prevented a full refinement of the structure. However, when crystals are grown from non-deoxygenated wet acetone, a second type of crystal can also be obtained. The dark, almost black crystals are the peroxo dinuclear complex **I**; the structure of the cation is shown in Fig. 2. The molecule consists of two pseudo octahedral Co(III) metal centers. Each metal atom is attached to two chelating Hdpa ligands and the centers are united by a peroxo group and a hydroxo group. The bridging hydroxo moiety is hydrogen bonded to an interstitial acetone molecule; the O···O separation is 2.81 Å. This type of complex is well established [15] and the O—O distance of 1.390(6) Å is in the expected range [16]. Other peroxo complexes of cobalt with Hdpa have been reported [17], but they have not been structurally characterized. One attempt to do such a characterization failed since the crystals turned out to be $[Co(Hdpa)_2(CO_3)]ClO_4$ [18].

The N—Co—N bond angles for $[Co(Hdpa)_2(CO_3)]ClO_4$ and for **I** are close to 90°, as expected for a six-coordinate cobalt atom. The presence of two chelating Hdpa groups and two additional ligands in the coordination sphere forces the Hdpa ligand to adopt a configuration in which the dihedral angles between the two pyridyl groups range from 36.9 to 43.3°. The non-planarity of the Hdpa ligand is typically found in six- [19], some five- [1b,20], and four-coordinate square planar Pd complexes [21].

$Co(Hdpa)Cl_2$ (II)

In acetonitrile, $CoCl_2$ dissolves to give a deep royal blue solution which upon layering with Et_2O yields royal blue crystals of $[Co(CH_3CN)_6][CoCl_3(CH_3CN)]_2 \cdot CH_3CN$ [22]. This material is composed of octahedral $[Co(CH_3CN)_6]^{2+}$ cations and tetrahedral $[CoCl_3(CH_3CN)]^-$ anions, the dimensions of which are very similar to those previously reported for compounds containing such ions [23]. The ionic

complex [$Co(CH_3CN)_6$][$CoCl_3(CH_3CN)$]$_2$ reacts with an acetonitrile solution of Hdpa to give an insoluble blue precipitate which dissolves in DMSO to produce, upon layering with CH_2Cl_2/Et_2O, dark blue crystals of **II**.

The mononuclear complex has a distorted tetrahedral geometry as shown in Fig. 3. The angles around the cobalt atom range from 94.0 to 116.5°, which is a large deviation from the idealized angle of 109.5°. The complex is stabilized by intermolecular hydrogen

bonding between N—H···Cl units as shown in Fig. 4. The N(2A)···Cl(2C) separation of 3.28 Å is similar to that found in complexes of the type $CoCl_2$(formamidine)$_2$ [24]. The N(1)—Co(1)—N(3) angle is only 94.0(1)°, but the small steric hindrance of the chloride ions allows the Hdpa fragment to the almost planar. The dihedral angle between the pyridyl groups is 5.6°, which is slightly smaller than that found in a copper analog (7.3°) [25]. A relatively small torsion angle is also found in copper(I) complexes such as [(Hdpa)CuI_2Cu(Hdpa)] and [Cu(Hdpa)$_2$][Cu(dpa)X_2], X = Cl, Br and I [26], but it can be slightly larger in others such as [Cu(Hdpa)$_2$]Cl in which one of the dihedral angles is 5.6° and the other is 16.7° [25,27]. However, in all pseudo-tetrahedral complexes with chelating Hdpa, there is a distinctive characteristic; the angle about the amine nitrogen attached to the pyridyl groups is in the range of 133.6 and 135.1°. This is also true for [Cu(Hdpa)$_2$]$(ClO_4)_2$ (134(1)°) [10]. This angle decreases slightly (131.1(4), 129.9(2) and 132.1(2)°) for the two polymorphs of the non-coordinated Hdpa molecule [28].

$Co(dpa)_2$ (**III**)

The reaction of Lidpa with $CoCl_2$ in a non-coordinating solvent such as toluene allows the isolation of bright red crystals of $Co(dpa)_2$, the structure of which is shown in Fig. 5. The four-coordinate cobalt atom is surrounded by two dpa anions which are related by a crystallographic 2-fold axis. The mol-

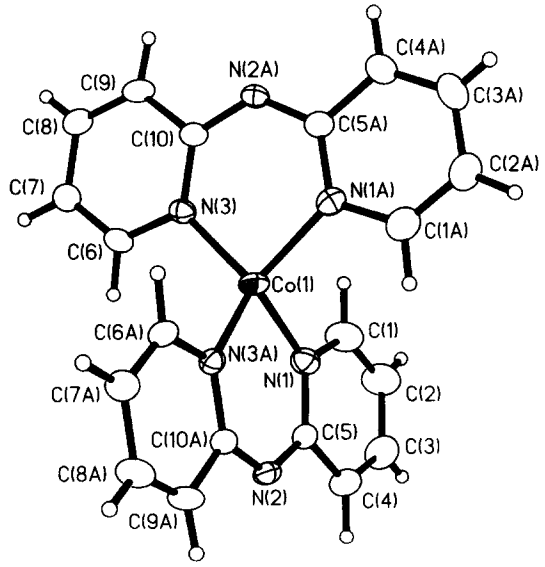

Fig. 5. Molecular structure of $Co(dpa)_2$ (**III**).

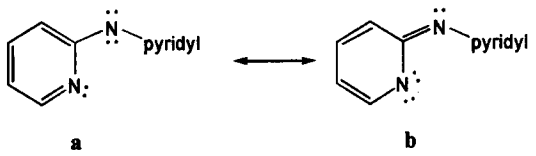
ecules pack in such a way as to show significant C—H···N interactions [29]. The C(6)···N(2B) separation is 3.41(3) Å and the N(2B)···H(6) distance is 2.44(3) Å. The nearly planar dpa^- anions display a torsion angle of the pyridyl groups of 3.6° and a C—N—C angle of 128.2(2)° at the bridging nitrogen. This angle is significantly smaller than those found in pseudo tetrahedral complexes where the neutral Hdpa molecule serves as a ligand (*vide supra*). The equivalent angles are even smaller (127.9°) in the copper analog [30] and in a Cu(3,3′-dimethyldpa)$_2$ [31] complex (128.1°). The N(1)—Co—N(3A) angle in **III** is 94.5(1)°, which is similar to that found in **II**.

It is reasonable to expect a decrease of the pyridyl—N—pyridyl angle for the anionic ligand relative to the neutral ligand since the lone pair of electrons would be expected to push the rings more strongly than a hydrogen atom. Another important observation is that there exists a marked difference in the C—C distances of the pyridyl rings with alternating long and short distances (see Table 3) which is very possibly due to the contribution of canonical forms such as **b**, which tends to localize single and double bonds.



a **b**

$[H_2dpa]_2[CoCl_4]$ (**IV**)

From the reaction mixture which contained $[Co(H_2O)_6][ClO_4]_2$, neutral Hdpa and an acidic solution of HCl in a methanol/acetonitrile mixture, sky blue crystals of a cation containing H_2dpa^+ species can be isolated. A drawing of an H_2dpa^+ cation and the corresponding $CoCl_4^{2-}$ anion is shown in Fig. 6. The anion dimensions are typical [32] of those found for other tetrahedral tetrachlorocobaltate species. The additional proton is located between the atoms N(1) and N(3) which provides certain similarities to the metal chelated dpa and Hdpa species. The torsion angle between the pyridyl groups is 7.0° and the angle of 129.2(4)° for the C(5)—N(2)—C(10) unit is smaller than the corresponding angle formed by the chelating Hdpa groups but larger than those found in complexes containing chelating anionic dpa groups. The ions pack in the crystal forming hydrogen bonds between the N(2)—H groups and a chloride ion of the $CoCl_4^{2-}$ anion.

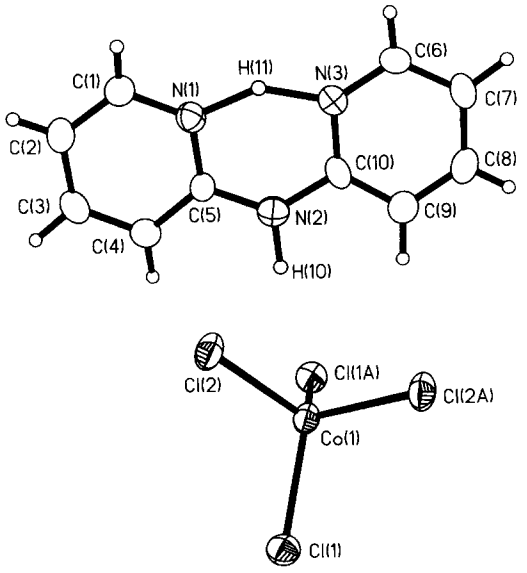


Fig. 6. Molecular structure of an H_2dpa^+ cation and the $CoCl_4^{2-}$ anion in $[H_2dpa]_2[CoCl_4]$ (**IV**).

Summary

2,2′-Dipyridylamine is known to act as a monodentate or a chelating bidentate ligand. The molecule can be deprotonated and the corresponding anion can be a chelating bidentate ligand or can be bridging a chain of three metal atoms. Under acidic conditions, the ligand can form the corresponding H_2dpa^+ cation. Structurally, such species have characteristics that make their identification relatively simple. In six-coordinate and square planar complexes, the neutral ligand chelates to the metal atom in such a way that a significant puckering of the pyridyl rings is observed (ca 35°); that puckering is significantly smaller (ca 5–7°) in four-coordinate pseudo tetrahedral complexes even though the N—M—N angles are only slightly greater than 90°. The anionic-chelating dpa^- groups in pseudo tetrahedral complexes are essentially planar (torsion angles of 3.6° or less) and have pyridyl—N—pyridyl angles which are ca 5° smaller than the corresponding ones in pseudo tetrahedral complexes which contain the chelating neutral ligand (127 vs 132° or more). The characteristic difference provides a general and reliable way to distinguish between structures **b** and **c** (Fig. 1), even when the presence or absence of a hydrogen atom on the bridging nitrogen atom cannot be established by other methods.

(Received 2 June 1997; accepted 23 June 1997)

Abstract—Four oxidation states (III, IV, V, and VI) of Pu may coexist under environmentally relevant conditions. An efficient method to determine the states actually present in various matrices would enhance the ability to model the fate and transport of plutonium in process streams and in the environment. This communication establishes that the L_3 X-ray absorption near-edge structure (XANES) spectra of Pu are primarily determined by the valence state and the presence or absence of the trans dioxo moiety, consistent with previous U and Np XANES studies. The edge energies were observed to shift progressively to higher energy with increasing valence, with an average 1.68 eV increase per formal oxidation state increase. In addition, the general spectral shape of the (III) and (IV) species is clearly different from the dioxo-containing (V) and (VI) species, with the first maximum much larger and sharper for the (III) and (IV) spectra than for the (V) and (VI) spectra. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: XANES; plutonium; oxidation state.

Chemical speciation, as the determinant of reactivity of the key radionuclides in nuclear waste (Sr, Cs, U, Np, Pu, Am, and Tc), is critical towards understanding and predicting their fate and transport in the environment [2–6]. The number of accessible oxidation states for transuranic ions in aqueous solution adds to the complexity of their chemistry. For plutonium, four oxidation states (III, IV, V, and VI) may coexist in aqueous solution [7]. X-ray absorption near-edge structure (XANES) spectroscopy is an established technique for the determination of oxidation state and local chemical environment, even at relatively low concentrations and without requiring extensive sample preparation that could induce artifacts [8]. The determination of edge energies and near-edge features of known Pu aquo species for different oxidation states will allow the determination of predominant oxidation states in complex matrices such as solution/solid-surface interfaces, amorphous solids, or radioactive tank wastes [9]. While XANES spectra of U and the complete suite of accessible Np oxidation states have been reported [10,11], there have been no systematic studies performed for Pu. We report here

the edge energies and near-edge features for plutonium aquo ions in oxidation states (III–VI).

Aqueous plutonium solutions containing a single oxidation state were prepared electrochemically [12], and the stability of the stock solutions was verified both before and after XANES analysis with UV–vis–NIR absorption spectroscopy. Each stock solution contained greater than 98% of a single plutonium species, although any effect of the X-ray beam on the actual sample was not directly addressed. Similar chemical environments around each of the plutonium cations were produced by preparing and studying the aquo complexes. Aquo ions of Pu^{3+}, Pu^{4+}, and PuO_2^{2+} were prepared in 1 M $HClO_4$, while PuO_2^{+} was prepared in perchlorate solution at pH 3 and subsequently stabilized with respect to disproportionation by adjusting the pH of the solution to 6 [12]. X-ray absorption measurements were performed in transmission ($Pu^{III,IV,VI}$) or fluorescence (Pu^{V}) mode at the Pu L_3-edge [13] and calibrated against a Zr foil [14]. The energies of the Pu absorption edges were determined in two ways: (1) as the inflection point of the edge and (2) as the energy of the arctangent in least squares fits of the XANES region using an arctangent plus Gaussian functions [15]. In the latter case, the arctangent represents the $2p_{3/2} \rightarrow$ continuum transition, and thus coincides with the onset of the absorbance, while the Gaussians fit the higher order features, including the main peak and the first EXAFS oscillations. The initial peak, or 'white line', has historically been assigned to the allowed bound final state $2p_{3/2} \rightarrow 6d$ transition [10,11,16,17], but recent work suggests that it may be better explained as EXAFS. A theoretical analysis of the transition will be reported elsewhere [18]. The type of fits described here are comparable to XANES fits reported for U and Np [10,11,16,17].

Pu L_3 edge spectra of the aquo ions are shown in Fig. 1, where significant shifts to higher energy with increasing valence are observed. In addition, the general shape of the near edge spectra for the (III) and (IV) species is clearly different from those of the dioxo-containing (V) and (VI) species (Fig. 1). Specifically, the main peak is much more distinct for the (III) and (IV) spectra, whereas the (V) and (VI) spectra exhibit a prominent shoulder on the high energy side of this peak. These characteristics are similar to the L_3 XANES of $U^{IV,VI}$ and $Np^{III-VII}$ [10,17]. The energies of the edge and 'white line' positions are listed in Table 1. The edge energy shifts determined by the second derivatives generally increase with the formal oxidation state of the absorbing metal atom, such that

[a] All energy positions are in eV, where the energy axis had been calibrated using the XANES edge from Zr foil at 17,999.35 eV. The arctan height, width, and edge are taken from variables k[1], k[2], and k[3], respectively, as defined in ref. [13].

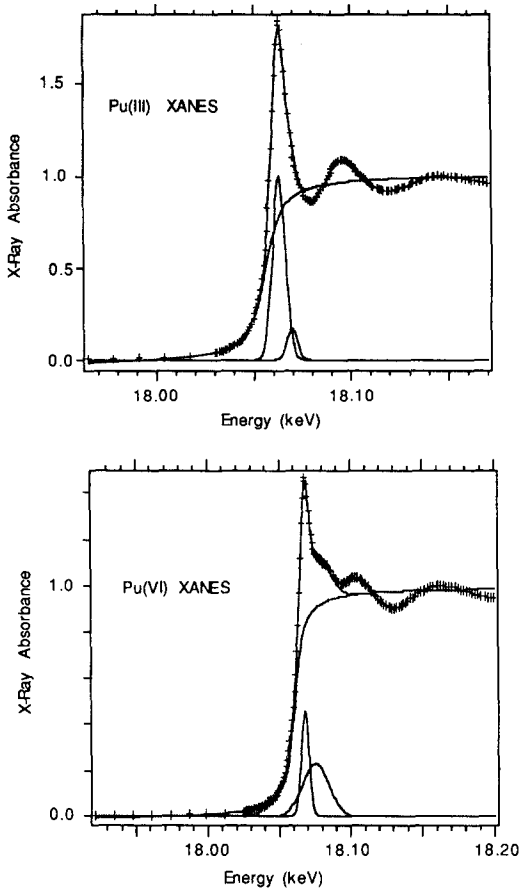

Fig. 2. Representative fits of the XANES for Pu^{III} and Pu^{VI}, representing the aquo- and dioxo-containing species, respectively.

(III), (IV/V), and (VI) are readily distinguished (Table 1). We note that while the overall shapes of the near edge spectra for (IV) and (V) states allow unambiguous assignment, their energies as determined by using only 2nd derivatives are quite similar. If the trend in edge shift reflects the charge, this might be explained by the increase in covalency (and diminution of difference in Pu charge) associated with the presence of the dioxo moiety in (V) and (VI) states. However, when fit to an arctangent and 2 Gaussians (Fig. 2), [15] which might be more sensitive to valence and less so to the positions and shapes of the other features of the edge, the arctangent (ionization) energies do increase progressively with formal oxidation state. The inset of Fig. 1 shows the excellent linear correlation between the arctan-based edge position and Pu oxidation state ($r^2 = 0.997$). Addition of a third Gaussian to the XANES deconvolution for the (V) and (VI) species affected the edge position only marginally (Table 1), and the general conclusion of higher edge position with oxidation state remains. Therefore, the arctangent fitting strategy avoids interference from the 'white line' when determining the energy of the edge.

This work shows that the primary determinants of Pu XANES are the valence state and the presence or absence of the trans-dioxo moiety, consistent with previous U and Np XANES studies [16,17,19,20]. Furthermore, this work establishes that XANES spectroscopy provides a rapid and straightforward means for determination of the average valence of Pu in species with primarily oxygen ligation, using a combination of the spectral features (III and IV vs V and VI) and the calculated arctangent edge energy. We anticipate that these findings will aid in our ability to determine the oxidation state of Pu in a variety of important complex chemical matrices such as aging radioactive wastes, process stream residues, glasses, ceramics, and soils.

12. ^{242}Pu was purified using ion chromatography (Lewatit MP-500) of Pu^{VI} in 9 M HCl ($PuCl_6^{2-}$), and eluted using 0.5 M HCl. Purified Pu^{IV} was oxidized to Pu^{IV} in fuming $HClO_4$, and the resulting solution diluted with 1 M $HClO_4$, and analyzed spectrophotometrically at 830 nm ($\varepsilon = 525$ M^{-1} cm^{-1}). Pu^{V} was prepared by placing Pu^{VI} in 0.2 M ClO_4, adjusting the pH to 3 using NH_4OH, followed by electrochemical reduction at a potential of 0.54 V (*vs* SCE). The pH was adjusted to 6, and the solution analyzed spectrophotometrically at 569 nm ($\varepsilon = 19$ M^{-1} cm^{-1}). Pu^{III} solutions were obtained by electrolytic reduction of Pu^{VI} at 0.51 V (*vs* SCE) in 1 M $HClO_4$, and analyzed spectrophotometrically at 600 nm ($\varepsilon = 37.5$ M^{-1} cm^{-1}). The Pu^{III} solution was oxidized electrochemically to Pu^{IV} at 1.2 V (*vs* SCE) in 1 M $HClO_4$. At this potential, Pu^{V} and Pu^{VI} could form, but the rate of formation for such irreversible reactions is small. Pu^{IV} is analyzed spectrophotometrically at 470 nm ($\varepsilon = 56.5$ M^{-1} cm^{-1}). Final Pu solution concentrations were 0.10 M for all samples except for Pu^{V}, which was 0.008 M.
13. XANES data were recorded at 295 K at the Stanford Synchrotron Radiation Laboratory (SSRL): unfocused beamline 4-2, Si(220), double-crystal monochromator, 3.0 GeV, 60–100 mA. The XANES region was taken as extending above the Pu edge to 18,120 eV.
14. The Pu L_3 edge spectrum normalized by setting the value of a polynomial fit through the pre-edge region to zero and that of a polynomial fit through the EXAFS region to unity at 18,120 eV. The spectra were calibrated by comparison of spectra for Zr foil, where the first inflection point was defined to be 17,999 eV.

(Received 16 December 1996; accepted 22 April 1997)

Abstract—The title complex was synthesized by reaction of *N,N′,N″*-tris(2-thienylmethyl)-*cis*-1,3,5-triaminocyclohexane (tachthioph) with copper(II) chloride in acetonitrile or methanol. Crystallographic characterization of Cu(tachthioph)$Cl_2 \cdot$MeCN reveals a typical Jahn–Teller-distorted square-pyramidal CuN_3Cl_2 coordination sphere. There is no interaction with the 2-methylenethiophene pendant arms. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: copper complexes; square-pyramidal; nitrogen donor ligands.

Tridentate ligand complexes of copper(II) chloride are of interest in bond cleavage of biological molecules, in that they catalyze hydrolysis of both unactivated peptide linkages and phosphodiester bonds [1]. Although Co^{III} complexes enhance rates of amide hydrolysis, only a few Cu^{II} complexes have been found to possess the appropriate properties for the catalytic hydrolysis of amide linkages [2,3]. We discuss herein the synthesis and X-ray structural characterization of *N,N′,N″*-tris(2-thienylmethyl)-*cis*-1,3,5-triaminocyclohexane copper(II) dichloride.

EXPERIMENTAL

Materials and methods

Anhydrous grade MeOH was obtained from Fisher. Et_2O was distilled from Na/K. $CuCl_2$ was from Aldrich. Tachthioph was prepared as previously reported [4].

Fast atom bombardment (FAB-MS) mass spectra were obtained on an Extrel 4000. Elemental analyses were performed by the University Instrumentation Center at UNH.

Preparation of Cu(tachthioph)Cl_2 To a colorless solution of tachthioph (0.0198 g, 4.74×10^{-5} mol) in MeOH (2 mL) was added a greenish–brown solution of $CuCl_2$ (0.0082 g, 6.1×10^{-5} mol) in MeOH (2 mL), affording a dark green solution. After standing for 2 h, ether (10 mL) was diffused, through the vapor phase, into the solution overnight. The green prisms were isolated, washed with ether, and dried under reduced pressure. Yield 0.015 g (2.7×10^{-5} mol, 57%). Anal. Calcd for $C_{21}H_{27}CuN_3S_3Cl_2 \cdot H_2O$: C, 44.24; H, 5.12; N, 7.37. Found: C, 44.79; H, 5.05; N, 7.56. MS (FAB, glycerol/H_2O matrix) *m/z*: 515 $[M\text{-}Cl]^+$, 480 $[M\text{-}2Cl]^+$. UV–vis (Methanol): λ_{max} 233.5 nm ($\varepsilon = 3.12 \times 10^4$).

Crystal structure determination

$[C_{21}H_{27}Cl_2CuN_3S_3][CH_3CN]$, green fragment, $0.20 \times 0.12 \times 0.04$ mm, $fw = 593.13$, triclinic, $a = 8.8282(5)$, $b = 10.9528(6)$, $c = 15.4888(9)$ Å, $\alpha = 72.061(1)°$, $\beta = 74.761(1)°$, $\gamma = 67.109(1)°$, $V = 1295.05(13)$ Å^3, space group $P\bar{1}$, $Z = 2$, $D_c = 1.521$ g/cm^3, μ (Mo-Kα) = 1.312 mm^{-1}, $\lambda = 0.71073$ Å.

Crystals were obtained by diffusion of ether, through the vapor phase, into an acetonitrile solution of Cu(tachthioph)Cl_2. A fragment was taken directly from the crystals in supernatant, sealed in epoxy and mounted on a glass fiber. Data were collected on a Siemens SMART/CCD area detector diffractometer ($-9 \leqslant h \leqslant 9$, $-12 \leqslant k \leqslant 12$, $-12 \leqslant l \leqslant 17$; $1.40 \leqslant \theta \leqslant 23.26°$) at -100°C with graphite-monochromated Mo-Kα radiation. 5262 reflections were measured, 3576 reflections were unique, and 3079 reflections with $I > 2\sigma(I)$ were considered to be observed for purposes of R value computation. The data were corrected for Lorentz and polarization factors.

The structure was solved by direct methods. Six positions were found to be disordered between *S* and *C*. It was not possible to resolve separate positions for each disordered pair, therefore each position was refined with partial *S* and partial *C* occupancy. The disorder was deduced to be 85%/15%. Thus, S(1C9), S(2C14), S(3C19) were refined at 85% occupancy sulfur and 15% occupancy *C*. Similarly, positions *C*(9S1), *C*(14S2), and *C*(19S3) were refined as 85% *C* and 15% *S*. The geometrically constrained hydrogen atoms were placed in calculated positions and allowed to ride on the bonded atom with $B = 1.2 \times$ Ueqv (C). The methyl hydrogen atoms were included as a rigid group with rotational freedom at the bonded carbon atom ($B = 1.2 \times$ Ueqv(*C*)). The remaining three hydrogen atoms were located from a difference Fourier map and allowed to ride on the bonded N atoms with $B = 1.2 \times$ Ueqv (*N*). Refinement of the non-hydrogen atoms was carried out with anisotropic temperature factors. Final values of R(all data) = 4.78%, R_w (all data) = 10.75%, R(obs data) = 3.74%, and

RESULTS AND DISCUSSION

The preparation of Cu(tachthioph)Cl_2 is straightforward. The acetonitrile solvate Cu(tachthioph)$Cl_2 \cdot$MeCN provided acceptable single crystals for diffraction study. A view of the molecule Cu(tachthioph)Cl_2 is provided in Fig. 1. Selected bond distances and angles are in Table 1. The metal coordination sphere is distorted square pyramidal, with N(3) in the apical position and N(1), N(2), Cl(1) and Cl(2) forming the square base. The distortion leads N(1) and Cl(2) towards the apical sites of a trigonal bipyramidal and N(2), N(3) and Cl(1) toward the equatorial sites. The apical bond distance Cu—N(3) of 2.288(3) Å is substantially longer than the basal ones as is typical of Jahn–Teller-distorted copper(II). This may be compared with the apical Cu—N distances of 2.246(4) and 2.231(4) Å in square-pyramidal Cu(1,4,7-triazacyclononane)Cl_2 [5] and Cu(1,4,7-triazacyclononane)Br_2 [6], respectively. Comparison may also be made to Cu(1,3,5-triamino-1,3,5-trideoxy-*cis*-inositol)$_2^{2+}$ [7] (Cu(taci)$_2^{2+}$), which is similar to the title compound in that it contains copper(II) coordinated by a *cis*-1,3,5-triaminocyclohexane-derivative group. In this octahedrally-coordinated complex, the longer Cu^{II}—N distance is 2.322(6) Å. The shorter Cu—N distances of the title compound are 2.065(3) (N(2)) and 2.069(3) Å (N(1)), which compare favourably with those of 2.086(4) Å for Cu(taci)$_2^{2+}$ and 2.063(4), 2.038(4) Å in Cu(1,4,7-triazacyclononane)Cl_2.

Copper(II)—chloride distances of Cu(tachthioph)Cl_2 (Cu—Cl(2) = 2.2914(10), Cu—Cl(1) = 2.3216(9) Å) are comparable to those of Cu(1,4,7-triazacyclononane)Cl_2 (2.268(1), 2.312(1) Å). The Cu—Cl(1) bond distance is significantly longer than Cu—Cl(2) due to the two hydrogen bonds accepted by Cl(1) (*vide infra*). The bite angles of N—Cu—N of Cu(tachthioph)Cl_2 (N = N(1), N(2), or N(3)) are 91.30(11), 92.06(11) and 86.43(11)° as compared to 85.7(2), 90.1(2), 89.9(2) and 94.3(2) in Cu(taci)$_2^{2+}$. The torsion angles C—C—C—C of the cyclohexyl ring, a measure of ligand distortion induced by the metal pushing the nitrogens outward (Table 1) [8,9] are not significantly different from those of Cu(cis-1,3,5-triaminocyclohexane)$_2^{2+}$, which range from 50.6(13) to 52.9(13)° [10].

The atoms N(1) and N(3) form single hydrogen bonds to Cl($\bar{1}$) in a molecule related by a crystallographic center of inversion resulting in a hydrogen-bonded dimer (H(1)$\cdots$Cl(1a) = 2.529(3) Å, N(1)—H(1)$\cdots$Cl(1a) = 167.34(6)°; H(3)$\cdots$Cl(1a) = 2.777(3) Å, N(3)—H(3)$\cdots$Cl(1a) = 158.79(6)°). The hydrogen bonding is completed by interactions to two terminal solvent molecules. N(2) donates a single hydrogen bond to the N atoms of the solvent (H(2)$\cdots$N(4) = 2.582(5) Å; N(2)—H(2)$\cdots$N(4) = 148.7(1)°) and the solvent methyl group participates in a very weak interaction with Cl(2) (H(23C)$\cdots$Cl(2) = 2.844(5) Å; C(23)—H(23C)$\cdots$Cl(2) = 132.2(1)°).

(Received 6 February 1997; revised 8 April 1997)

Abstract—The title compound is readily prepared from the rhenium carboxylate, $(dppe)(CO)_3ReC(O)OCH_3$, by prolonged stirring of a solution of the carboxylate in benzene/H_2O or THF/H_2O. The reaction involves the unusual *in situ* conversion of Re—C bonds to Re—O bonds. The X-ray structure of the title compound shows that the μ_2,η^2-carbonato ligand is present in the symmetrical *syn, syn* conformation in the solid state in contrast to the alternate *syn, anti* geometry reported for the related complex, $(diars)(CO)_3ReOC(O)ORe(CO)_3(diars)$.

Keywords: rhenium; 1,2-bis(diphenylphosphino)ethane; rhenium carboxylate complex; bridging carbonato complex; crystal structure.

There are now many examples of functional groups directly bonded to transition metals through a metal–carbon bond and many, although fewer, examples of organometallic compounds involving metal–oxygen single bonds (such as transition metal alkoxides). The facile insertion of CO_2 into an M—O bond of alkoxides leading to organometallic carbonates is a reaction that has become of increasing interest because of its relevance to reversible sequestering of this "green house" gas. Such insertion reactions and the wide variety of complexes that are thereby generated have been summarized in a recent excellent review [1]. Although there are now numerous examples of μ_2,η^2 organometallic carbonates and some bicarbonates [2–8], there are fewer examples of transition metals bridged by a single carbonato linkage, i.e. M—OC(O)O—M. These include complexes where M=Rh [4], Cu [9–11], Cr [12], Re [13], and Mn [14]. In only the last case has the formation of the bridging carbonato complex involved the conversion of M—C to M—O bonds. We wish to report here on the transformation of *fac*-$(dppe)(CO)_3Re\text{–}C(O)OC_2H_5$ to *fac*-$(dppe)(CO)_3Re\text{–}OC(O)O\text{–}Re(CO)_3(dppe)$. The X-ray crystal study of the bridging carbonato complex is also reported.

EXPERIMENTAL

All reactions were carried out under an atmosphere of argon. Solvents were used directly from bottles of certified purity. *fac*-$(dppe)(CO)_3ReC(O)OC_2H_5$ was prepared according to the literature method [15]. The IR spectra were recorded on a Perkin–Elmer 1600 Series FT-IR instrument. NMR spectra were recorded on a Bruker AC 250 (250.133 MHz, ^1H; 62.896 MHz, ^{13}C; 101.256 MHz, ^{31}P) spectrometer. Melting points were recorded on a Mel-Temp apparatus and are uncorrected. Elemental analyses were performed by Galbraith Laboratories, Inc.

Preparation of $(dppe)(CO)_3Re\text{–}OC(O)O\text{–}Re(CO)_3(dppe)$

A 0.50 g sample of *fac*-$(dppe)(CO)_3ReC(O)OC_2H_5$ was stirred with benzene or THF (50 cm^3) in the presence of water (0.5 cm^3) under argon for 7 d. The solution was evaporated to dryness and the solid residue was recrystallized from a dichloromethane/hexane mixture. The white precipitate that separated was collected by filtration, washed with hexane (3×15 cm^3), and dried *in vacuo*. Data: m.p. 160–162°C. IR (cm^{-1}, CH_2Cl_2): $\nu_{(C\equiv O)}$ 2028s, 1945s, 1887s and $\nu_{(C\equiv O)}$

1534m. Anal. Found: C, 48.89; H, 3.50. Calc. for $C_{59}H_{48}O_9P_4Re_2 \cdot CH_2Cl_2$: C, 48.62; H, 3.40. ^1H NMR (δ, $CDCl_3$): 7.45 (m, 40H, C_6H_5), 5.29 (s, 2H, CH_2Cl_2), 2.61 (m, 8H, CH_2). ^{13}C NMR (δ, CD_2Cl_2): 166.7 (μ-CO_3). ^{31}P NMR (δ, CD_2Cl_2, reference: 85% H_3PO_4): 33.6 (s).

Reaction of (dppe)$(CO)_3$Re–OC(O)O–Re$(CO)_3$(dppe) *with* HCl

A solution of 0.22 g of (dppe)$(CO)_3$Re–OC(O)O–Re$(CO)_3$(dppe) in benzene (40 cm^3) was treated with excess of concentrated HCl (5 cm^3). After stirring for 2 h, the excess acid was removed by extraction with water. The benzene solution was then concentrated and mixed with hexane, and the resultant mixture was cooled. The white microcrystals that separated were collected by filtration, washed with hexane (3×15 cm^3) and dried under vacuum to give *fac*-(dppe)$(CO)_3$ReCl in essentially quantitative yield. This complex has been reported previously [16].

Reaction of (dppe)$(CO)_3$Re–OC(O)O–Re$(CO)_3$(dppe) *with* p-*toluenesulfonic acid monohydrate*

A solution of 0.50 g of (dppe)$(CO)_3$Re–OC(O)O–Re$(CO)_3$(dppe) in 50 cm^3 of dichloromethane was stirred with a 10-fold excess of *p*-toluenesulfonic acid monohydrate (98.5%) at room temperature for 1 h. The excess acid was removed by extraction with water. The dichloromethane solution was concentrated and mixed with hexane, and the resultant mixture was cooled. The white microcrystals that separated were collected by filtration, washed with hexane (3×15 cm^3), and dried under vacuum to give *fac*-(dppe)$(CO)_3$ReOTs in about 68% yield. This compound has been characterized previously [17].

Single crystal X-ray diffraction study of (dppe)$(CO)_3$Re–OC(O)O–Re$(CO)_3$(dppe)$\cdot 2C_6H_6$

A colorless prism 0.12 mm × 0.20 mm × 0.28 mm in size was sealed in a glass capillary and then transferred to a Siemens R3 m/v diffractometer. Crystal data: $C_{59}H_{48}O_9P_4Re_2 \cdot 2C_6H_6$; monoclinic, space group $C2/c$ (No. 15); $a = 31.537(3)$ Å, $b = 9.437(1)$ Å, $c = 22.139(3)$ Å, $\beta = 98.52(1)°$, $V = 6516(1)$ Å^3, $Z = 4$, $D_{calcd} = 1.58$ gcm^{-3}. The cell dimensions were refined with monoclinic constraints employing 25 centered reflections having $11° < \theta < 17.5$. One quadrant of data ($-40 < h < 40$, $0 < k < 12$, $0 < l < 28$) was collected at 298 K out to a θ maximum of 27.5° using Mo—K_α ($\lambda = 0.071073$ Å) and 1.2 degree ω scans. A total of 8143 reflections were measured, 7488 were unique [$R_{(int)} = 0.0226$] and 5980 were observed [$F > 3\sigma(F)$]. Corrections were made for Lorentz-polarization and absorption effects. The minimum and maximum transmission factors were 0.5138 and 0.9730, respectively. The structure was solved by heavy-atom methods and refined on F by full-matrix least-squares with SHELXTL-PLUS [18]. The non-hydrogen atoms were refined with anisotropic displacement coefficients and the hydrogen atoms were included with a riding model. The refinements converged to $R(F) = 0.0391$ and $wR(F) = 0.0304$ with 419 variables; where $R(F) = \Sigma(||F_o| - |F_c||)/\Sigma|F_o|$ and $wR(F) = [\Sigma(W||F_o| - |F_c||^2)/\Sigma W|F_o|^2]^{1/2}$. The goodness-of-fit was 1.27. The final atomic coordinates and equivalent isotropic displacement parameters are given in Table 1, selected bond distances and angles are presented in Table 2, and a labeled diagram of the structure is provided as Fig. 1. Further details are given in the Supplementary Material.

RESULTS AND DISCUSSION

A bridging Re carbonato complex analogous to the one we report here has been prepared previously [13] from the methyl carbonato complex, Re$(CO)_3$(diars)OC(O)OCH_3. In this instance and in the preparation of a Cu bridging carbonato complex [9], the M—O bond is present in the precursor complex. In a preparation of the Re bridging carbonato compound we report here, the precursor complex is Re(dppe)$(CO)_3$C(O)OC_2H_5 in which the Re is bonded to a carbon atom. On prolonged stirring in benzene/water (or THF/H_2O) at room temperature, the Re-carbon bond in the starting compound is replaced by the Re-oxygen bonds of the bridging carbonato linkage. We have observed a similar transformation in the manganese analog [14] but were unable to secure a definite X-ray crystal structure of the bridging carbonato complex. The crystal structure reported here confirms the μ_2,η^2 linkage of our Re complex. The molecule possesses crystallographic 2-fold symmetry and an ReOC(O)ORe core with a *syn,syn* conformation. The Re—O, O—C(O)O and OC(=O)O distances are 2.127(3), 1.315(5) and 1.228(9) Å, respectively, and are normal. The ReOC(O)ORe core within the related (diars)$(CO)_3$ReOC(O)ORe$(CO)_3$(diars) [13] exhibits an alternate *syn,anti* geometry with comparable distances of 2.138(6), 1.308(10) and (*syn*) and 2.143(6), 1.296(10) and 1.245(10) Å (*anti*), respectively. The ReO—C(O)—ORe angle in our (dppe) complex is 111.4(6)° while that in the diars complex is 116.7(8)°. To the best of our knowledge, these two values represent the present lower and upper bounds for dinuclear centers bridged solely by the carbonato ligand. The 111.4(6)° value in our dppe complex is also comparable to the average value of 111° observed in transition metal carbonates, M–OC(O)–OCH_3.

There is a prior interesting report of the conversion of an M—C bond to an M—O bond consisting of the decarbonylation of an Mo–C(O)OMe complex to the corresponding Mo–OMe complex [19]. We suspect that this reaction proceeds by prior dissociation at the

acyl oxygen bond, followed by decarbonylation of the cation.

If only a small sample of the bridging carbonato complex is desired, the most convenient preparation consists of dissolving the methoxide, *fac*-$Re(CO)_3(dppe)OCH_3$ [17] in a minimum of benzene whereupon the desired transformation occurs in about 1 h. The properties of the bridging carbonato complex obtained by this procedure were indistinguishable from those of the carbonato complex obtained from the ethyl carboxylate. The crystal used for the X-ray diffraction study was obtained from the alkoxide in this fashion. Apparently the alkoxide, which is known to be a scavenger for carbon dioxide, reacts with adventitious carbon dioxide to form the corresponding methyl carbonate. The conversion of the methyl carbonate to the bridging carbonato complex is analogous to that reported for the related Re(diars) complex [13] and requires a very small quantity of water. Our benzene solvent was not dried but when benzene that had been carefully dried and degassed was used, no bridging bicarbonato complex was formed. On treatment of the bridging carbonato complex with HCl or *p*-toluenesulfonic acid monohydrate, CO_2 is immediately evolved and the corresponding covalent compounds $Re(CO)_3(dppe)Cl$ and $Re(CO)_3(dppe)OTs$ are formed, respectively, in high yield.

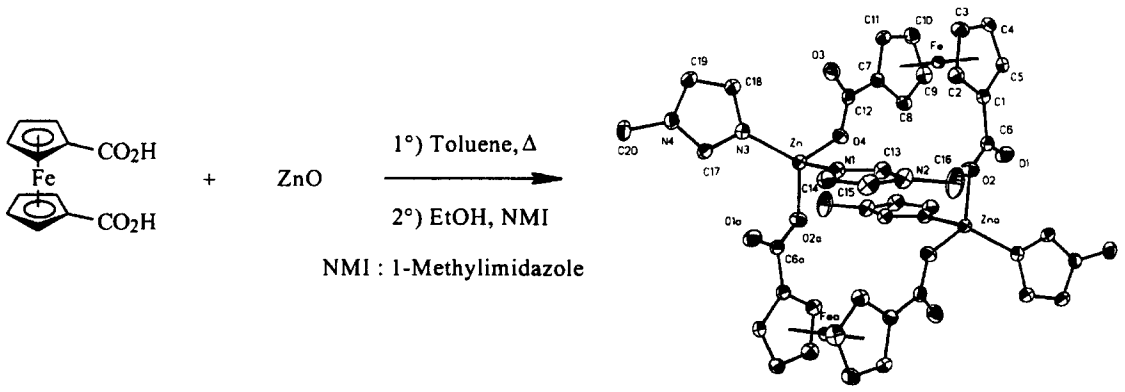
Abstract—The synthesis, spectral characterisation and X-ray structure determination of the first zinc(II) ferrocenedicarboxylate $[Zn(1,1'\text{-Ferdc})(1\text{-methylimidazole})_2]_2$, **1**, ($1,1'\text{-}H_2$ferdc = 1,1′-ferrocenedicarboxylic acid) is described. The molecular structure of **1** consists of a centrosymmetric cyclic dimer exhibiting a slightly distorted tetrahedral geometry around the zinc atoms. The ferrocenedicarboxylic acid acts as a *syn*-bound O,O′-bridging ligand. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: crystal structure; zinc complex; carboxylate; imidazole; ferrocene; dimer.



The zinc(II) carboxylates are known to be effective catalysts for the copolymerisation of CO_2 and epoxides [1]. The most efficient carboxylates are obtained from dicarboxylic acids and display most of the time polymeric structures [2]. The solid state structure of such carboxylates as well as the exact nature of the active site remain controversial. We became interested in systems involving soluble zinc(II) carboxylates which should allow an easier investigation of the reac-

* Author to whom correspondence should be addressed.

tion of carbon dioxide with epoxides. Carboxylic acids based on a ferrocene moiety afford monomeric as well as polymeric transition metal carboxylates [3–6]. Structural characterisations of mono- and dicarboxylato derivatives of ferrocene have been undertaken in the case of copper [5,6] and iron [4]. Surprisingly, no crystallographic data were available, to our knowledge, for ferrocenecarboxylates of zinc(II). The steric restrictions induced by the ferrocene fragment as well as the dependence of structure on additional coligands might produce new versatile zinc carboxylates. We decided therefore to undertake the synthesis and structural characterisation of such zinc carboxylates. We report here the first X-ray structure determination of a zinc(II) ferrocenecarboxylate.

The reaction of the 1,1′-ferrocenedicarboxylic acid [7] (1 equiv.), noted 1,1′-H_2Ferdc, with zinc oxide (1 equiv.) under reflux in toluene afforded an amorphous orange solid. After filtration, the orange precipitate was dissolved in a hot ethanolic solution of 1-methylimidazole (10 mol%), and was allowed to stand ca two weeks at 4°C and afforded orange needles (yield 40%). The spectroscopic results [8,9] suggest a non-polymeric compound presenting a "*O,O′*-bis(monodentate)" co-ordination of the dicarboxylate ligand with the formula [Zn(1,1′-ferdc)(1-methylimidazole)$_2$]$_n$. Successive recrystallisations yield finally to prismatic single crystals suitable for an X-ray structural characterisation.

Crystal data for **1**. $C_{40}H_{40}N_8O_8Zn_2Fe_2 \cdot 2C_2H_5OH$, Mr = 1187.52 gmol^{-1}, orange prisms, size 0.40 × 0.38 × 0.36 mm^3, triclinic, space group P-1 (No. 2), a = 10.114(2), b = 10.515(2), c = 13.735(4) Å, α = 112.07(1), β = 105.48(1), γ = 103.83(1)°, V = 1296.1(5) Å^3, Z = 1, $\rho_{calcd.}$ = 1.531 gcm^{-3}, μ (Mo–K_α) = 15.31 cm^{-1}, ψ-scan (*trans*$_{min}$: 0.531; *trans*$_{max}$ 0.991), F(000) = 616, 5558 reflections in h, $\pm k$, $\pm l$, measured in the range 2.43° ≤ Θ ≤ 26.29°, 5249 independent reflections, R_{int} = 0.022, 4713 reflections with $F_o > 4\sigma(F_o)$, 335 parameters, R = 0.041, wR^2 = 0.114, GOF = 1.024, largest difference peak: 1.19 e Å^{-3}.

X-ray diffraction data. CAD4 diffractometer using graphite-monochromated Mo–K_α radiation. The crystals were mounted in a cold nitrogen stream. Data were corrected for Lorentz, polarisation effects, and for absorption [17]. The structure was solved by direct methods (SHELXS) [18] and refined by full-matrix least squares techniques against F^2 (SHELXL-93) [19]. The hydrogen atoms were included at calculated positions with fixed thermal parameters; all nonhydrogen atoms were refined anisotropically. XP (Siemens Analytical X-ray Instruments, Inc.) was used for structure representations.

The molecular structure with atomic labelling is given in Fig. 1. The molecule is a centrosymmetric, cyclic dimer constituted by the linkage of two (1-methylimidazole)$_2$Zn ($O_2CC_5H_4$-Fe-$C_5H_4CO_2$) units. Only one example of such a cyclic bimetallic framework was previously reported in the case of the ferrocenophane [Fe(C_5H_4Se)$_2$Zr(C_5H_4-^{t}Bu)$_2$]$_2$ [10].

The so-formed macrocycle presents two bridging *O,O′*-ferrocenedicarboxylato moieties with a monodentate *syn*-co-ordination of the carboxy groups. The neutral imidazole ligands can be classified in two groups: the "exocyclic" imidazoles pointing out of the macrocycle and the "endocyclic" imidazoles pointing towards the cavity of the macrocycle. The overall conformation of this macrocycle can be regarded as an *anti* conformation in respect to the usual definition used with [1,1′] ferrocenophanes [11]. The shortest non-bonding contacts found within the dimer occur between acidic sp^2 carbons of the exocyclic imidazole moieties and pendant oxygen atoms of the carboxy groups [O(3)···C(18): 3.116(3) Å; O(3)···H(18): 2.450(3) Å and O(1a)···C(17): 2.973(3) Å; O(1a)···H(17): 2.254(3) Å]. These distant contacts cannot be considered as hydrogen bonds owing to the inappropriate angular geometry [12].

Each zinc atom occupies the centre of a tetrahedron characterised by a dihedral angle of 89.3(1)° between the planes defined by N(3)—Zn—N(1) and O(4)—Zn—O(2a). The angles within the polyhedron are shifted from the theoretical value and range from 97.0(1)° to 118.8(1)°, the N(3)—Zn—O(4) angle being the greatest observed in the molecule.

The Zn—O bond lengths, 1.982(3) and 1.975(3) Å, are within the range reported for tetrahedral environments [13]. The carboxylato groups are bound in a monodentate configuration as shown by the distances measured between pendant carboxylic oxygens and zinc atom [2.975(3) and 2.815(3) Å]. The Zn—N bond lengths, 1.997(3) and 2.010(3) Å, are similar to those found in other tetrahedral zinc complexes of imidazole derivatives as already documented with, e.g. [Zn(imidazole)$_2$(O_2CCH_3)$_2$] [14] [Zn—N: 1.996(2)–2.003(3) Å] and are shorter than those found in octahedral imidazole complexes like [Zn(quinaldinato)$_2$(1-methylimidazole)$_2$] [15] (2.144(2) Å). The η^5-C_5H_4 planes in the ferrocenedicarboxylate ligands are essentially coplanar, displaying a dihedral angle of 1.5(1)°; the cyclopentadienyles ligands deviate from the eclipsed conformation by 4.5(1)°. Individual Fe—C_{ring} distances range from 2.036(4) to 2.054(4) Å [mean Fe-ring distance: 1.652(3) Å] and are comparable to those found in other ferrocenecarboxylato compounds [4–6] [2.030(6)–2.071(3) Å]. As was found to be the case for ferrocenecarboxylato compounds of copper(II) [4,5], the O_2C—C_4H_5 fragments are not strictly planar. The torsionnal angles for theses moieties are 6.5(1)° and 12.5(1)° about the C(6)—C(1) and C(12)—C(7) linkages respectively.

The other bond lengths and bond angles found within the ferrocenecarboxylic acid and 1-methylimidazole molecules are in good agreement with those previously reported [15,16].

The crystal structure of the complex consists of separated discrete molecular units and ethanol molecules of solvatation which are separated by normal

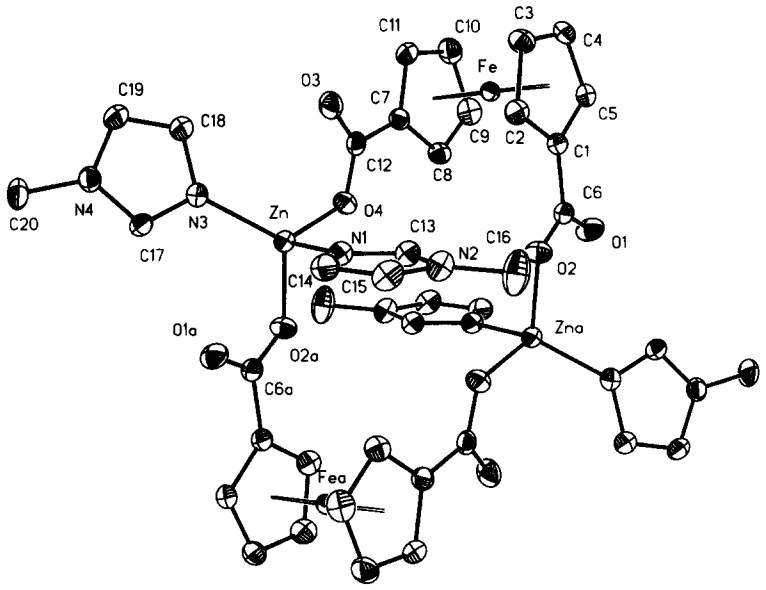


Fig. 1. Molecular structure of $[Zn_2(1,1'\text{-Ferdc})_2(1\text{-methylimidazole})_4]\cdot 2EtOH$ with 50% probability thermal ellipsoids. Solvent molecules and hydrogen atoms are omitted for clarity. Symmetry transformation used to generate equivalent atoms: (a): $1-x, -y, -z$. Key bond lengths (Å) and angles (°): Zn—O(4), 1.982(3), Zn—O(3) 2.975(3), Zn—O(2a) 1.975(3), Zn—O(1a) 2.815(3), Zn—N(3) 1.997(3), Zn—N(1) 2.010(3), C(6)—O(1) 1.230(5), C(6)—O(2) 1.289(4), C(3)—O(12) 1.243(5), C(4)—O(12) 1.281(4), Fe—Fe(a) 9.474(3), Zn—Zn(a) 5.682(3), Fe—Zn 5.696(3). N(1)—Zn—N(3) 112.25(9), O(2a)—Zn—O(4) 113.71(8), O(2a)-Zn-N(3) 112.07(8), N(3)—Zn—O(4) 101.95(9), O(1a)—C(6a)—O(2a) 122.4(2), O(3)—C(12)—O(4) 124.8(3).

Van der Waals distances. The crystal structure exhibits no abnormally short intermolecular contacts.

More work is currently in progress to control the degree of oligomerisation of such bimetallic compounds. Likewise, the dependence of the dimeric structure on the nature of the present neutral coligands has to be rationalised.

Abstract—The synthesis, structure, and characterization of the first example of a neutral vertex-sharing bi-icosahedral bimetallic (Au–Ag) cluster, $(MePh_2P)_{10}Au_{12}Ag_{13}Br_9$, with a novel 7-membered satellite ring of bridging halide ligands are reported. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: cluster of clusters; bi-icosahedral cluster; mixed-metal cluster; rotamer; roulettamer

Many high nuclearity clusters consist of smaller clusters as building blocks [1–3]. These clusters may be termed "clusters of clusters". Our recent synthetic and structural efforts in this area led to a series of vertex-sharing polyicosahedral mixed-metal clusters with the icosahedron as the basic building block [4–11]. Particularly interesting is the bi-icosahedral series wherein the relative rotation (Θ, in degrees) of the two icosahedra gives rise to different metal configurations (rotameric forms, R(Θ)), as exemplified by R(9) of $[(p\text{-}Tol_3P)_{10}Au_{13}Ag_{12}Cl_7]^{2+}$ (**1**) [4] and R(36) of $[(Ph_3P)_{10}Au_{13}Ag_{12}Br_8]^+$ (**2**) [5]. Here R(0) represents the staggered-eclipsed-staggered (ses) and R(36) the staggered-staggered-staggered (sss) configurations of the four metal pentagons of the bi-icosahedral metal framework. In fact, **1** and **2** are examples of two series of bi-icosahedral bimetallic clusters of the general formulas $[(R_3P)_{10}Au_{13}Ag_{12}X_7]^{2+}$ and $[(R_3P)_{10}Au_{13}Ag_{12}X_8]^+$, respectively, with a satellite ring of five or six halide ligands (hereafter referred to as 5- and 6-ring series, respectively) bridging the two inner silver pentagons, as portrayed in Chart I(a) and (b) for **1** and **2**, respectively. Within each series, different bridging ligand arrangements (roulettameric forms) have been observed. For example, for the 6-ring series, the roulettameric-rotameric forms, ranging from qd_5-R(0) [6]. to $o\text{-}q_2d_4$-R(0) [7], to $o\text{-}t_2d_4$-R(18) [8], to $p\text{-}t_2d_4$-R(36) [5], to $p\text{-}d_2t_4$-R(36) [9], have been observed. Here, d, t, and q denote double, triple, and quadruple bridging, respectively. We report herein the synthesis and structure of a new bi-icosahedral Au–Ag cluster $(MePh_2P)_{10}Au_{12}Ag_{13}Br_9$ (**3**) with an unprecedented roulettameric form which represents the first example of a novel 7-membered satellite ring (hereafter referred to as the 7-ring series) of bridging halide ligands (see Chart I(c)).

The title cluster compound **3** was synthesized by reducing a mixture of $MePh_2PAuBr$ and $[MePh_2PAgBr]_4$ in absolute ethanol with $NaBH_4$. The dark brown product, after removal of unreacted starting materials and impurities, was purified by recrystallization twice from CH_2Cl_2. Rectangular plate crystals of **3** were grown from CH_2Cl_2/EtOH (5 : 1

ratio) and characterized by X-ray crystallography,† elemental analysis,‡ ^{31}P NMR, and UV-Vis spectroscopy (*vide infra*). The results are consistent with the formulation $(MePh_2P)_{10}Au_{12}Ag_{13}Br_9 \cdot 9EtOH$. Figures 1(a) and (b) portray the molecular architecture of **3** while Fig. 1(c) depicts the 7-membered satellite ring of bridging bromide ligands. The metal framework can be described as two Au-centered icosahedra sharing a vertex (Ag13). There are 10 $MePh_2P$ ligands, each coordinated to one of the 10 peripheral Au atoms with an average Au-P distance of 2.29 Å. Seven bridging bromide ligands (Br1 to Br7) connect the two Ag_5 pentagons while two terminal bromide ligands (Br8 and Br9) coordinate to the two apical Ag atoms (Ag11 and Ag12) with an average Ag—Br distance of 2.53 Å. The two metal icosahedra are rotated by ca 36°, giving rise to the R(36) rotameric form of the metal configuration. The crystal structure showed that the title cluster is a neutral molecule with no anions, which is consistent with its solubility in nonpolar solvents such as toluene and insolubility in polar solvents such as CH_3CN. Hence, the title compound represents the first example of a neutral bimetallic bi-icosahedral Au—Ag cluster since all previously known bi-icosahedral Au—Ag clusters bear either +2 (5-ring series) or +1 (6-ring series) charges. As such, the title cluster completes the sequence of the progression from 5- to 6- to 7-membered satellite rings of bridging halide ligands for this particular series of bimetallic bi-icosahedral clusters, as exemplified by **1, 2,** and **3,** along with the change in the overall charge from +2 to +1 to 0, respectively (cf Chart I). This charge difference is due to the fact that these bi-icosahedral clusters conform to the Polyoctet rule of $8n = 8 \times 2 = 16$ electron system (namely, 25(M)–7(X) – 2 = 16, 25(M)–8(X) – 1 = 16, and 25(M)–9(X) = 16, for **1, 2,** and **3,** respectively) [11].

The most important structural feature of **3** is the 7-membered satellite ring of the bridging ligands around the "equator" of the bi-icosahedral metal core (see Fig. 1(c)). The seven bridging bromide ligands form a slightly distorted heptagon with an average Br ··· Br distance of 3.96 Å, very close to the van der Waals contact of 3.90 Å [12]. The seven bridging bromide ligands are coplanar with the shared vertex lying in the plane. The common plane bisects the cluster into two icosahedra. All seven bridging Br ligands can be considered as double bridging with an average Ag—Br distance of 2.70 Å. However, there are additional contacts at Ag9 ··· Br1, 3.41 Å; Ag5 ··· Br3, 3.37 Å; Ag10 ··· Br5, 3.23 Å and Ag1 ··· Br7, 3.34 Å so that Br1, Br3, Br5 and Br7 may also be considered as semi-triple bridging. All bromide ligands form extensive hydrogen bonds with the phosphine ligands. It is apparent that, with the less bulky $MePh_2P$ (in comparison with Tol_3P in **1** or Ph_3P in **2**), the "equatorial ring" of the bi-icosahedral cluster allows the accommodation of seven halide ligands.

The $^{31}P\{^1H\}$NMR spectrum (81.015 MHz, CH_2Cl_2 at RT) of **3** consists of a doublet at 47.9 ppm (standard 85% H_3PO_4) with ^3J(P–Ag) of 78 Hz. We interpret the doublet as due to the *para* Ag atom of the inner Ag_5 pentagon of the same icosahedron.§ The electronic spectrum (in CH_2Cl_2) of **3** (λ_{max}(nm), $\varepsilon \times 10^{-4}$ (M^{-1} cm^{-1}): 328, 5.16; 420, 2.19; 505, 2.54) is very similar to those observed for other vertex-sharing bi-icosahedral clusters [4–9]. However, the lowest-energy absorption, observed at 505 nm, is red shifted by 20 nm from **2**. This band, interpreted by us as the plasmon frequency [13], is sensitive to, and hence highly characteristic of, the metal combination, the ligand environment, as well as the overall charge. We believe the observed 20 nm shift of this absorption band to a longer wavelength is primarily due to a combination of the increased number of bridging halide ligands (from 6 to 7) and the reduced charge (from +1 to 0) in going from **2** to **3**.

As observed in other vertex-sharing polyicosahedral Au–Ag clusters [4–11], the metal–metal bond lengths of **3** follow the trend of Au–Au < Au–Ag ⩽ Ag–Ag (see Fig. 1 caption), indicating the bonding strength of Au–Au > Au–Ag ⩾ Ag–Ag. More importantly, the intraicosahedral metal–metal distances are shorter than the intericosahedral distances, indicating that intraicosahedral bonding is significantly stronger than the intericosahedral bonding. These observations provide strong structural support for the "cluster of clusters" description [11] of this class of vertex-sharing polyicosahedral clusters

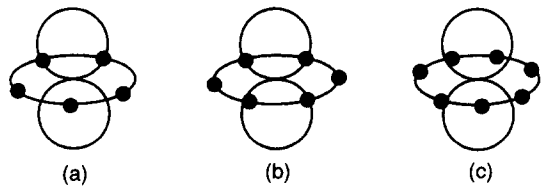

Chart I. Schematic representations of the 5-, 6-, and 7-membered satellite rings of bridging ligands (solid dots on ellipses) in vertex-sharing bi-icosahedral (open circles) clusters.

† Crystal data: Single-crystal X-ray diffraction data were collected at 173°K, using Siemens SMART X-ray diffractometer equipped with a CCD area detector and a Mo-target X-ray tube ($\lambda = 0.71073$ Å). $(MePh_2P)_{10}Au_{12}Ag_{13}Br_9 \cdot 9EtOH$: monoclinic $P2_1/c$, $a = 19.3984(5)$, $b = 29.9067(8)$, $c = 28.8959(7)$ Å, $\beta = 107.651(1)°$; $V = 15974.5(7)$ Å^3, and $Z = 4$. Anisotropic (heavy atoms)-isotropic (carbon atoms) refinement gave $R_1 = 7.1\%$ for 5166 independent reflections ($2\Theta \leqslant 45°$) with $I > 3\sigma$. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Center. See Notice to Authors, Issue No. 1.

‡ Anal. by Midwest Microlab (Indianapolis, IN) for dried crystalline samples of $(MePh_2P)_{10}Au_{12}Ag_{13}Br_9$ (MW = 6487.22), Calc. (found): C, 24.07 (24.65); H, 2.02 (2.09)%.

§ Further splittings due to the three *meta* Ag atoms and the two *ortho* Ag atoms were too small to be observed [14].

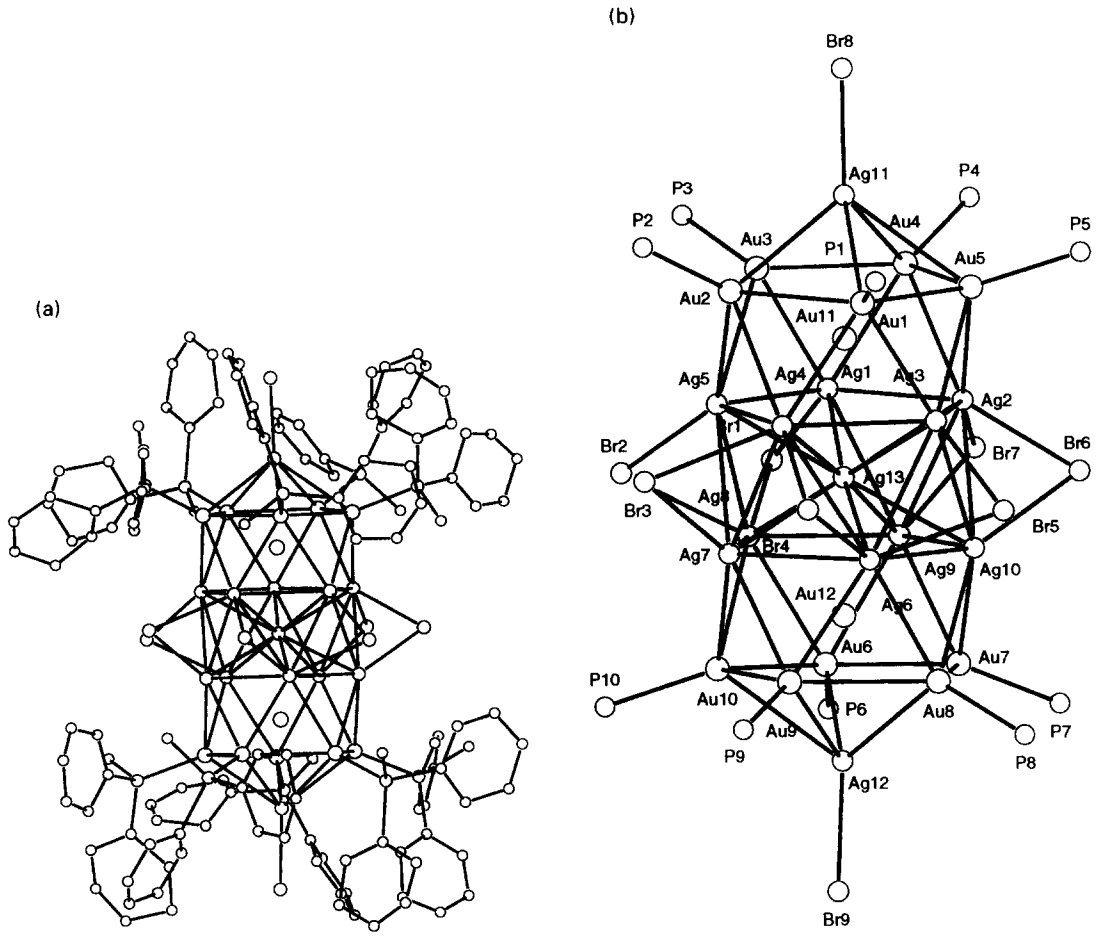

Fig. 1. The molecular architecture of the title cluster $(MePh_2P)_{10}Au_{12}Ag_{13}Br_9$(**3**): (a) general view; (b) the $P_{10}Au_{12}Ag_{13}Br_9$ core (same orientation as in (a)); and (c) the projection of the two silver pentagons onto the plane of the seven bridging Br ligands which form a 7-membered satellite ring around the equator of the bi-icosahedral cluster. The 7-membered Br ring can be described as a distorted heptagon with the following van der Waals contacts: Br1 ··· Br2, 4.00 Å; Br2 ··· Br3, 3.98 Å; Br3 ··· Br4, 3.83 Å; Br4 ··· Br5, 3.95 Å; Br5 ··· Br6, 3.99 Å; Br6 ··· Br7, 3.98 Å; Br7 ··· Br1, 3.96 Å. Some important metal–metal distances (in Å) are (averaged over the idealized D_{5d} symmetry and indicated by a representative bond): Au11—Au1, 2.695; Au11—Ag1, 2.874; Au11—Ag11, 2.804; Au11—Ag13, 2.699; Ag13—Ag1, 2.863; Au1—Au2, 2.894; Au1—Ag3, 2.904; Au1—Ag11, 2.995; Ag1—Ag2, 2.975; Ag1—Ag8, 3.101. Other important distances (averaged) are: Au—P, 2.29 Å; Ag—Br (terminal), 2.53 Å; Ag—Br (bridging), 2.70 Å. See text.

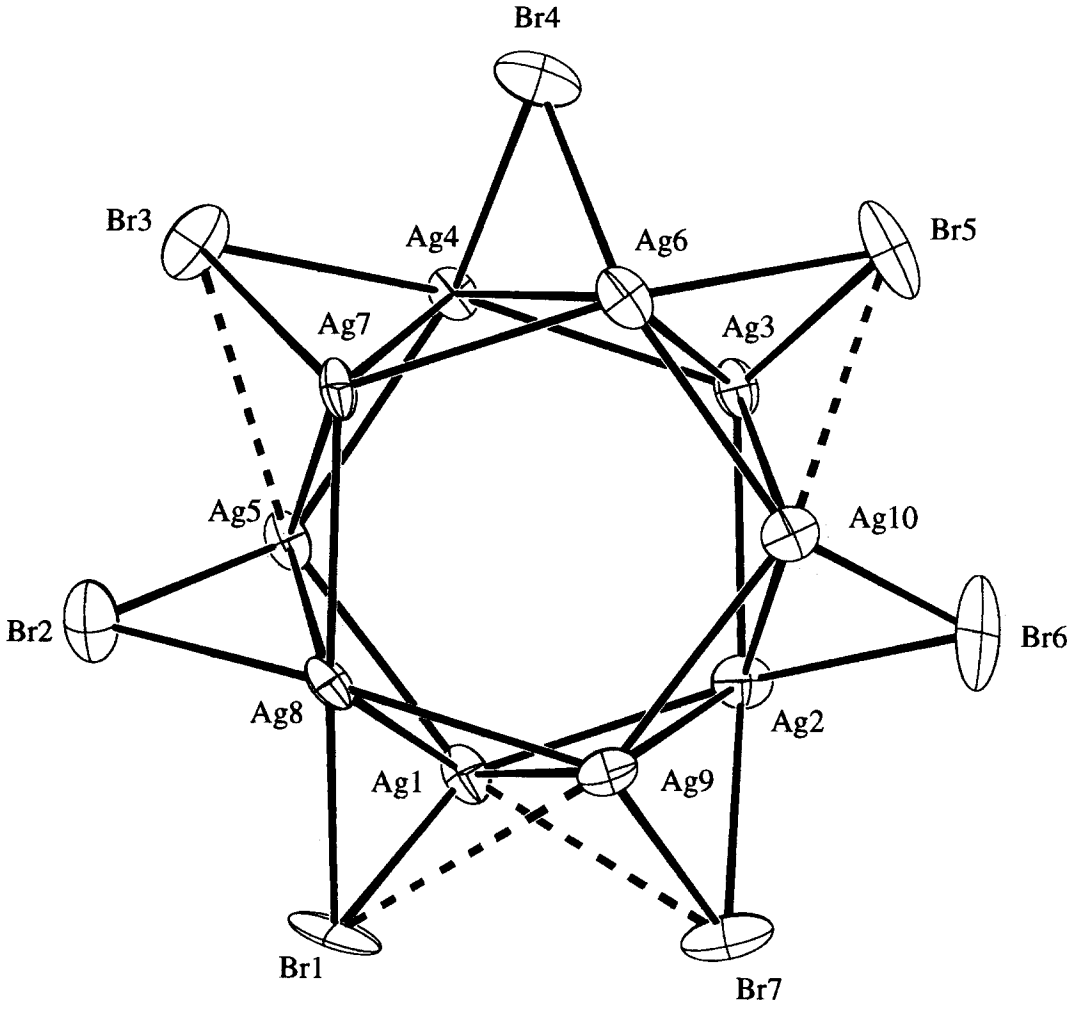

Fig. 1(c).

wherein the 13-atom centered icosahedron serves as the basic building block. In comparison with **2**, however, there is a slight but significant expansion of the two inner Ag pentagons, resulting in an increase in the average intraring Ag—Ag distance from 2.914 Å in **2** to 2.975 Å in **3** and an increase in the average intericosahedral Ag—Ag distance from 2.978 Å in **2** to 3.101 Å in **3**. These expansions are consistent with the increase in the number of bridging Br ligands from 6 (in **2**) to 7 (in **3**). Concomitantly, the average (icosahedral center)-to-(shared vertex) distance decreases from 2.845 Å in **2** to 2.699 Å in **3**.

Finally, the title compound **3** also represents the largest polyicosahedral Au–Ag clusters reported to date using $MePh_2P$ as ligands [14] which has a smaller cone angle [15] than Ph_3P. Apparently the sterically less bulky $MePh_2P$ allows the formation of the 7-membered ring of bridging Br ligands. Furthermore, this ligand also greatly enhances the solubility of these clusters in common organic solvents. As such it opens the door to other vertex-sharing mixed-metal polyicosahedral clusters based on this phosphine ligand as well as to further examples of vertex-sharing bi-icosahedral clusters with a 7-membered satellite ring of bridging halide ligands (work in progress).

Foreword

Recent advances in metal alkoxide and amide chemistry*

It is difficult to know to whom credit should be given for the synthesis of the first metal alkoxide, perhaps, in part, because one has to agree on the distinction between a metal and a metalloid. Ebelman [1] can reasonably be championed as the father of the field of SOL–GEL chemistry: $Si(OEt)_4 + H_2O \rightarrow SiO_2 + EtOH$. Probably Frankland [2] can be considered the patriarch of metal-amides following his discovery of zinc diethylamide. However, as we approach the turn of the third millennium, it is clear that one man, Donald Bradley, has, more than any other, contributed to the field of metal-alkoxides and amides during the latter half of the 20th century. He and his group pioneered the syntheses and characterizations of numerous metal-alkoxides and amides and mixed metal-alkoxides. In 1956, he formulated a structural theory for metal alkoxides [3] and later one for metal oxo-alkoxides [4]. He and his group were the first to recognize the importance of π-donation and the stabilization of otherwise coordinatively unsaturated species by either π-effects, as in $Mo(NMe_2)_4$ [5], or by steric effects as in $Cr(O^tBu)_4$ [6] and a host of three coordinate metal complexes such as $Cr(NPr^i_2)_3$ [7]. Some 30 years later this has led to the extensive use of π-donor ligands (alkoxides, siloxides, aryloxides, amides and imides) in organometallic chemistry as π-buffers and cyclopentadienyl alternatives [8]. However, Don Bradley was always attracted to the utility of metal-alkoxides and amides in the synthesis of high purity metal-oxides and nitrides [9] and I recall, as a graduate student in the 1960s, watching coworkers studying the hydrolysis of highly purified metal alkoxides and the ammonolysis of metal-amides together with the subsequent pyrolysis of the polymeric products. The target compounds of these endeavors were materials such as lithium niobate, silicon- and aluminum-nitride. What heresy this seemed to this author when one could have been recording the electronic and paramagnetic resonance spectra of say three coordinate transition metal ions and determining the ligand field parameters for metal ions in trigonal planar fields. Well the 1960s were the halcion days for Ligand Field theory, so the reader should forgive this author for some of his lack of foresight for the materials chemistry revolution based on the molecular approach, Le Chemie Douce, which was to explode in the 1980s. Of course, ^{17}O NMR spectroscopy, solid-state magic angle spinning NMR spectroscopy and even single crystal X-ray diffraction were either not available or were far from routine in the 1960s and 1970s and so it is now in the 1990s that we witness the world discovering at a rapid pace that which Don Bradley envisaged during his pioneering studies in the 1950s and 1960s. Every current journal in the field of inorganic chemistry seems to carry new work on metal or mixed metal-alkoxides/alcoholates and oxo-alkoxides and, with each structure, we see further verification of Bradleys structural theories. How many people, and how many times have metal-amide aminolyses been reinvestigated in the pursuit of the chemical vapor deposition of metal-nitride films? Others have surely perfected Bradley's dreams in the syntheses of high purity metal-oxide and -nitride films. Many a patent has been filed and several industrial processes now use this methodology. Even extension of the chemistry of trivalent amides of the 2nd and 3rd row transition metal ions molybdenum and tungsten has allowed a new lease of life to d^3-metal chemistry with the recent isolation of terminal phosphide and arsenide ligands, the cleavage of dinitrogen and the formation and characterization of the first terminal metal-carbide, $[L_3M{\equiv}C]^-$ [10].

Don Bradley has made numerous other significant contributions, particularly in the area of main group 13 : 15 semiconductor precursors but, in keeping with the policy laid down by the founding Editor of this journal, Sir Geoffrey Wilkinson, this is a thematic issue—one on recent developments of metal-alkoxide and amide chemistry. It is thus not an honor issue in the normal sense, but more a tribute to one of inorganic chemistry's true pioneers. What more can a chemist want from his colleagues than to be admired as a human being, highly respected as a scientist and to know that his or her thoughts and work have influenced others, both in his time and, indeed, will continue to do so in life's long afterglow.

(Received 5 November 1997; accepted 10 November 1997)

Abstract—The reactions of either (i) bulk metal in alcohol (EtOH or Pr^iOH); or (ii) the preformed metal alkoxides, $[M(OR)_2(ROH)_x]_n$ with a stoichiometric amount of $Ti(OPr^i)_4$ at reflux yielded the novel hydrocarbon soluble molecular aggregates $[MTi_2(OEt)_{10}(EtOH)_5]_n$ [M = Sr (**1**) and Ba (**2**)]; $[MTi_4(OEt)_{18}]$ [M = Sr (**3**) and Ba (**4**)]; $[M_2Ti(OEt)_8(EtOH)_5]_n$ [M = Sr (**5**) and Ba (**6**)]; and $[Sr_2Ti(OPr^i)_8(Pr^iOH)_3] \cdot 2Pr^iOH$ (**7**). All complexes have been characterized by elemental analyses and spectroscopic methods; (**3**) and (**7**) have also been characterized by X-ray crystallography. The structure of (**3**) is based on a "bow-tie" Ti_2SrTi_2 unit where the strontium is coordinated to two face sharing bioctahedral $Ti_2(OEt)_9^-$ units, via two "terminal" and two "bridging" ethoxo ligands from each $Ti_2(OEt)_9^-$ unit. In (**7**) the Sr_2Ti unit forms a triangle, bridged by three μ_2-Pr^iO ligands and capped by two μ_3-Pr^iO ligands, and further supported by six terminal Pr^iO/Pr^iOH ligands.

Keywords: titanium; strontium; isopropoxide; ethoxide; crystal structure.

In recent years, heterometallic alkoxides have been used as polymerization catalysts and as molecular precursors for high purity ceramic metal oxide superconductors and other speciality materials [1–3]. It is well established that, for obtaining semiconductors or superconductors by MOCVD techniques, the use of a "single source" precursor (in which the different elements are incorporated in a single precursor molecule) increases the quality of the final material [4]. The initial problem, however, is the synthesis of heterometallic compounds with the required ratios of the metals.

The use of heterometallic alkoxides as precursors for metal oxides gives rise to several important advantages over the use of traditional ceramic routes to these materials [3]. Firstly, the heterometallic oxides may be prepared directly from solutions via a sol-gel process [5], thus avoiding the use of calcination; if the products obtained are amorphous they can be converted into crystalline solids by the use of hydrothermal techniques [6]. Secondly, the purity and stoichiometry of the heterometallic oxides formed is wholly dependent on the stoichiometry of the parent molecular alkoxide complex [1].

Group 2 metal titanates are useful sol-gel precursors in the preparation of dense ferroelectric materials, thin film electronic components, and piezoelectric materials [1,5,7–20]. $BaTiO_3$ (which is just one of plethora of possible phases that metal titanates can

adopt, e.g. $BaTi_4O_9$, $Ba_4Ti_{13}O_{30}$, $Ba_6Ti_{17}O_{40}$) was first processed from metal alkoxide compound in 1969 by Mazdiyasni *et al.* [3]. They hydrolysed a 1 : 1 solution of barium isopropoxide and titanium amyloxide with three equivalents of water and observed an exothermic reaction. The $BaTiO_3$ was formed as a precipitate and dried at 50°C for 12 h (*in vacuo*). This powder was then calcined at 700°C, compacted under pressure, and sintered at 1300°C. This process (and its strontium equivalent) was patented by these workers in 1972 [8] and has remained the benchmark ever since. However, no attempt was made to isolate and structurally characterize the intermediate materials.

In the late 1970s and early 1980s Turova and coworkers [21–23] performed a series of syntheses to obtain various heterometallic alkoxides including some barium titanium alkoxides; however no conclusive data (e.g. NMR, X-ray, TGA studies) were published. Indeed, it is only recently that some data on the structures of this type of complex has started to appear in the literature [24,25]. For example, $[Ba_4Ti_{13}(\mu_3\text{-}O)_{12}(\mu_5\text{-}O)_6(\mu_1,\text{-}\eta^1\text{-}OCH_2CH_2OCH_3)_{12}(\mu_1,\mu_3,\text{-}\eta^2\text{-}OCH_2CH_2OCH_3)_{12}]$ was prepared from the methoxyethoxides of barium and titanium with the addition of six equivalents of water over a period of two months, and considered to be a possible precursor for the phase $Ba_4Ti_{13}O_{30}$ (a high frequency resonator) [26]. Similarly, $[Ba_4Ti_4(\mu_4\text{-}O)_4(\mu_3\text{-}OR)_2(\mu\text{-}OR)_8(OR)_6(ROH)_4][Ba_4Ti_4(\mu_4\text{-}O)_4(\mu_3\text{-}OR)_2(\mu\text{-}OR)_9(OR)_5(ROH)_3]$, a possible precursor for $BaTiO_3$ was prepared from a 1 : 1 mixture of barium metal and $Ti(OPr^i)_4$ in refluxing isopropanol [25]. The colour of the solution was stated to be "transparent dark yellow", suggesting that the solution had started to decompose. [These reactions normally produce colourless crystals from *clear* solutions of isopropanol or ethanol]. Hubert-Pfalzgraf *et al.* [7] recently isolated the mixed metal and mixed ligand compound $[Ba_2Ti_2(tmhd)_4(OEt)_{10}]$ by the reaction of $[Ti(OEt)_4]$ with "$Ba(tmhd)_2$". The structures of the compounds $[MTi_4(OEt)_{18}]$ (M = Ca and Ba) have been reported [27].

Apart from these compounds, we are not aware of any other structurally characterized Group 2/titanium alkoxide species. Some Group 1 metal titanates, e.g. $[LiTi(OPr^i)_5]_2$ have recently been structurally characterized and their NMR and infrared spectra discussed [28]. The dimeric complex was made from "BuLi and $Ti(OPr^i)_4$ in isopropanol. Also recently the syntheses of two $[MTi(OCH_2Pr^i)_5]$ complexes (M = Na or K) have been reported [29]. Many research groups [7,30–40] have produced heterometallic alkoxides and recent examples include: $[BaCu(C_2H_4O_2)_n(C_2H_4O_2)_2]$ (n = 3 or 6) [41], $[H_4BaCu_4(tmhd)_4(OCH_2CH_2OCH_3)_6]$ [42], $[Y_2Ba_2(O)(OEt)_8(tmhd)_6]$ (tmhd = 2,2-6,6-tetramethylheptanedionate) [41], $[BaY_2\{OCH(CF_3)_2\}_4(tmhd)_4]$ [44] and $[Mg_2Sb_4(OEt)_{16}]$ [45].

This paper aims to rectify the general lack of information on Group 2/titanium heterometallic alkoxides and describes the syntheses and characterization of several products obtained from reactions utilizing different stoichiometries of the metals (Ba/Sr : Ti), and also with different alkoxides (e.g. OEt, OPr^i). Single crystal X-ray studies of two of these materials are also reported.

RESULTS AND DISCUSSION

Syntheses of compounds (1)–(7)

Four different ratios of Group 2 metal ethoxide to titanium ethoxide [1 : 1, 1 : 2, 1 : 4, and 2 : 1 (M^{II} : Ti)] were studied, because these ratios mirror those found in the solid state end products. It was hoped that compounds with the correct in-built stoichiometry would be isolated. All reactions were carried out at reflux in EtOH or Pr^iOH with stirring for 1 h after addition of the titanium complex. (i) The use of one equivalent of $Ti(OEt)_4$ does not produce a 1 : 1 compound, but as seen for the isopropoxide based materials, 2 : 1 M : Ti compound [of the same formula as (**5**) and (**6**) below] are regularly obtained; (ii) two equivalents of $Ti(OEt)_4$ produce M = Sr (**1**) and M = Ba (**2**), (iii) four equivalents $Ti(OEt)_4$ M = Sr (**3**) and M = Ba (**4**), (iv) half an equivalent $Ti(OEt)_4$ M = Sr(**5**) and M = Ba (**6**), and (v) Pr^iOH, half an equivalent $Ti(OPr^i)_4$ (**7**). Formation of the 1 : 1 M^{2+} : Ti^{4+} stoichiometric compounds was not possible, due to the preference of these materials to form triangular based compounds [see structures of (**3**) and (**7**) later]. Similar behaviour was also noted for the isopropoxide compound (**7**) (i.e. when either a 1 : 1 or 2 : 1 ratio of the metals is utilized, *only* the 2 : 1 complex is formed). The reactions proceeded rapidly and generally without any colour change.

The heterometallic ethoxides could also be synthesized directly from the metal, without the need to use the preformed Group 2 ethoxide, in which case the metal was placed in a Schlenk tube, ethanol added with $Ti(OEt)_4$ (stoichiometrically as required) and the reaction mixture warmed to reflux. This resulted in a more rapid and vigorous reaction than that with the preformed ethoxide. Dissolution of the metal (pieces or chunks) was completed after 1.5 h. During this reaction a number of unusual colours were observed:

$$\text{Colourless} \xrightarrow{1\text{ min}} \text{Grey} \xrightarrow{10\text{ min}} \text{Purple/Pink} \xrightarrow{10\text{ min}} \text{Royal Blue} \xrightarrow{1\text{ h}} \text{Colourless}$$

The blue colour appeared to be generated by a Ti^{3+} species formed *in situ* which was then reoxidized to Ti^{4+} in the final complex (the products were all colourless crystals). Similar observations were also made earlier [28] during the synthesis of Group 1 titanates,

e.g., $[LiTi(OPr^i)_5]_2$. The formulations were based on C, H microanalyses, IR and multinuclear NMR studies. Complexes **3** and **7** were also characterized by X-ray analysis.

General physical data

The physical data for (**1**)–(**7**) are summarized in Table 1. The melting points of the compounds are considerably different from those of the starting materials (strontium and barium ethoxide), suggesting that they are definitely mixed metal compounds. All the compounds were extremely air and moisture sensitive. They were isolated as colourless crystalline solids, but with differences in their crystallinities; (i) the 1 : 2 compounds (**1**) and (**2**) were obtained as very large crystalline masses; (ii) the 1 : 4 complexes (**3**) and (**4**) were microcrystalline; and finally the 2 : 1 complexes (**5**)–(**7**) were obtained as large parallelpiped crystals that tended to grow upwards from the bottom of the Schlenk. They are all highly soluble in aromatic and hydrocarbon solvents and also in hot alcoholic solutions, but are *virtually insoluble* at 25 C in their respective parent alcohols. The 1 : 4 (M : Ti) complexes (**3**) and (**4**) are also soluble in long chain hydrocarbons such as hexadecane. None of the compounds sublime into the vapour phase, because they decompose to mixed metal oxides.

TGA/DSC studies

The results of TGA/DSC studies are summarized in Table 1. As expected, the compounds do indeed decompose to the stoichiometrically correct oxides except $[SrTi_4(OEt)_{18}]$ which partially sublimes before decomposing. The DSC results show that only the 1 : 4 stoichiometry complexes have definite melting points (ca 130 °C), whereas the other materials appear to dissolve in the released solvent (EtOH or Pr^iOH) at lower temperatures (50–100 °C), rather than actually melting.

Infrared spectroscopy

The infrared spectra of complexes (**1**)–(**7**) (Table 2) are very similar, and dominated by ligand vibrations [28]. The ν(M—O) bands are assigned on the basis of previous work on titanium alkoxides including extensive deuterium labeling studies of $Ti(OPr^i\text{-}d_7)_4$ by Hampden-Smith *et al.* [28].

NMR spectroscopy

Multinuclear NMR (^1H and $^{13}C\{^1H\}$ NMR (Table 3)) studies of (**1**)–(**7**) were carried out in C_6D_6 and C_7D_8 over a range of temperatures. The Sr based compounds gave sharper, well defined spectra, as observed

for other alkoxide complexes, e.g. the Group 2 ethoxides [46]. ^1H variable temperature NMR has proved very useful in studying these compounds.

1 : 2 *Stoichiometry compounds* (**1**) *and* (**2**)

The ^1H NMR spectrum for (**1**) shows some very broad peaks for the ethyl resonances. There appears to be at least three ethyl environments for the complex in solution. A variable temperature study of (**1**) revealed some interesting results; the OH resonance shifts upfield and at 70°C only two 2 ethyl environments are observed (one very broad and one sharp). The $^{13}C\{^1H\}$ spectrum shows two methyl resonances and at least four methylene resonances.

The ^1H NMR spectrum in C_6D_6 at room temperature of (**2**) shows one sharp and one broad ethyl environments. However on raising the temperature to 75°C the whole spectrum sharpens up; four ethyl resonances can be clearly seen, some of which were probably obscured by overlapping peaks at room temperature. The OH resonance shifts from δ 5.23 to

4.42 on raising the temperature to 75°C. This data is corroborated by the $^{13}C\{^1H\}$ NMR spectrum which shows three ethyl environments both at room temperature and at 75°C.

1 : 4 *stoichiometry compounds* (**3**) *and* (**4**)

The ^1H NMR of (**3**) in C_6D_6 at room temperature shows four ethyl environments and only one OH environment with a pair of sharp, well defined ethyl proton multiplets and three poorly defined pairs of resonances. At higher temperatures (70°C) the spectrum is better resolved with two ethyl environments observed, one sharp and the other broad; further, as the temperature is increased, the OH proton resonance shifts from δ 2.96 to δ 1.34. This suggests that there are only two ethyl environments at high temperature. In contrast, the $^{13}C\{^1H\}$ NMR spectrum shows there are four environments at both high and room temperatures.

The ^1H NMR of (**4**) in C_6D_6 at room temperature shows three ethyl environments (one sharp and two very broad), which on warming to 70°C merge to form just two (sharp) environments. At high temperatures the ethanol/ethoxide ligands are probably undergoing rapid exchange and so all that is observed in the spectrum is two sharp peaks. Also on warming the OH resonance shifts from δ 3.79 to δ 2.13. Integration shows the complex to have the formula $[BaTi_4(OEt)_{18}]$, but the crystals are probably wet. The $^{13}C\{^1H\}$ NMR corroborates this, showing three environments at room temperature.

2 : 1 *stoichiometry compounds* (**5**), (**6**) *and* (**7**)

Both compounds (**5**) and (**6**) show three environments for the alkoxide/alcohol ligands attached to the two metals. Compound (**5**), after careful drying in the glovebox, produced a spectrum (at room temperature) which is consistent with the formula $[Sr_2Ti(OEt)_8(EtOH)_5]_n$. The variable temperature study of (**5**) in C_6D_6 shows that the OH resonance associated with these peaks shifts by about 3 ppm down field over a 50°C range. Also two of the ethyl resonances broaden and lose all resolution as the temperature is raised; these peaks appear to be associated with the OH peak because they all broaden and decrease in intensity together (i.e. they are EtOH solvate/solvent). The $^{13}C\{^1H\}$ shows a similar set of environments to the proton NMR with three ethyl environments observed at both room temperature and 75°C.

The ^1H NMR of (**6**) in C_6D_6 at room temperature shows two ethyl environments and one OH environment with integrations consistent with the formulation $[Ba_2Ti(OEt)_8(EtOH)_5]_n$. On warming to 70°C, a third ethyl environment is seen, suggesting that this peak, at room temperature, overlapped with the other two. The $^{13}C\{^1H\}$ NMR spectra at both room temperature and 70°C show three ethyl environments.

The room temperature ^1H NMR spectrum of (**7**) in d_8-toluene reveals the presence of only one isopropoxide environment, with the methyl resonance observed at δ 1.42 and the methylene resonance at δ 4.47, in a ratio of 6 : 1. The resonance for the alcohol proton was found to be dependent on solvent, concentration and also temperature, and was observed between 3 and 6 ppm, with a OH : CH integration ratio of 0.4. A rapid proton exchange between the alcohol and alkoxide ligands is proposed at room temperature. On warming to 47°C the characteristic multiplet pattern of the CH peak is observed, with a similar shift of the alcohol proton peak from δ 6 to 2.95. On cooling a solution of the mixed metal isopropoxide in d_8-toluene down to −80°C, no significant changes in the spectrum were observed and we were unable to obtain a low temperature limiting spectrum due to sample precipitation and solution viscosity effects.

The ^1H and $^{13}C\{^1H\}$ NMR spectra of the alkoxides (**1**)–(**7**) show that it is possible to obtain some information on the ratio of alcohol to alkoxide ligands in the complexes, but further information (e.g. whether a species has a certain number of μ_3- or μ_3-bonded ligands) is not feasible due to the fast exchange regimes observed herein. A possibility would be to use ^{17}O NMR as shown by Day *et al.* [47] in a number of studies on titanium polyoxoalkoxides complexes such as $[\{Ti_7O_4\}(OEt)_{20}]$ and $[\{Ti_{11}O_{13}\}(OPr^i)_{18}]$. They have utilized 40 atom% ^{17}O-enriched H_2O to hydrolyze titanium alkoxides (such as $[Ti(OPr^i)_4]$ and $[Ti(OEt)_4]$), and then by studying the products via ^{17}O and $^{13}C\{^1H\}$ NMR spectroscopies it has been possible to assign the oxo-ligands thus obtained as either μ_3 or μ_2-bonded groups. However, such studies were not carried out in the present work, although we believe that there are grounds for a future study into this area using such materials.

Mass spectrometry

Mass spectrometric results were obtained for all the alkoxides (**1**)–(**7**), but no conclusive evidence of heterometallic molecules was observed in the gas phase. The ions observed all corresponded to $Ti(OR)_4$ break-up fragments and clusters of $[Ti(OR)_4]_n$ (R = Et or Pr^i) with the highest mass ions observed corresponding to the ion $[Ti_4(OEt)_{15}]^+$ {for (**3**) and (**4**)}. Similar results have been observed for a number of other heterometallic compounds, and this is probably due to breakdown of the heterometallic ensemble under the high vacuum utilized in the mass spectrometer.

X-RAY CRYSTAL STRUCTURES

Although all the heterometallic compounds were crystalline products, X-ray quality single crystals were

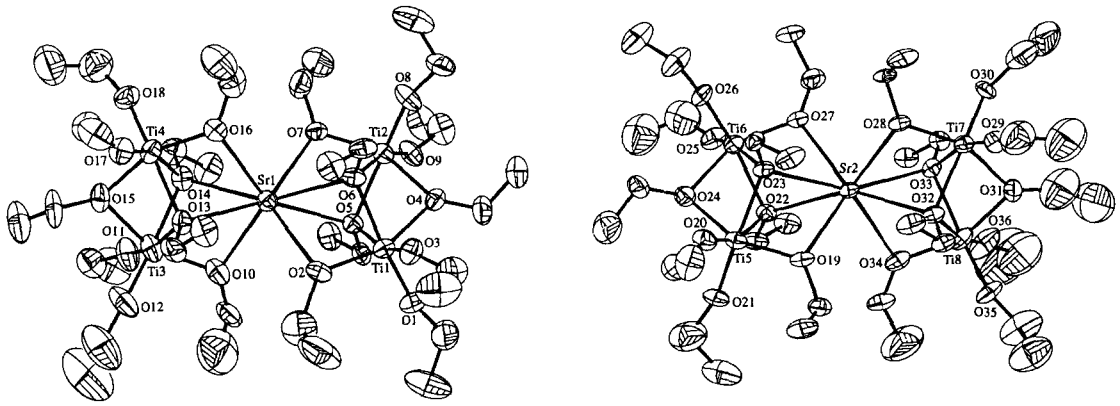

Fig. 1. Structures of the two independent molecules of $[SrTi_4(OEt)_{18}]$ (**3**) with the hydrogen atoms omitted for clarity. Thermal ellipsoids are drawn at 35% probability.

obtained only for (**3**) and (**7**) and for these two compounds full structural determinations were undertaken.

Structure of $[SrTi_4(OEt)_{18}]$ (**3**)

The crystal structure of (**3**) consists of discrete molecules of $[SrTi_4(OEt)_{18}]$ held together by van der Waals' forces. There are two molecules per asymmetric unit with very similar bond lengths and angles, differing mainly in the relative orientations of some of the ethoxy ligands. The structures of the two molecules are shown in Fig. 1, and selected geometry parameters are listed in Table 4. There are no solvate molecules in the lattice. The structure is based on a "bow-tie" or spiro Ti_2SrTi_2 unit where the strontium is coordinated to two face sharing bioctahedral $Ti_2(OEt)_9^-$ units. Each $Ti_2(OEt)_9^-$ unit utilizes two "terminal" and two "bridging" ethoxo ligands for coordination with the central strontium atom which achieves a coordination number of eight. The geometry around each Sr is best described as distorted square antiprismatic as indicated by the dihedral angles between the two $SrTi_2$ planes are 63.4 and 62.3° in the two molecules, respectively. For an ideal square antiprismatic geometry, the value of this angle is 45° and the four oxygen atoms on each $Ti_2(OEt)_9^-$ unit are staggered with respect to those of the second $Ti_2(OEt)_9^-$ unit. In contrast, an eclipsed arrangement would give a dihedral angle of 0 or 90°. The geometry around the titanium atoms is distorted octahedral with three different kinds of ethoxo ligands bonded to each metal. The Ti···Ti and Ti···Sr nonbonded distances in the two molecules fall into the very narrow ranges 3.027(2)–3.039(2) Å and 3.458(4)–3.479(3) Å, respectively. The Ti—O—Ti angles involving the μ_2-bridging ligands [91.8(2)–95.5(2)°] are close to the corresponding angles involving the μ_3-bridging ligands [91.5(2)–92.4(2)°]. However, the Ti—O—Sr angles involving the μ_2-bridging ligands [99.0(2)–100.0(2)°] are wider than the corresponding angles involving the μ_3-bridging ligands [93.38(14)–95.5(2)°].

The Ti—O distances span the range 1.774(6)–2.149(4) Å and can be grouped into four distinct categories: (i) the Ti—O (terminal) distances, range 1.764(6)–1.814(5), average 1.783 Å; (ii) the Ti—O (μ_2-Ti_2 bridging) distances, range 2.041(5)–2.077(6), average 2.059 Å, (iii) the Ti—O (μ_2-TiSr bridging) distances, range 1.875(5)–1.920(5), average 1.902 Å, and (iv) the Ti—O (μ_3-Ti_2Sr bridging) distances, range 2.081(4)–2.149(4), average 2.111 Å. The observed trend, Ti—O (μ_3-Ti_2Sr bridging) > Ti—O (μ_2-Ti_2 bridging) > Ti—O (μ_2-TiSr bridging) > Ti—O (terminal), underlines the dependence of the bond strength on the charge distribution of the ligand atom.

The Sr—O bond distances involve two types of bridging (i.e. μ_2- and μ_3-) ethoxide ligands, and lie in the narrow range 2.563(4)–2.620(5), average 2.594 Å; but unlike the Ti—O distances, these values appear not to be significantly dependent on the nature of bridging oxygen atoms. In fact, the average values for the Sr—O (μ_2-) and Sr—O (μ_3-) bonds, 2.605 and 2.590 Å, respectively, are nearly the same. This is somewhat surprising, since the bonds involving the μ_3-ligands are generally expected to be longer than those involving the μ_2-ligands. The fact that this does not happen with strontium in the present structure may be explained by assuming that the distortion in the $Ti_2(OEt)_9^-$ core would be bigger if the situation were different and that this is not thermodynamically favourable.

Complex (**3**) is a novel strontium titanium alkoxide which has coordinatively saturated the strontium metal centre via the use of μ_2- and μ_3-bridging ethoxide ligands from two Ti_2O_9 units. A similar structural framework was observed for $[BaZr_4(OPr^i)_{18}]$ [48], but no reliable results were reported therein due to incomplete model and unsatisfactory refinement.

Structure of $[Sr_2Ti(OPr^i)_8(Pr^iOH)_3]\cdot 2Pr^iOH$ (7)

The crystal structure of (7) consists of trinuclear molecules of $[Sr_2Ti(OPr^i)_8(Pr^iOH)_3]$ held together by strong hydrogen bonds involving the two solvated Pr^iOH molecules and forming a polymeric chain along the *a*-axis. The structure of a single complex molecule together with the associated solvate species is shown in Fig. 2, and selected bond lengths and angles are given in Table 5.

Complex (7) consists of a triangle of two strontium and one titanium atoms with metal–metal non-bonded distances of Sr(1)···Sr(2) 3.6350(13), Ti(1)···Sr(1) 2.399(2) and Ti(1)···Sr(2) 2.390(2) Å. The molecule is stabilized by a belt of three μ_2-isopropoxide ligands around the metal triangle and two μ_3-isopropoxide ligands above and below the plane of the metal atoms. Each metal centre is further coordinated by two terminally placed Pr^iO/Pr^iOH ligands. The basic Sr_2TiO_5 framework is similar to those observed in several other complexes, e.g., $[Ca_3(OPh)_5(hmpa)_6]^+[OPh]^-\cdot 2PhOH$ [49], $[Sr_3(OPh)_6(hmpa)_5]$ [49] and $[Sr_3(tmhd)_3(OSiPh_3)_3]\cdot 0.5C_6H_5Me$ [50]. The molecule possesses a crystallographic mirror plane of symmetry passing through the Sr, Ti and the μ_2-O atoms; the two uncoordinated Pr^iOH molecules also lie on the mirror plane. The overall structure is based on three octahedra, each sharing two of its "faces" with the other octahedra in a bifacial manner. The octahedral geometries around the metal centres are distorted, those around the Sr atoms very severely, due to the strain caused by the formation of bridges involving both μ_2- and μ_3-isopropoxide groups. The Sr···Sr and Sr···Ti distances are close to the respective values observed in other complexes, e.g., Sr···Sr 3.544(2)–3.654(2) Å in $[Sr_3(tmhd)_3(OSiPh_3)_3]\cdot 0.5C_6H_5Me$ [50], and Sr···Ti 3.458(4)–3.479(3) Å in (3). The μ_2-bridging oxygen atoms O(1), O(2) and O(3) are exactly planar, and the Sr—O—Sr/Ti angles involving these bridges are quite similar [96.0(2)–98.0(2)°]. The Sr—O—Sr/Ti angles involving the μ_3-oxygen atoms [O(4), O(4′)] are somewhat narrower [92.12(14)–93.7(2)°].

The Ti—O distances show considerable variations [1.816(4)–2.116(4) Å] depending on the nature of the alkoxide linkage. The unique distance involving the terminal ligands, 1.816(4) Å, is significantly shorter than those involving the μ_2-[O(1), O(3)] and μ_3-[O(4)] bridging groups, 1.991(6), 2.017(5), and 2.116(4) Å, respectively. These bond lengths correspond, respectively, to the Ti—O—C bond angles of 157.8 (average), 127.6 (average) and 131.0(4)°. The general increase in bond angle with decreasing bond length may be interpreted as due to an increase in the *s*-character of the oxygen bonding orbital. The Ti—O distance in the present compound involving the μ_3-ligand is very close to the average value in (3), but the average values involving the μ_2-SrTi bridging and terminal ligands [2.004 and 1.816(4) Å] are somewhat longer than the corresponding values [1.902 and 1.783 Å] in (3).

The Sr—O distances [2.399(6)–2.589(4)] also show considerable variations and fall into four different categories, i.e., (i) 2.399(6) and 2.426(6), average 2.413 Å for the μ_2-O (Sr_2 bridging), (ii) 2.493(6), 2.524(6), average 2.507 Å for the μ_2-O (SrTi bridging), (iii) 2.520(4), 2.528(4), average 2.524 Å for the μ_3-O (Sr_2Ti bridging), and (iv) 2.535(4), 2.589(4), average 2.562 Å for the terminal ligands. The order of these bond lengths is as expected, but the average value (2.502 Å) is considerably shorter than that (2.594 Å) in (3) and ~2.60 Å in the ionic oxides SrO and Sr_2TiO_4. The shorter Sr—O distances in (7) compared

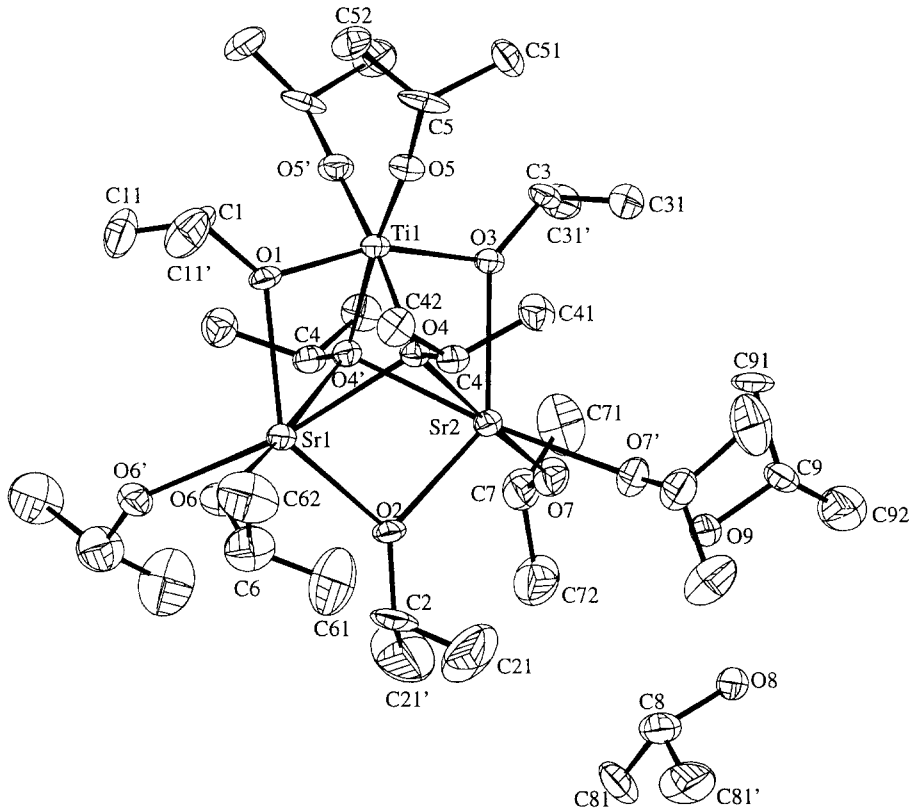

Fig. 2. Structure of the $[Sr_2Ti(OPr^i)_8(Pr^iOH)_3]\cdot 2Pr^iOH$ (**7**) with the hydrogen atoms omitted for clarity. Thermal ellipsoids are drawn at 50% probability. The primed atoms are related to the unprimed ones by a mirror plane of symmetry.

Symmetry transformations used to generate equivalent atoms: #1 $(x, y, 0.5-z)$.

with (**3**) may be correlated to the coordination number of strontium in the two compounds (six vs eight). The Sr—O bond lengths observed in the present complexes may also be compared with those observed in the two other strontium alkoxides, $[Sr_4(OPh)_8(PhOH)_2(thf)_2]$ [51] [average distances: Sr—O (terminal) 2.499 Å, Sr—O (μ_2-Sr_2 bridging) 2.449 Å, and Sr—O (μ_3-Sr_3 bridging) 2.535 Å] and $[Sr(OC_6H_2Bu^t_3)_2(thf)_3 \cdot 0.5thf]$ [52] (average distance: Sr—O (terminal) 2.314 Å].

This trinuclear isopropoxide supported aggregate has three alcohol groups present. On the basis of stereochemical considerations and bond length data, these three alcohols are most likely to be attached terminally solely to the two Sr atoms. Certainly the long Sr—O bonds [2.589(4) Å for Sr(1)—O(6) and 2.535(4) Å for Sr(2)—O(7)] involving the terminal ligands are compatible with this suggestion. The fact that the Sr(1)—O(6)/O(6′) bonds are longer than the Sr(2)—O(7)/O(7′) bonds also suggest that, most probably, two of the three alcoholic protons are attached to the O(6) and O(6′) atoms whilst the third is disordered between the O(7) and O(7′) atoms. Attachment of any alcohol molecule to Ti(1) is ruled out because of its high charge and relatively short Ti—O (terminal) bond.

The overall polyhedron observed for (**7**) is not very different to that observed for one half of $[SrTi_4(OEt)_{18}]$ (**3**) except that instead of a dimeric Ti_2O_9 unit as in (**3**), a dimeric Sr_2O_9 unit is observed in (**7**). An interesting aspect of the crystal structure of (**7**) is the role played by the two uncoordinated Pr^{i}OH molecules. As mentioned earlier, these species are involved in strong hydrogen bonding, between themselves and also with the Pr^{i}OH molecules coordinated to the two strontium atoms, and form a chain structure along the *a*-axis. The O···O distances involved in the unique hydrogen bonds are O(6)···O(8) (at $-0.5+x$, $-0.5-y$, z) 2.656, O(7)···O(9) (at x, y, $0.5-z$) 2.646, O(8)···O(9) (at x, y, z) 2.448 Å. The OH hydrogen atoms were not located, and so the donor and acceptor atoms could not be identified. However, the O···O distances are quite short and this indicates the presence of very strong hydrogen bonds between these atoms. In fact, the distance between the pair of solvated Pr^{i}OH molecules (2.448 Å) is one of the shortest to be found for such hydrogen bonded species. Such a network of hydrogen bonds could have important implications on the properties of this material.

With the structural data collected so far it is possible to infer the structures of the remaining complexes, i.e. the barium analogues of (**3**) and (**7**) are of similar structure; also the 2:1 (M^{II}:Ti^{4+}) ethoxide based complexes (**5**) and (**6**) probably have the same structural make-up as compound (**7**). A similar comparison may be drawn for the 1:2 stoichiometry complexes (**1**) and (**2**), with their structures comprising half of that observed for (**3**). It may be possible for this unit to dimerize and form a complex similar to that observed for $[BaZr_2(OPr^i)_{10}]_2$, an isopropoxide-linked (through barium) dimer [48].

CONCLUSIONS

The present study suggests that it is possible to produce heterometallic alkoxide complexes with a predefined stoichiometry. This could have important possibilities for ceramic production with only the phase required being grown from a specific precursor via sol-gel processing.

The interesting structural motifs observed for (**3**) and (**7**) may be extended to the other predefined stoichiometry complexes. The triangular based metal core is not unusual in itself, having been observed for a number of mixed metal alkoxides [1,48], but the lack of any coordinated solvent in the crystal structure of (**3**) is quite unusual. Both the IR and NMR studies of this complex suggest the presence of free or coordinated alcohol, but the X-ray structure does not show the presence of any alcohol. This may be due to desolvation when handling the crystals, or alternatively the sample was slightly "damp" with alcohol when subjected to IR and NMR analyses.

The TGA/DSC results show that the crystalline solids are converted to their metal oxides at relatively low temperatures. But large scale trials (and analysis of the residues by X-ray powder diffraction) are required. This may prove to be an area of future study in Group 2/titanium heterometallic alkoxides.

EXPERIMENTAL

General procedures and instrumentation

All manipulations were carried out under an atmosphere of dry (molecular sieves) argon (using standard dry-box and Schlenk techniques). All solvents were rigorously dried and then distilled from their respective drying agents by standard methods. Elemental analyses were performed by the microanalytical department of Imperial College. The melting points were measured under argon in sealed capillaries and are uncorrected values. Infrared spectra were recorded on a Perkin-Elmer FTIR 1720 spectrometer as Nujol or hexachlorobutadiene (HCB) mulls between 25×4 mm KBr plates. The solvents were pre-dried with 4 Å molecular sieves prior to use, and the samples were protected from the atmosphere by an O-ring-sealed Presslok holder. NMR data were recorded on a Jeol GS 270 NMR spectrometer, using the protio impurities of the deuterated solvent as reference for ^{1}H spectra and the ^{13}C resonance of the solvent as a reference for $^{13}C\{^1H\}$ spectra. The NMR samples were prepared in the glovebox using Wilmad 5 mm NMR tubes equipped with J. Youngs valves to ensure reproducibility of NMR spectra and ensure sample stability. All chemical shifts are positive to high frequency of the standard. Mass spectrometric studies were performed on

a Kratos MS 30 (University of London Mass Spectrometry Service at the Royal School of Pharmacy) or a VG Autospec-Q (Imperial College Mass Spectrometry Service) operating in Electron Impact (positive) mode (70 eV) using a direct insertion probe and operating over the temperature range 50–200°C. Some samples were involatile under these conditions and thus the "softer" Fast Atom Bombardment (positive) mode (30–35 eV) was utilized where necessary. The samples were prepared in micro sure-seal bottles. Controlled thermal analyses were studied using a Polymer Laboratories 1500H simultaneous thermal analyzer (STA), controlled by a Omni Pro 486DX-33 PC. The measurements were carried out in alumina crucibles (sample mass ~10–25 mg) under an atmosphere of flowing (25 cm^3/min) nitrogen gas, using heating rates of 5 or 10°C/min.

Starting materials

Strontium and barium metal granules were purchased from Alfa Chemicals and stored in an inert atmosphere glove-box. Larger samples of the metal were purchased from Inorgtech and stored under oil prior to use. When utilized they were washed three times with *n*-pentane/hexane to remove this oil. Nujol and hexachlorobutadiene were obtained from Aldrich Chemicals and dried over 4 Å molecular sieves prior to use. Ethanol (EtOH) and isopropanol (Pr^iOH) were also purchased from Aldrich, and dried and distilled before use. All gases were purchased from BOC Ltd.

NOTE: Strontium and barium metals and their solutions are toxic and must be handled with care and kept under an inert atmosphere. The materials described herein should be prepared under dry argon using thoroughly degassed and dry solvents.

Synthesis of $[SrTi_2(OEt)_{10}(EtOH)_5]_n$ **(1)**

Strontium metal pieces (0.86 g, 9.77 mmol) was placed in a flame dried Schlenk with EtOH (30 cm^3) and $Ti(OEt)_4$ (2 equiv., 19.54 mmol, 3.83 cm^3) and solution refluxed at 80°C. The metal dissolved in an hour leaving a clear solution. On standing at −25°C the solution yielded a large crop of colourless crystals which were filtered off. Yield: 6.32 g, 70%, two crops. Found: C, 42.12; H, 9.23. $C_{30}H_{80}O_{15}SrTi_2$ requires: C, 41.69; H, 9.33%. ^1H NMR: (C_6D_6, 67.94 MHz, 70°C), δ 1.06 (t, CH_3), 1.36 (s, CH_3), 2.76 (s, O*H*), 3.57 (q, CH_2), 4.39 (s, br, CH_2). $^{13}C\{^1H\}$ NMR: (C_6D_6, 67.94 MHz, 70°C), δ 18.33 (s, CH_3), 19.25 (s, CH_3), 58.20 (s, CH_2), 68.93 (s, vbr, CH_2). Mass spectrometry: only $Ti(OEt)_4$ breakup observed.

Synthesis of $[BaTi_2(OEt)_{10}(EtOH)_5]_n$ **(2)**

Barium metal pieces (1.36 g, 9.9 mmol) were placed in a flame dried Schlenk with EtOH (30 cm^3) and $Ti(OEt)_4$ (2 equiv., 19.8 mmol, 3.88 cm^3) and the solution refluxed at 80°C. All the metal dissolved over 1 h. On standing at −25°C the solution yielded a large crop of colourless crystals which were carefully filtered off. Yield: 6.91 g, 83%, two crops. Found: C, 38.89; H, 8.96. $C_{30}H_{80}O_{15}BaTi_2$ requires: C, 39.42; H, 8.82%. ^1H NMR: (C_6D_6, 270 MHz, 75°C), δ 1.05 (t, CH_3), 1.17 (t, CH_3), 1.35 (s, CH_3), 1.51 (t, CH_3), 3.38 (s, br, O*H*), 3.50 (d, CH_2), 4.28 (q, CH_2), 4.33 (q, CH_2), 4.42 (d, CH_2). $^{13}C\{^1H\}$ NMR: (C_6D_6, 67.94 MHz, 75°C), δ 18.17 (s, CH_3), 19.07 (s, CH_3), 19.16 (s, CH_3), 57.28 (s, CH_2), 64.13 (s, CH_2), 67.83 (s, br, CH_2). Mass spectrometry: only $Ti(OEt)_4$ breakup observed.

Synthesis of $[SrTi_4(OEt)_{18}]$ **(3)**

Strontium metal pieces (0.46 g, 5.23 mmol) were placed in a flame dried Schlenk and EtOH (30 cm^3) added. There was a vigorous exothermic reaction with hydrogen released and the solution turning grey. Then $Ti(OEt)_4$ (4 equivs, 20.9 mmol, 5.2 cm^3) was added and the solution heated to reflux with stirring. After 40 min, all the metal had dissolved with the product starting to deposit out of solution. Therefore more ethanol (20 cm^3) was added and the solution heated to 85°C for 1 h. This solution was then allowed to cool very slowly, producing large plate/flake like crystals. Yield: 4.79 g, 67%. Found: C, 40.02; H, 8.68. $C_{36}H_{90}O_{18}SrTi_4$ requires: C, 39.66; H, 8.82%. ^1H NMR: (C_6D_6, 270 MHz, 70°C), δ 1.00 (t, CH_3), 1.34 (s, O*H*), 1.37 (s, CH_3), 3.50 (q, CH_2), 4.40 (s, CH_2). $^{13}C\{^1H\}$ NMR: (C_6D_6, 67.94 MHz, 70°C), δ 17.95 (s, CH_3), 19.24 (s, CH_3), 24.87 (s, CH_3), 26.02 (s, CH_3), 58.99 (s, CH_2), 68.6 (m, CH_2). Mass spectrometry: only $Ti(OEt)_4$ breakup observed.

Synthesis of $[BaTi_4(OEt)_{18}]$ **(4)**

Barium metal ribbon (0.705 g, 5.13 mmol) was placed in a flame dried Schlenk and EtOH (30 cm^3) added. The metal dissolved very rapidly (i.e. 10 min) and the solution turned purple. Then $Ti(OEt)_4$ (4 equivs, 5.1 cm^3, 20.51 mmol) was added and the solution stirred at reflux for 1 h. The purple colour was discharged yielding a colourless solution. The solution was then allowed to return to room temperature very slowly when a large crop of small white feather like crystals were obtained. Yield: 6.09 g, 84%. Found: C, 38.26; H, 7.89. $C_{36}H_{90}O_{18}BaTi_4$ requires: C, 37.93; H, 7.96%. ^1H NMR: (C_6D_6, 270 MHz, 70°C), δ 0.99 (t, CH_3), 1.32 (s, CH_3), 2.13 (s, O*H*), 3.43 (q, CH_2), 4.38 (d, CH_2). Mass spectrometry: only $Ti(OEt)_4$ breakup observed.

Synthesis of $[Sr_2Ti(OEt)_8(EtOH)_5]_n$ **(5)**

Strontium metal ribbon (0.883 g, 10.03 mmol) and EtOH (30 cm^3) were placed in flame dried Schlenk

and stirred at reflux. Then $Ti(OEt)_4$ (1.24 cm^3, 0.5 equivs, 5.01 mmol) was added slowly to the reaction. The colour of the solution changed to purple to grey to blue and finally back to colourless. After all the metal had dissolved in 45 min, the solution was allowed to return to room temperature slowly. A large crop of crystals deposited, which were filtered off. Yield: 5.91 g, 85%. Found: C, 37.98; H, 8.76. $C_{26}H_{70}O_{13}Sr_2Ti$ requires: C, 38.39; H, 8.67%. ^1H NMR: (C_6D_6, 270 MHz, 75°C), δ 1.13 (t, CH_3), 1.23 (t, CH_3), 1.48 (t, CH_3), 3.77 (d, CH_2), 4.21 (q, CH_2), 4.36 (q, CH_2), 7.84 (s, O*H*). $^{13}C\{^1H\}$ NMR: (C_6D_6, 67.94 MHz, 75°C), δ 18.49 (s, CH_3), 19.19 (s, CH_3), 19.53 (s, CH_3), 57.66 (s, CH_2), 64.94 (s, CH_2), 68.73 (s, CH_2). Mass spectrometry: only $Ti(OEt)_4$ breakup observed.

Synthesis of $[Ba_2Ti(OEt)_8(EtOH)_5]_n$ (**6**)

Barium metal ribbon (1.36 g, 9.90 mmol) was placed in a flame dried Schlenk and EtOH (25 cm^3) added. An instant reaction occurred with hydrogen evolution and the solution became purple in colour. Then $Ti(OEt)_4$ (0.5 equiv., 1.23 cm^3, 4.45 mmol) was added and the solution set to stir at reflux for 1 h. On allowing to slowly cool to room temperature, a large crop of large needle-like crystals deposited out of solution. Yield: 2.23 g, first crop; 3.81 g, second crop; overall yield 71%. Found: C, 34.89; H, 7.67 $C_{26}H_{70}O_{13}Ba_2Ti$ requires: C 34.19; H, 7.73%. Mass spectrometry: only $Ti(OEt)_4$ breakup observed.

Synthesis of $[Sr_2Ti(OPr^i)_8(Pr^iOH)_3]\cdot 2Pr^iOH$ (**7**)

Strontium metal chunks (4.12 g, 46.8 mmol) and isopropanol (60 cm^3) were refluxed for 5 h in a flame dried Schlenk. The metal reacted with vigorous hydrogen gas evolution and dissolved to yield a near colourless solution of the alkoxide. Titanium isopropoxide $[Ti(OPr^i)_4]$ (6.4 cm^3, 23.4 mmol) was added carefully to the hot solution (an immediate, highly exothermic reaction involving the release of more gas was observed) and left to stir for 2 h at reflux. Filtration and subsequent cooling of the solution gave a large crop of white crystals. Yield: three crops of 10.22, 9.89 and 5.4 g, total yield 62%. Found: C, 46.93; H, 9.66 $C_{39}H_{96}O_{13}Sr_2Ti$ requires: C, 47.02; H, 9.71%. ^1H NMR: (C_6D_6, 270 MHz, 65°C), δ 1.24 (d, $^2J = 5.94$ Hz, CH_3), 3.27 (s, O*H*), 4.26 (s, br, $^2J = 5.94$ Hz, C*H*). $^{13}C\{^1H\}$ NMR: (C_6D_6, 67.94 MHz, 20°C), δ 26.47 (s,

Details in common: cell refinement by 250 reflections; fast area detector; Mo–K_α radiation, $\lambda = 0.71069$ Å, $T = 150$ *K*, refinement on F^2 using all unique data.

$^aR = \Sigma(\Delta F)/\Sigma(F_o)$; $wR_2 = [\Sigma\{w(\Delta F^2)^2\}/\Sigma\{w(F_o^2)^2\}]^{1/2}$.

^{b}The *R*-values calculated for data with $I > 2\sigma(I)$ only are given in parentheses.

CH_3), 66.02 (s, CH). Mass spectrometry: only ligand breakup observed.

X-ray crystallography for (**3**) *and* (**7**)

X-ray measurements for both compounds were made at 150 K using Mo–K_α radiation ($\lambda = 0.71069$ Å, graphite monochromator) on a Delft instrument FAST TV area detector diffractometer equipped with a rotating anode generator (50 Kv, 50 mA), a buffer board, a DEP image intensifier and an Oxford Cryostream low-temperature cooling system by following previously described procedures [53]. The data were corrected for Lorentz and polarization effects and also for absorption using the program DIFFABS [54]. The crystal data and details of data collection and structure refinements are presented in Table 6.

The structures were solved via direct methods (SHELX-S) [55] and difference electron density syntheses, and refined by full-matrix least squares on F^2 (SHELXL-93) [56] using all the unique data with intensities greater than 0. The secondary carbon atoms [C(3) and C(19)] in (**3**) and the tertiary carbon atoms [C(5) and C(9)] in (**7**) were disordered and two positions for each were refined with partial occupancies (0.50). All non-hydrogen atoms were anisotropic, with ISOR restraints being used for several atoms in both structures. The hydrogen atoms belonging to the partially occupied carbon atoms and neutral alcohol molecules in (**7**) were ignored; others were included in calculated positions (riding model). The final R-values are given in Table 6.

Atom coordinates, H-atom parameters, thermal parameters, full bond length and angles listings, and lists of observed and calculated structure factors have been deposited as supplementary material. All calculations were performed on Pentium 200 MHz personal computer. Sources of scattering factors are as in Ref. 70. The diagrams were drawn with the program SNOOPI [57].

(Received 5 November 1997; accepted 10 November 1997)

Abstract—The SO_2 inserted compounds $[M(O_2SOMe)_2(MeOH)_2]_\infty$ (M = Mg **1**; M = Ca **2**) were synthesized from the reaction of the corresponding $[M(OMe)_2]_\infty$ complexes in methanol, followed by recrystallization from either *n*-hexane or toluene. The reaction of COS or CS_2 gas with $[M(OMe)_2]_\infty$ in methanol, yielded the inserted products $[M(\{OCS\}OMe)_2(MeOH)_x]_n$ ($x = 2$, M = Mg **3**; $x = 3$, $n = 2$, M = Ca **4**) and $[M(S_2COMe)_2(MeOH)_x]_n$ ($x = 6$, M = Mg **5**; $x = 4$, M = Ca **6**), respectively. The analogous reaction of $[M(OMe)_2]_\infty$ (M = Mg, Ca) with CO_2 gas gave the mixed methoxide/methylcarbonato compounds $[Mg(O_2COMe)(OMe)(MeOH)_{1.5}]_n$ **7a** and $[Ca(O_2COMe)(OMe)(MeOH)]_n$ **8**. Recrystallization of **7a** from a "wet" hydrocarbon solvent mixture led to the crystalline product $[Mg_9(CO_3)(O_2COMe)_8(OMe)_8(MeOH)_{13}]\cdot MeOH\cdot C_7H_8$ **7b**. The corresponding insertion reaction of CO_2 gas with $[M(OEt)_2]_\infty$ (M = Mg, Ca) gave the mixed ethoxide/ethylcarbonato compounds $[M(O_2COEt)(OEt)(EtOH)_2]_n$ (M = Mg **9**; M = Ca **10**). Similarly, the reaction of CO_2 gas with $[Mg(OR)_2]_\infty$ (R = Pr^i, Bu^t) in the parent alcohol, resulted in the $[Mg(O_2COR)(OR)(ROH)]_n$ compounds (R = Pr^i **11**; R = Bu^t **12**). All compounds have been characterized by spectroscopic techniques including NMR (^{1}H and ^{13}C) and IR spectroscopy, and in selected cases by TGA/DSC. Complex **7b** was unambiguously characterized by single crystal X-ray diffraction. It was established that **7b** is a nonameric complex comprising of two Mg_4O_4 cubes, with a remote ninth magnesium atom held in position via two bridging methylcarbonato groups and an unusual μ_5-carbonate ligand. © 1998 Published by Elsevier Science Ltd. Keywords: insertion reactions; magnesium; calcium; ethoxide; methoxide.

INTRODUCTION

The insertion reactions of one-carbon-atom molecules (C_1 chemistry) are an important area of research. Although the major raw material for C_1 based chemistry is CO, CO_2 may also serve as a convenient reagent in reactions which mimic Fischer–Tropsch (F-T) process [1,2]. CO_2 is used as an industrial feedstock in the production of urea, carboxylic acids and organic carbonates [1,3]. Another promising area of current research is the laboratory synthesis of organic substances derived from CO_2, ranging from hydrocarbons to cyclic lactones [4]. In insertion reactions, an atom or a group of atoms is formally inserted between two atoms which were initially bound together, resulting in no change in the formal oxidation state of the metal [5].

$$M{-}X + YZ \rightarrow M{-}(YZ){-}X$$

One of the most common insertion reactions is that involving CO_2 and metal–carbon bonds of Grignard reagents [6–8]. The resulting carboxylate is subsequently hydrolysed to yield the corresponding organic acid. Insertion reactions of CO_2 have been extensively reported for metal–hydrogen, metal–carbon and metal–nitrogen bound compounds [9]. In contrast, the analogous carbon dioxide insertion reactions into M—OR bonds is an underdeveloped area with only few examples of authenticated insertion products [5].

The related insertion reactions of SO_2, COS and CS_2 have recently attracted attention. Such reactions are also of interest in their own right because of their roles in catalyst poisoning and air pollution treatment [10]. The detrimental environmental effects of SO_2 has resulted in a renewed interest in the chemistry of this ligand. Reactions of SO_2 with metal complexes have been exhaustively reported [11], in particular with the class "b" or soft metals [12]. Structural studies of these complexes reveal, as expected, S-co-ordinated SO_2 moieties. In contrast, class "a" and borderline metals have been relatively neglected. SO_2 is also extensively used as a feedstock in organic syntheses [13], for example, organomagnesium compounds are known to react with SO_2 to give sulfinic acids upon hydrolysis [12]. Insertion reactions of SO_2 into transition metal–carbon bonds to yield sulfinato-complexes have been widely studied [13]. In contrast, only a few SO_2 insertions reactions into metal–oxygen bonds have been reported [14,15]. Although magnesium and calcium complexes have found applications within SO_2 chemistry, there is a lack of reports on well characterized SO_2 complexes of the Group 2 metals. Furthermore, SO_2 complexes which are S-bonded have been observed frequently, while O-bonded complexes are rather rare. The reactions of COS with transition metals have also been widely studied and the area has been reviewed by Ibers [10,16]. Insertion reactions of COS into metal–hydrogen bonds have been widely reported [17], but the corresponding reactions into metal–oxygen bonds have been relatively neglected. Similarly, the co-ordination chemistry of CS_2 has been extensively studied since the preparation of the first transition-metal CS_2 complexes in 1967 [18]. In fact, CS_2 has proved to be a versatile ligand which forms complexes with almost every transition metal [10].

We have previously reported the reactions of the related molecules COS and SO_2 with $[Ca(OMe)_2]_\infty$, which led to the insertion products $[Ca(\{OCS\}OMe)_2(MeOH)_3]_2$ and $[Ca(O_2SOMe)_2(MeOH)_2]_\infty$, respectively [19, 20]. More recently, we reported the insertion reactions of COS gas with magnesium and strontium alkoxide compounds to give the inserted complexes $[Mg(\{OCS\}OEt)_2(EtOH)_4]$ and $[Sr_3(\{OCS\}OEt)_6(EtOH)_8]$ [21]. Such compounds are also of interest in their own right because of their potential as models for catalyst poisoning [10].

As early as 1897, Szarvasy [22] prepared a magnesium methylcarbonato-complex "$[Mg(O_2COMe)_2]_n$" from the reaction of magnesium methoxide with carbon dioxide. However, it was not until 60 years later that its use was first reported in synthetic organic reactions for introducing a carboxyl group into active hydrogen compounds such as primary nitro-alkanes [23]. Complexes of the general formula "$[M(O_2COR)_2]_n$" (M = Ca, Ma) are the suggested intermediates to oil-lube additives, the colloidal magnesium and calcium carbonates [24].

$$M(OR)_2 \xrightarrow{CO_2} [M(O_2COR)_2]_n \xrightarrow[H_2O,oil]{surfactant,\ promoters} MCO_3 + 2ROH$$

Scheme 1.

The only commercially available Group 2 metal alkylcarbonato complex is "$[Mg(O_2COMe)_2]_n$" [25] (Aldrich) which is available as either dimethylformide (5M) or methanol (0.5M) solutions [26]. However, this complex has not been fully characterized by spectral and structural methods. In the present paper, we report the preparation and properties of a range of inserted products of CO_2, SO_2, COS and CS_2 with magnesium and calcium alkoxides, and an X-ray structural characterization of the partially hydrolysed product $[Mg_9(\mu_5\text{-}CO_3)(\mu_2\text{-}O_2COMe)_4(O_2COMe)_4(\mu_3\text{-}OMe)_8(MeOH)_{13}]\cdot MeOH\cdot C_7H_8$, which may be viewed as an intermediate in the formation of colloidal magnesium carbonate.

EXPERIMENTAL

General procedures and instrumentation

All manipulations of reactants and products were carried out under nitrogen atmosphere (Schlenk techniques), argon atmosphere (Miller Howe 160 FF glove-box) or *in vacuo*, with exclusion of moisture and oxygen. Elemental analyses were performed by the microanalytical department of Imperial College. Melting points were measured under argon in sealed capillaries using an "Electrothermal" apparatus and are uncorrected. Infrared spectra were recorded on a Perkin–Elmer FTIR 1720 spectrometer as Nujol or hexachlorobutadiene (HCB) mulls between 25 × 4 mm KBr plates. The Nujol and HCB were both pre-dried with 4 Å molecular sieves prior to use and the samples were protected from the atmosphere by an O-ring sealed Presslock™ holder (Aldrich). Solution NMR spectra were recorded on a Jeol GS 270 MHz NMR spectrometer. ^1H NMR spectra were recorded for 16 scans at 270.16 MHz, whilst $^{13}C\{^1H\}$ NMR solution spectra were obtained at 67.94 MHz. Chemical shifts were referenced to tetramethylsilane (ca 1%) added by volume or using the *protio* impurities of the deuterated solvent. ^1H and $^{13}C\{^1H\}$ solid state NMR spectra were collected at 300.00 and 75.67 MHz, respectively, on a Bruker instrument at University College, London University Solid State NMR service. Mass spectra

were run on a VG Autospec. instrument at Imperial College. Controlled thermogravimetric analysis (TGA) and differential scanning calorimetric (DSC) measurements were done using a Polymer Laboratories 1500H simultaneous thermal analyzer, controlled by a Omni Pro 486DX-33 PC. The measurements were carried out in alumina crucibles (sample mass 11–25 mg) under an atmosphere of flowing (30 cm^3 min^{-1}) nitrogen gas, using a heating rate of 16 C min^{-1}.

CAUTION: Care should be taken by conducting all reactions in a ventilated fume cupboard.

Starting materials

All Group 2 alkoxide starting materials were prepared as described previously [21]. $[Mg(OR)_2]_n$ (R = Et, Pr^i, Bu^t) were prepared from the reaction of dibutylmagnesium (Aldrich) in *n*-hexane or heptane with the desired alcohol. $[Mg(OMe)_2]_n$ and $[Ca(OR)_2]_n$ (R = Me, Et) were prepared from the reaction of metal chips (Johnson Matthey) in alcohol. $[Ca(OMe)_2(MeOH)_2]_n$ was prepared from the corresponding homoleptic complexes or as described previously [21,27]. CO_2 was purchased from BOC and used as obtained. SO_2, COS and CS_2 were purchased from Aldrich Chemical Company.

Preparation of the SO_2 inserted complexes

$[Mg(O_2SOMe)_2(MeOH)_2]_n$ **1**. To a suspension of magnesium methoxide $\{[Mg(OMe)_2]_n\}$ (1.00 g, 11.63 mmol) in methanol (30.0 cm^3) was bubbled SO_2 gas at room temperature. This resulted in a vigorous exothermic reaction and dissolution of the methoxide to give a clear solution. The resulting solution was stirred for a further 30 min and a crystalline solid isolated at −20 C (2.19 g, 67%), m.p. desolvates >56 C (Found: C, 16.7; H, 4.8%. $C_4H_{14}MgO_8S_2$ requires C, 17.3; H, 5.0%); ν_{max}/cm^{-1} (Nujol) 3387 m, 1261 m, 1160 m, 1090 s, 1021 s, 987 s, 799 m, 725 m, 680 m, 599 m, 443 w, 353 w; (HCB) 3363 m, 2952 s, 2846 s, 1471 s, 1455 s, 1403 s; *m/z* (FAB^+) 214 [$Mg(O_2SOMe)_2$, 7], 115 [$Mg(O_2SOMe)$, 35], 95 [O_2SOMe, 20], 44 [SO_2, 40%].

$[Ca(O_2SOMe)_2(MeOH)_2]_n$ **2**. A similar experimental work up as that described for **1**, starting from calcium methoxide (1.35 g, 13.23 mmol) in methanol (30.0 cm^3) to obtain crystals of **2** at 0 C (1.83 g, 47%), m.p. desolvates >55 C (Found: 16.4; H, 4.6%. $C_4H_{14}CaO_8S_2$ requires C, 16.3; H, 4.8%); ν_{max}/cm^{-1} (Nujol) 3345 m, 1433 m, 1261 m, 1141 s, 1106 s, 1064 s, 1061 s, 1029 s, 855 w, 800 m, 722 m, 671 s, 646 s, 560 m, 458 w, 428 m, 309 m; (HCB) 3333 m, 2929 m, 2827 m, 1453 w, 1432 m; *m/z* (FAB^+) 595 [$Ca_3(O_2SOMe)_5$, 5], 461 [$HCa_2(O_2SOMe)_4$, 15], 365 [$Ca_2(O_2SOMe)_3$, 5], 135 [$Ca(O_2SOMe)$, 65], 95 [O_2SOMe, 16], 44 [SO_2, 36%].

Preparation of the COS inserted complexes

$[Mg(\{OCS\}OMe)_2(MeOH)_2]_n$ **3**. To a suspension of magnesium methoxide (1.25 g, 14.53 mmol) in methanol (30.0 cm^3) was bubbled COS gas at room temperature. This resulted in a vigorous exothermic reaction and precipitation of a white solid. The resulting solid was insoluble in alcohol and isolated by filtration. Yield: 2.50 g (63%) m.p. desolvates >67 C (Found: C, 26.2; H, 4.9%. $C_6H_{14}MgO_6S_2$ requires C, 26.7; H, 5.2%); ν_{max}/cm^{-1} (Nujol) 3428 s, 3287 s, 1505 s, 1431 s, 1261 m, 1246 m, 1186 s, 1125 s, 1105 s, 1043 s, 1020 s, 798 m, 733 s, 685 s, 671 s, 551 s, 513 s, 433 s, 342 m, 302 m; (HCB) 3436 s, 3311 s, 3093 s, 2991 s, 2941 s, 2836 s, 1505 s, 1449 s, 1432 s, 1375 s; *m/z* (FAB^-) 321 [$Mg_2(\{OCS\}OMe)_3$, 4], 115 [$Mg(\{OCS\}OMe)$, 23], 91 [$\{OCS\}OMe$, 48], 60 [COS, 15%].

$[Ca(\{OCS\}OMe)_2(MeOH)_3]_2$ **4**. To a suspension of calcium methoxide (1.75 g, 17.12 mmol) in methanol (30.0 cm^3) was bubbled COS gas at room temperature. This resulted in an exothermic reaction and dissolution of the methoxide to yield a yellow solution. The volume of the solution was reduced to ca 5 cm^3 and left to stand at room temperature for 12 h when a crystalline solid was isolated (2.64 g, 54%), m.p. desolvates >75 C (Found: C, 25.9; H, 5.9%. $C_7H_{18}CaO_7S_2$ requires C, 26.4; H, 5.7%); ν_{max}/cm^{-1} (Nujol) 3170 s, 1688 s, 1607 s, 1324 s, 1306 s, 1244 m, 1193 s, 1088 s, 1053 s, 1019 s, 923 m, 872 w, 820 m, 722 m, 680 m, 613 m, 558 s, 512 s, 327 s; (HCB) 3174 s, 2942 s, 2872 m, 2838 m, 2811 m, 1689 m, 1462 s, 1401 s, 1380 m, 1324 m, 1303 m; *m/z* (FAB^+) 131 [$Ca(\{OCS\}OMe)$, 15], 91 [$\{OCS\}OMe$, 58], 60 [COS, 12%].

Preparation of the CS_2 inserted complexes

$[Mg(S_2COMe)_2(MeOH)_6]_n$ **5**. To a suspension of magnesium methoxide (1.25 g, 14.53 mmol) in methanol (30.0 cm^3) was added CS_2 (2.18 cm^3, 36.33 mmol) at room temperature. This was an exothermic reaction, and on stirring the methoxide dissolved slowly to yield a yellow solution. The solution was stirred for a further 30 min and the volume reduced *in vacuo* by half; a crystalline solid was isolated at −20 C (3.49 g, 56%), m.p. disolvates >65 C (Found: C, 28.2; H, 6.8%. $C_{10}H_{30}MgO_8S_4$ requires C, 27.9; H, 7.0%); ν_{max}/cm^{-1} (Nujol) 3115 s, 1512 m, 1419 s, 1299 w, 1261 m, 1237 m, 1188 s, 1130 s, 1110 s, 1093 s, 1054 s, 1043 s, 1016 s, 951 s, 925 m, 801 m, 722 m, 657 s, 621 m, 574 m, 470 s, 424 s, 403 s, 341 m; (HCB) 3103 s, 2966 s, 2962 s, 2842 s, 2825 s, 2796 s, 1520 s, 1505 s, 1444 s, 1429 s, 1418 w; *m/z* (FAB^+) 286 [$HMg_6(O)_5(OMe)_2$, 15], 247 [$HMg_5(O)_4(OMe)_2$, 16], 227 [$Mg_3(OMe)_5$, 26], 141 [$Mg_2(OMe)_3$, 10], 116 [$Mg(S_2CO)$, 22], 76 [CS_2, 100%].

$[Ca(S_2COMe)_2(MeOH)_4]_n$ **6**. A similar experimental work up as described for **5** was used, starting from calcium methoxide (1.50 g, 14.70 mmol) in methanol

($30.0\ cm^3$). The volume of the solution was reduced to ca $5\ cm^3$, and then left to stand at $-20°C$. A crystalline solid was isolated after 4 h (3.80 g, 65%), m.p. desolvates $>60°C$ (Found: C, 25.0; H, 5.3. $C_8H_{22}CaO_6S_4$ requires C, 25.1; H, 5.8%); ν_{max}/cm^{-1} (Nujol) 3561 w, 3185 w, 1524 w, 1347 m, 1261 m, 1193 s, 1146 s, 1093 s, 1047 s, 1018 s, 945 m, 800 m, 723 m, 588 m, 564 m, 468 m, 352 m; (HCB) 3662 w, 3182 m, 2966 s, 2962 s, 2842 s, 2825 s, 2796 s, 1520 s, 1444 s, 1432 s, 1418 w, 1350 m; *m/z* (FAB^+) 229 [$Ca_3(O)(OMe)_3$, 23], 183 [$Ca_3(O)_2(OMe)$, 18], 127 [$Ca_2(O)(OMe)_2$, 16], 132 [$Ca(S_2CO)$, 9], 76 [CS_2, 100%].

Preparation of CO_2 *inserted complexes*

$[Mg(O_2COMe)(OMe)(MeOH)_{1.5}]_n$ **7a**. To a suspension of magnesium methoxide (1.30 g, 15.11 mmol) in methanol ($30.0\ cm^3$) was bubbled CO_2 gas at room temperature. This resulted in an exothermic reaction and dissolution of the methoxide after ca 30 min. The solution was reduced to dryness *in vacuo* to yield a white solid (2.08 g, 85%), m.p. decomposes $>300°C$ (Found: C, 29.4; H, 6.3%. $C_{4.5}H_{12}MgO_{5.5}$ requires C, 30.3; H, 6.7%); ν_{max}/cm^{-1} (Nujol) 3269 s, 1690 s, 1655 s, 1335 s, 1261 w, 1192 m, 1101 s, 1056 s, 1040 s, 934 m, 849 m, 825 s, 713 m, 629 m, 455 m; (HCB) 3273 s, 2950 s, 2924 s, 2826 s, 1690 s, 1655 s, 1457 s, 1404 s, 1339 s; *m/z* (EI^+) 227 [$Mg_3(OMe)_5$, 3], 181 [$Mg_3(O)(OMe)_3$, 10], 99 [$Mg(O_2COMe)$, 10], 77 [H_2O_2COMe, 64], 44 [CO_2, 25%].

$[Mg_9(CO_3)(O_2COMe)_8(OMe)_8(MeOH)_{13}]\cdot MeOH\cdot C_7H_8$ **7b**. In an attempt to grow single crystals of **7a**, the compound was first dissolved in methanol and then the solvent removed, which resulted in a white paste. This was redissolved in a mixture of toluene and hexane (2:1 *v/v*). Slow crystallizations over a period of 48 h at room temperature yielded a very small crop of needle-like crystals, which was crystallographically characterized as **7b**.

$[Ca(O_2COMe)(OMe)(MeOH)]_n$ **8**. To a suspension of the calcium methoxide (0.75 g, 7.35 mmol) in methanol ($30.0\ cm^3$) was bubbled CO_2 gas at room temperature for 30 min. This resulted in an exothermic reaction and precipitation of a white solid. The compound is insoluble in methanol and was isolated by filtration (1.02 g, 78%), m.p. decomposes $>300°C$ (Found: C, 26.3; H, 5.2%. $C_4H_{10}CaO_5$ requires C, 26.9; H, 5.6%); ν_{max}/cm^{-1} (Nujol) 3209 w, 1723 m, 1682 s, 1645 s, 1403 w, 1350 m, 1332 s, 1316 s, 1262 w, 1191 w, 1102 m, 1089 m, 1049 w, 1027 w, 918 w, 826 m, 820 m, 722 w, 698 w, 618 m, 373 w; (HCB) 3216 w, 2995 m, 2954 m, 2857 w, 2833 w, 1721 m, 1681 s, 1644 s, 1446 m, 1403 w, 1352 m, 1332 s, 1312 s; *m/z* ($EI.^+$) 405 [$Ca_5(CO_3)_2(O_2COMe)_3$, 20], 305 [$Ca_2(O_2COMe)_3$, 17], 263 [$Ca_3(CO_3)(OMe)_3$, 24], 229 [$Ca_3(O)(OMe)_3$, 40], 181 [$Ca_3(O)(OMe)_3$, 76], 127 [$Ca_2(O)(OMe)_2$, 37], 77 [H_2O_2COMe, 75], 44 [CO_2, 100%].

$[Mg(O_2COEt)(OEt)(EtOH)_2]_n$ **9**. A similar experimental work up as that described for **7a** was used, starting from magnesium ethoxide (1.50 g, 13.16 mmol) in ethanol ($20.0\ cm^3$), to yield a white solid (2.60 g, 79%), m.p. decomposes $>300°C$ (Found: C, 42.1; H, 8.7%. $C_9H_{22}MgO_6$ requires C, 43.2; H, 8.8%); ν_{max}/cm^{-1} (Nujol) 3445 m, 3231 m, 1652 s, 1326 s, 1175 s, 1104 s, 1056 s, 1014 m, 887 s, 824 s, 810 m, 722 s, 626 s, 433 s, 352 s; (HCB) 3446 m, 3219 m, 2979 s, 2931 s, 2854 s, 2823 m, 1651 s, 1471 s, 1411 s, 1377 s, 1329 s; *m/z* ($E.I.^+$) 134 [$Mg_3(O)_2(OCH_2)$, 12], 94 [$Mg_2(O)(OCH_2)$, 15], 76 [$H_2O_2COCH_2$, 20], 44 [CO_2, 25%].

$[Ca(O_2COEt)(OEt)(EtOH)_2]_n$ **10**. Experimental work up as described for **8** was used, starting from tetra-ethanol solvated calcium ethoxide (2.50 g, 7.96 mmol) in ethanol ($20.0\ cm^3$), to yield a white solid (1.61 g, 76%), m.p. decomposes $>300°C$ (Found: C, 39.8; H, 7.5%. $C_9H_{22}CaO_6$ requires C, 40.6; H, 8.3%); ν_{max}/cm^{-1} (Nujol) 3317 w, 1655 s, 1401 s, 1320 s, 1265 w, 1176 w, 1106 s, 1057 w, 1017, 985 w, 888 w, 825 m, 722 w, 615 w, 407 w, 353 w; (HCB) 3253 w, 2980 m, 2934 m, 2907 w, 1654 s, 1486 m, 1402 s, 1378 s, 1320 s; *m/z* ($E.I.^+$) 170 [$Ca_2(CO_3)(OCH_2)$, 7], 89 [H_2O_2COEt, 47], 44 [CO_2, 100%].

$[Mg(O_2COPr^i)(OPr^i)(Pr^iOH)]_n$ **11**. Experimental work up as described for **7a** was used, starting from magnesium *iso*-propoxide (2.00 g, 14.08 mmol) in *iso*-propoxide (2.00 g, 14.08 mmol) in *iso-propanol* (20.0 *cm*^{3}), to yield a white solid (3.53 g, 82%), m.p. decomposes $>300°C$ (Found: C, 48.3; H, 9.2%. $C_{10}H_{22}MgO_5$ requires C, 48.8; H, 8.9%); ν_{max}/cm^{-1} (Nujol) 3455 m, 3310 m, 1654 s, 1406 m, 1338 s, 1311 s, 1261 m, 1180 s, 1148 m, 1115 s, 1076 s, 954 m, 921 m, 856 m, 819 s, 727 m, 616 m, 479 m, 391 s, 316 m; (HCB) 3481 w, 3280 w, 2980 s, 2934 m, 2877 m, 1651 s, 1471 m, 1403 s, 1383 s, 1339 m, 1314 s; *m/z* ($E.I.^+$) 134 [$Mg_3(O)_2(OCH)$, 45], 105 [$H_2O_2COPr^i$, 20], 93 [$Mg_2(O)(OCH)$, 10], 90 [$H_2O_2COCH(Me)$, 70], 44 [CO_2, 100%].

$[Mg(O_2COBu^t)(OBu^t)(Bu^tOH)]_n$ **12**. To a suspension of magnesium *tert*-butoxide (1.25 g, 14.53 mmol) in *tert*-butanol ($20.0\ cm^3$) was bubbled CO_2 gas at room temperature. This resulted in an exothermic reaction and precipitation of a white solid, which was insoluble in and separated by filtration (3.59 g, 86%), m.p. decomposes $>300°C$ (Found: C, 53.4; H, 9.1%. $C_{13}H_{28}MgO_5$ requires C, 54.2; H, 9.7%); ν_{max}/cm^{-1} (Nujol) 3459 w, 3256 w, 3189 w, 1634 s, 1395 s, 1260 m, 1239 m, 1200 s, 1088 m, 1026 m, 954 s, 884 m, 823 m, 796 m, 766 m, 737 m, 574 m, 494 s, 422 m, 369 m, 330 m; (HCB) 3444 w, 3248 w, 3193 w, 2969 s, 2931 m, 2870 m, 1634 s, 1479 m, 1465 m, 1398 s, 1361 s.

Preparation of Carbon-13 labelled $^{13}CO_2$ *inserted compounds*

Compounds **13**, **14** and **15** were prepared by following procedures adopted for the corresponding

unlabelled CO_2 inserted compounds as described above.

$[Mg(O_2{}^{13}COMe(OMe)(MeOH)_{1.5}]_n$ **13**. ν_{max}/cm^{-1} (Nujol) 3404 m, 3256 m, 1604 s, 1300 s, 1193 m, 1099 s, 1059 s, 931 m, 799 s, 721 w, 628 m, 444 s, 303 m; (HCB) 3401 s, 3250 s, 2952 s, 2826 s, 1603 s, 1448 s, 1409 s, 1311 s.

$[Ca(O_2{}^{13}COMe)(OMe)(MeOH)_n$ **14**. ν_{max}/cm^{-1} (Nujol) 3213 s, 2003 w, 1674 m, 1633 s, 1597 s, 1132 s, 1307 s, 1290 s, 1191 m, 1155 m, 1099 s, 1086 s, 1048 s, 1027 s, 909 s, 796 s, 722 m, 696 m, 617 s, 372 m, 285 s; (HCB) 3217 w, 2995 w, 2953 w, 2852 w, 2833 w, 1676 m, 1634 s, 1598 s, 1442 m, 1308 s.

$[Ca(O_2{}^{13}COEt)(OEt)(EtOH)_2]_n$ **15**. ν_{max}/cm^{-1} (Nujol) 3207 m, 1621 s, 1298 s, 1172 m, 1156 m, 1102 s, 1081 s, 1056 s, 970 m, 881 s, 795 s, 722 m, 607 m, 476 s, 327 s, 289 s, 279 s (Nujol); (HCB) 3200 m, 2971 s, 2922 s, 2727 m, 2606 m, 1625 s, 1466 m, 1455 m, 1371 s.

Crystal structure determination of compound **7b**

X-ray measurements were made at 150(2) K using Mo–K_α radiation ($\lambda = 0.71069$ Å, graphite monochromator) on a Delft Instruments FAST TV area detector diffractometer equipped with a rotating anode generator (50 kV, 50 mA), a buffer board, a DEP image intensifier, and an Oxford Cryostream low temperature cooling system by following previously described procedure [28]. The cell parameters were obtained from the least-squares refinement of the diffractometer angles for 250 reflections. A total of 12,049 intensity data were collected from a volume corresponding to slightly more than a hemisphere of reciprocal space [$2.15 \leqslant \theta \leqslant 25.38^\circ$); $-12 \leqslant h \leqslant 10$, $-18 \leqslant k \leqslant 18$, $-25 \leqslant l \leqslant 18$], which gave 10,590 ($R_{int} = 0.0373$) unique data with intensities greater than zero. The data were corrected for Lorentz and polarization factors but not for absorption.

The structure was solved by direct methods (SHELXS86) [29] and difference electron density syntheses, and refined on F^2 by full matrix least-squares (SHELXL93) [30] using all unique data. All non-hydrogen atoms were refined anisotropically. The crystal was a poor diffractor and the data set contained an unusually large number of "unobserveds". Free refinement at the initial stage resulted in very elongated ellipsoids or "non-positive-definite" displacement coefficients for several atoms. Bond lengths associated with several terminal groups were also unrealistic. So the final cycles of refinement were carried out with (a) ISOR = 0.015 restraints for several atoms and (b) bond length constraints for several methoxy/methanol groups. The hydrogen atoms of the MeOH molecules were all ignored; other hydrogen atoms in the complex were included in calculated positions (riding model) with $U_{iso} = n \times U_{eq}$ of the parent carbon ($n = 1.2$ for CH and 1.5 for CH_3 groups). Residual electron densities ranged from -0.36 to 0.75 $eÅ^{-3}$ and indicated no features of stereochemical significance. The crystal data are summarized in Table 1, and selected bond lengths and angles are presented in Table 2. The final R-values are given in Table 1. Sources of scattering factors as in Ref. 30. The diagrams were drawn with the program SNOOPI [31]. The calculations were done on Pentium P5-90 personal computer. Further crystallographic details, fractional atom co-ordinates, thermal parameters, hydrogen

Spectra obtained from Nujol mull. ν_{as} = asymmetric stretch; ν_s = symmetric stretch; π = out of plane bend. X = S, Y = O for **1** and **2**; X = C, Y = S and Z = O for **3** and **4**; X = C, Y = S for **5** and **6**, X = C and Z = O for **7a**–**15**.

atom parameters, and full list of interatomic distances and angles are deposited as supplementary material.

RESULTS AND DISCUSSION

Synthesis

The insertion reactions of the small molecules SO_2, COS, CO_2 and CS_2 into Group 2 metal–alkoxide bonds described herein involved addition of the gases SO_2, COS, CO_2 and liquid CS_2, respectively, to the alkoxide compounds in solution. Such reactions have been studied previously using either condensation [6,7] or autoclave [32] techniques.

The reactions of CO_2, SO_2 and COS as gases with metal alkoxide suspensions/solutions at ambient temperatures resulted in exothermic reactions. The reactions were complete within ca 30 min. Similarly, reactions involving CS_2 proceeded exothermically and were accompanied by dissolution of the alkoxides. In contrast, the insertion of CO_2 into molybdenum–alkoxide [32] bonds requires harsher conditions (high pressures of CO_2 and reflux temperatures).

The molecules SO_2, COS and CS_2 produced the double insertion products **1**–**6** when M = Mg or Ca. Structural studies have shown that the inserted products adopt the range of bonding modes illustrated in Fig. 1. In contrast, the CO_2 reactions appear to proceed via a single insertion process. Scheme 2 illustrates a generalized reaction scheme for CO_2 insertions into a range of magnesium and calcium alkoxides to yield the alkoxy–alkylcarbonato complexes **7a**–**12**.

$$[M(OR)_2]_n + 2ROH \xrightarrow{CO_2} [M(O_2COR)(OR)(ROH)_x]_z$$

Scheme 2

Unfortunately, it did not prove possible to obtain single crystals of these products and recrystallization resulted in the formation of oligomeric species presumably due to hydrolysis reactions involving traces of moisture. For example, the X-ray structure of **7b** revealed, very surprisingly, the incorporation of a CO_3^{2-} group in a monomeric metal framework. It has not proved possible to confirm unambiguously the origin of this CO_3^{2-} ligand in complex **7b**, but it could result from the hydrolysis of small quantities of $[Mg(O_2COMe)(OMe)(MeOH)_{1.5}]_n$ **7a** with the elimination of methanol and the formation of magnesium carbonate; "$[Mg(CO)_3]_n$" (Scheme 3).

$$\text{"}[Mg(\mu_2\text{-}O_2COMe)(OMe)(MeOH)_{1.5}]\text{"} \xrightarrow{H_2O} \text{"}[Mg(CO_3)]_n\text{"} + 3.5MeOH$$

Scheme 3.

Complex **7b** probably represents an intermediate in this hydrolysis process. The overall reaction is given in Scheme 4.

$$9[Mg(O_2COMe)(OMe)(MeOH)_{1.5}]_n\ \mathbf{7a} + H_2O \xrightarrow{C_7H_8\text{/n-hexane}} 1.5MeOH + [Mg_9(CO_3)(O_2COMe)_8 \times (OMe)_8(MeOH)_{13} \cdot MeOH \cdot C_7H_8\ \mathbf{7b}$$

Fig. 1. Potential co-ordination modes for inserted moieties.

The reaction of CO_2 with the tetra-ethanol solvated calcium ethoxide $[\{Ca(OEt)_2(EtOH)_4\}_n]$ in toluene resulted in an increase in viscosity and "gelling" of the solution. However, on refluxing, evolution of CO_2 was observed and this was accompanied by a decrease in viscosity, implying a decarboxylation or extrusion reaction [21]. Significantly, the same reaction in ethanol resulted in precipitation of the complex $[Ca(O_2COEt)(OEt)(EtOH)_2]_n$ **10**. Further investigations support the view that CO_2 insertion into the Ca—OEt bond is occurring, but in toluene the ethylcarbonato ligand is unstable due to the absence of donor ligands such as ethanol co-ordinated to the metal. Similar observations were reported by Saegusa *et al.* [33], with *tert*-butyl isocyanide ligand stabilising the *tert*-butylcarbonato group by its σ-donating property.

$^{13}CO_2$ enrichment studies were performed for a range of magnesium and calcium alkoxides, which yielded the complexes **13**–**15**. Reaction conditions and work-up were similar to those of the unlabelled CO_2 experiments.

The insertion reactions of CO_2, SO_2 and COS into the Group 2 metal–alkoxide bonds are irreversible, and the resultant products **1**–**4** and **7a**–**15** are stable under reduced pressures (ca 1×10^{-2} Torr) and temperatures (up to 80°C). In contrast, the CS_2 inserted complexes **5** and **6** were unstable in the solid state.

Physical properties

Complexes **1**, **2** and **4**–**6** were isolated from methanol solutions as crystalline solids, whilst the complex

$[Mg(\{OCS\}OMe)_2(MeOH)_2]_n$ **3** was isolated as a white precipitate from methanol. Complexes **1**, **2** and **4**–**6** are soluble in methanol, in contrast, complex **3** is insoluble, indicating that it is a polymeric compound. Interestingly, the SO_2, COS and CS_2 calcium complexes **2**–**4** and **6** are soluble in methanol, whilst the CO_2 derivative **8** is insoluble. This may be due to the formation of the *bis*-inserted products with SO_2, COS and CS_2 in contrast to the mono-inserted products with CO_2. The solubilities of the inserted methoxide derivatives are significantly greater than those for $[Mg(OMe)_2]_n$ and $[Ca(OMe)_2]_n$, especially in DMSO [21]. The magnesium carbonato-derivatives **7a**, **9** and **11** are soluble in their parent alcohol and were isolated by removing the solvent. Complexes **8**, **10** and **12** were isolated as white insoluble precipitates.

The magnesium alkoxy alkycarbonato complexes **7**, **9** and **11** show good solubilities in their respective parent alcohols and DMSO, and are moderately soluble in toluene, whilst their calcium counterparts **8**, **10** are insoluble in their parent alcohols. This disparity in solubilities suggests different degrees of oligomerization; the calcium complexes are polymeric whilst the magnesium derivatives are more discrete oligomers. A noteworthy exception is the magnesium *tert*-butoxide derivative **12**, which is insoluble in *tert*-butanol.

Complexes **1**–**12** are air sensitive and readily hydrolyze to yield the corresponding metal carbonates, sulfites, thiocarbonates or dithiocarbonates. They are, however, stable at room temperature under an inert atmosphere and can be stored indefinitely in a glovebox. Furthermore, these complexes did not show sharp melting points, but decomposed at high temperatures.

Infra-red spectra

Sulphur dioxide inserted compounds. Complexes **1** and **2** exhibited asymmetric and symmetric stretching modes associated with alkylsulfito ligands corresponding to O-co-ordination: 1160 and 987 cm^{-1} (for **1**) and 1141 and 1064 cm^{-1} (for **2**), respectively, [34,35]. Similar stretching frequencies were observed for the recently structurally characterized iridium complex with an O-co-ordinated methylsulfito ligand [36]. Methylsulfito deformation vibrations δ(O—S—O) were observed at 680 cm^{-1} for **1**, and at 671 and 646 cm^{-1} for **2**. IR spectroscopic studies suggest different methylsulfito co-ordination modes in complexes **1** and **2**.

Carbonyl sulfide inserted compounds. IR spectra of complexes **3** and **4** are clearly different and imply dissimilar methylthiocarbonato co-ordination modes. Complex **4** exhibits ν(CO) stretching vibrations at 1688 and 1607 cm^{-1}, suggesting two distinct co-ordination modes (Table 2). In contrast, complex **3** displays a single ν(CO) stretching vibration at significantly lower frequency 1505 cm^{-1}. Similar stretching vibrations have been observed at 1620 and 1568 cm^{-1} for $[Sr_3(\{OCS\}OEt)_6(EtOH)_8]$ and 1568 cm^{-1} for $[Mg(\{OCS\}OEt)_2(EtOH)_4]$ [21]. The ν(C=S) stretching mode was observed at 1186 and 1193 cm^{-1} for **3** and **4**, respectively. Furthermore, complex **4** exhibited a ν(C—S) stretching mode at 923 cm^{-1}, suggesting two distinct methylthiocarbonato co-ordination modes. These peaks can be compared with the ν(C=S) stretching frequencies for $[Sr_3(\{OCS\}OEt)_6(EtOH)_8]$ and $[Mg(\{OCS\}OEt)_2(EtOH)_4]$ at 1176 and 1174 cm^{-1}, respectively, and ν(C—S) stretching mode at 930 cm^{-1} for $[Sr_3(\{OCS\}OEt)_6(EtOH)_8]$ [21]. Additional bands associated with methylthiocarbonato complexes are observed at 1125, 685, 671, 551 and 513 cm^{-1} for complex **3**, and 680, 613, 558, 512 cm^{-1} for complex **4**. Similar vibrational frequencies have been previously reported for manganese alkythiocarbonato complexes [37]. IR data for compound **3** suggest that the ligands display a mode of co-ordination similar to that illustrated in Fig. 1 (f) or (g), whilst complex **4** exhibits two distinct co-ordination modes [see Fig. 1, (b) and (g)].

Carbon disulfide inserted compounds. Characteristic IR group stretching modes associated with the dithiocarbonato ligand were observed for complexes **5** and **6** [38–40]. Complexes **5** and **6** exhibited bands corresponding to the ν(C=S) stretching modes at 1188 and 1193 cm^{-1} respectively, while the ν(C—S) stretching vibrations were observed at 951 cm^{-1} and 925 and 945 cm^{-1}, respectively (Table 2). The presence of both ν(C=S) and ν(C—S) stretching vibrations suggests that either unidentate co-ordination is present or, more likely, the chelating $\kappa^2 Y,O$ (Y = S) co-ordination mode is involved [Fig. 1, (f)].

Carbon dioxide inserted compounds. IR spectra of complexes **7a**–**12** exhibited characteristic stretching modes of the alkylcarbonato ligands (Table 2). The spectrum for **8** reveals three distinct asymmetric (1723, 1682, 1645 cm^{-1}) and symmetric (1350, 1331, 1316 cm^{-1}) stretching vibrations associated with methylcarbonato ligands, implying three different co-ordination modes for this ligand. The precise modes are hard to define due to the range of the potential bonding types (see Fig. 1). Similar stretching vibrations were also observed for complex **7a**. In contrast, the IR spectra for compounds **9**, **10**, **11** and **12** revealed two strong bands associated with the alkylcarbonato ligands in the region 1720–1520 cm^{-1} and 1350–1280 cm^{-1}, respectively, which could be assigned to the asymmetric ν_{as}(C—O) and symmetric ν_s(C—O) stretching modes, while a medium or weak out of plane bending (π) peak is observed between 856–810 cm^{-1} (Table 2). The ν(C—O)R stretching vibration expected around 1200–1100 cm^{-1} could not be assigned owing to overlap with ν(C—O) stretching modes of the alkoxide and alcohol ligands. Similar frequency ranges were reported by other workers [32,34,41–44]. The stretching and deformational vibrational frequencies associated with the alkyl vibrations were observed at their characteristic ranges.

Carbon-13 labelled $^{13}CO_2$ studies confirmed these assignments with an observed shift to lower frequencies for those bands associated with C—O vibrations in complexes **13–15**. The observed frequency shift was in close agreement with the calculated values, assuming the simple harmonic oscillator model (see Table 2). Comparison of the IR spectra of complexes **8** and **14** shows the expected shift to lower frequencies in **14**. In general, the IR bands corresponding to the ν_{as}(C—O) and ν_s(C—O) stretching modes were broad and yielded little structural information. It can be suggested, however, that a range of alkylcarbonato co-ordination modes are present.

Nuclear magnetic resonance spectra

Sulphur dioxide inserted compounds. ^{1}H NMR spectroscopic studies (Table 3) in $(CD_3)_2SO$ for complexes **1** and **2** at room temperature revealed a single broad resonance in each spectrum associated with methanol and methylsulfito ligands, indicative of an exchange process occurring between methanol and methylsulfito groups which is fairly fast compared to the NMR timescale. Similar fluxional behaviour was observed in the ^{13}C-$\{^1H\}$ NMR study for complex **2**, while the methylsulfito ligand were resolved in the corresponding spectrum for complex **1** (Table 4).

Carbonyl sulfide inserted compounds. ^{1}H NMR spectroscopic studies in $(CD_3)_2SO$ for complexes **3** and **4** clearly differentiated the methanol and methylthiocarbonato resonances (Table 3). The spectrum for complex **3** displayed two signals associated with two distinct methylthiocarbonato environments, whilst a single resonance was observed for **4**. Similar solution behaviour was observed in the ^{13}C-$\{^1H\}$ NMR spectra of **3** and **4** (Table 4). A characteristic thiocarbonato carbon signal, {O*C*S}OMe was observed in the ^{13}C-$\{^1H\}$ NMR spectra, and as expected, this was observed down-field from the carbonato carbon resonances. Darensbourg *et al.* [45,46] observed similar chemical shift positions for COS insertion products with tungsten alkoxides.

Carbon disulfide inserted compounds. ^{1}H NMR spectroscopic studies in $(CD_3)_2SO$ for complexes **5** and **6** (Table 3) revealed resonances due to both methanol and methylditiocarbonato ligands. Complex **5** displayed two signals, albeit at similar chemical shift positions, corresponding to two distinct methyldithiocarbonato environments, whilst a single resonance was observed for complex **6**, indicative of either one methyldithiocarbonato ligand environment or fluxional behaviour. ^{13}C-$\{^1H\}$ NMR solution studies (Table 4) exhibited a single distinctive resonance down-field for both **5** and **6** corresponding to the methyl group of the methyldithiocarbonato ligand. The dithiocarbonato carbon resonance S_2COMe was observed at low field (ca δ 230) with respect to the

[a]contains free $^{13}CO_2$ peak at δ 124.55.

carbonato (see later) and thiocarbonato and free CS_2 carbon signals (free CS_2 at ca δ 192). Other workers have also noted the dithiocarbonato carbon signal in a similar position [38,46,47].

Carbon dioxide inserted compounds. ^1H NMR studies in $(CD_3)_2SO$ for complexes **7a**–**12** revealed (Table 3) resonances associated with alkyl groups at chemical shift positions comparable with their respective alkoxide compounds [21]. Complex **7a** exhibited well resolved signals corresponding to methanol, methoxide and methylcarbonato ligands. In contrast, there was a lack of peak resolution for complexes **8**–**12**, indicative of superimposed signals or exchange processes occurring between alkoxide and alkycarbonato ligands which are rapid compared to the NMR timescale at room temperature. A noteworthy feature of the ^1H NMR spectra of complexes **9** and **10** is the multiplicity exhibited by OH and CH_2 protons of the ethanol ligands; OH and CH_2 resonances are resolved into triplets and pseudo quintets respectively (^3J = 4.95 Hz) indicative of a slow intra-molecular exchange process.

^{13}C-$\{^1H\}$ NMR solution studies for complexes **7a**–**12** (Table 4) also demonstrated fluxional behaviour between the alkoxide and alkycarbonato ligands. However, complexes **9** and **10** displayed an apparent shift to lower field (ca 3 ppm) of the ethylcarbonato α-carbon compared with their alkoxide signals (δ 60.6 for compound **9** compared to δ 58.4 for the corresponding alkoxide). The appearance of a very diagnostic signal at low field associated with the carbonato carbon, O_2COR (ca 157–166; cf free CO_2 at ca δ 124), is significant in the characterization for alkycarbonato complexes. This resonance has been found to be relatively unaffected by the alkyl substituents, it is possibly dependent on the mode of co-ordination [43,44].

Complexes **13**–**15**, the carbon-13 labelled $^{13}CO_2$ inserted compounds, allowed definitive assignments of the carbonato carbon signal $O_2{}^{13}COR$ to be made. Also evident from the ^{13}C-$\{^1H\}$ NMR spectra are the

weaker signals which were previously absent in the non-enriched complexes. In general, the carbonato signals derived from the carbon-13 labelled compounds yielded one or more intense resonances in solution than the analogous non-enriched complexes.

^{13}C-$\{^1H\}$ CPMAS NMR solid state studies were performed in order to provide additional structural information. The solution ^{13}C-$\{^1H\}$ NMR spectrum of complex **7a** revealed two almost identically shifted resonances associated with the carbonato carbon, while the solid state spectrum exhibited two signals separated by ca δ 4 ppm, indicative of two distinct methylcarbonato environments for the latter. Thus, exchange processes or time averaging effects are present in solution which give almost identical methylcarbonato environments. This is further supported by the presence of two signals (separated by ca δ 4 ppm) from the analogous carbon-13 labelled compound **13**. Similarly, the solution $^{13}C\{^1H\}$NMR of complex **14** exhibited two resonances for the carbonato carbon, but in the solid state, five well resolved signals were observed indicative of five distinct methylcarbonato environments. These findings were also observed for other complexes, although in some cases only one resonance was detected in both solution and solid state at comparable chemical shift positions.

The resonances corresponding to alkyl carbons of the alkoxide and alcohol ligands are similarly well resolved in the solid state spectra. For example, ^{13}C-$\{^1H\}$NMR spectrum for complex **8** in solution exhibits a single broad resonance due to the methoxide and methylcarbonato carbons, whilst the corresponding solid state spectrum is sufficiently discriminating to reveal a signal corresponding to the methoxide carbon and two signals due to the methlycarbonato carbons. This lends further support for the occurrence of exchange processes in solution at room temperature.

Multinuclear NMR (^1H and ^{13}C-$\{^1H\}$) variable temperature studies were investigated to determine the thermal stabilities of the alkycarbonato ligand. ^1H NMR variable temperature studies (20–80°C) for complex **10** resulted in a loss of resolution of the signals on increasing the temperature, accompanied by an up-field shift of the OH signal, while the other signals remained constant. Similar observations were noted for the complex $[\{Ca(OEt)_2(EtOH)_4\}_n]$ [21]. In contrast, no apparent changes were observed in the ^{13}C-$\{^1H\}$ NMR on increasing the temperature. Thus, the ethylcarbonato complex is thermally stable up to a temperature of 80°C. In contrast, solution NMR studies described by Chisholm *et al.* [32] on molybdenum alkoxy alkycarbonato complexes demonstrated decarboxylation at 80°C.

TGA/DSC and mass spectrometry studies

Thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC) studies were performed on complexes **2**, **4**, **6** and **7a**. The TGA analyses for compounds **2** and **4** revealed the loss of the co-ordinated methanol molecules below 100°C, followed by the decomposition of the homoleptic insertion products with the liberation of either SO_2 or COS gas [19–21].

The DSC curve of complex $[Ca(S_2COMe)_2(MeOH)_4]_n$ **6** provided several interesting features. An endotherm was observed over the range 32–100°C and three distinct peaks were apparent. The first is centred at 38°C, the second at 65°C and the third at 81°C. This was mirrored in the TGA plot with a single rapid weight loss of 72.8% corresponding to four methanol molecules and breakdown of the CS_2 inserted ligands. This intermediate was stable at 400°C whereupon a further weight loss of 7.8% was observed to give a residue of 18.5% at this temperature (CaS would give a residue of 18.8%). This weight loss is consistent with an endotherm centred at 447°C (-26.92 mcal mg^{-1}) in the DSC plot. A further slight weight loss between 480°C and 1200°C (to yield a residue of 13.7%) was proposed as loss of sulphur to give calcium metal (expected 10.5%).

The DSC curve of $[Mg(O_2COMe)(OMe)(MeOH)_{1.5}]_n$ **7a** shows two endotherms with shoulders. The first peak is broad and centred at 92°C (-81.27 mcal mg^{-1}), which is mirrored in the TGA plot with a 53.1% weight loss corresponding to loss of methanol and CO_2 (calculated 51.7%). The second endothermic reaction is observed at ca 440°C (-36 mcal mg^{-1}); this process is coupled with a simultaneous weight loss of 27.4% for methoxide and methyl groups to yield magnesium oxide residue by 460°C (final residue 22.5%; expected for MgO 22.5%). The first derivative curve of the TGA plot for complex **7a** suggests two overlapping reactions in the ranges 42–175°C and 375–470°C. The presence of these reactions is further supported by observations of shoulders in the corresponding DSC spectrum.

TGA/DSC studies have confirmed the stability of the inserted complexes to 80°C. Complexes **7a**, **2** and **4** decompose to the metal oxide powders, whilst complex **6** decomposes to yield the metal sulfide by 450°C with subsequent gradual sublimation of sulfur to yield the metal.

X-ray structural studies

The crystal structures of the inserted products **2** and **4** have been communicated previously [19,20]. In the present paper we describe for the first time the crystal structure of the interesting product **7b**.

The structure of the SO_2 inserted product **2** has been shown to be polymeric consisting of infinite zig-zag chains of $[Ca(O_2SOMe)(MeOH)_2]$ [19]. The methylsulfito ligand in this compound acts as both chelating and bridging ligand, whilst the methanol molecules are unidentate and terminally co-ordinated. The eight co-ordinate calcium centres are co-ordinated to two oxygen atoms of two bridging methylsulfito ligands

which are chelated to adjacent calcium atoms, two oxygen atoms from a co-ordinated methanol molecules and four oxygen atoms belonging to two chelating methylsulfito ligands. Compound **4** was shown to be centrosymmetric dimer with both *O*, *S*- and *O*,*O*-chelating methylthiocarbonato ligands and two bridging *O*,*O*-methylthiocarbonato ligands [20]. Each calcium is eight co-ordinate due to a chelating *O*,*S*-methylthiocarbonato ligand, a chelating and bridging *O*,*O*-methylthiocarbonato ligand, three oxygen atoms belonging to three terminally co-ordinated methanol molecules and one carbonyl oxygen chelating the second calcium and involved in the bridge formation.

Complex **7b** was obtained from complex **7a** as outlined in the Experimental Section. Slow crystallization from a mixture of slightly wet toluene and hexane (2 : 1 *v*/*v*) over 48 h at room temperature yielded needle-like colourless crystals, suitable for X-ray crystallography. The present study has revealed the true identity of this crystalline material **7b** as the nonameric metal aggregate $[Mg_9(CO_3)(O_2COMe)_8(OMe)_8(MeOH)_{13}]$; the crystals also contain one methanol and one toluene solvate (per complex mole) in the lattice.

The structure of **7b** is shown in Fig. 2, and the inner core is illustrated in Fig. 3. Selected interatomic distances and angles are presented in Table 5. The compound consists of nine magnesium atoms, each of them having six-co-ordinate, distorted octahedral geometries. The gross molecular structure consists of two distorted Mg_4O_4 cubes linked through a μ_5-carbonato and two bridging methylcarbonato groups; the ninth magnesium is linked to the Mg_4O_4 cubes through the unique carbonato and two other bridging methylcarbonato groups.

In both the cubane frameworks, the magnesium atoms are held in place by four μ_3-methoxide ligands, each magnesium being bonded facially to the oxygen atoms of three such ligands. However, there is no systematic pattern in the distribution of the ligands in the remaining co-ordination sites around the magnesium atoms. In the cubane containing Mg(1)–Mg(4), Mg(1) is also co-ordinated to two terminal methanol groups and a terminal methylcarbonato ligand, whilst Mg(3) and Mg(4) are each co-ordinated to two bridging methylcarbonato ligands and the μ_5-carbonate. The co-ordination geometry around Mg(2) is augmented by three terminal methanol ligands only. In the second cube containing Mg(5)–Mg(8), the octahedral co-ordination geometries are completed by two terminal methanols and a terminal methylcarbonato group for both Mg(6) and Mg(8), one terminal methanol, one terminal methylcarbonato group and one oxygen of the μ_5-carbonato ligand for Mg(7), and two bridging methylcarbonato ligands and one oxygen atom from the μ_5-carbonato group for Mg(5). The three terminal sites around the remaining magnesium

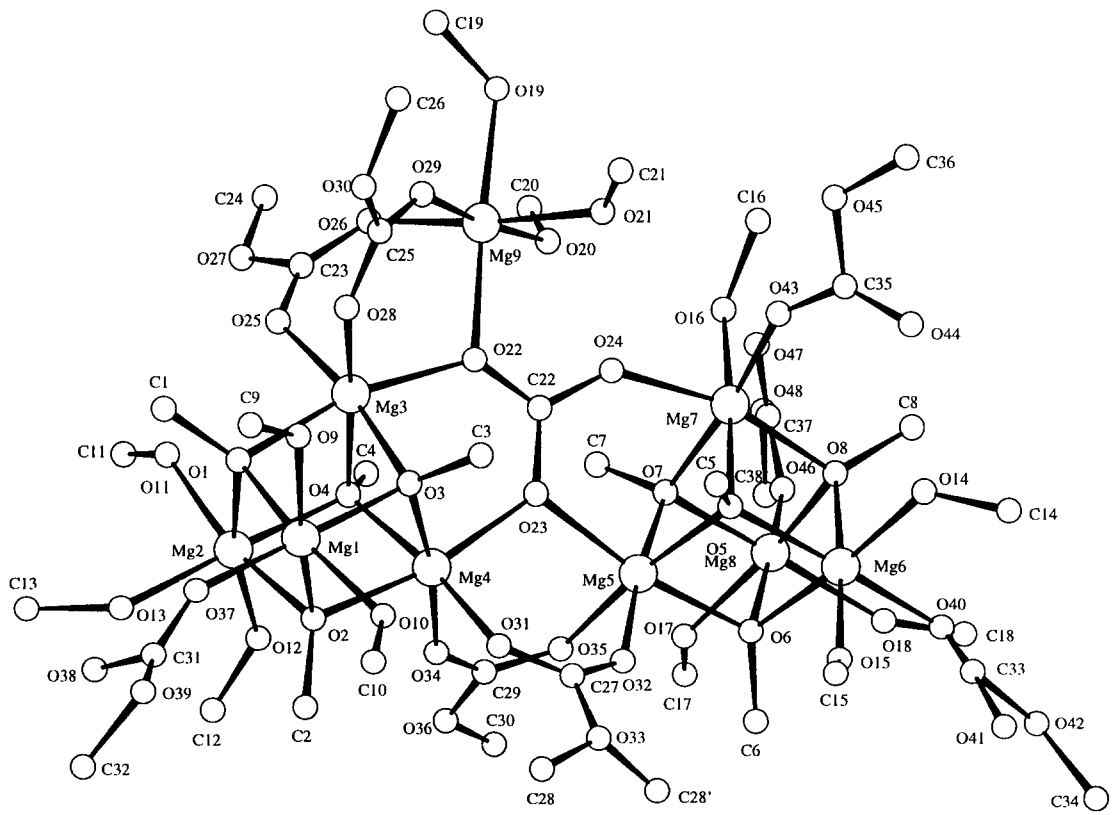

Fig. 2. The molecular structure of $[Mg_9(CO_3)(O_2COMe)_7(OMe)_9(MeOH)_{13}]$ **7b**, showing the atom numbering scheme.

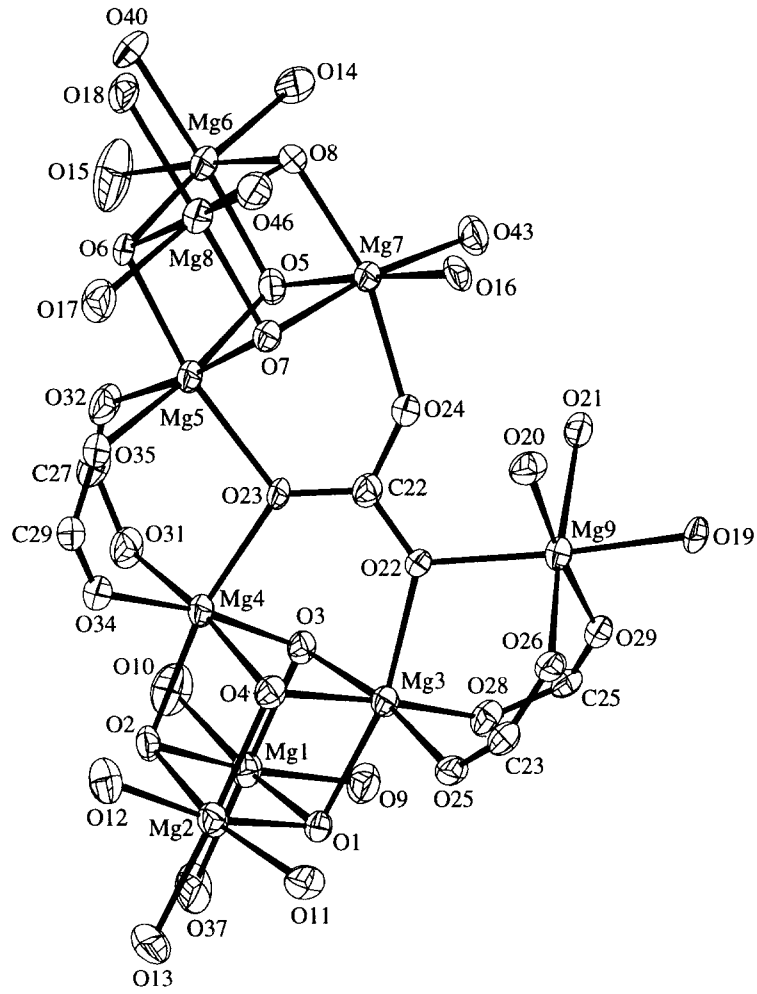

Fig. 3. A view of the $[Mg_9(CO_3)(O_2C)_7(O)_{22}]$ central core of complex **7b**.

atom, Mg(9) are occupied by three methanol molecules.

The Mg···Mg non-bonded distances involving the pair of magnesium atoms linking the two cubes [Mg(4)···Mg(5)], or one cube and the Mg(9) octahedron [Mg(3)···Mg(9)] are nearly identical and have values of 3.486(4) and 3.489(5) Å, respectively. The corresponding distances within the cubes are much smaller (by ca 0.34 Å) and lie in the narrow range 2.978(4)–3.186(5) Å (average value 3.119 Å).

The Mg—O bond distances in the complex **7b** may be divided into several groups. Those involving the μ-methoxide ligands in the cubane moieties span the range 2.050(7)–2.134(6) Å, average 2.089 Å. These bond lengths may be compared with the range 2.05–2.14 Å for μ_3-methoxide ligands in the recently reported complex "$[Mg(OMe)_2 \cdot 3.5MeOH]$" [48]. The internal O—Mg—O angles in both the cubes for complex **7b** are all acute [80.2(3)–87.3(3)°, average 82.8°] and the Mg—O—Mg angles are all obtuse [91.5(3)–100.1(3)°, average 96.6°]. O—Mg—O and Mg—O—Mg angles for "$[Mg(OMe)_2 \cdot 3.5MeOH]$" have been observed in similar ranges of 78.4–85.5° and 92.9–101.4°, respectively [48]. The second set of Mg—O bond distances involve the thirteen neutral methanol molecules which are all bonded terminally to the magnesium atoms. These distances range from 2.046(8)–2.155(8) Å, and have an average value of 2.102 Å. These distances are ca 0.03 Å longer than the Mg—O(μ_3-OMe) distances. Similar differences in the metal–oxygen bond lengths involving the μ_3-capping alkoxide groups and terminally bound neutral alcohol ligands have been observed in other cases, e.g. "$[Mg(OMe)_2 \cdot 3.5MeOH]$" [48] and $[Ca_4(O\text{-}Et)_4(tmhd)_4(EtOH)_4]$ [27]. The third set of Mg—O bond distances involve the terminally bound methylcarbonato ligands. The Mg—O bond distances in this group lie in the range 1.988(8) to 2.177(14) Å, with an average of 2.059 Å. The fourth set of Mg—O distances also involves the methylcarbonato groups, but this time they are co-ordinated in a slightly asymmetric bridging manner ($1\kappa O, 2\kappa O'$). The Mg—O bond distances are in the range 2.043(7)–2.166(7) Å, with an average of 2.076 Å. As expected the Mg—O(bridging)

methylcarbonato bond lengths are longer than those of the terminally bound ligands.

Finally, at the very centre of this molecule is a highly unusual bridging chelating μ_5-carbonate group ($1:2\kappa^2O;3:4\kappa^2O';5\kappa O''$) [49]. This ligand acts as a focal point holding together not only the two cubes, but also the single remote Mg(9) atom. The Mg—O(μ_5-CO_3) bond distances lie in the range 2.031(7)–2.148(6) Å, with an average bond length of 2.123 Å. This value is similar to that observed in

[$4MgCO_3 \cdot 4H_2O$], which has an average Mg—O(CO_3) distance of 2.10 Å [50]. The μ_3-carbonate ligand takes up a planar geometry with near equivalent C—O bond lengths and angles indicative of a fully delocalized system.

CONCLUSION

This study has shown that the Group 2 metal alkoxides are capable of undergoing a wide range of insertion reactions with unsaturated inorganic molecules. COS, CS_2 and SO_2 insert into both the alkoxide bonds to give well defined monomeric and oligomeric products which are more amenable to characterization than the parent alkoxides. CO_2 inserts into only one of the alkoxide bonds and the resultant compounds are difficult to characterize by structural techniques. Recrystallization of $[Mg(OMe)(O_2COMe)(MeOH)_{1.5}]_n$ has resulted in the isolation and definitive characterization of a hydrocarbon soluble intermediate in the formation of magnesium carbonate. The nonameric complex $[Mg_9(CO_3)(O_2COMe)_8(OMe)_8(MeOH)_{13}]$ **7b** contains methylcarbonato, methoxide and neutral methanol ligands. The presence of the μ_5-carbonate ligand in the structural core of this nonameric complex is unique. It is probable that partial hydrolysis may have occurred during recrystallization. The analogous CO_2 insertion reactions for calcium alkoxides have also been studied; however, unlike their magnesium analogues they are insoluble in non-co-ordinating solvents, suggesting the presence of polymeric species.

The isolation of what effectively is a partially hydrolyzed alkoxide carbonato-complex (**7b**) has implications for use of this compound as a sol-gel precursor to magnesium carbonate and ultimately the corresponding metal oxide. The solubility of this carbonate containing species in hydrocarbon solvent systems suggests that in principle relatively large aggregates can be formed and solubilized as long as the aggregate has a hydrophobic exterior.

β-Diketonate derivatives of titanium alkoxides: X-ray crystal structures and solution dynamics of the binuclear complexes $[\{Ti(OR)_3(dik)\}_2]$†

R. John Errington,* John Ridland, William Clegg, Robert A. Coxall and Jan M. Sherwood

Department of Chemistry, Bedson Building, University of Newcastle upon Tyne, NE1 7RU, U.K.

(Received 8 August 1997; accepted 26 September 1997)

Abstract—The crystal structures of the 2,4-pentanedionato (acetylacetonato, acac) and 2,2,6,6-tetramethylheptane-3,5-dionato (tmhd) compounds $[\{Ti(OR)_3(dik)\}_2]$ (dik = acac, R = Me, Et, Pr^i; dik = tmhd, R = Me, Pr^n, Pr^i), obtained from reactions between $Ti(OR)_4$ and one equivalent of dikH, have been determined for the first time. In the solid state, these compounds adopt centrosymmetric, alkoxide-bridged binuclear structures which in solution undergo ligand redistribution to give mixtures of $[\{Ti(OR)_3(dik)\}_2]$, $[Ti(OR)_2(dik)_2]$ and $Ti(OR)_4$. When R = Pr^i, the equilibrium favours the mononuclear compounds, whereas when R = Me, Et or Pr^n the binuclear compounds can be observed in the ^{1}H NMR spectra. Variable-temperature ^{1}H NMR spectra provide an insight into the dynamic behaviour of the methoxides $[\{Ti(OMe)_3(dik)\}_2]$, and possible ligand exchange mechanisms are discussed. No conclusive evidence was obtained for the existence of dimeric or monomeric $[Ti(OBu^t)_3(dik)]$ in the solid state or in solution. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: titanium alkoxides; β-diketonates; crystal structures; NMR; solution dynamics.

While the number of X-ray crystal structures of metal alkoxides continues to grow, detailed knowledge of their solution behaviour is remarkably sparse. In order to develop a better understanding of the solution dynamics in these systems, we have been studying early transition-metal alkoxides and their derivatives [1], particularly with regard to hydrolytic aggregation and sol–gel processing. β-Diketones are used as "modifiers" in sol–gel processing, but the literature is somewhat ambiguous about the structures and behaviour of the species present in solution before, and during, hydrolysis (details are discussed later in the paper). Titanium tetraalkoxides have been previously described to react with one or two equivalents of β-diketones (dikH) to give products formulated as $[Ti(OR)_3(dik)]$ and $[Ti(OR)_2(dik)_2]$ respectively [2]. Bradley and Holloway first showed that the mononuclear, octahedral disubstituted complexes $[Ti(OR)_2(dik)_2]$ have *cis* alkoxide groups, and their ^{1}H NMR investigations demonstrated the non-rigid nature of these structures in solution [3]. More detailed studies subsequently provided evidence for an intramolecular structural rearrangement via a twist mechanism [4]. By comparison, the nature of the monosubstituted compounds $[Ti(OR)_3(dik)]$ is less well established and, although their involvement in the β-diketone modified sol–gel hydrolysis of titanium alkoxides has been discussed [5], no crystal structures of representative examples have been determined. In this paper we describe the solid-state structures of a range of such compounds obtained from reactions involving pentane-2,4-dione (acacH) and 2,2,6,6-tetramethylheptane-3,5-dione (tmhdH). In addition, the solution behaviour of these compounds is discussed in the light of variable-temperature ^{1}H NMR results.

EXPERIMENTAL

All manipulations were carried out under dry, oxygen-free nitrogen using standard Schlenk techniques, or in a dry box fitted with a recirculation system. Hydrocarbon solvents were dried over and distilled

† Dedicated to Professor Don Bradley on the occasion of his 73rd birthday.

from sodium-benzophenone prior to use. Propan-2-ol and ethanol were dried over sodium, and methanol was dried over magnesium. Pentane-2,4-dione (acetylacetone, acacH) was fractionally distilled and stored under oxygen-free nitrogen. 2,2,6,6-Tetramethylheptane-3,5-dione (tmhdH), $Ti(OEt)_4$, $Ti(OPr^n)_4$ and $Ti(OPr^i)_4$ were used as received without further purification. $Ti(OBu^t)_4$ was prepared by adding *tert*-butanol to an "ammonia-neutralised" $TiCl_4$ solution in heptanes according to a method developed by Haslam [6], followed by distillation of the crude alkoxide. $Ti(OMe)_4$ was prepared by addition of $Ti(OPr^i)_4$ to a 40-molar excess of refluxing methanol, with subsequent collection of the resultant solid. IR spectra were recorded as mineral oil mulls between CsI plates on a Perkin–Elmer 598 spectrometer or on a Mattson Genesis FTIR spectrometer. Ambient-temperature ^1H and ^{13}C NMR spectra were recorded on a Bruker WP 200 spectrometer. ^{13}C and variable-temperature ^1H NMR spectra were recorded on JEOL Lambda 500 or Bruker AMX500 spectrometers. Elemental analyses were performed by the University of Newcastle upon Tyne microanalytical service.

Preparation of $[\{Ti(OMe)_3(acac)\}_2]$ **1**

(a) Methanol (10 cm^3, 247.2 mmol) was added to $Ti(OPr^i)_4$ (6.44 g, 22.65 mmol) and the mixture was stirred for 1 h to precipitate $[\{Ti(OMe)_4\}_4]$. The solvents were removed and the solids washed with hexanes (15 cm^3) then dried *in vacuo*. Yield of $[\{Ti(OMe)_4\}_4]$ 3.90 g, 100%. Toluene (20 cm^3) was added, the suspension was heated to 65–70 °C and pentane-2,4-dione (2.33 cm^3, 22.65 mmol) was then added by syringe to give a clear, dark red solution. A colourless microcrystalline solid was obtained by reduction of solvent volume and storage at −30 °C. The solid was collected by filtration, washed with cold toluene (acetone/solid CO_2 slush bath) and dried *in vacuo*. Yield 1.15 g, 21%. Found: C, 40.05; H, 6.66. $C_{16}H_{32}O_{10}Ti_2$ requires C, 40.02; H, 6.72%.

(b) $[\{Ti(OMe)_4\}_4]$ (1.00 g, 1.45 mmol) and $[Ti(OPr^i)_2(acac)_2]$ (2.12 g, 5.81 mmol) were placed in a Schlenk flask and dissolved in toluene (20 cm^3) to give a clear, pale yellow solution. Subsequent removal of solvents yielded a yellow oil (2.39 g). Crystals suitable for X-ray analysis were obtained by treatment of the oil with methanol (10 cm^3, 247.2 mmol), reduction of the solvent volume and storage at −5 °C. Yield: 0.39 g, 14%. Found: C, 39.27; H, 6.50. $C_{16}H_{32}O_{10}Ti_2$ requires C, 40.02; H, 6.72%.

Preparation of $[\{Ti(OEt)_3(acac)\}_2]$ **2**

Pentane-2,4-dione (3.37 cm^3, 32.82 mmol) was added slowly by syringe to a commercial solution of $Ti(OEt)_4$ in heptanes (Tilcom ETOL) (15.25 g, 32.82 mmol) to give a pale yellow solution. Removal of the solvents *in vacuo* yielded a yellow oil which subsequently crystallised. Yield 9.84 g. The crude product was washed with cold hexanes (15 cm^3, acetone/liquid N_2 slush bath) and dried *in vacuo*. Yield: 7.32 g, 79%. Crystals suitable for X-ray analysis were obtained by recrystallisation from hexanes (12 cm^3). Found: C, 47.28; H, 7.43. $C_{22}H_{44}O_{10}Ti_2$ requires C, 46.82; H, 7.86%. δ_H ($C_6D_5CD_3$, 200 MHz) 5.52, 5.48 (singlets, 2H), 4.82 (br, 12H), 2.03, 1.99, 1.98, 1.89 (singlets, 12H), 1.49 (br, 18H). δ_C ($C_6D_5CD_3$, 50.32 MHz) 191.9, 188.5, 103.5, 102.7, 73.1, 72.6, 69.0, 27.2, 26.7, 20.0 and 19.6.

Preparation of $[\{Ti(OPr^i)_3(acac)\}_2]$ **3**

(a) Pentane-2,4-dione (3.83 cm^3, 37.34 mmol) was added dropwise to $Ti(OPr^i)_4$ (10.62 g, 37.34 mmol) in hexanes (10 cm^3) at 0 °C to give a yellow solution. Crystals suitable for X-ray diffraction were obtained by recrystallisation of a portion of the crude product from propan-2-ol. Yield: 5.41 g, 45%. Found: C, 52.53; H, 9.20. $C_{28}H_{56}O_{10}Ti_2$ requires C, 51.86; H, 8.70%. δ_C ($C_6D_5CD_3$, 50.32 MHz) 190.0, 186.3, 101.5, 77.7, 75.4, 25.8, 25.7, 24.8, 24.7 and 24.5.

(b) $Ti(OPr^i)_4$ (2.75 cm^3, 9.32 mmol) was added to a solution of $[Ti(OPr^i)_2(acac)_2]$ (3.40 g, 9.32 mmol) in propan-2-ol (10 cm^3). Colourless crystals formed on storage at −30 °C. The solids were collected by filtration, washed with hexanes and dried *in vacuo*. Yield: 2.80 g, 46%. The unit cell was confirmed as that of compound **2** by X-ray diffraction.

Preparation of $[\{Ti(OMe)_3(tmhd)\}_2]$ **4**

2,2,6,6-Tetramethylheptane-3,5-dione (2.30 cm^3, 11.00 mmol) was added slowly by syringe to a clear solution of $Ti(OMe)_4$ (1.89 g, 11.0 mmol) in toluene (30 cm^3) at 30 °C. The resulting clear solution was stirred for 2 h before removal of the solvents *in vacuo*. The crude resinous product (3.58 g, 100%) was taken up in hexanes (10 cm^3) to give a cloudy solution, from which a finely divided white precipitate (0.76 g in total) was removed by filtration. Treatment of the solution with hexanes led to no further precipitation. The solvents were removed to yield a cloudy oil 2.90 g, 81%. Crystals suitable for X-ray diffraction were obtained by recrystallisation from hexanes (*ca.* 12 cm^3) at −30 °C. A sample was removed from the mother liquor and dried *in vacuo*. Found: C, 52.92; H, 9.14. $C_{28}H_{56}O_{10}Ti_2$ requires C, 51.86; H, 8.70%. δ_C ($C_6D_5CD_3$, 50.32 MHz) 201.5, 198.7, 93.7, 93.5, 64.3, 41.6 and 29.2.

Preparation of $[\{Ti(OEt)_3(tmhd)\}_2]$ **5**

2,2,6,6-Tetramethylheptane-3,5-dione (3.45 cm^3, 16.50 mmol) was added slowly by syringe to a commercial solution of $Ti(OEt)_4$ in heptanes (Tilcom

ETOL) (7.67 g, 16.5 mmol of Ti). The exothermic reaction produced a pale yellow solution. Reduction of the solvent volume *in vacuo* after 15 min resulted in rapid crystallisation of a colourless solid. The mixture was warmed to 60°C to dissolve the solids and the solution was left to cool to ambient temperature. The resulting crystalline solid was collected by filtration, washed with hexanes (2 × 5 cm^3) and dried *in vacuo*. Yield 3.75 g, 62%. δ_H ($C_6D_5CD_3$, 200 MHz) 6.13, 6.08, 6.06 (singlets, 2H), 4.99 (s), 4.79 (q), 4.57 (br) (total 12H), 1.64 (br), 1.47 (br), 1.27 (s) (total 54H). δ_C ($C_6D_5CD_3$, 50.32 MHz) 201.4, 198.3, 92.9, 72.2, 68.79, 41.2, 29.2, 19.9 and 19.8.

Preparation of $[\{Ti(OPr^n)_3(tmhd)\}_2]$ **6**

2,2,6,6-Tetramethylheptane-3,5-dione (4.54 cm^3, 21.75 mmol) was added dropwise to $Ti(OPr^n)_4$ (6.18 g, 21.75 mmol) in hexanes (20 cm^3). The solvent volume was reduced under reduced pressure until crystallisation commenced. The product was collected by filtration, washed with cold hexanes (20 cm^3, acetone/liquid N_2 slush bath) and dried *in vacuo*. Crystals suitable for X-ray diffraction were obtained by recrystallisation from hexanes (ca 10 cm^3). Yield: 4.30 g, 48%. Found: C, 59.23; H, 10.39. $C_{40}H_{80}O_{10}Ti_2$ requires C, 58.82; H, 9.87%. δ_H ($C_6D_5CD_3$, 200 MHz) 6.13, 6.08, 6.05 (singlets, 2H), 5.04 (br), 4.88 (br), 4.72 (t), 4.48 (br) (total 12H), 2.06 (br), 1.85 (sext), 1.65 (br) (total 12H), 1.51, 1.47, 1.42, 1.27 (singlets, 36H), 1.20 (m, 18H). δ_C ($C_6D_5CD_3$, 50.32 MHz) 202.4, 201.2, 200.1, 93.4, 93.3, 93.1, 79.0, 78.5, 78.0, 74.8, 42.3, 41.5, 41.2, 29.3, 28.7, 28.1, 27.6, 27.5, 27.1, 11.9, 11.7 and 11.2.

Preparation of $[\{Ti(OPr^i)_3(tmhd)\}_2]$ **7**

2,2,6,6-Tetramethylheptane-3,5-dione (3.40 cm^3, 16.70 mmol) was added dropwise to $Ti(OPr^i)_4$ (4.66 g, 16.37 mmol) in hexanes (10 cm^3) at 0°C. A pale yellow colour developed. A colourless crystalline solid was obtained at −30°C after reduction of the solvent volume. The product was collected by filtration, washed with ice-cold hexanes (20 cm^3) and dried *in vacuo*. Yield: 2.36 g, 35%. Crystals suitable for X-ray diffraction were obtained by recrystallisation of a portion of the crude product from hexanes at −5°C. Found: C, 59.41; H, 10.45. $C_{40}H_{80}O_{10}Ti_2$ requires C, 58.82; H, 9.87%. δ_H ($C_6D_5CD_3$, 200 MHz) 6.04 (s, 2H), 5.12 (sept, 2H), 4.73 (sept, 4H), 1.54 (d, 6H), 1.48 (s, 18H), 1.46 (d, 30H), 1.28 (s, 18H). δ_C ($C_6D_5CD_3$, 50.32 MHz) 201.2, 198.0, 93.08, 78.3, 77.2, 41.6, 41.5, 29.3, 29.1, 27.6 and 26.5.

Attempted preparation of $[Ti(OBu^t)_3(tmhd)]$ **8**

2,2,6,6-Tetramethylheptane-3,5-dione (1.46 cm^3, 7.00 mmol) was added to $Ti(OBu^t)_4$ (2.06 g, 6.06 mmol) in hexanes (10 cm^3). Colourless prisms were obtained from the colourless solution at −30°C. These were collected by filtration, washed with 2 × 5 cm^3 hexanes and dried *in vacuo*. Yield: 1.03 g. IR 1600 m, 1570 m, 1530 m, 1500 m, 1355 s, 1290 w, 1250 w, 1230 m, 1200 m, 1180 m, 1145 m, 1040 m, 1010 s, 970 w, 875 m, 790 m, 760 w, 740 w, 630 w, 585 m, 505 w, 495 w, 435 w and 375 w cm^{-1}. δ_C ($C_6D_5CD_3$, 50.32 MHz) 200.7, 197.1, 92.51, 83.8, 41.7, 41.4, 32.6, 29.3 and 29.1.

Preparation of $[Ti(OMe)_2(acac)_2]$ **9**

Pentane-2,4-dione (3.98 cm^3, 38.73 mmol) was added slowly by syringe to a suspension of $[\{Ti(OMe)_4\}_4]$ (3.33 g, 4.84 mmol) in toluene (30 cm^3) to give a pale yellow solution. Filtration and removal of the solvents *in vacuo* yielded a yellow oil which subsequently crystallised. Yield: 5.68 g, 95%. δ_H ($C_6D_5CD_3$, 200 MHz) 5.45 (s, 2H), 4.49 (s, 6H), 1.95 (s, 6H), 1.84 (s, 6H).

Preparation of $[Ti(OEt)_2(acac)_2]$ **10**

Pentane-2,4-dione (5.03 cm^3, 48.99 mmol) was added slowly by syringe to a commercial solution of $Ti(OEt)_4$ in heptanes (Tilcom ETOL) (11.38 g, 24.50 mmol of Ti). A pale yellow colour developed. Removal of the solvents *in vacuo* gave a quantitative yield of an orange oil which subsequently crystallised. δ_H ($C_6D_5CD_3$, 200 MHz) 5.50 (s, 2H), 4.80 (q, 4H), 1.98 (s, 6H), 1.89 (s, 6H), 1.46 (t, 6H). δ_C ($C_6D_5CD_3$, 50.32 MHz) 192.0, 188.5, 103.6, 73.1, 27.5, 26.8 and 19.7.

Preparation of $[Ti(OPr^i)_2(acac)_2]$ **11**

Pentane-2,4-dione (8.06 cm^3, 78.5 mmol) was added slowly by syringe to a solution of $Ti(OPr^i)_4$ (10.93 g, 38.4 mmol) in hexanes (10 cm^3) to give an orange solution. The solution was cooled to −30°C for 2 weeks to give **11** as colourless to pale yellow needles. These were removed by filtration and dried *in vacuo*. Yield: 1.82 g, 13%. δ_H ($C_6D_5CD_3$, 200 MHz) 5.47 (s, 2H), 5.19 (sept, 2H), 1.97 (s, 6H), 1.88 (s, 6H), 1.54 (d, 6H), 1.48 (d, 6H).

Preparation of $[Ti(OMe)_2(tmhd)_2]$ **12**

2,2,6,6-Tetramethylheptane-3,5-dione (6.20 cm^3, 30.13 mmol) was added slowly by syringe to a solution of $Ti(OMe)_4$ (2.55 g, 14.8 mmol) in toluene (30 cm^3) at 40°C. A pale yellow colour developed. A colourless microcrystalline solid was obtained by cooling the solution to −30°C after reducing its volume *in vacuo*. The product was collected by filtration, washed with cold hexanes (acetone/liquid N_2 slush bath) and dried *in vacuo*. Yield: 3.59 g, 75%. δ_H ($C_6D_5CD_3$, 200 MHz)

6.07 (s, 2H), 4.50 (s, 6H), 1.42 (s, 18H), 1.26 (s, 18H). δ_C ($C_6D_5CD_3$, 50.32 MHz) 201.5, 198.7, 93.7, 64.3, 41.3 and 29.2.

Preparation of $[Ti(OEt)_2(tmhd)_2]$ **13**

2,2,6,6-Tetramethylheptane-3,5-dione (4.51 cm^3, 23.85 mmol) was added slowly by syringe to a commercial solution of $Ti(OEt)_4$ in heptanes (Tilcom ETOL) (5.54 g, 11.90 mmol of Ti) to give a pale yellow solution. Removal of the solvents *in vacuo* after 15 min yielded a viscous, pale yellow oil. A pale brown waxy solid was obtained by extraction with hexanes and cooling the solution to −30°C. Yield: 3.99 g, 99%. δ_H ($C_6D_5CD_3$, 200 MHz) 6.04 (s, 2H), 4.75 (q, 4H), 1.44 (t, 6H), 1.43 (s, 18H), 1.25 (s, 18H). δ_C ($C_6D_5CD_3$, 50.32 MHz) 201.4, 198.3, 93.4, 72.1, 41.6, 41.3, 29.2, 29.1 and 19.9.

Preparation of $[Ti(OPr^n)_2(tmhd)_2]$ **14**

2,2,6,6-Tetramethylheptane-3,5-dione (2.83 cm^3, 13.57 mmol) was added slowly by syringe to a solution of $Ti(OPr^i)_4$ (1.81 g, 6.36 mmol) in hexanes (10 cm^3). The resulting colourless solution was heated to 54°C and stirred for 30 min before removal of the solvent under reduced pressure until crystallisation commenced. Hexanes (5 cm^3) were added and the solution was cooled to −30°C. The colourless crystalline solid was collected by filtration, washed with ice-cold hexanes (5 cm^3) and dried *in vacuo*. δ_H ($C_6D_5CD_3$, 200 MHz) 6.05 (s, 2H), 4.73 (t, 4H), 1.84 (sext, 4H), 1.46 (s, 18H), 1.28 (s, 18H), 1.20 (t, 6H).

Preparation of $[Ti(OPr^i)_2(tmhd)_2]$ **15**

2,2,6,6-Tetramethylheptane-3,5-dione (5.77 cm^3, 27.65 mmol) was added slowly by syringe to a water-cooled solution of $Ti(OPr^i)_4$ (3.93 g, 13.83 mmol) in hexanes (10 cm^3). The resulting pink solution was stirred for 20 min then solvent was removed *in vacuo* until crystallisation commenced. The solution was cooled to −30°C overnight to give a colourless solid which was collected by filtration, washed with cold hexanes (acetone/CO_2 slush bath) and dried *in vacuo*. Yield: 1.91 g, 26%. δ_H ($C_6D_5CD_3$, 200 MHz) 6.04 (s, 2H), 5.12 (sept, 2H), 1.47 (s, 18H), 1.28 (s, 18H), 1.54 (d, 6H), 1.46 (d, 6H). δ_C ($C_6D_5CD_3$, 50.32 MHz) 201.2, 198.0, 93.1, 78.3, 41.7, 41.7, 29.3, 29.1, 26.7 and 26.5.

X-ray crystallography

Crystal data for all six structures are given in Table 1 together with other information on the structure determination procedures. Crystals were examined at 160 K on a Siemens SMART CCD diffractometer with Mo–K_α radiation ($\lambda = 0.71073$ Å); cell parameters were refined from all strong reflections, and intensities were integrated from narrow frames (0.3° in ω) covering more than a hemisphere of data in each case. Absorption corrections were based on multiple and symmetry-equivalent reflections.

The structures were determined variously by heavy-atom and direct methods, and refined by full-matrix least squares on F^2 values for all data, with weighting $w^{-1} = \sigma^2(F_o^2) + (aP) + (bP)$, where $P = (F_o^2 + 2F_c^2)/3$. Anisotropic displacement parameters were refined for non-hydrogen atoms, and isotropic hydrogen atoms were included with riding model constraints. An isotropic extinction parameter x was refined, whereby F_c is multiplied by $(1 + 0.001xF_c^2\lambda^3/\sin 2\theta)^{-1/4}$. Residuals are defined as $Rw = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$ for all data, conventional $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ for reflections having $F_o^2 > 2\sigma(F_o^2)$. The structure of **3** shows minor disorder in two of the three Pr^i groups, which was resolved and refined with restraints. The structure of **6** has two independent molecules, both of which are extremely disordered, and only a relatively poor refinement could be achieved with many restraints and constraints.

Programs were standard Siemens data collection (SMART) and integration (SAINT) software [7], SHELXTL [8] and local programs. Atomic coordinates, displacement parameters and full geometry have been deposited at the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Solid-state structures

Colourless crystalline compounds $[\{Ti(OR)_3(dik)\}_2]$ were prepared from $Ti(OR)_4$ and one equivalent of dikH in appropriate solvents (Scheme 1). No solid products were obtained from the 1:1 reaction between $Ti(OBu^t)_4$ and acacH, and only crystalline **16** was isolated in the attempted preparation of **8** from $Ti(OBu^t)_4$ and tmhdH. Where crystalline products were obtained from oils, complete separation from oily material was often difficult, resulting in micro-

analysis results which deviated slightly from expected values.

Crystals of **1–4, 6** and **7** were suitable for X-ray diffraction studies and the structures are shown in Figs 1–6. Selected bond lengths and angles are collected in Table 2. All of these compounds have binuclear, centrosymmetric structures and the asymmetic alkoxide bridges reflect the stronger *trans* influence of the terminal alkoxides compared with the β-diketonates. The greatest difference between the two bridging bond distances occurs in the isopropoxides, which may be related to the much smaller amount (if any) of the

dimeric structure observed in the ^{1}H NMR spectra of these compounds by comparison with the primary alkoxide analogues, as discussed in the next section. The bond lengths are generally similar to those in the monomeric **11**, although the angles between terminal alkoxides and the angles subtended by the acac ligands are smaller than the analogous angles in **11** [99.8° and 83.59° (average) respectively] [9]. These results demonstrate that the steric bulk of the isopropoxide ligand is not sufficient to prevent association of the five-coordinate fragments Ti(OPr^i)$_3$(dik) by the formation of alkoxide bridges but, as discussed below, it does influence the lability of the dimeric species. Solid-state IR data for the binuclear alkoxides **1–7** (from mineral oil mulls) are collected in Table 3 for comparison with those for the mononuclear bis-diketonates **9–15**, which are given in Table 4.

A related binuclear structure has been reported for the chloro complex [{TiCl$_3$(acac)}$_2$], which undergoes ligand redistribution in solution to give $TiCl_4$ and [TiCl$_2$(acac)$_2$] [10], and similar behaviour has been proposed for the alkoxide analogues [11]. In view of the ambiguity associated with previous descriptions of the monosubstituted compounds [Ti(OR)$_3$(dik)] in the literature, we undertook a detailed NMR investigation of the solution properties of the structurally characterised dimers [{Ti(OR)$_3$(dik)}$_2$], and the results are described below.

Solution studies

In the ^{1}H NMR spectra of the isopropoxide complexes **3** and **7**, the major peaks present are due to a mixture of Ti(OPr^i)$_4$ and the bis-diketonate complexes **11** and **15** respectively, indicating that ligand redistribution occurs readily in solutions of the substituted secondary alkoxide complexes [{Ti(OPr^i)$_3$(dik)}$_2$], and that the equilibrium shown in Scheme 1 lies well towards the monomeric species at concentrations used to obtain the NMR spectra. Figure 7 shows the ^{1}H NMR spectrum of a solution of **3** at 273 K. The broadened methine septet and methyl doublet are due to the isopropoxide ligands of Ti(OPr^i)$_4$, while the sharp methine signal and the two sets of sharp doublets are due to the diastereotopic isopropoxide groups of the bis-acetylacetonate **11**. The remaining major singlets are due to the methine proton and the non-equivalent methyl groups of the acac ligands in **11**. The dimeric structure of **3** (Fig. 3) would be expected to give an ^{1}H NMR spectrum containing three methine septets and six methyl doublets due to the three diastereotopic isopropoxide groups, in addition to a singlet due to the methine peak of acac and two singlets due to the non-equivalent methyl groups of the acac ligands. Given the dynamic nature of the dimeric methoxide structures discussed below, the isopropoxide methine peaks would be expected to be significantly broadened, while rapidly exchanging acac methyl groups would give rise to a singlet in the ^{1}H NMR spectrum. There are small peaks in the ^{1}H NMR spectrum of **3** which may be due to the dimeric structure, (any associated isopropoxide methine peaks must be broadened into the baseline), although such peaks are even less evident in the ^{1}H NMR spectrum of **7**.

In the ^{1}H NMR spectra of products from attempted preparations of the tertiary alkoxide derivatives [Ti(OBu^t)$_3$(acac)] and the tmhd analogue **8**, only peaks due to Ti(OBu^t)$_4$ and [Ti(OBu^t)$_2$(dik)$_2$] are present (Fig. 8). This suggests that with bulky alkoxide groups either the equilibrium shown in Scheme 1 lies

even further towards the monomeric species and the concentration of dimer is too low to be observed by ^{1}H NMR, or the monosubstituted compounds are not formed. In this regard, it should be noted that the product from the attempted synthesis of $Ti(OBu^t)_3$(acac) was a liquid, and attempts to crystallise **8** from the 1 : 1 reaction between $Ti(OBu^t)_4$ and tmhdH yielded only the bis-diketonate **16**.

[a] Nujol mulls on CsI plates.

The ^{1}H NMR spectra of **1** and **4** show that ligand redistribution also occurs upon dissolution of these methoxide derivatives, but now the dimeric solid-state structures shown in Figs 1 and 4 can be identified as major components. Variable-temperature studies (Figs 9 and 10) reveal similar solution behaviour for the two compounds and also provide some insight into the dynamic nature of the dimeric structures in solution. At 303 K, the methoxide regions (between 4.0 and 4.7 ppm) of the ^{1}H NMR spectra contain one sharp peak due to the bis-diketonate complexes **9** or **12** in addition to two broad resonances and other

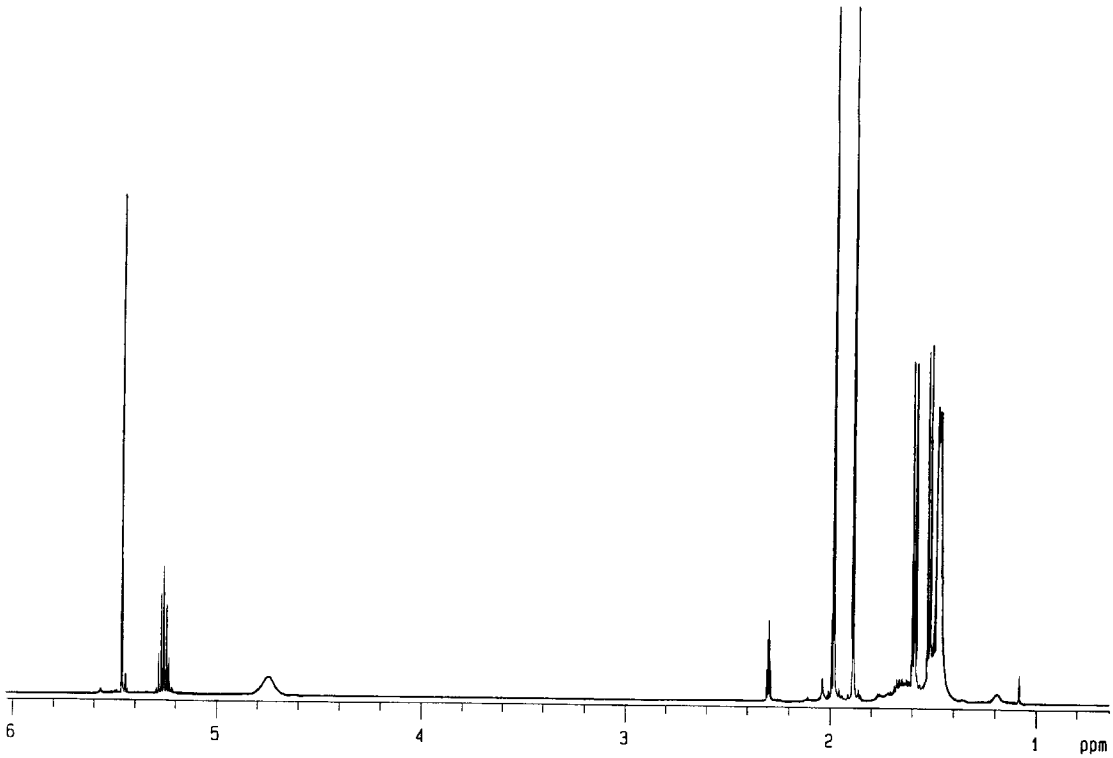

Fig. 7. ^{1}H NMR spectrum ($C_6D_5CD_3$, 273 K) of $[\{Ti(OPr^i)_3(acac)\}_2]$ (**3**).

minor peaks. At this temperature, the two broader, upfield peaks due to the methyl (1.8–2.1 ppm) or *tert*-butyl (1.2–1.6 ppm) groups of the diketonate ligands are those of **9** or **12** respectively, while the slightly lower-field singlet in each spectrum is due to rapidly exchanging alkyl substituents of the diketonate ligands in dimeric **1** or **4**. As the sample is cooled, the signals due to diketonate alkyl substituents in **9** and **12** sharpen, while the singlet due to methyl or *tert*-butyl groups in dimeric **1** or **4** broadens then splits into two singlets which sharpen down to 223 K. At 223 K the three methoxide resonances of dimeric **1** (Fig. 1) or **4** (Fig. 4) are clearly visible, in addition to the singlet due to **9** or **12** and other minor peaks, some of which are presumably due to $Ti(OMe)_4$. The ^{1}H NMR spectrum of $[\{Ti(OMe)_4\}_4]$ at 304 K contains four peaks at 4.16, 4.49, 4.50 and 4.65 ppm in the ratio 6:4:4:2, and is consistent with the structure shown in Fig. 11 if the terminal methoxide peaks are accidently equivalent or rapidly exchanging. These chemical shifts are somewhat temperature dependent, but peaks in the low-temperature ^{1}H NMR spectrum of **4** at 4.22, 4.46, 4.59 and 4.74 ppm can be assigned to $[\{Ti(OMe)_4\}_4]$ and similar peaks are observed in the low-temperature spectrum of **1**. The spectra in Figs 9 and 10 also show that the lower-field terminal methoxide peaks broaden and coalesce while the peak due to the bridging methoxide is still visible. This indicates that exchange between the two types of terminal methoxide in the dimers **1** and **4** is more rapid than terminal-bridging methoxide exchange, and possible mechanisms are discussed in more detail below.

Although the ethoxide and *n*-propoxide resonances in the variable-temperature ^{1}H NMR spectra of **2** and **6** respectively are complex and difficult to assign, the *β*-diketonate resonances behave in a similar fashion to those of **1** and **4**, suggesting that all of these primary alkoxide derivatives have similar solution dynamics. These NMR studies therefore demonstrate that the edge-shared bioctahedral structures of dimeric primary and secondary alkoxide complexes $[\{Ti(OR)_3(dik)\}_2]$ are dynamic in solution, and that ligand redistribution occurs when these compounds dissolve to give equilibrium mixtures of $Ti(OR)_4$, $[Ti(OR)_2(acac)_2]$ and $[\{Ti(OR)_3(dik)\}_2]$. To confirm this we synthesised **3** from a mixture of $Ti(OPr^i)_4$ and $[Ti(OPr^i)_2(acac)_2]$, and similarly prepared **1** by treating a mixture of $[\{Ti(OMe)_4\}_4]$ and $[Ti(OPr^i)_2(acac)_2]$ with methanol. These transformations must involve the transfer of a *β*-diketonate ligand from one titanium to another, presumably via a binuclear intermediate, and this process must be associated with the dynamic solution behaviour of the symmetric dimers $[\{Ti(OR-)_3(dik)\}_2]$. Scheme 2 shows a proposed mechanism for the ligand exchange processes observed in the ^{1}H NMR studies and for *β*-diketonate and alkoxide ligand transfer. The rapid exchange processes observed in mononuclear $[Ti(OR)_2(dik)_2]$ **V** have previously been ascribed to a fluxional twist mechanism

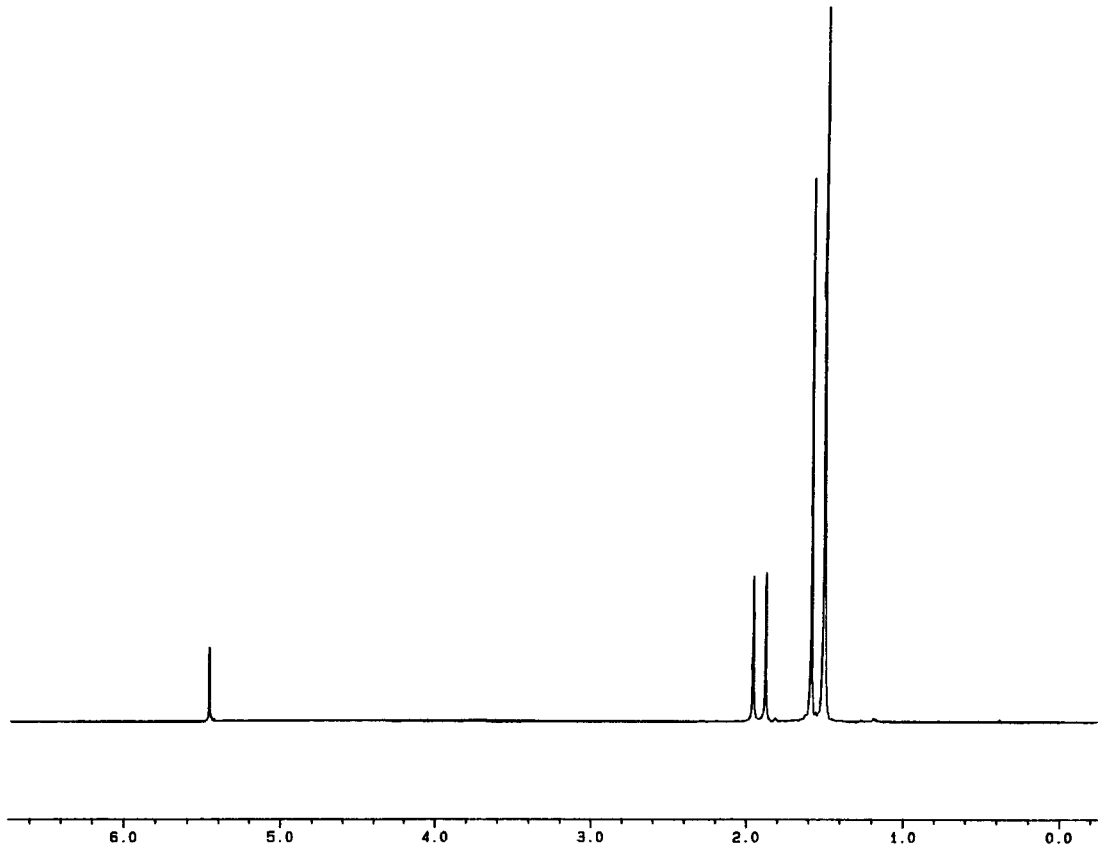

Fig. 8. ^{1}H NMR spectrum ($C_6D_5CD_3$, 297 K) of the product from the 1 : 1 reaction between $Ti(OBu^t)_4$ and acacH after removal of the volatiles.

[4] and, since the alkyl substituents of the diketonate ligands in $[\{Ti(OR)_3(dik)\}_2]$ **I** exchange more rapidly than those in **V**, it seems plausible to propose a similar mechanism for dimeric **I**. Such a process would exchange the alkyl groups of the diketonate and interchange the terminal alkoxide ligands. Cleavage of the longer bridging bond *trans* to a terminal alkoxide would generate 5- and 6-coordinate metal centres as in **II**. Berry pseudo-rotation at the 5-coordinate centre provides another mechanism for exchange of the terminal alkoxides and of the alkyl substituents on the β-diketonate, while rotation of the 6-coordinate fragment would either exchange terminal and bridging alkoxides, as in **III**, or bring the β-diketonate into a bridging position as in **IV**. Dissociation of **IV** would then produce $Ti(OR)_4$ and $[Ti(OR)_2(dik)_2]$. Studies in coordinating solvents are now in progress to provide further information about the mechanistic aspects of these ligand exchange processes.

CONCLUSIONS

Previous solution studies of $Ti(OR)_3(dik)$ complexes have been somewhat ambiguous. Molecular weight determinations on isolated solids gave values which were concentration dependent and smaller than those expected for binuclear species [2(b)], and results from EXAFS studies of $Ti(OR)_4$/acac systems (R = Pr^i and Et) were interpreted in terms of monomeric, five-coordinate $[Ti(OR)_3(acac)]$ for R = Pr^i, or a mixture of monomeric $[Ti(OR)_3(acac)]$ and dimeric $[\{Ti(OR)_3(acac)\}_2]$ for R = Et [5]. Our results demonstrate conclusively that centrosymmetric, binuclear $[\{Ti(OR)_3(dik)\}_2]$ can be isolated in the solid state for primary and secondary alkoxide derivatives, and that disproportionation occurs in solution to give $Ti(OR)_4$ and $[Ti(OR)_2(dik)_2]$. For R = Pr^i, disproportionation is essentially complete, but for primary alkoxides the dimeric species are present in solutions of appropriate concentrations for NMR studies (*ca.* 0.2 M). Based on the ^1H NMR results, mechanisms can be proposed to account for the fluxional and dynamic processes associated with ligand exchange and ligand transfer. No conclusive evidence has yet been obtained as to the nature of the compounds obtained from 1 : 1 reactions between $Ti(OBu^t)_4$ and acacH or tmhdH, so it is still unclear whether $Ti(OBu^t)_3(dik)$ can be prepared and, if so, whether these compounds are mononuclear or binuclear.

These results illustrate the complex nature of sol–gel precursor solutions generated from 1 : 1 reactions between $Ti(OR)_4$ and dikH and should help in understanding the subsequent hydrolysis and aggregation processes. We will describe the results of our hydrolysis studies on such systems in a forthcoming paper.

Chromium(VI) nitrido complexes: reactions with Brønsted acids and synthesis of organometallic derivatives

Aaron L. Odom and Christopher C. Cummins*

Department of Chemistry, Massachusetts Institute of Technology, Cambridge, MA 02139, U.S.A.

(Received 28 May 1997; accepted 26 September, 1997)

Abstract—The chromium(VI) nitrido complex $NCr(N\text{-}i\text{-}Pr_2)_3$ was prepared in 67% yield by vanadium(III)-mediated deoxygenation of coordinated nitric oxide. The iodide complex $NCr(I)(N\text{-}i\text{-}Pr_2)_2$, prepared by treatment of $NCr(N\text{-}i\text{-}Pr_2)_3$ with lutidinium iodide, was converted to $NCr(CH_2SiPhMe_2)(N\text{-}i\text{-}Pr_2)_2$ upon treatment with $Mg(CH_2SiPhMe_2)_2$. $NCr(N\text{-}i\text{-}Pr_2)_3$ reacts with 1 equiv. of phenol or $HOC(CF_3)_2Me$ to produce the mono-alkoxide complexes $NCr(OPh)(N\text{-}i\text{-}Pr_2)_2$ or $NCr(OC(CF_3)_2Me)(N\text{-}i\text{-}Pr_2)_2$ in respective yields of 89 and 77%. Spin saturation transfer measurements performed on $NCr(OC(CF_3)_2Me)(N\text{-}i\text{-}Pr_2)_2$ are indicative of $Cr—N_{amido}$ bond rotation with a first-order rate constant of ca 13 s^{-1}. Addition of an excess of $HOC(CF_3)_2Me$ to $NCr(N\text{-}i\text{-}Pr_2)_3$ produced the mono-amido complex $NCr(OC(CF_3)_2Me)_2(N\text{-}i\text{-}Pr_2)$ in 86% yield. Subjecting $NCr(N\text{-}i\text{-}Pr_2)_3$ to refluxing HS-*t*-Bu provided $NCr(S\text{-}t\text{-}Bu)_2(N\text{-}i\text{-}Pr_2)$ in 73% yield. Black $NCr(S\text{-}t\text{-}Bu)_2(N\text{-}i\text{-}Pr_2)$ evinces a monomeric structure in the solid state, according to single-crystal X-ray diffraction data, with a $Cr—N_{nitrido}$ distance of 1.543(6) Å. Bis-thiolate $NCr(S\text{-}t\text{-}Bu)_2(N\text{-}i\text{-}Pr_2)$ forms an adduct with $Cu(Et_2dtc)$, $NCr(N\text{-}i\text{-}Pr_2)[(\mu\text{-}S\text{-}t\text{-}Bu)_2Cu(Et_2dtc)]$, which was also characterized by X-ray diffraction. Reaction of $NCr(N\text{-}i\text{-}Pr_2)_3$ with two equiv. of phenol gave $NCr(OPh)_2(N\text{-}i\text{-}Pr_2)$ in 81% yield. Dialkyl $NCr(CH_2SiMe_3)_2(N\text{-}i\text{-}Pr_2)$ was obtained from $NCr(OPh)_2(N\text{-}i\text{-}Pr_2)$ upon treatment with $LiCH_2SiMe_3$ in 57% yield. Insertion of *tert*-butylisonitrile was observed upon treatment of $NCr(CH_2SiMe_3)_2(N\text{-}i\text{-}Pr_2)$ with excess *t*-BuNC to give $NCr(C(=N\text{-}t\text{-}Bu)CH_2SiMe_3)(CH_2SiMe_3)(N\text{-}i\text{-}Pr_2)$, which was isolated in 70% yield. The latter η^2-iminoacyl compound was characterized by X-ray diffraction, revealing a pseudo-square pyramidal ligand arrangement.

Keywords: chromium; nitrido; iminoacyl; protonolysis; amido; nitrosyl.

Recent developments in the activation of small molecules have led to the discovery of new routes to terminal nitrido complexes. For example, three-coordinate $Mo(N[R]Ar)_3$, where R is $C(CD_3)_2(CH_3)$ and Ar is 3,5-$C_6H_3Me_2$, was found to react with dinitrogen to form $NMo(N[R]Ar)_3$ via a linear μ-dinitrogen dinuclear complex intermediate [1]. In addition, the cleavage of nitric oxide to nitride and oxo functionalities by two metal centers was achieved. Bradley's nitrosyl $ONCr(N\text{-}i\text{-}Pr_2)_3$ [2], in particular, was found to serve as an oxo donor to $V(Mes)_3(THF)$ [3,4].

Much of the interest in reactions that produce terminal nitrido complexes stems from the possibility of producing useful chemical feedstocks like ammonia from strategic starting materials. Reactions that convert dinitrogen or NO_x gases to nitrido complexes could represent a useful first step toward achieving this goal. Also important in this context is to elucidate the chemistry of the resulting nitrido complexes. In a study conducted by Chisholm and co-workers [5] reactions of $NM(O\text{-}t\text{-}Bu)_3$, where M = Mo and W, with excess *i*-PrOH were investigated. Treatment of $NMo(O\text{-}t\text{-}Bu)_3$ with isopropanol led to exclusive alkoxide substitution given $NMo(O\text{-}i\text{-}Pr)_3$. The tungsten derivative $NW(O\text{-}t\text{-}Bu)_3$, in contrast, was exhaustively attacked by isopropanol giving $W(O\text{-}i\text{-}Pr)_6$.

In addition to chemistry where the nitrido nitrogen is an active participant, there is also an extensive chemistry in which a nitrido nitrogen acts as a spectator ligand [6–8]. For example, molybdenum(VI) nitrides can be synthesized with soft ligands such as thiolates [9] or hard ligands such as amides [1,8,10].

* Author to whom correspondence should be addressed.

Molybdenum organometallic complexes also have been synthesized [11] including the σ organometallic complex NMo(neopentyl)$_3$ [7]. Chromium(VI) derivatives with this large variety of ligands offer an exciting new field of study [12].

RESULTS AND DISCUSSION

Synthesis of NCr(N-*i*-Pr$_2$)$_3$ (3) *and nitric oxide cleavage*

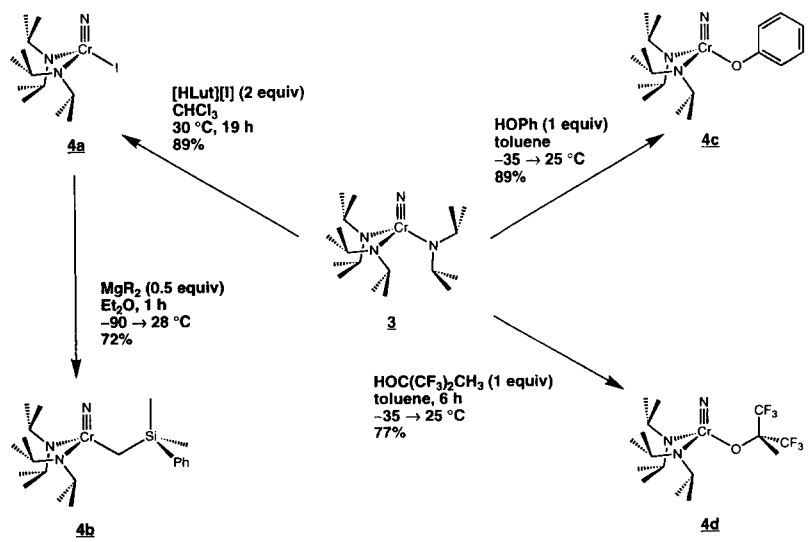
Bradley and co-workers synthesized Cr(N-*i*-Pr$_2$)$_3$ (**1**) by addition of 3 equiv. of LiN-*i*-Pr$_2$ to ethereal CrCl$_3$ [13]. Treatment of **1** with nitric oxide results in a rapid reaction to produce orange ONCr(N-*i*-Pr$_2$)$_3$ (**2**) [2]. The π acidic nitrosyl ligand induces a diamagnetic $\{ONCr\}^4$ low-spin electronic configuration, which results in a low N—O stretching frequency of 1643 cm^{-1}. Deoxygenation of **2** by two equiv. of V(mesityl)$_3$(THF)[3] gave rise to NCr(N-*i*-Pr$_2$)$_3$ (**3**) and OV(mesityl)$_3$, but the latter is trapped by an additional equiv. of V(mesityl)$_3$(THF) to form O[V(mesityl)$_3$]$_2$ [14]. The nitrido complex was easily separated from the vanadium(IV) μ-oxo species by pentane extraction [4].

The physical properties of beet-colored **3** are significantly different from those of **2** and **1**, consistent with the large difference in formal oxidation state. The solid state structure of **3** as determined by X-ray diffraction revealed an average Cr—N$_{amido}$ bond length that is ~0.3 Å shorter than found in **1**. The Cr—N$_{nitrido}$ distance of 1.544(3) Å in **3** is ~0.15 Å shorter than Cr—N$_{nitrosyl}$ bonds in ONCr[N(SiMe$_3$)$_2$]$_3$ and ONCr(I)(N[R]Ar$_F$)$_2$, where R = C(CH$_3$)(CD$_3$)$_2$ and Ar$_F$ = 2,5-C$_6$H$_3$FMe [15]. In addition, the ^{1}H NMR spectrum of **3** exhibits broad resonances for the amido ligands at room temperature. The broad nature of the peaks is attributed to hindered rotation around the Cr—N$_{amido}$ bonds and contrasts with the narrow line widths found in the ^{1}H NMR spectrum of ONCr(N-*i*-Pr$_2$)$_3$ (**2**).

Bis-amido chromium(VI) complexes (scheme 1)

(*i*) *Synthesis of* NCr(I)(N-*i*-Pr$_2$)$_2$(**4a**). Lutidinium iodide is conveniently synthesized in anhydrous form by the reaction of 2,6-lutidine, *tert*-butyl alcohol and ISiMe$_3$ in dry ether. Addition of 2.5 equiv. of lutidinium iodide to 1 equiv. of **3** initiated a color change of the reaction mixture to orange-red. Protolytic amido replacement was found to have occurred giving NCr(I)(N-*i*-Pr$_2$)$_2$ (**4a**) [16]. The lutidine by-product was easily separated by recrystallization. An attempt to produce NCr(I)$_2$(N-*i*-Pr$_2$) under forcing conditions only resulted in an intractable product and starting materials.

The ^{1}H NMR spectrum of **4a** is indicative of hindered rotation [17,26] around the Cr—N$_{amido}$ bonds. Four doublets are observed in the spectrum. These correspond to the diastereotopic methyl hydrogens, which are differentiated further by being syn or anti with respect to the nitrido nitrogen. Two septets are also observed in the spectrum, septets which correspond to methine hydrogens located syn and anti with respect to the nitrido group. A dramatic slowing of the Cr—N$_{amido}$ rotation rate in **4a** versus **3** is explicable in terms of a qualitative molecular orbital picture for the two molecules [18]. In NCr(N-*i*-Pr$_2$)$_3$ (**3**), the chromium has a degenerate set of two orbitals available for π bonding to the three amido substituents. The three amido π donor orbitals must compete for



Scheme 1.

the two metal π acceptor orbitals, resulting in a bond order for the amido substituents of one and two-thirds. The iodide complex **4a** has only two amides to donate into the two metal orbitals with proper symmetry for π bonding. Therefore, the amido substituents in NCr(I)(N-*i*-Pr_2)$_2$ may form two double bonds (formally) to the chromium center. The hindered rotation observed for **4a** is even more dramatic in light of the steric difference between NCr(I)(N-*i*-Pr_2)$_2$ (**4a**) and NCr(N-*i*-Pr_2)$_3$ (**3**). The iodide complex **4a,** which presumably is less sterically congested, exhibits characteristics indicative of slower amido rotation.

(*ii*) *Synthesis and thermal decomposition of* NCr($CH_2SiPhMe_2$)(N-*i*-Pr_2)$_2$ (**4b**). A nitrido alkyl complex NCr($CH_2SiPhMe_2$)(N-*i*-Pr_2)$_2$ (**4b**) was produced by addition of Mg($CH_2SiPhMe_2$)$_2$ to a cold solution of **4a** in ether [16]. NCr($CH_2SiPhMe_2$)(N-*i*-Pr_2)$_2$ **4b** is a rare example of a chromium(VI) organometallic complex [19]. The σ alkyl complex **4b** also is a rare example of an alkyl nitrido complex [7,11]. Orange NCr($CH_2SiPhMe_2$)(N-*i*-Pr_2)$_2$ (**4b**) was isolated in 72% recrystallized yield and has a ^{1}H NMR spectrum with four doublets and two septets assignable to the amido hydrogens.

The alkyl-nitrido complex **4b** is stable in solution at room temperature for hours without appreciable decomposition, but the compound decomposes at 60°C with a first order rate constant of $(2.4 \pm 0.1) \times 10^{-4}$ s^{-1} [16]. The data for the decomposition are consistent with β-hydrogen abstraction [20] from one of the amido substituents by the departing alkyl. The products included $PhSiMe_3$ (GC/MS and ^{1}H NMR), the imine Me_2C=N-*i*-Pr (tentative ^{1}H NMR identification), and diisopropylamine (^{1}H NMR). We have not characterized a black solid (possibly CrN [21]) produced during the thermolysis.

(*iii*) *Synthesis of* NCr(OPh)(N-*i*-Pr_2)$_2$ (**4c**). Addition of one equiv. of phenol to **3** in toluene caused the solution to change color to orange over a few minutes. The phenoxide NCr(OPh)(N-*i*-Pr_2)$_2$ (**4c**) product, which was purified by recrystallization from ether, was isolated in 88% yield.

Phenoxide **4c** is stable for long durations in solution at room temperature, and exhibits slightly different NMR properties from **4a** and **4b**. The compound displays four peaks for the methyl hydrogens and two peaks for the methine hydrogens as in the previously discussed bis-amido compounds. However, the peaks in NCr(OPh)(N-*i*-Pr_2)$_2$ are significantly broadened which suggests faster rotation around the Cr—N_{amido} bonds than in NCr(I)(N-*i*-Pr_2)$_2$ and NCr($CH_2SiPhMe_2$)(N-*i*-Pr_2)$_2$. The less hindered rotation is indicative of the greater π donating ability of the phenoxide ligand relative to the alkyl or iodide ligands.

(*iv*) *Synthesis of* NCr($OC(CF_3)_2Me$)(N-*i*-Pr_2)$_2$ (**4d**) *and spin saturation transfer* Phenol and HOC(CF_3)$_2$Me are often compared due to their similar pK_a' [22] but dramatically different π basicity [23]. Addition of one equiv. of HOC(CF_3)$_2$Me to a stirring solution of **3** cleanly produced NCr($OC(CF_3)_2Me$)(N-*i*-Pr_2)$_2$ (**4d**), which was isolated in 77% yield.

The ^{1}H NMR spectrum has the four-doublets-two-septets pattern indicative of hindered rotation about the Cr—N_{amido} bonds. The compound **4d,** unlike phenoxide **4c,** has sharp peaks in its spectrum corresponding to the amido ligands. The more hindered rotation found for **4d** relative to **4c** can be attributed to decreased π donation by the fluorinated alkoxide ligand relative to phenoxide and to the larger steric demands of the alkoxide ligand.

Magnetization transfer between the two methine hydrogens in **4d** was measured using the method of Dahlquist, Longmuir and Du Vernet [24]. The experiment was performed in C_6D_6 at room temperature, and the data are plotted in Fig. 1. The data were fit to $A_0 e^{-Xt}$, where t is the delay time and A_0 is the intensity of the selectively-irradiated peak in the difference spectrum at t = 0. The difference curve fit converged at A_0 = 178 (0.77) and X = 13.99 (0.096) with R = 0.9997. The sum curve fit converged at A_0 = 187 (0.59) and X = 0.428 (0.016) with R = 0.983. From the values of X a rate constant for amido rotation equal to 13.5 (0.1) s^{-1} is obtained, which correlates to $\Delta G^{\ddagger}$ = 16 kcal/mol [25].

Mono-amido chromium(VI) nitrido complexes (scheme 2)

(*i*) *Synthesis of* NCr($OC(CF_3)_2Me$)$_2$(N-*i*-Pr_2) (**5a**) *and spin saturation transfer.* Addition of excess

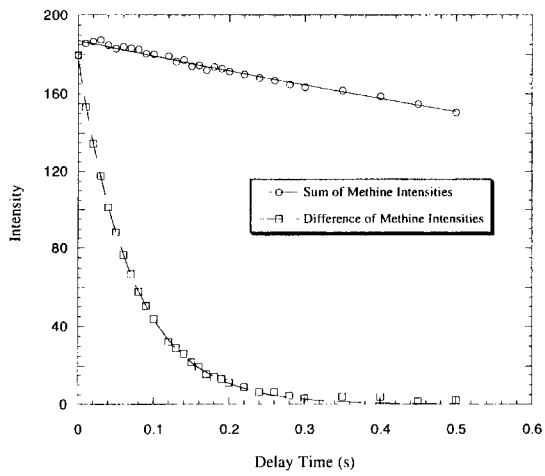


Fig. 1. Sum and difference in intensity plot for the two septets in NCr($OC(CF_3)_2Me$)(N-*i*-Pr_2)$_2$ (**4d**) in C_6D_6. The lines were fit to the equation $A_0 e^{-Xt}$, where A_0 is the initial intensity of the selectively pulsed peak and t is the delay time in seconds. X in the sum plot is equal to 1/T1. In the difference plot X is equal to 1/T1 + k(1) + k(−1). The sum curve fit converged at A_0 = 187(0.59) and X = 0.428(0.016) with R = 0.983. The difference curve fit converged at A_0 = 178 (0.77) and X = 13.99 (0.096) with R = 0.9997. The fits indicate a rate constant for the amido rotation of 13.5 (0.1) s^{-1} for k(1) + k(−1) which correlates to $\Delta G^{\ddagger}$ = 16 kcal/mol.

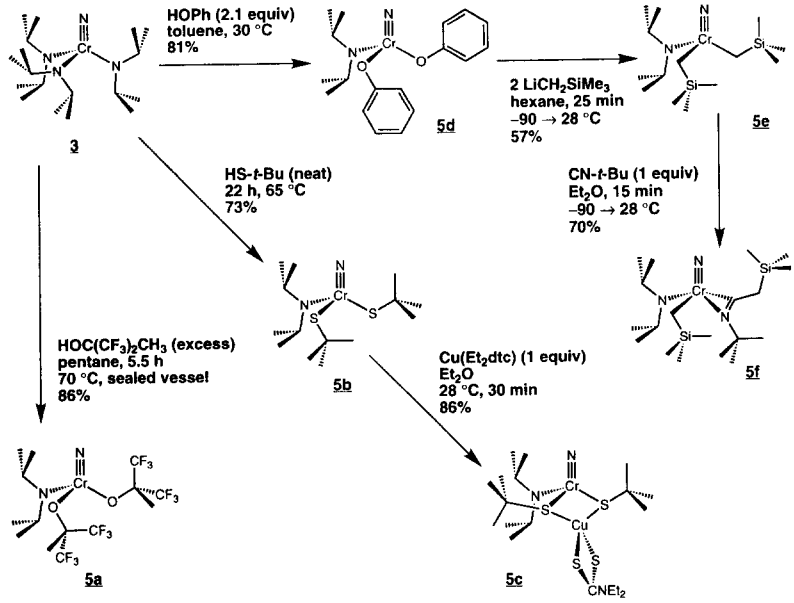

Scheme 2.

$HOC(CF_3)_2Me$ to **3** produced the bis-alkoxide complex $NCr(OC(CF_3)_2Me)_2(N\text{-}i\text{-}Pr_2)$ (**5a**). The reaction was quite slow and required heating at 70°C in a concentrated solution of the alcohol for 5 h. The production of **5a** was very clean and yielded 86% of the purified complex. This is in contrast to the reaction of **4a** with lutidinium iodide, which did not result in the clean production of $NCr(I)_2(N\text{-}i\text{-}Pr_2)$.

An alternative synthesis of **5a** involves heating $NCr(I)(N\text{-}i\text{-}Pr_2)_2$ in the neat alcohol for 12 h. Under these conditions $[H_2N\text{-}i\text{-}Pr_2]$ [I] precipitates from the solution, and **5a** is produced in 64% yield.

The ^1H NMR spectra of all of the mono-amido complexes exhibit two doublets for the methyl hydrogens and two septets for the methine hydrogens of the diisopropylamide. The inequivalence of the *iso*-propyl groups is attributed to syn and anti differentiation with respect to the nitrido functionality and is indicative of significant amido—chromium multiple bond character.

Spin saturation transfer experiments carried out for $NCr(OC(CF_3)_2Me)_2(N\text{-}i\text{-}Pr_2)$ (**4a**) did not indicate magnetization transfer between the methyl hydrogens of the amido substituent even at 90°C. The lack of transfer suggests a rotation rate constant of less than $\sim 0.3\ s^{-1}$ at that elevated temperature, and the activation energy required for rotation can be estimated to be $\geqslant 22$ kcal/mol. The activation energies associated with Cr—N_{amido} rotation in **4d** and **5a** are comparable with some of the larger $M{=}ER_2$ (where E is carbon or nitrogen) bond rotation activation energies found in the literature. The $M_2(NR_2)_6$ complexes of molybdenum and tungsten, where R is methyl or ethyl, have activation energies for amido rotation of 11 to 14 ± 0.5 kcal/mol [26]. Schrock and co-workers have measured the activation energies required for alkylidene rotation in several tantalum complexes [27]. $Cp_2Ta(Cl)(CHC(CH_3)_3)$, $Cp_2Ta(CH_2Ph)(CHPh)$ and $Cp_2Ta(CH_3)(CH_2)$ are reported to have values of $\Delta G^{\ddagger}$ for Ta=C rotation of 16.8 ± 0.1, 19.3 ± 0.1 and $\geqslant 21.4$ kcal/mol, respectively.

(ii) Synthesis and X-ray crystal structure of $NCr(S\text{-}t\text{-}Bu)_2(N\text{-}i\text{-}Pr_2)$ (**5b**). Group 6 nitrides with soft ligands such as thiolates are rare [9]. The scarcity of reports involving high oxidation state nitrido thiolate complexes could be construed as indicative of instability in this class of compounds. The most common decomposition route for thiolate complexes is S—S bond formation giving reduction at the metal center [28]. This decomposition can occur by thiolate radical loss from the metal with subsequent S—S bond formation, by reductive elimination of two thiolates on the same metal center or by dimerization with

reductive elimination from two metal centers. The decomposition mechanisms listed above allow the metal center to access its lower oxidation states and would seem to be favorable for a chromium(VI) thiolate complex. It was found, however, that refluxing *tert*-butylthiol will convert **3** to the quite stable thiolate complex NCr(S-*t*-Bu)$_2$(N-*i*-Pr$_2$) (**5b**) in 73% yield. The dark, highly crystalline product forms green or blue solutions depending on the solvent.

An X-ray diffraction study carried out on **5b** yielded a model exhibiting a monomeric structure in the solid state (Fig. 2). All of the structurally characterized chromium(VI) nitrido complexes are monomeric in the solid state, which contrasts with the polymeric structures of many molybdenum and tungsten nitrido compounds [29]. The nitrido nitrogen is surrounded closely by an isopropyl group from the amido substituent and the two *tert*-butyl groups of the thiolates. The structure exhibits a Cr—N(2) distance of 1.543(6) Å which is a typical Cr—$N_{nitrido}$ distance for this class of complexes [4,12,16]. The Cr(1)—N(1) distance in **5b** is ~0.09 Å shorter than the average Cr—N_{amido} distance in Cr(N-*i*-Pr$_2$)$_3$ and ~0.06 Å shorter than in NCr(N-*i*-Pr$_2$)$_3$. The shortening of the metal—N_{amido} bond is consistent with increased π bonding in the mono-amido Cr(VI) complex.

(iii) Synthesis and X-ray crystal structure of NCr(N-*i*-Pr$_2$)[(μ-S-*t*-Bu)$_2$Cu(Et$_2$dtc)] (**5c**). A blue ethereal solution of NCr(S-*t*-Bu)$_2$(N-*i*-Pr$_2$) (**5b**) gives an orange-brown reaction mixture when added to a slurry of Cu(Et$_2$dtc) [30]. The resultant complex NCr(N-*i*-Pr$_2$)[(μ-S-*t*-Bu)$_2$Cu(Et$_2$dtc)] (**5c**) has *tert*-butyl thiolate ligands bridging the chromium and cop-

per metal centers and is synthesized in 73% purified yield. The solid state structure of **5c** (Fig. 3) as determined by X-ray diffraction shows a $NCr(N\text{-}i\text{-}Pr_2)(S\text{-}t\text{-}Bu)_2$ fragment which is essentially unperturbed from the structure of **5b** (Fig. 2). The complex exhibits a pseudo-tetrahedral arrangement of sulfurs around the copper(I) metal center. The *tert*-butyl substituents enclose the nitrido nitrogen while the $Cu(Et_2dtc)$ fragment occupies a position on the opposite side of the S(1)—S(2)—N(1) plane [31].

(*iv*) *Synthesis of* $NCr(OPh)_2(N\text{-}i\text{-}Pr_2)$ (**5d**). Treatment of a toluene solution of **3** with two equiv. of phenol results in a rapid color change to dark orange and production of $NCr(OPh)_2(N\text{-}i\text{-}Pr_2)$ (**5d**). The reaction is complete in less than thirty min in dramatic contrast to the conditions for the synthesis of **5a**.

The bis-phenoxide complex **5d** is easily synthesized and isolated but is, however, somewhat thermally sensitive. The complex decomposes in solution at room temperature to yield an intractable solid. The nature of this decomposition, although currently unknown, is probably the result of Cr—O homolytic bond cleavage to reduce the oxidation state of the metal and produce phenoxide radical [32].

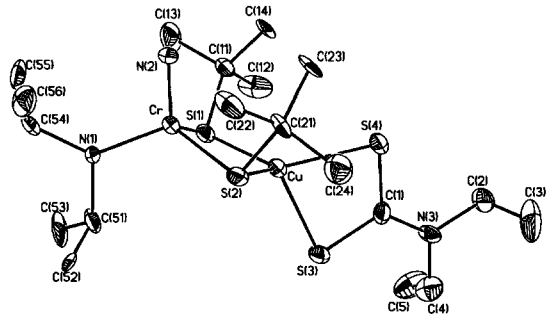

Fig. 3. ORTEP diagram of $NCr(N\text{-}i\text{-}Pr_2)[(\mu\text{-}S\text{-}t\text{-}Bu)_2Cu(Et_2dtc)]$ (**5c**). The ellipsoids are at the 35% probability level.

(*v*) *Synthesis and thermolysis of* $NCr(CH_2SiMe_3)_2(N\text{-}i\text{-}Pr_2)$ (**5e**). Addition of two equiv. of $LiCH_2SiMe_3$ to a cold solution of **5d** in pentane results in the formation of the chromium(VI) organometallic complex $NCr(CH_2SiMe_3)_2(N\text{-}i\text{-}Pr_2)$ (**5e**). The highly lipophilic compound was purified by recrystallization from hexamethyldisiloxane at -35°C in 57% yield.

The complex **5e** exhibits thermal stability similar to that found for **4b**. The compound can be stirred at room temperature overnight without substantial decomposition, but it decomposes rapidly at 60°C. The decomposition, though not as clean as found for **4b**, may proceed by a similar β-hydrogen abstraction mechanism. The ^1H NMR spectrum of the decomposition products revealed tetramethylsilane, $HN\text{-}i\text{-}Pr_2$ and the imine $Me_2C{=}N\text{-}i\text{-}Pr$ to be among the products. There is also a black solid produced during the thermolysis.

(*vi*) *Reactivity of* **5e** *with tert*-butyisonitrile. *The synthesis and X-ray crystal structure of* $NCr(C(=N\text{-}t\text{-}Bu)CH_2SiMe_3)(CH_2SiMe_3)(N\text{-}i\text{-}Pr_2)$ (**5f**). Addition of *t*-butyl isonitrile to an ethereal solution of **5e** produced a color change to yellow-green, forming the iminoacyl $NCr(C(=N\text{-}t\text{-}Bu)CH_2SiMe_3)(CH_2SiMe_3)(N\text{-}i\text{-}Pr_2)$ (**5f**). Only a single insertion reaction occurs even with 24 h exposure of the dialkyl to 10 equiv. of *t*-butyl isonitrile. The greater reactivity of $NCr(CH_2$

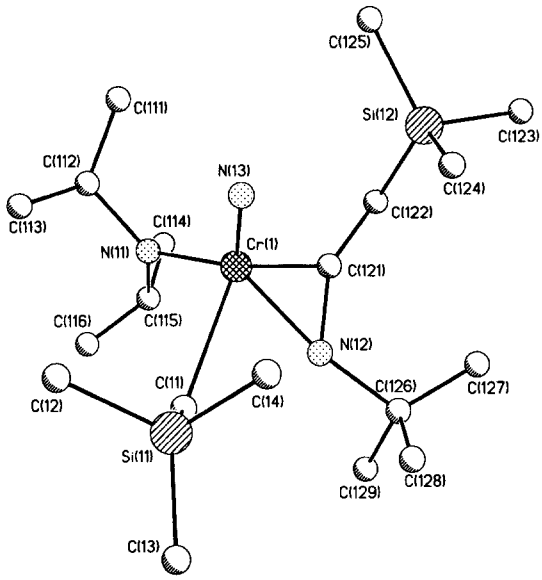

Fig. 4. PLUTO diagram of NCr(C(=N-*t*-Bu)CH_2 $SiMe_3$)(CH_2SiMe_3)(N-*i*-Pr_2) (**5f**). One of the two chemically equivalent molecules in the asymmetric unit is shown.

$SiMe_3)_2$(N-*i*-Pr_2) (**5e**) relative to NCr(C(=N-*t*-Bu)CH_2SiMe_3)(CH_2SiMe_3)(N-*i*-Pr_2) (**5f**) towards insertion can be attributed to electronic differences between the two complexes. The dialkyl can be described as a 14e complex with an available low energy orbital in the plane normal to the nitrido vector and passing through chromium. The iminoacyl complex **5f** has a 16e metal center and no low energy orbitals available, such that a second insertion reaction is unfavorable. Accordingly, treatment of the 16e monoalkyl complex **4b** with 10 equiv. of *t*-butyl isonitrile also gave no reaction even after 24 h reaction time.

An X-ray diffraction study (Fig. 4) carried out on **5f** clearly revealed the presence of an η^2-iminoacyl group. The four different ligands reside in a pseudo square pyramidal arrangement with the η^2-iminoacyl, amido and alkyl substituents residing in the basal plane and the nitrido nitrogen occupying the axial site.

Reactivity of the nitrido nitrogen in chromium(VI) nitrido complexes

(*i*) *Reaction of* 3 *with nucleophiles.* Nitrido complexes often react with nucleophiles to produce complexes with lower oxidation states for the central metal [8]. Nitrides react with phosphines to produce phosphiniminato complexes [33] or with sulfur to produce thionitrosyls [34]. Reactions of this type that effect a reduction of the metal center would seem favorable for chromium(VI). However, a clean addition reaction involving the nitrido nitrogen has not been observed. The microscopic reverse of the nitrosyl deoxygenation reaction does not occur on treatment of NCr(N-*i*-$Pr_2)_3$ (**3**) with 10 equiv. of pyridine-*N*-oxide or trimethylamine-*N*-oxide in CH_2Cl_2 over several d. Nitrido **3** does not react with a concentrated solution of S_8 in CS_2 even after two d. In addition, **3** does not react with neat triethylphosphine even with 24 h of reaction time. This lack of reactivity towards phosphines is especially intriguing due to the reactivity of NCr^{V}(TPP) with PMe_3 to produce $Me_3P{=}NCr^{III}$(TPP) [35].

(*ii*) *Reaction of* NCr(N-*i*-$Pr_2)_3$ *with water.* The nitrido functionality, although stable to a number of protic reagents, does react with water. Addition of 2 equiv. of water to a THF solution of **3** resulted in the precipitation of an insoluble black material, which has not been characterized. However, addition of a THF solution of **3** to an excess of water resulted in smooth hydrolysis of the nitrido nitrogen to form [H_2N-*i*-$Pr_2]_2[Cr_2O_7]$, which was isolated in 73% recrystallized yield.

EXPERIMENTAL

General considerations

All manipulations were carried out in a Vacuum Atmospheres dry box under a purified nitrogen atmosphere unless stated otherwise. Anhydrous ether was purchased from Mallinckrodt and freshly distilled from purple sodium benzophenone ketyl. Toluene was purchased from Mallinckrodt and purified by refluxing over molten sodium under nitrogen for at least two d. Pentane (EM Science) was distilled from purple sodium benzophenone ketyl. Distilled solvents were transferred under vacuum to glass vessels and stored in a Vacuum Atmospheres dry box prior to use. Nitric oxide (grade 5.0) was purchased from BOC corporation and used as supplied. *Tert*-butyl mercaptan was purchased from Aldrich, dried over activated 3 Å sieves for two d and then was distilled under nitrogen prior to use. *Tert*-butylisonitrile was purchased from Aldrich, degassed and stored over 3 Å sieves prior to use. Hexafluoro-2-methylisopropanol (hexafluoro-*tert*-butanol) purchased from PCR Chemical Company was degassed and dried over 3 Å sieves prior to use. (*N*,*N*-diethyldithiocarbaminato)copper(I) [30] and V(mesityl)$_3$(THF) [3] were made according to published procedures. All other solvents, including deuterated solvents, were degassed and stored over activated 3 Å sieves for at least 24 h before use. The sieves were activated by heating at approximately 200°C *in vacuo* overnight. Other chemicals were purchased from commercial sources and used as received. Cr(N-*i*-$Pr_2)_3$ [13], and (ON)Cr(N-*i*-$Pr_2)_3$ [2], were made according to literature methods. NCr(I)(N-*i*-$Pr_2)_2$ and NCr(CH_2SiMe_2Ph)(N-*i*-$Pr_2)_2$ were prepared as previously communicated [16].

Infrared spectra were recorded on a Perkin Elmer

1600 Series FTIR or a Biorad FTS 135. ^{1}H, ^{13}C, ^{15}N and ^{19}F NMR spectra were recorded on Varian VXR-500, Varian XL-300, or Varian Unity-300 spectrometers. ^{1}H and ^{13}C chemical shifts are reported with reference to solvent resonances (residual C_6D_5H in C_6H_6 as 7.15 ppm; C_6D_6 as 128.0 ppm; $CHCl_3$ in $CDCl_3$ as 7.24 ppm; $CDCl_3$ as 77.0 ppm) and were recorded at room temperature unless otherwise stated. ^{19}F NMR chemical shifts are reported with reference to external $CFCl_3$ as 0.00 ppm. ^{15}N NMR chemical shifts are reported with respect to external nitromethane at 380.2 ppm (relative to liquid NH_3 at 0.00 ppm). Combustion analysis were performed by Oneida Research Services, Whitesboro, NY or by Microlytics, South Deerfield, MA. Melting points were obtained in sealed glass capillaries and are uncorrected.

Synthesis and reactivity studies

(*i*) *Synthesis of* $NCr(N\text{-}i\text{-}Pr_2)_3$ (**3**). $(ON)Cr(N\text{-}i\text{-}Pr_2)_3$ (1.094 g, 2.859 mmol, 1 equiv.), V(mesityl)$_3$(THF) (2.983 g, 6.207 mmol, 2.17 equiv.), 35 ml of toluene and a stir bar were loaded into a 300 ml glass vessel equipped with a side arm. The mixture was stirred in a 65°C oil bath for 60 min, during which the solution turned from brown to red. The volatiles were removed *in vacuo*, and the contents of the bomb were extracted with pentane. The resultant beet solution was filtered through a bed of Celite on a sintered glass frit. Extraction left a less soluble, highly pyrophoric black solid on the frit. The product was recrystallized from ether in 67% yield (0.701 g, 1.91 mmol). ^{1}H NMR ($CDCl_3$): δ 3.93 (v br s, 1H), 1.28 (v br s, 6H). ^{13}C NMR ($CDCl_3$): δ 54 (v br s), 27 (v br s), 23 (v br s). FTIR ($NCr(N\text{-}i\text{-}Pr_2)_3$, $CHCl_3$) 1054.0 cm^{-1}. FTIR ($^{15}NCr(N\text{-}i\text{-}Pr_2)_3$, $CHCl_3$) 1029.0 cm^{-1}. ^{15}N NMR ($^{15}NCr(N\text{-}i\text{-}Pr_2)_3$, C_6D_6) δ 979. M.p. ca 110°C (subl). EIMS (high res.) calc. 366.281435 (M^+); found 366.28109, error range 0.00071. Anal. calcd for $C_{18}H_{42}N_4Cr$: C, 58.98; H, 11.55; N, 15.28; Found: C, 59.11; H, 11.13; N, 15.26.

(*ii*) *Reaction of* **4a** *with lutidinium iodide*. Into a 120 ml glass bomb equipped with a stopcock was loaded lutidinium iodide (108 mg, 2.5 equiv., 0.459 mmol), **4a** (72.2 mg, 1 equiv., 0.184 mmol), 7 ml of $CHCl_3$ and 7 ml of THF. The solution was placed in a 75°C oil bath and stirred for 18 h. A small amount of green insoluble material formed, and the ^{1}H NMR spectrum in $CDCl_3$ exhibited peaks corresponding only to the starting materials.

(*iii*) *NMR tube thermolysis of* $NCr(CH_2SiPhMe_2)(N\text{-}i\text{-}Pr_2)_2$ (**4b**) In a sealable NMR tube was loaded 40 mg of **4b** and 995 mg of C_6D_6. The sealed tube was heated to 60°C in an oil bath and was checked periodically over 7 h. All starting material had been consumed by the 7 h mark according to ^{1}H NMR analysis. The spectrum showed $PhSiMe_3$ (s, 0.18 ppm; m, 7.19 ppm; m, 7.44) which was also seen in the GC/MS of the reaction products ($M^+ = 150$). Also observed in the ^{1}H NMR was $HN\text{-}i\text{-}Pr_2$ (d, 0.93 ppm; sept, 2.76 ppm) and peaks attributable to $Me_2C{=}N\text{-}i\text{-}Pr$ (d, 1.14 ppm; s, 1.35 ppm; s, 1.80 ppm; sept, 3.43 ppm). No other peaks were observed in the NMR spectrum. A black insoluble material was formed during the thermolysis.

(*iv*) *Preparation of* $NCr(N\text{-}i\text{-}Pr_2)_2(OPh)$ (**4c**). In a 125 ml Erlenmeyer flask was loaded $NCr(N\text{-}i\text{-}Pr_2)_3$ (750 mg, 2.05 mmol, 1 equiv.), 40 ml of toluene and a stir bar. The solution was frozen in a cold well at liquid nitrogen temperature and then removed to a stir plate. Once the solution could be stirred as a cold slurry, a −35°C solution of HOPh (193 mg, 2.04 mmol, 1 equiv.) in 20 ml of toluene was added dropwise. The solution was allowed to warm and stir for 30 min. and the reaction mixture changed from a beet color to dark orange. The product was recrystallized from ether in 89% yield (653 mg, 1.82 mmol). ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.20 (br app s, 6H, Pr-*i*-CH_3), 1.25 (br app s, 6H, *i*-PrCH_3), 1.43 (br app s, 6H, *i*-PrCH_3), 1.84 (br app s, *i*-PrCH_3), 3.75 (br app s, 2H, *i*-PrCH), 5.04 (br app s, 2H, *i*-PrCH), 6.76 (t, J_{HH} = 6.6 Hz, 1H, p-Ph), 6.95 (d, J_{HH} = 8.1 Hz, 2H, m-Ph), 7.15 (t, J_{HH} = 7.8 Hz, 4H, o-Ph). $^{13}C\{^{1}H\}$ NMR (300 MHz, $CDCl_3$ −20°C): δ = 21.207 (*i*-PrCH_3), 21.502 (*i*-PrCH_3), 30.240 (*i*-PrCH_3), 30.546 (*i*-PrCH_3), 55.440 (*i*-PrCH), 58.417 (*i*-PrCH), 166.838 (ipso-OPh), 128.997 (o-OPh), 119.090 (m-OPh), 117.720 (p-OPh). M.p. 64–65°C. EIMS (low res.): *m/z* (%): 359 (23.76) [$M^{+\bullet}$]. Anal. calcd for $C_{18}H_{33}N_3OCr$: C, 60.14; H, 9.25; N, 11.69. Found: C, 60.40; H, 9.55; N, 11.50.

(*v*) *Preparation of* $NCr(N\text{-}i\text{-}Pr_2)_2(OC(CH_3)(CF_3)_2)$ (**4d**). In a 20 ml scintillation vial $NCr(N\text{-}i\text{-}Pr_2)_3$ (286 mg, 0.764 mmol, 1 equiv.), 10 ml of toluene and a stirbar were cooled to −35°C. To the cool, stirring solution was added a −35°C solution of $HOC(CH_3)(CF_3)_2$ (139 mg, 0.764 mmol, 1 equiv.) in 6 ml of toluene dropwise over a few min. The mixture was warmed to room temp. and stirred for 6 h. The volatiles were removed under vacuum and the orange product was recrystallized from pentane in 77% yield (262 mg, 0.586 mmol). ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.25 (m, 12H, *i*-PrCH_3), 1.45 (d, J_{HH} = 6.0 Hz, 6H, *i*-PrCH_3), 1.64 (s, 3H, *i*-PrCH_3), 1.78 (d, J_{HH} = 6.0 Hz, 6H, *i*-OPrCH_3), 3.71 (sept, J_{HH} = 6.0 Hz, 2H, *i*-PrCH), 4.94 (sept, J_{HH} = 6.0 Hz, 2H, *i*, PrCH). ^{19}F NMR (300 MHz, $CDCl_3$): δ = −78.51 ppm. $^{13}C\{^{1}H\}$ NMR (500 MHz, C_6D_6): δ = 20.2 (*i*-PrCH_3), 21.2 ($OC(CH_3)(CF_3)_2$), 29.79 (*i*-PrCH_3), 30.2 ($OC(CH_3)(CF_3)_2$), 55.7 (*i*-PrCH), 58.4 (*i*-PrCH), 79.9 ($OC(CH_3)(CF_3)_2$). M.p. 149–151°C. EIMS (low res.): *m/z* (%): 447(12.48) [$M^{+\bullet}$]. Anal. calcd for $C_{16}H_{31}N_3OF_6Cr$: C, 42.95; H, 6.98; N, 9.39. Found: C, 43.23; H, 7.15; N, 9.18.

(*vi*) *Spin saturation transfer experiments*. The magnetization transfer experiments were done by ^{1}H NMR using the method of Dahlquist, Longmuir and Du Vernet [24] in C_6D_6 at 294(1) K. In **4d**, mag-

netization transfer between the methine hydrogens of the amido substituents was examined. The technique involves a selective 180° pulse on one of the two methine peaks followed by a full spectrum 90° pulse. At zero delay time, the selectively-irradiated peak (P_1) appears inverted relative to the remainder of the spectrum. The delay time (t) between the selective and full spectrum pulses was varied. The peak heights of P_1 and the peak related to P_1 by rotation (P_2) vary with t if magnetization transfer occurs. The spectra are subtracted from the simple 90° pulse spectrum of the complex. At a delay time of zero P_1 displays twice the intensity in the difference spectrum, and all the other peaks (including P_2) are effectively eliminated in the subtraction. The sum of the intensities for P_1 and P_2 in the difference spectrum vary with the delay time as $A_0 e^{-(1/T1)t}$, where A_0 is the intensity of P_1 in the difference spectrum at $t = 0$ and T1 is the magnetization relaxation rate. A separate T1 determination gave the relaxation rates for P_1 and P_2 to be the same within the error of the experiment ($T1_{P1} = 1.667 \pm 0.01329$ s, $T1_{P2} = 1.664 \pm 0.01575$ s). The difference in the intensities of P_1 and P_2 in the difference spectra vary with t as $A_0 e^{-((1/T1)+k(1)+k(-1))t}$, where k(1) is the rate constant for the conversion of P_1 and P_2 and k(−1) is the rate constant for the conversion of P_2 to P_1. The sum and difference in the intensities for P_1 and P_2 are plotted and fit in Fig. 1. The fit was done to the equation $A_0 e^{-Xt}$. The difference in X for the sum and difference lines is the value k(1)+k(−1) and constitutes the rate constant for one full rotation. A_0 was refined and varies slightly in the sum and difference plots. The variation of A_0 is attributed to a small intensity value for P_2 in the $t = 0$ spectrum from incomplete quenching. The difference curve fit converged at $A_0 = 178$ (0.77) and $X = 13.99$ (0.096) with $R = 0.9997$. The sum curve fit converged at $A_0 = 187$ (0.59) and $X = 0.428$ (0.016) with $R = 0.983$. The fits indicate a value of 13.5 (0.1) s^{-1} for k(1)+k(−1) which correlates to $\Delta G^{\ddagger} = 16$ kcal/mol [25].

In **5a**, magnetization transfer between the methyl doublets was examined, but no transfer was observed. The lack of magnetization transfer is indicative of $k(1)+k(-1) \ll 1/T1$. The T1 values in s for the two doublets were found to be (2.365 ± 0.032883, 2.348 ± 0.02388) and (2.737 ± 0.2093, 2.783 ± 0.2198) by an inversion recovery experiment [37]. Therefore, placing the rate constant for the rotation at 0.3 s^{-1} is a conservative estimate, and the "real" activation energy could be much higher than 22 kcal/mol.

(*vii*) *Preparation of* NCr(N-*i*-Pr_2)(OC(CH_3)(CF_3)$_2$)$_2$ (**5a**). *Method A.* In a 20 ml scintillation vial was loaded NCr(N-*i*-Pr_2)$_3$ (0.571 g, 1.56 mmol, 1 equiv.), a stir bar and 5 ml of pentane. To the stirring solution was added HOC(CH_3)(CF_3)$_2$ (8 g, 440 mmol, 28 equiv.) dropwise. After a few min. of stirring the dark orange solution was transferred to a 120 ml glass bomb equipped with a stopcock. The solution was removed from the drybox and heated in an oil bath at 70°C with stirring. After heating $5\frac{1}{2}$ h the volatiles were removed *in vacuo* and the resulting orange solid was recrystallized from pentane to yield dark crystals of **5a** in 86% yield (0.704 g, 1.33 mmol).

Method B. In a 100 ml glass vessel equipped with a Teflon stopcock was loaded Cr(N)(I)(N-*i*-Pr_2)$_2$ (81 mg, 0.206 mmol, 1 equiv.), HOC(CH_3)(CF_3)$_2$ (3 g, 165 mmol, 800 equiv.) and a stir bar. The reaction mixture was heated at 74°C for 12 h to yield a colorless precipitate (likely [H_2N-*i*-Pr_2] [I]) and an orange solution. The volatiles were removed *in vacuo* and the resulting orange solid was extracted into a minimum of pentane and filtered. Cooling the solution gave the product as thin orange plates in 64% yield (57 mg, 0.132 mmol). ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 1.15$ (d, $J_{HH} = 6.5$ Hz, 6H, *i*-PrCH_3), 1.82 (s, $J_{HH} = 6.5$ Hz, 6H, *t*-BuCH_3), 4.16 (sept, $J_{HH} = 6.5$ Hz, 1H, *i*-PrCH), 5.51 (sept, $J_{HH} = 6.5$ Hz, 1H, *i*-PrCH). ^{13}C{^{1}H} NMR (500 MHz, C_6D_6): $\delta = 18.88$ (*i*-Pr*C*H_3), 19.35 (*i*-Pr*C*H_3), 28.89 (OC(*C*H_3)(CF_3)$_2$), 64.96 (*i*-Pr*C*H), 65.19 (*i*-Pr*C*H), 81.70 (O*C*(CH_3)(CF_3)$_2$), 124.28 (OC(CH_3)(*C*F_3)$_2$). M.p. 112–113°C. Anal. calcd for $C_{12}H_{20}N_2O_2F_{12}Cr$: C, 31.83; H, 3.82; N, 5.30. Found: C, 32.05; H, 3.89; N, 5.17.

(*viii*) *Preparation of* NCr(N-*i*-Pr_2)(S-*t*-Bu)$_2$ (**5b**). A 300 ml two neck flask equipped with a gas adapter was loaded with NCr(N-*i*-Pr_2)$_3$ (352 mg, 0.960 mmol) and a stir bar. The remaining neck was stoppered with a septum and then the flask was removed from the dry box. Dry *t*-butylmercaptan (160 ml, 1.42 mol) was transferred to the reaction flask via canula. The septum was replaced under counterflow of nitrogen with a water cooled condenser and the solution was refluxed for 22 h. The volatiles were removed *in vacuo*. The black solid was extracted with pentane and filtered through a sintered glass frit using celite as a filtering agent. The pentane solution yielded black needle crystals in 73% yield (232 mg, 0.696 mmol) on concentrating and cooling. ^{1}H NMR (300 MHz, $CDCl_3$): $\delta = 1.30$ (d, $J_{HH} = 6$ Hz, 6H, *i*-PrCH_3), 1.49 (d, $J_{HH} = 6$ Hz, 6H, *i*-PrCH_3), 1.70 (s, 18H, *t*-BuCH_3), 3.71 (sept, $J_{HH} = 6$ Hz, 1H, *i*-PrCH), 5.60 (sept, $J_{HH} = 6$ Hz, 1H, *i*-PrCH). ^{13}C{^{1}H} NMR (300 MHz, $CDCl_3$): $\delta = 18.76$ (*i*-PrCH_3), 28.72 (*i*-PrCH_3), 35.37 (*t*-BuCH_3), 50.62 (*t*-BuC), 58.74 (*i*-PrCH), 59.48 (*i*-PrCH). ^{13}C NMR (300 MHz, $CDCl_3$): $\delta = 18.76$ (q, *i*-PrCH_3), 28.72 (q, *i*-PrCH_3), 35.37 (q, *t*-BuCH_3), 50.62 (s, *t*-BuC), 58.74 (d, *i*-PrCH), 59.48 (d, *i*-PrCH). EIMS (low res.): *m/z* (%): 344(24)[$M^{+\bullet}$]. Anal. calcd for $CrN_2S_2C_{14}H_{32}$: C, 48.80; H, 9.36; N, 8.13. Found: C, 49.05; H, 9.82; N, 8.22.

(*ix*) *Preparation of* NCr[(μ-S-*t*-Bu)$_2$Cu(Et$_2$dtc)](N-*i*-Pr_2) (**5c**). To a slurry of Cu(Et$_2$dtc) (0.129 g, 0.652 mmol, 1 equiv.) in 10 ml of ether was added a solution of **5b** (0.225 g, 0.652 mmol, 1 equiv.) in 5 ml of ether. During the addition, a rapid color change from the blue of **5b** to dark brown occurred. The solution was homogeneous a few min. after the addition was complete. The solution was allowed to stir for 30 min. before the volatiles were removed

under vacuum. The dark brown product was recrystallized from ether in 86% yield (0.304 g). ^{1}H NMR (300 MHz, C_6D_6): δ = 0.691 (d, J_{HH} = 6 Hz, 6H, *i*-PrC*H*$_3$), 1.04 (t, J_{HH} = 7 Hz, 6H, EtC*H*$_3$), 1.59 (d, J_{HH} = 6 Hz, 6H, *i*-PrC*H*$_3$), 1.83 (s, 18H, *t*-BuC*H*$_3$), 3.17 (sept, J_{HH} = 6 Hz, 1H, *i*-PrC*H*), 3.70 (quar., J_{HH} = 7 Hz, 4H, EtC*H*$_2$) 3.77 (sept, J_{HH} = 6 Hz, 1H, *i*-PrC*H*). ^{13}C{^{1}H} NMR (300 MHz, C_6D_6): δ = 12.88 (*i*-PrC*H*$_3$), 19.56 (EtC*H*$_3$), 29.90 (*i*-PrC*H*$_3$), 34.63 (*t*-BuC*H*$_3$), 47.85 (EtC*H*$_2$), 54.08 (*t*-BuC), 57.24 (*i*-PrC*H*), 57.99 (*i*-PrC*H*). M.p. 99–102°C. Anal. calcd for $CrCuN_3S_4C_{19}H_{42}$: C, 41.02; H, 7.61; N, 7.55. Found: C, 40.81; H, 7.28; N, 7.53.

(*x*) *Preparation of* NCr(N-*i*-Pr$_2$)(OPh)$_2$ (**5d**). Into a one neck 150 ml round bottom flask was loaded a stir bar, 20 ml of toluene and NCr(N-*i*-Pr$_2$)$_3$ (604 mg, 1.65 mmol, 1 equiv.). Into this stirring solution was added phenol (326 mg, 2.1 equiv., 3.47 mmol) in 13 ml of toluene dropwise via pipette. During addition the solution changed from beet to dark orange in color. After thirty min. of reaction time, the volatiles were removed under vacuum. The resultant black solid was recrystallized to give a black powder in 81% yield (458 mg, 1.33 mmol). ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.15 (d, J_{HH} = 6.6 Hz, 6H, *i*-PrCH$_3$), 1.78 (d, J_{HH} = 6.6 Hz, 6H, *i*-PrCH$_3$), 4.07 (sept, J_{HH} = 6.6 Hz, 1H, *i*-PrCH), 5.19 (sept, J_{HH} = 6.6 Hz, 1H, *i*-PrCH), 6.84 (t, J_{HH} = 7.2 Hz, 2H, p-Ph), 7.04 (d, J_{HH} = 7.8 Hz, 4H, m-Ph), 7.13 (app. q, J_{HH} = 7.2 Hz, 4H, o-Ph). ^{13}C{^{1}H} NMR (300 MHz, $CDCl_3$): δ = 20.53 (*i*-PrCH$_3$), 29.28 (*i*-PrCH$_3$), 63.77 (*i*-PrCH), 64.29 (*i*-PrCH), 116.97 (p-Ph), 122.33 (m-Ph), 129.29 (o-Ph), 167.33 (ipso-Ph). ^{13}C NMR (300 MHz, $CDCl_3$): δ = 20.53 (q, J_{CH} = 128 Hz, *i*-PrCH$_3$), 29.28 (q, J_{CH} = 128 Hz, *i*-PrCH$_3$), 63.77 (d, J_{CH} = 128 Hz, *i*-PrCH), 64.29 (d, J_{CH} = 128 Hz, *i*-PrCH), 116.97 (d, J_{CH} = 167.3 Hz, p-Ph), 122.33 (d, J_{CH} = 158.9 Hz, m-Ph), 129.29 (d, J_{CH} = 159.7 Hz, o-Ph), 167.33 (s, ipso-Ph). EIMS (low res.): *m/z* (%): 352(27.67) [M$^+$]. Anal. calcd for $C_{18}H_{24}N_2O_2Cr$: C, 61.35; H, 6.86; N, 7.95. Found: C, 61.11; H, 6.91; N, 7.64.

(*xi*) *Preparation of* NCr(N-*i*-Pr$_2$)(CH$_2$SiMe$_3$)$_2$ (**5e**). NCr(N-*i*-Pr$_2$)(OPh)$_2$ (0.786 g, 2.23 mmol, 1 equiv.), a stir bar and 55 ml of hexane were loaded into a 250 ml round bottom flask. The flask was moved to a liquid nitrogen temperature cold well, and the solution was frozen. Once the solution was frozen the flask was removed to a stir plate to thaw. When the slurry could be stirred a near frozen solution of LiCH$_2$SiMe$_3$ (0.420 g, 4.46 mmol, 2 equiv.) in 55 ml of hexane was added dropwise over a few min. As the reaction mixture warmed the NCr(N-*i*-Pr$_2$)(OPh)$_2$ slowly went into solution and a colorless solid precipitated from the brown solution. The solution was allowed to stir for 5–10 min. after all the NCr(N-*i*-Pr$_2$)(OPh)$_2$ had dissolved (about 25 min. reaction time). The mixture was refrozen in the cold well and allowed to warm again until fluid. The cold solution was filtered into a chilled filter flask through a sintered glass frit using celite as a filtering agent. The filtered product was recrystallized from hexamethyldisiloxane giving light orange needles in 57% yield (432 mg, 1.27 mmol). The lipophilic purified material is thermally sensitive, but can be kept in solution at −35°C for long periods of time without noticeable decomposition. The material may also be kept in solution at room temperature overnight without substantial decomposition (<10%). M.p. 56–57°C. ^{1}H NMR (300 MHz, C_6D_6, 25°C): δ = −0.318 (d, J_{HH} = 10 Hz, 2H, CH$_2$), 0.347 (s, 18H, SiMe$_3$ CH$_3$), 0.870 (d, 6H, J_{HH} = 6.5 Hz, *i*-PrCH$_3$), 1.26 (d, 6H, J_{HH} = 6.5 Hz, *i*-PrCH$_3$), 2.12 (d, J_{HH} = 10 Hz, 2H, CH$_2$), 2.98 (sept, J_{HH} = 6.5 Hz, 1H, *i*-PrCH), 5.96 (sept, J_{HH} = 6.5 Hz, 1H, *i*-PrCH). ^{13}C{^{1}H} NMR (300 MHz, C_6D_6): d = 2.07 (s, SiCH$_3$), 21.1 (s, *i*-PrCH), 29.48 (s, *i*-PrCH), 56.47 (s, *i*-PrCH$_3$), 58.60 (s, *i*-PrCH$_3$), 69.16 (s, CH$_2$SiCH$_3$). ^{13}C NMR (300 MHz, C_6D_6, 25°C): δ = 2.07 (d, J_{CH} = 118 Hz, SiCH$_3$), 21.1 (s, J_{CH} = 133 Hz, *i*-PrCH), 29.48 (s, J_{CH} = 133 Hz, *i*-PrCH), 56.47 (s, J_{CH} = 117 Hz, *i*-PrCH$_3$), 58.60 (s, J_{CH} = 117 Hz, *i*-PrCH$_3$), 69.16 (s, J_{CH} = 116 Hz, CH$_2$SiCH$_3$). MS low res. EI: *m/z* (%): 340(0.42) [M$^+$]. Anal. calcd for $CrN_2Si_2C_{14}H_{36}$: c, 49.37; H, 10.65; N, 8.22. Found: C, 49.22; H, 11.11; N, 8.57.

(*xii*) *NMR tube thermolysis of* NCr(N-*i*-Pr$_2$)(CH$_2$SiMe$_3$)$_2$ (**5e**). In a sealable NMR tube was loaded ~12 mg of **5e** and 700 mg of C_6D_6. The tube was partially evacuated then sealed. The solution was warmed to 60°C in an oil bath. The thermolysis was complete after 5 h as indicated by the ^{1}H NMR spectrum of the solution. The spectrum exhibited decomposition products which included SiMe$_4$ (s, 0.018 ppm), HN-*i*-Pr$_2$ (d, 0.935 ppm; sept, 2.76 ppm) and Me$_2$C=N-*i*-Pr (d, 1.14 ppm; s, 1.35 ppm; s, 1.80 ppm; sept, 3.34 ppm) in a molar ratio of 3.29:1.85:2.18.

(*xiii*) *Preparation of* NCr(C(=N-*t*-Bu)CH$_2$SiMe$_3$)(CH$_2$SiMe$_3$)(N-*i*-Pr$_2$) (**5f**). A solution of **5e** (32.3 mg, 1 equiv., 0.0948 mmol) and 3 ml of ether in a 20 ml scintillation vial was frozen in the box cold well. The solution was allowed to warm until stirring before a cold solution of *tert*-butylisonitrile (10 μl, 1.0 equiv., 0.0948 mmol) in 2 ml of ether was added. The solution rapidly changed color from orange to yellow-green. After 15 min. of reaction time the volatiles were removed *in vacuo* and the resulting solid was recrystallized from hexamethyldisiloxane. **5f** was isolated in 70% yield (28.2 mg). ^{1}H NMR (300 MHz, C_6D_6): δ = 0.214 (s, 9H, SiCH$_3$), 0.711 (s, 9H, SiCH$_3$), 0.683 (d, 6H, J_{HH} = 6 Hz, *i*-PrCH$_3$), 0.713 (d, 6H, J_{HH} = 6 Hz, *i*-PrCH$_3$), 1.26 (d, J_{HH} = 11.7 Hz, H, CH$_2$), 1.38 (d, J_{HH} = 11.7 Hz, H, CH$_2$), 1.77 (d, J_{HH} = 6 Hz, H, CH$_2$), 1.81 (d, J_{HH} = 6 Hz, H, CH$_2$), 2.72 (d, J_{HH} = 11.7 Hz, H. CH$_2$), 2.86 (sept, J_{HH} = 6 Hz, 1H, *i*-PrCH), 3.31 (sept, J_{HH} = 6 Hz, 1H, *i*-PrCH). ^{13}C{^{1}H} NMR (300 MHz, C_6D_6): d = 2.07 (s, SiCH$_3$), 21.1 (s, *i*-PrCH), 29.48 (s, *i*-PrCH), 56.47 (s, *i*-PrCH$_3$), 58.60 (s, *i*-PrCH$_3$), 69.16 (s, CH$_2$SiCH$_3$). ^{13}C NMR (300 MHz, C_6D_6, 25°C): δ = (q, J_{CH} = 118 Hz, SiCH$_3$), (s, J_{CH} = 133 Hz, *i*-PrCH), (s, J_{CH} = 133 Hz, *i*-PrCH), (s, J_{CH} = 117 Hz, *i*-PrCH$_3$), (s, J_{CH} = 117 Hz, *i*-PrCH$_3$), (s, J_{CH} = 116 Hz, CH$_2$S-

iCH_3). MS low res. EI: *m/z* (%): 423(1.25) [M^+]. MS high res. EI: found: 423.25573 (0.00083) [M^+], calc.: 423.255715. M.p. 83–84°C. Anal. calcd for $CrN_3C_{19}H_{45}Si_2$: C, 53.85; H, 10.70; N, 9.92. Found: C, 54.64; H, 10.93; N, 9.96.

(*xiv*) *Reaction of* **3** *with excess water.* To a mixture of deoxygenated water (10 ml, ~1000 equiv.) and 12 ml of THF was added **3** (0.187 g, 0.510 mmol, 1 equiv.) as a solution in 20 ml of THF dropwise. The solution gradually took on an orange color as the addition was carried out. Once the addition was complete, the volatiles were removed *in vacuo*. The product [H_2N-*i*-Pr_2]$_2$[Cr_2O_7] was recrystallized from acetonitrile in 73% (0.153 g) yield. ^{1}H NMR (300 MHz, D_2O): δ = 1.28 (d, J_{HH} = 6 Hz, 24H, CH_3), 3.50 (sept, J_{HH} = 6 Hz, 4H, *i*-PrCH). Anal. calcd for $Cr_2N_2C_{12}H_{32}O_7$: C, 34.29; H, 7.67; N, 6.66. Found: C, 33.95; H, 7.51; N, 6.53.

(*xv*) *Extended Hückel calculations.* The calculations were done using the X-ray structural coordinates for NCr(N-*i*-Pr_2)$_3$ (**3**), monosubstituted NCr(N-*i*-Pr_2)$_2$(CH_2Si(Ph)Me_2) (**4b**), and disubstituted NCr(S-*t*-Bu)$_2$(N-*i*-Pr_2) (**5b**) as input for YAeHMOP ver 2 [38]. In each case the entire molecule was used in the calculation. The LUMO in each molecule was an orbital with metal-ligand π^* character with respect to all of the π donors. The calculated energies for the LUMOs of **3**, **4b** and **5b** were −9.567, −9.816, and −9.384 eV, respectively.

Crystallographic studies

X-ray diffraction data were collected using a Siemens Diffractometer. The detector includes a Mo Kα sensitive phosphor behind a Beryllium window which is 6 cm from the sample. The phosphor, which is activated by the crystal's X-ray diffraction, sends a signal via a fiber optic taper to a Charge Coupled Device (CCD). The CCD is cooled to ca. −55°C to reduce thermal noise. The CCD is read and the data collection controlled by a computer with a Pentium processor. The software for data collection, Siemens Molecular Analysis Research Tool (SMART v4.050), was developed by Siemens Industrial Automation, Inc. The data collection was done using a Siemens Platform three circle goniometer (χ set to 54.78°) and a water cooled Mo X-ray tube (λ = 0.71073 Å) operating at 50 kV/40 mA. A single crystal graphite monochromator was used. Prior to sample exposure the X-rays were columnated to 0.8 or 0.5 mm. The instrument is equipped with a Molecular Structure Corp. low temperature controller with a liquid nitrogen cooled inner stream and a heated dry N_2 outer stream. The temperatures were determined by a thermistor located within the low temperature device near the exit port and are uncorrected.

An initial unit cell determination was done using ω scans. Three sets of fifteen frames were collected with a −0.3° scan width. The starting positions for the first, second and third runs were (2θ = 337.02°, ω = 337.02°, φ = 0°), (2θ = 337.02°, ω = 337.02°, φ = 90°), and (2θ = 22.98°, ω = 22.98°, φ = 0°), respectively. From this frame data, a set of intense reflections were chosen and an initial cell was found through repeated least squares and Bravais lattice analysis.

The data were collected using ω scans in four separate runs using a −0.3° scan width. The first through fourth starting positions and number of frames collected were (2θ = −25°, ω = −26°, φ = 0°, no. frames = 606), (2θ = −25°, ω = −21°, φ = 88°, no. frames = 435), (2θ = −25°, ω = −23°, φ = 180°, no. frames = 230), and (2θ = −25°, ω = −23°, φ = 180°, no. frames = 50), respectively. The data collected constitute approximately a hemisphere plus an additional 40% of the Ewald sphere. The fourth run duplicates the first 50 frames of the initial run, and the data are corrected for crystal degradation by analyzing the intensity differences in reflections measured in these redundant frames. The data collections were done using 10 s correlated frames (2 × 5 s frames analyzed for anomalous intensity) with a 7 s total read out time. The total data collection time is approximately 6.5 h. Data storage, reduction and structure solution were done on a Silicon Graphics Indy equipped with a MIPS R5000 processor running at 180 MHz and 3 Gigabytes of a total disk space. Using the initial cell, the frame data were integrated to hkl/intensity data using the Siemens program package SAINT v4.050. The final unit cell was determined by SAINT using all the observed data.

The structures were solved and refined using SHELXTL Version 5.03, a program developed by G. M. Sheldrick and Siemens Industrial Automation, Inc. For absorption of a semi-empirical ψ-scan absorption correction was used, which includes all of the data as the basis set.

NCr(S-*t*-Bu)$_2$(N-*i*-Pr_2) (**5b**). Crystals grown from a concentrated ether solution at −35°C were quickly moved from a scintillation vial to a microscope slide containing Paratone N (an Exxon product). Under the microscope a black plate was selected and mounted on a glass fiber using wax. A total of 5293 reflections were collected ($-10 \leqslant h \leqslant 8$, $-13 \leqslant k \leqslant 13$, $-18 \leqslant l \leqslant 18$) in the θ range of 2.06 to 20.00° of which 1861 were unique (R_{int} = 0.0605). The structure was solved by direct methods in conjunction with standard difference Fourier techniques. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in calculated (d_{C-H} = 0.96 Å) positions. The largest peak and hole in the difference map were 0.254 and −0.315 e/Å^3, respectively. The least squares refinement converged normally.

NCr[(μ-S-*t*-Bu)$_2$Cu(Et_2dtc)](N-*i*-Pr_2) (**5c**). Crystals grown from a concentrated ether solution at −35°C were quickly moved from a scintillation vial to a microscope slide containing Paratone N. Under the microscope a black plate was selected and mounted on a glass fiber. A total of 7473 reflections were collected

($-12 \leqslant h \leqslant 14$, $-11 \leqslant k \leqslant 9$, $-23 \leqslant l \leqslant 19$) in the θ range of 1.69 to 20.00° of which 2590 were unique ($R_{int} = 0.0899$). The structure was solved by direct methods in conjunction with standard difference Fourier techniques. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in calculated ($d_{C-H} = 0.96$ Å) positions. The largest peak and hole in the difference map were 2.813 and -0.810 e/Å^3, respectively. The residual electron density resides near the S, Cu and Cr atoms. The least squares refinement converged normally.

NCr(C(=N-*t*-Bu)CH_2SiMe_3)(CH_2SiMe_3)(N-*i*-Pr_2) (**5f**). Crystals grown from a concentrated hexamethyldisiloxane solution at −35°C were quickly moved from a scintillation vial to a microscope slide containing Paratone N. Under the microscope a yellow plate was selected and mounted on a glass fiber. A total of 3916 reflections were collected ($-7 \leqslant h \leqslant 8$, $-11 \leqslant k \leqslant 11$, $-20 \leqslant l \leqslant 20$) in the θ range of 2.12 to 20.00 giving 2999 independent reflections ($R_{int} = 0.0449$). The structure was solved by direct methods in conjunction with standard difference Fourier techniques. The structure suffers from pseudo-symmetry problems. The two molecules in the asymmetric unit sit on either side of a pseudo-inversion center which tries to relate the alkyl and iminoacyl ligands on the two molecules. The pseudo-inversion center creates a pseudo-mirror plane in the molecule in P(−1) which runs through the $N_{iminoacyl}$—$N_{nitrido}$—N_{amido} atoms. Attempts to refine the structure in P(−1) as a disorder problem were less successful than refinement of models in P(1) with no inversion center between molecules. The Cr(1)—C(11) distance was restrained to be within a 3 σ range of 2.3 Å with σ of 0.05 Å. Only the Cr and Si atoms were refined anisotropically. Hydrogen atoms were placed in calculated ($d_{C-H} = 0.96$ Å) positions. The largest peak and hole in the difference map were 0.573 and -1.034 e/Å^3, respectively.

CONCLUDING REMARKS

Chromium(VI) nitrido compounds are available through nitric oxide cleavage using Cr(N-*i*-Pr_2)$_3$ and V(mesityl)$_3$(THF). The nitrido functionality displays remarkable kinetic stability towards a variety of acidic reagents. Among the products available by protolytic removal of one amido substituent were found to be NCr(I)(N-*i*-Pr_2)$_2$ (**4a**), NCr(OPh)(N-*i*-Pr_2)$_2$ (**4c**) and NCr($OC(CF_3)_2Me$)(N-*i*-Pr_2)$_2$ (**4d**). The monoalkyl complex NCr(N-*i*-Pr_2)$_2$($CH_2Si(Ph)Me_2$) (**4b**) was synthesized from the reaction of **4a** with Mg($CH_2SiPhMe_2$)$_2$. The products available by protolytic removal of two amido substituents were NCr($OC(CF_3)_2Me$)$_2$(N-*i*-Pr_2) (**5a**), NCr(S-*t*-Bu)$_2$(N-*i*-Pr_2) (**5b**) and NCr(OPh)$_2$(N-*i*-Pr_2) (**5d**). Thiolate **5b** coordinates Cu(Et_2dtc) to produce the bridging thiolate complex NCr(N-*i*-Pr_2)[(μ-S-*t*-Bu)$_2$Cu(Et_2dtc)] (**5c**). The reaction of **5d** with 2 equiv. of $LiCH_2SiMe_3$ produces NCr(N-*i*-Pr_2)(CH_2SiMe_3)$_2$ (**5e**). The chromium(VI) alkyl complexes **5e** and **4b** were found to decompose thermally with products indicative of β-hydrogen abstraction from the amido ligands. The 14e alkyl **5e** reacts with *tert*-butyl isonitrile to give an iminoacyl alkyl complex. The nitrido nitrogen is stable to some harsh acidic conditions, i.e. refluxing HS-*t*-Bu, but does undergo hydrolysis upon treatment with excess water.

Our results for the protolytic replacement of the amido substituents in nonpolar media on the complex NCr(N-*i*-Pr_2)$_3$ (**3**) are suggestive of two important kinetic factors which affect the viability of an amido protonation. The first is sterics. In a nonpolar environment, a mechanism involving the prior coordination of the incoming protic reagent with concomitant or subsequent proton transfer should be favored. Prior coordination of the protic reagent (e.g. an oxygen or sulfur lone pair) reduces the amount of charge separation in the intermediate or transition state vis-á-vis simple proton transfer followed by attack of the conjugate base. For such a mechanism, steric constraints at the metal center and at the incoming protic reagent could be exceedingly important but difficult to assess. The Lewis acidity of the metal center may play a role in the ease of coordination of an incoming Brønsted acid. Extended Hückel calculations incorporating the X-ray crystal structure coordinates of NCr(N-*i*-Pr_2)$_3$ (**3**), NCr(N-*i*-Pr_2)$_2$($CH_2Si(Ph)Me_2$) (**4b**), and NCr(S-*t*-Bu)$_2$(N-*i*-Pr_2) (**5b**) suggest that the LUMO energies decrease in the order **5b** > **3** > **4b**. This trend is consistent with the observation that **5b** is inert to excess HS-*t*-Bu, whereas **3** is attacked readily by the same reagent. Thus, we may propose that the greater the Lewis acidity of the chromium nitrido amido in question, the more readily will alcoholysis or thiolysis proceed.

In more polar media, the reactions may proceed by mechanisms involving greater charge separation in the transition states or intermediates. Accordingly, reaction of an almost 1:1 solution of THF/water with **3** provided [H_2N-*i*-Pr_2]$_2$[Cr_2O_7] in high yield.

Chromium(VI) nitrido complexes are now available for comparison with their molybdenum and tungsten analogs. Further investigation into the chemistry of these new complexes will serve to substantiate trends in nitrido chemistry of group 6. In addition, pseudo-tetrahedral high oxidation state chromium compounds comprise a new area of study in the already active area of chromium(VI) chemistry [36].

Heterometallic alkoxides containing alkoxometallate(IV) ligands: synthesis and structural comparison

Ram C. Mehrotra and Anirudh Singh

Department of Chemistry, University of Rajasthan, Jaipur 302004, India

(Received 12 May 1997; accepted 2 September 1997)

Abstract—A brief account of heterometallic alkoxides containing alkoxometallate(IV) (e.g., $\{M_2(OR)_9\}^-$, $\{M(OR)_5\}^-$, and $\{M(OR)_6\}^-$) ligands have been presented, with an emphasis on the correlation of their structural features on the basis of steric and allied factors. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: heterometallic alkoxides; nonaalkoxodimetallars; pentaalkoxometallates; hexaalkoxometallates.

The synthesis and characterization of a large number of stable heterometallic alkoxides [1–10] having two or more different metals in a molecular species has added a new dimension to our existing knowledge of heterometallic coordination chemistry. In view of the difficulties [11] in obtaining crystallographically suitable crystals for structural elucidation, doubts were expressed on the entity of such derivatives which appear to derive their stability mainly from a suitable juxtaposition of alkoxide (μ_2- or μ_3-) bridges between dissimilar metals. In 1989 Bradley described our work as "extremely important advances in the synthesis of heterometallic alkoxides, i.e. compounds containing two, three or four different metals in a cluster molecule" [12]. This work has now been followed with a crystallographic characterization of a number of these derivatives.

The synthesis of volatile and soluble (in organic solvents) sodium nona-alkoxodizirconates $NaZr_2(OR)_9$, by Bartley and Wardlaw [13] in 1958, added an entirely new dimension to the chemistry of heterometallic alkoxides, which were initially conceived as alkoxo salts by Meerwein and Bersin [14]. In fact, the first nona-alkoxodistannate derivative, $NaSn_2(OEt)_9$, was also described by Bradley *et al.* [15] in 1957 as an intermediate in their efforts to synthesize tin tetraalkoxides by the reactions of $SnCl_4$ with alkali metal alkoxides.

Mehrotra and Agrawal (1967) drew pointed attention to the uniqueness of $\{Zr_2(OPr^i)_9\}^-$ derivatives based on the non-conducting behaviour of $KZr_2(OPr^i)_9$ [16]; a simple structure was suggested [1] in 1978 involving two $\{Zr(OPr^i)_6\}$ octahedra sharing a face which appears to be confirmed by the X-ray structures [6–9,17,18] determined since 1984. The versatility of $\{M_2(OR)_9\}^-$ groups in responding to the desire of different metal atoms to achieve their preferred coordination state and geometry by the formation of alkoxo bridges (μ_2 or μ_3) with the heterometal atoms, has been demonstrated in a number of publications [19–27] from our laboratories. Veith *et al.* [28] recently (1996) re-emphasized "the versatility of $M_2(OR)_9$ groups in responding to the need of different metal atoms in order to build heterometallic alkoxide clusters".

Bradley [29] has also collaborated recently in a metrical comparison of an interesting series of derivatives $[MTi(OPr^i)_5]n$ (M=Li($n = 2$), Na($n = \infty$), K($n = \infty$)). Although all three congeners are dimeric [30] in benzene, only the lithium derivative exhibits in the solid state a dimeric structure with the standard M_4O_{16} arrangement involving titanium and lithium atoms in distorted trigonal–bipyramidal and tetrahedral geometries, respectively. However, sodium and potassium analogues depict polymeric structures with linear and non-linear alternating chains [29]. This has been ascribed to larger Na and K atoms leading to tight ion pairs being formed between the more electropositive alkali metal cations and the $\{Ti(OPr^i)_5\}^-$ anions.

In this article an attempt has been made for correlation amongst different types of heterometallic alkoxides of tetravalent metals on lines similar to that suggested for homometallic alkoxides by Bradley [31].

Consistent with the predominating influence of steric factors [32,33] in homometallic alkoxides, the bulk of the attached alkoxo groups in the chelating alkoxometallate ligands plays an important role in determining the geometry of the overall heterometallic system. The oligomerization in homometallic alkoxides arises from the tendency of the metal atom to attain the desired coordination state in the most economical manner [31] by alkoxo (μ_2-/μ_3-) bridge formation. Interestingly, the desired sterically permissible coordination state of the central heterometal atom can be attained by the requisite number of alkoxo group ligation from the potentially multidentate chelating alkoxometallate (e.g. $\{M_2(OR)_9\}^-$, $\{M(OR)_4\}^-$, $\{M(OR)_5\}^-$, or $\{M(OR)_6\}^{2-}$) ligands. For example, in $Ln\{(\mu_2\text{-}OPr^i)_2Al(OPr^i)_2\}_3$ [1,34] (Ln = a lanthanide) and $Ni\{(\mu_2\text{-}OMe)_3Al(OMe)\}_2$ [35] the bi- and tridentate, ligating modes of $\{Al(OPr^i)_4\}^-$ and $\{Al(OMe)_4\}^-$ respectively provide an octahedral environment of alkoxo ligands around both the lanthanide and nickel atoms. The role of the steric factor is reflected in the tertiary butoxo analogue, $Ni\{(\mu_2\text{-}OBu^t)_2Al(OBu^t)_2\}_2$ [36], in which $\{Al(OBu^t)_4\}^-$ units behave as bidentate ligands and provide a tetrahedral environment around nickel.

With the help of the above generalizations, we have been predicting mainly on the basis of NMR and other physicochemical data, the plausible structures of heterometallic alkoxides. Most of these (e.g. $KZr_2(OPr^i)_9(DME)$ [37], $(Pr^iOH)_2K\{Al(OPr^i)_4\}$ [38], $Er\{Al(OPr^i)_4\}_3$ [39], $Pr\{Zr_2(OPr^i)_9\}Cl_2$ [40], $[Cd\{Zr_2(OPr^i)_9\}(\mu\text{-}Cl)]_2$ [26] have been confirmed later by X-ray crystallographic determinations.

Compared to the tetrahedral $\{Al(OPr^i)_4\}^-$ and octahedral $\{M(OPr^i)_6\}^-$ (M=Nb or Ta) entities with bi- (and in some cases tri-) dentate ligands [3,6–10,18], a tetravalent metal like zirconium is capable of achieving hexacoordinate configuration in $\{Zr_2(OR)_9\}^-$ ligands with two face sharing octahedra and even simple models of these clearly depicted their capability of chelating another metal in a bidentate as well as tri- and tetradentate manner [6–10,18]; this has been confirmed later by X-ray crystallographic studies. In addition, $\{M(OR)_5\}^-$ and $\{M(OR)_6\}^{2-}$ units are also beginning to demonstrate their potentiality as chelating ligands.

In view of the X-ray crystallographic structures of a large number of title compounds being available during the last 12–13 years from ours as well as other laboratories, the main purpose of this article is to attempt for the first time a correlation of as many of these as possible in a logical fashion.

METHODS OF PREPARATION

The versatility of alkoxometallate(IV) groups such as $\{M_2(OR)_9\}^-$, $\{M(OR)_5\}^-$, and $\{M(OR)_6\}^{2-}$ (where M = a tetravalent metal, R = an alkyl or fluorinated alkyl) as chelating ligands, has resulted in a variety of novel heterometallic alkoxides. The synthetic route for these include the following:

(a) Reactions involving union of two different metal alkoxides [13,16,41–48];
(b) Interactions of alkali and alkaline earth metals with an appropriate metal isopropoxide isopropylate, $M_2(OPr^i)_8(Pr^iOH)_2$ (M=Zr, Hf, or Sn) [16,19,41,49];
(c) Reactions of metal (U [17], Sn [15]) chlorides or their complexes (e.g., $Nb_2Cl_4(OMe)_4(HOMe)_2$ [50]) with alkali metal alkoxides;
(d) Reactions of metal halides (chloride [19–27,40,51–53], iodide [28,54]/fluoride [53]) or their complexes [55,56] with alkali metal alkoxometallate(IV) ligands;
(e) Reactions of metal amides (e.g. $LiNMe_2$ [49b], $NaN(SiMe_3)_2$ [57], $Ba\{N(SiMe_3)_2\}_2(THF)_2$ [49a], $Sn\{N(SiMe_3)_2\}_2$ [58], $Pb\{N(SiMe_3)_2\}_2$ [58]) with tetravalent metal alkoxide alcoholates (e.g. $Zr_2(OPr^i)_8(Pr^iOH)_2$ [49,49b,58] and $M_2(OBu^t)_8(HOBu^t)$ (M = Th [57], U [48]));
(f) Reactions of $(NH_4)_2Ce(NO_3)_6$ with alkali metal t-butoxides [59];
(g) Reactions of potassium hydride with $Zr_2(OPr^i)_8(Pr^iOH)_2$ [37];
(h) Reaction of a metal chloride (e.g. $NbCl_5$ [50]) with magnesium in methanol.

The letter designations correspond to the letters used in Table 1 to identify synthetic routes to title derivatives.

STRUCTURAL INTERRELATIONSHIPS AND RESULTING DIVERSITIES

Solid state structural studies have been performed on a variety of system containing one or more $\{M_2(OR)_9\}^-$, $\{M(OR)_5\}^-$, and $\{M(OR)_6\}^{2-}$ units. Although a complete analysis of each structure is not the aim of this article, a brief summary of basic trends and general types of structures will be presented.

Out of the many operative factors [1,60] such as: (i) the empirical formula of the compound; (ii) the bulk of the alkoxo group; (iii) the size and formal oxidation state of the metal atom(s) in the basic skeleton; (iv) the presence of lone pair(s) of electrons on the metal atom(s); and (v) the d^n electron configuration for the transition metals (leading to pronounced ligand field effects), the steric factor and/or the presence of lone pair(s) appear to play a predominant role.

Bradley's proposal [31] for the lowest oligomerization state of homometallic alkoxides has been extended by Caulton *et al.* [44] in a modified form for heterometallic alkoxides, $M_aM'_b(OR)_m$. These types of derivatives with a low m/(a+b) ratio generally prefer closed polyhedral structures, in order

to endow suitably high coordination states to all metals.

Nonaalkoxodimetallate derivatives

Out of a number of alkoxometallate(IV) units mentioned above, the ligands of the type $\{M_2(OR)_9\}^-$ have so far been most extensively employed for the synthesis of derivatives which are generally volatile and soluble in organic solvents from which X-ray suitable crystals can be sometimes obtained.

The structure of an apparently free nonaalkoxodimetallate anion [50], $\{M_2(OR)_9\}$, shown in Fig. 1, can be envisaged as a face shared bi-octahedron:

The above structure in a simple anionic form is depicted in a few niobium(IV) solvent separated ion pair derivatives [50]: $[Na(MeOH)_6][Nb_2(OMe)_9]$, $[Mg(MeOH)_6]_2[Nb_2(OMe)_9]Cl_3$, and $[Mg(MeOH)_6][Nb_2(OMe)_9]I.2\,MeOH$.

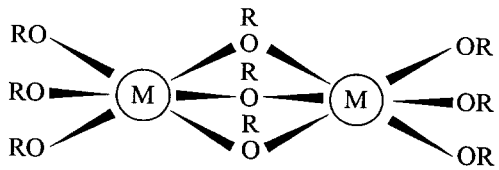

Fig. 1. Schematic structural representation of nonaalkoxodimetallate anion (M = a tetravalent metal).

This behaviour of the above methoxo complexes might arise from the unique property of solubility of methoxides of niobium in contrast to the insolubility of methoxides of other metals like Ti, Zr, Hf, Th, and Sn. Being a stronger donor, methyl alcohol saturates coordinatively the other metals (Na and Mg), and thus reduces their tendency to form methoxo bridges with $Nb_2(OMe)_9$ moiety. In almost all the other cases investigated so far, the confacial bi-octahedral unit $\{M_2(OR)_9\}^-$ forms alkoxo bridges with central metal atom(s), binding them in tetra-, tri-, or bi-dentate fashion.

(a) Tetra-dentate mode of coordination

A critical survey of a large number of such derivatives indicates the following idealized core structure (Fig. 2) in which all metals attain a six-coordination state.

The effect of factors such as size of M, size and valency of M′, bulk of alkoxo group, nature and presence of X···X (as a bidentate neutral ligand or zero/one/two monovalent unidentate ligand(s)).

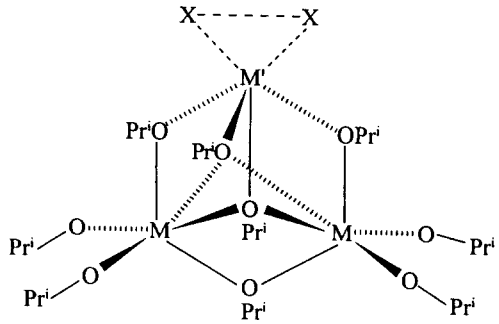

Fig. 2. Schematic structural representation of X-ray determined heterotrinuclear metal alkoxides in which all metal atoms attain coordination number six (e.g. (i) M=Zr(IV), M′=K, R=Pr^i, X···X=MeOC$_2$H$_4$OMe(**1**); (ii) M=Zr(IV), M′=Pr(III), R=Pr^i, X=Cl(**2**)).

The X-ray structural investigations on a number of other heterotrinuclear metal alkoxides such as [NaCe$_2$(OBu^t)$_9$] (**3**) [59], [NaTh$_2$(OBu^t)$_9$] (**4**) [59], [KU$_2$(OBu^t)$_9$] (**5**) [17], [CuCl{Zr$_2$(OPr^i)$_9$}] (**6**) [59], and [ICd{M$_2$(OPr^i)$_9$}] (M = Ti (**7**) [54], Zr (**8**) [61], Hf (**9**) [54], and Sn (**10**) [28]) revealed the presence of the generic structure shown in Fig. 3, wherein heterometal atoms or species are again bonded in tetradentate (η^4) fashion.

M=Ce (**3**) [59], M′=Na, R=Bu^t; M=Th (**4**) [57], M′=Na, R=Bu^t;

M=U (**5**) [17], M′=K, R=Bu^t; M=Zr, M′=CuCl (**6**) [53], R=Pr^i;

M=Ti (**7**) [54], M′=CdI, R=Pr^i; M=Zr (**8**) [61], M′=CdI, R=Pr^i

M=Hf (**9**) [54], M′=CdI, R=Pr^i; M=Sn (**10**) [28], M′=CdI, R=Pr^i

The structures of (**3**), (**4**), and (**5**) (Fig. 3) show that with bulkier OBu^t groups, the central metal (M′) Na or K is not ligated further and remains tetra-coordinate.

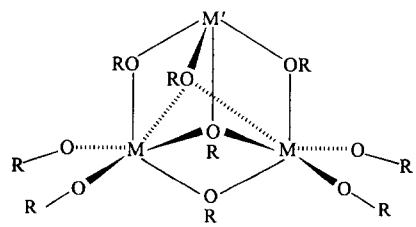
Another remarkable class of crystallographically characterized alkoxides include the dimeric [Ba{Zr$_2$(OPr^i)$_9$}(μ-OPr^i)]$_2$ (**11**) [49] and [Cd{Zr$_2$(OPr^i)$_9$}(μ-Cl)]$_2$ (**12**) (Fig. 4) [26]. In both these cases the heteroatom barium or cadmium is tetradentally bonded with a {Zr$_2$(OPr^i)$_9$}$^-$ unit, and the centrosymmetric dimers consist of two triangular BaZr$_2$(μ_3-OPr^i)$_2$(μ_2-OPr^i)$_3$(OPr^i)$_4^+$ or CdZr$_2$(μ_3-OPr^i)$_2$(μ_2-OPr^i)$_3$(OPr^i)$_4^+$ units linked by the barium or cadmium atoms via two isopropoxo and chloro bridges, respectively. all metal atoms are six coordinate and adopt distorted octahedral geometry.

By contrast, derivatives (**6**), (**7**), (**8**), (**9**) and (**10**) are monomeric with five-coordinate geometry around the copper atom in (**6**) and the cadmium atom in (**7**), (**8**), (**9**) and (**10**). The dimeric structure shown in Fig. 4 for the analogous chloro derivative is inhibited due to steric congestion in the cases of (**6**)–(**10**), arising from the smaller size (72 pm) of copper(II) (**6**) and the larger size (220 pm) of the iodo ligand [(**7**)–(**10**)].

An interesting derivative Ba{Zr$_2$(OPr^i)$_9$}$_2$ [49a] with eight coordinated barium has also been crystallographically characterized. The structure consists of a "bow tie" or spiro Zr$_2$BaZr$_2$ unit, wherein barium is coordinated tetradentally by two face-shared bioctahedral {Zr$_2$(OPr^i)$_9$}$^-$ units to yield almost a staggered conformation of eight-coordinate polyhedron around barium.

There are several interesting features in the solid state structures of nonaalkoxodimetallate derivatives which might be emphasized.

A general trend has been observed in heterometallic alkoxides containing alkoxometallate(IV) units such as {M$_2$(OPr^i)$_9$}$^-$ (M=Ce, Ti, Zr, Hf, Th, or U),



M = Ce (**3**),[59] M′ = Na, R = Bu^t; M = Th (**4**),[57] M′ = Na, R = Bu^t;

M = U (**5**),[17] M′ = K, R = Bu^t; M = Zr, M′ = CuCl (**6**),[53] R = Pr^i;

M = Ti (**7**),[54] M′ = CdI, R = Pr^i; M = Zr (**8**),[61] M′ = CdI, R = Pr^i

M = Hf (**9**),[54] M′ = CdI, R = Pr^i; M = Sn (**10**),[28] M′ = CdI, R = Pr^i

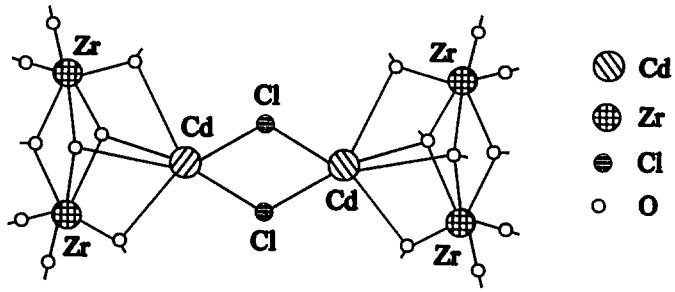

Fig. 4. X-ray crystal structure of $[Cd\{Zr_2(OPr^i)_9\}(\mu\text{-}Cl)]_2$ [26], depicted without the isopropyl group.

$\{M(OR)_5\}^-$ (M=Ti (R=Pr^i), Zr(R=Bu^t), and $\{M(OR)_6\}^{2-}$ (M=Ti (R=Pr^n), Zr(R=$CH(CF_3)_2$) that the $p\pi$–$d\pi$ interactions tend to make M—O_t distances shorter and M—O_t—C angles larger (approaching linearity) than those at the bridging sites (see Table 2). By contrast, a recent publication dealing with $Cd\{Sn_2(OPr^i)_9\}I$ revealed that Sn—O_t distances and Sn—O_t—C bond angles do not follow the above trend; this might arise from differences in main group and transition metal derivatives. A plausible suggestion could be that a short M—O_t bond results from a high degree of ionic character in early transition metal derivatives and an enhanced covalent nature of the Sn—O_t bond, but this difference in behaviour requires further intensive investigations.

Further, as expected from electronic considerations, M—μ_3—O are longer than M—μ_2—O which in turn are longer than M—O_t (terminal) distances. In the case of $\{M_2(OR)_9\}^-$ derivatives, both the above features are illustrated by a few examples in Table 2.

However, the more generally observed feature of increasing bond length with a higher bridging order appears to be reversed in a few cases (e.g. (**3**) [59], (**4**) [57], (**5**) [17], Table 2). These exceptions appear to be corroborative of the overshadowing tendency of such derivatives for attaining compactness of the structures in the process of which alkali metal atoms are apparently tucked in tighter to the "basket" formed by the four alkoxo oxygen atoms of $\{M_2(OR)_9\}^-$ unit.

(*b*) *Tri- and bi-dentate mode of coordination*

The possibility for $\{Zr_2(OPr^i)_9\}^-$ ligand to behave in a tridentate(η^3) manner suggested earlier for derivatives $[Co\{Zr_2(OPr^i)_9\}_2]$ [22] and $[Cu\{Zr_2(OPr^i)_9\}^2]$ [24] on the basis of electronic and other physicochemical data has now been X-ray crystallographically confirmed in cases of $LiZr_2(OPr^i)_9$ (Pr^iOH) (**11**) [49b] (Fig. 5) and $[Sn\{Zr_2(OPr^i)_9\}(\mu\text{-}I)]_2$ (**12**) [28] (Fig. 6). The small lithium ion (78 pm) interacts with a $\{Zr_2(OPr^i)_9\}^-$ unit via only three isopropoxo groups, rather than four, utilized by its heavier congeners such as Na^+ (98 pm) and K^+ (133 pm). Lithium appears to be too small to span the distance between isopropoxo groups on two different zirconium(IV) centres; the fourth coordination site on lithium is consequently occupied by an isopropanol molecule, which is hydrogen bonded to oxygen of a terminal isopropoxo group.

The derivative $[Sn\{Zr_2(OPr^i)_9\}(\mu\text{-}I)]_2$ (**12**) [28] (Fig. 6) consists of $\{Zr_2(OPr^i)_9\}^-$ unit interacting with Sn(II) in a tridentate (η^3) fashion as depicted for (**11**).

The structures of (**11**) and (**12**) clearly depict the influence of the nature (i.e. size and/or the presence of a lone pair of electrons) of the heterometal in determining the structural forms adopted by a heterometallic system. Tin(II) with its stereochemically active lone pair of electrons appears to inhibit the $\{Zr_2(OPr^i)_9\}^-$ ligand to bind it in a tetradentate fashion.

A remarkable result in this area is the structural characterization of $[Pb\{Zr_2(OPr^i)_9\}(\mu\text{-}OPr^i)]_2$ (**13**) [44,58] (Fig. 7), which shows a serpentine (not *closo*) structure with six-coordinate zirconium and four-coordinate lead.

Although the size of Pb(II) (132 pm) is larger than tin(II) (93 pm) the $\{Zr_2(OPr^i)_9\}^-$ unit binds the former in a bidentate (η^2) manner. This unusual ligating behaviour which was first suggested in derivatives of the types $Ln\{Zr_2(OPr^i)_9\}_3$ [40,62,63] (Ln = a lanthanide metal) and $Fe\{Zr_2(OPr^i)_9\}_3$ [64] has now been actually confirmed by X-ray crystallographic studies of (**13**). The bidentate coordination of $\{Zr_2(OPr^i)_9\}^-$ ligand is possibly due to the presence of a lone pair of electrons coupled with weaker Lewis acid character of lead(II) in this system.

The above description shows a delicate balance amongst the nature and size of the metal atom, the steric bulk of alkoxo ligand, and stoichiometry of the resulting stable heterobimetallic alkoxides. The current investigations in our laboratories reveal even more fascinating possibilities in these directions.

Pentaalkoxometallate derivatives

The role of steric effect in determining stoichiometry and structure of a heterometallic alkoxide is further well illustrated by the comparative stability of $M'M_2(OR)_9$ and $M'M(OR)_5$. For example, with isopropoxo(R) ligands all the tetravalent metals (M)

[17,28,37,54,57] such as Ce^{4+} (94 pm), Ti^{4+} (64 pm), Zr^{4+} (87 pm), Hf^{4+} (84 pm), Th^{4+} (99 pm), U^{4+} (97 pm), and Sn^{4+} (74 pm) form derivatives of the type $M'M_2(OR)_9$, while stable analogous tertiarybutoxo derivatives are known only for Ce (**3**) [59], Zr, Hf [43], Th (**4**) [57] and U (**5**) [17], when M′=Na or K. Although thermal stability of all these has not been investigated, the molecule $MZr_2(OBu^t)_9$ appears to be sterically strained leading to disproportionation to more stable $MZr(OBu^t)_5$. The tetravalent titanium and tin are relatively too small to accommodate six bulky OBu^t, groups around themselves and afford stable derivatives of formula $M'M(OBu^t)_5$ [42,64] only; it is also worth mentioning that analogous isopropoxo derivatives [16,29,30,64] for both of these metals are known. It is interesting that the derivative $[KZr(OBu^t)_5]_2$ isolated in 1967 by Mehrotra and Agrawal [16] has now been X-ray crystallographically [43] characterized showing six OBu^t groups around each larger zirconium atoms.

The above description shows that with a fine tuning in the size of the ligand, derivatives of different stoichiometries of the same tetravalent metal can be obtained as being revealed by current investigations in our laboratories.

Amongst the alkali metal derivatives of the type $M'M(OR)_5$, the lithium pentaisopropoxotitanate [30] (**14**) is dimeric (Fig. 8) to provide four- and five-coordination states to lithium and titanium centres, respectively.

By contrast, analogous derivatives of sodium and potassium are polymeric [30]. The importance of metal ion size is reflected in the fact that the infinite linear chains formed in $[NaTi(OPr^i)_5]_\infty$ (**15**) [29] consist of alternative five coordinate titanium centres and tetrahedral sodium atoms, whereas although potassium analogue $[KTi(OPr^i)_5]_\infty$ (**16**) [29] (Fig. 9) is structurally similar to (**15**), it consists of nonlinear continuous chains with potassium atoms in an extremely distorted form from idealized trigonal–bipyramidal geometry, revealing an arrangement between the ideal square bipyramid and trigonal–bipyramid. In both cases, the alkali metal acts as a bridge between discrete, mononuclear, trigonal bipyramidal pentaisopropoxotitanate units. This type of decreased linearity with increased alkali metal radii has also been observed for the other inorganic systems [65].

From the above descriptions two interesting questions arise: (i) why are the derivatives (**15**) and (**16**) of heavier alkali metals polymeric, when the lithium analogue (**14**) is a discrete dimeric molecule; and (ii) why are the polymeric chains non-linear in (**16**)?

To identify definite factors for such abnormalities would be a difficult task with the limited physicochemical data available to date. However, some logical explanations can be put forward. For example, the increase in alkali metal–titanium distances (290 pm, (**14**); 329 pm, (**15**); 336–355 pm, (**16**)) on descending the group could be responsible for nonlinearity of the polymeric chains in (**16**); and adoption of polymeric structures by (**15**) and (**16**), in contrast to the lithium analogue (**14**). This may be a consequence of the magnitudes of alkali metal (M′)/metal(M) radii ratios: in the $M'Ti(OPr^i)_5$ series; discrete molecules have been obtained for M′/M ratios of less than 1.4, whereas for M′/M ratios greater than 1.4, polymeric structures have been identified. This conclusion appears to be corroborated in $M'\{Sn(OBu^t)_3\}$ systems, in which due to the large size (93 pm) of Sn(II) both lithium and sodium derivatives are discrete dimeric solids with M′/Sn(II) ratios attaining values in the range 0.82 to 1. However, in the analogues of potassium and its heavier congeners, the ionic form is attained even with potassium when the M′/Sn(II) ratio becomes 1.40.

Apart from the size of the alkali metal present, the increase in the bulk of the alkoxo group from OPr^i to OBU^t has a predominant role in determining the stability and structures of derivatives of the type

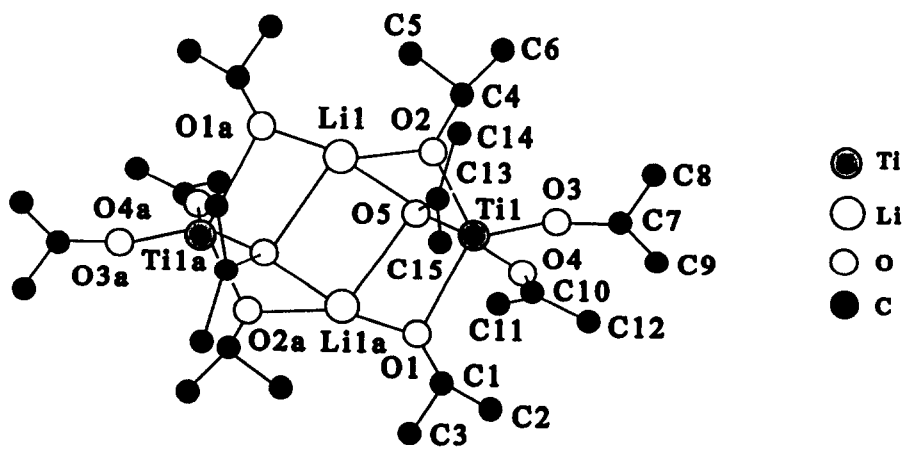

Fig. 8. X-ray crystal structure of $[LiTi(OPr^i)_5]_2$ [30].

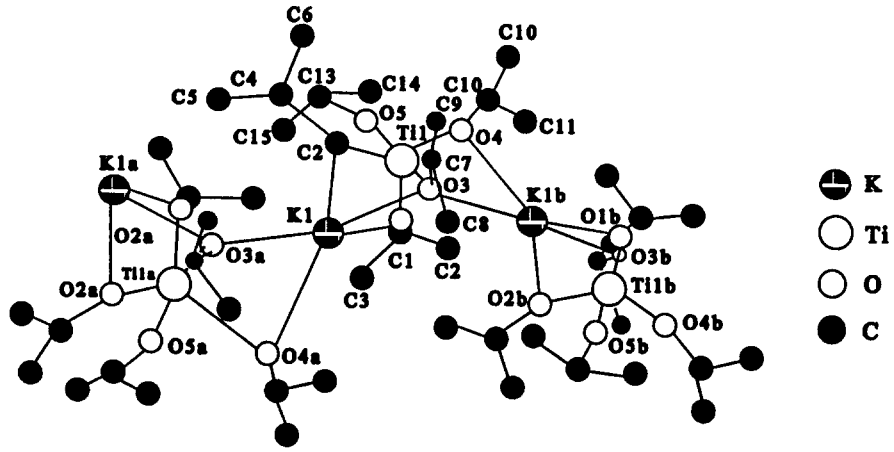

Fig. 9. X-ray crystal structure of $[KTi(OPr^i)_5]_\infty$ [29].

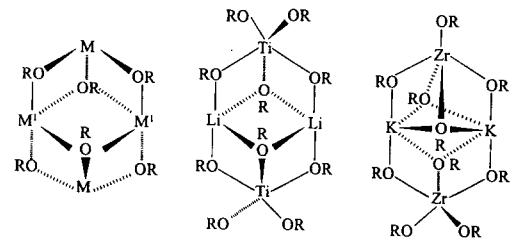
$M'M(OR)_5$. An interesting example arising from such influences is the crystallographically characterized discrete dimeric molecule $[KZr(OBu^t)_5]_2$ (**17**) [43] (Fig. 10), which is composed of two five-coordinate inequivalent zirconium centres, each depicting trigonal–bipyramidal geometry, and the two five-coordinate potassium atoms.

From the above crystallographic investigations structural correlationships between the two discrete dimeric molecules $[LiTi(OPr^i)_5]_2$ and $[KZr(OBu^t)_5]_2$ can be envisaged. For example, these structures appear to be related to the more symmetric $M'_2M_2(\mu_3\text{-}OR)_2(\mu_2\text{-}OR)_4$ unit shown in (I). In this M and M′ can have a varying number of terminal alkoxo ligands either on M, M′, or both in a process to attain sterically allowed coordinative saturation. For example, $Li_2Ti_2(OPr^i)_{10}$ adopts structure(II), with two terminal isopropoxo groups on each titanium (at site M) and no terminal ligand on lithium (at site M′), as in (II). In view of the larger size of K^+ ion compared to that of Li^+, a third μ_3-OR group is required to satisfy coordinative saturation of K^+ centres, as in (III).



(I) (II) (III)

Hexaalkoxometallate derivatives

Veith and co-workers [67,68], who have contributed richly in the area of heavy *p*-block metal anion complexes, emphasized that the "sandwich" type structure(IV) (based on the desire of metal ions to achieve their preferred coordination number and geometry involving the formation of alkoxo (μ_2- or μ_3-) bridg-

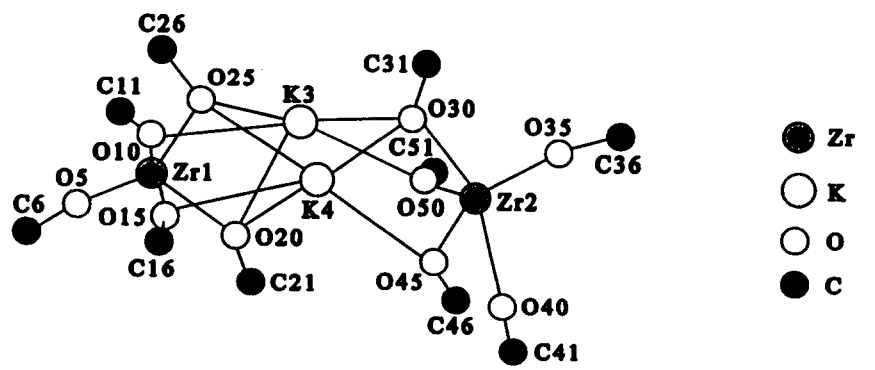


Fig. 10. X-ray crystal structure of $[KZr(OBu^t)_5]_2$. [43].

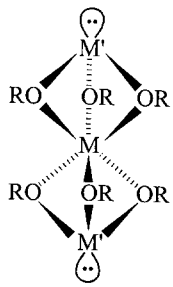
ing), when R is the sterically bulky OBu^t group, is of wide occurrence, and acceptability in heterobimetallic alkoxides involving the heavy main group ion (M′) contain a lone pair of electrons.

The presence of this type of basic skeleton has been crystallographically [46,47] established in the case of $Tl_2Zr\{OCH(CF_3)_2\}_6$ (**19**) (Fig. 11); the presence of M′ ··· F interactions with the CF_3 group plays a role in satisfying the coordination sphere of the thallium ion (M′) and in preventing further association of the trinuclear unit.

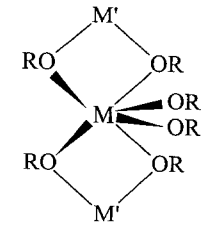
The structure of (**19**) (Fig. 11) is centrosymmetric, containing a crystallographic inversion centre at the zirconium atom, which is surrounded by six fluoroalkoxo groups in a distorted octahedron, capped on *trans* faces by Tl^+ ions giving the overall molecular unit $Tl(\mu_2\text{-}OR_f)_3Zr(\mu_2\text{-}OR_f)_3\,Tl(R_f{=}CH(CF_3)_2)$:

Interestingly, in other derivatives such as $Na_2Zr\{O\text{-}CH(CH_3)_2\}_6(C_6H_6)_2$ (**20**) [47], $Na_2Zr\{OCH(CF_3)\}_6(C_6H_6)$ (**21**) [47], $\{(COD)Rh\}_2\{Ti(OPr^n)_6\}$ (**22**) [56], and $\{(COD)RH\}_2\{Sn(OEt)_6\}$ (**23**) [55], the generic basic structural skeleton (V) $M'(\mu_2\text{-}OR)_2(OR)_2M(\mu_2\text{-}OR)_2M'$ is present.

The derivative (**20**) [47] depicts a special feature in that the Na^+ cations (M′) are loosely coordinated by



(IV)



(V)

η^6-benzene ligands (one to each Na^+); this prevents further association of the complexed unit by satisfying the coordination state of sodium cations. The structure of (**20**) shown in Fig. 12 is again a sandwich type compound similar to the thallium analogue (**19**) (Fig. 11) with the difference that lone pair sites are occupied by benzene ligands in (**20**) along with the presence of four doubly-bridged instead of six doubly-bridged fluoroalkoxo groups in (**19**). Crystallographic studies have also shown evidence of secondary heterometal (Na or Tl) ··· F interactions.

It is interesting that in the absence of one of the two η^6-ligated benzene molecules, the species $Na_2Zr\{O\text{-}CH(CF_3)_2\}_6(C_6H_6)$ adopts a structure with an infinite chain of alternating benzene and $Na_2Zr\{O\text{-}CH(CF_3)_2\}_6$ links.

It may not be out of place to mention that in view of the versatility of a $\{Zr_2(OPr^i)_9\}^-$ ligand which offers a variety of synthetic and structural possibilities and choices, it should be of considerable interest to investigate the chemistry of the $[Zr_2\{OCH(CF_3)_2\}_9^-$ ligand.

The derivatives (**22**) [56] and (**23**) [55] are structurally quite similar in adopting the basic skeleton shown in (**V**), wherein the heterometal (M′) sites are occupied by (COD) Rh^+ species and M=Ti (R=Pr^n) [56] or Sn (R=Et) [55] respectively. While the structure of the titanium derivative (**22**) (Fig. 13) possesses

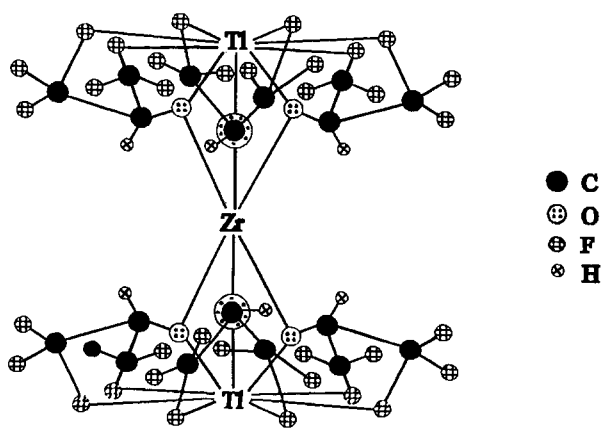


Fig. 11. X-ray crystal structure of $Tl_2Zr\{OCH(CF_3)_2\}_6$ [46,47].

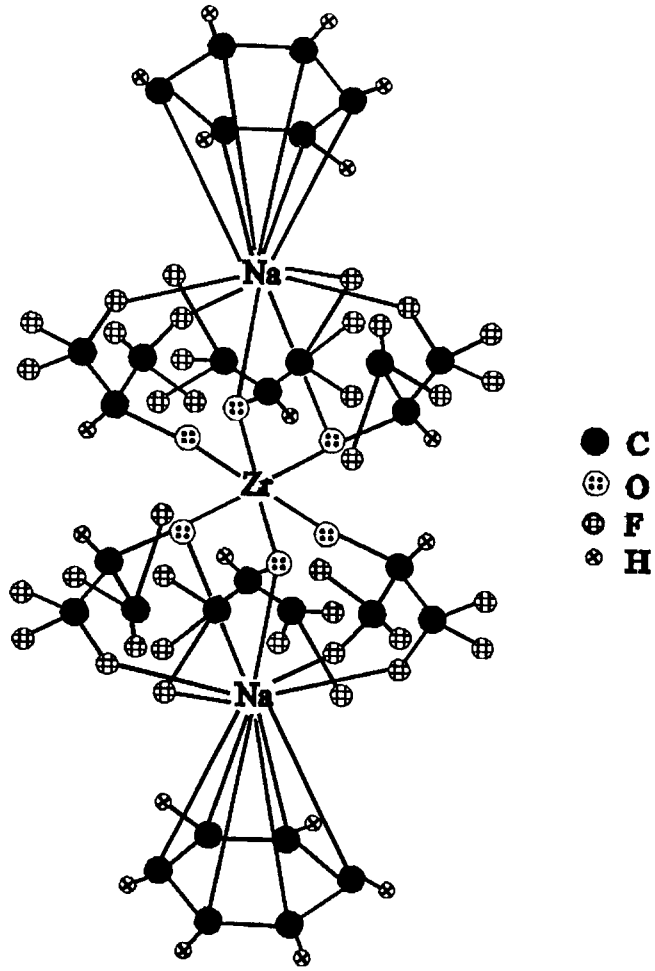

Fig. 12. X-ray crystal structure of $Na_2Zr\{OCH(CF_3)_2\}_6(C_6H_6)_2$.

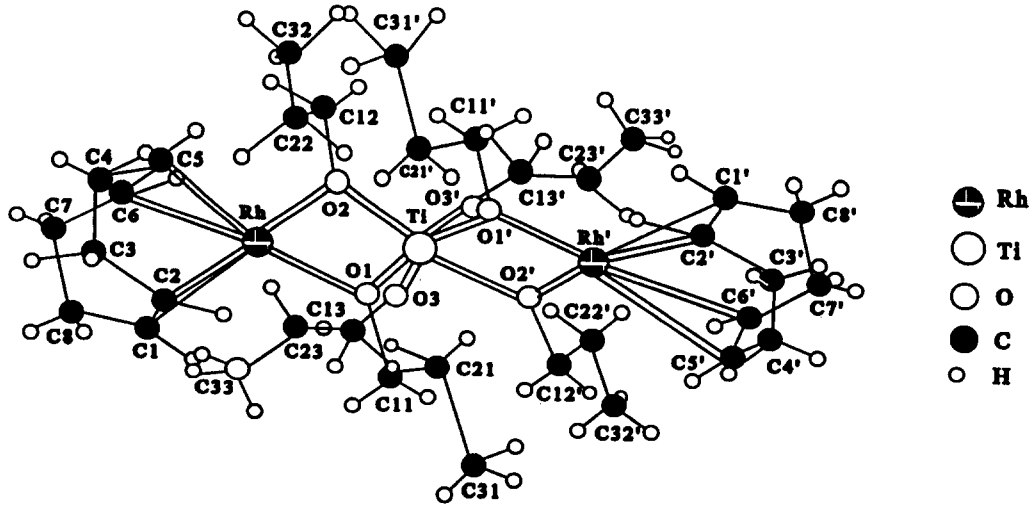

Fig. 13. X-ray crystal structure of $\{(COD)Rh\}_2\{Ti(OPr^n)_6\}$ [56].

a rigorous crystallographic C_2 symmetry, that of the tin derivative (**23**) depicts only approximate idealized C_2 symmetry. The most noticeable difference between the two is the different bonding mode for the two terminally bonded alkoxo groups which have a nearly linear (160(1)°) in (**22**) and a more bent angle (125.5°) in the case of (**23**). The acute M—O_t—C (terminal) bond angles appear to be a general feature in main group metal alkoxide [28,42,55,69] chemistry.

The structure (Fig. 14) for $(DME)_2$ $Na_2Ce(\mu_3\text{-}OBu^t)_2$ $(\mu_2\text{-}OBu^t)_2$ $(OBu^t)_2$ [59], is interesting in that (DME) Na^+ electrophiles occupy adjacent faces of the octahedron rather than *trans* faces, which would give a more linear Na/Ce/Na geometry.

Each sodium atom in the above structure (Fig. 14) is five-coordinate. The cerium atom adopts a distorted octahedral geometry wherein two OBu^t groups are terminal, two are double (μ_2-) bridging and two are triple (μ_3-) bridging.

Detailed investigations on similar derivatives of other tetravalent metals would be expected to throw light on the above mentioned structural diversities.

By contrast, $Tl_2Sn(OEt)_6$ (**24**) [45] exists, due to the lone pair on thallium, as a one dimensional polymer in the solid state (Fig. 15) with two types of ethoxo ligands, i.e. two double (μ_2-) bridging ethoxo ligands that bridge Tl and Sn and one triple (μ_3-) bridging ethoxo ligand that bridges two Tl centres and one Sn atom. Each Sn(IV) centre is in an octahedral environment while each Tl(I) centre adapts a distorted trigonal–bipyramidal geometry, with a lone pair occupying the vacant equatorial coordination site.

In view of the recent novel developments in the chemistry of the $\{Sn_2(OPr^i)_9\}^-$ ligand in our [27,40,51,70] as well as other [28] laboratories, it might also be of interest to investigate the Tl/Sn/OPr^i systems.

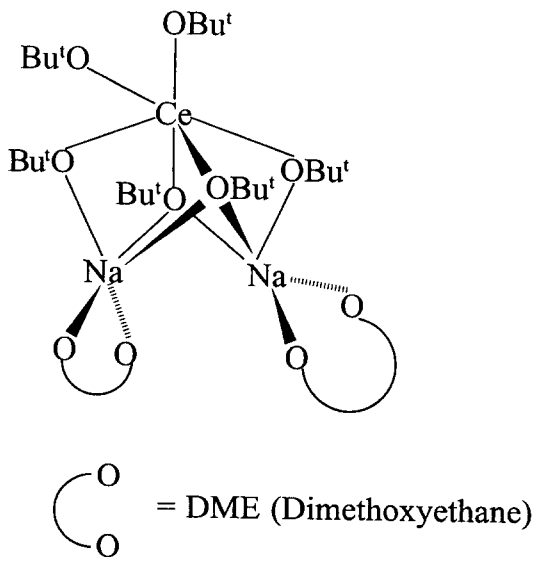

Fig. 14. Schematic structural representation of X-ray determined heterobimetallic alkoxide of cerium(IV) $(DME)_2$ $Na_2Ce(OBu^t)_6$ [59].

Heterotrimetallic alkoxides

Synthesis (by metathesis reaction) and characterization by physicochemical methods of a large number of interesting heterotrimetallic derivatives have been reported from our laboratories. However, X-ray crystal structures of only three derivatives $[\{Cd(OPr^i)_3\}Ba\{M_2(OPr^i)_9\}]_2$ (M=Ti (**25**) [54], Zr (**26**) [61], and Hf (**27**) [54]) have been elucidated so far.

The formation of the derivative (**26**) by the reaction shown below

$$2\{Zr_2(OPr^i)_9\}CdI + 2KBa(OPr^i)_3 \rightarrow [\{Cd(OPr^i)_3\}Ba\{Zr_2(OPr^i)_9\}]_2 + 2KI$$

has a distinctive feature, i.e. the exchange of central metal atoms between the two precursors used for its synthesis. This change is possibly favoured by the greater oxophilicity of barium(II) and its tendency for higher coordination numbers.

The structure shown in Fig. 16 depicts a crystallographic centre of symmetry and all Ba and Zr atoms as six-coordinate, while cadmium atoms are four-coordinate.

Hopefully, this interesting development will soon be followed by structural elucidation of other ter- as well as higher heterometallic alkoxides [40,52,71–73].

CONCLUSIONS

After the three seminal papers in 1957 [15], 1958 [13], and 1967 [16] on the title compounds, a new upsurge occurred in the field due to their X-ray structural elucidation and fastly emerging applications as precursors for novel materials by the Sol–Gel [74,75] and MOCVD [12] processes. It is gratifying to the authors that except for the series of soluble and volatile $M'_2Zr_3(OPr^i)_{14}$ (where M'=Li, Na, K) species reported [16] in 1967, all the other observations and inferences noted in the above publication [16] have been broadly corroborated during the last three decades by more sophisticated techniques. In addition to various suggestions for future lines of investigation mentioned in this paper already, it would also be interesting to establish the identity of these $M'_2Zr_3(OPr^i)_{14}$ complexes, particularly in view of the recent developments in the tetraisopropoxoaluminates of magnesium [76] and barium [77] with compositions different from the conventional $M'\{Al(OPr^i)_4\}_2$ (M'=Mg, Ca, Sr, Ba, etc.) described earlier from our laboratories [70] in our pursuit of "single source" precursors for a desired ceramic material. Furthermore, the synthesis and X-ray crystal structure [79] of a novel type of derivative $[Mg\{Ti_2(OEt)_8Cl\}(\mu\text{-}Cl)]_2$ with a $\{Ti_2(OEt)_8Cl\}^-$ in place of the usual

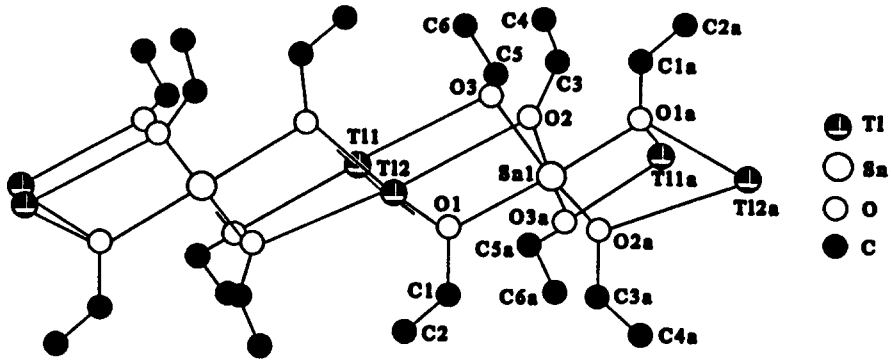

Fig. 15. X-ray crystal structure of $[Tl_2Sn(OEt)_6]_\infty$.

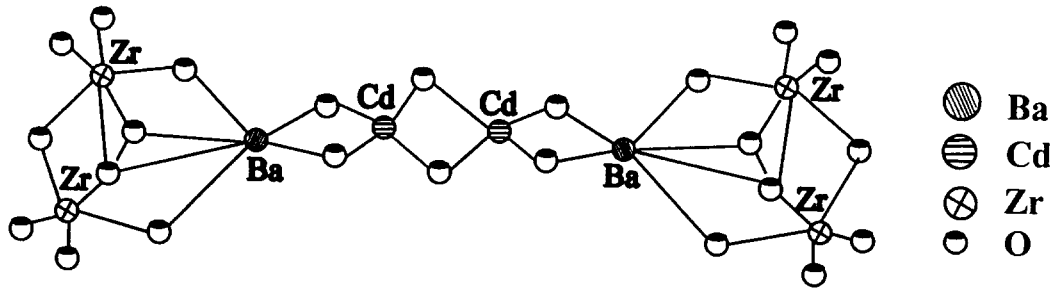

Fig. 16. X-ray crystal structure of $[\{Cd(OPr^i)_3\}Ba\{Zr_2(OPr^i)_9\}]_2$ [61].

$\{M_2(OR)_9\}^-$ unit has opened up a new dimension in heterometallic alkoxide chemistry; our recent [40,80] findings in this particular area are rather exciting, but the same are not being included in this article for sake of brevity.

Acknowledgements—Thanks are due to the Department of Science and Technology, New Delhi, for financial support of our work and to Professor D. C. Bradley, FRS, for his continued encouragement.

In view of the close association of one of the authors of this article with Professor Bradley in the formative years (1950–52) of homometallic alkoxide chemistry, and his highly innovative contributions to this field, we deem it a privilege to dedicate this article to Don C. Bradley on the occasion of his 73rd birthday.

(Received 26 May 1997; revised 13 August 1997)

Abstract—The compounds $W_2(NMe_2)_2(OCMe_2CF_3)_4$, **1**, $W_2(NMe_2)_2(OCMe(CF_3)_2)_4$, **2**, and $W_2(NMe_2)_2(OC(CF_3)_3)_4$, **3**, have been obtained from reactions between $W_2(NMe_2)_6$ and the respective fluoroalcohol in hydrocarbon solvents. The compounds **2** and **3** appear inert to further reaction with their fluoroalcohol at room temperature while **1** reacts further to give $W_2(OCMe_2CF_3)_6$. In solution NMR data indicate that all three compounds exist in a mixture of *anti*- and *gauche*-rotamers with restricted rotations about both W—N and W≡W bonds on the NMR time-scale. The solid-state molecular structure of **2** reveals a centrosymmetric $NO_2W{\equiv}WO_2N$ core with W—W = 2.3107(6) Å, W—N = 1.914(4) Å, W—O = 1.959(3) and 1.907(3) Å and angles W—W—O/N within the range 100 to 110°. The gas phase photoelectron spectra for **1**, **2** and **3** were obtained and are compared with that for $W_2(NMe_2)_6$. The introduction of the fluoroalkoxide ligands has a pronounced effect in stabilizing the metal and nitrogen lone-pair based ionizations, and this effect is amplified by the successive replacement of each methyl group by a trifluoromethyl group. Also for the compounds **1**, **2**, and **3** the lowest ionization bands clearly reveal the removal of the degeneracy of the W—W π MOs as expected for *anti* and *gauche* complexes. © 1998 Elsevier Science Ltd. Keywords: $W_2(NMe_2)_2(OR_f)_4$; photoelectron spectroscopic studies; single crystal X-ray structure.

The reactivity of a metal center is greatly influenced by the nature of the metal, its electronic configuration and the set of attendant ligands. These effects are clearly evident for $M_2(OR)_6$ compounds, where M = Mo and W, that share a common ethane-like structure $O_3M{\equiv}MO_3$, where the triple bond is cylindrical being composed of one σ and two π components $\sigma^2\pi^4$ [1,2]. The marked differences in reactivity as a function of metal is seen in the reductive cleavage of nitriles by $W_2(O^tBu)_6$, eqn (1), [3], whereas the complex $Mo_2(O^tBU)_6$ is inert with respect to reaction with MeC≡N under similar conditions.

(1) $W_2(O^tBu)_6 + MeC{\equiv}N \xrightarrow[\text{hexane}]{0\,^\circ C}$

$$(^tBuO)_3W{\equiv}N + (^tBuO)_3W{\equiv}CMe$$

However, upon changing the alkoxide from O^{t}Bu to $OCMe_2CF_3$ Schrock and co-workers noted [4] not a reductive cleavage analogous to (**1**) but rather a reversible Lewis base association, eqn (2).

* Dedicated to Professor D. C. Bradley, in appreciation and respect for his pioneering work on metal amides and metal alkoxides.

(2) $W_2(OCMe_2CF_3)_6 + 2MeC{\equiv}N \underset{\text{toluene-}d_8}{\rightleftharpoons} W_2(OCMe_2CF_3)_6(NCMe)_2$

In our studies of the activation of CO we have seen similar differences and noted that the behavior of $W_2(NMe_2)_2(OR_f)_4$ compounds (R_f = a fluoroalkyl group) is markedly different from that of $W_2(NMe_2)_6$ [5]. In this paper we report the preparation and characterization of a series of $W_2(NMe_2)_2(OR_f)_4$ compounds for which photoelectron spectroscopy reveals an interesting trend with the increase of substitution of Me by CF_3.

RESULTS AND DISCUSSION

Syntheses

The compounds $W_2(NMe_2)_2(OR_f)_4$, where $R = CMe_2CF_3$, **1**, $R = CMe(CF_3)_2$, **2**, and $R = C(CF_3)_3$, **3**, were prepared according to the alcoholysis reaction shown in eqn 3.

(3) $W_2(NMe_2)_6 + 4R_fOH \xrightarrow[\text{hydrocarbon}]{22\,^\circ C} W_2(NMe_2)_2(OR_f)_4 + 4HNMe_2$

The reaction involving $R_f = CMe_2CF_3$ represents a partial alcoholysis as in the presence of excess $Me_2(CF_3)COH$ the homoleptic alkoxide $W_2(OCMe_2CF_3)_6$ is formed. However, under similar conditions the compounds **2** and **3** are inert to further alcoholysis. In the case of the preparation of **3** the amine salt $Me_2NH_2^+OC(CF_3)_3^-$ is formed and is removed by vacuum sublimation at 45 °C, 10^{-2} Torr. A similar finding has been reported for the preparation of $Mo_2(NMe_2)_2(OC(CF_3)_3)_4$ in the reaction between $Mo_2(NMe_2)_6$ and $(CF_3)_3COH$ [6].

The new compounds **1**, **2** and **3** are orange, hydrocarbon-soluble, air-sensitive, crystalline solids at room temperature. They show moderate thermal stability and may be sublimed in the temperature range 85–110 °C at 10^{-3} Torr, with only minor decomposition. In solution the NMR data indicate the presence of *gauche*- and *anti*-rotamers with the *gauche* being the major rotamer. There is restricted rotation about both the W≡W and W—N bonds. The coalescence of proximal and distal NMe groups does not occur below 110 °C in toluene which places $\Delta G^{\neq}_{\text{rotation}} > 17$ kcal/mol in contrast to 11 kcal/mol in $W_2(NMe_2)_6$ [7].

Solid-state and molecular structure of $W_2(NMe_2)_2(OCMe(CF_3)_2)_4$, **2**, *and a discussion of bonding*

Compound **2** crystallizes from hexanes in the space group C_2/c with four molecules in the unit cell. A drawing of the molecular structure with the atom label scheme is shown in Fig. 1. Pertinent bond distances and bond angles are given in Table 1. The molecule is situated at a crystallographic inversion center which relates both halves of the molecule as shown. The staggered *anti* $NO_2W{\equiv}WO_2N$ unit is unexceptional and the W—W distance of 2.3207(6) Å is as expected [1,2]. The two W—O distances, 1.959(3) and 1.907(3) Å are longer than those seen in $W_2(OR)_6$ compounds which fall in a very narrow range 1.88(1) Å [8] and the W—N distances 1.914(4) Å are notably shorter than that in $W_2(NMe_2)_6$, 1.98(1) Å (ave) [7]. This is understandable in terms of the $OCMe(CF_3)_2$ ligand being a weaker σ- and π-donor relative to OR (R = alkyl) and NMe_2. Thus the successive replacement of the W—NMe_2 bonds by $OCMe(CF_3)_2$ bonds leads to

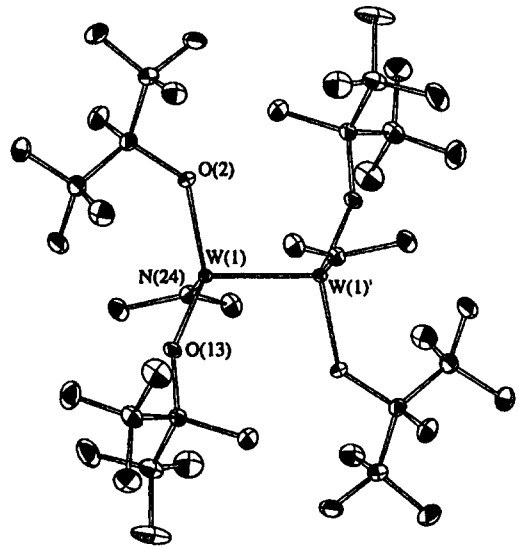

Fig. 1. An ORTEP drawing of the $W_2(NMe_2)_2(OCMe(CF_3)_2)_4$ molecule.

Table 1. Selected bond distances (Å) and bond angles (°) for $W_2(NMe_2)_2(OCMe(CF_3)_2)_4$

A	B	Distance
W(1)	W(1)′	2.3107(6)
W(1)	O(2)	1.959(3)
W(1)	O(13)	1.907(3)
W(1)	N(24)	1.914(4)
F	C	1.33(1) (ave)

A	B	C	Angle
W(1)′	W(1)	O(2)	100.78(10)
W(1)′	W(1)	O(13)	110.57(11)
W(1)′	W(1)	N(24)	99.85(14)
O(2)	W(1)	O(13)	115.45(15)
O(2)	W(1)	N(24)	117.90(17)
O(13)	W(1)	N(24)	110.42(17)

enhanced π-donation by the Me_2N ligands that remain at the W_2^{6+} center.

To a first order approximation one might expect the electron releasing properties of an alkoxide to correlate with the pKa of the free alcohol which are 18.6 for ^tBuOH, 11.4 for Me_2CF_3COH, 9.6 for $Me(CF_3)_2COH$, and 5.4 for $(CF_3)_3COH$ [9]. It should be noted too that with the change in pKa of the alcohol there is a similar change in the ionization energy of the oxygen lone-pair: compare 10.22 eV for ^tBuOH, 11.11 eV for CF_3Me_2COH and 11.93 eV for $(CF_3)_2MeCOH$, for example [10]. Thus for a compound of formula $W_2(NMe_2)_2(OR)_4$ the successive substitution of CF_3 for Me on the ^tBu group would lead to an increase in W—N π-bonding. This should manifest itself in (i) shorter W—N bonds, (ii) an increase in the barrier to W—N bond rotation and (iii) an increase in the kinetic barrier for subsequent alcoholysis to give $W_2(OR)_6$ since protonation of the amide nitrogen represents an important component to this ligand exchange reaction. Within the series of compounds reported here this is seen. As described elsewhere the metal centers become more Lewis acidic as the RO^- ligands donate less electron density to the metal centers [11]. This can be understood as the LUMOs of the M_2 complexes are the M—M δ and δ^* orbitals which, in the presence of π-donor ligands are raised in energy, since they are the metal receptor d orbitals for ligand to metal π-bonding [12].

Photoelectron spectroscopy

The He I photoelectron spectra of the low-valence regions of $W_2(NMe_2)_6$, $W_2(NMe_2)_2(OCMe_2(CF_3))_4$, $W_2(NMe_2)_2(OCMe(CF_3)_2)_4$, and $W_2(NMe_2)_2(OC(CF_3)_3)_4$ are shown in Fig. 2. The ionizations are represented by asymmetric Gaussian peaks [13], parameters for which are listed in Table 2. In this energy region, the spectrum of $W_2(NMe_2)_6$ contains ionizations that originate from the M—M σ orbital, the M—M π orbitals, and the six amide-based nitrogen lone-pair orbitals, while the spectra of the mixed amide/alkoxide compounds contain ionizations that originate from the M—M σ orbital, the M—M π orbitals, and the two amide-based nitrogen lone-pair orbitals. The primary orbital character associated with an ionization has been assigned by comparison to the PES of other triply-bonded Mo_2- and W_2-containing alkoxide and amide ligands [14,15], by comparison within this series of compounds, and by comparison to the results of Fenske–Hall calculations [16] on the model systems $M_2(NH_2)_2(OH)_4$ (M = Mo, W). The assignments listed in Table 2 reflect the primary character of the corresponding valence metal or ligand orbitals. However, it must be remembered that a completely accurate description of an orbital from which an ionization originates includes additional mixing with other valence metal or ligand orbitals.

The spectrum of $W_2(NMe_2)_6$ is shown in Fig. 2(A).

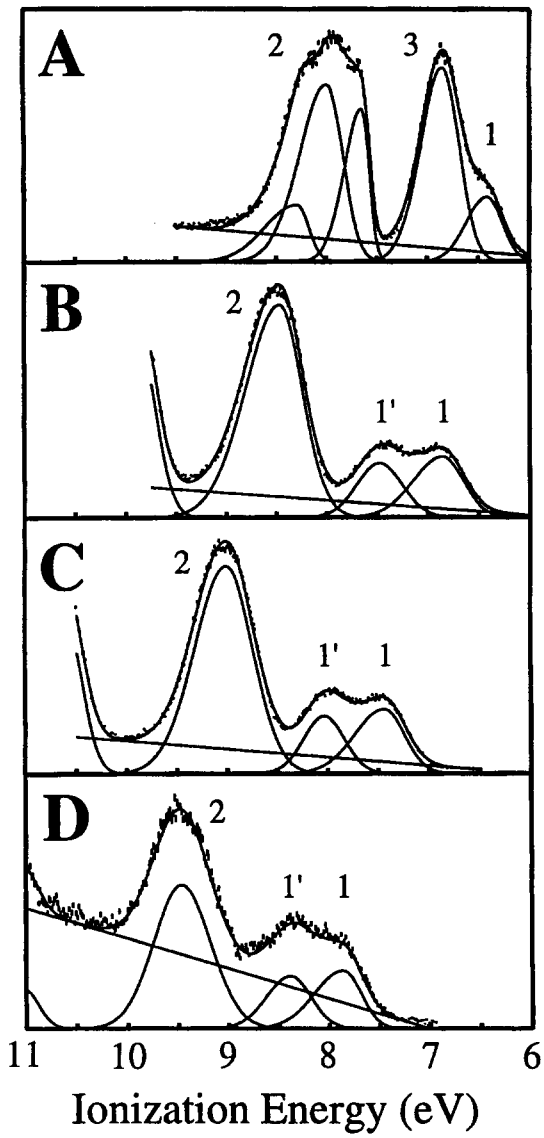

Fig. 2. He I photoelectron spectra of compounds of (**A**) $W_2(NMe_2)_6$, (**B**) $W_2(NMe_2)_2(OCMe_2(CF_3))_4$, (**C**) $W_2(NMe_2)_2(OCMe(CF_3)_2)_4$, and (**D**) $W_2(NMe_2)_2(OC(CF_3)_3)_4$.

Several differences are evident between the spectrum of this compound and the previously reported PES of $Mo_2(NMe_2)_6$ [13]. For $Mo_2(NMe_2)_6$, there is a complex series of overlapping ionizations in this region. The leading edge of the overlapping ionizations has been assigned to the nitrogen lone-pair orbitals of a_{2g} and a_{1u} symmetry that do not have the correct symmetry to interact with any of the metal-based orbitals and are nearly degenerate in energy. The spectrum of $W_2(NMe_2)_6$, in contrast, has two separate bands in this region. The band at lowest ionization energy has a shoulder on the low ionization energy side (labeled 1 in Fig. 2A) that is assigned to ionization from the W—W π orbital, which has been destabilized from the position of the Mo—Mo π ionization as is

Table 2. Fit parameters for photoelectron spectra

Compound	Position (eV)	Halfwidth High	Halfwidth Low	Rel. Area	Label	Assignment

typically seen for W-based versus Mo-based ionizations in compounds with multiple metal–metal bonds [17]. The main portion of this band (band 3) is assigned to ionization from the same non-interacting nitrogen lone-pair orbitals (a_{2g} and a_{1u}) that are the highest occupied molecular orbitals for $Mo_2(NMe_2)_6$. The ionization energies of these nitrogen lone-pairs are approximately the same for the Mo and W compounds, being shifted only 0.09 eV to higher ionization energy for the W analogue. The ionization band labeled 2 in Fig. 2(A) contains ionizations from the nitrogen lone-pair orbitals of e_g and e_u symmetry, as well as ionization from the W—W σ bond, based on the separations observed between the σ and π ionizations of other M—M triple-bonded complexes [10].

The spectra of the three mixed amide/alkoxide compounds are shown in Fig. 2(B)–(D). These compounds each have two ionizations from nitrogen lone-pairs in this region, which are assigned to band 2. The non-interacting lone-pair ionizations in band 3 for $W_2(NMe_2)_6$ are gone. Two small ionizations of about equal intensity are seen at the low ionization energy side of the spectra. While at first consideration it might be thought that the first two ionization bands, labeled 1 and 1′ in Fig. 2, could be assigned to the W—W π and σ ionizations, the data are not consistent with this assignment. Bands 1 and 1′ have relative areas (1 : 1′) ranging from 1.37 : 1.00 to 1.16 : 1.00. In general, the observed relative areas of the σ and π ionizations of tungsten and molybdenum hexaalkoxides are about 1 : 2 [14]. Also, bands 1 and 1′ are separated from each other by 0.53 eV to 0.63 eV for these compounds, while other W—W triple bonded systems have σ and π ionizations that are separated by 1.52 eV [$W_2(OCMe_3)_6$] to 1.74 eV [$W_2(OCMe(CF_3)_2)_6$] [10]. The bands 1 and 1′ are assigned to the two W—W π ionizations, which in the lowered symmetry of these molecules are no longer expected to be degenerate. These molecules are known to exist in an *anti* conformation in the crystalline phase and as a mixture of *anti* and *gauche* (primarily *gauche*) conformations in solutions. The gas-phase conformation is not explicitly known. However, Fenske–Hall calculations on the model complex $W_2(NH_2)_2(OH)_4$ predict that in the ground state these two metal based orbitals will be most separated in energy for the *anti* conformation and will be very little separated in the *gauche* conformation. This is because in the C_{2h} symmetry of the *anti* conformation the W—W π orbitals transform as b_u and a_u symmetry orbitals, which will have greatly different amounts of overlap with the alkoxide oxygen lone-pair orbitals. The Fenske–Hall calculations would therefore suggest the observed splitting of the π ionizations indicates that these molecules exist primarily in the *anti* conformation in the gas phase. The ionization band labeled 2, which is assigned to the two nitrogen lone-pair ionizations must also contain the W—W σ band ionization.

As fluorines are added to the alkoxide ligands, all of the ionizations in this region shift to lower ionization energy. These shifts are influenced by two factors. The first of these is the change in net charge potential felt at the metal or nitrogen centers, which is the result of the σ-donating ability and orbital charge distribution of the alkoxide ligands. The second factor is the orbital overlap interactions of the metal with the oxygen lone-pair orbitals of the alkoxides, forming bonding and anti-bonding pairs. As fluorines are added to the alkoxides, the oxygen lone-pairs are lowered in energy, thereby reducing their interactions with the W—W π orbital. The ionization labeled 1 shifts 0.59 eV as the number of fluorines per alkoxide is increased from three to six, and 0.41 eV as the number of fluorines is increased from six to nine. The non-additivity

of these shifts is likely due to geometry changes in the alkoxide ligands upon fluorination. The shifts of the W—W π ionizations with successive fluorinations of the alkoxide ligands are comparable to the shift of the W—W π ionizations when four amide ligands of $W_2(NMe_2)_6$ are replaced with four trifluoroalkoxide ligands.

While to this point we have considered the trends observed for the metal-based ionizations, the nitrogen-based ionizations give the most information about the reactivity of these molecules. Ionization band 2 is stabilized to approximately the same extent as the M—M π ionizations, and there is only a small amount of broadening of band 2 as fluorines are added to the alkoxides, which indicates that the W—W σ-bond ionization and amide nitrogen lone-pair ionizations are being stabilized by approximately the same amount. The nitrogen lone-pairs of the amides are stabilized by the same charge effect that causes some of the stabilization of the M—M π-bond ionizations. In addition, these two ligands orbitals interact with the W—W δ and δ^* orbitals in a π symmetry fashion [13]. The W—W δ and δ^* orbitals, in turn, have σ symmetry with respect to the four alkoxy ligands, which allows the alkoxides to directly remove electron density from the nitrogen lone-pairs. As previously noted, the pKas of the free alcohols are significantly lowered by successive substitution of CF_3 for Me on the ^{t}Bu group. The ionization energy of the oxygen lone-pairs for the free alcohols is stabilized by about 0.8 eV per successive substitution of CF_3 for Me, while the amide nitrogen lone-pair ionization energies are stabilized by approximately 0.5 eV per successive substitution. This would suggest that the pKas of the amide lone-pairs are being lowered approximately 5/8 as much as the pKas of the free alcohols. Due to the decrease of electron density at the nitrogens and the resulting lowering of pKa, the nitrogen lone-pairs are stabilized to such an extent that the amide ligands are no longer basic enough to be protonated and allow further ligand exchange.

EXPERIMENTAL SECTION

General methods

Standard air-sensitive Schlenk line and dry-box techniques were used. Aromatic and aliphatic hydrocarbon solvents were dried over sodium or potassium benzophenone ketyl under a N_2 flow, subjected to three freeze-thaw-degas cycles before use, and stored over 4 Å molecular sieves. The fluoroalcohols (from PCR) were distilled and subjected to three freeze-thaw-degas cycles prior to use.

Spectroscopic methods

Infrared spectra were obtained on a Perkin–Elmer 283 Spectrophotometer as Nujol mulls between NaCl plates or as pressed KBr pellets. ^{1}H NMR spectra were recorded on either a Varian GEM-300, a Nicolet 360, Varian I-400, or a Bruker AM-500 NMR spectrophotometer in dry, degassed toluene-d_8 or benzene-d_6. ^{1}H NMR chemical shifts are in ppm relative to the protio impurity in benzene-d_6 set at δ 7.15 or the CHD_2 quintet of toluene-d_8 set at δ 2.09. ^{13}C NMR spectra were recorded on Varian GEM-300, Varian I-400, or Bruker AM-500 spectrophotometers at 75, 100 and 125 MHz, respectively. ^{13}C NMR chemical shifts are in ppm relative to the triplet of benzene-d_6 set at δ 128.0 ppm or the downfield singlet of toluene-d_8 set at δ 137.5. ^{19}F NMR spectra were recorded on a Varian GEM-300 or a Nicolet 360 spectrophotometer at 282 and 340 MHz, respectively. ^{19}F NMR chemical shifts are in ppm relative to the external reference of CF_3COOH set at δ −76.5.

Photoelectron spectra were recorded using an instrument that features a 36 cm hemispherical analyzer (McPherson) and custom designed sample cells and detection and control electronics. The instrument and data collection and manipulation procedures have been described in detail elsewhere [19]. During collection the instrument resolution (measured using the full-width-at-half-maximum of the argon $^2P_{3/2}$ ionization) was 0.020–0.030 eV.

All samples sublimed cleanly with no detectable evidence of decomposition products in the gas phase or as a solid residue. The sublimation temperatures (in C, at 10^{-4} torr) were: $W_2(NMe_2)_6$, 99–102°; $W_2(NMe_2)_2(OCMe_2(CF_3))_4$, 94–98°; $W_2(NMe_2)_2(OCMe(CF_3)_2)_4$, 92–100°; $W_2(NMe_2)_2(OC(CF_3)_3)_4$, 67–73°. Temperatures were monitored using a "*K*" type thermocouple passed through a vacuum feedthrough and attached directly to the sample cell.

The spectra are represented analytically with the best fit of asymmetric Gaussians [13]. Each Gaussian is defined by its position, amplitude, half-width on the high binding energy side, and half-width on the low binding energy side.

Preparation of $W_2(OCMe_2CF_3)_4(NMe_2)_2$ (**1**). $W_2(NMe_2)_6$ (167 mg, 0.264 mmol) was dissolved in hexanes (10 ml). $HOCMe_2CF_3$ (203 mg, 1.58 mmol) was added to the solution via gas-tight ml syringe. The reaction was allowed to stir for 6 h and became dark red in color. The solvent was removed under vacuum. **1** was obtained in crystalline form (248 mg, 83%) from benzene 80°C to 23°C. ^{1}H NMR (300 MHz, toluene-d_8, 23°C): δ 4.10, 2.51, 1.90, 1.66, 1.16, 0.95 (6:6:6:6:6:6 for *gauche* rotamer) and 4.15, 2.37, 1.41, 1.35 (6:6:12:12 for *anti* rotamer). ^{19}F NMR (282 MHz, C_6D_6 ext. ref. to CF_3COOH at −23°C): δ −83.4, −83.8 (1:1 for *gauche* rotamer) and −83.6 (for *anti* rotamer).

Preparation of $W_2(OC(CF_3)_2Me)_4(NMe_2)_2$ (**2**). $W_2(NMe_2)_6$ (2.20 g, 3.48 mmol) was dissolved in 25 ml of hexanes. The fluoroalcohol (4.3 g, 24 mmol) was then added to the solution via syringe and the reaction stirred for several hours. An instantaneous reaction was evident based on the observation of a

color change to deep red, and microcrystals of the sparingly soluble product were formed. After 2 h, the solvent was evaporated *in vacuo* (23°C, 0.01 Torr) and 2.49 g of **2** (61% yield) was crystallized from hexanes (65 to −35°C). The crystalline material was dried *in vacuo* (23°C, 2 h, 0.01 Torr) prior to use. ^{1}H NMR (300 MHz, toluene-d_8, 23°C): δ 4.22, 2.47, 1.54 (6:6:12 for *anti* rotamer), 4.30, 2.34, 2.07, 1.21 (septet, $J_{H-F} = 1.5$ Hz) (6:6:6:6 for *gauche* rotamer). $^{13}C\{^1H\}$ NMR (75 MHz, toluene-d_8, 23°C): δ 82.36, 60.42, 39.37, 19.42 (s for *anti* rotamer), 82.60, 82.13, 60.11, 40.04, 20.24, 19.57 (s for *gauche* rotamer). ^{19}F NMR (340 MHz, toluene-d_8, 23°C): δ −78.75 (q, J_{F-F} = 10 Hz), −79.59 (q, $J_{F-F} = 10$ Hz) (*anti* rotamer), −78.87 (q, 6F, $J_{F-F} = 9$ Hz), −79.04 (s, 12F), −79.96 (q, 6F, $J_{F-F} = 9$ Hz) (*gauche* rotamer).

Preparation of $W_2(OC(CF_3)_3)_4(NMe_2)_2$ (**3**). $W_2(NMe_2)_6$ (167 mg, 0.264 mmol) was dissolved in hexanes (10 ml). $(CF_3)_3COH$ (500 mg, 2.12 mmol) was added to the solution via gas-tight ml syringe. The reaction was allowed to stir for 6 h and became pale orange–red in color. The solvent was removed under vacuum and $[Me_2NH_2][OC(CF_3)_3]$ was sublimed *in vacuo* at 60°C. **3** was obtained in microcrystalline form (195 mg, 53%) rom toluene 110°C to 23°C. ^{1}H NMR (300 MHz, toluene-d_8, 23°C): δ 2.42 (s, 12 H), 4.21 (6 H), 4.53 (6 H).

Crystallographic study.

General operating procedures and listings of programs have been previously given [19].

$W_2(NMe_2)_2(OCMe(CF_3)_2)_4$. A summary of crystal data collection is given in Table 3.

The structure was solved by initially locating the tungsten position from a Patterson map (SHELXS-86). The remaining non-hydrogen atoms were obtained from subsequent iterations of least-squares refinement and difference Fourier calculation. The center of the molecule is at a crystallographic center of symmetry. The difference Fouriers of the asymmetric unit had two persistent peaks of 4.1 and 2.6 e/Å^3 in the vicinity of the tungsten atom but at chemically unreasonable positions. It was then noted that each was separated from its symmetry equivalent position by 2.30 Å as compared with the observed W—W distance of 2.311 Å. It was therefore assumed that a small amount of disorder was present and two additional tungsten atoms, W(27) and W(28) in the tables of atomic coordinates were included in the refinement. The occupancies initially refined to approximately 2.0 and 1.5% and were fixed at these values for the final cycles of refinement. At these low levels of occupancy, any light atoms associated with the disorder would not be expected to be observed. Hydrogens were included in fixed calculated positions.

In the final cycles of refinement, the ordered non-hydrogen atoms were varied with anisotropic thermal parameters and the two disordered atoms were varied with isotropic thermal parameters to a final $R(F) = 0.029$ for the 244 total variables using all of the unique data. Data having $F < 3\sigma(F)$ were given zero weight and are indicated with asterisks in the appendix of F_o and F_c. The largest peak in the final difference map was 1.5 e/A^3 in the vicinity of the disorder. All other peaks were less than 0.9 e/A^3 and the deepest hole was −1.2 e/A^3.

(Received 3 July 1997; accepted 8 August 1997)

Abstract—The compounds $Ba(O_2CCH_3)_2(18\text{-crown-6})\cdot nH_2O$ and $Ba(O_2C(CH_2)_4CO_2)(18\text{-crown-6})\cdot nH_2O$ were prepared by the reaction between barium carbonate and the appropriate organic acid in the presence of 18-crown-6. These compounds were characterized by a variety of spectroscopic and analytical methods which showed that various hydrates could be formed. The species $Ba(O_2CCH_3)_2(18\text{-crown-6})\cdot 4H_2O$ (**1**) and $Ba(O_2C(CH_2)_4CO_2)(18\text{-crown-6})\cdot 8H_2O$ (**2**) were structurally characterized by single-crystal X-ray diffraction. In the solid state compound **1** was comprised of a Ba atom in the center of the 18-crown-6 ring with chelating acetate ligands being in the axial positions of the equitorial coordination plane. Water molecules were hydrogen bonded to the oxygen atoms of the acetate ligands. Compound **2** is an infinite polymer in the solid state with the Ba atom also in the center of the 18-crown-6 ring with each carboxylate group chelating to one Ba and each adipate bridging through the second carboxylate group of the dicarboxylate to another Ba atom. Compound **1** crystallizes in the monoclinic space group $P2_1/c$ with cell dimensions of $a = 9.512(1)$ Å, $b = 7.811(1)$ Å, $c = 16.906(1)$ Å, $\beta = 99.049(8)^\circ$, $V = 1240.5(3)$ Å^3 and $Z = 2$. Compound **2** crystallizes in the triclinic space group $P\bar{1}$ with cell dimensions of $a = 8.525(1)$ Å, $b = 9.769(1)$ Å, $c = 10.200(1)$ Å, $\alpha = 106.59(1)^\circ$, $\beta = 90.37(1)^\circ$, $\gamma = 110.34(1)^\circ$, $V = 757.4(1)$ Å^3 and $Z = 1$. Compounds **1** and **2** thermally decompose to evolve the 18-crown-6 ligand intact at approximately 200°C, prior to the thermal decomposition of the carboxylate ligand to form $BaCO_3$. Compounds **1** or **2** were mixed with $Ti(O\text{-}i\text{-}Pr)_4$ in ethanol, spin coated onto Pt substrates and heated to 400°C followed by annealing at 700°C for 1 h in air. Coumpound **1** resulted in formation of a mixture of $BaTiO_3$, $BaCO_3$ and TiO_2, while **2** produced only $BaCO_3$ films. The difference in reactivity of **1** and **2** may be connected to the availability of a thermal window for ester elimination as indicated by the TGA results. © 1998 Elsevier Science Ltd. Keywords: crown ether adducts; barium carbonate; organic acid.

In the past few years, the technological and commercial value of metal alkoxide compounds is beginning to be realized by their use as precursors for the formation of metal oxide materials [1–4]. The flexibility that metal alkoxide precursors provide, enables the formation of materials with a wide variety of compositions and microstructures. The pioneering work in the development of general synthetic strategies to these precursors and the recognition that they have value as precursors to materials was conducted in the research group of Professor Don Bradley, to whom this volume is dedicated [5,6].

* Author to whom correspondence should be addressed.

The conversion of metal alkoxide precursors to metal oxide materials has been performed using a variety of different reaction strategies including hydrolysis and thermolysis, the initial understanding of which was also pioneered by the same research team [2,7–13]. Bradley *et al.* were also amongst the first to recognize that metal alkoxide compounds could undergo ester elimination reactions which give rise to metal-oxo-metal bonds which are a fundamental building block of metal oxide materials [14]. The original studies involved the reactions between titanium alkoxides and silicon alkoxyacetates which resulted in the formation of metal siloxides. Since this time, a large variety of reactions between metal

alkoxides and metal carboxylates have been shown to result in the formation of metal oxide compounds, particularly in the formation of perovskite phase mixed metal oxides such as $BaTiO_3$ [8,9]. However, although the formation of esters has been established during some of these reactions, the reaction mechanism is not always clear as a result of the presence of other species such as free alcohol, free carboxylic acid and water, which together can also react to form esters as products [8]. To better understand the nature of the reaction between metal alkoxides and metal carboxylates, a number of research groups have been studying reactions between these reagents under conditions where there is less ambiguity in the interpretation of the reaction pathway by virtue of the absence of interfering species [8,9]. Our studies have focused on the investigation of some model tin-containing systems where the reactions can be followed conveniently by multinuclear NMR spectroscopy [15,16]. The general principles deduced from these reactions can then be applied to more technologically relevant systems in an attempt to control the outcome of these reactions [17,18].

In this paper, we describe the synthesis and characterization of two new barium carboxylate compounds which were prepared to investigate their reactivity towards titanium alkoxides to form barium titanate. In this context it is relevant to briefly review the formation of Group 2 element-containing materials.

There is considerable interest in the synthesis of derivatives of the Group 2 elements which have properties which make them suitable as precursors for the formation of Group 2 element-containing thin films [9]. These materials include perovskite phase ferroelectric ceramics such as $PbTiO_3$, $Ba_{1-x}Sr_xTiO_3$, $Pb_{1-x}Zr_xTiO_3$, and $SrBi_2Ta_2O_9$ [8,19,20], dielectric materials such as Sr_2AlTaO_6 [21,22], ceramic superconductors such as $YBa_2Cu_3O_{7-x}$ [23–25], magnetic materials such as $BaFe_{12}O_{19}$ [26,27], and display materials such as Ce-doped MS, where M = Ca, Sr, Ba and Ce-doped $CaGa_2S_4$. The precursor design criteria depend on which method of film deposition is employed. Chemical vapor deposition requires that the precursors have suitable volatility to be transported intact to at heated surface while liquid phase deposition techniques require that the precursors be soluble [28,29]. In each case, once the precursor is delivered to the substrate, it is desirable that it reacts in a way which involves complete elimination of the supporting organic ligands and formation of the desired product. The films are usually required to have the properties of high purity, a high level of crystallinity, theoretical density and be deposited at the lowest possible temperature.

The synthesis of suitable precursors of the Group 2 elements has presented a particular problem for the formation of Group 2 element-containing materials. The origin of this problem lies in the tendency of the Group 2 elements to form oligomeric species as a result of their high coordination numbers (typically Ca, Sr and Ba prefer coordination numbers of 8–12) and the resulting small charge-to-size ratio which is not conducive to the formation of high vapor pressure species for chemical vapor deposition applications. Recently, major advances have been made in the design of low nuclearity Group 2 element compounds through the use of neutral multidentate ligands to consume coordination sites at the Group 2 metal center. The most success in terms of preparing volatile Group 2 element compounds for CVD has been with the use of cyclic or acyclic polyethers or polyamines in conjunction with fluorinated β-diketonates and β-ketoiminates [22,30–38]. However, while β-diketonates appear to be the ligands which impart the highest volatility to metal–organic compounds, their thermal decomposition is often the source of problems associated with impurity incorporation in the film. This is especially true for the case of fluorinated β-diketonates which typically deposit metal fluorides, or at best, fluoride or carbon contaminated films [39,40].

As a result of this problem, we have been searching for alternative supporting ligands and reaction strategies which avoid the problems associated with fluorinated β-diketonates. These strategies include ester elimination reactions between metal carboxylate and metal alkoxide compounds to form metal oxides or sulfides according to the stoichiometry of eqn (1) [15,16,41]; ether elimination between metal alkoxides or siloxides [9,18] according to equation (2) and the elimination of anhydrides according to the stoichiometry of eqn (3) [42–44].

$$M(OR)_n + M'(OECR')_n \rightarrow MM'E_{n/2} + nRO_2CR' \quad (E = O \text{ or } S) \quad (1)$$

$$M(OR)_n + M'(OR')_n \rightarrow MM'O_{n/2} + nROR' \quad (2)$$

$$M(OECR)_n \rightarrow ME + n/2(RCO)_2E \quad (E = O \text{ or } S) \quad (3)$$

We have demonstrated that these are viable reaction strategies to make thin films of a variety of different materials under unusually mild conditions.

In this paper, we describe the synthesis, characterization and reactivity of two new barium carboxylate species which were prepared with the intention that (a) they have a low nuclearity and (b) to study their thermal reactivity. Crown ether ligands were used to induce low nuclearity in these compounds and carboxylate ligands were chosen for their potential reactivity towards other metal alkoxide compounds via ester elimination. The aim of this study was to determine whether the polyether ligands could be removed from the coordination sphere of Ba prior to thermal decomposition of the carboxylate ligands. If this is the case, then this provides a "thermal window" for the reaction of the unassociated barium carboxylate compound with a metal alkoxide to undergo ester elimination and remove the carboxylate

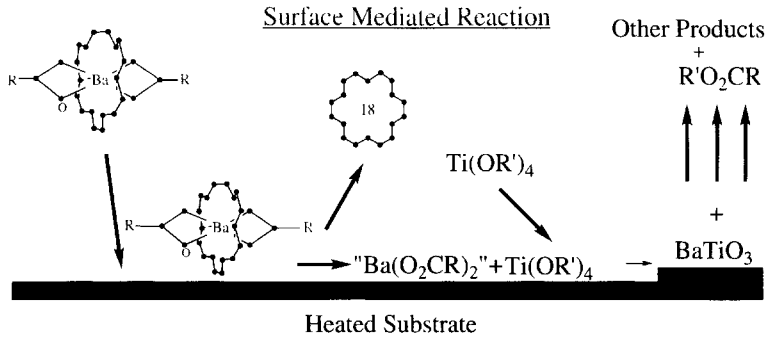

Fig. 1. Schematic representation of proposed substrate activated thermal "window" within which ester elimination may take place.

ligand intact and thus avoid formation of carbonates which would normally be expected in these systems. This strategy is illustrated schematically in Fig. 1, where a volatile metal carboxylate is delivered to a surface, the polyether ligand dissociates releasing a reactive "$M(O_2CR)_2$" species which can react with a metal alkoxide via ester elimination and the remaining alkoxide ligands are removed by thermally-induced elimination.

EXPERIMENTAL

All manipulations were carried out under an atmosphere of dry dinitrogen using standard Schlenk techniques. Hydrocarbon and ethereal solvents were distilled from sodium benzophenone ketyl and stored over 4 Å molecular sieves. The metal starting materials $BaCO_3$, $Ba(O_2CCH_3)_2$ and the carboxylic acids were purchased from Aldrich Chemical Co. The 18-crown-6 polyether was obtained from Strem Chemicals. All starting materials were used without further purification.

Elemental analyses (EA) were performed by Mrs R. Ju at the Department of Chemistry, University of New Mexico. Nuclear magnetic resonance spectra were recorded on a Bruker AC-250P NMR spectrometer by using the protio impurities of the deuterated solvents as reference for the ^1H NMR. Infrared data were recorded on a Perkin–Elmer model 1620 FTIR spectrophotometer. Thermogravimetric analyses were conducted on a Perkin–Elmer model TGA 7 analyzer in the temperature range of 30–900 C at 10 °C/min ramp rate. Powder X-ray diffraction data were recorded on a Siemens D5000 instrument. Thin films were placed upon a piece of plasticine on a thin film mount. The data were taken from 10–90°, the preset time was 8.0 s with a 0.040° step size. Single-crystal X-ray diffraction data were collected on a Nicolet R3m/v diffractometer. The structures were solved by either the Patterson method or direct methods using SHELXTL Plus and refined by the full-matrix least-squares method.

Synthesis and characterization

Synthesis of $Ba(O_2CCH_3)_2$(18-crown-6)·$4H_2O$ (**1**). $Ba(O_2CCH_3)_2$ (1.69g, 6.6 mmol) was dissolved in 25 cm^3 of distilled water and this solution was added to a solution of 18-crown-6 (1.75g, 6.6 mmol) dissolved in 25 cm^3 of distilled water. The mixture was stirred for 2 h. The solvent was removed under vacuum until a white crystalline (by XRD) solid remained. Yield: 3.37 g (98.5%). Colorless crystalline plates suitable for single-crystal X-ray diffraction analysis were obtained after recrystallization from water (Fig. 2). Similar results were obtained when $BaCO_3$ and acetic acid were used as reagents in plave of barium acetate. Elem. anal.: found % (calc. for $BaC_{16}H_{42}O_{16}$, $Ba(O_2CCH_3)_2$(18-crown-6)·$6H_2O$): C, 30.63 (30.61); H, 6.69 (6.74). Thermogravimetric analysis: Observed weight loss 66.24%, expected weight loss 66.65% (based on $BaCO_3$ formation, and $Ba(O_2CCH_3)_2$(18-crown-6)·$4H_2O$ starting material); ^1H NMR (250 MHz, 25 °C, D_2O): 3.57 ppm, s, crown; 1.72 ppm, s,

$C(O)CH_3$. IR (KBr, cm^{-1}): 3440 w, 3249 w, 2911 w, 1560 w, 1419 w, 1350 w, 1324 m, 1270 m, 1224 m, 1090 w, 996 m, 964 w, 931 m, 919 w, 829 w, 668 w.

Synthesis of $Ba(O_2C(CH_2)_4CO_2)$(18-crown-6)·$8H_2O$ (**2**). A colloidal solution of $BaCO_3$ (1.00g, 5.1 mmol) and 18-crown-6 (1.34g, 5.1 mmol) in 100 cm^3 of H_2O was heated to 70°C and stirred for 5 min. The $BaCO_3$ was only slightly soluble but the solution went completely clear upon addition of $HO_2C(CH_2)_4CO_2H$ (0.741g, 5.1 mmol). The solution was filtered and the solvent was removed under vacuum. Crystals suitable for single-crystal X-ray diffraction analysis were obtained from $EtOH/H_2O$ (Fig. 3). Elem. anal.: found % (calc. for $BaC_{18}H_{42}O_{15}$, $Ba(O_2C(CH_2)_4CO_2)$(18-crown-6)·$5H_2O$): C 33.66 (33.95), H 6.01 (6.65). Thermogravimetric analysis: observed weight loss 68.08%, expected weight loss 68.97% (based on $BaCO_3$ formation, and $Ba(O_2C(CH_2)_4CO_2)$(18-crown-6)·$5H_2O$ starting material); ^1H NMR (250 MHz, 25°C, D_2O): 3.56 ppm, s, crown; 2.01 ppm, t, O_2CCH_2-; 1.36 ppm, t, -$(CH_2)_2$-. IR (KBr): 3447 m, 2924 m, 1653 s, 1515 m, 1465 m, 1400 m, 1345 m, 1280 m, 1248 m, 1106 m, 1050 m, 965 m, 825 m, 668 m.

X-ray crystallographic data

Crystal data for $Ba(O_2CCH_3)_2$(18-crown-6)·$4H_2O$. $C_{16}H_{38}O_{14}Ba$, monoclinic, $P2_1/c$, $a = 9.5117(12)$, $b = 7.8112(9)$, $c = 16.906(2)$ Å, $\beta = 99.049(8)°$, $V = 1240.5(3)$ $Å^3$; $Z = 2$; $D_c = 1.584$g cm^{-3}; μ(Mo–K_α) = 23.73 cm^{-1}; $T = 25°C$, Siemens R3m/v, Mo–K_α. Of 3832 data ($4 < 2\theta < 55$), 2838 were independent, and 2036 were observed [$2\sigma(F_o)$]. The structure was solved by the Patterson method. Refinement: all non-hydrogen atoms anisotropic, all hydrogen atoms included in positions found in difference maps, $R(F) = 2.09\%$, $R(wF) = 2.23\%$, $GOF = 1.01$, $N_o/N_v = 13.5$, $\Delta(\rho) = 0.28$ $eÅ^3$, $\Delta/\sigma_{(max)} = 0.078$. SHELXTL software used for all computations (G. Sheldrick, Siemens XRD, Madison, WI, U.S.A.). An empirical (ψ-scan) correction was performed. The ratio of the transmission coefficients was 1.60. Crystallographic data are summarized in Table 1 and bond lengths and angles are reported in Table 2. Atomic positional parameters have been deposited with the Director, Cambridge Crystallographic Data Base.

Crystal data for $Ba(O_2C(CH_2)_4CO_2)$(18-crown-6)·$8H_2O$. $C_{18}H_{44}O_{18}Ba$, triclinic, $P\bar{1}$, $a = 8.5250(10)$, $b = 9.7690(10)$, $c = 10.2000(20)$ Å, $\alpha = 106.59(1)°$, $\beta = 90.37(8)°$, $\gamma = 110.34(1)°$, $V = 757.48(3)$ $Å^3$; $Z = 1$; $D_c = 1.504$g cm^{-3}; μ(Mo–K_α) = 23.73 cm^{-1}; $T = 25°C$, Siemens R3m/v, Mo–K_α. Of 6820 data ($2° \leqslant 2\theta° \leqslant 55°$), 3410 were independent, and 3321 were observed [$2\sigma(F_o)$]. The structure was solved by the Patterson method. Refinement: Fixed isotropic U set to 1.25 U (equiv.) of parent atom, all non-hydrogen atoms are isotropic, all hydrogen atoms included in positions found in difference maps, $R(F) = 4.44\%$, $R(wF) = 4.99\%$, $GOF = 0.89$, $N_o/N_v = 9.2$, $\Delta(\rho) = 2.87$ $eÅ^{-3}$, $\Delta/\sigma_{(max)} = 0.078$. SHELXTL software used for all computations (G. Sheldrick, Sie-

mens XRD, Madison, WI, U.S.A.). An empirical (ψ-scan) correction was performed. The ratio of the transmission coefficients was 1.12. Crystallographic data are summarized in Table 1 and bond lengths and angles are reported in Table 3. Atomic positional parameters have been deposited with the Director, Cambridge Crystallographic Data Base.

Spin-coating experiments

The following is the general procedure used for thin film deposition: A mixture of 0.100 g (0.16 mmol) of $Ba(O_2CCH_3)_2$(18-crown-6) and 0.0452 g (0.16 mmol) $Ti(O\text{-}i\text{-}Pr)_4$ was dissolved in 1.5 cm^3 of EtOH. A Pt/Si/SiO_2 wafer was placed upon a rotating mount and spun at 3000 rpm. A syringe containing the mixture of barium and titanium precursors was used to drop the solution on the wafer, three drops at a time followed by heating in an oven (in air) to 200°C for 5 min. When 21 drops, approximately 0.3 cm^3, were added the film was placed in an oven at 200°C for 5 min for the last time. The films were then annealed at 700°C for 1 h.

RESULTS AND DISCUSSION

The preparation of **1** involved adding the polyether ligand to barium acetate dissolved in water and stirring the solution. The solvent was removed under vacuum and crystalline powder remained (XRD). Compound **1** was recrystallized from H_2O. Compound **2** was synthesized by adding 18-crown-6 to a heated aqueous suspension of $BaCO_3$ and then reacting the mixture with adipic acid. The solvent was removed under vacuum and the crystalline powder (XRD) was recrystallized in a EtOH/H_2O mixture to give single-crystals of sufficient quality to be analyzed by single-crystal X-ray diffraction. The coordinated H_2O was removed under vacuum from complexes **1** and **2** but the resulting species, while dehydrated, exhibited relatively low solubility in other solvents other than water. Furthermore, care has to be taken not to remove the crown ether ligands during dehydration.

The thermogravimetric analysis and single-crystal structural data for **1** agree with the presence of four water molecules of crystallization. However, the sample submitted for elemental analysis was recrystallized from water and is consistent with the presence of six water molecules of crystallization. The difference in water content probably results from the recrystallization process. In the case of **2** elemental and thermogravimetric analyses show that the sample contains five water molecules whereas the recrystallized sample contains eight water molecules of crystallization. Again the difference in degree of hydration probably originates from the different methods by which the fractions were obtained.

There are two peaks in the ^1H NMR spectrum of **1** at 1.72 and 3.57 ppm consistent with the methyl protons of the acetate ligand and the methylene protons of the 18-crown-6, respectively. The ^1H NMR spectroscopic data for **2** shows a singlet associated with the methylene protons of the crown ether at 3.56 ppm and two multiplets derived from the methylene protons of the adipate ligand. The solution ^1H NMR spectra are consistent with the empirical formulae.

The presence of two ν(O—H) vibrational bands in the IR spectrum of **1** is consistent with the compound having two types of H_2O of crystallization with

ν(O—H) at 3421 cm^{-1} and 3249 cm^{-1}. The infra red spectroscopic data for **2** show a peak at 3447 cm^{-1} also consistent with the presence of H_2O. In **1**, the $\nu_{asym}(CO_2)$ can be assigned to the peak at 1560 cm^{-1} and $\nu_{sym}(CO_2)$ is likely the peak observed at 1419 cm^{-1}. These values are consistent with a general trend of values observed by Deacon *et al.* for a series of metal carboxylate and metal trifluorocarboxylate complexes [45]. Deacon *et al.* further suggest that it is possible to infer the mode of coordination of the carboxylate group to the metal center by measuring the difference between the asymmetric and symmetric $\nu(CO_2)$ stretches, $\Delta(CO_2)$. The literature values for a chelating or bridging mode of coordination in acetato complexes is $\Delta(CO_2) < 150$ cm^{-1}. The observed $\nu_{asym}(CO_2)$ and $\nu_{sym}(CO_2)$ peak positions lead to a $\Delta(CO_2)$ of 141 which is consistent with either a chelating or bridging mode of acetate coordination.

The assignment of the $\nu(CO_2)$ peaks associated with the metal adipate precursor is not as simple because there are four peaks which could be assigned to $\nu(CO_2)$. Deacon *et al.* warn that their conclusions are less likely to extend to other more complex carboxylate precursors such as those containing dicarboxylates [45]. Thus assigning structural inference in the adipate complex would be at best speculative and have not been attempted here.

The title compounds were structurally characterized in the solid state by single-crystal X-ray diffraction. The molecular structure and atom numbering scheme for **1** is shown in Fig. 2 and a view of the crystal structure of **1** is presented in Fig. 3 emphasizing the nature of water binding. In **1** the Ba atom lies in the center of the 18-crown-6 ring with chelating acetate ligands being in the axial positions of the equitorial coordination plane. Analogous structures have been observed for $Ba(hfac)_2$(18-crown-6) [32,33] and $Ba(O_2CC\text{-}t\text{-}Bu)_2$(18-crown-6) [46]. The Ba—O ether and carboxylate bond distances are similar in both **1** and $Ba(O_2CC\text{-}t\text{-}Bu)_2$(18-crown-6) and have average values of 2.805(45) Å and 2.823(10) Å ($Ba—O_{ether}$) and 2.881(6) Å and 2.834(18) Å ($Ba—O_{carboxylate}$), respectively. The O—C—O angles of the carboxylate ligands in the above compounds are almost identical at 123.8(3)° and 123.8(9)°, respectively.

There are two distinct types of water molecules involved in the hydrogen bonding in **1**. The water molecules of both types hydrogen bond to a carboxylate oxygen atom and two adjacent water molecules [O(6)···O(5) 2.808, O(6)···O(7a) 2.900 Å; O(7)···O(4) 2.864, O(7)···O(6c) 2.893 Å], however, the O···O distance between one type of water molecule and a carboxylate oxygen atom is larger by ca 0.06 Å. The fact that the water molecules are not coordinated to the barium atom suggests that the ten coordinate barium center is coordinatively saturated.

Both **1** and **2** are quite similar in their local geometry as shown by the molecular structure of **2** in Fig. 4. As in **1**, the barium atom in **2** resides at the center of the 18-crown-6 ring. Although compound **2** has a dicarboxylate ligand capable of chelating to the barium atom through both carboxylate groups, it instead bridges between two barium atoms to form an infinite polymer. This geometry allows the barium atom to sit at the center of the 18-crown-6 ring. It is expected based on size comparisons that this configuration provides the best interaction for the barium atom with the six oxygen atoms of the 18-crown-6 ether [47]. As in **1**, the oxygen atoms of the carboxylate ligands in **2** have hydrogen bonds from surrounding water molecules. However, the carboxylate groups in **2** are not symmetrically bound to the barium atom as in **1**. Two types of $Ba—O_{carboxylate}$ bond distances exist; a long bond at 2.979(4) Å and a short bond at 2.761(4) Å. The $Ba—O_{ether}$ bond distances are all similar and have an average value of 2.797(7) Å. The reason for the asymmetric bonding of the adipate ligand is not clear but may be a result of both hydrogen bonding and/or crystal packing. The $[Ba(O_2C(CH_2)_4CO_2)$(18-crown-6)$\cdot 8H_2O]_n$ chains pack in a staggered fashion such that the crowns of adjacent chains are aligned with the adipate bridges to give an [-adipate-crown-adipate-crown-]$_n$ sequence approximately perpendicular to the chain direction. This packing arrangement creates large serpentine channels in the crystal in which the waters of hydration reside, see Fig. 5.

The TGA data for **1** and **2** are shown in Fig. 6a and

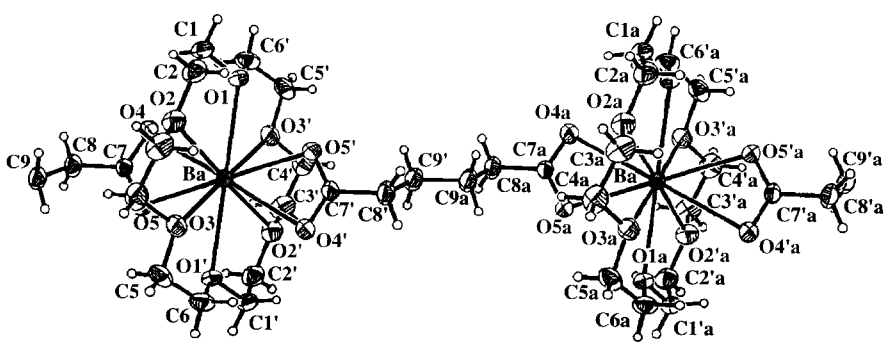

Fig. 4. The molecular structure of $Ba(O_2C(CH_2)_4CO_2)$(18-crown-6)$\cdot 8H_2O$.

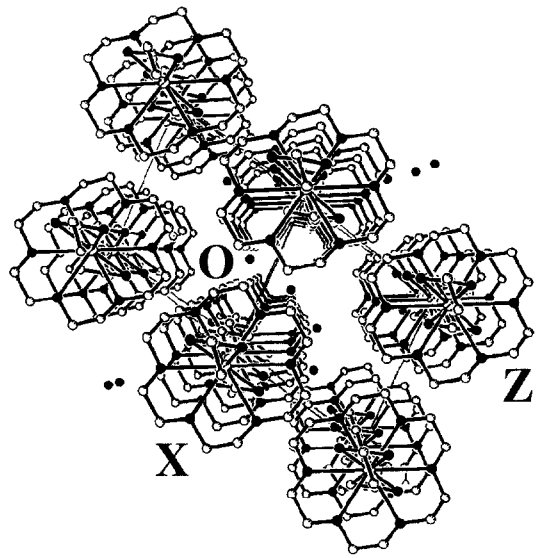

Fig. 5. The crystal structure of $Ba(O_2C(CH_2)CO_2)(18\text{-crown-}6)\cdot 8H_2O$.

6b. For **1** (see Fig. 6a), the total weight loss of ~66% is consistent with the decomposition to form $BaCO_3$ which was confirmed by powder XRD. The weight loss takes place in four distinct steps. The first two

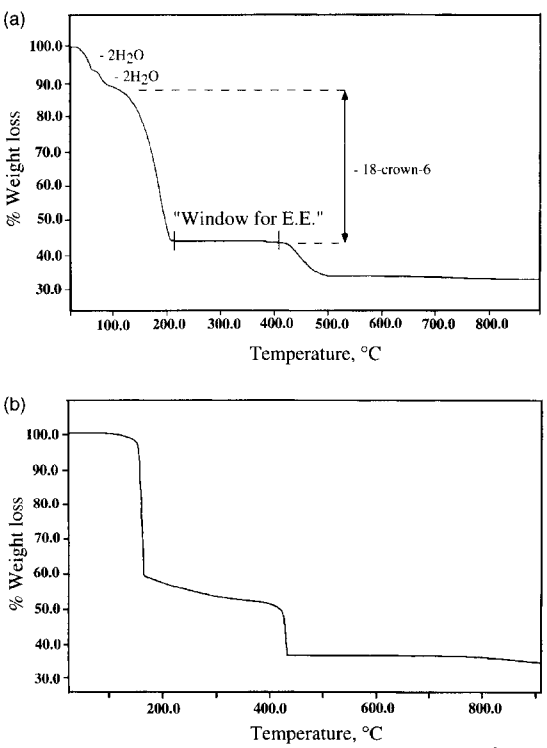

Fig. 6. Thermal gravimetric analysis data for (a) $Ba(O_2CCH_3)_2(18\text{-crown-}6)\cdot 4H_2O$ and (b) $Ba(O_2C(CH_2)_4CO_2)(18\text{-crown-}6)\cdot 5H_2O$.

occur between 50°C and 120°C and are consistent with loss of four water molecules, two in each step. This corresponds to the two different types of waters of crystallization observed by the IR spectroscopy data and shown in the crystal structure. The next step is consistent with loss of the 18-crown-6 ligand. Separate sublimation experiments reveal that the 18-crown-6 ligand is removed intact from the complex (as determined by ^1H NMR) on heating to 200°C. There is no further weight loss until around 410°C where reaction of the remaining organic substituents takes place with the formation of $BaCO_3$. This weight loss is complete by 500°C. The TGA data show that after the loss of water and crown ether, the barium acetate formed does not undergo a weight change over a temperature range of ~200°C. This provides a "window" for ester elimination where the barium acetate remains intact and is available to react with another species such as a metal alkoxide.

The TGA data for **2** (Fig. 6b) exhibits a two stage weight loss to give a product with mass, within the error limits, expected for formation of $BaCO_3$. The first stage of the decomposition begins at about 100°C and ends around 170°C. The total weight loss suggests the removal of the 18-crown-6 ligand and five equivalents of H_2O (55% calc., observed ~ 53.5%). The small step up to the inflection point corresponds closely to the loss of three equivalents of H_2O (~ 8.5%). The remaining weight loss corresponding to the reaction of the adipate ligand (calc. ~15%, observed ~14.5%) to form $BaCO_3$ at ~450°C. For **2**, there does not appear to be a thermal "window" for ester elimination analogous to the TGA of **1** above, because there is significant weight loss between the onset of thermal decomposition and the formation of $BaCO_3$ (i.e. there is no flat region in the TGA plot as there is for **1**). This may make this species unsuitable for clean reaction with a metal alkoxide.

Compound **1** was dehydrated and used as a precursor to form $BaTiO_3$ films via spin-coating by reaction with $Ti(O\text{-}i\text{-}Pr)_4$. An ethanol solution of **1** and $Ti(O\text{-}i\text{-}Pr)_4$ in a 1 : 1 mol ratio were spun onto a Pt/Si/SiO_2 wafer and between each coating the substrate and film were heated to 200°C for 5 min in air. The films were amorphous at this temperature (by XRD). On heating to 700°C for 1 h in air, X-ray diffraction showed the presence of crystalline perovskite phase $BaTiO_3$ and crystalline $BaCO_3$ (°) as the only crystalline phases (Fig. 7). The presence of some $BaCO_3$ is not unexpected since the deposition and annealing steps were performed in air and when dehydrated **1** was used to deposit a film without titanium precursor only $BaCO_3$ was deposited (XRD). Scanning electron microscopy revealed the film was approximately 10 μm thick and fairly extensively cracked as would be expected for such a thick film. The cross-sectional and surface views are shown in Fig. 8. Auger electron spectroscopy analysis of the film reveals the presence of Ba : Ti : O and C in the ratios of approximately 2 : 3 : 8 : 1, respectively. These data are consistent with

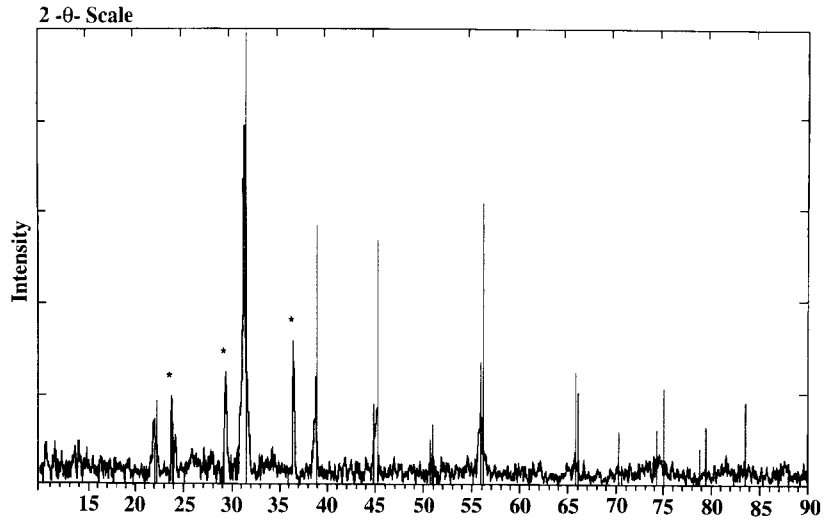

Fig. 7. X-ray diffraction data for thin film deposited by spin-coating an ethanol solution of $Ba(O_2CCH_3)_2$(18-crown-6) and $Ti(O\text{-}i\text{-}Pr)_4$.

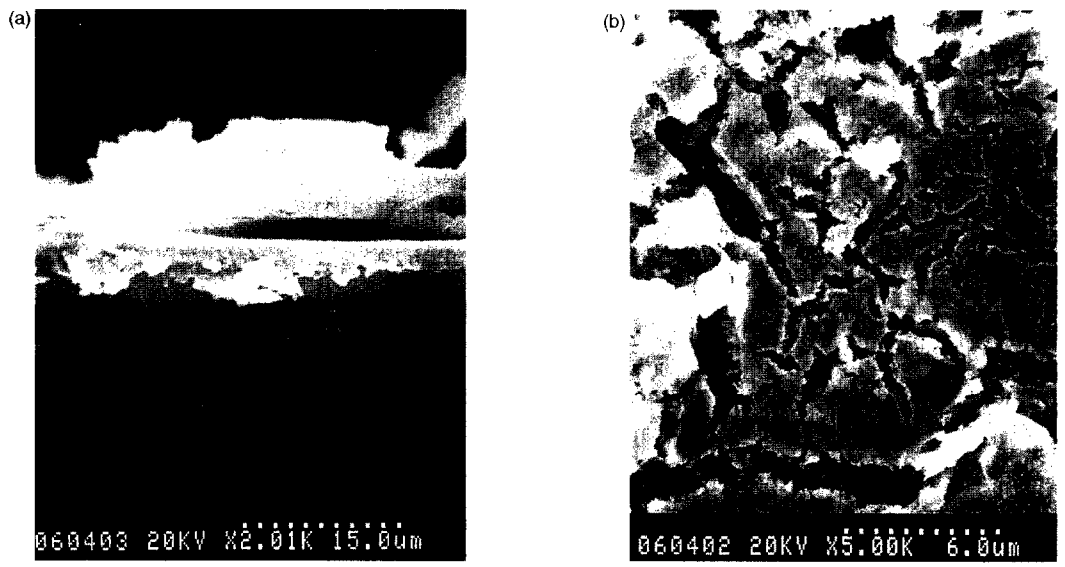

Fig. 8. (a) Scanning electron micrograph of a cross-section of the $BaTiO_3$ film formed from the deposition of $Ba(O_2CCH_3)_2$(18-crown-6) and $Ti(O\text{-}i\text{-}Pr)_4$ annealed at 700°C for 1 h. (b) Scanning electron microscopic image of the surface of the $BaTiO_3$ film formed from the deposition of $Ba(O_2CCH_3)_2$(18-crown-6) and $Ti(O\text{-}i\text{-}Pr)_4$ annealed at 700°C for 1 h.

the presence of $BaTiO_3$ and $BaCO_3$, as observed by X-ray diffraction and also the presence of amorphous TiO_2. Numerous attempts were made to determine the nature of the organic byproducts formed during this reaction both *in situ* using quadrupole mass spectroscopy and *ex situ* by conduction solid state experiments, but no unambiguous evidence for the formation of an ester could be obtained.

Attempts to form films under similar conditions from **2** proved unsuccessful with TiO_2 and $BaCO_3$ being the only identifiable crystalline phases present by XRD. When control experiments using **1** and **2** were performed without a titanium source, the only species obtained was barium carbonate as determined by XRD.

SUMMARY AND CONCLUSIONS

The synthesis and characterization of two new barium carboxylates has been described. The acetate complex is monomeric and may prove useful as a source of barium for CVD The oligomeric nature of the adipate complex rules out it usefulness as a CVD

precursor. The thermal behavior of **1** demonstrates the loss of the crown and carboxylate ligand takes place in two distinct steps while for **2**, there is significant weight loss from the onset of loss of the crown ether ligand to the onset of reaction of the adipate ligands. The reaction of compound **1** with $Ti(O\text{-}i\text{-}Pr)_4$ resulted in formation of $BaTiO_3$, although no evidence for a mechanism which involved ester elimination was obtained. Coumpound **2** did not form barium titanate under analogous conditions which may indicate the significance of the TGA data which showed the absence of a thermal "window" for ester elimination for **2**.

Acknowledgments—We would like to thank Texas Instruments for their financial support of this project, the NSF Chemical Instrumentation program for the purchase of a low field NMR spectrometer and AFOSR and the Camille and Henry Dreyfus Foundation for the purchase of the X-ray diffractometer. M.H.-S. would like to thank Prof. Don Bradley for many helpful discussions and much encouragement over the last 15 years.

Synthesis and reactivity of η^6-arene ruthenium anilide complexes

James M. Boncella,* Tegan M. Eve, Barry Rickman and Khalil A. Abboud

Department of Chemistry and Center for Catalysis, University of Florida, Gainesville, Florida 32611-7200, U.S.A.

(Received 23 June 1997; accepted 8 August 1997)

Abstract—The compounds, $(\eta^6\text{-}C_6Me_6)Ru(PMe_3)(R)(NR'R'')$; (R=Ph, R′=H, R″=Ph, **3**; R=Me, R′=H, R″=Ph, **4**; R=Ph, R′=H, R″=*p*-tol, **5**; R=Me, R′=Me, R″=Ph, **6**) are synthesized through the interaction of $(\eta^6\text{-}C_6Me_6)Ru(PMe_3)(R)(I)$ and the corresponding anilide salt, KNR′R″ in THF at low temperature. The reactions between these complexes and the unsaturated electrophilic reagents, CO_2 and dimethylacetylene dicarboxylate (DMAD) have been described. The typical reaction involves net insertion of the electrophile into the Ru anilide bond. Complex **6** reacts with H_2O giving the hydroxide complex, **11**, which reacts with CO_2 giving the bicarbonato complex, **12**. The X-ray crystal structure of **3** is reported. Compound **3** crystallizes in the monoclinic space group, $P2_1/n$, $a = 12.013(2)$ Å, $b = 16.700(3)$ Å, $c = 12.414(1)$ Å, $\beta = 97.35(2)$, $V = 2470.0(7)$ Å^3 and $Z = 4$. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: η^6-arene ruthenium anilide complexes; unsaturated electrophilic reagents; CO_2; DMAD.

We have been interested in the chemistry of late (group 8–10) transition metal amide complexes to investigate their reactivity and to examine the possibility of using them in stoichiometric or catalytic C—N bond forming reactions. The relative scarcity [1] of ruthenium compounds of this type sparked our interest in their chemistry. Our attention has been focused on the $(\eta^6\text{-}C_6Me_6)Ru(PMe_3)(R)(NHR)$ class of compounds because of their ease of preparation and the fact that they are isoelectronic with the $Cp^*Ir(PMe_3)(R)X$ (X = NHR, OR, etc.) compounds which have been demonstrated to participate in an interesting array of reactions [2]. Furthermore, the chemistry of $(\eta^6\text{-}C_6Me_6)Ru(PMe_3)(Ph)NHPh$ can be compared with other 18 e$^-$ group 8 anilide and imido complexes such as $(PMe_3)_4Ru(H)(NHPh)$[1h] and (*p*-Cym)OsNR [3]. In this paper we describe the synthesis, and characterization of a series of arene Ru anilide complexes. The reactivity of these molecules with the unsaturated electrophiles, CO_2 and dimethylacetylene dicarboxylate (DMAD) are also reported. The reaction of a hydroxide derivative with CO_2 to give a bicarbonato complex is also described.

EXPERIMENTAL

All procedures were performed using either Schlenk or dry box techniques, under an inert atmosphere of either argon or nitrogen. Pentane and diethyl ether (Et_2O) were distilled from sodium/benzophenone and subsequently degassed. Methylene chloride was distilled from P_2O_5 and degassed. Tetrahydrofuran (THF) was dried by refluxing over potassium metal prior to distillation and then degassed after distillation. Deuterated solvents were dried over molecular sieves and degassed prior to use. ^1H, ^{13}C, and ^{31}P NMR spectra were recorded on a Varian VXR-300 (300 MHz), or a General Electric QE-300 (300 MHz) spectrometer. Chemical shifts for ^1H and ^{13}C spectra were referenced to residual proton signals in the solvent and are reported relative to TMS; shifts for ^{31}P spectra are reported relative to external 85% H_3PO_4. Elemental analyses were performed by the University of Florida Analytical Services or Atlantic Microlab, Inc., Norcross, Georgia. Infrared spectra were recorded on a Perkins Elmer 1200 series spectrometer from KBr pellets which were prepared in an inert atmosphere glove box. Mass spectroscopy data were obtained with a Finnigan 4500 Gas Chromatograph/Mass Spectrometer using FAB techniques.

The following compounds were purchased from Aldrich Chemical Co., and were used without further purification: dimethylacetylene dicarboxylate, phenyl lithium, methyl lithium, sodium iodide, and para-toluidine. Aniline and *N*-methyl aniline were distilled from sodium metal.

The potassium amides were synthesized by reacting the appropriate aniline and KH in THF, with KN(Me)Ph being prepared by modified literature procedures [4]. $(\eta^6\text{-}C_6Me_6)Ru(PMe_3)Cl_2$ was prepared according to literature methods [5], and $(\eta^6\text{-}C_6Me_6)Ru(PMe_3)I_2$ was prepared by ion exchange with NaI and $(\eta^6\text{-}C_6Me_6)Ru(PMe_3)Cl_2$ under reflux in acetone following the procedure used for the synthesis of $Cp^*Rh(PMe_3)I_2$ [6].

Preparation of $(\eta^6\text{-}C_6Me_6)Ru(PMe_3)(Ph)I$ (**1**)

To a stirring solution of $(\eta^6\text{-}C_6Me_6)Ru(PMe_3)I_2$ (1.037 g, 1.748 mmol) in 75 ml of THF was added dropwise 1.07 ml of a 1.8 M solution of LiPh in toluene/Et_2O (1.9 mmol). The solution immediately turned from purple to orange-red. After 45 min the solvent was removed under reduced pressure to leave an orange-red oil. The product was extracted with Et_2O until the extracts were colorless. The combined extracts were reduced in volume and cooled to -20°C giving deep red crystals of **1** (0.599 g, 1.102 mmol) in 63% yield. Anal. Calc. for $C_{21}H_{32}IPRu$: C, 46.41; H, 5.94. Found: C, 46.11; H, 5.95.

Preparation of $(\eta^6\text{-}C_6Me_6)Ru(PMe_3)(Me)I$ (**2**)

To a stirring solution of $(\eta^6\text{-}C_6Me_6)Ru(PMe_3)I_2$ (3.50 g, 5.90 mmol) in 125 ml of THF was added dropwise 5.15 ml of a 1.26 M solution of LiMe in Et_2O (6.49 mmol). The solution immediately turned from purple to orange-red. After 45 min the solvent was removed under reduced pressure to leave a red oil. The product was extracted with Et_2O until the extracts were colorless. The combined extracts were reduced in volume and cooled to -20°C giving deep red crystals of **2** (2.12 g, 4.40 mmol) in 75% yield. Anal. Calc. for $C_{16}H_{30}IPRu$: C, 39.93; H, 6.28. Found: C, 39.04; H, 6.21. HRMS (FAB) (Calc.): 466.993 $(M\text{-}CH_3)^+$. (Found): 467.010 $(M\text{-}CH_3)^+$.

Preparation of $(\eta^6\text{-}C_6Me_6)Ru(PMe_3)(NHPh)(Ph)$ (**3**)

To a cold (-78°C) stirring solution of **1** (0.730 g, 1.436 mmol) in 100 ml of THF was added a solution of KNHPh (0.264 g, 2.015 mmol) in 25 ml of THF. After 45 min the reaction mixture was allowed to come to room temperature, whereupon it slowly turned from clear red to brown with white precipitates. After stirring 2 h longer, the solvent was removed under reduced pressure to leave a sticky solid. The product was extracted with Et_2O until the extracts were colorless. The combined extracts were reduced in volume and cooled to -50°C giving deep red crystals of 3 (0.404 g, 0.795 mmol) in 55% yield. IR (KBr): 3330.6 cm^{-1} ($\nu_{N\text{-}H}$). Anal. Calc. for $C_{27}H_{38}NPRu$: C, 63.74; H, 7.53; N, 2.75. Found: C, 62.85; H, 7.58; N, 2.67. HRMS (FAB) (Calc.): 509.1779 $(M+1)^+$. (Found): 509.1659 $(M+1)^+$.

Preparation of $(\eta^6\text{-}C_6Me_6)Ru(PMe_3)(NHPh)(Me)$ (**4**)

To a cold (-78°C) stirring solution of **2** (0.320 g, 0.665 mmol) in 50 ml of THF was added a solution of KNHPh (0.31 g, 0.997 mmol) in 25 ml of THF. After 45 min the reaction mixture was allowed to come to room temperature, whereupon it slowly turned from clear red to red-brown with white precipitates. After stirring 2 h longer, the solvent was removed under reduced pressure to leave a sticky solid. The product was extracted with Et_2O until the extracts were colorless. The combined extracts were reduced in volume and cooled to -50°C giving large, opaque red crystals of **5** (0.320 g, 0.718 mmol) in 72% yield. IR (KBr): 3329.7 cm^{-1} ($\nu_{N\text{-}H}$). Anal. Calc. for $C_{22}H_{36}NPRu$: C, 59.17; H, 8.13; N, 3.14. Found: C, 59.25; H, 8.18; N, 3.10.

Preparation of $(\eta^6\text{-}C_6Me_6)Ru(PMe_3)(NHC_6H_4CH_3)(Ph)$ (**5**)

To a cold (-78°C) stirring solution of **1** (0.980 g, 1.875 mmol) in 75 ml of THF was added a solution $KNHC_6H_4CH_3$ (0.393 g, 2.705 mmol) in 30 ml of THF. After 30 min the reaction mixture was allowed to come to room temperature, whereupon it slowly turned from clear red to orange-brown with white precipitates. After stirring 1 h longer, the solvent was removed under reduced pressure to leave a solid. The product was extracted with diethyl ether until the extracts were colorless. The combined extracts were reduced in volume and cooled to -50°C giving powdery orange crystals of **8** (0.608 g, 1.163 mmol) in 62% yield. IR (KBr): 3361.4 cm^{-1} ($\nu_{N\text{-}H}$). Anal. Calc. for: $C_{28}H_{40}NPRu$ C, 64.34; H, 7.71; N, 2.68. Found: C, 64.26; H, 7.72; N, 2.63.

Preparation of $(\eta^6\text{-}C_6Me_6)Ru(PMe_3)(NMePh)(Me)$ (**6**)

To a cold (-78°C) stirring solution of **2** (0.250 g, 0.519 mmol) in 40 ml of THF was added a solution of KNMePh (0.113 g, 0.778 mmol) in 25 ml of THF. After 45 min the reaction mixture was allowed to come to room temperature, whereupon it slowly turned from clear red to red-brown with white precipitates. After stirring 2 h longer, the solvent was removed under reduced pressure to leave a solid. The product was easily extracted with a small volume (25 ml) of diethyl ether. The extract was reduced in volume and

cooled to -50°C giving large, red crystals of **6** (0.130 g, 0.282 mmol) in 54% yield. Anal. Calc. for $C_{23}H_{38}NPRu$: C, 59.98; H, 8.32; N, 3.04. Found: C, 59.77; H, 8.28; N, 2.94.

Reaction of **3** *with carbon dioxide. Synthesis of* (η^6-C_6Me_6)Ru(PMe_3)(OC(O)NHPh)(Ph) (**7**)

Charging a sealable NMR tube with ~30 mg of **3** in C_6D_6 with an atmosphere of carbon dioxide afforded a maximum 57% yield of insertion product, **7**, leaving the remaining **3** unchanged. Vigorous bubbling of carbon dioxide through solutions of **3** (0.100 g, 0.197 mmol) in 25 ml of either toluene or diethyl ether for 0.5 h, followed by removal of the solvent under reduced pressure resulted in 70% and 43% respective yields of **7**.

Reaction of **4** *with carbon dioxide. Synthesis of* (η^6-C_6Me_6)Ru(PMe_3)(OC(O)NHPh)(Me) (**8**)

Vigorous bubbling of carbon dioxide through a stirring solution of **5** (0.551 g, 1.234 mmol) in 40 ml of diethyl ether for 0.5 h caused a color change from bright red to pale red-yellow. The solution was left stirring under an atmosphere of carbon dioxide for an additional 0.5 h, during which time a yellow precipitate formed. Removal of the solvent under reduced pressure resulted in a quantitative yield of product **8**. The reaction may also be carried out in a sealable NMR tube as described in the reaction of 3 with carbon dioxide to give 100% conversion to **8**. IR (KBr): 3301.7 cm^{-1} (ν_{N-H}); 1638.1 cm^{-1} ($\nu_{C=O}$). Anal. Calc. for $C_{23}H_{36}NO_2PRu$: C, 56.31; H, 7.40; N, 2.86. Found: C, 56.39; H, 7.44; N, 2.85.

Synthesis of (η^6-C_6Me_6)Ru(PMe_3)(OC(O)$NHC_6H_4CH_3$)(Ph) (**9**)

Vigorous bubbling of carbon dioxide through a stirring solution of **5** (0.702 g, 1.343 mmol) in 50 ml of toluene for 20 min caused a color change from bright red to pale brown-yellow. The solution was left stirring under an atmosphere of carbon dioxide for an additional 0.5 h, during which time a drab green oil formed. Removal of the solvent under reduced pressure left the green oil which was extracted into diethyl ether until the extracts were colorless. The combined extracts were reduced in volume and cooled to -20°C giving a dark green powder of **9**. The reaction may also be carried out in a sealable NMR tube as described in the reaction of 3 with carbon dioxide to give 100% conversion to **9**. IR (KBr): 3281.8 cm^{-1} (ν_{N-H}); 1631.8 cm^{-1} ($\nu_{C=O}$). Anal. Calc. for $C_{29}H_{40}NO_2PRu$: C, 61.47; H, 7.12; N, 2.47. Found: C, 61.25; H, 7.18; N, 2.41.

Synthesis of (η^6-C_6Me_6)Ru(PMe_3)[(MeOOC) C=C (COOMe)(NHPh)](Me) (**10**)

To a stirring solution of **4** (0.109 g, 0.244 mmol) in 30 ml of THF two equivalents of DMAD (0.06 ml) were added. The color of the solution immediately changed from red to dark green. The solution was allowed to stir for 0.5 h, after which the solvent was removed under reduced pressure leaving a thick, dark green oil. The oil was washed with 15 ml of pentane to remove excess DMAD, and the product was then extracted into diethyl ether until extracts were colorless. The combined extracts were reduced in volume and cooled to -50°C giving dark green powder as the product **9** (0.046 g, 0.078 mmol) in 32% yield. When this reaction is carried out in a sealed NMR tube with 0.020 g of 5 and a 10% excess of DMAD the reaction is observed to go to completion with the excess of DMAD left unreacted. IR (KBr): 3311.4 cm^{-1} (ν_{N-H}); 1702.0 cm^{-1} ($\nu_{C=O}$). Anal. Calc. for $C_{28}H_{42}NO_4PRu$: C, 57.13; H, 7.19; N, 2.38. Found: C, 57.03; H, 7.17; N, 2.41.

Synthesis of (η^6-C_6Me_6)Ru(PMe_3)(OC(O)OH) (Me)·H_2O (**11**)

Vigorous bubbling of carbon dioxide through a stirring solution of **6** (0.085 g, 0.185 mmol) in 40 ml of diethyl ether for 0.5 h caused a color change from bright red to pale yellow. The solution was left stirring under an atmosphere of carbon dioxide for an additional 0.5 h, during which time a pale yellow precipitate formed. The solvent was filtered off and the powder dried under reduced pressure to give 11 (0.058 g, 0.145 mmol) in 78% yield. IR (KBr): 1607.8 cm^{-1} ($\nu_{C=O}$). Anal. Calc. for $C_1H_{31}O_3PRu$: C, 47.10; H, 7.67. Found: C, 47.08; H, 7.35. Compound **11** can also be synthesized by bubbling CO_2 through a toluene solution of the hydroxide complex, **12** (*vide infra*).

Reaction of **6** *with water. Synthesis of* (η^6-C_6Me_6)Ru(PMe_3)(OH)(Me)·xH_2O (**12**)

A stirring solution of 10 (0.065 g, 0.141 mmol) in 20 ml of diethyl ether was prepared. Fifteen ml (six-fold excess) of deionized, degassed water was syringed into the solution three times at twenty minute intervals to give 18 equivalents of water. After the last addition the solution was stirred for 1 h, during which time a color change from bright red to yellow-brown was observed. Removal of solvent under reduced pressure afforded a brown oil. 15 ml of pentane was added to this oil and stirred for 1 h, after which the yellow-brown pentane solution was filtered off leaving a yellow powder. Drying the powder under reduced pressure afforded 12 in undetermined yield. IR (KBr): 3220 cm^{-1} (ν_{O-H}, broad).

X-ray crystal structure of **3**

Data were collected at room temperature on a Siemens R3m/V diffractometer equipped with a graphite monochromator utilizing MoK_α radiation ($\lambda = 0.71069$ Å). 50 reflections with $20.0° \leqslant 2\theta \leqslant 22.0°$ were used to refine the cell parameters. 9211 reflections (two equivalent sets) were collected using the ω-scan method (1.2° scan range and 3–6° scan speed depending on intensity). Four reflections were measured ever 96 reflections to monitor instrument and crystal stability (maximum correction on **I** was <1%). Absorption corrections were not applied based because of the crystal shape and small size.

The structure was solved by the heavy-atom method in SHELXTL plus [7] from which the locations of the Ru atom was obtained. All of the non-H atoms were located from a subsequent Difference Fourier map. The structure was refined in SHELXTL plus using full-matrix least squares. The non-H atoms were treated anisotropically. The H-atoms on C21 were calculated in idealized positions and the thermal parameter of H21c was fixed at 0.08. The rest of the H-atoms were obtained from a subsequent Difference Fourier map and were refined without any constraints, except H6′b and the H-atoms on Cl′ which have their thermal parameters fixed at 0.08. 409 parameters were refined and $\Sigma w\ (|F_o|-|F_c|)^2$ was minimized; $w = 1/(\sigma|F_o|)^2$, $\sigma(F_o) = 0.5\ k\mathbf{I}^{-1/2}\ \{[\sigma(\mathbf{I})]^2+(0.02\mathbf{I})^2\}^{1/2}$, **I**(intensity) = $(\mathbf{I}_{peak}-\mathbf{I}_{background})$(scan rate), and $\sigma(\mathbf{I}) = (\mathbf{I}_{peak}+\mathbf{I}_{background})^{1/2}$(scan rate), k is the correction due to decay and Lp effects, 0.02 is a factor used to down weight intense reflections and to account for instrument instability. The linear absorption coefficient was calculated from values from the *International Tables for X-ray Crystallography* [8]. Scattering factors for non-hydrogen atoms were taken from Cromer and Mann [9] with anomalous-dispersion corrections from Cromer and Liberman [10], while those of hydrogen atoms were from Stewart *et al.* [11].

RESULTS AND DISCUSSION

We have found that reaction of KNR′R″ with (η^6-C_6Me_6)Ru(PMe_3)(R)I in THF proceeds rapidly to give good to moderate yields of the corresponding anilide complexes as shown in eqn (1).

In our experience, the success of the synthesis of anilide complexes via nucleophilic displacement of leaving groups from η^6-arene complexes of ruthenium is dependent upon the nature of the leaving group and the nature of the metal associated with the anilide anion. The chemistry in eqn (1) works most efficiently when I^- is the leaving group and K^+ is the anilide counterion. This chemistry stands in contrast to earlier results from this laboratory [1g] which showed that the reaction between (η^6-C_6Me_6)Ru(PMe_3)Cl_2 and LiNHPh proceeds via a complicated mechanism involving the loss of PMe_3 to give the bimetallic complex [(η^6-C_6Me_6)$_2$Ru$_2$(μ_2-NHPh)$_3$]$^+$ as the anilide containing product. The presence of both the I^- and the R group in the starting material leads to cleaner and more predictable chemistry.

Compounds **3**–**6** are red, crystalline solids that are thermally stable, but air and moisture sensitive in solution and the solid state. They are soluble in ethereal solvents and aromatic hydrocarbons, and have been characterized via ^1H, ^{13}C and ^{31}P NMR spectroscopy. The NMR data for all the compounds reported are found in Tables 1–3. The ^1H NMR spectra typically display a single peak arising from the C_6Me_6 group as well as a doublet from the coordinated PMe_3 group. The methyl group in compounds **4** and **6** is responsible for a doublet at −0.13 and 0.40 ppm, respectively. There are a series of doublets and triplets in the aromatic region of the spectra that are due to the phenyl groups of the anilide or the Ru phenyl groups.

The NMR spectra of compound **6** are more complicated than those of **3**–**5** since more aromatic peaks are observed than can be accounted for if there is free rotation of the phenyl group in both the ^1H and ^{13}C spectra. In ^{13}C NMR spectrum of **6**, six peaks assignable to the aromatic carbons of **6** are observed. This observation is consistent with slow rotation of the

phenyl group on the NMR timescale and probably arises from steric interactions between the MeNPh group and the rest of the molecule. Hindered rotation about P—Ph and Rh—Ph groups has been observed in the isoelectronic, and closely related compounds, Cp*Rh(Ph)(X)(PR_3) [6]. Though we have not investigated the low temperature NMR behavior of compounds **3–5,** observable barriers to rotation about the Ru—Ph and N—Ph bonds might be expected by analogy with the Rh compounds.

Crystals of **3** suitable for a single crystal X-ray diffraction study were grown by slowly cooling a saturated Et_2O solution of **3** to −40°C. A thermal ellipsoid plot of **3** is shown in Fig. 1, while data collection parameters and selected bond lengths and angles are found in Tables 4 and 5. The compound has the expected three legged piano stool geometry with the PMe_3, NHPh, and Ph groups defining the "legs" of the piano stool. The angles between these groups are slightly less than 90° and suggest a significant steric influence from the C_6Me_6 group as is consistent with the observed hindered rotation of the phenyl groups in NMR spectra of **6**. The geometry about the nitrogen atom of the anilide is planar as is typically observed

in transition metal amide complexes even when the metal center is electronically saturated as in groups 8–10. The Ru—N—C(13) angle of 135° is also indicative of the steric congestion in the coordination sphere.

The bond lengths are generally unremarkable with the exception of the rather short distance of 1.360(5) between C13 and N in the anilide group. Shortened C—N bonds in other anilides of late transition metal complexes have been observed previously, and are consistent with some amount of stabilization of the nitrogen lone pair through π interaction with the phenyl ring [12]. Given the electronic saturation of the metal center in these complexes, π donation from the N to the metal is not possible, and interaction between the phenyl ring and the amide N may help to stabilize the complex.

We have explored the reactivity of compounds **3–6** with the unsaturated electrophiles CO_2 and DMAD. The reaction between CO_2 and compounds **3–5** results in the net insertion of the CO_2 into the Ru—N bond to give a metal carbamate complex as is shown in eqn (2). Given the electronic saturation at the metal centre, it is likely that these reactions occur via direct attack of the N lone pair on CO_2 followed by Ru—O bond formation. This type of reactivity is well precedented in other group 8–10 metal amido complexes [13]. Interestingly, the complexes display a range of reactivity with CO_2. When the reaction between **3** and excess CO_2 was monitored by ^1H NMR spectroscopy, the reaction proceeded to only 70% conversion, while the same reaction with **4** or **5** resulted in quantitative conversion to products. It would appear that the increased electron richness of the *p*-toluamide ligand in **5** and the better electron donating Me group in **4** (vs the Ph group in **3**) make the N atom more nucleophilic in **4** and **5** which allows the reaction to go to completion.

The differences in the reactivity of **3–5** are more obvious when these compounds are allowed to react with DMAD. Thus, while the anilide and *p*-toluamide complexes, **3** and **5** do not react with DMAD, complex **4** reacts to give a quantitative yield of the insertion product, **9**, eqn (3). It would appear that this difference in reactivity is due to the increased electron donating ability of the Me group of **4** relative to the Ph groups of **3** and **5** and is consistent with the reac-

tivity of these compounds with CO_2. Unfortunately, we cannot rule out the possibility that the observed differences in reactivity with DMAD are due to the difference in the steric effects of the Ru—Me and Ru—Ph groups.

The *N*-methyl anilide complex, **6,** is considerably more reactive than **3–5**. Instead of reacting with CO_2 to give the expected carbamate complex, the product of the reaction between **6** and CO_2 is the bicarbonate complex, $(\eta^6\text{-}C_6Me_6)Ru(PMe_3)(HCO_3)$, **11**. We believe that the conversion of **6** to **11** involves traces of H_2O in the CO_2 which either converts **11** to a hydroxide, **12,** which reacts further with CO_2, or that the product carbamate complex reacts with H_2O giving **11** as the reaction product.

In order to test this hypothesis, complex **6** was converted to the hydroxide complex, **12** through its reaction with water. Compound **12** is isolated as a yellow powder that is soluble in ethereal solvents, and insoluble in aliphatic hydrocarbons. The ^1H NMR spectrum of **12** shows two broad peaks at −4.40 and 3.99 ppm respectively that might be assigned to the hydroxide proton. Given the variability of the integration of the peak at 3.99 ppm from sample to sample, we are inclined to assign the peak at −4.40 ppm to the hydroxide proton by analogy with $Cp^*Ir(PMe_3)Ph(OH)$[2a], and the peak at 3.99 ppm to the water of hydration [14]. When **12** is allowed to react with CO_2, it is rapidly and quantitatively converted into the bicarbonate complex, **11** as shown in eqn (4). The nucleophilicity of the hydroxide group in **12** is expected and the reaction between other late transition metal hydroxides and unsaturated electrophiles is well precedented [2a,15].

Preliminary studies indicate that compound **12** does not react with ethylene at low to elevated temperatures and 1 atm pressure. This lack of reactivity differs from the related complex $Cp^*Ir(OH)(Me)(PMe_3)$, which has been shown to react with ethylene via a complicated mechanism with the net result being insertion of the ethylene into the Ir—O bond [2]. We are continuing to investigate the reactivity of **12** with a variety of substrates.

In summary, the synthesis of a series of anilide complexes of the type, $(\eta^6\text{-}C_6Me_6)Ru(PMe_3)(R)NR'Ph$, can be achieved via nucleophilic displacement of iodide from the corresponding precursor complexes using potassium anilides. Unsaturated electrophiles react with the anilide complexes by attacking the lone pair of the anilide nitrogen and resulting in net insertion of the electrophile into the Ru N bond. The nucleophilicity of the N (or in the case of **12,** O) atom of these complexes is likely due to the fact that the Ru atom in these 18 e^- complexes cannot function as a π acceptor toward the anilide or hydroxide donors.

(Received 30 April 1997; revision 8 August 1997

Abstract—A series of triamido stannanes of the general types $HC\{SiMe_2NR\}_3SnCH_3$ [R = p-Tolyl (**3**), t-Butyl (**4**)] and $MeSi\{SiMe_2N(R)\}_3SnR'$ [R = p-Tolyl and R' = $CH_2CH{=}CH_2$ (**5**), $CH_2CH{=}CHCH_3$ (**6**), $CH_2CH{=}CHC_6H_5$ (**7**), $CH_2(CH_3)C{=}CH_2$ (**8**); R = t-Butyl and R' = $CH_2CH{=}CH_2$ (**9**), $CH_2CH{=}CHCH_3$ (**10**)] have been synthesized by reacting the lithium triamidostannates $[HC\{SiMe_2NR\}_3SnLi(THF)_n]$ and $[MeSi\{SiMe_2NR\}_3SnLi(THF)_n]$ with the respective alkyl halides. For $HC\{SiMe_2NtBu\}_3SnCH_3$ a single crystal X-ray structure analysis established the detailed structural arrangements in this new class of compounds.

Keywords: tin; metal amides; tripodal amido ligands; metal nucleophiles.

We recently reported the synthesis and crystal structures of a series of group 14 triamido metallates which are stabilized by the tripodal amido ligands previously developed by us [1]. The alkali metal stannates were not only found to display a rich structural chemistry but have been employed in the synthesis of a variety of transition metal–tin heterobimetallics, essentially functioning as soft "donor ligands" [2]. A remarkable feature of their reactivity is the relative inertness to oxidative degradation in the coupling reactions leading to these species, a situation which is attributed to the electronegative substituents coordinated to the divalent tin centres. The most remarkable manifestation of this property is the synthesis and first structural characterization of a metal–metal bonded Ag—Sn complex as well as the stable metal–metal bonds established for several Au—Sn heterobimetallics containing gold in the oxidation states I, II and III [3].

In this paper we report first results of our investigations into the use of the triamido stannates as nucleophiles in the synthesis of new organo-tin reagents. Of these new systems allyltin derivatives were of special interest in view of their manifold application in organic synthesis [4–6].

EXPERIMENTAL

All manipulations were performed under an inert gas atmosphere of dried argon in standard (Schlenk) glassware which was flame dried with a Bunsen burner prior to use. Solvents were dried according to standard procedures and saturated with Ar. The deuterated solvents used for the NMR spectroscopic measurements were degassed by three successive "freeze–pump–thaw" cycles and dried over 4 Å molecular sieves. The centrifuge employed in some of the syntheses was a Rotina 48 by Hettich Zentrifugen, Tuttlingen, Germany, which was equipped with a specially designed Schlenk-tube rotor [7].

The ^{1}H-, ^{13}C-, ^{29}Si-, and ^{119}Sn-NMR spectra were recorded on a Bruker AC 200 spectrometer equipped with a B-VT-2000 variable temperature unit (at 200.13, 50.32, 39.76 and 74.63 MHz, respectively) with tetramethylsilane and $SnMe_4$ as references. Elemental analyses were carried out in the microanalytical laboratory of the Chemistry Department at Würzburg. The stannates $[HC\{SiMe_2N(4\text{-}CH_3C_6H_4)\}_3SnLi$-

$(THF)_3$] (**1a**), [$HC\{SiMe_2N[C(CH_3)_3]\}_2SnLi(THF)$] (**1b**) and [$MeSi\{SiMe_2N(4\text{-}CH_3C_6H_4)\}_3Sn\text{-}Li(THF)_3$] (**2a**), [$MeSi\{SiMe_2N[C(CH_3)_3]\}_3Sn\text{-}Li(THF)$] (**2b**) were prepared as reported previously by us [1,3]. All other chemicals used as starting materials were obtained commercially and used without further purification.

PREPARATION OF THE COMPOUNDS

$HC[SiMe_2N(4\text{-}CH_3C_6H_5)]_3SnMe$ (3)

$HC[SiMe_2N(4\text{-}CH_3C_6H_5)]_3SnLi(THF)_3$ (0.88 g, 1.04 mmol) (**1a**) and MeI (64 μl, 1.05 mmol) were stirred in thf (30 ml) at room temperature for 1 h. The solvent was removed *in vacuo* and the residue extract with toluene (20 ml). After filtration over Celite to remove the LiI formed in the reaction the colourless solution was concentrated to 8 ml and then stored at -35°C. Compound **3** was obtained as a colourless, crystalline solid after 24 h. Yield: 0.60 g (90%). ^{1}H-NMR (200.13 MHz, [D$_6$]benzene, 295 K): $\delta = -0.44$ (s, 1 H, HC), 0.33 [s, 3H, $SnCH_3$, $^2J(^{117/119}Sn\text{-}^1H) = 69$ Hz (broad)], 0.48 (s, 18 H, $Si(CH_3)_2$), 2.14 (s, 9 H, $CH_3C_6H_4$), 6.87 (m, 12 H, $CH_3C_6H_4$); $\{^1H\}^{13}$C-NMR (50.32 MHz, [D$_6$]benzene, 295 K): $\delta = -8.5$ ($SnCH_3$), 5.2 ($Si(CH_3)_2$), 10.5 (CH), 20.7 ($CH_3C_6H_4$), 125.6 (C^3), 129.9 (C^4), 130.3 (C^2), 147.7 (C^1). IR (KBr): 3010 w cm^{-1}, 2950 w, 2910 w, 2860 w, 1610 m, 1510 s, 1440 w, 1360 m, 1300 m, 1285 s, 1250 s, 1180 w, 1115 w, 1015 w, 980 w, 940 w, 925 w, 900 m, 845 s, 810 s, 775 m, 685 w; $C_{29}H_{43}N_3Si_3Sn$ (636.28); calcd C 54.74, H 6.76, N 6.61; found C 54.70, H 6.73, N 6.57.

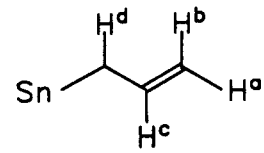
$HC\{SiMe_2N[C(CH_3)_3]\}_3SnMe$ (4)

To a stirred solution of $HC[SiMe_2NC(CH_3)_3]_3SnLi(THF)$ (**1b**) (1.05 g, 2.60 mmol) in diethylether (30 ml) MeI (0.16 ml, 2.60 mmol) was added through a syringe at room temperature. After stirring for 5 h the solvent was removed *in vacuo*. The residue was extracted with pentane (20 ml) and the solution was filtered through Celite. After concentration to 8 ml the solution was stored at -35°C. Compound **4** was obtained as a yellow crystalline solid within 48 h.

Yield: 1.07 g (77%); ^{1}H-NMR (200.13 MHz, [D$_6$]benzene, 295 K): $\delta = -0.93$ [s, 1 H, HC, $^4J(^{117/119}Sn\text{-}^1H) = 13.4$ Hz], 0.45 (s, 18 H, $Si(CH_3)_2$), 1.07 [s, 3 H, $SnCH_3$, $^2J(^{117/119}Sn\text{-}^1H) = 56.8/59.5$ Hz], 1.24 (s, 27 H, $C(CH_3)$). $\{^1H\}^{13}$C-NMR (50.32 MHz, [D$_6$]benzene, 295 K): $\delta = -6.8$ ($SnCH_3$), 9.6 ($Si(CH_3)_2$), 14.5 (CH), 35.4 ($C(CH_3)$), 54.7 ($C(CH_3)$); $\{^1H\}^{29}$Si-NMR (39.76 MHz, [D$_6$]benzene, 295 K): $\delta = 0.8$ ($Si(CH_3)_2$); $\{^1H\}^{119}$Sn-NMR (74.63 MHz, [D$_6$]benzene, 295 K): $\delta = -57.3$; IR (Nujol): $\nu = 3130$ vw cm^{-1}, 1997 vw, 1591 w, br, 1256 w, 1117 w, 1017 w, 868 w, 787 w, 719 w, 691 w; $C_{20}H_{49}N_3Si_3Sn$ (534.58) calcd C 44.94, H 9.24, N 7.86; found C 45.12, H 918, N 7.69.

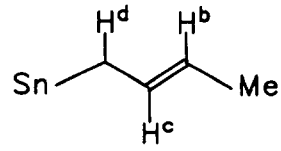
General procedure for preparation of $MeSi[SiMe_2N(4\text{-}CH_3C_6H_4)]_3Sn(allyl)$ (5–8)

To solutions of $MeSi[SiMe_2N(4\text{-}CH_3C_6H_4)]_3SnLi(THF)_3$ (0.88 g, 1.06 mmol) in toluene (30 ml) an equimolar amount of RX (X=Br, Cl; 1.06 mmol) was added in each case at room temperature and the reaction mixture was subsequently stirred for 1 h. After removal of LiX by centrifugation, the solvent was removed *in vacuo*. The residues were washed with cold pentane (5 ml). After drying for several hours compounds **6–9** were obtained as colourless analytical pure solids.



$MeSi[SiMe_2N(4\text{-}CH_3C_6H_4)]_3SnCH_2CH{=}CH_2$ (5)

Yield: 0.63 g, (86%); ^{1}H-NMR (200.13 MHz, [D$_6$]benzene, 295 K): $\delta = 0.18$ (s, 3H, CH_3Si), 0.56 (s, 18H, $Si(CH_3)_2$), 1.92 (d, $^3J_{HH} = 8.4$ Hz, $^2J_{SnH} = 99.4$ Hz, 2H, H^d), 2.11 (s, 9H, 4-$CH_3C_6H_4$), 4.20 (d, $^3J_{HH} = 16.8$ Hz, 1H, H^a), 4.35 (d, $^3J_{HH} = 9.13$ Hz, 1H, H^b), 4.87 (m, 1H, H^c), 6.91 (d, $^3J_{HH} = 8.2$ Hz, 6H, H^2), 7.05 (d, 6H, H^3); $\{^1H\}^{13}$C-NMR (50.32 MHz, [D$_6$]benzene, 295 K): $\delta = -15.0$ (CH_3Si), 3.4 ($Si(CH_3)_2$), 20.0 ($SnCH_2$), 20.7 (4-$CH_3C_6H_4$), 115.1 ($CH{=}CH_2$), 117.0 ($CH{=}CH_2$), 126.4 (C^2), 130.1 (C^3), 131.3 (C^4), 147.7 (C^1); $\{^1H\}^{29}$Si-NMR (39.76 MHz, [D$_6$]benzene, 295 K): $\delta = 4.4$ ($Si(CH_3)_2$), -91.4 ($SiCH_3$); $\{^1H\}^{119}$Sn-NMR (74.63 MHz, [D$_6$]benzene, 295 K): $\delta = -160.4$; $C_{31}H_{47}N_3Si_4Sn$ (692.77); calcd C 53.75, H 6.84, N 6.07; found C 53.58, H 6.97, N 5.99.



$MeSi[SiMe_2N(4\text{-}CH_3C_6H_4)]_3SnCH_2CH{=}CHCH_3$ (6)

Yield: 0.60 g (80%); ^{1}H-NMR (200.13 MHz, [D$_6$]benzene, 295 K): $\delta = 0.19$ (s, 3H, CH_3Si), 0.56 (s, 18H, $Si(CH_3)_2$), 1.15 (d, $^3J_{HH} = 5.1$ Hz,

$^5J_{SnH}$ = 43.7 Hz, 3H, CH=CHCH$_3$), 1.90 (dd, ^3J_HcHd = 6.9 Hz, ^4J_HbHd = 1.1 Hz, $^2J_{SnH}$ = 96.1 Hz, 2H, H^3), 2.10 (s, 9H, 4-CH$_3$C$_6$H$_4$), 4.4–4.6 (m, 2H, H^c u. General procedure for the preparation of MeSi{SiMe$_2$N[C(CH$_3$)$_3$]}$_3$Sn(allyl) (**9**, **10**)

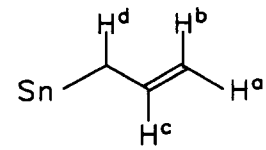
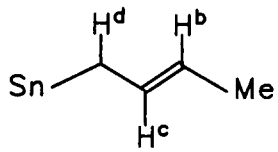
To a solution of MeSi{SiMe$_2$N[C(CH$_3$)$_3$]}$_3$SnLi(THF) (0.43 g, 0.68 mmol) in toluene (30 ml) an equimolar amount RX (X=Cl, Br, 0.68 mmol) was added and the reaction mixture subsequently stirred for 7 days at room temperature. After centrifugation of the LiX the solvent was removed *in vacuo*. The residue was washed with pentane (5 ml) and compounds **9** and **10** were obtained as colourless solids after vacuum-drying for several hours.



MeSi{SiMe$_2$N[C(CH$_3$)$_3$}$_3$SnCH$_2$CH=CH$_2$(**9**)

Yield: 0.33 g (81%); ^{1}H-NMR (200.13 MHz, [D$_6$]benzene, 295 K): δ = 0.08 (s, 3H, CH$_3$Si), 0.57 (s, 18H, Si(CH$_3$)$_2$), 1.33 (s, 27H, C(CH$_3$)), 2.79 (d, $^3J_{HH}$ = 8.0 Hz, $^2J_{SnH}$ = 81.1 Hz, 2H, H^d), 4.9–5.1 (m, 2H, H^b u. H^a), 6.0–6.3 (m, 1H, H^c); {^{1}H}^{13}C-NMR (50.32 MHz, [D$_6$]benzene, 295 K): δ = −13.9 (CH$_3$Si), 7.9 (Si(CH$_3$)$_2$), 36.2 (C(CH$_3$)$_3$), 40.1 (SnCH$_2$), 58.5 (C(CH$_3$)$_3$), 117.6 (CH=CH$_2$), 135.9 (CH=CH$_2$); {^{1}H}^{29}Si-NMR (39.76 MHz, [D$_6$]benzene, 295 K): δ = −3.2 (Si(CH$_3$)$_2$), −98.6 (SiCH$_3$); {^{1}H}^{119}Sn-NMR (74.63 MHz, [D$_6$]benzene, 295 K):

$\delta = -108.1$; $C_{22}H_{53}N_3Si_4Sn$ (590.72); calcd C 44.73, H 9.04, N 7.11; found C 44.95, H 9.19, N 7.28.



$MeSi\{SiMe_2N[C(CH_3)_3]\}_3SnCH_2CH{=}CHCH_3$ (**10**)

Yield: 0.33 g (79%); ^{1}H-NMR (200.13 MHz, [D$_6$]benzene, 295 K): $\delta = 0.09$ (s, 3H, CH_3Si), 0.58 (s, 18H, $Si(CH_3)_2$), 1.35 (s, 27H, $C(CH_3)$), 1.64 (d, $^3J_{HH} = 5.1$ Hz, 3H, $CH{=}CHCH_3$), 2.76 (d, $^3J_{HH} = 7.7$ Hz, $^2J_{SnH} = 78.6$ Hz, 2H, H^d), 5.2–5.5 (m, 1H, H^b), 5.7–5.9 (m, 1H, H^c); {^{1}H}^{13}C-NMR (50.32 MHz, [D$_6$]benzene, 295 K): $\delta = -13.9$ (CH_3Si), 7.9 ($Si(CH_3)_2$), 18.1 ($CH{=}CHCH_3$), 36.4 ($C(CH_3)_3$), 39.0 ($SnCH_2$), 58.5 ($C(CH_3)_3$), 125.6 ($CH{=}CHCH_3$), 132.2 ($CH{=}CH_2$); {^{1}H}^{29}Si-NMR (39.76 MHz, [D$_6$]benzene, 295 K): $\delta = -3.4$ ($Si(CH_3)_2$), -98.3 ($SiCH_3$); {^{1}H}^{119}Sn-NMR (74.63 MHz, $= -107.1$; $C_{23}H_{55}N_3Si_4Sn$ (604.75); calcd C 45.68, H 9.17, N 6.95; found C 45.93, H 9.04, N 6.88.

X-ray crystallographic study of **4**

Crysta data. $C_{20}H_{49}N_3Si_3Sn$, $M = 534.58$, hexagonal space group $P6_3$ (no. 173), $a = b = 10.2554(11)$, $c = 15.441(2)$ Å, $U = 1406.4(3)$ Å^3, $Z = 2$, $F(000) = 564$, $D_{calc} = 1.262$ Mg m^{-3}, μ(Mo-K_α) = 1.047 mm^{-1}.

Data collection. X-ray intensity data were collected from a colourless block shaped crystal of **4** (0.44 × 0.48 × 0.80 mm) in the θ-range 2.29–24.99° ($-1 \leqslant h \leqslant 11$, $-12 \leqslant k \leqslant 1$, $-1 \leqslant l \leqslant 18$) using a Siemens P4 four-circle diffractometer with graphite monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å). A total of 2342 independent reflections were collected of which 929 were unique ($R_{int} = 0.0218$).

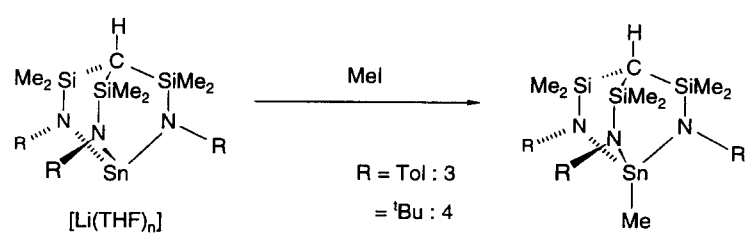
Structure solution and refinement [8].

The metal position was deduced from a Patterson synthesis and the remaining non-hydrogen atoms of the structure were identified in a series of Fourier and difference-Fourier maps. Hydrogen atoms were included in idealized positions and assigned $U_{iso} = 1.2\ U_{eq}$ of the parent carbon atom (methine) or $1.5\ U_{eq}$ of the parent carbon atom (methyl). After refinement with isotropic displacement parameters for all non-hydrogen atoms, an empirical absorption correction was applied (T_{max} 0.853, T_{min} 0.448). In the final cycles of full-matrix least squares refinement on F^2, non-hydrogen atoms were assigned anisotropic displacement parameters and refinement converged at $R_1 = 0.0518$, $wR_2 = 0.1336$ [$I > 2\sigma(I)$] and $R_1 = 0.0557$, $wR_2 = 0.1623$ (all data). The largest peak and trough in the final difference-Fourier map were 1.80 and -1.19 eÅ^{-3}, respectively, and the Flack absolute structure parameter refined to 0.26(12). We attribute the relatively high values of these parameters to the presence of a small quantity of complex of opposite chirality in the crystal but found no improvement in refinement by modelling racemic twinning. Supplementary data containing fractional atomic coordinates, thermal parameters and tables of bond lengths and angles have been deposited at the Cambridge Crystallographic Centre (CCDC).

RESULTS AND DISCUSSION

The reaction of the two previously reported lithium triamidostannates $[HC\{SiMe_2N(4\text{-}CH_3C_6H_4)\}_3SnLi(THF)_3]$ (**1a**), $[HC\{SiMe_2N[C(CH_3)_3]\}_3SnLi(THF)]$ (**1b**) with methyl iodide in ether solvents demonstrates to which degree the reactivity of the tin nucleophiles depends on the ligand periphery of the tripodal amido ligand. Whereas complete conversion of compound **1a** to the respective methyl stannane $[HC\{SiMe_2N(4\text{-}CH_3C_6H_4)\}_3SnMe]$ (**3**) has occurred after ca 30 min reaction time the analogous transformation using **1b** as starting material to give $[HC\{SiMe_2N[C(CH_3)_3]\}_3SnMe]$ (**4**) requires several hours reaction time (eqn 1). This probably is a consequence of the steric shielding of the nucleophilic centre by the bulky *tert*-butyl-groups in the latter.

The formulation of the methyl stannanes **3** and **4** is established by elemental analysis and the ^{1}H-, ^{13}C- and ^{29}Si-NMR spectroscopic data are consistent with the proposed structures of the compounds. The formation of the methyl–tin bonds could be directly inferred from the observed $^2J(^{117/119}Sn\text{-}^1H)$ coupling in **4**



(1)

[56.8/59.5 Hz]. In the ^{1}H-NMR spectrum of **3** the tin satellites of the methyl group were broad and the coupling constants of ^{117}Sn and ^{119}Sn isotopomers not resolved [^2J(SnH) = 69 Hz].

In order to establish the detailed structural parameters of these new triamidotin compounds a single crystal X-ray structure analysis of **4** was carried out. The molecular structure of **4** is shown in Fig. 1 and the principal metric parameters are listed in Table 1. Compound **4** crystallizes in the hexagonal space group $P6_3$ and the threefold symmetrical molecules are aligned along the crystallographic 3-fold axis, with the metal atom, the Sn-bound methyl group and the bridge head CH-unit on the 3-fold axis. As in the previously studied tripodal triamidotin compounds, the structural centre piece is the [2,2,2]bicyclooctane-related cage comprising the trisilylmethane unit and the triamidotin unit. These two units are slightly twisted with respect to each other [torsion angle C(1)—Si(1)—N(1)—Sn(1) 23.3(6)°] which is to be seen as a consequence of the steric repulsion of the methyl groups within the trisilylmethane unit rather than being due to the geometrical requirements of Sn—N binding in the molecule.

Although **4** is the first triamidotin(IV) compound containing a tripodal amido ligand to be structurally characterized, there are a number of crystal structures previously reported for the triamido stannates(II) and their Sn–metal bonded derivatives. It was therefore of particular interest to compare the metric parameters of the cage structure in these different systems. The ∠(N—Sn—N) angles in the triamidostannates(II) are close to 90° indicating little or no s–p hybridization at the tin atoms. These angles are increased in the Sn—M-heterobimetallics to values between 100 and 102°, while the ∠[N(1)—Sn(1)—N(1′)] value in the structure of **4** is 103.5(4)°. This may be indicative of a certain degree of s–p-hybridization in the tetravalent tin compound, given the low steric demand of the methyl group occupying the fourth coordination site. Another interesting feature is the contraction of the Sn—N bond in the Sn(IV) complex [d{Sn(1)—N(1)} = 2.093(10) Å] compared to those determined in the triamidostannates(II) containing tripodal amidoligands with a trisilylmethane framework which lie in the range of 2.15 Å [1]. Remarkably, the Sn—N bond lengths in the heterobimetallic systems are scattered around the value determined for **4** (although significant variations are observed). These structural parameters clearly set the tetravalent organotin compound **4** apart from the divalent tin derivatives of the tripodal amido ligands we previously characterized, although they lie well within the range of previously characterized alkyltriamidotin com-

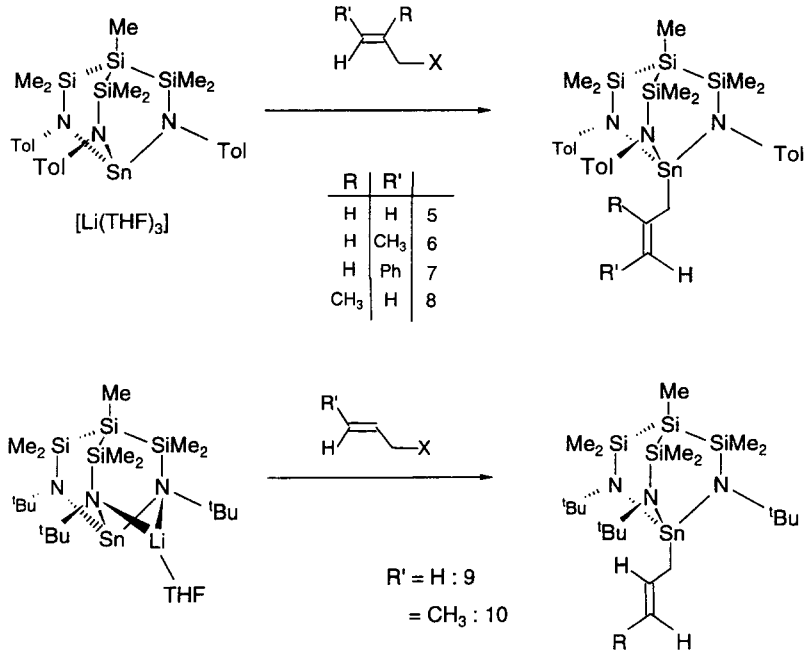
pounds [9]. The relatively high esd on the Sn—Me bond length is attributed to the slight disorder in the crystal (see Experimental section) and therefore does not permit its further discussion.

As stated above, one of the aims of this study was the preparation of a series of allyl triamidostannanes. For this purpose the two triamidostannates [MeSi $\{SiMe_2N(4\text{-}CH_3C_6H_4)\}_3$Sn-Li(THF)$_3$] (**2a**), [MeSi $\{SiMe_2N[C(CH_3)_3]\}_3$SnLi(THF)] (**2b**) containing a trisilylsilane ligand backbone were employed as metal nucleophiles. These systems were chosen since they are easier to isolate and to handle than the trisilylmethane analogues. In the reactions with a series of allyl halides a similarly marked difference in reactivity between the *p*-tolyl-*N* and the *tert*-butyl-*N* substituted species was observed. While the conversions of the former were



Scheme 1.

complete within less than 1 h of reaction time, the reaction of the stannate **2b** with the allyl halides took approximately 7 days to go to completion (Scheme 1). The formulation of the allyltriamidostannanes **5**–**10** was substantiated by the analytical and ^{1}H-, ^{13}C-, ^{119}Sn- and ^{29}Si-NMR spectroscopic data. The proton signals of the allyl CH_2/CHR groups which are bonded directly to the tin atoms are associated with sets of $^{117/119}$Sn satellites which were not resolved into the two isotopomers in most cases. The ^{2}J(Sn—H) coupling constants lie in the range of 96–100 Hz in **5**–**8** and are 81.1 and 78.6 Hz for **9** and **10**, respectively. In compound **8**, bearing the 2-methylallyl group ^{4}J(Sn—H) satellites were also observed with the proton signals of the methyl group [^{4}J(Sn—H) = 18.3 Hz)] and the olefinic protons [H^{b}: ^{4}J(Sn—H) = 36.9, H^{a}: ^{4}J(Sn—H) = 26.7 Hz (for labelling see Experimental section)].

CONCLUSIONS

The triamidostannates containing tripodal amido ligands which we reported previously are metal nucleophiles which may be employed in the synthesis of new organotin compounds. We are currently studying the synthetic potential of particularly the allyl tin compounds reported in this paper and plan to extend the study to include chiral amido ligands in the future.

Sterically induced *cis* isomerism in an Sb(III) imido dimer; synthesis, structure and solution dynamics of $[(Me_2N)Sb(\mu\text{-}NDipp)]_2$ (Dipp = 2,6-$Pr^i_2C_6H_3$)

(Received 14 April 1997; accepted 4 August 1997)

Abstract—The reaction of $[Sb(NMe_2)_3]$ with the sterically bulky amine $[DippNH_2]$ gives the unusual *cis* dimer $[(Me_2N)Sb(\mu\text{-}NDipp)]_2$ **1**, containing a puckered Sb_2N_2 core. ^1H NMR studies show that the *cis* conformation is retained in solution. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: *cis* isomerism; Sb(III) imido dimer; puckered Sb_2N_2 core.

We here report that the reaction of $[Sb(NMe_2)_3]$ with 2,6-diisopropylaniline ($DippNH_2$) (1 : 1 equivalents) (Scheme 1) gives the puckered *cis* dimer $[(Me_2N)Sb\{\mu\text{-}N(Dipp)\}]_2$ **1** [1]. Variable-temperature ^1H NMR studies illustrate that the *cis* conformation is retained in solution at and below room temperature. In earlier studies of dimethylamido Group 15 reagents [2] we showed that the reactions of a range of primary amines (RNH_2) with $[E(NMe_2)_3]$ (E = Sb or Bi; $x = 0-2$) give the *trans* dimers $[(Me_2N)E(\mu\text{-}R)]_2$ in the solid state and that the *cis–trans* equilibria occurring in solution for these species are markedly dependent on the degree of intramolecular bonding between functional groups (present on R) and the metal centres

$$2[Sb(NMe_2)_3] + 2[DippNH_2] \xrightarrow{\text{toluene}} [(Me_2N)Sb(\mu\text{-}NDipp)]_2 + 4Me_2NH$$

Scheme 1.

[2b,3]. The study presented here was undertaken in order to examine the potential disruption of the planar Sb_2N_2 units of these dimers by sterically demanding organic substituents, and the possible formation of monomeric species $[(Me_2N)Sb{=}NR]$.

A low-temperature (150 K) X-ray study was undertaken on **1** [4]. This shows that the complex exists as dimers, $[(Me_2N)Sb\{\mu\text{-}N(Dipp)\}]_2$, in the solid state. There are two crystallographically independent chemically equivalent molecules in the asymmetric unit which differ only slightly in their bond lengths and angles (one of which is shown in Fig. 1a). There are major distortions introduced by the incorporation of the sterically bulky Dipp groups into the Sb_2N_2 core framework. The bond lengths and angles within the planar cores of the *trans* dimers $[(Me_2N)Sb(\mu\text{-}NR)]_2$ [R = 3,4,5-$(MeO)_3C_6H_2$, 4-methylpyrid-2-yl] [2b] are similar to those found in **1** (Sb—N av. 2.06 Å, N—Sb—N av. 76.8°, Sb—N—Sb av. 100.6°). However, the Sb_2N_2 rings of **1** are butterfly shaped (with an average angle of 153.4° between the N wing-tips) (Fig. 1b).

The folding of these ring units and the surprising *cis* conformation of the NMe_2 groups with respect to the core stems from the extreme steric confrontation between the Pr^i substituents of the Dipp groups and the NMe_2 groups. In a planar *trans* arrangement these units would be brought into direct contact on each side of the Sb_2N_2 ring (Fig. 2a). However, the adoption of

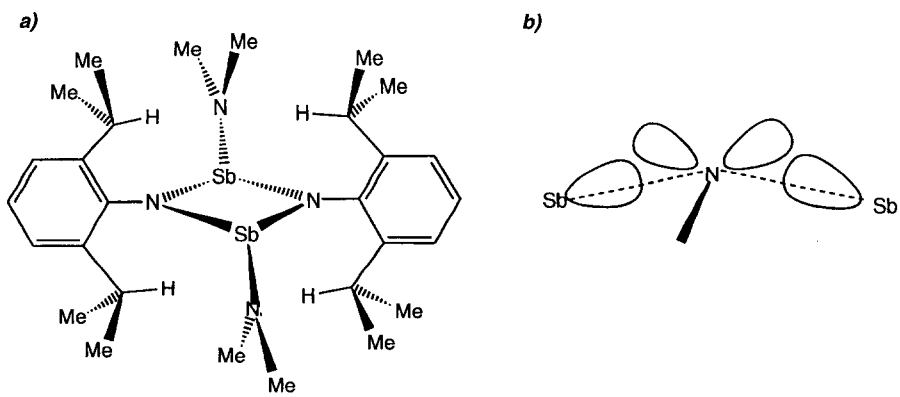

Fig. 2. (a) alternative planar *trans* arrangement showing steric congestion on both sides of the Sb_2N_2 ring, (b) disruption of the Sb—N bonding in the puckered rings of **1**.

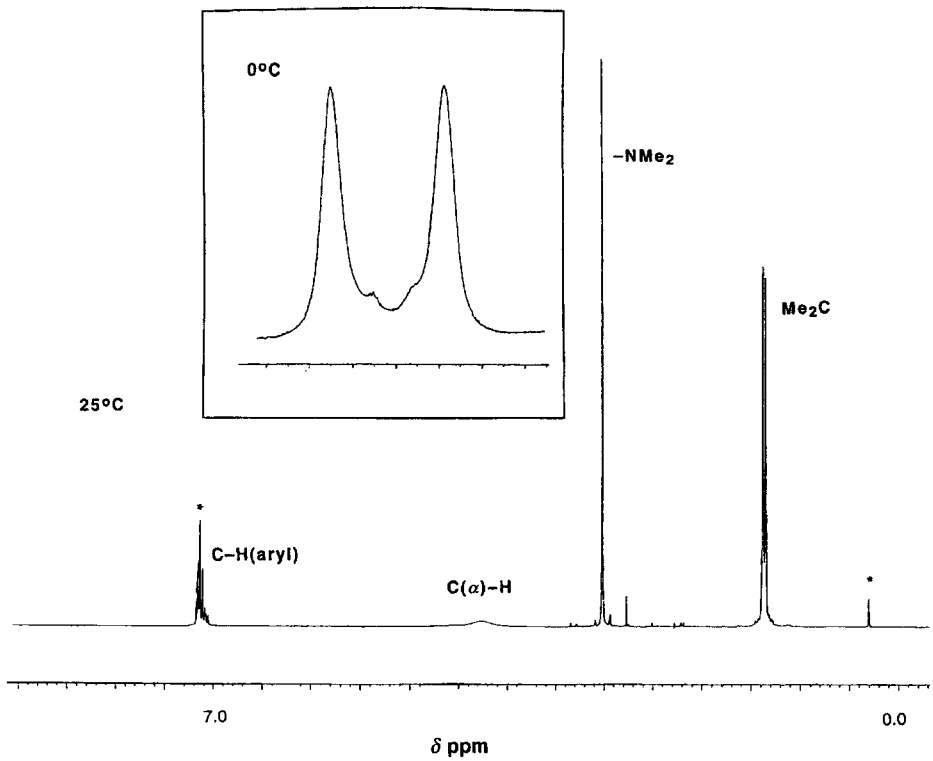

Fig. 3. ^{1}H NMR spectrum of **1** in toluene (250 MHz) (boxed inset shows the C(α)—H protons at 0°C).

a *cis* arrangement provides an overall release from the inherent steric congestion at the periphery of the core. By pivoting the DippN moieties away from the crowded side of the ring, maximum space is made available for the accommodation of the NMe_2 and Pr^i groups. This pivoting clearly disrupts the alignment of the Sb and N orbitals involved in ring bonding, which can no longer retain optimum overlap, and puckering of the ring results (Fig. 2b). The butterfly-shaped Sb_2P_2 core of the dimeric Sb(III) phosphinidine complex $[SbP(2,4,6\text{-}Bu^t_3C_6H_2)]_2$ (fold angle 103.2°) occurs as a result of an Sb—Sb bond [2.723(1) Å] [5]. The much longer Sb···Sb contacts in **1** (av. 3.18 Å) indicate that such bonding is not induced by the weakening of the Sb_2N_2 ring. Instead there is a compensatory shortening of the Sb—$N(Me_2)$ bonds compared to those present in the planar *trans* dimers [av. 1.99 Å in **1**; cf av. 2.02 Å] [2b].

Variable-temperature ^{1}H NMR studies show that the *cis* structure of **1** is maintained in toluene over a wide temperature range. Even at room temperature, two ill-defined overlapping septets [centred at δ 4.25] are observed for the α-C—H atoms of the two Pr^i substituents of each Dipp group. These are rendered inequivalent in the sterically congested *cis* structure by restricted rotation of the Me_2CH groups (Fig. 3). Although still poorly resolved, these resonances are fully separated at ca 0°C. Separate Me resonances for the Pr^i groups could not be resolved over the same temperature range, implying that there is little difference between their chemical environments. It cannot be deduced whether the interchange of the α-C—H protons of the Pr^i groups at higher temperature occurs by butterfly wing flapping (accompanied by N and Sb configurational inversion) or by simple rotation of the imido C—N bonds. However, no dissociation of **1** into monomers could be detected (down to ca −80°C), making a dissociation/re-association process less likely. In addition, rapid rotation of the Sb—NMe_2 bonds gives rise to only one Me resonance for **1**.

Although previous NMR studies of the dimers $[(Me_2N)Sb(\mu\text{-}NR)]_2$ [2b] and $[Bu^tSb(\mu\text{-}NBu^t)]_2$ [6] have shown that the distribution of the *cis* and *trans* isomers in solution is affected by the steric bulk and donor ability of the bridging imido groups, the observation of a *cis* dimer structure for **1** in the solid state and the persistence of this conformation in solution are unprecedented for such compounds. For the chloro-bridged amido Sn(II) complexes $[Sn(\mu\text{-}Cl)NR_2]_2$, *cis* and *trans* structures have been characterized in the solid state [7]. However, no correlation between the character of the organic substituents (R) and the preference for the *cis* or *trans* conformation appears to exist for these species.

(Received 25 April 1997; accepted 1 August 1997)

Abstract—Cp^*MCl_4 compounds (M = Mo or W) react with 2-amino-2′-hydroxydiphenylamine ($[H_2NNHOH]$) to yield complexes of the type Cp*M[HNNO]Cl. An X-ray study of the one electron reduction product, $\{Na(C_2H_5)_2O\}\{Cp^*Mo[HNNO]Cl\}$, showed it to contain square pyramidal $\{Cp^*Mo[HNNO]Cl\}^-$ ions weakly connected by bridging Na(ether) units. Cp* W[HNNO]Cl could be oxidized readily by AgOTf in acetonitrile to produce $\{Cp^*W[HNNO]Cl\}^+OTf^-$. Both Cp*M[HNNO]Cl compounds are reduced by hydrazine to give the diamagnetic compound, $Cp^*M[HNNO](NH_3)$. An X-ray structure of $Cp^*Mo[HNNO](NH_3)$ showed that the almost planar $[HNNO]^{3-}$ ligand and the ammonia ligand occupy the four basal positions in an approximately square pyramidal "piano stool" complex. Red crystalline Cp*W[HNNNH]Cl ($[HNNNH]^{3-} = [(2\text{-}NHC_6H_4)_2N]^{3-}$) could be prepared from Cp^*WCl_4 and 2,2′-diaminodiphenylamine. It can be oxidized with AgOTf or $NOPF_6$ to yield $\{Cp^*W[HNNNH]Cl\}X$ (X = OTf or PF_6). $\{Cp^*W[HNNNH]Cl\}PF_6$ reacts with three equivalents of NH_2NMe_2 to afford $Cp^*W[HNNNH](NNMe_2)$, with four equivalents of isopropylamine to produce Cp*W[HNNNH](N-*i*-Pr), and with water in the presence of K_2CO_3 to yield Cp*W[HNNNH](O). Cp*W[(HNNNH]Cl reacts with dimethyl zinc at 80° to give Cp*W[HNNNH]Me, which can be subsequently oxidized by silver triflate to give $\{Cp^*W[HNNNH]Me\}OTf$. Deprotonation of $\{Cp^*W[HNNNH]Me\}OTf$ with DBU yielded an imido complex, $Cp^*W[(2\text{-}N\text{-}C_6H_4)(2'\text{-}NH\text{-}C_6H_4)N]Me$ via loss of one of the two ligand NH protons. © 1998 Elsevier Science Ltd. Keywords: molybdenum; tungsten; 2,2′-diamidodiphenylamido; 2-amido-2′-oxydiphenylamido.

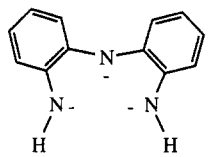
In the past few years we have synthesized and explored the chemistry of relatively high oxidation state tungsten or molybdenum complexes that will activate and reduce dinitrogen. In a series of studies we focused on complexes that contain the Cp^*MMe_3 core (M = W [1–5], Mo [3,6,7], or Re[8]). Some of the results that have emerged from these studies are as follows: (i) metals in a relatively high oxidation state (e.g. W(III) or W(IV)) can bind N_2 or partially reduce (N_2H_x) ligands; (ii) a 2π, 1σ arrangement of orbitals in such circumstances is favorable for stabilizing N_2H_x ligands; and (iii) a complex that contains bound hydrazine is a likely intermediate in which the N—N bond is cleaved to give ammonia. Recent investigations of the chemistry of tungsten and molybdenum phosphine complexes that is relevant to dinitrogen fixation has also begun to focus on the "mid" oxidation states for binding partially reduced (N_2H_x) ligands [9].

Unfortunately, there is at least one significant disadvantage to complexes that contain the Cp^*MMe_3 core. If we are to have any hope of reaching our long-term goal of developing a catalytic system for the reduction of dinitrogen using protons and electrons, methyl ligands eventually are protonated and lost as methane. Complexes that contain monodentate alkoxide ligands [10] did not prove to be suitable, in part because alkoxides also are readily protonated and can undergo ligand redistribution reactions that significantly complicate the chemistry in which we are interested. Therefore we looked for multidentate trianionic ligands that could take the place of the three methyl groups in the Cp^*MMe_3 core and that would be less susceptible than methyl ligands toward protonation and subsequent dissociation from the metal.

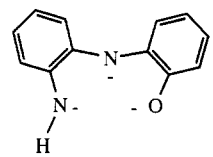
2,2′-Diaminodiphenylamine [11] and 2-amino-2′-hydroxydiphenylamine can be prepared by reducing

* Author to whom correspondence should be addressed.

the corresponding nitro compounds [12]. We felt that trianions derived from such compounds, $[HNNNH]^{3-}$ or $[HNNO]^{3-}$ (see below), would bind to Mo or W to yield complexes that contain Cp*M(HNNNH) or Cp*M(HNNO) cores. The *o*-phenylene rings should enforce planarity of the ligand system and therefore should encourage formation of pseudo five-coordinate complexes having a "piano stool" geometry. They also should discourage protonation of the amido nitrogen atoms. In this paper we report the synthesis of MCp*[HNNO] (M = Mo or W) and WCp*[HNNNH] complexes, X-ray structures of two MoCp*[HNNO] derivatives, and some chemistry that suggests that such ligands may prove useful for high oxidation state Mo or W chemistry.



$[HNNNH]^{3-}$

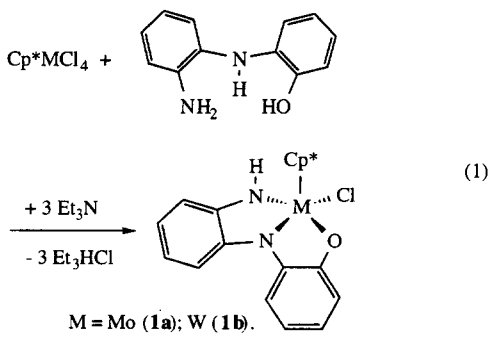


$[HNNO]^{3-}$

RESULTS AND DISCUSSION

Complexes containing the Cp*M[HNNO] *Core* (M = Mo, W)

Cp^*MoCl_4 reacts with 2-amino-2′-hydroxydiphenylamine in the presence of three equivalents of triethylamine to yield the 2-amido-2′-oxydiphenylamido ($[HNNO]^{3-}$) derivative **1a** [eqn (1)] as brown-black microcrystals in 65% isolated yield. An analogous reaction starting with Cp^*WCl_4 yielded Cp*W[HNNO]Cl (**1b**). Both **1a** and **1b** show ESR signals at $g \approx 2$, consistent with the presence of one unpaired electron. Although resonance forms can be drawn in which the metal is in a more reduced state, we prefer to view these as d^1 M(V) complexes.



(1)

Reaction of **1a** with Cp_2Co yields a diamagnetic species that we formulate as the d^2 complex, $\{Cp_2Co\}\{Cp^*Mo[HNNO]Cl\}$ (**2**) formed by one electron reduction of **1a** (Scheme 1). Reduction of **1a** with sodium amalgam in THF yields an analogous species (**3**) that is isolated as a sodium salt containing one equivalent of diethyl ether. The proton on nitrogen in the HNNO ligand could be observed at 7.80 ppm in the proton NMR spectrum of **3** as a broad singlet, but not in **2** (at 22°C), perhaps because in **2** the NH proton cannot be differentiated from aryl protons between 7.20 and 6.00 ppm. An X-ray study of **3** showed it to contain approximately square pyramidal $\{Cp^*Mo[HNNO]Cl\}^-$ ions weakly connected by bridging Na(ether) units (Fig. 1, Table 1) in a manner such that the O(2)—Na(1)—Na(2)—O(3) axis serves as a C_2 axis. The $[HNNO]^{3-}$ ligand is approximately planar. Unfortunately, the structure had to be refined with the Cp* and phenyl rings as rigid groups, and therefore the quality is not high. The Na—Cl bond lengths are ~2.70 Å, but the Na(1)—N(2) distance (2.55 Å) and Na(2)—O(1) distance (2.51 Å) suggest that these interactions are significant and that the sodium ions therefore are pseudo five-coordinate. The core bond lengths and angles in the $\{Cp^*Mo[HNNO]Cl\}^-$ ion are shown in Fig. 2 in order to illustrate that the approximately square pyramidal MoN_2OCl core geometry is roughly the same as that found for a more accurately determined structure discussed below. Reduction of **1b** proceeds similarly to yield what appears, by proton NMR, to be the tungsten analog of **2**, but this compound was not characterized further.

Cp*W[HNNO]Cl could be oxidized readily by AgOTf in acetonitrile to produce $\{Cp^*W[HNNO]Cl\}^+$ OTf^- (**4**) essentially quantitatively. The NH proton in **4** was located at 11.37 ppm in the proton NMR spectrum. We assume that there is no room for the triflate ion to bind strongly to the metal and therefore have formulated **4** as an ionic species. In contrast, **1a** was not oxidized under similar conditions to an analogous Mo(VI) species.

Compounds **1a** and **1b** are both reduced by hydrazine (2 equiv.) to give diamagnetic compounds with the formula Cp*M[HNNO](NH_3) (**5a** and **5b**, respectively). The only other observable product of these high yield reactions was $N_2H_5^+$ (according to NMR spectra), presumably as the chloride salt. The proton on nitrogen in the HNNO ligand and the ammonia protons could not be observed readily in either **5a** or **5b** as a consequence of facile proton exchange between these sites at room temperature. At low temperature the rate of the exchange process is slow enough that the HNNO proton can be observed near 8 ppm (8.34 ppm in **5a**; 8.27 ppm in **5b**) and the NH_3 proton around 3 ppm (2.96 ppm in **5a**; 3.68 ppm in **5b**). **5a** is also formed upon addition of excess hydrazine to **3**.

We speculate that the mode of formation of compounds **5a** and **5b** from **1a** and **1b** involves formation and decomposition of intermediate hydrazido(1-) species, Cp*M[HNNO](N_2H_3), as shown in eqns (2) and (3). This proposal is based on the fact that the W(V) complex, $Cp^*WMe_3(N_2H_3)$, which is pro-

posed to be formed upon deprotonation of $[Cp^*WMe_3(N_2H_4)]^+$, decomposes to yield 0.5 equiv. of $Cp^*Me_3W{=}NNH_2$, 0.5 equiv. of $Cp^*Me_3W{=}NH$, and 0.5 equiv. of NH_3 [1]. Since the proposed $Cp^*M[HNNO](N_2H_3)$ compounds would also contain the metal in the M(V) oxidation state, we propose

that they also are likely to be unstable with respect to an intermolecular decomposition reaction shown in eqn (3). However, details of the decomposition reaction are unclear at this stage. It is also not clear why M(IV) ammonia complexes are formed rather than M = NNH_2 or M = NH species.

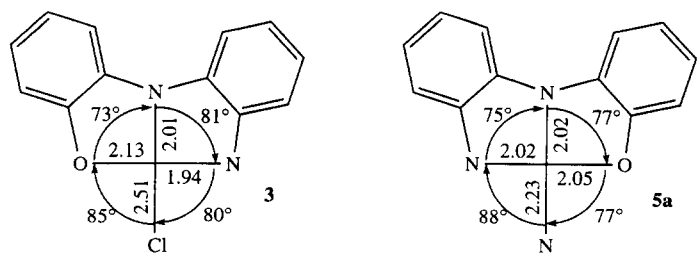
$$Cp^*M[HNNO]Cl + 2N_2H_4 \rightarrow N_2H_5Cl + \text{“}Cp^*M[HNNO](N_2H_3)\text{”} \quad (2)$$

$$\text{“}Cp^*M[HNNO](N_2H_3)\text{”} \rightarrow Cp^*M[HNNO](NH_3) + 0.5N_2 \quad (3)$$

Crystals of **5a** suitable for X-ray studies were obtained by recrystallization from an ether solution layered with pentane. The core structure of **5a** (Fig. 3) is similar to that found in **3** (Fig. 2). Relevant bond lengths and angles are listed in Table 2 and the core of **5a** is compared to that of **3** in Fig. 2. The 2-amidophenyl-2′-oxydiphenylamido ligand and the ammonia ligand occupy the four basal positions in a square pyramidal or “piano stool” arrangement typically found for pseudo-five-coordinate monocylopentadienyl complexes [13]. The $[HNNO]^{3-}$ ligand is close to being planar and the two Mo—N and one Mo—O bonds are all essentially the same length and relatively short (2.02 to 2.05 Å). The N(3)—Mo—N(2) and N(2)—Mo—O(1) bond angles are essentially equal, but the N(3)—Mo—N(1) bond angle is larger than the O(1)—Mo—N(1) bond angle by ~10°, perhaps because of steric repulsion between the proton on N(3) and the protons on ammonia. The Mo—N(1) distance (2.225(6) Å) is what one might expect for a dative Mo—N bond. The Cp* ligand is coordinated in an acentric fashion, with the Mo—C(17) distance being statistically longer that the other Mo—C distances. This circumstance is not unusual [14] and probably can be ascribed to greater repulsive forces between the ammonia ligand and the Cp* ligand compared to those between the flat HNNO ligand and the Cp* ligand. The protons on the ammonia ligand were not located in the X-ray study.

Synthesis and reactivity of complexes containing the $Cp^*W[(2\text{-}NH\text{-}C_6H_4)_2N]$ *core*

$Cp^*W[HNNNH]Cl$ (**6**; Scheme 2; $[HNNNH]^{3-}$ = $[(2\text{-}NHC_6H_4)_2N]^{3-}$) could be prepared from Cp^*WCl_4 and 2,2′-diaminodiphenylamine in the presence of at least three equivalents of triethylamine. Compound **6** is a red crystalline solid that is relatively soluble in CH_2Cl_2 and THF, but sparingly soluble in CH_3CN and hydrocarbons. It can be stored in air over a period of several weeks without significant decomposition. It does not react with water or methanol in the presence of triethylamine, nor does it react readily with NH_3 or N_2H_4. Compound **6** was not reduced by cobaltocene or zinc amalgam. It did react with excess sodium



O-Mo-N =129°; N-Mo-Cl = 131° O-Mo-N =126°; N-Mo-N = 131°

Fig. 2. A comparison of bond lengths and angles in **3** and **5a**.

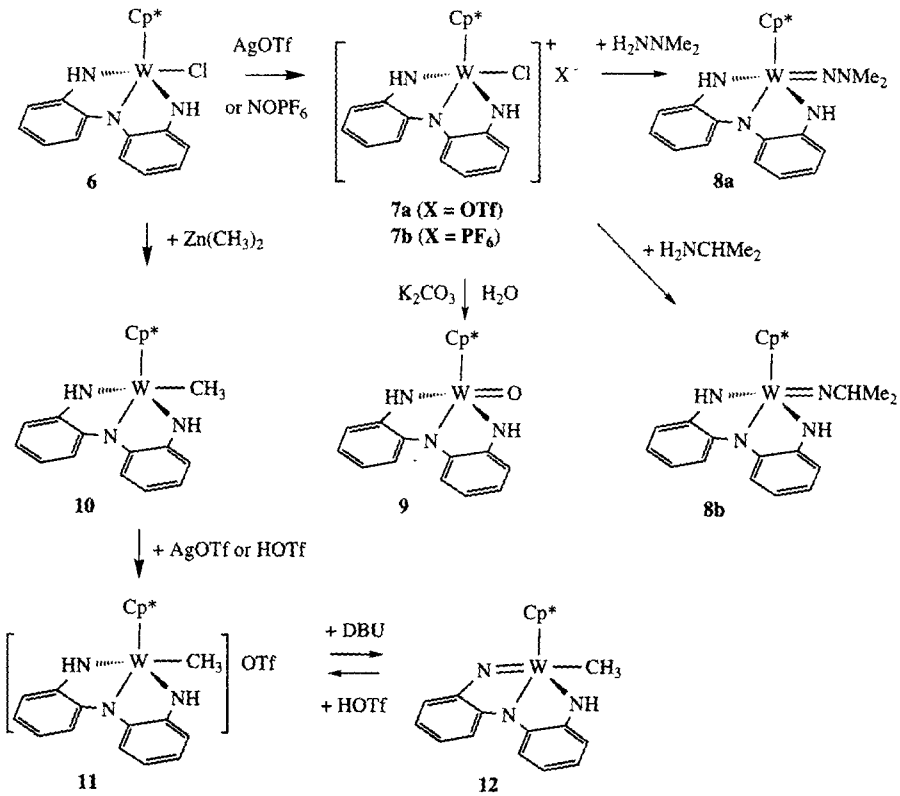

Scheme. 2.

amalgam in THF to produce an extremely air-sensitive diamagnetic species in low yield (30% from acetonitrile), but this product was not characterized.

Compound **6** can be oxidized readily. For example, it reacts cleanly with AgOTf or $NOPF_6$ to afford {Cp*W[HNNNH]Cl}X (X = OTf, **7a**; PF_6, **7b**) quantitatively. Both compounds are soluble in acetonitrile, but insoluble in other common organic solvents. ^1H NMR spectra of the two in CD_3CN are almost identical, consistent with their proposed ionic nature. The $[HNNNH]^{3-}$ ligand NH resonance is found as a broad singlet at 10.22 ppm in the proton NMR spectrum in CD_3CN.

Compound **7b** reacts with three equivalents of NH_2NMe_2 to afford Cp*W[HNNNH]($NNMe_2$) (**8a**) in moderate (37% isolated) yield. Compound **7b** also reacts with four equivalents of isopropylamine to produce Cp*W[HNNNH](N-*i*-Pr) (**8b**), and with water in the presence of K_2CO_3 to yield Cp*W[HNNNH](O) (**9**). Proton NMR spectra of **8** and **9** in C_6D_6 reveal the $[HNNNH]^{3-}$ ligand NH resonance at ~6.5 ppm.

Compound **6** reacts with dimethyl zinc slowly at

room temperature, and at 80° Cp*W[HNNNH]Me (**10**) is formed in good yield (67% isolated) in 1 h. Compound **10** is oxidized quantitatively by silver triflate to give {Cp*W[HNNNH]Me}OTf (**11**). Interestingly, an attempt to protonate **10** with one equivalent of triflic acid in CH_2Cl_2 led (slowly over a period of 3 days) to its oxidation to give **11** in moderate yield (65% isolated). The proton NMR spectrum of **11** in CD_3CN showed a resonance at 0.71 ppm, for the methyl group. Only four different aromatic protons were observed, consistent with the molecule having mirror symmetry. Compound **11** is a rare example of a cationic W(VI) alkyl complex (cf. $[Cp^*WMe_5]^+$). [15].

Deprotonation of **11** with DBU did not give $Cp^*W[HNNNH](CH_2)$, but an imido complex, $Cp^*W[(2\text{-}N\text{-}C_6H_4)(2'\text{-}NH\text{-}C_6H_4)N]Me$ (**12**), formed via loss of one of the two ligand NH protons. The NMR spectrum of **12** is relatively complex, as expected for a molecule having no symmetry. Normally eight proton resonances are observed in the aromatic region, but if **12** is contaminated with a trace of a proton source, even DBUHOTf, only four different aromatic proton resonances are observed, consistent with protonation and deprotonation of **12** being a fast and reversible process. Addition of one equivalent of HOTf to **12** yields **11** quantitatively. Formation of **12** should be compared to deprotonation of $[Cp^*WMe_5]^+$ to yield unstable $Cp^*WMe_3(CH_2)$ [15].

CONCLUSIONS

Multidentate amido ligands that contain *o*-phenylene links between amido nitrogens show some promise as supporting ligands for high oxidation state Cp*Mo or Cp*W chemistry. Among the interesting features of complexes that contain such ligands are the planar tridentate ligand backbone, the stability of the backbone to proton abstraction and cleavage reactions, and the ability of several complexes to be smoothly oxidized or reduced. For steric reasons, the parent (proton-substituted) versions of the two ligands described here are likely to be the only ones that can be put on Cp*M complexes to give approximately square pyramidal complexes. Conversely, more steric protection against bimolecular reactions is likely to be required if multidentate amido ligands are employed in the absence of other bulky ligands. In this context it should be noted that several tantalum complexes have been prepared that contain a pentafluorophenyl-substituted or trimethylsilyl-substituted version of the $[HNNNH]^{3-}$ ligand [16]. Other types of conformationally rigid multidentate amido ligands have appeared in the literature relatively recently [17–25]. It is interesting to note that cationic zirconium(IV) complexes containing the $[(t\text{-}BuN\text{-}o\text{-}C_6H_4)_2O]^{2-}$ ligand [22] are catalysts for the living polymerization of 1-hexene at room temperature or below. We expect that other examples of the utility of appropriately substituted multidentate amido ligands in high oxidation state chemistry, especially those that contain the *o*-phenylene backbone, will be forthcoming.

EXPERIMENTAL

General details

Standard experimental procedures can be found elsewhere [1]. All NMR chemical shifts are reported in ppm downfield from TSM (^1H and ^{13}C) external reference. Microanalyses (C, H, N) were performed in our laboratory using a Perkin–Elmer PE2400 microanalyzer. Cp^*MoCl_4 [26], Cp^*WCl_4 [15], 2,2′dinitrodiphenylamine [11], and 2-nitro-2′-hydroxydiphenylamine [12] were prepared as described in the literature.

Preparation of compounds

Cp*Mo[HNNO]Cl (**1a**). A yellow solution of 2-amino-2′-hydroxy diphenylamine (0.537 g, 2.68 mmol) and Et_3N (0.841 g, 8.31 mmol) in THF (10 ml) was added dropwise to a slurry of purple Cp^*MoCl_4 (1.00 g, 2.68 mmol) in 50 ml of THF at −40° C. The solution color changed to red-brown and some solid precipitated. The mixture was warmed to room temperature, stirred for 22 h, and filtered. The solid was washed with THF until the washings were colorless. The solvents were removed from the red-brown filtrate and the brown residue was recrystallized from a small amount of dichloromethane to give almost black microcrystals; yield 0.810 g (65%): ESR (CH_2Cl_2) $g = 1.98$; $\Delta_{1/2} = 9.9$ g. Anal. Calc. for $C_{22}H_{24}ClMoN_2O$: C, 56.97; H, 5.22; N, 6.04; Cl, 7.64. Found: C, 56.30; H, 5.19; N, 6.00; Cl, 7.69.

Cp*W[HNNO]Cl (**1b**). A yellow solution of 2-amino-2′-hydroxy diphenylamine (1.91 g, 9.55 mmol) and NEt_3 (3.00 g, 29.65 mmol) in THF (20 ml) was added to a red suspension of Cp^*WCl_4 (4.40 g, 9.55 mmol) in THF (100 ml) at −40° C. The solution color changed gradually to green-brown as a white solid deposited. The mixture was warmed to room temperature and stirred for 42 h. The reaction mixture was filtered and the solid was washed with THF until the washings were colorless. The volatile solvents were removed from the green-brown filtrate *in vacuo* and the residue was washed with cold dichloromethane (4 × 5 ml) to give a green solid; yield 4.48 g (85%): ESR (CH_2Cl_2) $g = 1.93$; $\Delta\nu_{1/2} = 18.5$ g. Anal. Calc. for $C_{22}H_{24}ClN_2OW$: C, 47.89; H, 4.38; N, 5.08. Found: C, 48.23; H, 4.44; N, 5.04.

$\{Cp_2Co\}\{Cp^*Mo[HNNO]Cl\}$ (**2**). A solution of 40 mg (0.21 mmol) of cobaltocene in 5 ml ether was added dropwise to a red-brown solution of 0.100 g (0.21 mmol) Cp*Mo[HNNO]Cl in 10 ml of THF. The color of the solution changed immediately to red.

After 24 h pentane was layered on top of the solution and the sample was kept at −30°C for 24 h to give brown microcrystals; yield 0.120 g (0.18 mmol, 86%): ^{1}H NMR (THF-d_8) δ 7.20–6.00 (m, 8, Ar*H*), 3.95 (s, 10, Cp), 1.25 (s, 15, Cp*). The $[HNNO]^{3-}$ ligand's NH proton was not located. It is believed either to be in the region of 7.20–6.00 ppm or to be too broad at 22°C to be observed readily. Anal. Calc. For $C_{32}H_{34}ClCoMoN_2O$: C, 58.86; H, 5.25; N, 4.29. Found: C, 58.87; H, 5.44; N, 4.08.

$\{Na[O(C_2H_5)_2]Cp^*Mo[HNNO]Cl\}_2$ (**3**). Sodium amalgam (1 equiv. of 0.05% Na/Hg) was added to a red brown solution of 200 mg (0.43 mmol) Cp*Mo[HNNO]Cl in 10 ml of THF. The mixture was stirred until the color changed to orange (20–30 min). The mixture was filtered and the residue was washed with THF until the washings were colorless. The solvents were removed from the orange filtrate *in vacuo* to give an orange glass. The orange glass was dissolved in a mixture of ether and pentane (1 : 1; 10 ml) and 10 ml of pentane was layered on top. Large brown crystals formed with time; yield 160 mg (0.33 mmol, 77%): ^{1}H NMR (THF-d_8) δ 7.80 (br s, 1 N*H*), 6.89–6.55 (m, 8, Ar*H*), 3.43–3.30 (q, 4, ether CH_2), 1.14–1.03 (t, 6, ether CH_3), 1.11 (s, 15 Cp*). Anal. Calc. for $C_{26}H_{34}ClMoN_2NaO_2$: C, 55.67; H, 6.11; N, 4.99. Found: C, 55.42; H, 5.76; N, 5.32.

$\{Cp^*W[HNNO]Cl\}OTf$ (**4**). A solution of AgOTf (0.265 g, 1.03 mmol) in CH_3CN (5 ml) was added dropwise to a green suspension of Cp*W[HNNO]Cl (0.570 g, 1.03 mmol) in CH_3CN (10 ml). A gray solid formed immediately and the color of the solution changed to red. The mixture was stirred at room temperature for 4 h and filtered. The solvent was removed from the filtrate *in vacuo* and the residue was extracted with dichloromethane. The red extract was reduced in volume and diethyl ether (15 ml) was layered on top. The mixture was cooled to −30 C to produce red-purple crystals which were isolated by filtration and dried *in vacuo*; yield 0.662 g (91%): ^{1}H NMR ($CDCl_3$ δ 11.37 (s, 1, N*H*), 7.65–6.80 (4 doublets and 4 triplets, 8, Ar*H*), 2.59 (s, 15, Cp*). Anal. Calc. for $C_{23}H_{24}ClF_3N_2O_4SW$: C, 39.42; H, 3.45; N, 4.00. Found: C, 39.52; H, 3.75; N, 3.85.

Cp*Mo[HNNO](NH_3) (**5a**). Hydrazine (28.9 μl, 0.91 mmol) was added to a red-brown solution of Cp*Mo[HNNO]Cl (0.210 g, 0.45 mmol) in THF (10 ml) at −40°C. The mixture was allowed to warm to room temperature. Over a period of 22 h the color changed gradually to green and a white solid formed. The mixture was filtered and the solvent was removed from the filtrate *in vacuo*. The residue was dissolved in ether (5 ml) and pentane was added just short of precipitating the product. Upon cooling this solution to −40°C, green crystals were formed and isolated by filtration; yield 0.188 g (93%): ^{1}H NMR (THF-d_8, −88°C) δ 8.34 (br s, 1 N*H*), 7.90–6.66 (m, 8, Ar*H*), 2.96 (br s, 3, NH_3), 1.1 (s, 15, Cp*). Anal. Calc. for $C_{22}H_{27}MoN_3O$: C, 59.32; H, 6.11; N, 9.43. Found: C, 59.44; H, 5.84; N, 9.19.

Cp*W[HNNO](NH_3) (**5b**). Hydrazine (73 μl, 2.29 mmol) was added to a green suspension of Cp*W[HNNO]Cl (0.418 g, 0.76 mmol) in THF (20 ml). The mixture was stirred at room temperature for 72 h. The color gradually changed to green-brown and a white solid formed. The mixture was filtered and the filtrate was reduced in volume *in vacuo*. Pentane (20 ml) was added to precipitate the product; yield 0.376 g (93%): ^{1}H NMR (THF-d_8, 23°C) δ 7.84–6.60 (m, 8, Ar*H*), 1.17 (s, 15, Cp*): ^{1}H NMR (THF-d_8, −84°C) δ 8.27 (br s, 1, N*H*), 7.85–6.58 (m, 8, Ar*H*), 3.68 (br s, 3, NH_3), 1.39 (s, 15, Cp*).

Cp*W[HNNNH]Cl (**6**). A solution of 2,2′-diaminodiphenylamine (2.86 g, 14.4 mmol) and triethylamine (4.50 g, 44.5 mmol) in THF (20 ml) was added dropwise to a red suspension of Cp^*WCl_4 (6.62 g, 14.4 mmol) in THF (100 ml) at −40°C. The color changed to dark red immediately and a white solid gradually deposited. After the addition was completed, the mixture was warmed to room temperature and stirred for 22 h. The reaction mixture was filtered and the solid was washed with THF until the washings were almost colorless. All volatile components were removed from the filtrate *in vacuo* and the red residue was dissolved in a minimum amount of hot dichloromethane. The solution was cooled to −40°C to yield small red crystals, which were isolated by filtration and dried *in vacuo*; yield 5.98 g (76%): ESR (CH_2Cl_2) $g = 1.94$; $\Delta\nu_{1/2} = 20.0$ g; IR (KBr, Nujol) cm^{-1} 3322 (ν_{NH}). Anal. Calc. for $C_{22}H_{25}ClN_3W$: C, 47.98; H, 4.58; N, 7.63. Found: C, 47.87; H, 4.70; N, 7.89.

$\{Cp^*W[HNNNH]Cl\}OTf$ (**7a**). A solution of AgOTf (1.706 g, 6.64 mmol) in CH_3CN (10 ml) was added dropwise to a red slurry of Cp*W[HNNNH]Cl (3.66 g, 6.64 mmol) in CH_3CN (50 ml) at room temperature. Silver metal formed and the solution changed to red-brown. The mixture was stirred for 1 h and filtered and the solid was washed with CH_3CN until the washings were colorless. The filtrate was reduced in volume (10 ml) and CH_2Cl_2 added to precipitate the product; yield 4.46 g (96%): ^{1}H NMR (CD_3CN) δ 10.23 (br s, 2, N*H*), 7.83 (d, 2, Ar*H*), 7.28 (d, 2, Ar*H*), 7.11 (t, 2, Ar*H*), 6.90 (t, 2, Ar*H*), 2.49 (s, 15, Cp*); IR (KBr, Nujol) cm^{-1} 3307 (ν_{NH}).

$\{Cp^*W[HNNNH]Cl\}PF_6$ (**7b**). A solution of $NOPF_6$ (0.284 g, 1.62 mmol) in CH_3CN (5 ml) was added dropwise to a cold (−40°C) suspension of Cp*W[HNNNH]Cl (0.894 g, 1.62 mmol) in CH_3CN (10 ml). Gas evolved and the color changed to yellow-brown. The mixture was warmed to room temperature and stirred for another hour. Solvents were removed *in vacuo* leaving a brown solid; yield 1.10 g (98%): ^{1}H NMR (CD_3CN) δ 10.22 (br s, 2, N*H*), 7.84 (d, 2, Ar*H*), 7.27 (d, 2, Ar*H*), 7.12 (t, 2, Ar*H*), 6.90 (t, 2, Ar*H*), 2.49 (s, 15, Cp*); IR (KBr, Nujol) cm^{-1} 3352 (ν_{NH}). Anal. Calc. for $C_{22}H_{25}ClF_6N_3PW$: C, 37.98; H, 3.62; N, 6.04. Found: C, 37.76; H, 3.65; N, 6.10.

Cp*W[HNNNH](η^1-NNMe$_2$) (**8a**). 1,1-Dimethylhydrazine (38 μl, 0.51 mmol) was added to a yellow-brown solution of $\{Cp^*W[HNNNH]Cl\}PF_6$ (0.116 g,

0.17 mmol) in CH_3CN (15 ml) at −40°C. The solution changed to green, then a yellow precipitate formed. The mixture was allowed to warm to room temperature and was stirred for 30 min. The reaction mixture was filtered and the yellow solid was washed with cold CH_3CN (5 ml) and dried *in vacuo*; yield 0.035 g (37%): ^{1}H NMR (C_6D_6) δ 8.11–6.90 (m, 8, Ar*H*), 6.35 (s, 2, N*H*), 3.04 (s, 6, NN*Me*$_2$), 1.50 (s, 15, Cp*); ^{1}H NMR (CD_2Cl_2) δ 7.86–6.75 (m, 8, Ar*H*), 6.69 (s, 2, N*H*), 3.63 (s, 6, NN*Me*$_2$), 1.60 (s, 15, Cp*); ^{13}C{^{1}H} NMR (CD_2Cl_2) δ 153.5–115.0 (6 singlets, Ar*C*), 111.8 (s, *C*$_5$Me$_5$), 48.9 (s, NN*Me*$_2$), 10.4 (s, C$_5$*Me*$_5$). Anal. Calc. for $C_{24}H_{31}N_5W$: C, 50.27; H, 5.45; N, 12.21. Found: C, 50.64; H, 5.22; N, 12.26.

Cp*W[HNNNH](N-*i*-Pr) (**8b**). A solution of *i*-PrNH_2 (0.49 ml, 5.75 mmol) in CH_3CN (5 ml) was added dropwise to a brown solution of {Cp*W[HNNNH]Cl}PF_6 (1.00 g, 1.44 mmol) in CH_3CN (10 ml) at −40°C. The solution changed to red immediately and a red precipitate formed. The mixture was warmed to room temperature and stirred for 16 h. The mixture was then cooled to −40°C and allowed to stand at this temperature for 12 h. The red solid was collected by filtration and washed with cold CH_3CN (5 ml). It was then extracted with toluene until the extracts were colorless. Solvents were removed from the combined extracts to give the red product; yield 0.575 g (70%): ^{1}H NMR (CD_2Cl_2) δ 7.75–6.68 (m, 8, Ar*H*), 6.49 (s, 2, N*H*), 5.63 (septet, 1, NC*H*Me$_2$), 1.74 (s, 15, Cp*), 1.29 (d, 6, NCH*Me*$_2$). Anal. Calc. for $C_{25}H_{32}N_4W$: C, 52.46; H, 5.63; N, 9.79. Found: C, 52.17; H, 5.83; N, 9.71.

Cp*W[HNNNH](O) (**9**). This complex could be prepared either from {Cp*W[HNNNH]Cl}PF_6 or {Cp*W[HNNNH]Cl}OTf. Degassed H_2O (29 μl, 1.61 mmol) was added to a mixture of {Cp*W[HNNNH]Cl}OTf (0.750 g, 1.07 mmol) and K_2CO_3 (0.760 g, 5.50 mmol) in CH_3CN (20 ml) at 0°C. The mixture was stirred at 0°C for 2 h, then warmed to room temperature and stirred for another 18 h. The volatile components were removed *in vacuo*. The residue was extracted with dichloromethane until the extracts were colorless. Dichloromethane was removed from the combined extracts *in vacuo* and the brown crystalline solid was washed with CH_3CN (2 × 5 ml) and dried *in vacuo*; yield 0.555 g, 98%): ^{1}H NMR ($CDCl_3$) δ 7.80–6.76 (m, 8, Ar*H*), 6.59 (s, 2, N*H*), 1.83 (s, 15, Cp*); IR (KBr, Nujol) cm^{-1} 3376 and 3247 (ν_{NH}), 885 (ν_{WO}). Anal. Calc. for $C_{22}H_{25}N_3OW$: C, 49.73; H, 4.74; N, 7.91. Found: C, 49.84; H, 5.07; N, 7.87.

Cp*W[HNNNH]Me (**10**). $ZnMe_2$ (0.16 ml, 2.32 mmol) was added to a suspension of Cp*W[HNNNH]Cl (0.920 g, 1.67 mmol) in toluene (15 ml). The reaction flask was sealed with a septum and was heated at 80°C for 1 h. The solution changed to red-purple and a green solid deposited. The mixture was cooled to room temperature and filtered. The green solid was washed with toluene until the washings were almost colorless. The residue was extracted with diethyl ether until the extracts were colorless. The combined ether extracts were chromatographed on a short alumina column using diethyl ether as eluent solvent. A red-purple band was collected. The volume of the solution was then reduced to ~3 ml *in vacuo*. The solution was cooled to −40°C. The red-purple solid was collected by decanting the supernatant liquid and was dried *in vacuo*; yield 0.570 g (64%): ESR (CH_2Cl_2) $g = 1.98$; $\Delta\nu_{1/2} = 17.3$ g. Anal. Calc. for $C_{23}H_{28}N_3W$: C, 52.09; H, 5.32; N, 7.92. Found: C, 52.39; H, 5.42; N, 7.89.

{Cp*W[HNNNH]Me}OTf (**11**). *Method A*. A cold (−40°C) solution of Cp*W[HNNNH]Me (0.114 g, 0.21 mmol) in CH_2Cl_2 (5 ml) was added quickly to a suspension of triflic acid (19 μl, 0.21 mmol) in CH_2Cl_2 (10 ml) at −40°C. The mixture was slowly warmed to room temperature and stirred for 3 days. The solution gradually changed from red-purple to green and a small amount of white solid formed. The mixture was filtered through a frit and the green filtrate reduced in volume (3 ml). Diethyl ether (15 ml) was layered on top. Green crystals grew slowly at 22°C. The crystals were isolated by decanting the mother liquor; yield 95 mg (65%): ^{1}H NMR (CD_3CN) δ 9.80 (br s, 2, N*H*), 7.68 (d, 2, Ar*H*), 7.07 (t, 2, Ar*H*), 7.05 (d, 2, Ar*H*), 6.85 (t, 2, Ar*H*), 2.31 (s, 15, Cp*), 0.71 (s, 3, *Me*). Anal. Calc. for $C_{24}H_{28}F_3N_3O_3SW$: C, 42.43; H, 4.15; N, 6.18. Found: C, 43.01; H, 4.26; N, 6.50.

Method B. To a purple solution of Cp*W[HNNNH]Me (0.300 g, 0.57 mmol) in THF (5 ml) was added dropwise a solution of AgOTf (0.145 g, 0.57 mmol) in THF (5 ml) at room temperature. A silver mirror formed immediately and a green solid deposited. Acetonitrile (10 ml) was added to the reaction mixture and the mixture was stirred for 30 min. The resulting mixture was filtered through a medium frit bedded with Celite. The green filtrate was reduced to ~3 ml *in vacuo*. Diethyl ether (15 ml) was layered on top. Green crystals formed with time at room temperature. The crystals were collected by decanting the supernatant liquid and dried *in vacuo*; yield 0.353 g (92%).

Cp*W[(2-N-C_6H_4)(2′-NH-C_6H_4)N]Me (**12**). DBU (27.3 μl, 0.18 mmol) was added to a green slurry of {Cp*W[HNNNH]Me}OTf (0.124 g, 0.18 mmol) in CH_2Cl_2 (10 ml) at −40°C. The color of the solution changed to red immediately. The mixture was warmed to room temperature and stirred for 1 h. All volatile components were removed *in vacuo* and the residue was extracted with diethyl ether until the extracts were colorless. The solvents were removed from the red extracts to give a red solid; yield 0.080 g (83%): ^{1}H NMR (CD_2Cl_2) δ 8.25 (br s, 1, N*H*), 7.54–6.26 (m, 8, Ar*H*), 2.01 (s, 15, Cp*), 0.46 (s, 3, *Me*); ^{1}H NMR ($CDCl_3$) δ 8.17 (br s, 1, N*H*), 7.61–6.30 (m, 8, Ar*H*), 2.01 (s, 15, Cp*), 0.54 (s, 3, *Me*); ^{13}C{^{1}H} NMR ($CDCl_3$) δ 158.8–114.6 (11 singlets, Ar*C*), 113.6 (s, *C*$_5$Me$_5$), 18.4 (s, W*Me*), 11.2 (s, C$_5$*Me*$_5$). Anal Calc. for $C_{23}H_{27}N_3W$: C, 52.19; H, 5.14; N, 7.94. Found: C, 52.61; H, 5.30; N, 8.15.

Crystal structure of $\{Na[O(C_2H_5)_2]Cp^*Mo[HNNO]Cl\}_2$ (**3**). An orange-brown prismatic crystal of dimension $0.25 \times 0.28 \times 0.47$ mm was mounted in a glass capillary in a nitrogen atmosphere. The data were collected at room temperature on a Rigaku diffractometer with a graphite-monochromated Mo–K_α radiation ($\lambda = 0.71069$ Å). Of the 3276 reflections that were collected, 3131 were unique, and equivalent reflections were merged. The intensities of three representative reflections measured after every 150 reflections remained constant throughout data collection, obtained from a least-squares refinement using the setting angles of 23 carefully centered reflections in the range $13.94° < 2\theta < 20.44°$ corresponded to a monoclinic cell with the dimensions $a = 15.367(4)$ Å, $b = 20.850(3)$ Å, $c = 12.271(2)$ Å and $\beta = 113.71(3)$ for $Z = 4$. Based on systematic absences the space group was determined to be C_2 (#5). The calculated density is 1.456 g/cm^3. A numerical absorption correction, using the program DIFABS, was applied, resulting in transmission factors ranging from 0.76 to 1.32. The structure was solved by Patterson's method. The final cycle of full matrix least-squares refinement was based on 1288 observed reflections ($I > 4\sigma(I)$) and 91 variable parameters and converged (largest parameter shift was 3.8 times its esd) with unweighted and weighted agreement factors of $R = 0.082$ and $R_w = 0.091$. The maximum and minimum peaks on the final difference Fourier correspond to 1.13 and -0.93 e$^-$/Å^3, respectively. All calculations were performed using the TEXAN crystallographic software package. Due to a disorder problem the pentamethylcyclopentadienyl ligand and all phenyl rings were refined as rigid groups.

Crystal structure of $Cp^*Mo[HNNO](NH_3)$ (**5a**). A green prismatic crystal with dimensions $0.3 \times 0.2 \times 0.2$ mm was mounted on a glass fiber under a stream of cold nitrogen gas from a liquid nitrogen bath. Data were collected at $-72°$C on an Enraf–Nonius CAD 4 diffractometer with a graphite-monochromated Mo–K_α radiation ($\lambda = 0.71069$ Å). Of the 8525 reflections that were collected, 4146 were unique, and equivalent reflections were merged. The intensities of three representative reflections measured after every 60 min remained constant throughout data collection, obtained from a least-squares refinement using the setting angles of 25 carefully centered reflections in the range $18.00° < 2\theta < 26.00°$ corresponded to a tetragonal cell with the dimensions $a = 19.105(2)$ Å and $c = 12.271(2)$ Å for $Z = 8$. Based on systematic absences the space group was determined to be $P4_2/n$ (#86). The calculated density is 1.322 g/cm^3. An empirical absorption correction, based on azimuthal scans of five reflections, was applied, resulting in transmission factors ranging from 0.95 to 1.00. The structure was solved by Patterson's method. The final cycle of full matrix least-squares refinement was based on 2044 observed reflections ($I > 4\sigma(I)$) and 252 variable parameters and converged (largest parameter shift was 0.00 times its esd) with unweighted and weighted agreement factors of $R = 0.045$ and $R_w = 0.037$. The maximum and minimum peaks on the final difference Fourier correspond to 0.47 and -0.69 e$^-$/Å^3, respectively. All calculations were performed using the TEXAN crystallographic software package.

Supplementary information covering experimental details, labelled ORTEP drawing, final positional parameters, final thermal parameters, and final observed and calculated structure factors for $\{NaO(C_2H_5)_2Cp^*Mo[(2\text{-}NH\text{-}C_6H_4)(2'\text{-}O\text{-}C_6H_4)N]Cl\}_2$ (16 pp) and $Cp^*Mo[(2\text{-}NH\text{-}C_6H_4)(2'\text{-}O\text{-}C_6H_4)N](NH_3)$ (20 pp) is available upon request.

(Received 28 May 1997; accepted 17 July 1997)

Abstract—Metal complexes of ligands with η^1-*O* coordinated carbonyl moieties are well-known throughout the inorganic literature. However, metal complexes containing authentic acid chloride ligands have not previously been isolated. The synthesis and characterization of compounds with the formula $W(X)Cl_3(OPh\text{-}2\text{-}COCl)$ (**2**) [X = O (**2a**), NC_6H_3-2,6-$(CH_3)_2$ (**2b**), and Ph_2C_2 (**2c**)] are reported. The crystal structures of **2a** and **2c** were solved, showing the interaction of the acid chloride carbonyl moiety with the tungsten center. Complex **2c** adopts a channelled structure having six-fold symmetric voids in the solid state. As was anticipated, the coordinated acid chloride of **2a** reacts readily with nucleophiles to produce the ester $WOCl_3(OPh\text{-}2\text{-}COPr^n)$ (**3**) and the amide $WOCl_3(OPh\text{-}2\text{-}CONHBu^t)$ (**4a**). A related amide complex $WOCl_3(OPh\text{-}2\text{-}CONH_2)$ (**4b**), synthesized by the reaction of $WOCl_4$ with salicylamide, displays an infinite-chain structure supported by hydrogen bonding between the amide group and the oxo ligand of an adjacent tungsten complex. The η^1-*O* coordinated nitro compounds $W(X)Cl_3(OPh\text{-}2\text{-}NO_2)$ (**5**) [X = O (**5a**), NC_6H_3-2,6-$(CH_3)_2$ (**5b**), and Ph_2C_2 (**5c**)] have also been isolated and the crystal structure of **5c** is reported. © 1998 Elsevier Science Ltd. Keywords: tungsten; salicylate; acid chloride; hydrogen bonding; materials.

During the 100 years of research that have gone into the development of the field of coordination chemistry, it has become apparent that virtually every generalization about the nature of metal ligand bonding is confounded by a range of exceptions. For example, arguments can be made regarding the tendency of carbon monoxide and other π-acceptor ligands to bind to transition metals with low formal oxidation states, but there are noteworthy examples of carbonyl ligand binding to formally highly oxidized metals. Although suitable ligands for supporting early transition metals in ultimate or penultimate formal oxidation states are typically ionic and strongly electron donating species such as halide, oxide, alkyl amide (R_2N^-), alkyl imido ($R\text{-}N^{-2}$) [1], alkoxide [2,3,4,5], thiolate [6], β-diketonate, cyclopentadienide and carboxylate [7] ligands, there are numerous examples of neutral σ-donor and π-acceptor ligands that support such complexes. While very weakly binding, the η^1-*O* coordinated carbonyl moieties is a class of ligands that pervades the literature in transition metal complexes for both high and low formal oxidation states.

Carboxylates [7], esters, aldehydes [8], ketones, and amides [9] are particularly common as η^1-*O* bound ligands, and are frequently encountered in association with highly Lewis acidic materials. The importance of such functional groups perhaps stems either from their ubiquitous presence in biological systems [10], or from their involvement in industrially important catalytic processes [11]. The stabilization of complexes containing such extraordinarily weak σ-donor ligands is usually accomplished by incorporating that σ-donor into ligand with another coordinating moiety, predisposing the system to a chelating interaction.

One ligand moiety in the group of carbonyl compounds for which there were previously no examples is the acid chloride. Access to a group of stable metal acid chlorides could provide a ready pathway for ligand-based electrophilic attachment of metals to tar-

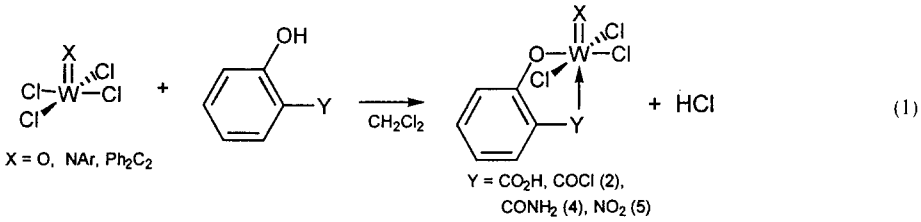
get molecules. Two other functional groups whose coordination chemistry has not been greatly elaborated for high oxidation state metals are nitro groups and primary or secondary amides (Fig. 1). Both η^1-*O* nitro and amide substituents provide the opportunity for constructing hydrogen bonded motifs of transition metal complexes for use in a range of materials applications.

In this paper, we report the synthesis of η^1-*O* coordinated complexes of these ligands with tungsten(VI) complexes, specifically those containing an oxo, aryl imido or η^2-diphenylacetylene units. We have begun to examine both the reactivity of these complexes and their potential to organize stable early transition metal compounds into inorganic/organic hybrid supramolecular materials.

RESULTS AND DISCUSSION

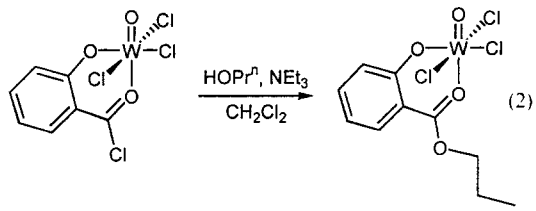
Synthesis and characterization of W(=X)Cl_3(OPh-2-Y) *complexes*

The complexes were synthesized in the same manner as analogous biphenolate and salicylate complexes [12]. The parent metal complex W(=X)Cl_4 was combined with the appropriate phenol in dichloromethane at ambient temperature [Eq. (1)] yielding the chelated phenoxide complex. The compounds were isolated as deep red to red-orange crystalline materials from dichloromethane/hexane solutions.



(1)

There is a considerable interest in compound **2**, as no acid chloride complexes have been reported previously. X-ray crystallographic studies of **2a** and **2c** will be discussed below. Given the inherent electrophilicity of both the tungsten and carbonyl moieties in complex **2**, either site may be attacked by nucleophiles. This behavior was examined through reactions of **2a** with alcohols or amines. Complex **2a** reacts with η-propanol to yield **3** with and fumes of HCl [Eq. (2)]. The reaction produces an ester which is isolated in modest yield (54%). The regiochemistry of propyl attachment is confirmed by a heteronuclear multiple bond connectivity (HMBC) NMR experiment [14]. HMBC shows coupling between the ^{1}H nuclei on the



(2)

a carbon of the *n*-propyl group to the carbonyl carbon of the ester. Low yields of amide products, such as the *N*-*t*-butyl salicylamide complexes (**4a**), can be obtained through similar reactions between **2a** and amines. It is unclear whether the low yields observed in these reactions are due to the formation of side products or to difficulty in separating the amide product from *t*-butylammonium chloride (*vide infra*).

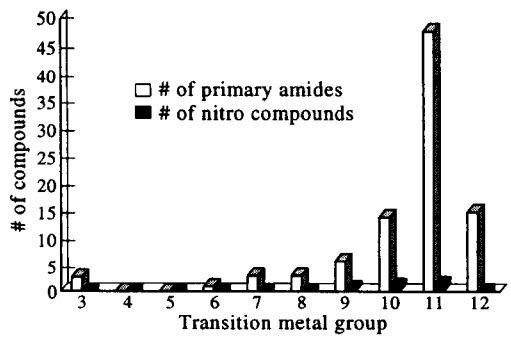


Fig. 1. Frequency of primary amides and nitro groups as η^1-*O* ligands in the Cambridge Structural Database (CSD) [13].

The unsubstituted salicylamide complex **4b** is readily prepared through the combination of $WOCl_4$ with salicylamide in a method analogous to the preparation of the salicylic acid compounds [12]. Because amides are well known synthons for supramolecular assembly in biological [15] and inorganic systems [16], complex **4b** also has potential for building similar structures. The poor solubility of **4b** in non-donor solvents like dichloromethane, chloroform, and toluene is probably caused by intermolecular associations in the solid state. Complex **4b** is more soluble in ether, THF, and very soluble in DMF. The amide groups are not likely to engage in hydrogen bonding with the carbonyl in an adjacent tungsten complex, due to steric hindrance

generated by η^1-*O* coordination of the amide. However, the terminal oxo group is accessible and does form a hydrogen bond with an adjacent amide molecule (*vide infra*).

Efforts were made to employ the nitro complexes **5** as hydrogen bond acceptors with hydrogen bond donors complexes. Given the fact that the amide N-H groups in **4b** will hydrogen bond to an oxo moiety, a carboxylic acid should also form a hydrogen bond with the oxo group of **5a**. Crystallization of an equimolar mixture of $WOCl_3$(OPh-2-NO_2) (**5a**) and $WOCl_3$(Hsal) in dichloromethane yielded only powdered $WOCl_3$(Hsal). Apparently, neither the nitro nor the terminal oxo groups of **5a** are sufficiently basic to bind the $WOCl_3$(Hsal) acid. It may be that the hydrogen bond donor (the Hsal complex) simply does not have the proper complementarity to form a hydrogen bond with the nitro group or the oxo group [17]. Alternatively, the formation of strong intermolecular hydrogen bonding in the $WOCl_3$(Hsal) lattice may favor the fractionation of the pure acid from **5a**. We are currently examining other hydrogen bond donors that will complement the use of **5** as a Brønsted base in supramolecular assemblies.

X-ray structure data

Compounds **2a, 2c, 4b,** and **5c,** have been characterized by X-ray crystallography. Selected bond distances and angles comparing these complexes are listed in Table 1. It is interesting to note the similarities of the nitro compound **5c** (Fig. 2) to the salicylic acid [12] and acid chloride **2c** (Fig. 3) complexes, the latter two having an obvious structural similarity. The W—$C_{C\equiv C}$ distances of all three diphenylacetylene compounds are identical within the 3σ crystallographic convention. The W—O_{trans} distances of **2c** and **5c** are slightly longer than that of the salicylate

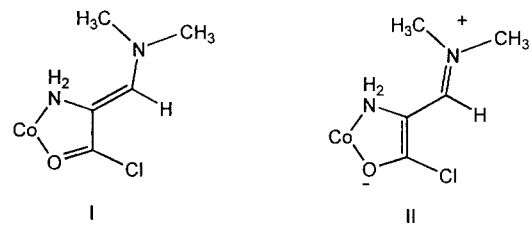
(Y = -CO_2H) by about 0.061(2) Å. This is probably due to the reduced σ-donor ability of the acid chloride and nitro groups compared to the acid. In all of the complexes, the W—O_{trans} bonds are severely weakened by the *trans* influence of the multiply bonded oxo or acetylene units. The η^1-*O* coordination of the respective groups does not seem to generate significant strain within the chelant moiety. The bond angles and distances in the carboxylate, acid chloride, and nitro groups are consistent with sp^2 hybridized central atom. Also noted in the table are the dihedral angles created by the chelant moiety and the tungsten center. As expected, these angles show the nearly planar arrangement of the coordinating group. The nitro group in **5c** has equal N—O bond lengths of 1.238(10) and 1.233(9) Å indicating that there is significant delocalization in this subunit. This is counter to the expectation that the bonded N—O unit will donate more electron density to tungsten and thereby exhibit greater N—O single bond character than the uncoordinated N—O group. The W—O interaction is evidently too weak to significantly perturb bonding in the NO_2 unit.

Relatively few coordination compounds containing acid chloride or nitroarene ligands exist for comparison with **2c** and **5c**. Even fewer examples of these complexes are observed among the early transition metals. A cobalt(III) complex of 3-(dimethylamino)-2-aminoacrylyl chloride (**I**) is the only example of an η^1-*O* bonded acid chloride [18]. Like the *o*-hydroxybenzoylchloride ligand in **2c**, the 3-(dimethylamino)-2-aminoacrylyl chloride binding to cobalt is stabilized *via* a chelate interaction. the acid chloride functionality in **2**, the chemistry of **I** is atypical of acid



chlorides [19]. The complex is unreactive to water and actually crystallizes as a hydrated salt. The reduced electrophilicity of the acid chloride carbon has its origins in strong π-donation by the dimethylamino group, which results in a ligand having primarily enolate character (**II**).

Monodentate nitroarene complexes are also very rare for the early transition metals (see Fig. 1), although a range of examples have been structurally characterized for Group 9 and 10 metals [20]. Nitro group coordination in these complexes is stabilized by the formation of either *o*-nitrophenolate or *o*-nitrophenyl chelates. Typical M—O distances in four and six coordinate palladium and rhodium complexes are 2.135(4) and 2.138(3) Å, respectively. These M—O distances are slightly shorter than the distance found in **5c**. The Pd—O bond of the *o*-nitrophenyl chelate is easily disrupted through the addition of phosphine and pyridine ligands, indicating that coordination of the nitro group to the palladium is extremely weak [20]. The nitro group of **5c** can also be compared with the coordination of nitrate ion [21]. The coordination of the *o*-nitrophenolate anion is naturally restricted to

an η^1-*O* mode by the six-membered ring formed by the phenolate unit. Crystallographically characterized metal nitrates are analyzed by a comparison of the metal oxygen distances, where M—O_{short} is the distance to the closer oxygen and M—O_{long} is the distance to the further oxygen [21]. The W—O_{short} distance in **5c** of 2.274(7) Å is longer than the characteristic M—O_{short} distance for third row transition metal nitrates. This long bond results from the strong *trans* influence of the acetylene ligand and the poor localization of negative charge density on the oxygens of the nitro group. The W—O_{long} distance is 4.342(7) Å, significantly longer than any reported for simple nitrate salts (M—O_{long} = 3.5 Å). The geometrical constraints imposed by the chelate ring will only permit η^1-*O* coordination mode of the NO_2 group.

The complexes all crystallize in different space groups, the most unusual being $R\bar{3}$ for **2c**. This complex crystallizes in a three-fold symmetric group due to π-interactions [22] between the salicoyl and acetylene units of neighboring molecules. The diphenylacetylene ligand is involved in two types of interactions: (1) π-stacking of C(21)—C(26) ring of the diphenyl acetylene to the C(31)—C(36) ring in an adjacent salicoyl chloride ligand at a distance of 3.749 Å and an interplanar angle of 0° and (2) a C—H $\cdots$ π interaction of the other acetylene phenyl group [C(11)—C(16)] to C(32) of a different salicoyl chloride unit at a distance of 3.654 Å and an angle of 132.9°. With an additional contact of a C—H $\cdots$ π interaction with another adjacent aryl ring C(13)—H(13) $\cdots$ [C(11)—C(26)] at a distance of 3.654 Å and a C—H $\cdots$ centroid angle of 117.3°, the molecule forms an unusual lattice structure that is highly ordered. The hexagonal crystallographic axis corresponds to the *c*-axis of the cell, generating a hexagonal-shaped channel (Fig. 4). The channel has a diameter of approximately 5–6 Å (accounting for large atom radii and hydrogen atoms) and is devoid of solvent molecules. The closest distance between carbon nuclei across the channel is 8.5 Å, while the closest carbon–chlorine distance is 7.8 Å. The absence of solvent is confirmed by NMR characterization of the bulk material. This is an unusual channel structure for a non-covalently bonded system [23]. Future studies will address the idea that molecules assembled by multiple π-interactions can be used to construct other materials containing large unoccupied void volumes.

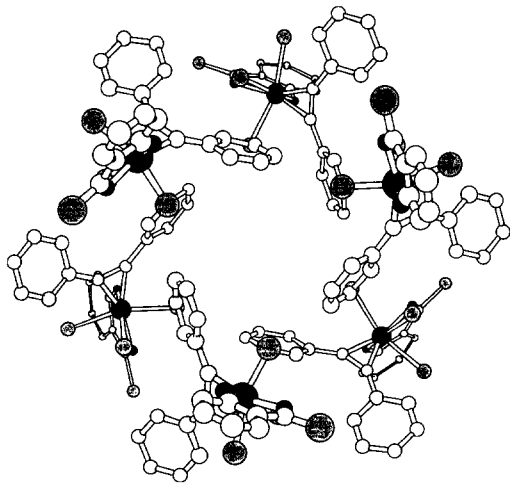


Fig. 4. View of W(η^2-Ph_2C_2)Cl_3(OPh-2-COCl) (**2c**) down the *c* crystallographic axis.

The acid chloride complex **2a** does not exhibit the same channel structure as **2c**. Its structure is typical of tungsten oxo compounds [24], with relevant bond distances and angles listed in Table 1. The only significant structural differences between the two oxo complexes in Table 1 is in the oxo ligand and the chelant moiety. The terminal oxo group bonds at a slightly shorter distance in **2a** than in related salicylate complexes [12]. This may be due to the decreased electron donating ability of the acid chloride compared to the acid, which allows the oxo ligand to interact more strongly with tungsten. This hypothesis is verified by the fact that the W—$O_{carbonyl}$ bond length is much longer in the acid chloride than the corresponding acid (by 0.108 Å). In all other respects, such as W—Cl and W—O_{Ph} bond lengths and corresponding bond angles, the molecular units of **2a** and **2c** are quite similar. Also, complex **2a** bears resemblance to **2c** in the intermolecular associations that are formed. The oxo group forms a 3.39(1) Å C—H $\cdots$ O hydrogen bond with the hydrogen atom on C(3) [25]. The C—H $\cdots$ O interaction lies along the *a* direction of the unit cell. Yet another close contact is observed between Cl(3) and the carbonyl carbon C(7) of an adjacent molecule. The atoms are separated by 3.488(9) Å, at an angle of 90° between the metal chloride bond and the plane of the acid chloride group. The two molecules involved in this interaction are related by the screw-axis in the crystal. The atomic organization of this contact is reminiscent of a nucleophilic substitution at a carbonyl carbon [26]. Lastly, the aromatic rings of the salicoyl chloride ligands stack at a distance of 4.033(6) Å and an interplanar angle of 0° [22].

The structure of the amide **4b** is a classic octrahedral tungsten oxychloride complex (Fig. 5, Table 2). It displays the *trans* effect typical of an oxo ligand with a long bond to the neutral η^1-*O* amide group [W—O_{amide} = 2.271(4) Å]. While the molecular unit appears to be rather mundane, the intermolecular interactions are quite fascinating. There is a hydrogen bond from the amide group of one tungsten atom to the oxo group of the adjacent molecule. This N—H $\cdots$ O_{oxo} interaction is 3.067(9) Å, with an apparent N—H $\cdots$ O angle of 117.7(10)° (Fig. 6). Actually, N—H $\cdots$ O interactions of this type are very common in organometallic coordination chemistry [9]. An average N—H $\cdots$ O distance of the interaction described here is 3.02(1) Å, with an angle of 155.9(5)°. The hydrogen bond between the amide and oxo group in **4b** continues through the lattice, making an infinite

one dimensional chain of hydrogen bonds. These one dimensional chains of complexes are arranged in a herringbone pattern. These strands are in turn held together by two other non-covalent interactions: (1) A close contact, possibly a van der Walls interaction, between a chloride ligand [Cl(3)] and an adjacent arene ring at a distance of 3.434 Å with an 89.9° contact angle, and (2) A C—H···Cl interaction between C(3) of the arene ring and Cl(1) of a nearby complex at a distance of 3.696 Å and an angle of 118.1°. Hydrocarbon C—H···Cl interactions are well known and have been observed in the assembly of other hydrogen bonded complexes [27]. All of these interactions help to stabilize the crystal lattice, which contributes to the poor solubility of **4b** in non hydrogen bonding solvents (*N*- or *O*-atom donor solvents). According to the Cambridge Structural Database (CSD), only one other group 6 complex with a coordinating primary amide moiety has been documented: $MoO_2Cl_2(CH_3CONH_2)$ [28]. This complex shows an analogous intermolecular oxo-amide hydrogen bond motif in the solid state at a distance of 3.042 Å and an angle of 158°.

EXPERIMENTAL

General procedures

All experiments were performed under a nitrogen atmosphere in a HE-553-2 Vacuum Atmospheres dry box or using standard Sclenk techniques. Benzene, toluene, hexane, and diethyl ether were purified by distillation over Na/benzophenone. Dichloromethane and *t*-butylamine were purified by distillation over CaH_2, followed by purging with dry nitrogen. NMR solvents (Cambridge Isotope Laboratories) were dried with 5 Å molecular sieves and degassed with dry nitrogen prior to use. Salicylic acid (H_2sal), and 2-nitrophenol ($HOPh\text{-}2\text{-}NO_2$) were used as received from Aldrich. Thionyl chloride was used as received from Eastman-Kodak. $W(=NC_6H_3\text{-}2,6\text{-}Me_2)Cl_4$ and $W(\eta^2\text{-}Ph_2C_2)Cl_4$ were prepared using published procedures. $WOCl_4$ was received as a gift from Hercules Research Company.

NMR spectra were recorded on Bruker AM-500 or DRX-400, Varian XL-300, or General Electric QE-300 spectrometers. ^1H and ^{13}C data are listed in parts per million (ppm) downfield from tetramethylsilane with ^1H data referenced by the solvent's residual proton peak. All NMR spectra are recorded at ambient temperature (~20°C) in $CDCl_3$ unless otherwise noted. All coupling constants are linked in hertz (Hz). Elemental analyses were performed by Desert Analytics (P.O. Box 41838, Tucson, AZ 85717).

Preparation of salicoyl chloride (HOPh-2-COCl) (**1**)

This procedure is based on several literature methods [29]. Salicylic acid (10.0 g, 72.4 mmol) was placed in a 250 cm^3 flask with a magnetic stirbar. A small amount of aluminum chloride (0.3 g, 2.25 mmol) was added, followed by dry benzene (60 cm^3). The mixture was fitted with a reflux condenser and thionyl chloride (7.92 cm^3, 108.6 mmol, 1.5 equiv.) was added

by syringe. As the yellow mixture was refluxed for 5 h, it became orange colored. The volume was then reduced to 30 cm^3 *in vacuo* and was stirred overnight. The volume of the viscous solution was further reduced *in vacuo* until the exterior of the flask was no longer cool to the touch. This gelatinous product was vacuum distilled twice into a liquid nitrogen cooled flask (to insure the complete removal of the solvent). The product is a colorless, non-viscous liquid at room temperature, whose density (1.3112 g/cm^3) and freezing point (18°C) match the literature values [30]. This material was stored at −20°C to prolong shelf life as autocondensation occurs more quickly at room temperature. The solid was melted immediately prior to each use and handled under nitrogen to prevent hydrolysis. Yield: 34% (2.90 cm^3, 3.80 g, 24.3 mmol).

Preparation of $WOCl_3$(OPh-2-COCl) (**2a**)

$WOCl_4$ (2.5017 g, 7.32 mmol) was slurried in dichloromethane (20 cm^3) in a 50 cm^3 Schlenk flask with a magnetic stirbar. Salicoyl chloride (0.87 cm^3, 7.28 mmol) was added slowly by syringe. The slurry became blood red upon addition of the first drop of salicoyl chloride. The addition of salicoyl chloride produced copious amounts of HCl over the 5 min required to add the liquid. The reaction was stirred an additional 25 min then the solvent was removed *in vacuo*. The product was recrystallized from toluene layered with hexane to yield a deep crimson microcrystalline material. X-ray quality crystals were recrystallized from dichloromethane layered with hexane. Yield: 96% (3.1811 g, 7.07 mmol). NMR data: ^1H (300 MHz): δ 8.48 (H, dd, 6-position of OPh-2-COCl), 8.01 (H, dt, 5-position), 7.46 (H, dt, 4-position), 7.22 (H, dd, 3-position). ^{13}C (500 MHz, $CDCl_3$): δ 178.86 (-COCl), 159.67, 140.25, 136.16, 129.40, 123.59 123.10. Mass spectrum (EI): 460 [M^+], 427 [$WOCl_3$(OPh-2-COCl)$^+$], 307 [$WOCl_3^+$], 272, 240 [$C_{14}H_8O_4^+$], 120 [$C_6H_4CO_2^+$], 92 [$C_6H_4O^+$], 64 [$COCl^+$]. Anal. calcd for $C_7H_7O_3WCl_4$. Calc.: 18.21% C; 0.87% H. Found: 18.89% C; 0.62% H.

Preparation of W(=NC_6H_3-2,6-Me_2)Cl_3(OPh-2-COCl) (**2b**)

This compound was prepared in a manner similar to **2a**. W(=NC_6H_3-2,6-Me_2)Cl_4 (1.6070 g, 3.61 mmol) was slurried in dichloromethane (30 cm^3) and salicoyl chloride (0.43 cm^3, 3.60 mmol) was added by syringe. The product was recrystallized from dichloromethane and isolated as a black microcrystalline material. Yield: 76% (1.5550 g, 2.75 mmol). NMR data: ^1H (400 MHz): δ 8.41 (H, dd, 6-H of -OPh-2-COCl), 7.93 (H, dt, 5-H), 7.35 (H, t, 4-H), 7.31 (2H, d, *m*-H's of imido), 7.08 (H, d, 3-H of -OPh-2-COCl), 6.74 (H, t, *p*-H of imido), 3.22 (6H, s, NC_6H_3-2,6-($\underline{C}H_3$)$_2$). ^{13}C: δ 180.73 (-$\underline{C}$OCl), 162.52, 150.13, 144.69, 141.33, 136.24, 133.15, 126.89, 126.42, 122.83, 121.56, 18.44 (NC_6H_3-2,6-($\underline{C}H_3$)$_2$). Anal. $C_{15}H_{13}NO_2WCl_4$. Calc.: 31.89% C; 2.32% H; 2.48% N; 25.10% Cl. Found: 31.53% C; 2.02% H; 2.37% N; 25.28% Cl.

Preparation of W(η^2-Ph_2C_2)Cl_3(OPh-2-COCl) (**2c**)

This compound was also prepared in a manner similar to **2a**. W(Ph_2C_2)Cl_4 (1.2087 g, 2.40 mmol) was slurried in 30 cm^3 dichloromethane and salicoyl chloride (0.28 cm^3, 2.35 mmol) was added by syringe. The solution was filtered through Celite and the volume reduced *in vacuo* to yield purplish–black blocks suitable for X-ray diffraction. Yield: 70% (1.0520 g, 1.69 mmol). NMR data: ^1H (400 MHz): δ 8.45 (H, dd, 6-H of -OPh-2-C = OCl), 8.16 (4H, *o*-H's of Ph_2C_2), 7.84 (H, dt, 5-H, of -OPh-2COCl), 7.77 (4H, t, *m*-H's of Ph_2C_2), 7.63 (2H, t, *p*-H's of Ph_2C_2), 7.36 (4-H of -OPh-2-COCl), 6.94 (3-H of -OPh-2-COCl). ^{13}C (partial): δ 179.79, (-$\underline{C}$OCl), 163.20, 141.41, 138.17, 136.41, 134.72, 134.11, 129.43, 125.44, 122.35, 119.47. Anal. calcd for $C_{21}H_{14}O_2WCl_4$. Calc.: 40.42% C; 2.26% H; 22.73% Cl. Found: 40.34% C; 1.98% H; 22.38% Cl.

Preparation of $WOCl_3$(OPh-2-COOPr^n) (**3**)

A 50 cm^3 Schlenk flask was charged with **2a** (0.8061 g, 1.79 mmol), a magnetic stirbar, and dichloromethane (25 cm^3). In a separate Schlenk flask, 1-propanol (0.13 cm^3, 1.74 mmol) and triethylamine (0.25 cm^3, 1.79 mmol) were mixed with dichloromethane (10 cm^3). The solution of **2a** was cooled to −78°C and the 1-propanol/triethylamine solution was added dropwise over 15 min. Fumes evolved during the addition (presumably HCl). After stirring an additional 45 min at −78°C, the reaction was allowed to warm to room temp (over thirty minutes) and stripped to dryness *in vacuo*. The dark red residue was taken up in hot hexane (5 × 10 cm^3) and filtered through Celite. The hexane was concentrated and allowed to cool, producing crystals of **3**. Yield: 54% (0.4673 g, 0.09 mmol). NMR data: ^1H (400 HMz): δ 8.24 (H, dd, 6-H), 7.86 (H, dt, 5-H) 7.35 (H, t, 4-H), 7.18 (H, d, 3-H), 4.65 (2H, t, $OC\underline{H}_2CH_2Ch_3$), 1.96 (2H, q, $OCH_2C\underline{H}_2CH_3$), 1.11 (3H, t, $OCH_2CH_2C\underline{H}_3$). ^{13}C: δ 169.77 (ester), 160.65, 137.37, 131.75, 129.30, 123.17, 118.94, 71.98 ($O\underline{C}H_2CH_2CH_3$), 22.26 ($OCH_2\underline{C}H_2CH_3$), 10.64 ($OCH_2CH_2\underline{C}H_3$).

Preparation of $WOCl_3$(OPh-2-CONHBu^t) (**4a**)

This compound was synthesized in a similar fashion to the ester complex **3**. A toluene solution of *t*-butylamine (0.27 cm^3, 2.57 mmol) was added to a toluene solution of **2a** (0.4673 g, 1.04 mmol) at −78°C. The reaction was filtered to remove the by-product, *t*-butylammonium chloride. The solid salt was washed with hot toluene (2 × 10 cm^3) and the filtrate solution

concentrated *in vacuo*. The solution was warmed to 60°C and allowed it to stand, yielding deep red block crystals. The poor yield may be due to association of the product with the *t*-butylammonium chloride. This hypothesis was corroborated by the fact that the precipitate yielded bright red solution upon cleaning the filter frit with acetone. Yield: 11% (0.0580 g, 0.012 mmol). NMR data (300 MHz): ^{1}H: δ 7.73 (H, t), 7.64 (H, d), 7.26 (H, t) 6.98 (H, bs, -CONH(CH$_3$)$_3$), 1.60 [9H, s, -CONH(CH$_3$)$_3$].

Preparation of $WOCl_3(OPh\text{-}2\text{-}CONH_2)$ **(4b)**

$WOCl_4$ (2.1900 g, 6.41 mmol) was weighed into a 50 cm^3 Schlenk flask with a magnetic stirbar. Dichloromethane (30 cm^3) was added via cannula, followed by solid salicylamide (0.8795 g, 6.41 mmol) from an addition tube. Upon addition of the salicylamide, a deep reddish-purple color developed and as the reaction proceeded, microcrystals of the same color began to precipitate. The mixture was stirred for eight hours, then the solid microcrystalline product was harvested by filtration (2.465 g 5.57 mmol). The supernatant solution volume was reduced and cooled to −20°C, yielding X-ray quality crystals (0.213 g, 0.48 mmol). Yield: 94% (2.678 g [total], 6.05 mol). NMR data: ^{1}H (300 MHz): δ 7.85 (H, t), 7.75 (H, d), 7.35 (H, t), 7.24 (H, d), 7.03 (H, broad s, CONH), 6.61 (H, broad s, CONH). The complex was not soluble enough in $CDCl_3$ to obtain a ^{13}C NMR spectrum. Anal. $C_7H_6O_3NWCl_3$. Calc.: 19.01% H, 3.17% N. Found: 19.24% C; 1.29% H, 3.22% N.

Preparation of $WOCl_3(OPh\text{-}2\text{-}NO_2)$ **(5a)**

A 50 cm^3 Schlenk flask was charged with $WOCl_4$ (1.3650 g, 4.00 mmol), a magnetic stirbar, and dichloromethane (30 cm^3). Solid 2-nitrophenol (0.5593 g, 4.02 mmol) was added by addition tube and the solution immediately changed to a deep red color. The mixture was stirred for 6 h, then filtered through Celite. The volume was reduced to 5 cm^3 and allowed to stand, producing blood red blocks. The liquid was decanted and the material dried for 6 h at room temperature (10^{-6} torr). The material appeared glassy rather than microcrystalline. Yield: 75% (1.3270 g, 2.99 mmol). NMR data: ^{1}H (300 MHz): δ 8.40 (H, dd, 6-H), 7.97 (H, dt, 5-H), 7.45 (H, dt, 4-H), 7.29 (H, d, 3-H). ^{13}C: δ 211.08 (C-NO$_2$), 195.24, 194.56 (O—C$_{ipso}$), 185.37, 183.52, 180.78. Anal. calcd for $C_6H_4O_4NWCl_3$. Calc.: 16.22% C; 0.91% H; 3.15% N. Found: 16.16% C; 0.68% H; 3.07% N.

Preparation of $W(=NC_6H_3\text{-}2,6\text{-}Me_2)Cl_3(OPh\text{-}2\text{-}NO_2)$ **(5b)**

This synthesis was carried out in a manner similar to that of **5a**. The filtrate was concentrated to 20 cm^3 and warmed to 40°C. Thin brown parallel-piped shaped crystals formed after standing overnight at room temperature. Two crops of these crystals yielded only small amounts of material (0.129 g, 0.23 mmol). The supernate was cooled to −20°C to produce more crystals which had a different morphology from the first crops. This material was block shaped and the blocks were clumped together. Both sets of crystals have identical ^{1}H and ^{13}C NMR spectra. Yield: 70% (0.727 g [total], 1.33 mmol). NMR data: ^{1}H (300 MHz): δ 8.32 (H, dd, 6-H), 7.86 (H, dt, 5-H), 7.30 (3H, mult, 4-H of OPh-2-NO$_2$ and *m*-H's of imido), 7.14 (H, d, 3-H), 6.72 (H, t, *p*-H of imido), 3.20 (6H, s, NC$_6$H$_3$-2,6-(CH$_3$)$_2$). ^{13}C: δ 157.05, 149.76, 144.43, 139.46, 136.27, 133.11, 126.96, 126.48, 125.84, 124.13, 18.01 (NC$_6$H$_3$-2,6-(CH$_3$)$_2$). Analytical Data for $C_{14}H_{13}O_3N_2WCl_3$. Calc.: 30.71% C; 2.39% H; 5.12% N. Found: 30.40% C; 2.21% H; 4.98% N.

Preparation of $W(\eta^2\text{-}Ph_2C_2)Cl_3(OPh\text{-}2\text{-}NO_2)$ **(5c)**

This synthesis was carried out in a manner similar to that of **5a**. The filtrate was concentrated to 5 cm^3 and layered with 7 cm^3 hexane. After standing at room temperature for 3 days, shiny, red–orange, X-ray quality needles were harvested by decanting the supernate solution. Yield: 87% (0.872 g, 1.44 mmol). NMR data: ^{1}H (300 MHz): δ 8.36 (H, dd, 6-H of OPh-2-NO$_2$), 8.17 (4H, dd, *o*-H's of Ph's), 7.79 (5H, t, *m*-H's of Ph's overlapped with 5-H of OPh-2-NO$_2$), 7.65 (2H, t, *p*-H's of Ph's), 7.33 (H, t, 4-H), 7.01 (H, d, 3-H). ^{13}C: δ 252.22 (Ph$_2$C$_2$), 158.52, 139.81, 138.14, 135.05, 134.79, 134.41, 129.51, 127.36, 125.35, 124.30. Anal. calcd for $C_{20}H_{13}O_3NWCl_3$. Calc.: 39.60% C; 2.33% H; 2.31% N. Found: 39.71% C; 2.07% H, 2.26% N.

Crystallographic structure determinations

Crystal, data collection, and refinement parameters are given in Table 3. Suitable crystals for single-crystal X-ray diffraction were sectioned and mounted in a thin-walled capillary flushed with nitrogen. The unit-cell parameters were obtained by the least-squares refinement of the angular settings of 24 reflections ($20 \leqslant 2\theta \leqslant 25$) for all structures except **2a** ($48 < 2\theta < 50$).

The systematic absences in the diffraction data are uniquely consistent with $P2_1/n$ for **2a** and **4b** while **5c** was assigned to *Pccn*. The unit-cell parameters, photographic data, systematic absences and occurrences of equivalent reflections in **2c** are consistent with rhombohedral space groups without *c*-glide absences. The *E*-statistics and the chemical composition suggested the space group, $R\bar{3}$, and this solution gave chemically reasonable and computationally stable results during refinement.

The structures were solved by direct methods, completed by subsequent difference Fourier syntheses and refined by full-matrix least-squares procedures. Semi-

Table 3. Summary of X-ray diffraction data for crystallographically characterized compounds

Compound	**2a**	**2c**	**4b**	**5c**
Empirical formula	$C_7H_4Cl_4O_3W$	$C_{21}H_{14}Cl_4O_2W$	$C_7H_6Cl_3NO_3W$	$C_{20.50}H_{15}Cl_4NO_3W$
Formula weight	461.77	623.97	458.30	648.98
Crystal color, habit	Deep red prism	Deep red block	Dark red block	Red thin plate

γ ( )	—	120	—	—

[a] Quantity minimized = $\Sigma\Delta^2$; $R = \Sigma\Delta/\Sigma(F_o)$; $R(w) = \Sigma\Delta w^{1/2}/\Sigma(F_o \cdot w^{1/2})$, $\Delta = |(F_o - F_c)|$.
[b] Quantity minimized = $R(wF^2) = \Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[(wF_o^2)^2]^{1/2}$; $R = \Sigma\Delta/\Sigma(F_o))$, $\Delta = |(F_o - F_c)|$.
[c] $R(wF^2)$, %.

empirical ellipsoid absorption corrections were applied to **2c** and **4b**, and a semi-empirical lamina absorption correction was applied to **5c**; all data with a glancing angle of $\leqslant 3^\circ$ to the prominent face [0 0 1] were rejected, affecting 163 reflections. One-half of a molecule of dichloromethane was located on a two-fold axis in **5c**. All non-hydrogen atoms were refined with anisotropic displacement parameters and all hydrogen atoms were treated as idealized contributions. Several of the remaining peaks from the difference map (1.06 to 1.46 e/Å^3 for **2c**, and 1.01 to 2.56 e/Å^3 for **4b**) were in chemically unreasonable positions (i.e. positions near the heavy atoms: 1.15 Å from W and 1.64 Å from Cl for **2c** and 0.86 to 1.58 Å from W for **4b**) and were considered noise. The structure of **2a** was solved using TeXsan software and Cromer and Waber's neutral atom scattering factors [31]. All software and sources of the scattering factors for **2c**, **4b**, and **5c** are contained in either SHELXTL version 4.2 or the SHELXTL version 5.03 program libraries (G. Sheldrick, Siemens XRD, Madison, WI).

CONCLUSIONS

A wide variety of weakly-coordinated functional groups can be used to satisfy the coordination sphere of the $W(X)Cl_3(OR)$ fragment. The electrophilic acid chloride complexes, $W(X)Cl_3(OPh\text{-}2\text{-}COCl)$, may have synthetic utility for the metallation of alcohols, amines, and nucleophilic metal complexes. Both $W(\eta^2\text{-}C_2Ph_2)Cl_3(OPh\text{-}2\text{-}COCl)$ and $WOCl_3(OPh\text{-}2\text{-}CONH_2)$ produce interesting lattice structures. $W(\eta^2\text{-}C_2Ph_2)Cl_3(OPh\text{-}2\text{-}COCl)$ arranges in a three-fold symmetric space group through weak intermolecular contacts involving the aryl subunits of the diphenyl acetylene and salicoyl chloride ligands. These contacts generate a star-shaped void whose internal diameter is 5–6 Å. This is a very unusual feature in non-covalently bonded solids. $WOCl_3(OPh\text{-}2\text{-}CONH_2)$ forms an infinite one-dimensional hydrogen bonded herringbone in the solid phase.

Crystal and molecular structure of $[Li_3(\mu_2\text{-}OAr)_3]$ (OAr = 2,6-diphenyl-3,5-di-tert-butylphenoxide); a cluster containing short Li—O distances†

Jonathan S. Vilardo, Phillip E. Fanwick and Ian P. Rothwell*

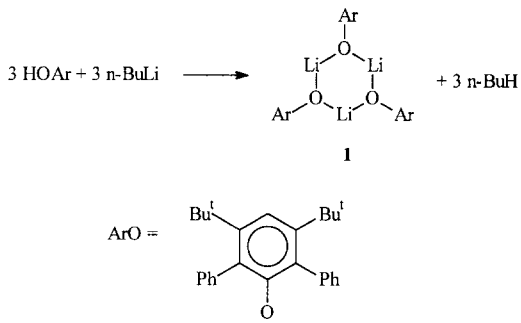
Department of Chemistry, 1393 Brown Building, Purdue University, West Lafayette, IN 47907-1393, U.S.A.

(Received 23 April 1997; accepted 17 July 1997)

Abstract—Reaction of 2,6-diphenyl-3,5-di-*tert*-butylphenol (HOAr) with one equivalent of *n*-BuLi in toluene generates the hydrocarbon soluble cluster $[Li_3(\mu_2\text{-}OAr)_3]$ **1**. The molecular structure of **1** consists of a six-membered ring (crystallographically imposed C_3 axis) of Li and O(aryloxide) atoms with alternating Li—O distances of 1.78(1) and 1.840(7) Å. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: crystal structure; molecular structure; $Li_3(\mu_2\text{-}OAr)_3$.

The structural chemistry of Group 1 metal compounds continues to attract considerable research attention [1]. This interest stems not only from the diverse structures adopted by these compounds but also by the recognition that the degree of aggregation of lithium reagents can strongly influence their reactivity [2]. In the case of lithium aryloxides the degree of oligomerization is sensitive to the steric nature of the phenoxide nucleus as well as the presence of Lewis bases. In the presence of THF the parent lithium phenoxide has been shown to adopt a hexameric structure $[(\mu_3\text{-}PhO)Li(THF)]_6$ in both the solid state (hexagonal prismatic) and solution (^{7}Li NMR) [3]. In contrast the lithium 2,6-di-*tert*-butylphenoxide forms the dinuclear $[Li(\mu_2\text{-}OC_6H_3Bu^t_2\text{-}2,6)(THF)]_2$ [4]. We have recently begun to investigate the transition metal chemistry of 3,5-disubstituted-2,6-diphenylphenoxides [5]. The presence of the *meta*-substituents severely reduces the tendency to undergo cyclometallation of the *ortho*-phenyl rings. In the case of 2,6-diphenyl-3,5-di-*tert*-butylphenoxide (the phenol first being synthesized by Barton *et al.* [6]) the bulky meta substituents render the ligand metallation



1

'immune' [5]. Furthermore they force the phenyl rings to adopt a conformation essentially perpendicular to the central phenoxide ring leading to a bulkier phenoxide ligand. In this note we report on the structure of the lithium derivative of this bulky phenol.

RESULTS AND DISCUSSION

The addition of a hexane solution of *n*-butyl lithium to a benzene solution of 2,6-diphenyl-3,5-di-*tert*-butylphenol (HOAr) [6] leads to a solution from which the lithium aryloxide **1** can be obtained as white crystals upon cooling a saturated toluene solution.

† Dedicated to Professor Don Bradley in recognition of his seminal contributions to metal alkoxide chemistry.

* Author to whom correspondence should be addressed.

The ^{1}H NMR spectrum of **1** in C_6D_6 shows a single set of aryloxide proton resonances. The molecular structure of **1** determined by X-ray diffraction is shown in Fig. 1. The molecule adopts a trinuclear structure with a crystallographically imposed three-fold rotation axis making the three lithium atoms and aryloxide ligands equivalent. The lithium atoms in **1** are formally two coordinate with C(22) and C(21) of the *ortho*-phenyl rings at distances of 2.478(8) and 2.689(8) Å. The presence of lithium bonds to unsaturated and saturated carbon fragments is an important characteristic of many lithium aggregates that typically do not contain Lewis bases [2c]. There is a distinct asymmetry to the aryloxide bridges in **1** as shown by the Li—O distances of 1.775(7), 1840(8) Å and Li—O—C angles of 113.8(3), 134.9(3)°. The short Li—O distance represents the shortest value for this parameter for a phenoxide bound to lithium.

In Table 1 are listed the molecular structures and Li-O(aryloxide) distances for lithium phenoxides contained in the Cambridge Crystallographic Database [3,4,7–18]. It can be seen that the two previously characterized trinuclear structures both contain 4-coordinate lithium atoms with the metal being chelated by the nitrogen atoms of amine or imine functionalities contained in the ortho positions of the phenoxide. The closest structural analogues to **1** are in fact the trimeric lithium amido compounds $[Li\{N(SiMe_3)_2\}]_3$ [19] and $[Li\{N(CH_2Ph)_2\}]_3$ [20] which contain a six membered ring of alternating Li and N(amido) atoms.

EXPERIMENTAL

All operations were carried out under a dry nitrogen atmosphere in a vacuum atmospheres Dri-Lab or by standard Schlenk Techniques. The hydrocarbon solvents were distilled from sodium benzophenone and stored under nitrogen until needed. 2,6-diphenyl-3,5-di-*tert*-butylphenol was made by a previous reported method [6] ^{1}H NMR spectra were recorded on a Varian Associates Gemini-200 spectrometer and referenced to protio impurities of commercial C_6D_6. The

'1,3-Dimetallabenzene' derivatives of niobium and tantalum

Patrick N. Riley, Robert D. Profilet, Michelle M. Salberg, Phillip E. Fanwick and Ian P. Rothwell*

Department of Chemistry, 1393 Brown Building, Purdue University, West Lafayette, IN 47907-1393, U.S.A.

(Received 23 April 1997; accepted 17 July 1997)

Abstract—The alkylidyne bridged compounds $[(cb)_2M(\mu\text{-}CSiMe_3)_2M(cb)_2]$ (**1a**, M = Nb; **1b**, M = Ta; cb = carbazole) react thermally with one equivalent of alkynes EtC≡CEt and $Me_3SiC{\equiv}CH$ to produce new organometallic derivatives **2** and **3**, respectively. The molecular structures of **2** and **3** are shown to consist of non-planar six-membered di-metallacycles originating from insertion of an alkyne unit into one of the alkylidyne bridges of **1**. Treatment of **1b** with 3,5-di-*tert*-butyl-2,6-diphenylphenol (ArOH) leads to the monophenoxide $[(ArO)(cb)Ta(\mu\text{-}CSiMe_3)_2Ta(cb)_2]$ **4**. Treatment of **4** with $Me_3SiC{\equiv}CH$ leads to the corresponding metallacycle $[(ArO)(cb)Ta(\mu\text{-}CSiMe_3)\{\mu\text{-}C(SiMe_3)CHC(SiMe_3)\}Ta(cb)_2]$ **5**. Structural parameters for **2b**, **3a**, **3b** and **5** obtained by X-ray diffraction show delocalization is present with four equivalent M—C and two equivalent C—C distances. The non-planar structure is best described as a twist of the planar [M(μ-C)—M] and [C—C—C] units within the ring. The non-planar structure of **2a** and **2b** is maintained in solution as evidenced by diastereotopic methylene protons for the CH_2CH_3 substituents. At elevated temperatures coalescence to a simple A_2B_3 pattern is observed. From the coalescence temperatures of 328 K for **2b** an activation barrier of 16.1(5) kcal mol^{-1} can be estimated for the adoption of a planar structure. The insertion of $Me_3SiC{\equiv}CH$ produces a 2,4,6-substitution pattern for **3a**, **3b** and **5** with the 5-H (*beta* to two metal centers) being downfield shifted to δ 8.43 (**3a**), 8.64 (**3b**) and 9.03 ppm (**5**). © 1998 Elsevier Science Ltd. All rights reserved

Keywords: niobium; tantalum; alkylidyne bridged compounds.

Metallacyclic compounds of the transition metals are an important class of organometallic species [1]. This is particularly the case where such compounds represent intermediates in catalytic cycles [2]. In a number of cases metallacyclic compounds exhibit properties that are derived directly from their cyclic nature. One important subset of such molecules are those deemed to possess aromatic character [3]. The work of Bleeke *et al.* has led to the generation of iridacycles whose structure and reactivity make a compelling case for being considered iridabenzenes [3]. During our investigation of the Group 5 metal chemistry of carbazole ligands we have isolated a series of dimetallacyclic compounds and in this paper we discuss the structure and reactivity of these molecules that can potentially be considered '1,3-dimetallabenzenes' [4].

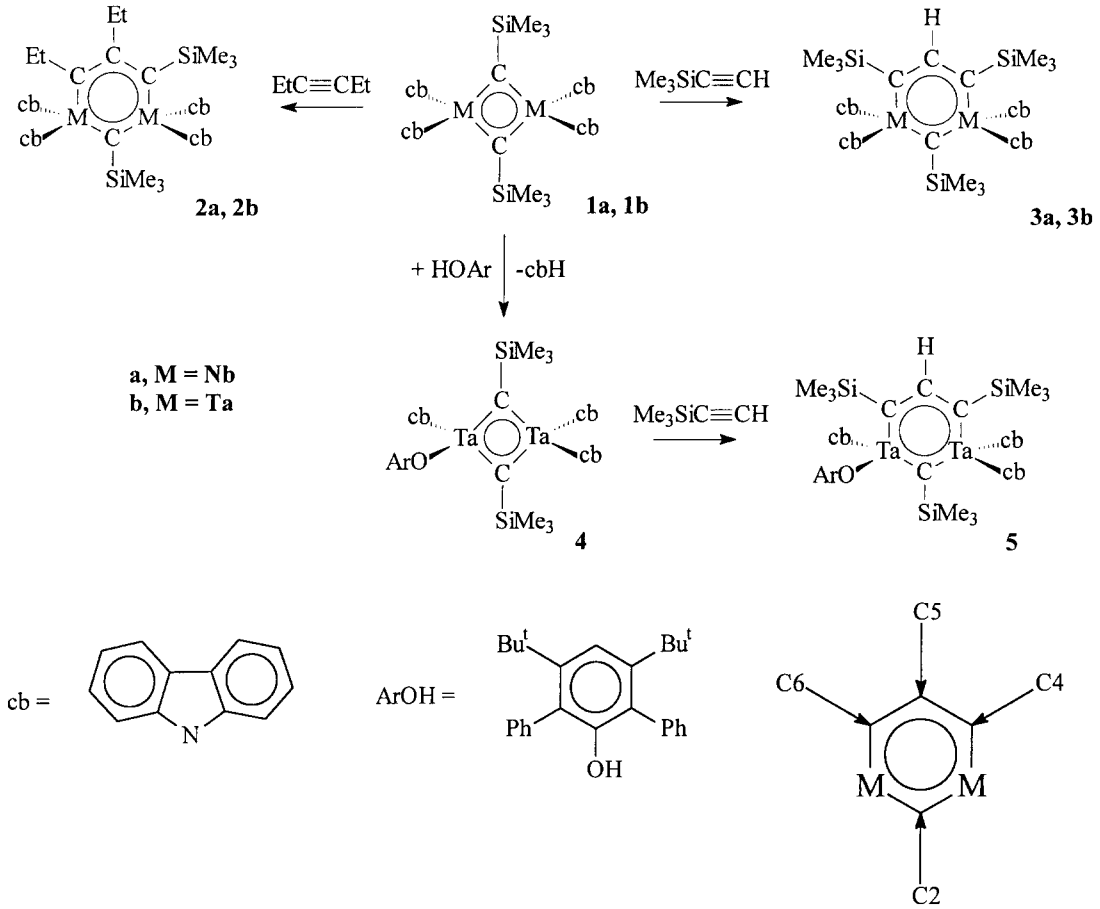
RESULTS AND DISCUSSION

Synthesis of compounds

The alkylidyne bridged compounds $[(cb)_2M(\mu\text{-}CSiMe_3)_2M(cb)_2]$ (**1a**, M = Nb; M = Ta, **1b**; cb = carbazole) [5] are only sparingly soluble in cold hydrocarbon solvents yielding blue and red solutions, respectively. When C_6D_6 solutions of **1** and excess 3-hexyne or $Me_3SiC{\equiv}CH$ are heated at 100°C a slow (monitored by ^1H NMR) conversion to much more soluble organometallic derivatives takes place. The resulting products have been characterized as arising from insertion of 1 equiv. of alkyne into a single alkylidyne bridge (Scheme 1). The new compounds **2** and

* Author to whom correspondence should be addressed.

† Dedicated to Professor Don Bradley in recognition of his seminal contributions to metal amide chemistry.



Scheme 1.

3 can be obtained crystalline from toluene or benzene solutions layered with hexane.

Attempts to obtain analogous compounds starting with the previously reported compound $[(Ph_2\text{-}2,6\text{-}C_6H_3O)_2Ta(\mu\text{-}CSiMe_3)_2Ta(OC_6H_3Ph_2\text{-}2,6)_2]$ [6] failed. The dark green tetra-phenoxide did not react with $Me_3SiC{\equiv}CH$ in C_6D_6 solution when heated at 100°C for days. The addition of the bulky, metallation immune phenol 3,5-di-*tert*-butyl-2,6-diphenylphenol (HOAr) [7,8] to benzene solutions of **1b** was found to lead to the clean formation of a soluble, monophenoxide $[(ArO)(cb)Ta(\mu\text{-}CSiMe_3)_2Ta(cb)_2]$ **4** and 1 equiv. of carbazole. This compound does react with one equivalent of $Me_3SiC{\equiv}CH$ to produce the corresponding dimetallacycle $[(ArO)(cb)Ta(\mu\text{-}CSiMe_3)\{\mu\text{-}C(SiMe_3)CHC(SiMe_3)\}Ta(cb)_2]$ **5**.

Solid state structures

The derivatives **2b, 3a, 3b** and **5** have been subjected to single crystal X-ray diffraction analysis. The molecular structures of **2b** and **3a** are shown in Figs 1 and 2. The tantalum complex **3b** (benzene solvate) is isomorphous and isostructural with **3a** (toluene solvate) and selected structural parameters are given in Tables 1 and 2. The molecular structure of **5** is shown in Fig. 3 with structural parameters contained in Table 3. The most noticeable feature of the molecular structures is the non-planarity of the six-membered ring. This distortion is most succinctly defined by the angle θ between the two planes defined by the [MCM] and [CCC] atoms within the six-membered ring. The carbon fragment and the atoms directly bound to it form a planar unit. The substituent to the carbon atom C(2) (Scheme 1) is also in the same plane as the [MC(2)M] unit. For the four molecules structurally characterized the value of θ lies in the narrow range 52–57 . The structures of **2b, 3** and **5** contrasts with that observed for the di-tungsten compound $[(Pr^iO)_2W(\mu\text{-}CSiMe_3)\{\mu\text{-}C(SiMe_3)CHC(SiMe_3)\}W(OPr^i)_2]$ **6** reported and analyzed a number of years ago by Chisholm and Heppert [9]. In d^1–d^1 **6** a much more severe distortion was observed leading to a structure best described as containing a dimetallated allyl ligand. Inspection of the interatomic distances for **2b, 3** and **5** (Fig. 4, Tables 1–3) show that the twisting does

bring C(4) to within 2.5–2.7 Å of the second metal center. This distance is, however, much longer than typically found for alkyl groups bound to Nb, Ta and also exceeds the distance to π-bound carbon groups such as η^6-arene ligands attached to these metal centers [10]. We, therefore, conclude that this is a non-bonding contact. Within the six-membered ring there is little structural evidence for localization of the bonding. The M—C(2) distances scan the narrow range of 1.975(9)–2.04(2) Å, negligibly longer than those found for the alkylidyne bridges in the 1,3-dimetallacyclobutadiene substrates **1a** and **1b**, 1.948(4)–1.971(3) Å. The M—C(4) and M—C(6) distances are comparable to each other in all four structures, 2.03(1)–2.11(2) Å, and only slightly longer than these distances. The C(4)—C(5) and C(5)—C(6) distances of 1.40(3)–1.48(3) Å are slightly longer than the value of 1.39 Å typically quoted for benzene [11].

The M—N distances to the carbazole ligands are 2.02(1)–2.08(2) Å, indistinguishable from values of 2.021(4)–2.065(2) Å found in **1a, 1b** [5]. Similarly, the orientation of the wedge shaped carbazole ligands is very similar to that observed in **1a, 1b** and a series of isocyanide derivatives [5]. The presence of the aryloxide ligand in **5** does not appear to dramatically affect the bonding of the adjoining carbazole ligand.

Solution structure and fluxionality

The ^{1}H NMR spectra of the 3-hexyne derivatives **2a** and **2b** are highly informative. The non-equivalent ethyl groups lead to two resolvable sets of multiplets. The non-planar structure yields a well-resolved ABX_3 pattern for one of the CH_2CH_3 groups while the other group [presumably attached to C(5)] is close to an A_2X_3 pattern. The presence of diastereotopic methylene protons for the C(6)-ethyl substituent confirms a non-planar structure is maintained in solution. As the temperature of a sample of **2b** in toluene-d_8 is raised, the diastereotopic methylene protons broaden and eventually coalescence at 55°C. From the coalescence temperature an activation barrier of 16.1(5) Kcal mol^{-1} is estimated. This barrier represents the energy loss on forming a planar structure for **2b**; i.e. the barrier to interconversion of the two enantiomers of **2b**.

The most interesting feature of the ^{1}H NMR of the 2,4,6-tris(trimethysilyl) derivative **3** and **5** is the chemical shift of the resonance for the proton C(5)—*H*. This appears as a singlet at δ 8.43, 8.64 and 9.03 ppm for **3a, 3b** and **5**, respectively. This particular proton is β-to two metal centers which may account for its low field position. These chemical shifts do compare with a value of δ 8.48 ppm for the β-proton in the vinyl ligand in $[Ta(OC_6H_3Bu^t\text{-}CMe_2CH_2)(OC_6H_3Bu^t_2\text{-}2,6)(Cl)(CH{=}CHPh)]$, [12] implying that there may be little ring current present in these compounds.

sphere Dri-Lab or by standard Schlenk techniques. Hydrocarbon solvents were dried by distillation from sodium/benzophenone and stored under dry nitrogen. Trimethylsilylacetylene and 3-hexyne were purchased from Aldrich Chemical Company and dried over molecular sieves prior to use. The ligand 2,6-diphenol-3,5-di-*tert*-butylphenol was prepared according to a literature procedure [7]. The compounds $[(cb)_2M(\mu\text{-}CSiMe_3)_2M(cb)_2]$ (**1a**, M = Nb; **1b**, M = Ta) were obtained by previously published procedures [5]. The ^1H and ^{13}C NMR spectra were recorded on Varian Associates Gemini 200 and General Electric QE-300 spectrometers. Microanalyses were performed in-house at Purdue University.

Preparation of $[(cb)_2Nb(\mu\text{-}CSiMe_3)\{\mu\text{-}C(Et)C(Et)C(SiMe_3)\}Nb(cb)_2$ **2a**

To a toluene (20 cm^3) solution of $[(cb)_2Nb(\mu\text{-}CSiMe_3)_2Nb(cb)_2]$ **1a** (0.40 g, 0.40 mmol) was added 1 equiv. of 3-hexyne (0.03 g, 0.40 mmol). The solution was heated at 110°C for 72 h. The resulting solution was filtered and the filtrate dried *in vacuo* to leave a

dark red solid. This solid was washed with hexane and dried *in vacuo*. The residue was recrystallized from a concentrated solution of toluene layered with hexane. Yield = 0.16 g (0.15 mmol, 38%). ^{1}H NMR (C_6D_6, 30°C): δ −0.77 (s, SiMe_3); 0.33 (s, Nb_2CSiMe_3); 0.13, 0.81 (t, CH_2CH_3); 1.56, 2.32 (br, CH_2CH_3). ^{13}C NMR (C_6D_6, 30°C): δ 1.3 (SiMe_3); 5.6 (Nb_2CSiMe_3).

Preparation of [(cb)$_2$Ta(μ-CSiMe$_3$){μ-C(Et)C(Et)C(SiMe$_3$)}Ta(cb)$_2$] **2b**

To a toluene (20 cm^3) solution of [(cb)$_2$Ta(μ-CSiMe$_3$)$_2$Ta(cb)$_2$] **1b** (0.50 g, 0.42 mmol) was added 1 equiv. of 3-hexyne (0.04 g, 0.42 mmol). The solution was heated at 110°C for 72 h. The resulting solution was filtered and the filtrate dried *in vacuo* to leave a dark red solid. This solid was washed with hexane and dried *in vacuo*. The residue was recrystallized from a concentrated solution of toluene layered with hexane. Yield = 0.30 g (0.23 mmol, 55%). Anal. calcd for $Ta_2C_{62}H_{60}N_4Si_2$: C, 58.21; H, 4.73; N, 4.38. Found: C, 57.91; H, 4.77; N, 4.22. ^{1}H NMR (C_6D_6, 30°C): δ −0.75 (s, SiMe_3); 0.34 (s, Ta_2CSiMe_3); 0.21, 0.84 (t, CH_2CH_3); 1.85, 2.40, 2.68 (br, CH_2CH_3); 6.59 (t, cb *meta-H*); 8.71 (d, cb *ortho-H*). ^{13}C NMR (C_6D_6, 30°C): δ 1.4 (SiMe_3); 6.7 (Ta_2CSiMe_3); 16.0 (CH_2CH_3); 27.2, 27.7 (CH_2CH_3); 253.9 (C*C*SiMe$_3$); 257.3 (C*C*Et); 393.0 (Ta$_2$-μ—*C*SiMe$_3$).

Preparation of [(cb)$_2$Nb(μ-CSiMe$_3$){μ-C(SiMe$_3$)CHC(SiMe$_3$)}Nb(cb)$_2$] **3a**

To a toluene (15 cm^3) solution of [(cb)$_2$Nb(μ-CSiMe$_3$)$_2$Nb(cb)$_2$] **1a** (0.25 g, 0.24 mmol) was added an excess of Me$_3$SiC≡CH (0.12 g, 1.22 mmol). The solution was heated at 110°C for 20 h. The resulting solution was filtered and the filtrate dried *in vacuo* to leave a dark red solid. This solid was washed with hexane and dried *in vacuo*. The residue was recrystallized from a concentrated solution of toluene layered with hexane. Yield = 0.04 g (0.04 mmol, 15%). ^{1}H NMR (C_6D_6, 30°C): δ −0.70 (s, SiMe_3); 0.07 (s, Nb_2CSiMe_3); 8.43 (s, C(5)-*H*); 8.60 (d, cb *ortho-H*). ^{13}C NMR (C_6D_6, 30°C): δ 0.10 (SiMe_3); 5.8 (Nb_2-μ-CSiMe_3); 267.9 (Nb*C*SiMe_3).

Preparation of [(cb)$_2$Ta(μ-CSiMe$_3$){μ-C(SiMe$_3$)CHC(SiMe$_3$)}Ta(cb)$_2$] **3b**

To a toluene (15 cm^3) solution of [(cb)$_2$Ta(μ-CSiMe$_3$)$_2$Ta(cb)$_2$] (0.10 g, 0.08 mmol) was added as excess of Me$_3$SiC≡CH (0.15 g, 1.83 mmol). The solution was heated at 110°C for 18 h. The resulting solution was filtered and the filtrate dried *in vacuo* to leave a dark red solid. This solid was washed with hexane and dried *in vacuo*. The residue was recrystallized from a concentrated solution of toluene layered with hexane. Yield = 0.02 g (0.02 mmol, 20%). Anal. calcd for $Ta_2C_{61}H_{60}N_4Si_3 \cdot C_7H_8$: C, 58.87; H, 4.94; N, 4.04. Found: C, 58.13; H, 5.03; N, 4.00. Crystals suitable for X-ray diffraction were obtained from a benzene solution layered with hexane. ^{1}H NMR (C_6D_6, 30°C): δ −0.63 (s, SiMe_3); 0.14 (s, Ta_2CSiMe_3); 8.64 (s, C(5)-*H*); 8.73 (d, cb *ortho-H*). ^{13}C NMR (C_6D_6, 30°C): δ −0.30 (SiMe_3); 5.6 (Ta_2-μ-CSiMe_3); 255.0 (Ta*C*SiMe$_3$); 386.5 (Ta_2-μ-*C*SiMe$_3$).

Preparation of [(ArO)(cb)Ta(μ-CSiMe$_3$)$_2$Ta(cb)$_2$], **4**

To a toluene (15 cm^3) solution of [(cb)$_2$Ta(μ-CSiMe$_3$)$_2$Ta(cb)$_2$] **1b** (0.50 g, 0.42 mmol) was added 2.2 equiv. of 2,6-diphenol-3,5-di-*tert*-butylphenol (0.33 g, 0.92 mmol). The solution was heated at 100°C for 6 d, then allowed to cool slowly during which time a yellowish-brown solid precipitated from solution. The solid was washed with hexane and dried *in vacuo*. Yield = 0.11 g (19%). Anal. calcd for $Ta_2C_{70}H_{71}N_3Si_2O$: C, 60.56; H, 5.15; N, 303. Found: 63.78; H, 5.06; N, 3.99. ^{1}H NMR (C_6D_6, 30°C): δ −0.18 (s, Ta_2CSiMe_3); 1.19 (s, C*C*Me$_3$). ^{13}C NMR (C_6D_6, 30°C): δ 5.32 (s, Ta$_2$-μ—CSiMe_3); 33.1 (CMe_3); 37.6 (*C*Me$_3$); 398.5 (Ta$_2$-μ-*C*SiMe$_3$).

Preparation of [(ArO)(cb)Ta(μ-CSiMe$_3$){μ-C(SiMe$_3$)CHC(SiMe$_3$)}Ta(cb)$_2$], **5**

To a C_6D_6 solution of [(OAr)(cb)Ta(μ-CSiMe$_3$)$_2$Ta(cb)$_2$] **4** (0.05 g, 0.04 mmol) was added one equiv. of Me$_3$SiC≡CH (0.004 g, 0.04 mmol). The solution was heated at 100°C for 96 h. The orange solution was filtered then layered with hexane producing yellow crystals of product which were washed with hexane and dried *in vacuo*. ^{1}H NMR (C_6D_6, 30°C): δ −0.79, −0.35 (s, SiMe_3); 0.53 (s, Ta_2CSiMe_3); 1.02, 1.12 (s, CCMe_3); 9.03 (s, C(5)-*H*). ^{13}C NMR (C_6D_6, 30°C): δ 0.45, 0.85 (SiMe_3); 7.77 (Ta$_2$-μ—CSiMe_3); 33.0, 33.6 (CCMe_3); 239.2 (Ta*C*SiMe$_3$); 361.1 (Ta$_2$-μ—*C*SiMe$_3$).

Crystallographic studies— Crystal data, data collection and experimental details of the crystallographic study are contained in the supplementary material.

Preparation of volatile molecular lithium–niobium alkoxides. Crystal structures of $[Nb(\mu\text{-}OCH_2SiMe_3)(OCH_2SiMe_3)_4]_2$ and $[LiNb(\mu_3\text{-}OCH_2SiMe_3)\text{-}(\mu_2\text{-}OCH_2SiMe_3)_2(OCH_2SiMe_3)_3]_2$†

(Received 29 May 1997; accepted 9 July 1997)

Abstract—New heterometallic alkoxides $[LiNb(OCH_2CMe_3)_6]_2$ (**4**), $LiNb(OCH_2CMe_3)_6(Me_3CCH_2OH)_2$ (**5**), and $[LiNb(OCH_2SiMe_3)_6]_2$ (**6**) have been prepared from the corresponding homometallic alkoxides. All are moderately soluble in hydrocarbons and sublime in moderate to good recoveries. The structure of **6** determined crystallographically contains an $Nb_2Li_2(\mu\text{-}O)_4(\mu_3\text{-}O)_2$ central-core geometry. Compound **4** appears to be isostructural on the basis of ^1H NMR data. Bulk pyrolysis of **4** gives crystalline $LiNbO_3$ under N_2 at 600°C. However, $LiNbO_3$ films are not obtained from **4** by spray MOCVD under conditions that give $LiNbO_3$ films from $[LiNb(OEt)_6]_x$. Crystallographic structure determination for the precursor compound $[Nb(\mu\text{-}OCH_2SiMe_3)(OCH_2SiMe_3)_4]_2$ (**3**) reveals an edge-shared bioctahedral geometry in which the μ-O atoms are distinctly pyramidal. This structure is maintained in solution; the pyramidal bridge configurations allow coexistence of syn and anti dimeric isomers. Precursor **3** also exhibits a dimer-monomer equilibrium for which $\Delta H = 63(3)$ kJ/mol and $\Delta S = 180(10)$ J/(K mol). © 1998 Elsevier Science Ltd. All rights reserved

Keywords: preparation; volatile; double alkoxide; crystal structure; dynamic behavior; precursor.

Herein we report the first *molecular* lithium–niobium (double) alkoxides of empirical formula $LiNb(OR)_6$. Unlike known *nonmolecular* lithium–niobium alkoxides [1,2], the new compounds are soluble in hydrocarbon solvents and sublime intact (*in vacuo*). On the basis of these characteristics, the new $LiNb(OR)_6$ derivatives may be useful lithium niobate ($LiNbO_3$) precursors [3].

Bradley and others have established the utility of alkoxide precursors to oxide materials by sol–gel processing (SGP) and metallo–organic chemical vapor deposition (MOCVD) [3–6]. Problems are often encountered with heterometallic alkoxides such as those from the $LiNb(OR)_6$ family. Although the known $LiNb(OR)_6$ compounds (R = Me, Et, *i*-Pr, *t*-Bu) [1] are sufficiently soluble in their respective parent alcohols for SGP of $LiNbO_3$ films, they dissociate to LiOR and $Nb(OR)_5$ upon volatilization, precluding $LiNbO_3$ growth by standard MOCVD [1,3].

The poor volatiles and hydrocarbon solubilities of $LiNb(OR)_6$ compounds are likely due to nonmolecular solid-state structures. $[LiNb(OEt)_6]_x$ is a helical polymer in the solid state, in which polymerization is achieved through μ-alkoxide bridges [2]. To our knowledge no other $[LiNb(OR)_6]_x$ compound has been structurally characterized (until now); however, the others likely exhibit related nonmolecular structures with extensive alkoxide bridging. Nonmolecularity limits the performance of alkoxide compounds as oxide precursors [5,7].

Despite these shortcomings, Wernberg, Gysling, and Braunstein *were* able to grow epitaxial $LiNbO_3$ by *spray* MOCVD using $[LiNb(OEt)_6]_x$ [8,9]. In spray

† This paper is dedicated to Professor Donald C. Bradley in honor of his pioneering contributions to inorganic and materials chemistry, and on the occasion of his 73rd birthday.

MOCVD a precursor *solution* is misted, evaporated, and the resulting dispersed precursor is rapidly vaporized just before entry into the film-deposition zone. This precursor-introduction method allows modestly volatile precursors to be effectively employed (volatilized), here without prior dissociation of the Li and Nb components. Wernberg and Gysling obtained precursor solutions of $[LiNb(OEt)_6]_\infty$ in toluene after long stirring periods (48 h), during which depolymerization of the nonmolecular structure apparently occurred [8]. We sought to improve the solubility and volatility of $[LiNb(OR)_6]_x$ precursors to increase the convenience of the spray MOCVD process and to determine if such enhancements increase the quality of the deposited $LiNbO_3$ films. We also sought to examine the MOCVD performance of alkoxides lacking H atoms β to oxygen.

We report that the new molecular derivatives $[LiNb(OR)_6]_2$ where R = CH_2CMe_3 and CH_2SiMe_3 dissolve rapidly and sublime *in vacuo* in moderate recoveries. The dimeric molecular structure of $[LiNb(OCH_2SiMe_3)_6]_2$ has been determined crystallographically, and the two compounds (R = CH_2CMe_3 and CH_2SiMe_3) appear to be isostructural on the basis of solution-phase spectral data. We have also prepared an alcohol adduct of empirical formula $LiNb(OCH_2CMe_3)_6(Me_3CCH_2OH)_2$; this compound exhibits the highest sublimation recovery of the new $LiNb(OR)_6$ derivatives. Our unsuccessful efforts to use one of the compounds as an $LiNbO_3$ precursor by spray MOCVD are discussed.

In the course of the work $LiOCH_2CMe_3$, $LiOCH_2SiMe_3$, and $[Nb(OCH_2SiMe_3)_5]_2$ were isolated and fully characterized, the latter by single-crystal X-ray diffraction. We also report the dynamic NMR behavior of $Nb(OCH_2SiMe_3)_5$, which includes monomer–dimer equilibria and alkoxide–ligand site exchange.

EXPERIMENTAL

General methods

All ambient-pressure procedures were carried out under dry nitrogen using standard inert-atmosphere techniques. $LiN(SiMe_3)_2$ was prepared from $HN(SiMe_3)_2$ and *n*-BuLi in hexane by modification of a literature procedure [10], and was sublimed (90–100°C, 10^{-4} torr) before use. $Nb(O\text{-}i\text{-}Pr)_5$ was prepared by a literature procedure [11]. Niobium pentachloride ($NbCl_5$) was obtained from Strem and used as received. 2,2-Dimethylpropan-1-ol (Me_3CCH_2OH), trimethylsilylmethanol (Me_3SiCH_2OH), and NH_3(g) were obtained from Aldrich and used as received. Trimethylsilylmethanol was stored over type 4A molecular sieves before use. Hexane, benzene, and toluene were distilled from sodium benzophenone ketyl.

C, H, and N analyses were performed by Oneida Research Services, Whitesboro, NY. For total metal analyses (Li+Nb), samples were hydrolyzed with a few drops of conc. NH_3(aq) in a quartz crucible, carefully dried, ignited over a gas-burner flame, and weighed as $LiNbO_3$. NMR spectra were recorded at a field corresponding to 300 MHz for ^1H and 75 MHz for ^{13}C. All reported sublimation temperatures correspond to the oil-bath temperatures employed.

Preparation of $LiOCH_2CMe_3$ (1)

Me_3CCH_2OH (3.0 g, 34 mmol) and $LiN(SiMe_3)_2$ (5.0 g, 30 mmol) were combined in benzene (25 cm^3) at room temperature, giving an exothermic reaction. The reaction mixture was stirred for 30 min, and then benzene and other volatiles were removed under reduced pressure. The residual solid was sublimed (135–140°C, 10^{-4} torr) to yield the product as a white solid (2.30 g, 22.8 mmol, 82%). M.p.: 220–223°C. Found: C, 63.49; H, 11.75. Calc. for $C_5H_{11}OLi$: C, 63.83; H, 11.78%.

1 is soluble in hydrocarbon solvents. ^1H NMR (δ, benzene-d_6, *unsublimed* **1**): 3.82 (s, 0.1 × 2 H, OCH_2), 3.67 (s, 0.9 × 2 H, OCH_2), 1.04 (s, 0.1 × 9 H, Me) 1.00 (s, 0.9 × 9 H, *Me*). ^1H NMR (δ, benzene-d_6, *sublimed* **1**): 3.82 (s, 0.1 × 2 H, OCH_2), 3.71 (s, 0.9 × 2 H, OCH_2), 1.04 (s, 0.1 × 9 H, *Me*) 1.01 (s, 0.9 × 9 H, *Me*). $^{13}C\{^1H\}$ NMR (ppm, benzene-d_6): 77.20 (OCH_2, minor), 76.92 (OCH_2, major), 34.31 (CMe_3), 27.64 (*Me*, minor), 26.96 (*Me*, major). IR (KBr, cm^{-1}): 2951 vs, 2864 m, 2791 w, 2690 w, 2643 vw, 1478 w, 1457 w, 1957 w, 1357 m, 1250 vw, 1106 vs, 1086 s, 1020 w, 891 vw, 748 vw, 570 m, 511 w, 573 w.

Preparation of $LiOCH_2SiMe_3$ (2)

Me_3SiCH_2OH (1.30 cm^3, 1.07 g, 10.3 mmol) and $LiN(SiMe_3)_2$ (1.67 g, 10.0 mmol) were combined in benzene (10 cm^3) at room temperature, giving an exothermic reaction. The reaction mixture was stirred for 30 min, and then benzene and other volatiles were removed under reduced pressure. The residual solid was sublimed (140–145°C, 10^{-4} torr) to yield the product as a white solid (0.83 g, 7.5 mmol, 75%). M.p.: 222°C. Found: C, 43.67; H, 10.02. Calc. for $C_4H_{11}OSiLi$: C, 43.61; H, 10.06%.

2 is soluble in hydrocarbon solvents. ^1H NMR (δ, benzene-d_6): 3.74 (s, 2H OCH_2), 0.20 (s, 9 H, $SiMe_3$). $^{13}C\{^1H\}$ NMR (ppm, benzene-d_6): 57.02 (OCH_2), −2.84 ($SiMe_3$). IR (KBr, cm^{-1}): 2957 m, 2896 w, 2740 m, 1615 w, 1418 vw, 1245 s, 1045 w, 857 vs, 837 sh s, 757 vw, 695 w, 671 vw, 528 b m, 442 b m.

Preparation of $Nb(OCH_2CMe_3)_5$ [12]

$NbCl_5$ (4.0 g, 14.8 mmol) and Me_3CCH_2OH (10.0 g, 113.5 mmol) were combined in benzene (60 cm^3). Excess anhydrous NH_3 gas was then added according

to the literature procedure [12] for the preparation of $Nb(OCH_2CH_2CHMe_2)_5$. The product was purified by sublimation (120°C, 10^{-2} torr), yielding a white solid (5.12 g, 9.7 mmol, 65%). ^1H NMR (δ, benzene-d_6): 4.25 (s, 10 H, OCH_2), 1.04 (s, 45 H, *Me*). $^{13}C\{^1H\}$ NMR (ppm, benzene-d_6): 85.26 (OCH_2), 33.96 (CMe_3), 26.61 (*Me*).

Synthesis of $[Nb(OCH_2SiMe_3)_5]_2$ (**3**)

Me_3SiCH_2OH (4.06 cm^3, 3.35 g, 32.1 mmol) and $Nb(O\text{-}i\text{-}Pr)_5$ (2.50 g, 6.43 mmol) were combined in benzene (50 cm^3). The solution was refluxed on a variable-return fractionating column [13]. Distillate was collected at 1–2 drops/min over 4–5 h to separate the liberated *i*-PrOH as its azeotrope with benzene. The azeotrope distilled initially at 72°C. As the reaction progressed the distillation temperature slowly increased to the boiling point of pure benzene (80.1 C), at which point the solution was allowed to cool. The benzene was removed under reduced pressure and the residual solid was sublimed (120–125°C, 10^{-4} torr) to yield **3** (2.95 g, 2.42 mmol, 75%) as a white crystalline solid. M.p.: 111–112°C. Found: C, 39.55; H, 9.43. Calc. for $C_{20}H_{55}O_5Si_5Nb$: C, 39.44; H, 9.10%.

3 is moderately soluble in hydrocarbon solvents. ^1H NMR (δ, benzene-d_6, 25°C): 4.75 (s, terminal OCH_2, anti dimer, 0.21×16 H), 4.72–4.67 ("m", vertical and μ OCH_2, syn dimer, low intensity), 4.52 (br s, μ OCH_2, anti dimer, 0.21×4 H), 4.43 (s, horizontal OCH_2, syn dimer, small shoulder), 4.40 (s, OCH_2, monomer, 0.79×10 H), 0.42 (s, μ *Me*, anti dimer, 0.21×18 H), 0.27 (s, terminal *Me*, anti dimer, 0.21×48 H), 0.17 (s, *Me*, monomer 0.79×45 H). ^1H NMR (δ, toluene-d_8, 25°C): 4.72 (br s, terminal OCH_2, anti dimer, 0.06×10 H), 4.68 (br s, μ or vertical OCH_2, syn dimer, 0.19×4 H), 4.66 (br s, μ or vertical OCH_2, syn dimer, 0.19×4 H), 4.55 (br s, μ or vertical OCH_2, syn dimer, 0.19×4 H), 4.51 (br s, horizontal OCH_2, syn dimer, 0.19×8 H), 4.44 (s, OCH_2, monomer, 0.750×10 H), 4.34 (br s, μ OCH_2, anti dimer, 0.06×4 H); 0.380 (br "m", μ *Me*, dimer, 0.25×18 H), 0.248 (br "m", terminal *Me*, dimer, 0.25×72 H), 0.173 (s, *Me*, monomer, 0.75×45 H). (See Results and Discussion for definition of "vertical" and "horizontal".) $^{13}C\{^1H\}$ NMR (ppm, benzene-d_6): 70.24 (OCH_2, monomer), 3.03 (*Me*, monomer). IR (KBr, cm^{-1}): 2957 m, 2898 w, 2858 w, 2796 w, 1416 w, 1246 s, 1209 vw, 106 sh w, 1070 s, 1049 s, 1037 m, 990 w, 855 vs, 761 m, 697 m, 673 m, 600 m, 569 s, 517 m, 449 m.

Preparation of $[LiNb(OCH_2CMe_3)_6]_2$ (**4**)

$LiOCH_2CMe_3$ (**1**, 0.71 g, 7.6 mmol) and $Nb(OCH_2CMe_3)_5$ (4.00 g, 7.57 mmol) were combined in benzene (20 cm^3) and the mixture was warmed (50–60°C) to produce a homogeneous solution. The solution was then evaporated *in vacuo* to *ca.* half its original volume. Product **4** crystallized upon cooling (−6°C), and was separated from the supernatant liquid and dried *in vacuo* (2.50 g). The supernatant liquid was evaporated and the residue sublimed (120–125°C, 10^{-4} torr) to yield additional **4** (1.42 g). Total yield: 3.92 g, 3.15 mmol, 83%. M.p.: 181–210°C. Found (sublimed **4**): C, 58.44; H, 10.98. Calc. for $C_{30}H_{66}O_6LiNb$: C, 57.86; H, 10.68%.

4 is moderately soluble in hydrocarbon solvents. ^1H NMR (δ, benzene-d_6): 4.28 (pseudo t, $^2J_{Ha\text{-}Hb} = 6.1$ Hz, 4 H, μ_3 $OCH_aH_bCMe_3$), 4.17 (br s, 20 H, terminal and μ_2 OCH_2), 1.10 (br s, 18 H, μ_3 $OCH_aH_bCMe_3$), 1.05 (s, 54 H, terminal *Me*), 1.04 (s, 36 H, μ_2 *Me*). ^1H NMR spectra of aged samples were considerably more complex. $^{13}C\{^1H\}$ NMR (ppm, benzene-d_6): 83.50 (μ_3 OCH_2), 82.48 (μ_2 OCH_2), 81.87 (terminal OCH_2), 34.42 (μ_3 CMe_3), 33.88 (terminal CMe_3), 33.82 (μ_2CMe_3), 27.35 (μ_3 CMe_3), 27.15 (terminal CMe_3), 26.56 (μ_2 CMe_3). IR (cm^{-1}, KBr): 2953 vs, 2901 m, 2866 s, 2692 vw, 1479 m, 1463 m, 1393 m, 1362 m, 1290 vw, 1259 vw, 1218 vw, 1072 vs, 1023 vs, 935 vw, 903 vw, 751 w, 650 s, 604 m, 462 m.

Pure **4** (0.220 g, 0.177 mmol) sublimed at 120–125°C, 10^{-4} torr (0.103 g, 0.083 mmol, 47% recovery). The ^1H NMR spectrum of the sublimate resembled that for *aged* **4**.

Preparation of $LiNb(OCH_2CMe_3)_6(Me_3CCH_2OH)_2$ (**5**)

Me_3CCH_2OH (2.0 g, 23 mmol), $LiOCH_2CMe_3$ (**1**, 0.53 g, 5.8 mmol), and $Nb(OCH_2CMe_3)_5$ (3.00 g, 5.67 mmol) were dissolved in benzene (10 cm^3). A white solid precipitated. The reaction mixture was warmed to redissolve the solid product, transferred to a water bath (50–55°C) in a Dewar flask, and allowed to cool slowly to room temperature. Colorless crystals of **5** formed, which were separated from the supernatant liquid and dried *in vacuo* (4.12 g, 5.15 mmol, 91%). M.p.: 182–191°C. Found: C, 60.02; H, 11.35. Calc. for $C_{40}H_{90}O_8LiNb$: C, 60.13; H, 11.35%.

Compound **5** is moderately soluble in hydrocarbon solvents. ^1H NMR (δ, benzene-d_6): 4.30 (s, 12 H, OCH_2), 3.35 (s, 4 H, CH_2 of alcohol), 3.32 (s, 2 H, *HO*), 1.16 (s, 54 H, *Me*), 0.82 (s, 18 H, *Me* of alcohol). $^{13}C\{^1H\}$ NMR (ppm, benzene-d_6): 82.11 (OCH_2 of alkoxy ligand), 74.11 (OCH_2 of alcohol), 34.04 (CMe_3 of alkoxy ligand), 32.60 (CMe_3 of alcohol), 27.43 (*Me* of alkoxy ligand), 26.09 (*Me* of alcohol). IR (cm^{-1}, KBr): 3430 b vw, 2951 vs, 2904 m, 2865 m, 2833 sh, w, 2701 vw, 1479 w, 1462 w, 1391 w, 1361 w, 1260 vw, 1217 vw, 1066 vs, 1022 s, 935 vw, 902 vw, 751 vw, 634 m, 597 sh w, 451 w.

Pure **5** (1.32 g, 1.65 mmol) sublimed at 120–125°C, 10^{-4} torr with loss of Me_3CCH_2OH to yield $[LiNb(OCH_2CMe_3)_6]_2$ (**4**) (0.85 g, 0.70 mmol, 82%). Calc. for $C_{30}H_{66}O_6LiNb$: Li + Nb, 16.03. Found: Li + Nb, 15.83. The ^1H NMR matched that of crystallized **4** (see above).

Preparation of $[LiNb(OCH_2SiMe_3)_6]_2$ (**6**)

$LiOCH_2SiMe_3$ (**2**, 0.45 g, 4.10 mmol) and $[Nb(OCH_2SiMe_3)_5]_2$ (**3**, 2.50 g, 2.05 mmol) were combined in benzene (10 cm^{-3}) and the mixture was warmed (50–60°C) to produce a homogeneous solution. Colorless crystals of **6** were deposited upon cooling to room temperature (20 h), which were separated from the supernatant liquid and dried *in vacuo* (1.29 g, 0.90 mmol, 44%). M.p.: 130–134°C. Found: C, 40.00; H, 9.40. Calc. for $C_{24}H_{66}O_6Si_6NbLi$: C, 40.08, H, 9.25%.

Compound **6** is moderately soluble in hydrocarbon solvents. ^1H NMR (δ, benzene-d_6): 4.53 (br s, 20 H, terminal and μ_2-OCH_2), 4.44–4.40 (m, 4 H, μ_3-OCH_aH_bSiMe$_3$), 0.26 (s, 90 H, terminal and μ_2 *Me*), 0.17 (s, 18 H, μ_3 *Me*). ^1H NMR spectra of aged samples were considerably more complex. $^{13}C\{^1H\}$ NMR (ppm, benzene-d_6): 67.28 (terminal-OCH_2), 66.61 (μ_3-OCH_2), 65.79 (μ_2-OCH_2), −1.54 (terminal Si*Me*$_3$), −2.36 (μ_2 Si*Me*$_3$), and −3.15 (μ_3 Si*Me*$_3$). IR (KBr, cm^{-1}): 2955 m, 2899 w, 2855 w, 2794 vw, 1416 vw, 1246 s, 1105 sh w, 1056 sh m, 1037 m, 853 vs, 760 w, 696 w, 673 w, 595 vw, 539 s, 501 m.

Pure **6** (0.26 g, 0.18 mmol) sublimed at 155–160°C, 10^{-4} torr (0.11 g, 0.077 mmol, 42% recovery). The ^1H NMR spectrum of the sublimate matched that of crystallized **6** (see above).

NMR study of the monomer–dimer equilibrium of **3**

A 0.0058 M sample was prepared by dissolving pure **3** in toluene-d_8. NMR probe temperatures were calibrated with methanol and ethylene-glycol standards. Spin-lattice relaxation times (T_1 values) for the ^1H resonances in **3** were determined with 180–90° inversion–recovery experiments at 298 K and 338 K. Cycle times for collection of FID pulses were set to 5× the longest T_1 to ensure quantitative integrations. Data were obtained by integrating methyl resonances; the total dimer contribution was determined by summing the dimer Me resonances. Data from OCH_2 resonances did not extend the temperature range over which meaningful results could be obtained; furthermore, integrations were less reliable due to monomer–dimer overlap at high temperatures and substantial peak broadening at low temperatures. The sample was not entirely dissolved at low temperatures; here the actual concentration was determined by: {[total (monomer + dimer) Me integration ÷ solvent Me integration]$_{lo\,T}$ ÷ [total (monomer + dimer) Me integration ÷ solvent Me integration]$_{hi\,T}$} × 0.0058 M. Data (T (K), [monomer]^2/[dimer]): 309, 3.98×10^{-2}; 298, 2.50×10^{-2}; 288, 9.92×10^{-3}; 278, 3.02×10^{-3}; 267, 6.24×10^{-4}; 257, 1.78×10^{-4}; 247, 6.16×10^{-5}; 236, 2.06×10^{-5}; 226, 9.38×10^{-6}. Thermodynamic quantities were determined by linear least-squares fitting of the data to $\{-\ln[\text{monomer}]^2/[\text{dimer}]\} = \Delta H/RT - \Delta S/R$: $\Delta H = 63(3)$ kJ/mol and $\Delta S = 180(10)$ J/K mol. Errors were estimated by standard procedures.

NMR study of the fluxional behavior of **3**

Exchange of vertical and horizontal terminal ligands (refer to Results and Discussion) in the anti dimer of **3** was observed at both the slow- and fast-exchange limits. A rate constant, ΔG, and error estimates were extracted from the coalescence data by standard methods. Data from OCH_2 resonances: ^1H NMR (δ, toluene-d_8, low-temperature limit) 4.76 (s), 4.70 (s); $T_c = 253(5)$ K; $\Delta\nu = 19.2(2)$ Hz. The rate constant $k_{253} = 42.7(4)$ s^{-1}, and $\Delta G_{253} = 54.0(4)$ kJ/mol.

Crystal structure determination for $[Nb(OCH_2SiMe_3)_5]_2$ (**3**)

A colorless prism ($0.25 \times 0.54 \times 0.42$ mm) obtained by slowly cooling a benzene solution of **3** was sealed in a glass capillary under N_2. Cell constants were determined from the setting angles of 25 centered reflections at 296 K using monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å) on a Siemens R3m/V diffractometer. Three standard reflections were measured every 97 reflections; no significant decay was observed. A total of 6269 reflections ($+h$, $\pm k$, $\pm l$) were collected. Lorentz, polarization, and empirical corrections were applied to the data set, from which 4802 unique reflections with $F > 6\sigma(F)$ were used in the subsequent structure analysis with the Siemens SHELXTL PLUS program package.

The space-group ($P\bar{1}$) was assigned from statistical data and subsequently confirmed by successful refinement and convergence. The position of the niobium atom was determined by direct methods. The remaining non-hydrogen atoms were found by successive full-matrix least-squares refinements and difference Fourier map calculations, and were then refined anisotropically. All hydrogen atoms were placed at idealized positions ($d_{C-H} = 0.96$ Å) and refined with a common, isotropic thermal parameter using the riding model. A final $R(F_o)$ value of 0.0330 was obtained. Crystallographic data are listed in Table 1. Atomic positional parameters and other details of data collection and analysis are summarized in the supplementary material.

Crystal structure determination for $[LiNb(OCH_2SiMe_3)_6]_2$ (**6**)

The same techniques employed for **3** were used for **6**, except for the differences noted below. A colorless plate ($0.20 \times 0.72 \times 0.40$ mm) grown directly from the reaction mixture at room temperature was used in the analysis. Cell constants were determined from the setting angles of 20 centered reflections, and data were

	3	**6**
Chemical formula	$C_{40}H_{110}Nb_2O_{10}Si_{10}$	$C_{24}H_{66}LiNbO_6$
a (Å)	11.360 (3)	12.921 (5)
b (Å)	12.100 (3)	20.742 (9)
c (Å)	14.863 (5)	16.637 (6)
α (°)	109.10 (2)	—
β (°)	111.46 (2)	96.22 (3)
γ (°)	91.21 (2)	—
V (Å^3)	1773.3 (9)	4433 (3)
Z	1	4
Formula weight	1218.0	719.2
Space group	$P\bar{1}$	$P2_1/n$
T (°C)	22	23
λ (Å)	0.71073	0.71073
ρ_{calcd} (g/cm^3)	1.141	1.078
μ (cm^{-1})	5.31	4.61
$R(F_o)^a$	0.0330	0.0693
$R_w(F_o)^b$	0.0427	0.1765
GOF	1.07	1.007 (on F^2)

$^a R(F_o) = \Sigma\|\|F_o| - |F_c\|\|/\Sigma|F_o|$.
$^b R_w(F_o) = \Sigma_w\|\|F_o| - |F_c\|^2/\Sigma w|F_o|^2)^{1/2}$; $w = [\sigma^2(F_o) + g(F_o)^2]^{-1}$.

collected in the ω mode. A total of 8346 reflections ($+h$, $+k$, $\pm l$) were collected and the $P2_1/n$ space group was assigned.

The position of the niobium atom was determined by heavy-atom methods. All non-hydrogen atoms were refined anisotropically using F^2 refinements of 7735 independent reflections. Because of disorder (see below), some of the Si—C bond distances were restrained to 1.87(1) Å during refinement. Hydrogen atoms were placed at idealized positions and refined with common isotropic thermal parameters using a riding model. Hydrogen atoms attached to disordered carbon atoms were assigned the appropriate site-occupancy factors. Some unresolved disorder remained, as evidenced by large thermal parameters for several carbon atoms. A final $R(F_o)$ value of 0.0693 was obtained. Crystallographic data are listed in Table 1. Atomic positional parameters and other details of data collection and analysis are summarized in the supplementary material.

The crystallographically unique portion of the molecule exhibited some disorder caused by conformational variations and apparent thermal motion of the pendant trimethylsilyl groups. Si(1) and its attached methylene and methyl groups were dissolved cooperatively over two related sets at 52% and 48% occupancies. Other methyl groups were also disordered: C(31)/C(31B), 51%/49%; C(42)/C(42B), 65%/35%; C(52)/C(52B), 57%/43%; and C(63)/C(63B), 52%/48%.

RESULTS AND DISCUSSION

$LiOCH_2CMe_3$ (**1**) *and* $LiOCH_2SiMe_3$ (**2**)

The new lithium alkoxides add to the presently known volatile examples [14]. They were prepared by alcoholysis as shown in eq. (1), and sublimed *in vacuo* at 135–145°C/10^{-4} Torr:

$$LiN(SiMe_3)_2 + ROH \xrightarrow[R = CH_2CMe_3\ (1)\ \ CH_2SiMe_3\ (2)]{} LiOR + HN(SiMe_3)_2 \quad (1)$$

^{1}H and ^{13}C NMR of **2** showed only one set of resonances corresponding to —CH_2 and $SiMe_3$ protons; however, compound **1** showed two sets of resonances for —CH_2 and CMe_3 protons suggesting that **1** existed as two different oligomers. Prior to sublimation **1** was a mixture of these postulated oligomers in a 9:1 ratio. The major oligomer sublimed with small downfield ^{1}H resonance shifts ($\Delta\delta$ OCH_2: 0.035 ppm; $\Delta\delta$ CH_3: 0.010 ppm). The minor oligomer sublimed inconsistently. It appeared to be the heavier oligomer as it sometimes remained in the sublimation vessel after sublimation of the major oligomer. On other occasions, the minor oligomer sublimed with the major oligomer with approximate retention of the oligomeric ratio.

$[Nb(OCH_2SiMe_3)_5]_2$ (**3**)

Compound **3** was prepared from Nb(O-*i*-Pr)$_5$ by alcohol exchange, and structurally characterized as shown in Fig. 1. The molecular structure is an edge-shared bioctahedral dimer with 8 terminal alkoxide ligands (4 "vertical" and 4 "horizontal" according to their dispositions in the dimer as oriented in Fig. 1) and 2 bridging alkoxide ligands, as is typical of $Nb(OR)_5$ compounds. Both $[Nb(\mu\text{-}OMe)(OMe)_4]_2$ [15] and $[Nb(\mu\text{-}OEt)(OCH_2CMe_3)_4]_2$ [16] exhibit solid-state structures similar to that of **3**.

However, the configuration of the bridging oxygen atoms in **3** differs from those in the previously known structural homologs. In **3**, the μ-O atoms (O2 and O2A, Fig. 1) are pyramidalized; the sum of the bond angles about these centers is 350.0 degrees. The corresponding bridging-oxygen centers in $[Nb(\mu\text{-}OMe)(OMe)_4]_2$ [15] and $[Nb(\mu\text{-}OEt)(OCH_2CMe_3)_4]_2$ [16] approach planarity more closely, having sums of the bond angles about them of 354.5, 355.0 and 357.0 degrees, respectively. The pyramidality of the bridging centers in **3** and the steric bulk of the bridging ligand allows syn and anti isomers of the dimeric structure to exist in solution (see below). In the solid state **3** adopts the anti geometry, in which the α-carbon atoms of the bridging alkoxide ligands are on the opposite sides of the horizontal plane defined by O4, O5, Nb, NbA, O4A, and O5A atoms (Fig. 1).

Variable-temperature ^{1}H NMR experiments

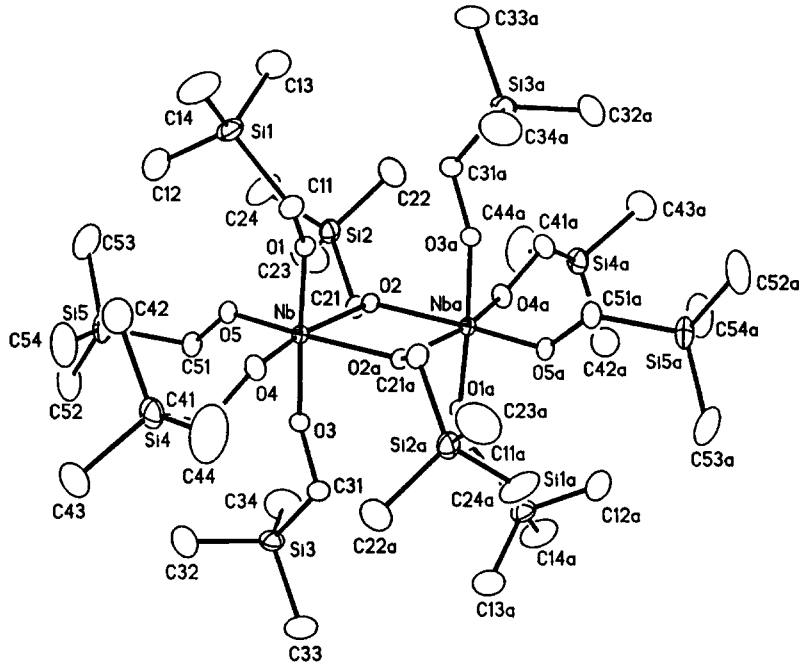

Fig. 1. Thermal ellipsoid plot (20% probability contours) of $[Nb(\mu\text{-}OCH_2SiMe_3)(OCH_2SiMe_3)_4]_2$ (**3**). Hydrogen atoms were omitted for clarity. Selected bond distances (Å): Nb—O(1), 1.902 (3); Nb—O(2), 2.134 (2); Nb—O(3), 1.902 (3); Nb—O(4), 1.919 (2); Nb—O(5), 1.896 (2); Nb—O(2A), 2.174 (2); O(1)—C(11), 1.415 (5); O(2)—C(21), 1.451 (4); O(3)—C(31), 1.408 (5); O(4)—C(41), 1.418 (4); O(5)—C(51), 1.423 (4). Selected angles (°): O(1)—Nb—O(2), 90.2 (1); O(1)—Nb—O(3), 174.6 (1); O(2)—Nb—O(3), 91.2 (1); O(1)—Nb—O(4), 86.4 (1); O(2)—Nb—O(4), 163.7 (1); O(3)—Nb—O(4), 90.8 (1); O(1)—Nb—O(5), 95.7 (1); O(2)—Nb—O(5), 94.6 (1); O(3)—Nb—O(5), 89.4 (1); O(4)—Nb—O(5), 101.6 (1); O(1)—Nb—O(2A), 88.8 (1); O(2)—Nb—O(2A), 71.7 (1); O(3)—Nb—O(2A), 86.6 (1); O(4)—Nb—O(2A), 92.3 (1); O(5)—Nb—O(2A), 165.6 (1); Nb—O(1)—C(11), 144.0 (2); Nb—O(2)—C(21), 121.1 (1); Nb—O(3)—C(31), 151.3 (2); Nb—O(4)—C(41), 133.0 (2); Nb—O(5)—C(51), 136.8 (3); C(21)—O(2)—Nb(A), 120.6 (2); Nb—O(2)—Nb(A), 108.3 (1).

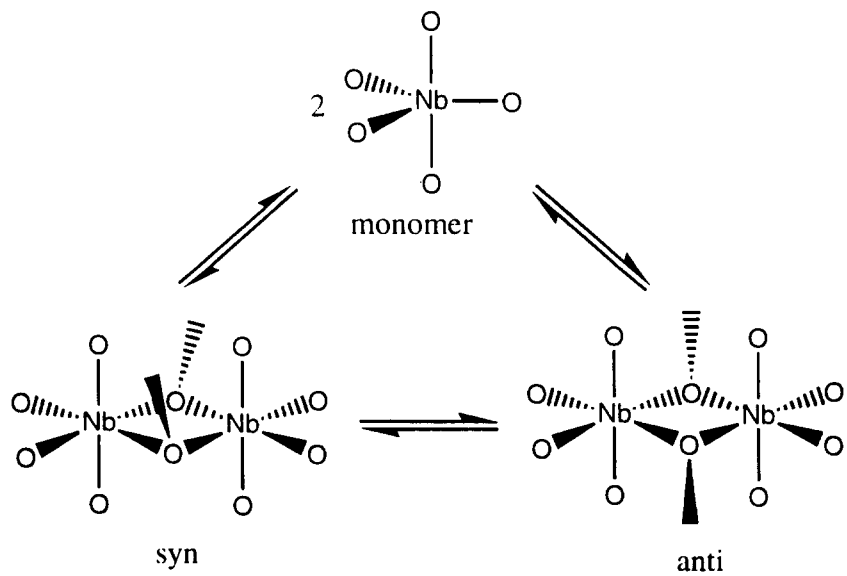
revealed dynamic equilibria between three species in solution, which we identify as monomeric, syn-dimeric, and anti-dimeric isomers of **3** (see Scheme 1). The monomer, producing a singlet resonance (Fig. 2), dominated at higher temperatures and represented at least 75% of the isomer population at room tem-



Scheme 1. Monomer-dimer equilibria for **3**.

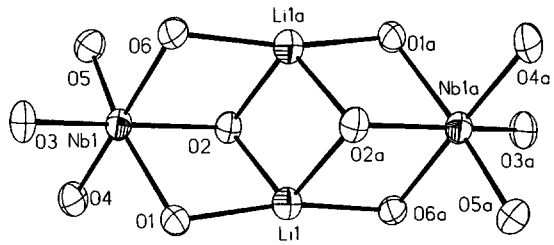


Fig. 2. Variable-temperature ^{1}H NMR spectra of $Nb(OCH_2SiMe_3)_5$ (**3**). (a) In the 205 K spectrum the 2 singlets assigned to terminal OCH_2 protons and the singlet assigned to bridging OCH_2 protons of the anti dimer are indicated by arrows. The horizontal OCH_2 protons of the syn dimer are also present at 205 K as a broad shoulder downfield of the bridging ligand of the anti dimer. This resonance sharpens as the dimer equilibrium shifts toward the syn isomer as indicated in the 226 K spectrum. Vertical and bridging ligands of the syn dimer are poorly resolved. The emerging monomer OCH_2 singlet is evident in the 257 K spectrum, and becomes the highest-intensity resonance in the higher T spectra (see the 360 K spectrum). (b) The monomer methyl resonance is indicated by arrows in the dimer-dominated equilibrium at 226 K and in the monomer-dominated equilibrium at 360 K.

perature and above. The anti isomer, producing 3 alkoxide resonances in the expected intensity ratios of 4:4:2 (Fig. 2), dominated at the lowest temperatures. The syn isomer, producing 4 alkoxide resonances in the ratios of 4:2:2:2 (some of which were obscured), was in its greatest relative abundance at intermediate temperatures (Fig. 2). The two dimers contributed greater than 90% to the total isomer population at temperatures below −35°C. Integrated intensities as a function of temperature allowed determination of the thermodynamic parameters for the equilibrium [total dimer] = [2 monomer]: ΔH = 63(3) kJ/mol and ΔS = 180(10) J/(K mol). This ΔH value was similar to that for the corresponding equilibrium in the Nb(O-*i*-Pr)$_5$ system (ΔH = 75(13) kJ/mol) [17].

Variable-temperature ^{1}H NMR spectra of the *anti*-**3** isomer (Fig. 2) also revealed site exchange of terminal alkoxide ligands that we label horizontal and vertical (according to the Fig. 1, Scheme 1 orientation). This type of exchange has been noted previously in 3 homologous $Nb(OR)_5$ compounds. The ΔG_{253} = 54.0(4) kJ/mol we measured from coalescence data for **3** is within the range of values determined for $[Nb(OMe)_5]_2$, $[Nb(OEt)_5]_2$, and $[Nb(O\text{-}i\text{-}Bu)_5]_2$ (50.6(4), 48.1(1.2), and 64.8(1.2) kJ/mol, respectively) [18,19]. The dynamic behavior of **3** is quite comparable to that in all earlier studies on homologous $Nb(OR)_5$ compounds and their tantalum analogs, except to our knowledge discrete syn and anti dimeric (edge-shared bioctahedral) isomers have not been previously observed in these systems.

$[LiNb(OCH_2CMe_3)_6]_2$ (**4**), $LiNb(OCH_2CMe_3)_6(Me_3CCH_2OH)_2$ (**5**), *and* $[LiNb(OCH_2SiMe_3)_6]_2$ (**6**)

The new Li–Nb heterometallic alkoxides were prepared by combining the corresponding homometallic alkoxides. The structure of **6** is shown in Fig. 3 and 4. Crystals of **4** grown from benzene proved to be unsuitable for single-crystal X-ray diffraction; however, we surmised that **4** is isostructural to **6** on the basis of spectroscopic data discussed below.

The central core of **6** (Fig. 3) contains an $Nb_2Li_2(\mu\text{-}O)_4(\mu_3\text{-}O)_2$ unit that is geometrically similar to the central units in $[MSn(O\text{-}t\text{-}Bu)_3]_2$ (M = Li, Na) [20] and $[LiTi(O\text{-}i\text{-}Pr)_5]_2$ [21]. The compound initially identified as $[LiNb(OEt)_5(OH)]_2$ also has an $Nb_2Li_2(\mu\text{-}O)_4(\mu_3\text{-}O)_2$ central core and an overall structure related to that of **6** [22], a reformulation of this compound as $[LiNbO(OEt)_4(EtOH)]_2$ has recently been suggested [7].

The structure of **6** differs from those of the related examples outlined above in a significant aspect: **6** possesses *asymmetrically* bridging μ_3-OR ligands. The triply bridging atom O2 lies closer to Li1 than to Li1 A by 0.187 (26) Å. That asymmetry is apparently manifested in the ^{1}H NMR of **6**, in which the methylene protons on the μ_3 ligand, μ_3-$OCH_aH_bSiMe_3$, produce an AB multiplet. If the μ_3 ligand bridged symmetrically, then its methylene protons would be chemically equivalent and appear as a singlet. All other features in the ^{1}H NMR spectrum of **6** are consistent with the solid-state structure, with the terminal, μ_2, and μ_3 ligands appearing as separate Me resonances in 6:4:2 ratios. Thus, the structure and bridge asymmetry of **6** observed in the solid state are apparently maintained upon dissolution.

The similarity of the ^{1}H NMR spectra of **6** and **4** suggest that they are isostructural. Like the spectrum of **6**, the spectrum of **4** contains a multiplet (in this case a pseudotriplet) that we assign to the μ_3-$OCH_aH_bCMe_3$ ligands in an asymmetrically bridged structure homologous to that for **6**. The spectrum of **4** also contains Me resonances in 6:4:2 ratios that we assign to the terminal, μ_2, and μ_3 ligands, respectively.

Both **6** and **4** underwent structural changes in solution upon standing, as evidenced by the increasingly complex ^{1}H NMR spectra obtained from aged samples. This may indicate that their dimeric molecular structures are unstable in solution with respect to oligomerization. Consequently, characteristic spectra for **4** and **6** were recorded immediately after dissolution of crystalline materials.

The structure of the alcohol adduct **5** is unknown,

although we infer that **5** is molecular rather than nonmolecular on the basis of its solubility, volatility, and the structures of the analogs **4** and **6**. The ^1H NMR spectrum of **5** is very simple, with all OCH_2CMe_3 ligands apparently equivalent. Presumably, the simplicity results from alkoxide–ligand site exchange among chemically inequivalent positions, although we did not investigate the variable-temperature NMR behavior of **5** to support this presumption. We note that **5** sublimed to give **4** in almost twice the recovery that was achieved in the sublimation of pure **4**, and that **4** sublimed in better recovery from the mother liquor remaining after crystallization of **4** than as a pure substance. Perhaps the alcohol ligands in **5** and residual alcohol present in the mother liquor inhibited oligomerization of **4** to nonvolatile structures during sublimation.

Attempted spray MOCVD using $[LiNb(OCH_2CMe_3)_6]_2$ (**4**)

To obtain a preliminary indication of the suitability of **4** as an $LiNbO_3$ precursor, samples of **4** were decomposed in quartz tubes under flowing N_2 at 600°C. Dark mirror coatings formed on the interior tube walls, which were found to be crystalline $LiNbO_3$ by X-ray powder diffraction (XRD), a promising indicator for the applicability of **4** as a spray MOCVD precursor.

We then assembled a hot-wall spray MOCVD reactor following closely the design reported by Wernberg, Gysling, and Braunstein [9]. We successfully reproduced the deposition of $LiNbO_3$ from $[LiNb(OEt)_6]_x$ using the solvent-evaporation-zone temperature, the precursor-decomposition-zone temperature, and the carrier gas (5% O_2 in Ar) and flow rate they reported [9].

However, we failed to deposit $LiNbO_3$ from **4** using the same experimental parameters. Precursor-decomposition-zone temperatures and carrier-gas flow rates above and below those employed with $[LiNb(OEt)_6]_x$ were also examined without success. The minimal deposits obtained did not produce detectable XRD intensities. In most runs, a much larger quantity of white solid collected as a non-adherent coating at the outlet constriction in the reactor and beyond. This material was insoluble in organic solvents, amorphous by XRD, and annealed (500°C) to give crystalline $LiNbO_3$ and traces of $LiNb_3O_8$. Gravimetric analyses established that most of the

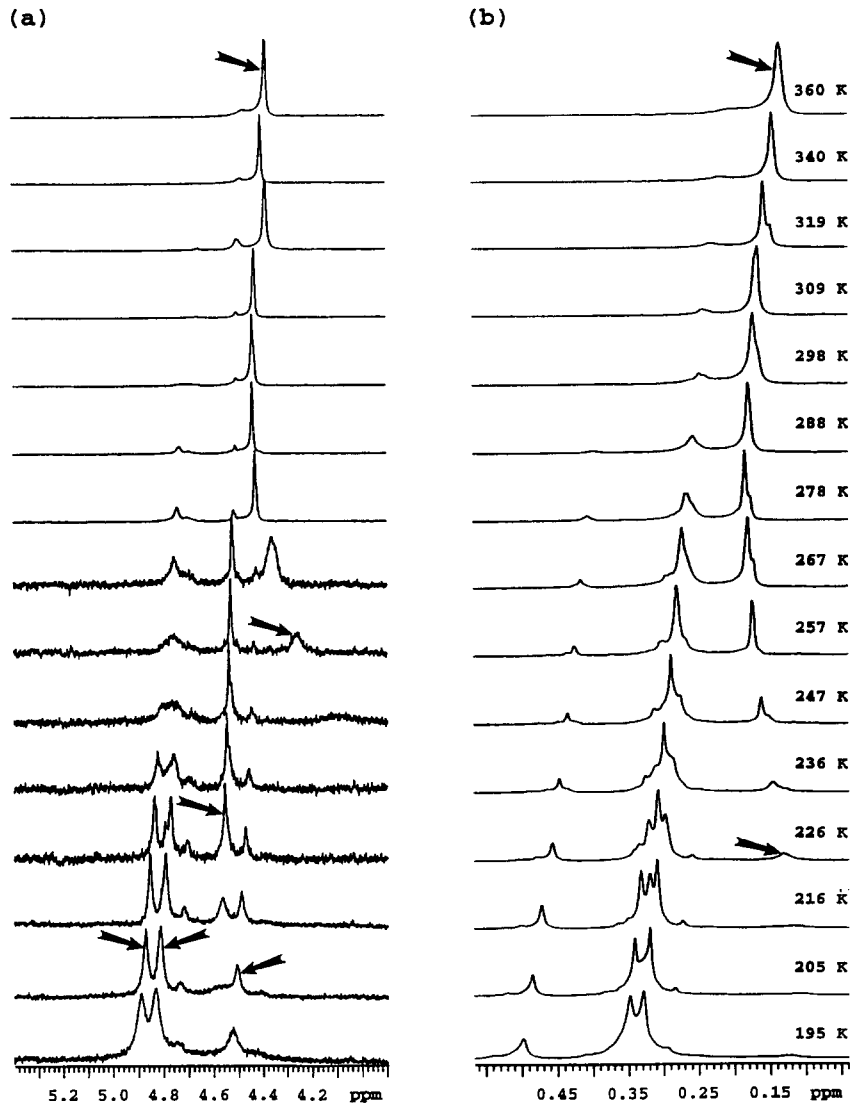

Fig. 4. Thermal ellipsoid plot (20% probability contours) of $[LiNb(\mu_3\text{-}OCH_2SiMe_3)(\mu_2\text{-}OCH_2SiMe_3)_2(OCH_2SiMe_3)_3]_2$ (**6**). Methyl-carbon and hydrogen atoms were omitted for clarity.

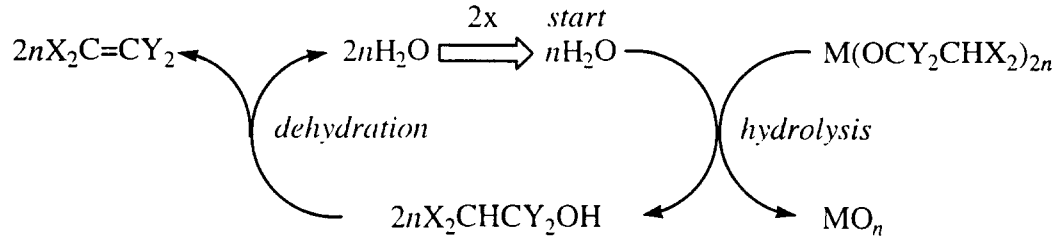
organic content had been removed from the material during passage through the reactor. These observations suggest that dissociation of the Li and Nb components of **4** was not occurring, but that **4** decomposed homogeneously in the gas phase to produce particles [23] rather than heterogeneously at the substrate to produce a film.

We expected that $[LiNb(OEt)_6]_n$ and **4** would exhibit differing decomposition behavior. In a classic study Bradley and Faktor established that alkoxide compounds having hydrogen atoms β to oxygen may decompose autohydrolytically in the gas phase at elevated temperatures and atmospheric pressure (Scheme 2) [24]. By this mechanism alkoxide decomposition is initiated by a trace of H_2O, which generates metal oxide and byproduct alcohol hydrolytically. The liberated alcohol is dehydrated to alkene on hot reactor surfaces, generating twice the original trace amount of H_2O. Each successive cycle doubles the amount of metal oxide and H_2O produced; hence, the mechanism is autohydrolytic. Because $[LiNb(OEt)_6]_n$ possesses hydrogens β to oxygen whereas **4** does not, only the former may decompose autohydrolytically.

We suggest that autohydrolysis is the likely decomposition mechanism for $[LiNb(OEt)_6]_n$ during spray MOCVD of $LiNbO_3$, although the mechanism has not been investigated [25]. If autohydrolytic $[LiNb(OEt)_6]_n$ decomposition initiates at the leading edge of the deposition substrate, then the H_2O concentration may increase steadily towards the trailing edge of the substrate, possibly causing nonuniform film growth. We considered that use of precursors like **4**, for which autohydrolysis is inoperative, might increase the area over which uniform $LiNbO_3$ films may be grown. Unfortunately, to date neither **4** nor its analogs have given $LiNbO_3$ films. Assigning the differing behaviors



Scheme 2. Autohydrolytic decomposition of alkoxide precursors.

of $[LiNb(OEt)_6]_n$ and **4** to the presence and absence of autohydrolysis, respectively, is tempting but currently speculative.

SUMMARY

To our knowledge **6** is the only completely characterized *molecular* $LiNb(OR)_6$ compound. The homolog **4** is spectroscopically similar to **6** and is presumably isostructural. All of **4**–**6** are moderately soluble and volatile, although the alcohol adduct **5** and impure **4** sublime in the greatest recoveries. Under static conditions, **4** decomposes to $LiNbO_3$ at temperatures comparable to those for $[LiNb(OEt)_6]_x$. However, in preliminary studies **4** has not been a similarly successful spray MOCVD precursor, perhaps for lack of the autohydrolytic decomposition pathway.

(Received 22 April 1997; accepted 7 July 1997)

Abstract—Reaction of $[Pt(en)Cl_2]$ (en = ethane-1,2-diamine) with thallium(I) carbonate (or in some cases K_2CO_3) and a polyfluorobenzene in hot pyridine (py) or 3-methylpyridine (tmpy) yields the [*N*,*N*′-bis (polyfluorophenyl)ethane-1,2-diaminato(2-)]platinum(II) complexes, $[Pt\{N(R)CH_2\}_2L_2]$ (L = py, R = *p*-HC_6F_4, C_6F_5, *p*-BrC_6F_4, *p*-IC_6F_4, *p*-MeC_6F_4, *p*-$C_6F_5C_6F_4$, 2,3,5-$F_3C_6H_2$, *p*-$O(H)CC_6F_4$, *p*-$MeOC_6F_4$; L = tmpy, R = *p*-HC_6F_4). Yields were markedly greater with the use of Tl_2CO_3 than reported for reactions of $[Pt(en)Cl_2]$ with thallium(I) polyfluorobenzoates. A new class of platinum(II) amides, namely [*N*-(phenyl)-*N*′-(polyfluorophenyl)ethane-1,2-diaminato(2-)]platinum(II) complexes, $[Pt\{N(Ph)CH_2CH_2N(R)\}L_2]$ (L = py, R = *p*-HC_6F_4, C_6F_5, *p*-MeC_6F_4, *p*-ClC_6F_4, *p*-BrC_6F_4; L = 4-methylpyridine, R = *p*-HC_6F_4), has been prepared by reaction of $[Pt(PhNHCH_2CH_2NH_2)I_2]$ with Tl_2CO_3 or a thallium(I) polyfluorobenzoate and a polyfluoroaromatic compound in pyridine or 4-methylpyridine. The complexes where R = *p*-MeC_6F_4, *p*-ClC_6F_4, *p*-BrC_6F_4 could be prepared only with Tl_2CO_3, which also provided cleaner products where both routes were used. The crystal structure of $[Pt\{N(Ph)CH_2CH_2N(p\text{-}MeC_6F_4)\}(py)_2]$ has been determined and shows a slightly distorted square planar coordination for platinum, with two amide and two *cis* pyridine nitrogen donors.

Keywords: platinum; organoamide; polyfluorophenyl; thallium(I) carbonate; CO_2 formation; X-ray structure.

The platinum(II) organoamides $[Pt\{N(R)CH_2\}_2(py)_2]$ (R = polyfluoroaryl) [1] have high biological activity against murine L1210 leukeamia cells and the *cis*-$[Pt(NH_3)_2Cl_2]$ (cisplatin) resistant variant [2]. Activity is also shown by representative compounds against HT-29 and BE human colon carcinoma cells in culture and against P388 leukeamia in mice, where the complexes R = *p*-HC_6F_4, C_6F_5, or *p*-IC_6F_4, have very good activity [2]. Recently, $[Pt\{N(p\text{-}HC_6F_4)CH_2\}_2(py)_2]$ has been shown to be active against the mouse plasmacytoma ADJ/PC6 [3(a)], a cell line in wide use for screening antitumour behavior of platinum complexes [3(b)]. The compounds are of particular interest, since the nitrogen donor atoms have no hydrogen substituents, a normal requirement for active platinum(II) complexes [4], and since *cis*-$PtCl_2(py)_2$ is inactive *in vivo* [2,5].

Unusually for platinum(II) organoamides [6–9], the complexes are stable to water [1], and this contrasts the extreme moisture sensitivity of simple analogues

† Part V is [16(d)].

‡ Dedicated to Professor Don Bradley, F.R.S., on the occasion of his 73rd birthday, in recognition of his outstanding and pioneering contribution to the chemistry of metal alkoxides and amides, and with thanks for professional advice, encouragement, and friendship over many years.

(e.g. $[Pt\{N(R)CH_2\}_2(bpy)]$ R = Me or H, bpy = 2,2′-bipyridine) [10]. Hitherto, the complexes have been prepared in yields of 6–44% by novel decarboxylation reactions from $[Pt(en)Cl_2]$ (en = ethane-1,2-diamine) and thallium(I) pentafluoro- or 2,3,5,6-tetrafluorobenzoate, usually with an added polyfluorobenzene (eq. (1) and (2)) [1].

$$[Pt(en)Cl_2] + 2TlO_2CC_6F_5 + 4py \rightarrow [Pt\{N(p\text{-}HC_6F_4)CH_2\}_2(py)_2] + 2TlCl + 2CO_2 + 2pyHF \quad (1)$$

$$[Pt(en)Cl_2] + 2TlO_2CC_6F_4H\text{-}p + 2RF + 4py \rightarrow [Pt\{N(R)CH_2\}_2(py)_2] + 2TlCl + 2CO_2 + 2p\text{-}H_2C_6F_4 + 2pyHF \quad (2)$$

Higher yield syntheses would be of major benefit, not only because of the cost of reagents, but also because of the need to generate sufficient amounts for continuing biological testing. A key step in the synthesis is considered to be deprotonation of $[Pt(en)Cl_2]$ by a highly carbanionic C_6F_5 or p-HC_6F_4 group generated by decarboxylation [1]. We have recently shown that deprotonation of $[Pd\{NH(R)CH_2CH_2NR'_2\}Cl_2]$ (R = polyfluorophenyl, R′ = Me or Et) compounds to give palladium(II) organoamides, $[Pd\{N(R)CH_2CH_2NR'_2\}(py)Cl]$, can be achieved with Tl_2CO_3 in pyridine [11]. This has now led to a successful attempt to prepare the target $[Pt\{N(R)CH_2\}_2(py)_2]$ complexes, including three new examples, by reaction of $[Pt(en)Cl_2]$ with Tl_2CO_3 (and some cases K_2CO_3) and a polyfluorobenzene labile to nucleophilic substitution, in pyridine. These syntheses are now described together with preparations of a new class of platinum(II) organoamides, namely $[Pt\{N(Ph)CH_2CH_2N(R)\}L_2]$ complexes (e.g. L = py, R = C_6F_5 or p-HC_6F_4), where use of Tl_2CO_3 proved more successful than thallium(I) polyfluorobenzoates. The structure of a typical new complex, $[Pt\{N(Ph)CH_2CH_2N(p\text{-}MeC_6F_4)\}(py)_2]$, has been determined by X-ray crystallography.

RESULTS AND DISCUSSION

Synthesis of $[Pt\{N(R)CH_2\}_2(py)_2]$ *complexes*

The previously synthesized and characterized [*N*,*N*′-bis(polyfluorophenyl)ethane-1,2-diaminato (2-)]dipyridineplatinum(II) complexes **1a–1g** [1] have now been prepared by reactions between dichloro(ethane-1,2-diamine)platinum(II), a polyfluoroaromatic compound, and thallium(I) or potassium carbonate in pyridine (eq. (3)). Three new organoamidoplatinum(II) complexes **1h, 1i** and **1j** were synthesized in pyridine or 3-methylpyridine (tmpy).

$$[Pt(en)Cl_2] + 2M_2CO_3 + 2RF + 2L \rightarrow [Pt\{N(R)CH_2\}_2L_2] + 2MCl + 2CO_2 + 2H_2O + 2MF \quad (3)$$

M = Tl; L = py; R = p-HC_6F_4 **1a**, C_6F_5 **1b**, p-BrC_6F_4 **1c**, p-IC_6F_4 **1d**, p-MeC_6F_4 **1e**, p-$C_6F_5C_6F_4$ **1f**, 2,3,5-$F_3C_6H_2$ **1g**, p-$O(H)CC_6F_4$ **1h**, p-$MeOC_6F_4$ **1i**; L = tmpy; R = p-HC_6F_4 **1j**; M = K, **1a–1c**.

Details of the preparations are given in Table 1. Syntheses of **1a** with differing mole ratios of M_2CO_3 : $[Pt(en)Cl_2]$ have shown that for M = K or Tl, a 2 : 1 stoichiometry gives higher yields (based on platinum) than a 1 : 1 stoichiometry. Raising the ratio to 4 : 1 for M = K gives only a minor increase in yield. These results are consistent with the stoichiometry of reaction (3). The reactions are sensitive to variation of the cation M. Thus, in the synthesis of **1a**, Tl_2CO_3 is more effective than K_2CO_3, whilst no **1a** could be isolated after use of Na_2CO_3. Similarly, in the syntheses of **1c** and **1d**, Tl_2CO_3 gave a considerably higher yield than K_2CO_3. The effects of the different cations, Tl > K > Na, are not understood at this stage. They cannot be related to the lattice energies of the metal chloride products, since NaCl has the highest lattice energy [12(a)–(c)], but reaction (3) fails with M = Na. The reaction mixtures are heterogenous with a number of reactants and products evidently near insoluble in pyridine or tmpy. In these circumstances, subtle solubility differences may have a considerable effect on the outcome. Possibly the solubility of TlCl compared with that of Tl_2CO_3 is more favourable than for NaCl in relation to Na_2CO_3. All three metal chlorides are reported to be insoluble in dry pyridine [12(d)–(f)], but subtle differences may be revealed by quantitative measurements, as observed for these salts in the polar organic solvent methanol, where the solubilities are TlCl < KCl < NaCl [13]. A similar sequence for pyridine would favour reaction (3), M = Tl. The variability in reactivity of K_2CO_3 with different fluorocarbons (reasonably reactive with C_6F_5H, C_6F_6, C_6F_5Br but unreactive with C_6F_5I) could reflect the effect of the added fluorocarbon on relative solubilities. Certainly, the reactivity of C_6F_5I to nucleophilic substitution (see reaction path) is not expected to be dramatically different from that of C_6F_5Br [14].

The yields from the preparations (3) are compared with those from reactions (1) and (2) in Table 2. From reaction (3) with M = K, the yields are generally comparable with those from (1) or (2), except in the synthesis of **1d** where reaction (2) is more effective. However, for M = Tl, reaction (3) normally gives *much* higher yields than (1) or (2), and this is particularly evident in the syntheses of **1d** in pyridine and of the new complex **1j** in tmpy. Moreover, the successful synthesis of **1h** and the detection of **1i** contrasts earlier failures to obtain these products by reaction (2) [1]. The successful synthesis of **1h** also led to an attempt to induce reaction (3) with the substrates $C_6F_5CF_3$ and o-$H_2C_6F_4$, which had failed in reaction

[a] All reactions with $[Pt(en)Cl_2]$ (1.0 mmol) in 10 cm^3 of pyridine or substituted pyridine.
[b] Yield of recrystallized, spectroscopically pure, product. Figures in parentheses are reported yields from reaction (1) or (2) [1].
[c] $KHCO_3$ used: At 80°C (1.5 h) **1a** (7%) and CO_2 (7%) were obtained.
[d] Because of the low yield, this compound was identified only by ^1H and ^{19}F NMR spectroscopy.
[e] $TlO_2CC_6F_5$ was used instead of Tl_2CO_3.

(2) [1], but no organoamidoplatinum(II) complexes were isolated despite evolution of the expected CO_2. Thus, reaction (3), M = Tl has a *major* advantage over (1) or (2) in terms of yield. In addition, it eliminates the need (and cost) to synthesize $TlO_2CC_6F_5$ or $TlO_2CC_6F_4H$-*p* from Tl_2CO_3 and the poly-

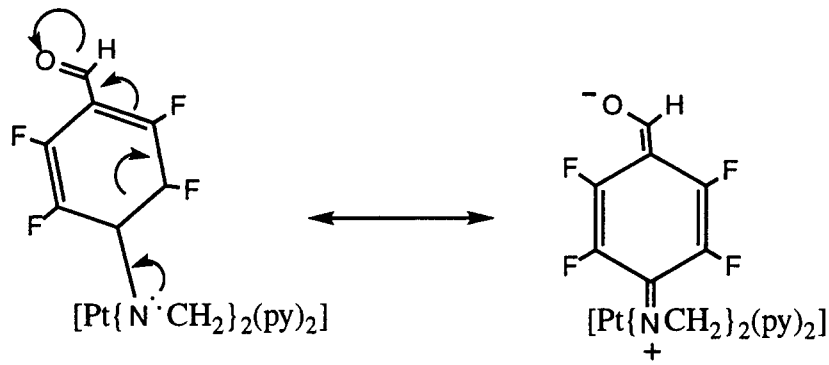
[a] All reactions with $[Pt\{NH(Ph)CH_2CH_2NH_2\}I_2]$ (1.0 mmol) in 10 cm^3 of pyridine or, in one case, 4-methylpyridine.
[b] Yield of recrystallized material which was analytically pure.
[c] 4-Methylpyridine was used as the solvent.
[d] Not reproducible.
[e] Yield of recrystallized material which was spectroscopically pure.



fluorobenzoic acids, and obviates the carbonation preparation of p-$HC_6F_4CO_2H$, which is not commercially available.

The crude products **1c**–**1e** showed the presence of small amounts of impurities, attributable to other isomers, $[Pt\{N(m\text{-}XC_6F_4)CH_2\}_2(py)_2]$ and $[Pt\{N(o\text{-}XC_6F_4)CH_2\}_2(py)_2]$ (X = Br, I or Me), which were removed by a single recrystallization. The complexes **1a**–**1g** had spectroscopic properties in agreement with those previously reported [1], whilst the new complexes **1h** and **1j** were microanalytically pure and had ^1H and ^{19}F NMR spectra (Experimental Section) consistent with the proposed structures, including $^3J_{Pt,H(py)}$ coupling constants. Complex **1j** gave a parent ion in the mass spectrum whereas **1h** gave no platinum containing peaks. Fragment ions indicative of the various ligands were evident. The infrared spectrum of **1h** gave an aldehyde ν(C=O) absorption at 1687 cm^{-1}. This is at lower energy than that of $C_6F_5C(H)O$ (1715 cm^{-1}) [15] suggesting that delocalization of the amido nitrogen lone pair into the polyfluorophenyl ring, established by X-ray diffraction of several polyfluorophenyl-substituted organoamidoplatinum(II) complexes [16], is extended to the carbonyl oxygen.

The aldehyde proton was observed at 9.79 ppm in the ^1H NMR spectrum, which is near the high frequency limit owing to the electron-withdrawing effect of the fluorocarbon substituent. Because the new complex **1i** was obtained only in low yield, it was identified solely by ^1H and ^{19}F NMR spectroscopy (Experimental Section).

The reaction path for the Tl_2CO_3 *based synthesis*

Reaction (3) is considered to involve initially the formation of $[Pt(en)(py)_2]CO_3$ (reaction 4)), since this complex was identified in the insoluble material from heating $[Pt(en)Cl_2]$ and Tl_2CO_3 in pyridine at 110°C. Formation of carbonato complexes from metal chlorides and ionic carbonates is a standard preparative method [17], but is unlikely here in a polar solvent which coordinates well to platinum.

$$[Pt(en)Cl_2] + Tl_2CO_3 + 2py \rightarrow [Pt(en)(py)_2]CO_3 + 2TlCl \quad (4)$$

That $[Pt(en)(py)_2]CO_3$ can be a precursor of the complexes **1** was shown by the reaction of the authentic compound (from $[Pt(en)(py)_2]Cl_2$ and Ag_2CO_3) with C_6F_5H in toluene/pyridine at 110°C, when CO_2 and **1a** were obtained. (The reaction could not be induced in toluene alone.)

$$2[Pt(en)(py)_2]CO_3 + 2C_6F_5H \xrightarrow{py} \mathbf{1a} + 2H_2O + 2CO_2 + [Pt(en)(py)_2]F_2 \quad (5)$$

Little CO_2 was evolved during reaction (4), hence deprotonation of $[Pt(en)(py)_2]^{2+}$ by CO_3^{2-}, giving the amide nucleophile $[Pt(NHCH_2)_2(py)_2]$ (which substitutes into polyfluoroarenes in the proposed path for reactions (1) and (2) [1]), can be ruled out, because the coproduced bicarbonate ions (reaction (6)) would decompose into CO_2 at the reaction temperature.

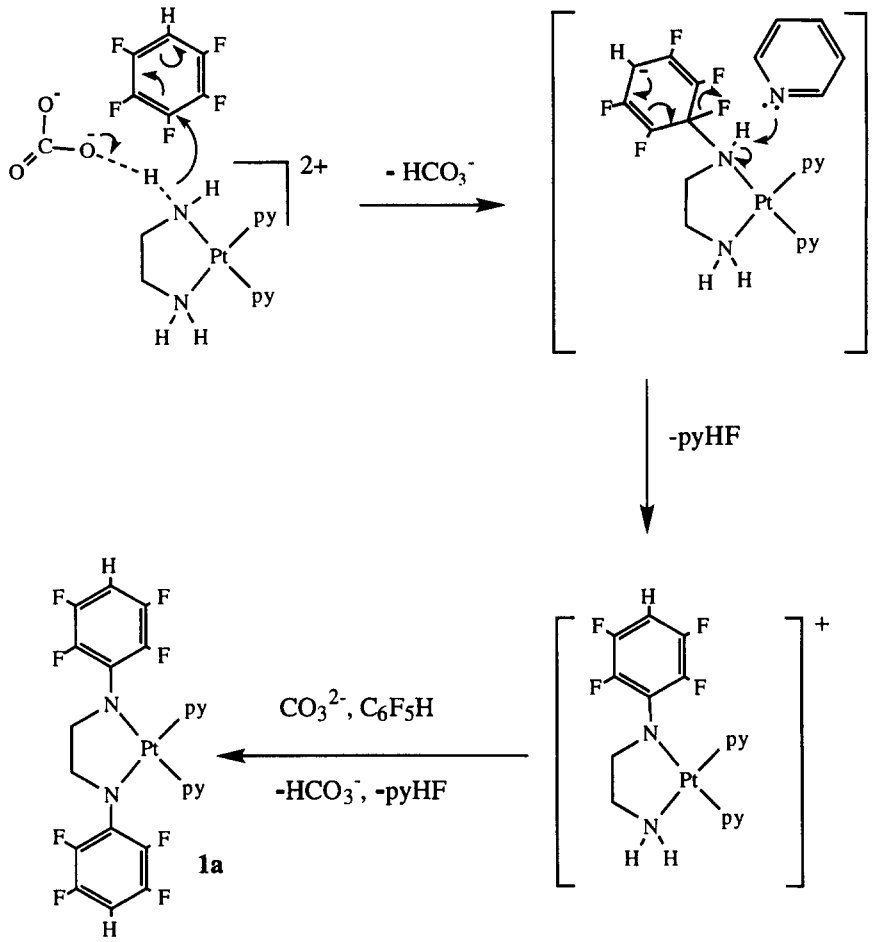
$$[Pt(en)(py)_2]CO_3 + Tl_2CO_3 \not\rightarrow [Pt(NHCH_2)_2(py)_2] + 2TlHCO_3 \quad (6)$$

This is demonstrated by the thermal decomposition of potassium bicarbonate in pyridine at 90–100°C.

$$2KHCO_3 \rightarrow H_2O + CO_2 + K_2CO_3 \quad (7)$$

In addition, $[Pt(en)Cl_2]$ does not react with C_6F_5H in pyridine in the absence of added base, e.g. CO_β^{2-} in the present systems. Thus a path involving displacement of a coordinated —NH_2 group of ethane-1,2-diamine by pyridine, and nucleophilic attack of the free —NH_2 on the polyfluoroarene can be excluded. Accordingly, we propose that hydrogen bonding between —NH_2 and CO_3^{2-}, e.g. in $[Pt(en)(py)_2]CO_3$, although insufficient to cause deprotonation (see reaction (6)), is strong enough to generate partial lone pair character on nitrogen and hence promote nucleophilic substitution in the polyfluoroarene, e.g. for C_6F_5H in Scheme 1.

Thus CO_2 evolution derives from thermal decomposition of HCO_3^- and reaction of pyridinium fluoride (Scheme 1) with CO_3^{2-} or HCO_3^-, e.g. $2pyHF + Tl_2CO_3 \rightarrow 2TlF + CO_2 + H_2O$. The plausibility of this reaction, which is consistent with pK_a values ($pyH^+ = 5.25$, $H_2CO_3 = 6.37$ and $HCO_3^- = 10.25$), was shown by CO_2 formation on

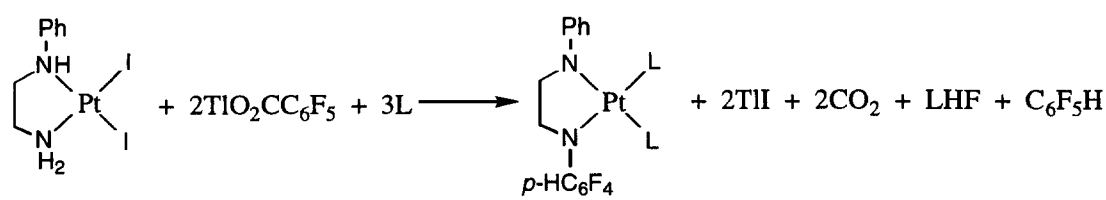


Scheme 1.

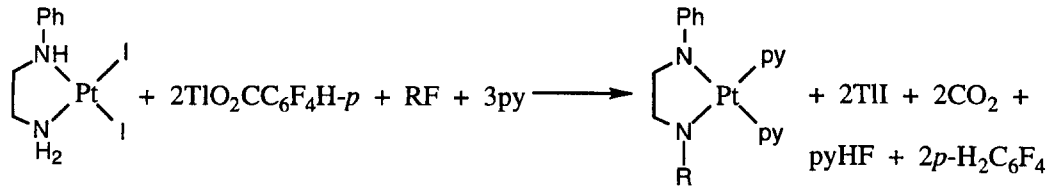
reaction of pyridinium mesitylenesulfonate with Tl_2CO_3 [18]. The proposed path explains the key observation that CO_2 evolution only occurs on addition of the polyfluoroarene. It is also consistent with a lower reaction temperature for reaction (3), RF = C_6F_5CHO, than for other polyfluoroarenes (Table 1), since the Meisenheimer intermediate (e.g. Scheme 1) can be stabilized by delocalization of charge onto the carbonyl oxygen. It is of interest that **1a** can also be prepared by reaction of $[Pt(en)Cl_2]$ with $KHCO_3$ and C_6F_5H in pyridine, but only at a temperature where decomposition of bicarbonate ions into carbonate, e.g. reaction (7), is observed.

Preparation of [N-(phenyl)-N′-(polyfluorophenyl) ethane-1,2-diaminato(2-)]dipyridineplatinum(II) complexes

Reactions utilizing thallium(I) polyfluorobenzoates or thallium(I) carbonate were also used to produce a new class of platinum(II) amides, namely [*N*-(phenyl) *N*′-(polyfluorophenyl)ethane-1,2-diaminato(2-)] dipyridineplatinum(II) complexes (eq. (8)–(10)). The complexes **2a–f** are light sensitive, especially when in solution, and great care was taken to minimize the exposure to light during their synthesis. Only three compounds, **2a–c**, were able to be synthesized by reac-

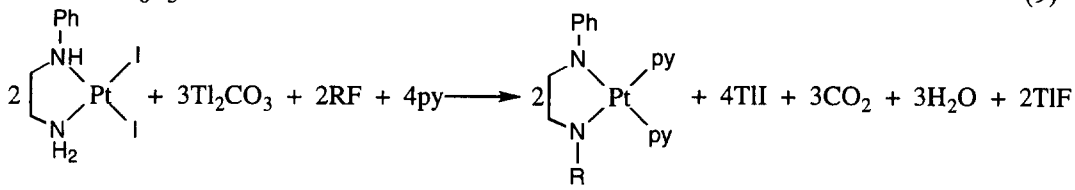


L= py **2a** or 4-methylpyridine (fmpy) **2b** (8)



$$+ 2TlO_2CC_6F_4H\text{-}p + RF + 3py \longrightarrow + 2TlI + 2CO_2 + pyHF + 2p\text{-}H_2C_6F_4$$

R=C_6F_5 **2c** (9)



$$2 + 3Tl_2CO_3 + 2RF + 4py \longrightarrow 2 + 4TlI + 3CO_2 + 3H_2O + 2TlF$$

R=*p*-HC_6F_4 **2a**, C_6F_5 **2c**, *p*-MeC_6F_4 **2d**, *p*-ClC_6F_4 **2e**, *p*-BrC_6F_4 **2f** (10)

tions (8) and (9). All attempts to obtain **2d** and **2f** by reaction (9) failed, whilst the preparation of **2c** by (9) was not reproducible. However, reaction (10) has been established as a general route by the successful syntheses of **2a** and **2c–2f**. When the preparation of **1a** was attempted with potassium carbonate, little CO_2 was evolved and no ether soluble products were formed. In general, it was observed that the reactions involving thallium(I) carbonate were cleaner and contained less dark coloured impurities than those involving thallium(I) polyfluorobenzoates (see Table 2). The syntheses (8)–(10) involve polyfluorophenylation of a single —NH_2 group by paths analogous to those for the two —NH_2 groups in reactions (1)—(3) respectively, together with the deprotonation of a coordinated —NHPh group.

All compounds (**2a–2f**) were obtained analytically pure. The infrared spectra of the complexes indicated the presence of the polyfluoroaromatic group by strong ν(CF) absorptions in the region 1000–900 cm^{-1}, as expected [1]. The presence of the monosubstituted phenyl group was indicated by strong characteristic absorptions at 749–746 cm^{-1} and 702–691 cm^{-1} for all complexes [19]. The electron impact mass spectra of the complexes **2a–2f** confirmed the presence of the organoamide and pyridine ligands, with $[PhNHCH_2CH_2NH(R)]^+$ as the highest observed peak in all spectra. The Fast Atom Bombardment mass spectrum of **2a** showed a protonated molecular ion. The UV-Vis spectra gave electronic absorption maxima and extinction coefficients in the range for platinum(II) polyfluorophenylamides [1]. Upon exposure to light, the absorption band weakened and insoluble decomposition products were formed.

Table 3. $^3J_{H,Pt}$ coupling constants (Hz) for **2a–2f**

Complex	CH_2NPh	H2,6(py) ppm	$^3J_{H,Pt}$	H2,6(py) ppm	$^3J_{H,Pt}$
2a	25	8.80	29	8.88	38
2b	—	8.59	32	8.69	23
2c	26	8.77	28	8.84	37
2d	—	8.83	29	8.86	35
2e	25	8.82	38	8.90	38
2f	—	8.82	29	8.89	38

The ^{19}F NMR chemical shifts of **2a–2f** were in good agreement with those calculated by use of substituent chemical shifts [1,20]. The ^1H NMR spectra revealed two different pyridine ligands and CH_2 groups, as expected from the unsymmetrical nature of the organoamide ligands. One CH_2 resonance is fairly constant (3.06–3.10 ppm) for all complexes **2a–2f** (Experimental Section), whilst the other resonance shows greater variation, 3.27–3.46 ppm. Thus, it can be concluded that the former is adjacent to the NPh group, whilst the latter is next to the varying NR group. The low frequency resonance is always a triplet as expected for CH_2 adjacent to the NPh group, whilst the other peak is always an unresolved complex multiplet since coupling is expected with *ortho*-fluorines in addition to the adjacent CH_2 group. The inequivalent pyridine ligands give overlapping, but distinctly recognizable *ortho* resonances. Only one resonance each is seen for the *meta* and *para* protons, but the peaks are unresolved multiplets in contrast to their usually well defined splitting patterns.

For **2a, 2c** and **2e**, ^{195}Pt satellites are observed on the resonance of the CH_2NPh group and the $^3J_{H,Pt}$ coupling constants (Table 3) approach the values for the CH_2 group in complexes of the type $[Pt\{N(R)CH_2\}_2(py)_2]$ (27–30 Hz) [1]. Approximate $^3J_{H,Pt}$ coupling constants can be determined from the overlapping H2,6 resonances of both pyridine ligands (Table 4). The larger, usually higher frequency values (32–38 Hz), which are similar to those of **1a–1e** (33–34 Hz) [1], may plausibly be assigned to the pyridine *trans* to —N(R) (R = polyfluorophenyl). However,

Table 4. Selected bond distances (Å) and angles (°) for **2d**

Pt—N(1)	1.991(5)	N(1)—Pt—N(2)	82.1(2)
Pt—N(2)	2.023(7)	N(1)—Pt—N(3)	173.7(3)
Pt—N(3)	2.042(5)	N(1)—Pt—N(4)	93.0(2)
Pt—N(4)	2.052(7)	N(2)—Pt—N(3)	94.0(2)
C(1)—N(1)	1.40(1)	N(2)—Pt—N(4)	175.1(2)
C(10)—N(2)	1.37(1)	N(3)—Pt—N(4)	90.9(2)
N(1)—C(8)	1.46(1)	C(1)—N(1)—C(8)	117.6(5)
N(2)—C(9)	1.47(1)	C(8)—N(1)—Pt	114.1(4)
		C(1)—N(1)—Pt	128.3(5)
		C(10)—N(2)—C(9)	118.6(6)
		C(9)—N(2)—Pt	107.8(3)
		C(10)—N(2)—Pt	127.1(4)

this must be qualified by the difficulty in resolving the overlapping satellites, the two high J values for **2e**, and inversion of the J value/frequency relationship with **2b**.

X-ray crystal structure of [Pt{N(Ph)CH_2CH_2N(*p*-MeC_6F_4)}$(py)_2$] **2d**

The molecular structure of [Pt{N(Ph)CH_2CH_2N(*p*-MeC_6F_4)}$(py)_2$] **2d** is displayed in Fig. 1. Crystallographic details are given in the Experimental Section, and selected bond distances and angles in Table 4. Two amide and two pyridine nitrogen donor atoms have an approximately square planar arrangement around platinum, with N—Pt—N bond angles (Table 4) distorted from 90°, the smallest being the bite angle of the chelating amide. The platinum centre is only 0.0411 Å out of the plane of donor atoms. The bond angles about the polyfluorophenylamide nitrogen N(1) (Σ360°) and phenylamide nitrogen N(2) (Σ354°) are distorted from tetrahedral (Σ328.5°) towards trigonal (Σ360°), indicative of substantial delocalization of the amide ion lone pair into the phenyl and polyfluorophenyl rings. This is confirmed by the bond distances between the amide nitrogens and carbon atoms of the polyfluorophenyl and phenyl groups, N(1)—C(1) = 1.40(1) and N(2)—C(10) = 1.37(1) Å, respectively, which are closer to N—C aromatic distances than to an N—C single bond length. Near triangular amide nitrogen stereochemistry and short N—C bond lengths, have also been observed in other fluorocarbon-stabilized platinum(II) amides [16], and in anilido-, *N*-phenylanilido and *N*-methylanilido-platinum(II) complexes, *trans*-[PtH(NHPh)$(PEt_3)_2$] [9], [PtCl$(NPh_2)(PEt_3)_2$] [21] and [PtMe(NMePh)$(Me_2PCH_2)_2$] [22], respectively. The Pt—N(py) bond distances (2.042(5), and 2.052(7) Å) are longer than in [Pt{N(*p*-HC_6F_4)CH_2}$_2$$(py)_2$] (1.98 Å) [16(a)] but comparable with those observed for other polyfluorophenylamidoplatinum(II) complexes (2.037–2.065 Å) [16(b)–16(d)]. No significant difference between the bond length *trans* to NPh or N(*p*-MeC_6F_4) is observed. The Pt—N(amide) bond distances (1.991(5) and 2.023(7) Å) are shorter than those observed for [Pt{N(*p*-HC_6F_4)CH_2}$_2$$(py)_2$] (2.08 Å) [16(a)], though in the range (1.995–2.017 Å) for other polyfluorophenylamidoplatinum(II) complexes [16(b)–16(d)]. The *p*-MeC_6F_4 and C_6H_5 rings are inclined at 56.2 and 47.9° respectively to the coordination plane, whilst the pyridines *trans* to NPh and N(*p*-MeC_6F_4) are inclined at 63.6° and 33.1° respectively, to the coordination plane, with a dihedral angle between the two pyridines of 67.2°. The larger inclination of the pyridine *trans* to NPh is due to the bulky *p*-MeC_6F_4 group *cis* to the pyridine.

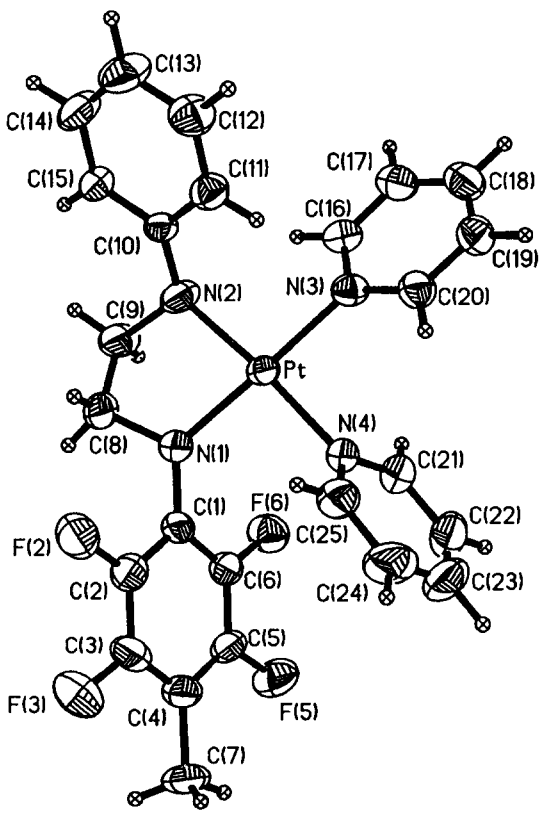


Fig. 1. The molecular structure of [Pt{N(Ph)CH_2CH_2N-(*p*-MeC_6F_4)}$(py)_2$] **2d**.

The new complexes **2** retain the stability to water observed for the complexes **1**, hence introduction of an NPh group does not create hydrolytic instability, although the complexes *trans*-[PtH(NHPh)$(PEt_3)_2$] [9], [PtCl$(NPh_2)(PEt_3)_2$] [21] and [PtMe(NMePh)$(Me_2PCH_2)_2$] [22] are moisture-sensitive. As judged by N—C(Ar) distances and sums of bond angles at amide nitrogen atoms, the extent of delocalization of the amide lone pair appears similar in water-stable and water-sensitive organoamidoplatinum(II) complexes (Table 4 and [9,16,21,22]). Possibly then, the origin of the water-stability of the polyfluorophenylamidoplatinum(II) complexes arises because the fluorocarbon substituents prevent release of electron density to the amide nitrogen on approach of an electrophile ($H^{\delta+}$ of water). However, electron release is

possible with unidentate phenylamide ligands. The stability of the Pt—NPh(CH_2—) bond of the complexes **2** by contrast with Pt—NMePh of [PtMe(NMePh)(Me_2PCH_2)$_2$] may derive from steric inhibition of the approach of water with the pyridine ligands and aryl groups substantially inclined to the coordination plane.

EXPERIMENTAL

General methods

Microanalyses were performed by Campbell Microanalytical Laboratories, University of Otago, New Zealand. Infrared spectra in the range 4000–650 cm^{-1} were recorded with a Perkin-Elmer 1600 F.T.I.R. spectrophotometer as Nujol and hexachlorobutadiene (HCB) mulls. ^1H and ^{19}F NMR spectra were recorded with a Bruker AM300 spectrometer; the solvent used was $(CD_3)_2CO$. Proton chemical shifts are referenced to internal tetramethylsilane and fluorine chemical shifts to internal trichlorofluoromethane. Mass spectra were recorded with a VG Micromass 7070F or VG-TRIO GC-Mass spectrometer. FAB mass spectra were recorded with a Kratos (AEI) MS30 mass spectrometer by Professor J. M. Miller, Brock University, Canada, using 3-nitrobenzyl alcohol as the matrix liquid. For platinum containing ions, clusters with the correct isotope pattern were observed. UV/Visible spectra were recorded with a Hitachi 150-20 spectrophotometer, the solvent being 95% ethanol. Molar (decadic) absorption coefficients are given in units of $dm^3\ mol^{-1}\ cm^{-1}$.

Solvents and reagents

Nitrogen gas was purified by passage through copper "catalyst" (BASF R3-11) and molecular sieves (4 Å). Diethyl ether was of anhydrous analytical grade. Light petroleum refers to the fraction boiling between 60–80°C. All pyridines were distilled and stored under nitrogen. Pyridine and 3-methylpyridine were refluxed over and distilled from potassium hydroxide pellets and stored over molecular sieves (4 Å). 4-Methylpyridine (fmpy) was dissolved in 20% (by volume) sulfuric acid when the non-basic impurities were removed by steam distillation. After addition of solid sodium hydroxide, fmpy was separated by decantation and then dried over and distilled from sodium hydroxide pellets. Literature methods were used to prepare thallium(I) pentafluorobenzoate [23], thallium(I) 2,3,5,6-tetrafluorobenzoate [23], potassium tetrachloroplatinate [24], dichloroethane-1,2-diamineplatinum(II) (by application [25(a)] of the Dhara method [25(b)]) and ethane-1,2-diaminedipyridineplatinum(II) chloride [26]. Polyfluoroaromatics were purchased from Bristol Organics, Imperial Smelting and Aldrich and were used without purification. Thallium(I) carbonate (Johnson Matthey) and *N*-phenylethane-1,2-diamine (Aldrich) were used without purification. Potassium and sodium carbonate were anhydrous and from Ajax chemicals.

Ethane-1,2-diaminedipyridine(II) carbonate

Ethane-1,2-diaminedipyridineplatinum(II) chloride (0.10 g, 0.20 mmol) was dissolved in water (10 cm^3) and freshly prepared silver(I) carbonate (0.60 g, 0.20 mmol) was added. The solution was stirred in the dark for 1 h. Silver chloride was filtered off and the filtrate was concentrated *in vacuo* until a precipitate formed. IR: 3417s(br), 3060s, 1647m, 1602m, *1458m*, 1448s, *1443s*, 1410w, 1370w, 1320w, 1157s, 1132m, 1073w, 1052s, 883w, 762m, 696m cm^{-1}. (Stretching frequencies italicized are assigned to ν(CO) of CO_3^{2-}.)

Diiodo(N-phenylethane-1,2-diamine)platinum(II)

Potassium iodide (8.8 g, 53 mmol) in water (10 cm^3) was stirred with a solution of K_2PtCl_4 (2.2 g, 5.3 mmol) in water (50 cm^3) for 1.5 h to give a dark brown solution. *N*-Phenylethane-1,2-diamine (0.8 g, 5.9 mmol) was added and the mixture stirred overnight. The resulting yellow precipitate was collected, washed with water, then resuspended in water (50 cm^3) and KI (5.0 g, 30 mmol) added. After 1 h the yellow solid was collected, washed with water, ethanol and ether and dried overnight under vacuum. Yield 2.8 g, 90%. m.p. 210–212°C (dec). Found: C, 16.9; H, 1.7; N, 5.1. $C_8H_{11}I_2N_2Pt$ requires: C, 16.4; H, 2.1; N, 4.8%. IR: 3219m, 3170w, 3127w, 1804w, 1634w, 1611s, 1492m, 1479m, 1415w, 1378w, 1197m, 1154m, 1075m, 1046s, 1022s, 780w, 759m, 721m, 693s cm^{-1}.

Syntheses of [N,N'-Bis(polyfluorophenyl)ethane-1,2-diaminato(2-)]dipyridineplatinum(II) complexes **1**

The compounds were prepared by three methods.

Method 1. Syntheses of complexes 1 using thallium (I), potassium or sodium carbonate. Dichloroethane-1,2-diamineplatinum(II) and thallium(I), potassium or sodium carbonate were placed in a Schlenk flask which was fitted with a condenser and connected to a barium hydroxide trap. The system was purged with nitrogen, and pyridine or a substituted pyridine and the appropriate polyfluoroaromatic compound were added by syringe. The mixture was then heated with stirring. The evolved CO_2 was swept into the barium hydroxide trap by nitrogen and was determined gravimetrically as $BaCO_3$ and the yields are given in Table 1. After the reaction was complete, the reaction mixture was cooled and the solvent removed *in vacuo*. The residue was stirred in light petroleum for at least 1 h, and the liquid was then decanted off. The residue was extracted with acetone which was filtered and concentrated *in vacuo* to 50 cm^3. Decolourizing char-

coal was added for complexes **1c, 1d** and **1i,** where the solutions were very dark. Light petroleum (20 cm^3) was added and evaporation continued until crystallization occurred, except for **1d,** which was crystallized from acetone alone, and **1h** and **1e,** where the acetone extract was evaporated to dryness. Products were recrystallized from acetone/light petroleum, except for **1c** (from Tl_2CO_3), **1d,** and **1e,** which were recrystallized from acetone, and **1h** and **1i,** which were purified by chromatography (below). Similar procedures were used for reactions with potassium and sodium carbonate. Reaction conditions and yields of products are indicated in Table 1. Complexes **1a–1g** were identified by the ^1H and ^{19}F NMR spectra, which were identical with those reported [1].

Method 2. Synthesis of **1a** *using potassium bicarbonate.* Dichloroethane-1,2-diamineplatinum(II), potassium bicarbonate, pyridine and pentafluorobenzene were stirred and heated under nitrogen. Work up was as for method 1. Conditions, amounts of reagents and the yield are given in Table 1.

Method 3. Synthesis of **1j** *using thallium(I) pentafluorobenzoate.* Dichloroethane-1,2-diamineplatinum (II), thallium(I) pentafluorobenzoate, 3-methylpyridine and pentafluorobenzene were stirred and heated under nitrogen. Work up was as for method 1. Conditions, amounts of reagents and the yield are given in Table 1.

[*N,N'-Bis*(2,3,5,6-*tetrafluoro*-4-*formylphenyl*)*ethane*-1,2-*diaminato*(2-)]*dipyridineplatinum(II)* **1h**

The crude black product was dissolved in a minimum of 1:1 acetone/light petroleum and passed through a neutral alumina column with elution by 1:1 acetone/light petroleum. The first yellow-orange band was collected, the solvent partly evaporated and more light petroleum added. Cooling at −10°C overnight gave orange-red crystals. m.p. 226–227°C (dec). Found: C, 41.0; H, 1.9; N, 7.4. $C_{26}H_{16}F_8N_4O_2Pt$ requires: C, 40.9; H, 2.1; N, 7.3%. ^{19}F NMR: −151.0, m, 4F, F3,5; −153.7, m, 4F, F2,6. ^1H NMR: 3.54, s with ^{195}Pt satellites $^3J_{H,Pt}$ 26 Hz, 4H, CH_2; 7.42, t, 4H, H3,5 (py); 7.96, t, 2H, H4 (py); 8.76, d with ^{195}Pt satellites $^3J_{H,Pt}$ 36 Hz, 4H, H2,6 (py); 9.79, s, 2H, CHO. UV/Visible spectrum: 430 nm (ε 71.4×10^3). [*N,N'-Bis*(2,3,5,6-*tetrafluoro*-4-*methoxyphenyl*)*ethane*-1,2-*diaminato*(2-)]-*dipyridineplatinum(II)* **1i**

The crude product was dissolved in acetone and passed through a neutral alumina column. The first yellow-orange band was collected, and the solution was concentrated *in vacuo* until a precipitate formed. The product which contained impurities was isolated. ^{19}F NMR: −153.3 d, 4F, F(2,6); −163.0 d, 4F, F(3,5). ^1H NMR: 3.08, s with ^{195}Pt satellites $^3J_{Pt,H}$ 27 Hz, 4H, CH_2; 3.76, s, 6H, CH_3; 7.25, t, 4H, H3,5 (py); 7.83, t, 2H, H4 (py); 8.61, s with ^{195}Pt satellites $^3J_{Pt,H}$ 30 Hz, 4H, H2,6 (py).

[*N,N'-Bis*(2,3,5,6-*tetrafluorophenyl*)*ethane*-1,2-*diaminato*(2-)]*di*(3-*methylpyridine*)*platinum(II)* **1j**

This complex was prepared both from Tl_2CO_3 and from $TlO_2CC_6F_5$ (Table 1). m.p. 160–161°C (dec). Found: C, 42.3; H, 2.6; N, 7.8. $C_{26}H_{20}F_8N_4Pt$ requires: C, 42.5; H, 2.7; N, 7.6%. ^{19}F NMR: −144.8, m, 4F, F3,5; −150.6, m, 4F, F2,6. ^1H NMR: 2.15, s, 6H, CH_3; 3.16, s with ^{195}Pt satellites $^3J_{H,Pt}$ 27 Hz, 4H, CH_2; 6.28, tt, 2H, *p*-HC_6F_4; 7.12, t, 2H, H5 (py); 7.64, d, 2H, H4 (py); 8.35, d, 2H, H6 (py); 8.50, d with ^{195}Pt satellites $^3J_{H,Pt}$ 38 Hz, 2H, H2 (py). UV/Visible spectrum: 358 nm (ε 9.0×10^3). IR: 2925w, 2902w, 2849w, 1634s, 1579m, 1496vs, 1474vs, 1445s, 1335m, 1283w, 1166w, 1149m, 1126vs, 1088m, 1044w, 982w, 926vs, 882m, 805m, 770m, 705w cm^{-1}. Mass spectrum: *m/z* 735 [1.9%, M^+]; 380 [1.9%, $C_{12}H_{13}N_2Pt^+$]; 354 [4%, $C_{14}H_6F_8N_2^+$]; 288 [1%, $C_6H_7NPt^+$]; 93 [100%, 3-$Mepy^+$].

Reaction path studies

Thermal stability of thallium(I) carbonate in pyridine. Thallium(I) carbonate (0.94 g, 2.0 mmol) was heated with stirring in pyridine at 115°C for 6.25 h. No CO_2 evolution was evident.

Attempted reaction of thallium(I) carbonate and pentafluorobenzene. Thallium(I) carbonate (2.0 mmol) and pentafluorobenzene (18.0 mmol) were heated in pyridine at 110°C for 1 h under nitrogen. No CO_2 evolution was evident and thallium(I) carbonate was recovered.

Attempted reaction of [*Pt*(*en*)*Cl*$_2$], *pentafluorobenzene and pyridine.* [Pt(en)Cl_2] (1.0 mmol), pentafluorobenzene (18.0 mmol) and pyridine (10 cm^3) were heated at 110°C for 1 h. No reaction was evident. No ether soluble products were obtained and only starting material was identified by infrared spectroscopy.

Reaction of [*Pt*(*en*)*Cl*$_2$], *Tl*$_2$CO$_3$, and pyridine. [Pt(en)Cl_2] (1.0 mmol), Tl_2CO_3 (2.0 mmol) and pyridine (10 cm^3) were heated at 110°C for 1 h. Only a slight liberation of CO_2 was evident. A sample of the insoluble material was isolated and its infrared spectrum was shown to be identical with that of [Pt(en)$(py)_2$]CO_3. Pentafluorobenzene was then added at 110°C producing CO_2 almost immediately. The reaction mixture was heated and stirred for an additional 30 min. Work up as for method 1 produced **1a** (30%), and CO_2 (70%).

Synthesis of **1a** *from ethane-1,2-diaminedipyridineplatinum(II) carbonate.* Ethane-1,2-diaminedipyridineplatinum(II) carbonate (0.10 g, 0.20 mmol) and pentafluorobenzene (1.0 cm^3, 9.0 mmol) were stirred in toluene (10 cm^3) at 110 °C for 1 h under nitrogen. Only a trace amount of CO_2 was detected. Pyridine (5 cm^3) was added at 110 °C and CO_2 was evolved. The resulting yellow reaction mixture was heated and stirred for a further 3 h. Work up was as for method 1 and yielded **1a,** as well as unreacted $[Pt(en)(py)_2]CO_3$.

Syntheses of [N-Phenyl-N′-(polyfluorophenyl)ethane-1,2-diaminato(2-)]dipyridineplatinum(II) complexes **2**

From thallium(I) penta- or 2,3,5,6-tetra-fluorobenzoate or thallium(I) carbonate. Diiodo(*N*-phenylethane-1,2-diamine)platinum(II), thallium(I) penta- or 2,3,5,6-tetra-fluorobenzoate or carbonate, and a polyfluorobenzene were reacted together in pyridine or 4-methylpyridine as in method 1 for $[Pt\{N(R)CH_2\}L_2]$ complexes. Yields of CO_2 were approximately quantitative for successful reactions. After reaction, the solvent was removed under vacuum. The residue was stirred in light petroleum for at least 1 h, and then extracted with ether, the solution being protected from the light at all times. The filtered ether extract was concentrated under reduced pressure to 50 cm^3. Light petroleum (20 cm^3) was added and evaporation continued until crystallization occurred. Reaction conditions and yields are indicated in Table 2. $^3J_{H,Pt}$ coupling constants are given in Table 3. Where the same complex was obtained from more than one reaction, the products had identical spectroscopic properties.

A similar procedure was used in the attempted synthesis of **2a** with potassium carbonate as the reagent. Little CO_2 evolution was observed, and no ether soluble products were obtained.

CRYSTALLOGRAPHY

Crystal Data for [Pt{N(Ph)CH_2CH_2N(*p*-MeC_6F_4)}$(py)_2$] **2d**

$PtC_{25}H_{22}F_4N_4$; *fw* = 649.6 g/mol; Monoclinic, space group $P2_1/c$. a = 13.845(3), b = 9.790(3), c = 18.405(6) Å; β = 110.73(1)°; V = 2333(1) Å^3, D_c = 1.85 g/cm^3; Z = 4; $F(000)$ = 1256; μ = 61.26 cm^{-1} for Mo-K_α radiation (λ = 0.71073 Å); 293(1) K. Cell parameters were determined from 24 accurately centred reflections measured between $24° < 2\theta < 30°$ and were calculated by the standard Philips program.

Structure determination

A representative yellow-orange acicular crystal of approximate dimensions ($0.10\times0.15\times0.30$ mm) was used for data collection. Intensity measurements were made on a Philips PW1100 diffractometer using graphite monochromated Mo-K_α radiation $6° < 2\theta \leqslant 60°$, operating in an ω scan mode with a symmetric scan range of $\pm(0.80+0.2\tan\theta)°$ in ω from the calculated Bragg scattering angle at a scan rate of 0.03° sec^{-1}. A total of 6800 unique data were collected ($\pm h$, $+k$, $+l$), 3408 of which were considered to be observed [$F \geqslant 6\sigma(F)$], and used in the final refinement. Three standard reflections monitored every 4 h showed no significant variation in intensity over the data collection period. Intensity data were processed as described previously [27]. A face-indexed numerical absorption correction was applied [28], on six crystal faces, the maximum and minimum transmission factors being 0.583 and 0.390, respectively. The atomic scattering factors for neutral atoms were taken from [29] and were corrected for anomalous dispersion by using values from [29]. All calculations were performed on a VAX 6250 computer. The program used for least-squares refinement was that due to Sheldrick [28].

The structure was solved by conventional Patterson and Fourier methods. Final refinement was full-matrix least-squares employing anisotropic thermal parameters for all non hydrogen atoms (single isotropic thermal parameter for hydrogen fixed at 0.08 Å^2—positioned in geometrically idealized positions: C—H 0.96 Å). At convergence (308 variables, 3408 observed data) R was 0.036 and wR 0.035 where

$$wR = \Sigma(|F_o| - |F_c|)\omega^{1/2}/\Sigma|F_o|\omega^{1/2}$$

and $\omega = [\sigma^2(F_o)]^{-1}$. The goodness of fit value $([\Sigma\omega(|F_o| - |F_c|)^2/(N_{observ.} - N_{params.})]^{1/2})$ was 1.29.

The synthesis of olefin, carbonyl and thiolate complexes of platinum(IV) in the [(η^5-C_5Me_5)Pt(IV)] system. Crystal and molecular structure of (η^5-C_5Me_5)$PtMe_2$[S(p-$CH_3(C_6H_4)$)]†

William A. Howard and Robert G. Bergman

Department of Chemistry, University of California, Berkeley, CA 94720, USA

(Received 9 June 1997; accepted 1 July 1997)

Abstract—A number of Cp*$PtMe_2X$ and Cp*$PtMe_2(L)^+(OTf)^-$ complexes have been prepared [Cp* = η^5-C_5Me_5; OTf = OSO_2CF_3; X = OTf, I, N_3, S(*p*-tol); L = CO, C_2H_4, CH_2=CHMe, NH_3, NH_2Bu^t]. The complexes Cp*$PtMe_2(CO)^+(OTf)^-$, Cp*$PtMe_2(C_2H_4)^+(OTf)^-$, and Cp*$PtMe_2(CH_2$=$CHMe)^+(OTf)^-$ represent a rare type of compound in which a π acid ligand is coordinated to a high valent metal center predominantly through σ-donation and π-backbonding plays only a limited role in the metal–ligand interaction. The arylthiolate complex, Cp*$PtMe_2$[S(*p*-tol)], has been structurally characterized by X-ray diffraction. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: platinum; Pt(IV); pentamethylcyclopentadienyl; alkene; azide; carbonyl; thiolate; azide; triflate complexes.

Although alkoxide complexes of platinum(II) have been well-studied [1], such derivatives of platinum(IV) are much rarer [2], and so the chemistry and the physical properties of these compounds have not been thoroughly examined. Bradley has done extensive work on the use of metal alkoxides as precursors for the deposition of metal oxides [3], and we have recently described the use of volatile *cis*-bis(η^2,η^1-pent-4-en-1-yl)platinum in the deposition of pure thin platinum films [4]. We sought to synthesize various alkoxide derivatives of platinum(IV) in order to study their fundamental chemistry and to examine their potential as precursors in chemical vapor deposition.

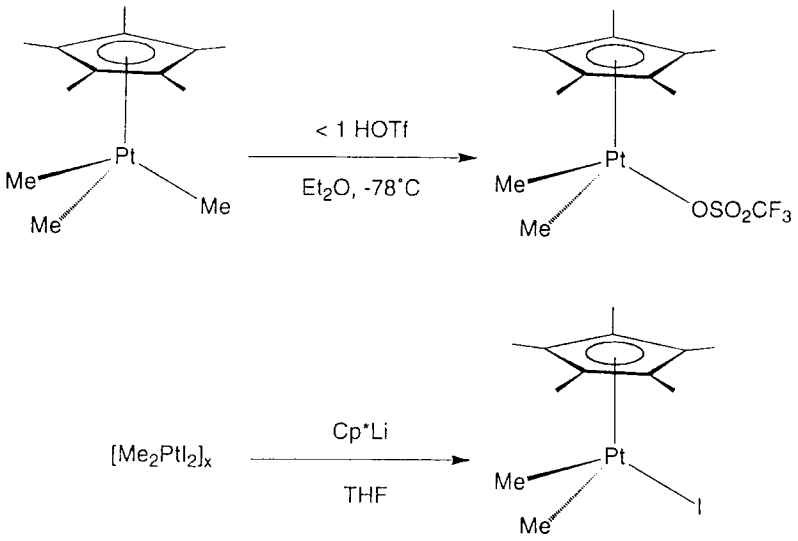
The pentamethylcyclopentadienyl ligand (*abbr.* Cp*) has been used to stabilize a variety of alkoxo and amido derivatives of the late transition metals such as Cp*$Ir(PPh_3)(OEt)(H)$ [5] and Cp*$Ni(PMe_3)(NH(p\text{-tol}))$ [6], but this ligand has not been used extensively in platinum chemistry. In fact, only seven [Cp*Pt] compounds had been reported in the literature before 1990 [7]. Since platinum(IV) complexes are invariably six-coordinate, the three-coordinate monovalent Cp* ligand seems ideally suited as an ancillary ligand for stabilizing alkoxide derivatives of Pt(IV). Useful synthetic routes into [Cp*Pt(IV)] compounds were provided independently by the research groups of Sharp [8] and Roesky [9] in 1990. These researchers described a number of [Cp*Pt(IV)] derivatives with halide and methyl ligands, but [Cp*Pt(IV)] complexes with oxygen-, nitrogen-, or sulfur-based ligands were not reported.

The goals of this work are to synthesize new derivatives of [Cp*Pt(IV)] having bonds between Pt and electronegative atoms such as O, S and N and to study the physical and chemical properties of these compounds. Although we have not been able to isolate and fully characterize simple Cp*-substituted platinum alkoxides or aryloxides, we have found the Cp* ligand to be useful for stabilizing several unusual [Pt(IV)-ligand] moieties, including some with Pt—O and Pt—S bonds. Platinum(IV) complexes with triflate, olefin, carbonyl, and arylthiolate functional groups have been isolated and are described herein.

RESULTS AND DISCUSSION

As shown in Scheme 1, Cp*$PtMe_2(OTf)$ (OTf = OSO_2CF_3) may be isolated as an air-stable,

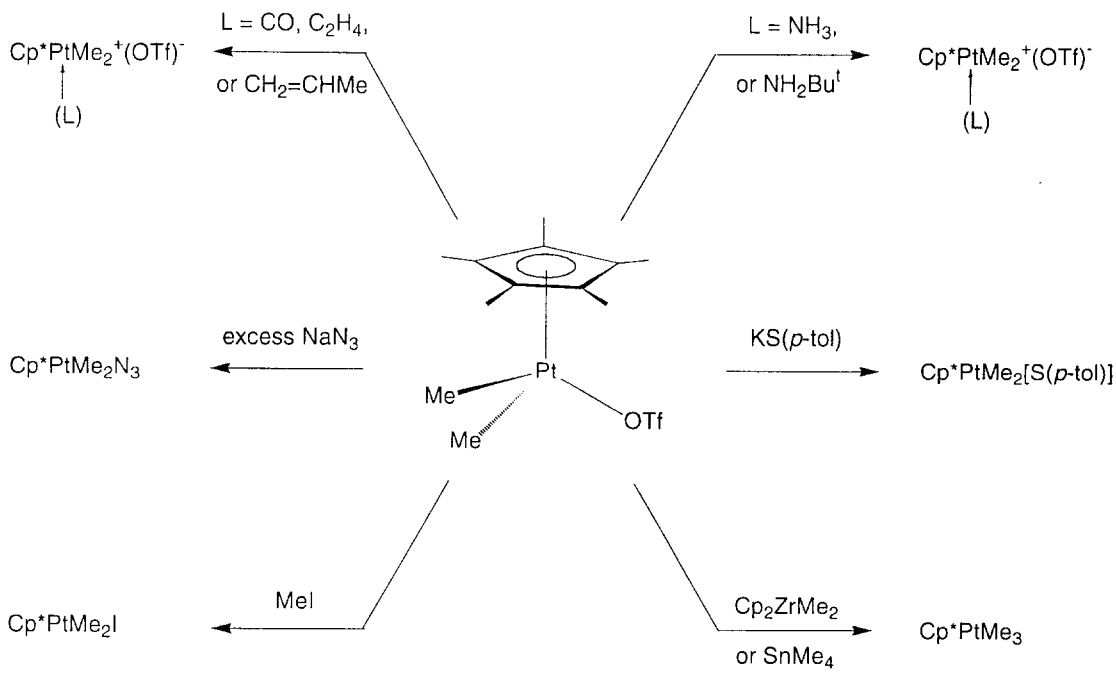
† Dedicated to Professor Donald C. Bradley, whose research has greatly influenced much of the work that has gone on in our group during the past several years.



Scheme 1.

bright orange crystalline solid in greater than 90% yield by reaction of Cp^*PtMe_3 [9] with slightly less than one equivalent of trifluoromethanesulfonic acid (i.e., triflic acid) at −78°C. Using more triflic acid only results in a lower yield of $Cp^*PtMe_2(OTf)$. The presence of the triflate ligand in $Cp^*PtMe_2(OTf)$ is confirmed by a singlet in the ^{19}F NMR spectrum (CD_2Cl_2) at −15.8 ppm and by very strong absorptions at 1294 cm^{-1}, 1250 cm^{-1}, 1176 cm^{-1}, and 1032 cm^{-1} in the infrared spectrum [10]. Also shown in Scheme 1 is the synthesis of Cp^*PtMe_2I, which may be isolated in 59% yield as an air-stable, reddish orange solid from the reaction of $[Me_2PtI_2]_x$ with Cp*Li at room temperature, similar to Sharp's synthesis of Cp^*PtMe_2Br [8].

The results of investigating the reactivity of $Cp^*PtMe_2(OTf)$ are illustrated in Scheme 2. The triflate ligand is easily displaced from the platinum center in $Cp^*PtMe_2(OTf)$ by various dative ligands (L) such as C_2H_4, CH_2=CHMe, Co, NH_3, and



Scheme 2.

NH_2Bu^t to afford the salts $Cp^*PtMe_2(L)^+(OTf)^-$, all of which may be isolated in ca. 85–95% yields. The bound ethylene ligand in $Cp^*PtMe_2(C_2H_4)^+(OTf)^-$ has resonances in the ^1H NMR spectrum at 3.71 ppm (s, $^2J_{Pt-H} = 52$ Hz) and in the $^{13}C\{^1H\}$ NMR spectrum at 72.3 ppm (s, $^1J_{Pt\,C} = 101$ Hz). The carbonyl ligand of $Cp^*PtMe_2(CO)^+(OTf)^-$ is characterized by a ν_{CO} stretching frequency of 2114 cm^{-1} in the infrared spectrum and by a singlet at 155.9 ppm in the $^{13}C\{^1H\}$ NMR spectrum (CD_2Cl_2). Ethylene coordination and carbon monoxide coordination to $Cp^*PtMe_2(OTf)$ are reversible, so that $Cp^*PtMe_2(OTf)$ may be regenerated simply by evaporating a solution of $Cp^*PtMe_2(L)^+(OTf)^-$ (L = C_2H_4, CO) to dryness. Both $Cp^*PtMe_2(NH_3)^+(OTf)^-$ and $Cp^*PtMe_2(NH_2Bu^t)^+(OTf)^-$ are stable under reduced pressure, however.

The π acidic carbonyl and olefin ligands in $Cp^*PtMe_2(L)^+(OTf)^-$ (L = CO, C_2H_4, CH_2=CHMe) are coordinated to cationic platinum (IV) centers. To our knowledge, only a handful of platinum(IV) carbonyl complexes [11–13] and only one other platinum(IV) olefin derivative [14] have been reported previously. In $Cp^*PtMe_2(L)^+(OTf)^-$ (L = CO, C_2H_4, CH_2=CHMe), the carbonyl and olefin ligands are bound to the platinum centers primarily through σ donation, and very little, if any, π backbonding is expected [15]. Indeed, the ν_{CO} stretching frequency in $Cp^*PtMe_2(CO)^+(OTf)^-$ is much higher than those for some Pt(II)carbonyl derivatives (1968–2044 cm^{-1}) and intermediate between those of other platinum(IV) carbonyl compounds (2060–2191 cm^{-1}) (see Table 1). Nevertheless, the ν_{CO} value for $Cp^*PtMe_2(CO)^+(OTf)^-$ is lower than 2143 cm^{-1}, the stretching frequency for free CO [16], which indicates that some degree of π backbonding does stabilize the [Pt—CO] bond.

In the absence of a dative trapping ligand, $Cp^*PtMe_2(OTf)$ slowly decomposes at room temperature to a mixture of compounds, one component of which is Cp^*PtMe_3. Presumably Cp^*PtMe_3 is formed when $Cp^*PtMe_2(OTf)$ abstracts a methyl group from another molecule of $Cp^*PtMe_2(OTf)$. Qualitatively, the rate of thermal decomposition is solvent dependent; $Cp^*PtMe_2(OTf)$ decomposes faster in THF than in benzene.

Table 1. ν_{CO} Stretching frequencies for carbonyl complexes of platinum(IV) and [Cp*Pt(II)]

Compound	ν_{CO} (cm^{-1})	Reference
$[PtCl_5(CO)]^-$	2191	12
$Cp^*PtMe_2(CO)^+(OTf)$	2114	this work
fac-$[Pt(I)(Me)_3(SMe_2)(CO)]$	2090	13
[Pt(Me)(I)(Cl)(py)(CO) $\{CH(py)CH_2CH_3\}]^+(Cl)^-$	2060	11
Cp*Pt(CO)(Cl)	2044	7c
Cp*Pt(CO)Pt(CO)Cp	2005, 1984	7c
$[Cp^*Pt(CO)]_2$	1989, 1968	7c

The formation of Cp^*PtMe_3 in the thermal degradation of $Cp^*PtMe_2(OTf)$ suggests that the electrophilic $Cp^*PtMe_2(OTf)$ has an affinity for methyl groups. Indeed, $Cp^*PtMe_2(OTf)$ can also abstract a methyl group from either Cp_2ZrMe_2 (Cp = η^5-C_5H_5) or $SnMe_4$ immediately to yield Cp^*PtMe_3 [17], but there is no reaction with $SiMe_4$.

$Cp^*PtMe_2(OTf)$ also demonstrates an affinity for halides and pseudohalides. Thus, treatment of a benzene solution of $Cp^*PtMe_2(OTf)$ with MeI slowly yields Cp^*PtMe_2I and MeOTf [18] within three hours at room temperature; no reaction was observed, however, between $Cp^*PtMe_2(OTf)$ and PhBr [19]. $Cp^*PtMe_2(OTf)$ readily reacts with excess NaN_3 in THF to yield $Cp^*PtMe_2N_3$, which exhibits a very strong $\nu(N_3)$ absorption in the infrared spectrum at 2008 cm^{-1} [20].

Sharp has indicated that the reaction of Cp^*PtMe_2Br with $LiNHBu^t$ only gives back the starting materials in low yields with no tractable products [8]. We reasoned that $Cp^*PtMe_2(OTf)$ may serve as a more useful precursor for amide and alkoxide derivatives of [Cp*Pt(IV)] since the triflate ligand is a better leaving group than the bromide ligand. A red solid, tentatively characterized as $Cp^*PtMe_2(OPh)$ [21], may be isolated by treating Cp*PtMe(OTf) with LiOPh in Et_2O at −78°C, but the yield is low and some other [Cp*Pt] by-products, one of which is Cp^*PtMe_3, are also formed.

Both $Cp^*PtMe_2(OTf)$ and Cp^*PtMe_2I react cleanly, however, with the sulfur-based nucleophile KS(*p*-tol) to afford $Cp^*PtMe_2[S(p\text{-tol})]$, which has been characterized by X-ray diffraction. An ORTEP diagram is shown in Fig. 1 while relevant crystallographic and metrical data are given in Tables 2 and 3. The X-ray study revealed the [Pt—S] bond length of 2.344(1) Å to be similar to the sum of the covalent radii (2.35 Å) of six-coordinate platinum(IV) (1.31 Å) and sulfur (1.04 Å) [22], and the [Pt—S—C] bond angle to be 108.4(2)°. With a maximum difference of 0.043(6) Å, there is little variation among the five aromatic [C—C] bond lengths in the Cp* ligand, contrasting with the structure of Cp^*PtMe_2Cl in which the Cp* ligand shows a small deviation toward "diene-like" geometry [9].

Although we are unaware of any other structurally characterized arylthiolate complexes of platinum(IV) with two-coordinate sulfur atoms, the cubic complex $[PtMe_3(\mu\text{-}SPh)]_4$, which contains four-coordinate sulfur atoms, has been structurally characterized [23]. The average [Pt—S] bond length [2.506(5) Å] and the average [Pt—S—C] bond angle [118.1(7)°] in $[PtMe_3(\mu\text{-}SPh)]_4$ are longer and greater, respectively, than those in $Cp^*PtMe_2[S(p\text{-tol})]$, which may be attributed to differences in the coordination numbers of the sulfur atoms. Some arylthiolate complexes of platinum(II) with two-coordinate sulfur atoms have been structurally characterized [24,25], and the

geometry of the [Pt—S—C] moieties in these compounds is similar to that of Cp*PtMe$_2$[S(*p*-tol)]. For example, the [Pt—S] bond length in [Cp(CO)Mn{μ-C(PMe$_3$) C$_6$H$_4$Me}Pt(*p*-tol)(PMe$_3$)] is 2.365(3) Å and the [Pt—S—C] bond angle is 109.3(3)° [26].

EXPERIMENTAL DETAILS

General considerations

Unless otherwise noted, all reactions and manipulations were carried out under nitrogen using standard Schlenk and vacuum techniques or in a Braun inert atmosphere box (N_2). Infrared spectra were taken on a Mattson Galaxy 3000—Fourier Transform Infrared spectrometer (FTIR). All ^{1}H, ^{13}C{^{1}H}, and ^{19}F NMR spectra were obtained at room temperature on a Bruker AMX-400 spectrometer at the frequencies 400 MHz, 100.6 MHz, and 376.5 MHz, respectively. ^{19}F NMR spectra were referenced externally to trichlorofluoromethane. Elemental analyses were performed by the University of California-Berkeley Microanalytical facility on a Perkin Elmer 2400 series II CHNO/S Analyzer. The single crystal X-ray analysis of Cp*PtMe$_2$[S(*p*-tol)] was carried out by Dr Frederick J. Hollander at the University of California, Berkeley X-ray facility.

Unless otherwise noted, reagents were purchased from commercial suppliers and used without further purification. Hexanes, pentane, diethyl ether, tetrahydrofuran, benzene, and toluene were distilled from sodium/benzophenone ketyl under N_2 prior to use. Methylene chloride was distilled from CaH_2 under N_2. $(Me_2PtI_2)_x$ [27], Cp*PtMe$_3$ [9], Cp*Li [28], and Cp_2ZrMe_2 [29] were synthesized according to published procedures. KS(*p*-tol) was synthesized by

treating a hexane solution of KH with a hexane solution of $HSC_6H_4CH_3$ and was recrystallized from hexane at $-35°C$.

Cp*PtMe$_2$(OTf)

Under N_2, a $-78°C$ solution of HOTf (260 μl, 2.94 mmol) in Et_2O (10 ml) was added slowly by cannula to a stirred solution of Cp*PtMe$_3$ (1.22 g, 3.25 mmol) in Et_2O (20 ml) which was immersed in a $-78°C$ bath. The mixture, which turned orange immediately, was allowed to warm to room temperature and stirred for 15 min. The volatile components were removed *in vacuo*, leaving a dark orange residue. The remainder of this procedure was carried out in the air. The product was extracted into C_6H_6 (10 ml), and the black extract was passed through a fritted column containing silanized silica (60 Å). The column was washed with C_6H_6 until the washes were colorless, and all washes were combined with the original filtrate. The volatile components of the bright orange filtrate were removed *in vacuo* leaving an orange crystalline solid which was washed with pentane (2×10 ml portions) and vacuum-dried. Yield: 1.41 g (94% based on HOTf). Anal. Calc. for $C_{13}H_{21}F_3O_3SPt$: C, 30.65%; H, 4.15%. Found: C, 30.45%; H, 4.42%. IR (KBr pellet, cm^{-1}): 2960 (m), 2897 (m), 2854 (w), 2802 (w), 1628 (w), 1527 (m), 1483 (w), 1452 (s), 1383 (s), 1350 (m), 1294 (vs), 1250 (vs), 1176 (vs), 1076 (w), 1032 (vs), 957 (w), 835 (m), 798 (w), 768 (m), 644 (vs), 615 (w) 582 (m), 548 (w), 521 (m). ^1H NMR (CD_2Cl_2): δ 1.79 ppm [s, 15 H, $\{\eta^5\text{-}C_5(CH_3)_5\}$, $^3J_{Pt\text{-}H} = 21$ Hz]; δ 1.40 ppm [s, 6 H, $2\{CH_3\}$, $^2J_{Pt\ H} = 70$ Hz]. ^{19}F NMR (CD_2Cl_2): -15.8 ppm [s]. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): 7.3 ppm [s, 2 C, 2 $\{CH_3\}$, $^1J_{Pt\text{-}C} = 724$ Hz]; 8.8 ppm [s, 5 C, $\{\eta^5\text{-}C_5(CH_3)_5\}$]; 109.3 ppm [s, 5 C, $\{\eta^5\text{-}C_5(CH_3)_5\}$, $^1J_{Pt\ C} = 40$ Hz]; 119.0 ppm [q, 1 C, $\{OSO_2CF_3\}$, $^1J_{C\text{-}F} = 312$ Hz].

Cp*PtMe$_2$I

A mixture of Cp*Li (0.17 g, 1.22 mmol) and $(Me_2PtI_2)_x$ (0.50 g, 1.05 mmol) in THF (5 ml) was stirred at room temperature overnight (ca 12 h). The volatile components were removed *in vacuo* leaving a dark brown–black residue. The remainder of this procedure was carried out in the air. The product was extracted from the dark residue with C_6H_6 (10 ml) and the extract was passed through a fritted column containing silica gel (60 Å particles). The silica column was washed with C_6H_6 until the washes were colorless, and these washes were combined with the initial C_6H_6 extract. The volatile components of the filtrate were removed *in vacuo* leaving a reddish orange crystalline solid which was washed with pentane (10 ml) at $-78°C$ and vacuum-dried. Yield: 0.30 g (59%). Anal. Calc. for $C_{12}H_{21}IPt$: C, 29.58%; H, 4.34%. Found: C, 29.47%; H, 4.42%. IR (KBr pellet, cm^{-1}): 2976 (s), 2958 (s), 2893 (vs), 2852 (m), 2721 (w), 1522 (s), 1493 (m), 1443 (vs), 1427 (s), 1377 (vs), 1350 (s), 1225 (vs), 1200 (m), 1153 (s), 1074 (w), 1022 (vs), 953 (w), 833 (w), 793 (w), 609 (w), 544 (m). ^1H NMR (CD_2Cl_2): δ 1.87 ppm [s, 15 H, $\{\eta^5\text{-}C_5(CH_3)_5\}$, $^3J_{Pt\text{-}H} = 14$ Hz]; δ 1.19 ppm [s, 6 H, 2 $\{CH_3\}$, $^2J_{Pt\text{-}H} = 81$ Hz]. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): -6.1 ppm [s, 2 C, 2 $\{CH_3\}$, $^1J_{Pt\text{-}C} = 678$ Hz]; 8.6 ppm [s, 5 C, $\{\eta^5\text{-}C_5(CH_3)_5\}$]; 107.0 ppm [s, 5 C, $\{\eta^5\text{-}C_5(CH_3)_5\}$, $^1J_{Pt\text{-}C} = 20$ Hz].

Cp*PtMe$_2$(C$_2$H$_4$)(OTf)

C_2H_4 (1 atm) was admitted to a Schlenk tube containing an orange, homogeneous solution of Cp*PtMe$_2$(OTf) (0.30 g, 0.59 mmol) in C_6H_6 (5 ml). The mixture, which immediately became cloudy and off-white, was stirred 5 min. at room temperature. The reaction mixture was then allowed to settle and the supernatant was decanted off the off-white product. The product was washed with benzene (2×5 ml) and pentane (1×10 ml) and dried by exposure to a gentle stream of air. Yield: 0.29 g (91%). Anal. Calc. for $C_{15}H_{25}F_3O_3SPt$: C, 33.52%; H, 4.69%. Found: C, 33.39%; H, 4.72%. $Cp^*PtMe_2N_3$

At -35°C, THF (3 ml) was added to a mixture of $Cp^*PtMe_2(OTf)$ (0.18 g, 0.35 mmol) and NaN_3 (0.12 g, 1.80 mmol). The mixture was stored at -35°C for 30 min. and then allowed to warm to room temperature and stirred for 20 min. The volatile components were removed *in vacuo* and the product was extracted from the solid residue into pentane (2 × 10 ml, 4 × 5 ml). The first extract was orange and the final extract was colorless. The extracts were filtered and combined. The filtrate was concentrated under reduced pressure so that the volume was approx. $\frac{1}{2}$ the original volume. The product, an orange crystalline solid, was crystallized from this concentrated pentane solution at -78°C, isolated by filtration, and dried *in vacuo*. Yield: 0.06 g (41%). Anal. Calc. for $C_{12}H_{21}N_3Pt$: C, 35.82%; H, 5.26%; N, 10.44%. Found: C, 35.42%; H, 5.23%; N, 9.99%. IR (KBr pellet, cm^{-1}): 2974 (s), 2960 (s), 2897 (s), 2812 (m), 2008 (vs), 1518 (s), 1446 (vs), 1431 (vs), 1381 (vs), 1354 (s), 1282 (vs), 1230 (s), 1205 (s), 1153 (s), 1095 (w), 1072 (m), 1028 (m), 951 (w), 837 (m), 798 (w),

619 (m), 582 (m), 548 (s). ^{1}H NMR (CD_2Cl_2): δ 1.78 ppm [s, 15 H, $\{\eta^5$-$C_5(CH_3)_5\}$, $^3J_{Pt-H} = 13$ Hz]; δ 0.96 ppm [s, 6 H, 2 $\{CH_3\}$, $^2J_{Pt-H} = 77$ Hz]. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): -0.3 ppm [s, 2 C, 2 $\{CH_3\}$, $^1J_{Pt-C} = 710$ Hz]; 8.1 ppm [s, 5 C, η^5-$C_5(CH_3)_5\}$]; 106.0 ppm [s, 5 C, $\{\eta^5$-$C_5(CH_3)_5\}$, $^1J_{Pt-C} = 26$ Hz].

Cp*PtMe$_2$[S(p-tol)]

At -35°C, THF (3 ml) was added to a mixture of Cp*PtMe$_2$OTf (0.18 g, 0.35 mmol) and KS(*p*-tol) (0.06 g, 0.37 mmol). The mixture was stored at -35°C for 30 min. and then allowed to warm to room temperature and stirred for 15 min. The volatile components were removed *in vacuo* and the product was extracted from the solid residue into pentane (3×10 ml, 2×5 ml). The first extract was red and the final extract was colorless. The extracts were filtered and combined. The filtrate was concentrated under reduced pressure so that the volume was approx. $\frac{2}{3}$ the original volume. The product, an orange crystalline solid, was crystallized from this concentrated pentane solution at -78°C, isolated by filtration, and dried *in vacuo*. Yield: 0.11 g (61%). Anal. Calc. for $C_{19}H_{28}SPt$: C, 47.19%; H, 5.84%. Found: C, 47.29%; H, 5.70%. IR (KBr pellet, cm^{-1}): 3059 (w), 2956 (m), 2895 (m), 2856 (m), 2812 (m), 1884 (w), 1630 (w), 1593 (w), 1514 (m), 1483 (s), 1444 (s), 1423 (s), 1383 (s), 1356 (m), 1259 (w), 1225 (m), 1211 (w), 1198 (m), 1176 (w), 1155 (m), 1101 (w), 1080 (s), 1016 (m), 951 (w), 933 (w), 847 (w), 829 (w), 806 (vs), 702 (w), 685 (w), 627 (m), 609 (m), 586 (w), 546 (m), 494 (vs), 465 (w), 449 (w), 440 (w), 417 (w). ^{1}H NMR (CD_2Cl_2): δ 1.73 ppm [s, 15 H, (η^5-$C_5(CH_3)_5$, $^3J_{Pt-H} = 9$ Hz]; δ 0.78 ppm [s, 6 H, 2 (CH_3), $^2J_{Pt-H} = 80$ Hz]; δ 2.21 ppm [s, 3 H, $\{SC_6H_4(CH_3)\}$]; δ 6.84 ppm [d, 2 H, $\{SC_6H_4(CH_3)\}$, $^3J_{H-H} = 8$ Hz]; δ 7.08 ppm [d, 2 H, $\{SC_6H_4(C_3)\}$, $^3J_{H-H} = 8$ Hz]. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): -3.9 ppm [s, 2 C, 2 (CH_3), $^1J_{Pt-C} = 690$ Hz]; 8.1 ppm [s, 5 C, (η^5-$C_5(CH_3)_5$]; 132.9 ppm [s, 5 C, (η^5-$C_5(CH_3)_5$, $^1J_{Pt-C} = 30$ Hz]; 21.1 ppm [s, 1 C, $SC_6H_4(CH_3)$]; 105.7 ppm [s, 2 C, $SC_6H_4(CH_3)$]; 128.9 ppm [s, 2 C, $SC_6H_4(CH_3)$]; 133.5 ppm [s, 1 C, $SC_6H_4(CH_3)$]; 137.1 ppm [s, 1 C, $SC_6H_4(CH_3)$].

Formation of Cp*PtMe$_2$[S(*p*-tol)] *from* Cp*PtMe$_2$I

THF-d_8 (1 ml) was added to a mixture of Cp*PtMe$_2$I (0.006 g, 0.01 mmol) and KS(*p*-tol) (0.006 g, 0.04 mmol). ^{1}H NMR spectroscopy revealed the formation of Cp*PtMe$_2$[S(*p*-tol)] to be complete within 30 min. at room temperature.

Reversibility of C_2H_4 *coordination to* Cp*PtMe$_2$(OTf)

A solution of Cp*PtMe$_2$(C_2H_4)$^+$(OTf)$^-$ (0.02 g, 0.04 mmol) in CH_2Cl_2 (5 ml) was magnetically stirred as the volatile components were slowly removed under reduced pressure, leaving a yellowish orange solid. ^{1}H NMR analysis (CD_2Cl_2) revealed the solid to be a mixture of Cp*PtMe$_2$(C_2H_4)$^+$(OTf)$^-$ (76%) and Cp*PtMe$_2$(OTf) (24%).

Reactivity of Cp*PtMe$_2$OTf *toward* SnMe$_4$

$SnMe_4$ (2 μl, 0.01 mmol) was added to a solution of Cp*PtMe$_2$OTf (0.007 g, 0.01 mmol) in $CDCl_3$ (1 ml). ^{1}H NMR spectroscopy revealed the formation of Cp*PtMe$_3$ to be complete within 5 min. at room temperature [17].

Reactivity of Cp*PtMe$_2$(OTf) *toward* Cp$_2$ZrMe$_2$

$CDCl_3$ (1 ml) was added to a mixture of Cp*PtMe$_2$-(OTf) (0.01 g, 0.02 mmol) and Cp$_2$ZrMe$_2$ (0.005 g, 0.02 mmol). ^{1}H NMR spectroscopy revealed the formation of Cp*PtMe$_3$ to be complete within 20 min. at room temperature [17].

Reactivity of Cp*PtMe$_2$(OTf) *toward* MeI

MeI (1 μl, 0.02 mmol) was added to a solution of Cp*PtMe$_2$(OTf) (0.006 g, 0.01 mmol) in C_6D_6 (1 ml). ^{1}H NMR spectroscopy revealed the formation of Cp*PtMe$_2$I and MeOTf to be complete within 3 h at room temperature [18].

X-Ray Structure Determination of Cp*PtMe$_2$[S(*p*-tol)]

Crystal data and refinement parameters for Cp*PtMe$_2$[S(*p*-tol)] are summarized in Table 2. An orange polyhedral crystal of Cp*PtMe$_2$[S(*p*-tol)] (approximate dimensions $0.12 \times 0.15 \times 0.27$ mm), obtained from a concentrated pentane solution at -35°C, was mounted on a glass fiber using Paratone N hydrocarbon oil. All measurements were made on a Siemens SMART diffractometer using graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Cell constants and an orientation matrix, obtained from a least-squares refinement using the measured positions of 5800 reflections with $I > 10\sigma(I)$ in the range $3.00 < 2\Theta < 45.00$°, correspond to a primitive monoclinic cell. Systematic absences were uniquely consistent with the space group $P2_1/c$ (No. 14). The data were collected at a temperature of -142 ± 1°C. Data were integrated using the program SAINT with box parameters of $1.6 \times 1.6 \times 0.6$° to a maximum 2Θ value of 52.1°. The data were corrected for Lorentz and polarization effects. No decay correction was applied. Analysis of the data with XPREP indicated the space group and allowed for calculation of the absorption coefficient. The structure was solved by direct methods and expanded using Fourier techniques. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in idealized positions after location on a difference Fourier map,

but not refined. All calculations were performed using the teXsan crystallographic software package of Molecular Structure Corporation.

Acknowledgements—Funding through NIH Grant No. GM-25459 is gratefully acknowledged. We thank Dr F. J. Hollander, Director of the UC Berkeley X-ray diffraction facility (CHEXRAY), for the structural characterization of $Cp^*PtMe_2[S(p\text{-tol})]$.

Bimetallic mixed-metal complexes of the salen(ᵗBu) ligands

Michael S. Hill, Pingrong Wei and David A. Atwood*†

Center for Main Group Chemistry, Department of Chemistry, North Dakota State University, Fargo, North Dakota 58105, U.S.A.

(Received 30 April 1997; accepted 25 June 1997)

Abstract—The Salen(ᵗBu) ligands, Salen(ᵗBu), (N,N′-ethylenebis(3,5-di-*tert*-butylsalicylideneimine) and Salpen(ᵗBu), (N,N′-propylenebis(3,5-di-*tert*-butylsalicylideneimine) can be combined with $GaEt_3$ to prepare the 'open' monometallic compounds, Salen(ᵗBu)H($GaEt_2$) (**1**) and Salpen(ᵗBu)($GaEt_2$) (**2**). These, in turn, can be converted to the bimetallic derivatives, Salen(ᵗBu)($GaEt_2$)$_2$ (**3**) and Salpen(ᵗBu)($GaEt_2$)$_2$ (**4**) by addition of $GaEt_3$. Alternatively, **3** and **4** can be made by the addition of two moles of $GaEt_3$ to the appropriate ligand. This was the method used to prepare Salben(ᵗBu)($GaEt_2$)$_2$ (**5**) (Salben(ᵗBu) = N,N′-butylenebis(3,5-di-*tert*-butylsalicylideneimine) and Salhen(ᵗBu)($GaEt_2$)$_0$ (**6**) [Salhen(ᵗBu) = N,N′-hexylenebis(3,5-di-*tert*-butylsalicylideneimine]. Compounds **1** and **2** can be utilized to form the unique mixed-metal derivatives L($GaEt_2$)(MR_2) (where L = Salen(ᵗBu), M : R = Al, Me (**7**); Al, Et (**9**); and L = Salpen(ᵗBu), M : R = Al, Me (**8**); Al, Et (**10**). At ambient temperatures in non-polar solvents, **7**–**12** do not undergo exchange of either the alkyl or MR_2 groups. All of the compounds were characterized by Mp, analyses, ^{1}H NMR, IR and, in the case of **1** and **3**–**6**, by X-ray crystallography. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: Group 13; salen(ᵗBu); bimetallic.

The Salen [1] class of ligands has been used extensively to support transition metal bonding schemes [2] and to a much lesser extent those of the main group elements. Some Group 13 examples include those incorporating aluminum [3] and gallium [4] alkyls, aluminum alkoxides [5] and aluminum cations [6]. The dominant structural motif for these complexes is one in which one metal is coordinated by all of the heteroatoms of the ligand in a planar arrangement [Fig. 1(a)]. In fact, many of the applications associated with these ligands rely upon this arrangement and the predominance of the chelate effect. For the main group elements there has historically been only one exception to this coordination mode. This is the bimetallic complex, Salpen($GaMe_2$)$_2$, which was formed using an excess of $GaMe_3$ in a heated, sealed tube reaction [4]. Unfortunately, these relatively harsh reaction conditions have given the false impression that extreme measures must be taken in order to prevent the Salen ligand from forming the monometallic chelate.

The Salen ligands have been shown to support bimetallic formulations for an alkyl borane [7] and a number of borates having the arrangement shown in Fig. 1(b) [8]. However, this is not surprising considering that boron generally does not go beyond a coordination number of four (a monomeric, fully chelated derivative would be five-coordinate). What we have recently discovered, however, is that the heavier congeners of the Group 13 elements, and in particular gallium, readily form open structures with the Salen ligands. Not only does this imply that monometallic [Fig. 1(c)] and bimetallic [Fig. 1(b)] open structures are accessible but that mixed metal derivatives may also readily be formed [Fig. 1(d)].

The potential isolation of dialkyl Group 13 derivatives having an open structure was implied in the proposed mechanism of formation of some of the first Salen-Al derivatives [3] as well as some tmtaa derivatives [9]. In this mechanism 1 equiv. of alkane is eliminated as the slow first step, followed by ring closure and elimination of a second equivalent of alkane. Under the conditions that were employed,

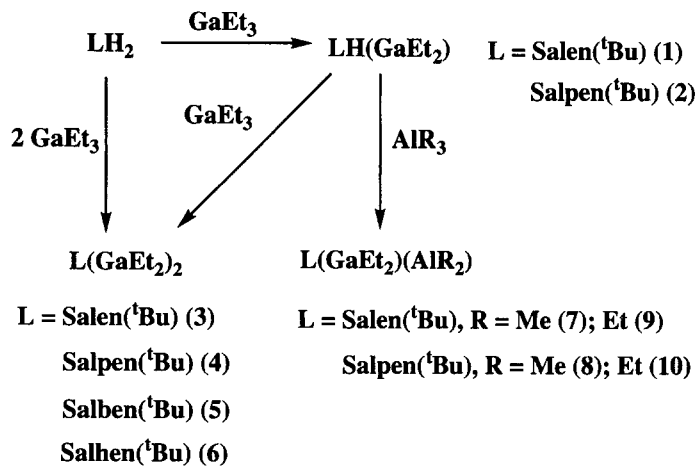

Scheme 1. Reactions leading to the formation of **1**–**10**.

however, the Salen intermediates were not able to be isolated.

One considerable limitation in using the Salen ligands lies in the fact that they are generally insoluble when bound in a neutral complex. Occasionally, this problem can be tempered somewhat by use of the Acen ligand [Figure 2(b)]. In order to avoid solubility problems altogether we have begun investigating derivatives that feature pendant alkyl groups. One such Salen derivative is Salen('Bu)H_2 [10] which possesses tertiary butyl groups at two positions on each of the phenol rings. The present work will explore the isolation and subsequent reactions of open Salen('Bu)–gallium combinations.

RESULTS AND DISCUSSION

Synthesis and Characterization

The monometallic compounds, **1** and **2**, are prepared in high yield by the addition of $GaEt_3$ to the ligand at 25°C. They can be refluxed in toluene for up to 4 h with effecting ring closure. Under these conditions the same reaction with either aluminum [11] or indium [12] reagents leads to ring closure and formation of the five-coordinate monometallic derivatives. Thus, the R_2Ga^- unit appears to be remarkably stable in relation to the aluminum and indium derivatives. The aqueous stability of Me_2Ga^+ serves as an

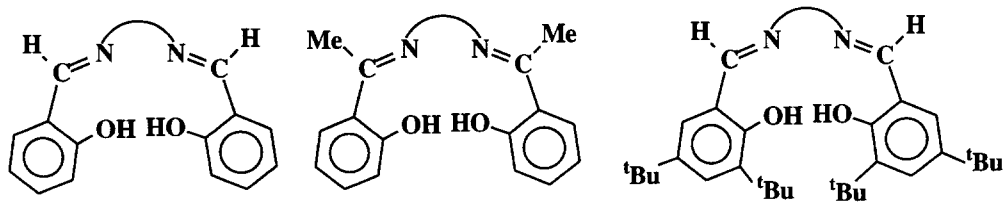

Fig. 2. General depiction of the Salen (a), Acen (b) and Salen('Bu) (c) ligands.

example of this fact [13]. The ^{1}H NMR data for **1** and **2** are consistent with an asymmetric structure in solution (Table 1). Specifically, there are two resonances for the imine (N=C*H*) groups. Addition of another mole of Et_3Ga to **1** and **2** leads to formation of the symmetric bimetallic derivatives, **3** and **4**. Alternatively, **3** and **4** (as well as **5** and **6**) can be formed by the addition of 2 moles of $GaEt_3$ to one of the ligands. Based upon the ^{1}H NMR data, these compounds are symmetric in solution. The Ga-Et resonances for **1–6** are fairly consistent and are similar to the shifts reported for other compounds containing the GaEt group such as the monometallic derivatives, LGaEt [L = Salen('Bu), Salophen('Bu) and Salomphen('Bu)] [14].

Formation of **1** or **2**, *in situ*, followed by addition of AlR_3, affords the mixed-metal derivatives, **7–10**. They are readily characterized by their distinctive ^{1}H NMR data in which there are two sets of resonances that can be ascribed to each of the MR_2 groups. The ethyls on each metal are equivalent as was seen in the homobimetallic complexes, **3–6**. There are two imine peaks (2H, total) that integrate with each set of the Ga-ethyl groups (CH_2CH_3, 6 H) in a 1 : 3 ratio. In contrast, the imine is observed as a sharp singlet for **3–6**. The CH : Me integration of 1 : 3 would also be observed if the solution consisted of a mixture of the respective bimetallic derivatives, $L(GaEt_2)_2$ and $L(AlR_2)_2$. However, in an equilibrium mixture these two species would be present with the mixed-metal as well and the ^{1}H NMR spectra would be correspondingly more complex. Thus, at ambient temperatures there is no evidence for either metal or alkyl exchange in solution **7–10**. A similar observation (that of a 'rigid' solution state geometry) has been made for Group 13 derivatives of the reduced Salen ligand, Salan [15].

Structural Characterization

A summary of data collection parameters and selected bond lengths and angles for compounds **1** and **3–6** are listed in Tables 2 and 3. In all of the structures (Figs 3–7) the gallium atoms are coordinated by the ligand and the two alkyl groups in a distorted Td geometry. Deviation from ideal angles are seen in a narrowed N—Ga—O angle and consequently widened C—Ga—C angles. According to Bent's Rule bonds to more electronegative atoms contain more *p* character [16]. Thus, the angles that the Salen ligands make are close to what would be observed in a tetraligated complex containing two heteroatoms and two alkyl functionalities. In $Me_2AlOAr(NH_2^tBu)$ [Ar = 2,6-('Bu)$_2$Ph], for instance, the O—Al—N angle is 99.2 (2)° while the C—Al—C angle is 115.9 (4)° [17]. This partially accounts for the stability of the MR_2 unit in these ligands. The Ga—O [av. = 1.92 (2) Å] and Ga—N [2.07 (3) Å] bond distances in the five-coordinate 'closed' structure of Salen('Bu)GaEt [14] the distances in **1**, and **3–6** are longer than [av. Ga—O = 1.87 (2); Ga—N = 2.02 (1) Å]. This is in keeping with the trend for larger bond lengths with increasing coordination numbers.

In bimetallic Salen borate derivatives [$L(BOR_2)_2$ (R = Me, Et)] highly ordered secondary structures are found in the packing diagrams of the compounds where L = Salben('Bu), Salpten('Bu) and Salhen('Bu). However, in **4–6** the length of the ligand backbone does not affect the packing diagrams of the compounds in any systematic way. Moreover, there are no significant deviations in the bond lengths and angles that can be correlated to the length of the ligand backbone.

EXPERIMENTAL

General considerations

All manipulations were conducted using Schlenk techniques in conjunction to an inert atmosphere glove box. All solvents were rigorously dried prior to use. NMR data were obtained on JEOL-GSX-400 and -270 instruments at 270.17 (^{1}H) MHz in $CDCl_3$ unless otherwise indicated. Chemical shifts are reported relative to $SiMe_4$ and are in ppm. Elemental analyses were obtained on a Perkin–Elmer 2400 Analyzer. Infrared data were recorded as KBr pellets on a Matheson Instruments 2020 Galaxy Series spectrometer and are reported in cm^{-1}. Both the infrared and elemental analyses for the compounds are listed in the supporting information. The reagent, 3,5-di-

[a] Samples were run in $CDCl_3$ at 270 MHz.

tert-butyl-2-hydroxybenzaldehyde was prepared according to the literature [18].

Details of the crystal data and a summary of data collection parameters for the complexes are given in Table 3. Data were collected on a Siemens CCD diffractometer using graphite monochromated Mo-K_α (0.71073 Å) radiation. All calculations were performed on a PC using the Siemens software package, SHELXTL-Plus.

Synthesis of salen(^{t}Bu)HGaEt$_2$ (**1**)

A solution of $GaEt_3$ (0.32 g, 2.03 mmol) in toluene (5 cm^3) was added to a stirred solution of Salen(^{t}Bu)H$_2$ (1.00 g, 2.03 mmol) in toluene (5 cm^3) at room temperature. The initial pale yellow solution became pale green upon stirring for 5 h. Removal of the solvent *in vacuo* yielded a green solid which was recrystallized at 25°C from methanol to yield the title compound as pale green needles (0.98 g, 77%). M.p. 99–100°C. A similar procedure performed with an additional 4 h reflux yielded an identical product in similar yield. ^{1}H NMR: 3.81–3.84 (br.s, 4H, CH_2H_2), 6.80 (d, 1H, Ph-*H*), 7.05 (d, 1H, Ph-*H*), 7.36–7.40 (m, 2H, Ph-*H*).

Synthesis of salpen(^{t}Bu)HGaEt$_2$ (**2**)

This compound was synthesized by an identical procedure to that outlined above from Salpen(^{t}Bu)H$_2$ (1.00 g, 1.98 mmol) and $GaEt_3$ (0.31 g, 1.98 mmol), *in vacuo* removal of the solvent yielded the title compound as pale green solid in stoichiometric yield. M.p. 52–56°C. ^{1}H NMR: 2.06–2.12 (m, 2H, $CH_2CH_2CH_2$), 3.51–3.70 (m, 4H, $CH_2CH_2CH_2$), 6.85 (d, 1H, Ph-*H*), 7.08 (d, 1H, Ph-*H*), 7.39–7.45 (m, 2H, Ph-*H*).

Synthesis of salen(^{t}Bu)(GaEt$_2$)$_2$ (**3**)

A solution of triethyl gallium (0.64 g, 4.06 mmol) in toluene (5 cm^3) was added at room temperature to a stirred solution of Salen(^{t}Bu)H$_2$ (1.00 g, 2.03 mmol) in toluene (20 cm^3). The resulting yellow solution was stirred for 24 h at which point removal of solvent resulted in a yellow solid which was recrystallized from toluene at −30°C to yield the title compound as a pale green crystalline solid (1.44 g, 95%). M.p. 109–111°C. Subsequent recrystallisation of a small portion realized crystals suitable for X-ray analysis. ^{1}H NMR: 3.70 (s, 4H, CH_2CH_2), 6.79 (d, 2H, Ph-*H*), 7.44 (d, 2H, Ph-*H*).

Synthesis of salpen(^{t}Bu)(GaEt$_2$)$_2$ (**4**)

This compound was synthesized via similar method to that above from triethylgallium (0.31 g, 1.98 mmol) and Salpen(^{t}Bu)H$_2$, (0.50 g, 0.99 mmol), recrystallisation from hexane at −30°C yielding the title

stirred solution of Salen('Bu)H_2 (1.00 g, 2.03 mmol) in toluene (15 cm^3). The resulting pale yellow solution was stirred for 15 min at which point a solution of trimethyl aluminum (0.147 g, 2.03 mmol) in toluene (5 cm^3) was added. After stirring for 2 h the solvent was removed under reduced pressure to yield a yellow solid which was crystallised as rectangular pale green blocks from toluene at −30°C (0.98 g, 72%). M.p. 108–110°C. ^{1}H NMR: 3.71–3.97 (m, 4H, CH_2-N), 6.76 (m, 1H, Ph-H), 6.90 76 (m, 1H, Ph-H), 7.43 (d, 1H, Ph-H), 7.52 (d, 1H, PhH), 7.97 (s, 1H, PhCH).

Synthesis of salpen('Bu)($GaEt_2$)($AlMe_2$) (**8**)

This compound was synthesized via a similar procedure to that outlined above employing triethyl gallium (0.31 g, 1.98 mmol), Salpen('Bu)H_2 (1.00 g, 1.98 mmol) and trimethylaluminum (0.142 g, 1.98 mmol), and recovered in stoichiometric yield by removal of solvent under reduced pressure. M.p. 84–86°C. ^{1}H NMR: 2.08–2.24 (m, 2H, $CH_2CH_2CH_2$) 3.56–3.65 (m, 4H, CH_2-N), 6.85 (m, 1H, Ph-H), 6.99 (m, 1H, Ph-H), 7.47 (d, 1H, Ph-H), 7.54 (d, 1H, PhH).

Synthesis of salen('Bu)($GaEt_2$)($AlEt_2$) (**9**)

This compound was synthesized with a similar procedure to that outlined above employing triethyl gallium (0.24 g, 1.52 mmol), Salen('Bu)H_2 (0.75 g, 1.52 mmol) and triethylaluminum (0.17 g, 1.52 mmol), and recovered in stoichiometric yield by removal of solvent under reduced pressure. M.p. 138–141°C (dec). ^{1}H NMR: 3.71–3.82 (m, 4H, CH_2-N), 6.76 (m, 1H, Ph-H), 6.88 (m, 1H, Ph-H), 7.44 (d, 1H, Ph-H), 7.50 (d, 1H, PhH).

Synthesis of salpen('Bu)($GaEt_2$)($AlEt_2$) (**10**)

This compound was synthesized with a similar procedure to that outlined above employing triethyl gallium (0.24 g, 1.52 mmol), Salpen('Bu)H_2 (0.77 g, 1.52 mmol) and triethylaluminum (0.17 g, 1.52 mmol), and recovered in stoichiometric yield by removal of solvent under reduced pressure. M.p. 93–94°C. ^{1}H NMR: 2.10–2.22 (m, 2H, $CH_2CH_2CH_2$), 3.57–3.62 (m, 4H, CH_2-N), 6.88 (m, 1H, Ph-H), 7.00 (m, 1H, Ph-H), 7.49 (d, 1H, Ph-H), 7.57 (d, 1H, Ph-H).

CONCLUSION

A wide range of bimetallic and mixed-metal group 13 compounds are accessible when using the Salen('Bu) ligands. Their formation relies on the fact that the chelated $GaEt_2$ fragment is remarkably stable. For example, it does not undergo intramolecular alkane elimination with the phenol portion of the ligand, nor does it react with MeOH under ambient conditions. Furthermore, the mixed-metal derivatives do not undergo scrambling of either the -R or -MR_2 groups.

(Received 29 April 1997; accepted 25 June 1997)

Abstract—Various synthetic routes to Ba–Ce mixed-metal species have been investigated No reaction was observed between $Ce_2(OPr^i)_8(Pr^iOH)_2$ (**1**) and barium isopropoxide. The enhanced acidity of the alcohol molecules of **1** has been used as a means to access to Ba–Ce species and to fix the stoichiometry between the metals. $Ba_2Ce_4(OPr^i)_{20}$ (**2**) has been obtained. This species is unstable in the presence of isopropanol giving $BaCe_4(OPr^i)_{18}$ (**3**). The reaction between **1** 2,2,6,6-tetramethylheptane-3,5-dione (thdH) and barium isopropoxide gives $Ba_4Ce_2(\mu_6\text{-}O)(thd)_4(\mu_3\text{-}OPr^i)_8(OPr^i)_2$ (**4**) independently of the stoichiometry used for the reaction. The reactions between **1**, barium isopropoxide and acetylacetone are more complex and different compounds, namely $Ba_2Ce_2O(acac)_2(OPr^i)_8$ (**5**) or $BaCe_2(acac)(OPr^i)_9$ (**6**) are formed depending on the experimental conditions. All compounds have been characterized by elemental analysis, FT-IR, ^1H and ^{13}C NMR. **4** was also characterized by X-ray diffraction. Hydrolysis–polycondensation reactions have been estimated for **4** and for **6**. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: cerium, barium, mixed-metal alkoxides, β-diketonates, sol-gel.

Cerium is involved in a variety of advanced oxide materials such as sensors, γ-scintillators, high Te superconductors [1]. Among them, barium cerates are of particular interest since solid electrolytes based on such formulations have been reported to have ionic conductivities similar to those of yttria stabilized zirconia (YSZ) but at lower temperatures [2]. The Ce(IV) isopropoxide solvate $Ce_2(OPr^i)_8(Pr^iOH)_2$ (**1**) has been known for many years namely as early as 1956, due to the contribution of Don Bradley to metal alkoxide chemistry [3]. It represents the most commonly used starting material for cerium(IV) chemistry with anionic oxygen donor ligands and organometallics [4].

We wish to report here our investigations between **1** and various barium species for the formation of Ba–Ce mixed-metal species. Whereas no reaction was observed by mixing the isopropoxides of the different metals at room temperature, the building up of Ba–Ce species could be achieved by the assistance of ancillary ligands, namely β-diketones or by using the enhanced acidity of the isopropanol ligand for the incorporation of barium. $Ba_2Ce_4(OPr^i)_{20}$, (**2**) $BaCe_4(OPr^i)_{18}$ (**3**), $Ba_4Ce_2O(thd)_4(OPr^i)_{10}$ (**4**), $Ba_2Ce_2O(acac)_2(OPr^i)_8$ (**5**) and $BaCe_2(acac)OPr^i)_9$ (**6**) were obtained and characterized by elemental analysis, FT-IR, ^1H and ^{13}C NMR. They represent, to the best of our knowledge, the first mixed-metal Ba-Ce species reported so far. The molecular structure of **4** was established by X-ray

† Author to whom correspondence should be addressed.

diffraction. Hydrolysis-polycondensation reactions were investigated for **4** and **6**.

EXPERIMENTAL

All reactions were achieved under inert atmosphere using Schlenk tube techniques. Solvents were dried and purified by distillation. $Ce_2(OPr^i)_8(Pr^iOH)_2$ (**1**) [5] and $Ba[N(SiMe_3)_2]_2(THF)_2$ [6] were obtained according to the literature. ^1H, ^{13}C NMR and IR spectra were run on Bruker AC-200 and IR-FTS 45 spectrometers respectively. IR spectra were obtained as Nujol mulls. Analyses were obtained from the Centre de Microanalyses du CNRS. TGA analyses of the powders obtained after hydrolysis were done with a Setaram system using a temperature ramp of 5°C/min.

Hydrolyses experiments were achieved in THF; water was added in THF (2 moles/l)

Synthesis of $[BaCe_2(OPr^i)_{10}]m$ (**2**)

1 (3.2 g, 3.7 mmol) in 20 cm^3 of toluene were added to barium chips (0.5 g, 3.7 mmol). Ammonia was bubbled through the medium for activation of the metal. The solution became brown. After consumption of barium, the medium was evaporated to dryness and the solid was redissolved in 10 cm^3 of hexane. $[BaCe_2(OPr^i)10]_m$ (2.6 g, 70%) was obtained at −25°C.

(3.2 g, 3.7 mmol) of **1** were added to $Ba[N(SiMe_3)_2]_2(THF)_2$ (2.3 g, 3.9 mmol) in 10 cm^3 of hexane. The solution turned yellow. $[BaCe_2(OPr^i)_{10}]_m$ (3.15 g, 80%) was isolated at 25°C. Calc. for $C_{30}H_{70}O_{10}BaCe_2$, 35.7; H, 7.5; Ba, 13.6; Ce, 27.8. Found: C, 35.3; H, 7.2; Ba, 13.8; Ce, 27.40%. IR (cm^{-1}): 1360sh, 1329m, 1160m, 1138m, 1124s, 991m, 976s, 966m, 944sh, 837m, 825m, 814m, 525m, 520sh, 466m, 442m, 412sh, 397m (νM—OR). ^1H NMR (C_7D_8, 25°C, ppm): 5.3m (1H, CH), 5.2 sept (J = 6.1 Hz, 4H, CH) 4.9m (5H, CH); 1.73, 1.4d (J = 6.1 Hz, 6:54, 60H, CH_3). ^1H NMR (C_7D_8, −70°C, ppm): 5.4, 5.2, 5.1, 4.9m (2:2:1:5, 10H, CH); 1.8, 1.7d (J = 6 Hz, 12:18, 30H, CH_3), 1.5d [30H, CH_3]. $^{13}C\{^1H\}$ NMR (C_6D_6, ppm): 78.3, 77.5, 71.0 (CH); 31.9, 28.3, 23.0 (CH_3).

Synthesis of $BaCe_4(OPr^i)_{18}$ (**3**)

Addition of isopropanol (0.5 cm^3) to a solution of **2** obtained from (2.75 mmol) of **1** and (2.78 mmol) of barium in toluene (10 cm^3) gave $BaCe_4(OPr^i)_{18}$ (65%). Anal. calcd for $C_{54}H_{126}O_{18}BaCe_4$: C, 36.8; H, 7.2; Ce, 31.8; Ba, 7.8. Found: C, 37.1; H, 7.4; Ce, 32.5; Ba, 8.4%. IR (cm^{-1}); 1358m, 1338s, 1327s, 1160s, 1128s, 1124s, 993s, 977s, 957s, 942sh, 918sh, 837m, 824m, 576m, 526s, 463sh, 445m, 416m, 401sh [ν(M—OR]. ^1H NMR (C_6D_6, 25°C, ppm): 5.3, 5.2, 4.95 sept (J = 6 Hz, 4:8:6, 18H, CH); 1.9, 1.6, 1.5, 1.4d (J = 6Hz, 12:36:30:30, 108H, Me) $^{13}C\{^1H\}$ NMR (C_6D_6, ppm): 79.3, 78.2, 77.8, 69.6 (CH); 28.7, 28.6, 28.4, 26.0 CH_3.

Synthesis of $Ba_4Ce_2O(thd)_4(OPr^i)_{10}$ (**4**)

thdH (0.17 cm^3, 0.82 mmol) was added to **1** (0.36 g, 0.42 mmol) in 20 cm^3 of toluene. This solution, which turned immediately from yellow to orange, was added to $[Ba(OPr^i)_2]_\infty$ (0.44g, 1.7 mmol) in 20 cm^3 of toluene. Crystals of **4** (0.35 g, 76%) were obtained at 4°C.

A suspension of $[Ba(OPr^i)_2]_\infty$ (0.6 g, 2.4 mmol) in 10 cm^3 of hexane was added to 0.5 g (0.6 mmoles) of $Ce(thd)_4$ in 15 cm^3 hexane. Solubilisation of $[Ba(OPr^i)_2]_\infty$ was observed. After 18 h., (0.5 g, 73%) of **4** were obtained. **4** was also formed by reacting **1** with $Ba(thd)_2$ (1:2 stoichiometry) but in poor yield (~20%). It is non-volatile (Dec: 150°C) Anal. Calcd for $C_{74}H_{146}O_{19}Ba_4Ce_2$: Ce, 12.9; Ba, 25.3; Found: Ce, 13.2; Ba, 25.6%. Unit cell parameters (−100°C): a = 18.07, b = 12.91, c = 19.24 Å; β = 96.23°.

The various compounds are soluble in polar solvents (THF, Et_2O, DME), slightly soluble in toluene or isopropanol and insoluble in hexane. **3** is insoluble in isopropanol.

Crystallography of $Ce_2Ba_4O(thd)_4(OPr^i)_{10}.C_7H_8$

Data were collected with two different crystals, the first of them being deteriorated after a few hours. Unit cell dimensions with estimated standard deviations were obtained from least squares refinements of the setting angles of 25 well-centered reflections. Two standard reflections were monitored periodically; for the first crystal, their intensities showed a regular decay; a correction was applied. Crystallographic data and other pertinent informations are summarized in Table 1. Corrections were made for Lorentz and polarization effects. Empirical absorption corrections (Difabs) [7] and a secondary extinction corrections were applied.

Computations were performed by using CRYSTALS [8]. Atomic form factors for neutral Ba, Ce, O and C were taken from Ref. [9], anomalous dispersion was taken in account. All atoms were anisotropically refined, except those of the toluene molecule. Least-squares refinements were carried out, in three blocks, by minimizing the function $\Sigma w(|F_o|-|F_c|)^2$, where F_o and F_c are the observed and calculated structure factors. Models reached convergence with $R = \Sigma(\|F_o|-|F_c\|)/\Sigma|F_o|$ and $Rw = [\Sigma(|F_o|-|F_c|)^2/\Sigma w(F_o)^2]^{1/2}$ having values listed in Table 1. The weighting scheme was unity. Criteria for a satisfactory complete analysis were the ratios of rms shift to standard deviation being less than 0.1 and no significant features in the final map. The structure consists of a centrosymmetric $Ce_2Ba_4O(thd)_4(OPr^i)_{10}$ molecule, O(1) lies on an inversion center. The structure also contains a disordered toluene molecule near an inversion center (0,1/2,1/2), its atoms were introduced with an occupancy factor of 0.5, except C(100), since C(100)′ (′: $-x$, $1-y$, $1-z$) is another atom of the ring, and C(102) which cannot be distinguished from the methyl group of the centrosymmetric molecule. The view of the molecule is done using Cameron [10].

Supplementary Material deposited at the Cambridge Crystallographic Data Centre: Tables of atomic coordinates, of anisotropic thermal parameters, of non-essential bond lengths and angles, list of observed and calculated structure factors.

RESULTS AND DISCUSSION

Synthesis and characterization

No reaction was observed between $Ce_2(OPr^i)_8(Pr^iOH)_2$, **1** and $[Ba(OPr^i)_2]_x$ in toluene at room temperature. Heating leads to the conversion of **1** into various oxo species [11] and was thus precluded. The formation of mixed-metal species was thus achieved at room temperature by using either the enhanced acidity of the coordinated alcohol molecules or by adding ancillary ligands, namely β-diketones to the mixture of metal alkoxides. By contrast to the former, the latter strategy does not allow to fix the stoichiometry between the metals [13]. Scheme 1 summarizes the various synthetic routes developed for access to Ba-Ce species. Characterization was achieved by elemental analysis, FT-IR and ^1H and ^{13}C NMR.

The reactivity of the coordinated alcohol molecules of $Ce_2(OPr^i)_8(Pr^iOH)_2$ was investigated toward barium bis(trimethylsilylamide) and metallic barium. Whereas $Ba[N(SiMe_3)_2]_2(THF)_2$ corresponds to a labile species, the barium chips need activation by ammonia, as observed previously for the synthesis of BaZr species [12] or other barium derivatives [14]. The mixed-metal species isolated in high yield ($\geq$70%) from hexane displays the expected stoichiometry between the metals and corresponds to $[BaCe_2(OPr^i)_{10}]m$, **2**. This species is unstable in the presence of isopropanol. Addition of small amounts of isopropanol (5% in volume) affords a new species, namely $Ce_4Ba(OPr^i)_{18}$, **3**, in which the stoichiometry between the metals has been modified. **3** is obtained in high yield (~65%), together with insoluble barium isopropoxide. The dissociation of **2** into the homometallic alkoxides $[Ba(OPr^i)_2]_x$ and $Ce_2(OPr^i)_8(Pr^iOH)_2$ is complete in pure isopropanol.

In the absence of crystals suitable for X-ray analysis, the structural information of **2** and **3** was gained by ^1H and ^{13}C NMR. Variable temperature ^1H NMR spectra point out the fluxional nature of compounds **2** and **3**. The CH groups of **2** resonate as three septuplets in a 1:4:5 integration ratio at room tempera-

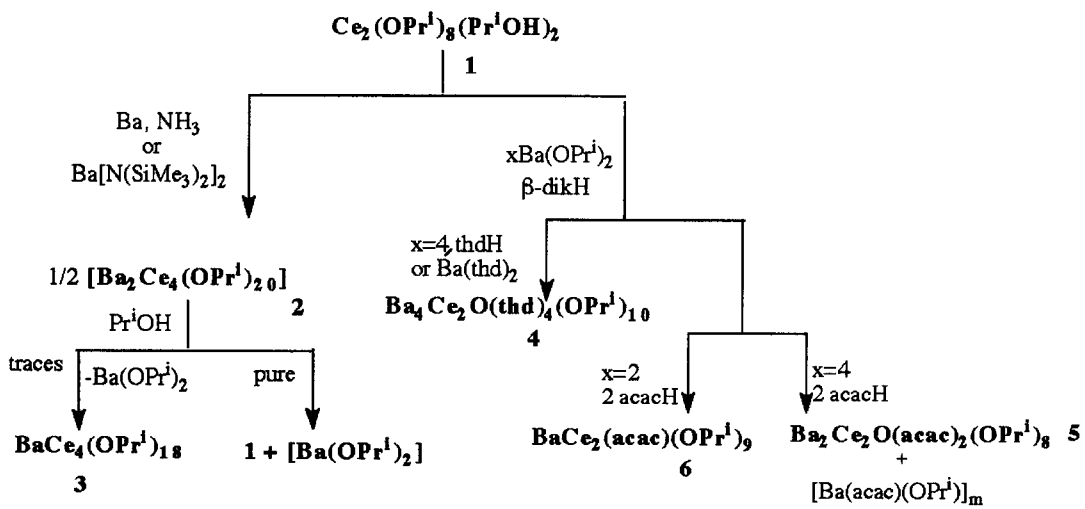


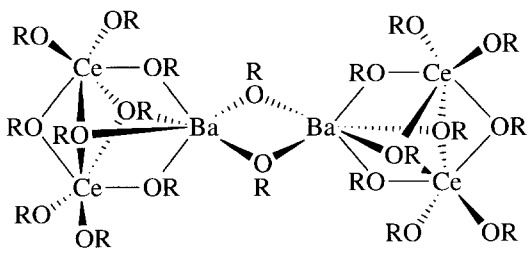
Scheme 1. Various synthetic routes to Ba–Ce species (all reactions in toluene at room temperature if not otherwise stated).

ture. At low temperature (−70°C), four multiplets are observed, their integration ratio being 2 : 2 : 1 : 5. The ^{1}H NMR as well as the ^{13}C NMR data indicate the presence of at least four types of magnetically non-equivalent alkoxide ligands. They are consistent with a dinuclear structural unit $Ba_2Ce_4(\mu_3\text{-}OPr^i)_4(\mu\text{-}OPr^i$-

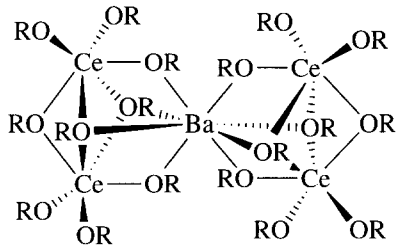
$)_8(OPr^i)_8$ in which all metals are 6-coordinate, analogous to that of $Ba_2Zr_4(OPr^i)_{20}$ [12]. It is built up on the $[Ce_2(\mu_3\text{-}OR)_2(\mu\text{-}OR)_3(OR)_4]^-$ fragment which has found precedent in $NaCe_2(OBut)_9$ [15]. The ligating ability of $M_2(OR)_9^-$ fragments has been well documented for tetravalent transition metals namely titanium [16], zirconium [17] and hafnium [18]. The integration ratio observed for **2** suggests that the most shielded multiplet at 4.9 ppm can be attributed to the OR ligands in terminal positions on cerium atoms, as well as to these bridging the cerium atoms. Structure A represents a structural type based on the assembly of two triangular units which has been observed for mixed-metal species having a $M_2M'_4$ stoichiometry, the bridging ligands being alkoxides [12,13] or chlorides as observed for $Cd_2Zr_4(\mu_3\text{-}OR)_4(\mu\text{-}OR)_6(OR)_8(\mu\text{-}Cl)_2$ [19], $Pr_2Al_4(\mu\text{-}OR)_8(OR)_8(\mu\text{-}Cl)_2(ROH)_2$ [20], R = Pr^i or $[MgTi_2(\mu_3\text{-}OR)_2(\mu\text{-}OR)_2(OR)_4(\mu\text{-}Cl)_2]_2(\mu\text{-}Cl)_2$ (R = Et) [13].

The 1 : 4 stoichiometry analogous to that of compound **3** has been observed for $BaM_4(OR)_{18}$ (M = Ti [16], Zr [12,17], an hydrolysis product, $BaZr_4(\mu_3\text{-}OH)(OPr^i)_{17}$ [21], $Sm_4Ti(\mu_5\text{-}O)(OPr^i)_{14}$ [22] and $YPr_4(\mu_5\text{-}O)(OPr^i)_{13}$ [23]. Compound **3** derives from **2** in the presence of isopropanol. Its spectroscopic data (FT-IR spectra as well as the chemical shifts in the ^1H NMR spectra) are quite similar to those of compound **2** and thus suggest small structural modifications. ^1H NMR spectra show three multiplets (integration ratio 4 : 8 : 6) for the CH groups at room temperature. Four types of magnetically different CH are observed in the ^{13}C NMR spectrum. These data are consistent with a structure of type B in which two $Ce_2(OR)_{9-}$ moieties are assembled around a central, eight coordinate barium atom. That structural type corresponds to the structures observed in the solid state for the $BaM_4(OR)_{18}$ species [12,16].

The use of β-diketones can be another way to promote the formation of mixed-metal species [13]. The reaction between $Ce(OPr^i)_2(thd)_2$, obtained *in situ* by reacting $Ce_2(OPr^i)_8(Pr^iOH)_2$, **1** and 4 equiv. of thdH, and barium isopropoxide (stoichiometry Ce : Ba 2 : 4) leads to a yellow solution. A mixed-metal species, $Ba_4Ce_2O(OPr^i)_{10}(thd)_4$, **4** crystallized out in high yield (76%). It is also easily obtained by reaction between cerium tetramethylheptanedionate and barium isopropoxide. By contrast, the reaction between barium tetramethylheptanedionate and cerium isopropoxide affords **4** in a poor yield. The FT-IR spectrum of **4** shows ν(C=O) absorption bands characteristic of tetramethylheptanedionate ligands. Their frequencies (1589, 1575 cm^{-1}) suggest that the β-diketonate ligands are linked to the barium atoms, rather than to the cerium ones.



A



B

This was confirmed by single crystal X-ray diffraction studies of **4**. Its molecular structure depicted in Fig. 1, corresponds to a centrosymmetrical hexanuclear cluster $Ba_4Ce_2(\mu_6\text{-}O)(\eta^2\text{-}thd)_4(\mu_3\text{-}OPr^i)_8(OPr^i)_2$. Selected bond lengths and angles are collected in Table 2. The hexanuclear cluster is a distorted octahedron with the metals assembled around a central oxo ligand O(1) and the two cerium atoms in the apical positions. All Ba_2Ce faces of the octahedron are capped by triply-bridging alkoxide ligands. The barium atoms bear also chelating tetramethylheptanedionates and are thus hexacoordinated. The cerium atoms are linked to one terminal OR group and are hexacoordinated. The cerium-oxygen bond distances spread over the range 2.06(1)–2.300(8) Å, with the cerium oxo bond distances having values intermediate between terminal and triply bridging Ce—OR bonds. The barium-oxygen ones are, as expected on the basis on the metal radii, longer and very from 2.561(9) to 3.006(1) Å. These distances vary in the order Ba—O(thd) (av. 2.572) < Ba-μ_3-OPr^i (2.803 Å av.) < Ba-μ_6O (av. 3.005 Å). The octahedron is flattened (non-bonding distances Ba(2)···Ba′(2) and Ce(1)···Ce′(1) are 6.068(1) and 4.47(2) Å, respectively) and the surrounding of the μ_6-oxo ligand O(1) is thus highly distorted since the Ce-O(1) bond lengths have a value of 2.24(1) Å only. These data are consistent with the distances reported in the literature for cerium and barium derivatives in which the metals have similar coordination numbers [11,24,25]. The Ce—O bond distances of **4** are for instance shorter than for $Ce_4(\mu_4\text{-}O)(OPr^i)_{14}$ [11]. The terminal Ce—OR bonds are associated to large Ce—O—C angles [171.2(10)°]. The structural type of **4** has precedent in the literature, it is related to that of $Zr_2Co_4(\mu_6\text{-}O)(acac)_4(\mu\text{-}OPr^n)_8(OPr^n)_2$ [26] and of $Ba_2Y_4(\mu_6\text{-}O)(thd)_4(\mu_3\text{-}OEt)_8$ [27]. The obtaining of oxo species is quite common for large, oxophilic metals such as

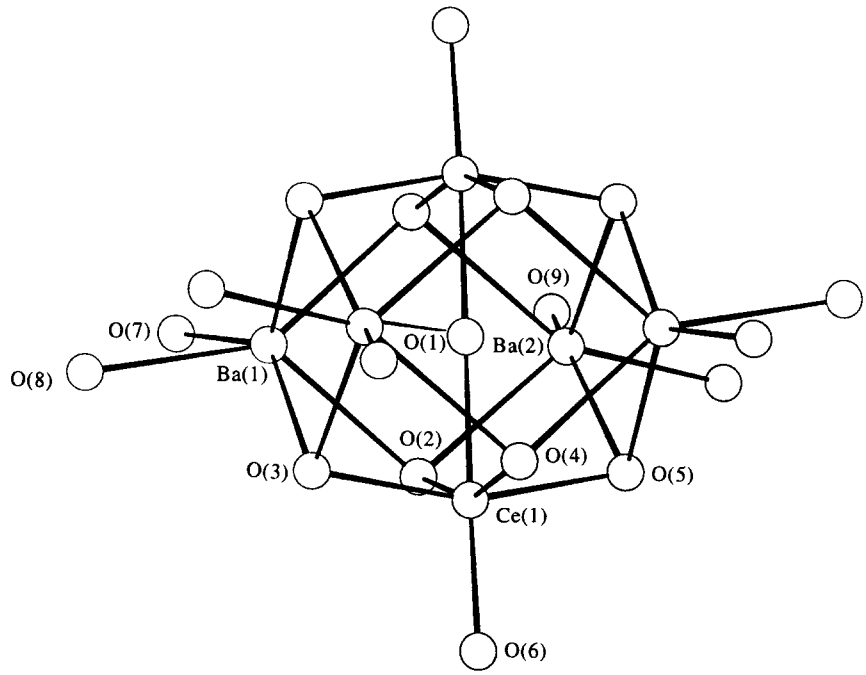


Fig. 1. Metal oxygen core of $Ce_2Ba_4(\mu\text{-}O)(thd)_4(\mu_3\text{-}OPr^i)_8(OPr^i)_2$ showing the atom numbering scheme.

lanthanides [1]. Various sources of the oxo ligand have been discussed. **4** is obtained in high and reproducible yields. These observations are in the favor of C—O bond cleavage reactions of the OR group as the origin of the O^{2-} ligand rather than adventitious hydrolysis.

The ^1H NMR spectra of **4** show two types of methine groups for the alkoxide ligands in a 4 : 1 integration ratio, all β-diketonate ligands appear magnetically equivalent. These data account for the retention of the solid state structure upon dissolution.

Acetylacetone is a more convenient β-diketone for sol–gel applications [28]. However, the reactions between **1**, barium isopropoxide and acetylacetone are less selective than for tetramethylheptanedione and three different compounds are formed by using a synthetic procedure similar to that of **4**. The mixed-metal species $Ba_2Ce_2O(acac)_2(OPr^i)_8$ (**5**) is isolated in about 35% yield. Attempts to increase the yield of **3** by adjusting the reaction conditions acacH-**1**-$Ba(OPr^i)_2$ (2 : 1 : 2 stoichiometry) did not give access to **5**, but afforded a new Ba—Ce species, $BaCe_2(acac)(OPr^i)_9$, **6**, isolated in ~80% yield together with a barium acetylacetonatoisopropoxide derivative characterized by ν(CO) stretching frequencies at 1588, 1548 cm^{-1}. **6** was also obtained by reaction between **2** and acetylacetone. No crystals suitable for a complete X-ray analysis could be obtained for **5** and **6**. By contrast with our observations with titanium ethoxide [28b], barium acetylacetonate is inert toward **1**. FT-IR spectra suggest that the acetylacetonate ligands are linked to the barium centers [ν(C=O) 1604; 1588, 1545 cm^{-1}) for **5** and for **6**, respectively. ^1H NMR spectra indicate that the β-diketonate ligands are magnetically equivalent. Variable temperature ^1H NMR spectra account for the fluxionality of species **5** and **6**. The CH groups of the alkoxide ligands of **5** resonate as two septuplets at 5.3 and 4.8 ppm displaying an integration ratio of 6 : 2 in the ^1H NMR spectrum and as three peaks in the ^{13}C NMR. The low temperature spectra (−45°C) of compound **6** show three types of CH groups in a 1 : 2 : 6 integration ratio. The overall NMR data are consistent with structure C for **5** and structure D for **6**.

The structures are based on tetranuclear or triangular units, respectively, with bridging alkoxide ligands and the alkaline earth metals bearing the acetylacetonate moieties. All metals are 6-coordinate. For structure C, the metals are assembled by a central μ4-oxo ligand and two faces of the tetrahedron are capped by triply bridging alkoxide ligands. The structure is thus related to that of $Pb_2Ti_2(\mu_4\text{-}O)(\mu_3\text{-}OPr^i)_2(\mu\text{-}OPr^i)_4(OPr^i)_4$ and of its acetylacetonate derivative [29]. The triangular unit of structure D is capped by two triply bridging alkoxide ligands. Structure D derives from structure A by cleavage of the bridging Ba—OR—Ba bond by the chelating acetylacetone ligand.

The reactions between cerium isopropoxide, barium isopropoxide and β-diketones, namely 2,2,6,6-tetramethylheptane-3,5-dione or acetylacetone, are less selective for the latter. Similar observations have been reported in the literature. For instance, the reaction between $Zr(OR)_4$ and $Co(acac)_2$ (1 : 2.5 stoichiometry) afforded $Zr_2Co_2(acac)_2(\mu_3\text{-}OR)_2(\mu\text{-}OR)_4(OR)_4$ and $Zr_2Co_4(\mu_6\text{-}O)(\mu\text{-}OR)_8(OR)_2(acac)_4$ (R = Pr^n) [26,30]. No influence of the stoichiometry

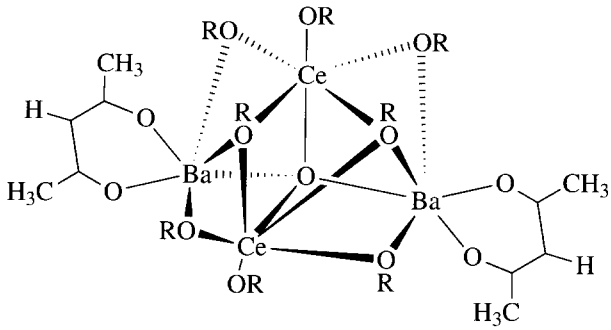
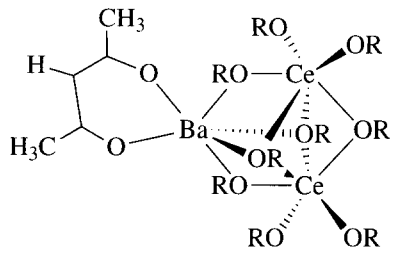
between the reactants seems to have been reported so far for the M : M′(OR)/thdH systems. Another surprising feature is that, independently of the synthetic route used-addition of the β-diketone, use of cerium β-diketonate derivatives-, all β-diketonate ligands are borne by the barium centers in the final product. The β-diketonate ligands are generally linked to the two different metals for most structurally characterized



C



D

mixed-metal β-diketonatoalkoxides known so far and their formation proceeds via ligand redistribution reactions [13,31]. Our observations indicate thus a higher affinity of barium vs cerium for the chelating β-diketonate.

Hydrolysis–polycondensation reactions

None of the Ba–Ce species reported is volatile but their solubility allows their transformation by solution routes. The hydrolysis polycondensation reactions of **4** and of **6** were investigated in THF solutions (0.01 M). Hydrolysis was achieved at room temperature by addition of water diluted in THF and for an hydrolysis ratio $h = 100$ ($h = [H_2O]/[CeBa\ precursor]$). Formation of precipitates, white and yellow, respectively, occurs immediately. FT-IR spectra of these powders show the presence of $\nu(C{=}O)$ absorption bands at 1589, 1576 and 1588 and 1545 cm^{-1} respectively. These observations indicate the presence of residual β-diketonate ligands and thus of differential hydrolysis as generally observed for diketonatoalkoxides [24,21,28].

TGA measurements performed under nitrogen indicate that the loss of the organic residues occurs essentially between ~100°C and 600°C. An endothermic peak is observed around 800°C on the TDA profile of the powder (**4a**) resulting from the hydrolysis of **4**. X-ray powder diffraction (XRD) at various temperatures was achieved. Whereas the powder resulting hydrolysis of **6** was amorphous at room temperature, that derived from **4** indicated the presence of some metastable (decomposition occurred around 200°C) crystalline material. Crystallisation started at ≈600°C for **4a** (Fig. 2). At 800°C, barium carbonate (orthorhombic) and cubic cerium oxide are clearly identified. Crystalline barium cerate $BaCeO_3$ is obtained at 1000°C together with an amorphous barium oxide matrix. The powder derived from the hydrolysis of **6** leads to barium cerate and cubic cerium oxide which are crystallized at 900°C. In both cases, $BaCeO_3$ is obtained together with a binary oxide as a result of the stoichiometry of the mixed-metal species used as precursor.

Solid state routes to $BaCeO_3$ are essentially based on the reactions between barium carbonate and cerium oxide and occur around 1350°C [32]. Thus, despite the quite high conditions of crystallisation of $BaCeO_3$ via the above chemical routes, a reduction of about 450°C is observed. The mildest conditions of crystallization of the $BaCeO_3$ perovskite phase (750°C) have been reported so far with a modified Pechini process, EDTA being used instead the usual citric acid [2b]. Facile formation of barium carbonate has been reported previously for chemical routes [2a], as a result, treatment at 1000°C was necessary in order to get rid of that undesired phase. Conversion of the $BaCe_2(acac)(OPr^i)_9$ species **6** appears more interesting than that of **4** which generates barium carbonate as intermediate. The formation of barium carbonate can result from the decomposition of the β-diketonate ligand. However, no barium carbonate was detected in the powders resulting from the hydrolysis-polycondensation for other mixed-metal barium species supported by β-diketonate ligands such as $Ba_2Ti_2(thd)_4(OEt)_8(EtOH)_2$ or $Ba_2Ti_2(acac)_4(OEt)_8$ [28b]. The facile formation of $BaCO_3$ suggests easy segregation of the Ba–Ce species in the course of the polycondensation process as well as C—C bond cleavage reactions of the organic moieties during the thermal treatment (no absorption bands characteristics of $BaCO_3$ were observed by FT-IR on the amorphous powders obtained at room temperature) [34]. This was confirmed by the fact that hydrolysis of a mixture of barium and cerium isopropoxides (Ba : Ce, 1 : 1 stoichiometry) gave results similar to these based on the use of Ba–Ce species. Facile segregation could be favored by the fact that all β-diketonate ligands are linked to barium. Strong assembling and chelating ligands seem thus required for a better homogeneity. On the other hand, the easy conversion of $Ba_2Ce_4(OPr^i)_{20}$ into $BaCe_4(OPr^i)_{18}$ (and/or its complete dissociation) in the presence of isopropanol shows that the parent alcohol is not necessarily the best solvent for the processing of mixed-metal species.

Copper(II)/alkaline-earth metal(II) and copper(II)/lanthanides(III) mixed metal complexes containing bifunctional pyridyl alcohol or amino alcohol ligands†

Suning Wang

Department of Chemistry, Queen's University, Kingston, Ontario, Canada K7L 3N6

(Received 17 March 1997; accepted 25 June 1997)

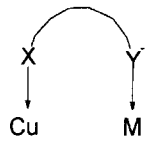
Abstract—The utility of bifunctional ligands such as hydroxypyridine and 1,3-bis(dimethylamino)-2-propanol in the synthesis of mixed metal complexes containing lanthanides, alkaline-earth metals, and copper is examined. The focus of this article is on the syntheses, crystal structures, thermal and magnetic properties of the mixed metal complexes obtained by our group. The role of these mixed metal complexes in the precursor solution for the $YBa_2Cu_3O_{7-x}$ film is also discussed. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: copper; lanthanides; alkaline-earth metal; structures; properties.

The recent intense research interest in mixed metal complexes containing copper, lanthanides, and alkaline-earth metal ions was motivated, to a large extent, by the discovery of high T_c copper oxide based superconductors nearly a decade ago [1]. The most important member of the copper oxide based superconductors is the $YBa_2Cu_3O_{7-x}$ superconductor (1-2-3 superconductor). It has been well established that the replacement of the yttrium ion by members of the lanthanide family does not significantly perturb the superconductivity of the 1-2-3 superconductor. Other important copper oxide based superconductors include $Bi_2Sr_2CaCu_2O_{8+x}$ and $Bi_2Sr_2Ca_2Cu_3O_{10+x}$. The T_c of these superconductors is well above the boiling point of liquid nitrogen, making some of the practical applications possible. Bulk powder samples of these superconductors can be obtained readily by conventional ceramic production techniques. The production of high quality superconductive films, a highly desired form for practical applications, still remains, however, as a non-trivial task. The commonly used chemical method for film production of superconductors is *via* chemical vapor deposition (CVD). The CVD method has been demonstrated to be able to produce good quality of films, but limited by the availability of volatile precursor compounds [2]. Alternatively, one can mix the corresponding compounds of all components together in solution and coat them onto the substrate via spin coating or dip coating process. This method requires that all components are soluble in solution. One way to improve the solubility of the metal compounds in organic solvents is to bind suitable organic ligands to the metal centers. Due to the inherent different nature of the metal ions present in superconductors, their requirements for ligands are quite different. For example, a copper(II) ion binds well with oxygen or nitrogen donor atoms in an essentially covalent fashion while lanthanide(III) ions have a poor affinity to neutral nitrogen donor atoms and a relatively good affinity to negatively charged donor atoms such as oxygen, due to the ionic nature of the lanthanide–ligand bond [3]. Our strategy was therefore to employ bifunctional ligands which contain both a neutral coordinating site and a negatively charged coordinating site so that they can bind to two different metal ions (Fig. 1).

The bifunctional ligands (Fig. 2) used in our study include 2-hydroxyl pyridine (2-PyOH), 1,3-bis(dimethylamino)-2-propanol (bdmapH), and 2,6-bis[(dimethylamino)methyl]-4-methylphenol(bdmmpH). A variety of mixed metal complexes have been synthesized by using these ligands. This review

† Dedicated to Prof. D. C. Bradley on the occasion of his 73rd birthday.



$M = Y^{3+}$, Ln^{3+}, alkaline-earth met

Fig. 1. The selective binding of a bifunctional ligand to two different metal ions.

will focus on the syntheses and structures of the mixed metal complexes. Magnetic properties and the relevance of these compounds to superconductors will be addressed.

The serendipitous discovery of $Y_2Cu_8(\mu_4\text{-}O)_2(\mu\text{-}2\text{-}PyO)_{12}(\mu\text{-}Cl)_2(NO_3)_4(H_2O)$ *and* $Nd_2Cu_8(\mu_4\text{-}O)_2(\mu\text{-}2\text{-}PyO)_{12}(\mu\text{-}Cl)_2(OCH_3)_4(H_2O)_4$

The 2-hydroxyl pyridine ligand has been demonstrated earlier by Goodgame and coworkers to be very useful in the synthesis of mixed metal compounds such as [4] $Cu_4Ln_2(2\text{-}PyO)_8(2\text{-}PyOH)_4(OH)_2(NO_3)_4(H_2O)_2$. Most of the earlier syntheses carried out by Goodgame's team were done in either aqueous solutions or in methanol by using copper(II) nitrate or copper(II) hydroxide as the copper source. With the hope to obtain new mixed metal complexes which are soluble in organic solvents, we tried a few modifications to Goodgame's syntheses by using $Cu(OCH_3)_2$, instead of $Cu(NO_3)_2$ or $Cu(OH)_2$, as the starting material and CH_2Cl_2 or THF as the solvents. The dark green crystals isolated initially from the reaction of $Y(NO_3)_3 \cdot 4H_2O$, $Cu(OCH_3)_2$, and 2-hydroxyl pyridine in a 1 : 4 : 6 ratio in CH_2Cl_2 was found to have the formula of $Y_2Cu_8(\mu_4\text{-}O)_2(\mu\text{-}2\text{-}PyO)_{12}(\mu\text{-}Cl)_2(NO_3)_4(H_2O)_2$ (**1**), an entirely different compound from that of Goodgame! Compound **1** can also be obtained by using methanol as the solvent. The key difference between the composition of compound **1** and those of Goodgame's compounds is the presence of the chloride ligands in **1**, which is responsible for the formation of a new molecule with beautiful and unique structural features. Where did the chlorine come from? After analyzing the starting materials, we found out that the chlorine came with $Cu(OCH_3)_2$ (about 3%, sufficient to produce compound **1** in a quantitative yield!). The company who supplied this compound told us that due to technical problems it is difficult to keep the chlorine content in $Cu(OCH_3)_2$ below 1%. Without the chlorine impurity, it is very likely that we would have reproduced Goodgame's compound. In order to introduce the chloride ligands into the reaction mixture in a controlled fashion, we replaced $Y(NO_3)_3 \cdot 4H_2O$ with $YCl_3 \cdot xH_2O$ in the reaction which did not yield crystalline products. The replacement of $Y(NO_3)_3 \cdot 4H_2O$ by $NdCl_3 \cdot 6H_2O$, however, produced dark green crystals with the formula of $Nd_2Cu_8(\mu_4\text{-}O)_2(\mu\text{-}2\text{-}PyO)_{12}(\mu\text{-}Cl)_2(OCH_3)_4(H_2O)_4$ (**2**).

The structures [5,6] of compounds **1** and **2** resemble each other, as shown in Figs 3 and 4. The Y^{III} and Nd^{III} ions are surrounded by negatively charged oxygen atoms from the deprotonated 2-PyOH, the oxo, the nitrate, or the methoxyl ligands while the pyridyl groups are bound exclusively to the copper(II) centers, demonstrating the preferential coordinating pattern of the 2-PyOH ligand. The oxo ligands were believed to come from the reaction of H_2O with base such as the methoxy ligand. The most important feature in these two structures is the central core unit $M_2Cu_4O_{10}$ where the M^{III} ions are linked to the four copper(II) ions *via* eight oxygen atoms of $2\text{-}PyO^-$ and two oxide ligands. The structural feature displayed by the central core units of **1** and **2** closely resembles that [1] found in 1-2-3 superconductor (Fig. 5).

Magnetic susceptibility measurements revealed that antiferromagnetic exchanges between Cu^{II}–Cu^{II} centers, Nd^{III}–Nd^{III} centers, and Cu^{II}–Nd^{III} centers dominate in these two compounds.

Several other interesting copper(II)/lanthanides (III) mixed metal complexes containing either 2-hydroxyl pyridine or 6-methyl 2-hydroxyl pyridine ligands and displaying complex structural features have been reported by Winpenny and co-workers [7] which further demonstrated the usefulness of 2-hydroxyl pyridine based ligands for the syntheses of copper/lanthanides compounds. However, there is one weakness associated with the 2-hydroxyl pyridine compounds, that is, most of them have very poor solubility in common organic solvents, limiting their practical applications.

Copper(II)/lanthanides(III) complexes of 1,3-*bis(dimethylamino)-2-propanol*

To improve the solubility of the mixed metal compounds, we decided to investigate the coordination chemistry of 1,3-bis(dimethylamino)-2-propanol (bdmapH). The bdmapH ligand has several advantages over the 2-hydroxyl pyridine ligand. First of all, it has three binding sites, two neutral amino groups and one hydroxyl group which can be deprotonated readily to bind to a highly electropositive metal ion such as a lanthanide ion. Secondly, it contains four methyl groups which would enhance the solubility of the metal complexes in organic solvents.

The syntheses of our mixed metal complexes of bdmapH are based on two routes. In the first route, $Ln(O_2CR)_3$ and $Cu(O_2CR)_2$, where R is either a methyl group or a trifluoromethyl group, were used as the starting material to react with the bdmapH ligand. The products from the reactions where acetate compounds were used usually have poor solubility and are difficult to grow single crystals. The reactions where trifluoroacetate compounds were employed often produced soluble crystalline products. The compound that we have been able to isolate successfully is a trinuclear complex [8] with the formula of $LaCu_2(bdmap)_3(O_2CCF_3)_4$ (**3**). The reaction scheme for compound **3** is shown in eq. (1).

$$\begin{aligned} &La(O_2CCF_3)_3 + 0.5\,Cu(O_2CCF_3)_2 \\ &\qquad + 1.5\,Cu(OCH_3)_2 + 3bdmapH \\ &= LaCu_2(bdmap)_3(O_2CCF_3)_4 + 3CH_3OH. \end{aligned} \quad (1)$$

The metal atoms in compound **3** has a triangular arrangement (Fig. 6). The lanthanum(III) ion is linked to two copper(II) ions *via* three oxygen atoms of the deprotonated bdmapH ligands (bdmap). Two of the oxygen atoms act as doubly bridging atoms while the third one acts as a triply bridging atom. The two copper(II) ions are bridged together by one bdmap ligand. The lanthanum ion is surrounded predominately by oxygen atoms. The two La—N bonds are very long [2.85(2) Å], reflecting the poor affinity

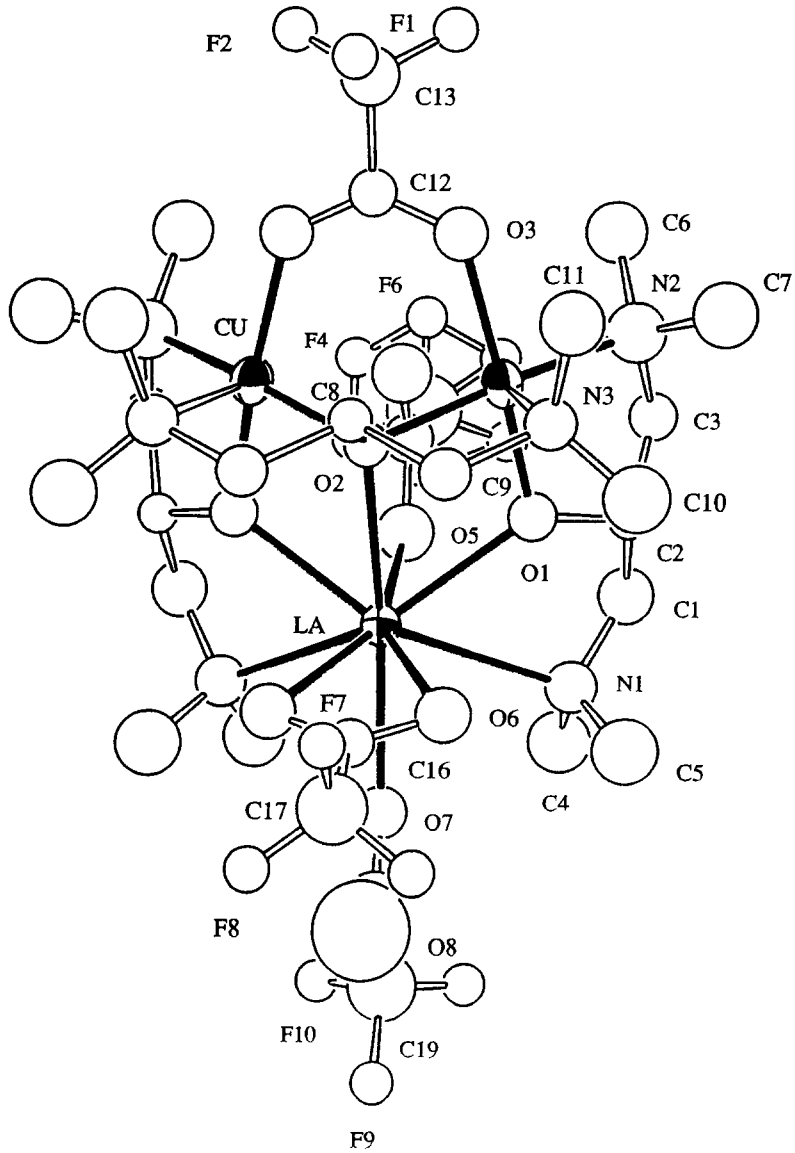

Fig. 6. The crystal structure of $LaCu_2(O_2CCF_3)_4(bdmap)_3$ (**3**).

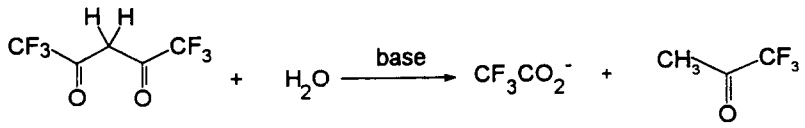
of lanthanide ions to the neutral amino binding site. The Cu—Cu separation distance is 3.265(6) Å. The magnetic exchange between these two CU^{II} ions was found to be weakly antiferromagnetic ($J = -6.0$ cm^{-1}), established by magnetic susceptibility measurements. Compound **3** is soluble in common organic solvents such as CH_2Cl_2 and THF. Upon heated under oxygen, it decomposes cleanly to the corresponding oxide composition $LaCu_2O_{3.5}$ at 420°C. A triangular structure similar to that of **3** has been observed in compound $[YCu_2(OCH_2CH_2OCH_3)_3(hfacac)_2(tmhd)_2]$ where tmhd = 2,2,6,6-tetramethylheptane-3,5-dionate and the bifunctional ligand, 2-methoxy ethanol, was used as the bridging ligand [9].

In the second route $Ln(O_2CR)_3$ was replaced with $Ln(hfacac)_3$ (hexafluoroacetylacetonato). $Cu(O_2CR)_2$ or $Cu(OCH_3)_2$ was used as the copper(II) starting material to react with the bdmapH ligand. Various products have been isolated from the reactions, depending on the starting materials of lanthanum and copper and their relative ratio. One major factor contributed to the complexity of these reactions is the poor stability of the hfacac ligand towards nucleophiles [10] which has also been observed by other research groups [11]. A typical decomposition reaction of the neutral hfacacH molecule in the presence of a base is shown in Scheme 1.

The reaction of $Cu(O_2CCH_3)_2(H_2O)$, $Ln(hfacac)_3$, Ln = Pr, Nd, and bdmapH in a 1 : 2 : 3 ratio in THF yielded a trinuclear compound with the formula of $LnCu_2(hfacac)(bdmap)_3(O_2OCH_3)_2(O_2CCF_3)(hfacacH)$ (**4**). The trifluoroacetate ligand came from the decomposition of one of the hfacac ligand. In the



Scheme 1.

crystal lattice, the neutral hfacacH molecule exists in an enol form stabilized by the formation of hydrogen bonds between the oxygen atoms of the hfacacH and the non-coordinating amino group [N(4)] in the complex. As shown in Fig. 7, the basic structural features of **4** resemble that of **3**. The lanthanide ion in **4** is linked to two copper(II) ions through three oxygen atoms of the bdmap ligands in a similar fashion as that observed in **3**. Unlike compound **3** where two amino groups are weakly bound to the lanthanide ion, in compound **4** only one amino group is bound to the lanthanide center, perhaps due to the increased steric bulkiness imposed by the hfacac ligand and the hydrogen bond formation. The magnetism in compound **4** has been found to be dominated by the paramagnetic lanthanide(III) ion. Upon heated under oxygen, compound **4** decomposed to the corresponding oxide composition of $LnCu_2O_{3.5}$ at approximate 310°C, about 100°C lower than that of **3**. The presence of the hfacac ligand in **4** apparently helped to lower the thermal decomposition temperature [12].

The reaction of $Cu(OCH_3)_2$, $Ln(hfacac)_3$, Ln = Pr, Y, and bdmapH in a 1 : 1 : 2 ratio in THF, attempted for the synthesis of $LnCu(bdmap)_2(hfacac)_3$ yielded an unusual blue compound with the formula of $LnCu(bdmapH)_2(hfacac)_2(O_2CCF_3)L$ (**5**) where L = 2-methyl-2,4,6-tris(trifluoromethyl)-1,3-dioxane-4,6-diolato. The trifluoroacetate ligand in the com-

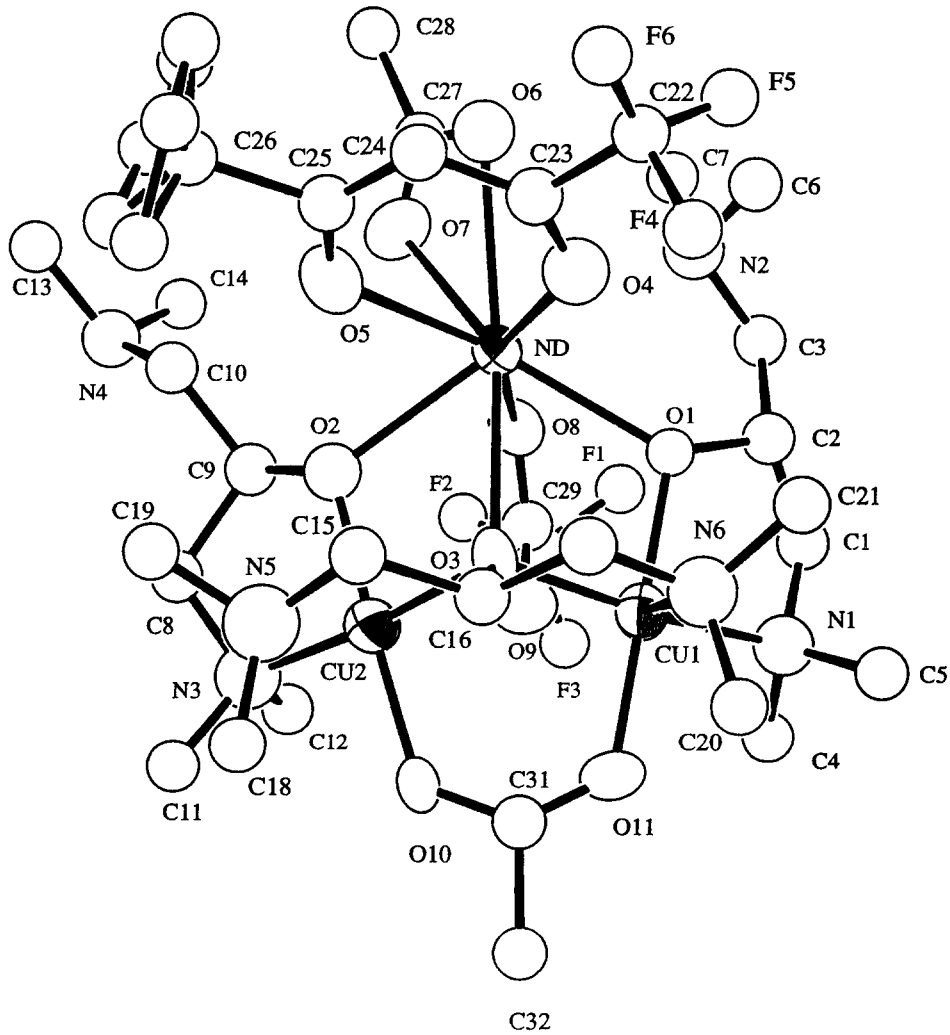


Fig. 7. The crystal structure of $NdCu_2(hfacac)(bdmap)_3(O_2CCH_3)_2(O_2CCF_3)(hfacacH)$ (**4**).

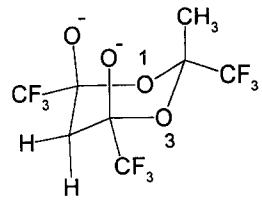

Fig. 8. The 2-methyl-2,4,6-tris(trifluoromethyl)-1,3-dioxane-4,6-diolato ligand.

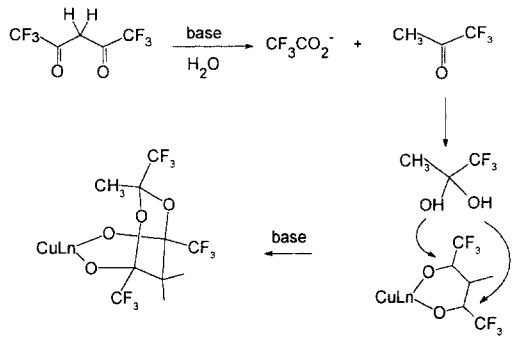
pound was again formed from the decomposition of the hfacac ligand. The unusual ligand L can be viewed as a derivative of 1,3-dioxane-4,6-diol, as shown in Fig. 8. The L ligand has a chair conformation with two trifluoromethyl groups occupying the 4 and 6 equatorial positions and two oxygen atoms occupying the 4 and 6 axial position. The CF_3 and CH_3 groups on position 2 display a 50%/50% disorder over the axial and the equatorial positions. The ligand L can be considered as the cycloaddition product of a 1,1,1-trifluoro-2,2-propanediol molecule to the hfacac ligand, promoted by the metal complex (Scheme 2). The 1,1,1-trifluoro-2,2-propanediol is the hydration product of tirfluoroacetone. The adventitious water molecules in the solvent and bdmapH are believed to be responsible for the diol formation. The details of the formation mechanism of ligand L have not yet been understood.

The complicated structure of compound **5** is better shown by using a line drawing diagram (Fig. 9). The lanthanide ion is linked to the copper(II) ion *via* two



Scheme 2.

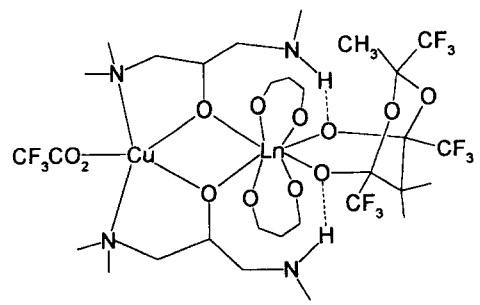


Fig. 9. The structure of compound **5**, LnCu(bdmapH)$_2$(hfacac)$_2$(O_2CCF_3)L.

oxygen atoms of the bdmapH ligand. The proton originally bound to the oxygen atom of the bdmapH is shifted to the non-coordinating amino site and forms a hydrogen bond with the oxygen atom of the L ligand. The lanthanide ion is surrounded again by negatively charged oxygen atoms only.

Alkaline-earth metal(II)/copper(II) complexes of 1,3-*bis(dimethylamino)*-2-*propanol*

The bdmapH ligand is useful not only in the syntheses of lanthanides/copper complexes, but also in the syntheses of alkaline-earth metal/copper complexes, due to the similar ionic nature of lanthanide-ligand bonds and alkaline-earth metal–ligand bonds. We have found that various mixed metal complexes containing alkaline-earth metal ions and copper(II) ions can be obtained readily by using reactions similar to those for the syntheses of lanthanides/copper complexes. The structures and compositions of these new complexes are highly dependent on the reaction conditions, stoichiometry, and the reagents. For example, from the reaction of $Ca(O_2CCF_3)_2$, $Cu(OCH_3)_2$, and bdmapH in a 1 : 1 : 2 ratio in THF, a dinuclear complex with the formula of $CaCu((O_2CCF_3)_2(bdmap)_2(H_2O)$ (**6**) was isolated [13]. As shown in Fig. 10, the linkage between Ca^{II} and Cu^{II} in compound **6** resembles that found in compound **5**, that is, these two metal ions are linked together through the oxygen atoms of the bdmap ligands. The copper(II) center has a square pyramidal geometry with the O(6) atom occupying the axial position [Cu—O(6) = 2.397(8) Å]. As found in the Ln/Cu complexes, the Ca—N bonds are much longer than those of Ca—O bonds, again reflecting the relatively poor affinity of the highly electropositive Ca^{II} ion towards the neutral amino group. Compound **6** forms a dimer in the solid state through the formation of intermolecular hydrogen bonds between the non-coordinating oxygen atom of the trifluoroacetate ligand and the H_2O ligand. There is also an intramolecular hydrogen bond between O(7) and O(4) [2.72(1) Å].

Interestingly, from the analogous reaction of $Sr(O_2CCF_3)_2$, $Cu(OCH_3)_2$, and bdmapH in a 1 : 1 : 2 ratio in THF, a tetranuclear complex with the formula of $[SrCu(O_2CCF_3)_2(bdmap)_2]_2$ (**7**) was obtained [13]. Compound **7** consists of two dinuclear units $SrCu(O_2CCF_3)_2(bdmap)_2$, joined together through two trifluoroacetate bridges. As shown in Fig. 11, the structure of the dinuclear portion is similar to that of compound **6**. The coordination environment of the Sr^{II} ion on **7** resembles that of the Ca^{II} ion in **6**. The difference between **6** and **7** is due to the coordinated H_2O ligand which is absent in **7**. In **7**, the coordination site occupied by a H_2O in **6** is filled by the oxygen atom of the bridging trifluoroacetate ligand. It is very likely that the water molecule in **6** came from the bdmapH reagent which is difficult to be completely

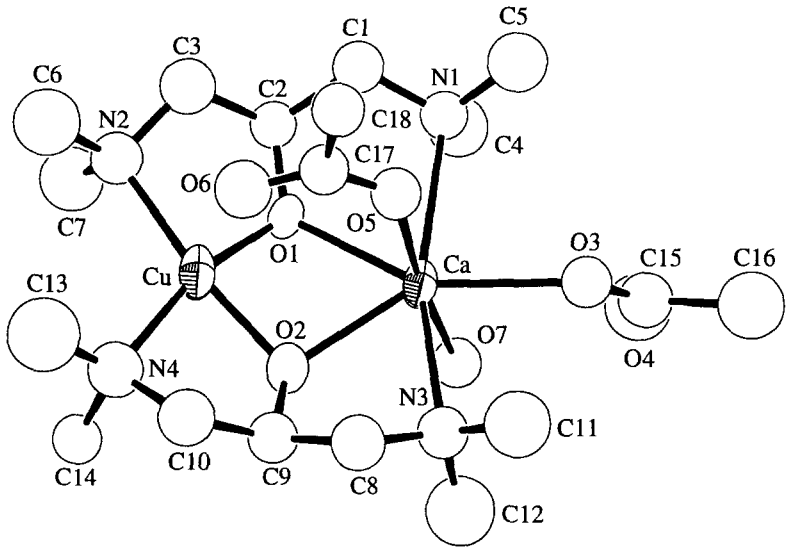

Fig. 10. The crystal structure of $CaCu(O_2CCF_3)_2(bdmap)_2(H_2O)$ (**6**). For clarity, the fluorine atoms are omitted.

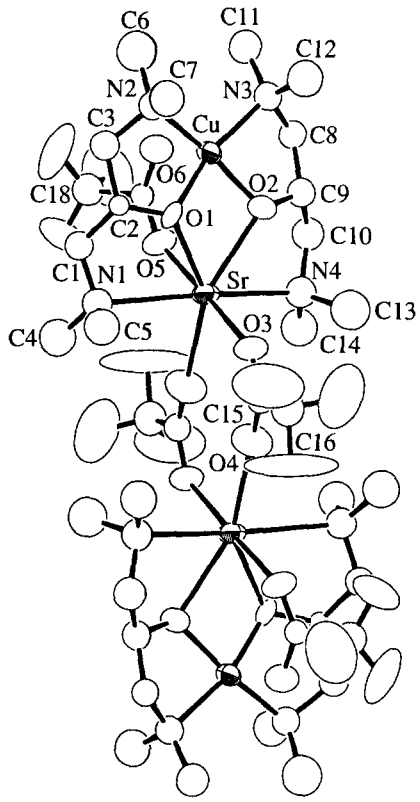

Fig. 11. The crystal structure of $[SrCu(O_2CCF_3)_2(bdmap)_2(H_2O)]_2$ (**7**).

free of water. However, it is not obvious why the Ca^{II} ion in **6** picked up the water while the Sr^{II} ion in **6** did not. One possible explanation is that the Ca^{II} ion has a higher tendency to undergo hydration due to its relatively small size, in comparison to that of the Sr^{II} ion.

When $Sr(O_2CCF_3)_2$, $Cu(OCH_3)_2$, and bdmapH were reacted in a 1:2:3 ratio in THF, a trinuclear complex with the formula of $SrCu_2(O_2CCF_3)_3(bdmap)_3$ (**8**) was produced [14]. The structure of **8** is very similar to that of $LaCu_2(O_2CCF_3)_4(bdmap)_3$ (**3**) (Fig. 12). The Sr^{II} ion is linked to the two copper(II) ions by three oxygen atoms of the bdmap ligands in a similar fashion as that observed in **3**. The Cu–Cu separation distance is 3.271(4) Å, similar to that found in **3**. Magnetic exchanges between the two copper(II) ions in **8** was found to be weakly antiferromagnetic with the exchange constant $J = -17\ cm^{-1}$.

When $Sr(O_2CCF_3)_2$, $Cu(OCH_3)_2$ and bdmapH were reacted in a 1:2:4 ratio in THF, an interesting hex-

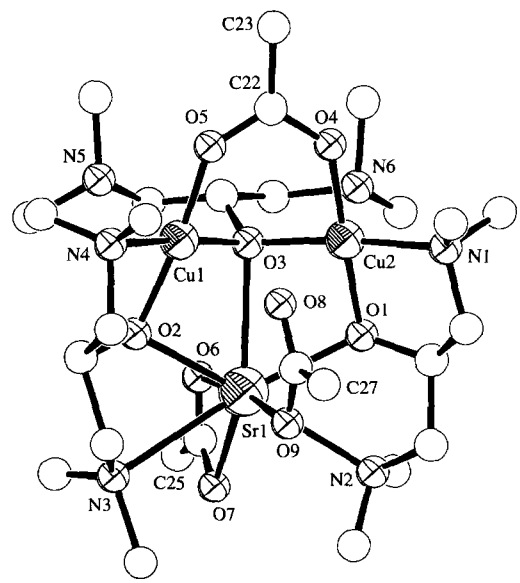

Fig. 12. The crystal structure of $SrCu_2(O_2CCF_3)_3(bdmap)_3$ (**8**). For clarity, the fluorine atoms are omitted.

anuclear complex with the formula of $Sr_2Cu_4(O_2CCF_3)_4(bdmap)_6(\mu_3\text{-}OH)_2$ (**9**) was isolated [13]. The presence of excess bdmapH ligand in this reaction was necessary to ensure the formation of the hydroxide ligands. The structure of compound **9** is given in Fig. 13. There are two $SrCu(O_2CCF_3)_2(bdmap)_2$ units in **9** with a structure somewhat resembling that of **7**, except that one of the amino group is not coordinated to the Sr^{II} center, but formed a hydrogen bond with the hydroxide ligand. These two SrCu units are linked to the dinuclear $Cu_2(OH)_2$ unit *via* two bdmap ligands and the two hydroxide ligands. The $Cu_2(OH)_2$ portion is planar with a short Cu^{II}–Cu^{II} distance [2.865(5) Å] and unusually small Cu—O—Cu angle [93.5(7)°] which would result in a ferromagnetic exchange between the two Cu^{II} centers, based on some of the well established empirical relationship between the exchange constant *J*, Cu—Cu distance, and Cu—O—Cu angle. Unfortunately we have not been able to carry out the study of magnetic properties of this compound.

When the trifluoroacetate salts were replaced with the corresponding acetate salts in the syntheses described above, there were either no reactions or the products were too insoluble to grow single crystals. The only acetate analogous compound [14] which we were able to synthesize is $SrCu_2(O_2CCH_3)_3(bdmap)_3$ (**10**) with a structure identical to that of **8**.

Unlike the lanthanides/copper complexes which undergo facile thermal decomposition to form the corresponding oxides even in the presence of fluorinated ligands such as trifluoroacetate or hfacac, the thermal decomposition patterns of alkaline-earth metal/copper complexes are dramatically affected by the presence of fluorinated ligands [13,14]. For example, upon heated under oxygen, compound **6** decomposed to CaF_2/CuO at about 280°C while compound **7** decomposed to SrF_2/CuO at 390°C. Compound **8** decomposed thermally to SrF_2/2CuO at about 400°C while the acetate analogous compound **10** decomposed initially to form $Sr(CO_3)$/2CuO and did not form SrO/2CuO until about 800°C. We concluded that the presence of fluorinated ligand does lower the thermal decomposition temperature, but the fluorine contamination becomes a serious problem with the alkaline-earth metal compounds due to the high stability of the MF_2 phase. The fluorine contamination problems could be overcome by introducing oxide or hydroxide ligands into the complexes. For example, we have observed that compound **9**, $Sr_2Cu_4(O_2CCF_3)_4(bdmap)_6(\mu_3\text{-}OH)_2$, decomposed cleanly to the SrO/2CuO composition at about 330°C. No fluorine contamination was observed in spite of the presence of trifluoroacetate ligands. The difference between compound **9** and compound **6**, **7**, or **8** is the presence of two hydroxide ligands which bind to both Sr^{II} and Cu^{II} ions. We believe that these hydroxide ligands prevented the formation of the SrF_2 phase.

The reaction of $Ba(O_2CCF_3)_2$ with $Cu(OCH_3)_2$ and bdmapH always yielded blue oily products. The com-

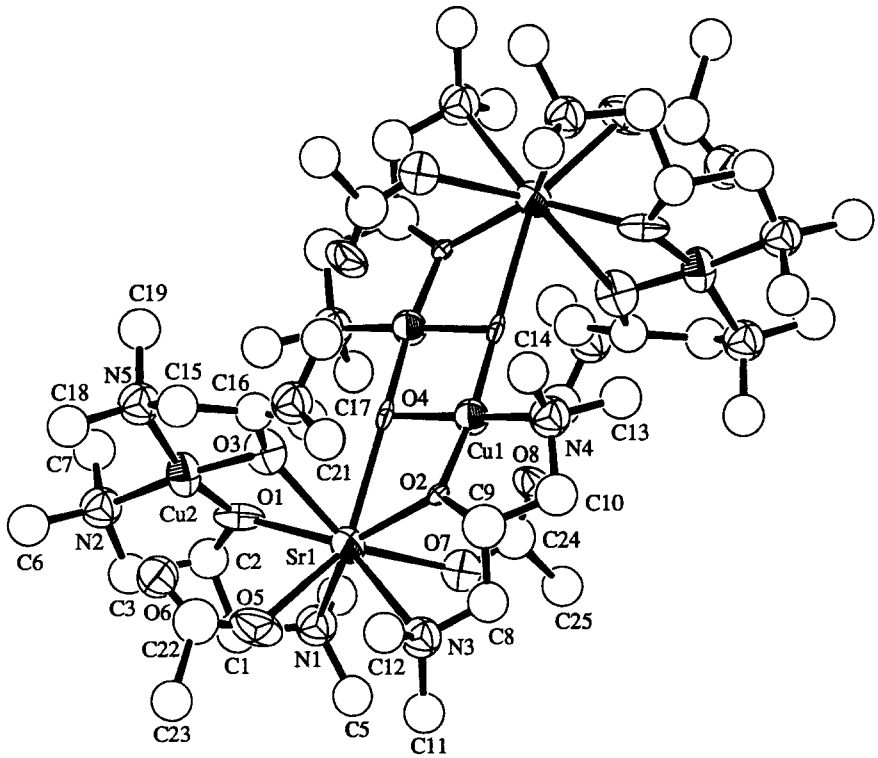

Fig. 13. The crystal structure of $Sr_2Cu_4(O_2CCF_3)_4(bdmap)_6(\mu_3\text{-}OH)_2$ (**9**). For clarity, the fluorine atoms are omitted.

position of these products still remains as a mystery to us. To encourage the formation of crystalline products, we added 2-hydroxyl pyridine to the reaction. The only crystalline compound isolated from these reactions was $BaCu_4(bdmap)_4(2\text{-}PyO)_4(O_2CCF_3)_2$ (**11**) which can be obtained in good yield from the reaction of $Ba(O_2CCF_3)_2$, $Cu(OCH_3)_2$, bdmapH, and 2-PyOH in a 1 : 4 : 4 : 4 ratio in THF [15]. Compound **11** has an interesting sandwich structure with the Ba^{II} ion seating in the center of the sandwich as shown in Fig. 14. The Ba^{II} ion is surrounded by eight oxygen atoms, 4 from the 2-PyO and 4 from the bdmap ligands. The nitrogen atoms are coordinated exclusively to the copper(II) ions. The two dinuclear copper(II) units are twisted about 60° from each other. The Cu—Cu distances in the dinuclear units are 2.919(7) Å and 2.921(7) Å while the Cu—O—Cu angles range from 89(1) to 97(1)°. The magnetic exchange in this complex has been found to be weakly antiferromagnetic.

Lanthanides/copper complexes of 2,6-bis[(dimethylamino)methyl]-4-methylphenol

We have demonstrated that 1,3-bis(dimethylamino)-2-propanol is a very useful ligand for the syntheses of mixed metal complexes involving lanthanides, alkaline-earth metal, and copper. However, it is difficult to control the products formed from the reactions due to their high dependency on the stoichiometry of all starting materials and reaction conditions. We were therefore interested in developing a more systematic and controlled approach for the synthesis of mixed metal complexes. One possibility is to use copper(II) complexes which contain appro-

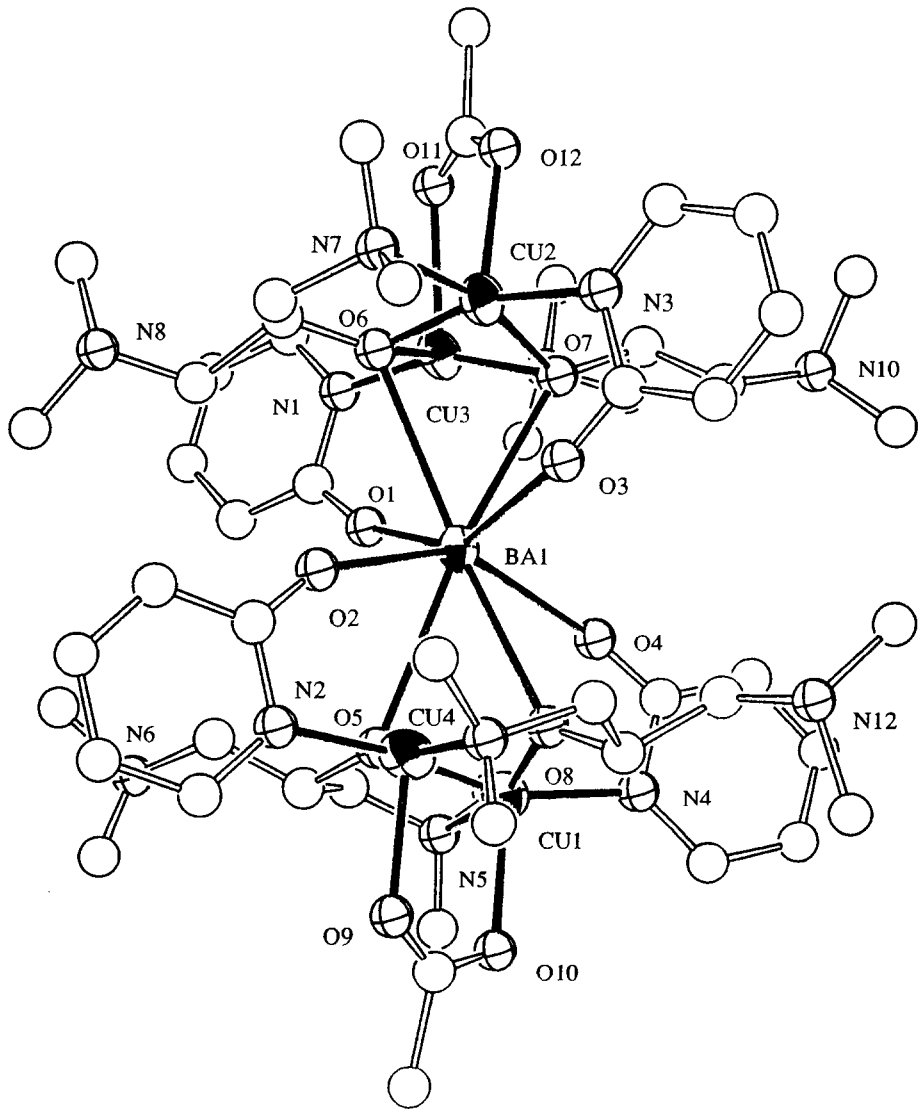

Fig. 14. The crystal structure of $BaCu_4(bdmap)_4(2\text{-}PyO)_4(O_2CCF_3)_2$ (**11**). For clarity, the fluorine atoms are omitted.

priate aminoalcohol ligands and vacant binding sites as the starting material. We have not been able to synthesize such a copper complex by using the bdmapH ligand. We have succeeded, however, in synthesizing a useful mononuclear copper(II) complex by using the bdmmpH ligand, $Cu(bdmmp)_2(H_2O)$ (**12**). The structure [16] of **12** is shown in Fig. 15. The oxygen atom of the phenolato group is bound to one copper(II) ion only, making it possible to bind to a second metal center such as a lanthanide ion. The other important feature of this compound is that it contains a coordinated H_2O ligand which forms two hydrogen bonds with two non-coordinating amino groups. This H_2O could potentially serve as a source of oxide or hydroxide ligands which are capable of bridging several metal ions. Indeed, when compound **12** was reacted with $Ln(hfacac)_3$ (Ln = Pr) in a 1 : 1 ratio, a dinuclear complex with the formula of $LnCu(bdmmp)(bdmmpH)(OH)(hfacac)_3$ (**13**) was obtained. The H_2O ligand in **12** became a bridging hydroxide ligand for the Cu^{II} and the Ln^{III} ions in **13** by losing one of its protons to the amino group [16]. We believe that the conversion of H_2O to OH^- in **13** is promoted by both the basic amino group and the lanthanide(III) ion which is known to have a high affinity toward water molecules. The singly coordinated oxygen atom from one of the bdmmp ligand in **12** became a bridging ligand to link the Cu^{II} and Ln^{III} ions together in **13**. For clarity, the structure of **13** is represented as a line drawing diagram in Scheme 3. When $Ln(hfacac)_3$ is replaced with $Ln(O_2CCF_3)_3$ (Ln = La) in the reaction, a tetranuclear complex with the formula of $[LnCu(bdmmp)(bdmmpH)(OH)(O_2CCF_3)_3]_2$ (**14**) was obtained. Compound **14** contains two dinuclear LnCu units linked together through four bridging trifluoroacetate ligands. The structure of the dinuclear LnCu unit in **14** is similar to that of **13** as shown in Scheme 3. The difference between compound **13** and compound **14** lies on the difference between the hfacac ligand and the trifluoroacetate ligand—the former almost always functions as a bidentate chelate ligand while the latter has the tendency to function as a bridging ligand.

Compound **13** is one of the few rare examples of discrete dinuclear CuLn complexes. The Pr–Cu separation distance in **13** is 3.538(2) Å. Magnetic susceptibility data indicated that the magnetic exchange between the Pr^{III} ion and the Cu^{II} ion is weakly antiferromagnetic [16].

Production of superconducting films by using a solution precursor system

One advantage provided by the bdmapH ligand is that it significantly improves the solubility of the metal compounds in organic solvents. For example, the mixture of $Y(O_2CCH_3)_3$, $Ba(O_2CCH_3)_2$, and $Cu(O_2CCH_3)_2$ in a 1 : 2 : 3 ratio produces precipitates in the solvents such as THF. The addition of acetic acid to the THF solution (1 : 5) improves the solubility at high temperature, but results in co-precipitation when the solution is cooled to ambient temperature. We have found that the co-precipitation can be prevented by adding a small amount of bdmapH to the solution (2 bdmapH per copper) [8a]. The solution obtained is dark blue and homogeneous. The viscosity of this solution can be adjusted readily by adjusting the amount of solvents. We believe that the bdmapH ligand forms complexes with the metal ions in the solution to increase their solubility. Although we have not been able to isolate any crystalline mixed metal compounds directly from the solution of the mixture, we believe that it is likely that some of the complexes formed in solution may be the same or related to those we obtained by independent syntheses, as described in earlier sections. The precursor solution made of $Y(O_2CCH_3)_3$, $Ba(O_2CCH_3)_2$, $Cu(O_2CCH_3)_2$, and bdmapH can be coated readily to a MgO (100) substrate via a spin-coating process. Subsequent heating and annealing treatments produced 1-2-3 films on the substrate. Superconducting films oriented along C

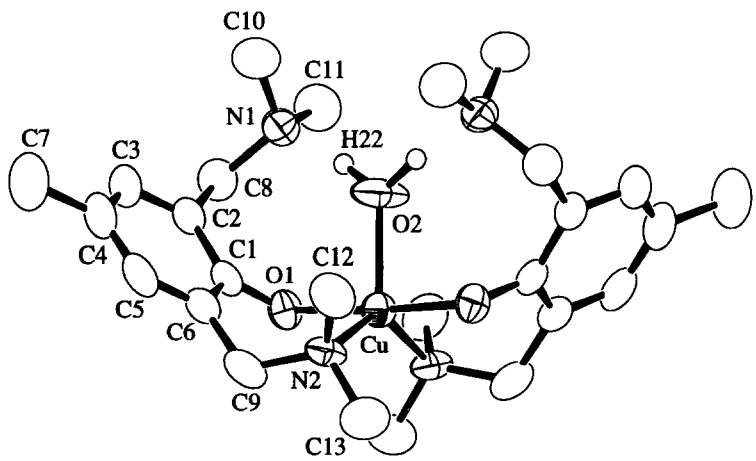

Fig. 15. The crystal structure of $Cu(bdmmp)_2(H_2O)$ (**12**).

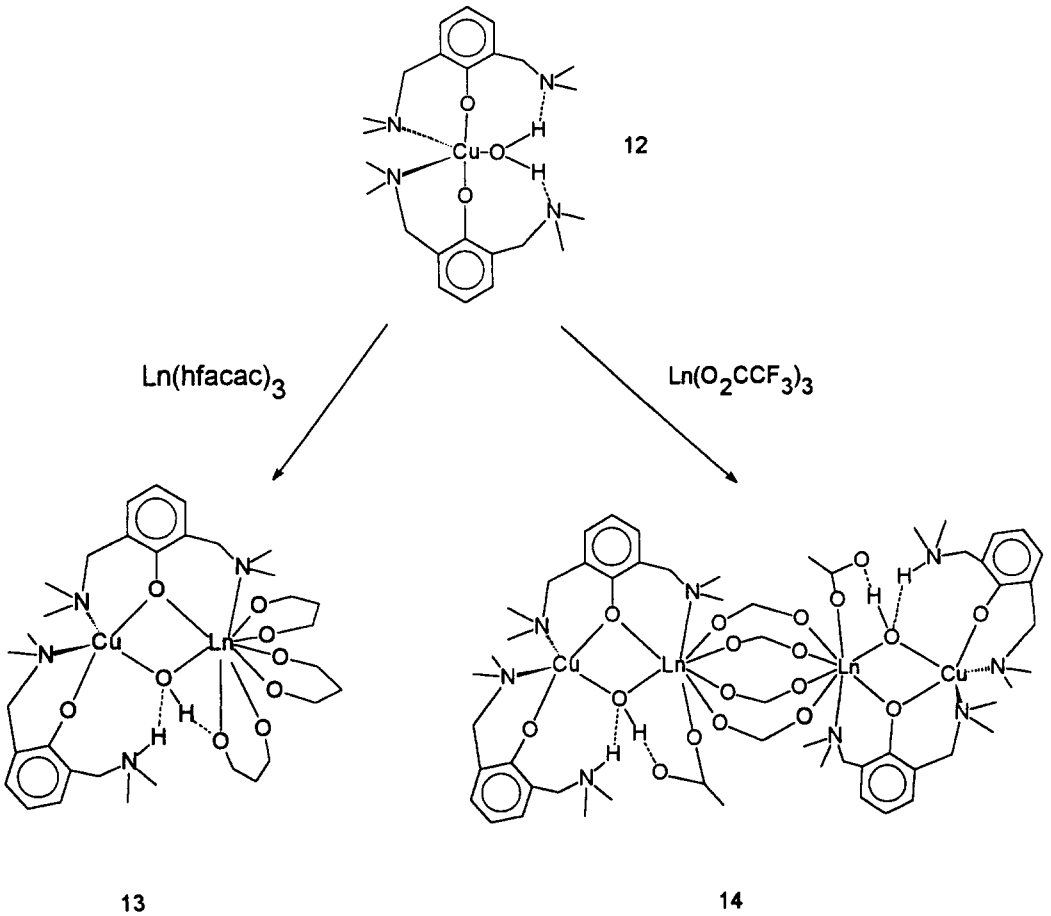

Scheme 3.

axis were obtained by repeated coating, heating, and annealing processes [17].

Summary

2-Hydroxyl pyridine and amino alcohol are efficient ligands for binding to both copper(II) ions and electropositive ions such as alkaline-earth metal and lanthanide ions. The structures and compositions of the mixed metal complexes obtained by using these ligands are highly dependent on the stoichiometry of the starting materials, the solvents, and the adventitious water molecules in the system. The $Cu(bdmmp)_2(H_2O)$ compound is a useful precursor complex for the systematic syntheses of mixed metal complexes. The presence of fluorinated ligands in the complexes generally lowers the thermal decomposition temperature substantially. However, fluorine contamination due to the formation of the MF_2 phase become a serious problem for complexes containing alkaline-earth metal ions. Introducing oxide or hydroxide bridging ligands in these complexes could minimize this problem. The bdmapH ligand is a useful cross-linking reagent for 1-2-3 superconducting films produced by a solution precursor system *via* spin coating. Magnetic exchange between paramagnetic lanthanide ions and copper(II) ions are weak. The magnetic exchange between copper(II) centers in these complexes are usually dominated by antiferromagnetism.

(Received 27 May 1997; accepted 23 June 1997)

Abstract—The synthesis of a series of trisaminopyridinato metal(III) complexes (metal = Ti, V and Cr) is reported. The titanium complex is synthesized by reduction of the monochloro Ti^{IV} complex (4-Me-TMS-APy)$_2$Ti(NMe$_2$)Cl (4-methyl-2-trimethylsilylaminopyridine = 4-Me-TMS-APyH) using sodium amalgam as a reducing agent. The vanadium complex is prepared *via* a salt elimination route using $VCl_3(THF)_3$ and 3 equiv of *in situ* lithiated 4-Me-TMS-APyH. The chromium complex is made *via* benzene elimination from $Ph_3Cr(THF)_3$ and 3 equiv of 4-Me-TMS-APyH. All three compounds are paramagnetic and the IR spectra of the compounds fit very well in the finger print range. The X-ray crystal structure analyses of the titanium and the chromium complexes establish their mononuclear structures with a strongly disturbed octahedral coordination geometry. The EPR spectra of the Ti^{III} and Cr^{III} complexes are reported. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: aminopyridinato ligands; titanium; vanadium; chromium; EPR spectra.

M^{III} amido complexes of the early transition metals were first described by Bürger and Wannagat [1] and simultaneously exploited by Bradley *et al.* [2]. They were investigated with regard to structural aspects and the nature of the amido metal bond [3]. Approaches nowadays using chelating amido ligands are focused on the design of well defined reactive pockets at such reduced metal centers, for instance, to activate substrates *via* oxidative addition pathways [4]. We are interested in following this tendency by exploring the capability of aminopyridinato ligands [5–7]. Due to the flexibility in the binding mode of such ligands it might be possible to stabilize reduced and thus reactive early transition metal centers *via* steric shielding, on the one hand, and to offer furthermore the opportunity of creating a reactive pocket *via* ligand rearrangement and/or metal pyridine bond cleavage if substrates are present in order to activate them. In this paper we report on the synthesis and structure of trisaminopyridinato complexes, (4-Me-TMS-APy)$_3$M (M = Ti, V, Cr and 4-Me-TMS-APyH = 4-methyl-2-trimethylsilylaminopyridine) as well as on EPR investigations of the three complexes. Amidinato ligands might be considered as the most related ligand system to aminopyridinato ligands and selected examples of six-coordinated complexes have been published for vanadium [8], titanium [9], and chromium [10].

EXPERIMENTAL

Materials and procedures

Solvents were dried and freshly distilled from sodium tetraethylaluminate under argon prior to use. 4-Methyl-2-trimethylsilylaminopyridine was prepared according to a method published previously [7] as well as (4-Me-TMS-APy)$_2$Ti(NMe$_2$)Cl. Trichlorotris-(tetrahydrofuran)vanadium(III) [16] and triphenyl-

* Author to whom correspondence should be addressed.

† Dedicated to Don Bradley in recognition of his outstanding contributions to amido metal chemistry.

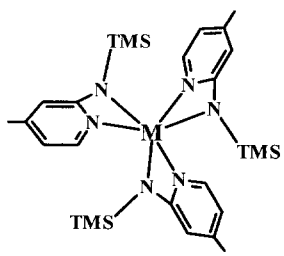
tris(tetrahydrofuran)chromium(III) [17] were synthesized according to literature methods. All manipulations were performed with rigorous exclusion of oxygen and moisture using standard Schlenk-technique.

Physical measurements

Elemental analyses were performed with a Leco CHNS-932 elemental analyzer. The IR-spectra were recorded on a Nicolet Magna 550 spectrometer. X-ray data were collected on a STOE-IPDS diffractometer using monochromated Mo-K_α radiation. The structures were solved by direct methods (SHELXS-86) [18] and refined by full matrix least square techniques against F^2 (SHELXL-93) [19], XP (Siemens Analytical X-ray Instruments, Inc.) was used for structure representations. Further details of the crystal structure investigations are available upon request from the Director of the Cambridge Crystallographic Data Center, 12 Union Road, GB-Cambridge CB2 1EZ (U.K.), on quoting the full journal citation. EPR spectra of $\approx 1 \times 10^{-2}$ M solutions of the compounds in hexane were recorded with a Bruker ESP 300E spectrometer at X-band frequency ($n \approx 9.5$ GHz) at $T = 295$ K and 110 K.

Preparation of tris(4-methyl-2-trimethylsilylamino-pyridinato)titanium(III), (1)

486 mg (1 mmol) of (4-Me-TMS-APy)$_2$Ti(NMe$_2$)Cl was added to a slurry of 23 mg (1 mmol) of sodium as sodium amalgam in 30 cm^3 of hexane and stirred for 24 h at room temperature. The reaction mixture was filtered, the solvent was reduced to half *in vacuo* and stored at -78 °C to yield 269 mg (46%) of **1**. IR (Nujol, cm^{-1}): 1600 and 1535 ν(ar C=C), 1316, 1292, 1245 δ_S(CH$_3$—Si), 1172, 1022, 962, 873 ν(N—Si), 843 γ(CH$_3$—Si), 788 δ(ar C—H), 766 γ(CH$_3$—Si), 727 δ(ar C—H), 589. $C_{27}H_{45}N_6Si_3Ti$ (585.83): Calc. C 55.36, H 7.74, N 14.35; found C 53.64, H 7.71, N 13.93%. We attribute the low carbon values of **1** and **3** to metal (Ti, V as well as Si) carbide formation.



M = Ti, V and Cr

Preparation of tris(4-methyl-2-trimethylsilylamino-pyridinato)chromium(III), (2)

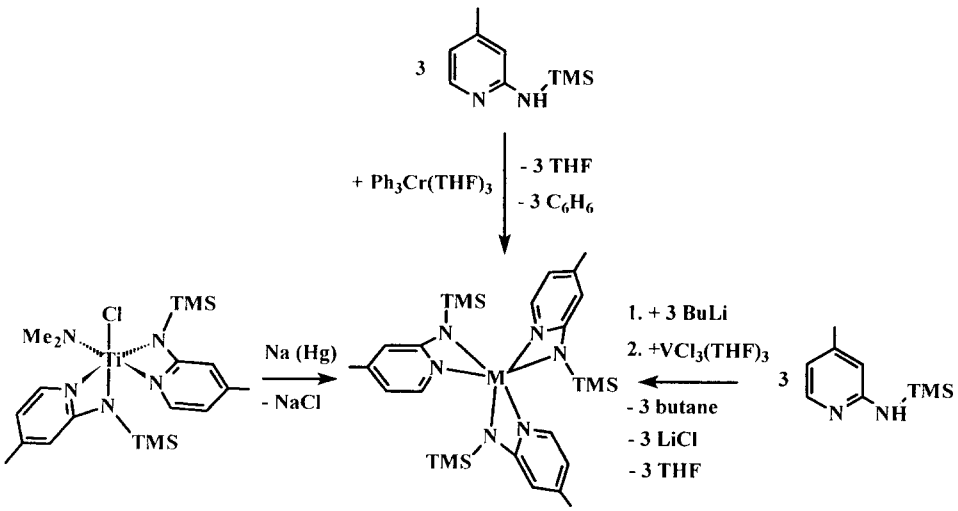
To a solution of 999 mg (2 mmol) of triphenyltris(tetrahydrofuran)chromium(III) in 30 cm^3 of THF was added 1.3 cm^3 (6 mmol) of 4-methyl-2-trimethylsilylaminopyridine at -40 C. The mixture was stirred for 24 h at room temperature. The solvent was removed *in vacuo*, the residue was taken up with hexane and filtered. At -78 °C 696 mg (59%) of **2** was slowly crystallized. IR (Nujol, cm^{-1}): 1606 and 1532 ν(ar C=C), 1326, 1293, 1243 δ_S(CH$_3$—Si), 1172, 1024, 970, 873 ν(N—Si), 840 γ(CH$_3$—Si), 783 δ(ar C—H), 766 γ(CH$_3$—Si), 730 δ(ar C—H), 591. $C_{27}H_{45}N_6Si_3Cr$ (589.95): Calc. C 54.97, H 7.69, N 14.25; found C 55.12, H 7.98, N 14.16%.

Preparation of tris(4-methyl-2-trimethylsilylamino-pyridinato)vanadium(III), (3)

To a solution of 1.9 cm^3 (9 mmol) of 4-methyl-2-trimethylsilylaminopyridine in 30 cm^3 of THF was added slowly *via* stirring 5.6 cm^3 (9 mmol) of a 1.6 M hexane solution of *n*-butyllithium at -40 °C. This mixture was stirred for 2 h at room temperature. 1.121 g (3 mmol) of trichlorotris(tetrahydrofuran)-vanadium(III) was partly solved in 25 cm^3 of THF. The lithiated ligand was added to this mixture and stirred for an additional 48 h at room temperature. The solvent was removed *in vacuo*, the residue was taken up with hexane and filtered off from LiCl. Crystallisation from hexane at -78 °C yielded 1.272 g (72%). IR (Nujol, cm^{-1}): 1603 and 1538 ν(ar C=C), 1315, 1291, 1247 δ_S(CH$_3$—Si), 1172, 1021, 969, 870 ν(N—Si), 840 γ(CH$_3$—Si), 787 δ(ar C—H), 767 γ(CH$_3$—Si), 729 δ(ar C—H), 592. $C_{27}H_{45}N_6Si_3V$ (588.89): Calc. C 55.07, H 7.70, N 14.27; found C 53.69, H 7.53, N 13.92%.

RESULTS AND DISCUSSION

The reduction of (4-Me-TMS-APy)$_2$Ti(NMe$_2$)Cl (smoothly prepared *via* amine elimination starting from (Me$_2$N)$_3$TiCl [11] and 2 equiv of 4-Me-TMS-APyH) with sodium amalgam in hexane leads to (4-Me-TMS-APy)$_3$Ti (**1**) according to Scheme 1. It is proposed that after the reduction the dimethylamido ligand is exchanged by an aminopyridinato ligand. Thus titanium dimethylamido species should be obtained as byproducts. Unfortunately, no such amido complexes were detected by NMR, which might be explained by possible paramagnetism. A salt elimination reaction of 3 equiv of *in situ* lithiated 4-Me-TMS-APyH and TiCl$_3$(THF)$_3$ failed. Compound **1** is a dark purple complex. Solution magnetic susceptibility measurements on **1** obtained in benzene solution by the method of Evans [12] gave $\mu_{eff} = 1.99$ μ_b, which is in accordance with one unpaired electron. Due to its paramagnetic nature an X-ray analysis was



Scheme 1. Synthesis of **1**, **2** and **3**.

carried out. Suitable crystals could be obtained after keeping a highly saturated hexane solution over two weeks at −78°C. A perspective ORTEP drawing of the molecular structure of **1** is shown in Fig. 1 as well as key bond distances and angles. Some important crystallographic features are shown in Table 1. The coordination geometry is best described as strongly disturbed octahedral. The virtual D_3 symmetry common to all of the homoleptic tris-chelated compounds [10] is not accomplished due to ligand asymmetry. The averaged Ti—N_{amido} bond length in **1** (2.09 Å {0.2 Å longer than the titanium amido bond normally [7]}), is different compared to the averaged Ti—$N_{pyridine}$ distance in **1**. The latter is 2.15 Å and only slightly shorter as the common titanium pyridine bond length [7]. Thus a weak metal amido and a typical pyridine bond are observed. Due to the analogy of the bonding situation of (4-Me-TMS-APy)$_2$Ti(NMe$_2$)Cl [7] and **1** in the solid state a similar behaviour in solution like ligand rotation *via* pyridine titanium bond cleavages is proposed.

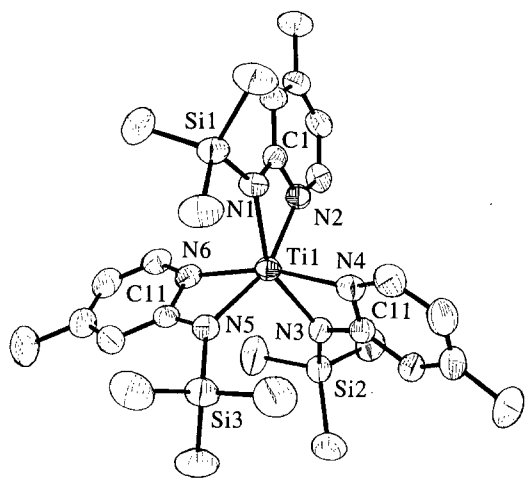


Fig. 1. Structural representation of **1**. Hydrogen atoms are omitted for clarity. The thermal ellipsoids correspond to 30% probability. Selected bond lengths (Å) and angles (°): C(1)—N(2) 1.359(4), C(1)—N(1) 1.370(4), C(6)—N(3) 1.369(4), C(6)—N(4) 1.372(4), C(11)—N(5) 1.351(4), C(11)—N(6) 1.383(4), N(1)—Ti(1) 2.069(3), N(2)—Ti(1) 2.186(3), N(3)—Ti(1) 2.094(3), N(4)—Ti(1) 2.137(3), N(5)—Ti(1) 2.103(2), N(6)—Ti(1) 2.126(3), N(2)—C(1)—N(1) 111.4(3), N(3)—C(6)—N(4) 109.9(3), N(5)—C(11)—N(6) 110.7(3), N(5)—Ti(1)—N(6) 64.28(10), N(3)—Ti(1)—N(4) 64.05(10), N(1)—Ti(1)—N(2) 63.90(10).

The reaction of 3 equiv of 4-Me-TMS-APyH with $Ph_3Cr(THF)_3$ leads *via* benzene elimination [13] to (4-Me-TMS-APy)$_3$Cr (**2**), a dark red chromium compound analogous to **1** (Scheme 1). The use of aryl elimination routes to synthesize Cr^{III} amido complexes is unusual and offers an attractive alternative approach to salt elimination routes. The high magnetic susceptibility of $\mu_{eff} = 4.47\ \mu_b$ indicates **2** to have three unpaired electrons. The single-crystal X-ray structure analysis of **2** establishes its monomeric structure as shown in Fig. 2 including principal bond distances and angles. Crystallographic data are listed in Table 1. The chromium complex is isomorphous to **1** and the general structural arrangements are equivalent. The averaged Cr—N_{amido} bond length (2.06 Å) is equal to the averaged Cr—$N_{pyridine}$ (2.04 Å) distance. Thus a delocalised binding mode with equivalent nitrogen metal bonds as those known for benzamidinate [14] complexes is proposed for **2**, which is in contrast to the binding situation in complex **1**.

Selected bond lengths (Å) and angles (°): C(1)—N(1) 1.341(8), C(1)—N(2) 1.377(9), C(6)—N(3) 1.361(7), C(6)—N(4) 1.359(9), C(11)—N(6) 1.355(7), C(11)—N(5) 1.354(7), N(1)—Cr(1) 2.056(6), N(2)—Cr(1) 2.054(5), N(3)—Cr(1) 2.079(6), N(4)—Cr(1) 2.024(6), N(5)—Cr(1) 2.066(5), N(6)—Cr(1) 2.027(5), N(1)—C(1)—N(2) 112.6(7), N(3)—C(6)—N(4) 109.6(7), N(6)—C(11)—N(5) 110.0(6), N(6)—C(11)—C(12) 118.9(6), N(1)—Cr(1)—N(2) 66.7(2), N(6)—Cr(1)—N(5) 65.6(2), N(4)—Cr(1)—N(3) 65.6(2).

The reaction of 3 equiv of *in situ* generated "4-Me-TMS-APyLi" with $VCl_3(THF)_3$ affords $(4\text{-Me-TMS-APy})_3V$ (**3**), a dark orange crystalline material according to Scheme 1. Compound **3** is a paramagnetic high-spin complex. Solution magnetic susceptibility measurements [12] on **3** obtained in benzene solution gave $\mu_{eff} = 3.67\ \mu_b$, significantly higher than 2.83 μ_b, the spin-only value for two unpaired electrons. The IR spectra of **1**, **2** and **3** are in accordance to each other as seen in the finger print plot (Fig. 3). Thus an analogous structural arrangement is assumed. **1**, **2** and **3** are very sensitive to air and moisture and very well soluble in hydrocarbon solvents. Due to the extremely high solubility the isolated yields of crystalline materials are always moderate.

The trisaminopyridinato M^{III} complexes have been studied by EPR in solutions at $T = 295$ K and 110 K. EPR spectra were obtained for the Ti^{3+} ($3d^1$) and the Cr^{3+} ($3d^3$) complexes, but not for the V^{3+} ($3d^2$) species. The room-temperature EPR spectra observed consist of a symmetrical single line with linewidths of 3 mT for Ti^{3+} and more than 200 mT for Cr^{3+}. The isotropic g values are found to be $g_0 = 1.936 \pm 0.003$ and $g_0 = 2.000 \pm 0.005$ for the titanium and the chromium complex, respectively. In Fig. 4(a) the frozen solution EPR spectrum of **1** is shown. The spectrum of the titanium complex consists of the liquid solution of a single line also. However, the linewidth is larger ($\Delta B_{pp} = 6.5$ mT) and slightly anisotropic indicating a small **g** anisotropy. It is also centered at $g = 1.936$.

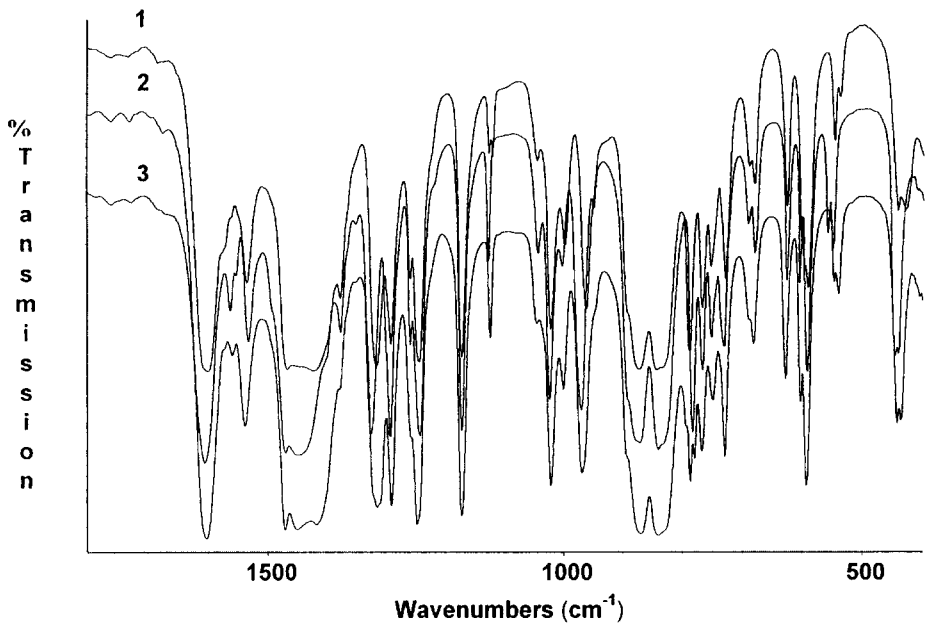

Fig. 3. IR spectra (Nujol) of **1**, **2** and **3** in the finger print range.

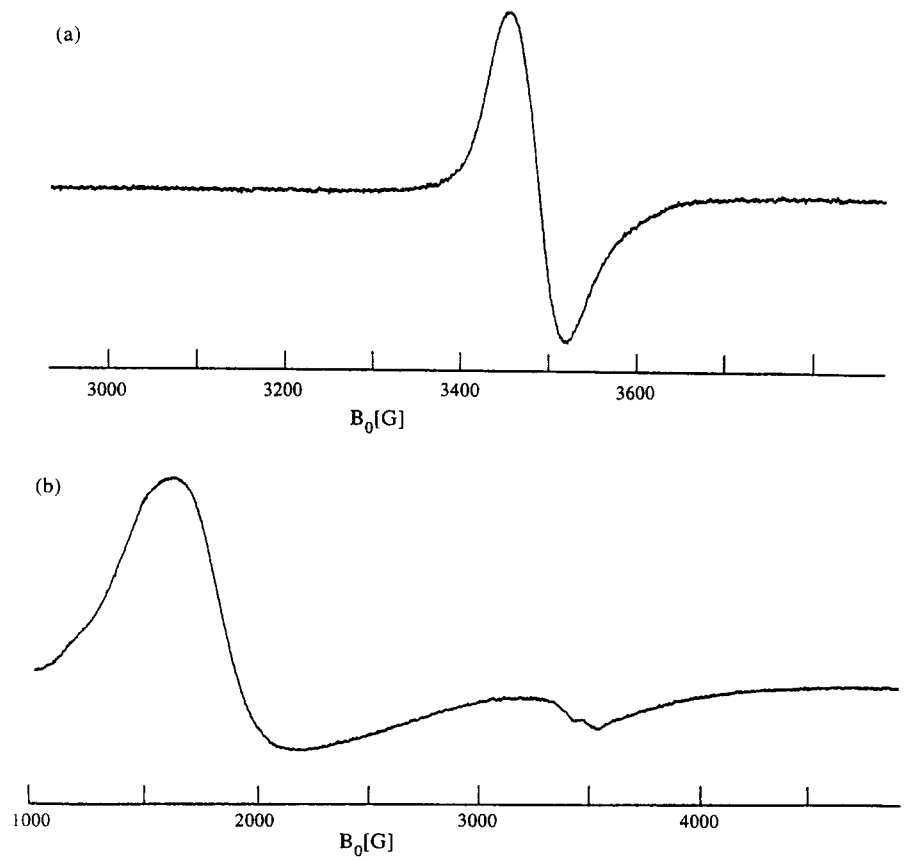

Fig. 4. X-band EPR spectra of (4-Me-TMS-APy)$_3$Ti (a) and (4-Me-TMS-APy)$_3$Cr (b) in frozen hexane, $T = 110$ K.

Due to the small anisotropy of the line observed the individual components of the **g** tensor cannot be derived (nor by the simulation programs available). The observation of ^{47,49}Ti hyperfine interactions is prevented because of the large linewidth and the low natural abundance of the isotopes ^{47}Ti and ^{49}Ti. Figure 4(b) represents the frozen solution EPR spectrum of the chromium complex. In the field range up to 1 T no additional EPR signals were observed. The spectrum consists of signals in the $g = 6$–4 and $g = 2$ region which is in agreement with a $S = 3/2$ spin-system having a fine structure interaction $\mathbf{S} \times \mathbf{D} \times \mathbf{S}$ which exceeds the electron Zeeman interaction $m_B \mathbf{g} \times \mathbf{B} \times \mathbf{S}$ in magnitude. According to the numerous $\mathbf{S} = 3/2$ spectra simulations published by Mabbs and Collision [15] the fine structure parameter D is found to be $\geqslant 1$ cm^{-1}; also a rhombic distortion is indicated (see $g = 2$ region). The EPR spectra are in good agreement with what can be drawn from the crystal structure analyses which provide disturbed octahedral symmetries for the complexes under study. For the vanadium(III) complex no EPR spectrum has been observed in the temperature range applied. This is not surprising, since for V^{3+} in an octahedral environment the orbital ground state is a triplet one which will be split by lower-symmetric ligand field components. Obviously, this splitting is not large and thus results in short spin-lattice relaxation times which prevent the detection of EPR spectra in the temperature range studied.

(Received 7 May 1997; accepted 23 June, 1997)

Abstract—The complexes $[WOCl_3(OAr)]_x$ (Ar = 4-*tert*-butylphenyl **1**, 2,6-dimethylphenyl **2**, 2,6-di-*iso*-propylphenyl **3**) are prepared by reacting HOAr with an excess of $[WOCl_4]$ but are thermodynamically unstable forming bis-phenoxide complexes on standing. Debutylation occurs with 2,6-di-*tert*-butylphenol but a monophenoxide **4** was prepared with the lithium phenoxide. The complex debutylates and forms bis-phenoxides on standing. An X-ray crystal structure of **2** shows a dimeric chloro-bridged structure with terminal oxo and 2,6-dimethylphenoxide ligands. The oxo ligand acts essentially as a $1\sigma, 2\pi$ donor to tungsten [W—O(1) bond length 1.679(4) Å] and the phenoxide as a $1\sigma, 1\pi$ donor [W—O(2) bond length 1.820(4) Å]. The phenyl ring positions to reduce interactions of the methyl substituents with the oxo and chloro ligands but NMR spectra show rapid phenoxide rotation in solution. Variable temperature NMR spectral studies of **4** show the *tert*-butyl groups lock the rotation which may be important in the debutylation process. The complexes have limited catalytic potential due to instability. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: phenoxide; oxo; tungsten.

Phenoxide complexes of tungsten are of interest in the field of C—H activation [1], alkene metathesis [2] and polymerisations [3]. Most often the complexes used contain two or more phenoxides which are effective π-donor ligands. However the number of phenoxides in a complex is not always easy to control. This is demonstrated in the preparation of a series of complexes with the general formula $[WCl_{6-x}(OAr)_x]$ ($x = 2$, 3 and 4) where the reaction was sensitive to the phenol used and did not seem to follow any definite pattern with regard to the steric or electronic properties of the phenol [4]. Our interest in phenoxide complexes of tungsten is in the production of cost effective complexes for use in catalytic processes. We report here the preparation and properties of monophenoxy-oxo complexes of tungsten(VI) which are derived from the inexpensive compound $[WOCl_4]$ and commercially available phenols using simple reaction procedures.

RESULTS AND DISCUSSION

Initial attempts to replace one of the chloro ligands in $[WOCl_4]$ with a phenoxide ligand using a 1:1 ratio of reactants, invariably led to mixtures containing mono and bis-phenoxide complexes which proved difficult to separate analytically pure. However, an appreciable excess of $[WOCl_4]$ was found to suppress formation of the bis-phenoxide which was always present with $[WOCl_4]$:phenol ratios less than about 1.5:1. Thus when a dichloromethane solution of *p*-*tert*-butylphenol was added to $[WOCl_4]$ dissolved in diethyl ether, the purple monophenoxide complex $[WOCl_3(OC_6H_4Bu^t\text{-}4)]_x$ **1**, was formed in 90% yield.

$$\text{excess } [WOCl_4] + HOC_6H_4Bu^t\text{-}4 \rightarrow [WOCl_3(OC_6H_4Bu^t\text{-}4)]_x \ \mathbf{1}$$

If toluene was used in place of diethyl ether, the reaction produced significant amounts of the bis-phenoxide complex, probably as a result of the lower solubility of $[WOCl_4]$ in this solvent. Complex **1** formed as a somewhat impure powder which failed to

produce crystals for a structure determination. Both the ^1H and ^{13}C-$\{^1H\}$ NMR spectra showed single resonances for the appropriate hydrogen and carbon atoms with the *ipso* carbon resonance occurring at δ 160.29 in the ^{13}C-$\{^1H\}$ NMR spectrum.

Reaction of 2,6-dimethylphenol, or its trimethylsilyl ether derivative, with $[WOCl_4]$ gave a crystalline purple complex analysing as the mono phenoxide $[WOCl_3(OC_6H_3Me_2\text{-}2,6)]_x$, which was shown to be a chloro-bridged dimer **2** by X-ray crystallography.

$$\text{excess } [WOCl_4] + HOC_6H_3Me_2\text{-}2,6 \rightarrow [WOCl_3(OC_6H_3Me_2\text{-}2,6)]_2$$

$$\text{excess } [WOCl_4] + Me_3SiOC_6H_3Me_2\text{-}2,6 \rightarrow [WOCl_3(OC_6H_3Me_2\text{-}2,6)]_2$$

The structure (Fig. 1) showed the molecule to be dimeric with the two halves centrosymmetrically related. Each tungsten atom adopts a distorted octahedral coordination geometry with chloro ligands making up the asymmetric bridge. The oxo ligand lies *trans* to the longer bridge with a terminal chloride ligand lying *trans* to the other. The remaining coordination sites are filled by terminal phenoxide and chloride ligands which are mutually *trans*. Selected bond lengths and angles are contained in Table 1. The W—Cl(1) distance [2.394(2) Å] is marginally shorter than the equivalent W—Cl bond in the structurally related complex $[WCl_4(NCHMe_2)]_2$ [2.418(4) Å] [5], but the W—Cl(1′) distance [2.876(2) Å], *trans* to the oxo ligand, is considerably longer than in the imido complex [2.736(5) Å] reflecting the stronger *trans* influence of the oxo ligand [6]. The W—Cl(3) bond length in **2** [2.303(2) Å], is of similar magnitude to the analogous bond in the imido complex [2.285(4) Å], and both these distances are similar to the remaining *trans* related terminal W—Cl bonds in the imido complex [W—Cl, 2.310(4) and 2.285(4) Å]. The equivalent positions to these two chlorides are occupied by *trans* oriented phenoxide and chloro ligands in **2**, where the W—Cl(2) distance is lengthened to 2.325(2) Å, indicating the phenoxide exerts a *trans* influence. A similar situation exists in $[WCl(NPh)(OEt)_2(\mu\text{-}OEt)]_2$

where an alkoxide ligand lies *trans* to a chloro ligand [7].

It is of interest to assess the π-donor contributions from the oxo and phenoxide ligands in **2**, especially in view of the phenoxide ligand preferring a terminal position rather than the expected bridging mode. The W—O(1) bond length [1.679(4) Å] is significantly shorter than those found for $[WCl_2(O)_2(bipy)]$ (bipy = 2,2′-bipyridyl), [1.745(3) and 1.792(2) Å] [8] and $[WCl_2(O)(NCMe_3)(bipy)]$ [1.716(5) Å] [9] where neither the oxo or imido ligands appear to dominate the π-donation. While the oxo ligands in these complexes may be lengthened somewhat by a hydrogen bond type interaction to the bipy ligand, the short W—O(1) bond in **2** is probably best represented by a 1σ, 2π donor interaction which leaves the phenoxide ligand as a 1σ, 1π donor if the electron count is to be maximised. However, significant orbital sharing can still be expected so that the oxo and phenoxide ligands cannot be regarded as pure 1σ, 2π or 1σ, 1π donors, respectively. The W—O(2) bond distance [1.820(4) Å] is similar to those found in $[WCl_4(OC_6H_3Ph_2\text{-}2,6)_2]$ where a high degree of ligand to metal π-donation is expected [4]. The W—O(2)—C(1) bond angle [167.6(4)°] is larger than that found for the two phenoxides in $[WCl_4(OC_6H_3Ph_2\text{-}2,6)_2]$ [141.8(6) and 149.3(6)°] [4] being closer to linearity than expected but may be influenced by crystal packing forces in much the same way as W—N—C bond angles are in imido complexes [10]. The phenyl ring rotates only slightly to remove unfavourable steric interactions of the *ortho* methyl groups with O(1) and Cl(1′) which appears to allow the C(1) *p*-orbital to maximise overlap with the O(2)—W(1) π-donor system. In the absence of strong crystal packing forces, there would seem to be conflict in the solid state between steric and electronic influences which could be more significant if there were larger substituents in the *ortho* positions. In solution however, the phenoxide ligand is rotating rapidly on the NMR time scale as only one methyl resonance is observed. π-Donation is maximised in the complex apparently by having a terminal phenoxide ligand rather than a weaker π-donor chloro ligand. Overall the bonding situation in solution for the terminal phenoxide is reflected by the *ipso* carbon resonance in the $^{13}C\text{-}\{^1H\}$ NMR spectrum which appears at δ 164.16.

Several exploratory reactions were carried out to determine the reactivity of **2**. The chloro bridge remains intact after dissolving the solid in thf (tetrahydrofuran) or diethyl ether but addition of pyridine (py) gave $[WOCl_3(OC_6H_3Me_2\text{-}2,6)(py)]$ as shown by a 1:1 ratio of phenoxide and py ligands in the ^1H NMR spectrum. Insertion of carbon monoxide into the M—O phenoxide bond did not occur, even under pressure with heating in benzene while reaction with *tert*-butylisocyanate yielded a mixture of products. Reduction with 2 equiv. of Na/Hg amalgam in the presence of trimethylphosphine gave an unstable complex identified as $[WOCl(OC_6H_3Me_2\text{-}2,6)(PMe_3)_3]$ on the basis of its ^1H NMR spectrum. This showed a 1:3 phenoxide to PMe_3 ligand ratio with a triplet and doublet in a 2:1 ratio for the phosphines thus indicating a *mer* geometry [11].

In an attempt to resolve the issue of conflict between electronic and steric influences suggested by the X-ray crystal structure of **2**, an excess of $[WOCl_4]$ was reacted with phenols bearing larger substituents in the 2,6 positions of the phenyl ring. Reaction with 2,6-di-*iso*-propylphenylphenol gave the complex $[WOCl_3(OC_6H_3Pr^i_2\text{-}2,6)]_x$ **3**, for which NMR spectra showed a single species with an *ipso* carbon resonance at δ 161.34. When the complex was allowed to stand for several days in the solid state or heated in a solvent, NMR spectra and elemental analysis showed the presence of the bis-phenoxide complex $[WOCl_2(OC_6H_3Pr^i_2\text{-}2,6)]_x$.* Indeed NMR spectra of **2**, left to stand for several days at room temperature, also showed the presence of the analogous bis-phenoxide complex.

Reaction of 2,6-di-*tert*-butyl-4-methylphenol, or the trimethylsilyl ether derivative, with excess $[WOCl_4]$ again led to a purple solid but NMR spectra indicated one of the *tert*-butyl groups had been removed. We believe the complex is $[WOCl_3(OC_6H_3Bu^t\text{-}2\text{-}Me\text{-}4)]_x$ but it also appears to form a bis-phenoxide on standing. Lithium 2,6-di-*tert*-butyl-4-methylphenoxide reacted with an excess of $[WOCl_4]$ to form a single product with an *ipso* carbon resonance at δ 165.07 which is apparently $[WOCl_3(OC_6H_2Bu^t_2\text{-}2,6\text{-}Me\text{-}4)]_x$ **4**. However NMR spectra show that on recrystallisation or allowing the complex to stand, de-*tert*-butylation and the formation of the bis-phenoxide complexes takes place.

The ^1H and $^{13}C\text{-}\{^1H\}$ NMR spectra of a freshly prepared sample of **4** show two resonances for the *tert*-butyl groups. This suggests a structure similar to that of the dimeric complex **2** where the phenoxide ligand does not rotate about the asymmetric centre. The chemical shift difference, Δ, of the two non-equivalent *tert*-butyl groups in the ^1H NMR spectrum show a significant solvent dependence, on changing $CDCl_3$ to the more anisotropic toluene-d^8 (Δ_{CDCl_3} = 0.006 ppm; $\Delta_{toluene\text{-}d^8}$ = 0.15 ppm). The non-equivalent aromatic protons display characteristic first order splitting patterns with a coupling constant typical of a *meta* arrangement (1.9 Hz). Variable temperature ^1H NMR spectral studies in toluene-d^8 showed the *tert*-butyl group proton resonances broadened but did not coalesce up to the boiling point of the solvent (110°C) indicating the *tert*-butyl groups effectively lock the phenoxide into a specific conformation. In contrast, the spectra of the *iso*-propyl and methyl analogues, **3** and **2**, show the phenoxides are free to rotate.

* A range of bis phenoxide complexes have been prepared and will be reported at a later date.

EXPERIMENTAL

Elemental analysis were obtained by Dr A. G. Cunninghame and associates, University of Otago, New Zealand. All reactions and subsequent manipulations were carried out under dry, oxygen-free nitrogen using standard bench-top techniques. $[WOCl_4]$ was prepared by reaction of H_2WO_4 in thionyl chloride [13] and phenols were used as received. The trimethylsilylethers were prepared by reacting sodium amide with the appropriate phenol in diethyl ether, adding chlorotrimethylsilane and fractionally distilling the product. Hexane and diethyl ether were dried over and distilled from sodium wire/benzophenone under nitrogen and dichloromethane from finely ground calcium hydride. ^{1}H NMR (400.14 MHz) and ^{13}C-$\{^1$H$\}$ NMR (100.6 MHz) spectra were recorded on a Bruker AM400 spectrometer.

Preparation of $[WOCl_3(C_6H_4Bu^t\text{-}4)]_x$ (**1**)

A solution of *p-tert*-butylphenol (0.30 g, 2.0 mmol) in dichloromethane (25 cm^3) was added to a solution of $[WOCl_4]$ (1.71 g, 5.0 mmol) in diethyl ether (25 cm^3) and dichloromethane (40 cm^3) and the resulting purple solution stirred overnight. Removal of the solvent followed by drying *in vacuo* afforded a purple amorphous solid which was extracted into hexane (40 cm^3) and filtered through celite. Removal of the solvent afforded the analytically pure complex. Yield 0.82 g (90%) of **1** as a moisture-sensitive purple powder. ^{1}H NMR ($CDCl_3$) δ, 1.34 (s, 9H, ^{t}Bu), 7.18 (d, 2H$_m$, $^3J_{HH}$ = 8.7 Hz), 7.54 (d, 2H$_o$, $^3J_{HH}$ = 8.7 Hz). ^{13}C-$\{^1$H$\}$ NMR ($CDCl_3$) δ 31.48 (CMe_3), 34.75 (CMe_3), 120.14 and 126.43 (C_o and C_m), 155.03 (C_p), 160.29 (C_{ipso}). Found: C, 26.67; H, 2.89. Calc. for $C_{10}H_{13}Cl_3O_2W$: C, 26.37; H, 2.89%.

Preparation of $[WOCl_2(\mu\text{-}Cl)(O\text{-}C_6H_3Me_2\text{-}2,6)]_2$ (**2**)

Method A. A solution of 2,6-dimethylphenol (0.45 g, 3.68 mmol) in diethyl ether (20 cm^3) was added dropwise to a solution of $[WOCl_4]$ (1.75 g, 5.12 mmol) in diethyl ether (50 cm^3) and the resulting purple solution stirred overnight. The workup was identical to that of **1** using hexane as the extraction solvent. Removal of the solvent afforded analytically pure **2** as a moisture-sensitive purple glassy solid (1.5 g, 95%) which was recrystallised from hexane at -20°C. ^{1}H NMR ($CDCl_3$) δ, 2.66 (s, 6H, 2Me), 6.95 (d, 1H$_p$, $^3J_{HH}$ = 7.6 Hz), 7.23 (d, 2H$_m$, $^3J_{HH}$ = 7.6 Hz). ^{13}C-$\{^1$H$\}$ NMR ($CDCl_3$) δ, 17.19 (Me), 128.34 (C_m), 132.61 (C_p), 134.25 (C_o), 164.16 (C_{ipso}). Found: C, 22.44; H, 2.12. Calc. for $C_{16}H_{18}Cl_6O_4W_2$: C, 22.48; H, 2.12%.

Method B. A solution of 2,6-dimethylphenyltrimethylsilylether (0.71 g, 3.65 mmol) in diethyl ether (15 cm^3) was added dropwise to a solution of $[WOCl_4]$ (3.13 g, 9.16 mmol) in diethyl ether (70 cm^3) and the mixture stirred overnight. Workup as for method A afforded an identical product to method A. Yield 1.44 g (92%).

Preparation of $[WOCl_3(OC_6H_3Pr^i_2\text{-}2,6)]_x$ (**3**)

In an analogous procedure to that of **1**, $[WOCl_4]$ (1.5 g, 4.39 mmol) and 2,6-di-*iso*-propylphenol (0.50 g, 2.80 mmol) afforded 1.2 g (92%) of **3** as a moisture-sensitive purple wax. ^{1}H NMR ($CDCl_3$) δ, 1.35 (d, 12H, $CHMe_2$, $^3J_{HH}$ = 6.7 Hz), 3.08 (sept, 2H, $2CHMe_2$, $^3J_{HH}$ = 6.7 Hz), 7.10 (t, 1H$_p$, $^3J_{HH}$ = 7.7 Hz), 7.31 (d, 2H$_m$, $^3J_{HH}$ = 7.7 Hz). ^{13}C-$\{^1$H$\}$ NMR ($CDCl_3$) δ, 23.92 ($CHMe_2$), 30.20 ($CHMe_2$), 123.83 (C_m), 133.25 (C_p), 145.15 (C_o), 161.34 (C_{ipso}). Found: C, 26.32; H, 3.47. Calc. for $C_{12}H_{17}Cl_3O_2W$: C, 29.81; H, 3.54%.

Preparation of $[WOCl_3(OC_6H_2Bu^t_2\text{-}2,6\text{-}Me\text{-}4)]_x$ (**4**)

A solution of lithium 2,6-di-*tert*-butyl-4-methylphenoxide was prepared by the addition of *n*-BuLi (1.8 M, 1.6 cm^3, 2.88 mmol) in hexane to a solution 2,6-di-*tert*-butyl-4-methylphenol (0.62 g, 2.81 mmol) in diethyl ether (30 cm^3) at 0°C followed by stirring for 4 hours at room temperature. This solution was then added dropwise to a solution of $[WOCl_4]$ (1.75 g, 5.12 mmol) in diethyl ether (50 cm^3) at -78°C over a period of 20 minutes then stirred at room temperature overnight. After removal of the solvent and drying *in vacuo*, the purple wax was washed with cold (-78°C) hexane (10 cm^3) and further dried. Workup as for **1** afforded 1.0 g (68%) of **4** as a moisture-sensitive waxy solid. ^{1}H NMR ($CDCl_3$) δ, 1.55 (s, 9H, Bu^t), 1.55 (s, 9H, Bu^t), 2.84 (s, 3H, Me), 7.23 (d, 1H$_m$, $^4J_{HH}$ = 1.9 Hz), 7.27 (d, 1H$_m$, $^4J_{HH}$ = 1.9 Hz). ^{13}C-$\{^1$H$\}$ NMR ($CDCl_3$) δ, 30.31 (Me), 30.59 (CMe_3), 34.10 (CMe_3), 35.54 (CMe_3), 36.03 (CMe_3), 125.56 and 127.36 (C_m), 144.21 (C_p), 147.49 and 147.73 (C_o), 165.07 (C_{ipso}).

Crystallography

Data were collected on a Siemens SMART diffractometer. The data collection covered a nominal sphere of reciprocal space, by a combination of four sets of exposures. Each set had a different phi angle for the crystal and each exposure covered 0.3° in α. Coverage of the unique data set is at least 98% complete to 56° in 2θ. Crystal decay was monitored by repeating the initial frames at the end of data collection and analysing the duplicate reflections. Unit cell parameters were obtained by least squares fit of all data with $I > 10\sigma(I)$. Lorentz and polarisation reflections were applied and absorption corrections by the method of Blessing [14].

The structure was solved by Patterson and Fourier techniques and refined by full matrix least squares.

All non-hydrogen atoms were allowed to assume anisotropic thermal motion. Hydrogen atoms were placed geometrically and refined with a riding model with U_{iso} constrained to 1.2 times U_{eq} of the carrier atom. Data collection and refinement parameters are given in Table 2 and Table 1 lists important bond lengths and angles. The structure is illustrated in Fig. 1 which gives the numbering scheme. Programs used were SHELXS [15] for structure solution and SHELXL [16] for refinement.

CONCLUSIONS

This work shows that monophenoxy derivatives of $[WOCl_4]$ can be prepared but the complexes are not particularly stable. This feature seems to increase as the size of the substituents in the 2,6-positions of the phenyl ring become larger. Methyl and *iso*-propyl substituents allow rapid rotation of the phenoxide ligand to occur but *tert*-butyl groups lock this process. This could well be a factor in the debutylation which takes place on standing, and may be related to similar debutylations of 2,6-di-*tert*-butyl substituted phenols initiated by strong Lewis acids such as $AlCl_3$ which is utilised extensively in phenol chemistry [12]. Overall, these monophenoxy-oxo complexes do not appear to rate as potential catalysts due to their inherent instability.

Pyridine, isocyanide, carbodiimide and allene adducts of hexakis(trifluoromethyl *t*-botoxy)ditungsten. A comparison of ligand binding to $W_2(O^tBu)_6$ and $W_2(OCMe_2CF_3)_6$†

(Received 2 May 1997; accepted 23 June 1997)

Abstract—$W_2(OR)_6$ compounds, where R = ^{t}Bu and CMe_2CF_3, both reversibly bind pyridine in hydrocarbon solvents to form adducts $W_2(OR)_6L_2$. Pyridine binds more strongly to the fluoroalkoxide but the structural parameters of the compounds $W_2(OCMe_2CF_3)_6(C_6H_5N)_2$ and $W_2(O^tBu)_6(4\text{-}CH_3C_6H_4N)_2$ reveal an essentially identical $W_2O_6N_2$ core with W—W = 2.39(1) Å, W—O = 1.92–1.95 Å and W—N = 2.26(1) Å. Both compounds were crystallographically characterized in the space group $C2/c$ and each molecule has rigorous C_2 symmetry. Allene and 1,3-di-*p*-tolylcarbodiimide form 1 : 1 adducts with $W_2(OCMe_2CF_3)_6$ in which the substrate is bound parallel to the M-M axis, i.e. μ-η^2,η^2-C_3H_4 and μ-η^2,η^2-ArNCNAr-$W_2(OCMe_2CF_3)_6$. Also $W_2(OCMe_2CF_3)_6$ and $W_2(OSi^tBuMe_2)_6$ bind two equivalents of xylylisocyanide to afford $W_2(OR)_6(\eta^1\text{-CNAr})_2$. For $W_2(OCMe_2CF_3)_6(\eta^1\text{-CNAr})_2$, the molecular structure has been determined by X-ray crystallography and shows a nearly eclipsed central $W_2O_6C_2$ skeleton with W—W = 2.44(1) Å, W—O = 1.94(1) Å (av.) and W—C = 2.14(1) Å, whereas the W—W—O angles span the range 105–114°, the W—W—C angles are 83(1)°. Similarly, $W_2(OCMe(CF_3)_2)_4(NMe_2)_2$ forms a *bis* adduct upon reaction with the isocyanide. However, the molecular structure of $W_2(OCMe(CF_3)_2)_4(NMe_2)_2(\eta^1\text{-CNAr})_2$ shows a staggered arrangement of the two ligands about the ditungsten center where W—W = 2.382(1) Å, W—O = 2.00(1) Å (av.), W—N = 1.93(1) Å (av.) and W—C = 2.14(1) Å (av.) with a C—W—W—C dihedral angle of 41.9°. These reactions and their products are compared for $W_2(OR)_6$ compounds where R = ^{t}Bu, ^{t}BuMe$_2$Si and CMe_2CF_3. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: tungsten; M-M triple bonds; alkoxides; isocyanide; carbodiimide; allene.

The reactivity of a metal center is greatly influenced by its attendant ligands and perhaps nowhere is this more apparent than in catalysis. In our studies of the reactivity of compounds containing $(M{\equiv}M)^{6+}$ bonds we find that the nature of the metal, Mo versus W, and the attendant ligand set greatly influence reactivity but in a way in which we do not yet fully understand. For example, $W_2(O^tBu)_6$ and NO react in the presence of pyridine (py) to give $W(O^tBu)_3(NO)(py)$ [1] by cleavage of the W—W triple bond whereas NO and $W_2(OSi^tBuMe_2)_6$ yield N_2 and oxotungsten siloxides [2]. $Mo_2(O^tBu)_6$ dissolves in acetonitrile whereas $W_2(O^tBu)_6$ and MeC≡N react virtually instantaneously at room temperature to give $(^tBuO)_3W{\equiv}N$ and $(^tBuO)_3W{\equiv}CMe$ [3]. $W_2(OCMe_2CF_3)_6$ and MeC≡N on the other hand react in solution to give an equilibrium wherein acetonitrile forms a σ- or η^1-N bound adduct, eq. (1) [4].

$$W_2(OCMe_2CF_3)_6 + 2MeC{\equiv}N \rightleftharpoons W_2(OCMe_2CF_3)_6(NCMe)_2 \quad (1)$$

While some of these remarkable differences in reactivity may be traced to thermodynamics, we are inclined to the view that kinetic factors are also important if not the dominant factors influencing reactivity

[5]. Thus the frontier orbital energies of the substrates and metal centers involved are most significant. In this paper we compare further some reactivity studies of $W_2(OCMe_2CF_3)_6$, and other W_2^{6+} complexes supported by poorer π-donors, with the closely related compound $W_2(O^tBu)_6$.

RESULTS AND DISCUSSION

Syntheses and reactivity studies

Pyridine binds to both $W_2(O^tBu)_6$ and $W_2(OCMe_2CF_3)_6$ in hydrocarbon solutions. By ^1H NMR spectroscopy the binding is seen to be reversible according to eq. (2). The position of the equilibrium lies in favor of the binding to the trifluorobutoxide compound but an accurate measurement of K_{eq} has not been determined by these NMR studies. The equilibrium is dynamic on the NMR time-scale as is rotation about the M—M bond axis and for R = ^{t}Bu these are not frozen out until *ca* -30°C in toluene-d_8.

$$W_2(OR)_6 + 2py \rightleftharpoons W_2(OR)_6(py)_2 \qquad (2)$$

Crystals suitable for an X-ray study were obtained for $W_2(O^tBu)_6$(4-Me-py)$_2$ from hexane and for $W_2(OCMe_2CF_3)_6(py)_2$ from benzene. Both compounds are dark brown, hydrocarbon-soluble, air-sensitive crystalline compounds.

Allene, $CH_2{=}C{=}CH_2$, and 1,3-di-*p*-tolylcarbodiimide form 1 : 1 adducts with $W_2(OCMe_2CF_3)_6$ while $W_2(OSi^tBuMe_2)_6$ is unreactive with these substrates. The new 1 : 1 adducts are green, hydrocarbon-soluble, air-sensitive crystalline compounds. Formation of these 1 : 1 adducts parallels the behavior of $W_2(O^tBu)_6$ [6]. However, the compound $W_2(O^tBu)_6(C_3H_4)$ is thermally unstable and, in solution, reacts to give the products derived from propyne, namely $W(O^tBu)_3$(CMe) and $W(O^tBu)_3$(CH) though that latter compound can only be detected in solution because it rapidly decomposes in the absence of a Lewis base such as py or quinuclidine [7]. Further reaction with allene gives the more thermally stable compound $W_2(O^tBu)_6(\mu\text{-}\eta^1,\eta^3\text{-}C_3H_4)(\eta^2\text{-}C_3H_4)$ [6a]. No such reactivity is observed for $W_2(OCMe_2CF_3)_6(C_3H_4)$, and the 1:1 adduct is unreactive in the presence of excess allene.

$W_2(OCMe_2CF_3)_6$, $W_2(OSi^tBuMe_2)_6$ and $W_2(OCMe(CF_3)_2)_4(NMe_2)_2$ react with aryl isocyanides to form bis adducts. For the fluoroalkoxide complexes, the xylylisocyanide adducts formed crystals suitable for X-ray studies. The coordination of the isocyanide ligand is evidently sufficiently strong that significant dissociation is not observed in solution at room temperature. The formation of the 2 : 1 adducts in the reactivity of these alkoxide supported W_2-complexes differs from the formation of the 1 : 1 adducts in the chemistry of $W_2(O^tBu)_6$. In the latter case, the isocyanide [8] and the carbonyl [9] form a bridge across the two metal atoms. The mixed amido-fluoroalkoxide compound $W_2(NMe_2)_2(OCMe(CF_3)_2)_6$ also forms a 2 : 1 adduct with xylylisocyanide and pyridine.

NMR and other spectral characterization data are given in the Experimental Section.

The two molecules are seen to be remarkably similar in their solid-state structures. The W—W distances, 2.40(1) Å and the W—O distances, which range from 1.92 to 1.96 Å, are essentially identical within the 3σ criterion. Despite the more favorable binding of pyridine to $W_2(OCMe_2CF_3)_6$ this is not reflected in the W—N distances: 2.27(1) Å versus 2.25(1) Å for the 4-Me-pyridine ligand in $W_2(O^tBu)_6(4\text{-Me-py})_2$. However, once again within the criterion of 3σ these W—N distances have to be viewed equivalent. Thus, the structures of the pyridine adducts offer no insight to the rather different reactivities of the two $W_2(OR)_6$ compounds.

$W_2(OCMe_2CF_3)_6(4\text{-Me-}C_6H_4CNCC_6H_4\text{-4-Me})$ crystallized in the space group $P\bar{1}$ with a molecule of *n*-hexane at the crystallographic center of symmetry. The *n*-hexane was refined at 78% partial occupancy and the three carbon atoms in the asymmetric unit of this solvent molecule showed some disorder. Despite these problems the structure of the ditungsten complex was refined satisfactorily, at least with respect to

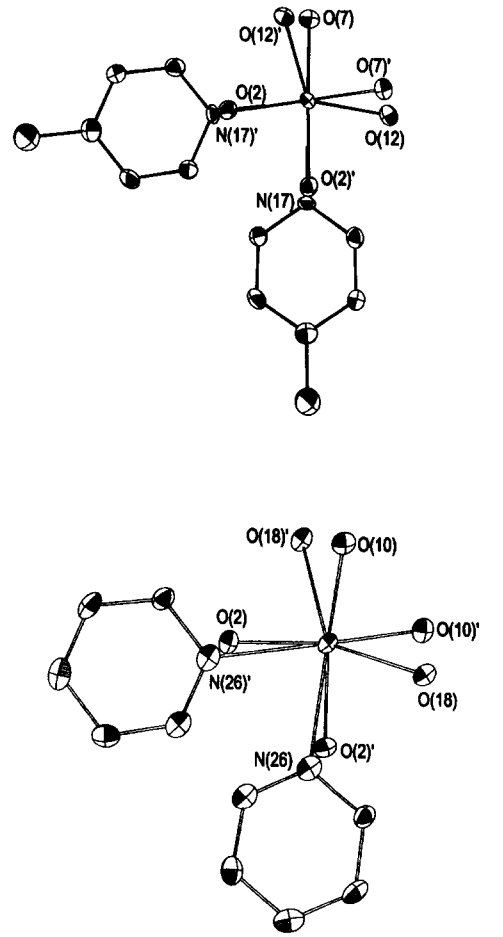

Fig. 3. Views of the central skeleton of the $W_2(O^tBu)_6(4\text{-Me-py})_2$ and $W_2(OCMe_2CF_3)_6(py)_2$ molecules looking down the M—M—axis.

gross features of the molecular geometry. An ORTEP drawing of the molecule is given in Fig. 4. The bridging carbodiimide lies parallel to the M—M axis in a $\mu\eta^2,\eta^2$ manner. This imposes an eclipsed geometry for the O_3WWO_3 skeleton. Selected bond distances and bond angles are given in Table 3.

The W—W distance of 2.52 Å is the range expected for a $(W{\equiv}W)^{8+}$ moiety consistent with the view that the carbodiimide is partially reduced. This is also reflected in the η^2-C—N distances of 1.28 Å and the N—C—N angle of 155°. The W—N distances, 2.08(1) Å (av.) and the W—C distances 2.19(1) Å (av.) also imply a strongly bound carbodiimide ligand. There is very little difference in the metrical parameters reported for $W_2(O^tBu)_6(\mu\eta^2,\eta^2\text{-ArNCNAr})$ by Cotton *et al.* [6b] with those found for the present structure.

$W_2(OCMe_2CF_3)_6(\mu\text{-}CH_2CCH_2)$. An ORTEP view of the molecule is given in Fig. 5 with selected bond distances and bond angles listed in Table 4. Superficially, the molecule is similar to the carbodiimide structure described previously but the W—W distance of 2.59 Å is significantly longer implying a greater degree of oxidation of the ditungsten center. Also the C—C—C angle of 141° deviates more from linearity than does the N—C—N angle. The C—C distances of 1.46 Å (av.) are comparable to Csp^2–Csp^2 single bond distances, certainly greatly reduced from those in free allene. The structure resembles in every way that of $W_2(O^tBu)_6(\mu\eta^2,\eta^2\text{-}C_3H_4)$ reported earlier [6a]. The W—O distances of the OR ligands trans to the W—C bonds are longer than those that are mutually trans implying that the allene ligand exerts a higher trans-influence [10] than the fluoroalkoxide.

$W_2(OCMe_2CF_3)_6(CNxylyl)_2$. An ORTEP drawing of the molecule is given in Fig. 6 and selected bond distances and bond angles are given in Table 5. The molecule has virtual but not crystallographically imposed C_2 symmetry. The W—W distance of 2.44(1) Å is longer than that expected for a triple bond but only slightly, c.f. the pyridine adducts described earlier. This can be understood in terms of the xylylisocyanide ligands acting as π-acceptor ligands. The central $W_2O_6C_2$ core is very similar to that seen for the $W_2(OCMe_2CF_3)_6(CO)_2$ molecule [11]. Note the

W—W—C angles are 83° (av.) and the dihedral angle between the two W—W—C planes is close to 90° which facilitates a mixing of W—W d_π and Wd_π—CNπ^* bonding as described for the dicarbonyl adduct previously [11]. A view looking down the M—M axis of the central $W_2O_6(CN)_2$ core is shown in Fig. 7.

$W_2(OCMe(CF_3)_2)_4(NMe_2)_2(CNxylyl)_2$. An ORTEP diagram of the molecule showing the atom numbering scheme is given in Fig. 8. Selected bond distances and angles are given in Table 6. The molecular structure contrasts with that seen for the *bis*-isocyanide and *bis*-carbonyl adducts of $W_2(OCMe_2CF_3)_6$ in that the core is made up of two staggered four coordinate W atoms, where the C(47)—W(1)—W(2)—C(57) angle is 41.9°. The W—W distance of 2.380(1) Å is only slightly

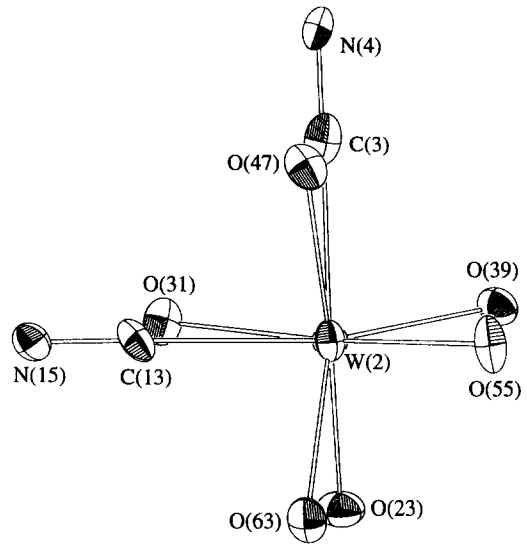

Fig. 7. A view of the central skeleton of the $W_2(OCMe_2CF_3)_6(CNxylyl)_2$ molecule looking down the M—M bond axis.

longer than that observed in $W_2(OCMe(CF_3)_2)_4(NMe_2)_2$ and significantly shorter than the W—W distances in the *bis*-carbonyl and *bis*-isocyanide adducts of $W_2(OCMe_2CF_3)_6$. The two W—W—C angles are 90.2(2)° and 88.6(2)°. The W—N distances of 1.93(1) Å (av.) and W—O distances of 2.00(2) Å (av.) are notably longer than in the parent compound $W_2(OCMe(CF_3)_2)_4(NMe_2)_2$ [12] which reflects the increase in coordination number at the metal center.

EXPERIMENTAL

General operating procedures for the manipulation of air-sensitive samples were observed.

Preparation of $[W_2(O^tBu)_6(py)_2]$. Pyridine (1 cm^3) was added to a solution of $W_2(O^tBu)_6$ [13] (153 mg, 0.190 mmol) in 10 cm^3 of dry, degassed benzene at 23°C. The solution was stirred at 23°C for 1 h and the solvent was reduced under vacuum. Crystallization in dry, degassed toluene at −20°C gave dark red microcrystals in 81% yield. The crystals obtained when using pyridine were not suitable for a single crystal X-ray study. The use of 4-Me-pyridine during the preparation did afford crystals (from hexanes) of $[W_2(O^tBu)_6(4\text{-Me-py})_2]$ (**1-Me**) suitable for study by X-ray analysis. ^{1}H NMR for **1** (300 MHz, C_7D_8, −30°C) δ = 8.43 (br. multiplets, 2H), 6.85 (br. multiplets, 1H), 6.55 (br. multiplets, 2H), 2.40 (18H), 1.53 (18H), 1.20 (18H). ^{1}H NMR for **1** (300 MHz, C_7D_8, 16°C) δ = 1.59 (54H). $^{13}C\{^1H\}$ NMR for **1** (75 MHz, C_7D_8, −30°C) δ = 151.3, 135.0, 122.5 (NC_5H_5); 82.0, 76.4, 74.4 ($C(CH_3)$); 34.8, 33.4, 33.1 ($C(CH_3)$).

Preparation of $[W_2(OCMe_2CF_3)_6(py)_2]$. Pyridine (1 cm^3) was added to a solution of $W_2(OCMe_2CF_3)_6$ [4] (170 mg, 0.15 mmol) in 10 cm^3 of dry, degassed benzene at 23°C. The solution was stirred at 23°C for 1 h

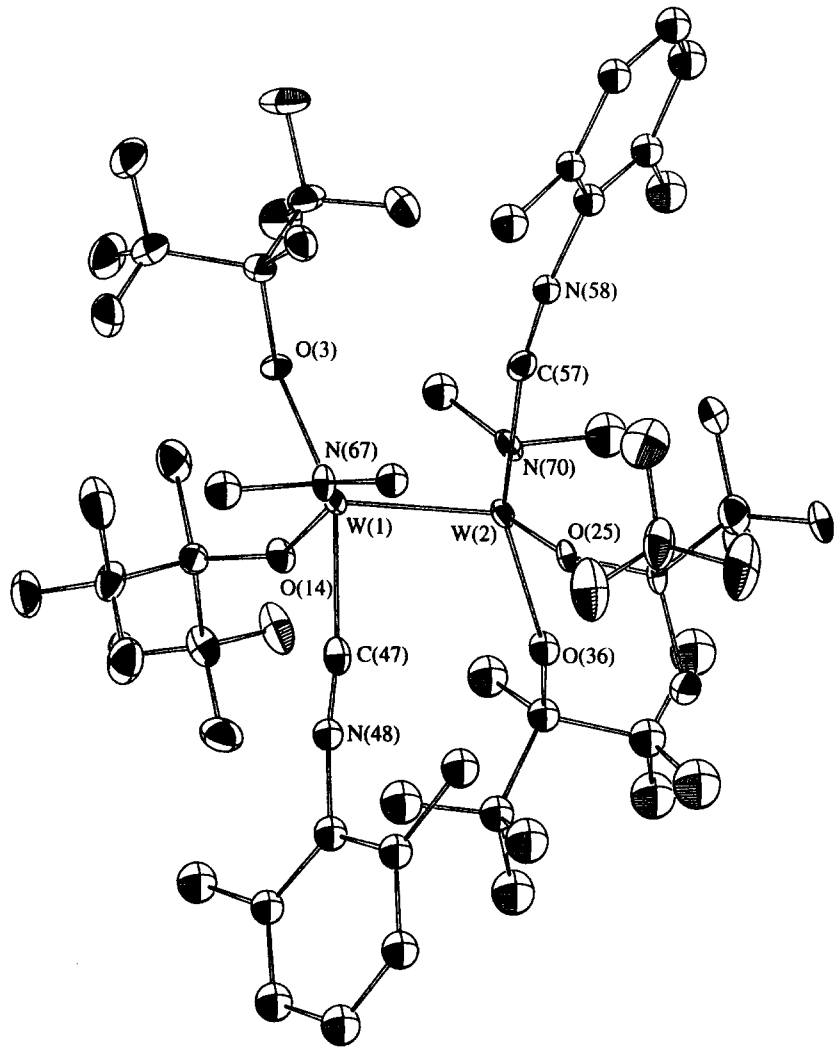

Fig. 8. An ORTEP drawing of the $W_2(OCMe(CF_3)_2)_4(NMe_2)_2(CNxylyl)_2$ molecule.

and the solvent was reduced under vacuum. Crystallization from dry, degassed benzene (65–23°C) gave X-ray quality black crystals in 68% yield. ^1H NMR (300 MHz, C_7D_8, −80°C) $\delta = 8.43$ (br. multiplets, 2H), 6.85 (br. multiplets, 1H), 6.55 (br. multiplets, 2H), 1.95 (6H), 1.50 (6H), 1.33 (6H), 1.31 (6H), 0.92 (6H), 0.86 (6H). $^{19}F\{^1H\}$ NMR (283 MHz, C_7D_8, 16°C, ext. ref. CF_3CO_2H $\delta = -78.45$) $\delta = -80.8$ (br. 12F), −82.2 (6F). $^{19}F\{^1H\}$ NMR (283 MHz, C_7D_8, −50°C, ext. ref. CF_3CO_2H $\delta = -78.45$) $\delta = -78.8$ (6F), −79.0 (6F), −80.1 (6H).

Preparation of $W_2(OCMe_2CF_3)_6(CN\text{-}2,6\text{-}Me_2C_6H_3)_2$. $W_2(OCMe_2CF_3)_6$ [4] (200 mg, 0.18 mmol) and xylylisocyanide (91 mg, 0.71 mmol) solids were added to a 30 cm^3 Schlenk flask in a nitrogen glove box. Hexanes (3 cm^3) were added and the solution was concentrated. Brown, tetragonal thin plates (199 mg, 81%) were obtained at −35°C. Recrystallization from Et_2O at −35°C yielded crystals for the X-ray study. ^1H NMR (300 MHz, C_7D_8, 23°C): δ 2.52 (s, 12H), 2.29 (s, 6H), 2.21 (s, 6H), 1.49 (s, 6H), 1.20 (s, 12H), 1.18 (s, 6H), 6.5–6.9 (br. multiplets 6H). $^{19}F\{^1H\}$ NMR (340 MHz, C_7D_8, 23°C): δ −75.9 (s, 6F), −76.2 (s, 6F), −84.4 (s, 6F).

Preparation of $W_2(OSi^tBuMe_2)_6(CN\text{-}2,6\text{-}Me_2C_6H_3)_2$. $W_2(OSi^tBuMe_2)_6$ [2] (25 mg, 0.022 mmol) and $CN\text{-}2,6\text{-}Me_2C_6H_3$ (34 mg, 0.22 mmol) were dissolved in 0.6 cm^3 of toluene-d_8 in an NMR tube. The kinetically labile **4** did not yield a crystalline compound. ^1H NMR (300 MHz, C_7D_8, −20°C): δ 6.6–7.1 (br, 6H), 2.0 (s, 12H), 1.16 (s, 18H), 1.06 (s, 18H), 0.943 (s, 18H), 0.34 (s, 6H), 0.33 (s, 6H), 0.26 (s, 18H), 0.24 (s, 6H).

Preparation of $W_2(OCMe(CF_3)_2)_4(NMe_2)_2(CN\text{-}2,6\text{-}Me_2C_6H_3)_2$. $W_2(OC(CF_3)_2Me)_4(NMe_2)_2$ [13] (150 mg, 0.13 mmol) and $CN\text{-}2,6\text{-}Me_2C_6H_3$ were combined in a 30 cm^3 Schlenk flask in a nitrogen glove box. THF (10 cm^3) was added to the flask followed by reduction in volume to concentrate the solution. Crystallization at −35°C gave bundles of deep red fibers which were separated by sublimation of excess isocyanide at 23°C to give 160 mg (85%). Recrystallization from CH_2Cl_2

gave X-ray quality deep red cubes. ^{1}H NMR (300 MHz, C_7D_8, 80°C): δ 6.6–7.0 (br, 6H), 4.64 (s, 6H), 2.58 (s, 6H), 2.39 (s, 12H), 1.69 (s, 12H). ^{1}H NMR (300 MHz, C_7D_8, −40°C): δ 6.6–7.0 (br, 6H), 4.55 (s, 3H), 4.52 (s, 3H), 2.53 (s, 3H), 2.14 (s, 3H), 2.02 (s, 3H), 1.76 (s, 3H), 1.71 (s, 3H), 1.19 (s, 3H).

Preparation of $W_2(OCMe_2CF_3)_6(\mu,\eta^2,\eta^2\text{-}CH_2CCH_2)$. $W_2(OCMe_2CF_3)_6$ [4] (25 mg, 0.022 mmol) was dissolved in 0.6 cm^3 of C_7D_8 in an NMR tube equipped with a J. Young valve. Allene (10 equiv.) was transferred at −196°C to the NMR tube by means of a calibrated gas manifold. The reaction mixture was thawed and placed at −35°C for 24 h. Analysis by ^{1}H NMR spectroscopy at −20°C allows an estimated yield of 85% with the remaining tungsten containing compound being $W_2(OCMe_2CF_3)_6$. Addition of a large excess of allene (>20 equiv.) results in the formation of a transparent solid proposed to be polyallene. ^{1}H NMR (300 MHz, C_7D_8, −20°C): δ 1.66, 1.37, 1.04 (s, 12H), 7.57 (s, 4H). $^{13}C\{^1H\}$ NMR (75 MHz, C_7D_8, −20°C): δ 265.1, 95.0, 85.1 (q), 81.4 (q), 25.1 (s), 24.8 (s), 24.1 (s). $^{19}F\{^1H\}$ NMR (340 MHz, C_7D_8, −20°C): δ −80.4 (s, 6F), −81.0 (s, 12F).

Preparation of $W_2(OCMe_2CF_3)_6(\mu,\eta^2,\eta^2\text{-4-Me-C}_6H_4N{=}C{=}N{=}C_6H_4\text{-4-Me})$. $W_2(OCMe_2CF_3)_6$ [4] (275 mg, 0.244 mmol) 4-Me-C_6H_4-N=C=N-C_6H_4-4-Me (119 mg, 0.535 mmol) were combined in a 30 cm^3 Schlenk flask in a nitrogen atmosphere glove box. Hexanes (5 cm^3) were added to the Schlenk flask. Reduction of the volume followed by crystallization at −35°C afforded dark green cubes (280 mg, 85%) that were suitable for X-ray analysis. ^{1}H NMR (300 MHz, C_7D_8, 23°C): δ 6.99 (d, $^3J_{HH}$ = 32 Hz), 6.80 (d, $^3J_{HH}$ = 32 Hz), 1.85, 1.71, 1.46 (s, 12H). $^{19}F\{^1H\}$ NMR (340 MHz, C_7D_8, 23°C): δ −80.0 (s, 6F), −80.8 (s, 12F).

Single crystal X-ray crystallographic studies— General operating procedures and listings of programs have been previously given [14]. A summary of crystallographic data is given in Table 7. Complete listings of atomic coordinates have been deposited with the Cambridge Crystallographic Data Center.

CONCLUSIONS

The molecular structures of the pyridine, carbodiimide and allene adducts of $W_2(O^tBu)_6$ and $W_2(OCMe_2CF_3)_6$ are remarkably similar and belie the otherwise very different reactivities of the two complexes. This, of course, supports the view that structural data rarely provide much insight into reactivity. The relative thermal stability of the allene adduct reported here leads us to propose that the greater reactivity of the *t*-butoxide arises because the more basic ^{t}BuO ligand promotes an allene to propyne isomerization. That $W_2(OCMe_2CF_3)_6(\mu,\eta^2,\eta^2\text{-}CH_2CCH_2)$ does not react with additional allene to give a compound of the type $W_2(OR)_6(\mu,\eta^1,\eta^3\text{-}C_3H_4)(\eta^2\text{-}C_3H_4)$ as seen for R = ^{t}Bu may reflect the less easily oxidized and less π-basic W_2 core when supported by $(CF_3)Me_2CO$ ligands. This too may be the reason for the formation of the 2:1 isocyanide and carbonyl adducts with $W_2(OCMe_2CF_3)_6$ as compared to the $W_2(O^tBu)_6(\mu\text{-L})$ compounds (L = CO, CNAr). The latter contain highly reduced C—O and C—N bonds as a result of extensive back-bonding from the W_2 $d\pi$ electrons [8,9].

In the compound $W_2(OCMe(CF_3)_2)_4(NMe_2)_2$ which contains both strongly π-donating amide ligands and weakly π-donating $(CF_3)_2MeCO$ ligands the metal centers are sufficiently Lewis acidic to bind xylylisocyanide (2 equiv.). This contrasts with the behavior of $W_2(NMe_2)_6$ and testifies to the electronic

influence of the $OCMe(CF_3)_2$ ligands at the ditungsten center.

Obviously the results reported here merely add to our knowledge of the chemistry of $W_2(OR)_6$ compounds but do not provide quantitative information concerning the factors influencing the vastly different reactivity seen toward certain substrates such as MeC≡N. However, more quantitative studies are underway.

Isolation and structural characterization of the polymetallic zirconium alkoxide complexes, $Zr_3O(OCH_2CMe_3)_9Cl$, $Zr_3O(OCMe_3)_9(OH)$, and $Na_4Zr_6O_2(OEt)_{24}$†

(Received 30 April 1997; accepted 23 June, 1997)

Abstract—Three polymetallic zirconium alkoxide complexes have been isolated and structurally characterized which show that by proper combination of zirconium precursor and alkoxide, this small class of compounds can be expanded. The trimetallic neopentoxide complex $[(NpO)_2Zr]_3(\mu\text{-}ONp)_3(\mu_3\text{-}Cl)(\mu_3\text{-}O)$, **1**, ($Np = CH_2CMe_3$) can be isolated from the reaction of $ZrCl_4$ with four equivalents of $KOCH_2CMe_3$ in THF. The trimetallic *tert*-butoxide complex, $[(^tBuO)_2Zr]_3(\mu\text{-}O^tBu)_2(\mu\text{-}OH)(\mu_3\text{-}O^tBu)(\mu_3\text{-}O)$, **2**, can be isolated from the reaction of $ZrCl_4$ with 3.3 equivalents of $LiOCMe_3$ in THF. The reaction of $Zr(OEt)_4$ with one equivalent of $NaOSiMe_3$ in THF formed the mixed-metal polymetallic complex, $\{Na_2[(EtO)Zr]_3(\mu\text{-}OEt)_7(\mu_3\text{-}OEt)_2(\mu_3\text{-}O)\}_2$, **3**. These results show that the common $M_3(\mu\text{-}E)_3(\mu_3\text{-}E)_2$ structural motif with E being a ligand donor atom can be obtained with zirconium alkoxides. © 1998 Elsevier Science Ltd. Keywords: zirconium; alkoxide; polymetallic; heterometallic; oxide.

Zirconium is a desirable metallic component in a variety of materials which have useful practical properties [1]. Attempts to manufacture defect-free zirconium-containing materials using molecular zirconium chemistry [2] as an alternative route to the usual thermal/mechanical techniques are hampered by the fact that there are few polymetallic zirconium precursors in the literature. Indeed, this problem was recognized as early as 1985 [3], but still has not been rectified. Crystallographically characterized homometallic molecular compounds containing three or more zirconium atoms are limited to: $Zr_3S_3(S^tBu)_2(BH_4)_4(THF)_2$ [3], $[Zr_3O(OH)_3(C_6H_5CO_2)_3(C_5H_5)_3][C_6H_5CO_2]$ [4], $Zr_3O(CCO)(O_2CN^iPr_2)_6(C_5H_5)_2$ [5], $Zr_3O(OH)_4Cl_3(C_5Me_5)_3$ [6], $Zr_4[CH_3C(CH_2O)_3]_2(O^iPr)_{10}$ [7], $Zr_4O(O^iPr)_{10}(acac)_4$ [8], $Zr_5H_4Cl_{14}(PR_3)_5$ ($PR_3 = PMe_3, PEt_3, PhMe_2$) [9], $Zr_5(tritox)_5(N)(NH)_4(NH_2)_4$ [10], $Zr_6(tritox)_6(N)(NH)_6(NH_2)_3$ [10], $Zr_6S_6(S^tBu)_4(BH_4)_8(THF)_2$ [11], $Zr_6Cl_{14}H_4(PR_3)_4$ (R = Me, Et, Pr) [12], $(Zr_6Cl_{18}H_5)(HPPh^tBu_2)$ [12], and $Zr_{13}O_8(OMe)_{36}$ [13]. The number of crystallographically characterized polyzirconium alkoxide complexes, a class of compounds which would be desirable as precursors for sol gel processing, is particularly small despite the fact that zirconium alkoxide compounds have been known for many years [14].

In comparison to this limited collection of polymetallic zirconium complexes, an extensive variety of polymetallic alkoxides is available for other metals [15]. For example, neighboring element yttrium forms numerous classes of polymetallic species with simple alkoxide ligands and polymetallic alkoxides of

titanium, lanthanides, actinides, and the Groups 5 and 6 transition metals are also known. The polymetallic alkoxides of these neighboring elements frequently contain a central trimetallic core connected by triply bridging ligands above and below the triangular plane and three doubly bridging ligands in the plane. In alkoxide complexes, the ligand donor atoms, E, in this $M_3(\mu_3\text{-}E)_2(\mu\text{-}E)_3$ unit, are typically oxygen atoms provided by alkoxide, hydroxide, or oxide ligands or, in some cases, they are halide ions. This trimetallic core appears to be a good building block for making larger arrays of yttrium, lanthanide, and actinide polymetallic species. For example, the yttrium *tert*-butoxide complex $Y_3(\mu_3\text{-}O^tBu)(\mu_3\text{-}Cl)(\mu\text{-}O^tBu)_3(O^tBu)_3Cl(THF)_2$ can be converted to $Y_{14}(O^tBu)_{28}Cl_{10}O_2(THF)_4$, which contains four $Y_3(\mu_3\text{-}E)_2(\mu\text{-}E)_3$ units [16].

Formation of trimetallic zirconium analogs of the common yttrium alkoxides, $Y_3(\mu\text{-}O^tBu)_3(\mu_3\text{-}Z)_2(O^tBu)_4L_2$ (Z = O'Bu, Cl, O; L = ether or alcohol), would require some modification of the ligand content to achieve charge balance, since Zr^{IV} requires one more anionic ligand per metal than Y^{III}. This could be accomplished by replacement of both neutral L ligands by OR^- and by replacing one of the monoanionic ligands by dianionic oxide, e.g. $Zr_3(\mu\text{-}OR)_3(\mu_3\text{-}O)(\mu_3\text{-}OR)(OR)_6$. If no dianionic ligands are present in a trimetallic zirconium analog of $Y_3(OR)_9L_2$, charge balance would require an extra ligand, e.g. $Zr_3(\mu\text{-}OR)_3(\mu_3\text{-}OR)_2(OR)_7$. This would require at least one zirconium center to be 7-coordinate instead of the favored 6-coordination. If these $Zr_3O(OR)_{10}$ or $Zr_3(\mu\text{-}OR)_{12}$ complexes are too sterically crowded to be stable, polymetallic species could only form if smaller ligands can be substituted for alkoxides. Halide and hydroxide monoanions and oxide and sulfide dianions would be the most useful in this regard.

The $M_3(\mu_3\text{-}E)_2(\mu\text{-}E)_3$ core has actually been observed for zirconium when E = S in the case of $Zr_3S_3(S^tBu)_2(BH_4)_4(THF)_2$ [3]. Since this complex has three dianionic sulfide ligands, only six monoanions are required and there is room for two THF ligands to bind. A complex containing two of these trimetallic units is also known, $Zr_6S_6(S^tBu)_4(BH_4)_8(THF)_2$ [3]. The isolation of the actinide alkoxide complex $U_3(O^tBu)_{10}O$ [17] indicates that the tetravalent nature of a metal does not prohibit formation of trimetallic alkoxide complexes of formula $M_3(\mu_3\text{-}E)_2(\mu\text{-}E)_3$ with tetravalent metals, but the larger size of the actinide metals reduces the problems with steric crowding. Polymetallic $Ti_4(OMe)_{16}$ [18], $Ti_4(OEt)_{16}$ [19], $W_4(OEt)_{16}$ [20], and $Th_4(OEt)_{16}(py)_2$ [21] complexes are known, but have structures which lack one of the μ_3-ligands in the $M_3(\mu_3\text{-}E)_2(\mu\text{-}E)_3$ structure.

To determine if polymetallic zirconium alkoxide complexes related to species such as $Y_3(\mu\text{-}O^tBu)_3(\mu_3\text{-}Z)_2(O^tBu)_4(THF)_2$ [16], $Zr_3S_3(S^tBu)_2(BH_4)_4(THF)_2$ [3], and $U_3(O^tBu)_{10}O$ [17] could be formed with simple alkoxide ligands, we have examined several combinations of zirconium precursors with alkoxide ligands known to give polymetallic species with other metals. We report here the isolation of three examples of trimetallic zirconium alkoxides which demonstrate that polymetallic zirconium complexes of this type are accessible with the proper combination of ligands. An attempt to make a mixed sulfide alkoxide is also reported.

EXPERIMENTAL

The chemistry described below was performed under nitrogen using Schlenk, vacuum line, and glove box techniques. Solvents were purified as previously described [22]. NMR spectra were recorded at 25°C using a General Electric QE 300 spectrometer. Elemental analyses were performed by Analytische Laboratorien, Gummersbach, Germany and on a Carlo Erba EA 108 instrument. LiO'Bu was obtained by reacting HO'Bu and *n*-butyllithium in hexanes and was dried under high vacuum. $ZrCl_4$ and $Zr(OEt)_4$ (Aldrich) were used as obtained.

$[(Me_3CCH_2O)_2Zr]_3(\mu\text{-}OCH_2CMe_3)_3(\mu_3\text{-}Cl)(\mu_3\text{-}O)$, **1**

In the glovebox, a freshly prepared sample of $KOCH_2CMe_3$, obtained by reacting KH (160 mg, 4.0 mmol) with $HOCH_2CMe_3$ (350 mg, 4.0 mmol) in 10 cm^3 of THF, was added to a solution of $ZrCl_4$ (233 mg, 1.0 mmol) in 10 cm^3 of THF. The resulting cloudy solution was stirred for 48 h and centrifuged to remove a small amount of pale yellow solid. The supernatant was evaporated to dryness using a rotary evaporator. Recrystallization from hexane did not produce high quality crystals, but recrystallization from toluene at −40°C was successful (170 mg, 45%). Anal. Calcd for $C_{45}H_{45}O_{10}ClZr_3$: C, 48.72; H, 9.00; Zr, 24.67. Found: C, 49.09; H, 9.10; Zr, 24.50. IR (Nujol): 1458 s, 1375 s, 1142 w, 1110 m, 1010 w, 725 m, 665 w, 650 m cm^{-1}. ^1H NMR (C_6D_6) δ 4.25 (s, 6H, $CH_2C(CH_3)_3$), 4.01 (s, 6H, $CH_2C(CH_3)_3$), 3.94 (s, 6H, $CH_2C(CH_3)_3$), 1.16 (s, 27H, $CH_2C(CH_3)_3$), 1.06 (s, 27H, $CH_2C(CH_3)_3$), 1.16 (s, 27H, $CH_2C(CH_3)_3$). ^{13}C NMR (C_6D_6): δ 82.3 ($CH_2C(CH_3)_3$), 80.3 ($CH_2C(CH_3)_3$), 33.6 ($CH_2C(CH_3)_3$), 33.0 ($CH_2C(CH_3)_3$), 26.4 ($CH_2C(CH_3)_3$), 26.2 ($CH_2C(CH_3)_3$).

$[(Me_3CO)_2Zr]_3(\mu\text{-}OCMe_3)_2(\mu\text{-}OH)(\mu_3\text{-}OCMe_3)(\mu_3\text{-}O)$, **2**

A mixture of $LiOCMe_3$ (266 mg, 3.33 mmol) and Li_2S (16 mg, 0.33 mmol) in 10 cm^3 of THF was added to a vial containing $ZrCl_4$ (233 mg, 1.0 mmol) in 10 cm^3 of THF. The resulting mixture was stirred for 24 h and centrifuged to remove a small amount of solid. The solution was evaporated to dryness and then extracted with hexanes. Slow evaporation of the hexanes solution at ambient temperature for several days

produced crystalline **2** (270 mg, 84%). X-ray quality crystals were grown from toluene at −40°C. Anal. Calcd for $C_{36}H_{82}O_{11}ClZr_3$: C, 44.78; H, 8.57; Zr, 28.36. Found: C, 43.38; H, 8.34; Zr, 28.10. IR (Nujol): 1458 s, 1375 s, 1142 w, 1110 m, 1010 w, 725 m, 665 w, 650 m cm^{-1}. ^1H NMR (C_6D_6) δ 1.85 (s, $C(CH_3)_3$), 1.74 (s, $C(CH_3)_3$), 1.68 (s, $C(CH_3)_3$), 1.57 (s, $C(CH_3)_3$), 1.52 (s, $C(CH_3)_3$), 1.49 (s, H, $C(CH_3)_3$), 1.47 (s, H, $C(CH_3)_3$), 1.46 (s, H, $C(CH_3)_3$). ^{13}C NMR (C_6D_6): 76.3 (s, $C(CH_3)_3$, 75.7 (S, $C(CH_3)_3$), 74.3 (s, $C(CH_3)_3$), 73.6 (s, $C(CH_3)_3$), 34.1 (s, $C(CH_3)_3$), 33.8 (s, $C(CH_3)_3$), 33.2 (s, $C(CH_3)_3$), 32.9 (s, $C(CH_3)_3$), 33.6 (s, $C(CH_3)_3$), 32.3 (s, $C(CH_3)_3$). **2** can also be made analogously in similar yield in the absence of Li_2S.

$\{Na_2[(EtO)Zr]_3(\mu\text{-}OEt)_7(\mu_3\text{-}OEt)_2(\mu_3\text{-}O)\}_2$, **3**

A suspension of $Zr(OEt)_4$ (271 mg, 1 mmol) in 10 cm^3 of THF was reacted with $NaOSiMe_3$ (112 mg, 1 mmol) in 5 cm^3 of THF. Most of the $Zr(OEt)_4$ went into solution as the mixture was stirred over a 48 h period. The resultant solution was centrifuged to remove a small amount of solid (~20 mg). The volume of the supernatant was reduced to half using a rotary evaporator and then transferred to the freezer at −38°C to give colorless crystals (30 mg, 10%). Anal. Calcd for $C_{48}H_{120}O_{26}Na_4Zr_6$: C, 32.89; H, 6.90; Zr, 31.23. Found: C, 32.74; H, 6.80; Zr, 31.45. ^1H NMR (THF-d_8) δ 4.33 (m, 4H, CH_2CH_3), 4.25 (m, 6H, CH_2CH_3), 4.12 (m, 14H, CH_2CH_3), 1.43 (m, 9H, CH_2CH_3), 1.34 (m, 21H, CH_2CH_3), 1.26 (m, 6H, CH_2CH_3). ^{13}C NMR (THF-d_8) 73.0, 65.1, 63.8 (CH_2CH_3), 21.5, 20.9, 14.7 (CH_2CH_3). IR (Nujol): 1460 s, 1376 s, 1244 w, 1152 w, 1089 w, 1055 m, 930 m, 833 m, 722 w cm^{-1}.

General aspects of X-ray data collection, structure determination, and refinement

Crystals were coated with Paratone oil, mounted on a glass fiber, and transferred to the nitrogen cold stream of a Siemens P4 diffractometer. Determination of Laue symmetry, crystal class, unit cell parameters and the crystal's orientation matrix was carried out according to standard procedures [23]. Intensity data were collected at 163 K using a 2θ–ω scan technique with Mo-K_α radiation (details are given in Table 1). No significant decay was observed during data collection. Data were corrected for Lorentz and polarization effects and were placed on an absolute scale. The raw data were processed with a modified version of CARESS [44]. All calculations were carried out using the SHELXL program [25]. The analytical scattering factors for neutral atoms were used throughout the analysis [26]. All of the structures were solved by direct methods and refined on F^2 by full-matrix least squares techniques.

$[(Me_3CCH_2O)_2Zr]_3(\mu\text{-}OCH_2CMe_3)_3(\mu_3\text{-}Cl)(\mu_3\text{-}O)$, **1**

The diffraction symmetry of a colorless crystal of dimensions $0.40 \times 0.33 \times 0.27$ mm was $2/m$ with systematic absence $h01$ for $h+1 = 2n+1$. The two possible space groups are Pn and $P2/n$. The noncentrosymmetric space group Pn was found to be the correct choice. At convergence $wR2 = 0.1011$ and GOF = 1.047 to 257 variables against all 7360 unique data. As a comparison for refinement on F, $R1 = 0.0359$ for those 6886 data with $F > 4\sigma$ (F). It was necessary to constrain the geometry of the neopentoxide ligands defined by atoms C(41)–C(45) by using the atoms C(8)–C(10) as a reference model.

$[(Me_3CO)_2Zr]_3(\mu\text{-}OCMe_3)_2(\mu\text{-}OH)(\mu_3\text{-}OCMe_3)(\mu_3\text{-}O)$, **2**

The diffraction symmetry of a colorless crystal of dimensions $0.16 \times 0.17 \times 0.60$ mm was $2/m$ with systematic absence $0k0$ for $k = 2n+1$. The two possible space groups are $P2_1$ and $P2_1/m$. The centrosymmetric space group $P2_1/m$ was found to be the correct choice. At convergence $wR2 = 0.0999$ and GOF = 1.055 for 241 variables against all 4455 unique data. As a comparison for refinement on F, $R1 = 0.0407$ for those 3516 data with $F > 4\sigma$ (F).

$\{Na_2[(EtO)Zr]_3(\mu\text{-}OEt)_7(\mu_3\text{-}OEt)_2(\mu_3\text{-}O)\}_2$, **3**

A colorless crystal of dimensions $0.05 \times 0.13 \times 0.36$ mm was mounted on a glass fiber and transferred to a Siemens P4 rotating anode diffractometer. There were no systematic absences nor diffraction symmetry other than the Friedel condition. The centrosymmetric space group $P\bar{1}$ was assigned and later determined to be the correct choice. The molecule is located on an inversion center. Carbon atoms C(18), C(19) and C(24) are disordered. Two components (site occupancy = 0.5) were included for each of the three atoms to account for this disorder. Hydrogen atoms associated with C(19B) were not included. At convergence, $wR2 = 0.1550$ and GOF = 1.017 for 371 variables against all 4955 unique data. As a comparison for refinement on F, $R1 = 0.0563$ for those 3163 data with $F > 4\sigma$ (F).

RESULTS AND DISCUSSION

$[(Me_3CCH_2O)_2Zr]_3(\mu\text{-}OCH_2CMe_3)_3(\mu_3\text{-}Cl)(\mu_3\text{-}O)$, **1**

The reaction of $ZrCl_4$ with 4 equiv. of $KOCH_2CMe_3$ in THF gives a white microcrystalline product which upon recrystallization from toluene gives **1** in 45% yield. The ^1H NMR spectrum of **1** in C_6D_6 contains three resonances of equal intensity in the methylene region and three larger resonances of equal intensity in the methyl region which indicated that **1** was not a

simple monometallic $Zr(OR)_4$ or bimetallic $(RO)_3Zr(\mu\text{-}OR)_2Zr(OR)_3$ complex. The ^{13}C NMR spectrum contained six resonances, two each in the methyl region, the methylene region, and the quaternary carbon region. X-ray crystallography revealed that **1** is a trimetallic zirconium alkoxide which has retained one chloride ligand per three metals and has incorporated an oxide ligand, i.e. $Zr_3O(OCH_2CMe_3)_9Cl$, **1**. The source of the oxide ligand is unknown, but the isolation of oxide/alkoxide complexes in reactions of this type is not uncommon [4,5,27–29].

The structure of complex **1**, Figs 1 and 2, is analogous to those of compounds such as $Y_3(\mu\text{-}O^tBu)_3(\mu_3\text{-}O^tBu)(\mu_3\text{-}Cl)(O^tBu)_4L_2$ [16], $La_3(\mu\text{-}O^tBu)_3(\mu_3\text{-}O^tBu)_2(O^tBu)_4(^tBuOH)_2$ [16], and $Zr_3S_3(S^tBu)_2(BH_4)_4(THF)_2$ [3]. Replacement of two neutral ligands with monoanions and incorporation of a dianionic oxide achieves charge balance in this $M_3(\mu\text{-}E)_3(\mu_3\text{-}E)_2$ structure which contains all six-coordinate zirconium centers. Hence, the three zirconium atoms comprise a triangle which has $\mu\text{-}OCH_2CMe_3$ ligands bridging each edge. Each zirconium is ligated by two terminal neopentoxide ligands. Above the zirconium triangle is a μ-Cl ligand and below is a μ_3-O ligand. Each zirconium center has a distorted octahedral environment and overall the complex has three fold rotational symmetry.

Selected bond lengths and angles are given in Table 2. All of the bridging Zr—OR distances are within the narrow range 2.161(4)–2.171(4) Å and as expected they are longer than the 1.914(4)–1.947(4) Å terminal Zr—OR distances. These distances are comparable to the average bridging (2.170 Å) and terminal (1.943 Å) Zr—O^{i}Pr distances in $[(^iPrO)_3Zr(\mu\text{-}O^iPr)(^iPrOH)]_2$ [30]. The 2.082(3)–2.090(3) Å $Zr\text{–}\mu_3\text{-}O$ distances are intermediate between these ranges. In comparison, the corresponding Zr—μ_3-O distances in $[Zr_3(\mu_3\text{-}O)(\mu\text{-}OH)_3(C_6H_5COO)_3(\eta^5\text{-}C_5H_5)_3][C_6H_5COO]$ range from 2.059(4) to 2.079(4) Å [5]. Since no compound containing a Zr_3—(μ_3-Cl) arrangement has previously been reported in the literature, no direct comparisons can be made with the 2.847(1)–2.886(1) Å Zr—μ_3-Cl distances, but an analogous arrangement occurs in several yttrium complexes. For example, in $Y_3Cl_2(O^tBu)_7(THF)_2$ and $Y_3Cl(O^tBu)_8(THF)_2$ [17], Y—μ_3-Cl distances are 2.831(10)–2.885(10) and 2.820(5)–2.897(2) Å, respectively. Considering the differences in the ionic radii of six-coordinate Zr^{IV} (0.72 Å) and Y^{III} (0.90 Å), the distances found in **1** are longer than expected [31]. On the other hand, the 3.2956(8)–3.3021(7) Å Zr···Zr distances are shorter than the 3.50–3.63 Å Y···Y distances in $Y_3Cl(O^tBu)_8(THF)_2$. The Zr···Zr distances in **1** are also on the short end of the 3.278(2)–3.574(2) Å range of distances in $Zr_3S_3(S^tBu)_2(BH_4)_4(THF)_2$ [3] and are shorter than the 3.468(1)–3.507(1) Å range in $Zr_6S_6(S^tBu)_4(BH_4)_8(THF)_2$ [3]. The sulfur compounds may have

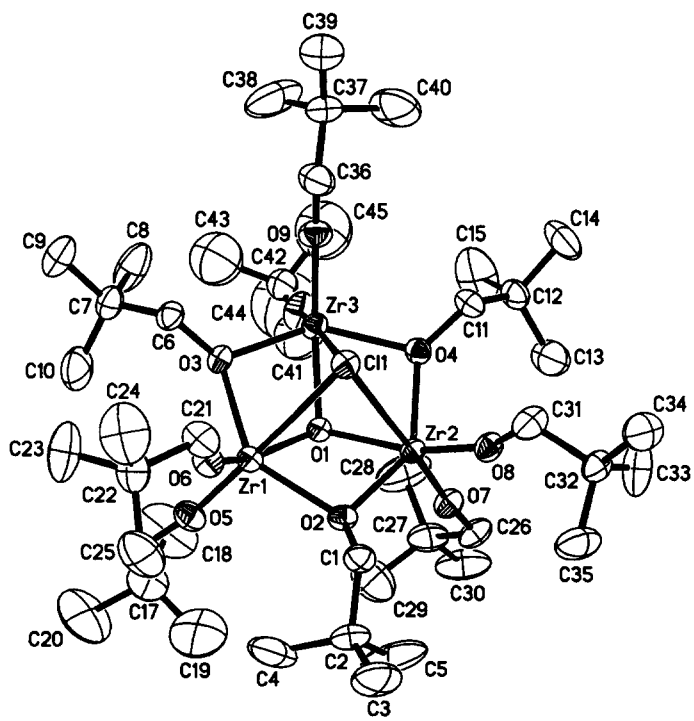

Fig. 1. Molecular structure of $Zr_3O(OCH_2CMe_3)_9Cl$, **1**, with thermal ellipsoids drawn at the 50% probability level.

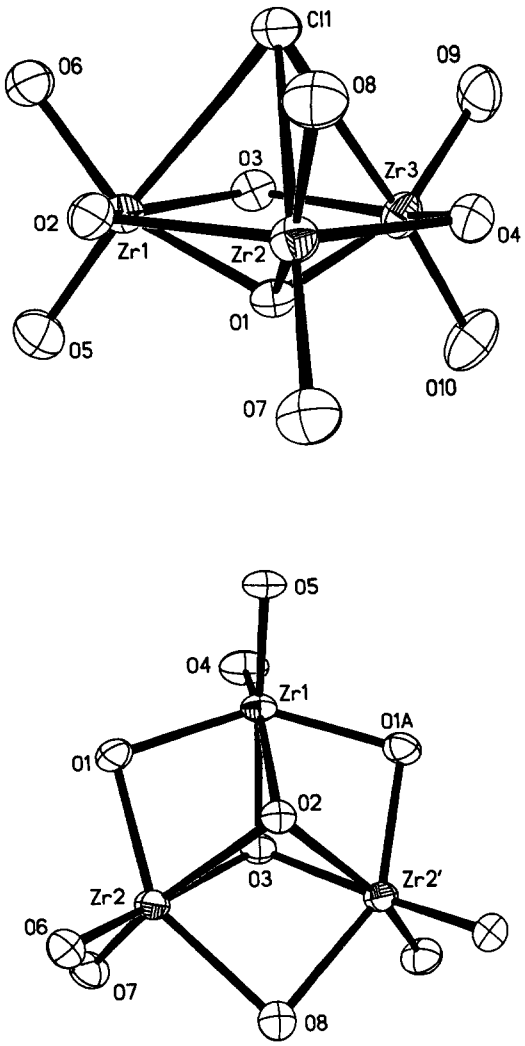

Fig. 2. Side view of metal oxygen halide framework of $Zr_3O(OCH_2CMe_3)_9Cl$, **1**, and top view of metal oxygen framework of $Zr_3O(OCMe_3)_9(OH)$, **2**.

longer Zr···Zr distances due to the larger size of the bridging atoms.

$[(Me_3CO)_2Zr]_3(\mu\text{-}OCMe_3)_2(\mu\text{-}OH)(\mu_3\text{-}OCMe_3)(\mu_3\text{-}O)$, 2

In an attempt to make a mixed ligand zirconium *tert*-butoxide sulfide of formula $Zr_3(\mu\text{-}OR)_3(\mu_3\text{-}S)(\mu_3\text{-}OR)(OR)_6$, $ZrCl_4$ was treated with 3.33 equiv. of $LiOCMe_3$ and 0.33 equiv. of Li_2S. Again the ^1H and ^{13}C NMR spectra of the product were not structurally definitive and the complex was characterized by X-ray crystallography, Figs 2 and 3.

The product isolated from this reaction, **2**, was indeed a trimetallic zirconium alkoxide, but no sulfur was incorporated. Instead, incorporation of oxide and hydroxide ligands occurred. Since **2** can be obtained in similar yields in reactions in the absence of lithium sulfide, it is unlikely that it is formed by hydrolysis of a sulfide intermediate. Again the source of the oxide and hydroxide ligands is not known, but the synthesis of **2** is reproducible and the compound is readily isolated as the favored product of this ligand metal combination.

The structures of **1** and **2** are closely related. Both contain a $Zr_3(\mu_3\text{-}O)(\mu_3\text{-}Z)(\mu_2\text{-}O)_3$ core as a structural feature. In the case of **2**, the triply bridging atoms are supplied by one *tert*-butoxide ligand and one oxide and the doubly bridging oxides arise from two *tert*-butoxide ligands and the hydroxide. The hydrogen on the hydroxide was not located crystallographically, but the bond distances are consistent with its location on O(8). The 2.101(7) Å average Zr—μ_3-O distance is similar to that observed in **1**. The terminal Zr—O(O^{t}Bu) distances range from 1.918(4) to 1.961(3) Å and are shorter than the bridging 2.162(3) and 2.182(3) Å Zr—O(μ_2-O^{t}Bu) distances which are shorter than the 2.391(4) and 2.373(3) Å Zr—O(μ_3-O^{t}Bu) lengths. The 2.326(3) Å Zr—O(8) distance is significantly longer than the other Zr—O(μ_3-O) distances and is consistent with a Zr—OH bond [4]. The 3.2207(7) and 3.2533(8) Å Zr···Zr distances are slightly shorter than those in **1**.

$\{Na_2[(EtO)Zr]_3(\mu\text{-}OEt)_7(\mu_3\text{-}OEt)_2(\mu_3\text{-}O)\}_2$, 3

In contrast to zirconium alkoxides in which the R group is propyl or larger, zirconium ethoxide, '$Zr(OEt)_4$' is essentially insoluble in THF. However, a suspension of this material in THF reacts with sodium salts such as $NaOSiMe_3$ and $NaOCH_2CH_3$ to form solutions from which crystals of the mixed-metal $Na_4Zr_6(OEt)_{24}O_2$, **3**, were isolated. In our hands, $NaOSiMe_3$ was the best reagent to reproducibly introduce sodium and solubilize $Zr(OEt)_4$. Since NMR spectra were not informative, **3** was characterized by X-ray diffraction.

Complex **3** (Fig. 4), consists of six octahedrally coordinated zirconium centers and four five coordinate sodium atoms bridged with ethoxide ligands and two μ_5-O ligands. The condensed ZrO_6 units are reminiscent of the condensed MO_6 units in polymolybdates and polytungstates [32]. Complex **3** contains $Zr_3(\mu_3\text{-}O)(\mu\text{-}OR)_3$ subunits and can be considered as two $[(EtO)_3Zr_3(\mu_3\text{-}O)(\mu\text{-}OEt)_9]^{2-}$ units bridged with four sodium atoms. Four alkali metals have previously been observed to connect pairs of zirconium atoms in $K_4Zr_2O(O^iPr)_{10}$, a complex which also can be formed by a variety of alkali metal reagents [28]. As usual, the terminal Zr—O distances, 1.937(6)–1.951(7) Å, are longer than the bridging ones. The bridging ethoxide ligands are of two types: in each half of the structure, three connect zirconium atoms and six bridge zirconium to sodium. The Zr—O distances for the zirconium bridging ligands, 2.139(7)–2.197(6) Å have larger values than the Zr—O dis-

tances of the ligands connecting zirconium to sodium, 2.020(6)–2.074(6) Å.

The formation of direct zirconium analogs of the common $Y_3(\mu\text{-}O^tBu)_3(\mu_3\text{-}Z)_2(O^tBu)_4L_2$ compounds of yttrium is not possible using just the eleven ligands in these systems. For charge balance, either an extra alkoxide (requiring 7-coordinate zirconium) or an oxide ligand must be incorporated. In each of the new complexes described here, an oxide ligand has been incorporated. In addition, in the case of **1** and **2**, halide and hydroxide ligands are found in the products. Inclusion of such small monoanionic ligands aids in forming polymetallic species since it reduces the steric crowding around the Zr_3 unit.

The isolation of **1–3** shows that analogs of $Y_3(\mu\text{-}O^tBu)_3(\mu_3\text{-}Z)_2(O^tBu)_4L_n$ complexes can indeed be made with zirconium if oxide, halide and hydroxide ligands are incorporated. This means that a variety of polymetallic zirconium species should be accessible if the necessary coligands required for charge balance and steric minimization can be included. Deliberate incorporation of the most desirable of these ligands, oxide and hydroxide, is not easy since the salts of these ligands are typically insoluble in the ether solvents commonly used. Furthermore, simple addition of these salts provides no guarantee that they will be incorporated as was observed in the reaction leading to complex **2**. On the other hand, hydrolysis of Zr—OR groups and C—O cleavage reactions can occur in these systems and can provide these ligands [27–29]. The incorporation of oxide into each of the complexes reported here is reminiscent of the consistent formation of the oxide $Y_5O(O^iPR)_{13}$ in preparations of '$Y(O^iPr)_3$' [29].

The progression of ligand sizes in the three structures reported here shows how ligand bulk can affect aggregation. The ethoxide group is the least sterically demanding and allows the most aggregation. Neopentoxide is next largest in this series and the structure of **1** shows that these ligands are not too bulky to form a $[(RO)_2Zr(\mu\text{-}OR)]_3$ unit provided there are small ligands in the μ_3-capping positions. The structure of complex **2** suggests that a trimeric $[(^tBuO)_2Zr]_3$ unit cannot accommodate three doubly-bridging μ-O^{t}Bu ligands around the triangle and will require either μ-OH or μ-O ligands to form a $M_3(\mu_3\text{-}E)_2(\mu\text{-}E)_3$ structure.

CONCLUSIONS

This study shows that trimetallic zirconium alkoxide complexes can be obtained from combinations of monozirconium precursors with simple alkoxide reagents. As is the case for other early metal and f element alkoxide systems, the syntheses are highly dependent on the precise combination of reagents. Structurally, there are similarities with other early metal and f element alkoxide complexes which may be useful in designing more extended systems with zirconium.

(Received 30 April 1997; accepted 12 June 1997)

Abstract—The THF adduct of rhenium trichloride, $Re_3(\mu\text{-}Cl)_3Cl_6(THF)_3$, reacts with trimethylphosphine and $NaOPr^i$ to give the chloro-hydride $Re_3(\mu\text{-}OPr^i)_3Cl(H)(OPr^i)_4(PMe_3)$ and the dimer $\{Re_3(\mu\text{-}OPr^i)_3Cl(OPr^i)_4\}_2(\mu\text{-}Cl)_2$ in moderate yields. On the basis of spectroscopic studies and an X-ray crystal structure, the hydride ligand in the chloro–hydride cluster is proposed to occupy a site *trans* to Cl and *cis* to PMe_3. The hydride ligand is proposed to originate from isopropoxide β-hydrogen elimination. Ethylene and 2-butyne react with the phosphine-hydride cluster to yield ethyl and 2-butenyl clusters, respectively, and sodium isopropoxide reacts to give $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5(PMe_3)$. The latter compound is more conveniently prepared by reacting PMe_3 with the homoleptic isopropoxide cluster $Re_3(\mu\text{-}OPr^i)_3(OPr^i)_6$. In contrast, the analogous reaction of PMe_3 with the homoleptic neopentoxide cluster $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6$ gives a simple phosphine adduct, $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6(PMe_3)$. The reaction of $Re_3(\mu\text{-}Cl)_3Cl_6(THF)_3$ with trimethylphosphine and sodium neopentoxide produces the reduced cluster $Re_3(\mu\text{-}Cl)(\mu\text{-}OCH_2Bu^t)_2Cl(OCH_2Bu^t)_4(PMe_3)_2$ in low yield. There are 13 electrons available for Re–Re bonding in the reduced cluster but its structure is not significantly different from similar 12-electron clusters. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: rhenium; alkoxide; clusters; phosphine; hydride; β-hydrogen elimination.

We recently reported the synthesis of homoleptic trirhenium(III) alkoxide clusters [1–3] and used them as sources of hydride clusters (*via* alkoxide β-hydrogen elimination) in reactions with alkenes and alkynes [4,5]. As part of our studies, we became interested in preparing derivatives with halide ligands that could be used to synthesize alkyl, cationic and reduced alkoxide clusters. Reactions of $Re_3Cl_9(THF)_3$ with less than 9 equiv. of sodium alkoxides does not give clean alkoxide-halide products, producing instead mixtures that include the homoleptic alkoxide clusters. We therefore turned to reactions of $Re_3Cl_9(THF)_{3-n}(PMe_3)_n$ clusters [6] with sodium alkoxides in the expectation the phosphine ligands could block complete substitution of the halides and stabilize the resulting halides to oligomerization *via* chloride or alkoxide bridges.

Herein we report on reactions of $Re_3Cl_9(THF)_3$ with sodium isopropoxide and neopentoxide in the presence of trimethylphosphine that yield $\{Re_3(\mu\text{-}OPr^i)_3Cl(OPr^i)_4\}_2(\mu\text{-}Cl)_2$, $Re_3(\mu\text{-}OPr^i)_3Cl(H)(OPr^i)_4(PMe_3)$ and $Re_3(\mu\text{-}Cl)(\mu\text{-}OCH_2Bu^t)_2Cl(OCH_2Bu^t)_4(PMe_3)_2$ clusters, and chemistry derived from or motivated by the isolation of these products, including the synthesis of $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6(PMe_3)$, $Re_3(\mu\text{-}OPr^i)_3H(OPr^i)_5(PMe_3)$, $Re_3(\mu\text{-}OPr^i)_3Cl(Et)(OPr^i)_4(NCMe)$ and $Re_3(\mu\text{-}OPr^i)_3Cl(\eta\text{-}C(Me)=C(H)Me)(OPr^i)_4$.

RESULTS AND DISCUSSION

A summary of our synthetic results is presented in Scheme 1. The X-ray crystal structures of $\{Re_3(\mu\text{-}OPr^i)_3Cl(OPr^i)_4\}_2(\mu\text{-}Cl)_2$, $Re_3(\mu\text{-}OPr^i)_3Cl(H)(OPr^i)_4(PMe_3)$, $Re_3(\mu\text{-}Cl)(\mu\text{-}OCH_2Bu^t)_2Cl(OCH_2Bu^t)_4(PMe_3)_2$ and $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6(PMe_3)$ were determined.

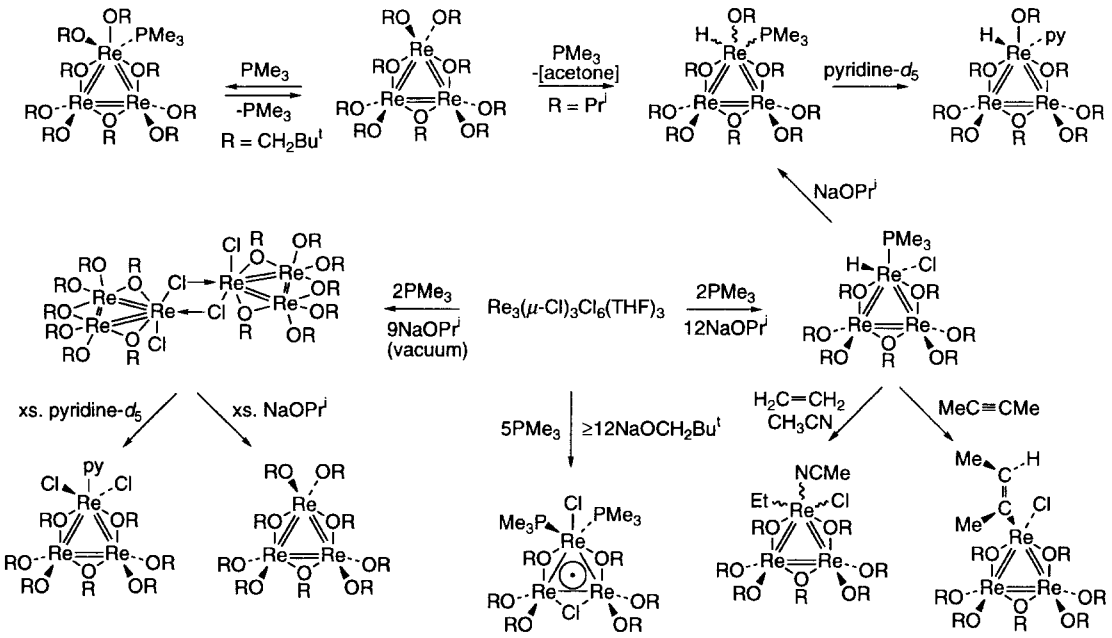


Scheme 1.

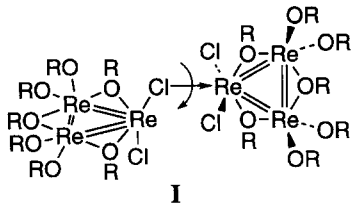
$\{Re_3(\mu\text{-}OPr^i)_3Cl(OPr^i)_4\}_2(\mu\text{-}Cl)_2$

The addition of 2–3 equiv. of PMe_3 to $Re_3(\mu\text{-}Cl)_3Cl_6(THF)_3$ in THF, which presumably forms $Re_3(\mu\text{-}Cl)_3Cl_6(PMe_3)_2(THF)$ or a mixture of $Re_3(\mu\text{-}Cl)_3Cl_6(PMe_3)_3$ and starting material [6,7], followed by the slow addition of 9 equiv. of $NaOPr^i$ to the reaction mixture produces, after workup, dark red crystals of the cluster dimer $\{Re_3(\mu\text{-}OPr^i)_3Cl(OPr^i)_4\}_2(\mu\text{-}Cl)_2$ in moderate yield. In the synthesis it is critical for phosphine to be removed *in vacuo* from the reaction mixture after the $NaOPr^i$ addition or otherwise the product cannot be isolated. When $NaOPr^i$ is added to the cluster dimer, the known homoleptic isopropoxide cluster [1,2] $Re_3(\mu\text{-}OPr^i)_3(OPr^i)_6$ is produced. Several attempts to prepare the cluster dimer without using phosphine in the reaction mixture failed, but it is reasonable to expect that the proper reaction conditions to produce the dimer in the absence of phosphine will be found eventually.

The room temperature ^1H NMR spectrum of $\{Re_3(\mu\text{-}OPr^i)_3Cl(OPr^i)_4\}_2(\mu\text{-}Cl)_2$ in C_6D_6 consists of four broad doublets of equal intensity arising from the methyl groups of the terminal isopropoxide ligands, two broad doublets and one sharp doublet arising from the methyl groups of the bridging isopropoxide ligands, and two broad septets (2:2) and one misshapen septet (relative intensity 3) arising from the methine groups. The misshapen septet is a broad septet of relative intensity 2 overlapping a septet of intensity 1. All of the broad resonances become sharp as the sample is cooled from room temperature to 10°C. The data are consistent with the structure shown in Scheme 1 (i.e. a structure with virtual C_s symmetry) and the solid state structure (*vide infra*). It should be noted that the room temperature ^1H NMR spectrum recorded for a $CDCl_3$ solution is identical to that reported by Wilkinson and co-workers for a compound with the proposed formulation $Re_3(\mu\text{-}Cl)(\mu\text{-}OPr^i)_2Cl(OPr^i)_5$ [8]. It is clear '$Re_3(\mu\text{-}Cl)(\mu\text{-}OPr^i)_2Cl(OPr^i)_5$' is in fact the dimer $\{Re_3(\mu\text{-}OPr^i)_3Cl(OPr^i)_4\}_2(\mu\text{-}Cl)_2$ on the basis of our NMR data and X-ray crystal structure. However, all attempts to prepare the cluster dimer using the reported procedure [8], which did not involve trimethylphosphine, have thus far failed.

To probe the cause of the broadening in the ^1H NMR resonances at room temperature, high temperature spectra were collected for a toluene-d_8 solution. At 85°C, the temperature at which some decomposition occurs, the spectrum consists of three septets in a 1:2:4 ratio and three doublets in a 2:4:8 ratio where the doublets of intensity 4 and 2 are in the bridging isopropoxide region. The doublet that was sharp in the room temperature spectrum remained sharp over the entire temperature range examined. The doublet of intensity 8 could be interpreted as a sharp doublet superimposed on a very broad doublet. If this interpretation is correct, the data are consistent with a dynamic process that gives the molecule two perpendicular mirror planes (i.e. gives it virtual C_{2v} symmetry). A plausible mechanism to account for this data is a dimer $\rightleftharpoons$ monomer equilibrium; the monomer $Re_3(\mu\text{-}OPr^i)_3Cl_2(OPr^i)_4$ would have virtual C_{2v} symmetry because of rapid C—O bond rotation coupled with rapid inversion at oxygen for the bridg-

ing isopropoxide ligands. Another possibility is a process involving Cl debridging and the bond rotation shown in **I**. Indirect support for the equilibrium pro-



I

posal comes from the reaction of $\{Re_3(\mu\text{-}OPr^i)_3Cl(O\text{-}Pr^i)_4\}_2(\mu\text{-}Cl)_2$ with pyridine-d_5 in benzene-d_6, which gives an ^1H NMR spectrum consisting of three septets in a 4 : 2 : 1 ratio and four doublets in a 4 : 4 : 4 : 2 ratio. The spectroscopic data are consistent with formation of the pyridine adduct $Re_3(\mu\text{-}OPr^i)_3Cl_2(OPr^i)_4(py)$ having the C_{2v} structure shown in Scheme 1.

$Re_3(\mu\text{-}OPr^i)_3Cl(H)(OPr^i)_4(PMe_3)$

The addition of 2–4 equiv. of PMe_3 to $Re_3(\mu\text{-}Cl)_3Cl_6(THF)_3$ in THF followed by the slow addition of 12 equiv. of $NaOPr^i$ to the reaction mixture produces, after workup, green blocks of $Re_3(\mu\text{-}OPr^i)_3Cl(H)(OPr^i)_4(PMe_3)$ in moderate yield. The dimer $\{Re_3(\mu\text{-}OPr^i)_3Cl(OPr^i)_4\}_2(\mu\text{-}Cl)_2$ can be found in the mother liquor.

The spectroscopic data for $Re_3(\mu\text{-}OPr^i)_3Cl(H)(O\text{-}Pr^i)_4(PMe_3)$ are consistent with the structure shown in Scheme 1 and the solid state structure (*vide infra*). The ^1H NMR spectrum (C_6D_6) consists of seven equal intensity doublets, four in the bridging and three in the terminal isopropoxide ligand regions, arising from the methyl protons, a doublet arising from the phosphine methyl protons, four methine septets in a 1 : 2 : 2 : 2 ratio, and a doublet at $\delta -6.3$ due to the hydride ligand with phosphorous coupling (42 Hz). In the IR spectrum there is a sharp, medium intensity band at 1979 cm^{-1} that can be assigned to a terminal hydride stretch; as a comparison, the Re—H stretching bands for $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5$ and $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5(py)$ occur at 1991 and 2002 cm^{-1}, respectively [2].

We have reported recently several examples of trirhenium(III) alkoxide clusters acting as sources of terminal hydride clusters *via* observed or proposed alkoxide β-hydrogen elimination reactions [1–5]. On this basis, we propose that the source of the hydride ligand in $Re_3(\mu\text{-}OPr^i)_3Cl(H)(OPr^i)_4(PMe_3)$ is isopropoxide β-hydrogen elimination. In an attempt to observe acetone, the reaction to form the hydride cluster was carried out in an NMR tube but the ^1H NMR spectra of the mixture were too complex to conclude whether acetone was present.

$Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5(PMe_3)$

The NMR-tube scale reaction of $Re_3(\mu\text{-}OPr^i)_3Cl(H)(OPr^i)_4(PMe_3)$ with excess $NaOPr^i$ in benzene-d_6 gives a new hydride cluster, $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5(PMe_3)$. On a large scale, $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5(PMe_3)$ is more conveniently synthesized by the reaction of $Re_3(\mu\text{-}OPr^i)_3(OPr^i)_6$ with excess PMe_3 in hexanes, from which the hydride can be isolated as green crystalline blocks in moderate yield. When the reaction of $Re_3(\mu\text{-}OPr^i)_3(OPr^i)_6$ with excess PMe_3 is carried out in an NMR tube, $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5(PMe_3)$ is formed in $\geqslant 95\%$ yield (*vs* C_6Me_6 internal standard) within minutes, and 1 equiv. of acetone is produced for every molecule of product cluster. The cluster $Re_3(\mu\text{-}OPr^i)_3(OPr^i)_6$ is known to exist in solution as an equilibrium mixture of $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5$ and acetone [1,2]. In these reactions the phosphine acts as a trapping reagent to form the phosphine-hydride cluster in the same way that pyridine, olefins and alkynes can act as hydride traps to form a pyridine adduct, and alkyl and alkenyl clusters [1,2,4].

The ^1H NMR spectrum of $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5(PMe_3)$ in CD_2Cl_2 consists of eight equal intensity methyl doublets, with five in the terminal and three in the bridging isopropoxide regions, a doublet arising from the phosphine methyl protons, and four methine septets in a 1 : 1 : 2 : 4 ratio. Three of the septets are not well resolved. The pattern of methyl resonances indicates clearly that the cluster has mirror symmetry but the stereochemistry at the unique Re is ambiguous (i.e. it is unclear whether there is a *trans* or *cis*-P—Re—H arrangement, and if it is *cis*, whether the hydride is in the plane of the Re_3 triangle). In the closely related, structurally characterized hydride cluster $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5(py)$ the hydride is perpendicular to the Re_3 plane and there is a *trans*-py-Re-H arrangement. The cluster $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5(PMe_3)$ can be converted to the pyridine adduct by adding a drop of pyridine-d_5 to a benzene-d_6 solution of $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5(PMe_3)$. On the basis of the structural precedent of $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5(py)$ and the conversion of the phosphine cluster to the pyridine adduct, it is reasonable to suggest that $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5(PMe_3)$ has a structure analogous to the pyridine adduct. On the other hand, the P-H coupling constant in $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5(PMe_3)$ is about 15 Hz less (27 *vs* 42 Hz) than the coupling constant in $Re_3(\mu\text{-}OPr^i)_3Cl(H)(O\text{-}Pr^i)_4(PMe_3)$, which an X-ray crystallographic study (*vide infra*) shows has a *cis*-P—Re—H arrangement. This suggests $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5(PMe_3)$ has *cis*-P—Re—H stereochemistry. A crystal structure of $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5(PMe_3)$ is needed to resolve the structural ambiguity.

The IR spectrum of $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5(PMe_3)$ has a medium intensity band at 1923 cm^{-1} that can be assigned to a terminal Re—H stretch.

$Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6(PMe_3)$

The synthesis of $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5(PMe_3)$ from PMe_3 and $Re_3(\mu\text{-}OPr^i)_3(OPr^i)_6$ suggested that the

analogous neopentoxide cluster, $Re_3(\mu\text{-}OCH_2Bu^t)_3(H)(OCH_2Bu^t)_5(PMe_3)$, might also be synthesized by reacting $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6$ with PMe_3. The reaction produces, however, only the simple phosphine adduct $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6(PMe_3)$ as crystalline green blocks in moderate yield. Some PMe_3 is lost from the cluster when it is held under dynamic vacuum for an extended period of time, which may account for why the chemical analysis is close to a $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6$ stoichiometry. When the reaction is carried out in an NMR tube (benzene-d_6; 5–6 equiv. of PMe_3), the phosphine adduct forms within several hours in >95% yield (*vs* C_6Me_6 internal standard). In contrast, we reported recently that the NMR tube-scale reactions of $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6$ with PMe_2Ph under forcing conditions produces what appears to be $Re_3(\mu\text{-}OCH_2Bu^t)_3(H)(OCH_2Bu^t)_5(PMe_2Ph)$ [$\delta(ReH)$ −3.1, J_{PH} = 30 Hz, C_6D_6] but the hydride was not formed cleanly [3]. The difference in reactivity of $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6$ and $Re_3(\mu\text{-}OPr^i)_3(OPr^i)_6$ with PMe_3 under mild conditions—formation of $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6(PMe_3)$ *vs* $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5(PMe_3)$ and acetone—is consistent with our previous findings [2] that $K_{eq} \approx 6 \times 10^{-4}$ M at room temperature for the equilibrium $Re_3(\mu\text{-}OPr^i)_3(OPr^i)_6 \rightleftharpoons Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5 + O{=}CMe_2$ and the analogous neopentoxide β-hydrogen elimination equilibrium, if it exists at all, favors strongly the homoleptic cluster [3].

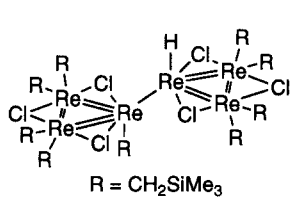
The room temperature ^1H NMR spectrum of $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6(PMe_3)$ is fully consistent with the structure shown in Scheme 1 and the solid state structure (*vide infra*), having three AB quartets, a singlet and two doublets (due to weak P–H coupling) in the methylene region, and six singlets in the Bu^t region in a 1:1:1:2:2:2 ratio. The phosphine peak is obscured in the spectrum by one of the methyl resonances at ≈1 ppm, which was proven by preparing the PMe_3-d_9 complex and obtaining its $^2H\{^1H\}$ spectrum. To test the stability of the adduct in solution, a toluene-d_8 solution containing excess PMe_3 was heated in the NMR probe. At 60°C, the adduct was stable, but at 80°C complete dissociation occurred giving $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6$ and free PMe_3. Upon cooling the sample, the adduct reformed slowly.

$Re_3(\mu\text{-}Cl)(\mu\text{-}OCH_2Bu^t)_2Cl(OCH_2Bu^t)_4(PMe_3)_2$

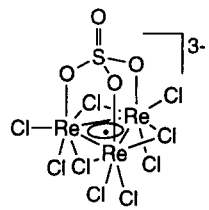
The successful isolation of the isopropoxide derivatives $Re_3(\mu\text{-}OPr^i)_3Cl(H)(OPr^i)_4(PMe_3)$ and $\{Re_3(\mu\text{-}OPr^i)_3Cl(OPr^i)_4\}_2(\mu\text{-}Cl)_2$ from reactions of sodium isopropoxide and rhenium chloride in the presence of trimethylphosphine prompted us to attempt similar reactions using sodium neopentoxide. Various stoichiometries were used but in only one case was a clean product isolated. The reaction of $Re_3(\mu\text{-}Cl)_3Cl_6(THF)_3$ in THF with five equiv. of PMe_3 followed by the slow addition of ⩾12 equiv. of $NaOCH_2Bu^t$ gave low (≈12%), reproducible yields of the reduced cluster $Re_3(\mu\text{-}Cl)(\mu\text{-}OCH_2Bu^t)_2Cl(OCH_2Bu^t)_4(PMe_3)_2$, which was identified by X-ray crystallography. Electron counting indicates there are 13 electrons available for Re—Re bonding in the cluster. Consistent with the compound being paramagnetic, the ^1H NMR spectrum has only broad, ill-defined resonances that do not sharpen when the sample is warmed or cooled.

The identity of the reducing agent in the synthesis of $Re_3(\mu\text{-}Cl)(\mu\text{-}OCH_2Bu^t)_2Cl(OCH_2Bu^t)_4(PMe_3)_2$ has not been determined. Walton and co-workers [9,10], however, have observed reduction of rhenium(III) chloride by monodentate tertiary phosphines under forcing conditions to yield the Re^{II} dimers $[ReCl_2(PR_3)_2]_2$ and Wilkinson *et al.* have reported reduction of $Re_3Cl_3(CH_2SiMe_3)_6$ by PMe_3 to give the Re^{II} dimer $[ReCl(CH_2SiMe_3)(PMe_3)_2]_2$ [11]. These reports suggest the preparation of $Re_3(\mu\text{-}Cl)(\mu\text{-}OCH_2Bu^t)_2Cl(OCH_2Bu^t)_4(PMe_3)_2$ involves phosphine reduction of rhenium(III). More logical preparations of the reduced cluster using reducing agents such as magnesium and Na/Hg have thus far failed.

Only two other examples of well characterized 13-electron Re_3 clusters are known. Wilkinson, Hursthouse and co-workers reported the crystal structure of the hexanuclear cluster **II** [12,13] in which the extra



II



III

electron has been used to couple two 13-electron Re_3 fragments *via* a Re—Re bond, and Mertis *et al.* reported the electrochemical reduction of Re_3Cl_9 in aqueous hydrochloric acid from which the triply-bridged sulphato derivative **III** could be isolated [14].

Reactions of $Re_3(\mu\text{-}OPr^i)_3Cl(H)(OPr^i)_4(PMe_3)$ *with ethylene and 2-butyne*

To test the reactivity of the Re—H bond in $Re_3(\mu\text{-}OPr^i)_3Cl(H)(OPr^i)_4(PMe_3)$, reactions with ethylene and 2-butyne were carried out. The reaction of ethylene with $Re_3(\mu\text{-}OPr^i)_3Cl(H)(OPr^i)_4(PMe_3)$ gave the ethyl cluster $Re_3(\mu\text{-}OPr^i)_3Cl(Et)(OPr^i)_4(MeCN)$ in low yield after a workup that included exposure to excess acetonitrile. The reaction carried out in an NMR tube was not clean, which accounts for the low yield of the large scale reaction. The reaction of $Re_3(\mu\text{-}OPr^i)_3Cl(H)(OPr^i)_4(PMe_3)$ with 2-butyne gave the 2-butenyl cluster $Re_3(\mu\text{-}OPr^i)_3Cl(\eta\text{-}C(Me){=}CMe(H))(OPr^i)_4(PMe_3)$ in 44% yield as green needles after workup and crystallization from CH_2Cl_2/CH_3CN.

Proton NMR spectra for the ethyl and 2-butenyl clusters indicate they have virtual mirror symmetry in solution as illustrated in Scheme 1. The ethyl ligand in $Re_3(\mu\text{-}OPr^i)_3Cl(Et)(OPr^i)_4(MeCN)$ gives rise to a quartet and triplet. The stereochemistry at the Re(Cl)Et(MeCN) center cannot be assigned on the basis of NMR spectra but it is likely that the strong σ-donor ethyl ligand is perpendicular to the Re_3 plane as in the case of the hydride ligand in structurally characterized $Re_3(\mu\text{-}OPr^i)_3H(OPr^i)_5(py)$ [2]. The butenyl proton of $Re_3(\mu\text{-}OPr^i)_3Cl(\eta\text{-}C(Me)=CMe(H))(OPr^i)_4$ appears as a quartet and one of the methyl groups gives rise to a doublet. NOE experiments suggest the methyl groups are mutually *cis*, as expected for an insertion product.

X-ray crystal structures of $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6(PMe_3)$, $Re_3(\mu\text{-}OPr^i)_3Cl(H)(OPr^i)_4(PMe_3)$, $\{Re_3(\mu\text{-}OPr^i)_3Cl(OPr^i)_4\}_2(\mu\text{-}Cl)_2$ *and* $Re_3(\mu\text{-}Cl)(\mu\text{-}OCH_2Bu^t)_2Cl(OCH_2Bu^t)_4(PMe_3)_2$

Thermal ellipsoid plots are shown in Figs 1–4 and selected bond distances and angles are presented in Tables 1 and 2. The clusters $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6(PMe_3)$, $Re_3(\mu\text{-}OPr^i)_3Cl(H)(OPr^i)_4(PMe_3)$, $\{Re_3(\mu\text{-}OPr^i)_3Cl(OPr^i)_4\}_2(\mu\text{-}Cl)_2$ crystallize with CH_2Cl_2 in the lattice.

The cluster $\{Re_3(\mu\text{-}OPr^i)_3Cl(OPr^i)_4\}_2(\mu\text{-}Cl)_2$ is situated about an inversion center and $Re_3(\mu\text{-}Cl)(\mu\text{-}OCH_2Bu^t)_2Cl(OCH_2Bu^t)_4(PMe_3)_2$ is bisected by a crystallographic two-fold axis. The hydride ligand in $Re_3(\mu\text{-}OPr^i)_3Cl(H)(OPr^i)_4(PMe_3)$ was not located crystallographically, but there is a 'missing' ligand at Re(1) *trans* to Cl(1) that is the likely hydride site. This assignment is consistent with the spectroscopic data as well. There are no unusual bond angles associated with the clusters, but there are some interesting differences in analogous bond distances.

[a] Re(n,m) is the midpoint between atoms Re(n) and Re(m).

The Re—Re bond distances [2.374(1)–2.392(1) Å] in $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6(PMe_3)$, $Re_3(\mu\text{-}OPr^i)_3Cl(H)(OPr^i)_4(PMe_3)$ and $\{Re_3(\mu\text{-}OPr^i)_3Cl(OPr^i)_4\}_2(\mu\text{-}Cl)_2$ are comparable to those found in $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6$, $[Na(THF)_2][Re_3(\mu\text{-}OCH_2Bu^t)_3H(OCH_2Bu^t)_6]$, $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5$, $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5(py)$, and $Re_3(\mu\text{-}OPr^i)_3(\eta\text{-}CPh{=}CH_2)(OPr^i)_5$ [2.357(1)–2.383(2) Å] [2–4] but the distances in the reduced cluster $Re_3(\mu\text{-}Cl)(\mu\text{-}OCH_2Bu^t)_2Cl(OCH_2Bu^t)_4(PMe_3)_2$ are slightly longer [2.4182(7) and 2.4801(4) Å]. In the latter case, the longer of the two distances is associated with the chlorine-bridged Re(2)—Re(2′) bond. For comparison, the Re–Re distances in $Re_3(\mu\text{-}Cl)_3(OBu^t)_6$ are 2.436(3)–2.439(3) Å and the chlorine-bridged Re–Re distance in $Re_3(\mu\text{-}Cl)(\mu\text{-menthoxo})_2Cl(menthoxo)_5$ is 2.422(3) Å while the alkoxide-bridged distances are 2.368(3) and 2.376(3) Å [8]. It is tempting to suggest that the slightly longer Re–Re distances in the reduced cluster indicate the added electron occupies a Re–Re antibonding MO but the effect, if it exists at all, is small and we hesitate to draw any firm conclusions.

The Re–P distances in $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6(PMe_3)$ [2.488(3) Å] and $Re_3(\mu\text{-}Cl)(\mu\text{-}OCH_2Bu^t)_2Cl(OCH_2Bu^t)_4(PMe_3)_2$ [2.474(3) Å] are not significantly different from one another but they are both shorter than the distances in $Re_3(\mu\text{-}OPr^i)_3Cl(H)(OPr^i)_4(PMe_3)$ [2.534(3) Å] and $Re_3(\mu\text{-}Cl)_3Cl_6(PMe_3)_3$ [2.634(4) Å] [7]. In all the clusters, the $Re\text{–}O_{terminal}$ distances are not significantly different from each other with the exception of Re(1)—O(1) and Re(1)—O(2) in $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6(PMe_3)$, which are, respectively, greater than 0.09 Å and 0.13 Å longer than the other terminal distances. It appears that the sterically congested Re(1) site in $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6(PMe_3)$ is associated with longer distances with respect to the other alkoxide clusters.

The $Re\text{–}Cl_{terminal}$ distance in $Re_3(\mu\text{-}OPr^i)_3Cl(H)(OPr^i)_4(PMe_3)$ [2.421(2) Å] is almost 0.1 Å longer than the $Re\text{–}Cl_{terminal}$ distance in $\{Re_3(\mu\text{-}OPr^i)_3Cl(OPr^i)_4\}_2(\mu\text{-}Cl)_2$ [2.344(4) Å], where the distance is comparable to those in $Re_3(\mu\text{-}Cl)_3Cl_6(PMe_3)_3$ [2.310(3) Å]. In the phosphine-hydride cluster the terminal chlorine is *trans* to H, which has a high *trans* influence, and in the latter, chlorine is *trans* to a bridging chloride, a low *trans* influence ligand [15]. The $Re\text{–}Cl_{bridge}$ distances in the cluster dimer are longer than the $Re\text{–}Cl_{terminal}$ distance, and the Re–Cl(2′) distance is especially long, suggesting that the dimer is held together weakly.

EXPERIMENTAL

General techniques and reagents

All manipulations were carried out in a nitrogen-filled glovebox or by using standard Schlenk techniques. Solvents were purified by using standard techniques and stored in the drybox over molecular sieves until they were needed. Rhenium metal was purchased from Cleveland Refractory Metals. The compounds $Re_3(\mu\text{-}Cl)_3Cl_6(THF)_3$ [13, 16, 17], $Re_3(\mu\text{-}OPr^i)_3(OPr^i)_6$ and $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6$ were prepared according to the literature methods [1–3]. Proton and ^{13}C NMR spectra were referenced internally to solvent proton and carbon-13 resonances, respectively. Spectra were collected on a 300-MHz instrument. Elemental analyses were performed by Oneida Research Services, Whitesboro, NY.

Syntheses

$\{Re_3(\mu\text{-}OPr^i)_3Cl(OPr^i)_4\}_2(\mu\text{-}Cl)_2$. Trimethylphosphine (1.8 mmol) was added *via* a calibrated vacuum manifold to a frozen red solution of $Re_3Cl_9(THF)_3$ (0.98 g, 0.90 mmol) in THF (50 cm^3). The color of the solution gradually changed to purple as it was stirred at room temperature for 12 h. Sodium isopropoxide (0.66 g, 8.1 mmol) was then added slowly and the color of solution gradually changed to brown over a period of 0.5 h. At this point the flask was attached to a vacuum line and the stopcock was opened to vacuum for about 1 min. The stopcock was closed and the mixture was stirred at room temperature for another 6 h. The volatile components were then removed under reduced pressure. The brown residue was extracted with hexanes (5×15 cm^3), and the combined extracts were filtered through Celite. The volatile components were removed *in vacuo* from the filtrate, the residue was dissolved in CH_2Cl_2, and the resulting solution was concentrated *in vacuo* to ≈ 10 cm^3. The flask was transferred to a freezer where it was kept at $-35°C$ for 12 h, producing dark red crystals. Yield 0.35 g (37%) (Found: C, 23.45; H, 4.45. $C_{42}H_{98}Cl_4O_{14}Re_6$ requires C, 24.18; H, 4.73%). ^1H NMR (C_6D_6, 10°C): δ 1.15 (d, 12, $J_{HH} = 6$ Hz, $OCHMe_2$), 1.20 (d, 12, $J_{HH} = 6$ Hz, $OCHMe_2$), 1.29 (d, 12, $J_{HH} = 6$ Hz, $OCHMe_2$), 1.32 (d, 12, $J_{HH} = 6$ Hz, $OCHMe_2$), 1.73 (d, 12, $J_{HH} = 6$ Hz, $OCHMe_2$), 2.03 (d, 12, $J_{HH} = 6$ Hz, $OCHMe_2$), 2.26 (d, 12, $J_{HH} = 6$ Hz, $OCHMe_2$), 4.43 (sept, 4, $J_{HH} = 6$ Hz, $OCHMe_2$), 5.20 (sept, 6, $J_{HH} = 6$ Hz, $OCHMe_2$), 5.62 (sept, 4, $J_{HH} = 6$ Hz, $OCHMe_2$). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 26.7 (4, $OCHMe_2$), 27.4 (4, $OCHMe_2$), 27.5 (4, $OCHMe_2$), 28.0 (4, $OCHMe_2$), 28.3 (4, $OCHMe_2$), 29.7 (4, $OCHMe_2$), 30.1 (4, $OCHMe_2$), 70.1 (4, $OCHMe_2$), 71.6 (2, $OCHMe_2$), 76.5 (4, $OCHMe_2$), 76.8 (4, $OCHMe_2$). IR (Nujol, CsI, cm^{-1}): 1319m, 1167m, 1146w, 1099s, 980s, 955s, 914s, 849s, 833s, 721w, 638m, 615m, 601m, 538w, 444w, 432w.

$Re_3(\mu\text{-}OPr^i)_3Cl(H)(OPr^i)_4(PMe_3)$. Trimethylphosphine (1.8 mmol) was added *via* a calibrated vacuum manifold to a frozen red solution of $Re_3Cl_9(THF)_3$ (0.98 g, 0.90 mmol) in THF. The mixture was warmed to room temperature and the color gradually changed to purple as it was stirred for 12 h. Sodium isopropoxide (0.90 g, 11 mmol) was added slowly and the color of the solution gradually changed to green

over a period of 15 min. After 2 h, the volatile components were removed under reduced pressure, and the residue was extracted with hexanes (4×15 cm^3). The extracts were combined and filtered through Celite. The volatile components were removed *in vacuo* from the green filtrate, and the residue was dissolved in CH_2Cl_2/CH_3CN (5:1). The solution was concentrated to 5 cm^3 and the flask was transferred to the freezer where it was kept at −35 °C for 12 h. The product crystallized as green blocks. Yield 0.31 g (38%) (Found: C, 26.41; H, 4.96. $C_{24}H_{59}ClO_7PRe_3$ requires C, 26.57; H, 5.48%). ^{1}H NMR (C_6D_6): δ −6.32 (d, 1, $^2J_{PH}$ = 42 Hz, Re-*H*), 1.05 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 1.16 (d, 9, $^2J_{PH}$ = 9 Hz, P*Me*$_3$), 1.24 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 1.33 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 1.39 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 1.72 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 1.79 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 1.81 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 4.55 (sept, 2, J_{HH} = 6 Hz, OC*H*Me$_2$), 4.72 (sept, 2, J_{HH} = 6 Hz, OC*H*Me$_2$), 4.96 (sept, 1, J_{HH} = 6 Hz, OC*H*Me$_2$), 5.08 (sept, 2, J_{HH} = 6 Hz, OC*H*Me$_2$). ^{13}C{^{1}H} NMR (C_6D_6): δ 15.0 (d, 3, J_{PC} = 23 Hz, P*Me*$_3$), 26.6 (4, OCH*Me*$_2$), 27.2 (2, OCH*Me*$_2$), 27.4 (2, OCH*Me*$_2$), 27.5 (2, OCH*Me*$_2$), 28.5 (4, OCH*Me*$_2$), 72.4 (1, OCHMe$_2$), 73.0 (2, OCHMe$_2$), 76.0 (2, OCHMe$_2$), 77.8 (2, OCHMe$_2$). ^{31}P{^{1}H} NMR (C_6D_6): −11.0. IR (Nujol, KBr, cm^{-1}): ν (Re—H) 1979m, 1452s, 1418m, 1400w, 1371s, 1319s, 1285m, 1208m, 1165s, 1101s, 1044m, 963s, 874m, 845s, 833s, 733m, 700m, 671w, 625m, 615m, 596m, 569w, 536w, 469s, 451s, 419s, 405s.

$Re_3(\mu\text{-}OPr^i)_3Cl(CH_2CH_3)(OPr^i)_4(CH_3CN)$. Ethylene (0.90 mmol) was added *via* a calibrated vacuum manifold to a frozen green solution of $Re_3(\mu\text{-}OPr^i)_3Cl(H)(OPr^i)_4(PMe_3)$ (0.20 g, 0.18 mmol) in hexane. The solution was warmed to 50 °C and stirred at this temperature for 2 days. The solution volume was then reduced *in vacuo* to 2 cm^3. Acetonitrile (20 cm^3) was added, which caused a green solid to precipitate. Yield: 0.042 g (21%). ^{1}H NMR (C_6D_6): δ 0.05 (t, 3, J_{HH} = 8 Hz, CH_2CH_3), 0.58 (s, 3, CH_3CN), 0.97 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 1.14 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 1.18 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 1.28 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 1.70 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 1.80 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 1.81 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 3.43 (q, 2, J_{HH} = 8 Hz, CH_2CH_3), 4.43 (sept, 2, J_{HH} = 6 Hz, OC*H*Me$_2$), 4.90 (2 overlapping sept, 3, OC*H*Me$_2$), 5.15 (sept, 2, J_{HH} = 6 Hz, OC*H*Me$_2$). ^{13}C{^{1}H} NMR (C_6D_6): δ −1.37 (1, CH_3CN), 23.7 (1, CH_2CH_3), 26.5 (1, CH_2CH_3), 26.6 (2, OCH*Me*$_2$), 27.3 (4, OCH*Me*$_2$), 27.4 (4, OCH*Me*$_2$), 27.7 (2, OCH*Me*$_2$), 29.4 (2, OCH*Me*$_2$), 67.5 (1, OCHMe$_2$), 72.9 (2, OCHMe$_2$), 74.8 (2, OCHMe$_2$), 77.8 (2, OCHMe$_2$), 93.4 (1, CH_3CN). IR (Nujol, KBr, cm^{-1}): 1373m, 1364m, 1319w, 1200w, 1167w, 1103s, 961s, 928s, 845s, 833s, 723w, 698w, 635w, 623w, 615w, 596w, 534w, 465m, 457m, 442m, 430m.

$Re_3(\mu\text{-}OPr^i)_3Cl(\eta\text{-}C(Me)=C(H)Me)(OPr^i)_4$. 2-Butyne (0.90 mmol) was added *via* a calibrated vacuum manifold to a frozen green solution of $Re_3(\mu\text{-}OPr^i)_3Cl(H)(OPr^i)_4(PMe_3)$ (0.20 g, 0.18 mmol) in hexanes (15 cm^3). The solution was warmed to 50 °C and left to stir at this temperature for 12 h. The mixture was filtered, and the volatile components were removed *in vacuo* from the filtrate. The green residue was dissolved in CH_2Cl_2/CH_3CN (5:1) and the solution was concentrated *in vacuo* to 5 cm^3. The flask was transferred to a freezer where it was kept at −35 °C for 12 h. The product crystallized as green needles. Yield: 0.86 g (44%) (Found: C, 28.31; H, 5.34. $C_{25}H_{56}ClO_7Re_3$ requires C, 28.25; H, 5.31). ^{1}H NMR (C_6D_6): δ 1.10 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 1.15 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 1.25 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 1.28 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 1.53 (s, 3, *Me*C=CHMe), 1.71 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 1.76 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 1.81 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 2.15 (d, 3, J_{HH} = 6.6 Hz, MeC=CH*Me*), 4.45 (q, 1, J_{HH} = 6.3 Hz, MeC=C*H*Me), 4.53 (sept, 2, J_{HH} = 6 Hz, OC*H*Me$_2$), 4.90 (2 overlapping sept, 3, OC*H*Me$_2$), 5.18 (sept, 2, J_{HH} = 6 Hz, OC*H*Me$_2$). ^{13}C{^{1}H} NMR (C_6D_6): δ 9.5 (1, MeC-CH*Me*), 22.9 (1, *Me*CCHMe), 26.0 (2, OCH*Me*$_2$), 26.8 (2, OCH*Me*$_2$), 26.9 (2, OCH*Me*$_2$), 27.0 (2, OCH*Me*$_2$), 27.5 (2, OCH*Me*$_2$), 28.0 (2, OCH*Me*$_2$), 28.7 (2, OCH*Me*$_2$), 72.1 (2, OCHMe$_2$), 72.7 (2, OCHMe$_2$), 72.9 (1, OCHMe$_2$), 79.5 (2, OCHMe$_2$), 119 (1, MeC=*C*HMe), 128 (1, Me*C*=CHMe). $Re_3(\mu\text{-}OPr^i)_3H(OPr^i)_5(PMe_3)$. Trimethylphosphine (0.78 mmol) was added *via* a calibrated vacuum manifold to a frozen green solution of $Re_3(OPr^i)_9$ (0.14 g, 0.13 mmol) in hexanes (15 cm^3). The solution was warmed to room temperature and stirred for 12 h. The volatile components were then removed under reduced pressure. The green residue was dissolved in CH_2Cl_2/CH_3CN (5:1), and the solution was concentrated *in vacuo* to 3 cm^3. The flask was transferred to a freezer where it was kept at −35 C for 12 h. The product crystallized as green blocks, which were isolated by removing the mother liquor with a pipet and washing with cold CH_2Cl_2 (2×5 cm^3). Yield: 0.77 g (56%) (Found: C, 29.04; H, 5.99. $C_{27}H_{66}O_8PRe_3$ requires C, 29.26; H, 6.00%). ^{1}H NMR (CD_2Cl_2): δ −4.40 (d, 1, $^2J_{PH}$ = 27 Hz, Re-*H*), 0.74 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 0.79 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 0.90 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 1.06 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 1.13 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 1.21 (d, 9, $^2J_{PH}$ = 7.5 Hz, P*Me*$_3$), 1.47 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 1.53 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 1.55 (d, 6, J_{HH} = 6 Hz, OCH*Me*$_2$), 4.01 (sept, 1, J_{HH} = 6 Hz, OC*H*Me$_2$), 4.41 (sept, 1, J_{HH} = 6 Hz, OC*H*Me$_2$), 4.51 (sept, 4, J_{HH} = 6 Hz, OC*H*Me$_2$), 4.61 (sept, 2, J_{HH} = 6 Hz, OC*H*Me$_2$). ^{13}C{^{1}H} NMR (CD_2Cl_2): δ 13.7 (d, 3, J_{PC} = 17 Hz, P*Me*$_3$), 26.3 (2, OCH*Me*$_2$), 26.4 (2, OCH*Me*$_2$), 26.5 (2, OCH*Me*$_2$), 26.7 (2, OCH*Me*$_2$), 27.27 (2, OCH*Me*$_2$), 27.32 (2, OCH*Me*$_2$), 27.7 (2, OCH*Me*$_2$), 30.2 (2, OCH*Me*$_2$),

72.1 (2, $OCHMe_2$), 72.3 (2, $OCHMe_2$), 72.6 (2, $OCHMe_2$), 72.9 (2, $OCHMe_2$). $^{31}P\{^1H\}$ (CD_2Cl_2): −27.5 (s). IR (Nujol, CsI, cm^{-1}) ν(Re—H) 1923m, 1622m, 1371s, 1319s, 1283m, 1206w, 1165s, 1105s, 1028w, 963s, 833s, 731m, 679m, 623s, 594s, 573s, 536m, 430m.

$Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6(PMe_3)$. Trimethylphosphine (1.1 mmol) was added *via* a calibrated vacuum manifold to a frozen green solution of $Re_3(OCH_2Bu^t)_9$ (0.30 g, 0.22 mmol) in hexanes (20 cm^3). The solution was warmed to room temperature and stirred for 12 h. The volatile components were then removed under reduced pressure. The green residue was dissolved in CH_2Cl_2, the solution was concentrated *in vacuo* to 4 cm^3, and the flask was transferred to a freezer where it was kept at −35°C for 12 h. The product crystallized as green blocks, which were isolated by removing the mother liquor *via* a pipet and washing with cold CH_2Cl_2 (2 × 5 cm^3). Yield: 0.23 g (73%) (Found: C, 39.76; H, 7.54. $C_{48}H_{108}O_9PRe_3$ requires C, 40.63; H, 7.67%). ^1H NMR (C_6D_6): δ 0.98 (s, 18, OCH_2CMe_3), ≈1 (PMe_3, see text), 1.025 (s, 9, OCH_2CMe_3), 1.03 (s, 18, OCH_2CMe_3), 1.25 (s, 9, OCH_2CMe_3), 1.37 (s, 9, OCH_2CMe_3), 1.41 (s, 18, OCH_2CMe_3), 3.16 and 4.36 (AB q, 2, J_{HH} = 10 Hz, OCH_2CMe_3), 3.55 and 4.89 (AB q, 2, J_{HH} = 10 Hz, OCH_2CMe_3), 3.94 (d, 2, $^4J_{PH}$ = 2.7 Hz, OCH_2CMe_3), 4.37 (d, 2, $^4J_{PH}$ = 2.7 Hz, OCH_2CMe_3), 4.43 (s, 2, OCH_2CMe_3), 4.58 and 4.83 (AB q, 2, J_{HH} = 12 Hz, OCH_2CMe_3). $^{31}P\{^1H\}$ (C_6D_6): δ −22.3. IR (Nujol, KBr, cm^{-1}): 2951s, 2911s, 2864s, 1478s, 1464m, 1443w, 1416w, 1391s, 1373w, 1360s, 1300w, 1271w, 1258w, 1213m, 1142w, 1080m, 1065m, 1038s, 1013s, 972s, 932w, 907w, 783w, 754w, 737m, 671m, 638w, 619w, 604w, 584w, 482m, 469s, 453m, 436m.

$Re_3(\mu\text{-}Cl)(\mu\text{-}OCH_2Bu^t)_2Cl(OCH_2Bu^t)_4(PMe_3)_2$. Trimethylphosphine (4.5 mmol) was added *via* a calibrated vacuum manifold to a frozen red solution of $Re_3Cl_9(THF)_3$ (0.98 g, 0.90 mmol) in THF. The color of the solution gradually changed to purple as it was stirred at room temperature for 12 h. Sodium neopentoxide (1.2 g, 11 mmol) was then added slowly until the solution turned green. The mixture was stirred at room temperature for 12 h during which time the green color persisted. (If the green color did not persist, more $NaOCH_2CMe_3$ (≈0.5 g) was added until the green color returned.) The volatile components were then removed under reduced pressure, and the residue was extracted with hexanes (5 × 20 cm^3). The extracts were combined and filtered through Celite. The green filtrate was concentrated *in vacuo* to *ca* 5 cm^3 and the flask was transferred to a freezer where it was stored at −35°C for 12 h. The product formed as small green crystals. The crystals were isolated and washed with acetonitrile (2 × 10 cm^3), and then dried *in vacuo* for 4 h. Yield: 0.15 g (12%) ^1H NMR (C_6D_6): δ 0.8 (br), 5.3 (br). IR (Nujol, KBr, cm^{-1}): 1416w, 1391m, 1377s, 1362m, 1298w, 1279m, 1258w, 1217w, 1042s, 1007s, 955s, 855w, 756w, 739w, 729w, 675s.

Crystal structure determination of $\{Re_3(\mu\text{-}OPr^i)_3(Cl(OPr^i)_4\}_2(\mu\text{-}Cl)_2 \cdot 2CH_2Cl_2$

Crystal data. $C_{42}H_{98}O_{14}Cl_4Re_6 \cdot 2CH_2Cl_2$, M = 2256.26, orthorhombic, space group $Pbca$, a = 17.300(3), b = 17.800(3), c = 23.533(3) Å, U = 7247 Å^3, T = −50°C, Mo-K_α (λ = 0.71073 Å), Z = 4, D_c = 2.07 g cm^{-3}, $F(000)$ = 4256, μ = 104.7 cm^{-1}. Crystal size: 0.18 × 0.22 × 0.44 mm.

Data collection. The air sensitive brown prismatic blocks were manipulated under mineral oil. Nicolet R3 four-circle diffractometer equipped with an LT-2 low-temperature device, ω mode with scan width $\Delta\theta = 1.30 + (K_{\alpha 2} - K_{\alpha 1})$°, scan speed range 1.5–15.0° min^{-1}, graphite-monochromated Mo-K_α radiation; 5236 reflections measured ($4 \leqslant 2\theta \leqslant 45$°, h, k, l), 3278 independent with $I > 3\sigma(I)$. Lorentz and polarization corrections were applied, as well as a semi-empirical absorption correction based on ten reflections having chi values between 70 and 90°. Two standard reflections were measured every 2 h or after every 100 data collected, and these showed no significant variation.

Structure solution and refinement. The Laue symmetry was determined to be mmm, and from the systematic absences the space group was shown to be $Pbca$. The structure was solved by interpretation of a Patterson map, which revealed the positions of three independent Re atoms in the asymmetric unit, consisting of one-half molecule situated about an inversion center. Remaining atoms were found in subsequent difference Fourier syntheses. The hydrogen atoms were placed in calculated positions and constrained to riding motion, with a single variable isotropic temperature factor for all of them. A molecule of methylene chloride solvent was also located and refined with 70% occupancy factors. After all shift/esd ratios were less than 0.1 convergence was reached with R, R_w = 0.037, 0.037 (GOF = 1.33). The weighting scheme was $w = [\sigma(F)]^{-2}$. No unusually high correlations were noted between any of the variables in the last cycle of full-matrix least squares refinement, and the final difference density map showed a maximum peak of about 1.1 e/Å^3. All calculations were made using Nicolet's SHELXTL PLUS (1987) package of programs [18].

Crystal structure determination of $Re_3(\mu\text{-}OPr^i)_3Cl(H)(OPr^i)_4(PMe_3) \cdot CH_2Cl_2$

Crystal data. $C_{24}H_{59}O_7PClRe_3 \cdot CH_2Cl_2$, M = 1169.78, triclinic, space group $P\bar{1}$, a = 11.365(3), b = 11.857(3), c = 16.101(2) Å, α = 80.44(1), β = 84.60(1), γ = 69.50(1)°, U = 2003 Å^3, T = −50°C, Mo-K_α (λ = 0.71073 Å), Z = 2, D_c = 1.94 g cm^{-3}, $F(000)$ = 1116, μ = 94.4 cm^{-1}. Crystal size: 0.12 × 0.17 × 0.60 mm.

Data collection. The air sensitive dark green columns were manipulated under mineral oil. Nicolet R3 four-circle diffractometer equipped with an LT-2 low-

temperature device, ω mode with scan width $\Delta\theta = 1.25 + (K_{\alpha 2} - K_{\alpha 1})^\circ$, scan speed range 1.5–15.0° min^{-1}, graphite-monochromated Mo-K_α radiation; 7066 reflections measured ($4 \leqslant 2\theta \leqslant 50^\circ$, h, $\pm k$, $\pm l$), 5948 independent with $I > 3\sigma(I)$. Lorentz and polarization corrections were applied, as well as a semi-empirical absorption correction based on psi scans of ten reflections having chi values between 70 and 90°. Two standard reflections were measured every 2 h or after every 100 data collected, and these showed no significant variation.

Structure solution and refinement. The Laue symmetry was determined to be $\bar{1}$, and the space group was shown to be $P\bar{1}$ or $P1$. $P\bar{1}$ was assumed from the beginning because the unitary structure factors displayed centric statistics. The structure was solved by interpretation of a Patterson map, which revealed the positions of the Re atoms. Remaining atoms were found in subsequent difference Fourier syntheses. The hydrogen atoms were placed in calculated positions and constrained to riding motion, with a single variable isotropic temperature factor for all of them. The hydrogen atom that is postulated to be attached to Re(1) was not located. After all shift/esd ratios were less than 0.1 convergence was reached with R, $R_w = 0.029$, 0.031 (GOF = 1.81). The weighting scheme was $w = [\sigma(F)]^{-2}$. No unusually high correlations were noted between any of the variables in the last cycle of full-matrix least squares refinement, and the final difference density map showed a maximum peak of about 1.5 e/Å^3 between Re(1) and Re(3). This density was assumed to be spurious since the IR spectrum indicated the presence of a terminal rather than a bridging hydride ligand. All calculations were made using Nicolet's SHELXTL PLUS (1987) package of programs [18].

Crystal structure determination of $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6(PMe_3)\cdot CH_2Cl_2$

Crystal data. $C_{48}H_{108}O_9PRe_3\cdot CH_2Cl_2$, $M = 1504.06$, monoclinic, space group $P2_1/c$, $a = 17.506(6)$, $b = 18.990(8)$, $c = 19.332(7)$ Å, $\beta = 93.12(3)^\circ$, $U = 6417$ Å^3, $T = -50$°C, Mo-K_α ($\lambda = 0.71073$ Å), $Z = 4$, $D_c = 1.56$ g cm^{-3}, $F(000) = 3000$, $\mu = 58.7$ cm^{-1}. Crystal size: $0.40 \times 0.50 \times 0.60$ mm.

Data collection. The air sensitive bright green prismatic blocks were manipulated under mineral oil. Nicolet R3 four-circle diffractometer equipped with an LT-2 low-temperature device, ω mode with scan width $\Delta\theta = 1.30 + (K_{\alpha 2} - K_{\alpha 1})^\circ$, scan speed range 2.0–15.0° min^{-1}, graphite-monochromated Mo-K_α radiation; 8350 reflections measured ($4 \leqslant 2\theta \leqslant 45^\circ$, h, k, $\pm l$), 6103 independent with $I > 3\sigma(I)$. Lorentz and polarization corrections were applied, as well as a semi-empirical absorption correction based on ten reflections having chi values between 70 and 90°. Two standard reflections were measured every 2 h or after every 100 data collected, and these showed no significant variation.

Structure solution and refinement. The Laue symmetry was determined to be $2/m$, and from the systematic absences the space group was shown to be $P2_1/c$. The structure was solved by interpretation of a Patterson map, which revealed the positions of the Re atoms. Remaining atoms were found in subsequent difference Fourier syntheses. The hydrogen atoms were placed in calculated positions and constrained to riding motion, with a single variable isotropic temperature factor for all of them. Three of the Bu^t groups were found to be disordered, and these were treated by introducing ideal rigid bodies at each location and allowing them to rotate independently while constraining the isotropic temperature factors to be equal. The occupancy factors refined to 70 : 30 for C7 : C7′ and C22 : C22′, and 60 : 40 for C37 : C37′. A very heavily disordered molecule of methylene chloride was also located, and the two major orientations were refined as ideal rigid bodies having 50% occupancies. After all shift/esd ratios were less than 0.2 convergence was reached with R, $R_w = 0.036$, 0.037 (GOF = 1.39). The weighting scheme was $w = [\sigma(F)]^{-2}$. No unusually high correlations were noted between any of the variables in the last cycle of full-matrix least squares refinement, and the final difference density map showed a maximum peak of about 1.8 e/Å^3 located near Re. All calculations were made using Nicolet's SHELXTL PLUS (1987) package of programs [18].

Crystal structure determination of $Re_3(\mu\text{-}Cl)(\mu\text{-}OCH_2Bu^t)_2Cl(OCH_2Bu^t)_4(PMe_3)_2$

Crystal data. $C_{36}H_{84}Cl_2O_6P_2Re_3$, $M = 1304.52$, monoclinic, space group $C2/c$, $a = 12.239(1)$, $b = 19.644(2)$, $c = 20.825(2)$ Å, $\beta = 102.238(6)^\circ$, $U = 4893.0(8)$ Å^3, $T = 23$°C, Mo-K_α ($\lambda = 0.71073$ Å), $Z = 4$, $D_c = 1.77$ g cm^{-3}, $F(000) = 2548$, $\mu = 77.16$ cm^{-1}. Crystal size: $0.06 \times 0.09 \times 0.11$ mm.

Data collection. A dark block was mounted in a 0.7-mm O.D. Lindeman capillary under nitrogen. Enraf-Nonius CAD-4 diffractometer, ω mode with scan width $\Delta\theta = 0.8 + 0.35 \tan\theta$, scan speed range (0.67–8° min^{-1}, graphite-monochromated Mo-K_α radiation; 4660 reflections measured ($2 \leqslant 2\theta \leqslant 50^\circ$, h, k, $\pm l$), 4456 unique ($R_{int} = 0.020$), 2435 observed with $F > 6\sigma(F)$. Lorentz and polarization corrections were applied, as well as a semi-empirical absorption correction based on five reflections having chi values between 70 and 90°. Three standard reflections were measured every 3600 sec and these showed no significant variation.

Structure solution and refinement. The structure was solved by interpretation of a Patterson map, which revealed the positions of the two independent Re atoms. Remaining atoms were found in subsequent difference Fourier syntheses. Hydrogen atoms were entered in idealized geometries and allowed to ride on

the appropriate carbon atom [$U(H) = 1.3U_{eq}(C)$]. All non-hydrogen atoms were refined with anisotropic thermal parameters. Convergence was reached with R, $R_w = 0.032$, 0.036 (GOF = 1.48). The weighting scheme was $w = [0.04F^2 + (\sigma F)^2]^{-1}$. The final difference map showed a maximum peak of about 0.83 e/Å^3 near the Re atoms. All calculations were made using the MolEN package of programs [19].

CONCLUSION

The isopropoxide clusters $Re_3(\mu\text{-}OPr^i)_3Cl(H)(OPr^i)_4(PMe_3)$ and $\{Re_3(\mu\text{-}OPr^i)_3Cl(OPr^i)_4\}_2(\mu\text{-}Cl)_2$ were prepared from rhenium chloride and sodium isopropoxide in the presence of trimethylphosphine. In the chloro–hydride cluster the hydride ligand is proposed to occupy a site *trans* to Cl and *cis* to PMe_3. The source of the hydride ligand is thought to be isopropoxide β-hydrogen elimination. Reactions of the hydride cluster under mild conditions with ethylene and 2-butyne yield ethyl and 2-butenyl clusters, respectively, and the reaction with sodium isopropoxide gives $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5(PMe_3)$. The cluster $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5(PMe_3)$ is more conveniently prepared by reacting PMe_3 with $Re_3(\mu\text{-}OPr^i)_3(OPr^i)_6$, a reaction in which PMe_3 traps $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5$ from its equilibrium with $Re_3(\mu\text{-}OPr^i)_3(OPr^i)_6$ and acetone. The analogous reaction of PMe_3 with the less sterically crowded homoleptic neopentoxide cluster $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6$ gives the phosphine adduct $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6(PMe_3)$. In contrast to the reactions of rhenium chloride with trimethylphosphine and sodium isopropoxide, a similar reaction involving sodium neopentoxide gave the reduced cluster $Re_3(\mu\text{-}Cl)(\mu\text{-}OCH_2Bu^t)_2Cl(OCH_2Bu^t)_4(PMe_3)_2$. This cluster has 13 electrons available for Re–Re bonding, but its structure is not significantly different from similar 12-electron clusters. Trimethylphosphine is apparently the reducing agent in the preparation of the reduced cluster.

Acknowledgments—Acknowledgement for support is made to the Robert A. Welch Foundation. We are grateful to J. Korp for his technical assistance with the X-ray crystallographic analyses.

Supplementary Data—Atomic coordinates, thermal parameters, bond lengths and angles, have been deposited at the Cambridge Crystallographic Data Centre (CCDC).

(Received 29 April 1997; accepted 11 June 1997)

Abstract—By reaction of $PbCl_2$ with 3 equivalents of $NaOSi(O^tBu)_3$, the ate complex $NaPb[OSi(O^tBu)_3]_3$ was obtained. This compound possesses a structure containing a 3-coordinate, trigonal prismatic lead center, and a 6-coordinate Na atom encapsulated in an oxygen matrix formed by the bridging siloxy and *tert*-butoxy groups of the $-OSi(O^tBu)_3$ ligands. The neutral lead complex $Pb[OSi(O^tBu)_3]_2 \cdot {}^tBuOH \cdot CH_3CN$ was obtained from reaction of $Pb_3(\mu\text{-}O^tBu)_6$ with $HOSi(O^tBu)_3$. The tin complex $KSn[OSi(O^tBu)_3]_3$, prepared from $SnCl_2$ and $KOSi(O^tBu)_3$, is isomorphous with $NaPb[OSi(O^tBu)_3]_3$. The bismuth compounds $Bi[OSi(O^tBu)_3]_3$ and $Bi[OSi(O^tBu)_2Ph]_3$ were obtained by similar methods. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: tin; lead; bismuth; alkoxide; siloxide; precursor.

The pioneering work of Donald Bradley and coworkers has sparked considerable interest in the synthesis and characterization of binary metal alkoxides and 'double alkoxides' [1]. Such compounds display interesting structures and often provide convenient chemical pathways to metal oxide materials. Much of the recent interest in alkoxide complexes stems from their use as ceramic precursors, *via* the sol–gel process involving hydrolysis of M—OR bonds, or *via* chemical vapor deposition routes to thin films [2]. We have been exploring an alternative route to mixed-metal alkoxides *via* low-temperature thermolyses of single-source molecular precursors containing $-OSi(O^tBu)_3$ and $-O_2P(O^tBu)_2$ ligands [3,4]. For example, we have found that the alkoxy(siloxy) complex $Zr[OSi(O^tBu)_3]_4$ readily converts at low temperatures (100–150°C) to homogeneous zirconia–silica materials [4]. These conversions typically occur at low temperature, give materials with high surface areas, and are compatible with nonpolar media. Here we describe the synthesis of main group-metal alkoxy(siloxy) complexes, and structural information for lead and tin derivatives.

† Dedicated to Professor Donald Bradley, in recognition of his many pioneering contributions to the field of metal alkoxide and metal amide chemistry.

EXPERIMENTAL

All manipulations were performed under an atmosphere of argon or nitrogen using Schlenk techniques and/or a Vacuum Atmospheres glovebox. Dry, oxygen-free solvents were employed throughout. Elemental analyses were performed at Mikroanalytiches Labor Pascher or Desert Analytics Laboratories. Infrared spectra were recorded on a Perkin–Elmer 1330 or a Mattson Galaxy Series Fourier Transform infrared spectrometer. NMR spectra were obtained with a GE QE-300 instrument at 300 (^1H), 75.5 (^{13}C) and 59.6 (^{29}Si) MHz, or on a Bruker AMX 400 spectrometer at 400 (^1H) and 100.6 (^{13}C) MHz. Thermal analyses were performed on a Dupont 951 Thermogravimetric Analyzer. The compounds $HOSi(O^tBu)_3$ [5], $NaOSi(O^tBu)_3$ [6], $KOSi(O^tBu)_3$ [7], $HOSi(O^tBu)_2Ph$ [3b], $[Pb(O^tBu)_2]_3$ [8], and $Bi(O^tBu)_3$ [9] were prepared according to literature procedures.

$NaPb[OSi(O^tBu)_3]_3$. 1,2-Dimethoxyethane (120 cm^3) was added to a solid mixture of $PbCl_2$ (3.00 g, 0.0108 mol) and $NaOSi(O^tBu)_3$ (9.27 g, 0.0324 mol). The reaction mixture was stirred for 1 h and then refluxed for 8 h. The volatile material was removed

under dynamic vacuum and the remaining white solid was dried for 12 h under dynamic vacuum. The product was extracted into pentane (75 cm^3), and concentration and cooling (to -30 °C) of this solution yielded 7.31 g (66%) in three crops. Anal. Calcd for $C_{36}H_{81}NaO_{12}PbSi_3$: C, 42.4; H, 8.00. Found: C, 41.9; H, 7.68. ^1H NMR (300 MHz, benzene-d_6, 22 °C) δ 1.50 (s, CMe_3). $^{13}C\{^1H\}$ NMR (75.5 MHz, benzene-d_6, 22 °C) δ 32.33 (CMe_3) 71.91 (CMe_3). ^{29}Si NMR (59.6 MHz, benzene-d_6, 22 °C) δ −88.67. IR (Nujol, CsI, cm^{-1}): 1382 s, 1360 vs, 1236 s, 1360 vs, 1210 s sh, 1190 vs, 1040 vs br, 1020 vs, 1000 vs, 980 vs, 960 s sh, 910 w sh, 822 s, 790 w sh, 700 s, 695 s sh, 512 m, 484 m, 424 m, 380 w, 350 w, 300 w.

$Pb[OSi(O^tBu)_3]_2 \cdot {}^tBuOH \cdot CH_3CN$. Benzene (100 cm^3) was added to a solid mixture of $[Pb(O^tBu)_2]_3$ (6.73 g, 0.0063 mol) and $HOSi(O^tBu)_3$ (10.08 g, 0.038 mol). The mixture was stirred for 0.5 h and then the volatile material was removed under dynamic vacuum. The remaining white solid was dried for 12 h under dynamic vacuum. This solid was dissolved in benzene (70 cm^3), and concentration of this solution followed by layering with acetonitrile afforded 8.38 g of the product as colorless crystals in 52% yield. Anal. Calcd for $C_{30}H_{67}NO_9PbSi_2$: C, 42.4; H, 7.95. Found: C, 42.5; H, 7.82. ^1H NMR (300 MHz, dichloromethane-d_2, 22°C): δ 1.34 (s, 63 H, $SiOCMe_3$, $HOCMe_3$) 1.97 (s, 3 H, NCMe). IR (Nujol, CsI, cm^{-1}): 2307 vw, 2275 w, 1383 m, 1360 s, 1238 m, 1210 m sh, 1190 s, 1040 s br, 1020 s sh, 955 s, 910 w sh, 822 m, 797 w sh, 628 w, 510 m, 480 m, 436 m, 375 w br, 340 w br.

$KSn[OSi(O^tBu)_3]_3$. A 5.00 g sample of $KOSi(O^tBu)_3$ (16.7 mmol) and 1.05 g of $SnCl_2$ (5.52 mmol) were combined in a 100 cm^3 Schlenk flask in the glovebox. After the solution was stirred at room temperature for 30 min, it was heated at reflux for 17 h. Vacuum evaporation of the solvent and subsequent recrystallization from cold pentane (−78 °C) gave 4.0 g (4.22 mmol, 81%) of $KSn[OSi(O^tBu)_3]_3$ (m.p. 89 °C dec). Anal. Calcd for $C_{36}H_{81}KO_{12}Si_3Sn$: C, 45.6; H, 8.61. Found: C, 46.0; H, 8.66. ^1H NMR (benzene-d_6, 400 MHz) δ 1.48. $^{13}C\{^1H\}$ NMR (benzene-d_6, 100.6 MHz) δ 32.3 ($OCMe_3$), 73.5 ($OCMe_3$). IR (Nujol, NaCl, cm^{-1}): 1460 s, 1448 s, 1382 m, 1362 s, 1243 s, 1190 s, 1065 vs, 1025 s, 913 m, 821 w, 702 m, 649 w, 517 w, 491 w, 425 w.

$Bi[OSi(O^tBu)_3]_3$. Method 1: THF (30 cm^3) was added to a solid mixture of $BiCl_3$ (0.300 g, 0.952 mmol) and $NaOSi(O^tBu)_3$ (0.818 g, 2.85 mmol) at room temperature. The cloudy solution was stirred for 11 h. The volatile material was removed under dynamic vacuum and the remaining white residue was dried under dynamic vacuum for 12 h. Extraction of the white residue with pentane (20 cm^3), concentration, and cooling gave the product as white crystals (0.276 g, 29%). Method 2: THF (30 cm^3) was added to a solid mixture of $BiCl_3$ (0.300 g, 0.952 mmol) and $KOSi(O^tBu)_3$ (0.864 g, 2.85 mmol) at room temperature. Workup is similar to that in Method 1 above. The yield was 0.281 g (30%). Method 3: Benzene (30 cm^3) was added to a solid mixture of $Bi(O^tBu)_3$ (0.334 g, 0.780 mmol) and $HOSi(O^tBu)_3$ (0.619 g, 2.34 mmol). The clear solution was stirred for 1 h. The volatile material was removed under dynamic vacuum and the remaining white residue was dried for 12 h under dynamic vacuum. Dissolution in pentane, filtration, and concentration gave 0.246 g (32%). Anal. Calcd for $C_{36}H_{81}BiO_{12}Si_3$: C, 43.3; H, 8.71. Found C, 43.2; H, 8.22. ^1H NMR (300 MHz, benzene-d_6, 22 °C) δ 1.49 (s, 81 H, CMe_3). $^{13}C\{^1H\}$ NMR (75.5 MHz, benzene-d_6, 22 °C) δ 32.00 (CMe_3), 72.93 (CMe_3). IR (Nujol, CsI, cm^{-1}): 1385 m, 1361 s, 1240 m, 1209 m sh, 1190 s, 1055 vs, 1020 m sh, 907 vs, 827 w, 798 vw, 698 m, 634 w, 544 w, 488 m, 455 w sh, 420 vw, 375 vw sh, 350 vw sh.

$Bi[OSi(O^tBu)_2Ph]_3$. Toluene (25 cm^3) was added to a solid mixture of $Bi(O^tBu)_3$ (0.300 g, 0.700 mmol) and $(^tBuO)_2PhSiOH$ (0.564 g, 2.10 mmol). The colorless solution was stirred for 1.5 h and then the volatiles were removed under dynamic vacuum. The remaining white residue was dissolved in pentane (10 cm^3). The pentane was removed under dynamic vacuum to remove traces of *tert*-butyl alcohol. The white solid was redissolved in pentane (10 cm^3). Filtration, concentration and cooling to −78 °C gave the product (0.330 g, 47%) as a white crystalline solid. Anal. Calcd for $C_{42}H_{69}BiO_9Si_3$: C, 49.9; H, 6.88. Found C, 49.6; H, 7.11. ^1H NMR (300 MHz, benzene-d_6, 22 °C) δ 1.40 (s, 54 H, CMe_3), 7.21, 7.23, 7.26, 7.28 (m, 9 H, Ph) 8.12, 8.12, 8.14, 8.15 (m, 6 H, Ph). IR (Nujol, CsI, cm^{-1}): 3060 vw sh, 3020 vw sh, 1616 vw, 1590 vw, 1428 m, 1388 m, 1362 s, 1240 m, 1200 m sh, 1188 m, 1120 s, 1050 s, 1020 s sh, 900 s, 822 w, 808 m, 790 m, 712 s, 645 m, 545 m, 480 m br, 350 w br.

X-ray structure determinations for $Na[Pb[OSi(O^tBu)_3]_3$ *and* $KSn[OSi(O^tBu)_3]_3$. Crystal, data collection, and refinement parameters are collected in Table 1. Colorless crystals of both compounds were photographically characterized and determined to belong to the monoclinic crystal system. Systematic absences in the diffraction data uniquely determined the space group. Azimuthal scans indicated that no correction for absorption was required for $KSn[OSi(O^tBu)_3]_3$; standard ψ-scan data were used to provide a correction for $NaPb[OSi(O^tBu)_3]_3$. The structures were solved by direct methods, completed from difference Fourier maps, and refined with anisotropic thermal parameters for all nonhydrogen atoms, except for the carbon atoms in $NaPb[OSi(O^tBu)_3]_3$ which were held isotropic to conserve data. Hydrogen atomat contributions were idealized. In $KSn[OSi(O^tBu)_3]_3$, several of the *tert*-butyl groups were rotationally disordered over two sites in varying degrees; in two cases, the groups at C(9) and C(33) were disordered over two sites about equally and both sites were refined. At C(25) and C(29), the second form was only about 10% occupied and was ignored. All computations used SHELXTL 4.2 or 5.1 software (G. Sheldrick, Siemens XRD, Madison, WI.).

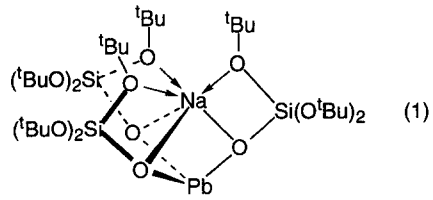
RESULTS AND DISCUSSION

Lead complexes

Addition of 2 or 3 equiv. of $NaOSi(O^tBu)_3$ to $PbCl_2$ in THF or 1,2-dimethoxyethane (DME) gave the monomeric 'ate' complex $NaPb[OSi(O^tBu)_3]_3$ [eq. (1)]. Crystals suitable for X-ray crystallography were obtained by crystallization of the compound from pentane at −35°C. An ORTEP drawing is shown in Fig. 1, and bond distances and angles are listed in Table 2. The 6-coordinate sodium atom is encapsulated in an oxygen matrix formed by bridging siloxy and *tert*-butoxy groups from the $-OSi(O^tBu)_3$ ligands. The lead atom is 3-coordinate and possesses a trigonal prismatic coordination geometry that presumably reflects the presence of a stereochemically active lone pair. For comparison, the complex $Pb_3(\mu\text{-}O^tBu)_6$ possesses a geometry similar to $NaPb[OSi(O^tBu)_3]_3$ in that the terminal lead atoms are 3-coordinate and trigonal prismatic [8]. The Pb-O distances in $NaPb[OSi(O^tBu)_3]_3$ range from 2.12 to 2.15 Å and are slightly shorter than the terminal Pb—O distances in $Pb_3(O^tBu)_6$ (2.17 Å). The O—Pb—O angles in the latter complex (av. 80.3°) are more acute than those observed in $NaPb[OSi(O^tBu)_3]_8$ (av. 87.3°).

Unlike many other alkoxy(siloxy) complexes which are quite thermally labile, $NaPb[OSi(O^tBu)_3]_3$ displays a sharp melting point at 174–175°C. Thermogravimetric analysis (TGA) of the compound under oxygen (Fig. 2) revealed a precipitous weight loss with an onset temperature of *ca* 300°C. The weight loss at 1100°C was *ca* 70%. The TGA trace of this compound under argon displayed an onset temperature of *ca* 200°C and a gradual weight loss of 60% to 400°C. Powder X-ray diffraction (PXRD) of the black material obtained from thermolysis of $NaPb[OSi(O^tBu)_3]_3$ heated to 400°C and held at that temperature under oxygen showed the presence of Pb metal as the only crystalline product present.

$$PbCl_2 + 3\,NaOSi(O^tBu)_3 \xrightarrow{THF} \quad (1)$$



In an attempt to form a neutral lead(II) siloxide, the trimeric complex $Pb_3(O^tBu)_6$ [8] was stirred with 6 equiv. of $HOSi(O^tBu)_3$ in benzene. Removal of the volatile material and drying under extended dynamic vacuum gave an extremely soluble, waxy solid. Dis-

solution in benzene and layering with acetonitrile afforded colorless crystals of $Pb[OSi(O^tBu)_3]_2 \cdot {}^t$BuOH · NCMe. Addition of *tert*-butyl alcohol to a dichloromethane-d_2 solution of $Pb[OSi(O^tBu)_3]_2 \cdot {}^t$BuOH · NCMe results in an upfield shift of the ^{t}Bu resonance without separation of the resonances due to $OSi(O^tBu)_3$ and HO^tBu. Attempts to form $Pb[OSi(O^tBu)_3]_2 \cdot {}^t$BuOH · NCMe by the reac-

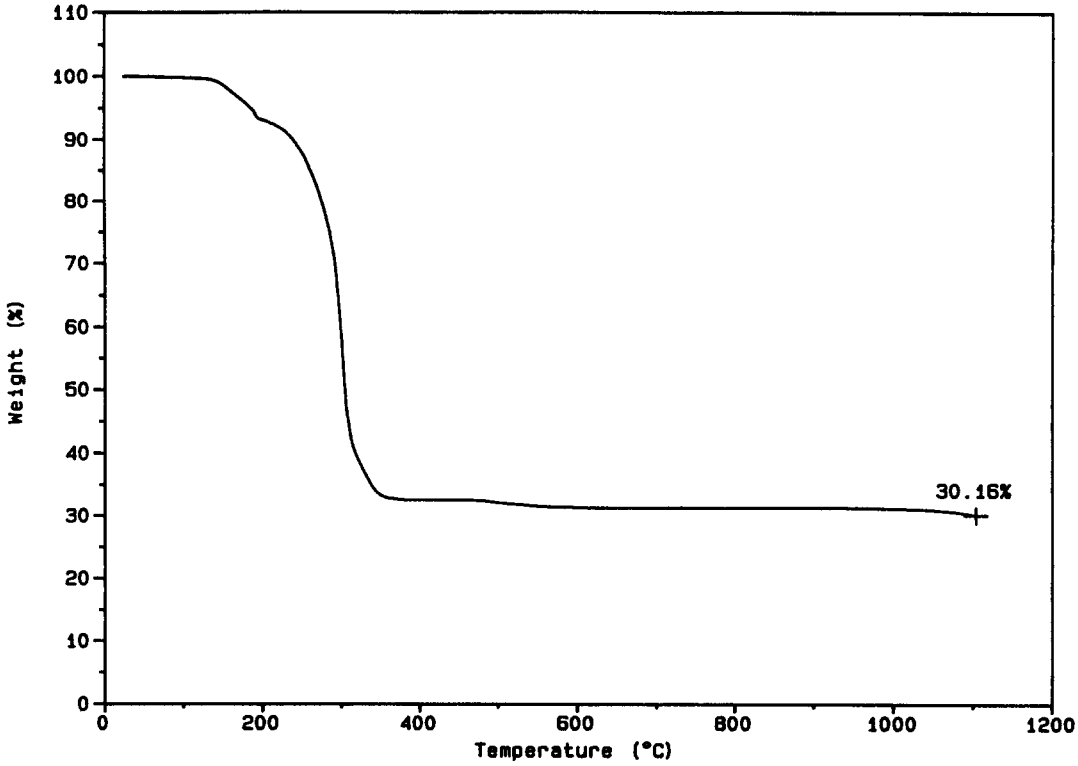

Fig. 2. Thermal gravimetric analysis curve for $NaPb[OSi(O^tBu)_3]_3$ under oxygen.

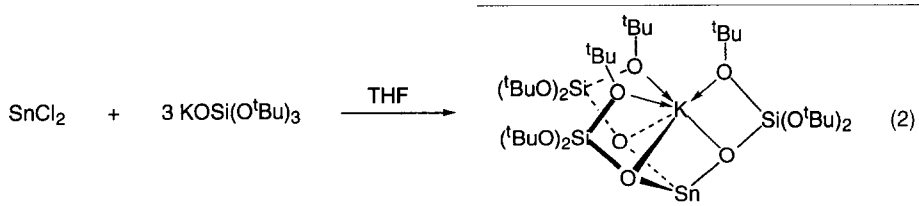
tion of $PbCl_2$ with $HOSi(O^tBu)_3$ in refluxing toluene/acetonitrile in the presence of pyridine were unsuccessful. In addition, there was no reaction between $Pb[OSi(O^tBu)_3]_2 \cdot {}^tBuOH \cdot NCMe$ and $NaOSi(O^tBu)_3$ in benzene-d_6 at room temperature.

The tin complex $KSn[OSi(O^tBu)_3]_3$

Reaction of $SnCl_2$ with 3 equiv. of $KOSi(O^tBu)_3$ in THF resulted in formation of the ate complex $KSn[OSi(O^tBu)_3]_3$ in near quantitative yield [eq. (2)]. The product was crystallized from cold pentane and isolated in 80% yield as colorless needles. A TGA analysis of $KSn[OSi(O^tBu)_3]_3$ revealed a rapid weight loss starting at 200°C, with the decomposition being completed at about 350°C (88% weight loss).



(2)

Related Sn^{II} heterobimetallic complexes of the type $[MSn(^tOBu)_3]_n$ have been reported [10], and Caulton and coworkers have described potassium siloxide 'ate' complexes of tin(II), such as $(DME)_2K(\mu\text{-}OSiPh_3)_3Sn$ and $K(\mu\text{-}OSiMe_2{}^tBu)_3Sn$ [11].

The molecular structure of the compound is shown in the ORTEP drawing of Fig. 3, and selected bond distances and angles are given in Table 3. The structure is isomorphous with $NaPb[OSi(O^tBu)_3]_3$, and in many respects the molecules are similar. The K···Sn separation of 3.483(2) Å is somewhat greater than the corresponding Na···Pb distance of 3.150(6) Å, resulting in a slightly expanded $M(\mu\text{-}O)_3M'$ cage for the former compound. For comparison, the K···Sn distances in $(\eta^2\text{-}DME)_2K(\mu\text{-}OSiPh_3)_3Sn$ and $(\eta^2\text{-}DME)(\eta^1\text{-}DME)K(\mu\text{-}OSiPh_3)_3Sn$ are 3.515, 3.460 and 3.480 Å, respectively. Note that the K—O—Sn angles (54°) are considerably more acute than the Na—O—Pb angles (85°) in $NaPb[OSi(O^tBu)_3]_3$, which reflects different ionic radii for the component metal centers. The O—Sn—O angles in $KSn[OSi(O^tBu)_3]_3$ (av. 89°) are very similar to the corresponding angles observed for $(\eta^2\text{-}DME)_2K(\mu\text{-}$

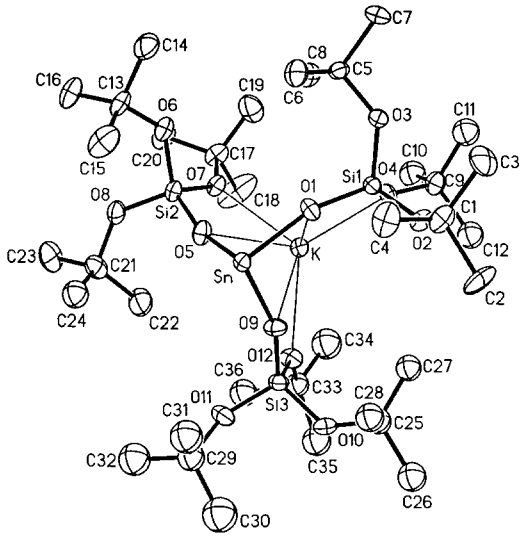


Fig. 3. ORTEP view of the molecular structure of KSn[O-Si(O^{t}Bu)$_3$]$_3$

OSiPh$_3$)$_3$Sn and (η^2-DME)(η^1-DME)K(μ-OSiPh$_3$)$_3$Sn (87–90°). Such acute angles have been rationalized on the basis of Fenske-Hall calculations as arising from a compromise between maximizing Sn—O σ-interactions while minimizing unfavorable Sn—O π-interactions and O—O nonbonded contacts [11].

Bismuth complexes

Addition of THF to a solid mixture of 3 equiv. of NaOSi(O^{t}Bu)$_3$ or KOSi(O^{t}Bu)$_3$ and BiCl$_3$ resulted in formation of Bi[OSi(O^{t}Bu)$_3$]$_3$. This complex was also obtained by addition of benzene to a solid mixture of 3 equiv. of HOSi(O^{t}Bu)$_3$ and Bi(O^{t}Bu)$_3$ [9]. Isolation was achieved by crystallization from pentane at −78 °C. Hydrolysis of Bi[OSi(O^{t}Bu)$_3$]$_3$ with excess water in benzene-d_6 resulted in formation of HOSi-(O^{t}Bu)$_3$ (3 equiv. by ^{1}H NMR spectroscopy) and a white precipitate. This complex is quite thermally labile, as shown by a TGA analysis under oxygen, which revealed a low onset temperature for decomposition at *ca* 90 °C followed by an abrupt weight loss of approximately 40% to just under 200 °C. This is followed by a smoother weight loss of approximately 25% to 375 °C.

A bismuth alkoxy(siloxy) complex was also formed in the reaction of Bi(O^{t}Bu)$_3$ with 3 equiv. of HOSi-Ph(O^{t}Bu)$_2$. This highly soluble complex, Bi[OSi-Ph(O^{t}Bu)$_2$]$_3$, was isolated as a white solid from pentane at −78 °C. Crystals suitable for X-ray crystallography were not obtained via repeated crystallizations.

(Received 24 April 1997; accepted 11 June, 1997)

Abstract—The review provides a description of main events in the development of chemistry of metal alkoxides in Russian and summarizes the results obtained by the authors. The studies of solubility and vapor pressure in the $M(OR)_n$-ROH (R = Li, Mg, Ca, Sr, Ba, Tl) systems permitted the determination of the composition of the solvates formed and the optimization of the isolation conditions for distinct derivatives. The electrochemical synthetic approach to the alkoxide and 2-methoxyethoxide derivatives of III–VIII Group elements has been elaborated. Improvement of the MCl_n with NaOR metathesis conditions led to practically quantitative yields of alkoxides.

The examples of the structures of polynuclear oxoalkoxides, earlier erroneously considered to be ortho-derivatives, i.e. '$M(OR)_n$', are given. It has been stated that among the alkoxoderivatives of Zr and Hf these are only $M(OC_2H_4OMe)_4$ and $M(OR)_4 \cdot ROH$ (R = Pr^i, Bu^t) that exist as individual compounds, while the samples of those with different R contain oxocomplexes of $M_3O(OR)_{10}$ and $M_4O(OR)_{14}$ composition. The questions connected with the origin of oxogroups in the molecules of alkoxides and their influence on the properties of the samples are discussed. The irreproducibility of the physicochemical constants for the samples (physical state, melting points, solubility in alcohols, intensity of coloration) is caused by different 'chemical' (synthetic procedures, isolation conditions) and thermal prehistory and storage times; it originates from the difference in their molecular composition (different fractions of different types of oligomeric and polymeric $[M(OR)_n]_m$ and $M_xO_y(OR)_z$ aggregates).

Formation of bimetallic alkoxides is studied using the plotting of 20°C solubility isotherms in $M(OR)_n$–$M'(OR)_m$–Solvent systems. Different kinds of systems are considered and the composition and structure of bimetallic complexes and oxocomplexes, originating from their decomposition, are described. Decomposition of alkoxomolybdates and -tungstates in solutions may result in crystallization of complex oxides as the final products. The example of $MTiO_3$ (M = Mg, Ba) oxide preparation is discussed as most illustratively demonstrating the need in studies of metal alkoxides interaction in solution for the optimization of synthesis of oxides by the sol-gel technique. © 1998 Elsevier Science Ltd. Keywords: Metal alkoxides; electrochemical synthesis; oxoalkoxides; physicochemical analysis.

The studies of metal alkoxides started in Russia about 100 years ago. In 1899 at the Sankt-Peterburg University, V. E. Tishchenko (an apprentice of Butlerov and Mendeleev) presented a thesis entitled 'On the action of aluminium amalgam on alcohols: aluminium alkoxides, their properties and reactions' [1]. In spite of the national celebrity status, which the Tishchenko reaction (the transformation of aldehydes into esters on action of $Al(OR)_3$) received, this latter work remained unknown by foreign chemists, as it was published only in Russian in the Journal of Russian Physicochemical Society. However, in this work (i) some general methods of synthesis of metal alkoxides have been elaborated, the regularities of variations in the values of physicochemical constants along hom-

* Author to whom correspondence should be addressed.

† Dedicated to Professor D. C. Bradley on the occasion of his 73rd birthday.

ologous series (ii), and on the ramification of organic radicals (iii) were formulated, the main thermolysis pathways (iv) and main directions of metal alkoxides application in organic synthesis (v) were determined. This work undoubtedly represented the first systematic investigation of the properties of one of the most important classes of alkoxides, performed at very high standard and might serve as an example of fundamental and comprehensive approach to the problem even for the modern researchers.

In the 1950s the group under Professor A. N. Nesmeyanov at the Institute of Organic Chemistry of the USSR Academy of Sciences initiated one of the first systematic studies of titanium alkoxides. The synthetic approaches to these compounds (in particular, $TiCl_4$ alcoholysis reactions in presence of NH_3 or Py) were worked out and the products of their partial haloidation and hydrolysis were investigated for the first time [2].

Fundamental synthetic and physicochemical studies of lithium alkoxides were carried out in Moscow at the L. Ya. Karpov Institute of Physical Chemistry in the early 1960s by T. V. Talalaeva *et al.* [3]. The synthesis of nearly all representatives of the LiOR homologous series was reported and the molecular complexities of these compounds were determined. The structures of aggregates present in solid, liquid and gaseous phases ($n = 3$–9), were deduced on the basis of IR and NMR spectral data compared with those calculated theoretically in relation to different structural models.

The first X-ray single crystal investigation of the structure of a metal alkoxide, namely $W(OPh)_6$, was carried out in 1957 by Yu. T. Struchkov at the Moscow State University. It has been found that in the octahedral molecule of this compound, the Ph-rings are placed around the W atom in rendered conformation (like propeller blades) thus totally protecting it sterically [4]. The authors referred to this circumstance to explain the unusually high stability of tungsten phenoxide to hydrolysis even in acidic media. Later, during many years it was Yu. T. Struchkov, who headed the X-ray structure studies of homo- and heterometallic alkoxides at A. N. Nesmeyanov Institute of Organoelement Compounds of Russian Academy Sciences. More than 50 structures of metal alkoxides (of the total of several hundreds known today) [5] were determined in his laboratory.

In 1957 at the Department of Inorganic Chemistry of the Moscow State University, a study of beryllium alkoxides was initiated by Professor A. V. Novoselova in connection with the problem of the preparation of high purity materials for the nuclear industries [6]. Her laboratory was one of the centers of physicochemical analysis of inorganic compounds and, naturally, this approach (plotting of property versus composition diagrams) was applied to the studies of metal alkoxides. The objects of our studies became methoxides and ethoxides of magnesium and alkaline earth metals and, later, the derivatives of a broad spectrum of elements—from Ia to VIIIb Groups of the Periodic Table. The following standard research scheme was usually applied:

—Optimization of synthesis, isolation and purification conditions for distinct derivatives.

—Investigation of their physicochemical properties such as solubility in organic solvents, thermal properties, spectral characteristics, crystal structure etc. (in connection with the chemical and thermal prehistory and 'age' of the samples).

—Study the complex formation with the derivatives of other elements, investigation of properties and crystal structures of bimetallic complexes.

—One of the most important directions was connected with the studies of oxoalkoxides—the conditions of their formation, their properties and molecular structures and the determination of the possible origin of oxogroups in the coordination spheres of metal atoms.

—Optimization of preparation conditions for some simple and complex oxides produced from metal alkoxides.

The results obtained in all of the mentioned research directions were produced to contribute to the elaboration of the scientific principles of sol–gel technology [7].

Studying the literature on the chemistry of metal alkoxides during the past 40 years, we paid special attention to the works of Professor D. C. Bradley, whose classic investigations promoted the creation of the modern science of metal alkoxide chemistry. Being unfortunately not acquainted with him personally, we nevertheless consider him as our teacher in the field of chemistry that we have chosen for our research. In addition to the MSU employees, these are the former graduates of the abovementioned laboratory working at Karpov Institute and Institute of Organoelement Compounds who counterpart in our research activity.

1. SYNTHESIS OF METAL ALKOXIDES

The provision of the industries of oxide materials with a broad assortment of accessible alkoxide derivatives that can be prepared using simple and inexpensive techniques is one of the principal conditions of its development. In spite of the considerable attention that is paid in the modern literature to the derivatives of alcohols with more and more sterically demanding and ramified radicals, our research remained concentrated mainly on the derivatives of the first representatives of the homologous series and those of 2-methoxyethanol.

Having experimentally analyzed the numerous (but not always reliable) literature data and having optimized the known approaches and developed some new techniques, we have concentrated our attention on three main approaches applicable in both laboratory and industrial practice.

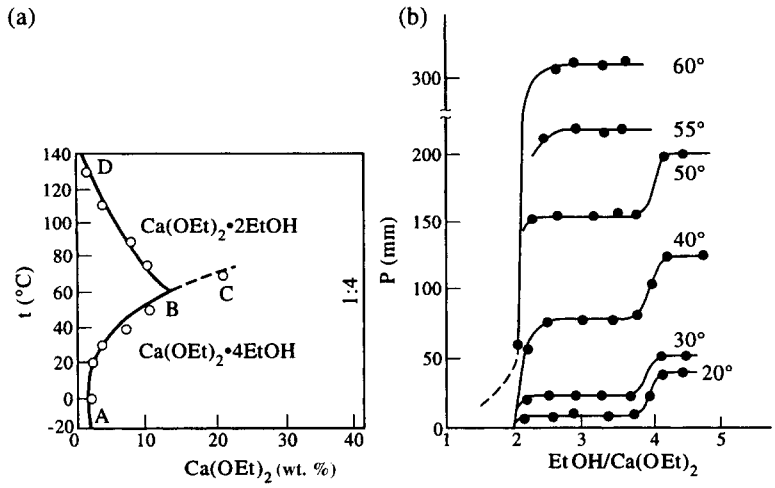

Fig. 1. Solubility (a) and vapor pressure (b) in the $Ca(OEt)_2$–EtOH system.

For the preparation of the derivatives of akaline, alkaline earth metals, magnesium and aluminium, the reaction of metals with alcohols did not meet any obstacles in the synthesis of methoxides, ethoxides etc. however the conditions of their isolation and the compositions of the solvates formed could be improved. For this purpose, the solubility polytherms in $M(OR)_n$ (s)–ROH (l) were investigated, and the tensimetric study of $M(OR)_n$ (s)–ROH (g), where M = Li, Mg, Ca, Sr, Ba, R = Me, Et was carried out [8]. As examples, the state diagram in the $Ca(OEt)_2$–EtOH binary system and the vapor pressure isotherms in it are given in Fig. 1. There was established the existence of a 1:4 solvate, that loses two moles of EtOH under mother liquor at 60°C forming a 1:2 solvate. The solubility of the latter decreases with temperature due to the exothermal effect of its dissolution (−29.5 kJ/mol). The thermodynamic functions of the reaction.

$$Ca(OEt)_2 \cdot 4EtOH(s) \Leftrightarrow Ca(OEt)_2 \cdot 2EtOH(s) + 2EtOH(g)$$

are $\Delta H_T = 162.5$, $\Delta G_{298} = 39.1$ kJ/mol, $\Delta S_T = 414.1$ J/mol K. Considerable increase in the solubility of 1:4 solvate with temperature (ΔH of dissolution = +37.8 kJ/mol) permits its recrystallization from alcohol. The loss of the last ROH molecule by disolvate (as it also takes place in the case of other metal alkoxide solvates) is accompanied by partial solvolysis and appearance of oxogroups in its structure. The latter, even in microammounts, changes considerably the properties of the samples (see below). In spite of the idea of ionic nature of alkaline earth solvates being well-established in the literature, the publications of the last years testify their molecular nature. Cubane-like molecules were found in the structures of $Mg(OMe)_2 \cdot 3.5$ MeOH [9] and $Ba(O\text{-}Bu^t)_2 \cdot {}^tBuOH$ [10].

Interaction of thallium metal with EtOH is worth special mention. Contradiction in the literature data left it unclear that TlOEt might be prepared if the presence of water, which is the other product of this reaction. The investigation of the TlOEt solubility polytherm in EtOH has shown that this system undergoes layering and thus water is quantitatively transferred into the upper alcohol layer, while the alkoxide—free from hydrolysis products—forms a lower layer as a heavy viscous oil (Fig. 2) [11].

For the preparation of Group III–VIII metal alkoxides, the application of the electrochemical method, based on anodic dissolution of metals in anhydrous alcoholic media in presence of conductive additives, proved to be the most promising. This technique was patented by the Monsanto Corporation in 1972 for the preparation of ethoxides of Si, Ge, Ti, Zr, Ta [12],

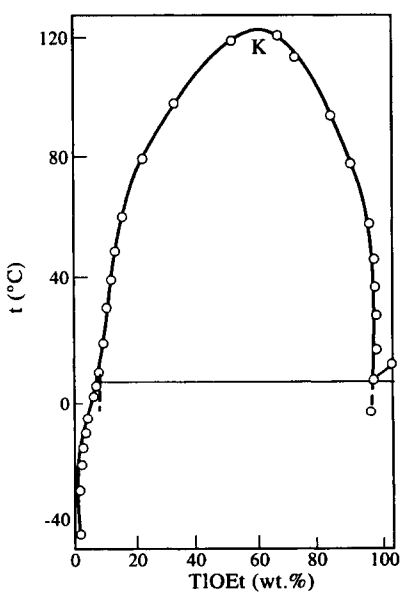

Fig. 2. Solubility polytherm in the TlOEt–EtOH system.

and was applied by Lehmkuhl *et al.* for the synthesis of Fe^{II}, Co and Ni alkoxides [13]. We have substantially widened the spectrum of products prepared by this method [14a]. The preparation techniques exploiting this approach were developed for soluble $M(OR)_n$, M = Sc, Y, La, Ln [14b], Ti, Zr, Hf, Nb [14a], Ta [14c], R = Me, Et, Pr^i, Bu^n; $MO(OR)_4$, M = Mo, W, R = Me, Et, Pr^i [14d]; 2-methoxyethoxides of Y, Ln, Sn^{II}, Zr, Hf, Nb, Ta, Fe^{III}, Co, Ni [14e], which are concentrated in electrolyte and several insoluble products such as $Bi(OMe)_3$ [14f], $Cr(OR)_3$ (R = Me, Et, $MeOC_2H_4$) [14g], $V(OR)_3$ [14d], $Ni(OR)_2$ (R = Me, Pr^n, Pr^i) [14h], $Cu(OR)_2$, R = ^{n}Bu, C_2H_4OMe [14i], $Re_4O_2(OMe)_{16}$ [14j], which precipitates from it in the cell. $[Bu_4N]Br$ or cheaper reagents such as lithium salts were used as conductive additives. It is worth noting that the oxidation state of a metal in the derivative to be prepared is dependent upon the nature of alcohol. Thus in contrast to the anodic oxidation of iron in aliphatic alcohols, which provides a route to air-sensitive solid $Fe(OR)_2$ [13], the same process, when carried out in 2-methoxyethanol, gives a liquid $Fe_n(OC_2H_4OMe)_{3-2n}$, which is perfectly stable and soluble in donor organic solvents [14e]. The latter can serve as a versatile precursor of Fe_2O_3-based materials. The anodic oxidation of several metals in the same $MeOC_2H_4OH$-based electrolyte turned to be a very convenient route to prepare film-forming solutions (with prescribed stoichiometries such as ZrO_2-Y_2O_3, $PbZr_{1-x}Ti_xO_3$, $Ba_xSr_{1-x}TiO_3$) [15]*.

One of the most attractive advantages of the electrochemical technique is provided by its simplicity: as the initial reagents are used pure metals (which, in contrast to anhydrous halides, are easier to handle and are always commercially available), the volumes of organic solvents applied are also considerably reduced. One disadvantage of this technique one can mention is the difficulty to remove the admixtures of alkoxide chlorides or bimetallic alkoxides in the case when LiCl is used as a conductive additive [14c]. When the industrial application is considered, these are such features as its high productivity, continuous and non-pollutive character (as hydrogen is the major side-product) that are of prime importance. At present the technological schemes are developed for electrochemical production of a number of derivatives, first and foremost for the large-scale production of $Ti(OBu)_4$ [16].

Besides the electrochemical synthesis, especially in the cases when its application is impossible due to cathodic reduction of an alkoxide formed (leading to lower oxidation state derivatives or to electrochemical refinement of the metal), we applied the well-known metathesis reaction:

$$MCl_n + n\text{NaOR} \rightarrow M(OR)_n + n\text{NaCl}\downarrow$$

M = In, Y, La, Ln, Ti, Ge, Bi, V^{IV}, $[VO]^{2+}$, $[VO]^{3+}$, Nb, $[NbO]^{3+}$, W, $[M'O]^{4+}$, $[M'O_2]^{2+}$ (M′ = Mo, W), Fe^{III}

Low yields of final products, described in literature, were increased to practically quantitative ones due to elimination of the alcoholysis processes for MCl_n (strong Lewis acids), which is accompanied by formation of alkoxide chlorides and subsequently the polymeric oxoalkoxides. For this purpose the initial chloride was always introduced into reaction with NaOR on cooling and vigorous stirring in the form of solution or suspension in ether or hydrocarbon solvent. Destruction of bimetallic alkoxide chloride intermediates was achieved by prolonged heating of the reaction mixtures under reflux or by complete removal of the solvent [17, 14b, f, d].

2. OXOALKOXIDES

Polymeric metal oxoalkoxides obtained by hydrolysis or thermolysis of $M(OR)_n$ were for a long time considered as being of practical interest as materials for thermally stable, hydrophobic and protective coatings [18, 19]. A new period in the history of oxoalkoxides was connected with the oligomeric oxoalkoxide complexes, which were structurally characterized at the end of the 1960s [20]. The role played by these derivatives in the chemistry of metal alkoxides turned out to be extremely important. A whole series of compounds, described as '$M(OR)_n$' were found in particular to contain oxogroups in their structures. The latter usually have the structural function of polydentate bridges and therefore were present in the composition in very low quantities. This circumstance, in combination with the presence of solvating alcohol molecules or alcohol molecules included into the holes of the crystal lattice (originating from the complex shape of oxoalkoxide molecules), leads in many cases to microanalysis data that do not differ from those of $M(OR)_n$. The IR spectra in such cases give very often insufficient information as the M—O—M vibration frequencies rarely are characteristic enough. Therefore, the main role in the characterization of oxoalkoxides should be played by X-ray single crystal studies.

A well-known example is provided by crystalline isopropoxides of rare earth elements which turned in fact to be pentanuclear oxocomplexes $Ln_5(\mu_5\text{-}O)(\mu_3\text{-}OR)_4(\mu\text{-}OR)_4(OR)_5$ [21,22]. 'Crystalline aluminium ethoxide' (formed on prolonged heating of polymeric $Al(OEt)_3$ under benzene with subsequent evacuation and recrystallization from CS_2) was found to be in fact

* The application of 2-methoxyethoxides in general has granted a considerable progress in sol–gel technology. On the first hand, due to the possibility of chelation they turned out to be better soluble than $M(OA1K)_n$—the derivatives of the same metals in alcohols, THF and even hydrocarbons. On the other hand, they seem to be rather more stable to hydrolysis, and in some cases to redox processes, and form more stable sols when the excess of water is applied.

an oxoethoxide—$Al_{10}(\mu_4\text{-}O)_2(\mu_3\text{-}O)_2(\mu\text{-}OEt)_{14}(OEt)_{18}$ (Fig. 3a). The molecule consists of two pentamers bound by planar μ_3-O-groups in a $[Al_2O_2]$ cycle. Aluminium atoms possess tetrahedral, octahedral and trigonal bipyramidal coordination. Such decanuclear molecules are, according to mass-spectral data, also present in the gas phase [23]. It is worth noting that the known '$Fe(OEt)_3$' (dark orange–brown crystals that precipitate quantitatively from solutions in alcohol) is isomorphous to the described Al compound and is also an oxoderivative, but easier isolable and more stable [17e].

The crystalline product that precipitates from the yellow solutions of $Ca(OEt)_2$, obtained on reflux (on drying of the alcohol, for example) possesses '$Ca(OEt)_2 \cdot 2EtOH$' composition, but its crystal structure is built up of $Ca_6(\mu_4\text{-}O)_2(\mu_3\text{-}OEt)_4(OEt)_4 \cdot 14EtOH$ hexanuclear molecules, consisting of two $[Ca_4O_4]$ cubes sharing a common $[Ca_2O(oxo)_2]$ face [24] (Fig. 3b), its metal–oxygen core is analogous to that of $Li_5Sm(OBu^t)_8$ [25].

The structure of the well-known catalyst and reductive agent '$AlCl(OPr^i)_2$', which is widely used in organic synthesis, is actually built up of $Al_4(\mu_4\text{-}O)(\mu\text{-}OPr^i)_5[H(OPr^i)_2]Cl_4$ tetrahedral molecules, which are also present in the gas phase (Fig. 3c). All Al atoms in this structure are pentacoordinated (trigonal bipyramids); two of the four terminal OR-groups are connected by a hydrogen bond (i.e. one of them should be a solvating alcohol molecule) [26]. The molecules of crystalline 'lead isopropoxide obtained by anodic oxidation of lead in alcohol are octahedral $Pb_6(\mu_3\text{-}O)_4(\mu_3\text{-}OPr^i)_4$ aggregates with oxo- and alkoxide groups placed in turn over the faces of octahedron (Fig. 3d). This compound is a structural analog of tin and lead hydroxides—$M_6O_4(OH)_4$ [27].

The most impressive result was obtained on investigation of the physicochemical characteristics and, in particular, mass-spectra of zirconium and hafnium alkoxides ['$M(OR)_4$']. The amorphous samples having this composition, in fact contain admixtures of oxocomplexes such as $M_3O(OR)_{10}$ and $M_4O(OR)_{14}$, which are present in the solid state, in solution and in the gas phase [28]. The structure of the trinuclear species, deduced on the basis of NMR data, is analogous to that of the known triangular Th, Mo and U^{IV} oxoalkoxide clusters, i.e. $M_3(\mu_3\text{-}O)(\mu_3\text{-}OR)(\mu\text{-}OR)_3(OR)_6$, R = ^{i}Pr, ^{t}Bu [29–31], while that of tetranuclear ones contains an $[M_4]$ tetrahedron. As the ultimate proof, confirming the presence of oxoligands in the species of '$Hf(OEt)_4$' one can consider the isolation from its solution in toluene of the hexanuclear $[Hf_3O(OEt)_{10}(EtOH)]_2$ complex, whose structure is built up of two abovementioned triangular fragments connected by two extra solvating alcohol molecules (Fig. 3e). These are only liquid $M(OC_2H_4OMe)_4$ and $M(OR)_4 \cdot ROH$ solvates (R = ^{i}Pr, ^{t}Bu, M = Zr, Hf,) that can be considered to be individual products [28].

The minimal nuclearity among the oxoalkoxide species is demonstrated by tantalum oxoisopropoxide, $Ta_2(\mu\text{-}O)(\mu\text{-}OPr^i)(OPr^i)_7 \cdot {}^i$PrOH. This compound is a structural analog of $[M(OPr^i)_4 \cdot {}^i PrOH]_2$ (M = Zr, Hf) [32], containing however a bridging oxogroup instead of μ-OR-group in its structure (Fig. 3f). This compound is formed on short-time reflux of $Ta(OPr^i)_5$ in alcohol (for example, in the course of electrosynthesis). On long-term storage of such a solution, a product of rather more profound condensation, characterized as $Ta_7(\mu_3\text{-}O)(\mu\text{-}O)_8(\mu\text{-}OPr^i)_4(OPr^i)_{13}$ (Fig. 3g) [14c] is precipitated.

In spite of quite the considerable number of oxoalkoxides known at present, the satisfactory and ultimate answer to the question about their possible origin still cannot be given. It is very important to mention that the majority of the abovementioned species were isolated on prolonged storage (after heat treatment of solutions etc.) and are therefore the products of some kind of decomposition processes. The presence of oxogroups in the structures of the first isolated compounds of this kind, i.e. $Ti_7O_4(OEt)_{20}$, $Nb_8O_{10}(OEt)_{20}$* [20] and $Zr_{13}O_8(OMe)_{36}$ [33] was explained by occurrence of uncontrolled reactions of microhydrolysis.

Later, however, it has been proved that the same compounds are also formed under the conditions of complete isolation from moisture; the first one was prepared on heating of $Ti(OEt)_4$ solutions in alcohol in an autoclave [34], the second—on storage of liquid $NbO(OEt)_3$ samples in the sealed samples [17c]. The oxogroups apparently originate under these conditions due to quite different processes, such as ether elimination for example:

$$—M—OR + RO—M— \xrightarrow[-R_2O]{} —M—O—M—$$

This kind of decomposition, which was observed for the first time by Bradley (who described the formation of two oxo-tertbutoxides $NbO(OBu^t)_3$ and $Nb_2O(OBu^t)_8$ on action of ^{t}BuOH on $Nb(OEt)_5$ [35]), is very characteristic of the alkoxides of rhenium [36], tungsten and especially molybdenum [14d, 37]. It proved to be practically impossible to isolate the derivatives of $Mo(OR)_6$ series (its tungsten analogs are not much more stable either). The following sequence of transformations takes place on storage:

$$M(OR)_6 \xrightarrow[R_2O]{} MO(OR)_4 \xrightarrow[-R_2O]{} MO_2(OR)_2$$

and is accelerated by the traces of moisture, on heating and especially in presence of alkali alkoxides (see below).

This reaction may play a very important role in the processes of hydrolysis of metal alkoxide, when the precipitation of crystalline oxide phases takes place already from the solutions in organic solvents. For

* It was recently proved that $Ta_8O_{10}(OEt)_{20}$, isomorphous to its niobium analog, crystallizes on hydrolysis from $Ta(OEt)_5$ solution in EtOH.

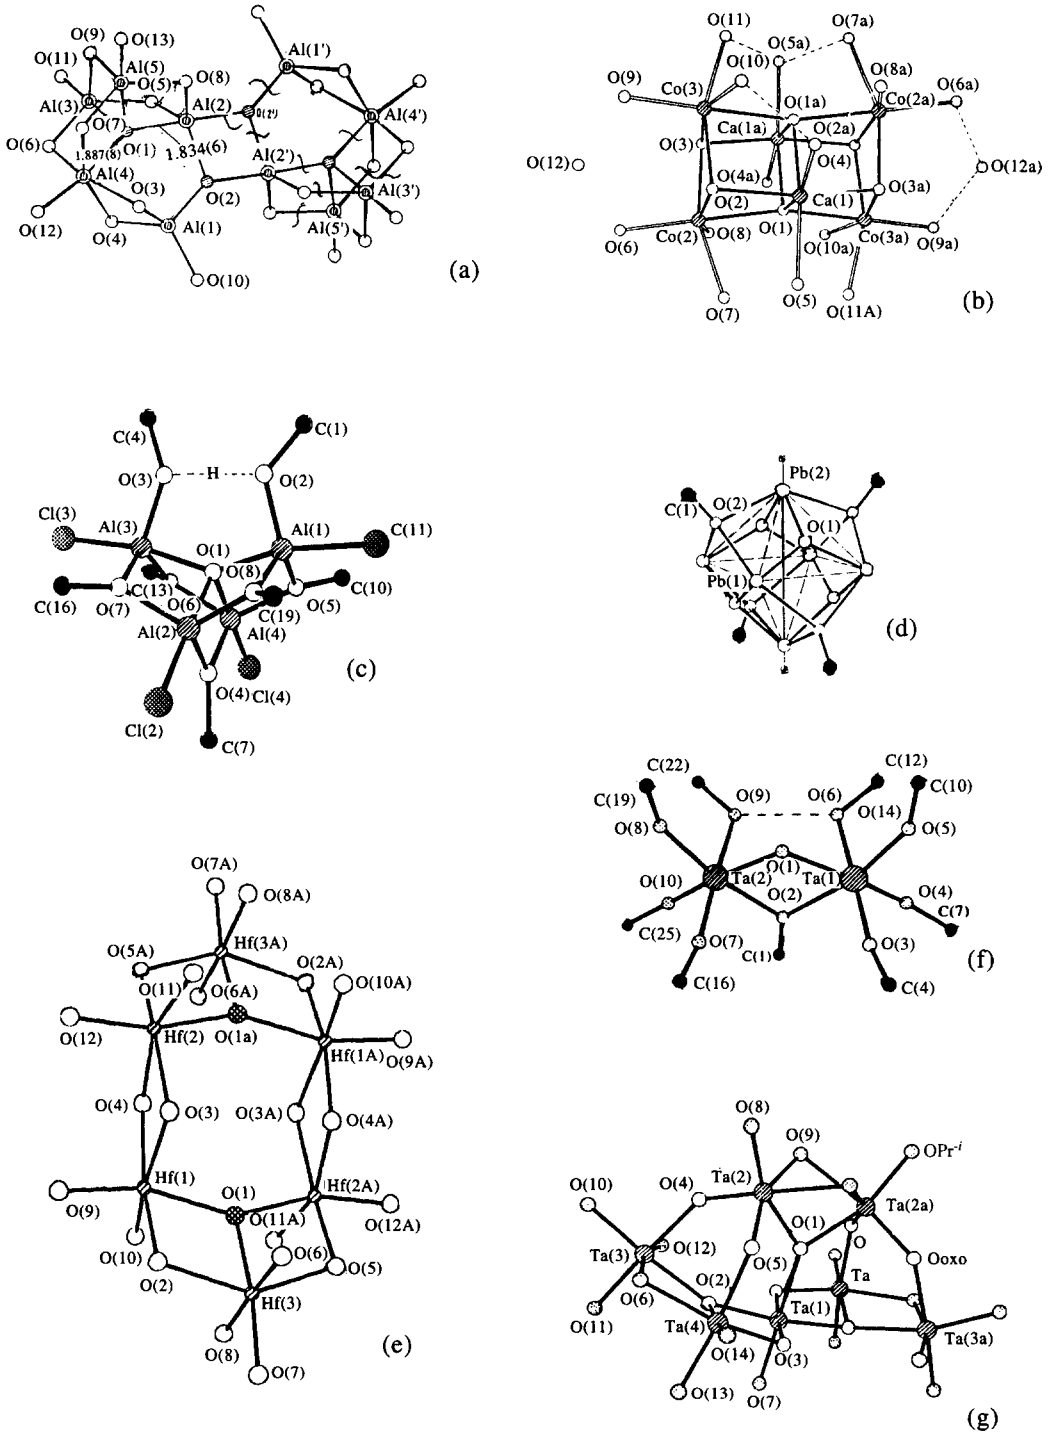

Fig. 3. Structures of oxoalkoxide complexes: $M_{10}(\mu_4\text{-}O)_2(\mu_3\text{-}O)_2(\mu\text{-}OEt)_{14}(OEt)_8$, M = Al, Fe (a), marks show the points of fraction leading to oligomeric molecules detected in the gas phase; $Ca_6(\mu_4\text{-}O)_2(\mu_3\text{-}OEt)_4(OEt)_4 \cdot 14EtOH$ (b); $Al_4(\mu_4\text{-}O)(\mu\text{-}OPr^i)_5[H(OPr^i)_2]Cl_4$ (c); $Pb_6(\mu_3\text{-}O)_4(\mu_3\text{-}OPr^i)_4$ (d); $[Hf_3O(OEt)_{10}(EtOH)]_2$ (e); $Ta_2(\mu\text{-}O)(\mu\text{-}OPr^i)(OPr^i)_7 \cdot {}^iPrOH$ (f); $Ta_7(\mu_3\text{-}O)(\mu\text{-}O)_8(\mu\text{-}OPr^i)_4(OPr^i)_{13}$ (g).

example, in action of the excess of water on $Bi(OEt)_3$ in benzene, the formation of α-Bi_2O_3 phase was observed (the presence of ether was detected by GLC). At the same time, the precipitates obtained in ethanol were always amorphous, while in 2-methoxyethanol the formation of very stable sols took place; in both latter cases no trace of ether could be detected [38].

The appearance of oxogroups in the molecules of alkaline and alkaline earth metals and lanthanum (and, possibly, lanthanides) alkoxides can be caused by uncontrolled oxidation (by the traces of oxygen dissolved in the solvents used or present in atmosphere). The primary products of oxidation contain —OOR and —OOH groups [39], which undergo radical decomposition that produces water, and gives rise to oxo- and HCOO-groups in the structures of the species.* The yellow coloration observed in the samples is due to the presence of free radicals R$^{\cdot}$ producing a sharp singlet in the ESR spectra of these samples [40]. Such reactions can occur only in the case of the most ionic alkoxides, for which dissociation in solutions is accompanied by liberation of OR^- anions, able to react with O_2. These are 2-methoxyethoxides that demonstrate the most pronounced trend toward oxidation. Thus among the derivatives of lanthanides, only the derivative of yttrium (which is the most electronegative element among them) might be isolated free from oxogroups as $[Y(OC_2H_4OMe)_3]_{10}$ [41]. Gadolinium 2-methoxyethoxide can be isolated already as $Gd_6(\mu_4\text{-}O)(OR)_{16}$ [42]. On reaction of Ba with the same alcohol under the most complete isolation from oxygen and moisture, Caulton *et al.* were only able to isolate an oxoalkoxide $Ba(\mu_6\text{-}O)(OR)_{10}\cdot 4ROH$ composition [43]. At the same time the derivatives of MeOH and *t*-ROH turn to be much more stable to oxidation, for example, such lanthanum derivatives as $La_3(OBu^t)_9(^tBuOH)_2$ [44] and $[La(OCPh_3)_3]_2\cdot 3C_7H_8$ [45] have recently been isolated and structurally characterized.

The most pronounced difference between oxo- and orthoforms can be observed in case of polymeric $M(OR)_n$. The oligomeric nature of oxoalkoxides containing minimal amounts of oxogroups originating from uncontrolled microhydrolysis or -oxidation leads to a substantial increase in their solubility and reactivity. Thus, $[Ba(OBu^n)_2]_x$, synthesized by reaction of Ba with alcohol in hydrocarbon is totally insoluble in butanol and does not react with $Ta(OBu)_5$. However, when [mol9]0.05 of the oxogroup per Ba atom appears in its composition, it can be dissolved in BuOH to up to the concentration of ~40 wt%, which permits the preparation of its mixed solutions with tantalum butoxide, containing metals in any desired ratios [40,46]. Therefore, the solubility in alcohols or reactivity in the reactions of complex formation can serve as the 'indicators' of purity of the samples of $M(OR)_n$. At the same time, the $M(OR)_2\cdot 4ROH$, M = Mg, Ca, Ba, R = Me, Et, being soluble in alcohols are comparably stable to oxidation [8], due presumably to the solvation effect.

Also at the same time, the multinuclear $M_xO_y(OR)_z$, which have good solubility in hydrocarbons, can only usually be dissolved in alcohols on heating (or mechanical destruction under solvent) due to solvolytic destruction of their huge molecules. Therefore, their solubility never reaches the equilibrium values [17c]. The only exception to this rule seems to be $Ta_2O(OPr^i)_8\cdot {}^iPrOH$, whose molecules, presumably, remain intact in solution in alcohol [14c].

Formation of oxoalkoxides occurs, naturally, also in the course of controlled oxidation of low-valent $M(OR)_x$ derivatives by oxygen. As an example of such a process we can mention the formation of $MoO_2(OR)_2$ in the colored electrolytes (containing admixtures of Mo^V) put in contact with dry air [14d].

3. PARTICULAR FEATURES OF THE PHYSICOCHEMICAL BEHAVIOR OF METAL ALKOXIDES. 'COORDINATION POLYMERISM'

During the last two decades, the data on irreproducibility of characteristics of distinct alkoxides, such as $Al(OEt)_3$ [47], $Al(OPr^i)_3$ [20], $Ga(OPr^i)_3$ [20], $Ti(OMe)_4$ [48], have been quoted many times in literature.

It was found out that the variations in the values of 'physicochemical constants' of the samples, i.e. physical state, melting and sublimation points, solubility in alcohols, intensity of coloration etc., are dependant upon their 'prehistory', that is the thermal regime of their synthesis, nature of solvent, they were separated from, their storage time ('age') and so on, and are characteristic of the majority of the alkoxide derivatives of Group III–VIII metal alkoxides. The data obtained using such techniques as mass spectrometry, cryoscopy, IR spectroscopy and X-ray powder diffraction proved metal alkoxides to be able to form in each case, species of different sizes and structures capable of undergoing mutual transformations. The presence of different oligomeric and polymeric species in one and the same sample hinders its crystallization and causes irreproducibility of its characteristics. The assembly of these phenomena we have designated by a term 'coordination polymerism'. The simplest examples of such phenomena are provided by the existence of two different forms of titanium methoxide and of tungsten oxomethoxide. The well-known tetranuclear $[Ti(OMe)_4]_4$ molecules exist in the structure of crystals obtained from solutions in toluene. The action of alcohol provides the samples that are insoluble in organic solvents and possess polymeric structure according to

* Formation of formate groups independent of the alkoxide group R is due to oxidative destruction of C—C bonds and can be observed due to rather characteristic HCOO valence bands in IR spectra.

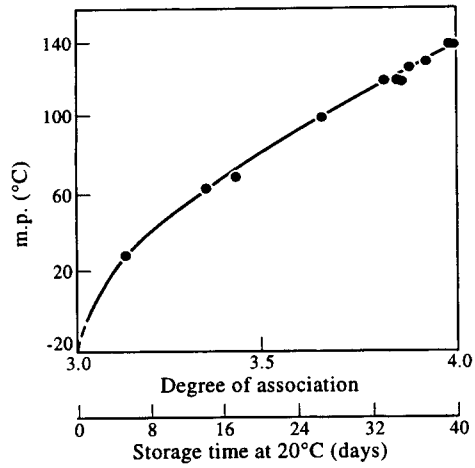

Fig. 4. Melting point versus molecular complexity ('age' of the samples) diagram for $[Al(OPr^i)_3]_n$.

the IR data obtained [48]. The oligomeric form of tungsten methoxide crystallized out from solutions in toluene or THF and was built up of $[WO(OMe)_3(\mu\text{-}OMe)]_2$ dimeric molecules [49]. From the solutions in alcohol (obtained by metathesis of $WOCl_4$ with NaOMe) the polymeric form, containing in its structure the asymmetric W=O···W bridges (analogous to those existing in the structure of $WOCl_4$) was obtained [50].

A classic example of an alkoxide, which samples demonstrate variable molecular composition, is provided by $Al(OPr^i)_3$, whose transformations in solutions were very thoroughly studied in the 1960s and 70s by vibration and NMR spectroscopy and tensimetry [20,51–53]. The freshly distilled liquid samples contain the trimeric $[(RO)_2Al(\mu\text{-}OR)_2]_2AlOR$ molecules, which have a chain structure with a pentacoordinate central Al atom and tetrahedrally coordinated peripheric ones [51] (its structural analog is the crystalline aluminium alkoxide chloride $Al_3Cl_5(\mu\text{-}OPr^i)_4$ [54]). On prolonged storage (about 40 days), the samples solidify forming crystals built up of tetrameric $Al[(\mu\text{-}OR)_2Al(OR)_2]_3$ molecules [55] (their structure was earlier predicted by Bradley [52]). The process of 'aging', i.e. the increase in the melting point up to 140°C and in the molecular complexity from 3 to 4 can be illustrated by Fig. 4, which plots the melting points vs. storage time in the phase diagram for trimer–tetramer system. Thus, in contrast to the data of Figgen and Gerding [53a], there are no different distinct solid forms of $Al(OPr^i)_3$, however two kinds of species coexist in the samples in different ratios. They are conserved in solution in hydrocarbons but on action of alcohol commence the crystallization of the form consisting of tetrameric molecules; the concentration of solutions decreases to a value corresponding to the equilibrium solubility of the latter. The samples that contain both kinds of species, when treated with alcohol, first undergo the extraction of unlimited soluble trimer, and thus provide very concentrated solutions. From the latter the tetrameric form subsequently crystallizes and thus the concentration decreases until it reaches the same value of equilibrium solubility. It is possible to suppose that in solution in alcohol, the molecules of trimer that contain pentacoordinate metal atoms are solvated and form larger aggregates *via* hydrogen bonding, which decompose producing tetrameric molecules, containing hexacoordinated Al atoms. Thus the steric unsaturation of the coordination polyhedron of the central aluminium atom makes the phase containing it unstable thermodynamically [55]. In the mass-spectra of some samples of aluminium isopropoxide, reported in [53b,c] in addition to the fragments of trimer and tetramer were found several ions with high m/z, which we could attribute to the fragments of oxodecamers [presumably analogous to $Al_{10}O_4(OEt)_{22}$]: $Al_9O_4(OPr)^+_{18}$ (1369), $Al_8O_4(OPr)^+_{15}$ (1165), $Al_7O_3(OPr)^+_{14}$ (1063), $Al_7O_4(OPr)^+_{12}$ (969), $Al_6O_3(OPr)^+_{11}$ (859).

Even greater pronounced coordination polymerism is characteristic of 2-methoxyethoxides. Presence of the ether function in the molecule provides an alternative for the saturation of the coordination sphere of the metal atom—in addition to OR-bridging groups these are oxygen atoms of ether groups that can enter it due to chelation. THe analysis of the structures of $M(OC_2H_4OMe)_n$ shows that the alkoxy oxygen atoms can be mono-, bi- and tridentate, while the ether oxygen atoms can be monodentate or not be coordinated at all. These factors provide an additional basis for coordination polymerism. This is probably the reason for the fact that most of the known 2-methoxyethoxides are liquids; the crystals can usually be obtained with low yields from the solutions in hydrocarbons.

Properties of the samples of $Al(OEt)_3$, described in the literature, appeared so different that it was usually supposed that several forms of this product existed, and in particular, polymeric β-form ('solvated') and oligomeric α-form ('non-solvated'). The first one can be obtained on prolonged heating of metal with an excess of alcohol in the presence of $HgCl_2$. The second is obtained from xylene or on heating of the first one, especially when carried out in the presence of aromatic hydrocarbons. The latter form is soluble and highly reactive. Its properties vary over a wide range, from viscous liquid to an amorphous solid with a m.p. of about 105–146°C, depending on the conditions of the synthesis of samples (heating rate etc.). The action of alcohol on the soluble liquid samples again transforms them into polymeric solids. In addition, there are two crystalline forms known (obtained from solutions in alcohol or in CS_2), to which the compositions '$Al(OEt)_3$' (shown to be $Al_{10}O_4(OEt)_{22}$, as it was mentioned above [23]) and '$Al(OEt)_2(OH)$' were ascribed. In the mass-spectra of all the forms, in addition to the fragments of $[Al(OEt)_3]_n$, where $n = 2$–4, fragments of oxoethoxides were found, containing from 4 to 10 metal atoms per fragment (Fig. 5). Relative intensities

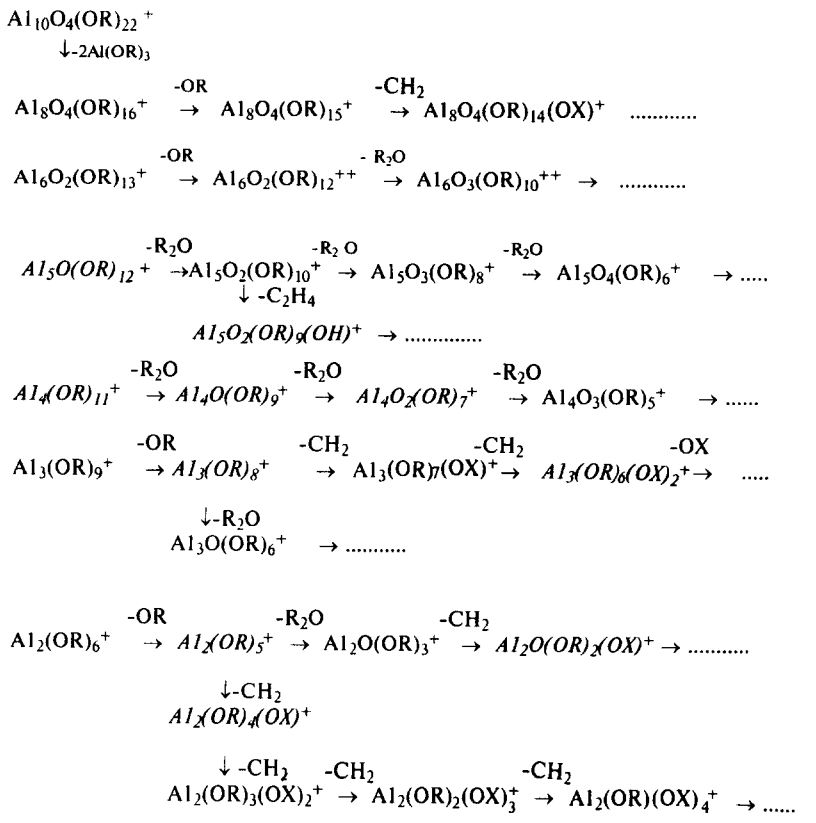

Fig. 5. Fragmentation scheme in the mass-spectra of $[Al(OMe)_3]_n$ and $[Al(OEt)_3]_n$ (the ions, observed by Oliver and Worrall [56], are printed in italic, X = H for methoxide and Me for ethoxide).

of peaks corresponding to ortho- and oxoforms testify that the composition of the samples can vary in a comparably wide range depending on the conditions of their synthesis and their thermal prehistory* [47].

Some information about the structure of oligomeric oxoalkoxides present in the amorphous samples, solutions or gas phase, can be obtained by reconstructing them from the X-ray molecular structures of polynuclear oxoalkoxide species, considering the oxo-groups as the points of condensation. Thus, in the molecule of $Al_{10}O_4(OEt)_{22}$ (Fig. 3a), one can trace the fragments corresponding to the tetra-, penta-, hexa- and octanuclear oxocomplexes, detected in the mass-spectra. It should be noted that the average molecular complexity for the '$Al(OEt)_3$' samples (corresponding to the decamer) in solution [58] and in the gas phase is the same (4.4). The same types of ortho- and oxo-oligomeric fragments were found in the mass-spectra of $Al(OMe)_3$ [47] (Fig. 5). On storage, the samples of polymeric methoxide and ethoxide undergo partial crystallization (with conservation of a major part as an amorphous matrix) with the formation of a layered structure of bayerite $Al(OH)_3$-type, which after 5 years of storage is converted to the more stable gibbsite $Al(OH)_3$-type [59].

'True' $Fe(OEt)_3$ is a polymer with the same kind of structure. It precipitates as yellow powder on action with liquid ethoxides of titanium or niobium on solutions of $Fe_{10}O_4(OEt)_{22}$ in alcohol [60a]. Apparently, the exchange reaction of the oxocomplexes of two metals in solution leads to formation of the least soluble product, which is iron ethoxide. Mass-spectra of iron ethoxide contain the fragments of oxoalkoxide species (from penta- to binuclear) and those of $Fe(OEt)_3$ monomers and dimers.

The properties of the samples of $Fe(OPr^i)_3$, which do not contain oxocomplexes, also vary over a wide range: m.p. 88–150°C (the latter value was obtained

*To be able to judge if the mass-spectral data provide adequate information about the molecular composition of the condensed phase, we compared them with those of X-ray single crystal, cryoscopic, ebulloscopic etc. studies of more than 50 oligomeric alkoxides and oxoalkoxides [57]. It was found that the size of species present in the samples is usually not dependent on their physical state. Mass-spectra of polymers, which are difficult to reproduce, contain only small fragments. As the first step of fragmentation is connected with the loss of an OR-group, it is possible to distinguish the oxofragments, formed under fragmentation due to electron impact or via loss of an ether molecule by an ortho-fragment and those originating from really existing oxoalkoxide molecules.

after a year of storage), color changes on action of ROH on the melt or on 'aging' from reddish brown to light yellow, solubility decreases from ~7% to 0. Fragments of orthotrimers, dimers and monomers were detected in the mass-spectra.

In addition to the examples discussed above, the coordination polymerism has been observed for samples of '$Zr(OR)_4$' and '$Hf(OR)_4$' [28], $NbO(OR)_3$ [17c], $MoO(OR)_4$ [37] and $MO_2(OR)_2$ (M = Mo, W) [37,70]. It is worth noting that for molybdenum oxoalkoxides, the polymerization occurs in presence of NaOR admixtures and proceeds *via* formation of OR-bridges, while dioxoderivatives of both molybdenum and tungsten undergo spontaneous polymerization with formation of oxobridges of M=O···M type. Polymerism of nickel ethoxide and isopropoxide is due to the presence of both octahedrally and tetrahedrally coordinated nickel atoms in their polymeric structures [14h].

The existence of different molecular forms was observed even for some heterometallic alkoxides. Thus, melting of $[NaWO_2(OC_2H_4OMe)_3]_2$ is associated with transformation of *cis*-$[WO_2]$ groups (where W=O bonds are terminal) into W=O···W chains, and of tetranuclear oligomers into a polymeric structure [70].

The data presented above, permits the tracing of some regularities in the transformations of properties of distinct alkoxide samples that occur due to poly- and oligomerization:

1. Molecular complexity increases on aging and on action of alcohols due, presumably to solvation of the 'young' forms, containing sterically unsaturated metal atoms. The next step is connected with formation of hydrogen bonds between solvated molecules and subsequent condensation with formation of OR-bridges and release of solvating alcohol molecules. This process is followed by the increase in the melting and sublimation temperatures, and decrease in solubility and weakening of coloration. In the mass-spectra, the increased evaporation temperature increases the fraction of low-nuclearity fragments.

2. Thermal treatment of the samples or their dissolution in aromatic hydrocarbon solvents leads to their oligomerization (in the latter case, probably, due to partial breakage of alkoxide bridges and formation of π-complexes). Products of this process display lower thermal constants, higher solubility in alcohols and more intense color. Their mass-spectra contain fragments corresponding to polynuclear oligomers present in the condensed phase. The scheme of these transformations is shown in Fig. 6.

Mastering these regularities, it is possible in many cases to modify the molecular composition of the samples and their properties. Describing the behavior of samples of distinct alkoxides it is very often difficult to distinguish the influence of the two main factors—non-uniform molecular composition of orthoforms and presence of oxoderivatives.

4. BIMETALLIC ALKOXIDES AND SYNTHESIS OF COMPLEX OXIDES

Heterometallic alkoxides have recently become a topic of special attention as the precursors of complex oxide materials for modern industries [71]. Their studies mainly deal with their preparation, the compounds described recently being characterized usually by X-ray single crystal studies, IR and NMR spectral data.

For determination of the composition and relative stability of bimetallic alkoxides, formed in solution and in the solid state, we applied the approach of physicochemical analysis based on investigation of the solubility isotherms in $M(OR)_n$–$M'(OR)_m$–L systems, where L is the solvent (alcohol, ether, hydrocarbon etc.) at 20°C. This approach, usually applied to the studies of inorganic salts interaction in aqueous media, turned out to be very fruitful for the studies of metal alkoxides. It permits us to test the interaction of components in the possible range of M : M′ ratios and determine the composition of the complexes formed in this system.

Let us consider examples of different types of interaction in ternary systems, displayed graphically in the Gibbs–Roseboom triangular diagrams (Fig. 7).

1. In the NaOMe–$Fe(OMe)_3$–MeOH system, no interaction takes place; polymeric iron methoxide remains insoluble at any concentration of NaOMe and the $Fe(OMe)_3$ crystallization curve lies on the side of the triangle [72].

2. Polymeric $Ba(OBu^n)_2$ dissolves in solutions of $Ti(OBu)_4$ in alcohol due to formation of the complex of composition $BaTi_4(OR)_{18}$ (which does not exist however in the solid state) as the curve corresponding to the crystallization of barium butoxide lies along the 1:4 section of the diagram [73]*.

3. Both components, i.e. $Bi(OEt)_3$ and $WO(OEt)_4$, are poorly soluble in pure alcohol, but in the presence of each other are transferred into solution due to formation of complexes with 3:2 and 1:1 compositions [75].

4. Both components $Ba(OMe)_2$ and $Ta(OMe)_5$ are soluble in alcohol, but the extrapolation of the $Ba(OMe)_2$·MeOH crystallization curve to the opposite side of the triangle testifies the formation of a 1:2 complex in solution (in an analogous system, containing isopropoxides as components, there exists a crystalline complex with *cis*-$[(^iPrOH)_2BaTa_2(OPr^i)_{12}]$ structure) [46].

---

*The consideration of more than 200 systems of AX_n–BX_m–L type, covering a wide spectrum of compounds and solvents, led us to a conclusion that there exists a connection between the position of the poorly soluble component crystallization curve in the diagram and the composition of the complex, which it forms in solution. The M : M′ ratio in the complex can be found by extrapolation of the crystallization curve for the poorly soluble component to the opposite side of the triangle [74].

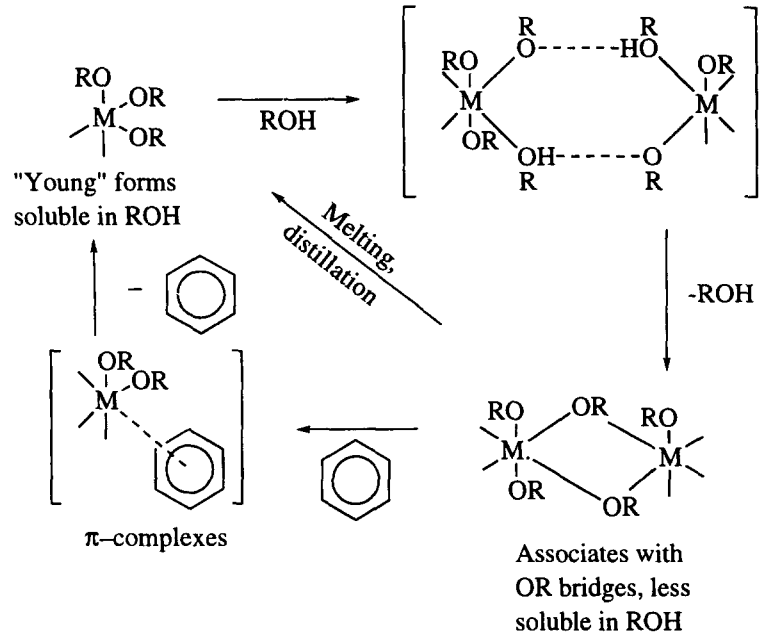

Fig. 6. General scheme of changes in molecular compositions of metal alkoxides under the action of different factors.

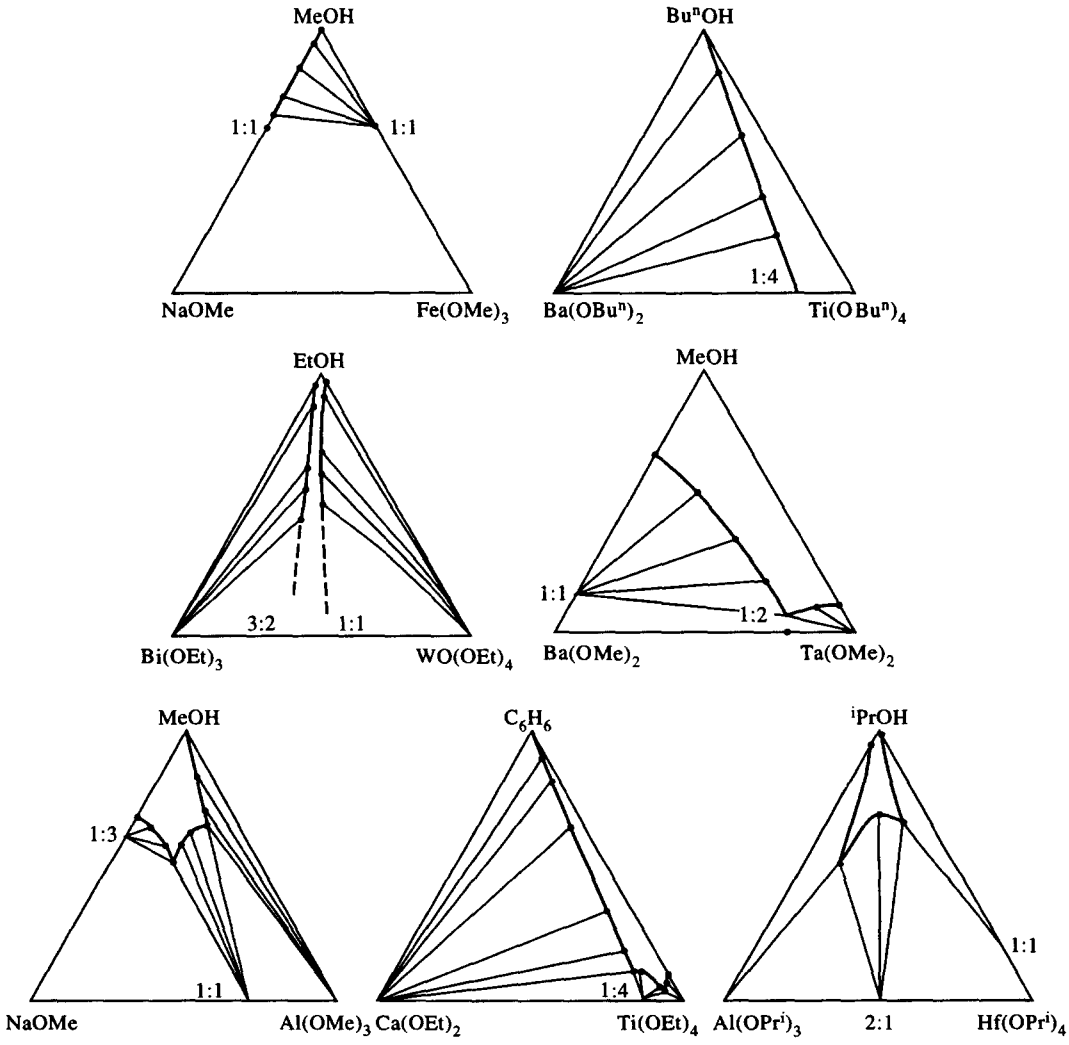

Fig. 7. Solubility isotherms in $M(OR)_n$–$M'(OR)_m$–L systems at 20 °C (wt %).

5. In the following three systems we observed the formation of crystalline bimetallic complexes $NaAl(OMe)_4$, $Ca[Ti_2(OEt)_9]_2$ and *cis*-$(Pr^iO)_2Hf[Al(OPr^i)_4]_2$. It is interesting to note that the first exists in the alkaline alkoxide excess and undergoes solvolysis in pure alcohol (analogous to hydrolysis of sodium aluminate). Therefore the eutonic point (corresponding the equilibrium of three phases) is situated on the 1:1 section of the diagram [76]. Calcium ethoxotitanate is formed in the excess of $Ti(OEt)_4$ [77], as the acidity of the latter exceeds substantially that of $Al(OR)_3$ and the difference in acidity for the two components in this system is more pronounced than in the previous one. Finally, in the system, formed by two 'acidic' alkoxides like those of Hf and Al the complex can stay in equilibrium with the solutions of both components and does not undergo solvolysis on action of alcohol.

The results were obtained by investigation of more than 50 systems, where the formation of alkoxoaluminates, -titanates, -zirconates, -hafnates, -niobates, -tanatlates, -molybdates, -tungstates and -ferrates (see Table 1) permitted the optimization for the conditions of their synthesis and those of the preparation of solutions for sol–gel application.

Let us consider the molecular structures of some of the complexes discovered in the abovementioned systems. Among the alkoxotitanates of alkaline earth elements, there are complexes of 1:4 composition, which possess the highest stability. Crystal structures of calcium and barium ethoxotitanates were found to be built up of $M^{II}[Ti_2(OEt)_9]_2$ symmetric molecules, where the central atom coordinates two $[Ti_2(OR)_9]$ groups (two octahedra sharing a common face). They are attached to the M^{II} ions *via* two μ_3- and two μ_2-OR-groups. The coordination number of barium and, quite unexpectedly, calcium atoms is equal to 8 (Fig. 8a) [73b]. These molecules as well as those of $BaZr_4(O-Pr^i)_{18}$ and $BaZr_4(OH)(OPr^i)_{17}$ described by Caulton [86] are highly stable. They are present in solutions of all barium alkoxotitanates (even in the cases when their existence in the solid state has not been proved) and in gas phase for alkoxozirconates [85].

Quite an unexpected result was obtained when investigating interactions of magnesium and titanium ethoxides. It turned out that the complex formed has a variable $MgTi_{4-x}(OEt)_{16-4x}\cdot(EtOH)_{2x}$ composition and conserves a structure analogous to that of $[Ti(OEt)_4]_4$ [20], where part of the $[Ti(OR)_4]$ group is substituted by $[Mg(OR)_2(ROH)_2]$. It is possibly due to the striking likeness of the Ti and Mg covalent radii (Fig. 8b) [83]. Formation of complexes with a variable composition is quite unusual for alkoxides having molecular structures.

The $NaMO_2(OC_2H_4OMe)_3]_2$ (M = Mo, W) and $[NaWO(OEt)_5(EtOH)]_2$ (Fig 8c, d) [75a] complexes are examples of the same tetranuclear type structure. While in the structure of the first of these two complexes, the bonding parameters (such as M—O bond lengths and M—O—C valent angles) change regularly depending on the nature of the OR-groups (terminal, μ_2-, μ_3-). Those having a sodium ethoxotungstate structure are independent of the structural function of the ligand, which permits one to consider all OR-groups as terminal and the molecule as an aggregate of ion pairs, i.e. $[Na(EtOH)_2]_2^+$ $[WO(OEt)_5]_2^-$. An example of a heteronuclear compound, containing a metal–metal bond in its structure is provided by the $(MeO)_2MoO(\mu\text{-}OMe)_3ReO(OMe)_2$ molecule (two octahedra sharing a common face) obtained by anodic dissolution of rhenium in methanol in the presence of $MoO(OMe)_4$ [89].

In addition to complex formation, there are the decomposition processes leading to the formation of bimetallic oxoalkoxides that are characteristic of the majority of the abovementioned systems. Besides the factors affecting the decomposition of homometallic alkoxides that have been considered above, one should at this point emphasize the role of alkaline or alkaline earth alkoxides (or, possibly, in some cases, the products of their uncontrolled oxidation) in the decomposition of the bimetallic complexes. Thus on the $MoO(OR)_4$ interaction with NaOR (R = Et, ^{i}Pr) in alcohols, these are $[NaMo_2O_4(OR)_5(ROH)]_2$ complexes that can be isolated and they already contain one extra μ-O-group per molybdenum atom than the initial species (Fig. 8e) [75]. Interaction of $MoO(OR)_4$ with the excess of NaOR or action of the latter on $[NaMo_2O_4(OR)_5(ROH)]_2$ complexes leads to crystallization Na_2MoO_4 already at room temperature.* (It is worth noting that microadmixtures of NaOR promote polymerization of $MoO(OR)_4$ and thus stabilize their samples against ether elimination.) The same reaction provided an access to the crystalline phases of Na_2WO_4, Bi_2MoO_6 (ferroelectric), cubic solid solutions in the Bi_2O_3-WO_3 system (δ'-phase, ionic conductor due to mobility of oxygen ions).

The extreme trend to oxidation, demonstrated by butoxides of lithium, barium etc. leads to a rapid increase of their solubility in the solutions of $Ti(OBu)_4$ in comparison with that displayed in the diagrams (Fig. 7) and provides a route to solutions with the desired component ratios.

The composition (stoichiometry) and structures of oxoalkoxo complexes are in general quite different from those found for bimetallic complexes free from oxoligands in the same systems (Table 1). This permits them to be used as precursors of the oxide phases in the sol–gel route. A good example can be seen in the preparation of $BaTiO_3$. In freshly prepared solutions containing Ba : Ti = 1:1, these are the above-

* 2-methoxyethoxomolybdates are more stable due, apparently, to the chelation of alkaline or alkaline earth metal (Li, Na, Ba) atoms in their structures, the ratio of the size and effective charge being optimal for $NaMoO_2(OC_2H_5OMe)_3]_2$.

Table 1. Complex formation in systems $M(OR)_n$–$M'(OR)_m$–L at 20°C (composition of the complexes is designated by M : M′ : ROH ratio; by * are marked the complexes, for which the X-ray structures have been determined)

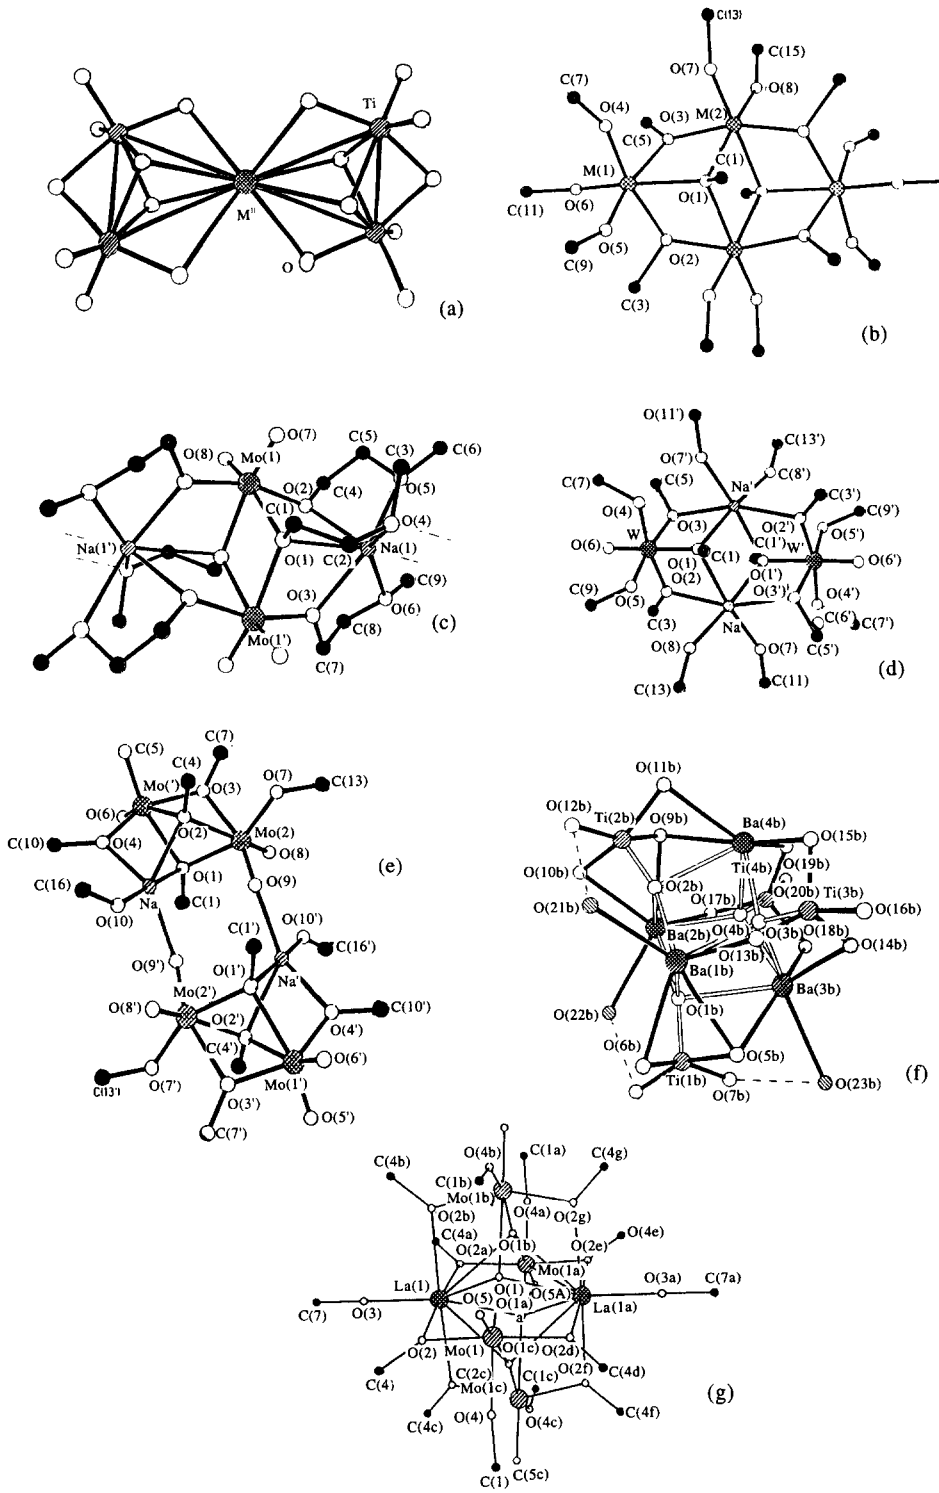

Fig. 8. Structures of selected bimetallic alkoxides: $M^{II}[Ti_2(OEt)_9]_2(M^{II} = Ca, Ba)$ (a); $[Mg_xTi_{4-x}(OEt)_{16-4x}(EtOH)_{2x}]$ (b); $[NaMO_2(OC_2H_4OMe)_3]_2$, M = Mo, W (c); $[NaWO(OEt)_5(EtOH)]_2$ (d); $[NaMo_2O_4(OR)_5(ROH)]_2$ (R = Et, ^{i}Pr) (e); $[BaTiO(OPr^i)_4(^iPrOH)_{7.8}]_4$ (f); $La_2Mo_4O_4(\mu\text{-}OPr^i)_8(OPr^i)_6$ (g).

mentioned complexes with 1:4 compositions and free $Ba(OR)_2$ that are present. This explains the fact that their application for the preparation of single-phase $BaTiO_3$ always leads to a failure. However, if before hydrolysis they were subjected to prolonged reflux, giving rise to formation of 1:1 complexes, $BaTiO_n(OR)_{6-2n}$, true precursors of barium titanate, they can produce its single-phase samples when

applied in sol–gel synthesis. One of the latter compounds, $[BaTiO(OPr^i)_4(^iPrOH)_{7/8}]_4$ (Fig. 8f) was isolated and subjected to X-ray single crystal investigation. In the center of its molecule lies a distorted $[Ba_4O_4]$ cube with metal atoms and oxoligands put in place of the vertexes. The oxoligands belong to $[TiO(OR)_4]$ groups; the solvate molecules, attached to Ba atoms, form intramolecular hydrogen bonds with the nearest OR-groups [73c]. It is worth noting that the Ba—O—Ti bridging fragments are already present in the structure of this molecule. The cubane-like structures related to this one have recently been found for $[BaNbO(OEt)_5(HOEt)_{1.5}]_4$ [87a] and $[MgTaO(OBu^n)_5(Bu^nOH)]_4$ [46]. One can suppose that this structural type may be observed for oxocomplexes of such stoichiometry containing atoms of bi- and polyvalent metals independently on the nature of the latter and the organic radicals.

For the preparation of $MgTiO_3$ it was found to be highly advantageous to use the solutions of butoxides, prepared by reaction of magnesium metal with $Ti(OBu)_4$ in butanol in 1:1 ratio. The reaction is accompanied by partial reduction of Ti^{IV} compounds into green $Ti^{III,IV}$ derivatives. Their subsequent oxidation by dry air leads to formation of soluble $MgTiO_n(OBu)_{6-2n}$ [83].

Here are some other examples of heterometallic alkoxide structures. A complex possessing an unusual $LiTa_9O(OEt)_{20}\cdot 2EtOH$ composition has an uncompleted Keggin structure of nine $[TaO_6]$ octahedra surrounding a $[LiO_4]$ tetrahedron, having one free vertex turned into the outer space [46]. On interaction of '$La(OPr^i)_3$' with $MoO(OPr^i)_4$ in hexane on heating, a hexanuclear $La_2Mo_4O_8(\mu\text{-}OR)_8(OR)_6$ molecule having a tetragonal bipyramidal *trans*-$[La_2Mo_4]$ metal atom arrangement was formed (Fig. 8g). It differs from the other known hexanuclear molecules with 2:4 metal atom ratios by the absence of μ_6-O atom in its center [90].

In conclusion, let us consider the role played by oxogroups in the process of complex formation. The example dealing with the interaction of butoxides of lithium and tantalum has already been discussed above. The isopropoxides of Zr (Hf, Ta) react with $Al(OPr^i)_3$ only after prolonged heating of solutions in alcohol [78]. One can suppose, therefore, that the complex formation for alkaline or alkaline earth alkoxides does not need any 'activation' because of the practically inevitable presence of microamounts of oxogroups in their samples.

It is very interesting to note that from solutions, which certainly contain oxocomplexes, may crystallize bimetallic alkoxides free from these ligands. For example, we can mention $HfAl_2(OPr^i)_{10}$ or $LaNb_2(OPr^i)_{13}$, precipitating from solution containing $La_5O(OR)_{13}$ [87], $Ba[Zr_2(OEt)_9]_2$, formed in the presence of zirconium oxoethoxide [85] and so on. The crystallization of this or that product depends upon their solubility; that is the least soluble compound that precipitates, the mother liquor being depleted or enriched in oxoligands [the analogous situation being described for the crystallization of $Fe(OEt)_3$].

We have proved that the isopropoxides of the late transition metals (Fe, Co, Ni etc.) in contradiction with the data of [91–93], do not interact with the isopropoxides of Al, Nb, Ta on complete isolation from moisture and the data on formation of volatile bimetallic species does not take place. On prolonged heating in the presence of traces of moisture, the dissolution of polymeric $M(OR)_2$ does occur giving rise to bimetallic oxoalkoxo-complexes as viscous non-volatile liquids described, for example, by Teyssie *et al.* [94]. In spite of the absence of complex formation between the methoxides of sodium and iron (Fig. 7), the interaction of NaOMe with the solution of $FeCl_3$ in methanol (apparently containing oxogroups, formed on alcoholysis of the chloride) gives a crystalline $Na_2[Fe_6(\mu_6\text{-}O)(OMe)_{18}]\cdot 6MeOH$ complex [88].

CONCLUSIONS

We would like to underline, that the physicochemical approach that we applied to the studies of metal alkoxides is the natural development of ideas and methodology, demonstrated in the pioneering works of D. C. Bradley. To the latter belong the detailed investigation of the properties of alkoxides and the regularities of their variation along the homologous series and in the groups of the Periodic Table, determination of the molecular composition of the samples and the structures of the species present. The Structural Theory developed by D. C. Bradley has acted as a powerful driving force for the initiation of wide-range structure studies that are carried out at present.

Investigation of the decomposition pathways of metal alkoxides and reactions of their hydrolysis laid the scientific background of the modern sol–gel route to oxide materials.

Ortho-substituted aryl diamido complexes of zirconium: observation of rotameric isomers†

Frédéric Guérin, Orin Del Vecchio and David H. McConville*

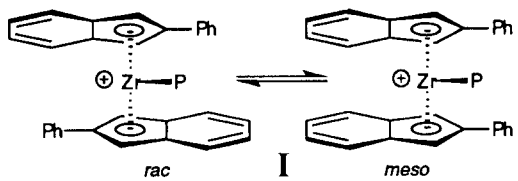
Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, British Columbia, Canada V6T 1Z1

(Received 10 April 1997; accepted 11 June 1997)

Abstract—Zirconium complexes bearing a series of ortho-substituted aryl diamido ligands [2,6-$(RNCH_2)_2NC_5H_3]^{2-}$ (R = 2-PhC_6H_4 (BPhP); 2-$^iPrC_6H_4$ (BMPP); 2-$^tBuC_6H_4$ (BMBP), 2-^{i}Pr-6-MeC_6H_3 (MPPP)) have been synthesized. The mixed amide complexes [2,6-$(RNCH_2)_2NC_5H_3$]$Zr(NMe_2)_2$ are prepared in high yield from 2,6-$(RHNCH_2)_2NC_5H_3$ and $Zr(NMe_2)_4$. The mixed amides react with excess $ClSiMe_3$ to afford the dichlorides [2,6-$(RNCH_2)_2NC_5H_3$]$ZrCl_2$ in nearly quantitative yield. Dimethyl complexes are prepared from [2,6-$(RNCH_2)_2NC_5H_3$]$ZrCl_2$ and 2 equiv. of MeMgCl. NMR spectroscopy has been used to identify rotameric isomers derived from restricted rotation about the N—C_{ipso} bond of the ligand. The aryl groups in (BPhP)ZrX_2 complexes freely rotate at all temperatures (−80 to +80°C) while (BMPP)ZrX_2 (X = NMe_2, Cl, Me) derivatives adopt *meso* and *rac* rotamers at low temperatures. In contrast, (BMBP)ZrX_2 and (MPPP)ZrX_2 (X = NMe_2, Cl, Me) compounds are locked at all temperatures. (BMBP)$ZrCl_2$ is isolated as a single isomer, likely the *meso* rotamer, while (MPPP)$ZrCl_2$ is a near statistical mixture of *meso* and *rac* isomers. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: zirconium complexes; isomer; rotamer.

Tremendous progress has been made over the past 15 years on the design and preparation of single-site group 4 catalysts for the polymerization of α-olefins [1–3]. Efforts in this area have been concerned with the way in which the catalytic activity and stereoregularity can be altered with changes to the ancillary ligands. For example, the ingeniously designed C_2-symmetric compound *rac*-ethylenebis(η^5-tetrahydroindenyl) $ZrCl_2$ [4] and the left/right C_s-symmetric derivative isopropyl(η^5-Cp-1-η^5-fluorenyl)$ZrCl_2$ [5] are catalyst precursors for the isospecific and syndiospecific polymerization of propylene, respectively. Building upon the structure/property relationship in metallocene complexes, Waymouth and Coates recently reported the details of a new zirconium catalyst that takes advantage of an 'oscillating' ligand environment [6]. The putative cationic complex $[(2\text{-Ph-indenyl})_2ZrP]^+$ (**I**) (P = polymer chain) can adopt one of two possible isomeric structures; a *rac* species which polymerizes propylene in an isospecific manner or a *meso* complex



I

which gives rise to blocks of atactic polypropylene. The interconversion of these species on the polymerization time scale affords stereoblock polypropylene, a thermoplastic elastomer.

Although the metallocene class of compounds have been successful, there is a growing interest in alternative ligand systems; in particular, attention has focused on nitrogen-based ligands [7–13]. For example, chelating diamide complexes of titanium serve as precursors for the highly active [14] and living [15] polymerization of α-olefins. In addition, pyridine diamide complexes of zirconium are active catalysts for the polymerization of ethylene [16]. With the oscillating catalyst tenet in hand, we set out to prepare diamide ligands bearing potentially oscillating aryl substituents at nitrogen. Herein we describe the syn-

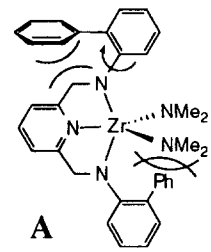
thesis and fluxional behavior of ortho-substituted aryl diamido complexes of zirconium.

RESULTS AND DISCUSSION

2,6-Bis(bromomethyl)pyridine [17] reacts with 2 equiv. of LiNHR (R = 2-PhC_6H_4; 2-$^iPrC_6H_4$; 2-$^tBuC_6H_4$, 2-^{i}Pr-6-MeC_6H_3) in THF at −78°C to afford the pyridine diamine ligands (**1a–d**) in 63–93% yield (Scheme 1).

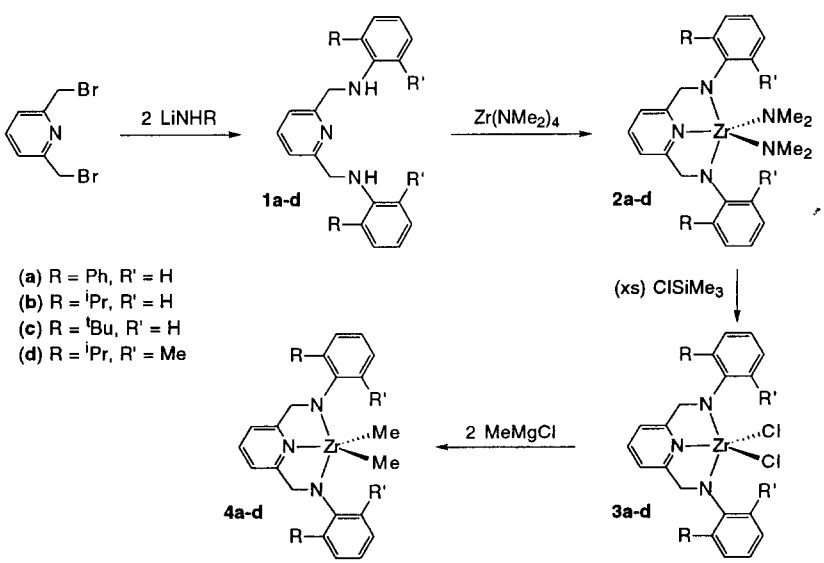
The ligands are white crystalline solids, except **1a** which was isolated as a yellow oil. We have previously reported [16,18] that amine elimination reactions [19] are an excellent method for appending bulky chelating diamide ligands to zirconium. The pyridine diamine ligands **1a–d** react cleanly with $Zr(NMe_2)_4$ [20] at 23°C to afford the mixed amide complexes (**2a–d**) in nearly quantitative yield as evidenced by ^{1}H NMR spectroscopy. The reaction between $Zr(NMe_2)_4$ and the 2-*tert*-butyl substituted ligand **1c** is fast at −80°C, as no intermediates are observed by ^{1}H NMR spectroscopy. These aminolysis reactions are unaffected by the presence of excess dimethylamine [21], hence we observe only the kinetic products. The amide complexes **2a–c** are isolated as yellow solids in >90% yield, however, the high solubility of compound **2d** in hexanes limits its isolation.

The temperature invariant proton NMR spectrum of complex **2a** exhibits a single sharp resonance for the methylene protons of the ligand (CH_2N) and a singlet for the dimethylamido groups. These resonances are consistent with some degree of free rotation about the N—C_{ipso} bond which yields a structure with local C_{2v}-symmetry. Using the X-ray coordinates [16] of $[(RNCH_2)_2NC_5H_3]ZrMe_2$ (R = 2,6-$Et_2C_6H_3$) as a starting point, modelling studies [22] on derivative **2a** predict a large barrier to rotation about the N—C_{ipso} bond when the *o*-phenyl groups pass by the dimethylamido groups (**A**). Therefore, the spectroscopically observed C_{2v}-symmetry likely arises from the *o*-phenyl groups passing by the methylene protons of the ligand backbone. Furthermore, these calculations suggest that the ease of rotation decreases in the following way: *o*-Ph > *o*-^{i}Pr > *o*-^{t}Bu (*vide infra*).



A

The room temperature ^{1}H NMR spectrum of complex **2b** exhibits a single sharp resonance for the methylene protons of the ligand (CH_2N) and a single doublet for the isopropyl methyl groups. Again these resonances are consistent with some degree of free rotation about the N—C_{ipso} bond (C_{2v}-symmetry). The low temperature (−80°C) limiting ^{1}H NMR spectrum of compound **2b** in d_8-toluene shows three $N(CH_3)_2$ resonances in a ratio of 1 : 1 : 1.2. In addition, overlapping resonances are observed for the methylene protons of the ligand (CH_2N—two AB quartets), the isopropyl methyls ($CHMe_2$—four doublets), and the isopropyl methines ($CHMe_2$—two septets). These resonances are in agreement with about a 1.67 : 1 mixture of the C_s-symmetric *meso* and C_2-symmetric *rac* rotameric isomers in solution at −80°C (Fig. 1). The above resonances coalesce at −40°C



Scheme 1.

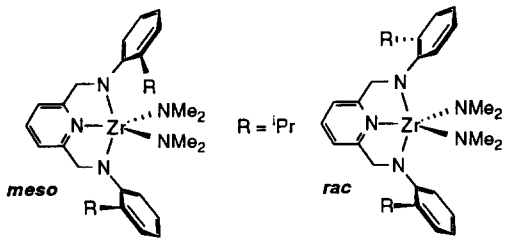


Fig. 1.

yielding a barrier to rotation of the aryl groups of $\Delta G\ddagger = 11.2$ (5) kcal mol^{-1}.

In contrast to both **2a** and **2b**, the room temperature ^{1}H NMR spectrum of compound **2c** shows resonances for two distinct species whose relative intensities do not change from -80°C to $+80$°C. Consistent with the presence of the *rac* isomer is an AB quartet for the ligand methylene protons (CH_2N), a single sharp resonance for the chemically equivalent dimethylamido groups, and a singlet for the equivalent ^{t}Bu groups. In addition to these resonances, the *meso* isomer displays a separate singlet for the ligand methylene protons, two inequivalent dimethylamido resonances, and a singlet for the *tert*-butyl group. Although an AB pattern is expected for the ligand methylene protons, if the chemical shift difference between H_A and H_B is small ($\Delta\nu \leqslant 0.4$ Hz), an apparent singlet is observed [23]. Integration of the $N(CH_3)_2$ groups indicates a *meso*/*rac* ratio of about 2.6 : 1. As noted above, this ratio is unaffected by added dimethylamine. The carbon NMR spectrum of **2c** also shows two species in about a 2.6 : 1 ratio.

Jordan has reported [21] that the reaction of $(EBI)H_2$ [EBI = 1,2-bis(1-indenyl)ethane] with Zr $(NMe_2)_4$ yields $(EBI)Zr(NMe_2)_2$ in a *meso*/*rac* ratio of 1 : 13. However, the reaction of $Me_2Si(C_5H_4$-3-^{t}Bu$)_2$ and $Zr(NMe_2)_4$ yields $[Me_2Si(C_5H_3$-3-^{t}Bu$)_2]Zr(NMe_2)_2$ in a *meso*/*rac* ratio of 2 : 1 [24]. In the latter example the higher *meso* preference is assigned to a lateral deformation of the *ansa* ligand system. We speculate that a similar 'deformation' may occur in these systems whereby the metal adopts a square-based pyramidal (sbp) geometry instead of a trigonal bipyramidal (tbp) confirmation, thus relieving the steric strain associated with the *meso* isomer relative to the *rac* (Fig. 2).

The energy difference between sbp and tbp geometries is expected to be quite small given the d^0 electronic configuration of zirconium. In fact, this change in hybridization has been observed for other

Fig. 2.

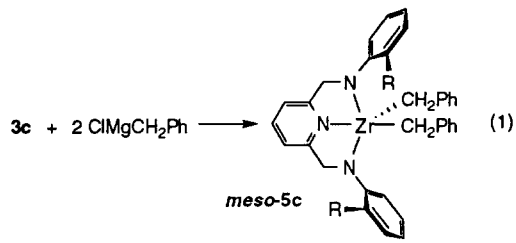
d^0 group 4 complexes bearing the pyridine diamide ligand. The mononeophyl complex $[2,6\text{-}(RNCH_2)_2NC_5H_3]TiBr(CH_2CMe_2Ph)$ (R = 2,6-$Me_2C_6H_3$) [25] displays a sbp geometry in the solid state with the largest group ($-CH_2CMe_2Ph$) occupying the apical position. This geometry minimizes the interaction between the orthomethyl groups of the aryl and the bulky neophyl ligand. We should add that it is not possible to distinguish between the proposed sbp and tbp complexes by NMR spectroscopy since both compounds possess C_s-symmetry.

The proton NMR spectrum of compound **2d**, which bears an isopropyl group in the 2-position and a methyl moiety in the 6-position of the aryl, shows resonances for two rotameric isomers. In this case, there is a slight bias for the *rac* isomer (*meso*/*rac*, 1 : 1.13). The near 1 : 1 correspondence between these species is also observed in the carbon NMR spectrum of **2d**. Given that these species do not interconvert (from -80°C to $+80$°C), even in the presence of excess dimethylamine, suggests that during the aminolysis reaction the aryl groups have little influence on one another; in other words, a near statistical distribution of isomers is produced.

The mixed amide complexes **2a–d** react with excess $ClSiMe_3$ to afford the dichloride derivatives (**3a–d**) in 80–96% isolated yield (Scheme 1). Upon addition of $ClSiMe_3$ the solutions turn black which we attribute to minor impurities given the high isolated yields. The orthophenyl substituted complex **3a** displays limited solubility in common organic solvents. The ^{1}H NMR spectrum of **3a** shows a sharp singlet for the ligand methylene protons (CH_2N), consistent with rapid rotation about the N—C_{ipso} bond. The proton NMR spectrum of **3b** at 23°C shows broad featureless resonances for the methylene (CH_2N), the isopropyl methine, and the isopropyl methyl protons of the ligand. At temperatures above $+60$°C the spectrum is consistent with rapid rotation of the aryl group. The low temperature (-60°C) limiting spectrum of **3b** displays resonances for the two rotamers in a ratio of about 2 : 3, however, it is not possible to discern which isomer predominates since the spectra of C_s- and C_2-symmetric compounds are indistinguishable (requires NMR active groups in the equatorial plane of a tbp). In this case the barrier to aryl group rotation is $\Delta G\ddagger = 13.8$ (5) kcal mol^{-1}.

The *meso*/*rac* ratio in the mixed amide complex **2c** is 2.6 : 1. Interestingly, upon reaction with excess $ClSiMe_3$ a single isomer of the dichloride complex **3c** is formed. We have followed this reaction by ^{1}H NMR spectroscopy and found that no other products are formed. It is not possible to determine which isomer is present, however, the following results suggest that the *meso* rotamer is formed preferentially. The reaction of **3c** with two equiv. of $PhCH_2MgCl$ yields the *meso* dibenzyl complex (**5c**) in quantitative yield by proton NMR spectroscopy [eq. (1)].

The ^{1}H NMR spectrum of **5c** shows a single AB quartet for the ligand methylene protons (CH_2N),



one *tert*-butyl resonance, and two benzyl resonances ($ZrCH_2Ph$); all in accordance with the presence of the *meso* isomer. Compound **5c** can also be prepared from $Zr(CH_2Ph)_4$ [26] and ligand **1c**. As noted above, a sbp geometry in compound **5c** would reduce the steric interactions between the benzyl groups and the *tert*-butyl groups. The monoalkyl derivatives [2,6-$(RNCH_2)_2NC_5H_3$]ZrClR′ and (R = 2-^{t}BuC$_6$H$_4$; R′ = CH_2CMe_2Ph, CH_2SiMe_3), prepared from compound **3c** and the corresponding alkylating reagent, also display resonances associated with only the *meso* isomer [27].

As expected, the proton NMR spectrum of compound **3d** displays resonances for two rotamers in a ratio of about 1 : 1.15. It would appear that no change in the isomeric ratio, within limits of detection, takes place during the metathesis reaction with $ClSiMe_3$. Furthermore, no change in this ratio is observed upon heating to 80°C.

The dichloride complexes **3a–c** react with 2 equiv. of methyl Grignard to afford the dimethyl derivatives (**4a–c**) in 67–85% yield as white crystalline solids (Scheme 1). The spectroscopic data for the Zr–Me groups is consistent with other related dimethyl species [17]. The proton NMR spectrum of the 2-phenylaryl substituted complex **4a** displays resonances for a single C_{2v}-symmetric species down to −80°C.

The 2-isopropylaryl substituted complex **4b** exhibits fluxional behavior. A stacked plot of a portion of the ^{1}H NMR spectrum of complex **4b** at several temperatures is shown in Fig. 3. The spectrum at 23°C displays a singlet at 4.84 ppm for the ligand methylene protons (CH_2N), a septet at 3.57 ppm for the isopropyl methine ($CHMe_2$), a doublet at 1.31 ppm for the chemically equivalent isopropyl methyl groups ($CHMe_2$), and a singlet for the Zr–Me_2 groups at 0.46 ppm. The low temperature limiting spectrum (−60°C) shows an AB quartet for the ligand methylene protons, a broad resonance for the isopropyl methine, a broad pattern for the isopropyl methyl groups, and three broad zirconium methyl resonances in a ratio of 1 : 1.3 : 1. We assign these resonances to a *meso/rac* mixture in a ratio of 1.5 : 1. The above resonances coalesce at −20°C yielding a barrier to rotation of the aryl groups of $\Delta G‡ = 12.0$ (5) kcal mol^{-1}.

The reaction of **3c** with bulky alkylating reagents affords exclusively *meso* type complexes (*vide supra*). Interestingly, the reaction of **3c** with two equiv. of methyl Grignard yields a mixture of rotameric isomers

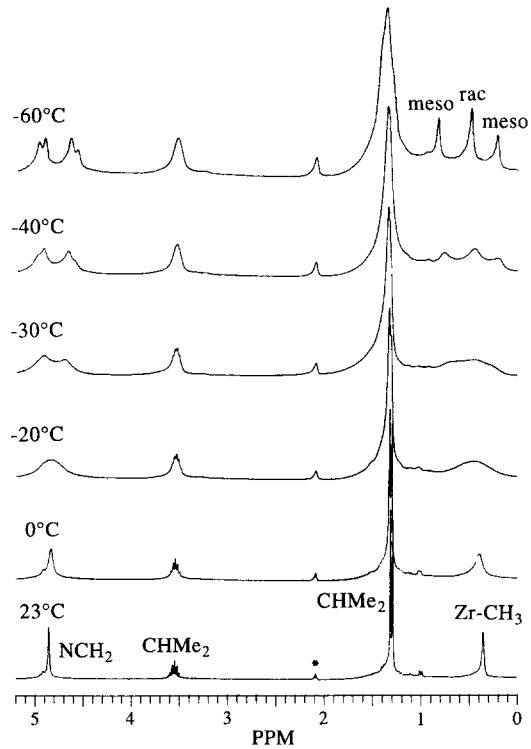


Fig. 3. Variable temperature ^{1}H NMR spectra of **4b** in d_8-toluene (* denotes solvent).

in a ratio of about 3 : 1 (*meso/rac*). The temperature invariant (−80°C to +80°C) ^{1}H NMR spectrum of **4c** shows two slightly off-centred AB quartets for the ligand methylene protons, two *tert*-butyl resonances, and three Zr–*Me* singlets (ratio, 1.5 : 1 : 1.5). Interestingly, the 2-*tert*-butyl substituted ligand appears to isomerize readily under metathetical type conditions, yet is stable to such processes under thermal conditions. We are currently examining the details of the transformation. Consistent with the lack of rotation in the 2,6-disubstituted aryl complexes [17,26], the dimethyl compound **4d** shows the same *meso/rac* ratio (1 : 1.14) as does the dichloride precursor **3d**.

EXPERIMENTAL

General details

All experiments were performed under a dry nitrogen atmosphere using standard Schlenk Techniques or in an Innovative Technology Inc. glovebox. Solvents were distilled from sodium/benzophenone ketyl (THF, hexanes, diethylether) or molten sodium (toluene). 2-Isopropylaniline, 2-*tert*-butylaniline, 2-phenylaniline, and 2-isopropyl-6-methylaniline were purchased from Aldrich and distilled under reduced pressure before use. MeMgCl and $ZrCl_4$ were purchased from Aldrich and used as received. 2,6-

Bis(bromomethyl)pyridine was prepared using previously reported synthesis [18]. Unless otherwise specified, proton (300 MHz) and carbon (75.46 MHz) NMR spectra were recorded in C_6D_6 at approximately 23°C on a Varian 300-XL spectrometer. The proton chemical shifts were references to internal C_6D_5H ($\delta = 7.15$ ppm) and the carbon resonances to C_6D_6 ($\delta = 128.0$ ppm). Some resonances are obscured by C_6D_6 and/or are overlapping. The elemental analysis were performed using sealed tin cups on a Fisons Instruments model 1108 elemental analyzer by Mr Peter Borda of this department. The following abbreviations for the ligands are used: 2,6-$(RHNCH_2)_2$ NC_5H_3 ($(BPhP)H_2$, R = 2-PhC_6H_4; $(BMPP)H_2$, R = 2-$^i PrC_6H_4$; $(BMBP)H_2$, R = 2-$^t BuC_6H_4$, $(MPPP)H_2$, R = 2-^{i}Pr-6-MeC_6H_3).

(BPhP)H$_2$ (**1a**). A THF (150 cm^3) solution of LiNHR (5.144 g, 29.4 mmol) was added slowly to a stirring THF (100 cm^3) solution of 2,6-bis(bromomethyl)pyridine (3.890 g, 14.7 mmol) at −78°C. The mixture was warmed to room temperature and stirred for 12 h. The solution was quenched with a saturated $NaHCO_3$ solution (100 cm^3) and extracted with dichloromethane. The solvent was removed *in vacuo* to give a yellow oil (**1a**) which was used as isolated (6.000 g, 13.6 mmol, 93%). ^{1}H NMR δ 7.50 (d, 4H, m Ar/Ph), 7.09–7.40 (m, 10H, Ar/Ph), 6.97 (t, 1H, py), 6.80 (t, 2H, Ar/Ph), 6.73 (d, 2H, Ar/Ph), 6.60 (d, 2H, Ar), 5.15 (t, 2H, N*H*), 4.08 (d, 4H, NCH_2). ^{13}C{^{1}H} δ 158.28, 145.17, 140.31, 136.79, 130.61, 129.84, 129.16, 128.17, 127.39, 119.27, 117.64, 111.26, 49.25. MS (EI) *m/z* 441.220 (M^+). Calcd for $C_{31}H_{27}N_3$: 441.220.

(BMPP)H$_2$ (**1b**). The preparation of compound **1b** is identical to **1a** except for the work up. LiNHR (5.335 g, 37.4 mmol) and 2,6-bis(bromomethyl)pyridine (5.000 g, 18.9 mmol) yield a white solid. The solid was dissolved in a minimal amount of an ether, hexanes added until the solution is cloudy, and cooled to −30°C. A white crystalline solid (**1b**) was isolated by filtration and dried under vacuum (4.500 g, 12.0 mmol, 63%). ^{1}H NMR δ 7.18 (dd, 2H, Ar), 7.11 (dd, 2H, Ar), 6.97 (m, 1H, py), 6.84 (td, 2H, Ar), 6.77 (d, 2H, py), 6.62 (dd, 2H, Ar), 4.77 (br s, 2H, N*H*), 4.29 (s, 4H, NCH_2), 2.87 (sept, 4H, C*H*Me$_2$), 1.23 (d, 12H, CH*Me*$_2$). ^{13}C{^{1}H} δ 158.68, 144.98, 136.94, 132.43, 127.21, 125.31, 119.77, 118.09, 111.33, 49.61, 27.70, 22.49. MS (EI) *m/z* 373.252 (M^+). Calcd for $C_{25}H_{31}N_3$: 373.252.

(BMBP)H$_2$ (**1c**). The preparation of compound **1c** is identical to **1b**. LiNHR (5.865 g, 37.8 mmol) and 2,6-bis(bromomethyl)pyridine (5.000 g, 18.9 mmol) gave **1c** as a white crystalline solid (5.820 g, 14.4 mmol, 76%). ^{1}H NMR δ 7.35 (d, 2H, Ar), 7.16 (dd, 2H, Ar), 7.02 (td, 1H, py), 6.84 (d, 2H, Ar), 6.82 (t, 2H, py), 6.628 (d, 2H, Ar), 4.24 (broad s, 2H, NH), 4.32 (s, 4H, NCH_2), 1.49 (s, 18H, *t*-Bu). ^{13}C{^{1}H} δ 158.39, 146.24, 137.04, 133.55, 54.52, 55.33, 54.48, 56.22, 49.82, 34.41, 30.08. MS (EI) *m/z* 401.283 (M^+). Calcd for $C_{27}H_{35}N_3$: 401.283.

(MPPP)H$_2$ (**1d**). The preparation of compound **1d** is identical to **1b**. LiNHR (7.750 g, 49.9 mmol) and 2,6-bis(bromomethyl)pyridine (5.000 g, 18.9 mmol) gave **1d** as a white crystalline solid (4.910 g, 12.2 mmol, 65%). ^{1}H NMR δ 7.13 (d, 2H, Ar), 7.00–7.03 (m, 5H, py/Ar), 6.75 (d, 2H, py), 4.34 (s, 2H, N*H*), 4.18 (s, 4H, NCH_2), 3.45 (sept, 2H, C*H*Me$_2$), 2.31 (s, 6H, Me), 1.21 (d, 12H, CH*Me*$_2$). ^{13}C{^{1}H} δ 159.01, 145.46, 141.45, 136.75, 131.21, 128.88, 124.13, 123.39, 120.29, 55.33, 27.99, 24.16, 19.03. MS (EI) *m/z* 401.283 (M^+). Calcd for $C_{27}H_{35}N_3$: 401.283.

(BPhP)Zr(NMe$_2$*)*$_2$ (**2a**). A toluene solution of $Zr(NMe_2)_4$ (3.635 g, 13.6 mmol) was added to a toluene solution (50 cm^3) of **1a** (6.000 g, 13.6 mmol) and stirred for 12 h. The solvent was removed *in vacuo* and the resulting solid extracted with hexanes (3 × 50 cm^3) and filtered through Celite. The volume of the filtrate was reduced and the solution cooled to −30°C, affording **2a** as a yellow crystalline solid (7.715 g, 12.5 mmol, 92%). ^{1}H NMR δ 7.74 (d, 2H, Ar/Ph), 7.71 (d, 2H, Ar/Ph), 7.32–7.36 (m, 4H, Ar/Ph), 6.98–7.11 (m, 8H, Ar/Ph), 6.56 (t, 1H, py), 6.00 (d, 2H, py), 4.66 (s, 4H, NCH_2), 2.94 (s, 12H, N*Me*$_2$). ^{13}C{^{1}H} δ 164.67, 153.33, 143.59, 137.46, 135.30, 131.95, 128.45, 128.32, 128.196, 127.76, 126.34, 122.55, 116.93, 63.29, 41.92.

(BMPP)Zr(NMe$_2$*)*$_2$ (**2b**). The preparation of compound **2b** is identical to **2a**. $Zr(NMe_2)_4$ (2.150 g, 8.03 mmol) and **1b** (3.000 g, 8.03 mmol) gave **2b** as a yellow crystalline solid (4.100 g, 7.44 mmol, 93%). ^{1}H NMR δ 7.41 (dd, 2H, Ar), 7.32 (dd, 2H, Ar), 7.21 (td, 2H, Ar), 1.11 (td, 2H, Ar), 8.87 (t, 1H, py), 6.42 (d, 2H, py), 4.93 (s, 4H, NCH_2), 3.53 (sept, 4H, C*H*Me$_2$), 2.76 (s, 12H, NMe$_2$), 1.29 (d, 12H, CH*Me*$_2$). ^{13}C{^{1}H} δ 164.64, 152.91, 145.71, 137.59, 129.27, 126.32, 126.14, 124.04, 117.34, 67.26, 42.03, 27.29, 25.23.

(BMBP)Zr(NMe$_2$*)*$_2$ (**2c**). The preparation of compound **2c** is identical to **2a**. $Zr(NMe_2)_4$ (2.150 g, 8.04 mmol) and **1c** (3.000 g, 8.03 mmol) gave **2c** a yellow crystalline solid (3.987 g, 7.24 mmol, 90%). The following data is for both rotamers (*meso*/*rac*, 2.6 : 1). ^{1}H NMR δ 7.48 (t, Ar), 7.24 (t, Ar), 7.07 (t, Ar), 6.90 (t, py), 6.49 (d, py), 4.91 (s, *meso* NCH_2), 4.90 (AB quartet, $^2J_{HH}$ = 20.0 Hz, *rac* NCH_2), 3.01 (s, *meso* N*Me*$_2$), 2.65 (s, *rac* N*Me*$_2$), 2.42 (s, *meso* N*Me*$_2$), 1.57 (s, *rac* C*Me*$_3$), 1.51 (s, *meso* C*Me*$_3$). ^{13}C{^{1}H} δ 163.88, 163.14, 156.07, 154.46, 146.67, 137.73, 132.32, 132.12, 128.90, 127.94, 126.95, 126.76, 124.30, 123.73, 117.25, 68.40, 43.25, 42.15, 41.05, 36.56, 32.64, 32.41.

(MPPP)Zr(NMe$_2$*)*$_2$ (**2d**). The preparation of compound **2d** is identical to **2a**. $Zr(NMe_2)_4$ (2.671 g, 10.0 mmol) and **1d** (4.010 g, 10.0 mmol) gave **2d** as a yellow crystalline solid (3.090 g, 5.34 mmol, 54%). The following data is for both rotamers (*meso*/*rac*, 1 : 1.13). ^{1}H NMR δ 7.23–7.27 (m, Ar/Ph), 7.05–7.16 (m, Ar/Ph), 6.93 (t, py), 6.48 (d, py), 4.68 (AB quartet, $^2J_{HH}$ = 20.3 Hz, *rac* NCH_2), 4.65 (AB quartet, $^2J_{HH}$ = 20.3 Hz, *meso* NCH_2), 4.00 (sept, *meso* C*H*Me$_2$), 3.82 (sept, *rac* C*H*Me$_2$), 2.88 (s, *meso* N*Me*$_2$), 2.57 (s, *rac* N*Me*$_2$), 2.32 (s, *rac* Me), 2.30 (s, *meso* N*Me*$_2$), 2.19 (s, *meso* Me), 1.39 and 1.38 (d, *meso*

CHMe_2), 1.32 and 1.29 (d, *rac* CHMe_2). $^{13}C\{^1H\}$ δ 164.12, 163.81, 152.39, 152.12, 146.41, 146.38, 137.60, 137.54, 135.37, 135.10, 123.86, 123.77, 117.25, 65.06, 64.92, 42.59, 41.33, 40.08, 27.64, 26.92, 26.76, 24.28, 24.04, 19.16, 19.07.

(*BPhP*)$ZrCl_2$ (**3a**). Excess $ClSiMe_3$ (2 cm^3) was added dropwise to a toluene solution (50 cm^3) of compound **2a** (2.315 g, 3.74 mmol) at 23°C. The solution was stirred for 12 h during which time **3a** precipitated as a beige solid. Hexanes (100 cm^3) was added and the solution was cooled to −30°C for 12 h. The solid was isolated by filtration and dried under vacuum (2.152 g, 3.57 mmol, 96%). ^1H NMR δ 8.44 (d, 2H, Ph), 7.80–7.90 (m, 4H, Ph), 6.90–7.40 (m, 12H, Ar/Ph), 6.39 (t, 1H, py), 5.84 (d, 2H, py), 4.54 (s, 4H, NCH_2). Compound **3a** is poorly soluble in organic solvents which precludes its convenient characterization by $^{13}C\{^1H\}$ NMR.

(*BMPP*)$ZrCl_2$ (**3b**). The preparation of compound **3b** is identical to **3a**. Excess $ClSiMe_3$ (2 cm^3) and **2b** (1.500 g, 2.72 mmol) affords **3b** as a beige solid (1.190 g, 2.23 mmol, 82%). ^1H NMR δ 7.98 (br d, 2H, Ar), 7.29 (m, 2H, Ar), 7.15 (m, 4H, Ar), 6.89 (t, 1H, py), 6.34 (d, 2H, py), 4.73 (br s, 4H, NCH_2), 3.48 (br sept, 4H, C*H*Me_2), 1.33 (br s, 12H, CHMe_2). $^{13}C\{^1H\}$ (d_8-toluene, 80°C) δ 164.31, 147.20, 146.33, 138.63, 130.34, 127.41, 127.33, 126.74, 117.71, 69.32, 27.60, 25.01.

(*BMBP*)$ZrCl_2$ (**3c**). The preparation of compound **3c** is identical to **3a**. Excess $ClSiMe_3$ (2 cm^3) and **2c** (1.000 g, 1.73 mmol) affords **3c** as a beige solid (0.860 g, 1.54 mmol, 89%). ^1H NMR δ 7.95 (d, 2H, Ar), 7.47 (d, 2H, Ar), 7.18 (m, 4H, Ar), 6.81 (t, 1H, py), 6.34 (d, 2H, py), 4.78 (AB quartet, $^2J_{HH}$ = 20.1 Hz, 4H, NCH_2), 1.47 (s, 18H, *t*-Bu). $^{13}C\{^1H\}$ δ 162.66, 147.23, 146.05, 138.79, 131.46, 131.01, 127.46, 127.16, 117.76, 70.21, 37.09, 33.31.

(*MPPP*)$ZrCl_2$ (**3d**). The preparation of compound **3d** is identical to **3a**. Excess $ClSiMe_3$ (2 cm^3) and **2d** (1.700 g, 2.94 mmol) affords **3d** as a beige solid (1.327 g, 2.36 mmol, 80%). The following data is for both rotamers (*meso*/*rac*, 1:1.15). ^1H NMR (CD_2Cl_2) δ 8.04 (t, py), 7.52 (d, py), 7.09–7.25 (m, Ar), 5.06 (AB quartet $^2J_{HH}$ = 21.3 Hz, NCH_2), 5.05 (AB quartet $^2J_{HH}$ = 21.3 Hz, NCH_2), 3.56 (sept, C*H*Me_2), 3.48 (sept, C*H*Me_2), 2.35 (s, Me), 2.31 (s, Me), 1.35 (d, CHMe_2), 1.32 (d, CHMe_2), 1.18 (d, CHMe_2), 1.16 (d, CHMe_2). $^{13}C\{^1H\}$ NMR ($CDCl_2$) δ 164.16, 164.12, 147.52, 147.38, 145.22, 145.19, 141.53, 139.92, 136.18, 136.05, 129.33, 128.74, 128.70, 128.51, 127.41, 126.87, 125.59, 125.21, 124.77, 118.74, 67.20, 67.16, 28.03, 27.91, 27.73, 27.54, 23.81, 23.42, 19.50, 19.46.

(*BPhP*)$ZrMe_2$ (**4a**). MeMgCl (3.70 cm^3, 0.99 M, 3.67 mmol) were added to a CH_2Cl_2 (25 cm^3) solution of compound **3a** (1.000 g, 1.66 mmol) at −78°C. The mixture was stirred for 12 h and then the solvent removed *in vacuo*. The resulting solid was extracted with toluene and filtered through Celite. The solvent was removed *in vacuo* and the remaining solid dissolved in a minimum amount of CH_2Cl_2 and cooled to −30°C for 12 h. **4a** was isolated as a white crystalline solid and dried under vacuum (0.625 g, 1.11 mmol, 67%). ^1H NMR δ 8.10 (d, 2H, Ph), 7.73 (d, 4H, Ph), 7.38 (d, 2H, Ar/Ph), 7.28–7.31 (m, 2H, Ar/Ph), 7.08–7.15 (m, 6H, Ar/Ph), 6.99 (m, 2H, Ar/Ph), 6.49 (t, 1H, py), 5.93 (d, 2H, py), 4.62 (s, 4H, NCH_2), 0.73 (s, 6H, Zr-*Me*). $^{13}C\{^1H\}$ NMR δ 164.02, 148.94, 142.66, 137.59, 136.82, 133.01, 129.06, 128.68, 128.49, 128.17, 126.84, 125.21, 116.97, 64.51, 42.38 (Zr-*C*H_3). Anal. Calcd for $C_{33}H_{31}N_3Zr$: C, 70.67; H, 5.57; N, 7.49. Found: C, 70.60; H, 5.55; N, 7.19.

(*BMPP*)$ZrMe_2$ (**4b**). MeMgCl (0.78 cm^3, 3.0 M, 2.35 mmol) was added to a diethylether (23 cm^3) solution of compound **3b** (0.500 g, 0.94 mmol) at 23°C. The mixture was stirred for 12 h and then the solvent removed *in vacuo*. The resulting solid was extracted with toluene and filtered through Celite. The solvent was removed *in vacuo* and the remaining solid dissolved in a minimum amount of diethylether and cooled to −30°C for 12 h. **4b** was isolated as a white crystalline solid and dried under vacuum (0.445 g, 0.90 mmol, 85%). ^1H NMR δ 7.69 (m, 2H, Ar), 7.36 (m, 2H, Ar), 7.20 (m, 4H, Ar), 6.87 (t, 1H, py), 6.38 (d, 2H, py), 4.84 (s, 4H, NCH_2), 3.57 (sept, 4H, C*H*Me_2), 1.31 (d, 12H, CHMe_2), 0.46 (br s, 6H, Zr-*Me*). $^{13}C\{^1H\}$ NMR δ 164.02, 148.50, 147.54, 131.08, 129.27, 127.21, 127.67, 126.29, 117.35, 58.31, 41.23 (Zr-*C*H_3), 27.25, 25.39. Anal. Calcd for $C_{27}H_{35}N_3Zr$: C, 65.81; H, 7.16; N, 8.53. Found: C, 66.03; H, 7.18; N, 8.68.

(*BMBP*)$ZrMe_2$ (**4c**). The preparation of compound **4c** is identical to **4b**. MeMgCl (0.52 cm^3, 3.0 M, 1.55 mmol) and **3c** (0.350 g, 0.62 mmol) gave **4c** as a white crystalline solid (0.234 g, 0.45 mmol, 73%). The following data is for both rotamers (*meso*/*rac*, 3:1). ^1H NMR δ 7.78 (d, Ar), 7.54 (d, Ar), 7.20 (m, Ar), 6.87 (t, py), 6.43 (d, py), 4.91 (AB quartet, $^2J_{HH}$ = 20.7 Hz, *meso* NCH_2), 4.83 (AB quartet, $^2H_{HH}$ = 20.7 Hz, *rac* NCH_2), 1.55 (s, *rac t*-Bu), 1.49 (s, *meso t*-Bu), 0.82 (s, *meso* Zr-Me), 0.62 (s, *rac* Zr-Me), 0.26 (s, *meso* Zr-Me). $^{13}C\{^1H\}$ NMR δ 163.66, 163.21, 149.43, 147.18, 137.90, 133.98, 132.75, 130.93, 127.06, 126.92, 126.02, 125.88, 117.47, 70.03, 69.71, 45.71 (Zr-CH_3), 44.73 (Zr-*C*H_3), 39.57, 37.18, 33.34. CONCLUSIONS

A series of ortho-substituted aryl diamide complexes of zirconium have been prepared in high yield. Depending on the size of the ortho substituent on the aryl group, rotameric isomers, derived from restricted rotation about the N—C_{ipso} bond, can be observed spectroscopically and the barriers to isomerization measured. In the case of the 2-phenylaryl moiety, rapid isomerization is observed at all temperatures regardless of the substituents bound to zirconium in the equatorial plane. The 2-isopropylaryl substituted complexes exhibit fluxional behavior with the low temperature limiting ^{1}H NMR spectra showing resonances for species consistent with *meso* and *rac* rotamers. In contrast, the 2-*tert*-butylaryl derivatives are 'locked' as five coordinate species but can isomerize during metathesis reactions at the metal center. The 2-isopropyl-6-methyl complexes are also locked, however, the rotameric ratios remain the same in all derivatives of this ligand system. We are currently studying the α-olefin polymerization chemistry of these and other complexes.

(Received 11 June 1997)

Abstract—The elaboration of monophasic organic inorganic hybrid materials is an important extension of metal alkoxide chemistry. These solids are obtained by hydrolytic polycondensation from a molecular precursor containing -Si(OR)$_3$ groups (at least two) covalently bound to an organic moiety. Using solid state ^{13}C NMR it is possible to demonstrate that, in all cases studied until now, the organic units are bound to the oxide matrix after hydrolysis. ^{29}Si permits the evaluation of the degree of polycondensation. All the solids obtained are kinetically controlled: their texture is highly dependent on all the parameters governing the kinetics of polycondensation (catalyst, temperature, solvent, concentrations, etc.). It is also possible to demonstrate that the geometry of the organic molecule is an important factor for both the texture and the short range organization of the solid. Weak interactions (charge transfer complexes) have been evidenced as possible controlling parameters for the solid formation. Short range organization in the hybrid material can be demonstrated using the easy polymerisation of bisacetylenic units which has been observed by heating the solid formed by hydrolytic polycondensation of [(MeO)$_3$Si]$_2$C$_4$.

The relationship between the porosity formed in the solid after elimination of the organic unit and the size of this unit was considered. A mild selective cleavage for Si—C bonds has been found and used for eliminating the organic moiety. After cleaving and recovering the organic molecule a monodispersed porosity is observed. However, there is no relation between the size of the pores and the size of the molecule. This fact is certainly due to a reorganization of the solid occurring during the Si—C bond cleavage. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: monophasic hybrid materials; kinetic control of solid formation; shortage organisation; rearrangement of the solid.

The elaboration of solids by sol–gel is one of the natural extensions of metal alkoxide chemistry [1–3]. This way permits access to materials through a very simple one pot procedure summarized in Scheme 1. The molecular precursor undergoes an inorganic polymerization which leads to a highly crosslinked solid through a hydrolytic polycondensation of which the two first steps are:

(i) The nucleophilic attack of water at the metal which can be catalyzed (or not), the possible catalysts being acids, bases, or nucleophiles.

(ii) The condensation reaction which corresponds to the M—O—M bond formation and which can occur either via a homo or a hetero condensation [1–3].

The process is highly complex when polysubstitutions and polycondensations are occurring. These reactions are in competition with redistribution reactions. Moreover they can lead either to cyclic or linear oxide units. In the case of silica, generally considered as the most simple [1–4], Scheme 2 presents some of the possibilities [5]. It is interesting to point out the complexity of these processes and also the lack of basic knowledge of the kinetics where polyfunctional metals are involved. For instance in the case of silicon, the kinetics of monofunctional alkox-

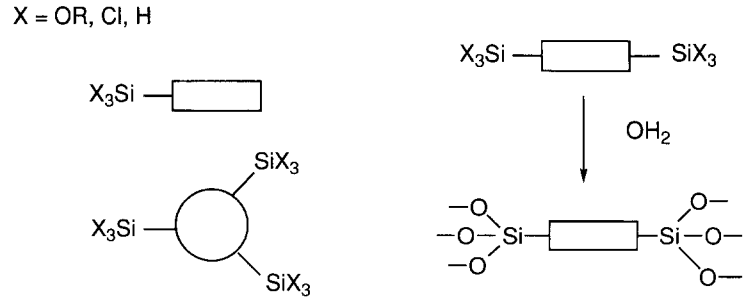
ysilane R_3SiOR are known [6]. However the only reliable results concerning the relative successive rates of Si—OR hydrolysis in $Si(OR)_4$ were reported only recently by Chojnowski *et al.* [7].

Although the fundamental knowledge is poor, the sol–gel route nevertheless remains very attractive because of the very convenient access to the solid, and because of the wide possibilities opened by this method.

The organic–inorganic hybrid materials is one of them [8]. This new class of solids corresponds to a new field of investigations growing up very quickly [9] and opening the elaboration of new materials. This review will be limited to our recent interest devoted to the study of the *monophasic* organic–inorganic hybrid solids [10].

These kind of hybrids are formed by organic units bound to an inorganic matrix by at least one metal carbon covalent bond. They are obtained with precursors from which the inorganic matrix can be built up around the organic moiety through the hydrolytic polycondensation as illustrated in Scheme 3 [8–10].

Obviously the number of metals which permit this polycondensation with conservation of the covalent metal–carbon bonds is limited. For example, Si, P, Ge, As, B, Sn are opening possibilities. However between them, silicon seems to be the most convenient from many aspects: well known chemistry [6], stability of Si—C bond, well documented sol–gel methodology [1–2], facility of identification and commercially available starting reagents.



Scheme 3.

Identification of the solids

The preparation of solids is performed by hydrolytic polycondensation from a molecular precursor containing SiX_3 groups covalently bound to an organic unit [10–21]. The inorganic matrix is built up around the organic moieties by polycondensation of SiX_3.

In all cases studied until now, it is possible to demonstrate, by use of ^{13}C solid state NMR, that the organic structure is maintained during the solid's formation procedure, without Si—C bond cleavage. This cleavage should be detected by modification of both the ^{13}C and ^{29}Si signals. In this last case, the formation of Q units in the range of -100 to -110 ppm could be observed. It is also possible to estimate the degree of polycondensation around silicon by ^{29}Si NMR [8f–10b]. One illustrative example is given in the case of polycondensation of precursor A and B [17–19] (Fig. 1).

Table 1 lists most the organic spacer which have been studied until now.

Kinetic control of the solid

It is very important to point out that the texture* of all the solids obtained is kinetically controlled. This means that all parameters which can modify the kinetics of the polycondensation process are of importance for the nature of the material elaborated. It is possible to demonstrate that BET and porosity of the solids obtained from the same precursor, are highly sensitive to all the parameters able to modify the kinetics of polycondensation (nature of the leaving group, solvent, concentration of the reagents, catalyst temperature, etc.). A few examples are given in Table 2 [11–19].

The nature of the organic units can also be a drastic parameter. The comparison of the solids obtained from the polycondensation performed in the same experimental conditions from the two spacers represented in the Scheme 4 is well illustrated [17–19].

With the rigid spacer ($n = 0$), a hydrophilic solid is obtained instead of a hydrophobic one with the more flexible ($n = 2$). In this last case, the organic groups are located at the surface, in agreement with both the reactivity observed towards $Cr(CO)_6$, and with the mass peaks detected by SIMS (Secondary Ion Mass Spectrometry) [22] which are characteristic of phenyl (77) and tolyl (91) and which do not exhibit any SiOH (45). In contrast, the rigid spacer exhibits very poor reactivity in accordance with the hydrophilicity observed and the results of SIMS. The phenyl groups are not chemically accessible. They cannot be detected by SIMS, only SiOH (45) is observed at the surface of the solid.

The experiments described show that the nature of the organic spacer is an important factor in the control of the formation of the solid in the polycondensation reaction. They suggest that interactions between the organic units might play an important role in the formation of the solid. Two obvious conclusions can be revealed from this assumption. If this hypothesis is correct, weak interactions should be able to modify the nature of the solid. Moreover, the possible interactions between the organic spacers during the formation of the solid might induce a short range organisation between the organic units. These two points will be illustrated.

Weak interactions and solid organisation

The great influence of the weak interactions can be evidenced by studying the effect of charge transfer complexes on the solid formation. It is known that terthiophene and TCNQ can form such complexes [29]. We have used this weak interaction in order to consider its influence on the formation on monophasic hybrid solids. As illustrated in Scheme 5 bis(trimethoxylsilyl) terthiophene (**I**) is giving a charge complex (**II**) with TCNQ [14]. By cohydrolysis with $Si(OMe)_4$, a solid (**III**) is obtained which exhibits a poor specific surface (6 $m^2\ g^{-1}$), a visible absorption similar to (**II**) and a higher conductivity (10^{-6} s cm^{-1} instead of 10^{-10}). The absorption spectrum provides

*The texture of the solid is the sum of the macroscopic parameters which permits the identification = density, specific surface area (BET), volume and nature of porosity, granulometry, etc....

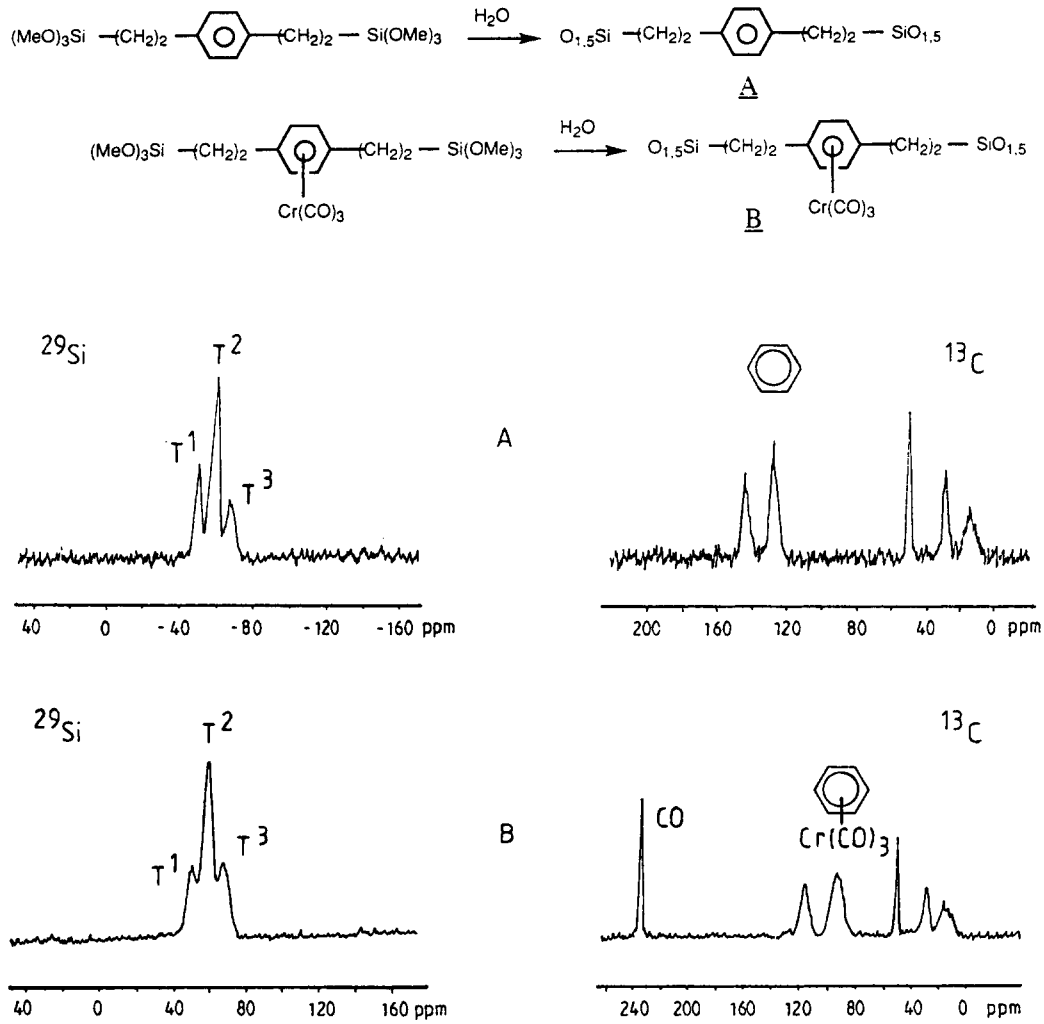


Fig. 1. ^{29}Si and ^{13}C NMR features observed before (A) and after complexation (B) with $Cr(CO)_3$.

evidence that the charge transfer complex is maintained in the solid. Washing with ether–acetone mixture, we observe the disappearance of both conductivity and visible spectrum corresponding to the destruction of the charge transfer complex [14]. This experiment illustrates how weak this interaction is since a washing permits its elimination. It is interesting to compare the BET measured on (**III**) and (**IV**) (6 and 9 $m^2\ g^{-1}$ respectively) with the value of the solid (**IV'**) (566 $m^2\ g^{-1}$) obtained from hydrolytic polycondensation performed on (**I**) in the same experimental conditions.

The two solids (**IV**) and (**IV'**) have the same IR and NMR features but are corresponding to two different arrangements in the solid.

A possible short range organisation in the solid

For the detection of possible short range organisation in the solid, diyne units have been chosen because of their very selective reactivity. The polymerization of the diacetylene groups occurs topochemically [24–26], that is, a particular arrangement of the triple bonds with respect to one another is required. As illustrated in Scheme 6, the 1–4 addition, leading to enyne formation, requires the diacetylene units to be parallel to each other [27].

Gels containing diacetylene units have been prepared from 1,4-bis(trimethoxy-silyl)buta-1,3 diyne. These solids exhibit the NMR and IR features of the starting precursor: ^{13}C NMR $\delta = 79.4$ and 87.8 *C*—*C*≡*C*—Si, IR: $\nu = 2202$ and 2091 cm^{-1}. After heating at 200°C under argon, the formation of enynes and the associated crosslinking in the solid was detected by spectroscopy (^{13}C NMR $\delta = 133$, ^{29}Si NMR; $\delta = -74$, IR $\nu = 2169\ cm^{-1}$) [28]. Moreover, the same spectroscopic features were found regardless of whether gelation was performed before the crosslinking (route A) or whether the crosslinking was induced by irradiation before the gelation (route B) (Scheme 7).

It is interesting to compare this polymerization with the crosslinking observed in the case of polymers $[—SiR_2—C{\equiv}C—C{\equiv}C—]_n$ for which the DTA curve

is highly dependent on the organization in the solid [27]. In the DTA curve of crystalline polymers of this type (R = Me, Et), a sharp peak occurs at 200°C that can be attributed to the crosslinking reaction. In contrast, the poor crystalline (R≡Ph) or non-crystalline polymers (R≡$SiMe_3$) are crosslinked only between 250 and 350°C. In the case of gels, the crosslinking reaction starts at lower temperatures as shown in Fig. 2. The DTA curve exhibits an exothermic transformation between 120 and 350°C with a maximum at 250°C.

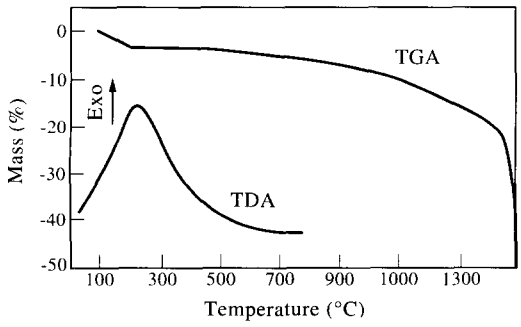

Fig. 2. TDA and TGA curves observed.

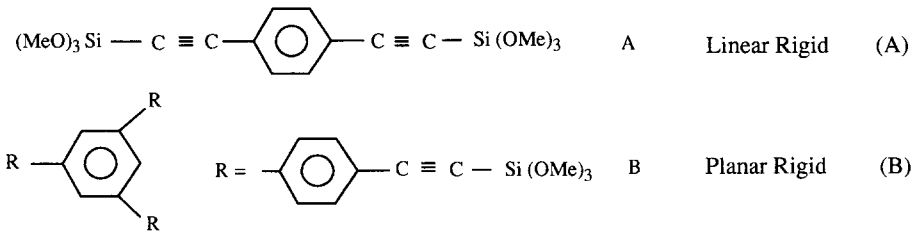
The facile reaction between the diyne fragments at a relatively low temperature within the amorphous gel may be indicative of a favourable arrangement of the diyne moieties. The enyne formation involves parallelism between several diacetylenic units inside the solid. These results suggest the formation of short range organization in the silica network that permit the 1–4 addition between the organic units, and which is too short for detection by XRD.

Finally the last example discussed in this review is in connection with the possibilities open by molecular imprinting.

Structure of the organic spacer and porosity

It is beneficial to include organic moieties in solids and to induce a porosity by their elimination. Generally the elimination of the organic part is performed by oxidative reactions (air, ozone, etc.) which completely destruct the molecular skeleton, with an increase of the specific surface area [29]. Since the oxidation methods are liable to provide some modifications of the silica network, because of the local increase of temperature, and in order to avoid the



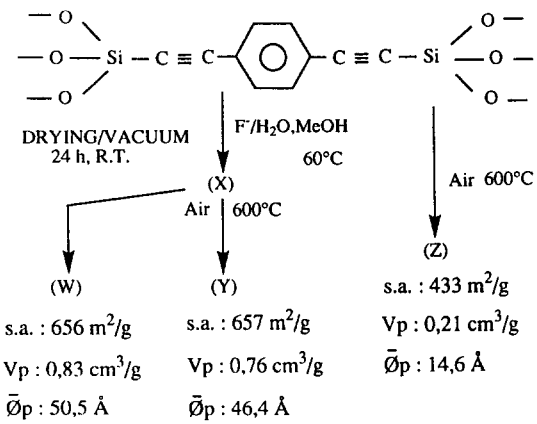
Scheme 8.

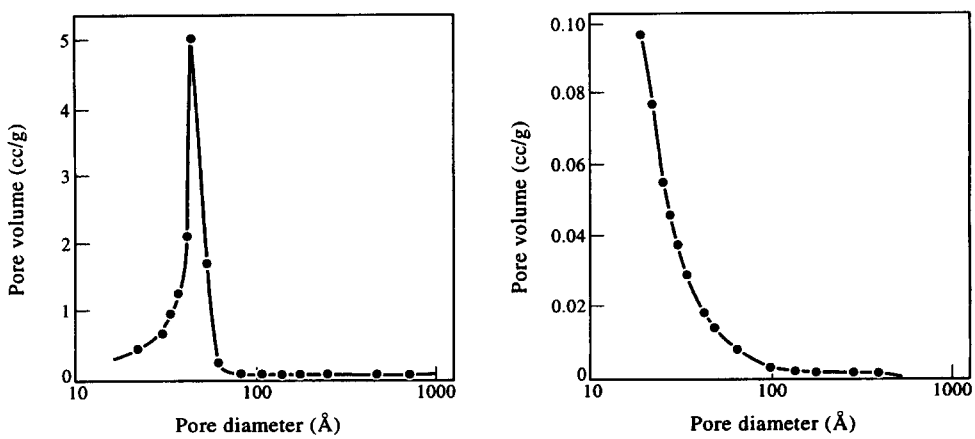
sacrificial route, we have prepared systems in which it is possible to perform a chemically induced selective cleavage.

During our previous work [30] we have observed that Si—C≡C—C≡C— may be cleaved by H_2O (or MeOH) in the presence of NH_4F at 60°C leading to the formation of SiOH or (SiOMe) one part, and HC≡C—C≡CH species as the other part. By extension of this method, it is possible to cleave the Si–ethynyl bonds selectively and to recover the organic molecules almost quantitatively (80–95%). This chemical cleavage is followed by a thermal treatment at 600°C, after which the remaining amount of carbon is very low (less than 0.5%) [31,32].

As a first step, we studied the silica gels containing organic molecules with a well determined geometry and precursors (A), (B) and (C) have been prepared. (See Scheme 8).

The gelation of (A), (B) and (C) is performed in the same conditions [room temperature, no catalyst, solvent = THF, precursor concentration 1M or 3M under inert atmosphere (nitrogen) and stirring, aging





Scheme 9.

Table 3. Comparison of specific surface area of (A), (B), and (C) before and after elimination of the organic moiety. (Chemical treatment followed by heating at 600°C)

	A Linear rigid	B Planar rigid	C Linear flexible

Pore vol. (cm^3/g)	0.76	1.16	0.72
Pore size (Å)	46	65	70
Size of the molecule which was eliminated (Å)	8	7	8.4↔4.6

one week, filtration, washing with Et_2O, grinding and drying at room temperature under vacuum]. The cleavage of Si—C≡C bonds permits the almost quantitative separation of the organic moiety. Table 3 gives the specific areas and porosity measured: in all cases the specific surface area increases with elimination of the organic moiety. Moreover the porosities are highly depending on the geometric feature of the molecule.

It is also of interest to compare the selective cleavage reported here with the sacrificial route using air oxidation. The oxidation route (600°C/air) leads to a highly dispersed microporosity. In contrast, a very narrow porosity is obtained when the chemical cleavage is followed by a thermal treatment performed in the same conditions (600°C/air). This difference was observed with (A), (B) and (C).

Scheme 9 shows the difference between the two routes in the case of (A).

Another interesting observation (cf. Table 3) is the fact that in all cases, the size of the pores is wider than the size of the molecule eliminated. This result is in agreement with the presence of a short range organization induced by the organic moieties inside the amorphous solid network, and also with a possible reorganization of the silica network induced by the F^- catalyst during the chemical cleavage of the Si—C≡C— bond.

CONCLUSION

The results presented here show the wide possibilities which are presented by the monophasic organic–inorganic hybrid solids. These materials are prepared by the elaboration of an oxide network (generally SiO_2) around an organic moiety using an hydrolytic polycondensation. This method of elaboration permits the formation of kinetically controlled solids. Factors influencing the kinetics of polycondensation, and also weak interactions between the organic units are able to modify the nature and the texture of the resulting solid. The materials obtained exhibit a short range organization which can be evidenced by chemical reactivity and by porosities studies performed after elimination of organic units.

(Received 17 May 1997; accepted 7 June 1997)

Abstract—The reaction of the lithium amide, [2-(6-methyl)pyridyl]trimethylsilylamido-lithium, with antimony(III) or bismuth(III) trichloride in diethyl ether gives the bis-amido antimony(III) or bismuth(III) chloride $[\{2\text{-}(6\text{-Me})C_5H_3N\}NSiMe_3]MCl_2$ [M = Sb (**1**) or Bi (**2**)] as colourless or yellow prisms respectively. The antimony complex is monomeric in the solid state whereas the bismuth complex is dimeric with bridging chlorides. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: antimony(III); bismuth(III); amido-complexes; N-functionalised; lithium; chloro.

Compounds containing heavier Group 15 elements (As, Sb, Bi) have attracted interest in recent times because of their importance as heterogeneous catalysts (in particular bismuth [1]) as well as precursors for superconducting materials in MOCVD processes [2,3]. Many trivalent phosphorus and arsenic amides have been well characterised. In comparison structurally characterised amide compounds of Sb^{III} and Bi^{III} are limited. This is a result of the inherent instability of such complexes [4].

The majority of arsenic, antimony and bismuth amides which have been structurally characterised have been in the 3+ oxidation state, and have largely been found with 'simple', or unfunctionalised amide ligands in trigonal pyramidal coordination geometries about the metal centre. In the related fields of Group 15 metal alkyl and thiol chemistry the use of bulky ligands with the donor functional groups capable of also interacting with the metal centres have been investigated. Examples include the bulky N-functionalised alkyl ligand-$C(SiMe_3)_2C_5H_4N$-2 [5] and the aryl ligand (dimethylamino)methyl benzene [6], as well as the thiol ligands pyridine-2-thiolate and 3-(trimethylsilyl)pyridine-2-thiolate [7]. These studies give hypercoordinated products where the coordination number has been expanded through intermolecular Lewis base-metal/metalloid interactions.

To date this approach of incorporating functional groups has not been explored for amide complexes of arsenic, antimony and bismuth. To this effect, we have undertaken studies involving the bulky amide ligand **A** derived from the amine group deprotonation of 6-methyl-2-trimethylsilylaminopyridine **HN′pyMe** (**HA**). We have previously used this ligand to stabilise low aggregate complexes of late transition metals by acting as a two electron-pair donor through the amido atom and the N-pyridyl functionalities [8,5]. Herein we report the synthesis and structural elucidation, by X-ray diffraction, of the bis-amido complexes of antimony and bismuth containing **A**. Our interest in preparing these compounds arose out of two important considerations; firstly to ascertain how such compounds would compare structurally with other structurally characterised pntictide amides given the

HN'pyMe (**HA**)

presence of a potentially ligating pyridyl nitrogen, and secondly to investigate the potential use of these compounds as starting reagents for mixed Group 13/15 single source precursors for MOCVD.

EXPERIMENTAL

Syntheses

All manipulations were carried out using standard Schlenk and glove box techniques under an atmosphere of high purity argon or nitrogen. Solvents were dried then freeze/thaw degassed prior to use. The aryl amide [HN'pyMe] **HA**, was prepared according to the literature procedure [9]. Bu^{n}Li was obtained from Metallgesellschaft (AG), Germany, as a 1.60 M solution in hexane and was standardised prior to use. All other reagents were obtained from Aldrich and the $SbCl_3$ and $BiCl_3$ were purified by sublimation before use. ^{1}H NMR spectra were recorded on a Bruker AC-200 spectrometer in deuterated benzene and referenced to the residual ^{1}H resonances of the solvent (δ 7.15). ^{13}C NMR spectra were recorded in deuterated benzene on a Bruker AC-200 spectrometer operating at 50 MHz using broad band proton decoupling and were referenced to the ^{13}C resonances of the deuterated solvent (δ 128.0). ^{15}N NMR spectra were recorded in deuterated benzene on a Bruker DRX500 spectrometer operating at 50.7 MHz using broad band proton decoupling and were referenced to the external ^{15}N resonance of nitromethane (δ 0). Elemental analyses were performed by the Chemical and Micro-Analytical Services Pty. Ltd, Melbourne. Melting points were determined in sealed glass capillaries under argon and are uncorrected.

Synthesis of chloro-bis[6-*methyl*-2-*pyridyltrimethylsilylamido*-N,N']-*antimony(III)*, **1**. A solution of $(LiN'pyMe)_2$ (0.76 g, 2.04 mmol) in diethyl ether was slowly added to a stirred solution of $SbCl_3$ (0.44 g, 1.93 mmol) in diethyl ether (20 cm^3) at -80°C. A white precipitate was gradually formed upon addition. The mixture was stirred and allowed to warm to room temperature overnight. The suspension was filtered and volatiles were removed from the filtrate *in vacuo*. Colourless crystals of the **1** were grown from hexane at room temperature (0.43 g, 43%).

M.p. 93–95°C; ^{1}H NMR (200 MHz, C_6D_6) δ 0.41, 0.45 (2 × 9H, s, SiCH_3), 1.75, 1.80 (2 × 3H, s, CH_3), 6.17–5.95 (2 × 2H, m, C_5H_3N) 6.96–6.78 (2 × 1H, m, C_5H_3N); ^{13}C NMR (50 MHz, C_6D_6) δ 2.22, 3.49 (SiCH$_3$), 20.3, 21.6 (CH$_3$), 109.8, 109.9, 112.1, 113.4, 139.2, 140.8, 152.8, 154.1, 161.4 (C_5H_3N); ^{15}N NMR (50.7 MHz, C_6D_6) $\delta -119$ (C_5H_3N); anal: found C 41.58, H 5.87, N 10.65, calc. for $C_{18}H_{30}N_4Si_2SbCl$ C 41.91, H 5.86, N 10.86.

Synthesis of chloro-bis[6-*methyl*-2-*pyridyltrimethylsilylamido*-N,N']-*bismuth(III)*, **2**. A solution of LiN'PyMe in diethyl ether was prepared from HN'PyMe (0.70 g, 3.9 mmol) and Bu^{n}Li (2.4 ml of a 1.6 M hexane solution) at 0°C. After stirring for 2 h, the yellow solution was gradually added to a solution of $BiCl_3$ (0.53 g, 1.6 mmol) in diethyl ether (20 cm^3). A white precipitate was gradually formed upon addition. The resulting yellow mixture was stirred and allowed to warm to room temperature overnight with stirring for 16 h. The solution was filtered and volatiles removed *in vacuo*. Yellow prisms of **2** were grown from toluene at -30°C (0.61 g, 60%).

M.p. 185–187°C; ^{1}H NMR (200 MHz, C_6D_6) δ 036, 0.49 (2 × 9H, s, SiCH_3), 1.75, 2.36 (2 × 3H, s, CH_3), 6.35–6.91 (2 × 2H, m, C_5H_3N), 7.03–7.22 (2 × 1H, m, C_5H_3N); ^{13}C NMR (50 MHz, C_6D_6) δ 0.19, 2.46 (SiCH$_3$) 22.51, 24.52 (CH$_3$), 106.69, 110.95, 112.19, 113.69, 130.76, 137.51, 138.95, 152.49, 156.94, 163.69 (C_5H_3N); ^{15}N NMR (50.7 MHz, C_6D_6) δ -126 (C_5H_3N); anal: found C 35.19, H 4.81, N 9.67%, calc. for $C_{18}H_{30}N_4Si_2BiCl$ C 34.65, H 5.01, N 9.29%.

Crystal structure determinations

Crystals of **1** suitable for X-ray structure determination were grown from hexane solutions at ambient temperature and were mounted in sealed capillaries under an argon atmosphere. Crystals of compounds **2** suitable for X-ray structure determination were grown from toluene solutions at -30°C and were mounted in sealed capillaries under an argon atmosphere. Unique room temperature four circle diffractometer data sets were measured using an Enraf–Nonius CAD4 diffractometer ($2\theta/\theta$ scan mode; monochromatic Mo-K_α radiation, $\lambda = 0.7107$ Å; $T \sim 295$ K) yielding 7576 independent reflections, 4552 with $I \geqslant 3.0\sigma(I)$ being considered 'observed' for **1** and 5510 independent reflections, 3830 being considered 'observed' for **2** and used in the full matrix least squares refinements after absorption correction. Anisotropic thermal parameters found were refined for the non-hydrogen atoms (x, y, z, U_{iso}) being included constrained at estimated values. Convention residuals R, R_w [statistical weights, derivative of $\sigma^2(I) = \sigma^2(I_{diff}) + 0.0004\sigma^4(I_{diff})$] are quoted at convergence. Neutral atom complex scattering factors were employed, computation using the XTAL 3.4 program system implemented by S. R. Hall [10]. A summary of crystal and solution and refinement data is given in Table 1. Non-hydrogen and important hydrogen atom coordinates are given in supplementary material. Molecular projections showing numbering schemes are given in Figs 1 and 2. Important molec-

RESULTS AND DISCUSSION

The monomeric diamido antimony chloride and the dimeric diamido bismuth chloride complexes **1** and **2** were prepared *via* the metathesis between the metal trichlorides and the lithiated complex of **A** in the appropriate stoichiometric amounts (Scheme 1). Compounds **1** and **2** were isolated as colourless and yellow crystals, respectively. Both are thermally stable, air and moisture sensitive, and have been characterised using ^1H, ^{13}C and ^{15}N NMR spectroscopy, microanalysis, and X-ray single crystal diffraction studies.

While complexes **1** and **2** are isolated from the stoichiometric reactions with the lithiated complex of **A**, surprisingly compound **1** is also formed for a 1:1 ratio of amide to $SbCl_3$. In addition complex **2** forms from the reaction with a ratio of amide to $BiCl_3$ of 3:1. This can be attributed to the redistribution of the ligands while in solution and the preferential crystallisation of the monochloride complexes as the least soluble species. Redistribution reactions have been noted for both antimony and bismuth aryl and alkyl complexes [11,12].

The thermal stability of these compounds is in contrast to complexes formed using the conjugate base of the analogous alkyl ligand, 2-[bis(trimethylsilyl) methyl]pyridine (R). In this case, the treatment of $AsCl_3$ and $SbCl_3$ with 2 equiv. of the lithium derivative of this ligand yielded intractable oils accompanied by the rapid loss of $ClSiMe_3$ while for the analogous reaction with $BiCl_3$, a red crystalline solid was obtained only below 0°C. Above 0°C this solid decomposes to give orange crystals which by X-ray structure determination has been shown to be the substituted allylic complex, (E)-$[BiR(CH_2CH{=}C)$-$(SiMe_3)(C_5H_4N\text{-}2)]\{R = [C(SiMe_3)_2C_5H_4N\text{-}2]^-\}$ [5]. This stability difference can possibly be explained by a combination of two characteristics; firstly, the addition of a methyl group on the six position of the pyridyl ring increases the steric bulk of the ligand enough to help stabilise the compound, secondly, considering the M—N bond is stronger than the M—C bond, the

replacement of the alkyl group with an amido moiety may increase the stability of the R_2MCl compound. Increasing the stability of compounds by the addition of a methyl moiety to the 6 position pyridyl ring has been highlighted in a comparison of Group 11 compounds where the compounds, $[\{2\text{-Me-}C_5H_3N\text{-}6\text{-}C(SiMe_3)_2\}M]_2$ (M=Cu, Ag, Au), are substantially more stable than the unsubstituted analogues $[\{C(SiMe_3)_2C_5H_4N\text{-}2\}M]_2$ (M=Cu, Ag, Au) [13].

The ^1H and ^{13}C NMR spectra of the diamido antimony chloride and diamido bismuth chloride complexes exhibit two sets of resonances due to the amido ligands being inequivalent. This is supported by the solid state structures from X-ray determination. No significant differences are seen between the coordinated ligand in both compounds and the free ligand; the J_{H-H} values of the pyridyl *m*-protons for the antimony and bismuth compounds are 7.21 and 8.48 Hz, respectively (*cf.* 7.31 for the free ligand). The ^{15}N NMR spectra show a significant upfield shift from the N(pyridyl) from the free ligand (δ −105) through the bis-amido antimony compound (δ −119) to the bismuth diamide (δ −126). This corresponds to the interaction between the metal and the N(pyridyl) becoming stronger as the metal becomes more electropositive. No N(amido) resonance was observed due to relaxation time and concentration problems. A downfield shift in ^{13}C NMR spectra for carbons associated with amido moieties bound to Group 15 elements has been noted before and is attributed to the increasing size of the central atom [14,15].

X-ray structure commentary

Structure of **1**. The compound chloro-bis[6-methyl-2-pyridyltrimethylsilylamido-*N*,*N'*]-antimony (**1**) crystallises as colourless prismatic crystals in the triclinic space group $P\bar{1}$ (no. 2) with four molecules in the unit cell. Two pseudosymmetrically related molecules make up the asymmetric unit of the structure. Both of these are identical within experimental error and can be best described as bis-amido antimony monochloride (Fig. 1).

Primary coordination places the antimony in a three coordinate trigonal pyramidal environment where the stereochemically active lone pair of the antimony occupies the vertex of the pyramid which is common for antimony(III) compounds. Internal coordination from the pyridyl nitrogen centres gives the antimony an overall five coordinate, distorted trigonal bipyramidal environment. To our knowledge, this compound is the first monochloride antimony(III) which has internal coordination from a Lewis basic pyridyl nitrogen. The ligands chelate the antimony centre, forming four membered rings and are bound *cis* with one of the amido ligands bound in the equatorial positions and the other having the amide nitrogen occupying the third equatorial position and the pyridyl nitrogen coordinated at the axial position. The chloride moiety occupies the remaining axial position. It is the steric constraint caused by the bite angle of the ligand and the influence of the antimony lone pair of electrons which prevents the coordination environment from being ideal trigonal bipyramidal. The trimethylsilyl group of the equatorial bound amide ligand is such that it is situated above the pyridyl ring of the other ligand while its associated trimethylsilyl group is directly opposite the pyridyl ring on the N—N—N plane. This results in the two ligands being inequivalent.

Important bond distances and angles for **1** and **2** are given in Table 2. Discussions on the diamido antimony complex will use the molecular geometries of the Sb(1) structure. The Sb—N (amide) bond distances are 2.095(8) and 2.127(8) Å for the equatorial/equatorial bound ligand and equatorial/axial bound ligand, respectively. These are comparable to the Sb—N bond distances of the four membered cyclic diamido compound $Me_2Si(N^tBu)_2SbCl$ which are 1.995(6) Å [16]. The lengthening of the Sb—N bond in the pyridyl amide in compound **1** is in accordance with the higher coordination number of the antimony centre in this compound compared to the diamido compound.

The Sb—N(pyridyl) bond distances of 2.401(8) and 2.607(9) Å for the axial and equatorial nitrogen centres are substantially longer than those of the amido nitrogen centres. The significant difference in the two bond lengths can be attributed to the lone pair of the antimony pushing the equatorial bound pyridyl ring away from the antimony through lone pair/bonding pair repulsions. However, the distances are in the range for the Sb—N(pyridyl) bond distances for the four coordinate antimony compound $[C(SiMe_3)_2C_5H_4N\text{-}2]SbCl_2$ and the six coordinate antimony compound $[Sb(2\text{-}SC_5H_4N)_3]$. These bond distances have the range of 2.371–2.837 Å, respectively [5,7].

The Sb—Cl bond distance of 2.492(4) Å is comparable to the Sb–Cl bond distance of 2.472(3)° for the cyclic antimony diamido species, $Me_2Si(N^tBu)_2SbCl$ [15], and in contrast exhibits no weak Sb···Cl interactions between each molecule. The N—Si bond distances of 1.735(9) and 1.757(8) Å are not significantly different to that of a typical silylamide (*ca* 1.73 Å [4]). However they are significantly longer than those found in the lithium amide LiA [1.705(5) Å] [9]. This is consistent with the largely covalent nature of the Sb—N bond placing minimal additional electronic charge density on the nitrogen centre.

The N(amide)—Sb—Cl bond angles of 88.9(2) and 90.2(2)° are as expected for a trigonal bipyramidal coordination geometry where the chloride occupies an axial position and the amides occupy equatorial positions. In comparison, the N(pyridyl)—Sb—Cl bond angle of the equatorial/equatorial ligand is much larger, being 116.7(2)°, for two reasons. Firstly, the acute ligand bite angles of 56.4(3) and 59.5(3)°, themselves prohibit an approach to a near ideal bipyramidal geometry. The difference in the bite angles of

the two ligands is in accordance with the lengthening of the N—Sb bond distance of the equatorial/equatorial ligand compared to the equatorial/axial ligand caused by the interaction of the lone pair of electrons on the antimony of the former ligand. Secondly, the stereochemically active lone pair of electrons of the antimony centre contributes to the distortion. These two factors can also be seen in the Cl—Sb—N(pyridyl) bond angle of the equatorial/axial ligand. At 146.1(2)°, it is significantly more acute when compared with the 180° for an ideal trigonal bipyramidal coordination geometry. All other bond distances and angles for the diamido antimony (**1**) are unexceptional.

Structure of **2**. The compound chloro-bis[6-methyl-2-pyridyltrimethylsilylamido-*N*,*N*′]-bismuth (**2**) crystallises as yellow prismatic crystals in the triclinic space group $P\bar{1}$ (no. 2) with two molecules in the unit cell, the asymmetric unit comprising of a discrete, dimeric molecule with crystallographic C_i symmetry and a four membered planar Bi_2Cl_2 ring core (Fig. 2). This compound is best described as a chloro-bridged bis-amido bismuthine.

As with the diamido antimony chloride complex **1**, the amido ligands chelate the bismuth centre, forming four membered chelate rings. The diamido bismuth chloride, complex **2**, also exhibits both primary coordination from the amido nitrogens of the ligand and dative bonding with the pyridyl nitrogens. Overall, the bismuth centre is six coordinate and has a distorted octahedral environment. This deviation from an ideal octahedron is most probably due to both the stereochemically active lone pair on the bismuth atom and the small bite angle of the ligand. The arrangement of the ligands around the bismuth atom is similar to that of the antimony compound in that one amido ligand has both the N(amide) and N(pyridyl) occupying two equatorial positions while the other amido ligand has the N(amide) coordinated at an equatorial position and the N(pyridyl) coordinated at the axial position. The chloro-moiety again occupies the axial position of the first bismuth atom but bridges to the second bismuth through the equatorial position. This difference in structure from the bismuth diamide compared to the antimony diamide can be attributed to the difference in atomic size of the bismuth compared to antimony. As such, higher coordination numbers and higher association of bismuth compounds are well documented [17–20].

Important bond angles and distances are given in Table 2. The Bi—N(amide) bond distances are 2.15(1) and 2.271(8) Å for the equatorial/equatorial bound ligand and equatorial/axial bound ligand, respectively. These distances are comparable to the Bi—N bond distances of the four membered cyclic diamido compound $Me_2Bi(N^tBu)_2BiCl$ and the triamido bismuthine compound $Bi(NPh)_3$ which are 2.124(9) [16] and 2.17(2)–2.26(3) Å [21], respectively.

As expected, the Bi—N(pyridyl) bond distances of 2.49(1) and 2.60(1) Å for the axial and equatorial nitrogen centres are again substantially longer than the Bi—N(amide) bond distances. These bond distances are comparable with the four coordinate bismuth compound $[C(SiMe_3)_2C_5H_4N\text{-}2]BiCl_2$ whose Bi—N(pyridyl) bond length is 2.485(9)° [5] and are relatively short when compared with the six coordinate trithiol bismuth compound $[Bi(2\text{-}SC_5H_3N\text{-}3\text{-}SiMe_3)_3]$ whose Bi—N(pyridyl) bond lengths are 2.69(2)–2.83(2)° [7]. In a similar manner to a pattern identified by Cowley *et al.* [6], when comparing similar arsenic, antimony and bismuth triaryl compounds that exhibit internal coordination, the average difference in the Bi—N bond lengths of **2** is 0.33 Å which is considerably smaller than the average difference in the Sb—N bond lengths in **1** which is 0.408 Å. This reflects the stronger interaction of the more Lewis acidic bismuth centre with the nitrogen atom compared to the interaction within the antimony complex **1**.

The Bi—Cl bond distance 2.629(4) Å is comparable to the Bi—Cl bond distance of 2.748(4) Å for the chloro bismuth compound $Me_2Bi(N^tBu)_2BiCl$ [16]. The bismuth diamide also exhibits a weak Bi···Cl interaction of 3.554(6) Å to the next molecule to forming a weak dimeric compound. Again, this is comparable to $Me_2Bi(N^tBu)_2BiCl$ which has a weak Bi···Cl interaction distance of 3.047(4) Å where the molecules form an infinite chain [16]. The N—Si bond distance of 1.75(1) Å is not significantly different to that of a typical N—Si bond distance (1.73 Å) which shows that there is a large covalent nature associated with the Bi—N bond similar to the Sb—N in the previously described compound.

The N(amide)—Bi—Cl bond angles of 88.0(3) and 99.8(3)° are as expected for a distorted octahedral coordination geometry where the chloride and N(amide) are *cis* relative to each other. The equatorial bound N(pyridyl)—Bi—Cl bond angle is much larger at 109.6° while the axial bound pyridyl ring has an N(pyridyl)—Bi—Cl bond angle of 153.5(3)°, which is again much smaller than the expected 180°. Again, these distortions from ideal octahedral geometry can be explained by the effect of the stereochemically active lone pair of the bismuth and the acute bite angles of the ligands [57.4(3)° and 56.8(3)°]. All other bond distances and bond angles for the bismuth diamide compound **2** are unexceptional.

CONCLUSION

We have been able to prepare and structurally characterise products obtained from the reaction of amide HN′pyMe with Bu″Li and the metal trichloride (M = Sb, Bi) in the ratio of 2 : 1. The product obtained from the antimony trichloride reaction has been isolated as monomeric $(MepyN')_2SbCl$ while the product obtained from the bismuth trichloride reaction has been obtained as the weakly dimeric compound $[(MepyN')_2BiCl]_2$. The difference in association

between the two compounds can be attributed to the larger atomic size of bismuth compared to antimony, which allows the bismuth centre to coordinate to the chloride atom of the next molecule. The increase in atomic size from arsenic to bismuth may also explain the difficulty in isolating the analogous arsenic diamide. Both compounds exhibit covalent character unlike the largely ionic nature of the corresponding lithium amide. We are currently pursuing the chemistry of these compounds as well as the synthesis of the mono-amido- and tris-mido-compounds of the heavier Group 15 elements.

(Received 2 May 1997; accepted 7 June 1997)

Abstract—Titanium complexes containing the novel tridentate 2,2′-sulfinylbis(6-*tert*-butyl-4-methylphenoxo) ligand (sibmp) were synthesized and characterized. Treatment of titanium tetra-*iso*-propoxide with 2,2′-sulfinylbis(6-*tert*-butyl-4-methylphenol) (sibmpH_2) in 1 : 1 molar ratio afforded red–orange, sparingly soluble di-*iso*-propoxo derivative [Ti(sibmp)(O-*i*-Pr)$_2$]$_2$·0.5 Et_2O. The single-crystal structure analysis was performed and revealed a dimeric centrosymmetric structure with a planar Ti_2O_2 core. The titanium center is approximately octahedral with a S=O function intramolecularly coordinated at the titanium center. Treatment of sibmpH_2 with titanium tetra-*iso*-propoxide in 2 : 1 molar ratio gave yellow Ti(sibmp)$_2$ with a C_2-symmetric spirocyclic structure. The dark red dichloro complex [Ti(sibmp)Cl_2] was prepared by reacting titanium tetrachloride with sibmpH_2. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: bis(phenolato) ligand; tridentate ligand; titanium alkoxide; L-alkene polymerization catalyst.

Homogeneous 1-alkene polymerization catalysts based on titanium complexes with bulky bidentate bis(phenolato) ligands [1] are currently of some interest as alternatives for the widely used metallocene catalysts. We are studying the coordination chemistry of various sterically demanding dianionic ligands related to the 2,2′-methylenebis(6-*tert*-butyl-4-methylphenolato) ligand (mbmp) [2], which have been modified to contain a bridge different from the methylene link [3a,b,9]. In particular, it was noted that the sulfide bridge imparts significant increase in the polymerization activity of the titanium complexes containing the 2,2′-thiobis (6-*tert*-butyl-4-methylphenolato) (tbmp) when activated with methyl aluminoxane [1]. We describe here the synthesis and characterization of complexes incorporating the tridentate 2,2′-sulfinylbis(6-*tert*-butyl-4-methylphenolato) ligand along with the structure determination of a dimeric titanium complex that reveal an intramolecularly coordinated O-sulfinyl function [4].

RESULTS AND DISCUSSION

When a solution of freshly distilled Ti(O-*i*-Pr)$_4$ in diethyl ether was layered at room temperature with a solution of 2,2′-sulfinylbis(6-*tert*-butyl-4-methylphenol) (sibmpH_2) [5] in diethyl ether, a nearly quantitative yield of Ti(sibmp) (O-*i*-Pr)$_2$ was obtained over a period of 24 h as well-formed orange-red crystals which retain approximately 0.25 equiv. of diethyl ether molecule per titanium in the lattice. The ether molecules could be completely removed in vacuum to give analytically pure Ti(sibmp) (O-*i*-Pr)$_2$ as red powder. In contrast to soluble Ti(mbmp) (O-*i*-Pr)$_2$ [2c], but very similar to Ti(tbmp) (O-*i*-Pr)$_2$ [3], Ti(sibmp) (O-*i*-Pr)$_2$ turned out to be only sparingly soluble in most of the common non-polar and polar organic solvents. Only in hot (170) dimethyl sulfoxide was it possible to attain sufficient solubility to record a ^{1}H NMR spectrum that is compatible with the formulation Ti(sibmp) (O-*i*-Pr)$_2$. Crystals of the diethyl ether solvate were, however, suitable for single-crystal X-ray diffraction (Fig. 1). The compound crystallized in the centrosymmetric space group *P*1 with two monomeric units per unit cell. The dimeric structure is bridged by two *iso*-propoxo ligands which together

† Dedicated to D. C. Bradley on the occasion of his 73rd birthday.

with the two titanium centers form a planar Ti_2O_2 core, typical for many doubly oxygen-bridged dititanium complexes [6]. Each titanium center is octahedrally coordinated by two bridging *iso*-propoxo groups and one terminal *iso*-propoxo group facing the sibmp ligand. Most notably, the sulfinyl bridge *trans* to the terminal *iso*-propoxo group is intramolecularly coordinated at the titanium center *via* the oxygen atom. The titanium–oxygen bond length of 2.149(3) Å appears to be slightly longer than that for other neutral oxygen donors coordinated at a tetravalent titanium center. For example, the titanium–oxygen bond distance in the titanium adduct of an organic carbonyl derivative such as ethyl acetate is 2.029(3) Å ($[TiCl_4(H_3CCOOC_2H_5)]_2$) [7] and phosphoryl derivatives such as $POCl_3$ in $[TiCl_4(POCl_3)]_2$ show a corresponding value of 2.10(2) Å [8]. The somewhat unexpected dimeric structure may be ascribed to the higher Lewis-acidity of the titanium center, since the S=O bridge can be assumed to increase the Brönsted acidity of the OH function substantially, thus decreasing the basicity of the phenolate anion and leading to a more Lewis-acidic metal center. In agreement with this explanation, the π-donor property of the phenoxo ligands is not pronounced, as evidenced by the averaged Ti—O bond lengths of 1.897(3) and 1.933(3) Å, typical for a Ti—O single bond, and concomitantly, the angles at the oxygen of 139.2(3) and 140.6(2)° are significantly less obtuse. In comparison, $Ti(mbmp)Cl_2$ contains corresponding bond distances of 1.742(3) and 1.759(3) Å and bond angles of 143.5(3) and 155.8(3)° [2a,c], reflecting a strong $p\pi$–$d\pi$ interaction.

An example of mononuclear titanium complex containing the sibmp ligand was obtained by slowly adding neat $Ti(O\text{-}i\text{-}Pr)_4$ to a solution of two equivalents of $sibmpH_2$ in diethyl ether to give the spirocyclic complex $Ti(sibmp)_2$ which was isolated as yellow crystals soluble in diethyl ether. $Ti(sibmp)_2$ shows NMR spectroscopic features that are similar to those of the complex $Ti(mbmp)_2$ previously described by us [2c]. Thus the molecule of $Ti(sibmp)_2$ does not possess any mirror plane, resulting in sibmp ligands of which the two phenoxo groups are inequivalent. For the probable octahedral geometry with intramolecular S=O—coordination, $Ti(sibmp)_2$ is expected to adopt a C_2-symmetrical structure as depicted in Scheme 1. Treatment of $sibmpH_2$ with titanium tetrachloride in 1 : 1 molar ratio in dichloromethane at room temperature afforded $Ti(sibmp)Cl_2$ as dark red micro-crystals. Because of the Lewis acidity comparable to that of $Ti(mbmp)Cl_2$ [2c], labile Lewis base adducts are formed with both diethyl ether and THF.

In conclusion, a new tridentate ligand sibmp has been introduced that promises to become a useful ancillary ligand for Lewis-acidic metal centers, in particular for homogeneous polymerization catalysts [9].

EXPERIMENTAL

General considerations

All operations were performed under an inert atmosphere of argon using standard Schlenk-line or glovebox techniques. THF and diethyl ether were distilled from sodium benzophenone ketyl. Pentane and hexane were purified by distillation from sodium/triglyme benzophenone ketyl. 2,2′-Thiobis(6-*tert*-butyl-4-methylphenol) was prepared according to a procedure described in ref. [10]. All other chemicals were commercially available and used as received unless otherwise stated. ^1H NMR and ^{13}C NMR spectra were recorded on a Bruker AMX 200 or AM 400 spectrometer. Mass spectra were obtained on a Varian CH7 spectrometer. Elemental analyses were performed by the Microanalytical Laboratory of this department.

2,2′-*Sulfinylbis*(6-tert-*butyl*-4-*methylphenol*). 2,2′-Sulfinylbis(6-*tert*-butyl-4-methylphenol) was prepared by oxidation of 2,2′-thiobis(6-*tert*-butyl-4-methylphenol) with hydrogen peroxide and isolated as colorless crystals in 91% yield; ^1H NMR ($CDCl_3$, 25°C): δ 1.38 (s, 18 H, $C(CH_3)_3$), 2.20 (s, 6

Bis{2,2′-*sulfinylbis*(6-tert-*butyl*-4-*methylphenolato*)}-*titanium*. A solution of sibmpH$_2$ (753 mg, 2.01 mmol) in diethyl ether was slowly treated with titanium tetra(*iso*-propoxide) (0.295 cm^3, 1.01 mmol) under vigorous stirring. After stirring for 2 h, the microcrystalline precipitate was filtered off, washed with hexane and dried *in vacuo*. Yellow crystals (470 mg) were isolated in 30% yield. ^{1}H NMR (CDCl$_3$, 25°C): δ 1.23, 1.51 (s, 18 H, 6,6′-C(CH$_3$)$_3$), 2.21, 2.22 (s, 6 H, 4,4′-CH$_3$), 6.81, 7.03 (d, $^4J_{HH}$ = 1.5 Hz, 2 H, 3,3′-C$_6$H$_2$), 7.13 (2 overlapping d, $^4J_{HH}$ = 1.5 Hz, 4 H, 5,5′-C$_6$H$_2$); ^{13}C{^{1}H} NMR (CDCl$_3$, 25°C): δ 20.74 (4,4′-CH$_3$), 29.35, 29.88 (C(*C*H$_3$)$_3$), 35.23, 35.71 (C(*C*H$_3$)$_3$), 123.93, 124.64 (C-3,3′), 125.56, 127.03 (C-2,2′), 126.91, 128.25 (C-4,4′), 131.49, 133.16 (C-5,5′), 139.04, 139.40 (C-6,6′), 158.11, 159.26 (C-1,1′); EI MS: *m/z* 792 (100%, M$^+$). Anal. Calcd for C$_{44}$H$_{56}$O$_6$S$_2$Ti: C, 66.65; H, 7.12. Found: C, 66.08; H, 6.86.

Dichloro{2,2′-*sulfinylbis*(6-tert-*butyl*-4-*methylphenolato*)}*titanium*. A solution of sibmpH$_2$ (1.72 g, 4.59 mmol in 8 cm^3) in dichloromethane was slowly added to a solution of titanium tetrachloride (0.87 g, 4.59 mmol) in dichloromethane. Immediate color change of the solution to dark brown was observed. After cooling to −78°C for 24 h, the mother liquor was filtered off and the dark brown crystals dried *in vacuo* to afford 2.10 g (93%) of the product. ^{1}H NMR (CD$_2$Cl$_2$, 25°C): δ 1.39 (s, 18 H, C(CH$_3$)$_3$), 2.29 (s, 6 H, 4-CH$_3$), 7.06 (d, $^4J_{HH}$ = 1.8 Hz, 2 H, 3-C$_6$H$_2$), 7.27 (d, $^4J_{HH}$ = 1.8 Hz, 2 H, 5-C$_6$H$_2$); ^{13}C{^{1}H} NMR (CD$_2$Cl$_2$, 25°C): δ 20.69 (4-CH$_3$), 29.25 (C(*C*H$_3$)$_3$), 35.38 (C(*C*H$_3$)$_3$), 124.12 (C-3), (C-2, -4 not detected), 133.40 (C-5), 144.96 (C-6), 156.96 (C-1); EI MS: *m/z* 490 (14%, M$^+$). Anal. Calcd for C$_{22}$H$_{30}$O$_3$Cl$_2$STi: C, 53.78; H, 5.74. Found: C, 53.80; H, 6.02.

Di(iso-*propoxo*){2,2′-*sulfinylbis*(6-tert-*butyl*-4-*methylphenolato*)}*titanium*. A hexane solution of sibmpH$_2$ (1.20 g, 3.20 mmol in 7 cm^3) was layered on top of an ethereal solution of titanium tetra(*iso*-propoxide) (0.91 g, 3.20 mmol in 10 cm^3). After standing for 4 h at room temperature precipitation of orange crystals was complete. The mother liquor was filtered off, and the crystals were washed with 10 cm^3 of hexane to give 1.57 g of product (91%). Single crystals suitable for X-ray diffraction could be obtained by this method. ^{1}H NMR ((CD$_3$)$_2$SO, 170°C): δ 1.09 (br s, 12 H, CH(CH$_3$)$_2$), 1.39 (s, 18 H, ((CH$_3$)$_3$), 2.15 (s, 6 H, 4-CH$_3$), 3.60 (br m, 1 H, C*H*(CH$_3$)$_2$), 3.84 (br m, 1 H, C*H*(CH$_3$)$_2$),

6.87 (br s, 2 H, 3-C_6H_2), 7.00 (br s, 2 H, 5-C_6H_2); IR (Kbr): ν 2959 m, 1439 s, 1296 m, 1273 m, 1128 ms, 1024 m, 985 m, 860 m, 825 s, 624 m, 552 m, 536 m, 460 m cm^{-1}; EI MS: m/z 538 (23%, $M^+/2$), 479 (16%, $M^+/2-C_3H_7O$): Anal. Chelating amides of lithium. Synthesis, structure and coordination chemistry†

Michael D. Fryzuk,* Garth R. Giesbrecht, Samuel A. Johnson, James E. Kickham and Jason B. Love

Department of Chemistry, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Z1

(Received 10 April 1997; accepted 6 June 1997)

Abstract—A limited review of the use of mixed-donor ligands that contain amides is presented. By combining amides with phosphines and amines in a chelating array, a variety of tridentate and macrocyclic ligands have been prepared. The synthesis and structures of a variety of lithium derivatives are presented since these are the typical starting materials in the preparation of transition metal, main group and lanthanide complexes that incorporate these ligand systems. It is found that the structures of these lithium derivatives depend on the nature of the other donors present in the chelating array. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: amide; phosphine; amine; tridentate; macrocycle; lithium.

One of the tenets of inorganic chemistry is that steric hindrance can force low coordination numbers [1]. For this reason, bulky ligands have prospered in all areas of coordination chemistry ranging from organometallic complexes to catalyst precursors. It is only fitting that due credit be given to D. C Bradley who was one of the pioneers of this idea some forty years ago [2]. In the research to be summarized here, the connection to Bradley and co-workers is particularly strong since they were one of the first groups to investigate the preparation of late metal–amide complexes [3]. The use of the bulky *bis*(trimethylsilylamide) donor, $[N(SiMe_3)_2]^-$ [4,5], to generate Co^I, Ni^I and Co^{II} amides also having monodentate phosphine donors provided the seeds of inspiration for the design [6] of tridentate amidodiphosphine ligands of the type **I** (Fig. 1). As it turned out, not only could this ligand bind to the late metals [7] but its coordination chemistry with the early metals and the lanthanides was also particularly rich [8].

From a practical point of view, the synthesis of metal amides relies on access to alkali metal amide precursors, for example, amides of lithium in particular have been shown to be extremely useful in this regard [9]. In addition, lithium amides have been widely used in organic chemistry since they are mild bases capable of deprotonating a wide variety of substrates [10]. For these reasons, the solid state and solution structures of such species have been the subject of considerable research [9–14]. In this paper, we outline some of our efforts in the synthesis and structures of lithium amides that are part of a tridentate or a macrocyclic array of donors. In addition, we review some of the coordination chemistry that these amide-based ligands display.

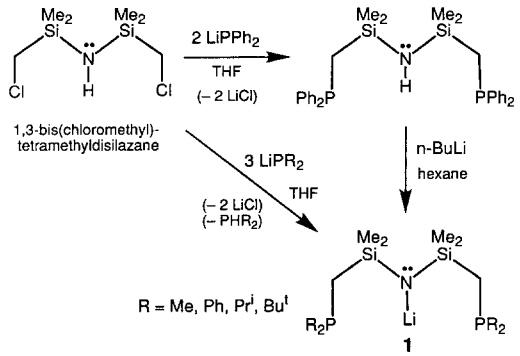

Scheme 1.

methyldisilazane, $HN(SiMe_2CH_2Cl)_2$, to prepare a series of tridentate ligands that incorporated an amide unit with two flanking phosphine donors [15,16]. The general synthetic sequence is shown in Scheme 1; diaryl or dialkylphosphide nucleophiles react smoothly with the commercially available, starting disilazane to produce either the amine or the amide derivatives, depending on the basicity of the phosphide.

The lithium amidodiphosphine derivative **1** serves as the key starting material in the preparation of both early and late transition metal complexes. However, its solid state and solution structure could not be unambiguously determined. The structure shown in Scheme 1 as an acyclic monomer was based more on convenience than spectroscopic data, and on the basis of recent studies of lithium disilylamides, is probably naive and unrealistic. A more reasonable structure is a dimer involving each amide bridging two lithiums as shown in **2** (Fig. 2). Although we have no direct evidence for this dimeric form or its structure, it is known that the phosphine donors do not coordinate to the lithium ions at any temperature since $^{31}P\{^1H\}$ NMR spectra show no coupling to ^7Li. Solution molecular weight studies in benzene were not reproducible. The propensity for lithium amide structures to incorporate robust amide bridges [9–11] is the sole rationale for the proposed structure of **2**.

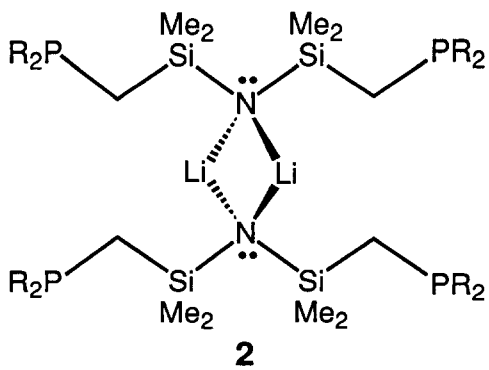

Fig. 2. Proposed solution structure of **1**.

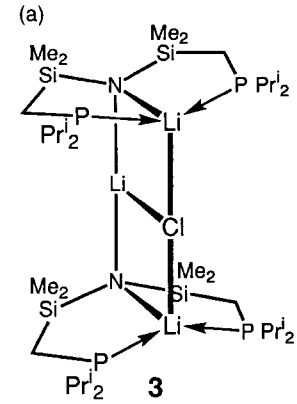

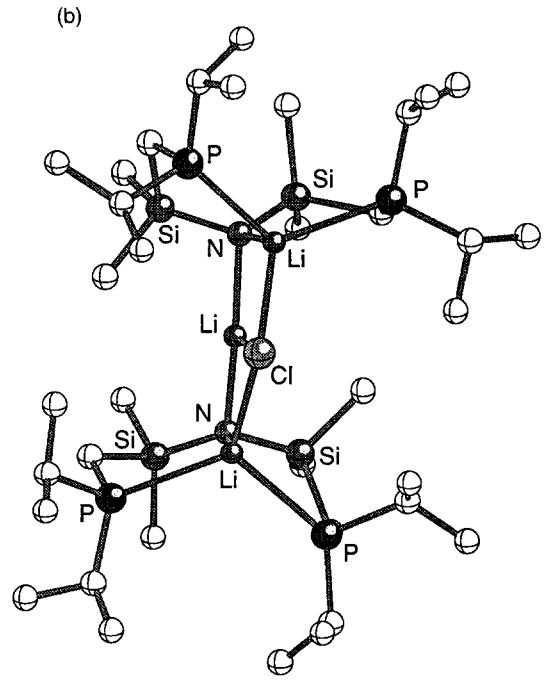

Fig. 3. Solid state structure of **3**.

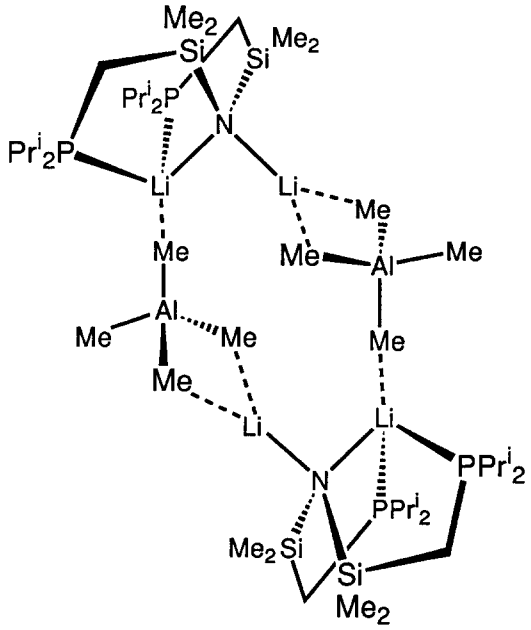
Recently, we have obtained some structural data on derivatives of the lithium amidodiphosphine **1** (R = Pr^i) [17]. An X-ray crystal structure of the LiCl adduct, $\{LiN(SiMe_2CH_2PPr^i_2)_2\}_2LiCl$ (**3**) (Fig. 3), shows a ladder motif involving three lithium ions; in this case, the phosphine donors bind to the lithium centres both in solution (on the basis of ^7Li and $^{31}P\{^1H\}$ NMR spectroscopic studies) and in the solid state. A related adduct was also structurally characterized; addition of $LiAlMe_4$ to **1** produced the adduct $LiN(SiMe_2CH_2PPr^i_2)_2 \cdot LiAlMe_4$ (**4**) (Fig. 4). In the solid state, **4** is a dimer as shown below, but the solution NMR data suggest that this dimer can break up rather easily to form monomer **4**.

An even more complicated adduct was isolated from the reaction of **1** (R = Pr^i) with $NaBEt_4$; the solid state structure shows an infinite polymeric form of the formula $\{LiN(SiMe_2CH_2PPr^i_2)_2 \cdot NaBEt_4\}_x$ (**5**).



4

Fig. 4. Solid state structure of **4**.

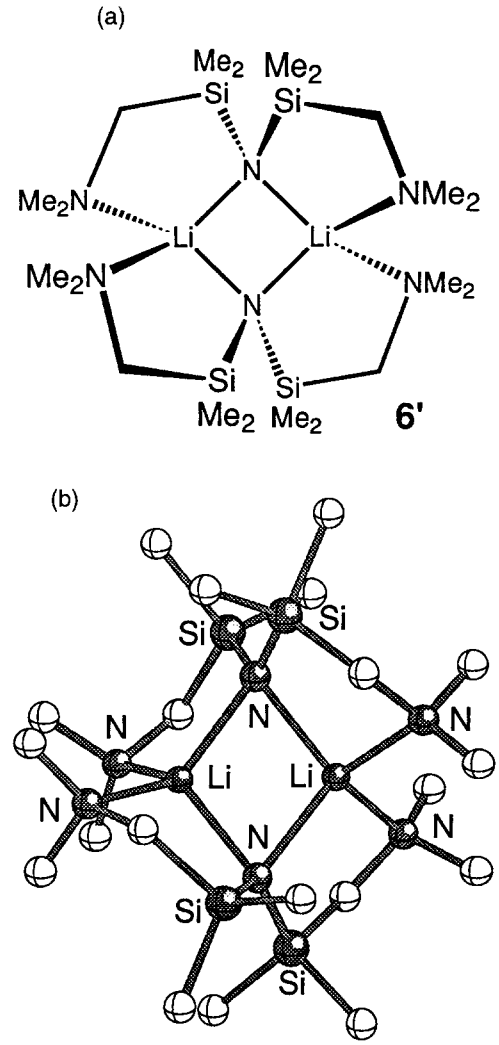


Fig. 5. Solid state structure of **6**.

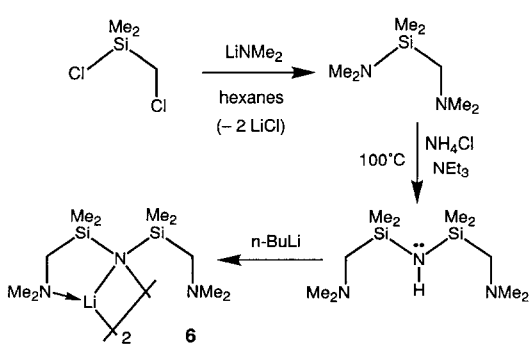
We have examined the coordination chemistry of **1** with many metals in all the parts of the periodic table. Some of the early work has been reviewed [6–8]. More recently, we have continued our efforts by examining main group elements such as Al and Ga and the Group 3 element Sc [18,19], as well as the ability of this ligand to stabilize unusual oxidation states such as Zr^{III} [20].

Buoyed by our success of combining the amide donor with phosphines in an acyclic chelating array, we decided to try and synthesize a tridentate system with the amide donor flanked by amine donors, in this case, NMe_2 units [21]. Attempts to extend the synthesis of **1** shown in Scheme 1 to the all nitrogen analogue initially met with failure. For example, the reaction of $LiNMe_2$ with the disilazane did not produce any products that could be conclusively identified. However, an efficient synthesis was achieved by a protection-deprotection sequence as shown in Scheme 2. The NMe_2 donor is introduced first before amine exchange with ammonia to produce the disilyltriamine. Subsequent deprotonation produces the dimeric amidodiamine **6**.

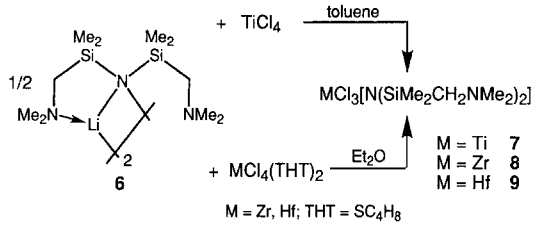


Scheme 2.

In contrast to the aforementioned amidodiphosphine **1** for which we proposed a dimeric formulation as **2**, the dimeric form of **6** is evident from symmetry considerations at low temperature in solution (by ^1H NMR spectroscopy) and from the X-ray crystal structure. The overall D_2 geometry is shown in Fig. 5 as **6'**.

As is often seen in lithium amide structures, a dimer is formed having the amide unit bridging two lithium ions; in this case, the dimethylamino donors bind to the lithium in contrast to that proposed for **2** where no evidence for phosphine coordination to lithium was evident.

The coordination chemistry with the amidodiamine **6** has been initiated [21]. With the Group 4 elements, distorted octrahedral complexes have been isolated as shown in eq. (1).



The titanium complex **7** displays a meridional arrangement of the tridentate ancillary ligand while both the heavier members **8** and **9** have the ligand in a facial orientation (Fig. 6). In these latter derivatives the distortion from octrahedral is so large that a bicapped tetrahedral [22] description could also be applicable.

Attempts to prepare a yttrium complex with this ligand system have met with mixed results. Shown below (Fig. 7) is the X-ray structure of the main product isolated from this reaction; the product has the molecular formula $[(Me_2NCH_2SiMe_2)_2N]YCl(\mu\text{-}Cl)_2Li[HN(SiMe_2CH_2NMe_2)_2]$ (**10**) wherein one equivalent of the ligand has been protonated and is bound to coordinated LiCl while the other is the expected, tridentate amidodiamine ligated to the yttrium. The source of the proton in the triamine bound in a bidentate fashion to the lithium ion is under investigation [23].

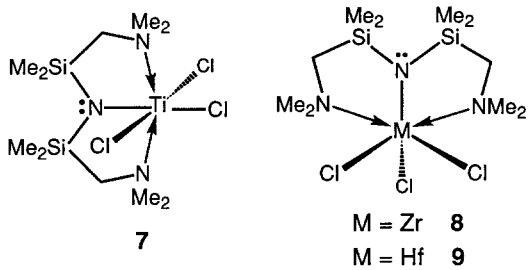


Fig. 6. Geometry of amidodiamine complexes of Ti, Zr and Hf.

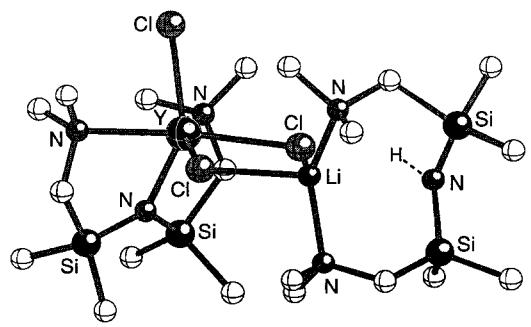

Fig. 7. Solid state structure of **10**.

Cyclic tetradentate diamide arrays

In the tridentate systems described above, the amide unit serves to anchor the ligand to the metal thereby forcing the ligand arms to bind by the virtue of their proximity, in other words, by the chelate effect. However, while the stability of the flanking arms binding to the metal is enhanced by this design, we have amassed considerable evidence that is consistent with facile phosphine and amine arm dissociations [21,22], at least for complexes of the early metals. While such kinetic processes could be beneficial (e.g., liberating sites on the metal for activation), we were also interested in designing new ligand systems that would be resistant to ligand dissociation. It seemed logical that a cyclic system could achieve this goal because the ligands would be constrained by the intrinsic inability of an appropriately designed cyclic system to expand [24]. One possible macrocyclic system is shown in Fig. 8 as **II**.

In this macrocyclic system, two amides and two phosphines are arranged trans to each other in a 12-membered ring. The synthesis of this ligand is shown in Scheme 3. The first step follows the general sequence shown in Scheme 1 wherein addition of two equiv. of primary phosphide to the disilazane generates a material that still has protons attached to the phosphorus atoms; subsequent addition of another equivalent of the disilazane and four equiv. of n-BuLi results in excellent yields of *syn*-$Li_2(THF)[P_2N_2]$ (**11**) and *anti*-$Li_2(THF)_2[P_2N_2]$ (**12**) [25]. We ascribe the high chemical yield in this last step as due to the template effect by the dilithio diamide-bridged motif. The two isomeric forms of this macrocyclic precursor can be separated by fractional crystallization and each form displays unique coordination behaviour with transition and main group elements.

The coordination chemistry of these new macrocyclic diamidodiphosphines is in progress and already we are seeing some differences in reactivity of metal complexes that incorporate this ligand system. For

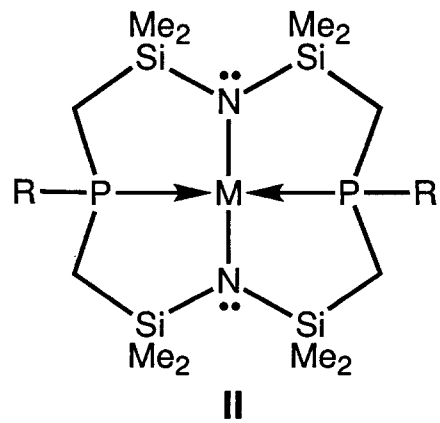

Fig. 8. Complexed macrocyclic diamidodiphosphine ligand **II**.

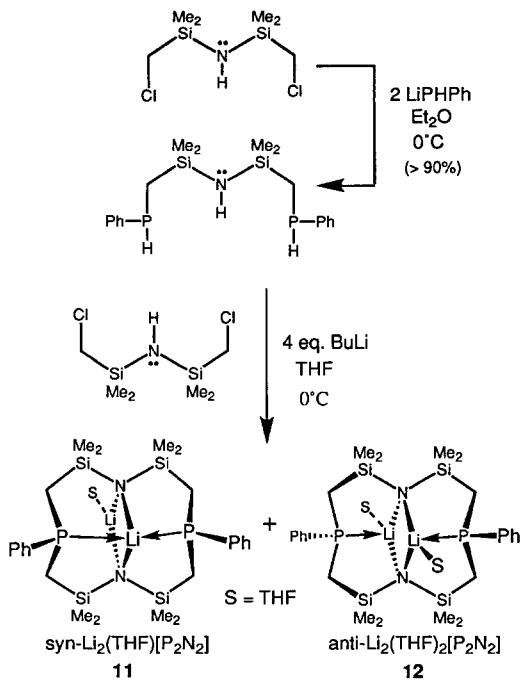
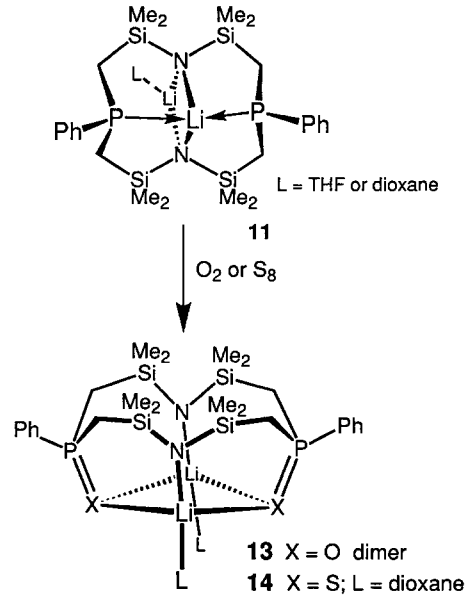


Scheme 3.



Scheme 4.

example, dinuclear zirconium dinitrogen complexes of the *syn*-$[P_2N_2]$ macrocycle show intriguing reactivity with dihydrogen and silanes without loss of the coordinated N_2 fragments [26].

Recent work from our laboratory has also shown that the phosphine donors of the macrocyclic arrays can be oxidized to generate the corresponding phosphine oxide and sulfide derivatives; we have been able to structurally characterize the corresponding *syn* derivatives that were prepared by the general route in Scheme 4; the reaction of the *syn* dilithio derivative **11** (either the THF or dioxane adduct) with dioxygen

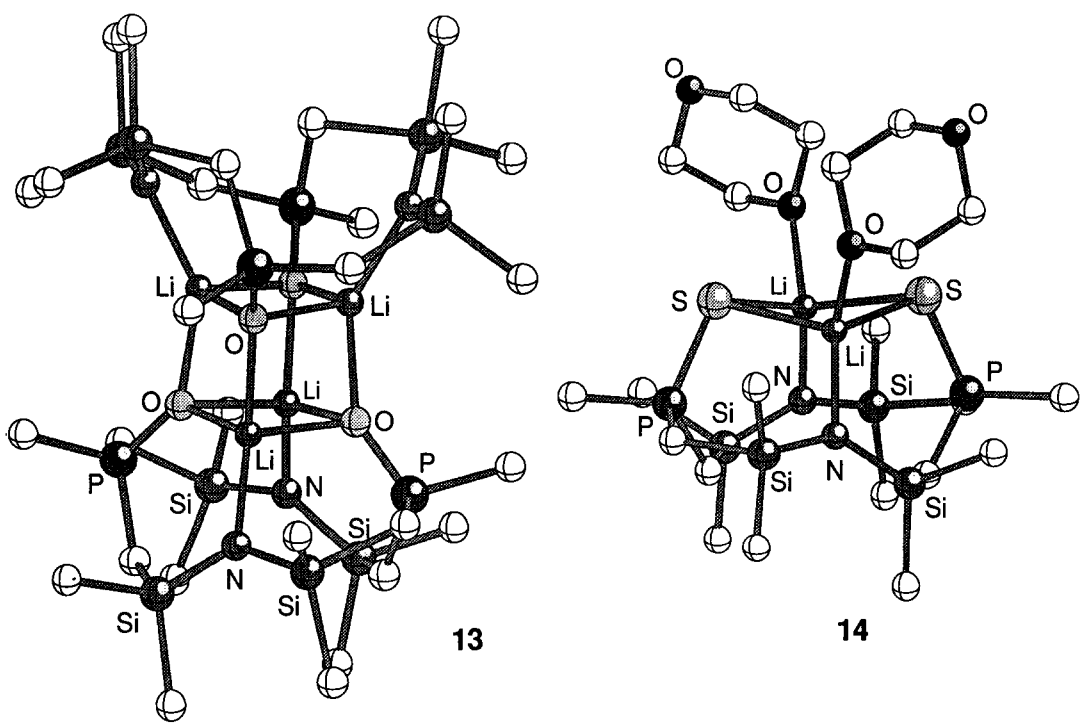


Fig. 9. Solid state structures of **13** and **14**.

or molecular sulfur produces the corresponding oxide **13** and the sulfide **14,** respectively [27]. The solid state structures (Fig. 9) are also given and show that the phosphine oxide derivative has a dimeric structure involving a cube of lithium ions and four oxygens from the phosphine oxide functionalities. The sulfide derivative was recrystallized from dioxane and this is apparently a strong enough donor for lithium to break up any dimeric forms that are similar to **13**. The coordination chemistry of these new macrocyclic ligands is in progress.

CONCLUSION

By building on the early work of Bradley and others who initiated studies on metal amide complexes, a huge literature now exists on the coordination chemistry and reactivity of amide derivatives [28]. Our approach has been to use the amide unit as an integral part of a chelating structure that when coordinated to a metal forces multidentate interactions. The starting point has typically involved the synthesis of lithium amides having chelating donors such as phosphines but recently we have included amine donors and most recently phosphine oxide and sulfides. What is evident at this stage is that the structures of the lithium amides vary from system to system; nevertheless, these derivatives do serve as efficient reactants for the incorporation of these mixed donor ancillary ligands onto transition metals and other elements.

Acknowledgements—Funding for the research was generously provided by NSERC of Canada. We also thank Dr Steven J. Rettig for his continued enthusiasm and dedication in solving many of the X-ray structures discussed here.

Trivalent uranium chemistry: molecular structure of $[(Me_3Si)_2N]_3U$

Joanne L. Stewart* and Richard A. Andersen

Department of Chemistry, University of California and Chemical Sciences Division, Ernest Orlando Lawrence Berkeley National Laboratory, Berkeley, CA 94720, U.S.A.

(Received 18 April 1997; accepted 5 June 1997)

Abstract—The X-ray crystal structure (−110°C); space group $P\bar{3}$ 1c, $a = b = 16.370(2)$ Å, $c = 8.302(1)$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, $V = 1926.7(1)$ Å^3, $Z = 2$; shows that the geometry of $U[N(SiMe_3)_2]_3 \cdot 1/3$ cyclohexane is pyramidal, consistent with deductions made on the basis of infrared spectroscopy. The U—N distance is 2.320(4) Å and the N—U—N angle is 116.24(7)°. The solid state magnetic susceptibility from 35–280 K gives μ_{eff} of 3.354(4) with $\theta = -13$ K and 3.385(4) B.M. with $\theta = -11$ K at 5 and 40 kGauss, respectively. The effective magnetic moments are similar to that found for UF_3 and other trivalent uranium metallocenes, consistent with a $5f^3$ electron configuration. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: uranium (III); sylylamide; X-ray; magnetic moment.

The idealized geometry of binary, three-coordinate compounds, ML_3, is either trigonal planar (D_{3h} symmetry), pyramidal (C_{3v}) or T-shaped (C_{2v}). Molecular orbital models based upon Walsh diagrams [1a,b], VSEPR concepts based upon electron pair repulsion [1c], or a pure electrostatic model (the polarized-ion model) [1d,e] have been used to rationalize molecular geometry. The metal trihalides have been studied extensively at high temperature in the gas phase [2a,b] and in the solid state by matrix isolation spectroscopy [2c]. The principal difficulty in studies of molecules formed under 'extreme' conditions is establishing the identity and constitution of the species under study, as illustrated by a study of matrix-isolated TiF_n species [2d]. One way around some of these problems is to prepare and isolate ML_3 compounds that can be shown to be pure, monomeric compounds by normal physical studies. This is a rather difficult task since three-coordinate molecules are coordinatively unsaturated and the compounds often exist in equilibrium among various species depending upon the phase, temperature, solvent, etc. One way to prevent molecular association is to use sterically bulky ligands. Many examples of the use of steric effects to prevent association are in the literature of ML_3 compounds [3]. A particularly illustrative example is found in organoaluminum chemistry; Me_3Al is a dimer in the solid state [4a,b], though its vapor is composed of monomer and dimer species [4c]. The organoaluminum compound with bulky ligands, $(Me_3C)_3Al$, is a monomer under all conditions [4d].

The bis(trimethylsilyl)amido ligand, $(Me_3Si)_2N$, forms an extensive set of ML_2 [5] and ML_3 [6] compounds with the *np*, 3*d*, and 4*f* block metals. For $M[N(SiMe_3)_2]_3$ only monomeric compounds are known in the solid state and in gas phase though the geometry depends upon the phase. The *p*-block metals where M is Al, Ga, In, Tl are isostructural in the solid state with $P\bar{3}1c$ symmetry [7]. The molecules have trigonal planar geometry and their idealized symmetry is D_3 since the ligands are molecular propellars with the Me_3Si-blades giving the molecules a 'handedness'. In the first-row transition series, where M is Ti, V, Cr, Mn, and Fe, the molecules are isostructural with the *np*-block metals [8] and the geometry is trigonal planar [3,8]. Compounds where M is Sc or the 4*f*-block metal, Nd, Eu, or Yb crystallize in the space group $P\bar{3}$ 1c, though the geometry is nonplanar in each case [3,9]. The gas phase structures, where M is Ce, Pr, and La have been determined by electron diffraction and these

This paper is dedicated to Don Bradley who, along with U. Wannagat, was the pioneer in silylamide chemistry, on the occasion of his 73rd birthday.

are also pyramidal [10]. Perhaps the most interesting example in the $[(Me_3Si)_2N]_3M$ series is that of scandium, which is found to be pyramidal in solid state by X-ray diffraction [9b] though planar in gas phase by electron diffraction [11].

Several years ago we prepared the silylamide derivative of the heaviest, naturally occurring element, uranium and showed that the molecule is monomeric in gas phase [12]. Though the solid state structure was not available, we suggested that the molecule was pyramidal on the basis of its infrared spectrum. In this paper we show that this deduction is correct.

Molecular structure

An ORTEP diagram of $[(Me_3Si)_2N]_3U$ is shown in Fig. 1. Table 1 lists the crystal data. The molecule crystallizes in the space group $P\bar{3}1c$ as do all trissilylamide metal compounds that have been crystallographically characterized. The uranium compound is pyramidal, and the uranium atom is disordered above and below the plane defined by the three nitrogen atoms by 0.456(1) Å. The U—N distance of 2.320(4) Å is unique though two comparisons may be made. The Nd—N and Ce—N distances in $[(Me_3Si)_2N]_3Nd$ in the solid state and $[(Me_3Si)_2N]_3Ce$ in the gaseous state are 2.29(2) Å [4c] and 2.33(4) Å [5], respectively. The radii tabulated by Shannon [8] show that trivalent uranium in six coordination is 0.02 Å larger than trivalent cerium and 0.05 Å larger than neodymium. Extrapolation of these values gives a U—N distance of 2.34 or 2.35 Å, close to that observed.

The reason for the pyramidal geometry of $[(Me_3Si)_2N]_3U$ is not straightforward. The pyramidal geometry observed in the crystal structures of $[(Me_3Si)_2N]_3M$, where M is Sc or Eu, was suggested to be due to the lack of M—N π-bonding in these compounds, the explicit deduction being that the planarity of $[(Me_3Si)_2N]_3M$ was due to M—N π-bonding [9b]. A comprehensive study of the gas phase photoelectron spectroscopy of planar or pyramidal $[(Me_3Si)_2N]_3M$ compounds showed that the extent of M—N

Largest Δ/σ in final least-square cycle	0.02

Intensity standards: 4, 4, −4; 11, −5, −1; −5, 11, 1; measured every hour of X-ray exposure time. Over the period of data collection there was a 1.4% decay in intensity.

Orientation standards: 3 reflections were checked after every 100 measurements. Crystal orientation was redetermined if any of the reflections were offset from their predicted positions by more than 0.1°. Reorientation was required once throughout the data collection. The cell constants listed were determined at the end of data collection.

π-bonding in these compounds is insignificant [14]. Hence, differential π-bonding cannot account for the change in geometry. Solid state packing forces are likely to be unimportant (except for scandium) since La, Ce, and Pr are pyramidal in the gaseous state [10] as are Nd [9c] and Eu [9b] in the solid state.

Both electrostatic and covalent models have been used to rationalize the geometry of nonlinear ML_2 species and nonplanar ML_3 species. In the electrostatic, or polarized-ion model for ML_3 compounds, the geometry is largely determined by the size of the central ion and the size of the anionic ligands, L. Qualitatively, as the LML angle gets smaller than 120°, L···L repulsions will develop which will be destabilizing. For the smaller metals, i.e., those of the 3*d*-transition series, the planar geometry is determined largely by the L···L repulsions. As the metal ions get larger the intra-ligand repulsions become less destabilizing on bending and the pyramidal geometry is less unfavorable. In addition, bending LML away from 120° induces a dipole moment in the direction opposite of the bending. The interaction of the induced dipole moment with the negatively charged ligands is stabilizing (a charge-dipole interaction). Since the induced dipole moment is proportional to the polarizability, which is proportional to the size of the metal ion, the largest ions should be the most pyramidal. This is consistent with the experimental facts [10].

The polarized-ion model has been used in a quantitative manner to account for the non-linear geometry of gaseous BaF_2 [15], and in a qualitative way to rationalize the geometry and the thermodynamic properties of gaseous alkaline earth halides, oxides, and metallocenes [1d,16,17]. It has been pointed out in a theoretical study on ML_2 species, that bond angle calculations using this method are very sensitive to the polarizability value (α_m) chosen for the metal [18c]. This sensitivity to parameter choice decreases as the polarizability of the metal increases.

A covalent or orbital hybridization model has also been used to explain the non-linear geometry of ML_2 and the pyramidal geometry of ML_3 compounds [18]. The stability of the non-linear or non-planar configurations are rationalized by the involvement of metal *d*-orbitals in bonding. For example, *ab initio* calculations have been performed on $U(CH_3)_3$ which serves as a model compound for the pyramidal com-

pound $U[CH(SiMe_3)]_3$ [19]. The pyramidal geometry is said to be due to the involvement of 6*d* orbitals in the U—C bonding. It is crucial to remember that the polarized-ion model is purely electrostatic and it allows electron exchange (covalency) by polarization, whereas the molecular orbital model introduces polarization by including *d*-orbitals. Both models account for the experimental facts, and arguments over which model is to be preferred are largely semantic [20].

EXPERIMENTAL

The silylamide, $[(Me_3Si)_2N]_3U$, was prepared as previously described [12]. The infrared spectrum and melting point were identical to those previously reported but the ^1H NMR spectrum (20°C, C_6D_6) is a singlet at -11.4 ($\nu_{1/2} = 15$ Hz) rather than at -18.1 ppm as previously described. A plot of the inverse susceptibility as a function of temperature for $[(Me_3Si)_2N]_3U$ is shown in Fig. 2. The magnetic moment (μ_B) is 3.354(4) B.M. ($\Theta = -13$ K) at 5 kGauss and 3.385(4) B.M. ($\Theta = -11$ K) at 40 kGauss over the temperature range of 35–280 K. The shape of the curve and the magnetic moment are similar to those previously reported for other trivalent uranium compounds [21].

X-ray crystallography of $[(Me_3Si)_2N]_3U_{1/3}(C_6H_{12})$

Deep purple crystals of the compound were obtained by slow cooling of a saturated cyclohexane solution to -15°C. Crystals of appropriate size were mounted in 0.3 mm thin-walled quartz capillaries in an inert-atmosphere glove box. The capillaries were removed from the box and flame sealed. Preliminary precession photographs indicated trigonal Laue symmetry and yielded preliminary cell dimensions.

The crystal used for data collection was of approximate dimensions 0.39 mm × 0.20 mm × 0.20 mm. It was transferred to an Enraf–Nonius CAD-4 diffractometer and cooled to -110°C by a cold flow apparatus previously calibrated by a thermocouple placed at the sample position. The crystal was centered in the beam. Accurate cell dimensions and orientation matrix were determined by a least-squares fit to the setting angles of the unresolved MoKα components of 24 symmetry related reflections with 2θ between 24 and 30°. The search yielded the same Laue symmetry as the precession photographs and systematic absences indicated the space group to be either $P31c$ or $P\bar{3}\,1c$. The normalized structure factor statistics suggested the choice of the acentric space group, however, a successful solution in the acentric group could not be achieved. A successful solution was found using the space group $P\bar{3}\,1c$. The final cell parameters and specific data collection parameters are given in Table 1.

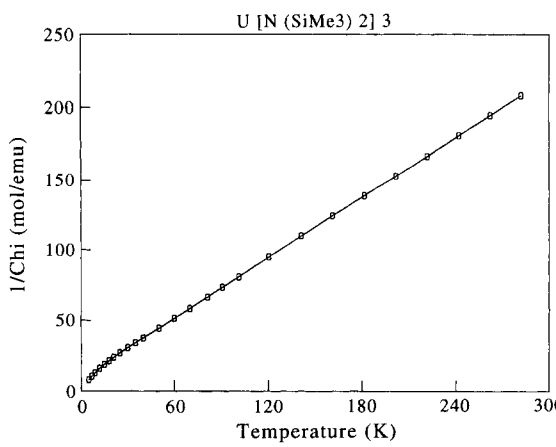

Fig. 2. Plot of inverse magnetic susceptibility *vs* temperature (K) for $[(Me_3Si)_2N]_3U$.

The 1886 raw intensity data were converted to structure factor amplitudes and their esds by correction for scan speed, background and Lorentz-polarization effects. Inspection of the intensity standards showed no appreciable decay in intensity (1.4%) during data collection. Inspection of the azimuthal scan data showed a variation $I_{min}/I_{max} = 0.90$ for the average curve. An empirical correction for absorption, based on the azimuthal scan data, was applied to the intensities. Removal of systematically absent data and averaging of redundant data left 905 unique data. The redundant data were averaged with an agreement factor, based on F_{obs}, of 1.5% for observed and accepted data and 3.9% for all data.

The structure was solved by Patterson methods and refined *via* standard least-squares and Fourier techniques. In a difference Fourier map calculated following refinement of all non-hydrogen atoms with anisotropic thermal parameters, peaks corresponding to the expected positions of all of the hydrogen atoms were found, as well as a large peak near the origin (*vide infra*). All hydrogens were included in the structure factor calculations in their expected positions based on idealized bonding geometry. All hydrogens were assigned isotropic thermal parameters 1.15 Å^2 larger than the equivalent B_{iso} of the atom to which they were bonded. None of the hydrogens were refined in least squares.

After the hydrogen atoms were included in the structure, a model for the electron density near the origin was developed. Hursthouse and Rodesiler found that $Fe[N(SiMe_3)_2]_3$ crystallized with a channel running down the *z*-axis that is large enough to accommodate a benzene molecule [8d]. Successful refinement of solvent molecules in the channel has not been achieved in any of the tris(bis(trimethylsilyl)amido) metal structures. In $[(Me_3Si)_2N]_3U$, the large peak near the origin in the difference Fourier map was able to be refined with anisotropic thermal parameters as a carbon atom with 1/3 occupancy. The symmetry generated positions gave reasonable bond lengths and angles that showed the atom to be part of a disordered

cyclohexane ring. The hydrogen atoms of the cyclohexane molecule were not included. The thermal parameters showed the carbon atom to be severely anisotropic: B(1,1) = 4.7(6), B(2,2) = 3.7(5), B(3,3) = 19(1), with the motion (or disorder) in the z-direction. This model accounted nicely for the electron density found in the channel and the largest peaks in the final difference Fourier map are now associated with the uranium and are not found in the channel. A packing diagram, that shows the C_6H_{12} molecule is in the Supplementary Material.

The quantity minimized by the least squares was $\Sigma w(|F_o| - |F_c|)^2$, where w is the weight of a given observation. The p-factor, used to reduce the weight of intense reflections, was set to 0.03 throughout the refinement. The analytical forms of the scattering factor tables for the neutral atoms were used and all non-hydrogen scattering factors were corrected for both the real and imaginary components of anomalous dispersion.

Inspection of the residuals ordered in ranges of $\sin(\theta/\lambda)$, $|F_o|$, and parity and value of the individual indices showed no unusual features or trends. A secondary extinction parameter was refined in the final cycles of least squares. Seven reflections were rejected as "bad" data in the final refinement, based on their high values of $w \times \Delta^2$. The highest and lowest peaks in the final difference Fourier map had electron densities of 0.364 and -0.215 $e^{-1}/Å^3$, respectively, and were associated with the uranium atom.

(Received 29 March 1997; accepted 5 June 1997)

Abstract—$[Ru_2(chp)_4(thf)][BF_4]$(Hchp = 2-chloro-6-hydroxypyridine) has been prepared and structurally characterized. The Ru–Ru distance is 2.2660(6) Å. Comparison of the structure of this Ru_2^{5+} compound with that of the previously known Ru_2^{4+} complex, $Ru_2(chp)_4(thf)$, reveals that the changes caused by the increase in oxidation state are similar to those previously observed for the Ru_2^{5+} to Ru_2^{6+} oxidation, with the metal–metal bond becoming slightly longer, by 0.005(1) Å, and all the metal–ligand bond lengths decreasing slightly.

Keywords: paddlewheel complexes; ruthenium; diruthenium; bond lengths; metalometal bonds.

Recognition of the existence of compounds containing multiply-bonded dimetal units occurred more than 30 years ago [1]. Soon after the earliest work, which dealt with dirhenium and dimolybdenum compounds, the first diruthenium compound, $Ru_2(O_2CCH_3)_4Cl$ was reported by Geoffrey Wilkinson and coworkers [2a]. A few years later it was found to have a Ru–Ru bond [2b] and thus a vigorous and fruitful effort began whereby dozens of diruthenium compounds containing Ru_2^{4+}, Ru_2^{5+} and Ru_2^{6+} cores have been prepared and characterized.

In the investigation of these molecules, as well as multiply-bonded dimetal compounds of other transition elements, the length of the metal–metal bond and its relation to bond order, has been one of the main areas in which research has focused [1]. Because changes in the ligand set surrounding the dimetal unit may have large effects on the molecular geometry [1], it is desirable to structurally compare molecules in which the only change is in the electron configuration [3].

Recently, we published a study in which the structure of an Ru_2^{6+} compound, $[Ru_2(ap)_4Cl][FeCl_4]$ (Hap = 2-anilinopyridine), was compared with that of an Ru_2^{5+} complex which contains exactly the same set of ligands, $Ru_2(ap)_4Cl$ [4]. Despite the fact that Ru_2^{4+} compounds have been known for almost as long as those of Ru_2^{5+} [1], there has not been, to date, a similar study in which two complexes of diruthenium containing exactly the same ligand set, but with these two core oxidation states, are compared. Since we have recently reported the structure of 0,4-$Ru_2(chp)_4(thf)$ (Hchp = 2-chloro-6-hydroxypyridinate) [5], the preparation and structural characterization of $[Ru_2(chp)_4(thf)]^+$ became our goal in order to make such a comparison.

EXPERIMENTAL

The work described here was carried out under an atmosphere of dry N_2 except where otherwise indicated. Solvents were of commercial grade, and freshly distilled from Na/K under an atmosphere of dry N_2 prior to use. $Ru_2(chp)_4Cl$ [6] and $Ru_2(chp)_4(thf)$ [5] were prepared according to published procedures. $AgBF_4$ was purchased from the Aldrich Chemical Co. and used as received. The IR spectrum was recorded from a KBr pellet on a Perkin–Elmer 1600-PC spectrophotometer. The magnetic susceptibility measurements were performed using a modified Gouy method, using a Johnson Mathey MSB-1 balance. Before calculating magnetic moments, the magnetic sus-

† Dedicated to Prof. D. C. Bradley on the occasion of his 73rd birthday.

ceptibilities were corrected for diamagnetic contributions from the ligands and counterions by using correction coefficients estimated from Pascal's constants [7]. Both of the samples used for the magnetic measurement were ground and subjected to a vacuum for 1 h prior to use.

Synthesis of $[Ru_2(chp)_4(thf)][BF_4]$

In a Schlenk tube equipped with a magnetic stirring bar were placed, under an atmosphere of dry N_2, 0.15 g of $Ru_2(chp)_4Cl$ and 0.04 g $AgBF_4$. After the tube was sealed with a rubber septum and connected to a vacuum line, 10 cm^3 of THF, freshly distilled from Na/K under an atmosphere of dry N_2, were introduced using a syringe. This immediately resulted in a purple solution from which a fine, white precipitate, presumably AgCl, started forming. Stirring was continued for 2 h, and the solution filtered through a short plug of Celite and layered with 30 cm^3 of hexanes. Diffusion of the hexanes into the THF solution yielded a large crop of small prismatic crystals. Yield 0.142 g (88%).

IR (KBr, cm^{-1}): 2924 w, 1950 m, 1533 m, 1442 s, 1434 s, 1388 w, 1348 m, 1261 w, 1174 w, 1084 s, 1016 m, 929 w, 791 m, 720 m, 667 w, 630 m.

X-ray crystallography

While all the crystals examined were well shaped, their diffraction patterns revealed them to be twinned to a certain extent. However, careful choosing and trimming of a crystal yielded a specimen which did not appear to be twinned by inspection of axial diffraction photographs.

The crystal was mounted on the end of a thin quartz fiber with the aid of a small amount of a hydrocarbon grease and rapidly placed in the cold stream equipping the Nonius FAST area detector diffractometer. General procedures for this instrument have been reported elsewhere [8], but changes which have since been implemented in data collection and reduction have not yet been fully described, and are given below. The new procedures were devised to ensure that more accurate intensities are obtained, and that substantial amounts of redundant data, in the form of reflections equivalent both through azimuthal vector rotation and symmetry equivalents, are measured in order that an accurate empirical absorption correction may be performed.

After optical centering of the crystal in the X-ray beam, centering of reflections for crystal orientation, determination and refinement of crystallographic parameters and verification of crystallographic symmetry through the use of axial images, the instrument was set for data collection. The detector was set at a distance of 40 mm from the crystal, and the swing angle driven to 19°. This detector position allows data to be collected up to $2\theta = 51°$, and works well for crystals where the longest axis of the (primitive) unit cell does not exceed 30 Å. These parameters may be suitably modified to minimize reflection overlap in crystals with longer axes. Raw data were collected as series of oscillation images, each representing a 0.2° increment of one of three scans. One 220° scan about the ϕ axis was done with $\kappa = 33°$, and $\omega = 180°$. Subsequently, two 72° rotations about the ω axis were performed, one with $\omega = 205°$, $\kappa = -160°$ and $\phi = -75°$, and a second with ϕ rotated 90° from this, i.e., $\phi = 165°$ [9].

The images thus obtained were processed with an off-line version of MADNES [10], using an ellipsoid fit procedure as described by Kabsch [11]. Prior to extraction of reflection intensities from the images, a small portion of the data was processed in order to determine the appropriate size of the 'shoebox' to be fitted around each reflection, that both includes the complete reflection, and minimizes the amount of background measured, thus further decreasing the likelihood that the refection intensities may be skewed by encroachment by neighboring reflections. In this case a width of 0.7 mm and a length of 0.16° were deemed appropriate. Using these parameters, the three sets of images were processed, yielding three separate sets of data. These files contain F^2 and $\sigma(F^2)$ is given for each reflection, as well as additional information specifying where each reflection was positioned, both physically on the detector, and rotational angle in the general scan.

The three data files were then processed and fused into one file, containing the intensity data along with crystal dependent polar coordinates for the direction of the incident and reflected beams as found for each reflection, by using a locally modified version of the program ABSURD [12]. The data were corrected for absorption anisotropy effects and merged using a local adaptation of the program SORTAV [13]. In this case a total of 19,622 reflections were processed, with maximum and minimum transmission coefficients of 0.891(10) and 0.659(5), yielding 6549 unique reflections after merging ($R_{merge} = 4.96\%$).

A solution was obtained by using direct methods as programmed in SHELXS-86 [14], from which the complete molecule of $[Ru_2(chp)_4(thf)]^+$ was found. Remaining atoms were found by successive iterations of least squares cycles followed by Fourier synthesis using the program SHELXL-93 [15]. All hydrogen atoms in the main molecule were found and were freely refined in the final least squares cycle. Selected crystallographic parameters and details of the refinement are given in Table 1, and a listing of selected bond lengths and angles is found in Table 2. A thermal ellipsoid plot of the $[Ru_2(chp)_4(thf)]^+$ molecule is given in Fig. 1.

In addition to a molecule of $[Ru_2(chp)_4(thf)]^+$, a $[BF_4]^-$ counterion and a THF molecule of crystallization, the unit cell also contains an area of diffuse solvent which was modeled as a highly disordered THF molecule, in which the atoms were refined with a common isotropic displacement parameter.

Magnetic susceptibility measurements

Magnetic susceptibility of $[Ru_2(chp)_4(thf)][BF_4]$. Since this compound is not air sensitive or moisture sensitive, the sample was prepared, and the measurement made, in air. In a carefully calibrated tube were placed 0.1201 g of finely powdered $[Ru_2(chp)_4(thf)][BF_4]$, and the measurement made. Calculations revealed a magnetic moment of 3.82 B.M.

Magnetic susceptibility of $Ru_2(chp)_4(thf)$. This compound is exceedingly air sensitive, both in solution and as a solid. For this reason, the preparation of the sample was carried out under an atmosphere of dry Ar. In the sample tube were placed 0.1325 g of $Ru_2(chp)_4(thf)$, and the tube sealed with the aid of a rubber septum. The sample was then rapidly transferred to the balance, and from the measurement a magnetic moment of 2.87 B.M. was calculated.

DISCUSSION

Synthesis of $[Ru_2(chp)_4(thf)][BF_4]$

The synthesis of the compound was quite straightforward, consisting in the mere removal of the axial halide from $Ru_2(chp)_4Cl$ with $AgBF_4$ in THF. The reactants were placed together in the Schlenk tube under an atmosphere of dry N_2 because of the extremely hygroscopic character of $AgBF_4$. When the silver salt is allowed to absorb atmospheric moisture undesirable side products are formed in which the water is found coordinated to the diruthenium unit [16].

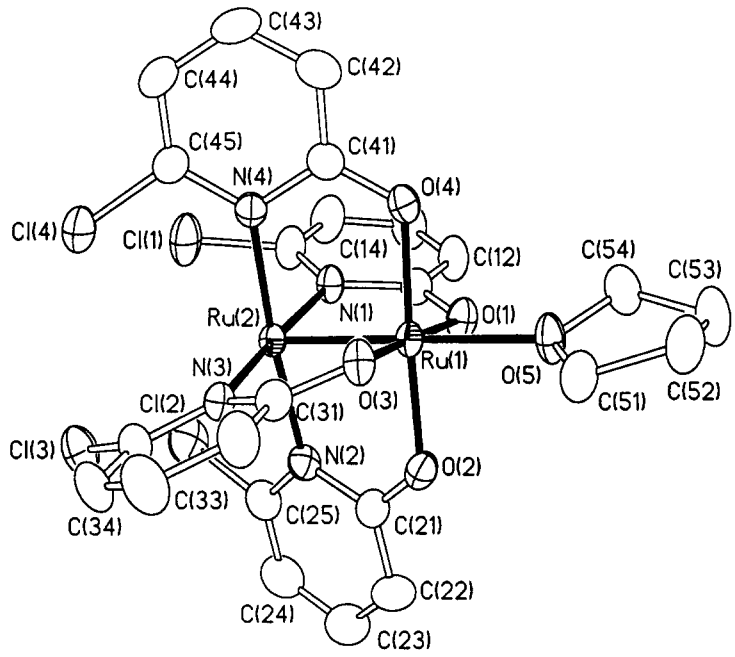

Fig. 1. Thermal ellipsoid plot of $[Ru_2(chp)_4(thf)]^+$.

Magnetic properties

As expected the Ru_2^{5+} compound has magnetic properties consistent with the presence of three unpaired electrons per formula unit, thus confirming the $\pi^{*2}\delta^{*1}$ electronic configuration for this molecule. The Ru_2^{4+} complex is paramagnetic, with magnetic properties consistent with the existence of two unpaired electrons per molecule. This rules out the possibility of a $\pi^{*4}\delta^{*0}$ ground state, but cannot distinguish between the other two reasonable options, $\delta^{*2}\pi^{*2}$ or $\pi^{*3}\delta^{*1}$. A choice between these two can be made on the basis of the molecular structure.

Structure of $[Ru_2(chp)_4(thf)]^+$ *and comparison with* $Ru_2(chp)_4(thf)$

The structure determined for $[Ru_2(chp)_4(thf)]^+$ is that which was expected: the four chp^- ligands remain arranged about the Ru_2 unit such that all four chlorine atoms are at the same end of the molecule, and the molecule of THF is found coordinated to the axial position unencumbered by the pendant halogens, i.e., the 0,4-regioisomer. The length of the Ru–Ru bond is found to be 2.2660(6) Å, well within the range expected for Ru_2^{5+} compounds, intermediate between $Ru_2(chp)_4Cl$ (Ru–Ru = 2.2835(15) Å) [17] and $[\{Ru_2(chp)_4\}_2]^{2+}$ (Ru—Ru = 2.254(1) Å) [5].

In going from the Ru_2^{4+} to the Ru_2^{5+} state the Ru–Ru bond lengthens slightly, while all the metal–ligand bonds shorten significantly, as had been found for the Ru_2^{5+} to Ru_2^{6+} oxidation,[4] and these changes are summarized in Table 3. These changes are consistent with the changes observed in electronic ground state for the Ru_2 unit, and clearly show that in the ground state of the Ru_2^{4+} complex the electronic configuration is $\delta^{*2}\pi^{*2}$ for the following reasons. While an oxidation resulting from the removal of an antibonding δ^* electron from the Ru–Ru bond, accompanied by a slight increase in electrostatic repulsion between the two metal atoms would result in the slight increase found in metal–metal distance, removal of a strongly antibonding π^* electron would result in a large decrease in metal–metal distance, unlikely to be completely offset by the electrostatic effect referred to. The fact that δ^* electrons are only weakly antibonding was first proven by the series of compounds $[Re_2Cl_4(PMePh_2)_4]^{n+}$ (n = 0, 1, 2), in which removal of the δ^* electrons results in only small changes in metal–metal bond length [3].

The increased electrostatic attraction between the metal atoms and the anionic chp^- ligands results in the shortening of the M–N and $M–O_{chp}$ bonds. The same is true for the $Ru–O_{thf}$ bond since even though this ligand is neutral, it has an electrostatic dipole moment such that a partial negative charge lies on the O. This, in combination with the fact that the thf is a monodentate ligand, and therefore somewhat more susceptible to deformation by packing forces [17], explains the large decrease in $Ru–O_{thf}$ bond length.

CONCLUSIONS

From the comparison of the structures and magnetic properties of these two complexes it is clear that

Table 3. Comparison of selected bond lengths (Å) in $Ru_2(chp)_4(thf)$ and $[Ru_2(chp)_4(thf)]^+$. Numbers in parentheses are either crystallographic s.u.'s or average crystallographic s.u.'s

	Ru–Ru	Average Ru—N	Average Ru—O_{chp}	Ru—O_{thf}
$Ru_2(chp)_4(thf)$	2.2609(8)	2.121(5)	2.047(4)	2.251(4)
$[Ru_2(chp)_4(thf)]^+$	2.2660(6)	2.102(4)	1.978(4)	2.212(3)
Δ	0.0051	−0.019	−0.069	−0.039

the oxidation arises from the removal of a weakly antibonding δ^* electron, changing the electronic configuration from $\pi^{*2}\delta^{*2}$ to $\pi^{*2}\delta^{*1}$. In removing this weakly antibonding electron from the Ru–Ru orbital manifold the gains achieved in bonding are easily offset by the increased electrostatic repulsion between the metal atoms caused by the oxidation, and results in a slight increase in metal–metal distance, a change similar to that observed for the Ru_2^{5+} to Ru_2^{6+} oxidation.

(Received 3 March 1997; accepted 5 June 1997)

Abstract—Liquid samples of $MoO(O^iPr)_4$ (**I**), kept at room temperature in complete isolation from oxygen and moisture, nearly completely solidify after approximately 2 months of storage. GLC-MS analysis of the liquid residue showed it containing approximately equal amounts of ^iPrOH and acetone and excess of $^iPr_2O$. Multinuclear NMR (^{13}C, ^{17}O and ^{95}Mo) investigation of this reaction in solution in toluene proved that acetone and ether elimination occur simultaneously. The solid product of the reaction was identified as $Mo_6O_{10}(O^iPr)_{12}$ (**II**). © 1998 Elsevier Science Ltd. All rights reserved

Keywords: $MoO(O^iPr)_4$; acetone; ether.

The preparation and properties of $MoO(O^iPr)_4$ (**I**) have been first described by Chisholm *et al.* in the fundamental work devoted to the investigation of the oxidation of $Mo_2(OR)_6$ and $[Mo(OR)_4]_x$ ($x = 1$ or 2) compounds by molecular oxygen [1]. While the dimeric isopropoxide of molybdenum(IV) (Mo=Mo) undergoes a facile one-step, oxidative addition process in hydrocarbon media, leading directly to **I**:

$$Mo_2(O^iPr)_8 + O_2 \rightarrow 2MoO(O^iPr)_4) \quad (1)$$

the derivative of molybdenum(III) Mo≡Mo) follows a complex oxidation pathway associated with the formation of two structurally identified intermediates—$Mo_3O(O^iPr)_{10}$ and $Mo_6O_{10}(O^iPr)_{12}$ (**II**). The average reaction equation can in this case be formulated as

$$Mo_2(O^iPr)_6 + O_2 \rightarrow MoO_2(O^iPr)_2 + 2^iPrO\cdot \quad (2)$$

The free radicals thus formed recombine to give an equimolar mixture of acetone and isopropanol. Only microamounts of **I** were obtained by Chisholm and co-workers using reaction (1). For the synthetic purposes, the same authors prepared it by metathesis of $MoOCl_4$ with ROH in the presence of Et_3N [2]. No ageing phenomenon was noticed for **I**, described as a yellow liquid, distillable at 60°C/10^{-4} torr without decomposition. In later publications the preparation of the samples of **I** (identical in appearance and spectral characteristics to those mentioned in [1,2]) by metathesis of $MoOCl_4$ with NaOR and by anodic oxidation of molybdenum metal in ROH was described [3,4]. The tendency to ether elimination, being a general feature of molybdenum(VI) alkoxides [4], was also observed for **I** and the phenomenon becomes especially pronounced in reactions with the alkoxides of electropositive metals, for example [5]

$$2La(O^iPr)_3 + 4MoO(O^iPr)_4 \rightarrow$$

$$La_2Mo_4O_8(O^iPr)_{14} + 4^iPr_2O \quad (3)$$

The later publications also emphasis the inapplicability of distillation for the purification of **I**, because of contamination with dioxoderivative caused by ether elimination [3]. The samples of **I** described in [3–5] were purified by extraction with hexane and thus the contamination by alkaline metals might not be totally excluded.

* Author to whom correspondence should be addressed.

The present communication is devoted to the description of phenomena observed for the spectrally pure samples of **I** on storage.

EXPERIMENTAL

All compounds described in this work are highly sensitive to moisture and oxygen and therefore all operations with them were carried out under inert atmosphere conditions employing a vacuum line or a glove box.

Dehydration of alcohols, ROH, was performed by refluxing over magnesium (R = Me), and aluminum (R = ^{i}Pr) alkoxides with subsequent distillation. Toluene and hexane were refluxed over sodium and then distilled over $LiAlH_4$. Pyridine was stored over anhydrous KOH and distilled over a fresh portion of KOH prior to use.

The carbon and hydrogen contents in the samples were determined using conventional combustion techniques. The molybdenum content was determined gravimetrically as MoO_3. Hydrated oxides were precipitated from solutions by hot 1:1 diluted HNO_3, washed with the deionized water on the filter and annealed to constant weight at 400°C. The lithium content was determined by flame photometry with an FLAPHO-4 device.

IR spectra were recorded with a Specord IR 75 in Nujol or hexachlorobutadiene mulls. Crystalline solid samples were identified using powder diffractometry (DRON 3M). GLC-MS tests were carried out using an MAT 311A Varian device (source temperature 200°C, SE-30 separation column). All NMR spectra were recorded on a Varian Unity 300 MHz spectrometer. TMS was used as reference for the ^{13}C spectra, ^{17}O-enriched (approx. 2%) water for the ^{17}O and MoO_4^{2-} (aq) for the ^{95}Mo spectra.

*Preparation of the spectrally pure samples of **I** and decomposition study.*

Approximately 1 g of $MoO(OMe)_4$ prepared by anodic oxidation of molybdenum in methanol [6], and containing less than 10 ppm of Li because of repeated recrystallisation prior to use, was dissolved in 20 cm^3 ^{i}PrOH. The solution was slowly evaporated to dryness in dynamic vacuum at room temperature. This operation was repeated trice. The product turned to be a bright yellow solid (mp 18°C) identified by IR and ^{13}C NMR spectra as pure $MoO(P^iPr)_4$. About 5 g $MoO(O^iPr)_4$ was dissolved in toluene to give a 1 M solution. An analogous sample, to which 0.2 g pyridine was added, was also prepared. Both solutions were sealed in evacuated ampoules and stored in darkness.

*X-ray single crystal investigation of **II**.*

A crystal was chosen from the crop that precipitated from the solution of **I** after two months of storage. It was sealed in a glass capillary tube under argon in a dry box, and mounted on the goniometer head of a CAD4 diffractometer. Unit cell parameters were obtained by indexing 25 randomly found reflections in an angular range $3.6 < \theta < 12.7°$ at ambient temperature. The triclinic unit cell parameters $a = 13.289(8)$, $b = 11.469(8)$, $c = 10.047(6)$ Å, $\alpha = 106.86(9)$, $\beta = 91.5(1)$, $\gamma = 98.95(9)°$ were refined based on 24 well-centered reflections in the angular range $8 < \theta < 12°$ and appeared to differ slightly from those obtained for $Mo_6O_{10}(O^iPr)_{12}$: $a = 13.082$, $b = 11.478$, $c = 9.760$ Å, $\alpha = 106.40$, $\beta = 91.85$, $\gamma = 99.81°$ [1]. Data collection in the angular range $1 < \theta < 4°$ was performed, and intensities of observed reflections were compared with those simulated using the cell dimensions and atomic parameters listed in [1]. A comparison of related intensities of 45 reflections showed no difference between the investigated and reported phases, and proved their chemical identity. However, minor structural changes due to the organic tail rotation on going from 160 to 291 K cannot be ruled out, and the increase in the unit cell volume could be indicative of this.

RESULTS AND DISCUSSION

The unusual ageing phenomenon described in this paper was first observed for the liquid samples of **I** sealed in the evacuated glass ampules and left for prolonged storage in a darkness at room temperature (24°C). It was observed that their colour slowly changed from bright yellow to dark reddish-brown. After approximately 2 weeks the precipitation of a solid started. The samples solidified nearly completely in 9–10 weeks being transformed into a reddish-orange solid and minor amounts of a pale non-viscous liquid. The molybdenum content in the liquid phase was very low (2%), while the IR spectrum in the Mo=O and Mo—OR vibration region revealed the pattern characteristic of **I** (see [1–3]). This made us believe that the liquid phase could be a mixture of the organic products of decomposition of **I**. It was subjected to a GLC-MS investigation that showed it to consist of three main components: acetone and isopropanol in approximately equal amounts, and excess of isopropylether. The presence of the latter compound was anticipated and the mechanism of its formation has been discussed in the literature [4]. In contrast, the presence of an equimolar mixture of the ketone and alcohol was unexpected and may be explained by three different scenarios. The simplest one can be regarded as a spontaneous radical decomposition, analogous, for example, to that of $U(OMe)_6$, subjected to laser irradiation [7]:

$$2MoO(P^iPr)_4 \rightarrow 2MoO(O^iPr)_3 + 2^iPrO\cdot \quad (4a)$$

$$2^iPrO\cdot \rightarrow {}^iPrOH + CH_3COCH_3 \quad (4b)$$

However, the activation energy for such a reaction

ought to be rather high, and would therefore presumably require a photochemical initiation, which is unlikely considering that the samples were stored in darkness. The second possibility involves a β-hydrogen transfer from the methyne group of the ligand directly to the metal atom, analogous to that observed for $[Re(O^iPr)_3]_3$ [8], followed by the interaction of a hydride intermediate with an unreacted molecule of **I**:

$$MoO(O^iPr)_4 \rightarrow MoO(O^iPr)_3H + CH_3COCH_3 \quad (5a)$$

$$MoO(O^iPr)_3H + MoO(O^iPr)_4 \rightarrow 2MoO(O^iPr)_3 + {}^iPrOH \quad (5b)$$

The third reaction pathway may be analogous to the mechanism established for the catalytical activity of molybdenum oxides in the methanol conversion into formaldehyde [9] and involves the β-hydrogen transfer from the ligand to the oxo oxygen atom, again followed by the interaction with a molecule of **I**:

$$MoO(O^iPr)_4 \rightarrow Mo(O^iPr)_3(OH) + CH_3COCH_3 \quad (6a)$$

$$Mo(O^iPr)_3(OH) + MoO(O^iPr)_4 \rightarrow 2MoO(O^iPr)_3 + {}^iPrOH \quad (6b)$$

All these possible explanations are associated with the reduction of **I** and the formation of Mo^V derivatives. The identification of the solid product of ageing proved this to be the case. The solid formed revealed an IR spectrum identical to that described for compound **II** [1] and was by microanalysis found to have almost the same composition, i.e. $Mo_6O_{10}(O^iPr)_{12}$ (see Fig. 1). In addition, its X-ray powder pattern turned out to be very similar to that calculated for **II** using the unit cell parameters given in [1].

In order to investigate the kinetics of the above mentioned decomposition processes, the ^{13}C and ^{17}O NMR spectra were recorded for the samples of the 1 M solution of **I** in toluene approximately every second week for 2 months. The spectra of the freshly prepared samples were in agreement with the presence of pure **I** in the solution (^{13}C δ, ppm: 78.2 (*C*H), 23.1 and 20.2 (CH_3); ^{17}O δ, ppm: 897 sharp (*O*=Mo, to compare with 894 in ref [1]) and 292 broad (R*O*—Mo). After the first 2 weeks of storage two sharp and intense new peaks appeared in the low-field region: at 99.7 ppm, corresponding to a R_2C=O group coordinated by a metal centre, and at 61.7 ppm, presumably originating from the *C*H fragments in isopropylether. The peak at 78 ppm becomes noticeably broadened, most likely because of exchange with released molecules of isopropyl alcohol. In the high-field region a new peak at 26.5 ppm appears, that with a certainty can be attributed to the CH_3 groups of acetone. The changes are even more pronounced after approximately 4 weeks of storage. It should be noted that at this point the peak at 78 ppm splits further into two broad resonances at 81 (weaker) and 76 (stronger), thus indicating the appearance of structurally distinguishable alkoxide ligands. The ^{17}O spectrum also demonstrates rather important changes: both resonances observed for **I** are shifted up-field to 868 and 188 ppm, respectively, and two new sharp peaks corresponding to oxoligands appear at 573 and 84 ppm. A considerable change is also observed in the ^{95}Mo: the peak at +47 ppm, corresponding to pure **I** [10] is considerably decreased in intensity and a new broad peak at −17 has become predominant.

All these observations are in agreement with the simultaneous elimination of acetone and ether and partial reduction of Mo^{VI} into Mo^V, that eventually transforms $MoO(O^iPr)_4$ (**I**) nearly quantitatively into $Mo_6O_{10}(O^iPr)_{12}$ (**II**). This suggestion is further supported by the X-ray pattern identification of a crystal formed on ageing of a solution of **I** in toluene with compound **II**.

It is to be noted that the addition of amines to the samples of **I** prevents coloration and thus is likely to hinder the described decomposition pathway.

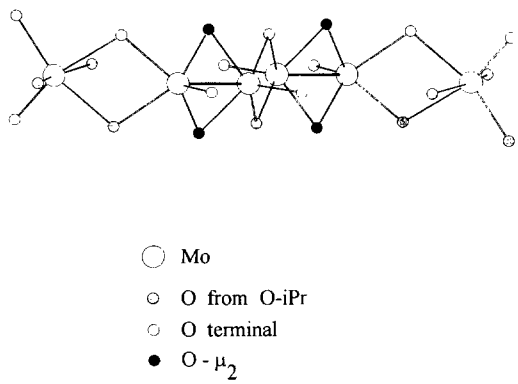

Fig. 1. Molecular structure of $Mo_6O_{10}(O^iPr)_{12}$ (**II**), generated using the atomic coordinates published by Chisholm *et al.* [1]; carbon atoms are omitted for clarity.

(Received 24 April 1997; accepted 17 May 1997)

Abstract—Reactions of the *p*-tolylimido vanadium(V) complex $[V(NTol)Cl_3]$, **1**, with sodium dithiocarbamate salts $Na[S_2CNR_2]$ yield an homologous series of organoimido vanadium(V) dithiocarbamate systems $[TolN{\equiv}V(S_2CNR_2)_xCl_{(3-x)}]$ [$x = 1$: R = Et (**2a**), Me (**2b**); $x = 2$: R = Et (**3a**), Me (**3b**); $x = 3$: R = Et (**4a**), Me (**4b**)]; the electronic and ^{51}V NMR spectra of these complexes are described. Zn reduction of complexes **3** affords impure products whose ESR spectra are consistent with the presence of the V(IV) systems $[V(NTol)(S_2CNR_2)_2]$, **5**. Reaction of $VOCl_3$ with 0.5 equiv. of *p*-OCN—C_6H_4–NCO yields the *p*-phenylenediimido complex $[Cl_3V{\equiv}NC_6H_4N{\equiv}VCl_3]$, **6**. Dissolution of **6** in THF produces an adduct $[(THF)_3Cl_3V{\equiv}NC_6H_4N{\equiv}VCl_3(THF)_3]$, **7**, whose THF ligands are weakly bound. $VOCl_3$ reacts with an equimolar amount of *p*-OCN—C_6H_4—NCO to produce the mononuclear complex *p*-$[Cl_3V{\equiv}NC_6H_4$—NCO], **8**. The reaction of **8** with $OWCl_4$ in refluxing toluene affords an insoluble product analyzing as the expected heterobinuclear system $[Cl_3V{\equiv}NC_6H_4N{\equiv}WCl_4]$, **9**, but treatment of this product with THF yields a mixture shown by ^1H NMR to contain both **7** and its ditungsten analogue $[(THF)Cl_4W{\equiv}NC_6H_4N{\equiv}WCl_4(THF)]$, indicating that an unusual intermetallic exchange of imido ligands has occurred. The chloride ligands of **6** can be substituted by $[S_2CNEt_2]$ or [O'Bu] anions to afford $[(Et_2NCS_2)_3V{\equiv}NC_6H_4N{\equiv}V(S_2CNEt_2)_3]$, **11**, and $[('BuO)_3V{\equiv}NC_6H_4N{\equiv}V(O'Bu)_3]$, **12**, respectively. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: organoimido vanadium(V) dithiocarbamate systems; intermetallic exchange; imido ligands.

The first examples of vanadium dithiocarbamate complexes, $V(S_2CNR_2)_4$, were prepared by Bradley and Gitlitz by the action of CS_2 on the corresponding tetrakis(dialkylamides) $V(NR_2)_4$ [1]. Subsequent investigations [2] revealed that $V(S_2CNEt_2)_4$ was thermally and oxidatively unstable and that upon exposure to O_2, the oxo vanadium dithiocarbamates $O{\equiv}V(S_2CNEt_2)_3$ [3] and $O{\equiv}V(S_2CNEt_2)_2$ [4] were produced. Since oxo and organoimido ligands are isoelectronic, and often form congruent sets of transition metal complexes [5], we became interested in the arylimido analogues of these oxo-vanadium systems. In this contribution, we report an homologous series of tolylimido vanadium dithiocarbamate complexes of the form $[TolN{\equiv}V(S_2CNR_2)_xCl_{(3-x)}]$ and describe the preparation and preliminary reactivity studies of a divanadium phenylenedi-imido complex *viz.*, $[Cl_3V{\equiv}NC_6H_4N{\equiv}VCl_3]$.

RESULTS AND DISCUSSION

Tolylimido vanadium(V) complexes

The starting material for these syntheses is *p*-tolylimido vanadium(V) trichloride [6], $V(NTol)Cl_3$, **1**, which is one of a large number of arylimido vanadium(V) complexes conveniently prepared from the reaction of $VOCl_3$ with the corresponding arylisocyanate ArNCO [7]. The substitution reactions of **1** with anhydrous sodium dithiocarbamates $Na[S_2CNR_2]$ (R = Me, Et) in CH_2Cl_2 at room temperature occur as shown in eq. (1). All of these solid products display good solubility in chlorinated hydrocarbon solvents and are moderately soluble in toluene, with the diethyl dithiocarbamate species as a class displaying higher solubility than the dimethyl derivatives.

$$\mathbf{1} + x\,Na[S_2CNR_2] \xrightarrow{CH_2Cl_2} TolN{\equiv}V(S_2CNR_2)_xCl_{(3-x)} + x\,NaCl \quad (1)$$

$x = 1$: R = Et, **2a**; R = Me, **2b**

$x = 2$: R = Et, **3a**; R = Me, **3b**

$x = 3$: R = Et, **4a**; R = Me, **4b**

The ^1H NMR spectra of the monosubstituted species **2a** and **2b** each reveal a single environment for the alkyl groups within the dithiocarbamate ligands, suggesting that the dithiocarbamates bind in the equatorial plane *cis* to the tolylimido ligand, but this observation alone is insufficient to deduce their probable geometries. For the disubstituted systems **3a** and **3b**, ^1H NMR spectra again indicate that the dithiocarbamates are contained in the equatorial plane *cis* to the tolylimido ligand: for **3a**, the S_2CNEt_2 groups produce a single methyl triplet δ 1.27 and a pair of methylene ABX_3 multiplets (due to the diastereotopic CH_2 protons) centered at δ 3.78 while for **3b**, a single resonance for the S_2CNMe_2 groups is observed at δ 3.36. These observations are consistent with a pseudo-octahedral structure for complexes **3** in which the chlorine atom occupies the position *trans*-to the tolylimido ligand as shown in Fig. 1. For the trisubstituted complexes **4**, ^1H NMR spectra suggest the adoption of a pentagonal bipyramidal structure (Fig. 1). Thus, the methyl groups of the S_2CNEt_2 ligands of **4a** appear as two triplets of relative intensity 5:1, as observed for the isoelectronic species $[PhN{\equiv}Mo(S_2CNEt_2]^+$ [9]; the methyl groups of the S_2CNMe_2 ligands of **4b** appears as five singlets of relative intensity 2:1:1:1:1. Pentagonal bipyramidal structures have been established crystallographically both for $O{\equiv}V(S_2CNEt_2)_3$ [3b] and $[Ph_3CN{\equiv}Mo(S_2CNMe_2)_3]^+$ [10].

The ^{51}V NMR spectra of these complexes have been recorded as $CDCl_3$ solutions and the results are collected in Table 1. For the mono-substituted complexes **2**, the ^{51}V chemical shifts are perturbed only slightly upfield of that of the $V(NTol)Cl_3$ parent (**1**, 305; **2a**, 301; **2b**, 289 ppm). Incorporation of a second dithiocarbamate ligand induces a moderate upfield shift (**3a**, 166; **3b**, 161 ppm), while extreme upfield shifts are observed for the tris(dithiocarbamate) complexes (**4a**,

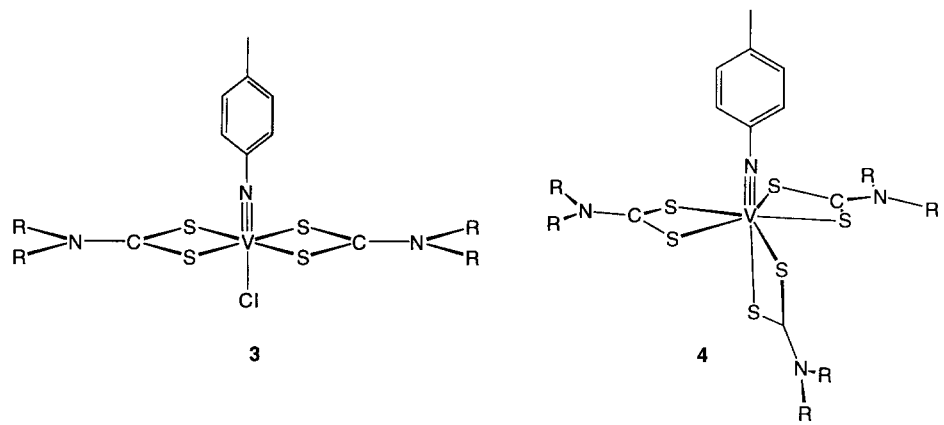

Fig. 1. Proposed structures for complexes **3** and **4**.

$V(NTol)(S_2CNEt_2)_3$ (**4a**)	−565	1780	520
$V(NTol)(S_2CNMe_2)_3$ (**4b**)	−574	1530	393

[a] $CDCl_3$ solution, 298 K, 105.2 MHz, relative to external $VOCl_3/CDCl_3$ (75% v/v), positive values denote downfield chemical shifts.

[b] $C_6H_5CH_3$ solution, 298 K.

−565; **4b**, −574 ppm). The linewidths of these resonances in all cases are sufficiently broad (*ca* 400–2600 Hz) so as to preclude the resolution of ^{51}V–^{14}N spin coupling; such coupling constants have been observed to range from 92–112 Hz in related $V(NR)X_3$ systems (R = alkyl, aryl; X = alkoxide, aryloxide, alkyl) [7b,11]. Within each set, the ^{51}V chemical shift of a given S_2CNMe_2 complex is observed at slightly higher field than that of its S_2CNEt_2 counterpart, an observation which is consistent with the greater electron donation capability of the S_2CNMe_2 ligand. It is interesting to note that the progressive upfield shift in $\delta(^{51}V)$ observed upon successive replacement of chloride by S_2CNR_2 ligands in this series is opposite to the effect induced by replacement of chloride by monodentate thiolates. Thus, Preuss [12] finds that successive substitution of chloride by *tert*-butyl thiolate in the series $[V(N^tBu)(S^tBu)_xCl_{(3-x)}]$ drives the ^{51}V chemical shifts downfield ($x = 0$, 8; $x = 1$, 232; $x = 2$, 330; $x = 3$, 467 ppm).

The electronic spectra of complexes **2, 3,** and **4** in the range 350–700 nm have been recorded as toluene solutions (Table 1). In all cases, shoulders in the visible region are observed superimposed upon an intense and broad feature tailing out of the UV region. The energies of these visible region absorptions increase with progressive incorporation of dithiocarbamate ligands. As previously noted for the series $[V(NTol)(OR)_xCl_{(3-x)}]$ (R = ^{t}Bu,2,6-$Me_2C_6H_3$) [7b], there is a correlation between $\delta(^{51}V)$ and (ΔE^{-1}) for the $[V(NTol)(S_2CNR_2)_xCl_{(3-x)}]$ complexes as shown in Fig. 2. Such a correlation implies that the dominant factor governing the observed ^{51}V chemical shifts is the paramagnetic shielding term σ_{para} [7b,13].

Attempts to generate the d^1 systems $[V(NTol)(S_2CNR_2)_2]$ from the corresponding $[V(NTol)(S_2CNR_2)_2Cl]$ complexes **3,** as shown in eq. (2), have been only partially successful. Thus, treatment of either **3a** or **3b** with an excess of Zn powder in CH_2Cl_2 at room temperature afforded dark yellow–brown solutions after 18 h reaction time. Workup led to dark brown powders which displayed broad and indistinct ^1H NMR spectra. ESR spectra of these products (298 K, $CDCl_3$ solution) revealed the characteristic eight line spectra expected for V(IV) with a d^1_{xy} configuration (**5a**: $g = 1.976$, $A(^{51}V) = 89.1$ G; **5b**: $g = 1.991$, $A(^{51}V) = 89.9$ G). While these values are very close to those reported for the analogous vanadyl

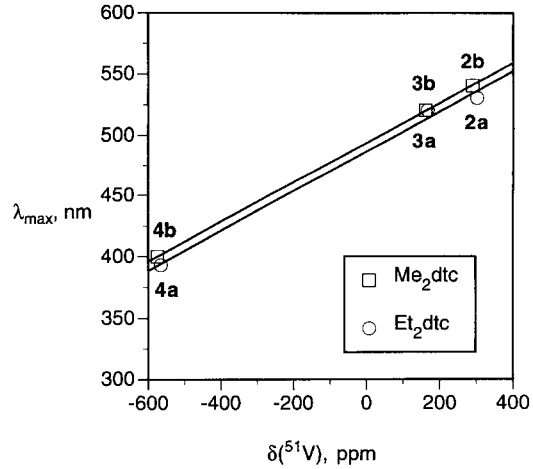

Fig. 2. Correlation of $\delta(^{51}V)$ with visible region λ_{max}. See text for numbering scheme.

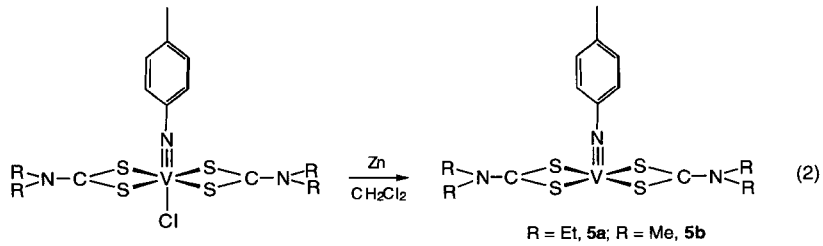
complexes [2,4b], elemental analysis results on complexes **5** indicated that these products were not obtained in a pure state.

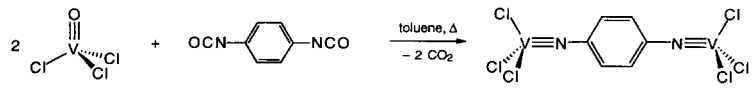
Phenylenedi-imido vanadium(V) complexes

A variety of organodi-imido bridged systems $[L_nM{\equiv}N{-}R{-}N{\equiv}ML_n]$ are known for M = Mo, W, Re and U, but to our knowledge no such complexes have been reported for vanadium [14–17]. An entry point to such systems is provided by the *p*-phenylenedi-imido complex $[Cl_3V{\equiv}NC_6H_4N{\equiv}VCl_3]$, **6,** which can be prepared in high yield as shown in eq. (3). **6** is obtained as a brown solid which is soluble (with adduct formation) in THF, but which is insoluble in other common organic solvents suggesting that unsolvated **6** exists as an intermolecularly associated species in the solid state. When **6** is dissolved in THF, an intense yellow–brown solution is formed from which a brown solid product **7** can be obtained. The ^1H NMR spectrum of **7** reveals the incorporation of three THF ligands per vanadium atom [eq. (4)].

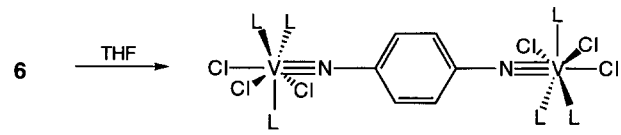
The THF ligands are easily lost from **7**; storage *in vacuo* induces the formation of a complex shown by elemental analysis to be a mono-THF complex of **6,** *viz.* $[Cl_3V{\equiv}NC_6H_4N{\equiv}VCl_3]\cdot THF$, in which we believe the THF molecule to be simply a guest in the



(2)



6 (3)



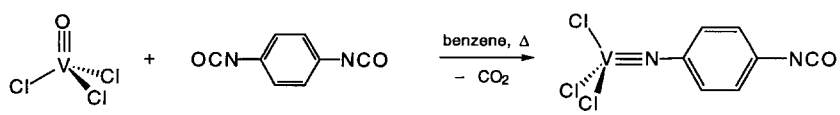
7 (L = THF) (4)

lattice. Similar facile loss of coordinated THF has been noted for analogous [ArN≡VCl_3] systems, for which both mono- and bis-THF adducts can be isolated [7b,18]. The ^{51}V NMR spectrum ($CDCl_3$, 298 K) of **7** displays a broad (fwhm = 2200 Hz) resonance at δ 380 ppm; the corresponding resonance for [TolN≡VCl_3(THF)] is observed at δ 374 ppm (fwhm = 1900 Hz) [7b].

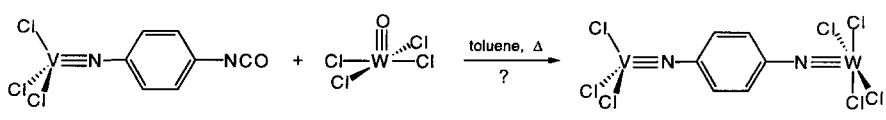
The reaction between $VOCl_3$ and an equimolar amount of *p*-phenylene diisocyanate affords the mononuclear complex [OCN—C_6H_4N≡VCl_3], **8**, in high yield as shown in eq. (5). The ^{51} NMR resonance for **8** is observed at δ 283 ppm (fwhm = 750 Hz), within the range previously observed for various *p*-substituted phenylimido vanadium trichloride complexes, [X—C_6H_4N≡VCl_3] [7b].

The presence of the pendant isocyanate function within **8** suggested the possibility of using it to construct heterobimetallic phenylenedi-imido systems of the type [Cl_3V≡NC_6H_4N≡ML_n], but our preliminary investigations of such reactions have uncovered unexpected results. Thus, reaction between **8** and $WOCl_4$ in refluxing toluene [eq. (6)] produces a brown powder whose elemental analysis is a reasonable agreement with that expected for the presumptive product [Cl_3V≡NC_6H_4N≡WCl_4], **9**. As observed for **6**, **9** is insoluble in common non-donor solvents, but is readily soluble in THF. Surprisingly, however, the ^{1}H NMR spectrum of the material obtained after workup of a solution of **9** in THF revealed the presence of both **7** and its ditungsten analogue [(THF)Cl_4W≡N-C_6H_4N≡WCl_4(THF)] [14c]; the spectrum contained no resonances attributable to a THF complex of **9**. Thus, we conclude that an unusual example of an intermetal exchange of imido ligands [19] has occurred leading to a net disproportionation of **9**. As shown in Scheme 1 (which is a simplistic representation that does not attempt to account for additional intermolecular associations), a plausible intermediate in this redistribution reaction is a heterobimetallic *bis*-(μ-imido) species. At this stage, the actual nature of the brown product isolated from the reaction of eq. (6) remains uncertain—as does any potential involvement of THF in promoting the disproportionation—and distinguishing among the possibilities shown in Scheme 1 (i.e. authentic **9**, or the *bis*-(μ-imido) species, or a 1 : 1 mixture of homobimetallic species **6** and **10**) is not yet possible.

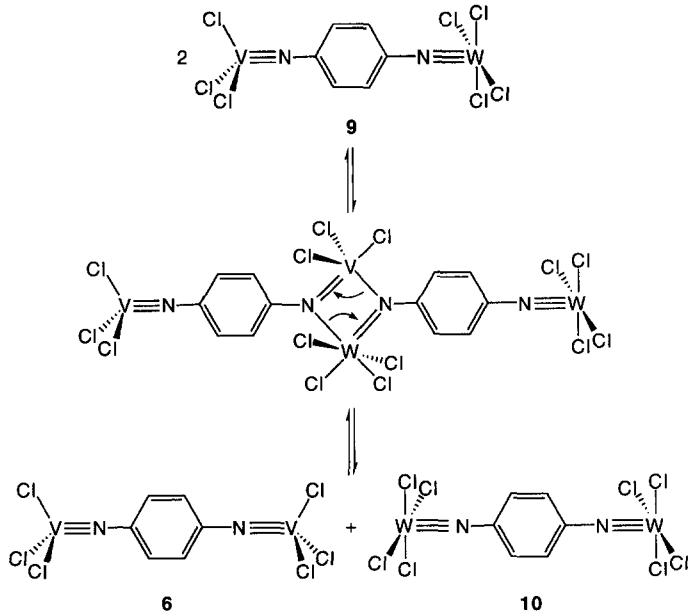
The chloride ligands of **6** undergo substitution by dithiocarbamates and *tert*-butoxide in reactions analogous to those of eq. (1) but, in reactions designed to replace either one or two chlorides at each vanadium center, ^{1}H NMR spectra of the products indicated that mixtures of variously substituted products were obtained. A pure product, **11**, has been obtained in the case of complete substitution of all six chlorides by [S_2CNEt_2] as shown in eq. (7). **11** is obtained as a mahogany solid in *ca* 60% yield. No discernable ^{51}V NMR resonance could be observed for **11**, presumably due to the extreme breadth of the signal. Similarly, the reaction of **6** with 6 equiv. of KO^{t}Bu proceeds with complete chloride substitution to pro-



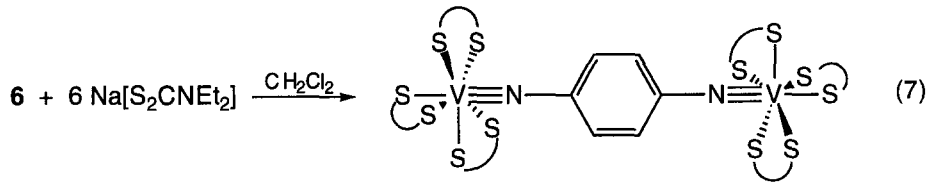
8 (5)

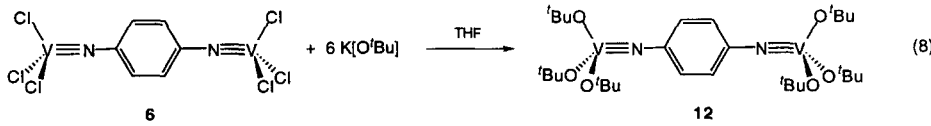


8 9 (6)



Scheme 1. A possible pathway for the disproportionation of **9**.





duce the hexakis(*tert*-butoxide) product **12** [eq. (8)]. **12** is obtained as a dark orange powder which is extremely soluble in common organic solvents, including hexane. The ^{51}V NMR resonance for **12** is observed at δ −638, a value only slightly downfield of that for the corresponding tolylimido system [TolN≡V(O^{t}Bu)$_3$] (δ −654) [7b]. Although the resonance for **12** is relatively narrow (fwhm = 345 Hz), ^{51}V–^{14}N spin coupling could not be resolved in this case; for [TolN≡V(O^{t}Bu)$_3$], this coupling constant was observed to be 111 Hz [7b].

EXPERIMENTAL

All reactions and manipulations were carried out either *in vacuo* or under an atmosphere of purified dry nitrogen. Solvents employed were dried and distilled prior to use. Sodium dialkyldithiocarbamate salts were prepared by treatment of the corresponding amine with NaOH in the presence of CS_2, and were dried *in vacuo* at 100°C prior to use. V(NTol)Cl$_3$ was prepared as previously described [7b]. Other reagents were obtained from commercial sources.

Elemental analyses were performed by Galbraith Laboratories, Knoxville, TN. ^1H (400.1 MHz) and ^{51}V (105.2 MHz) NMR spectra were obtained on an IBM/Bruker WM-400 instrument at 298 K and are referenced to internal Me_4Si and external $VOCl_3/CDCl_3$ (75% v/v), respectively. ESR spectra were recorded with a Bruker ER 200D spectrometer operating near 9.27 GHz and were calibrated using DPPH as an external field marker. Electronic spectra in the range 350–700 nm were recorded with a Cary 14 spectrophotometer.

V(NTol)(S$_2$CNEt$_2$)Cl$_2$ (**2a**)

A portion of V(NTol)Cl$_3$ (0.500 g, 1.91 mmol) was placed in a reaction flask and *ca* 5 g of Celite was

added as a filtration aid. An addition sidearm containing $Na(S_2CNEt_2]$ (0.326 g, 1.91 mmol) was attached, and 25 cm^3 of CH_2Cl_2 was introduced by vacuum distillation. After complete dissolution of the vanadium complex, the dithiocarbamate salt was added to the stirred solution at room temperature, causing a rapid color change from dark green to orange–red. After 30 min, the reaction was filtered on a medium porosity sintered glass frit and the filtrate was taken to dryness. The dark red–purple solid product was triturated with pentane (*ca* 30 cm^3), collected by filtration and dried *in vacuo*. If necessary, the product can be recrystallized to remove traces of V(NTol)$(S_2CNEt_2)_2Cl$ (**3a**) by the addition of hexane to a concentrated CH_2Cl_2 solution. Anal. Calcd (found) for $C_{12}H_{17}N_2S_2Cl_2V$: C, 38.41 (38.92); H, 4.57 (4.89); N, 7.47 (7.49). ^1H NMR ($CDCl_3$): δ 7.24 (AA′BB′ q, $J_{AB} = 7.92$ Hz, 4 H, $C_6H_4CH_3$), 3.86 (q, 4H, CH_2CH_3), 2.43 (*s*, 3H, $C_6H_4CH_3$), 1.34 (t, 6H, CH_2CH_3). ^{51}V NMR ($CDCl_3$): δ 301 (fwhm = 415 Hz). λ_{max} ($C_6H_5CH_3$): 530 nm.

V(NTol)$(S_2CNMe_2)Cl_2$ (**2b**)

Prepared and purified as for **2a,** using V(NTol)Cl_3 (0.500 g, 1.91 mmol) and $Na[S_2CNMe_2]$ (0.273 g, 1.91 mmol); the product is a dark red solid. ^1H NMR ($CDCl_3$): δ 7.24 (AA′BB′ q, $J_{AB} = 8.02$ Hz, 4H, $C_6H_4CH_3$), 3.36 (s, 6H, CH_3), 2.43 (s, 3H, $C_6H_4CH_3$). ^{51}V NMR ($CDCl_3$): δ 289 (fwhm = 439 Hz). λ_{max} ($C_6H_5CH_3$): 540 nm.

V(NTol)$(S_2CNEt_2)_2Cl$ (**3a**)

Prepared as for **2a,** using V(NTol)Cl_3 (0.500 g, 1.91 mmol) and $Na[S_2CNEt_2]$ (0.652 g, 3.80 mmol) and stirring at room temperature for 60 min. The dark red product is obtained as the CH_2Cl_2 hemisolvate. Anal. Calcd (found) for $C_{17.5}H_{28}N_3Cl_2S_4V$: C, 39.19 (39.07); H, 5.23 (5.53); N, 7.84 (7.72). ^1H NMR ($CDCl_3$): δ 7.30 (AA′BB′ q, $J_{AB} = 8.32$ Hz, 4 H, $C_6H_4CH_3$), 5.29 (s, 1H, CH_2Cl_2) 3.82 (ABX_3 m, 4H, CH_2CH_3), 3.74 (ABX_3 m, 4H, CH_2CH_3), 2.43 (s, 3H, $C_6H_4CH_3$), 1.27 (t, 12H, CH_2CH_3). ^{51}V NMR ($CDCl_3$): δ 166 (fwhm = 2610 Hz). λ_{max} ($C_6H_5CH_3$): 520 nm.

V(NTol)$(S_2CNMe_2)_2Cl$ (**3b**)

Prepared as for **2a,** using V(NTol)Cl_3 (0.500 g, 1.91 mmol) and $Na[S_2CNMe_2]$ (0.545 g, 3.81 mmol), and stirring at room temperature for 60 min; the product is a dark red solid which can be purified by recrystallization from CH_2Cl_2/hexane. ^1H NMR ($CDCl_3$): δ 7.31 (AA′BB′ q, $J_{AB} = 8.06$ Hz, 4 H, $C_6H_4CH_3$), 3.36 (s, 12H, CH_3), 2.42 (s, 3H, $C_6H_4CH_3$). ^{51}V NMR ($CDCl_3$): δ 161 (fwhm = 1870 Hz). λ_{max} ($C_6H_5CH_3$): 520 nm.

V(NTol)$(S_2CNEt_2)_3$ (**4a**)

Prepared as for **2a,** using V(NTol)Cl_3 (0.500 g, 1.91 mmol) and $Na[S_2CNEt_2]$ (0.978 g, 5.72 mmol), and stirring at room temperature for 90 min; the product is a dark yellow solid which can be purified by recrystallization from CH_2Cl_2/hexane. Anal. Calcd (found) for $C_{22}H_{37}N_3S_6V$: C, 43.98 (43.60); H, 6.21 (6.22); N, 9.24 (9.18). ^1H NMR ($CDCl_3$): δ 7.03 (AA′BB′ q, $J_{AB} = 8.08$ Hz, 4H, $C_6H_4CH_3$), 3.81 (m, br, 12H, CH_2CH_3), 2.27 (s, 3H, $C_6H_4CH_3$), 1.27 (t, br, 15H, CH_2CH_3), 1.17 (t, br, 3H, CH_2CH_3). ^{51}V NMR ($CDCl_3$): δ −565 (fwhm = 1780 Hz). λ_{max} ($C_6H_5CH_3$): 393 nm.

V(NTol)$(S_2CNMe_2)_3$ (**4b**)

Prepared as for **2a,** using V(NTol)Cl_3 (0.500 g, 1.91 mmol) and $Na[S_2CNMe_2]$ (0.818 g, 5.72 mmol), and stirring at room temperature for 90 min; the product is a dark yellow solid which can be purified by recrystallization from CH_2Cl_2/hexane. ^1H NMR ($CDCl_3$): δ 7.04 (AA′BB′ q, $J_{AB} = 8.14$ Hz, 4 H, $C_6H_4CH_3$), 3.42 (s, 6H, CH_3), 3.37, 3.35, 3.31, 3.28 (s, 3H each, CH_3), 2.27 (s, 3H, $C_6H_4CH_3$). ^{51}V NMR ($CDCl_3$): δ −574 (fwhm = 1530 Hz). λ_{max} ($C_6H_5CH_3$): 390 nm.

V(NTol)$(S_2CNEt_2)_2$ (**5a**)

A reaction vessel was charged with **3a** (0.300 g, 0.616 mmol) and Zn powder (1.45 g; 22.2 mmol), and CH_2Cl_2 (*ca* 50 cm^3) was admitted by vacuum distillation. The reaction mixture was stirred at room temperature for 24 h, and the color of the solution changed from orange–red to yellow–brown. The mixture was filtered, the filtrate was taken to dryness and the resultant dark brown powder was triturated with pentane, and dried *in vacuo*. Elemental analyses were not satisfactory. ESR ($CDCl_3$, 298 K): octet, $g = 1.976$, $A(^{51}V) = 89.1$ G.

V(NTol)$(S_2CNME_2)_2$ (**5b**)

Prepared as for **5a,** using **3b** (0.300 g, 0.695 mmol) and Zn powder (1.36 g, 20.8 mmol) and stirring at room temperature for 18 h; the product is a dark brown powder. Elemental analyses were not satisfactory. ESR ($CDCl_3$, 298 K): octet, $g = 1.991$, $A(^{51}V) = 89.9$ G.

p-$[Cl_3V{\equiv}NC_6H_4N{\equiv}VCl_3]$ (**6**)

A portion of $VOCl_3$ (2.5 cm^3, 26 mmol) in toluene (*ca* 120 cm^3) was added to a reaction flask bearing a reflux condenser, and an additional sidearm containing *p*—OCN—C_6H_4—NCO (2.00 g, 12 mmol) was attached. As the solution was being warmed to reflux temperature, the diiocyanate was added in por-

tions over a few minutes. After 45 h of refluxing, the dark green–brown solution was cooled and the dark brown solid product was collected by filtration, washed with CH_2Cl_2 until the washings were colorless, and dried *in vacuo* at 55°C for 12 h to yield 4.23 g (84%) of **6**. anal. Calcd (found) for $C_6H_4N_2Cl_6V_2$: C, 17.21 (17.35); H, 0.96 (1.11); N, 6.69 (6.79).

p-[(THF)$_3$Cl$_3$V≡NC$_6$H$_4$N≡VCl$_3$(THF)$_3$] (**7**)

At room temperature, 0.25 g of **6** were dissolved in 50 cm^3 of THF, and the intense yellow–brown solution was stirred at room temperature for 30 min. Evaporation of the solvent afforded a brown solid, which was dried *in vacuo* for 6 h. ^{1}H NMR ($CDCl_3$): δ 7.78 (s, 4 H, C_6H_4), 4.04 (t, 24H, OCH_2CH_2), 1.96 (quintet, 24H, OCH_2CH_2). ^{51}V NMR ($CDCl_3$): δ 380 (fwhm = 2200 Hz). The THF ligands of **7** are weakly bound and storage *in vacuo* induces the loss of five of them, forming a brown mono(THF) adduct, **6**·THF. Anal. Calcd (found) for $C_{10}H_{12}N_2OCl_6V_2$: C, 24.47 (24.69); H, 2.46 (2.92); N, 5.71 (5.76).

p-[Cl$_3$V≡NC$_6$H$_4$—NCO] (**8**)

A solution of $VOCl_3$ (2.8 cm^3, 29 mmol) in 25 cm^3 of benzene was added dropwise over the course of 1 h to a stirred solution of *p*-OCN—C_6H_4—NCO (4.88 g, 30 mmol) in *ca* 100 cm^3 of benzene at 60°C. The green solution was refluxed for 36 h and solvent was removed *in vacuo*. The brown solid residue was washed with hexane (*ca* 30 cm^3), collected by filtration and dried *in vacuo* at 60°C to yield 6.74 g (79%) of **8**. Anal. Calcd (found) for $C_7H_4N_2OCl_3V$: C, 29.05 (28.94); H, 1.39 (1.45); N, 9.65 (9.68). ^{1}H NMR ($CDCl_3$): δ 7.32 (AA′BB′ q, J_{AB} = 8.30 Hz, 4 H, C_6H_4). ^{51}V NMR ($CDCl_3$): δ 283 (fwhm = 750 Hz).

p-[Cl$_3$V≡NC$_6$H$_4$N≡WCl$_4$] (**9**)

A mixture of $WOCl_4$ (0.36 g, 1.03 mmol) and **8** (0.30 g, 1.03 mmol) was dissolved in toluene (*ca* 50 cm^3) forming a green solution. The solution was refluxed for 24 h, during which time the color became yellow–brown. After cooling to room temperature, the brown solid product was collected by filtration, washed with CH_2Cl_2 until the washings no longer showed a green color, and dried under vacuum to yield 0.36 g (60%) of a product analyzing as **9**. Anal. Calcd (found) for $C_6H_4N_2Cl_7VW$: C, 12.27 (12.36); H, 0.69 (1.20); N, 4.77 (4.07).

p-[(Et$_2$NCS$_2$)$_3$V≡NC$_6$H$_4$N≡V(S$_2$CNEt$_2$)$_3$] (**11**)

A portion of Na[S$_2$CNEt$_2$] (1.03 g, 6.0 mmol) was added to a suspension of **6** (0.42 g, 1.0 mmol) in 50 cm^3 CH_2Cl_2 containing *ca* 5 g of Celite as a filtration aid. The red reaction mixture was stirred at room temperature for 90 min and filtered. The residue remaining on the frit was washed with CH_2Cl_2 (2 × 50 cm^3); these washings were combined with the filtrate and taken to dryness. The dark red solid residue was washed with hexane (50 mL) and dried under vacuum to yield 0.65 g (59%) of mahogany **11**. anal Calcd (found) for $C_{36}H_{64}N_8S_{12}V_2$: C, 39.46 (39.86); H, 5.89 (6.06); N, 10.23 (10.33). ^{1}H NMR ($CDCl_3$): δ 6.78 (s, 4H, C_6H_4), 3.80 (m, br, 24H, CH_2), 1.25, 1.16 (overlapped m, br, 36H, CH_3).

p-[('BuO)$_3$V≡NC$_6$H$_4$N≡V(O'Bu)$_3$] (**12**)

A portion of K[O'Bu] (2.50 g, 22.3 mmol) was added to a solution of **6** (1.50 g, 3.58 mmol) in 100 mL of THF containing *ca* 3 g of Celite as a filtration aid. An orange color developed immediately and the reaction was stirred at room temperature for 18 h, filtered and the filtrate was taken to dryness. The solid residue was extracted into hexane (50 cm^3), filtered and taken to dryness yielding 1.77 g (77%) of dark orange **12**. ^{1}H NMR($CDCl_3$): δ 7.06 (s, 4H, C_6H_4), 1.41 (s, 54H, CH_3). ^{51}V NMR ($CDCl_3$): δ −638 (fwhm = 345 Hz).

(Received 9 May 1997; accepted 12 May 1997)

Abstract—The piperidinyl-substituted aluminium azide, $[(pip)_2AlN_3]_2$ (**5**) (pip = piperidinyl, $\overline{N(CH_2)_4CH_2}$), has been synthesised via the reaction between $[(pip)_2AlCl]_2$ and one equivalent of NaN_3. A related pyrrolyl derivative, $[(Me_2N(H))Al(pyr)_3]$ (**7**) (pyr = pyrrolyl, $\overline{N(CH)_3CH}$), was prepared via the dimethylamine elimination reaction between $[Al_2(NMe_2)_6]$ and six equivalents of pyrrole. A third aluminium amido complex, $[Li(Al(NH^tBu)_4)]_2$ (**9**), has been isolated from the salt elimination reaction between $AlCl_3$ and an excess of $LiNH^tBu$. all three compounds have been characterised by X-ray crystallography; compounds **5** and **9** are dimeric in the solid state, whereas **7** is monomeric. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: aluminium; azide; amide; X-ray.

The Group 13 nitrides (AlN, GaN, InN) continue to generate significant interest for applications in advanced microelectronic and optoelectronic devices [1]. In the context of metalorganic chemical vapour deposition (MOCVD) techniques, these materials are currently prepared by the reaction of ER_3 (E = Al, Ga, In; R = alkyl) with ammonia at temperatures in excess of 900°C [1]. Unfortunately, the use of such high temperatures results in a loss of stoichiometry due to nitrogen deficiency and also introduces thermal stresses in the resulting films. Accordingly, attention has turned recently to the development of single-source precursors in an attempt to lower the thermal budget [1]. Our own work focused initially on a new class of GaN precursors that embody labile amido substituents and an azide nitrogen source, a prime example being $[(Me_2N)Ga(N_3)(\mu\text{-}NMe_2)]_2$ (**1**) [2]. However, the solid state structure of **1** comprises a polymeric chain of dimeric units, thus limiting the volatility of this precursor. In a subsequent development, we discovered [3] that treatment of **1** with pyridine afforded $[Ga(N_3)_3(py)_3]$ (**2**) (py = pyridine), the first example of a structurally characterised tris-(azide) of gallium [4]. The use of azides as the nitrogen source has also been investigated for precursors to aluminium nitride (AlN). Thus, Gladfelter, Evans *et al.* deposited AlN on several substrates at temperatures as low as 400°C by using dialkylaluminium azides [5]. Moreover, a trisazido-aluminium complex possessing a structure similar to that of **2**, $[Al(N_3)_3(py)_3]$ (**3**), has been reported and some related azides, $[Me_2N(CH_2)_3]_2Al(N_3)$ (**4**) and $[AlMe_2(N_3)(N(H_2)^tBu)]$ have been used to grow epitaxial AlN films above 800°C [6]. A number of aluminium amido complexes of the type $[R_{3-n}Al(NR'_2)_n]$ (R = Me, Et, n = 1 or 3) have been used to grow AlN at lower temperatures; however, the resulting AlN films were found to be contaminated with high levels of carbon [7].

In order to explore further the utility of azides or amides as the nitrogen source in AlN precursors we have synthesised a number of azido or amido aluminium precursors which possess an all nitrogen coordination sphere.

RESULTS AND DISCUSSION

With a view to developing an AlN precursor featuring an azide nitrogen source, the colourless crystalline compound **5** was prepared in high yields by means of a two-step procedure as summarised in Scheme 1. Analytical and spectroscopic data were consistent with the empirical formulation, $[(pip)_2AlN_3]_2$ (**5**) (pip = piperidine, $\overline{N(CH_2)_4CH_2}$);

$$AlCl_3 + 2Li(pip) \xrightarrow[-2LiCl]{\text{pentane, -78 °C}} [(pip)_2AlCl]_2$$

$$[(pip)_2AlCl]_2 \xrightarrow[\text{dibenzo-18-crown-6}]{CH_2Cl_2} [(pip)_2AlN_3]_2 \quad \mathbf{5}$$

$$pip = \overline{N(CH_2)_4CH_2}$$

Scheme 1.

however, in order to establish both the degree of oligomerisation and the stereochemistry at aluminium it was necessary to appeal to X-ray crystallography. Compound **5** crystallises in the triclinic space group $P\bar{1}$ and the solid state comprises an array of dimeric units (Fig. 1): a selection of bond lengths and angles

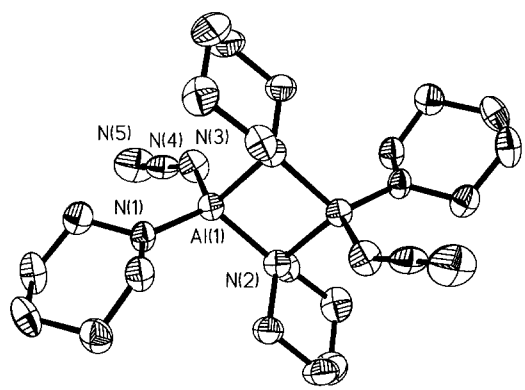

Fig. 1. Molecular structure of $[(pip)_2AlN_3]_2$ (**5**) showing the atom numbering scheme. Ellipsoids are drawn at the 30% level. Hydrogen atoms are omitted.

appears in Table 1. The dimer is formed by means of two bridging piperidinyl (pip) groups, and the resulting Al_2N_2 core is planar by virtue of its location on a crystallographic centre of symmetry. The nonbridging positions are occupied by pip and N_3 groups, resulting in the overall geometry about the aluminium centre being approximately tetrahedral [*av.* N—Al—N 108.9(2) Å]. The Al—N_3 bond distances of 1.805(5) Å in **5** are considerably shorter than those in $[Al(N_3)_3(py)_3]$ **3** [*av.* Al—N 1.971(2) Å] and $N_3Al[(CH_2)_3NMe_2]_2$ **4** (Al—N 1.897(2) Å) even though all three complexes involve terminal azide ligands [6]. The metrical parameters for the azide moieties are typical of those reported for a variety of covalent azides both in terms of the N—N—N bond angle [176.5(7)°] and also with respect to the observation of two significantly different N—N bond distances [1.169(6) and 1.122(6) Å] [8]. The average Al—N(pip) bond lengths are 1.765(4) (terminal pip) and 1.935(5) Å (bridging pip), both of which correspond well to those previously reported for $[Al_2(NMe_2)_6]$ [9] and $[Al_2(pyd)_6]$ (**6**) (pyd = pyrrolidine, $\overline{N(CH_2)_3CH_2}$) [10]. Only one other piperidinyl aluminium complex has been crystallographically characterised prior to **5**,

namely the lithium salt $[(thf)_2LiAl(pip)_4]$ [10]. It is also worth noting that the structure of **5** is similar to that of the related gallium complex $[(Me_2N)Ga(N_3)(\mu\text{-}NMe_2)]_2$ **1**, which is also dimeric by virtue of bridging dimethylamido groups [3].

With a view to investigating the use of the pyrrolyl group as the nitrogen source and in an attempt to isolate a mononuclear, monomeric AlN precursor, $[Al_2(NMe_2)_6]$ was treated with six equivalents of pyrrole at room temperature in hexane solution (Scheme 2). Elemental analytical data, together with ^1H and ^{13}C NMR spectral information, were consistent with the formation of a complex of formula $[(Me_2N(H))Al(pyr)_3]$ (**7**) (pyr = pyrrole, N(CH)$_3$CH). We note, however, that the N—H resonance for the Me_2NH group was not observed in the ^1H NMR spectrum of **7**. An X-ray crystallographic study revealed that the solid state structure of **7** comprises monomeric units, one of which is depicted in Fig. 2; selected bond lengths and angles are presented in Table 1. It is interesting to note the formation of the monomeric amine adduct, $[(Me_2N(H))Al(pyr)_3]$ **7**, rather than a dimeric species of the type $[Al_2(pyr)_6]$ (**8**). Compound **6** [10] is similar to the anticipated product **8**; however, the preparation of **6** involves the reaction of alane with three equivalents of pyrrolidine rather than amine elimination, hence a compound analogous to **7** is not possible. Compound **7** crystallises in the triclinic space group $P\bar{1}$ with no unusually short intermolecular contacts between the monomeric units. The geometry about the aluminium center is approximately tetrahedral [*av.* N—Al—N 109.44(9) Å] with the average Al—N_{pyr} bond length of 1.825(2) Å being much shorter than the N → Al donor bond from the Me_2NH ligand [Al—N(4) 1.933(2) Å] as expected. In a related complex, $[Me_3Al(NH_2{}^tBu)]$ [11], the N → Al bond length of 2.027(3) Å is slightly longer than that in **7** which probably results from increased steric interactions from the *tert*-butyl group. The average Al—N_{pyr} bond length is similar to the terminal Al—N bond lengths found in dimeric species such as **6** [10] and $[Al_2(NMe_2)_6]$ [9].

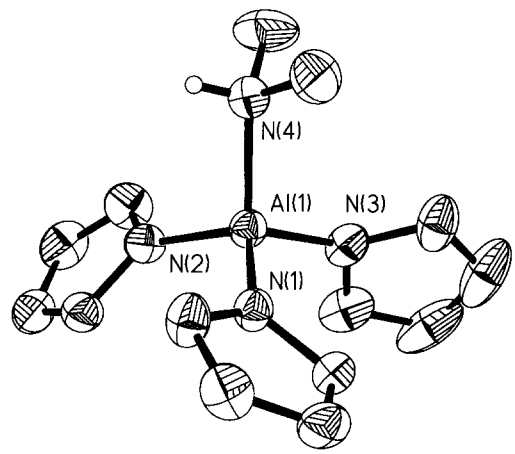

Fig. 2. Molecular structure of $[(Me_2N(H))Al(pyr)_3]$ (**7**) showing the atom numbering scheme. Ellipsoids are drawn at the 30% level. Hydrogen atoms are omitted.

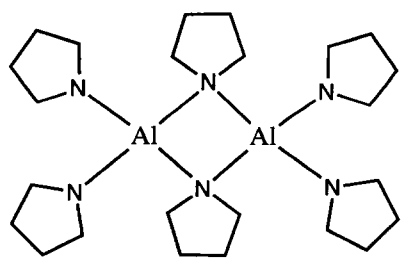
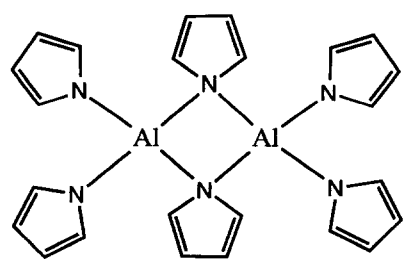
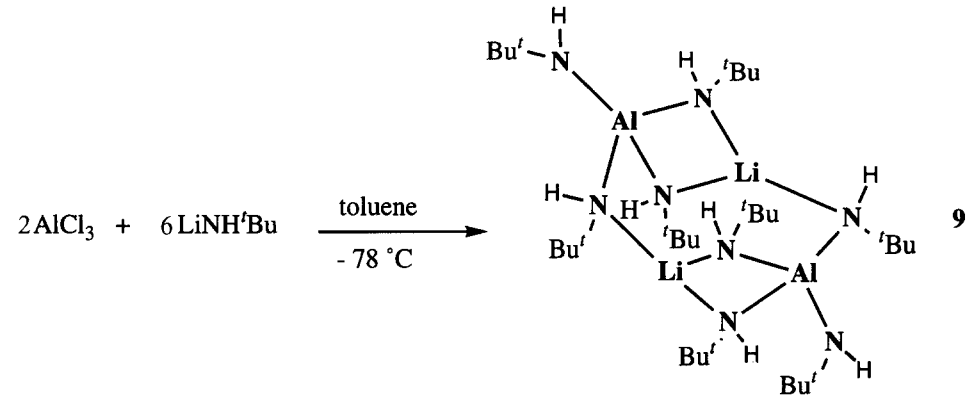
The reaction between $AlCl_3$ and three equivalents of $LiNH^tBu$ was carried out in an attempt to form an example of an aluminium trisamide of the type $[Al(NH^tBu)_3]_n$. However, analytical and spectroscopic



6



8



Scheme 3.

data were indicative of the formation of a lithium salt of formula $[Li(Al(NH^tBu)_4)]_2$ (**9**) (Scheme 3). The ^1H NMR of **9** exhibits a sharp singlet resonance in the ^tBu region, suggesting dynamic behaviour and, as in the case of **7**, the N—H resonances for the NH^tBu groups were not observed. An X-ray crystallographic study revealed that the solid state structure of **9** comprises dimeric units; selected bond lengths and angles are presented in Table 1. Compound **9** crystallises in the triclinic space group $P\bar{1}$ with no unusually short intermolecular contacts between dimeric units. The dimer is formed by means of two lithium cations bridging two $[Al(NH^tBu)_4]^-$ anions as shown in Fig. 3 (the Al—N—Li skeleton is shown in bold-face in Scheme 3). In turn each lithium cation in **9** is bonded to three nitrogen atoms of a NH^tBu group (*av.* Li—N 2.08(1) Å) with only a weak interaction to Al [Al(1)—Li(1a) 2.701(9) Å and Al(1)—Li(1) 3.236(9) Å]. The geometry about the aluminium center is approximately tetrahedral [*av.* N—Al—N 108.85(2) Å] with the terminal Al—N(4) bond length of 1.795(4) Å being shorter than the bridging Al—N bond lengths [*av.* 1.891(4) Å] as expected. These metrical parameters are similar to those reported for some related lithium salts of aluminium amides which have been reported previously, namely $[(pydH)_2LiAl(pyd)_4]$ [10], $[(thf)_2LiAl(pip)_4$ [10], and $[(thf)_2LiAl(NMe_2)_4]$ [12], all of which can be described as a solvated lithium cation bound to a tetrahedral $[Al(NR_2)_4]^-$ anion. Other pertinent lithium salts are $[(thf)_nLiAl(mes)_2(NH^tBu_2)_2]$ [13] (mes = 2,4,6-trimethylphenyl) (n = 1 or 2) and $[(thf)_4Li][Al(^tBu)_2(^tBu)(NDipp)]$ [13], (Dipp = 2,6-diisopropylphenyl), the latter being an anion–cation pair with no contacts between Li and the nitrogen of the amide for steric reasons.

In summary, three new aluminium complexes have been synthesised and structurally characterised. Complexes **5** and **7** are possible precursors for AlN and detailed chemical vapour deposition experiments are in progress.

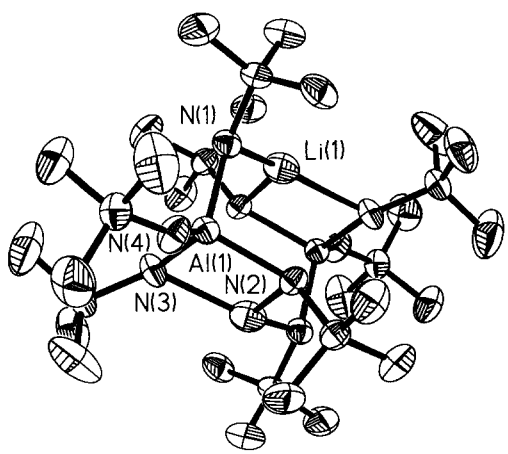


Fig. 3. Molecular structure of $[Li(Al(NH^tBu)_4)]_2$ (**9**) showing the atom numbering scheme. Ellipsoids are drawn at the 30% level. Hydrogen atoms are omitted.

EXPERIMENTAL

General procedures

All manipulations were performed under a dry, oxygen-free dinitrogen or argon atmosphere using standard Schlenk techniques or a HE-493 Vacuum Atmospheres drybox. Unless otherwise stated, all solvents were dried over sodium and distilled from sodium benzophenone ketyl under argon prior to use. The reagent $[Al_2(NMe_2)_6]$ was prepared according to the literature method [9]. All other reagents were obtained from commercial sources and used without further purification. Elemental analyses were performed by Atlantic Microlab, Inc., Norcross, GA.

Physical measurements

Mass Spectra (CIMS) were run on a Finnagan MAT 4023 instrument, and NMR spectra were recorded on a GE QE-300 spectrometer (^1H 300.19 MHz; ^{13}C, 75.48). NMR spectra are referenced to

C_6D_6 which was dried over sodium-potassium alloy and distilled prior to use; ^1H and ^{13}C chemical shifts are reported relative to $Si(CH_3)_4$ (0.00 ppm). Melting points were obtained in sealed glass capillaries under argon and are uncorrected.

Synthesis of $[(pip)_2AlN_3]_2$ **5**

n-Butyllithium (16.2 cm^3, 1.6 M solution in hexane) was added dropwise to a stirred solution of piperidine (2.76 g, 32.4 mmol) in diethyl ether (40 cm^3) at −78°C. After stirring for 12 h and being allowed to warm to room temperature, the resulting yellow solution was added dropwise to a solution of $AlCl_3$ (2.16 g, 16.2 mmol) in diethyl ether (30 cm^3) at −78°C. The solution was stirred for 12 h, pumped to dryness *in vacuo* to give a yellow oil which was dissolved in pentane (40 cm^3). After filtration over Celite, the solvent was removed *in vacuo* giving a yellow oil which was redissolved in CH_2Cl_2 (40 cm^3). Sodium azide (1 g, 16.2 mmol) and dibenzo-18-crown-6 (0.1 g) were added and the solution was stirred for 12 h, after which time the mixture was filtered over celite and the solvent removed *in vacuo*. Pentane (20 cm^3) was added and the resulting solution was stored at −20°C. After a few days at this temperature, X-ray quality crystals of **5** were obtained, m.p. 87–88°C. FTIR 2132.40 cm^{-1} (N_3). HRMS: calcd mass for $C_{20}H_{41}N_{10}Al_2$ 475.314649; found 475.312555. ^1H NMR (300.15 MHz, C_6D_6) δ 0.90 (t, 8H, *p*-$\overline{N(CH_2)_4CH_2}$), 1.27 (t, 16H, *m*-$\overline{N(CH_2)_4CH_2}$), 2.46 (d, 16H, *o*-$\overline{N(CH_2)_4CH_2}$), $^{13}C\{^1H\}$ NMR (75.14 MHz, C_6D_6) δ 22.9 (*o*-$\overline{N(CH_2)_4CH_2}$), 23.6 (*m*-$\overline{N(CH_2)_4CH_2}$), 44.7 (*p*-$\overline{N(CH_2)_4CH_2}$).

Synthesis of $[(Me_2N(H))Al(pyr)_3]$ **7**

Pyrrole (0.59 g, 8.8 mmol) was dissolved in hexane (10 cm^3) and added dropwise to a solution of $[Al(NMe_2)_3]_2$ (0.46 g, 2.9 mmol) in hexane (50 cm^3) at 25°C resulting in the immediate formation of white precipitate. The reaction mixture gradually turned pink as it was stirred for 15 h. The solvent was removed *in vacuo* giving a pink solid which was dissolved in toluene, filtered over celite, and stored at −20°C. X-ray quality crystals of **7** were obtained after 24 h (0.72 g, 92%), m.p. 80°C (dec), 140–142°C (melts). HRMS: calcd mass for $C_{14}H_{19}N_4Al$ 271.148942; found 271.150338. ^1H NMR (300.15 MHz, C_6D_6) δ 1.27 [s, 6H, $N(CH_3)_2$], 6.64 [d, 6H, β-$\overline{N(CH)_3CH}$], 2.46 [d, 6H, α-$\overline{N(CH)_3CH}$], $^{13}C\{^1H\}$ NMR (75.14 MHz, C_6D_6) δ 37.55 [$N(CH_3)_3$], 111.41 [β-$\overline{N(CH)_3CH}$], 112.33 [α-$\overline{N(CH)_3CH}$].

Synthesis of $[Li(Al(NH^tBu)_4)]_2$ **9**

t-Butyllithium (11.6 cm^3, 1.7 M solution in pentane) was added dropwise to a solution of $^tBuNH_2$ (2.0 cm^3, 1.39 g, 1.9 mmol) in hexane (30 cm^3) at −78°C resulting in a cloudy white slurry. The stirred slurry

was allowed to warm to 25°C over a 2 h period. The resulting ^{t}BuN(H)Li reagent was added dropwise over a 1.5 h period to a solution of $AlCl_3$ (0.84 g, 6.3 mmol) in hexane (30 cm^3) at −78°C. The reaction mixture was stirred for 15 h then filtered over Celite. The volume of the resulting clear, colourless solution was reduced by half and stored at −20°C. X-ray quality crystals of **9** were obtained after 12 h (1.22 g, 60%), m.p. 155°C (dec). HRMS: calcd mass for $C_{32}H_{80}N_8Al_2Li$ 637.630388; found 637.629682. ^{1}H NMR (300.15 MHz, C_6D_6) δ 1.43 (s, 36H, ^{t}Bu).

X-ray crystallography

Crystals of **5** were grown from pentane solutions at −20°C whereas crystalline samples of **7** and **9** were grown from toluene solutions stored at −20°C. Crystals of **5, 7** and **9** were mounted in thin-walled glass capillaries and sealed under argon. Data were collected on an Enraf Nonius diffractometer at 25°C with graphite monochromated Mo-Kα radiation (λ = 0.71073 Å). Accurate unit cell parameters were determined by recentering 25 optimal high angle reflections. Three standard reflections were measured every 1800 s during data collection, and no decreases in intensities were noted. Corrections were applied for Lorentz-polarization and absorption effects. The structures were solved for the heavy atoms by direct methods. Subsequent difference syntheses gave all other non-hydrogen atomic positions and these were refined by full-matrix least squares on F^2 using the Siemens SHELXL PLUS 5.0 (PC) software package [14]. All non-hydrogen atoms were allowed anisotropic thermal motion. Hydrogen atoms were included at calculated positions (C—H 0.96 Å) and were refined using a riding model and a general isotropic thermal parameter. Crystallographic data and details of the data collection procedures and structure refinement for **5, 7** and **9** are presented in Table 2. Further details on the crystal structure analysis are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, U.K. by quoting the full journal citation.

(Received 7 April 1997; accepted 12 May 1997)

Abstract—Reaction of $Ga(^tBu)_3$ with the 1,3-diphenylamidine [PhN(H)C(H)=NPh, H-dpam] yields monomeric $(^tBu)_2Ga(dpam)$ (**1**). The partial hydrolysis of **1** results in the isolation of $(^tBu)_2Ga(\mu\text{-dpam})(\mu\text{-OH})Ga(^tBu)_2$ (**2**), whose structure consists of a gallium dimer in which the amidine and hydroxide ligands bridge two $Ga(^tBu)_2$ moieties. Reaction of $[Me_2Ga(\mu\text{-Cl})]_2$ with H-dpam results in the complex $[H_2\text{-dpam}][Me_2GaCl_2]$ (**3**). The solid state structure of **3** indicates the presence of a hydrogen bonded cation–anion complex, in which the core has a twisted eight-membered ring configuration. The versatility of amidines as both chelating and bridging ligands to gallium is discussed with respect to the predominance of bridging and chelating modes of coordination of carboxylates and triazenides, respectively. Reaction of 2-(methylamino)pyridine (H-map) with $Ga(^tBu)_3$ allows for the isolation of $(^tBu)_2Ga(map)$ (**4**). In contrast, reaction with $[(^tBu)_2Ga(\mu\text{-Cl})]_2$ and $[Me_2Ga(\mu\text{-Cl})]_2$ yields the Lewis acid base adducts, $(^tBu)_2GaCl(H\text{-map})$ (**5**) and $Me_2GaCl(H\text{-map})$ (**6**), respectively. Reaction of compound **6** with $^nPrNH_2$ does not result in the deprotonation of the H-map ligand, but ligand metathesis and the formation of $(^tBu)_2GaCl(NH_2{}^nPr)$ (**7**). The structures of **2, 3, 6,** and **7** have been determined by X-ray crystallography. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: amidine; aminopyridine; hydrogen bonding; hydrolysis; gallium.

We have become interested in the structural relationships between potentially isolobal [1] (and isoelectronic) ligands as they pertain to their coordination to the Group 13 metals: aluminum, gallium and indium. Our initial studies in this area involved a comparison of carboxylates (**I**) [2] and their isolobal analogs, 1,3-diphenyl triazenide ligands (**II**) [3,4,5,6]. We have demonstrated that despite the clear isolobal relationship between the parent ligands [7], the propensity of triazenides to act as a chelating rather than bridging ligand (as is observed for carboxylates) to aluminum, gallium or indium, suggests that they are better considered equivalent to acetylacetenoates. While we originally ascribed the differences in coordination of carboxylates and triazenides to the greater steric strain that would be imposed on a chelating carboxylate than is observed for the triazenide [8], it is possible that the presence of aryl (or alkyl) substituents on the 1,3 positions of the triazenide may add a steric component to the difference in observed coordination. In order to determine if it is steric rather than ring strain factors controlling the preferred coordination mode for carboxylates and triazenides it would be desirable to study a hybrid class of ligand, such as a dialkylamidines (**III**) [9]. A particular advantage of the amidines is that the steric bulk at both carbon (*R'*) and nitrogen (*R*) may be tuned as desired. Dialkylamidine complexes of transition metals have been well studied; however, compared to the extensive chemistry of carboxylate compounds a limited number of compounds

(V)

of the Group 13 metals have been reported for amidines [10,11]. The dialkylamidine compounds of gallium were shown by X-ray crystallography to be both chelating and bridging, suggesting that amidines are potentially more flexible ligands for the Group 13 metals than either carboxylates or triazenides. Our studies involve the reactions of 1,3-diphenylamidine (H-dpam, **III**, R = Ph, R' = H).

Alternative isolobal (and isoelectronic) analogs of an amidine are 2-(methylamino)pyridine (H-map, **IV**) and 2-mercaptopyridine ligand (H-Spy, **V**). The latter has previously been demonstrated to form both bridging and chelating complexes with aluminum, gallium and indium [12,13].

In order to determine the relative coordination modes for these isolobal ligands we have investigated the reactions of 1,3-diphenylamidine (H-dpam) and 2-(methylamino)pyridine (H-map) with gallium trialkyls and di-alkyl chlorides. The initial results of this study are presented herein.

RESULTS AND DISCUSSION

Amidine compounds

Reaction of $Ga(^tBu)_3$ with one equivalent of H-dpam yields $(^tBu)_2Ga(dpam)$ (**1**), with the con-

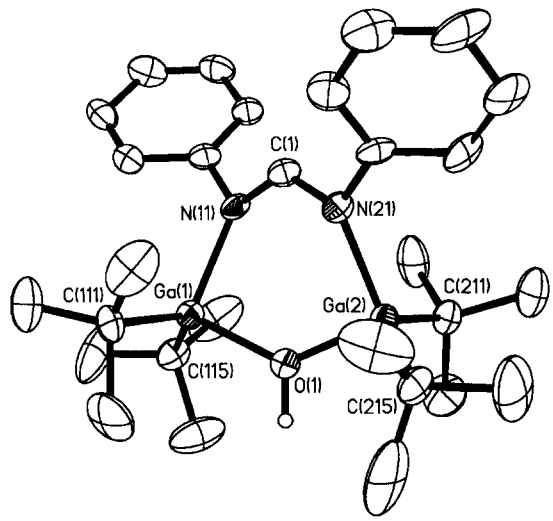

Fig. 1. The molecular structure of one of the crystallographically independent molecules of $(^tBu)_2Ga(\mu$-dpam$)(\mu$-OH$)Ga(^tBu)_2$ (**2**). Thermal ellipsoids are shown at the 30% level and organic hydrogen atoms are omitted for clarity.

comitant liberation of iso-butane. Based upon mass spectrometry (M^+ = 378) compound **1** appears to be isostructural to the 1,2,3-triphenylamidine compound Me_2Ga(PhNCPhNPh) [11].

Compound **1** undergoes partial hydrolysis to liberate dpam-H and the dimeric hydroxide compound, $(^tBu)_2Ga(\mu$-dpam$)(\mu$-OH$)Ga(^tBu)_2$ (**2**), whose molecular structure is shown in Fig. 1; selected bond lengths and angles are given in Table 1. Two independent molecules are present in the asymmetric unit; however, all bond lengths and angles are close to or within experimental error between the two molecules (see Table 1). The Ga_2ON_2C cycle occupies a twist boat conformation (see Fig. 2) as a consequence of the steric interaction between the *tert*-butyl and phenyl groups [2]. The coordination around each gallium is distorted tetrahedral, with the smallest angles being

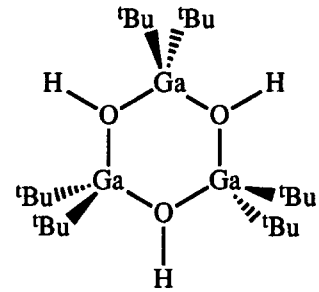
intra-ring, i.e., N—Ga—O [93.4(2)–94.4(2)°]. The Ga—N bond lengths [2.020(7)–2.032(6) Å] are within the range reported for chelating amidine compounds of gallium [2.009(2)–2.141(2) Å] [10,11]. As is typical for amidine ligands the N—C bond distances within the amidine core [1.30(1)–1.34(1) Å] are intermediate between those of isolated N—C single (*ca* 1.45 Å) and N=C double bond (*ca* 1.28 Å) lengths, consistent with delocalization of the N···C···N π-bond. The Ga—O—Ga angle [132.0(3), 132.4(3) Å] is smaller than that reported for [(^{t}Bu)$_2$Ga(μ-OH)]$_3$ (**VI**) [143.0(2) Å] [14].

Whereas Barker *et al.* have previously reported that the reaction of 1,2,3-triphenylamidine with $GaMe_3$ yields Me_2Ga(PhNCPhNPh) [11], the reaction of H-dpam with [$Me_2Ga(\mu$-Cl)]$_2$ does not result in alkane elimination but the formation of the salt, [H_2-dpam][Me_2GaCl_2] (**3**) (see Experimental), whose formation presumably occurs *via* the series of reactions shown in Eqs 1–3. We note that while Me_2Ga(PhNCPhNPh) [11] and Me_2Ga(PhNCMeNPh) [10] have been previously reported, we were unable to isolate Me_2Ga(dpam) under the present reaction conditions.



(VI)

$$Me_2GaCl + H\text{-dpam} \rightarrow Me_2Ga(dpam) + HCl \quad (1)$$

$$H\text{-dpam} + HCl \rightarrow [H_2\text{-dpam}]Cl \quad (2)$$

$$Me_2GaCl + [H_2\text{-dpam}]Cl \rightarrow [H_2\text{-dpam}][Me_2GaCl_2] \quad (3)$$

The structure of [H_2-dpam][Me_2GaCl_2] (**3**) is shown in Fig. 3; selected bond lengths and angles are given in Table 2. The coordination environment about

Table 2. Selected bond lengths (Å) and angles (°) for $[H_2$-dpam$][Me_2GaCl_2]$ (**3**)

Ga(1)—Cl(1)	2.307(4)	Ga(1)—C(11)	1.95(2)

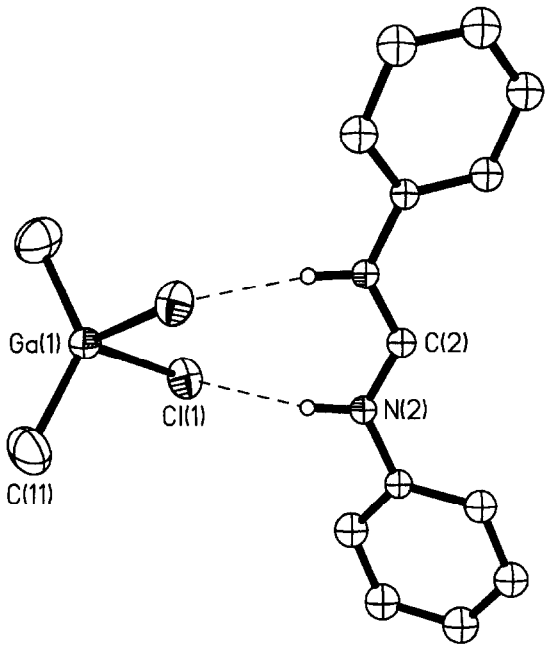

Fig. 3. The structure of $[H_2$-dpam$][Me_2GaCl_2]$ (**3**). Thermal ellipsoids are shown at the 30% level and organic hydrogen atoms are omitted for clarity.

Ga(1) is similar to previously characterized anion in $[Me_4As][Me_2GaCl_2]$ [15]. The Ga(1)—Cl(1) bond distance [2.307(4) Å] is slightly longer than non-hydrogen bonded terminal analogs [2.276(4), 2.277(4) Å] consistent with the hydrogen bonding interaction. Similarly, the Cl(1)—Ga(1)—Cl(1a) bond angle in **3** [97.4(1)°] is smaller than that in $[Me_4As][Me_2GaCl_2]$ [99.7(1)°], presumably due to the constraints of the two N—H···Cl hydrogen bonds. The hydrogen bonded anion–cation complex forms an unusual twisted 8-membered ring (see Fig. 4). The N—H···Cl hydrogen bonding distances [2.13(4) Å] is slightly shorter than recently observed for $[H_2N^iPr_2][MeGaCl_3]$, 2.43(7), 2.60(7) Å [16].

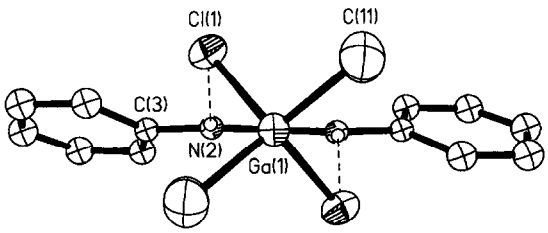

Fig. 4. $[H_2$-dpam$][Me_2GaCl_2]$ (**3**) viewed along the Ga(1)···C(1) vector demonstrating the conformation of the $GaCl_2H_2N_2C$ cycle.

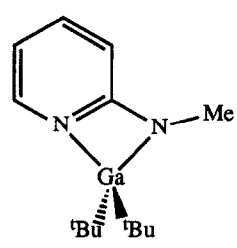
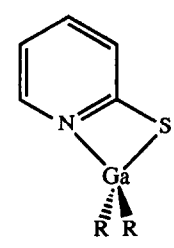
Amidines: intermediaries between carboxylates and triazenides

We have previously suggested that the propensity of carboxylate ligands to act as bridging rather than chelating ligands to the Group 13 metals is due to the topotactic nature of the reaction [2], since no reorganization of the O—C—O framework is required in going from the 'free' carboxylic acid to the bridging carboxylate ligand. In particular the O—C—O angle in the free ligand (*ca* 123°) is similar to the range we have reported for bridging complexes (122–125°), and distinct to that observed and calculated for chelating carboxylates [2,17]. This is represented graphically in Fig. 5. In contrast, the N—N—N angle in bridging triazenide complexes is significantly larger than that for free and chelating triazenides (see Fig. 5) in accord with the observed preference of the latter mode of coordination.

The observations herein, and previously [10,11], that amidines exist as both bridging and chelating ligands suggests that they are more flexible ligands to Group 13 metals than either triazenides or carboxylates. This effect may be expected based on the rationale used for the triazenide and carboxylate preferential binding [2,8]. Thus, from Fig. 5 it is seen that the N—C—N angle in 'free' amidines occurs in between the values observed for chelating and bridging coordination. Furthermore, in both carboxylates and triazenides the intra-ligand angle is essentially invariant; however, the N—C—N angle in amidines may be



(**4**)



(**VII**)

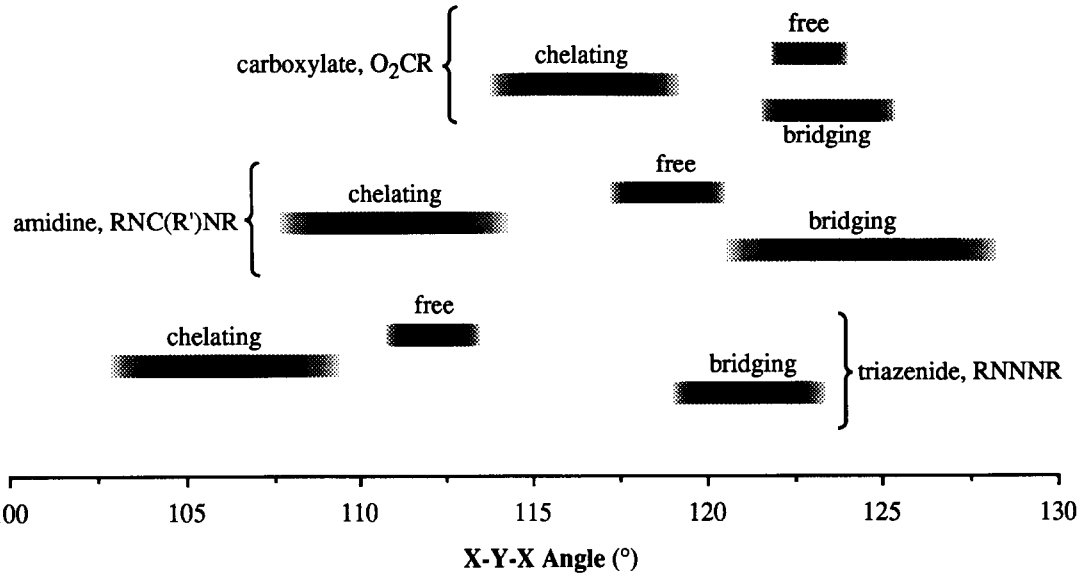


Fig. 5. Graphical representation of the X—Y—X bond angle (°) for triazenides, amidines, and carboxylates in chelating and bridging complexes as well as the 'free' ligand.

increased through the use of sterically demanding groups at either or both C and N. Thus, amidine ligands offer an entry into a diverse range of Group 13 metal complexes. Our studies in this regard are continuing.

2-(*Methylamino*)*pyridine compounds*

Reaction of $Ga(^tBu)_3$ with 2-(methylamino)pyridine (H-map) yields $(^tBu)_2Ga$(2-map) (**4**). Mass spectra of compound **4** indicate it to be monomeric in the gas phase (see Experimental), and thus analogous to $(R)_2Ga(Spy)$ (**VII**, R = Me,^{t}Bu).

As was observed for H-dpam (*vide supra*), the reaction of H-map with $[R_2Ga(\mu\text{-Cl})]_2$ (R = Me,^{t}Bu) does not result in alkane elimination, but yields the Lewis acid–base complexes, Me_2GaCl(2-map) (**5**) and $(^tBu)_2$ GaCl(2-map) (**6**). The molecular structure of Me_2GaCl(2-map) (**6**) has been determined by X-ray crystallography and is shown in Fig. 6; selected bond lengths and angles are given in Table 3.

The 2-(methylamino)pyridine ligand in compound **6** coordinates *via* the pyridine nitrogen, consistent with the greater Lewis basicity of pyridine over a secondary amine. It is interesting to note that the configuration of the Me_2GaCl moiety in the solid state (**VIII**) with respect to the 2-(methylamino)pyridine ligand precludes N—H···Cl hydrogen bonding (i.e. **IX**). In addition to the lack of intra-molecular N—H···Cl hydrogen bonding, there is no evidence for inter-molecular hydrogen bonding from the crystal packing. The ν(N—H) stretch in the IR spectra of compound **6** is unchanged between solution (3327 cm^{-1}, CH_2Cl_2) and the solid state (3329 cm^{-1}, KBr disk), suggesting that no N—H···Cl hydrogen bonding occurs to the methyl amine of the H-map ligand. Similarly the change observed for compound **5** (3346 cm^{-1}, CH_2Cl_2 versus 3354 cm^{-1}, KBr disk) is consistent with no hydrogen bonding.

Reaction of compound **6** with ^{n}PrNH$_2$ does not result in the deprotonation of the H-map ligand, but ligand metathesis and the formation of $(^tBu)_2$

GaCl($NH_2{}^n$Pr) (**7**), whose structure has been confirmed by X-ray crystallography. The molecular structure of compound **7** is shown in Fig. 7; selected bond lengths and angles are given in Table 4. The Ga(1)—N(1) distance [2.067(4) Å] is similar to that observed for the pyridine donor in compound **6** (*vide supra*). In addition the Ga(1)—Cl(1) bond [2.285(2) Å] is essentially the same as that observed for compound **6**; however, while there is no evidence for intramolecular hydrogen bonding in **7**, the crystal packing (Fig. 8) shows strong inter-molecular N—H···Cl hydrogen bonding.

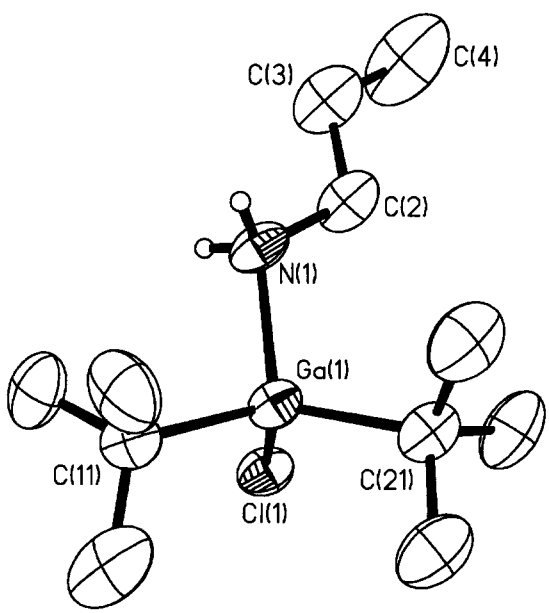

Fig. 7. The molecular structure of (^{t}Bu)$_2$GaCl($NH_2{}^n$Pr) (**7**). Thermal ellipsoids are shown at the 30% level and hydrogen atoms are omitted for clarity.

EXPERIMENTAL

All operations were carried out using Schlenk techniques or in an argon atmospheric VAC glovebox. The synthesis of Ga(^{t}Bu)$_3$ [18,19] [(^{t}Bu)$_2$Ga(μ-Cl)]$_2$ [20], and [Me_2Ga(μ-Cl)]$_2$ [21] are reported elsewhere. ^{1}H and ^{13}C NMR analysis was carried out on a Bruker WM-250 MHz spectrometer. Mass spectra analysis was obtained on a Finnegan MAT95 mass spectrometer with an electron beam energy of 70 eV for EI mass spectra. IR analysis was carried out on a Perkin–Elmer 1600 Series FT-IR spectrometer using Nujol mulls.

(^{t}Bu)$_2$Ga(dpam) (**1**)

H-dpam (1.82 g, 8.31 mmol) was dissolved in degassed toluene (50 cm^3) and the solution was cooled to −78°C. Ga(^{t}Bu)$_3$ (2.0 cm^3, 8.31 mmols) was then added slowly and the mixture was left to stir overnight while warming to room temperature. The solution was filtered, concentrated *in vacuo*, and cooled (−22°C). Several crops of pale yellow crystals were collected by filtration and subsequent recooling of the filtrate. MS (EI, %): *m/z* 378 (M^+, 7), 321 (M^+—^{t}Bu, 98), 265 (M^+—2^{t}Bu, 80), 196 (dpam, 7), 57 (^{t}Bu, 27). IR (cm^{-1}): 2961 (m), 2924 (m), 2338 (m), 1265 (s), 1084

(^{t}Bu)$_2$Ga(μ-dpam)(μ-OH)Ga(^{t}Bu)$_2$ (**2**)

To a hexane (50 cm^3) suspension of H-dpam (1.0 g, 5.1 mmol) was added Ga(^{t}Bu)$_3$ (1.2 g, 5.0 mmol) dropwise to provide a clear solution. The solution was allowed to stir at ambient temperature for 1 h. The solvents and volatiles were removed *in vacuo* to yield the colorless solids. The product was re-dissolved in wet CH_2Cl_2 and recrystallized at -24°C. Yield: 69%. MS (EI, %): *m*/*z* 523 [M$^+$—^{t}Bu, 100], 321. IR (cm^{-1}): 2928 (m), 2839 (m), 1650 (vs), 1589 (s), 1532 (m), 1489 (m), 1308 (w), 1292 (w), 1201 (m), 1025 (w). ^{1}H NMR: δ 7.33 [2H, dd, J(H—H) = 7.8 Hz, *m*-C*H*], 7.09 [1H, t, J(H—H) = 7.8 Hz, *p*-C*H*], 7.08 [2H, d, J(H—H) = 7.8 Hz, *o*-C*H*], 2.36 (1H, s, O*H*), 1.28 [1H, s, NC(*H*)N], 1.04 [36H, s, C(CH_3)$_3$]. ^{13}C NMR: δ 129.8 (*m*-*C*H), 126.0 (*p*-*C*H), 124.8 (*o*-*C*H), 31.7 [C(*C*H$_3$)$_3$], 24.1 (N*C*N).

[H_2-dpam][Me_2GaCl_2] (**3**)

To a CH_2Cl_2 solution (2.0 cm^3) of H-dpam (0.42 g, 2.2 mmol) was added dropwise an Et_2O solution (2.0 cm^3) of [Me_2Ga(μ-Cl)]$_2$ (0.29 g, 2.2 mmol) at -78°C. The solution mixture was stirred overnight and allowed to rise to anambient temperature. The solvents and volatiles were removed under vacuum to yield a yellow oily residue. The residue was sublimed at *ca* 140°C to obtain pale yellow crystals. Yield: 49%. MS (EI, %): *m*/*z* 294 (M$^+$—2 Cl, 38), 279 [(M$^+$—2 Cl—Me, 100]. IR (cm^{-1}): 3398 (w), 1650 (vs), 1590 (s), 1495 (w). 1307 (w), 1201 (w). ^{1}H NMR: δ 7.2 (2H, br s, N—*H*), 7.2–6.8 (10H, m, C_6H_5), 2.11 [1H, s, NC(*H*)N], 0.30 [6H, s, Ga—CH_3]. ^{13}C NMR (δ): 129.8 (*o*-*C*H), 123.9 (*p*-*C*H), 120.0 (*m*-*C*H), 1.76 (Ga—*C*H$_3$).

(^{t}Bu)$_2$Ga(map) (**4**)

To H-map (0.9 g, 8.31 mmol) in hexane (50 cm^3) was added Ga(^{t}Bu)$_3$ (2.0 g, 8.31 mmol) at -78°C. After warming to room temperature and stirring overnight, the mixture was filtered, and after removal of all volatiles yielded a yellow oil. MS (EI, %): *m*/*z* 233 (M$^+$—^{t}Bu, 18), 177 (M$^+$—2^{t}Bu, 20), 107 (map, 82), 57 (^{t}Bu, 12). R(cm^{-1}): 2960 (s), 2837 (s), 1608 (s), 1501 (m), 1419 (m), 1296 (m), 1086 (s), 1009 (s), 799 (s), 656 (m). ^{1}H NMR (C_6D_6): δ 7.02 [1H, d, J(H—H) = 7.5, 6-C*H*], 6.92 [1H, dd, J(H—H) = 7.5, 4-C*H*], 5.81 [1H, dd, J(H—H) = 7.5, 5-C*H*], 5.77 [1H, d, J(H—H) = 6.8 Hz, 3-C*H*], 2.67 (3H, s, NCH_3), 1.22 [18H, s, C(CH_3)$_3$]. ^{13}C NMR (C_6D_6): δ 144.3 (6-*C*H), 140.2 (4-*C*H), 107.1 (5-*C*H), 103.8 (3-*C*H), 30.6 [C(*C*H$_3$)$_3$], 24.1 (N*C*H$_3$).

(^{t}Bu)$_2$GaCl(H-map) (**5**)

To neat H-map (0.40 g, 3.9 mmol) was added [(^{t}Bu)$_2$Ga(μ-Cl)]$_2$ (0.86 g, 3.9 mmol) at ambient temperature. The resulting colorless oily product was agitated for 1 h. Hexane (2 cm^3) was added and stirred additional 1 h. The solvent and volatiles were removed *in vacuo* to yield a colorless solid. The material was recrystallized from CH_2Cl_2 at -24°C. Yield: 79%. MS (EI, %): *m*/*z* 269 (M$^+$—^{t}Bu, 36), 233 (M$^+$—^{t}Bu—Cl, 18), 183 [(^{t}Bu)$_2$GaCl, 75]. IR (cm^{-1}): 3309 (s, br), 2952 (s), 2939 (s), 2839 (s), 1711 (w), 1661 (s), 1625 (vs), 1581 (vs), 1540 (s), 1474 (s), 1423 (m), 1362 (w), 1350 (w), 1172 (s), 1078 (w), 997 (w), 814 (m), 508 (w). ^{1}H NMR: δ 7.65 [1H, d, J(H—H) = 7.5, 6-C*H*], 6.73 [1H, dd, J(H—H) = 7.5, 4-C*H*], 5.92 [1H, dd, J(H—H) = 7.5, 5-C*H*], 5.61 [1H, d, J(H—H) = 6.8 Hz, 3-C*H*], 1.99 [3H, d, J(H—H) = 5.0 Hz, NCH_3], 1.36 [18H, s, C(CH_3)$_3$]. ^{13}C NMR: δ 144.8 (6-*C*H), 140.7 (4-*C*H), 111.4 (5-*C*H), 108.1 (3-*C*H), 30.9 [C(*C*H$_3$)$_3$], 28.5 [N*C*H$_3$].

Me_2GaCl(H-map) (**6**)

To neat H-map (0.20 g, 1.9 mmol) was added [Me_2Ga(μ-Cl)]$_2$ (0.25 g, 1.9 mmol) at ambient temperature. The resulting colorless oily product was agitated for 30 min and then set in a freezer (-24°C) overnight to obtain crystalline solids. Yield: 93%. MS (EI, %): *m*/*z* 227 [M$^+$—Me, 15], 207 (M$^+$—Cl, 10), 191 (M$^+$—Cl—CH_4, 15), 121 (MeGaCl, 21), 108 (map-H, 100), 99 (GaMe_2, 41). IR (cm^{-1}): 3682 (w), 3331 (m, br), 1663 (s), 1626 (s), 1579 (s), 1537 (m), 1472 (m), 1170 (m), 1007 (w). ^{1}H NMR: δ 7.49 [1H, d, J(H—H) = 7.5, 6-C*H*], 7.40 (1H, br, N—*H*), 6.70 [1H, dd, J(H—H) = 7.5, 4-C*H*], 5.86 [1H, dd, J(H—H) = 7.5, 5-C*H*], 5.58 [1H, d, J(H—H) = 6.8 Hz, 3-C*H*], 1.97 [3H, d, J(H—H) = 5.0 Hz, NCH_3], 0.26 (6H, s, Ga—CH_3). ^{13}C NMR: δ 158.8 (6-*C*H), 143.8 (6-*C*H), 141.4 (4-*C*H), 112.7 (5-*C*H), 108.3 (3-*C*H), 29.0 (N*C*H$_3$), -2.9 (Ga—*C*H$_3$).

(^{t}Bu)$_2$GaCl(NH$_2$^{n}Pr) (**7**)

To (^{t}Bu)$_2$GaCl(H-map) (1.1 g, 4.1 mmol) was added NH$_2$^{n}Pr (0.25 g, 4.2 mmol) and the mixture stirred for 1 h. As this slightly exothermic reaction cooled down to ambient temperature, needle like crystals were formed. Yield: 96%. MS (EI, %): *m*/*z* 220 (M$^+$—^{t}Bu, 37). ^{1}H NMR: δ 2.21 (1H, br, NH$_a$), 1.86 (1H, br, NH$_b$), 1.24 [18H, s, C(CH$_3$)$_3$], 1.07 [2H, t, J(H—H) = 7.2 Hz, NH$_2$CH_2], 0.68 [2H, qt,

Crystallographic studies

Crystals of compounds **2, 3, 6,** and **7** were sealed in a glass capillary under argon and mounted on the goniometer of an Enraf–Nonius CAD-4 automated diffractometer. Data collection and cell determinations were performed in a manner previously described [22], using the $\theta/2\theta$ scan technique. Pertinent details are given in Table 3. The structures were solved by Patterson or direct Fourier methods, and the model refined using full-matrix least squares techniques. All non-hydrogen atoms were refined anisotropically, except for compound **3** in which Ga(1), Cl(1), and C(11) were the only atoms refined anisotropically. Except for the hydroxide and amine hydrogens, all hydrogen atoms were calculated and constrained to 'ride' upon the appropriate atoms [d(C—H) = 0.95 Å, U(H) = $1.3B_{eq}$(C)]. The hydroxide and amine hydrogens were located in the difference map, and their isotropic thermal parameter was allowed to 'ride' upon the heavy atom [U(H) = $1.3B_{eq}$(O) or $1.3B_{eq}$(N)]. All computations were performed using MolEN [23] or SHELX86 [24]. A summary of cell parameters, data collection, and structure solution is given in Table 5. Scattering factors were taken from ref. [25].

(Received 2 May, 1997; accepted 5 May 1997)

Abstract—The title compound crystallises as a hexane hemisolvate from 1 : 1 : 1 or 2 : 1 : 2 reaction mixtures of the lithium primary amide $Bu^tN(H)Li$, potassium *t*-butoxide Bu^tOK, and the diamine TMEDA in hexane solution. An X-ray crystallographic study reveals that it exists as a discrete cage species with a central oxo (O^{2-}) anion, coordinated to the eight cations of a surrounding 16-vertex (Li_8O_8) polyhedron, two opposing sides of which are each bridged by a TMEDA-chelated K^+ cation. Made up of μ_3O-Li_3 and μ_2O-Li_2 interactions, the Li_8O_8 polyhedron can be regarded in common terminology for alkali metal based structures, as an incomplete stack arrangement of two tetrameric $(Li—O)_4$ cyclic rings. The eight Li^+ cations form a distorted dodecahedron and the eight alkoxide O atoms form a distorted square antiprism. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: alkali metals; alkoxide; cage complex; crystal structure; oxide.

The growing technological importance of metal oxides in, for example, electronic and ceramic materials, has rekindled enthusiasm for fundamental studies of metal alkoxides, which make excellent precursors for the deposition of metal oxides. This point is highlighted in a recent review by Bradley [1]. Intermediate in composition between molecular metal alkoxides and macromolecular metal oxides, metal oxide alkoxide combinations represent a structural link between the two extremities; as such, they have attracted special attention. Here, in this paper, we report an unprecedented mixed alkali metal oxide alkoxide in $[Li_8K_2(O)(Bu^tO)_8 \cdot 2TMEDA]$, (**1**). This was produced unexpectedly during a study of lithium amide/potassium alkoxide reactions, the intended aim of which was to grow crystals of a model superbase comparable to the previously reported trimetallic lithium–sodium–potassium formulation $[\{LiNaK[PhN(H)]_2(Bu^tO) \cdot 2TMEDA\}_2]$ [2].

RESULTS AND DISCUSSION

Synthesis and characterisation

Treating the lithium primary amide $Bu^tN(H)Li$,[3] freshly prepared from equimolar amounts of *n*-butyllithium and *t*-butylamine, with potassium *t*-butoxide (Bu^tOK) in the presence of N, N, N′, N′-tetramethylethylenediamine (TMEDA) resulted in mauve coloured solutions which deposited large colourless rhombic crystals of $\mathbf{1} \cdot \frac{1}{2}C_6H_{14}$. Two distinct stoichiometries of the respective reactants, 1 : 1 : 1 and 2 : 1 : 2, gave this same crystalline product, and both reactions were found to be reproducible. Disregarding the oxide component, the yield of **1** can be estimated to be typically 45–50%, based on consumption of potassium *t*-butoxide (weighed as the anhydrous

material). No other solid products were forthcoming from the filtrates (following removal of **1**) despite prolonged cooling at freezer temperatures. These observations imply that the formation of **1** is probably kinetically driven. Considering only the 1 : 1 : 1 reaction, all of the amide anions, nearly all of the K^+ cations, and (since the yield of **1** falls well short of quantitative) some butoxide anions, Li^+ cations and TMEDA molecules, must remain in solution. Clearly, therefore, given the complexity of this mixture, a variety of aggregated species could be present in solution, of which **1** is presumably the least soluble. Once isolated, the rhombic crystals of $\mathbf{1} \cdot \frac{1}{2}C_6H_{14}$ are robust, showing no visible signs of decomposition when stored in an argon-filled dry box for several weeks. Their melting point (218–220 °C) distinguishes them from the reactants Bu'OK (m.p. 256–258 °C) and $[\{Bu'N(H)Li\}_8]$ (decomp. to dark brown solid from about 260 °C), both of which could have potentially crystallised in an unreacted state from solution. The absence of amide groups was confirmed by the lack of N—H bonds in the IR spectrum of **1**: the air-exposed spectrum revealed the presence of both lithium and potassium through the hydroxide (O—H) stretches at 3676 and 3506 cm^{-1} respectively. As its highly polar core is hidden by an outer shell of lipophilic *t*-butyl groups (see discussion of structure below), **1** possesses appreciable solubility in arene solvents, thus enabling a ^1H NMR spectrum to be recorded in deutero–toluene solution. Importantly, the integration ratio found for Bu^t : TMEDA (8 : 2) is in agreement with the stoichiometry determined by the X-ray diffraction study, confirming that the crystal structure is representative of the bulk solid product. Furthermore, the presence of chemically distinct types of $Bu'O^-$ anions in the crystal structure is echoed by the observation of a series of overlapping Bu^t(*Me*) resonances, centred at 1.52 ppm. This chemical shift value intimates a lower shielding of the Bu^t hydrogen atoms compared to those in pure Bu'OK (corresponding value, 1.01 ppm), which is consistent with the lower ionicity of the small alkali metal.

An essential question regarding the synthesis of **1** remains to be answered: what is the source of the oxido (O^{2-}) ligand? We believe it stems from a trace amount of moisture in Bu'OK, a solid noted for its strong hygroscopic nature. This reactant was used as supplied by Aldrich, and as no special precautions were taken when transferring it in the open atmosphere to the Schlenk tube, it could have easily picked up moisture during the process. On the other hand, if moisture had been present prior to the addition of the alkoxide, then the lithium amide (or at an earlier stage, *n*-butyllithium) would surely have removed it according to the decomposition reaction shown in eq. (1). Metal alkoxides are known to react stoichiometrically with water to form the corresponding alcohol and metal oxide [1]. Equation (2) illustrates this reaction for an alkali metal (M). Such a process could have occurred *in situ* here, as a pre-requisite to the formation of **1**. In this connection, the formula of **1** is best represented as $(Bu'OK)_2(Bu'OLi)_6(Li_2O)(TMEDA)_2$, i.e., containing one molecule of lithium oxide. Whether this molecule is generated directly through the reaction in equation 2 (with M = Li) or indirectly by a metal exchange process involving an *in situ* form of K_2O, remains an open question.

$$Bu'N(H)Li + H_2O \rightarrow Bu'NH_2 + LiOH \quad (1)$$

$$2ROM + H_2O \rightarrow 2ROH + M_2O \quad (2)$$

Moisture is often suspected to be the source, when oxygen centres turn up adventitiously in structures determined by X-ray diffraction. A good example, pertinent to **1**, is crystalline $[(Bu'OLi)_{10}(LiOH)_6]$ [4], which was obtained by exposing a concentrated Bu'O-Li/hexane solution to moist air over a prolonged period; but this product of partial hydrolysis differs from **1** by having hydroxide (OH^-), rather than oxide, anions. However, the latter anions do appear in the monolithium-tetramagnesium cresylate $[LiMg_4O(R)_7 \cdot 4THF]$ [R=*o*-Me(C_6H_4)O] [5] and the tetradecalithium amide $[Li_{14}(O)\{(H)N(c\text{-}C_5H_9)\}_{12}]$ [6], both of which were synthesised serendipitously from reactions that may have inadvertently involved trace quantities of moisture. Unexpected oxide–alkoxide complexes of barium have also been recently reported in $[H_4Ba_6(O)(OCH_2CH_2OCH_3)_{14}]$ [7] and $[H_3Ba_6(O)(OBu^t)_{11}(OCEt_2CH_2O)(THF)_3]$ [8]: the sources of their oxo components are not known.

Returning to **1**, its synthesis can be regarded in part as an incomplete metathetical process between lithium *t*-butylamide and potassium *t*-butoxide as two molecules of the latter compound remain incorporated within the cage framework of the lithium *t*-butoxide derived product. There is some similarity here with the aforementioned trimetallic dimer $[\{LiNaK[PhN(H)]_2(Bu'O) \cdot 2TMEDA\}_2]$ [2], since it also contains cocomplexed potassium *t*-butoxide molecules which resist metathesis (in contrast to sodium *t*-butoxide molecules in the same reaction mixture which react with lithium anilide to formally produce lithium *t*-butoxide and sodium anilide molecules). This preference of the potassium alkoxide for co-complexation over anion exchange has also been demonstrated in the synthesis of the twenty-membered polyhedral cage species $[\{(cyNLi)_3Sb\}_2(Bu'OK)_3 \cdot (toluene)_x]$ [9].

X-ray crystallographic study

The crystal structure of $\mathbf{1} \cdot \frac{1}{2}C_6H_{14}$ shows a discrete, molecular arrangement (Fig. 1), built around an oxo (O^{2-}) core. Directly surrounding the core is a 16-vertex (Li_8O_8) polyhedral cage, the oxygen atoms of which belong to butoxide anions. In keeping with the terminology commonly used in alkali metal architecture, this polyhedron is best described as a 'stack' of two tetrameric $(Li—O)_4$ cyclic rings [10]. Figure 2 emphasises this point in showing one ring stacked on

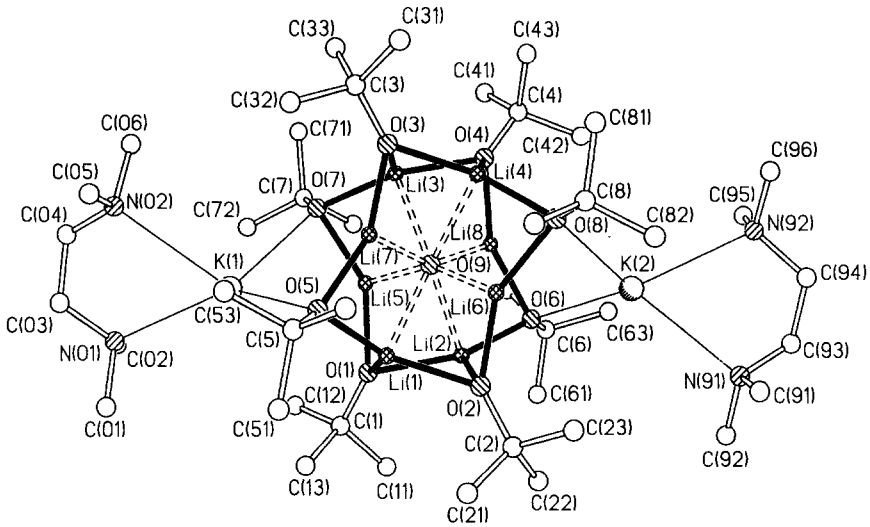

Fig. 1. Molecular structure of **1** without hydrogen atoms.

top of the other (the central oxo is also visible). These rings are highly puckered (r.m.s. deviations 0.269 and 0.261 Å from their respective mean planes, which are inclined at only 0.7° to each other). Stacked-ring structures, as typified by the sodium *t*-butoxide hexamer [made up of two trimeric $(Na—O)_3$ rings, as pictured in Fig. 3], [11] generally have each cation in the 'top' ring bonded to its vertical anion neighbour in the 'bottom' ring and *vice versa*: overall this creates a cage with an enclosed volume which is usually vacant. In **1**, this volume is, in contrast, occupied by the oxo anion, and as a consequence the intermolecular ring to ring bonding is incomplete: between the rings there are four bonded pairs [Li(1)—O(2), Li(2)—O(2), Li(3)—O(3), Li(4)—O(4)] and four non-bonded pairs [Li(5)/O(5), Li(6)/O(6), Li(7)/O(7), Li(8)/O(8)]. Positioned at the outermost points of the polyhedron, the oxygen atoms in this latter group make up for the lack of these bonds by interacting with a K^+ cation: O(5), O(7) and O(6), O(8) each 'chelate' to one of two K^+ cations (Fig. 4). Occupying positions at opposite ends of an axis running through the oxo centre [K···O(9)···K angle, 166.9°], the K^+ cations are also each chelated by a single TMEDA molecule. The eight *t*-butyl groups projecting outwards from the core complete the structure.

Table 1 lists selected bond lengths and angles within **1**. Two distinct sets of Li^+ cations make up the μ_8-coordination of the oxo centre. The four-coordinate type [Li(1) to Li(4)], which participate in intermolecular ring to ring bonding, form long bonds to this oxygen (mean length, 2.195 Å); the other set not involved in the intermolecular ring to ring bonding [Li(5) to Li(8)] are drawn closer to O(9) (mean length, 1.895 Å), reflecting their smaller overall coordination number (three). This $\mu_8O—Li_8$ coordination is unusual. It contrasts with the oxide amide cage species $[Li_{14}(O)\{(H)N(c\text{-}C_5H_9)\}_{12}]$ [6], the Li—O bonds of which are similar in length [1.888(10) Å] to the short

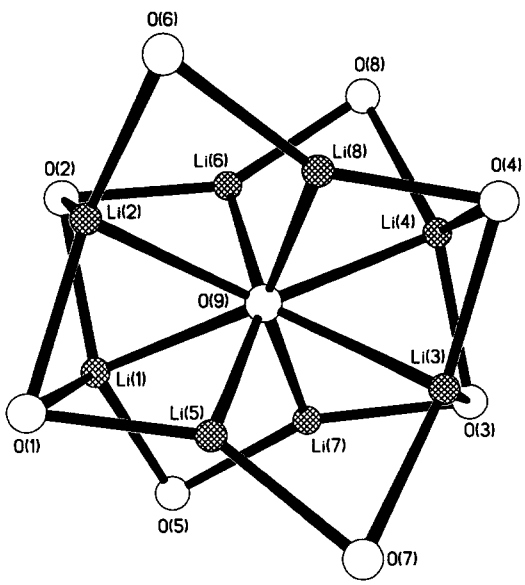

Fig. 2. Core of **1** emphasising its stacked-ring nature.

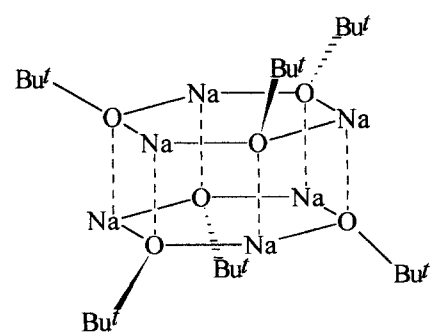

Fig. 3. Hexameric stack structure of sodium *t*-butoxide.

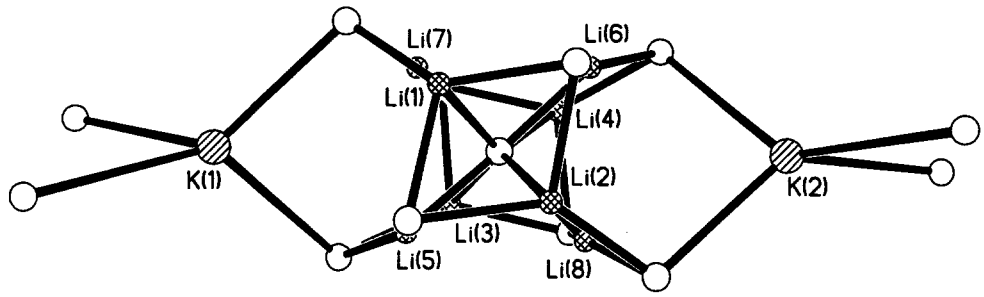

Fig. 4. Section of **1** showing the metal-ligand coordinations.

set in **1**. It also differs from the μ_5O—$LiMg_4$ coordination upon which the oxide cresylate structure of $[LiMg_4O(R)_7 \cdot 4THF]$ [R=*o*-Me(C_6H_4)O] is founded [its solitary Li—O (oxo) bond is 1.89(2) Å long] [5]. The bond angles around O(9) cover a wide range [61.2(2)—151.3(3)°]; this oxo anion lies essentially at the centroid of the Li_8 polyhedron, which is a distorted dodecahedron. Turning to the Li—O (butoxide) bonds, the twelve involving Li(1) to Li(4) are generally longer (mean value, 2.006 Å) than the eight involving Li(5) to Li(8) (mean value, 1.901 Å). The eight oxygen atoms form a distorted square antiprism (seen perpendicular to the two square faces in Fig. 2). Due in part to the incomplete intermolecular ring to ring bonding, the butoxide anions separate into those μ_3O—Li_3 bonded [O(1) to O(4)] and those μ_3O—Li_2K bonded [O(5) to O(8)]. No regular hexameric $[(Bu^tOLi)_6]$ unit or fragment thereof, which would be based predominately on μ_3O—Li_3 bridging, is therefore evident, in contrast to that recently reported for the partially-hydrolysed butoxide $[(Bu^tOLi]_{10} \cdot (LiOH)_6]$: the starting point for aggregation is presumably a short-lived monomeric Li_2O molecule, which would have a strong attraction for Bu^tOLi molecules as they form. The K—O bonds which open up the stacked-ring $(Li_4O_4)_2$ substructure have a mean length of 2.795 Å. Both types of butoxide O atoms [O(1) to O(4); O(5) to O(8)] occupy distorted tetrahedral environments [mean bond angles: 105.3 and 106.8°, respectively], characteristically with obtuse C—O—M and acute M—O—M angles (excepting Li—O—K angles which span the range 75.7–119.8°). The four-coordinate set of Li^+ cations deviate more from an ideal tetrahedral geometry than the three-coordinate set do from an ideal trigonal planar geometry as indicated by their respective mean bond angles (104.2 and 119.3°). Due to a reduction in angular constraints, the mean bond angle about the larger K^+ cations (109.3°) more closely approaches the tetrahedral value, though individually the bond angles are severely distorted, primarily as a consequence of the limited bite size of TMEDA (mean bond angle subtended at K^+ by the diamine is 64.1°).

In conclusion, a new mixed lithium–potassium, mixed oxide–alkoxide salt has been synthesised, though the origin of the oxide component remains uncertain. An X-ray diffraction study has revealed an incomplete stack arrangement of two tetrameric $(Li—O)_4$ cyclic rings with an encapsulated oxo core; two open faces, one on either side of the stack, are each bridged by a TMEDA-chelated K^+ cation.

EXPERIMENTAL

Synthesis of $[Li_8K_2(O)(Bu^tO)_8 \cdot 2TMEDA]$, **1**

Reactions were carried out in Schlenk tubes under a protective atmosphere of dry, oxygen-free argon gas. Freshly distilled *tert*-butylamine (10 mmol) was slowly added to a hexane solution of Bu^nLi (10 mmol) at room temperature, and the mixture was stirred for about 30 min by which time gas evolution (butane) had ceased. The resulting pale yellow solution was injected *via* a gas-tight syringe to a white suspension of Bu^tOK (10 mmol) in hexane. A reaction ensued immediately, following which a fine, beige precipitate was obtained. The mixture was subsequently surrounded by a hot water bath maintained at 60°C for one hour. TMEDA (10 mmol) was then introduced to produce a slightly cloudy, mauve solution, which was subsequently filtered through celite. Cooling of the filtrate (to 4°C), yielded large colourless rhombic crystals of **1**. IR spectra (Nujol mull; cm^{-1}) 2954s, 2858s, 2725w, 2367m, 1470m, 1384m, 1344w, 1304w, 1212m, 1153m, 1081w, 1027w, 988m, 948w, 783w, 724m and 611w; (after exposing mull to air for 2 s) 3676s, 3506m, 2929s, 2850s, 1463s, 1378s, 1212m, 1166w, 1093w, 1034m, 984w, 895w, 822w, 717m and 597w. Elemental analyses, Found C, 54.1; H, 11.0; N, 6.4; Li, 5.2; K, 8.1. g cm^{-3}, $\mu = 0.18$ mm^{-1} (Mo-Kα radiation, $\lambda = 0.71073$ Å), $F(000) = 2224$, $T = 160$ K, crystal size $0.60 \times 0.42 \times 0.18$ mm. Measurements were made on a Siemens SMART CCD area-detector diffractometer. Cell parameters were refined from the observed ω angles of all strong reflections in the complete data set. Intensities were integrated from several series of frames, each 0.3° in ω, covering more than a hemisphere of reciprocal space. No absorption or extinction corrections were necessary. 33833 reflections were collected ($\theta_{max} = 25°$, maximum indices 34, 18, 26), giving 11981 unique data, $R_{int} = 0.0548$.

The structure was determined by direct methods and refined by full-matrix least-squares on F^2 values, with weighting $w^{-1} = \sigma^2(F_o^2) + (0.1315P)^2 + 4.2059P$, where $P = (F_o^2 + 2F_c^2)/3$. Anisotropic displacement parameters were refined for all non-hydrogen atoms, and isotropic hydrogen atoms were included with riding model constraints. Two-fold disorder of orientation was resolved for one Bu^t group; no hydrogen atoms were included for the *n*-hexane solvent molecule positioned on an inversion centre, for which the displacement parameters are rather large, indicating possible unresolved disorder. At convergence, $wR = \{\Sigma[w(F_o^2 - F_c)^2]/\Sigma[w(F_o^2)^2]\}^{1/2} = 0.2675$ for all data, conventional $R = 0.0911$ on F values of 6935 reflections with $F_o^2 > 2\sigma(F_o^2)$, goodness of fit = 1.047 for all F^2 values and 644 refined parameters. A final difference syntheses shows no features outside the range $+0.73$ to -0.34 e$Å^{-3}$.

Programs were standard Siemens control (SMART) and integration (SAINT) software [12], SHELXTL [13], and local programs. Atomic coordinates, displacement parameters and full geometry have been deposited at the Cambridge Crystallographic Data Centre.

Reactions of the stable bis(amino)silylene Si[{N(CH$_2$Bu^t)}$_2$C$_6$H$_4$-1,2] with multiply bonded compounds†

Barbara Gehrhus and Michael F. Lappert*

The Chemistry Laboratory, University of Sussex, Brighton BN1 9QJ, U.K.

(Received 14 April 1997; accepted 5 May 1997)

Abstract—Treatment of the title silylene [abbreviated as Si(NN)] under mild conditions with various unsaturated organic compounds has yielded the following series of tetravalent silicon compounds: Si(NN)Si(NN)(X)Y [XY = OCRR′ (R,R′ = Ph$_2$; Ph,Me or Ad′; Ad′ = Ad minus H, Ad = adamantyl), NCBu^t or C(SiMe$_3$)CPh], 2-C$_6$H$_4$Si(NN)N(R)CHR′ [R,R′ = SiMe$_3$,Ph or Bu^t,(H)Si(NN)], 2-C$_6$H$_4$Si(NN)OSi(H){N(R)C$_6$H$_4$NR-2}CPh (R = CH$_2$Bu^t), Si(NN)(Bu^t)X [X = CN or Si(NN)CN], [Si(NN)]$_2$NAd and Si(NN)N(Ad)N:NAd. © 1998 Elsevier Science Ltd. Keywords: silicon; silylenes; oxidative addition reactions; organosilicon compounds.

Recently we reported the isolation of the thermally stable bis(amino)silylene Si[{N(CH$_2$Bu^t)}$_2$C$_6$H$_4$-1,2], **1** and showed that **1** is highly reactive towards MeI, EtOH or a chalcogen [1]. We now present extensions of this study of the reactivity of **1** by focusing on reactions with compounds containing multiple bonds, as summarised in Scheme 1.

The treatment of **1** with (i) RR′CO, (ii) Bu^{t}CN or (iii) PhCCSiMe$_3$ gave (i) the disilaoxetane (cf. [2]) **2** (R = R′ = Ph), **3** (R = Me, R′ = Bu^t), or **4** (RR′ = Ad′; Ad′ = Ad minus H, Ad = adamantyl), (ii) the disilazetine (cf. [3]) **5** or (iii) the disilabutene (cf. [4]) **6**. These reactions are believed to have proceeded *via* a three-membered ring intermediate **A** which with a second molecule of **1** gave the appropriate compound Si(NN)Si(NN)(X)Y [X-Y = OCRR′, NCBu^t or C(SiMe$_3$)CPh]. Attempts to isolate compound **A**, but using an excess of the unsaturated organic reagent, were unsuccessful, although a stable silaoxirane [5] and silacyclopropene [6] have recently been described.

Reaction of **1** with the imine Ph(R)C:NR′ (R,R′ = Ph,SiMe$_3$ or H,Bu^t) did not give a four-membered ring product. Instead we propose that an azasilacyclopentane intermediate underwent an intramolecular rearrangement to afford compound **7** or (after formal insertion of **1** into a C—H bond) **8**, respectively. The mechanism leading to **7** and **8** is similar to that described for the gas phase reaction of dimethylsilylene with benzophenone yielding a siloxaindane [7].

However (cf. compound **2**), when **1** was added slowly to a hot solution of Ph$_2$CO in benzene, the fused tetracyclic ring compound **9** was obtained. The reaction pathway is believed to have some similarities with that described above for **7**, whereby the oxo (O in place of NSiMe$_3$) analogue of **7** is a further intermediate which reacts with **1**.

Treatment of **1** with *t*-butyl isonitrile led to different products depending on the reaction conditions. When **1** was added slowly to an excess of Bu^{t}NC the 1:1 oxidative adduct **10** was formed; but by reversing the order of addition compound **11** was isolated. A silaketenimine (or a Lewis acid–base adduct) (cf. [8]) is proposed to have been the common intermediate which either rearranged to **10** or with **1** afforded **11**.

A similar dependence upon reaction conditions was shown when **1** was treated with adamantyl azide. In this system, a silaimine (cf. [9]) is a plausible inter-

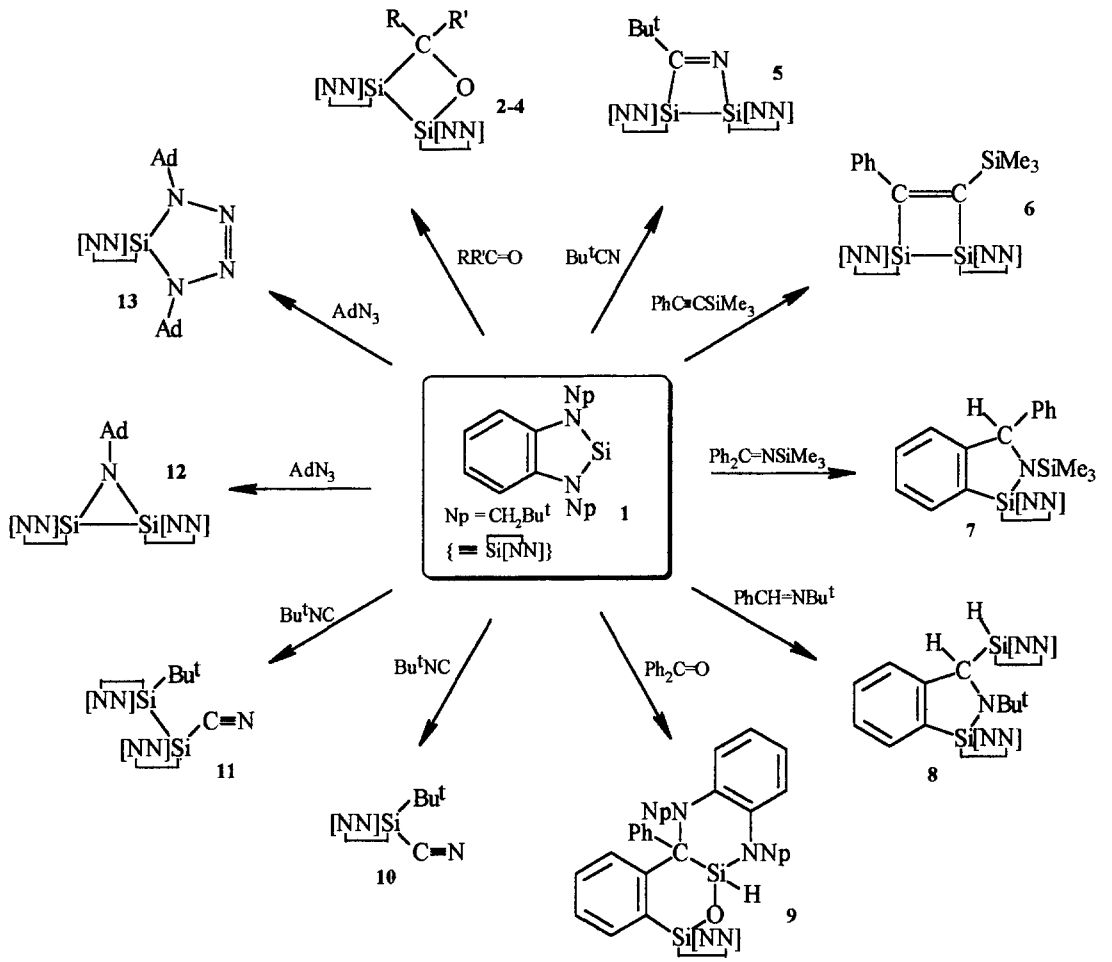

Scheme 1.

mediate which reacts with silylene **1** (adding the azide to a solution of **1**) to give **12**, or with azide (adding **1** to a solution of azide) to form **13**.

Each of the compounds **2**–**13** has been fully characterised by their NMR and MS spectra and gave satisfactory elemental analytical data [for example, ^{29}Si NMR spectral chemical shifts (δ): **2** 9.66, 21.96; **3** 6.44, 19.97; **4** 5.03, 21.04; **5** 19.02, 26.33; **6** −9.11, 13.03, 22.58; **7** 6.44, −5.49; **8** −4.16, −12.66; **9** −15.45, −28.18; **10** −17.84; **11** −15.96, −39.31; **12** −28.49 and **13** −38.13]. The structures of the crystalline compounds **2, 5, 8, 9** and **11** have been further established by single crystal X-ray diffraction studies. Detailed experimental data as well as mechanistic aspects will be described in the full papers.

In conclusion, the reactions of Scheme 1 demonstrate that **1**, although thermally stable, is a highly reactive species and shows distinct differences to the reaction behaviour of its transient relatives.

(Received 2 May 1997)

Abstract—The reaction of two molar equivalents of $Li\{N[C(CH_3)_2(CH_2)_3C(CH_3)_2]\}$ with $ZnCl_2$ in diethyl ether yields the title compound **1**, which was characterized by ^1H, ^{13}C and ^{14}N NMR, melting point, elemental analysis, mass spectrometry and single crystal X-ray diffraction. The structural characterization permits the first direct comparison of di(aryl)amide and di(triorganosilyl)amide examples with a di(alkyl)amide composition, thereby probing the nature of the Zn–N interaction. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: di(alkyl)amide composition; Zn–N interaction.

The II–VI wide band gap semiconductor ZnSe, operating in the blue region of the visible spectrum, possesses potential as one component of versatile optoelectronic devices [1–10] however, achievement of reproducible, high level *p*-type doping presents a significant challenge in improving and controlling their luminescent properties [11–15]. Zinc *bis*(disilyl) amide compounds have been shown to meet some of these demands; however, it has been of interest to prepare silicon-free analogs [16,17]. In this report, the attention is focused on obtaining a novel zinc amide of related interest to the above study. To facilitate the preservation of the zinc–nitrogen bond during the thermal growth process, an appropriate ligand, possessing easily splittable and stable fragments, was selected. This approach involves the use of silicon-free ligands to prepare homoleptic zinc-*bis*(dialkylamide) compounds $Zn[NR_2]_2$, featuring the metal atom in a low-coordination sphere. Compounds possessing such a structure might have a different stability, compared with $Zn\{N[Si(CH_3)_3]_2\}_2$ [18]. To date, little has been done on the zinc-*bis*(amide) compounds to test the validity of this relationship. The commensurately scarce structural information on silicon-free zinc amide compounds is complemented by dimeric species having the metal atom stabilized by an alkyl group or an intermolecular coordinative bond derived from a localized lone-pair presence on nitrogen: $[MeZnN(C_6H_5)_2]_2$ [19], $\{Zn[N(C_6H_5)_2]_2\}_2$ [20] and $[HZnN(CH_3)CH_2CH_2N(CH_3)_2]_2$ [20].

RESULTS AND DISCUSSION

During the investigation of the gas phase decomposition mechanism of zinc-*bis*(amide) compounds, a need emerged for examples which contained substituents at the nitrogen atom other than silicon [16,17]. It was surmised that the consequence of removing the stabilization imparted to the Zn—N bond by the silyl units might lend additional insight into the mechanism of incorporation of nitrogen into epitaxially grown ZnSe. The structural variation chosen for this exploration was one which employed tertiary carbon atoms at the amide linkage. From earlier work, it was known that *t*-Bu groups can be inserted successfully in the place of one of the tri-

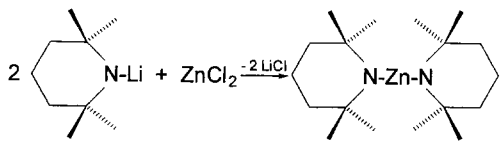
methylsilyl moieties [25a]. Thus, eq. (1) represents, to our knowledge, the initial report of the preparation, isolation and definitive structural characterization of a zinc-*bis*(amide) devoid of any stabilization attributed to silicon-containing species. The utilization of lithium tetramethylpiperidide in a reaction with zinc dichloride cleanly produces a homoleptic zinc-*bis*(dialkylamide) derivative, which was purified by repeated sublimation, to yield colorless and thermally stable needles [21]. The molecular composition of compound **1**, determined by X-ray diffraction techniques [22], is depicted in Fig. 1.



(1)

Our studies on compounds with differently bonded nitrogen atoms in zinc-*bis*(*bis*(trimethylsilyl)amide) [18] (I) and zinc-*bis*(tetramethylpiperidide) (II) aimed also at elucidating the distinction in the stability of the Zn—N bonds displayed by these compounds. Because of the different electronic nature of (II), π-overlap between the fully occupied, unhybridized p-orbital on the nitrogen and available empty 4p-orbitals on the zinc atom may perturb the Zn—N σ-bond. However, no obstacles exist for such a favorable electron density flow from the p-orbital on the trigonal–planar nitrogen, perpendicular to the Zn, N, Si plane, toward the zinc atom in (I). The ability of silicon to stabilize an adjacent negative charge by electrostatic forces is well known [18]. The Zn—N bond in (II) also is reflected in the fact that the strong partially positive charged zinc atom lacks any associated σ-electron-donating groups. By attaching the metal atom to a robust and space-requiring ligand, such as tetramethylpiperidide, the molecule resides in a kinetically stable state, limiting the exposure not only of the metal center to a possible nucleophilic approach, but also shielding the nitrogen atoms against electrophilic attack. Thus, it is possible to stabilize the Zn—N bond, without relying on the employment of silicon atom substituent imparted stabilization. It is noted that the absence of any phenyl rings in (II) removes from consideration the argument relating to interactions of π-systems with the central metal atom to impart stability in such low coordination number, homoleptic transition element *bis*(disilylamide) compounds [23].

The Zn—N interatomic distance for compound **1** (Table 1) is highly commensurate with the GPED value of $Zn\{N[Si(CH_3)_3]_2\}_2$ [24], as well as displaying consistency with the value portrayed by $Zn\{N[Si(CH_3)_3][C(CH_3)_3]\}_2$ [25a], however, the data reported for $Zn\{N[Si(C_6H_5)_2(CH_3)]_2\}_2$ [23] is longer (0.03 Å) than that for the other three examples available for comparison. In the case of the latter compound, the interatomic distance elongation most likely is attributable to the intramolecular stress induced by the sterically encumbered nature of the *bis*(triorganosilyl)amide ligand selected for the investigation. The good level of agreement between the other values (Table 1) would indicate that the range for a typical covalent Zn—N interatomic distance falls within 1.81–1.82 Å.

To probe the stress placed upon the Zn—N interaction in these compounds the ^{14}N NMR data may be compared for $Zn\{N[C(CH_3)_2(CH_2)_3C(CH_3)_2]\}_2$ and $Zn\{N[Si(CH_3)_3][C(CH_3)_3]\}_2$. They are almost identical (at -267 and -290 ppm respectively) and indicate a comparable degree of orbital hybridization and bond ionicity for the electronically stabilized *di*(silyl) example and the relatively unstabilized *tetra*(organo) example.

The stability imparted by the trimethylsilyl moiety to metal–nitrogen interactions in element amide complexes was recognized by Bradley in 1972 [26]. Over the ensuing quarter century, this observation has been applied to the successful isolation of hundreds of

examples of compounds of this popular ligand. Thus, the present initial structural characterization of a *bis*(dialkylamide) compound of zinc has potential ramification in other areas of metal–nitrogen chemistry. These presently are undergoing active exploration, and will be described as they become available. Therefore, $Zn\{\overline{N[C(CH_3)_2(CH_2)_3C(CH_3)_2]}\}_2$, while sterically stabilized, apparently exhibits only slightly less covalent character than $Zn\{N[Si(CH_3)_3]_2\}_2$. Such comparison previously has been conducted for Ga, Ge, Sn and Li homologues of $^-\{\overline{N[C(CH_3)_2(CH_2)_3C(CH_3)_2]}\}$ and $^-\{N[Si(CH_3)_3]_2\}$ [27].

21. General comments: due to the extreme oxygen- and moisture-sensitivity of the zinc amides, all manipulations were performed under dried and purified nitrogen or argon atmosphere on the vacuum line by employing standard Schlenk or inert gas-filled glove box techniques. The solvents were degassed and freshly distilled from sodium or potassium/benzophenone prior to use. All obtained compounds have been characterized by satisfactory elemental analysis, NMR, as well as mass spectroscopy.

Physical measurements: ^{1}H, ^{13}C and ^{14}N NMR spectra were recorded on Varian Gemini 300 MHz and Bruker 400 MHz instruments respectively; microanalysis was performed on a Perkin-Elmer 2400 Series II Elemental Analyzer; mass spectrum was obtained on a VG Instruments 70SE spectrometer; zinc content was determined on a Perkin-Elmer OPTIMA 3000 ICP-OES analyzer.

Experimental procedure: to a solution of 11.15 g (78.93 mmole) of tetramethylpiperidine in 100 mL of diethyl ether in a 250 mL Schlenk flask, 41.5 mL of a *n*-BuLi/hexane solution (1.90 mol/L) was added through a syringe at 0°C over a period of 30 min. The formed pale yellow solution then was refluxed for 1 h and, after attaining ambient temperature on its own, was stirred for an additional hour at this temperature. A solution of 5.37 g (39.40 mmole) of zinc dichloride in 100 mL of diethyl ether was added through a cannula to the formed lithium tetramethylpiperidide at 0°C over a period of 1 h. After stirring overnight, lithium chloride was separated by Schlenk filtration and the diethyl ether was removed at reduced pressure. The crude reaction product was isolated from the salt residue by vapor transfer. Ensuing sublimation of this material afforded zinc-*bis*(tetramethylpiperidine) as colorless and crystalline needles. Yield: 4.4 g (32%); m.p. = 59°C; sublimation conditions: 135°C/0.01 Torr; ^{1}H NMR [C_6D_6, δ, ppm], 1.72–1.64 (m, 4H, CH_2), 1.35 (t, 8H, CH_2), 1.25 (s, 24H, CH_3); ^{13}C NMR [C_6D_6, δ, ppm], 52.96 (s, $C(CH_3)_2$), 39.45 (s, CCH_2), 36.82 (s, $C(CH_3)_2$), 19.50 (s, CCH_2CH_2); ^{14}N NMR [C_6D_6, δ, ppm], −267.52 (s); MS (EI, 70 eV, m/z (%), 185°C): 345 [M^+], 330 [M^+-CH_3], 315 [M^+-$2CH_3$], 204 [M^+-$\overline{N[C(CH_3)_2(CH_2)_3C(CH_3)_2}$], 126 [$C(CH_3)_2(CH_2)_3C(CH_3)_2]^+$; Anal. Calcd. for $C_{18}H_{36}N_2Zn_1$: C, 62.50; H, 10.49; Zn, 18.90. Found: C, 62.25; H, 10.61; Zn, 19.10.

22. Crystal data: $C_{18}H_{36}N_2Zn_1$, crystal size: $(0.27 \times 0.25 \times 0.30)$ mm^3, $M_r = 345.86$, monoclinic, space group $P2_1/n$, $a = 11.465(3)$ Å, $b = 11.643(4)$ Å, $c = 15.676(3)$ Å, $\beta = 110.587(14)°$, $V = 1958.9(9)$ Å^3, $Z = 4$, $D_{calc} = 1.173$ g/cm^{-3}, $R = 0.0490$, $R_w = 0.0356$, $T = 185$K, absorption coefficient = 1.251 mm^{-1}, $F(000) = 752$, diffractometer: Enraf-Nonius CAD-4, radiation: $Mo_{K\alpha} = 0.71069$ Å, aperture: 2.1 mm, scan angle: $(0.80 + 0.35 \tan\theta)°$, variable scan time: max. 45 s, scan technique: ω-2θ, theta range for data collection: $2° < 2\theta < 50°$, index ranges: $0 \leqslant h \leqslant 13$, $0 \leqslant k \leqslant 13$, $-18 \leqslant l \leqslant 18$, reflections collected: 3896, independent reflections: 3159 [R(int) = 0.0262], goodness-of-fit: 1.025, largest diff. peak and hole: max. 0.382 eÅ^{-3} and min. −0.359 eÅ^{-3}.

New perspectives in the tailoring of hetero (bi- and tri-) metallic alkoxide derivatives†

Michael Veith,* Sanjay Mathur* and Charu Mathur

Institute of Inorganic Chemistry, University of Saarland, P.O. 151150, D-66041 Saarbrücken, Germany

(Received 22 April 1997)

Abstract—Metal alkoxides containing more than one sort of metallic element are predominantly known in the field of heterobimetallic derivatives. In order to pass to heterotrimetallic homoleptic alkoxides bimetallic alkoxides have to be prepared which are at the same time heterobimetallic and heteroleptic. They serve as starting materials in salt elimination reactions leading to heterotrimetallic homoleptic alkoxides. The structural entity serving as a building block in these reactions must be kinetically stable in order to survive in the synthetic procedures. Besides heterotermetallic alkoxides, heterobimetallic alkoxides with halides and cyclopentadienyl as ancillary ligands and transition metal complexes of new mixed-metal alkoxy derivatives are presented. Besides the syntheses and the structural characterization reactivity, spectral aspects in view of dynamic or static structures and applications of hetero(bi- and tri-)metallic alkoxides are discussed. © 1997 Elsevier Science Ltd. All rights reserved.

Keywords: heterobimetallic alkoxides; heterotrimetallic alkoxides; heteroleptic alkoxides; transition metal complexes of heterometal alkoxides.

1. INTRODUCTION

Within the realm of M–O–C derivatives, metal alkoxide chemistry has seen an impressive growth over the last decade. The importance of metallo–organic derivatives as versatile precursors to ultra-pure oxide-ceramics [1] in conjunction with the fact that most of the advanced ceramics are multimetallic in nature e.g., $YBa_2Cu_3O_{7-\delta}$ [2], $HgBa_2CuO_4$ [3], $Bi_2Sr_2CaCu_2O_8$ [4] has led to the present interest in the tailoring of heterometal alkoxides. The chemical synthesis routes provide better control over purity, composition, homogeneity and microstructure which are crucial parameters for high performance materials. In addition, the precursors used are generally readily purifiable (*via* crystallization/distillation) and the possibility of variable atomic ratios in the precursors allow for novel compositions not easily obtainable, by other conventional routes. The versatility of chemical routes largely depends on the availability of heterometal molecules as precursors and in view of the metal combinations being immense, a large number of new heterometal alkoxides and allied derivatives with novel structural and bonding features have been characterized in the recent years [5]. However, the formation of a thermodynamically favoured heterometal alkoxide assembly is subject to various factors such as the atomic size of the metallic elements and steric bulk of the alkoxo ligands and the synthesis of a heterometal precursor with targeted ratio of metallic elements cannot be achieved by simply mixing the two or more components in required molar ratios. The metal stoichiometry in the isolated product is thus often inappropriate for the material science requirements. The appropriate metal ratio is of prime consideration in assessing the feasibility of heterometal alkoxides as precursors to useful multi-component metal oxides. Moreover, the growing realization that a 'single-source' precursor with different metals assembled in one molecule in the desired metal ratios (for instance '$YBa_2Cu_3(OR)_{13}$' for $YBa_2Cu_3O_{7-\delta}$) can lead to morphologically pure samples of multi-component ceramics, constitutes one of the continuing synthetic challenges in heterometal alkoxide chemistry. Of central importance to this theme are the developments of new synthetic principles (e.g., the use of novel alkoxometallate units or metallic elements in

† Dedicated to Prof. D. C. Bradley for his pioneering work on metal alkoxides and on the occasion of his 73rd birthday.

* Authors to whom correspondence should be addressed.

unusual oxidation states) which will allow the rational synthesis of stable heterometallic systems with desired metal combinations. It is relevant to mention that the existence of heterotermetallic alkoxides as discrete molecular species in the solution and solid state has been recently established [6], employing coordinatively unsaturated species $\{M'(OPr^i)_3\}^-$ (M = Ba, Sr, Ca) towards well-characterised halide heterobimetallic alkoxides, $ICd\{M_2(OPr^i)_9\}$ (M = Sn, Ti, Zr, Hf).

A comprehensive discussion of the various aspects of metal alkoxide chemistry has been made in some recent reviews [5]. In view of the above and the limited scope of the present article, this review is not intended to be an all-inclusive treatment of heterometal alkoxide chemistry and we confine to the research carried out in our laboratories on heterometal alkoxide derivatives, however, a relevant reference is made to other recent examples not covered in earlier reviews. Owing to the pronounced tendency of heterometal alkoxides to undergo redistribution reactions, dynamic rearrangement of the ligands around the metallic centres and rapid site exchange among alkoxy groups, the spectroscopic pattern of heterometal systems are often deceptive and present an over-simplified picture of metal stoichiometry and molecular symmetry [5b]. In view of the above, special emphasis is given in this article, to the heterometal alkoxide derivatives whose identity has been established by X-ray crystallography. We outline in this review our recent research on three new classes of heterometal alkoxide derivatives namely (i) hetero*ter*metallic alkoxides (ii) hetero*bi*metallic alkoxides with *halide(s)* and *cyclopentadienyl* as ancillary ligand(s) and (iii) the *transition metal complexes* of new mixed-metal alkoxy derivatives. The subject matter entails the synthesis, structure, reactivity, spectral aspects and applications of the hetero (bi- and tri-) metallic alkoxides.

2. HETEROBIMETALLIC ALKOXIDES

2.1 *Homoleptic heterobimetallic alkoxides*

The reactions involving component alkoxides (Lewis acid–base interactions) or metathesis of all the metal–halogen bonds in metal halides by alkali metal alkoxometallates (salt elimination reactions) represent the most general synthetic routes to heterobimetallic alkoxy derivatives based on only one type of alkoxy ligands (homoleptic).

2.1.1 *Synthesis*

(*i*) *Lewis acid–base reactions.* The ability of metal alkoxides ($M(OR)_x$) to form mixed-metal species $MM'(OR)_{x+y}$ is well-known [7] and is exemplified among the alkali metal derivatives of a large number of metal alkoxides (eqs 1–9) [8–17]. The oligomeric nature of the constituent alkoxides is not considered in the equations illustrated below. Some of the reactions (eqs 2, 4, 6 and 7) do not represent pure Lewis acid–base interactions as the product formation involves addition or release of neutral molecules (alcohol, THF, dioxane), however, in view of their similar formation (donor–acceptor interaction of two component alkoxides), they are included in the following discussion.

$$M'OBu^t + M(OBu^t)_2 \rightarrow 1/n\{M'M(OBu^t)_3\}_n \quad (1)$$

M = Ge, Sn, Pb

M′ = Li, Na, K, Rb, Cs

$$KOPr^i + Al(OPr^i)_3 \xrightarrow{2Pr^iOH} 1/n\{KAl(OPr^i)_4(Pr^iOH)_2\}_n \quad (2)$$

$$M'OBu^t + M(OBu^t)_3 \rightarrow 1/n\{M'M(OBu^t)_4\}_n \quad (3)$$

M = Sb; M′ = K, Rb, Cs

M = Bi; M′ = K

$$2KOBu^t + Sb(OBu^t)_3 \xrightarrow{C_4H_8O_2} K_2Sb(OBu^t)_5 \cdot (C_4H_8O_2) \quad (4)$$

$$M'OPr^i + Ti(OPr^i)_4 \rightarrow 1/n\{MTi(OPr^i)_5\}_n \quad (5)$$

M′ = Li, Na, K

$$KOPr^i + 2Ti(OPr^i)_4 \xrightarrow{2THF} (THF)_2KTi_2(OPr^i)_9 \quad (6)$$

$$2LiOPr^i + [Hf(OPr^i)_4 \cdot Pr^iOH]_2 \rightarrow \{LiHf(OPr^i)_5\}_2 + 2Pr^iOH \quad (7)$$

$$KOBu^t + M(OBu^t)_4 \rightarrow 1/n\{KM(OBu^t)_5\}_n \quad (8)$$

M = Sn, Zr

$$LiOEt + Nb(OEt)_5 \rightarrow 1/n\{LiNb(OEt)_6\}_n \quad (9)$$

In analogy to alkali metal alkoxometallates, a large number of molecular heterobimetallic alkoxides of various di-, tri-, tetra- and penta-valent metallic elements have been obtained following the Lewis acid–base principle. Some typical examples are shown below (eqs 10–15) [18–22].

$$2/m[M(OBu^t)_2]_m + 1/n[M'(OBu^t)_2]_n \rightarrow M'\{M(OBu^t)_3\}_2 \quad (10)$$

M = Ge, Sn m = 2; M = Pb m = 2

M′ = Mg, Ca, Sr, Ba

$$6/n[Pb(OPr^i)_2]_n + 6/n[Zr(OPr^i)_4]_n \rightarrow Pb_4Zr_2(OPr^i)_{16} + Pb_2Zr_4(OPr^i)_{20} \quad (11)$$

$$4/n[Pb(OPr^i)_2]_n + 2/n[Zr(OPr^i)_4]_n \rightarrow Pb_4Zr_2(OPr^i)_{16} \quad (12)$$

$$1/n[Ba(OPr^i)_2]_n + 3Ti(OPr^i)_4 \rightarrow \{Ti(OPr^i)_5\}Ba\{Ti_2(OPr^i)_9\} \quad (13)$$

$$1/2[Al(OPr^i)_3]_4 + 1/2[Hf(OPr^i)_4 \cdot Pr^iOH]_2 \rightarrow Al_2Hf(OPr^i)_{10} + Pr^iOH \quad (14)$$

$$1/n[Ba(OPr^i)_2]_n + Nb_2(OPr^i)_{10} \xrightarrow{Pr^iOH} BaNb_2(OPr^i)_{12}(Pr^iOH)_2 \quad (15)$$

The heterometal alkoxides based on Lewis acid–base reactions generally involve the reaction of an alkoxide of molecular nature with unsaturated metal alkoxides $[M(OR)_x]_n$ [5a]. However, mixing two component metal alkoxides do not always result in a heterobimetallic compound and this synthetic strategy is found to be inoperative in many cases, for instance, K, Rb and Cs *tert*-butoxides react with $Sn(OBu^t)_4$ to form compounds $MSn(OBu^t)_5$ (M = K, Rb, Cs), however, no heterometal derivatives are formed with lithium and sodium *tert*-butoxides [15]. Similarly, attempts made to use $As(OBu^t)_3$ as a Lewis acid in the reaction with alkali metal *tert*-butoxides $MOBu^t$ (M = Li, Na, K, Rb, Cs) failed even at elevated temperatures and after long reaction times [10]. Furthermore, no heterometal derivative results in the reaction involving Sn^{II} and Ge^{II} *tert*-butoxides whereas, $Sn_2(OBu^t)_4$ and $Pb_3(OBu^t)_6$ react in appropriate molar ratio to yield $PbSn_2(OBu^t)_6$, which has been characterised in the solid state [18b]. Although depolymerization of $[Pb(OPr^i)_2]_n$ takes place in the presence of $[Zr(OPr^i)_4]_n$ to yield Pb–Zr mixed metal alkoxides, no mixed-metal species is formed when $Ti(OPr^i)_4$ is used [19]. $[Sr(OBu^t)_2]_n$ undergo a facile reaction with $Sn_2(OBu^t)_4$ to form $SrSn_2(OBu^t)_6$ while $[Ca(OBu^t)_2]_n$ do not react even under drastic conditions; this discriminating reactivity of calcium and strontium *tert*-butoxides toward $Sn_2(OBu^t)_4$ is shown to be selective for the quantitative separation of Sr and Ca [18].

(*ii*) *Salt elimination reactions.* Substitution of all halide ligands in a metal halide by anionic alkoxometallates is another synthetic pathway for the construction of heterometal alkoxide molecules (eqs 16–20) [5a,c,d,23–25]. The alkali metal derivatives (eqs 1–9) described in the preceding sub-section are interesting reagents to transfer metallo-ligands of the type $\{M^{II}(OR)_3\}^-$, $\{M^{III}(OR)_4\}^-$, $\{M^{IV}(OR)_5\}^-$, $\{M^{V}(OR)_6\}^-$ and $\{M_2^{IV}(OR)_9\}^-$ to an electropositive metal centre and have been used as building blocks in the construction of a variety of heterometal alkoxides.

$$2M'Br + Na_2M_2(OBu^t)_6 \rightarrow 2M'M(OBu^t)_3 + 2NaBr \quad (16)$$

M = Ge, Sn, Pb; M′ = In, Tl

$$[6M'X_2 + 4Na_2M_2(OBu^t)_6 \rightarrow 3M'_2M_2(OBu^t)_8 + 8NaX] \quad (17)$$

M′ = Co, Ni; M = Ge

M′ = Mg, Cr, Mn, Co, Ni; M = Sn

M′ = Co; M = Pb

$$M'Cl_2 + Na_2M_2(OBu^t)_6 \rightarrow M'M_2(OBu^t)_6 + 2NaCl \quad (18)$$

M′ = Mg, Cr, Mn, Zn; M = Ge

M′ = Mn, Zn; M = Pb

$$ErCl_3 + 3/n[KAl(OPr^i)_4]_n \rightarrow Er\{Al(OPr^i)_4\}_3 + 3KCl \quad (19)$$

$$MCl_2 + 2/n[KAl(OR)_4]_n \rightarrow M\{Al(OR)_4\}_2 + 2KCl \quad (20)$$

M = Be, Mg, Zn, Cd, Hg, Mn, Fe, Co, Ni, Cu;

OR = OPr^i, OBu^t

The transmetallation reactions using large, soft and polarizable metal cations (e.g., Tl^+, Ba^{2+}) represent another means of inducing salt-elimination reactions as shown in the following examples (eqs 21–23) [5a,26].

$$TlSn(OBu^t)_3 + InBr \rightarrow InSn(OBu^t)_3 + TlBr \quad (21)$$

$$ZnCl_2 + Tl_2Sn(OEt)_6 \rightarrow (EtO)ZnSn(OEt)_5 + 2TlCl \quad (22)$$

$$2Ba\{OCH(CF_3)_2\}_2 + CuCl_2 \rightarrow BaCu\{OCH(CF_3)_2\}_4 + BaCl_2 \quad (23)$$

Although anion-exchange reactions between a mixed metal alkoxide $MM'(OR)_x$ (M = an alkali metal) and a metal halide ($M''X_n$) appears a possible synthetic route to build heteronuclear species, the transfer of $\{M'(OR)_x\}^-$ moiety does not always take place as desired and in a number of cases, no reaction occurs when an alkali metal alkoxide is treated with a metal halide (eqs 24–26) [10,20].

$$CuCl_2 + 2/n[KTi(OPr^i)_5]_n \rightarrow Cu(OPr^i)_2 + 2Ti(OPr^i)_4 + 2KCl \quad (24)$$

$$CaCl_2 + 2/n[KSb(OBu^t)_4]_n \rightarrow Ca(OBu^t)_2 + 2Sb(OBu^t)_3 + 2KCl \quad (25)$$

$$CuI + 1/n[KSb(OBu^t)_4]_n \rightarrow 1/4[Cu(OBu^t)]_4 + Sb(OBu^t)_3 + KI \quad (26)$$

(*iii*) *Miscellaneous methods.* Other common preparative routes to heterobimetallic alkoxides involve

(i) the reaction of two different metals with an alcohol (eq. 27) [27] (ii) the reaction of a metal with a metal alkoxide in the presence of parent alcohol (eqs 28–29) [28,29] (iii) reaction of a metal amide [19], alkyl [30] or hydride [31] with a metal alkoxide alcoholate (eqs 30–32) and (iv) alcoholysis of a mixture of two different metal amides (eq. 33) [32].

$$Mg + 2Al + 10Pr^iOH \rightarrow (Pr^iOH)_2MgAl_2(OPr^i)_8 + 4H_2 \quad (27)$$

$$2Ba + 2[Zr(OPr^i)_4 \cdot Pr^iOH]_2 \xrightarrow{4Pr^iOH} Ba_2Zr_4(OPr^i)_{20} + 2H_2 \quad (28)$$

$$M + 4Ti(OEt)_4 \xrightarrow{2EtOH} M\{Ti_2(OEt)_9\}_2 + H_2 \quad (29)$$

$M = Ba, Ca$

$$6Pb[N(SiMe_3)_2]_2 + 3[Zr(OPr^i)_4 \cdot Pr^iOH]_2 \xrightarrow{6Pr^iOH} Pb_2Zr_4(OPr^i)_{20} + Pb_4Zr_2(OPr^i)_{16} + 12HN(SiMe_3)_2 \quad (30)$$

$$2CuX + [Zr(OPr^i)_4 \cdot Pr^iOH]_2 \rightarrow Cu_2Zr_2(OPr^i)_{10} + 2XH \quad (31)$$

$X = mesityl$

$$KH + [Zr(OPr^i)_4 \cdot Pr^iOH]_2 \rightarrow KZr_2(OPr^i)_9 + Pr^iOH + H_2 \quad (32)$$

$$Y[N(SiMe_3)_2]_3 + 2Ba[N(SiMe_3)_2]_2 + 8Bu^tOH \rightarrow YBa_2(OBu^t)_7(Bu^tOH) + 7HN(SiMe_3)_2 \quad (33)$$

In an interesting synthetic approach, heterometallic Ce^{IV} alkoxides $(DME)_2Na_2Ce(OBu^t)_6$ and $NaCe_2(OBu^t)_9$ have been obtained by the reaction of ceric ammonium nitrate with appropriate amounts of sodium *tert*-butoxide (eqs 34–35) [33].

$$(NH_4)_2Ce(NO_3)_6 + 8NaOBu^t \xrightarrow{THF/DME} (DME)_2Na_2Ce(OBu^t)_6 + 2NH_3 + 6NaNO_3 + 2Bu^tOH \quad (34)$$

$$2(NH_4)_2Ce(NO_3)_6 + 13NaOBu^t \rightarrow NaCe_2(OBu^t)_9 + 4NH_3 + 12NaNO_3 + 4Bu^tOH \quad (35)$$

2.1.2 *Structural and spectral features*

The binding mode (terminal, μ_2- or μ_3-) of alkoxy ligands and the nature of metal atoms play a governing role in the structural frameworks (e.g., molecular or polymeric linear arrays or closed polyhedral units) formed among the various thermodynamically accessible heterometal alkoxo clusters (Table 1). The bridging propensity of the alkoxide groups and the strength of alkoxy bridges between similar as well as different metal atoms generally preclude the coordination expansion of metallic constituents by any alternative mechanism, for instance, adding up solvent molecules (containing a donor atom) as donor ligands. In view of the above, the number of doubly (μ_2-) and triply (μ_3-) bridging alkoxide groups are important in determining the nuclearity of the resulting complex and their presence can result in different frameworks e.g., the potassium penta-*tert*-butoxy stannate, $[KSn(OBu^t)_5]$ [15] devoid of alkoxy groups in μ_3-configuration is a one-dimensional polymer (Fig. 9) whereas, zirconium compound with an identical formulation $[KZr(OBu^t)_5]$ [16] but containing a triply bridging alkoxy group is observed as a dimer in the solid state (Fig. 10). The effect of the size of metal atoms is evident in the solid state structures of $(DME)KZr_2(OPr^i)_9$ [31] and $(Pr^iOH)LiZr_2(OPr^i)_9$ [29]; whereas potassium derivative shows a closed triangular (KZr_2) structure, the smaller lithium atom ($Li^+ = 0.70$ Å; $K^+ = 1.33$ Å) fails to adopt a closed MM'_2 structural motif and displays an open structure.

A remarkable variety of structures [5,8,18,34] is observed among the tris-(*tert*-butoxo)stannate (-germanate or plumbate) derivatives of the alkali (eq. 1) and alkaline earth (eq. 10) metals. Whereas the stannates of lithium and sodium form cage-like molecular structures (**I**), the similar derivatives of heavier K, Rb and Cs are polymeric (**II**) (see Fig. 1). The Li and Na compounds are dimers of formula $M_2Sn_2(\mu_3\text{-}OBu^t)_2(\mu_2\text{-}OBu^t)_4$ (**I**) with no terminal ligands on either of the metallic elements and pyramidal tin(II) presumably possesses a stereochemically active electron lone pair. The polycyclic $Sn_2O_6M_2$ (M = Li, Na) core consists of two analogous seco-norcubane subunits, sharing a face. Alternatively, the structure can be viewed as two pyramidal $Sn(OBu^t)_3^-$ units linked by two alkali metal atoms. The heavier congeners (K, Rb, Cs) form a one-dimensional chain of interlinked SnO_3M units (**II**), the alkali metals are additionally coordinated by two oxygen atoms of a second cage to give a polymeric arrangement in the crystal. The higher coordination number observed for heavier alkali metal atoms is possibly favoured by their larger size. The room temperature ^1H NMR spectra of the alkali metal alkoxo-stannates show a single alkoxide environment. In case of $M_2Sn_2(OBu^t)_6$ (M = Li, Na) derivatives, the cryoscopic measurements indicate that a dimeric structure is maintained in the solution. However, the gas phase nuclearity as determined by mass spectroscopy, shows the sodium compound to be dimer while lithium analog is a monomer.

The general structural type (Fig. 2) observed in the interaction of Lewis basic *tert*-butoxides of divalent Ge, Sn and Pb with polymeric alkoxides of alkaline earth metals (eq. 10) can be designated as a bis (Janus-head) structural motif (**III**) [34]. The metal-oxygen framework, as found in the X-ray crystallographic

[a] μ_2-OR = doubly bridging alkoxo ligands.
[b] μ_3-OR = triply bridging alkoxo ligands.

studies [18], displays two trigonal bipyramids joined together at a common apex, defined by the heterometal partner. Consequently in all structures, the central element is six-fold coordinated by the alkoxide oxygens while the outer metals occupying the terminator positions are three-fold coordinated and possess presumably a lone pair of electrons. The detailed comparison of bond lengths and angles in the different derivatives show that the ability of the monoanionic $M(OBu^t)_3^-$ unit to accommodate a metal atom with respect to its size follows the order $Sn(OBu^t)_3^- < Ge(OBu^t)_3^- < Pb(OBu^t)_3^-$ [18b]. This trend is especially evident in the transition metal derivatives (see sub-section 2.1.2).

Although a large number of heterometallic alkoxides containing aluminium are based on the $\{Al(OPr^i)_4\}^-$ unit [5c], the ligating properties of this monoanionic alkoxometallate unit is not well-established. Most of the studies propose a bidentate ligating mode which indeed has been observed in the solid

state structures of $[ClPr\{Al(OPr^i)_4\}_2(Pr^iOH)]_2$ [35], and $[Mg\{Al(OPr^i)_4\}_2(Pr^iOH)_2]$ [27]. However, other structurally characterised examples with an $\{Al(OPr^i)_4\}^-$ unit bridging (i) two metals through single alkoxide bridges (e.g., $[Mo_2(O_2CCH_3)_2\{Al(OPr^i)_4\}_2]$ [36] or (ii) two metals by a double OR bridge to one and a single bridge to the second (e.g., $[Mg_2Al_3(OPr^i)_{13}]$ [37]) are also known.

The attempts made to establish the identity and formulation of heterometal alkoxides by single crystal X-ray diffraction analysis are generally frustrated by their organic periphery (which makes them extremely soluble in common organic solvents) and physical state (viscous liquids or waxy solids). These problems can be overcome, in some cases, by using coordinating solvents (alcohol, THF, ether, pyridine, DME) which serve as neutral ligands and complete the coordination sphere of involved metal(s) to offer more tractable (coordinatively saturated) systems suitable for single crystal X-ray crystallography. A structural study performed on the single crystals obtained from an isopropanol solution of potassium tetraisopropoxyaluminate, $KAl(OPr^i)_4$ (eq. 2), revealed a polymer of composition $[(Pr^iOH)_2K\{Al(OPr^i)_4\}]_n$ [9] with chains of alternating K and Al atoms joined by doubly bridging isopropoxy groups (Fig. 3). Aluminium is present in a tetrahedral environment while potassium additionally coordinated by two neutral Pr^iOH molecule displays a severely distorted octahedral coordination sphere.

The alkali metal alkoxy antimonates and bismuthates obtained according to eq. 3 exhibit only one signal in their ^1H NMR spectra. The X-ray structural study performed on crystalline samples of $KSb(OBu^t)_4$ [10] and $KBi(OBu^t)_4$ [10] reveal the compounds to be made up of one-dimensional arrangements of $M(OBu^t)_4^-$ ($M = Sb^{III}$, Bi^{III}) units linked through potassium atoms situated at inversion centres and coordinated by four alkoxo groups in a single plane. The coordination figure of both Sb^{III} and Bi^{III} resembles a ψ-trigonal bipyramid where one of the equatorial site is occupied by the electron lone pair. Although identical in stoichiometry, the two compounds crystallise with slightly different structures (Fig. 4), whereas the *pseudo*-trigonal bipyramid $Sb(OBu^t)_4^-$ unit possesses a two fold axis of symmetry [Fig. 4(a)], the analogous $Bi(OBu^t)_4^-$ unit lacks it [Fig. 4(b)].

The crystal structure of $K_2Sb(OBu^t)_5 \cdot$ dioxane [10] obtained (eq. 4) on varying the K : Sb metal stoichiometry in eq. 3 reveals an infinite array of molecules linked through the oxygen atoms of dioxane molecules (Fig. 5). The repeating unit consists of an O_5 trigonal bipyramid, the equatorial edges of which

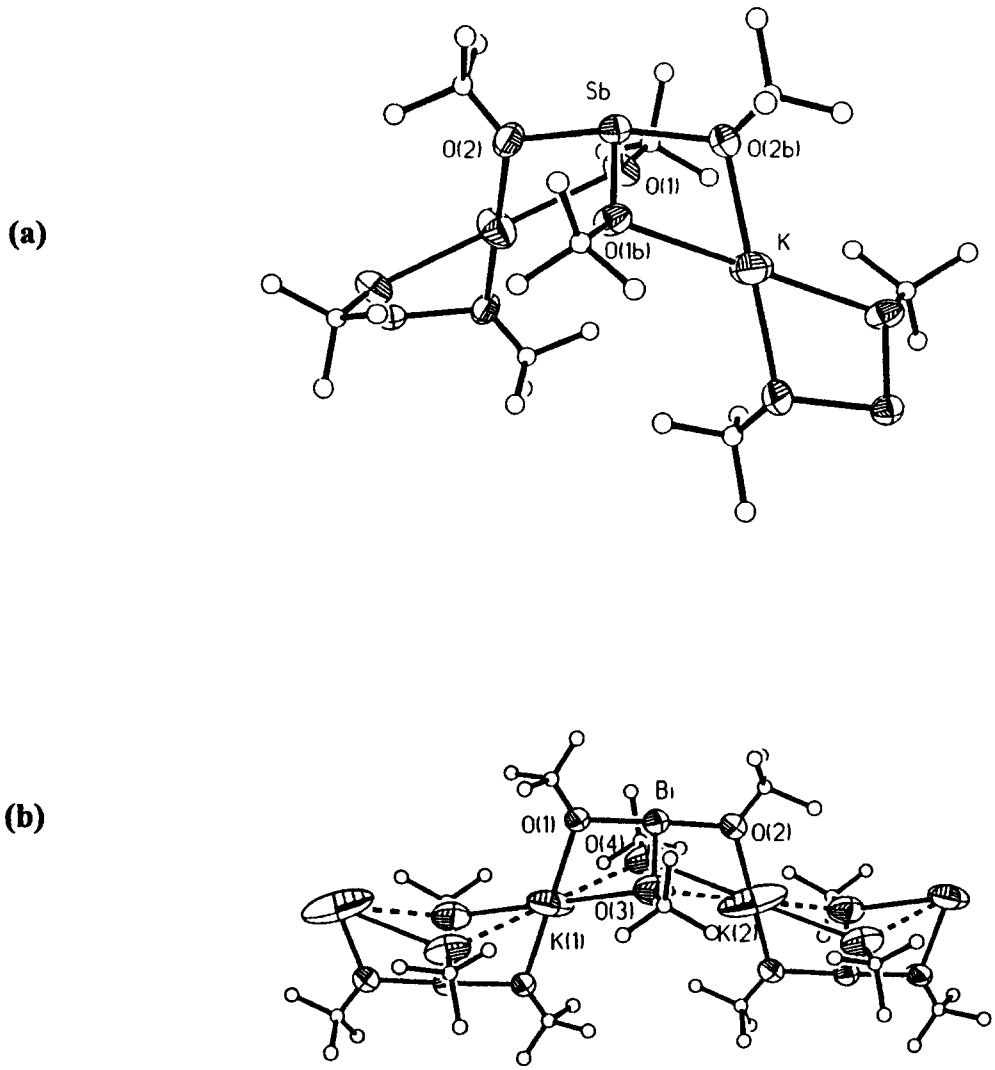

Fig. 4. A section of the one-dimensional structures of (a) $[KSb(OBu^t)_4]_n$ and (b) $[KBi(OBu^t)_4]_n$ [10].

are centred by two potassium and one antimony atom. Antimony(III) bonded to four oxygen atoms exhibits a *pseudo*-trigonal bipyramidal coordination while potassium atoms are trigonally bipyramidally coordinated.

Among the alkali metal titanium alkoxide derivatives $M\{Ti(OPr^i)_5\}$ (M = Li, Na, K), (eq. 5) described by Hampden-Smith *et al.* [11], the lithium derivative is found to be dimeric in the solid state. The X-ray structure of $[LiTi(OPr^i)_5]_2$ (Fig. 6) shows two approximately trigonal-bipyramidal titanium atoms joined by lithium bridges. If the terminal OPr^i ligands on titanium atoms are removed, the core structure parallels the metal–oxygen framework observed for $[LiSn(OBu^t)_3]_2$ (Fig. 1). All the derivatives undergo an alkoxide ligand exchange process that is rapid on the ^1H NMR time scale at ambient temperature. However, low-temperature (−20°C) NMR studies reveal two types of ligand environments for $[LiTi(OPr^i)_5]_2$ in intensity ratio 4 : 1 which is consistent with the empirical formula $[LiTi(OPr^i)_5]$ but not with the solid state structure which shows three different alkoxide environments. A limiting spectrum displaying the three unique isopropoxy environments could not be obtained even at −120°C.

The use of alkali metal NMR in examining the solution behaviour of $[MTi(OPr^i)_5]$ derivatives along with the X-ray structural characterization of Na and K substituted titanium isopropoxide derivatives is recently reported [12]. Both $[NaTi(OPr^i)_5]_n$ and $[KTi(OPr^i)_5]_n$ are polymeric species wherein the alkali metal acts as a bridge between discrete mononuclear trigonal-bipyramidal $Ti(OPr^i)_5^-$ units. The one-dimensional polymer $[NaTi(OPr^i)_5]_n$ is linear and exhibits alternating five coordinate titanium moieties and tetrahedrally surrounded sodium atoms. With respect to the coordination numbers of the metallic elements, the structure is comparable to that of

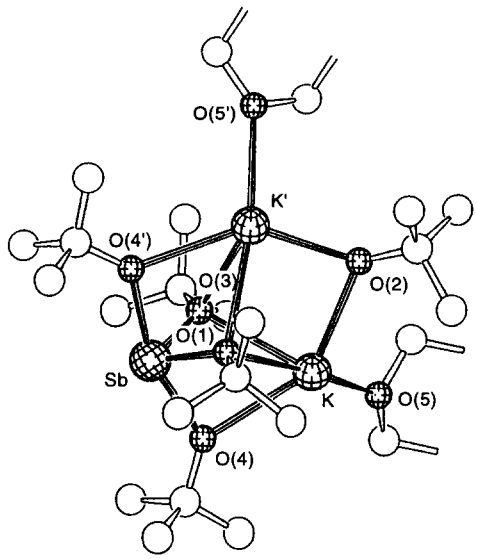

Fig. 5. A section of the dioxane-bridged structure of $[K_2Sb(OBu^t)_5 \cdot \text{dioxane}]$ [10].

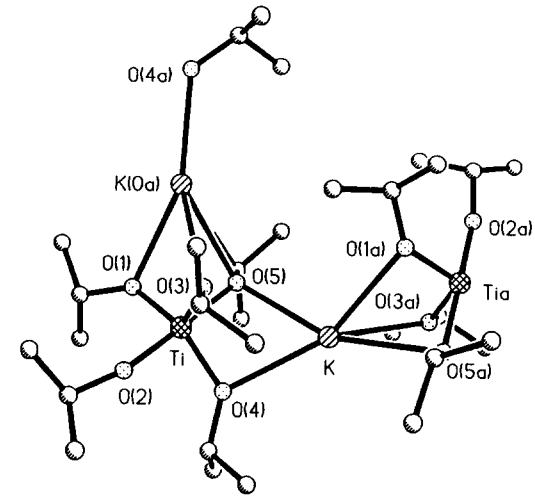

Fig. 7. A portion of the one-dimensional structure observed for $[KTi(OPr^i)_5]_n$ [13].

$[KSn(OBu^t)_5]_n$. In contrast to the sodium derivative, the potassium analog exhibits a penta-coordination for the K atoms. The non-linear continuous chain found in the solid state is a reminiscent of the structure observed for $[KSn(OBu^t)_3]_n$ with K atoms being present in a highly distorted trigonal-bipyramidal geometry. We have simultaneously solved the structure for potassium derivative (Fig. 7) [13].

The seco-norcubane core ($M_2M'_2O_6$) (**I**) is a recurrent structural feature among heterometallic alkoxides based on M:M' = 1:1 stoichiometry; a modification of this framework has been observed in the solid state structure of $[LiHf(OPr^i)_5]_2$ [14] (eq. 7) which displays a dimeric arrangement with two Hf^{IV} atoms present in a distorted octahedron of OPr^i ligands while the lithium atoms are three-fold coordinated and display a trigonal pyramidal geometry (Fig. 8). The central $Li_2Hf_2O_6$ unit in $[LiHf(OPr^i)_5]_2$ (Fig. 8) is an interesting variant of the metal–oxygen core observed in $[LiSn(OBu^t)_3]_2$ (Fig. 1) and $[LiTi(OPr^i)_5]_2$ (Fig. 6) with lithium occupying the position of tin (titanium) and hafnium that of lithium. Thus in

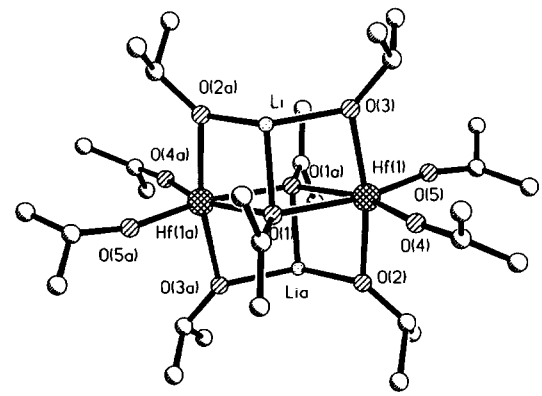

Fig. 8. Molecular structure of $[LiHf(OPr^i)_5]_2$. Unlabelled atoms are carbon [14].

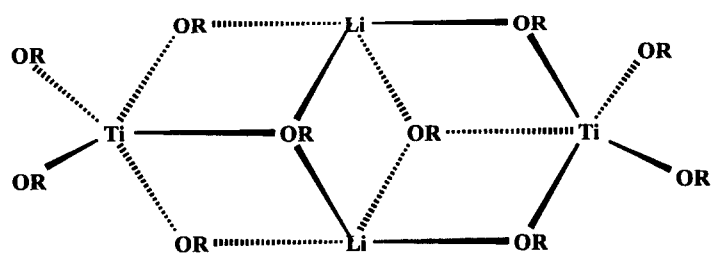
contrast to the four coordinate lithium atoms in Sn^{II} and Ti^{IV} derivatives, the lithium centres in Hf^{IV} compound are three coordinate. Further, the hafnium derivative is stereochemically rigid and the spectral data indicate that the dimeric form persists in solution.



(R = Pr^i)

Fig. 6. Schematic representation of the molecular structure of $[LiTi(OPr^i)_5]_2$ [11].

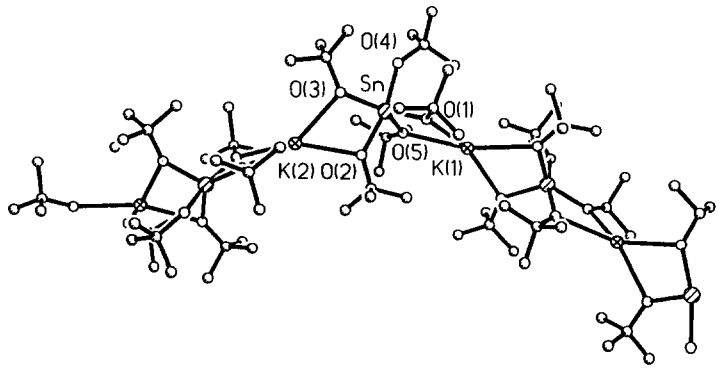


Fig. 9. A section of the crystal structure of $[KSn(OBu^t)_5 0.5C_7H_8]_n$ [15]. The toluene molecule is not shown.

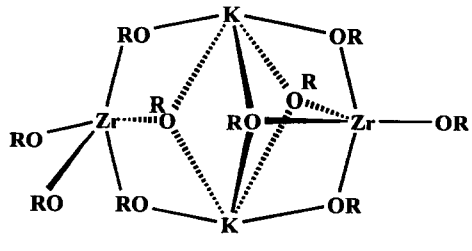
The ligand geometries at heterometal centres in the above examples based on $M_2M'_2O_6$ core can be attributed to the tendency of the metallic element to achieve a preferred configuration or higher coordination numbers. Thus tin(II), devoid of any terminal ligands in $[M\{Sn(OBu^t)_3\}]_2$ (M = Li, Na) derivatives possesses a stereochemically active lone pair and the preferred pyramidal configuration whereas the tendency of larger tetravalent metals to be in a hexa-coordination is reflected in $[LiHf(OPr^i)_5]_2$ where a bond to lithium is sacrified to attain an octahedral ligand environment for Hf^{IV}.

The structural characterisation of $[KSn(OBu^t)_5]_n$ [15] (eq. 8) reveals that the compound crystallises with a half molecule of toluene per repeating unit. In the crystal, four- and five-fold coordinated potassium and tin(IV) atoms, respectively are interlinked via alkoxy bridges to give a one dimensional helical chain $(O_2SnO_2K)_n$ (Fig. 9). Alternatively, the polymer results from the trigonal bipyramids of *tert*-butoxy ligands built about Sn^{IV} which are interlinked by two structurally different potassium atoms.

In contrast to the polymeric structure observed for $[KSn(OBu^t)_5]_n$ (Fig. 9), the zirconium analogue [16] is dimeric in the solid state (Fig. 10). Both the metals (K and Zr) are five-coordinate, however, the disposition of two $Zr(OBu^t)_5^-$ unit is asymmetric with one Zr atom sharing four of its OBu'-groups in bridging the '$KZr(OBu^t)_5$' fragments while the other shares only three. This makes Zr^{IV} centres inequivalent (Fig. 10), however potassium centres are equalised by a mirror plane. The molecule is highly fluxional and even at −75°C, the ^1H NMR spectrum remains a singlet.



(R = Bu^t)

Fig. 10. Schematic representation of the molecular structure of $[KZr(OBu^t)_5]_2$ [16].

On the basis of solubility differences, two structurally and stoichiometrically different products $[Pb_2Zr_4(OPr^i)_{20}]$ and $[Pb_4Zr_2(OPr^i)_{16}]$ can be isolated from a 1:1 mixture of lead and zirconium isopropoxides (eq. 11) [19]. Both the products were also obtained by mixing lead amide and zirconium isopropoxide in 2:1 molar ratio, in the presence of isopropanol (eq. 30). The latter derivative could be obtained quantitatively on employing the correct stoichiometry of component alkoxides (eq. 12). A rigorous centrosymmetric structure is observed in $Pb_4Zr_2(OPr^i)_{16}$ where two $(Pr^iO)_3Zr(\mu_2\text{-}OPr^i)_3Pb$ are linked by a $Pb_2(OPr^i)_4$ unit (Fig. 11a). The solid state structure of $Pb_2Zr_4(OPr^i)_{20}$, with Pb : Zr ratio 1 : 2, can be derived from that of $Pb_4Zr_2(OPr^i)_{16}$ by replacing the $Pb(OPr^i)_2$ units with a $Zr(OPr^i)_4$ moiety on either side of the $Pb_2(OPr^i)_4$ core (Fig. 11b).

Formation of the alkali and alkaline earth metal alkoxometallates of compositions $M_2M'_3(OPr^i)_{14}$ and $M''M'_3(OPr^i)_{14}$ (M = Na, K; M' = Zr^{IV}, Hf^{IV}; M'' = Mg, Ca, Sr, Ba), respectively is reported and the proposed structures of these derivatives suggest a hexa-coordination for the tetravalent metals [7]. However, there is no report available on the existence of a $M_3(OPr^i)_{14}^{-2}$ substructure in the solid state, although a modification of $M_3(OR)_{14}^{-2}$ structural unit has been observed in the solid state structure of heterobimetallic acetato-*oxo*-alkoxide $PbZr_3O(OAc)_2(OPr^i)_{10}$ [1e]. In order to examine the formation of a dianionic sequestering unit $\{Ti_3(OPr^i)_{14}\}^{2-}$, a Ba–Ti mixed metal alkoxide was prepared by reacting $Ba(OPr^i)_2$ with $Ti(OPr^i)_4$ (eq. 13) [20] in 1:3 stoichiometry. The analytical and cryoscopic data of the crystalline product indicate the formation of a monomeric heterometal species with the anticipated Ba : Ti (1 : 3) stoichiometry and possibly the $Ti_3(OPr^i)_{14}^{2-}$ unit. The solid state structure, however, revealed a

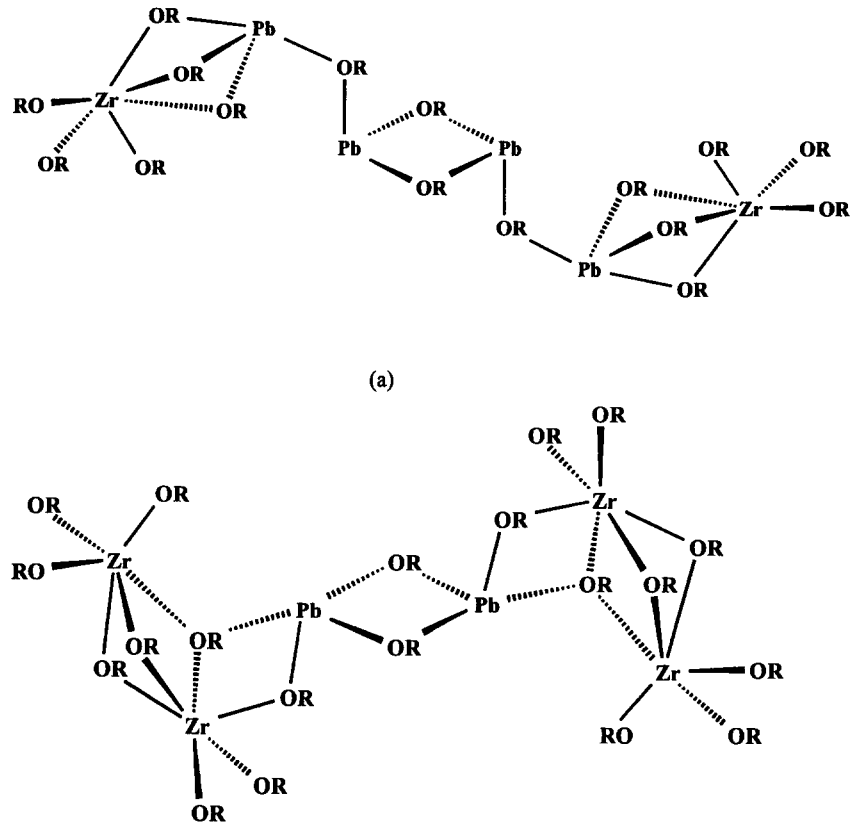


Fig. 11. Schematic representation of the molecular structures of (a) $[Pb_4Zr_2(OPr^i)_{16}]$ and (b) $[Pb_2Zr_4(OPr^i)_{20}]$ [19].

different geometry and arrangement of ligands but with the desired Ba : Ti metal ratio. The X-ray structure (Fig. 12) shows Ba^{2+} in a distorted trigonal prismatic geometry formed by the tetra- and bi-dentate interaction of monoanionic $\{Ti_2(OPr^i)_9\}^-$ and $\{Ti(OPr^i)_5\}^-$ units, respectively. The ^1H NMR spectrum at $-53^\circ C$ shows seven sets of methyl resonances

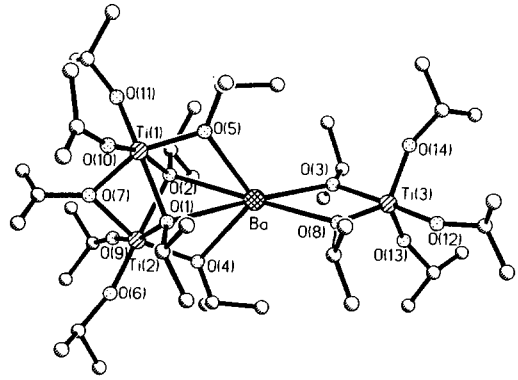

Fig. 12. The molecular structure of $[BaTi_3(OPr^i)_{14}]$ [20].

whose relative and total intensities are consistent with the retention of heterometal framework in solution. The above observations are corroborated by ^{13}C CP MAS NMR data.

Recently, the X-ray structure determination [21] of a previously reported hafnium-aluminium heterometal derivative, $Al_2Hf(OPr^i)_{10}$, (eq. 14) confirmed the proposed structure of Mehrotra *et al.* [38]. The molecule (Fig. 13) consists of an octahedrally coordinated Hf^{IV} atom bearing two bidentate $Al(OPr^i)_4^-$ sub-units and two terminal OPr^i ligands. The aluminium atoms are slightly distorted from a regular tetrahedral geometry.

The barium–niobium heterobimetallic isopropoxide obtained from the isopropanol solution of two alkoxides (Ba : Nb = 1 : 2, eq. 15) is shown by X-ray crystallographic study to have the composition $[Ba\{Nb(OPr^i)_6\}_2(Pr^iOH)_2]$ [22]. The molecule consists of a chain of three octahedra built around one barium(II) and two niobium(V) atoms. The central BaO_6 octahedron shares two neighbouring edges with the peripheral NbO_6 units to give a molecular framework shown in Fig. 14.

The lanthanum–niobium isopropoxide LaN-

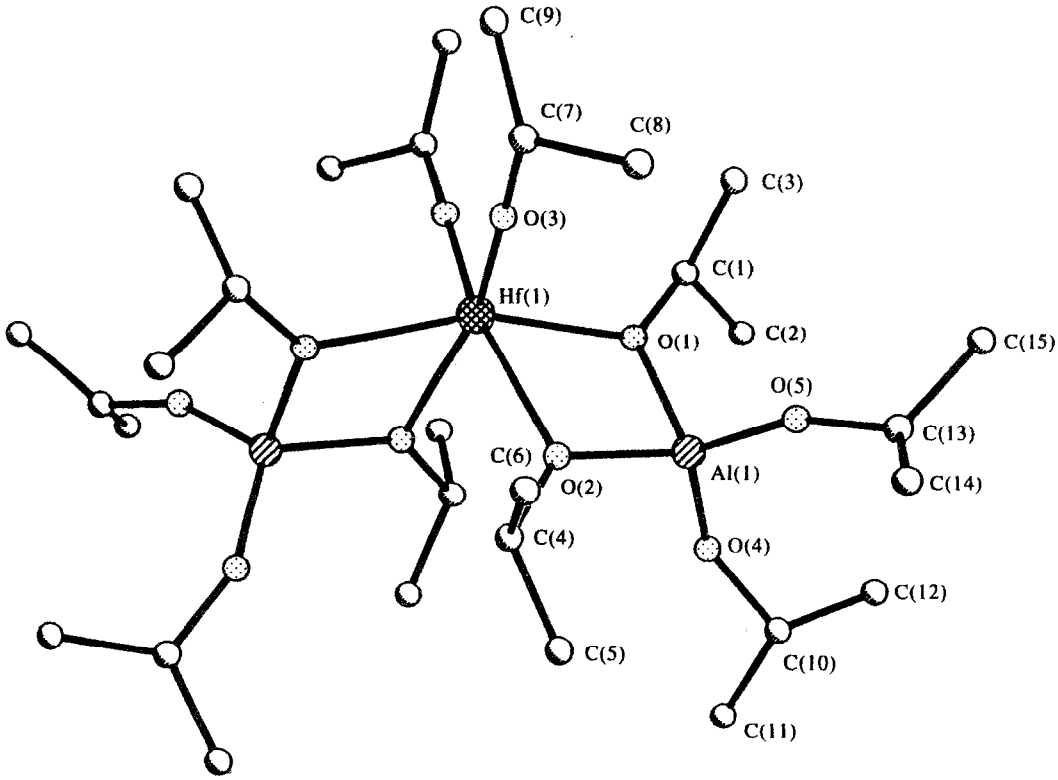

Fig. 13. A ball and stick representation of the molecular structure of $[Al_2Hf(OPr^i)_{10}]$ [21].

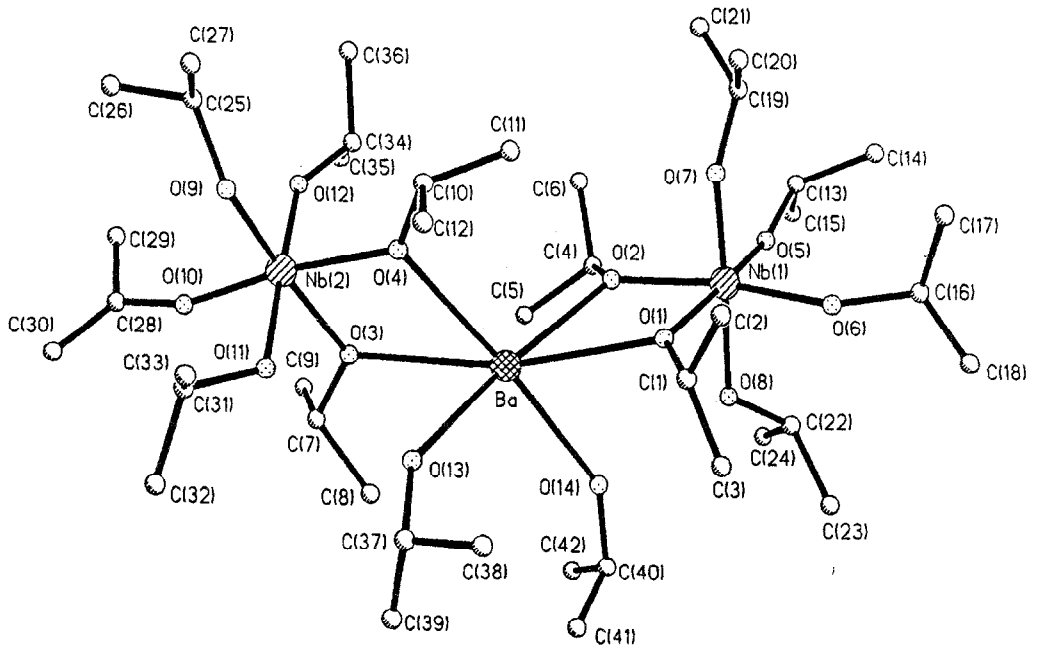

Fig. 14. Molecular structure of $[Ba\{Nb(OPr^i)_6\}_2(Pr^iOH)_2]$ [22].

$b_2(OPr^i)_{13}$ [22] crystallises from the solutions containing two alkoxides in La : Nb = 1 : (1–3) molar ratios. The molecule (Fig. 15) in the solid state reveals the central La atom in a strongly distorted octahedron of OPr^i ligands which shares a face with one NbO_6 octahedra and an edge with the other. The noteworthy

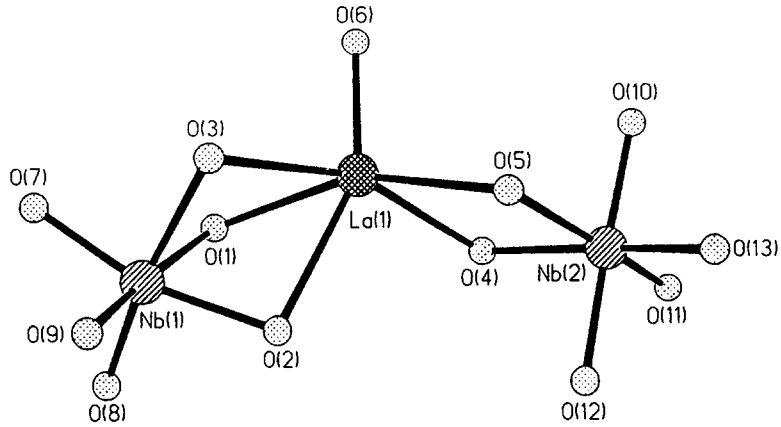

Fig. 15. Metal–oxygen core of $[(Pr^iO)La\{Nb(OPr^i)_6\}_2]$ [22].

structural feature is the ambidentate (bi- and tri-) ligating behaviour of $\{Nb(OPr)_6\}^-$ moiety.

Following the salt elimination principle, we have reported on the synthesis, structural characterization and reactivity of a variety of heterometal derivatives formed by the use of chelating $\{M(OBu^t)_3\}^-$ ($M = Ge^{II}$, Sn^{II}, Pb^{II}) anions toward main group and transition metals [5a,18]. Unlike the solid state structures observed for the alkali metal tris-(*tert*-butoxy) stannates (-germanates or -plumbates) (Fig. 1), the analogous derivatives of monovalent indium and thallium (eq. 16) are obtained as monomeric cage (**IV**) of the type $M(\mu\text{-}OBu^t)_3M'$ (M = Sn, Ge; M′ = In Tl; M = Pb, M′ = Tl) (Fig. 16). The $M'MO_3$ core represents a distorted trigonal bipyramid where the oxygen and metal atoms occupy the equatorial and apical positions, respectively. The cationic fragment $\{Sn(\mu\text{-}OBu^t)_3Pb\}^+$ with a structure similar to that of $MM'(OBu^t)_3$ (**I**) compounds has been observed as a component of the multimetallic compound $Pb_7Sn_6I_8(OBu^t)_{18}$ [25].

Depending upon the size of metal and the geometrical softness of the $\{M(OBu^t)_3\}^-$ ligands, two structural forms are observed for the transition metal derivatives; the smaller 3d cations form compounds of the general formula $(OR)M(\mu\text{-}OR)_2M'(\mu\text{-}OR)_2M'(\mu\text{-}OR)_2M(OR)$ (**V**) (M = Sn, Ge, Pb; M′ = Ni, Cr, Co, Mn) (eq. 17) with the main group and transition metal stoichiometry being 1 : 1. The metal–oxygen

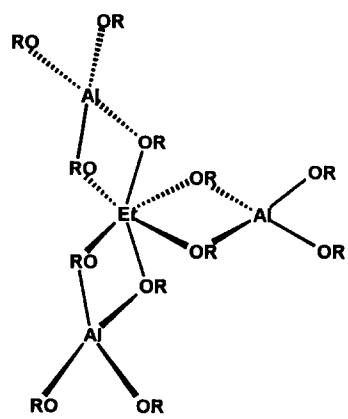
skeleton (Fig. 17) of these derivatives exhibits a bidentate ligating mode of $\{M(OR)_3\}^-$ (M = Sn(II), Ge(II), Pb(II)) units in contrast to the tridentate behaviour observed in the structural types **I**–**IV**. The transition metal in the observed framework (**V**) occupies a four fold-coordination site which can be described as a spiro metallic centre in a distorted oxygen tetrahedron. The overall metal–oxygen skeleton (**V**) can be seen as three four-membered rings arranged in a perpendicular manner. The transition metals (M′) are quasi-tetrahedrally coordinated while the group 14 elements bearing a dangling alkoxo ligand are in a pyramidal 3-fold oxygen environment. On the other hand, if tris-(*tert*-butoxy)-germanate or -plumbate, is used against metal halides of Cr, Mn or Zn compounds with the general formula $M(\mu\text{-}OR)_3M'$ $(\mu\text{-}OR)_3M$ are obtained (eq. 18) which have a structure similar to alkaline earth derivatives (**III**) based on tridentate $\{M(OR)_3\}^-$ units. In all these derivatives (**I**–**V**), the terminal positions of main group elements present in the subvalent state (ns^2 configuration) function as potential Lewis basic sites which have been used to obtain transition metal derivatives (see sub-section 2.1.3) [34].

The X-ray diffraction analysis performed recently on an erbium–aluminium (Er : Al = 1 : 3) bimetallic isopropoxide (eq. 19) reveals a molecular formula

$ErAl_3(OPr^i)_{12}$ [24] analogous to that proposed for $LnAl_3(OPr^i)_{12}$ [7] compounds (Ln = lanthanide atom). In the light of structure determination (Fig. 18), the molecular formula can be precisely expressed as $Er\{(\mu_2\text{-}OPr^i)_2Al(OPr^i)_2\}_3$ where each of the three tetrakis-isopropoxy aluminate ligands coordinate the central atom Er^{III} *via* two OPr^i groups. The structural framework of $Er\{Al(OPr^i)_4\}_3$ differs from the related compound $Al\{Al(OPr^i)_4\}_3$ [39,40] in the coordination figures of hexa-coordinate central atoms. In case of aluminium isopropoxide, the central Al^{III} has almost an ideal octahedral geometry, whereas, the erbium complex displays a distorted trigonal prismatic coordination for Er^{III} which is in accordance with the tendency of lanthanide elements to prefer a prismatic geometry (over octahedral).

It has been reported that the complex formation of $Al(OPr^i)_3$ with $[Ni(OPr^i)_2]_n$ do not give the previously reported $[Ni\{Al(OPr^i)_4\}_2]$ and only the mixture of two corresponding alkoxides results [41]. However, we have been able to synthesise and structurally characterise the analogous *tert*-butoxide derivative. The sublimable nature of $[Ni\{Al(OBu^t)_4\}_2]$ speaks for the stability of such derivatives. The compound i shown by the X-ray crystallographic study [13] is monomeric in the solid state and the structure (Fig. 19) [27] is similar to that proposed by Mehrotra *et al.* for $M\{Al(OR)_4\}_2$ derivatives [5c,d] (eq. 20). The molecular architecture can be viewed as bidentate interactions of two tetrahedral $Al(OBu^t)_4^-$ moieties to the Ni^{2+} centre. The two '$NiAl(OBu^t)_2$' four-membered rings fused at a common end (Ni^{II}) are perpendicular to each other. Both Ni^{II} and Al^{III} are quasi-tetrahedrally coordinated by the *tert*-butoxy ligands, the distortion being more significant in the case of nickel.

The heterobimetallic compound $[Mg\{Al(OBu^t)_4\}_2]$ [25] with Mg:Al stoichiometry appropriate for $MgAl_2O_4$ spinel is obtained from the reaction of



(R = Pr^i)

Fig. 18. Schematic representation of the molecular framework of $Er\{Al(OPr^i)_4\}_3$ [24].

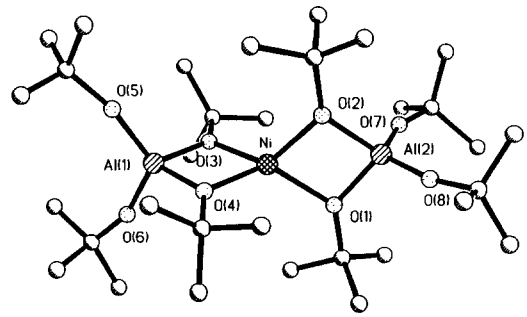


Fig. 19. Ball and stick drawing of the molecular structure of $[Ni\{Al(OBu^t)_4\}_2]$ [13].

$MgCl_2$ with $NaAl(OBu^t)_4$ in 1 : 2 molar ratio. The X-ray diffraction study shows a spirocyclic core made up of two planar AlO_2Mg four-membered rings joined at magnesium (Fig. 20). With two terminal ligands present on each of the aluminium atoms, all the metallic elements are present in a four-fold coordination of oxygen atoms. The angular distortions, due to the formation of four-membered $Al(\mu\text{-}OBu^t)_2Mg$ rings, are reflected in the distorted tetrahedral geometries of Mg^{II} and Al^{III} centres.

The isopropoxide analogue of $[Mg\{Al(OBu^t)_4\}_2]$ derivative is synthesised by the reaction of the two metals in isopropanol (eq. 27). The compound crystallises as $[(Pr^iOH)_2Mg\{Al(OPr^i)_4\}_2]$ [27] and the solid state structure (Fig. 21) exhibits two $\{Al(OPr^i)_4\}^-$

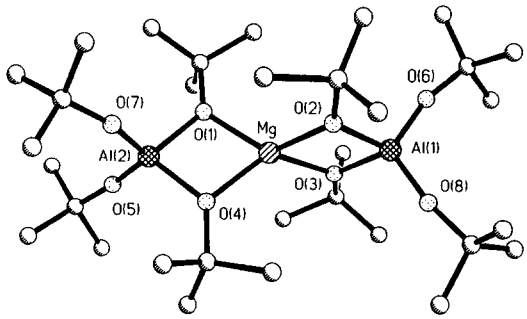

Fig. 20. Molecular structure of $[Mg\{Al(OBu^t)_4\}_2]$ [25].

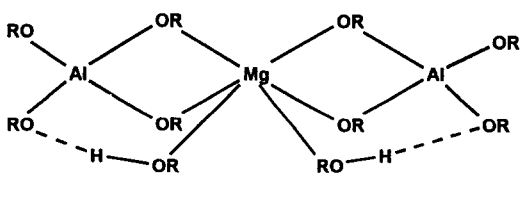

(R = Pr^i)

Fig. 21. Schematic representation of the molecular structure observed for $[(Pr^iOH)_2Mg\{Al(OPr^i)_4\}_2]$ [27].

units coordinating the central atom Mg^{II} in a bidentate fashion. The coordination sphere of magnesium is completed by two adduct alcohol molecules which show Al(R)—O···H(OR)M interactions with one of the terminal OPr^i-groups of each $\{Al(OPr^i)_4\}^-$ moiety.

The effect of the ramification of alkyl group on the coordination numbers of the metals present in the heterometallic alkoxides is nicely illustrated in the derivatives $[Mg\{Al(OBu^t)_4\}_2]$ and $[Mg\{Al(OPr^i)_4\}_2 \cdot (Pr^iOH)_2]$. Whereas the central atom Mg^{II} is tetra-coordinate in the *tert*-butoxide derivative, it achieves a hexa-coordination by two coordinating alcohol molecules in the latter case. Although both the heterometal precursors have a Mg : Al ratio suitable for $MgAl_2O_4$ ceramic, the 'base free' *tert*-butoxide compound appears to be a better choice as the presence of stabilising ligands in the latter case can lead to a higher percentage of carbonaceous impurities in the resulting mixed-metal oxide.

The $M'\{M_2(OR)_9\}_2$ (M′ = Ba, Ca; M = Ti, Zr) derivatives [20,42,43] (eqs 28 and 29) contain a central eight coordinated metal atom bound to two face-sharing biooctahedral $M_2(OR)_9^-$ units. Although the X-ray data in the case of Ba–Zr mixed-metal compound, could not be refined satisfactorily, the molecule is proposed to have a similar spiro $M_2M'M_2$ arrangement. A similar structure has been proposed for the derivative $[Ba\{Ti_2(OPr^i)_9\}_2]$ (Fig. 22) [20].

A Cu^I–Zr^{IV} mixed-metal species is obtained by the reaction of copper(I) mesityl and zirconium isopropoxide isopropanolate (eq. 31) [30]. The X-ray diffraction study shows the molecule, $Cu_2Zr_2(OPr^i)_{10}$, to result from a union of confacial bioctahedral $Zr_2(OPr^i)_9^-$ substructure and a bent $(Cu_2(OR))^+$ unit bound together by the two bridging OPr^i groups of $Zr_2(OPr^i)_9$ fragment. The eight membered metal-oxygen ring (Fig. 23) is essentially planar.

The yttrium–barium (1 : 2) heterobimetallic $YBa_2(OBu^t)_7(Bu^tOH)$ [32] obtained by the alcoholysis of a mixture of yttrium and barium amides (eq. 33) displays a triangular structure (Fig. 24) commonly adopted by $M'M_2$ heterometallic alkoxides. All metals are five-coordinate, with the terminal ligand on one of the barium atoms being an alcohol molecule. The crystal structure comprises chains of YBa_2 triangles held together by hydrogen bonds between adduct alcohol molecule of one YBa_2 unit to a terminal alkoxo group of another unit.

The sodium–thorium heterometallic alkoxide $NaTh_2(OBu^t)_9$, described by Clark *et al.*, involves the deprotonation of the coordinated alcohol in $Th_2(OBu^t)_8(Bu^tOH)$ with $NaN(SiMe_3)_2$ [44]. The crystal structure (Fig. 25) shows discrete $NaTh_2(OBu^t)_9$ molecules. There is no terminal ligand attached on the alkali atom, however, no intermolecular interactions between the sodium atom of one molecule and oxygen atoms of adjacent molecules are observed. A similar structure is observed for the related derivatives $KU_2(OBu^t)_9$ and $NaCe_2(OBu^t)_9$, reported by Cotton *et al.* [45] and Evans *et al.* [33], respectively.

Heterometal alkoxides of Ce^{IV} have been obtained, using ceric ammonium nitrate and sodium *tert*-butoxide as starting materials (eqs 34 and 35). The derivatives $(DME)_2Na_2Ce(OBu^t)_6$ [33] and $NaCe_2(OBu^t)_9$ [33] characterised by single crystal X-ray diffraction technique reveal molecular frameworks based on

Na_2Ce and $NaCe_2$ triangles, respectively (Figs 25 and 26). Whereas cerium is hexa-coordinate in both the derivatives, the sodium atoms display penta- and tetra-coordination, respectively.

2.1.3 *Reactions*

Heterobimetallic alkoxides with subvalent main group metals (ns^2 configuration) situated at the apices of one or two (fused) trigonal bipyramids act as excellent electron donors to various transition metal carbonyls. This synthetic strategy has allowed the construction of a large number of derivatives with one-dimensional arrays of metallic elements held together by direct metal–metal and M—O(R)—M bonds [34]. The difference in the reactivity of the ns^2 elements follow the sequence $In^I \gg Ge^{II} > Sn^{II} > Tl^I, Pb^{II}$. The efforts made to attach transition metal carbonyl at Tl^I or Pb^{II} ends were not successful. For a particular ns^2 element, the reactivity follow the order: $Ni(CO)_4 > Fe_2(CO)_9 > Mo(CO)_6 > Cr(CO)_6 > W(CO)_6$. A number of metal carbonyl complexes of mixed-metal alkoxides have been characterised in the solid state. Some representative frameworks of the heterometal assemblies containing three or four different metals are shown in Fig. 27.

The pronounced tendency of metal atoms to increase their coordination numbers makes the heterobimetallic alkoxides labile species and neutral metal alkoxide molecules can be added as building blocks, to modify the coordination figure of the central metal atom or to change the nuclearity of the complex [5,7]. Three soluble barium–titanium containing heterobimetallic isopropoxides with manipulable Ba : Ti stoichiometries and nuclearity have been obtained by using $Ti(OPr^i)_4$ as a building block towards polymeric $[Ba(OPr^i)_2]_n$ [20]. The dimeric compound $[BaTi_2(OPr^i)_{10}]_2$ with Ba : Ti ratio 1 : 2, reacts with one equivalent of $Ti(OPr^i)_4$ to afford mononuclear species $BaTi_3(OPr^i)_{14}$ which can be converted into $BaTi_4(OPr^i)_{18}$ by an additional mole of $Ti(OPr^i)_4$ (eq. 36).

$$1/2[BaTi_2(OPr^i)_{10}]_2 \xrightarrow{Ti(OPr^i)_4} BaTi_3(OPr^i)_{14} \xrightarrow{Ti(OPr^i)_4} BaTi_4(OPr^i)_{18} \quad (36)$$

A similar interconversion has been reported for Pb–Zr mixed-metal alkoxides where the lead-rich derivative $[Pb_4Zr_2(OPr^i)_{16}]$ can be converted into the zirconium-rich analogue $[Pb_2Zr_4(OPr^i)_{20}]$ by reacting it with an appropriate amount of zirconium alkoxide and *vice-versa* (eqs 37 and 38) [19].

$$Pb_4Zr_2(OPr^i)_{16} + 6Zr(OPr^i)_4 \rightarrow 2Pb_2Zr_4(OPr^i)_{20} \quad (37)$$

$$Pb_2Zr_4(OPr^i)_{20} + 6/n[Pb(OPr^i)_2]_n \rightarrow 2Pb_4Zr_2(OPr^i)_{16} \quad (38)$$

Discrete heterometallic alkoxy derivatives have a defined stoichiometry at the molecular level and are thus attractive precursors in sol–gel processing of mixed-metal oxides. Although extensive studies have been made to understand the initial stages of hydrolysis and the mechanisms of conversion of homo-metallic alkoxides to metal oxides, the key studies using heterometallic precursors are missing, however, a few scattered reports available show interesting structural and nuclearity changes. The controlled hydrolysis reaction (eq. 39) of $[LiTi(OPr^i)_5]_2$ proceeds with the retention of metal stoichiometry, however the degree of aggregation grows and the resulting molecule $[LiTiO(OPr^i)_3]_4$ [46] is tetrameric, possibly due to the greater bridging ability of an oxo (O^{2-}) ligand in comparison to the alkoxide group.

$$2[LiTi(OPr^i)_5]_2 + 4H_2O \rightarrow [LiTiO(OPr^i)_3]_4 + 8Pr^iOH \quad (39)$$

However, the controlled hydrolysis of $Ba\{Zr_2(OPr^i)_9\}_2$ shows no change in the metal ratios or segregation of the molecule and $BaZr_4(OPr^i)_{17}(OH)$ [46] is obtained with a structure similar to that of parent compound (Fig. 22).

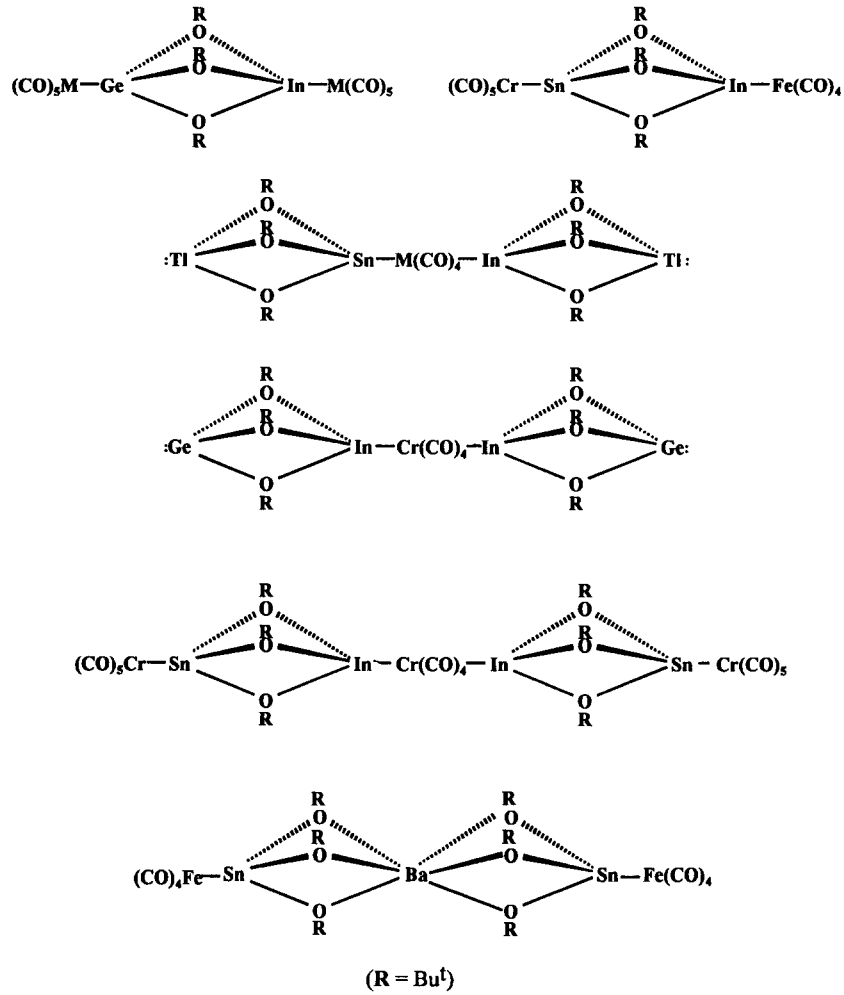

Fig. 27. Schematic representation of the frameworks observed in the transition metal derivatives of some mixed-metal alkoxides [34].

2.2 *Heteroleptic heterobimetallic alkoxides*

In contrast to the large number of reports available on the structural characterization of homoleptic heterometal alkoxides, the structurally characterized examples of halide heterometallic alkoxides are scarce. Prior to our investigations, the well-characterised chloride heterobimetallic alkoxides were limited to $[ClMg\{Ti_2(OEt)_8Cl\}]_2$ [47], $[ClM\{Zr_2(OPr^i)_9\}]_2$ (M = Cd [48], Cu [30]) and $[ClPr\{Al(OPr^i)_4\}_2(Pr^iOH)]_2$ [35]. Although a large number of chloro alkoxometallates are reported, the absence of single crystal X-ray diffraction studies together with *oxo* forming and salt retaining [49] tendency of heterometal alkoxide derivatives has made their formulation and identity ambiguous. In our continuing investigations on halo-functionalised heterometallic alkoxides, we have found that these 'intermediates' are generally soluble and stable compounds (most of them sublime/distill *in vacuo* without any extensive decomposition) and show enormous potential as attractive synthons for incorporating other ligands (OR^-, $OSiMe_3^-$, $OSiPh_3^-$, $C_5H_5^-$) in the heterometal assembly. It is worth noting that use of halide heterobimetallic alkoxides towards cyclopentadienyl reagents has furnished the first examples of an elusive class of cyclopentadienyl containing heterobimetallic alkoxides [50,51]. More interestingly, the metathesis of metal–halogen bonds using suitable alkalimetal alkoxometallates has offered novel molecular alkoxide assemblies containing three different metals (see Section 3) [6,14]. Although the class of heteroleptic alkoxides would, in principle, include the heterometal alkoxide derivatives based on other hetero-ligands such as hydride, oxide, β-diketonates, carboxylates, siloxides, aryloxides, etc., the present article is limited to heterobimetallic derivatives containing halide and cyclopentadienyl as ancillary ligands.

2.2.1 *Synthesis*

(*i*) *Salt elimination reactions.* In view of our interest in the halo-alkoxometallates as interesting synthons (see Section 3) and dearth of information about their structural features, we have investigated the solution and solid state characterization of a number of halide heterobimetallic derivatives illustrated in eqns 40–46 [6,13,14,51,52]

$$MX_2 + KM'_2(OPr^i)_9 \rightarrow XM\{M'_2(OPr^i)_9\} + KX \quad (40)$$

$M = Cd$; $X = I$; $M' = Sn^{IV}, Ti^{IV}, Zr^{IV}, Hf^{IV}$

$M = Fe, Cu$; $X = Cl$; $M' = Ti^{IV}, Hf^{IV}$

$$MX_2 + KM'_2(OPr^i)_9 \rightarrow \tfrac{1}{2}[XM\{M'_2(OPr^i)_9\}]_2 + KX \quad (41)$$

$M = Sn$; $X = Cl$; $M' = Zr, Hf$

$M = Pb$; $X = I$; $M' = Ti, Zr$

$$BaI_2 + KM_2(OPr^i)_9 \rightarrow \tfrac{1}{2}[IBa\{M_2(OPr^i)_9\}]_2 + KI \quad (42)$$

$M = Sn, Ti, Zr, Hf$

$$CdI_2 + KTa(OPr^i)_6 \xrightarrow{2Pr^iOH} [ICd\{Ta(OPr^i)_6\}(Pr^iOH)_2] + KI \quad (43)$$

$$2CdI_2 + 2KOPr^i + Nb(OPr^i)_5 \xrightarrow{C_7H_8} \tfrac{1}{2}[I_2Cd_2Nb(OPr^i)_7]_2 + 2KI \quad (44)$$

$$2MCl_3 + 2KM'_2(OPr^i)_9 \rightarrow 2/n[Cl_2M\{M'_2(OPr^i)_9\}]_n + 2KCl \quad (45)$$

$M = Bi$; $M' = Ti, Zr, Hf$; $n = 2$

$M = In, Y$; $M' = Ti, Zr, Hf$; $n = 1$

$$SnI_4 + nKTi(OPr^i)_5 \rightarrow [I_{4-n}Sn\{Ti(OPr^i)_5\}_n] + nKI \quad (46)$$

$n = 1$–3

The first examples of cyclopentadienyl containing heterobimetallic alkoxides have been synthesised by treating various alkali metal alkoxometallates with cyclopentadienyl tin(II) chloride (eqs 47 and 48). Alternatively, these heteroleptic derivatives become accessible on reacting well-characterised halide–heterobimetallic alkoxides with sodium cyclopentadienide [50,51]

$$(C_5H_5)SnCl + KM(OBu^t)_3 \rightarrow (C_5H_5)Sn(\mu\text{-}OBu^t)_2M(OBu^t) + KCl \quad (47)$$

$M = Sn, Ge$

$$(C_5H_5)SnCl + KM_2(OPr^i)_9 \rightarrow (C_5H_5)Sn\{M_2(OPr^i)_9\} + KCl \quad (48)$$

$M = Zr, Hf$

(*ii*) *Miscellaneous methods.* The Lewis acid–base interaction of a metal halide and alkoxide (eqs 49 and 50) provides an alternative to the salt elimination reaction for the synthesis of halo functionalised heteremetal alkoxides [47,53]

$$MgCl_2 + 2Ti(OEt)_4 \rightarrow \tfrac{1}{2}[ClMg\{Ti_2(OEt)_8Cl\}]_2 \quad (49)$$

$$BiCl_3 + OV(OPr^i)_3 \xrightarrow{3HOC_2H_4OCH_3} \tfrac{1}{2}[BiCl_3OV(OC_2H_4OCH_3)_3]_2 + 3Pr^iOH \quad (50)$$

2.2.2 *Structural and spectral features*

In the course of our ongoing investigations, we have synthesised and characterised a large number of heteroleptic heterometal alkoxides based on chelating alkoxometallate units of the type $\{M(OR)_3\}^-$ (M = Ge, Sn, Pb), $\{M(OR)_4\}^-$ (M = Al, Ga, Sb, Bi), $\{M(OR)_5\}^-$ (M = Sn, Ti, Zr, Hf), $\{M(OR)_6\}^-$ (M = Nb, Ta) and $\{Ma_2(OR)_9\}^-$ (M = Sn, Ti, Zr, Hf). The structurally characterised examples of various heteroleptic heterobimetallic alkoxides are assembled in Table 2.

Salient features of the structurally characterised compounds based on face-sharing bioctahedral $\{M_2(OR)_9\}^-$ sub-structure are (i) the gradation of the metal–oxygen bond lengths within the $M_2(OPr^i)_9^-$ unit [M—O (terminal) < M—(μ_2-OM) (doubly bridging, μ_2-) < M-(μ_3-OM) (triply bridging, μ_3-)] which corroborates the loss of electron density at the oxygen with each successive bridge and (ii) the greater opening of the terminal M—O—C bond angles which is presumably a consequence of metal–oxygen multiple bond order and steric factors. The most commonly observed mode of ligation for $M_2(OPr^i)_9^-$ type sequestering anions is the use of four alkoxy oxygen atoms (two terminal and two bridging) to form a pocket to accommodate the cationic fragment. The size of the pocket depends on the size of the M^{IV} cation and M ··· M vector and its compatibility to the size of heterometal partner decides the stability of the resulting complex. The chemistry of confacial bioctahedral $M_2(OR)_9^-$ units is dominated by the use of zirconium and the formation of analogous bioctahedral substructure by tetravalent tin, titanium and hafnium was not investigated before. The solid state structures of $ICdSn_2(OPr^i)_9$ [52], $ICdTi_2(OPr^i)_9$ [6] and $ICdHf_2(OPr^i)_9$ [6] derivatives reported by us, provide the first structural evidence for the existence of a $M_2(OPr^i)_9^-$ unit, based on Sn^{IV}, Ti^{IV} and Hf^{IV}. Owing to the facts, such as (i) the monomeric and non-adduct forming behaviour of $Ti(OPr^i)_4$ [7] (cf. isopropoxides

[a] μ_2-OR = doubly bridging alkoxo ligands.
[b] μ_3-OR = triply bridging alkoxo ligands.
[c] The contribution of cyclopentadienyl ligand in the ligand count is being considered to be unity.

of tetravalent Sn, Zr and Hf are dimeric alcoholates $[M(OPr^i)_4 \cdot Pr^iOH]_2$) (ii) the known heterometal compounds where the use of homometallic Ti and Zr alkoxides as building blocks results in the formation of products with different metal ratios as well as different structural features and (iii) the 'belief' that smaller Ti^{4+} cation cannot achieve hexa-coordination due to the steric bulk of OPr^i ligands [19b] which results from the paucity of structurally characterised six-coordinate titanium isopropoxide derivatives, the use of alkali metal alkoxo-titanates in the formation of heterometal derivatives remain unexplored. In view of above and the importance of titanium containing ceramics [54] we have synthesised a number of mixed-metal derivatives based on mono-anionic $\{Ti_2(OPr^i)_9\}^-$ and $\{Ti(OPr^i)_5\}^-$ units (Tables 1 and 2).

The iodide cadmium nonaisopropoxo-distannate (-dititanate, -dizirconate and -dihafnate) derivatives [6,52] (eq. 40) are isostructural and the molecule can be viewed as a tetra-dentate interaction of the anionic con-facial bioctahedral $\{M_2(OPr^i)_9\}^-$ (M = Sn, Ti, Zr, Hf) unit to a cationic CdI^+ fragment. The coordination polyhedron of cadmium bearing iodide as a terminal ligand resembles a distorted trigonal bipyramid whereas each tetravalent metal centre (Sn, Ti, Zr, Hf) is hexa-coordinate and displays a distorted octahedral geometry.

In the case of $ICd\{Ti_2(OPr^i)_9\}$ derivative (Fig. 28), the Cd-(μ_2-OTi) distances are found to be longer than Cd-(μ_3-OTi) distances. The relatively small size of titanium atom results in shorter Ti—OPr^i terminal distances which consequently show longer Cd—μ_2-OTi contacts. The pocket formed by short μ_3- and long μ_2-contacts is not suitable for binding Cd^{2+} strongly and the poor fit of Cd^{2+} in the 'arms' of

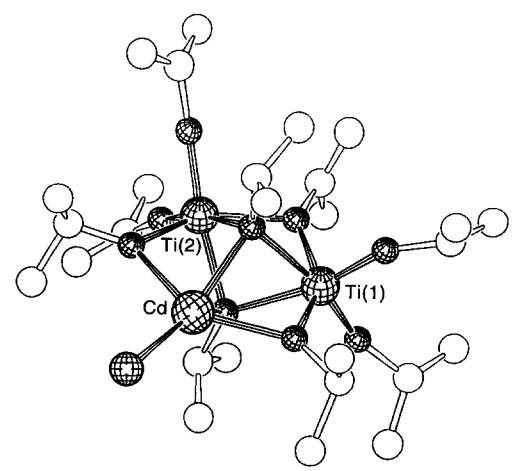

Fig. 28. Molecular structure of $ICd\{Ti_2(OPr^i)_9\}$ [6b].

$Ti_2(OPr^i)_9^-$ unit is evident in the thermal lability of $ICd\{Ti_2(OPr^i)_9\}$, whereas the $ICd\{M_2(OPr^i)_9\}$ derivatives based on larger Zr^{IV} and Hf^{IV} atom sublime almost quantitatively, when heated *in vacuo* [6b]. The cryoscopic and multinuclear spectroscopic data indicate the $ICd\{M_2(OPr^i)_9\}$ derivatives to be monomeric in solution which is corroborated by the solid state CP MAS ^{113}Cd NMR studies. The ^1H NMR spectra of these derivatives suggest a C_{2v} molecular symmetry in the solution as displayed in a characteristic set of four signals in the intensity ratio 4:2:2:1. Further, the similar ^{113}Cd chemical shifts in solution and solid state indicate that the binding mode of $M_2(OPr^i)_9^-$ unit to cadmium is retained in both the states. The mononuclear nature of the iodo-heterobimetallic derivatives in the vapour phase can be inferred in a representative case on recording a chemical ionization mass spectrum (M^+) for $ICd\{Hf_2(OPr^i)_9\}$ which exhibits a molecular ion corresponding to the monomer [6b].

The presence of an NMR active heterometal partner, as shown for cadmium compounds, facilitates the probing of structural behaviour of heterometal alkoxide derivatives in the solution and solid state. This assumes special significance among heterometal alkoxides where the ^1H and ^{13}C NMR spectra are often not structurally diagnostic, due to the high fluxionality of these derivatives in solution. In view of the above, our initial investigations were focused on metals (^{113}Cd, ^{119}Sn, ^{207}Pb) whose coordination state could be studied by NMR spectroscopy in both the solution and solid state.

New bimetallic halide isopropoxides of divalent Sn and Pb are accessible by the metathesis reactions of their halides and alkali metal salts of $M_2(OPr^i)_9^-$ anions containing Ti, Zr and Hf atoms (eq. 41) [50,52]. In contrast to the monomeric Cd^{II} derivatives, $ICd\{M_2(OPr^i)_9\}$, the analogous derivatives of Sn^{II} and Pb^{II} are found to be dimeric species. The molecular structure of $[ISn\{M_2(OPr^i)_9\}]_2$ (M = Zr, Hf) shows (Fig. 29) a tridentate interaction of $M_2(OPr^i)_9$ unit with Sn^{II} which deviates from the typical tetra-dentate ligating mode of $M_2(OR)_9^-$ moieties presumably due to the presence of the stereochemically active lone pair at tin. The central $Sn_2I_2O_6$ unit can be described as two SnI_2O_3 trigonal bipyramids joined along a common edge. Alternatively, when the lone pair of electrons at tin(II) is considered to be stereochemically active, the tin geometry resembles a distorted octahedron in which one of the axial sites is occupied by the non-bonding electron pair.

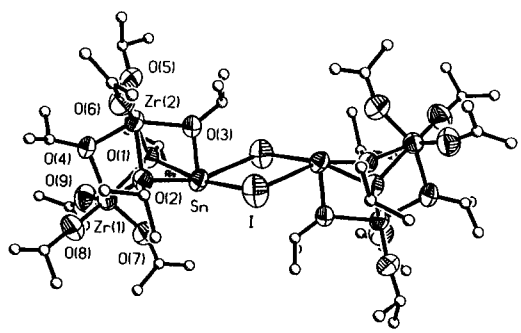

Fig. 29. Molecular structure of $[ISn\{Zr_2(OPr^i)_9\}]_2$ [52].

Whereas $[ISn\{Zr_2(OPr^i)_9\}]_2$ [52] is a centrosymmetric dimer, the chloride tin-dizirconate (dihafnate) molecule [50] adopts, in the solid state, a dimeric form *via* long Sn···Cl interactions (Fig. 30) between chlorine of one molecule and the tin atom of a second molecule, nevertheless their deviation from C_i symmetry is small. The bidentate coordination of the $M_2(OPr^i)_9^-$ unit has also been observed in $[Pb_2Zr_4(OPr^i)_{20}]$ [12]. If the long Sn···Cl interactions are taken into account, the coordination sphere of tin(II) can be termed as '3 + 1'. Most striking is the change in the ligating behaviour of $M_2(OPr^i)_9^-$ units to similar SnX^+ (X = Cl, I) fragments; the $M_2(OPr^i)_9$ sub-structures act as bi- and tri-dentate ligands for chloride and iodide derivatives, respectively. As inferred by the cryoscopic studies (molecular complexity, $\eta = 1.4$–1.6), the dimeric form of $[XSn\{M_2(OPr^i)_9\}]_2$ derivatives is not maintained in the solution. A 2 monomer ⇔ dimer equilibrium, is indicated in the solution by ^{119}Sn NMR spectra which has been confirmed by variable temperature ^{119}Sn NMR studies. The effect of the nature of metal atoms is seen among iodo derivatives of bivalent cadmium and tin. The $ICd\{M_2(OPr^i)_9\}$ derivatives (Fig. 28) exhibit a closed triangular (CdM_2) framework however, the replacement of $Cd^{(II)}$ by Sn^{II} of almost similar size (Cd^{2+} = 0.99 Å, Sn^{2+} = 1.02 Å) gives an open structure (Fig. 29). This possibly results from the tendency of tin(II) atom to achieve a pyramidal configuration and to retain a stereochemically active lone pair consequently, a dimeric framework is preferred (despite the bulk of iodide ligands) over a monomeric closed triangular structure. The role of halide ligands in the nuclearity and coordination numbers of metals has also been observed for Cd–Zr mixed-metal alkoxides where the substitution of chloride, in the dimeric $[ClCd\{Zr_2(OPr^i)_9\}]_2$ [45] containing a six-coordinate cadmium, by bulkier iodide ligand produces monomeric $ICd\{Zr_2(OPr^i)_9\}$ with a five coordinate cadmium.

The discovery of the super-conducting properties of a number of copper containing oxide-ceramic [55] materials has resulted in an unprecedented search for soluble copper containing derivatives which can be used as precursors to ceramic materials *via* sol–gel processes. The reactions of copper(II) chloride with $KM_2(OPr^i)_9$ (M = Ti, Hf) in 1:1 stoichiometry offered halide heterobimetallic alkoxide of the type $ClCu\{M_2(OPr^i)_9\}$ (eq. 40) [14,20]. The zirconium analogue $ClCu\{Zr_2(OPr^i)_9\}$ is also known [30]. Their solid state structures resemble closely to the structures observed for $ICd\{M_2(OPr^i)_9\}$ compounds, a perspective drawing is shown for the titanium analog

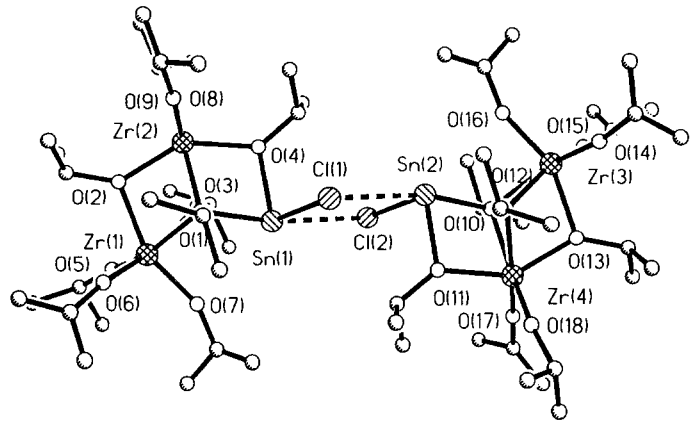

Fig. 30. Molecular structure of $[ClSn\{Zr_2(OPr^i)_9\}]_2$ [50].

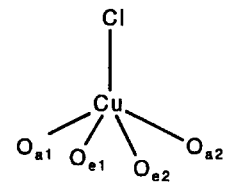
(Fig. 31). The $\{(Pr^iO)_3M(\mu_2\text{-}OPr^i)_3M(OPr^i)_3\}^-$ unit coordinate Cu^{II} through four oxygen atoms of the OPr^i groups, two of which also bridge the two M^{IV} centres. The core of the molecules comprise a heterometallic isosceles CuM_2 triangle with similar non-bonded $Cu\cdots M$ distances; the triangular base is capped on both the sides by a μ_3-OPr^i ligand, two Cu—M and the third M—M side of the triangular core are each bridged by a μ_2-OPr^i group.

The five-coordinate copper in $ClCu\{M_2(OPr^i)_9\}$ derivatives (M = Ti, Zr, Hf) constitute a distorted trigonal bipyramid with four oxygen and one chlorine ligand where the axial (doubly bridging) OPr^i ligands are bound to copper in a symmetrical fashion. Among the equatorial ligands, the average Cu—(μ_3-O) distance is longer than the copper contact to much larger chloride ion and chloride is apparently the most tightly bound ligand to copper. This observation can be understood in terms of Jahn-Teller distortion (Cu^{II}, d^9) which makes copper coordination sphere flexible to display both normal coordinated (Cu—L) and longer semi-coordinated ($Cu\cdots L$) bonds [56,57]. In view of the above, the copper coordination in $ClCu\{M_2(OPr^i)_9\}$ derivatives can be viewed as '3+2' with three strong (Cl, O_{a1}, O_{a2}) and two weak (O_{e1}, O_{e2}) interactions.



In view of the paramagnetic influence of Cu^{II}, these derivatives exhibit simple Curie–Law behaviour deduced from a linear relationship between the change in ^1H NMR isotropic shift with respect to the temperature. The monomeric nature of $ClCu\{M_2(OPr^i)_9\}$ derivatives is supported by the cryoscopic measurements which rules out the possibility of interacting paramagnetic centres to give dimeric diamagnetic species of the type '$Cu(\mu\text{-}Cl)_2Cu$'.

Iodide heterobimetallic derivatives of barium of the formula $[IBa\{M_2(OPr^i)_9\}]_2$ (M = Sn, Ti, Zr, Hf) [13] (eq. 42) are dimeric in the solution and solid state. The molecular structure (Fig. 32) can be analysed as a union of three face-sharing octahedra built about

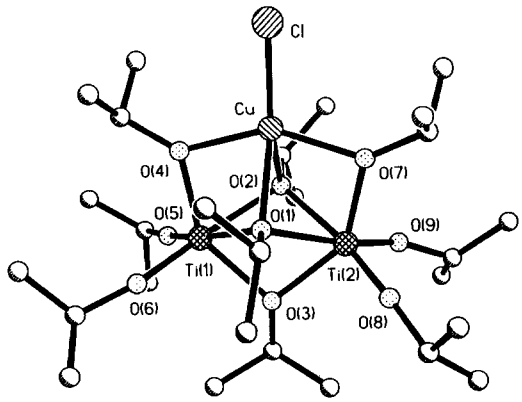


Fig. 31. Molecular structure of $ClCu\{Ti_2(OPr^i)_9\}$ [20].

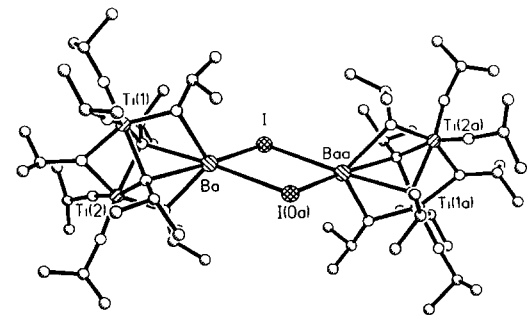

Fig. 32. Molecular structure of $[IBa\{Ti_2(OPr^i)_9\}]_2$ [13].

two Ti (Sn, Zr, Hf) and one Ba atom. The monomeric formulation 'IBa$\{Ti_2(OPr^i)_9\}$' of these derivatives is a ligand deficient modification of M_3L_{11} structural unit observed in the solid state structures of $[Cl_2Y\{Ti_2(OPr^i)_9\}]$ [20] and $[(OPr^i)ClY\{Ti_2(OPr^i)_9\}]$ [13]. Owing to the ligand deficit, the simplest structural change to attain a M_3L_{11} motif involves the dimerisation *via* 'terminal' iodide ligands. The other MM'_2L_{10} derivatives supporting the proposed dimerisation are $[ClCd\{Zr_2(OPr^i)_9\}]_2$ [48] and $[BaZr_2(OPr^i)_{10}]_2$ [46].

Although structurally characterised halide heterobimetallic alkoxides based on tri-, tetra-, penta- and nona-alkoxometallate are known, reports available on halo-functionalised heterometal alkoxy derivatives based on $M(OPr^i)_6^-$ fragments (M = Nb, Ta) are relatively scarce. Equation 43 illustrates the synthesis of a monomeric monoiodo cadmium hexaisopropoxo-tantalate [13]. The molecule (Fig. 33) is formed by the bidentate ligation of $Ta(OPr^i)_6^-$ unit to Cd^{II} bearing an iodide ligand. The cadmium atom is additionally coordinated by two alcohol molecules to display a quasi-trigonal bipyramidal geometry whereas the ligand disposition around tantalum represents a slightly distorted octahedron.

An attempted synthesis of a halide-free Cd—Nb mixed metal alkoxide with 1 : 1 metal stoichiometry gave a dimeric iodo-complex with Cd–Nb stoichiometry 2 : 1 (eq. 44) [13]. The molecular structure reveals two tetrahedral Cd^{II} fragments '$ICd(OPr^i)_3$' and '$I_2Cd(OPr^i)_2$' (Fig. 34) bound to the octahedral $Nb(OPr^i)_6^-$ moiety in bi- and mono-dentate fashion, respectively. The observation of two resonances, corresponding to two chemically inequivalent Cd^{II} centres in the solution and solid state ^{113}Cd CP MAS NMR spectra provides evidence that the heterometallic framework observed in the solid state is also maintained in the solution.

As indicated in eqs 40–43, the reactions of divalent metal halides with alkali metal alkoxometallates in 1 : 1 stoichiometry offer mono-halo heterometallic derivatives. In a similar manner di- and tri-halo functionalised heterometallic alkoxides are obtained on employing tri- and tetravalent metal halides, respectively. Dichloro-yttrium-nonaisopropoxo-dimetallate compounds of the type $Cl_2Y\{M_2(OPr^i)_9\}$ (M = Ti, Zr, Hf) [13,20] have been synthesised (eq. 45) quantitatively by the equimolar reaction of YCl_3 and $KM_2(OPr^i)_9$ derivatives. The derivatives are stereochemically rigid and the NMR spectra are indicative of the structural pattern existing in the solution.

The X-ray diffraction analysis performed on a representative titanate derivative reveals a monomeric species (Fig. 35) formed by a face-sharing fusion of three octahedra built about a yttrium and two titanium atoms. Each metal atom bears two terminal ligands which are chlorides in the case of yttrium. The central $M_3O_9Cl_2$ unit of the compound represent a modified M_3X_{11} structural type observed in other metal alkoxides e.g., $La_3(OBu^t)_9$ $(Bu^tOH)_2$ [58]. In contrast to the monomeric yttrium derivatives, the analogous bismuth derivatives [13] have a dimeric structure. The molecular structure of $[Cl_2Bi\{Zr_2$

(R = Pr^i; L = Pr^iOH)

Fig. 38. Schematic representation of the molecular structure of $[ClPr\{Al(OPr^i)_4\}_2(Pr^iOH)]_2$ [35].

$(OPr^i)_9\}]_2$ is shown in Fig. 36. One of the chlorine atoms present at bismuth interact with the bismuth atom of another '$Cl_2Bi\{Zr_2(OPr^i)_9\}$' unit to give the observed dimeric form. Similar to the solid state structures of $[ISn\{M_2(OPr^i)_9\}]_2$ compounds, the $[Cl_2Bi\{Zr_2(OPr^i)_9\}]_2$ derivative displays a tridentate behaviour of $M_2(OPr^i)_9$ (M = Zr, Hf) units.

A series of iodo-heterobimetallic Sn^{IV}–Ti^{IV} derivatives [13] are obtained by the interaction of SnI_4 and $KTi(OPr^i)_5$ in appropriate molar ratios (eq. 46). The derivatives are highly fluxional at room temperature, however, structurally diagnostic spectra are obtained on lowering the temperature. The cryoscopic and VT ^{119}Sn NMR studies indicate the monomeric behaviour in solution. The X-ray diffraction study performed on a diiodo-derivative shows (Fig. 37) a six-coordinate tin(IV) surrounded by two iodide and two bidentate $\{Ti(OPr^i)_5\}^-$ ligands. The two titanium atoms are present in a distorted trigonal bipyramidal arrangement of alkoxo ligands.

The chloro(propan-2-ol)bis(tetraisopropoxoaluminato)-prasesodymium(III) dimer, $[ClPr\{Al(OPr^i)_4\}_2(Pr^iOH)]_2$ [35] represent the only halide heterometallic alkoxide based on a bidentate $\{Al(OPr^i)_4\}^-$ moiety (Fig. 38). The centrosymmetric dimer consists of two triangular $Al_2Pr(\mu\text{-}OPr^i)_4(OPr^i)_4(Pr^iOH)^+$ units linked by two chloride bridges. Praseodymium is hepta-coordinate and the coordination polyhedron formed by five oxygens and two bridging chlorine atoms can be envisaged as a distorted capped trigonal prism.

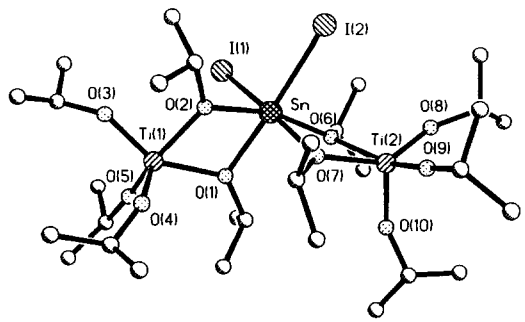

Fig. 37. Molecular structure of $[I_2Sn\{Ti(OPr^i)_5\}_2]$ [13].

Although the reactions involving metal halides and an alkali metal reagent proceed quantitatively in most of the cases and the desired target product is obtained in a 'clean' way (no undesirable side products), examples are known where alkali metal or halide ions remain attached to give 'ate' complexes. This problem of salt retention is more frequently encountered in the homo- as well as hetero-metallic alkoxide chemistry of yttrium and lanthanide metals. Evans *et al.* have reported [59] on the simple chloro-alkoxometallates of the type $Y_3(OBu^t)_8Cl(THF)_2$ and $Y_3(OBu^t)_7Cl_2(THF)_2$ obtained as the major products in the reactions of YCl_3 with 3 and 2 equiv. of $NaOBu^t$, respectively. Mixed-metal alkoxides representing a new class of $LnNa_8(OBu^t)_{10}Cl$ (Ln = Y, Eu) complexes [60] are obtained in high yields (70–90%) in the reactions involving $LnCl_3$ and 10 equiv. of $NaOBu^t$. Interestingly, a hydroxy derivative $YNa_8(OBu^t)OH$ belonging to this class is also formed in a similar reaction between YCl_3 and $NaOBu^t$ (which reportedly was contaminated by impurities such as NaOH). Other typical examples include chloride heterobimetallic aryloxide of the type $[ClM(OR)_3Na]$ (M = La, Y; R = $C_6H_2(CH_2NMe_2)$-2-6-Me-4) [61] and $[ClY_2(OR')_6Na]$ (R' = $C_6H_4(CH_2NMe_2)$) [61] obtained in the reaction of lutetium or yttrium trichloride with three equivalents of sodium aryloxides. The problem of salt retention is more frequently observed in the case of smaller alkali-metal ions (Li^+, Na^+) and can be overcome to a certain extent by using potassium derivatives presumably due to the higher insolubility of KCl, in common organic solvents, in comparison to that of LiCl and NaCl. However, this problem is not always eliminated by the use of heavier alkali metals, e.g. the reaction of anhydrous $LnCl_3$ (Ln = Nd, Er, Lu) with potassium arlyoxide results, irrespective of the amount (3 or 4 equiv.) of KOAr used, in the formation of $KLn(OAr)_4$ derivatives [62].

The halide heterobimetallic ethoxide $[ClMg\{Ti_2(OEt)_8Cl\}]_2$ (eq. 49) obtained by the dissolution of $MgCl_2$ in $Ti(OEt)_4$ is the only well-characterised derivative that represent an alternative synthetic route to halide heterometallic alkoxides. The molecule is observed as a centrosymmetric dimer in the solid state and the overall structure is similar to that of $[IBa\{Ti_2(OPr^i)_9\}]_2$ derivative (Fig. 32). The central atom, magnesium, coordinated by the three oxygen and one chlorine atom of the modified face-sharing biocta-hedral unit $\{Ti_2(OEt)_8Cl\}^-$ and bearing a 'terminal' chloride ligand dimerises ($Mg(\mu\text{-}Cl)_2Mg$) to achieve the M_3X_{11} form.

A new chloro bismuth–vanadium heterobimetallic oxoalkoxide $[BiCl_3OV(OC_2H_4OCH_3)_3]_2$ [53] is obtained (eq. 50) by the reaction of $BiCl_3$ with $OV(OPr^i)_3$ in 2-methoxyethanol. The X-ray structural study reveals the vanadium atom in a distorted octa-hedral environment whereas, bismuth is present in a distorted capped octahedron of chlorine and oxygen atoms. The $OC_2H_4OCH_3$ group binds to vanadium in a bidentate fashion which contrasts the monodentate mode observed in homometallic 2-methoxy ethoxide derivatives of Pb^{II} [63] and Bi^{III} [64].

The single crystal X-ray diffraction analysis performed on $(C_5H_5)Sn(\mu\text{-}OBu^t)_2Ge(OBu^t)$ [51] (eq. 47) reveals (Fig. 39a) a nearly planar four-membered SnO_2Ge ring terminated at Sn^{II} by the cyclopentadienyl ring and at Ge^{II} by the OBu^t group. The two terminal ligands occupy *cis* positions with respect to the plane of the ring. The sum of the angles around Ge^{II} and Sn^{II} indicate a stereochemically active lone pair giving the two bivalent metal atoms a trigonal pyramidal configuration. Interestingly, a similar reaction between $(C_5H_5)SnCl$ and $KPb(OBu^t)_3$ afford an unanticipated product $(C_5H_5)Pb(\mu\text{-}OBu^t)_2Sn(OBu^t)$ [50] which involves a transfer of cyclopentadienyl group from tin to lead. However, the overall molecular framework remains the same. Owing to the presence of two NMR active metal nuclei, the solution spectral data were indicative of a transfer of the $C_5H_5^-$ ligand from tin to lead. The most interesting feature in the solid state structures of the two derivatives is the different hapticity of the $C_5H_5^-$ ligands toward the tin and lead atoms. The tin germanate shows a peripherally ($\eta^{1/3}$) bonded cyclopentadienyl ring (Fig. 39a) possessing a diene character whereas, a centrally bonded (η^5) cyclopentadienyl ring (Fig. 39b) is observed in the tin plumbate.

Out of the $[(C_5H_5)Sn\{M_2(OPr^i)_9\}]$ (M = Zr, Hf)

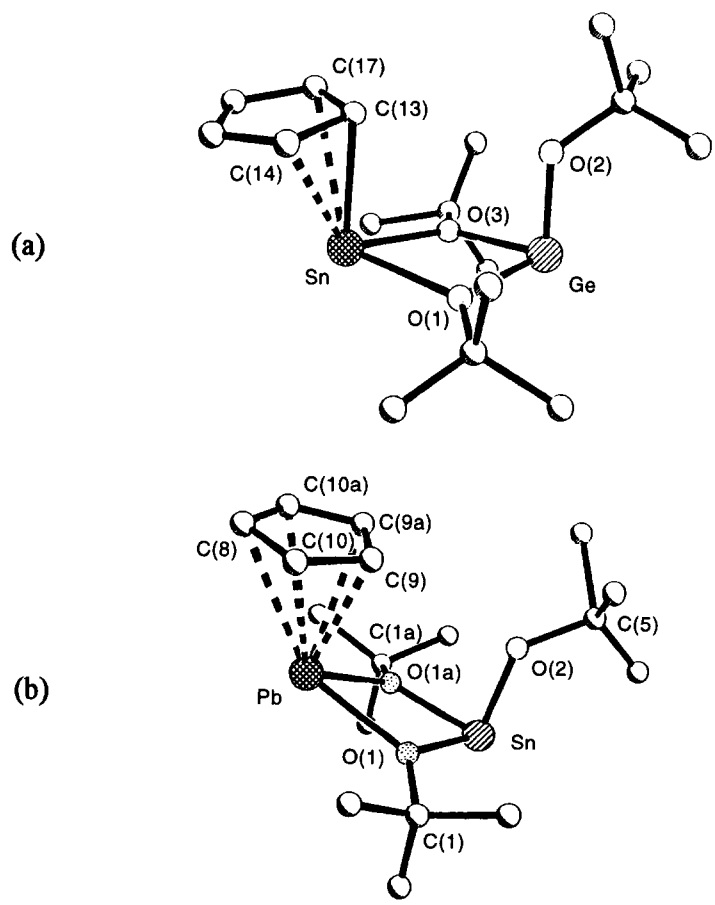

Fig. 39. Molecular structures of (a) $(C_5H_5)Sn(\mu\text{-}OBu^t)_2Ge(OBu^t)$ [51] and (b) $(C_5H_5)Pb(\mu\text{-}OBu^t)_2Sn(OBu^t)$ [50].

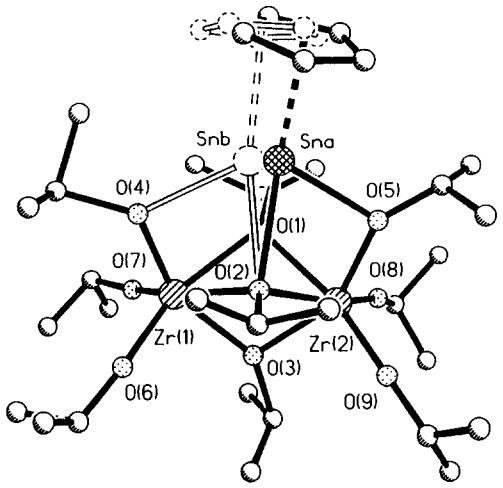

Fig. 40. Molecular structure of $[(C_5H_5)Sn\{Zr_2(OPr^i)_9\}]$ [50]. The unfilled line shows the partially occupied tin and cyclopentadienyl sites.

[50] derivatives (eq. 48), the zirconium compound characterized by X-ray crystallographic study (Fig. 40) features a $(C_5H_5)Sn^+$ fragment disordered with a 80:20 occupancy between the doubly bridging arms of the $Zr_2(OPr^i)_9^-$ unit. An interesting aspect of these heteroleptic ($C_5H_5^-/OR^-$) derivatives is their nuclearity with respect to that of the precursors. The substitution of chloride in dimeric $[ClSn\{M_2(OPr^i)_9\}]_2$ (M = Zr, Hf) complexes by a ligand (Cp^-) of higher bulk and denticity renders the product monomeric. This synthetic strategy can be used for obtaining more tractable heterometallic species as in contrast to the extraordinary bridging tendency of OR ligands, a cyclopentadienyl bridging would be thermodynamically disfavoured and can result in less associated heterometallic systems.

A recent study reports the formation of heteroleptic ($C_5HMe_4^-/OMe^-$) titanium(III)–magnesium (II) derivative $[(C_5HMe_4)_2Ti(\mu\text{-}OMe)_2]_2Mg$ [65] by the methanolysis of the hydride complex $[(C_5HMe_4)_2Ti(\mu\text{-}H_2)]_2Mg$. The molecule (Fig. 41) contains two non-equivalent octamethyl titanocene moieties each bonded through two bridging methoxy groups to the central magnesium atom.

2.2.3 *Reactions*

The halo-functionalised heterometal alkoxides are interesting synthons and the substitution of anionic halide ligand by an appropriate alkoxo, aryloxo, siloxo or cyclopentadienyl ligand results in a variety of heteroleptic heterometal alkoxy derivatives. Some typical reactions examined (eq. 51) are shown below.

$$XM\{M'_2(OR)_9\} + M''L \rightarrow LM\{M'_2(OR)_9\} + M''X \quad (51)$$

$M = Sn^{II}, Cd^{II}$; $M' = Ti, Zr, Hf$; $M'' = Na, K$

$L = OPr^i, OBu^t, OSiMe_3, OSiPH_3, C_5H_5$;

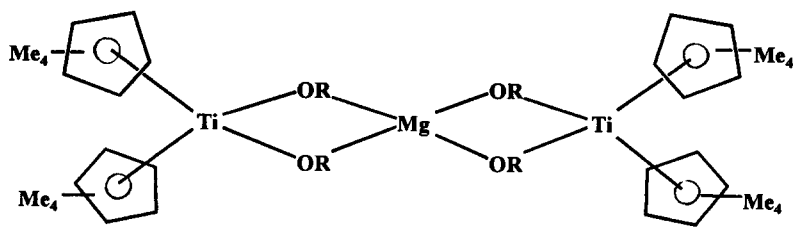
$X = Cl, I$

A controlled alcoholysis of $CpSn(OBu^t)_2Ge(OBu^t)$ gives a product devoid of cycopentadienyl group and shows only one single environment in the ^{119}Sn NMR spectrum which differs from the ^{119}Sn NMR chemical shift of $[Sn(OBu^t)_2]_2$ and suggests the formation of a tin–germanium heterobimetallic compound with 1:1 metal stoichiometry. However, no such product is formed on reacting $[Sn(OBu^t)_2]_2$ and $[Ge(OBu^t)_2]_2$ in equimolar ratio [18b]. Mixed ligand heterometal systems are of considerable interest as they provide access to metal stoichiometries not achievable by pure alkoxide constituent. Efforts to obtain definitive structural information about this compound by single crystal X-ray crystallography are currently underway.

$$(C_5H_5)Sn(\mu\text{-}OBu^t)_2Ge(OBu^t) + Bu^tOH \rightarrow {}' SnGe(OBu^t)_4{}' + C_5H_6 \quad (52)$$

In analogy to the heterobimetallic derivatives based on main group elements with ns^2 configuration, the novel cyclopentadienyl containing heterobimetallic alkoxides function as soft ligands too and have been used to synthesise elusive examples of heterotermetallic derivatives illustrated below (eq. 53) [66].

$$(C_5H_5)Sn(\mu\text{-}OBu^t)_2Ge(OBu^t) + Mo(CO)_6 \rightarrow (C_5H_5)Sn(OBu^t)_3Ge\text{-}Mo(CO)_5 + CO \quad (53)$$



(R = Me)

Fig. 41. Representation of the molecular structure of $[(C_5HMe_4)_2Ti(\mu\text{-}OMe)_2]_2Mg$ [65].

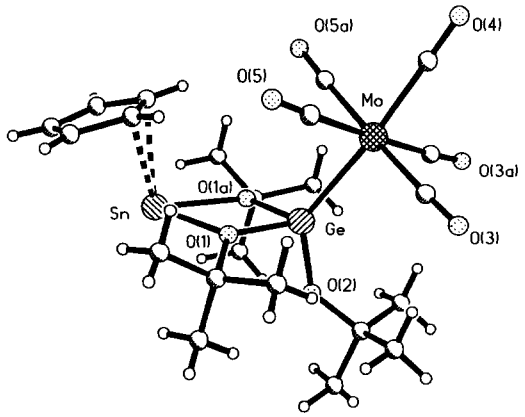


Fig. 42. Molecular structure of $[(C_5H_5)Sn(OBu^t)_3Ge\text{-}Mo(CO)_5]$ [66].

The X-ray structural study shows (Fig. 42) the selective coordination of metal carbonyl fragment at the Ge^{II} centre, protracted attempts to attach another $Mo(CO)_5$ unit at Sn^{II} were not successful. This observation is of considerable interest when compared with the high reactivity of Sn^{II} centre found in the heterobimetallic alkoxides of the type $Sn(\mu\text{-}OBu^t)_3M$ and $[Sn(\mu\text{-}OBu^t)_3]_2M'$ (see Section 2.1).

3. HETEROTERMETALLIC ALKOXIDES

Until recently the hetero*ter*metallic nature of the alkoxide clusters based on *three* different metals was considered ambiguous and the identity of the examples reported [67] mainly on the basis of elemental analysis and low resolution ^1H NMR data, in a few cases, was considered to be unreliable. This scepticism was supported by the fact that despite extensive investigations on metal alkoxide chemistry by various research groups, the existence of heterotermetallic alkoxides as discrete molecular species in solution and the solid state could not be unequivocally established. The reactive halide group in halo-functionalised heterobimetallic alkoxides, described in Section 2, can be replaced by a number of anionic alkoxometallate ligands to obtain new heterometal species containing three different metals. The elimination of salt (KCl, KI, etc.) as an insoluble product provides a thermodynamic assist and the yields are nearly quantitative in these reactions. The isolation and characterisation of novel heterotermetallic alkoxides demonstrate that salt elimination is not merely an ion-exchange phenomenon and if appropriate combinations of halide precursors and alkali reagents are chosen, it can prove to be an efficient strategy for the directed synthesis of heterometal alkoxide systems.

3.1 *Synthesis*

We have synthesised a large variety of heterotermetallic alkoxides employing both salt elimination and Lewis acid–base reactions (eqs 54–56) [6,13,14].

(i) Salt elimination reactions

$$ICd\{M_2(OPr^i)_9\} + KM'(OPr^i)_3 \rightarrow \tfrac{1}{2}[\{Cd(OPr^i)_3\}M'\{M_2(OPr^i)_9\}]_2 + KI \quad (54)$$

$M = Sn, Ti, Zr, Hf$; $M' = Ba, Sr, Ca$

$$1/2[IBa\{Zr_2(OPr^i)_9\}]_2 + KHf_2(OPr^i)_9 \rightarrow \{Hf_2(OPr^i)_9\}Ba\{Zr_2(OPr^i)_9\} + KI \quad (55)$$

$$1/2[IBa\{M_2(OPr^i)_9\}]_2 + KM'(OPr^i)_6 \rightarrow \{M'(OPr^i)_6\}Ba\{M_2(OPr^i)_9\} + KI \quad (56)$$

$M = Sn, Ti, Zr, Hf$; $M' = Nb, Ta$

(ii) Lewis acid–base reactions

The halide-free heterometallic alkoxides can also undergo Lewis acid–base reactions with another alkoxide to give novel heterotermetallic systems as illustrated in the following examples (eqs 57–60) [13].

$$\tfrac{1}{2}[BaTi_2(OPr^i)_{10}] + \tfrac{1}{2}M_2(OPr^i)_{10} \rightarrow \{M(OPr^i)_6\}Ba\{Ti_2(OPr^i)_9\} \quad (57)$$

$M = Nb, Ta$

$$\tfrac{1}{2}[BaTi_2(OPr^i)_{10}] + 2/n[Zr(OPr^i)_4]_n \rightarrow Ba_2Zr_2Ti_2(OPr^i)_{20} \quad (58)$$

$$(Pr^iO)Cd\{Hf_2(OPr^i)_9\} + Ti(OPr^i)_4 \rightarrow \{Ti(OPr^i)_5\}Cd\{Hf_2(OPr^i)_9\} \quad (59)$$

$$(Pr^iO)Cd\{Hf_2(OPr^i)_9\} + \tfrac{1}{2}[Ta(OPr^i)_5]_2 \rightarrow \{Ta(OPr^i)_6\}Cd\{Hf_2(OPr^i)_9\} \quad (60)$$

3.2 *Structural and spectral features*

Recently, we reported on the first synthesis and structural characterization of a series of novel heterotermetallic isopropoxides of general formula $[\{Cd(OPr^i)_3\}M'\{M'_2(OPr^i)_9\}]_2$ (M' = Ba, Sr, Ca; M = Sn, Ti, Zr, Hf) [6,13,14] (eq. 54). The most remarkable phenomenon encountered in the formation of these heterotermetallic derivatives is the exchange of the central atoms (Cd and Ba) between the precursors $ICd\{M_2(OPr^i)_9\}$ and $KM'(OPr^i)_3$. Astonishingly, no catastrophic breakdown or change in the structural features of the precursor complexes occurs and the $M_2(OR)_9^-$ sub-structure in the obtained heterotermetallic compounds binds to the alkaline earth metal atom rather than to the cadmium as anticipated in the targeted molecule. The rearrange-

ment of metallic elements in the formation of heterometallic framework is an unprecedented phenomenon in metal alkoxide chemistry and emphasises the need of single-crystal X-ray crystallographic studies in the complete characterization of heterometal alkoxides. The generality of the reaction has been examined for various $M_2(OR)_9^-$ ($M = Sn^{IV}$, Ti^{IV}, Zr^{IV}, Hf^{IV}) structures and alkaline earth metals (Ba, Sr, Ca). The mechanism for the observed switching of metals is not clear, however, it is possibly induced by the greater oxophilicity and tendency of larger alkaline earth metal cations to achieve higher coordination numbers. Another interesting aspect of this study is the role of multidentate $M_2(OPr^i)_9^-$ unit in the formation of heterotermetallic systems, which exhibit extraordinary versatility in binding the different metal atoms (Cd in the precursor and an alkaline earth element in the resulting complex) leading to the formation of a thermodynamically favoured heterotermetallic framework.

The $[\{Cd(OPr^i)_3\}M'\{M_2(OPr^i)_9\}]_2$ (M' = Ba, Sr, Ca; M = Sn, Ti, Zr, Hf) derivatives are isostructural and the heterotermetallic framework (Fig. 43) can be viewed as a combination of two triangular $BaM_2(\mu_3\text{-}OPr^i)_2(\mu_2\text{-}OPr^i)_3(OPr^i)_4^+$ units which are joined together by a $[(Pr^iO)_2Cd(\mu_2\text{-}OPr^i)_2Cd(OPr^i)_2]^{2-}$ unit. Alternatively, the structures can be described as a spirocyclic linking of two $Ba(OPr^i)_2L$ ($L = M_2(OPr^i)_9^-$) units to a four membered $Cd_2(OPr^i)_2$ ring. The novel potassium alkoxometallates $KM'(OPr^i)_3$ act as a source to generate coordinatively unsaturated '$M'(OPr^i)_3^-$' species which owing to the propensity of M'^{2+} to command higher coordination number initiates a rearrangement of metal atoms to form a stable heterotermetallic system that optimally fulfills the requirements of different metal atoms.

In contrast to the deceptively simply spectroscopic pattern generally exhibited by the heterometal derivatives, the solution ^1H and ^{13}C NMR spectra of $[\{Cd(OPr^i)_3\}M'\{M'_2(OPr^i)_9\}]_2$ [6,13,14] compounds are structurally informative. The retention of the dimeric structure (Fig. 43) in solution is indicated by the cryoscopic molecular weight measurements and is corroborated by the similar ^{113}Cd NMR chemical shifts observed in both solution and the solid state. In view of the wide dispersion and extreme sensitivity of the ^{113}Cd chemical shifts to the local coordination environments, the presence of cadmium in the heterobimetallic precursor and the resulting heterotermetallic species has proved a valuable tool in studying the structural behaviour of these derivatives.

Following the eq. 54, we have recently been able to characterise a novel heterotermetallic alkoxide of composition $Ba_2Zr_2Ti_2(OPr^i)_{20}$ [13] which represents the first example of a structurally characterised heterotrimetallic alkoxide based on 1 : 1 : 1 metal stoichiometry. The molecule is highly symmetrical and exhibits a 1 : 1 metal disorder of tetravalent elements [27]. Figure 44 shows one of the possible modes of disordering of Ti^{IV} and Zr^{IV}. The structural features are closely related to that of $[IBa\{M_2(OPr^i)_9\}]_2$ derivatives.

4. APPLICATIONS

The versatility of metal alkoxides as convenient precursors to advanced ceramic materials *via* sol–gel and MOCVD processes, is widely acclaimed, however, the use of well-characterised 'single source' precursors for these purposes remain extremely limited primarily due to the non-suitability of metal ratios present in the available molecules and that required in the desired ceramics. Among the useful heterometallic precursors,

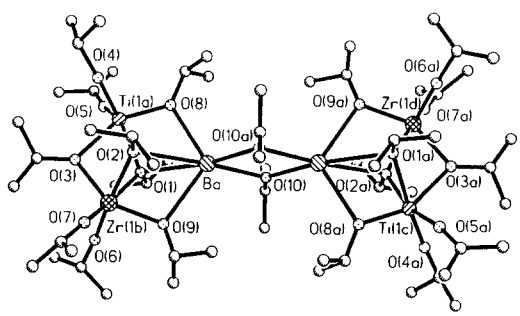

Fig. 44. Molecular structure of $[Ba_2Zr_2Ti_2(OPr^i)_{20}]$ [13].

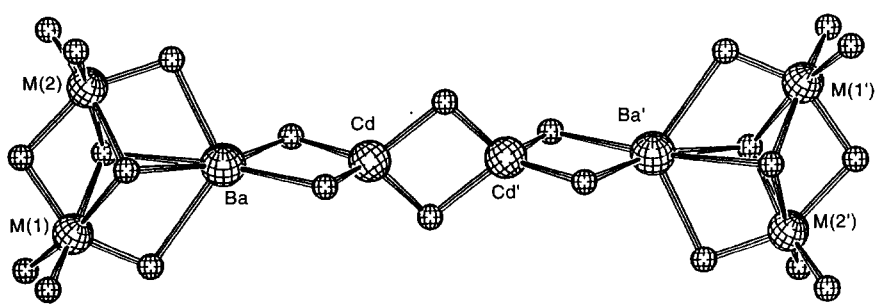

Fig. 43. Representation of the metal–oxygen skeleton observed in $[\{Cd(OPr^i)_3\}Ba\{M_2(OPr^i)_9\}]_2$ derivatives (M = Sn, Ti, Zr, Hf) [6,13].

$[LiNb(OEt)_6]_n$ [17] is a well-known example. Owing to the presence of Li/Nb atomic ratio corresponding to lithium niobate ceramic, useful for its ferro- and piezo-electric properties, $[LiNb(OEt)_6]_n$ has been used in numerous studies to obtain high quality $LiNbO_3$ films and powders [68].

Although volatile heterometal alkoxides are attractive precursors for the deposition of mixed-metal oxides by chemical vapour deposition technique, their use in obtaining multimetallic ceramics has not been pursued and lack of systematic studies make it a thrust area for research. In an attempt to develop new and effective routes to advanced ceramics, we have examined a number of homo- and hetero-metallic alkoxides to deposit new materials on a variety of substrates (quartz, silicon, copper, aluminium) by the MOCVD process. The *tert*-butoxides of bivalent Ge, Sn and Pb as well as their heterometal derivatives $M'M_2(OBu^t)_6$ ($M = Ge$, $M' = Sr$, Ba; $M = Sn$, $M' = Ca$, Sr, Ba; $M = Pb$, $M' = Ca$, Ba) when subjected to a single source chemical vapour deposition process produced biphasic metal/metal-oxide composites of the type M/MO_2 or $M/M'MO_3$ [69]. In all the cases, the uniform dispersion of metallic particles in a ceramic matrix (MO_2 or $M'MO_3$) has been confirmed by X-ray diffraction, electron spectroscopy, energy dispersion X-ray analysis (EDX) and photoelectron spectroscopy (XPS). The bivalent metal M^{II} ($M = Ge$, Sn, Pb) in the precursors undergo disproportionation (from +2 oxidation state) to give an elemental (M^0) phase and the phase containing formal M^{IV} cation. The composites consist of ball-shaped particles on which smaller particles are placed in a fractal manner. In the case of the composite $Sn.BaSnO_3$, the core of the ball-shaped particles has been analysed as pure elemental tin. The fundamental novel feature observed in the preparation of these composites is the chemically driven synthesis of two distinct phases with a regular dispersion of one (metallic phase) into another (ceramic phase). Further, on a hot substrate, all components are unified at the shortest distance possible which makes the adjustment of the physical parameters less important as the decomposition is predominantly chemical in nature.

Magnesium aluminium spinel ($MgAl_2O_4$) is a promising electronic material [70] and thin films of $MgAl_2O_4$ using single molecular precursors have been deposited *via* both sol–gel and MOCVD techniques. However, the higher carbon content in the resulting material or higher decomposition temperature for the precursor molecule are the intrinsic problems that persist. To design precursors with reduced organic part and enhanced volatility, we have synthesised new Mg–Al hydrido heterobimetallic alkoxides of the type $[Mg\{Al(OBu^t)_3H\}_2]$ [25] and $[Mg\{Al(OBu^t)_2H_2\}_2]$ [25]. The single crystal diffraction study performed in the case of mono-hydrido derivative reveals a molecular structure similar to that of $[Mg\{Al(OBu^t)_4\}_2]$ (Fig. 20) where one of the terminal OBu^t groups on each of the Al atoms has been replaced by a hydride ligand. The modified heterometallic derivatives have indeed proved to be extraordinary precursors for the deposition of $MgAl_2O_4$ thin films, on a variety of substrates, with significantly low decomposition temperatures and minimum carbon impurities [25].

5. CONCLUSIONS AND OUTLOOK

The present review outlines the recent research performed on heterometal alkoxides and emphasises the potential of halide heterobimetallic alkoxides as attractive synthons to heterotermetallic alkoxides and cyclopentadienyl containing heterobimetallic systems. The successful characterization of various stable and soluble heterotermetallic alkoxides is an exciting development which provides optimism, for the first time, for the synthesis of single source precursors to important ternary ceramics e.g., PZT [71] and PNM [72]. The stepwise chelation of a central metal atom by different alkoxometallate units, opens up new possibilities in the rational construction of heteropolymetallic ensemble, following a building block approach. However, the use of presently known alkoxometallate ligands towards various metal halides impose a limitation of fixed metal stoichiometries and the heterometal systems resulting from charge neutralisation principle, although of considerable academic interest can not serve as 'molecules of utility'.

The synthesis of single source precursors with desired combination of metallic elements require novel alkoxometallate anions based on metals present in unusual oxidation states or with inherent versatility in displaying different coordination numbers. The possibilities of modifying the heterometal alkoxides by introducing hetero-ligands such as a cyclopentadienyl, hydride, siloxide etc. can be advantageous in achieving new metal ratios and new type of reactivity. The sub-valent state of Group 14 elements in $M'M_2(OBu^t)_6$ (Section 2) play a key role in the chemical vapour decomposition process (Section 4) since the use of $[Ga(OBu^t)_3]_2$ as precursor in a CVD process gave only Ga_2O_3 and no elemental gallium was detected. However in cases where variable oxidation states of the metallic elements are not stable, a similar phenomenon could be induced by using hydride containing alkoxides [73]. The hydride modified alkoxides represent a promising class of heteroleptic alkoxide derivatives and it is relevant to add that using aluminium and gallium hydrido alkoxides of the type $[HM(OBu^t)_2]_2$ and $[H_2M(OBu^t)]_2$ ($M = Al$, Ga), we have obtained nanoscaled Al/Al_2O_3 and Ga/Ga_2O_3 composites, respectively [73]. We have recently shown that hydride containing Mg–Al heterobimetallic alkoxides are excellent precursors to pure $MgAl_2O_4$ ceramic. The emerging chemistry of polynuclear metal hydrido alkoxides and the potential for the development of new types of reactivity has recently been reviewed by Chisholm [74]. The hydrido alkoxides are highly reactive species and their reac-

tions with hydroxy reagents of the type $(C_6H_5)_3SiOH$ and $(C_6H_5)_2Si(OH)_2$ has led to novel molecular alumopolysiloxanes [75]. Also compounds involving siloxide ligands are attractive precursors for the dispersion of metallic elements in SiO_2 or Al_2O_3 matrices. We have reported on the new heterosiloxanes of bivalent Group 14 elements of the type $[Ph_3SiOM(\mu\text{-}OBu^t)]_2$ (M = Ge, Sn, Pb) [76]. This approach can be extended to mixed-metal systems. The reactivity studies on heterometal alkoxides are limited to a few reports. Ligand exchange or controlled hydrolysis reactions are of great importance in the context of sol–gel process where the precursor is often dissolved in an alcohol/protic reagent (of different pK_a and steric demands) used as solvent and the isolation and characterization of partially modified 'intermediate' molecules can throw light on the chemical transformation process taking place at molecular level.

In view of the inherent difficulties (e.g. twinning, plasticity, loss of crystallinity at ambient temperature) associated with the deceptively simple spectral patterns commonly observed in metal alkoxide chemistry, the structure determination by X-ray crystallography is often not straightforward and the unambiguous characterization of heterometal derivatives, in the absence of X-ray crystallographic data, requires an arsenal of complementary analytical techniques for instance multinuclear solution and solid state NMR studies, mass spectroscopy. The variable temperature NMR studies can provide useful information about the degree of aggregation of the complex, the coordination number at metal centres and the number of unique ligand environments present in the molecule. The use of NMR active nuclei can be of immense help in probing the solution structure and other associative-dissociative processes (monomer–dimer equilibrium) occurring in the solution especially in those cases where the single-crystal subjected to the X-ray diffraction analysis is not representative of the bulk material. Also, the molecular weight studies assume special significance in view of the tendency of heterometal alkoxides to dissociate in the solution.

Preface

This Polyhedron Symposium-in-Print entitled "Recent Progress in Organometallic Chemistry" is dedicated to Professor Wolfgang A. Herrmann on the occasion of his 50th birthday. It is intended to reflect the various facets of the research endeavours that his former students, postdoctoral and other close associates are presently engaged in. We hope that the contributions collected here are also representative of the increased breadth and sophistication that organometallic chemistry has achieved over the last two decades. Since the late seventies organometallic chemistry has progressed in such way that it now encompasses not only the late transition metals, but also early transition metals and lanthanides as well as the radioactive element technetium. While structure determinations by X-ray diffraction and nuclear magnetic resonance spectroscopy helped improve substantially the understanding of the properties of the various metals, the design of novel ligand systems has opened up new applications in homogeneous catalysis, a discipline that has particularly benefited from the advances in organometallic chemistry.

Selective conversion of an ethylene to an ethylidene ligand in reactions of a hydrido(ethylene) complex of tantalum with iodofluorocarbons. Molecular structure of $[Ta(\eta^5\text{-}C_5H_5)_2(\eta^1\text{-}CHCH_3)I]$†

(Received 30 September 1997; accepted 17 November 1997)

Abstract—Reactions of $[TaCp_2(C_2H_4)H]$ (**3**) with perfluoro-*n*-butyl iodide or perfluorobenzyl iodide cleanly yield the iodo(ethylene) complex $[TaCp_2(C_2H_4)I]$ (**4**) together with the hydrofluorocarbons $CF_3CF_2CF_2CF_2H$ and $C_6F_5CF_2H$, respectively. In sharp contrast, reactions of **3** with perfluoro-iso-propyl iodide or pentafluorophenyl iodide cleanly afford the isomeric iodo(ethylidene) complex $[TaCp_2(CHCH_3)I]$ (**5**). No interconversion of **4** and **5** is observed under these reaction conditions, indicating that each is formed under conditions of kinetic control. The structure of **5** has been confirmed by X-ray crystallography. Similar results to give much more thermally sensitive products are observed for the niobium analogues. Possible mechanisms for these highly selective reactions are discussed. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: ethylene; ethylidene ligand; iodofluorocarbons.

For some time we have been interested in the introduction of fluoroalkyl groups into organometallic complexes as a means of enhancing their solubilities in saturated fluorocarbons and supercritical CO_2, thereby allowing stoichiometric and catalytic chemistry to be conducted in these unusual media [1]. In a number of cases we have shown that reactions of low valent organometallic complexes with fluoroalkyl iodides can lead to fluoroalkylation at the metal center or at cyclopentadienyl rings, depending on the ligands present on the metal, and the structure of the fluoroalkyl iodide [2,3].

Recently we described the chemistry of $[WCp_2(C_2H_4)]$ (**1**: Cp = η^5-C_5H_5) with the secondary fluoroalkyl iodide $(CF_3)_2CF$-I, in which *exo*-fluoroalkylation at the cyclopentadienyl ring was observed, followed by loss of ethylene and hydrogen migration to the metal to afford **2** [4]. Similar results were obtained using the molybdenum analogue of **1**. Evidence for a fluoroalkyl carbanion intermediate was obtained in this system [4]. The tertiary fluoroalkyl iodide $(CF_3)_3C$-I affords fluoroalkylation at the ethylene ligand [4], whereas the major products using primary fluoroalkyl and perfluorobenzyl iodides result from fluoroalkylation at the metal [5].

As a seemingly logical extension of this chemistry we chose to examine the corresponding reactions of fluoroalkyl iodides with $[TaCp_2(C_2H_4)H]$ (**3**), which is isoelectronic with **1**. In this paper we describe the results of these reactions, which unfortunately lead not to fluoroalkylated organometallic complexes, but which reveal a remarkably selective reaction leading to isomerization of coordinated ethylene to ethylidene. In hindsight it is fortunate that we chose to look at the secondary fluoroalkyl iodide $(CF_3)_2CF$-I

† Dedicated to Prof. Dr W. A. Herrmann on the occasion of his 50th birthday.

first, since the results of corresponding reactions of primary fluoroalkyl iodides might be regarded as quite mundane.

RESULTS AND DISCUSSION

Reaction of **3** with perfluoro-*n*-butyl iodide, $CF_3CF_2CF_2CF_2$-I, in an NMR tube in C_6D_6 afforded clean and quantitative conversion to the known [6] iodo(ethylene) complex **4**, along with $CF_3CF_2CF_2CF_2H$. The presence of the hydrofluorocarbon was confirmed by both ^{19}F and ^1H NMR spectroscopy [7]; observation of the ^1H NMR resonance as a triplet of triplets at δ 4.82 ppm serves as a ready identification of this product. Similarly, reaction of **3** with perfluorobenzyl iodide, $C_6F_5CF_2$-I, under the same conditions generated **4** and the corresponding hydrofluorocarbon $C_6F_5CF_2$-H; once again the hydrofluorocarbon was readily identified by its characteristic proton resonance at δ 6.14 ppm, with strong triplet coupling to the adjacent CF_2, and the appropriate ^{19}F NMR resonances. Treatment of **3** with I_2 also led exclusively to **4**.

In sharp contrast, reaction of **3** with the secondary fluoroalkyl iodide, $(CF_3)_2CF$-I, afforded the expected hydrofluorocarbon product $(CF_3)_2CF$-H, identified by a characteristic doublet of septets at δ 3.54 ppm in the ^1H NMR spectrum, but none of the iodo(ethylene) complex **4** was observed. Instead the organometallic product exhibited two resonances for inequivalent cyclopentadienyl rings, together with a doublet CH_3 resonance at δ 5.14 ppm coupled by 9 Hz to a quartet CH resonance at δ 11.58 ppm. Observation of corresponding ^{13}C NMR resonances at δ 270.2 (CH) and 35.5 (CH_3) confirmed the presence of an ethylidene rather than an ethylene ligand, and allowed for-

mulation of the product as complex **5**. Complex **5** was also the exclusive organometallic product formed on treatment of **3** with pentafluorophenyl iodide, C_6F_5I; C_6F_5H was readily identified as the hydrofluorocarbon product. Reaction of **3** with the tertiary iodide, $(CF_3)_3C\text{-}I$, led to extensive molecular demolition of both components, with no readily identifiable organometallic or organic fragments. The ethylene ligand in **4** and the ethylidene ligand in **5** showed no further reactivity on treatment with any of the fluorocarbon iodides, indicating that each product is formed under conditions of kinetic control.

While it is formed cleanly as determined by NMR spectroscopy, isolation of complex **5** as extremely air sensitive crystals could only be achieved in 44% yield. The crystals were subjected to a single crystal X-ray diffraction study. An ORTEP diagram is presented in Fig. 1. Details of the crystallographic determination are provided in Table 1, and some key bond distances and angles are presented in Table 2. The Ta=C(11) distance of 2.024(11) Å is identical within experimental error to that in the methylidene complex $[TaCp_2(CH_2)CH_3]$, [8]; a characteristically obtuse angle of 140.9(12)° is observed for Ta—C(11)—C(12). As observed in $[TaCp_2(CH_2)CH_3]$ [8] and related complexes [6], the plane of the alkylidene ligand lies perpendicular to the plane of I—Ta—C(11), with a high barrier to rotation about the Ta=C bond [9] leading to inequivalent

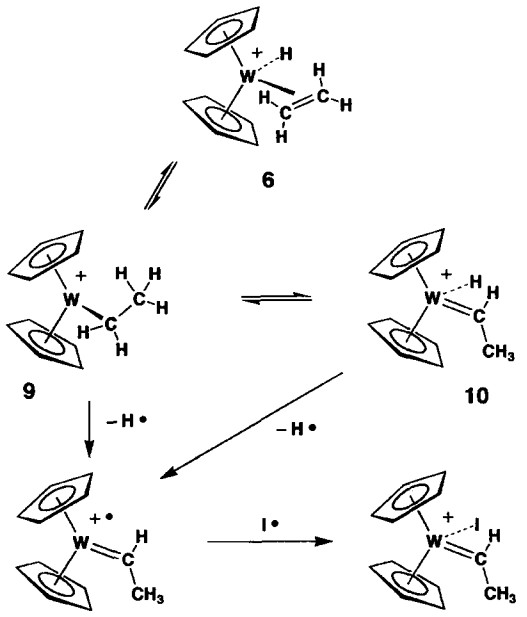
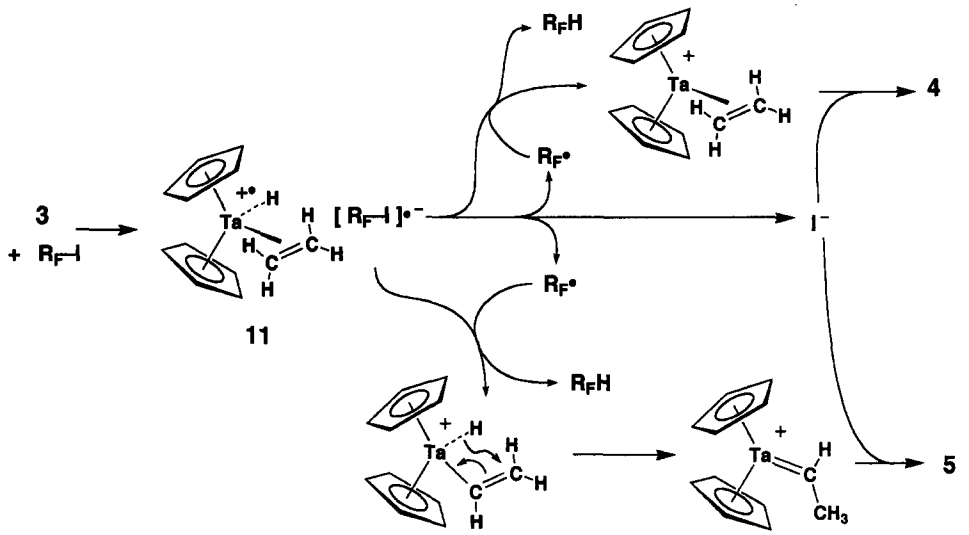
resonances for the cyclopentadienyl rings in the ^1H and ^{13}C NMR spectra.

Examples of conversion of ethylene to ethylidene ligands are rare indeed; only two examples appear to have been observed. The only known example in tantalum chemistry has been reported by Schrock [10], in which the complex $[TaL(C_2H_4)]$ $\{L = N(CH_2CH_2NSiMe_3)_3\}$ is isomerized to its thermodynamically more stable isomer $[TaL(CHCH_3)]$ by the primary phosphine $PhPH_2$, in a series of α- and β-hydrogen elimination and addition reactions. However, the first such example, and that most relevant to our observations, was reported by Cooper, in which the tungsten complex **6** is converted to **7** on treatment with I_2 [11]. The mechanism suggested by Cooper is presented in Scheme 1, with isomerization of **6** to its ethylidene isomer **10** occurring via the ethyl intermediate **9**. Deuterium labeling studies could not distinguish whether the proposed hydrogen atom loss, with $I^\bullet$ as the acceptor, occurred directly from the α-carbon of intermediate **9**, or from the metal-hydride position of **10**. Numerous attempts on our part to selectively label the tantalum complex **3** with deuterium, by treatment of the iodo complex **4** with BD_4^- Et_3BD^-, or AlD_4^-, led to samples of **3** in which deuterium was scrambled between the metal position and the two ends of the coordinated olefin. This indicates that **3** is indeed in equilibrium with an ethyl isomer, analogous to **9**, but also that ethylene rotation in **3**, while known to be slow on the NMR timescale [12], is sufficiently rapid on the timescale required for reaction workup that complete deuterium scrambling occurs. In the absence of selectively labeled **3** it is clearly not possible to ascertain which H is lost to give **4** or **5**, and makes mechanistic discussion more speculative than would normally be desirable. However based on our previous results, and other observations from the chemistry of iodofluorocarbons, one possible mechanism can be suggested.



Scheme 1.

The chemistry of iodofluorocarbons is replete with examples in which the first step is electron transfer [13–15], with the radical anion thus generated, $[R_F\text{-}I]^{\bullet -}$, being known to give I^- and $R_F^\bullet$, at least when R_F is a primary fluoroalkyl [13]. Abstraction of the metal-bound H (the weakest bond to hydrogen in the intermediate radical cation intermediate **11**) can then occur when $R_F^\bullet$ is a relatively small primary or benzylic radical, as shown in Scheme 2, with final trapping by



Scheme 2.

I^- completing the reaction to give **4**. An analogous pathway presumably occurs using I_2. But why then do the secondary iodides afford a different organometallic product? If the initial step of the mechanisms is the same, it is possible that the significantly more sterically demanding secondary radicals are too large to get close enough to abstract the metal bound hydrogen, and accordingly are restricted to abstracting a more peripheral hydrogen from the ethylene ligand. The resultant vinyl complex could rearrange to the ethylidene intermediate, which is then trapped by iodide to give **5**. Without the ability to selectively label the hydride or ethylene ligands we have no means of testing the required consequences of reaction scheme, and further discussion would be even more speculative. We should point out however that there may well be a completely different mechanism operating for primary or benzylic, versus secondary and aromatic iodofluorocarbons, as we [4,5] and others [13–15,17] have established in different systems. However we do not see any traces of $CF_3CF{=}CF_2$, the fluoroolefin signature of a fluorocarbanion intermediate [4], in any reactions using $(CF_3)_2CF$-I, and so it is certainly possible that the chemistry observed here really does represent different selective chemistry of fluoroalkyl radical intermediates.

Finally, we have carried out some reactions using the niobium analogue of **3**. Reaction of $[NbCp_2(C_2H_4)H]$ with perfluorobenzyl iodide affords $C_6F_5CF_2$-H and an organometallic product whose ^1H NMR spectrum showed a cyclopentadienyl singlet at δ 6.14 ppm, and two pseudo triplets at δ 2.14 and 1.16 ppm, consistent with formation of $[NbCp_2(C_2H_4)I]$. The product was sufficiently thermally unstable that we were unable to isolate it from the reaction mixture; this compound does not appear to have been prepared before, although the corresponding chloride has been reported [16]. In contrast, reaction of $[NbCp_2(C_2H_4)H]$ with perfluoro-iso-propyl iodide affords $(CF_3)_2CF$-H and the corresponding iodo-(ethylidene) niobium analogue of **5**, which was identified by NMR spectroscopy, but was so unstable that correct microanalysis results could not be obtained. Thus the corresponding niobium chemistry appears to parallel the tantalum results, except that the organometallic products are much more thermally sensitive and difficult to handle.

EXPERIMENTAL SECTION

General considerations

All reactions were performed in oven-dried glassware, using standard Schlenk techniques, under an atmosphere of dinitrogen which had been deoxygenated over BASF catalyst and dried over Aquasorb®, or in a Braun Drybox. Benzene was distilled from sodium immediately before use. IR spectra were recorded on a Perkin–Elmer FTIR 1600 Series spectrometer. NMR spectra were recorded on a Varian Unity Plus 300 FT spectrometer. ^1H and $^{13}C\{^1H\}$ NMR spectra are referenced as ppm downfield from TMS. ^{19}F NMR spectra were referenced to $CFCl_3$ (0.00 ppm). Microanalyses were performed by Schwarzkopf Microanalytical Laboratory, Woodside, NY. $I(CF_2)_3CF_3$ (Aldrich), C_6F_5I, $ICF(CF_3)_2$ and $ICF_2C_6F_5$ (PCR) were purified by washing with a solution of sodium thiosulfate to remove iodine, followed by washing with water and then drying over magnesium sulfate and deoxygenation by several cycles of freeze-evacuate-thaw. $[TaCp_2(C_2H_4)H]$ [12a] and $[NbCp_2(C_2H_4)H]$ [12b] were prepared according to literature procedures.

Reaction of $[TaCp_2(C_2H_4)H]$ *with* $(CF_3)_2CFI$; *preparation of* $[TaCp_2(CHCH_3)I]$ **(5)**

$[TaCp_2(C_2H_4)H]$ (**3**) (0.070 g, 0.206 mmol) was dissolved in benzene (6 ml). $(CF_3)_2CFI$ (0.035 ml, 0.206 mmol) was added and the solution turned orange-/brown. It was stirred for 15 min then filtered. The solvent was removed and the residue was dissolved in benzene (12 ml) and filtered. The solvent volume was reduced and hexane was added to precipitate the product. Recrystallization from benzene/hexane afforded $[TaCp_2(CHCH_3)I]$ (**5**) (0.040 g, 43.5%), as exceedingly air sensitive, deep orange brown crystals, m.p. 140–142°C. ^1H NMR (C_6D_6) δ 11.58 (q, $J_{HH} = 8.9$ Hz, 1H, =CH); 5.16 (s, 5H, C_5H_5); 5.12 (s, 5H, C_5H_5); 3.14 (d, $J_{HH} = 8.9$ Hz, 3H, CH_3). $^{13}C\{^1H\}$ NMR (C_6D_6) δ 270.2 (s, Ta=C); 102.5 (s, C_5H_5); 101.9 (s, C_5H_5); 35.5 (s, CH_3). Anal. calc. for $C_{12}H_{14}ITa$; %C 32.31, %H 3.16. Found: %C 31.91, %H 3.46.

The reaction was carried out on the same scale in an NMR tube using C_6D_6 as solvent, and showed essentially complete formation of **5** along with a stoichiometric amount of $(CF_3)_2CFH$; ^1H NMR (C_6D_6) δ 3.54 (1H, dsept, $^2J_{FH} = 43.0$, $^3J_{FH} = 5.3$ Hz). ^{19}F NMR (C_6D_6) δ −76.39 (6F, dd, $^3J_{FH} = 5.3$, $^3J_{FF} = 11.6$ Hz), −214.0 (1F, dsept, $^2J_{FH} = 43.0$, $^3J_{FF} = 11.6$ Hz). The reaction is not completely quantitative as there is always formation of small amounts of insoluble yellow solid which could not be characterized.

A similar NMR tube reaction using C_6F_5I afforded clean formation of **5** along with C_5F_5H.

Crystallographic structure determination of $[TaCp_2(CHCH_3)I]$ **(5)**

Crystal, data collection, and refinement parameters are given in Table 1. The systematic absences in the diffraction data of **5** were uniquely consistent for space group *Pbca* whose correctness was subsequently confirmed by chemically reasonable and computationally stable results of refinement. The structure was solved using direct methods, completed by subsequent difference Fourier synthesis and refined by full-matrix least-squares procedures. All non-hydrogen atoms were refined with anisotropic displacement coefficients, and all hydrogen atoms were treated as idealized contributions. Empirical absorption corrections were applied by using the program DIFABS. There are two high peaks (ca 2 e/Å^3) in the vicinity of the tantalum and iodine atoms respectively, that have no apparent chemical relevance.

All software and sources of the scattering factors are contained in the SHELXTL (version 5.03) program library (G. Sheldrick, Siemens XRD, Madison, WI). Program DIFABS is described by Walker and Stuart in *Acta Cryst.*, 1983, **A39,** 158.

Reaction of $[TaCp_2(C_2H_4)H]$ *with* $C_6F_5CF_2I$; *preparation of* $[TaCp_2(C_2H_4)I]$ **(4)**

As described above, reaction of $[TaCp_2(C_2H_4)H]$ with a stoichiometric amount of $C_6F_5CF_2I$ in C_6D_6 an NMR tube afforded clean conversion to $[TaCp_2(C_2H_4)I]$, whose ^1H NMR data matched those in the literature [12], and a stoichiometric amount of $C_6F_5CF_2H$; ^1H NMR (C_6D_6) δ 6.14 (1H, t, $^2J_{FH} = 52.5$ Hz). ^{19}F NMR (C_6D_6) δ −113.75 (2F, dtd, $^2J_{FH} = 52.5$, $^4J_{FF} = 8.5$, $^6J_{FF} = 2.3$ Hz, CF_2), −144.19 (2F, m, F_{ortho}), −149.92 (1F, m, F_{para}), −161.19 (2F, m, F_{meta}).

An analogous reaction with $CF_3CF_2CF_2CF_2$-I afforded **4** and a stoichiometric amount of $CF_3CF_2CF_2CF_2H$; ^1H NMR (C_6D_6) δ 4.82 (1H, tt, $^2J_{FH} = 51.3$, $^3J_{FH} = 4.8$ Hz). ^{19}F NMR (C_6D_6) δ −81.77 (3F, m, CF_3), −128.08 (2F, m, CF_2), −130.40 (2F, m, CF_2), −137.33 (2F, m, $^2J_{FH} = 51.3$, CF_2).

Reaction of $[NbCp_2(C_2H_4)H]$ *with* $(CF_3)_2CFI$; *preparation of* $[NbCp_2(CHCH_3)I]$

$NbCp_2(C_2H_4)H$ (0.065 g, 0.258 mmol) was dissolved in benzene (5 ml) and $(CF_3)_2CFI$ (0.038 ml, 0.270 mmol) was added giving a red/brown solution. This was stirred for 15 min then filtered. The solvent was removed giving a brown residue and a small amount of orange solid which was much less soluble in benzene. The brown residue was dissolved in benzene (5 ml) and filtered. The solvent volume as reduced to approximately 0.5 ml and hexane was added to complete precipitation of the product. It was recrystallized from benzene/hexane to afford the product as an extremely air sensitive solid (0.029 g, 29.8%); m.p. dec. 140°C, ^1H NMR (C_6D_6) δ 13.15 (q, $J_{HH} = 9.0$ Hz, 1H, =CH); 5.25 (s, 5H, C_5H_5); 5.17 (s, 5H, C_5H_5); 2.70 (d, $J_{HH} = 9.0$ Hz, 3H, CH_3); $^{13}C\{^1H\}$ NMR (C_6D_6) δ 102.3 (br s, C_5H_5); 36.9 (s, CH_3), the carbene carbon could not be observed, possibly due to quadrupolar broadening by the Nb nucleus. Anal. calc. for $C_{12}H_{14}INb$: %C 38.12, %H 3.73. Found, %C 36.85, %H 3.72. Due to the extreme air sensitive nature of this compound, these are the best microanalyses we could obtain. An analogous reaction carried out in an NMR tube showed clean formation of $[NbCp_2(CHCH_3)I]$ along with a stoichiometric amount of $(CF_3)_2CFH$.

Supplementary material—Details of the X-ray structure determinations, tables of atomic coordinates and anisotropic thermal parameters, bond lengths and bond angles, anisotropic displacement parameters, and hydrogen atom coordinates for **5** are available from author R.P.H. upon request.

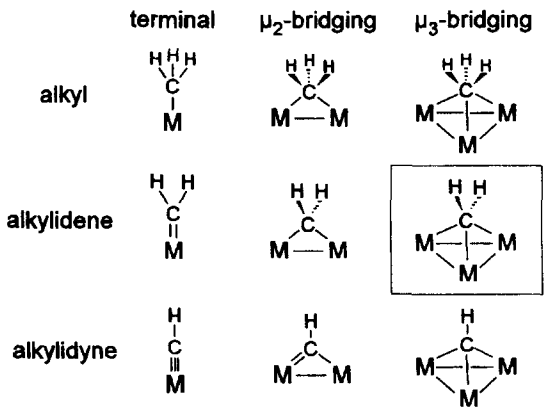
(Received 2 November 1997; accepted 20 November 1997)

Abstract—The dynamic behaviour of the methylidene ligand in the triangular cluster complex, $Cp^*Rh(CpCo)_2(CO)_2(\mu\text{-}CH_2)$ **3**, has been investigated using multidimensional NMR techniques. Two distinct processes have been identified whereby the methylidene ligand moves between bridging different metal–metal bonds in the complex: (1) methylidene jumps from a Rh—Co bond to the Co—Co bond and (2) degenerate methylidene jumps between the two Rh—Co bonds of the metal triangle. An intermediate has been observed for the latter process. Based on ^1H and ^{13}C NMR data, we propose that the methylidene ligand in this intermediate occupies a triply-bridging coordination position above the metal triangle, simultaneously interacting with all three metal atoms in the complex. To our knowledge, this is the first observation of an intermediate involved in the dynamic behaviour of an alkylidene ligand. Furthermore, it is only the second example of a μ_3-methylidene ligand to be reported. The implications of these results in the areas of alkylidene mobility on metal surfaces and catalysis are discussed. © 1998 Elsevier Science Ltd

Keywords: alkylidene; cluster complex; μ_3-methylidene ligand.

C_1-based hydrocarbon fragments (alkyl, alkylidene and alkylidyne) form one of the most important sets of ligands in organometallic chemistry [1]. When present in discrete mononuclear or polynuclear metal complexes, the series of alkyl, alkylidene and alkylidyne ligands normally assumes one of three coordination modes: terminal, bridging two metal atoms (μ_2, or "μ") or bridging three metal atoms (μ_3 or triply-bridging) (Scheme 1). Within the coordination manifold for the alkylidene ligand, many examples are known for both the terminal and μ_2 geometries. In contrast, very few examples of complexes containing a triply-bridging alkylidene ligand have been reported [2].

Although similar to the ubiquitous carbon monoxide ligand in a number of respects [3], alkylidene ligands are, in general, less labile and exhibit a smaller range of coordination geometries in cluster complexes. While CO ligands may be found simultaneously in all three geometries in a cluster



Scheme 1. η^1-Alkyl, alkylidene and alkylidyne coordination modes in organometallic chemistry.

complex, the alkylidene ligand shows a marked preference for the bridging, μ_2, coordination mode [3,4]. Furthermore, CO ligands are frequently fluxional at room temperature in cluster complexes and rapidly exchange between two or all three coordination modes. Alkylidene ligands are rarely fluxional at room temperature and generally exhibit significantly larger barriers toward interchanging coordination positions or modes.

The first example of a $\mu_2 \rightleftarrows$ terminal geometry interchange for an alkylidene ligand was described by Knox and coworkers [5] for the complex $[Cp^*Ru(CO)]_2(\mu\text{-}CO)(\mu\text{-}CMe_2)$ **1**. The high barrier (80 kJ mole^{-1}) to inter-conversion of *cis* and *trans* isomers for **1** led Knox to propose that the intermediate/transition state for this process involved a terminally coordinated propylidene ligand (**1′**).

Theopold and Bergman [6] described a similar *cis/trans* isomerization for the mixed metal complex $CpRh(CpCo)_2(\mu\text{-}CH_2)(CO)_2$ **2**. Of interest with regard to the results described here is their observation of two fluxional processes for **2**; a low energy process ($\Delta G^{\neq} \approx 54$ kJ mole^{-1}) involving terminal $\rightleftarrows$ bridging inter-conversion of the CO ligands in the *trans* isomer and a high energy ($\Delta G^{\neq} \approx 75$ kJ mole^{-1}), *cis/trans* isomerization for which a mechanism involving bridge-to-terminal inter-conversion for the μ-CH_2 group was proposed. Finally, Holmgren and Shapley [7] described the first and only example of alkylidene fluxionality in a cluster complex. NMR spin saturation transfer experiments and a high $\Delta G^{\neq}$ (ca 73 kJ mole^{-1}) for the movement of a μ-methylidene ligand between Ru—Ru edges in the trinuclear complex $Ru_3(CO)_{10}(\mu\text{-}CH_2)$ led to the proposal of a mechanism again involving a species having a terminal methylidene ligand.

In the examples above and all other cases of alkylidene fluxionality no intermediates have been observed. A theoretical study [8] of the bonding and dynamics of C_1-hydrocarbon species on metal surfaces described the properties of terminal, μ_2- and μ_3-coordination geometries of a methylidene group on models for several different metal surfaces. An important conclusion of this study was that although M—C interactions increase in the more highly bridging geometries, the total energy of the system (metal surface + methylidene fragment) increased as well which lead to the prediction that the μ_3-coordination would be the least stable geometry of the three.

In this report we describe the dynamics of the μ-methylidene ligand in the trinuclear complex $Cp^*Rh(CpCo)_2(CO)_2(\mu\text{-}CH_2)$ **3**. Two distinct processes have been identified in the movement of the bridging methylidene ligand in **3**:methylidene jumps between Rh—Co and Co—Co bonds and degenerate methylidene jumps between the two Rh—Co bonds in the complex. An intermediate which exists in dynamic equilibrium with the two major isomers for the complex is observed for the latter process. The properties of the methylidene ligand in the intermediate have been studied via high field, multidimensional NMR techniques and are inconsistent with a terminal coordination geometry. We therefore propose that this intermediate involves a μ_3-methylidene ligand simultaneously interacting with the three metal atoms in the complex.

EXPERIMENTAL

General

All solvents were reagent grade and were further purified via distillation under nitrogen from Na/K alloy or CaH_2. Air sensitive complexes were handled under nitrogen using Schlenk techniques or under helium in a glove box. Anaerobic chromatography was performed using silica gel which had been degassed under dynamic vacuum overnight and thereafter stored under nitrogen. NMR samples were prepared by vacuum transfer of the deuterated solvent followed by flame sealing of the tube. $Cp^*Rh(CO)_2$ [9], $CpCo(C_2H_4)_2$ [10], $(CpCo)_2Cp^*Rh(CO)_2$ [11] were prepared according to literature procedures. Diazomethane, CH_2N_2 was prepared in ether solution ($\sim$1 M) from Diazald (Aldrich) following a literature procedure [12].

Caution! Diazomethane is toxic and potentially explosive in concentrated solution or when pure. All manipulations of diazomethane should be conducted in an adequately ventilated hood and care should be taken not to allow concentrated samples to develop.

$^{13}CH_2N_2$ enriched diazomethane was prepared via the same procedure using Diazald-99%-^{13}C (Aldrich).

$Cp^*Rh(^{13}CO)$

In a Schlenk vessel, 400 mg of the dicarbonyl complex were dissolved in methylene chloride. A separate

flask containing 1 L of ^{13}CO gas with a glass breakseal was connected to this vessel via an O-ring joint. The methylene chloride solution of the dicarbonyl was degassed via 4 freeze–pump–thaw cycles. With the two flasks isolated, the breakseal was broken and the solution stirred for 3 days. At 24 h intervals aliquots from the solution were analysed by mass spectrometry. After removing solvent, the residue was sublimed onto a cold finger under vacuum. The final enrichment was 81% (65% $Cp^*Rh(^{13}CO)_2$, 31.5% $Cp^*Rh(^{13}CO)(^{12}CO)$, 3.4% $Cp^*Rh(^{12}CO)_2$). This sample was used to prepare the doubly labelled alkylidene via the unsaturated cluster complex $(CpCo)_2Cp^*Rh(^{13}CO)_2$ and $^{13}CH_2N_2$ as described below.

$(CpCo)_2Cp^*Rh(CO)_2(CH_2)$ 3

In a glove box, between 200 and 500 mg of $(CpCo)_2Cp^*Rh(CO)_2$ were dissolved in degassed ether in a Schlenk flask. The solution was frozen and an ether solution of diazomethane at −78°C was added via cannula. The solutions were allowed to melt and were stirred together for 5–10 min whereupon all volatiles were removed under vacuum. The residue was chromatographed under nitrogen to give the alkylidene complex **3a** in 40% yield. Spectral data (IR, NMR) are summarized in the text and Table 1. Analysed (found) for $C_{23}H_{25}O_2Co_2Rh$; C: 49.66 (49.63) H: 4.85 (4.86).

NMR spectroscopy

Standard NMR experiments were performed on a Bruker AMX400WB spectrometer equipped with an QNP probehead. The $^1H\{^{13}C\}$ HMQC experiment was performed on an MAX600 spectrometer employing BIRD for suppression of the C-12 signal. The $^1H\{^{13}CO\}$ HMBC experiment was performed on a Bruker DRX600 spectrometer equipped with a *z*-axis gradient TBI probe. The gradient enhanced HMBC pulse sequence $90°(^1H)\text{-}d6\text{-}90°/(^{13}C)\text{-}d17\text{-}180°(^{13}C)\text{-}t_{1/2}\text{-}G_z(1)\text{-}180°(^1H)\text{-}G_z(2)\text{-}t_{1/2}\text{-}90°(^{13}C)\text{-}G_z(3)\text{-}$ acquire was used with the delay d6 set to 140 ms and d17 equals the total duration of the gradients $G_z(1)$ and $G_z(2)$ (2 ms). Selective excitation of the carbonyl ligands was accomplished by using Gaussian shaped pulses on the carbon channel with a bandwidth of 10 kHz centred at 250 ppm. 400 increments were acquired with 64 scans each, with phase sensitive detection in f1 using TPPI. Coherence selection was achieved by setting the gradient strength $G_z(1):G_z(2):G_z(3) = 50:30:40$ with a gradient length of 1 ms each.

RESULTS AND DISCUSSION

Reaction of the unsaturated cluster complex $Cp^*Rh(CpCo)_2(CO)_2$ [11] with diazomethane in ether solution gives two major products. The first involves the incorporation of the intact diazomethane molecule

3a

into the complex in the form of a μ_3-hydrazone ligand. The properties of this complex will be described in a future publication. The second product is the methylidene complex **3a** wherein a methylidene and two CO ligands bridge the Rh—Co and Co—Co edges of the triangular cluster complex.

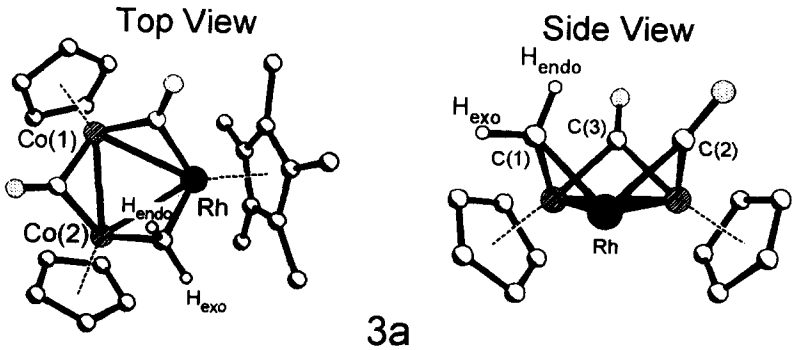
The structure of **3a** in the crystal [13] reveals that the μ_2-methylidene ligand is disordered between the two Rh—Co edges while the CO ligands occupy bridging positions on the remaining Rh—Co and Co—Co edges in the complex. All three bridging ligands are found on the same side of the plane of the metal atoms in a "crown" arrangement while the Cp and Cp* ligands all occupy positions beneath this plane (Fig. 1).

Spectroscopic data (Table 1) for **3a** are in accord with its structure in the solid state. IR spectra for **3a** both in solution and in the solid state, show two stretches at 1793 and 1829 cm^{-1} (KBr) consistent with the presence of edge-bridging CO ligands in the complex. In the proton NMR, two singlets are observed for the Cp ligand protons and one for the Cp* protons with the expected 1 : 1 : 3 intensity ratio. The methylidene protons are diastereotopic and two, non-identical doublet-of-doublets are observed for these protons (Fig. 2). Both signals show a geminal coupling between the two protons of 0.5 Hz ($^2J_{HH}$). Although small in comparison to what is observed in most other bridging methylidene systems [3] a similar value for geminal coupling has been reported for the related dinuclear system **2** [6]. Unequal two-bond coupling between the rhodium and each of the methylidene protons is also observed; ^2J = 0.5 and 2.4 Hz for the downfield and upfield signals, respectively.

NOESY spectra for **3a** show a large cross peak between the signals of the methylidene protons consistent with their close proximity. An additional cross peak is also observed between the down field methylidene proton resonance and the signals for the Cp* and one of the Cp ligands. Based on these data we assign the methylene proton resonance at 5.972 ppm to the "exo" proton that is directed out, away from the triangle of metal atoms and the resonance at 6.674 ppm to the "endo" proton which is above the metal triangle

The ^{13}C spectrum for **3a** is also consistent with its structure in the solid state. Two carbonyl ligand signals are observed at 250.0 and 262.7 ppm. The upfield signal is split into a doublet (J = 50 Hz) due to coupling to rhodium and may be assigned to the CO ligand bridging the Rh—Co edge. Both the CO ligand signals are significantly broadened at room temperature due to quadrupole interactions with the cobalt nuclei and can only be observed clearly at low temperature. The methylidene carbon signal is observed at 140.5 ppm. It is split into a doublet ($^1J_{RhC}$ = 33 Hz) due to coupling to rhodium. Un-decoupled spectra show additional, unequal coupling of this carbon to each of the methylidene protons which, based on the information above, may be specifically assigned to the exo ($^1J_{CH}$ = 146.9 Hz) and endo ($^1J_{CH}$ = 138.8 Hz) protons. The carbon signals for the Cp and Cp* ligands are observed in the usual ranges.

When **3a** is left in solution overnight a new set of



3a

Fig. 1. Two views of the molecular structure of **3a** in the solid state. In the side view the Cp* ligand coordinated to rhodium has been removed for clarity.

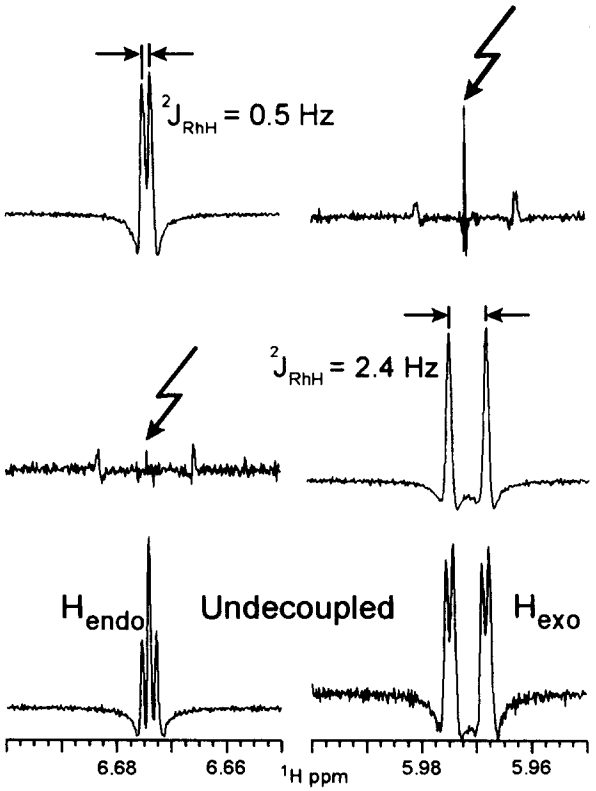


Fig. 2. Illustration of homonuclear ^1H decoupling experiments elucidating the proton–proton and rhodium–proton coupling for the methylidene ligand protons of **3a**.

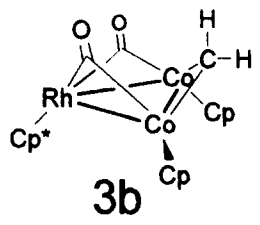
signals appears at the expense of those assigned to **3a**. Analysis of this new set of NMR signals leads to the identification of a second isomer of **3** in which the methylidene ligand bridges the Co—Co bond with the two carbonyl ligands bridging Rh—Co bonds (**3b**). Both sets of CO and Cp ligands in **3b** each give rise to single signals reflecting mirror symmetry for the molecule. The methylidene carbon and two protons lie in the plane of symmetry through the molecule which bisects the Co—Co bond. As expected the two methylidene protons are again diastereotopic and give rise to two multiplets ($\delta(H_{endo}) = 7.02$; $\delta(H_{exo}) = 7.12$ ppm)). Surprisingly, the exo methylidene hydrogen couples to the rhodium ($J_{RhH} = 0.6$ Hz) whereas any rhodium coupling to the endo hydrogen is too small to be observed (>0.2 Hz). The ^{13}C resonance for the two CO ligands in **3b** exhibits the expected coupling to rhodium (50 Hz) and a chemical shift value almost identical to the analogous CO ligand in **3a** (249 vs 250 ppm, respectively). The methylidene ^{13}C shift in **3b** is 135.1 ppm. When the methylidene ligand bridges the Co—Co bond, however, no rhodium-to-carbon coupling is observed. A complete summary of the ^1H and ^{13}C data for isomers **3a** and **3b** is presented in Table 1.

The kinetics and thermodynamics for the equilibrium isomerization of **3a–3b** in toluene solution



have been studied via a VT NMR. At 330 K the rate for the conversion of **3a** to **3b** is 1.8×10^{-4} s^{-1} with a free energy of activation of 104 kJ mol^{-1}. The equilibrium constant for the mixture at room temperature is 2.63 (favouring **3b** and statistically normalized for the presence of two enantiomers of **3a**) which corresponds to a free energy of -1.2 kJ mol^{-1}.

Having determined that methylidene migration occurs in **3a**, we were also interested in mapping the proton exchange pathways between the four magnetically distinct methylidene protons of **3a** and **3b**. Phase sensitive NOESY experiments offer an attractive method to address this question. At temperatures where exchange is slow, negatively phased cross peaks within the methylidene proton signal sets for **3a** and **3b** are observed. As the temperature is raised and

exchange of the methylidene ligand between the Rh—Co and Co—Co edges enters the time scale of the experiment, positively phased cross peaks should be observed between these sets of methylidene protons reflecting the mapping function for proton exchange and thus the stereochemistry involved in the methylidene ligand jump. Unfortunately, decomposition of **3a** ensues before temperatures high enough to bring the exchange rate into the time scale of the experiment could be reached. However, two new exchange phenomena are observed (Fig. 3). First, the NOE derived cross peak between the signals of the methylidene protons of **3a** became weaker, nulled and then grew again as a positively phased cross peak as the temperature was raised. This is clear evidence that an exchange pathway exists which equilibrates the two methylidene protons of **3a** and which does not involve a double jump mechanism involving **3b** as an intermediate (**3a** ⇄ **3b** ⇄ **3a**'). Furthermore, an additional exchange derived cross peak appeared between the protons of **3a** and a hitherto unobserved signal at 8.3 ppm. Subsequent 1 D spectra of **3a** confirmed that a small doublet (1.4 Hz) is present in spectra of **3a** at room temperature.

Further NOESY experiments optimized for the observation of cross peaks in the Cp region of the spectrum also gave rise to an exchange derived cross peak between the two Cp signals of **3a**. Quantitative analysis of cross peak intensity versus temperature for the three processes described above gave consistent results (350 K : $k_{rate} = 0.13\ s^{-1}$; $\Delta G^{\neq} = 92$ kJ/mole) indicating that a single process is involved in all of these processes: (1) exchange between the two methylidene proton signals; (2) exchange of the identities of the two Cp rings and (3) exchange of both methylidene proton signals of **3a** with a new signal in a species which we now refer to as **3c**.

Exchange of the identities of the Cp rings in **3a** rules out a mechanism in which the methylidene ligand remains bridging a single Rh—Co edge but rotates about an axis through the carbon and between the two protons. Furthermore, an intermediate in which the HCH plane of the methylidene is parallel to the Rh—Co bond (rotated 90° with respect to the orientation in **3a**) is not consistent with the observation of a single resonance for both protons nor is it likely based on the results of previous theoretical studies [8].

Further information concerning the identity of **3c** was clearly required. When crystals of **3a** are dissolved in deuterated methylene chloride at 0°C, no trace of the signal at 8.3 ppm was observed (Fig. 4). Upon warming the sample to room temperature this signal appears within a few minutes. Careful monitoring of the Cp and Cp* regions of the spectrum also reveals the emergence of one signal for each set of protons at 4.57 and 1.62 ppm, respectively. The maximum concentration of **3c** in the presence of **3a** and **3b** is ca 1% based on integrations of the methylidene protons signals. From these data we identify **3c** as a separate species in equilibrium with **3a** and **3b** which is involved

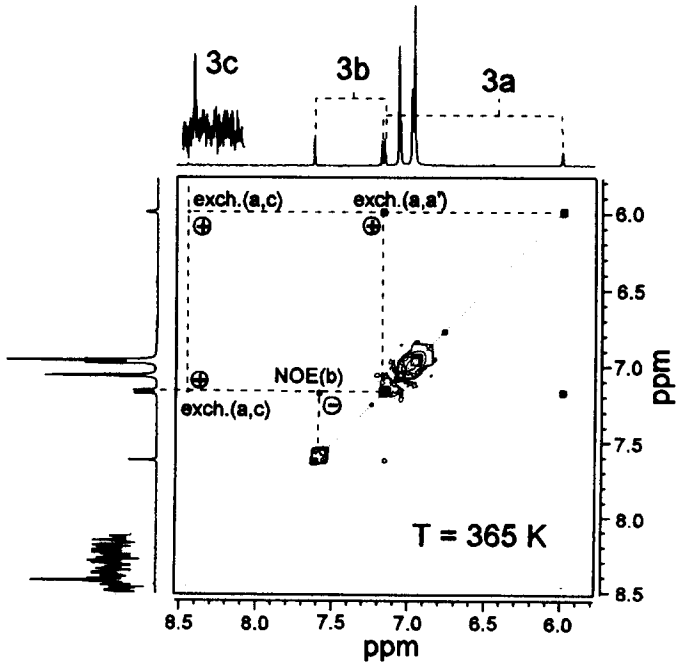


Fig. 3. Phase sensitive NOESY spectrum (methylidene region) for a mixture of **3a**, **3b** and **3c** in toluene-d_8 at 365 K. The cross peak labelled NOE(b) is derived from NOE interactions between the methylidene protons of **3b**. Cross peaks labelled exch(a,a') and exch(a,c) are derived from a dominant chemical exchange process involving the methylidene protons of **3a** and the methylidene protons of **3a** and **3c**, respectively.

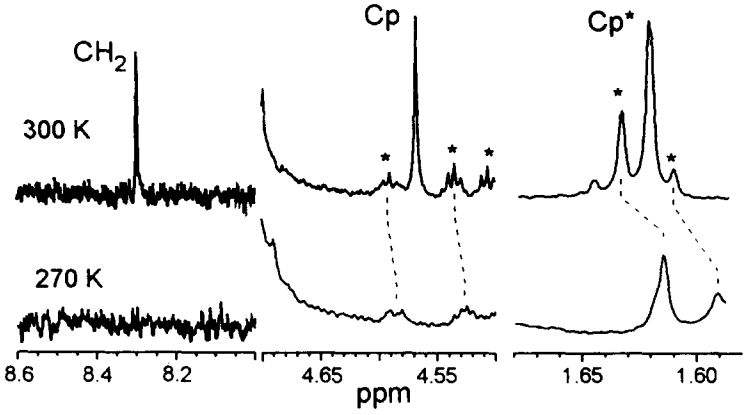

Fig. 4. Variable temperature ^1H NMR spectra illustrating the formation of the methylidene, Cp and Cp* signals of **3c** at 300 K. Signals marked with "*" are natural abundance ^{13}C satellites from the signals for the Cp and Cp* ligands of **3a**.

in the direct migration of the methylidene ligand between the Rh—Co edges of **3a**. To our knowledge, this is the first observation of an intermediate involved with alkylidene fluxionality where the ground-state structures involve μ_2-alkylidene coordination modes.

Our attention now focused on obtaining further spectroscopic data which would allow us to propose a more detailed picture for the structure of **3c**. ^{13}C NMR data were critical in these efforts for several reasons. First, the chemical shift of the alkylidene ligand is quite sensitive to its coordination mode. Herrmann has pointed out that the chemical shift ranges for the terminal vs μ_2-bridging coordination geometries are distinct with the terminal range considerably downfield (240–370 ppm) of that for the bridging mode (100–210 ppm) [3]. Furthermore, both the observation and magnitude of any Rh—C coupling for the methylidene ligand in **3c** can be used to distinguish between bridging and terminal coordination modes. The Rh—C coupling constant for a ligand terminally coordinated to rhodium should be roughly double that for the same ligand in a bridging mode [14]. Finally, the observation any C—C scalar coupling between the carbonyl and the alkylidene ligands would reveal possible bonding between these ligands in **3c**. For these reasons, ^{13}C enriched samples of **3a** were prepared in which only the alkylidene ligand or both the alkylidene and CO ligands were enriched (see Experimental).

In order to exclude mistaking signals from trace impurities for those of **3c**, multidimensional pulse techniques in which only ^{13}C signals correlated to proton chemical shifts and coupling constants already known for **3c** were considered in our assignments. Using an equilibrated sample of **3a**, 99% enriched in ^{13}C at the methylidene carbon, an inverse detected, ^1H $\{^{13}C\}$ correlation spectrum (HMQC pulse sequence) was obtained at $-50°C$ (Fig. 5). In addition to the expected cross peaks in the methylidene region for **3a** and **3b**, a cross peak correlating the methylidene proton resonance of **3c** to a carbon signal at 145.5 ppm was detected. Furthermore, Rh—C coupling of 29 Hz was observed for this cross peak. A second, identical experiment using doubly labelled **3a** (>80% enriched in both the methylidene and CO ligands) failed to show any extra coupling due to possible bond formation between the methylidene and CO ligands in **3c**.

Neither the chemical shift nor the Rh—C coupling constant observed for the methylidene-derived ^{13}C resonance of **3c** are consistent with a terminal coordination mode. Failure to observed additional C—C coupling in the double label experiment indicates that the methylidene remains independent of the CO ligands in **3c**. Both the observed rhodium–proton (1.4 Hz) and rhodium–carbon coupling (29 Hz) are similar to analogous couplings observed in **3a**. Therefore some type of geometry that maintains interaction with the rhodium is necessary. Although no ^{13}C NMR shifts for μ_3-alkylidene ligands have been reported, based on the trends observed for the carbonyl ligand in terminal, μ_2 and μ_3-geometries, the two bridging geometries should have similar and overlapping chemical shift ranges. These arguments, together with overall C_s symmetry in **3c** (single signals for the methylidene and Cp ligand protons) lead us to propose that **3c** contains a triply-bridging methylidene ligand as shown in the illustration of **3c**. Having the HCH plane parallel to the Co—Co bond vector in **3c** is also consistent with the chemical exchange of the exo and endo proton identities when **3c** functions as the intermediate in the movement of the methylidene ligand between Rh—Co edges in **3a**. We cannot, however, rule out the possibility that the methylidene ligand rotates freely in the triply-bridging geometry in **3c** as one theoretical study has predicted [8].

Having addressed the question of the coordination mode of the methylidene ligand in **3c** we conclude our initial investigations into the identity of this complex with a look at the disposition of the carbonyl ligands

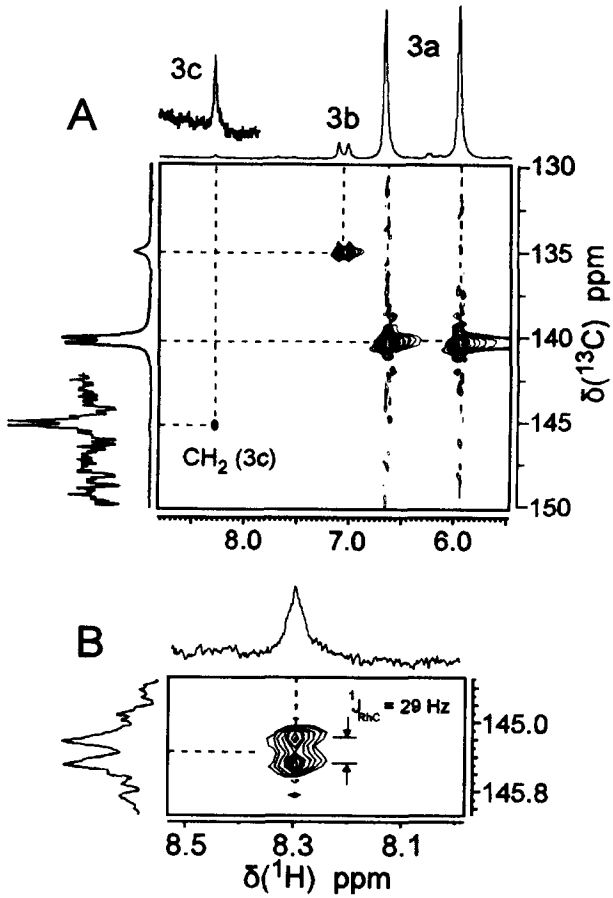

Fig. 5. Methylidene region of the HMQC spectrum of ^{13}C enriched (99%) **3a**, **3b** and **3c** (CD_2Cl_2, 300 K). A: Cross peaks relating the methylidene protons of each isomer with their respective carbon signals. B: Expansion of the cross peak for **3c** illustrating Rh—C coupling of 29 Hz.

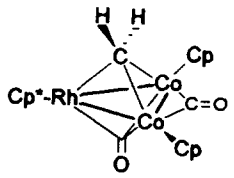

3c

in this complex. IR spectra of equilibrium mixtures of **3a–3c** exhibit an extra band at 1655 cm^{-1} which suggests the presence of a triply-bridging CO ligand in **3c**. Further evidence for a μ_3-CO ligand in **3c** comes from heteronuclear NMR experiments. Using the ^{13}C enriched sample described above, a heteronuclear multiple bond correlation (HMBC) experiment employing long range couplings gave rise to peak correlating the methyl group protons of the Cp* ligand with a shift at 257 ppm in the carbon spectrum (Fig. 6). A rhodium–carbon coupling constant of 39 Hz was observed for this signal.

Although the signal for the Cp* ligand in **3c** is not as distinctive as that for the methylidene ligand, we are confident of our assignment of the signal at 257 ppm to one of the CO ligands in **3c** through additional H/Rh correlations in which both the Cp* and methylidene signals give rise to cross peaks with the same rhodium chemical shift [15]. Our inability to observe coherence transfer between the methylidene protons and the CO ligand of **3c** may be due to the fact that only two protons are involved in this 3-bond coupling path while 15 protons are involved in the 4-bond path between the Cp* and carbonyl ligand. Although the coupling path involves more legs, the increase in intensity for the second mechanism due to the larger proton spin reservoir appears to facilitate a larger overall transfer of coherence between these two spin populations.

The observed chemical shift and Rh—C coupling constant for one of the CO ligands in **3c** is inconsistent with that expected for a terminal CO ligand. The shift

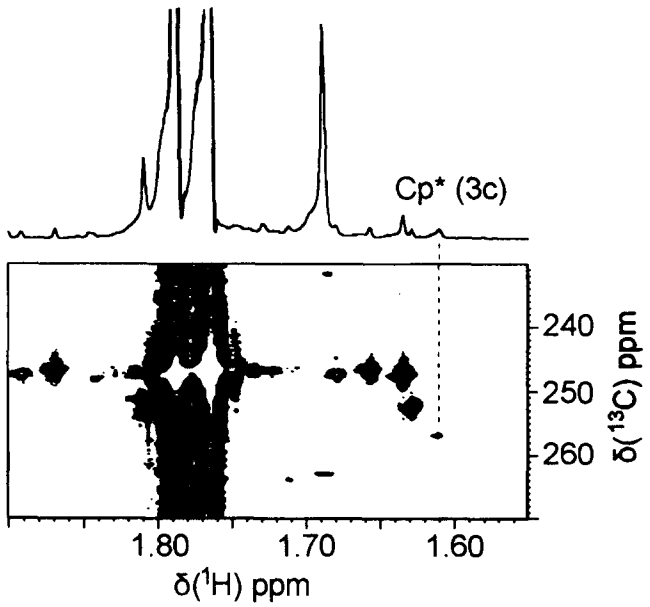

Fig. 6. HMBC spectrum for a sample containing doubly labelled (methylidene 99% ^{13}C); CO (80% ^{13}C) **3a**, **3b** and **3c** showing signal correlating the Cp* proton signal of **3c** with a shift at 257 ppm in the carbon spectrum.

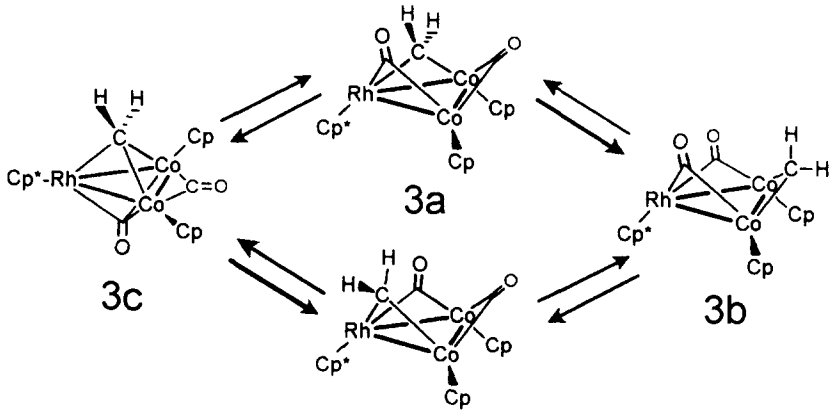

Scheme 2.

is intermediate between the values observed for the μ_2-CO ligands bridging either Rh—Co or Co—Co bonds in **3a** and **3b** and is therefore consistent with a bridging CO ligand interacting with both metals. These NMR data, together with the stretching frequency in the IR and C_s symmetry for the complex as a whole, support the assignment of one of the two CO ligands in **3c** as a triply-bridging ligand, presumably on the side opposite that of the μ_3-methylidene ligand. Unfortunately, it is not possible to describe in more detail the fluxional behaviour of the CO ligands without knowing whether the two distinct ligands exchange identities as the methylidene ligand jumps between Rh—Co edges. Our attempts to obtain these data have been thwarted to date by excessive broadening of the CO signals at temperatures where exchange could be monitored.

Our understanding of the methylidene dynamics in the isomer family **3a–3c** is summarized in Scheme 2. Two separate processes account for the movement of the methylidene ligand between the Rh—Co and Co—Co edges of this complex. The first is a "high" energy process involving the direct movement of the methylidene ligand from the Rh—Co (**3a**) to Co—Co edge (**3b**). The second process is degenerate and involves the movement of the methylidene between the two Rh—Co edges. An intermediate (**3c**) has been observed for the second process. Based on detailed NMR studies we propose that this intermediate is composed of the three metals interacting with a triply

bridging methylidene and a triply-bridging carbonyl ligand on opposite sides of the plane of the metals. The final CO ligand in **3c** presumably bridges the Co—Co edge.

These investigations have lead to the first observation and characterization of an intermediate in the movement of a methylidene ligand between metal–metal bonds in a cluster complex. Furthermore, this intermediate contains a triply-bridging methylidene ligand. In contrast to other coordination modes for the alkylidene ligand, the μ_3 geometry is very rare and until the present study no examples were known involving late transition metal cluster complexes. For this reason, it has not been seriously considered as a possible intermediate in alkylidene dynamics in cluster complexes and, more importantly, on the surfaces of metal crystals such as those frequently involved in heterogeneous catalysts [1,16] As catalyst scientists extend theoretical models for such systems, it is important that correct models for surface species and kinetic pathways are used. We suggest here that the triply-bridging coordination geometry be included among the models both as a viable coordination mode and for alkylidene dynamics on metal surfaces.

Acknowledgment—The authors would like to thank the Petroleum Research Fund administered by the American Chemical Society. We also wish to thank Dr Christian Griesinger for helpful discussions and the use of NMR instrumentation in his laboratories in obtaining HMBC spectral data.

(Received 7 October 1997; accepted 10 November 1997)

Abstract—Chloro(dimethyl)silyl-η^5-cyclopentadienyl group 4 metal complexes of the type $[M(\eta^5\text{-}C_5H_4SiMe_2Cl)Cl_3]$ (M = Ti **1**, Zr **2**) react with thallium salts $Tl(C_5H_4R)$ (R = H, $SiMe_3$) to give mixed dicyclopentadienyl derivatives $[M(\eta^5\text{-}C_5H_4R)(\eta^5\text{-}C_5H_4SiMe_2Cl)Cl_2]$, (M = Ti, R = H **3**, R = $SiMe_3$ **4**; M = Zr, R = H **5**, R = $SiMe_3$ **6**) in high yield. Hydrolysis of complexes **3** and **4** affords the dinuclear complexes $[Ti(\eta^5\text{-}C_5H_4R)Cl_2]_2\{\mu\text{-}[(\eta^5\text{-}C_5H_4SiMe_2)_2O]\}$ (R = H **7**, R = $SiMe_3$ **8**) containing a siloxanyl bridge, by elimination of two equivalents of HCl. Reactions of complexes **1** with hydroxo containing reagents such as anhydrous LiOH and $SiPh_2(OH)_2$ give the derivatives $[Ti(\eta^5\text{-}C_5H_4SiMe_2Cl)Cl_2]_2(\mu\text{-}O)]$, **9** and $Ti[\mu\text{-}(\eta^5\text{-}C_5H_4SiMe_2OSiPh_2\text{-}\eta^1\text{-}O)]Cl_2$, **10** identified by analytical, spectrometric and spectroscopic data. Treatment of analogous complex **2** with water produces the dimeric monocyclopentadienyl zirconium trichloride adduct $[Zr(\eta^5\text{-}C_5H_4SiMe_2OH)Cl_3]_2$, **11**. Compound **11** has been characterized by X-ray crystallography. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: titanium; zirconium; siloxanediyl cyclopentadienyl; hydroxide.

Cyclopentadienyl transition metal complexes have been the subject of considerable interest for many years due to their synthetic and catalytic applications [1]. Particularly relevant has been the development of new dicyclopentadienyl group 4 metal derivatives because of their application as catalysts in homogeneous polymerization of α-olefins [2]. For this reason, a large number of such complexes with variously functionalised substituents on the cyclopentadienyl rings have been synthesized and spectroscopically and structurally characterized [3].

The aim of combining the properties of the homogeneous and heterogeneous catalysts [4], extending and improving the industrial applications of these compounds, has promoted a growing interest in the study of transition metal complexes based on functionalized cyclopentadienyl ligands allowing their attachment to organic polymers and inorganic surfaces. Several approaches have been studied. Polysiloxanes have been investigated as useful polymers for supporting organometallic complexes [5]. Metallocene derivatives containing silyl groups in the side chain of the cyclopentadienyl ligand have also been synthesized and used as models, either by anchoring them to organic or inorganic substrates, or by polymerising them to organometallic polymers [6].

Chlorosilyl-η^5-cyclopentadienyl group 4 metal complexes are good candidates to prepare supported catalysts using the Si—Cl bond as a reactive site [7]. We have previously reported chloro(dimethyl)silyl-η^5-cyclopentadienyl group 4 metal derivatives $M(\eta^5\text{-}C_5H_4SiMe_2Cl)Cl_3$ (M = Ti **1**, Zr **2**) [8] and their reactions with amines and amides. In this paper, we describe the synthesis and reactivity of these and other new dicyclopentadienyl complexes of titanium and zirconium with different hydroxo containing reagents

as an important step in the investigation of suitable anchoring systems for the immobilization of the corresponding active metal centers.

RESULTS AND DISCUSSION

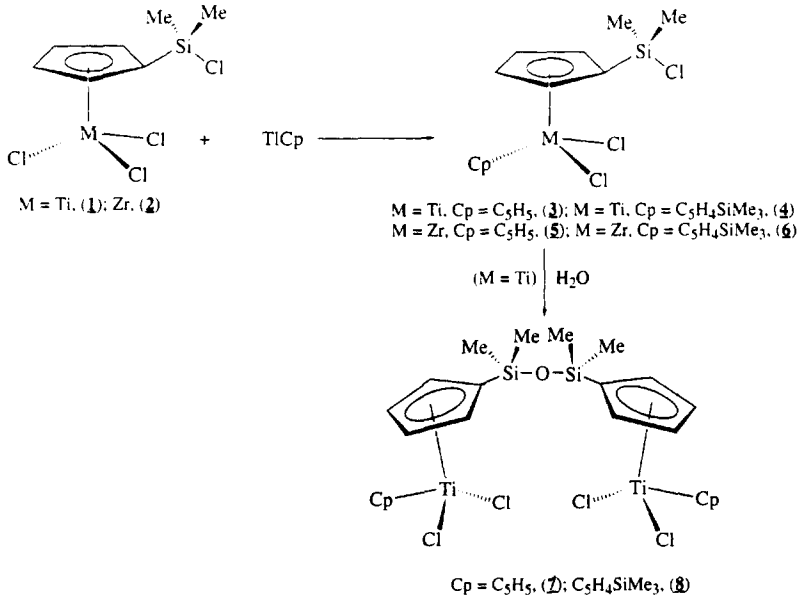
Synthesis of mixed dicyclopentadienyl derivatives and their reactions with water

The reaction of the trichloro metal compounds $M(\eta^5\text{-}C_5H_4SiMe_2Cl)Cl_3$ (M = Ti **1**; Zr **2**) with one equiv. of the thallium salts $Tl(C_5H_4R)$ (R = H, $SiMe_3$) afforded the corresponding mixed dicyclopentadienyl derivatives $M(\eta^5\text{-}C_5H_4R)(\eta^5\text{-}C_5H_4SiMe_2Cl)Cl_2$, (M = Ti, R = H **3**, R = $SiMe_3$ **4**; M = Zr, R = H **5**, R = $SiMe_3$ **6**) in high yield (80–90%), by modification of the procedure previously described [9]. Complexes **3** and **6** have been recently mentioned in the literature, although not fully characterized [10].

All these complexes show the characteristic thermal stability of group 4 dicyclopentadienyl derivatives [1b] but are moisture sensitive due to the hydrolysis of the $SiMe_2Cl$ moiety. They are insoluble in hydrocarbons, and soluble in toluene and chlorinated solvents.

Reactions of titanium complexes **3** and **4** with one equiv. of water yielded the corresponding dinuclear complexes $[Ti(\eta^5\text{-}C_5H_4R)Cl_2]_2\{\mu\text{-}[(\eta^5\text{-}C_5H_4SiMe_2)_2O]\}$ (R = H **7**, R = $SiMe_3$ **8**) in 50% yield based on titanium, by means of the intermolecular hydrolysis of the Si—Cl bonds to give the siloxanediyl fragment $[(\eta^5\text{-}C_5H_4SiMe_2)_2O]^{2-}$ binding both titanium centres with evolution of HCl. This behaviour, which reveals that a selective reaction of the Si—Cl bonds without modification of the Ti—Cl bonds takes place, is different from that observed for the monocyclopentadienyl derivatives $Ti(\eta^5\text{-}C_5H_4SiMe_2Cl)Cl_3$ [8] for which simultaneous unselective reaction of both Si—Cl and the more covalent Ti—Cl bonds was observed. The reaction is also different from that observed [8] for the bis[chloro(dimethyl)silyl-η^5-cyclopentadienyl]zirconium complex $Zr(\eta^5\text{-}C_5H_4SiMe_2Cl)_2Cl_2$ in which the same selective hydrolysis of the Si—Cl bonds led to the mononuclear *ansa*-derivative $Zr[\mu\text{-}\{(\eta^5\text{-}C_5H_4SiMe_2)_2O\}]Cl_2$ in an intramolecular reaction. Complexes **7** and **8** show physical and spectroscopic properties similar to those observed for the related derivatives $[Ti(C_5H_5)Cl_2]_2\{\mu\text{-}[(\eta^5\text{-}C_5H_4)_2E]\}$ (E = $SiMe_2$; $(SiMe_2O)_2SiMe_2$; $SiMe_2(CH_2)_nSiMe_2$, n = 1 or 2) with variable interannular bridge lengths [11]. Complexes **7** and **8** are air and moisture stable, soluble in chlorinated solvents, but sparingly soluble in toluene and insoluble in hydrocarbons.

The spectroscopic and analytical data for compounds **3**–**8** and all of the other complexes described in this paper, are given in the Experimental Section and will not be discussed, except where appropriate. ^{1}H NMR spectra of complexes **3**–**8** show the expected resonances of the cyclopentadienyl ring protons as two sets of pseudotriplets due to an AA′BB′ spin system [11]. The value of $\Delta\delta = \delta_d - \delta_p$ for complex **7** (δ_d and δ_p being the chemical shifts of the distal and proximal protons of the bridged cyclopentadienyl rings respectively) is 0.30 ppm, slightly smaller than the value observed for the *ansa*-compound $Ti[\mu\text{-}\{(\eta^5\text{-}C_5H_4SiMe_2)_2O\}]Cl_2$ ($\Delta\delta$ = 0.41 ppm) [6a,12], where the ligand is acting as a chelating group. Such a value has been used as a spectroscopic parameter for dis-



Scheme 1.

tinguishing the chelating and the bridging coordination modes of the cyclopentadienyl ligands bridged by silyl groups [13,14]. The lower value of $\Delta\delta$ observed for $Ti[\mu\text{-}\{(\eta^5\text{-}C_5H_4SiMe_2)_2O\}]Cl_2$ can be attributed to the large interannular bridge angle formed by the two cyclopentadienyl rings and the metal centre, which induces a relaxation of the constrained environment of the metal [13]. These electronic and steric dispositions shown by the *ansa*-derivatives having large interannular bridges are similar to those found for the unbridged counterparts with substituted cyclopentadienyl ligands. In both types of complexes similar values of $\Delta\delta$ have been obtained indicating, in this case, that this spectroscopic parameter cannot be used to distinguish between the chelating and the bridging disposition of the dicyclopentadienyl ligand. However, the relative chemical shifts of the bridgehead carbon of the cyclopentadienyl rings could be used to distinguish between the two types of coordination. It has been observed that in chelating compounds, this resonance appeared at fields higher than the proximal and distal carbon resonances of the same ring [13], while for a bridging coordination mode, in dinuclear derivatives [11a,14] or for unbridged mononuclear substituted metallocene analogues [15], the reverse was observed. This feature has been explained as the result of a redistribution of the π-electron density of the ring in the *ansa*-metallocene caused by the bridge and the presence of the silicon atom [13a], resulting in shielding the C_{ipso} atom but deshielding the remaining ring carbon atoms. In contrast, complexes with an interannular hydrocarbon link do not present this spectroscopic behaviour for the C_{ipso} atom [16]. The ^{13}C NMR spectrum of complex **7** exhibits two signals at δ 121.0 and 129.2 assigned to the distal and proximal carbons of the bridging cyclopentadienyl rings and one resonance of lower intensity at δ 129.3 attributed to the C_{ipso}. These data are in agreement with a bridging coordination mode of the $[(\eta^5\text{-}C_5H_4SiMe_2)O]^{2-}$ fragment in **7**. An analogous result was observed for complex **8**. The same spectroscopic characteristics [11a] have been found in other complexes containing shorter bridges like those with the $[(\eta^5\text{-}C_5H_4)_2SiMe_2]^{2-}$ fragment. The IR spectra for complexes **7** and **8** show no absorptions due to hydroxo groups or Ti—O—Ti linkage. In addition, the mass spectra of the two compounds are in agreement with their dinuclear formulation.

Reactions of monocyclopentadienyl derivatives with hydroxo containing reagents

We have previously reported that both Si—Cl and Ti—Cl bonds in compound **1** are simultaneously involved in reactions with water and amines, whereas reactions with nucleophilic Grignard reagents or highly polar lithium amides take place selectively at the Ti—Cl bond [8,17]. In order to obtain additional information about this different reactivity we have studied the reaction of **1** with $SiPh_2(OH)_2$ and LiOH.

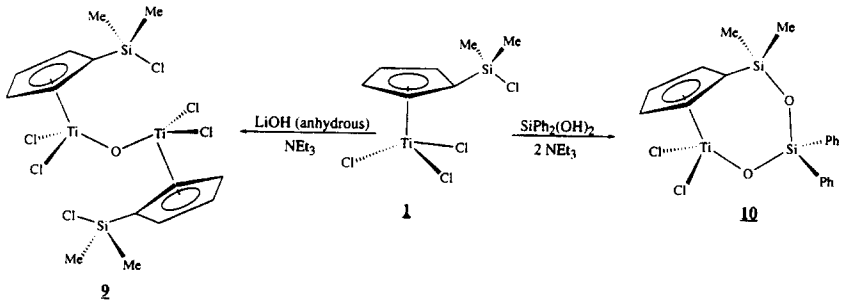
Complex **1** reacts with one equiv. of $SiPh_2(OH)_2$ in the presence of two equiv. of NEt_3 to afford the mononuclear derivative $Ti[\mu\text{-}(\eta^5\text{-}C_5H_4SiMe_2OSiPh_2\text{-}\eta^1\text{-}O)]Cl_2$ **10,** characterized by its analytical and spectroscopic data. This reaction involves both Si—Cl and Ti—Cl bonds as does the similar reaction with water. Treatment of **1** with anhydrous LiOH in a 1 : 1 molar ratio in the presence of one equiv. of dry NEt_3 gives the new oxo derivative $[Ti(\eta^5\text{-}C_5H_4SiMe_2Cl)Cl_2]_2(\mu\text{-}O)$, **9** as yellow crystals in a 42% yield and a white precipitate of $HCl\cdot NEt_3$, on the basis of their analytical and spectroscopic data.

The formation of the dinuclear complex $[Ti\{(\eta^5\text{-}C_5H_4SiMe_2\text{-}\eta^1\text{-}O)\}Cl_2]_2$ obtained by hydrolysis of **1** [8] or the recently reported compound $(TiCl_2)_2(\mu\text{-}O)\{\mu\text{-}[(\eta^5\text{-}C_5H_4SiMe_2)_2O]\}$ [12] is not detected in this reaction. The synthesis of the dinuclear complex **9** suggests that the reaction of **1** with LiOH proceeds with intermolecular elimination of HCl from the Ti—Cl bonds. In contrast, the mononuclear "constrained geometry derivatives" $Ti[\mu\text{-}(\eta^5\text{-}C_5H_4SiMe_2\text{-}\eta^1\text{-}NR)]Cl_2$ [17] are obtained in the reaction of **1** with LiNHR, involving the formation of the amidotitanium derivative $[Ti(\eta^5\text{-}C_5H_4SiMe_2Cl)(Cl_2)(NHR)]$ and further intramolecular HCl elimination from the silicon-bonded chlorine of the same molecule. In addition, the IR spectrum of **9** shows a broad absorption band at 798 cm^{-1} attributed to a Ti—O—Ti fragment [18] and its mass spectrum is consistent with a dinuclear structure.

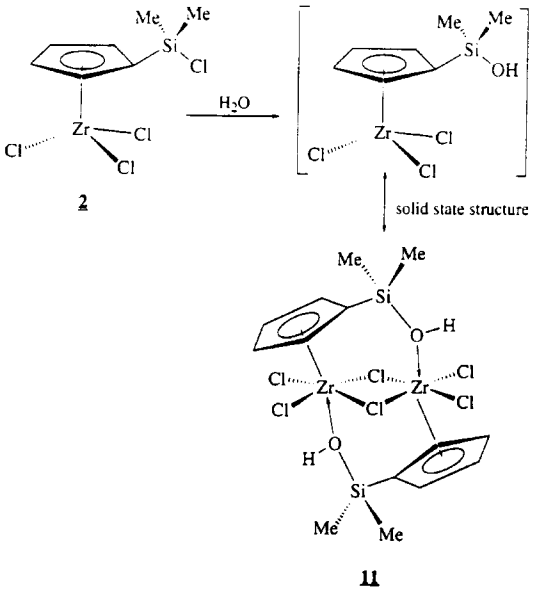
However, the reaction of the zirconium complex **2** with one equiv. of water under the same conditions has been decribed to give a white solid, insoluble in all common solvents [8]. The IR spectrum for this substance shows an absorption band at 3604 cm^{-1} attributed to the presence of a Si—OH group [19] and the NMR data are not reported because of its lack of solubility in the most common deuterated solvents. By using the method described in the experimental section we were successful in isolating single crystals of this compound suitable for definitive characterization by diffraction methods. The structure corresponds to a dimer of the monocyclopentadienyl zirconium trichloride unit $[Zr\{\eta^5\text{-}C_5H_4SiMe_2(\mu\text{-}OH)\}(\mu\text{-}Cl)Cl_2]_2$, **11** with both zirconium atoms bridged by two chlorines and the OH groups. This result confirms that the Si—Cl bonds of the chlorodimethylsilyl cyclopentadienyl substituted zirconium complex **2** react selectively with water, in contrast with the unselective hydrolysis observed for complex **1** [8].

Description of the crystal structure of $[Zr\{\eta^5\text{-}C_5H_4SiMe_2(\mu\text{-}OH)\}(\mu\text{-}Cl)Cl_2]_2$, **11**

Figure 1 shows an ORTEP view of **11** along with the numbering scheme used. Selected bond lengths and angles with their standard deviations are listed in Table 1. The X-ray determination shows **11** as a dimer of two $[Zr(\eta^5\text{-}C_5H_4SiMe_2OH)Cl_3]$ units. The metal



Scheme 2.



Scheme 3.

centre can be considered as having a distorted octahedral environment, surrounded by a silyl substituted cyclopentadienyl ligand that occupies one coordination site, four chlorine atoms defining the equatorial positions (two of which act as terminal atoms and the other two bridging the adjacent zirconium atoms) and a hydroxy group bound to the silicon of the neighbouring silyl group of the other cyclopentadienyl unit in a *trans* position with respect to the ring. The metal atom is located above the plane defined by its chloride substituents (0.5785 Å). The Zr—Cl terminal distances are slightly different (Zr(1)—Cl(2), 2.435(2) Å and Zr(1)—Cl(3), 2.456 (2) Å) despite the symmetry of the molecule. The dimer is centrosymmetric and exhibits the trapezoidal $[Zr_2(\mu\text{-}Cl)_2]$ fragment found in analogous monocyclopentadienyl zirconium derivatives [20] and other related cyclopentadienyl free ligand complexes [21]. The two Zr—Cl bridging distances are longer than the terminal Zr—Cl bonds and remain inequivalent (Zr(1)—Cl(1), 2.612(1) Å and Zr(1)—Cl(1a), 2.646(1) Å).

The Zr—Cp(centroid) bond distance of 2.216 Å can be compared to the values reported for other similar complexes such as 2.19 Å for $Zr(C_5H_5)Cl_3$ [20a] or 2.20 Å for $Zr(\eta^5\text{-}C_5H_5)_2Cl_2$ [22] but is smaller than in the related complex $Zr[\eta^5\text{-}C_5H_3\text{-}1,3\text{-}(SiMe_2CH_2P^iPr_2)_2]Cl_3$ (2.260 Å) [23]. The loss of the polymeric structure found in $Zr(\eta^5\text{-}C_5H_5)Cl_3$ must be attributed to the formation of the hydroxo adduct, *trans* to the cyclopentadienyl group. The Zr(1)—O(1) bond distance of 2.321(4) Å is comparable to that found in other monocyclopentadienyl zirconium adduct complexes such as $Zr(\eta^5\text{-}C_5H_5)Cl_3 \cdot 2THF$ (2.393 and 2.314 Å) or $Zr(\eta^5\text{-}C_5H_4Me)Cl_3 \cdot 2THF$ (2.377 and 2.310 Å) [24], although higher than that observed for terminal hydroxo complexes such as $Zr(\eta^5\text{-}C_5Me_5)_2(OH)_2$ (1.982 and 1.975 Å) [25] or $Zr(\eta^5\text{-}C_5Me_5)_2(OH)Cl$ (1.950 Å) [25].

If the centroid of the silyl-substituted ring is considered as a coordination site bonded to zirconium, the structure of **11** can be viewed as showing an eight-membered ring $(Zr—O—Si—Cp)_2$ with two interanular Zr—Cl—Zr connections (Fig. 2*A*). This eight-membered core has also been observed in other titanium and zirconium compounds: $[TiCl_2\{\mu\text{-}(\eta^5\text{-}\eta^1\text{-}C_5H_4SiMe_2O)\}]_2$ [8] (Fig. 2*B*) and $[Zr\{\eta^5\text{-}C_5H_4SiMe_2(\mu\text{-}O)\}Cl_2\{H_2NCH(Me)Ph\}]_2$ [17] (Fig. 2*C*). The zirconium derivative (*A*) exhibits a "chair conformation" similar to that found in the titanium compound (*B*), with the main plane of this chair conformation perpendicular to the plane defined by the zirconium and the bridged chlorine atoms (Fig. 3). The zirconium compound (*C*) shows a planar disposition for the cycle. The difference between the $(M—O—Si—Cp)_2$ cores displayed in *A* and *B* is a variation in those atoms located out of the plane. In compound **11** (*A*), the silicon atoms are located at ±0.6101 Å from the plane defined by the rest of the atoms, whereas in the structure *B* the cyclopentadienyl rings are located out of the plane. The structure *C* can also be considered as two lateral Zr—Cp—Si—O "oxazirconacycle" rings connected by a central $[Zr(\mu\text{-}O)]_2$ ring with the angle values substantialy away from linearity ($\alpha = 141.6$ and $\beta = 108.2°$). The

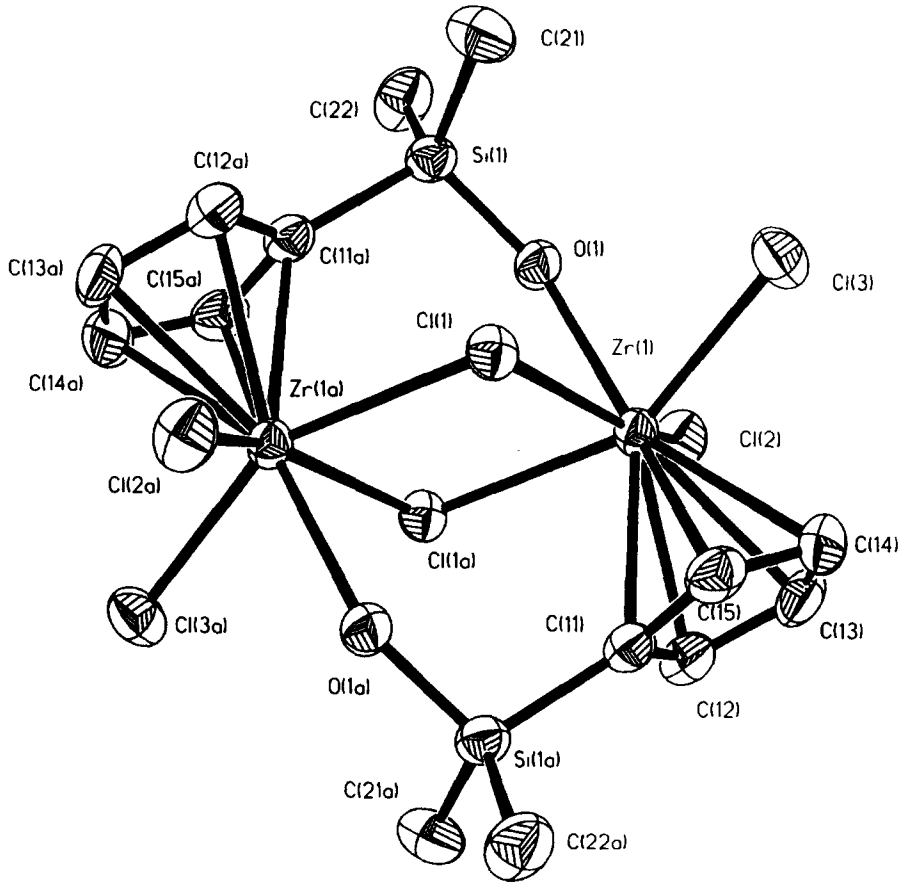


Fig. 1. ORTEP view of the molecular structure of $[Zr\{\eta^5\text{-}C_5H_4SiMe_2(\mu\text{-}OH)\}(\mu\text{-}Cl)Cl_2]_2$ **11** with the atom-numbering scheme.

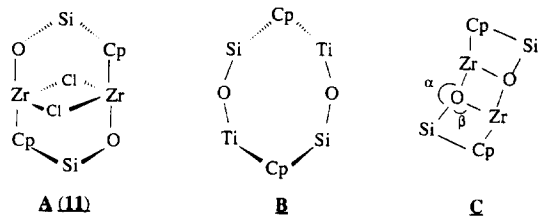

Fig. 2. Comparison of the eight-membered cores defined in the compounds $[Zr\{\eta^5\text{-}C_5H_4SiMe_2(\mu\text{-}OH)\}(\mu\text{-}Cl)Cl_2]_2$ (*A*, **11**). $[TiCl_2\{\mu\text{-}(\eta^5\text{-}\eta^1\text{-}C_5H_4SiMe_2O)\}]_2$ (*B*) and $[Zr\{\eta^5\text{-}C_5H_4SiMe_2(\mu\text{-}O)\}Cl_2\{H_2NCH(Me)Ph\}]_2$ (*C*).

O(1)—Zr(1)—Cp(1) angle in *A* is almost linear (178.76°) whereas the value of the Si(1)—O(1)—Zr(1) and C(11a)—Si(1)—O(1) angles are 141.4(2) and 108.4(6)° respectively. The Zr(1)—Zr(1a) distance in compound **11** is 4.081 Å, larger than that found in the compound *C* (3.597 Å). The Ti—O—Si angle in the titanium compound *B* is larger (160.2°) than that found in *C* but smaller than that found in *A*. The metallic environment has a direct influence on the difference between these structures. Whereas the coordination around the titanium atom in *B* is pseudotetrahedral, the zirconium atom in *A* and *C* shows a pseudooctahedral environment and they adopt a disposition which allows their connection through the chlorine or oxygen bridges.

The formation of the adduct in complex **11** is related to the structure of the starting material **2**, in which the hydroxo group has probably been replaced by a chlorine atom. Therefore, we tentatively assume a dimeric structure in the solid state for complex **2**, instead of a polymeric structure that may be envisaged for less hindered substituted cyclopentadienyl ligands.

EXPERIMENTAL

All manipulations were performed under argon using Schlenk and high-vacuum line techniques or a glove box model HE-63. Solvents were purified by distillation under argon from an appropriate drying agent (sodium for toluene, sodium-potassium alloy for hexane and P_2O_5 for dichloromethane). $SiPh_2(OH)_2$ (Aldrich) and anhydrous LiOH (Ventron) were commercially obtained and used without further purification. NEt_3 (Fluka) was distilled from sodium before use and stored over 4 Å molecular sieves. $Ti[\eta^5\text{-}C_5H_4SiMe_2Cl]Cl_3$, **1** [8], $Zr[\eta^5\text{-}C_5H_4SiMe_2Cl]Cl_3$, **2** [8], $Tl(C_5H_5)$ [26] and $Tl(C_5H_4SiMe_3)$ [27] were prepared by known procedures. C, H and N microanalyses were performed on a Perkin–Elmer 240B and/or Heraeus CHN-O-Rapid microanalyzer. Electron impact (EI) mass spectra were recorded at 70 eV on a Hewlett-Packard 5988A spectrometer. IR spectra were recorded on a Perkin–Elmer 883 spectrophotometer using KBr pellets; only selected MS and IR data are reported. NMR spectra, measured at 25°C, were recorded on a Varian Unity FT-300 (^{1}H

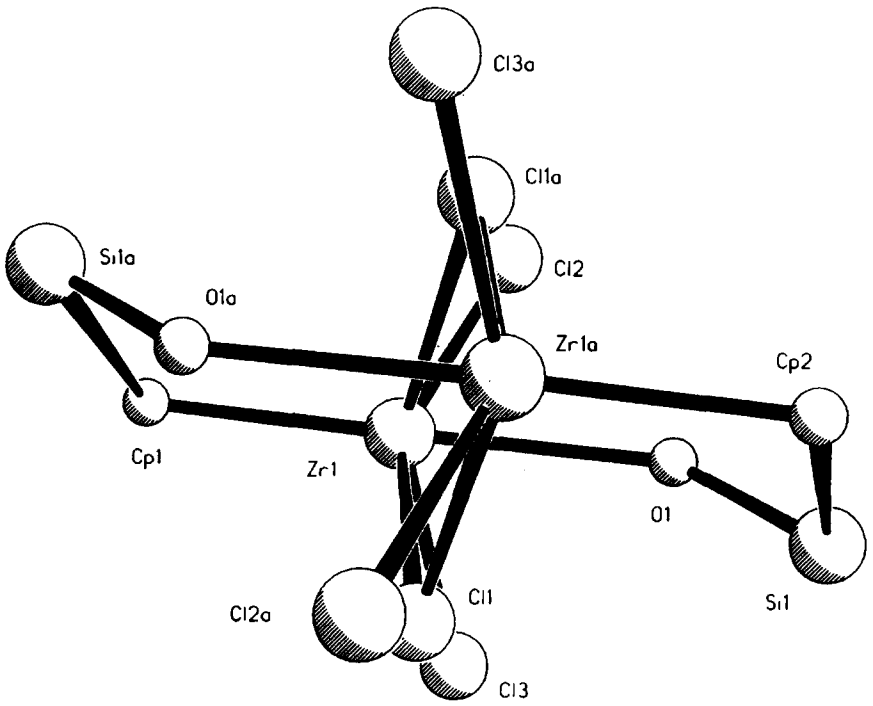

Fig. 3. "Chair-conformation" view of the eight-membered core found in compound **11**.

NMR at 300MHz, ^{13}C NMR at 75 MHz) spectrometer and chemical shifts are referenced to TMS via residual protons (^{1}H) or the carbon resonances (^{13}C) of the solvent.

Synthesis of $Ti(\eta^5\text{-}C_5H_5)(\eta^5\text{-}C_5H_4SiMe_2Cl)Cl_2$ (**3**)

A mixture of **1** (4.7 g, 15.1 mmol) and $Tl(C_5H_5)$ (4.1 g, 15.2 mmol) in 100 ml of toluene was refluxed for 5 h. A deep red solution was formed. The reaction mixture was filtered and the residue washed with dichloromethane (2 × 25 ml). The solutions were combined and solvent was removed *in vacuo*. The resulting crystalline solid was washed with cold hexane (2 × 50 ml) and dried under vacuum to obtain a red powder identified as **3** (4.2 g, 12.3 mmol, 82% yield). Anal. cald. for $C_{12}H_{15}Cl_3SiTi$: C: 42.20; H: 4.43. Found: C: 42.84; H: 4.36. ^{1}H NMR ($CDCl_3$): δ 0.74 (s, 6H, $SiMe_2$); 6.59 (s, 5H, C_5H_5); 6.61 (m, 2H, C_5H_4); 6.89 (m, 2H, C_5H_4). ^{1}H NMR (C_6D_6): δ 0.76 (s, 6H, $SiMe_2$): 5.65 (m, 2H, C_5H_4); 5.92 (s, 5H, C_5H_5) 6.42 (m, 2H, C_5H_4). $^{13}C\{^{1}H\}$ NMR ($CDCl_3$): δ 3.2 ($SiMe_2$); 119.7, 129.0 ($C_{2\text{-}5}$, C_5H_4); 120.6 (C_5H_5); 128.0 (C_{ipso}, C_5H_4). MS: *m/z* [assignment, R_{int} (%)]: 342 [M^+, 2]; 327 [$(M\text{-}CH_3)^+$, 1]; 305 [$(M\text{-}Cl)^+$, 12]; 277 [$(M\text{-}C_5H_5)^+$, 100]; 122 [$(C_5H_4SiMe_2)^+$, 92].

Synthesis of $Ti(\eta^5\text{-}C_5H_4SiMe_3)(\eta^5\text{-}C_5H_4SiMe_2Cl)Cl_2$ (**4**)

The same procedure described to prepare complex **3** using **1** (3.8 g, 12.2 mmol) and $Tl(C_5H_4SiMe_3)$ (4.2 g, 12.3 mmol) gave **4** as a reddish-brown powder (4.5 g, 10.9 mmol, 89% yield). Anal. cald. for $C_{15}H_{23}Cl_3Si_2Ti$: C: 43.54; H: 5.60. Found: C: 43.41; H: 5.50. ^{1}H NMR ($CDCl_3$): δ 0.27 (s, 9H, $SiMe_3$); 0.75 (s, 6H, $SiMe_2$); 6.56 (m, 2H, C_5H_4); 6.60 (m, 2H, C_5H_4); 6.81 (m, 4H, C_5H_4). ^{1}H NMR (C_6D_6): δ 0.28 (s, 9H, $SiMe_3$); 0.80 (s, 6H, $SiMe_2$); 5.74 (m, 2H, C_5H_4); 5.84 (m, 2H, C_5H_4); 6.37 (m, 2H, C_5H_4); 6.47 (m, 2H, C_5H_4). $^{13}C\{^{1}H\}$ NMR ($CDCl_3$): δ 0.0 ($SiMe_3$); 3.3 ($SiMe_2$); 118.2, 120.3, 129.8, 130.0 ($C_{2\text{-}5}$, C_5H_4); 128.3, 133.6 (C_{ipso}, C_5H_4). Synthesis of $Zr(\eta^5\text{-}C_5H_5)(\eta^5\text{-}C_5H_4SiMe_2Cl)Cl_2$ (**5**)

A mixture of **2** (10.6 g, 29.8 mmol) and $Tl(C_5H_5)$ (8.1 g, 30 mmol) in 200 ml of toluene was refluxed for 5 h. A colourless solution was formed. After filtration, the residue was washed with dichloromethane (2 × 75 ml). The solutions were combined and solvent was removed *in vacuo*. The resulting crystalline solid was washed with cold hexane (2 × 75 ml) and dried under vacuum to obtain an off-white powder identified as **5** (9.6 g, 27 mmol, 84% yield). Anal. cald. for $C_{12}H_{15}Cl_3SiZr$: C: 37.45; H: 3.93. Found: C: 37.30; H: 3.98. ^{1}H NMR ($CDCl_3$): δ 0.73 (s, 6H, $SiMe_2$); 6.49 (s, 5H, C_5H_5); 6.57 (m, 2H, C_5H_4); 6.79 (m, 2H, C_5H_4). ^{1}H NMR (C_6D_6): δ 0.67 (s, 6H, $SiMe_2$); 5.77 (m, 2H, C_5H_4); 5.91 (s, 5H, C_5H_5) 6.34 (m, 2H, C_5H_4). $^{13}C\{^{1}H\}$ NMR ($CDCl_3$): δ 3.1 ($SiMe_2$); 116.3 (C_5H_5); 117.0, 125.2 ($C_{2\text{-}5}$, C_5H_4); 121.7 (C_{ipso}, C_5H_4). MS: *m/z* [assignment, R_{int} (%)]: 384 [M^+, 4]; 369 [$(M\text{-}CH_3)^+$, 1]; 349 [$(M\text{-}Cl)^+$, 9]; 319 [$(M\text{-}C_5H_5)^+$, 100]; 122 [$(C_5H_4SiMe_2)^+$, 67].

Synthesis of $Zr(\eta^5\text{-}C_5H_4SiMe_3)(\eta^5\text{-}C_5H_4SiMe_2Cl)Cl_2$ (**6**)

The same procedure described to prepare complex **5** using **2** (5.3 g, 14.9 mmol) and $Tl(C_5H_4SiMe_3)$ (5.1 g, 14.9 mmol) gave **6** as an off-white powder (5.7 g, 12.4 mmol, 84% yield). Anal. cald. for $C_{15}H_{23}Cl_3Si_2Zr$: C: 39.41; H: 5.07. Found: C: 39.84; H: 5.19. ^{1}H NMR ($CDCl_3$): δ 0.28 (s, 9H, $SiMe_3$); 0.73 (s, 6H, $SiMe_2$); 6.53 (m, 4H, C_5H_4); 6.69 (m, 2H, C_5H_4); 6.74 (m, 2H, C_5H_4). ^{1}H NMR (C_6D_6): δ 0.28 (s, 9H, $SiMe_3$); 0.73 (s, 6H, $SiMe_2$); 5.83 (m, 2H, C_5H_4); 5.90 (m, 2H, C_5H_4); 6.34 (m, 2H, C_5H_4); 6.41 (m, 2H, C_5H_4). $^{13}C\{^{1}H\}$ NMR ($CDCl_3$): δ 0.0 ($SiMe_3$); 3.1($SiMe_2$); 115.8, 116.5, 125.8, 126.1 ($C_{2\text{-}5}$, C_5H_4); 121.7, 127.1 (C_{ipso}, C_5H_4). MS: *m/z* [assignment, R_{int} (%)]: 456 [M^+, 1]; 441 [$(M\text{-}CH_3)^-$, 30]; 421 [$(M\text{-}Cl)^+$, 4]; 319 [$(M\text{-}C_5H_4SiMe_3)^+$, 41]; 122 [$(C_5H_4SiMe_2)^+$, 100].

Synthesis of $[Ti(\eta^5\text{-}C_5H_5)Cl_2]_2[(\mu\text{-}\eta^5\text{-}\eta^5\text{-}C_5H_4SiMe_2)_2O]$ (**7**)

Distilled water (174 μl, 9.7 mmol) was added to 150 ml of dry toluene. This mixture was stirred for 15 h and then **3** (3.3 g, 9.7 mmol) was dissolved in portions. The reaction mixture was stirred at room temperature for 3 days. During the course of the reaction, a red crystalline solid formed which was collected by filtration, washed with both cold toluene (15 ml) and hexane (2 × 30 ml) and dried under vacuum at 110°C for 2 h to give **7** (1.6 g, 2.5 mmol, 53% yield based on starting complex **3**). Anal. cald. for $C_{24}H_{30}Cl_4OSi_2Ti_2$: C: 45.88; H: 4.81. Found: C: 46.42; H: 4.77. ^{1}H NMR ($CDCl_3$): δ 0.35 (s, 12H, $SiMe_2$); 6.56 (s, 10H, C_5H_5); 6.58 (m, 4H, C_5H_4); 6.88 (m, 4H, C_5H_4). $^{13}C\{^{1}H\}$ NMR ($CDCl_3$): δ 2.0 ($SiMe_2$); 120.4 (C_5H_5); 121.0, 129.2 ($C_{2\text{-}5}$, C_5H_4); 129.3 (C_{ipso}, C_5H_4). MS: *m/z* [assignment, R_{int} (%)]: 628 [M^+, not observed]; 378 [$(M\text{-}Cp_2TiCl_2)^+$, 14]; 343 [$(M\text{-}Cp_2TiCl_2\text{-}Cl)^+$, 9]; 248 [$(Cp_2TiCl_2)^+$, 23]; 183 [$(CpTiCl_2)^+$, 100]; 122 [$(C_5H_4SiMe_2)^+$, 41].

Synthesis of $[Ti(\eta^5\text{-}C_5H_4SiMe_3)Cl_2]_2[(\mu\text{-}[\eta^5\text{-}\eta^5\text{-}C_5H_4SiMe_2)_2O]$ (**8**)

The same procedure described to prepare complex **7** using **4** (2.9 g, 7.0 mmol) and distilled water (126 μl,

7.0 mmol) gave **8** as a microcrystalline red solid (1.3 g, 1.7 mmol, 49% yield based on starting complex **4**). Anal. cald. for $C_{30}H_{46}Cl_4OSi_4Ti_2$: C: 46.63; H: 6.00. Found: C: 46.23; H: 5.79. ^{1}H NMR ($CDCl_3$): δ 0.27 (s, 18H, $SiMe_3$); 0.35 (s, 12H, $SiMe_2$); 6.52 (m, 4H, C_5H_4); 6.58 (m, 4H, C_5H_4); 6.77 (m, 4H, C_5H_4); 6.81 (m, 4H, C_5H_4). ^{1}H NMR (CD_2Cl_2): δ 0.28 (s, 18H, $SiMe_3$); 0.36 (s, 12H, $SiMe_2$); 6.55 (m, 4H, C_5H_4); 6.60 (m, 4H, C_5H_4); 6.77 (m, 4H, C_5H_4); 6.80 (m, 4H, C_5H_4). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 0.0 ($SiMe_3$); 2.1 ($SiMe_2$); 119.7, 120.0, 129.8, 130.2 (C_{2-5}, C_5H_4); 129.3, 133.2 (C_{ipso}, C_5H_4). MS: *m/z* [assignment, R_{int} (%)]: 772 [M^+, not observed]; 392 {[($C_5H_4SiMe_3)_2TiCl_2]^+$, 2}; 378 {[M-($C_5H_4SiMe_3)_2TiCl_2]^+$, 100}; 343 {[M-($C_5H_4SiMe_3)_2TiCl_2$-Cl]$^+$, 26}; 255 [($C_5H_4SiMe_3$)$TiCl_2^+$, 36]; 122 [($C_5H_4SiMe_2$)$^+$, 38].

Synthesis of [Ti(η^5-$C_5H_4SiMe_2Cl$)Cl_2]$_2$(μ-O) (**9**)

A suspension of anhydrous LiOH (93 mg, 3.8 mmol) and NEt_3 (0.53 ml, 3.8 mmol) was added to a solution of **1** (1.2 g, 3.8 mmol) in 50 ml of toluene. The reaction mixture was allowed to stir at room temperature for 20 h and then filtered. Solvent was completely removed from the resulting orange-yellow solution *in vacuo* to give **10** as a yellow solid which was further purified by recrystallization from a mixture of toluene (20 ml) and hexane (40 ml) at -40°C (0.46 g, 0.8 mmol, 42% yield based on starting complex **1**). Anal. cald. for $C_{14}H_{20}Cl_6OSi_2Ti_2$: C: 29.55; H: 3.54. Found: C: 29.90; H: 3.52. ^{1}H NMR ($CDCl_3$): δ 0.46 (s, 12H, $SiMe_2$); 7.06 (m, 4H, C_5H_4); 7.22 (m, 4H, C_5H_4). ^{1}H NMR (C_6D_6): δ 0.29 (s, 12H, $SiMe_2$); 6.22 (m, 4H, C_5H_4); 6.64 (m, 4H, C_5H_4). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 1.3 ($SiMe_2$); 126.4, 129.1 (C_{2-5}, C_5H_4); 139.3 (C_{ipso}, C_5H_4). MS: *m/z* [assignment, R_{int} (%)]: 568 [M^+, not observed]; 553 [(M-CH_3)$^+$, 3]; 277 [($C_5H_4SiMe_2TiCl_2$)$^+$, 75]; 122 [($C_5H_4SiMe_2$)$^+$, 100]. IR (KBr, cm^{-1}): ν(Ti—O—Ti) = 798.

Synthesis of Ti($\eta^5C_5H_4SiMe_2OSiPh_2$-$\eta^1$-O)$Cl_2$ (**10**)

To a cooled (-60°C) suspension of **1** (2.0 g, 6.4 mmol) in 100 ml of hexane, a suspension of $SiPh_2(OH)_2$ (1.39 g, 6.4 mmol) and NEt_3 (1.77 ml, 12.8 mmol) was added. The cold bath was allowed to warm to room temperature and the reaction mixture was stirred overnight and then filtered. The resulting solution was concentrated *in vacuo* to 10 ml and stored overnight at -30°C to obtain yellow needles identified as **9**. The product was further purified by recrystallization from hexane (1.3 g, 2.9 mmol, 45% yield). Anal. cald. for $C_{19}H_{20}Cl_2O_2Si_2Ti$: C: 50.12; H: 4.43. Found: C: 50.14; H: 4.75. ^{1}H NMR ($CDCl_3$): δ 0.48 (s, 6H, $SiMe_2$); 6.75 (m, 2H, C_5H_4); 7.13 (m, 2H, C_5H_4); 7.37–7.41 (m, 6H, Ph); 7.62–7.65 (m, 4H, Ph). ^{1}H NMR (C_6D_6): δ 0.17 (s, 6H, $SiMe_2$); 6.26 (m, 2H, C_5H_4); 6.50 (m, 2H, C_5H_4); 7.13–7.15 (m, 6H, Ph); 7.76–7.80 (m, 4H, Ph). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 0.1 ($SiMe_2$); 125.3, 125.6 ($C_{2\ 5}$, C_5H_4); 128.0, 130.8, 134.2 (C_{ortho}, C_{meta}, C_{para}, Ph); 130.3 (C_{ipso}, C_5H_4); 133.0 (C_{ipso}, Ph). MS: *m/z* [assignment, R_{int} (%)]: 454 [M^+, 13]; 439 [(M-CH_3)$^+$, 23]; 377 [(M-Ph)$^+$, 50]; 300 [(M-2Ph)$^+$, 52].

Synthesis of [Zr{η^5-$C_5H_4SiMe_2$(μ-OH)}(μ-Cl)Cl_2]$_2$ (**11**)

Distilled water (0.1 ml, 5.6 mmol) was added to 50 ml of dry toluene. This mixture was stirred for 15 h and after this time this solution was added dropwise over a period of 2 h to a solution of **2** (2.0 g, 5.6 mmol) in 200 ml of dry toluene cooled to 0°C. The reaction mixture was stirred at room temperature overnight. During the course of the reaction, off-white crystals formed (some of them suitable for X-ray crystallographic analysis) which were collected by filtration, washed with dichloromethane (50 ml) and hexane (2 × 50 ml) and dried under vacuum to give **11** (0.9 g, 1.3 mmol, 47% yield). Anal. cald. for $C_{14}H_{22}Cl_6O_2Si_2Zr_2$: C: 24.96; H: 3.29. Found: C: 24.49; H: 3.32. IR (KBr, cm^{-1}): ν(Si—OH) = 3604. NMR data are not reported because the product was insoluble in common deuterated solvents.

Crystal structure determination of [Zr{η^5-C_5H_4Si Me_2(μ-OH)}(μ-Cl)Cl_2]$_2$ (**11**)

Off-white crystals of compound **11** were obtained by crystallization from dry toluene and a suitable sized crystal was mounted in a Lindemann tube and mounted in an Enraf-Nonius CAD 4 automatic four-circle difractometer with graphite monochromated Mo–K_α radiation (λ = 0.71073 Å). Crystallographic and experimental details are summarized in Table 2. Data were collected at room temperature. Intensities were corrected for Lorentz and polarization effects in the usual manner. No absorption or extintion correction were made. The structure was solved by direct methods (SHELXL 90) [28] and refined by least squares against F^2 (SHELXL 93) [29]. All non-hydrogen atoms were refined anisotropically, and the hydrogen atoms were introduced from geometrical calculations and refined using a riding model with thermal parameters equivalent to those of the atoms to which they are bonded. The hydrogen atom of the hydroxo group was not included. Calculations were carried out on an ALPHA AXP(Digital) workstation.

Supplementary material—A list of the positional parameters and their standard deviations, a complete list of bond lengths and angles, anisotropic displacement parameters, the calculated fractional coordinates of the hydrogen atoms and a list of observed and calculated structure factors are available from author T. C. upon request.

Acknowledgments—We are grateful to the DGICYT (Project PB-92-0178-C) and University of Alcalá for financial support

Table 2. Crystal, experimental data and structure refinement procedures for compound **11**

Formula	$C_{14}H_{22}Cl_6O_2Si_2Zr_2$
Crystal habit	Prismatic
Color	white
Crystal size	$0.25 \times 0.30 \times 0.35$mm
Symmetry	Monoclinic, $P2_1/a$
Unit cell dimensions	
a (Å)	8.767(1)
b (Å)	16.115(1)
c (Å)	9.1480(1)
β (°)	115.71(1)
V, Å^3	1164.4(2)
Z	4
D_{calc}, g cm^{-3}	1.915
M_w	335.82
$F(000)$	660
μ, cm^{-1}	16.946
Scan mode	$\omega/2\theta$ $2.47 < \theta < 28.18$
No. of reflections	
Measured	3095
Independent observed	2863 ($R_{int} = 0.0190$)
Range of h, k, l	$-11 < h < 0, -21 < k < 0, -12 < l < 12$
Standard reflections	3 every 200 refl.
Refinement method	Full matrix least squares on F^2.
Final R indices ($I > 2\sigma(I)$)[a]	$R_1 = 0.0330, wR_2 = 0.0749$
R indices (all data)	$R_1 = 0.0514, wR_2 = 0.1117$
Weighting scheme	calc. $\omega = 1/[\sigma^2(F_o^2) + (0.0846P)^2 + 10.1458P]'$ where $P = (F_o^2 + 2F_c^2)/3$
Max peak in final diff. map (e/Å3)	0.975
Min peak in final diff. map (e/Å3)	−0.753
Goodness-of-fit on F^2	0.537

[a] $R_1 = \Sigma\|F_o| - |F_c|/\Sigma|F_o|$; $wR_2 = \{[\Sigma\omega(F_o^2 - F_c^2)]/[\Sigma\omega(F_o^2)^2]\}^{1/2}$.

of this research. S.C. acknowledges the MEC for providing a fellowship. A.M. is grateful to the Consejería Educación (CAM) for a fellowship.

(Received 15 October 1997; accepted 14 November 1997)

Abstract—Addition of an excess hexamethylphosphoric triamide (abbr. HMPA) to a neutral complex $SmI(\eta^8\text{-}C_8H_8)(thf)$ (**1**) (C_8H_8 = 1,3,5,7-cyclooctatetraene), which was prepared by a direct reaction of metallic samarium with C_8H_8 in the presence of iodine in THF, afforded a cationic samarium complex $[Sm(\eta^8\text{-}C_8H_8)(hmpa)_3]I$ (**2**). Complex **2** can also be prepared by a simple one-pot reaction of stoichiometric amounts of metallic samarium, cyclooctatetraene, and iodine in the presence of an excess HMPA at 50°C. With a catalytic amount of iodine, ionic complexes of general formula $[Ln(\eta^8\text{-}C_8H_8)(hmpa)_n][Ln(\eta^8\text{-}C_8H_8)_2]$ [Ln = La and n = 4 (**6**); Ln = Sm and n = 3 (**7**)] were obtained by treating metallic lanthanum or samarium, respectively, with cyclooctatetraene in the presence of HMPA. The structure of the diamagnetic complex **6** as well as the paramagnetic complexes **2** and **7** was determined by ^1H NMR spectroscopy. Crystal structures of **2** and **7** were revealed by X-ray analyses, indicating that these complexes comprised of a cationic $[Sm(\eta^8\text{-}C_8H_8)(hmpa)_3]^+$ and an anionic part; for **2** and **7** being I^- and $[Sm(\eta^8\text{-}C_8H_8)_2]^-$, respectively. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: lanthanum; samarium; cyclooctatetraene; hexamethylphosphoric triamide; cationic complex; anionic complex; sandwich complex; half-sandwich complex.

Dianion of 1,3,5,7-cyclooctatetraene ($C_8H_8^{2-}$) is one of the aromatic cyclic hydrocarbons. This dianion has attracted less interest as the unique π-conjugated multicenter ligand for organometallic complexes, though cyclopentadienyl ligand ($C_5H_5^-$) and its derivatives have been utilized as the unique and versatile ligands for a wide variety of organometallic complexes including organolanthanoid complexes [1]. The size of the dianion ligand is larger than that of cyclopentadienyl, and thus this ligand is expected to have the capability of suitably coordinating to highly electropositive lanthanide elements, producing various mono- and bis-cyclooctatetraenyl-lanthanoid complexes [2–4]. These complexes have so far been classified into three categories (1) the half sandwich type $Ln(\eta^8\text{-}C_8H_8)XL_n$, (2) the cationic half sandwich type $[Ln(\eta^8\text{-}C_8H_8)L_n]^+$, and (3) the anionic sandwich type $[Ln(\eta^8\text{-}C_8H_8)_2]^-$. These complexes have been mostly prepared by the metathesis reaction of lanthanoid halides with alkali compounds such as $K_2(C_8H_8)$. The isolation of the product from the resulting salt has been difficult and hampered due to the strong interaction between the salt and the organolanthanoid complexes. The salt-

free method (oxidative reaction of low-valent organolanthanoid complexes [5–11], the reaction of metallic lanthanoid with organomercury compounds [12–16], and so on) has been developed recently by several research groups. We have developed a more convenient synthetic method, i.e., the reaction of metallic lanthanoid with oxidant which gives simple crystallization affording pure compounds in modest yields [17–23].

As an extension of our synthetic strategy, we report on the synthesis of a cationic monocyclooctatetraenyl lanthanoid complex $[Sm(\eta^8\text{-}C_8H_8)(hmpa)_3]I$ (**2**) and ionic complexes of general formula $[Ln(\eta^8\text{-}C_8H_8)(hmpa)_n][Ln(\eta^8\text{-}C_8H_8)_2]$, [Ln = La and $n = 4$ (**6**); Ln = Sm and $n = 3$ (**7**)] which were derived from metallic lanthanoids and cyclooctatetraene in the presence of HMPA with a stoichiometric or a catalytic amount of iodine. Crystal structures of **2** and **7** comprised of a cationic $[Sm(\eta^8\text{-}C_8H_8)(hmpa)_3]^+$ and an anionic part; and for **2** and **7**, I^- and $[Sm(\eta^8\text{-}C_8H_8)_2]^-$, respectively, were characterized crystallographically.

RESULTS AND DISCUSSION

Synthesis of cationic cyclooctatetraenyl-lanthanoid complexes

We have previously reported that the reaction of metallic samarium with equimolar amounts of cyclooctatetraene and iodine in THF resulted in the quantitative formation of a violet complex, which became opaque under the flow of argon, indicating that the THF ligand is labile, and readily released under reduced pressure to give $(\eta^8\text{-}C_8H_8)SmI(thf)$ (**1**) (eqn (1)) [17,19]; in accordance with the lability of the THF ligand of a samarocene complex $Cp^*_2Sm(thf)_2$ which gives Cp^*_2Sm in high vacuum [24]. Hexamethylphosphoric triamide (= HMPA) is known to be much stronger donor ligand and sometimes causes the cleavage of the Ln—X bond to give a cationic lanthanoid complexes; e.g., $[Yb(hmpa)_4(thf)_2]I_2$ [25], $[\{Yb(hmpa)_3\}(\mu\text{-}SPh)_3\{Yb(hmpa)_3\}][SPh]$ [23], and $[Ln(Spy)_2(hmpa)_3]I$ (Ln = Pr, Nd, Sm, Eu, Er, Yb) [22]. Thus, addition of HMPA to a THF solution of **1** gave rise to a cationic complex $[(\eta^8\text{-}C_8H_8)Sm(hmpa)_3]^+I^-$ (**2**) (eqn (2)). It is tempting to speculate that the reactions depicted in eqns (1) and (2) proceeded in one-pot; this was the case that a reaction mixture involving equimolar amounts of metallic samarium, cyclooctatetraene, and iodine in the presence of an excess HMPA, resulted in the formation of **2** in 34% yield.

$$\mathrm{Sm\,(metal)} + C_8H_8 + 1/2\,I_2 \xrightarrow[\mathrm{THF}]{} (\eta^8\text{-}C_8H_8)SI(thf) \quad \textbf{(1)}$$

$$\mathbf{1} + \mathrm{ex.\ HMPA} \xrightarrow[\mathrm{THF}]{} [(\eta^8\text{-}C_8H_8)Sm(hmpa)_3]I \quad (2)$$

2

The ^1H NMR spectrum of **2** in THF-d_8 displayed a singlet at δ 10.7 due to a dianionic C_8H_8 ligand together with a broad resonance around δ 2.58 assignable to the HMPA ligand. Although chemical shift values of paramagnetic lanthanide complexes depend on the condition, especially the concentration and the temperature, the chemical shift value of $\eta^8\text{-}C_8H_8$ of **2** is comparable to that found for Sm(III)—C_8H_8 complexes such as **1** (δ 12.4) [17,19], $([Sm(\mu\text{-}SC_6H_5)(\eta^8\text{-}C_8H_8)(thf)_2]_2$ (**3**) (δ 11.2) [18,19], $[Sm(\mu\text{-}SeC_6H_5)(\eta^8\text{-}C_8H_8)(thf)_2]_2$ (**4**) (δ 11.5) [18], and $[Sm(\mu\text{-}SC_6H_2Pr^i_3\text{-}2,4,6)(\eta^8\text{-}C_8H_8)(thf)]_2$ (**5**) (δ 11.3) [18,19].

These Sm(III)-calcogenolate complexes **3** and **4** together with $[(\eta^8\text{-}C_8H_8)CeCl(thf)_2]_2$ [26], $(\eta^8\text{-}C_8H_8)CeI(thf)_3$ [19], and $(\eta^8\text{-}C_8H_8)Sm(Spy)(hmpa)_2$ [27] adopt four-legged piano-stool geometry, whereas **5** [18,19] and $(\eta^8\text{-}C_8H_8)Yb(py)_3$ [28] have been crystallographically determined to have three-legged piano-stool geometry. On the basis of integration ratio (approximately 8 : 54) of protons due to one $\eta^8\text{-}C_8H_8$ and three HMPA ligands, respectively, three HMPA ligands presumably coordinated to the samarium center, corresponding to the neutral formulation of $(\eta^8\text{-}C_8H_8)SmI(hmpa)_3$ as opposed to a cationic formulation of **2**, which ultimately determined by X-ray crystallography (*vide infra*), it thus was difficult to assign the ^1H NMR spectrum of **2** to a cationic HMPA complex of Sm(III).

Cationic lanthanide(III) complexes of general formula $[Ln(\eta^8\text{-}C_8H_8)(hmpa)_n][Ln(\eta^8\text{-}C_8H_8)_2]$ [Ln = La and $n = 4$ (**6**); Ln = Sm and $n = 3$ (**7**)] were prepared in modest yields by the direct reaction of metallic lanthanoid with C_8H_8 in the presence of catalytic amounts of iodine (for activating lanthanide metal) and an excess HMPA at 50°C for several days (eqn (3)). Once isolated as crystals, complexes **6** and **7** have very low solubility in common organic solvents such as toluene or THF.

$$2\,\mathrm{Ln\,(metal)} + 3\,C_8H_8 + \mathrm{ex.\ HMPA} \xrightarrow[\mathrm{THF}]{} [Ln(\eta^8\text{-}C_8H_8)(hmpa)_n][Ln(\eta^8\text{-}C_8H_8)_2] \quad (3)$$

6 Ln = La; $n = 4$

7 Ln = Sm; $n = 3$

Structure of **6** made of a cationic $[La(\eta^8\text{-}C_8H_8)(hmpa)_4]^+$ and an anionic $[La(\eta^8\text{-}C_8H_8)_2]^-$ can be determined on the basis of ^1H NMR spectroscopy, while that of complex **7** comprised of a cationic $[Sm(\eta^8\text{-}C_8H_8)(hmpa)_3]^+$ and an anionic $[Sm(\eta^8\text{-}C_8H_8)_2]^-$ was characterized by ^1H NMR spectroscopy together with an X-ray crystallographic study (*vide infra*). The ^1H NMR spectrum of **6** in THF-d_8 displayed two singlet resonances due to two kinds of C_8H_8 ligands at δ 6.17 and 5.74 in the ratio of 1 : 2; thus these corresponded to the cationic and anionic parts, respectively. In addition to the signals of the C_8H_8 ligands, a broad singlet was observed at δ 2.44 due to the four HMPA molecules coordinated to the

lanthanum center of the cationic part. In contrast to the formulation of the complex **6**, the cationic center of the complex **7** has three HMPA ligands; the ^{1}H NMR spectrum of **7** in THF-d_8 exhibited a rather broad singlet of the HMPA ligands around δ 2.28 together with two singlets at δ 13.2 and 10.1 due to two kinds of C_8H_8 protons. The different number of the coordinated HMPA ligands between **6** and **7** might be attributed to the difference of ionic radii; larger lanthanum(III) center (1.061 Å) [29] can accept four HMPA ligands but smaller samarium(III) center (0.964 Å) [29] favors a three-legged piano-stool geometry as determined by X-ray analysis (*vide infra*).

Molecular structures of $[Sm(\eta^8\text{-}C_8H_8)(hmpa)_3]I$ **(2)** *and* $[Sm(\eta^8\text{-}C_8H_8)(hmpa)_3][Sm(\eta^8\text{-}C_8H_8)_2]$ **(7)**

The molecular structures of **2** and **7** are shown in Figs 1 and 2, and the selected bond distances and angles are listed in Table 2. Complexes **2** and **7** have the ionic structure composed of a cationic $[Sm(\eta^8\text{-}C_8H_8)(hmpa)_3]^+$ and an anionic part, I^- for **2** and $[Sm(\eta^8\text{-}C_8H_8)_2]^-$ for **7**. There is no significant interaction between the cationic and the anionic moieties in both of **2** and **7**. To the best of our knowledge, these are the first examples of the discrete cationic monocyclooctatetraenyl-lanthanoid complexes. though a unique dimeric complex of $[Nd(\eta^8\text{-}C_8H_8)(thf)_2]^+(\mu\text{-}\eta^2:\eta^8\text{-}(C_8H_8))[Nd(\eta^8\text{-}C_8H_8)]^-$, in which two carbon atoms of one cyclooctatetraenyl ligand of $[Nd((\eta^8\text{-}C_8H_8)_2]^-$ coordinates to the neighboring cationic monocyclooctatetraenyl Nd center in $[Nd(\eta^8\text{-}C_8H_8)(thf)_2]^+$, has been reported previously [30,31].

In each cationic part of **2** and **7**, the dianionic planar C_8H_8 rings coordinate to the samarium in η^8 fashion, and thus each samarium metal adopts the three-legged piano-stool geometry surrounded with three HMPA molecules. The distance (1.95 Å for both of **2** and **7**) between samarium and the centroid of the C_8H_8 ring is not exceptional; being comparable to that of monocyclooctatetraenyl-Sm(III) complexes such as **3** (1.97 Å) [19], **4** (1.94 Å) [19], **5** (1.90 Å) [19], $Sm(\eta^5\text{-}NC_4H_2Bu^t_2\text{-}2,5)(\eta^8\text{-}C_8H_8)(thf)$ (1.913(3) Å) [32], and $Sm(\eta^8\text{-}C_8H_8)(\eta^5\text{-}C_5H_4PPh_2)$ (1.984 Å) [33]. As normal as expected for ionic complexes, the average distance (1.975 Å) between samarium metal and the centroid of the C_8H_8 ring in the anionic part of **7** is comparable to that found in the cationic part of **7** (1.95 Å) and a samarium(III) complex $[Li(thf)_2\{\mu\text{-}(\eta^2:\eta^8\text{-}C_8H_8)\}Sm\{CH(SiMe_3)_2\}_2]$ (1.969(1) Å) [34],

and also is comparable to that found for anionic sandwich complexes of formula $[Ln(\eta^8\text{-}C_8H_8)_2]^-$ such as $[Li(thf)_4][Ce(III)(\eta^8\text{-}C_8H_8)_2]$, (2.043 Å) [35], $[(\eta^8\text{-}C_8H_8)Er(\mu\text{-}\eta^8\text{-}C_8H_8)K(\mu\text{-}\eta^8\text{-}C_8H_8)Er(\mu\text{-}\eta^8\text{-}C_8H_8)K(thf)_4]$ [36], and $[K(C_4H_{10}O_2)][Yb(II)(\eta^8\text{-}C_8H_8)_2]^-$ (2.03 Å) ($C_4H_{10}O_2$ = dimethoxyethane) [37,38], which are characterized crystallographically, on taking into account the difference of ionic radii of Ln metal.

The Sm—O(hmpa) distances of **2** (av 2.31(1) Å) and **7** (av 2.331(4) Å) are comparable to that of HMPA-samarium(III) complexes, e.g., $Sm(SPh)_3(hmpa)_3$ (av 2.299(4) Å) [23], $SmI_3(hmpa)_2(H_2O)_5$ (av 2.253(4) Å) [39], and $SmI_3(hmpa)_3(H_2O)_4$ (av 2.297(4) Å) [39], but shorter than that found for a HMPA-Sm(II) complex $SmI_2(hmpa)_4$ (av 2.500(6) Å) [[25]; the observed different distances found for Sm(II) and Sm(III) complexes can be explained on taking account the difference of ionic radii of Sm(II) and Sm(III) (0.19–0.20 Å for Sm(II/III)) [40].

CONCLUSION

In this paper, we have demonstrated that the reactions of metallic lanthanum and samarium with cyclooctatetraene in the presence of an excess HMPA afforded cationic complexes **6** and **7**, respectively. Reaction of metallic samarium with stoichiometric amounts of cyclooctatetraene and iodine in the presence of an excess HMPA gave a cationic complex **2**. Both of the reactions are very convenient and rationally selective routes for the preparation of the corresponding cationic monocyclooctatetraenyl–lanthanoid compounds.

C_8H_8 presents the centroid of a cyclooctatetraenyl ligand.

EXPERIMENTAL

General procedures

All manipulations involving air- and moisture-sensitive organometallic compounds were carried out by using the standard Schlenk techniques under an argon atmosphere. THF was dried over sodium benzophenone ketyl. Hexamethylphosphoric triamide was purified by distillation after drying over CaH_2. 1,3,5,7-Cyclooctatetraene was purchased from Aldrich Chemical, Co. Inc. and used without further purification. SmI(η^8-C_8H_8)(thf) was prepared according to the literature procedure [17,19].

Nuclear magnetic resonance [^{1}H (270 MHz)] spectra were measured on a JEOL JNM-EX270 spectrometer. Elemental analyses were performed at Elemental Analysis Center, Faculty of Science, Osaka University. All melting points were measured in sealed tubes and were not corrected.

Addition of HMPA to SmI(η^8-C_8H_8)(thf) (**1**)

To a violet solution of **1** (0.17 g, 0.36 mmol) in THF (5 ml) was added HMPA (0.26 ml, 1.5 mmol) at room temperature. Rapid reaction occurred and red solids were precipitated. Recrystallization of red precipitation from THF afforded a cationic complex [Sm(η^8-C_8H_8)(hmpa)$_3$]I (**2**) (0.16 g, 49% yield) as red crystals, mp > 300°C (decomp). ^{1}H NMR (THF-d_8, 35°C): δ 10.7 (s, 8H, C_8H_8), 2.58 (brs, 54H, Me(hmpa)). Anal. Calc. for $C_{26}H_{62}IN_9O_3P_3Sm$: C, 33.98, H, 6.80, N, 13.73. Found: C, 33.82, H, 6.83, N, 13.73.

Preparation of [Sm(η^8-C_8H_8)(hmpa)$_3$]I (**2**) *from metallic samarium*

A reaction mixture of samarium metal (0.30 g, 2.0 mmol), C_8H_8 (0.22 ml, 2.0 mmol), HMPA (1.0 ml, 5.7 mmol), iodide (0.25 g, 1.0 mmol) in THF (40 ml) was stirred at room temperature for 12 h to give a red solution. Removal of insoluble impurities by centrifugation and followed by concentration afforded **2** (0.62 g, 34% yield) as red microcrystals.

Preparation of [La(η^8-C_8H_8)(hmpa)$_4$][La(η^8-C_8H_8)$_2$] (**6**)

A reaction mixture of lanthanum metal (0.42 g, 3.0 mmol), C_8H_8 (0.50 ml, 4.4 mmol), HMPA (3.0 ml, 17 mmol) and a catalytic amount of iodine in THF (40 ml) was stirred at 50°C for a period of 10 days. After removal of insoluble impurities, the resulting pale yellow solution was concentrated and then cooled to −20°C to give **6** as pale yellow crystals in a quantitative yield. ^{1}H NMR (THF-d_8, 35°C): δ 6.17 (s, 8H, C_8H_8 of a cationic part), 5.74 (s, 16H, C_8H_8 of an

anionic part), 2.44 (brs, 72H, Me(hmpa)). Complex **6** is highly air- and moisture-sensitive, and thereby the elemental analysis of **6** did not give a satisfactory result.

Preparation of $[Sm(\eta^8\text{-}C_8H_8)(hmpa)_3][Sm(\eta^8\text{-}C_8H_8)_2]$ (**7**)

A reaction mixture of samarium metal (0.30 g, 2.00 mmol), C_8H_8 (0.40 ml, 3.55 mmol), HMPA (3.0 ml, 17.2 mmol) and a catalytic amount of iodine in THF (40 ml) was stirred at 50°C for a period of 5 days to give a deep red-purple solution. Removal of insoluble impurities followed by concentration and cooling to −20°C afforded the deep red crystals of **7** (0.54 g, 47% yield), mp > 300°C (decomp). ^{1}H NMR (THF-d_8, 35°C): δ 13.2 (s, 16H, C_8H_8 of an anionic part), 10.1 (s, 8H, C_8H_8 of a cationic part), 2.28 (brs, 54H, Me(hmpa)). Complex **7** is highly air- and moisture-sensitive, and the elemental analysis of **7** did not give a satisfactory result.

Crystallographic data collections and structure determinations of **2** *and* **7**

Data collections. The crystals of **2** and **7** suitable for X-ray diffraction studies were sealed in glass capillaries under argon atmosphere, and then each crystal of the two complexes was mounted on four-circle data collection instruments (Rigaku AFC-5R for **2** and Rigaku AFC-7R for **7**) using Mo–K_α radiation (λ = 0.71069 Å). The units cell parameters at 23°C were determined by a least-squares fit to 2θ values of 25 strong higher reflections for both of the two complexes. For each complex, three standard reflections were chosen and monitored every 150 reflections. No decay correction was applied for complex **2**, while a linear correction factor was applied to the raw data (6.89% decay) for **7**. Empirical absorption corrections for both of the two complexes were carried out based on azimuthal scans. All data were corrected for Lorentz and polarization effects.

Structure determination of **2**. Measured non-equivalent reflections with $I > 3.0\sigma(I)$ were used for the structure determination. The systematic absences of $(0kl)$ with k = odd, $(h0l)$ with l = odd, and $(hk0)$ with h = odd uniquely determined the space group to be *Pbca*. The structure was solved by a heavy atom Patterson method and expanded using Fourier techniques, and refined by the full-matrix least squares method. Three carbon atoms and two nitrogen atoms of one HMPA ligand were refined isotropically, and the remaining carbon and nitrogen atoms as well as samarium, oxygen, and phosphorus atoms were refined anisotropically. In the final refinement cycle (full-matrix), hydrogen atom coordinates were included at idealized positions, and the hydrogen atoms were given the same temperature factor as that of the carbon atoms to which they were bonded. All calculations were performed using the TEXSAN crystallographic software package.

Structure determination of **7**. The systematic absences of $(h0l)$ with $h0l$ = odd and $(0k0)$ with k = odd for non-equivalent reflections with $I > 2.0\sigma(I)$ resulted in the specification to the space group $P2_1/n$. The structure was solved by a direct method (SHELX86) [41] and expanded using Fourier techniques, and refined by the full-matrix least squares method. All non-hydrogen atoms (carbon, nitrogen, oxygen, phosphorus and samarium atoms) were refined anisotropically. In the final refinement cycle (full-matrix), the H-atoms of C_8H_8 and HMPA were included in the refinement on calculated positions riding on their atoms (C—H_{sp2} = 0.93 Å, C—H_{sp3} = 0.96 Å, U_{iso} = 1.2 U_{eq} (e) Å^2).

Supplementary material—Final positional parameters, final thermal parameters, bond distances, angles, and torsion angles for the complexes **2** and **7** (45 pages) are available from author K.M. upon request.

Zirconium, hafnium and yttrium complexes containing two linked amido–tetramethylcyclopentadienyl ligands: Synthesis, reactivity and molecular structure of $Hf(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2NiPr)_2$†

Jun Okuda,* Francisco Amor, Karen E. du Plooy, Thomas Eberle, Kai C. Hultzsch and Thomas P. Spaniol

Institut für Anorganische Chemie und Analytische Chemie, Johannes Gutenberg-Universität, J.-J.-Becher-Weg 24, D-55099 Mainz, Germany

(Received 1 November 1997; accepted 24 November 1997)

Abstract—Zirconium and hafnium complexes $M(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2NR')_xCl_{(4-2x)}$ (M = Zr, Hf; x = 1, 2; R′ = *i*Pr, *t*Bu) containing one or two linked amido–tetramethylcyclopentadienyl ligands $C_5Me_4SiMe_2NR'$ have been synthesized by the reaction of the dilithium derivative $Li_2(C_5Me_4SiMe_2NR')$ with $MCl_4(THF)_2$. The crystal structure of the hafnium complex $Hf(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2NiPr)_2$ has been determined by a single-crystal X-ray diffraction study and shows a C_2-symmetric helical metallocene, in which the amido ligands are bonded as π-donor ligands with Hf—N bond lengths of 2.115(2) Å. The isoelectronic heterobimetallic yttrium complex $Li[Y(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2NCH_2CH_2OMe)_2]$ reacts with phenylacetylene to give the bis(phenylacetylide) derivative $Li[Y\{\eta^5\text{-}C_5Me_4SiMe_2NH(CH_2CH_2OMe)\}_2(C{\equiv}CPh)_2]$. © 1998 Elsevier Science Ltd. Keywords: zirconium; hafnium; yttrium; amido–cyclopentadienyl; alkynyl complex.

Homogeneous α-olefin polymerization catalysts based on titanium complexes that contain the linked amido–cyclopentadienyl ligand $C_5Me_4SiMe_2NR'$ (R′ = alkyl, aryl) have recently gained considerable technological importance through the efficient synthesis of new types of polyethylenes and copolymers with comonomers such as 1-octene and styrene [1]. The linked amido–cyclopentadienyl ligand was introduced by Bercaw and Shapiro to successfully develop the first single-component catalysts $[Sc(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2NtBu)R'']$ (R″ = H, alkyl) for the living polymerization of propylene [2]. Compared with Brintzinger-type *ansa*-metallocenes, the increased Lewis acidity together with a sterically open ligand sphere [3,4] appear to accommodate the bulkier comonomers better. In the course of synthetic and structural studies on group 4 metal complexes of general formula $M(\eta^5:\eta^1\text{-}C_5R_4SiMe_2NR')X_2$ (M = Ti, Zr, Hf; X = halide, amido, alkyl) [3,4] we have isolated and characterized several complexes containing two linked amido–cyclopentadienyl ligands with different amido and cyclopentadienyl substituents $M(\eta^5:\eta^1\text{-}C_5R_4SiMe_2NR')_2$ [3c,d]. Such compounds have attracted some attention as C_2-symmetric metallocenes and were also shown to form by aminolysis reactions [5], sometimes more reproducibly than by the salt metathesis reactions using the dianion of the ligand [6]. More recently, we have discovered that isoelectronic heterobimetallics of the general type $Li[Ln(\eta^5:\eta^1\text{-}C_5R_4SiMe_2NCH_2CH_2X)_2]$ (Ln = Y, Lu; C_5R_4 = C_5Me_4, C_5H_4, C_5H_3tBu; X = OMe, NMe_2) can be obtained when a tridentate linked amido–cyclopentadienyl ligand is used [7]. Here we describe the preparation and characterization of zirconium, hafnium, and yttrium complexes containing two amido-functionalized tetramethylcyclopentadienyl ligands $C_5Me_4SiMe_2NR'$ along with some reactivity studies.

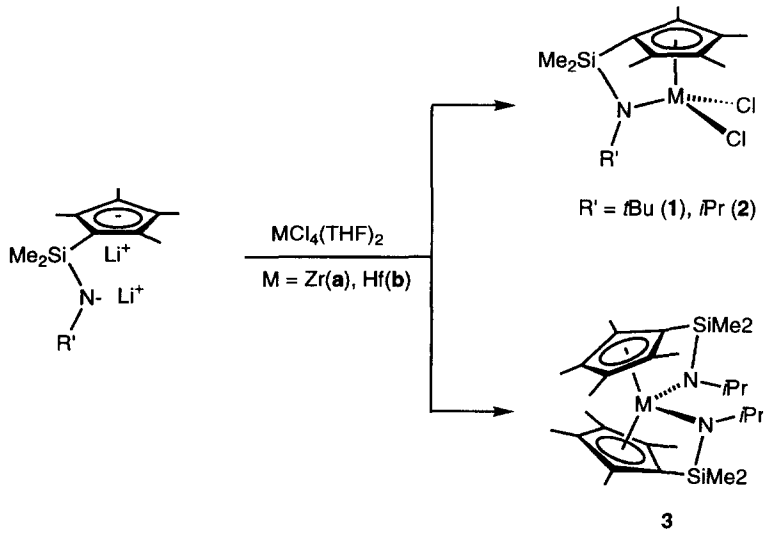
RESULTS AND DISCUSSION

As was independently noted by other authors [4–6], we too have occasionally observed the formation of group 4 metal complexes of the type $M(\eta^5:\eta^1\text{-}C_5R_4SiMe_2NR')_2$ containing two amido-functionalized cyclopentadienyl ligands $C_5Me_4SiMe_2NR'$. Generally, the larger metals, zirconium and hafnium, have a greater tendency to form such complexes than titanium. For example, for R′ = allyl and M = Zr the metallocene derivative $Zr(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2NCH_2CH{=}CH_2)_2$ is exclusively formed in the reaction of $Li(C_5Me_4SiMe_2NCH_2CH{=}CH_2)$ with $ZrCl_4(THF)_2$, whilst the reaction with $TiCl_3(THF)_3$, followed by oxidative chlorination with $PbCl_2$ results in the expected formation of the mono(ligand) complex $Ti(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2NCH_2CH{=}CH_2)Cl_2$ [3c,d]. We suspected that the nature of the amido substituent R′ may play a decisive role, and in fact, we observe no formation of the metallocene for R′ = *t*Bu, even when an excess of the dilithium salt is employed. Thus in the reaction of $Li_2(C_5Me_4SiMe_2N\textit{t}Bu)$ under various conditions and independently of the solvent only the mono(ligand) complexes $M(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2N\,\textit{t}Bu)Cl_2$ (**1**) (**a** = Zr, **b** = Hf) are detected and isolated as colourless crystals in good to moderate yields. The synthesis of the zirconium complex **1a** was previously described by Petersen *et al.* [4c]. These findings may suggest that the complexation of the amido group precedes that of the cyclopentadienyl moiety.

On the other hand, when the *iso*-propylamido ligand $Li_2(C_5Me_4SiMe_2N\textit{i}Pr)$ is employed in the complexation reaction with $MCl_4(THF)_2$, a mixture of the mono(ligand) and metallocene are formed under a variety of conditions for M = Zr. For M = Hf, the mono(ligand) complex $Hf(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2N\textit{i}Pr)Cl_2$ (**2b**) can be prepared only in toluene, whereas in THF, the metallocene $Hf(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2N\textit{i}Pr)_2$ (**3b**) is formed in moderate yields. We suspected therefore that the higher solubility of the dilithium derivative would cause higher local concentrations of the dianion leading to the preferred formation of the bis(ligand) complex. In fact, reactions in THF tend to increase the yield of the metallocene over that of the mono(ligand) complex. However, it is remarkable that the latter does not react with an excess of the dilithium derivative to give the metallocene complex, suggesting different intermediates on the way to both products. Evidently, the situation is more complicated and no conclusive explanation can be given at this time.

The significantly more soluble, C_2-symmetric metallocenes $M(\eta^5:\eta^1\text{-}C_5R_4SiMe_2NR')_2$ are easily distinguished from the C_s-symmetric mono(ligand) complexes $M(\eta^5:\eta^1\text{-}C_5R_4SiMe_2NR')Cl_2$ by the chirality which results in pairs of diastereotopic methyl resonances. One remarkable feature is the low-field shift for the methine proton that is recorded as a multiplet at δ = 4.13 and 3.99 for **3a** and **3b**, respectively. Preliminary studies reveal that the formally 20-electron metallocene $M(\eta^5:\eta^1\text{-}C_5R_4SiMe_2NR')_2$ **3a** and **b** are capable of initiating the polymerization of ε-caprolactone, albeit at much slower rates than the isolelectronic rare earth complexes $Li[Ln(\eta^5:\eta^1\text{-}C_5R_4SiMe_2NCH_2CH_2X)_2]$ also mentioned below [7].

An ORTEP diagram of the molecular structure of complex **3b** is depicted in Fig. 1. Crystallographic data are compiled in Table 1, selected bond distances and angles are listed in Table 2. The compound residing on a crystallographic C_2-axis adopts the typical bent metallocene configuration in agreement with the solution structure. The angle between the two cyclopentadienyl rings is 127.9°, similar to the values found in the literature for non-linked hafnocenes such as



Scheme 1.

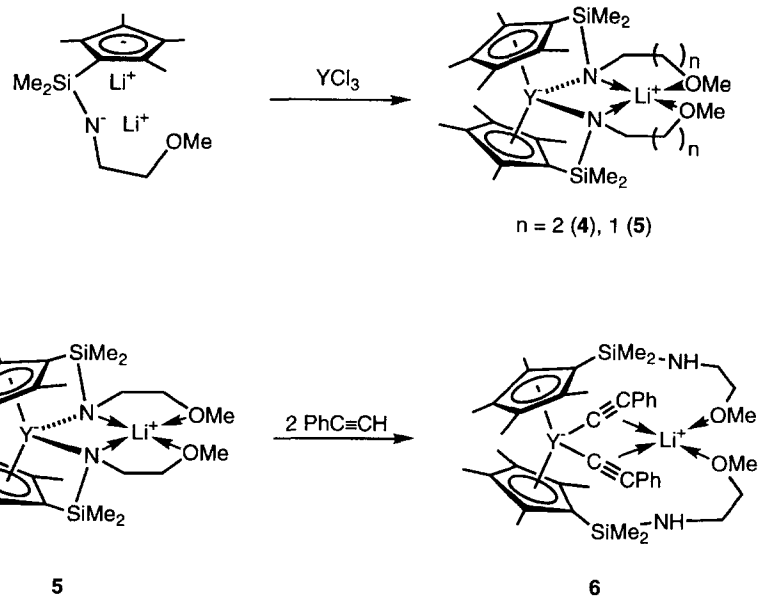
		C(13)—C(12)—C(14)	109.4(3)

$Hf(\eta^5\text{-}C_5H_5)_2(CH_2Ph)_2$ (128.2°) [8a] and $Hf(\eta^5\text{-}C_5Me_5)(\eta^5\text{-}C_5H_5)Cl_2$ (130.6°) [8b], but significantly smaller than in the decamethylhafnocene derivative $Hf(\eta^5\text{-}C_5Me_5)_2(H)(NMe_2)$ (139.1°) [9]. The distances between the hafnium center and the centroid of each five-membered ring of 2.29 Å are somewhat longer than those observed in comparable hafnocene complexes (about 2.2 Å) [8,9]. The tetramethylcyclopentadienyl ligands are bonded in a pentahapto fashion as judged by the sum of the angles at the ring (540°) and the metal to ring-carbon distances ranging from 2.476(2) to 2.698(2) Å. The angle at hafnium N—Hf—N′ is 96.2(1)°, significantly smaller than that found in $Zr(\eta^5:\eta^1\text{-}C_5H_4SiMe_2NPh)_2$ (106.5(8)°) [5a]. This can be accounted for by the presence of the bulkier phenyl rings on the amido nitrogen atoms and the possibility of gear meshing of the two *iso*-propyl groups in **3b**.

The Hf—N bond length of 2.115(2) Å is slightly longer than the Hf—N distances observed in amido complexes where the amido ligand acts as a 3-electron ligand (2.027(8) Å in $Hf(\eta^5\text{-}C_5Me_5)_2(H)(NMe_2)$ [9], 2.041(4), 2.065(3) in $Hf(\eta^5\text{-}C_5Me_5)(NiPr_2)_3$ [10a], 2.065(3) in $Hf(\eta^5:\eta^1\text{-}C_{13}Me_8SiMe_2CH_2NtBu)Cl_2$ [10b]). However, the nitrogen atom is trigonal planar, the sum of the angles at the nitrogen atom being 360°. These observations support the view that the π-electrons are delocalized over both nitrogen atoms, a feature found in the only other structurally authenticated derivative $Zr(\eta^5:\eta^1\text{-}C_5H_4SiMe_2NPh)_2$ (Zr—N bond length 2.137(2), 2.127(2) Å) [5a]. In the isoelectronic yttrium complex $Li[Y(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2NCH_2CH_2OMe)_2]$ (**5**) pyramidalization of the amido nitrogen atoms are detectable, but not particularly pronounced [7a]. According to the theoretical model by Lauher and Hoffmann for d^0-metallocenes Cp_2MX_2 containing two potential π-donors such as amido or alkoxo ligands [11], only one lone pair of electrons can be accommodated in the empty a_1 orbital of the Cp_2MX_2 unit. In some d^0-Cp_2MX_2 complexes, structural evidence for the localization of a single and double bond can be found [11,12].

Reaction of two equivalents of $Li_2(C_5R_4SiMe_2NCH_2CH_2X)$ (C_5R_4 = C_5Me_4, C_5H_4, C_5H_3tBu; X = OMe, NMe_2) with anhydrous $LnCl_3$ (Ln = Y, Lu) has been shown to give the C_2-symmetric heterobimetallic lanthanocenes $Li[Ln(\eta^5:\eta^1\text{-}C_5R_4SiMe_2NCH_2CH_2X)_2]$ in high yield, whereas in the presence of one equivalent of the dilithium salt, inseparable product mixtures are formed [7]. In order to investigate the influence of the length of the amido side chain, an additional methylene carbon was introduced. The reaction of anhydrous YCl_3 with $Li_2(C_5Me_4SiMe_2NCH_2CH_2CH_2OMe)$ gives colourless crystals of $Li[Y(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2NCH_2CH_2CH_2OMe)_2]$ (**4**) for which a C_2-symmetric heterobimetallic structure analogous to that of $Li[Y(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2NCH_2CH_2OMe)_2]$ (**5**) can be assumed based on the NMR spectroscopic data and elemental analysis.

The electronically "oversaturated" metallocene unit $[Ln(\eta^5:\eta^1\text{-}C_5R_4SiMe_2NCH_2CH_2X)_2]^-$ incorporates two π-donating amido ligands and can be assumed to show nucleophilic behaviour toward electrophiles. All heterobimetallic complexes have been



Scheme 2.

shown to be active catalysts for the polymerization of ε-caprolactone [7]. In order to prove the nucleophilicity of the amido substituents, the reaction with a weak Brönsted acid has been studied. Thus, the reaction of Li[Y(η^5 : η^1-$C_5Me_4SiMe_2NCH_2CH_2OMe)_2$] with two equivalents of phenylacetylene leads to the formation of colourless crystals of the bis (acetylide) complex Li[Y{η^5-$C_5Me_4SiMe_2NH(CH_2CH_2O$-Me)}$_2$(C≡CPh)$_2$] (**6**) with the structure proposed in Scheme 2. The ^{1}H NMR and ^{13}C NMR spectrum of **6** consists of only one signal for the methyl groups on the silicon and two signals for the methyl groups on the cyclopentadienyl ring. Additional evidence for the loss of the helical chiral structure of the starting material is the observation of an AA′XX′ instead of the ABCD pattern for the four methylene protons of the ligand side-chain. The methylene protons next to the oxygen of the side chain give rise to a triplet, whereas a doublet of triplets are observed for the methylene protons attached to the $NHSiMe_2$ group due to the coupling to the amine proton. The latter is recorded at δ 1.40 as a triplet with $^3J_{HH}$ = 7.8 Hz. The coordination of the acetylide ligand to both yttrium and lithium in solution is obvious from the ^{13}C NMR spectrum that shows a doublet of a quartet for the α-carbon of the acetylide ligand at δ 141.2 ($^1J_{YC}$ = 49.9 Hz, $I(^{89}Y) = \frac{1}{2}$; $^1J_{LiC}$ = 7.3 Hz, $I(^7Li) = \frac{3}{2}$) (Fig. 2), whereas a doublet at δ 114.9 ($^2J_{YC}$ = 10.1 Hz) is found for the β-carbon. A similar bridging coordination of the acetylide ligands to yttrium and lithium atom was found in the crystallographically confirmed structure of $Cp^*_2Y(\mu$-C≡$CCMe_3)_2$ Li(THF) [13]. However no coupling of lithium to carbon was observed in the ^{13}C NMR spectrum of this complex. A bridging mode of two acetylide ligands are quite common in dimeric

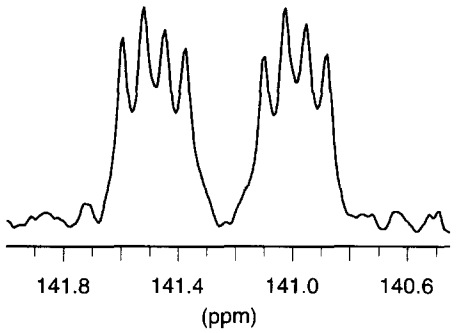


Fig. 2. ^{13}C NMR signal for the acetylide α-carbon atom in Li[Y{η^5-$C_5Me_4SiMe_2NH(CH_2CH_2OMe)$}$_2$(C≡CPh)$_2$] (**6**).

lanthanocenes of the type [Ln(η^5-$C_5R_5)_2(\mu$-C≡$CR')_2$] [14]. The chemical shifts and coupling constants for the sp-hybridized α-carbon atom of the acetylide ligand are in the normal range for terminal acetylide complexes, such as $Cp^*_2Y(\mu$-C≡$CCMe_3)_2$Li(THF) (δ 127.0, $^1J_{YC}$ = 46 Hz) [13], Cp^*_2Y(C≡CPh)(OEt_2) (δ 146.95, $^1J_{YC}$ = 70.9 Hz) [15], (DAC)Y(C≡CPh) (THF) (DAC = 4,13-Diaza-18-crown-6; δ 149.1, $^1J_{YC}$ = 46.9 Hz) [16]. The ^{13}C–^{7}Li coupling constant is slightly smaller than that observed in LiC≡C*t*Bu ($^1J_{LiC}$ = 16 Hz in THF at −90°C) [17a] and Li*t*Bu ($^1J_{LiC}$ = ca 10 Hz in toluene at room temperature) [17b].

In conclusion, we have shown that the apparent 20-electron configuration in the metallocenes of the type [M(η^5 : η^1-$C_5R_4SiMe_2NR')_2$] (M = Zr, Hf, Ln^+) results in some nucleophilic behaviour, the polymerization activity toward ε-caprolactone being one

example. It will be interesting to see whether this type of metallocene complexes exhibits further novel reactivities. One principal drawback, however, would be the loss of the helical chirality upon modification of the amido function.

EXPERIMENTAL

General considerations

All operations were performed under an inert atmosphere of argon using standard Schlenk or glovebox techniques. THF, toluene and hexane were purified by distillation from sodium/benzophenone ketyl. $MCl_4(THF)_2$ (M = Zr, Hf) [18], $Li_2(C_5Me_4SiMe_2NiPr)$ [3j], $Li_2(C_5Me_4SiMe_2NtBu)$ [2a] and $Li_2(C_5Me_4SiMe_2NCH_2CH_2CH_2OMe)$ [7c] were synthesized according to published procedures. YCl_3 (ALFA) was used as received. Li*n*Bu was used as received and titrated prior to use [19]. NMR spectra were recorded on a Bruker DRX 400 spectrometer at 25°C, mass spectra on a Finnigan 8230 spectrometer. Elemental analyses were performed by the Microanalytical Laboratory of this department.

$Zr(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2NtBu)Cl_2$ (**1a**) [4c]

A mixture of $ZrCl_4(THF)_2$ (2.61 g, 6.92 mmol) and $Li_2(C_5Me_4SiMe_2NtBu)$ (1.82 g, 6.92 mmol), obtained by double deprotonation of $(C_5Me_4H)SiMe_2NHtBu$ using Li*n*Bu in hexane, was treated dropwise with 35 ml of toluene at −60°C and stirred for 3 days at room temperature. Filtration of the reaction mixture through glass fibre, followed by concentrating the filtrate and recrystallization at −20°C afforded 2.11 g (74% yield) of colourless crystals. ^1H NMR (C_6D_6): δ 0.53 (s, 6 H, $SiCH_3$), 1.44 (s, 9 H, $C(CH_3)_3$), 2.07 (s, 6 H, ring CH_3), 2.13 (s, 6 H, ring CH_3). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 6.0 ($SiCH_3$), 11.9, 14.7 (ring CH_3), 33.1 ($C(CH_3)_3$), 56.6 ($C(CH_3)_3$), 101.2 (ring C attached to Si), 131.5, 134.2 (ring C). EI MS: *m/z* 410 (3%, M^+), 395 (51%, M^+-CH_3), 340 (5%, M^+-2Cl). Anal. calc. for $C_{15}H_{27}Cl_2NSiZr$: C, 43.77; H, 6.61; N, 3.40. Found C, 43.33, H, 6.84, N, 3.54.

$Hf(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2NtBu)Cl_2$ (**1b**)

Following a procedure analogous to that described for the preparation of **1a**, $Li_2(C_5Me_4SiMe_2NtBu)$ (1.00 g, 3.80 mmol) was reacted with $HfCl_4(THF)_2$ (1.76 g, 3.80 mmol) to give **1b** (0.50 g, 38% yield) as colourless microcrystals. ^1H NMR (C_6D_6): δ 0.44 (s, 6 H, $SiCH_3$), 1.29 (s, 9 H, $C(CH_3)_3$), 1.98, 2.08 (s, 6 H, ring CH_3). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 6.2 ($SiCH_3$), 11.5, 14.4 (ring CH_3), 33.9 ($C(CH_3)_3$), 55.3 ($C(CH_3)_3$), 100.7 (ring C attached to Si), 130.1, 131.8 (ring C). EI MS: *m/z* 500 (9%, M^+), 464 (18%, M^+-Cl), 429 (7%, M^+-2Cl). Anal. calc. for $C_{15}H_{27}NSiCl_2Hf$: C, 36.12; H, 5.41; N, 2.80. Found: C, 36.68; H, 6.97; N, 3.05.

$Zr(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2NiPr)Cl_2$ (**2a**)

This compound can only be prepared as an inseparable mixture with $Zr(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2NiPr)_2$ (**3a**) (*vide infra*). ^1H NMR (C_6D_6): δ 0.15 (s, 6 H, $SiCH_3$), 1.08 (d, $^3J_{HH}$ = 6.3 Hz, 6 H, $CH(CH_3)_2$), 1.97, 2.12 (s, 6 H, ring CH_3), 3.03 (sept, $^3J_{HH}$ = 6.6 Hz, 1 H, $CH(CH_3)_2$).

$Hf(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2NiPr)Cl_2$ (**2b**)

Toluene (30 ml) was added to a solid mixture of $Li_2(C_5Me_4SiMe_2NiPr)$ (1.50 g, 6.02 mmol) and $HfCl_4(THF)_2$ (2.80 g, 6.02 mmol) at −78°C. The mixture was stirred overnight, the solution was filtered, concentrated and cooled to −30°C to give a white solid. Extraction with hexane (2 × 10 ml) followed by filtration and cooling afforded 0.58 g (20% yield) of **2b** as colourless microcrystals. ^1H NMR (C_6D_6): δ 0.26 (s, 6 H, $SiCH_3$), 0.85 (d, $^3J_{HH}$ = 6.6 Hz, 6 H, $CH(CH_3)_2$), 2.14, 2.19 (s, 6 H, ring CH_3), 3.05 (sept, $^3J_{HH}$ = 6.6 Hz, 1 H, $CH(CH_3)_2$). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 1.0 ($SiCH_3$), 12.3, 15.9 (ring CH_3), 26.1 ($CH(CH_3)_2$), 48.8 ($CH(CH_3)_2$), 107.9 (ring C attached to Si), 131.4, 133.4 (ring C). EI MS: *m/z* (%) 450 (3%, M^+-Cl), 415 (6%, M^+-2Cl).

$Zr(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2NiPr)_2$ (**3a**)

A mixture of $ZrCl_4(THF)_2$ (0.62 g, 1.64 mmol) and $Li_2(C_5Me_4SiMe_2NiPr)$ (0.82 g, 3.29 mmol) was treated dropwise with 35 ml of toluene at −60°C and stirred for 2 days at room temperature. Filtration of the extracts, followed by concentrating the filtrate and cooling to −50°C afforded 0.30 g of pale yellow crystals, yield: 33%. ^1H NMR (C_6D_6): δ 0.65, 0.78 (s, 3 H, $SiCH_3$), 1.29 (d, $^3J_{HH}$ = 6.3 Hz, 3 H, $CH(CH_3)_2$), 1.35 (d, $^3J_{HH}$ = 6.6 Hz, 3 H, $CH(CH_3)_2$), 1.96 (s, 6H, ring CH_3), 2.09, 2.42 (s, 3 H, ring CH_3), 4.13 (m, 1 H, $CH(CH_3)_2$). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 8.6, 8.9 ($SiCH_3$), 11.4, 12.1, 13.6, 15.3 (ring CH_3), 28.8, 29.6 ($CH(CH_3)_2$), 52.7 ($CH(CH_3)_2$), 107.3 (ring C attached to Si), 122.9, 124.5, 125.9, 128.6 (ring C). EI MS: *m/z* 560 (24%, M^+), 545 (39%, M^+-CH_3) 517 (17%, M^+-CHMe_2), 501 (100%, $M^+-NH_2CHMe_2$), 460 (25%, $M^+-CHMe_2-NCHMe_2$), 387 (27%, $M^+-Me_2SiNHCHMe_2-NCHMe_2$). Anal. calc. for $C_{28}H_{50}N_2Si_2Zr$: C, 59.83; H, 8.83; N, 4.98. Found: C, 62.37; H, 9.34; N, 6.10.

$Hf(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2NiPr)_2$ (**3b**)

Following a similar procedure described for the preparation of **2b**, $Li_2(C_5Me_4SiMe_2NiPr)$ (1.00 g, 4.01 mmol) was reacted with $HfCl_4(THF)_2$ (1.86 g, 4.01

mmol) in THF to obtain $Hf(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2NiPr)_2$ (**3b**) (0.65 g, 25% yield) as colourless crystals, suitable for X-ray diffraction studies. ^1H NMR (C_6D_6): δ 0.53, 0.64 (s, 3 H, $SiCH_3$), 1.18, 1.23 (d, $^3J_{HH}$ = 6.4 Hz, 3 H, $CH(CH_3)_2$), 1.88, 1.90, 2.02, 2.30 (s, 3 H, ring CH_3), 3.99 (m, 1 H, $CH(CH_3)_2$). $^{13}C\{^1H\}$ NMR (C_6D_6): δ 8.6, 8.7 ($SiCH_3$), 11.5, 12.2, 13.6, 15.3 (ring CH_3), 28.9, 30.0 ($CH(CH_3)_2$), 52.1 ($CH(CH_3)_2$), 106.4 (ring C attached to Si), 121.6, 124.6, 125.0, 127.2 (ring C). EI MS: *m/z* 650 (52%, M^+), 591 (13%, $M^+ - NH_2CHMe_2$), 534 (20%, $M^+ - Me_2SiNHCHMe_2$), 505 (97%, $M^+ - Me_2SiNHCHMe_2 - 2\,CH_3$). Anal. calc. for $C_{28}H_{50}N_2Si_2Hf$: C, 51.81; H, 7.82; N, 4.31. Found: C, 47.80; H, 7.82; N, 3.79.

$Li[Y(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2NCH_2CH_2CH_2OMe)_2]$ (**4**)

YCl_3 (223 mg, 1.14 mmol) and $Li_2(C_5Me_4SiMe_2NCH_2CH_2CH_2OMe)$ (638 mg, 2.28 mmol) were combined in a flask and pre-cooled THF (15 ml) was added at −78°C with stirring. The resulting mixture was allowed to warm to room temperature and stirred for 13 h. The solvent was removed *in vacuo* and the crude product extracted with 2 × 10 ml of toluene. LiCl was filtered off and the clear solution was concentrated to 2 ml. After crystallization at −25°C for 24 h, the mother liquor was decanted off and the crystals were dried *in vacuo* to yield 605 mg (85%) of **4** as pale yellow microcrystals. ^1H NMR (C_6D_6): δ 0.52, 0.64 (s, 6 H, $SiCH_3$), 1.50 (m, 4 H, $NCH_2CH_2CH_2O$), 2.08, 2.17, 2.21, 2.32 (s, 6 H, ring CH_3), 2.81 (s, 6 H, OCH_3), 2.92, 3.09 (m, 2 H, CH_2O), 3.38 (m, 4 H, NCH_2); ^{13}C NMR (C_6D_6): δ 2.3, 9.3 ($SiCH_3$), 10.8, 12.0, 13.4, 15.7 (ring CH_3), 37.2 ($NCH_2CH_2CH_2O$), 46.9 (NCH_2), 58.9 (OCH_3), 74.8 (CH_2O), 105.8 (ring C attached to Si), 120.0, 121.3, 121.4, 124.3 (ring C). Anal. calc. for $C_{30}H_{54}LiN_2O_2Si_2Y$: C, 57.49; H, 8.68; N, 4.47. Found: C, 51.06; H, 8.28; N, 4.42.

$Li[Y\{\eta^5\text{-}C_5Me_4SiMe_2NH(CH_2CH_2OMe)\}_2(C{\equiv}CPh)_2]$ (**6**)

$Li[Y(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2NCH_2CH_2OMe)_2]$ (**5**) (57 mg, 95 μmol) was dissolved in C_6D_6 (0.5 ml) and phenylacetylene (20 mg, 196 μmol) was added at room temperature. The solution was kept at 5°C overnight, before the NMR spectra were recorded. The compound was isolated by removal of the solvent *in vacuo* and the crude product recrystallized from hexane at −30°C to yield 63 mg (83%) of **6** as colourless microcrystals. ^1H NMR (C_6D_6): δ 0.54 (s, 12 H, $SiCH_3$), 1.40 (t, $^3J_{HH}$ = 7.8 Hz, 2 H, NH), 2.21, 2.52 (s, 12 H, ring CH_3), 2.67 (dt, $^3J_{HH}$ = 7.8 Hz, $^3J_{HH}$ = 5.5 Hz, 4 H, NCH_2), 2.83 (s, 6 H, OCH_3), 2.89 (t, 4 H, $^3J_{HH}$ = 5.5 Hz, CH_2O), 6.99 (m, 2 H, 4-C_6H_5), 7.07 (m, 4 H, 3-C_6H_5), 7.49 (m, 4 H, 2-C_6H_5); ^{13}C NMR (C_6D_6): δ 1.8 ($SiCH_3$), 11.9, 15.6 (ring CH_3), 41.5 (NCH_2), 58.3 (OCH_3), 75.0 (CH_2O), 111.7 (ring C attached to Si), 114.9 (d, $^2J_{YC}$ = 10.1 Hz, C≡*C*Ph), 121.4, 125.3 (ring C), 126.5 (*ipso*-C_6H_5), 126.9 (*para*-C_6H_5), 128.4 (*meta*-C_6H_5), 131.7 (*ortho*-C_6H_5), 141.2 (dq, $^1J_{YC}$ = 49.9 Hz, $^1J_{LiC}$ = 7.3 Hz, *C*≡CPh). Anal. calc. for $C_{44}H_{62}LiN_2O_2Si_2Y$: C, 65.81; H, 7.78; N, 3.49. Found: C, 65.86; H, 8.50; N, 4.56.

X-ray crystal structure analysis of **3b**

Crystal data for **3b** are summarized in Table 1. The compound, obtained as colourless crystals by cooling a concentrated pentane solution, crystallizes in the monoclinic space group *C*2/*c* (No. 15). Data collection in the range $3.4° < \theta < 29.9°$ was performed using ω-scans on an Enraf-Nonius CAD-4 diffractometer with graphite-monochromated Mo-K_α radiation. Data correction for Lorentz polarization and absorption (empirically using PSI-scans) was carried out using the program system MolEN [20a]. From 7235 measured reflections, all 4310 independent reflections were used and 251 parameters were refined by full-matrix least-squares against all F_o^2 data (SHELXL-93) [20b]. The structure was solved using direct methods (SHELXS-86) [20c] and difference Fourier syntheses and refined with anisotropic thermal parameters for non-hydrogen atoms. All hydrogen atoms were refined with isotropic thermal parameters. The refinement converged with $R = 0.0182$, $wR_2 = 0.0360$ for all observed F_o data, goodness-of-fit 1.097. Listings of all crystal data and refinement parameters, atomic parameters including hydrogen atoms, thermal parameters, and bond lengths and angles have been deposited at the Cambridge Crystallographic Centre.

(Received 7 October 1997; accepted 24 October 1997)

Abstract—Reactions of the tricarbonyl-molybdenum and -tungsten complexes $[M(CO)_3(MeCN)_3]$ (M = Mo, W) or $[Mo(CO)_3(mesitylene)]$ with equimolar amounts of $[Ti(\eta^5\text{-}Cp')\{(\eta^5\text{-}C_5H_3)(SiMe_2)_2(C_5H_4)\}Cl_2]$ ($Cp' = C_5H_5$, C_5Me_5) lead to the heterodinuclear compounds $[Ti(\eta^5\text{-}Cp')Cl_2\{\mu\text{-}[(SiMe_2)_2(\eta^5\text{-}C_5H_3)_2]\}MH(CO)_3]$. These dinuclear complexes are isolated as single *cis*- and *trans*-isomers or as mixtures of both depending on the starting complex and the reaction conditions. The molar ratio of the two resulting isomers is controlled by thermodynamic and kinetic factors which prevent the application of stereoselective methods for some of the products. Reaction of the hydrido *cis*- and *trans*-complexes with CCl_4 in CH_2Cl_2 allows the isolation of chloro complexes $[Ti(\eta^5\text{-}Cp')Cl_2\{\mu\text{-}[(SiMe_2)_2(\eta^5\text{-}C_5H_3)_2]\}MCl(CO)_3]$ of the same configuration. All of the new heterodinuclear compounds reported were characterized by their analytical composition, IR and NMR spectroscopy and the molecular structure of *cis*-$[Ti(\eta^5\text{-}C_5Me_5)Cl_2\{\mu\text{-}[(SiMe_2)_2(\eta^5\text{-}C_5H_3)_2]\}WH(CO)_3]$ was studied by X-ray diffraction methods. © 1998 Elsevier Science Ltd. Keywords: heterodinuclear complexes; titanium-molybdenum; titanium-tungsten; cyclopentadienyl

Heterodinuclear organometallic complexes containing two metals with very different reactivity in close proximity have received considerable attention [1] because they may produce cooperative effects and new reactivity patterns when used in stoichiometric and catalytic reactions. Particular efforts have focused on complexes containing both early electron-deficient and middle or late electron-rich transition metals. Several strategies using different bridging groups have been used to prepare complexes of this type with and without metal–metal bonds. On of the most intensively studied [2] groups of compounds is that formed by using cyclopentadienylphosphine systems as bridging groups which are η^5-coordinated to the early or middle group 4–6 transition metal and phosphorus-coordinated to the late transition metal. However most of the reported heterodinuclear compounds involving group 4 metals are phosphido- [3a–c] and carbonyl- [3d–g] bridged complexes.

In recent years many dinuclear complexes containing bridging cyclopentadienyl systems have been described. They include fulvalene [4a–e] derivatives and those containing cyclopentadienyl rings singly bridged by different alkyl [5] and silyl [6] groups. Some similar trinuclear compounds have also been reported [7]. Although numerous homodimetallic complexes of this type have been synthesized and investigated, the range of synthetic methods available to isolate heterodinuclear compounds is limited mainly to the late transition metal derivatives.

We reported [8] the use of dilithium or dithallium salts of the [{1,1′:2,2′-bis(dimethylsilanediyl)}bis(η^5-cyclopentadienyl)] ($CpSi_2Cp$) dianion to prepare homodinuclear group 4 and 6 metal complexes containing the dicyclopentadienyl system as a bridging ligand. Related reactions using the monolithium salt of the ligand prepared as reported elsewhere [9] gives access to complexes containing only one of the cyclopentadienyl rings η^5-coordinated to the group 4 metal center, leading to mono- and mainly mixed dicyclo-

pentadienyl-type derivatives $[M(\eta^5Cp')(\eta^5\text{-}CpSi_2C_5H_4)Cl_2]$ [10]. In these complexes the other cyclopentadiene moiety remains available for further reactions with a second different metal complex. Herein we report the application of this strategy to study migration reactions of the acidic cyclopentadiene ring proton to molybdenum and tungsten carbonyls as a method to prepare heterodinuclear compounds of the type *cis*- and *trans*-$[TiCp'Cl_2\{\mu\text{-}(CpSi_2Cp)\}MH(CO)_3]$ ($Cp' = C_5H_5$, C_5Me_5; $CpSi_2Cp = (SiMe_2)_2(\eta^5\text{-}C_5H_3)_2$) containing one titanium and one group 6 metal fragment. Conversion of the hydrido into the chloro complexes and the structural characterization of all these compounds is also reported.

RESULTS AND DISCUSSION

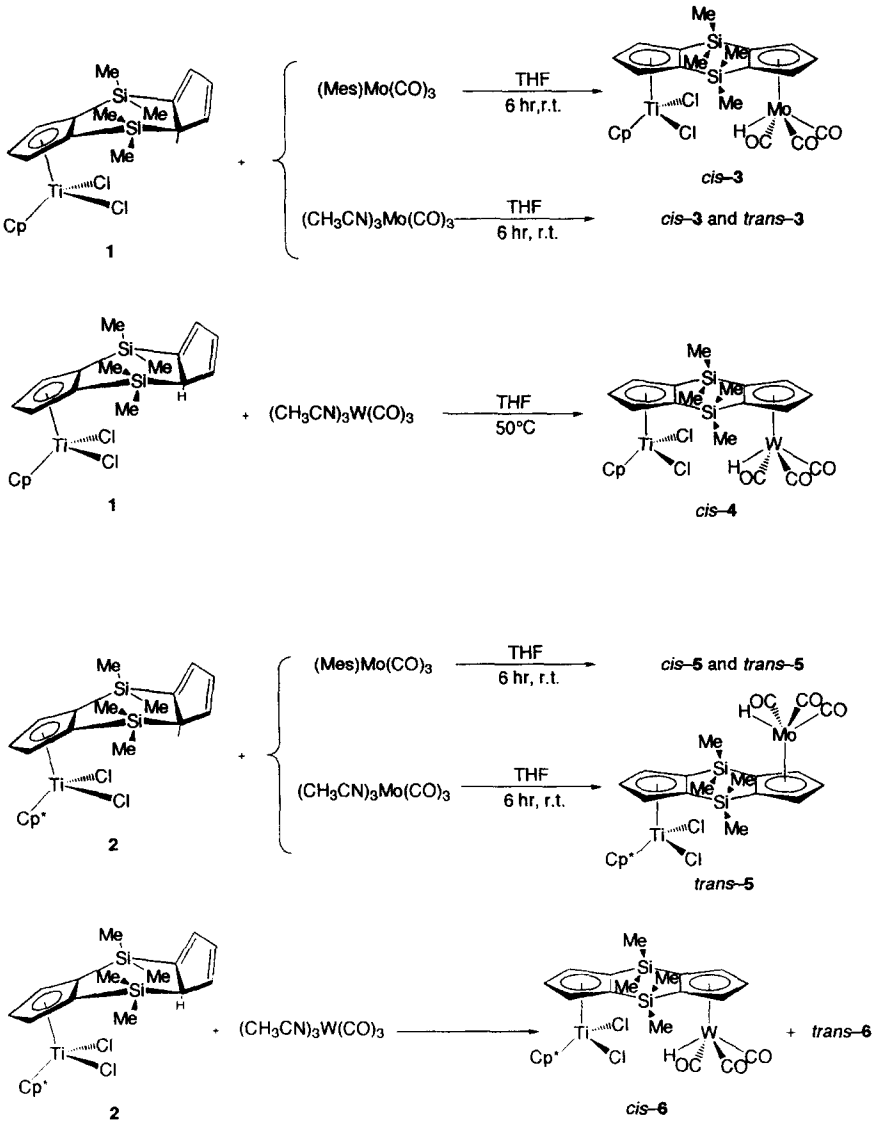
Reactions of the mixed dicyclopentadienyl titanium complexes $[Ti(\eta^5\text{-}Cp')\{(\eta^5\text{-}C_5H_3)(SiMe_2)_2(C_5H_4)\}Cl_2]$ [$Cp' = C_5H_5$ (**1**), C_5Me_5 (**2**)] with equimolar amounts of $[M(CO)_3(MeCN)_3]$ (M = Mo, W) or $[Mo(CO)_3$(mesitylene)] resulted in migration of the acidic ring hydrogen of the cyclopentadiene moiety to the group 6 metal with elimination of the acetonitrile or mesitylene ligands, which were replaced by the η^5-coordinated cyclopentadienyl ring to give the hydrido tricarbonyl complexes $[TiCp'Cl_2\{\mu\text{-}(CpSi_2Cp)\}MH(CO)_3]$ [$Cp' = C_5H_5$, M = Mo (**3**), W (**4**); $Cp' = C_5Me_5$, M = Mo (**5**), W (**6**)], as shown in Scheme 1.

The rigidity of the bridging dicyclopentadienyl ligand is responsible for the formation of different stereoisomers in this type of dinuclear compound for which six different structural dispositions have been found in the solid by X-ray diffraction studies. Two were reported [11] to belong to a *trans*-configuration of the two metal centers with the central six-membered ring of the ligand exhibiting either a boat or an essentially planar conformation, and the other two show the metal fragments in a *cis*-disposition occupying either the internal or the external faces of the boat configuration of the central ring of the ligand. In addition we have recently reported [8f] two new configurations: one *cis*-configuration showing an almost planar disposition of the central ring of the ligand and a *trans*-configuration with the ligand exhibiting a chair disposition. It is not easy to explain the preferential formation of one of these structures when the two metals are not connected either by metal–metal bonds or through additional ligand bridges, because it results from the contribution of many different factors including the conformation of the starting complex and the mechanism followed by the reaction leading to the final product.

It has been reported [9] that the monoalkali-metal derivatives of the ligand exist at low temperature as a mixture of two stable enantiomers which show fluxional behavior being interconverted at higher temperatures through a silatropic rearrangement. Solutions of the starting titanium complexes **1** and **2** may contain an enantiomeric mixture of two stereoisomers, showing the cyclopentadiene proton in *cis*- and *trans*-disposition with respect to the metal fragment in variable molar ratios of both stereoisomers at different temperatures. It must be expected that hydrogen transfer to the group 6 metal in the *cis*- and *trans*-isomers should lead, respectively, to the heterodinuclear complex with the same *cis*- or *trans*-disposition of the metal fragments. However this transformation which is thermodynamically and kinetically controlled may give different molar ratios of the resulting stereoisomers for each reaction and under different conditions even assuming that the hydrogen transfer process follows the same mechanism. For these reasons, using the pure solid complexes **1** and **2**, we observed that the *cis*- or *trans*-configuration of the resulting final heterodimetallic product depends on the solvent, the temperature and time of reaction and the nature of the carbonyl derivative $M(CO)_3(MeCN)_3$ or $Mo(CO)_3$(mesitylene) used as the starting compound. Both *cis*- and *trans*-isomers can be easily distinguished by ^1H NMR spectroscopy because, although both show the same pattern of resonances due to an ABB′ spin system for both nonequivalent cyclopentadienyl rings bonded to the different metal fragments, the difference between the chemical shifts of the two nonequivalent silyl-methyl singlets is larger for the *cis*- than for the *trans*-isomer (see Experimental).

Reaction of complex $[Ti(\eta^5\text{-}C_5H_5)\{(\eta^5\text{-}C_5H_3)(SiMe_2)_2(C_5H_4)\}Cl_2]$ (**1**) with $[Mo(CO)_3$(mesitylene)] in THF at room temperature for 6 h led to *cis*-$[Ti(\eta^5\text{-}C_5H_5)Cl_2\{\mu\text{-}[(SiMe_2)_2(\eta^5\text{-}C_5H_3)_2]\}MoH(CO)_3]$ (*cis*-**3**) isolated as a red solid in 95% yield whereas the same reaction carried out with $[Mo(CO)_3(MeCN)_3]$ under the same conditions led to mixtures of *cis*-**3** and *trans*-**3** in different molar ratios, the *trans*-isomer always being the main component. Separation of the isomers was not possible. The reaction of complex **1** with $[W(CO)_3(MeCN)_3]$ at 50°C for 4 h led to the stereoselective formation of *cis*-$[Ti(\eta^5\text{-}C_5H_5)Cl_2\{\mu\text{-}[(SiMe_2)(\eta^5\text{-}C_5H_3)_2]WH(CO)_3]$ (*cis*-**4**) isolated as a red solid in 95% yield. In contrast, reaction of $[Ti(\eta^5\text{-}C_5Me_5)\{(\eta^5\text{-}C_5H_3)(SiMe_2)_2(C_5H_4)\}Cl_2]$ (**2**) with $[Mo(CO)_3$(mesitylene)] in THF at room temperature gave a mixture of *cis*-**5** and *trans*-**5** with the *cis*-isomer being the main product, whereas use of $[Mo(CO)_3(MeCN)_3]$ under the same conditions resulted in the stereoselective formation of *trans*-$[Ti(\eta^5\text{-}C_5Me_5)Cl_2\{\mu\text{-}[(SiMe_2)(\eta^5\text{-}C_5H_3)_2]MoH(CO)_3]$ (*trans*-**5**), isolated as a red solid in 85% yield. In the reaction of $[W(CO)_3(MeCN)_3]$ with compound **2** we sometimes obtained *cis*-**6** and sometimes a mixture of *cis*-**6** and *trans*-**6**, *cis*-**6** being the main product. This reaction was carried out under various conditions: in THF or dichloromethane at room temperature for 24 h or in THF at 50°C for 4 h but the results of the reactions were unpredictable.

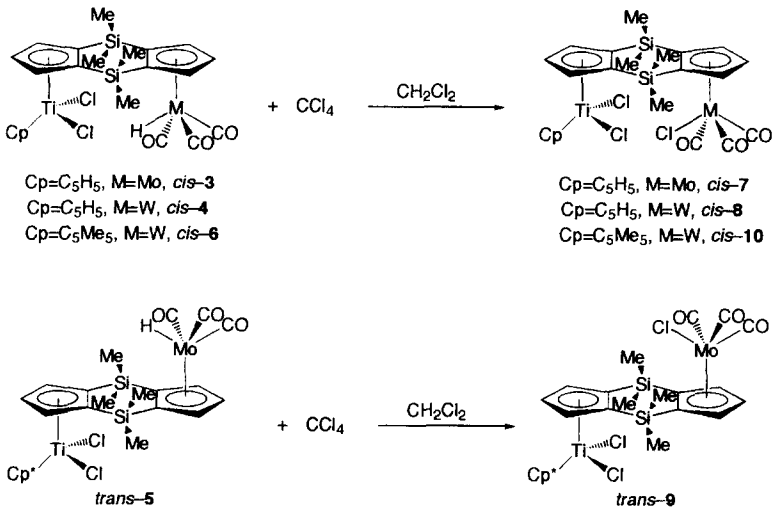
Complexes **3**–**6** are air stable for short periods, insoluble in alkanes but soluble in aromatic solvents,



Scheme 1.

ethers and dichloromethane. They react with CCl_4 (see Scheme 2) at room temperature to be transformed into the related chlorotricarbonyl derivatives *cis*-$[TiCp'Cl_2\{\mu\text{-}Si_2(\eta^5\text{-}Cp)_2\}MCl(CO)_3]$ (Cp′ = Cp, M = Mo *cis*-**7**, W *cis*-**8**, Cp′ = Cp*, M = Mo *trans*-**9**, Cp′ = Cp*, M = W *cis*-**10**) in yields higher than 90%. These compounds are air stable red solids insoluble in alkanes and in toluene but soluble in ethers and dichloromethane.

All of the new heterodinuclear complexes were identified by elemental analysis and IR, ^1H and ^{13}C NMR spectroscopy. All of the compounds show the presence of one dicyclopentadienyl-type titanium fragment and one pseudo-square pyramidal hydrido or chloro tricarbonyl group 6 metal fragment, each bonded to one of the two cyclopentadienyl rings of the bridging ligand, with no interaction between the metal centers. The IR spectra of all the complexes show the expected two absorption bands between 2054 and 1914 cm^{-1}. The high field resonance due to the hydrido ligand in complexes **3**–**6** was observed between δ −4.86 and δ −7.48 ppm. The ^1H NMR spectra of all of the complexes show the presence of two nonequivalent cyclopentadienyl rings each with the expected ABB′ spin system proton resonances. Two pairs of nonequivalent silyl–methyl groups provide two additional singlets with a difference in their chemical shifts for the *cis*-isomers (0.25 ppm) larger than that observed for the *trans*-isomers (less than 0.06 ppm). The ^{13}C NMR spectra show the expected two singlets for the silyl–methyl carbon atoms and six resonances due to the nonequivalent two C_β and two pairs of C_{ipso} and C_α ring atoms, together with one or two singlets for the additional cyclopentadienyl or



Scheme 2.

pentamethylcyclopentadienyl ring carbons respectively and two low field resonances due to the CO ligands, which could not be observed for some of the complexes (see Experimental).

Crystals suitable for X-ray study were obtained for complex *cis*-**6** whose molecular structure is shown in Fig. 1 together with the atomic labeling scheme. Selected bond distances and angles are given in Table 1.

The structure of **6** shows a *cis*-disposition of the two metal fragments bonded to the external faces of the cyclopentadienyl rings in order to place the two metal centers farther apart (6.298 Å), in the asymmetric molecule. Both cyclopentadienyl rings are planar and bound to the titanium and tungsten atoms in a slightly asymmetric η^5-fashion [the W—C distances range from 2.327(9) to 2.340(8) Å with a W—Cp(centroid) distance of 1.99 Å; the Ti—C distances range from 2.347(8) to 2.496(8) Å]. The dihedral angle between the two bridging cyclopentadienyl rings is 37.7(3)°. The central ring formed by the two silicon and the four carbon-ipso atoms is not planar in such a way that the dihedral angles between the mean planes containing Si(1), Si(2), C(11), C(12) and Si(1), Si(2), C(21), C(22) and the corresponding cyclopentadienyl ring are 13.7(3)° and 12.3(2)°, respectively, and the Si(1) and Si(2) atoms

O(3A)—C(3A)—W(1)	153(3)	O(1)—C(1)—W(1)	177(2)
O(2)—C(2)—W(1)	173(3)	O(3)—C(3)—W(1)	176(3)

lie 0.348(2) Å and 0.291(2) Å, respectively, above the plane of the ring bonded to tungsten, and 0.195(2) Å and 0.479(2) Å above the plane of the ring bonded to titanium.

The titanium fragment shows the typical disposition of a bent dicyclopentadienyl system with an angle between the rings of 52.9(3)° with normal Ti—Cl distances [average 2.341(3) Å]. The tungsten fragment shows a pseudo-square pyramidal coordination in which the hydrido ligand, which could not be localized, presumably occupies the fourth position between the two C(2)O(2) and C(3)O(3) carbonyl ligands for which the C(2)—W(1)—C(3) angle is more open [109(1)°] than the other two [C(1)—W(1)—C(2) of 82(1)° and C(1)—W(1)—C(3) of 75(1)°] although the disorder found for the positions occupied by the carbonyl ligands prevents a rigorous assignment of their bonding situation.

EXPERIMENTAL

Reagents and general techniques

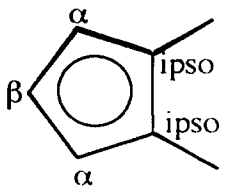
All reactions were carried out in dried Schlenk tubes under argon or nitrogen, and the manipulations were carried out using syringes or cannulas through Subaseals. Solvents were dried and distilled under nitrogen: tetrahydrofuran from sodium benzophenone ketyl; hexane and pentane from sodium and potassium amalgam; dichloromethane from P_2O_5 and carbon tetrachloride from $CaCl_2$. Unless otherwise stated, reagents were obtained from commercial sources and used as received. IR spectra were recorded in Nujol mulls for solids over the range 4000–200 cm^{-1} or in solution over the range 2500–1500 cm^{-1} on a Perkin–Elmer 583 spectrophotometer. IR data are given in cm^{-1}. The ^1H and ^{13}C NMR spectra were recorded at 200 and 50 MHz respectively on a Gemini 200 spectrometer, at 299.95 and 75.43 MHz respectively on a Varian Unity 300 spectrometer and at 499.85 and 125.7 MHz on a Varian Unity 500 Plus spectrometer; chemical shifts, in ppm, are positive downfield relative to external $SiMe_4$, and coupling constants are in Hz. C, H, and N analyses were performed with a Perkin–Elmer 240-B instrument.

The compounds $[Ti(\eta^5\text{-}C_5H_5)Cl_2\{(\eta^5\text{-}C_5H_3)[Si(CH_3)_2]_2(C_5H_4)\}]$ and $[Ti(\eta^5\text{-}C_5Me_5)Cl_2\{(\eta^5\text{-}C_5H_3)[Si(CH_3)_2]_2(C_5H_4)\}]$ were prepared as reported elsewhere [10b].

Synthesis of cis-$[Ti(\eta^5\text{-}C_5H_5)Cl_2\{(\eta^5\text{-}C_5H_3)_2[Si(CH_3)_2]_2\}MoH(CO)_3]$ (*cis*-**3**)

THF (50 ml) was added to a mixture of $[Ti(\eta^5\text{-}C_5H_5)Cl_2\{(\eta^5\text{-}C_5H_3)[Si(CH_3)_2]_2(C_5H_4)\}]$ (1.43 g, 3.35 mmol) and $[Mo(CO)_3(mesitylene)]$ (1.01 g, 3.35 mmol). After stirring for 6 h at room temperature the resulting red solution was concentrated to dryness *in vacuo* leaving a red solid which was washed with pentane and identified as complex *cis*-**3** (1.93 g, 95%). Anal. calc. for $C_{22}H_{24}Cl_2MoO_3Si_2Ti$: C, 43.51; H, 3.98. Found: C, 43.87; H, 4.06. ^1H NMR (300 MHz, C_6D_6): δ −4.91 (s, 1H, Mo-*H*), 0.10 (s, 6H, Si-*Me*), 0.61 (s, 6H, Si-*Me*), 4.98 (d, J = 2.4 Hz, 2H, $C_\alpha C_5H_3$), 5.10 (t, J = 2.4 Hz, 1H, $C_\beta C_5H_3$), 5.44 (t, J = 2.4 Hz, 1H, $C_\beta C_5H_3$), 5.94 (s, 5H, C_5H_5), 6.52 (d, J = 2.4 Hz, 2H, $C_\alpha C_5H_3$). $^{13}C\{^1H\}$ NMR (125 MHz, C_6D_6): 3.1 (Si-*C*H_3), 3.4 (Si-*C*H_3), 95.9 (C_β *C*$_5H_3$), 96.8 (C_α *C*$_5H_3$), 109.1 (C_{ipso} *C*$_5H_3$), 113.3 (C_β *C*$_5H_3$), 119.8 (*C*$_5H_5$), 133.2 (C_α *C*$_5H_3$), 138.7 (C_{ipso} *C*$_5H_3$), 223.8 (*C*O). IR (nujol): ν_{CO} 2015, 1915 cm^{-1}. IR (THF): ν_{CO} 2020, 1928 cm^{-1}.

When the reaction was carried out under the same experimental conditions using the equimolar amount of $[Mo(CO)_3(MeCN)_3]$ a mixture of *cis*-**3** and *trans*-**3** was obtained after concentrating the resulting red solution to dryness. The complex *trans*-**3** could not be isolated. ^1H NMR (300 MHz, C_6D_6): δ −5.43 (s, 1H, Mo-*H*), 0.40 (s, 6H, Si-*Me*), 0.44 (s, 6H, Si-*Me*), 5.06 (t, J = 2.4 Hz, 1H, $C_\beta C_5H_3$), 5.09 (d, J = 2.4 Hz, 2H, $C_\alpha C_5H_3$), 5.45 (t, J = 2.4 Hz, 1H, $C_\beta C_5H_3$), 5.92 (s, 5H, C_5H_5), 6.48 (d, J = 2.4 Hz, 2H, $C_\alpha C_5H_3$).



Synthesis of cis-$[Ti(\eta^5\text{-}C_5H_5)Cl_2\{(\eta^5\text{-}C_5H_3)_2[Si(CH_3)_2]_2\}WH(CO)_3]$ (*cis*-**4**)

THF (50 ml) was added to a mixture of $[Ti(\eta^5\text{-}C_5H_5)Cl_2\{(\eta^5\text{-}C_5H_3)[Si(CH_3)_2]_2(C_5H_4)\}]$ (1.14 g, 2.91 mmol) and $[W(CO)_3(MeCN)_3]$ (1.24 g, 2.91 mmol). After stirring for 4 h at 50°C the resulting red solution was concentrated to dryness *in vacuo* leaving a red solid which was washed with pentane and identified as complex *cis*-**4** (1.91 g, 94%). Anal. calc. for $C_{22}H_{24}Cl_2O_3Si_2TiW$: C, 38.01; H, 3.48. Found: C, 37.74; H, 3.55. ^1H NMR (300 MHz, $CDCl_3$): δ −6.82 (s, 1H, W-*H*), 0.32 (s, 6H, Si-*Me*), 0.57 (s, 6H, Si-*Me*), 5.58 (d, J = 2.4 Hz, 2H, $C_\alpha C_5H_3$), 5.74 (t, J = 2.4 Hz, 1H, $C_\beta C_5H_3$), 6.40 (t, J = 2.4 Hz, 1H, $C_\beta C_5H_3$), 6.54 (s, 5H, C_5H_5), 7.10 (d, J = 2.4 Hz, 2H, $C_\alpha C_5H_3$). $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): 3.1 (Si-*C*H_3), 3.6 (Si-*C*H_{38}), 94.7 ($C_\beta C_5H_3$), 95.6 ($C_\alpha C_5H_3$), 106.2 (C_{ipso} *C*$_5H_3$), 113.8 (C_β *C*$_5H_3$), 120.1 (*C*$_5H_5$), 133.4 (C_α *C*$_5H_3$), 139.2 (C_{ipso} *C*$_5H_3$), *C*O was not observed. IR (nujol): ν_{CO} 2012, 1914 cm^{-1}; IR(THF): ν_{CO} 2016, 1920 cm^{-1}.

Synthesis of trans-$[Ti(\eta^5\text{-}C_5Me_5)Cl_2\{(\eta^5\text{-}C_5H_3)_2[Si(CH_3)_2]_2\}MoH(CO)_3]$ (*trans*-**5**)

THF (50 ml) was added to a mixture of $[Ti(\eta^5\text{-}C_5Me_5)Cl_2\{(\eta^5\text{-}C_5H_3)[Si(CH_3)_2]_2(C_5H_4)\}]$ (1.48 g, 2.97 mmol) and $[Mo(CO)_3(MeCN)_3]$ (0.9 g, 2.97 mmol). After stirring for a night at room temperature the resulting red solution was concentrated to dryness *in vacuo* leaving a red solid which was washed with pentane and identified as complex *trans*-**5** (1.88 g, 93%). Anal. calc. for $C_{27}H_{34}Cl_2MoO_3Si_2Ti$: C, 47.87; H, 5.06. Found: C, 47.59; H, 5.25. ^1H NMR (300 MHz, C_6D_6): δ −5.54 (s, 1H, Mo-*H*), 0.47 (s, 6H, Si-*Me*), 0.59 (s, 6H, Si-*Me*), 1.70 (s, 15H, C_5Me_5), 5.05 (m, 3H, $C_\alpha C_5H_3 + C_\beta C_5H_3$), 5.68 (t, J = 2.4 Hz, 1H, $C_\beta C_5H_3$), 6.48 (d, J = 2.4 Hz, 2H, $C_\alpha C_5H_3$). $^{13}C\{^1H\}$ NMR (50 MHz, C_6D_6): 2.5 (Si-*C*H_3), 4.7 (Si-*C*H_3), 13.5 (C_5Me_5), 97.5 ($C_\beta C_5H_3$), 98.8 ($C_\alpha C_5H_3$), 105.2 (C_{ipso} *C*$_5H_3$), 117.4 (C_β *C*$_5H_3$), 129.6 (*C*$_5$Me$_5$), 131.5 (C_α *C*$_5H_3$), 137.7 (C_{ipso} *C*$_5H_3$), 227.9 and 228.0 (*C*O).

IR (nujol): ν_{CO} 2016, 1920 cm^{-1}; IR(THF): ν_{CO} 2018, 1928 cm^{-1}.

When the reaction was carried out with $Mo(CO)_3$ (mesitylene) in the same conditions, a mixture of *cis*-**5** and *trans*-**5** was obtained after concentrating to dryness and washing with pentane. Complex *cis*-**5** could not be isolated. ^1H NMR (300 MHz, C_6D_6): δ −4.86 (s, 1H, Mo-*H*), 0.20 (s, 6H, Si-*Me*), 0.73 (s, 6H, Si-*Me*), 1.73 (s, 15H, C_5Me_5), 5.02 (d, J = 2.4 Hz, 2H, C_α C_5H_3), 5.11 (t, J = 2.4 Hz, 1H, C_β C_5H_3), 6.65 (t, J = 2.4 Hz, 1H, C_β C_5H_3), 6.51 (d, J = 2.4 Hz, 2H, C_α C_5H_3).

Synthesis of cis-[Ti(η^5-C_5Me_5)Cl_2\{(η^5-C_5H_3)$_2$ [Si$(CH_3)_2]_2$\}WH$(CO)_3$] (*cis*-**6**)

THF (50 ml) was added to a mixture of [Ti(η^5-C_5Me_5)Cl_2 \{(η^5-C_5H_3)[Si$(CH_3)_2]_2(C_5H_4)$\}] (1.38 g, 2.77 mmol) and [$W(CO)_3(MeCN)_3$] (1.08 g, 2.77 mmol). After stirring for 4 h at 50°C the resulting red solution was concentrated to dryness *in vacuo* leaving a red solid which was washed with pentane and identified as complex *cis*-**6** (1.95 g, 92%). Anal. calc. for $C_{27}H_{34}Cl_2O_3Si_2TiW$: C, 42.37; H, 4.48. Found: C, 42.59; H, 4.59. ^1H NMR (300 MHz, $CDCl_3$): δ −6.78 (s, 1H, W-*H*), 0.31 (s, 6H, Si-*Me*), 0.55 (s, 6H, Si-*Me*), 2.04 (s, 15H, C_5Me_5), 5.56 (d, J = 2.4 Hz, 2H, C_α C_5H_3), 5.71 (t, J = 2.4 Hz, 1H, C_β C_5H_3), 6.09 (t, J = 2.4 Hz, 1H, C_β C_5H_3), 6.66 (d, J = 2.4 Hz, 2H, C_a C_5H_3). $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): 2.8 (Si-*C*H_3), 4.9 (Si-*C*H_3), 13.8 (C_5Me_5), 95.0 (C_β C_5H_3), 95.7 (C_α C_5H_3), 106.0 (C_{ipso} C_5H_3), 116.0 (C_β C_5H_3), 130.1 (C_5Me_5), 131.8 (C_α C_5H_3), 139.0 (C_{ipso} C_5H_3), *C*O was not observed. IR (nujol): ν_{CO} 2012, 1920 cm^{-1}; IR(THF): ν_{CO}: 2016, 1922 cm^{-1}.

When the reaction yielded a mixture of isomers, we were unable to isolate complex *trans*-**6**. ^1H NMR (300 MHz, $CDCl_3$): δ −7.48 (s, 1H, W-*H*), 0.43 (s, 6H, Si-*Me*), 0.48 (s, 6H, Si-*Me*), 2.02 (s, 15H, C_5Me_5), 5.62 (d, J = 2.4 Hz, 2H, C_α C_5H_3), 5.76 (t, J = 2.4 Hz, 1H, C_β C_5H_3), 6.18 (t, J = 2.4 Hz, 1H, C_β C_5H_3), 6.63 (d, J = 2.4 Hz, 2H, C_α C_5H_3).

Synthesis of cis-[Ti(η^5-C_5H_5)Cl_2\{(η^5-C_5H_3)$_2$[Si$(CH_3)_2]_2$\}MoCl$(CO)_3$] (*cis*-**7**)

CCl_4 (2 ml) was added to a solution of complex *cis*-**3** (1 g, 1.65 mmol) in CH_2Cl_2 (40 ml). After stirring for a night, the solution was concentrated to dryness *in vacuo* leaving a red solid which was washed with pentane and recrystallized from a mixture CH_2Cl_2: pentane 1 : 1 at −40°C to give *cis*-**7** as a red solid (0.95 g, 90%). Anal. calc. $C_{22}H_{23}Cl_3MoO_3Si_2Ti$: C, 41.17; H, 3.61. Found: C, 41.69; H, 4.19. ^1H NMR (300 MHz, $CDCl_3$): 0.33 (s, 6H, Si-*Me*), 0.57 (s, 6H, Si-*Me*), 5.55 (d, J = 2.4 Hz, 2H, C_α C_5H_3), 6.25 (t, J = 2.4 Hz, 1H, C_β C_5H_3), 6.40 (t, J = 2.4 Hz, 1H, C_β C_5H_3), 6.56 (s, 5H, C_5H_5), 7.13 (d, J = 2.4 Hz, 2H, C_α C_5H_3). $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): 1.8 (Si-*C*H_3), 3.0 (Si-*C*H_3), 96.7 (C_β C_5H_3), 105.8 (C_{ipso} C_5H_3), 111.6 (C_α C_5H_3), 113.9 (C_β C_5H_3), 120.3 (C_5H_5), 133.5 (C_α C_5H_3), 139.1 (C_{ipso} C_5H_3), 222.8 and 242.5 (*C*O). IR (nujol): ν_{CO} 2045, 1946 cm^{-1}; IR(CH_2Cl_2): ν_{CO} 2054, 1976 cm^{-1}.

Synthesis of cis-[Ti(η^5-C_5H_5)Cl_2\{(η^5-C_5H_3)$_2$[Si$(CH_3)_2]_2$\}WCl$(CO)_3$] (*cis*-**8**)

This complex was obtained by the same procedure described for *cis*-**7** starting from *cis*-**4** (1 g, 1.44 mmol) as a red solid (1 g, 95%). Anal. calc. for $C_{22}H_{23}Cl_3O_3Si_2TiW$: C, 36.21; H, 3.18. Found: C, 35.84; H, 3.15. ^1H NMR (300 MHz, $CDCl_3$): δ 0.36 (s, 6H, Si-*Me*), 0.60 (s, 6H, Si-*Me*), 5.57 (d, J = 2.4 Hz, 2H, C_α C_5H_3), 6.41 (m, 2H, 2C_β C_5H_3), 6.57 (s, 5H, C_5H_5), 7.13 (d, J = 2.4 Hz, 2H, C_α C_5H_3). $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): 2.0 (Si-*C*H_3), 3.2 (Si-*C*H_3), 96.4 (C_β C_5H_3), 102.7 (C_{ipso} C_5H_3), 110.0 (C_α C_5H_3), 113.9 (C_β C_5H_3), 120.4 (C_5H_5), 133.4 (C_α C_5H_3), 139.2 (C_{ipso} C_5H_3), 214.2 and 232.4 (*C*O). IR (nujol): ν_{CO} 2013, 1952 cm^{-1}; IR(CH_2Cl_2): ν_{CO} 2046, 1958 cm^{-1}.

Synthesis of trans-[Ti(η^5-C_5Me_5)Cl_2\{(η^5-C_5H_3)$_2$[Si$(CH_3)_2]_2$\}MoCl$(CO)_3$] (*trans*-**9**)

This complex was obtained by the same procedure described for *cis*-**7** starting from *trans*-**5** (1 g, 1.47 mmol) as a red solid (0.97 g, 93%). Anal. calc. for $C_{27}H_{33}Cl_3O_3Si_2TiMo$: C, 45.55; H, 4.67. X-ray structural determination for **6**

Red crystals of compound **6** were obtained by crystallization from THF and a suitable sized crystal in a Lindemann tube was mounted in an Enraf-Nonius CAD 4 automatic four-circle diffractometer with graphite monochromated Mo–K_α radiation ($\lambda = 0.71069$ Å). Crystallographic and experimental details are summarized in Table 2. Data were collected at room temperature. Intensities were corrected for Lorentz and polarization effects in the usual manner. No absorption or extinction corrections were made. The structure was solved by direct methods (SHELXL 90) [12] and refined by least squares against F^2 (SHELXL 93) [13]. A severe disorder appeared in the coordination sphere of the W atom and two different sets of carbonyl groups with similar occupancies were found. Unfortunately the second set shows the angle of one carbonyl group with an important deviation from linearity. All non-hydrogen atoms were refined anisotropically and the hydrogen atoms were introduced from geometrical calculations and refined using a riding model with thermal parameters equivalent to those of the atoms to which they are bonded. It was not possible to find the hydrogen atom bonded to W due to the disorder and this atom could not be included in any way. Calculations were carried out on an ALPHA AXP (Digital) workstation.

Supplementary material—Tables of positional parameters and their estimated standard deviations (Table 1), full list of bond lengths (Å) and angles (°) (Table 2), anisotropic displacement parameters (Table 3), hydrogen coordinates and isotropic displacement parameters (Table 4), and structure factors (Table 5) are available from author P.R. upon request.

Acknowledgment—The authors are grateful to DGICYT (Project PB-920178C) and CAM (I + D 0033/94) for financial support. A.M. is grateful to CAM for fellowship.

(Received 8 October 1997; accepted 10 November 1997)

Abstract—Protonation of $CpMo(\eta^3\text{-}C_3H_5)(CO)_2$ followed by reactions with several diazole ligands produce the molybdenum half-sandwich complexes $[CpMo(CO)_2L_2]^+$ (L_2 = Bisimidazole (H_2Biim), pyrazole $(Hpz)_2$, Cpz_4, and $[Bpz_4]^-$) in good yields. Deprotonation of $[CpMo(CO)_2(H_2Biim)]^+$ gives the anionic complex $[CpMo(CO)_2(Biim)]^-$.

The structure of $[CpMo(CO)_2(H_2Biim)][ReO_4]$ was determined by X-ray single crystal analysis. The coordination geometry around the molybdenum atom in the complex cation $[CpMo(CO)_2(H_2Biim)]^+$ can be described as a distorted square pyramid. The basal plane is defined by two nitrogen atoms of H_2Biim bidentate ligand and two carbon atoms of carbonyl groups. The apical position is occupied by five carbon atoms of the $\eta^5\text{-}C_5H_5$ ligand. The Mo centre lies at 0.94(1) Å from the basal plane in the apical direction.

$[CpMo(CO)_2(Biim)]^-$ reacts with $ClReO_3$ or $MeReO_3$ (MTO) to give binuclear complexes of the formula $[\{CpMo(CO)_2\}(\mu\text{-}Biim)\{Re(X)O_3\}]Na$ (X = Cl, CH_3) in quantitative yields. $[CpMo(CO)_2(\mu\text{-}Cpz_4)][BF_4]$ reacts with $ClReO_3$ to yield $[\{CpMo(CO)_2\}(\mu\text{-}Cpz_4)\{Re(Cl)O_3\}][BF_4]$. The corresponding adduct $[\{CpMo(CO)_2\}(\mu\text{-}Cpz_4)\{Re(Cl)O_3\}][BF_4]$ can not be obtained in a pure form. The reaction of $[Bpz_4]^-$ with $ClReO_3$ yields the known Bpz_4ReO_3, with $MeReO_3$ the sensitive $[Bpz_4\{Re(CH_3)O_3\}]K$ is obtained. Deprotonation of the molybdenocene complex $[Cp_2Mo(H_2Biim)]^{2+}$ leads to the neutral compound $Cp_2Mo(Biim)$. The latter compound can be reacted with CH_3ReO_3 or $ClReO_3$ to form $[\{Cp_2Mo\}(\mu\text{-}Biim)\{Re(X)O_3\}]$ (X = CH_3, Cl). A ^{95}Mo NMR investigation shows the influence of the overall charge of the complex and the electron donor capability on the Mo centre. It is shown by ^{95}Mo, ^{17}O, ^1H NMR, and IR spectroscopy that the donor capability of the molybdenocene to the rhenium(VII) centre in the binuclear complexes is not very pronounced and can be compared to the strength of organic nitrogen donor complexes, e.g. 2,2′-bipyridyl. In donor solvents temperature dependent, rapid dynamic exchange processes can be observed. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: Re(VII) oxides; Mo/Re binuclear complexes; bisimidazole and polypyrazolyl ligands.

The interaction of metal centres through ligand bridges is a very important aspect of coordination chemistry which is present in many ligand substitution and electron transfer mechanisms and is widely used by nature in metalloenzymes [1a]. The elaborate design and assembling of appropriate interacting centres has produced novel molecular magnets [1b] and the search for cooperative effects in catalysis has led to an extensive study of early-late heterobimetallic complexes [2,3]. On the other hand, interactions between bridged metals in high and low oxidation states has been scarcely studied. Since its own discovery of the multigram synthesis of CH_3ReO_3,

* Author to whom correspondence should be addressed.

trivially nicknamed MTO [4], Herrmann *et al.* have intensively explored the chemistry of Re(VII) oxides and produced a variety of organic and inorganic $XReO_3$ complexes. These form adducts of the general formula $XReO_3 \cdot L_n$ ($n = 1, 2$), mainly with *N* donor ligands which modulate the electronic and reactivity characteristics of the oxo ligands [5]. In this respect, organometallic ligands can play an important role inasmuch as their electronic properties may be further tuned by the manipulation of variables absent in organic ligands, e.g. net charge, metal oxidation state and metal spin.

Following these ideas, the present work describes the synthesis and characterization of binuclear adducts formed between high-oxidation state $XReO_3$ complexes and organometallic ligands bearing bridges with *N* donors like bisimidazole (H_2Biim), pyrazole (Hpz), tetrapyrazolyborate [Bpz_4^-] and tetrapyrazolylmethane (Cpz_4). Molybdenocene, Mo(IV), and $[CpMo(CO)_2]^+$, Mo(II), derivatives were chosen for their high thermodynamic and kinetic stability. $ClReO_3$ was used because if forms more stable complexes with electron donors than most organorhenium(VII) oxides [5]. Being the most stable organorhenium(VII) derivative known to date and by far the most thoroughly examined Re(VII) complex, MTO provides a probe to evaluate the bonding characteristics of these organometallic ligands [4,5].

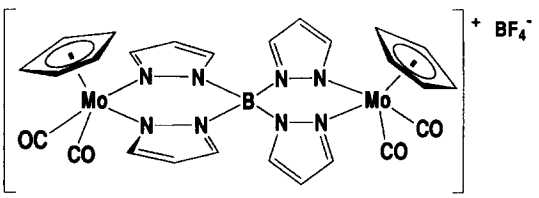
RESULTS AND DISCUSSION

Synthesis and characterization of the organometallic ligands

The molybdenum based organometallic ligands used in this work are of two types. Type I ligands comprise a variety of half-sandwich complexes, derived from $CpMo(\eta^3\text{-}C_3H_5)(CO)_2$ (**1**) of the general formula $[CpMo(CO)_2L_2]^+$ (L_2 = bisimidazole (H_2Biim) (**2**), pyrazole $(Hpz)_2$ (**3**), Cpz_4 (**4**) and $[Bpz_4]^-$ (**5**)) (**I**) whereas type II ligands are confined to the molybdenocene derivative $Cp_2Mo(Biim)$ (**7**), derived from $[Cp_2Mo(H_2Biim)]^{2+}$ (**6**).

Table 1 summarizes ^{95}Mo data, selected ^1H shifts and selected IR vibrations for these molecules and their adducts with $XReO_3$ compounds. Type I molecules are prepared as depicted in Scheme 1, following the method first used by Cutler *et al.* [6] and later by Romão *et al.* [3c–g,i] to prepare a wide range of cyclopentadienyl and indenyl cations of the general formula $[(\eta^5\text{-}Cp')M(CO)_2L_2]BF_4$ (L = N, P, S, and O ligands) [3a,b].

The starting complex **1** [3c,d] is protonated with $HBF_4 \cdot OEt_2$ in CH_2Cl_2 at room temperature and the resulting red solution treated with the diazole ligand L to give the products **2**–**4** in yields of ca 80–90%. The crystal structure of the $[ReO_4]^-$ salt of $\mathbf{2}^+$ (**2a**) is described below. In the case of the $[Bpz_4]^-$ ligand it was not possible to isolate the known complex ligand $[CpMo(CO)_2(k^2\text{-}Bpz_4)]$ [7] and the binuclear species $[\{CpMo(CO)_2\}_2(\mu\text{-}Bpz_4)][BF_4]$ (**5**) was formed instead. The ^1H-NMR spectrum of this complex shows only one singlet for the Cp groups and six singlets belonging to pyrazol-protons of $[Bpz_4]^-$. The ^{95}Mo-NMR shows one signal at 108 ppm. Two ν(CO) IR vibrations can be observed. In keeping with these data we propose the structure of **5** as depicted below with both equivalent Cp rings and Mo atoms.



5

In order to prepare the organometallic ligand with the bisimidazole bridge the cation **2** was deprotonated by reaction with excess NaH in THF. The resulting anionic complex $[CpMo(CO)_2(Biim)]Na$ (**8**) was isolated in good yield. It is a very hygroscopic and air sensitive species freely soluble in Et_2O, THF and CH_2Cl_2. The similar deprotonation of the bispyrazole cation **3** was attempted but the expected anionic complex $[CpMo(CO)_2(pz)_2]^-$ could not be isolated pure. The alternative preparation from [CpMo-

$[\{Cp_2Mo\}(\mu\text{-}Biim)\{Re(Cl)O_3\}]$	**17**	5.65	—	−40

All the ^{95}Mo spectra were recorded in NCMe at room temperature, the spectra of **16, 17** in nitromethane.

$(CO)_2(NCCH_3)_2]^+$ and Kpz gave similarly disappointing results.

The spectroscopic data in Table 1 allows for some comparisons between the properties of the organometallic ligands **4** and **8** to be made assuming that they correlate with the electronic richness of the metal in these structurally very similar species. In agreement with the expected trend, **8** which bears the more electron rich anionic ligand has the lower values of ν(CO). This general trend is paralleled by the values of the chemical shifts of the Cp rings in the ^1H-NMR spectra where **8** presents the more shielded resonance at $\delta(^1H) = 5.65$ ppm. However, these criteria do not seem very sensitive to the variations which occur upon coordination of the free *N* donor atoms. The comparison of the ν(CO) and δ Cp (^1H-NMR) resonances between **2** and **8** is illustrative of the small differences found suggesting that most of the electron density gained upon deprotonation of **2** remains on the bisimidazole ring of **8** while the electron density of the other ligands (Cp and CO) is not influenced significantly. This point will be again found upon coordination of **4** and **8** to $XReO_3$ complexes (see below). A much more sensitive measure of the differences felt in the environment of the Mo atom of all these complexes is given by the ^{95}Mo-NMR chemical shifts which, however, are not so straightforward to interpret [8]. Indeed, the comparison of the ^{95}Mo-NMR chemical shift of the precursor compound $CpMo(\eta^3\text{-}C_3H_5)(CO)_2$ ($\delta(^{95}Mo) = -1625/-1804$ ppm (endo/exo isomer)) [3i], with those of **2–5** and **8** reveals the vast dissimilarity of bonding environments at the molybdenum in both types of compounds with the same formal oxidation state and built upon the same fragment $[CpMo(CO)_2]^+$. However, the similar chemical and structural environments of the Mo in complexes **2–5** and **8** allows for some conclusions to be drawn. The chemical shift of compounds **2–5** and **8** differs significantly and should reflect the donor capability of the ligand L, a better donor producing a more shielded resonance. Accordingly, the capability of electron donation to the Mo centre measured by the value of the ^{95}Mo NMR chemical shifts decreases in the order $(Biim)^{2-}$ (**8**) > H_2Biim (**2**) > $(Hpz)_2$ (**3**) > Cpz_4 (**4**). The Cpz_4 ligand is the weakest donor of the series, leading to a difference of ca 390 ppm between the ^{95}Mo NMR chemical shifts of **4** and **8**. This order of decreasing donation to the central Mo parallels that predicted on the basis on the respective ν(CO) frequencies $(Biim)^{2-} > H_2Biim > (Hpz)_2 > Cpz_4$ and is very similar to the one based on the values of δ Cp (^1H-NMR) chemical shifts $H_2Biim \geqslant (Biim)^{2-} > (Hpz)_2 > Cpz_4$.

The first attempted synthesis of the metallocene ligand (type II) introduced the novel preparation of Cp_2MoI_2 (**9**) from $[Cp_2Mo(CO)I][BF_4]$ and $(n\text{Bu})_4NI$ in CH_2Cl_2. The reaction of **9** with $TlBF_4$ and H_2Biim leads to the known $[Cp_2Mo(H_2Biim)][BF_4]_2$ (**6**) [9]. However, this complex is best prepared from $[Cp_2Mo(NCCH_3)_2][BF_4]_2$ and H_2Biim in boiling *N*-methylformamide/aceton. Complex **6** can be deprotonated with an excess of NaH to form the new organometallic ligand $Cp_2Mo(Biim)$ (**7**). This very reactive complex which was fully characterized, displays a ^{95}Mo-NMR signal at −390 ppm which is an upfield shift of 215 ppm relative to **6**. This shift is due to the higher electron density of the neutral molecule and is almost twice the one observed in the closely related transformation of **2** to **8**.

Molecular and crystal structure of $[CpMo(CO)_2(H_2Biim)][ReO_4]$ (**2a**)

The structure of the complex (**2a**) which was unexpectedly obtained from very slow decomposition of

[{CpMo(CO)$_2$}(μ-Biim){Re(CH$_3$)O$_3$}]Na (**10**) was established by X-ray single crystal diffraction analysis. The asymmetric unit is composed by one discrete [CpMo(CO)$_2$(H$_2$Biim)]$^+$ cation and one discrete [ReO$_4$]$^-$ anion. Figure 1 shows the X-ray single crystal structure of [CpMo(CO)$_2$(H$_2$Biim)][ReO$_4$] with the labelling scheme adopted.

The complex cation and complex anion are close to each other leading to intermolecular interactions N—H···O between one oxygen of the anion with both uncoordinated nitrogen atoms of H$_2$Biim ligand [N(24)—H(24)···O(1) 2.119 Å, 145.2° and N(27)—H(27)···O(1) 2.188 Å, 139.2°]. In the crystal structure these donor atoms still establish hydrogen bonds with two other oxygen atoms of the anion. [N(24)—H(24)···O(3) 2.458 Å, 126.6° ($-x+1$, $-y$, $-z$) and N(27)—H(27)···O(4) 2.211 Å, 131.6° ($-x+1$, $-y+1$, $-z$)].

Table 2 lists selected bond lengths and angles for the complex cation. The coordination geometry around the molybdenum centre can be described as a distorted square pyramid. Two nitrogen atoms of the bisimidazole ligand, and two carbons from carbonyl groups define the basal plane. The η^5-C$_5$H$_5$ ring occupies the apical position. The Mo atom lies at 0.94(1) Å from the least square plane, through N(21), N(30), C(41) and C(51), in the apical direction. The vector Mo–Cp (Cp = centroid of the Cp ring) is perpendicular to the plane of the Cp ring; the dihedral angle between them is 90.1°. The subtended angles at the Mo centre range from 72.8(6)° to 126.3(9)°. Similar geometric arrangements, with comparable structural parameters, have been found for other derivatives of the type [CpMo(CO)$_2$LL'] [10]. The Mo—C—O angles of 175(3)° and 179(2)° show that the carbonyl ligands are bonded linearly to molybdenum centre. The average bond lengths Mo—N 2.19(2) Å and Mo—C 1.94(2) Å fall in the expected range of 2.118–2.239 Å and of 1.906–1.986 Å for Mo—C for Mo—N bond lengths, respectively. These ranges were obtained with structural data available from Crystallographic Cambridge Data Base for com-

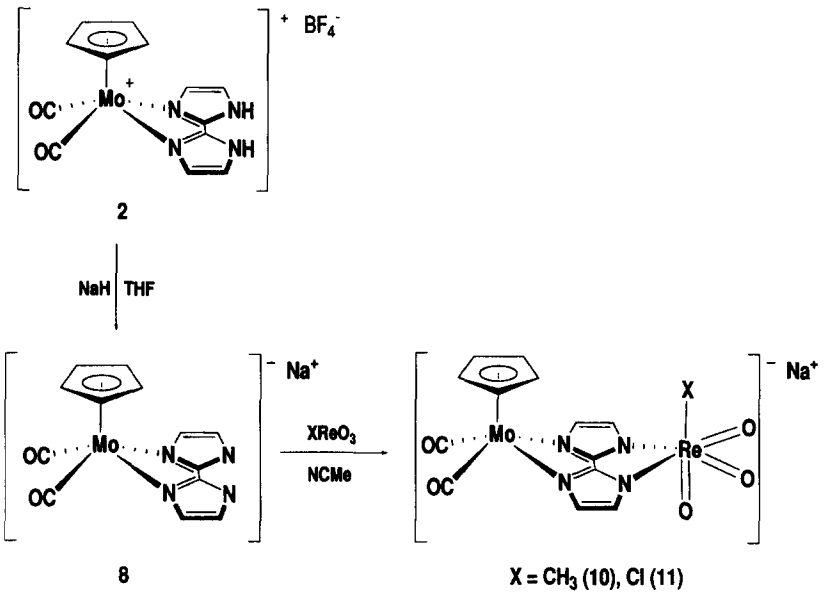
pounds related with the complex cation under study [11].

Synthesis and characterization of the binuclear complexes with $XReO_3$

Reaction of the complexes **4** and **8** with CH_3ReO_3 and $ClReO_3$, respectively, leads to immediate formation of the complexes $[\{CpMo(CO)_2\}(\mu\text{-Biim})\{Re(CH_3)O_3\}]Na$ (**10**), $[\{CpMo(CO)_2\}(\mu\text{-Biim})\{Re(Cl)O_3\}]Na$ (**11**), and $[\{CpMo(CO)_2\}(\mu\text{-Cpz}_4)\{Re(Cl)O_3\}][BF_4]$ (**12**) according to Schemes 2 and 3. $ClReO_3$ was prepared *in situ* from $ClSiMe_3$ and Re_2O_7 for these reactions as reported before [5b].

A clean compound of composition $[\{CpMo(CO)_2\}(\mu\text{-Cpz}_4)\{Re(CH_3)O_3\}][BF_4]$ (**13**), however, could not be obtained. Several by products were formed which we were not able to remove in appropriate manner. The analogous reaction between $KBpz_4$ and $ClReO_3$ yielded neither the adduct $[Re(Cl)O_3(k^2\text{-Bpz}_4)]K$ nor the dimer $[\{Re(Cl)O_3\}_2(\mu\text{-Bpz}_4)]$ but the already known $(k^3\text{-Bpz}_4)(ReO_3)$ (**14**) [12] and KCl (Scheme 4). Obviously, the Cl—Re bond is weak enough to be split to form the neutral Re complex and the salt KCl. Reaction of $KBpz_4$ with CH_3ReO_3 leads to a very sensitive, yellow complex of formula $[Bpz_4(CH_3)ReO_3]K$ (**15**).

IR spectrum of this compound at room temperature show ligand fragments, $KReO_4$ and ReO_3. The formation of $KReO_4$ can also be observed by ^{17}O-NMR. If the reaction is performed at $-45°C$ the product is more stable. A proton NMR of compound **15** displays the signal for the Re—CH_3 group at $\delta(^1H) = 1.83$ ppm in acetone, compared to free MTO at 2.63 ppm in the same solvent. This shift difference clearly indicates the formation of a donor adduct of MTO with the $[Bpz_4]^-$ anion. However, even with excess of MTO



Scheme. 2.

R = $N_2C_3H_3$ (**14**)

Scheme. 4.

a complex of the composition [{$Re(CH_3)O_3$}(μ-Bpz_4)]K could not be obtained. Complex **15** changed its colour during slow warming up to room temperature from yellow to black, yielding the same decomposition products as mentioned above.

The stability of all these adducts in solution is relatively limited and thwarted all attempts of growing crystals suitable for X-ray crystallography. The crystals of **2a** were obtained during the prolonged attempted crystallization of **10** from CH_2Cl_2/Et_2O. Decomposition of **10** by adventitious water, eventually induced by light, is the most plausible explanation for the observed transformation. In fact, it is well known that MTO decomposes to $[ReO_4]^-$ and CH_4 upon reaction with OH^- [4]. The rather basic character of **8** and the easy dissociation of **10** in solution (discussed below) create the conditions for this decomposition pathway. A similar process is certainly operative in the decomposition of the adducts with $ClReO_3$ all of which are very moisture sensitive decomposing with formation of $[ReO_4]^-$(IR evidence). It is known that the adduct $ClReO_3 \cdot$ bipy [5b], although originally reported as air stable, decomposes in air to the also colourless $[Hbipy]^+[ReO_4]^-$ like ('Bubipy)$Re(CH_3)O_3$ [5].

The original ^{95}Mo-NMR signal of **8** is shifted ca 25 ppm downfield after the addition of $(CH_3)ReO_3$ to form **10**. The original ^{95}Mo-NMR signal of **4** is also influenced by the addition of $(CH_3)ReO_3$ and $ClReO_3$, respectively: in both cases a downfield shift of ca 20 ppm is observed, indicating the electron withdrawing influence of the Re(VII) fragment. In keeping with the previously mentioned lack of sensitivity of the ν(CO) and δ Cp (^{1}H-NMR) chemical shifts these values remain almost constant for **10–12**. ^{17}O-NMR experiments performed in CD_3CN indicate a relatively weak Re–N interaction because the chemical shift of the Re bound oxo groups is only insignificantly different from that of free CH_3ReO_3 ($\delta(^{17}O) = 824$ ppm) and $ClReO_3$ ($\delta(^{17}O) = 825$ ppm) in the same solvent at room temperature and above. Despite the octahedral coordination of the Re centre in **10–12** only one ^{17}O-NMR signal can be observed at room temperature and above. In an octahedrally coordinated complex one would expect two oxygen signals in a 1:2 ratio due to the chemically different oxo groups in apical and equatorial positions. However, this result is not unexpected as it is known that in donor solvents, e.g. CH_3CN and THF, rapid solvent/ligand exchange takes place at the Re(VII) centre at room temperature leading only to one "mediated" signal [13]. In the case of **10–12** cooling down the solution leads only to a significant broadening, but not to separation into two signals. The explanation for such an exchange process is based on Scheme 3. In our experience with related complexes this broadening is not mainly caused by the natural line broadening of the ^{17}O-core during cooling but by the slowing down of the exchange processes. It is not possible, however, to separate the signals into two distinct peaks with the temperature range available in the solvents CD_3CN and THF. This indicates a relatively weak Re–N interaction in the examined complexes **10–12**. From the ν(ReO) vibrations the force constants of the Re=O vibrations were calculated (see Table 3) according to Ref. [14]. The results show that the Re=O force constants in the the solid state (IR measurements were performed in KBr) are of an equal order of magnitude to those in complexes of $ClReO_3$ and CH_3ReO_3 with organic donor ligands, e.g. 2,2′-bipyridyl [5b]. It is known that these complexes also undergo exchange equilibria with donor solvents in solution [13]. Unfortunately, such good strong donors are the only solvents capable of dissolving such ionic adducts and limit the scope of our studies. Therefore the study of neutral adducts formed from neutral organometallic ligands and $XReO_3$ complexes was considered as a possibility of avoiding such problems. It should be noted in this context that it has been tried before to link CH_3ReO_3 with other organo transition metal complexes with bipyrimidine (bpm) to generate neutral products. However, this approach did not lead to stable products. Only CH_3ReO_3(bpm) could be isolated [5i].

Reaction of **7** with CH_3ReO_3 leads to [{Cp_2Mo}(μ-Biim){$Re(CH_3)O_3$}] (**16**) which is well soluble in ace-

Table 3. Force constants F(ReO) and symmetric and asymmetric stretching vibrations ν(Re=O) of selected Re(VII)O_3 complexes

tone (Scheme 5). The ^{1}H-NMR signal of the CH_3-Re group appears at 1.39 ppm which is more than 1.2 ppm low field shifted relative to free CH_3ReO_3 (δ(^{1}H) = 2.63 ppm) [5]. Shifts of this magnitude are usually caused by strong Lewis bases fixed to the Re(VII) centre. The ^{95}Mo signal of **16** is observed at −48 ppm representing a much higher shift than the one observed between the neutral and the protonated form of the ligand, **7** and **6** respectively. This good agreement between the ^{1}H and ^{95}Mo-NMR data point to the strongly electron withdrawing nature of the Re(VII) fragment which obviously leads to considerable deshielding of the Mo(IV) core. The ^{17}O-NMR spectrum in nitromethane as a solvent shows one signal at 828 ppm. This is only a minor shift difference to free CH_3ReO_3 (δ(^{17}O) = 818 ppm in nitromethane) but clearly shows a shift change caused by the reaction of the Re(VII)trioxo moiety with an electron donor. A similar shift is observed upon coordination of MTO to methoxyanilins [13a]. The chemical shift of the cyclopentadienyl ligands also reflects the lower electron density around the Mo core in **16** relative to **7**. In the cationic complex **6** the Cp groups show up at δ (^{1}H) = 5.83 ppm. Removal of two protons leads to a shift of the Cp signal of about 0.3 ppm to higher field. Addition of the electron withdrawing CH_3ReO_3 causes a downfield shift of ca 0.1 ppm. The data obtained for the adduct [{Cp_2Mo}(μ-Biim){Re(Cl)O_3}] (**17**) closely resemble the data of compound **16**. However, following the general trend already noted above, **17** is less stable and decomposes relatively quickly in air and is also less soluble in most solvents preventing the obtention of ^{17}O-NMR data of sufficient quality.

EXPERIMENTAL

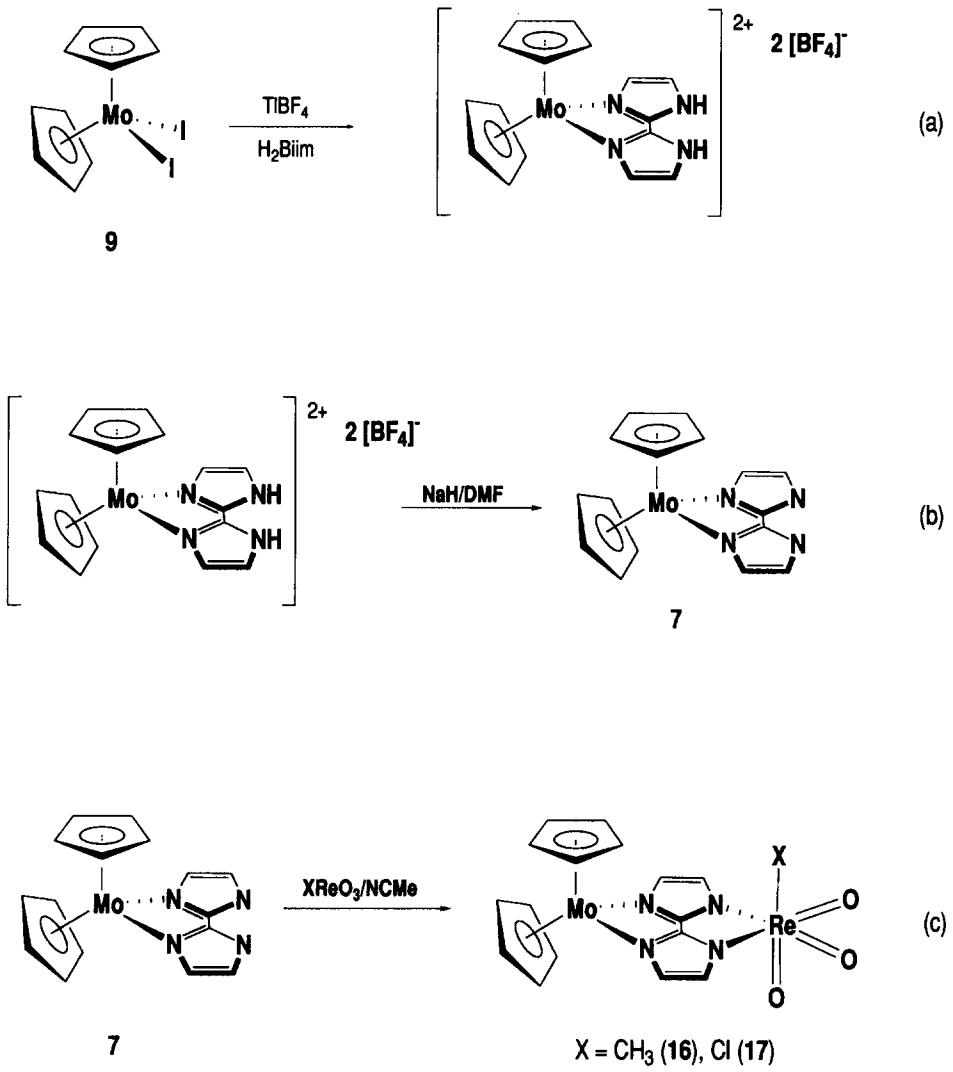
All preparations and manipulations were done with standard Schlenk techniques under an oxygen-free and water-free argon atmosphere. Solvents were dried by standard procedure THF, Et_2O, pentane, and hexane over Na/benzophenone ketyl; acetonitrile and dichloromethane were distilled after refluxing several hours over P_2O_5. Acetone was distilled over K_2CO_3 and kept over 4 Å molecular sieves. Microanalyses were performed at the TUM (Garching) and at the ITQB (Oeiras). ^{1}H NMR spectra were obtained with a Bruker CXP 300 spectrometer. Infrared spectra were recorded on a Unican Mattson Mod 7000 FTIR spectrophotometer using KBr pellets and/or in solution. ^{17}O-NMR and ^{95}Mo-NMR spectra were measured at 54.14 MHz on a JEOL JNM and a GX-400 BRUKER ADVANCED DPX-400. ^{17}O labelled Re_2O_7 and CH_3ReO_3 were prepared according to the literature [13a,15]. CpMo(η^3-C_3H_5)(CO)$_2$ [3], [Cp_2Mo(CO)I][BF_4] [3i], KBpz$_4$ [16], H_2Biim [9], Cpz$_4$ [17], were prepared as described previously.

Preparation of [CpMo(CO)$_2$(H_2Biim)][BF_4] (**2**)

A solution of CpMo(η^3-C_3H_5)(CO)$_2$ (0.50 g, 1.94 mmol) in CH_2Cl_2 (15 ml) was treated with HBF_4 · Et_2O (1 equivalent). After 10 min, H_2Biim was added (0.33 g, 2.50 mmol) and the reaction left for 4 h at room temperature. The resulting orange solution was filtered, evaporated to dryness, extracted with acetone. After concentration to ca 5 ml and addition of ether, an orange microcrystalline product precipitated. The mother liquor was filtered off and the remaining precipitate was washed with ether and dried in an oil vacuum pump. Yield, 90%. Found: C, 35.76; H, 2.39; N, 12.63, Mo 22.28. Calc. for $C_{13}H_{11}BF_4N_4O_2Mo$: C, 35.65; H, 2.53; N, 12.79, Mo 21.90%. Selected IR (KBr, ν cm^{-1}): 3457 s, 3105 m, 1965 vs (C≡O), 1875 vs (C≡O), 1526 m, 1421 m, 1086 vs, 760 s. ^{1}H NMR ($NCCD_3$, 300 MHz, r.t., δ ppm): 7.52 (d, 2H, H_2Biim); 7.41 (d, 2H, H_2Biim); 5.63 (s, 5H, Cp).

X-ray analysis of [CpMo(CO)$_2$(H_2Biim)][ReO_4] (**2a**)

Crystal data [CpMo(CO)$_2$(H_2Biim)][ReO_4], $C_{13}H_{11}MoN_4O_6Re$, M = 601.40, triclinic a = 6.537



Scheme. 5.

(7), $b = 8.340(8)$, $c = 16.966(18)$ Å, $\alpha = 96.40(1)$, $\beta = 100.29(1)$, $\delta = 105.42(1)°$, $V = 865(2)$ Å, space group $P_{\bar{1}}$, $Z = 2$, $D_c = 2.309$ g cm^{-3}, $F(000) = 564$, $\mu = 7.753$ mm^{-1}.

X-ray data were collected with graphite monochromated Mo–K_α radiation (0.71073 Å) on a Mar-research image plate system in Reading University. The crystal was positioned at 75 mm from the plate. An exposure time of 2 min was used per 2° frame collected. Data analysis was carried out with XDS program [18].

The coordinates of the molybdenum and rhenium atoms were determined by direct methods, and the positions of the remaining non-hydrogen atoms were subsequently found by successive difference Fourier syntheses.

The structure refinement was carried out by full matrix least square method on F^2. Some cycles with isotropic temperature factors for all non hydrogen atoms gave R value of 0.2413 for all *hkl* data. At this point refinement an empirical absorption was applied to the data, using a version of DIFABS program [19], modified for Mar-research image plate system geometry. The R value then lowered to 0.2021. Anisotropic parameters were used for all non hydrogen atoms. Hydrogen atoms were included in the refinement in geometric positions giving thermal parameters equivalents to 1.2 times those of the atom to which they were attached. The final refinement of 227 parameters converged R values of 0.0907 for 1918 reflections with $I > 2\sigma(I)$ and 0.1235 for 2594 unique reflections and GOF of 1.180. A weighting scheme with the form $w = 1/[\sigma^2(F_o^2) + (0.1372P)^2 + 15.70P]$, and $P = [\max(F_o^2) + F_o^2]/3$ was used. In the last difference Fourier map the residual electronic density was in the range 3.048 to -5.501 e Å^{-3}. The highest

peak and deepest hole were both situated within 0.89 Å of the rhenium atom.

All calculations required to solve and to refine the structure were carried out with SHELXS and SHELXL within the SHELX97 package [20]. The molecular diagram was drawn with ORTEP II [21].

Additional material is available from the Cambridge Crystallographic Data Centre and comprises atomic co-ordinates, thermal parameters and all bond lengths and angles.

Preparation of $[CpMo(CO)_2(Hpz)_2][BF_4]$ **(3)**

A solution of $CpMo(\eta^3\text{-}C_3H_5)(CO)_2$ (0.50 g, 1.94 mmol) in CH_2Cl_2 (15 ml) was treated with $HBF_4 \cdot Et_2O$ (1 equivalent). After 10 min, pyrazole was added (0.29 g, 4.25 mmol) and the reaction left for 3 h at room temperature. After concentration to ca 5 ml and addition of ether, a violet product precipitated mixtd with a dark oil. Upon addition of pentane an oily residue separated which was solidified after repeated washings and scratching with pentane. Yield, 83%. Found: C, 35.42; H, 2.74; N, 13.05. Mo, 21.51. Calc. for $C_{13}H_{13}BF_4N_4O_2Mo$: C, 35.49; H, 2.98; N, 12.73 Mo, 21.80%. Selected IR (KBr, ν cm^{-1}): 3352 s, 3119 m, 1979 vs (C≡O), 1875 vs (C≡O), 1528 m, 1476 vs, 1406 m, 1355 m, 1084 vs, 1049 vs, 771 s, 606 m. ^1H NMR ($NCCD_3$, 300 MHz, r.t., δ ppm): 7.79 (s, 2H, Hpz); 7.47 (s, 2H, Hpz); 6.49 (s, 2H, Hpz); 5.77 (s, 5H, Cp).

Preparation of $[CpMo(CO)_2(Cpz_4)][BF_4]$ **(4)**

A solution of $CpMo(\eta^3\text{-}C_3H_5)(CO)_2$ (0.50 g, 1.94 mmol) in CH_2Cl_2 (20 ml) was treated with $HBF_4 \cdot Et_2O$ (1 equivalent). After 10 min, Cpz_4 was added (0.54 g, 1.93 mmol) and the reaction left for 6 h at room temperature. The resulting solution was filtered and taken to dryness. The residue was washed with ether (10 ml). Further recrystallization from CH_2Cl_2/Et_2O gave the violet compound in 91%. Found: C, 41.93; H, 3.36; N, 19.01. Calc. for $C_{20}H_{17}F_4N_8O_2Mo$: C, 41.12; H, 2.93; N, 19.18%. Selected IR (KBr, ν cm^{-1}): 3130 m, 1979 vs (C≡O), 1890, vs (C≡O), 1410 s, 1321 s, 1051 vs, 1029 vs, 874 s, 762 s, 602 m. ^1H NMR ($NCCD_3$, 300 MHz, r.t., δ ppm): 8.97 (s, Cpz_4); 8.68 (s, Cpz_4); 8.38 (s, Cpz_4); 8.29 (s, Cpz_4); 7.45 (s, Cpz_4); 6.78 (s, Cpz_4); 6.00 (s, Cp).

Preparation of $[\{CpMo(CO)_2\}_2(\mu\text{-}Bpz_4)][BF_4]$ **(5)**

A solution of $CpMo(\eta^3\text{-}C_3H_5)(CO)_2$ (0.50 g, 1.94 mmol) in CH_2Cl_2 (20 ml) was treated with $HBF_4 \cdot Et_2O$ (1 equivalent). After 10 min, $KBpz_4$ was added (0.61 g, 1.94 mmol) and the reaction left for 2 h at room temperature. The resulting solution was filtered and taken to dryness. The residue was washed with ether (10 ml). Further recrystallization from CH_2Cl_2/Et_2O gave the compound in 96% yield. Found: C, 39.34; H, 2.70; N, 13.63; Mo, 24.27. Calc. for $C_{26}H_{22}B_2F_4N_8O_4Mo_2$: C, 39.04; H, 2.77; N, 14.01; Mo, 23.98%. Selected IR (KBr, ν cm^{-1}): 3117 m, 1964 vs (C≡O), 1873; vs (C≡O), 1389 s, 1292 s, 1070 vs, 826 s, 762 s. ^1H NMR ($NCCD_3$, 300 MHz, r.t., δ ppm): 8.14 (s, 2H, Bpz_4); 7.87 (s, 2H, Bpz_4); 7.79 (s, 2H, Bpz_4); 6.81 (s, 2H, Bpz_4); 6.73 (s, 2H, Bpz_4); 6.39 (s, 2H, Bpz_4); 5.70 (s, 10H, Cp).

Preparation of $[Cp_2Mo(H_2Biim)][BF_4]_2$ **(6)**

Method (a). A solution of $[Cp_2Mo(NCCH_3)_2][BF_4]_2$ (1.20 g, 2.50 mmol) in acetone/*N*-methylformamide (NMF), (20/10 ml) was treated with H_2Biim (0.33 g, 2.50 mmol) and refluxed for 12 h. The resulting orange solution was concentrated and a mixture of pentane/ether was added until precipitation of the orange product occurred. The complex obtained was washed with Et_2O and dried in vacuum. Yield 90%.

Method (b). A mixture of solid Cp_2MoI_2 (1.00 g, 2.08 mmol), H_2Biim (0.28 g, 2.08 mmol) and $TlBF_4$ (1.21 g, 4.16 mmol) was weighed in a Schlenk tube. Acetone and *N*-methylformamide (NMF) was added and refluxed for 12 h. The resulting orange solution was filtered, taken to the dryness, washed with Et_2O and dried in vacuum. Yield 87%. EA and IR (KBr) data are in agreement with Ref. [9].

Preparation of $Cp_2Mo(Biim)$ **(7)**

A solution of $[Cp_2Mo(H_2Biim)(CO)_2][BF_4]_2$ (0.50 g; 0.93 mmol) in DMF (15 ml) was treated with an excess NaH (2.50 mmol) for 2 h with vigorous stirring. The resulting yellow-orange solution was filtered and evaporated to dryness. The product was recrystallized from CH_2Cl_2/Et_2O. Yield, 85%. Found: C, 53.38; H, 3.81; N, 15.43. Calc. for $C_{16}H_{14}N_4Mo$: C, 53.64; H, 3.94; N, 15.64%. IR (KBr, ν cm^{-1}): 3107 m, 1383 vs, 1195 s, 1138 s, 1096 vs, 995 m, 841 s, 741 s, 708 m; ^1H NMR (CD_3NO_2, 400 MHz, r.t., δ ppm): 7.41 (s, 2H, Biim); 6.70 (s, 2H, Biim); 5.50 (s, 10H, Cp).

Preparation of $[CpMo(CO)_2(Biim)]Na$ **(8)**

A suspension of $[CpMo(H_2Biim)(CO)_2][BF_4]$ (0.50 g; 1.14 mmol) in THF (20 ml) was treated with excess NaH for 1 h with vigorous stirring. The resulting orange solution was filtered and evaporated to dryness. The residue was extracted with dichloromethane and taken to dryness to give a powder in 79% yield. Found: C, 41.97; H, 2.59; N, 14.82; Mo, 25.79. Calc. for $C_{13}H_9N_4NaO_2Mo$: C, 41.96; H, 2.44; N, 15.05; Mo, 25.78%. Selected IR (KBr, ν cm^{-1}): 3113 m, 1954 vs (C≡O), 1871 vs (C≡O), 1406 s, 1134 m, 812 m, 756 m, 542 m. ^1H NMR ($Me_2CO\text{-}d_6$, 300 MHz, r.t., δ ppm): 7.42 (d, 2H, H_2Biim); 7.36 (d, 2H, H_2Biim); 5.65 (s, 5H, Cp).

Preparation of Cp_2MoI_2 (**9**)

A solution of $[Cp_2Mo(CO)I][BF_4]$ (1.0 g, 2.10 mmol) in dichloromethane (20 ml) was treated with excess of $(nBu)_4NI$ (0.92 g, 2.50 mmol). The solution was irradiated and refluxed for 8 h. A green precipitate formed slowly, and the solution became almost colorless. After being concentrated and cooled the precipitate was filtered, and washed CH_2Cl_2/Et_2O. Yield, 87%. EA, IR (KBr) and ^1H NMR data are in agreement with Ref. [22].

Preparation of $[\{CpMo(CO)_2\}(\mu\text{-Biim})\{Re(CH_3)O_3\}]Na$ (**10**)

A solution of $MeReO_3$ (0.23 g; 0.91 mmol) in NCMe (5 ml), was added to a solution of 0.91 mmol of the deprotonated ligand $[CpMo(CO)_2(Biim)]Na$. A violet solution formed after a few seconds. The reaction mixture was stirred for 15 min. After concentration to ca 5 ml and addition of ether, a microcrystalline product precipitated. The mother liquor was filtered off and the remaining precipitate was washed with Et_2O/pentane and dried in vacuum. Yield 85%. Found: C, 26.86; H, 2.19; N, 8.87, Re, 30.10. Calc. for $C_{14}H_{11}N_4NaO_5MoRe$: C, 27.06; H, 1.95; N, 9.02, Re 29.97%. Selected IR (KBr, ν cm^{-1}): 3115 m, 1958 vs (C≡O), 1863, vs (C≡O), 1599 m, 1404 s, 1011 m, 959 s, 949 s (sym (Re=O)), 920 vs (asym (Re=O)), 815 m, 754 s, 538 m. ^1H NMR (CD_2Cl_2, 300 MHz, r.t., δ ppm): 7.19 (s, 2H, Biim); 7.09 (s, 2H, Biim); 5.40 (s, 5H, Cp); 1.83 (s, 3H, Me).

Preparation of $[\{CpMo(CO)_2\}(\mu\text{-Biim})\{Re(Cl)O_3\}]Na$ (**11**)

A solution of Re_2O_7 (0.20 g, 0.41 mmol) in NCMe (5 ml), was treated with 0.82 mmol of Me_3SiCl. After 5 min, 0.82 mmol of the ligand $[CpMo(CO)_2(Biim)]Na$ was added to the solution. A pale yellow-brown solution formed after a few seconds. The reaction mixture was stirred for 15 min. After concentration and addition of ether, an orange microcrystalline product precipitated. The mother liquor was filtered off and the remaining precipitate was washed with Et_2O/pentane and dried under oil pump vacuum. Yield 82%. Found: C, 24.55; H, 1.50; N, 8.29, Re, 28.70. Calc. for $C_{13}H_9ClN_4NaO_5MoRe$: C, 24.33; H, 1.41; N, 8.73, Re, 29.01%. Selected IR (KBr, ν cm^{-1}): 3117 m, 1962 vs (C≡O), 1865, vs (C≡O), 1516 m, 1408 s, 935 s (sym (Re=O)), 918 vs (asym (Re=O)), 908 s, 820 m, 758 s, 540 m. ^1H NMR ($NCCD_3$, 300 MHz, r.t., δ ppm): 7.50 (d, 2H, Biim); 7.39 (d, 2H, Biim); 5.62 (s, 5H, Cp).

Preparation of $[\{CpMo(CO)_2\}(\mu\text{-}Cpz_4)\{Re(Cl)O_3\}][BF_4]$ (**12**)

A solution of Re_2O_7 (0.15 g, 0.31 mmol) in THF (5 ml), was treated with 0.62 mmol of Me_3SiCl. After 5 min, 0.62 mmol of the ligand $[CpMo(CO)_2(Cpz_4)][BF_4]$ was added to the solution. A violet solution formed after a few seconds. The reaction mixture was stirred for 15 min. After concentration and addition of ether, a violet product precipitated. The mother liquor was filtered off and the remaining precipitate was washed with Et_2O/pentane and dried under oil pump vacuum. Recrystallization from $NCMe/Et_2O$ gave the compound in 81% yield. Found: C, 27.71; H, 2.20; N, 12.84. Calc. for $C_{20}H_{17}BClF_4N_8O_5MoRe$: C, 28.14; H, 2.01; N, 13.12%. Selected IR (KBr, ν cm^{-1}): 3123 m, 1979 vs (C≡O), 1894 vs (C≡O), 1408 s, 1321 s, 1087 s, 1049 s, 935 s (sym (Re=O)), 918 vs (asym (Re=O)), 908 vs, 876 s, 764 s, 598 m. ^1H NMR ($NCCD_3$, 300 MHz, r.t., δ ppm): 8.99 (s, Cpz_4); 8.68 (s, Cpz_4); 8.38 (s, Cpz_4); 8.28 (s, Cpz_4); 7.47 (s, Cpz_4) 6.78 (s, Cpz_4); 6.01 (s, Cp).

Attempted preparation of $[\{CpMo(CO)_2\}(\mu\text{-}Cpz_4)\{Re(CH_3)O_3\}][BF_4]$ (**13**)

A solution of CH_3ReO_3 (0.15 g, 0.62 mmol) in THF (5 ml), was treated with 0.62 mmol of the ligand $[CpMo(CO)_2(Cpz_4)][BF_4]$. A brownish-yellow solution formed after a few seconds. The reaction mixture was stirred for 15 min. After concentration and addition of ether, a brown product precipitated. The mother liquor was filtered off and the remaining precipitate was washed with Et_2O/pentane and dried under oil pump vacuum. However, the product turned out to be impure and despite several attempts it was not possible to remove the impurities satisfactorily. The impurities could be observed in both the NMR and the IR spectra and prevented a proper characterization of this complex.

Preparation of Bpz_4ReO_3 (**14**)

A solution of Re_2O_7 (0.20 g, 0.41 mmol) in NCMe (5 ml), was treated with 0.82 mmol of Me_3SiCl. After 5 min, 0.82 mmol of the $KBpz_4$ was added to the solution. A pale yellow solution formed after a few seconds. The reaction mixture was stirred for 15 min and then taken to dryness. The residue was extracted with dichloromethane (20 ml) taken to dryness and dried in oil pump vacuum. Yield, 86%. EA, IR (KBr) and ^1H NMR data are in agreement with Ref. [12].

Preparation of $Bpz_4(CH_3)ReO_3$ (**15**)

A cooled solution of CH_3ReO_3 (0.10 g, 0.42 mmol) in NCMe (5 ml, −45°C), was treated with 0.42 mmol of $KBpz_4$. A pale yellow solution formed after a few seconds. The reaction mixture was stirred for 15 min and then taken to dryness. The residue was extracted with cold dichloromethane (20 ml), again taken to dryness and dried in oil pump vacuum at −20°C.

Yield, 56%. Found: C, 27.39; H, 2.35; N, 19.40. Calc. for $C_{13}H_{15}BN_8O_3Re$: C, 27.57; H, 2.66; N, 19.75%; IR (KBr, ν cm^{-1}): 3148 m, 1661 m, 1505 m, 1416 m, 1391 s, 1290 s, 1217 m, 1190 m, 1098 vs, 1051 s, 920 m (Re=O), 855 m, 822 s, 779 m, 752 m, 581 m, 625 m; ^{1}H NMR (Me_2CO-d_6, 400 MHz, r.t., δ ppm): 7.48 (s, 4H, pz), 7.18 (s, 4H, pz), 6.07 (s, 4H, pz), 1.83 (s, 3H, Re-CH_3).

Preparation of [{Cp_2Mo}(μ-Biim){$Re(CH_3)O_3$}] (**16**)

A solution of $MeReO_3$ (0.30 g, 1.20 mmol) in NCMe (15 ml), was treated with 1.20 mmol of the ligand Cp_2Mo(Biim). An orange precipitate formed after a few seconds. The reaction mixture was stirred for 15 min. After addition of ether (5 ml), all the microcrystalline product precipitated. It was filtered and washed with Et_2O/pentane and dried in vacuum. Yield 96%. Found: C, 33.38; H, 2.74; N, 9.23. Calc. for $C_{17}H_{17}N_4O_3MoRe$: C, 33.61; H, 2.82; N, 9.22%. Selected IR (KBr, ν cm^{-1}): 3113 m, 2287 s, 1576 m, 1393 s, 1132 s, 953 s, (sym (Re=O)), 924 vs (asym (Re=O)), 841 m, 748 s, 698 m. ^{1}H NMR (Me_2CO-d_6, 300 MHz, r.t., δ ppm): 7.46 (s, 2H, Biim); 6.86 (s, 2H, Biim); 5.61 (s, 10H, Cp); 1.39 (s, 3H, Me).

Preparation of [{Cp_2Mo}(μ-Biim){$Re(Cl)O_3$}] (**17**)

A solution of Re_2O_7 (0.60 g, 1.24 mmol) in NCMe (5 ml), was treated with 2.48 mmol of Me_3SiCl. After 5 min 1.20 mmol of the ligand Cp_2Mo(Biim) were added to the solution. An orange precipitate formed after a few seconds. The reaction mixture was stirred for 15 min. After addition of ether (5 ml), all the microcrystalline product precipitated. It was filtered and washed with Et_2O/pentane and dried in vacuum. Yield 91%. Found: C, 30.85; H, 2.35; N, 9.03. Calc. for $C_{16}H_{14}N_4ClO_3MoRe$: C, 30.61; H, 2.25; N, 8.92%. Selected IR (KBr, ν cm^{-1}): 3103 m, 2855 s, 1543 m, 1422 s, 1140 s, 931 s, (sym (Re=O)), 918 vs (asym (Re=O)), 870 m, 744 s, 623 m. ^{1}H NMR (Me_2CO-d_6, 300 MHz, r.t., δ ppm): 7.32 (s, 2H, Biim); 6.94 (s, 2H, Biim); 5.65 (s, 10H, Cp).

CONCLUSIONS

Organomolybdenum ligands of the type [CpMo-$(CO)_2L_2$] are easily prepared and coordinate Re(VII) trioxo complexes to yield binuclear Mo/Re systems with bridging pyrazolyl type ligands. The Re—N bond in these complexes is relatively weak when compared to certain Lewis base adducts of organohenium oxides or rheniumoxo halides with related heterocyclic ligands. In donor solvents these complexes undergo rapid exchange reactions of the $XReO_3$ fragment with the solvent. This exchange can be avoided by use of neutral ligands which, like Cp_2Mo(Biim), give adducts soluble in apolar, non-coordinating solvents. In these cases a strong Re–N interaction can be preserved, for exchange equilibria in solution play only a minor role. In general, the results obtained with the neutral Mo/Re complexes show relevant spectroscopic changes in both metal fragments which result from the combination of molecules in a high and in a low oxidation state. This has given further impetus to the synthesis of appropriate ligands of this type and the study of their adducts with group VI and VII oxides which is currently being undertaken in our laboratories.

Supplementary material—Full tables of bond distances and bond angles, a table of the general displacement parameter expressions and a listing of structure factors are available from author C.C.R. upon request.

Trichlorogermyl complexes of molybdenum and tungsten bearing cyclopentadienyl ligands: Synthesis, structure and isomerization studies†

Alexander C. Filippou,* Johannes G. Winter, Michael Feist, Gabriele Kociok-Köhn and Isolde Hinz

Institut für Anorganische und Allgemeine Chemie, Humboldt-Universität zu Berlin, Hessische Strasse 1–2, D-10115 Berlin, Germany

(Received 17 October 1997; accepted 14 November 1997)

Abstract—Molybdenum and tungsten trichlorogermyl complexes of the type *cis*-(η^5-C_5R_5)M(CO)$_2$ (PMe_3)$GeCl_3$ (**2b–2d**) (**2b**: M = W; R = H; **2c**: M = Mo; R = Me; **2d**: M = W; R = Me) were obtained by the stereoselective insertion reaction of $GeCl_2$ into the metal-chlorine bond of *cis*-(η^5-C_5R_5)M(CO)$_2$(PMe_3)Cl (**1b–1d**). Simultaneous thermal analysis (TG-DTA) of **2b–2d** revealed an exothermic solid-state isomerization of **2b–2d** to *trans*-(η^5-C_5R_5)M(CO)$_2$(PMe_3)$GeCl_3$ (**3b–3d**) and the thermoanalytical results were used to prepare the *trans* isomers **3b–3d** in large scale. In comparison, the trichlorogermyl complex *cis*-CpW(CO)$_2$(CNEt)$GeCl_3$ (**5**) was found to undergo an endothermic isomerization in the melt to afford a mixture of **5** and *trans*-CpW(CO)$_2$(CNEt)$GeCl_3$ (**6**) in a 1 : 1.2 ratio. The complexes **2b–2d, 3b–3d** and **6** were fully characterized and the solid-state structures of the isomers **2d** and **3d** were determined by single-crystal X-ray diffraction analyses.

Keywords: germylene; insertion; isomerization; molybdenum; tungsten.

In recent years germylenes (germanediyls) were used as versatile precursors in the synthesis of new organogermanium compounds, like Ando's 1,2-digermacyclobutane [$CH_2Ge[CH(SiMe_3)_2]_2]_2$ [1], Egorov's germylene radical anion $Ge[CH(SiMe_3)_2]_2^-$ [2], Sekiguchi's cyclotrigermene $Ge_3(Si^tBu_3)_4$ [3] and cyclotrigermenium cation $[Ge_3(Si^tBu_3)_3]^+$ [4], Wiberg's tetrahedrotetragermane $Ge_4(Si^tBu_3)_4$ [5], and Power's transition-metal germylyne complex $Cp(CO)_2Mo{\equiv}GeC_6H_3$-2,6-$Mes_2$ [6]. In this context several new germylenes were prepared and their fascinating chemistry is currently in rapid progress [7]. One of the oldest known divalent germanium compounds is $GeCl_2$, which is not stable under normal conditions [8]. Stabilization of $GeCl_2$ is achieved upon complexation with cyclic ethers [9], nitrogen bases [10], phosphanes [11] and arsanes [12] to give $GeCl_2$(Do) adducts (Do = donor). Among these adducts the $GeCl_2$(1,4-dioxane) complex [9] has been used mostly as $GeCl_2$ source and has been shown to insert readily into σ-bonds [13,14]. Using this reactivity of $GeCl_2$(1,4-dioxane) we have prepared recently several Mo^{II} and W^{II} trichlorogermyl and dichlorogermyl complexes of the general formula (η^5-C_5R_5)M-(CO)$_{3-m}$(L)$_m$$GeCl_{3-n}H_n$ (R = H, Me; M = Mo, W; L = EtNC, PMe_3; m, n = 0, 1) starting from the corresponding M^{II} chloro and hydrido complexes [15]. Interestingly, the trimethylphosphine derivative *cis*-CpMo(CO)$_2$(PMe_3)$GeCl_3$ (**2a**) was found to isomerize in CH_2Cl_2 solution at room temperature to *trans*-CpMo(CO)$_2$(PMe_3)$GeCl_3$ (**3a**), whereas the ethylisocyanide derivative *cis*-CpW(CO)$_2$(EtNC)$GeCl_3$ (**5**) retained its configuration under the same conditions [15a]. *Cis-trans* isomerism of "four-legged piano-stool" complexes containing a cyclopentadienyl ligand [16] have been observed for various transition metals in solution under thermal or photochemical conditions [17]. In comparison, *cis-trans* isomerization reactions of "four-legged piano-stool" complexes occurring in the solid state are rare [18]. The observed *cis-trans* isomerization of **2a** to **3a** [15a]

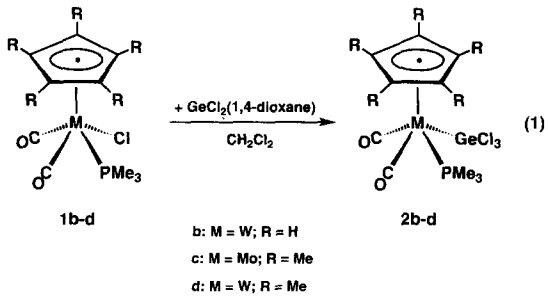
prompted us to prepare the related trichlorogermyl complexes *cis*-(η^5-C_5R_5)M(CO)$_2$(PMe$_3$)GeCl$_3$ (**2b–2d**) (**2b**: M = W; R = H; **2c**: M = Mo; R = Me; **2d**: M = W; R = Me) and to study their structure and isomerization reactions to *trans*-(η^5-C_5R_5)M(CO)$_2$(PMe$_3$)GeCl$_3$ (**3b–3d**).

RESULTS AND DISCUSSION

Starting materials for the reactions described below were the Mo^{II} and W^{II} chloro complexes *cis*-(η^5-C_5R_5)M(CO)$_2$(PMe$_3$)Cl (**1b–1d**) (**1b**: M = W; R = H; **1c**: M = Mo; R = Me; **1d**: M = W; R = Me). Treatment of these compounds with one equivalent of GeCl$_2$(1,4-dioxane) in CH$_2$Cl$_2$ at −78°C, and subsequent warming of the reaction solutions to ambient temperature, resulted in a rapid and clean insertion of GeCl$_2$ into the metal-chlorine bond of **1b–1d** to give the trichlorogermyl complexes *cis*-(η^5-C_5R_5)M(CO)$_2$(PMe$_3$)GeCl$_3$ (**2b–2d**) (eqn (1)).



(1)

Evidence for the selective formation of **2b–2d** was given by the IR spectra of the reaction solutions, which showed that the two ν(CO) absorptions of the starting materials at 1949 and 1848 cm^{-1} (**1b**), 1944 and 1850 cm^{-1} (**1c**) and 1931 and 1837 cm^{-1} (**1d**) had been replaced at the end of the reactions by those of the products at 1967 and 1892 cm^{-1} (**2b**), 1961 and 1892 cm^{-1} (**2c**) and 1953 and 1878 cm^{-1} (**2d**), respectively. Working up of the reaction solutions afforded the trichlorogermyl complexes **2b–2d** as yellow, microcrystalline solids in high yields. The new complexes are soluble in CH$_2$Cl$_2$ and THF, but sparingly soluble in Et$_2$O and *n*-pentane and were fully characterized. Thus, the IR spectra of **2b–2d** show in the region of 2200–1500 cm^{-1} two ν(CO) absorption bands (Table 1).

The higher energy absorption of the symmetric ν(CO) vibration is more intense than the lower energy absorption of the antisymmetric ν(CO) vibration indicating the presence of the *cis*-isomer [15,19]. Both ν(CO) absorptions of **2b–2d** appear at higher wavenumbers than those of the chloro complexes **1b–1d** showing that insertion of GeCl$_2$ into the metal–chlorine bond reduces the electron density at the metal center and weakens thereby the metal ($d\pi$)—CO(π^*) back bonding (Table 1). Furthermore, the ν(CO) absorptions of the Cp derivatives **2a** [ν(CO) in CH$_2$Cl$_2$: 1976 and 1907 cm^{-1}] [15] and **2b** are observed at higher frequency than those of the Cp* derivatives **2c** and **2d**, respectively, indicating the weaker electron donating properties of the Cp ligand compared with the Cp* ligand (Cp* = C_5Me_5).

The ^{1}H, ^{31}P{^{1}H} and ^{13}C{^{1}H} NMR spectra also support the structures proposed for **1b–1d** and for **2b–2d** (Tables 2 and 3).

Thus, the ^{1}H NMR spectra of **1b–1d** and **2b–2d** display a doublet resonance for the methyl protons of the PMe$_3$ ligand and a singlet or doublet resonance for the Cp and Cp* ring protons (Table 2). The ^{13}C{^{1}H} NMR spectra of **1b–1d** and **2b–2d** display two resonances for the inequivalent carbonyl ligands, indicating in agreement with the IR spectra the pres-

[a] The isocyanide carbon resonance of **6** was not observed.

ence of the *cis* isomer (Table 3). The carbonyl resonances of the chloro complexes **1b–1d** appear as doublets due to ^{13}C–^{31}P coupling. In comparison, only the lower-field carbonyl resonance of the trichlorogermyl complexes **2b–2d** is split to a doublet, the ^{13}C–^{31}P coupling of the higher-field carbonyl–carbon resonance being too small to be resolved. The lower field carbonyl–carbon resonance of **1b–1d** and **2b–2d** with the large ^2J(PC) coupling constant is assigned to the CO ligand, which is disposed in *cis* position relative to the PMe_3 ligand [15]. Finally, the carbonyl resonances of the trichlorogermyl complexes **2b–2d** are found at higher field than those of the chloro complexes **1b–1d**. This is in full agreement with previous NMR studies on Group VI transition metal carbonyl complexes, which have shown that a weaker metal–carbonyl back bonding causes a shielding of the carbonyl–carbon nucleus [20].

The solid state structure of **2d** was determined by a single-crystal X-ray diffraction study. Suitable crystals were obtained after slow evaporation of a CH_2Cl_2 solution of **2d** at room temperature. A ZORTEP drawing of the molecular structure of **2d** with the atom-labeling scheme adopted is shown in Fig. 1. Selected bond lengths and angles of **2d** are listed in Table 4.

Complex **2d** has the expected square pyramidal coordination geometry of a "four-legged piano-stool" complex with a *cis* disposition of the trichlorogermyl and the trimethylphosphine ligand. The W—C(ring) bond lengths range from 228.6(5) to 238.6(5) pm and have an average value of 233.6 pm, which is close to

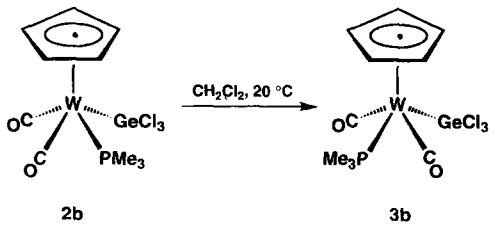
that of $Cp^*W(CO)_3GeCl_3$ [$(W—C_{ring})_{av.}$ = 232.6 pm] [15]. The tungsten–carbonyl groups are approximately linear, with the W—C—O bond angles being 174.8(5) and 174.9(5)°, respectively. The W—CO bonds of **2d** [$(W—CO)_{av.}$ = 195.4 pm] are shorter than those of $Cp^*W(CO)_3GeCl_3$ [$(W—CO)_{av.}$ = 199.5 pm] indicating in full agreement with the IR and NMR spectroscopic data a stronger $M(d\pi)—CO(\pi^*)$ back bonding in **2d** than in $Cp^*W(CO)_3GeCl_3$ [15a].

The major focus of interest is on the structural features of the trichlorogermyl ligand. The tetrahedral coordination of the germanium atom in **2d** is strongly distorted as shown by the Cl—Ge—Cl bond angles with an average value of 98.01° and the W—Ge—Cl bond angles with an average value of 119.27° (Table 4). Furthermore, a comparison of the compounds $GeCl_4$, $Cp^*W(CO)_3GeCl_3$, *cis*-$Cp^*W(CO)_2(EtNC)GeCl_3$ and *cis*-$Cp^*W(CO)_2(PMe_3)GeCl_3$ (**2d**) reveals a continous increase of the Ge—Cl bond lengths [$GeCl_4$: $(Ge—Cl)_{av.}$ = 211.3 pm; $Cp^*W(CO)_3GeCl_3$: $(Ge—Cl)_{av.}$ = 217.9 pm; *cis*-$Cp^*W(CO)_2(EtNC)GeCl_3$: $(Ge—Cl)_{av.}$ = 219.6 pm; **2d**: $(Ge—Cl)_{av.}$ = 220.6 pm] and a continuous decrease of the Cl—Ge—Cl bond angles [$GeCl_4$: (Cl—Ge—Cl) = 109.5°; $Cp^*W(CO)_3GeCl_3$: $(Cl—Ge—Cl)_{av.}$ = 100.2°; *cis*-$Cp^*W(CO)_2(EtNC)GeCl_3$: $(Cl—Ge—Cl)_{av.}$ = 99.1°; **2d**: $(Cl—Ge—Cl)_{av.}$ = 98.01°] as one chloro substituent in $GeCl_4$ is replaced by a more and more electropositive metal carbonyl fragment [15a,21]. These trends can be explained, if one suggests a stronger hyperconjugation between the metal carbonyl fragment and the trichlorogermyl ligand, as the electron density at the metal center is enhanced [22]. Alternatively, the observed trends can be explained using the atom rehybridization model of Bent [23]. Using this model one would also predict in the absence of any steric effects an elongation of the W—Ge bond in the series **2d** < *cis*-$Cp^*W(CO)_2(EtNC)GeCl_3$ < $Cp^*W(CO)_3GeCl_3$. In fact, the W—Ge bond of $Cp^*W(CO)_3GeCl_3$ [$(W—Ge)_{av.}$ = 256.2(2) pm] is longer than that of *cis*-$Cp^*W(CO)_2(EtNC)GeCl_3$ (W—Ge = 254.4(2) pm), but similar in length to that of **2d** [W—Ge = 255.90(5) pm]. This suggests an opposing steric to the electronic effect of the PMe_3 ligand on the W—Ge bond length of **2d**. Experimental evidence for an increased steric repulsion between the trimethylphosphane and the trichlorogermyl ligand in **2d** is given by the larger Ge—W—P angle of 81.71(3)° compared with the Ge—W—$C_{isonitrile}$ bond angle of *cis*-$Cp^*W(CO)_2(C-NEt)GeCl_3$ [75.2(4)°] and the Ge—W—$C_{CO(cis)}$ bond angles of $Cp^*W(CO)_3GeCl_3$ [$(Ge—W—C)_{av.}$ = 74.1°] [15a].

The tungsten complex **2b** isomerizes in CH_2Cl_2 solution at ambient temperature to the thermodynamically more stable isomer *trans*-$CpW(CO)_2(PMe_3)GeCl_3$ (**3b**) (eqn (2)).



2b 3b (2)

This indicates that insertion of $GeCl_2$ into the W—Cl of **1b** to give **2b** is a stereoselective reaction. *cis-trans* isomerization of **2b** was monitored by IR and NMR spectroscopy to be complete after 2 days and to be slightly slower than that of the analogous molybdenum complex *cis*-$CpMo(CO)_2(PMe_3)GeCl_3$ (**2a**) [15a]. In comparison, the related Cp* derivatives *cis*-$Cp^*M(CO)_2(PMe_3)GeCl_3$ (**2c**: M = Mo; **2d**: M = W) were found to be stable with respect to isomerization under the same conditions. Thus, no evidence for the formation of the *trans* isomers could be found even after 15 days in CH_2Cl_2 solution at ambient temperature. However, complexes **2c** and **2d** undergo as **2b** a selective isomerization to *trans*-$Cp^*M(CO)_2(PMe_3)GeCl_3$ (**3c**: M = Mo; **3d**: M = W), when heated in the solid-state. This was shown by simultaneous thermal analysis (STA), the results of which are summarized in Table 5.

The STA curves (T, TG, DTG and DTA) of the tungsten complex **2d** are depicted in Fig. 2 and the DTA curves of **2b–3d** are shown in Fig. 3. When complex **2d** was heated two DTA effects were recorded, for which no considerable mass loss was observed (Fig. 2).

The first transition occurs at $T_e = 182°C$, is exothermic ($\Delta H_{iso} = -17$ kJ/mol) and corresponds to the solid-state isomerization of *cis*-$Cp^*W(CO)_2(PMe_3)GeCl_3$ (**2d**) to the thermodynamically more stable isomer *trans*-$Cp^*W(CO)_2(PMe_3)GeCl_3$ (**3d**). Evidence for this was given by a separate STA run, in which **2d** was heated under the same conditions to

Table 5. Thermal analysis data of **2b–3d** and **5** obtained from STA curves (T, TG, DTG, DTA), visual inspection and IR spectroscopic characterization after various thermal treatments from 20°C to T_{max} (heating rate: 5°C/min, purge gas: argon; for further details of the STA experiments see experimental section); used abbreviations: m.p.: melting, dec.: decomposition, iso.: *cis-trans* isomerization, ph.: phase transition

[a] Thermal decomposition of the complex was observed.

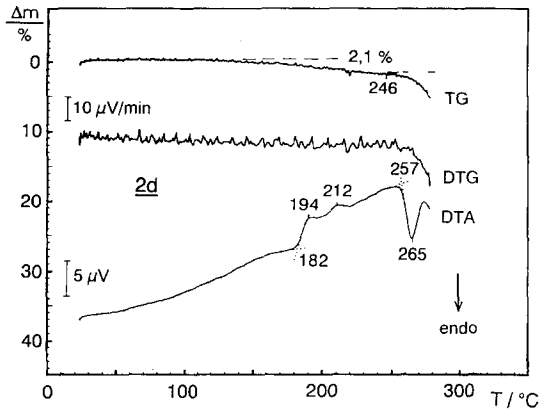

Fig. 2. STA curves (T, TG, DTG and DTA) of **2d**.

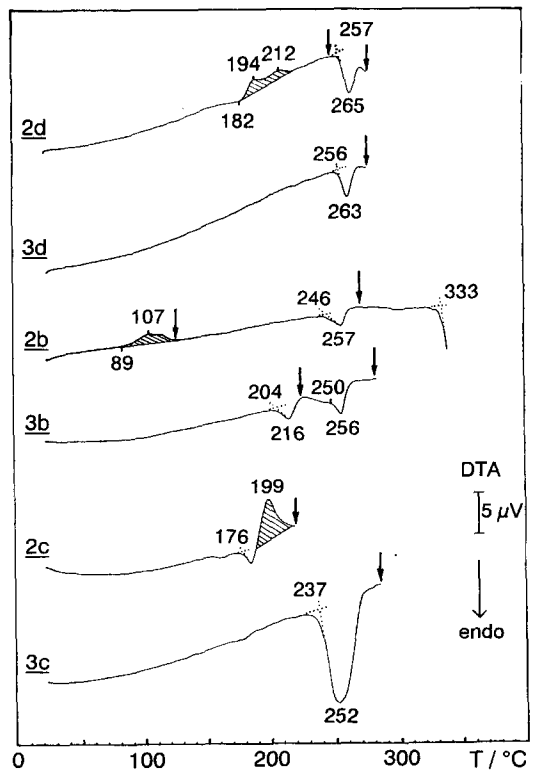

Fig. 3. DTA curves of the *cis* isomers **2b–2d** and the *trans* isomers **3b–3d**. The arrows indicate T_{max} of the separate STA runs carried out for sample characterization (Table 5, Experimental). Hatched areas were used for the calculation of the isomerization enthalpy.

245°C (Table 5). The resulting pale-yellow solid was identified by its characteristic ν(CO) absorptions in CH_2Cl_2 at 1943 (m) and 1866 (vs) cm^{-1} to be the *trans* isomer **3d** (Table 1). The exothermic isomerization of **2d** to **3d** is followed by an endothermic transition, which occurs at $T_e = 257$°C (Fig. 2) and corresponds to the melting of the *trans* isomer **3d** with almost the same enthalpy of fusion ($\Delta H_f = 18$ kJ/mol) as that determined separately for the *trans* isomer **3d** ($\Delta H_f = 20$ kJ/mol) (Fig. 3, Table 5).

Similarly, the molybdenum complex **2c** was found to undergo an exothermic solid-state *cis-trans* isomerization to **3c** at $T_p = 199$°C ($\Delta H = -54$ kJ/mol) (Fig. 3, Table 5). After heating to 220°C (T_{max}) the sample was allowed to cool to room temperature and the obtained pale-yellow solid was identified by its characteristic ν(CO) absorptions in CH_2Cl_2 at 1955 (m) and 1881 (vs) cm^{-1} to be the *trans* isomer **3c** (Tables 1 and 5). The solid-state isomerization of **2c** shows a small endothermal pre-effect at $T_e = 176$°C that was not studied any further (Fig. 3). In a separate run the *trans*-isomer **3c** was observed to melt at $T_e = 237$°C (Fig. 3, Table 5). Melting of **3c** was accompanied by a considerable mass loss of 8.3% indicating the concomitant decomposition of **3c**.

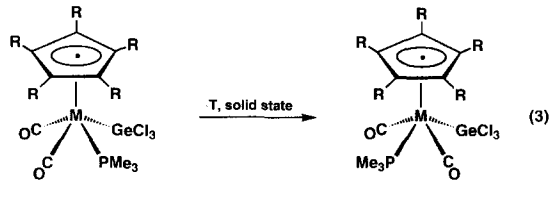
Finally, the STA of the cyclopentadienyl derivative **2b** shows three processes (Fig. 3, Table 5). The first transition at $T_i = 89$°C is exothermic ($\Delta H = -12$ kJ/mol), is not accompanied by a mass loss and corresponds to the solid-state isomerization of **2b** to the *trans* isomer **3b**. This was verified by a separate STA experiment, in which complex **2b** was heated under the same conditions to $T_{max} = 120$°C and the resulting pale-yellow solid was identified by IR spectroscopy to be the *trans* isomer **3b** (Table 1, Table 5). The solid-state isomerization of the cyclopentadienyl derivative **2b** occurs at a much lower temperature than that of the pentamethylcyclopentadienyl derivatives **2c** and **2d** (Table 5) suggesting a smaller activation barrier for the *cis-trans* transformation of **2b**. This is in full agreement with the observations in CH_2Cl_2 solution (eqn (2)).

The second transition in the DTA curve of **2b** is endothermic and corresponds to the melting of the *trans* isomer **3b** ($T_e = 246$°C) with almost the same enthalpy of fusion as that determined for the *trans* isomer **3b** ($\Delta H_f = 6$–9 kJ/mol) (Fig. 3). After melting the slight accompanying mass loss accelerates considerably and shows the complete decomposition of molten **3b** above 300°C (Fig. 3, Table 5). Surprisingly, the DTA curve of a pure sample of the *trans* isomer **3b**, prepared by isomerization of **2b** in solution, shows a further endothermic transition ($\Delta H = 7$ kJ/mol), which occurs at $T_e = 204$°C before melting (Fig. 3, Table 5). Heating of **3b** in a separate STA experiment to $T_{max} = 220$°C followed by visual inspection and IR spectroscopic characterization did not show any change of the sample suggesting that the endotherm at $T_e = 204$°C might correspond to a phase transition. No evident explanation can be proposed, why this endotherm is not observed in the DTA curve of **2b**. Possibly the *trans* isomer **3b** formed upon heating of **2b** is amorphous so that crystallinity and/or ordering phenomena do not occur as in the case for the separately prepared *trans* isomer **3b**.

Two mechanisms can be envisaged for the solid-state isomerization of **2b–2d** to **3b–3d**. The first one

involves a rearrangement of **2b–2d** via a Cp(Cp*) capped trigonal bipyramidal intermediate and has been suggested for the most thermal *cis-trans* isomerizations of "four-legged piano-stool complexes" in solution (intramolecular mechanism) [17]. The second mechanism involves a ligand dissociation from the *cis* isomer to give a 16e-complex intermediate followed by rearrangement and ligand association to generate the *trans* isomer. This mechanism has been suggested for some photochemically-induced *cis-trans* isomerizations of "four legged piano-stool complexes" (intermolecular mechanism) [17m,18a]. Dissociation of a carbonyl or trimethylphosphane ligand is unlikely to be the initial step of the solid-state *cis-trans* isomerization of **2b–2d,** because the volatile ligands would be expected to be removed by the purge gas leading to considerable decomposition during isomerization. However, an intermolecular mechanism involving an ionic 16e-intermediate formed from **2b–2d** after heterolytic cleavage of the metal–halogen bond cannot be excluded on the basis of the present results. Such a mechanism has been proposed for the photochemical *trans-cis* isomerization of the rhenium complexes $(\eta^5\text{-}C_5H_4R)Re(CO)(L)(X)_2$ (R = H, alkyl; L = CO, $P(OR)_3$; X = Br, I) on the surface of silica gel [18c].

The thermoanalytical results of **2b–3d** were used to prepare the *trans* isomers in large scale. For this purpose 100–400 mg of the *cis* isomers **2b, 2c** and **2d** were weighted under argon in Schlenk tubes, which then were evacuated and heated in an oven for 20–30 min at 130, 205 and 230°C respectively (eqn (3)). In order to achieve a reasonable reaction time the oven temperature was chosen about 20–40°C higher than the temperature obtained in the STA experiments for the solid-state isomerization of **2b, 2c** and **2d**. Heating was accompanied by a color change of the solids from yellow to pale-yellow. After cooling the Schlenk tubes to room temperature the *trans*-isomers **3b, 3c** and **3d** were isolated as air-stable, pale-yellow solids in high yields.



(3)

The IR and NMR spectroscopic data of **3b–3d** show unequivocally the *trans* arrangement of the carbonyl ligands in these compounds (Tables 1–3). Thus, two ν(CO) absorptions are observed in the IR spectra at 1955 and 1877 cm^{-1} (**3b**), 1955 and 1881 cm^{-1} (**3c**) and 1943 and 1866 cm^{-1} (**3d**) (Table 1). For all three compounds the higher energy absorption of the symmetric ν(CO) vibration is less intense than the lower energy absorption of the antisymmetric ν(CO) vibration as expected for a *trans* disposition of two carbonyl ligands in a "four-legged piano-stool complex" [15,19]. The ν(CO) absorptions of the trichlorogermyl complexes **3b** and **3d** appear at higher wavenumbers than those of the chloro complexes *trans*-$CpW(CO)_2(PMe_3)Cl$ [ν(CO) in CH_2Cl_2: 1961 and 1865 cm^{-1}] and *trans*-$Cp^*W(CO)_2(PMe_3)Cl$ [ν(CO) in CH_2Cl_2: 1943 and 1846 cm^{-1}], respectively [24]. This suggests as in the case of the *cis* isomers that insertion of $GeCl_2$ into the W—Cl bond causes a reduction of the electron density at the metal center and thereby weakens the metal ($d\pi$)—CO(π^*) back bonding. Additional support for the *trans* arrangement of the carbonyl ligands in **3b–3d** is given by the ^{13}C NMR spectra, which display besides the expected resonances for the PMe_3 and Cp/Cp* ligands only one resonance for the equivalent carbonyl–carbon nuclei at δ 223.1 (**3b**), 238.0 (**3c**) and 231.0 (**3d**) (Table 3). This resonance is split to a doublet due to ^{13}C–^{31}P-coupling, the magnitude of the coupling constant (21.7–31.9 Hz) being indicative of a *cis* disposition of the CO ligands relative to the PMe_3 ligand [15]. The carbonyl–carbon signals of the trichlorogermyl complexes **3b** and **3d** appear at higher field than those of the chloro complexes *trans*-$CpW(CO)_2(PMe_3)Cl$ [δ(CO) = 232.4, ^2J(PC) = 18.1 Hz (CD_2Cl_2, 20°C)] and *trans*-$Cp^*W(CO)_2(PMe_3)Cl$ [δ(CO) = 240.3, ^2J(PC) = 20.3 Hz (CD_2Cl_2, 20°C)], respectively [24]. This indicates in agreement with the IR spectra that the metal ($d\pi$)—CO(π^*) back bonding in the trichlorogermyl complexes is weaker than that in the chloro complexes.

The solid state structure of **3d** was determined by a single-crystal X-ray diffraction study. Suitable single crystals were obtained after slow evaporation of a CH_2Cl_2 solution of **3d** at ambient temperature. A ZORTEP plot of the molecular structure of **3d** with the atom-labeling scheme adopted is shown in Fig. 4. Selected bond lengths and angles of **3d** are listed in Table 6.

The *trans* isomer **3d** shows like the *cis* isomer **2d** the expected square pyramidal coordination geometry of a "four-legged piano stool" complex with similar bonding parameters of the Cp* ligand [**3d**: $(W—C_{ring})_{av.}$ = 234.5 pm, W—Cp* = 200.0 pm; **2d**: $(W—C_{ring})_{av.}$ = 233.6 pm, W—Cp* = 199.9 pm] (Cp* denotes the center of the pentamethylcyclopentadienyl ring) and the carbonyl ligands [**3d**: $(W—CO)_{av.}$ = 197.4 pm; **2d**: $(W—CO)_{av.}$ = 195.5 pm]. The tetrahedral coordination geometry of the germanium atom is in **3d** as in the *cis* isomer **2d** strongly distorted. Thus, the Cl—Ge—Cl bond angles of **3d** are more acute than that of an ideal tetrahedron having an average value of 98.6°, which is similar to that of the *cis* isomer **2d** [$(Cl—Ge—Cl)_{av.}$ = 98.01°]. Consequently, the W—Ge—Cl bond angles of **3d** are more obtuse than

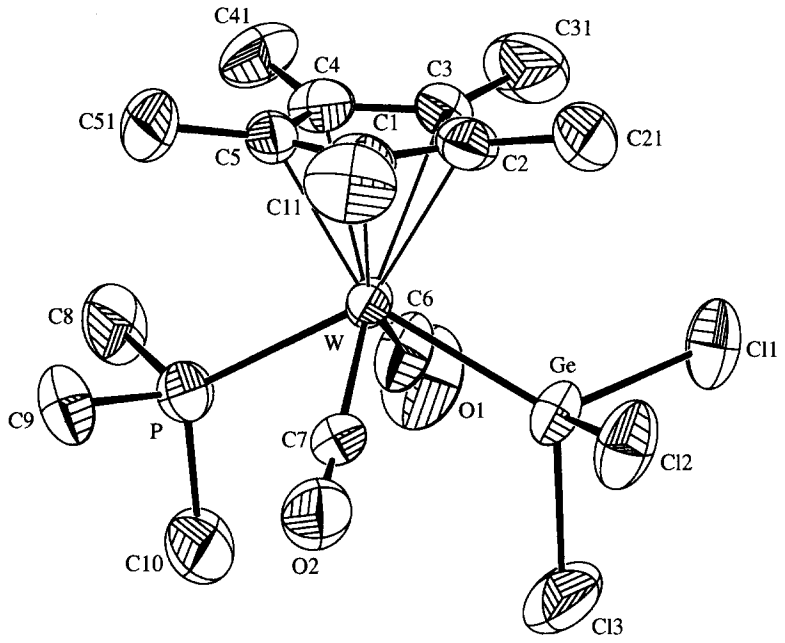


Fig. 4. ZORTEP plot of the molecular structure of **3d** with thermal ellipsoids drawn at the 50% probability level.

Table 6. Selected bond lengths (pm) and bond angles (°) with estimated standard deviations for **3d**

W—C(1)	236.6(9)	Ge—W—P	124.65(6)
W—C(2)	236.4(7)	Ge—W—C(6)	76.2(3)
W—C(3)	233.6(10)	Ge—W—C(7)	73.3(3)
W—C(4)	231.9(10)	P—W—C(6)	76.4(3)
W—C(5)	234.2(9)	P—W—C(7)	74.3(3)
W—C(6)	196.7(11)	C(6)—W—C(7)	112.4(4)
W—C(7)	198.1(9)	W—Ge—Cl(1)	120.03(12)
W—Ge	251.59(14)	W—Ge—Cl(2)	118.64(9)
W—P	248.7(3)	W—Ge—Cl(3)	117.94(11)
Ge—Cl(1)	220.9(3)	Cl(1)—Ge—Cl(2)	98.69(13)
Ge—Cl(2)	219.7(3)	Cl(2)—Ge—Cl(3)	99.0(2)
Ge—Cl(3)	219.1(3)	Cl(1)—Ge—Cl(3)	98.2(2)

that of an ideal tetrahedron and have an average value of 118.87°, which is also similar to that of the *cis* isomer **2d** [(W—Ge—Cl)$_{av.}$ = 119.27°]. Furthermore, the Ge—Cl bond lengths of both isomers are similar [**3d**: (Ge—Cl)$_{av.}$ = 219.9 pm; **2d**: (Ge—Cl)$_{av.}$ = 220.6 pm] and considerably longer than that of $GeCl_4$ [(Ge—Cl)$_{av.}$ = 211.3(3) pm] (see discussion of the structure of **2d** for interpretation). However, the W—Ge bond of **3d** is with 251.59(14) pm considerably shorter than that of the *cis* isomer **2d** with 255.90(5) pm. This shortening can be attributed to the weaker *trans* influence of the PMe_3 ligand compared with the carbonyl ligand and the reduction of steric repulsion between the trichlorogermyl and the trimethylphosphane ligand in the *trans* isomer **3d**. The strong *trans* influence of the carbonyl ligand is also reflected in the longer W—P bond of **2d** [251.33(12) pm] compared with that of **3d** [248.7(3) pm] [25].

Furthermore, we wanted to elucidate the influence of other 2e-donor ligands than PMe_3 on the thermal behavior of the half-sandwich trichlorogermyl complexes and therefore studied the ethyl isocyanide derivative *cis*-$CpW(CO)_2(EtNC)GeCl_3$ (**5**) by STA (Fig. 5).

Three endothermal DTA effects were observed upon heating of **5**. The first transition occurring at T_e = 96°C corresponds to the melting of **5** (ΔH_f = +17 kJ/mol) (Fig. 5) [15a]. This was verified by a separate STA run in which **5** was heated under the same conditions to T_{max} = 115°C (Table 5). The resulting red melt solidified upon cooling to room temperature to a glass-like mass, that was identified

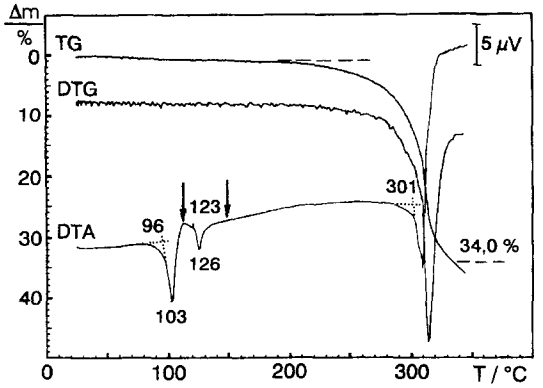

Fig. 5. STA curves (T, TG, DTG and DTA) of **5**. The arrows indicate T_{max} of the separate STA runs carried out for sample characterization (Table 5, Experimental).

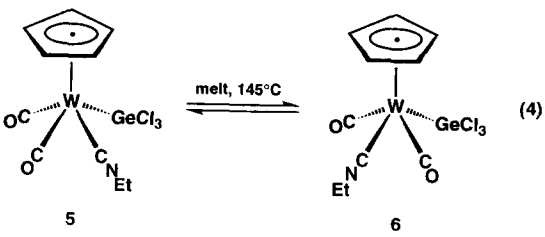
by IR spectroscopy to be the *cis* isomer **5** (Table 1). Molten **5** undergoes at $T_i = 123°C$ an endothermic transition ($\Delta H = +4$ kJ/mol), which is not accompanied by a mass loss and corresponds to a *cis-trans* isomerization process leading to an equilibrium mixture of **5** and **6** (ratio **5**/**6** = 1 : 1.2) (Fig. 5, Table 5) (eqn (4)).



This was evidenced by a separate STA run, in which after heating of **5** to $T_{max} = 145°C$ the red melt was allowed to cool to room temperature and the resulting solid was shown by IR and ^1H NMR spectroscopy to be the above mentioned mixture of isomers (Tables 1 and 2). In addition, this transformation was carried out in preparative scale and the mixture of **5** and **6** was fully characterized (see Experimental). Complex **5** isomerizes also in CH_2Cl_2 solution at ambient temperature. Isomerization is however very slow, leading only after several weeks to the thermodynamic equilibrium between **5** and **6**, that favors slightly the *cis* isomer (**5**/**6** ratio : 1.1 : 1).

Finally, a third endotherm is observed in the DTA curve of **5** at $T_e = 301°C$ and is accompanied by a total mass loss of 34% indicating extensive decomposition of the sample.

The observed *cis-trans* isomerizations of **2b**, **2c** and **2d** are rare examples of solid-state reactions in organometallic chemistry that need further attention. Preliminary studies show that also other molybdenum and tungsten trichlorogermyl complexes containing cyclopentadienyl ligands undergo an isomerization in the solid-state.

EXPERIMENTAL

Standard inert-atmosphere techniques were used for all syntheses and sample manipulations. The solvents were dried by standard methods (pentane over CaH_2, Et_2O over Na/benzophenone, CH_2Cl_2 over P_2O_5 and Na/Pb alloy), distilled under argon and stored over 4 Å molecular sieves prior to use. Elemental analyses were obtained from the Zentrale Analytische Gruppe des Instituts für Chemie der Humboldt Universität zu Berlin. IR spectra were recorded on a Bruker IFS-55 spectrometer. ^1H, $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectra were recorded on a Bruker AM 300 spectrometer in dry deoxygenated methylene-d_2-chloride. The ^1H and $^{13}C\{^1H\}$ NMR spectra were calibrated against the solvent signals (methylene-d_2-chloride, δ_H 5.32 and δ_C 53.8 ppm) and the $^{31}P\{^1H\}$-NMR spectra against an external 85% H_3PO_4 aqueous solution. Mass spectra were obtained with a HP 5995A spectrometer; *m/z* values are given relative to the ^{98}Mo, ^{184}W, ^{74}Ge and ^{35}Cl isotopes. Melting points were determined using a Büchi 530 melting point apparatus and are not corrected. The samples used for the determination of the melting points were sealed in capillary tubes under argon.

The complexes *cis*-(η^5-C_5R_5)M(CO)$_2$(PMe_3)Cl (**1b**–**1d**) (**1b**: M = W; R = H; **1c**: M = Mo; R = Me; **1d**: M = W; R = Me) were obtained by chlorination of the hydrido complexes *cis*/*trans*-(η^5-C_5R_5)M(CO)$_2$(PMe_3)H [26] with CCl_4. Chlorination of *cis*/*trans*-(η^5-C_5R_5)M(CO)$_2$(PMe_3)H afforded first *cis*-/*trans*-mixtures of the chloro complexes (η^5-C_5R_5)M(CO)$_2$(PMe_3)Cl. The *trans* isomer isomerized then in solution at room temperature to the *cis* isomer [24]. $GeCl_2$(1,4-dioxane) was prepared following the procedure reported by Nefedov *et al.* [27]. Complex **5** was prepared as described previously [15a].

The simultaneous thermal analysis (STA) curves (T, DTA, TG, DTG) were obtained with a Netzsch-Thermoanalyser STA 429 using the mini sample holder system (platinum crucibles, sample mass 6–12 mg, Pt/PtRh10 thermoelements, α-Al_2O_3 as reference, heating rate 5°C/min, purge gas: argon, flow rate 100 ml/min). Determination of the characteristic temperatures in the STA curves (T_i, initial; T_e, extrapolated onset; T_p, peak) was carried out following international recommendations [28]. A caloric calibration of the measuring system using appropriate standard substances [29] preceded the enthalpimetric evaluation of the DTA curves and yielded at best values with an accuracy of 10–12%. In order to give a meaningful interpretation of the processes observed during thermal analysis, separate STA runs were carried out under identical conditions (sample mass, heating rate). In these runs the samples were heated to the relevant temperatures obtained from the overview

STA experiments and then were cooled under argon to room temperature. The obtained samples were compared with authentic samples by visual inspection and were characterized by IR spectroscopy and/or ^1H NMR spectroscopy. The arrows on the DTA curves (Figs 3 and 5) indicate these distinguished temperatures of characterization. The control STA experiments of the *cis* isomers **2b–2d** and **5** were reproduced in a preparative scale to obtain the *trans* isomers **3b–3d** and a mixture of **5** and **6**, respectively (see synthesis of **3b–3d** and **5/6** below).

cis-$CpW(CO)_2(PMe_3)GeCl_3$(**2b**)

A mixture of 84 mg (0.20 mmol) of **1b** and 49 mg (0.21 mmol) of $GeCl_2$(1,4-dioxane) was suspended at −78°C in 30 ml of CH_2Cl_2 and the suspension was allowed to warm to room temperature and stirred for 1 h. During this time the red solution brightened. Completion of the reaction was confirmed by IR spectroscopy. The solution was then filtered from some insoluble gray material through a filter canula and the filtrate was evaporated to dryness. The residue was washed twice with 5 ml of an Et_2O/pentane (1/3) mixture to afford complex **2b** as a yellow, microcrystalline solid. Yield: 106 mg (95%). Found: C, 21.23; H, 2.64; Cl, 20.12; P, 4.99; $C_{10}H_{14}Cl_3GeO_2PW$ (559.99). Calc.: C, 21.45; H, 2.52; Cl, 18.99; P, 5.53%. EI-MS (70 eV): *m/z* 560 $[M]^+$, 525 $[M—Cl]^+$, 388 $[M—CO—GeCl_2]^+$, 360 $[M—2\ CO—GeCl_2]^+$ (base peak).

cis-$Cp^*Mo(CO)_2(PMe_3)GeCl_3$ (**2c**)

Following the procedure described above for the synthesis of **2b**, complex **2c** was isolated as a yellow, microcrystalline solid after treatment of 204 mg (0.51 mmol) of **1c** with 118 mg (0.51 mmol) of $GeCl_2$(1,4-dioxane) in 40 ml of CH_2Cl_2 for 3 h at room temperature. Yield: 271 mg (98%). Found: C, 32.64; H, 4.65; Cl, 20.15; $C_{15}H_{24}Cl_3GeMoO_2P$ (542.22). Calc.: C, 33.23; H, 4.46; Cl, 19.61%. EI-MS (70 eV): *m/z* 544 $[M]^+$, 509 $[M—Cl]^+$, 453 $[M—Cl—2\ CO]^+$, 400 $[M—GeCl_2]^+$, 372 $[M—GeCl_2—CO]^+$, 344 $[M—GeCl_2—2CO]^+$, 268 $[M—GeCl_2—2\ CO—PMe_3]^+$ (base peak).

cis-$Cp^*W(CO)_2(PMe_3)GeCl_3$ (**2d**)

Following the procedure described above for the synthesis of **2b**, complex **2d** was obtained as a yellow, microcrystalline solid after treatment of 234 mg (0.48 mmol) of **1d** with 109 mg (0.47 mmol) of $GeCl_2$(1,4-dioxane) in 40 ml of CH_2Cl_2 for 3 h at room temperature. Yield 244 mg (81%). Found: C, 28.06; H, 3.77; Cl, 16.93; P, 4.42; $C_{15}H_{24}Cl_3GeO_2PW$ (630.13). Calc.: C, 28.59; H, 3.84; Cl, 16.88; P, 4.92%. EI-MS (70 eV): *m/z* 630 $[M]^+$, 595 $[M—Cl]^+$, 519 $[M—Cl—PMe_3]^+$, 486 $[M—GeCl_2]^+$, 458 $[M—GeCl_2—CO]^+$, 430 $[M—GeCl_2—2\ CO]^+$ (base peak).

trans-$CpW(CO)_2(PMe_3)GeCl_3$ (**3b**)

A 100 ml Schlenk tube was charged with 151 mg (0.27 mmol) of **2b** and tightly closed with a glass stopper. The Schlenk tube was evacuated and placed in an oven at 130°C for 20 min. During this time the color of the yellow solid changed to pale yellow. Subsequently, the Schlenk tube was slowly cooled to room temperature and filled with argon. Selective formation of **3b** was revealed by an IR spectrum of a small sample of the pale-yellow, microcrystalline solid in CH_2Cl_2. Yield: quantitative. M.p.: 246°C. Found: C, 21.30; H, 2.44; Cl, 18.41; P, 5.52; $C_{10}H_{14}Cl_3GeO_2PW$ (559.99). Calc.: C, 21.45; H, 2.52; Cl, 18.99; P, 5.53%.

trans-$Cp^*Mo(CO)_2(PMe_3)GeCl_3$ (**3c**)

Following the procedure described above for the synthesis of **3b**, complex **3c** was obtained as a pale-yellow, microcrystalline solid after heating 344 mg (0.63 mmol) of **2c** at 205°C for 20 min. M.p.: 237°C (dec.). Yield: quantitative. Found: C, 32.88; H, 4.82; Cl, 19.81; P, 5.39; $C_{15}H_{24}Cl_3GeMoO_2P$ (542.22). Calc.: C, 33.23; H, 4.46; Cl, 19.61; P, 5.71%. EI-MS (70 eV): *m/z* 544 $[M]^+$, 509 $[M—Cl]^+$, 453 $[M—Cl—CO]^+$, 433 $[M—Cl—PMe_3]^+$, 372 $[M—GeCl_2—CO]^+$, 344 $[M—GeCl_2—2CO]^+$, 268 $[M—GeCl_2—2\ CO—PMe_3]^+$ (base peak).

trans-$Cp^*W(CO)_2(PMe_3)GeCl_3$ (**3d**)

Following the procedure described above for the synthesis of **3b**, complex **3d** was obtained as a pale-yellow, microcrystalline solid after heating of 104 mg (0.17 mmol) of **2d** at 230°C for 15 min. M.p.: 256°C. Yield: quantitative. Found: C, 28.07; H, 4.09; Cl, 15.66; $C_{15}H_{24}Cl_3GeO_2PW$ (630.13). Calc.: C, 28.59; H, 3.84; Cl, 16.88%. EI-MS (70 eV): *m/z* 630 $[M]^+$, 595 $[M—Cl]^+$, 519 $[M—Cl—PMe_3]^+$, 486 $[M—GeCl_2]^+$, 458 $[M—GeCl_2—CO]^+$, 430 $[M—GeCl_2—2\ CO]^+$.

cis/trans-$CpW(CO)_2(CNEt)GeCl_3$ (**5/6**)

A Schlenk tube was charged with 230 mg (0.42 mmol) of *cis*-$CpW(CO)_2(CNEt)GeCl_3$ (**5**), then evacuated and heated at 145°C for 15 min. During this time the sample molt to give a dark-red melt. After cooling the Schlenk tube to room temperature the melt solidified to a glassy red residue, which was dissolved in 20 ml of CH_2Cl_2. The solution was then filtered from some insoluble material through a filter canula and the filtrate was concentrated to ca 2 ml and treated with 20 ml of pentane. The resulting yellow

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$.
[b] $wR_2 = [\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]]^{1/2}$.

precipitate was allowed to settle and the supernatant solution was removed. The precipitate was washed once with 10 ml of pentane and dried *in vacuo* to give the mixture of the two isomers **5** and **6** as a yellow, microcrystalline solid. Yield: 212 mg (92%).

Crystal structure determination of **2d** *and* **3d**

A summary of the crystal data, data collection and refinement for **2d** and **3d** is given in Table 7. Data collection for **2d** was performed on a STOE IPDS area detector equipped with a low temperature device and for **3d** on a STOE STADI4 four circle diffractometer. Lattice parameters derived from the setting angles of 28 reflections in the range of $27° \leqslant 2\theta \leqslant 33°$ for **3d** and from 5000 reflections after data collection for **2d**. Data for **3d** were collected in the ω-2θ scan mode. The crystal of **2d** was oscillated in 1.4° steps to yield 129 exposures and each of them was exposed for 4 min. Intensity data were integrated and converted into a SHELX *hkl*-file with the STOE IPDS software [30]. The input files for the SHELX programs were prepared with the program UTILITY [31]. Structure solution was performed with Patterson methods for **3d** and direct methods for **2d** (SHELXS-86) [32] and subsequent difference-Fourier synthesis (SHELXL-93) [33]. Refinement on F^2 was carried out by full-matrix least squares techniques (SHELXL-93). Non hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included using a riding model with $d_{CH} = 0.96$ Å and $U_{iso} = 0.08$ Å^2. Neutral atom scattering factors were taken from Cromer and Mann [34]. Illustrations were performed with ZORTEP [35].

(Received 25 September 1997; accepted 24 October 1997)

Abstract—Compounds $CpCrCl_2L$ (L = PMe_2Ph, **1**; $PMePh_2$, **2**; PPh_3, **3**) have been prepared. Their magnetic moment is in accord with the presence of three unpaired electron and a variable temperature ^1H NMR investigation of **1** shows Curie–Weiss behavior. The ^1H NMR, EPR and UV-visible spectra are in agreement with those of other previously reported compounds of the same family. An electrochemical investigation shows the accessibility of an irreversible reduction process. A parallel sodium reduction investigation of complexes $CpCrCl_2L$ (L = PMe_3 and η^1-dppe) suggests that the reduction process is followed by immediate chloride loss, and then by a ligand redistribution process to afford chromocene and unstable inorganic phosphine complexes of Cr(II). © 1998 Elsevier Science Ltd. All rights reserved

Keywords: $CpCrCl_2$; reduction chemistry; Curie-Weiss behavior.

We have investigated in some detail a class of stable organometallic radicals based on the $CpMoCl_2(PR_3)_2$ stoichiometry and have shown that they undergo a dissociative phosphine exchange process [1]. The supposed 15-electron $CpMoCl_2(PR_3)$ intermediate is probably favored by the release of pairing energy, since it is calculated to adopt a spin quartet ground state [2,3], while the associative path is disfavored by sterics and the high energy HOMO of the precursor. Attempts to stabilize and isolate such an intermediate, which is isostructural and isoelectronic with stable Cr(III) complexes, have been to date unfruitful [4,5]. The relative stability of the 17-electron $S = 1/2$ structure for CpMo(III) complexes and of the 15-electron $S = 3/2$ structure for CpCr(III) complexes have been rationalized on a theoretical standpoint by differences in M—PR_3 bonding and electron pairing energy [2,3].

We have thus become interested in examining the corresponding phosphine exchange process on the 15-electron Cr(III) compounds. For this purpose, a larger number of complexes was required than previously available and an exchange reaction that would be amenable to a kinetic study. We report here the synthesis of these complexes, a study of their physical properties to complement those already available in the literature, and an electrochemical and chemical reduction study. The phosphine exchange kinetic studies are in progress and will be presented in a later contribution.

EXPERIMENTAL

All operations were carried out under an atmosphere of dinitrogen. Solvents were dehydrated by conventional methods and distilled directly from the dehydrating agent prior to use (THF and Et_2O from Na/benzophenone, hexane from Na/K, heptane and toluene from Na, and CH_2Cl_2 from P_2O_5). NMR spectra were recorded on a Bruker AC200 spectrometer; the peak positions are reported with positive shifts downfield of TMS as calculated from the residual solvent peaks (^1H) or downfield of external 85% H_3PO_4 (^{31}P). For each ^{31}P-NMR spectrum, a sealed capillary containing H_3PO_4 was immersed in the same NMR solvent used for the measurement and this was

used as the external reference. Visible spectra were recorded on a Kontron Uvikon 810/820 spectrophotometer. EPR spectra were recorded on a Bruker ESP300 spectrometer equipped with an X-band microwave generator. The cyclic voltammograms were obtained with a Radiometer analog potentiostats (model PRT30-01) or with a Radiometer digital electrochemical analyzer (model DEA332). The electrochemical cell was a locally modified Schlenk tube with fittings for a platinum disk working electrode, a Pt wire counterelectrode, an SCE reference electrode, and a nitrogen inlet. Bu_4NBF_4 (ca 0.1 M) was used as supporting electrolyte. All potentials are reported relative to the ferrocene standard, which was added to each solution and measured at the end of the experiments. The magnetic susceptibility measurements were carried out with a Johnson Matthey magnetic balance, which operates by a modified Gouy method. The molar susceptibilities for the calculation of the magnetic moments were corrected for the diamagnetism of the ligands by using Pascal's constants. The elemental analyses were by M-H-W Laboratories, Phoenix, Arizona or were carried out at the Université de Bourgogne with a Fisons Instruments EA1108 analyzer. $CrCl_3(THF)_3$ was prepared according to the literature from $CrCl_3 \cdot 6H_2O$ and $SOCl_2$ in THF [6]. Solid $CpNa(THF)_x$ was prepared from Na and freshly cracked CpH in THF, followed by evaporation, precipitation by addition of hexane, filtration, and vacuum drying. The amount of residual THF was determined by acid-base titration after quenching with degassed water. Compounds $CpCrCl_2L$ (L = PMe_3, PEt_3, η^1-dppe) were prepared as previously described [7,8]. PMe_2Ph (Aldrich), $PMePh_2$ (Strem) and PPh_3 (Aldrich) were used as received without further purification.

Synthesis of $CpCrCl_2(PMe_2Ph)$, **1**

A blue solution of $CpCrCl_2(THF)$ was prepared *in situ* from $CrCl_3(THF)_3$ (0.496 mg, 1.325 mmol) and $NaCp(THF)_{0.46}$ (0.17 g, 1.4 mmol) in THF (20 ml). The ligand PMe_2Ph (0.2 ml, 1.4 mmol) was added, causing an immediate change of color to a deeper blue. The mixture was evaporated to dryness and the residue is extracted with CH_2Cl_2 (2 ml). After filtration, the slow diffusion of a hexane layer (15 ml) produced 0.364 g of blue crystals of **1** (84% yield). Elemental analysis: calculated for $C_{13}H_{16}Cl_2CrP$: C, 47.88; H, 4.94. Found: C, 47.92; H, 4.83. ^1H NMR ($CDCl_3$ δ/ppm ($w_{1/2}$/Hz)): 250 (3600) (Cp), 11.4 (49) (p-Ph), 5.28 (61) (m-Ph), −27 (740) (Me). $\mu_{eff} = 3.81$ μ_B ($\chi_g = 18.6 \cdot 10^{-6}$ cgsu, molar diamagnetic correction: $5.6 \cdot 10^{-2}$ cgsu). EPR (toluene, 105 K): $g_x = 4.480$; $g_y = 3.590$; $g_z = 1.990$. Visible (CH_2Cl_2, λ_{max}/nm (ε/cm^{-1} M^{-1})): 458 (394), 620 (666).

Synthesis of $CpCrCl_2(PMePh_2)$, **2**

A blue solution of $CpCrCl_2(THF)$ was prepared *in situ* from $CrCl_3(THF)_3$ (0.740 mg, 1.97 mmol) and $NaCp(THF)_{0.46}$ (0.24 g, 2.0 mmol) in THF (30 ml). The ligand $PMePh_2$ (0.28 ml, 2.0 mmol) is added, causing an immediate change of color to a deeper blue. The mixture was evaporated to dryness and the residue was extracted with CH_2Cl_2 (2 ml). After filtration, the slow diffusion of a hexane layer (20 ml) produced 0.598 g of blue crystals of **2** (78% yield). Elemental analysis: calculated for $C_{18}H_{18}Cl_2CrP$: C, 55.69; H, 4.67. Found: C, 55.90; H, 4.65. ^1H NMR (acetone-d^6, δ/ppm ($w_{1/2}$/Hz)): 255 (2700) (Cp), 9.75 (48) (p-Ph), 7.13 (70) (m-Ph), −21 (600) (Me). $\mu_{eff} = 3.73$ μ_B ($\chi_g = 14.7 \cdot 10^{-6}$ cgsu, molar diamagnetic correction: $7 \cdot 10^{-2}$ cgsu). EPR (toluene, 105 K): $g_x = 4.489$; $g_y = 3.590$; $g_z = 1.994$. Visible (CH_2Cl_2, λ_{max}/nm (ε/cm^{-1} M^{-1})): 480 (230), 666 (926).

Synthesis of $CpCrCl_2(PPh_3)$, **3**

A blue solution of $CpCrCl_2(THF)$ was prepared *in situ* from $CrCl_3(THF)_3$ (0.493 mg, 1.31 mmol) and $NaCp(THF)_{0.46}$ (0.17 g, 1.4 mmol) in THF (30 ml). The ligand PPh_3 (0.378 g, 1.44 mmol) was added, causing an immediate change of color to a deeper blue. The mixture evaporated to dryness and the residue is extracted with CH_2Cl_2 (2 ml). After filtration, the slow diffusion of a hexane layer (20 ml) produced blue crystals of **3**. These were recrystallized several times by the same procedure, until the ^1H and ^{31}P NMR spectra indicated the complete elimination of free PPh_3. Yield 0.204 g, 34%. Elemental analysis: calculated for $C_{23}H_{20}Cl_2CrP$: C, 61.35; H, 4.48. Found: C, 60.64; H, 4.43. ^1H NMR ($CDCl_3$, δ/ppm ($w_{1/2}$)): 260 (4500) (Cp), 9.32 (46) (p-Ph), 7.97 (73) (m-Ph). $\mu_{eff} = 3.76$ μ_B ($\chi_g = 12.77 \cdot 10^{-6}$ cgsu, molar diamagnetic correction: $2.32 \cdot 10^{-2}$ cgsu). EPR (toluene, 105 K): $g_x = 4.306$; $g_y = 3.635$; $g_z = 1.989$. Visible (CH_2Cl_2, λ_{max}/nm (ε/cm^{-1} M^{-1})): 518 (135), 662 (461).

Sodium reduction of $CpCrCl_2(PMe_3)$

Compound $CpCrCl_2(PMe_3)$ (0.689 g, 2.62 mmol) was dissolved in THF (60 ml) and the resulting blue solution was transferred into a Schlenk where 1% sodium amalgam (64 mg, 2.8 mmol of Na) had previously been prepared. The resulting mixture was stirred at room temperature for 12 h to afford rapid precipitation of a white solid, presumably NaCl. The final solution had a dark color. After filtration through Celite, the dark solution was evaporated to dryness and the residue was extracted with hexane and filtered. Cooling the resulting yellow-brown solution to −80°C afforded brown crystals, which were identified as Cp_2Cr by elemental analysis and comparison of the ^1H NMR ($\delta_{Cp} = 320$ ppm) and cyclic voltammetric properties (rev. oxidation at $E_{1/2} = -1.1$ V vs Cp_2Fe) with those reported in the literature [9]. Further work-up of the residue of the

hexane extraction did not lead to other soluble products.

Sodium reduction of $CpCrCl_2(\eta^1$-dppe)

Compound $CpCrCl_2(\eta^1$-dppe) (2.039 g, 3.48 mmol) was dissolved in THF (30 ml) and the resulting blue solution was transferred into a Schlenk where 1% sodium amalgam (80 mg, 3.5 mmol of Na) had previously been prepared. The resulting mixture was stirred at room temperature for 12 h to afford a brown suspension with precipitation of a white solid. After filtration through Celite, the solution was evaporated to dryness and the residue was extracted with hexane and filtered. Cooling the resulting yellow-brown solution to −80 C afforded brown crystals of Cp_2Cr (see previous section). The residue of the extraction is a beige solid which is soluble in THF. Its ^1H and ^{31}P NMR spectrum in C_6D_6 shows only the presence of free dppe. After nitric acid attack, the solution gives a positive test for the chloride ion.

A solid identical in appearance and solubility properties to this beige residue is obtained by sodium amalgam reduction of $CrCl_3(THF)_3$. Treatment of this solid with dppe in THF does not lead to any observable change.

RESULTS AND DISCUSSION

The new compounds $CpCrCl_2L$ (L = PMe_2Ph, **1**; $PMePh_2$, **2**; PPh_3, **3**) have been prepared by following the same protocol previously used for the analogous compounds where L = PMe_3, PEt_3, η^1-dmpm, η^1-dmpe, and η^1-dppe [7,8]. This consists of exchange of THF by the appropriate phosphine on compound $CpCrCl_2(THF)$, which is obtained *in situ* from $CrCl_3(THF)_3$ and NaCp.

The spin quartet ground state for the class of 15-electron CpCr(III) compounds has previously been established [10]. In accordance with previous findings, the measured magnetic moments for compounds **1–3** is close to the spin-only value expected for three unpaired electrons. The ^1H-NMR properties of compounds **1–3** are also in accord with those reported for similar compounds [7,8]. The relatively short electronic relaxation times for the magnetic states of the spin quartet compounds are responsible for the observation of paramagnetically shifted but relatively sharp NMR resonances for the protons. Only the resonance of the *ortho* phenyl protons could not be clearly identified. Furthermore, the coordinated P nucleus does not lead to the observation of any resonance in the ^{31}P NMR spectrum. The short electronic relaxation times are also responsible for the absence of an EPR spectrum at room temperature for these complexes. A rhombic spectrum, however, can be observed in the glassy state at low temperature, in conformity with previous analogues [8,11].

A variable temperature magnetic study had apparently not been carried out on any of the previously reported complexes of this class. Compound **1** has been investigated in detail in $CDCl_3$. The position of the ^1H NMR resonances for the various observed protons as a function of the inverse temperature gives straight lines (see Fig. 1), in accordance with the expected Curie–Weiss behavior of the magnetically diluted complex.

Complexes **1–3,** like the previously reported analogues, are blue. Visible absorption bands are therefore expected. Indeed, compounds **1–3** show a strong (ε = 500–1000 cm^{-1} M^{-1}) and broad absorption in the 600–750 nm region, which is probably the overlap of two or more transitions, in addition to a weaker (ε = 150–500) and more blue-shifted (450–500 nm) absorption. These spectra are similar to those previously reported for $CpCrCl_2(L)$ (L = η^1-dmpm, -dmpe, and -dppe) [8]. Although qualitatively similar, the spectra of the various compounds show significant differences, with the more methyl-substituted derivatives showing slightly blue shifted and more intense absorption bands relative to more phenyl-substituted derivatives. This feature is being exploited for the determination of the ligand exchange kinetics by stopped-flow with visible monitoring. A preliminary ^1H NMR investigation shows that the $CpCrCl_2(PMe_3)/PMe_3$ self-exchange process is too slow for accurate kinetics to be determined by the line-broadening technique, while the use of PMe_3-d^9 shows that it is too fast for a classic mixing and monitoring study.

To the best of our knowledge, an electrochemical

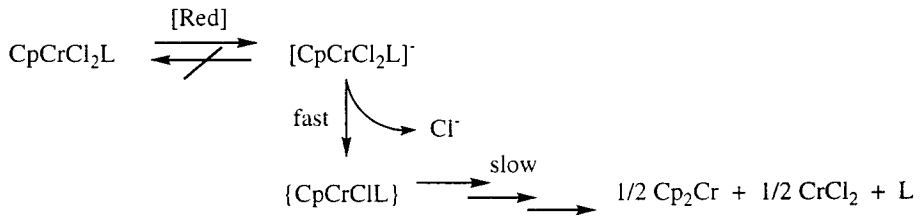
investigation has never been reported for dichloride CpCr(III) complexes of this stoichiometry. On the other hand, coordination compounds of Cr(III) are known to afford, by reduction, related complexes of Cr(II). The related alkyl derivative $[Cp^*CrMe(dmpe)]^+$ has been shown to undergo a reversible electrochemical and chemical reduction to the neutral Cr(II) complex [12]. We have therefore carried out a cyclic voltammetric investigation on compounds **1**–**3**, as well as on the previously reported analogous complexes with PMe_3, PEt_3, and η^1-dppe ligands. As expected, a reduction process takes place (wave A in Fig. 2). This, however, is irreversible and is followed by a smaller intensity, irreversible oxidation wave at a more positive potential (wave B in Fig. 2). The spectrum is qualitatively identical for all compounds investigated, with the related potentials being collected in Table 1. The voltammogram of compound $CpCrCl_2(\eta^1$-dppe) is characterized also by a second reduction wave at $E_{p,c} = -1.98$ V.

The results of a chemical reduction study suggest a possible explanation for the cyclic voltammetric results. A sodium amalgam reduction was carried out on compounds $CpCrCl_2(PMe_3)$ and $CpCrCl_2(\eta^1$-dppe). The PMe_3 complex gave rise to a mixture of Cp_2Cr and uncharacterized inorganic species. The dppe complexes analogously gave rise to Cp_2Cr and free dppe, accompanied by a beige solid that contains chloride and that appears identical to a solid obtained by sodium amalgam reduction of $CrCl_3(THF)_3$. Therefore, we propose the mechanism shown in Scheme 1 for both the electrochemical and chemical reductions.

Following the reduction process to the 16-electron Cr(II) anion, a fast chemical process must occur according to the electrochemical study. This is likely to be loss of the chloride ion, since the chemical reduction study shows rapid precipitation of a white solid, presumably NaCl. The presumed CpCrClL intermediate is not susceptible to oxidation at accessible potentials, since the oxidation scan of the voltammogram does not show oxidation waves of the same intensity as the initial reduction wave. Given that this complex is electron deficient (14-electron), it is reasonable to imagine that its oxidation might be difficult. This proposed intermediate proceeds to an apparent ligand redistribution reaction, since chromocene has been identified as one of the products for the reduction of both PMe_3 and dppe complexes. Isolated chromocene shows an oxidation process at a potential corresponding to process B in Fig. 2.

The stoichiometry of the ligand redistribution process in Scheme 1 allows a second product of stoichiometry $CrCl_2L_2$. However, a $CrCl_2(PMe_3)_2$ complex is not known and our attempts to characterize the inorganic material produced by the reduction of the PMe_3 complex have been unfruitful. The same ligand redistribution process occurs for the reduction of the dppe complex. In this case, a 6-coordinate $CrCl_2(dppe)_2$ complex might be obtained. This would be similar to the reported $CrCl_2(LL)_2$ complexes with LL = dmpe [13] and dippe [14]. However, a previous report shows that the $CrCl_2(dppe)_x$ complex is rather unstable and easily loses dppe [15]. Our



Scheme 1.

observations are fully consistent with these previous findings.

It is to be noted that, while a 14-electron $CpCrCl(PMe_3)$ intermediate is likely to gain stability by formation of a di-μ-chloro bridged dimer, opening the way to ligand scrambling with formation of the proposed products of Scheme 1, the corresponding $CpCrCl(\eta^1$-dppe) intermediate also has the possibility of stabilizing itself by chelation and formation of a mononuclear 16-electron $CpCrCl(\eta^2$-dppe). The result of the electrochemical and chemical reduction studies clearly indicate that either this does not occur, or the phosphine chelation process must be a fast and reversible process. Interestingly, however, the analogous 16-electron $Cp^*Cr(CH_3)$(dmpe) complex is stable [12]. This difference could be attributed to the ability of the chloride ligand to bridge the two metals and/or to the greater ionic character of the Cr—Cl bond relative to the Cr—CH_3 bond, also favoring the ligand exchange process.

In conclusion, we have synthesized a greater number of 15-electron complexes of the $CpCrCl_2L$ family and thoroughly investigated their physical and spectroscopic properties. A preliminary investigation shows that a study of the phosphine exchange kinetics is accessible by fast mixing methods. The reduction of these derivatives to the Cr(II) state triggers a ligand redistribution reaction with formation of chromocene and unstable inorganic Cr(II)-phosphine complexes.

(Received 25 September 1997; accepted 22 October 1997)

Abstract—The synthesis and spectroscopic and structure chemical properties of complexes with the ligands *trans*-2-pyrazol-1-ylcyclohexan-1-ol (**1**), *cis*-(1-amino)(2-pyrazol-1-yl)cyclohexane (**2**) and 2-pyrazol-1-ylcyclohexanonoxime (**4**) coordinated to a variety of first and second row transition metals are described. These new systems bear cycloalkane backbones, which give rise to rigid ligand arrangements at the metal centre. X-ray crystallographic investigations of the copper(II) complexes $CuCl_2(\mathbf{1})_2 \cdot (H_2O)_2$ (**5e**) and $[Cu(\mathbf{1})_2](CuCl_4)$ (**5f**) proved the coordination of two different enantiomers of ligand **1** to one copper centre. Owing to their d^9 configuration, both octahedrally coordinated metal centres show typical Jahn-Teller distortions with either loosely bound chloro ligands or bridging $CuCl_4^{2-}$ anions occupying the apical positions. The copper(II) complex $[CuCl_2(\mathbf{2})]_2 \cdot$ (**6**) forms dimers in the solid state, wherein the trigonal bipyramidally coordinated Cu centres are linked by bridging chloro ligands. © 1998 Elsevier Science Ltd. Keywords: chiral ligands; amino alcohols; transition metal complexes; crystal structure.

During the last years, complexes of 1,2-amino alcohols have been applied for MOCVD [2] and, in the case of chiral systems, as catalysts for enantioselective transformations [3]. While the coordination chemistry of aliphatic 1,2-amino alcohols is well established [4], relatively few transition and main group element complexes bearing chelating 1,3-amino alcohols [5] or 1,2-amino alcohols with aromatic *N*-donor sites [6], have been structurally investigated. We are interested in 1,3-amino alcohols with aromatic pyrazolyl *N*-donor fragments, where both donor sites are attached to a rigid cyclolkane backbone. These ligands can be obtained easily and in high yields by nucleophilic attack of a pyrazole derivative to an epoxicycloalkane. The reaction leads, under opening of the oxirane ring, to the corresponding 1,2-*trans* configurated cycloalkanols, with both substituents in equatorial orientation (Scheme 1).

Since we are interested in these compounds as chiral ligands for enantioselective catalysis, we worked out a route for kinetic resolution of the resulting racemates. In the presence of lipase B from *candida antarctica*, the esterification of the (*R*,*R*)-enantiomers is performed with enantiomeric excesses of more than 95% [7]. The resulting esters can be separated from the alcohols by crystallization or preparative MPLC. Following this procedure, both enantiomers of the chelate ligands are available in amounts of several grams in high stereochemical purity. These new chiral compounds are also versatile starting materials for the synthesis of enantiomerically pure multidentate ligand systems. In this paper, we report the coordination chemistry of *trans*-2-pyrazol-1-ylcyclohexan-1-ol (**1**)

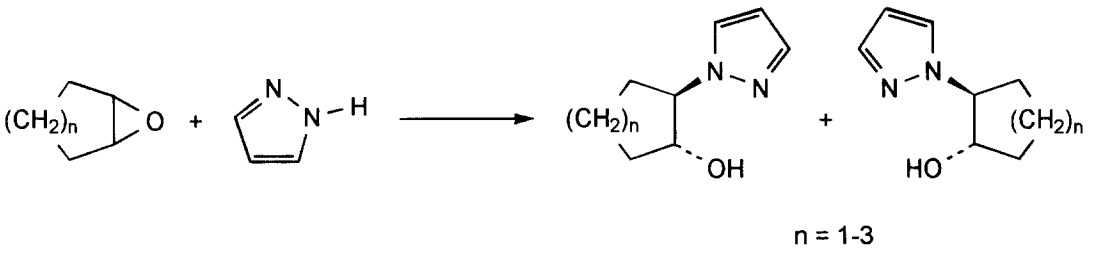


Scheme 1.

and two other new pyrazolylcyclohexane derivatives, chelated to first and second row transition metals.

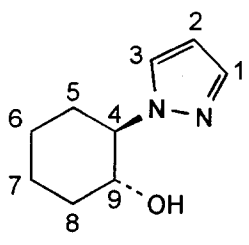
EXPERIMENTAL

General

trans-2-Pyrazol-1-ylcyclohexan-1-ol (**1**), *cis*-(1-amino)(2-pyrazol-1-yl)cyclohexane (**2**) and $(C_6H_5CN)_2PdCl_2$ were synthesized according to published procedures [7a, 7c, 8]. All other starting materials were purchased from Aldrich. The NMR (Bruker DPX 400), infrared (Perkin–Elmer 1600 Series FTIR) and mass spectra (GC–MS: Hewlett-Packard gaschromatograph HP 5890 and mass selective detector HP 5970) and all elemental analyses were carried out at the *Anorganisch-chemisches Institut der TU München*. The NMR spectra are assigned according to Scheme 2.

rac-2-Pyrazol-1-ylcyclohexanone (**3**)

DMSO (22 ml, 330 mmol) is added to a solution of **1** (22.6 g, 138 mmol) in CH_2Cl_2 (100 ml) stirred at $-60°C$ and kept under nitrogen. After 30 min, oxalic chloride (12.2 ml, 152 mmol) is added dropwise, with keeping the temperature carefully at $-60°C$. After 1 h, triethylamine (89 ml, 640 mmol) is added. The reaction mixture is stirred for 1 h at $-60°C$ and then quenched by the addition of water (100 ml). The aqueous layer is separated and extracted with CH_2Cl_2 (4×30 ml), the combined organic phases are washed with brine and dried over $MgSO_4$. Removing the solvent and sublimation *in vacuo* yields **3** (15.5 g, 95 mmol, 69%) as a colourless solid. IR (KBr): ν (C=O) 1714 vs, cm^{-1}; ^1H NMR δ_H (400.13 MHz, 25°C, $CDCl_3$) ppm: 7.52 (d, 1H, $^3J_{1,2}$ 2.0 Hz, 1-H), 7.40 (d, 1H, $^3J_{2,3}$ 2.5 Hz, 3-H), 6.31 (t, 1H, 2-H), 5.01 (dd, 1H, $^3J_{4,5\text{-eq}}$ 5.5 Hz, $^3J_{4,5\text{-ax}}$ 13.0 Hz, 4-H), 2.61–1.70 (m, 8H, CH_2); $^{13}C\{^1H\}$ NMR δ_C (100.25 MHz, 25°C, $CDCl_3$) ppm: 204.9 (C-9), 139.0 (C-1), 128.7 (C-3), 105.8 (C-2), 69.0 (C-4), 41.0 (C-8), 34.3 (C-5), 27.1 (C-7), 24.6 (C-6); MS (EI) m/z (%): 164 (19) [M^+], 136 (35) [$(M—CO)^+$], 107 (27) [$C_8H_{11}^+$], 95 (38) [$C_3H_3N_2$-$C_2H_4^+$], 81 (53) [$C_3H_3N_2$-CH_2^+], 69 (100) [$C_3H_5N_2^+$], 55 (14) [$C_4H_7^+$], 41 (34) [$C_3H_5^+$].



Scheme 2.

rac-2-Pyrazol-1-ylcyclohexanonoxime (**4**)

1.0 M NaOH (30 ml) is added dropwise to a solution of **3** (4.59 g, 28 mmol) and $[NH_3OH]Cl$ (1.93 g, 28 mmol) in H_2O (100 ml). After 12 h of stirring, the resulting precipitate is filtered off, washed with H_2O and dried *in vacuo*, yielding **4** (4.5 g, 25 mmol, 90%) as a colourless microcrystalline solid. Found: C, 60.28; H, 7.29; N, 23.55. Calc. for $C_9H_{13}N_3O$: C, 60.32; H, 7.31; N, 23.45%. IR (KBr): ν (O—H) 3261 s, ν (C=N) 1672 w, cm^{-1}. ^1H NMR δ_H (400.13 MHz, 25°C, $CDCl_3$) ppm: 7.59 (s, 1-H), 7.47 (s, 3-H), 6.29 (s, 2-H), 4.86 (m, 2H, 4-H, OH), 2.59–1.65 (m, 8H, CH_2). $^{13}C\{^1H\}$ NMR δ_C (100.25 MHz, 25°C, $CDCl_3$) ppm: 157.5 (C-9), 139.7 (C-1), 130.6 (C-3), 106.4 (C-2), 62.9 (C-4), 33.5 (C-8), 26.1 (C-5), 23.7 (C-7), 23.6 (C-6). MS (EI) m/z (%): 179 (12) [M^+], 162 (14) [$(M—HO)^+$], 147 (1) [$(M—NH_2O)^+$], 110 (6) [$(M—C_3H_5N_2)^+$], 81 (54) [$C_6H_9^+$], 69 (100) [$C_3H_5N_2^+$], 32 (4) [NH_2O^+].

Synthesis of transition metal complexes, general procedure

10 mmol of the ligand and 5 mmol of the corresponding metal salt are dissolved in MeOH and heated under reflux conditions for 6 h. After removal of the solvent *in vacuo*, the resulting microcrystalline solids are washed with diethylether and dried *in vacuo*. Recrystallization from MeOH gives crystalline materials.

[Dichlorobis(2-pyrazol-1-ylcyclohexan-1-ol)chromium(III)]chloride (**5a**)

From $[Cr(H_2O)_6]Cl_3$; yield: 52%, green microcrystalline solid. Found: C, 43.74; H, 6.13; N, 11.32. Calc. for $C_{18}H_{28}Cl_3CrN_4O_2$: C, 44.05; H, 5.75; N, 11.42%. IR (KBr): ν (O—H) 3413 vs, 3131 s, cm^{-1}.

Dichlorobis(2-pyrazol-1-ylcyclohexan-1-ol)iron(II) (**5b**)

From $[Fe(H_2O)_6]Cl_2$; yield: 56%, yellow microcrystalline solid. Found: C, 46.94; H, 6.18; Cl, 15.42; Fe, 12.12; N, 12.25. Calc. for $C_{18}H_{28}Cl_2FeN_4O_2$: C, 47.08; H, 6.15; Cl, 15.44; Fe, 12.16; N, 12.20%. IR (KBr): ν (O—H) 3152 vs, cm^{-1}.

Dichlorobis(2-pyrazol-1-ylcyclohexan-1-ol)cobalt(II) (**5c**)

From $[Co(H_2O)_6]Cl_2$; yield: 82%, violet microcrystalline solid. Found: C, 46.61; H, 6.15; N, 12.05. Calc. for $C_{18}H_{28}Cl_2CoN_4O_2$: C, 46.77; H, 6.10; N, 12.12%. IR (KBr): ν (O—H) 3138 vs, cm^{-1}.

Dichlorobis(2-pyrazol-1-ylcyclohexan-1-ol)nickel(II) (**5d**)

From $[Ni(H_2O)_6]Cl_2$; yield: 92%, pale green microcrystalline solid. Found: C, 46.43; H, 6.25; Cl, 15.25; N, 12.44; Ni, 13.02. Calc. for $C_{18}H_{28}Cl_2N_4NiO_2$: C, 46.79; H, 6.11; Cl, 15.35; N, 12.13; Ni, 12.70%. IR (KBr): ν (O—H) 3121 vs, cm^{-1}.

Dichlorobis(2-pyrazol-1-ylcyclohexan-1-ol)copper(II) dihydrate (**5e**) *and* [bis(2-pyrazol-1-ylcyclohexan-1-ol)copper(II)]tetrachlorocuprate(II) (**5f**)

From $Cu(H_2O)_2Cl_2$; yield: 54%. Recrystallization from MeOH results first in the formation of blue crystals of **5e** and finally in the formation of a small amount (< 10%) of green crystals of **5f**. Analytical data of **5e**: Found: C, 42.77; H, 6.41; Cl, 14.15; Cu, 12.50; N, 11.35. Calcd. for $C_{18}H_{28}Cl_2CuN_4O_2 \cdot (H_2O)_2$: C; 42.98, H, 6.41; Cl, 14.10; Cu, 12.63; N, 11.14%. IR (KBr): ν (O—H) 3287 vs, 3142 vs, cm^{-1}. Analytical data of **5f**: Found: C, 35.80; H, 4.75; Cl, 23.67; Cu, 21.00; N, 9.43. Calc. for $C_{18}H_{28}Cl_4Cu_2N_4O_2$: C, 35.96; H, 4.69; Cl, 23.59; Cu, 20.11; N, 9.32%. IR (KBr): ν (O—H) 3133 s, cm^{-1}.

[Bis(2-pyrazol-1-ylcyclohexan-1-ol)zinc(II)] tetranitratozincate(II) (**5g**)

From $[Zn(H_2O)_6](NO_3)_2$; yield: 90%, colourless microcrystalline solid. Found: C, 30.00; H, 4.43; N, 15.28. Calc. for $C_{18}H_{28}N_8O_{14}Zn_2$: C, 30.40; H, 3.97; N, 15.76%. IR (KBr): ν (O—H) 3484 s, ν (NO_3) 1386, 1353, cm^{-1}. ^1H NMR δ_H (400.13 MHz, 25°C, CDCl3) ppm: 7.87 (d, 1H, $^3J_{1,2}$ 2.5 Hz, 1-H), 7.75 (d, 1H, $^3J_{2,3}$ 2.5 Hz, 3-H), 6.53 (t, 1H, 2-H), 4.18 (ddd, 1H, $^3J_{8,9ax}$ 4.0 Hz, $^3J_{8,9eq}$ 9.8 Hz, $^3J_{4,9}$ 12.0 Hz, 9-H), 3.79 (ddd, 1H, $^3J_{4,5ax}$ 4.5 Hz, $^3J_{4,5eq}$ 8.2 Hz, 4-H), 2.72 (br, 1H, OH), 2.26–1.31 (m, 8H, CH_2). ^{13}C NMR δ_C (100.13 MHz, 25°C, CDCl3) ppm: 141.0 (C-1), 131.0 (C-3), 106.8 (C-2), 75.2 (C-9), 64.4 (C-4), 34.2 (C-8), 29.5 (C-5), 24.4 (C-6), 23.5 (C-7).

(Acetylacetonato)(*cis*-dioxo)(*rac-trans*-2-pyrazol-1-ylcyclohexyloxy)molybdenum(VI) (**5h**)

A solution of **1** (0.83 g, 5.00 mmol) in absolute ethanol (10 ml) is added within a period of 5 min to a solution of $MoO_2(acac)_2$ (0.82 g, 2.50 mmol) in absolute ethanol (20 ml). After stirring at room temperature for 2 d, the solvent is removed *in vacuo* and the resulting pale orange residue is washed several times with diethylether and dried *in vacuo*. Yield: 72%, colourless microcrystalline, air and moisture sensitive solid. Found: C, 42.65; H, 5.12; N, 7.18; Mo, 24.30. Calc. for $C_{14}H_{20}MoN_2O_5$: C, 42.87; H, 5.14; N, 7.14; Mo, 24.46%. IR (KBr) ν (C=O) 1615 s, 1517 vs, ν (Mo=O) 924 vs, 904 vs, cm^{-1}. ^1H NMR δ_H (400.13 MHz, 25°C, $CDCl_3$) ppm: 7.59 (d, 1H, $^3J_{1,2}$ 2.5 Hz, 1-H), 7.28 (d, 1H, $^3J_{2,3}$ 2.5, 3-H), 6.31 (t, 1H, 2-H), 5.70 (s, 1H, CO-CH-CO), 4.47 (br, 2H, 4-H, 9-H), 2.14 (s, 3H, CH_3), 2.05 (s, 3H, CH_3), 2.52–1.29 (m, 8H, CH_2). $^{13}C\{^1H\}$ NMR δ_C (100.25 MHz, 25°C, $CDCl_3$) ppm: 190.6 (2 × CO), 139.4 (C-1), 128.3 (C-3), 105.6 (C-2), 104.0 (CO—*C*H—CO), 85.4 (C-9), 63.7 (C-4), 33.5 (C-8), 29.5 (C-5), 27.8 (C-6), 26.2 (C-7), 24.1 (2 × CH_3).

(1-Amino-2-pyrazol-1-ylcyclohexan)dichlorocopper(II) (**6**)

From $Cu(H_2O)_2Cl_2$; yield: 38%, turquoise microcrystalline solid. Found: C, 36.12; H, 4.95; Cl, 23.28; Cu, 20.10; N, 14.02. Calc. for $C_9H_{15}Cl_2CuN_3$: C, 34.68; H, 4.85; Cl, 22.75; Cu, 20.39; N, 13.48%. IR (KBr): ν (N—H) 3443 s, 3249 s, 3202 s, cm^{-1}.

Dichloro(2-pyrazol-1-yl-cyclohexanonoxime)palladium(II) (**7**)

$PdCl_2(C_6H_5CN)_2$ (0.38 g, 1.00 mmol) is added to a slurry of **4** (0.18 g, 1.00 mmol) in CH_2Cl_2 (15 ml). The resulting orange coloured clear solution is stirred for 30 min, filtered to remove traces of elemental pal-

ladium and added dropwise to *n*-pentane (50 ml). **7** precipitates as a bright orange coloured microcrystalline solid, which is washed with diethylether (2 × 50 ml) to remove benzonitrile and dried *in vacuo*. Yield: 92%. Found: C, 30.41; H, 3.70; N, 11.87. Calc. for $C_9H_{13}Cl_2N_3OPd$: C, 30.32; H, 3.68; N, 11.79%. IR (KBr): *v* (O—H) 3136 s, 3118 s, 3100 s, *v* (C=N) 1652 w, cm^{-1}. ^1H NMR δ_H (400.13 MHz, 25°C, DMSO-d_6) ppm: 8.04 (s, 1-H), 7.66 (s, 3-H), 6.38 (s, 2-H), 5.55 (m, 2H, 4-H, OH), 2.59–1.65 (m, 8H, CH_2). $^{13}C\{^1H\}$ NMR δ_C (100.25 MHz, 25°C, DMSO-d_6) ppm: 162.3 (C-9), 142.0 (C-1), 132.9 (C-3), 107.4 (C-2), 59.7 (C-4), 28.4 (C-8), 26.0 (C-5), 21.4 (C-7), 20.2 (C-6).

Crystallographic structure determination of the copper complexes **5e**, **5f** *and* **6**

Crystals were fixed inside a Lindemann class capillary. The intensity data were obtained at 293 K (**5e**, **5f**) and 193K(**6**) with graphite monochromated Mo-K_α radiation on an Enraf Nonius CAD4 diffractometer (**5e**), an Enraf-Nonius MACH3 diffractometer (**5f**) and on a STOE IPDS (**6**). Preliminary positions of heavy atoms were found by direct methods (SIR92 [9]), while positions of the other non-hydrogen atoms were determined from successive Fourier difference maps coupled with an initially isotropic least squares refinement (SHELXL93 [10]) in the program system STRUX-V [11]. The hydrogen atoms of **5e** and **5f** were located in the difference Fourier maps and refined with isotropic temperature parameters. For **6**, hydrogen atoms were placed in calculated positions and included in the structure factor calculations but not refined. Additional crystal data, data collection and refinement parameters are presented in Table 1.

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Fachinformationszentrum Karlsruhe as supplementary publication with the CSD numbers 408002 (**5e**), 408003 (**5f**) and 408004 (**6**).

RESULTS AND DISCUSSION

Ligand synthesis

In the case of the amino alcohol **1**, obtained by reaction of epoxycyclohexane and pyrazole, the 1,2-*trans*-substitution pattern at the cycloalkane ring leads to an equatorial arrangement of the substituents and therefore to a chelate system with low steric demand, which should not cause severe problems of steric repulsion when coordinated to a transition metal centre. However, the steric demand of this type of ligands can be increased by a stereochemical inversion of the CH—OH carbon atom, leading to a 1,2-*cis* substituted cyclohexane. This type of substitution pattern will give rise to an almost perpendicular orientation of the cyclohexane fragment with respect to the plane defined by the metal atom and both donor centres of the chelate ligand. We thoroughly investigated the transformation of the hydroxy compound **1** into the corresponding amine **2**, which proceeds under inversion of the configuration [1] and which can either be achieved by tosylation, reaction with NaN_3 and reduction of the resulting azide or by a so-called Mitsunobu amination [12] (Scheme 3). Another way to influence the stereochemical properties of the chelate ligand is to oxidize the alcohol to the corresponding ketone **3**. Reaction of **3** with hydroxylammonium chloride leads to the oxime **4** (Scheme 3).

The molecular geometry of **3** and **4** is proved by their spectroscopic properties. While a broad absorption at 3245 cm^{-1} in the infrared spectrum of **1**, characteristic for a OH function included in hydrogen bonding, this absorption is no longer observed for **3**. However, an intense C=O absorption at 1714 cm^{-1} appears. In the infrared spectrum of the oxime **4**, a new absorption at 3261 cm^{-1} can be assigned to the O—H vibration of the N—OH fragment and a weak absorption at 1672 cm^{-1} is characteristic for the C=N vibration of oximes. The ^1H NMR and ^{13}C spectra of **3** and **4** differ only marginally. A large coupling constant ($^3J_{HH}$ = 13 Hz) of the proton of the CH-pz (pz = pyrazolyl) group proves the equatorial orientation of the pyrazole fragment at the six-membered aliphatic ring system. ^{13}C NMR resonances at 204.9 and 157.5 ppm are characteristic for aliphatic ketones and oximes, respectively.

Transition metal complexes

trans-2-Pyrazol-1-ylcyclohexan-1-ol (**1**) dissolved in methanol reacts with a variety of two- and trivalent first row transition metal halides in a 2 : 1 ratio, giving the chelate complexes **5a–g** (Scheme 4). However, the reaction of two equivalents of **1** with $MoO_2(acac)_2$ does not lead to the corresponding bischelate complex $MoO_2(\mathbf{1})_2$ but stops at the mono adduct $MoO_2(acac)(\mathbf{1})$ (**5h**).

This result is in contrast to observations of Herrmann *et al.*, who investigated ligand exchange reactions of $MoO_2(acac)_2$ in the presence of a series of 2-pyridinylmethanols. They found molybdenum complexes of the type $MoO_2(L—L)_2$ (L—L = 1-pyridinylmethanolato ligand) [13]. Only when the pyridine ring of the chelate ligand is *ortho* substituted, the steric demand of the ligand gives rise to the formation of a dinuclear molybdenum(VI) derivative of the type $[MoO_2(L—L)]_2(\mu\text{-}O)$. In our case, the reaction stops at the mono adduct **5h**, presumably for steric reasons. The second acetylacetonato ligand is not split off the metal centre to allow further nucleation. Owing to the strong Lewis-acidic Mo(VI) centre, the hydroxy function of the chelate ligand is deprotonated, forming a hydroxo donor moiety, manifested by the absence of an OH absorption in the infrared spectrum of **5h**. The oxo ligands are coor-

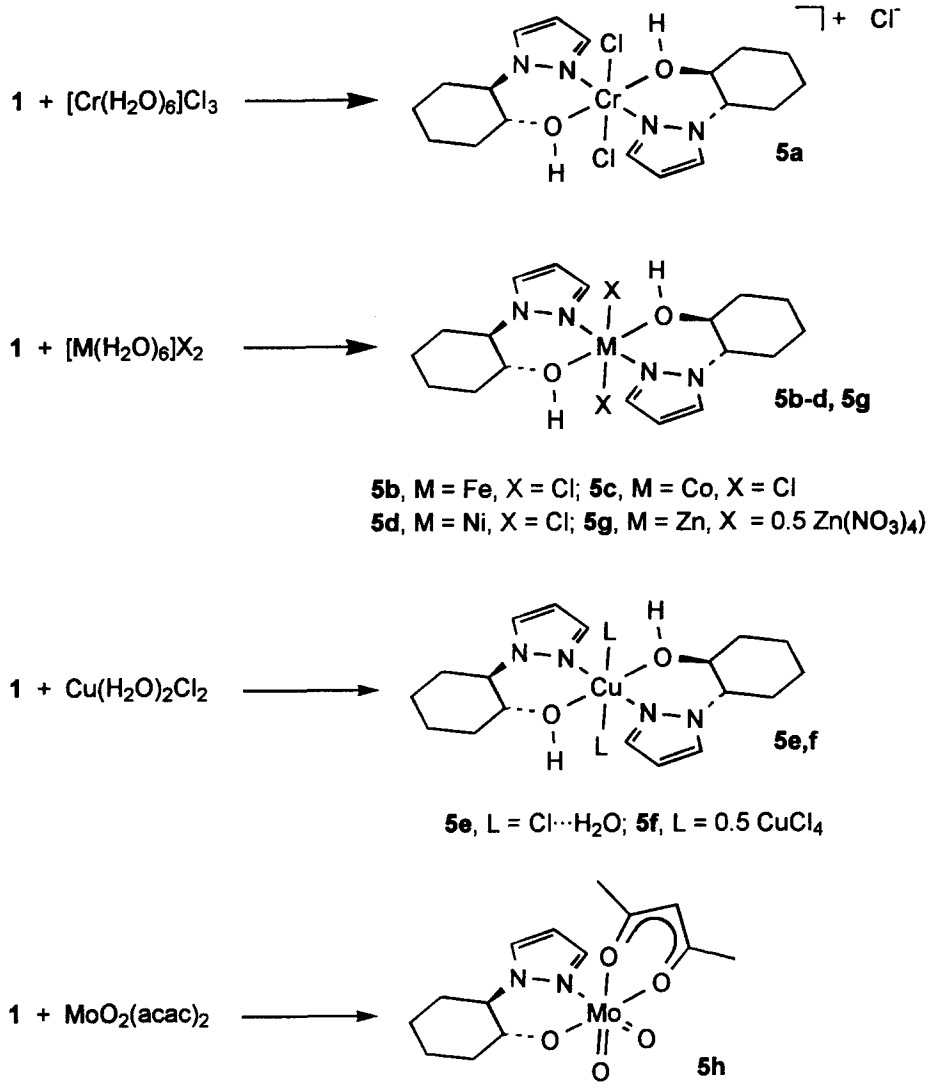


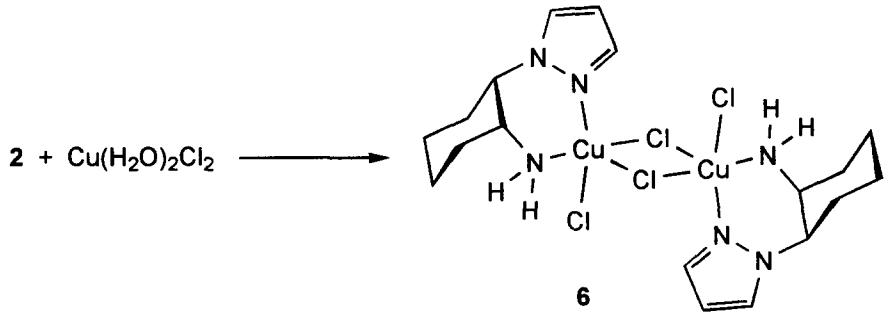
Scheme 4.

dinated in *cis* geometry, resulting in two Mo=O absorptions (924 vs and 904 vs cm^{-1}). Coordination shifts the ^1H NMR resonances of the protons at the substituted carbon atoms of the cyclohexane ring for about 0.67 ppm and the ^{13}C NMR resonance of the *C*H—OH group for about 12.3 ppm to lower field with respect to the free ligand **1**. In contrast to **5h**, the chelate ligands of the complexes **5a–g**, bearing two- and trivalent first row transition metal centres, are not deprotonated at the OH group, which is proved by elemental analysis as well as by infrared spectroscopy. The IR spectra show intense absorptions at 3150–3120 cm^{-1}, characteristic for coordinated hydroxy functions.

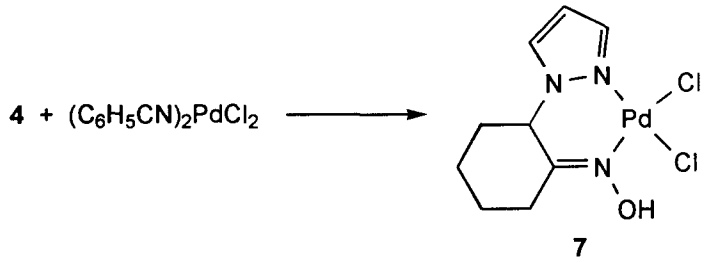
Reacting two equivalents of **1** with $Cu(H_2O)_2Cl_2$ in methanol gives $CuCl_2(\mathbf{1})_2 \cdot (H_2O)_2$ (**5e**), which should be comparable in its structure chemical features with the complexes **5a–d**. $[Cu(\mathbf{1})_2](CuCl_4)$ (**5f**), which is structurally comparable to **5g** and bears two differently coordinated copper(II) centres, was obtained as a side product in less than 10% yield. The solid state structures of both copper complexes were determined by means of X-ray structure analysis and will be discussed later on.

The amine **2** reacts with $Cu(H_2O)_2Cl_2$ in methanolic solution to yield the chelate complex $CuCl_2(\mathbf{2})$ (**6**) (Scheme 5). Since four-coordination by two amino and two chloro ligands is not observed for copper(II) centres, a bridging coordination of chloro ligands leads to the formation of a dinuclear complexes in the solid state, as it was found in a variety of Cu(II) complexes bearing chelating amines [14]. The solid state structure of the copper complex **6** was determined by means of X-ray structure analysis and will be discussed later on.

Reaction of the chelating oxime **4** with $(C_6H_5CN)_2PdCl_2$ gives, under exchange of the labile benzonitrile ligands, the palladium oxime complex **7** in almost quantitative yield (Scheme 6).



Scheme 5.



Scheme 6.

The chelating complexation of the Pd(II) centre by two nitrogen donors is proved by both infrared and NMR spectroscopic data of **7**. While the C=N stretching frequency shifts from 1672 (**4**) to 1652 cm^{-1} (**7**), the ν(O—H) shifts about 140 cm^{-1} to lower wavenumbers, indicating both, reduced C=N and O—H bond strengths. The coordination of the pyrazolyl moiety in **7** is manifested by a shift of the aromatic ^1H and ^{13}C NMR resonances to lower field, as well as a low-field shift of the ^{13}C resonance of the oxime carbon atom proves the coordination of the C=NOH group.

X-ray structure analysis

Figure 1 shows the coordination geometry of the metal centre of **5e**, which crystallizes from methanol as deep blue prisms in the monoclinic space group $P2_1/n$. The copper(II) ion, which is a centre of inversion, is coordinated in a distorted octahedral mode with long axial copper chlorine interactions and two chelate ligands occupying the equatorial positions of the polyhedron. All bond angles between the donor sites and the metal centre are close to 90°. Characteristic bond lengths and angles are presented in table 2.

Owing to the symmetry of **5e**, both enantiomers of **1** are found to coordinate one copper(II) ion, with the cyclohexane ring occupying a chair conformation. We suppose this mode of coordination to be the thermodynamically favoured one, since **5f** shows the same geometry and since we do not find any indications for the formation of diastereomers in the NMR spectra of the diamagnetic zinc complex **5g**. The Cu—N and Cu—O distances of **5e** are observed as expected [17]. The electronic configuration (d^9) of the copper centre leads to a typical Jahn-Teller distortion, with long Cu—Cl distances of 2.962(1) Å. For that reason, two additional molecules of water are included in the solid state structure of **5e**, forming stabilizing hydrogen bonds to the chloro ligands. The analogous complexes **5a–d** crystallize without adduct formation with water or methanol. Hydrogen bonding finally results in a two dimensional network shown in Figure 2.

In the complex **5f**, the weak coordination of the axial chloro ligands to the d^9 configurated copper(II) centre is not stabilized by hydrogen bonding but by involving an excess of $CuCl_2$ to form $CuCl_4^{2-}$ anions, which act as linkers between $[Cu(\mathbf{1})_2]^{2+}$ cations. **5f** crystallizes as green prisms in the monoclinic space group C2/c. Figure 3 shows a plot of the resulting chains parallel to the crystallographic c-axis, characteristic bond parameters are given in Table 2. This mode of chain formation by $CuCl_4^{2-}$ anions linking two transition metal centres has been observed only in two cases before [18].

Cu(1) is coordinated in a distorted octahedral mode with a Cu(1)—Cl(1) distance being about 0.14 Å shorter than in **5e**. The reason for this finding is a hydrogen bridge between OH and Cl(2) of the $CuCl_4^{2-}$ anion, which leads to the formation of a six-membered ring consistent of Cu(1), O(1), H(10), Cl(2), Cu(2), and

Cl(1). Cu(2) is coordinated in a distorted tetrahedral mode with short Cu(2)—Cl(1) and Cu(2)—Cl(2) distances of 2.233(1) and 2.267(1) Å. The interatomic distance between Cu(1) and Cu(2) is 4.293(1) Å.

The X-ray structure analysis of **6** shows a dinuclear Cu(II) complex, with the copper centres linked by bridging chloro ligands. These chloro ligands occupy two of the equatorial positions at the trigonal bipyramidally coordinated copper ions, while the 1,2-*cis*-substituted chelate ligands occupies the third equatorial (pyrazole) and one of the axial (NH_2) positions. Intra- and intermolecular hydrogen bondings of the NH_2 protons not only stabilize the dinuclear structures but also lead to the formation of infinite chains along the crystallographic a-axis. Figure 4 shows a plot of the one dimensional network of the hydrogen

bondings in the solid state structure of **6**, characteristic bond parameters are given in Table 3.

As predicted, the 1,2-*cis* substituted cyclohexane ring of the *N,N'*-chelate ligand, which is again observed in the energetically favourable chair conformation, is orientated almost perpendicular to the plane defined by Cu, N(2) and N(3).

CONCLUSION

The special requirements of 1,2-disubstituted cyclohexane backbones (either *trans* or *cis*) open an access to chelate ligand with completely different stereochemical properties, which may be of interest for applications in enantioselective catalysis. We were

(Received 6 October 1997; accepted 10 November 1997)

Abstract—$[NEt_4]_2[Tc(Cl)_3(CO)_3]$ was prepared directly from $[NBu_4][TcO_4]$. Dissolution of $[NEt_4]_2[Tc(Cl)_3(CO)_3]$ in water yielded the aqua ion $[Tc(OH_2)_3(CO)_3]^+$ which, upon titration with 1 eq. of OH^-, gave the tetranuclear complex $[\{Tc(\mu_3\text{-}OH)(CO)_3\}_4]$ in quantitative yield and of which the structure could be elucidated. Reaction of $[\{Tc(\mu_3\text{-}OH)(CO)_3\}_4]$ with HC_5Me_5 gave the important starting material $[(C_5Me_5)M(CO)_3]$ (M = Tc, Re). To achieve complexes in higher oxidation states with the $C_5Me_5^-$ ligand, oxidation was performed with $[Br_2]$ for the rhenium and the corresponding technetium complex. Oxidation in trifluoroacetic acid yielded *cis/trans*-$[(C_5Me_5)M(Br)_2(CO)_2]$ (M = Tc, Re). Oxidation in dichloromethane gave in both cases the seven co-ordinate, $18e^-$ M(III) complex $[(C_5Me_5)MBr(CO)_3]^+$. The structure of the rhenium complex was elucidated. It was found that oxidation took place at the metal centre and the $C_5Me_5^-$ ring to yield $[(CO)_3M(\mu\text{-}Br)_3M(CO)_3]$ as the counterion. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: Technetium; carbonyls; oxidation; halogenation; titration.

During the past decade, the organometallic chemistry of metal complexes in the high oxidation states has received enormous attention. This widespread interest has been initialized by the synthesis of several novel organometallic rhenium complexes in its highest possible valency of +VII. These compounds were in particular $[(C_5Me_5)ReO_3]$ and $[CH_3ReO_3]$ [1–9]. The chemistry of these compounds, gave an insight into their various properties, ranging from fundamentally novel compounds and mechanisms to application in catalytic processes [10–12]. The question arose, would the lower homologues parallel the corresponding rhenium chemistry or differ principally as found within group 8 transition metals. Far less is known of the organometallic chemistry of technetium in the lower valencies and practically nothing is known in the high valencies [13,14].

The reasons for this fact, which are three-fold, have to be explained. (i) During the period of exploration of pure organometallic chemistry 30–40 years ago, the artificial element technetium was very rare and not at all readily available. Nevertheless, a few fundamental complexes have been synthesized and characterized during this time [15–17]. (ii) One of the isotopes, Tc-99(m), possesses interesting decay characteristics for application in nuclear medicine. Consequently, coordination chemistry in aqueous systems was investigated thoroughly with the goal of yielding compounds to be applied in life sciences. Obviously, the main focus was put onto classical Werner type complexes rather than on organometallics. (iii) In addition, the gap in behaviour between organometallic complexes of technetium and those of rhenium was so small that investigations in this field of technetium chemistry was not encouraged.

It is known in particular from the group 8 elements,

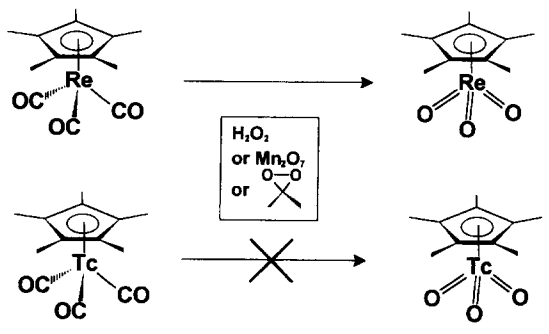
* Author to whom correspondence should be addressed.

that analogue compounds in high oxidation states display fundamentally different behaviour. The question arose again, would the small gap in low valent 7 complexes become that large when going from oxidation states +I to +VII, thus, resulting in principally different reactivity. Indeed, the answer was found to be "yes" for the complex $[CH_3TcO_3]$ compared to $[CH_3ReO_3]$ [18]. The former is able to oxidize alkenes stereospecifically without additional oxidants, whereas the latter acts as oxidation catalyst only in the presence of additional agents.

Consequently, similar investigations were intended for $[(C_5Me_5)TcO_3]$. $[(C_5Me_5)ReO_3]$ can be prepared conveniently by several methods, whereas the analogues Tc compound resisted all preparative attempts to date (Scheme 1) [19]. A polymeric complex of composition $[Tc(\mu\text{-}O)_3Tc(C_5Me_5)]_n$ has been described as the product of H_2O_2 oxidation of $[(C_5Me_5)Tc(CO)_3]$ in tiny amounts [20]. We doubted this formulation for spectroscopic reasons [18] and it was recently suggested from analysis of X-ray data, that the complex was in fact $[(C_5Me_5)ReO_3]$ [19]. It seemed that not only the higher oxidation potential of Tc was responsible, since, even with highly oxidizing agents such as $[Mn_2O_7]$ or dioxirane, no reactions were found. We concluded from our own attempts to oxidize $[(C_5Me_5)Tc(CO)_3]$ with any of these oxidants, that catalytic decomposition, particularly of dioxirane and Mn_2O_7, took place. Vigorous O_2 evolution was observed at $-78°C$, when adding the oxidant to $[(C_5Me_5)Tc(CO)_3]$ or *vice versa*. $[(C_5Me_5)Tc(CO)_3]$ was usually re-isolated quantitatively. Nevertheless, it can be concluded from theoretical calculations, that $[(C_5Me_5)TcO_3]$ should exist [21,22] and, thus, different approaches are demanded.

Nowadays, enough technetium is available, an interest in high valent organometallic chemistry emerged, but now, for safety reasons, it is relatively difficult to synthesize synthons of technetium, i.e. $[Tc_2(CO)_{10}]$, on which organometallic chemistry is ultimately based. The motivation for this study was, thus, to bypass $[Tc_2(CO)_{10}]$ and to find a convenient pathway to $[(C_5Me_5)Tc(CO)_3]$ as a source for attempted preparations of $[(C_5Me_5)TcO_3]$, starting finally from $[TcO_4]^-$ under laboratory conditions.

We have developed a strategy to the quantitative preparation of $[TcCl_3(CO)_3]^{2-}$ [23] which can be treated as an analogue of $[TcCl(CO)_5]$, giving access to almost any complex containing the "*fac*-$Tc(CO)_3$" moiety including the important $[(C_5H_5)Tc(CO)_3]$ and $[(C_5Me_5)Tc(CO)_3]$.



Scheme 1. Literature preparations of $[(C_5Me_5)ReO_3]$ from $[(C_5Me_5)Re(CO)_3]$ and unsuccessful attempts in case of the analogues technetium compound.

EXPERIMENTAL

All chemicals have been purchased from Fluka AG Buchs and used without further purification. Since none of the complexes is sensitive against water, no special drying of solvents was required. The starting materials have been prepared as described earlier, however the modified protocol given below allowed a better isolated yield. IR spectra have been recorded on a Perkin–Elmer 16PC instrument, NMR spectra on Gemini 2000 system running at 300 MHz. The titration experiments were performed using a Metrohm 665 potentiometer and a Metrohm 615 automatic dispenser.

Synthesis of $[NEt_4]_2[TcCl_3(CO)_3]$ (1)

A 1 M solution of BH_3 in tetrahydrofurane (THF) (7 cm^3, 7 mmol) was added to a solution of $[NB_4]Cl$ (0.61 g, 2.2 mmol) in THF (17 cm^3). H_2 evolved from H_2O present in $[NB_4]Cl$. A slow stream of CO was bubbled through this solution for 10 min. A solution of $[NB_4][TcO_4]$ (0.3 g, 0.74 mmol) dissolved in THF (5 cm^3) was dropped over a 10 min period into the solution. After each addition the colour changed to yellow and then back to colourless. After addition was finished, CO bubbling was continued for 3 h at r.t. or 1 h at 50–60°C. After this period the solution was colourless. Excess BH_3 was then neutralized by the addition of 1 M HCl (1 cm^3). H_2 should be generated thereby indicating the presence of excess BH_3. THF was evaporated and ethanole (7 cm^3) added. To the clear solution $[NEt_4]Cl$ (0.6 g, 3.7 mmol) was added and stirred over night. A white powder precipitated, which was filtered. Washing with cold EtOH and drying *in vacuo* gave an analytically pure product of **1** (0.35 g, 87 %). IR (cm^{-1}): 2989 w, 2028 vs, 1902 vs, 1458 m, 1184 w, 798 w, 668 w, 638 w, 500 w. ^{99}Tc NMR (δ, D_2O): −876 (s, $\Delta_{1/2}$ = 67 Hz). Anal. Calc. for $C_{19}H_{40}Cl_3O_3Tc$: Tc, 17.7%. Found 18.0%.

Synthesis of $[\{Tc(\mu_3\text{-}OH)(CO)_3\}_4]$ (3)

1 (0.17 g, 0.31 mmol) was dissolved in water (5 cm^3) and a 1 M solution of NaOH (310 μl) added. The solution turned turbid and was overlayered with 30 cm^3 of diethylether (Et_2O) and stirred over night. Et_2O was separated and the aqueous layer again washed

with Et_2O. The combined Et_2O phases were dried over Mg_2SO_4, separated and evaporated, leaving **3** as a white powder in analytically pure form (0.065 g, 98%). IR (KBr, cm^{-1}): 3611 s, 3599 s, 2044 vs, 1919 vs, 835 w, 792 m, 668 m, 639 m, 535 m. ^{99}Tc NMR (δ, D_2O): -565 (s, $\Delta_{1/2} = 130$ Hz).

Synthesis of $[(C_5H_5)Tc(CO)_3]$

1 (0.25 g, 0.45 mmol) was slurried in THF (5 cm^3) in a round bottom flask and $Ag[PF_6]$ (0.23 g, 0.9 mmol) dissolved in THF was added. AgCl and most of $[NEt_4][PF_6]$ precipitated immediately. Freshly sublimed $Tl[C_5H_5]$ (0.125 g, 0.46 mmol) was added and the mixture heated to 60°C for a few hours. The reaction was cooled to -20°C and filtered cold to remove TlCl, $[NEt_4][PF_6]$ and AgCl. THF was evaporated, the residue dissolved in Et_2O and, upon cooling to -30°C, colourless crystals of the product were collected (0.085 g, 77%). The synthesis for the rhenium complex was performed identically. IR (KBr, cm^{-1}): 2029 vs, 1949 vs. 1H NMR (δ, $CDCl_3$): 4.45. ^{99}Tc NMR (δ, $CDCl_3$): -1716 (s, $\Delta_{1/2} = 180$ Hz).

Synthesis of $[(C_5Me_5)Tc(CO)_3]$ (**4**)

3 (0.08 g, 0.1 mmol) was mixed in a small Schlenk tube with $[HC_5Me_5]$ (65 μl, 0.48 mmol). The mixture was brought to 150°C for 30 min during which period it became a colourless solution. On cooling to r.t., the contents solidified. Recrystallization from hexane at -30°C or column chromatography (silica gel, hexane) yielded **3** as a white powder (0.12 g, 95 %). The proceeding of the reaction and the radiochemical purity could be monitored by TLC on silica gel using hexane as a mobile phase, $R_f = 0.3$. IR (KBr, cm^{-1}): 2989 w, 2007 vs, 1904 vs, 1458 m, 1184 w, 798 w, 668 w, 638 w, 500 w. ^{99}Tc NMR (δ, D_2O): -1874. ^1H NMR (δ, $CDCl_3$): 2.07 (s, CH_3). ^{13}C NMR (δ, $CDCl_3$): 11.7 (CH_3).

Synthesis of $[(C_5Me_5)Tc(CO)_3Br][(CO)_3Tc(\mu\text{-}Br)_3Tc(CO)_3]$ (**5**)

4 (0.12 g, 0.38 mmol) was dissolved in dichloromethane (CH_2Cl_2) and Br_2 (40 μl, 0.75 mmol) was dropped to the solution. The colour turned to red–brown and then after a few hours to deep blue–green. The solvent was evaporated and the residue extracted with Et_2O to remove unreacted **4** and organic decomposition products. The brown–yellow residue was dissolved in CH_2Cl_2 and overlayered with hexane. After several days brown–yellow crystals of X-ray quality (in case of rhenium) were collected (0.062, 48% relative to Tc). Synthetic conditions were identical when the reaction was performed with the corresponding rhenium complex. IR (KBr, cm^{-1}): 2108 s, 2062 s, 2048 s, 2018 s, 1914 vs,br, 1896 vs,br. ^1H NMR (δ, $CDCl_3$): 2.27 (s, CH_3). ^{13}C NMR (δ, $CDCl_3$): 15.7 (CH_3).

X-ray crystallography

Unit cell parameters and intensity data for compounds **3** and **5** were obtained on a CAD-4 diffractometer. The unit cell parameters were determined by least square refinement of the setting angles of 25 centred reflections with $6.7 < \theta < 15.9°$ (**3**) and $8.3 < \theta < 13.4°$ (**5**) respectively. Crystallographic data and final R indices for both complexes are summarized in Table 1. Both structures were solved using the Patterson methode (SHELXS86) and refined on F^2 using SHELXL93 [24]. Literature values were taken for atomic scattering factors [25]. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms could be localized in compound **3**, were introduced at calculated positions in **5** and refined isotropically for both compounds. Psi-scan absorption correction was applied in both compounds. ZORTEP was used for drawings [26]. Presentations of the complexes are depicted in Figs 2 and 3. Important bond lengths and angles are given in Tables 2 and 3.

RESULTS AND DISCUSSION

Synthesis of $[(C_5H_5)Tc(CO)_3]$ and $[(C_5Me_5)Tc(CO)_3]$ *from* $[TcCl_3(CO)_3]^{2-}$

Common approaches to cyclopentadienyl complexes are usually performed either by oxidative addition to the homoleptic carbonyls or by sub-

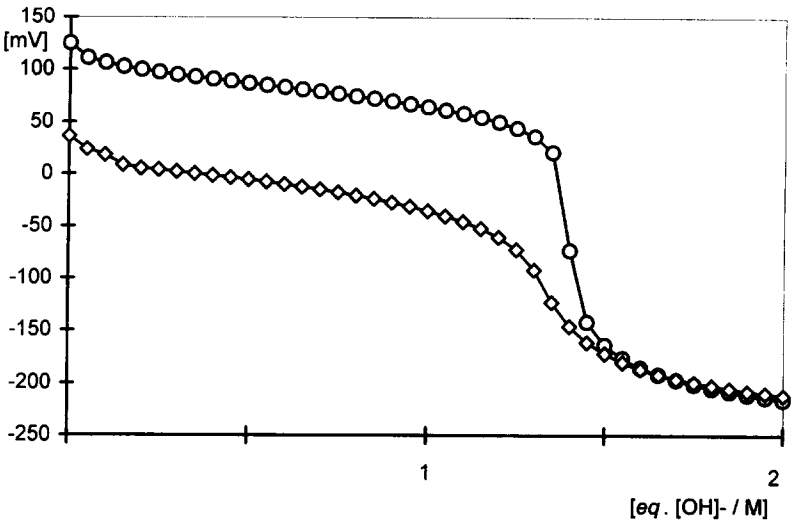

Fig. 1. Titration curves of $[Re(OH_2)_3(CO)_3]^+$ (above) and $[Tc(OH_2)_3(CO)_3]^+$ (below) with 0.01 M NaOH. "[M]" = 1.15 10^{-3} M, I = 0.1 (KNO_3).

stitution of a halide and two other ligands, mostly CO's, with the corresponding cyclopentadienyl salts of mono-cations. In the case of Tc, $[Tc_2(CO)_{10}]$ is applied to the former and $[TcCl(CO)_5]$ to the latter process [27,28]. Both compounds are prepared by high pressure approaches, thus, it was important to use $[TcCl_3(CO)_3]^{2-}$ as the starting material for both compounds by a more convenient pathway. Different attempts to use directly $[TcCl_3(CO)_3]^{2-}$ (**1**) as a precursor failed. Thus, precipitation of two halides with $Ag[PF_6]$ led to the formation of $[TcCl(THF)_2(CO)_3]$. Both, AgCl and $[NEt_4][PF_6]$, readily precipitated from THF. Subsequent reaction with $Tl[C_5H_5]$ led straight forward and in very good yield to $[(C_5H_5)Tc(CO)_3]$.

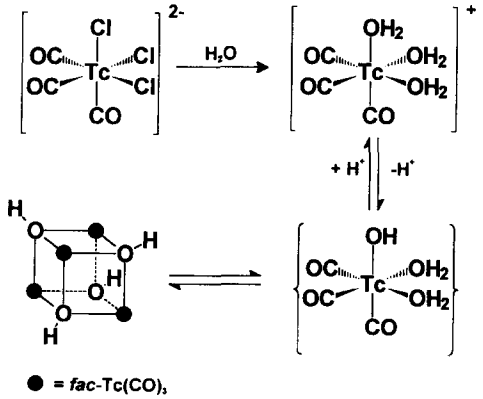
The corresponding salts of HC_5Me_5 are difficult to prepare and even more difficult to handle with tiny amounts of Tc-complexes. An alternative approach had to be developed, that allowed a more general

approach to complexes of differently substituted cyclopentadienyl derivatives.

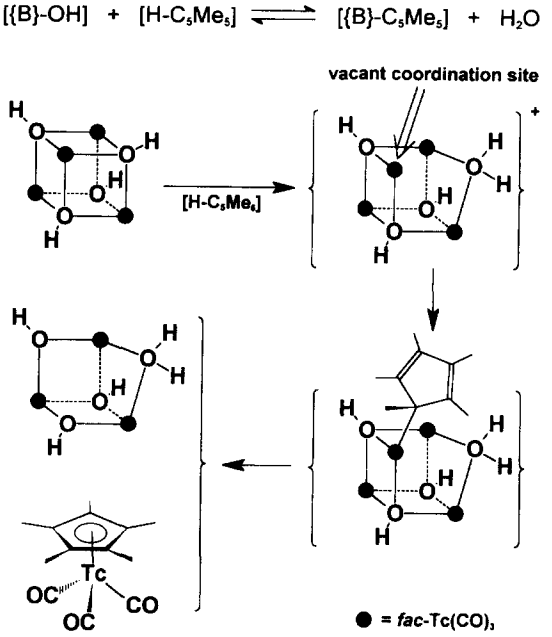
Dissolution of **1** in water yielded readily the stable organometallic aqua ion $[Tc(OH_2)_3(CO)_3]^+$ (**2**). The complete substitution of Cl^- by H_2O could be confirmed by IR spectroscopy in the νCO region but also by the more sensitive ^{99}Tc NMR spectroscopy. Aqueous solutions show one single signal at −876 ppm (relative to $[TcO_4]^-$). Considering the nuclear spin of 9/2 would expect a rather broad line, however in a relatively symmetric complex, small half line width of 67 Hz were found. On precipitating the Cl^- with Ag^+ salts of weakly coordinating anions, the position of the resonance remained essentially unchanged.

2 can be considered as a Broenstedt acid, undergoing deprotonation upon titration with OH^-. Recently, we reported about the determination of the pK_a values of the corresponding complex $[Re(OH_2)_3(CO)_3]^+$ which was found to be a relatively strong mono-cationic acid [29,30]. The species $[Re(OH)(OH_2)_2(CO)_3]$ and $[Re_2(OH)_2(OH_2)_4(CO)_6]$ were derived from a mechanistic model but could not be observed directly due to oligomerization to anionic di- and tri-nuclear complexes. $[Tc(OH_2)_3(CO)_3]^+$ was found to obey the same mechanistic pathway, the formation constants however being significantly lower than those of rhenium (Fig. 1). From identical calculations, the mono-deprotonated intermediate $[Tc(OH)(OH_2)_2(CO)_3]$ should be present in very low concentrations but could be isolated as its tetranuclear complex $[\{Tc(\mu_3\text{-}OH)(CO)_3\}_4]$ (**3**) by extraction into diethylether in quantitative yields. $[Tc(OH)(OH_2)_2(CO)_3]$ is obviously not able to accept the high electron density provided by a terminal OH^- group but tends to bridge two different Tc-centres with concerted loss of a water ligand (Scheme 2). The formation is reversible, therefore **3** can be considered as a Broenstedt acid.

Protonation of **3** in a non-coordinating solvent would easily generate an electronically unsaturated 14 e^- or 16 e^- species. It could reasonably be expected that such an intermediate coordinates to any potential ligand present in solution. HC_5Me_5 can act as both, as a weak acid and as a ligand system occupying the free sites generated upon protonation.



Scheme 2. Aquatization of $[TcCl_3(CO)_3]^{2-}$ and subsequent formation of $[\{Tc(\mu_3\text{-}OH)(CO)_3\}_4]$ by titration with 1 eq. of OH^-.



Scheme 3. Acid-base reaction between $[H\text{-}C_5Me_5]$ and "$[(CO)_3Tc]$-OH" leading to the formation of $[(C_5Me_5)Tc(CO)_3]$.

These two properties of HC_5Me_5 coupled with the basicity of **3** make the important synthon $[(C_5Me_5)Tc(CO)_3]$ (**4**) easily accessible by an acid-base reaction with subsequent coordination of the conjugated base to the coordinatively unsaturated metal centre. The thermodynamically favoured η^5-coordination led to the cleavage of the remaining "μ_3-OH" bridges and generated further terminal OH ligands which are more susceptible for protonation and cleavage (Scheme 3).

The overall process allows the preparation of **4**, directly from $[TcO_4]^-$ in two steps without applying high pressure conditions. Thus, by the presented methodology, a useful base is given for the exploration of organometallic technetium chemistry in low and, probably, also for high oxidation states finally.

Oxidation of $[(C_5Me_5)M(CO)_3]$ (*M = Tc, Re*) *with* Br_2

The original reaction conditions for the preparation of $[(C_5Me_5)ReO_3]$ were straight forward in that $[(C_5Me_5)Re(CO)_3]$ could be oxidized by a number of oxidizing agents such as H_2O_2, Mn_2O_7 or dioxirane [31,32]. Other low valent organometallic complexes of i.e. molybdenum could be oxidized in a similar way.

However, all these attempts failed in the case of the analogous technetium complexes. No reaction was found with H_2O_2 and even under vigorous conditions, the educt $[(C_5Me_5)Tc(CO)_3]$ could be isolated at the end of the "reaction" almost quantitatively. The very powerful agent Mn_2O_7 readily decomposed into MnO_2 and O_2 when dropped into a solution of **4** at temperatures of $-78°C$ or higher. No traces of any oxidized technetium compounds could be detected. The same behaviour was also observed for dioxirane. The decomposition rate of these oxidizing agents and the fact that the technetium compound could be reisolated, resembled a catalytic decomposition process. This assumption was partly supported by the observation, that small amounts of **4**, dropped into solutions of either of these oxidants, resulted readily in their decomposition. These qualitative results led to a strategy of initial oxidation by elemental halogens and, subsequently, further oxidation with oxygen transfer agents (Scheme 4).

One of these intermediates achieved by oxidative addition reaction should be $[(C_5Me_5)Tc(Br)_2(CO)_2]$. The *cis* and *trans* isomers have been described and are easily prepared by a literature protocol for rhenium and technetium [28].

It was intended to modify the described protocol in order to increase yield and distribution ratio between *cis*- and *trans*-isomers. Instead, oxidation in CH_2Cl_2 with Br_2 lead to quantitative isolation of the cation $[(C_5Me_5)MBr(CO)_3]^+$ (M = Re, Tc) with the dinuclear complex $[(CO)_3M(\mu\text{-}Br)_3M(CO)_3]^-$ as a counterion (**5**). The cation has been prepared for rhenium but in a different way [33,34]. Under these conditions and even at low temperatures, only trace amounts of $[(C_5Me_5)M(Br)_2(CO)_2]$ could be detected by chromatographic methods. Obviously, halogen attack does not occur exclusively at the metal centre but also at the $C_5Me_5^-$ ring. This ring oxidation lead to cleavage and release as it is known from other reactions. The unusually stable dimer $[(CO)_3M(\mu\text{-}Br)_3M(CO)_3]^-$ was then built up, resisting in its pure form attack from halogens. In parallel to the oxidation of the $C_5Me_5^-$ ring system, oxidative addition took also place at the metal centre to yield the M(III) complex cation $[(C_5Me_5)MBr(CO)_3]^+$. It is interesting to note, that the principal differences found in attempts to oxidize with potential oxygen transfer reagents is not found with the halogens. Rate of oxidation and product distributions could well be monitored by chromatography or by NMR spectroscopy and were found to be essentially the same for both elements.
