 1.88 mmol) in Et_2O (20 cm^3) led to immediate dissolution. 2.3 g (87%) of $[Pr_4O_2(OPr^i)_5(OSiMe_3)_3]_m$ were obtained after evaporation to dryness.

Table 1. Microanalytical and FT-IR data of various praseodymium alkoxides

Compound	Synthesis (yield, %)	Analytical data (%) Found (Calc.) C	H	N	IR ν(M—OR) cm − 1

Synthesis of $[Pr(OC_2H_4NMe_2)(thd)_2]_2$

A solution of 2,2,6,6-tetramethylheptane-3,5-dione (7.1 g, 38.5 mmol) in diethyl ether (20 cm^3) was added to a solution of $Pr(OC_2H_4NMe_2)_3$ (7.8 g, 19.23 mmol) in the same solvent (50 cm^3). After 1 h, the solution was evaporated to dryness. $Pr(OC_2H_4NMe_2)(thd)_2$ was obtained by sublimation at 170°C/10^{-3} mm of Hg (95%). M.p. = 105–110°C, $\mu = 3.30$ μB, M.W. (C_6D_6) = 1250 (calc. 678.9). TGA (N_2, 1 atm): 240–380°C sublimation, residue 18%.

The same product was obtained if the reaction was carried out in a 1:1 stoichiometry, although in a lower yield (40%). Cell parameters (−100°C) $a = 13.554(2)$, $b = 18.607(2)$, $c = 21.886(2)$ Å, $\beta = 25.05(3)°$, monoclinic, $P2_1$ or $P2_1/m$, but the structure could not be solved.

Synthesis of $Y_4PrO(OPr^i)_{13}$

$Pr_5O(OPr^i)_{13}$ (0.67 g, 0.45 mmol) was added to a solution of $Y_5O(OPr^i)_{13}$ (2.21 g, 1.8 mmol) in THF (40 cm^3). The reaction medium was stirred for 18 h at room temperature giving a light green solution. The resulting solid was recrystallized in toluene. $PrY_4O(OPr^i)_{13}$ (2.3 g, 80%) is soluble in all common solvents except petroleum ether. Found: C, 36.6; H, 7.1. Calc. for $C_{39}H_{91}O_{14}PrY_4$: C, 35.7; H, 6.4%. IR(cm^{-1}): 1337vs, 1171vs, 1130vs, 1009vs; 995s, 978s; 952s, 836m, 828m; 535s, 494s, 453s, 420s, 396s [ν(M—OR)]; ^1H NMR (C_6D_6): δ 4.45 (sept, $J = 6$ Hz, 13H), 1.63 (d, $J = 6$ Hz, CH_3, 48H), 1.48 (d, $J = 6$ Hz, CH_3, 30H); ^{13}C-{^1H} NMR (C_6D_6): δ 67.4, 68 (CH), 28.5, 27.8 br (CH_3).

Synthesis of $Pr_4TiO(OPr^i)_{14}$

$Pr_5O(OPr^i)_{13}$ (0.73 g, 0.5 mmol) in toluene (30 cm^3) were added to $Ti(OPr^i)_4$ (0.183 cm^3, 0.6 mmol). The reaction medium was stirred at room temperature for 48 h. A crop of green crystals, soluble in toluene, THF and isopropanol, but poorly soluble in hexane, analysing as $Pr_4TiO(OPr^i)_{14}$ (0.5 g, 71%), was obtained at −20°C. Found: Pr, 12.8; Ti, 16.6. Calc. for $C_{42}H_{98}O_{15}Pr_4Ti$: Pr, 12.0; Ti, 16.3%. IR [cm^{-1}]: 1332m, 1151vs, 1125vs [ν(C—O)]; 994vs, 987s, 954m, 850w, 834m, 830w, 824w, 645m, 613m, 555m, 517m, 473m, 445m [ν(M—O)].

Crystallography of $[Pr_8O_4(OC_2H_4OMe)_{16}(OPMe_3)_2]$ *and* $[YPr_4O(OPr^i)_{13}]$

Crystals of $[Pr_8O_4(OC_2H_4OMe)_{16}(OPMe_3)_2]$ (**2b**) and $[YPr_4O(OPr^i)_{13}]$ were grown from the reaction medium. Crystals of **2b** were obtained when the methoxethoxide derivative crystallized in the presence of $OPMe_3$. A selected crystal was mounted on an Enraf–Nonius CAD-4 diffractometer; cell parameters were obtained from the setting of 25 well-centred reflections. Crystallographic data and other pertinent information are given in Table 2.

Table 2. Crystallographic data for $[Pr_8O_4(OC_2H_4OMe)_{16}(OPMe_3)_2]$ and for $[YPr_4O(OPr^i)_{13}]$

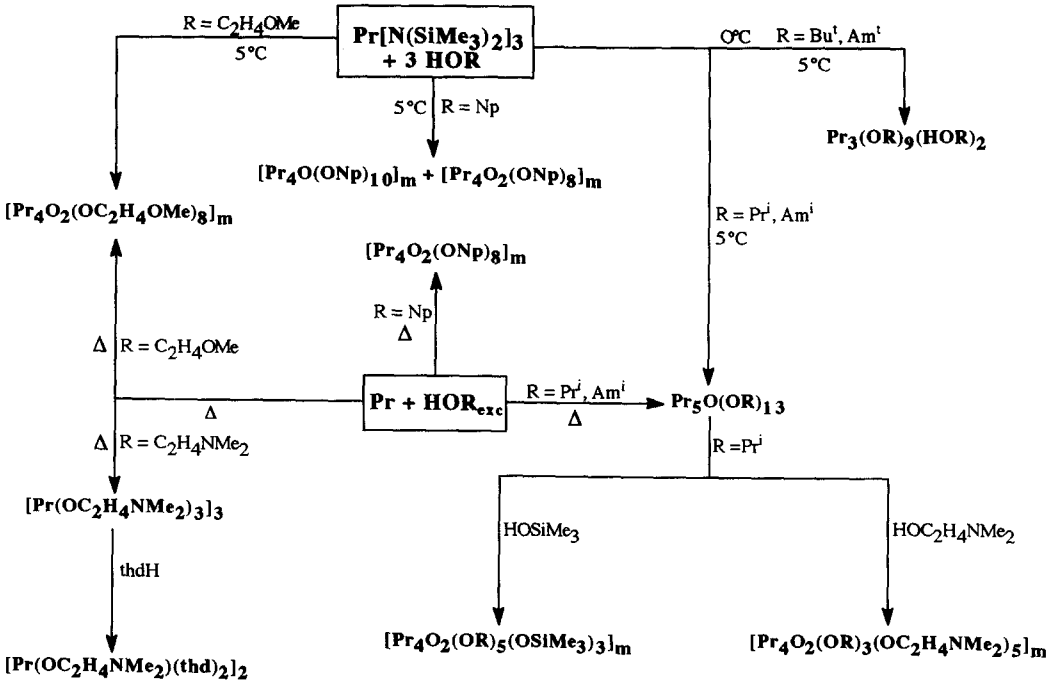
Data were collected for $[Pr_8O_4(OC_2H_4OMe)_{16}(OPMe_3)_2]$ and $[YPr_4O(OPr^i)_{13}]$ at low temperature (−100°C) using graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å). Metal atoms were found using SHELXS [12]. All remaining non-hydrogen atoms were located on successive difference electron density maps. The structures were refined by least-squares techniques with approximation (in three blocks) to the normal matrix using CRYSTALS II [13]. The hydrogen atoms were not included in the refinement. 4168 and 2360 reflections with $I > 3\sigma(I)$ were used to solve and refine the structures of $[Pr_8O_4(OC_2H_4OMe)_{16}(OPMe_3)_2]$ ($R = 0.036$, $R_w = 0.040$, 461 variables) and of $[YPr_4O(OPr^i)_{13}]$ ($R = 0.059$, $R_w = 0.066$, 330 variables), respectively. Anomalous dispersion terms were applied. Empirical absorption corrections using DIFABS [14] were made. Atomic coordinates, non-essential bond lengths and angles and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

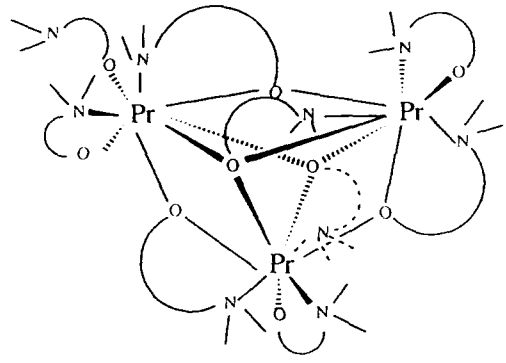


Synthesis and characterization

Various synthetic routes to praseodymium alkoxides have been investigated, namely reaction between the metal and alcohols, alcohol interchange reactions and alcoholysis of the bis-trimethylsilylamide derivative ($Pr[N(SiMe_3)_2]_3$) (Scheme 1). The various products, generally light yellow–green microcrystalline solids, have been characterized by elemental analysis, FT-IR, NMR, molecular weight data and X-ray diffraction for $[Pr_8O_4(OC_2H_4OMe)_{16}(OPMe_3)_2]$ and for $[PrY_4O(OPr^i)_{13}]$. Table 1 summarizes the most relevant characteristics of the novel praseodymium alkoxide derivatives.

The reaction between praseodymium chips and isopropanol proceeds as for yttrium and the lanthanides (samarium, gadolinium, ytterbium,...), with the formation of an oxo species $Pr_5O(OPr^i)_{13}$ (**1**) (see also ref. [15]). However in contrast with the derivatives of these lanthanides, **1** is sensitive to "ageing" and becomes progressively insoluble in non-polar as well as polar solvents. The formation of **1** proceeds *via* a soluble solvate which can be isolated as a crystalline material [ν(OH) 3358 cm^{-1}] but which is converted into **1** by loss of the labile Pr^iOH molecules during drying. The use of an alcohol with a longer carbon chain, isoamyl alcohol $Me_2CHC_2H_4OH$ for instance, leads to a compound having the same empirical formula but which appears to remain soluble over time. The presence of the M_5O core is supported by numerous M—OR vibrations in the IR spectra for the isopropoxide and isoamyloxide derivatives (519, 482, 444, 397 and 497, 489, 458, 422 cm^{-1}, respectively) and a pattern comparable to that observed for the well-characterized $M_5O(OPr^i)_{13}$ (M = Y, Yb) species [1b].

As a general feature, the work-up of the praseodymium derivatives resulting from direct reactions between the metal and alcohols appeared to be more tedious than for the other lanthanides investigated so far (formation of oily and/or insoluble products, metallic colloids difficult to separate, change in the colour promoted by O-donor solvents). These drawbacks are more important in the case of alcohols with high boiling points such as 2-methoxyethanol, and $[Pr_4O_2(OC_2H_4OMe)_8]_m$ (**2a**) could only by crystallized out in moderate yields (25%).



The formation of oxo species displaying mostly a poor solubility appears as another general trend for praseodymium. Thus, while the reaction between yttrium and 2-methoxyethanol gives a decamer,

Scheme 1. Various synthetic routes to praseodymium derivatives (all reactions in toluene at room temperature if not otherwise stated).

$Y_{10}(OC_2H_4OMe)_{30}$, soluble in petroleum ether [16], a similar reaction with praseodymium offers, after isolation from diethyl ether (no solubility in hexane), oxo clusters based on a $Pr_4O_2(OR)_8$ empirical formulation. Indeed, the generation of oxo ligands, shown to display a μ_4 coordination mode (see below) allows praseodymium to achieve large coordination numbers in molecular aggregates. In view of the limited solubility of most of these oxo species, bulky and/or functional alkoxide ligands were selected as a means to stabilize species of smaller nuclearity, soluble and/or volatile. This strategy allowed the isolation of $Pr(OC_2H_4NMe_2)_3$ shown to be trimeric by molecular weight measurements in benzene. A structure based on a bi-capped triangular unit analogous to that established for $Pr_3[\mu_3\text{-}OCMe(CF_3)_2]_2[\mu\text{-}OCMe(CF_3)_2]_3[OCMe(CF_3)_2]_4$ is likely [3]. The $\mu 3,\eta^2$ bridging-chelating coordination mode of the aminoalkoxide ligand has found precedent for $[Ba_5(OH)(\mu_3,\eta^2\text{-}OCHMeCH_2NMe_2)_4(thd)_5]$ and for $[Ba_2Cu(\mu_3,\eta^2\text{-}OCHMeCH_2NMe_2)_2(thd)_4(Pr^iOH)_2]$ [17]. The functionality of the $OC_2H_4NMe_2$ ligand allows praseodymium to be eight-coordinated without the presence of oxo ligands in the metal coordination sphere. However, despite its low nuclearity, this species remains non-volatile.

Alcoholysis reactions of bis-trimethylsilylamides generally represent an alternative, clean route to metal alkoxides and this synthetic procedure has allowed the isolation of praseodymium fluoroisopropoxides by Bradley *et al.* [3]. Indeed, this procedure facilitates the isolation of the derivatives and $Pr_3(OR)_9(ROH)_2$

($R = Bu^t, Am^t$) species have been isolated in high yields (70%) (see also ref. [15]). In the case of neopentyl alcohol, two types of oxo derivatives $[Pr_4O(ONp)_{10}]_m$ and $[Pr_4O_2(ONp)_8]_m$ were isolated successively over four days (yield 42 and 23%, respectively). One can notice that the latter was the only compound isolated from the reaction between the metal and the alcohol that proceeds at higher temperature. These observations illustrate again the trend of praseodymium to form oxo species. The reactions involving $Pr[N(SiMe_3)_2]_3$ appear more prone to side reactions than in the case of lanthanum or yttrium.

Reactivity

Various reactions aimed at obtaining stable and/or soluble praseodymium derivatives were investigated.

The reaction between **1** and 2-methoxyethanol (15 equivalents) proceeds quite easily at room temperature with formation of the oxo species $[Pr_4O_2(OC_2H_4OMe)_8]_m$ in about 65% yield. Introduction of trimethylsiloxide ligands in the metal coordination sphere generally offers more soluble compounds. Alcoholysis reactions of **1** were also achieved at room temperature with trimethylsilanol and dimethylaminoethanol. Dissolution was observed in both cases, the reactions proceed with formation of heteroleptic species of general formulae $[Pr_4O_2(OR)_3(OR')_5]_m$ ($R = SiMe_3$, $R' = Pr^i$; $R = Pr^i$, $R' = C_2H_4NMe_2$). Attempts to obtain trimethylsiloxide derivatives by reaction between **1** and Me_3SiOAc were less selective owing to the formation of acetato derivatives, evidenced in the FT-IR spectra by $\nu(CO_2)$ vibrations at 1559 cm^{-1} resulting from C—O bond cleavage reactions [1b].

Another aspect of the ageing phenomenon is the change in colour from green to reddish-green while solubility properties are retained. This colour change is favoured by oxygen donor solvents such as diethyl ether or THF and by heating, but was not further investigated.

Mixed-metal species are another means to achieve solubilization and/or stabilization [1b]. Such reactions were explored between **1** and $Ti(OPr^i)_4$. The reactions proceed with dissolution of the $Pr_5O(OPr^i)_{13}$ derivative and formation of new species in which the metals achieve a 4:1 stoichiometry. The 4:1 stoichiometry was anticipated for the reaction with titanium isopropoxide and a structure similar to that of $[Sm_4Ti(\mu_5\text{-}O)(\mu_3\text{-}OPr^i)_2(\mu\text{-}OPr^i)_6(OPr^i)_6]$ [18] is likely for $[Pr_4TiO(OPr^i)_{14}]$. This analysis is supported by the similarity of the FT-IR pattern observed for the ν(M—OR) region. IR and ^1H NMR data for $[PrY_4O(OPr^i)_{13}]$ are in favour of the formation of a new species, different from the starting metal alkoxides. X-ray diffraction studies on single crystals account for the presence in the solid of pentanuclear aggregates displaying a $[M_5(\mu_5\text{-}O)(\mu_3\text{-}OPr^i)_4(\mu\text{-}OPr^i)_4(OPr^i)_5]$ core (see below) but in which the different metals are disordered.

The reactions between $[Pr(OC_2H_4NMe_2)_3]_3$ and 2,2,6,6-tetramethyl-3,5-heptanedione (thdH) were considered as a means of achieving volatile derivatives, which could also be used as synthons for the build-up of heteroleptic mixed-metal species [17]. $Pr(OC_2H_4NMe_2)(thd)_2$ appears to be more stable than $Pr(OC_2H_4NMe_2)_2(thd)$ and is obtained independently of the stoichiometry, 1:1 or 1:2, of the reaction. It appears as a dimer by molecular weight data measurements. It sublimes at *ca* 170°C/10^{-3} mm of Hg and is thus less volatile than the homoleptic praseodymium tetramethylheptanedionate $[Pr(thd)_3]_2$ (180°C/10^{-2}). These observations were also confirmed by the TGA measurements. The thermograms (under 1 atmosphere of nitrogen) indicate that the sublimation of $Pr_2(thd)_6$ occurs between 220 and 310°C but only in the temperature range 240–380°C for $[Pr(OC_2H_4NMe_2)(thd)_2]_2$.

The FT-IR spectra of the homoleptic alkoxides, or their oxo analogues, display essentially the absorption bands of the organic groupings and those of the ν(M—OR) vibrations below 600 cm^{-1}. The molecules solvated by the parent alcohol are characterized by ν(OH) absorption bands around 3380 cm^{-1}. The β-diketonatoalkoxide shows the classic C=O absorptions around 1550–1600 cm^{-1}. The assignment of the M—oxo vibration in metal alkoxides is generally difficult owing to the versatility of the coordination modes of this ligand and the numerous absorption bands related to the organic groups. The spectra of $[Pr_4O(ONp)_{10}]_m$ and $[Pr_4O_2(ONp)_8]_m$ differ mainly in a strong band at 798 cm^{-1}, tentatively attributed to a μ_n-O—Pr vibration. The low frequency of the stretching C—H vibrations (2614 cm^{-1}) observed for the neopentyloxide derivative obtained by the direct route (from the metal), suggests agostic Pr···C—H bonding, as established by X-ray diffraction for $[Ln(OCH_2Bu^t)_3]_4$ [19]. The Pr_4O_2 or Pr_5O cores are characterized by more Pr—OR absorption bands than for the non-oxo $Pr_3(OR)_9(ROH)_2$ species.

The paramagnetism of the Pr^{3+} ion causes large pseudo-contact shifts, and the peaks observed are often quite broad. The dispersion of the chemical shifts might be observed over about 140 ppm, especially for the heteroleptic derivatives $[Pr_4O_2(OR)_3(OR')_5]_m$, but assignment is difficult in view of the various structures possible. (No molecular weight data by the Signer method, and therefore information of the nuclearity, could be obtained in view of the evolution of these structures during the measurements.) The ^1H NMR spectra of $Pr_5O(OPr^i)_{13}$ display a broad peak at δ 3.16 for the CH groups (hfw $\approx$ 120 Hz) while the CH_3 groups appear as broad singlets, at δ 1.35, 0.9 and 0.4 (integration ratio 5:4:4, hfw $\approx$ 60 Hz), confirming the retention of the M_5O_{14} core in solution.

Molecular structures of $[Pr_8O_4(OC_2H_4OMe)_{16}(OPMe_3)_2]$ (**2b**) *and* $[Y_4PrO(OPr^i)_{13}]$

The molecular structure of the methoxyethoxide adduct **2b** consists of discrete centrosymmetric aggregates of eight praseodymium atoms (Fig. 1), the metals all being eight coordinate. Selected bond lengths and angles are given in Table 3. The aggregate is formed by assembling two $[Pr_4(\mu_4\text{-}O)(\mu_2,\eta^2\text{-}OR)_3(\mu_2\text{-}OR)(OR)]$ units. These subunits, in which the metals form a nearly planar arrangement, are connected by two μ_4-oxo ligands, four triply bridging chelating μ_3,η^2 alkoxo groups and two doubly bridging chelating μ_2,η^2 ones. The two basic units, which are roughly parallel to each other, are slightly translated, thus giving the cluster represented in Fig. 1. The arrangement is quite regular with non-bonding metal–metal distances varying from 3.6031(9) to 3.9188(6) Å. These values are

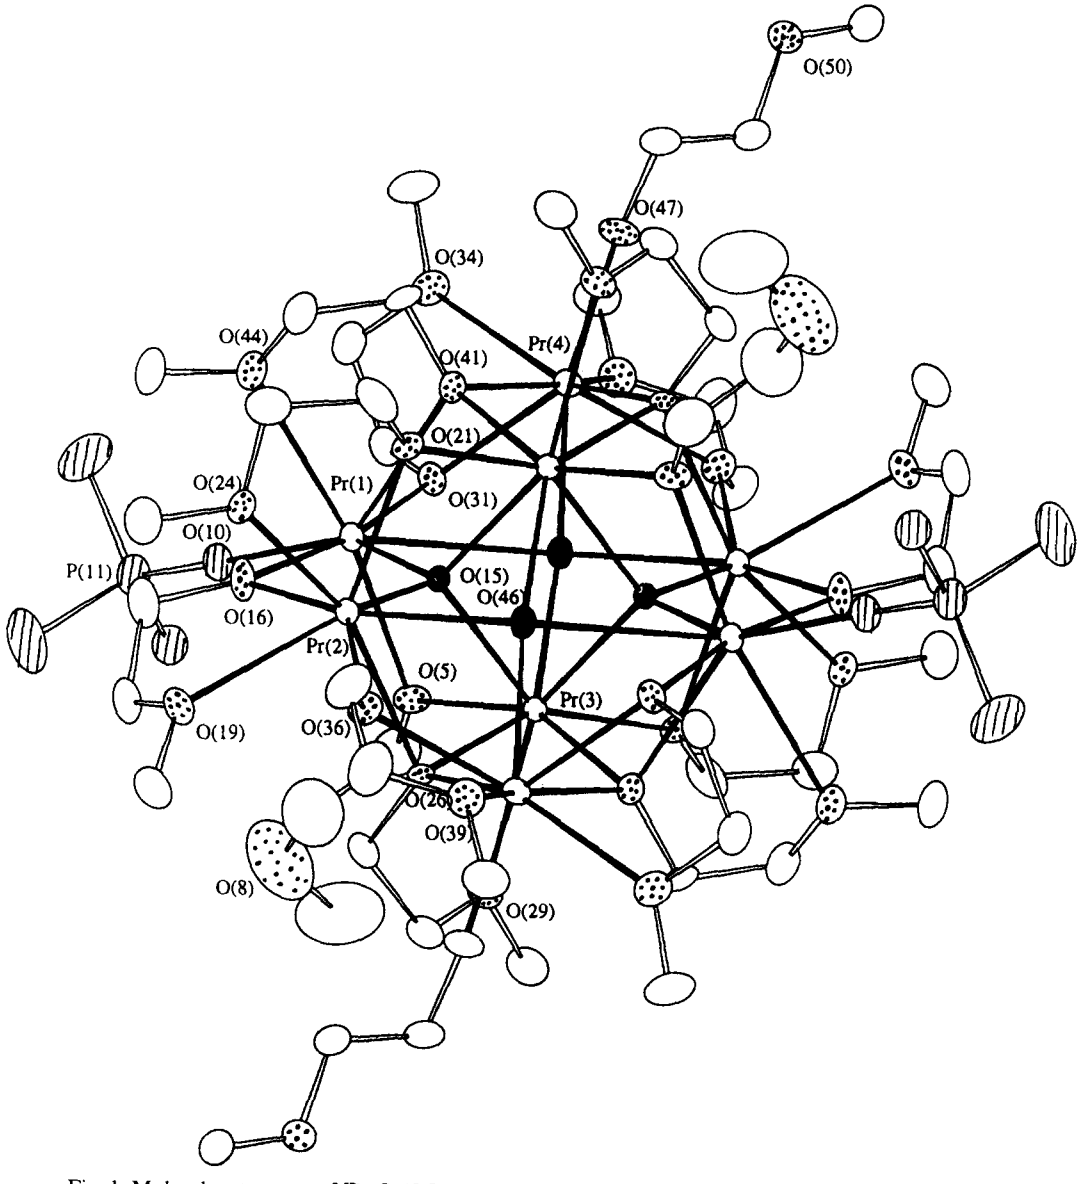


Fig. 1. Molecular structure of $[Pr_4O_2(OC_2H_4OMe)_8(OPMe_3)]_2$ (**2b**) showing the atom-labelling scheme.

in the range of these observed for $[Pr(OCMe(CF_3)_2]_3$ [3].

Metal–oxygen distances range from 2.224(6) to 2.762(6) Å. The O^{2-} ligands are of two types. The oxygens O(15), which connect the two building blocks, have a tetrahedral environment with quite regular Pr—O distances [2.276(5) −2.330(5) Å]. The other oxo ligands, O(46), have a less regular surrounding with Pr—O distances varying from 2.488(6) to 2.762(5) Å. Another feature is their distortion towards a planar geometry [O—Pr—O angles between 82.1(1) and 95.7(2)°] although the sum of the angles around the oxygen (354.4°) and the distance from the Pr(1)Pr(2)Pr(3)Pr(4) plane (0.415 Å) indicates possible pyramidal geometry. The octanuclear cluster displays four types of alkoxide ligand. The praseodymium alkoxide distances follow the pattern previously observed for 2-methoxyethoxide derivatives [6,20]: Pr—OR (terminal) < μ_2,η^2-Pr—OR < μ_3,η^2-Pr—OR < Pr—O(ether).

The metal–oxygen bond distances are quite large, as a result of the metal eight coordination, although the values are comparable with those observed for the other praseodymium alkoxide derivatives structurally characterized [3,5b]. The terminal Pr—OR bonds have a value of 2.224(6) Å, with large associated Pr—O—C angles [174.6(6)°]. Two praseodymium atoms bear trimethylphosphine oxide ligands; the Pr(1)—O(10) coordination bonds [2.292(6) Å] and the Pr(1)—O(10)—P(11) angle [174.0(4)°] are in agreement with the data available on other lanthanide–phosphoryl adducts [21]. The presence of

[a] Atoms labelled ′ correspond to −x, −y, −z.

$OPMe_3$ is also confirmed by additional absorption bands in the FT-IR spectrum (with respect to **2a**) at 995 and 950 cm^{-1}.

Compound **2b** represents the first example of eight coordination for lanthanides in alkoxide chemistry (without carboxylates or β-diketonates as ancilliary ligands), the usual coordination number being generally six, with increase to seven for functional alkoxide groups [1]. The tendency for praseodymium to have larger coordination numbers than other lanthanides is also reflected by the seven coordination observed for the mixed-metal isopropoxide $[PrAl_2Cl(OPr^i)_8(Pr^iOH)]_2$ [5] and by $[Pr(OCMe(CF_3)_2)_3]_3$, in which the metals are seven and eight coordinated, depending on the number of secondary Pr···F bonds [3]. Tetranuclear lanthanide alkoxides have found precedent for isopropoxides as illustrated by $[Nd(OPr^i)_3(Pr^iOH)]_4$ [1b] or by $Ln_4(OCH_2Bu^t)_{12}$ (Ln = La, Nd) [19]. The presence of agostic Ln···H—C interactions in the solid for the latter, and of solvated alcohol molecules complementing the metal coordination sphere in the neodymium isopropoxide, allows the lanthanides to reach six coordination. Tetranuclear oxoalkoxide lanthanide moieties in which the lanthanides are six coordinated have been stabilized in mixed-metal alkoxides, namely $[Y_4(\mu_3\text{-}OBu^t)_2(\mu\text{-}OBu^t)_4(OBu^t)_4(\mu_4\text{-}O)\ (\mu\text{-}Cl)_2Li_4(\mu\text{-}OBu^t)_2]_2$ [22] and $Sm_4(\mu_4\text{-}O)(OPr^i)_{10}Ti(OPr^i)_4$ [18]. The metallic M_4 framework results from the assembly of two triangular subunits and so corresponds to a butterfly arrangement. The elimination of the solvated alcohol molecules of the lanthanide isopropoxide derivatives leads to oxo species as a means of retaining the six coordination [1b]. The compounds having the formulation $[Pr_4O_2(OR)_8]_m$ or $[Pr_4O_2(OR)_3(OR')_5]_m$ are likely to display metal oxygen frameworks related to that of **2b**. Octanuclear aggregates have been reported in lanthanide chemistry as well as in alkoxide chemistry. They result, generally, from hydrolytic polycondensation reactions. $[Er_8(\mu_4\text{-}O)(thd)_{10}(\mu_3\text{-}OH)_{12}]$ represents the first example of assembly *via* a planar

oxo ligand [23]. $Nb_8O_{10}(OEt)_{20}$ [24], $Ti_8O_6(OBz)_{20}$ (Bz = benzyl) [24], and $[Mo_8O_8Cl_6(\mu_3\text{-}O)_4(OH)_2(\mu\text{-}OH)_4(\mu\text{-}OEt)_4(EtOH)_4$ [26] obtained by microhydrolysis of alkoxides, have *closo* structures, while the structure of $[Mo_8O_{16}(OMe)_8(PMe_3)_4$ [27], which is derived from the photo-oxidation of a molybdenum carbonyl derivative, is based on a puckered cycle.

$Y_4PrO(OPr^i)_{13}$ possess a M_5O_{14} core similar to that of $Y_5O(OPr^i)_{13}$ [28], the metals all being six coordinated (Fig. 2). The yttrium and praseodymium atoms could not however be distinguished and the electron density of the metal atoms corresponds in fact to the average value for four yttrium and one praseodymium atom, these atoms are depicted Y*. Selected bond lengths and angles for $[Y_4PrO(OPr^i)$ are collected in Table 4. The isopropoxide ligands are of three types, four of them are triply bridging, four doubly bridging and five terminal. Metal–oxygen distances range from 2.01(2) to 2.49(2) Å and follow the pattern previously observed for $Y_5O(OPri)_{13}$: Y*—OR (terminal) < Y*—μ-OR < Y*—μ_3-OR ~ Y*—(μ_5—O) with the terminal Y*—OR bond distances being shorter than the sum of the covalent radii (2.35 Å). The cluster is quite regular with non-bonding metal–metal distances varying from 3.402(3) to 3.539(3) Å; the μ_5-oxo ligand is near the centre of the basal plane. As expected, the Y*—O and Y*···Y* distances are slightly longer than for the homometallic yttrium derivative.

In conclusion it appears that praseodymium alkoxide chemistry displays specific features with respect to other lanthanides. While praseodymium shares with other lanthanides formulations such as $Pr_5O(OPr^i)_{13}$ and $Pr_3(OR)_9(ROH)_2$, it displays a trend for high coordination numbers and thus more condensed oxo species. Secondary bonds such as Pr···F, Pr···H—C might contribute to the increase in the coordination number, as well as the generation of several oxo ligands even by reaction in mild conditions.

(Received 10 May 1996; accepted 1 July 1996)

Abstract—Reaction of the phenylhydrazinium ($PhN_2H_4^+$) ion with the labile aquo complexes of [Ru^{III}(HEDTA)(H_2O)] (EDTA = ethylenediaminetetraacetate) was studied electrochemically employing sampled DC, cyclic voltammetry and differential pulse techniques in 0.2 M CH_3COONa and H_2SO_4 mixture between pH 1.0 and 4.5 at 25°C. It produced two phenylhydrazinium complexes, namely [Ru^{III}(HEDTA)(N_2H_4Ph)]$^+$ and [Ru^{III}(EDTA)(N_2H_4Ph)] in the rapid aquo-substitution reactions. The second-order rate constants, k_1, for the formation of the former, and k_2 for the latter are 0.98 and 36.85 M^{-1} s^{-1}, respectively, as determined spectrophotometrically by following the intensity of the LMCT band at 420 nm. The complex, [Ru^{III}(HEDTA)(N_2H_4Ph)]Cl · $2H_2O$ was prepared and characterised by physicochemical methods. These phenlhydrazinium complexes were reduced by two electrons at $E_{1/2} = -0.175$ V *vs* SCE, producing one mole of NH_3 and the corresponding Ru^{III}–NH_2Ph complexes in subsequent rapid decomposition steps. The unstable Ru^{III}–NH_2Ph complexes were rapidly hydrolysed to one mole of NH_2Ph and the respective aquo complex. One-electron reduction steps for the regenerated aquo complex at ($E_{1/2}$) −0.254 V and the unhydrolysed Ru^{III}–NH_2Ph complex at −0.417 V were also observed. Phenylhydrazine was reduced to ammonia and aniline by constant potential coulometry at −0.200 V(Hg) *vs* SCE, in the presence of [Ru^{III}(HEDTA)(H_2O)] at 100 : 1 molar ratio. The turnover number (per mole of catalyst per hour) with respect to ammonia is 5.98 and 2.82 at pH 2.8 and 1.9, respectively. The probable mechanisms for the electroreduction of the above phenylhydrazinium complexes and the catalytic reduction of phenylhydrazine to NH_3 and NH_2Ph, are proposed. Keywords: Ru^{III}–EDTA; phenylhydrazine; interaction; electrocatalysis; ammonia; aniline

We have studied the chemistry of Ru–EDTA complexes extensively [1–7] and the present work is a continuation of our efforts to develop a simple water-soluble metal complex for activating and reducing the N—N bonded molecules to ammonia and/or amines in order to elucidate the pathways for N—N bond reductions in homogeneous solution. Metal bound hydrazine is considered to be the active intermediate in nitrogen fixation by primitive organisms, e.g. *Azotobacter*, carrying a nitrogenase system [8–11]. Our earlier communications [8,12,13], revealed the reduction of hydrazinium [12] and azide [13] ions, surprisingly, at unexpected potentials of the Hg electrode catalysed by Ru–EDTA complexes in aqueous acidic conditions. To obtain more mechanistic details and to study the substitutional effect on the coordinated N of hydrazine in this intriguing N—N bond reduction, we have selected phenylhydrazine as a substrate in the present study. The results of spectrophotometric, kinetic and electrochemical studies of the interaction of phenylhydrazine with Ru^{III}–EDTA complexes in aqueous acidic solutions are reported. The results are correlated with the data reported for hydrazinium and azide ions.

EXPERIMENTAL

Materials

$K[Ru^{III}(HEDTA)Cl]\cdot 2H_2O$ was prepared from $K_2[Ru^{III}Cl_5(H_2O)]$ by previously reported methods, and was characterised [14,15]. This complex, as evidenced earlier [12,16] by spectrophotometric and kinetic data, quickly changes to $[Ru^{III}(HEDTA)(H_2O)]$ ($pK_a = 2.37$) in aqueous solution of pH 1.0–4.5. Hence, $[Ru^{III}(HEDTA)(H_2O)]$ has been considered as the precursor in this study. Phenylhydrazine hydrochloride (N_2H_4PhCl) was obtained from Allied Chemicals, U.S.A. and used as a source for $N_2H_4Ph^+$ ion. All other chemicals used were of AR grade.

$[Ru^{III}(HEDTA)(N_2H_4Ph)]Cl\cdot 2H_2O$ was prepared by dissolving $K[Ru^{III}(HEDTA)Cl]\cdot 2H_2O$ (100 mg, 0.2 mmol) phenylhydrazine hydrochloride (30.66 mg, 0.21 mmol) in the minimum quantity of water. The resulting dark yellow solution was stirred for 2 h at 45° under Ar atmosphere. The product was precipitated with absolute alcohol, filtered and washed repeatedly with 9 : 1 acetone–water mixture and dried *in vacuo*. Found: C, 33.7; H, 4.4; N, 9.8. Calc. for $[Ru^{III}(HEDTA)(N_2H_4Ph)]Cl\cdot 2H_2O$: 33.5; H, 4.1; N, 9.4%. IR (cm^{-1}): 3210 (N—H stretching), 1750 (COOH), 1640 (coordinated COO^-), 1420 and 1080 (N—H deformations).

pH-metric titrations

N_2H_4PhCl was titrated with standard NaOH (0.1 M) solution as usual [14] and from the resulting pH data, the acid dissociation constant (pK_a) of $NHPh\cdot NH_3^+$ ion was calculated as 5.15 ± 0.01 at 25°C. Similar titrations were carried out with $[Ru^{III}(HEDTA)(H_2O)]$, in the absence and presence of one equivalent of N_2H_4PhCl. This data revealed that the acidic proton on the more basic nitrogen in $NHPh.NH_3^+$ is unaffected during its interaction with the Ru^{III} centre. This is sufficient to prove the coordination of $N_2H_4Ph^+$ at the sixth vacant position on Ru^{III} through its weak basic NHPh group.

Measurements and method

Electrochemical measurements such as sampled DC, differential pulse polarography (DPP), cyclic voltammetry (CV) and differential pulse voltammetry (DPV), were performed with EG&G Princeton Applied Research models: 174A polarographic analyzer, 175 universal programmer with a high-precision *X–Y* recorder. A three-electrode assembly of EG&G PAR model 303, comprising a Pt wire auxiliary, SCE reference and a dropping mercury electrode (DME) of 3.85 mg s^{-1} or a hanging mercury drop electrode (HMDE) of 0.021 cm^2 was used. All *E–i* plots were recorded under Ar in the potential range +0.2 to −0.8 V. The electrochemical cell was thermostatted to 25°C within ±0.1°C. Controlled potential coulometry (CPC) was carried out using a EG&G PAR model 173 galvanostat and 179 digital integrator in a three-compartment cell. The auxiliary Pt mesh and the reference SCE electrodes were separated from the main compartment cell by fine (G4) glass frits. The main compartment contained Hg-pool (1-inch convex surface diameter) as the working electrode with a glass disk agitator just above the mercury surface. A 30-ml solution containing 0.2 M CH_3COONa, 30 μmol $K[Ru^{III}(HEDTA)Cl]\cdot 2H_2O$ and 30 mmol N_2H_4PhCl, having the pH adjusted to the required value (1.9 or 2.8) with H_2SO_4 solution, was electrolysed for 10 h at −0.200 V under Ar. The quantity of ammonia produced was estimated at 1 h intervals using an Orion 940 ion analyser equipped with an ammonia-sensing electrode [12]. Aniline, produced along with ammonia, was tested using vanadium(V) salt [17].

The electronic absorption spectra were recorded at 25°C using a Shimadzu UV–vis NIR scanning spectrophotometer, model UV-3101 PC. Kinetic studies were carried out on a Hi-Tech stopped-flow spectrophotometer, SF-51 coupled to an Apple data processor. The observed rate data for the formation of the phenylhydrazinium complex were obtained by monitoring absorbance changes in the growth of the characteristic LMCT band at 420 nm. Experiments were conducted under pseudo-first-order conditions of excess phenylhydrazine hydrochloride concentration. The ionic strength of the kinetic solution was adjusted with 2 M KCl. The temperature was maintained to 25±0.1°C using a built-in thermostatic cell compartment.

RESULTS AND DISCUSSION

Voltammetry

The *E–i* responses of $[Ru^{III}(HEDTA)(H_2O)]$ species in the absence and presence of one equiv. N_2H_4PhCl at pH 2.8 were examined at the DME (sampled DC, DPP) and the HMDE (CV and DPV). In the absence of N_2H_4PhCl, the complex exhibited a cathodic wave at $E_{1/2} = -0.213$ V in sampled DC and a pair of cathodic (−0.236 V) and anodic (−0.173 V) peaks in CV, which conforms with the reported values assigned for the $Ru^{III/II}$ couple [12,13].

In the presence of N_2H_4PhCl, after 3–5 min of equilibration, $[Ru^{III}(HEDTA)(H_2O)]$ showed three closely separated reduction waves in sampled DC (Fig. 1a) at $E_{1/2} = -0.155$, −0.233 and −0.407 V. The overall wave height at −0.5 V is nearly three and a half times larger than that of the $[Ru^{III}(HEDTA)(H_2O)]$ one-electron wave. These changes are accounted for by the formation and subsequent participation of phenylhydrazinium complexes in the electrochemical processes. The $E_{1/4}-E_{3/4}$ values of these waves were measured as 30, 55 and 60 mV which indicated the first wave as a two-electron process and

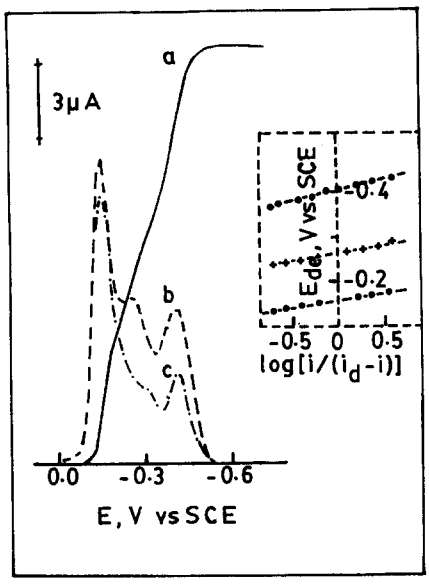

Fig. 1. Voltammetric responses of $[Ru^{III}(HEDTA)(H_2O)]$ (1 mM) in the presence 1 equiv. of N_2H_4PhCl. (a) Sample DC, (b) DPP, (c) DPV. pH = 2.8. Inset: Plots of E_{de} *vs* log $\{i/(i_d-i)\}$ for the polarographic steps shown in (a).

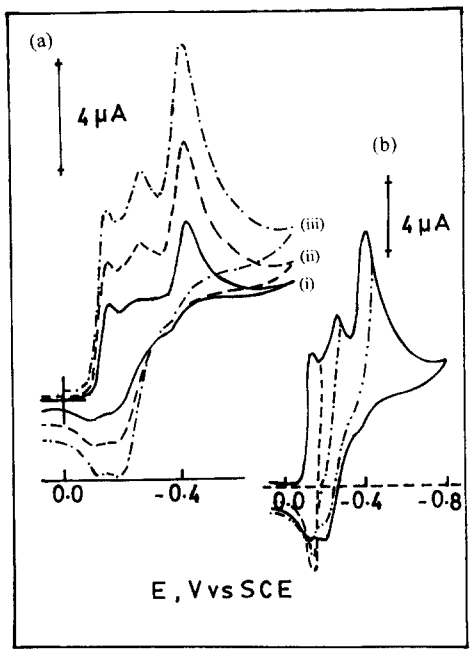

Fig. 2. Cyclic voltammograms of $[Ru^{III}(HEDTA)(H_2O)]$ (1 mM) in the presence of 1 equiv. N_2H_4PhCl at the potential scan speed (a) (i) 0.02, (ii) 0.05, (iii) 0.1 V s^{-1} and (b) 0.1 V s^{-1} at various switching potentials.

the last two as one-electron processes. The plots of E_{de} *vs* $\log i(i_d-i)$ were linear as seen in the inset of Fig. 1 indicating that all three waves in Fig. 1a are diffusion controlled and reversible at the DME.

The behaviour of $[Ru^{III}(HEDTA)(H_2O)]$ in the presence of 0.1–100 equiv. N_2H_4PhCl was also studied. The diffusion current at -0.5 V had increased linearly with the concentration of N_2H_4PhCl between 0.1–1.0 equivalent, whereas the changes in the overall total diffusion current and the $E_{1/2}$ values at higher equivalents of N_2H_4PhCl were inconspicuous. However, the height of the second wave had reached a minimum value at $[N_2H_4PhCl]/[Ru^{III}(HEDTA)(H_2O)] \geqslant 10$. A plot of the mole ratio of N_2H_4PhCl to the complex against the diffusion current at -0.5 V suggested the formation of monomeric phenylhydrazinium adducts; namely $[Ru^{III}(HEDTA)(N_2H_4Ph)]^+$ and $[Ru^{III}(EDTA)(N_2H_4Ph)]$, as was confirmed spectrophotometrically.

Figure 1 (b and c) shows the DPP and DPV responses of the above solution. While the position of these peaks correlated with the $E_{1/2}$ values of the corresponding waves in Fig. 1a, the second peak diminished and moved to cathodic potentials in DPV. Whilst, in CV, three cathodic peaks at -0.157, -0.270 and -0.456 V in the forward scan, and two anodic peaks at -0.118 and -0.185 V (counterparts of the first two) in the reverse scan (Fig. 2a), were observed. There was no anodic counterpart to the third cathodic response. Peak intensities of all three cathodic (CV) responses varied as a function of the square root of the scan speed, while peak positions remained static. Although, the two anodic peaks appeared closely separated at scan speeds <0.1 V s^{-1} (see Fig. 2a, part ii) or the potentials were switched to the foot of the second/third cathodic waves (see Fig. 2b), they diminished slowly as the scan approached 0.02 V s^{-1}.

The effect of pH on the $E_{1/2}$ of the waves in Fig. 1a, and the difference in diffusion current at -0.5 V in the absence and presence of 1 and 100 equiv. of N_2H_4PhCl, were measured. The half-wave potential of the waves in Fig. 1(a) was not shifted significantly. However, the enhanced current at -0.5 V changed considerably, as shown in Fig. 3. The rise in the diffusion current was a maximum in the pH range 2.0–3.5. The lowering of enhanced diffusion current between pH 1.0 and 2.0 is the result of the low rate of formation of $[Ru^{III}(HEDTA)(N_2H_4Ph)]^+$, while that at pH > 3.5 is owing to the stabilization of the $[Ru^{III}(EDTA)(N_2H_4Ph)]$ complex.

Spectrophotometry

The reaction of $[Ru^{III}(HEDTA)(H_2O)]$ with N_2H_4PhCl in 0.2 M CH_3COONa and H_2SO_4 mixture (pH 2.8) accompanied the spectral change producing a new absorption (ligand to metal charge transfer) band at 420 nm. Spectral changes that occurred immediately after the addition of N_2H_4PhCl to a solution of $[Ru^{III}(HEDTA)(H_2O)]$ in different molar ratio at pH 2.8 are shown in Fig. 4a. The kinetics of the reaction were studied as a function of $[N_2H_4PhCl]$ and pH under pseudo-first-order conditions at 25°C. The values of observed rate constant of formation (k_{obs})

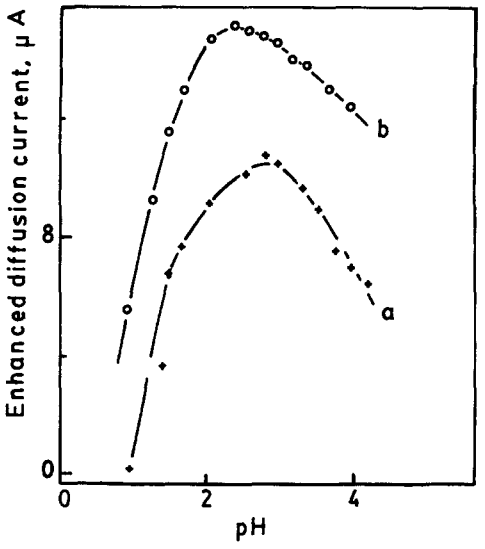

Fig. 3. Influence of solution pH on the enhanced diffusion current (Δi_d) at -0.45 V in the presence of (a) 1, (b) 100 equiv. of phenylhydraine. [Ru^{III}(HEDTA)(H_2O)], 1 mM.

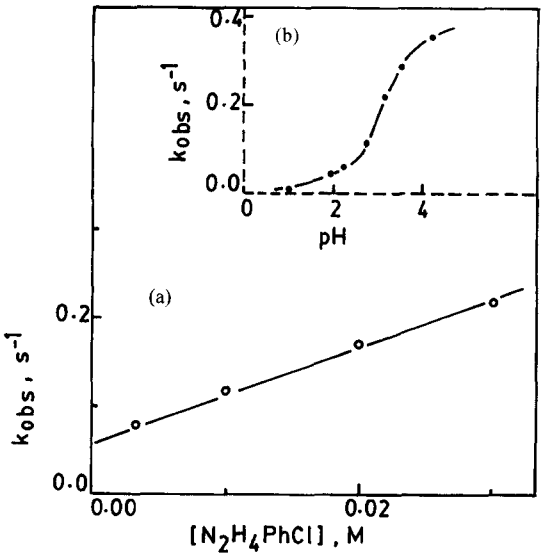

Fig. 5. (a) Plot of k_{obs} *vs* [N_2H_4PhCl]. [Ru^{III}(HEDTA)(H_2O)], 0.5 mM, pH 2.8. (b) Plot of k_{obs} *vs* pH: [Ru^{III}(HEDTA)(H_2O)], 0.5 mM; [N_2H_4PhCl], 0.02 M.

of the hydrazinium adduct changed linearly with [N_2H_4PhCl]. The plot of k_{obs} *vs* [N_2H_4PhCl] (Fig. 5a) showed an appreciable intercept which indicated the presence of reverse reaction of products. The ratio of intercept to slope was 94.1 which was in good agreement with the slope-to-intercept ratio, ($K_{eq.} = 77$) [16] obtained from the plot of $(\Delta A)^{-1}$ *vs* $[N_2H_4PhCl]^{-1}$ (Fig. 4b).

The pH-observed rate constant profile (k_{obs}), which

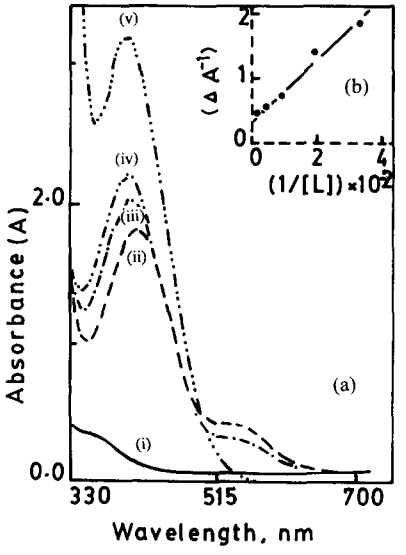

Fig. 4. (a) Absorption data of [Ru^{III}(HEDTA)(H_2O)] (2 mM) immediately after the addition of N_2H_4PhCl at 25°C. $10^3 \times$ [N_2H_4PhCl]: (i) 0.0, (ii) 0.5, (iii) 1.0, (iv) 2.0, (v) 10 M. pH 2.8. (b) Plot of the reciprocal absorbance change (ΔA^{-1}) at 420 nm *vs* the reciprocal N_2H_4PhCl concentration. [Ru^{III}(HEDTA)(H_2O)] (1 mM) was dissolved in 0.2 M CH_3COONa and H_2SO_4 mixture at 25°C. pH = 2.8.

is quite similar to those of the [Ru^{III}(HEDTA)(H_2O)] substitution reactions [6,18], is shown in Fig. 5b. A sharp increase in k_{obs} in the pH range 2.0–4.5 is attributed to the acid dissociation equilibrium of the carboxylic acid of the HEDTA ligand, since the dissociation of the proton of the bound $N_2H_4Ph^+$ in the pH range investigated here was not observed in the pH-metric titration of 1 : 1 K[Ru^{III}(HEDTA)Cl]·$2H_2O$ and [N_2H_4PhCl]. Thus, the pH dependence in Fig. 5b is attributed to the participation of two types of Ru^{III}–EDTA complexes in Eq. (1) as indicated in reactions (2) and (3).

$$[Ru^{III}(HEDTA)(H_2O)] \overset{K_a}{\rightleftharpoons} [Ru^{III}(EDTA)(H_2O)]^- + H^+ \quad (1)$$

$$[Ru^{III}(HEDTA)(H_2O)] + N_2H_4Ph^+ \overset{k_1}{\rightarrow} [Ru^{III}(HEDTA)(N_2H_4Ph)]^+ + H_2O \quad (2)$$

$$[Ru^{III}(EDTA)(H_2O)]^- + N_2H_4Ph^+ \overset{k_2}{\rightarrow} [Ru^{III}(EDTA)(N_2H_4Ph)] + H_2O \quad (3)$$

The rate expression for the above reactions can be expressed as

$$K_{obs} = \{k_1[H^+] + k_2K_a\}\{[N_2H_4Ph^+]\}/\{[H^+] + K_a\} \quad (4)$$

Where $K_a = 2.37$. From the plot of K_{obs} $\{[H^+] + K_a\}/[N_2H_4Ph^+]$ *vs* $[H^+]$, the second-order rate constants k_1 and k_2 were evaluated as 0.98 and 36.85 M^{-1} s^{-1}, respectively, which were found to be larger (about two orders of magnitude) than the

values of the corresponding hydrazinium complexes [12].

Mechanism of electroreduction of phenylhyrazinium complexes

Figure 6a depicts the voltammetric (sampled DC and CV) responses of $[Ru^{III}(HEDTA)(N_2H_4Ph)]Cl \cdot 2H_2O$, which showed the characteristic absorption band at 440 nm (Fig. 6b) in 0.2 M CH_3COONa and H_2SO_4 mixture at pH 2.8. Three reduction waves identical to those given in Fig. 1a were observed in sampled DC (Fig. 6a, part i). The first two waves at ($E_{1/2}$) −0.175 and −0.254 V were poorly resolved, while the third appeared as a low, intense wave at −0.417 V. The CV response in Fig. 6a part ii had further confirmed that the reduced species at −0.175, −0.254 and −0.417 V were coupled to some complex chemical reactions. In the exhaustive electrolysis at −0.5 V *vs* SCE, $[Ru^{III}(HEDTA)(N_2H_4Ph)]Cl \cdot 2H_2O$ consumed total charge equivalent to three electrons per Ru atom, which produced one equiv. ammonia and aniline. The CV of the reduced solution exhibited a pair of cathodic and anodic peaks close to those at −0.270 and −0.185 V, respectively, as shown in Fig. 4a part (ii) or those of the aquo complex. On the basis of these results, the mechanisms for the electroreduction of phenylhydrazinium adducts $[Ru^{III}(HEDTA)(N_2H_4Ph)]^+$ and $[Ru^{III}(EDTA)(N_2H_4Ph)]$ in Figs 1 and 2 are as shown in Scheme 1.

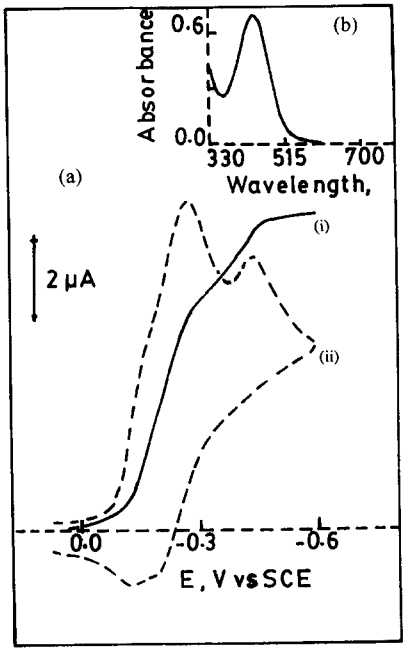

Fig. 6. Voltammetric responses: (i) sampled DC; (ii) CV at scan speed = 0.1 V s^{-1} and (b) absorption spectrum of $[Ru^{III}(HEDTA)(N_2H_4Ph)]Cl \cdot 2H_2O$ (1 mM) in 0.2 M CH_3COONa and H_2SO_4 mixture at 25°C, pH, 2.8.

It is significant to note that the addition of $PhNH_3Cl$ to a solution of $[Ru^{III}(HEDTA)(H_2O)]$ under the present experimental conditions showed no remarkable change in the voltammetric behaviour of the $Ru^{III/II}$ couple and the absorption spectra of the latter. In other words, this accounts for the very low stability of $LRu^{III}NH_2Ph$ and $LRu^{II}NH_2Ph^-$ complexes in solution, as predicted in Scheme 1.

Catalytic reduction of phenylhydrazine

Phenylhydrazine hydrochloride (100 equiv.) in 0.2 M CH_3COONa and H_2SO_4 mixture (pH 2.8 or 1.9) containing one equiv. $K[Ru^{III}(HEDTA)Cl] \cdot 2H_2O$ was electrolysed at −0.200 V *vs* SCE in order to estimate the catalytic activity of the Ru^I–EDTA complexes of phenylhydrazine. As expected, phenylhydrazine was reduced to give NH_3 and NH_2Ph, justifying the first reduction wave at ($E_{1/2}$) −0.175 V as a multi-electron wave. The quantity of ammonia produced in the 10-h reaction was linear (Fig. 7) and consistent with the mechanism shown in Scheme 2. The turnover number, with respect to moles of ammonia formed per mole of catalyst per hour, is 5.98 at pH 2.8 and 2.82 at pH 1.9, and the coulombic efficiency was 100%.

The reduced solution, after 10 h electrolysis, showed all the electrochemical features that are shown in Figs 1 and 2 and produced ammonia when electrolysis was continued further, at the turnover rate found before. This proved that the efficiency of the metal remained intact during the turnover of phenylhydrazine reduction.

The data presented here, and previously, attests to the excellent ability to ruthenium metal, in its EDTA complexes, in transferring electrons from the external electron source (Hg electrode) to the bound N—N bonds, and the superior electron conducting nature of the Ru—N bond of nitrogenous (hydrazines/azide)

$$LRu^{III}N_2H_4Ph \underset{-2e,-0.175}{\overset{+2e}{\rightleftharpoons}} LRu^{I}N_2H_4Ph^{2-} \xrightarrow[-NH_3]{+H^+} LRu^{III}NH_2Ph \xrightarrow[-NH_2Ph]{+H_2O} LRu^{III}H_2O$$

compounds. Apparently, these intrinsic properties of the metal were not altered by a change in the N—N bond order from 1.0 to 2.5, or phenyl ring substitution on the coordinated N of the $N_2H_5^+$ ion. However, the turnover rate of formation of NH_3 with N_2H_4PhCl was found to be less than the expected value (of one-half) of the turnover rate obtained with $N_2H_5HSO_4$ [12]. This slight deviation could be attributed to the combined effects of hydrophobic nature and steric and electrostatic repulsions in the reduced complexes, caused by the phenyl ring present on the bound NHPh group.

(Received 9 January 1996; accepted 9 April 1996)

Abstract—2,4-Disubstituted-5-imino-Δ^2-1,3,4-telluradiazolines were isolated together with α-tellurocyanatobenzaldehyde arylhydrazones when potassium tellurocyanate was reacted with hydrazidoyl bromides in DMSO solution. *N*-Acetyl derivatives were prepared by reaction of 5-imino-Δ^2-1,3,4-telluradiazolines with acetic anhydride. Reaction of 2-amino-benzyl iodide with KTeCN afforded the novel heterocyclic tellurium compound 1,4-dihydro-2-imino-3-telluraquinoline, which, on treatment with acetic anhydride, gave the acetyl derivative. The acetyl derivative was hydrolysed with HCl/H_2O to afford 1-*N*-acetyl-4-hydro-3-telluraquinolin-2-one. Copyright © 1997 Elsevier Science Ltd

Keywords: potassium tellurocyanate; telluradiazolines; telluraquinolines; hydrazidoyl halides; 2-aminobenzyl tellurocyanate; tellurides.

Potassium selenocyanate has been the object of much more intensive study by organic chemists than its less stable tellurium counterpart [1,2]. As is well known, the reaction of hydrazidoyl halides with KSeCN in ethanol gives the corresponding 5-imino-Δ^2-1,3,4-selenadiazolines [3,4], which are easily hydrolysed to their corresponding 5-oxo compounds [4]. The corresponding reaction of potassium tellurocyanate with hydrazidoyl halides has not previously been reported. It was, therefore, of interest for us to see whether hydrazidoyl bromide will undergo a similar cyclization reaction with potassium tellurocyanate. Reaction of 2-aminobenzyl iodide with potassium tellurocyanate is also reported.

EXPERIMENTAL

(*a*) *Physical measurements*

Melting points were determined on a Gallenkamp apparatus and are uncorrected. Infrared (KBr) spectra were recorded in the range 4000–200 cm^{-1} on a Pye–Unicam SP3-300s spectrophotometer. Elemental analyses were performed on an EA-1108 Carlo–Ebra elemental analyser. ^1H NMR spectra were recorded in $CDCl_3$ solution containing TMS as internal standard using a Jeol EX-90 instrument.

(*b*) *Synthesis*

All reactions were carried out under argon, α-bromobenzaldehyde phenylhydrazone and α-bromo-4-nitrobenzaldehyde-2,4-dinitrophenylhydrazone were prepared by mixing equimolar amounts of arylhydrazine and aldehyde in ethanol/acetic acid solution as previously described [5].

α-Tellurocyanatobenzaldehyde phenylhydrazone (**1**) *and* 2,4-*diphenyl*-5-*imino*-Δ^2-1,3,4-*telluradiazoline* (**2**)

A solution of potassium tellurocyanate was readily prepared by stirring together 5 mmol each of powdered tellurium and dry powdered KCN in dry DMSO (15 cm^3), at 100°C for 1 h under argon according to Spencer *et al.* [6]. To the resulting pale yellow solution, cooled to room temperature and diluted with dry

* Author to whom all correspondence should be addressed.

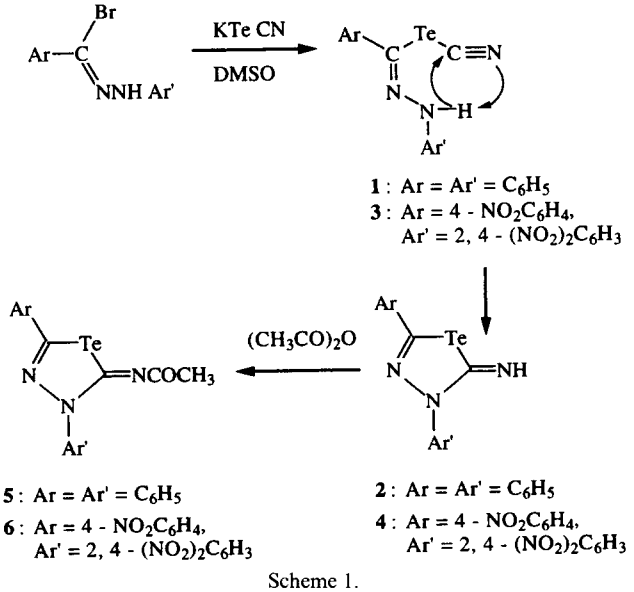
DMSO (15 cm^3), was added dropwise with stirring a solution of α-bromobenzaldehyde phenylhydrazone (1.4 g, 5 mmol) in dry DMSO (15 cm^3). The reaction mixture was stirred at room temperature for 4 h and filtered. The filtrate was poured into distilled water (200 cm^3), which was then extracted with dichloromethane (3×30 cm^3). The combined extracts were dried ($MgSO_4$) and then evaporated under reduced pressure to yield a red–brown oil consisting of two components according to TLC. Column chromatography [silica; toluene/methanol (19 : 1)] gave compound **1** as a red crystalline solid and compound **2** as a red–brown crystalline solid. Recrystallization of **1** from CCl_4 gave red crystals, m.p. 136–137°C. Recrystallization of **2** from carbon tetrachloride gave reddish brown crystals m.p. 169–170°C.

α-Tellurocyanato-4-nitrobenzaldehyde-2′,4′-dinitrophenylhydrazone (**3**) *and 5-imino-2-(4′-nitrophenyl)-4-(2′,4′-dinitrophenyl)-Δ²-1,3,4-telluradiazoline* (**4**)

The reaction of KTeCN with α-bromo-4-nitrobenzaldehyde-2′,4′-dinitrophenylhydrazone in dry DMSO was carried out as described in the above method. The resulting solution was poured into distilled water (200 cm^3), extracted with chloroform (3×50 cm^3) and dried ($MgSO_4$). The extracts were evaporated under reduced pressure to afford a brown precipitate consisting of two components. Extraction of the brown solid with THF using a Soxhlet extractor was continuous. The extract was evaporated to give an orange–yellow precipitate. Recrystallization from toluene/ethanol (9 : 1) gave orange–yellow crystals of α-tellurocyanto-4-nitrobenzaldehyde-2′,4′-dinitrophenylhydrazone.

The remaining residue was recrystallized from ethanol/THF (4 : 1) and gave a yellow precipitate, m.p. 290–292°C.

5-N-Acetylimino-2,4-diphenyl-Δ²-1,3,4-telluradiazoline (**5**) *and 5-N-acetylimino-2-(4′-nitrophenyl)-4-(2′,4-dinitrophenyl)-Δ²-1,3,4-telluradiazoline* (**6**)



The corresponding 5-imino-1,3,4-telluradiazoline (11 mmol) was refluxed in acetic anhydride (20 cm^3) for 20 min. The resulting solution was cooled to room temperature, poured into iced distilled water, stirred for 30 min and then extracted with chloroform (3×25 cm^3). The combined extracts were washed with aqueous sodium bicarbonate and water, dried ($MgSO_4$) and evaporated under reduced pressure to yield a red–brown solid. Recrystallization from ethanol gave red crystals. Compound **5**, m.p. 75–76°C. Compound **6**, m.p. 272°C.

1,4-Dihydro-2-imino-3-telluraquinoline (**7**)

To 10 mmol of KTeCN in dry DMSO[6] was added 2-aminobenzyl iodide (2.32 g, 10 mmol) in 15 cm^3 of dry DMSO over 15 min. The yellow solution was stirred for 2 h. The resulting solution was filtered, poured into water (500 cm^3) and left overnight. A dark brown solid was formed, filtered and recrystallized from ethanol/hexane to give orange crystals, m.p. 75–77°C.

1-N-Acetyl-4-hydro-2-imino-3-telluraquinoline (**8**)

Compound **6** (1.04 g, 4 mmol) was refluxed in acetic anhydride (20 cm^3) for 20 min. The mixture was cooled to room temperature and then poured onto

crushed ice. The orange precipitate was collected and washed several times with water and finally with ethanol. Recrystallization from ethanol gave orange crystals, m.p. 90–92°C.

1-*N*-*Acetyl*-4-*hydro*-2-*imino*-3-*telluraquinolin*-2-*one* (**9**)

A solution of **7** (0.7 g, 2.3 mmol) in 50 cm^3 of distilled water containing 15 cm^3 of 1 N HCl was refluxed for 2 h, then cooled to room temperature. The acidic solution was neutralized with NaOH solution, extracted with CH_2Cl_2 (3×25 cm^3), dried ($MgSO_4$), filtered and evaporated. Recrystallization from petroleum ether (60/80) gave yellow crystals, m.p. 131–133°C.

RESULTS AND DISCUSSION

Many selenadiazolines have been prepared by the action of sodium or potassium selenocyanate on hydrazidoyl halides [4]. It was therefore, of interest to determine whether or not the same reaction was operative in organic tellurocyanate chemistry. it was found that the reaction of KTeCN with hydrazidoyl bromides under argon gave a mixture of products from which a good yield of the desired telluradiazolines (**2** and **4** in 64 and 71% yields, respectively), together with a 29 and 18% yield of the corresponding organotellurocyanate (i.e. **1** and **3**, respectively) were obtained (Scheme 1). Reaction of **2** and **4** with acetic anhydride gave **5** and **6**, respectively, in good yields (Scheme 1).

The methods used for the preparation of all these new compounds are shown in Scheme 1. Yields, melting points, colour and C, H, N analytical data for the compounds are shown in Table 1. All compounds gave satisfactory elemental analyses. Compound **3** is exceptional and its elemental analysis is more in agreement with the presence of a residual diethyl ether molecule.

Distinction of the two products (**1** and **2**) and (**3** and **4**) by IR spectroscopy was relatively easy. Compounds **1** and **3** show strong bands at 2240 and 2230 cm^{-1}, respectively, which are attributed to ν(Te—CN) [7]. The bands assigned to ν(Te—CN) were absent from the spectra of **2** and **4**, Table 1.

In general, the IR spectra of compounds **1**–**6** gave characteristic bands. Compounds **2** and **4** showed bands assignable to the imino group at 3200 and 3280 cm^{-1}, respectively. The presence of an acetyl group in **5** and **6** was also confirmed from their IR data, (Table 1).

We expected that the reaction of 2-aminobenzyl iodide with potassium tellurocyanate would lead to the corresponding 2-aminobenzyl tellurocyanate, but instead we obtained the novel heterocycle **7**. The reaction may have first afforded the organic tellurocyanate intermediate, which then cyclized spontaneously to the new cyclic telluride (**7**) (Scheme 2). Treatment of **7** with acetic anhydride yielded the corresponding *N*-acetyl derivative (**8**) in 60% yield, which was subsequently hydrolysed by HCl/H_2O to give **9** in 84% yield (Scheme 2). This supports the acetylation of the amino group rather than the imino group.

The important IR frequencies are listed in Table 1. The spectrum of **9** reveals the appearance of two strong bands, one at 1660 cm^{-1} and another at 1715 cm^{-1} which are attributed to the stretching vibrations

of the ring and side chain carbonyl groups, respectively. The spectrum of **8** shows only one ν(C=O) at 1720 cm^{-1} as a strong band.

The ν(Te—$C_{aliphatic}$) vibrations in the IR spectra for all the compounds (**1**–**9**) are consistent with those reported previously for alkyltellurium compounds [8,9].

^{1}H NMR spectra for compounds **1**, **2** and **3** were measured in $CDCl_3$. These compounds gave complex aryl proton signals at *ca* δ 6.96–8.00 and a broad signal due to NH protons at δ 6.30 and 9.21 for **1** and **2**, respectively. The spectrum of **3** revealed an acetyl signal at δ 2.20.

In conclusion, a new and convenient one-pot synthesis of new cyclic tellurides containing nitrogen, using potassium tellurocyanate as a tellurating agent, has been described.

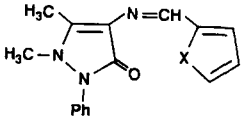
Synthesis and characterization of oxovanadium(IV) and dichlorovanadium(IV) complexes of biologically active 4-aminoantipyrine derivatives

Ali El-Dissouky,* Aziza K. Shehata and Ghada El-Mahdey

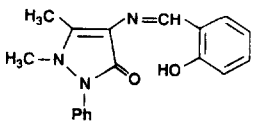
Chemistry Department, Faculties of Science and Education, Alexandria University, Alexandria, Egypt

(Received 18 September 1995; accepted 4 April 1996)



Abstract—A new series of oxovanadyl complexes of the Schiff base ligands 4-(2-pyrrolyl methylideneamino)antipyrine (PyAAP), 4-(2-thienylmethylideneamino)antipyrine (TAAP), 4-furfurylideneaminoantipyrine (FAAP) and 4-(2-hydroxybenzylideneamino)antipyrine (SAAP), have been synthesized and characterized by different physical techniques. The spectral and magnetic data indicate a distorted square pyramidal structure for all complexes. The selective deoxygenation of the oxovanadyl complexes $[(PyAAP\text{-}H)_2(VO)_2SO_4]$ and $[(SAAP\text{-}H)_2VO]$, which gave a good yield of the corresponding dichloro compounds $[L_2VCl_2]$, L = PyAAP-H or SAAP-H, is made by using different deoxygenating agents in different solvents and at various temperatures. The purity and the percentage yield of the products are found to be solvent, temperature and deoxygenating agent dependent. Spectral and magnetic studies are used to elucidate the structure of the dichloro derivatives. The solvent effects upon the electronic spectra of the oxovanadyl complexes and the corresponding dichloro derivatives are ascertained. Copyright © 1997 Elsevier Science Ltd

Keywords: antipyrine; vanadium(IV); spectra; synthesis; magnetism; chlorination.



It is becoming increasingly apparent that the chemistry of vanadium is of great importance to a wide variety of biological and industrial systems. Recently, it was found that there is a series of nitrogenase metalloenzymes which have vanadium at the active site [1–8]. In these enzymes vanadium appears to shuttle between V^{2+} and V^{4+} and is possibly bound to an iron–sulfur cluster, as it is difficult for direct linking of iron–sulfur clusters [9] and V^{4+}. Furthermore, the role of vanadium in the biosphere is very important. It has been found that mammals require vanadium at the nano- to pico- molar level, and several lower organisms have a vanadium requirement at a much higher level [3,10].

Vanadium is also important in the fuel industry [9–11]. Vanadium occurs naturally and can be in high concentrations in heavier crude oil. It affects the industry because its necessary removal poisons the heterogeneous catalysis used in processing [12–14]. The intermediate species in the transformation of the naturally occurring VO^{2+} complexes to vanadium sulfide on the upgrading catalyst surface are not well characterized. Some evidence suggests that VO^{2+} is deoxygenated to V(IV) [13,15]. Vanadium compounds have also been used to generate slurry-type catalysts to upgrade heavy oils and assist in coal liquefaction. Clearly the activation of the V=O bond is a critical part in the fuel industry.

Due to the importance of vanadium compounds, we aimed to prepare and characterize some biologically active vanadyl complexes of antipyrine derivatives (I) followed by the deoxygenation of the isolated complexes to form dichloro derivatives.

EXPERIMENTAL

Synthesis of the organic ligands

The organic ligands were prepared according to the following method: a solution of the corresponding aldehyde (1.0 or 1.1 g, 0.01 mol of furan-2-aldehyde or thiophene-2-aldehyde, respectively) in EtOH (20 cm^3) was added to a solution of 4-aminoantipyrine (2.1 g, 0.01 mol) in 50 cm^3 of the same solvent. The reaction mixture was refluxed on a water bath for 1–2 h. Upon cooling to room temperature the solid formed in each case was isolated by filtration and recrystallized from EtOH and dried *in vacuo* over P_4O_{10}.

Synthesis of oxovanadyl complexes

All vanadyl complexes of the 4-aminoantipyrine Schiff bases were prepared by the general method; namely, the salt $VOSO_4 \cdot 2H_2O$ (2.0 g, 0.01 mol) was dissolved in water (15 cm^3) and the solution was added to a warm, stirred solution of the corresponding organic compound (6.2, 6.5, 6.3 or 6.8 g; 0.022 mol of PyAAP, TAAP, FAAP or SAAP, respectively) in ethanol (50 cm^3). An aqueous solution (15–20 cm^3) of NaOAc (0.3 M solution) was added and the suspension was stirred for 2 h. The corresponding crystalline product was filtered off, washed with water, EtOH, diethyl ether and dried *in vacuo* over P_4O_{10}.

Synthesis of dichlorovanadium complexes, $[(PyAAP\text{-}H)_2VCl_2]$ *and* $[(SAAP\text{-}H)_2VCl_2]$

The synthesis was carried out under dry, purified dinitrogen gas. Different deoxygenating agents such as $SOCl_2$, PCl_5 or CH_3COCl and different solvents were used. The following procedure was applied, $[(PyAAP\text{-}H)_2(VO)_2SO_4]$ (2.0 g, 0.025 mol) or $[(SAAP\text{-}H)_2VO]$, (1.8 g, 0.0025 mol) was dissolved in 50 cm^3 of the appropriate solvent (toluene, CH_2Cl_2, bezene or dioxene). In all cases a dark green or dark brown solution was obtained. The solution was degassed and the deoxygenating agent (1.0, 1.8 or 0.6 g of $SOCl_2$, PCl_5 or CH_3COCl, respectively; 0.80 mol) was added while stirring at room temperature. In some cases a boiling condition was utilized. The reaction mixture was stirred at room temperature overnight and then layered with the appropriate solvent and placed in a freezer. The crystalline product in each case was filtered off and dried. Recrystallization from CH_2Cl_2 or $C_2H_4Cl_2$/hexane mixture lead to pure materials as determined from their physical measurements.

Elemental analysis

Carbon, hydrogen and nitrogen contents in each sample were estimated at the Microanalysis Unit, Cairo University. Vanadium content was determined by igniting a suitable accurate weight in silica crucible to a constant weight. The product was VO_2, in which the vanadium content was determined. Chlorine and sulfur contents were determined argentometrically and gravimetrically, respectively [16].

Physical measurements

Molecular weight for each sample was determined by the method of depression of freezing point. The other physical measurements and the elemental analyses were carried out as previously reported [16].

RESULTS AND DISCUSSION

The oxovanadyl complexes were found to be air stable, soluble in most common organic solvents, but insoluble in water. The formulation of the complexes was based on the elemental analysis, molecular weight determination and the molar conductivity values (Table 1).

The selective deoxygenation of the two complexes $[(PyAAP\text{-}H)_2(VO)_2SO_4]$ and $[(SAAP\text{-}H)_2VO]$ which gave pure and high percentage yields of the corresponding dichloro complex $[(L_2VCl_2]$, L = PyAAP-H or SAAP-H, was made by using $SOCl_2$, PCl_5 and CH_3COCl. It was found that both oxo-complexes react to a different extent with the three different deoxygenating agents. Furthermore, the purity of the reaction product and percentage yield were found to be solvent and temperature dependent (Table 2).

Under refluxing conditions, $SOCl_2$ reacts with the oxo-vanadyl complexes in dry benzene producing a pure and good yield of $[L_2VCl_2]$. This reaction may proceed according to eq. (1).

$$[L_2VO] + SOCl_2 \xrightarrow{\text{dry benzene}} [L_2VCl \cdot SO_2Cl] \rightarrow [L_2VCl_2] + SO_2 \quad (1)$$

In 1,4-dioxan, PCl_5 gives the best dichloro complexes at room temperature according to eq. (2).

$$2PCl_5 \rightleftharpoons PCl_4 \cdot PCl_6 + [L_2VO] \xrightarrow{\text{1,4 dioxan}} [LVCl \cdot ClPOCl_3] \rightarrow [LVCl_2] + POCl_3 \quad (2)$$

Acetyl chloride was found to be the best deoxygenating agent in toluene at room temperature, since it leads to the formation, in high yield, of dichloro derivatives. The reaction mechanism may proceed by electrophilic attack of the CH_3COCl on vanadyl oxygen, as shown in eq. (3).

$$[L_2VO] + 3CH_3COCl \xrightarrow{\text{toluene}} [L_2VCl_2] + (CH_3COO)_2O + CH_3{-}C_6H_4{-}COCH_3 \quad (3)$$

In all cases, 50% of the deoxygenating agent has been employed to minimize the extent of hydrolysis of $SOCl_2$, PCl_5 or CH_3COCl. This is in addition to the use of dry solvents. The above reactions would suggest

the formation of a *cis* isomer as previously reported [17]. It was found that *cis/trans* isomerization is rapid, allowing for the formulation of the observed *trans* isomer [17]. Table 2 summarizes the products from the reaction of the vanadyl complexes with the different deoxygenating agents, as shown from the spectroscopic studies.

Vibrational spectra

Table 3 lists the most important and characteristic bands of the IR spectra of oxovanadyl and the dichloro derivatives. The absence of bands at 968 and 986 cm^{-1} characteristic of V=O in $[(PyAAP\text{-}H)_2(VO)_2SO_4]$ and $[(SAAP\text{-}H)_2VO]$, respectively, indicates the conversion to the dichloro complexes. This observation is taken as a good parameter for the completeness of the deoxygenation process. The low value of $\nu(V{=}O)$ for $[(PyAAP\text{-}H)_2(VO)_2SO_4]$ may be taken as evidence for the polymeric nature of this complex as shown from its IR spectrum. Its deoxygenation may proceed according to eq. (4)

$$[(PyAAP\text{-}H)_2(VO)_2SO_4) \rightleftharpoons [(PyAAP\text{-}H)_2VO] + VOSO_4$$

$$[(PyAAP\text{-}H)_2VO] + \begin{matrix}SOCl\\ \text{or } PCl_5\\ \text{or } Ch_3COCl\end{matrix} \rightarrow [(PyAAP\text{-}H)_2VCl_2] + \begin{matrix}SO_2\\ \text{or } POCl_3\\ \text{or } (CH_3CO_2)O\end{matrix} \quad (4)$$

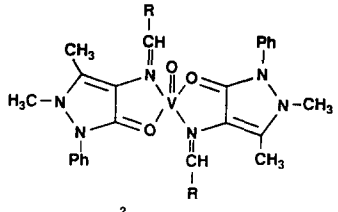
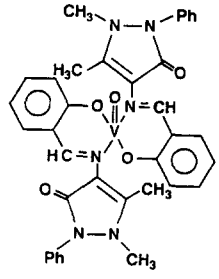
The ν(C=O) mode in the parent Schiff base, except SAAP, shifts to lower wavenumbers by *ca* 20 cm^{-1} in the case of their oxovanadyl complexes, indicating the bond of the amide oxygen to vanadium, but not in the case of complex [(SAAP-H)$_2$VO]. The band in the range 1613–1590 cm^{-1} in the free organic compounds due to ν(C=N) is shifted to 1590–1572 cm^{-1} upon complexation. This observation suggests that the C=N bond is weakened due to coordination of the azomethine-N to vanadium. The splitting of this band in the investigated complexes, except [(PyAAP-H)$_2$(VO)$_2$SO$_4$], suggests that the two azomethine groups are distorted below and above the horizontal plane. The broad band at 3434 cm^{-1} with a band width of 1660 cm^{-1} in the spectrum of SAAP, is assigned to hydrogen bonded OH. Furthermore, the existence of a broad weak band at 1915 cm^{-1} can be taken as evidence for the presence of intramolecular hydrogen bonding of the type O—H···N. This was also supported by the appearance of the ν(C—O) phenolic band at 1267 cm^{-1}. Upon complexation, the bands at 3434 and 1915 cm^{-1} disappeared and that at 1267 cm^{-1} was shifted to 1305 cm^{-1}, indicating the bonding of the ionized phenolic oxygen to vanadium.



The spectrum of (PyAAP) shows a broad band at 2964–3156 cm^{-1} due to the different vibrational modes of –NH– of the pyrrole ring, and is absent in [(PyAAP-H)$_2$(VO)$_2$SO$_4$] indicating its deprotonation upon complexation. The spectra of FAAP and SAAP display bands at 1505 and 1332 cm^{-1} due to C—O—C and C—S—C, respectively. These bands were found to be largely unaffected upon complexation, indicating the non-bonding nature of the oxygen and sulphur in the heterocyclic rings.



The far-IR spectra for all complexes except [(PyAAP-H)$_2$VCl$_2$] display a band at 338–360 cm^{-1} due to ν(V—O). The spectrum of [(PyAAP-H)$_2$VCl$_2$] exhibits a band at 1660 cm^{-1} due to ν(C=O) indicating that the amide oxygen is not bonded to vanadium. The band in the range 468–432 cm^{-1} is assigned to ν(V—N) of the azomethine group. In addition, the spectra of [(PyAAP-H)$_2$(VO)$_2$SO$_4$] and [(PyAAP-H)$_2$VCl$_2$] exhibit another band at 443 and 436 cm^{-1} assignable to ν(V—N)$_{pyrrole}$. The dichloro complexes exhibit bands at 303 and 309 cm^{-1} due to ν(V—Cl) in [(PyAAP-H)$_2$VCl$_2$] and [(SAAP-H)$_2$VCl$_2$], respectively.

The diagnostic IR band frequencies of the sulphate anions indicate its ionic nature in [(FAAP)$_2$VO]SO$_4$ and [(TAAP)$_2$VO]SO$_4$ and act as a bridging group in the case of [(PyAAP-H)$_2$(VO)$_2$SO$_4$] [18].

It appears, therefore, that PyAAP behaves as a monobasic tridentate ligand in [(PyAAP-H)$_2$(VO)$_2$SO$_4$] and as a monobasic bidentate ligand in [(PyAAP-H)$_2$VCl$_2$]. In the first complex the vanadyl group is coordinated to PyAAP *via* ketoamide oxygen, azomethine and pyrrole nitrogen atoms. In the second it is coordinated via the azomethine and pyrrole nitrogen atoms. The previously mentioned IR data indicate the bidentate nature of SAAP, through the azomethine nitrogen and the phenolate oxygen atoms. The other and ligands (FAAP and TAAP) appear to be neutral bidentate ligands coordinated to VO *via* the azomethine-N and ketoamide oxygen atoms. Accordingly, the following structures could be assumed.

One can observe that the ν(C=N) for the dichloro complexes appears at a lower wavenumber than that for the starting oxovanadyl complexes. This is consistent with the observations reported for *trans*-dihalo complexes of V(IV) [19–21], and can be rationalized by considering the metal complex symmetry and the nature of the ligands. ESR studies of several V(IV) dihalide complexes [22] revealed that on going from the vanadyl structure (where the metal is somewhat out of the plane of the equatorial ligands) to the *trans* structure (where the metal is in the plane of the ligands) stabilizes both the σ-bonding d_{xy} orbital, slightly, and the π-bonding $d_{x^2-y^2}$ orbital, greatly, due to increased orbital overlap. This, in turn, increases delocalization and effectively reduces the charge on the ligand. This results in a decrease in frequency of the diagnostic ligand bands. Contrary to the *trans* structure, the orbital overlap of the *cis* structure is reduced, because the deviation from the ligand plane is increased. This localizes the charge on the ligand, and results in increasing the frequencies of the diagnostic ligand bands. Furthermore, the geometry of $VCl_2(t\text{-}C_4H_9COCHCO)\text{-}t\text{-}C_4H_9)_2$ is determined by examining the V—Cl bands in the far IR [23]. The reported assignment of 362 cm^{-1} for the *trans* geometry matches ours of 364 and 356 cm^{-1} for $[(PyAAP\text{-}H)_2VCl_2]$ and $[(SAAP\text{-}H)_2VCl_2]$, respectively. The previously mentioned evidence indicates that $[(PyAAP\text{-}H)_2VCl_2]$ and $[(SAAP)_2VCl_2]$ also have a *trans* geometry.

Magnetic and electronic spectral data

The positive spin–orbit coupling [24] (λ) for oxovanadium(IV) complexes exhibits a room temperature magnetic moment very close to the spin only value (1.73 B.M.) [25]. The complexes under investigation, except $[(PyAAP\text{-}H)_2(VO)_2SO_4]$, also exhibit room temperature magnetic moments in the range 1.73–1.78 B.M. corresponding to one unpaired spin. The value for $[(PyAAP\text{-}H)_2(VO)_2SO_4]$ of 1.61 B.M. indicates the possibility of a magnetic exchange interaction between the vanadyl centres through the bridging sulphate group, or possibly some V(V) impurity.

The electronic spectral data of the oxovanadium complexes and the dichloro derivatives, either as solid or solution, are summarized in Table 4. No bands are found at lower energies, and splitting of the low energy band is found, as in the case of $[VO(N\text{-}CH_3)_3]Cl_2$ [26]. The large extinction coefficients for $[(SAAP\text{-}H)_2VO]$, $[(FAAP)_2VO]SO_4$ and $[(TAAP)_2VO]SO_4$ compared with $[(PyAAP\text{-}H)_2(VO)_2SO_4]$ may arise from a greater metal–ligand bond covalency and/or a larger distortion from the C_{2v} symmetry assumed for this type of complex. The bands with smaller molar extinction coefficients can be assigned to *d–d* transitions. The spectrum of $[(PyAAP\text{-}H)_2(VO)_2SO_4]$ exhibits two intense *d–d* transition at about 15,800 and 12,820 cm^{-1}, and a third one of lower intensity at 21,300 cm^{-1}, all of which are on the tail of a charge transfer band. In $CHCl_3$, three well-defined bands are observed, with no great change in position, indicating that no geometrical change in $CHCl_3$ took place. The increase in the intensities of these bands may be attributed to the disproportionation of the polymeric complex $[(PyAAP\text{-}H)_2(VO)_2SO_4]$ [eq. (5)], followed by the interaction of the solvent molecules, organized around $[(PyAAP\text{-}H)_2VO]$, with the dipole of the complex.

$$[(PyAAP\text{-}H)_2(VO)_2SO_4] \rightleftharpoons [(PyAAP\text{-}H)_2VO] + VOSO_4 \quad (5)$$

In the excited Frank–Condon state, the solvent molecules do not have enough time to rearrange in response to the dipole in the excited complex $[(PyAAP\text{-}H)_2VO]$. There is a possible hydrogen bonding formation between the oxovanadyl group and the active hydrogen in $CHCl_3$. This is confirmed from the red shift of the charge transfer band as given in Table 4. The effects of $CHCl_3$ on the band positions in the case of the other oxovanadium complexes (Table 4) are similar to those for $[(PyAAP\text{-}H)_2(VO)_2SO_4]$. The spectral features are consistent with those reported for square pyramidal oxovanadium complexes [27–29].

The spectral bands of all complexes in DMSO exhibit a drastic change in the positions and intensities of the *d–d* transitions as well as the charge transfer bands,

indicating solvent coordination to the sixth coordination site of the oxovanadyl complexes. These spectral features are consistent with those reported for similar compounds [27,28].

The energy level and MO calculations on square pyramidal oxovanadium complexes [28–31] revealed that the vanadium 3*d* orbital populations are $d_{x^2-y^2}$ (b_2) < d_{xz}, d_{yz} (e^*_π) < d_{z^2}(b^*_1) < d_{xy} (a^*_1). This ordering is consistent with the assignment of the $b_2(d_{xy}, d_{xz}) \rightarrow b_1(d_{z^2})$ transition for the lowest energy band (12,660–13,300 cm^{-1}). The band at 15,600–16,350 cm^{-1} is due to the $b_2 \rightarrow e^*_\pi$ transition, while that at 20,600–22,500 cm^{-1} is assigned to the $b_2 \rightarrow a^*_1$ transition. In DMSO, three *d–d* transitions in the range of 13,800–14,200, 16,800–17,480 and 22,030–24,000 cm^{-1} are assigned to $b_2 \rightarrow b^*_1$, $b_2 \rightarrow e^*_\pi$ and $b_2 \rightarrow a_1$ transitions, respectively, characteristic for a distorted octahedral oxovanadium complex [30,31]. On the basis of the data available, it appears that these complexes have a tetragonally distorted structure. The transition due to $b_2 \rightarrow b_1$ (16,800–17,480 cm^{-1}) is taken as 10 Dq. Therefore the ligands could be ordered according to their strengths as: SAAP > PyAAP > FAAP > TAAP. This ordering may be attributed to the effect of the moiety bonded to the azomethine group [C_4H_4O (FAAP); C_4H_5N (PyAAP); C_6H_4O (SAAP); C_4H_4S (TAAP)].

The spectra of $[(PyAAP\text{-}H)_2VCl_2]$ and $[(SAAP\text{-}H)_2VCl_2]$ as Nujol mulls and as $CH_2Cl_2/SOCl_2$ (19 : 1 V/V) solutions are identical and similar to those reported for various dichlorovanadium(IV) complexes in an octrahedral ligand field [32]. The Nujol mull spectra exhibit only two *d–d* transitional bands at 13,200, 13,400 and 16,100, 16,350 cm^{-1} for $[(PyAAP\text{-}H)_2VCl_2]$ and $[(SAAP\text{-}H)_2VCl_2]$, respectively. The third band may be buried under the intense absorption originating at 20,000 cm^{-1}. The two bands could be assigned to $b_2 \rightarrow b^*_1$ and $b_2 \rightarrow e^*_\pi$ transitions, respectively.

(Received 31 May 1996; accepted 12 August 1996)

Abstract—The magnesium phenylselenolate complex [Tp$^{p\text{-Tol}}$]MgSePh has been synthesized by the reactions of [Tp$^{p\text{-Tol}}$]MgMe with PhSeH and Ph_2Se_2. The molecular structure of [Tp$^{p\text{-Tol}}$]MgSePh has been determined by X-ray diffraction. Copyright © 1997 Elsevier Science Ltd

Keywords: magnesium; selenium; chalcogen; selenolate.

As recently noted by Arnold, the chemistry of selenolate and tellurolate complexes is poorly developed compared with that of their alkoxide and thiolate counterparts [1]. Indeed, we are aware of only three structurally characterized selenolate or tellurolate complexes for magnesium, namely $Mg[Se(C_6H_2Bu^t_3)]_2(THF)_2$ [2], $[\eta^2\text{-}Bu^tSi(CH_2PMe_2)_3]Mg[SeSi(SiMe_3)_3]_2$ [3] and $Mg[TeSi(SiMe_3)_3]_2(THF)_2$ [3], each of which is distinguished by the presence of a bulky substituent on the chalcogen [4]. In this paper, we describe the synthesis and structural characterization of a magnesium phenylselenolate complex supported by tris (pyrazolyl)hydroborato ligation [5,6].

Our previous studies have demonstrated that the tris(pyrazolyl)hydroborato ligand system allows facile access to a series of alkoxide complexes, e.g. [Tp$^{Bu^t}$]MgOR (R = Et, PR^i, Bu^t, Ph), *via* the alcoholysis reactions of the methyl derivative [Tp$^{Bu^t}$]MgMe [7,8]. The ability to synthesize such a series of alkoxide derivatives suggested that the heavier chalcogenolate analogues may also be isolated by adoption of a similar approach. Indeed, we have found that the phenylselenolate complex [Tp$^{p\text{-Tol}}$]MgSePh is formed instantaneously by the reaction of [Tp$^{p\text{-Tol}}$]MgMe [9] with PhSeH, and is accompanied by the elimination of methane [Eq. (1)].

Furthermore, [Tp$^{p\text{-Tol}}$]MgSePh is also obtained by treatment of [Tp$^{p\text{-Tol}}$]MgMe with Ph_2Se_2 [Eq. (1)], a

Table 1. Comparison of Mg—Se bond lengths

	d(Mg—Se)/Å	Reference
[Tp$^{p\text{-Tol}}$]MgSePh	2.495(4)	This Work
[Tp$^{p\text{-Tol}}$]MgSeH	2.465(2)	9
{[Tp$^{p\text{-Tol}}$]Mg}$_2$Se	2.406(2)	9
Mg[Se(C$_6$H$_2$Bu$^t_3$)]$_2$(THF)$_2$	2.536(3)	2
	2.539(3)	
[η^2-Bu^{t}Si(CH$_2$PMe$_2$)$_3$]Mg[SeSi(SiMe$_3$)$_3$]$_2$	2.483(8)	3
	2.500(8)	

reaction that is accompanied by elimination of the selenoether PhSeMe [10]. A precedent for the latter transformation is provided by the reactions of Grignard reagents with diaryldiselenides. Specifically, the reactions of Ar_2Se_2 with RMgX have been employed in the syntheses of selenoethers ArSeR, with the presumption that the magnesium selenolate species ArSeMgX are formed as by-products [11]; however, the ArSeMgX complexes thus generated were neither isolated nor characterized.

The molecular structure of [Tp$^{p\text{-Tol}}$]MgSePh has been determined by X-ray diffraction, as illustrated in Fig. 1 [12]. The coordination environment is distorted tetrahedral, with average N—Mg—N and N—Mg—Se angles of 91 and 124°, respectively. The Mg—Se bond length of 2.495(4) Å in [Tp$^{p\text{-Tol}}$]MgSePh is close to the sum of the respective covalent radii (2.54 Å) [13] and lies within the range 2.41–2.54 Å observed for the rather limited number of structurally

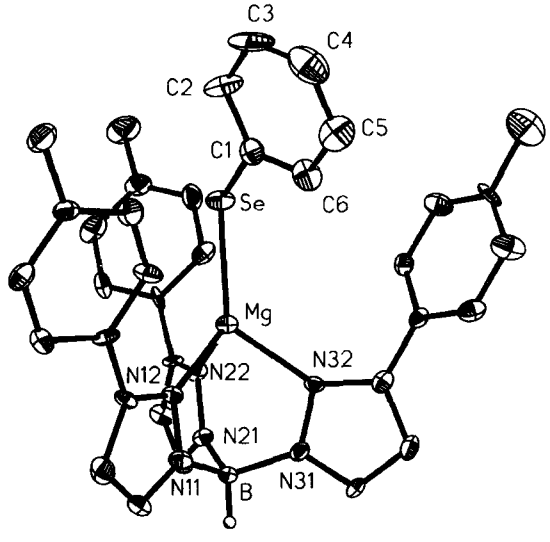

Fig. 1. Molecular structure of [Tp$^{p\text{-Tol}}$]MgSePh. Selected bond lengths (Å) and angles (°): Mg—Se 2.495(4), Mg—N(12) 2.129(14), Mg—N(22) 2.100(11), Mg—N(32) 2.098(9), Se—C(1) 1.927(14); Se—Mg—N(12) 131.1(3), Se—Mg—N(22) 112.5(5), Se—Mg—N(32) 128.0(4), N(12)—Mg—N(22) 93.0(5), N(12)—Mg—N(32) 90.5(5), N(22)—Mg—N(32) 90.8(4), Mg—Se—C(1) 109.7(7).

characterized magnesium selenolate and selenide complexes (Table 1).

The most relevant structural comparisons of [Tp$^{p\text{-Tol}}$] MgSePh are with its tris(pyrazolyl)hydrobraoto relatives, [Tp$^{p\text{-Tol}}$]MgSeH and {[Tp$^{p\text{-Tol}}$]Mg}$_2$Se [9]. Thus, the Mg—Se bond length in [Tp$^{p\text{-Tol}}$]MgSePh [2.495(4) Å] is marginally longer than that in [Tp$^{p\text{-Tol}}$] MgSeH [2.465(2) Å], a difference that is presumably a result of the greater steric demands of a phenyl versus hydrogen substituent. The Mg—Se bond length in [Tp$^{p\text{-Tol}}$]MgSePh is also considerably longer than that in the dinuclear complex {[Tp$^{p\text{-Tol}}$] Mg}$_2$Se [2.406(2) Å]; however, such a difference is not immediately rationalized in terms of steric demands since a phenyl substituent is considerably less sterically encumbered than a {[Tp$^{p\text{-Tol}}$]Mg} group. A possible explanation for the longer Mg—Se bond length in [Tp$^{p\text{-Tol}}$]MgSePh compared with that in {[Tp$^{p\text{-Tol}}$] Mg}$_2$Se resides with the bond angle at selenium: *viz.* the Mg—Se—Ph bond angle of 109.7(7)° [14] in [Tp$^{p\text{-Tol}}$]MgSePh sharply contrasts with the 180.0° bond angle at selenium in {[Tp$^{p\text{-Tol}}$]Mg}$_2$Se. Linear M—Se—M moieties are often attributed to the existence of π donation from Se to an electron-deficient metal centre [15], which may therefore provide a rationalization for the shorter Mg—Se bond length in {[Tp$^{p\text{-Tol}}$]Mg}$_2$Se. However, even if π donation is responsible for the shorter Mg—Se bond length in {[Tp$^{p\text{-Tol}}$]Mg}$_2$Se, it should be noted that the existence of π interactions may be merely a consequence of a linear geometry being dictated by steric interactions between the two bulky {[Tp$^{p\text{-Tol}}$]Mg} moieties. In other words, the linear geometry of {[Tp$^{p\text{-Tol}}$] Mg}$_2$Se is not a consequence of π donation, but rather that efficient π interactions are consequence of a linear geometry. In this regard, it should be noted that the linearity at tellurium in the scandium complex [Me$_2$Si(C$_5$H$_3$Bu^t)$_2$Sc(PMe$_3$)]$_2$Te has been rationalized in terms of a steric rather than electronic argument [16].

The phenylselenolate complex [Tp$^{p\text{-Tol}}$]MgSePh has also been studied by ^{77}Se NMR spectroscopy. Interestingly, [Tp$^{p\text{-Tol}}$]MgSePh is characterized by a ^{77}Se NMR signal at δ 9 ppm, significantly different from those observed for [Tp$^{p\text{-Tol}}$]MgSeH [δ −486] and {[Tp$^{p\text{-Tol}}$] MgSe}$_2$ [δ − 582]. Large ^{77}Se NMR chemical shift ranges for similar complexes are not unusual.

Indeed, it has previously been noted that selenolate complexes in general exhibit a very large ^{77}Se NMR chemical shift range [1].

In summary, $[Tp^{p\text{-}Tol}]MgSePh$, a rare example of a structurally characterized magnesium selenolate complex, has been synthesized by the reactions of $[Tp^{p\text{-}Tol}]MgMe$ with either PhSeH or Ph_2Se_2.

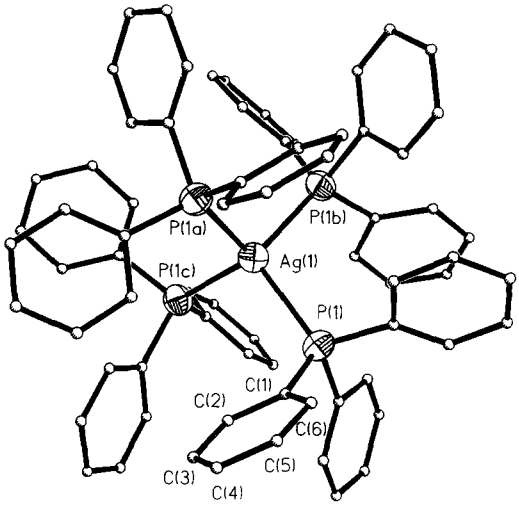
(Received 25 April 1996; accepted 24 July 1996)

Abstract—The reaction of $Ag(PPh_3)_2NO_3$ and $K_4Mo(CN)_8$ in H_2O/CH_2Cl_2 gave an emulsion, from which light yellow crystals were obtained. Elemental analysis, IR spectra and X-ray diffraction verified that the compound is a hexamolybdate with two tetra(triphenylphosphine)silver cations acting as counter ions, $[Ag(PPh_3)_4]_2Mo_6O_{19} \cdot 3CH_2Cl_2$. Oxidation of Mo^{IV} to Mo^{VI} took place when $Mo(CN)_8^{4-}$ was hydrolysed.
Copyright © 1997 Elsevier Science Ltd

Keywords: synthesis; crystal structure; coordination compounds; hydrolysis reaction; polymetallate; phase-transfer process.

Octacyanides of molybdenum(IV) have been a subject of interest for many years from the point of view of structure, reactivity and photochemistry [1]. Recently, we have demonstrated that many inorganic clusters and coordination compounds derived from $MS_nO_{4-n}^{2-}$ (M = Mo and W) exhibit very interesting non-linear optical properties (NLO) [2,3]. Attempts at imitating $MS_nO_{4-n}^{2-}$ (M = Mo and W) with $Mo(CN)_8^{4-}$ to synthesize polynuclear coordination compounds resulted in the formation of polymolybdate. It is interesting to understand the formation process of the polymolybdate and its complex counter ions. A solution of $Ag(PPh_3)_2NO_3$ in CH_2Cl_2 was mixed with a solution of $K_4Mo(CN)_8$ in water giving a white emulsion. This emulsion was placed in air for several days and its colour remained unchanged. As the solvent was evaporated light yellow cubic crystals were produced. Elemental analyses, IR spectra† and X-ray diffraction verified that the compound comprises a polymolybdate and two tetra(triphenylphosphine) silver cations $[Ag(PPh_3)_4]_2Mo_6O_{19} \cdot 3CH_2Cl_2$ (**1**).



The X-ray structure‡ of **1** shows that the silver

‡ *Crystal data*: $C_{147}H_{126}Ag_2Cl_6Mo_6O_{19}P_8$: cubic, space group *Fm3m*, $a = 24.500(3)$ Å, $Z = 4$, $V = 14707(7)$ Å^3, $D_c = 1.596$ g cm^{-3}, $F(000) = 6912$. A total of 712 independent reflections were collected using an Enraf–Nonius diffractometer with graphite-monochromated Mo-K_α radiation and ω scans. The structure was solved by direct methods using SAPI-91 and refined with a full-matrix least-squares technique using SHELXTL-PC program package to give $R = 8.32\%$ and $R_w = 8.82\%$ for 553 independent observed [$F > 6.0s(F)$]. An empirical absorption correlation was applied. The Mo, Ag and O atoms were refined anisotropically. The highly disordered phenyl rings of Ph_3P were refined isotropically as rigid hexagons. The solvate CH_2Cl_2 was derived from the difference Fourier map.

atom is coordinated by four triphenylphosphines in a tetrahedral geometry, in which the four phosphine ligands are identical (Fig. 1). This is unusual except for the report of $Ag(PPh_3)_4ClO_4$, in which the phosphine silver complex possesses a crystallographic threefold axis: four phosphine ligands are at two independent positions coordinating to the silver atom [4]. The Ag—P distance of 2.635(4) Å in the title compound is shorter than the Ag—P distances of 2.668(5) and 2.659(2) Å in $Ag(PPh_3)_4ClO_4$. The hexmolybdate anions lie at the origin and face-centre position of the cubic cell, and possess octahedral symmetry.

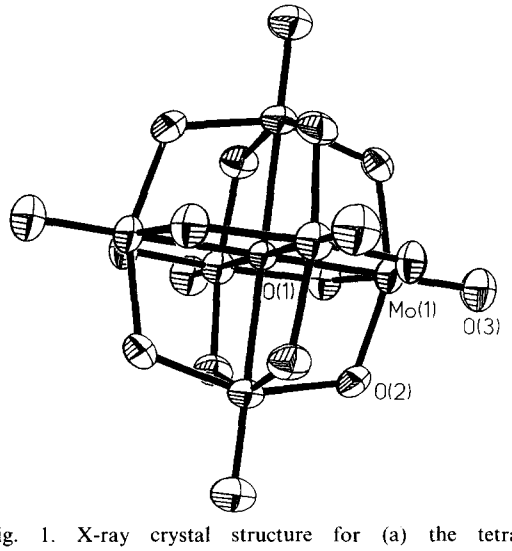

Fig. 1. X-ray crystal structure for (a) the tetra-(triphenylphosphine) silver cation and (b) the polymolybdate anion of **1**. Selected bond lengths (Å); Ag—P 2.635(4); Mo(1)—O(1) 2.316(2); Mo(1)—O(2) 1.921(5); Mo(1)—O(3) 1.618(16).

The formation of the product is reasonable. A number of studies have been made on the kinetics and mechanism of the photoreaction of octacyano complexes of Mo^{IV} and W^{IV} with or without organic base ligands, and some intermediates have been isolated and characterized [1]. In the first step, one of the cyano ligands in $Mo(CN)_8^{4-}$ is replaced by the hydroxyl ion, yielding $Mo(CN)_7(OH)^{4-}$. Further hydrolysis results in more cyano ligands being replaced. In addition, it is known that Ag^+ can ligate CN^- and enhance the hydrolysis process [5,6]. The interesting fact is that an oxidation reaction has taken place at the same time. The Mo^{IV} is oxidised to Mo^{VI}, which exists as molybdates. The oxidant is probably oxygen in the air or silver(I) in the solution, the mechanism of which is unknown at present. The MoO_4^{2-} ions can polymerize to polymolybdate in acidic solution. The overall reaction may be as follows:

$$6Mo(CN)_8^{4-} + 19H_2O - 12e^- \rightarrow Mo_6O_{19}^{2-} + 48CN^- + 38H^+.$$

The examples of hexamolybdate crystallizing with complex cations as counter ions are $[M_2(MeCN)_{10}][Mo_6O_{19}]_2$ (M = Re, Rh, Mo, W) [7,8], $[FeCl(DMF)_5][Mo_6O_{19}]$ [9], $[(PhC_5Me_5)Cl(MeCN)_2]_2Mo_6O_{19}$ [10], $[Mo_2(\eta\text{-}C_5H_5)_2(CO)_4(\mu\text{-}H)(\eta\text{-}Ph_2PCH_2PPh_2)]_2[Mo_6O_{19}]\cdot 4THF$ [11], $[Mo(CO)_2(\eta\text{-}Ph_2PCH_2P(Se)Ph_2)]_2[Mo_6O_{19}]\cdot 4CH_3NO_2$ [12], $[(18\text{-crown-}6)K]_2Mo_6O_{19}\cdot H_2O$ [13] and $[Mo_2(S_2CNEt_2)_4]_2Mo_6O_{19}$ [14]. These were all synthesized in organic solvents. In some cases, the $Mo_6O_{19}^{2-}$ anions are acquired by the anion exchange, while in others they are produced by the oxidation reaction of the corresponding low-valent molybdenum reactants. Recently, we synthesized $[MoS_4Cu_4(\gamma\text{-MePy})_4][Mo_6O_{19}]$ [15], in which a large cluster cation was obtained with the reaction of thiomolybdate and copper(I) in γ-methylpyridine and the hexamolybdate was produced by the oxidation of thiomolybdate. The title compound, on the contrary, is produced in a mixed solvent. It is interesting that a synthetic route to obtain crystals of polymetallates and large complex cations through a phase-transfer process may be derived. Polymolybdate anions are readily generated and dissolved in water, while organic phosphine complex cations are only soluble in organic solvents. Combination of these two species in mixed solvents results in crystallization of polymetallates with large complex cations.

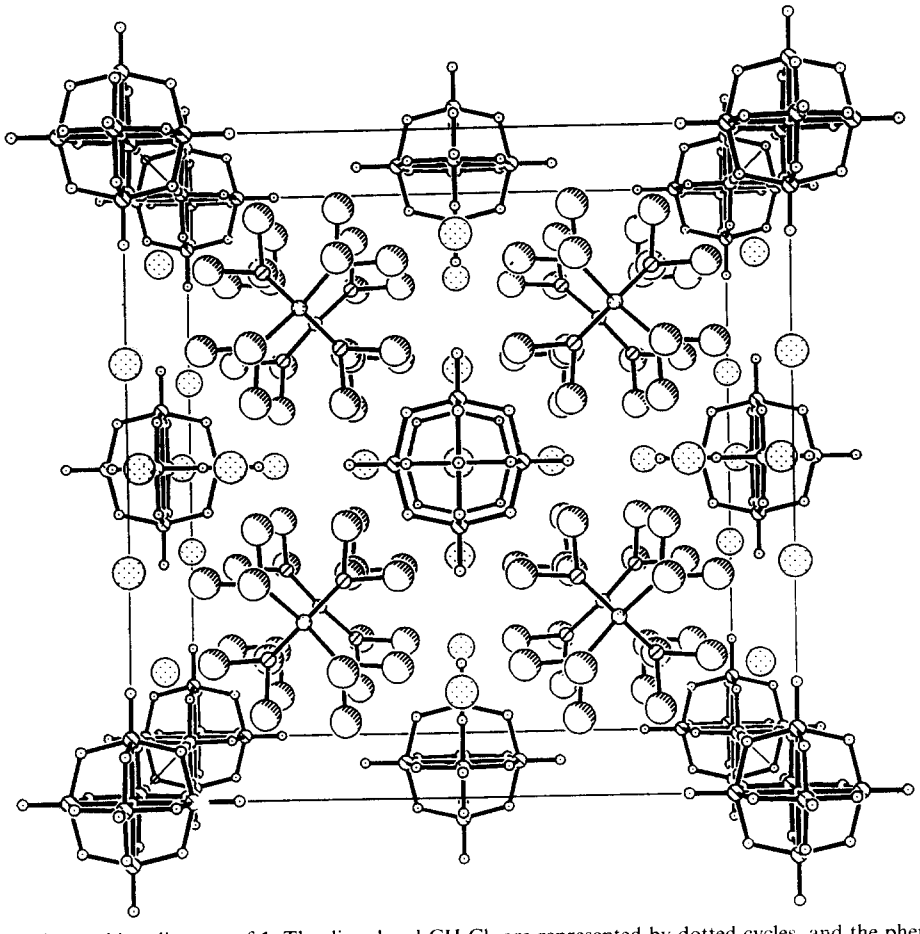

Fig. 2. Molecular packing diagram of **1**. The disordered CH_2Cl_2 are represented by dotted cycles, and the phenyl rings by hatched ones.

(Received 24 May 1996; accepted 15 July 1996)

Abstract—The crystallization of bis(perchlorate)tris(phenanthroline)cadmium(II) [$Cdphen_3 \cdot (ClO_4)_2$] in the presence of *para*-nitroaniline (PNA) yielded a co-crystal 1:2 adduct, $Cdphen_3(ClO_4)_2 \cdot 2PNA$ (**1**); which exhibits weak second-harmonic-generation activity even though it has a centrosymmetric space group. Copyright © 1997 Elsevier Science Ltd

Keywords: cadmium(II) complexes; phenanthroline-N^1,N^{10} complexes; crystal structures; second-harmonic-generation activity; molecule recognition; self-assembly.

Molecular recognition and self-assembly of molecules are generally based on a strong (O—H···O and N—H···O hydrogen bonds), weak (van der Waals, $\pi \cdots \pi$ stacking) and potentially weak (C—H···Y hydrogen bonds, Y=O, N) intermolecular interactions [1–3]. However, a massive research effort has recently been focused on the intermolecular interactions between organic molecules [4]. Few organic–metal complexes were used as a host to recognize an organic guest molecules through hydrogen bonds [5, 6]. On the other hand, chemists and physicists have endeavoured to search for a new method of removing crystalline centrosymetric geometry in guest molecules so that the criteria for SHG (second-harmonic generation) may also be satisfied in a centrosymmetric crystal structure [7, 8]. As we know, organic materials that have π-conjugate systems with an electron donor and acceptor are highly efficient non-linear optical (NLO) materials. Unfortunately, *para*-nitroaniline, having a centrosymmetric crystal structure, exhibits no SHG activity in bulk [9]. We report here the synthesis, characterization and crystal structure of bis(perchlorate)tris(phenanthroline-N^1,N^{10}) cadmium–bis(*para*-nitroaniline) (**1**), which displays weak SHG activity even though it has a centrosymmetric space group. As far as we are aware, this is the first example of crystal engineering design through hydrogen bond interaction between an organic NLO molecule and a metal complex and may give a new insight into NLO molecule recognition by an anion.

The reaction of $(phen)_3Cd(ClO_4)_2$ with two equiv. of *para*-nitroaniline in a solution of ethanol and water (v/v 1:1) yielded a yellow solution, from which pale yellow columnar crystals of **1** were isolated in 60–70% yield after evaporation of the solution at room temperature for a few days. The infrared spectrum of **1** exhibits a diagnostic band for perchlorate (1108 cm^{-1}) at a higher wavenumber compared with normal perchlorate (1080 cm^{-1}) probably owing to hydrogen bonds. Two absorption bands at 3450 and 3362 (m) cm^{-1} may be assigned to the ν_{NH} stretching frequency. In the far-IR spectrum of **1**, the ν_{Cd-N} (274 and 244 cm^{-1}) bands observed, were in the normal region. Moreover, thermogravimetric analysis (TGA) of **1** reveals that the first decomposition event takes place

at *ca* 247°C, suggesting that perchlorate ion is strongly hydrogen bonded to NH_2 in *para*-nitroaniline to form a stable composite, **1**. On the basis of weight changes, the first process of weight loss (23.9%) corresponds to the loss of two *para*-nitroaniline (theoretical loss: 24.4%), by an endothermal process.

The Cd atom in **1** (Fig. 1) exhibits a slightly distorted octabhedral geometry in which the Cd atom is coordinated to six N atoms from three phenanthrolines.* The Cd—N bond lengths are in the expected range. [10] A striking feature of **1** is that the perchlorate anion recognizes *para*-nitroaniline guest molecules through hydrogen bonds (Fig. 2). To our knowledge, organic non-linear optical material recognition by the anion in a metal complex through hydrogen bonding is unprecedented in the self-assembly process. It is found, somewhat surprisingly, that the perchlorate anion in **1** displays some shape selectivity in the recognition process. While *para* and *meta*-nitroaniline were efficiently assembled, the *ortho* isomer, was not recognized. This is different from that observed in $[Cd(4,4'\text{-bipy})_2 \cdot (NO_3)_2 \cdot (o\text{-}Br_2C_6H_4)_2]_\infty$ (only *ortho*-dibromobenzene included) [5] and $[Cd(4,4'\text{-bipy})_2 \cdot (H_2O)_2 \cdot (o\text{-}NO_2C_6H_4NH_2)_2 \cdot (4,4'\text{-bipy})](ClO_4)_2$(only *ortho*-nitroaniline included) [6]. It is noteworthy that when *para*- and *meta*-nitroaniline exists simultaneously in solution, *para*-nitroaniline is recognized preferentially to separate fom *meta*-nitroaniline. It is very interesting to note that **1** exhibits weak SHG response, probably owing to the perchlorate ion having a little disorder in the crystal (higher thermal parameter) [11] even though **1** has a centrosymmetric space group. Furthermore, as Eaton pointed out [8], when the structure with disorder was solved with a centrosymmetric space group, the observation of SHG is reliable and the structure may be assigned as an acentric space group. On the other hand, the disorder in the crystal may provide the local dissymmetry needed to support charge separation [11] while material having low-lying charge-transfer states,

*Crystal data for **1**: monoclinic, $C2/c$, a = 25.072(4), b = 10.752(3), c = 19.407(2) Å, β = 116.62(1)°, V = 4677(3) Å^3, Z = 4, D = 1.60 g cm^{-3}, F (000) = 2288, μ = 6.53 cm^{-1}. The intensity data were collected on an Enraf–Nonius CAD-4 diffractometer at 296 K, using graphite-monochromated Mo-K_α radiation (λ = 0.71069 Å), ω–2θ scan mode. 4439 reflections were measured in the range $2 \leqslant 2\theta \leqslant 50°$. 4347 unique reflections, 3675 of which, with $I > 3\sigma(I)$, were used for refinement. Intensities were corrected for Lorentz and polarization effects and empirical absorption. The structure was solved by direct methods using MITHRIL. The Cd atom was located in an E map and the remaining non-H atoms were located using DIRDIF. Hydrogen atoms were placed in geometrically calculated positions with C—H = 0.95 Å, but were not included in the refinement. The structure was refined by full-matrix least-squares techniques with anisotropic displacement parameters for all non-H atoms. All calculations were performed on a VAX3100 computer using the TEXSAN program package, refined on F, number of parameters 330, R = 0.048, R_w = 0.057, S = 1.66. Final difference maps showed no peaks >0.44 or < −0.93 Å. All Δ/ρ values <0.01. Atomic coordinates bond lengths and angles and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.

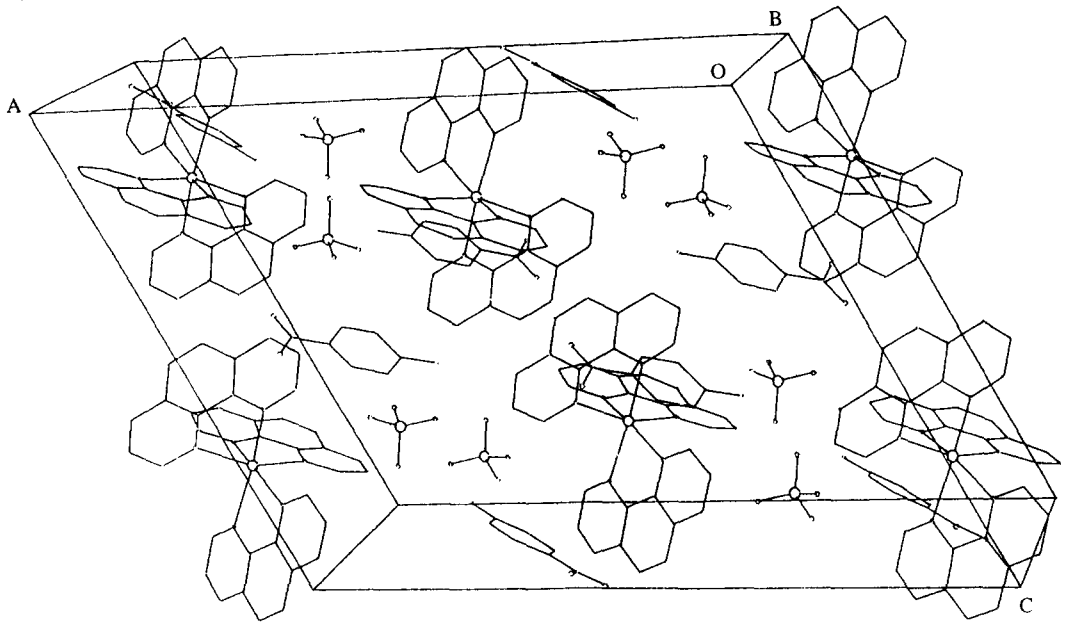

Fig. 2. Unit cell diagram of **1**.

or experiencing large changes in molecular dipole moment upon photo-excitation is potentially SHG active [12].

BOOK REVIEW

Gmelin Handbook of Inorganic and Organometallic Chemistry, 8th Edition, Supplement Volume B8. **Ternary Silicon–Fluorine–Hydrogen Compounds,** 212+xiii pp., Springer–Verlag, Berlin, 1996, Price 1330 DM, ISBN 3-540-93728-5.

This volume is the latest of the Gmelin Institute's comprehensive series on silicon compounds to appear. It picks up the story from 1959, and reviews the literature from all sources (including patents) right up to November 1995. As always, it is thorough, logically organized, reliable and critical: ambiguities, inconsistencies and errors in publications are noted and, where possible, resolved. Besides the compounds defined by the title, there is also a short section on silicon–fluorine–noble gas systems.

If a random group of inorganic chemists were asked to give some example of Si–F–H compounds, then no doubt most would choose hexafluorosilicic acid, H_2SiF_6, while some might suggest the fluorosilanes, SiH_3F, SiH_2F_2 ad $SiHF_3$. After that, there might be a long pensive pause. The coverage in this volume affords some support for these choices, since the SiH_xF_{4-x} (x = 1–3) compounds take up over 80 pages, while nearly 60 are devoted to H_2SiF_6. In both cases, it becomes clear that this is due in part to their industrial significance. Fluorosilanes, for example, have been widely proposed in patents (and actually used, which is not the same thing) as precursors for the deposition of amorphous solids comprising fluorinated and hydrogenated silicon (a-Si : F, H); these find application in solar cells and other electronic devices. Hexafluorosilicic acid is made on a large scale, often as a valuable by-product from environmental control of the SiF_4 and HF released when phosphate fertilizers are made from fluoride-containing rock. The acid is then used to synthesize a wide range of fluorine-containing chemicals, including ceramic glazes, insecticides, cryolite for aluminium production and (until recently) CFCs.

This volume goes on, however, to provide many surprises for that random group of inorganic chemists (and sometimes for this reviewer) because of the very large number of other Si–F–H compounds that appear. Not only are there simple molecules such as SiHF, SiH_2F and $SiHF_2$, together with positive and negative ions derived from them, but also di- and polysilane derivatives such as SiF_3SiH_3, $SiF_3SiH_2SiF_3$ and $(SiF_3)_3SiH$. In earlier years, it was part of the mythology of inorganic silicon chemists that such SiF_3 derivatives readily disproportionated, giving SiF_4; it now appears that this instability was due to small amounts of impurities.

In many cases, the species described have not been isolated, but are inferred from the results of more or less sophisticated computational procedures. Thus, for instance, the standard enthalpy of formation, preferred structure, fundamental vibrational modes and even the chemical reactivity of unknown $SiH_2F_3^-$ have been predicted. It appears too that small molecules such as SiHF provide a tempting test-bed for theoretical chemists, spectroscopists and physicists: for this particular compound, some five pages of the volume include detailed results of measurements or calculations of its rotational constants, molecular geometry of both ground and excited states, thermodynamic functions, time-resolved fluorescence, dissociation enthalpies, Zeeman effects, proton affinity and so on.

One of the rewarding aspects of reading a concentrated work of reference such as this is the discovery of intriguing facts, forgotten references, new associations of ideas, and interesting experiments which, surprisingly, have never been done. In the first few pages of this book, for example, it is noted that dissolution of crystalline silicon in HF leads to a surface terminated with Si—H and some Si—F bonds (a process utilized in the fabrication of electronic devices), while the last page tells of calculations performed on the experimentally unknown cluster $Si_{10}H_{13}F$. This cluster serves as a model for the surfaces of the pore walls in porous silicon, in which the ratio of H to F terminating atoms is similar—very different systems yielding interesting connections. Again, in the section dealing with Si–F compounds and noble gases, it is noted that in the gas phase there is only very weak interaction, denoted by small changes in the infrared spectrum. It therefore seems very strange that these systems have apparently never been studied by matrix isolation techniques at low temperature. On a lighter note, there is a reference to one publication describing the use of SiH_2F_2 to fluorinate, and presumably enhance, tooth enamel; it seems unlikely, however, that a spray for daily home use which delivered this HF-producing gas would be a great commercial success.

Once again, the authors of this series of volumes deserve the thanks of all those involved in silicon science and technology; like its predecessors, this book provides an invaluable resource of critically surveyed and authentic information.

Synthesis, crystal structure and magnetic properties of a manganese(III) complex with bound water and double hydrogen-bonding bridges

Xiang Shi Tan,[a] Dao Feng Xiang,[a] Wen Xia Tang[a]* and Min Qin Chen[b]

[a] State Key Laboratory of Coordination Chemistry, Coordination Chemistry Institute, Nanjing University, Nanjing 210093, P.R. China

[b] Research Center of Analysis & Measurement, Fudan University, Shanghai 200433, P.R. China

(Received 6 June 1996; accepted 22 August 1996)

Abstract—The new manganese(III) complex $\{[HimH]^+[Mn(sal)_2(py)H_2O]^-\}_2$ (sal = salicylate, $C_7H_4O_3$; py = pyridine, C_5H_5N; $[HimH]^+$ = imidazole cation, $C_3H_5N_2$) has been prepared and characterized by X-ray analysis and magnetic measurements. The structure of the title complex consists of imidazole cations and two types of mononuclear Mn^{III} complex anions of $[Mn(1)(sal)_2(py)(H_2O)]^-$ and $[Mn(2)(sal)_2(py)(H_2O)]^-$. Each manganese(III) ion displays elongated octahedral geometry with water and pyridine molecules occupying axial sites. The equatorial plane is defined by four oxygen atoms from salicylates. Each Mn^{III} complex unit is linked to its neighbors above and below by pairs of Ow—H···O hydrogen bonds between bound water and two noncoordinating carboxylate oxygens of salicylates of the adjacent Mn^{III} units forming an infinite chain running parallel to the crystallographic *c*-axis. The two types of chains are cross-linked by N—H···O hydrogen bonds with imidazolium bridges. The magnetic properties of the title complex are reported and discussed. Copyright © 1997 Elsevier Science Ltd

Keywords: manganese; manganese complexes; crystal structures; magnetism; syntheses; hydrogen bonds.

The chemistry of manganese in various oxidation states is currently receiving much attention owing to its importance in many biological systems, such as superoxide dismutation [1], and peroxide disproportionation [2]. The most important is the realization that manganese plays an essential and specific role in the water-oxidizing complex of photosystem II (PSII) [3]. We now report the preparation, structure and magnetic properties of the title manganese(III) complex with bound water, which are important to understand the photosynthetic water oxidation center (WOC), since the ligand of water and its hydrogen bonding to carboxylate groups may be providing a glimpse into how the WOC binds its substrate H_2O and activates it to deprotonation, a necessary step in water oxidation. The compound is also interesting for its novel hydrogen bonding character.

EXPERIMENTAL

Preparations

$(NBu^n_4)MnO_4$ [4] was prepared as described previously. $[Mn_3O(O_2CPh)_6(Im)_2(H_2O)]$ was synthesized according to a similar method to that used for $[Mn_3O(O_2CPh)_6(py)_2(H_2O)]\cdot CH_3CN$ [5]. Other chemicals were reagent grade and used as received.

To a stirred brown solution of $[Mn_3O(O_2CPh)_6(Im)_2(H_2O)]$ (0.50 mmol) in CH_3CN was added solid salicylic acid (2.0 mmol). The acid soon dissolved and the brown solution turned deep black gradually. The resulting solution was stirring for 30 min and filtered in order to remove a green–gray precipitate. The black crystals of the title complex were grown by diffusion in pyridine/ether atmosphere at room temperature and collected by filtration, washed with CH_3CN and Et_2O, and dried *in vacuo*. The yield was 53.5% (based on Mn). The crystals were suitable for

X-ray crystallography. Found C, 53.5; H, 4.0; N, 8.4; Mn, 11.6. Calc. for $C_{44}H_{40}Mn_2N_0O_{14}$: C, 53.7; N, 3.9; N, 8.5; Mn, 11.2%.

X-ray crystallography

A suitable single crystal was mounted on glass fibre and aligned on an Enraf-Nonius CAD-4 diffractometer for data collection. Cell parameters were determined on the basis of 25 reflections with $12 < \theta < 13°$. Intensity data were obtained with graphite-monochromated Mo-$K\alpha$ radiation ($\lambda = 0.71073$ Å) and ω–2θ scan mode in the range $0 < 2\theta < 50°$ at room temperature. During data collection, the intensity of three standard reflections monitored at 3600 s of X-ray exposure time showed no significant decay. After taking into account Lorentz and polarization effects, an empirical absorption correlation based on a series of PSI scans was applied to the data. Relative transmission coefficients ranged from 0.706 to 0.997. The structure solution by the direct methods (MULTAN-86) revealed the metal-atom coordinates and subsequently difference Fourier methods yielded positions of all the remaining non-H atoms and most of the hydrogen atoms. All non-H atoms were refined anisotropically by unit-weight full-matrix least-squares, while the hydrogen atoms, located from the difference Fourier maps, were riding on the related carbon atoms with fixed isotropic thermal parameters in the refinement. Refinement converged at $R = 0.048$ and $Rw = 0.053$ for 2083 observed reflections with $I > 3\sigma(I)$ of 3839 unique ones. A final difference-Fourier map exhibited no significant peaks greater than 0.40(6) e Å^{-3}. Scattering factors were taken from International Table for X-ray crystallography (1974). All computations were performed on a Micro Vax II computer using SDP/VAX and ORTEP programs.

Physical measurements

Magnetic measurements on powder samples were measured by using a CAHN-2000 Faraday-type magnetometer in the 77–300 K temperature range. The apparatus was calibrated with $[Ni(en)_3]S_2O_3$ (en = ethylenediamine). Diamagnetic corrections were made using Pascal's constants.

RESULTS AND DISCUSSION

Description of the crystal structure

Parameters for data collection and refinement are given in Table 1. Selected bond distances and angles are listed in Table 2. Important hydrogen-bonding parameters are listed in Table 3. The structures for the title complex are showed in Fig. 1 and 2, respectively. The crystal structure consists of imidazolium cations and two types of independent mononuclear

manganese(III) complex units, $[Mn(1)(sal)_2(py)(H_2O)]^-$ (Mn1 unit) [Fig. 1(a)] and $[Mn(2)(sal)_2(py)(H_2O)]^-$ (Mn2 unit) [Fig. 1(b)]. As illustrated in Fig. 1(a, b), each Mn^{III} ion is hexacoordinate and possesses and NO_5 ligand environment by virtue of two bidentate salicylate ligands that form an equatorial plane and two axial ligands of a pyridine and a H_2O molecule. Each Mn^{III} unit has C_2 symmetry, with the rotation axis passing through O(w1), Mn(1), N(11) and C(14) for the Mn(1) unit and O(w2), Mn(2), N(31) and C(34) atoms for the Mn(2) unit. In terms of angles within the coordination sphere, $MnNO_5$ is close to an octahedron. The ranges of *cis* and *trans* angles at the Mn^{III} centers are 88.1(2)–92.0(2)°, 178.0(2)–180.1(6)° for the Mn(1) unit and 88.1(2)–91.9(2)°, 177.8(2)–180.1(6)° for the Mn(2) unit, respectively. The equatorial Mn–phenolic oxygen (O_p) and Mn–carboxylate oxygen (O_c) bond lengths are 1.878(4) [Mn(1)—O(1)], 1.917(4) Å [Mn(1)—O(9)] for the Mn(1) unit and 1.871 Å [Mn(2)—O(21)], 1.910(4) Å [Mn(2)—O(29)] for the Mn(2) unit, respectively, and close to those in $[Mn_4(sal)_4(H_2O)_4(py)_8]_n[salH]_{2n}\cdot 4npy$ [Mn—O_p = 1.854(5)–1.874(6) Å, Mn—O_c = 1.883(6)–1.928(6) Å] [6]. The axial Mn—Ow distances are 2.213(7) [Mn(1)—O(w1)] and 2.225(7) Å [Mn(2)—O(w2)], respectively, which are distinctly longer than those in the equatorial plane and similar to that in [Mn(sal)(bpy)(MeOH)Cl]·MeOH [7]. Such marked axial elongation is typical for a high-spin d^4 system.

There is a significant hydrogen-bonding interaction between neighboring Mn(1) units of Mn(2) units, involving two Ow—How of the water on one Mn^{III} unit and two non-coordinating carboxylate oxygens of salicylates on the adjacent Mn^{III} units. These interactions lead to a chain structure running parallel to the crystallographic c-axis, as an example the Mn(2)

types of Mn^{III} unit chains are cross-linked by N—H···O hydrogen bonds with imidazolium bridges. All the hydrogen bonding parameters are listed in Table 3.

Magnetic properties

The temperature dependence of the magnetic susceptibility per $[HimH]^+[Mn(sal)_2(py)(H_2O)]^-$ for the title compound in the form of χ_M *vs* T is shown in Fig. 3. The magnetic moment of the compound per

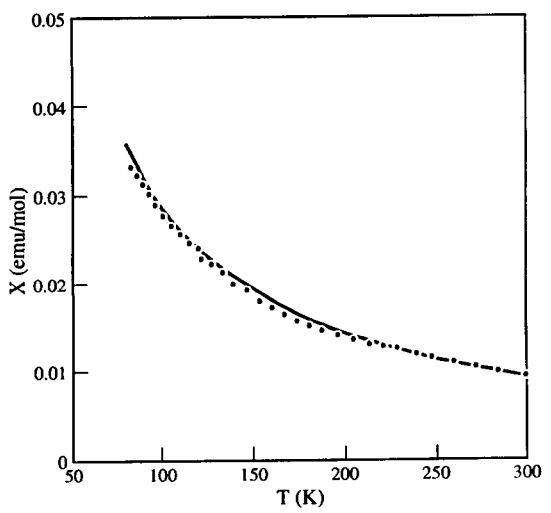

Fig. 3. Temperature dependence of the molecular magnetic susceptibility per $[HimH]^+$ $[Mn(sal)_2(py)(H_2O)]^-$ for the title complex.

$[HimH]^+[Mn(sal)_2(py)(H_2O)]^-$ for the title complex at 285 K is 4.88 B.M., which is close to spin-only value of 4.89 B.M. expected for one uncoupled high-spin Mn^{III} ion ($S = 2$). When the temperature is lowered, the magnetic moment of the title complex decreases slightly and reaches a value of 4.70 B.M. at 78 K, which may be due to zero-field splitting of the ground state and intermolecular magnetic interaction. The crystal structure of the title complex shows the Mn^{III} centre to exist in a distorted octahedral arrangement as a result of the Jahn–Teller effect. Due to the axial distortion and spin-orbit coupling, the $S = 2$ state is split into three zero-field split levels, $Ms = 0, \pm 1$ and ± 2, the separation between Ms = 0 and ± 1 and between Ms = 0 and ± 2 being D and $4D$, respectively. By use of spin-Hamiltonian formalism of the form [eq. (1)] [8] in which any rhombic splitting was ignored, D is the ZFS parameter).

$$H = DS_z^2 + g\beta H \cdot S \qquad (1)$$

the following equation for the principal magnetic susceptibility can be derived [8,9]:

$$X_{\parallel} = 2Ng^2\beta^2/KT \cdot (e^{-D/KT} + 4e^{-4D/KT})/(1 + 2e^{-D/KT} + 2e^{-4D/KT})$$

$$X_{\perp} = Ng^2\beta^2/3D \cdot (18 - 14e^{-D/KT} - 4e^{-4D/KT})/(1 + 2e^{-D/KT} + 2e^{-4D/KT})$$

$$X_M = (X_{\parallel} + 2X_{\perp})/3.$$

To describe the intermolecular interactions, a molecular field term [10] was added and the expression for the magnetic susceptibility becomes:

$$X'_M = X_M/(1\text{-}2xJ'X_M/Ng^2\beta^2). \qquad (2)$$

Using eq. (2) the data of the compound were analyzed at 77–300 K and the best fit parameters obtained are $g = 2.00$ $D = -4.51$ cm^{-1}, $zJ' = -0.83$ cm^{-1}, and $R = 8.23 \times 10^{-4}$, where $R = \Sigma(X_{calcd} - X_{obs})^2/\Sigma(X_{obs})^2$.

The D value found here is in agreement with the literature data in the range -1 to -8 cm^{-1} for some high-spin Mn^{III} complexes [6,7,11]. The zJ' value at -0.83 cm^{-1} reflects the possibility of weak antiferromagnetically intermolecular exchange interaction through hydrogen bonds and magnetic dipole–dipole interactions.

(Received 10 May 1996; accepted 22 August 1996)

Abstract—Cu^{II} reacted with the polyfunctional nitroxide 4-(1′-carboxy-2′-oxopropylidene)-2,2,5,5-tetramethyl-3-imidazolidine-1-oxyl (H_2L; $Cu/H_2L = 1:2$) to yield $Cu(LH)_2(H_2O)_2$, which was characterized by strong fixation of water molecules exclusively by hydrogen bonds. In the interaction of $Cu(LH)_2(H_2O)_2$ with an additional amount of Cu^{II} ($Cu/H_2L = 1:1$), the ligands moved towards each other in parallel directions to form the binuclear compound $Cu_2L_2(H_2O)_5$. This process is very unusual in coordination chemistry. Copyright © 1997 Elsevier Science Ltd

Keywords: complexes with nitroxides; structure; unusual reaction.

Many current studies of metal complexes with stable nitroxides are concerned with the search for the combinations of nitroxide functional groups that provide effective complexation in solutions and lead to the formation of metal-ion-induced self-assembly chain, layered and frame heterospin polymers in solids, which is favorable for the occurrence of cooperative magnetic phenomena [1–3]. This is a challenging problem, therefore, the nitroxide derivatives used in the syntheses become increasingly complicated, involving several functional groups [4–8]. In this work, we synthesized the Cu^{II} complexes with the polyfunctional nitroxide 4-(1′-carboxy-2′-oxopropylidene)-2,2,5,5-tetramethyl-3-imidazolidine-1-oxyl (H_2L). Since H_2L contains both enamineketone and α-ketocarboxylate functional groups and each of them is favorable to the formation of chelate rings [structures **a** and **b** in Scheme 1], it was difficult to predict which chelate ring would be formed preferably. Nevertheless, on both cases, there was a possibility of bonding to one more metal ion due to the free donor [carboxylate (**a**) or amino (**b**)] group, which is, in principle, favorable to the formation of polymeric compounds. This determined our choice of Cu^{II}. If the first step of the complex formation followed path (a), the additional Cu^{II} could be bonded through the carboxylate group. The resulting classical bridging copper carboxylates could form polymeric layers (Fig. 1). In path (b), the introduction of additional Cu^{II} should lead to the for-

* Author to whom correspondence should be addressed.

Scheme 1.

mation of polymeric structures due to bonding to the nitrogen of the secondary amino groups.

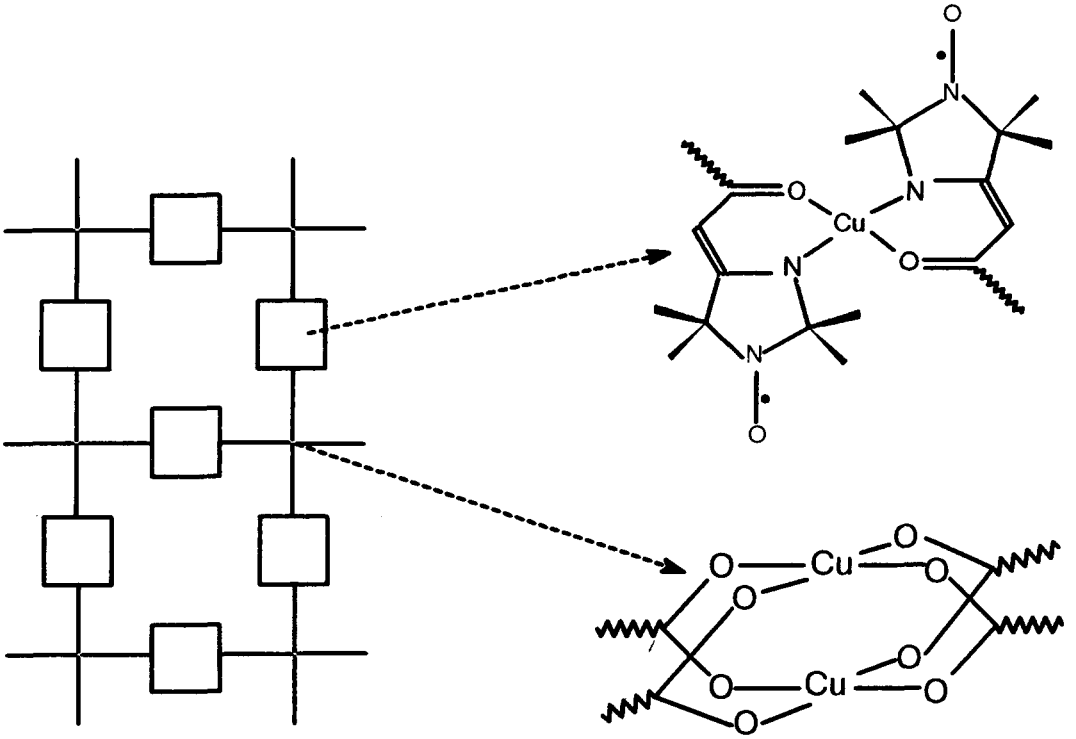
It should be noted that H_2L arises in the hydrolysis of the ethyl carboxylate HA, which was used to obtain layered polymeric CuA_2 capable of ferromagnetic ordering [9]. The layered polymeric structure of solid CuA_2 was formed due to the coordination of the N•—O oxygens of neighboring molecules by copper ions. We could not rule out a similar way of coordination of the nitroxide in the Cu^{II} complexes with H_2L (Scheme 1).

The above considerations seem to be quite reasonable. Therefore, it was rather unexpected that when the Cu : L proportion in the reaction mixture reached 1 : 1, the initially formed mononuclear complex transformed into the binuclear one. During this transformation the polyfunctional ligands moved toward each other, which is unusual for the chemistry of coordination compounds. This process can be presented by Scheme 2. The scheme shows that, in fact, one of the ligands creeps on copper ions like a caterpillar. Therefore, we designated this process as a caterpillar-like reaction. For metal complexes with paramagnetic organic ligands, this reaction is reported for the first time [10].

EXPERIMENTAL

Preparation of $Cu(HL)_2(H_2O)_2$

A solution of $Cu(CH_3COO)_2(H_2O)$ (0.88 g, 4.4 mmol) in water (40 cm^3) was added to a solution of H_2L (2 g, 8.8 mmol) in ethanol (40 cm^3). The resulting



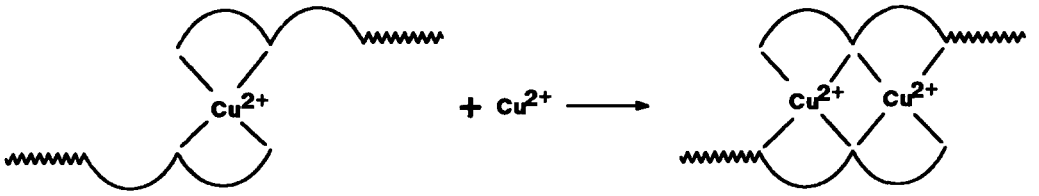


Fig. 1. Hypothetical scheme of the layered polymeric structure. Squares denote bischelate fragments; the intersection points of the straight lines correspond to binuclear carboxylate nodes.

Scheme 2.

mixture was stirred and refluxed for 5 min, then it was evaporated to a small bulk and the solid precipitate was filtered off, washed with water and dried *in vacuo* over $Mg(ClO_4)_2$. Recrystallization from an EtOH : H_2O mixture (1 : 1) afforded green octahedra of $Cu(HL)_2(H_2O)_2$ in 60% yield (1.7 g).

Noteworthy is that the recrystallization from hot absolute ethanol produces light green crystals of $Cu(HL)_2(C_2H_5OH)_2$ (75% yield), which are unstable in air, since the water molecules slowly replace the alcohol ones.

Preparation of $Cu_2L_2(H_2O)_5$ *and* Cu_2L_2

A solution of H_2L (0.45 g, 2 mmol) in ethanol (10 cm^3) was added to a solution of $Cu(CH_3COO)_2(H_2O)$ (0.4 g, 2 mmol) in water (10 cm^3). Then NaOH (0.14 g, 3.5 mmol) was added to the mixture. The reaction mixture was heated to boiling and ethanol was evaporated in a rotary evaporator. The water (10 cm^3) was added to the mixture and the solution was cooled to 0°C. The resulting deep green octahedra were filtered off, washed with water and dried *in vacuo* over $Mg(ClO_4)_2$. Recrystallization from an EtOH : H_2O mixture (1 : 1) afforded deep green crystals of $Cu_2L_2(H_2O)_5$ in 70% yield (0.47 g).

$Cu_2L_2(H_2O)_5$ can also be obtained by:

(a) heating an equimolar mixture of $Cu(HL)_2(H_2O)_2$ [or $Cu(HL)_2(C_2H_5OH)_2$)] and $Cu(CH_3COO)_2(H_2O)$ in a water : ethanol (1 : 1) solution, followed by adding a base and allowing the solution to stand for 24 h; or

(b) heating an ethanol–water solution of CuA_2 with NaOH, followed by adding $Cu(CH_3COO)_2(H_2O)$.

Cu_2L_2 was obtained in quantity by keeping $Cu_2L_2(H_2O)_5$ *in vacuo* at 70°C for 5–6 h.

Analytical data for $Cu(HL)_2(H_2O)_2$, $Cu(HL)_2(C_2H_5OH)_2$, $Cu_2L_2(H_2O)_5$ and Cu_2L_2 are in good agreement with the corresponding theoretical values.

Physical measurements

The IR spectra of the compounds tabletted in KBr were recorded on a UNICAM-75-IR spectrophotometer in the range 400–4000 cm^{-1}. The TG and DTA curves were obtained using a Paulik–Paulik–Erdey derivatograph for 50 mg samples in air at a heating rate of 2.5 K min^{-1}. The magnetic susceptibilities of the polycrystalline samples of the title complexes were measured by the Faraday technique over the temperature range 4.2–300 K. The samples were sealed in quartz ampoules. The molar magnetic susceptibilities were calculated as corrected for the atomic diamagnetism and temperature-independent paramagnetism of Cu^{2+}.

Crystal structure determination

Experimental data for the single crystals of $Cu(HL)_2(H_2O)_2$ and $Cu_2L_2(H_2O)_5$ were collected on the automatic four-circle diffractometers SYNTEX $P2_1$ and CAD4, respectively, using a standard procedure. The parameters of the monoclinic unit cells and the details of data collection and structure refinement are listed in Table 1. The structures were solved by direct methods (SHELXS-86) [11] and refined by the full-matrix least-squares procedure in the anisotropic approximation for all nonhydrogen atoms. For both structures hydrogen atoms were located on difference Fourier maps and included in the refinement in the isotropic approximation. All calculations concerning the structure refinement were performed using the SHELXL-93 programs [12]. Selected bond length distances and bond angles are given in Tables 2 and 3.

RESULTS

Mononuclear complex

$Cu(CH_3COO)_2(H_2O)$ interacts with H_2L (1 : 2) in a water : ethanol mixture to form the solvated bischelate $Cu(HL)_2$. In numerous attempts to obtain single crystals of this product we revealed the following. The second and third recrystallization of the product from water-containing ethanol yield green crystals of $Cu(HL)_2(H_2O)_2$ together with light green crystals of $Cu(HL)_2(C_2H_5OH)_2$. Increasing the H_2O/C_2H_5OH ratio in the solvent used for the recrystallization shar-

ply increases the amount of the $Cu(HL)_2(H_2O)_2$ crystals. When the $H_2O : C_2H_5OH$ ratio is close to 1 : 1 and higher, only the $Cu(HL)_2(H_2O)_2$ crystals are isolated in the solid phase. Pure $Cu(HL)_2(C_2H_5OH)_2$ [without $Cu(HL)_2(H_2O)_2$ admixture] is obtained by the recrystallization of the complex from absolute ethanol. The $Cu(HL)_2(C_2H_5OH)_2$ crystals are unstable in air, since the water molecules slowly replace alcohol molecules [13]. In $Cu(HL)_2(H_2O)_2$, in contrast, water molecules are strongly bound. The complex does not lose water on heating (neither in air or *in vacuo*) up to the decomposition temperature ($\sim 120°C$). This is rather unusual since in $Cu(HL)_2(H_2O)_2$ the water molecules are not coordinated by the metal ion, being held in the solid complex due to hydrogen bonds (Fig. 2).

Crystal structure and magnetic properties of $Cu(HL)_2(H_2O)_2$

The $Cu(HL)_2(H_2O)_2$ complex has a molecular structure. A centrosymmetric molecule of the complex is shown in Fig. 2. The paramagnetic ligand is bonded in a bidentate fashion to the copper atom by the oxygens of the deprotonated carboxylate group and the keto group of the enamineketone fragment. In the resulting five-membered chelate ring, the Cu—O bond lengths are on the average 1.915 Å, the OCuO angle being 85.05(3)°. Thus, two coordinated LHs form a centrosymmetric square around the copper atom. The water molecules are outside the coordination sphere of the metal. The N—H hydrogen of the ligand forms the H(1n1)···O(1) bond (2.124 Å), with the coordinated enamineketone oxygen and the H(1n1)···O(1w) bond (1.906 Å) with the water molecule, which is also bonded to the noncoordinated carboxyl oxygen of the ligand of the neighboring molecule [H(1w)···O(112′) is equal to 2.196 Å]. As mentioned above, the involvement of the water molecules in several hydrogen bonds tends to hold them strongly in solid $Cu(HL)_2(H_2O)_2$.

In $Cu(HL)_2(H_2O)_2$ both intra- and intermolecular distances between the paramagnetic centers are rather large: within the molecules, the Cu···—•O distances are 7.900 Å, the shortest intermolecular distances Cu···O•— are no less than 5.152 Å and the shortest —•O···O•— and Cu···Cu distances are 5.862 Å. The large separation of the paramagnetic centers determines their weak interaction. Figure 3 shows the experimental and theoretical functions $\mu_{eff}(T)$ for $Cu(HL)_2(H_2O)_2$. The experimental data are adequately described by the theoretical curve, which was constructed according to the model of the isolated exchange cluster O•—N···Cu^{2+}···N—•O for $g_{Cu} = 2.07$, $J = -2.5\,cm^{-1}$ and $zJ' = -0.1\,cm^{-1}$. The analytical expressions used in calculating the exchange cluster O•—N···Cu^{2+}···N—•O are given elsewhere
