Scheme 4. Oxidative addition of $[(C_5Me_5)Tc(CO)_3]$ with Br_2 as the gate to $[(C_5Me_5)TcO_3]$?

SUMMARY AND CONCLUSION

The question of the preparation of high valent organometallic technetium compounds is inherently coupled to the question of how to prepare conveniently low valent technetium compounds. The problem could be solved by the synthesis of $[NEt_4]_2[TcCl_3(CO)_3]$ directly from $[TcO_4]^-$ with the oxophilic, non coordinating reducing agent BH_3·THF at 1 atm of CO. $[NEt_4]_2[Tc(Cl)_3(CO)_3]$ can be considered as a starting material for Tc(I) chemistry comparable to $[TcX(CO)_5]$. Addition of 1 eq. of OH^- to an aqueous solution of **1** yielded the important synthon $[\{Tc(\mu_3\text{-}OH)(CO)_3\}_4]$. Protonation of the *in situ* base OH^- generates unsaturated complexes, able to adopt even weakly coordinating ligands. This behaviour was used to overcome the difficulties in preparing $[(C_5Me_5)Tc(CO)_3]$. The simple acid base reaction between $[\{Tc(OH)(CO)_3\}_4]$ and HC_5Me_5 made $[(C_5Me_5)Tc(CO)_3]$ quantitatively accessible and open the further development of Tc(I) chemistry with η^5-coordinating ligands. Finally, since all attempts to oxidize $[(C_5Me_5)Tc(CO)_3]$ to higher valencies failed to date, halogenation might be an alternative initial step. Reaction with Br_2 yielded the two compounds *cis*/*trans*-$[(C_5Me_5)M(Br)_2(CO)_2]$ and $[(C_5Me_5)MBr(CO)_3]^+$ (M = Tc, Re). $[(C_5Me_5)TcBr(CO)_3]^+$ is the first Tc(III) complex containing three CO ligands bound to the metal centre.

Both complexes can be considered as intermediates in the preparation of $[(C_5Me_5)TcO_3]$.

(Received 2 October 1997; accepted 31 October 1997)

Abstract—The coupling of [3]-ferrocenophan-1-one **1** with McMurry type reagents to yield olefins *E,Z*-bis([3]-ferrocenophane-1-ylidene) **2a,b** is described. In the case of the $TiCl_3$/Zn reagent only pinacol rearrangement to complex **3** subsequent to coupling takes place in high yield. In contrast, upon addition of pyridine the reaction proceeds to the olefins in high yield. The X-ray structure of **3** and the electrochemistry of the olefins **2a,b** is described. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: McMurry coupling; pinacol rearrangement; ferrocenyl ketones; biferrocenes; electrochemistry; crystal structure.

The reductive coupling of organic carbonyls by low valent transition metal compounds is a valuable tool for the preparation of diols and olefins [1]. Recently Fürstner and his group have established a reliable system based on the couple $TiCl_3$/Zn [2], which also exists as a catalytic version [3]. There are several reports on the possible mechanism of the McMurry reaction showing the course of the coupling being strongly dependent on the nature of the reagent used [4]. In the field of ferrocene chemistry several coupling reactions of ferrocenyl ketones to the corresponding olefins have been reported [5]. We are interested in the self exchange electron transfer of biferrocenes and therefore pursued the preparation of olefins **2a,b**, in which the ferrocene moieties have a fixed orientation relative to one another. We herein describe the preparation of compounds **2a,b** by using the McMurry reaction starting from ferrocenophanone **1**, as well as preliminary results on the electrochemistry of **2a,b**.

RESULTS

Preparation of E,Z-Bis([3]-ferrocenophane-1-ylidene) **2a,b**

Since the coupling of organic carbonyls with low valent metals very much depends on the system in use, we initially set out to synthesize compounds **2a,b** by coupling ferrocenophanone **1** with the classical McMurry reagent $TiCl_3/LiAlH_4$ [6]. As expected the coupling results in a mixture of the *E*- and *Z*-isomers with a ratio of $E/Z = 2:1$, but the yields are poor (37% overall yield), because of the hydrogenation of a considerable amount of ketone **1** to [3]-ferrocenophane under the reaction conditions. Recently Fürstner and his group [2] published the so called "instant method" which leads to excellent yields for the coupling of organic carbonyls. Therefore, in a second attempt, complex **1** was treated with a mixture of $TiCl_3$ and Zn (Ti/Zn = 2:5) in refluxing dimethoxyethane. After 24 h the starting material vanished and a new compound **3** had been formed. As shown by tlc this new compound was not identical with the olefins **2a,b**. After purification of the reaction mixture by flash chromatography on silica, a pale-yellow compound **3** was isolated in 70–80% yield.

Under conditions of the catalytic variant of the "instant method" [3], i.e. using $(CH_3)_3SiCl$ as oxygen scavenger, the main product again is complex **3** (30%). Additionally, the silylated diol **4** also forms in 12% yield. The synthesis of olefins **2a,b** under conditions of the "instant method" could eventually be achieved by adding 2 equiv. of pyridine to the reaction mixture. In this case the olefins **2a,b** are obtained in 70% overall yield with varying ratios of *E*- and *Z*-isomer. Up untill now we are not able to find a clear trend in the variation of the *E/Z*-ratio but in a few runs we noticed a higher amount of *Z*-isomer, when the reaction was conducted only to low conversion.

Spectroscopic characterization of compounds **2a,b** *and* **3**

The ^{1}H-MNR spectrum of **3** is temperature dependent exhibiting several coalescence transitions due to inversion of the transannular bridges which is typical for ferrocenophanes of this kind [7]. The ^{13}C-NMR spectrum shows a signal at $\delta = 206$ ppm for a keto function. This is also detected in the IR-spectrum by a CO-stretching mode at ν (CO) = 1697 cm^{-1}. The olefins **2a,b** exhibit clear olefinic signals in the ^{13}C-NMR spectra at $\delta = 134$ and 136 ppm, respectively. Due to their symmetric constitution no IR signals were recorded in the olefinic C–C vibrational region, whereas in the Raman spectrum absorptions are found at ν(C=C) = 1620 and 1628 cm^{-1}. A distinction between the *E*- and *Z*-isomers **2a,b** can be made on the basis of the ^{1}H-NMR signals of the cyclopentadienyl (cp) ligands. In the case of the *E*-isomer three multiplets at $\delta = 4.17$ (8H), 4.13 (4H) and 4.02 (4H) ppm are found, whilst the *Z*-isomer exhibits four signals with $\delta = 4.15$ (4H), 4.01 (4H), 3.98 (4H) and 3.93 (4H) ppm. The difference in the appearance of the cp-ring protons may be due to anisotropy effects. In fact, protons in α-position of the

ipso-carbon atom of the cyclopentadienyl ring which is bonded to the olefin moiety, may be within the ring current area of the other cyclopentadienyl ring bound to the olefin moiety. Such a situation can only be found in the *Z*-isomer which then leads to an upfield shift of these protons (ca 0.2 ppm).

X-ray diffraction studies on complex **3**

Orange-red crystals of **3** suitable for X-ray structure determination were grown from a mixture of *n*-hexane/methylenechloride at −30°C. The crystallographic data are shown in Table 1 and the characteristic bond parameters are given in Table 2. The molecular structure of **3** is depicted in Fig. 1. It shows two ferrocenophane molecules tied together by a spiro-carbon atom, which is part of transannular trimethylene- and tetramethylene-2-on-bridges. It is further directly connected to a cyclopentadienyl ligand at each ferrocene moiety. According to the asymmetric surrounding of the spiro carbon atom C1, the tetrahedral angles range from 105 to 114°. In general, the distances and angles are very similar to corresponding mononuclear complexes. For instance, the aperture gap in the [3]-ferrocenophane part (cp1/cp1′) is ca 11° with an opening of the wedge opposite to the *ansa*-bridge. In the [4]-ferrocenophan-2-on (cp2/cp2′) moiety the opening of the aperture gap (ca 5°) is directed towards the interannular C_4-bridge. These values are more or less identical to that found in [3]- and [4]-ferrocenophanes [7,8] indicating that there is no steric strain within the molecule. The cyclopentadienyl rings in [3]-ferrocenophane part are coordinated in an eclipsed conformation, whereas in the [4]-ferrocenophane part, the cp rings are slightly rotated (ca 11°) towards a staggered conformation.

Electrochemistry of **2a,b** *and* **3**

The original impetus of this work was the preparation of the olefins **2a,b** in order to generate mixed valence biferrocenes with a rigid spacer. It was of interest therefore to investigate the electrochemical behaviour of these complexes. The cyclovoltammetric measurements for **2a,b** are depicted in Fig. 2 and the data are listed in Table 3.

They show **2a** having only one oxidation step. The wide separation of the reduction and oxidation wave (Δ = 113 mV) and their broadened wave forms imply that the second electron transfer step may be very close to the first one. In the *Z*-isomer **2b** two clear oxidation waves are present with narrow separations of the reduction and oxidation waves (Δ = 67 mV), which is typical for reversible one-electron transfer processes [10]. Compound **3**, not surprisingly, exhibits two reversible oxidation waves. Similar effects have

been found recently by Bildstein and his coworkers in the case of di- and tetraferrocenyl substituted ethylene [5c].

DISCUSSION

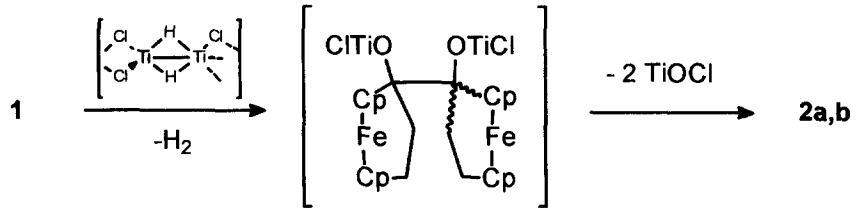
The reactions described above show that the C-C-coupling step of ferrocenophanone **1** takes place with any McMurry reagent. This rules out stereochemical reasons for the different performances of the various coupling reagents. The results can be best interpreted using the mechanistic schemes introduced by Bogdanović and his coworkers [4c]. These mechanisms show indeed, that formation of the diolate state can be reached with any low valent Ti reagent, but the formation of the olefin is strongly dependent on the oxidation state of the Ti centres of the intermediates. In the case of the classical McMurry reagent $TiCl_3$/Li-AlH_4 the active species is a dinuclear hydridotitaniumchloride where the metal centres have the formal oxidation state +II. Elimination of H_2 leads to Ti(I). Reaction with ketones first leads to a dimeric diolate complex were the +II oxidation state of the Ti-centres has been restored. From this dinuclear intermediate the olefin can be liberated by formation of TiOCl.

This +I/+III change in oxidation states is not present in the "instant method". Here the active intermediate is the dinuclear diolate complex **A** with Ti-centres exhibiting oxidation state +III. This species is in a disproportional equilibrium with the mononuclear diolate complex **B** and $TiCl_2ZnCl_2(DME)_2$ **C**, which is only slightly soluble. According to Bogdanović, elimination of the olefin takes place at the dinuclear intermediate **A**.

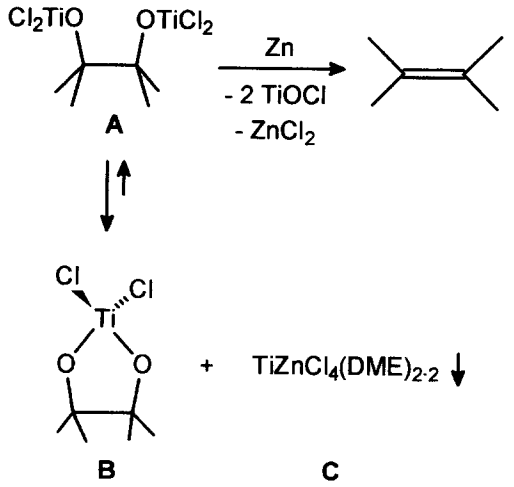
This requires a second reduction step with Zn. Since the equilibrium is mainly on the side of the mononuclear diolate **B** only a low concentration of **A** will be formed, which could be responsible for the high yields of olefin formed with the "instant method".

In the case of the coupling of ferrocenophanon **1** the second reduction step is hindered by a fast pinacol rearrangement starting from mononuclear diolate **B** to forming complex **3**. The reason for this rearrangement to **3** may be the Lewis acidity of $ZnCl_2$ which forms during the course of the reaction and which is able to open the mononuclear diolate. This is supported by the strong ability of the ferrocene moiety to stabilize carbenium ions [11], which should be formed during the pinacol rearrangement. It should be noted at this point that trying to bring about the coupling without Ti-reagent but using elemental Zn in form of a Clemmensen type reaction no reaction takes place at all. A similar behaviour has been found very recently by Bildstein and his coworkers [5c,12]. They found that Clemmensen reduction of ferrocenyl ketones takes place only when small traces of protons are present. In order to find out if the pinacol rearrangement was peculiar to ferrocenophanone **1**, we treated acetylferrocene under conditions of the "instant method". Here a pinacol rearrangement also takes place, albeit in a reduced yield of 3,3-bis(ferrocenyl)butan-2-one **5** and some formation of the corresponding olefins *E,Z*-2,3-bis(ferrocenyl)but-2-en **6a,b** (olefin 8%, pinacolon 31%). Further support for the view of $ZnCl_2$ being the Lewis acid needed for the rearrangement comes from the fact, that upon addition of pyridine the reaction is reversed. Therefore, no pinacol rearrangement but formation of the olefins **2a,b** in good yields is detected. The fact that the *Z*-isomer **2b** is formed in variable yields by using the "instant method" could be due to **2b** being thermally not stable under the reaction conditions. This could be ruled out, since refluxing **2b** in dimethoxyethane for a prolonged time does not lead to the formation of *E*-isomer **2a**, nor does it detectably decompose.

The electrochemistry as studied so far is surprising. If one considers the Fe—Fe distances in the *E*- and *Z*-isomer being not very different, one would expect an influence of the positive charge created by the first



Scheme 3.



Scheme 4.

oxidation on the second oxidation step. This is only present in the case of the *Z*-isomer. In the *E*-isomer the two Fe-centres seem to be independent, thus showing only a very weak coupling. The difference between the two structures is that in the case of the *Z*-isomer two cyclopentadienyl rings can be positioned face-to-face. This opens up an electron transition through the π-system of the cyclopentadienyl ligands. Such an electron transfer has been favoured by Newton upon theoretical considerations [13]. In order to find out if such a mechanism is feasible in such systems, the preparation and structural investigation of similar derivates is pursued.

EXPERIMENTAL

All reactions were performed with standard Schlenk techniques with dried solvents under an argon atmosphere. Solvents were dried by standard methods and distilled under N_2. Pyridine and TMEDA were dried over Na and distilled prior to use. $TiCl_3$ was purchased from Strem Chemicals. $TiCl_3/LiAlH_4$ (2:1), acetylferrocene were purchased from Aldrich. All commercial reagents were used without further purification. [3]-Ferrocenophan-1-one was prepared according to the literature [15]. Flash column chromatography was done using silica 60 (230–400 mesh), purchased from Aldrich.

Infrared spectra were recorded on a Perkin–Elmer 1600. Raman spectra were recorded on a Riber Jobin Yvon Instruments S.A. spectrometer coupled with a Kr-laser unit from Coherent Innova 301, excitation wave length 647.1 nm. ^{1}H-NMR and ^{13}C-NMR spectra were recorded on a Bruker DPX-400 or JEOL JNM-GX-400 instrument and calibrated against residual protons of the deuterated solvents. The mass spectra were conducted on a double focusing Finnigan MAT 90 instrument. Cyclovoltammograms were recorded on a HEKA potentiostat PG 28. Elemental analysis were carried out at the microanalytical laboratory of the Technische Universität München.

Reaction of [3]-ferrocenophan-1-one **1** *with* $TiCl_3/LiAlH_4$

A mixture of 2.145 g (12.4 mmol $TiCl_3$) $TiCl_3/LiAlH_4$ (2:1) was suspended in 30 ml dry THF at −78°C. The stirred suspension was allowed to warm to room temperature during 16 h. After the dropwise addition of 1.2 g (5.0 mmol) [3]-ferrocenophan-1-one **1** in 20 ml dry THF the reaction mixture was stirred at room temperature until the evolution of H_2 was finished, then the reaction was quenched with 10 ml 2 M HCl. After extraction with CH_2Cl_2 the organic layer was washed with saturated $NaHCO_3$ solution and dried over anhydrous $MgSO_4$. After removal of the solvent the products were seperated by flash column chromatography (eluent *n*-hexane/ethylacetate 10:1 → 1:1). The first orange band eluted from the column yielded 0.169 g (0.75 mmol, 15%) [3]-ferrocenophane. The second band gave 0.416 g (0.93 mmol, 37%) of the desired olefins **2a,b**. The *E*- and *Z*-olefins (*E*/*Z* 2:1) were obtained as pale-yellow crystals after crystallisation from CH_2Cl_2/*n*-hexane.

2b. ^{1}H-NMR ($CDCl_3$, 400.13 MHz, ppm): δ = 4.15 (t, 4H), 4.01 (t, 4H), 3.98 (t, 4H), 3.93 (t, 4H), 2.71 (m, 4H), 2.24 (m, 4H). ^{13}C-NMR ($CDCl_3$, 100.63 MHz, ppm): δ = 133.2, 86.6, 83.1, 70.6, 70.2, 68.6, 68.1, 37.8, 27.5. Raman: ν(C=C) = 1628 cm^{-1}. MS (CI): *m*/*z* = 448 [M$^+$]. Found: C, 69.09; H, 5.61; Fe, 23.74. Calc. for $C_{26}H_{24}Fe_2$: C, 69.68; H, 5.40; Fe, 24.92.

Reaction of [3]-ferrocenophan-1-one **1** *with* $TiCl_3/Zn$ (1:2:5)

A suspension of 2.458 g (10.2 mmol) [3]-ferrocenophan-1-one **1**, 3.275 g (21.0 mmol, 2 equiv.) $TiCl_3$, 3.267 g (50.0 mmol, 5 eq) Zn dust in 100 ml dry DME was refluxed for 20 h. The reaction mixture was cooled to room temperature and filtered through a short pad of silica. After washing the silica with CH_2Cl_2 the combined filtrates were evaporated. The purification of the residue by flash column chromatography (eluent *n*-hexane/ethylacetate 1:0 → 10:1) yielded 1.879 g (4.0 mmol, 78%) of the pinacolone **3** after crystallization from CH_2Cl_2/*n*-hexane. Only a trace of olefins **2a,b** could be detected.

3. ^{1}H-NMR (C_6D_6, 400.13 MHz, *T* = 70°C, ppm): δ = 4.1–3.5 (m, 16H), 2.93 (ddd, 1H, ^2J = 12 Hz,

$^3J_{cis}$ = 11 Hz, $^3J_{trans}$ = 3 Hz), 2.67 (ddd, 1H, ^2J = 12 Hz, $^3J_{cis}$ = 11 Hz, $^3J_{trans}$ = 3 Hz), 2.44 (ddd, 1H, ^2J = 11 Hz, $^3J_{cis}$ = 9 Hz, $^3J_{trans}$ = 2 Hz), 2.20 (ddd, 1H, ^2J = 11 Hz, $^3J_{cis}$ = 9 Hz, $^3J_{trans}$ = 2 Hz), 2.11 (m, 2H, ^2J = 6 Hz, $^3J_{cis}$ = 11, $^3J_{trans}$ = 3 Hz), 1.90 (ddd, 1H, ^2J = 15 Hz, $^3J_{cis}$ = 9 Hz, $^3J_{trans}$ = 2 Hz), 1.76 (ddd, 1H, ^2J = 15 Hz, $^3J_{cis}$ = 9 Hz, $^3J_{trans}$ = 2 Hz). ^{13}C-NMR ($CDCl_3$, 100.63 MHz, ppm): δ = 206.0, 91.6, 88.5, 87.2, 71.5–67 (cp), 54.8, 44.2, 41.4, 26.9, 21.5. IR (CH_2Cl_2): ν(CO) = 1697 (s). MS(CI, %): m/z = 464 (100) [M^+], 436 (14) [$M^+ - CO$]. Found: C, 66.85; H, 5.28; Fe, 23.47. Calc. for $C_{26}H_{24}Fe_2O$: C, 67.28; H, 5.21; Fe, 24.06.

Reaction of [3]-ferrocenophan-1-one **1** *with* $TiCl_3$/Zn/Pyridine (1 : 2 : 5 : 2)

This reaction was carried out under the same conditions according to the preceeding procedure. No pinacolone **3** could be obtained. After purification the desired olefins **2a,b** obtained as a pale-yellow mixture of crystals with a yield of 70% (variable E/Z ratios).

Reaction of [3]-ferrocenophan-1-one **1** *with* $TiCl_3$/Zn/$(CH_3)_3SiCl$ (1 : 0.1 : 5 : 5)

To a suspension of 3.123 g (13 mmol) [3]-ferrocenophan-1-one **1,** 0.203 g (1.3 mmol, 0.1 equiv.) $TiCl_3$, 4.241 g (65 mmol, 5 equiv.) Zn dust in 55 ml dried MeCN was added dropwise 8.4 ml (65 mmol, 5 equiv.) $(CH_3)_3SiCl$. The reaction mixture was refluxed for 2 h according to Fürstners procedure. After cooling with an ice bath the suspension was filtered through silica. The silica layer was washed with ethylacetate and the combined filtrates were freed from solvent. Purification by flash column chromatography (eluent *n*-hexane/ethylacetate 10 : 1 → 1 : 1) gave as the first zone 0.52 g (0.54 mmol, 12%) of the yellow silylated diol-4 which was recrystalized from CH_2Cl_2/*n*-hexane. The second zone contained 0.895 g (1.9 mmol, 30%) of pinacolone 3. ^{1}H-NMR ($CDCl_3$, 400.13 MHz, ppm): δ = 4.09 (t, 2H), 4.00 (t, 2H), 3.95 (t, 2H), 3.94 (t, 2H), 3.92 (t, 2H), 3.88 (t, 2H), 3.75 (t, 2H), 3.73 (t, 2H), 2.39 (m, 6H), 2.16 (m, 2H), 0.35 (s, 18H). ^{13}C-NMR ($CDCl_3$, 100.63 MHz, ppm): δ = 92.3, 84.4, 81.5, 71.0, 69.3, 69.0, 68.0, 67.3, 66.4, 66.2, 66.0, 41.5, 21.3, 3.4. MS (CI, %): m/z = 626 (46) [M^+], 313 (27) [M^{2+}], 241 (42), 154 (100). Found: C, 60.91; H, 6.71; Fe,17.57; Si, 9.07. Calc. for $C_{32}H_{42}Fe_2O_2Si_2$: C, 61.34; H, 6.76; Fe, 17.83; Si, 8.97.

Reaction of acetylferrocene with $TiCl_3$/Zn (1 : 2 : 5)

Acetylferrocene reacts under the conditions of formation of compound **3** to yield 0.34 g (0.77 mmol, 31%) pinacolone **5** and 0.09 g (0.21 mmol, 8%) olefins **6a,b** starting from 1.15 g (5.0 mmol) acetylferrocene.

5. ^{1}H-NMR ($CDCl_3$, 400.13 MHz, ppm): δ = 4.16 (t, 4H), 4.08 (t, 4H), 4.07 (s, 10H), 2.04 (s, 3H), 1.86 (s, 3H). ^{13}C-NMR ($CDCl_3$, 100.63 MHz, ppm): δ = 264.5, 93.5, 68.8, 67.7, 67.0, 50.7, 27.6, 24.1. IR (CH_2Cl_2, cm^{-1}) ν(CO) = 1702. MS (CI, %): m/z = 440 (100) [M^+], 397 (17) [$M^+ - COCH_3$], 255 (10) [$M^+ - Fc$]. Found: C, 65.67; H, 5.62. Calc. for $C_{24}H_{24}Fe_2O$: C, 65.48 H, 5.50.

6a. ^{1}H-NMR ($CDCl_3$, 400.13 MHz, ppm): δ = 4.04 (s, 10H), 4.02 (t, 4H), 3.87 (t, 4H), 2.09 (s, 6H). ^{13}C-NMR ($CDCl_3$, 100.63 MHz, ppm): δ = 127.7, 90.4, 69.4, 68.6, 66.7, 22.6.

6b. ^{1}H-NMR ($CDCl_3$, 400.13 MHz, ppm): δ = 4.29 (t, 4H), 4.20 (t, 4H), 4.14 (s, 10H), 2.13 (s, 6H). ^{13}C-NMR ($CDCl_3$, 100.63 MHz, ppm): δ = 127.8, 90.6, 69.0, 68.9, 67.5, 22.0.

CONCLUSION

We have shown to our knowledge for the first time that in Ti based McMurry type coupling reactions of ferrocenyl ketones, pinacol rearrangement reactions can be the main reaction path. Since this behaviour of the ferrocenyl moiety is dependant on the reagent used, it could help to detect mononuclear diolate intermediates in other McMurry systems and thus distinguish between mechanisms proved by Bogdanovic and mechanisms which may be similar to that found by Ephritikhine [14].

Acknowledgement—We thank Prof. B. Bogdanovic and Dr A. Fürstner for helpful discussions. We also thank the staff of the microanalytical laboratorium of the Technische Universität München under supervision of Mr M. Barth, as well as Mrs R. Dumitrescu and Dr G. Raudaschl-Sieber for recording the mass and the Raman spectra. Financial support of this work by the Deutsche Forschungsgemeinschaft (SFB 377) and the Fonds der Chemischen Industrie is gratefully acknowledged.

Sterically demanding ferrocene-based *tris*(1-pyrazolyl)borate ligands†

Eberhardt Herdtweck, Frank Peters, Wolfgang Scherer and Matthias Wagner*

Anorganisch-chemisches Institut der Technischen Universität München, Lichtenbergstr. 4, D-85747 Garching, Germany.

(Received 6 October 1997; accepted 10 November 1997)

Abstract—Ferrocene-based mono- and bifunctional *tris*(1-pyrazolyl)borates bearing either methyl or phenyl substituents at the 3-positions of their pyrazolyl rings have been obtained from $FcB(NMe_2)_2$ and 1,1′-$fc[B(NMe_2)_2]_2$ (Fc: ferrocenyl; fc: ferrocenylene) and the corresponding pyrazole derivatives via a transamination reaction. All novel ligands have been characterized as their thallium(I) complexes, and the molecular structure of $FcB(pz^{Ph})_3Tl$ (pz^{Ph}: 3-phenylpyrazolyl) has been determined by X-ray crystallography. The compound features monomeric units with tridentate $[FcB(pz^{Ph})_3]^-$ ligands in the crystal lattice, which is in striking contrast to the sterically less congested complex $FcB(pz)_3Tl$, that forms polymeric rods in the solid state. For the purpose of comparison, the single crystal X-ray structure of the ferrocene-free parent compound $HB(pz)_3Tl$ (pz: pyrazolyl) has also been investigated, which again revealed the conventional structural motif of monomeric complexes. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: ferrocene; tris(1-pyrazolyl)borates; thallium complexes.

Tris(1-pyrazolyl)borate (scorpionate) ligands [1,2] have found extensive use in numerous different areas of coordination chemistry. Although a large variety of scorpionates $[R'B(pz^R)_3]^-$ (R′ = H, alkyl, aryl; pz^R = pyrazolyl, substituted pyrazolyl) has been prepared until today, examples of redox-active derivatives [3] as well as of ligands bearing more than one $[R'B(pz^R)_3]^-$ unit are still surprisingly scarce [4].

For this reason, we became interested in the design and synthesis of novel ferrocene-based mono-(**[1H]**$^-$; Fig. 1) and bifunctional (**[2H]**$^{2-}$; Fig. 1) *tris*(1-pyrazolyl)borates [5,6]. The investigation of their corresponding metal complexes revealed structural motifs that are unprecedented in the coordination chemistry of this class of ligands.

The molybdenum complex $FcB(pz)_3Mo(CO)_2(\eta^3\text{-}CH_2C(CH_3)CH_2)$, **1H-Mo**, (Fig. 2) preferentially adopts a chiral conformation with the ferrocenyl unit and the allyl substituent occupying two different segments of the scorpionate moiety, as has been shown both in the solid state (crystal structure determination) and in solution (low-temperature NMR spectroscopy) [6]. The thallium(I) derivative $FcB(pz)_3Tl$ **1H-Tl**, (Fig. 2) provided the first example of a *tris*(1-pyrazolyl)borate complex featuring a polymeric structure in the crystal lattice. Each thallium atom binds to two pyrazolyl rings of one scorpionate ligand and to one pyrazolyl ring of another ligand, thereby deviating from the usually observed tridentate coordination mode [5]. These cited observations already suggest the steric demands of the ferrocenyl substituent to have an influence on the pending scorpionate fragment. It is the purpose of this paper

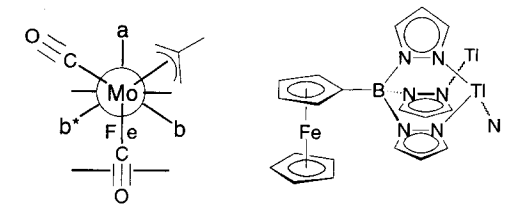

Fig. 2. The chiral molybdenum complex **1H-Mo** and polymeric **1H-Tl**.

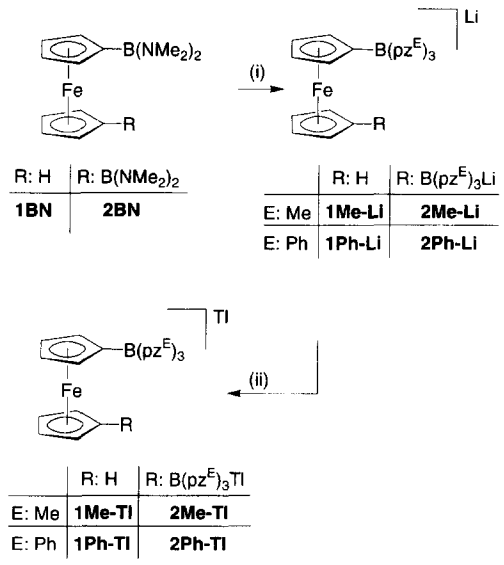


Scheme 1. Preparation of sterically demanding ferrocene-based *tris*(1-pyrazolyl)borate ligands and their thallium complexes. (i) R = H: +1 $Lipz^E$, +2 Hpz^E, toluene/THF, 12 h reflux; R = $B(NMe_2)_2$: +2 $Lipz^E$, +4 Hpz^E, toluene/THF, 12 h reflux. (ii) R = H: +1 $TlNO_3$, THF/H_2O; R = $B(pz^E)_3Li$: +2 $TlNO_3$, THF/H_2O.

to gather more definite evidence on this point. Special emphasis will be put on identifying those factors, that are responsible for the polymerisation of **1H-Tl**.

Apart from **1H-Tl** there are 11 structurally characterized thallium(I) scorpionate complexes currently available from the Cambridge Crystal Structure File (Release 5.10) [7]. All of them are monomeric and share two common features: (i) Sterically demanding substituents occupy the 3-positions of the pyrazolyl rings. (ii) In addition to the three pz^R moieties, the boron centre bears a small hydrogen atom. In contrast, **1H-Tl** offers a largely unrestricted access space to the metal on one hand and possesses a bulky and pronounced non-symmetric ferrocenyl group at boron on the other. Either of these two peculiarities may lead to the unique polymeric solid state structure of **1H-Tl** and thus requires more detailed examination. To be able to study both effects independently, we have prepared the sterically demanding ferrocene-based scorpionate complexes **1Me-Tl** to **2Ph-Tl** (Scheme 1) and the uncongested ferrocene-free compound $HB(pz)_3Tl$, **3H-Tl** (Fig. 3). **1Ph-Tl** and **3H-Tl** have been investigated by X-ray crystallography. Apart from the structural problems discussed so far, sterically demanding scorpionates L are generally required to support monomeric ML(X) species of the first-row transition metals (X = e.g. alkyl, hydride, hydroxide, halide) [8,9] and to stabilize highly reactive metal complexes kinetically [2].

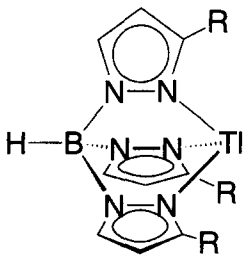
Henceforth, the abbreviation Fc will be used for the monosubstituted ferrocenyl unit $(C_5H_5)Fe(C_5H_4)$, while fc stands for the 1,1′-disubstituted moiety $(C_5H_4)Fe(C_5H_4)$. The 3-substituent at the pyrazolyl (pz) rings is denoted by a superscript; thus HPz^{Me} is 3-methylpyrazole and Hpz^{Ph} is 3-phenylpyrazole.

RESULTS AND DISCUSSION

Syntheses

The lithium salts **1Me-Li** and **1Ph-Li** of the monofunctional scorpionates are synthesized from $FcB(NMe_2)_2$ [5,6], **1BN**, with 1 equiv. of $Lipz^E$ and 2 equiv. of Hpz^E in refluxing toluene/THF (**1Me-Li**: E = Me, **1Ph-Li**: E = Ph; Scheme 1). Without further purification the crude products are converted to the respective Tl(I) complexes **1Me-Tl** and **1Ph-Tl** by metathesis with $TlNO_3$ in THF/H_2O. The same method was applied to transform the commercially available sodium salt $HB(pz)_3Na$, **3H-Na**, into **3H-Tl**.

The bifunctional lithium scorpionates **2Me-Li** and **2Ph-Li** are accessible from 1,1′-fc$[B(NMe_2)_2]_2$ [5,6], **2BN**, 2 equiv. of $Lipz^E$ and 4 equiv. of Hpz^E (**2Me-Li**: E = Me, **2Ph-Li**: E = Ph; Scheme 1). The synthesis of **2Me-Li** suffered from only moderate yield, and the compound was contaminated with small amounts of Hpz^{Me} even after several purification steps. However,



3H-Tl : R = H
3Tol-Tl : R = p-tolyl

Fig. 3. Ferrocene-free *tris*(1-pyrazolyl)borato thallium(I) reference complexes.

analytically pure thallium complexes **2Me-Tl** and **2Ph-Tl** are readily obtained upon reaction of **2Me-Li** and **2Ph-Li** with $TlNO_3$.

All compounds **1Me-Li** to **2Ph-Tl** are stable towards air and moisture even for extended periods of time.

Spectroscopic properties

The ^{11}B NMR signals of **1Me-Li** to **2Ph-Tl** appear in the range between -1 and $+2$ ppm, thereby testifying to the presence of tetracoordinated boron nuclei.

The Fc substituents of **1Me-Li** to **1Ph-Tl** give rise to three resonances, while two resonances are found for the disubstituted fc backbones of **2Me-Li** to **2Ph-Tl** both in the ^1H- and the ^{13}C NMR spectra. In all cases only one set of signals is observed for the pyrazolyl units of the scorpionate ligands. On the basis of these NMR patterns it is obvious, that the methyl (phenyl) substituents of each derivative **1Me-Li** to **2Ph-Tl** are attached either only at the 3- or only at the 5-positions of the scorpionate fragments, and the formation of isomeric products can consequently be ruled out. Since bulky substituents are well-known to have a strong tendency to occupy the 3-positions of *tris*(1-pyrazolyl)borate ligands [2,7], it can be safely assumed, that this holds for **1Me-Li** to **2Ph-Tl**, too. This view is also supported by the X-ray crystal structure determination of **1Ph-Tl** (see below).

The ^1H and ^{13}C NMR shift values of **1Me-Li** to **2Ph-Tl** all appear in the expected regions and thus do not merit further discussion. The NMR spectra of the lithium salts are rather similar to those of the thallium complexes, with the exception of the proton resonances of the methyl substituents, which are shifted to lower field by 0.85 ppm upon going from **1Me-Li** to **1Me-Tl**.

X-ray crystallography

Orange crystals of **1Ph-Tl** were obtained by layering its CH_2Cl_2 solution with benzene. The compound crystallizes together with 0.5 equiv. of benzene (triclinic; space group $P\bar{1}$; Table 1). Large colourless crystals of **3H-Tl** (monoclinic; space group $P2_1$; Table 1) were grown from toluene by slow evaporation of the solvent.

In contrast to polymeric **1H-Tl** [5], the more crowded derivative **1Ph-Tl**, as well as the ferrocene-free parent compound **3H-Tl**, feature the common structural motif of monomeric units in the solid state (Figs 4, 5). Thallium coordination occurs in a tridentate fashion in both molecules.

Similar to **1H-Mo** (Fig. 2), the ferrocenyl substituent in **1Ph-Tl** is located in the uncongested cleft between two pyrazolyl rings, thereby placing the third pz^{Ph} substituent (N(1) to C(3)) in a unique position almost perpendicular to the cyclopentadienyl ring. The $B(pz^{Ph})_3Tl$ fragment deviates significantly from an ideal C_3-symmetry, since its individual Tl—N bond lengths differ by as much as 0.083 Å (Tl—N(2): 2.519(5) Å, Tl—N(4): 2.563(5) Å, Tl—N(6): 2.602(5) Å; Table 2).

The mean value Tl—N = 2.561 Å in ferrocene-based **1Ph-Tl** is almost identical to that found in the related ferrocene-free **3Tol-Tl** (Fig. 3; Tl—N = 2.576 Å) [10], but is considerably shorter than that of polymeric **1H-Tl** (Tl—N = 2.698 Å) [5]. The difference Δ(Tl—N) between the mean Tl—N values of **1H-Tl** and **1Ph-Tl** amounts to Δ(Tl—N) = 0.137 Å. In **1Ph-Tl**, the bond angles at Tl (N(2)—Tl—N(4) = 74.9(2)°, N(2)—Tl—N(6) = 70.6(2)°, N(4)—Tl—N(6) = 75.2(2)°) fall in the usually observed range for thallium(I) scorpionate complexes [9], and surprisingly similar values are found even in the polymeric congener **1H-Tl** (N(2)—Tl—N(4) = 70.9(2)°, N(2)—Tl—N(6A) = 83.2(1)°, N(4)—Tl—N(6A) = 92.4(1)°; Tl—N(6A) is the intermolecular bond).

The ferrocene-free **3H-Tl** crystallizes with two crystallographically independent molecules (**3H-Tla**, **3H-Tlb**) in the asymmetric unit (Fig. 5). While **3H-Tla** possesses three Tl—N bonds of similar length (2.603(7) Å, 2.605(7) Å, 2.621(7) Å), one shorter and two significantly longer Tl—N bonds are found in **3H-Tlb** (2.549(7) Å, 2.667(7) Å, 2.668(7) Å). The mean values Tl—N in **3H-Tla** (2.610 Å) and **3H-Tlb** (2.628 Å) are, however, very close, but still larger than in the sterically congested congener **3Tol-Tl** (Tl—N = 2.576 Å). Consequently, even though sterically demanding substituents at the 3-positions of the pyrazolyl rings are known to efficiently protect scorpionate complexes from intermolecular attack, there appears to be no major intramolecular repulsion between the three phenyl groups both in **3Tol-Tl** and in **1Ph-Tl**.

CONCLUSION

Tl—N bonds in thallium scorpionate complexes are not very strong, and the corresponding potential energy minima appear to be rather shallow. The actual coordination geometry of the Tl centres is therefore likely to be influenced by crystal packing forces which, however, are difficult to estimate quantitatively. Nevertheless, on the basis of the structural data available, we suggest the following qualitative interpretation of factors leading to polymeric or non-polymeric thallium *tris*(1-pyrazolyl)borate complexes in the solid state.

From the molecular structure of **3H-Tl** it is evident, that the absence of bulky substituents at the 3-positions of the pyrazolyl rings does not by itself lead to the generation of a polymeric thallium(I) scorpionate. A comparison of **3H-Tl** with **1H-Tl** indicates the Fc group to be required to induce polymerization, and the critical factor appears to be the degree of steric crowding at boron. In the hypothetical tridentate

coordination mode, both the C(6)—H(6) and the C(9)—H(9) vector would point towards the Fc backbone (cf. **1Ph-Tl**). This sterically congested arrangement can be improved by rotating one of the two pyrazolyl rings by ca 90° about the B—N axis. The scorpionate fragment now still acts as a chelating ligand, and on the other hand establishes only one unfavourable short distance to the ferrocene backbone (Fig. 6; marked with an asterisk). The dangling pyrazolyl donor, which can only act as a bridging ligand, consequently induces the formation of polymeric rods. In **1H-Tl**, short intermolecular distances of about 4 Å are found between adjacent ligands (Fig. 6; short distances are marked with a "#"). It is obvious that, for example, a phenyl ring occupying the 3-positions of the scorpionate ligands will not fit into this limited space, and consequently **1Ph-Tl** is forced to adopt a different (monomeric) solid state structure.

The conclusion which asserts itself in view of the facts just summarized is that steric congestion due to an Fc substituent at boron, facilitates the formation of thallium(I) *tris*(1-pyrazolyl)borate coordination polymers (**1H-Tl**). However, this effect may be outweighed by (i) the steric demands of bulky substituents in the 3-positions of the pyrazolyl rings (**1Ph-Tl**) and (ii) the use of metal complex fragments with a high affinity to strongly coordinating chelate ligands (**1H-Mo**). In both cases, a tridentate coordination mode leading to monomeric units is strongly favoured.

EXPERIMENTAL

All reactions and manipulations of air-sensitive compounds were carried out in dry, oxygen-free argon using standard Schlenk ware or in an argon-filled drybox. Solvents were freshly distilled under N_2 from Na/K alloy-benzophenone (toluene, hexane, THF) or from CaH_2 (CH_2Cl_2) prior to use. NMR: Jeol JMN-GX 400 and Bruker DPX 400 (abbreviations: s = singlet, d = doublet, tr = triplet, vtr = virtual triplet, q = quartet, n.r. = multiplet expected but not resolved, br = broad, n.o. = not observed, Fc = $(C_5H_5)Fe(C_5H_4)$, fc = 1,1′-$(C_5H_4)Fe(C_5H_4)$, Ph = C_6H_5, *i* = ipso, *o* = ortho, *m* = meta, *p* = para, pz = pyrazolyl fragment in pz^{Me} and in pz^{Ph}). NMR spectra were recorded at ambient temperature. ^{11}B NMR shifts are given relative to external $BF_3 \cdot Et_2O$. MS (CI, FAB mode): Finnigan MAT 90. Elemental analyses: Microanalytical laboratory of the Technische Universität München.

The compounds $FcB(NMe_2)_2$ (**1BN**) [5,6], 1,1′-$fc[B(NMe_2)_2]_2$ (**2BN**) [5,6], and Hpz^{Ph} [8] were synthesized according to literature procedures. The lith-

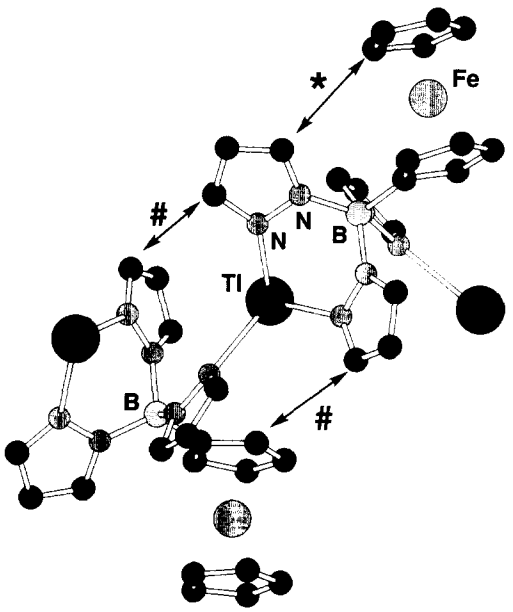

Fig. 6. Section of a polymeric rod of **1H-Tl**; short inter- (#) and intramolecular (*) contacts are marked.

ium pyrazolides $Lipz^{Me}$ and $Lipz^{Ph}$ were obtained from the respective pyrazoles (Hpz^{Me}, Hpz^{Ph}) and *n*-butyl lithium in toluene.

Synthesis of $FcB(pz^{Me})_3Li$ (**1Me-Li**)

1BN (2.91 g, 10.25 mmol) in toluene (100 ml) was treated dropwise with stirring at ambient temperature with a solution of $Lipz^{Me}$ (0.99 g, 11.25 mmol) in THF (30 ml). Hpz^{Me} (1.85 g, 22.53 mmol) in toluene (20 ml) was added and the red-orange solution refluxed for 12 h. The clear solution was allowed to cool to ambient temperature and concentrated *in vacuo* to a volume of 50 ml, whereupon an orange precipitate formed, which was collected on a frit (G3), triturated with toluene (10 ml) and hexane (30 ml) and dried *in vacuo*. Yield: 3.88 g (85%).

^{11}B NMR (128.3 MHz, $CDCl_3$): δ 0.2 ($h_{1/2}$ = 320 Hz). ^1H NMR (400 MHz, $CDCl_3$): δ 1.50 (very br, 9H, CH_3), 4.05 (br, 2H, C_5H_4), 4.35 (s, 5H, C_5H_5), 4.44 (br, 2H, C_5H_4), 5.85 (br, 3H, pz-H4), 8.3 (very br, 3H, pz-H5). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ 12.2 (br, CH_3), 69.2 (C_5H_5), 69.7, 75.3 (C_5H_4), n.o. (C_5H_4-*i*), 103.8 (pz-C4), 137.4 (pz-C5), 150.0 (br, pz-C3). Found: C, 59.63; H, 5.75; N, 18.73. Calc. for $C_{22}H_{24}BFeLiN_6$ [446.07]: C, 59.24; H, 5.42; N, 18.84%.

Synthesis of $FcB(pz^{Me})_3Tl$ (**1Me-Tl**)

1Me-Li (0.69 g, 1.55 mmol) in THF (20 ml) was treated dropwise with stirring at ambient temperature with a solution of $TlNO_3$ (0.45 g, 1.69 mmol) in deionized and degassed water (10 ml), whereupon a yellow precipitate formed. The slurry was stirred for 1 h, and filtered through a frit (G3). The insoluble material was triturated with water (10 ml) and hexane (20 ml) and dried *in vacuo*. Yield: 0.93 g (94%).

^{11}B NMR (128.3 MHz, $CDCl_3$): δ 0.4 ($h_{1/2}$ = 120 Hz). ^1H NMR (400 MHz, $CDCl_3$): δ 2.35 (s, 9H, CH_3), 4.21 (s, 5H, C_5H_5), 4.26, 4.46 (2 × vtr, 2 × 2H, J(HH) = 1.8 Hz, C_5H_4), 5.92 (d, 3H, J(HH) = 2.0 Hz, pz-H4), 7.97 (n.r., 3H, pz-H5). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ 13.4 (br, CH_3), 69.0 (C_5H_5), 69.9, 75.4 (C_5H_4), n.o. (C_5H_4-*i*), 104.0 (pz-C4), 136.1 (pz-C5), 148.4 (pz-C3). CI-MS: *m/z* 644 [M^+; 100%]; 358 [$M^+ - Tlpz^{Me}$; 60%]. Found: C, 41.63; H, 3.85; N, 13.16. Calc. for $C_{22}H_{24}BFeN_6Tl$ [643.51]: C, 41.06; H, 3.76; N, 13.06%.

Synthesis of $FcB(pz^{Ph})_3Li$ (**1Ph-Li**)

1Ph-Li was synthesized similar to **1Me-Li** from **1BN** (1.46 g, 5.14 mmol), $Lipz^{Ph}$ (0.85 g, 5.66 mmol) and Hpz^{Ph} (1.63 g, 11.31 mmol). Yield: 2.93 g (81%).

^{11}B NMR (128.3 MHz, $CDCl_3$): δ 0.3 ($h_{1/2}$ = 260 Hz). ^1H NMR (400 MHz, $CDCl_3$): δ 4.34 (s, 5H, C_5H_5), 4.45, 4.56 (2 × vtr, 2 × 2H, J(HH) = 1.5 Hz, C_5H_4), 6.32 (d, 3H, J(HH) = 2.0 Hz, pz-H4), 7.21 (tr, 3H, J(HH) = 7.5 Hz, Ph-*p*), 7.29 (vtr, 6H, J(HH) = 7.5 Hz, Ph-*m*), 7.61 (d, 6H, J(HH) = 7.5 Hz, Ph-*o*), 8.18 (br, 3H, pz-H5). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ 69.1 (C_5H_5), 70.1, 75.6 (C_5H_4), n.o. (C_5H_4-*i*), 101.9 (pz-C4), 126.9 (Ph-*o*), 127.1 (Ph-*p*), 128.2 (Ph-*m*), 135.0 (Ph-*i*), 136.1 (pz-C5), 152.6 (br, pz-C3). Found: C, 69.64; H, 5.21; N, 12.33. Calc. for $C_{37}H_{30}BFeLiN_6$ [632.29] × 1.0 THF [72.11]: C, 69.91; H, 5.44; N, 11.93%.

Synthesis of $FcB(pz^{Ph})_3Tl$ (**1Ph-Tl**)

1Ph-Tl was synthesized similar to **1Me-Tl** from **1Ph-Li** × 1 THF (0.59 g, 0.84 mmol) and $TlNO_3$ (0.25 g, 0.94 mmol). X-ray quality crystals were obtained from benzene/CH_2Cl_2. Yield: 0.64 g (88%).

^{11}B NMR (128.3 MHz, $CDCl_3$): δ 1.2 ($h_{1/2}$ = 250 Hz). ^1H NMR (400 MHz, $CDCl_3$): δ 4.21 (s, 5H, C_5H_5), 4.31, 4.48 (2 × vtr, 2 × 2H, J(HH) = 1.8 Hz, C_5H_4), 6.54 (d, 3H, J(HH) = 2.5 Hz, pz-H4), 7.29 (tr, 3H, J(HH) = 7.5 Hz, Ph-*p*), 7.36 (vtr, 6H, J(HH) = 7.5 Hz, Ph-*m*), 7.60 (d, 6H, J(HH) = 7.5 Hz, Ph-*o*), 8.11 (d, 3H, J(HH) = 2.5 Hz, pz-H5). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ 68.9 (C_5H_5), 70.0, 74.9 (C_5H_4), n.o. (C_5H_4-*i*), 103.2 (pz-C4), 126.6 (Ph-*o*), 127.6 (Ph-*p*), 128.8 (Ph-*m*), 133.7 (Ph-*i*), 137.1 (pz-C5), 152.6 (br, pz-C3). CI-MS: *m/z* 830 [M^+; 100%]; 482 [$M^+ - Tlpz^{Ph}$; 70%]. Found: C, 54.08; H, 4.07; N, 9.67. Calc. for $C_{37}H_{30}BFeN_6Tl$ [829.72] × 0.5 THF [72.11]: C, 54.10; H, 3.96; N, 9.70%.

Synthesis of 1,1′-fc[B(pz^{Me})$_3$Tl]$_2$ (**2Me-Tl**)

2BN (2.96 g, 7.73 mmol) in toluene (80 ml) was treated dropwise with stirring at ambient temperature with a solution of $Lipz^{Me}$ (1.36 g, 15.45 mmol) in THF (30 ml). Hpz^{Me} (2.55 g, 31.06 mmol) in toluene (20 ml) was added and the orange solution refluxed for 12 h, whereupon an orange precipitate gradually formed. The slurry was allowed to cool to ambient temperature, all insolubles were separated by filtration and extracted with toluene (2 × 10 ml). The combined filtrates were concentrated *in vacuo* to a volume of 10 ml, and stored at −30°C for 12 h. A yellow microcrystalline solid of 1,1′-fc[B(pz^{Me})$_3$Li]$_2$ was obtained, which was collected on a frit (G3), triturated with hexane (10 ml) and dried *in vacuo*. The crude product still contained small amounts of Hpz^{Me}, but could be purified by conversion into the thallium(I) complex.

2Me-Li (0.65 g, 0.92 mmol) in THF (40 ml) was treated dropwise with stirring at ambient temperature with a solution of $TlNO_3$ (0.54 g, 2.03 mmol) in deionized and degassed water (10 ml), whereupon a yellow precipitate immediately formed. The slurry was stirred for 1 h and filtered through a frit (G3). The insoluble material was triturated with water (2 × 10 ml) and hexane (5 ml) and dried *in vacuo*. Yield: 0.53 g (52%).

^{11}B NMR (128.3 MHz, $CDCl_3$): δ 0.4 ($h_{1/2}$ = 270 Hz). ^{1}H NMR (400 MHz, $CDCl_3$): δ 2.37 (s, 18H, CH_3), 4.38, 4.39 (n.r., 2 × 4H, C_5H_4), 5.95 (d, 6H, *J*(HH) = 1.8 Hz, pz-H4), 8.03 (n.r., 6H, pz-H5). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ 13.5 (br, CH_3), 72.0, 76.0 (C_5H_4), n.o. (C_5H_4-*i*), 104.2 (pz-C4), 136.1 (pz-C5), 148.5 (pz-C3). FAB-MS: *m/z* 1102 [M^+; 5%], 530 [$M^+ - 2$ $Tlpz^{Me}$; 85%], 449 [$M^+ - 2$ $Tlpz^{Me} - pz^{Me}$; 100%]. Found: C, 37.09; H, 3.59; N 15.13. Calc. for $C_{34}H_{38}B_2FeN_{12}Tl_2$ [1100.97]: C, 37.09; H, 3.48; N, 15.27%.

Synthesis of 1,1′fc[B(pz^{Ph})$_3$Li]$_2$ (**2Ph-Li**)

2BN (1.97 g, 5.14 mmol) in toluene (100 ml) was treated dropwise with stirring at ambient temperature with a solution of $Lipz^{Ph}$ (1.56 g, 10.39 mmol) in THF (25 ml). Neat solid Hpz^{Ph} (3.00 g, 20.81 mmol) was added through a powder funnel and the orange mixture refluxed for 12 h, whereupon a yellow precipitate gradually formed. The slurry was allowed to cool to ambient temperature. All insolubles were collected on a frit (G3), triturated with toluene (2 × 10 ml) and hexane (10 ml) and dried *in vacuo*. The combined filtrates were slowly concentrated *in vacuo* to yield a second crop of **2Ph-Li**. Yield: 5.00 g (90%).

^{11}B NMR (128.3 MHz, $CDCl_3$): δ −0.1 ($h_{1/2}$ = 300 Hz). ^{1}H NMR (400 MHz, $CDCl_3$): δ 4.67, 4.69 (2 × n.r., 2 × 4H, C_5H_4), 6.36 (d, 6H, *J*(HH) = 1.5 Hz, pz-H4), 7.26 (tr, 6H, *J*(HH) = 7.5 Hz, Ph-*p*), 7.34 (vtr, 12H, *J*(HH) = 7.5 Hz, Ph-*m*), 7.64 (d, 12H, *J*(HH) = 7.5 Hz, Ph-*o*), 8.3 (very br, 6H, pz-H5). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ 72.2, 76.3 (C_5H_4), n.o. (C_5H_4-*i*), 102.1 (pz-C4), 126.9 (Ph-*o*), 127.1 (Ph-*p*), 128.2 (Ph-*m*), 134.9 (Ph-*i*), 136.3 (pz-C5), 152.8 (br, pz-C3). Found: C, 70.70; H, 4.29; N, 15.91. Calc. for $C_{64}H_{50}B_2FeLi_2N_{12}$ [1078.54]: C, 71.27; H, 4.64; N, 15.58%.

Synthesis of 1,1′-fc[B(pz^{Ph})$_3$Tl]$_2$ (**2Ph-Tl**)

2Ph-Li (1.06 g, 0.98 mmol) in THF (60 ml) was treated dropwise with stirring at ambient temperature with a solution of $TlNO_3$ (0.58 g, 2.18 mmol) in deionized and degassed water (15 ml), whereupon a yellow precipitate formed. The slurry was stirred for 1 h, and filtered through a frit (G3). The insoluble material was triturated with water (5 ml) and hexane (10 ml) and dried *in vacuo*. Yield: 1.24 g (82%).

^{11}B NMR (128.3 MHz, $CDCl_3$): δ 0.7 ($h_{1/2}$ = 300 Hz). ^{1}H NMR (400 MHz, $CDCl_3$): δ 4.40, 4.43 (2 × n.r., 2 × 4H, C_5H_4), 6.56 (d, 6H, *J*(HH) = 2.0 Hz, pz-H4), 7.29 (tr, 6H, *J*(HH) = 7.5 Hz, Ph-*p*), 7.36 (vtr, 12H, *J*(HH) = 7.5 Hz, Ph-*m*), 7.60 (d, 12H, *J*(HH) = 7.5 Hz, Ph-*o*), 8.16 (n.r., 6H, pz-H5). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ 72.0, 75.3 (C_5H_4), n.o. (C_5H_4-*i*), 103.3 (pz-C4), 126.6 (br, Ph-*o*), 127.7 (Ph-*p*), 128.9 (Ph-*m*), 133.7 (Ph-*i*), 137.2 (pz-C5), 152.7 (br, pz-C3). FAB-MS: *m/z* 1474 [M^+; 5%], 778 [$M^+ - 2$ $Tlpz^{Ph}$; 100%], 635 [$M^+ - 2$ $Tlpz^{Ph} - pz^{Ph}$; 90%]. Found: C, 52.99; H, 4.10; N 10.91. Calc. for $C_{64}H_{50}B_2FeN_{12}Tl_2$ [1473.40] × 1.0 THF [72.11]: C, 52.85; H, 3.78; N, 10.88%.

Synthesis of HB(pz)$_3$Tl (**3H-Tl**)

3H-Na (0.53 g, 2.25 mmol) in THF (30 ml) was treated dropwise with stirring at ambient temperature with a solution of $TlNO_3$ (0.66 g, 2.48 mmol) in deionized and degassed water (15 ml) and stirred for 2 h. The clear colourless solution was slowly concentrated under reduced pressure, whereupon a colourless precipitate formed, which was collected on a frit (G3), triturated with H_2O (2 × 10 ml) and dried *in vacuo*. Yield: 0.86 g (92%). X-ray quality crystals of **3H-Tl** were grown by slow evaporation of its toluene solution at ambient temperature.

^{11}B NMR (128.3 MHz, $CDCl_3$): δ −2.1 ($h_{1/2}$ = 220 Hz). ^{1}H NMR (400 MHz, $CDCl_3$): δ 4.65 (q, 1H, *J*(HH) = 105 Hz, BH), 6.19 (vtr, 3H, *J*(HH) = 1.6 Hz, pz-H4), 7.53, 7.72 (2 × d, 2 × 3H, *J*(HH) = 1.6 Hz, pz-H3,5). ^{13}C NMR (100.5 MHz, $CDCl_3$): δ 104.1 (pz-C4), 135.6, 139.2 (pz-C3,5). Found: C, 25.90; H, 2.59; N, 20.20. Calc. for $C_9H_{10}BN_6Tl$ [417.40]: C, 25.90; H, 2.41; N, 20.13%.

Crystal structure determination of **1Ph-Tl**

Suitable crystals were grown by layering a CH_2Cl_2 solution of **1Ph-Tl** with benzene at ambient temperature. The compound crystallizes together with 0.5

equiv. of benzene, $C_{37}H_{30}BFeN_6Tl \cdot 0.5\ C_6H_6$, $fw = 868.76$; crystal size $0.41 \times 0.28 \times 0.13$ mm, triclinic space group $P\bar{1}$ (I.T. No. 2), $a = 10.5622(6)$ Å, $b = 13.3208(9)$ Å, $c = 14.0361(9)$ Å, $\alpha = 62.057(6)°$, $\beta = 80.559(6)°$, $\gamma = 72.687(6)°$, $V = 1664.8(2)$ Å^3, $Z = 2$; $\rho_{calc} = 1.733$ g cm^{-3}; $F000 = 854$; $\mu = 53.1$ cm^{-1}. Crystal data, together with details of the data collection and structure refinement, are listed in Table 1. Preliminary examination and data collection were carried out on an imaging plate diffraction system (IPDS; STOE&CIE) equipped with a rotating anode (ENRAF NONIUS FR591; 50 kV; 80 mA; 4.0 kW) and graphite monochromated Mo–K_α radiation ($\lambda = 0.71073$). The data collection was performed at 163(2) K within the θ-range of $2.0° < \theta < 25.6°$ with an exposure time of 2.5 min per image (rotating scan modus from $\varphi = 0°$ to 164° with $\Delta\varphi = 1°$). A total number of 10,403 reflections were collected, from which a sum of 5835 independent reflections remained and were used for all calculations. Data were corrected for Lorentz and polarization effects [11]. Corrections for intensity decay and absorption effects are based on the program DECAY (SF = 4) [11]. The unit cell parameters were obtained by least squares refinements of 4557 reflections with the program CELL [11,12]. The structure was solved by direct methods and refined by full-matrix least squares calculations with anisotropic thermal parameters for all non-hydrogen atoms of **3Ph-Tl** and isotropic thermal parameters for benzene. All hydrogen atoms were calculated in ideal positions. Full matrix least squares refinements were carried out by minimizing $\Sigma w(F_o^2 - F_c^2)^2$ with SHELXL weighting scheme $(w = 1/[\sigma^2(F_o^2) + (0.090 \cdot P)^2 + 0.0000 \cdot P]$ where $P = (F_o^2 + 2 \cdot F_c^2)/3)$ and stopped at shift/err < 0.001, $wR_2 = 0.1155$, and $R_1 = 0.0490$ for all data; GOOF = 1.027, 421 parameters, residual electron density +3.20 e Å^{-3}, −3.64 e Å^{-3} (Tl residual). Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International Tables for X-Ray Crystallography* [13]. All calculations were performed on a DEC 3000 AXP workstation with the STRUX-V system [14], including the programs PLATON-92 [15], PLUTON-92 [15], SIR-92 [16], and SHELXL-93 [17].

Atomic coordinates have been deposited with the Cambridge Crystallographic Data Centre.

Crystal structure determination of **3H-Tl**

Suitable crystals of **3H-Tl** were grown by slow evaporation of its toluene solution at ambient temperature. There are two crystallographically independent molecules in the asymmetric unit (**3H-Tla, 3H-Tlb**), $C_9H_{10}BN_6Tl$, $fw = 417.41$; crystal size $0.20 \times 0.20 \times 0.10$ mm, monoclinic space group $P21$ (I.T. No. 4); $a = 7.7812(3)$ Å, $b = 9.3364(4)$ Å, $c = 16.9680(6)$ Å, $\beta = 91.761(4)°$, $V = 1232.1(1)$ Å^3, $Z = 4$; $\rho_{calc} = 2.250$ g cm^{-3}; $F000 = 768$; $\mu = 130.9$ cm^{-1}. Crystal data together with details of the data collection and structure refinement are listed in Table 1. Preliminary examination and data collection were carried out on an imaging plate diffraction system (IPDS; STOE&CIE) equipped with a rotating anode (ENRAF NONIUS FR591; 50 kV; 80 mA; 4.0 kW) and graphite monochromated Mo–K_α radiation ($\lambda = 0.71073$). The data collection was performed at 173(2) K within the θ-range of $2.5° < \theta < 27.8°$ with an exposure time of 3 min per image (rotating scan modus from $\varphi = 0.0°$ to 270.0° with $\Delta\varphi = 1°$). A total number of 15,671 reflections were collected, from which a sum of 5762 independent reflections remained and were used for all calculations (12 systematically absent reflections rejected). Data were corrected for Lorentz and polarization effects [11]. Corrections for intensity decay and absorption effects are based on the program DECAY (SF = 3) [11]. The unit cell parameters were obtained by least squares refinements of 5000 reflections with the program CELL [11,12]. The structure was solved by the Patterson method and refined by full-matrix least squares calculations with anisotropic thermal parameters for all non-hydrogen atoms. All hydrogen atoms were calculated in ideal positions. Full matrix least squares refinements were carried out by minimizing $\Sigma w(F_o^2 - F_c^2)^2$ with SHELXL weighting scheme $(w = 1/[\sigma^2(F_o^2) + (0.0510 \cdot P)^2 + 0.0000 \cdot P]$ where $P = (F_o^2 + 2 \cdot F_c^2)/3)$ and stopped at shift/err < 0.001, $wR_2 = 0.0870$, and $R_1 = 0.0353$ for all data; GOOF = 1.043, 306 parameters, residual electron density +4.35 e Å^{-3}, −1.64 e Å^{-3} (Tl residual), Flack parameter = −0.0032 (0.0108). (Structure refinement of the enantiomorphic model gave values $wR_2 = 0.134$, and $R_1 = 0.0498$ for all data; GOOF = 1.052, Flack parameter = 1.0529 (0.0196).) Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International Tables for X-Ray Crystallography* [13]. All calculations were performed on a DEC 3000 AXP workstation with the STRUX-V system [14], including the programs PLATON-92 [15], PLUTON-92 [15], SIR-92 [16] and SHELXL-93 [17].

Atomic coordinates have been deposited with the Cambridge Crystallographic Data Centre.

(Received 13 October 1997; accepted 31 October 1997)

Abstract—In addition to (*R*,*S*)-BINAPHOS, several related phosphine-phosphite ligands have been prepared and their use in Pd(II) catalyzed asymmetric alternating copolymerization of propene with carbon monoxide was examined. Small changes of the ligand substituents caused drastic changes of the stereo regularity of the product, which reveals that not only the electronic bias of (*R*,*S*)-BINAPHOS but also its steric demand is essential to produce completely isotactic copolymer from propene and CO in highly enantioselective fashion.

Keywords: palladium; phosphine-phosphite; propene; carbon monoxide; asymmetric copolymerization.

The alternating copolymerization of olefins with carbon monoxide is of great interest due to the potential use of the resulting polymer as a new material [1]. When α-olefins such as propene and styrene are used, control of regio- and enantioselectivities of the olefin insertion becomes a problematic issue for obtaining stereoregular polyketones. Thus, asymmetric copolymerization using chiral catalysts is now attracting much attention. Most of the successful reports on this subject deal with C_2 symmetrical bidentate ligands [2]. Recently, we have demonstrated that a cationic Pd(II) complex of unsymmetrical chiral bidentate phosphine–phosphite, (*R*,*S*)-BINAPHOS (=(*R*)-2-diphenylphosphino-1,1′-binaphthalen-2′-yl (*S*)-1,1′-binaphthalen-2,2′-diyl phosphite) [3], serves as an efficient catalyst for the asymmetric copolymerization of propene with carbon monoxide [4]. Highly isotactic polyketone was obtained with high enantioselectivity. The unique unsymmetrical character of this ligand attracted our attention, and thus we further investigated the catalytic activities of Pd(II) complexes bearing related phosphine–phosphite ligands. Here we report the synthesis of some chiral and achiral phosphine–phosphite ligands and their use in the copolymerization.

EXPERIMENTAL

Phosphine–phosphite ligands were prepared as follows. Detailed procedures have been reported elsewhere [3]. (*R*)-2-Diarylphosphino-2′-hydroxy-1,1′-binaphthyls or their analogs were prepared according to the literature procedure [10]. These phosphine parts were combined with 1,1′-binaphthyl-2,2′-diyl chlorophosphite in the presence of triethylamine in ether. After aqueous work up, the crude products were purified by silica-gel column chromatography. ^{31}P NMR of the products are summarized in Table 1. Other spectroscopic data are as follows. (*R*,*S*)-$(Me_2C_6H_3)_2$-Et_2-BINAPHOS: ^{1}H NMR ($CDCl_3$) δ 1.99 (s, 6H, $ArCH_3$), 2.07 (s, 6H, $ArCH_3$), 6.00 (d, J = 9.0 Hz, 1H, aromatic), 6.72–8.00 (m, aromatic, 29H). Found: C, 80.37; H, 5.32. Calcd for $C_{56}H_{42}P_2O_3$: C, 81.54; H, 5.13. (*R*,*S*)-(*c*-Pen)$_2$-BINAPHOS: ^{1}H NMR ($CDCl_3$) δ 0.50–2.20 (m, aliphatic, 18H), 6.71–8.04 (m, aromatic, 24H). [Pd(Me)(MeCN){(*R,S*)-H_8-BINAPHOS}]·[B{3,5-$(CF_3)_2C_6H_3$}$_4$]: ^1H NMR ($CDCl_3$) δ 0.42 (m, 1H, aliphatic), 0.65 (m, 1H, aliphatic), 1.00–2.00 (m, 10H, aliphatic), 1.12 (bd, $J_{P-H} = 7.3$ Hz, 3H, PdCH_3), 2.38 (m, 1H), 2.56 (m, 1H), 3.01 (m, 2H), 2.30 (bs, 3H, CH_3CN), 5.30 (d, $J = 9.0$ H, 1H, aromatic), 6.95–7.98 (m, 25H).

Asymmetric copolymerization of propene (3 atm) with CO (20 atm) was carried out in CH_2Cl_2 (2 mmol) using cationic Pd complexes (0.011 mmol) as catalysts in a 100-mL auto-clave at 20°C. The detailed procedure has been reported in our previous report [4].

RESULTS AND DISCUSSIONS

Ligand synthesis

The phosphine–phosphite ligands employed here are summarized in Chart 1. In (*R,S*)-($Me_2C_6H_3$)$_2$-BINAPHOS, two methyl groups are placed at 3- and 5-position in each of the phenyl groups of the parent (*R,S*)-BINAPHOS. The phenyl groups of (*R,S*)-BINAPHOS are replaced by cyclopentyl and ethyl groups in (*R,S*)-(*c*-Pen)$_2$-BINAPHOS and (*R,S*)-Et_2-BINAPHOS, respectively. Instead of 2,2′-dihy-

droxy-1,1′-binaphthyl, 5,5′,6,6′,7,7′,8,8′-octahydro-2,2′-dihydroxy-1,1′-binaphthyl was used to construct the phosphine site in (*R,S*)-H_8-BINAPHOS [5]. In addition to the BINAPHOS derivatives, achiral phosphine–phosphites **1** and **2** were prepared. The ^{31}P NMR data for the ligands are all listed in Table 1.

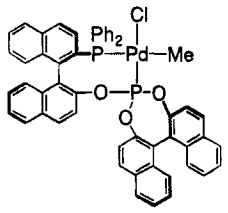
Preparation of Pd(II)-complexes

Neutral complexes Pd(Me)(Cl)(ligand) were prepared by admixture of the ligands with Pd(Me)(Cl)(cod). In Table 1, ^{31}P NMR data for the neutral complexes are summarized. A 5 : 1 mixture of isomers was obtained for Pd(Me)(Cl){(*R,S*)-BINAPHOS} and we previously determined the structures of the major and the minor complexes to be *SP*-4-2 and *SP*-4-3, respectively [4b]. Theoretical studies also suggested that the methyl group is stable at trans to a phosphine (corresponding to SP-4-2) than at trans to a phosphite (corresponding to *SP*-4-3) [4b]. Hence we tentatively determine the structure of the major complexes to be *SP*-4-2.

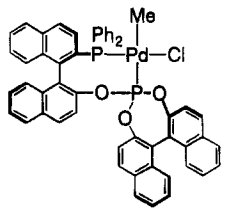
The neutral complexes were converted into the corresponding cationic complexes by treatment with $NaBAr_4$ (Ar = 3,5-$(CF_3)_2C_6H_3$). With BINAPHOS derivatives and **2**, single species were obtained, their ^{31}P NMR data are also shown in Table 1. Their structures were analogously assigned to be *SP*-4-3 on the basis of [*SP*-4-3-Pd(Me)(MeCN){(*R,S*)-BINAPHOS}]·[BAr_4] [4b]. From neutral complex Pd(Me)(Cl) (**1**), the corresponding cationic species was not formed and a complex mixture resulted. BINAPHOS derivatives form 8-membered palladacycle when they coordinate to Pd(II), whereas phosphine–phosphite **1** and **2** give 6- and 7-membered ring, respectively. The less stability of [Pd(Me) (MeCN)(**1**)]·[BAr_4] may be attributed to its smallest chelation-ring size.

Alternating copolymerization of propene with CO catalyzed by cationic Pd(II) complexes

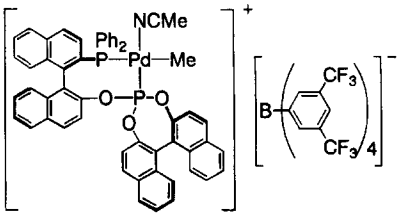
Propene was copolymerized with carbon monoxide using the cationic Pd(II)-complexes as catalysts. The



SP-4-2-Pd(Me)(Cl) {(*R,S*)-BINAPHOS}



SP-4-3-Pd(Me)(Cl) {(*R,S*)-BINAPHOS}



SP-4-3-[Pd(Me)(MeCN){(*R,S*)-BINAPHOS}]·[B{3,5-$(CF_3)_2C_6H_3$}$_4$]

complexes bearing BINAPHOS derivatives were all active for the copolymerization and completely alternating copolymers were obtained. The head-to-tail selectivity and isotacticity of the copolymers were determined by ^1H and ^{13}C NMR spectroscopy. When (*R*,*S*)-($Me_2C_6H_3$)$_2$- and (*R*,*S*)-(*c*-Pen)$_2$-BINAPHOS were used as a ligand, highly isotactic polyketone was obtained in a manner similar to the reaction with (*R*,*S*)-BINAPHOS. With (*R*,*S*)-Et_2-BINAPHOS, however, polyketone was formed with lower regioselectivity. The presence of head-to-head and tail-to-tail structures were suggested by ^{13}C NMR. Three peaks were observed for the carbonyl carbon at 208, 212, 215 ppm and their ratio was roughly estimated to be 1 : 6.5 : 1. The peaks were assigned to tail-to-tail, head-to-tail, and head-to-head structures, respectively, according to the literature values [6]. Comparison of the result with (*R*,*S*)-(*c*-Pen)$_2$- and that with (*R*,*S*)-Et_2-BINAPHOS suggests that the different steric demand in the phosphine site substantially affects the regioselectivity. We previously proposed a model in which propene insertion to an acyl-palladium bond takes place via propene coordination to Pd at a cis site to a phosphine than to a phosphite in a Pd–phosphine–phosphite complex (Scheme 1) [4]. In this model, 1,2-insertion of propene is favored over 2,1-insertion, probably due to the steric repulsion between one of the phenyl groups in the phosphine and the methyl group of propene. This model is consistent with the present considerable substituent-effect. That is, the phosphine site located cis to the coordination site of propene, most effectively, controls the regio- and enantioselectivities of the propene insertion. The use of achiral phosphine–phosphite **2** gave a polyketone with even lower regioselectivity, the ratio of tail-to-tail, head-to-tail, and head-to-head being 1 : 3.6 : 1. The low regio regularity should be attributed to either the absence of chirality or the less steric demand in the phosphite site.

The yield and molecular weight of the copolymers were compared by quenching the polymerization after 6 h as described in Table 2. Among the BINAPHOS derivatives, Pd(II)-(*R*,*S*)-H_8-BINAPHOS complex showed the highest yield and molecular weight. The propene conversion to the copolymer is plotted against the reaction time in Fig. 1 in order to compare the two ligands, (*R*,*S*)-BINAPHOS and (*R*,*S*)-H_8-BINAPHOS. With (*R*,*S*)-H_8-BINAPHOS, the initial

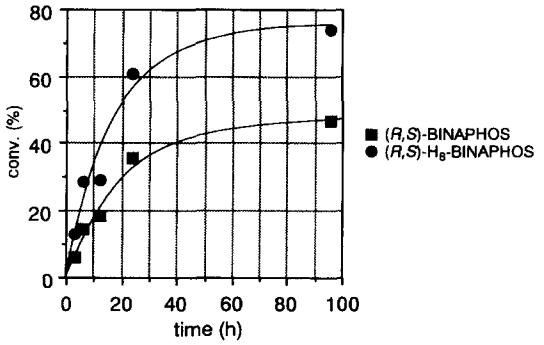


Fig. 1.

reaction rate is almost twice as high as with (*R*,*S*)-BINAPHOS. The living nature of the Pd(II)-(*R*,*S*)-H_8-BINAPHOS-catalyzed copolymerization has been disclosed as shown in Fig. 2. Prolonged reaction time with (*R*,*S*)-H_8-BINAPHOS, however, resulted in a molecular weight (96 h, Mn = 49,000, Mw/Mn = 1.57) similar to that with (*R*,*S*)-H_8-BINAPHOS (96 h, Mn = 65,000; Mw/Mn = 1.60). Most probably, the deposition of polymer in this solvent inhibits further growth of the polymer.

We previously reported that higher enantioselectivity was achieved with H_8-BINAP (5,5′,6,6′,7,7′,8,8′) - octahydro-2,2′ - diphenylphos - phino-1,1′-binaphthyl) than with BINAP (2,2′-diphenylphosphino-1,1′-binaphthyl) in Rh(I)-catalyzed asymmetric hydrogenation of α,β-unsaturated carboxylic acids [5a]. The larger bite angle, P–Rh–P, is suggested to cause stronger steric demand around the reaction site of Rh(I) center. Here in this study, (*R*,*S*)-H_8-BINAPHOS should chelate to the Pd(II) center with larger P–Pd–P angle than (*R*,*S*)-BINAPHOS and thus the Pd(II) is less exposed in the (*R*,*S*)-H_8-BINAPHOS complex. Recently, Leitner and his coworkers reported that a ligand with a larger steric block around

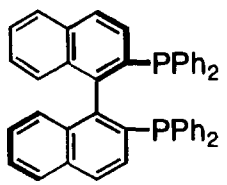
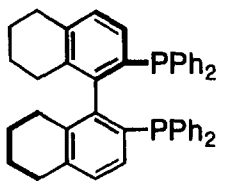
the metal center resulted in higher catalytic activity in the Rh(I)-catalyzed reduction of carbon dioxide to formic acid [7]. They explained this phenomenon that the less solvation due to the steric hindrance caused the higher catalytic activity. A parallel interpretation is applicable for the present result that a favorable approach of monomers, propene and carbon monoxide, than of solvents, e.g. acetonitrile and CH_2Cl_2, has been realized in the (*R*,*S*)-H_8-BINAPHOS complex.



(*R*)-BINAP



(*R*)-H_8-BINAP

CD spectra of the polyketones

The UV and CD spectra of the polyketones obtained with (*R*,*S*)-BINAPHOS, (*R*,*S*)-($Me_2C_6H_3$)$_2$-BINAPHOS, and (*R*,*S*)-H_8-BINAPHOS exhibit the absorption due to the carbonyl group at essentially the same wave length (λ_{max} = 272–276 nm). The agreement of λ_{max} between UV and CD suggests that the UV absorption corresponds to the single CD absorption but not to a sum of multiple ones. The dissymmetry factor g was calculated in such a way as $g = (\Delta\varepsilon)/(\varepsilon)$ [8]. For the copolymers obtained with (*R*,*S*)-BINAPHOS, (*R*,*S*)-($Me_2C_6H_3$)$_2$-BINAPHOS, and (*R*,*S*)-H_8-BINAPHOS, the g values were substantially the same, suggesting that the enantiometric homogeneity of the polymers is essentially the same [9]. We previously determined the enantiomeric excess of the chirotopic carbons to be at least 95% *ee* (*S*) in the propene-CO copolymer obtained with (*R*,*S*)-BINAPHOS [4b]. Hence it is suggested that the copolymers produced with (*R*,*S*)-($Me_2C_6H_3$)$_2$-BINAPHOS and (*R*,*S*)-H_8-BINAPHOS have almost complete enantiomerical purity, too. It is noteworthy that (*R*,*S*)-(*c*-Pen)$_2$-BINAPHOS gave a polyketone with the opposite sign of CD absorption to the one with BINAPHOSs bearing diarylphosphino groups. This means that the chirotopic carbons in this copolymer have *R* absolute configuration. Thus the study reveals that the enantiofacial selection for propene by a ligand heavily depends on the structure and the electronic circumstance of the phosphine site.

CONCLUSION

The present study reveals that a Pd(II) complex of (*R*,*S*)-H_8-BINAPHOS is a more active catalyst compared to that of (*R*,*S*)-BINAPHOS for alternating copolymerization of propene with carbon monoxide. Completely isotactic copolymer was obtained in high optical purity with (*R*,*S*)-H_8-BINAPHOS, (*R*,*S*)-($Me_2C_6H_3$)$_2$-BINAPHOS, and (*R*,*S*)-(*c*-Pen)$_2$-BINAPHOS. The opposite enantioface of propene was selected by (*R*,*S*)-(*c*-Pen)$_2$-BINAPHOS. Copolymer with low regio regularity was obtained with (*R*,*S*)-Et_2-BINAPHOS. Thus slight change around the phos-

phine site strongly affects the stereo regularity of the polyketone. The use of achiral phosphine–phosphites **1** and **2** resulted in no reaction and formation of stereo irregular polyketone, respectively. Therefore, we conclude that not only the electronic bias of (*R,S*)-BINAPHOS but also its steric demand is essential to produce completely isotactic copolymer from propene and CO in highly enantioselective fashion.

(Received 4 November 1997; accepted 18 November 1997)

Abstract—In this paper the synthesis, characterization and properties of various Pd(II) complexes with 2-acylphenolates as chelating ligands are reported. The compounds are easily accessible by stirring 2-acylphenoles with Pd(II) complexes in the presence of potassium *tert*-butoxide. Cyclometallated tri(*o*-tolyl)phosphine derivatives and allyl palladium complexes were chosen as palladium precursor. The solid state structures of the complexes 2-acetylphenolato-[*o*-(di-*o*-tolylphosphino)benzyl]palladium(II) (**2**), 2-benzoylphenolato-[*o*-(di-*o*-tolylphosphino)benzyl]palladium(II) (**4**) and 2-acetyl-1-naphtholato-[*o*-(di-*o*-tolylphosphino)benzyl] palladium(II) (**6**) were further studied by X-ray diffraction analyses. In all complexes the palladium center is coordinated in a square planar fashion. Interestingly, coordination of the 2-acylphenolates to palladium results in a significant perturbation of the delocalization within the aromatic ring. The strong hydrogen-bond acceptor behavior of the phenolic oxygen as well as the *cis*/*trans*-isomerisation is discussed in terms of the solid structure (**2, 4** and **6**) and the NMR shifts observed in various solvents. © 1998 Elsevier Science Ltd. Keywords: palladacycles; π-allylpalladium complexes; hydrogen bonds

The chemistry of late transition metal alkoxide complexes has recently attracted much attention [1]. Such complexes are important intermediates in various transition metal-catalyzed reactions [2], including the palladium-catalyzed formation of carbon-oxygen bonds [3] and the rhodium and palladium mediated activation of C—O single bonds [4]. During the last few years important aspects of the chemistry of palladium(II) alkoxide and aryloxide complexes were established elegantly by van Koten *et al.* and others [5–8]. However, there are only few reports of palladium alkoxide complexes containing an additional donor group (usually nitrogen or phosphorus) [7,8]. Pd(II)-complexes with easily accessible 2-acylphenolates and related ligands are surprisingly rare in the literature and, to the best of our knowledge, there is no structural characterization of such compounds [9]. An interesting feature of palladium and other late transition metal alkoxides is the formation of intermolecular O—H···O hydrogen bonds to an aditional alcohol [10]. The formation of O—H···O hydrogen bonding has important effects on the properties and self organization of the corresponding metal complexes [11]. In addition to an O—H···O interaction there are few examples known with C—H···O hydrogen bonds [6,8,12]. Here the carbon atom participating in the C—H···O hydrogen bond is attached to a heteroatom (O,N), which coordinates to a metal center. Thus, this interaction is a model of the initial stage of a base-assisted β-hydride elimination.

In cooperation with Herrmann *et al.* we have been engaged in the synthesis of cyclometallated palladium complexes of tri(*o*-tolyl)phosphine, e.g. **1**, as efficient catalysts or catalyst-precursors for important C—C coupling reactions [13]. Recently, we have shown that cyclometallated palladium complexes are also suitable

* Dedicated to Prof. Dr. Drs. h. c. W. A. Herrmann on the occasion of his 50th birthday.

† Author to whom correspondence should be addressed.

for C—N coupling processes [14]. In order to synthesize model complexes for similar C—O coupling reactions, as well as to study the behavior of 2-acylphenolates as ligand, we were interested in the preparation of cyclometallated palladium complexes containing the 2-acylphenolate ligand.

Herein, we report for the first time on the synthesis and properties of this class of complexes. The synthesis and characterisation of π-allylpalladium complexes containing 2-acylphenolate ligands is presented. These π-allylpalladium complexes with additional coordination of a phenoxide ligand are interesting as model compounds for the palladium-catalyzed *O*-arylation and phenoxycarbonylation of allylic substrates leading to allyl–aryl ethers and unsaturated esters, respectively [15].

RESULTS AND DISCUSSION

Preparation of the aryloxopalladium(II) complexes

The palladium phenolate complexes **2–6** were readily prepared by stirring a solution of the palladacycle **1** [13] and 2 equiv. of the corresponding 2-acylphenol together with 2 equiv. of potassium *tert*-butoxide in toluene at room temperature (Scheme 1). Good to very good yields (76%–92%) were obtained after crystallization from toluene/pentane.

The addition of a strong base is crucial for the success of the reaction. Only starting material was isolated from the reaction mixture of **1** and 2-acylphenol if sodium acetate was used as base. Using 2-hydroxybenzophenone as ligand, the synthesis is succesful if performed under reflux conditions. However, in case of 2-hydroxyacetophenone as ligand, palladium black is formed under such reaction conditions. This may be due to formation of enolates from the acetophenone.

The palladium(II) phenolate complexes **9–12**, which contain an η^3-allyl unit, were prepared in a similar way to compounds **2–6**. Addition of 2 equiv. of the 2-acylphenol and 2 equiv. of potassium *tert*-butoxide to a toluene solution of the corresponding π-allylpalladium chloride dimer and stirring the mixture for approximately 7 h at ambient temperature yielded the desired products (Scheme 2). When weak bases, such as sodium acetate, were employed, starting material was recovered unchanged. Though precipitation of palladium black seems to be inevitable during the course of the reaction, the allylic complexes **9–12** were isolated in reasonable yields of 73–88% as yellow solids.

The allylic complexes **9–12** are less stable than the corresponding phosphapalladacycles **2–6**. Toluene solutions of **9–12** decomposed slowly with metal deposition at room temperature. In the solid state (room temperature) their yellow color darkens within a few days due to formation of elemental palladium. In the case of **9**, the *O*-allylated ligand could be detected (^{1}H NMR) as a decomposition product resulting from reductive elimination.

Molecular structures of the complexes **2**, **4** *and* **6**

Compounds **2**, **4** and **6** were characterized by X-ray diffraction analysis. Selected bond distances and angles are given in Table 1.

The molecular structure of **2** is depicted in Fig. 1. The structure consists of a palladium atom which is coordinated in a square planar fashion by a cyclometallated tri(*o*-tolyl)phosphine and a chelating 2-acetyl phenolate ligand. Two geometric isomers are possible with the phenolic oxygen located *cis* or *trans* to the phosphorus atom and both were observed in solution (*vide infra*). In complex **2** O31, the phenolic oxygen and O11, the carbonyl oxygen of the parent 2-acetyl phenol ligand, are located *trans* to the phosphorus atom P and C27 of the phosphine ligand, respectively. The principal coordination sphere is close to planar, the maximum deviation being 0.047(2) Å. The distances Pd—P = 2.223(1) Å and Pd—C27 = 2.010(4) Å compare favorably with those observed in **1** (2.216(1) Å and 2.021(5) Å, respectively) [16].

The phenolic oxygen palladium bond Pd—O31 = 2.042(2) Å was significantly shorter than

the carbonyl oxygen palladium bond Pd—O11 = 2.110(2) Å and associated with this effect are different C—O bond distances (C3—O31 = 1.302(4) Å, C1—O11 = 1.254(4) Å). However, the difference is not as much as one would expect for a purely phenolic C—O single and a C=O double bond. The distances for C1—C2 = 1.427(5) Å and C2—C3 = 1.427(5) Å are equal, which is surprising as these are an aromatic and a single bond in the parent ligand, respectively, and should therefore differ more. Distances within the fused benzene ring deviate from the normal sixfold symmetry with short bonds for C6—C7 and C4—C5 (1.335(8) Å and 1.356(7) Å, respectively). The significant differences in the two Pd—O and the two C—O bond lengths indicate that the presence of the fused benzene ring has attenuated the resonance system in the chelate ring, of the type found in most metal complexes with β-diketones, such as acylacetonato complexes.

The interpretation of these results in terms of resonance structures is in line with the assumption that the delocalisation within the aromatic ring (Scheme 3, A) is less significant and that the acac-type delocalization (Scheme 3, B) makes an important contribution to the overall structure and reactivity of this molecule. Analogous effects have been observed in the complexes $Ni(C_9H_9O_2)_2$ [17], $C_9H_9O_2$ = 2-acetyl-4-methyl-phenol and $Cu(C_8H_7O_2)_2py$ [18], $C_8H_7O_2$ = 2-aceto-phenol, py = pyridine.

Regarding hydrogen bonds of the coordinated oxygen atoms there is a short contact between O11 and the methyl group C47. The non-bonded distance O11 · · · C47 = 3.13 Å is considerably shorter than the sum of the van-der-Waals radii of oxygen and an averaged radius for the methyl group indicating a weak hydrogen bond between C47—H · · · O11. Recent studies of such C—H · · · O contacts show their importance as secondary interactions and in determining the crystal packing [11].

The molecular structure of complex **4** is similar to the structure of complex **2** except that in **4** the carbonyl oxygen O11 is located *trans* to the phosphorus atom and the phenolic oxygen O31 is *trans* to C27 (Fig. 2). This geometry avoids steric conflict between the phenyl group attached to C1 and the *o*-tolyl groups attached to the phosphorus atom. The distances Pd—P = 2.198(1) Å, Pd—C27 = 2.022(2) Å in **4** are comparable to those observed in **2**. However, the distances of palladium to the oxygen atoms are different with Pd—O31 = 2.092(1)Å longer and Pd—O11 = 2.087(1) Å slightly shorter than in compound **2**, probably reflecting the different *trans*-influence of phosphorus and carbon. As expected, the phenolic C3—O31 bond (1.290(3) Å) is longer than the C1—O11 bond (1.244(2) Å), but again the difference is less pronounced compared to a localized C—O single and a C=O double bond. The asymmetry in the aromatic ring is more pronounced than in complex **2** with C4—C5 and C6—C7 being short (1.361(3) Å and 1.367(3) Å, respectively) and C2—C3 being long (1.441(3) Å). Again, this effect can be explained in terms of resonance structure B. The phenyl ring attached to C1 is not conjugated with the chelate ring being twisted by 52° to the plane defined by Pd, O31, O11, C1, C2, C3.

There are short contacts between O31 and the methyl groups of the *o*-tolyl rings. The non-bonded distances C · · · O are longer than those observed in **2**, however, there are two weak contacts with methyl groups (O31 · · · C37 = 3.31Å; O31 · · · C47 = 3.40 Å). The hydrogen atoms of the methyl groups were clearly located in the difference map and allow to further characterize the geometry around O31. The distance of H37a to O31 is 2.40 Å (H37a—C37 = 0.91 Å) and the angle O31 · · · H37a—C37 is 176°. The distance of H47b to O31 is 2.59 Å (H47b—C47 = 0.86 Å) and the angle O31 · · · H47b—C47 is 155°. The oxygen atom is in a pseudotetrahedral environment with an angle H37a · · · O31 · · · H47b = 98°. This arrangement is clearly indicative of C—H · · · O interactions.

The X-ray structure of the complex **6** is shown in Fig. 3. The overall geometry of **6** is very similar to that observed in **2** (Fig. 1). The steric requirement of the naphthyl group favors the position of the phenolic oxygen *trans* to phosphorus. Bond distances to palladium (Pd—P = 2.221(1) Å, Pd—C27 = 2.017(2) Å,

Pd—O31 = 2.057(2) Å and Pd—O11 = 2.104(2) Å) as well as the carbon-oxygen distances (C3—O31 = 1.293(3) Å and C1—O11 = 1.254(3) Å) are nearly identical to those observed in **2**. The naphthyl ring has a short bond C6—C7 = 1.336(4) Å, relatively short bonds for C5a—C5b = 1.358(5) Å and C4a—C4b = 1.375(4) Å and long bonds for C2—C7 = 1.443(3) Å and C3—C4 = 1.457(3) Å indicating partially localized double bonds. A similar asymmetry of the naphthyl ring has been detected in the complex $Cd(C_{12}H_8O_2)_2bpy$, $C_{12}H_8O_2$ = 2-acetyl-1-hydroxy-naphthalene, bpy = 2,2′-bipyridine [25]. As observed in **2**, there is a short contact between O11 and the protons of the methyl group C47 with a non-bonded distance O11 ··· C47 = 3.17 Å.

Solution studies

Obviously, the complexes **2–6** can exist as two isomers, with the phenolic oxygen *cis* or *trans* towards

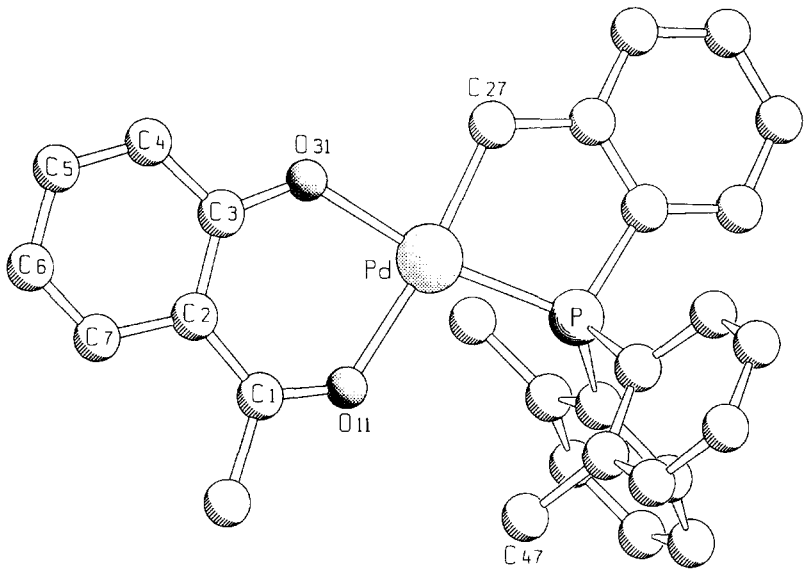

Fig. 1.

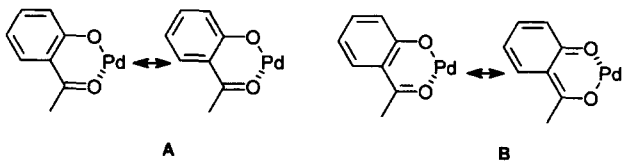

Scheme 3.

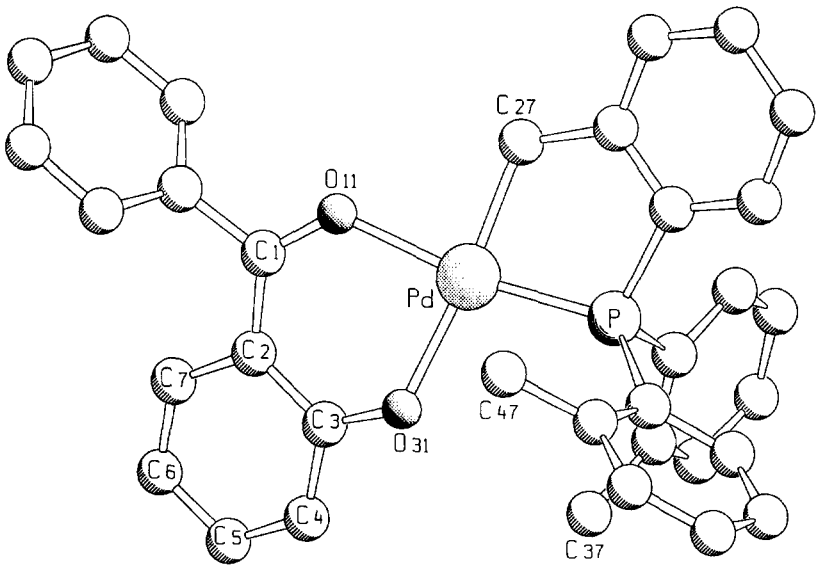

Fig. 2.

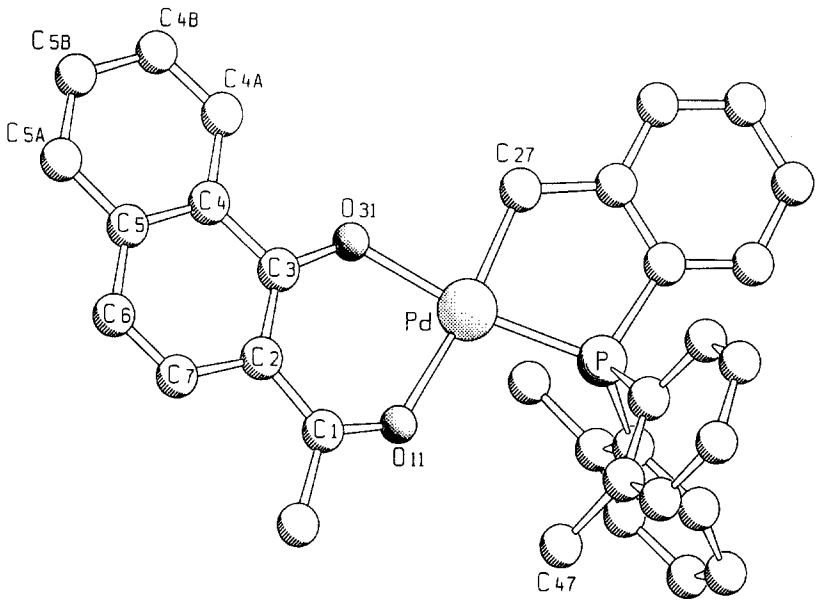

Fig. 3.

the phosphorus atom (Scheme 4). Depending on the substituent R″ the *cis*- or *trans*-isomer can be preferred. This was exemplified by the geometry of complexes **2, 4,** and **6** in the solid state. To further investigate isomerization processes and the ratio between the two isomers, NMR experiments were performed in various solvents. For each of the two geometric isomers of **2–6** distinct $^{31}P\{^1H\}$NMR signals were observed.

We provisionally assign the high field $^{31}P\{^1H\}$NMR signal to **D** and the low field signal to **C**. The intensity of the high field signal is always higher than that of the low field signal for each of the compounds **2–6**.

Taking into account the ability of the oxygen atoms in **2–6** to participate in hydrogen bonding, the *cis*-/*trans*-isomerization should be affected by the solvent. To study the isomerization phenomenon in further detail, the $^{31}P\{^1H\}$NMR spectrum of **2** was recorded in 10 different solvents. In $CDCl_3$, two signals were observed at 35.7 ppm and 34.2 ppm. The ratio of the intensities of the two signals (K) changed slightly upon warming. It changes from 0.11 (25°C) to 0.14 (50°C) reversibly. A similar effect was observed in toluene-d_8 as solvent: K changes from 0.44 (25°C) to 0.50 (50°C). As expected, the nature of the solvent has a dramatic effect on K (Table 2).

As shown in Table 2, K can vary from 0 to 0.5. There seems to be no correlation between K and either

Table 2. K values of **2** in different solvents (K = intensity of the ^{31}P NMR low field signal to the intensity of the high field signal)

Solvent	Ratio of ^{31}P NMR intensities	K
MeOD/2-BuOH	0:100	0
$CDCl_3$	10:90	0.11
CD_2Cl_2	14:86	0.16
DMSO-d_6	17:83	0.21
C_6H_5Cl	22:78	0.29

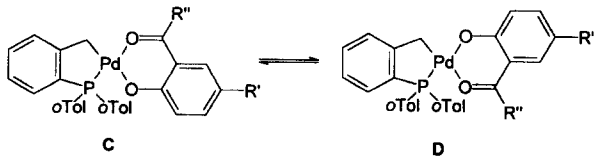
Toluene-d_8	31:69	0.44
CCl_4	33:67	0.48



Scheme 4.

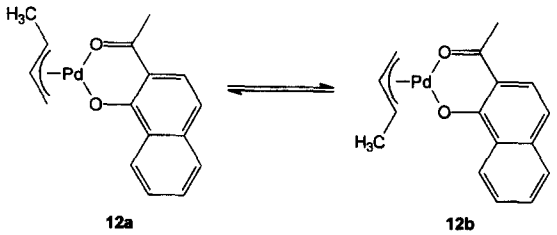
the E_T^N-values as empirical parameter of solvent polarity [20] or the π^*-scale of solvent dipolarity/polarity [21]. Obviously, K is affected by other properties of the solvent. As mentioned earlier, phenolate complexes usually behave as strong hydrogen bond acceptors (HBA). In the solid state even hydrogen bonds from the benzylic protons of the *o*-tolyl substituents are formed (stabilizing **C**). An interaction of the phenolic oxygen with the solvent would be easier in form **D** because of minor sterical hindrance. Since hydrogen bond acceptors usually are also electron-pair donors, K should be affected by both the ability of the solvent to act as hydrogen bond donor (HBD) α and the solvent acceptor number AN [22].

This argumentation is in good agreement with the observed data. Alcohols and chloroform are good HBD solvents and therefore K is low, leading to **D** as the predominant species in solution. On the other hand, tetrachloromethane or toluene are not able to form hydrogen bonds. Thus high values are observed for K. The same tendency is observed if correlating K with the acceptor number A [22].

The ^{1}H and ^{13}C NMR spectra of the allylic complexes exhibit some interesting features concerning the dynamic solution behavior of the η^3-allyl unit. In the case of **9** the ^{13}C NMR (room temperature) shows a broad signal at 55.2 ppm similar to a doublet which is assigned to C1/C3 of the η^3-allyl ligand. Apparently, the absorptions for these carbon atoms almost coalescence, indicating a rotation of the allyl group. The ^{1}H NMR of **9** exhibits only one absorption each for the *syn* and *anti* hydrogens.

In contrast, in the ^{13}C NMR spectrum of **12** each of the signals for C1, C3 of the crotyl moiety and CH_3 of the phenolate ligand consists of two sharp peaks (C1: 51.39 ppm, 50.35 ppm; C3: 72.60 ppm, 71.48 ppm; CH_3: 27.71 ppm, 27.16 ppm), arising from the stereoisomers **12a** and **12b** (Scheme 5). Therefore the rotation of the allyl unit is slow compared to the NMR time scale. The resonances of the aromatic carbon atoms of the 2-acylphenolate-ligand are not influenced by the orientation of the crotyl ligand; only one peak per carbon atom is observed for both stereoisomers.

The ratio of the *cis*/*trans* isomers of **12** can be determined from the ^{1}H NMR spectrum (25°C, $CDCl_3$; 63:37).



12a **12b**

Scheme 5.

In the ^{1}H and ^{13}C NMR spectra of compounds **10** and **11** there is no evidence for a hindered rotation of the allyl moiety as only one absorption appears for each atom. However, this may be due to very similar chemical environments in both stereoisomers.

EXPERIMENTAL

General comments

NMR spectra (^{1}H, ^{13}C, ^{31}P) were recorded on a Jeol JMX-GX 400 instrument. FAB-MS spectra were recorded on a Varian MAT 311a. Elemental analyses were carried out by the Microanalytical Laboratory at the TU München. IR spectra were recorded on a Perkin–Elmer 1600.

The palladacycle **1** was prepared as reported previously [13]. Bis(η^3-allyl)di(μ-chloro)dipalladium(II) (**7**) and bis[(1,2,3-η)-2-butenyl]di(μ-chloro)palladium (II) (**8**) were prepared from the corresponding allylic chlorides according to the literature [23].

The substituted phenoles and 2-acetyl-1-naphthole were obtained from Aldrich and were used without further purification. All operations were carried out under an atmosphere of argon using standard Schlenk techniques. All solvents were dried according to standard procedures.

X-ray crystal structure determination

Suitable single crystals of **2** and **4** for the X-ray diffraction studies were grown by slow diffusion of pentane into the sample solution in toluene. Suitable crystals of **6** were obtained by recrystallization of the compound from chloroform. The structures were solved by a combination of direct methods, difference-Fourier syntheses and least-squares methods. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International Tables for X-Ray Crystallography* [24]. All calculations were performed on a DEC 3000 AXP workstation with the STRUX-V [25] system, including the programs PLATON-92 [26], PLUTON-92 [26], SIR-92 [27] and SHELXL-93 [28].

Data collection

A summary of the crystal and experimental data is reported in Table 3. Preliminary examination and data collection were carried out on an imaging plate diffraction system (IPDS; STOE&CIE) (**2, 4**) or a CCD system (KappaCCD; NONIUS) equipped with a rotating anode (NONIUS FR591; 50 kV; 80 (**2, 4**)/60 (**6**) mA) and graphite monochromated Mo–K_α radiation. Data collection were performed at 293 (193 and 293) K within the θ-range of $3.1° < 2\theta < 50.2°$ ($4.1° < 2\theta < 51.2°$; $6.8° < 2\theta < 61.7°$) with an

exposure time of 5.0 min (5.0 min; 25 s) per image (rotation scan modus from $\phi = 0.0°$ (75°; 0°) to 290° (293°; 360°) with $\Delta\phi = 1°$). A total number of 14,253 (11,358; 19,521) reflections were collected. After merging a sum of 4487 (4724; 7528) independent reflections remained and were used for all calculations (2, 3, 2 reflections were suppressed during refinements on compounds **2, 4, 6,** respectively). Data were corrected for Lorentz and polarization effects. The unit cell parameters were obtained by full-matrix least-squares refinements of 4813 (4815; 15,927) reflections with the program Cell [29a] (DENZO-SMN [29b]).

The structures were solved using the heavy atom method. In **2** additional toluene as solvent is disordered over two positions which are related by a center of symmetry. In **6** the $CHCl_3$ is disordered over two positions which are related by a rotation around the C—H axis. For **4** all hydrogen atoms were located, for **2** all hydrogen atoms with exception of the toluene hydrogen atoms were located and refined. The hydrogen atoms of toluene in **2** and the hydrogen atoms in **6** were generated geometrically and allowed to ride on their respective parent carbon atoms. In **2** and **6** the hydrogen atoms were assigned fixed isotropic temperature factors (1.2 $U_{equiv.}$ and 1.5 $U_{equiv.}$ of the parent carbon atom for aromatic and other CH groups, respectively). Full matrix least squares refinement of all non-hydrogen atoms with anisotropic temperature factors led to convergence. Owing to the high disorder of $CHCl_3$ in **6,** the R values are higher.

General procedure for the synthesis of complexes **2–6**

0.10 g (0.21 mmol) of the palladacycle **1** is stirred together with 2.0 equiv. of the corresponding 2-acylphenole and 47 mg (0.42 mmol) potassium *tert*-butoxide in 10 ml toluene. After approximately 12 h the reaction mixture is filtered and the solvent is removed *in vacuo*. Analytically pure samples of the phenolate complexes are obtained by crystallization from toluene/pentane.

2-Acetylphenolato-[*o*-(di-*o*-tolylphosphino)benzyl] palladium(II) (**2**) (*yellow needles, 86% yield*)

^{1}H NMR ($CDCl_3$, 20°C, 400 MHz): δ = 7.58–6.82 (15H, m, H_{Ar}); 6.44 (1H, m, H_{Ar}); 3.65 (2H, s, broad, CH_2); 2.85 (3H, s, broad, $CH_{3\,(Benzyl)}$); 2.50 (3H, s, broad, $CH_{3\,(Benzyl)}$); 2.42 (3H, s, $CH_{3\,(Acetyl)}$). $^{31}P\{^1H\}$ NMR ($CDCl_3$, 20°C, 161.85 MHz, with integral *I*): δ = 35.7 (s, *I* = 10%); 34.2 (s, *I* = 90%). General procedure for the synthesis of complexes **9**–**12**

0.30 g (0.82 mmol) of the π-allylpalladium chloride complex (**7**) (0.32 g (0.82 mmol) of the π-(1-methylallyl)palladium chloride complex (**8**)) are stirred together with 2.0 equiv. of the protonated ligand and 184 mg (1.64 mmol) potassium *tert*-butoxide in 13 ml toluene at ambient temperature. After some hours the initially orange solution turns black due to precipitated palladium-metal which is removed by filtration (celite) to obtain a yellow solution. The solvent is removed *in vacuo* and the yellow residue is washed with two 15 ml portions of pentane. The allyl complexes can be recrystallized from toluene/pentane at −78°C. The numeration of the atoms of the ligands are similar to the X-ray studies of the aforementioned compounds.

η^3-Allyl-(2-benzoylphenolato)palladium(II) (**9**) (*yellow needles, 88% yield*)

MS (FAB): m/z = 346 [M^+], 289 [M^+ − crotyl − 2H]. $C_{16}H_{16}O_2Pd$ (346.72): calc. C 55.4, H 4.7; found C 54.9, H 4.7.

CONCLUSION

Pd(II)-complexes with chelating 2-acylphenolate ligands and cyclometallated tri(*o*-tolyl)phosphine or allyl units, respectively, are easily available in good yields by treatment of an appropriate Pd(II)-precursor with the corresponding 2-acylphenole and a strong base such as potassium *tert*-butoxide. X-ray diffraction analyses of **2, 4** and **6** show that the coordination sphere of palladium is close to square planar. The conjugated aromatic system of the free ligands is partially disrupted through coordination to the metal. The different *cis*-/*trans*-stereochemistry observed for compounds **2, 6** and **4** can be correlated with the steric requirement of the 2-acylphenolate ligand. All structures exhibit short $CH_3 \cdots O$ distances which is indicative of C—H···O interactions. This phenomena was further studied in solution using complex **2**. The ratio of **C** to **D** depends on the ability of the solvent to act as a hydrogen donor, replacing a $CH_3 \cdots O$ by a H-solvent···O interaction. The NMR spectra of the allyl and crotyl complexes displayed that the former one is highly dynamic at room temperature while the latter ones exist as two stable isomers in solution.

Reactions of methyl iridium complexes with H_2, CO or O_2 in H_2O and DMSO†

David P. Paterniti and Jim D. Atwood*

Department of Chemistry, University at Buffalo, State University of New York, Buffalo NY 14260-3000, U.S.A.

(Received 17 October 1997; accepted 10 November 1997)

Abstract—New water soluble alkyl iridium(I) complexes were synthesized and their reaction with small molecules (H_2, CO and O_2) in DMSO or H_2O examined. Hydrogenation of *trans*-Ir$(CH_3)(CO)(TPPMSK)_2$ [TPPMSK = $(P(C_6H_5)_2(m\text{-}C_6H_4SO_3K))_2$] in DMSO produced CH_4 and Ir$(CO)(H)(TPPMSK)_3$ as major products. Carbonylation of *trans*-Ir$(CH_3)(CO)L_2$ (L = TPPMSK or TPPMS [TPPMS = $P(C_6H_5)_2(m\text{-}C_6H_4SO_3Na)$]), in DMSO, produced Ir$(C(O)CH_3)(CO)_2L_2$. Reactions in water were complicated by rapid hydrolysis of the Ir—CH_3 bond forming CH_4 and *trans*-Ir$(CO)(OH)L_2$. The hydrolysis was inhibited by excess L allowing the reactions to be studied in water. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: water soluble; TPPMS; iridium; hydrolysis; carbonylation

Recent needs for environmentally-friendly catalytic systems that generate less hazardous waste, easier product separation, decreased price, increased safety and catalyst recycling led to the development of water-soluble catalysts, where hydrophilic ligands make an organometallic complex soluble in water [1–8]. The use of water-soluble organometallic complexes as catalysts for hydroformylation [2–4] continues to increase [7], in part, due to the success of the Ruhrchemie/Rhône-Poulenc process [8], where propylene is converted to butanal using a Rh(CO)$H(TPPTS)_3$ catalyst. While no mechanistic information pertaining to the carbonylation of a water-soluble rhodium alkyl complex has been reported, a water-soluble methyl iridium(I) complex offers an excellent opportunity to model carbonylation in water. We report here the synthesis of *trans*-Ir$(CO)(CH_3)(TPPMS)_2$; the attempted synthesis of *trans*-Ir$(CO)(CH_3)(TPPTS)_2$; carbonylation of *trans*-Ir$(CO)(CH_3)L_2$ (L = PPh_3, TPPMSK or TPPMS) in DMSO; the hydrolysis of the CH_3—Ir bond from *trans*-Ir$(CO)(CH_3)(TPPMS)_2$; and carbonylation of *trans*-Ir$(CO)(CH_3)(TPPMS)_2$ in H_2O with 5% excess TPPMS (TPPMS = $PPh_2(m\text{-}C_6H_4SO_3Na)$, TPPMSK = $PPh_2(m\text{-}C_6H_4SO_3K)$, TPPTS = $P(m\text{-}C_6H_4SO_3Na)_3$).

EXPERIMENTAL

Materials

$IrCl_3 \cdot 3H_2O$ was purchased or borrowed from Johnson Matthey. Triphenylphosphine, *n*-octylamine, fuming sulfuric acid (20% and 30% SO_3 w/w) and CH_3Li were purchased from Aldrich Chemical Co. Deuterated solvents were purchased from Cambridge Isotope Labs, Aldrich Chemical Co. or MSD Labs and were used as received, unless otherwise noted. CO was obtained from Matheson. Solvents used outside the glove-box were used as received without further drying or purification unless otherwise noted. Water was triply distilled and deionized while D_2O and d_6-DMSO were degassed on a high-vacuum line (three freeze-pump-thaw cycles) in a tube fitted with a Teflon stopcock. Solvents used within the glove-box were dried and degassed. The compounds: *trans*-Ir$(CO)(CH_3)(PPh_3)_2$ [9], *trans*-Ir$(CO)(CH_3)(TPPMSK)_2$ [10], $[Ir(CO)_3(PPh_3)_2]ClO_4$ [11], $[Ir(CO)_2(PPh_3)_3]ClO_4$ [11], TPPMS [12] and TPPMSK [10] were prepared as previously described.

Instrumental measurements

Infrared spectra were obtained on a Perkin–Elmer Paragon 1000 FT-IR using 0.5 mm NaCl or 0.1 mm CaF_2 (DMSO or H_2O) cells while solid-state spectra

* Author to whom correspondence should be addressed.

† Dedicated to Prof. Dr W. A. Herrmann on the occasion of his 50th birthday.

were recorded as KBr disks. All spectra are reported in wavenumbers (cm^{-1}). UV-visible spectra were obtained on a Hewlett Packard 8452A diode array spectrophotometer employing a quartz cuvette of 1 cm path length. All UV-visible data are reported in nanometers.

^1H and ^{31}P NMR spectra were recorded on Varian VXR-400 or 500 MHz spectrometers. ^1H NMR spectra were referenced to the deuterated solvent and all NMR spectra contained resonances corresponding to aromatic protons, but these resonances were not assigned. ^{31}P NMR spectra were referenced to an external sample of 85% H_3PO_4 in D_2O (reference was set to 0.0 ppm) and were proton decoupled. For ^1H and ^{31}P NMR spectra that were recorded in H_2O, a sealed D_2O reference was placed into the sample for signal locking. Solvent suppression techniques were utilized during the acquisition of ^1H NMR spectra in water. All chemical shifts (δ) are reported in ppm and all coupling constants (J) are reported in Hz.

trans-Ir(CO)(CH_3)(TPPMS)$_2$

93 mg of *trans*-Ir(CO)$(CH_3)(PPh_3)_2$ and 90 mg of TPPMS were suspended in 10 ml of THF. The solution was stirred for 3 days before collecting the product on a fine sintered glass filter where it was washed sequentially with THF, ether and hexane, yield 54 mg or 46%. ^{13}C NMR(DMSO-d_6) δ 1.2(s) ppm (decoupled). Elemental analysis found: C(46.51), H(3.68), P(5.76) and S(6.60) error limit $\pm$0.3%. Requires: C(46.43), H(3.39), P(6.31) and S(6.51) for a formula of *trans*-Ir(CO)$(CH_3)(P(C_6H_5)_2(C_6H_4SO_3Na\cdot\frac{1}{2}H_2O))_2$. The infrared and NMR properties of *trans*-Ir(CO)(CH_3)(TPPMS)$_2$ were consistent with PPh_3 [9] and TPPMSK [10] analogues (Table 1).

trans-Ir(CO)$(CH_3)L_2$ (L = TPPMSK *or* TPPMS) *with* O_2 *in DMSO*-d_6

NMR-scale solutions of *trans*-Ir(CO)$(CH_3)L_2$ (L = TPPMSK or TPPMS) in DMSO-d_6 were reacted with O_2 overnight to produce dioxygen complexes Ir(CO)$(CH_3)(O_2)L_2$. The dioxygen complexes could not be deoxygenated under nitrogen. The spectral characteristics of Ir(CO)$(CH_3)(O_2)L_2$ (L = TPPMSK or TPPMS) (Table 1) were similar to Ir(CO)$(CH_3)(O_2)(PPh_3)_2$ [9].

trans-Ir(CO)(CH_3)(TPPMS)$_2$ *in water as a function of time*

Using the method previously described for preparing NMR scale samples, a 0.02 molar aqueous chilled solution of *trans*-Ir(CO)(CH_3)(TPPMS)$_2$ was flame sealed while under vacuum. ^{31}P and ^1H NMR spectra were recorded over time at 50°C. Almost immediately after sealing the NMR tube, CH_4 was observed. Analysis of the solution shortly after, revealed *trans*-Ir(CO)(OH)(TPPMS)$_2$ [13] and CH_4 with no *trans*-Ir(CO)(CH_3)(TPPMS)$_2$ present.

Analyses conducted 1.25 h, 2 h and 3 days later revealed no new products. The NMR tube was opened and the infrared spectrum and pH were recorded (pH = 8.6). To complete the characterization of the iridium product, the water was removed by vacuum and the residue dissolved in DMSO-d_6 and combined with 10 mg of *trans*-Ir(CO)(CH_3)(TPPMS)$_2$ for NMR characterization. The ^1H NMR and ^{31}P NMR spectra clearly showed equal quantities of *trans*-Ir(CO)(OH)(TPPMS)$_2$ and *trans*-Ir(CO)(CH_3)(TPPMS)$_2$. The pH and spectral characteristics of *trans*-Ir(CO)(CH_3)(TPPMS)$_2$ in H_2O were identical to *trans*-Ir(CO)(OH)(TPPMS)$_2$ [10].

Kinetic investigations for reactions of *trans*-Ir(CO)(CH_3)(TPPMS)$_2$ *with* H_2O *and with* D_2O

In a 25 ml Schlenk flask, a 5×10^{-3} M stock solution of *trans*-Ir(CO)(CH_3)(TPPMS)$_2$ in DMSO was prepared, sealed with a rubber septum and removed from the glove-box. With the aid of a 250 μl Hamilton syringe, a 200 μl aliquot of stock metal solution was withdrawn from the sealed Schlenk flask and mixed with 3800 μl of degassed H_2O (or D_2O) in a 1-cm quartz cell adapted for air-sensitive work. Utilizing conventional UV-visible spectroscopic techniques, absorption changes were monitored at 404 nm [14] for the disappearance of *trans*-Ir(CO)(CH_3)(TPPMS)$_2$ as a function of time for at least five half-lives.

The following rate constants were measured: $k_{obs} = 0.083 \pm 0.003$ s^{-1} (H_2O reaction) and $k_{obs} = 0.081 \pm 0.005$ s^{-1} (D_2O reaction).

trans-Ir(CO)$(CH_3)L_2$ (L = PPh_3, TPPMSK *or* TPPMS) *with* CO *in DMSO*-d_6

Solutions of *trans*-Ir(CO)$(CH_3)L_2$ (L = PPh_3, TPPMSK or TPPMS) were prepared in DMSO. Bubbling CO through the solutions for at least 2 h produced Ir$(C(O)CH_3)(CO)_2L_2$, Ir$(C(O)CH_3)(CO)_3L$ and L. Subjecting the mixture of Ir$(C(O)CH_3)(CO)_2L_2$, Ir$(C(O)CH_3)(CO)_3L$ and L to a N_2 purge for at least 1 h resulted in the disappearance of Ir$(C(O)CH_3)(CO)_3L$ and L, reduction in the amount of Ir$(C(O)CH_3)(CO)_2L_2$ and the appearance of Ir$(CO)_2(CH_3)L_2$ and *trans*-Ir(CO)$(CH_3)L_2$. The products from carbonylation and decarbonylation reactions (Table 1) were identical for analogous reactions involving PPh_3 and P(*p*-tolyl)$_3$ analogues reported in non-polar solvents [9,15].

Attempted carbonylation of impure *trans*-Ir(CO)(CH_3)(TPPTS)$_2$ *in* H_2O

Using NMR scale procedures, an aqueous solution containing 23% *trans*-Ir(CO)(OH)(TPPTS)$_2$, 51%

[a] DMSO; [b] DMSO-d_6; [c] H_2O; [d] solution contained 44.8% *trans*-$Ir(CO)(CH_3)$(TPPMS)$_2$, 25.2% *trans*-$Ir(CO)(OH)$(TPPMS)$_2$, 17.1% $[Ir(CO)_2$(TPPTS)$_3]OH$, 12.8% $Ir(CO)_2(CH_3)$(TPPMS)$_2$ and initially 5% TPPMS added; [e] solution contained 23.3% *trans*-$Ir(CO)(OH)$(TPPTS)$_2$, 50.9% *trans*-$Ir(CO)(CH_3)$(TPPTS)$_2$ and initially 17.4% TPPTS; [f] D_2O; [g] solution contained 79% $Ir(C(O)CH_3)(CO)_2$(TPPMS)$_2$, 21% $[Ir(CO)_2$(TPPMS)$_3]OH$ and initially 5% TPPMS added; [h] solution contained 41% $Ir(CO)_2(CH_3)$(TPPMS)$_2$, 33% $Ir(C(O)CH_3)(CO)_2$(TPPMS)$_2$, 26% $[Ir(CO)_2$(TPPMS)$_3]OH$ and initially 5% TPPMS added; [i] solution contained 51.3% $[Ir(CO)_2$(TPPTS)$_3]OH$, 28.3% $Ir(CO)_2H$(TPPTS)$_2$, 10.8% $Ir(C(O)CH_3)(CO)_2$(TPPTS)$_2$, 9.5% $[Ir(CO)_3$(TPPTS)$_2]OH$ and 17% TPPTS (initially).

trans-$Ir(CH_3)(CO)$(TPPTS)$_2$ and 17% TPPTS (obtained by TPPTS exchange for PPh_3 on *trans*-$Ir(CO)(CH_3)(PPh_3)_2$ in a biphasic reaction) was subjected to a CO atmosphere. Analysis of the product after 2 h showed $[Ir(CO)_2$(TPPTS)$_3]^+OH^-$ (51%), $Ir(CO)_2H$(TPPTS)$_2$ (28%), $Ir(C(O)CH_3)(CO)_2$(TPPTS)$_2$ (11%) and $[Ir(CO)_3$(TPPTS)$_2]^+OH^-$ (9%). The spectroscopic properties of $[Ir(CO)_2$(TPPTS)$_3]^+OH^-$, $[Ir(CO)_3$(TPPTS)$_2]^+OH^-$, $Ir(CO)_2H$(TPPTS)$_2$ and $Ir(C(O)CH_3)(CO)_2$(TPPTS)$_2$ correlated well with those of their PPh_3 analogues (Table 1).

trans-$Ir(CO)(CH_3)$(TPPMS)$_2$ *with 5% added* TPPMS *and excess* CO *in* H_2O

An aqueous solution of *trans*-$Ir(CO)(CH_3)$(TPPMS)$_2$ containing 5% TPPMS (prepared using NMR-scale procedures) was subjected to a CO purge for 2 h. Solution analysis revealed $Ir(C(O)CH_3)(CO)_2$(TPPMS)$_2$ (79%) and $[Ir(CO)_2$(TPPMS)$_3]^+OH$ (21%). The infrared and NMR properties of $Ir(C(O)CH_3)(CO)_2$(TPPMS)$_2$ in H_2O (Table 1) were similar to $Ir(C(O)CH_3)(CO)_2(PPh_3)_2$ [9], $Ir(C(O)CH_3)(CO)_2(P(p\text{-tolyl})_3)_2$ [9] and nearly identical to $Ir(C(O)CH_3)(CO)_2L_2$ (TPPMSK and TPPMS) in DMSO-d_6 (Table 1). Subjecting the product mixture to a N_2 purge for 2.5 h resulted in some decarbonylation ($Ir(CO)_2(CH_3)$(TPPMS)$_2$ (40%), $Ir(C(O)CH_3)(CO)_2$(TPPMS)$_2$ (32%), $[Ir(CO)_2$(TPPMS)$_3]OH$ (25%), *trans*-$Ir(CO)(CH_3)$(TPPMS)$_2$ (2%) and a trace of *trans*-$Ir(CO)(OH)$(TPPMS)$_2$). The spectral characteristics of $Ir(CO)_2(CH_3)$(TPPMS)$_2$ were consistent with the PPh_3 and P(*p*-tolyl)$_3$ analogues [9,15] and corresponding analogues in DMSO-d_6 from Table 1.

RESULTS AND DISCUSSION

Synthesis

The methyl complex of TPPMS (*trans*-$Ir(CO)(CH_3)$(TPPMS)$_2$) is prepared by ligand exchange on

trans-$Ir(CO)(CH_3)(PPh_3)_2$ (eqn (1)), using stoichiometric amounts of

$$\textit{trans}\text{-}Ir(CO)(CH_3)(PPh_3)_2 + 2L \xrightarrow{THF} \textit{trans}\text{-}Ir(CO)(CH_3)L_2(\downarrow) + 2PPh_3L = TPPMS \quad (1)$$

TPPMS and *trans*-$Ir(CO)(CH_3)(PPh_3)_2$, where *trans*-$Ir(CO)(CH_3)(TPPMS)_2$ precipitates slowly in THF. The characterization data shown in Table 1 confirm the product formulation.

In DMSO the reactions of *trans*-$Ir(CO)(CH_3)(TPPMS)_2$ with CO, H_2 and O_2 are completely analogous to the reactions of *trans*-$Ir(CO)(CH_3)(PPh_3)_2$ in organic solvents. Studies of reactions of *trans*-$Ir(CO)(CH_3)(TPPMS)_2$ in water are impeded by rapid hydrolysis [18].

$$\textit{trans}\text{-}Ir(CO)(CH_3)L_2 + H_2O \rightarrow \textit{trans}\text{-}Ir(CO)(OH)L_2 + CH_4$$
$$L = TPPMS \quad (2)$$

The presence of free TPPMS slows the hydrolysis such that the complex can be characterized in water and carbonylation can be examined. Rate studies on the hydrolysis in the absence of TPPMS give a rate constant of $(1.5 \pm 0.2) \times 10^{-3}\ s^{-1}\ M^{-1}$ and do not show a large deuterium isotope effect from D_2O. Attempts to prepare *trans*-$Ir(CO)(CH_3)(TPPTS)_2$ from *trans*-$Ir(CO)(CH_3)(PPh_3)_2$ by biphasic exchange in toluene/H_2O produced a mixture of the hydroxy and methyl complexes. However, previous characterization of the hydroxy complex allowed spectroscopic characterization of *trans*-$Ir(CO)(CH_3)(TPPTS)_2$ (see Table 1).

Carbonylation of *trans*-$Ir(CO)(CH_3)(TPPMS)_2$ containing a 5% excess of TPPMS shows competition between hydrolysis ($Ir(CO)_2(TPPMS)_3^+$ in 21% yield) and carbonylation with $Ir(C(O)CH_3)(CO)_2(TPPMS)_2$ formed in 79% yield. This experiment demonstrates that carbonylation of an iridium alkyl occurs in water giving the acyl which is not hydrolyzed, consistent with the effectiveness of hydroformylation in water with $HRh(CO)(TPPTS)_3$ with a large excess of TPPTS[2–4].

Purging the mixture of $Ir(C(O)CH_3)(CO)_2(TPPMS)_2$ and $Ir(CO)_2(TPPMS)_3^+$ in water with N_2 for 2.5 h leaves the cationic complex unchanged and forms some $Ir(CO)_2(CH_3)(TPPMS)_2$. While neither $Ir(C(O)CH_3)(CO)_2(TPPMS)_2$ or $Ir(CO)_2(CH_3)(TPPMS)_2$ were isolated the spectroscopic characterizations are very similar to the reactions in DMSO and analogous reactions of PPh_3 complexes in organic solvents (see Table 1) [9]. Indeed, except for hydrolysis of *trans*-$Ir(CO)(CH_3)(TPPMS)_2$, the carbonylation of *trans*-$Ir(CO)(CH_3)L_2$ (L = TPPMS, P(*p*-tolyl)$_3$ and PPh_3) is unchanged from solvents such as toluene to DMSO and water. Figure 1 shows a ^{31}P spectrum of carbonylation of *trans*-$Ir(CO)(CH_3)(TPPMS)_2$ in an NMR tube (limited CO).

Two aspects of the hydrolysis of *trans*-$Ir(CO)(CH_3)(TPPMS)_2$ are quite interesting. First, the reaction is inhibited by TPPMS and second, the five-coordinate methyl complex, $Ir(CO)_2(CH_3)(TPPMS)_2$ does not appear to hydrolyze. We have previously suggested that square-planar iridium complexes exist in H_2O with a hydrogen bond along the *z* axis [19]. If such hydrogen bonding provides the route to hydrolysis of *trans*-$Ir(CO)(CH_3)(TPPMS)_2$ then excess TPPMS could block the site and slow hydrolysis. Such hydrogen bonding does not exist for five-coordinate iridium complexes [19]. A similar protonated square-planar platinum intermediate was suggested for reductive elimination of CH_4 from reaction of HCl with $Pt(Cl)(CH_3)(PEt_3)_2$ in CH_3OH [20–22]

In reactions with O_2 and H_2 in DMSO, *trans*-$Ir(CO)$

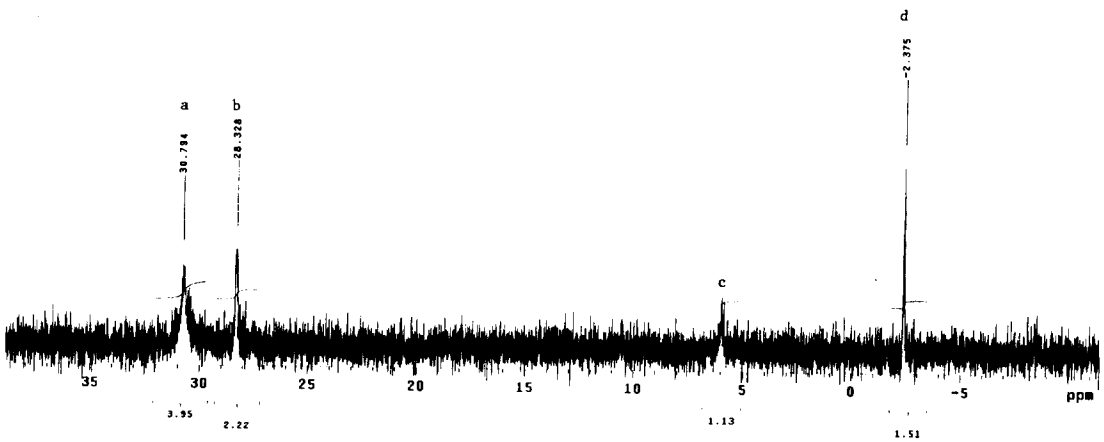

Fig. 1. A ^{31}P NMR spectrum of *trans*-$Ir(CO)(CH_3)(TPPMS)_2$ in D_2O with 5% added TPPMS in the presence of 0.74 atm of CO. The peak labeled (a) is *trans*-$Ir(CO)(CH_3)(TPPMS)_2$, (b) is *trans*-$Ir(CO)(OH)(TPPMS)_2$, (c) is $Ir(CO)_2(CH_3)(TPPMS)_2$ and (d) is $[Ir(CO)_3(TPPMS)_2^+][OH^-]$.

$(CH_3)(TPPMS)_2$ behaves just as the PPh_3 analogues with $Ir(CO)(CH_3)(O_2)(TPPMS)_2$ (Table 1) formed irreversibly with O_2 and methane eliminated from reaction with H_2. With the concentration of H_2 significantly lower, the *fac*- and *mer*-$Ir(CO)(H)_3(TPPMS)_2$ complexes are accompanied by $Ir(CO)(H)(TPPMS)_3$.

CONCLUSION

Methyl iridium complexes containing water-soluble phosphine ligands react with H_2, CO and O_2 much like their PPh_3 analogues, but have the additional complication in H_2O of hydrolysis of the Ir—CH_3 bond. The hydrolysis is inhibited by excess ligand and apparently occurs only for the square-planar complex.

(Received 13 August 1997; accepted 26 November 1997)

Abstract—Investigation of the coordination conditions at the 2,6-bis(diphenylphosphinomethyl)pyridine-rhodium(I) fragment $[Rh(PNP)]^+$ by X-ray crystallography showed a square planar geometry of the neutral chloro and the cationic piperidine complexes, [Rh(PNP)Cl] (**1**) and $[Rh(PNP)(pip)]BF_4$ (**2**). New cationic rhodium(I) complexes [Rh(PNP)L]X (L = pyridine, X = SO_3CF_3 **3**; L = CH_3CN, X = SO_3CF_3 **4a**, X = BF_4 **4b**; L = DMSO, X = SO_3CF_3 **5**) have been synthesized from the ethylene complexes $[Rh(PNP)(C_2H_4)]X$ by substitution of the ethylene by the ligand L (L = py, CH_3CN, or DMSO). The complexes **3–5** were characterized by IR spectroscopy, ^1H-, ^{13}C-, and ^{31}P-NMR spectroscopy and X-ray crystallography. The influence of the ligands on the structure of the complexes was investigated. The *cis* influence was determined by measurement of the coupling constant J_{P-Rh} and the average length of the Rh—P bonds and the *trans* influence by the length of the Rh—N(1) bond. © 1998 Elsevier Science Ltd. Keywords: cationic rhodium(I) complexes; 2,6-bis(diphenylphosphinomethyl)pyridine; X-ray crystal structure analyses; ethylene substitution; *cis* and *trans* influence.

The hydroamination of olefins, that is the N–H addition at the C–C double bond represents the simplest amine synthesis. It is especially interesting from the point of view of atom economy, since no by-product is formed (cf. eqn (1)). Although during the last decades several catalytic routes have been discovered using structurally different catalysts, until now no convenient catalyst for the hydroamination of olefins is known [1].

We have found that the cationic ethylene rhodium(I) complex $[Rh(C_2H_4)(PPh_3)_2(Me_2CO)]PF_6$, is the first complex which catalyzes the addition of secondary amines such as piperidine to the ethylene at

room temperature and under normal pressure [2,3], but only a low productivity is reached.

Using the tridentate ligand 2,6-bis(diphenylphosphinomethyl)pyridine (PNP) [4] cationic olefin rhodium(I) complexes [Rh(PNP)(olefin)]X (olefin = ethylene, styrene; X = BF_4, PF_6, CF_3SO_3) have been synthesized and characterized as model compounds for the catalyst complex [5]. The corresponding amine complexes [Rh(PNP)(HNR_2)]X (HNR_2 = piperidine, $HNMe_2$, $HNEt_2$) were obtained from the olefin complexes and secondary amines by substitution of the olefin without attack at the C–C double bond [5]. These Rh(PNP) complexes have been used as models to study the course and mechanism of the catalytic reaction.

In this paper we present the X-ray structure analyses of the neutral chloro-complex [Rh(PNP)Cl] [6] and the cationic piperidine complex [Rh(PNP)(pip)]BF_4 [5], report the synthesis and characterization of further monoligand complexes [Rh(PNP)L]X, and give a comparison of the structure of Rh(PNP) complexes as they change with the ligand variation.

EXPERIMENTAL

General

All reactions were carried out under dry argon. Ethanol, acetone and acetone-d_6 were refluxed over 4 Å molecular sieves and degassed by bubbling argon. Toluene, THF and diethyl ether were refluxed over Na/benzophenone and toluene-d_8 over K/Na alloy. Pyridine, acetonitrile and DMSO were dried over 4 Å molecular sieves and distilled before use.

Infrared spectra were recorded in nujol ([Rh(PNP)Cl] **1**) or as KBr pellets (cationic complexes **2**–**5**) on a Perkin-Elmer FT-IR 16 spectrometer. The ^{1}H-, ^{13}C-{^{1}H}, and ^{31}P{^{1}H}-NMR spectra were recorded at 300, 75, and 121 MHz respectively, on a Varian Gemini 300 NMR spectrometer. The ^{1}H- and ^{13}C-NMR shifts were referenced to the resonance of the residual protons of the solvents. The ^{31}P-NMR shifts were referenced to an external reference of 85% H_3PO_4. Elemental analyses of C, H and N were carried out on a LECO CHN 932 analyzer and Rh was determined using a photometric method [7].

The complex [{RhCl(COT)$_2$}$_2$] (COT = cyclooctene) was prepared according to the procedure in [8].

Synthesis of [Rh(PNP)Cl] (**1**)

The procedure described in [6] was slightly modified: A solution of 4.1 g (8.6 mmol) of 2,6-bis(diphenylphosphinomethyl)pyridine in 200 ml of toluene was added dropwise to a solution of 3.1 g (8.6 mmol) of [{RhCl(COT)$_2$}$_2$] in 200 ml of toluene over 5 hours. The resulting suspension was stirred overnight. The mixture of yellow and red solids which precipitated was filtered off and washed with 30 ml of ethanol to obtain the crude red product. Another fraction was obtained crystallized by concentration of the mother liquor (toluene solution) to 30 ml under reduced pressure. Both fractions were collected and recrystallized from refluxing toluene.

Yield: 2.6 g (4.3 mmol, 50%). M.p.: 230°C. ^{31}P-NMR δ (ppm) in toluene-d_8: 21.4, ($J_{P\text{-}Rh}$ = 152 Hz).

Synthesis of [Rh(PNP)(pip)]BF_4 (**2**)

The complex **2** was obtained from the reaction of [Rh(PNP)(C_2H_4)]BF_4 with an excess of piperidine according to the procedure in [5].

Synthesis of [Rh(PNP)[(py)]SO_3CF_3 (**3**)

1 ml (12 mmol) of pyridine was added to a suspension of 926 mg (1.2 mmol) of [Rh(PNP)(C_2H_4)]-SO_3CF_3 [5] in 15 ml of THF. The solid dissolved with evolution of gas and the solution changed in colour to orange. After stirring for 1 h the reaction mixture was filtered and the crude product was precipitated by dropwise addition diethyl ether to the filtrate. The orange-yellow solid was collected by filtration, washed with diethyl ether and dried in vacuum. The crude product was recrystallized from refluxing THF.

Yield: 716 mg (0.89 mmol, 74%). M.p.: 191°C. Found: C, 55.31; H, 3.80; N, 3.64; Rh 13.07. Calc. for $C_{37}H_{32}F_3N_2O_3P_2RhS$: C, 55.10; H, 3.99; N, 3.47; Rh, 12.76%. IR ν (cm^{-1}): 1604, 1564 (py); 1266, 1224, 1154, 1030, 638, 572 (CF_3SO_3). ^{1}H-NMR: δ (ppm): 4.36 (vt, N = 4.4 Hz, 4H, CH_2P), 7.15 (t, $J_{H\text{-}H}$ = 7.5 Hz, 2H, py), 7.49–7.38 (m, 14H, py[PNP], Ph), 7.65–7.60 (m, 9H, py[PNP], Ph), 7.74 (t, $J_{H\text{-}H}$ = 7.9 Hz, 1H, py), 8.75 (d, $J_{H\text{-}H}$ = 5.0 Hz, 2H, py). ^{13}C-NMR: δ (ppm): 43.6 (vt, N = 12.7 Hz, CH_2P), 122.7 (vt, N = 5.8 Hz, 3,5-py[PNP]), 126.0 (s, 3,5-py), 129.8 (vt, N = 4.8 Hz, PC_{meta}), 131.3 (s, PC_{para}), 133.3 (vt, N = 7.2 Hz, PC_{ortho}), 137.3 (s, 4-py[PNP]), 137.4 (s, 4-py), 155.3 (s, 2-py), 163.8 (vt, N < 3 Hz, 2,6-py[PNP]).

Syntheses of [Rh(PNP)(CH_3CN)]X (X = SO_3CF_3 **4a**, X = BF_4 **4b**) *and* [Rh(PNP)(DMSO)]SO_3CF_3 (**5**)

The complex **4a** was prepared from the reaction of 862 mg (1.14 mmol) of [Rh(PNP)(C_2H_4)]SO_3CF_3 and 5 ml of acetonitrile and complex **4b** from 693.3 mg (1.00 mmol) of [Rh(PNP)(C_2H_4)]BF_4 and 5 ml of acetonitrile in 15 ml of THF respectively. The complex **5** was prepared from 805 mg (1.06 mmol) of [Rh(PNP)(C_2H_4)]SO_3CF_3 and 1 ml of DMSO in 15 ml of THF. The complexes **4a**, **4b** and **5** were isolated in the same manner described for the complex **3**, except that the crude products precipitated as oils upon dropwise addition of diethyl ether to the reaction solution.

The oils crystallized after several hours. The crude products were recrystallized from refluxing THF.

4a: Yellow-brown crystalline solid, yield: 779 mg (0.89 mmol, 78%). M.p.: 126–130°C. Found: C, 52.92; H, 3.89: N, 4.04; Rh, 13.04. 5: Yellow crystalline solid, yield: 763 mg (0.97 mmol, 91%). M.p.: 138–142°C. Found: C, 51.57; H, 4.34: N, 2.05; Rh, 12.18. Calc. for $C_{34}H_{33}F_3NO_4P_2RhS_2 \cdot 1/2\ (CH_3)_2CO$: C, 51.37; H, 4.43; N. 1.66; Rh, 12.22%. IR ν (cm^{-1}): 1600, 1562, (py); 1272, 1224, 1162, 1028, 636, 572 (CF_3SO_3); 1100 (DMSO). ^{1}H-NMR δ (ppm): 2.68 (s, 6H, CH_3), 4.51 (vt, N = 4.4 Hz, 4H, CH_2P), 7.59–7.54 (m, 14H, py, Ph), 7.86 (t, J_{H-H} = 7.8 Hz, 1H, py), 7.99–7.94 (m, 8H, Ph). ^{13}C-NMR δ (ppm): 44.2 (vt, N = 12.4 Hz, CH_2P), 50.6 (s, CH_3), 123.1 (vt, N = 5.3 Hz, 3,5-py), 130.1 (vt, N = 5.0 Hz, PC_{meta}), 132.2 (s, PC_{para}), 134.3 (vt, N = 6.8 Hz, PC_{ortho}), 140.5 (s, 4-py), 162.8 (vt, N < 3 Hz, 2,6-py).

X-ray structural analyses

A data collection and structure determination summary for the compounds **1**–**5** is given in Table 1. An empirical absorption correction for **1** and **5** (Ψ-scan, 10 reflections) and **2**, **3** and **4b** (SADABAS [9]) was applied. The structures were solved by Patterson methods and refined with a full matrix least-squares algorithm using the programs SHELXS-86 [10] and SHELXL-93 [11], respectively. Anisotropic displacement parameters for all nonhydrogen atoms were used. For compounds **1** and **5** the hydrogen atoms were placed in calculated positions and refined isotropically. The hydrogen atoms for the compounds **2**, **3** and **4b** could be located in difference Fourier syntheses and were included in the final cyclus of the refinement with isotropic displacement parameters. The numbering of the atoms for the 2,6-bis (diphenylphosphinomethyl)pyridine-rhodium(I) fragment $[Rh(PNP)]^+$ is the same for compounds **1**–**5**.

Further details of the crystal structure determination are deposited at the Fachinformationszentrum Karlsruhe, D-76344 Leopoldshafen-Eggenstein, and may be obtained by quoting the depository numbers CSD 407975 (**1**), CSD 407974 (**2**), CSD 407973 (**3**), CSD 407972 (**4b**), CSD 407971 (**5**).

RESULTS AND DISCUSSION

X-ray structure analysis of [Rh(PNP)Cl] (**1**) *and* [Rh(PNP)(pip)]BF_4 (**2**)

The structure of the chloro-PNP-rhodium(I) complex [Rh(PNP)Cl] (**1**) [6] represents the origin for further ligand variation at the $[Rh(PNP)]^+$ fragment. Therefore the characterization of **1** by X-ray crystallography is a contribution of fundamental importance for our model studies.

The chloro-complex **1** was prepared according to the literature procedure [6], except that toluene was used as a solvent. When the PNP ligand solution was added dropwise to the solution of $[\{RhCl(COT)_2\}_2]$ the yellow dinuclear complex $[Rh_2(PNP)_3]Cl_2$ as well as the red chloro-complex precipitated. The dinuclear complex could be separated by extraction of the mixture with ethanol, leaving the red chloro-complex **1** as a solid. Further concentration of the mother liquor (toluene solution) gave a further preciptate of **1**, from which X-ray quality single crystals could also be obtained. The melting point of 230°C and the characteristic IR bands for the pyridine ring vibrations at 1550 and 1586 cm^{-1} of **1** are in good agreement with the literature data [6]. In the ^{31}P-NMR spectrum a doublet appears at 21.4 ppm ($J_{P\ Rh}$ = 152 Hz). The molecular structure of the chloro-complex is shown in Fig. 1. The PNP ligand atoms and Cl are coordinated to the rhodium atom in a nearly square planar geometry. The N(1)–Rh–Cl(1) angle (178.10(12)°) is not significantly distorted from the linearity whereas the P(1)–Rh–P(2) (163.53(5)°) is relatively small due to the steric constraints of two five-membered rings formed by coordination of the PNP ligand at the rhodium atom. The Rh–Cl(1) distance (2.344(2) Å) is significantly shorter than that found, for example, in $[RhCl(PPh_3)_3]$ (red allotrope, 2.376(4) Å) [12].

As reported in [5], the X-ray crystal structure analysis of the cationic olefin complexes [Rh(PNP)(olefin)]BF_4 show a square planar coordination geometry of the complex cation without any close interaction of the Rh with the BF_4^- ion. The related piperidine complex [Rh(PNP)(pip)]BF_4 **2**, obtained from the reaction of the ethylene complex [Rh(PNP)(C_2H_4)]BF_4 with an excess of piperidine [5] is also without coordination interaction between the central atom and the anion. Single crystals suitable for X-ray crystal structure analysis were obtained from a solution of **2** in acetone overlayered with diethyl ether. The molecular structure of the complex cation of **2** is shown in Fig. 2. The Rh–N(2) distance (2.122(3)Å) is

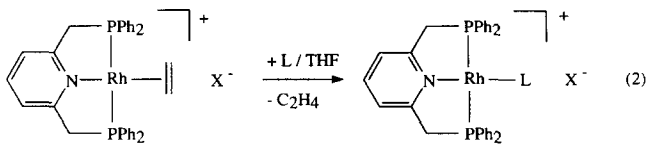
Synthesis and characterization of [Rh(PNP)L]X (L = py, X = SO_3CF_3 **3**; L = CH_3CN, X = SO_3CF_3 **4a**, X = BF_4 **4b**)

To investigate the variation of the *N*-bonding conditions ($Nsp^3 \rightarrow Nsp^2 \rightarrow Nsp$) at the $[Rh(PNP)]^+$ fragment the pyridine and acetonitrile complexes [Rh(PNP)L]X (L = py, X = SO_3CF_3 **3**; L = CH_3CN, X = SO_3CF_3 **4a**, X = BF_4 **4b**) were synthesized. The complexes $[Rh(PNP)(C_2H_4)]X$ (X = SO_3CF_3, BF_4) were used as starting compounds since they are easily accessible [5]. When an excess of the respective ligand L was added to a suspension of the ethylene complex in THF at room temperature it reacted immediately by displacement of ethylene, cf. eqn. (2).

The complexes **3**, **4a** and **4b** were obtained in good yields as crystalline solids which are stable in air and are soluble in acetone, THF, and ethanol and insoluble in diethyl ether and hydrocarbons such as toluene or hexane. In the IR spectrum of **3**, **4a** and **4b** the bands observed at about $\nu = 1603$ cm^{-1} and 1565 cm^{-1} indicate coordination of the pyridine ring of the tridentate PNP-ligand [4]. The different absorption bands for the $CF_3SO_3^-$ anion (see Experimental section) found in the spectra of the complexes **3** and **4a** as well the band at 1062 cm^{-1} found for the BF_4^- anion, suggest that these anions are not coordinated to rhodium [14,15], as was also found for the ethylene and piperidine complexes [Rh(PNP)L]X (L = C_2H_4, piperidine; X = SO_3CF_3, BF_4) [5]. The complexes **4a** and **4b** show the characteristic bands of coordinated acetonitrile at about 2280 and 2330 cm^{-1} [16].

The complexes **3**, **4a** and **4b** were further characterized by ^{31}P-, ^1H-, and ^{13}C-NMR spectroscopy. In



L = pyridine, X = CF_3SO_3 **3**
L = CH_3CN, X = CF_3SO_3 **4a**
X = BF_4 **4b**

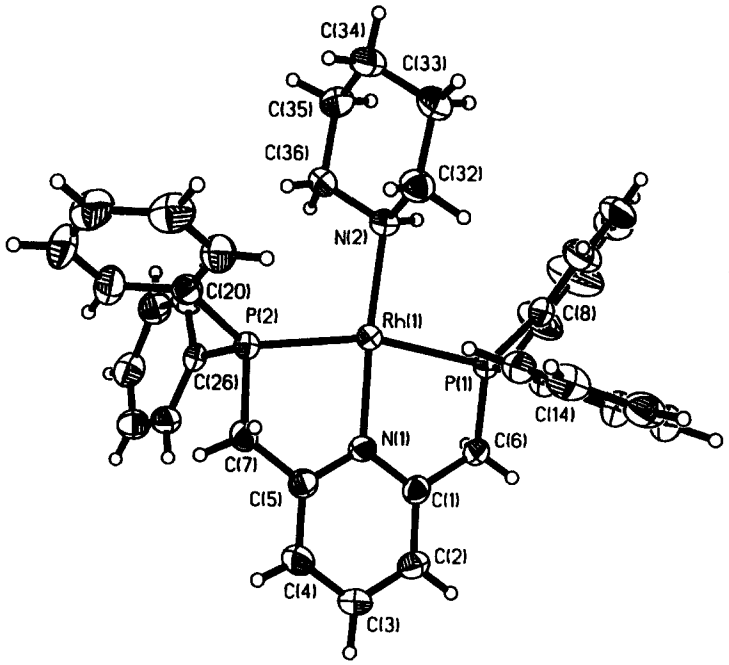


Fig. 2. ORTEP drawing structure of the cation of $[Rh(PNP)(pip)]BF_4$ **2**. Selected bond lengths [Å] and angles [°]: Rh—N(1) 2.062(3), Rh—N(2) 2.122(3), Rh—P(1) 2.2512(10), Rh—P(2) 2.3051(10), P(1)—C(6) 1.837(4), P(2)—C(7) 1.835(4), P(1)—Rh—P(2) 163.43(4), N(1)—Rh—P(1) 81.25(9), N(1)—Rh—P(2) 82.33(9), N(1)—Rh—N(2) 175.57(12), C(32)—N(2)—Rh 112.6(3), C(36)—N(2)—Rh 116.4(2).

the ^{31}P-NMR spectrum a doublet was found at 30.9 ppm ($J_{P\text{-}Rh}$ = 152 Hz) for **3**, 31.7 ppm ($J_{P\text{-}Rh}$ = 142 Hz) for **4a** and 30.6 ppm ($J_{P\text{-}Rh}$ = 143 Hz) for **4b**. The ^{1}H- and ^{13}C-NMR chemical shifts of the coordinated ligands (pyridine, acetonitrile) were shifted down field in comparison to the free ligand, as presented in Table 2.

Suitable single crystals of the pyridine complex **3** were obtained from a solution of the complex in acetone overlayered with diethyl ether while single crystals of **4b** were obtained from a concentrated solution of **4b** in acetone. The molecular structures of the complex cations $[Rh(PNP)(py)]^+$ and $[Rh(PNP)(CH_3CN)]^+$ are shown in Figs 3 and 4, respectively. Both exhibit a square planar coordination geometry. The X-ray crystal structure analyses of **3** and **4b** confirms the non-coordination of the $CF_3SO_3^-$ as well as the BF_4^- ions. The pyridine ligand in the complex **3** is nearly perpendicularly orientated to the coordination plane. An almost linear arrangement of Rh–N(2)–C(33)–C(32) is generated by the end-on coordination of the acetonitrile in the complex **4b** (C(33)–N(2)–Rh 173.7(3)°, N(2)–C(33)–C(32) 177.1(5)°) similar to that found for the structurally related cationic acetonitrile complex $[Rh(PPh_3)_3(CH_3CN)]BF_4$ (C–N–Rh 169.5(11)°, N–C–C 177.2(14)°) [17].

Table 2. ^{1}H- and ^{13}C-NMR chemical shifts of the free and coordinated ligands L (pyridine, acetonitrile) in **3** and **4a**

	^{1}H-NMR		^{13}C-NMR	
Ligand	Free	Coordn	Free	Coordn
Pyridine (**3**)	8.62, 7.69, 7.29	8.75, 7.74, 7.15	149.9, 136.2, 124.2	155.3, 137.4, 126.0
CH_3CN (**4a**)	1.93	2.40	118.2, 1.3	130.7 ($J_{C\text{-}Rh}$ = 11.4 Hz), 3.8

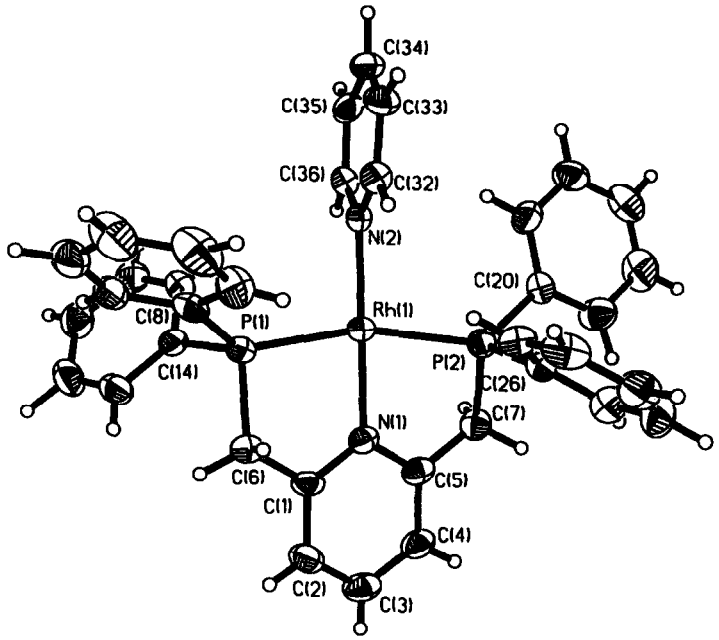

Fig. 3. ORTEP drawing structure of the cation of $[Rh(PNP)(py)]SO_3CF_3$ **3**. Selected bond lengths [Å] and angles [°]: Rh—N(1) 2.068(4), Rh—N(2) 2.063(4), Rh—P(1) 2.2705(12), Rh—P(2) 2.2819(13), P(1)—C(6) 1.835(5), P(2)—C(7) 1.836(5), P(1)—Rh—P(2) 163.06(4), N(1)—Rh—P(1) 83.12(10), N(1)—Rh—P(2) 81.20(10), N(1)—Rh—N(2) 177.37(14), C(32)—N(2)—Rh 122.9(3), C(36)—N(2)—Rh 120.3(3).

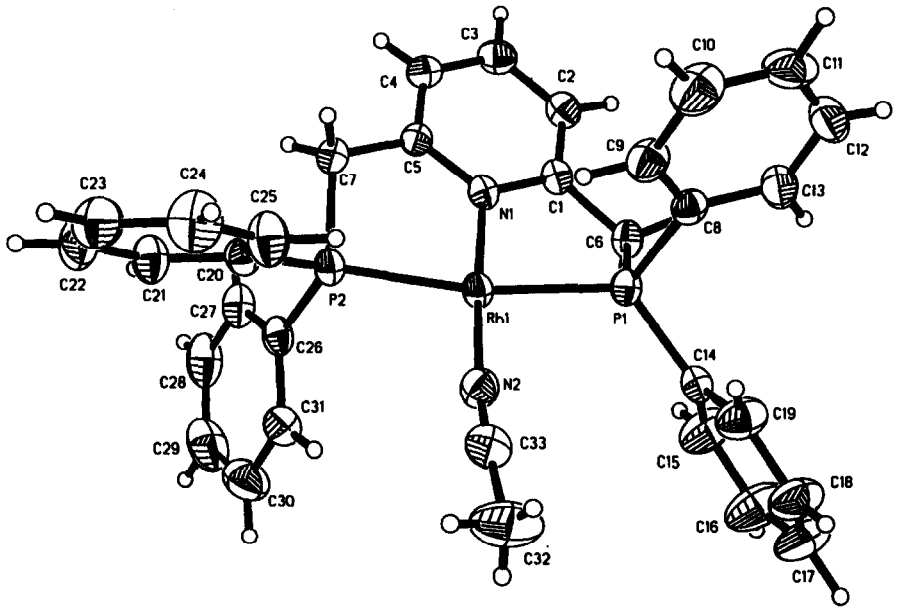

Fig. 4. ORTEP drawing structure of the cation of $[Rh(PNP)(CH_3CN)]BF_4$ **4b**. Selected bond lengths [Å] and angles [°]: Rh—N(1) 2.045(3), Rh—N(2) 1.984(3), Rh—P(1) 2.2648(8), Rh—P(2) 2.2770(8), P(1)—C(6) 1.828(3), P(2)—C(7) 1.838(4), P(1)—Rh—P(2) 166.34(4), N(1)—Rh—P(1) 82.82(7), N(1)—Rh—P(2) 83.54(7), N(1)—Rh—N(2) 175.53(14), C(33)—N(2)—Rh 173.7(3), N(2)—C(33)—C(32) 177.1(5).

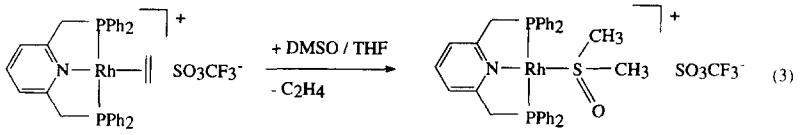
Comparing the Rh–N(2) distances in the *N*-donor ligand complexes [Rh(PNP)L]X (L = piperidine, pyridine, acetonitrile) a significant shortening of this bond length is observed according to the hybridization of the nitrogen atom ($Nsp^3 \rightarrow Nsp^2 \rightarrow Nsp$): 2.122(3) for **2**, 2.063(4) for **3** and 1.984(3) for **4b**.

Attempts at the preparation of O-donor ligand complexes

In a manner analogous to the synthesis of the *N*-donor complexes **2–4**, attempts were made to prepare complexes with strong *O*-donor ligands such as HMPT, DMSO and DMF from the ethylene complex $[Rh(PNP)(C_2H_4)]SO_3CF_3$. However, the ethylene could not be substituted by HMPT and DMF. Even after refluxing of the ethylene complex with an excess of HMPT or DMF in THF over several hours, only the starting complex could be isolated. Also acetone and THF both showed no tendency to coordinate. This is in contrast to the coordination of *O*-donor ligands to the rhodium(I) in the complexes $[Rh(C_2H_4)_2(solv)_2]^+$ (solv = THF, acetone) [18] or in the catalyst complex $[Rh(C_2H_4)(PPh_3)_2(Me_2CO)]PF_6$. This indicates the weak affinity of the rhodium(I) in the PNP-complex toward *O*-donor ligands, which are not able to compete with the coordinated ethylene. With HMPT the coordination may be additionally suppressed by steric hindrance as similarly observed for the sterically comparable di-*iso*-propylamine which also did not react with the ethylene complex [5].

DMSO, however, reacts immediately when it is added dropwise to a suspension of the ethylene complex in THF at room temperature. The reaction solution changed in colour to yellow and the evolution of gas was observed. However, the isolated complex proved to be an *S*-donor ligand complex (cf. eqn (3)) as shown by IR spectroscopy and X-ray crystal structure analysis (*vide infra*), cf. Fig. 5.



(3)

5

The complex $[Rh(PNP)(DMSO)]SO_3CF_3$ (**5**) is a yellow air stable crystalline solid. The complex was characterized by IR, ^{31}P-, ^1H-, and ^{13}C-NMR spectroscopy. In the IR spectrum of **5** the bands at 1600 and 1562 cm^{-1} indicate the coordination of the PNP pyridine ring while those of the triflate ion indicate its non-coordination as was observed for **3** and **4**. The band at 1100 cm^{-1}, assigned as $\nu(S{=}O)$, lies in the expected range for *S*-coordinated DMSO [19,20]. The ^{31}P-NMR spectrum exhibits a doublet at 36.7 ppm (J_{P-Rh} = 145 Hz). The ^1H-NMR signal of CH_3 of the coordinated DMSO at 2.68 ppm is shifted down field in comparison with the free molecule (2.49 ppm) as but not so far as it is expected for an *S*-bonded mode of DMSO [19].

X-ray quality single crystals were obtained from a solution of the complex in acetone overlayered with diethyl ether. The molecular structure of the complex cation of **5** is shown in Fig. 5. The Rh–S distance (2.1873(10) Å) is comparable to the Ru–S distance (2.188(3) Å) found in the Ru(II) complex $[Ru(NH_3)_3(DMSO)][PF_6]_2$ [21] which was described as particularly short. This may be an indication of a partial double bond character arising from d_π–p_π back donation from the metal to the sulfur. However, the S–O distance (1.473(3) Å) is not lengthened but lies within the range of the average bond length of *S*-coordinated sulfoxides [20].

Structural influences of L on the $[Rh(PNP)]^+$ fragment

In both ^{31}P NMR spectroscopy and the solid state structure, as determind by X-ray crystallography, of complexes of the type $[Rh(PNP)L]^+$ (L = Cl, py, CH_3CN, DMSO, olefin amine) the influence of different ligands on the Rh–P (*cis*) and Rh–N (*trans*) could be seen.

In Table 3 the ^{31}P-NMR results of the new cationic monoligand complexes **3–5** are assembled together with those of the chloro-, olefin, and amine PNP–rhodium(I) complexes. These are arranged in order of decreasing phosphorus–rhodium coupling constant J_{P-Rh}. Although in general the *cis* influence of a ligand is expected to be relatively small compared to its *trans* influence [22, 23] and the coupling constant J_{P-Rh} reflects only one aspect of the phosphorus–rhodium bond (primarily the s-orbital contribution to the bond order) the principal trend concerning the donor/acceptor strength can be seen in this series of the ligands. While for the σ-donor ligands (amines, chloride, and pyridine) relatively high values of J_{P-Rh} between 149 and 157 Hz were observed the phosphorus–rhodium coupling constant decreases with the increasing π-acceptor strength of the other ligands in the order: $DMSO \approx CH_3CN < C_2H_4 <$ styrene.

The influence of the negative charge of the chloro ligand can be seen in the significant up field shift to

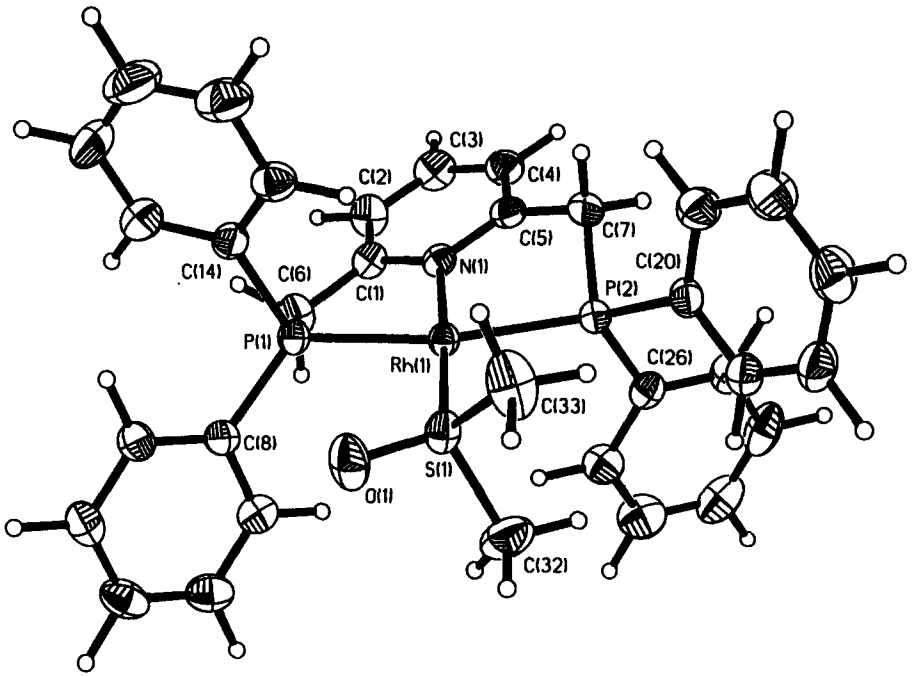


Fig. 5. ORTEP drawing structure of the cation of $[Rh(PNP)(DMSO)]SO_3CF_3 \cdot \frac{1}{2}(CH_3)_2CO$ **3**. Selected bond lengths [Å] and angles [°]: Rh—N(1) 2.093(2), Rh—S(1) 2.1870(9), Rh—P(1) 2.2696(8), Rh—P(2) 2.2884(8), S(1)—O(1) 1.474(3), S(1)—C(32) 1.786(4), P(1)—C(6) 1.839(3), P(2)—C(7) 1.841(3), P(1)—Rh—P(2) 163.76(3), N(1)—Rh—P(1) 81.84(7), N(1)—Rh—P(2) 81.91(7), N(1)—Rh—S(1) 177.48(7), O(1)—S(1)—Rh 118.76(10), C(33)—S(1)—Rh(1) 113.3(2), C(32)—S(1)—C(33) 100.5(2), O(1)—S(1)—C(32) 106.4(2).

Table 3. ^{31}P–NMR data of the PNP–rhodium(I) complexes

Complex		δ ppm	J_{P-Rh}[Hz]	Solvent

[Rh(PNP)Cl]	**1**	21.4	152	Toluene-d_8
$Rh(PNP)(py)]SO_3CF_3$	**3**	30.9	152	Acetone-d_6
$[Rh(PNP)(pip)]BF_4$	**2**	34.9	149	Acetone-d_6
$[Rh(PNP)(DMSO)]$-SO_3CF_3	**5**	36.7	145	Acetone-d_6
$[Rh(PNP)(CH_3CN)]BF_4$	**4b**	30.6	143	Acetone-d_6
$[Rh(PNP)(C_2H_4)]SO_3CF_3$	[5]	38.2	131	Acetone-d_6
$[Rh(PNP)(styrene)]BF_4$	[5]	41.7	126	Acetone-d_6

21.4 ppm. This is in contrast to the cationic complexes which are all observed at a lower field than 30 ppm. Since different structural and electronic factors of the neutral ligands have to be take into consideration it is difficult to explain completely the ordering of the ^{31}P-NMR shifts of the corresponding PNP complexes. However, comparing for example the pyridine and the styrene complexes (30.9 and 41.7 ppm, resp.) the main features of their bonding character are distinguishable, the strong σ-donating of the pyridine and the strong π-accepting property of the styrene, which seem to have an unambiguous effect on the total electron density of the $[Rh(PNP)]^+$ fragment.

Further information about the extent of the influence of the ligands on the structure of the complex fragment is obtained from the X-ray crystal structures of these complexes. In each of these complexes the PNP and the respective ligand L generates a nearly square planar coordination geometry (cf. Figs 1–5). In all cases a P(1)–Rh–P(2) angle of 163° was observed (cf. Table 4) comparable to that found in the olefin complexes of 161° [5]. Presumably, the geometric strain by the two five-membered rings formed by the coordination of the chelate PNP ligand at the rhodium atom does not allow any appreciable variation of the coordination geometry in the $[Rh(PNP)]^+$ moiety.

No significant distortion of the N(1)–Rh–L angle from linearity was observed with variation of the ligand L ranging from 178.10(12)° (Cl) to 175.55(14)° (pip). It is to be noted that in rhodium(I) complexes of the analogous type [Rh(ttp)(L)]X with the tridentate triphosphine ligand $PhP(CH_2CH_2CH_2PPh_2)_2$ (ttp), which forms two six-membered rings in the chelate structure, significant *trans* influence and steric distortion effects of a series of σ-donor and π-acceptor ligands L were distinguishable [24].

While the influence of the ligands L on the distortion from the planar coordination geometry is not pronounced in the Rh(PNP) complexes an influence

[Rh(PNP)(pip)]BF_4	2.062(3)	2.2512(10) 2.3051(10)	2.1212(3)	175.57(12)	163.43(4)
[Rh(PNP)(py)]SO_3CF_3	2.068(4)	2.2705(12) 2.2819(13)	2.063(4)	177.37(14)	163.06(4)
[Rh(PNP)(CH_3CN)]BF_4	2.045(3)	2.2648(8) 2.2770(8)	1.9884(3)	175.53(14)	166.34(4)
[Rh(PNP)(DMSO)]SO_3CF_3	2.093(2)	2.2696(8) 2.2884(8)	2.1873(10)	177.48(7)	163.76(3)
[Rh(PNP)(C_2H_4)]BF_4	2.092(4)	2.2690(13) 2.3001(13)	Rh—C(32) 2.142(6) Rh—C(33) 2.157(6)	N—Rh—C(32) 156.3(3) N—Rh—C(33) 166.8(2)	161.39(5)
[Rh(PNP)(styrene)]BF_4	2.102(3)	2.2916(10) 2.3004(11)	Rh—C(32) 2.144(5) Rh—C(33) 2.201(4)	N—Rh—C(32) 157.0(2) N—Rh—C(33) 165.8(2)	161.96(4)

on the Rh–N(1) and Rh–P bond length could be detected. An examination of the Rh–P bond length shows that in complexes bearing more bulky ligands such as piperidine or DMSO the bond length are significantly different. This feature is also found in the PEt_3 complex [Rh(ttp)(PEt_3)]AsF_6 [24] caused by intramolecular interaction between the ligand moiety and the phenyl rings of the diphenylphosphino groups.

However, on the ^{31}P-NMR time scale in each case the both phosphorus atoms of the PNP complexes are equivalent, and comparing the ordering of $J_{P\text{-}Rh}$ to the average of the Rh–P(1) and Rh–P(2) distances (2.261 Å Cl, 2.271 Å CH_3CN, 2.276 Å py, 2.278 Å pip, 2.279 Å DMSO, 2.284 Å C_2H_4, 2.296 Å styrene) a good agreement exists, reflecting the expected *cis* influence of the ligands.

The order of increasing Rh–N(1) bond length is also consistent with the expected strength of the *trans* influence of these ligands. The shortest Rh–N(1) bond length (2.040 Å), is found in the case of Cl^-, the σ-donor ligand with the highest electronegativity. On the other hand significant Rh–N(1) bond lengthening occurs with the *S*- and *C*-ligands with the lowest electro-negativity: 2.092 Å for DMSO, 2.092 Å for C_2H_4, and 2.102 Å for styrene. In general, however, the *trans* influence of these ligands observed in the Rh(PNP) complexes is scarcely larger than the *cis* influence.

CONCLUSION

In a manner analogous to the secondary amines it was shown that also the *N*-donor ligands pyridine and acetonitrile and the DMSO, as an *S*-donor ligand, can liberate the ethylene from [Rh(PNP)(C_2H_4)]X by the formation of the respective ligand complexes [Rh(PNP)L]X (L = py, CH_3CN, DMSO) which were fully characterized by ^{1}H-, ^{13}C-, and ^{31}P-NMR spectroscopy. On the other hand HMPT, DMF, THF and acetone are not able to displace the ethylene, indicating the weak affinity of the $[Rh(PNP)]^+$ fragment toward *O*-donor molecules. The results of the ^{31}P-NMR spectroscopy and X-ray crystal structure analyses of the chloro, amine, and olefin complexes allowed a *cis* and *trans* influence series to be established. The order Cl ≈ piperidine ≈ py < DMSO–CH_3CN < C_2H_4 < styrene observed from $J_{P\text{-}Rh}$ and the average Rh–P bond lengths in the Rh(PNP) complexes characterizing the *cis* influence is in good agreement with that of the *trans* influence on the Rh–N(1) bond length which is slightly pronounced. Both *cis* and *trans* influence of these ligands are obviously consistent with in general the expected order concerning their electronegativity. However, the $[Rh(PNP)]^+$ fragment must be characterized as a rigid complex moiety which is rather insensitive toward a variety of ligands.

Since the formation and the cleavage of a Rh–C σ-bond play an essential role in the catalytic cycle of the hydroamination of ethylene it is of interest to investigate its nature in the related organo–PNP–rhodium(I) complexes, which we have already prepared as further model compounds in this complex series which will be reported in another paper.

(Received 13 November, 1997; accepted 24 November 1997)

Abstract—The synthesis of the bis(dimethylsilyl)amide complexes $[MN(SiHMe_2)_2]$ (M = Li (**1**), Na (**2**), K (**3**)) was accomplished in high yield (>95%) by various standard procedures. Additionally, a novel trans-silylamination reaction has been applied to synthesize the sodium derivative **2**. The alkali metal amide complexes which are readily soluble in aliphatic hydrocarbons were characterised by means of IR and ^1H, ^{13}C and ^{29}Si NMR spectroscopy. A single crystal X-ray diffraction study of the sodium derivative **2** revealed the formation of an infinite, all-planar ladder structure. Compound **2** crystallizes from *n*-hexane at −35°C in the orthorhombic space group *Pnma* with $a = 5.4439(2)$ Å, $b = 15.7268(9)$ Å, $c = 10.9751(6)$ Å, $V = 939.63(8)$ Å^3 and $Z = 4$. Least squares refinement of the model based on 873 reflections converged to a final $\omega R_2 = 0.1124$. © 1998 Elsevier Science Ltd. All rights reserved

INTRODUCTION

Alkali metal silylamide complexes are convenient amide transfer reagents [1]. This synthetic approach has been thoroughly studied in the case of the $[N(SiMe_3)_2]$ group to isolate low-coordinated main group and transition monometallic complexes [2]. Compared to the dialkyl congeners, in particular LDA (lithium diisopropylamide) [3], their utilization in deprotonation reactions is limited. However, the changed nucleophilicity/basicity makes them still promising reagents in proton abstraction reactions involving substrates carrying valuable functional groups [4] and for the isolation of reaction intermediates [5]. The solid state chemistry of both solvent-free and solvated alkali metal amides not only revealed intriguing structural features such as ring-laddering [6], but often is an important parameter in terms of evaluating complex reactivity [7]. The solid state structures of $CMN(SiMe_3)_2]$, the most utilized silylamide complexes, have been studied in detail and their structural patterns as depicted in Fig. 1 seem to reflect not only ionic size effects [8–11]. Both the sodium and potassium derivative form close intramolecular $M\cdots CH_3$ contacts often termed agostic interactions [12].

Very recently we introduced the sterically reduced bis(dimethylsilyl)amide ligand, $N(SiHMe_2)_2$ [13], as a kinetically less restricted and spectroscopically prolific moiety into organo-f-element chemistry [14]. A detailed synthetic study on $La[N(SiHMe_2)_2]_3(thf)_2$

revealed that product formation is markedly affected by the nature and solvation of the alkali metal of the amide precursor [15], a fact well-known in salt elimination and proton abstraction applications [16]. Herein, we present synthetic, spectroscopic, and structural details of these novel alkali metal silylamide compounds.

RESULTS AND DISCUSSION

Synthesis and spectroscopy

The synthesis of the alkali metal amide complexes $[MN(SiHMe_2)_2]$ (M = Li (**1**), Na (**2**), K (**3**)) was accomplished according to well established procedures [3] as comprised in Scheme 1. In addition, a novel transsilylamination reaction was applied to prepare the sodium derivative **2**. The pK_a discrepancy of the parent silylamines [(pK_a(THF): 25.8 ($HN(SiMe_3)_2$), 22.6 ($HN(SiHMe_2)_2$)] [17] and the low Lewis acidity of the alkali metal cation facilitate such a transamination reaction [18]. Compounds **1**, **2** and **3** were obtained in almost quantitative yield and characterized by IR and NMR spectroscopy and elemental analysis. Compound **2** slowly dissolves in *n*-hexane, whereas the lithium and potassium derivative are readily soluble in aliphatic hydrocarbons, a behaviour which was previously ascribed to a strong ion-pairing interaction between the metal cation and the amide anion [10]. The melting points decrease in the order **3** (139–141°C) > **1** (127–129°C) > **2** (116–120°C). Upon melting all three silylamides decompose into a white solid which does not melt until 320°C.

The spectroscopic details of the silylamide ligands of a homologous series are known to reflect the extent of the ionic character of the M—N bonding [19]. Both the Si—H and Si—CH_3 magnetic resonances are shifted upfield in the case of the more ionic M—N bond of the larger alkali metal (Table 1). The decreased Si—H coupling, observed for the more ionic complex, is in accord with a weaker Si—H bonding and can be explained by an increased $p_\pi(N)$–$d_\pi(Si)$ back donation. This trend is further emphasized by the $\nu_{as}(NSi_2)$ vibration frequency within the homologous series (**1** (1060), **2** (1048), **3** (1098 cm^{-1}); solid state). The Si—H stretch vibration is often used as a meaningful probe for metal···(Si—H) agostic interactions [14,20]. The lithium and potassium silylamide **1** and **3** show a Si—H stretch vibration in the non-interacting range both in the solid state and in solution (Table 1) [21]. However, compound **2** shows a considerable shift to lower energy (1960 cm^{-1}) and the presence of a still lower energy shoulder at approximately 1930 cm^{-1} in the solid state, while only a very strong SiH stretch vibration at 2004 cm^{-1} appears in benzene solution. This supports the presence of Na···(Si—H) agostic interactions in the solid state. The non-agostic behaviour of **2** in solution is also consistent with the normal ^1J(Si,H) coupling constant of 164 Hz. Very recently Li···(Si—H) agostic interactions were reported for $[(SiHMe_2)_2CC(SiHMe_2)_2][Li(OEt_2)]_2$ and shown to be stable even in solution (ν(SiH) = 1937 cm^{-1}; ^1J(Si,H) = 141 Hz) [22]. Na···(Si—H) interactions have been noted earlier for the cage compound $[Na_B(O_3C_5H_{11})_6(SiH_3)_2]$ [23].

Solid state structure of $[NaN(SiHMe_2)_2]_n$ **(2)**

Due to the limited solubility of **2** in aliphatic hydrocarbons single crystals could be successfully grown from a saturated *n*-hexane solution at −35°C. The X-ray structure analysis revealed the formation of an all-planar, infinite ladder structure. Figures 2 and 3 show structure diagrams of a ladder segment arrangement and the long range packing, respectively. Tables 2 and 3 list selected bond lengths and angles and crystallographic parameters. The unit cell consists of two independent ladder segments, displaying no intermolecular interaction (distance >4 Å).

The core features, comprising a distorted rope ladder pattern, are emphasized in Fig. 2. Each ladder segment is composed of antiparallel Na—N rungs of equal lengths (2.456(2) Å) and parallel Na—N edges which deviate markedly in lengths. This indicates alternating covalent (2.449(3) Å) and donor bonding (3.115(3) Å), according to a vertical Na—N ··· Na—N ··· edge. The Na—N bond distances compare well with those of other sodium silylamides [24], as exemplified by the 2.355(3) Å in polymeric $[NaN(SiMe_3)_2]_n$ [9] or the 2.509(4) Å in dinuclear [LiNa $\{N(SiMe_3)_2\}_2(THF)_3$] [24f]. The long Na—N edge is longer than previously reported Na—N donor bond lengths (e.g., 2.54 Å in $[Na_{10}(NMe_2)_{10}(tmeda)_4]$) [25]

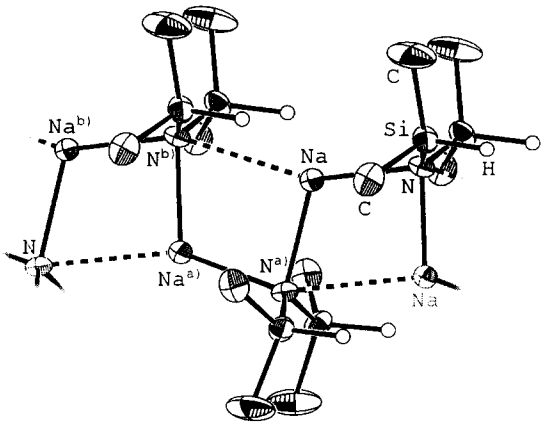

Fig. 2. Representative ORTEP style plot of polymeric $[NaN(SiHMe_2)_2]_n$ **(2)**. Thermal ellipsoids are drawn at the 50% probability level.

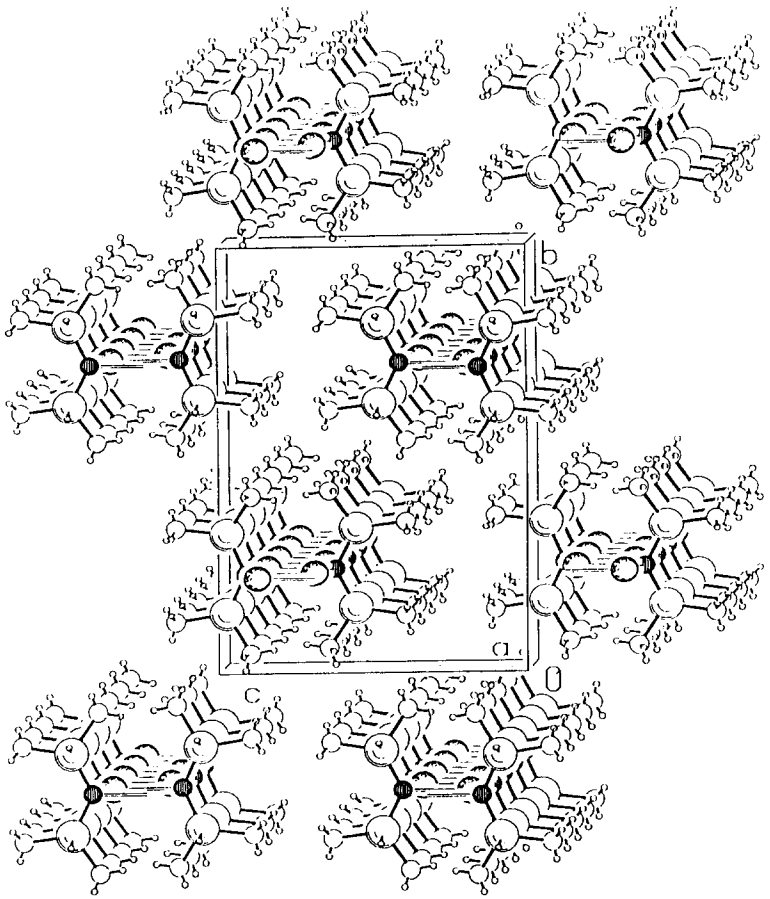

Fig. 3. Unit cell plot of polymeric $[NaN(SiHMe_2)_2]_n$ **(2)** along the crystallographic *a*-axis, showing the all-planar, all-stacked laddered structure.

and causes the significantly differing internal bridge angles NaN^bNa^a/N^a NaN^b and $NaN^bNa^a/NNaN^a$ of 84.5/92.6° and 71.5/111.4°, respectively (Fig. 2). The sodium and nitrogen core atoms are 3- and 5-coordinated, respectively, affording a T-shape coordination geometry at the sodium. Each two $SiHMe_2$ groups of the μ_3-amide moieties extend out of the all-planar arrangement in an all-transoid and all-stacked fashion (Fig. 3) which certainly minimizes the intramolecular steric hindrance. Simultaneously, this conformation allows for a perfect shielding of each side of the ladder core and brings the silicon hydrides pairwise within bonding distance of the donor-attached sodium cations. The $SiHMe_2$ groups are disordered with respect to the Si–N bond and could be resolved such that the positions near the donor-attached sodium cation are alternatively occupied by hydrogen atoms (82%) and methyl groups (18%) [26].

The observed $SiHMe_2$ orientation may be governed both by steric and electronic factors. On the one hand, location of the H atom at the disordered site results in a reasonably short Na···H distance of 2.51 Å, while methyl population affords improbably short Na···C distances (2.51(1) Å). This certainly argues in favour of steric restriction.

On the other hand, according to the solid state IR spectrum the formation of close $Na(\delta+)\cdots SiH(\delta-)$ contacts seems to be plausible, and therefore, might affect the orientation of the amide substituents, perhaps even direct the ladder arrangement. Close Si—H contacts with electron-deficient metal centers are meanwhile well-established and were shown to be very stable in the case of a diagostic interaction [14d]. Also low-coordinated alkali metal centers were often shown to extend their coordination sphere by, e.g., close $Na(\delta+)\cdots CH_3(\delta-)$ contacts [27]. Figure 4 emphasizes both the SiH positions and a possible diagostic interaction with the sodium atom, resulting in a formally 5-coordinated metal centre. However, the proposed Na···(Si—H) contacts should be considered as a loose diagostic interaction due to the spectroscopic results. A distinct widening of the Si—N—Si angle is not observed. Interestingly, the same overall structural features were found in $[Na(NC_4Me_4)]_n$ (**4**), a polymeric 2,3,4,5-tetramethyl-1-sodiopyrrole, which crystallizes in the monoclinic space group $P2_1/n$ [28]. A detail of the laddering in complex **4** is schematically redrawn in Fig. 4, representing that the electronically and sterically unsaturated sodium atoms are additionally coordinated by the π-system of the pyrrole rings.

The lateral connection of the planar trapezium-like ladder segments afford the all-planar band structure of **2**. In general, laddering is a well-known structural motif for alkali metal salts, bearing organic counter ligands such as alkyls, amides, alkoxides and phosphides [6,29,30]. Factors such as the size of the organic

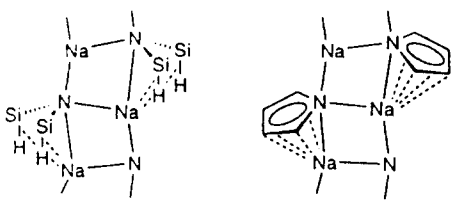

Fig. 4. Structural details of the laddering motifs of $[NaN(SiHMe_2)_2]_n$ (**2**) and $[Na(NC_4Me_4)]_n$ (**4**) [26]. The methyl groups at the silicon atoms are omitted for clarity.

counter ligand, the presence and type of coordinating coligands (chelating/non-chelating), and the presence of different alkali metal ions direct the formation and extent of laddering. Two previous contributions, featuring complex **4** [28] and an intermetallic ladder in $[LiNa\{N(CH_2Ph)_2\}_2(OEt_2)_2]$ (Na—N: rung, 2.398(3) Å; edge 2.539(3) Å) [31], revealed that sodium amides also tend to associate laterally. In contrast, the more bulky $SiMe_3$ substituents in $[NaN(SiMe_3)_2]_n$ counteract additional close Na—N donor bonding (Na···N, 5.297(3) Å) and the laddering motif is replaced at the expense of an infinite chain structure (Na—Na—Na, 141.98°; N—Na—N, 150.22°; Na—N—Na, 101.99°) [9]. However, the formally 2-coordinated sodium atoms in $[NaN(SiMe_3)_2]_n$ probably also form additional close intramolecular contacts to methyl groups as crystallographically evidenced for the isostructural $[Na\{CH(SiMe_3)_2\}]_n$ (Na···H, 2.40–2.65 Å) [32]. Comparison can also be drawn to the solid state structure of the most important amide derivative, LDA. The infinite helical arrangement of LDA shows nearly linear N—Li—N units (average 176°), exhibiting 2-coordinate lithium atoms [3]. Although the changed basicity of the $N(CHMe_2)_2$ and $N(SiHMe_2)_2$ ligands may affect the aggregation/bridging of the "$M(NR_2)$" monomers, these ligands are similarly sized and display similar coordination behavior, as evidenced by, e.g., M···(E—H) agostic interactions [33]. However, the smaller lithium metal sterically disfavours any N—Li—N bending and hence prevents laddering.

CONCLUSION

The bis(dimethylsilyl)amide ligand provides alkali metal complexes $[MN(SiHMe_2)_2]$ (M = Li, Na, K) which are readily soluble in aliphatic hydrocarbons. X-ray structure analysis revealed the formation of a rare infinite all-planar ladder structure of the sodium derivative. The existing all-stacked orientation of the $SiHMe_2$ in the solid state can be rationalized on the basis of steric and electronic considerations. The presence of an agostic Na···(Si—H) interaction is supported by the solid state IR spectrum of $[NaN(SiHMe_2)_2]_n$. We are currently exploiting the coordination behaviour of the $N(SiHMe_2)_2$ ligand towards other sterically and electronically unsaturated metal centres.

EXPERIMENTAL SECTION

The alkali metal amide complexes described below were handled under nitrogen using standard Schlenk, vacuum line and glovebox techniques. NaH and KH (Aldrich) were subsequently washed with toluene and *n*-hexane and dried *in vacuo*. $NaNH_2$, KNH_2 and $[NaN(SiMe_3)_2]$ were prepared according to the literature [34]. Physical measurements have been described previously [35]. Elemental analyses were performed by the microanalytical laboratory in Munich.

Bis(dimethylsilyl)amido lithium, **1**

1,1,3,3-Tetramethyldisilazane (20.00 g, 150.0 mmol) was placed in a 500 ml flask, dissolved in *n*-hexane (150 ml) and cooled to −78°C. Then a 1.6 molar solution of *n*-butyllithium in *n*-hexane (90.0 ml, 144 mmol) was added over a period of 30 min under vigorous stirring. After complete addition, the white suspension was allowed to warm up to ambient temperature, stirred for another 2 h and evaporated to dryness, leaving **1** (19.78 g, 142.0 mmol, 99%) as a voluminous white powder. IR (Nujol, cm^{-1}): 1990(br) vs, 1254 s, 1240 m, 1090 s, 1060 s, 948 m, 897 s, 820 m, 780 m, 749 m, 739 m, 696 w, 678 w, 644 w, 629 m, 600 w, 508 m; ^1H NMR (400 MHz, C_6D_6, 25°C): δ 4.65 (sp, $^1J(Si,H) = 168$ Hz, $^3J(H,H) = 2.8$ Hz, 2 H, SiH), 0.23 (d, $^3J(H,H) = 3.0$ Hz, 12 H, $SiCH_3$); $^{13}C\{^1H\}$ NMR (100.5 MHz, C_6D_6, 25°C): δ 3.60 (s, $SiCH_3$); $^{29}Si\{^1H\}$ NMR (79.5 MHz, C_6D_6): δ 28.64. $^{15}N\{^1H\}$ NMR (14.9 MHz, C_6D_6): δ—136. Anal. Calc. for $C_4H_{14}LiNSi_2$: C, 34.5; H, 10.1; N, 10.1. Found: C, 35.5; H, 9.7; N, 9.5.

Bis(dimethylsilyl)amido sodium, **2**

Method A. NaH (0.348 g, 14.50 mmol) was placed in a 50 ml flask, dispersed in *n*-hexane (10 ml) and cooled to −78°C. Then a solution of 1,1,3,3-tetramethyldisilazane (2.000 g, 15.00 mmol) in 15 ml of *n*-hexane was added over a period of 30 min under vigorous stirring, while gas evolution indicates the reaction. After complete addition, the white suspension is allowed to warm up to ambient temperature, stirred for another 2 h and evaporated to dryness, leaving **2** (2.207 g, 14.21 mmol, 98%) as a voluminous white powder.

Method B. According to method A with $NaNH_2$ (0.566 g, 14.50 mmol) instead of NaH. **2** is obtained as a white powder (2.196 g, 14.14 mmol, 98%).

Method C. According to method A with $[NaN(SiMe_3)_2]$ (2.659 g, 14.50 mmol) instead of NaH. **2** is obtained as a white powder (2.210 g, 14.22 mmol, 98%) and can be crystallized from *n*-hexane at −35°C as long needles. IR (Nujol, cm^{-1}) 2924 vs, 2853 vs, 2724 m, 1961 brm, 1926 (br)m, (2 × (Si—H)), 1460 vs, 1377 s, 1304 w, 1251 m, 1152 m, 1048 brs, 969 m, 889 s, 833 m, 782 m, 762 m, 722 s, 668 m, 629 w, 594 w; ^1H-NMR (400 MHz, C_6D_6, 25°C) 4.82 (br, s, 2 H, SiH), 0.26 (br, d, $^3J(H,H) = 22.2$ Hz, 12 H, $SiCH_3$); $^{13}C\{^1H\}$ NMR (100.5 MHz, C_6D_6, 25°C) 5.63 (s, $SiCH_3$); Anal. Calc. for $C_4H_{14}NNaSi_2$: C, 30.9; H, 9.1; N, 9.0. Found: C, 30.85; H, 8.8; N, 10.8.

Bis(dimethylsilyl)amido potassium, **3**

Method A. KH (0.582 g, 14.50 mmol) was placed in a 50 ml flask, dispersed in *n*-hexane (10 ml) and

cooled to −78°C. Then a solution of 1,1,3,3-tetramethyldisilazane (2.000 g, 15.00 mmol) in 15 ml of *n*-hexane was added over a period of 30 min under vigorous stirring, while gas evolution indicates the reaction. After complete addition, the white suspension was allowed to warm up to ambient temperature, stirred for another 2 h and evaporated to dryness, leaving **3** (2.477 g, 14.2 mmol, 98%) as a voluminous white powder.

Method B. According to method A with KNH_2 (0.799 g, 14.50 mmol) instead of KH. **3** is obtained as a white powder (2.458 g, 14.10 mmol, 98%). IR (Nujol, cm^{-1}): 1980 vs, 1308 w, 1254 s, 1149 sh, 1098(br) vs, 956 m, 930 s, 886 vs, 828 m, 813 m, 772 m, 752 m, 669 m, 638 w, 618 m, 580 w; ^1H NMR (400 MHz, C_6D_6, 25°C): δ 4.94 (sp, $^1J(Si,H) = 162$ Hz, $^3J(H,H) = 2.8$ Hz, 2 H, SiH), 0.26 (br, $^3J(H,H) = 2.6$ Hz, 12 H, $SiCH_3$); $^{13}C\{^1H\}$ NMR (100.5 MHz, C_6D_6, 25°C): δ 5.5 (s, $SiCH_3$); Anal. Calc. for $C_4H_{14}KNSi_2$: C, 28.0; H, 8.2; N, 8.2. Found: C, 28.3; H, 7.8; N, 8.25.

X-ray data collection, structure determination, and refinement for $[NaN(SiHMe_2)_2]_n$, **2**

Suitable single crystals of complex **2** were obtained from a saturated *n*-hexane solution at −35°C. The structure was solved by a combination of direct methods, difference-Fourier syntheses and least-squares refinements. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International Tables for X-Ray Crystallograpy*. All calculations were performed on a DEC 3000 AXP workstation with the STRUX-V system, including the programs PLATON-92, PLUTON-92, SIR-92 and SHELXL-93 [36].

A brief summary of the crystallographic data are reported in Table 3. Preliminary examination and data collection were carried out on an imaging plate diffraction system (IPDS; Stoe & Cie) equipped with a rotating anode (ENRAF NONIUS FR591; 50 kV; 60 mA) and graphite monochromated MoK_α radiation. The data collection was performed at 163 K within the θ-range of $4.18° < \theta < 25.58°$ with an exposure time of 7.5 min per image (oscillation scan modus from $\phi = 0.0°$ to 264° with $\Delta\phi = 1°$). A total number of 9555 reflections were collected. 873 systematic absent reflections were rejected from the original data set. After merging a sum of 873 independent reflections remained and were used for all calculations. Data were corrected for Lorentz and polarization effects. A correction for intensity decay effects (icing) with the program DECAY [36a] was applied. The unit cell parameters were obtained by least-squares refinements of 3804 reflections with the program CELL [36a]. All "heavy atoms" of the asymmetric unit were anisotropically refined. The methyl hydrogen atoms at C(1) and C(2) were refined free with one but fixed thermal parameter ($B_H = 1.2 \cdot B_C$). Hydrogen atoms at the silicon atom and the disordered (18%) carbon atoms were calculated in ideal positions (riding model; $d_{Si,H} = 1.50$ Å; $d_{C-H} = 0.98$ Å; $B_H = 1.2 \cdot B_{Si,C}$). Full-matrix least-squares refinements were carried out by minimizing $\Sigma\omega(F_o^2 - F_c^2)^2$ with SHELXL-93 weighting scheme and stopped at shift/err < 0.001. Further details of the crystal structure investigations are available on request from the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-76344 Eggenstein-Leopoldshafen 2, on quoting the depository number CSD-380 the names of the authors and the journal citation.

Organometallic chemical vapour deposition of cobalt/indium thin films using the single-molecule precursors $[(CO)_4Co]_aInR_{3-a}$ ($R = CH_2CH_2CH_2NMe_2$; $a = 1$–3)

Roland A. Fischer*, Jurij Weiß and Wolfram Rogge

Lehrstuhl für Anorganische Chemie II, Ruhr-Universität Bochum, D-44780 Bochum

(Received 30 October 1997; accepted 27 November 1997)

Abstract—Pure cobalt indium alloy thin films of the nominal compositions $Co_{0.50}In_{0.50}$, $Co_{0.66}In_{0.33}$ and $Co_{0.75}In_{0.25}$ were grown by OMCVD using volatile organometallic precursors of the general formula $[(CO)_4Co]_a$-InR_{3-a} [$R = CH_2CH_2CH_2N(CH_3)_2$; **1**: $a = 1$; **2**: $a = 2$; **3**: $a = 3$]. These organometallic compounds contain direct Co—In bonds and allow molecular control of the metal ratio of the grown films. The distribution of the metals were uniform throughout the films. The films were examined by AES depth profiling, SEM-EDX and X-ray diffraction. The phase composition of the films follows the phase diagram of the Co/In system, e.g. reflections of the crystalline phases Co, $CoIn_2$ and $CoIn_3$ were detected. Due to the multi-phase nature of the films, the coatings were unstable with respect to interfacial reactions with InP, e.g. the formation of CoP was observed by X-ray diffraction. © 1998 Elsevier Science Ltd. Keywords: OMCVD; cobalt; indium; thin alloy films.

The deposition of mixed metal thin alloy films is usually achieved by physical techniques like sputtering or evaporation. Chemical deposition methods, in particular organometallic chemical vapour deposition, offer among other benefits the possibility to use molecular precursors of low thermodynamic stability to deposit the material at comparably mild conditions. At low substrate temperatures (200–400°C) OMCVD processes are typically controlled by the kinetics of the surface reactions, relevant for the decomposition of the molecular precursors to yield the thin solid coating. Some examples exist showing, that specifically tailored so-called single molecule precursors may lead to metastable phases [1] or even novel materials, which cannot be made by traditional methods [2]. In extension of our ongoing studies of OMCVD of transition metal aluminides [3] and gallides [4,5] we selected the Co/In system for the studies presented here, because the binary Co/In system exhibits a large immiscibility gap.

Cobalt and indium peritectally form two crystallographically characterized intermetallic phases: $CoIn_2$ at 550°C (monoclinic; $a = 5.393$ Å, $b = 17.845$ Å, $c = 9.218$ Å, $\beta = 88.73°$), and $CoIn_3$ at 490°C (tetragonal; $a = 6.832$ Å, $c = 7.098$ Å) [6]. A phase Co_1In_1 described by A. N. Khalpova does not exist [7]. The phase diagram exhibits an immiscibility gap (from 23 to 75 At.-% indium) at the monotectical temperature of 1286°C [8,9]. Small single crystals of $CoIn_2$ and $CoIn_3$ were grown at the surface of solid cobalt grains disperged into molten indium at 400°C [10]. These cobalt indides can also be synthesized by rapid arc melting. We were interested to investigate the phase composition of Co/In films grown from organometallic single molecule precursors at even lower temperatures of 200–250°C. The precursor molecules employed in this study, $(CO)_4Co$-$In[(CH_2)_3NMe_2]_2$ **1** [11], $[(CO)_4Co]_2In[(CH_2)_3NMe_2]_2$ **2** [12] and $[(CO)_4Co]_3In$ **3** [13] contain a covalent direct Co—In bond (Scheme 1). By using this molecular approach the constituents of the alloy are already mixed together in an atomic scale. The precursors were synthesized by methods described elsewhere [11–13].

RESULTS AND DISCUSSION

Precise molecular control of the thin film composition

The deposition experiments were carried out using a common horizontal isothermal hot wall tube reactor filled with various substrates, typically with microscope slides made of borosilicate glass. The respective precursor (**1–3**) was sublimed through the heated tube *in vacuo* and the deposited coatings on the substrates were characterized analytically ex situ after the deposition *ex-situ*. Very pure (C, N, O < 1 at.-% by AES) mixed metal thin films representing the *exact* metal ratio Co:In of the organometallic precursor compound, e.g. 1:1, 2:1 and 3:1 (by AAS), were obtained independently from the settings of the OMCVD apparatus (see Tables 1 and 2, e.g. temperature of the oven and the precursor reservoir; pressure). The precursor compound quantitatively decomposes to yield the metallic coatings. Such an exact reproduction of the metal stoichiometry of the precursor in the films is not necessarily observed, when so-called mixed-metal single molecule precursors are used for OMCVD experiments. In the related cases of the deposition of β-CoGa films using $(CO)_4Co$-$Ga(C_2H_5)_2[N(CH_3)_3]$ [4] or ε-NiIn films using [η^5-C_5H_5](CO)Ni-In[$(CH_2)_3NMe_2$]$_2$ [14] thermally comparably stable organometallic fragments of low molecular weight, e.g. $Ga(C_2H_5)_3$ or (η^5-C_5H_5)In, are produced at the surface via the decomposition of the precursors and desorb before further fragmentation. This mechanism explains the formation of transition metal rich films M_1E_{1-x} (M = Co, Ni; E = Ga, In). In the case of the CoIn-precursors **1–3** however, a related mechanism which allows the "escape" of the indium as stable alkylindium compound, e.g. In[$(CH_2)_3NMe_2$]$_3$ [15], does not exist. The In—C_{alkyl} bond energy is rather low (ca 47 kcal mol^{-1}) and the splitting of the alkyl group is kinetically favoured by facile β-hydrogen elimination (Scheme 2). For example, when BrIn[$(CH_2)_3NMe_2$]$_2$ is passed through a hot quartz tube at 250°C *in vacuo*, InBr collects at the colder parts outside the tube quantitatively. Also, the azide derivative (N_3)In[$(CH_2)_3NMe_2$]$_2$ serves as low temperature single-molecule precursor for stoichiometric, polycrystalline InN [16]. These examples show, that the organometallic fragments {In[$(CH_2)_3NMe_2$]$_2$} as well as {In[$(CH_2)_3NMe_2$]} are ideally suited to release the In atom at low substrate temperatures, even below 250°C. The cobalt fragment, $\{(CO)_4Co\}$, is known to be thermally quite labile and splits off the CO-groups easily, releasing the Co atom. Under the quoted experimental conditions, there exists no mechanism to convert the transition metal constituent into a organometallic compound which is stable against further fragmentation. This explains why the metal ratios of the molecular precursors **1–3** are perfectly retained in the grown mixed-metal thin films.

Chemical purity

Thin films grown with precursor **1** were studied with respect to chemical purity in some detail. Table 1 contains the results of the chemical and spectroscopic thin film analysis. The level of impurities (C, H, N, O) is below 1 atom-% by elemental analysis of the collected macroscopic quantities (50–100 mg) of the alloy, which peeled off from the wall of the reactor upon rapid cooling. AES and depth profiling [Fig. 1(a), (b)] revealed that the signals for C, N and O were below the detection limits throughout the bulk of the

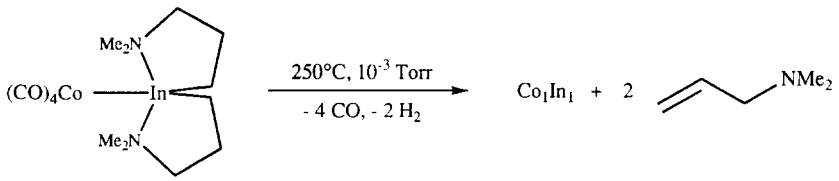
deposited coatings. The same was observed by EDX and WDX spectroscopy. A SIMS analysis of film #2 showed only the background signal for C and N throughout the bulk of the film [Fig. 1(c)]. A primary beam of oxygen ions was used for the SIMS experiment. Therefore Fig. 1(c) does not tell the contents of O-impurities in the film. The concentration of the impurities arising from the alkyl ligands (C and N) are thus certainly far below 1 atom-%. The occurrence of oxygen impurities in the AES spectra may be due to impure precursor samples as well as caused by the leaking rate of the OMCVD apparatus.

The use of carbonyl group (CO) containing precursors for OMCVD applications is still a matter of controversial discussion. In principle, CO molecules can dissociatively chemisorb at metal surfaces, which ultimatively will lead to a more or less severe incorporation of carbidic carbon and oxygen atoms into the growing film. This autocatalytic mechanism is very important for the growth of "early" transition metals, e.g. Ti, Cr or Mo, from carbonyl compounds [17]. In the case of "late" transition metals (Co, Ni), this mechanism is much less a problem [18]. Nothing is known to date about the chemisorption of CO on a mixed phase polycrystalline CoIn surface. But our results may at least indicate that the residual carbon impurities are likely to be graphitic or hydrocarbons (C : H ~ 1, by combustion analysis, see Experimental) but are not essentially carbidic. Firstly, high carbon contents never occur combined with high oxygen contents, but are accompanied with rather high hydrogen levels (measured by combustion analysis; see C/H ratios of Table 1). This situation is very similar to the case of the growth of β-CoGa films or mixed phase CoAs films using tetracarbonylcobaltato substituted alkylgallanes [4] or amidoarsanes, e.g. $(CO)_4CoAs[\eta^2$-$(^tBuNCH_2CH_2N^tBu)]$, respectively [19]. In summary the obtained Co/In films proved to be rather pure when compared to other metal films deposited from organometallic precursors under similar conditions [20].

Thin film morphology

Figure 2 shows SEM images of some representative but thick Co/In films of about 2 μm. A uniform coverage of the surface with dendritic grains of about 1 μm length and ca. 0.2–0.3 μm thickness can be seen. These grains proved to be of uniform composition using SEM-EDX (resolution: 300 × 300 nm) and AES (resolution: 50 × 50 nm). The growth of the films follows the model of Movchan and Demchishin [21] which



1

Scheme 2. Decomposition of precursor **1** during film growth.

explains the dendritic morphology as seen in the cross sectional view of the $Co_{0.75}In_{0.25}$ film [Fig. 2(c)]. The specific resistivity for the $Co_{0.75}In_{0.25}$ films were checked at room temperature with a standard four point probe (FP 2000 Fa. Veeco; AC current). Depending on the impurities and the size of the crystallites, resistivities ranging from 170–1000 $\mu\Omega$ cm were measured.

Crystallinity, phase identity and thin film reactions

The X-ray powder diffraction pattern of film $Co_{0.50}In_{0.50}$ [Fig. 3(a)] of Table 1 (sample #2) exhibits the characteristic reflections for the two stable intermetallic compounds of the Co/In systems $CoIn_2$ and $CoIn_3$. According to the Co/In phase diagram the 1 : 1 composition of the film requires elemental cobalt as the third phase. However, reflections due to crystalline Co could not be detected. Probably the respective reflections due to Co were too broad (very small crystallites) to be observed. For the cobalt rich films ($Co_{0.66}In_{0.33}$ and $Co_{0.75}In_{0.25}$) of Table 2 the X-ray diffraction patterns [Fig. 3(b), (c)] show evidence for $CoIn_2$ and $CoIn_3$ besides α-Co. Heating of the Co_3In alloy at 400°C in hydrogen atmosphere and the so achieved recrystallization results in sharpened XRD reflections as one would expect (larger crystallites). There was no indication for any other reflections arising from some novel, probably metastable CoIn phase. For the grown films an estimation of the typical crystallite size of about 1 μm length and 0.2–0.3 μm width was made based on the diffraction patterns and using Scherrer's formula [22].

Co/In films of a 1 : 1 metal ratio were deposited at 250°C on InP(100). The AES depth profile of such a $Co_{0.50}In_{0.50}$ film grown on InP showed the presence of a significant and constant concentration of P throughout the film and a ratio for Co : In of 0.67 rather than the expected 1.0. The presence of the crystalline phases CoP, $CoIn_2$ and $CoIn_3$ were affirmed by X-ray diffraction. As deduced from thermodynamics, the pure phases $CoIn_2$ and $CoIn_3$ should be rather stable with respect to chemical reaction at the interface [23,24]. The driving force of the segregation of large amounts of In and P into the growing film is the presence of "excess" metallic cobalt, which forms CoP and additional amounts of $CoIn_2$ and $CoIn_3$.

CONCLUSION

It was demonstrated that comparably pure Co/In films can be easily grown using the single molecule precursors **1**–**3**. These organometallic compounds contain direct Co—In bonds and labile bonded ancillary ligands. They allow unusually precise molecular control of the metal ratio of the grown films. The distribution of the metals were uniform throughout the films. The phase composition of the films follows the phase diagram of the Co/In system. No new Co/In phase could be detected. Due to the multi-phase nature of the films, e.g. the presence of excess Co, the coatings are unstable with respect to interfacial reactions with InP. An atomically abrupt interface CoIn/InP, which would be necessary for the construction of thermodynamically stable Schottky barriers useful for microelectronic devices and similar to related CoGa/GaAs heterostructures [21,22], cannot be formed with these films. The results however show, that related organometallic alkylindium derivatives of cobalt carbonyl complexes with a $CoIn_2$ stoichiometry may well be suited to yield sufficiently chemically pure single phased $CoIn_2$ films which should be stable on InP surfaces and may be interesting as metal contacts.

EXPERIMENTAL

Precursor preparation, characterization and handling

All manipulations were carried out under dry and oxygen-free nitrogen or argon atmosphere using oven-dried glassware. Solvents were freshly distilled from Na/K alloy. The synthesis of $[(CO)_4Co]_aInR_{3-a}$ [R = $CH_2CH_2CH_2N(CH_3)_2$; **1**: $a = 1$; **2**: $a = 2$; **3**: $a = 3$] on a typical scale of 10–20 mmol (5–10 g) has been described in detail elsewhere (see Scheme 1) [11–13]. The compounds sublime quantitatively without decomposition at 50–90°C and 0.1–10 Pa with practical rates up to 1–2 $g \cdot h^{-1}$. All manipulations with the precursor compounds should be carried out by a skilled person using inert-gas techniques and a closed apparatus (e.g. Schlenk-line or glove box) in combination with a good ventilated hood. Due to the significant volatility of the compounds, and their partial hydrolysis in air to yield volatile toxic $(CO)_4CoH$, care must be taken to avoid inhalation. The com-

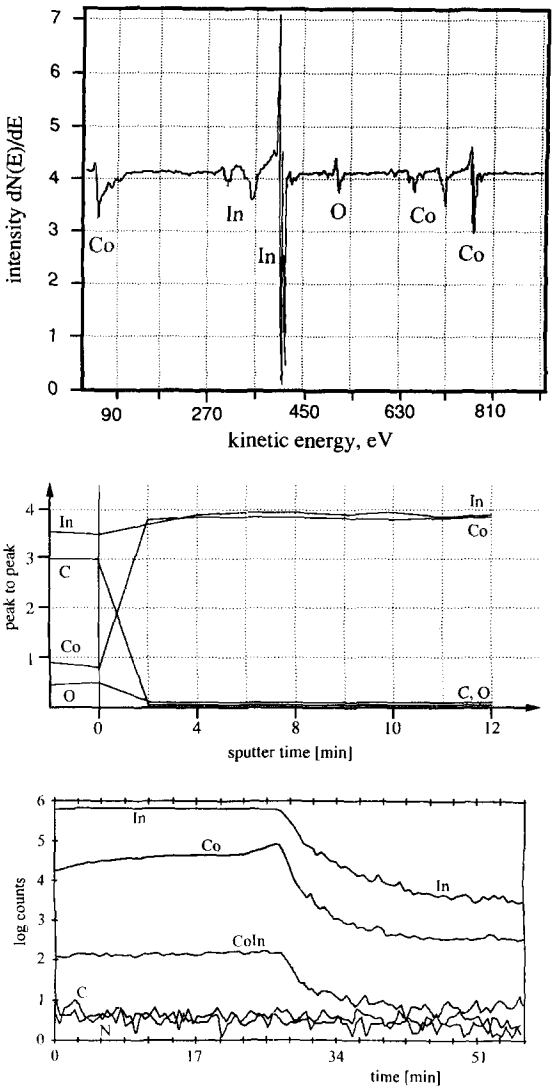


Fig. 1. (a) AES survey plot for a typical $Co_{0.50}In_{0.50}$ thin film grown at 250°C, 10 mTorr (sputter cleaned film #2, Table 1) ⟨1⟩. (b) AES depth profile of the same film ⟨on a quartz substrate⟩. The surface of the grown films was always covered with high hydrocarbon and oxygen impurities, which is probably caused by the condensation of non fragmented precursor molecules and hydrolysis of those upon exposition of the films to the air by opening the reactor after the experiment was finished. Those impurities are removed by a 1–2 min of initial sputter cleaning (Ar ions) of the surface. (c) SIMS depth profile analysis of the same film for the secondary ions Co^+, In^+, $CoIn^+$, C^+ and N^+, giving qualitative evidence for very low C and N contaminations.

pounds are not pyrophoric and can be stored under inert gas atmosphere with cooling (−10°C) for an unlimited period of time. Any residues of the precursors can be safely destroyed either by careful oxidative acid hydrolysis with dilute H_2O_2/H_2SO_4 (with cooling to 0°C) or by dissolution into isopropanol/KOH. NMR spectra were recorded using a JEOL GMX 400 spectrometer (C_6D_6, 20°C). Elemental analysis were obtained from the Microanalytic Laboratory of the Technical University Munich. Mass spectra were recorded on Finnigan MAT 90 (EI, 70 eV) and Varian MAT 311a (FI and CI with isobutene) spectrometers. Gas chromatographic analyses were performed using a HP 5890 equipped with a mass selective detector system (HP 5970B). A fused silica capillary column (HP-1, # 19091Z-102) with 100% methylpolysiloxane ($l = 50$ m, $\phi = 0.2$ mm, film thickness 0.33 μm) was used. The molar fractions of the observed gaseous constituents are reported on the bases of non-calibrated total ion currents.

Film deposition by OMCVD

The vacuum OMCVD experiments were carried out in an isothermal horizontal hot wall quartz tube reactor described in detail elsewhere [14]. The substrates for CVD studies consisted of borosilicate microscope slides, quartz, silicon(111) slides and InP(100) slides, which were cleaned by degreasing in trichloroethylene, isopropanol/acetone, rinsing with deionized water and treated by usual etching procedures. After charging the reactor with various substrates the system was evacuated to a base pressure of $< 10^{-4}$ Pa (turbo molecular pump, Edwards EXT 150) and heated to 350°C for several hours. The precursor reservoir was loaded under an inert gas atmosphere with 1–2 g of the precursor compound and cooled to −30°C. Then the valve to the reactor was opened and the system was evacuated again to 10^{-4} Pa for several hours. The temperature of the furnace was set at the desired value and was allowed to stabilize. The temperature of the precursor reservoir was then adjusted to 35–80°C allowing the precursors to sublime through the hot zone at pressures of 0.1–10 Pa. Reflective metallic depositions formed on the wall of the tube and on the substrates. Carrier gases were not used in these experiments.

Thin film characterization

The films obtained were examined *ex situ* by various surface analytic tools (SIMS, AES and SEM-EDX) and X-ray powder diffraction. The metal ratio was determined independently by AAS after quantitative dissolution of representative films in aqueous nitric acid (p.a.; 6.5 weight-%). Thick films were grown on the walls of the reaction tube, which peeled of by rapid cooling of the tube (10°C · sec^{-1}). After collecting typical quantities of 50–100 mg of the deposited material, classical combustion analysis was performed (C, H, and N). The compositions of the films were uniform over the plated areas of typically ~3 cm^2 (AES mapping and profiling). The EDX-spectra were recorded using a scanning electron microscope JEOL JSM-35C equipped with an EG&G Ortec System 5000 X-ray analysator system. A typical standardless program for quantitative analysis "AUTOZAP" 3.08 ("ZAF"-

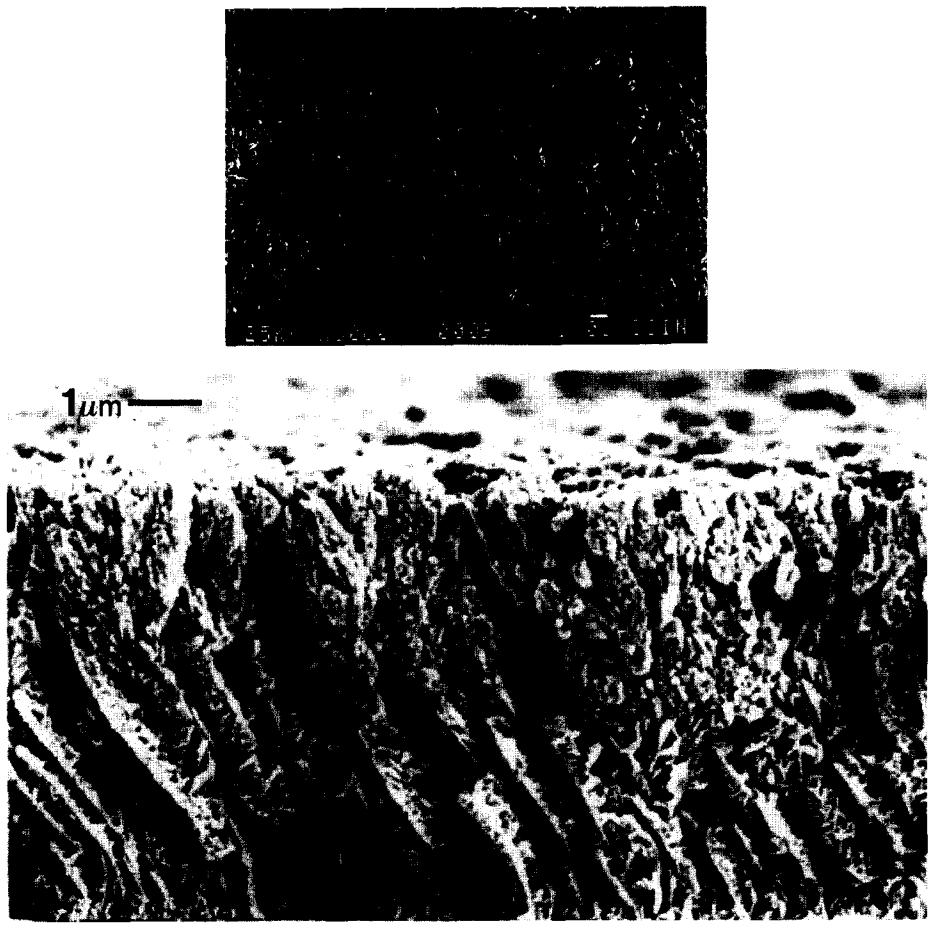

Fig. 2. (a) SEM image of the $Co_{0.50}In_{0.50}$ film #2 of Table 1 grown from **1** on borosilicate glass. (b) SEM image (cross section) of a $Co_{0.75}In_{0.25}$ film grown from **3**.

correction) was employed. The obtained values for the Co and In contents were found to be valid within a relative error of $\pm 10\%$ (comparison with AAS values). AUGER electron spectra were recorded using a PHI 595 spectrometer with a base pressure of 2–4×10^{-7} Pa and a working pressure of 2–5×10^{-6} Pe with a standard cylindrical mirror analyzer (3 keV primary beam energy, 0.2 μA primary beam intensity, a maximum of 500 Å lateral resolution; rate of argon ion sputtering 300 Å sec^{-1} on Ta_2O_5 for an area of 1×1 mm). Typical data collection time was 30 min for 1 keV scan width. The films were cleaned first by 5 min of argon ion (Ar^+, 3 keV) sputtering (5×5 mm area) at a pressure of 5×10^{-4} Pa. The quantitative analysis was based on differentiated spectra and accepted standard sensitivity factors for C (0.18), N (0.32), O (0.50) and Co (0.27). The usual sensitivity factor for In of 1.0 however had to be corrected to 0.30 in our case, on the basis of the AAS and EDX values. This may probably be due to the effect of preferential sputtering of In. The specific resistivity of the deposited metallic coatings were routinely checked by a usual commercial four point probe system at room temperature with an AC current (FPP-5000, Veeco). The analytical data are compiled in Tables 1 and 2.

Structural characterization

The X-ray diffraction patterns were recorded on a Huber-Guinier-Diffractometer 653; Ge-monochromated Cu $K_{\alpha 1}$ ($\lambda = 1.54059$ Å) using the step scanning method with an angle of incidence of 3°, a scan width of 0.005° (counting time of 10 s) and a rotating probe head. The X-ray diffraction patterns of $Co_{0.75}In_{0.25}$ were recorded on a Siemens-D500-Diffractometer, graphite secondary monochromator, Cu $K_{\alpha 1,2}$ ($\lambda_1 = 1.54059$ Å, $\lambda_2 = 1.54443$ Å), using step scanning method (C 0.02°, 2Θ) with beam divergence of 0.3° (counting time 14 s). The measured d-values were calibrated against polycrystalline Si powder.

By-product analysis

The exhaust gases of the vacuum OMCVD experiments were monitored *in situ* by a quadrupolar mass

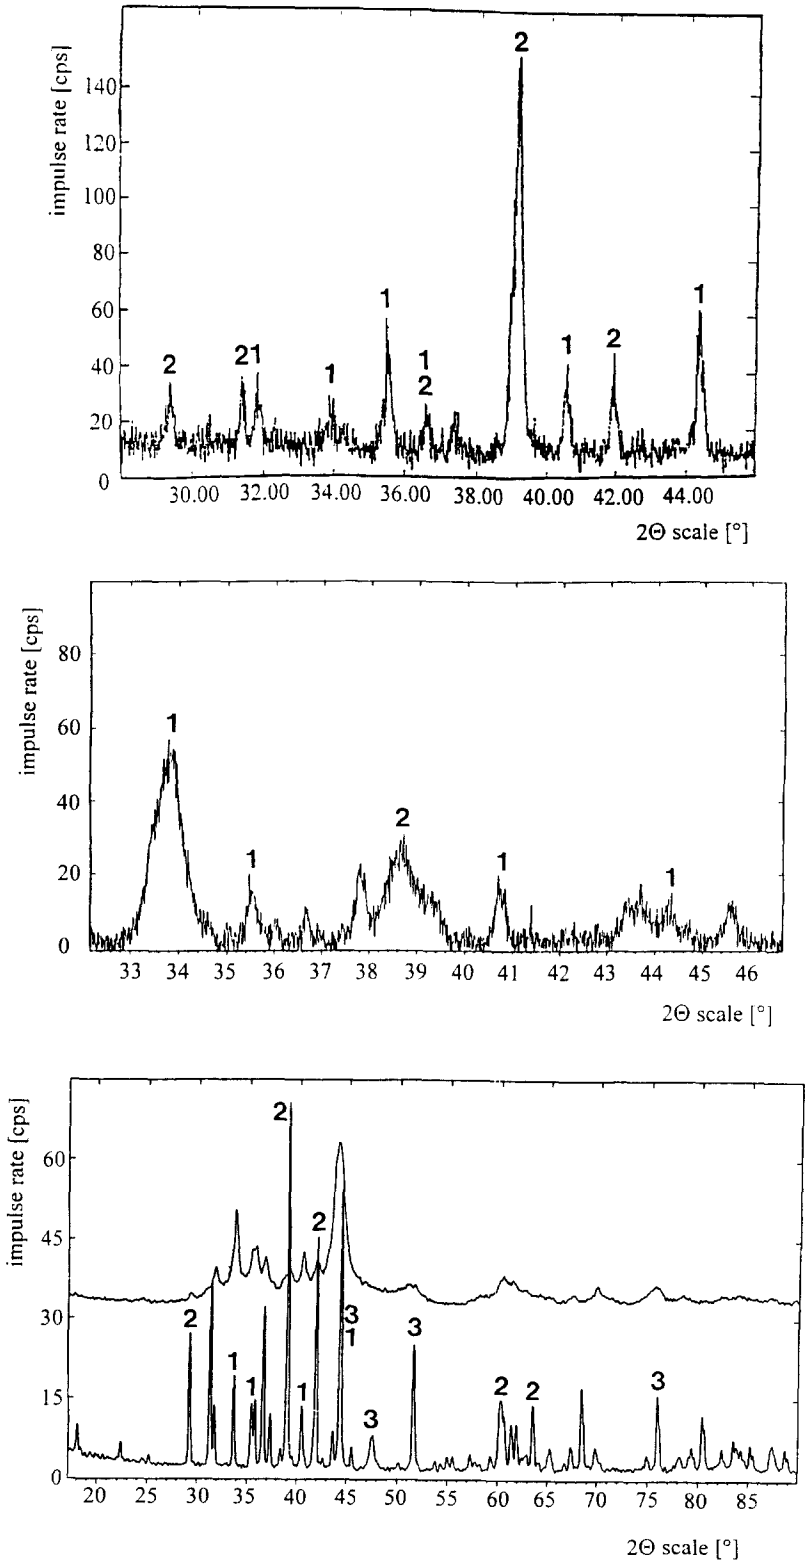

Fig. 3. (a) XRD pattern of the $Co_{0.50}In_{0.50}$ film #2 of Table 1. (b) XRD pattern of the $Co_{0.66}In_{0.33}$ film (Table 2). (c) XRD pattern of the $Co_{0.75}In_{0.25}$ film (Table 2). The observed reflections are denoted as follows: **1** = $CoIn_2$, **2** = $CoIn_3$, **3** = Co [6,10,25].

spectrometer (gas analysis system HPR30-HAL/3F, 1–510 a.m.u.; HIDEN) which was connected to the apparatus by a gas sampling unit with a pin-hole ($\emptyset = 0.7$ mm). The condensables were collected in cold trap attached to the reactor chamber. After the deposition experiment was completed, the cold trap was isolated from the remaining apparatus and the contents were vacuum-transferred into a NMR-tube. C_6D_6 was added and the NMR tube was sealed. The tube contents were analyzed by ^1H NMR and ^{13}C NMR spectroscopy. Subsequently the NMR tube was opened again and the contents were characterized by a GC-MS analysis system. The results of a typical experiment with **1** as precursor (#2 of Table 1) are as follows. The predominant species ($\Sigma > 99$mol.%; GC/MS) of the collected condensable effluent were identified as $Me_2C{=}CH_2$, $H_2C{=}CHCH_2NEt_2$, *cis*-/*trans*-$CH_3CH{=}CHNEt_2$ and $CH_3CH_2CH_2NEt_2$. The ratio of unsaturated to saturated amines was calculated to 4 : 1. The metal content of the condensables was measured in various experiments after aqueous work up (hydrolysis with HNO_3, 6.5 wt.-%) using AAS showing only negligible traces of Co and In.

Abstract—Mixed ligand triangulotriruthenium cluster carbonyls, $Ru_3(CO)_9(\mu\text{-}Ph_2AsCH_2AsPh_2)(L)$ (L = PPh_3, PCy_2Ph, $P(OCH_3)_3$) and $Ru_3(CO)_8(\mu\text{-}Ph_2AsCH_2AsPh_2)(\mu\text{-}Ph_2PCH_2PPh_2)$ were synthesised and characterised by microanalysis, IR, ^1H, ^{13}C and ^{31}P NMR spectrometry. Single crystal X-ray structure determination of $Ru_3(CO)_9(\mu\text{-}Ph_2AsCH_2AsPh_2)(PCy_2Ph)$ and $Ru_3(CO)_8(\mu\text{-}Ph_2AsCH_2AsPh_2)(\mu\text{-}Ph_2PCH_2PPh_2)$ are reported. In both the clusters, the triruthenium framework is planar. In $Ru_3(CO)_9(\mu\text{-}Ph_2AsCH_2AsPh_2)(PCy_2Ph)$, the monodentate phosphine occupies an equatorial position for steric reasons. The effect of trisubstitution is explicit in the highly significant differences observed in Ru—Ru distances (2.8301(6), 2.8653(7) and 2.8873(7) Å) in the present compound compared to $Ru_3(CO)_{10}(\mu\text{-}Ph_2AsCH_2AsPh_2)$. The observed Ru—As distances are 2.4508(7) and 2.4331(7) Å respectively and the Ru—P distance is 2.362(1) Å. In the case of $Ru_3(CO)_8(\mu\text{-}Ph_2AsCH_2AsPh_2)(\mu\text{-}Ph_2PCH_2PPh_2)$, the chelating ligands occupy four equatorial positions. Two of the Ru—Ru distances are similar in length (2.848(2), 2.850(2) and 2.828(2) Å). However, positional disorder is associated with As and P atoms. Other bond parameters are normal. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: crystal structure; steric effect; triruthenium; carbonyl cluster; phosphine substitution.

Synthetic and structural reports on substituted triangulotriruthenium clusters have always been on the rise for their interesting structural variations and related catalytic activity [1]. The metal–metal bond rupture in clusters under catalytic reaction conditions is of concern [2]. The stability of the clusters have been ensured by the presence of a bridging or a capping ligand. Identification of a new radical initiation synthetic route by the Adelaide group has enabled a host of new substituted triangulotriruthenium clusters to be identified and characterised [3,4]. A large number of substituted derivatives, $Ru_3(CO)_{12-n}L_n$ (L = group 15 ligand) have been reported [5–7]. The effect of substitution on the triruthenium clusters manifests itself in many ways [8] with a decrease in the molecular symmetry. Also, introduction of a non-CO ligand, in general results in the lengthening of M—M bonds and only smaller molecules, such as isocyanides, occupy axial positions. However, the

trend in increase of M—M bond distances is only marginal. The group 15 ligands allow a degree of tuning of the reactivity of mixed ligand clusters [7]. In the case of a chelating ligand substituted cluster viz, $Ru_3(CO)_{10}(\mu\text{-}Ph_2PCH_2PPh_2)$, only the equatorial position gets activated for subsequent substitution [8]. A number of substituted carbonyls such as $Ru_3(CO)_9(\mu\text{-}Ph_2PCH_2PPh_2)L$ (L: $P(OCH_3)_3$) have been reported from our laboratory [9]. In continuation of our interest in the substituted clusters, we report the synthesis and characterisation of $Ru_3(CO)_9(\mu\text{-}Ph_2AsCH_2AsPh_2)(L)$ [L = PPh_3, PCy_2Ph (Cy: cyclohexyl), $P(OCH_3)_3$] and X-ray structures of $Ru_3(CO)_9(\mu\text{-}Ph_2AsCH_2AsPh_2)(PCy_2Ph)$ and $Ru_3(CO)_8(\mu\text{-}Ph_2AsCH_2AsPh_2)(\mu\text{-}Ph_2PCH_2PPh_2)$.

EXPERIMENTAL

Materials

$Ru_3(CO)_{12}$ (Aldrich), $Ph_2AsCH_2AsPh_2$(dpam), $Ph_2PCH_2PPh_2$(dppm), PCy_2Ph (Press Chemical Co) and $P(OCH_3)_3$ (BDH) were used as received. Kieselgel $60GF_{254}$ was used for TLC separations. The THF solvent was dried over sodium wire and freshly distilled for every reaction. Oxygen free nitrogen was used to maintain an inert atmosphere. Microanalysis was performed using a model 240 × A from Control Equipment Corporation. IR spectra were recorded with a Mattson 1000 FTIR spectrometer in a NaCl solution cell (0.1 mm). NMR spectra were recorded in $CDCl_3$ with a Bruker B2H 300/52.

(Bis(diphenylarsino)methane)decacarbonylruthenium(0), $Ru_3(CO)_{10}(\mu\text{-}Ph_2AsCH_2AsPh_2)$. The compound was prepared by using the phenylketyl initiator route as previously reported [4].

(Bis(diphenylarsino)methane)nonacarbonyl(triphenylphosphino)ruthenium(0), $Ru_3(CO)_9(\mu\text{-}Ph_2AsCH_2AsPh_2)(PPh_3)$. $Ru_3(CO)_{10}(\mu\text{-}Ph_2AsCH_2AsPh_2)$ (100 mg, 0.0947 mmol) and PPh_3 (26 mg, 0.0995 mmol) were stirred THF (25 ml) under nitrogen. About 0.2 ml of diphenylketyl radical anion initiator was introduced into the reaction mixture under a current of nitrogen. The reaction mixture turned intense red. After 2 h of stirring, the solvent was removed under vacuum. The reaction mixture was separated using TLC (cyclohexane: acetone, 80:20). Three bands appeared including a minor quantity of the starting material. The major band (red) $R_f = 0.85$, was separated and characterised. Yield = 47.5 mg, 38.9 %, m.p. 223–225° C. (Found: C, 48.40 ; H, 2.90; Calc.: C, 48.42; H, 2.89). IR (cyclohexane), ν(CO) 2054 w, 1994 vs, 1976 vs, 1943 sh cm^{-1}. ^1H NMR ($CDCl_3$) δ 7.3–7.7 (m, 25 H, Ph), δ 4.0 (s, 2H, CH_2), ^{13}C NMR($CDCl_3$) δ 129.0–137.0 (m, Ph), δ 198.6 (m, CO), ^{31}P NMR($CDCl_3$) δ 35.5 (s, PPh_3).

(Bis(diphenylarsino)methane)nonacarbonyl(trimethylphosphite)ruthenium(0), $Ru_3(CO)_9(\mu\text{-}Ph_2AsCH_2AsPh_2)P(OCH_3)_3$. $Ru_3(CO)_{10}(\mu\text{-}Ph_2AsCH_2AsPh_2)$ (100 mg, 0.0947 mmol) and $P(OCH_3)_3$ (12mg, 0.094 mmol) in THF (25 ml) was added with 0.2 ml of initiator solution. The resultant mixture was stirred for 30 min and then the solvent was removed under vacuum. The products were separated using TLC. Three bands appeared including a very small quantity of the starting material and the major band was separated ($R_f = 0.50$, benzene: ethanol; 90:10). Yield: 31.1 mg, 28.5%, m.p. 219°C (Found: C, 38.50; H, 2.72; Calc.: C, 38.49; H, 2.71). IR (cyclohexane) ν(CO) 2083 w, 2067 w, 2040 w, 1988 s, 1967 vs, 1925 sh, 1912 sh cm^{-1}. ^1H NMR ($CDCl_3$) δ 7.2–7.4 (m, 20H, Ph); δ 4.0 (s, 2H, CH_2); δ 3.6–3.8 (m, 9H, CH_3). ^{13}C NMR ($CDCl_3$) δ 30.0 (s, CH_3) δ 198.6 (m, CO); ^{31}P NMR ($CDCl_3$) δ 55.5–57.5 (d, P).

(Dicyclohexyl)phenylphosphino)(bis(diphenylarsino)methane) nonacarbonylruthenium(0), $Ru_3(CO)_9(\mu\text{-}Ph_2AsCH_2AsPh_2)(PCy_2Ph)$. $Ru_3(CO)_{10}(\mu\text{-}Ph_2AsCH_2AsPh_2)$ (100 mg, 0.0947 mmol) and PCy_2Ph(27.3 mg, 0.0995 mmol) in dry THF (25 ml) were added with 0.1 ml initiator and stirred for 4 h. The product as a major band was separated by TLC which contained four bands in all with a very minor quantity of the starting material; dichloromethane: ethanol; 90:10; $R_f = 0.26$; yield, 53.0 mg., 43.2%; m.p. 214–216°C. Found, C, 47.95; H, 3.77; Calc., 47.97; H,3.79. IR (cyclohexane) ν(CO) 2052 w, 1989 vs, 1973 vs, 1938 m cm^{-1}. ^1H NMR ($CDCl_3$) δ 7.25–7.45 (m, 25H, Ph); δ 4.0 (s, 2H, CH_2); δ 1.52 (s, 22H, Cy). ^{13}C NMR ($CDCl_3$) δ 128.5–130.0 (d, Ph), δ 199.0 (m, CO); ^{31}P NMR ($CDCl_3$) δ 41.5 (s, P).

(Bis(diphenylarsino)methane)(bis(diphenylphosphino)methane)octacarbonylruthenium(0), $Ru_3(CO)_8(\mu\text{-}Ph_2AsCH_2AsPh_2)(\mu\text{-}Ph_2PCH_2PPh_2)$. $Ru_3(CO)_{10}(\mu\text{-}Ph_2AsCH_2AsPh_2)$ (100 mg, 0.0947 mmol) and $Ph_2PCH_2PPh_2$ (38.22 mg, 0.0994 mmol) in THF (25 ml) under dry nitrogen was added with 0.1 ml initiator and stirred for 6 h. The product as a major band was separated by TLC which contained five bands including trace amounts of the starting material; hexane: acetone; 80:20; $R_f = 0.50$; yield, 44.2 mg, 35.5%, m.p. 240°C. IR (cyclohexane) ν(CO) 2081 w, 2040 w, 2013 w, 1981 sh, 1963 vs, 1896 w cm^{-1}. ^1H NMR ($CDCl_3$) δ 7.1–7.4(m, 40H, Ph); δ 5.85 (s, 2H, CH_2); δ 3.6–3.8 (q, 2H, CH_2). ^{13}C NMR ($CDCl_3$) δ 124.0–128 (m, Ph), δ 198.8 (m, CO); ^{31}P NMR ($CDCl_3$) δ 18.0–24.0 (dd, P).

X-ray data collection

Determination of cell constants and data collection were carried out at room temperature (293 K) with Mo–K_α radiation on a Siemens P4 diffractometer equipped with a graphite monochromator. Data were recorded by $\theta/2\theta$ scan technique and were corrected for Lorentz and polarisation effects. The structure was solved by direct methods with SHELXTL-PC [11] and refined by full-matrix least squares technique on F^2 with SHELXL93 [12]. All the hydrogens were fixed

geometrically with the HADD utility [11]. The relevant data collection and refinement parameters are given in Table 1.

RESULTS AND DISCUSSION

Microanalysis of the compounds agreed well with the proposed molecular formulae for all the reported compounds within the experimental errors.

IR spectra

Isolation of a number of specifically substituted derivatives of $Ru_3(CO)_{12}$ has enabled a definitive ν(CO) spectral information possible on different entities [4,6]. As the number of substituents increases, the frequencies of the bands decrease in magnitude in general. Similarly, as the basicity of the ligand increases, the frequencies of the bands show a decrease. In the present study, trisubstituted, $Ru_3(CO)_9(\mu\text{-}Ph_2AsCH_2AsPh_2)(L)$ clusters show two strong bands of almost equal intensities characteristically, one band at $\sim$ 1960 and the other at $\sim$ 2000 cm^{-1}. In the case of the tetra-substituted cluster, six bands were observed, of which the one at 1963 cm^{-1} was the strongest and appears to be the characteristic band similar to earlier observations [4].

NMR spectra

^{1}H NMR spectra of all the compounds showed a multiplet around δ 7.0 characteristic of the phenyl groups. Other than that, the signal at δ 4.0 is due to the CH_2 protons. For the methoxy protons, the signal appeared at δ 3.6–3.8. In the case of the dicyclohexylphenylphosphine-cluster the signal at 1.52 ppm corresponds to the cyclohexyl protons. ^{13}C NMR spectra of all the substituted clusters showed a prominent signal around δ 128.5–130.0 ppm characteristic of the phenyl carbons. The carbonyl carbons in all the clusters showed as a multiplet at $\delta \sim$ 198.6 ppm. In addition, the methoxy carbons appeared at δ 30.0 ppm for the corresponding cluster. ^{31}P NMR spectra showed signals at δ values 35.5, 41.5 and 55.5–57.5 ppm for PPh_3, PCy_2Ph and $P(OCH_3)_3$ substituted clusters respectively. The observed trend is in keeping with their relative basicities. In the case of $Ru_3(CO)_8$ $(\mu\text{-}Ph_2AsCH_2AsPh_2)(\mu\text{-}Ph_2PCH_2PPh_2)$, ^{1}H NMR showed signals corresponding to phenyl and methylene protons at δ values 7.1–7.4, 5.85 ($Ph_2AsCH_2AsPh_2$) and 3.6–3.8($Ph_2PCH_2PPh_2$) respectively. In the range of δ: 124.0–128.0, ^{13}C NMR spectrum showed signal due to phenyl carbons and ^{31}P NMR spectrum showed signals due to the P atoms at 18.0–24.0 ppm split by by the methylene protons.

X-ray crystal structures

The ORTEP plot of $Ru_3(CO)_9(\mu\text{-}Ph_2AsCH_2AsPh_2)(PCy_2Ph)$ is shown in Fig. 1. The selected bond parameters are given in Table 2. The triangulotriruthenium framework is planar. The three Ru—Ru distances are 2.8301(6), 2.8653(7) and 2.8873(7) Å. All three distances are significantly different from each other. A comparison of the

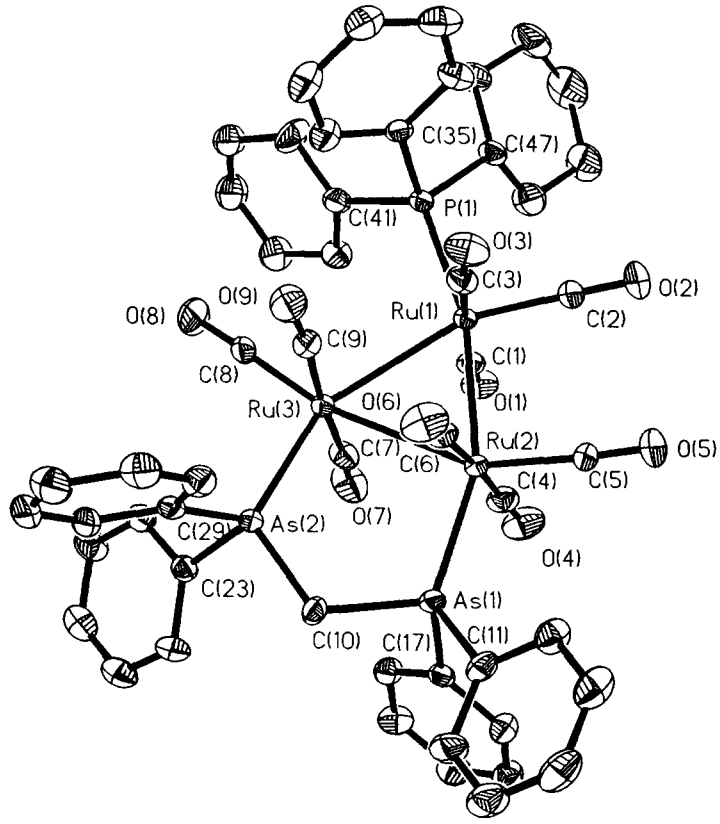

Fig. 1. ORTEP plot of $Ru_3(CO)_9(\mu\text{-}Ph_2AsCH_2AsPh_2)(PCy_2Ph)$.

Ru—Ru distances of $Ru_3(CO)_{10}(\mu\text{-}Ph_2AsCH_2AsPh_2)$ [10] (2.817(1), 2.845(1), 2.840(1) Å) clearly shows that the dissimilarities have increased as a consequence of further substitution. Relatively, significant lengthening observed in Ru(1)—Ru(3) bond reflects itself in the shortening of the Ru(3)—Ru(2) bond. The equatorial Ru—C bond distances (mean: 1.853(6) Å) are shorter than the axial (mean: 1.922(6) Å) as observed in the parent $Ru_3(CO)_{12}$ cluster [13]. The Ceq—Ru—Cax angles are close to 90° and Cax—Ru—Cax angles are close to 180° excepting the ones associated with Ru(1) which show considerable deviations due to the bulky monodentate PCy_2Ph. The Ru—P distance in the compound is 2.362(1) Å. The Ru—As distances in the present compound are 2.4508(7) and 2.4331(7) Å; which are asymmetric clearly compared to the distances observed in $Ru_3(CO)_{10}(\mu\text{-}Ph_2AsCH_2AsPh_2)$ (2.430(1), 2.422(1) Å) [10]. The substituent, (PCy_2Ph) on Ru(1) is on an equatorial position for steric reasons and Ru—P-(Cy_2Ph) bond is *trans* to the Ru_3As_2 plane. The cyclohexyl rings are in the preferred chair conformation. The bond parameters associated with the phenyl rings are normal.

The ORTEP plot of $Ru_3(CO)_8(\mu\text{-}Ph_2AsCH_2AsPh_2)(\mu\text{-}Ph_2PCH_2PPh_2)$ is shown in Fig. 2 and selected bond parameters are given in Table 3. The triangulotriruthenium frame work is planar as observed in the other structure. Two of the Ru—Ru distances are similar, viz. 2.850(2) and 2.848(2) Å whereas the third bond is significantly shorter (2.828(2) Å) than the other two. The two chelating ligands occupy equatorial positions. However, unlike the case of the PCy_2Ph analogue, the bond distances are not affected to a greater extent compared to the $Ru_3(CO)_{12}$ [13], $Ru_3(CO)_{10}(dppm)$ [14] and $Ru_3(CO)_{10}(dpam)$ [10]. The equatorial Ru—C bonds are shorter (mean: 1.83(2) Å) and the axial Ru—C bonds are longer (mean: 1.90(2) Å). Positional disorder associated with arsenic and phosporous atoms in the present structure excludes a rigorous comparison of the bond parameters. The distances corresponding to As(1) and As(2) on the basis of a higher site occupancies (site occupancies: As(1): 0.6333, As(2): 0.6333) from the metal centre are 2.394(2) and 2.404(2) Å. Similarly, Ru—P distances correponding to higher site occupancies are 2.359(3) and 2.345(3) Å. The bond parameters associated with the phenyl rings are normal.

Therefore, the steric effects due to the presence of

[a] Positional disorder is associated with As and P atoms and hence four Ru—As and four Ru—P bonds and related bond angles are listed.

PCy_2Ph in the strucure very clearly manifests itself in the dissimilarities associated with the Ru—Ru bonds but such a dissimilarity is reduced to a larger extent in the cluster with two chelating ligands, however disorder associated with the latter precludes a detailed comparison.

Abstract—Single crystal structure of $[Zn_2(dpt)_2(\mu\text{-}OH)](ClO_4)_3$ (dpt = bis(3-aminopropyl) amine) shows that two units of Zn(dpt) are bridged by oxygen atom of the hydroxo group. Each Zn-atom possesses distorted tetrahedral geometry. Analogous complexes $[Zn_2L_2(\mu\text{-}OH)](ClO_4)_3$ [L = bis(3-aminopropyl) methylamine(medpt), bis(2-aminoethyl)methylamine(medien)] have been synthesised. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: hydroxo bridged zinc(II); triamine; zinc(II) triamine complex; single crystal structure.

The synthesis and structural characterisation of classical Werner type coordination compounds of zinc(II) with *N*- and *O*-donor ligands have in the past few years experienced a dramatic resurgence [1]. This is undoubtedly triggered by the rapidly growing knowledge of the structures of zinc-containing active sites of a variety of enzymes. In the active centre of zinc containing enzymes, the zinc ion is mostly attached in a tetrahedral fashion to three aminoacid side chains while a water molecule or a OH group occupies the fourth coordination site. This basic L_3ZnX arrangement has been found in several protein crystal structure determinations [2,3]. So triamine complexes of zinc have been widely used for model studies to elucidate the role of zinc(II) ion and the detailed reaction mechanism in zinc containing enzymes [4–12]. Because of the lability of zinc complexes and the diverse coordination possibilities for zinc, it is unexpectedly difficult to obtain this simple coordination pattern, L_3ZnX in model complexes [1]. With the simple linear chain triamines such as bis(3-aminopropyl) amine(dpt), (2-aminoethyl)(3-aminopropyl)amine (aepn), and bis(2-aminoethyl)amine (dien) number of studies have been reported [13–16]. The stability as well as C^{13}-NMR spectral studies on $[Zn(dpt)(OH)]^+$ and $[Zn(aepn)(OH)]^+$ are documented [13–15]. Curtis *et al.* [16] isolated $[Zn_2(dpt)_2(OH)](ClO_4)_3$ in the solid state owing to its high stability constant. Recently number of single crystal structure analyses of linear chain triamine complexes of zinc are reported [17,18], but hydroxo bridged triamine complexes of zinc lacks single crystal structural information. Here we report the syntheses and characterisation of $[Zn_2(medpt)_2(\mu\text{-}OH)]^{3+}$ and $[Zn_2(medien)_2(\mu\text{-}OH)]^{3+}$ [medpt = bis(3-aminopropyl)methylamine and medien = bis(2-aminoethyl)methylamine] and also single crystal structure of $[Zn_2(dpt)_2(\mu\text{-}OH)](ClO_4)_3$.

EXPERIMENTAL

Materials

Bis(3-aminopropyl)amine(dpt), bis(3-aminopropyl)methylamine(medpt) and bis(2-aminoethyl)

methylamine(medien) were purchased from Aldrich Chemical Company Inc. and used as received. All other chemicals used were of AR grade.

Physical measurements

Elemental analysis, IR spectrum (halocarbon mull/KBr disc at ambient temperature) have been carried out in Perkin–Elmer 2400 Series(II) CHN Analyser, Perkin–Elmer 783 Infrared Spectrophotometer, respectively.

Synthesis of $[Zn_2(dpt)_2(\mu\text{-}OH)](ClO_4)_3$ (**1**)

Synthesised according to the procedure described by Curtis *et al.* [16]. Yield: 75%. Found: C, 20.2; H, 4.9; N, 11.8; O, 29.2; Cl, 15.1; Zn, 18.5. Calc. for $C_{12}H_{35}N_6O_{13}Cl_3Zn_2$ (**1**): C, 20.3; H, 4.9; N, 11.8; O, 29.3; Cl, 15.0; Zn, 18.4. IR spectra (cm^{-1}): 3530 (s) (νOH); 3320 (s) (sym νNH_2); 3270 (s) (assym νNH_2); 2940 (s) (νCH_2); 1590 (s) (δNH_2); 1470 (s), 1430 (w), 1380 (w) (δCH_2); 1325 (w), 1290 (br), 1260 (m) ($\rho_w CH_2$).

Synthesis of $[Zn_2(medpt)_2(\mu\text{-}OH)](ClO_4)_3$ (**2**)

Medpt(1.5 mmol, 0.217 gm) in ethanol (5 cm^3) was added slowly with stirring to $Zn(ClO_4)_2 \cdot 6H_2O$ (1 mmol, 0.372 g) in ethanol and 2,2-dimethoxypropane mixture (1 : 1) (5 cm^3). The resulting mixture digested on a steam-bath for 10 mins. The white crystals separated were filtered off and washed with ethanol and dried in a $CaCl_2$-desiccator. Yield: 50%. Found: C, 22.8; H, 5.3; N, 11.3; O, 28.2; Cl, 14.5; Zn, 17.6. Calc. for $C_{14}H_{39}N_6O_{13}Cl_3Zn_2$ (**2**): C, 22.8; H, 5.3; N, 11.4; O, 28.2; Cl, 14.4; Zn, 17.7. IR spectra (cm^{-1}): 3530 (s) (νOH); 3320 (s) (sym νNH_2); 3265 (s) (assym νNH_2); 2940 (m) (νCH_2); 1590 (s) (δNH_2); 1470 (s), 1445 (m), 1385 (w) (δCH_2); 1335 (w), 1315 (m) 1290 (w), 1275 (s) ($\rho_w CH_2$).

Synthesis of $[Zn_2(medien)_2(\mu\text{-}OH)](ClO_4)_3$ (**3**)

Medien (1.5 mmol, 0.176 g) in ethanol (5 cm^3) was added slowly with stirring to $Zn(ClO_4)_2 \cdot 6H_2O$ (1 mmol, 0.372 g) in ethanol and 2,2-dimethoxypropane mixture (1 : 1) (5 cm^3). The resulting mixture digested on a steam-bath for 10 mins. The white crystals separated were filtered off and washed with ethanol and dried in a $CaCl_2$-desiccator. Yield: 40%. Found: C, 17.6; H, 4.4; N, 12.2; O, 30.4; Cl, 15.6; Zn, 19.1. Calc. for $C_{10}H_{31}N_6O_{13}Cl_3Zn_2$ (**3**): C, 17.6; H, 4.5; N, 12.3; O, 30.5; Cl, 15.6; Zn, 19.2. IR spectra (cm^{-1}): 3510 (s) (νOH); 3325 (m) (sym νNH_2); 3280 (s) (assym νNH_2); 2950 (w) (νCH_2); 1590 (s) (δNH_2); 1465 (s), 1420 (w), 1380 (w) (δCH_2); 1360 (w), 1315 (s) 1290 (w), 1270 (w) ($\rho_w CH_2$).

X-ray diffraction structural study

Colourless crystal suitable for X-ray data collection were obtained by recrystallisation of **1** from acetonitrile solution. The block shaped crystals used for X-ray data collection having dimensions of 0.22 mm × 0.22 mm × 0.29 mm was mounted in a glass capillary. The unit cell parameter and the orientation matrix were determined by least squares refinement using the setting angles of 25 centred reflections ($12^\circ < 2\theta < 22.5^\circ$) measured on an Enraf-Nonious diffractometer with graphite monochromated Mo–K_α radiation. Intensity data were collected at 298 K using a ω-2θ scan technique up to a maximum 2θ of 50°. The weak reflections ($I < 6.0\sigma(I)$) were rescanned and the counts were accumulated to ensure good counting statistics. Crystal and instruments stabilities were monitored with a set of three standard reflections measured every 97 minutes of X-ray exposure time; in all cases no significant variation was found. 5246 reflections were measured ($h \rightarrow 0$ to 16, $K \rightarrow 0$ to 14, $l \rightarrow -19$ to 19) which after data reduction ($R_{int} = 0.0451$) gave 2499 unique reflections. The data were corrected for Lorentz and polarisation effects [19]. An empirical absorption correction based on ψ-scans was also applied resulting in transmission factors ranging from 0.63 to 1.00. Crystal data are summarised in Table 1.

The structure was solved by Patterson method followed by successive Fourier synthesis and refined through full-matrix block least-squares on F^2 with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were constrained to ride on the respective carbon or nitrogen atoms (C—H 0.97 Å, N—H 0.900 Å) with an isotropic displacement parameter equal to 1.2 the equivalent isotropic displacement parameter of their parent atom. During last stage of refinement seven reflections (042; 031; 044; 055; 017; 405; 687) were omitted for refinement procedure due to extinction effect. At convergence (maximum parameter shift/esd 0.070), the final residuals were $R1 = 0.0659$; $wR2 = 0.1755$; for 2492 reflections with $I > 2\sigma(I)$, goodness of fit (GoF) = 1.027. Final difference Fourier map showed the maximum and minimum peak hights at 0.97 $eÅ^{-3}$ and -1.02 $eÅ^{-3}$, respectively. The largest one being within 0.91 Å of Zn atom, and having no chemical significance. The perchlorate ion shows symmetry imposed disorder, deviations from tetrahedral geometry and could not be modelled satisfactorily. The high displacement parameters for perchlorate anions are typical for this group for a refinement on room temperature data. Complex neutral-atom scattering factors were used [20]. All calculations were carried out using SHELXS-86 [21], SHELXL-93 [22], PARST [23] and ZORTEP [24] programs. Selected bond lengths [Å] and bond angles [°] are listed in Table 2.

RESULTS AND DISCUSSION

A ZORTEP view of **1** with atom numbering scheme is shown in Fig. 1. Solution of crystal structure reveals

that two units of Zn(dpt) are bridged by one oxygen atom. The bridging angle is 134.3(4)°. Each Zn possesses distorted tetrahedral geometry. The degrees of distortion from an ideal tetrahedral geometry are reflected in the valence angle around zinc [range: 99.3(3)° to 121.2(4)°]. The average angles of O—Zn—N and N—Zn—N are 111.7° and 106.8° respectively which are close to that of $[Zn([12]aneN_3)OH]^+$ [7] (([12]aneN$_3$) = 1,5,9-triazacyclododecane). The Zn atom is 0.74 Å above the plane of the three nitrogen atom. The six membered chelate ring Zn—N1—C1—C2—C3—N2 adopts a stable chair conformation with Zn and C2 atom lying 0.705 Å and 0.553 Å respectively on opposite side of the least square plane through remaining endocyclic atoms, the maximum in plane atom deviation being 0.040 Å for C3 atom. The other six membered chelate ring Zn—N2—C4—C5—C6—N3 also adopts chair conformation with Zn and C5 atom lying 0.58 and 0.53 Å respectively on opposite side of the least square plane (maximum deviation C4 0.09 Å). The Zn—O distance is 1.889(3) Å. The Zn—N (primary) distances are 1.979(6) Å and 2.012(7) Å and the Zn—N (secondary) distance is 2.043(6) Å. The Zn···Zn distance in this complex is 3.481 Å. The Zn···O bond lengths, the bridging angles and the Zn···Zn closest distance in analogous hydroxo bridged zinc complexes are listed in Table 3. The solid state packing of complex **1** is mainly governed by several hydrogen bonding between perchlorate anion, amine nitrogen and bridging oxygen. IR spectrum of complex **1** gives strong absorption band at 3530 cm^{-1} corresponding to ν_{O-H} stretching vibration. Similar strong band corresponding to ν_{O-H} stretching vibration has also been

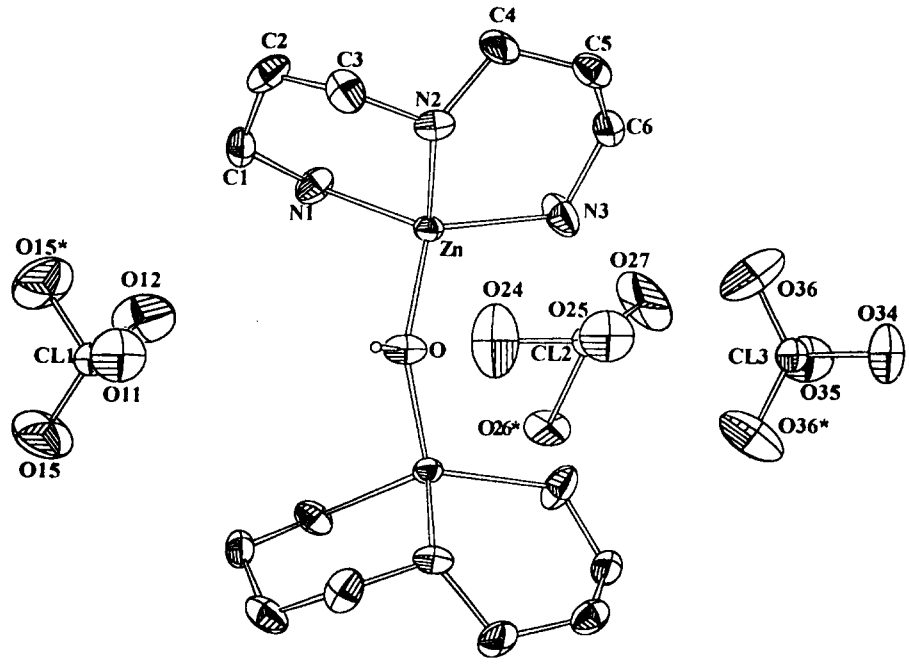

Fig. 1. ZORTEP view of complex **1** showing thermal ellipsoides of the 50% probability level ("*" marked atoms are symmetry related atoms).

Table 3. Some structural parameters of zinc complexes with OH bridge

Complex	Zn···Zn Å	Zn···O Å	Zn—O—Zn	C.N.	Ref.
$[L^1_6Zn_2(\mu\text{-}OH)](ClO_4)_3$	3.54	1.91*	137°	4	[25]

(Received 16 July 1997; accepted 2 October 1997)

Abstract—Two open-chain hexadentate N_6 ligands containing two pyridyl groups, 1,13-bis(2-pyridyl)-2,5,9,12-tetraazatridecane (bpytd) and 1,14-bis(2-pyridyl)-2,6,9,13-tetraazatetradecane (bpytt), have been synthesized as their tetrahydrochloride salts and their proton association constants and stability constants of Co(II), Ni(II), Cu(II) and Zn(II) chelates have been determined by potentiometry. The stability constants are higher than those for analogous hexadentate N_6 ligands containing one pyridyl moiety, which are in turn higher than those for analogous aliphatic N_6 ligands. The Ni(II) complexes $[Ni(bpytd)](ClO_4)_2 \cdot H_2O$ (**1**) and $[Ni(bpytt)](ClO_4)_2$ (**2**) have been synthesized and their structures have been determined by three-dimensional X-ray diffraction methods. Their geometries at nickel are six-coordinate pseudo-octahedra, with pyridyl nitrogen atoms being mutually *cis* for **1** and *trans* for **2**. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: protonation; stability; structure; complexes.

Our recent interest has been in the development of new open-chain saturated polyamine ligands containing pyridyl or imidazoyl groups and the investigation on their interactions with first-row transition metal ions [1,2]. The stability constants of the ligands with the metal ions are higher than those of the analogous aliphatic polyamines [1–6]. The saturated polyamines, which are soluble and stable in water, have been synthesized by hydrogenation of aldimino groups in parent Schiff bases [1,2,7].

This paper describes the preparation of two new potentially hexadentate N_6 ligands, 1,13-bis(2-pyridyl)-2,5,9,12-tetraazatridecane (bpytd) and 1,14-bis(2-pyridyl)-2,6,9,13-tetraazatetradecane (bpytt) by hydrogenation of —C=N bonds of parent Schiff bases and their protonation constants and stability constants of metal chelates. These ligands contain one or two propylenic spacers, which make six-membered chelate rings, between the aliphatic nitrogen atoms. In a previous paper we reported the preparation of 1,12-bis(2-pyridyl)-2,5,8,11-tetraazadodecane (pytrien) with all ethylenic spacers, which make five-membered chelate rings, between the aliphatic nitrogen atoms [1]. It is our intention to establish whether or not the presence of propylenic spacers has an effect on the equilibrium constants and the structure of metal complexes coordinated with the ligands. Structures of the nickel(II) complexes $[Ni(bpytd)](ClO_4)_2 \cdot H_2O$ (**1**) and $[Ni(bpytt)](ClO_4)_2$ (**2**) are reported and compared with the structure of $[Ni(pytrien)](ClO_4)_2$ [7].

EXPERIMENTAL

Preparation

1,13-*Bis*(2-*pyridyl*)-2,5,9,12-*tetraazatridecane* · *tetrahydrochloride*(*bpytd*·4*HCl*). To a solution of pyridine-2-carboxaldhyde (2.14 g, 0.02 mol) in absolute methanol (25 ml) was added *N*,*N*′-bis(2-aminoethyl)-1,3-propane diamine (1.80 g, 0.01 mol), and the solution was refluxed overnight under dinitrogen atmosphere. Sodium borohydride (1.51 g, 0.04 mol) was added in small parts to the solution, and the mixture was neutralized to pH 7.0–7.5 with concentrated hydrochloric acid in an ice bath and filtered to remove the white solid formed. The filtrate was further acidified to pH 2 and allowed to stand at 4°C for 6 h. The white crystals formed were filtered off, washed with H_2O/methanol (5/95, v/v) and air-dried. Yield: 3.3 g (68%). Anal. Found: C, 46.9; H, 7.0; N, 17.0. Calc. for $C_{19}H_{34}N_6Cl_4$: C, 46.7; H, 7.0; N, 17.2. ^{1}H NMR (D_2O-DMSO-d_6): 8.50 (2H, d, *J*(CH) 7.35 Hz, pyridine H), 7.91 (2H, t, *J*(CH) 8.57, 14.25 Hz, pyridine H), 7.47 (4H, m, pyridine H), 4.33 (4H, s, pyridylmethyl), 3.40 (8H, s, ethylene), 3.50 (4H, t, *J*(CH) 11.61, 12 Hz, propylene), 2.10 (2H, m, propylene); ^{13}C NMR (D_2O-DMSO-d_6): 147.3, 145.4, 137.2, 122.2, 121.6, 48.1, 42.0, 40.9, 40.3, 19.9. IR (cm^{-1}): 2940 (s), 2755 (vs), 2705 (vs), 2555 (s), 2405 (s), 1590 (s), 1465 (s), 1435 (s), 1040 (s), 805 (w), 758 (s).

1,14-*Bis*(2-*pyridyl*)-2,6,9,13-*tetraazatetradecane tetrahydrochloride* (*bpytt*·4*HCl*). *N*,*N*′-bis(3-aminopropyl)ethylenediamine (1.95, 0.01 mol) and 5 ml of triethylorthoformate were slowly added to a solution of pyridine-2-carboxaldehyde (2.14 g, 0.02 mol) in absolute methanol (20 ml). The yellow solution was concentrated with a rotary evaporator and the remaining yellow oil was subsequently dissolved in methanol (40 ml). Sodium borohydride (1.51 g, 0.04 mol) was added in small portions to the solution, and the mixture was neutralized to pH 7.0–7.5 with concentrated hydrochloric acid in an ice bath and filtered to remove the white solid formed. The white filtrate was further acidified to pH 2 and allowed to stand at 4°C for 6 h. The white crystals formed were filtered off, washed with H_2O: methanol (5:95, v/v) and air-dried. Yield: 4.0 g (79%). Anal. Found: C, 48.0; H, 7.5; N, 16.5. Calc. for $C_{20}H_{36}N_6Cl_4$: C, 47.8; H, 7.2; N, 16.7; ^{1}H NMR (D_2O-DMSO-d_6): 8.52 (2H, d, *J*(CH) 7.35 Hz, pyridine H), 7.90 (2H, t, *J*(CH) 3.48, 10.77 Hz, pyridine H), 7.47 (2H, m, pyridine H), 4.34 (4H, s, pyridylmethyl), 3.38 (4H, s, ethylene), 3.14 (8H, m, propylene), 2.10 (4H, m, propylene); ^{13}C NMR (D_2O-DMSO-d_6): 146.5, 146.0, 136.6, 122.1, 121.6, 47.7, 42.3, 41.5, 40.2, 19.8. IR (cm^{-1}): 2947 (vs), 2700 (vs), 2400 (vs), 1490 (s), 1461 (s), 1432 (s), 1267 (w), 1032 (w), 1019 (w), 763 (s). Mass: 355 $[MP\text{-}4HCl]^+$.

[Ni(bpytd)]$(ClO_4)_2 \cdot H_2O$ (**1**) *and* [Ni(bpytt)]$(ClO_4)_2$ (**2**). The complex **1** was prepared by the following method. A mixture of sodium acetate trihydrate (0.54 g, 4 mmol) and bpytd · 4HCl (0.48 g, 1 mmol) in absolute methanol (30 ml) was stirred for 30 min and filtered. Nickel acetate tetrahydrate (0.24 g, 1 mmol) was added to the filtrate. Excess sodium perchlorate (0.50 g, 4 mmol) dissolved in methanol was added to the resulting pink solution and then the mixture was stored at room temperature during 2 days. The pink parallelepiped crystals formed were filtered off, washed with a small amount of cold methanol, and air-dried. Recrystallization from methanol: CH_3CN (1 : 1, v/v) afforded crystals suitable for X-ray crystallographic analysis. Yield: 53% (0.32 g) Anal. Found: C, 37.2; H, 4.9; N, 13.6. Calc. for $NiC_{19}H_{32}N_6O_9Cl_2$: C, 37.2; H, 4.6; N, 13.7; λ_{max} (CH_3CN) = 535 nm (ε = 13 M^{-1} cm^{-1}); molar conductance (CH_3CN) = 285 Ω^{-1} M^{-1} cm^{-2}; IR (cm^{-1}): 3304 (s), 3270 (s), 3200 (s), 2920 (s), 2880 (s), 1600 (s), 1430 (s), 1230 (w), 1090 (vs), 762 (s), 622 (vs).

The complex **2** was synthesized by the method given for **1** except that it was isolated in a refrigerator. Yield: 60% (0.36 g) Anal. Found: C, 39.3; H, 4.9; N, 13.6. Calc. for $NiC_{20}H_{32}N_6O_8Cl_2$: C, 39.4; H, 4.6; N, 13.8; λ_{max}(CH_3CN) = 524 nm (ε = 42 M^{-1} cm^{-1}); molar conductance (CH_3CN) = 279 Ω^{-1} M^{-1} cm^{-2}; IR (cm^{-1}): 3290 (s), 3170 (w), 2940 (s), 1650 (s), 1481

(w), 1431 (s), 1284 (w), 1092 (vs), 955 (s), 903 (w), 764 (s), 624 (vs).

Equilibrium constant determinations

All titrations were carried out in aqueous solution under dinitrogen atmosphere on a Metrohm 605 pH meter. In all cases, the ligand was present at 1.00×10^{-3} M. Solutions were adjusted to 0.10 M ionic strength by the addition of KNO_3 at 25.0 ± 0.1°C. The proton association constants (K_H^n) of the ligand (L), which are defined by $[H_nL]/[H][H_{n-1}L]$, were determined by titration of the protonated ligand with standardized KOH in absence of complexing metal ions and then by calculation of the results by the aid of a computer program of PUKAS [8].

The stability constants (K_{ML}) of metal (M) chelates, which are defined by [ML]/[M][L], were determined by titration of the protonated ligand with KOH in the presence of metal ions. The titrations were performed on 1 : 1 molar ratios of the ligand with the metal ions. Titration curves were calculated using a computer program of BESTA [8].

Physical measurements

UV-vis electronic absorption spectra were recorded on a Shimadzu UV-160A spectrophotometer. ^{1}H- and ^{13}C-NMR spectra were recorded with a Bruker AM-300 spectrometer and reported as δ in ppm relative to DMSO-d_6 (2.64 ppm for ^{1}H and 39.7 ppm for ^{13}C). Infrared spectra of the powdered samples (KBr discs for ligands and mulls for complexes) were taken using a Shimadzu IR 440 spectrophotometer. Mass spectra were obtained with a Kratos 25-RFA GC-Mass spectrometer and elemental analysis were performed on a Carlo Erba Model 1160.

Crystal structure determination

A selected crystal was set up on an automatic diffractometer. Unit cell dimensions with estimated standard deviations were obtained from least-squares refinements of the setting angles of 25 well centered reflections. Two standard reflections were monitored periodically; they showed no change during data collection. Corrections were made for Lorentz and polarization effects. Empirical absorption correction (DIFABS) [9] and an extinction correction were applied. Computations were performed by using the PC version of CRYSTALS [10]. Atomic form factors for neutral Ni, Cl, O, N, C and H were taken from Ref. 11. Real and imaginary parts of anomalous dispersion were taken into account. The structure was solved by direct methods (SHELXS) [12] and successive Fourier maps. Some hydrogens could be found on difference maps and the other hydrogens were geometrically located. They were all given an overall isotropic thermal parameter. All non-hydrogen atoms were anisotropically refined. Full matrix least-square refinements were carried out by minimizing the function $\Sigma w(F_0 - |F_c|)^2$ where F_0 and F_c are the observed and calculated structure factors, respectively. Models reached convergence with $R = \Sigma(|F_0 - |F_c||)/\Sigma w\ F_0$ and $Rw = [\Sigma w(F_0 - |F_c|)^2/\Sigma w(F_0)^2]^{1/2}$, each reflection being assigned a weight unity. Criteria for a satisfactory complete analysis were the ratios of rms shift to standard deviations being less than 0.1 and no significant features in the last difference map.

RESULTS AND DISCUSSION

Syntheses and characterization

The ligands, 1,13-bis(2-pyridyl)-2,5,9,12-tetraazatridecane (bpytd) and 1,14-bis(2-pyridyl)-2,6,9,13-tetraazatetradecane (bpytt), were isolated as tetrahydrochloride salts by hydrogenation of C=N bonds of the Schiff bases obtained from condensation reactions of pyridine-2-carboxyaldehyde with *N,N'*-bis(2-aminoethyl)-1,3-propanediamine and *N,N'*-bis(3-aminopropyl)-1,3-ethylenediamine, respectively. For the case of bpytt, H_2O which was formed by the condensation reaction was removed by addition of triethylorthoformate. The ligands were characterized by elemental analysis, IR, ^{1}H- and ^{13}C-NMR and mass spectra (see Experimental section).

The complexes **1** and **2** were synthesized by the reactions of methanolic solution of 1 equiv. of the respective ligand with 4 equiv. of sodium acetate and 1 equiv. of nickel acetate, followed by the addition of sodium perchlorate. The values of molar conductance of **1** and **2** in CH_3CN indicate that the complexes are 1 : 2 electrolytes. The perchlorate anions in the complexes were identified by their IR spectra.

Equilibrium constants

Protonation constants of bpytd and bpytt have been studied in 0.10 M KNO_3 in aqueous solution at 25.0°C. Their stepwise protonation constants were calculated from potentiometric equilibrium curves and are listed in Table 1, together with the corresponding values for 1,12-bis(2-pyridyl)-2,5,8,11-tetraazadodecane (pytrien). The constants from K_H^1 to K_H^4 correspond to those of protonation of aliphatic amine groups and the constant K_H^5 corresponds to that of protonation on one of nitrogen atoms in pyridyl moieties, considering that the nitrogen atom on the pyridyl moiety is less basic than those on aliphatic amines [13]. Each stepwise protonation constant for bpytt is similar to that for bpytd but is higher than for pytrien. The results are expected from the fact that the electrostatic repulsions between protonated aliphatic nitrogen atoms are mitigated for the ligands having propylenic spacers between the aliphatic nitrogen atoms [14].

Titrations of bpytd·4HCl in the presence of the ions Co(II), Ni(II), Cu(II) and Zn(II) with KOH yield neutralization curves. The chelate stability constants (K_{ML}) obtained from the curves are listed in Table 2, along with those of bpytt, pytrien, 1-amino-13-(2-pyridyl)-3,6,9,12-tetraazatridecane (aptatd) and *N,N'*-dimethyl-3,6,9,12-tetraazatetradecane-1,14-diamine(Me_2linpen). As expected on the basis of the general Irving–Williams order, the stability constants for all ligands given follow the order: $Co^{2+} < Ni^{2+} < Cu^{2+} > Zn^{2+}$. The stability constants for the ligands (e.g. pytrien, bpytd and bpytt) carrying two pyridyl moieties increase in the order: pytrien < bpytt < bpytd. The order might be explained to some extent by taking account of two factors, i.e. the size of chelate rings and the steric strain, even though the factors are hard to be evaluated quantitatively.

The stability constants for ligands used in this study are higher for each metal chelate than those for ligands (e.g. aptatd) carrying one pyridyl moiety, which are in turn higher than those for the aliphatic N_6 ligands (e.g. Me_2linpen) [15]. The results are in agreement with the general trend that the stability constants for first-row transition metal ions of pyridyl-containing ligands are higher than those of analogous polyamines [1–6]. This enhanced stability is partially attributed to π bonding between the pyridyl π or π^* orbitals and *d* orbitals of appropriate metal ions. But the π bonding alone is not likely to offer sufficient explanation of the enhanced stability of Zn(II) ion with the d^{10} electronic configuration because the *d* orbitals of zinc are too low in energy to overlap strongly with ligand orbitals. As explained by Martell *et al.* [6], there are entropic and enthalpic differences between chelation by an aliphatic amine and chelation by nitrogen bound in a more rigid pyridyl ring. The aliphatic amines must sacrifice rotational freedom about the C—N bonds in order to chelate a metal ion, leading to the less favorable entropies.

X-ray crystal structures of $[Ni(bpytd)](ClO_4)_2 \cdot H_2O$ *and* $[Ni(bpytt)](ClO_4)_2$

Cations in these complexes have distorted octahedral coordination geometry, as shown in Figs 1 and 2. Selected bond distances and angles for each cation are listed in Tables 3 and 4. In both cations the ligands are coordinated to nickel atom through six nitrogen atoms involving two pyridyl (N1 and N6) and four secondary amine nitrogen atoms (N2, N3, N4 and N5). The bond lengths between Ni and pyridyl nitro-

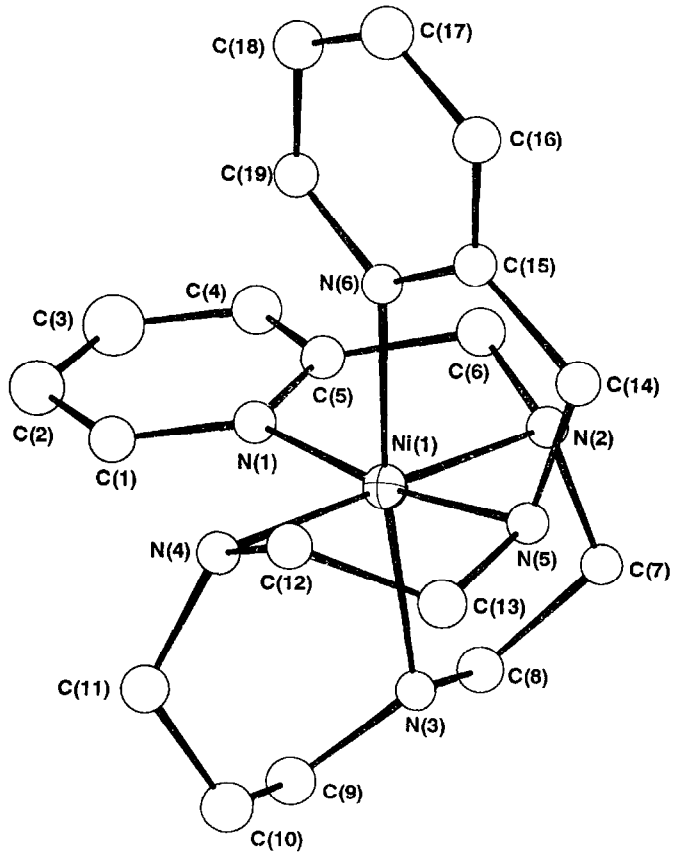

Fig. 1. CAMERON drawing of the molecular structure of $[Ni(bpytd)]^{2+}$ cation showing 30% probability thermal ellipsoids.

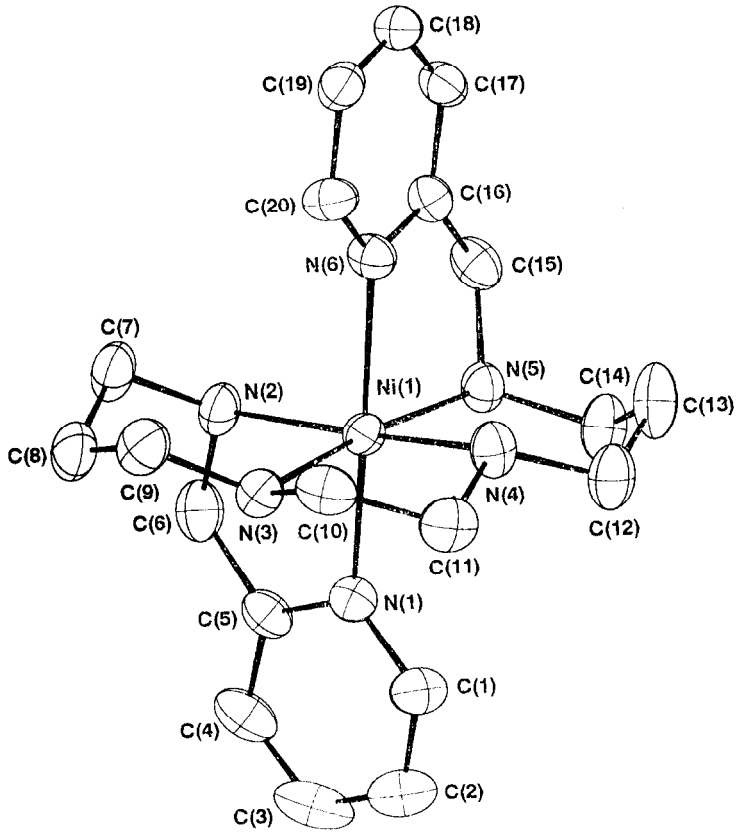

Fig. 2. CAMERON drawing of the molecular structure of $[Ni(bpytt)]^{2+}$ cation showing 30% probability thermal ellipsoids.

gen atoms are not really different from those between Ni and amine nitrogen atoms. The structure of $[Ni(bpytd)]^{2+}$ cation is similar to that [7] of $[Ni(pytrien)]^{2+}$ cation in that the pyridyl nitrogen atoms are mutually *cis*. In both cations four chelate bond angles subtended by each ligand at the nickel atom are similar to each other but one chelate bond angle N(3)—Ni(1)—N(4) for the former cation is closer to 90° than the corresponding angle for the latter cation, because of the presence of the propylenic space. In the structure of $[Ni(bpytt)]^{2+}$ cation the pyridyl nitrogen atoms are mutually *trans*. The bond angles are more deviated from those in an octahedral geometry in the order: $[Ni(bpytt)]^{2+} < [Ni(bpytd)]^{2+} < [Ni(pytrien)]^{2+}$. For example, bond angles such as N(2)—Ni(1)—N(3) and N(4)—Ni(1)—N(5) for $[Ni(bpytt)]^{2+}$ are almost rectangular because of the presence of two propylenic spacers between aliphatic nitrogen atoms. The deviation in the bond angles seems to result in decreasing the stability of metal complexes.

Supplementary material. Tables (Tables S1-1–5 for **1** and S2-1–5 for **2**) of X-ray crystallographic data, including complete refined positional parameters, anisotropic thermal parameters, bond distances, bond angles and observed/calculated structure factors are available from the authors upon request.

Abstract—The title Schiff base (^{tBu}SalcamH$_2$) obtained by condensation of enantiomerically pure (1*R*,3*S*)-1,2,2-trimethyl-1,3-cyclopentanediamine with 3,5-di-*tert*-butylsalicylic aldehyde was used as a ligand to prepare Ni(II), Cu(II), Mn(III), and Fe(III) 1 : 1 complexes. The compounds were characterized by physicochemical methods. Catalytic activity of (^{tBu}Salcam)MnCl complex was tested in the reactions of single oxygen atom transfer. © 1998 Elsevier Science Ltd. Keywords: chiral salen type complexes; nickel complex; copper complex; manganese complex; iron complex.

INTRODUCTION

Transition metal complexes with Schiff bases derived from diamines (salen-type ligands) have been studied broadly in view of their significance as biomimetic catalysts. During the last decade increasing interest in the catalyzed asymmetric synthesis has brought much attention to the chiral metal complexes of this class [1]. So far, the chiral salen-type ligands used, including the most spectacular Jacobsen catalyst, (^{tBu}Salchl)MnCl designed for enantioselective epoxidation were obtained from optically active 1,2-diamines and rather little is known about the corresponding 1,3-diamine derivatives [2].

The outstanding catalytic activity of (^{tBu}Salchl)MnCl based on chiral 1,2-cyclohexanediamine prompted us to study other salen-type transition metal complexes. Previously, we have investigated the catalytic role played by the achiral (^{tBu}Salen)Mn(III) complex in the epoxidation of olefins in the presence of 4-alkoxypyridine 1-oxides [3]. Now, we attempt to modify the spatial relations within a ligand by introducing chiral, conformationally affixed 1,3-cyclopentanediamine instead of 1,2-cyclohexanediamine used in (^{tBu}Salchl)MnCl. Such a modification renders two faces of the complexes unequivalent. This may lead to the new conditions for chirality transfer in the catalyzed reaction.

In this paper we report the synthesis and physicochemical characterization of new homochiral ligand: N,N′-bis(3,5-di-*tert*-butylsalicylidene)-(1*R*,3*S*)-1,3-diamine-1,2,2-trimethylcyclopentane (^{tBu}SalcamH$_2$) and their complexes with Ni(II), Cu(II), Mn(III), and Fe(III) ions. We studied their

stereochemistry by 2D NMR and other spectral methods. Additionally, catalytic activity of the respective manganese(III) complex in the oxidation reactions was examined and its performance was compared with that for Jacobsen catalyst.

EXPERIMENTAL

FT IR spectra in KBr pellets were performed on a Perkin-Elmer 1725X instrument. Electronic spectra were recorded on a Cary-5 or Beckman UV 5240 spectrophotometer. The circular dichroism spectra were taken with a JASCO 600 J instrument. EPR spectra were recorded with Bruker 100TT instrument. Magnetic susceptibility measurements were carried out using the Gouy method at the temperature range of 77–300 K. Mass spectra were obtained at a Finnigan MAT TSQ 700 spectrometer by the Electro-Spray Ionization method at 4.5 kV ionisation potential and 250°C capillary temperature in acetonitrile solvent. ^{1}H NMR spectra were obtained with a Bruker AMX300 spectrometer using standard procedures for COSY and NOESY measurements and fast-pulse sequence (repetition time 0.1 s) for paramagnetic manganese(III) and iron(III) complexes. The chloroform-d was the solvent in all cases. The residual solvent peak at 7.24 ppm was used as internal chemical shift standard. Cyclic voltammograms were taken on an Electrochemical Analysis Software analyser, model 270 using a solution of metal complex (5.0 mM) in methylene dichloride containing tetrabutylammonium chloride (0.10 M) as a supporting electrolyte at 0.5 $Vsec^{-1}$ scan rate. GC/MS spectra were determined on a Hewlett-Packard 5890 II gas chromatograph (25 m capillary column) with a Hewlett Packard mass spectrometer 5971 A operating on the electron impact mode (70 eV). Separations of products by chromatography were performed on silica gel 60 (230–400 mesh) purchased from Merck or florisil from Fluka. Thin layer chromatography analyses were performed using silica gel 60 precoated plates (Merck).

Syntheses of ligands

Preparation of the known chiral diamine **1** used for the Schiff base synthesis was carried out as described by Sato and coworkers [4]. GC: over 98% purity. $[\alpha]^{578} = +30.5°$ (c 1.0, ethanol). Yield 94%.

N,N'-bis(3,5-*di*-tert-*butylsalicylidene*)-(1R,3S)-1,3-*diamine*-1,2,2-*trimethylcyclopentane*, (**2**), ((^{tBu}*Salcam*)H_2). To a solution of chiral diamine **1** (0.290 g, 2.04 mmol) in abs. ethanol (10 ml) 3,5-di-*tert*-butylsalicyl aldehyde (0.955 g, 4.08 mmol) was added and the mixture was refluxed for 1 h. After ethanol was evaporated, the crude product was purified by chromatography on florisil (eluent: *n*-hexane + 6% di-isopropyl ether). Thus obtained oily product has solidified after standing for a few days at room temperature. M.p. 186–186.5°C; 84% yield; $[\alpha]^{578} = +10.4°$ (c 0.996, CCl_4); IR (film, cm^{-1}): $\gamma_{C=N}$ 1633, γ_{C-O} 1480, γ_{C-N} 2872, 2888, 2964; ^{1}H NMR ($CDCl_3$, δ, ppm, the assignments based on COSY and NOESY experiments, for numbering, see: scheme 1): 1.30, 1.29 (two *s*, 18H, *t*-Bu_9 and *t*-Bu_{16}); 1.30 (*s*, 3H, Me_1); 1.43, 1.42 (two *s*, 18H, *t*-Bu_{11} and *t*-Bu_{18}); 0.97, 0.95 (two *s*, 6H, $2Me_2$); 2.35–1.97 (m, 4H, H_4 and H_5); 3.55 (*t*, 1H, $J = 9.4$ Hz, H_3); 7.20, 7.09 (two *d*, 2H, H_8 and H_{15}); 7.37, 7.36 (two overlapping doublets, 2H, $J = 2.8$ Hz $H_{10} + H_{17}$); 8.34 (*s*, 2H, H_6 and H_{13}); 13.83, 14.20 (two *s*, 2 × 1H, two O*H* 12 and 19). UV-Vis {λ [nm] (ε)}: 230 (5.26×10^4); 265 (4.03×10^4); 330 (1.07×10^4); 425 (150). Anal. Calc. for $C_{38}H_{58}N_2O_2$: C 79.39; H 10.17; N 4.87. Found: C 79.55; H 10.09; N 4.47.

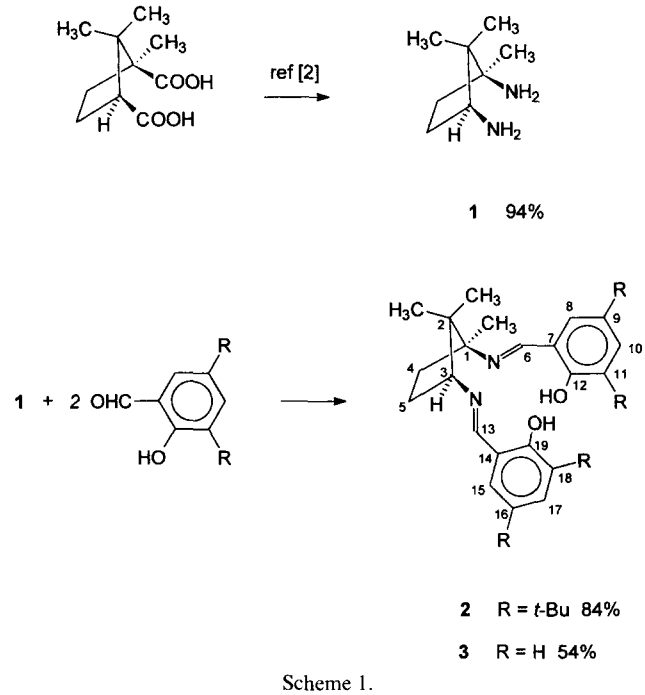
N,N'-bis(*salicylidene*)-(1R,3S)-1,3-*diamine*-1,2,2-*trimethylcyclopentane*, (**3**) (*SalcamH*$_2$). The synthesis and purification of ligand **3** was done according to the same procedure as in case of ligand **2** (see scheme 1). The product was recrystallized from toluene/hexane. Yield 54%, m.p. 159.5–160°C, $[\alpha]^{578} = +27.7°$ (1.02 mol × dm^{-3} in CCl_4), $\gamma_{C=N}$ 1630, γ_{C-O} 14..., γ_{C-H} 2872, 2900, 2988. ^{1}H NMR ($CDCl_3$): 0.94, 0.95 and 1.30 (three *s*, 3 × 3H) 2 × Me_2 and Me_1 1.75–2.35 (m, 4H, $H_4 + H_5$); 3.58 (*t*, 1H, $J = 9.4$ Hz, H_3); 6.84–7.32 (multiplets, 8H, aromatic H); 8.33 (*s*, 2H, $H_6 + H_{13}$); 13.58–14.09 (two *s*, 2 × 1H, two O*H* 12 and 19). Anal. Calc. $C_{22}H_{26}N_2O_2$: C 75.36; H 7.47; N 8.02. Found: C 75.20; H 7.22; N 7.94. MS 351 {$(SalcamH_3)^+$}.

Syntheses of complexes

(^{tBu}*Salcam*)*Ni*. The nickel(II) complex of **2** was obtained by dropwise addition of 0.175 g $Ni(CH_3COO)_2 \cdot 4H_2O$ (0.703 mmol) dissolved in 10 ml ethanol into stirred mixture containing 0.403 g (0.701 mmol) **2** in 4 ml methylene dichloride, 6 ml ethanol and 5 ml water, containing 0.056 g sodium hydroxide under reflux. The heating was continued 1 h and then the product (^{tBu}Salcam)Ni was extracted with petroleum ether. Organic phase was dried over sodium sulphate and the solvents were evaporated. The crude product was purified by chromatography on silica gel with 90 : 9 : 1 hexane : chloroform : ethanol mixture with increasing gradient of ethanol. Yield 33%.

(^{tBu}Salcam)Ni Anal. Calc. $C_{38}H_{56}N_2O_2Ni$: C 72.26; H 8.94; N 4.44. Found: C 72.11; H 8.94; N 4.17, MS 632 {(^{tBu}Salcam)Ni^+}, IR $\gamma_{C=N}$ 1612 cm^{-1}, ^{1}H NMR (see results and discussion). UV-Vis{λ [nm] (ε)}: intraligand: 233 (2.98×10^4); 280 (2.90×10^4); 338 (5.0×10^3); 357 (*sh*, 4.57×10^3); CT bands: 251 (3.85×10^4); 427 (6.3×10^3); 413 (*sh*, 5.95×10^3); *d–d* transitions: 525 (*sh*, 287); 637 (102). CD (λ_{max} [nm], ($\Delta\varepsilon$)): 512 (+0.41); 610 (+0.19); 700 (−0.63).

(^{tBu}*Salcam*)*Cu*. The copper(II) complex was prepared similarly as the nickel(II) one. The $CuSO_4$ dissolved in 4 ml H_2O was used for metal insertion. Yield 37%.



Scheme 1.

(*t-Bu*Salcam)Cu Anal. Calc. $C_{38}H_{56}N_2O_2Cu$: C 71.72; H 8.87; N 4.40. Found: C 71.72; H 9.05; N 4.21, MS 636 {(*t-Bu*Salcam)Cu^+}, IR $\gamma_{C=N}$ 1617 cm^{-1}, UV-Vis{λ [nm] (ε)}: intraligand: 238 (5.97×10^4); 282 (3.79×10^4); 315 (1.13×10^4); CT bands: 251 (4.91×10^4); 389 (1.41×10^4); 413 (*sh*, 1.02×10^4); *d–d* transition: 627 (490). CD (λ_{max} [nm], ($\Delta\varepsilon$)): 530 (+1.61); 640 (−2.74). Magnetic moment. 1.77 BM, EPR (methylene dichloride solution, 77 K): $g_{iso}=2.204$, $A_{\perp}=199\times10^{-4}$ cm^{-1}; (room temperature): $g_{iso}=2.204$, $A_{iso}=81\times10^{-4}$ cm^{-1}.

(*t-Bu*Salcam)*MnCl*. To a refluxing solution of **2** (0.408 g, 0.710 mmol) and $Mn(CH_3COO)_2\cdot4H_2O$ (0.174 g, 0.710 mmol) in 13.5 ml ethanol aqueous potassium hydroxide solution (0.130 g, 5 ml H_2O) was added dropwise and heating was continued until all solids dissolved. Then the saturated ethanolic solution of lithium chloride was added and refluxing was continued over next 0.5 h. The solvents were evaporated and the solid residue was extracted with methylene dichloride, the solution was dried over sodium sulfate and then chromatographed twice on silica gel with the mixture 1:1 chloroform:hexane and then 3:1 chloroform:acetonitrile solvents. The crystals of (*t-Bu*Salcam)MnCl·CH_2Cl_2 (as found by thermogravimetric analysis) were grown from methylene dichloride:hexane solution. Yield 30%.

(*t-Bu*Salcam)MnCl (solvent removed under vacuum) Anal. Calc. $C_{38}H_{56}N_2O_2MnCl$: C 68.81; H 8.51; N 4.22; Cl 5.34 Found: C 71.72; H 9.05; N 4.21, MS 628 {$(C_{38}H_{56}N_2O_2Mn)^+$}, IR $\gamma_{C=N}$ 1611 cm^{-1}, UV-Vis{λ [nm] (ε)} (in solution): intraligand: 225 (3.22×10^4); 280 (2.80×10^4); 357 (6.7×10^3); CT bands: 242 (3.10×10^4); 418 (5.64×10^3); *d–d* transitions: 525 (1.25×10^3); 740 (324). (in solid state); *d–d* transitions (λ [nm]): 525, 725, 815. CD (λ_{max} [nm], ($\Delta\varepsilon$)): 555 (+0.77); 660 (+0.90). Magnetic moment 4.52 BM. ^{1}H NMR: −294; −155 ppm (intensity ratio 2:1, total intensity 2H, H_6+H_{13}); −24.4; −19.8 ppm (aromatic C-H, 2H).

(*t-Bu*Salen)*MnX* (*X* = *Cl,Br*). The complexes have been prepared as described previously [3]. UV-Vis (λ [nm], *d–d* transitions only): (*t-Bu*Salen)MnCl (in solution): 505, 705, 822; (in solid state): 500, 715, 800 (*t-Bu*Salen)MnBr (in solid state): 505, 700, 800.

(*Salcam*)*MnCl*. The synthetic procedure to obtain the manganese complex of **3** was the same as that in case of (*t-Bu*Salen)MnX.[3] MS 403 {$(C_{22}H_{26}N_2O_2Mn^+$}, IR $\gamma_{C=N}$ 1611 cm^{-1}, UV-Vis{λ [nm] (ε)} (in solution): *intraligand*: 314 (8.02×10^3); 393 (4.60×10^3); 417 (3.65×10^3); 488 (1.02×10^3); *d–d* transition: 728 (2.33×10^2). CD (λ_{max} [nm], ($\Delta\varepsilon$)): 251 (−2.27); 266 (+0.42); 286 (−2.94); 310 (+0.97); 323 (−0.25); 346 (−1.26); 382 (+3.28); 425 (−2.02); 470 (−0.25); 535 (+0.84); 650 (+0.081). Magnetic moment 4.52 BM. ^{1}H NMR: −250; −200 ppm (intensity ratio 2:1, total intensity 2H, H_6+H_{13}); −26.9, −20.2, −17.7, −16.6 (aromatic C-H, 4H).

(*t-Bu*Salcam)*FeCl*. In a typical procedure the iron(III) complex was obtained on 1 mmolar scale by dissolving iron(III) chloride and **2** in ethanol followed by solvent removal and extraction (*t-Bu*Salcam)FeCl with methylene dichloride. The product was purified by chromatography on silica gel with chloroform:ethyl acetate eluent with increasing gradient of ethyl acet-

ate. Finally the violet complex was eluted with 9:1 ethyl acetate:acetonitrile eluent. Pure (^{tBu}Salcam)FeCl was recrystallized from mixture of methylene dichloride and hexane. The solid violet (^{tBu}Salcam)FeCl cocrystallized with one molecule of hexane per two molecules of (^{tBu}Salcam)FeCl ($C_{38}H_{56}N_2O_2FeCl \cdot 1/2\ C_6H_{14}$).

(^{tBu}Salcam)FeCl · 1/2 C_6H_{14}: Anal. Calc. $C_{41}H_{63}N_2O_2FeCl$: C 69.93; H 8.98; N 3.96; Found: C 69.73; H 9.17; N 3.99; MS (for hexane-free complex) 628 {(^{tBu}Salcam)Fe^+}, IR $\gamma_{C=N}$ 1610, UV-Vis{λ [nm] (ε)}: intraligand: 232 (2.59×10^4); 290 (1.13×10^4); 324 (1.00×10^4); CT bands: 263 (2.74×10^4); 389 (1.41×10^4); 413 (*sh*, 1.02×10^4); *d–d* transition: 627 (490). Magnetic moment 5.70 BM, EPR (solid sample): $g = 1.87, 2.31, 4.42$. ^{1}H NMR: 103.6; 100.5 ppm (2H, $H_6 + H_{13}$); 65.0; 58.6 ppm (H_{10} and H_{17}); 41.0; 31.0 ppm (H_8 and H_{15}).

Catalytic oxidations

Oxidation of thioanisole. A solution of thioanisole, $C_6H_5SCH_3$ in CH_2Cl_2 (2 ml 1.0 M) containing 4-phenylpyridine N-oxide (0.4 mmol), Bu_4NCl (0.1 mmol), and (^{tBu}Salcam)MnCl (0.1 mmol) was vigorously stirred with 2.28 ml 1.0 M NaOCl(aq) for 4 h at 0°C. The reaction mixture was washed with water, brine, and dried over anh. Na_2SO_4. The methylene dichloride phase was filtered through the short pad of silica gel. The fractions obtained were evaporated, weighted and subjected to GC/MS analysis, which indicated that 69% of starting material was recovered and the sulfoxide yield was 18%. The enantioselectivity was estimated by two independent methods: the observed specific rotation $[\alpha]_D - 14.6°$ (Polarimeter AA-5, Optical Activity Ltd.) and the gas chromatography on Chirasil-val column (Alltech) gave the same value of $10 \pm 0.5\%$ ee.

Oxidation of styrene. Analogous conditions as previously described [3] were used to test the two-phase epoxidation of styrene with aqueous sodium hypochlorite in the catalytic presence of (^{tBu}Salcam)MnCl. The reaction proceeded 6 h. Products were analyzed by GC/MS. It was found that 8% of epoxide and 2% of phenylacetic acid were formed, with $\leqslant 12\%$ ee for epoxide (by specific rotation).

Oxidation of norbornene with dimethyldioxirane (DMDO). The epoxidation of norbornene into exo-2,3-epoxynorbornane with dimethyldioxirane in the presence or absence of complex was monitored by ^{1}H NMR spectroscopy by disappearance of resonance at 6.0 ppm (protons 2 and 3 of norbornene) and growing of resonance at 3.0 ppm (from exo-epoxide). In a typical procedure the manganese complex was dissolved in deuterated acetone (concentration was variable within 1–8 mM region) containing 0.01 M norbornene, the solutions were frozen at liquid nitrogen, then the DMDO (as 0.2 M solution in acetone-d_6) was added to the reaction mixture in NMR tube and the solution was warmed up quickly to 233 K in the cavity of NMR spectrometer. The reaction was then followed by sampling every 2 min. The results are collected as a graph at Fig. 5.

RESULTS AND DISCUSSION

Synthesis

Recently Sato *et al.*, have reported the successful preparation of enantiomerically pure (1*R*,3*S*)-1,2,2-trimethyl-1,3-cyclopentanediamine (**1**) and application of its N,N-dimethyl derivatives as chiral ligands for asymmetric reaction [4]. On the other hand, the striking catalytic activity of chiral manganese(III) complex with Schiff base derived from optically active 1,2-cyclohexyldiamine and sterically hindered 3,5-di-*tert*-butylsalicylaldehyde (^{tBu}Salchl)MnCl in enantioselective epoxidation of olefins [1] prompted us to study the properties of similar Schiff base containing **1** as a structural element. Thus we prepared the ligand **2** in 84% yield reaction of **1** with 3,5-di-*tert*-butylsalicylaldehyde. It has been demonstrated that the presence of bulky substituents at the 3,3′- and 5,5′-positions of the salen-type ligand had a marked effect on the selectivity of catalyzed reaction [5]. For the purpose of comparison we also synthesized the ligand **3** (SalcamH_2)—the Schiff base derived from **1** and unsubstituted salicyl aldehyde. The complexes were prepared by heating the equimolar amounts of **2** and corresponding metal ion salts in ethanol in alkaline conditions, followed by chromatographic purification. The satisfactory elemental analyses and mass spectral data confirmed the simple 1:1 ligand to metal stoichiometry of nickel(II) and copper(II) complexes and 1:1:1 ligand:metal ion:chloride stoichiometry of manganese(III) and iron(III) complexes. The coordination compounds were then characterized by spectral methods, magnetic susceptibility measurements, and electrochemical measurements (in case of manganese(III) complex).

Magnetic, electrochemical and spectral (UV-Vis, CD, IR, EPR) studies

Magnetic susceptibility measurements indicated that expected diamagnetic nickel(II) is formed, and in the series of copper(II), manganese(III), and iron(III) complexes the mononuclear compounds are formed with the values of magnetic moments corresponding to one unpaired electron in the case of Cu(II) complex and a high-spin electronic configuration for manganese(III) and iron(III) complexes (see: Experimental). The linear $(\chi)^{-1}$ vs T relationship demonstrated that no intermolecular magnetic exchange was present in either of the complexes studied. The EPR spectrum of copper(II) complex showed a hyperfine structure corresponding to N_2O_2 coordination mode in square planar complexes [6]. The

EPR spectrum of iron(III) complex is typical for that type of electronic configuration. Also the *d–d* transitions observed in UV-Vis spectra correspond to high-spin configuration of manganese(III) and iron(III) five-coordinated square-pyramidal complexes. The CD spectra obtained for the same *n*-hexane solutions revealed the Cotton effects observed for the respective electronic absorptions. A comparison of these effects for the *d–d* bands in (^{t}Bu-Salcam)MnCl and (*R,R*)-(^{t}BuSalchl)MnCl shows that in both cases the coordination sphere of Mn(III) bears the chirality of ligands [7]. The observed relay of chirality to the metal can be potentially extended to the reactant in a catalytic process.

The examination of infrared absorption spectra revealed 21–23 cm^{-1} shift of $\gamma_{C=N}$ upon coordination of Fe(III), Mn(III), and Ni(II), and only 16 cm^{-1} shift in the Cu(II) complex [8]. This difference correlates with the energy of CT band (mainly $d_{xy} \rightarrow \pi^*$) localized on the azomethine group which is shifted 30–44 nm to higher energy for Cu(II) complex in comparison with the corresponding bands for the other three complexes. In the contrary, the shift of phenolic ν_{C-O} to the larger wavelengths is the smallest in case of Cu(II) complex. These two tendencies reflect the relative strength of the coordination bonds; in the case of Cu(II) complex, Cu(II)—N bond seems to be relatively the strongest of all the complexes studied.

Cyclic voltammetry indicated that (^{t}Bu-Salcam)MnCl, unlike its achiral analogue (^{t}Bu-Salen)MnCl [3] is oxidizable reversibly in a one-electron process at a platinum electrode. The difference in peak potentials of 53 mV ($E_{1/2}$ 1.004 V vs AgCl/Ag), the peak current ratio near unity, and the identity of both single and multiple scan cyclic voltammograms demonstrated the reversibility and simplicity of electron transfer. Coulommetric experiment showed that one electron was transferred and the EPR spectrum of oxidized sample confirmed the presence of Mn(IV) complex (eight-line hyperfine structure, g_{iso} 2.068, A_{iso} 80.2 Gs). The same EPR spectrum was obtained when (^{t}BuSalcam)MnCl in methylene dichloride was oxidized with aqueous sodium hypochlorite. It seems that the observed redox behavior of (^{t}BuSalcam)MnCl and its low catalytic activity (vide infra) are caused by strong stabilization of Mn(IV) species, thus unfavorably shifting an equilibrium from Mn(V)=O to Mn(IV) species [3]. Moreover, both chemical and electrochemical oxidations of this complex were unaffected by the presence of additional ligand (4-dodecyloxypyridine N-oxide). Because this ligand strongly activated the catalytic action of (^{t}Bu-Salen)MnCl [3], we suppose that a steric hindrance imposed by 1,3-cyclopentanediimine bridge prevents the complexation of additional, axial ligand.

^{1}*H NMR Studies*

The ^{1}H NMR spectrum of **2** (Fig. 1) indicated that two substituted salicyl rings are almost magnetically equivalent. Similarly the slight chemical shift difference between two methyl groups at carbon-2 indicated that they are only slightly diastereotopic. Consequently, free rotation around C_1—N and C_3—N bonds of free ligand can be assumed. It is not the case in the diamagnetic nickel(II) complex, for which total assignment was based on the 2D COSY and NOESY techniques. The spectra were taken at room temperature and the relevant fragments of COSY and NOESY spectra together with connectivity pattern are shown at Figs 2–4.

The scalar cross-peak in COSY map allowed to assign four doublets in the aromatic region of spectrum into the corresponding pair of C—H coupled pairs, i.e. H_8—H_{10} and H_{15}—H_{17} ones. By default two singlets at 7.16 and 7.04 ppm were assigned to azomethine protons H_6 and H_{13}. The singlet resonances in the region 1.7–0.8 ppm belong to *tert*-butyl and methyl protons. Two singlets at 1.60 and 0.87 ppm are scalary coupled and they originate from methyl substituents at C_2. Those cross-peaks are not labelled on the COSY map presented at Fig. 2a, 2b presents the expanded region of COSY spectrum containing the multiplet pattern of resonances corresponding to protons at C_1-C_3. Every of five protons resonates at different field. The resonances from axial protons are shifted upfield. The most intense cross-peaks are observed between geminal protons (H_{4a}—H_{4b}—cross-peak 2 and H_{5a}—H_{5b}—cross-peak 4) and vicinal protons H_3—H_{4a}—cross-peak 1. The weaker cross-peaks 3 and 5 illustrate the vicinal coupling between equatorial H_{4b} and H_{5b} and axial H_{4a} and H_{5a}, respectively. The cross-peak 6 originate from weak vicinal coupling between H_{5a} and H_{4b}. The doublet at 2.82 ppm has been identified as originate from H_3 based on NOESY experiment.

The crucial starting point of spectral assignments are two pairs of cross-peaks observed in NOESY experiment, i.e. those corresponding to spatial interaction between azomethine and aromatic protons: H_{13} vs H_{15} and H_6 vs H_8 (cross-peaks *a* and *b* at Fig. 3a, respectively). The sequence of NOE cross-peaks: *c* (between H_8 and *t*-Bu_9), *d* (between *t*-Bu_9 and H_{10}), *e* (between H_{10} and *t*-Bu_{11}) combine the resonances within one part of the ligand, whereas those labelled as *f* (between H_{15} and *t*-Bu_{16}-Fig. 3b), *g* (between *t*-Bu_{16} and H_{17}), and *h* (between H_{17} and *t*-Bu_{18}) give the total assignment of all aromatic and azomethine protons (Fig. 3b). The observed NOE cross-peak *i* (Fig. 3c) between azomethine proton H_{13} and H_3 allowed to unambiguously complete the assignment. Furthermore, the spatial contacts between: H_3 and Me_{2a} (cross-peak *j*), vicinal methyls 1 and 2a and 2b (cross-peaks *k* and *l*, respectively) were observed (Fig. 3d). The connectivity pattern with the arrowed NOE cross-peaks is presented at Fig. 4 for clarity.

The ^{1}H NMR spectrum of (^{t}BuSalcam)FeCl complex at room temperature is typical for high-spin Fe(III) complexes with Schiff bases [9a,b]. The doubled resonances from azomethine protons are the most shifted

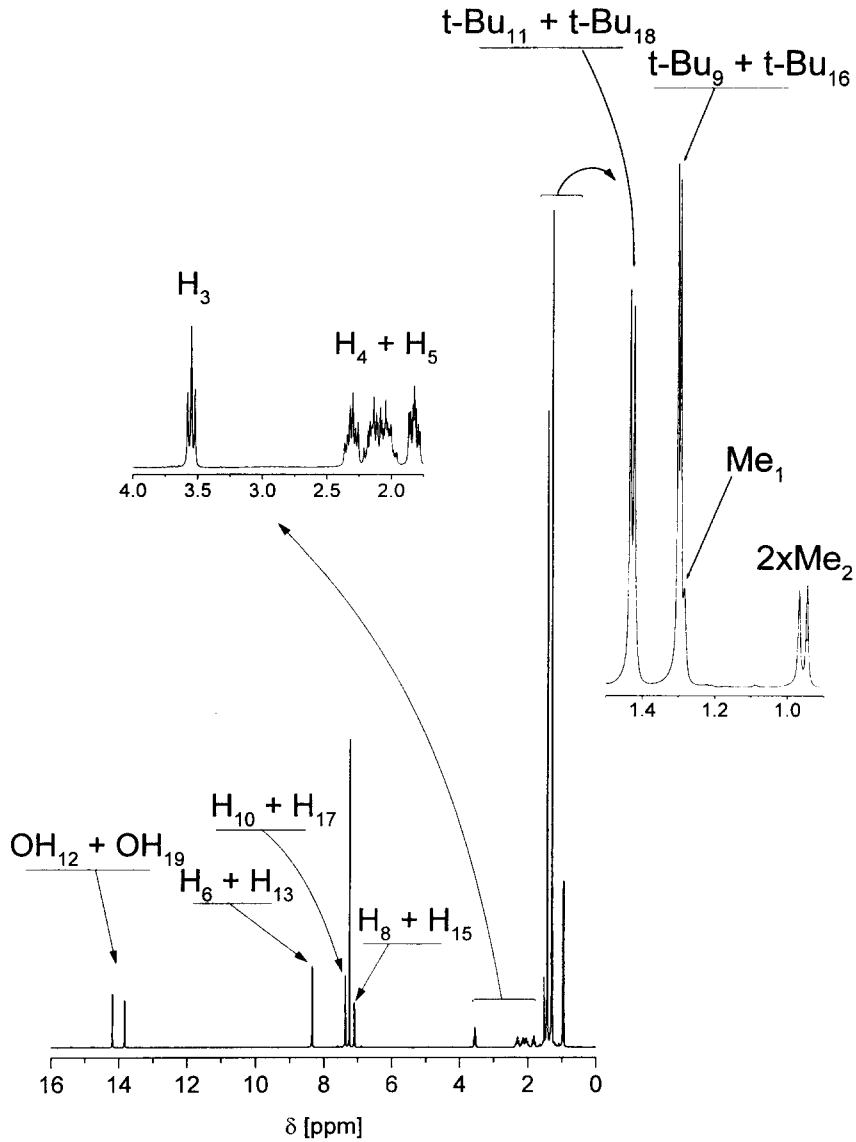


Fig. 1. ^{1}H NMR spectrum of ^{tBu}SalcamH$_2$ in chloroform-*d* at 293 K. Resonance assignment according to Scheme I.

downfield (100 ppm). Also the chemical shift of H_{10} and H_{17} phenyl protons are within the expected region. The resonances between 15 and 0 ppm can be assigned based upon integral intensity, whereas those at around 40 and 30 ppm arise from H_8 and H_{15} protons. The (^{tBu}Salcam)FeCl complex is easily convertible into binuclear μ-oxo species by shaking the chloroform solution of (^{tBu}Salcam)FeCl with KOH-saturated D_2O. The spectrum changes dramatically and all resonances are then present in the region of 15–0 ppm. (14.3 ppm for H_{10} and H_{17} and 10.3 ppm for H_8 and H_{15}) [9c].

The ^{1}H NMR spectrum of (^{tBu}Salcam)MnCl complex is well-resolved due to short electronic relaxation time of manganese(III) complexes in high-spin configuration (10^{-10}–10^{-11} s [9d] and spread over wide range of chemical shift. Phenyl proton resonances are located within the region $-15 \div -30$ ppm (assignment based on comparison with Mn(Salcam)Cl). The azomethine protons are shifted upfield to -150 and -300 ppm for Mn(^{tBu}Salcam)Cl and -200 and -250 ppm for the Mn(Salcam)Cl. For comparison the azomethine resonance in case of mononuclear [Mn(salpn)(H_2O)](ClO_4) complex is shifted upfield to -94.2 ppm [9e]. Two azomethine resonances of (^{tBu}Salcam)MnCl have different intensity: The integral intensity ratio of lower to higher shifted resonances is about 2:1 and arise from two different

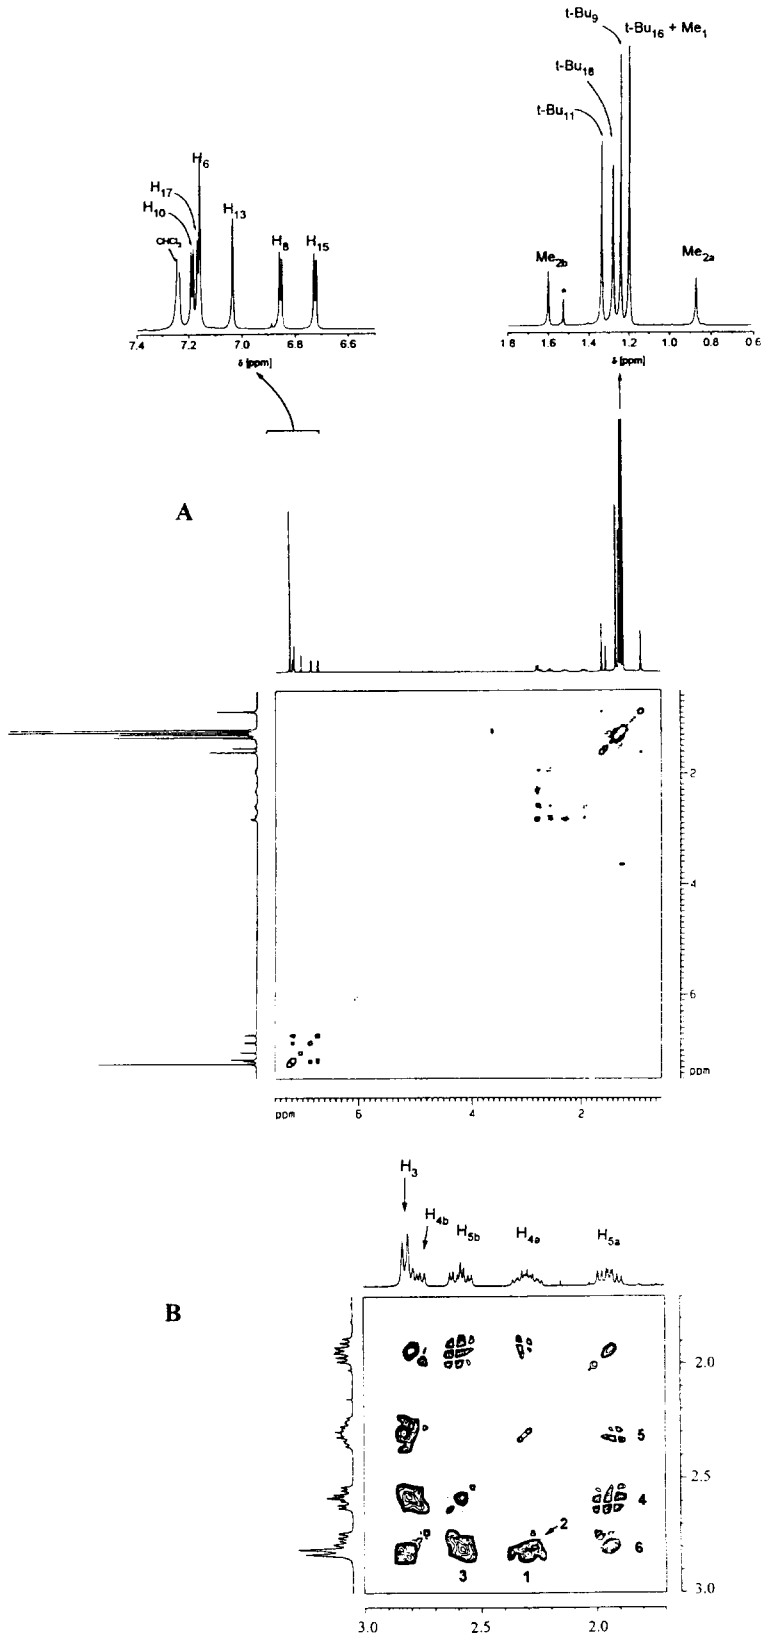

Fig. 2. (A) 2-D ^{1}H NMR COSY spectrum of ($^{t\text{-}Bu}$Salcham)Ni(II) complex in chloroform-*d* at 293 K. Two upper insets represent the expanded region of 1-D projection. The labelling of resonances was made according to Scheme I. (B) The expended region of the COSY map demonstrating the scalar couplings within aliphatic proton region.

complexes, bearing axial chloride bound at opposite sides of the complex plane. Interestingly, the solid complex, isolated from the methylene dichloride/hexane solvent mixture has the chloride ion coordinated on the opposite side in respect to C_3 [10].

Catalytic studies

The examination of catalytic activity of (^{tBu}Salcam)MnCl complex in oxidation of methyl phenyl sulfide with sodium hypochlorite in methylene dichloride/water system in the presence of 4-phenylpyridine N-oxide and Bu_4NCl indicated rather low catalytic performance with slight enantioselectivity (10% ee). Similar result was obtained in the two-phase catalytic epoxidation of styrene ($\leqslant$ 12% ee).

A series of manganese(III) complexes with salen-

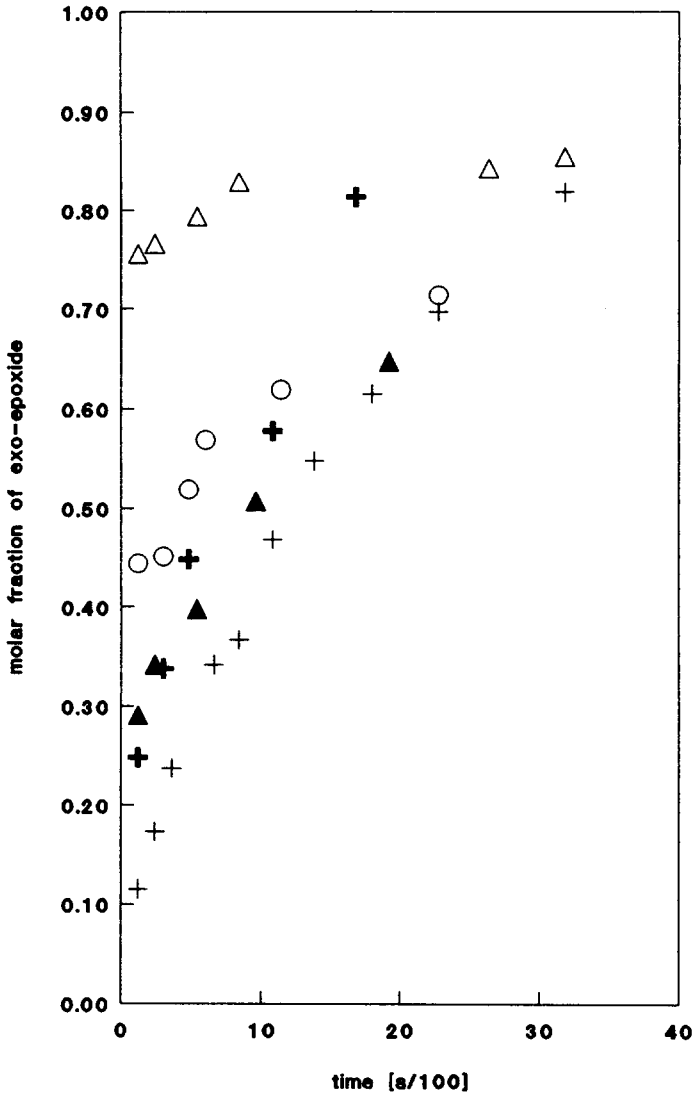

Fig. 5. The time course of catalytic oxidation of norbornene with dimethyldioxirane in presence of (^{tBu}Salchl)Mn(III)Cl (c = 7.9 mM—open triangles, c = 1.4 mM—open circles), (^{tBu}Salcam)Mn(III)Cl (c = 3.7 mM—bold crosses), (Salcam)Mn(III)Cl (c = 3.9 mM—solid triangles), and blank (light crosses).

type ligands were tested for catalytic activity in the homogenous epoxidation of olefin using dimethyldioxirane in acetone. Dioxiranes are strong oxidants and single oxygen transfer agents [11]. It has been demonstrated that they are able to stereoselectively oxidise many organic [11] and inorganic [12] substrates. Manganese(III)-porphyrin has been reported as efficient catalyst in epoxidation of uracil derivatives with dimethyldioxirane (DMDO) [13]. Here the reaction of epoxidation of norbornene into exo-2,3-epoxynorbornane with dimethyldioxirane has been chosen to test the catalytic activity of (^{tBu}Salcam)MnCl, (Salcam)MnCl, and (^{tBu}Salchl)MnCl. The results are collected as a graph at Fig. 5. All the studied complexes indicated some activity in the testing reaction. However, only the (^{tBu}Salchl)MnCl complex was substantially active catalyst (75% conversion in 10 min, blank–12%). Both (^{tBu}Salcam)MnCl and (Salcam)MnCl showed limited catalytic activity (50% and 40% conversion in 10 min, respectively). Moreover, the (^{tBu}Salcam)MnCl and (^{tBu}Salchl)MnCl complexes presumably persist untouched (they remain catalytic activity after 20 min) whereas the non-protected with t-butyl substituents (Salcam)MnCl looses its activity within 20 min. While the catalytic activity of the title compound is rather

low, it is noteworthy that high activity of (^{t}Bu-Salchl)MnCl complex is confirmed in the DMDO/norbornane test.

CONCLUSIONS

It seems probable that the low activity of (^{t}Bu-Salcam)MnCl and (Salcam)MnCl is due to steric hindrance imposed by 1,3-cyclopentanediimine moiety around the metal center and marginal stereoselectivity is consistent with the fact that both faces of the complexes are involved in binding single oxygen (the starting chloride species bears chloride ions coordinated axially on both sides, although the opposite sides in case of (^{t}Bu Salcam)MnCl are less equivalent than those in case of (Salcam)MnCl (as it demonstrated by large differences of the chemical shift of azomethine protons of two isomers in NMR spectra). Presumably in the former complex the metal ion is more sterically crowded and that induces large dipolar contributions of opposite sign into isotropic shift experienced by azomethine protons. Indeed, the molecule of (^{t}Bu-Salcam)MnCl complex is substantially tetrahedrally distorted from square planar geometry as it was indicated by X-ray crystallographic studies of solvent-free crystals [10].

Axial additions in nickel(II) complexes of 3,14-dimethyl-2,6,13,17-tetraazatricyclo[14,4,$0^{1,18}$,$0^{7,12}$]docosane: syntheses and crystal structures of the octahedral nickel(II) complexes

(Received 21 July 1997; accepted 19 September 1997)

Abstract—The complex $[NiL]Cl_2 \cdot 2H_2O$ (L = 3,14-dimethyl-2,6,13,17-tetraazatricyclo[14,4,$0^{1,18}$,$0^{7,12}$]docosane) undergoes axial additions with monodentate ligands ($X = N_3^-$, NCS^-). The octahedral $[NiLX_2]$ complexes have been characterised and structures established by X-ray crystallography. The crystal structures of $[NiL(N_3)_2]$ **1** and $[NiL(NCS)_2]$ **2** show that both structures are centrosymmetric and the nickel centre has an axially elongated octahedral geometry with two nitrogen atoms of the axial ligands. Electronic spectra and redox potentials of the complexes also reveal a high-spin octahedral geometry, which is reflected by the nature of the axial ligands. © 1998 Elsevier Science Ltd. Keywords: octahedral nickel(II) complexes with 14-membered tetraaza macrocyle.

Macrocyclic polyamines with C-alkyl substituents of the macrocyclic ring and their metal complexes have attracted considerable attention because of their structural and chemical properties, which are often quite different from those of the unalkylated macrocyclic ligands [1–14]. Several factors influence the chemical properties and structures of metal complexes of macrocylic ligands [1]. These factors are the metal ion, ring size, degree of unsaturation and types and number of substituents on the macrocyclic ring. Difference in kinetic stability of two isomers of 5,12-dialkylcyclam (cyclam = 1,4,8,11-tetraazacyclotetradecane) nickel (II) complexes have been reported by McAuley *et al.* [4]. It is evident that the stereochemistry of the ligands contributes in an important way to the electron-transfer processes of the macrocyclic nickel complexes. Comparable work on the 5,7,7,12,14,14-hexamethylcyclam complexes is hindered by the large numbers of isomers that contribute further to the steric effects [2]. We recently reported the preparation and X-ray structure of $[NiL]Cl_2 \cdot 2H_2O$ [10]. In addition, Mochizuki *et al.* [15] showed that *trans*-[Ni(cyclam)$(OH_2)_2$]$Cl_2 \cdot 4H_2O$ has the octahedral geometry and longer Ni—N (secondary amine) bond distances (2.065 and 2.072 Å) when compared with that of square-planar $[NiL]Cl_2 \cdot 2H_2O$ (1.941 and 1.954 Å) [10]. Furthermore, the spectrochemical study of a series of high-spin $[NiAX_2]$ (A = tetraaza macrocyclic ligands; $X = Br^-$, Cl^-, N_3^- and NCS^-) was reported by Busch *et al.* [16]. In this study, it was found that the ligand field strengths for axial ligands reflect the normal spectrochemical series. Redox potentials for these complexes are also consistent with the spectral results.

In the present study, we report the syntheses and properties of $[NiLX_2]$ (L = 3,14-dimethyl-2,6,13,17-tetraazatricyclo[14,4,$0^{1,18}$,$0^{7,12}$]docosane; $X = N_3^-$ and NCS^-). To understand the nature of the axial ligands, the solid state X-ray crystal structures of

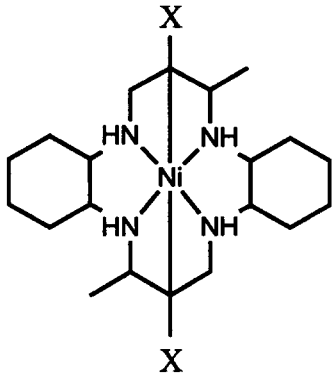
$[NiLX_2]$ complexes are determined and compared to their solution structures by the electronic absorption spectroscopy and cyclic voltammetry.



(X: N_3^-, NCS^-)

EXPERIMENTAL

Materials

All solvents were reagent grade and purified according to the literature [17]. All chemicals used in syntheses were of reagent grade and were used without further purification. The macrocyclic ligand L and complex $[NiL]Cl_2 \cdot 2H_2O$ were prepared as described previously [10,18].

Measurements

Infrared spectra were recorded as KBr pellets on a Perkin–Elmer Paragon 1000 FT–IR spectrophotometer, electronic spectra with a Jasco Uvidec-610 spectrophotometer. High-resolution fast atom bombardment mass spectrometry (FAB mass) were performed by using a Jeol JMS-HA 110A/110A instrument. Elemental analyses were carried out by the Korea Research Institute of Chemical Technology, Taejeon, Korea. Cyclic voltammograms were obtained by using a BAS 100BW electrochemical system. All measurements were made on 0.01 M tetraethylammonium perchlorate–dichloromethane solution at 20°C. A hanging mercury dropping electrode for cathodic voltammetry and a platinum disc electrode of about 2 mm diameter for anodic voltammetry were used as the working electrodes. The counter electrode was a coiled platinum wire and a saturated calomel electrode was used as a reference electrode. The solution was degassed with high purity nitrogen prior to carrying out the electrochemical measurements.

Synthesis of $[NiL(N_3)_2]$ (1)

To a methanol solution (20 cm^3) of $[NiL]Cl_2 \cdot 2H_2O$ (251 mg, 0.5 mmol) was added NaN_3 (65 mg, 1 mmol) and the mixture was heated for 30 min on a steam bath. The solution was filtered to remove the sodium chloride. The solution was then evaporated to dryness. The resulting solid was extracted into chloroform and recrystallized by adding acetonitrile. The violet crystals were collected by filtration and dried *in vacuo* (yield: 187 mg, 78%). Calc. (found) for $NiC_{20}H_{40}N_{10}$: C, 50.1 (49.9); H, 8.4 (8.5); N, 29.2 (29.1)%. IR (KBr, cm^{-1}): 3218 s (ν NH), 2036 vs (ν N_3). Electronic spectra ($CHCl_3$): λ_{max}, nm (ε, M^{-1} cm^{-1}): 528 (10.7), 317 (2133) and 244 (5770). FAB mass (CH_2Cl_2, m/z): 479 $(M)^+$.

Synthesis of $[NiL(NCS)_2]$ (2)

To a methanol solution (20 cm^3) of $[NiL]Cl_2 \cdot 2H_2O$ (251 mg, 0.5 mmol) was added KSCN (97 mg, 1 mmol) and the mixture was heated for 30 min on a steam bath. The solution was filtered to remove the potassium chloride. The solution was then taken to dryness and the resulting solid dissolved in acetonitrile/water (1:1, 10 cm^3). When this mixture was allowed to stand for a few days, a quantity of violet crystals precipitated. These were filtered off, washed with diethyl ether and dried *in vacuo* (yield: 192 mg, 75%). Calc. (found) for $NiC_{22}H_{40}N_6S_2$ C, 51.7 (51.5); H, 7.9 (8.0); N, 16.4 (16.4)%. IR (KBr, cm^{-1}): 3212 s (ν NH) and 2062 vs (ν SCN). Electronic spectra ($CHCl_3$): λ_{max} nm (ε, M^{-1} cm^{-1}): 510 (9.9), 323 (20) and 245 (5398). FAB mass (CH_2Cl_2, m/z): 511 $(M)^+$.

Crystallography

Analyses on single crystals of $[NiL(N_3)_2]$ (1) and $[NiL(NCS)_2]$ (2) were carried out with an Enraf–Nonius CAD4 diffractometer. A summary of the data collection and details of the structure refinement is given in Table 1. The violet crystals of **1** and **2** were mounted on the diffractometer and used for data collections with graphite-monochromated Mo–K_α radiation (0.71069 Å). Unit-cell parameters and a crystal orientation matrix were determined by least-squares fit of 25 reflections. An asymmetric unit of intensity data were collected in the ω-2θ scan mode. A total of 2265 and 2451 unique reflections of **1** and **2** were measured, of which 2086 and 1980 with $[F_o > 3\sigma(F_o)]$ were used in the structure determination. The intensity data were collected for Lorentz and polarization effects. No absorption correction was applied. The structure was solved by direct methods and refined by full matrix least-squares refinement (NRCVAX and SHELXL-93) [19,20]. All non-hydrogen atoms were placed with a combination of difference Fourier and least-squares calculations. Hydrogen atoms in methyl groups were located from difference Fourier maps,

other hydrogen atoms were placed in calculated positions. Anisotropic thermal parameters were used for all non-hydrogen atoms and isotropic thermal parameters were used with the hydrogen atoms. The positions of hydrogen atoms were fixed during the least-squares process. Full crystallographic details, atomic coordinates, interatomic distance and angles, hydrogen atom coordinates, anisotropic displacement parameters and structure factor tables for **1** and **2** have been deposited with the editor as supplementary material.

RESULTS AND DISCUSSION

Crystal structures of complexes

The ligand skeleton of the present compounds contains the most stable *trans*-III conformation with two gauche five-membered and two chair six-membered chelate rings. Two methyl groups on the six-membered chelate rings are *anti* with respect to the N_4 plane. The N—Ni—N angles of the six-membered chelate rings are longer than those of the five-membered chelate rings. An inversion centre of these complexes exists on the central nickel(II) ion.

An ORTEP drawing of $[NiL(N_3)_2]$ (**1**) with atomic labelling scheme is shown in Fig. 1 and selected bond lengths and angles in Table 2. The crystal structure of **1** shows that the nickel(II) ion is coordinated by the secondary amines of the macrocycle and that the axial positions are bonded by two nitrogen atoms of the azide ligands. The average Ni—N (secondary amines) distance [2.085(2) Å] is significantly longer than in the square-planar geometry of $[NiL]Cl_2 \cdot 2H_2O$ [1.948(4) Å] [10], but is similar to that observed for high-spin octahedral nickel(II) complexes with 14-membered tetraaza macrocyclic ligands [15,21–25]. However, the four Ni—N distances in NiN_4 plane are shorter than the axial Ni—N(3) distance of 2.175(2) Å, indicating an axially elongated octahedral geometry. The axial Ni—N(3) linkages are bent slightly off the perpendicular to the NiN_4 plane by 1.0–4.6°. The axial Ni—N(3) bond distance and Ni—N(3)—N(4) angle [119.8(2)°] are similar to those observed for catena-(μ-N_3) $[Ni(cyclam)](ClO_4) \cdot H_2O$ [26]. Furthermore,

Ni—N(2)—C(7)	112.5(2)	N(3)—C—S	177.2(3)

Primes denote the symmetry equivalent $-x, -y, -z$.

the azido group is slightly asymmetric [N(3)—N(4) = 1.172(3) and N(4)—N(5) = 1.161(4) Å] and linear [N(3)—N(4)—N(5) angle = 179.2(3)], as found for monodentate azido ligands in complex **1**.

An ORTEP diagram of $[NiL(NCS)_2]$ (**2**) with atomic labelling scheme is shown in Fig. 2 and selected bond lengths and angles in Table 3. The coordination environment around nickel(II) ion shows a six-coordinated octahedron with two nitrogen atoms of thiocyanate ligands and four nitrogen atoms of the macrocyclic ligand. The average Ni—N (secondary amines) distance [2.083(3) Å] is similar to that found in **1** and shorter than the axial Ni—N(3) distance of 2.115(3) Å, giving an axially elongated octahedral geometry. Also, the axial Ni—N(3) bond is not perpendicular to the NiN_4 plane with N(3)—Ni—N(1) and N(3)—Ni—N(2) angles of 86.1(1) and 92.5(1)°. The Ni—N(3)—C and N(3)—C—S angles related to the thiocyanate ligand are 143.7(3) and 177.2(3)°, respectively.

Spectra and properties of the complexes

The complexes **1** and **2** are stable in the solid state and are soluble in water, acetonitrile, nitromethane, methylene chloride and chloroform. The infrared spectra of the complexes **1** and **2** are listed in Table 4. The infrared spectra of these complexes show a band at *ca.* 3200 cm^{-1}, which is assigned to the ν (NH) of the coordinated secondary amines. That the spectrum of **1** contains only a single very strong broad band at 2036 cm^{-1} associated with the azide stretching mode is consistent with the crystal structure of **1**. For complex **2** the infrared data are consistent with the N-bonded thiocyanato structure as a strong broad band at 2062 cm^{-1} is characteristic of Ni—N bonding [27] which shows the crystal structure of **2**. The electronic absorption spectra (Table 4) of complexes **1** and **2** in chloroform solution show maximum absorptions at 528–510, 317–323 and 244–245 nm. The wavelengths of the *d–d* bands for the present complexes are 65–47

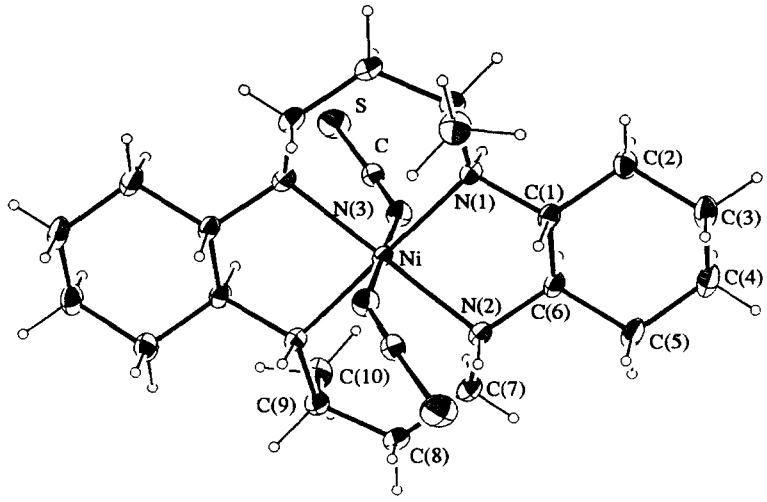

Fig. 2. An ORTEP drawing of $[NiL(NCS)_2]$ (**2**) with the atomic labelling scheme.

Table 4. Infrared and electronic spectral data

Complex	IR (cm^{-1}) ν (NH)	ν (N_3)	ν (SCN)	Electronic, λ_{max}, nm (ε, M^{-1} cm^{-1})[a]
$[NiL][ClO_4]_2$[b]	3185 (s)			463(73)[c]
$[NiL(N_3)_2]$ (**1**)	3218 (s)	2036 (vs)		528(10.7), 317(2133), 244(5770)
$[NiL(NCS)_2]$ (**2**)	3212 (s)		2062 (vs)	510(9.9), 323(20), 245(5398)

[a] In chloroform solution at 25°C.

[c] In nitromethane solution.

nm longer than that of $[NiL][ClO_4]_2$ (463 nm) [18], indicating that the complexes **1** and **2** have a six-coordinated octahedral geometry. However, the wavelength of the *d–d* band of **1** is somewhat longer than that of **2** in spite of the similar average Ni—N (secondary amines) bond distance. This fact can be reasonably explained by the spectrochemical series ($N_3^- < NCS^-$). A similar result was observed for related octahedral nickel(II) complexes of 14-membered tetraaza macrocyclic ligands [16].

Cyclic voltammetry data for nickel(II) complexes in 0.01 M TEAP-CH_2Cl_2 solution are given in Table 5. The complexes **1** and **2** exhibit two one-electron waves corresponding to Ni(II)/Ni(III) and Ni(II)/Ni(I) processes. The more negative potentials for **1** and **2**, compared with $[NiL][ClO_4]_2$, are resulted from the structural geometry (high-spin octahedral vs low-spin square-plane), which makes the oxidation of Ni(II) to Ni(III) easier and the reduction to Ni(I) difficult. Meanwhile, although complexes **1** and **2** have a similar average Ni—N (secondary amines) bond distance, the redox potentials for **2** are slightly more positive than those for **1** indicating that those of complex **2** are difficult to oxidize and easier to reduce. This result can be reflected by the π-donor ability of the axial ligands as observed in the visible spectra of these complexes.

Table 5. Cyclic voltammetric data for the nickel(II) complexes[a]

Complex	Potentials (V) vs Ag/AgCl Ni(II)/Ni(III)	Ni(II)/Ni(I)
$[NiL][ClO_4]_2$[b]	+1.08	−1.28
$[NiL(N_3)_2]$ (**1**)	+0.66	−1.54
$[NiL(NCS)_2]$ (**2**)	+0.79	−1.30

[a] Measured in 0.01 M TEAP-CH_2Cl_2 solution at 20°C.

(Received 16 July 1997; accepted 19 September 1997)

Abstract—The compound $[(CH_3)_3CNH_3]_4[SiMo_{12}O_{40}] \cdot 2H_2O$ has been synthesized and characterized chemically by means of FT-IR and Raman spectroscopy, microanalyses and thermal analyses. The X-ray diffraction crystal analysis reveals the presence of the Keggin cluster, *t*-butylammonium cations and water molecules joined by means of electrostatic interactions and hydrogen contacts. On the other hand, an electrochemical study using cyclic voltammetry was carried out, showing reversible cathodic redox processes. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: silicododecamolybdate; *tert*-butylammonium cation; crystal structure.

The chemistry of Mo(VI), W(VI) and V(V) in aqueous solution is dominated by the formation of iso- and heteropolyoxometalates that can be viewed as discrete fragments of close-packed extended oxide structure [1].

During the last two decades this class of compounds has aroused increasing interest due to their unique properties including size, electron transfer abilities, thermal stability and lability of lattice oxygen [2]. In addition, some of these compounds have found applications in analytical and clinical chemistry [3], as well as in the fields of catalysis [4], photochemistry [5], medicine and biology [6] and material science [7]. The most active area of applications is catalysis, being the Keggin type anions [8] the most widely employed as homogeneous and heterogeneous catalysts [9]. The Keggin polyanion can be formulated as $[X^{n+}M_{12}O_{40}]^{(8-n)-}$ (M = Mo, W; X = Si, P, Ge, S, B, ...). Their structure result from the association of four M_3O_{13} units tetrahedrally disposed around the central atom X. According to Baker and Figgis [10], there are five possible isomers, α, β, γ, δ and ε, which differ by rotation of one, two, three of four M_3O_{13} groups by $\pi/3$. Until now, only the α and β isomers are known as isolated polyanions [11]. Other isomers, such as ε, are known as polycations $\{[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$ [12] and as part of larger structures [13].

Several structures containing the $[\alpha\text{-}SiMo_{12}O_{40}]^{4-}$ anion are known from the literature: $H_4[SiMo_{12}O_{40}] \cdot 13H_2O$ [14], $(CH_6N_3)_4[SiMo_{12}O_{40}] \cdot H_2O$ [15], $(NH_4)_3[(C_4H_9)_2NH_2][SiMo_{12}O_{40}] \cdot 2H_2O$ [16], $(TTF)_2^0$ $(TTF_4)^{2+}(H^+)(Et_4N)^+[SiMo_{12}O_{40}]$ [17], $[Fe(C_5Me_5)_2]_4[SiMo_{12}O_{40}] \cdot DMF$ [18] and $(DMNP)_2(MNP)_2[SiMo_{12}O_{40}] \cdot 2DMF$ [19].

In the present paper, we report the synthesis, vibrational study, crystal structure, thermal behaviour and electrochemical properties of $[(CH_3)_3NH_3]_4[SiMo_{12}O_{40}] \cdot 2H_2O$.

EXPERIMENTAL

General and instrument

All chemicals were procured commercially and used without subsequent purification. Microanalyses of carbon, nitrogen and hydrogen were performed on a Perkin-Elmer 240 C-, H-, N-analyser and silicon and molybdenum were determined thermogravimetrically as $SiO_2 + MoO_3$ after thermal decomposition of the samples in an argon–oxygen atmosphere.

IR spectra were recorded on a Nicolet 740 FT-IR spectrometer as KBr pellets in the spectral region 4000–400 cm^{-1}. Raman spectra were made on a Nicolet 950 FT Raman spectrometer equipped with a Spectra Physics $Nd:YVO_4$ laser (1064 nm, 1.5 W) as static powder samples. A Setaram TAG 24S 16 thermobalance was used to obtain simultaneously the differential thermal analysis (DTA) and thermogravimetric analysis (TGA) curves, in a synthetic air atmosphere and in an inert atmosphere of argon with a heating rate of 5°C min^{-1}.

The electrochemical study was carried on by means of cyclic voltammetry in a polargraph PAR 174A coupled to a register X-Y Houston 2000. The cell of measurement consists of three electrodes: Ag/AgCl(s)/KCl as reference electrode, a Pt wire as auxiliary electrode and an electrode of glassy C METROHM (diameter = 3 mm) as working electrode. KCl 1 M was used as electrolyte and the concentration of the electroactive specie was of the order of 10^{-3} M. All the solutions were deoxygenated passing a current of nitrogen before the measurement. The potential scan was done at a speed of 20 $mV \cdot s^{-1}$ in the range from 1.0 V to −2.0 V.

Synthesis of $[(CH_3)_3CNH_3]_4[SiMo_{12}O_{40}] \cdot 2H_2O$

To a solution of $[(CH_3)_3CNH_3]_4[Mo_8O_{26}] \cdot 6H_2O$ [20] (1.15 g, 0.72 mmol) in 50 ml of water were added 5 ml of Na_2SiO_3(aq) (0.31 M, 1.55 mmol SiO_2) and the solution was acidified with HCl (3 M) up to pH = 1 (yellow solution). Crystals of the compound appeared after two weeks. Found: C, 8.9; H, 2.4; N, 2.6; ($MoO_3 + SiO_2$) 83.08. Calc. for $C_{16}H_{52}Mo_{12}N_3O_{42}Si$: C, 8.89; H, 2.46; N, 2.62; ($MoO_3 + SiO_2$) 83.84%.

X-ray diffraction

Single crystals suitable for X-ray analysis of the compound were obtained as described above. Structural measurements were performed on a Philips PW1100 diffractometer (graphite monochromated MoKα radiation, $\lambda = 0.71069$ Å). The data were collected at 295 K using ω–2θ scan technique up to 50° in 2θ. The intensities were corrected for Lorentz and polarization effects. Neutral atoms scattering factors and anomalous dispersion factors were taken from the literature [21].

The structure has been solved using the program DIRDIF92 [22] finding the anion $[SiMo_{12}O_{40}]^{4-}$ and three of the *t*-butylammonium cations. The last *t*-butylammonium cation and the position of the water molecules were located on successive Fourier maps. An empirical absorption correction (DIFABS) [23] was applied when all the non-hydrogen atoms had been located. The crystal structure was then refined with anisotropic thermal parameters for all the non-hydrogen atoms by full-matrix least-squares analysis. The hydrogen atoms were generated at geometrically fixed positions. Most calculations were carried out using the XRAY 76 [24] system running on a Micro VAXII computer. Table 1 summarizes crystal data and data collection procedures for this compound.

RESULTS AND DISCUSSION

Thermal decomposition

The thermal decomposition of $[(CH_3)_3CNH_3]_4[SiMo_{12}O_{40}] \cdot 2H_2O$ starts with the loss of the water molecules in both atmospheres yielding the anhydrous salt that is stable up to 240°C approximately. This stability range is similar to the one observed for the compound tris(*tert*-butylammonium)phosphododecamolybdate(VI) dihydrate [25]. Then, the decomposition of the anhydrous salt takes place in both atmospheres without stable intermediate products (Table 2). In oxidant atmosphere it occurs in three exothermic steps finishing at 440°C in a stable residue that corresponds to $MoO_3/SiO_2 = 12:1$, but only the existence of MoO_3 could be confirmed by means of Powder Diffraction Data. While in inert atmosphere, the decomposition of the anhydrous salt takes place in two overlapping steps followed by a progressive mass loss, the process finishes at 600°C. The presence of Mo(V) in the black final residue has been confirmed by means of EPR.

Figure 2 shows the TG, DTG and DTA curves corresponding to the thermal decomposition in synthetic air and argon atmospheres of the compound.

Vibrational spectroscopy

The infrared and Raman spectra of the title compound are shown in Fig. 3. A systematic study of the cation-size effect on the vibrational spectra of Keggin polyanions has been performed by Rochcchiccioli-Deltcheff [26]. The anion–anion electrostatic interactions are responsible for a strong increase in the stretching frequencies. These interactions can be considered as perturbations on the charge-density distribution, on the geometry of the anion and on the vibrational spectra with respect to isolated anion. Table 3 lists the values of the frequencies of the stretching modes for the compound together with the $H_4[SiMo_{12}O_{40}]$ (higher anion–anion interactions) and $(TBA)_4[SiMo_{12}O_{40}]$ (neglected anion–anion interactions) for comparison.

[a] Progressive weight loss

Crystal structure of $[(CH_3)_3CNH_3]_4[SiMo_{12}O_{40}] \cdot 2H_2O$

The asymmetric unit consists of a $[SiMo_{12}O_{40}]^{4-}$ anion, four *t*-butylammonium cations and two water molecules. The silicododecamolybdate(VI) anion adopts the α-Keggin structure in which a central tetrahedron SiO_4 is surrounded by twelve MoO_6 octahedra that are disposed in four groups Mo_3O_{13} of three edge-sharing octahedra, each group is joined to the adjacent

polyanion: four O_a atoms which connect Si and Mo atoms; twelve bridging O_b atoms, located in the shared corners between two Mo_3O_{13} units; twelve O_c atoms, which connect edge-sharing MoO_6 octahedra in Mo_3O_{13} units, and twelve terminal oxygen atoms, O_t.

The Mo atoms are not at the centre of the octahedron but located towards the terminal oxygen atom giving the following distribution of distances: Mo—O_t (short): 1.671–1.701 Å; Mo—O_{b-c} (medium): 1.801–2.063 Å; Mo—O_a (long): 2.323–2.362 Å. The Si—O distances are in the range 1.624–1.638 Å (Table 4).

Figure 4 shows the projections onto the plane (011). The anions and water molecules are placed in shells parallel to the plane (100) at two different x levels ($x = \frac{1}{4}$ and $x = \frac{3}{4}$). The *t*-butylammonium cations are located between the shells of polyanions forming an extended network of hydrogen contacts of the types N—H···O, N—H···O_w, O_w—H···O, C—H···O and C—H···O_w, however, hydrogen contacts between the water molecules are not observed (Table 5). Cations **1** and **2** are joined to three different polyanions and to the water molecule $O(41)_w$ while cations **3** and **4** form hydrogen contacts with oxygen atoms from two different silicododecamolybdate(VI) anions and with the water molecule $O(42)_w$.

Electrochemical studies

Table 6 summarizes the cathodic and anodic peak potentials (mV) as well as the difference potential for the tetrakis(*tert*-butylammonium)silicododecamolybdate(VI) dihydrate. Figure 5(a) shows the voltamperogram for this compound done at a sensitivity of 20 μA. Three reversible processes that involve one e^- are observed. If the measurement is done at a sensitivity of 100 mA, three more cathodic processes are observed but only the last two are revers-

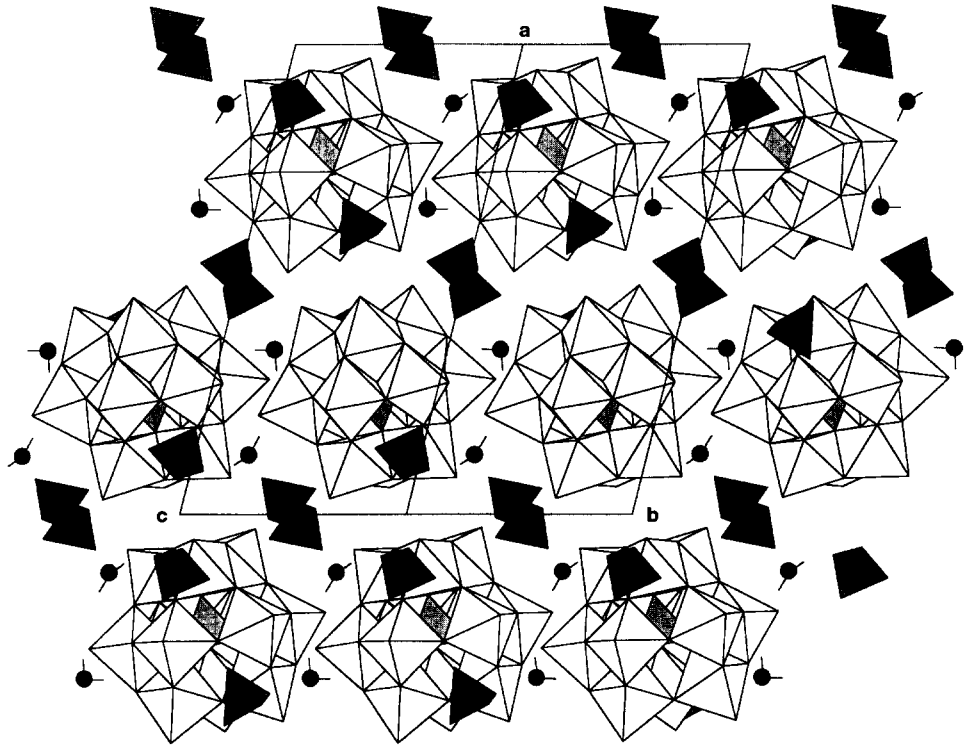

Fig. 4. View along the [0 1 1] direction. *tert*-Butylammonium cations are represented by tetrahedra for clarity.

ible [Fig. 5(b)]. The first of them corresponds to a process of 2 e^- ($\Delta Ep = 40$ mV) and the second one to a process of 1 e− ($\Delta Ep = 60$ mV). The peaks at −1310 mV and −1070 mV are wide and asymmetric, fact that could be due to the existence of two overlapping processes. The reversibility criteria used was $\Delta E_p = E_c - E_a = 59/n$ mV (n = number of electrons).

Table 6. Cathodic and anodic peak potential (E_c) and (E_{pa}) (mV), difference of potential for the cyclic voltamperogram of the compound at a sensitivity of 20 μA and 100 mA, respectively

Sensitivity 20 μA			Sensitivity 100 μA		
E_c	E_a	ΔE_p	E_c	E_a	ΔE_p

(Received 5 May 1997; accepted 15 September 1997)

Abstract—The palladium complex $[PdCl_2(PhCN)_2]$ reacts readily with metal bis(dialkyl dithiocarbamates) $[M(S_2CNR_2)_2]$ (M = Pb, Zn, Cd, Hg, Cu, Ni, MoO_2, VO; R = Et, Bu^n), in refluxing dichloromethane, to afford the known complexes $[\{PdCl(S_2CNR_2)\}_2]$ in virtually quantitative yield. In boiling acetonitrile the diphosphine complexes $[PdX_2(Ph_2PCH_2CH_2PPh_2)]$ (X = Cl, Br) react readily with bi- and trivalent metal diethyl dithiocarbamates $[M(S_2CNEt_2)_n]$ (M = Pb, Zn, Cd, Hg, Ni, MoO_2, VO $n = 2$; M = Co, Fe, Mn, $n = 3$) to afford salts of the general form $[Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)]_2^+[MX_4]^{2-}$. Diethyl dithiocarbamates of copper(II) and silver(I) form salts of the $[Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)]^+$ cation containing linear $[CuX_2]^-$ and $[AgX_2]^-$ anions respectively (X = Cl, Br). The X-ray crystal structures of $[Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)][CuCl_2]$ and $[Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)][AgCl_2]\cdot 0.5CH_2Cl_2$ are reported. © 1998 Elsevier Science Ltd. Keywords: palladium; dithiocarbamate halometallate anions; crystal structure.

Dithiocarbamate ligands display a rich and varied coordination chemistry providing a wide range of transition and main group metal complexes, many of which have important chemical and biological properties [1–4]. Most transition metals form bis-and/or tris-(dithiocarbamato) complexes in which the sulfur atoms of the chelate dithiocarbamate ligands possess nonbonding lone pairs. Such complexes should in principle be capable of acting as S-donor ligands to other metal centres and thereby generating homo- or hetero-polynuclear complexes. This behaviour pattern is commonly encountered with transition metal aminothiolate complexes *cis*-$[M(N–S)_2]$ and *fac*-$[M(N–S)_3]$ (N–S = 2-aminoethane thiolate or L-cysteinate) which form S-bridged polynuclear species by acting as bidentate or tridentate S-donor ligands respectively towards a variety of class b metal ions [5]. However, it is a relatively rare phenomenon in dithiocarbamate coordination chemistry. The few structurally characterised homonuclear examples in which the chelate dithiocarbamate ligands bridge through sulfur to a second metal centre include the ruthenium complexes $[Ru_2(Et_2NCS_2)_5][BF_4]$ [6], $[\{Ru(CO)(S_2CNEt_2)_2\}_2]$ and $[Ru_3(CO)_3Cl_2(S_2CNEt_2)_4]$ [7], the cobalt complex $[Co_2(S_2CNEt_2)_5][BF_4]$ [8] and the rhodium complex $[Rh_2(S_2CNMe_2)_5][BF_4]\cdot 0.5CH_2Cl_2$ [9]. In addition several bis(dithiocarbamato) complexes exist in the solid state as dimers (e.g. $[Cu(S_2CNEt_2)_2]_2$ [10], $[Zn(S_2CNEt_2)_2]_2$ [11]) or polymers (e.g. $[Mn(S_2CNEt_2)_2]_n$ [12]), with chelate dithiocarbamate ligands bridging through sulfur to a second metal atom. Structurally characterised examples of heteronuclear complexes in which chelate dithiocarbamate ligands bridge through sulfur to a second metal atom are even less common. The best established examples are the iron/zinc species $[(p\text{-}ClPhNC)_2Fe(S_2CNEt_2)_2ZnI_2]$ [13], and some adducts of copper(I) halides with tris(dithiocarbamato) complexes $[M(S_2CNR_2)_3]$ (M = Co, Rh, Cr) [14–18]. Finally, several authors have reported "het-

erobimetallic" dithiocarbamato bridged complexes "$MM'_2(S_2CNR_2)_6$" and "$[MM'(S_2CNR_2)_4]_n$" (M = Zn, Cd, Hg; M′ = VO, Mn, Fe, Co, Ni, Cu, Zn) formed by adding stoichiometric amounts of simple metal salts MX_2 (X = $MeCO_2$, NO_3) and M^IY_2 (Y = NO_3, Cl, $1/2SO_4$) to a solution of sodium dithiocarbamate in 4:1 acetone:water. However, our investigations show that the products are simple mixtures of mononuclear bis- or tris(dithiocarbamato) complexes [19]. In an attempt to synthesise further examples of heteropolynuclear complexes containing S-bridging dithiocarbamate ligands we are investigating the reactions of bis- and tris(dithiocarbamato) complexes $[M(S_2CNR_2)_n]$ (n = 2, 3) with a range of soft (class b) metal ions. In the present paper we describe the reactions of dithiocarbamato complexes with the palladium species $[PdCl_2(PhCN)_2]$ and $[PdX_2(Ph_2PCH_2CH_2PPh_2)]$ (X = Cl, Br), and the characterisation of products isolated therefrom.

EXPERIMENTAL

All solvents used were dried over molecular sieves prior to use. 1,2-bis(diphenylphosphino)ethane was purchased from Lancaster Synthesis, palladium chloride and bromide from Johnson Matthey. Metal dithiocarbamates were prepared from the metal nitrates and the sodium salt of the ligand in aqueous media and recrystallised from dichloromethane/petroleum spirit 60–80°C. Dichloro[bis(benzonitrile)]palladium(II) was prepared by dissolving palladium(II) chloride in benzonitrile on a steam bath over a period of 5 h, cooling to room temperature and filtering off the precipitated product. Dichloro- and dibromo[1,2-bis(diphenylphosphino)ethane]palladium(II) were prepared by dissolving the relevant palladium halide in acetonitrile under reflux and adding the stoichiometric amount of diphosphine to the filtered solution thus obtained. Both complexes were recrystallised from dichloromethane. Infrared spectra were recorded using Perkin–Elmer 983G (4000–500 cm^{-1}) and Perkin–Elmer FTIR System 2000 (500–100 cm^{-1}) as cesium iodide pellets. NMR spectra were recorded using a Bruker AM360 spectrometer at 360 MHz (^1H) and 145 MHz (^{31}P) in $CDCl_3$ solutions and were referenced to $SiMe_4$ and external H_3PO_4 85% respectively. Melting points were recorded in sealed tubes under nitrogen using an Electrothermal apparatus. Elemental analyses were performed at the Microanalytical Laboratory, University College London.

Di-μ-chlorobis(N,N-*di*-n-*butyldithiocarbamato*) *dipalladium(II)*

Dichloro[bis(benzonitrile)] palladium (0.384 g, 1.00 mmol) and bis(*N*,*N*-di-*n*-butyldithiocarbamato) copper (0.236 g, 0.50 mmol) were refluxed in dichloromethane (60 ml) for 30 min. The solution obtained was filtered from an insoluble brown precipitate and evaporated to dryness under reduced pressure. The residue was washed with diethyl ether (2 × 10 ml) and dried *in vacuo* for 3 h. Slow evaporation of a benzene solution of the product afforded dark orange–red crystals. Yield: 0.312 g, 90%; m.p. 118–120°C. [Reaction with other bis-dithiocarbamato complexes $M(S_2CNR_2)_2$ (M = Pb, Zn, Cd, Hg, Ni, MoO_2, VO) on a similar scale using the same method afforded the same product (R = Bu^n) or an analogous product (R = Et).]

(N,N-*diethyldithiocarbamato*)[1,2 - *bis*(*diphenylphosphino*)*ethane*]*palladium(II) tetrachlorozincate* 0.5 *dichloromethane*

Dichloro[1,2-bis(diphenylphosphino)ethane]palladium (0.230 g, 0.40 mmol) and bis(*N*,*N*-diethyldithiocarbamato)zinc (0.072 g, 0.20 mmol) were refluxed in acetonitrile (60 cm^3) with stirring for 1 h. The solution obtained was filtered and evaporated to dryness under reduced pressure. The oily residue that formed was dissolved in dichloromethane (5 cm^3) and the complex reprecipitated by the addition of diethyl ether (60 cm^3). The fine yellowish–white powder obtained was filtered off, washed with diethyl ether and dried *in vacuo*. Yield: 0.278 g, 92%; m.p. 149–151°C.

The following complexes were obtained on a similar scale by the same method:

(*N*,*N*-diethyldithiocarbamato)[1,2-bis(diphenylphosphino)ethane]palladium(II) tetrabromozincate 0.5 dichloromethane as yellowish–white fine powder. Yield: 93%; m.p. 142–144°C.

(*N*,*N*-diethyldithiocarbamato)[1,2-bis(diphenylphosphino)ethane]palladium(II) tetrachlorocadmate dichloromethane(1/2) as yellowish–white fine powder. Yield: 92%; m.p. 140–142°C.

(*N*,*N*-diethyldithiocarbamato)[1,2-bis(diphenylphosphino)ethane]palladium(II) tetrabromocadmate as yellowish–white fine powder. Yield: 93%; m.p. 135–137°C.

(*N*,*N*-diethyldithiocarbamato)[1,2-bis(diphenylphosphino)ethane]palladium(II) tetrachloromercurate(II) as yellowish–white fine powder. Yield: 93%; m.p. 163–165°C.

(*N*,*N*-diethyldithiocarbamato)[1,2-bis(diphenylphosphino)ethane]palladium(II) tetrabromomercurate(II) as yellowish–white fine powder obtained using chloroform (8 cm^3) instead of dichloromethane. Yield: 92%; m.p. 140–142°C.

(*N*,*N*-diethyldithiocarbamato)[1,2-bis(diphenylphosphino)ethane]palladium(II) tetrachloroplumbate 1.0 chloroform as yellowish–white fine powder obtained using chloroform (8 cm^3) instead of dichloromethane. Yield: 93%; m.p. 104–106°C.

(*N*,*N*-diethyldithiocarbamato)[1,2-bis(diphenylphosphino)ethane]palladium(II) tetrabromoplumbate 0.5 dichloromethane as yellowish–white fine powder. Yield: 95%; m.p. 116–118°C.

(*N,N*-diethyldithiocarbamato)[1,2-bis(diphenylphosphino)ethane]palladium(II) tetrachloronickelate as light green fine powder. Yield: 91%; m.p. 144–146°C.

(N,N-*diethyldithiocarbamato*)[1,2 - *bis*(*diphenylphosphino*)*ethane*]*palladium*(*II*) "*trichloroargentate*(*I*)" 0.5 *dichloromethane*

Dichloro[1,2 - bis(diphenylphosphino)ethane]palladium (0.230 g, 0.40 mmol) and (*N,N*-diethyldithiocarbamato)silver (0.102 g, 0.40 mmol) were refluxed in acetonitrile (60 cm^3) for 1 h. The solution obtained was filtered through celite to remove the fine greyish–white precipitate of silver chloride formed and evaporated to dryness under reduced pressure. The oily residue obtained was dissolved in dichloromethane (10 cm^3) and the complex was reprecipitated by the addition of diethyl ether (75 cm^3). The fine yellowish–white powder obtained was filtered off, washed with diethyl ether and dried *in vacuo*. Yield: 91%; m.p. 166–168°C.

(*N,N* - diethyldithiocarbamato)[1,2 - bis(diphenylphosphino)ethane]palladium(II) "tribromoargentate(I)" 1.0 chloroform was similarly obtained as yellowish–white fine powder using chloroform (12 cm^3) instead of dichloromethane. Yield: 90%; m.p. 122–124°C. (See the Discussion section for a statement concerning the nature of the "trichloroargentate" and "tribromoargentate" anions.)

(N,N - *diethyldithiocarbamato*)[1,2-*bis*(*diphenylphosphino*)*ethane*]*palladium*(*II*) *dichlorocuprate*(*I*)

Dichloro[1,2 - bis(diphenylphosphino)ethane]palladium (0.230 g, 0.40 mmol) and bis(*N,N*-diethyldithiocarbamato)copper (0.072 g, 0.20 mmol) were refluxed in acetonitrile (60 cm^3) for 1 h. The solution obtained was filtered and evaporated to dryness under reduced pressure. The oily residue that formed was dissolved in dichloromethane (10 cm^3) and the complex was reprecipitated by the addition of diethyl ether (75 cm^3). The fine light green powder obtained was filtered off, washed several times with diethyl ether to remove all the tetraethylthiuram disulfide byproduct, and dried *in vacuo*. Yield: 90%; m.p. 173–175°C.

The following complex was obtained on a similar scale by the same method:

(*N,N*-diethyldithiocarbamato)[1,2-bis(diphenylphosphino)ethane]palladium(II) dibromocuprate(I) as brownish–green fine powder. Yield: 93%; m.p. 160–162°C.

(N,N - *diethyldithiocarbamato*)[1,2 - *bis*(*diphenylphosphino*)*ethane*]*palladium*(*II*) *tetrachlorocobaltate*(*II*) 0.5 *dichloromethane*

Dichloro[1,2 - bis(diphenylphosphino)ethane]palladium (0.230 g, 0.40 mmol) and tris(*N,N*-diethyldithiocarbamato)cobalt (0.101 g, 0.20 mmol) were refluxed in acetonitrile (70 cm^3) for 10 h. The solution obtained was filtered and evaporated to dryness under reduced pressure. The oily residue that formed was dissolved in dichloromethane (10 cm^3) and reprecipitated by the addition of diethyl ether (75 cm^3). The fine green powder obtained was filtered off, washed several times with diethyl ether to remove all the tetraethylthiuram disulfide byproduct, and dried *in vacuo*. Yield: 90%; m.p. 100–102°C.

The following complex was obtained on a similar scale by the same method:

(*N,N*-diethyldithiocarbamato)[1,2-bis(diphenylphos-phino)ethane]palladium(II) tetrabromocobaltate(II) as green fine powder. Yield: 89%; m.p. 143–145°C.

(N,N-*diethyldithiocarbamato*)[1,2-*bis*(*diphenylphosphino*)*ethane*]*palladium*(*II*) *tetrachloroferrate*(*II*) 0.5 *chloroform*

Dichloro[1,2-bis(diphenylphosphino)ethane]palladium (0.230 g, 0.40 mmol) and tris(*N,N*-diethyldithiocarbamato)iron (0.100 g, 0.20 mmol) were refluxed in acetonitrile (70 cm^3) for 1 h under nitrogen. The solution obtained was filtered and evaporated to dryness under reduced pressure. The oily residue that formed was dissolved in chloroform (12 cm^3) and the complex reprecipitated by the addition of diethyl ether (75 cm^3). The slightly air sensitive olive green powder obtained was filtered off, washed several times with diethyl ether to remove all the tetraethylthiuram disulfide byproduct, and dried *in vacuo*. Yield: 92%; m.p 130–132°C.

The following complexes were obtained on a similar scale by the same method:

(*N,N*-diethyldithiocarbamato)[1,2-bis(diphenylphosphino)ethane]palladium(II) tetrabromoferrate(II) 0.5 dichloromethane as air sensitive dark olive green fine powder obtained using dichloromethane (10 cm^3) instead of chloroform. Yield: 92%; m.p. 116–118°C.
(*N,N*-diethyldithiocarbamato)[1,2-bis(diphenylphosphino)ethane]palladium(II) tetrachloromanganate (II) as light yellow fine powder. Yield: 89%; m.p. 147–149°C.
(*N,N*-diethyldithiocarbamato)[1,2-bis(diphenylphosphino)ethane]palladium(II) tetrabromomanganate(II) as light yellow fine powder. Yield: 93%; m.p. 139–141°C.

(N,N - *diethyldithiocarbamato*)[1,2 - *bis*(*diphenylphos - phino*)*ethane*]*palladium*(*II*) *tetrachlorodioxomolybdate*(*VI*) 0.5 *dichloromethane*

Dichloro[1,2-bis(diphenylphosphino)ethane]palladium (0.230 g, 0.40 mmol) and bis(*N,N*-diethyldithiocarbamato)dioxomolybdenum(VI) (0.085 g, 0.20 mmol) were refluxed in acetonitrile (60 cm^3) for

1 hour. The solution obtained was filtered and evaporated to dryness under reduced pressure. The oily residue that formed was dissolved in dichloromethane (10 cm^3) and the complex reprecipitated by the addition of diethyl ether (75 cm^3). The yellowish white powder obtained was filtered off, washed with diethyl ether and dried *in vacuo*. Yield: 94%; m.p. 118–120°C.

The following complexes were obtained on a similar scale by the same method:

(*N*,*N*-diethyldithiocarbamato)[1,2-bis(diphenylphosphino)ethane]palladium(II) tetrachlorooxovanadate(IV) as light green fine powder. Yield: 93%; m.p. 126–128°C.

(*N*,*N*-diethyldithiocarbamato)[1,2-bis(diphenylphosphino)ethane]palladium(II) tetrabromooxovanadate(IV) as light green fine powder. Yield: 89%; m.p. 135–137°C.

Crystallography. X-ray crystal structures have been determined for $[Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)]^+[CuCl_2]^-$ (**1**) and $[Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)]^+[AgCl_2]^- \cdot 0.5CH_2Cl_2$ (**2**). In each case crystals were obtained from the powdered product by slow crystallisation from a mixture of $CH_2Cl_2/C_6H_5CH_3$.Crystal data were collected on a four-cycle automated Picker diffractometer using Ni filtered Cu—Kα and zirconium filtered Mo—Kα radiation, respectively, with pulse-height analysis. Data reduction and all computations were carried out with the NRCVAX package [20]. Crystal data for compounds (**1**) and (**2**) are set out in Table 1. Atomic coordinates, thermal parameters and bond lengths and angles have been deposited at the Cambridge Crystallographic Data Centre (CCDC).

RESULTS AND DISCUSSION

Initial attempts to prepare heteronuclear complexes involved the reaction of bis(dithiocarbamato) complexes $M(S_2CNR_2)_2$ (M = Pb, Zn, Cd, Hg, Cu, Ni, MoO_2, VO; R = Et, Bu^n) with $PdCl_2(PhCN)_2$. As anticipated, the labile weakly bound PhCN ligands are readily displaced. However the "$PdCl_2$" residues, instead of coordinating to the intact $M(S_2CNR_2)_2$ complexes through the sulfur atoms, underwent a ligand exchange process leading to formation of the known complexes $[PdCl(S_2CNR_2)]_2$ [21]. When the ratio of reagents was adjusted to take account of the new reaction stoichiometry the yield of the palladium complex became almost quantitative. An X-ray crystal structure determination of $[PdCl(S_2CNBu^n_2)]_2$, by one of us (S.C.N.), has been reported elsewhere [22].

The reactions of the palladium(II) diphosphine complex $PdCl_2(Ph_2PCH_2CH_2PPh_2)$ with bis(dithiocarbamate) complexes were then investigated in an attempt to displace the chloride ligands from the soft "$Pd(Ph_2PCH_2CH_2PPh_2)^{2+}$" moiety and generate cationic complexes of the general form $[\{(Ph_2PCH_2CH_2PPh_2)Pd\}_2M(S_2CNEt_2)_2]^{4+}$. Once again, ligand exchange was the preferred reaction pathway and chlorometallate salts of the general form $[Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)]_2[MCl_4]$ were obtained in good yield. When the corresponding reactions were attempted with the tris(dithiocarbamato) complexes

$M(S_2CNEt_2)_3$ (M = Mn, Fe, Co) the facile ligand exchange reactions were accompanied by concomitant reduction of the trivalent metal to the divalent state. Thus the products were again salts of the general form $[Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)]_2[MCl_4]$. The reaction of $Cu(S_2CNEt_2)_2$ with $PdCl_2(Ph_2PCH_2CH_2PPh_2)$ was also accompanied by reduction, this time to afford copper(I) in the form of the dichlorocuprate(I) salt $[Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)][CuCl_2]$. An attempt to prepare the analogous silver(I) complex $[Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)][AgCl_2]$ from the silver(I) dithiocarbamate afforded a complex which gave elemental analyses corresponding to the stoichiometry $[Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)]_2[AgCl_3]$. However, a crystal selected for X-ray diffraction study was found to have the stoichiometry $[Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)][AgCl_2]\cdot 0.5CH_2Cl_2$. Closer examination of the bulk sample revealed evidence for the presence of two crystal forms. We therefore conclude that the elemental analyses data reflect the presence of a ca 50/50 mixture of $[Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)][AgCl_2]$ and $[Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)][Cl]$. Formation of a silver chloride precipitate, corresponding to 91% of the calculated mass, is consistent with reaction sequence given in Scheme 1. However, on the basis of the available evidence it is not possible to determine whether the dissociation of the $AgCl_3^{2-}$ anion to form $AgCl_2^-$ and Cl^- occurred during the initial synthesis or in the course of the procedure used to grow crystals for the X-ray structure determination.

An essentially similar set of reactions involving the dibromopalladium complex $PdBr_2(Ph_2PCH_2CH_2PPh_2)$ gave the corresponding bromometallate complexes $[Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)]_2[MBr_4]$ (M = Pb, Zn, Cd, Hg, Co, Fe, Mn, MoO_2, VO) and $[Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)][M'Br_2]$ (M' = Cu, Ag) in good yield. Again the elemental analyses data for the silver(I) product were consistent with the presence of ca 50% of the simple halide salt $[Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)][Br]$.

The complex salts were characterised by elemental analyses (Table 2), infrared spectroscopy (Table 3) and ^1H and $^{31}P\{^1H\}$ NMR.The dichlorocuprate(I) and dichloroargentate(I) salts were also structurally characterised by X-ray diffraction methods. The elemental analyses data indicated the presence of

$$2PdCl_2(Ph_2PCH_2CH_2PPh_2) + 2Ag(S_2CNEt_2) \rightarrow [Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)]_2[AgCl_3] + AgCl$$

$$[Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)]_2[AgCl_3] \rightarrow [Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)][AgCl_2] + [Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)][Cl]$$

CH_2Cl_2 or $CHCl_3$ of solvation in many instances. This was confirmed for the dichloroargentate(I) salt by X-ray diffraction and, for the other complexes, by detection of a ^1H NMR signal (δCH_2Cl_2 5.3 ppm, $\delta CHCl_3$ 7.27 ppm). The infrared spectra showed bands attributable to coordinated S_2CNEt_2 and $Ph_2PCH_2CH_2PPh_2$ ligands but were mainly employed to characterise the halometallate anions. With the exception of the $PbCl_4^{2-}$, $PbBr_4^{2-}$, $AgCl_2^-$, $AgBr_2^-$ anions, for which we were unable to find reliable data, the infrared spectra recorded agreed well with the literature values for the anions concerned. All the salts, save those containing paramagnetic anions, displayed essentially identical ^1H and $^{31}P\{^1H\}$ NMR data consistent with the presence of the $[Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)]^+$ cation. A typical data set is as follows: $^1H\delta$1.3(t), CH_3CH_2N; 3.80(q) CH_3CH_2N; 3.1(d $^2J_{HP}$ 22.3 Hz) PCH_2CH_2P; 7.55 (m) and 7.75 (m), C_6H_5. $^{31}P\{^1H\}$ δ59.5 (s). Changes associated with variations in the nature of the anion present are $\pm$0.05 ppm and $\pm$0.5 ppm for ^1H and $^{31}P\{^1H\}$ resonances respectively.

Two aspects of these reactions need further comment. First, the dithiocarbamate ligands transferred quantitatively to the "$Pd(Ph_2PCH_2CH_2PPh_2)^{2+}$" moiety even when the other metal involved was relatively soft in character, i.e. Hg^{2+}, Pb^{2+}. This suggests that soft palladium(II) further softened by the presence of the coordinated diphosphine ligand has a particularly high affinity for the dithiocarbamate anion. Second, in the reaction involving tris(dithiocarbamato) complexes, the ligand exchange and the accompanying redox reactions occurred readily even when the relatively inert low spin d^6 cobalt(III) dithiocarbamate was involved. This behaviour contrasts sharply with that of the corresponding cobalt(III) 2-aminoethane thiolate complex *fac*-$[Co(SCH_2CH_2NH_2)_3]$ which binds intact to soft metal centres as a tridentate S-donor ligand [5].

The halometallate salts, though obtained in high yield and purity, did not readily afford crystals for X-ray crystallography. However crystals of adequate size and quality were obtained for the dichlorocuprate(I) and dichloroargentate(I) salts. Their crystal structures were therefore determined in order to confirm the nature of the cation and more importantly, given the absence of unambiguous spectroscopic data, to establish the stoichiometry and structure of the chlo-

roargentate anion present. The crystal structures of the dichlorocuprate(I) and dichloroargentate(I) salts are illustrated in PLUTO plots (Figs 1 and 2, respectively). The atomic labelling scheme employed for the $[Pd(S_2CNEt_2)(Ph_2PCH_2CH_2PPh_2)]^+$ cations is given in Fig. 3. Selected bond lengths and bond angles for both salts are presented in Table 4.

The dichlorocuprate(I) salt contains eight molecules per unit cell, only two of which are shown in Fig. 1. The geometry of the Pd complex cation is essentially square planar, however, the bond angles subtended at the palladium atom reflect the narrow bites of the diphosphine and diethyldithiocarbamate chelate ligands. The central coordination of the diphosphine and the S_2CN part of the diethyl dithiocarbamate moiety are closely coplanar with the Pd atom. The plane of C(4)—N—C(6) is however twisted 8.1(8)° from the coordination plane due, presumably, to packing forces. The copper atoms of the two independent $[CuCl_2]^-$ ions lie in the $z = 0$ plane on different two-fold special positions (four of each per unit cell). Whereas Cu(2) lies on the centre of symmetry at the origin and thus the ion is linear symmetric: Cu(2)—Cl(2) = 2.085(9) Å, Cu(1) lies on a diad axis with Cu(1)—Cl(1) = 2.055(6) Å and with the angle Cl(1)—Cu(1)—$Cl(1)_a$ = 1.7(3)°. The data found for the $[CuCl_2]^-$ anion are in good agreement with those previously reported for a range of dichlorocuprate(I) salts containing a variety of counter cations [23].

The dichloroargenate(I) salt contains four molecules per unit cell, two of which are shown in Fig. 2. The geometry of the cation is essentially the same as in the dichlorocuprate(I) salt. In contrast to the $[CuCl_2]^-$ ion the $[AgCl_2]^-$ anion has, to the best of our knowledge, been characterised by X-ray diffraction methods only in the complex salt [K(Crypt 2,2,2)][$AgCl_2$] [24]. The dimensions recorded for the $[AgCl_2]^-$ ion in the present study (Table 4) agree well with those previously reported for [K(Crypt 2,2,2)][$AgCl_2$]. The anion is essentially linear and the Ag atom does not lie on a special position. The crystal also contains two molecules of dichloromethane of crystallisation per unit cell. These lie too close to the centre of symmetry for both motifs to be present sim-

ultaneously and are thus given half occupancy. The two Cl atoms refined anisotropically but the carbon would not.

Finally the crystal structures of the complexes (**1**) and (**2**) reveal the presence of a number of short contact distances between the chloride ligands of the MCl_2^- anions and the phenyl hydrogens of the complex cations (Table 5, Figs 4 and 5) which we attribute to H-bonding interactions. Hydrogen bonding between C—H moieties and chloride anions [25,28] or chloride ligands [25–27] is now a well established phenomenon. The H···Cl distances and C—H···Cl angles found for complexes (**1**) and (**2**) are well within the range of values associated with this type of interaction (H···Cl = 2.569–2.944 Å; C—H···Cl = 119.3–169.2°) [25]. Indeed the H···Cl distances are all at the lower end of the range, and suggest the presence of relatively strong C—H···Cl interactions. There is also a short interatomic distance (see Table 5) between a phenyl proton and one of the chlorine atoms of the disordered CH_2Cl_2 solvent molecule, which we take to indicate the presence of a $ClCH_2$—Cl···H—C hydrogen bonding interaction.

Acknowledgements—We thank Dr C. A. Koh for the use of the Perkin–Elmer FTIR System 2000 instrument.

Table 5. C—H···Cl Hydrogen bonding interactions in complexes **1** and **2**

Complex	Interaction	H···Cl Distance (Å)	Angle (°)
1	C(27)—H(27)···Cl(1)	2.553	147.0

Theoretical investigation of the π-bonding ability of P-, S-, and N-containing ligands in group 6 transition metal complexes

S.-H. Park,† M. C. Milletti* and N. Gardner

Department of Chemistry, Eastern Michigan University, Ypsilanti, Michigan 48197, U.S.A.

(Received 28 March 1997; accepted 12 September 1997)

Abstract—The π-bonding ability of several ligands bonding through N, P, and S to group 6 transition metals was studied via non-empirical molecular orbital calculations. The ability of the ligands to donate or accept π electrons to or from the metal was compared in 1,2-$Mo_2[P(t\text{-}Bu)_2]_2[NMe_2]_4$ **[I]** and 1,2-$W_2[P(t\text{-}Bu)_2]_2[NMe_2]_4$ **[II]**; $(PSO)Cr(CO)_4$ **[III]** and $(PSO)W(CO)_4$ **[IV]** (PSO = 2-diphenyl phosphino methyl-2-phenylthiomethyl-1-methoxy propane); and $[W(2\text{-}Spy)(CO)_4]^-$ **[V]** and $[Mo(2\text{-}Spy)(CO)_4]^-$ **[VI]** (2-Spy = 2-thiol pyridine). Mulliken population analyses were used to study how two different atoms compete for π-bonding with the metal. Both NMe_2 and PMe_2 are π donors to the metal in complexes **[I]** and **[II]**. Overall, the phosphido ligand is a better π donor than the amido ligand. The PSO ligand in complexes **[III]** and **[IV]** is a good π acceptor and phosphorus is a better π acceptor than sulfur in both complexes. The 2-Spy ligand in the two anionic complexes, **[V]** and **[VI]**, is a good π acceptor. π back-donation from the metal *d* orbitals to the ligand is mostly through the nitrogen of the pyridine ring rather than the sulfur external to the pyridine ring. The electron density withdrawn from the metal through the nitrogen is delocalized throughout the π-conjugated ring. The π-accepting ability of the 2-Spy ligand in the two complexes is about the same.

The observed differences in the π-bonding ability of the ligands are explained in terms of the accessibility of the ligand molecular oribitals and the geometry of the complexes. A comparison of π-bonding between the two linking atoms in the same bidentate ligand is also made in terms of the type and energy of ligand orbitals (compound **[III]** vs **[IV]** and **[V]** vs **[VI]**). A direct comparison is made between electron density distribution and crystallographic bond lengths. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: π-bonding; ligands; molecular orbitals.

One of the most common areas of inquiry involving transition metal complexes concerns the bonding of the ligands to the metal centers, be it by examining structures or spectroscopic data. Due to the rapid development of computer systems and the success of many semiempirical molecular orbital models in explaining bonding behavior of large systems, it is possible to investigate bonding in complex transition metal systems using easy-to-interpret molecular orbital calculations.

The main objective of this work is to study the π-bonding ability of ligands bonding via N-, P-, and S-atoms to group 6 transition metals, Cr, Mo, and W. The investigation was carried out by performing Fenske-Hall [1] molecular orbital calculations on three pairs of related transition metal complexes: 1,2-$Mo_2[P(t\text{-}Bu)_2]_2[NMe_2]_4$ **[I]** and 1,2-$W_2[P(t\text{-}Bu)_2]_2[NMe_2]_4$ **[II]** [2]; $(PSO)Cr(CO)_4$ **[III]** and $(PSO(W(CO)_4$ **[IV]**, PSO = 2-diphenylphosphino-methyl-2-phenylthiomethyl-1-methoxy propane [3a]; $[Mo(2\text{-}Spy)(CO)_4]^-$ **[V]** and $[W(2\text{-}Spy)(CO)_4]^-$ **[VI]**, 2-Spy = 2-thiol pyridine [4].

The first pair of complexes contains ligands of the type PR_2 and NR_2. These ligands are good electron donors to metals because the bonding atoms have unshared electron pairs. In the Mo and W dimers, the ligands are bonded to the same metal center and therefore compete for the same metal *d* orbitals to overlap with their readily accessible lone pairs in π-fashion. This pair of complexes, therefore, affords the opportunity of comparing the electron-donating

† Current address: Department of Chemistry, Loyola University of Chicago, Chicago, Illinois 60626, U.S.A.

ability of PR_2 and NR_2 ligands. Furthermore, the two dimers enable a comparison of π-donating ability to differing metal centers: Mo and W.

In complexes **[III]** to **[VI]**, the PSO and $[2\text{-Spy}]^-$ ligands are bidentate to Cr or W and Mo or W, respectively. These ligands are expected to donate electron density from filled σ orbitals and to accept electron density from the filled $d\pi$ orbitals on the metal centers into their empty $p\pi$ orbitals. In this process, they compete with CO ligands, which are also known to be good π acceptors. Complexes **[III]**–**[VI]**, therefore, provide a comparison of π-accepting ability among P-, S-, and N-containing ligands when they bond with Cr, W, and Mo.

From the results of the calculations, conclusions will be drawn about the efficacy of PR_2, NR_2, 2-Spy, and PSO ligands as π acceptors or π donors to metal centers as a function of metal identity. The results will be analyzed in terms of electron density distribution and energies of molecular orbitals.

COMPUTATIONAL PROCEDURE

All molecular orbital calculations were carried out using the Fenske-Hall nonempirical method [1]. The atomic basis sets for carbon, nitrogen, oxygen, phosphorus, and sulfur were constructed according to Clementi's specifications for ground state atomic functions [5]. The $2p$ and $3p$ orbitals of these atoms were double-ξ, in which two different sets of coefficients and exponents are used to describe a single atomic basis function. Basis sets for P- and S-atoms included single-ξ $3d$ functions. The hydrogen exponent was set to 1.16 [6].

The basic functions employed for the metals were obtained from atomic X-α calculations on sets of optimized, orthonormal Slater-type orbitals (STOs) [7]. The exponents for these valence atomic orbitals were set to prevent the outer valence orbitals from being too diffuse [8,9]. The chromium $4s$ and $4p$ exponents were set to 2.0; the molybdenum $5s$ and $5p$ exponents were set to 2.2; and the tungsten $6s$ and $6p$ exponents were set to 2.4.

1,2-$Mo_2[P(t\text{-}Bu)_2]_2[NMe_2]_4$ *and* 1,2-$W_2[P(t\text{-}Bu)_2]_2[NMe_2]_4$

The structure of complexes **[I]** and **[II]** was obtained from structural data given in the literature [2]. The butyl groups on the phosphine ligands were substituted with methyl groups to facilitate analysis of the results. Such substitutions have been shown not to affect Mulliken population significantly [6]. The geometry of both complexes is shown in Fig. 1.

$(PSO)Cr(CO)_4$ *and* $(PSO)W(CO)_4$

X-ray crystal structures of **[III]** and **[IV]** were taken from the literature [3b]. The coordinates derived from the X-ray data for these molecules were idealized to an octahedral geometry in order to simplify analysis of the molecular orbitals (see Fig. 2). The phenyl groups

attached to both phosphorus and sulfur atoms were substituted by hydrides for simplicity of interpretation and greater ease in the computation.

$[W(2\text{-Spy})(CO)_4]^-$ *and* $[Mo(2\text{-Spy})(CO)_4]^-$

Since crystal structure data for these two molecules was not available, the energy minimization procedure of the Spartan software package [10] that employs the empirical molecular mechanics method based on the SYBYL force field [11] was used to obtain the geometry of $[Mo(2\text{-Spy})(CO)_4]^-$. This procedure was used to refine the preliminary structures constructed by using known bond lengths and angles from related compounds [12,13]. For the calculation of $[W(2\text{-Spy})(CO)_4]^-$, tungsten was substituted into the position of molybdenum and all other atom coordinates were unchanged. The structures of $[W(2\text{-Spy})(CO)_4]^-$ and $[Mo(2\text{-Spy})(CO)_4]^-$ are shown in Fig. 3. From this result, the position of the four carbonyl ligands bonded to the metal was idealized to an octahedral geometry. The difference in atomic coordinates between the preliminary structure and the optimized structure using molecular mechanics was minimal. For example, the ∠NMS angle obtained by the molecular mechanics optimization is 68.7°, which compares favorably to the value (67.0°) from the crystal structure data of a related complex [12].

RESULTS AND DISCUSSION

The study of π-bonding patterns in the metal complexes of interest in this work was accomplished mainly through the analysis of molecular orbital (MO) diagrams. From the MO diagram of the ligand in a specific metal complex, information regarding its function in the compound was obtained: specifically, whether the ligand is a π donor or a π acceptor. If the ligand MO diagram shows low-lying, unoccupied π orbitals, the ligand will function as a good π acceptor. If the ligand has high-energy, filled valence π orbitals, it can act as a π donor to the metal. In either type of ligand, the presence of a high-lying σ-orbital suggests it can form a σ bond with the metal. The quantitative analysis of π-bonding in the metal complexes was accomplished by using a Mulliken population analysis [14].

Relative π-donating ability of amido and phosphido ligands in [I] *and* [II]

The relative π-donating ability of ligands such as OR, SR, NR_2, and PR_2 is currently not well understood. Two of the transition metal dimers under study, [I] and [II], allowed an analysis of the relative π-donating ability of an amido and a phosphido ligands, $N(CH_3)_2$ and $P(CH_3)_2$, to transition metal centers. These compounds also allowed a comparative analysis of π donation to a second row transition metal, Mo, vs a third row metal, W. The tungsten and molybdenum complexes have identical valence electron counts and the same ligands bonded to the metal. However, the two compounds have different conformations when they crystallize, anti and gauche respectively, as shown in Fig. 1.

An analysis of the MO diagram for [I] shows that the HOMO and SHOMO (second highest occupied molecular orbital) of the complex are mainly W—NR_2 π in character, while the occupied MOs at lower energy are PR_2 π and W—NR_2 π. In these molecular orbitals, the filled π orbitals of the phosphido and amido ligands donate electron density into empty metal *d* orbitals. Therefore, both phosphido and amido ligands are π donors in this complex.

The MO diagram for [II] is qualitatively similar to that of [I]. The HOMO is mainly Mo—NR_2 π in character while the SHOMO is mainly Mo—PR_2 π. At lower energy, again the orbitals are a mixture of Mo—PR_2 and Mo—NR_2 π bonds as in the case of the tungsten dimer. However, in the molybdenum dimer the mixing of orbitals is much more extensive, due in part to the lower symmetry of the complex.

A Mulliken population analysis is given in Table 1. The relative π-donating ability of the ligands, PMe_2 and NMe_2, to the two metal centers, W and Mo, may be inferred from these results. PMe_2 loses more π-electron density in both of the metal complexes (in [I] 0.1 e^- and in [II] 0.1–0.2 e^-), and therefore is a better π donor than NMe_2. This can be explained by the fact that, in both complexes, the energy of the PR_2 π orbital is closer than that of the NR_2 π orbital to the energy of the metal *d* orbitals. In other words, PR_2 is better

able to form a bonding molecular orbital with metal *d* orbitals than NR_2. Furthermore, the π-donating ability of the PMe_2 ligand and that of two of the NME_2 ligands (L_2 and L_3) decreases in going from molybdenum to tungsten. On the other hand, π-electron donation from the NR_2 L_1, L_4 ligands increases slightly in going from Mo to W.

Relative π-accepting ability of the PSO ligand in [III] *and* [IV]

Polydentate ligands have been studied extensively [15–18]. The synthesis of a tripodal phosphine ligand with two different π acceptor atoms (P and S) and its complexation to tungsten and chromium have been reported by Liu *et al.* [3]. The geometry of this ligand, 2-diphenyl-phosphinomethyl-2-phenylthiomethyl-1-methoxypropane, whose name will be abbreviated as PSO, is shown in Fig. 2(a). A theoretical investigation of the bonding in the complexes (PSO)$Cr(CO)_4$ and (PSO)$W(CO)_4$, shown in Fig. 2(b), will allow a comparison of P and S π-accepting ability between first and third row transition metals.

The MO diagram for the PSO ligand shows that the HOMO and the SHOMO are both σ with respect to the position of the metal center. The presence of a set of three low-lying virtual π orbitals indicates that PSO may fulfill the requirement of a good π acceptor.

The MO diagram for (PSO)$Cr(CO)_4$ is shown in Fig. 4. A fairly large gap separates the third highest occupied molecular orbital from the next set of occupied orbitals, which represent σ-bonding between the PSO ligand and the metal center. The HOMO and SHOMO and the third highest occupied MO are mainly bonding combinations of metal and CO π^* orbitals while the LUMO and unoccupied MOs at higher energy are anti-bonding combinations between the metal center and the PSO π orbitals. In conclusion, the PSO ligand acts both as a σ donor and a π acceptor in this complex.

The MO diagram for the (PSO)$W(CO)_4$ complex shows that the LUMO and MOs at higher energy have the same characteristics as in the chromium complex, indicating that there is π-back bonding from the tungsten *d* orbitals to the empty π orbitals of the PSO ligand.

A more quantitative description of the amount of electron donation from the metal to the ligand was

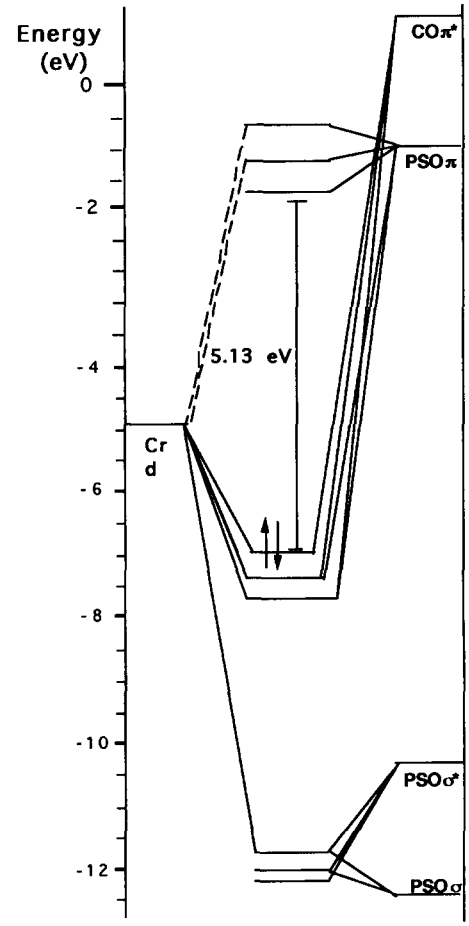

Fig. 4. MO diagram for (PSO)$Cr(CO)_4$.

obtained through a Mulliken population analysis. The data (shown in Table 2) indicates that the amount of π back donation from tungsten is greater than that from chromium. It is also of interest to differentiate between P and S in terms of the amount of back donation. This is done by looking at contributions from individual atoms to the electron density population of the ligand π orbitals participating in bonding with the metal.

More specifically, the PSO ligand receives electrons through the 3*p* and 3*d* orbitals of P and S. The combination of 3*p* and 3*d* is of π symmetry with respect

Table 2. Amount of π back donation to the PSO ligand in the complexes $W(CO)_4(PSO)$ and $Cr(CO)_4(PSO)$

	Orbital occupation of PSO orbitals	Total π back donation
PSO	$(\pi)^0(\pi^{nb})^0(\pi^*)^0$	
$W(CO)_4(PSO)$	$(\pi^b)^{0.31}(\pi^{nb})^{0.23}(\pi^*)^{0.01}$	0.55
$Cr(CO)_4(PSO)$	$(\pi^b)^{0.28}(\pi^{nb})^{0.22}(\pi^*)^{0.01}$	0.50

to the electron rich metal *d* orbital. Hence, a Mulliken population analysis has been employed at the atomic level to investigate how π-electron density is apportioned between P and S in the atomic orbitals specified above. The amount of π back donation to the individual P and S atoms in the tungsten complex are $0.33e^-$ and $0.16e^-$, respectively. In the case of the Cr complex, P withdraws $0.34e^-$ and S withdraws $0.13e^-$ (see Table 3).

As it is shown in Table 3, phosphorus is a better π acceptor than sulfur in both **[III]** and **[IV]**. In both metal complexes, the amount of π back donation to P ($0.33–0.34e^-$) is approximately two times greater than that to S ($0.13–0.16e^-$). As it was already shown in Table 2, the total π back donation to the PSO ligand was greater in the tungsten complex than in the chromium complex when we consider that π electrons were mainly back donated to empty *p* and *d* orbitals on P and S.*

The strength or amount of π acceptance of sulfur and phosphorus in an octahedral metal carbonyl complex can also be analyzed by inspecting the metal–carbonyl distance. Since the amount of π back donation to phosphorus is greater than that to sulfur, the competition in π back donation between phosphorus and sulfur should be evident from differences in the corresponding metal to carbonyl (M-C) distances [19]. The $W—C_{trans\ to\ sulfur}$ distance (1.88 Å) and $W—C_{trans\ to\ phosphorus}$ distance (1.94 Å) from the crystallographic data [3a] are consistent with our results. The same is true for the $Cr—C_{trans\ to\ sulfur}$ distance (1.806 Å) and $C—C_{trans\ to\ phosphorus}$ distance (1.820 Å) [3a]. The shorter distance between the carbonyl *trans* to the sulfur and the metal can be attributed to the fact that the amount of π back donation from the metal to sulfur is less than that to phosphorus. Consequently, the carbonyl ligand *trans* to S receives more π-electron density than another CO *trans* to P. Since the M—C bond becomes stronger as the amount of M to CO back-bonding increases, a carbonyl ligand *trans* to a sulfur atom will have a shorter M—C bond than one *trans* to phosphorus.

The results of the calculations are also confirmed when comparing the two equatorial carbonyls: the one *trans* to P has a longer M—C bond length in both complexes, since our data shows that P is a better π acceptor than S in the PSO ligand.

Relative π-bonding ability of S and N in the 2-Spy ligand in complexes **[V]** *and* **[VI]**

The relative π-bonding ability of sulfur and nitrogen bonded to group 6 transition metals in the two anionic complexes $[Mo(2\text{-}Spy)(CO)_4]^-$ and $[W(2\text{-}Spy)(CO)_4]^-$ was also investigated. The synthesis of these compounds has been carried out by Sanchez-Palaez *et al.* [4]. These compounds are of interest because π-accepting properties of N and S in this kind of bidentate ligand have never been studied.

The MO diagram of the bidentate ligand pyridine-2-thiol (2-Spy) shows that the highest occupied molecular orbital is σ with respect to the metal and it is predominantly localized on the sulfur atom (67% of the electron density in the MO). The diagram therefore suggests that the 2-Spy ligand can donate σ-electron density to the metal using the lone pair of electrons localized on the sulfur. The LUMO is π in character and localized on the nitrogen. The next highest molecular orbital is also π but it is mainly localized on the sulfur atom. Nitrogen also has lone pair electrons but it lies at a much lower energy (−6.13 eV) than the lone pair on sulfur (at −2.43 eV) which

* The sum of π back donation to P and S in Table 4 is less than the total amount of π back-donation shown in Table 3 because the numbers in Table 4 do not take into account π electron density that is delocalized onto the rest of the PSO ring.

Table 3. Comparison of π-back bonding to phosphorus and sulfur in the two metal complexes, $W(CO)_4(PSO)$ and $Cr(CO)_4(PSO)$

	AO occupations of P and S	π back donation to P	π back donation to S
Free PSO ligand	$(P\ 3p,\ 3d)^{1.74}\ (S\ 3p,\ 3d)^{2.64}$		
$W(CO)_4(PSO)$	$(P\ 3p,\ 3d)^{2.07}\ (S\ 3p,\ 3d)^{2.80}$	0.33	0.16
$Cr(CO)_4(PSO)$	$(P\ 3p,\ 3d)^{2.08}\ (S\ 3p,\ 3d)^{2.77}$	0.34	0.13

	Orbital occupation of [2-Spy]$^-$ orbitals[a]	Total π back donation
2-Spy	$(\pi^N)^0(\pi^S)^0$	
$[W(2\text{-Spy})(CO)_4]^-$	$(\pi^N)^{0.49}(\pi^S)^{0.05}$	0.54
$[Mo(2\text{-Spy})(CO)_4]^-$	$(\pi^N)^{0.48}(\pi^S)^{0.04}$	0.52

[a] π^N is for the π orbitals of [2-Spy]$^-$ ligand localized on phosphorus and π^S is for the π orbitals of [2-Spy]$^-$ ligand localized on sulfur.

is involved in the HOMO. Consequently, S and N are in a position to be good π acceptors.

The MO diagrams based on our calculations for $[W(2\text{-Spy})(CO)_4]^-$ and $[Mo(2\text{-Spy})(CO)_4]^-$ confirm the π-back bonding characteristics predicted above. In Fig. 5, the LUMO of the ligand is stabilized by bonding with one of the W *d* orbitals. This represents the metal-to-ligand π-back bonding interaction through nitrogen in this molecule. The molybdenum complex shows a similar pattern of π-back bonding. The π donation from the ligand to the metal expected from the ligand MO diagram is also confirmed by the MO diagrams of the complexes. That is, the SHOMO of the ligand, which is a π orbital localized on sulfur, donates π electrons to the empty metal *d* orbitals in the SHOMO of the complex.

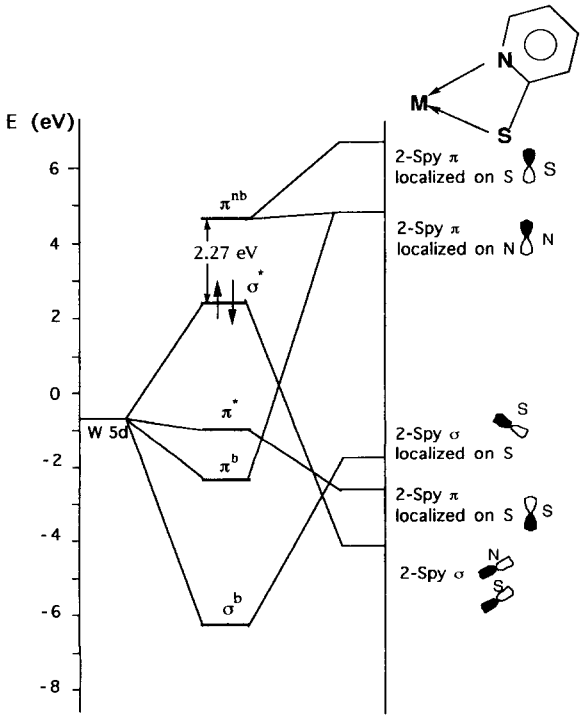

Fig. 5. MO diagram for the $[W(2\text{-Spy})(CO)_4]^-$ complex.

The π-electron density populations of the [2-Spy]$^-$ ligand before and after complexation with W and Mo are shown in Table 4. The amount of π back donation to the ligand is greater in the tungsten complex than in the molybdenum complex. Therefore the 2-Spy ligand acts as a better π acceptor in the tungsten complex than in the molybdenum complex. This can be explained by considering the energy differences between metal atomic orbitals and ligand molecular orbitals. The W *d* orbitals are closer in energy to the ligand LUMO than the Mo *d* orbitals and are therefore better able to donate π-electron density to the LUMO. The amount of π back donation to the 2-Spy ligand in both the tungsten and molybdenum complexes is not negligible (0.52–0.54e$^-$). However most of these electrons are transferred through nitrogen (0.48–0.49e$^-$): the empty ligand orbital localized on nitrogen is more accessible by the metal *d* electrons in terms of energy than that localized on sulfur.

The main channel for σ-bonding from the 2-Spy ligand to the metal is through sulfur, as explained earlier, but π electron back donation occurs mostly through nitrogen. These are consistent with the energy levels of the molecular orbitals localized on sulfur and nitrogen in the case of both σ-donation and π back donation. However, if the Mulliken populations for individual atomic orbitals are investigated, Table 5 shows that the π-electron density population on the nitrogen atom is negligibly small (0.02e$^-$ for the W complex and 0.01e$^-$ for the Mo complex). This may be attributed to π conjugation in the 2-Spy ligand. That is, the π-electron density taken from the metal through nitrogen is now delocalized through the pyridine ring via conjugated π orbitals.

CONCLUSIONS

Non-empirical Fenske-Hall molecular orbital calculations have been used to study the π-bonding ability of ligands bonding through N, S, and P to the metals Cr, Mo, and W. A qualitative description of the π-bonding pattern was obtained in each of the metal complexes through an analysis of the molecular orbital diagram. The relative amount of π-bonding in ligands bonding through N vs P; P vs S; and N vs S

Table 5. Comparison of π-electron density at nitrogen and sulfur as a result of π back donation from the metal in two anionic metal complexes, $[W(2\text{-Spy})(CO)_4]^-$ and $[Mo(2\text{-Spy})(CO)_4]^-$

	AO occupations of N and S	π density at N	π density at S
Free ligand	$(N\,2p_z)^{1.19}$ $(S\,3p_z)^{1.77}$		
$[W(2\text{-Spy})(CO)_4]^-$	$(N\,2p_z)^{1.21}$ $(S\,3p_z)^{1.82}$	0.02	0.05
$[Mo(2\text{-Spy})(CO)_4]^-$	$(N\,2p_z)^{1.20}$ $(S\,3p_z)^{1.82}$	0.01	0.05

to the same metal was obtained through Mulliken population analyses, as was the amount of π-bonding of the same ligand to different metal atoms. The results are summarized below.

The amido (NMe_2) and the phosphido (PMe_2) ligands in the dimers $1,2\text{-}Mo_2[P(t\text{-}Bu)_2]_2[NMe_2]_4$ and $1,2\text{-}W_2[P(t\text{-}Bu)_2]_2[NMe_2]_4$ are π donors to the metal. Overall, the phosphido ligand is a better π donor than the amido ligand in both metal complexes. The π-donating ability of the PMe_2 groups is greater toward molybdenum than towards tungsten. On the other hand, the π-donating ability of the NMe_2 ligand in the L_1 and L_4 positions in the molybdenum dimer is poorer than in the tungsten dimer.

The PSO ligand in $(PSO)Cr(CO)_4$ and $(PSO)W(CO)_4$ is a good π acceptor and also a ligand-to-metal σ donor. The π-accepting ability of the PSO ligand in $(PSO)W(CO)_4$ is greater than that in $(PSO)Cr(CO)_4$. In addition, phosphorus is a better π acceptor than sulfur in both complexes but the difference in π-bonding between the two metal complexes is negligible.

The 2-Spy ligand in the two anionic complexes $[Mo(2\text{-Spy})(CO)_4]^-$ and $[W(2\text{-Spy})(CO)_4]^-$ is a good σ donor as well as a good π acceptor. It also has some ability to donate π-electron density to the metal through ligand molecular orbitals localized on nitrogen. The π-accepting ability of the 2-Spy ligand in $[Mo(2\text{-Spy})(CO)_4]^-$ and $[W(2\text{-Spy})(CO)_4]^-$ is about the same. The ligand to metal σ-donation is from the lone pair of electrons on sulfur, and most of the metal to ligand π-accepting occurs through nitrogen. A Mulliken population analysis performed on the 2-Spy ligand's atomic orbitals shows a negligibly small π-electron density on N and S. This is attributed to the delocalization of the π electrons through the conjugated bonds in the pyridine ring.

In conclusion, the relative π-bonding ability of different ligands to group 6 metals was successfully investigated at the non-empirical level. By studying bidentate or polydentate ligands which bond through N, S, and P atoms in group 6 transition metal complexes, we were able to obtain relative order (or magnitude) of π-bonding ability.

(Received 2 July 1997; accepted 11 September 1997)

Abstract—The organotin(IV) complexes, $ROCOCH_2CH_2SnCl_3 \cdot nL$ (R = Me, Et, *n*-Pr, Allyl, *n*-Bu, *i*-Bu; $n = 1, 2$; L = dibutylsulfoxide) have been synthesized and characterized. The spectral data (IR, ^1H and ^{13}C NMR) indicate that the 1 : 1 ($n = 1$) and 1 : 2 ($n = 2$) complexes are all hexa-coordinated tin compounds, and the carbonyl oxygen is coordinated to intramolecular tin atom in 1 : 1 complexes and is free in 1 : 2 complexes. The crystal structure of $EtOCOCH_2CH_2SnCl_3 \cdot L$ shows that the tin atom adopts a distorted octahedral geometry via the oxygens of dibutylsulfoxide and intramolecular carbonyl group to tin coordination. © 1998 Elsevier Science Ltd. Keywords: β-alkoxycarbonylethyltin trichloride; dibutylsulfoxide; complex; synthesis; characterization; crystal structure.

Since Hutton *et al* [1,2] developed a novel route to the preparation of β-alkoxycarbonylethyltin trichlorides, $ROCOCH_2CH_2SnCl_3$, these compounds have received considerable attention because of the variety of coordination geometries regarding the tin atom and also their applicability as a PVC stabilizer with low mammalian toxicities [3–10]. The crystal structure of $CH_3OCOCH_2CH_2SnCl_3$ [3] revealed that the central tin atom was penta-coordinated with the intramolecular carbonyl oxygen to tin atom coordination. However, the IR data indicated that the intramolecular coordination can be broken by external donor molecules, such as 2,2′-bipyridyl, 1,10-phenanthroline, etc. [4–8]. In order to go further into the coordinated chemistry of $ROCOCH_2CH_2SnCl_3$, we have synthesized and characterized the 1 : 1 and 1 : 2 complexes of the organotin compounds with monodentate ligand dibutylsulfoxide (L) and have determined the crystal structure of $EtOCOCH_2CH_2SnCl_3 \cdot L$.

EXPERIMENTAL

All chemicals were of reagent grade and used without further purification. The solvents used were dried over $CaCl_2$ and distilled before use. Carbon and hydrogen analyses were carried out with a Perkin-Elmer 2400 elemental analyzer, and tin was determined gravimetrically as SnO_2. Melting points were measured on a WRS-1 melting point apparatus. IR spectra (4000–400 cm^{-1}) were recorded on an Alpha Centauri FT-IR spectrophotometer in KBr pellets. ^1H and ^{13}C NMR spectra in $CDCl_3$ against TMS as internal standard were recorded on a Bruker AC-80 FT-NMR spectrometer.

Preparation of $ROCOCH_2CH_2SnCl_3$

The compounds, $ROCOCH_2CH_2SnCl_3$ (R = Me, Et, *n*-Pr, Allyl, *n*-Bu, *i*-Bu), were prepared from $SnCl_2$, HCl and $CH_2{=}CHCO_2R$ by methods previously reported [2,8].

Preparation of $ROCOCH_2CH_2SnCl_3 \cdot L$

A solution of L (0.81 g, 5 mmol) dissolved in 40 cm^3 benzene was added dropwise to a stirred solution of

$ROCOCH_2CH_2SnCl_3$ (5 mmol) in 40 cm^3 benzene. The reaction mixture was refluxed for 1 h. The colourless crystals which formed in the concentrated solution were filtered off and recrystallized from benzene–petroleum ether (b.p. 70–90°C) (1 : 1, v/v). The yields, melting points, analysis, IR and NMR data of the complexes are listed in Tables 1 and 2.

Preparation of $ROCOCH_2CH_2SnCl_3 \cdot 2L$

An ether solution (30 cm^3) of $ROCOCH_2CH_2SnCl_3$ (5 mmol) was added slowly to a stirred solution of L (1.62 g, 10 mmol) in 30 cm^3 of ether. The reaction mixture was stirred continuously for 1 h at room temperature. The colourless semi-solids at the bottom were obtained by removing ether, and washed with ether and dried *in vacuo*. The results are listed in Tables 1 and 2.

Crystal structure determination of $EtOCOCH_2CH_2SnCl_3 \cdot (n\text{-}C_4H_9)_2SO$

Crystal data. $C_{13}H_{27}Cl_3O_3Sn$, M = 488.45, orthorhombic, space group $P2_12_12_1$, $a = 7.832(2)$, $b = 11.648(2)$, $c = 22.952(5)$ Å, $V = 2093.8(8)$ Å^3, $Z = 4$, $D_c = 1.59$ g cm^{-3}, $F(000) = 984$, $\mu(\text{Mo-}K_\alpha) = 1.708$ mm^{-1}, $\lambda = 0.71073$ Å, $T = 293(2)$ K.

Data collection and structure solution and refinement.

A colourless crystal with the dimensions $0.3 \times 0.2 \times 0.2$ mm was mounted on a Nicolet R3m/E four circle diffractometer. Graphite monochromated Mo-K_α radiation was used for the X-ray measurement. The unit-cell parameters were determined from a least-squares fit of the angular setting of 25 reflections in the range $2.5 < \theta < 13°$. The intensity of 2213 reflections were measured ($0 \leqslant h \leqslant 9$, $0 \leqslant k \leqslant 13$, $0 \leqslant l \leqslant 27$) by using the θ–2θ scan technique to $2\theta_{max} = 50°$. 2139 of these are independent reflections ($R_{int} = 0.0397$) and 1807 of these with $I \geqslant 2\sigma(I)$ were assumed to be observed reflections. Two standard reflections were remeasured every 50 reflections during the data collection and no significant intensity variation was observed (< 5%). The data were corrected for Lorentz and polarization effects and an empirical absorption correction based on ψ scans was applied, with transmission factors from 0.772 to 0.992. These

calculations were performed using program package SHELXTL [11]. The systematic extinction conditions $h00$, $h = 2n+1$; $0k0$, $k = 2n+1$; $00l$, $l = 2n+1$ are compatible with $P2_12_12_1$ space group. The structure was solved in this space group by direct methods in SHELXTL program [11] and refinement on F^2 was performed using SHELXL-93 program [12] by full-matrix least squares, with anisotropic displacement parameters for all non-H atoms. All H-atoms positions were located in calculated positions and isotopically refined. The weighing scheme was $w = 1/[\sigma^2(F_o^2)+(0.0409P)^2+0.6286P]$ where $P = (F_o^2+2F_c^2)/3$; an isotropic extinction correction was applied with $F_{corr} = F_c/k[1+0.001xF_c^2\lambda^3/\sin 2\theta]^{0.25}$ [x refined to 0.005(4)]. The refinement converged to final $R[F^2 > 2\sigma(F^2)] = 0.0362$. $wR(F^2) = 0.0785$, for 1807 unique observed reflections, $S = 1.081$. The maximum and minimum heights of 0.438 and -0.333 e Å^{-3}, respectively. The maximum Δ/σ in the last refinement cycle was 0.0. Atomic scattering factors were taken from the programs mentioned [11,13]. Molecular graphics were drawn with the program package SHELXTL [11].

RESULTS AND DISCUSSION

The complexes, $ROCOCH_2CH_2SnCl_3 \cdot nL$ were obtained by the reaction of $ROCOCH_2CH_2SnCl_3$ with dibutylsulfoxide ligand in appropriate molar ratios (1 : 1 or 1 : 2).

$$ROCOCH_2CH_2SnCl_3 + nL \rightarrow ROCOCH_2CH_2SnCl_3 \cdot nL.$$

The 1 : 1 complexes ($n = 1$) are colourless crystals with sharp melting points and the 1 : 2 complexes ($n = 2$) are colourless semi-solids. They are soluble in benzene, ethanol and chloroform, but insoluble in ethyl ether and petroleum ether. The observed molar conductances of the complexes in nitrobenzene at room temperature are in the range 3.96–5.27 ohm^{-1} cm^2 mol^{-1}, indicating that the compounds are non-electrolytes [14].

Spectroscopic properties of the complexes

The characteristic IR bands of the complexes relevant to their molecular structures are listed in Table 1. Among the stretching modes, the ν(C=O) band in the 1640–1740 cm^{-1} region is known to depend on the nature of coordination of the carbonyl oxygen to metal atom [4,5]. The ν(C=O) bonds of the 1 : 2 complexes (~1730 cm^{-1}) are in the same region as that of the free fatty acid ester (~1740 cm^{-1}), in which the carbonyl group is not coordinated to the tin atom, whereas the ν(C=O) bands of the 1 : 1 complexes (1650–1664 cm^{-1}) exhibit remarkable red shift from that of the free fatty acid ester. Such results clearly indicate that the coordination of the carbonyl oxygen to tin is maintained in the 1 : 1 complexes, but such a coordination is broken to accommodate two dibutylsulfoxide ligands. Compared with ν(S=O) of free dibutylsulfoxide (1038 cm^{-1}), the ν(S=O) of the complexes shifts to a lower frequency (948–966 cm^{-1}), confirming its coordination to tin via oxygen [15]. Thus, it may be seen that all the complexes are hexa-coordinated to tin.

The ^{1}H and ^{13}C NMR data listed in Table 2 also support the presence of carbonyl oxygen to tin coordination in the 1 : 1 complexes. $\delta(^1H)$ of CH_2O in the 1 : 1 complexes shows a downfield shift by 0.11–0.18 ppm compared to that of the corresponding 1 : 2 complexes, and the $\delta(^{13}C)$ values of C=O and CH_2O in the 1 : 1 complexes are deshielded by 1.09–2.61 ppm (C=O) and 0.71–1.33 ppm (CH_2O), respectively, relative to those of the corresponding 1 : 2 complexes. The coordination of carbonyl oxygen to tin in the 1 : 1 complexes causes the deshielding of CH_2OCO. However, when the coordination is broken by an external ligand, the shielding of CH_2OCO is recovered again.

Crystal structure of $EtOCOCH_2CH_2SnCl_3 \cdot L$

The molecular geometry and the atomic numbering scheme for $EtOCOCH_2CH_2SnCl_3 \cdot L$ are shown in Fig. 1. Bond lengths and bond angles are given in Table 3. The complex exists as a discrete molecule which contains a five-membered chelate ring, formed via ester carbonyl oxygen to tin coordination. The tin atom is hexa-coordinated with the coordinating atoms C(1), Cl(1), Cl(2), Cl(3), O(1) and O(2) in a distorted octahedral arrangement. The bond angles of C(1)—Sn(1)—Cl(1), O(1)—Sn(1)—Cl(3) and O(3)—Sn(1)—Cl(2) are 158.3(2), 170.4(2) and 174.3(2)°, respectively. The bond distances Sn(1)—O(1) (2.350(6) Å), Sn(1)—Cl(1) (2.372(2) Å), Sn(1)—Cl(2) (2.421(2) Å), Sn(1)—Cl(3) (2.401(2) Å), Sn(1)—C(1) (2.146(8) Å) are slightly longer than those (2.347(5), 2.303(2), 2.357(2), 2.317(2), 2.139(9) Å, respectively) in $CH_3OCOCH_2CH_2SnCl_3$ [3]. This indicates that the dibutylsulfoxide oxygen atom to tin coordination weakens the coordination of the other five atoms, compared with penta-coordinate compounds $ROCOCH_2CH_2SnCl_3$. The bond length Sn(1)—O(1) (2.350(6) Å) is longer than Sn(1)—O(3) (2.225(5) Å), and shows that O(3) coordination to tin is stronger than O(1). Thus, when L/EtOCO $CH_2CH_2SnCl_3$ is beyond a 1 : 1 mole ratio, the intramolecular coordination Sn—O(1) is replaced by the oxygen atom of L and the 1 : 2 complex is formed.

(Received 19 June 1997; accepted 1 September 1997)

Abstract—The 1:1 reactions of $FeCl_2 \cdot 4H_2O$ and $FeCl_3$ with the biheteroaromatic ligand 2-(2′-pyridyl)quinoxaline (L) were studied in methanol. The new complexes $[Fe_2Cl_4L_2]$ (**1**) and $[Fe_2Cl_4L_2]Cl_2$ (**2**) were isolated and characterized by elemental analyses, conductivity measurements, magnetic susceptibilities at room temperature and spectroscopic (IR, far-IR, ligand field, ^{57}Fe Mössbauer) techniques. The X-ray crystal structure of **1** consists of two Fe^{II} centres bridged by two chloro ligands, with a terminal chloride and a chelating molecule of L completing five-coordination at each metal. The geometry at iron is distorted trigonal bipyramidal with the bridging chlorides occupying apical and equatorial sites of each Fe^{II} atom. A five-coordinate dinuclear structure is also assigned for the cation of complex **2**. All data are discussed in terms of the nature of bonding and known or assigned structures. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: crystal structures; iron complexes; 2-(2-pyridyl)quinoxaline complexes; ^{57}Fe Mössbauer spectroscopy.

A unifying theme in some of our recent work has been the desire to establish the products from the reaction of the biheteroaromatic ligand 2-(2′-pyridyl) quinoxaline (L) with metal salts, mainly halides, as it has become apparent that this chemistry is rich in structural types, reactivity characteristics and ligand's coordination modes [1–9]. Ligand L, which can potentially combine the chelating properties of 2,2-bipyridine [10] with the bridging behaviour of quinoxaline [11], belongs to a family of heteroaromatic nitrogen heterocycles whose coordination chemistry is currently a subject of intense research efforts [12–17]. The study of complexes of these ligands is important in understanding electron transfer processes, mixed-valent complexes, excited-state acid-base properties of inorganic systems and magnetic coupling interactions; moreover, it finds applications in catalysis, bioinorganic materials chemistry.

Our work to-date has been concentrated on complexes with $3d^7$ (Co^{II}), d^8 (Ni^{II}, Pd^{II}, Pt^{II}), $3d^9$ (Cu^{II}) and d^{10} (Cu^{I}, Zn^{II}, Cd^{II}, Hg^{II}) metal ions. It thus seemed natural to seek to extend this chemistry further to d^5 and d^6 metal ions, and allow comparisons and contrasts to be made concerning the influence of the electronic structure of the metal on the structure of the products and on the coordination mode of L. In this report, we describe the identity of the solid products obtained from the 1:1 reactions of iron(II) and iron(III) chlorides with L and their study with a number or physical techniques. The iron(II) complex has

* Author to whom correspondence should be addressed.

been structurally characterized by single-crystal X-ray crystallography.

EXPERIMENTAL

All manipulations were performed under aerobic conditions using materials and solvents as received. L was synthesized as described previously [1]. Elemental analyses, physicochemical measurements and spectroscopic techniques were carried out by published methods [4,18–20].

Preparation of $[Fe_2Cl_4L_2]$ (1)

To a stirred pale green solution of $FeCl_2 \cdot 4H_2O$ (0.2 g, 1.0 mmol) in MeOH (10 ml) was added a solution of L (0.21 g, 1.0 mmol) in the same solvent (10 ml) to give a pale brown solution. The flask was stored at ambient temperature for 2 days, and the resulting brown crystals of **1** were collected by filtration, washed with cold MeOH (2 × 5 ml) and Et_2O (2 × 5 ml) and dried *in vacuo* over silica gel. The yield was 0.22 g (66%). Some crystals were suitable for X-ray crystallography. Anal. Calc. for $C_{26}H_{18}N_6Cl_4Fe_2$: C, 46.74; H, 2.72; N, 12.58; Cl, 21.23. Found: C, 46.98; H, 2.65; N, 12.70; Cl, 20.74%.

Preparation of $[Fe_2Cl_4L_2]Cl_2$ (2)

Solutions of $FeCl_3$ (0.16 g, 1.0 mmol) in MeOH (10 ml) and of L (0.21 g, 1.0 mmol) in the same solvent (10 ml) were combined, and the homogeneous solution obtained was stirred at ambient temperature overnight. The resultant red solution was then concentrated *in vacuo* to about 8 ml and kept at 0°C. After a few hours, a brown-red powder of **2** formed, which was filtered off, washed with cold MeOH (5 ml) and Et_2O (2 × 5 ml), and dried in air. Further concentration of the filtrate, and washings and storage at 0°C gave a further quantity of the complex. The total yield was 0.28 g (75%). Anal. Calc. for $C_{26}H_{18}N_6Cl_6Fe_2$: C, 42.26; H, 2.46; N, 11.38; Cl, 28.79. Found: C, 42.40; H, 2.31; N, 11.12; Cl, 29.60%.

X-ray crystallography and structure solution

Crystal data and details of the data collection and data processing are listed in Table 1. A crystal of **1** of approximate dimensions 0.3 × 0.3 × 0.2 mm was selected and X-ray diffraction data were collected at 20°C on a Siemens $P2_1$ automated diffractometer using graphite-monochromated Mo–K_α radiation (λ = 0.71073 Å). Unit cell parameters were derived by least-squares fit of 15 centred reflections. Throughout the data collection, three standard reflections were monitored periodically and no decay was observed.

The structure was solved by direct methods using SHELXS-85 [21] and refined by full-matrix least-squares techniques on F^2 with SHELXL-93 [22]. All non-hydrogen atoms were readily located and refined with anisotropic thermal parameters. All hydrogen atoms were placed in fixed, calculate positions. Selected bond lengths and angles of **1** are given in Table 2.

2

Although 2-(2′-pyridyl)quinoxaline(L) was reacted with iron chlorides in mole ratios of 1 : 1, 2 : 1 and 3 : 1, complexes of 1 : 1 stoichiometry (**1**, **2**) were obtained in all cases. This behaviour contrasts with that of nickel(II), palladium(II), copper(II) and cadmium(II) [1–3,5,9], all of which form a complete set of 1 : 1 and 1 : 2 chloro complexes with L. [6,9].

The complexes are microcrystalline (**1**) or powder-like (**2**) and stable in the normal laboratory atmosphere; the iron(II) complex is stable to aerial oxidation so that L is capable of stabilizing iron(II). Complex **1** is insoluble in all common organic solvents, except MeOH, DMF and DMSO. For this compound the molar conductivity values in DMF (Λ_M = 43 S cm^2 mol^{-1}) and DMSO (Λ_M = 10 S cm^2 mol^{-1}) are intermediate to the values for a non-electrolyte and a 1 : 1 electrolyte [23], suggesting decomposition. The iron(III) complex **2**, on the other hand, is soluble in a variety of polar or relatively polar organic solvents, supporting an ionic formulation. Conductivity measurements for $\sim 10^{-3}$ M solutions (assuming a dimer formulation) of **2** at 25°C indicated this complex to be [23] a 1 : 2 electrolyte in Me_2CO (Λ_M = 191 S cm^2 mol^{-1}), MeOH (Λ_M = 177 S cm^2 mol^{-1}), MeCN (Λ_M = 262 S cm^2 mol^{-1}), DMF (Λ_M = 154 S cm^2 mol^{-1}) and DMSO (Λ_M = 72 S cm^2 mol^{-1}).

Description of structure

The molecular structure of $[Fe_2Cl_4L_2]$ (**1**) is shown in Fig. 1. The two iron(II) centres are bridged by two chloro ligands; in addition to the bridging chloro atoms, each Fe^{II} atom is coordinated to a chelating L molecule and a terminal chloride giving five-coordinate N_2Cl_3 ligand donor sets. The two metal centres are related by a crystallographically imposed centre of symmetry and, thus, the bridging Fe_2Cl_2 unit is strictly planar.

In contrast to the conformation of free L [4], in the coordinated L molecule the pyridine nitrogen and the nearest quinoxaline nitrogen are located on the same side of the carbon–carbon bond (C(5)—C(6)) which connects the two moieties; this is a consequence of the chelate effect. The two individually planar portions of L in **1**—the pyridine and the quinoxaline ring—are slightly twisted our of coplanarity, the angle between their best planes being 8.7°. In the free ligand the two planar moieties are more coplanar, planes making an angle of 3.4°. This slight, but significant, bending of L in **1** is illustrated in Fig. 2.

The Fe—Cl bond lengths are normal for iron(II) complexes with chloro ligands [24]. The iron-bridging chloro distances (2.391(1), 2.511(1) Å) are longer than the iron-terminal chloro distance (2.279(1) Å) as expected. There is a difference (ca 0.1 Å) in bond between the two Fe—N bonds, with the metal to pyridine-nitrogen (N(1)) distance being shorter; this may reflect a difference in donor strength of the respective nitrogen atoms. The same trend has been observed in complexes of L with Pd^{II} [9], Cu^{I} [6], Zn^{II} [5] and Hg^{II} [4,7,8]. In $[Cu_2Cl_4L_2]$ [2,3], however, the copper(II) to pyridine-nitrogen distance (2.106(5) Å) is longer than the copper(II) to quinoxaline-nitrogen distance (2.021(5) Å), emphasizing the importance of the metal ion in determining the relative donor strength of the two nitrogen atoms.

The coordination geometry about iron(II) is distorted trigonal bipyramidal. The atoms Cl(1), Cl(2) and N(1) form the equatorial plane with Fe(1) being displaced 0.100 Å from the plane toward the bridging

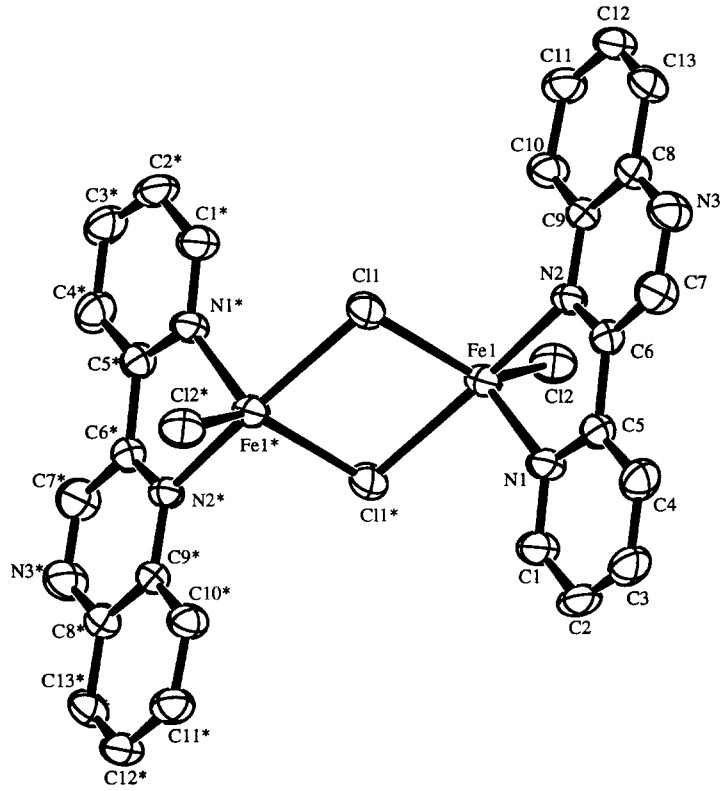

Fig. 1. Molecular structure of **1** with the atom labelling scheme.

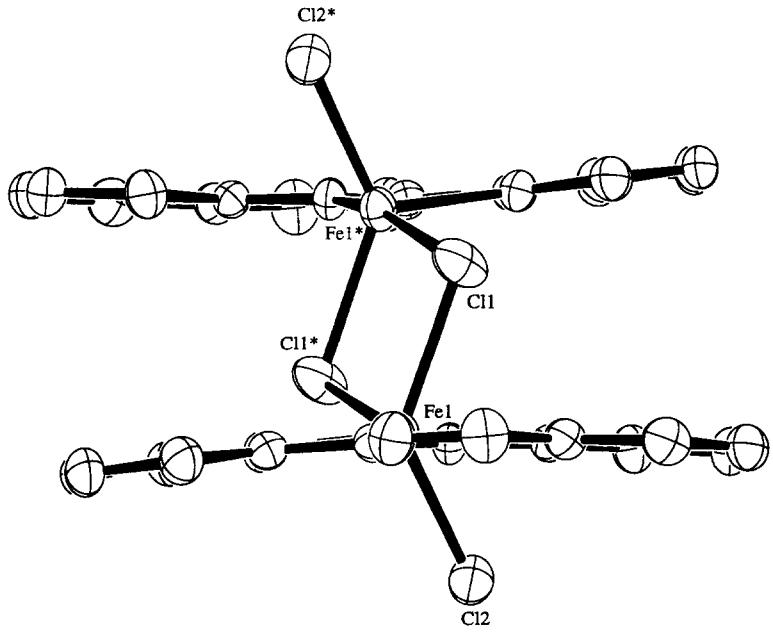

Fig. 2. A view of the molecular structure of **1** emphasizing the slight bending of **L**.

chloride Cl(1*). Thus, in the ligand arrangement encountered in **1**, the two Fe^{II} coordination spheres share a common edge involving equatorial and axial chloro atoms. The N(2)—Fe(1)—Cl(1*) axis is not linear, 164.1(1)°, deviating from perpendicularity to the equatorial plane. The bond angles in the equatorial plane of **1** are 112.1(1), 113.4(1) and 133.9(1)°. The effect of the chelate ring is mainly observed in the N(1)—Fe(1)—N(2) bond angle which deviates (4.2° from the idealized value. The chelating nature of L and the presence of the bridging chlorides affect significantly the details of the coordination sphere about the metal and presumably are responsible for the observed distortion. The axial Fe(1)—N(2) and Fe(1)—Cl(1*) bonds are longer than the respective equatorial bonds. This observation parallels the results reported for other high-spin trigonal iron(II) complexes [25]. Complex **1** joins a handful [25,26] of structurally characterized diferrous complexes with each iron(II) atom being in a trigonal bipyramidal coordination environment; to our knowledge, this is the first such complex with a Fe_2^{II} $(\mu\text{-Cl})_2$ core.

The structure of $[Fe_2Cl_4L_2]$, as detailed in the discussion above, shows remarkable similarity to the molecular structures of $[Cu_2Cl_4L_2]$ [2,3], $[Hg_2Cl_4L_2]$ [4], $[Hg_2Br_4L_2]$ [5] and $[Hg_2I_4L_2]$ [7].

Room-temperature magnetic moments and electronic spectra

The effective magnetic moment of **1** at 25°C (μ_{eff}) is 5.28 BM per iron(II). This value is typical of a high-spin Fe^{II} complex with both a spin contribution and a classic orbital contribution and it appears to exclude very strong ferro- or antiferromagnetic coupling; however, it is difficult to rule out weaker interactions.

The solid-state electronic (diffuse reflectance) spectrum of **1** exhibits one maximum at 9.1 kK and the tail of another band whose maximum is centred somewhere between 4.5 and 5.5 kK, assigned to the one-electron *d-d* transitions $^5E'' \rightarrow {}^5A_1'$, $^5E'' \rightarrow {}^5E'$ under D_{3h} symmetry, respectively [27]. The bond positions are consistent with the high-spin, five-coordinate Fe^{II} N_2Cl_3 chromophore [28], established by the X-ray study. The spectrum also exhibits two charge-transfer bands at 17.2 and 26.2 kK predominantly of the metal to ligand class [27,29].

The effective magnetic moment of **2** at 25°C is 4.90 BM per iron(III). This value is somewhat reduced from the normal high-spin Fe^{III} value of 5.92 BM and shows evidence of weak to moderate antiferromagnetic coupling, indicating a dimeric or polymeric structure [30].

The diffuse reflectance spectrum of the iron(III) complex exhibits several very weak, spin-forbidden *d-d* bands between 12.5 and 23.5 kK and two intense presumed ligand-to-metal charge-transfer absorptions at 26.2 and 28.1 kK [27].

IR and far-IR spectra

The mid-IR spectra of complexes **1** and **2** are similar to those of the 1:1 and 1:2 complexes in which L behaves as a bidentate chelate [1–9]. The characteristic in-plane and out-of-plane pyridine-ring bands at 620 and 401 cm^{-1} respectively, are shifted upwards in **1** (648 and 416 cm^{-1}) and **2** (651 and 419 cm^{-1}), showing the involvement of the pyridine nitrogen in bonding to iron [31]. The ca 960 cm^{-1} region is viewed as the key to differentiate between monodentate terminal and bidentate bridging coordination of the quinoxaline ring [32,33]. The spectrum of the free ligand shows a strong band at 960 cm^{-1}. The appearance of a single, sharp band at 969 and 967 cm^{-1} in the spectra of **1** and **2**, respectively, i.e. the fact that this band does not split on complexation, is typical of the monodentate quinoxaline coordination [32].

The far-IR data of the prepared complexes give an insight into the structure and bonding in the solid state. Assignments of metal-ligand stretching vibrations in Table 3 have been carefully given by considering the frequencies of the internal modes of L, the variation in band frequency with changing the oxidation state of iron and literature reports [28,34–36]. The far-IR spectra of both complexes show one clear terminal Fe—Cl stretch, two bands in the Fe—Cl bridging region and two Fe—N stretching modes. Thus, the data seem incompatible with a monomeric skeleton, but they can be explained on the basis of chloro-bridged structures (dimeric or polymeric), while the complexes still contain terminal Fe—Cl bonds. This spectroscopic behaviour is consistent with the X-ray structure of **1** and suggests a similar structure for the iron(III) complex. Our proposal for a dinuclear $[Fe_2(\mu\text{-Cl})_2Cl_2L_2]Cl_2$ structural type in **2** is further supported by the fact that one of the ν(Fe—Cl) bands appears at 348 cm^{-1}; this frequency is characteristic of terminal chlorides in pentacoordinate Fe^{III} species [35]. The observed wavenumbers of the (Fe—N) modes agree well with the literature data for other iron(II) and iron(III) complexes with chelating N-donor heterocycles [36].

^{57}Fe-Mössbauer spectroscopy studies

Zero-field Mössbauer spectra of polycrystalline samples of **1** and **2** were measured at 4.2 and 298 K. The spectra measured at 4.2 K are shown in Figs 3 and 4. Mössbauer spectral parameters obtained from least-squares fit to the experimental points assuming Lorentzian absorption lines are summarized in Table 4.

The spectrum of **1** consists of a single quadrupole-split doublet. The isomer shift δ is in the range expected for a high-spin Fe^{II} cation surrounded by a mixture of aromatic imine nitrogen atoms and chloro ligands [37]. The slight increase in the quadrupole splitting ΔE_Q as the temperature is decreased is typical

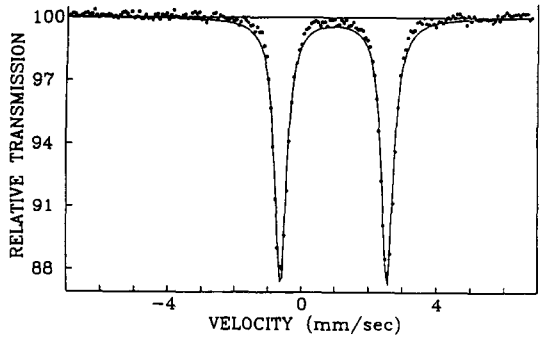

Fig. 3. Mössbauer spectrum of polycrystalline **1** at 4.2 K. The solid line is the best fit to the data with the spectral parameters listed in Table 5.

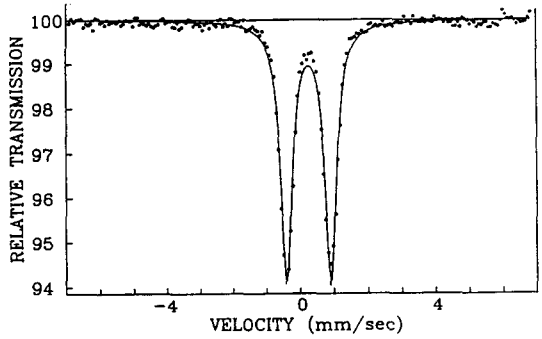

Fig. 4. Mössbauer spectrum of polycrystalline **2** at 4.2 K. The solid line is the best fit to the data with the spectral parameters listed in Table 5.

for high-spin ferrous systems [25,28], due to changes in the Boltzman populations of the low-lying electronic states that form as a consequence of spin-orbit and low-symmetry crystal field perturbations. It is interesting to note that the ΔE_Q value for **1** is significantly larger than reported quadrupole splitting values for six-coordinate dinuclear ferrous centres, but similar to those reported for five-coordinate dinuclear ferrous sites [25]; such differences are ascribed to the inherently less symmetric five-coordinate ligand

Table 4. ^{57}Fe-Mössbauer spectral parameters (mm s^{-1}) for the prepared complexes

Complex	T(K)	δ^a	ΔE_Q	Γ^b
1	298	0.92	3.00	0.21
	4.2	1.08	3.16	0.21
2	298	0.21	1.24	0.20
	4.2	0.35	1.31	0.21

[a] Isomer shift relative to iron foil at room temperature.
[b] Full width at half peak height.

environments compared to the more symmetric octahedral iron(II) sites [38]. The observed line width (full width at half maximum: $\Gamma_{298\ K} = \Gamma_{4.2\ K} = 0.21$ mm s^{-1}) is consistent with equivalent iron sites. Observations that the two sites have equivalent ΔE_Q values with similar temperature dependencies suggest that the two ferrous centres experience equivalent environments [25], consistent with the centrosymmetric structure of **1**.

The spectrum of **2** consists of only a single quadrupole-split doublet at both temperatures with no evidence of iron contaminants. No magnetic hyperfine interactions were observed in zero applied field. The isomer shift value is within the range expected for high-spin iron(III) in non-sulfur environments [20,26,39,40]. The relatively low δ value may indicate a five-coordinate iron(III) complex [35,40,41]. The temperature dependence of δ is that expected for a second-order Doppler shift [42]. The large value of the quadrupole splitting parameter (ca 1.3 mm s) indicates a highly unsymmetrical electric field [43]. A relatively narrow half-line width (ca 0.2 mm s) is observed for **2** indicating that only one type of iron site is present [42].

CONCLUSIONS

The present work has shown that the reactions of iron(II) and iron(III) chlorides with 2-(2′-pyr-

idyl)quinoxaline (L) in MeOH lead to the 1 : 1 complexes as the only products. The dimeric molecular structure of $[Fe_2Cl_4L_2]$ (**1**) reflects the great tendency of L to give dinuclear, doubly halogen-bridged, five-coordinate complexes [2–5,7].

Several molecular structures are possible for a product with the empirical formula $FeCl_3L$. These include (i) a neutral monomeric, five-coordinate complex, $[FeCl_3L]$; (ii) an ionic pseudotetrahedral monomer, $[FeCl_2L]Cl$; (iii) a neutral dimeric, six-coordinate complex, $[Fe_2(\mu\text{-}Cl)_2Cl_4L_2]$; (iv) a cationic dinuclear, five-coordinate species, $[Fe_2(\mu\text{-}Cl)_2Cl_2L_2]Cl_2$; (v) an ionic $[FeCl_2L_2][FeCl_4]$ product containing a six-coordinate cation and a tetrahedral anion; (vi) a neutral six-coordinate polymer, $[Fe(\mu\text{-}Cl)Cl_2L]_n$; (vii) a polymer consisting of cationic chains of five-coordinate Fe^{II} centres and single chloro bridges, $[Fe(\mu\text{-}Cl)ClL]_n(Cl)_n$; (viii) structures based on the mixed bidentate-monodentate bridging coordination [1,5,9] of L. The physical and spectroscopic study of **2**, presented above, leaves us with possibility (iv). If our proposal is correct, this means that the electronic configuration ($3d^5$ vs sd^6) and the size of the metal ion have little structural consequence.

Although the adducts formed between $FeCl_3$ and bidentate aromatic nitrogen bases, particularly 1,10-phenanthroline (phen) and 2,2′-bipyridine (bpy), have been widely studied in the older literature by way of a variety of synthetic and physical procedures, structural studies in this area in the last 15 years cast some doubt on the adequacy and validity of characterization of a number of these. It has been shown that complexes may be formed with a variety of stoichiometries and that, depending on the nature of the recrystallization solvent, these may be covalent or ionic in nature, with varying and variable solvation stages. For example, the structurally characterized Fe^{III}/Cl/phen complexes are $[FeCl_2(phen)_2][FeCl_4]$ [44,55], *fac*-$[FeCl_3(phen)(MeOH)]\cdot MeOH$ [46], *fac*-$[FeCl_3(phen)(H_2O)]$ [46], $[(phenH)[FeCl_4(phen)]\cdot 1^1/_2H_2O$ [46,47], *mer*-$[FeCl_3(phen)(DMF)]$ [48], $[FeCl_2(phen)_2][FeCl_4(phen)]\cdot MeCN$ [45] and $[Fe_2OCl_2(phen)_4]Cl_2\cdot 4.5H_2O$ [49].

SUPPLEMENTARY MATERIAL

Tables of atomic coordinates and anisotropic thermal parameters of non-hydrogen atoms, complete lists of bond lengths and angles, least-squares planes and dihedral angles, a crystal packing diagram, and observed and calculated structure factors for **1** are available from the authors on request.

Acknowledgements—The far-IR spectra of complexes **1** and **2** were obtained at the Laboratorium Anorganische Scheikunde, Rijksuniversitair Centrum Antwerpen, Belgium; we wish to thank Professor H. O. Desseyn for this convenience. The ^{57}Fe-Mössbauer spectra were recorded at the Institut of Materials Science, NRCPS "Demokritos", Aghia Paraskevi Attikis; we thank Dr A. Simopoulos for this convenience and for helpful discussions.

(Received 27 May 1997; accepted 28 August 1997)

Abstract—Copper(II) complexes were prepared from the dinucleating octadentate ligand tetra-1,4,8,11-(2-pyridylmethyl)-1,4,8,11-tetraazacyclotetradecane (tpmc). The five-coordinate complexes $[Cu_2(tpmc)X](ClO_4)_3$ (with X = F, Cl, Br, or I) were characterized by chemical analysis, absorption spectroscopy and cyclic voltammetry. The data show the dinculear Cu(II) complexes to be five-coordinate with a bridging halide donor. All display chemically reversible redox behavior, with two one-electron reductions observed in acetonitrile at glassy carbon. The values for $E^{0'}$ range from 118 to −126 mV vs SCE for the first reduction, and from −122 to −241 mV for the second reduction. Catalysis of the oxidation of 3,5-di-*tert*-butylcatechol to 3,5-di-*tert*-butylquinone using these complexes was studied. Correlations among reactivity, binding constants, and reduction potentials were determined. These correlations show that the rate of the oxidation reaction is linearly correlated to the binding of the halide bridge; the most reactive complex ($[Cu_2(tpmc)I](ClO_4)_3$) is the one with the smallest binding constant while the least reactive ($[Cu_2(tpmc)Cl](ClO_4)_3$) has the largest binding constant. Electrochemical data showed a non-linear relationship between the complexes' ability to oxidize 3,5-di-*tert*-butylcatechol and their reduction potentials. Comparisons to the naturally occurring enzyme tyrosinase are made. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: copper(II) complexes; appended cyclams; catalysis.

Macrocyclic ligands with additional donor atoms appended to the ring have generated considerable interest because of their capacity to bind and transport metal ions, for the potential to prepare and study their mixed-valence forms, and as models for metalloproteins [1]. We particularly are interested in using transition metal complexes of appended macrocycles as models for copper-containing proteins. Copper is a component of a variety of proteins which function as mono-oxygenases, dioxygenases, in dioxygen transport, and in electron-transfer systems [2–3]. Due to their intriguing structural, spectroscopic and reactivity properties, we are involved in studying the protein hemocyanin and the related enzyme tyrosinase. Hemocyanins are found in the hemolymph of molluscs and arthropods and are responsible for binding and transporting oxygen while tyrosinase is found widely in mammals, plants, bacteria, and fungi and is responsible for the browning of fruits and vegetables and in melanin pigment formation [4–6]. It functions by catalyzing the oxidation of phenol to catechol (creolase activity) and the subsequent oxidation of catechol to quinone (catecholase activity).

Considerable chemical and spectroscopic evidence indicated that the active site of tyrosinases were virtually identical to the hemocyanins with the enhanced accessibility of tyrosinase to binding substrate molecules being the only difference [7–10]. However, recent data suggests that the two coppers of tyrosinase

* Author to whom correspondence should be addressed.

are found in different chemical environments with only one of the coppers being identical to the coppers found in hemocyanin [11–13].

We have been engaged in a project to systematically study the ability of Cu(II) complexes to catalyze the air oxidation of catechols in a fashion similar to that found for tyrosinase [14–16]. Our earlier work showed that modifications in the geometry, donor atoms, exogeneous donors, bridging groups, and mononuclear vs dinuclear systems all play a role in the reactivity of the complexes. Additionally, the electrochemical features of the complexes have been shown to be of considerable importance in modulating their reactivity.

Macrocyclic ligands derived from the 1,4,8,11-tetraazacyclotetradecane (cyclam) ring are of considerable utility because of the existence of hard nitrogen donors in the cavity of the ring and the potential to build binding sites from arms appended to the ring nitrogens. We recently reported the synthesis of a novel appended cyclam, tetra-1,4,8,11-(3,5-dimethylpyrazoylmethyl)-1,4,8,11-tetraazacyclotetradecane and a preliminary report of the catalytic properties of its Cu(II) complexes [17]. In this paper, we report the synthesis of a series of Cu(II) complexes with the formula $[Cu_2(tpmc)X](ClO_4)_3$ with (X = F, Cl, Br, or I) derived from the octadentate ligand tetra-1,4,8,11-(2-pyridylmethyl)-1,4,8,11-tetraazacyclotetradecane. This ligand contains cyclam in the backbone with pyridylmethyl arms attached to each of the four hard nitrogens (Fig. 1). The electrochemical features of the complexes have been determined, the reactivity of these complexes towards 3,5-di-*tert*-butylcatechol was assessed, and comparisons between the catalytic properties and their equilibrium binding constants and/or reduction potentials drawn.

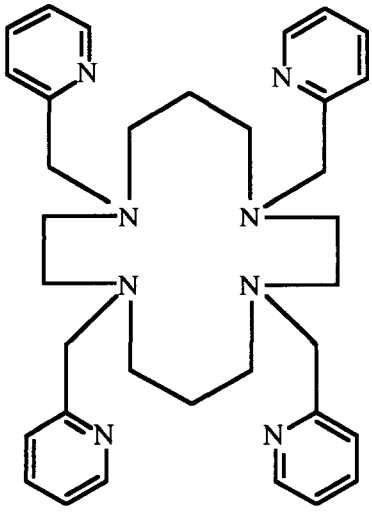

Fig. 1. Tpmc ligand.

EXPERIMENTAL

All reagents and solvents were purchased from commercial sources and used as received unless noted otherwise. Tetra-1,4,8,11-(2-pyridylmethyl)-1,4,8,11-tetraazacyclotetradecane, $[Cu_2(tpmc)F](ClO_4)_3$, $[Cu_2(tpmc)Cl](ClO_4)_3$, $[Cu_2(tpmc)Br](ClO_4)_3$ and $[Cu_2(tpmc)I](ClO_4)_3$ were prepared by the literature methods [18,19]. Melting points were obtained with the use of a Fisher-Johns apparatus and are uncorrected. C, H, and N chemical analyses were performed at Desert Analytical, Tucson, AZ. Metal contents were determined complexometrically by indirect titration with Na_2H_2edta and zinc acetate after destruction of the sample with concentrated nitric acid [20]. Halogen contents were determined by potentiometric titration with silver nitrate. IR spectra were recorded on a Nicolet 5ZDX instrument.

Kinetics were followed spectrophotometrically on a Uvikon 860 spectrophotometer by following the appearance of 3,5-di-*tert*-butylquinone over time using the 390 nm peak. The metal complex (0.3 cm^3 of a 1×10^{-3} M methanol/acetonitrile (7 : 3 solution)) and a 2.0 cm^3 solution (1.0×10^{-1} M methanol solution) of 3,5-di-*tert*-butylcatechol were equilibrated separately to 25°C and then added together in a spectrophotometric cell at 25°C.

Cyclic voltammetric data were collected using an IBM EC/225 voltammetric analyzer and a Soltec Model VP-6415S X–Y recorder. All scans were done at 0.050 V/s with glassy carbon electrodes (3 mm diameter; BAS, West Lafayette, IN) in acetonitrile (Burdick and Jackson, spectrophotometric grade) that contained 0.10 M tetrabutylammonium perchlorate (Eastman 99%) or tetraethylammonium tetrafluoroborate (Aldrich 99%) as the supporting electrolyte. In all cases, the concentration of the metal complex was 1×10^{-3} M. The glassy carbon electrodes were polished with 0.3- and 0.05-μm alumina on microcloth pads (Buehler, Lake Bluff, IL) and sonicated in distilled water for 30 s before use to remove alumina particles.

A three-electrode system was used in all the measurements, with potentials in acetonitrile recorded vs a Ag/Ag^+ non-aqueous reference electrode. The fill solution for this reference electrode was acetonitrile containing 0.01 M $AgNO_3$ and 0.1 M tetrabutylammonium perchlorate. The potential of this reference was measured daily vs an aqueous saturated calomel electrode (SCE) and an appropriate correction made (typically ca 300 mV) so that the $E^{0'}$ values for each complex could be reported vs SCE. Aqueous voltammetry was done in 0.1 M TRIS buffer adjusted to pH 7.00 with HCl. Potentials in TRIS were recorded vs an aqueous Ag/AgCl reference. A platinum wire served as the auxiliary electrode. The glass cell consisted of a vial of ca 5.0 cm^3 volume with a fitted Teflon cap. All solutions were purged with dry nitrogen prior to data collection.

Caution. Although there were no incidents in our

laboratory, transition metal perchlorates may explode violently. They should be prepared in small quantities and handled with care.

RESULTS

Synthesis

The ligand tetra-1,4,8,11-(2-pyridylmethyl)-1,4,8,11-tetraazacyclotetradecane was designed to allow for the binding of two copper ions in a dinuclear arrangement. The ligand was prepared with cyclam and 2-picolychloride serving as the starting materials [18].

The Cu(II) complexes were prepared either by mixing a solution of the ligand with Cu(II) perchlorate hexahydrate and the appropriate sodium salt (NaBr, NaF) or by adding the sodium salt (NaCl, NaI) to $[Cu_2(tpmc)](ClO_4)_4$. The complexes were analyzed by elemental analyses, absorption spectroscopy and infra-red spectroscopy. In all cases, the complexes are dinuclear with each five-coordinate Cu(II) bound to two aliphatic nitrogens, two pyridyl nitrogens and a bridging halide donor.

Electrochemistry

In the catalysis of 3,5-di-*tert*-butylcatechol to 3,5-di-*tert*-butylquinone, the Cu(II) complex is reduced to Cu(I). For this reason, we have studied the electrochemical properties of the complexes **1–4** to determine whether there is a correlation between their reduction potentials and catalytic abilities. The reduction potentials for complexes **1–4** were measured by cyclic voltammetry at a glassy carbon electrode in acetonitrile. The cyclic voltammetry data are shown in Table 1 and the cyclic voltammograms for the representative $[Cu_2(tpmc)Br](ClO_4)_3$ and $[Cu_2(tpmc)Cl](ClO_4)_3$ complexes are shown in Fig. 2. The average of the peak potentials from the cyclic voltammetry is taken as an approximation of the formal potential, $E^{0'}$. In all cases, the Cu(II) metal centers are reduced to Cu(I) in two successive one electron reductions.

In all cases, the reduced form of the complex displays high chemical stability on the time scale of the

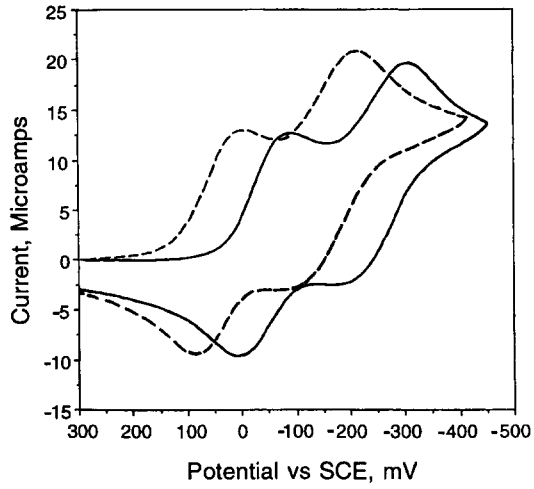

Fig. 2. Cyclic voltammograms recorded at a glassy carbon electrode in acetonitrile: (--) 1.0 mM solution of $[Cu_2(tpmc)Cl](ClO_4)_3$ (**1**); $E^{0'} = -27$ mV, $\Delta E_p = 96$ mV for first reduction; $E^{0'} = -241$, $\Delta E_p = 114$ mV for second reduction. (---) 1.0 mM solution of $[Cu_2(tpmc)Br](ClO_4)_3$ (**2**); $E^{0'} = +35$ mV, $\Delta E_p = 81$ mV for first reduction; $E^{0'} = -185$, $\Delta E_p = 140$ mV for second reduction. The scan rate was 50 mV/s and the supporting electrolyte was 0.1 M tetrabutylammonium perchlorate in both cases.

Table 1. Cyclic voltammetry,[a] binding constants, and kinetic data[b] for the oxidation of 3,5-di-*tert*-butylcatechol for $[Cu_2(tpmc)X](ClO_4)_3$ complexes

Complex	$E^{0'}$ (mV)[c] first wave	$E^{0'}$ (mV)[c] second wave	Binding constants [19]	Activity (μmol substrate/mg catalyst per min)
$[Cu_2(tpmc)Cl](ClO_4)_3$ (**1**)	−27	−241	4.80	0.0005
$[Cu_2(tpmc)Br](ClO_4)_3$ (**2**)	35	−185	3.77	0.264
$[Cu_2(tpmc)F](ClO_4)_3$ (**3**)	−126	—	3.03	0.274
$[Cu_2(tpmc)I](ClO_4)_3$ (**4**)	118	−122	2.76	0.362

[a]Electrochemistry was performed in an acetonitrile solution that contained 0.10 M tetrabutylammonium perchlorate or tetraethylammonium tetrafluoroborate as the supporting electrolyte. The concentration of the metal complex was 1×10^{-3} M. All complexes undergo chemically reversible oxidation-reduction reactions at a glassy carbon electrode with a Ag/Ag^+ non-aqueous reference electrode and a platinum wire as the auxiliary electrode. Scans were done at 0.050 V/s.

[b]Kinetics were performed spectrophotometrically at 25°C with 0.3 cm^3 of a 1.0×10^{-3} M methanol solution of metal complex and 2.0 cm^3 of a 1.0×10^{-1} M methanol solution of 3,5-di-*tert*-butylcatechol.

[c]The average of the peak potentials is taken as an approximation of the formal potential $E^{0'}$. All potentials are reported vs the aqueous saturated calomel reference (SCE). See the text for details.

cyclic voltammetry experiment; ratios of reverse to forward currents (i_{pa}/i_{pc}) are close to 1.0 for all complexes at a scan rate of 0.050 V/s.

A number of inferences can be drawn from the electrochemical data. First, although the complexes are symmetrical, the two copper(II) ions are not reduced at the same potential. There are other examples of this type of behavior for dinuclear Cu(II) complexes [21]. Secondly, as would be expected, the electrochemical data show that the reduction potentials of the copper(II) complexes are dependent on the nature of the halide bridging donors. The $E^{0'}$ values for the first reduction range from a low of 118 mV for $[Cu_2(tpmc)I](ClO_4)_3$ to a high of -126 mV for $[Cu_2(tpmc)F](ClO_4)_3$ For complexes **1–4**, there is a fairly smooth decrease in the reduction potential as the size of the bridging group increases. These values are displayed in Table 1. The data suggests that $[Cu_2(tpmc)F](ClO_4)_3$ is best able to stabilize the Cu(II) form at the expense of the copper(I) form in the copper(II)/(I) couple, while $[Cu_2(tpmc)I](ClO_4)_3$ is more likely to exist in the copper(I) form. For the second wave, there is also a smooth decrease in the values of $E^{0'}$ as the size of the bridging anion increases (the second wave could not be measured for the $[Cu_2(tpmc)F](ClO_4)_3$ complex).

In contrast to the results obtained in acetonitrile, all of the complexes display the same reduction potentials for both the first and second waves when dissolved in pH 7.00 TRIS buffer. The first reduction peak potential occurs at -200 mV (± 3 mV) vs Ag/AgCl and the second peak potential occurs at -310 mV (± 10 mV) for all complexes. It is possible that in this solvent system, H_2O replaces the bridging donor resulting in formation of the same complex in all cases.

Catalytic properties

The reactivity of the Cu(II) complexes, **1–4**, towards 3,5-di-*tert*-butylcatechol under catalytic conditions (0.3 cm^3 of a 1.0×10^{-3} M methanol–acetonitrile (7 : 3) solution of catalyst and 2.0 cm^3 of a 0.1 M methanolic solution of 3,5-di-*tert*-butylcatechol) in the presence of atmospheric O_2 was studied using electronic spectroscopy by following the appearance of the absorption maximum of the quinone at 390 nm over time. Our previous kinetic studies were performed in methanol but solubility constraints forced us to use this solvent mix. The results of the oxidations are presented in Fig. 3 and the data compiled in Table 1. All of the complexes are catalytically active in the oxidation of 3,5-di-*tert*-butylcatechol to 3,5-di-*tert*-butylquinone, however, it can be seen that the chloride complex is exceedingly slow in its ability to catalyze the oxidation reaction. We have seen similar results where varying the nature of a bridging or exogeneous donor greatly affects the rate of oxidation [14–16].

The activities of the complexes range from a high

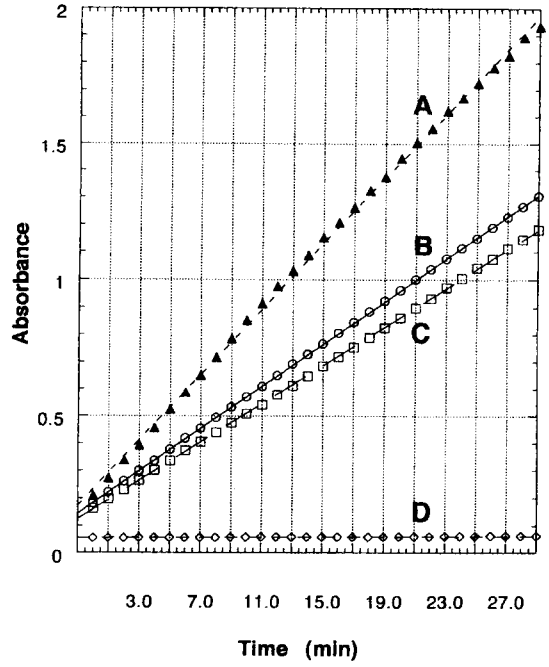

Fig. 3. Plot of absorbance vs time for $[Cu_2(tpmc)X](ClO_4)_3$ catalyzed oxidation of 3,5-di-*tert*-butylcatechol. Performed at 25°C in a CH_3OH solution of 1×10^{-1} M 3,5-di-*tert*-butylcatechol and 1×10^{-3} M metal complex: (A) $[Cu_2(tpmc)I](ClO_4)_3$; (B) $[Cu_2(tpmc)F](ClO_4)_3$; (C) $[Cu_2(tpmc)Br](ClO_4)_3$; (D) $[Cu_2(tpmc)Cl](ClO_4)_3$.

of 0.191 μmol substrate/mg catalyst per min for the $[Cu_2(tpmc)I](ClO_4)_3$ complex to a low of 0.00085 μmol substrate/mg catalyst per min for the $[Cu_2(tpmc)Cl](ClO_4)_3$ complex. Tyrosinase, the enzyme that catalyzes this reaction in nature, has two coppers per active site and it is thought that the binding of catechol involves simultaneous binding of the catechol by the two coppers with the transfer of two electrons to the coppers. Therefore, it is surprising that the values are so low for the dinuclear complexes **1–4** since we have seen more robust catalysis by a number of mononuclear species [14].

DISCUSSION

The two-electron oxidation of substituted *o*-catechols to quinones is one of the reactions that the copper-containing enzyme tyrosinase catalyzes. We previously have shown that changing the nature of the fifth donor atom, the counterion, or any bridging group bound to the copper ions has an effect on the rate of catalysis [14–16]. Others have also studied the oxidation reaction to try to determine the factors responsible for effective catalysis to occur [22–37]. In addition, it has been shown that electron transfer from catechol to the Cu(II) can begin only after catechol and the Cu(II) species form a Cu(II) catecholate intermediate [38]; this situation would require a vacant

coordination site on the metal so that complexation of the catechol can occur. Our premise is that the ease of dissociation of the halide bridge would greatly affect the ability of the complexes to catalyze this oxidation process. Therefore, in this work we are attempting to determine if there is a correlation between the ability of the complexes to catalyze the oxidation with the magnitude of their binding constants. In addition, since we have shown that reduction potentials are an important contributor to the catalytic properties of Cu(II) complexes [14], we have also compared the reactivity to the ease of reduction of the complexes.

Correlation with binding constants

The specific complexes, **1–4,** studied here were chosen because formation constants for the reaction:

$$[Cu_2(tpmc)]^4 + X \rightleftharpoons [Cu_2X(tpmc)]^{3+}$$

have been previously determined [19]. The binding constants (as determined by Vuckovic and co-workers) are displayed in Table 1. As shown, $[Cu_2(tpmc)I](ClO_4)_3$ is the least stable (binding constant = 2.76) while the $[Cu_2(tpmc)Cl](ClO_4)_3$ is the most stable complex (binding constant = 4.80). We assume that prior to oxidation, dissociation of the bridging donor will occur so that a vacant coordination site will be available for the binding of the catechol. Therefore, the larger the binding constant for the association of the bridging group, the slower the reaction will proceed if this step is part of the rate determining step of the reaction. In comparing the binding constants to catalytic rates, a reasonable straight line which correlates binding constants with activities can be seen (Fig. 4). This is consistent with a dissociative mechanism where the halogen bridge must leave prior to the complexation of the catechol and subsequent oxidation. Dissociation of the halide will leave two vacant coordination sites (one on each copper) so binding to the catechol should be readily attainable. However, since the Cu–Cu distance [19] in complex **1** is 4.47 Å and for complex **3** is 3.99 Å (and we would expect this value to increase after dissociation of the halide), the coppers could be too far apart for effective simultaneous binding of the two oxygens of the catechol. This would severely limit the rate of the reaction, a result that is borne out by our catalytic results.

Correlations with reduction potentials

In the oxidation of catechol to quinone, the Cu(II) ions are reduced to Cu(I). The reduction potentials of complexes **1–4** have been obtained in order to determine if there is also a correlation between the ease of reduction of the coppers and the rate of oxidation of 3,5-di-*tert*-butylcatechol. We have shown previously

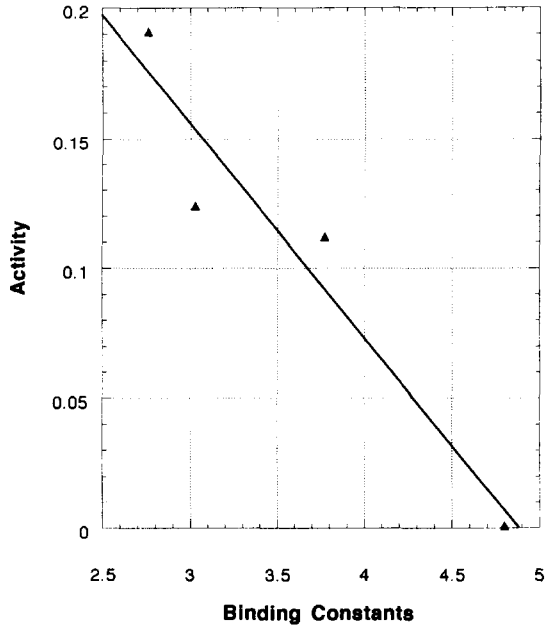

Fig. 4. Plot of binding constants vs activities for catalyzed oxidation of 3,5-di-*tert*-butylcatechol by $[Cu_2(tpmc)X](ClO_4)_3$ complexes.

that electrochemical potentials play a role in determining the reactivity properties of copper(II) complexes (although steric features of the ligands seem to be more important factors) [14].

In assessing whether there is a correlation between redox potentials and catalytic properties, a lack of a trend in these values is evident. Although the complex with the most positive potential (**4**) is the most catalytically active, the second most active complex (**3**) is the one with the most negative potential. Indeed, complex **1,** which has an intermediate value for its reduction potential, is essentially non-catalytic. For this series of Cu(II) complexes, it appears that the redox properties are secondary in importance to the binding constants in determining the catalytic properties of the complexes.

It is also worthwhile to consider whether the complexes' reduction potentials correlate with their binding constants. From the electrochemical values, it can be seen that the complex which is easiest to reduce ($[Cu_2(tpmc)I](ClO_4)_3$) is also the one whose halide bridge most easily dissociates. However, this trend does not hold throughout the series. For example, **3** has the second lowest binding constant but has the most negative reduction potential.

CONCLUSIONS

We have studied the air oxidation of 3,5-di-*tert*-butylcatechol to 3,5-di-*tert*-butylquinone by a series of dinuclear copper(II) complexes formed from a macrocyclic ligand. It is clear that the binding con-

stant between the copper(II) ion and the halogen bridge directly influences the redox properties of the complexes. However, there is no direct correlation between the reduction potentials and the ease of oxidation, a result which affirms earlier work that we performed on mononuclear copper(II) complexes [14–15].

It is also clear that the nature of the bridging group has profound effects on the capability of the complexes to perform the oxidation. As the magnitude of the binding constant decreases, the ability of the complex to bind to the substrate increases and the oxidation becomes more efficient. The positive correlation between the magnitude of the binding constant and the rate of oxidation for the complexes suggests that a dissociative mechanism is at work with the loss of the halogen bridge preceding the binding of the catechol. This confirms the results of Rogic [38] in which he shows that a vacant coordination site on the metal must be attained so that complexation of the catechol can occur. Work on related complexes which have bridging groups that are capable of dissociating is on-going.

2-D COSY and NOESY ^{1}H NMR spectral studies on pyrazine-bridged dizinc(II)diporphyrin complex

Stanisław Wołowiec*

Department of Chemistry, University of Wrocław 14 Joliot-Curie 14, 50-383 Wrocław, Poland

(Received 5 June 1997; accepted 26 August 1997)

Abstract—The dinuclear [Zn(TTP-*m*-O-(CH_2)–)]$_2(CH_2)$ complex **1** (where TTP-*m*-O = 5-(*meta*-hydroxyphenyl)-10,15,20-tritolylporphyrin dianion) coordinates axially nitrogen bases; pyrazine (Py) and pyrimidine. The solid 1 : 1 Py : **1** adduct has been isolated and identified as dinuclear complex (μ-Py) [Zn(TTP-*m*-O-$(CH_2)-]_2(CH_2)$ **2** with pyrazine base bridging intramolecularly two zinc(II) metal ions based upon variable temperature 1-D and 2-D ^{1}H NMR spectral measurements. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: dizinc(II)diporphyrin; pyrazine bridging; 2-D ^{1}H NMR spectroscopy.

In the previous papers of the series, dealing with dinuclear complexes of diporphyrins linked via flexible spacer, the coordination properties of diiron(III) and iron(III)/copper(II) diporphyrins with cyanide in organic solvents have been studied [1,2]. It has been found that the two proximal metal ions promote the formation of μ-cyanide dinuclear complexes in CN^--deficient solutions.

The dimetallic complexes of diporphyrins were studied extensively from the viewpoint of their catalytic activity [1,2] and references cited therein. The dicobalt(II) and dicopper(II) complexes of diporphyrins with flexible polyhydrocarbon spacer attached to the *meso*-phenyl ring of porphyrin showed high catalytic activity in two-electron oxidation of 3,5-di-*t*-butyl catechol with dioxygen in contrast to mononuclear porphynatocobalt(II) complexes [3]. The coordination of nitrogen bases to dizinc(II) complexes of *meso*-(tetraryl)porphyrin-based diporphyrins with the polyhydrocarbon spacer of variable length attached to *ortho*-, *meta*-, or *para*- *meso*-phenyl were studied in detail [3,4]. It has been found that the dizinc(II) complex of diporphyrin with a three-carbon spacer attached to *ortho*-phenyl Zn^{II}TTP*o*-O$(CH_2)_3$O-*o*TPPZn^{II}, coordinated two molecules of lutidine with $K_1/K_2 = 160$ while for its analogue Zn^{II}TTP*p*-O$(CH_2)_3$O-*p*TTPZn^{II} the ratio $K_1/K_2 = 1$. The low value of K_2 for the former is due to the steric hindrance from the second *ortho*-appended Zn(II)porphyrin half, which makes one face of Zn(II)porphyrin moiety less accessible for coordination of the second monodentate axial nitrogen base [4]. When a suitable heteroaromatic base with two nitrogen atoms (1,*n*-bis(4-pyridyl)alkane, where $n = 0$, 2, or 3) was applied as a ligand for dizinc(II) complex with face–face diporphyrin, with two diamido-type spacers attached to *ortho*- position of 5,15-*meso*-phenyls, and strapped on the opposite porphyrin face by another diamido substituent attached to 10,20-*meso*-phenyls, the intramolecular bridging of the nitrogen base was found to be dependent on the geometric factors of the studied systems [5]. In those rigid host–guest systems the best tuning between interporphyrin distance and the length of guest was achieved in the case of phenylenediamido spacer and 4,4′-bipyridyl as a guest [5]. The affinity of 4,4′-bipyridyl and other nitrogen bases to coordinate to zinc(II)porphyrin has been utilized in ligand-templated synthesis of cyclic and linear porphyrin oligomers [6,7]. A number of papers have been published in which di- and oligoporphyrins were assembled to study the energy transfer and photoinduced electron transfer in dizinc(II)diporphyrins adjacent together by means of coordinated, bridging axial nitrogen base [8,9].

Here the spontaneous conformational adjustment between the dizinc(II) diporphyrin with single, flexible spacer adjacent into *meso*-aryl substituents on both

* E-mail: sw@wchuwr.chem.uni.wroc.pl

porphyrin halves and pyrazine (and not pyrimidine) led to the isolation of pyrazine:Zn^{II}TTP*m*-O$(CH_2)_3$O-*m*TPPZn^{II} 1:1 adduct. The complex was studied by means of the ^{1}H NMR 2D COSY and NOESY spectral methods.

EXPERIMENTAL

Syntheses

Synthesis of [Zn(TPP-*m*-O-(CH_2)–)]$_2(CH_2)$ (**1**). The diporphyrin (H_2TTP-*m*-O-$(CH_2)_3$-O-*m*-$TPPH_2$) was synthesized according to the modified method of Little [10,1]. Zinc(II) ion was inserted by dropwise addition of 20-fold excess of zinc(II) chloride in methanol into the chloroform solution of (H_2TTP-*m*-O-$(CH_2)_3$-*O*-*m*-$TPPH_2$) under reflux in the presence of solid zinc(II) carbonate. The complex was separated chromatographically from impurities and solid materials on basic alumina (methylene dichloride eluent).

^{1}H NMR (the assignments based on ^{1}H 2D COSY and NOESY experiments, for numbering see Scheme 1): 8.90 ppm (8H, AB system, J_{AB} = 4.8 Hz, δ_A = 8.91 ppm, δ_B = 8.89 ppm, pyrrole β-H, 12,13(17,18)), 8.87 ppm (8H, AB system, J_{AB} = 4.8 Hz, δ_A = 8.90 ppm, δ_B = 8.85 ppm, pyrrole β-H, 2,3(7,8)), 8.05 ppm (4H, doublet, J_{om} = 7.9 Hz, o_3+o_4), 8.00 ppm (4H, doublet, J_{om} = 7.9 Hz, o_1), 7.96 ppm (4H, doublet, J_{om} = 7.9 Hz, o_2), 7.74 ppm (2H, singlet, o_6), 7.73 ppm (2H, doublet, J_{om} = 7.2 Hz, o_5), 7.53 ppm, (2H, doublet of doublets, J_{om} = 7.2 Hz, J_{mp} = 7.7 Hz, m_5), 7.50 ppm (4H, doublet, J_{om} = 7.9 Hz, m_3+m_4) 7.43 ppm (4H, doublet, J_{om} = 7.9 Hz, m_1), 7.39 ppm (4H, doublet, J_{om} = 7.9 Hz, m_2), 7.26 ppm (2H, doublet, J_{pm} = 7.7 Hz, p), 4.33 ppm (4H, triplet, $J_{\alpha\beta}$ = 6.1 Hz, $CH_{2(\alpha)}$), 2.66 ppm (6H, singlet, methyl at 15-*meso*-phenyl), 2.60 ppm (12H, singlet, methyls at 10- and 20-*meso*-phenyls), 2.36 (2H, quintet, $CH_{2(\beta)}$). UV–Vis (λ[nm], (ε [mol^{-1} × dm^3])): 423 (6.57×10^6); 552 (1.24×10^5); 594 (1.15×10^5).

Synthesis of (Py){[Zn(TTP-*m*-O-(CH_2)–)]$_2(CH_2)$} (**2**) Equimolar amounts of **1** and pyrazine were dissolved in chloroform (0.2 M) and hexane was carefully layered over the chloroform solution. The mixture was left for slow codiffusion of solvents at 0°C. Large, purple crystals were formed after 2 days. The crystals contained three molecules of solvent per one molecule of (Py){[Zn(TTP-*m*-O-(CH_2)–)]$_2(CH_2)$} (determined by integration of resonances in the ^{1}H NMR spectrum of $2 \times 3CHCl_3$). The crystals were too fragile to be mounted in X-ray diffractometer and therefore the weakly bound chloroform molecules were removed from the solid by a high vacuum applied overnight to the isolated crystals. Inspection of the ^{1}H NMR spectrum indicated that solvent molecules were no longer present. The crystals turned into powder after evaporation of the solvent.

Methods and reagents

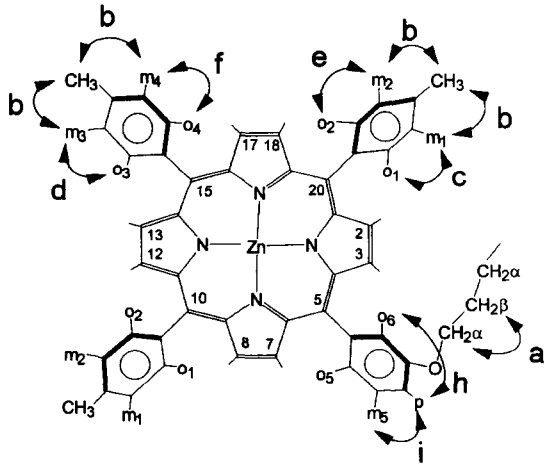
^{1}H NMR spectra were obtained with a Bruker AMX300 spectrometer operating in the quadrature mode at 300 MHz. The 2-D COSY and NOESY spectra were collected by use of 1024 points in t_2 over desired bandwidth and 512 t_1 blocks with 16 scans per block in which four dummy scans were included. Repetition time was 2 s in all cases, the mixing time was 0.6 s for NOESY measurements. The NOESY spectra were processed in the phase-sensitive or magnitude modes. The deuterated solvents used were obtained from Glaser AG. The residual chloroform peak at 7.24 ppm was used as the internal chemical shift standard in presented spectra. The UV–Vis spectra were taken with HP 8453 diode-array spectrophotometer.

The equilibrium constant for the reaction:

$$Zn/Zn + py \rightleftharpoons Zn(\mu\text{-py})Zn$$

has been determined by both UV–Vis and ^{1}H NMR spectral titration at 295 K.

In the UV–Vis titration procedure 4.2×10^{-6} M solution of **1** in chloroform has been titrated with pyrazine stock solutions to achieve variable concentration of pyrazine within $2.15 \times 10^{-6} \div 0.2$ M region. A slight shift of Soret band into 422 nm and red shift of the Q-bands into 560 and 600 nm upon pyrazine coordination were found. Well resolved isosbestic points at 557 and 598 nm in the region of Q-bands up to 9.4×10^{-3} M pyrazine concentration were observed. The UV–Vis data were worked up at two wavelengths: 552 nm (corresponding to starting complex **1**) and 600 nm (corresponding to the maximum of the pyrazine adduct). Putting the two-parameter fitting procedure (equilibrium constant K and absorbance of the pyrazine adduct A_∞) into the equation:



Scheme 1.

$$K = \frac{(A - A_0)}{(A_0 - A_\infty) \cdot [\text{py}]}$$

gave the averaged value of $K = 2.0(\pm 0.3) \times 10^4\ \text{M}^{-1}$.

In the ^{1}H NMR titration, 0.0038 M solution of **1** in $CDCl_3$ has been titrated with 0.2 M stock solution of pyrazine using the microsyringe technique. The pyrrole β-H resonances shifted from 8.93 ppm (δ_f) into 8.58 ppm (δ_c, the final chemical shift achievable upon the increase of pyrazine concentration above 0.005 M). The pairs of data, observed averaged chemical shift vs total pyrazine concentration, were fitted into the equation obtained by combination of the equations:

$$\delta = \delta_f \cdot p_f + \delta_c \cdot p_c,$$

where p_f and p_c are the populations (molar contributions) of free and pyrazine-coordinated dizinc(II)diporphyrin, respectively, and δ is observed chemical shift in titration procedure,

$$p_f + p_c = 1, K = \frac{p_c}{p_f \cdot [\text{py}]_f}$$

where $[\text{py}]_f$ is the concentration of free pyrazine. The solution of the resulting quadratic equation leads to the final relationship:

$$\delta = \frac{(\delta_f - \delta_c) \cdot \{C_0 \cdot \text{K} - [\text{py}]_0 \cdot \text{K}}{2 \cdot \text{C}_0 \cdot \text{K}} + \\ + \frac{\sqrt{[(1 + [\text{py}]_0 \cdot \text{K} - \text{C}_0 \cdot \text{K})2 + 4 \cdot \text{C}_0 \cdot \text{K}]}\}}{2 \cdot \text{C}_0 \cdot \text{K}} + \delta_c$$

where C_0 = the concentration of **1** and $[\text{py}]_0$ = the total concentration of pyrazine.

One-parameter fitting procedure resulted in the value of $K = 1.2(\pm 0.5) \times 10^4\ \text{M}^{-1}$.

Molecular mechanics calculations using the HyperChem software (Autodesk) were carried out and displayed on a PC 486 computer. The standard MM+ force field, with the constrains set on coordination bonds to achieve the geometry around the zinc(II) central ion were adapted from the published X-ray crystallographic data on pentacoordinate pyridine Zn(II)porphyrin complexes [11,12].

RESULTS AND DISCUSSION

The 1-D ^{1}H NMR *spectral results on coordination of pyrazine and pyrimidine to* **1**

Previously we have examined the ^{1}H NMR spectra of (H_2TTP-*x*-O-$(CH_2)_n$-O-*x*-TPPH_2) diporphyrin (n = 2,3, x = *o*-, *m*-, and *p*-) in detail [1]. In case of *ortho*-appended diporphyrins the ring current originated from neighbouring porphyrin macrocycle induced large upfield shifts of spacer-attached phenyl ring protons. It was not the case for the diporphyrin used here and consequently all resonances from aromatic *meso*-phenyls were grouped within the region of: 8.08–7.76 ppm (*ortho*); 7.58–7.40 ppm (*meta*); and 7.30 ppm (*para*). Nevertheless, the asymmetry imposed by one different *meso*-substituent (5-*meso*-substituted phenyl versus three *p*-methylphenyls) resulted in non-equivalence of β-pyrrole resonances, which gave one AB spectrum (2,3(7,8)) and a singlet (12,13(17,18)). Also, the presence of large aromatic porphyrin macrocycle appended at the *meta* position of *meso*-phenyl induced substantial up and down non-equivalence of *ortho* and *meta* 10- and 20-*meso*-phenyl protons. Both of these tendencies are even more pronounced in the case of dizinc(II) complex **1**, where all the β-pyrrole rings bear non-equivalent pairs of protons (two AB spectra, see Experimental).

The coordination of heteroaromatic bases: pyrazine and pyrimidine has been monitored by titration of **1** with these ligands. It was found that the system was in fast exchange on the ^{1}H NMR timescale. The chemical shift of ligands was always ligand concentration dependent. However, the isolation of solid **2** of fixed stoichiometry (1 : 1 of **1** : pyrazine) indicated that the complex of that stoichiometry is particularly stable in solid state. The crystal structure of **2** was not available. Thus it was necessary to find the method to determine if pyrazine bridges two Zn(II) intra- or intermolecularly in **2**. Neither mass spectrometric nor osmometric measurement results gave a definite answer to that question, due to the fast exchange between free and coordinated axial ligand processes taking place in solution **2**. However, an inspection of the ^{1}H NMR spectra showed that the chemical shift of **2** measured at three different solvents (chloroform, methylene dichloride and toluene), at four different temperatures (between 190 and 273 K), was only slightly dependent on concentration of **2**. Considering the possible routes leading to the formation of intramolecularly bridged dizinc(II) species (sequence of reactions (1) and (2)) and an intermolecularly bridged complex (sequence of reactions (1), (3), and (4)):

$$\text{Zn/Zn} + \text{py} \rightleftharpoons \text{pyZn/Zn} \quad (1)$$

$$\text{pyZn/Zn} \rightleftharpoons \text{Zn}(\mu\text{-py})\text{Zn} \quad (2)$$

$$\text{pyZn/Zn} + \text{py} \rightleftharpoons \text{pyZn/Znpy} \quad (3)$$

$$2\text{pyZn/Znpy} \rightleftharpoons \{\text{pyZn/Znpy})\}_2 \quad (4)$$

where Zn/Zn represents the starting complex **1**, pyZn/Zn corresponds to the species containing monodentate coordinate pyrazine, Zn(μ-py)Zn represents intramolecularly bridged dinuclear complex, pyZn/Znpy corresponds to the dinuclear complex containing two pyrazine coordinated via one nitrogen donor, and $\{\text{pyZn/Znpy})\}_2$ represents tetranuclear species with two pyrazine ligands bridging two dizinc(II)diporphyrin molecules), one may expect that in the case of intermolecular bridging, the chemical shift of pyrazine resonance or any porphyrin proton (the o_6 resonance was monitored as the most sensitive to pyrazine coordination) should substantially depend on [2] due to associative character of reaction (4). In

fact, within the concentration range used (0.01–0.5 M) the chemical shift of both pyrazine and o_6 protons are almost independent of concentration of **2**. Thus, it was assumed that **2** is a dizinc(II) complex bridged intramolecularly with pyrazine ligand. This conclusion was then strongly supported by the fact that when pyrimidine was used instead of pyrazine, the ligand resonances were considerably less shifted upon coordination if compared to **2**. The coordination shift in the latter case was comparable with that for TTPZn(II) mononuclear analogue (Table 1). The downfield coordination shift of 2-H of axial ligand (pyrmidine and pyridine), due to porphyrin ring current effect, was comparable (4.2 and 4.9 ppm, respectively) in both cases, suggesting the monodentate binding mode of pyrmidine into **1**. Intramolecular bridging of two zinc(II) centres of pyrazine in **2** leads to a larger coordination shift ($\Delta = 7.9$ ppm) due to additive ring current shifts from two porphyrin macrocycles.

The estimation of the equilibrium constant for the reaction of the formation of **2** (reactions (1)+(2)) based on UV–Vis and ^{1}H NMR spectral titrations gave the values 2.0 (± 0.3) $\times 10^4$ and 1.2 (± 0.5) $\times 10^4$ M^{-1}, respectively, which are in fair agreement despite the fact that three orders of magnitude of different concentrations were used in those two experiments. The value of $\log K = 4.3$ found for **1** is larger than that for binding of pyridine or bipyridyl to monomeric zinc(II)porphyrins and comparable to those found for bridging coordination to rigid dizinc(II)diporphyrins which are not well-suited to adopt the ligand due to steric reasons [5,6]. In some cases of face-to-face dizinc(II)diporphyrins the cooperative coordination led to $\log K$ as large as 7.4 [5] and 8.8 [6]. Here the cooperative effect is not large due to the fact that two porphyrins are adjacent together with flexible spacer.

The ^{1}H NMR spectrum of **2** in chloroform at room temperature consists of broad resonances both from the phenyl ring of diporphyrin macrocycle and from the pyrazine ligand. The spectrum changes remarkably at lower temperatures (Fig. 1). The pyrazine res-

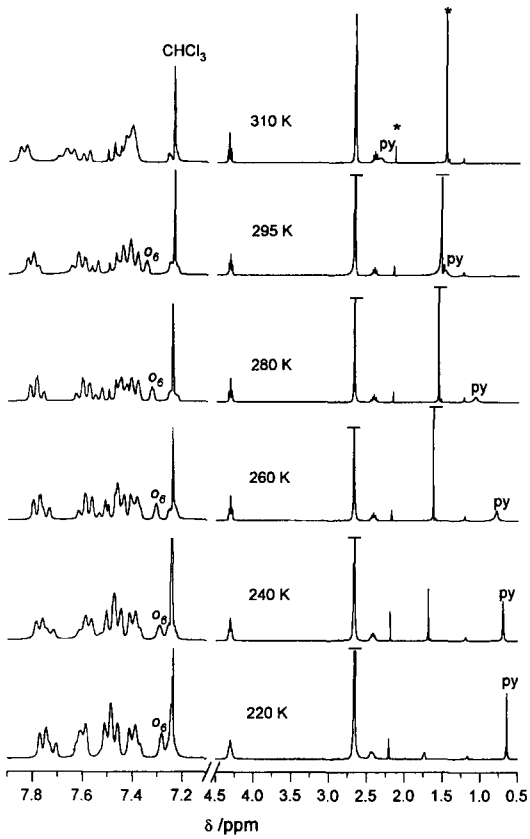


Fig. 1. The variable temperature ^{1}H NMR spectra of **2** in chloroform-*d*. The pyrazine hydrogen resonance is labelled as py, the impurity and residual water at 1.75 ppm resonances are labelled with asterisk.

Table 1. The ^{1}H NMR chemical shifts δ and coordination shift Δ (in parentheses) of pyrazine and pyrimidine protons for free and coordinated ligands (measured for 0.04 M $CDCl_3$ solutions)

	Temperature	pyrimidine			pyrazine
Composition of solution	[K]	δ 2 (Δ)	δ 4,6 (Δ)	δ 5 (Δ)	δ (Δ)
	295	9.2	9.71	7.3	8.6
	220	9.2	8.74	7.4	8.6
1 : *1* **1** : pyrimidine	310	6.25	6.82	6.37	
	295	5.76	6.51	6.23	
	280	5.37	6.27	6.13	
	260	4.98	6.04	6.04	
	240	4.83	6.03	5.91	
	220	4.80 (4.2)	6.05 (2.7)	5.90 (1.3)	
1 : *1* **1** TTPZn(II) : pyrazine	220				3.67 (4.93)
2	220				0.69 (7.91)

onance shifts 1.7 ppm upfield upon lowering temperature by 90° and further temperature decrease (down to 180 K in methylene dichloride-d_2 solvent) does not cause either the chemical shift changes or splitting of pyrazine or aliphatic resonances. Obviously, even in methylene dichloride solvent, at 180 K the rotation of pyrazine ligand around coordination bonds remains fast on NMR scale. Simultaneously the resonances from aliphatic spacer broaden and some changes are observed within an aromatic region of spectrum. Total assignment of resonances of **2** could provide some detailed information on the molecular structure of **2**. Therefore, 2-D ^{1}H NMR measurements were performed, particularly to analyze the crowded aromatic part of the ^{1}H NMR spectrum. The standard 2D ^{1}H NMR COSY and NOESY methods were used.

The total assignments of ^{1}H NMR *resonances based on* 2-D COSY *and* NOESY *results*

At 280 K the aromatic resonances in the region of 7–8 ppm are sharp and well-resolved and the COSY experiment allows to assign the resonances of *meso*-phenyls. The COSY map is presented in Fig. 2(A) and (B). The cross-peak **a** between α and β methylene protons of spacer was obvious and the cross-peak **b** between *p*-methylphenyl protons and the protons in aromatic region (Fig. 2(A)) allowed to identify the *meta*-phenyl proton resonances and provided a suitable starting point to analyze the cross-peaks within the aromatic region (Fig. 2(B)). Thus, two overlapping doublets of doublets of the relative intensity 2 : 1 at 7.8 ppm were assigned to the *ortho*-protons o_1 and o_3 (see the connectivity pattern at Scheme 1) located at the opposite side of porphyrin macrocycle plane to the appended second porphyrin ring. They were combined with the *meta* protons m_1 and m_3 via cross-peaks **c** and **d** (Fig. 2(B)). Two overlapping doublets of doublets of relative intensity 1 : 2 centred at 7.6 ppm belong to o_4 and o_2 protons, respectively and were coupled with the m_4 and m_2 resonances via cross-peaks **f** and **e**, respectively. It was assumed that *ortho* protons located at the same side of porphyrin plane as appended porphyrin ring (o_2 and o_4) should resonate at higher fields than o_1 and o_3. Corresponding pairs of *otho* protons are weakly coupled (cross-peak **g**). The 5-*meso*-phenyl ring protons gave the cross-peak pattern consistent with the couplings between *para* proton (overlapped with chloroform residual resonance at 7.24 ppm) and *meta* proton (triplet centred at 7.50 ppm at this temperature) by cross-peak **i** and *ortho*- proton o_6 located at the appended porphyrin side) by cross-peak **h**. The remaining cross-peak (not marked) corresponds to the vicinal coupling between o_5 (the resonance at 7.55) and m_5. As expected, the magnetic non-equivalence between *ortho* protons at the 5-*meso*-phenyl ring, attached via spacer to the second porphyrin was the largest of all *meso*-phenyls. The resonance of o_6 was the most upfield shifted of all

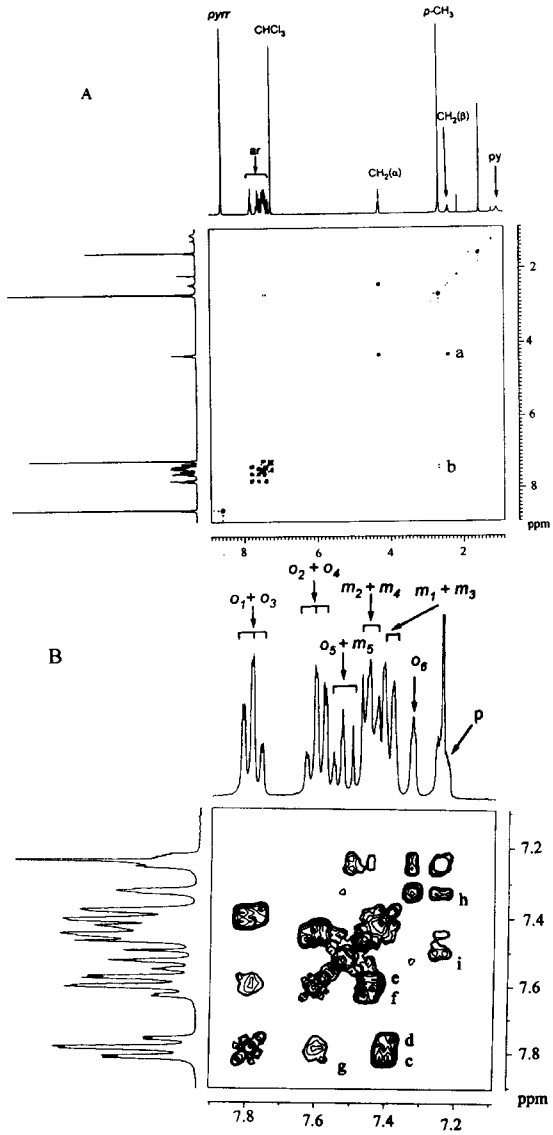

Fig. 2. The COSY map of **2**: (A), full spectrum taken at 280 K; (B), the expanded aromatic region. The abbreviations used are: *pyrr*: β-H pyrrole resonances; ar: the resonances of *meso*-phenyl protons; other labels follow those used in Scheme 1.

aromatic *ortho* and *meta* protons and it was located at a very fortunate position between other aromatic resonances from the downfield side and residual chloroform plus *para* proton resonance from the high-field side.

This connectivity pattern (presented at Scheme 1) was then confirmed by NOE cross-peaks obtained in NOESY experiment performed at 230 K. At this temperature the resonance from pyrazine protons is sharp and that provided a good opportunity to observe the spatial proximity of that proton with the porphyrin protons. The relevant fragments of NOESY map are presented in Fig. 3(A) and (B).

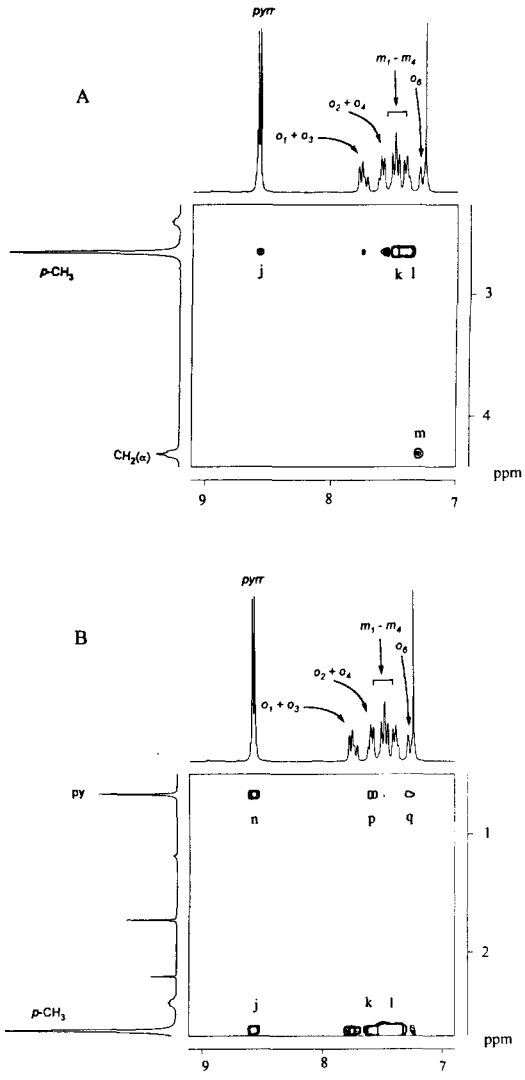

Fig. 3. The relevant fragments of NOESY spectrum of **2** taken at 230 K.

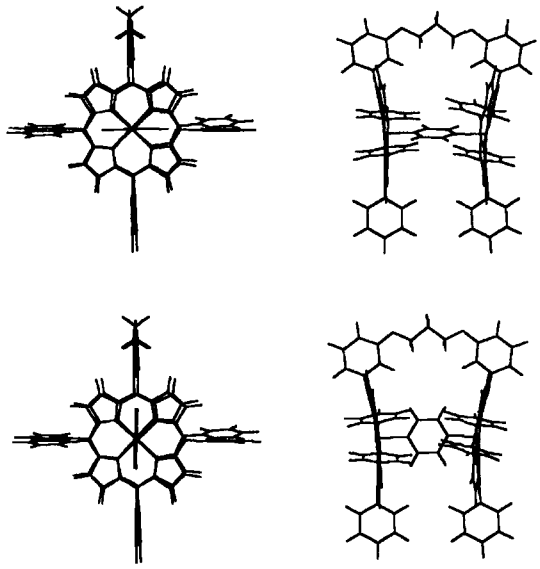

Fig. 4. Two projections of isomer **A** (upper pair) and **B** (lower pair) of **2** as obtained by MM+ calculations (using HyperChem program).

The observed cross-peaks: **j** between β-pyrrole and *p*-methyl protons, cross-peaks **k** and **l** between *p*-methyl and *meta* protons within porphyrin macrocycle were expected. The cross-peak **m** between α-methylene protons and o_6 confirmed the assignment of the latter unambiguously. The NOE cross-peaks **n, p,** and **q** indicated the spatial proximity of pyrazine protons to the β-pyrrole, o_2 o_4, and o_6, respectively (Fig. 3(B)) proving the proper assignment of o_2 and o_4 protons as those located at the same side of porphyrin macrocycle as appended porphyrin and bridging aromatic pyrazine ring.

The conformation of **2** *based on molecular model and* ^{1}H NMR *chemical shift*

In order to analyze details of confirmation of the intramolecularly bridged dinuclear complex the molecular model of **2** was constructed by means of HyperChem program. The set of constraints was imposed, in particular the Zn(II)—N(pyrrole) = 2.06 and Zn(II)—N(axial) = 2.14 Å bond lengths based on mean values taken from crystallographically established structures of pyridine pentacoordinate complexes of Zn(TPyP) and Zn(TPP–C_3Py) [11,12]. The resultant two conformations of **2** are presented in Fig. 4. The bridging pyrazine ring is located in the cavity along the C_{10}–C_{20} in case of rotational isomer **A,** whereas the isomer **B** bears the pyrazine ring rotated 90° along the coordination bonds. Although the free rotation of pyrazine can be reasonably assumed due to observation of NOE effects between pyrazine protons and all *ortho* phenyl protons located at the same side of porphyrin macrocycles as the bridging pyrazine, the analysis of chemical shift changes of *ortho* protons upon coordination indicates that the larger effect reveal o_6 (0.49 ppm upfield at 220 K) and o_4 (0.43 ppm upfield) protons in comparison with o_2 (0.35 ppm upfield). This suggests the larger contribution of rotational isomer **A,** for which the closest through-space contact estimated from molecular model between pyrazine proton and o_2 equals 2.81 Å whereas the distances between pyrazine protons and o_6 and o_4 are 3.16 and 2.91 Å, respectively, in isomer **B.**

Thus the dominating conformation of **2** can be represented by isomer **A** in Fig. 4. The pyrazine-bridged, diamagnetic dizinc(II) diporphyrin complex obtained as crystalline adduct serves a good standard for estimation of the isotropic shift for paramagnetic complexes with bridging pyrazine [13].

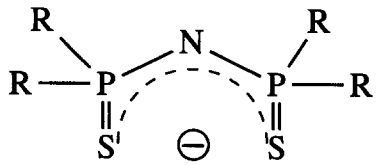
(Received 27 May 1997; accepted 8 August 1997)

Abstract—Complexes of the general formula $\{M(CO)_3[(Ph_2PS)_2N](CH_3CN)\}$ (M = Tc, Re) have been prepared by the reaction of $(Et_4N)_2[M(CO)_3X_3]$ (M = Tc, Re; X = Cl, Br) with sodium bis(diphenylthiophosphoryl)amide, $Na[(Ph_2PS)_2N]$, in acetonitrile. The metal is six-coordinate with facially arranged carbonyl ligands. Bis(diphenylthiophosphoryl)amide is deprotonated and bonded as S,S′-chelate with Tc—S distances of 2.526(3) and 2.546(3) Å. Acetonitrile occupies the sixth coordination position. The rhenium compound is isomorphous and the bonding situation in $\{Re(CO)_3[(Ph_2PS)_2N](CH_3CN)\}$ is similar to that in its technetium analogue. $(Et_4N)[Re(CO)_3Br_2(CH_3CN)]$ crystallizes from a hot acetonitrile solution of $(Et_4N)_2[Re(CO)_3Br_3]$ despite the fact that in solution only $[Re(CO)_3(CH_3CN)_3]^+$ can be detected spectroscopically. It has a facial arrangement of CO groups in an octahedral co-ordination geometry. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: technetium; rhenium; carbonyl complexes; sulphur donor ligands; X-ray structures.

Bis(dialkylthiophosphoryl)amides and bis(diarylthiophosphoryl)amides (**I**) have been shown to be a versatile class of ligands which can easily be substituted to meet the specific requirements of the metals to be co-ordinated or of potential applications of the products [1,2]. Complexes with the tetraphenyl substituted amide have been discussed as models for the co-ordination sites of metalloenzymes [1]. Tetrahedral bis-co-ordinated complexes with divalent metal ions have been confirmed for Ni^{II} and Cu^{II} by X-ray crystallography and EPR spectroscopy [3,4].

The capabilities of the ligands to adopt the specific



I

co-ordination requirements of the metals makes them interesting for the chemistry of technetium and rhenium which is of interest for diagnostic (^{99m}Tc: γ-emitter, half-life: 6 h) or therapeutic (^{186}Re, β^--emitter) nuclear medicine [5,6]. Rossi *et al.* [7,8] studied the co-ordination behaviour of $Ph_2P(X)NH(X)PPh_2$

* Author to whom correspondence should be addressed.

(X = O or S) and $K[Ph_2P(Se)N(Se)PPh_2]$ towards the $[ReO]^{3+}$ core and reported a considerable tendency for the products to decompose with loss of chalcogen donor atoms. It has been found more recently that the nitrogen containing $[ReN]^{2+}$ and $[ReNMe]^{3+}$ cores are more suitable to stabilize complexes with the "soft" sulphur donor sites of $[(Ph_2PS)_2N]^-$ than the oxorhenium(V) centre [9,10]

In the present paper, synthesis and structures of technetium(I) (using the long-lived isotope ^{99}Tc which is a weak β^--emitter with $t_{1/2} = 2.12 \times 10^5$ years) and rhenium(I) tricarbonyl complexes are described which demostrate that bis(diphenylthiophosphoryl)amide is also able to stabilize monomeric, low-valent metal complexes.

EXPERIMENTAL

The starting complexes $(Et_4N)_2[Tc(CO)_3Cl_3]$ and $(Et_4N)_2[Re(CO)_3Br_3]$ have been prepared by procedures reported previously [11,12]. $(Ph_2PS)_2NH$ was prepared from PPh_2Cl, $NH(SiMe_3)_2$ and sulphur as outlined in ref. 13 and converted into the sodium salt by the reaction with NaOMe. IR spectra were recorded as KBr pellets on a Perkin-Elmer Specord 75 IR. Mass spectra were recorded on a MAT TSQ-70 spectrometer (Finnigan). For FAB measurements xenon was used as primary beam gas. The ion gun was operated at 8 kV and 100 μA (probe temperature: 30°C) nitrobenzylalcohol was used as the matrix. ^{99}Tc and ^{31}P NMR spectra were recorded on Varian Gemini 2000 (300 MHz) and JEOL EX-270 spectrometers with H_3PO_4 and NH_4TcO_4 as references.

CAUTION! ^{99}Tc is a weak β-emitter. Although radiation from small amounts of material is completely absorbed by the glass walls, all operations have been carried out in a specially equipped laboratory under well ventilated hoods to avoid contamination or ingestion.

$\{Tc(CO)_3[(Ph_2PS)_2N](CH_3CN)\}$

55 mg (0.1 mmol) $(Et_4N)_2[Tc(CO)_3Cl_3]$ were dissolved in 10 ml acetonitrile and a solution of 51 mg (0.11 mmol) $Na[(Ph_2PS)_2N]$ in 5 ml CH_3CN was added dropwise. The colourless reaction mixture was heated under reflux for 1.5 h and the volume was reduced to about 3 ml. After standing overnight, colourless crystals formed which were filtered off and washed with a small amount of cold methanol. Recrystallization from CH_3CN. Yield: 80%. Found: Tc, 15.7%; $C_{29}H_{23}N_2O_3P_2S_2Tc$ requires: Tc, 15.3%. IR: ν(CO) 1925, 1953, 2035 cm^{-1} (st), ν(CN) 2362 cm^{-1} (w). ^{99}Tc-NMR: −1266 ppm (s).

$\{Re(CO)_3[(Ph_2PS)_2N](CH_3CN)\}$

The complex was prepared as the technetium analogue starting from 77 mg (0.1 mmol) $(Et_4N)_2[Re(CO)_3Br_3]$ and 51 mg (0.11 mmol) $Na[(Ph_2PS)_2N]$ in acetonitrile. Colourless crystals. Yield: 75%. Found: C, 44.65; H, 3.23; N, 3.91; S, 8.15%; $C_{29}H_{23}N_2O_3P_2S_2Re$ requires: C, 45.79; H, 3.03; N, 3.68; S, 8.42%. IR: ν(CO) 1919, 1948, 2043 cm^{-1} (st), ν(CN) 2362 cm^{-1} (w). ^{31}P-NMR: 38.7 ppm (s). FAB^+ MS: $m/z = 760$ ($[M]^+$, 5% B), $m/z = 719$ $\{(Re(CO)_3[(Ph_2PS)_2N]\}^+$, 100% B), $m/z = 691$ $\{(Re(CO)_2[(Ph_2PS)_2N]\}^+$, 45% B), $m/z = 663$ $\{(Re(CO)[(Ph_2PS)_2N]\}^+$, 20% B).

$\{Re(CO)_3[(Ph_2PS)_2N](py)\}$

76 mg (0.1 mmol) $\{Re(CO)_3[(Ph_2PS)_2](CH_3CN)\}$ were dissolved in 10 ml $CHCl_3$ and a few drops of pyridine were added. The mixture was heated on reflux for 10 min and allowed to cool to room temperature. Upon slow evaporation of the solvent a colourless solid precipitated which was removed by filtration and rinsed with a minimum amount of cold methanol. Yield 65%. Found: C, 47.92; H, 3.10; N, 3.19%; $C_{32}H_{25}N_2O_3P_2S_2Re$ requires C, 48.12; H, 3.13; N, 3.51%. IR: ν(CO) 1924, 1962, 2020 cm^{-1} (st). ^{31}P-NMR: 38.5 ppm (s). FAB^+ MS: $m/z = 798$ ($[M]^+$, 5% B), $m/z = 719$ ($\{Re(CO)_3[(Ph_2PS)_2N]\}^+$, 100% B), $m/z = 691$ ($\{Re(CO)_2[(Ph_2PS)_2N]\}^+$, 25% B), $m/z = 663$ ($\{Re(CO)[(Ph_2PS)_2N]\}^+$, 20% B).

$(Et_4N)[Re(CO)_3Br_2(CH_3CN)]$

77 mg (0.1 mmol) $(Et_4N)_2[Re(CO)_3Br_3]$ were dissolved in 10 ml acetonitrile and refluxed for 1 h. Upon slow evaporation of the solvent colourless crystals formed which were collected and rinsed with a minimum amount of cold water to remove $(Et_4N)Br$. Yield: almost quantitative. Found: C, 25.85; H, 3.91; N, 4.31%; $C_{13}H_{23}N_2O_3Br_2Re$ requires: C, 25.91; H, 3.82; N, 4.65%. IR: ν(CO) 1945, 1971, 2055 cm^{-1} (st), ν(CN) 2360 cm^{-1} (w). FAB^- MS: $m/z = 472$ ($[M]^-$, 7% B), $m/z = 431$ ($[Re(CO)_3Br_2]^-$, 100% B), $m/z = 403$ ($[Re(CO)_2Br_2]^-$, 15% B), $m/z = 475$ ($[Re(CO)Br_2]^-$, 20% B), $m/z = 350$ ($[Re(CO)_3Br]^-$, 60% B).

X-Ray structure determinations

The intensities for the X-ray determinations were collected on an automated single crystal diffractometer of the type CAD4 (Enraf-Nonius, Delft) using Mo-K_α radiation with ω-scans. The unit cell dimensions were determined from the angular settings of 25 high-angle reflections. The structures were solved by Patterson synthesis using SHELXS86 [14]. Subsequent Fourier-difference map analyses yielded the positions of the non-hydrogen atoms. Refinement was performed using SHELXL93 [15]. The hydrogen atoms were included at calculated positions and refined using the "riding model" option of

SHELXL93. Crystal data and more details of the data collections and refinements are contained in Table 1. Additional information on the structure determinations has been deposited at the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Recently, we reported on the synthesis of $(Et_4N)_2[M(CO)_3X_3]$ complexes (M = Tc, Re; X = Cl, Br) starting directly from the tetrabutylammonium permetallates and applying 1 atm of CO [11,12]. Dissolution of the complexes in co-ordinating solvents results in the replacement of only the weakly bound halide ligands and the formation of solvent complexes of the composition $[M(CO)_3(solv)_3]^+$. The course of the ligand exchange can easily be followed by IR spectroscopy [11]. After removing X^- by silver ions the addition of PF_6^- results in precipitation of the solvent complexes. Thus, the dissolution of $(Et_4N)_2[Re(CO)_3Br_3]$ or $(Et_4N)_2[Tc(CO)_3Cl_3]$ in acetonitrile and addition of $AgPF_6$ represents high yield syntheses of the well known complexes $[M(CO)_3(CH_3CN)_3]PF_6$. For further ligand exchange reactions, however, the readily soluble solvent complexes can be used without isolation. In particular, chelating ligands and good π-acceptors easily replace the weakly bound solvent ligands from the electron-rich metal centre. Upon dissolution of $(Et_4N)_2[Re(CO)_3Br_3]$ in acetonitrile and slow evaporation of the solution without removing the bromide anions $(Et_4N)[Re(CO)_3Br_2(CH_3CN)]$ can be isolated.

The reactions of the *in situ* generated $[M(CO)_3(CH_3CN)_3]^+$ cations with approximately equimolar amounts of sodium bis(diphenylthiophosphoryl) amide (**I**) in acetonitrile, give the neutral complexes $\{M(CO)_3[(Ph_2PS)_2N](CH_3CN)\}$ in good yields. Co-ordination of a second molecule $(Ph_2PS)_2N^-$ could not be observed, even when a large excess of ligand was used. In the latter case, however, the formation of considerable amounts of $(Ph_2PS)_2NH$ is observed when the solvent has not been tried very carefully prior to use. This causes serious problems in the isolation of pure $\{M(CO)_3[(Ph_2PS)_2N](CH_3CN)\}$ complexes and can be avoided by an $(Et_4N)_2[M(CO)_3X_3]/Na[(Ph_2PS)_2N]$ ratio not exceeding 1 : 1.1.

$\{Tc(CO)_3[(Ph_2PS)_2N](CH_3CN)\}$ is a colourless solid which crystallizes as large plates directly from the reaction mixture. The compound is soluble in warm acetonitrile, only sparingly soluble in alcohols and nearly insoluble in hydrocarbons. No decomposition could be detected in the solid state over a period of 4 weeks. In coordinating solvents (e.g. thf or pyridine), however, a ligand exchange acetonitrile vs solvent can be observed. This is a route for the synthesis of further derivatives containing the $\{Tc(CO)_3[(Ph_2PS)_2N]\}$ moiety.

The infrared spectrum of $\{Tc(CO)_3[(Ph_2PS)_2N](CH_3CN)\}$ in KBr shows a typical "*fac*-$Tc(CO)_3$" pattern for a slightly distorted C_{3v} symmetry with intense bands at 2035 (A_1), 1953 and 1925 (E) cm^{-1}. The coordinated acetonitrile shows a weak band at 2362 cm^{-1}. The ^{99}Tc resonance of the diamagnetic technetium(I) complex ($4d^6$) can be observed at -1266 ppm vs TcO_4^-. This value agrees well with those found for other neutral technetium(I) tricarbonyls. Cationic compounds of comparable structures show significantly highfield shifted ^{99}Tc NMR signals [18–20].

$\{Tc(CO)_3[(Ph_2PS)_2N](CH_3CN)\}$ crystallizes triclinic in the space group $P\bar{1}$. An ORTEP representation [21] of the molecular structure along with the atomic numbering scheme is given in Fig. 1. Selected bond lengths and angles are summarized in Table 2. The metal has a distorted octahedral coordination sphere with facially arranged carbonyls. The Tc—S bond lengths of 2.526(3) and 2.546(2) Å are longer by about 0.1 Å than those in the five-coordinate bis-chelate $\{Tc^VN[(Ph_2PS)_2N]_2\}$ [10]. This can easily be understood by the strong *trans* influence of the carbonyls. A similar tendency has been observed at Tc^V complexes when phosphines are co-ordinated *trans* to $(Ph_2PS)_2N^-$ [22]. The P—S distances are lengthened by a mean value of 0.07 Å and the P—N distances shortened by 0.09 Å with regard to the pro-ligand [23]. This relates to delocalization of electron density in the chelate rings although the six-membered ring is not planar. The pairs of P—S and P—N distances are almost equal as is expected for a chelate ring with delocalized electron density. The same situation has been observed in the structures of Re^V with $[(Ph_2PS)_2N]^-$ [7–10]. In contrast to that, the indium(III) complex $\{In[(Ph_2PS)_2N]_2Cl\}$ shows a "non-symmetric" co-ordination of the ligand with different S—P and P—N bond lengths in the chelate rings suggesting co-ordination with distinct "thiolate" and "phosphorus sulphide" donor sites [24].

M—N(51)—C(52)	173.6(5)	174.0(7)

Deviations from an idealized octahedron can be observed for the first co-ordination sphere of technetium in $\{Tc(CO)_3[(Ph_2PS)_2N](CH_3CN)\}$ (*cis* angles between 82.0 and 98.9°). The Tc—C bond *trans* to CH_3CN is slightly longer than the others suggesting a somewhat stronger *trans* influence of the acetonitrile ligand compared with the sulphur donor sites.

The bonding situation in $\{Re(CO)_3[(Ph_2PS)_2N](CH_3CN)\}$ is very similar to that in the technetium analogue. Therefore, the corresponding bond lengths and angles are compared in Table 2. An ellipsoid representation of the rhenium complex is given in Fig. 2. In both complexes M—N bond to the acetonitrile ligand is long by 2.155(6) and 2.147(6) Å, respectively. The suggested lability of this position is confirmed by the chemical behaviour of the complexes.

Dissolution of $\{Re(CO)_3[(Ph_2PS)_2N](CH_3CN)\}$ in $CHCl_3$ and addition of pyridine results in the for-

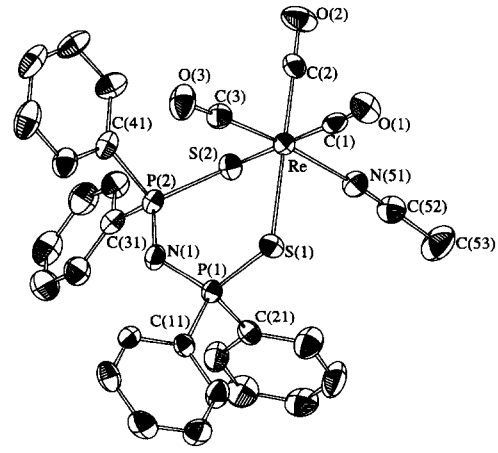

Fig. 2. Molecular structure [21] of $\{Re(CO)_3[(Ph_2PS)2N](CH_3CN)\}$ along with the atomic numbering scheme.

mation of $\{Re(CO)_3[(Ph_2PS)_2N](py)\}$ which can be isolated upon evaporation of the solvent. The colourless solid has been characterized spectroscopically.

The lability of acetonitrile ligands in rhenium tricarbonyl complexes can also be demonstrated by evaporation of a CH_3CN solution of $[Re(CO)_3(CH_3CN)_3]^+$ which has been prepared by dissolution of $[Re(CO)_3Br_3]^{2-}$ without removing the bromide ions by addition of a silver salt. Despite the infrared spectrum of such a solution, it is clearly identical to those of isolated $[Re(CO)_3(CH_3CN)_3]^+$ and solutions from which Br^- has been completely removed [11] and a ligand re-exchange CH_3CN vs Br^- can be observed upon concentration and colourless crystals of the $(Et_4N)[Re(CO)_3Br_2(CH_3CN)]$ deposit.

$(Et_4N)[Re(CO)_3Br_2(CH_3CN)]$ crystallizes triclinic in the space group $P\bar{1}$. Figure 3 shows an ORTEP plot of the complex anion. Table 3 contains selected bond lengths and angles. The facially arranged carbonyl ligands induce long Re—Br bond lengths of 2.623(2) and 2.632(2) Å, respectively. These values are in agreement with other Re—Br bonds in rhenium(I) complexes and in *trans* position to CO (2.633(1) – 2.662(1) Å in $[Re(CO)_3Br_3]^{2-}$ [12], 2.638(1) Å in [Re2(CO) $6Br_2$(tetraphos)] [12], 2.624(1) – 2.647(2) Å in rhenium(I) tricarbonyl complexes with thiourea derivatives [25]), but longer than in the rhenium(III) complex *cis*-$[Re(CO)_2Br4]^-$, where the Re—Br bond *trans* to CO is 2.542(1) Å [26]. As observed in the $\{Re(CO)_3[(Ph_2PS)_2N](CH_3CN)\}$ complexes, the Re—(CO) bond *trans* to acetonitrile is slightly longer than the others (0.04 Å in $[Re(CO)_3Br_2(CH_3CN)]^-$). The co-ordination geometry of rhenium comes close to an idealized octahedron with *cis* angles between 86.1(2) and 93.6(2)° and *trans* angles between 177.2(2) and 179.1(3)°.

CONCLUSIONS

$[M(CO)_3X_3]^{2-}$ complexes (M=Tc, Re; X=Cl, Br) can be used as reactive starting materials for the synthesis of further rhenium(I) and technetium(I) tricarbonyl complexes. The halide ligands are only weakly bound and readily substituted by co-ordinating solvents. Addition of chelating ligands like $[(Ph_2PS)_2N]^-$ results in neutral, monomeric metal(I) tricarbonyl complexes with one remaining co-ordinated solvent molecule. The *in situ* produced $[Re(CO)_3(solvent)_3]^+$ complexes show a ligand rearrangement (solvent vs halide) upon concentration of their solutions.

(Received 6 May 1997; accepted 8 August 1997)

Abstract—Six new μ-oxamido heterobinuclear complexes have been synthesized and identified as $[Cu(oxae)Fe(L)_2]SO_4$, where oxae denotes the N,N′-bis(2-aminoethyl)oxamido dianion and L represents 1,10-phenanthroline(phen); 5-nitro-1,10-phenanthroline (NO_2-phen); 5-chloro-1,10-phenanthroline (Cl-phen); 5-methyl-1,10-phenanthroline (CH_3-phen); 2,2′-bipyridine (bpy) and 4,4′-dimethyl-2,2′-bipyridine (Me_2bpy). Based on the elemental analyses, spectroscopic studies, magnetic moments at room temperature and molar conductivity measurements, extended oxamido-bridged structures consisting of a copper(II) and an iron(II) ions, which have a square planar environment and an octahedral environment, respectively, are proposed for these complexes. The $[Cu(oxae)Fe(bpy)_2]SO_4$ (**1**) and $[Cu(oxae)Fe(phen)_2]SO_4$ (**2**) complexes have been characterized by variable temperature magnetic susceptibility (4.2–300 K) and the observed data were least-squares fitted to the susceptibility equation derived from the spin Hamiltonian including single-ion zero-field interaction for the iron(II) ion, $\hat{H} = -2J\hat{S}_1 \cdot \hat{S}_2 - D\hat{S}_{z1}^2$, giving the exchange integrals $J = -30.6$ cm^{-1} for (**1**) and $J = -31.8$ cm^{-1} for (**2**). These results are commensurate with antiferromagnetic interactions between adjacent metal ions within each molecule. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: μ-oxamido; copper(II); iron(II); heterobinuclear complex; synthesis; magnetism.

The synthesis and magnetic investigations of heterobinuclear transition-metal complexes propagated by multi-atom bridges are of current interest, not only for gaining some insight into the pathways of electron transfers in biological systems [1–3], but also for obtaining information about designing and synthesizing molecule-based magnets [4,5] and for investigating the spin-exchange mechanism between paramagnetic metal ions [5–7]. It is known that the mononuclear complexes *N,N′*-bis(alkylaminoalkyl) oxamidocopper(II) act as bidentate chelating ligands toward a second metal to form binuclear complexes [8–15]. The effective bridging function of μ-oxamido has been revealed by X-ray analysis for some of these complexes [9,11,12,13,16,17]. Quite recently, we utilized *N,N′*-bis(2-aminopropyl)oxamidocopper(II), [Cu(oxap)], as a bidentate mononuclear fragment to prepare the heterobinuclear complexes [18] $[Cu(oxap)Fe(L)_2]SO_4$ (L = bpy, Me_2bpy, phen, CH_3-phen, NO_2-phen, Cl-phen) and to study their magnetic properties. In order to provide more examples of oxamido-bridged heterobinuclear Cu(II)–Fe(II) complexes to investigate further the structural variation effects upon spin-coupling, in this paper, six new heterometal binuclear complexes, $[Cu(oxae)Fe(L)_2]SO_4$ (L = bpy, Me_2bpy, phen, NO_2-phen, CH_3-phen, Cl-phen) have been synthesized by using *N,N′*-bis(2-aminoethyl)oxamidocopper(II) (abbreviated as Cu(oxae)) as bridging ligand and the magnetic properties of the $[Cu(oxae)Fe(bpy)_2]SO_4$ (**1**) and $[Cu(oxae)Fe(phen)_2]SO_4$ (**2**) complexes have also been studied.

EXPERIMENTAL

Materials

All the reagents used in the synthesis were analytical grade. $FeSO_4 \cdot 7H_2O$ was recrystallized by a general method before use. The terminal ligands 1,10-phenanthroline(phen); 5-nitro-1,10-phenanthroline (NO_2-phen); 5-chloro-1,10-phenanthroline (Cl-phen); 5-methyl-1,10-phenanthroline (CH_3-phen); 2,2′-bipyridine (bpy) and 4,4′-dimethyl-2,2′-bipyridine (Me_2bpy) (analytical grade) were purchased from Perking Chemical Company. The starting material Cu(oxae) was synthesized as previously described [19].

Synthesis of new heterobinuclear Cu(II)–Fe(II) *complexes*

The methods used to prepare the complexes are virtually identical and are exemplified by [Cu(oxae)Fe(bpy)$_2$]SO_4. To a suspension of Cu(oxae) (94.2 mg, 0.4 mmol) stirred in methanol (5 cm^3) was added successively a solution of $FeSO_4 \cdot 7H_2O$ (111.2 mg, 0.4 mmol) in methanol (10 cm^3) and a solution of bpy (125 mg, 0.8 mmol) in methanol (10 cm^3) under N_2 at room temperature. After stirring for 2 h, the solution was filtered. Greenish microcrystals were obtained, washed several times with methanol, water and diethyl ether and dried over P_2O_5 under reduced pressure.

All analytical data, colors, yields and melting points of the complexes are collected in Table 1. In the solid state all the complexes are fairly stable in air, in order to facilitate physical measurements.

Physical measurements

Carbon, hydrogen and nitrogen elemental analyses were performed with a Perkin–Elmer elemental analyzer Model 240. The metal contents were determined by EDTA titration. IR spectra were recorded with a NICOLET FT-IR 5DX spectrometer using KBr pellets. Electronic spectra (in DMF solutions) were measured on a Varian Cary, Model 219, spectrophotometer. Molar conductances were measured with a DDS-11A conductometer. The magnetic susceptibility measurements at room temperature were carried out by Gouy's method using Hg[Co(SCN)$_4$] as the calibrant. Variable-temperature magnetic susceptibilities (4.2–300 K) were performed at the Institute of Physics, Chinese Academy of Sciences, China, using a vibrating sample magnetometer Model CF-1. Diamagnetic corrections were made with Pascal's constants [20] for all the constituent atoms. The effective magnetic moments were calculated by the equation $\mu_{eff} = 2.828\ (\chi_M T)^{1/2}$, where χ_M is the molar magnetic susceptibility corrected for diamagnetisms of the constituting atoms.

RESULTS AND DISCUSSION

Synthetic route and molar conductance of the complexes

One strategy for the synthesis of heterobinuclear complexes is to use the reaction of a simple metal salt with a mononuclear fragment that can function as ligands to a second metal ion [12–15, 21–24]. In this study, our purpose was to obtain Cu(II)–Fe(II) heterobinuclear complexes, therefore, this synthetic

Table 1. Elemental analysis, yield, color and melting point (M.P.) of the complexes

(6)	Dark-blue	76	311	49.5 (49.5)	4.4 (4.2)	14.2 (14.4)	8.0 (8.2)	7.1 (7.2)

(1) = [Cu(oxae)Fe(bpy)$_2$]SO_4, (2) = [Cu(oxae)Fe(phen)$_2$]SO_4, (3) = [Cu(oxae)Fe(Me_2bpy)$_2$]SO_4, (4) = [Cu(oxae)Fe(NO_2-phen)$_2$]SO_4, (5) = [Cu(oxae)Fe(Cl-phen)$_2$]SO_4, (6) = [Cu(oxae)Fe(CH_3-phen)$_2$]SO_4.

method was adopted and *N,N'*-bis(2-aminoethyl)oxamidocopper(II), [Cu(oxae)] was chosen as a bidentate mononuclear fragment, simultaneously, 1,10-phenanthroline (phen); 5-nitro-1,10-phenanthroline (NO_2-phen); 5-chloro-1,10-phenanthroline (Cl-phen); 5-methyl-1,10-phenanthroline (CH_3-phen); 2,2'-bipyridine (bpy) and 4,4'-dimethyl-2,2'-bipyridine (Me_2bpy) were used as terminal ligands, respectively. Indeed, elemental analyses indicate that the reaction of Cu(oxae) with $FeSO_4 \cdot 7H_2O$ and L (L = bpy, Me_2bpy, phen, NO_2-phen, Cl-phen, CH_3-phen) yielded the heterobinuclear complexes of the general formula $[Cu(oxae)Fe(L)_2]SO_4$. All the Cu(II)–Fe(II) binuclear complexes are sparingly soluble in water, ethanol, carbon tetrachloride, chloroform and benzene, but soluble in acetonitrile, DMF and DMSO to give stable solutions at room temperature. The $[Cu(oxae)Fe(bpy)_2]SO_4$ and $[Cu(oxae)Fe(phen)_2]SO_4$ complexes can be recrystallized in an acetonitrile/ethanol (1:2) mixture. In spite of our many efforts, single crystals suitable for X-ray crystallography have not yet been obtained for these complexes. For the six Cu(II)–Fe(II) binuclear complexes, the molar conductance values (10^{-3} mol·L^{-1} acetonitrile solution) fall in the expected range for 1:1 electrolytes [25] (see Table 2), indicting that the sulfate anion is situated outside the metal coordination sphere.

The binuclear complexes were further characterized on the basis of the following result.

Infrared spectra

The bonding mode of the iron(II) ion to the mononuclear fragment [Cu(oxae)] was investigated by IR spectroscopy. The most relevant IR absorption bands from the IR spectra of the complexes along with their assignments are shown in Table 2. Only the selected infrared bands will be discussed here. The carbonyl stretching vibration at 1615 cm^{-1} for Cu(oxae) is considerably shifted towards higher frequencies (ca 20–40 cm^{-1}) in the binuclear complexes. Therefore, in general, when the deprotonated amide nitrogen is coordinated to the metal ion, its amide I band shifts considerably towards lower wavenumbers. In the case of an oxamide dianion coordinated to two metal ions as a bridging ligands, the amide I band reverts to near its original position (in the protonated species) [8]. Although the amide I band is due to a composite N—C=O vibration, it can essentially be seen as $\nu_{C=O}$; it is likely that the bond order of C=O (carbonyl) in the binuclear complexes is higher than in the corresponding mononuclear complex Cu(oxae). This shift has often been used as a diagnostic indicator for oxamido-bridged structures [8]. On the other band, the C=O deformation at 720 cm^{-1} of the ligand complex, [Cu(oxae)], disappeared in the spectra of the binuclear complexes. This fact may be attributed to the coordination of the carbonyl oxygens to the Fe(II) ion [26]. In addition, the $-NH_2$ vibration at 3250 cm^{-1} for Cu(oxae) and —N=C— stretching vibration at 1530–1540 cm^{-1} for terminal ligand (bpy, Me_2bpy, phen, NO_2-phen, Cl-phen, CH_3-phen) were present for all the binuclear complexes and a broad band was observed at about 1120 cm^{-1}, which is typical for a non-coordinated sulphate anion [27].

Electronic spectra

The electronic absorption spectral data for these complexes (DMF solutions) are given in Table 2). As shown in Table 2, the electronic spectra of the six

complexes are similar to each other. Two *d–d* bands centered at $(11.2–11.0)\times10^3$ cm^{-1} and $(18.5–18.0)\times10^3$ cm^{-1} are observed. The weak band $(11.2–11.0)\times10^3$ cm^{-1} is due to the $^5T_{2g}\rightarrow{}^5E_g$ transition and is characteristic of a high spin octahedral configuration around iron(II) [28], whilst the strong band $(18.5–18.0)\times10^3$ cm^{-1} may be attributed to the *d–d* transition of the "inside" copper(II) in a square-planar environment. The frequency is lower than that for the mononuclear copper(II) complex $(18.7\times10^3$ $cm^{-1})$. Such a red shift of the *d–d* band may be attributed to the decreased planarity of the (CuN_4) chromophore on forming a binuclear complex with an iron(II) ion [29]. In addition, a stronger absorption in the short wavelength range (see Table 2) may be attributable to the charge-transfer absorption bands, which may be due to the spin-exchange interaction between the copper(II) and iron(II) ions through the π-path orbital set up by an oxamido bridge [8]. Further investigation of these and similar systems is required in order to obtain more detailed assignment for charge transfer.

Based on the composition of these complexes, their IR and electronic spectra, conductivity measurements, magnetic characterization (*vide infra*) and the crystal structure of the analogous complexes [11–13], these complexes are proposed to have extended oxamido-bridged structures and to consist of the iron(II) ion in an octahedral environment and the copper(II) ion in a square-planar environment, as shown in Fig. 1.

Magnetic properties

The observed magnetic moment per binuclear complex at room temperature shown in Table 2 is considerably less than the spin-only value (5.20 B.M.) for heterobinuclear complexes of Cu(II)–Fe(II) in the absence of exchange interaction. This suggests the operation of an antiferromagnetic spin-exchange interaction in these complexes [30]. In order to obtain further information on the structure of the complexes, variable-temperature susceptibility (4.2–300 K) data were collected for complexes (**1**) and (**2**), the temperature dependences of the susceptibilities (χ_M) and magnetic moments (μ_{eff}) for both binuclear complexes are shown in Fig. 2. From Fig. 2 it is evident that the magnetic moments decrease steadily with decreasing temperature, implying the existence of an antiferromagnetic spin-exchange interaction within each molecule [31]. This is consistent with the room-temperature magnetic moments of the complexes.

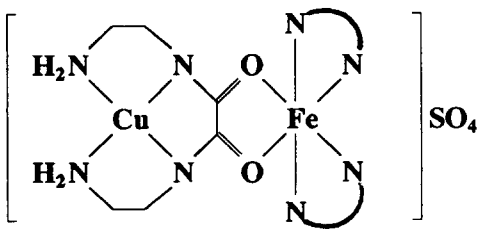

Fig. 1. Plausible coordination environments of the complexes (NN = bpy, Me_2bpy, phen, NO_2-phen, Cl-phen, CH_3-phen)

In order to understand quantitatively the magnitudes of spin-exchange interaction, the magnetic analysis for the complexes was initially carried out with the susceptibility eqn (1) based on the Heisenberg spin-exchange operator $(\hat{H}=-2J\hat{S}_1\cdot\hat{S}_2)$ for the Cu(II)–Fe(II) binuclear cluster:

$$\chi_M=\frac{N\beta^2g^2}{4kT}\left[\frac{10+35\exp(5J/kT)}{2+3\exp(5J/kT)}\right] \quad (1)$$

where χ_M denotes the susceptibility per binuclear complex and the other symbols have their usual meanings. The best fit parameters are $J=-28.5$ cm^{-1}, $g=2.04$ for (**1**); $J=-29.6$ cm^{-1}, $g=2.01$ for (**2**). The agreement factors F, defined here as $F=\Sigma[(\chi_M)_{obs}-(\chi_M)_{calc}]^2/\Sigma(\chi_M)_{obs}$ are then equal to 8.9×10^{-3} (**1**), 7.7×10^{-3} (**2**), respectively. However, the observed and calculated values do not satisfactorily fit this equation, especially at low temperature, because it neglects the single ion zero-field interaction of the iron(II) ion [30]. Considering the zero-field splitting of iron(II), a susceptibility equation was adopted based on the modified Heisenberg operator, $\hat{H}=-2J\hat{S}_1\cdot\hat{S}_2-D\hat{S}_{z1}^2$, where D is axial zero-field splitting parameter for the Fe(II) ion. In this case, the expression for the molar susceptibility (χ_M) is given by eqn (2)

$$\chi_M=\frac{N\beta^2g^2}{4kT}\left[\frac{25\exp(A)+9\exp(B)+\exp(C)+9\exp(G)+\exp(E)}{\exp(A)+\exp(B)+\exp(C)+\exp(G)+\exp(E)}\right] \quad (2)$$

$A=(35J/4+4D)/kT$
$B=(25J/4+5D/2+(25J^2/4-9DJ/2+9D^2/4)^{1/2})/kT$
$C=(25J/4+D/2+(25J^2/4-DJ/2+D^2/4)^{1/2})/kT$
$G=(25J/4+5D/2-(25J^2/4-9DJ/2+9D^2/4)^{1/2})/kT$
$E=(25J/4+D/2-(25J^2/4-DJ/2+D^2/4)^{1/2})/kT$

As shown in Fig. 2, good least-squares fits to the experimental data were attained with eqn (2) for the present case. The agreement factors are given in Table 3. Compared with a simple model $(\hat{H}=-2J\hat{S}_1\cdot\hat{S}_2$, $F\approx10^{-3})$, a much better fit was obtained with the operator including zero-field splitting. The magnetic parameters thus determined are $J=-30.6$ cm^{-1}, $g=2.06$, $D=-1.8$ cm^{-1} for $(Cu(oxae)Fe(bpy)_2)SO_4$ (**1**) and $J=-31.8$ cm^{-1}, $g=2.04$, $D=-2.0$ cm^{-1} for $(Cu(oxae)Fe(phen)_2)SO_4$ (**2**). The results indicated that the complexes showed an antiferromagnetic spin-exchange interaction within each binuclear unit. The weak antiferromagnetic spin-exchange interaction between iron(II) and copper(II) ions within each molecule may be explained by several models which have so far been proposed [32–34]. According to these mod-

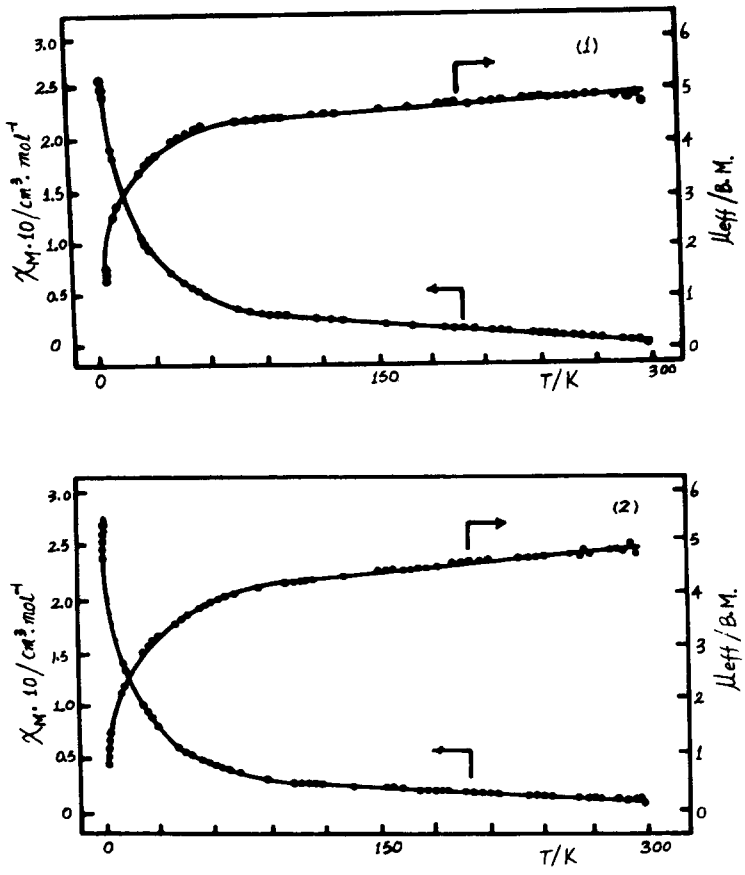

Fig. 2. Variable temperature magnetic susceptibility for $[Cu(oxae)Fe(bpy)_2]SO_4$ (**1**) and $[Cu(oxae)Fe(phen)_2]SO_4$ (**2**). The solid line represents the results of the least-squares fitting of the parameter of eqn (2) with experimental data.

Table 3. Magnetic data of the complexes

Complex	$-J$ (cm^{-1})	g	$-D$ (cm^{-1})	10^5F	Ref.

els, strict orbital orthogonality results in ferromagnetism ($J > 0$), otherwise an antiferromagnetic coupling ($J < 0$) should be involved in the system. On the basis of the crystal structure of a complex [12] that is analogous to the present complexes, if the whole molecular symmetry is considered to be C_{2v}, the 3d metallic orbitals of copper(II) and iron(II) ions transform [35] as $a_1(d_{z^2}$ and $d_{x^2-y^2})$, $a_2(d_{yz})$, $b_1(d_{xy})$ and $b_2(d_{zx})$. Around the copper(II) ion, there is just one unpaired electron which occupies the b_1 orbital, and around iron(II) there are four unpaired electrons which populate the a_1, a_2, b_1 and b_2 orbitals. Because there is no orthogonality between b_1(Cu) and b_1(Fe), namely $S = \langle b_1(Cu)|b_1(Fe)\rangle \neq 0$, antiferromagnetic exchange interactions should be observed in these complexes.

If we compare the present magnetic data with those previously reported for the analogous μ-oxamido copper(II)–iron(II) binuclear complexes [18] $[Cu(oxap)Fe(L)_2]SO_4$ (where oxap = *N*,*N*′-bis(2-aminopropyl) oxamido dianion, L = bpy and phen), which are given in Table 3, we can obtain the following results for the magnetic interaction: $[Cu(oxae)Fe(bpy)_2]SO_4$ ($J = -30.6$ cm^{-1}) > $[Cu(oxap)Fe(bpy)_2]SO_4$ ($J = -20.9$ cm^{-1}); $[Cu(oxae)Fe(phen)_2]SO_4$ ($J = -31.8$ cm^{-1}) > $[Cu(oxap)Fe$

$(phen)_2]SO_4$ ($J = -22.5$ cm^{-1}). In fact, these complexes have essentially the same skeletal structure and their IR and electronic spectra are also similar. The only difference between $[Cu(oxap)Fe(L)_2]SO_4$ and $[Cu(oxae)Fe(L)_2]SO_4$ (L = bpy and phen) is that there are two methyl ($-CH_3$) substituents in the former. Its presence may have effects on both electronic and molecular structures [36]. However, the electronic influence of the methyl groups on overlap between the magnetic orbitals should be small in view of its remoteness from the bridging site. On the other hand, the presence of this substituent will cause a decrease in coplanarity between the coordination environment of the copper(II) and that of the adjacent iron(II) ion, resulting in a decrease in overlap between the two magnetic orbitals. This would explain the differences in J values for these complexes.

Further investigations on this and similar systems are still required in order to get a deeper insight into the influence of the substituents in terminal ligands on magnetic interactions.

(Received 18 April 1997; accepted 6 August 1997)

Abstract—Treatment of $[M_2Cl_2(\mu\text{-}Cl)_2(PR_3)_2]$ (M/PR_3=Pt/PEt_3, Pt/PBu_3, Pt/PMe_2Ph, Pt/$PMePh_2$, Pd/PMe_2Ph) with AgO_2PPh_2 at room temperature, gave diphenylphosphinato-bridged binuclear complexes $[M_2Cl_2(\mu\text{-}O_2PPh_2)_2(PR_3)_2]$. These complexes were characterized by NMR spectroscopy and elemental analysis. Crystal and molecular structure of $[Pt_2Cl_2(\mu\text{-}O_2PPh_2)_2(PMe_2Ph)_2]$ has been determined by single crystal X-ray diffraction. The eight-membered metallocyclic ring "$Pt_2(O_2P)_2$" has a boat conformation with Pt···Pt separation of 3.2212(6) Å. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: palladium; platinum; NMR; diphenylphosphinate; X-ray.

Recently, we have isolated and characterized a series of binuclear palladium and platinum complexes of the type $[M_2X_2(\mu\text{-}Y)_2(PR_3)_2]$ containing anionic 1-, 2-, and 3-atom bridging ligands [1,2,3–6]. The latter family of ligands showed unusual behaviour. With certain ligands, such as dithiophosphate, only mononuclear complexes were formed exclusively [7] while others, such as 2-mercaptopyridinate, showed monomer⇌dimer equilibrium in solution [8]. However, ligands with smaller "bite" gave binuclear complexes with (e.g. carboxylate, triazenide) [3,4] or without (e.g. amidine, 2-hydroxypyridinate) [5,6] M—M interactions in a d^8 metal ion configuration. This has motivated us to examine molecules containing anionic 3-atom bridging ligands with different bite.

Diphenylphosphinic acid is isostructural and isoelectronic to carboxylic acids and is known to behave in a bridging fashion [9]. However, the ligand bites for two series of ligands are different, which may assist in stabilizing different structural forms. Indeed this is the case. For example, $[Pd_2Ph_2(\mu\text{-}OAc)_2(PPh_3)_2]$ has a "boat" conformation [10] with Pd···Pd distance of 3.079 Å while $[Pd_2Ph_2(\mu\text{-}O_2PPh_2)_2(PPh_3)_2]$ has a "chair" conformation [11] with Pd···Pd separation of 5.35 Å.

In view of the above and as part of our ongoing programme, we have synthesized and characterized binuclear complexes of palladium and platinum containing the bridging Ph_2PO_2-group.

RESULTS AND DISCUSSION

Treatment of $[M_2Cl_2(\mu\text{-}Cl_2)(PR_3)_2]$ with silver salt of diphenylphosphinic acid in 1 : 2 molar ratio readily gave diphenylphosphinato-bridged binuclear palladium and platinum complexes $[M_2Cl_2(\mu\text{-}O_2PPh_2)_2(PR_3)_2]$ **(I)** (M=Pt, PR_3=PEt_3, PBu_3, PMe_2Ph or $PMePh_2$; M=Pd, PR_3=PMe_2Ph) as cream coloured crystalline solids. When these samples were left in solution ($CDCl_3$ or C_6D_6) at room temperature for a few hours, some new species were formed (see Experimental). The ^1H NMR spectra of these complexes exhibited expected integration and peak multiplicities. The ^{31}P NMR spectra of these complexes displayed a single resonance for tertiary phosphine with platinum satellites (Table 1). The magnitude of ^1J(Pt–P) can be compared with the analogous acetato-bridged platinum complexes [3]. The bridging diphenylphosphinato group, in ^{31}P NMR spectra, also gave a single resonance which did not

(M = Pd or Pt)

I

show ^2J platinum-phosphorus coupling. The $^{195}Pt\{^1H\}$ NMR spectrum of $[Pt_2Cl_2(\mu\text{-}O_2PPh_2)_2(PEt_3)_2]$ in C_6D_6 exhibited a doublet at δ −2988 ppm with ^1J(Pt–P) 4193 Hz. Unlike the spectra of acetato-bridged binuclear platinum complexes [3], the ^{31}P and ^{195}Pt NMR spectra for diphenylphosphinato-bridged molecules did not show any ^nJ(Pt···Pt) couplings. Absence of such couplings may be interpreted as increased platinum–platinum separation in these complexes due to increased ligand bite. In order to ascertain this conclusion structure of at least one complex, $[Pt_2Cl_2(\mu\text{-}O_2PPh_2)_2(PMe_2Ph)_2]$ has been established by X-ray diffraction.

The molecular structure of $[Pt_2Cl_2(\mu\text{-}O_2PPh_2)_2(PMe_2Ph)_2]$ together with the crystallographic numbering scheme is shown in Fig. 1. Selected bond lengths and angles are given in Table 2. The molecule consists of two square planar platinum atoms each coordinated with two *cis* oxygen atoms, a chloride group and a phosphine ligand. The two platinum atoms in the molecule are held together by two diphenylphosphinate bridges. The eight-membered central metallocyclic ring "$Pt_2(O_2P)_2$" has a boat-like conformation similar to the one reported for a number of acetato-bridged binuclear complexes, such as $[Pt_2(OAc)_2(\mu\text{-}OAc)_2(PPh_3)_2]$ (Pt···Pt = 3.10 Å) [12], $[Pd_2Cl_2(\mu\text{-}OAc)_2(PMe_2Ph)_2]$ (Pd···Pd = 2.946(2) Å) [13], $[Pd_2Ph_2(\mu\text{-}OAc)_2(PPh_3)_2]$ (Pd···Pd = 3.079(4) Å [10], $[Pd_2(\mu\text{-}OAc)_2(\eta^3\text{-}C_3H_5)_2]$ (Pd···Pd = 2.94 Å) [14]. It is noteworthy that the eight-membered metallocyclic ring in $[Pd_2Ph_2(\mu\text{-}O_2PPh_2)_2(PPh_3)_2]$ adopts a chair-like conformation with mean Pd···Pd distance of 5.35 Å [11].

The increased bite distance of O_2PPh_2 group as compared to acetate is reflected in lengthening of Pt···Pt separation [3.2212(6) Å]. The two Pt–P and Pt–Cl distances are essentially identical and compare well with the reported values [15]. There are distinctly two types of Pt–O distances [16], owing to different *trans* influence of the chloride and phosphine ligand. The Pt–O distances *trans* to chloride are shorter (~0.1 Å) than those *trans* to the phosphine.

EXPERIMENTAL

Diphenylphosphinic acid [17] and $[M_2Cl_2(\mu\text{-}Cl)_2(PR_3)_2]$ (M=Pd or Pt) [18] were prepared according to literature methods. All reactions were carried out in dried and distilled analytical grade solvents under a nitrogen atmosphere. ^1H, $^{31}P\{^1H\}$ and $^{195}Pt\{^1H\}$ NMR spectra were recorded on a Bruker DPX-300 spectrometer in freshly prepared $CDCl_3$ solutions unless otherwise specified. Chemical shifts are referred to internal chloroform peak (δ 7.26 ppm) for ^1H, external 85% H_3PO_4 for ^{31}P and external Na_2PtCl_6 solution in D_2O for ^{195}Pt. Elemental analysis were carried out by the Analytical Chemistry Division of this research centre.

Preparation of $[Pt_2Cl_2(\mu\text{-}O_2PPh_2)_2(PMe_2Ph)_2]$

To a stirred dichloromethane solution (15 cm^3) of $[Pt_2Cl_2(\mu\text{-}Cl)_2(PMe_2Ph)_2]$ (114 mg, 0.14 mmol) was added solid AgO_2PPh_2 (98 mg, 0.30 mmol). Colour faded immediately. The whole was stirred vigorously at room temperature for 3 h, and then centrifuged. Solution was filtered and the filtrate was concentrated *in vacuo*. The residue was recrystallized from dichloromethane–hexane mixture at 0°C. Yellow crystals thus obtained were separated, washed with hexane and dried in vacuum (yield 101 mg, 62%). Similarly all other complexes were prepared and the pertinent data are given in Table 1. When solutions of these complexes were left at room temperature for a few hours, an equilibrium between the parent species and a mixture of new species was established as revealed by ^{31}P and ^{195}Pt NMR spectroscopy. For example, spectra of a 24 h old benzene solution of $[Pt_2Cl_2(\mu\text{-}O_2PPh_2)_2(PEt_3)_2]$ showed a number of peaks which remained unchanged even after 3 days [δ ^{31}P: 42.8, 40.5 (parent complex), 38.2, 36.4 (O_2PPh_2); 8.6 (^1J(Pt–P) = 4122 Hz), 1.0 (d, 14 Hz), 0.78, 0.4, −0.1,

X-ray crystallography

All measurements were made at 20 ± 2°C on a Rigaku AFC6S diffractometer using graphite monocromated Mo–K_α radiation (λ = 0.71073 Å). Crystal data and data collection details are given in Table 3. The data were corrected for Lorentz and polarization effects. The structure was solved by a combination of the Patterson method and direct methods [19] and refined by full-matrix least-squares on F^2. Neutral atom factors were taken from Cromer and Waber [20]. Anomalous dispersion effects were included in F_{calc} [21]. All calculations were performed using the TEXSAN [23] crystallographic software package of the Molecular Structure Corporation. The numbering scheme employed is shown in Fig. 1, drawn with the ORTEP program [24].

Table 3. Crystal data and structure refinement details for $[Pt_2Cl_2(\mu\text{-}O_2PPh_2)_2(PMe_2Ph)_2]$

Empirical formula	$C_{40}H_{42}Cl_2O_4P_4Pt_2$
Formula weight	1171.70
Temperature	293(2) K
Wavelength	0.71073 Å
Crystal system	Monoclinic
Space group	$P2_1/n$
Unit cell dimensions	a = 16.953(3) Å
	b = 11.850(2) Å
	c = 20.831(3) Å
	β = 97.662(8)°
Volume	4147.7(1) Å^3
Z	4
Density (calculated)	1.876 Mg/m^3
Absorption coefficient	7.061 mm^{-1}
F(000)	2256
Crystal size	0.09 × 0.6 × 0.22 mm
θ range for data collection	2.10 to 27.50°
Index ranges	$0 \leqslant h \leqslant 19$, $0 \leqslant k \leqslant 15$, $-27 \leqslant l \leqslant 26$
Reflections collected	9446
Independent reflections	9112 (R_{int} = 0.0429)
Absorption correction	Semi-empirical from Ψ-scans
Max. and min. transmission	0.6564 and 0.2609
Refinement method	Full-matrix least-squares on F^2
Data/restraints/parameters	9108/0/516
Goodness-of-fit on F^2	1.037
Final R indices [$I > 2\sigma(I)$]	$R1$ = 0.0461, $wR2$ = 0.0901
R indices (all data)	$R1$ = 0.0884, $wR2$ = 0.1073
Extinction coefficient	0.00005(3)
Largest diff. peak and hole	1.498 and -1.135 eÅ^{-3}

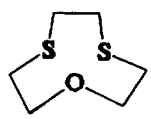
(Received 6 June 1997: accepted 15 July 1997)

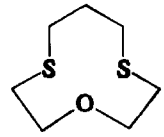
Abstract—The complexes $[Ag(L1)(PPh_3)][CF_3SO_3]$, $[Cu(L1)(PPh_3)][ClO_4]$ and $[Ni(L2)_2][ClO_4]_2$ have been prepared. L1 = 1-oxa-4,7-dithiacyclononane and L2 = 1-oxa-4,8-dithiacyclodecane. NMR, conductance and electrochemical properties are described. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: macrocycles; thioethers; metal complexes; X-ray structures.

The appearance in 1981 of Murray and Hartley's review [1] of the coordination chemistry of thioethers provoked considerable interest in them as monodentate and eventually as polydentate donors. Since that time, a substantial body of knowledge has been accumulated concerning these donors in both cyclic and acyclic ligands and this knowledge has begun to appear in current reviews [2,3]. More recently, interest in modification of complex properties by incorporation of other donors, in particular nitrogen, has become apparent [4–7] but little effort has been devoted to ethereal oxygen as a modifier [8,9]. As part of our long term interest in complexes of thioether [10] and modified thioether ligands [11], we have examined the structures and a few properties of nickel, copper and silver complexes of L1 and L2 that contain both ether and thioether donors as well as phosphine donors in some cases. The results are compared to those from studies of other related N,S-donor macrocyclic ligand complexes.



L1



L2

EXPERIMENTAL

Commercially available reagents were obtained from the Aldrich Chemical Co. Inc., or from Morton Thiokol Alfa Products Inc. and were used without further purification. Preparations for ligands L1 and L2 have been reported previously [10,12]. NMR data were obtained by using a General Electric 300-NB instrument. Magnetic susceptibility data were obtained at room temperature by the Faraday method. The calibrant was $HgCo(NCS)_4$. Electrochemical measurements were carried out under a nitrogen atmosphere at room temperature by using a Cypress Systems, Inc., CS-1087 computer-controlled potentiostat. Solution concentrations were 10^{-3} mol/L in complex and 0.1 mol/L in supporting electrolyte (tetraethylammonium perchlorate). Voltammograms were recorded in acetonitrile by using a glassy carbon working electrode that was pre-polished with 0.3 μm Al_2O_3, a platinum counter electrode and an aqueous saturated calomel reference electrode checked periodically relative to a 1.0×10^{-3} mol/L solution of ferrocene in acetonitrile containing 0.1 mol/L tetraethylammonium perchlorate for which the ferrocene/ferrocenium reduction potential was 400 mV. The ref-

erence electrode was separated from the bulk of the solution by a porous Vycor tube. Junction potential corrections were not used. Conductance data were obtained by using a General Radio Co. Type 1605-AH bridge with impedance comparator and a constant-temperature bath adjusted to 25°C. X-ray diffraction data were collected by using a Rigaku AFC6S diffractometer. Analyses were performed by Canadian Microanalytical Service Ltd.

Preparation

$[Ag(L1)(PPh_3)][CF_3SO_3]$. Solutions of L1 (66 mg, 0.40 mmol) in methanol (5 cm^3) and $AgCF_3SO_3$ (103 mg, 0.400 mmol) in methanol (5 cm^3) were mixed and stirred for 5 min. To this solution was added $P(C_6H_5)_3$ (105 mg, 0.400 mmol) in methanol (10 cm^3). The resulting solution was allowed to evaporate slowly to a final volume of ~ 2 cm^3 when colourless crystals formed that were collected and washed with a little cold methanol and dried in air. Yield: 129 mg (47%). Anal. calcd for $C_{25}H_{27}AgF_3O_4PS_3$: C, 43.93; H, 3.98. Found: C, 43.54; H, 3.80. NMR ($CDCl_3$, in ppm from TMS int. std.), ^1H; 7.47 (m, 15H) C_6H_5, 3.68 (t, $J = 5.1$ Hz, 4H) $—CH_2OCH_2—$, 3.09 (s, 4H) $—SCH_2CH_2S—$, 2.84 (t, $J = 5.1$ Hz, 4H) $—CH_2SCH_2CH_2SCH_2—$.

$[Cu(L1)(PPh_3)][ClO_4]$. Solutions of L1 (82 mg, 0.50 mmol) in acetonitrile (10 cm^3) and $[Cu(CH_3CN)_4][ClO_4]$ (164 mg, 0.500 mmol) in acetonitrile (10 cm^3) were mixed and refluxed with stirring for 2 h before being cooled to room temperature. To the solution was added $P(C_6H_5)_3$ (131 mg, 0.500 mmol) in acetonitrile (5 cm^3). The solution was allowed to evaporate slowly to a final volume of ~ 4 cm^3 when colourless crystals formed that were separated, washed with a small amount of acetronitrile and dried in air. Yield: 215 mg (73%). Anal. calcd for $C_{24}H_{27}ClCuO_5PS_2$: C, 48.89; H, 4.62. Found: C, 48.70; H, 4.65.

$[Ni(L2)_2][ClO_4]_2$. A solution of $Ni(ClO_4)_2 \cdot 6H_2O$ (180 mg, 0.492 mmol) in methanol (5 cm^3) to which was added nitromethane (20 cm^3) was mixed with a solution of L2 (178 mg, 1.00 mmol) in nitromethane (10 cm^3). The deep blue solution that formed was filtered and left standing to evaporate solvent slowly until blue needle-like crystals formed. These were collected, washed with small amounts of dichloromethane, acetone and finally diethyl ether and dried in air. Yield: 212 mg (69%). Anal. calcd for $C_{14}H_{28}Cl_2NiO_{10}S_4$: C, 27.38; H, 4.59; S, 20.88; Ni, 9.56. Found: C, 27.29; H, 4.59; S, 20.39; Ni, 9.06. $\mu_{eff} = 2.98$ B.M. (22°C). ($\Lambda_M = 230$ ohm^{-1} cm^2 mol^{-1} in nitromethane at 4.6×10^{-4} mol/L).

X-ray studies

A summary of crystallographic data for $[Ag(L1)(PPh_3)][CF_3SO_3]$, $[Cu(L1)(PPh_3)][ClO_4]$ and $[Ni(L2)_2][ClO_4]_2$ is in Table 1. The diffraction intensities were collected at 299 K by the ω–2θ scan technique at a scan speed of 8°/min to a maximum 2θ value of 50.1°. Three standards were measured after every 150 reflections and no significant crystal decay was detected. The space groups were determined by systematic absences, packing considerations, a statistical analysis of intensity distribution and the successful solution and refinement of the structures. Unit cell parameters (Table 1) were determined by a least squares refinement of the setting angles for 19 reflections in the range $41.68 \leqslant 2\theta \leqslant 44.82°$ ($[Ag(L1)(PPh_3)][CF_3SO_3]$), 20 reflections in the range $38.43 \leqslant 2\theta \leqslant 43.35°$ ($[Cu(L1)(PPh_3)][ClO_4]$) and 18 reflections in the range $25.86 \leqslant 2\theta \leqslant 38.34°$ ($[Ni(L2)_2][ClO_4]_2$). Lorentz and polarization factors were applied and corrections were made for absorption. The structures were solved by direct methods [13,14] and refined by full matrix least-squares [15] with counting statistics weights. H-atom positions were calculated then refined and the hydrogens were assigned isotropic thermal parameters 20% greater than those of their bonding partners but the thermal parameters were not refined. H-atom positions were fixed for the final round of least squares refinement. Non-hydrogen atoms were refined anisotropically except in the structure of $[Cu(L1)(PPh_3)][ClO_4]$ where the ClO_4^- ion was refined isotropically and in the structure of $[Ni(L2)_2][ClO_4]_2$ where the disordered carbon, C(6), and most of the perchlorate oxygens were refined isotropically. The final cycle of refinement was based on 4032 observed reflections [$I > 2.00\sigma(I)$] and 380 variables ($[Ag(L1)(PPh_3)][CF_3SO_3]$), 1232 observed reflections [$I > 2.00\sigma(I)$] and 105 variables ($[Cu(L1)(PPh_3)][ClO_4]$) and 1348 observed reflections [$I > 2.00\sigma(I)$] and 139 variables ($[Ni(L2)_2][ClO_4]_2$) and converged. All calculations were performed with the TEXSAN crystallographic software package [16] of Molecular Structure Corporation. Scattering factors were taken from the usual source [17].

RESULTS AND DISCUSSION

The structure of $[Ag(L1)(PPh_3)][CF_3SO_3]$ is shown in Fig. 1 while selected bond lengths and angles are in Table 2.

There is a distorted pseudo-tetrahedral array of donor atoms about the silver with bond angles that lie in the range 85.41(4)–140.31(3)°. Angles at silver also involving atoms within the heterocyclic ring are all less than 86° due to formation of chelate rings whereas those between ring donors and the phosphorus atom are all greater than 113° and one [P—Ag—S1 = 140.31(3)°] is much greater. The range and magnitude of these angles are not unlike those reported for $[Ag_2L_2]^{2+}$ (L = 2,5,8,11-tetrathia[12](2,5)thiophenophane) [18]. The Ag—S bond lengths in $[Ag(L1)(PPh_3)][CF_3SO_3]$ [2.552(1), 2.572(1) Å] can be compared with those in $[Ag_2L_2]^{2+}$ (L = 2,5,8,11-

tetrathia[12](2,5)thiophenophane) [18] which have an average length of 2.695 Å and a range of 2.564–2.995 Å. The Ag—P length [2.3697(9) Å] can be compared with that in *anti*-$[Ag_2(L')(PPh_3)_2]^{+2}$ (L' = 2,5,8,17, 20,23-hexathia[9](1,2)[9](4,5)cyclophane) [19] which is 2.407(3) Å and the Ag—O distance [2.640(3) Å] with that in $[(CH_2O)_6Ag_2][Ag][AsF_6]_3$ [2.458(5) Å] [20] or those in $[Ag([15]aneS_2O_3)]^+$ [2.667(5), 2.690(4), 2.492(4) Å] [21]. The conformation adopted by the ligand is [3,3,3] as a result of the interaction of the ether oxygen with the silver atom.

The structure of $[Cu(L1)(PPh_3)][ClO_4]$ is shown in Fig. 2 and selected bond lengths and angles are in Table 3.

The heterocyclic ligand is disordered about a three-fold axis with a chalcogen and two carbon atoms in the asymmetric unit. It was not possible to model the fragments separately so 'S(1)' represents 2/3 of a sulfur atom and 1/3 of an oxygen atom modelled with a 5/6 sulfur occupancy. Similarly C(7) and C(8) are a 2/3–1/3 superposition of two different methylene carbons which is reflected in the high thermal parameters of the two 'atoms'. The coordination geometry around copper is pseudo-tetrahedral with

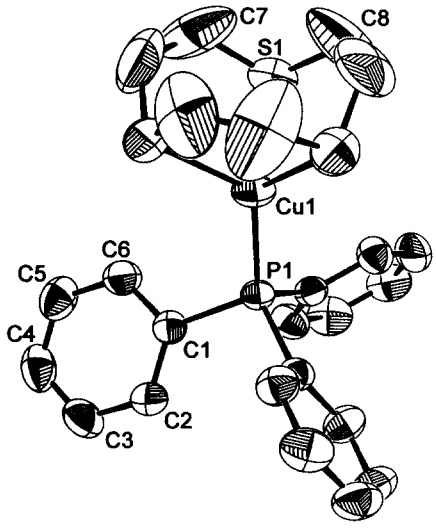

Fig. 2. The structure of $[Cu(L1)(PPh_3)]^+$.

bond angles at copper of 89.01(6)° for those within chelate rings while those involving the phosphorus atom are 125.96°. The bond lengths for all three Cu–L1 bonds have been determined to be the same [2.334(2) Å] while the Cu—P distance is found to be 2.188(2) Å. These may be compared to the Cu—S distances in $[Cu(3,6\text{-dithiaoctane})_2]^+$ which vary from 2.280(4) to 2.318(5) with an average of 2.303 Å [22] and to those in $[Cu(L)_2]^+$ (L = 2,5,8-trithia[9](2,5)thiophenophane) [23] which range from 2.301(3) to 2.392(3) with an average of 2.340 Å. Likewise, the Cu—P distance can be compared to those of 2.262(9) and 2.272(6) Å in $[(Cy_3P)_2(pzH)Cu]ClO_4 \cdot CH_3OH$ [24] or 2.190(2), 2.252(3) and 2.260(3) Å in $[Cu_2Br_2(PPh_3)_3]$ [25]. In the latter, one Ph_3P is in a sterically unencumbered position much like that in $[Cu(L1)(PPh_3)][ClO_4]$ and the corresponding Cu—P distances [2.190(2) and 2.188(2) Å] are very similar. Apparently, the change from two bridging bromines (as in $[Cu_2Br_2(PPh_3)_3]$) to two thioether and one ether (as in $[Cu(L1)(PPh_3)][ClO_4]$) as additional ligands has almost no influence on the Cu—P distance. There are few examples of Cu^I—O bond lengths in the literature but the Cu—O distance of 2.334(2) Å in $[Cu(L1)(PPh_3)][ClO_4]$ is longer than observed distances to carboxylate oxygens [1.923(5), 2.134(5), 1.945(6) and 2.107(6) Å] [26] and shorter than those to ether oxygens [27] [2.510(11) and 2.432(8) Å]. The Cu—O distance in $[Cu(L1)(PPh_3)][ClO_4]$ is also longer than those of 1.917(9) and 2.015(11) Å in the mixed-valence compound $[Cu_3Br_4(DMF)_2(H_2O)]_n$ in which the formal oxidation state of the copper atoms is on average 1.33 [28]. In fact, this distance is not unlike that in the Cu^{II} complex $CuCl_2 \cdot L$ (L = 1,9-bis(2-thienyl)-5-oxa-2,8-dithianonane) [11] [2.30(1) Å] which illustrates the ability of Cu to accommodate changes in oxidation state with or without a change in bond length in a manner reminiscent of its accommodating behaviour noted above with respect to bonds to phosphorus. The conformation of the ligand in this structure is [3,3,3], similar to that found in the analogous silver complex (*vide supra*) as a result of interaction between the oxygen atom of the ligand and the copper atom.

The structure of $[Ni(L2)_2][ClO_4]_2$ is shown in Fig. 3 and selected bond lengths and angles are in Table 4. The Ni—S lengths in pseudo-octahedral $[Ni(L2)_2][ClO_4]_2$ are 2.353(2) and 2.390(2) Å. The Ni—O bonds, which are not mutually *trans*, are 2.115(5) Å long. The larger Ni—S distance is typical of those in

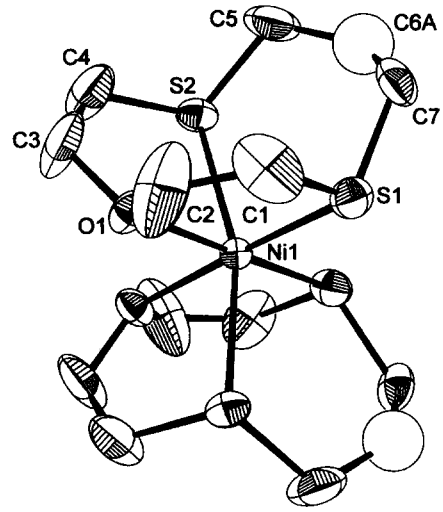

Fig. 3. The structure of $[Ni(L2)_2]^{2+}$.

both linear [29] and cyclic [10] polythioether complexes. The smaller, however, is significantly shorter than the average length (2.43 Å) [1] of Ni—S bonds found in octahedral monodentate ligand complexes and slightly shorter than the usual range of lengths in cyclic ligand complexes as, for example, in $[Ni(9S3)_2]^{2+}$ [2.375(3)–2.400(5) Å] (9S3 = 1,4,7-trithiacyclononane) [30]. The general shortening is probably due to compression caused by use of a cyclic ligand while the extreme shortening may arise from the fact that the bond involved [Ni—S(1)] is *trans* to an ether oxygen. If thioethers participate in π-acid bonding whereas ethers do not, this would be the result expected. The Ni—O distance is unremarkable [29,31]. Bond angles range from 83.2(2) to 99.34(8)° and the greatest deviation from linearity across the Ni atom involves the angle S(2)—Ni—S(2) which is 163.2(1)°.

Coordination of L1 to Ag in $[Ag(L1)(PPh_3)][CF_3SO_3]$ produces a negligible (0.02, 0.04 ppm) shift in the nmr resonance frequencies (compared to the free ligand) [12] of hydrogens adjacent to the metal-bound thioether sites but a much larger (0.27 ppm) shift for hydrogens adjacent to the ethereal oxygen. This confirms the indication in the X-ray study that the oxygen atom is interacting with the silver atom. Coordination of the ligand also changes the coupling constants in the apparent triplet signals from 9.6 Hz in the free ligand to 5.1 Hz in the complex.

The cyclic voltammetric response of $[Ni(L2)_2][ClO_4]_2$ is very similar to that of its analogue with [20]aneO_2S_4 [10], the dimer of L2. That ligand supplies the same O_2S_4 donor set as two equivalents of L2 but in a single ring. Thus, $[Ni(L2)_2][ClO_4]_2$ is electrochemically silent between -0.7 and $+0.7$ V *vs* SCE unless the initial potential is set at less than -0.7 V or a scan into that region precedes a scan to $> +0.7$ V. Under the latter conditions, a wave at $+0.23$ V *vs* SCE occurs followed by a reduction wave at -1.06 V and then a minor return wave at -0.75 V and finally the major wave at $+0.23$ V *vs* SCE. On the basis of these observations, metal-based oxidation seems relatively unfavourable and the observed reduction is irreversible.

The conductivity of $[Ni(L2)_2][ClO_4]_2$ is roughly that of the 1:2 electrolytes, $[Ni(L)(H_2O)][ClO_4]_2 \cdot CH_3OH$, ($\Lambda_M$ = 205 ohm^{-1} cm^2 mol^{-1} in acetonitrile at 5.0×10^{-4} mol/L) (L = 1,9-bis(2-pyridyl)-2,5,8-trithianonane) [29] and $[Co(L')][ClO_4]_2$ (Λ_M = 199 ohm^{-1} cm^2 mol^{-1}) (nitromethane; 2.5×10^{-4} mol/L) (L′ = 1,12-bis(2-pyridyl)-2,5,8,11-tetrathiadodecane) [32] the structures and properties of which we have reported previously.

CONCLUSIONS

The ligand 1-oxa-4,7-dithiacyclononane (L1) adopts a [3,3,3] conformation in both the Ag^I and Cu^I complexes examined in this study and in this respect it resembles other [9]aneX_3 (X = N,S) ligands [33,34]. The interaction of ethereal oxygen with Cu^I and Ag^I by L1 is also observed in the behaviour of L2 with nickel. Thus, addition of an extra methylene to the ring does not alter substantially the ligands' coordination behaviour. In the literature, there are few X-ray structures of Cu^I or Ag^I involving ether or phosphine ligands and fewer still that have thioether donors as well, and it is usually argued that Cu^I and Ag^I being 'soft' acids should have little affinity for the 'hard' base oxygen. The present results are therefore significant in the sense that they show both thioether and ether donors coordinated to Cu^I and Ag^I. The X-ray structure of $[Ni(L2)_2][ClO_4]_2$ provides further evidence of the π-bonding capability of thioether sulfur through the observation of its short Ni—S bond *trans* to —O— compared to the longer Ni—S distance *trans* to —S—.

(Received 12 June 1997; accepted 10 July 1997)

Abstract—The cerium(III) β-diketonate compounds $[Ce_2(\beta\text{-diket})_6(tetraglyme)]$ [β-diket = etbd (1-ethoxy-4,4,4-trifluorobutane-1,3-dionate) **1**, hfpd (1,1,1,5,5,5-hexafluoropentane-2,5-dionate) **2** and hfod (1,1,1,2,2,3,3-heptafluoro-7,7-dimethyloctane-4,6-dionate) **3** and tetraglyme = $CH_3O(CH_2CH_2O)_4CH_3$] were synthesised from the reaction of $CeCl_3 \cdot 7H_2O$ and tetraglyme with an aqueous ethanolic solution of Na(β-diket). The unusual reaction of cerium ammonium nitrate, $[Ce(NH_4)_2(NO_3)_6]$, and Hetbd in an ammoniacal mixture of dimethoxyethane resulted in the ammonium cerium(III) salt, $[NH_4][Ce(etbd)_4]$ **4**, rather than the expected cerium(IV) species. All compounds were characterised by spectroscopic methods and in the cases of **1** and **4**, also by X-ray crystallography. The structure of $[Ce_2(etbd)_6(tetraglyme)]$ **1** consists of two $Ce(etbd)_3$ moieties bridged by a tetraglyme molecule. The two Ce atoms in this molecule are eight and nine coordinate respectively with distorted docahedral and monocapped square antiprismatic geometries. The crystal structure of **4** is stabilised by an extensive hydrogen bonding network involving the NH_4^+ cation and one oxygen atom from each of the four etbd ligands belonging to the $[Ce(etbd)_4]^-$ anion, with additional $NH_4^+ \cdots F_3C(etbd)$ interactions. The Ce atom in the $[Ce(etbd)_4]^-$ anion is eight coordinate with a distorted square antisprismatic geometry. All the complexes are air and moisture stable, and some compounds have good volatilities and thermal stabilities, as demonstrated by sublimation and TGA/DSC studies. © 1998 Elsevier Science Ltd. Keywords: cerium(III) β-diketonates; tetraglyme; chemical vapour deposition (CVD); X-ray structure.

Ceria supported gadolinia with the composition $Ce_{0.9}Gd_{0.1}O_{1.95}$ (CSG) is an attractive material for low temperature solid oxide fuel cells (SOFCs) [1]. These materials can operate satisfactorily at substantially lower temperatures (ca 400–600°C) compared to present SOFC electrolytes. The preparation of thin films of ceria (CeO_2) from chemical vapour deposition (CVD) has led to a number of recent reports of volatile molecular precursors [2]. Previous reports of cerium alkoxides resulted in either large, involatile oligomers or extremely air and thermally sensitive compounds which were unsuitable for CVD [3]. The thermal properties and stability of some cerium(IV) β-dike-

tonates make them more suitable as CVD precursors for ceria films and examples of these type of species include compounds where β-diketonate = pd (pentane-2,4-dionate) [4,5] tmhd (2,2,6,6-tetramethylheptane-2,4-dionate) [6] and dppd (1,3-diphenylpropane-1,3-dionate) [7]. In contrast, there are hardly any known examples of well characterised eight coordinate cerium(III) β-diketonates which have been evaluated as CVD precursors to thin films of ceria, and this is despite the fact that they have been shown to give films of ceria (CeO_2) rather than the expected cerous oxide (Ce_2O_3).

It has been shown that volatilities and thermal stabilities of many homoleptic lanthanide(III) β-diketonates are often improved by chelation to multidentate glyme(s) despite the increase in molecular weight [8,9]. Examples in which glyme moieties are observed to bridge between two [Ln(tmhd)$_3$] molecules include; [Ln$_2$(tmhd)$_6$(tetraglyme)] (Ln = Er [8] Gd [9]), [Ln$_2$(tmhd)$_6$(triglyme)] (Ln = Y [10], Eu [11], Tb [11] or Tm [12]), [EuY(tmhd)$_6$(triglyme)] [12] and [Gd$_2$(tmhd)$_6$(heptaglyme)] [9]. The saturation of available metal coordination sites via multidentate chelates often result in lower melting points and increased volatility and air and moisture stability with respect to the homoleptic analogues. Furthermore, fluorinated β-diketonates generally give more volatile compounds than their non-fluorinated structural analogues, because of the reduced van der Waals' interactions between molecules. Such precursors can often produce CeO_2 films which contain significant amounts of fluoride contamination; this may, however, be reduced by using water vapour in conjunction with inert carrier gases [2]. The present work is a continuation of our investigations to study the volatility characteristics of lanthanide(III) β-diketonate compounds which may be potential MOCVD precursors to their metal oxides [8]. Several cerium(III) β-diketonates were investigated for thermal stability and volatility by sublimation studies and by simultaneous thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC). The X-ray structures of two of the complexes are also reported.

EXPERIMENTAL

General procedures

All reactions were conducted in round bottom flasks without any special precautions to exclude air. Elemental analyses were performed by the microanalytical department at Imperial College. The melting points were measured under nitrogen in capillaries and are uncorrected. Infrared spectra were recorded on a Perkin Elmer FTIR 1720 spectrometer as Nujol results between 25 × 4 mm^2 KBr plates. The Nujol was pre-dried with 4Å molecular sieves prior to use and the samples were protected from the atmosphere by an O-ring sealed Presslock™ holder (Aldrich Chemicals). The NMR solution samples were prepared in the glove-box, using 5 mm NMR tubes fitted with Young's valves. Solution NMR spectra were recorded on a Jeol GS 270 NMR spectrometer. ^{1}H NMR spectra were recorded at 270.16 MHz. Chemical shifts were referenced to the *protio* impurities of the deuterated solvent. Mass spectra were run on a VG Autospec. instrument at the Mass Spectrometry Department at Imperial College (FAB$^+$ mode). Controlled TGA and DSC measurements were done using a Polymer Laboratories 1500H simultaneous thermal analyzer, controlled by an Omni Pro 486DX-33 PC. The weight of the samples investigated was between 14–27 mg. The measurements were carried out in alumina crucibles under an atmosphere of flowing (25 cm^3 min^{-1}) nitrogen gas, using heating rates of 15°C min^{-1}.

Starting materials

All hydrocarbon solvents (BDH), gaseous ammonia (BOC) and NaOH (BDH) pellets were used as obtained. $CeCl_3 \cdot 7H_2O$ was obtained from Janssen Chemica, Hhfpd (Inorgtech) was obtained as a gift, whilst Hetbd, Hhfod and tetraglyme were purchased from Aldrich. All ligands were used as obtained. **CAUTION**: care should be taken when using ammonia gas by performing all ammoniation reactions in a well-ventilated fume cupboard.

Synthesis of [Ce$_2$(etbd)$_6$(tetraglyme)] **1**

NaOH pellets (0.93 g, 23.2 mmol) were dissolved in distilled water (5.0 cm^3) and 95% EtOH (50.0 cm^3), and to this solution was added Hetbd (4.27 g, 23.2 mmol) with stirring. Separately, $CeCl_3 \cdot 7H_2O$ (2.98 g, 8.0 mmol) was dissolved in a mixture of EtOH (10.0 cm^3), distilled water (5.0 cm^3) and tetraglyme (0.89 g, 4.0 mmol). The Na-etbd solution was then added dropwise via a dropping funnel to the cerium chloride solution over a period of 20 min. The mixture was filtered to remove a white precipitate, the volume of the filtrate reduced to ca 10.0 cm^3 and the mixture redissolved in CH_2Cl_2 (50.0 cm^3). Removal of the organic layer by decantation and reducing the volume to ca 15 cm^3, resulted in the precipitation of a white solid. The mixture was filtered and the solvent removed to give a red oil, which on standing yielded an orange coloured crystalline product. Yield: 5.20 g (81%), m.p. 103–106°C. (Found: C, 35.1; H, 3.7. Calc. for $Ce_2C_{46}H_{58}O_{23}F_{18}$: C, 34.5; H, 3.6%.) IR: 1719, 1676 (br), 1562, 1450, 1366, 1285, 1217, 1183, 1133, 1095, 1035, 923, 847, 796, 741, 676, 582, 520 cm^{-1}.

Synthesis of [Ce$_2$(hfpd)$_6$(tetraglyme)] **2**

Compound **2** was prepared by following similar procedure as employed for **1**, using Hhfpd (5.20 g,

25.0 mmol) rather than Hetbd. The product was obtained as orange needles. Yield: 4.81 g (66%); m.p. 125–128°C (Found: C, 26.9; H, 1.7. Calc. for $Ce_2C_{40}H_{28}O_{17}F_{36}$: C, 27.5; H, 1.6%.) IR: 1656, 1645, 1557, 1537, 1376, 1255, 1203, 1143, 1085, 944, 870, 800, 740, 659, 527, 462 cm^{-1}.

Synthesis of $[Ce_2(hfod)_6(tetraglyme)]$ **3**

The procedure adopted for **1** was also used for the preparation of **3**, using the diketone Hhfod (7.40 g, 25.0 mmol) rather than Hetbd. Removal of all volatiles yielded a red viscous oil. Yield: 7.79 g (82%). (Found: C, 37.2; H, 3.7. Calc. for $Ce_2C_{70}H_{82}O_{17}F_{42}$: C 37.0, H, 3.6%.) IR: 1625, 1535, 1393, 1346, 1280, 1239, 1120, 1067, 1021, 967, 938, 909, 832, 791, 754, 687, 476 cm^{-1}: ^1H NMR ($CDCl_3$, 270 MHz, 20°C), δ −14.66 (s, 4H, CH_2-glyme), −9.95 (s, 4H, CH_2-glyme), −9.20 (s, br, 6H, CH_3-glyme), −5.56 (s, 4H, CH_2-glyme), −5.17 (s, 4H, CH_2-glyme), 0.42 (s, 54H, Bu^t of hfod), 13.23 (s, 6H, CH of hfod).

Synthesis of $[NH_4][Ce(etbd)_4]$ **4**

CAN, $[Ce(NH_4)_2(NO_3)_6]$, (3.43 g, 6.26 mmol) was dissolved in a mixture of dimethoxyethane (DME) (50.0 cm^3) and Hetbd (4.60 g, 25.0 mmol). Gaseous ammonia was then introduced into the mixture for 45 min, giving an exothermic reaction and an orange colour after ca 5 min. The solution was stirred for a further hour, filtered and then washed with petroleum ether (2×5.0 cm^3). Removal of all volatiles yielded an orange oil which gave dark orange crystals upon standing. Yield: 4.56 g (81%); m.p. decomposes slowly above 145°C (Found: C, 33.1; H, 3.2; N, 1.5. Calc. for $CeC_{24}H_{28}O_{12}NF_{12}$: C, 32.4; H, 3.1; N, 1.6%.) IR: 3199 (br), 1654, 1577, 1491, 1448, 1366, 1285, 1217, 1182, 1131, 1035, 915, 796, 677, 581, 419 cm^{-1}.

X-ray crystallography

Single crystals of $[Ce_2(etbd)_6(tetraglyme)]$ **1** and $[NH_4][Ce(etbd)_4]$ **4**, suitable for X-ray work, were mounted using silicone oil and then transferred to the goniostat. Crystallographic measurements for both compounds were made at 150 K using Mo-K_α radiation ($\lambda = 0.71069$ Å, graphite monochromator) on a Delft instruments FAST TV area detector diffractometer equipped with a rotating anode generator (50 kV, 50 mA), a buffer board, a DEP image intensifier, and an Oxford Cryostream low temperature cooling system by following previously described procedures [13]. The unit cell parameters were obtained by least squares refinement of the diffractometer angles for 250 reflections within the θ ranges 1.80–25.03° (**1**) and 1.78–25.10° (**4**). The intensity data were collected within the same θ ranges from volumes corresponding to slightly more than a hemisphere of reciprocal space; both data sets were corrected for Lorentz and polarisation factors and also for absorption effects using the program DIFABS [14].

The structures were solved by direct methods (SHELXS86) [15] and difference electron density syntheses, and refined on F^2 by full matrix least-squares (SHELXL93) [16] using all unique data with intensities greater than 0. The non-hydrogen atoms were anisotropic. The hydrogen atoms belonging to the NH_4 group in compound **4** were experimentally located and refined isotropically with the four N—H distances constrained to remain the same [final value 0.94(2) Å]. Other hydrogens in the structures were included in calculated positions (riding model) with $U_{iso} = n \times U_{eq}$ of the parent carbon ($n = 1.2$ for CH and CH_2, and 1.5 for CH_3 groups). The maximum residual electron densities in the final difference maps were very close to the cerium atoms [2.018 e $Å^{-3}$ (**1**) and 1.227 e $Å^{-3}$ (**4**)] and indicated no features of stereochemical significance. The final R (on F)/R_w (on F^2) values were 0.0608/0.1179 for **1** and 0.0638/0.0880 for **4** for all unique data and 810 and 468 parameters respectively. The corresponding R-values for 6069 (**1**) and 3619 (**4**) data with $I > 2\sigma(I)$ were 0.0460/0.1152 and 0.0382/0.0848 respectively. Sources of scattering factors as in [15]. The diagrams were drawn with the program SNOOPI [17]. The calculations were done on a Pentium P5-90 personal computer. The crystal data and details of data collection and structure refinement are presented in Table 1. Fractional atom co-ordinates, thermal coefficients, hydrogen atom parameters, and full lists of bond lengths and angles are available as supplementary data.

RESULTS AND DISCUSSION

Synthesis

The reaction of $CeCl_3 \cdot 7H_2O$ in the presence of half an equivalent of tetraglyme with an aqueous ethanolic solution of ca three molar equivalents of [Na(etbd)] yielded the product $[Ce_2(etbd)_6(tetraglyme)]$ **1**. Similar reactions with the sodium salts of Hhfpd and Hhfod (ca three molar equivalents with respect to Ce metal) produced the corresponding glyme adducted complexes $[Ce_2(\beta\text{-diket})_6(tetraglyme)]$ [β-diket = hfpd (**2**) and hfod (**3**)]. Water was effectively removed from these compounds by dissolving them in chloroform and separating the aqueous and organic layers.

$$2CeCl_3 \cdot 7H_2O + 6Na(hfpd) + tetraglyme \xrightarrow{\text{(i) } H_2O/EtOH,\ \text{(ii) } CH_2Cl_2} [Ce_2(hfpd)_6(tetraglyme)]\,\mathbf{3} + 6NaCl + 14H_2O$$

Cerium ammonium nitrate (CAN), $[Ce(NH_4)_2(NO_3)_6]$, has been shown to be a versatile reagent for the synthesis of monomeric cerium(IV) β-diketonates [12]

[c] The *R*-values for observed data only $[I > 2\sigma(I)]$ are given in parentheses.

alkoxides [18], and siloxides [19]. In the present work, we aimed at synthesising a *tetrakis*(β-diketonate)Ce^{IV} derivative by reacting CAN with four molar equivalents of the β-diketone, Hetbd, using ammonia as a base to facilitate deprotonation of the β-diketone, however, we obtained the ammonium *tetrakis*(β-diketonate)cerium(III) salt, $[NH_4][Ce(etbd)_4]$ **4**. Clearly, ammonia has acted as a reducing agent during the reaction. The reduction of the Ce^{IV} to Ce^{III} has been observed previously and may be attributed to the excellent oxidizing potential of CAN [20]. Compound **3** was obtained as red oil, whilst **1**, **2** and **4** were orange crystalline solids. All the compounds were stable in air and moisture.

Spectroscopic characterisation

The IR spectra of complexes **1**–**4** (Nujol mulls) show several bands characteristic of the coordinated β-diketonate ligands, with strong absorptions between 1577 and 1535 cm^{-1} corresponding to C⋯O and C⋯C vibrational stretches [11]. In complexes **1**–**3**, the ν(C—O) stretching modes due to coordinated tetraglyme are located in the range 1095–1067 cm^{-1}, whilst M—O (metal–oxygen) stretches involving the β-diketonate ligands are observed in the range 419–520 cm^{-1}. In compound **4**, a broad peak centered at 3199 cm^{-1} is attributed to the ν(N—H) stretches of the ammonium cation (broadness caused by hydrogen bonding), and is comparable to similar bands in other ammonium compounds [13].

NMR spectra for all the complexes gave broad and shifted peaks due to their paramagnetism. In the case of compound **2**, however, the peaks have been tentatively assigned previously [21] (also given in the Experimental section).

Thermal analyses and mass spectrometry

Simultaneous TGA and DSC studies were undertaken for the three glyme-bridged compounds **1**–**3** and the ammonium salt **4** to evaluate their suitability as CVD precursors. $[Ce_2(etbd)_6(tetraglyme)]$ **1** melts between ca 103–106°C in a capillary, whilst a sharp

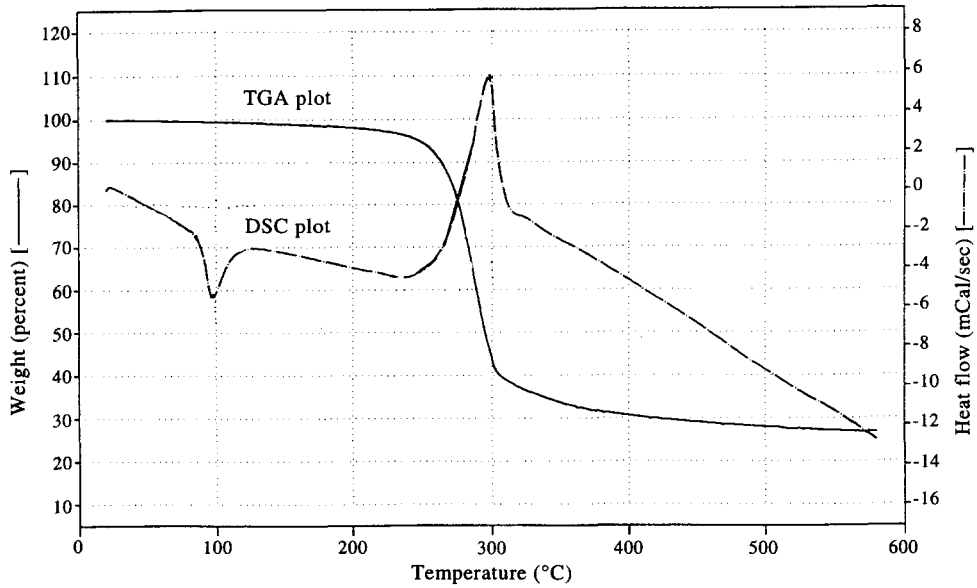

Fig. 1. The TGA plot for $[Ce_2(etbd)_6(tetraglyme)]$ **1**.

endotherm is observed for this process at 98.0°C (−4.79 mcal mg^{-1}) in the DSC curve. Sublimation studies revealed that this compound decomposes without sublimation at 255°C/10^{-2} Torr to give a black oil at the bottom of the sublimation vessel. The TGA plot for this compound (Fig. 1) shows a residue of ca 27% at 550°C, which is much higher than expected for CeO_2 (calc. 21.5%) but very close to that expected for CeF_4 (calc. 27.0%). In comparison, $[Ce_2(hfod)_6$ (tetraglyme)] **3** sublimes quantitatively (ca 235°C) at 0.1 Torr, whilst the TGA studies show the loss of over 87% of the material between ca 200–350°C to give a final residue of ca 9% by 500°C [21]. This is in contrast with $[Ce_2(hfpd)_6(tetraglyme)]$ **2**, which sublimes with substantial decomposition at 249°C (10^{-2} Torr). The TGA plot for this compound shows a weight loss of ca 80% by 340°C due to sublimation, followed by a further weight loss process up to 600°C (residue of 4.7%) due most probably to a combination of decomposition and sublimation. The DSC curves of compounds **2** and **3** show broad exotherms corresponding to the sublimation reactions. The TGA plot for the complex salt $[NH_4][Ce(etbd)_4]$ **4** shows that the compound decomposes slowly over the temperature range 90–700°C, with at least two overlapping weight loss processes. The residue left at 700°C is ca 35% of the original weight, which is much higher than that expected for either CeO_2 (calc. 19.3%) or CeF_4 (calc. 24.3%) and probably contains a substantial amount of carboneceous products. The corresponding DSC curve is complicated showing a very broad endotherm centred at ca 159.3°C due to several overlapping reactions. The compound decomposes (without sublimation) at ca 240°C/10^{-2} Torr to give a black solid of unknown composition.

Mass spectroscopic studies for the complexes **1**–

Table 2. Assignments for selected molecular ions in the mass spectra of complexes **1**–**4**

	1	**2**	**3**	**4**
$[Ce_2(L)_2(F)_2(4g)]^+$	—	—	1425(trace)	—

$[Ce(F)_2]^+$	—	178(8)	178(16)	—

Key: L = β-diketonate; 4g = tetraglyme.

4 (Table 2) are consistent with the stoichiometries suggested for the compounds. The FAB^+ spectra for all the tetraglyme hemi-adducted compounds **1–3** show $[Ce(L)_2(tetraglyme)]^+$, $[Ce(L)_2]^+$, (L = corresponding β-diketonate) or similar fragments and a peak at 400 amu corresponding to $[CeF_2(tetraglyme)]^+$. A trace peak in the mass spectrum of **3** at 1425 amu was also assigned as the glyme bridged ion $[Ce(L)_3(F)_2(4g)]^+$.

Crystal structure of $[Ce_2(etbd)_6(tetraglyme)]$ **1**

A single crystal X-ray study was undertaken for $[Ce_2(etbd)_6(tetraglyme)]$ **1** to unambiguously identify the bonding modes of the glyme ligand. A SNOOPI plot of the structure is shown in Fig. 2 and selected bond lengths and angles are given in Table 3. The structure of the complex consists of two $Ce(etbd)_3$ moieties unsymmetrically bridged by a tetraglyme molecule. Ce(1) is eight coordinated with six oxygens from three chelating etbd ligands and with two chelating oxygens from one end of the tetraglyme molecule, whilst Ce(2) is nine co-ordinated with six oxygens from three chelating etfa ligands and with the remaining three oxygens from the tetraglyme. In the case of $[Er_2(tmhd)_6(tetraglyme)]$ [8], the glyme ligand was observed to bind via two of the oxygen atoms from each end of the polyether (the middle oxygen uncoordinated). However, in the gadolinium analogue $[Gd_2(tmhd)_6(tetraglyme)]$ [9], the two moieties are bridged in an asymmetric manner resulting in an uncoordinated oxygen at one end of the polyether chain [9]. This suggests that a lanthanide cation larger than Gd^{3+} should be able to bind additionally to the third outer oxygen of the polyether chain and indeed, this phenomenon has been observed in the structure of compound **1**. The coordination polyhedra around the cerium atoms show considerable distortions from idealised geometries (Fig. 3); that around Ce(1)

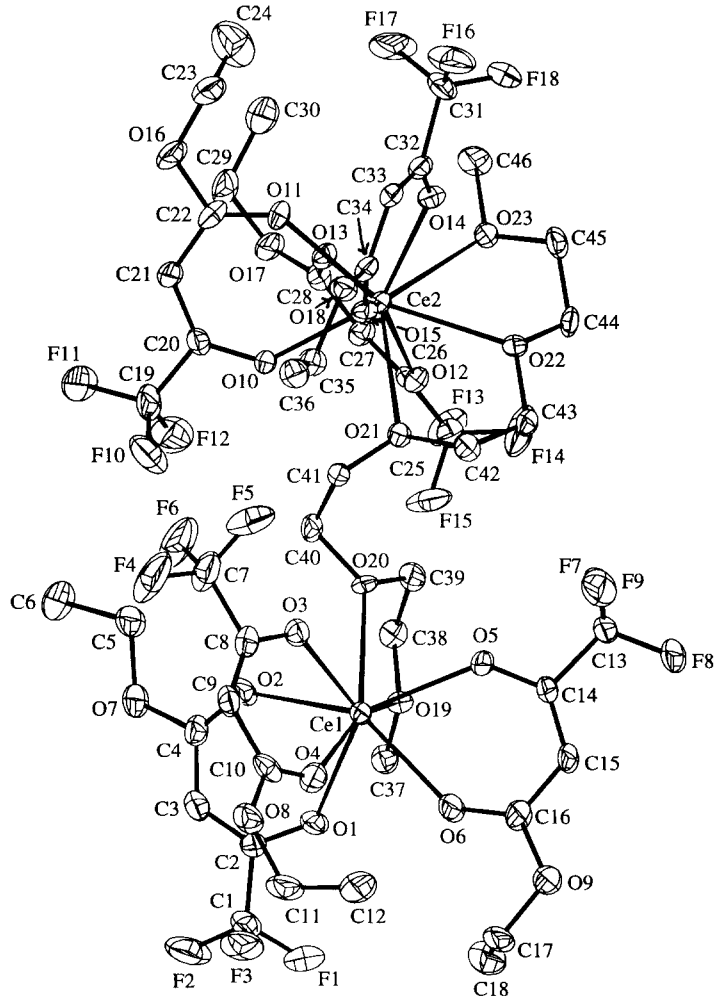

Fig. 2. Molecular structure of $[Ce_2(etbd)_6(tetraglyme)]$ **1** showing the atom numbering scheme. The hydrogen atoms have been omitted for clarity.

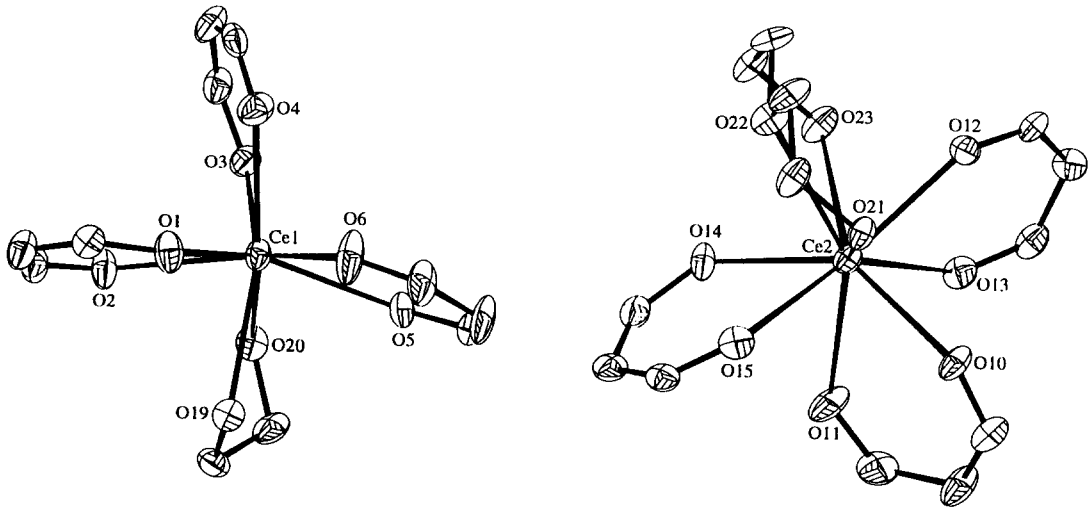

Fig. 3. Illustration of the coordination polyhedra around Ce(1) (distorted dodecahedron) and Ce(2) (distorted monocapped square antiprism) in $[Ce_2(etbd)_6(tetraglyme)]$ **1**.

approximates to a distorted dodecahedron and that around Ce(2) may be described as monocapped square antiprism. In the latter case, the capping atom O(21) lies on the face defined by O(10), O(12), O(15) and O(22).

The Ce—O bond lengths for each cerium atom fall into three distinct categories. The longest Ce—O bonds are associated with the glyme ligands; Ce—O bonds with the β-diketonate ligands are much shorter, but these can be clearly subdivided into two groups. It is also observed that the bonds to Ce(2) are in general longer than the corresponding bonds with Ce(1); this is however expected on the basis of the increase in coordination number of Ce(2) compared with Ce(1) [nine vs eight]. The Ce(1)—O(glyme) bonds are 2.623(5) and 2.586(5) Å (average 2.605 Å), the Ce(2)—O(glyme) bonds are 2.650(5), 2.633(5) and 2.702(5) Å (average 2.662 Å), the longest bond is associated with the terminal oxygen. This lengthening of the Ce—O bonds with the two terminal oxygens may be attributed to the steric crowding due to the methyl groups on these oxygens.

Examination of the Ce—O(etbd) distances reveal several interesting features which merit discussion in somewhat greater detail. Thus, the effect of varying the coordination numbers for the two metals as well as the asymmetry in the Ce—O bonds for each β-diketonate ligand are clearly reflected in the Ce—O bonds. These points are best illustrated in Fig. 4, which shows the average values of the relevant bond lengths associated with the $Ce(O_2C_3)$ chelates for each cerium. For both the metal centres, the Ce—O(etbd) chelate distances are clearly asymmetric and fall into two narrow ranges: 2.390(5)–2.444(5), average 2.408 Å and 2.464(5)–2.488(5), average 2.472 Å for Ce(1), and 2.384(5)–2.452(5), average 2.420 Å and 2.476(5)–2.508(5), average 2.496 Å for Ce(2). The variations for these two sets of values (between **a** and **a′** in Fig. 4) reflecting the asymmetry in the Ce—O(etbd) chelates bonds are 0.064 Å for Ce(1) and 0.076 Å for Ce(2). The effect of increased coordination number for Ce(2) is also reflected in these bonds being slightly but systematically longer by ~0.02 Å than the corresponding bonds with Ce(1). Another feature relates to the C—C distances within the O_2C_3 fragment of the chelates; it is observed that for each β-diketonate, the two C—O bond lengths (**b** and **b′** in Fig. 4) are always different [1.277(9)–1.292(9), average 1.296 Å and 1.228(10)–1.239(9), average 1.234 Å for Ce(1) and 1.274(9)–1.283(9), average 1.278 Å and 1.208(9)–1.243(9), average 1.229 Å for Ce(2)], with the longer distances being associated with those oxygens having shorter bonds with cerium. Similarly, the two C—C distances in each chelate (**c** and **c′** in Fig. 4) are also different [1.341(11)–1.347(11), average 1.344 Å and 1.418(12)–1.456(12), average 1.433 Å for Ce(1) and 1.352(11)–1.361(10), average 1.357 Å and 1.427(12)–1.441(11), average 1.434 Å for Ce(2)]. These variations in the C—O and C—C bonds (by ca 0.05 and 0.09 Å respectively) are systematic and consistent with the suggestion that the O_2C_3 moieties in this structure are not completely delocalised as commonly observed in metal β-diketonate chelate structures, but one canonical form (**A** rather than **A′** in Fig. 4) predominates. This is an interesting situation and may be correlated with the effects of the substituents on the chelate ring, i.e. electron withdrawing CF_3 and electron donating EtO groups on the two carbons C_α and C_β respectively in Fig. 4. The Ce-etbd chelate rings show slight folding about the O···O axis [4.6(5)–15.2(2)° for Ce(1) and 1.9(3)–14.7(3)° for Ce(2)]. The O—Ce—O chelate angles for the etbd ligands lie in a very narrow range,

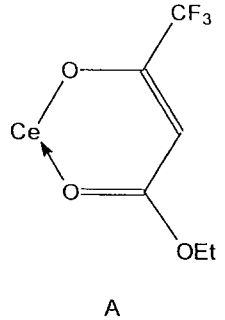
C(45)—O(23)—Ce(2)	112.0(4)		

68.8(2)–70.2(2), average 69.6°, and those with tetraglyme in the range 62.5(2)–63.5(2), average 63.0°; these values are comparable with the corresponding values in other polyether adducts of lanthanide β-diketonate complexes [8,9]. It is also noted that in contrast with structure **4** (see later), the two types of Ce—O—C_α and Ce—O—O_β angles (Fig. 4) have nearly similar values [133.5(5)–136.1(5), average 135.0° and 135.8(5)–139.7(6), average 137.5° for Ce(1); 133.8(5)–135.5(5), average 134.7° and 134.0(5)–136.6(5), average 135.5° for Ce(2)]. The C—F, C—C and C—O bond lengths involving the CF_3 and ethoxide substituents on the β-diketonate and the tetraglyme ligands have normal values; the C—O—C angles involving the ethoxides lie in the narrow range 115.2(6)–117.7(6)°, whilst those in the tetraglyme molecule show larger variations 109.6(5)–117.5(6)°, most probably due to the chelating/bridging bonding modes of the glyme ligand. Other geometry parameters associated with the structure are as expected. The dimeric molecules are held together in the crystal by weak H···F/O interactions (≥2.51 Å) and van der Waals' forces.

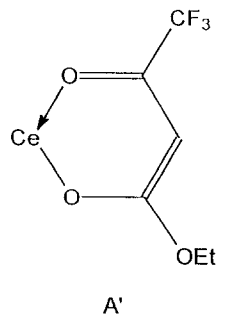
Crystal structure of $[NH_4][Ce(etbd)_4]$ **4**

The structure of the complex anion $[Ce(etbd)_4]^-$ in **4** is shown in Fig. 5 and selected bond distances and

	Complex **1**		Complex **4**
	Ce(1)	Ce(2)	Ce(1)
a =	2.408	2.420	2.454
a′ =	2.472	2.496	2.468
b =	1.286	1.278	1.293
b′ =	1.234	1.229	1.234
c =	1.344	1.357	1.352
c′ =	1.433	1.434	1.432



A



A'

Fig. 4. Average bond lengths (Å) in the $Ce(O_2C_3)$ chelate in **1**, and the two possible cannonical forms **A** and **A′**.

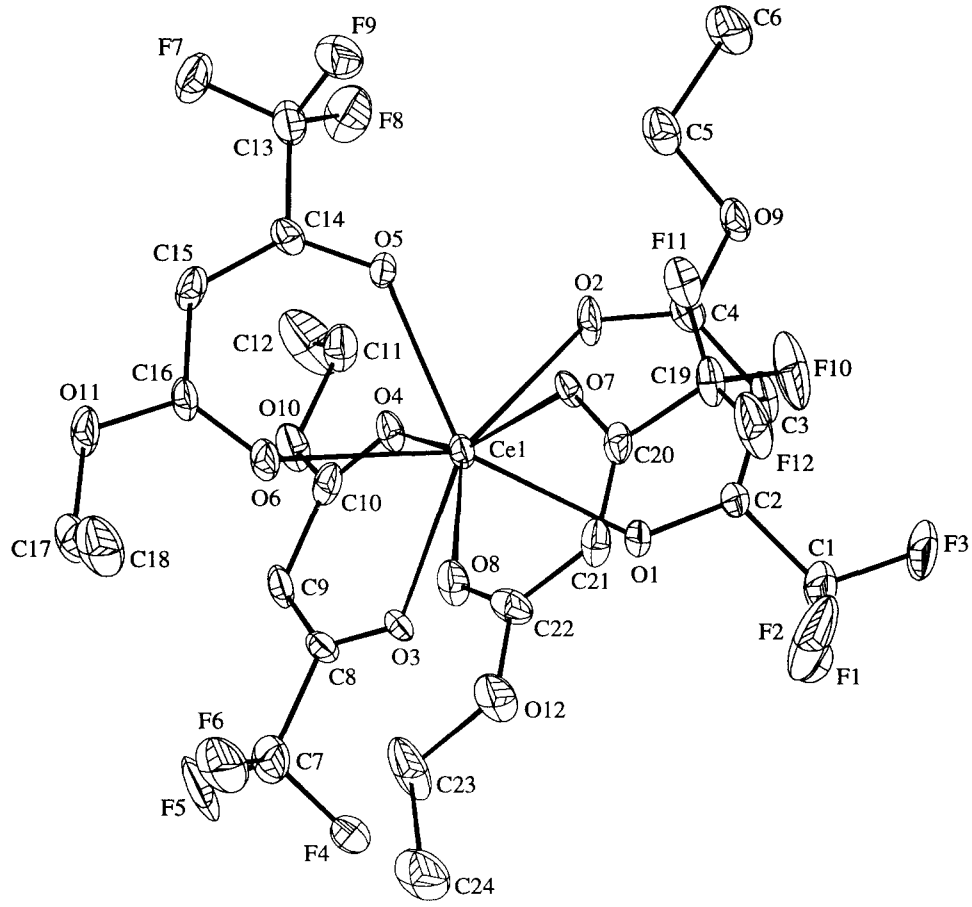


Fig. 5. Structure of the $[Ce(etbd)_4]^-$ anion in **4**, showing the atom numbering scheme. The hydrogen atoms have been omitted for clarity.

angles in the anion are presented in Table 4. All four β-diketonate ligands are chelated to the eight coordinate cerium ion, as shown in Fig. 6, in a distorted square antiprismatic arrangement. In fact, the distortion from ideal geometry is large enough to approximate the coordination geometry even as a bicapped trigonal prism.

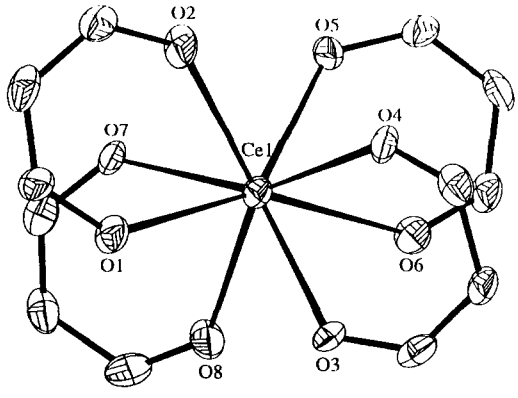

Fig. 6. Illustration of the coordination geometry (distorted square antiprism) of the $[Ce(etbd)_4]^-$ anion in **4**.

The two types of Ce—O distances in the present complex ion (**a** and **a**′ in Fig. 4) lie in the ranges 2.444(4)–2.460(4), average 2.454 Å, and 2.457(4)–2.477(4), average 2.468 Å respectively (average of all eight Ce—O distances 2.461 Å). The difference in the values for **a** and **a**′ in **4** (Fig. 4) is very small (0.014 Å) compared with 0.064 Å (for the eight coordinate Ce) and 0.076 Å for (nine coordinate Ce) in compound **1**. Nevertheless, we feel that these differences suggest asymmetry in the Ce—O chelate bonds. Certainly, the asymmetry in both the C—O and C—C bonds in the chelate rings 1.275(7)–1.300(7), average 1.293 Å (**a**), 1.223(6)–1.247(7), average 1.234 Å (**a**′), [Δ(**a**–**a**′) = 0.059 Å] and 1.345(8)–1.361(8) average 1.352 Å (**c**), 1.419(8)–1.448(8), average 1.432 Å (**c**′), [Δ(**c**–**c**′) = 0.080 Å] follow the same trend as observed in other structures [12], and therefore it may be concluded that the canonical form **A** is predominant in this complex anion also. The situation is again explained in terms of the electron withdrawing or electron

releasing effects of the substituents (CF_3 and OEt groups respectively) on the C_α and C_β atoms in Fig. 4. The Ce-etbd chelate rings are non-planar and are folded by 14.0(3)–22.5(1)° about the O···O axis. The O—Ce—O chelate angles lie in the narrow range 68.90(13)–70.02(13), average 69.6° and these are comparable with the corresponding values in **1** and other β-diketonate complexes [12]. The C—O—C angles involving the ethoxide substituents on the β-diketonate ligands are 115.3(5)–117.4(5)° and comparable with the corresponding values in **1**.

The gross crystal structure of $[NH_4][Ce(etbd)_4]$ **4** consists of $[NH_4]^+$ cations and $[Ce(etbd)_4]^-$ anions held together by an extensive network of N—H···O/F hydrogen bonds and short interactions. The dimensions of hydrogen bonds and other important short contacts are presented in Table 5. It is observed that all four hydrogen atoms of the $[NH_4]^+$ cation are involved in fairly strong hydrogen bonds (H···O ≥ 2.30 Å) with the chemically equivalent oxygen atoms O(1), O(3), O(5) and O(7) on the four etbd ligands which are all bonded to C_α (Fig. 4). One effect of these hydrogen bonds is manifested in the fact that the Ce—O(1)/O(3)/O(5)/O(7)—C_α angles [129.5(3)–132.5(3), average 130.7°] are narrowed down by ca 5° compared with the Ce—O(2)/O(4)/O(6)/O(8)—C_β angles [133.6(4)–136.5(4), average 135.6°]. In the absence of similar hydrogen bonds, no such differences in the corresponding Ce—O—C angles are observed in **1**.

The structures of compounds **1** and **4** may be compared with several other related lanthanide complexes. In eight coordinate complexes of the type MX_4, where X is a bidentate ligand such as β-diketonate, the coordination geometry is predominantly either square antiprismatic or dodecahedral [22], but small potential energy differences between these two forms often lead to considerable distortions from the idealised geometries and intermediate forms are also found. It is difficult to predict *a priori* the particular geometry

Table 5. Dimensions of the hydrogen bonds and short interactions in $[NH_4][Ce(etbd)_4]$ **4**. Distances in (Å) and angles in (°)

adopted in a given compound since it depends on a number of factors such as the nature and bulk of the ligands, the oxidation state and ionic radii of the central metal, and inter-ligand and intermolecular interactions including any hydrogen bonding. In the Ce^{III} complex **1**, the two different Ce^{III} centres have different coordination numbers (eight and nine) and different geometries (dodecahedral and monocapped square antiprismatic) with large distortions from idealised polyhedra, due mainly to the bonding of the metal centres with the polyether molecule. In the Ce^{III} complex **4**, where all the four chelating ligands are the same, the observed geometry is best described as square antiprismatic. Similar coordination type was also reported for the homoleptic Ce^{IV} complexes [α-$Ce(pd)_4$] [4], [β-$Ce(pd)_4$] [5], α-[$Ce(tmhd)_4$] [6], [$Ce(dppd)_4$] [7] and [$Ce(pmhd)_4$] (pmhd = 1-phenyl-6-methylhexane-1,3-dionate) [23]. This situation is in contrast with a number of salt like compounds, e.g., $[C_9H_8N][Ce(ttbd)_4]$ {ttbd = 4,4,4-trifluoro-1-(2-thienyl)butane-1,3-dionato} [24], $[NH_4][Pr(ttbd)_4]\cdot H_2O$ [25] and [Cs][$Y(hfpd)_4$] [26], where the metal atoms are all in +3 oxidation state, but the coordination geometry is distorted dodecahedral. Distorted dodecahedral geometry was also observed in the Ce^{IV} complex β-[$Ce(tmhd)_4$] [23].

CONCLUSIONS

Our work has emphasised once more that the presence/strength of intermolecular interactions in β-diketonate compounds has a great influence on the volatility characteristics and hence on their potential as CVD precursors for ceria (CeO_2). The physical and structural properties of compound **4** appear to suggest that the extensive hydrogen bonding between the NH_4^+ cation and the β-diketonate ligands in the $[Ce(etbd)_4]^-$ anion are responsible for its low volatility (decomposes on attempted sublimation), and this makes this complex unsuitable as a CVD precursor for the preparation of ceria. Compound **1** decomposes without sublimation at 255°C, whilst **2** sublimes with substantial decomposition at 249°C, suggesting that both these tetraglyme adducted products are of only marginal importance as CVD precursors. However, the other tetraglyme adduct, $[Ce_2(hfod)_6(tetraglyme)]$ (also known as CFT), is an air and moisture stable compound with excellent thermal stability and volatility and it sublimes quantitatively at ca 220°C/10^{-2} Torr. This compound was obtained as a viscous oil and preliminary results have shown that uniform carry-over rates are obtained in our CVD apparatus compared to the solid precursors. Unlike other cerium precursors to ceria which are currently in use, such as [$Ce(tmhd)_4$] and [$Ce(hfod)_4$], CFT does not appear to undergo any pyrolysis from prolonged heating at ca 250°C in a CVD bubbler [2]. Indeed, thin films of ceria have been grown on a variety of substrates using CFT and the results have been reported recently [21].

Acknowledgements—The authors would like to thank the E.S.P.R.C. (M.B.H., K.M.A.M. and J.A.D.) for support, the Leverhulme Trust (J. McA.), and B.P. for endowing D.M.P.M.'s chair. Thanks to Hilary O'Callaghan and Patrick Barrie who performed some of the spectroscopic/analytical measurements. We would also like to thank Inorgtech Chemicals for gifts of chemicals.

(Received 13 January 1997; accepted 2 July 1997)

Abstract—The isolation from "cobalt(III) acetate" and characterisation by single crystal X-ray diffraction (refined to $R = 0.087$, $R_w = 0.084$) of the symmetric neutral cubane, $[Co_4(\mu_3\text{-}O)_4(\mu\text{-}CH_3CO_2)_4(C_5H_5N)_4]$, and of the hexafluorophosphate salt (refined to $R = 0.078$, $R_w = 0.073$) of the trimeric dication, the partial cubane, $[Co_3(\mu_3\text{-}O)(\mu\text{-}OH)_3(\mu\text{-}CH_3CO_2)(CH_3CO_2)(C_5H_5N)_6]^{2+}$, are reported. The cubane crystallises as its chloroform solvate, $[Co_4(\mu_3\text{-}O)_4(\mu\text{-}CH_3CO_2)_4(C_5H_5N)_4] \cdot 5CHCl_3$, whilst the partial cubane crystallises as its water solvate, $[Co_3(\mu_3\text{-}O)(\mu\text{-}OH)_3(\mu\text{-}CH_3CO_2)(CH_3CO_2)(C_5H_5N)_6][PF_6]_2 \cdot 2H_2O$. The cubane and partial cubane dication have average Co···Co distances of 2.818(8), 2.683(6) and 2.918(6), 2.767(5) Å, respectively, and average Co—μ_3-O distances of 1.86 and 1.91 Å, respectively. © 1998 Elsevier Science Ltd. Keywords: cobalt acetate; cubane; trimeric.

Metal carboxylates have attracted extensive study because of the range of structural types and magnetic, bonding, catalytic, etc. properties which they exhibit. Thus, for example, a trimeric iron species of the basic acetate, oxo-centred type has been isolated from solutions which oxidise alkanes, and copper acetate and chromium acetate were the first compounds for which δ- and quadruple metal–metal bonding were postulated [1–4].

Cobalt carboxylates are of particular practical interest as they are the most widely used industrial homogeneous catalysts, predominantly for the oxidations of a variety of hydrocarbons [5–11]. Paradoxically, however, the structure and composition of "$[Co(OAc)_3]$" (OAc = CH_3COO^-) are incompletely established [12–22]. Although "well defined green octahedrons" were reported in 1924 and a trimeric structure was proposed in 1929 [13,14], amorphous materials are generally produced from the variety of preparative methods developed by various workers [13–15,22–26]. Thus, "$[Co(OAc)_3]$" has been postulated to consist of various combinations of monomers, dimers, trimers and mixed valence trimers.

† Part III. Beattie, J. K., Hambley, T. W., Klepetko, J. A., Masters, A. F. and Turner, P., *Polyhedron*, 1997, in press.

Analogous triangular, homo- and heteronuclear, single and mixed valence, oxo-centred basic acetate derivatives have long been known for many transition metals, whilst related dimeric, hydroxy-bridged cobalt(III) amine cations were prepared by Werner [27–29].

A significant breakthrough in the structural chemistry of "cobalt(III) acetate" was reported in 1973 by Uemura *et al.*, who showed that crystalline derivatives could be isolated from "cobalt(III) acetate" by the addition of aromatic nitrogen bases as co-ligands [26]. Thus, for example, addition of pyridine and $NaClO_4 \cdot H_2O$ to a methanolic solution of "cobalt(III) acetate", prepared by ozonolysis of cobalt(II) acetate tetrahydrate in acetic acid, produced $[Co_3O(OAc)_6(py)_3][ClO_4]$ (py = C_5H_5N), formulated, on the basis of solid state infra-red spectra and powder X-ray diffraction, to contain the cation (**1**). Solid $[Co_3O(OAc)_6(py)_3][ClO_4]$ was obtained in less than quantitative yield. However, structural characterisation of "cobalt(III) acetate", its constituents or its derivatives was still lacking. Subsequently, Sumner reported the crystallographic characterisation of salts of the symmetric, dinuclear, hydroxy-bridged cation, $[Co_2(\mu\text{-}OH)_2(\mu\text{-}OAc)(OAc)_2(py)_4]^+$, (**2**), and the trinuclear, oxo-centred cations, $[Co_3(\mu_3\text{-}O)(\mu\text{-}OH)_2(\mu\text{-}OAc)_3(py)_5]^{2+}$, (**3**) and $[Co_3(\mu_3\text{-}O)(\mu\text{-}OR)(\mu\text{-}OAc)_5(py)_3]^+$, (**4**), using the strategy used by Uemura to obtain crystalline, pyridine-containing derivatives [30,31,34].

We have recently shown that dimeric cations such as (**5**) and (**6**) can also be isolated from "cobalt(III) acetate" solutions using pyridine as a co-ligand [32]. The cations (**5**) and (**6**) are formally derived from (**2**) by the successive interchange on each cobalt atom of a pyridine ligand with the non-hydrogen bonded acetate oxygen atom.

Recently, we reported the structure of the "parent", symmetric cation $[Co_3(\mu_3\text{-}O)(\mu\text{-}OAc)_6(py)_3]^+$, (**7**) [33], previously isolated by Sumner and Steinmetz from metal-catalysed autoxidation reactions, and prepared by them from the reaction of $[Co_3(\mu_3\text{-}O)(\mu\text{-}OH)(\mu\text{-}OAc)_5(py)_3]^+$, (**4a**), with acetic acid/acetic anhydride [34].

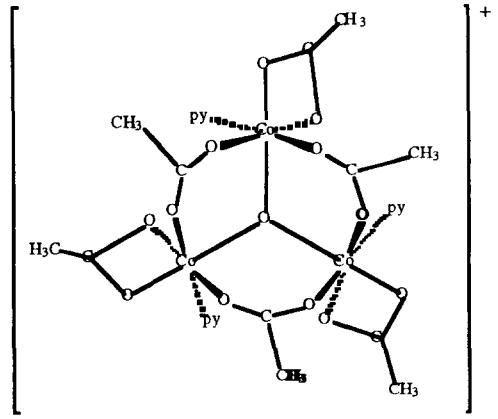
$$[Co_3O(OH)(OAc)_5(py)_3]^+ + HOAc \xrightarrow{Ac_2O,\,-H_2O} [Co_3O(OAc)_6(py)_3]^+$$

(**4a**) (**7**)

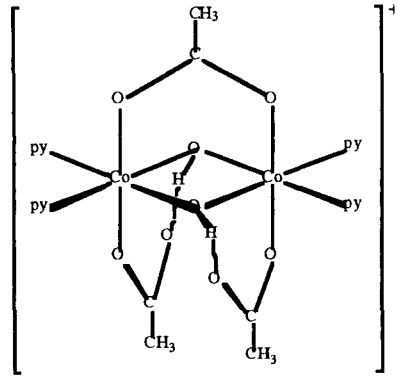
Trinuclear $[Co_3(\mu_3\text{-}O)(\mu\text{-}OH)(\mu\text{-}OAc)_5(py)_3]^+$, (**4a**), was itself prepared in 81% yield as its PF_6^- salt by the addition of aqueous NH_4PF_6 to a solution obtained from the peracetic acid oxidation of cobalt(II) acetate in warm aqueous acetic acid in the presence of pyridine.

In attempting to produce stable analogues of potential models of the photosynthetic water oxidation centre in plants and bacteria, Dimitrou *et al.* prepared in good (69%) yield, $[Co_2(\mu\text{-}OH)_2(\mu\text{-}OAc)(OAc)_2(bpy)_2][ClO_4]$, (**8**, bpy = bipyridyl), the bipyridyl analogue of (**2**), by H_2O_2 (3 equivalents) oxidation of $[Co(OAc)_2(H_2O)_4]$ in methanol/water at 50°C in the presence of bipyridine, followed by the addition of $LiClO_4$ [35]. A similar reaction at room temperature in ethanol/water with a deficiency of bipyridine and excess (10 equivalents) of H_2O_2 yielded (51% as the ClO_4^- salt) the partial cubane dication $[Co_3(\mu_3\text{-}O)(\mu\text{-}OH)_3(\mu\text{-}OAc)(OAc)(bpy)_3]^{2+}$ (**9**). Reaction of (**8**) with Li_2O_2 in hot dimethylsulfoxide generated the ClO_4^- salt of the dicationic cubane, $[Co_4(\mu_3\text{-}O)_4(\mu\text{-}OAc)_2(bpy)_4]^{2+}$, (**10**), in 64% yield. Although not isolated from, nor hitherto observed in, typical "cobalt(III) acetate" solutions, structures of the types (**9**) and (**10**) are clearly of interest in the examination of the constitution of "cobalt(III) acetate".

Similarly, oxidation of $[Co(PhCO_2)_2]$ with aqueous H_2O_2 in dimethylformamide or acetonitrile leads to the mixed-valence octanuclear $[Co_8(\mu_4\text{-}O)_4$



(**1**)



(**2**)

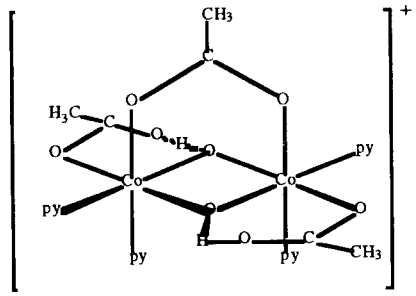
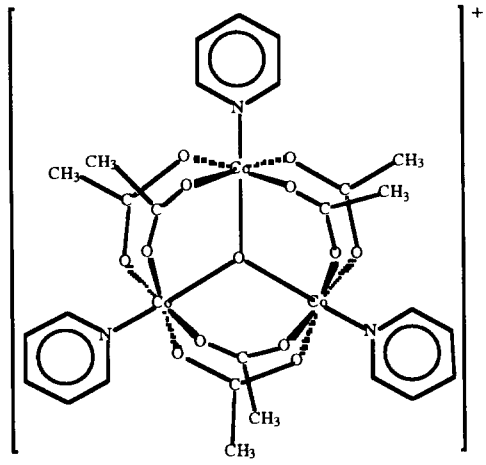
(5)



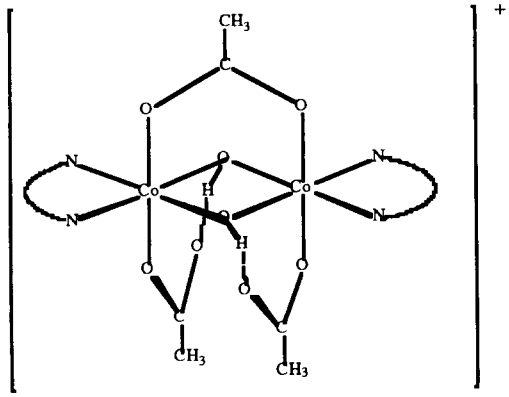
(6)



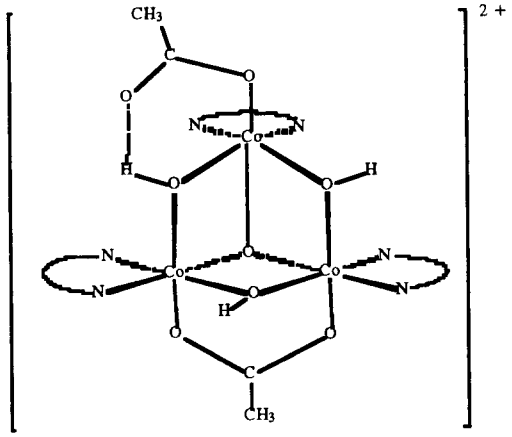
(7)

$(PhCO_2)_{12}(L)_3(H_2O)]$ (L = DMF, MeCN, H_2O) [36, 37]. We have recently shown that the mixed valence octanuclear $[Co_8(\mu_4\text{-}O)_4(\mu\text{-}OAc)_6(\mu\text{-}OMe)_4(Cl)_4(OH_n)_4]$ (n = 1 or 2) is produced in good yield during the recrystallisation of "cobalt(III) acetate" from methanol over several months in the presence of a halide source such as CH_2Cl_2 or AX (A = H^+, Li^+, NH_4^+; X = Cl^-) [38].

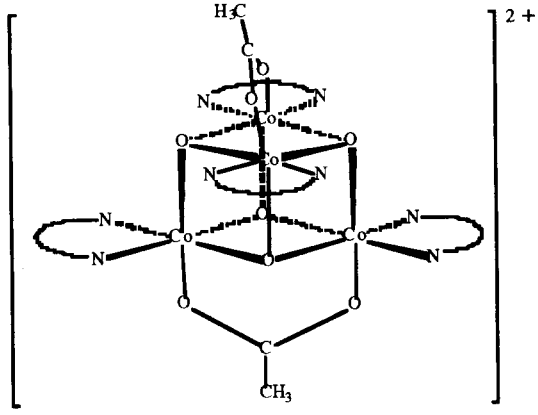
In continuation of our studies on the constitution of "cobalt(III) acetate" we report here the isolation



(8)



(9)



(10)

from "cobalt(III) acetate"/pyridine of the neutral cubane, $[Co_4(\mu_3\text{-}O)_4(\mu\text{-}OAc)_4(py)_4]$, (**11**), the synthesis of the partial cubane, the trinuclear dication, $[Co_3(\mu_3\text{-}O)(\mu\text{-}OH)_3(\mu\text{-}OAc)(OAc)(py)_6]^{2+}$, (**12**), as its hexafluorophosphate salt, and the structural characterisation of these compounds.

EXPERIMENTAL

WARNING: perchlorate salts are potentially explosive and must be treated with care.

Chemicals

Cobalt(II) acetate tetrahydrate and lithium peroxide (both Aldrich), acetic acid (Biolab), light petroleum (BDH), acetic anhydride, ammonium hexafluorophosphate, dichloromethane, dimethylformamide, dimethylsulfoxide, ethanol, methanol and sodium perchlorate hydrate (all Merck), acetonitrile, chloroform, pyridine (all Ajax) and hydrogen peroxide (27.5%, Pacific) were of analytical reagent grade and were used as received. Dimethylsulfoxide was dried over molecular sieves (4A) for several days before use.

The compounds $[Co_2(\mu\text{-}OH)_2(\mu\text{-}OAc)(OAc)_2(py)_4][PF_6]$, (**2**)$[PF_6]$ and (**5**)$[PF_6]$, $[Co_3(\mu_3\text{-}O)(\mu\text{-}OAc)_6(py)_3][PF_6]$, (**7**)$[PF_6]$, and $[Co_3(\mu_3\text{-}O)(\mu\text{-}OH)(\mu\text{-}OAc)_5(py)_3][PF_6]$, (**4a**)$[PF_6]$, were prepared by published methods [32,34]. "Cobalt(III) acetate" was prepared using the following adaptation of a reported method [26]. Cobalt(II) acetate tetrahydrate (12.5 g, 0.05 mol) was stirred overnight in acetic acid (125 cm^3) precipitating anhydrous pink cobalt(II) acetate with some pink cobalt(II) acetate remaining dissolved. The mixture was then ozonated (20 l (O_2)/h) with a

Wallace and Tiernan laboratory ozonator (model BA-023012) ("250 V") for 19 h. The solution turned from pink to dark brown within several minutes. The resulting green solution was evaporated *in vacuo* at $< 20°C$ to give dark green crude "cobalt(III) acetate" (11.0 g). Crude "cobalt(III) acetate" (10.0 g) was then crushed and dissolved in chloroform (~ 200 cm^3) and the solution filtered. Light petroleum (60–80°C; ~ 500 cm^3) was then added to the filtrate and the green "pure" "cobalt(III) acetate" isolated by filtration and dried *in vacuo* (8.1 g, 69% as "$Co(OAc)_3$"). Selected IR data (KBr): ν_{max}/cm^{-1}. 1576 (vs), 1420 (vs), 1347 (w), 1044 (w), 1030 (w), 957 (w), 890 (w), 805 (w), 747 (vw), 720 (vw), 698 (s), 631 (m), 581 (vw), 496 (w), 414 (w).

Tetrakis[(*μ-acetato-κO*: *κO′*)-*μ*$_3$-*oxo*-(*pyridine*)*cobalt* (*III*)], $[Co_4(\mu_3\text{-}O)_4(\mu\text{-}OAc)_4(py)_4]$ (**11**)

Method A—Formation from "cobalt(III) acetate". In a sealed vessel, pyridine (0.4 g, 5 mmol) and $NaClO_4 \cdot nH_2O$ (0.2 g, $\sim$ 1 mmol) were added to a dark green solution of "pure" "cobalt(III) acetate" (1.0 g, 4.2 mmol as "$Co(OAc)_3$") in methanol (10 cm^3) and the mixture stirred briefly. The mixture was left at room temperature for 1 h and filtered. Small brown crystals were collected by filtration, washed with diethyl ether and dried in air (0.01 g). The solid was identified by ESI/MS and solution ^{1}H NMR in CD_3CN and CD_2Cl_2 as a mixture of mainly $[Co_3(\mu_3\text{-}O)(\mu\text{-}OMe)(\mu\text{-}OAc)_5(py)_3][ClO_4]$, a smaller amount of (**4a**)$[ClO_4]$ and another species not readily identified. The filtrate was left for another 10 h, precipitating more solid (0.3 g) which was collected by filtration and dried over silica gel. The ^{1}H NMR in CD_3CN and CD_2Cl_2 showed the material also consisted of (**4a**)$[ClO_4]$ and $[Co_3(\mu_3\text{-}O)(\mu\text{-}OMe)(\mu\text{-}OAc)_5(py)_3][ClO_4]$, as well as other products not easily identified by ^{1}H NMR. After removal of the solvent *in vacuo*, a dark brown paramagnetic solid was obtained (0.58 g). The solid was washed through alumina with acetonitrile, to give an olive/green solution. The solvent was removed and the solid dried *in vacuo*. ^{1}H NMR in CD_3CN showed the solid to contain a mixture of species including the cubane, (**11**), (**5**), (**2**), (**3**) and other species not easily or previously identified by 200 MHz ^{1}H NMR. Selected IR data (KBr): ν_{max}/cm^{-1} 3110 (w), 3071 (w), 3046 (w), 3005 (w), 2926 (w), 1606 (w), 1550 (sh, s), 1540 (vs), 1485 (m), 1451 (m), 1414 (s), 1338 (m), 1214 (m), 1152 (w), 1073 (w), 1048 (w), 1019 (vw), 761 (m), 694 (s), 647 (sh), 632 (s), 585 (m), 572 (m). UV/Vis (CH_2Cl_2): 604 (sh) nm ($\varepsilon_M = 509\ M^{-1}\ cm^{-1}$), 484 (sh) nm ($\varepsilon_M = 893\ M^{-1}\ cm^{-1}$), 364 nm ($\varepsilon_M = 9342\ M^{-1}\ cm^{-1}$). ^{1}H NMR (200 MHz; CD_3Cl): δ 8.37 (d, 8H), δ 7.59 (t, 4H), δ 7.16 (t, 8H), δ 1.99 (s, 12H). ^{13}C NMR (200 MHz; CD_3Cl): δ 186.86, δ 153.47, δ 124.46, δ 138.62, δ 26.63. ESI/MS: 853 ($[M+H]^+$), 774 ($[M+H\text{-}py]^+$), 695 ($[M+H\text{-}2py]^+$).

Method B—Direct ozonation oxidation method. Cobalt(II) acetate tetrahydrate (3.125 g, 12.5 mmol) was dissolved in water (25 cm^3). Acetic acid (10 cm^3, 18 M) and pyridine (1.00 g, 12.6 mmol) were then added to the mixture and stirred (1 h). The reaction mixture was then ozonated (2 h) during which the solution changed colour from pink/red to dark olive/brown. After ozonolysis the reaction mixture was immediately and quickly heated ($\sim 65°C$) and ammonium hexafluorophosphate (1.36 g, 8.3 mmol) dissolved in water (5 cm^3) was added. The resulting mixture was allowed to cool to room temperature and subsequently kept at low temperature (5d, $< 5°C$). The product mixture of small crystals (2.6 g) was collected by filtration, washed with water, and dried over silica gel overnight. ^{1}H NMR indicated that the solid contained a mixture of mainly (**4a**)$[PF_6]$ with smaller amounts of (**3**)$[PF_6]_2$ and a material formulated as $[Co(\mu\text{-}OH)_2(\mu\text{-}OAc)(OAc)_2(py)_3(solvent)][PF_6]$ [32] and trace amounts of the dimeric species (**2**)$[PF_6]$. The filtrate was again kept at low temperature for several days after which a second crop of solid material was filtered, washed with a little water and dried (0.02 g). The remaining filtrate was extracted into methylene chloride (3×50 cm^3), the combined methylene chloride extracts washed with water, hydrogen carbonate solution and finally sodium chloride solution and the solvent removed by rotary evaporation at room temperature. The resulting brown solid was finally dried *in vacuo* (0.55 g). The solid obtained from the methylene chloride extract was found to contain a mixture of mainly the oxo-centred trimers (**7**)$[PF_6]$, (**4a**)$[PF_6]$, (**3**)$[PF_6]_2$ and the cubane (**11**) as observed by solution ^{1}H NMR and TLC. The cubane, (**11**), can be isolated from the mixture using column chromatography.

Method C—Preparation from $[Co_2(\mu\text{-}OH)_2(\mu\text{-}OAc)(OAc)_2(py)_4][PF_6]$. A procedure similar to that reported [35] for the preparation of $[Co_4(\mu_3\text{-}O)_4(\mu_2\text{-}OAc)_2(bpy)_4]^{2+}$ was used to synthesise $[Co_4(\mu_3\text{-}O)_4(\mu_2\text{-}OAc)_4(py)_4]$. Crystals suitable for X-ray crystallographic analysis were obtained by this method. Under nitrogen, $[Co_2(\mu\text{-}OH)_2(\mu\text{-}OAc)(OAc)_2(py)_4][PF_6]$ ((**2**)$[PF_6]$) (0.079 g, 0.1 mmol) and lithium peroxide (0.023 g, 0.5 mmol) were stirred and heated to 55°C (15 min) in dimethylsulphoxide (5 cm^3). The original red solution changed colour to olive/brown during the reaction and after cooling the reaction mixture was filtered. Chloroform (25 cm^3) was added to the filtrate and the mixture left stoppered ($< 5°C$). Over one week large dark olive crystals formed and were subsequently filtered, dried in air and identified as pure (**11**) (0.01 g, 23%) by using solution ^{1}H NMR and IR. The salts (**5**)$[PF_6]$, (**7**)$[PF_6]$, (**4a**)$[PF_6]$, or (**12**)$[PF_6]_2$ can be used in place of (**2**)$[PF_6]$, with yields of 21, 27, 48 and 8%, respectively, depending on the crystallisation time and temperature. Similarly, (**4a**)$[PF_6]$ can be reacted with Li_2O_2 as above, but in DMF, rather than in DMSO to produce predominantly (**11**). Alternatively, (**4a**)$[PF_6]$ can be

reacted as above with DMSO in the presence or absence of KOH (in place of Li_2O_2) to give (**11**) in yields of 23 and 58%, respectively.

Acetato(μ-acetato-κO: κO′)-tris(μ$_3$-hydroxo)-μ$_3$-oxo-hexakis(pyridine)tricobalt(III) hexafluorophosphate, $[Co_3(\mu_3\text{-}O)(\mu\text{-}OH)_3(\mu\text{-}OAc)(OAc)(py)_6][PF_6]_2$, (**12**)$[PF_6]_2$

Method A—Direct ozonation oxidation method. Cobalt(II) acetate tetrahydrate (3.125 g, 12.5 mmol) dissolved in water (25 cm^3) was stirred with pyridine (2.00 g, 25.3 mmol) and the pink/red solution ozonated (2 h). The resulting dark brown solution was quickly heated (~70°C) and added to an aqueous solution of ammonium hexafluorophosphate (1.36 g, 8.3 mmol in 5 cm^3). After cooling to room temperature a brown solid was collected by filtration, washed with water, and dried over silica gel overnight (3.7 g). Solution ^{1}H NMR in CD_3CN showed the solid to contain a mixture of species including (**5**), (**3**), (**2**), (**12**), (**6**) and trace amounts of other species. The filtrate was extracted into methylene chloride (3 × 100 cm^3), the combined methylene chloride extracts evaporated to 5 cm^3 and layered with diethylether. After 24 h a brown solid was filtered (0.6 g) and was found to consist of a mixture of (**2**), (**5**), (**12**), (**6**), (**3**) and trace amounts of other species as identified by solution ^{1}H NMR in CD_3CN.

Method B. The synthesis of $[Co_3(\mu_3\text{-}O)(\mu\text{-}OH)_3(\mu\text{-}OAc)(OAc)(py)_6][PF_6]_2$ was adapted from that reported for $[Co_3(\mu_3\text{-}O)(\mu\text{-}OH)_3(\mu\text{-}OAc)(OAc)(bpy)_3][ClO_4]_2$ [35]. Cobalt(II) acetate tetrahydrate (1.24 g, 5.0 mmol) was dissolved in water (4 cm^3) and subsequently stirred (15 min) with ethanol (24 cm^3) and pyridine (0.8 g, 10.1 mmol) to form a purple solution. The stirred cobalt(II) solution was treated dropwise with hydrogen peroxide (5.8 cm^3) over ~45 min. The solution changed colour to dark brown and increased in temperature to 37°C during the addition of hydrogen peroxide. Ammonium hexafluorophosphate (0.55 g, 3.4 mmol) dissolved in ethanol (2 cm^3) and water (1 cm^3) was then added and the solution was stirred briefly (5 min) and then left covered at room temperature. After one week a microcrystalline solid (typically ~0.22 g) was separated by filtration, the filtrate was retained and the solid was dried over silica gel. The crude dried solid was extracted into acetonitrile and a small amount of purple paramagnetic material was removed by filtration. The acetonitrile was evaporated and the resulting brown solid was found to contain mainly (**12**)$[PF_6]_2$ with trace amounts of (**5**)$[PF_6]$ and (**3**)$[PF_6]_2$ as identified by ^{1}H NMR in CD_3CN. The remaining original reaction mixture filtrate was cooled (<5°C) for one week and then filtered. A brown precipitate (0.15 g) was obtained from the supernatant and found (^{1}H NMR) to contain a mixture of species including (**5**)$[PF_6]$, (**3**)$[PF_6]_2$, (**12**)$[PF_6]_2$ with others as yet unidentified. The remaining dark brown filtrate was evaporated to dryness *in vacuo* to give a dark brown solid (1.42 g). ^{1}H NMR in CD_3CN, after filtration through alumina, revealed the extract contained a mixture of pyridine containing species including (**2**)$[PF_6]$, (**5**)$[PF_6]$, (**3**)$[PF_6]_2$, and others as yet unidentified. Pure brown/orange (**12**)$[PF_6]_2$ ($Rf \simeq 0.24$) was obtained by chromatographing small amounts of the first microcrystalline material through a short column of flash silica using 4 : 1 methylene chloride : acetonitrile as eluent after examination by TLC ((**5**)$[PF_6]$, $Rf \simeq 0.35$ and (**3**)$[PF_6]_2$, $Rf \simeq 0.43$). Anal. $[Co^{III}_3(\mu_3\text{-}O)(\mu\text{-}OH)_3(\mu\text{-}OAc)_2(py)_6][PF_6]_2$ (**12**)$[PF_6]_2$. Selected IR data (KBr): ν_{max}/cm^{-1} 1609 (w), 1490 (w), 1451 (m), 1385 (w), 1331 (w), 1218 (w), 1074 (w), 1049 (w), 1021 (w), 880 (m), 844 (vs), 765 (w), 700 (m), 693 (m), 600 (br), 558 (s). Selected ^{1}H NMR (200 MHz; CD_3CN, TMS): −2.75 (s, 1H), −0.36 (s, 1H), 0.88 (s, 3H), 2.15 (s, 3H), 5.17 (s, 1H). ^{13}C NMR (200 MHz; CD_3CN, TMS): 24.73, 25.61, 156.5, 151.93, 152.79, 153.84, 155.31, 155.48, 125.43, 126.16, 126.25, 126.45, 126.74, 140.43, 140.66, 140.92, 141.06, 185.02, 189.85. ESI/MS: 981.0 ($[M\text{-}PF_6]^+$), 418 ($[M\text{-}2PF_6]^{2+}$).

Structure determinations

Discrete single dark green-olive crystals of the cubane, $[Co_4(\mu_3\text{-}O)_4(\mu\text{-}OAc)_4(py)_4]\cdot 5CHCl_3$, ((**11**)·$5CHCl_3$), were obtained as the $CHCl_3$ solvate by leaving a DMSO solution in contact with $CHCl_3$ for several weeks below 5°C. Crystals of (**11**)·$5CHCl_3$ lost solvent readily. Accordingly a green plate was quickly mounted and cooled to −50°C. Small prismatic red crystals of the PF_6^- salt of the partial cubane, $[Co_3(\mu_3\text{-}O)(\mu\text{-}OH)_3(\mu\text{-}OAc)(OAc)(py)_6][PF_6]_2 \cdot 2H_2O$, ((**12**)$[PF_6]_2\cdot 2H_2O$), were obtained by slow crystallisation from the mother liquor over two weeks. X-ray diffraction measurements were made with a Rigaku AFC7R diffractometer employing graphite monochromated Cu-K_α radiation generated with a 12 kW direct drive rotating anode. Primitive cell constants were obtained from a least-squares refinement using the setting angles of 22(25) (for the cubane, ((**11**)·$5CHCl_3$), and (in parentheses) partial cubane, ((**12**)$[PF_6]_2\cdot 2H_2O$), respectively) reflections in the range $41.15(18.40) < 2\theta < 69.80(23.78)°$. The data were collected at $-50(21) \pm 1$°C using ω–2θ scans to a maximum 2θ value of 110.1(100.1)°. Omega scans of several intense reflections, made prior to data collection, had an average width at half-height of 0.19(0.34)°. The data were collected with scans of $(1.47(1.21) + 0.35 \tan\theta)°$ at a speed of 32.0(16.0)°/min (in omega). The weak reflections ($I < 15.0\sigma(I)$) were rescanned up to 10 scans, and the counts were accumulated. Stationary background counts were recorded on each side of the reflection. The ratio of peak counting time to background counting time was 2 : 1. Over the course of data collection, the intensities of three

representative reflections, measured every 150 reflections, decreased by 3.2(3.8)%. Empirical absorption corrections based on azimuthal scans of three reflections were applied to each set of data, with transmission factors ranging from 0.33(0.73) to 1.00. The data were also corrected for Lorentz and polarisation effects.

All calculations were performed using the teXsan crystallographic software package [39]. The structures were solved by direct methods and expanded using Fourier techniques [40,41]. The solution of the cubane structure in Pnma (#62), revealed a $[Co_4(\mu_3\text{-}O)_4(\mu\text{-}OAc)_4(py)_4]$ cluster bisected by a mirror plane and surrounded by five chloroform molecules distributed over six sites (a chloroform on a general site was assigned half occupancy). Two chloroform molecules straddle the same mirror that splits the complex, and one of these has a two-fold rotational disorder about the mirror plane. Not all of the non-hydrogen atoms could be refined anisotropically. Hydrogen atoms were included in the full matrix refinement at calculated positions with group temperature factors. Hydrogen atoms were not attached to four of the five chloroform molecules. In the case of the partial cubane salt, $[Co_3(\mu_3\text{-}O)(\mu\text{-}OH)_3(\mu\text{-}OAc)(OAc)(py)_6][PF_6]_2$, the limited data obtained from the small crystal, (1765 observed reflections, $(I > 1.5\sigma(I))$ precluded the anisotropic refinement of all of the non-hydrogen atoms. Hydrogen atoms were included in the full matrix refinement at calculated positions with group temperature factors. The hydroxyl and water hydrogen atoms could not be located and were not included at calculated positions in the refinement model. One of the hexafluorophosphate counterions was found to be severely disordered.

The residual weighting scheme for each solution was based on counting statistics and included a statistical uncertainty factor ($p = 0.003$). Neutral atom scattering factors were taken from Cromer and Waber [42]. Anomalous dispersion effects were included in the structure factor calculation [43], and the values for $\Delta f'$ and $\Delta f''$ were those of Creagh and McAuley [44]. The values for the mass attenuation coefficients are those of Creagh and Hubbell [45].

Full tables of bond lengths and angles, listings of atomic coordinates, observed and calculated structure factors and anisotropic thermal parameters are available as supplementary material (Tables S1–S16). Selected interatomic bond lengths and bond angles are given in Tables 2–5.

RESULTS AND DISCUSSION

Following the procedure of Uemura *et al.*, the known trimers, $[Co_3(\mu_3\text{-}O)(\mu\text{-}OR)(\mu\text{-}OAc)_5(py)_3]^+$ (R = H, Me), were isolated as their brown ClO_4^- or PF_6^- salts from methanol solutions of "cobalt(III) acetate" and pyridine. These materials were not known at the time of the work of Uemura *et al.* who correctly predicted that the structure of the solid first precipitated by this method differs from that of the $[M_3(\mu_3\text{-}O)(OAc)_6(solvent)_3]^{n+}$ species known at that time. Small amounts of additional, as yet unidentified, species were also precipitated in the present work, the total amount of characterised and uncharacterised precipitated salts accounting for approximately half of the "cobalt(III) acetate". Removal of the solvent left a dark brown paramagnetic solid, found to consist of the neutral diamagnetic tetramer $[Co_4(\mu_3\text{-}O)_4(\mu\text{-}OAc)_4(py)_4]$, (**11**), in a mixture of other species, some previously identified, others currently unidentified. The tetramer was characterised by vibrational, electronic, ^{1}H and ^{13}C NMR and electrospray mass spectroscopies. The single ^{1}H NMR resonance due to the acetate protons (δ 1.99 ppm in CD_3CN) and the simple set of pyridine resonances suggested a species of high symmetry in solution, whilst the mass spectrum indicated a tetramer. This structure was confirmed as a cubane by single X-ray diffraction and is illustrated in Fig. 1.

The cubane, $[Co_4(\mu_3\text{-}O)_4(\mu\text{-}OAc)_4(py)_4]$, (**11**), can also be isolated by direct ozonolysis of $[Co(OAc)_2(H_2O)_4]$ in water/acetic acid/pyridine (25/10/1 v/v), followed by precipitation of (**4a**), (**3**) and (**2**) with NH_4PF_6, extraction into dichloromethane and chromatographic separation from (**7**), (**4a**) and (**3**), or by reaction of Li_2O_2 with the dimers (**2**) or (**5**) or with the trimers (**7**), (**4a**) or with the trinuclear partial cubane (**12**) in dimethylsulfoxide or with the trinuclear (**4a**) in dimethylformamide. Alternatively, trimeric (**4a**) can be heated in dimethylsulfoxide in the presence or absence of KOH. The reaction of (**2**) with Li_2O_2 in DMSO is analogous to the preparation of $[Co_4(\mu_3\text{-}O)_4(\mu\text{-}OAc)_2(bipy)_4]^{2+}$ by Dimitrou *et al.* [35]. Interestingly, the neutral cubane, $[Co_4(\mu_3\text{-}O)_4(\mu\text{-}OAc)_4(py)_4]$, is formed, rather than

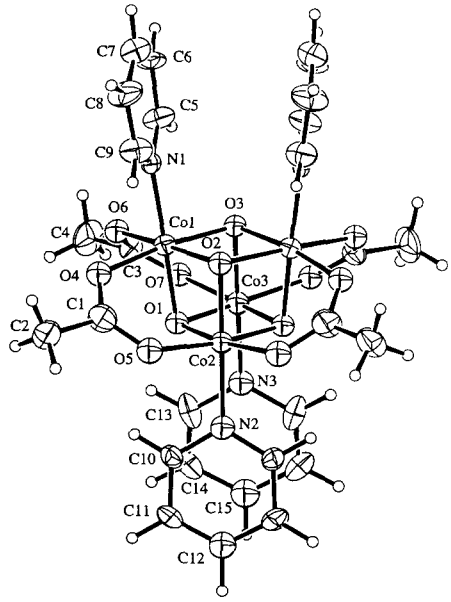

Fig. 1. ORTEP [46] illustration of the cubane, $[Co_4(\mu_3\text{-}O)_4(\mu\text{-}OAc)_4(py)_4]$, (**11**), showing the atom numbering scheme.

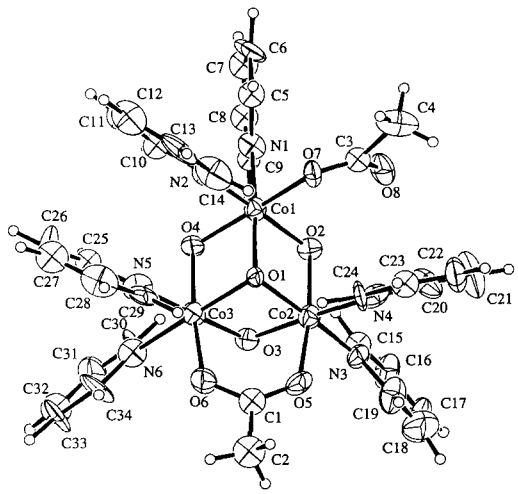

Fig. 2. ORTEP [46] illustration of the trimeric partial cubane dication, $[Co_3(\mu_3\text{-}O)(\mu\text{-}OH)_3(\mu\text{-}OAc)(OAc)(py)_6]^{2+}$, (**12**), showing the atom numbering scheme.

$[Co_4(\mu_3\text{-}O)_4(\mu\text{-}OAc)_2(py)_8]^{2+}$, the analogue of the known bipyridyl derivative.

Ozonation of $[Co(OAc)_2(H_2O)_4]$ in water/pyridine (13/1 v/v), followed by brief heating results in a mixture of products. The partial cubane dication, $[Co_3(\mu_3\text{-}O)(\mu\text{-}OH)_3(\mu\text{-}OAc)(OAc)(py)_6]^{2+}$, (**12**), can be isolated from this mixture as its PF_6^- salt. Alternatively, oxidation of $[Co(OAc)_2(H_2O)_4]$ by H_2O_2 in water/ethanol/pyridine (4/24/1 v/v) followed by treatment with NH_4PF_6 generates an unidentified paramagnetic purple solid from which (**12**)$[PF_6]_2$ can be chromatographically separated from salts of the dimeric cations (**2**) and (**5**) and of the trimeric cation (**3**). The compound was characterised spectroscopically (vibrational, ^1H NMR, ^{13}C NMR and electrospray mass spectra). A trinuclear formulation is suggested by the mass spectrum, whilst the ^1H NMR indicates two different acetate and three different hydroxyl (one of which is involved in hydrogen bonding) environments in solution. Restricted rotation of some of the pyridine ligands about the Co–N axes is also suggested by the ^1H NMR spectrum. The trinuclear structure of the cation was confirmed by single crystal X-ray crystallography and is illustrated in Fig. 2. Salient NMR data of these compounds are collected in Table 1.

The cubane has possibly previously escaped notice as a "constituent" or derivative of "cobalt(III) acetate" because of its high solubility in the solvents used, its colour and lack of charge. Indeed, the formation of the cubane from salts of any of (**2**), (**5**), (**12**), (**4a**) or (**7**) in d^6-DMSO can be monitored by ^1H NMR. The predominant species is invariably the cubane (**11**) with some free pyridine and trace amounts of other, at present unidentified, species. The variable yields of cubane from the different preparations are thus mainly due to the high solubility of this neutral species. Solution ^1H NMR spectra in CD_2Cl_2, D_2O, CD_3CN, CD_3OD and $(CD_3)_2SO$ at room temperature are consistent with the solid state structure and retention of T_d symmetry in these solvents. However, a different ^1H NMR spectrum is obtained in CD_3CO_2D at room temperature. Two pyridine environments are apparent, consistent with the formation of the diprotonated species, $[Co_4(\mu_3\text{-}O)_2(\mu\text{-}OH)_2(\mu\text{-}OAc)_4(py)_4]^{2+}$. After further rearrangements over several weeks at room temperature, the oxo-centred trimers, (**2**) and (**7**) were observed as the predominant species. However, in CD_3OD at room temperature, ^1H NMR shows the cubane (**11**) to be stable for several months, unlike (**4a**), for example, which slowly converts to other species in this solvent.

X-ray crystallographic analysis of (**11**)

Single crystals of (**11**) are composed of discrete $[Co_4(\mu_3\text{-}O)_4(\mu\text{-}OAc)_4(py)_4]$ molecules with the five chloroform molecules of crystallisation per tetramer located in large channels in the crystal lattice between the tetramers. The tetranuclear species contains four cobalt atoms and four oxygen atoms located at alternate corners of a slightly distorted cube in a typical $[M_4(\mu_3\text{-}O)_4]$ cubane type arrangement. Every cobalt atom is surrounded by a slightly distorted octahedron of two oxygen atoms from bridging acetate ligands, a nitrogen atom of a pyridine ligand and three neighbouring $[Co_4(\mu_3\text{-}O)_4]$ core oxygen atoms.

Each $[Co_4(\mu_3\text{-}O)_4(\mu\text{-}OAc)_4(py)_4]$ molecule is bisected by a crystallographic mirror plane. Consequently, two Co···Co distances are observed, that (average 2.818 Å) bridged by two oxo ligands only, and that (average 2.683 Å) bridged by two oxo ligands

Table 1. Selected spectrophotometric data for selected polynuclear cobalt(III) carboxylate species. ^{1}H NMR chemical shifts (ppm) of the acetate, hydroxy and pyridine protons in some cobalt complexes (200 MHz)

and a bidentate acetate ligand. These distances are marginally shorter (oxo bridged) and longer (carboxylate bridged) than the corresponding distances (average 2.852(2) and 2.665(2) Å) in $[Co_4(\mu_3\text{-}O)_4(\mu\text{-}OAc)_2(bpy)_4]^{2+}$, (**10**) [35]. The bis-oxo bridged Co···Co distances have no exact parallel in the known structures of tri- and tetranuclear pyridine-ligated basic cobalt(III) acetate complexes; however, the oxo/carboxylate bridged Co···Co distances are the shortest yet reported in these species. The pyridine planes containing N(2) and N(3) are inclined at 18.3(8)° and those containing N(1) and N(1*) are inclined at 16.4(8)°. The N(1) to N(1*) contact is 3.37(4) Å and that between N(2) and N(3) is 3.26(4) Å.

Each cobalt-centred octahedron is tilted slightly into the cubane core presumably because of steric interactions between the pyridine ligands which are oriented perpendicular to the cube faces bridged by two oxo ligands only and because of the bridging acetate arrangement around the $[Co_4(\mu_3\text{-}O)_4]$ core. The core μ_3-oxygen atoms are on average 1.01(1) Å out of their respective trimeric Co_3 planes.

Other structural parameters of (**11**) are similar to those of species containing the $[Co_4(\mu_3\text{-}O)_4]^{4+}$ (or $[Co_4(\mu_4\text{-}O)_4]^{4+}$) core; $[Co_4(\mu_3\text{-}O)_4(\mu\text{-}O_2CC_6H_4\text{-}p\text{-}Me)_2(bpy)_4]^{2+}$, $[Co_4(\mu_3\text{-}O)_3(\mu_3\text{-}OH)(\mu\text{-}O_2CC_6H_4\text{-}p\text{-}Me)_2(bpy)_4]^{3+}$, $[Co_4(\mu_4\text{-}O)_4(\mu\text{-}O_2CPh)_{12}(MeCN)_3(H_2O)]$ and $[Co_8(\mu_4\text{-}O)_4(\mu_3\text{-}OMe)_4(\mu\text{-}O_2CMe)_6(O)_4(Cl)_4]$ [35–38].

X-ray crystallographic analysis of (**12**) $[PF_6]_2$

The dication of $[Co_3(\mu_3\text{-}O)(\mu\text{-}OH)_3(\mu\text{-}OAc)(OAc)(py)_6][PF_6]_2\cdot 2H_2O$ is an oxo-centred trinuclear cobalt(III) cluster containing six pyridine, one bidentate bridging acetate, one monodentate acetate, and three bridging hydroxyl ligands. Each cobalt atom is situated in a slightly distorted octahedral environment. The $[Co_3(\mu_3\text{-}O)(\mu\text{-}OH)_3]$ core can be considered as a partial cubane, lacking the fourth cobalt atom to

achieve a full cubane ($[Co_4(\mu_3\text{-}O)_4]$) configuration. Alternatively the molecule can be viewed as consisting of three edge sharing octahedra sharing a central μ_3-oxygen atom at a common vertex.

Each pair of cobalt atoms is bridged by a hydroxyl ligand. The atoms Co(2) and Co(3) are also bridged by a bidentate acetate ligand. Atom Co(1) is coordinated to the oxygen of a monodentate acetate ligand. This monodentate acetate ligand is hydrogen bonded to the hydroxyl ligand bridging Co(1) and Co(2). Two pyridine ligands complete the coordination about each cobalt atom.

Table 4. Selected intramolecular distances (Å) involving the nonhydrogen atoms for $[Co_3O(OH)_3(OAc)_2(py)_6][PF_6]_2\cdot 2H_2O$, (**12**)$[PF_6]_2\cdot 2H_2O$

Co(1)—Co(2)	2.900(5)	Co(2)—O(3)	1.92(1)

Estimated standard deviations in the least significant figure are given in parentheses.

The μ_3-O atom is approximately 0.96 Å out of the Co_3 plane, a displacement similar to that (0.97 Å) in the bipyridine-containing partial cubane, $[Co_3(\mu_3\text{-}O)(\mu\text{-}OH)_3(\mu\text{-}OAc)(OAc)(bpy)_3]^{2+}$, (**9**) [35].

The hydrogen bonding distance between the acceptor monodentate acetate carbonyl oxygen atom and the hydroxyl oxygen donor atom is approximately 2.63(2) Å, typical of distances involved in similar bridging hydroxyl/monodentate acetate hydrogen bonding interactions observed within the dimeric species (**2**), (**5**) and (**6**) [32]. $[Co_3(\mu_3\text{-}O)(\mu\text{-}OH)_3(\mu\text{-}OAc)(OAc)(py)_6][PF_6]_2\cdot 2H_2O$ crystallises in the centrosymmetric space group $P2_1/c$ (#14); therefore both enantiomers of the molecule are present in the unit cell. The structural parameters of (**11**) and (**12**) may be compared with those of related polynuclear basic acetate cobalt(III) species collected recently [33].

CONCLUSIONS

To our knowledge isolation of a cubane ($[Co_4(\mu_3\text{-}O)_4]$) type moiety from "cobalt(III) acetate" chem-

istry is unprecedented with the exception of the octameric cobalt acetate species $[Co_8(\mu_4\text{-}O)_4(\mu\text{-}OAc)_6(\mu_3\text{-}OMe)_4(Cl)_4(OH_n)_4]$ ($n = 1$ or 2) which contains the "$[Co_4(\mu_3\text{-}O)_4]$" unit "capped" by two $[Co_2(\mu_3\text{-}OMe)_2]$ dimers [38].

The presence of cubane and partial cubane type structures in "cobalt(III) acetate" formed from the ozonation oxidation of cobalt(II) acetate tetrahydrate in acetic acid has not been suggested previously, despite much investigation on this system. This unusual neutral pyridine-containing cobalt(III) acetate cubane $[Co_4(\mu_3\text{-}O)_4(\mu\text{-}OAc)_4(py)_4]$ was isolated from solutions of cobalt(III) acetate in methanol after the addition of pyridine. The cubane has also been synthesised from the ozone oxidation of cobalt(II) acetate solutions containing pyridine and directly from various pyridine containing cobalt(III) acetates. The isolation of the cubane and of the mixed valence octameric cobalt acetate species from cobalt acetate solutions, suggests that cobalt cubanes and related structures may be significant in the chemistry of cobalt acetates. Similar species with acetic acid in place of pyridine may be constituents of "cobalt(III) acetate". Thus, for example, the possibility that pyridine ligands simply took the place of solvent acetic acid or water ligands without substantially altering the reaction chemistry was suggested by the report that the cobalt(III) clusters, $[Co_3(\mu_3\text{-}O)(\mu\text{-}OH)_n(OAc)_{6-n}(py)_3][PF_6]$ ($n = 0, 1$), are catalyst precursors for the autoxidation of aromatic hydrocarbons [30].

We have noted previously that the μ_3-oxygen atom is located in the Co_3 plane of the symmetric trimer, $[Co_3(\mu_3\text{-}O)(\mu\text{-}OAc)_6(py)_3]^+$, (**7**), and that as the bidentate bridging carboxylate ligands are successively replaced by monodentate bridging ligands, the μ_3-oxygen atom is displaced from the Co_3 plane [33]. A change in the hybridization of the μ_3-oxygen atom from sp^2 to sp^3 and a corresponding change in reactivity accompanies this displacement from the Co_3 plane. The present pair of complexes complete the series of pyridine ligated acetate derivatives with the μ_3-oxygen atom displacement being 0.04, ~0.35, 0.71, 0.96 and 1.01 Å for $[Co_3(\mu_3\text{-}O)(\mu\text{-}OAc)_6(py)_3]^+$, (**7**), $[Co_3(\mu_3\text{-}O)(\mu\text{-}OR)(\mu\text{-}OAc)_5(py)_3]^+$, (**4**), $[Co_3(\mu_3\text{-}O)(\mu\text{-}OH)_2(\mu\text{-}OAc)_3(py)_5]^{2+}$, (**3**), $[Co_3(\mu_3\text{-}O)(\mu\text{-}OH)_3(\mu\text{-}OAc)(OAc)(py)_6]^{2+}$, (**12**) and $[Co_4(\mu_3\text{-}O)_4(\mu\text{-}OAc)_4(py)_4]$, (**11**), respectively. The Co···Co separations in these pyridine ligated "cobalt(III) acetate" derivatives vary over about 0.5 Å, from ~3.2 Å when the cobalt atoms have a $(\mu\text{-}O)(\mu\text{-}OAc)_2$ bridge, to ~2.7 Å for a $(\mu\text{-}O)_2(\mu\text{-}OAc)$ bridge. In all these derivatives, the Co—N and Co—O (acetate) distances are relatively constant at 1.96–1.99 Å and 1.87–1.99 Å, respectively, and the Co—$(\mu_3\text{-}O)$ distances vary between 1.80 and 1.92 Å [33].

Protonation of the cubane core has been achieved

and may be possible to a greater extent than with the bipyridine containing cubane where charge build-up was suggested to inhibit further protonation. The demonstration of the $[Co_4(\mu_3\text{-}O)_4]^{n+}$ core within the mixed valence octanuclear, $[Co_8(\mu_4\text{-}O)_4(\mu\text{-}OAc)_6(\mu_3\text{-}OMe)_4(Cl)_4(OH_n)_4]$ ($n = 1$ or 2), and of the ready synthesis of $[Co_4(\mu_3\text{-}O)_4(\mu\text{-}OAc)_4(py)_4]$, (**11**) in solution suggests a hitherto unexpected importance of this $[Co_4(\mu_3\text{-}O)_4]^{n+}$ unit in cobalt acetate chemistry.

Axial ligational properties of macrocyclic cobalt complexes

M. Radhakrishna Reddy, K. Hussain Reddy* and K. Mohana Raju

Department of Chemistry, Sri Krishnadevaraya University, Anantapur 515 003, India

(Received 20 February 1997; accepted 27 June 1997)

Abstract—Macrocyclic cobalt complexes have been prepared by template synthesis using acetylacetone and different aromatic diamines *viz.* 1,2-diaminobenzene and 3,4-diaminotoluene for the first time. These complexes have been alkylated using CH_3I and/or C_2H_5Br in the presence of pyridine and/or imidazole to obtain corresponding macrocyclic organocobalt complexes. The parent cobalt complexes and their alkyl derivatives have been characterized by elemental analyses, conductivity data, magnetic susceptibility measurements, electronic, infrared and ^1H NMR spectral data. Various ligand field parameters have been calculated. Electrochemical behaviour of these complexes has been studied by cyclic voltammetry. Axial ligation properties of parent cobalt complexes are supported by syntheses, electronic spectra and cyclic voltammetric studies. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: macrocyclic cobalt complexes; ascial ligation; template synthesis; electronic spectra; cyclic voltammetry.

The cobaloximes [1] prepared using dimethylglyoxime ligand have been used as models for many B_{12} reactions. Subsequently cobalt complexes of SALEN [2,3] ACACEN [4] and oxime-schiff base ligands [5] have been derived as models for vitamin B_{12}. There has been considerable interest in the chemistry of macrocyclic metal complexes [6] which are considered as better model compounds for metalloporphyrins and metallocorrins for their intrinsic structural properties.

Spontaneous self-assembly reactions have been considered as vehicles for reliable and economical preparation of macrocyclic complexes. Although macrocyclic nickel(II) and copper(II) complexes derived using substituted acetylacetone and unsubstituted aromatic diamines have been synthesized and characterized to demonstrate the advantages of template synthesis by Jaeger [7–11] and Chipperfield [12], the corresponding macrocyclic cobalt complexes are not investigated. Recently, we have reported [13–15] macrocyclic nickel(II) and copper(II) complexes of acetylacetone buckled with different diamines. In the light of lacuna identified and in continuation of our earlier studies herein we report the synthesis, characterization, spectral studies and electrochemistry of macrocyclic cobalt complexes (**I**) and (**VI**) derived using acetylacetone and different diamines *viz.* 1,2-diaminobenzene and 3,4-diaminotoluene. Studies on corresponding alkylated derivatives are also carried out in support of axial ligational properties.

* Author to whom correspondence should be addressed.

EXPERIMENTAL

All the solvents used were of AR grade. Cobalt(II) chloride hexahydrate (Qualigens): 1,2-diaminobenzene and 3,4-diaminotoluene (Fluka AG); and iodomethane (Merck), bromoethane (Merck), pyridine (Qualigens) and Imidazole (spectrochem) were used in the present study.

Synthesis of complexes **I** *and* **VI**

A 250 cm^3 Erlenmeyer flask was charged with spinbar, cobalt(II) chloride hexahydrate (2.298 g, 0.0097 mol) aromatic diamine (0.0194 mol), dry butanol (30 cm^3) and acetylacetone (2.0 cm^3, 0.0194 mol) added by syringe. The flask was set upon a hot plate stirrer and equipped with a reflux condenser. The mixture was brought to a brisk reflux and continued for 8 h. The flask was removed from the hot source and allowed to cool. Then methanol (15 cm^3) was added and the mixture was cooled on ice–salt bath for at

least 15 min. Then an oily layer was separated out. The oily layer was treated with water and stirred vigorously to obtain black coloured substance. It was collected, washed with hot water, then with cold methanol and dried *in vacuo*.

Synthesis of alkyl derivatives

In a Schlenk tube, a saturated methanolic solution of macrocyclic cobalt complex (**I**) and (**VI**) (0.0042 mol) was taken and stirred under nitrogen atmosphere. Sodium hydroxide (0.0042 moles) and pyridine/imidazole (0.0021 mol) were added to the contents of the tube. The stirred suspension was then cooled to -5°C and stirred for 15 min. Then solid $NaBH_4$ (0.0042 mol) followed by alkylating agent (CH_3I or C_2H_5Br, 0.0021 mol) were added. The solution was gradually warmed to 20°C and stirred for a further 30 min. The solution was evaporated to half the volume and stirred with 20 cm^3 of water and filtered. It was collected washed with aqueous methanol and ether and then dried *in vacuo*. The yield, colour and melting points for all the complexes are given in Table 1.

Physical measurements

The elemental analyses were performed by the HERAEUS (Mikro standard 8304071) Carbon and Hydrogen Analyzer. The magnetic susceptibility measurements were made using a vibrating sample magnetometer (VSM) operating at a field strength of 2–8 KG. The electrical conductivity measurements were made in dimethylformamide (DMF) (*ca* 10^{-3} M) at room temperature (27 ± 2°C) using a Systronic 303 direct reading conductivity bridge. The electronic spectra for all complexes in the UV–vis region (180–1100 nm) were recorded with Schimadzu UV-160A spectrophotometer. The IR spectra were recorded in the ranges 4000–400 cm^{-1} (in KBr) and 450–50 cm^{-1} (in polyethylene) using Bruker IFS 66V FT-IR Spectrophotometer. ^1H NMR spectra were recorded on an

X	$[C_2H_5Co(C_{24}H_{26}N_4)C_3H_4N_2]$	Brown (>300)	66.19 (66.17)	6.61 (6.65)	10.61 (10.65)	6.3

AMX-400 MHz high resolution NMR instrument in DMSO-d_6 solvent at room temperature. The cyclic voltammetry was performed with a BAS model CV-27 controller and a conventional three electrode, Ag/AgCl reference electrode, glassy carbon working electrode and platinum counter electrode. Nitrogen was used as a purge gas and all solutions were 0.1 M concentration in $TBAClO_4$.

RESULTS AND DISCUSSION

Attempts to isolate free ligands using acetylacetone and aromatic diamines were, however, unsuccessful. Hence the corresponding macrocyclic complexes were prepared by using the template method.

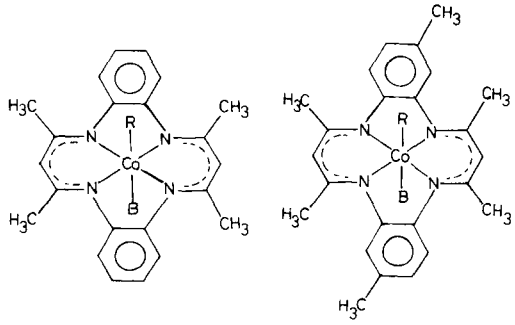
All the complexes are insoluble in water but readily soluble in methanol dimethylformamide and dimethylsulfoxide. The conductivity measurements show their non-electrolytic nature and the molecular weights of cobalt complexes are consistent with monomers.

Magnetic susceptibility and electronic spectra

The magnetic moment values of parent macrocyclic cobalt complexes are found to be in the 2.1–2.7 BM range as expected for low spin cobalt(II) complexes [16]. All alkyl derivatives (**II, III, IV, V, VII, VIII, IX** and **X**) are found to be diamagnetic.

In the electronic spectra of macrocyclic cobalt complexes (**I** and **VI**) (in DMF), two bands are observed in 16,103–16,530 (ν_2) and 22,371–22,936 cm^{-1} (ν_3) assigned to $^4T_{1g}(F) \rightarrow {}^4A_{2g}(F)$ and $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ transitions respectively in favour of an octahedral geometry [17]. The ν_1 values are calculated using the following equation.

$$\nu_1 = 5\,Dq - 7.5\,B + 1/2(225\,B^2 + 100\,Dq^2 + 180\,Dq\,B)^{1/2}$$



I. R and B absent
II. R=CH_3; B = Py
III. R=CH_3; B = Im
IV. R= C_2H_5; B= Py
V. R= C_2H_5; B = Im
VI. R and B absent
VII. R= CH_3; B= Py
VIII. R = CH_3; B= Im
IX. R = C_2H_5; B = Py
X. R = C_2H_5; B = Im

The interelectronic repulsion (B) and 10 Dq for all cobalt complexes are found to be in the range of 916–940 and 8074–8359, respectively. The ratio of observed ν_2 to calculated ν_1 lie between 2.22 and 2.36 as required for an octahedral cobalt complex [18]. The values of Dq, B, B_{35} and ν_2/ν_3 are given in Table 2. The electronic spectral data suggests an octahedral geometry for the present cobalt complexes facilitated by axial coordination of solvent (DMF) molecules.

Electronic spectral data of alkyl complexes are given in Table 3. The most intense bands in the highest energy region have been assigned [19] to $\pi \rightarrow \pi^*$ transition of equatorial ligand. The lowest energy band found in 21,000–25,000 cm^{-1} has been assigned to Co—C charge transfer transition. This band shifts to longer wavelength with increasing electron donating ability of alkyl groups and axial bases.

IR spectra

In the IR spectra of the complexes, the stretching and deformation vibrations of NH_2 are absent suggesting the formation of parent macrocyclic cobalt complexes (**I**) and (**VI**). Strong bands appearing in the range 1614–1634 cm^{-1} are assigned [20–23] to the stretching vibration of coordinated and conjugated ν(C=N) group present in all the complexes. Bands characteristic of acetylacetone moiety are observed in the 1450–1456 [ν_{asy}(C—CH_3)] and 1372–1394 cm^{-1} [ν_{sym}(C—CH_3)] regions in the IR spectra of all complexes. Characteristic bands are observed in the far IR spectra of complexes. Bands in the 432–466 cm^{-1} region are assigned to ν(Co—N) vibrations [24–27] suggesting the participation of conjugated (and equatorial) nitrogen in coordination. In organocobalt complexes bands observed in 312–341 and 235–269 cm^{-1} regions are tentatively assigned [19] to Co—C and Co—N (axial base) vibration, respectively.

^1H NMR spectra

All complexes are characterized by high resolution (400 MHz) ^{1}H NMR spectra. These spectral data incorporating chemical shifts (δ), multiplicity and the proton assignment are presented in Table 4. Broad multiplets centered between 6.6–7.1 ppm are observed in low field strength regions of spectra due to aromatic protons. As expected, methyl protons of the equatorial ligand resonate at high field strength (2.09–2.38 ppm). The spectra of methyl cobalt complexes show a singlet in 0.68–0.88 ppm range, where as the spectra of the ethylcobalamins exhibit two signals corresponding to methylene and methyl protons in 1.56–1.77 and 0.68–0.93 ppm, respectively. The signals due to the coordinated pyridine and Imidazole in the present complexes gave broad multiplets. However, the signals due to α and β protons of the pyridine are obscured by the signals due to aromatic protons of equatorial ligand.

Electrochemical studies

The CV data of all the complexes are given in Table 5. The cyclic voltammograms of unalkylated complexes (**I**) and (**VI**) have cathodic peaks in the range -0.71 to -0.79 V, corresponding to Co^{III}/Co^{II} reduction couple which is irreversible. These non-alkylated complexes have reversible one electron [$Co^{II} \rightarrow Co^{I}$] couple with $E_{1/2}$ in the range -1.12 to 1.17 V. The $E_{1/2}$ values of (**I**) may be compared with interest. Complex **VI** has macrocyclic ligand containing two methyl groups. It is reduced at more negative potentials in comparison with complex **I**. This suggests that the complexes with less electron donating ligands have less negative $E_{1/2}$ values than those of ligands containing electron donating groups.

In general, CV of alkylcobalt complexes show two one electron reduction corresponding to $Co^{III} \rightarrow Co^{II}$ and a further $Co^{II} \rightarrow Co^{I}$ reduction. Except for **II, III, IV** and **V** complexes, all other alkyl cobalt complexes show reversible one electron reduction. The complexes of **II, III, IV** and **V** shows an irreversible reduction at E_{pc} in the range -1.00 to 1.38 V which corresponds to the $Co^{II} \rightarrow Co^{I}$ couple.

It is interesting to compare the half wave potentials of present complexes containing different axial bases. It is observed that the imidazole coordinated complexes are reduced at less negative potentials [29].

The second reduction wave (cathodic peak) which is irreversible is present in the CV of all alkylated complexes that correspond to Co^{II}/Co^{I} reduction couple.

Inspection of the data reveals that the nature of alkyl groups have profound effect [30] on the first

(Received 27 March 97; accepted 25 June 97)

Abstract—The blue complex *cis*-$[Ni(dipren)_2(NO_3)](NO_3)$ **1** and the greenish blue *cis*-$[Ni(dipren)_2(H_2O)_2](NO_3)_2 \cdot 2H_2O$ **2** (dpren/dpren = dipropyl/diisopropylethane-1,2-diamine) have been synthesized. Complex **2** upon heating loses four water molecules in a single step and undergoes melting accompanied with colour change, greenish blue to deep green, **2a**. Configuration of the complexes **1, 2** and **2a** have been proposed to be *cis*-octahedral on the basis of magnetic, IR and electronic spectroscopic studies and confirmed in case of complex **1** by X-ray single crystal structure analysis. The role of steric factor of the alkyl groups on the selectivity of coordinating mode of nitrate ion is studied. © 1998 Elsevier Science Ltd. All rights reserved.

Keywords: *N,N'*-dipropylethane-1,2-diamine; *N,N'*-diisopropylethane-1,2-diamine; nitratobis(*N,N'*-dipropylethane-1,2-diamine)nickel(II) nitrate; *cis*-octahedral geometry of nickel(II); nickel(II) diamine complex; thermochromism.

N,N/N,N'-dialkyl (where alkyl groups are methyl/ethyl) substituted ethane-1,2-diamine complexes of Ni^{II} nitrate were reported by Goodgame *et al.* in 1963 [1,2]. Later on Ihara *et al.* carried out thermal studies of these complexes and showed novel deaquation–anation reaction in the solid state [3,4]. Ray Chaudhuri *et al.* also studied such type of complexes where they observed thermally induced phase transition phenomena besides deaquation–anation reaction and the study reveals that nitrate anion plays an interesting role in the formation of configuration depending on the nature of the diamines, solvents, temperature etc. [5,6]. For example *N,N'*-dimethylethane-1,2-diamine produces both *cis*-and *trans*-isomer on changing the solvent, propan-2-ol to methanol, and the *cis*-isomerises to *trans* on thermal excitation in the solid state [5], whereas, *N,N'*-diethylethane-1,2-diamine yields only *cis*-complex which does not isomerise to *trans* [6]. However, studies with symmetrically substituted diamines with alkyl groups having longer chain length are not yet reported. The present paper reports the syntheses and characterization of *N,N'*-dipropylethane-1,2-diamine (dpren) and *N,N'*-diisopropylethane-1,2-diamine (dipren) complexes of nickel(II) nitrate, their thermal studies in the solid state and X-

ray single crystal structure analysis of *cis*-nitratobis(dpren)nickel(II) nitrate.

EXPERIMENTAL

Materials

High purity *N,N'*-dipropylethane-1,2-diamine (dpren) and *N,N'*-diisopropylethane-1,2-diamine (dipren) were purchased from Aldrich Chemical Company Inc. and used as received. All other chemicals used were of analytical reagent grade.

Physical measurements

Thermal analysis (TG-DTA) were carried out using a Shimadzu DT-30 thermal analyser under a flow of dinitrogen (flow rate: 30 cm^3 min^{-1}). The sample (particle size of 150–200 mesh) was heated in a platinum crucible at a rate of 10°C min^{-1} with inert alumina as a reference. Elemental analyses were performed using a Perkin-Elmer 240C elemental analyser. IR-spectra (4000–400 cm^{-1}) were taken at 27°C using a Perkin-Elmer IR 783 where KBr/Nujol was used as medium/reference material. Electronic spectra (1400–200 nm) were obtained at 27°C using a Hitachi UV-VIS-NIR model U-3410 where Nujol was used as a medium as well as a reference. The magnetic susceptibility was measured at 27°C using an EG and G PAR 155 vibrating sample magnetometer, where $[HgCo(SCN)_4]$ was used as a reference material and diamagnetic corrections were made using Pascal's constants. Molar conductances were measured using a Systronics 304 conductivity meter, where cell constant was calibrated with 0.02 M KCl solution and dry methanol was used as solvent.

Preparation of the complexes

Cis-$[Ni(dpren)_2(NO_3)](NO_3)$ **1** was synthesized by adding the acetonitrilic solution (5 cm^3) of the diamine (2 mmol) to the acetonitrilic solution (10 cm^3) of nickel(II) nitrate hexahydrate (1 mmol). The resulting blue coloured solution was kept in a $CaCl_2$-desiccator. After a few days fine blue crystals were separated out, which were filtered and washed with propan-2-ol and dried in a $CaCl_2$-desiccator (yield, 73%). Single crystals suitable for X-ray analysis were obtained by recrystallisation of the complex from acetonitrile-butanol (1 : 1) mixture. (Found: C, 40.7; H, 8.4; N, 17.8; Ni, 12.5. Calc. for $NiC_{16}H_{40}N_6O_6$: C, 40.7; H, 8.5; N, 17.8; Ni, 12.5%. $\mu_\beta = 3.1$; λ_{max}(Nujol) = 924, 575 and 364 nm; $\Lambda = 92\ \Omega^{-1}\ cm^2\ dm^{-3}$).

Cis-$[Ni(dipren)_2(H_2O)_2](NO_3)_2 \cdot 2H_2O$ **2** was prepared by adding dry acetonitrilic solution (5 cm^3) of the diamine (2 mmol) to the dry butanolic solution (10 cm^3) of anhydrous nickel(II) nitrate (1 mmol), obtained by refluxing $Ni(NO_3)_2 \cdot 6H_2O$ in 2,2-dimethoxypropan. The resulting mixture was refluxed for 10–15 min and was kept in a $CaCl_2$-desiccator. After a few days greenish blue complex was separated out, which was filtered and washed with dry butanol and dried in a $CaCl_2$-desiccator (yield, 62%). (Found: C, 35.4; H, 8.9; N, 10.3; Ni, 10.8. Calc. for $NiC_{16}H_{48}N_6O_{10}$: C, 35.4; H, 8.8; N, 10.3; Ni, 10.8%. $\mu_\beta = 3.1$; λ_{max}(Nujol) = 1034, 625 and 382 nm; $\Lambda = 105\ \Omega^{-1}\ cm^2\ dm^{-3}$). Preparation of single crystals suitable for X-ray analysis was unsuccessful.

X-ray diffraction structural study

A single crystal of complex **1** was mounted on a Siemens P4 diffractometer. Lattice parameters were determined by least squares refinement of the angular settings ($5.15 < \theta < 12.47$) of 26 well-centered reflections. Intensity data were collected using graphite monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å) using ω-scan mode. The stability of the crystals were measured during X-ray exposure by monitoring three standard reflections after every 97 reflections. Intensity data were corrected for Lorentz and polarisation effects [7]. An empirical absorption correction was applied (T_{min}/T_{max} 0.645/0.762). The structure was solved by the Patterson method followed by Fourier syntheses and refined through full-matrix least squares calculations. Anisotropic full-matrix refinements based on F^2 were carried out for all non-hydrogen atoms. During the refinements the crystal structure was found to be disordered. The carbon atoms [C(9), C(10), C(15), C(16)] were found to occupy [C(9), C(10), C(15), C(16) with site occupancy factor 0.6 and C(9′), C(10′), C(15′), C(16′) with site occupancy factor 0.4] two positions. The hydrogen atoms, except those attached to disordered atoms, were clearly visible in the difference map. The located hydrogen atoms, with isotropic thermal parameters 1.2 times U_{eq} of the atom to which the respective hydrogen atom attached to the final structure factors calculations, were treated as fixed contributors. Complex neutral atom scattering factors [8] were used throughout the refinement. All calculations were carried out using SHELXS 86 [9], SHELXL 93 [10], PARST [11] and ORTEP II [12] programs. Crystallographic data are summarised in Table 1. Selected bond distances and angles are listed in Table 2.

RESULTS AND DISCUSSION

N,N'-dipropylethane-1,2-diamine (dpren) and *N,N'*-diisopropylethane 1,2-diamine (dipren) yielded complexes with nickel(II) nitrate having composition, $Ni(dpren)_2(NO_3)_2$ **1** and $Ni(dipren)_2(NO_3)_2 \cdot 4H_2O$ **2** respectively, as is evident from their elemental analyses. The former one is blue whereas the latter one is greenish blue. Magnetic susceptibility data of both the complexes correspond to octahedral nickel(II). Electronic spectral study also corroborates this. The

$^d S = [\Sigma\{w(F_o^2 - F_c^2)^2\}/(N-P)]^{1/2}$, where N is the number of data and P is the total number of parameters refined.

complexes exhibit IR-bands due to $\nu(NH_2)$ and $\nu(CH_2)$, are comparable to those of similar diamine systems, where the chelate character of the diamines have been established by X-ray single crystal analyses [13,14]. In complex **1** either both the nitrate groups are coordinated or one of them coordinated in a bidentate fashion to maintain its octahedral geometry. Thus, it is now essential to know the exact mode of coordination of the nitrate ions so that the actual configuration of the complex can be assigned. IR spectra have been studied to determine the mode of coordination of the NO_3^- ion at the region of 1700–1800 cm^{-1}, where the combination band of ν_1-symmetric stretching and the double degenerate in-plane bending mode (ν_4) of coordination of nitrate ions in metal complexes have been assigned [15,16]. Complex **1** exhibits IR-bands at 1778, 1740 and 1708 cm^{-1} (Fig. 1). The peak at ~1740 cm^{-1} suggests the presence of free NO_3^- ion. The large separation (70 cm^{-1}) between the other two peaks indicates that the other NO_3^- ion is acting as bidentate ligand. Thus, in complex **1**, one of the nitrate ions is coordinated in a bidentate fashion and the remaining one is uncoordinated which is corroborated by its molar conductance datum (*vide supra*). The complex **1** exhibits no splitting of d–d band in its electronic spectrum (Nujol) at near-IR region and thereby suggesting its *cis*-configuration (Fig. 2) [17]. On the other hand, complex **2** shows only one very sharp and strong IR band at ~1763 cm^{-1} (Fig. 1) which indicates the presence of free nitrate ions in the complex and molar conductance datum of the complex is typical to 1:2 electrolyte suggesting noncoordination of nitrate ions. All these, indirectly suggest the coordination of two water molecules in complex **2** and the IR-band at ~700 cm^{-1} corroborates this. These two water molecules may be either in *cis* or in *trans*-positions. Electronic spectrum in the near-IR region shows no splitting in d–d bands

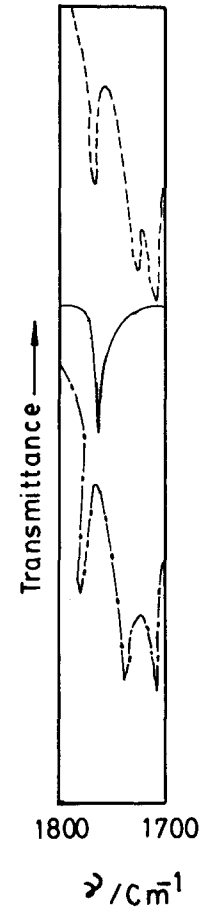

Fig. 1. IR spectra (Nujol) of *cis*-[Ni(dpren)$_2$(NO$_3$)](NO$_3$) **1** (–·–·–); *cis*-[Ni(dipren)$_2$(H$_2$O)$_2$](NO$_3$)$_2$·2H$_2$O **2** (—) and *cis*-[Ni(dipren)$_2$(NO$_3$)](NO$_3$) **2a** (– – –).

indicating *cis*-configuration and thereby the water molecules are in *cis*-positions.

The complex **1** upon heating starts to decompose at ~245°C, whereas, complex **2** starts to lose water at ~145°C and becomes dehydrated accompanied by melting at ~180°C with change in colour, greenish-blue to deep green. The molten species, **2a** undergoes solidification on cooling to ambient temperature. Magnetic susceptibility (3.1 μ_β at 27°C) and electronic spectrum [λ_{max}(Nujol) = 1015, 621 and 380 nm] of **2a** suggest it possesses an octahedral geometry. It can be stored in a desiccator but it reverts in humid atmosphere (90% or above). However, it exhibits IR-spectrum similar to that of complex **1** at the region of 1700–1800 cm^{-1} (1765, 1730 and 1708 cm^{-1}) which indicates that the coordinating mode of nitrate ions in this complex is alike to that of complex **1** and near-IR spectrum also corroborates this. It is interesting to note that the chromophore around nickel(II) does not alter on deaquation–anation reaction. The cause of colour change is proposed to be due to change in ligand field strength.

Table 3. Hydrogen bonding geometry

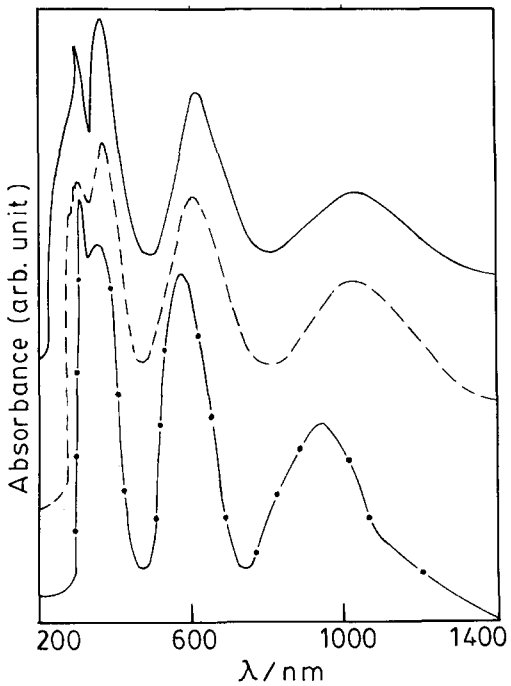

Fig. 2. Electronic spectra (Nujol) of *cis*-[Ni(dpren)$_2$(NO$_3$)](NO$_3$) **1** (–·–); *cis*-[Ni(dipren)$_2$(H$_2$O)$_2$](NO$_3$)$_2$·2H$_2$O **2** (– – –) and *cis*-[Ni(dipren)$_2$(NO$_3$)](NO$_3$) **2a** (—).

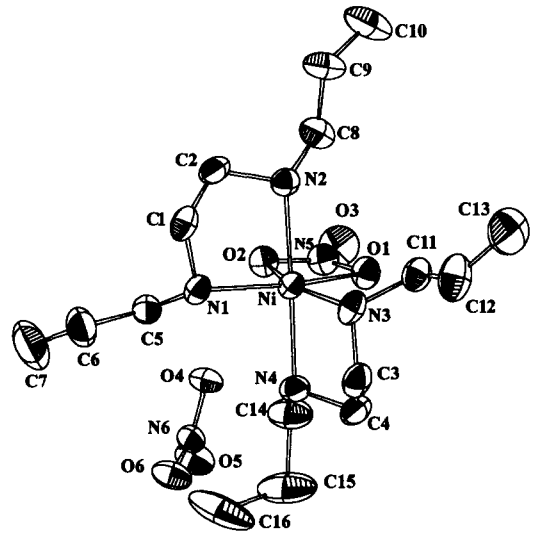

Fig. 3. ORTEP-plot, *cis*-[Ni(dpren)$_2$(NO$_3$)](NO$_3$) **1** with atom numbering scheme.

An ORTEP view of the complex **1** with the atom numbering scheme is shown in Fig. 3. The crystal structure consists of discrete [Ni(dpren)$_2$NO$_3$] cation and NO$_3$ anion. The ligand moieties [dpren and NO$_3$] are monometallic and bidentate. The coordination polyhedron around the metal is best described as a distorted octahedron. The two nitrogen atoms (N1, N3) of the diamines and two oxygen atoms (O1, O2) of the *cis*-bidentate nitrate group define the equatorial plane and the remaining-two N atoms (N2, N4) of the diamine ligands are in axial position [N2—Ni—N4 175.4(1)°]. The N2—Ni—N4 axis is nearly orthogonal to the equatorial plane [angle ranges from 83.3(2)° to 98.1(1)°]. The cluster of complex **1** has a two-fold axis that passes through the metal atom and the mid point of two oxygen atoms (O1, O2) of the coordinating nitrate group and the equatorial plane, containing the two fold axis, serves as a mirror. So the molecule has approximate C_{2v} symmetry. The five membered chelate rings, Ni—N1—C1—C2—N2 and Ni—N3—C3—C4—N4 display open envelope geometries with the flap atoms C2 and C4 0.602 Å and 0.595 Å, respectively, away from the least squares planes through the remaining endocyclic atoms. The dihedral angle between the planar parts of the chelate rings is 100.6(2)°. The Ni—N, Ni—O distances are consistent with the corresponding nickel(II) diamine/nitrato-diamine complexes [14, 18]. Complex **1** is stabilised mainly by intermolecular and intramolecular hydrogen bonds which control overall chelate ring conformations. The crystal packing is dominated by the strings of molecules which are held together by an extensive intermolecular hydrogen bonding network. These are given in Table 3.

From the report presented above it may be inferred

that as the chain length of the alkyl group increases, nickel(II) nitrate prefers to form *cis*-octahedral bis (diamine) species over its *trans*-isomer. If the steric effect is increased as is exerted by isopropyl group, nitrate ion coordination becomes difficult. Thus, the mode of coordination of nitrate ions may selectively be controlled by using appropriate diamine. Here, it may be mentioned that for higher alkyl substituted diamines, solvent and temperature have little effect on the overall configuration of the complex.

(Received 17 March 1997; accepted 25 June 1997)

Abstract—Physicochemical studies on two oxovanadium(IV) heterochelates involving the biologically active ONO donor ligand, dipicolinic acid (DPA) is reported. Structure of the complex $[VO(DPA)(ophen)]\cdot 3H_2O$ has been determined and this led to the understanding of the geometry of the donor sites around the oxovanadium(IV) centre of other related complexes. Electrochemical behavior of the complexes were explored by cyclic voltammetry. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: oxovanadium(IV) heterochelates; structural study; dipicolinic acid ligand; electrochemical investigation.

Design and synthesis of heterochelate complexes are generally intended to study the effect of unsymmetrical ligand fields on transition metal acceptor centres. This effect is expected to be revealed in their electronic, IR spectra, magnetic moment values, electrochemical activity, chemical reactivity and of course in their structures.

A host of mixed ligand oxovanadium(IV) complexes including some heterochelates involving the biologically active versatile ligand dipicolinic acid (DPA) has been reported [1,2]. It is surprising that no structural study of any of them has been reported to date. This paper deals mainly with the X-ray crystallographic study of the heterochelate $[VO(DPA)(ophen)]\cdot 3H_2O$ which may be considered as the representative of the class [VO(DPA)(B—B)] where B—B is a neutral bidentate chelating ligand. The crystal structure of this complex allowed us to predict the disposition of the donor sites of the mother complex $[VO(DPA)(H_2O)_2]H_2O$ (**1**) from which the heterochelates are prepared. Electronic, infrared spectra, magnetic moment values and electrochemical behavior of these complexes are also reported and discussed here.

EXPERIMENTAL

All chemicals were of reagent grade and used without further purification. Tetraethylammonium perchlorate (TEAP) used for electrochemical work was prepared as reported in literature [3]. All operations were performed under purified dinitrogen.

Physical measurement

IR spectra were recorded at room temperature on a Perkin Elmer 783 spectrophotometer as KBr pellets. Magnetic moments of solid complexes at 298 K were determined using a PAR model 155 vibrating sample magnetometer with $Hg[Co(SCN)_4]$ as the calibrant. Electronic spectra were recorded in DMF solution with Shimadzu Model UV-2100 spectrophotometer and cyclic voltammetric experiments were performed using BAS CV-27 electrochemical analyser and a BAS XY recorder at 298 K. The electrodes used were glassy carbon working electrode, Pt wire counter electrode and a Ag/AgCl reference electrode separated from the working compartment by a salt bridge fitted with a medium glass frit. Under identical conditions the value of the $E_{1/2}$ of the ferrocene/ferrocenium couple is found to be ± 0.59 V ($\Delta E = 250$ mV). Electrical

conductivity in solution was measured by a Philips PR 9500 conductivity bridge. C, H and N were analysed by Perkin Elmer 2400 CHNS/O analyser.

Synthesis of complexes

$[VO(DPA)(H_2O)_2]H_2O$ (**1**): 0.5 gm (1.75 mmole) of $VOSO_4$ and 0.4 gm (2.45 mmole) of dipicolinic acid were dissolved in hot water (20 cm^3) when a bright green solution was obtained. It was then cooled to 5°C, the precipitated excess acid was filtered off and the filtrate kept overnight in a refrigerator. Shiny blue crystals were filtered, washed with rectified spirit and dried in air for a few hours (yield 60%). Found: C, 29.32; H, 3.18; N, 4.70. Calc. for $[VO(DPA)(H_2O)_2]H_2O$: C, 29.37 H, 3.15; N, 4.89%.

$[VO(DPA)(ophen)]\cdot 3H_2O$ (**2**): 0.3 gm (1.04 mmole) of blue $[VO(DPA)(H_2O)_2]H_2O$ reacts readily in aqueous solution with a 0.25 gm (1.25 mmole) alcoholic solution of o-phenanthroline to provide a chocolate brown crystalline product, which was washed with alcohol and dried over anhydrous $CaCl_2$ (yield 65%). Found: C, 48.32; H, 3.80; N, 7.60. Calc. for $[VO(DPA)(ophen)]3H_2O$: C, 48.93; H, 3.65; N, 7.73%.

$[VO(DPA)(bipy)]H_2O$ (**3**): The same method was employed with bipyridine in place of phenanthroline to provide yellowish brown crystals (yield 60%). Found: C, 49.82; H, 3.18; N, 10.10. Calc. for $[VO(DPA)(bipy)]H_2O$: C, 50.25; H, 3.20; N, 10.34%.

Crystal structure determination

A brown prismatic crystal of $0.30 \times 0.40 \times 1.0$ mm^3 was chosen for diffraction study. The compound crystallised in the monoclinic space group $P2_1/c$. The unit cell dimensions and cell volume are given in Table 1. Intensity data were collected on a MSC/Rigaku Raxis-

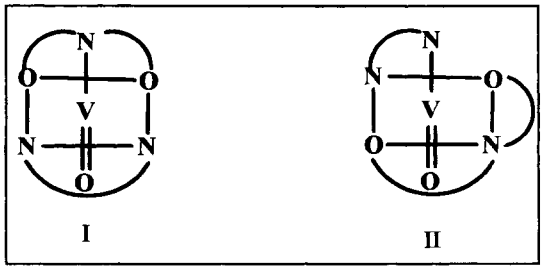
IIC imaging plate diffractometer using graphite monochromatised Mo-K_α radiation ($\lambda = 0.71073$ Å) from a rotating anode generator powered at 60 KV and 90 mA. A total of 6980 reflections were collected, with 3799 independent reflections ($R_{int} = 1.84\%$), covering indices $-17 \leqslant h \leqslant 17$, $-17 \leqslant k \leqslant 17$; $0 \leqslant l \leqslant 13$, by oscillation photographs (30 frames in total), with $\phi = 0-180°$, $\Delta\phi = 6.0°$ at a scan rate of 8 minutes per frame [4,5]. The intensities were corrected for Lorentz and polarization effects and for absorption using the ABSCOR program. The structure was solved by direct method. All non-hydrogen atoms were refined anisotropically by full matrix least squares, with riding model for hydrogen atoms, using the SHELXTL-PC package [6]. For 3188 observed reflections ($|F_o| \geqslant 6\sigma(|F_o|)$), refinement converged ($\Delta/\sigma = 0.001$) with $R_F = 0.056$ and $wR = 0.071$. The weighing scheme was $w = [\sigma^2|F_o| + 0.0001\,|F_o|^2]^{-1}$. Goodness of fit $S = 3.32$. Selected bond lengths and bond angles are given in Table 2. Figure 1 shows the ORTEP diagram and atom numbering scheme of (**2**) and Fig. 2 its packing diagram.

Description of the structure

The deprotonated dipicolinic acid acting as a tridentate chelating agent coordinates to the VO^{+2} centre through the heterocyclic ring nitrogen N(1) and the carboxylate oxygens O(3) and O(4). All three of them occupy three positions of a distorted square plane (Fig. 1), the fourth position being occupied by one of the ophen nitrogen atoms N(3). The oxygen atom of the vanadyl moiety lie above the plane defined by O(3)—N(1)—O(4)—N(3), while the position *trans* to the vanadyl oxygen is occupied by the N(2) nitrogen atom of the coordinated ophen. The V—O(5) distance of 1.581(3) Å is a little shorter than is generally found in most VO^{+2} complexes with a nitrogen donor attached to its trans position [7–9]. Of the two V—N bonds generated by the coordinated ophen, the V—N(2) bond *trans* to the V=O bond is longer (2.312 Å) than the other V—N(3) bond (2.126 Å). Thus the vanadium(IV) centre exists in a distorted octahedral donor environment. The deviation of the vanadium atom from the plane defined by O(3)—N(1)—O(4)—N(3) is 0.2910 Å and the dihedral angle between the mean planes defined by the aromatic ligands is 93.90°. Figure 1 shows that O(1w), O(2w) and O(3w) form part of the asymmetric unit. O(1w) is directly H-bonded with O(1) of the molecule. Each of the O(1w), O(2w) and O(3w) are connected to the symmetry generated O(1b), O(2a) and O(4c) respectively with transformation codes *a*(x, $1+y$, z); *b*($1-x$, $1-y$, $-z$); *c*(x, $0.5-y$, $-0.5-z$). Two of the oxygens O(1w) and O(2w) form three hydrogen bonds whereas O(3w) is connected by only two hydrogen bonds. Molecules are packed within the lattice through this type of hydrogen bonds. O(1w) exhibits two-fold disorder and accordingly atom O(1w) and O(1'w) are assigned 0.7 and 0.3 occupancy respectively.

RESULTS AND DISCUSSION

The complex $[VO(DPA)(ophen)]\cdot 3H_2O$ is expected to be 6-coordinated with the vanadyl oxygen occupying one coordination position and it may exist in the following two forms:



Only crystal and molecular structure determination can identify the form in which it actually exists. From the preceding description of the structure it is clear that the form II is the actual disposition of the coordination sites. It leads to an interesting observation that one of the two nitrogen atoms [N(2)] of the ophen moiety has manifested its weaker donor character, compared to the other, through its larger V(1)—N(2) bond length (Table 2). It also corroborates the previous observation that in many oxovanadium(IV) complexes of N—O donors, the weakest donor is generally found to occupy the position trans to the vanadyl oxygen [10]. From the structure of this compound it is clear that the dianionic tridentate DPA moiety behaves as a planar tridentate chelating ligand. This finding allows us to formulate the structure of (3) in which the coordinated ophen of (2) is replaced by a very similar ligand bipy. It also helps us to make a logical guess about the geometry of the coordination environment of the oxovanadium(IV) moiety of the complex $VO(DPA)(H_2O)_2]H_2O$ (1) from which the complex (2) was first prepared. Facile reaction of ophen on (1) at even a low temperature of 2–5°C indicates that the two coordinated water molecules are *cis* to each other, which is consistent with the planar disposition of DPA as well as the placement of the weakest ligand in a position trans to the V=O oxygen. The conclusion may be extended to other complexes of the type [VO(DPA)(B—B)] and [VO(DPA)X_2] where B—B is a neutral bidentate chelating ligand and X is a neutral monodentate donor. The structure of the other reported compound [VO(DPA)(bipy)]H_2O should also be similar so far as the disposition of the donor sites around the VO^{+2} acceptor centre are concerned. Structure determination of one compound of a related series of compounds, in this case, has been of much help in understanding the geometry of the donor sites around the central metal ion of a host of structurally related complexes.

Infrared spectra. The ν(V=O) mode is an accepted

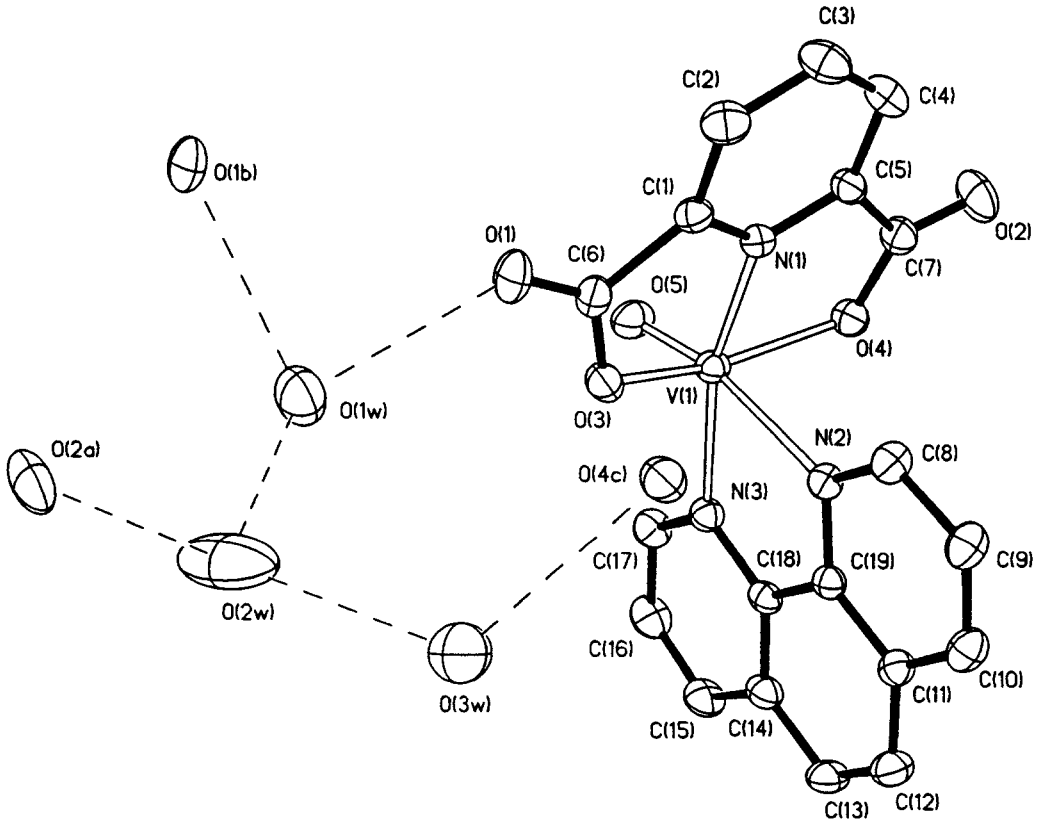


Fig. 1. ORTEP diagram and atom numbering scheme of $[VO(DPA)(ophen)]3H_2O$ (2).

leverage [11–13] which can be utilised for recognising the relative σ-donor capacity of the donor *trans* to the vanadyl oxygen Greater the σ-donor capacity of the ligand lesser is the ν(V=O). The values of ν(V=O) of the complexes (**1**), (**2**) and (**3**) are given in Table 3. It is seen that the ν(V=O) in (**1**) is observed at 980 cm^{-1} while those of (**2**) and (**3**) are at 978 cm^{-1}. These values indicate that both ophen and bipy are a little stronger σ-donors than the two water molecules and there is no difference between ophen and bipy in this respect. But it is well known that ophen and bipy are much higher up in the spectrochemical series than

Table 3. IR, magnetic moment, UV and electrochemical results

[a] Condition: Solvent, DMF; supporting electrolyte, TEAP (0.1 M); working electrode, platinum; reference electrode, SCE; solute concentration, 10^{-3} M; scan rate, 0.4 V/sec; and temperature, 298 K. $E_{1/2}$ is calculated as the average of anodic (E_{pa}) and cathodic (E_{pc}) peak potential.

[b] $\Delta E = E_p - E_{pc}$.

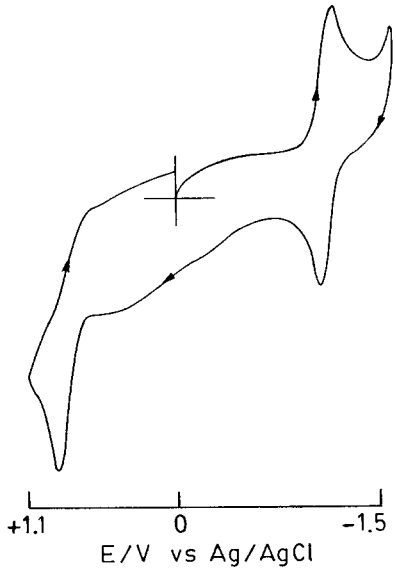

Fig. 3. Cyclic voltammogram of [VO(DPA)(ophen)]$3H_2O$ (**2**) in DMF at 298 K with scan rate 0.4 V/sec.

water yet the difference observed here is marginal. This opens up an interesting question, is the frequency of the ν(V=O) regulated solely by the ligand *trans* to the vanadyl oxygen atom, or is it the nature of the main ligand that exerts significant control on the change? From our study it appears that the second factor is more important. Magnetic moment values corresponds to the presence of one unpaired d-electron in all the three complexes.

Electronic spectra. UV spectra of VO^{+2} complexes are well documented and discussed [14–17]. Electronic spectra of the compounds (**1**), (**2**) and (**3**) (Table 3) both in solid state and in DMF solution exhibit three bands in the 11,800–22,005 cm^{-1} region. The bands in the 11,800–13,400 cm^{-1} (Band I), 16,300–18,800 cm^{-1} (Band II) and 20,000–22,050 cm^{-1} (Band III) are attributed to the transition $b_2 \rightarrow e_{\pi}^{*}$, $b_2 \rightarrow b_1^{*}$ and $b_2 \rightarrow a_1^{*}$ respectively. The position of the λ_{max} in both (**2**) and (**3**) is almost identical.

Electrochemistry. The results of the cyclic voltammetric studies are listed in Table 3 and the cyclic voltammogram of (**2**) is shown as the representative (Fig. 3). Potential separation between the anodic and the cathodic waves (ΔE) for the process V(IV)/V(III) (Table 3) indicates that the process is irreversible for (**1**) and reversible for both (**2**) and (**3**)—the slightly higher values compared to the ideal Nernstial value of 59 mV may be attributed to uncompensated solution resistance [18]. On the oxidation side, however, only the oxidation step V(IV)/V(V) could be observed for all the three complexes. It is clear that the differences between the V(IV)/V(III) and V(IV)/V(V) potentials of the three compounds are quite small. Such small differences point to the fact that keeping in line with the closely similar spectral and magnetic moment data, the electrochemical properties of (**1**), (**2**) and (**3**) are quite comparable. The basic reason behind such similarities is the presence of the same principal ligand in the same disposition of its donor points in all the three complexes and the consequent structural similarity. Otherwise the spectral, magnetic and electrochemical properties of the compound (**1**) which contains two water molecules in place of the ophen in (**2**) and bipy in (**3**) could not exhibit such close similarity.

CONCLUSION

This work may be regarded as a useful example where the structure determination of one key member of a related series of compounds can lead to a general idea of the geometry of the donor sites present in other related complexes. It also illustrates that if the major ligand of a related series of heterochelates behaves similarly, the nature of the secondary ligand belonging to the same class does not significantly affect the properties as well as the coordination geometry of the resultant heterochelates.

(Received 29 April 1997; accepted 20 June 1997)

Abstract—A new dinuclear manganese(II) complex bridged by bridging ligand butane 1,4-dicarboxylic acid, $[Mn_2(BIPY)_4(BTD)(H_2O)_2] \cdot (ClO_4)_2 \cdot 2H_2O$ has been prepared and structurally characterized by X-ray crystallography. The crystal structure comprises a dinuclear cation, perchlorate anions and lattice water molecules. Each Mn^{II} dimer unit is linked to its neighbours by the two noncoordinating carboxylate oxygens of BTD^{2-} ligand, the bound water and two bridging water molecules through double hydrogen bonds, forming an infinite chain running parallel to the crystallographic *b*-axis. The electrochemical properties of the complex was studied in CH_3CN by cyclic voltammetry (CV). The temperature-dependent magnetic susceptibility data (75–300 K) were fitted based on $H = -2Js_1s_2$, yielding the intramolecular coupling constant J value of $-0.137\ cm^{-1}$. Besides, the complex shows a catalase-like activity in pyridine. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: manganese complexes; dinuclear complexes; crystal structures; magnetism; butane 1,4-dicarboxylic acid; 2,2′-bipyridine.

In recent years there has been considerable interest in coordination chemistry of manganese complexes with carboxylate ligands, due to the fact that polynuclear metal carboxylates are good candidates for the investigation of exchange-coupling interactions between adjacent metal ions [1,2], and at the same time the interest has been fuelled by the identification of a number of Mn-containing enzymes [3]. In addition to the tetra-Mn photosynthetic water-oxidizing complex, several Mn-containing non-haem catalases have also been isolated and characterised [4-6]. Manganese catalases catalyse the disproportionation of hydrogen peroxide into water and molecular oxygen and this process is important for cell detoxification. The Mn catalases are known to contain two manganese ions at their active center [7] and the enzyme can exist in at least four different oxidation states: a reduced Mn^{II}/Mn^{II} form, a mixed-valence Mn^{II}/Mn^{III} form, an oxidized Mn^{III}/Mn^{III} form, and an inactive superoxidized Mn^{III}/Mn^{IV} form [8]. It is generally believed that the disproportionation reaction is catalysed by the interconversion of the two oxidation states Mn^{III} Mn^{III} and Mn^{II} Mn^{II} [8–10]. However, the active-site structure is not proven and the H_2O_2 proportionation mechanism remains unclear [8]. Accordingly at this stage it is of value to use simple model complexes to gain insight into the structure and catalytic mechanism of Mn catalase and much effort has been made [11–14]. As part of our ongoing studies into the coordination chemistry of dicarboxylic acid [15,16], we succeeded in preparing the title complex, $Mn_2(BIPY)_4(BTD)(H_2O)_2] \cdot (ClO_4)_2 \cdot 2H_2O$. To our knowledge the title complex is the first structurally characterized dinuclear manganese complex with extended bridging BTD^{2-} ligand [17]. The complex is also interesting for its novel hydrogen bonding character. Here the synthesis, crystal structure, magnetic

* Authors to whom correspondence should be addressed.

properties and electrochemical properties of the title complex are described, together with its catalytic activity towards the disproportionation of H_2O_2.

EXPERIMENTAL

Preparations

All reagents were reagent grade and used as received. Piperidinium salt of butane 1,4-dicarboxylic acid was prepared in a similar method to piperidinium salt of terephthalic acid [18].

A methanolic solution (20 cm^3) of bipyridine (0.8 mmol) and piperidinium salt of butane 1,4-dicarboxylic acid (0.2 mmol) was slowly added to a solution (20 cm^3) of manganese(II) perchlorate hexahydrate (0.4 mmol) in the same solvent with continuous stirring. The yellow powder separated during the addition was filtered off. Light yellow prismatic single crystals of the title complex suitable for X-ray analysis were obtained in a 64% yield after two weeks by slow evaporation of the mother-liquor at room temperature. Anal: Calc. for $C_{11}H_{11.5}Cl_{0.5}Mn_{0.5}N_2O_4$: C, 47.03; H, 4.13; N, 9.98; Mn, 9.78. Found: C, 47.25; H, 4.16; N, 10.12; Mn, 9.98%. IR (KBr matrix) cm^{-1}: ν_a(COO), 1580; ν_s(COO), 1410 (the results suggested the unidentate coordination mode of the dicarboxylate).

Caution: Metal perchlorate salts containing organic ligands are potentially explosive and should be handled with great care.

Physical measurements

Magnetic susceptibility data on powder samples were measured over a temperature range of 75–300 K at 6000 G by using a CAHN-2000 Faraday-type magnetometer. The apparatus was calibrated with $[Ni(en)_3]S_2O_3$ (en = ethylenediamine). Diamagnetic corrections were made using Pascal's constants.

X-ray crystallography

A summary of the crystal data, intensity collection and structure refinement is given in Table 1. The intensities were collected at 294 K on a Rigaku RAXIS IIC imaging-plate diffractometer using Mo-K_α radiation ($\lambda = 0.71073$ Å) from a rotating-anode generator operating at 50 kV and 90 mA ($2\theta_{max} = 55.2°$); 60 oscillation frames in the range of 0–180° [19], exposure 8 min per frame for the title complex.

The structure of the title complex was solved by direct methods. All non-hydrogen atoms were refined anisotropically by full-matrix least squares (on F). Hydrogen atoms of the ligand and the solvent molecules were placed in calculated positions (C—H 0.96 Å), assigned fixed isotropic thermal parameters, and allowed to ride on their respective parent atoms. The contributions of these hydrogen atoms were included in the structure-factor calculations.

w^{-1}	$\sigma^2(F) + 0.0000F^2$

All computations were carried out on a PC-486 computer, using the SHELXTL-PC program package [20]. Analytical expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated [21].

RESULTS AND DISCUSSION

Structure description

Selected bond lengths and angles are listed in Table 2. The labelled molecular structure and the packing arrangement of molecules in a unit cell are depicted in Figs 1 and 2, respectively.

The complex crystallizes in the triclinic space group $P\bar{1}$ and possess a dinuclear structure bridged by adianion of butane 1,4-dicarboxylic acid, which acts as a bidentate ligand and each carboxy group of the dicarboxylate is coordinated to a manganese atom unidentately (using O1). Each of the two symmetry related Mn^{II} atoms has a distorted octahedral N_4O_2 coordination geometry. Each metal is surrounded by two chelating bipy groups, one carboxylate oxygen atom [O1] from the bridging BTD^{2-} ligand and the oxygen atom [O1w] of a water molecule which is in a syn-position with respect to the coordinated carboxylate oxygen [O1] of the bridging TBD^{2-} ligand. The Mn—N (bipy) average bond length is 2.255(4)

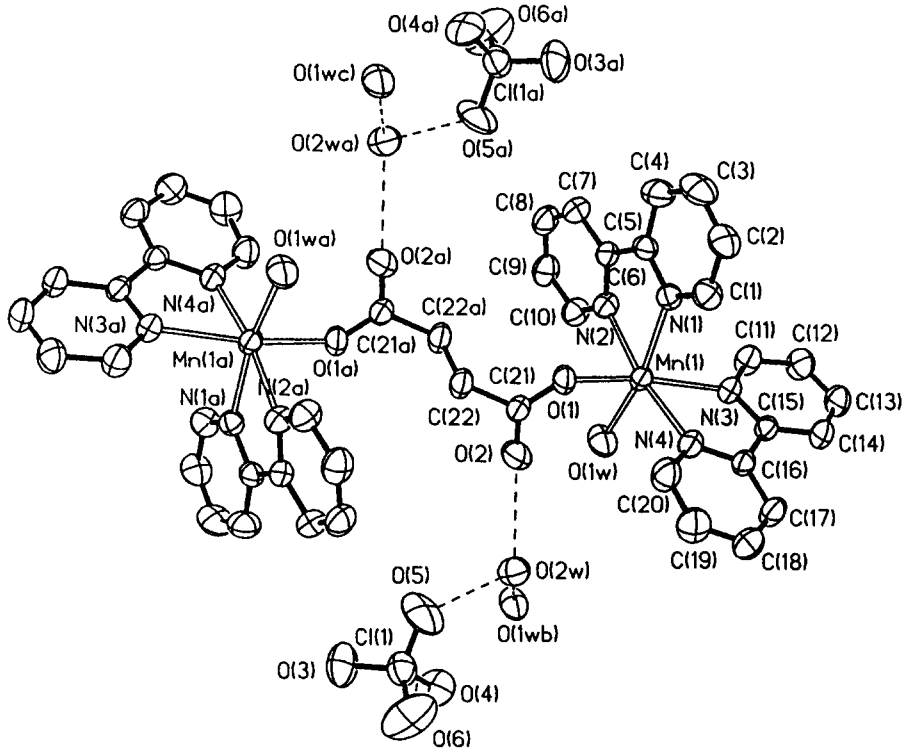

Fig. 1. Molecular structure of the title complex. Hydrogen atoms are omitted for clarity.

Å, the bond lengths of Mn—O1 (carboxylate) and Mn—O1w (water) are 2.118(3) and 2.148(4) Å, respectively. These bond lengths are similar to those reported for other manganese(II) complexes [16]. Large deviations of bond angle from 90° of the idealized octahedral geometry are found for angle N1—Mn1—N2 [72.7(1)] and angle N3—Mn1—N4 [72.4(1)] which are restricted by the bipy five-membered chelate ring. So the Mn ion has a distorted-octahedral coordination geometry. The best equatorial plane is defined by atoms O1w, N1, N2 and N4. The largest deviation from the mean plane is 0.0818 Å for N2 and the Mn atom is 0.0116 Å out of this plane. The Mn···Mn separation is 8.717 Å. Each of

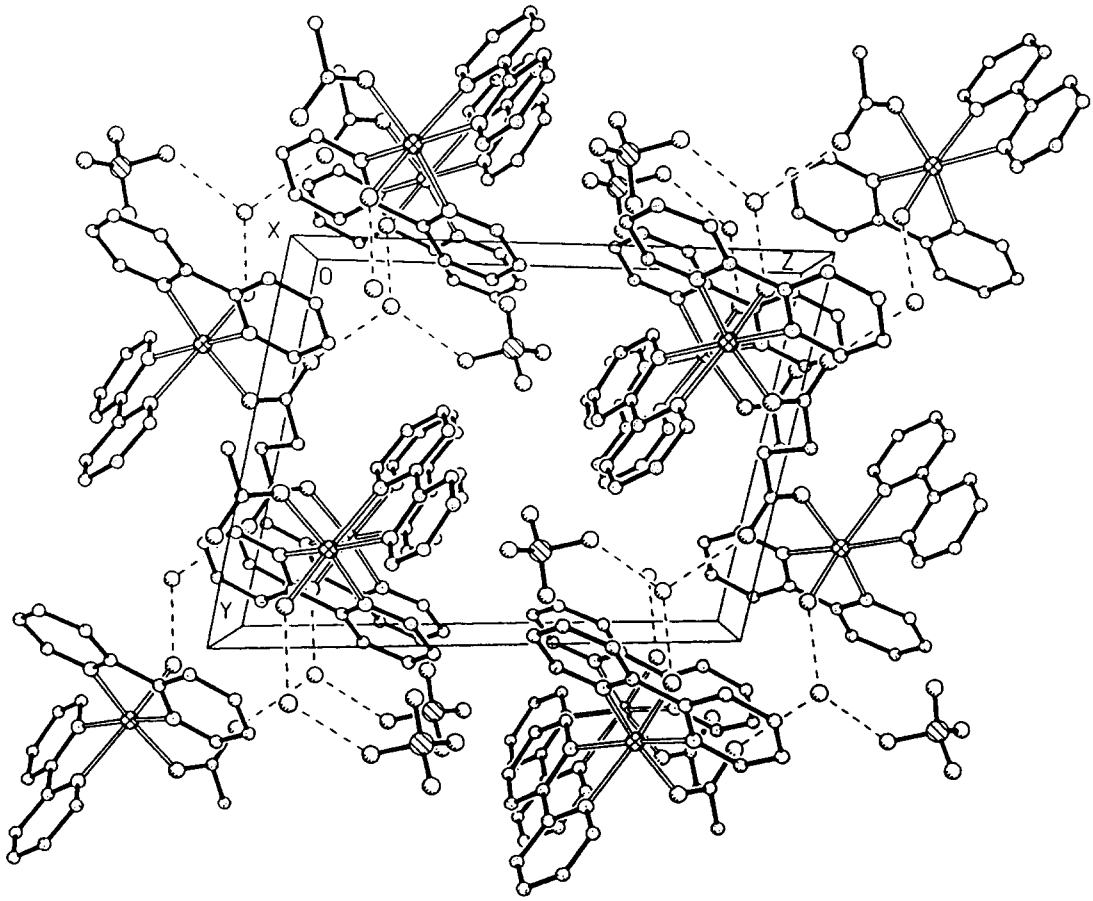

Fig. 2. Packing arrangement of molecules in the unit cell.

the bipy ligands is coplanar. The perchlorate groups have their expected tetrahedral geometry.

There is significant intermolecular association between two adjacent molecules of the complex caused by the presence of two bridging water molecules (O2w). Each of the two bridging water molecules is hydrogen bonded to the uncoordinated carboxylate oxygen (O2) in one molecule and the oxygen (O1w) of the coordinated water in another molecule, respectively, forming two hydrogen-bonding bridges between two molecules (Fig. 2). Furthermore, a perchlorate is also hydrogen bonded to each of the bridging water oxygens (O2w). All the hydrogen bonding parameters are listed in Table 2.

Magnetic properties

The temperature dependence of the magnetic susceptibility for the title complex in the form of χ_M vs T is shown in Fig. 3. The effective magnetic moment at 300.20 K is 8.29 B.M. which is slightly lower than the spin-only value of 8.36 B.M. expected for two uncoupled high-spin Mn^{II} ions. Upon cooling, the magnetic moment value decreases slowly from 8.29 B.M. at 300.2 K to 7.84 B.M. at 75 K, showing the presence of extremely weak antiferromagnetic exchange interaction. Assuming isotropic exchange, the exchange Hamiltonian is $H = -2JS_1S_2$ with

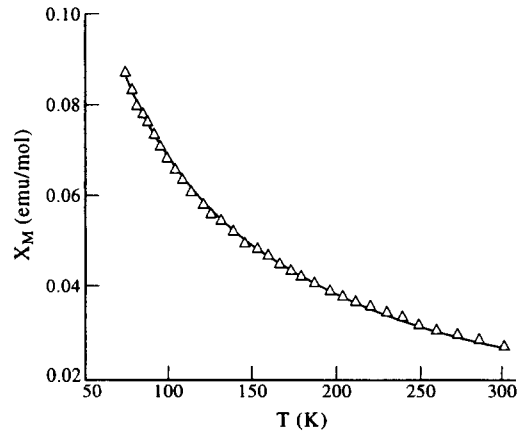

Fig. 3. The plot of χ_M/T for the title complex. The solid line represents best fit of data according to eq. (2).

$S_1 = S_2 = 5/2$, and the magnetic susceptibility per dinuclear molecule is given by eq. (1) [22] where N, g, β, x are Avogadro's constant, g factor, Bohr magneton, and $x = J/kT$, respectively, and J is the exchange coupling constant for the dinuclear molecule.

$$\chi_M = 2Ng^2\beta^2/kT[(e^x + 5e^{3x} + 14e^{6x} + 30e^{10x} + 55e^{15x})/(1 + 3e^x + 5e^{3x} + 7e^{6x} + 9e^{10x} + 11e^{15x})] \quad (1)$$

Improving on the calculated expression, a molecular field (zJ') [23] was added so as to describe the inter-dimer Mn^{II} unit exchange interactions. The expression for the magnetic susceptibility of the title complex becomes:

$$\chi_M = \chi_M/[1 - 2zJ'\chi_M/Ng^2\beta^2] \quad (2)$$

Using eq. (2), the least-squares fitting with an assumed g value of 2.00 gives the parameters: $J = -0.137$ cm^{-1}, $zJ' = -0.05$ cm^{-1} and $R = 2.35 \times 10^{-4}$ [$R = \Sigma(\chi_{calc} - \chi_{obs})^2]/\Sigma(\chi_{obs})^2]$. The magnetic susceptibility calculated by using the fit parameters is shown as the solid line in Fig. 3.

The magnetic exchange interaction through bridging BTD ligands is very weak. The J is slightly smaller than those of other Mn^{II} complexes bridged by terephthalate, isophthalate or *trans* butene diacid salt ligands ($J = -1.04 - -0.53$) [15,24].

Electrode process

The cyclic voltammogram of the title complex in CH_3CN containing 0.1 mol dm^{-3} TBAP is shown in Fig. 4. The oxidation of $[Mn_2(BIPY)_4(BTD)(H_2O)_2] \cdot (ClO_4)_2 \cdot 2H_2O$ at +0.14 V is assigned to two concident one-electron processes ($Mn_2^{III}/Mn^{III}\,Mn^{II}$ and $Mn^{III}\,Mn^{II}/Mn_2^{II}$) which is quasi-reversible. This is based on the following observations: the ratio of the cathodic-to-anodic peak currents, i_{pa}/i_{pc}, is not unity, the separation between the anodic and cathodic peak potentials, ΔE_p (125 mV), remains constant with increase of scan rate from 0.05 to 0.2 V/s, and the ratio of (peak current)/(scan rate)$^{1/2}$, $i_p/V^{1/2}$, is independent of the scan rate (0.05–0.2 V/s) [25].

Hydrogen peroxide disproportionation studies

Into a closed vessel containing the title complex (10 mg) and pyridine (1 cm^3), aqueous hydrogen peroxide (2.90 M, 1 cm^3, 2.90 mmol) was added and the mixture was stirred and thermostated at 13°C, and the O_2 evolved was measured volumetrically. The title complex in pyridine vigorously catalyze the disproportionation of H_2O_2. The time courses of the dioxygen evolution are shown in Fig. 5(a). During the first 30 s of the reaction, each molecular of the title complex on average disproportionated 250 molecules of H_2O_2. In addition we also examined the catalase activity of a mononuclear Mn^{III} complex, $[Mn^{III}(sal)(bipy)(H_2O)_2] \cdot (ClO_4) \cdot H_2O$, which was reported by us earlier [26] under the identical conditions and the results are shown in Fig. 5(b). During the first 30 s of the reaction, each molecule of the mononuclear complex on average disproportionated 22 molecules of H_2O_2. Obviously the title complex shows much higher catalase activity than the mononuclear complex. However, the reaction of either of the two complexes alone with H_2O_2 were very sluggish. As

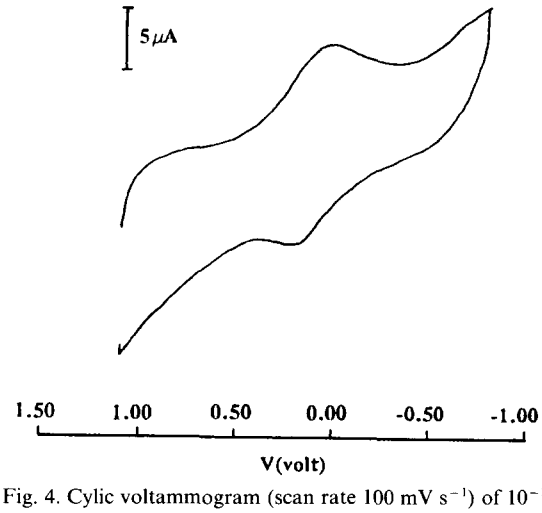

Fig. 4. Cylic voltammogram (scan rate 100 mV s^{-1}) of 10^{-3} M solutions of the title complex in CH_3CN (0.1 M TBAP) at a glassy-carbon electrode (298 K), and Ag/AgCl as a reference electrode.

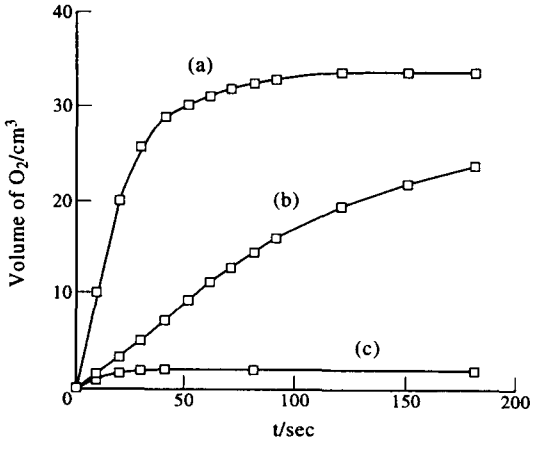

Fig. 5. Time course of O_2 evolution in H_2O_2 disproportionation by the title complex. (a) The title complex (10 mg, 8.9×10^{-3} mmol), with added pyridine (1 cm^{-3}); (b) the mononuclear complex (10 mg, 1.9×10^{-2} mmol), with added pyridine (1 cm^{-3}); (c) pyridine only. Conditions: H_2O_2 (2.9 M, 1 cm^3, 2.9 mmol), at 13°.

expected, the base pyridine by itself did not react with H_2O_2 (Fig. 5(c)). The above results show that the catalase-like activity of the two manganese complexes was greatly enhanced in the presence of pyridine base, and it is in agreement with literature reports [27]. Although the effects of added pyridine on the rate of disproportionation of H_2O_2 in the manganese-containing systems are indeed quite marked the exact role of the heterocyclic base in these catalytic reactions is unclear [28].

(Received 23 April 1997; accepted 20 June 1997)

Abstract—The TPPTS · Ln (Ln = Sc, Y, La, Nd, Sm, Gd, Ho; and TPPTS = tris (m-(sulfonatophenyl) phosphine) were synthesized from the precursor TPPTS · Na_3 and oxides of rare earth. The chemical composition of TPPTS · Ln was determined by elemental analysis and ICP-AES. The XPS showed that the sulfonate group in the complexes was coordinated with rare earth in a bridging tridentate manner. IR, Raman, ^{31}P NMR and TG-DTA graphs were recorded and discussed. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: synthesis; rare earth; water-soluble phosphine; TPPTS · Ln complex.

The use of trisulfonated triphenylphosphine trisodium salt P-(m-$C_6H_4SO_3$)Na_3 (TPPTS · Na_3) for the development of a water-soluble homogeneous catalyst has attracted a great deal of attention in recent years [1–6]. The well known aqueous-phase hydroformylation catalyst HRh(CO)(TPPTS · Na_3)$_3$, as reported by Kuntz [2], was utilized in industrial process [7]. Some other metal complexes based on TPPTS · Na_3 ligand as catalyst in various chemical process are also reported, such as the hydrogenation [8], the catalytic substitution of allylic substrates [9] and alkylation [10]. The water-soluble catalysts solved the problem of separating catalyst from the reaction media. Notably, a wide variety of coordination compounds with TPPTSNa_3 as a ligand has been reported by Herrmann *et al.* [1]. The cations of water-soluble phosphine (TPPTS) which were reported were Na^+, K^+ and R_4N^+ [11]. No literature about corresponding compounds which contained Ln^{3+} have been published up to now according to our knowledge. The trivalent rare earth metal ion (Sc^{3+}) can enhance the catalytic activity of the transition metal in formylation [12]. It is therefore considered that TPPTS can be used as a bridging ligand because the oxygen atoms of three sulfonic groups can coordinate with rare earths while the phosphorus atom can coordinate with transition metal. The complexes with bridging ligands TPPTS modified with rare earth ion (III) may be both water-soluble and highly active in some water-organic catalytic process.

More recently we have synthesized TPPTS · Ln · xH_2O compounds. The TPPTS · Ln with $NiCl_2$, $PdCl_2$, $RhCl_3$, respectively as a catalytic system were also investigated in the hydroformylation of 1-heptene. The TPPTS · Y with $RhCl_3$ and TPPTS · Ho with $NiCl_2$ demonstrated the more satisfactory results than TPPTS · Na_3 [13].

As a part of our series of works, this paper described the synthesis and properties of TPPTS · Ln · $8H_2O$ (Ln = Sc, Y, La, Sm, Nd, Ho). The composition of these complexes was characterized by elemental analysis, ICP-AES. The IR and Raman spectroscopes, XPS, TG-DTA and molar conductivity were also discussed.

EXPERIMENTAL

Starting materials

The rare earth oxides were obtained from Rare Earth Research Institute, Hunan, China. The purity

* Author to whom correspondence should be addressed.

of rare earth oxides is greater than 99.9%. TPPTS·Na_3 was synthesized according to the patent with some changes [2(a)]. 30 g triphenylphosphine (TPP) (0.113 mol) was added to the 250 ml fuming sulfuric acid (50 wt% SO_3) in an ice bath under argon and stirred vigorously. The reaction temperature was slowly allowed to increase to 20°C for 1 h. After 24 h at 22°C, the reaction solution was added slowly to 300 cm^3 chilled degassed water. The aqueous solution was neutralized by 50% NaOH with vigorous stirring under ice temperature. TPPTS·Na_3 was separated and purified according to the literature [14(a)]. The formula of TPPTS·Na_3 was P-(m-$C_6H_4SO_3Na)_3$·$4H_2O$. The yield of highly pure product was about 35%. IR spectra was consistent with the literature [3(a)]. The ^{31}P NMR appeared at −5.25 ppm. This confirms that the compound contained no corresponding oxide (^{31}P NMR, 34.8 ppm) [14].

Synthesis of the complexes

Air-sensitive materials were manipulated in an inert atmosphere using Schlenk techniques. TPPTS·Na_3 5 g was dissolved in about 10 cm^3 degassed water. The solution after treated with the acidic cationic-exchange column (80–120 mesh, $\phi 2 \times 40$ cm) was concentrated under vacuum to 25 cm^3. The concentrated solution stirred with rare earth oxides *ca* 1.5 g (excesses) at room temperature until the pH of the mixture was about 6–7 and filtered. The filtrate was evaporated under the vacuum. The residual solid was refluxed with 40 cm^3 absolute ethanol for 2 h under nitrogen. The mixture was filtered and the solid dried under vacuum. Yield is around 75%.

Chemical analysis

In order to avoid the interference between P and S, the contents of P, S and rare-earth cation were readily determined by ICP-AES (Inductively Coupled Plasma-Atomic Emission Spectrum), and the contents of C and H were obtained by the typical elemental analysis.

Spectroscopic and structural analysis

For IR analysis, a Nicolet 60 SXB FT-IR spectrometer was used (as KBr disks). The samples for Raman were analyzed in the solid state using the Nicolet 910 FT-Raman spectrometer fitted with a Nd : YAG 1.064 μm laser. The samples of TPPTS·Sc and TPPTS·Ho for XPS was dehydrated under dynamic vacuum at 190–200°C for 6 h and cooled to the room temperature under nitrogen. The XPS spectra were recorded on KRATOS (XSAM 800). ^{31}P NMR spectra were recorded on a JEDL JNM-90G spectrometer using 85% H_3PO_4 as internal standard. Shimadzu DT-40 was used for TG-DTA.

RESULTS AND DISCUSSION

Synthesis and properties

The formation of the TPPTS·Ln complexes by the reaction of the rare earth oxides with aqueous $TPPTSH_3$ occurs according to the following equation:

$$1/2Ln_2O_3 + TPPTSH_3 \xrightarrow[20\text{–}25^\circ C]{} TPPTS \cdot Ln + 3/2\,H_2O$$

$$Ln = Sc, Y, La, Nd, Sm, Gd, Ho$$

$$TPPTSH_3 = P\text{-}(m\text{-}C_6H_4SO_3H)_3$$

The tris(m-sulfonatophenyl) phosphine acid ($TTPTSH_3$) can be obtained from two methods. One is from the unneutralized aqueous reaction mixture of TPP with oleum. The other is from the pure TPPTS·Na_3 treated with acidic cation-exchange column. The acid $TPPTSH_3$ which was separated according to the first method was always a phosphonium sulfate with the formula $[HP\text{-}(m\text{-}C_6H_4SO_3H)_3]_2SO_4$ [15]. It cannot be adapted to prepare the corresponding rare earth complex because $Ln_2(SO_4)_3$ which formed due to an extra sulfate in the phosphonium sulfate was difficult to remove. The $TPPTSH_3$ from the second method was not thermally stable and readily oxidized, the temperature of reaction should not exceed 50°C and all manipulation must be carried out in an inert atmosphere.

The TPPTS·Ln·xH_2O complexes are more thermally stable as shown by DTA analysis. These complexes were pale yellow powders except that the TPPTS·Nd was pale violet and very soluble in water. The results of chemical analysis were given in Table 1. From these results the formula of these complexes were determined as P-(m-C_6H_4-$SO_3)_3$Ln·$8H_2O$. The water content in TPPTS·Ln complexes was higher than in usual rare earth complexes because of the highly hydrophilic properties of TPPTS·Ln. It was possible that these complexes absorbed water from air before chemical analysis.

Vibrational spectroscopy

Since these complexes had similar IR and Raman spectra, this indicated that TPPTS·Ln has a similar manner of coordination. The possible assignments of TPPTS·Na_3, TPPTS·Y and TPPTS·Sm which were chosen as representatives were given in Table 2.

The broad band at 3287 ~ 3454 cm^{-1} and the strong band near 1640 cm^{-1} in IR spectra of all complexes were assigned to ν_{OH} and δ_{HOH}, respectively. Comparison of IR and Raman spectra of TPPTS·Ln complexes with those of TPPTS·Na_3 showed that the stretching frequency of S—O in TPPTS·Na_3 appeared at 1206 cm^{-1} with a very strong band and at 1040 cm^{-1} with a broad band and deforming frequency at 623 cm^{-1} [14], while these bands of TPPTS·Ln were observed at 1170, 1037 and 617 cm^{-1}

respectively. The stretching frequency of C—S shifted from 799 cm^{-1} (in TPPTS · Na_3) to 810 cm^{-1}. It was clear that comparing with TPPTS · Na_3 the frequencies of $\nu_{S\text{-}O}$ and $\delta_{S\text{-}O}$ in TPPTS · Ln shifted to the lower frequencies and $\nu_{C\text{-}S}$ moved to the higher frequency. The asymmetric stretching peak of SO_3 groups in IR spectra of the TPPTS · Na_3 at around 1200 cm^{-1} split into 4 shoulder peaks and widened in TPPTS · Ln. All these shifts and changes of IR and Raman spectra as noted previously corroborated the geometric deformation brought about by coordination and are similar to those of $M(ClO_4)_3$ (M = Mn, Co, Ni ...) [16] and $Ln(CF_3SO_3)_3$ [17] complexes, in which ClO_4 and CF_3SO_3 are bridging tridentate. Namely the coordination of SO_3 induced a lengthening of the S—O bond and a shorting of the C—S bond.

The ^{31}P NMR spectra of TPPTS · La and TPPTS · Sm which were chosen as representatives were recorded. The single peak appeared at δ-6.20 ppm and δ-5.60 ppm, respectively. This indicated no corresponding oxides.

TG-DTA and molar conductivity

All complexes showed the similar TG-DTA graphs as typically given in Fig. 1 for TPPTS · $Sm8H_2O$. The TG curve indicated TPPTS · $Sm8H_2O$ weight-loss stages. TPPTS · $Sm8H_2O$ completely dehydrated at

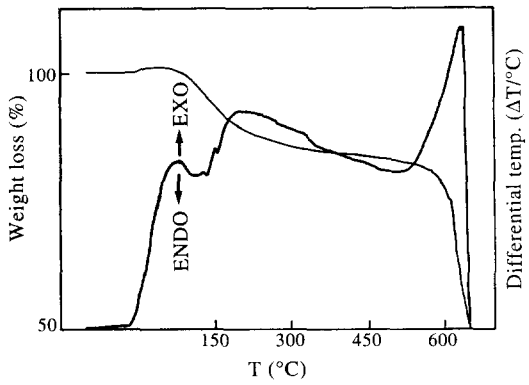

Fig. 1. Typical TG-DTA curves of TPPTS · Sm.

about 322°C (found: 18.32%; theo: 18.16%). This was consistent with the results of elemental analysis and ICP-AES. TG curve also indicated that TPPTS · Sm8H_2O lost five moles of crystalline water from 40 to 150°C (found 12.54%; theo: 12.18%), then lost three moles of coordinated water from 150 to 322°C. Therefore it was evident that only three moles of water are coordinated with the central rare earth ion. The TG-DTA showed that these complexes are stable to 425°C.

The molar conductivity of these complexes which were measured in water or in methanol were 3.0 ~ 4.5 S cm^{-2} mol^{-1} at 25°C. The very low conductivity indicated these complexes were non-electrolytes [18].

XPS studies

To get further insight into the nature of bonding, XPS of the TPPTS · Sc and TPPTS · Ho were recorded in powder form at room temperature. The results of XPS of TPPTS · Sc, TPPTS · Ho, TPPTS · Na_3 and Ln_2O_3 are given in Table 3. TPPTS · Sc (533.16 eV) and TPPTS · Ho (533.12 eV) with that of TPPTS · Na_3 (532.02 eV) showed that the oxygen in TPPTS · Sc and TPPTS · Ho tends to lose electron as a donator because of increase of the binding energy, and that Sc in TPPTS · Sc and Ho in TPPTS · Ho meanwhile tends to accept the electron as an acceptor because the binding energy of Sc^{2P} in TPPTS · Sc decreased from 401.9 eV (Sc^{2P} in Sc_2O_3) to 400.09 eV and Ho^{4d} in TPPTS · Ho decreased from 164.4 eV (in Ho_2O_3) to 162.87 eV. The oxygen 1 s peaks of the TPPTS · Sc is symmetric, which showed the oxygen atoms of TPPTS · Ln coordinated with the lanthanide ion in an identical form.

Table 3. Binding energy (eV) for TPPTS · Na_3, TPPTS · Sc, TPPTS · Ho and Ln in Ln_2O_3

Complexes	O^{1s}	S^{2p}	Ln in complexes	Ln in oxides
TPPTS · Na_3	532.02	168.45	—	—
TPPTS · Sc	533.16	168.63	400.09[a]	401.9[a]
TPPTS · Ho	533.12	168.76	162.87[b]	164.4[b]

[a] Sc^{2p}.
[b] Ho^{4d}.

From the results and previous analysis, it was proposed that the SO_3 groups in TPPRS · Ln complexes are bridging tridentate and that coordinating number of rare earth is 12 which contained three molecular coordinated water. The coordinating manner in TPPTS · Ln as we suggested previously is shown in following formula:

Ruthenium(II) bipyridine complexes with modified phenolic Schiff base ligands. Synthesis, spectroscopic characterization and Redox properties

Kripa Devi Keerthi, Bidyut Kumar Santra and Goutam Kumar Lahiri*

Department of Chemistry, Indian Institute of Technology, Powai, Bombay—400 076, India

(Received 14 April 1997; accepted 20 June 1997)

Abstract—A group of stable new ruthenium(II) mixed-ligand tris-chelated complexes of the type $[Ru(bpy)_2L]ClO_4$ (**1–6**), (bpy = 2,2′-bipyridine; L = deprotonated form of the HL ligands, *o*-(HO)—C_6H_3(R)C(R′)=N—CH_2—C_6H_5 or *o*-(HO)—C_6H_3(R)C(R′)=N—NH—C_6H_5; where R = H, *p*-NO_2 and R′ = H, CH_3) have been synthesized and characterized. The complexes are essentially diamagnetic and behave as 1 : 1 electrolytes in acetonitrile solution. They display two metal-to-ligand-charge-transfer (MLCT) transitions near 500 and 400 nm respectively and intra ligand π–π^* transitions in the UV-region. In acetonitrile solution the complexes exhibit weak emission from the lowest energy MLCT band at room-temperature. The quantum yields of the complexes are found to be in the range 0.0004–0.01. In acetonitrile solution the complexes show quasi-reversible ruthenium(II)–ruthenium(III) oxidation couples in the range 0.33 → 0.70 V and irreversible ruthenium(III)–ruthenium(IV) oxidations in the range 1.53 → 1.95 V vs SCE. Two successive reversible bipyridine reductions are observed for each complex in the ranges −1.4 → −1.62 V and −1.59 → −1.85 V vs SCE respectively. The presence of trivalent ruthenium in the oxidized solution for one complex **5** is evidenced by the rhombic EPR spectrum with *g* values, $g_1 = 2.389$, $g_2 = 2.081$ and $g_3 = 1.810$. The EPR spectrum of the coulometrically oxidized species, $\mathbf{5}^+$ has been analyzed to furnish values of axial ($\Delta = 4745\ cm^{-1}$) and rhombic ($V = 3692\ cm^{-1}$) distortion parameters as well as the energies of the two expected ligand field transitions ($v_1 = 3071\ cm^{-1}$ and $v_2 = 6819\ cm^{-1}$) within the t_2 shell. One of the ligand field transitions has been observed experimentally at 6578 cm^{-1} by near-IR spectrum which is close to the computed v_2 value. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: ruthenium; synthesis; spectra; redox; electronic structure.

The chemistry of ruthenium-bipyridine complexes has been the focus of continuous research activity since the discovery of their important redox, photophysical and photochemical properties [1]. Several ruthenium-bipyridine complexes have been exploited in solar energy schemes [2], in the oxidation of water to dioxygen [3], in the conversion of chloride ion to chlorine [4] and in the electrochemical reduction of acetylene to ethylene and ethane [5]. This has also been used to investigate photochemically induced charge-transfer [6], ligand substitution [7], stereochemical isomerization processes [8], and finally to probe important metal–ligand interactions [9]. In fact these properties have spurred the development of newer ruthenium bipyridine systems either by incorporating desired groups within the bipyridine moiety itself or by using other types of donor sites along with the $[Ru(bpy)_2]$ core to form mixed ligand tris-chelates to modulate the photo-redox activities of this class of complexes.

The present work originates from our interest to introduce phenolic Schiff base ligands (HL) having CH_2 or NH spacer [OH—C_6H_3(R)C(R′)=N—CH_2—C_6H_5 or OH—C_6H_3(R)C(R′)=N—NH—C_6H_5, Scheme 1] as a third ligand in the $[Ru(bpy)_2]$ core to prepare new mixed ligand ruthenium-bipyridine complexes of type $[Ru(bpy)_2L]$ to understand the

effect of newly inducted groups on the redox and spectroscopic properties of the $[Ru(bpy)_2]$ core system.

Herein we report the synthesis of six complexes of the kind having RuN_5O chromophore, their redox properties, spectroelectrochemical correlation, preliminary photophysical aspects and electronic structure of one of the electrogenerated trivalent congeners.

RESULTS AND DISCUSSION

Synthesis

Six phenolic Schiff base ligands used for the present study are abbreviated HL^1–HL^6 respectively. The ligands are primarily classified into two groups, HL^1–HL^3 (**A**) and HL^4–HL^6 (**B**) depending on the nature of the spacer (CH_2 or NH) present in between the imine nitrogen and phenyl ring and within each group the three ligands differing with respect to substituents present either on the phenolic ring or on the imine fragment (Scheme 1). The anionic form of the ligands (L^-) bind to the metal ion as bidentate N, O coordinators forming six membered chelate ring (**ML**) systems.

The complexes, $[Ru(bpy)_2(L)]^+$ (**1–6**) (bpy = 2,2′-bipyridine) have been synthesized from $[Ru(bpy)_2CO_3]$ following the general decarbonation synthetic route shown in eqn (1):

$$Ru(bpy)_2CO_3 + HL \xrightarrow[\Delta]{MeOH} [Ru(bpy)_2L]^+ + HCO_3^- \quad (1)$$

The red colored cationic complexes have been isolated as perchlorate salts and the crude products were purified by column chromatography using a silica gel column.

The microanalytical data of the complexes are shown in Table 1. The results are in very good agreement with the calculated values thus confirming the gross composition of the mixed ligand tris chelates $[Ru(bpy)_2L]ClO_4$ (**1–6**). The complexes exhibit 1 : 1 conductivity in acetonitrile solution (Π_M, 140–155 Ω^{-1} cm^2 M^{-1}). Solid state magnetic moment measurements at room temperature indicate that all the monocations (**1–6**) are essentially diamagnetic (t_{2g}^6, idealized, S = 0).

Spectral study

IR spectra. FTIR spectra of the complexes were recorded as KBr discs. The $\nu_{(C=N)}$ stretching frequency of the free ligands (HL) appears near 1630 cm^{-1} which has been shifted to 1600 cm^{-1} in accordance with the coordination of the azomethine function to the metal

ion [10]. The O—H stretch in the free ligands is observed as a prominent bond near 3400 cm^{-1}. This band is absent in the complexes as expected. A very strong and broad band near 1100 cm^{-1} and a strong and sharp vibration band near 630 cm^{-1} are observed for all the complexes due to the presence of ionic perchlorate.

^1H NMR spectra. ^1H NMR spectra of the complexes were recorded in $CDCl_3$ solvent using a 300 MHz instrument. The representative spectra of complexes **3** and **6** are shown in Fig. 1. The O—H proton of the free ligands appears as a broad peak near 14 ppm as expected [11]. The absence of OH proton of the free ligand (HL) in the spectra of the complexes suggests coordination through the phenolato oxygen. The methylene protons (—CH_2) appear as a singlet near 4.8 ppm for the free ligands (HL^1–HL^3), the same protons are observed for the corresponding complexes (**1–3**) as a doublet of doublet near 4.9 ppm (Fig. 1(a)). The —NH proton for the free ligands (HL^4–HL^6) appears near 5.5 ppm as a broad peak, whereas for the corresponding complexes (**4–6**) the same is observed as a triplet near 6.0 ppm due to the nitrogen nuclear spin ($I = 1$) (Fig. 1(b)).

The presence of asymmetric ligands L in the complexes make all the six aromatic rings inequivalent. The complexes **1, 2, 4, 5** and **3, 6** thus possess twenty-five and twenty-four non-equivalent aromatic protons respectively. Since the electronic environment of many aromatic hydrogen atoms are similar, their signals may appear in a narrow chemical shift range. In fact aromatic regions of the spectra are complicated due to the overlapping of several signals which has precluded the identification of individual resonances. However, the direct comparison of the intensity of the aromatic region proton signals with that of the clearly observable —CH_2 protons (δ, 4.9 ppm) for the complexes **1–3** reveal the presence of the expected twenty-five aromatic protons and one azomethine (CH=N) proton for the complex **1**, twenty-five aromatic protons for the complex **2** and twenty-four aromatic protons and one azomethine proton for the complex **3** (Fig. 1(a)).

Similarly the direct comparison of the intensity of the aromatic protons with that of the clearly observable —NH proton (δ, 5.8 ppm) reveals the presence of the calculated number of protons in the aromatic region for the complexes **3–6** (Fig. 1(b)).

Methyl (CH_3) protons for the complexes **2** and **5** have appeared as a singlet at 2.51 and 2.49 ppm respectively.

Electronic spectra. Solution electronic spectra of the complexes were recorded in acetonitrile solvent in the UV-visible region (200–700 nm). The spectral data are listed in Table 1 and the representative spectra are shown in Fig. 2. The presence of different acceptor levels in the complexes may be responsible for the observed multiple absorptions [12]. The complexes exhibit primarily two bands in the visible region near 500 nm and 400 nm respectively (Table 1).

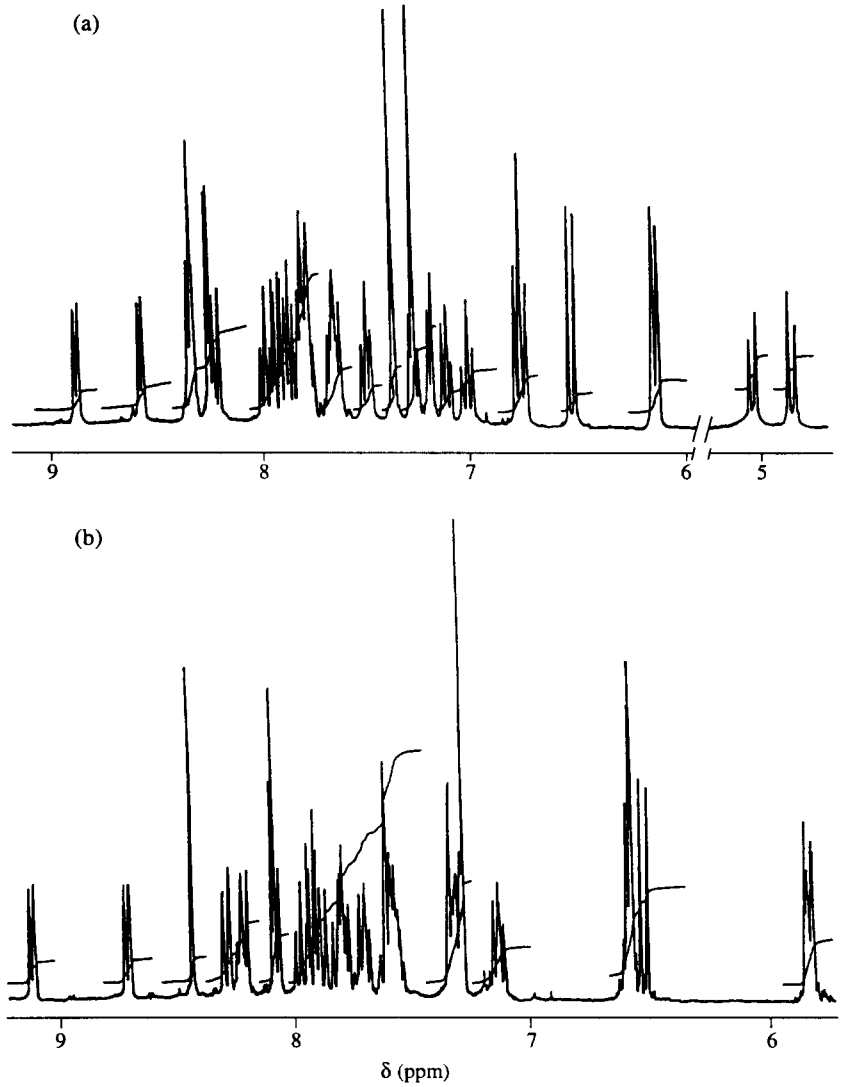

Fig. 1. ^{1}H NMR spectra of (a) $[Ru^{II}(bpy)_2L^3]ClO_4$, **3** and (b) $[Ru^{II}(bpy)_2L^6]ClO_4$, **6** in $CDCl_3$.

The origin of these two bands in the visible region has been assigned on the basis of reported spectra of $Ru(bpy)_2^{2+}$ complexes having other kinds of chelating third ligands [13]. Two different kinds of bipyridine acceptor levels, one symmetric (χ) and one antisymmetric (ψ) have developed with respect to the C_2 axis of bipyridine ligand and the transitions from metal filled $d\pi$ orbital to those two π^* orbitals result in the observed two MLCT bands. The lower energy band near 500 nm is considered to be $\pi(Ru) \rightarrow \pi^*(\psi)$ and the higher energy band near 400 nm may be due to $d\pi(Ru) \rightarrow \pi^*(\chi)$ transitions.

The higher energy bands in the UV-region are of intra-ligand (π–π^*) type or charge-transfer transitions involving energy levels which are higher in energy than the ligand lowest unoccupied molecular orbital (LUMO).

The lowest energy MLCT band of $[Ru(bpy)_3]^{2+}$ appears at 450 nm in acetonitrile solution [14]. Thus the replacement of one strong π-acidic symmetric bipyridine ligand by an asymmetric phenolato Schiff base ligand (L) in the complexes (**1–6**) decreases the energy of the same transition. Lower ligand field strength of the ligands L compared to the bipyridine ligand and the overall lowering of the molecular symmetry while going from $[Ru(bpy)_3]^{2+}$ to complexes **1–6** might be the probable reasons for the observed shift of MLCT band. The observed red shifts of the lowest energy MLCT bands for the complexes **3** and **6** (where nitro group is present in the ligands L^3 and L^4) as compared to $[Ru(bpy)_3]^{2+}$ are not as much as that of the other four complexes (**1, 2, 4, 5**) (Table 1).

Room temperature emission spectra. Emission properties of the complexes have been studied in acetonitrile solvent at room temperature. Excitations of the complexes in acetonitrile solution, at the top of

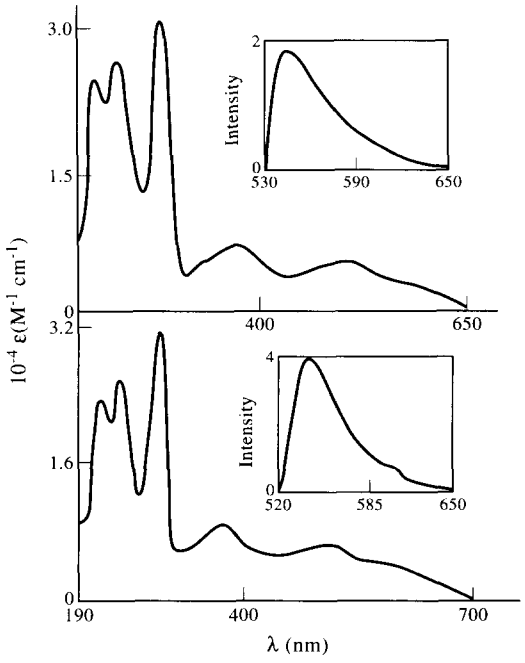

Fig. 2. Electronic spectra of (a) $[Ru^{II}(bpy)_2L^2]ClO_4$, **2** and (b) $[Ru^{II}(bpy)_2L^5]ClO_4$, **5** in acetonitrile. The insets show the emission spectra of the corresponding complexes at 298 K in acetonitrile.

the lowest energy MLCT bands (λ_{max}, near 500 nm for the complexes **1, 2, 4, 5** and near 480 nm for the complexes **3** and **6**) exhibit weak emissions near 550 nm (Table 2, Fig. 2). The origin of these emission spectra are further confirmed by the excitation spectra of the corresponding same solutions. Intensity of the observed emission spectra of the complexes under each class of ligands L, **A** and **B** follows the order **3** < **1** < **2** and **6** < **4** < **5** respectively. The complexes having keto based Schiff base ligands, **2** and **5** are exhibiting the strongest emissions and within the two classes of ligands, **A** and **B**, the complexes having ligands of type **B** (phenyl hydrazine derived Schiff base) are more effective from an emission point of view.

The quantum yields of the complexes are determined by comparison with the reported quantum yield of $[Ru(bpy)_3][PF_6]_2$ complex in acetonitrile solution ($\phi_{em,r} = 0.062$) [15]. For the calculation of quantum yield of the complexes, the excitation wave lengths are chosen such that the standard reference and sample absorptions are equal. The quantum yield of the emission process is calculated by following the reported method, eqn (2), where A_s, A_r are the absorption values of sample and reference, I_s, I_r are the emission intensities of sample and reference and n_s, n_r are the refractive indices of sample and reference.

$$\phi_{em,s} = \phi_{em,r}(A_r/A_s)(I_s/I_r)(n_s/n_r)^2 \quad (2)$$

Since A_s and A_r are equal and the refractive indices are assumed to be similar, eqn (2) can then be modified to eqn (3).

$$\phi_{em,s} = \phi_{em,r}(I_s/I_r) \quad (3)$$

The calculated quantum yields for the complexes are listed in Table 2. The quantum yields for the complexes **2** and **5** are much higher than the rest (Table 2).

Redox properties

Redox properties of the complexes have been studied in acetonitrile solution by cyclic voltammetry (CV) using a platinum working electrode. Complexes are electroactive with respect to metal as well as ligand centers and display four redox processes in the potential range +2 V vs saturated calomel electrode (SCE). Representative voltammograms are shown in Fig. 3 and the reduction potentials data are depicted in Table 3. The assignments of the responses to specific couples in Table 3 are based on the following considerations.

The ruthenium(III)–ruthenium(II) couple. All the complexes display one reversible oxidation process (Fig. 3) which is assigned to the metal oxidation, eqn (4). The one-electron nature of the responses is estab-

Table 2. Emission data[a]

lished by current height and constant potential coulometry data.

$$[Ru^{III}(bpy)_2L]^{2+} + e^- \rightleftharpoons [Ru^{II}(bpy)_2L]^+ \quad (4)$$

The presence of trivalent ruthenium in the oxidized solution is confirmed by characteristic rhombic EPR spectrum of the ruthenium(III) congener (see later). The formal potential of the couple (eqn 4) varies depending on the nature of ligands L. The complexes having phenyl hydrazine derived ligands L (**4–6**) are exhibiting lower reduction potentials compared to the corresponding complexes derived from benzylamine based ligands L (**1–3**) and within each class the reduction potential follows the order **3** > **1** > **2** and **6** > **4** > **5** respectively as expected. Thus a potential shift of maximum 300 mV has been observed in each class depending on the substituents present (Table 3), which implies the stability of the bivalent ruthenium in the case of NO_2 substituted ligand (L^3 or L^6) is more as compared to the others.

Under identical experimental conditions, the ruthenium(III)–ruthenium(II) reduction potential of $[Ru(bpy)_3]^{2+}$ appears at 1.29 V [13,14]. Thus substitution of one bipyridine ligand from the $[Ru(bpy)_3]^{2+}$ by a σ-donating phenolato Schiff base ligand, L, results in a decrease of ruthenium(III)–ruthenium(II) potential by 0.6–1 V depending on the particular R and R′ groups present in the ligands L. The reduction of overall charge of the complex cation from +2 in $[Ru(bpy)_3]^{2+}$ to +1 in the present complexes provides further electrostatic stabilization of the oxidized trivalent Ru^{III}—L species which has possibly originated from the σ-donor character of the phenolato group [16]. This decrease of metal oxidation potential (Ru^{II}–Ru^{III}) while going from $[Ru(bpy)_3]^{2+}$ to $[Ru(bpy)_2L]^+$ complexes and the reversible nature of the voltammograms (Fig. 3) suggests the possibility of isolating trivalent congeners of the complexes under the present mixed ligand tris chelated environment.

Although the ruthenium(II)–ruthenium(III) oxidation potentials for the present complexes are reasonably low, the oxidized trivalent congeners are not too stable to isolate (see later section).

[f] In acetonitrile solution.

Search for ruthenium(IV)–ruthenium(III) couple. The complexes exhibit a second irreversible oxidation process in the range 1.5–1.9 V vs SCE (Fig. 3). Although the current height of this irreversible process is ~1.5 times more than the previous one-electron process ($Ru^{III} \rightleftharpoons Ru^{II}$), the one-electron nature of this second oxidation process has been established with the help of the differential pulse voltammetry (Fig. 3). This second oxidation process could be due to either $Ru^{III} \rightarrow Ru^{IV}$ oxidation or oxidation of the coordinated ligand L. The potential difference between the two successive processes, in the range ~1.1–1.2 V, is comparable well with the reported observed potential difference between the two successive redox processes for the ruthenium center ($Ru^{II/III}$–$Ru^{III/IV}$) in mononuclear systems [17,10,16]. Since the free ligands (HL) do not show any redox activity within the specified potential range (±2 V), therefore it may be reasonable to consider the second irreversible oxidative process as ruthenium(III) → ruthenium(IV) oxidation.

Ligand reductions. The complexes display two successive reductions in the ranges −1.40 → −1.62 V and −1.57 → −1.85 V (Table 3, Fig. 3). The one-electron nature of these couples has been established by current height consideration. The observed two reductions are assigned to be due to the reductions of the coordinated bipyridine ligands. 2,2′-bipyridine is a well known potential electron-transfer center and each bipyridine can accept two electrons in one electrochemically accessible LUMO [18]. Since the complexes (**1**–**6**) have two bipyridine units, four one-electron reductions are therefore expected. However, in practice we have observed two reductions corresponding to eqns (5) and (6) within the ±2 V potential range.

$$[Ru^{II}(bpy)_2(L)]^+ + e^- \rightleftharpoons [Ru^{II}(bpy)(b\bar{p}y)(L)] \quad (5)$$

$$[Ru(bpy)(b\bar{p}y)(L)] + e^- \rightleftharpoons [Ru(b\bar{p}y)(b\bar{p}y)(L)]^- \quad (6)$$

The other expected two reductions could not be seen possibly due to solvent cut-off.

Spectroelectrochemical correlation. The lowest energy metal to ligand charge-transfer (MLCT) bands of the complexes (**1**–**6**) are observed in the range 510–475 nm (Table 1). The reduction potentials of the reversible ruthenium(III)–ruthenium(II) couple for the complexes and the first ligand reduction (reduction of the diimine fragment) have been detected in the ranges 0.33 → 0.70 V and −1.40 → −1.62 V vs SCE respectively. The lowest energy MLCT transition involves excitation of the electron from the filled t_{2g}^6 orbital of ruthenium(II) to the lowest π^* orbital of the bipyridine ligand (dominated by the diimine, —N=C—C=N— fragment). Now the associated energy of the MLCT band for each complex can be predicted from the experimentally observed electrochemical data by considering the following eqns (7) and (8) [19].

$$\nu_{MLCT} = 8065(\Delta E^0) + 3000 \quad (7)$$

$$\Delta E^0 = E^0_{298}(Ru^{III}/Ru^{II}) - E^0_{298}(L) \quad (8)$$

Here, E^0_{298} (Ru^{III}/Ru^{II}) and E^0_{298} (L) are the formal potentials (in V) of the ruthenium(III)–ruthenium(II) couple and the first ligand reduction respectively. The ν_{MLCT} is the frequency of the lowest energy MLCT transition (in cm^{-1}). The factor 8065 in eqn (7) is used to convert potential difference, ΔE from volt to cm^{-1} and the term 3000 cm^{-1} is of empirical origin. The calculated and experimentally observed ν_{MLCT} transition frequencies for the complexes are depicted in Table 3 and there is a linear relationship between the ν_{MLCT} and ΔE (Fig. 4). Here, the calculated values for all the complexes lie within the 900 cm^{-1} of the experimentally observed MLCT energies which are in very good agreement with the previously observed correlation in the other mixed ligand ruthenium bipyridine and other related systems [20].

Electrogeneration of trivalent ruthenium congener and distortion parameters. Chemical oxidation of the complexes (**1**–**6**) in acetonitrile solvent by aqueous cerric ammonium sulfate or cerrium(IV) in 0.1 M aqueous $HClO_4$ resulted initially in a green solution corresponding to the trivalent congener of the complexes and which then eventually decomposed to an unidentified product even at 273 K.

In order to trap the trivalent analogues of (**1**–**6**) we have tried to oxidize the complexes by a constant potential coulometric technique. Coulometric oxidations of the complexes at a potential 200 mV positive to the corresponding E_{pa} of Ru^{II}/Ru^{III} couple in acetonitrile solution at 273 K produced a green solution in all cases. The observed coulomb count corresponds to 1 e^- transfer for all the complexes (Table 3). The coulometrically oxidized species ($\mathbf{1}^+$–$\mathbf{6}^+$) are not stable enough to be isolated in pure solid state and this has precluded its further characterization.

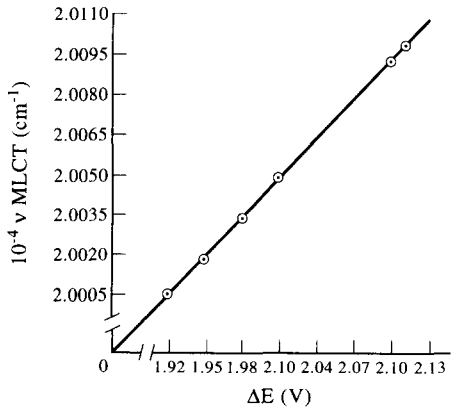

Fig. 4. Least squares plot of the lowest energy metal-to-ligand charge-transfer band (ν_{MLCT}, cm^{-1}) vs the difference in potential (ΔE, (V)) between the $Ru^{II/III}$ couple and the first bipyridine reduction.

However, in the case of complex 5^+ the situation is better to some extent which has allowed us to record the EPR and electronic spectrum of the oxidized species (5^+). X-band EPR spectrum of 5^+ is recorded by quickly freezing the green solution (liquid N_2). The rhombic nature of the spectrum (Fig. 5) at 77 K ($g_1 = 2.389$, $g_2 = 2.081$ and $g_3 = 1.810$) is characteristic of trivalent ruthenium(III) in a distorted octahedral environment (low-spin Ru^{III}, t_{2g}^5, $S = 1/2$) [21]. In the UV-visible region electronic spectrum of the oxidized complex, 5^+ shows one broad ligand to metal charge transfer (LMCT) band at 774 nm [11] and ligand based transitions in the UV region (Fig. 6).

The theory of EPR spectra of distorted octahedral low-spin d^5 (idealized t_{2g}^5, ground term $^2T_{2g}$) complexes are documented in literature [22,10,16,17,21]. The distortion of pseudo-octahedral complexes is expressed as the sum of axial (Δ) and rhombic (V) components. The t_2 orbital consists of the components $t_2(xy)$, $t_2^+(xz)$ and $t_2^-(yz)$. The degeneracy of t_2 orbital is partially removed by axial distortion (Δ), which placed t_2^0 (b) above t_2^+/t_2^- (e). The superimposed rhombic distortion (V) then further splits (e) into t_2^+ and t_2^-.

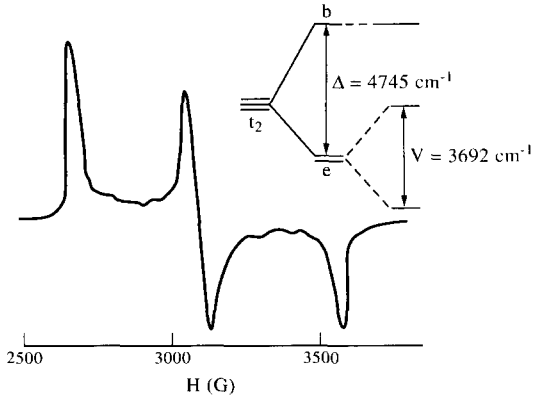

Fig. 5. X-band EPR spectrum and t_2 splittings of the coulometrically oxidized complex $[Ru^{III}(bpy)_2L^5]^{2+}$, 5^+ in acetonitrile solution at 77 K.

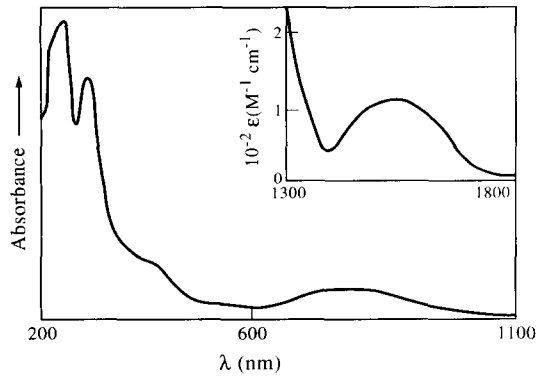

Fig. 6. Electronic spectrum of the coloumetrically oxidized complex $[Ru^{III}(bpy)_2L^5]^{2+}$, 5^+ in acetonitrile. The inset shows the electronic spectrum of 5^+ in the range 1300–1800 nm.

The distortion parameter (Δ and V) and the energies of two optical transitions (ν_1 and ν_2) from ground to upper Kramers doublets can be obtained from the analysis of EPR spectrum using the g tensor theory of low-spin d^5 ions.

The EPR spectrum provides only the absolute g values and so neither their signs nor the correspondence of g_1, g_2 and g_3 to g_x, g_y and g_z are known. There are forty-eight possible combinations based on the labelling (x, y, z) and signs chosen for the experimentally observed g values. For the present case we have chosen the combination $-g_1 > -g_2 > g_3$ as this particular set gives the reasonable value of orbital reduction factor, ($k < 1.0$). The value of k for all other combinations of g parameters does not fall within the limit ($k < 1.0$) and hence is rejected. The computed values of orbital reduction factor (k), axial distortion (Δ), rhombic distortion (V) and the two optical transitions (ν_1 and ν_2) for the complex, 5^+ are 0.606 cm^{-1}, 4745 cm^{-1}, 3692 cm^{-1}, 3071 cm^{-1} and 6819 cm^{-1} respectively. The spin-orbit coupling constant (λ) of the ruthenium(III) is taken as 1000 cm^{-1} [22].

The computed ν_2 band has been observed experimentally by near IR spectrum in the expected position, 6578 cm^{-1} (ε, M^{-1} cm^{-1}, 110) (Fig. 6). In view of the involved approximation in the theory, the agreement between the experimentally observed ν_2 and the calculated ν_2 band value is excellent [23]. Due to instrumental limitation (maximum wavelength scan up to 2200 nm) it has not been possible to compare the ν_1 band. Here axial distortion (Δ) is ~ 1.3 times more than the rhombic (V) distortion.

CONCLUSIONS

We have thus observed the effect of the presence of phenolic Schiff base ligands having CH_2 or NH spacer (**A** or **B**) as a third ligand in the $[Ru(bpy)_2]$ core with respect to redox and photophysical aspects. The presence of both the classes of ligands (**A** and **B**) in the complexes (**1**–**6**) facilitate the successive ruthenium(II) $\rightleftharpoons$ ruthenium(III) and ruthenium(III) $\rightarrow$ ruthenium(IV) oxidations and make the complex environment susceptible to undergo room temperature emission from the lowest energy metal-to-ligand-charge-transfer (MLCT) band. In general, the complexes (**4**–**6**) having the third ligand with NH spacer (Class **B**), are more effective than the ligands with CH_2 spacer (Class **A**) from the emission point of view and in particular ketone based third ligands (L^2 and L^5) in both the classes (**A** and **B**) are more suitable with respect to emission efficiency. In addition, correlations between the energies of the lowest MLCT absorption bands and the electrochemical redox potentials of the complexes follow an excellent linear

relationship in accordance with the other $Ru(bpy)_2L$ systems.

EXPERIMENTAL

Materials

Commercial ruthenium trichloride (S.D. Fine Chemicals, Bombay, India) was converted to $RuCl_3 \cdot 3H_2O$ by repeated evaporation to dryness with concentrated hydrochloric acid. The *cis*-$[Ru(bpy)_2CO_3]$ was prepared according to the reported procedure [24]. 2-hydroxy-5-nitrobenzaldehyde, benzylamine and 2-hydroxyacetophenone were obtained from Aldrich, U.S.A. Other chemicals and solvents were reagent grade and used as received. Silica gel (60–120 mesh) used for chromatography was purchased from S.D. Fine Chemicals, Bombay, India. For spectroscopic and electrochemical studies HPLC grade solvents were used. Commercial tetraethylammonium bromide was converted to pure tetraethyl ammonium perchlorate (TEAP) by following an available procedure [25].

Physical measurements

Solution electrical conductivity was checked using a Systronic conductivity bridge, 305. Electronic spectra (700–200 nm) were recorded using a Shimadzu UV 265 spectrophotometer. Near IR spectrum was recorded by using a Hitachi 330 spectrophotometer. Infrared (4000–400 cm^{-1}) spectra were taken on a Nicolet spectrophotometer with samples prepared as KBr pellets. Magnetic susceptibility was checked with a PAR vibrating sample magnetometer. ^1H NMR spectra were obtained with the use of a 300 MHz Varian FT-NMR spectrometer. Cyclic voltammetric measurements were carried out using a PAR model 362 scanning potentiostat electrochemistry system. A platinum wire working electrode, a platinum wire auxiliary electrode, and an aqueous saturated calomel reference electrode (SCE) were used in a three-electrode configuration. TEAP was the supporting electrolyte and the solute concentration was $\sim 10^{-3}$ M. The half wave potential E^0_{298} was set equal to 0.5 $(E_{pa} + E_{pc})$, where E_{pa} and E_{pc} are anodic and cathodic cyclic voltammetric peak potentials respectively. The scan rate used was 50 mV s^{-1}. The coulometric experiments were done with a PAR model 370-4 electrochemistry apparatus incorporating a 179, digital coulometer. A platinum wire gauze working electrode was used in coulometric experiments. All experiments were carried out under dinitrogen atmosphere and are uncorrected for junction potentials. EPR measurement was made with a Varian model 109 E-line X-band spectrometer fitted with a quartz dewar for measurements at 77 K (liquid nitrogen). The spectrum was calibrated by using tetracyanoethylene (TCNE) ($g = 2.0037$). The elemental analyses were carried out with a Carlo Erba (Italy) elemental analyzer. Solution emission properties were checked using a SPEX-fluorolog spectrofluorometer.

CAUTION! Perchlorate salts of metal complexes are generally explosive. Care should be taken while handling such complexes.

Treatment of EPR data

An outline of the procedure can be found in our recent publications [16].

Synthesis of ligands and complexes

The ligands HL^1–HL^3 and HL^4–HL^6 were prepared by condensing benzylamine and phenylhydrazine respectively with appropriate 2-hydroxyaldehydes and ketone at 273 K in methanol solvent.

The complexes (**1–6**) were achieved using general methods. Yields varied in the range 70–75%. Specific details are given for one representative case.

Bis(2,2′-bipyridine)(N-benzyl salicylideneimine) ruthenium(II) perchlorate $[Ru(bpy)_2L^1]ClO_4$ (**1**). $Ru(bpy)_2CO_3$ (200 mg, 0.42 mmol) was dissolved in 20 cm^3 of methanol and heated to reflux for 10 min. To this solution the ligand HL^1 (173 mg, 0.84 mmol) was added. The resulting mixture was heated to reflux over a period of 5 h. The initial violet solution gradually turned to a red color. The progress of the reaction was monitored periodically by TLC. The volume of the solvent was then reduced under reduced pressure and the concentrated solution was treated with an excess of saturated aqueous sodium perchlorate solution. The dark red colored precipitate thus obtained was collected by filtration and washed thoroughly with cold methanol and a little ice-cold water. The solid mass was then dried *in vacuo* over P_4O_{10}.

The crude product was then purified by column chromatography on a silica gel (60–120 mesh) column. Unreacted excess ligand was eluted first with benzene and was rejected. The pure complex was eluted with a 2:1 ratio of benzene and acetonitrile solvents. On removal of the solvent mixture under reduced pressure fine crystalline complex $[Ru(bpy)_2(L^1)]ClO_4$ was obtained. Yield: 75%.

Synthesis and characterisation of copper(II) complexes derived from methylene bridged bis(tridentate) ligands

P. Kamatchi and M. Kandaswamy*

Department of Inorganic Chemistry, School of Chemistry, University of Madras, Madras-25, India

(Received 23 April 1997; accepted 19 June 1997)

Abstract—New methylene bridged bis(tridentate) binucleating ligands, bis[2-hydroxy-5-chloro{(4-methyl-piperazin-1-yl)methyl} phenyl]methane (L^1H_2), bis[2-hydroxy-3-{(1-imino-*N*,*N*-dimethyl aminopropyl)ethyl}-5-chlorophenyl]methane (L^2H_2) and bis[2-hydroxy-3-{(1-imino-*N*,*N*-diethylaminopropyl)ethyl}-5-chloro-phenyl] methane (L^3H_2) and their copper(II) complexes have been synthesised and reported. These complexes have been characterised by elemental analysis, electronic and ESR spectroscopy. The binuclearity of these complexes were confirmed by FAB mass spectroscopy. Electrochemical studies of the complexes suggested that the reduction processes are quasi-reversible single step two electron transfer $Cu^{II}Cu^{II}/Cu^{I}Cu^{I}$ at negative potentials (−0.2 to −0.6 V). The magnetic moment μ_{eff} (per Cu) for these complexes at 298 K are found in the range 1.71 to 1.83 B.M. Variable temperature magnetic susceptibility measurements revealed the absence of exchange coupling between Cu^{II} centres. ESR spectra of these complexes at liquid nitrogen temperature (77 K) are similar to mononuclear copper(II) complex with nuclear spin 3/2. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: binucleating ligands; bistridentate ligands; copper(II) complexes; hexadentate ligands; binuclear copper(II) complexes; electrochemical studies.

The synthesis of multidentate ligands have attracted considerable attention in recent years [1–7]. This interest has arisen because such ligands can accommodate two metal centres and thus may provide the basis of models for the active sites of biological systems [8–10], and serve as multi-metal-centred catalysts [7d,11]. The development of multidentate ligands [12–15] through various approaches has led to the successful synthesis of homo and heterobinuclear metal complexes [7c,d,16,17].

Several series of complexes utilise ligands that hold the metals in close fixed arrangements, as in the case of molecular A-frames [18], cofacial diporphyrins [19], side-by-side macrocycles [20], and macrocyclic inclusion complexes [14,21]. A different series of complexes utilise more flexible ligands, which provide a less restricted environment for a second metal centre relative to the first metal. Examples for this series of complexes include wishbone complexes [22], earmuff complexes [23] and other similar complexes [24]. The ligands containing two remote multidentate donor sets separated by rigid [22a] or flexible [2,4,25] bridges form binuclear complexes. In these complexes metal ions are held at a sufficiently long distance such that the two sets of donor groups could not coordinate to the same metal ion. Earlier reports on binuclear Cu^{II} complexes of remote donor set ligands linked *via* phenyl, biphenyl [26,27] and pyrazine [6,7a] groups show a considerable amount of antiferromagnetic interaction between the two Cu^{II} centres.

In this paper we report the syntheses of bis(tridentate) binucleating ligands by introducing sp^3 carbon (—CH_2— group) between the 1,1′sp^2 carbons of the phenyl rings containing the tridentate moieties. The binuclear copper(II) complexes using these ligands were synthesised and characterised. The elec-

tro-chemical and magnetic properties of these complexes were investigated.

EXPERIMENTAL

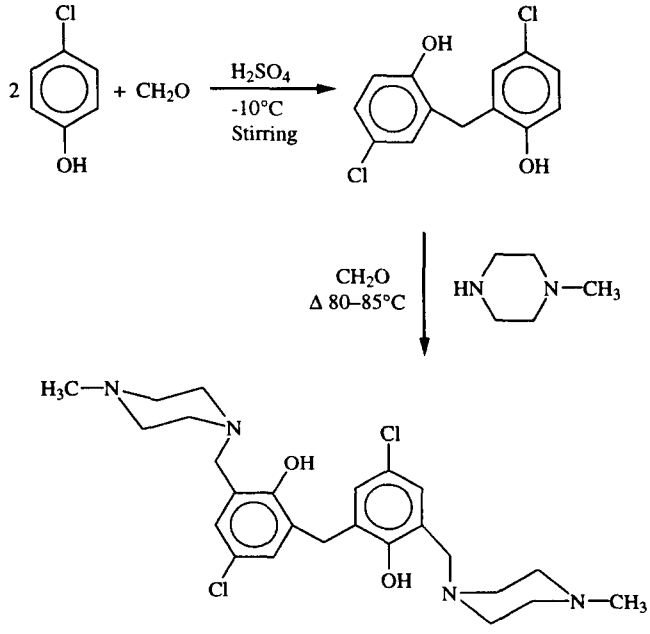
Physical measurements

Elemental analyses were carried out with a Heraeus-CHN-Rapid Analyser, ^{1}H NMR spectra were recorded using a 90 MHz spectrometer (model EM 390) and IR spectra were recorded on a Shimadzu IR-408 spectrometer using KBr discs. Electronic spectra were recorded on a Hitachi-320 spectrophotometer. The FAB mass spectra were recorded on a Jeol SX 102/DA-6000 mass spectrometer. The X-ray diffraction study of the ligand L^1H_2 was carried out on an Enraf-Nonius CAD-4 diffractometer using graphite-monochromatised Cu-K_α radiation in the range $0 < 2\theta < 140$. Variable temperature (77–298 K) magnetic susceptibility measurements were performed on the Princeton Applied Research Model-155 vibrating sample magnetometer operating at 5000 gauss and calibrated with metallic nickel supplied with the instrument. ESR measurements were carried out using a Bruker ER-200D-SRC spectrometer. Electrochemical measurements were carried out using an apparatus comprising of a PAR model-175 universal programmer, model-173 potentiostat/galvanostat, Model-176 current follower and Model-179 coulomb/ampere hour meter (EG & G Ltd.) and Hitachi (057) Perkin-Elmer X–Y recorder. Platinum foil was used both as working and counter electrodes and Ag/AgCl as the reference electrode. TBAP was used as the supporting electrolyte (0.1 M) and all the solutions were around 10^{-3} M concentration.

Materials

Methanol (AR) and DMF (HPLC grade) were obtained from SD Fine Chemicals. Tetrabutylammonium perchlorate was obtained from Fluka and was recrystallised from methanol. 2,2′-dihydroxy-5,5′-dichlorodiphenylmethane was synthesised by the literature method [25]. All other chemicals and solvents were of reagent grade and were used as received. Distilled ethanol was used for the syntheses.

1. *Synthesis of bis*[2-*hydroxy*-5-*chloro*{(4-*methylpiperazin*-1-*yl*)*methyl*}*phenyl*]*methane* (L^1H_2). The ligand, L^1H_2, was synthesised by mixing 2,2′-dihydroxy-5,5′-dichlorodiphenylmethane (6.725 g, 0.025 mol) and *N*-methyl piperazine (5.75 g, 0.057 mol) in 75 cm^3 ethanol. Formaldehyde (35%, 6.25 ml, 0.066 mol) was added slowly with stirring (Scheme 1). The mixture was then heated to reflux on a water bath for 24 h with 1 cm^3 addition of formaldehyde at each 8 h interval. Finally, ethanol was removed *in vacuo* and the resulting oil was washed with saturated aqueous sodium carbonate solution, extracted with diethyl



L^1H_2 Bis [2-hydroxy-5-chloro {(4-methylpiperazin-1-yl) methyl} phenyl] methane

Scheme 1.

ether and evaporated at room temperature. The white product obtained was recrystallised from hot methanol. Yield: 9 g (73%), m.p.: 162°C. (Found: C, 60.79; H, 6.92; N, 11.40. Calc. for $C_{25}H_{34}N_4O_2Cl_2$: C, 60.85; H, 6.90; N, 11.36%.) ^{1}H NMR spectrum ($CDCl_3$): δ 6.7–6.9 (d, 4H, aromatic CH), δ 3.9 (s, 2H, Ar—CH_2—Ar), δ 3.6 (s, 4H, benzylic CH_2), δ 2.5 (s, 16H, NCH_2) and δ 2.2 (s, 6H, NCH_3); IR spectrum (KBr disc): 3050 cm^{-1} (phenolic OH), 2850 cm^{-1} (NCH_2) and 1450 cm^{-1} (aromatic skeleton); mass spectrum: m/z 494 ($m+1$).

Synthesis of precursor compounds

2. *Synthesis of 2,2′-diacetoxy-5,5′-dichlorodiphenylmethane.* The compound 2,2′-dihydroxy-5,5′-dichlorodiphenylmethane (10 g) was dissolved in 100 cm^3 of acetic anhydride and a catalytic amount of conc. H_2SO_4 was added. The solution was refluxed in an oil bath for 1 h, poured into ice-cold water and extracted with diethyl ether. The ethereal phase was washed with sodium bicarbonate solution (5%, 200 cm^3) and distilled water (100 cm^3), treated with active charcoal and dried over anhydrous sodium sulphate. By evaporation of the filtrate to dryness a white solid was obtained. The crude was recrystallised from hot ethanol. Yield: 8.5 g (65%), m.p.: 100°C.

3. *Synthesis of 2,2′-dihydroxy-3,3′-diacetyl-5,5′-dichloro diphenylmethane* (P.C.−1). Anhydrous aluminium trichloride (15 g, 0.112 mol) was heated in an oil bath at 140°C for 5 min and the compound 2,2′-diacetoxy-5,5′-dichlorodiphenylmethane (5 g, 0.02 mol) was added with stirring. The temperature was allowed to rise to 170–180°C and maintained for 20 min. After cooling, the compound was added to 200 cm^3 of 2N HCl. The insoluble material was filtered, washed with water and dried. The crude product was recrystallised from hot ethanol to give pale green needle shaped crystals. Yield: 3.5 g (70%), m.p.: 203°C. ^{1}H NMR spectrum: δ 7.6–7.4 (d, 4H, aromatic CH), δ 4 (s, 2H, Ar—CH_2—Ar), δ 2.62 (s, 6H, acetyl CH_3). IR spectrum (KBr disc): 3150 cm^{-1} (phenolic OH), 1640 cm^{-1} (C=O), 1450 cm^{-1} (aromatic skeleton).

Synthesis of copper(II) complexes

Synthesis of complexes (**1a–1d**). *Synthesis of* $[Cu_2L^1(ClO_4)_2]\cdot 2H_2O$ (**1a**). The ligand L^1H_2 (1.64 g, 3.3 mmol) and lithium hydroxide (0.28 g, 6.6 mmol) was dissolved in ethanol. Two equivalents of $Cu(ClO_4)_2\cdot 6H_2O$ (2.5 g, 6.6 mmol) in ethanol was added to the above solution and refluxed. The solution was filtered when hot, allowed to cool to room temperature and left as such. After a few days the dark green colour product formed was filtered, washed with water, dried and recrystallised from ethanol. Yield: 2 g (70%).

The same procedure was adopted to prepare other complexes (**1b–1d**) by varying the copper(II) salts.

Synthesis of complexes (**2a–3d**). *Synthesis of* $[Cu_2L^2(ClO_4)_2]\cdot 2H_2O$ (**2a**). The mixture of 2,2′-dihydroxy-3,3′-diacetyl-5,5′-dichlorodiphenylmethane (0.624 g, 2 mmol) with 3-di-methylamino-1-propylamine (0.7 cm^3, 4 mmol) in ethanol was refluxed for 1 h to obtain a clear yellow-orange solution. Then two equivalents of copper perchlorate hexahydrate (1.55 g, 4.2 mmol) in ethanol was added and refluxed for 6 h and filtered. The green colour product was filtered and washed with chloroform to remove unreacted ketones. The solid was recrystallised from ethanol. Yield: 1 g (62%).

The above procedure was adopted to prepare other complexes (**2b–3d**) by varying the amine as well as copper(II) salts (Scheme 2).

RESULTS AND DISCUSSION

The ligand L^1H_2 is made by the Mannich reaction of one equivalent of 2,2′-dihydroxy-5,5′-dichlorodiphenylmethane, two equivalents of *N*-methylpiperazine in the presence of formaldehyde (35%) in ethanol medium. The ligand was characterised by elemental analysis, ^{1}H NMR, IR, mass spectroscopy and X-ray crystallographic methods. The orientation of two tridentate moieties bridged through the methylene group has been identified from the ORTEP diagram [28] of Fig. 1.

Copper(II) complexes

The syntheses of copper(II) complexes (**1a–1d**) were achieved by the reaction of one equivalent of ligand L^1H_2 and two equivalents of copper salts in ethanol medium. To synthesise the complexes (**2a–3d**), first the ligands L^2H_2 and L^3H_2 were prepared *in situ* by condensation of one equivalent 2,2′-dihydroxy-3,3′-diacetyl-5,5′-dichlorodiphenylmethane and two equivalents of 3-dialkylamino-1-propylamine in ethanol, followed by the addition of two equivalent of copper(II) salts in ethanol to the reaction mixture.

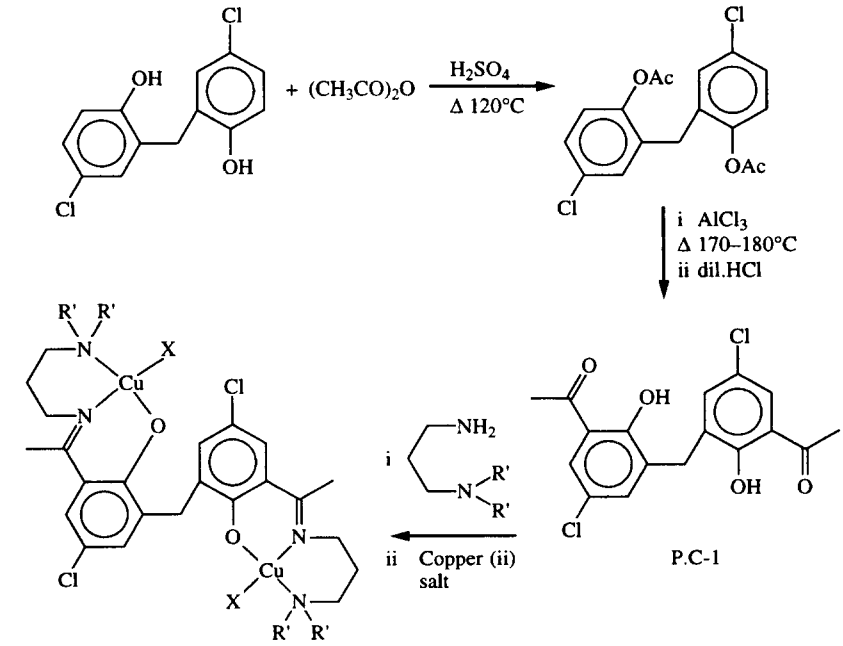
Elemental analysis of these compounds are consistent with the theoretical values (Table 1). These complexes were found to have the composition $[Cu_2L(X_2)]\cdot nH_2O$ where X = ClO_4, OAc, Cl, Br and L = binucleating ligands.

FAB mass spectra

The positive-ion FAB mass spectra of complexes **1b, 2a** and **3b** show peaks corresponding to dipositive binuclear core $[Cu_2L]^{2+}$. Peaks corresponding to various mass units are given in Table 2. The FAB mass spectrum of complex **2a** is given in Fig. 2.

Spectral and magnetic studies

The IR spectra of these complexes show that a broad band around 3300–3500 cm^{-1} can be attributed



$[Cu_2L^2X_2]$; R', R' = CH_3

$[Cu_2L^3X_2]$; R', R' = C_2H_5

X = ClO_4, OAc, Cl, Br

P.C-1 2, 2'-dihydroxy-3, 3'-diacetyl-5, 5'-dichlorodiphenylmethane

[a] Relative to base peak.

to the coordinated water molecules present in the complexes. The formation of the Schiff base is confirmed [29,30] from the band around 1580–1600 cm^{-1} corresponding to the C=N stretching vibration and is lower than the vibrational frequency of the C=O group of the precursor compound for which the stretching vibration is observed at 1640 cm^{-1}. The IR spectra of perchlorato complexes show splitting of ν_3 mode at 1100 cm^{-1} corresponding to weakly coordinated ClO_4^- anion in the solid state [31,32]. For acetato complexes the stretching vibration observed around 1615–1620 cm^{-1} is due to the acetate anion [33]. The band observed around 1520–1540 cm^{-1} for all the complexes (**2a–3d**) has been assigned to (C⋯O) of phenol [34].

Electronic spectra of these complexes were recorded in DMF solvent. The UV-vis spectral data for the complexes are given in Table 3. The d–d transitions are observed for perchlorato complexes around 630–660 nm, acetato complexes around 640–660 nm, chloro complexes around 660–740 nm and bromo complexes around 660–750 nm. On comparing with perchlorato and acetato complexes the corresponding chloro or bromo complexes exhibit λ_{max} at lower energy regions. This may be due to the deviation of metal ions from their square-basal coordination plane upon halide ion coordination [35]. The high energy transition located around 350–460 nm are attributed to ligand-to-metal charge transfer transition. The other high energy transition observed in the range 260–290 nm is assigned to the intraligand transition [36].

The ESR spectrum of complex (**1b**) was recorded in frozen DMF solution at liquid nitrogen temperature (77 K) and is shown in Fig. 3. This ESR spectrum is similar to a mononuclear Cu^{II} complex [37,38] with nuclear spin 3/2 ($g_\perp = 2.03$, $A_\parallel = 175$ G (1 G = 1×10^{-4} T) and $g_\parallel = 2.2$); three of four expected hyperfine signals are seen, with the fourth being hidden under the $g_\perp$ line. The effective magnetic moments, μ_{eff} (per Cu), of these complexes were measured and found in the range 1.71–1.83 B.M. at 298 K. Variable temperature magnetic susceptibility measurements (77–298 K) show absence of exchange coupling between Cu^{II} centres. This is due to the discontinuity in the electron delocalisation of two phenyl rings by the sp^3 carbon of the methylene group [5,27].

Cyclic voltammetric studies

The electrochemical property of all the complexes (**1a–3d**) were studied by cyclic voltammetry. The electrochemical data such as cathodic peak potential (E_{pc}), anodic peak potential (E_{pa}), peak separation (ΔE_p) and redox potential $E_{1/2}$ are given in Table 4. Cyclic voltammogram of complexes **1b** and **3d** recorded in dmf are given in Fig. 4.

In the cathodic potential range 0 to −1.3 V all the

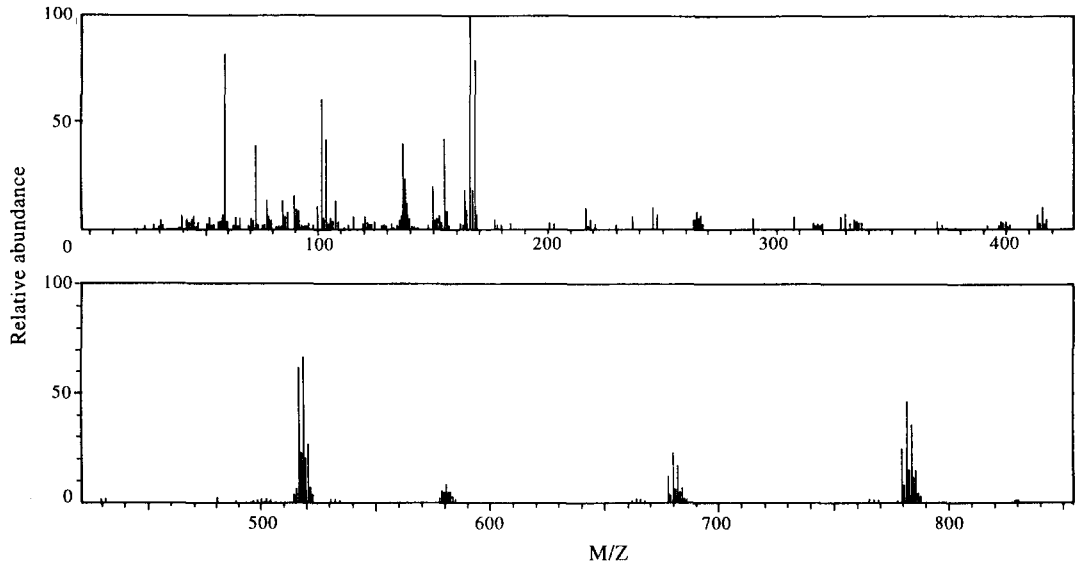

Fig. 2. Positive-ion FAB mass spectrum of complex $[Cu_2L^2(ClO_4)_2] \cdot 2H_2O$ (**2a**) in m-Nitrobenzyl alcohol at room temperature with accelerating voltage 10 kV.

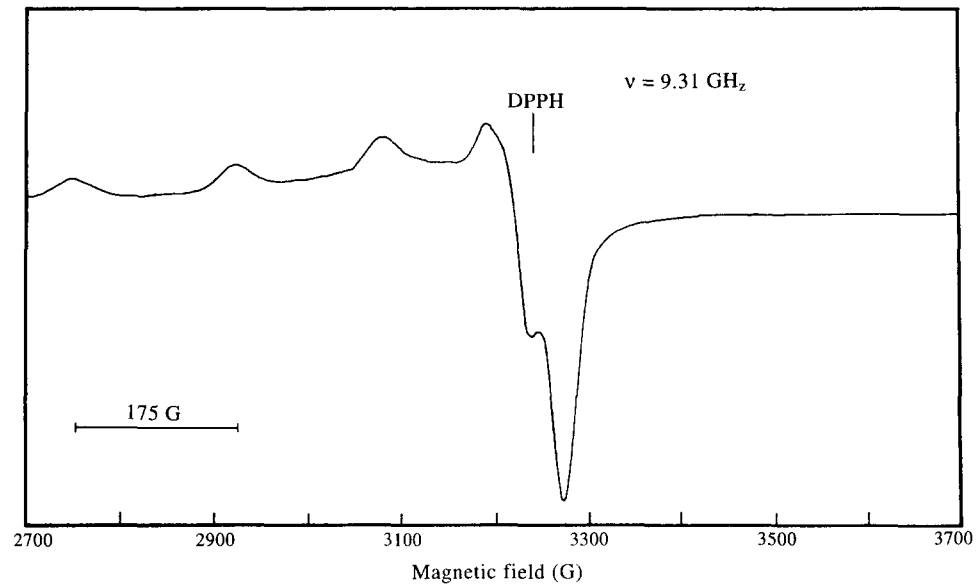

Fig. 3. ESR spectra of complex $[CuL^1(OAc)_2] \cdot 2HO$ (**1b**) determined in DMF at 77 K.

complexes exhibit two quasi-reversible charge transfer steps at different potentials. The quasi-reversible reduction of the complexes is evident from the following observations; $E_{1/2}$ values were independent of scan rate, ΔE_p values vary with the scan rate and these values were found to be more than 60 mV/sec and the ratio of cathodic and anodic currents were not equal. In all the complexes the well defined peaks, observed in the potential range -0.2 to -0.6 V were due to the reduction of $Cu^{II}Cu^{II}$ to $Cu^{I}Cu^{I}$. Coulometric experiments conducted at constant potentials (-0.62 V; slightly higher than the first reduction potential) indicate the consumption of two electrons per molecule. The second ill-defined waves observed in the potential range -0.7 to -1.2 V are due to the reduction of $Cu^{I}Cu^{I}$ to $Cu^{0}Cu^{0}$. This is evident from the deposition of reduced copper on the electrode surface. Based on the observations, it is reasonable to suggest that the reduction process may involve the following steps:

Table 3. Electronic spectral data for the complexes (in dmf)

Name of the complexes	λ_{max}(nm) (ε, $dm^3\ mol^{-1}\ cm^{-1}$) Charge transfer band	d–d band
1a	290 (13780), 438 (1510)	640 (260)

$$Cu^{II}Cu^{II} \underset{E^1_{pa}}{\overset{E^1_{pc}}{\rightleftharpoons}} Cu^{I}Cu^{I} \underset{E^2_{pa}}{\overset{E^2_{pc}}{\rightleftharpoons}} Cu^{0}Cu^{0}$$

For perchlorato complexes the first reduction takes place in the potential range −0.26 to −0.29 V, acetato complexes in the range −0.23 to −0.36 V, chloro complexes in the range −0.44 to −0.58 V and bromo complexes in the range of −0.46 to −0.53 V. For perchlorato and acetato complexes the observed first reduction potentials are in the range −0.23 to −0.36 V and for chloro and bromo complexes −0.44 to −0.53 V. The higher reduction potential for chloro and bromo complexes are due to the change in the nature and number of coordinating atoms [38–40].

SUMMARY

Binucleating bis(tridentate) ligands and their copper(II) complexes were synthesised. These complexes were characterised by elemental analysis, IR, and UV-vis spectroscopy. ESR spectra of these complexes are similar to the mononuclear Cu^{II} complex with nuclear spin 3/2. The magnetic moment μ_{eff} (per Cu) of these complexes were measured and found in the range 1.71–1.83 B.M. at 298 K. In the potential range −0.2 to −0.6 V all these complexes undergo quasi-reversible two-electron single-step reductions ($Cu^{II}Cu^{II}/Cu^{I}Cu^{I}$) at the same potential.

(Received 21 July 1997; accepted 17 October 1997)

Abstract—Treatment of $[MBr_2(CO)_3(NCMe)_2]$ (M = Mo or W) with a slight excess of $RS(CH_2)_2SR$ (R = Ph, C_6H_4F-4) in CH_2Cl_2 at room temperature gave the acetonitrile displaced products $[MBr_2(CO)_3\{RS(CH_2)_2SR\text{-}S,S'\}]$. The complex with M = W, R = Ph was crystallographically characterised and has a distorted capped octahedral geometry with one carbonyl group in the capping position, two carbonyls and one sulfur atom in the capped face, and one sulfur and two bromines in the uncapped face. Reaction of $[WBr_2(CO)_3(NCMe)_2]$ with two equivalents of $RS(CH_2)_2SR$ in CH_2Cl_2 at room temperature gives the cationic complexes $[WBr(CO)_3\{RS(CH_2)_2SR\text{-}S\}\{RS(CH_2)_2SR\text{-}S,S'\}]Br$. Similarly, treatment of $[WBr_2(CO)_3(NCMe)_2]$ with one and two equivalents of $Ph_2P(S)CH_2P(S)Ph_2$ in CH_2Cl_2 at room temperature afforded $[WBr_2(CO)_3\{Ph_2P(S)CH_2P(S)Ph_2\text{-}S,S'\}]$ and $[WBr(CO)_3\{Ph_2P(S)CH_2P(S)Ph_2\text{-}S\}\{Ph_2P(S)CH_2P(S)Ph_2\text{-}S,S'\}]Br$ respectively. Reaction of $[MBr_2(CO)_3(NCMe)_2]$ with one equivalent of $MeS(CH_2)_2S(CH_2)_2SMe$ in CH_2Cl_2 at room temperature gave $[MoBr_2(CO)_2\{MeS(CH_2)_2S(CH_2)_2SMe\text{-}S,S',S''\}]$ and $[WBr_2(CO)_3\{MeS(CH_2)_2S(CH_2)_2SMe\text{-}S,S'\}]$ respectively. Finally, reaction of equimolar quantities of $[MoBr_2(CO)_2(NCMe)_2]$ and ttob (ttob = 2,5,8-trithia[9]-*o*-benzenophane) gives the S_3 bonded complex $[MoBr_2(CO)_2(ttob\text{-}S,S',S'')]$. © 1998 Elsevier Science Ltd. Keywords: seven-coordinate; molybdenum(II); thioether; tungsten(II); crystal structure; sulfur donor ligands.

Molybdenum and tungsten complexes containing sulfur donor ligands are important for a number of reasons, including, for example, the fact that the active site of the nitrogenase enzyme contains molybdenum with attached sulfur donor ligands [1–3]. A number of iodocarbonyl complexes containing neutral sulfur donor ligands have been described. Over the years we have reported the reactions of $[MI_2(CO)_3(NCMe)_2]$ with thioureas [4,5], thioacetamide [5,6], $SPPh_3$ [7], S_2CPCy_3 [8], $RS(CH_2)_2SR$ [9], $MeS(CH_2)_2S(CH_2)_2SMe$ [9], $Ph_2P(S)CH_2P(S)Ph_2$ [10], trithiamacrocyclic ligands [11] and tetrathiamacrocyclic ligands [12]. However, apart from the 2,5-dithiahexane complexes $[MX_2(CO)_3(2,5\text{-dithiahexane})]$ (M = Mo or W; X = Br or I) reported by Mannerskantz and Wilkinson [13] in 1962 and our crystallographically characterised complex $[MoBr(CO)_2\{Me_8[16]aneS_4\text{-}S,S',S'',S'''\}][MoBr_3(CO)_4]$ [12,14] very few bromocarbonyl seven-coordinate complexes of molybdenum(II) and tungsten(II) containing neutral sulfur donor ligands have been described.

In our initial report of the synthesis of the highly versatile seven-coordinate complexes $[MX_2(CO)_3(NCMe)_2]$ (M = Mo or W; X = Br or I) in 1986 [15] it was suggested that the dibromo complexes were considerably less stable than their diiodo counter-

* Author to whom correspondence should be addressed.

parts. However, more recently in 1994 [16] we have described an improved synthesis of the dibromotricarbonyl complexes $[MBr_2(CO)_3(NCMe)_2]$, by reacting *fac*-$[M(CO)_3(NCMe)_3]$ (prepared *in situ* [17]) with an equimolar amount of Br_2 at $-78°C$. In this paper, we describe the reactions of the dibromo complexes $[MBr_2(CO)_3(NCMe)_2]$ (M = Mo or W) with the neutral sulfur donor ligands, $RS(CH_2)_2SR$ (R = Ph or $C_6H_4CF_3$-4), $Ph_2P(S)CH_2P(S)Ph_2$, $MeS(CH_2)_2S(CH_2)_2SMe$ and ttob (ttob = 2,5,8-trithia[9]-*o*-benzenophane). The X-ray crystal structure of $[WBr_2(CO)_3\{PhS(CH_2)_2SPh\text{-}S,S'\}]$ is also discussed.

EXPERIMENTAL

All reactions described in this paper were carried out using standard Schlenk line techniques. The starting materials $[MBr_2(CO)_3(NCMe)_2]$ (M = Mo or W) [15,16], $RS(CH_2)_2SR$ (R = Ph or $C_6H_4CF_3$-4) [18], $Ph_2P(S)CH_2P(S)Ph_2$ [19], $MeS(CH_2)_2S(CH_2)_2SMe$ [9] and ttob [20] were prepared by published methods. All chemicals used were purchased from commercial sources, and CH_2Cl_2 was dried over phosphorus pentoxide and distilled before use.

Elemental analyses (C, H and S) were obtained using a Carlo Erba Elemental Analyser MOD 1108 (using helium as a carrier gas). IR spectra were recorded on a Perkin–Elmer 1600 FT IR spectrophotometer. The ^1H NMR spectra were recorded on a Bruker AC 250 MHz NMR spectrometer at the University of Wales, Bangor, and referenced to $SiMe_4$.

$[WBr_2(CO)_3\{PhS(CH_2)_2SPh\text{-}S,S'\}]$ (2)

To a stirred solution of $[WBr_2(CO)_3(NCMe)_2]$ (0.21 g, 0.41 mmol) in CH_2Cl_2 (15 cm^3) under a stream of dry nitrogen was added $PhS(CH_2)_2SPh$ (0.11 g, 0.45 mmol). The resulting solution was stirred for 2 h before filtering over a fine frit and the solvent was removed *in vacuo* to produce an orange brown powder. The powder was dissolved in a minimum of CH_2Cl_2 and cooled to $-15°C$ to give orange crystals of $[WBr_2(CO)_3\{PhS(CH_2)_2SPh\text{-}S,S'\}]$ (**2**) (0.12 g, 0.19 mmol, 45%), one of which was suitable for X-ray crystallography.

A similar reaction of $[MoBr_2(CO)_3(NCMe)_2]$ (0.19 g, 0.45 mmol) with $PhS(CH_2)_2SPh$ (0.12 g, 0.46 mmol) followed by recrystallisation from CH_2Cl_2 gave the brown complex $[MoBr_2(CO)_3\{PhS(CH_2)_2SPh\text{-}S,S'\}]$ (**1**) (0.11 g, 0.18 mmol, 40%).

$[WBr_2(CO)_3\{4\text{-}FC_6H_4S(CH_2)_2C_6H_4F\text{-}4\text{-}S,S'\}]$ (4)

To a stirred solution of $[WBr_2(CO)_3(NCMe)_2]$ (0.25 g, 0.49 mmol) in CH_2Cl_2 (20 cm^3) under a stream of dry nitrogen was added $4\text{-}FC_6H_4S(CH_2)_2SC_6H_4F$-4 (0.15 g, 0.51 mmol). The resulting solution was stirred for 23 h before filtering over a fine frit and the solvent was removed *in vacuo* to produce an orange brown powder. The powder was dissolved in a minimum of CH_2Cl_2 and cooled to $-15°C$ to give the orange complex $[WBr_2(CO)_3\{4\text{-}FC_6H_4S(CH_2)_2SC_6H_4F\text{-}4\text{-}S,S'\}]$ (**4**)(0.15 g, 0.22 mmol, 44%).

A similar reaction of $[MoBr_2(CO)_3(NCMe)_2]$ (0.19 g, 0.45 mmol) with $4\text{-}FC_6H_4S(CH_2)_2SC_6H_4F$-4 (0.13 g, 0.45 mmol) in CH_2Cl_2 for 4 h followed by recrystallisation from CH_2Cl_2 gave the brown complex $[MoBr_2(CO)_3\{4\text{-}FC_6H_4S(CH_2)_2SC_6H_4F\text{-}4\text{-}S,S'\}]$ (**3**) (0.13 g, 0.21 mmol, 46%).

$[WBr(CO)_3\{PhS(CH_2)_2SPh\text{-}S\}\{PhS(CH_2)_2SPh\text{-}S,S'\}]Br$ (5)

To a stirred solution of $[WBr_2(CO)_3(NCMe)_2]$ (0.21 g, 0.41 mmol) in CH_2Cl_2 (15 cm^3) under a stream of dry nitrogen was added $PhS(CH_2)_2SPh$ (0.21 g, 0.83 mmol). The resulting solution was stirred for 17 h before filtering over a fine frit and the solvent was removed *in vacuo* to produce an orange brown powder. The powder was dissolved in a minimum of CH_2Cl_2 and cooled to $-15°C$ to give the brown complex $[WBr(CO)_3\{PhS(CH_2)_2SPh\text{-}S\}\{PhS(CH_2)_2SPh\text{-}S,S'\}]Br$ (**5**) (0.15 g, 0.17 mmol, 41%).

A similar reaction of $[WBr_2(CO)_3(NCMe)_2]$ (0.19 g, 0.37 mmol) with $4\text{-}FC_6H_4S(CH_2)_2SC_6H_4F$-4 (0.21 g, 0.75 mmol) followed by recrystallisation from CH_2Cl_2 gave the brown complex $[WBr(CO)_3\{4\text{-}FC_6H_4S(CH_2)_2SC_6H_4F\text{-}4\text{-}S\}\{4\text{-}FC_6H_4S(CH_2)_2SC_6H_4F\text{-}4\text{-}S,S'\}]Br$ (**6**) (0.17 g, 0.18 mmol, 47%).

$[WBr_2(CO)_3\{Ph_2P(S)CH_2P(S)Ph_2\text{-}S,S'\}]$ (7)

To a stirred solution of $[WBr_2(CO)_3(NCMe)_2]$ (0.07 g, 0.14 mmol) in CH_2Cl_2 (15 cm^3) under a stream of dry nitrogen was added $Ph_2P(S)CH_2P(S)Ph_2$ (0.07 g, 0.15 mmol). The resulting solution was stirred for 4 h before filtering over a fine frit and the solvent was removed *in vacuo* to produce a green sticky oil. The oil was washed with hexane and then dissolved in a minimum of CH_2Cl_2 and cooled to $-15°C$ to give the green complex $[WBr_2(CO)_3\{Ph_2P(S)CH_2P(S)Ph_2\text{-}S,S'\}]$ (**7**) (0.08 g, 0.09 mmol, 60%).

A similar reaction of $[WBr_2(CO)_3(NCMe)_2]$ (0.07 g, 0.14 mmol) with $Ph_2P(S)CH_2P(S)Ph_2$ (0.14 g, 0.29 mmol) in CH_2Cl_2 gave the green complex $[WBr(CO)_3\{Ph_2P(S)CH_2P(S)Ph_2\text{-}S\}\{Ph_2P(S)CH_2P(S)Ph_2\text{-}S,S'\}]Br$ (**8**) (0.08 g, 0.06 mmol, 45%).

$[MoBr_2(CO)_2\{MeS(CH_2)_2S(CH_2)_2SMe\text{-}S,S',S''\}]$ (9)

To a stirred solution of $[MoBr_2(CO)_3(NCMe)_2]$ (0.30 g, 0.72 mmol) in CH_2Cl_2 (15 cm^3) under a stream of dry nitrogen was added $MeS(CH_2)_2S(CH_2)_2SMe$ (0.13 g, 0.73 mmol). The resulting solution was stirred for 5 h before filtering over cellite and the solvent was removed *in vacuo* to produce a red oily solid. The

oil was washed with hexane and then dissolved in a minimum of CH_2Cl_2 and cooled to $-15°C$ to give the red brown complex $[MoBr_2(CO)_2\{MeS(CH_2)_2S(CH_2)_2SMe\text{-}S,S',S''\}]$ (**9**) (0.20 g, 0.40 mmol, 55%).

A similar reaction of $[WBr_2(CO)_3(NCMe)_2]$ (0.29 g, 0.57 mmol) with $MeS(CH_2)_2S(CH_2)_2SMe$ (0.11 g, 0.575 mmol) in CH_2Cl_2 (15 cm^3) for 12 h followed by washing with hexane and recrystallisation from CH_2Cl_2 gave the green complex $[WBr_2(CO)_3\{MeS(CH_2)_2S(CH_2)_2SMe\text{-}S,S'\}]$ (**10**) (0.19 g, 0.31 mmol, 54%).

$[MoBr_2(CO)_2\{ttob\text{-}S,S',S''\}]$ (**11**)

To a stirred solution of $[MoBr_2(CO)_3(NCMe)_2]$ (0.41 g, 0.99 mmol) in CH_2Cl_2 (15 cm^3) under a stream of dry nitrogen was added ttob (0.26 g, 1.00 mmol). The resulting solution was stirred for 4 h before filtering over cellite and the solvent was removed *in vacuo* to produce a brown solid. The solid was washed with hexane and then dissolved in a minimum of CH_2Cl_2 and cooled to $-15°C$ to give the brown complex $[MoBr_2(CO)_2\{ttob\text{-}S,S',S''\}]$ (**11**) (0.34 g, 0.59 mmol, 60%).

Crystallography. Crystal data for **2** are given in Table 1, together with refinement details. Data were collected with Mo-K_α radiation using the MAR Research Image Plate System. The crystal was positioned at 80 mm from the Image Plate. 95 Frames were measured at 2° intervals with a counting time of 2 min. Data analysis was carried out with the XDS program [21]. The structure was solved using direct methods with the Shelx86 program [22]. Apart from the carbon atoms in the carbonyl groups, the non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were included in geometric positions and given thermal parameters equivalent to 1.2 times those of the atom to which they were attached. An absorption correction was applied using DIFABS [23]. The structure was then refined using Shelx1 [24]. All calculations were carried out on a Silicon Graphics R4000 Workstation at the University of Reading. Bond lengths and angles in the metal coordination sphere are given in Table 2.

RESULTS AND DISCUSSION

The reaction of $[MBr_2(CO)_3(NCMe)_2]$ (M = Mo or W) with a slight excess of $RS(CH_2)_2SR$ (R = Ph or C_6H_4F-4) in CH_2Cl_2 at room temperature gave the seven-coordinate complexes $[MBr_2(CO)_3\{RS(CH_2)_2SR\text{-}S,S'\}]$ (**1–4**) in reasonable yields. Complexes **1–4** were characterised by elemental analysis C, H and S (Table 3), IR spectroscopy (Table 4) and ^1H NMR spectroscopy (Table 5). All four complexes are soluble in dichloromethane and DMSO, but are totally insoluble in diethyl ether, the molybdenum com-

plexes being more soluble than their tungsten analogues. Complexes **1**–**4** are all very air-sensitive in solution and only slightly less so in the solid state, and much less stable than their diiodo analogues. Hence, the complexes were handled in air only for very short periods of time and decomposed very rapidly in solution. Conductivity measurements in acetone showed complexes **1**–**4** to be non-electrolytes as was expected.

The IR spectra of complexes **1**–**4** were recorded as KBr disks. No solution infrared spectra were obtained due to the extremely air-sensitive nature of the complexes. Three carbonyl stretching bands were observed for all of the four complexes (Table 4). This is consistent with the complexes being seven-coordinate tricarbonyl complexes and having one conformation in the solid-state. The ^{1}H NMR spectra (Table 5) showed the coordinated thioether resonances to be shifted slightly downfield compared to the free thioether ligands.

The solid-state structure of the tungsten complex **2** has been solved by X-ray crystallography and is shown in Fig. 1, together with atomic numbering scheme. It is likely that the three other complexes **1, 3** and **4** will have similar geometries in the solid state. The structure can best be considered as a distorted capped octahedron with one carbonyl C(100) in the capping position, two carbonyls C(200), C(300) and one sulfur S(2) in the capped face and the two bromides and the other sulfur S(1) in the uncapped face. The structure is very similar to that previously found for $[WI_2(CO)_3\{4\text{-}MeC_6H_4S(CH_2)_2SC_6H_4Me\text{-}4\text{-}S,S'\}]$ [9] both in the details of their metal coordination spheres and in the conformation of the Ph—S—CH_2—CH_2—S—Ph moiety. In the present structure one bromine atom Br(1) is *trans* to the carbonyl group C(300) at 2.659(4) Å while the other Br(2) is *trans* to S(2) at 2.626(3) Å. The two W—S(1) distances are equivalent within experimental error despite their different positions in the coordination sphere {2.557(7), 2.573(7) Å}. More variation is obtained for $[WI_2(CO)_3\{4\text{-}MeC_6H_4S(CH_2)_2SC_6H_4Me\text{-}4\text{-}S,S'\}]$ [9] where the mutually *trans* W—S and W—I are shorter at 2.54(3), 2.836(1) Å than those *trans* to carbonyl 2.59(3), 2.875(1) Å.

The reactions of $[WBr_2(CO)_3(NCMe)_2]$ with two equivalents of $RS(CH_2)_2SR$ (R = Ph or C_6H_4F-4) gave the cationic complexes $[WBr(CO)_3\{RS(CH_2)_2SR\text{-}S\}\{RS(CH_2)_2SR\text{-}S,S'\}]Br$ (R = Ph or 4-FC_6H_4) (**5** and **6**) respectively in good yield. Complexes **5** and **6** were characterised by elemental analysis C, H and S (Table 3), IR spectroscopy (Table 4) and ^{1}H NMR spectroscopy (Table 5). The found sulfur analysis for complex **5** is low, and is most likely to be due to the instability of this complex when exposed to air. Both complexes were soluble in dichloromethane and DMSO, but are totally insoluble in diethyl ether. They are very air-sensitive in solution, and only slightly less so in the solid state. Conductivity measurements in acetone showed both complexes to be typical 1 : 1 electrolytes (Λ_m = 123 and 126 S cm^2 mol^{-1}). These data suggest that one of the sulfur atoms from the second thioether ligand has displaced one of the bromide groups from the starting material.

The IR spectra of both complexes are recorded as KBr disks. Three carbonyl stretching bands were observed for both complexes (Table 4). This is consistent with the complexes being seven-coordinate and having one conformation in the solid-state. The ^{1}H NMR spectra (Table 5) again showed the coordinated thioether resonances to be shifted downfield compared to those of the free thioethers. In these cases, however, resonances are also observed for the uncoordinated end of the monodentately bound thioether ligand. It may be likely that given the similarities in spectroscopic data between complexes **5** and **6** and the crystallographically characterised product **2**, they will have similar solid-state structures, i.e. capped octahedral (Fig. 2). Several unsuccessful attempts were made to obtain ^{31}P NMR spectra for complexes **5** and **6**. These very weak spectra showed a number of resonances due to rapid decomposition of the complexes in solution.

Treatment of $[WBr_2(CO)_3(NCMe)_2]$ with one or two equivalents of $Ph_2P(S)CH_2P(S)Ph_2$ gave the green seven-coordinate complexes $[WBr_2(CO)_3\{Ph_2P(S)CH_2P(S)Ph_2\text{-}S,S'\}]$ (**7**) and $[WBr(CO)_3\{Ph_2P(S)CH_2P(S)Ph_2\text{-}S\}\{Ph_2P(S)CH_2P(S)Ph_2\text{-}S,S'\}]Br$ (**8**)

[a] Spectra recorded in dimethylsulfoxide at 25°C and referenced to $SiMe_4$.

Hence, the complexes were handled in air only for very short periods and were used very quickly in order to avoid decomposition. Conductivity measurements of complex **7** showed the complex to be a non-electrolyte in acetone, however, complex **8** was shown to be a typical 1 : 1 electrolyte (Λ_m = 128 S cm^2 mol^{-1}) in acetone. The conductivity data suggests that in complex **8** one of the sulfur atoms from the second diphosphine disulfide ligand has displaced one of the bromide ligands from the starting material.

The IR spectra of both complexes were recorded as KBr disks. Three carbonyl stretching bands were observed for both complexes (Table 4). This is consistent with the complexes being seven-coordinate and having one conformation in the solid-state. The ^{1}H NMR spectra (Table 5) again showed the coordinated diphosphine disulfide resonances to be shifted slightly downfield compared to those of the free ligand. Similar reactions were attempted with the molybdenum complex $[MoBr_2(CO)_3(NCMe)_2]$, however no pure products could be isolated, which is probably due to their greater instability.

The reaction of $[MBr_2(CO)_3(NCMe)_2]$ with an equimolar amount of $MeS(CH_2)_2S(CH_2)_2SMe$ in CH_2Cl_2 at room temperature gave the seven-coordinate dicarbonyl complex $[MoBr_2(CO)_2\{MeS(CH_2)_2S(CH_2)_2SMe\text{-}S,S',S''\}]$ (**9**) and the tricarbonyl complex $[WBr_2(CO)_3\{MeS(CH_2)_2S(CH_2)_2SMe\text{-}S,S'\}]$ (**10**), respectively in high yield. Complexes **9** and **10** were characterised by elemental analysis C, H and S (Table 3), IR spectroscopy (Table 4) and ^{1}H NMR spectroscopy (Table 5). Both complexes are soluble in dichloromethane and DMSO but are totally insoluble in diethyl ether; the molybdenum complex is less soluble than its tungsten analogue. Both complexes are very air-sensitive in solution and only slightly less sensitive in the solid state. Conductivity measurements in acetone showed both complexes to be non-electrolytes. The IR spectra of both complexes were recorded as KBr disks (Table 4). Complex **9** showed two carbonyl stretching bands suggesting a dicarbonyl complex while three carbonyl stretching bands were observed for complex **10**.

The ^{1}H NMR spectra (Table 5) of both complexes showed the coordinated thioether resonances to be shifted downfield compared to those of the free thioethers. However, in the case of complex **10** a resonance

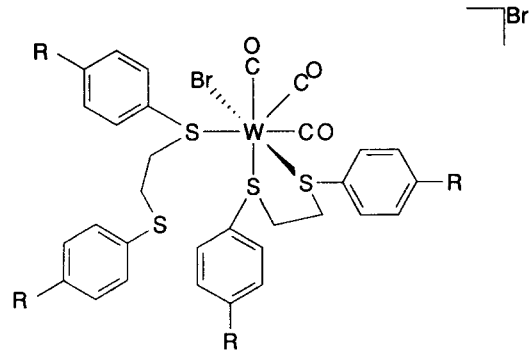

Fig. 2. Proposed structure of $[WBr(CO)_3\{RS(CH_2)_2SR\text{-}S\}\{RS(CH_2)_2SR\text{-}S,S'\}]Br$ (**5** and **6**) (R = Ph or $C_6H_4CF_3$-4).

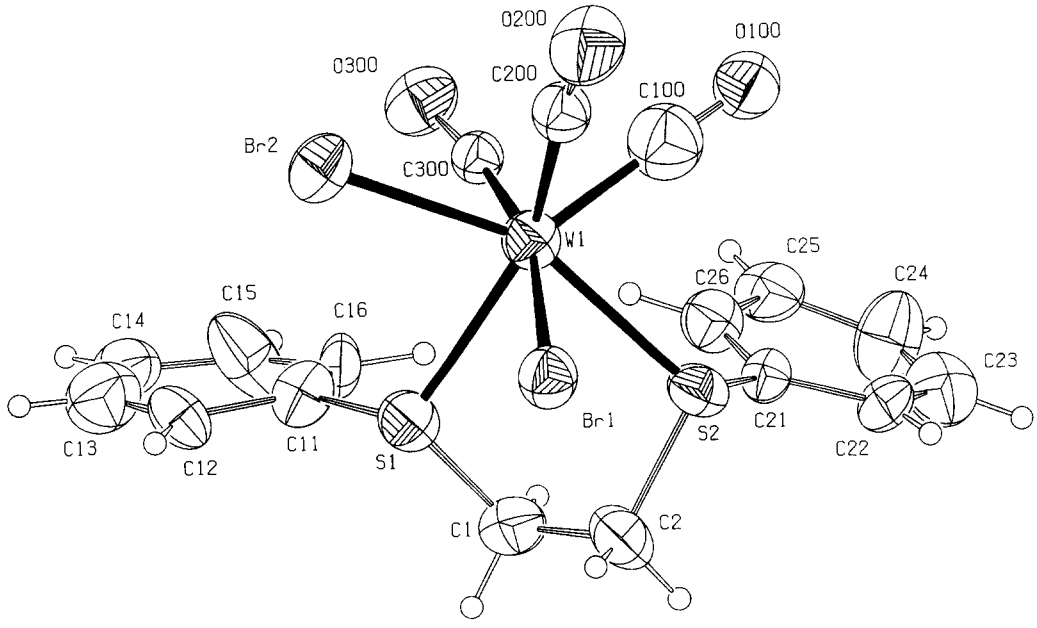

Fig. 1. The structure of **2**, together with the atom numbering scheme. Ellipsoids are shown at 30% probability. Hydrogen atoms are drawn with small arbitrary radii.

can be assigned to the methyl group of the uncoordinated sulfur atom. The geometry for complex **9** may be a capped octahedron (Fig. 3) for the dicarbonyl molybdenum complex $[MoBr_2(CO)_2\{MeS(CH_2)_2S(CH_2)_2SMe\text{-}S,S',S''\}]$ (**9**) since the previously confirmed crystallographically determined structure of the diiodo-complex $[WI_2(CO)_2\{MeS(CH_2)_2S(CH_2)_2SMe\text{-}S,S',S''\}]$ [9], is capped octahedral, and their spectral properties are also very similar. Several unsuccessful attempts to prepare the analogous tungsten complex $[WBr_2(CO)_2\{MeS(CH_2)_2S(CH_2)_2SMe\text{-}S,S',S''\}]$ were made by using longer reaction times. The greater lability of molybdenum carbonyl complexes compared to tungsten carbonyl complexes is well known [25].

Treatment of $[MoBr_2(CO)_3(NCMe)_2]$ with an equimolar amount of 2,5,8-trithia[9]-*o*-benzeneophane (ttob) gave the seven-coordinate dicarbonyl complex $[MoBr_2(CO)_2\{ttob\text{-}S,S',S''\}]$ (**11**) in high yield. Complex (**11**) was light brown in colour and was characterised by elemental analysis C, H and S (Table 3), IR spectroscopy (Table 4) and ^1H NMR spectroscopy (Table 5). The complex was soluble in dichloromethane and DMSO but was totally insoluble in diethyl ether. As expected the complex was very air-sensitive in both solution and in the solid state and hence was handled accordingly. Conductivity measurements in acetone showed the complex to be a non-electrolyte. The IR spectrum was recorded as a KBr disk (Table 4). The complex showed two carbonyl stretching bands suggesting a dicarbonyl complex similar to that of previously described complex (**9**). Similar reactions of $[WBr_2(CO)_3(NCMe)_2]$ with an equimolar amount of 2,5,8-trithia[9]-*o*-benzeneophane (ttob) were attempted, but resulted in a mixture of unstable products. Attempts to separate the products were unsuccessful due to decomposition occurring while recrystallisation was attempted.

In conclusion, the results described in this paper closely mimic those previously observed for the related reactions of the diiodo complexes, $[MI_2(CO)_3(NCMe)_2]$ with neutral sulfur donor ligands previously described.

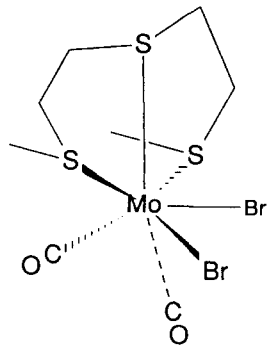

Fig. 3. Proposed structure of $[MoBr_2(CO)_2\{MeS(CH_2)_2S(CH_2)_2SMe\text{-}S,S',S''\}]$ (**9**).

(Received 1 September 1997; accepted 16 October 1997)

Abstract—The syntheses and structural characterization of $NiLX_2$ (X = H_2O (**1**), N_3^- (**2**) and NCS^- (**3**); L = 2,5,9,12-tetramethyl-1,4,8,11-tetrazacyclotetradecane) complexes are reported. The crystal structures of $NiLX_2$ complexes have an axially elongated octahedral geometry with two axial ligands and adopt the *trans*-III conformation. The equilibrium of **1** $NiL^{2+} + 2H_2O \rightleftarrows NiL(H_2O)_2^{2+}$ has been studied in aqueous solution over a temperature range, yielding $\Delta H^\circ = -7.1 \pm 0.1$ kJ mol^{-1} and $\Delta S^\circ = -18.7 \pm 0.3$ J K^{-1} mol^{-1}. Electronic absorption spectra of $NiLX_2$ complexes show that two absorption bands ($^3B_{1g} \rightarrow {}^3E_g^c$ and $^3B_{1g} \rightarrow {}^3E_g^b$) reflect the normal spectrochemical series for axial ligands but one absorption band ($^3B_{1g} \rightarrow {}^3B_{2g}$) depends in reciprocal fashion in the range 300–800 nm. Cyclic voltammetry of $NiLX_2$ complexes exhibit two one-electron waves corresponding to Ni(II)/Ni(III) and Ni(II)/Ni(I) processes. The redox potentials of the complexes are influenced significantly by the nature of the axial ligands. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: octahedral nickel(II) complexes; tetramethyl tetraaza macrocycle.

Macrocyclic polyamine complexes of bivalent transition metals have been of great interest due to their importance as an essential metalloenzyme active site [1]. Typically the 14-membered tetraamine macrocycle cyclam (1,4,8,11-tetraazacyclotetradecane) is well recognized as an example among the macrocyclic polyamines in coordination chemistry [2]. Since the physical and chemical properties of the metal complexes are closely related to the structural features of the corresponding macrocyclic ligands, numerous efforts in this area have been directed toward the synthesis of new types of cyclam analogs. These include the variation of the ring size [3,4], functionalization of the cyclam skeleton [5], attachment of pendant donors to tetraamines [6], introduction of variable degrees of unsaturation [7] and introduction of substituents to the methylene carbon skeleton [6–12]. There have been reported that the modified cyclam complexes show considerable changes in physical and chemical properties, structures and catalytic efficiency [5,13,14]. Among the previously reported scope of cyclam analogs, few examples which possess additional groups at the carbon atoms of dimethylene linkages are known. Recently, the nontemplate condensation reaction of methyl vinyl ketone, 1,2-diaminopropane and perchloric acid followed by reduction with $NaBH_4$, resulting 2,5,9,12-tetramethyl-1,4,8,11-tetraazacyclotetradecane which contains four *anti* methyl groups on the macrocyclic ring, has been described [15,16]. Of much interest with this ligand is the effect on structures of metal complexes, oxidation states of the inserted metal ions and stabilities of metal complexes.

In this paper we report the syntheses and characterization of $NiLX_2$ (X = H_2O (**1**) N_3^- (**2**) and NCS^- (**3**); L = 2,5,9,12-tetramethyl-1,4,8,11-tetraazacyclotetradecane) complexes. We have investigated the

equilibrium, spectroscopic and electrochemical properties of these complexes. Furthermore to understand the nature of the axial ligands the solid state X-ray crystal structures of $NiLX_2$ complexes are determined and compared to their solution structures by electronic absorption spectroscopy and cyclic voltametry.

EXPERIMENTAL

Materials

All solvents were reagent grade and purified according to the literature [17]. Distilled water was used for all reactions. Reagent grade $NiCl_2 \cdot 6H_2O$, methyl vinyl ketone, 1,2-diaminopropane, perchloric acid and $NaBH_4$ were purchased from Aldrich. All other reagents were reagent grade.

Analytical methods

Infrared spectra were recorded as KBr pellets on a Perkin–Elmer Paragon 1000 FT-IR spectrophotometer. Electronic absorption spectra were obtained on a Jasco Uvidec-610 spectrophotometer. High-resolution fast atom bombardment mass spectrometry (FAB mass) were performed by using a Jeol JMS-HA 110A/110A instrument. Element analyses were carried out by the Korea Research Institute of Chemical Technology Taejeon, Korea.

Preparation of ligand (L)

The ligand L was prepared according to previously published procedures [15,16]. Calc. (found) for $C_{14}H_{32}N_4$: C, 65.6 (65.7); H, 12.6; H, 12.6 (12.6); N, 21.9 (21.7)%. IR (KBr, cm^{-1}): 3248 (ν NH), 3212 (ν NH), 2962, 2918, 2874, 2732, 1473, 1452, 1382, 1163, 1121, 1093, 941, 834, 831, 781, 621, 568 and 506. FAB mass (CH_2Cl_2 m/z): 256.4 $(M)^+$.

Preparation of $[NiL(H_2O)_2]Cl_2$ (1)

A methanol solution (20 cm^3) of L (256 mg, 1 mmol) and $NiCl_2 \cdot 6H_2O$ (238 mg, 1 mmol) was heated at reflux for 2 h. The solution was cooled to room temperature and the solvent was removed. The crude product was dissolved in 10 cm^3 of water, filtered and recrystallized by adding 10 cm^3 of acetonitrile. Violet crystals of **1** were collected by filtration and dried *in vacuo* (Yield: 300 mg, 71%). Calc. (found) for $NiC_{14}H_{36}N_4O_2Cl_2$: C, 39.8 (39.6); H, 8.6 (8.5); N, 13.3 (13.5)%. IR (KBr, cm^{-1}) 3239 (ν NH), 2967, 2878, 1659 (ν HOH), 1452, 1382, 1113, 1066, 1001, 947 and 741. Electronic spectra ($CHCl_3$): λ_{max} nm (ε, M^{-1} cm^{-1}): 352 (15.6), 534 (8.2) and 685 (4.0). FAB mass (CH_2Cl_2 m/z): 422.1 $(M)^+$.

Preparation of $[NiL(N_3)_2]$ (2)

To a methanol solution (20 cm^3) of **1** (127 mg. 0.3 mmol) was added NaN_3 (39 mg, 0.6 mmol) and the mixture was heated for 30 min on a steam bath. The solution was filtered to remove the sodium chloride. The solution was then evaporated to dryness. The resulting mauve solid was extracted into chloroform and recrystallized by adding 10 cm^3 of acetonitrile. Light brown crystals of **2** were collected by filtration and dried *in vacuo* (Yield: 91 mg, 76%). Calc. (found) for $NiC_{14}H_{32}N_{10}$: C, 42.1 (42.3); H, 8.1 (8.0); N, 35.1 (35.0)%. IR (KBr, cm^{-1}): 3192 (ν NH), 2964, 2910, 2870, 2032 (ν N_3), 1443, 1378, 1336, 1178, 1115, 1024, 988, 961, 942, 903, 836 and 615. Electronic spectra ($CHCl_3$): λ_{max}, nm (ε, M^{-1} cm^{-1}): 343 (17.6), 528 (10.3) and 712 (2.9). FAB mass (CH_2Cl_2, m/z): 399.2 $(M)^+$.

Preparation of $[NiL(NCS)_2] \cdot H_2O$ (3)

To methanol solution (20 cm^3) of **1** (127 mg, 0.3 mmol) was added KSCN (58 mg, 0.6 mmol) and the mixture was heated for 30 min on a steam bath. The solution was filtered to remove the potassium chloride. The solution was then evaporated to dryness and the resulting solid dissolved in acetonitrile/water (1 : 1, 10 cm^3). When this mixture was allowed to stand for a few days, a quantity of violet crystals precipitated. These were filtered off, washed with diethyl ether and dried *in vacuo* (Yield: 105 mg, 78%). Calc. (found) for $NiC_{16}H_{32}N_6S_2 \cdot H_2O$: C, 42.8 (42.6); H, 7.6 (7.7); N, 18.7 (18.8)%. IR (KBr, cm^{-1}): 3215 (ν NH), 2929, 2873, 2064 (ν SCN), 1447, 1379, 1114, 1060, 1009, 934, 899, 833, 784 and 480. Electronic spectra ($CHCl_3$): λ_{max}, nm (ε, M^{-1} cm^{-1}): 332 (15.1), 508 (9.7) and 735 (2.5). FAB mass (CH_2Cl_2, m/z): 449.3 $(M)^+$.

Equilibrium measurements

Measurements were carried out on a Uvidec-610 spectrophotometer with 1 cm quartz cell. The cell

containing solution was maintained in a temperature-controlled air-bath. The temperature of the solution was determined by the resistance of a calibrated thermistor. The concentration of **1** in an ionic strength of 0.10 M $NaClO_4$ was 6.04×10^{-3} M.

Electrochemical measurements

Cyclic voltammograms were recorded using a BAS 100BW electrochemical system. All measurements were made on 0.01 M tetraethylammonium perchloratedichloromethane solution at 20.0 ± 0.1°C. A hanging mercury dropping electrode for cathodic voltammetry and platinum disc electrode of about 2 mm diameter for anodic voltammetry were used as the working electrode. The counter electrode was a coiled platinum wire and a saturated calomel electrode was used as a reference electrode. The solution was degassed with high purity nitrogen prior to carrying out the electrochemical measurements.

X-ray structure analysis

Analyses on single crystals of $[NiL(H_2O)_2]Cl_2$ (**1**), $[NiL(N_3)]$ (**2**) and $[NiL(NCS)_2] \cdot H_2O$ (**3**) were carried out with an Enraf-Nonius CAD4 X-ray diffractometer. A summary of crystal data, data collection, and refinement for all crystallographically characterized compounds are given in Table 1. Violet crystal of **1**, light brown crystal of **2** and violet crystal of **3** (approximated dimensions $0.2 \times 0.2 \times 0.2$, $0.2 \times 0.3 \times 0.2$ and $0.4 \times 0.3 \times 0.1$ mm^3) were mounted on the diffractometer, and used for data collections at room temperature with graphite-monochromated Mo–K_α radiation ($\lambda = 0.71069$ Å). Accurate cell parameters and a crystal orientation matrix were determined by least-squares fit of 25 reflections. An asymmetric unit of intensity data were collected in the ω-2θ scan mode. Intensity data were corrected for Lorentz and polarization effects. No absorption correction was applied. The structure was solved by direct methods and refined by full matrix least-squares refinement (NRCVAX and SHELXL-93) [18,19]. All non-hydrogen atoms were placed with a combination of difference Fourier and least-squares calculations. Hydrogen atoms in methyl group were located from different Fourier maps, other hydrogen atoms were placed in calculated positions. Anisotropic thermal parameters were used for all non-hydrogen atoms and isotropic thermal parameters were used with the hydrogen atoms. The positions of hydrogen atoms

RESULTS AND DISCUSSION

Structural descriptions

The ligand skeleton of the present compounds take the most stable *trans*-III conformation with two chair form six-membered and two gauche five-membered chelate rings. An inversion center of these complexes exits on the central nickel(II) ion. The N—Ni—N angles of the six-membered chelate rings are larger than those of the five-membered chelate rings.

An ORTEP diagram of $[NiL(H_2O)_2]Cl_2$ (**1**) with the atomic numbering scheme is shown in Fig. 1 and selected bond lengths and angles in Table 2. The crystal structure of **1** consists of $[NiL(H_2O)_2]^{2+}$ cation and two Cl^- anions which is very similar to that of *trans*-$[Ni(cyclam)(H_2O)_2]Cl_2 \cdot 4H_2O$ [20]. Two water molecules axially coordinate to the central nickel(II) ion, which is six-coordinate in the high-spin octahedral geometry. The average bond distance of Ni—N is 2.074(3) Å, which is comparable to those found in *trans*-$[Ni(cyclam)(H_2O)_2]Cl_2 \cdot H_2O$ [2.069(7) Å] [20] and $[Ni(cyclam)Cl_2]$ [2.058(8) [21] and 2.067(2) Å [22]]. The Ni—O distance of 2.194(2) Å is slightly longer than those of the cyclam complexes [2.176(2) [20] and 2.16 Å [23]]. Substitution of the methyl groups on the macrocyclic chelate rings may have detrimental effect on the coordination of water molecules to the central nickel(II) ion. Figure 2 shows the four hydrogen-bonding chelate rings involving the chlorides, water molecule, secondary amines of macrocycle and the central nickel(II) ion (Table 3).

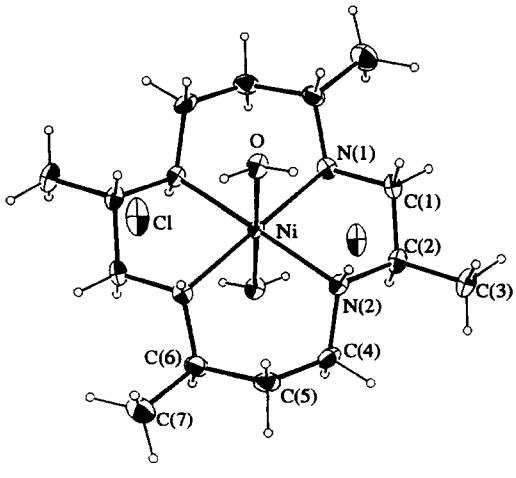

Fig. 1. ORTEP diagram of **1** with the atom-numbering scheme.

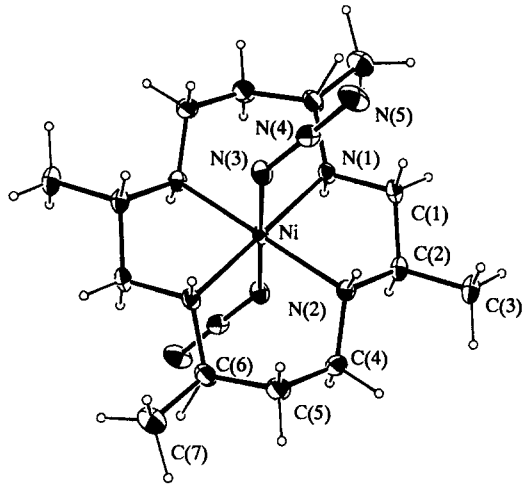

Fig. 2. Hydrogen-bond system of **1**.

An ORTEP diagram of $[NiL(N_3)_2]$ (**2**) with atomic numbering scheme is shown in Fig. 3 and selected bond lengths and angles in Table 2. The crystal structure of **2** reveals a six-coordinated octahedral geometry with bonds from the nickel(II) ion to the secondary amine nitrogens of the macrocycle and to the two axial azide ligands. The Ni—N(3) linkage is bent slightly off the perpendicular to the NiN_4 plane by 0.45–5.43°. The average bond distance of 2.075(3) Å, between nickel and secondary nitrogen, which is close to that found for **1** and shorter than the Ni—N(3) distance of 2.161 Å indicates an axially elongated octahedral geometry. The apical Ni—N(3) bond distance and Ni—N(3)—N(4) angle [128.2(2)°] are similar to the observed for catena-(μ-N_3)[Ni(cyclam)]$(ClO_4) \cdot H_2O$ [24] and [(Ni(Me_2[14]-1,3-dieneN$_4$)(μ-N(3)$_n$)]$(ClO_4)_n$ [25]. Both azido groups which act monodentate ligands are slightly asymmetric [N(3)—N(4) = 1.177(4) and N(4)—N(5) = 1.161(4) Å] and linear within the experimental error [N(3)—N(4)—N(5) angles = 179.0(3)°].

An ORTEP diagram of $[NiL(NCS)_2] \cdot H_2O$ (**3**) with the atomic numbering scheme is shown in Fig. 4 and selected bond lengths and angles in Table 2. There are two crystallographically independent $[NiL(NCS)_2]$ complexes, in each of which resides at a center of symmetry. The crystal structure of **3** confirms a six-coordinated octahedral geometry with bonds from the nickel(II) ion to the secondary amine nitrogens of the macrocycle and to the two axial thiocyanate ligands. The total stereochemistry of the ligands in **3** is essentially the same and very similar to that found for $[Ni(cyclam)(NCS)_2]$ [22]. The two axial Ni—N-(thiocyanato) distances are similar (2.109(7) and 2.100(7) Å) and longer than the average distance of Ni(1)—N_4 and Ni(2)—N_4 plane [2.094(6) and 2.080(6) Å], giving an axially elongated octahedral

geometry. Of particular interest is the wide variety of orientation modes of the thiocyanate ligands. The Ni(1)—N(1) and Ni(2)—N(2) linkage is bent slightly off the perpendicular to the NiN_4 plane by 2.7–3.1° and 1.5–3.3°, respectively. The two Ni—N—C angles related to the thiocyanate ligands are Ni(1)—N(1)—C(1) [154.6(6)°] and Ni(2)—N(2)—C(2) [162.2(5)°]. The thiocyanate sulfur atom

forms two hydrogen bonding O···S(2) [3.371(14) Å] and O···S(1)^{i} [$1+x$, $1+y$, z, 3.532(12) Å] with adjacent water molecule.

Equilibrium studies of **1**

Complex **1** exists in aqueous solution as an equilibrium mixture of a yellow, square-planar, low-spin species and a violet, octahedral, high-spin species according to eqn (1) [4,28]. The equilibrium was studied over a temperature range as shown in Fig. 5.

$$[NiL]^{2+} + 2H_2O \overset{K}{\rightleftarrows} [NiL(H_2O)_2]^{2+} \qquad (1)$$

The yellow square-planar species has a single d-d band in aqueous solution at 460 nm. This band is due exclusively to the square-planar species, and the proportion of the square-planar species was found to increase with increasing temperature. On addition of 7.2 M $NaClO_4$, the absorption coefficient of the band at 460

nm eventually reaches a limiting value ($\varepsilon = 121.8$ M^{-1} cm^{-1}) which is taken as the molar absorption coefficient of the square-planar chromophore. Moreover, heating this solution does not increase the absorbance any further indicating that the ε value is not temperature-dependent. The equilibrium constant of the square-planar to octahedral conversion K ($K = \varepsilon/\varepsilon_{lim} - \varepsilon$) was determined at different temperatures in the range 8.2–77.8°C for the solution of **1** in 0.10 M $NaClO_4$. A plot of ln K against $1/T$ makes ΔH° and ΔS° values available. Thermodynamic parameters shown in Table 4 for the square-planar to octahedral conversion of $[NiL]^{2+}$ are compared with those for corresponding complexes of macrocycles. The reactions are exothermic due to the formation of two axial Ni—OH_2 bonds in the octahedral species. However, this effect is counterbalanced to some degree by the weaker Ni—N bond in the octahedral species, where the Ni—N bonds are somewhat longer [2.074(3) Å] than those observed in the square-planar species [Ni—N 1.90–1.91 Å] [26,27]. Constriction of two water molecules also leads to a negative entropy change. The entropy change of **1** is considerably lower than those observed in cyclam [28] and isocyclam [4]. This may be attributed to the elongation of the axial Ni—OH_2 bond by the substitution of the tetramethyl groups on the macrocycle.

Spectroscopic studies

The electronic absorption bands of $NiLX_2$ complexes in $CHCl_3$ solution are summarized in Table 5. All complexes investigated in this study show three absorption bands [$^3B_{1g} \rightarrow {}^3E_g^c$, $^3B_{1g} \rightarrow {}^3E_g^b$, and $^3B_{1g} \rightarrow {}^3B_{2g}$] [29] in the range 300–800 nm. Two absorption bands [$^3B_{1g} \rightarrow {}^3E_g^c$ and $^3B_{1g} \rightarrow {}^3E_g^b$] of complexes increase toward higher energies in the order of $H_2O < N_3^- < NCS^-$, which is reasonably explained by the spectrochemical series, but one absorption band [$^3B_{1g} \rightarrow {}^3B_{2g}$] depends in a reciprocal fashion. This observation is consistent with previously reported work for the spectrochemical properties of nickel(II) macrocyclic complexes [29]. The electronic spectra of **1** in the solid state (KBr pellet) was observed at 531 and 348 nm, which are similar to those of $CHCl_3$ solution. One pertinent feature of **1** in parallel with the solid state X-ray structural result is the dominant population of octahedral species in $CHCl_3$ solution. This is an evidence by the presence in the absorption band centered at 534 nm (high-spin chromophore) compared to band centered at 460 nm (low-spin chromophore) in aqueous solution. It is well understood that **1** exists in equilibrium mixture of the square planar (low-spin) and octahedral (high-spin) species aqueous solution as shown eqn (1).

The prominent IR bands in $NiLX_2$ complexes are also listed in Table 5. The IR spectra of the complexes show a band at ca 3200 cm^{-1}, which is assigned to the ν(NH) of the coordinated secondary amines. An absorption band at 1659 cm^{-1} for in **1** was assigned to HOH bending vibration of coordinated water [30], which is agreed with the crystal data of **1**. A single very strong band at 2032 cm^{-1} of **2** was associated with the azide stretching mode is consistent with the crystal structure of **2**. For **3** the IR data are in accordance with the N-bonded thiocyanato structure as a strong broad band at 2064 cm^{-1} is characteristic of Ni—N bonding [30] which reveals the crystal structure of **3**.

Electrochemistry

Cyclic voltametry data for $NiLX_2$ complexes in 0.01 M TEAP-CH_2Cl_2 solution are given in Table 6. The

complexes exhibit two one-electron waves corresponding to Ni(II)/Ni(III) and Ni(II)/Ni(I) processes. It is of interest to compare the redox potentials for $NiLX_2$ complexes with the axial ligands. The electron density on the nickel atom of these complexes is decreased with the axial ligands in the order of **1** > **2** > **3**. This fact indicates that the oxidation process is unfavorable but the reduction process if favorable. The order of series reflects the π-donor ability of the axial ligands, stabilizing the Ni(III) and Ni(I) center in the order of $NCS^- > N_3^- > H_2O$. This is consistent with the spectral results discussed previously.

(Received 18 August 1997; accepted 16 October 1997)

Abstract—Six new iron(III) binuclear complexes have been synthesized and characterized, namely $[Fe_2(CA)L_4](ClO_4)_4$ [L denotes 2,2′-bipyridine (bpy); 1,10-phenanthroline (phen); 4,4′-dimethyl-2,2′-bipyridine (Me_2bpy); 5-methyl-1,10-phenanthroline (Me-phen); 5-chloro-1,10-phenanthroline (Cl-phen) and 5-nitro-1,10-phenanthroline (NO_2-phen)], where CA represents the dianion of chloranilic acid. Based on elemental analyses, molar conductivity and magnetic moment measurements, and spectroscopic studies, it is proposed that these complexes have CA-bridged structures and consist of two iron(III) ions in a distorted octahedral environment. The complexes $[Fe_2(CA)(bpy)_4](ClO_4)_4$ (**1**) and $[Fe_2(CA)(phen)_4](ClO_4)_4$ (**2**) were characterized by variable temperature magnetic susceptibility measurements (4–300 K) and the observed data were successfully simulated by the equation based on the spin Hamiltonian operator, $\hat{H} = -2J\hat{S}_1 \cdot \hat{S}_2$, giving the exchange integral $J = -2.1$ cm^{-1} for (**1**) and $J = -5.8$ cm^{-1} for (**2**). This result indicates that there is a weak antiferromagnetic spin-exchange interaction between two of the Fe(III) ions within each molecule. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: μ-chloranilato; iron(III); binuclear complex; magnetism; synthesis; characterization.

Chloranilate dianions (abbreviated as CA), due to their peculiar structure, could be good candidates in supporting long-distance magnetic exchange interactions. Many works have been published on binuclear copper(II) complexes containing the μ-chloranilato ligand [1–5]. The effective bridging function of μ-chloranilato and the long-distance antiferromagnetic exchange interactions of these complexes have been revealed by single-crystal X-ray and magnetic analyses. However, to our knowledge no binuclear iron(III) complex bridged by a chloranilate group of this kind has so far been reported. In order to provide more examples of chloranilato-bridged binuclear complexes and to understand better the magnetic properties of this kind of complexes, this paper deals with the synthesis, characterization and magnetism of six new iron(III) binuclear complexes using the dianion of chloranilic acid as bridging ligand: $[Fe_2(CA)L_4](ClO_4)_4$ [where CA = dianion of chloranilic acid; L = 2,2′-bipyridine (bpy); 1,10-phenanthroline (phen); 4,4′-dimethyl-2,2′-bipyridine (Me_2bpy); 5-methyl-1,10-phenanthroline (Me-phen); 5-chloro-1,10-phenanthroline (Cl-phen) and 5-nitro-1,10-phenanthroline (NO_2-phen), respectively].

EXPERIMENTAL

Materials

All the reagents used in the synthesis were analytical grade. Hydrated iron(III) perchlorate was prepared and purified by the literature method [6]. Chloranilic acid (H_2CA), 2,2′-bipyridine (bpy); 1,10-phenanthroline (phen); 4,4′-dimethyl-2,2′-bipyridine (Me_2bpy); 5-methyl-1,10-phenanthroline (Me-phen); 5-chloro-1,10-phenanthroline (Cl-phen) and 5-nitro-

* Author to whom correspondence should be addressed.

1,10-phenanthroline (NO_2-phen) were analytical grade and used as commercially obtained.

Synthesis of iron(III) binuclear complexes

All six complexes were prepared in a similar fashion as typified by $[(Fe_2(CA)(bpy)_4](ClO_4)_4$. To an absolute methanol solution (10 cm^3) of chloranilic acid (0.2 mmol, 41.8 mg) was successively added dropwise an acetonitrile solution (10 cm^3) of $Fe(ClO_4)_3 \cdot 6H_2O$ (0.4 mmol, 186.2 mg) and a solution of bpy (0.8 mmol, 125.0 mg) in 10 cm^3 of methanol with stirring. The mixture was refluxed for 3 h to yield dark-brown microcrystals, which were filtered, washed with methanol and diethyl ether several times and dried over P_2O_5 under reduced pressure. All the analytical data, yields, colors and melting points of the complexes are collected in Table 1. In the solid state all the complexes are fairly stable in air so as to allow physical measurements.

Measurements

Analysis for C, H and N were carried out on a Perkin–Elmer elemental analyser model 240. Metal contents were determined by EDTA titration. The infrared spectra were measured on a Shimadzu infrared spectrometer model 810 in KBr pellets. The electronic spectra (DMF solution) were measured on a Perkin–Elmer Hitachi-240 spectrophotometer. Molar conductances were measured (DMF solution) with a DDS-11A conductometer. Magnetic susceptibility measurements at room temperature were carried out by Gouy's method using $Hg[Co(SCN)_4]$ as the calibrant. Variable temperature magnetic susceptibilities were measured at the Institute of Physics, Chinese Academy of Sciences, using a vibrating magnetometer Model CF-1 (sensitivity $m = 10^{-4}$ emu). Diamagnetic corrections were made with Pascal's constants [7] for all the constituent atoms and effective magnetic moments were calculated by the equation $\mu_{eff} = 2.828 (\chi_M T)^{1/2}$, where χ_M is the molar magnetic susceptibility corrected for diamagnetisms of the constituting atoms.

RESULTS AND DISCUSSION

Composition of the complexes

On the basis of elemental analyses and physical data listed in Table 2 it is reasonable to conclude that the reaction of chloranilic acid (H_2CA) with $Fe(ClO_4)_3 \cdot 6H_2O$ and L (L = bpy, phen, Me_2bpy, NO_2-phen, Cl-phen, Me-phen) in 1:2:4 mole ratio yielded the binuclear complexes of the general formula $[Fe_2(CA)L_4](ClO_4)_4$, as expected. All the Fe(III)—Fe(III) binuclear complexes are sparingly soluble in water, ethanol, carbon tetrachloride, chloroform and benzene, but soluble in DMF and DMSO to give stable solutions at room temperature. For the six complexes, the molar conductance values in DMF solution at 25°C (see Table 2) fall in the expected range for 1:4 electrolytes [8], indicating that the four perchlorate anions are situated outside the metal coordination sphere.

In spite of our many efforts, single crystals suitable for X-ray crystallography have not yet been obtained for these complexes. However, the binuclear structures are supported by the following results.

Infrared spectra

In order to clarify the mode of bonding, the IR spectra of the free ligand (H_2CA) and binuclear iron(III) complexes were studied and assigned on the basis of a careful comparison of the latter with the free ligand. The most relevant IR absorption bands due to the complexes along with their assignments are shown in Table 2. We will only discuss the selected infrared bands. In the IR spectra of the six complexes, a very strong peak at 1520–1530 cm^{-1} and a medium peak at 1385–1380 cm^{-1} is observed due to C=O stretching vibrations of the CA ligand. This agrees with D_{2h} symmetry for the CA ligand and suggests a

bridging *bis*-bidentate coordination mode [3]. The *bis*-bidentate coordination modes of the bridging ligand have been revealed by X-ray diffraction analyses of analogous complexes [1,2]. On the other hand, the —N=C— vibrations for the terminal ligands (bpy, phen, Me_2bpy, NO_2-phen, Cl-phen, Me-phen) were shifted to higher frequencies in their binuclear complexes (see Table 2) suggesting that the N atoms of the terminal ligands coordinate with the metal ion. In addition, a broad intense band centered at ca 1100 cm^{-1} and a strong sharp band at ca 630 cm^{-1}, typical for a non-coordinated perchlorate group [9,10], were present for all binuclear complexes. This is consistent with the conductance data of the complexes.

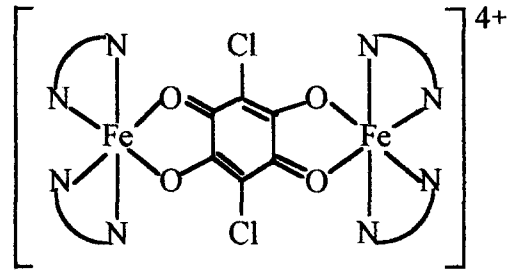

Fig. 1. Coordination environments of the complexes (N $\widehat{\text{N}}$ = bpy, phen, Me_2bpy, Me-phen, NO_2-phen, Cl-phen).

Electronic spectra

As shown in Table 3, the electronic spectra of the six complexes in DMF solutions are similar. Three very weak absorptions ($\varepsilon < 0.1$) were observed. The assignments (see Table 3) of these d-d bands are commensurate with a six-coordinated octahedral geometry [11]. In addition, a broad band at about 500–510 nm was observed in the electronic spectra of the complexes. It is attributed to charge-transfer bands arising from CA ligand, as expected for *p*-benzoquinones [12], further supporting a bridging *bis*-bidentate coordination proposed for CA.

Based on the composition of these complexes, their infrared spectra, electronic spectra, conductivity measurements and magnetic data (*vide infra*), these complexes are proposed to have an extended CA-bridged structure and to contain two Fe(III) ions bridged by the CA ligand in a *bis*-bidentate fashion and each iron(III) ion has an octahedral coordinated environment, as shown in Fig. 1.

Magnetic properties

The observed magnetic moment per binuclear complex at room temperature shown in Table 2 is less than

Table 3. Electronic spectral bands and assignments of the complexes

Complex	UV (nm) CT	^6A_1g–^4T_1g(G)	^6A_1g–^4T_2g(G)	^6A_1g–^4E_g(G)
(1)	500	858	535	390
(2)	505	850	530	395
(3)	508	850	535	385

(5)	510	850	530	390
(6)	500	850	535	380

the spin-only value (8.37 B.M.). This suggests the operation of an antiferromagnetic spin-exchange interaction in these complexes [13]. Being interested in the magnetic behavior of the complexes, variable-temperature (4–300 K) magnetic susceptibility data were further collected for complexes $[Fe_2(CA)(bpy)_4](ClO_4)_4$ (**1**) and $[Fe_2(CA)(phen)_4](ClO_4)_4$ (**2**) and are shown in Fig. 2 in the form of the χ_M, μ_{eff} versus T plot, χ_M being the molar magnetic susceptibility, μ_{eff} the effective moment and T the absolute temperature. From Fig. 2 it is evident that the magnetic behaviors of the two complexes are similar. When the temperature is lowered, the effective magnetic moments values decrease steadily from 8.30 B.M. for (**1**) and 8.28 B.M. for (**2**) at 300 K to 7.01 B.M. (**1**) and 6.98 B.M. (**2**) at 27.15 K and to 3.45 B.M. (**1**) and 3.38 B.M. (**2**) at 4.50 K. Thus, the observed magnetic behavior clearly demonstrates the operation of a weak intramolecular antiferromagnetic spin-exchange interactions between high-spin iron(III) ions through the CA-bridge within each binuclear unit [14,15]. This is consistent with the room temperature magnetic moment data of the complexes. The rapid decrease of the magnetic moment below 4.50 K may be attributed to an intermolecular antiferromagnetic interaction and/or a zero-field splitting of the iron(III) ion. As can be seen in other cases [16–18], the contribution of the intermolecular interaction and the zero-field

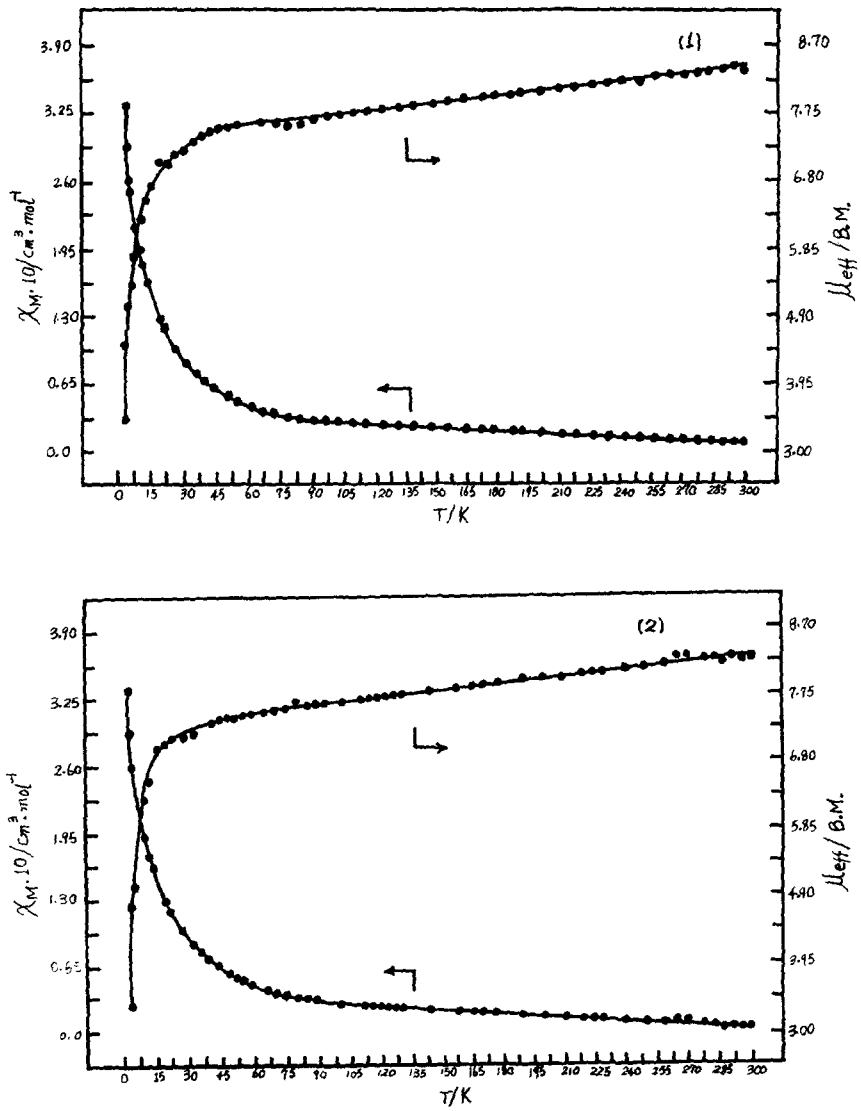

Fig. 2. Temperature variation of χ_M (lower curve) and μ_{eff} (upper curve) for the complexes $[Fe_2(CA)(bpy)_4](ClO_4)_4$ (**1**) and $[Fe_2(CA)(phen)_4](ClO_4)_4$ (**2**). The curve is based on equation (1) using the magnetic parameters given in the text (•), experimental data, (—), calculated curve as described in text.

splitting are evidently weaker than the intramolecular spin exchange and can be negligible. In order to understand quantitatively the magnitude of the spin-exchange interaction, the magnetic analysis was carried out using the susceptibility equation (1) which includes the fraction of a small amount of uncoupled iron(III) impurity (ρ) based on the Heisenberg operator ($\hat{H} = -2J\hat{S}_1 \cdot \hat{S}_2, S_1 = S_2 = 5/2$):

$$\chi_M = (2N\beta^2 g^2/kT)[A/B](1-\rho) + (2.19g^2/T)\rho \quad (1)$$

where

$$A = \exp(2J/kT) + 5\exp(6J/kT + 14\exp(12J/kT) + 30\exp(20J/kT) + 55\exp(30J/kT)$$

$$B = 1 + 3\exp(2J/kT) + 5\exp(6J/kT) + 7\exp(12J/kT) + 9\exp(20J/T)) + 11\exp(30J/kT)$$

and χ_M denotes the molecular susceptibility per binuclear complex, and the remaining symbols have their usual meanings. As shown in Fig. 2, good least-squares fit to the experimental data were obtained with equation (1) for complexes (**1**) and (**2**). This also indicates that the effect of the intermolecular interaction and the zero-field splitting in this case is nominal. The magnetic parameters thus determined and the agreement factor F, defined here as $F = \Sigma[(\chi_M)_{calc} - (\chi_M)_{obs}]^2/\Sigma(\chi_M)_{obs}$ are: $J = -2.1$ cm^{-1}, $g = 2.00$, $\rho = 0.002$, $F = 1.5 \times 10^{-5}$ for (**1**); $J = -5.8$ cm^{-1}, $g = 2.01$, $\rho = 0.004$, $F = 2.1 \times 10^{-5}$ for (**2**). These results indicate that the complexes are essentially binuclear and undergo weak antiferromagnetic spin-exchange interaction between the iron(III) ions within each molecule. The J values of the present complexes are very similar with those of related chloranilato-bridged copper(II) binuclear complexes previously reported [1,2]. The weak antiferromagnetic behavior for these systems may be explained as follows. (i) The distance between metal ions in chloranilato-bridged complexes is rather long [7.843 Å for Cu(II)—Cu(II)] [3]. (ii) Two substituents (Cl) on hydranilic acid may influence the electronic structure of the bridged group. It is well known that the delocalization of the d electrons of the metal towards the bridging atom is one of the main factors affecting the magnetic exchange interaction, while the delocalization extent is determined by the energy gap between the d orbital and bridged atom orbital [19]. Since the chlorine atoms are electron-withdrawing groups which cause decreases in the electron density of the bridged group. The reduction of electron density on the bridged group decreases the electron-electron repulsion and reduced the bridged orbital levels. This will in turn lead to a larger energy gap between the metal and the highest occupied molecular orbitals of the bridge [20] and lower delocalization of the metal orbitals towards the oxygen atoms of bridge, so as to decrease the antiferromagnetic interaction [19].

(Received 12 July 1995, accepted 8 October 1997)

Abstract—Cobalt(II), nickel(II) and copper(II) complexes with BOP-H_2 (dibenzoinlidene-*o*-phenylenediamine) and BPP-H_2 (dibenzoinlidene-*p*-phenylenediamine) of general formulae $[M(H_2L)X_2]$, $[M_2(H_2L)_2X_4]$, $[M(L)]$ and $[M_2(L)_2]$ (where M = Co, Ni, Cu; X = Cl or NO_3; H_2L and L are the neutral and dibasic forms of the ligands) have been prepared by the reaction of the corresponding metal salts with the two ligands in neutral and basic media. The complexes were characterised by elemental analysis, electrical conductance, magnetic susceptibility and spectral measurements. The studies revealed two different actions of the ligands, neutral tetradentate in neutral medium giving hexacoordinated metal atoms with octahedral geometry and dibasic tetradentate in alkaline solution giving tetrahedral and square planar structures © 1998 Elsevier Science Ltd. All rights reserved

Keywords: cobalt(II); nickel(II); copper(II); phenylene diamine derivatives.

A great deal of work has been reported on the synthesis and structural investigation of different types of Schiff bases and their complexes with transition and non-transition elements [1–6]. The importance of Schiff bases in their action as ligands is due to the ease and flexibility of their synthetic procedures as well as the sensitivity towards the central metal atom [7–9]. The majority of Schiff bases that give stable complexes usually act as multidentate N—N and N—O donors with the formation of mononuclear complexes. In some cases stable oxygen-bridges polynuclear complexes have been reported [6,10,11]. Aside from the interesting ligational properties, these Schiff bases have important biological activity [12–14].

We have reported previously the synthesis of many Schiff bases derived from the reactions of benzoin with acid hydrazides [5,6] or aminophenol [15]. In these complexes the ligands act as tri- and tetradentates forming mononuclear and oxygen-bridged binuclear complexes. In this paper we report the synthesis of Schiff bases derived from the reaction of benzoin with *o*- and *p*-phenylenediamine and the study of their complexes with cobalt(II), nickel(II) and copper(II).

EXPERIMENTAL

Analysis and physical measurements

The complexes and the ligands were analysed for carbon, hydrogen and nitrogen using a 1106 CE microanalyser. Conductivity measurements were carried out using a 10^{-3} M solution in dimethylformamide on a LF-42 digital conductivity meter at 25°C. The magnetic susceptibility measurements were made by the Faraday method at room temperature using a Bruker BM6 instrument.

Diamagnetic corrections for the ligands were calculated using Pascal's constants [16]. Infrared absorption spectra were recorded on Pye-Unicam Sp-2000 and Sp-1100 spectrophotometers (200–4000 cm^{-1}) as KBr discs. The electronic spectra were recorded on a Shimadzu UV-160 spectrophotometer for 10^{-3} M solution of the compounds in DMF at 25°C, using a 1 cm quartz cell.

MATERIALS AND METHODS

All the chemicals were of AnalaR. B.D.H., Aldrich or Fluka grade used without further purification. Synthesis of the ligands: the Schiff base ligands, BOP-

H_2 and BPP-H_2, were prepared by the reaction of *o*- or *p*-phenylenediamine with benzoin (in 1:2 molar ratio) in absolute ethanol following the standard procedure reported for similar compounds [6].

Preparation of the complexes

The complexes were prepared by the following general procedure using the appropriate stoichiometries for the metal salt and ligand. A warm ethanolic solution of the metal salt (0.01 mol in 15 cm^3) was added to a warm stirred ethanolic solution of the ligand (0.01 mol in 20 cm^3). The resulting mixture was then treated in two different ways. In the first, the mixture was refluxed on a water bath for about 5–6 h. The solution was then evaporated to about half its volume and on cooling a crystalline product separated out. In the second method, 0.1 M potassium hydroxide was added slowly, with constant stirring, to the mixture till pH 8–8.5. At this pH complete precipitation occurred and the mixture was digested on a water bath for about 10 min and then cooled. The separated complexes from both methods were filtered off, washed with cold ethanol, diethylether and dried *in vacuo*.

RESULTS AND DISCUSSION

The new complexes were synthesized in good yield by the reaction of the metal salts with the two ligands in neutral and basic media according to the following equations:

$$MX_2 + \text{BOP-}H_2 \rightarrow [M(\text{BOP-}H_2)X_2]$$

$$2MX_2 + 2\text{BPP-}H_2 \rightarrow [M_2(\text{BPP-}H_2)_2X_4] \quad (1)$$

$$MX_2 + \text{BOP-}H_2 + 2KOH \rightarrow [M(BOP)] + 2KCl + 2H_2O$$

$$2MX_2 + 2\text{BPP-}H_2 + 4KOH \rightarrow [M_2(BPP)_2] + 4KX + 4H_2O \quad (2)$$

where M = Co, Ni, Cu; X = Cl or NO_3; BOP-H_2 BPP-H_2 are the neutral forms of the ligands derived from *o*- and *p*-phenylenediamine, respectively, and BOP, BPP are the dibasic form of the same ligands. The complexes gave satisfactory analytical data (Table 1) indicating 1:1 metal-to-ligand stoichiometry for all of them. The complexes are air stable at room temperature but they decompose without melting at temperatures above 250°C. All the complexes are insoluble in water but they are soluble to a limited extent in methanol, ethanol, DMF and DMSO. Their low electrical conductances in DMF are consistent with the given formulation (Table 1) indicating non-electrolytic nature [17]. The active sites of the ligands and their coordination to the metal atoms as well as the structure of the resulting complexes were inferred by spectral and magnetic measurements.

Infrared spectra

The bonding of the ligands to the metal atom was characterised by comparison of the main infrared absorption bands of the free ligands and their complexes. Each ligand contains two symmetrical benzoinlidene groups (HO—C—C=N—) which show OH and C=N function in the same infrared region. The important bands of the free ligands and their complexes are given in Table 2.

For complexes formed in neutral medium (**1**), $[M(\text{BOP-}H_2)X_2]$ and $[M_2(\text{BPP-}H_2)_2X_4]$, the bands due to ν(OH) and δ(OH) vibrations showed negative shift of about 100–130 and 30–40 cm^{-1}, respectively, suggesting the involvement of alcoholic hydroxyle in coordination through their oxygen atoms.

The observation of a ν(C—O) band at lower frequency by 30–40 cm^{-1} and its splitting into two peaks (due to C—O—H) was considered to be further support for the coordinate of alcohol groups without deprotonation (Fig. 1) as observed in similar complexes [6]. The shifting of ν(C=N) band to lower values by 25–30 cm^{-1} indicates the participation of the two azomethine nitrogen atoms in bonding [8,9,18]. Additional bands, not observed in the free ligands' spectra located at about 1530, 1280 and 930 cm^{-1} are attributed to νN—O of unidentate coordination of nitrato groups [19]. The chloro complexes exhibit bands in the range 280–290 cm^{-1} and are assigned to the stretching frequency of coordinated chloride ions [20].

For **2** complexes formed in basic solution, [(BOP)] and $[M_2(BPP)_2]$, the disappearance of OH-stretching and deformation bands indicates the action of the ligands in their dibasic forms. This coordination was confirmed by the negative shift of the single ν(C—O) band by 30–35 cm^{-1}. Furthermore, the C=N stretching bands in their complexes were lowered by 25–30 cm^{-1} and thus suggesting bond formation through azomethine groups similar to that observed in **1** complexes [8].

In both types, new bands were noticed in the infrared spectra at 440–450 and 480–485 cm^{-1} and assigned to stretching modes of M—N and M—O, respectively [21,22].

Electronic spectra and magnetic moments

The μ_{eff} values and the positions of the electronic spectral bands together with the proposed geometries are given in Table 3. The electronic spectra of the complexes in DMF indicate two different structural configurations. For cobalt(II) complexes of **1**, two bands were observed and assigned to $^4T_1g(F) \rightarrow {}^4T_2g(F)(\nu_1)$ and $^4T_1g(F) \rightarrow {}^4T_1g(P)(\nu_3)$ transitions, respectively, in an octahedral environment [23]. [a] As in Table 1.
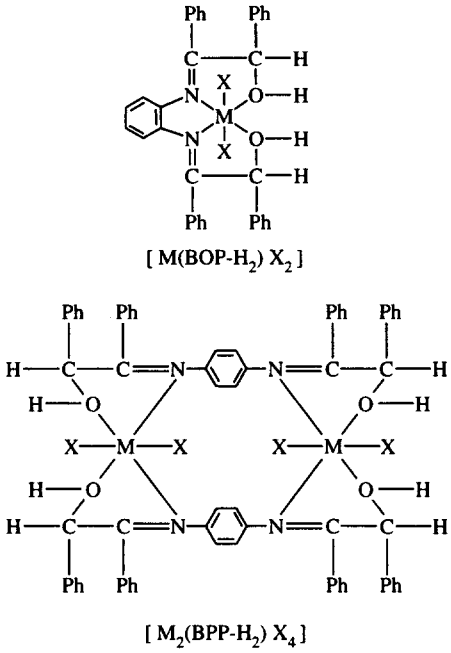
[b] X = Cl or NO_3.

ν_2 band due to $^4T_1g(F) \rightarrow {}^4A_2g(F)$ transition could not be observed, as it is a two electron process and is much weaker than the other two transitions [24]. Therefore the ν_2 transition remain almost unobserved because of its weakness and proximity to a strong ν_3 transition [25]. However the values of ν_2 bands have been calculated and the results are in good agreement with Tanabe–Sugano diagram for a d^7 ion in an octahedral environment where ν_2 and ν_3 transitions are predicted to lie almost at the same position [26]. The electronic spectra of nickel(II) complexes of **1** exhibit three bands attributed to ν_1, ν_2 and ν_3 which correspond to the transitions $^3A_2g(F) \rightarrow {}^3T_2g(F)$, $^3A_2g(F) \rightarrow {}^3T_1g(F)$ and $^3A_2g(F) \rightarrow {}^3T_1g(P)$, respectively. The spectra of both nickel(II) complexes referred to considerable distortion for octahedral symmetry (not observed for



[M(BOP-H_2) X_2]

[M_2(BPP-H_2) X_4]

Fig. 1.

cobalt(II) complexes) since the calculated energy difference between $^3T_1g(P)$ and $^3T_1g(F)$ levels (14,500 cm^{-1}) is greater by about 5200 cm^{-1} than the difference ν_3–ν_2 (~9300 cm^{-1}). This is presumably due to interligand interaction and repulsion causing elongation of metal–ligand bonds and thus leading to distortion of the octahedron [27]. In the case of copper(II) **1** complexes a broad asymmetric band was observed and assigned to the three combined transitions $^2B_1g \rightarrow {}^2A_1g$, $^2B_1g \rightarrow {}^1B_2g$ and $^2B_1g \rightarrow {}^2Eg$ of tetragonally distorted octahedral environment around copper(II) ion due to the Jahn–Teller effect [28–30].

The effective magnetic moments for BOP-H_2 complexes measured at room temperature fall in the range expected for high-spin octahedral geometries [31] for cobalt(II), d^7, nickel(II), d^8, and copper(II), d^9, systems consistent with the presence of three, two and one unpaired electrons, respectively. On the other hand, the μ_{eff} values for BPP-H_2 complexes were less than those expected. The lower values may be attributed to binuclear dimeric structure as observed for similar complexes and ascribed as antiferromagnetic coupling of the unpaired electrons on the adjacent metal ions [32].

The complexes of **2** exhibit two different geometries as found from the electronic spectra and magnetic moments. Cobalt(II) and nickel(II) complexes exhibit two bands due to $^4A_2(F) \rightarrow {}^4T_2(P)$. $^4A_2(F) \rightarrow {}^4T_1(F)$ and $^3T_1(F) \rightarrow {}^3A_2(F)$, $^3T_1(F) \rightarrow {}^3T_1(P)$ transitions and assigned to ν_2 and ν_3, respectively. The low energy transition $^4T_2(F) \rightarrow {}^4T_2(F)$ and $^3T_1(F) \rightarrow {}^3T_2(F)$ of the unobserved band ν_1 was theoretically calculated [24]. The positions and intensity of these bands are consistent with tetrahedral geometry for the tetracoordinated cobalt(II) and nickel(II) complexes [23]. For copper(II) complexes, only one broad band was observed in their electronic spectra. This band is attributed to the $^2B_1g \rightarrow {}^2Eg$ transition which is consistent with square planar geometry around the copper(II) ion [33]. Once again, all the complexes were found to be paramagnetic with magnetic moments (Table 3), for BOP-complexes consistent with three, two and one unpaired electron, while for BPP-complexes lower μ_{eff} values were observed (as in **1**) and attributed to superexchange mechanism.

From the above discussion and on the bases of the data given in Tables 1–3, the following conclusion can be drawn. Both ligands act as tetradentate forming hexacoordinate complexes (in neutral medium) with most probable octahedral or distorted octahedral

structures. In basic medium, they act as dibasic tetradentate forming tetrahedral and probably distorted planar [for cobalt(II) and nickel(II)] and square planar [for copper(II)] complexes. Mononuclear complexes were obtained with BOP ligand, while BPP acts as bridging ligand forming dinuclear complexes as shown in Figs 1 and 2.

EPR studies on irradiated group VI tetrachalconide ions

Tim Ecclestone, Stuart H. Laurie,* Martyn C. R. Symons and Fatai A. Taiwo

Department of Chemistry, De Montfort University, The Gateway, Leicester LE1 9BH, U.K.

(Received 21 July 1997; accepted 7 October 1997)

Abstract—EPR measurements have been made at X-band frequency and at 77 K on γ-irradiated glassy solutions of salts of the d^0 chalconide anions MX_4^{2-} (M = Cr, X = O; M = Mo, X = O or S; M = W, X = O or S). Annealing of the irradiated solutions revealed broad high-field spectral features attributable to one-electron addition to the anions. The exception being WS_4^{2-}, for which no EPR signal was detectable at 77 K or above. The results point to the added electron being predominantly located on the metal centre (d^1). The g-shifts are interpreted in terms of a distorted T_d geometry with a $d_{x^2-y^2}$ configuration. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: EPR; γ-irradiation; tetrachalconides; group VI.

INTRODUCTION

Early work by one of us demonstrated that conversion of MnO_4^- into MnO_4^{2-} and MnO_4^{3-} occurred in alkaline solutions [1–3], similarly CrO_4^{2-} was observed to convert to CrO_4^{3-} simply by dissolution in concentrated aqueous alkali at room temperature [3]. It was also shown that exposure of potassium chromate crystals to ionizing radiation gave an EPR spectrum assignable to CrO_4^{3-} ions [4]. EPR spectra were also obtained [5,6] for MnO_4^{2-}, MnO_4^{3-} and FeO_4^{2-}. These early studies have been summarised in a review [7]. At about the same time Banks *et al.* [8] showed that CrO_4^{3-} ions formed at very high temperatures in Ca_3PO_4Cl doped with chromate, the Cr(V) centres were characterised by EPR and optical spectroscopy. It is also worth noting that the concentrated alkaline solutions referred to above evolve oxygen, formed from the solvent water [9]. It was suggested that this reaction involved an initial electron transfer from OH^- ions [1,2,9]. So far as we know this novel source of ·OH (·O$^-$) radicals has never been exploited or refuted.

We know of no comparable studies for d^1 Mo or W tetraoxides or tetrasulphides. A report [10] on irradiated calcium tungstate describes a centre with g values greater than the free spin value (2.0023) which, in our view, seems to arise from the electron-loss centre $O_3W—O^{\circ-}$ and not the expected d^1 derivative WO_4^{3-}. The lowest orbitals available for an added electron in these tetrahedral anions are the $e_2 d_{x^2-y^2}$ and d_{z^2} pair and the $p(\pi)$ orbitals of the ligands. The orbital degeneracy is strongly lifted by distortions to give either $d^1_{z^2}$ or $d^1_{x^2-y^2}$ ground-states, both these have g tensor components less than the free-spin value.

The aim of the present work was to prepare and contrast the CrO_4^{3-}, MoX_4^{3-} and WX_4^{3-} d^1 complex ions (X = O or S). One particular reason for this arose from the finding of Mo(V) and W(V) centres in some new ternary metal sulphides prepared from the d^0 MoS_4^{2-} and WS_4^{2-} ions [11,12] and the need to prepare and characterise simple MS_4^{3-} centres for comparison. This can readily be achieved using ionizing radiation coupled with matrix isolation. By selecting suitable solvents in which the substrate (Su) is soluble and which freezes to a glassy solid without phase separation, only electron addition to give Su^- centres occurs initially [13]. Hence, we set out to add one electron only to the d^0 CrO_4^{2-}, MoO_4^{2-}, WO_4^{2-}, MoS_4^{2-} and WS_4^{2-} anions. Recently there has been a strong revival of interest in the high-valence states of transition metals. This is in part because of the realisation that anions such as CrO_4^{2-} are potential carcinogens, and in part because of the recognition that high-valence states, especially of iron, are of potential importance in biological redox processes [14].

EXPERIMENTAL

Ammonium or potassium salts of the tetraoxo ions of AnalaR or Puriss grade were used (the cation was found to have no influence in the dilute systems used). $(NH_4)_2MoS_4$ and $(NH_4)_2WS_4$ were prepared by standard literature methods and their purities verified by their UV/VIS and IR spectra [15,16].

For irradiation the compounds were dissolved in de-gassed deuterated water–methanol (D_2O–CD_3OD) mixtures which formed glassy solids on freezing at 77 K. Frozen pellets were irradiated at 77 K in a Vickrad ^{60}Co gamma source at doses between 10^3 and 10^4 Gy.

First derivative EPR spectra were measured at 77 K using a Bruker EMX 6/1 X-band spectrometer set at a frequency of ca 9.7 GHz using 100 KHz modulation in a T_{102} rectangular cavity. Operating conditions were 10 mW microwave power, 7G modulation amplitude, centre field 3488G, sweep width 3000G, time constant 20.48 min and scan time 41.94 s with multiple accumulations to enhance the signal-to-noise ratio. Qualitative assignment of spin Hamiltonian parameters was by simulation using the Simfonia program (Bruker). After the first measurements the samples were subsequently annealed by warming above 77 K to eliminate solvent radicals, and re-cooling rapidly back to 77 K for further EPR measurements. This annealing cycle was continued until no further changes were observed apart from some loss in the solute-radical spectra.

RESULTS AND DISCUSSION

In all cases, except for WS_4^{2-} solutions, broad high-field features were observed in addition to the signals from solvent radicals in the free-spin region. The broad features can be assigned to electron capture species. That electron capture species had formed rather than trapped electrons was indicated by the absence of any narrow ESR singlet and the absence of any intense (purple-black) colouration. In all cases these high-field features were broad and ill defined at 77 K but narrowed irreversibly on annealing. Clear parallel ($\parallel$) and perpendicular ($\perp$) features were then resolved (see, for example, Figs 1 and 2).

Only WS_4^{2-} failed to give any detectable EPR spectrum after irradiation. The EPR spectrum of any electron capture species in this case is most likely to be too broad to be detected at 77 K. This is not unexpected; in fact, it is more surprising that we were able to detect the WO_4^{3-} species, despite the very large g-shifts (see Table 1). Weak features observed on either side of the main peaks are assignable to the presence of low abundant magnetic nuclei, i.e., ^{53}Cr (9.5%, $I = 3/2$), ^{95}Mo (15.9%, $I = 5/2$) and ^{97}Mo (9.55%,

$I = 5/2$) (Fig. 1). The hyperfine features from the two Mo isotopes were not separately resolved. Unfortunately, the main features for WO_4^{3-} were always so broad that the expected satellite features from ^{183}W (14.28%, $I = 1/2$) were not resolvable (see Fig. 2).

Interpretation of spectra

The observed g-shifts suggest that the (T_d) e_2 d orbitals of the central metal ion must have been extensively split as a result of marked deviations from the pure T_d symmetry of the parent di-anions. In the present examples these distortions appear to place the $d_{x^2-y^2}$ level below the d_{z^2} level in contrast, for example, with the results reported by McGarvey and co-workers [8] for CrO_4^{3-}. For the $d^1_{x^2-y^2}$ systems the order $g_\parallel < g_\perp < FS$ is expected, whilst for the d_{z^2} configuration the order is $g_\perp < g_\parallel \approx FS$ (FS = the free spin value of 2.0023), see Table 1.

The form of the hyperfine splitting for ^{53}Cr and $^{95/97}Mo$ also accord with expectation for a $d^1_{x^2-y^2}$ configuration. Both $A_\parallel$ and $A_\perp$ are assigned "positive" values in order to obtain data of the expected form [we note that all the magnetic nuclei have negative moments so that signs are reversed compared with

those for the more usual positive nuclei]. This choice of signs results in "positive" values for both A_{iso} and 2B (Table 2), where 2B is the purely anisotropic dipolar interaction term. The "positive" signs with A_{iso} and 2B and their magnitude are in accord of the assignment of the $d_{x^2-y^2}$ orbital as the singly occupied molecular orbital (SOMO).

It is of interest to compare these results for the CrO_4^{3-} anion with those of McGarvey and co-workers [8]. Their d^1 anion was generated thermally in a phosphate lattice. In this case, the mode of distortion from T_d symmetry would be strongly influenced by lattice requirements, this would explain the inversion of g values compared with our results. Furthermore, the spin Hamiltonians clearly show that their Cr (V) nuclei are not purely axial in symmetry; $|A_x| \neq |A_y|$, (see Table 1). The estimated spin density on the metal ion in this case is ~50%, a strong indication of less charge transfer from the oxo-ligands to the metal than in our system with a metal spin density of ~94%. The form of the ^{53}Cr hyperfine components fit nicely with a $d_{z^2}^1$ assignment. It was earlier suggested that for d^1 systems with $|A| > |B|$ the ground-state would be consistent with a $d_{z^2-y^2}^1$ configurations, whilst if $|A| < |B|$ it should be $d_{z^2}^1$. Reported experimental data do not support this as a general rule; so we prefer to argue from the relative g-values as above. It seems clear from the CrO_4^{3-} results that small changes in symmetry induced by the environment, can switch the system between $d_{x^2-y^2}^1$ and $d_{z^2}^1$ configurations.

For the present study, a further strong possibility, especially on annealing, would be protonation of the anions. The parent anions would already be strongly solvated so that movement of H^+ within such units would be facile. However, there was no direct evidence of protonation having occurred.

Table 2. Estimated spin-densities on Mo and W centres

Complex	A_{iso}/G[a]	2B/G	Spin-densities on metal
CrO_4^{3-} [b]	+38.0	+19.9	94%
CrO_4^{3-} [c]	+18.0	+10.0	50%
MoO_4^{3-}	+50.7	+23.3	90%
MoS_4^{3-}	+43.0	+28.0	91%
WO_4^{3-}	[d]		

[a] G = 10^4T.
[b] From Ref. [9],
[c] From Ref. [8],
[d] No hyperfine features resolved.

CONCLUSIONS

This study underlines the utility and simplicity of the use of ionizing radiation coupled with dilute glassy media for generating one-electron addition at low temperatures. These systems are ideal for study by EPR spectroscopy. From this work it appears that the d^1 anions CrO_4^{3-}, MoO_4^{3-} and WO_4^{3-} have very similar structures, the larger g-value shifts for WO_4^{3-} being a reflection of the large spin-orbit coupling constant for tungsten. The similarity in magnetic parameters of MoO_4^{3-} and MoS_4^{3-} is consistent with the electron being predominantly located on the metal centre (d^1), this is further supported by the spin-density values shown in Table 1. [Although these estimated values are regarded as approximations only our experience has always been that the method does give qualitatively meaningful values of spin-densities.]

Interaction of the polyfunctional 2-mercaptonicotinic acid with the ruthenium(III)-edta complex

Francisca N. Rein and Henrique E. Toma*

Instituto de Química, Universidade de São Paulo, C. Postal 26077, CEP 05599–970, São Paulo, SP, Brazil

(Received 18 May 1997; accepted 6 October 1997)

Abstract—Ruthenium(III)-edta reacts with the 2-mercaptonicotinic ligand in aqueous solution yielding a red product (λ_{max} = 530 nm) coordinated at the S atom. This species undergoes deprotonation with an apparent pK_a = 3.80, generating a blue complex in which the ligand is (*S,N*)-bidentate. In the presence of two times excess of ruthenium(III)-edta a binuclear species is formed, involving two bidentate (*N,S*) and (*S,O*) coordination modes for the bridging ligand. The corresponding mixed-valence species exhibits a strong intervalence band at 8000 cm^{-1}, involving an electronic coupling energy of 990 cm^{-1}. An extensive investigation is reported for the complexes, based on kinetics, cyclic voltammetry and spectroelectrochemistry. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: ruthenium-edta; mixed-valence complex; polyfunctional ligand.

The coordination chemistry of polyfunctional ligands can be particularly interesting from the point of view of their selective binding to transition metal ions and formation of extended structures. As a matter of fact, polyfunctional ligands are widespread in biological systems, including the aminoacids and nucleic acids, and in addition, the properties of their metal derivatives can be exploited in the area of molecular materials [1], and in supramolecular chemistry and devices [2].

In this work we focused on the reaction of the 2-mercaptonicotinic acid (H_2mnic) with the ruthenium-(III)-edta complex in aqueous solution. This polyfunctional molecule exhibits three potential binding sites for transition metal ions, and can act as a monodentate, bidentate and bridging ligand, as illustrated in Scheme (1).

In fact, all these species can be generated, under controlled conditions, in the presence of the $[Ru^{III}(edta)]^-$ complex. The investigation of their kinetics, redox and spectroelectrochemical properties, is reported herein.

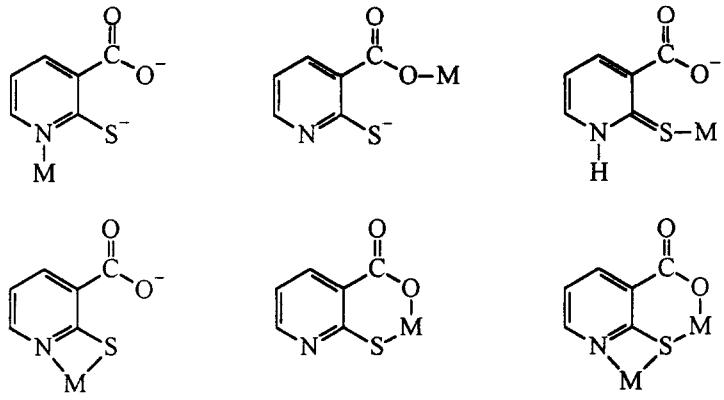
EXPERIMENTAL

The $[Ru^{III}(Hedta)H_2O]\cdot 4H_2O$ complex, here denoted $Ru^{III}A$, was obtained according to the procedures previously reported in the literature [3,4]. Found: C, 25.4; H, 4.0; N, 5.9. Calc. for $RuC_{10}H_{23}N_2O_{13}$: C, 25.0; H, 4.8; N, 5.8. The blue complex $Na_3[Ru^{III}(edta)(mnic)]\cdot 8H_2O$ was prepared by reacting 0.070 g (0.15 mmol) of $Ru^{III}A$ with 0.024 g (0.15 mmol) of mnic (Aldrich), in 10 cm^3 of water, under an argon atmosphere. After 10 min the pH was raised up to 6.50 by adding a 0.1 mol dm^{-3} NaOH solution, and the mixture was evaporated to dryness using a rotary evaporator. The dark solid was dissolved in 10 cm^3 of methanol, and precipitated by adding 15 cm^3 of diethyl ether. The blue complex was colleted on a filter, washed with ether and dried under vacuum. Found: C, 25.6; H, 3.8; N, 5.3. Calc. for $Na_3RuC_{16}H_{31}N_3O_{18}S$: C, 25.4; H, 4.1; N, 5.5.

The electronic spectra of the complexes were recorded on a Hewlett-Packard model 8452-A diode-array spectrophotometer, or on a Guided-Wave model 260 fiber-optics instrument. Cyclic voltammetry was carried out using a Princeton Applied Research Corp. (PARC) model 173 potentiostat and



Scheme 1.

model 175 universal programmer. A glassy carbon working electrode and a platinum wire auxiliary electrode were employed for the measurements vs the Ag/AgCl (1 M KCl) reference electrode ($E^{\circ} = 0.222$ V vs SHE). The reversible behavior of the voltammetric waves has been evaluated, considering, simultaneously, the separation of the anodic and cathodic peaks (typically in the 60–70 mV range), their similar intensities; and the linear response of the peak currents vs the square root of the scan rates.

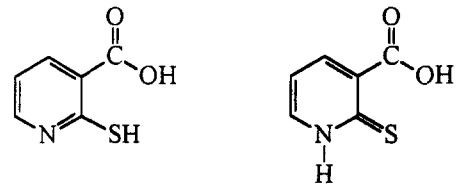
Spectroelectrochemical measurements were carried out using the PARC 173 potentiostat in parallel with the diode-array or Guided Wave spectrophotometer. A three-electrode system was designed for a rectangular quartz cell of 0.025 cm internal path length. A gold minigrid was used as a transparent working electrode, in the presence of a small Ag/AgCl reference electrode and of a platinum auxiliary electrode. The kinetics of the substitution reactions involving $Ru^{III}A$ and $Hmnic^{-}$ were investigated using an Applied Photophysics stopped-flow instrument.

Molecular modeling and semiempirical calculations were carried out using the ZINDO/1 method, at a refinement level of 1×10^{-5} kcal.

RESULTS AND DISCUSSION

The 2-mercaptonicotinic acid undergoes three successive acid-base equilibria, leading to characteristic changes in the UV spectra, as shown in Fig. 1. a–c.

The electronic spectrum of the neutral H_2mnic species (pH 2.00) consists of three bands at 224 ($\varepsilon = 5100$ mol^{-1} dm^3 cm^{-1}), 296 (11,400) and 362 nm (3100), which can be compared with the $\pi \rightarrow \pi^*$ bands observed at 230, 247 and 324 nm for the 2-mercaptopyridine compound [5]. Analogously to the related examples reported in the literature [5–7], 2-mercaptonicotinic acid can be better represented by a tautomeric structure exhibiting a protonated N-atom and a thione group, as in Scheme (2).



Scheme 2.

In the pH range from 2–7, the $\pi \rightarrow \pi^*$ bands are shifted to lower wavelengths. The calculated pK_a from the spectrophotometric measurements was 3.68, corresponding to the deprotonation of the carboxylic group. Above pH 7 there is a decay in $\pi \rightarrow \pi^*$ band around 360 nm, and the absorption spectra approach those of typical aromatic N-heterocyclic compounds. The calculated pK_a was 9.75, in comparison with 9.81 for 2-mercaptopyridine [5], corresponding to the deprotonation of the N—H group. The H_2mnic compound can be protonated below pH 0 at the C=S group, leading to dramatic changes in the electronic spectra, as shown in Fig. 1 A. The calculated pK_a was -0.71 in comparison with -1.38 for the 2-mercatopyridine [5].

The reaction of $Ru^{III}A$ with H_2mnic below pH 4 leads to a red product absorbing at 530 nm ($\varepsilon_{max} = 2400$ mol^{-1} dm^3 cm^{-1}), while above this pH, a deep blue ($\lambda_{max} = 616$ nm, $\varepsilon_{max} = 2100$ mol^{-1} dm^3 cm^{-1}) complex is formed. As a matter of fact, the red and blue species coexist in equilibrium in the 3–6 pH range, as shown in Fig. 2, with an apparent $pK_a = 3.80$. A similar behavior has already been observed for the reaction of $Ru^{III}A$ with 2-mercaptopyridine [8], with an apparent $pK_a = 4.35$.

According to the previous work [8], the red complex can be ascribed to the coordination of the thione (C=S) group to the $[Ru^{III}(edta)]^{-}$ complex, as in Scheme (3).

The characteristic band in the visible corresponds to a charge-transfer transition from the ligand C=S donor group to the d_{π} orbitals of Ru^{III} [8,9].

The blue complex results from the deprotonation

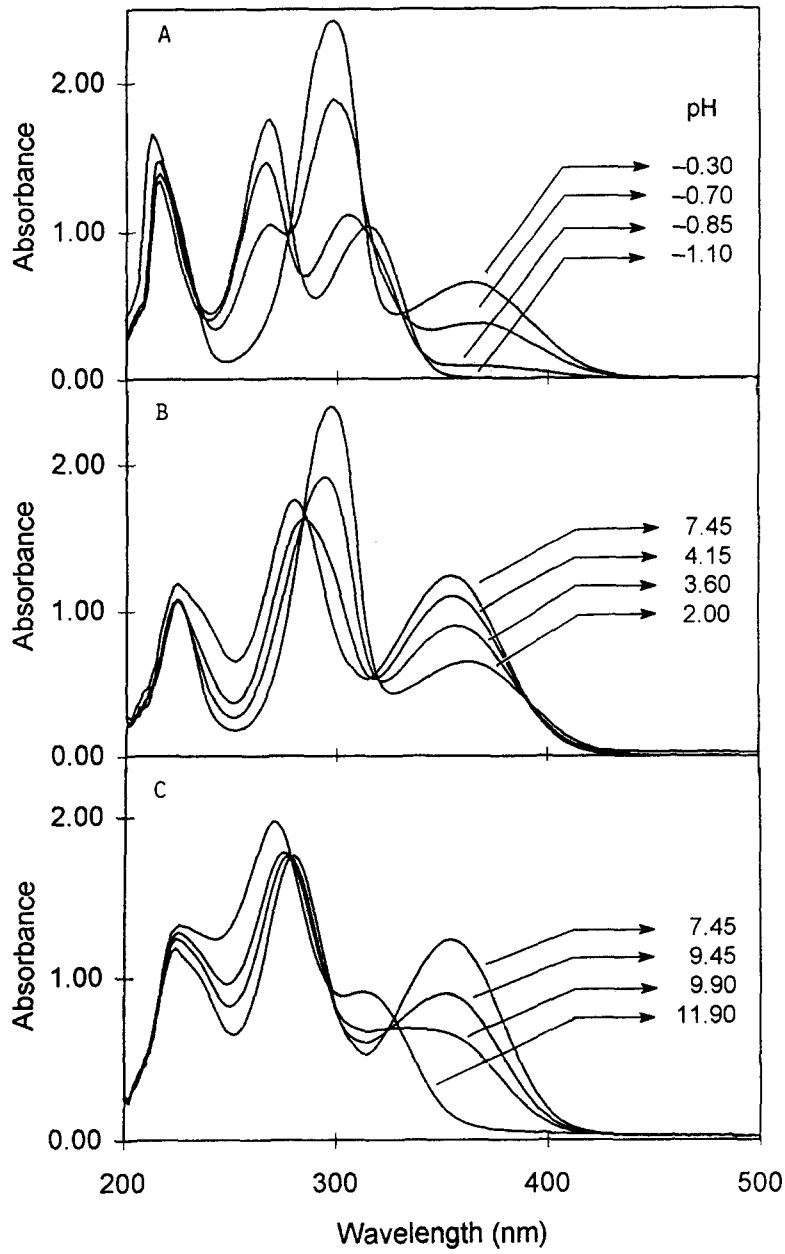


Fig. 1. Electronic spectra of the 2-mercaptonicotinic acid in aqueous solution (pH 2.00) showing the changes due to (a) protonation ($pK_a = -0.71$), and (b, c) successive deprotonation ($pK_a = 3.68$ and 9.75) equilibria.

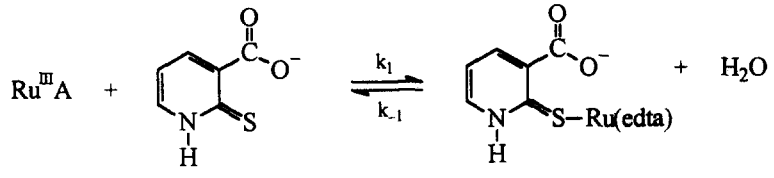

Scheme 3.

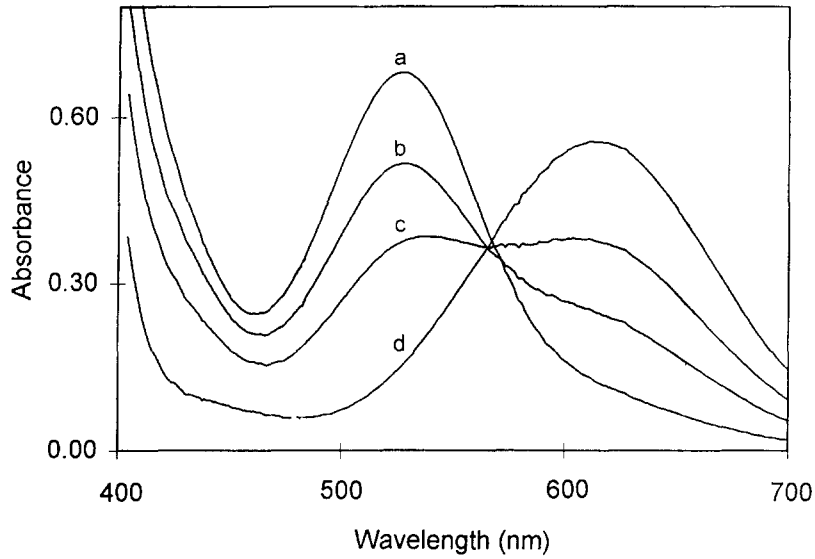

Fig. 2. Electronic spectra of the $[Ru^{III}(edta)(mnic)]^{3-}$ complex, at pH (a) 2.00, (b) 3.50, (c) 4.00 and (d) 6.60, showing the interconversion of the red and blue species.

of the N—H site, and formation of a bidentate structure, as shown in Scheme (4).

Its blue color arises from a ligand-to-metal charge-transfer transition involving the deprotonated —N=C—S^- group and the Ru^{III} d_π orbitals [8].

The decrease of the pK_a of the N—H group from 9.75 in the $Hmnic^-$ ligand to 3.80 in the $[Ru^{III}(edta)(Hmnic)]^{2-}$ complex can be explained considering the Lewis acidity of the Ru^{III} ion and the additional stabilization provided by the chelate ring in the product.

Formation kinetics

The formation of the red complex and its conversion into the blue complex can be monitored by using stopped-flow techniques, according to two well separated consecutive steps, proceeding at time scales of 100 ms and 100 s, respectively, as shown in Fig. 3. For both steps, the kinetics were typically of first order. The observed rate constants for the formation of the red complex were 11, 15 and 18 s^{-1} for $[Hmnic^-] = 0.9$, 1.3 and 1.7 mmol dm^{-3}, respectively, leading to a second order kinetic constant (k_1) of $1.2 \pm 0.1 \times 10^4$ mol^{-1} dm^3 s^{-1} ($T = 25°C$, [KCl] = 0.10 mol dm^{-3}, 0.01 mol dm^{-3} acetate buffer). This step

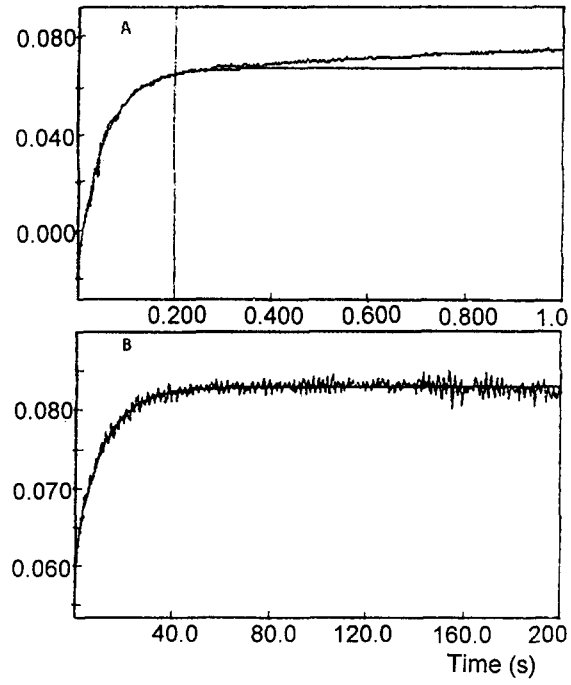

Fig. 3. Stopped-flow kinetic plots for the reaction of $[Ru^{III}(edta)]^-$ with $Hmnic^-$, showing (a) the rapid formation of the red complex, and (b) its conversion to the blue species (pH 3.80, 0.01 mol dm^{-3} acetate buffer, $I = 0.10$ mol dm^{-3} KCl).

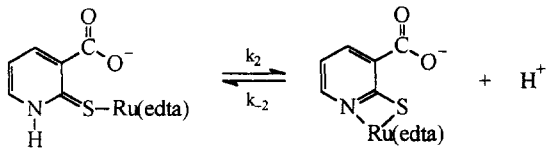

Scheme 4.

involves the substitution of the labile water molecule in $[Ru(edta)H_2O]^-$, which is known to proceed via an associative mechanism in aqueous solution [10,11].

The conversion of the red complex to the blue species proceeds to the equilibrium at pH 3.80, with an observed rate constant of $0.094 \pm 0.002\ s^{-1}$ which does not depend on the concentration of the 2-mercaptonicotinic ligand. As for a typical equilibrium kinetics, the observed rate constants should be expressed in terms of the forward and reverse rate constants, i.e., $k_{obs} = k_{forward} + k_{reverse}$.

Since $k_{obs} = k_2 + k_{-2}[H^+]$ and $K_2 = (k_2/k_{-2}) = 1.6 \times 10^{-4}$ mol dm^{-3}, one can calculate $k_2 = 0.048\ s^{-1}$ and $k_{-2} = 3.0 \times 10^2$ mol^{-1} dm^3 s^{-1}.

Dissociation kinetics

The dissociation of the blue $[Ru^{III}(edta)(mnic)]^{3-}$ complex proceeds very slowly even in the presence of a high excess of pyridine as the entering ligand, leading to the decay of the characteristic charge-transfer bands in the visible region. The kinetics were typically of first order, with $k_{obs} = 6.3 \pm 0.2 \times 10^{-4}\ s^{-1}$, independently of the concentration of pyridine above 0.1 mol dm^{-3}, [KCl] = 0.1 mol dm^{-3}, pH 5.50.

Based on the microscopic reversibility principle, the following Scheme (5) can be proposed for the substitution kinetics:

$$Ru^{III}(NS\text{-}mnic) + H^+ \overset{K_2^{-1}}{\rightleftharpoons} Ru^{III}(S\text{-}Hmnic)$$

$$Ru^{III}(S\text{-}Hmnic) + H_2O \underset{k_1}{\overset{k_{-1}}{\rightleftharpoons}} Ru^{III}A + Hmnic$$

$$Ru^{III}A + py \overset{k_{py}}{\rightleftharpoons} Ru^{III}py + H_2O \qquad (5)$$

Assuming a steady state approximation for $[Ru^{III}A]^-$

$$-\frac{d[Ru^{III}(NS-mnic)]}{dt} = k_{obs}[Ru^{III}(NS-mnic)]$$

where

$$k_{obs} = \frac{k_{py}k_{-1}K_2^{-1}[H^+][py]}{k_1[Snic] + k_{py}[py]}$$

Since [py] ≫ [mnic], and k_1 is of the same magnitude as k_{py} [10], the expression for k_{obs} reduces to

$$k_{obs} = k_{-1}K_2^{-1}[H^+]$$

Therefore, considering that $[H^+] = 3.2 \times 10^{-6}$ mol dm^{-3}, and $K_2^{-1} = 6.3 \times 10^3$ mol^{-1} dm^3, one can calculate $k_{-1} = 3.2 \times 10^{-2}\ s^{-1}$, from the observed rate constants, and

$$K_1 = \frac{k_1}{k_{-1}} = \frac{1.1 \times 10^4}{3.2 \times 10^{-2}} = 3.4 \times 10^5 \text{ mol}^{-1} \text{ dm}^3$$

Cyclic voltammetry and spectroelectrochemistry

The electrochemical behavior of the $[Ru(edta)(mnic)]^{3-}$ complex in aqueous solution is typically reversible, as shown in Fig. 4. The $E_{1/2}$ values for

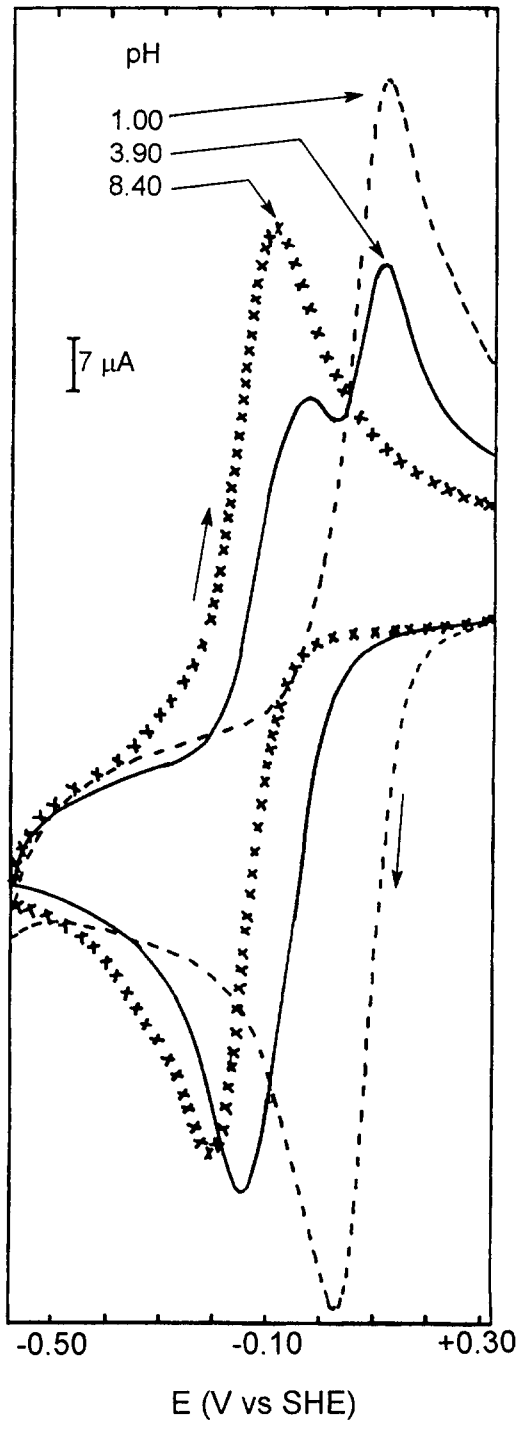

Fig. 4. Cyclic voltammograms of the $[Ru^{III}(edta)(mnic)]^{3-}$ complex at several pHs, scan rate = 100 mV s^{-1}, $I = 0.10$ mol dm^{-3} KCl.

the red and blue species can be evaluated from the measurements below pH 2 and above pH 5, as 0.080 and −0.150 V, respectively. At intermediate pHs the interconversion of the two species in the reduced form proceeds slow enough to be detected by cyclic voltammetry. The kinetic constant for the conversion of $[Ru^{II}(edta)(NS\text{-}mnic)]^{4-}$ into $[Ru^{II}(edta)(S\text{-}Hmnic)]^{3-}$ can be calculated from the cyclic voltammograms obtained at several scan rates using Nicholson and Shain equation [12], as previously reported for the 2-mercaptopyridine complex [8]. The calculated constant was $0.104 \pm 0.002\ s^{-1}$, in comparison with $1.9\ s^{-1}$ for the 2-mercaptopyridine analogue.

Typical spectroelectrochemical results are shown in Fig 5. The reduction of the red complex proceeds in a reversible way, leading to rise of a strong band at 460 nm (4500) ascribed to a ruthenium(II)-to-mnic^{2-} $d_\pi \rightarrow p_\pi^*$ charge transfer transition. In the case of the blue complex the reduction leads to the decay of the typical band at 616 nm (2100) and to the rise of a strong metal-to-ligand charge-transfer band at 425 nm (2100). The E° values obtained spectroelectrochemically for the red and blue complexes were 0.080 and −0.150 V, respectively, in excellent agreement with those estimated by cyclic voltammetry.

Based on the redox potentials and equilibrium con-

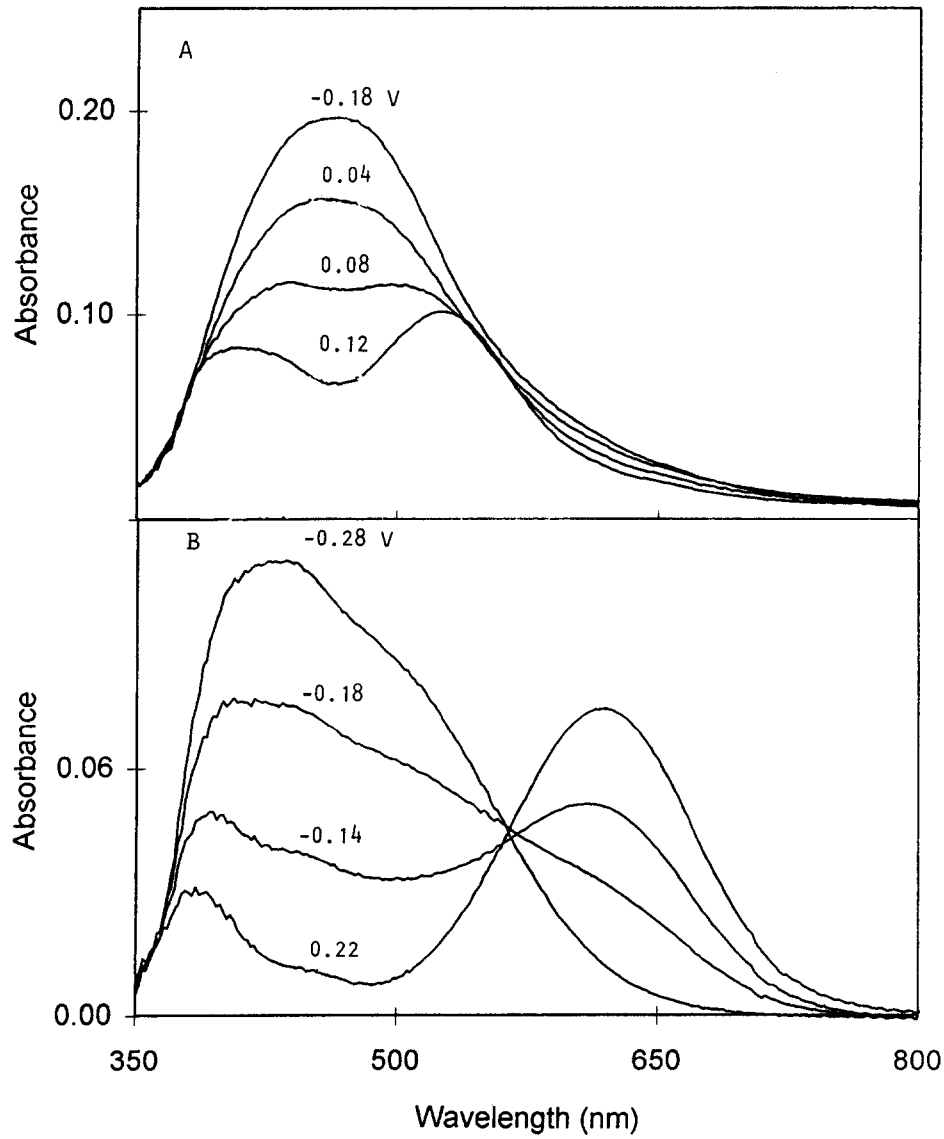

Fig. 5. Spectroelectrochemical behavior of the (a) red and (b) blue forms of the $[Ru^{III}(edta)(mnic)]^{3-}$ complex, at pH 2.0 and 7.0 respectively.

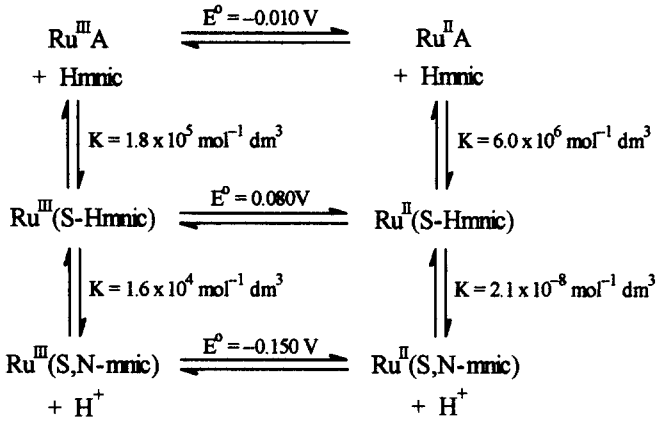

Scheme 6.

stants for the formation of the red and blue complexes, a square thermodynamic cycle can be solved, as previously described [8], in order to calculate the corresponding constants for the reduced species. The complete data are summarized in Scheme (6).

Binuclear complex

The formation of binuclear species was investigated by reacting the mononuclear blue complex with an equivalent amount of $[Ru^{III}A]^-$. The experiments were performed using relatively high concentrations of the complexes, e.g. 50 mmol dm^{-3}, in order to minimize the dissociation of the product. Under such conditions, the reaction led to an intensification and broadening of the characteristic charge transfer band at 600 nm, suggesting the involvement of the thiolate group in the new chromophore group. It should be noticed that ruthenium(III)-carboxylate complexes do not display charge-transfer bands in the visible region.

Typical cyclic voltammograms for the 1 : 1 mixture of the $[Ru^{III}(edta)(mnic)]^{3-}$ and $[Ru^{III}A]^-$ complexes are shown in Fig. 6. Their broad shape reflects composite waves which can be deconvoluted in terms of two reversible peaks exhibiting $E_{1/2} = -0.120$ and -0.040 V. In contrast, the simulation of the composite voltammograms in terms of the starting $[Ru^{III}(edta)(mnic)]^{3-}$ and $[Ru^{III}A]^-$ complexes ($E_{1/2} = -0.150$ and -0.010 V), showed two well resolved peaks, departing from the observed results.

In addition to the spectroscopic and electrochemical results, a definite evidence for the formation of the binuclear complex was obtained spectroelectrochemically, as shown in Fig. 7.

When the applied potential was close to the first $E^\circ = -0.040$ V, a new, strong absorption band appeared in the near infrared region, at 1200 nm. The intensity of this band reached its maximum in the mixed valence region (-0.040 to -0.120 V), decaying completely after the second $E^\circ = -0.120$ V, due to the formation of the totally reduced species. A careful treatment of the spectroelectrochemical data, as shown in Fig. 7 (inset), was consistent with a composite Nernst behavior involving two reversible, monoelectronic redox processes with $E^\circ = -0.040$ and -0.120 V, in excellent agreement with the cyclic voltammetry.

The absorption band in the near infrared region is characteristic of the mixed valence binuclear species, and its high intensity ($\varepsilon = 1200$ mol^{-1} dm^3 cm^{-1}) indicates a substantial electronic coupling between the two metal ions. The binding of the second ruthenium complex by means of the carboxylate group is not favored kinetic and thermodynamically in this case. As a matter of fact, most of the reactions of $[Ru(edta)]^-$ complexes have been carried out in acetate buffer, with no evidence of binding interactions [10]. On the other hand, coordination at the carboxylate group would increase the metal–metal separation, decreasing the extent of the electronic coupling. In contrast, the thiolate group is a strong nucleophile and its binding to $[Ru^{III}(edta)]^-$ would facilitate the formation of a bidentate structure, involving the vicinal carboxylate group. Therefore, the bidentate binuclear complex is expected to exhibit two types of ruthenium centers, represented, in terms of their binding modes, as $Ru^{III}(N,S)$ and $Ru^{III}(S,O)$, or as in Scheme (7).

The simulated structure for the binuclear complex, based on ZINDO/1 calculations, is illustrated in Fig. 8. As one can see, the two metal complexes are not located in the molecular plane of the 2-mercaptonicotinic ligand. The distortion from coplanarity, due to steric reasons, shortens the metal-metal distance to only 4.5 Å.

The electronic coupling, expressed by H_{ab}, can be calculated according to the equation

$$H_{ab} = 2.05 \times 10^{-2} \frac{(\varepsilon_{max} \nu_{max} \Delta\nu_{1/2})^{1/2}}{R}$$

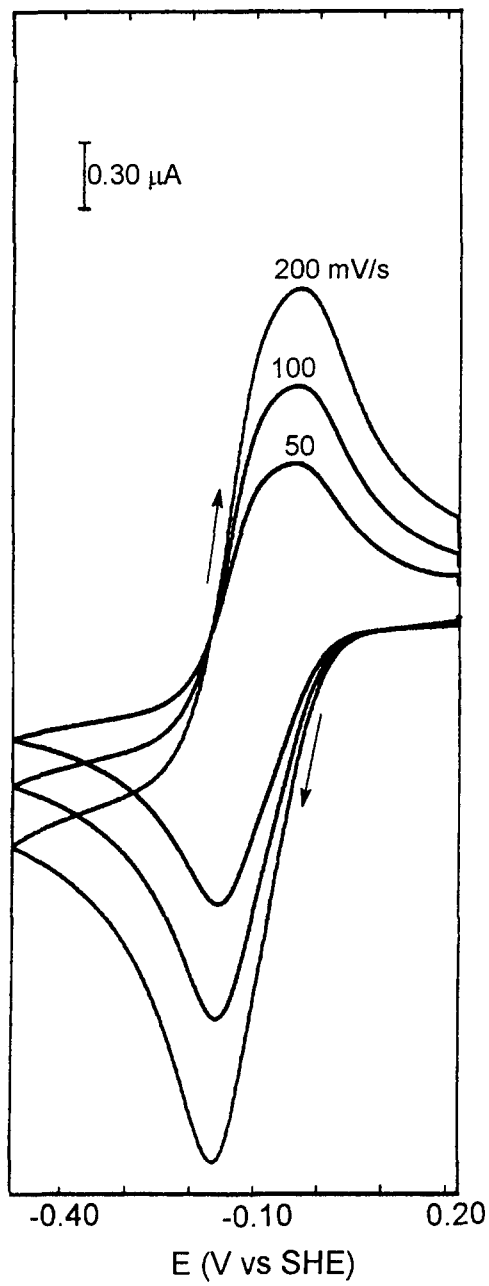

Fig. 6. Cyclic voltammetry of the binuclear $[\{Ru^{III}(edta)\}_2(mnic)]^{4-}$ complex, 50 mmol dm^{-3}, in D_2O, $pD = 6.5$, $I = 1$ mol dm^{-3} KCl.

where, R is the metal–metal distance, and ε_{max}, ν_{max} and $\Delta\nu_{1/2}$ are the extinction coefficient (1200 mol^{-1} dm^3 cm^{-1}), maximum wavenumber (8000 cm^{-1}) and half bandwidth of the intervalence band. In this way, $H_{ab} = 990$ cm^{-1}, indicating a substantial interaction between the two metal centers via the bridging ligand. This value is considerably higher than those observed for typical binuclear mixed valence complexes [13].

The involvement of a common thiolate group in the bridged complex is probably responsible for the increase in the electronic coupling between the two ruthenium centers. The importance of this group becomes evident by comparing the properties of the 2-mercaptonicotinic species with those of the nicotinic analogue. As a matter of fact, the results obtained in this work for the nicotinic ligand indicated that only the mononuclear, N-(pyridine) coordinated complex is formed with $[Ru^{III}(edta)]$. In addition, the spectroelectrochemical measurements carried out under identical conditions for the 2-mercaptonicotinic complex, provided no evidence for intervalence transitions in the near-infrared region.

It is interesting to note that the substantial intervalence coupling, as suggested by the optical data, is not apparent in the electrochemistry of the binuclear complex. As a matter of fact, in most typical, symmetric mixed valence complexes, a high degree of electronic coupling is reflected in the electrochemical behavior by an increase in the separation between the redox potentials. However, it should be mentioned that the electrochemical criterion applies well to most conventional mixed valence complexes where the σ-bond strength is nearly constant for the several redox states involved, so that the E° splitting arises mainly from the π-electron delocalization effects.

In the present case, the binuclear complex is quite asymmetric, and each metal center exhibits a typical E° value. Therefore, in contrast to the symmetrical systems, the two E° values reflect the contrasting metal ion environments, rather than the splitting associated with the stabilization of the mixed-valence complex. On the other hand, the E° values are also related to the metal–ligand affinities, as expressed by the ratio of the equilibrium constants for the $Ru^{II}L$ and $Ru^{III}L$ complexes, i.e., $\log K^{II}/K^{III}$. In this way, the changes in the metal–ligand affinities can shift the redox waves in any direction, depending on the nature of the complex, complicating the interpretation of the electrochemical data.

In order to evaluate this point, the closely related 2-mercaptobenzoic ligand, containing a bidentate (S,O) group, was employed to simulate the $Ru(S,O)$ moiety in the binuclear complex. In fact, the reaction of the 2-mercaptobenzoic ligand with $[Ru^{III}(edta)]^-$ led to a blue complex ($\lambda_{max} = 598$ nm), exhibiting an absorption spectrum coinciding with that proposed for the $Ru(S,O)$ moiety in the binuclear complex. However, the $E_{1/2}$ for the 2-mercaptobenzoic complex was -0.36 V, in contrast to -0.12 V observed for the corresponding center in the binuclear species. This result is consistent with the decrease of the σ-donor strength of the bridging sulfur atom in the mixed valence complex, as a consequence of the electron withdrawing effects from the coordinated metal ions.

A similar conclusion was obtained by comparing the E° value for the 2-mercaptopyridine complex, e.g. -0.105 V [8], with that for the corresponding $Ru(N,S)$ center in the binuclear complex ($E^\circ = -0.040$ V). Again, reflecting the decrease in the σ-donor strength of the bridging sulfur atom, there is

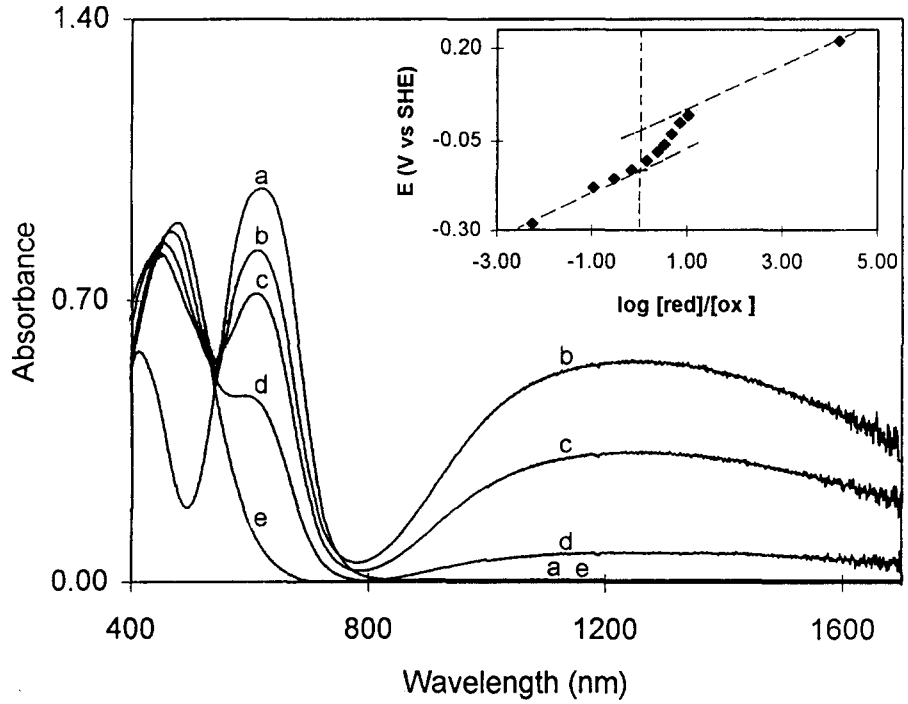

Fig. 7. Spectroelectrochemical behavior of the binuclear $[\{Ru^{III}(edta)\}_2(mnic)]^{4-}$ complex, 50 mmol dm^{-3}, in D_2O, $pD = 6.5$, $I = 1$ mol dm^{-3} KCl, at (a) 0.20, (b) −0.08, (c) −0.13, (d) −0.18 and (e) −0.33 V, showing the intervalence band at 1200 nm for the mixed valence species. Inset: Nerst plot, indicating two redox couples at $E^{\circ} = -0.040$ ($Ru^{III,III}/Ru^{III,II}$) and −0.120 V ($Ru^{III,II}/Ru^{II,II}$), respectively.

Acid-catalysed hydrolysis kinetics of carbonato cobalt(III) complexes with nonlabile tripodal quadridentate ligands

Y. Kitamura,* S. Murakami and A. Shibata

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790, Japan

(Received 4 August 1997; accepted 3 October 1997)

Abstract—Acid-catalysed hydrolysis reaction velocity was studied by the stopped-flow method at 25°C, ionic strength (I) of 2.0 ($NaClO_4$) and $[H^+] = 0.02$–1.0 M (M = mol dm^{-3}) for seven cobalt(III) bidentate carbonato complexes $[CoL(O_2CO)]^{n+}$ with a uninegative or a dinegative tripodal quadridentate ligand L of *fac*(*N*)-5-dptma, *mer*(*N*)-5-dptma, *fac*(*N*)-i-dtma, *mer*(*N*)-i-dtma, *mer*(*N*)-i-2,3-ma, *cis*(*O*)-aeida and *trans*(*O*)-aeida where 5-dptma stands for *N*,*N*-bis(3-aminopropyl)glycinato, i-dtma for *N*,*N*-bis(2-aminoethyl)glycinato, i-2,3-ma for *N*-(2-aminoethyl)-*N*-(3-aminopropyl)glycinato, and aeida for *N*-(2-aminoethyl)-*N*-(carboxymethyl)glycinato. The time course of the absorbance of the acidic aqueous solution of the reactant complex was followed at relevant wavelength in the UV region and was analysed according to a program for the consecutive first-order reactions with two experimental rate constants k_{fast} and k_{slow}. In the cases of L = *fac*(*N*)-5-dptma, *mer*(*N*)-i-dtma and *trans*(*O*)-aeida, both the k_{fast} and the k_{slow} increase with the increasing acidity of the solution. These results are incompatible with the current mechanism predicting one acidity dependent and the other acidity independent rate constants. Therefore, we have assumed additionally the deprotonation equilibrium from the intermediate complex *cis*-$[CoL(OH_2)(O_2COH)]^{n+1}$ giving rise to an inert monodentate carbonato complex *cis*-$[CoL(OH_2)(O_2CO)]^{n+}$ and derived from the acidity dependences of the k_{fast} and the k_{slow} the relevant equilibrium and rate constants. In the case of L = *mer*(*N*)-5-dptma, the k_{slow} changes slightly with the acidity attaining a flat maximum around $[H^+] = 0.2$ M, which we have interpreted by assuming an amphoteric character of the *mer*(*N*)-$[Co(5\text{-dptma})(OH_2)(O_2COH)]^+$. © 1998 Elsevier Science Ltd. Keywords: carbonato cobalt(III) complex; acid hydrolysis velocity; tripodal quadridentate ligand.

The acid-catalysed hydrolysis reaction of a cobalt(III) complex with a bidentate carbonato ligand has been studied for about 40 years.

$$\underset{\mathbf{1}}{[CoL(O_2CO)]^{n+}} + 2H^+ + H_2O \rightarrow \underset{\mathbf{4}}{[CoL(OH_2)_2]^{n+2}} + CO_2 \quad (1)$$

where L is the nonlabile ligand occupying the residual four coordination sites of the coordination octahedron. The interesting features of this reaction are that with L = $(NH_3)_4$ one water oxygen in the product diaqua complex **4** stems from the reactant complex **1** [1] and that with L = $(en)_2$ the velocity accelerates in D_2O, where en stands for ethylenediamine [2]. In accordance with these features the current mechanism is shown in Scheme 1. A preprotonation to the bidentate carbonato ligand in **1** occurs with the equilibrium constant K; one of the Co—O(bicarbonato) bonds in the bidentate bicarbonato complex **2** cleaves with the first order rate constant $k_{Co\text{-}O}$; and the O—C bond in the monodentate bicarbonato complex **3** cleaves with the first-order rate constant $k_{O\text{-}C}$ [3].

In this mechanism, the time course of the absorbance in the UV-vis region is given by eqn (2).

$$|A_t - A\infty| = M\exp\left(-\frac{k_{Co\text{-}O}K[H^+]}{1+K[H^+]}t\right) + N\exp(-k_{O\text{-}C}t) \quad (2)$$

where A_t and $A\infty$ are the absorbances of the reacting solution at reaction time t and at infinity. M and N

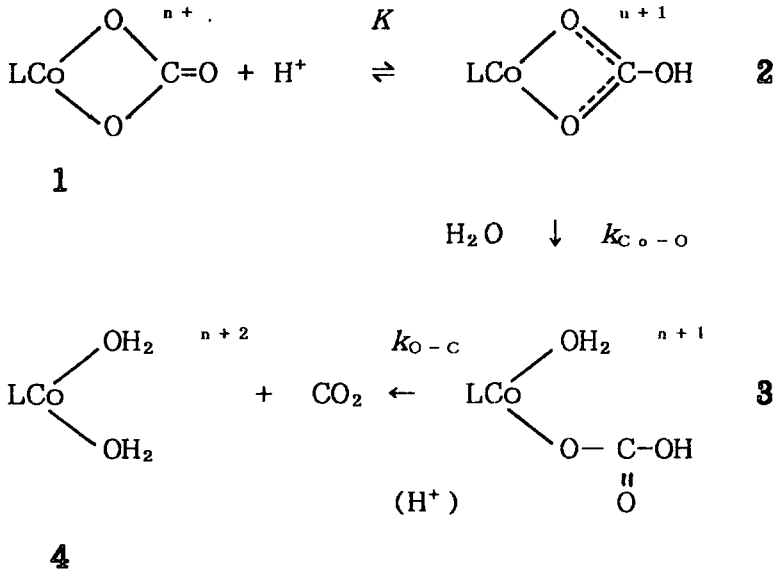


Scheme 1. Current mechanism for reaction 1.

are constants independent of t, which are given by the M'' (eqn (11)) and the N'' (eqn (12)) to be mentioned later respectively with neglection of the K_a nor the K_b value. The velocity of reaction 1 has been studied with various L ligands. The results up to 1982 have been summarized in a review [4]. It was considered that the experimental first-order rate constant k_{obs} is composed of two components

$$k_{obs} = k_0 + Kk_{Co\text{-}O}[H^+]$$

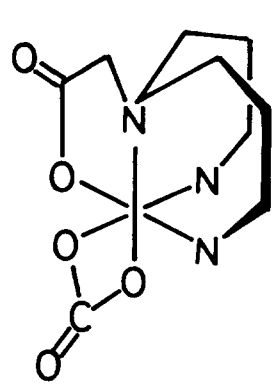
where k_0 is the spontaneous hydrolysis rate constant of the reactant complex **1**. The magnitudes of k_0 and $Kk_{Co\text{-}O}$ were experimentally determined and it was demonstrated that the magnitude of $Kk_{Co\ O}$ depends significantly on the variation of the L ligand. However, the magnitude of K was not experimentally determined and therefore the magnitude of $k_{Co\text{-}O}$ was not explicitly known. The magnitudes of $k_{O\ C}$ was experimentally determined only at limited acidity for several L ligands: $k_{O\text{-}C} = 0.4\text{–}60\ s^{-1}$ at 25°C [4]. Recently, we have studied reaction 1 with certain L ligands and pointed out that the experimentally estimated magnitudes at 25°C of K differ significantly from the assumed value $10^{-6}\ M^{-1}$: with L = (methylamine)$_4$ $K = 0.7\ M^{-1}$ at $I = 2.0$ ($NaClO_4$); with L = (ethylamine)$_4$ $K = 0.8\ M^{-1}$ at $I = 2.0$ ($NaClO_4$); with L = (propylamine)$_4$ $K = 1.3\ M^{-1}$ at $I = 1.0$ ($NaClO_4$) [5]. Buckingham *et al.* studied reaction 1 with nine L ligands at $[H^+] = 0.1\text{–}1.0$ M. $I = 1.0$ ($NaClO_4$) and 25°C [3,6]. They have shown that the k_0 is negligibly small and have analysed the time course of the absorbance in the visible region of the reacting solution according to the non-linear least-squares-fitting routine for consecutive first-order reactions.

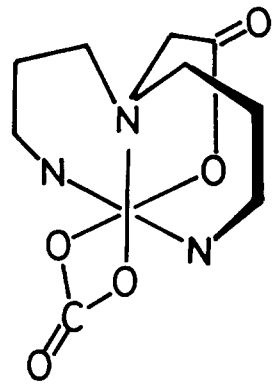
$$|A_t - A\infty| = m\exp(-k_{fast}t) + n\exp(-k_{slow}t) \qquad (3)$$

where k_{fast} and k_{slow} are the faster and the slower experimental first-order rate constants with m and n being constants independent of t. They have obtained one acidity dependent and the other acidity independent experimental first-order rate constants and assigned them to the $k_{Co\text{-}O}K[H^+]/(1+K[H^+])$ and the $k_{O\text{-}C}$ in eqn (2), respectively. They have shown that the magnitudes of K (0.4–1.5 M^{-1}) and $k_{O\text{-}C}$ (0.3–4.1 s^{-1}) are rather independent of the kind of L, whereas the magnitude of $k_{Co\text{-}O}$ (0.008–85 s^{-1}) depends significantly on the variation of L and pointed out that the great variation of the $k_{Co\text{-}O}$ may be ascribable to the differing abilities to transfer the *exo*-O proton to the *endo*-O ring oxygen in the intermediate **2**.

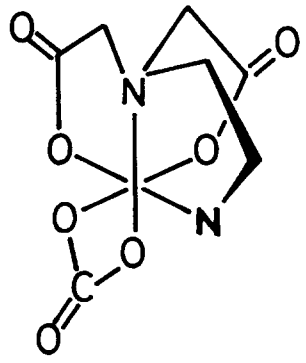
In the present report, we are interested in reaction 1 with further variation of L ligand. We have studied reaction 1 with four tripodal quadridentate ligands: *N,N*-bis(3-aminopropyl)glycinato $H_2NCH_2CH_2CH_2N(CH_2COO^-)CH_2CH_2CH_2NH_2$ (5-dptma); *N,N*-bis (2-aminoethyl)glycinato $H_2NCH_2CH_2N(CH_2COO^-)CH_2CH_2NH_2$ (i-dtma); *N*-(2-aminoethyl)-*N*-(3-aminopropyl)glycinato $H_2NCH_2CH_2CH_2N(CH_2COO^-)CH_2CH_2NH_2$ (i-2,3-ma) and *N*-(2-aminoethyl)-*N*-(carboxymethyl)glycinato $H_2NCH_2CH_2N(CH_2COO^-)_2$ (aeida). As shown in Fig. 1, the 5-dptma, i-dtma and i-2,3-ma ligands coordinate to cobalt(III) with three nitrogen and one oxygen atoms in the *fac*(*N*) or the *mer*(*N*) mode; the aeida ligand with two nitrogen and two oxygen atoms in the *cis*(*O*) or the *trans*(*O*) mode. We have treated seven among eight possible bidentate carbonato complexes bearing these quadridentate ligands, since we have obtained only one isomer of the i-2,3-ma carbonato complex. Thus, our reactant complexes are nonelectrolyte or of uninegative charge, whereas most of the carbonato cobalt(III) complexes studied hitherto are of unipositive charge [3,6]. We have analysed the time course of the UV absorbance of the reacting solution accord-

Fac(N)- [Co(CO_3)(5-dptma)] *Mer(N)*- [Co(CO_3)(5-dptma)]





Cis(O)- [Co(aeida)(CO_3)]$^-$ *Trans(O)*- [Co(aeida)(CO_3)]$^-$



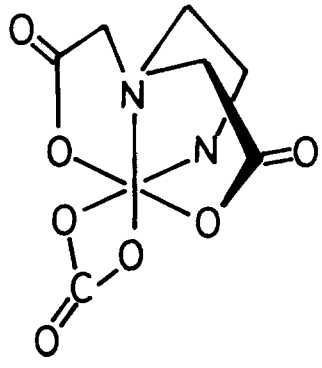


Fig. 1. Structures of the reactant carbonato complexes.

ing to eqn (3) and have found that for certain carbonato complexes both the k_{fast} and the k_{slow} increase with the increasing acidity of the solution. These results are incompatible with the current mechanism predicting one acidity dependent pseudo first-order rate constant $k_{Co\text{-}O}K[H^+]/(1+K[H^+])$ and the other acidity independent first-order rate constant $k_{O\text{-}C}$ as given by eqn (2). Therefore, we interpret our results assuming an additional deprotonation equilibrium from the species **3** giving rise to an inert monodentate carbonato complex.

EXPERIMENTAL

Materials

Analytical grade reagents and distilled water were used. The concentration $[H^+]$ of the hydronium ion in the solution was determined by titration against NaOH, where potassium hydrogen phthalate was used as a primary standard. The preparations of *fac*(*N*)-[Co(CO_3)(5-dptma)]·$2H_2O$ and *mer*(*N*)-[Co(CO_3)(5-dptma)]·$5H_2O$ have been described in a previous report [7]. The other bidentate carbonato complex samples were derived from relevant precursors and were isolated by the fractional precipitation technique. The isomeric purity was checked by the glycinato ring proton resonance spectra (Table 1). In the case of [Co(CO_3)(i-dtma)], the AB quartet pattern corresponds to the *fac*(*N*)-isomer, where the two glycinato protons exist in different environments and the singlet to the *mer*(*N*) isomer, where the two glycinato protons exist in a similar environment. In the case of [Co(aeida)(CO_3)]$^-$, one AB quartet pattern with 4H intensity corresponds to the *trans*(*O*)-isomer where the two glycinato rings are equivalent and two AB quartet patterns each with 2H intensity

[a] δ = 0 ppm for 2-methyl-2-propanol.
[b] Prepared in the corresponding carbonato complex solution by addition of a drop of 60% aqueous $HClO_4$.
[c] Collapsed quartet.

to the *cis*(*O*)-isomer, where the two glycinato rings are inequivalent. In the case of [Co(CO_3)(i-2,3-ma)], we cannot assign the isomerism on the AB quartet pattern, since both the *fac*(*N*) and the *mer*(*N*) isomers of this complex will show such pattern. We examined the UV-vis absorption spectra of the aquachloro precursor and of the diaqua hydrolysis product and assigned them to the *mer*(*N*) isomers (Table 1). On this base we presume the *mer*(*N*) structure of our [Co(CO_3)(i-2,3-ma)]. The broad half widths of the first bands 180 nm of [CoCl(i-2,3-ma)(H_2O)]$^+$ and 152 nm of [Co(i-2,3-ma)(H_2O)$_2$]$^{2+}$ are also reported for the *mer*(*N*) isomers of similar Co(III) complexes. For example, half widths 180, 180, 146 and 135 nm have been reported for the first bands of *mer*(*N*)-[Co(Cl)(5-dptma)(H_2O)]$^+$, *mer*(*N*)-[Co(Cl)(i-dtma)(H_2O)]$^+$, *mer*(*N*)-[Co(5-dptma)(H_2O)$_2$]$^{2+}$ and *mer*(*N*)-[Co(i-dtma)(H_2O)$_2$]$^{2+}$, respectively [7].

Fac(*N*)-[Co(CO_3)(i-dtma)]. A mixture of *mer*(*N*)-[Co(Cl)(i-dtma)(H_2O)]ClO_4 (18.6 g), $NaHCO_3$ (8.5 g) and water (30 cm^3) was stirred at 50°C for 2 h [8]. After the filtration, the filtrate was combined with two volumes of ethanol. Resultant oily lower layer was separated by decantation. It was warmed, while the container wall was rubbed with a glass rod. Resultant precipitates of the carbonato complex were collected and dissolved in minimum amount of water. It was evaporated and the resultant violet crystals were collected from the hot solution. They were washed with methanol and recrystallized from hot water. Yield: 2 g. Found: C, 30.1; H, 5.0; N, 14.8%. Calcd for $CoC_7H_{14}O_5N_3$: C, 30.1; H, 5.1; N, 15.1%.

Mer(*N*)-[Co(CO_3)(i-dtma)]·H_2O. The filtrate in the above procedure for the *fac*(*N*) isomer was combined with equal volume of ethanol. Pink crystals separated on rubbing the container wall. They were collected prior to contamination with the violet crystals of the *fac*(*N*) isomer. They were washed with ethanol and recrystallized from the minimum amount of water by addition of two volumes of ethanol. Yield: 4 g. Found: C, 28.1; H, 5.5; N, 13.7%. Calcd for $CoC_7H_{16}O_6N_3$: C, 28.3; H, 5.4; N, 14.1%.

Mer(*N*)-[CoCl(i-2,3-ma)(H_2O)]ClO_4. *Mer*(*N*)-[Co(i-2,3-ma)(NO_2)$_2$]·H_2O (20 g) was treated with conc. HCl (100 cm^3) and warmed until the gas evolution cease [9]. It was filtered and the filtrate was evaporated to near dryness. The resulting green precipitates (18 g) presumably of [$CoCl_2$(i-2,3-ma)] were collected and washed with ethanol. These (5 g) were dissolved in water (20 cm^3) and drops of $HClO_4$ (60%) were added to the solution. The resulting blue precipitates (4 g) were recrystallized from water and washed with methanol and ether. Found: C, 21.9; H, 4.7; N, 10.9%. Calcd for $CoC_7H_{18}O_7N_3Cl_2$: C, 21.8; H, 4.7; N, 10.9%.

Mer(*N*)-[Co(CO_3)(i-2,3-ma)]·4H_2O. A mixture of *mer*(*N*)-[CoCl(i-2,3-ma)(H_2O)] ClO_4 (2.6 g), $NaHCO_3$ (1.5 g) and water (8 cm^3) was stirred at 50°C for 2 h. After the filtration, ethanol was added to the filtrate. The resultant pink precipitates were collected and washed with methanol and ether. Found: C, 26.2; H, 4.8; N, 11.1%. Calcd for $CoC_8H_{24}O_9N_3$: C, 26.3; H, 4.4; N, 11.5%. The same substance was obtained from the latter filtrate left for some while.

Trans(*O*)-Na[Co(aeida)(CO_3)]·4H_2O. *Trans*(*O*)-[Co(aeida)(H_2O)$_2$]NO_3 (10 g) and $NaHCO_3$ (5.1 g) were dissolved in hot water (30 cm^3) [10]. After filtration the filtrate was combined with ethanol (80 cm^3) and kept in a refrigerator overnight. Resultant violet precipitates were collected and washed with ethanol. Yield: 7 g. Found: C, 21.8; H, 3.9; N, 7.2%. Calcd for $CoC_7H_{18}O_{11}N_2Na$: C, 21.7; H, 4.7; N, 7.2%. We assume that the water of crystallization of this complex is removed during the pre-drying treatment for the elemental analysis.

Cis(*O*)-Na[Co(aeida)(CO_3)]·H_2O. The latter fil-

trate in the above procedure for the *trans(O)* isomer was concentrated to 5 cm^3 and filtered. The filtrate was combined with ethanol (10 cm^3) and warmed slightly. Resultant red–violet precipitates were aged in a refrigerator overnight. They were collected; washed with 70% methanol and methanol; and were recrystallized from minimum amount of water by the addition of two volumes of ethanol. Yield: 1 g. Found: C, 25.1; H, 3.6; N, 8.3%. Calcd for $CoC_7H_{12}O_8N_2Na$: 25.2; H, 3.6; N, 8.4%.

CAUTION! Although we have experienced no difficulty with the cobalt(III) complexes reported here, these should be regarded as potentially explosive and be handled accordingly.

Kinetic measurements

A Unisoku RS-450 stopped-flow apparatus was used for the kinetic measurements. The reaction temperature was controlled at 25.0±0.1°C. Equal volumes of the complex solution (I = 2.0, $NaClO_4$) and of the perchloric acid solution (I = 2.0, $NaClO_4$) were mixed in a cell (path length = 1 cm). The time course of the absorbance was checked at several wavelengths in the UV-vis region and was recorded at relevant wavelength where substantial change of the absorbance can be observed. It was analyzed using a computing routine the Unisoku kinetic analysis program version 1.1 according to eqn (3) through the following procedures. Certain latter part of the trace was regarded as a curve for the single first order process and treated with the Guggenheim's method. The magnitude of k_{slow} was estimated from the gradient of the linear relation between $\ln|A_{t+\Delta t}-A_t|$ and t with Δt being a half of the relevant time interval. The constant n was so selected as to make the resultant term $n\exp(-k_{slow}t)$ reproduce the part of the trace. The difference between the original trace and thus calculated trace $n\exp(-k_{slow}t)$ was treated with the Guggenheim's method and the magnitude of k_{fast} was estimated. This operation was repeated a few times. Finally, k_{slow} was estimated on the original trace after six half lives of the fast process ($4.14/k_{fast}$s) and k_{fast} on the difference trace from t = 0 to five half lives of the fast process ($3.45/k_{fast}$s). The reliability of k_{fast} or k_{slow} was checked by the correlation coefficient (generally 0.999) of the Guggenheim's linear plot. Thus, in some cases, both k_{fast} and k_{slow} were reliable enough, whereas in other cases only one of them was reliable. Alternatively, the whole trace was well approximated as a curve for a single first-order process. This occurs in the cases of *mer(N)*-[$Co(CO_3)$(5-dptma)] at 306.8 or 290 nm; of *mer(N)*-[$Co(CO_3)$(i-2,3-ma)] at 301.6 or 290 nm; of *trans(O)*-[Co(aeida)$(CO_3)]^-$ at 280 nm. Four independent runs were performed and the average values of the k_{fast} or the k_{slow} are given in Table 2. In the case of *trans(O)*-[Co(aeida)$(CO_3)]^-$ ($[H^+]$ = 0.151–0.504 M), the traces were alternatively analyzed using the Unisoku nonlinear least-squares-fitting routine *ANALYSIS EXE* according to eqn (3). The resultant values of the k_{fast} and the k_{slow} by this method (not given in this report) were essentially the same as the corresponding ones obtained by the above mentioned method.

Spectral determination of K.

The zero-time absorbance (A_{obs}) of the reacting solution was estimated by the extrapolation of the A_t to t = 0 over the mixing dead time 2 ms (Table 2). The absorbance A_1 due to the species **1** was measured by the stopped-flow mixing of the complex solution (I = 2.0, $NaClO_4$) with 2 M $NaClO_4$ solution and is given in Table 2 as the A_{obs} at $[H^+]$ = 0 M. Value of K was calculated therefrom by the linear plot between $1/(A_1-A_{obs})$ and $1/[H^+]$ as described by Buckingham *et al.* [3].

$$\frac{1}{(A_1-A_{obs})}=\frac{1}{K(A_1-A_2)[H^+]}+\frac{1}{(A_1-A_2)} \quad (4)$$

where A_2 represents the absorbance of the species **2**.

Apparatus

A JEOL-GSX-270-FT-NMR instrument and a Shimadzu UV-2200 UV-vis spectrophotometer were used.

RESULTS AND DISCUSSION

Isomerization of the diaqua hydrolysis product

The NMR spectra were measured for the D_2O solutions of the carbonato complex after about 30 min from the treatment by $HClO_4$ (Table 1.b). In the cases of *mer(N)*-[$Co(CO_3)$(i-dtma)] and *mer(N)*-[$Co(CO_3)$(i-2,3-ma)] the resultant solutions contain only the corresponding *mer(N)* diaqua product and in other cases the solutions are more or less contaminated with the isomeric diaqua product; 4% *mer(N)* isomer from *fac(N)*-[$Co(CO_3)$(i-dtma)], 2% *cis(O)* isomer from *trans(O)*-[Co(aeida)$(CO_3)]^-$ and 20% *trans(O)* isomer from *cis(O)*-[Co(aeida)$(CO_3)]^-$. In similar experiments for *fac(N)*- and *mer(N)*-[$Co(CO_3)$(5-dptma)], complete retention of the isomeric configuration has been demonstrated during the acid-catalysed hydrolysis [7]. Assuming that the mechanism is common for the seven carbonato complexes treated here, we consider that the acid-catalysed hydrolysis (eqn (1)) proceeds with retention of the isomeric configuration and that the diaqua product isomerizes subsequently more or less. In the cases of *fac(N)*-[$Co(CO_3)$(i-dtma)] and *trans(O)*-[Co(aeida)$(CO_3)]^-$ the isomerization extent may be negligible. The isomerization velocity was followed spectrophotometrically at 540 nm for the solution of *cis(O)*-[Co(aeida)$(CO_3)]^-$ (7 mM) in 2 M $HClO_4$.

Table 2. Experimental rate constants, zero-time absorbances and the equilibrium or rate constants derived therefrom for the acid-catalyzed hydrolyses of carbonato cobalt(III) complexes at 25°C and $I = 2.0$ ($NaClO_4$)

Rate constant of 7.7×10^{-4} s^{-1} was estimated at 25°C for the isomerization

cis(*O*)-[Co(aeida)$(H_2O)_2$]$^+$ ⇌ *trans*(*O*)-[Co(aeida)$(H_2O)_2$]$^+$

This velocity is slow enough compared with the hydrolysis velocity. Thus, we consider that the isomerization of the diaqua product does not interfere with the kinetic course of the acid hydrolysis of *cis*(*O*)-[Co(aeida)(CO_3)]$^-$.

Spontaneous hydrolysis

Absorption spectrum (300–600 nm) of the neutral aqueous solution of each of our seven carbonato complexes remained unchanged during 1 h with the total concentration ~5 mM of the cobalt(III) complex at I = 2.0 ($NaClO_4$) and 25°C. Therefore, we neglect the contribution of the spontaneous hydrolysis.

Acid-catalyzed hydrolysis

The experimental rate constants k_{fast} and k_{slow} and the zero-time absorbance data A_{obs} are summarized in Table 2 with the equilibrium or the rate constants derived therefrom. The values of the k_{fast} or the k_{slow} are calculated according to eqn (6), (8), (9) or (13) to be mentioned later, using the derived values of the constants and are given as k_{calc} in Table 2. These k_{calc}'s agree satisfactorily with the corresponding values of the k_{fast} or the k_{slow} and justify the treatments by these equations. In the cases of *fac*(*N*)-[Co(CO_3)(5-dptma)], *mer*(*N*)-[Co(CO_3)(i-dtma)] and *trans*(*O*)-[Co(aeida)(CO_3)]$^-$, both the k_{fast} and the k_{slow} increase with the increasing acidity of the solution as illustrated in Fig. 2. These results are incompatible with the current mechanism that predicts one acidity dependent and the other acidity independent rate constants as given by eqn (2). Therefore, we propose the modification I for the current mechanism: a deprotonation equilibrium from the species **3** giving rise to an inert monodentate carbonato complex **5**. According to this modified mechanism I (Scheme 2), the time course of the absorbance is given by eqn (5).

$$|A_t - A\infty| = M' \exp\left(-\frac{k_{Co-O}K[H^+]}{1+K[H^+]}t\right) + N' \exp\left(-\frac{k_{O-C}[H^+]}{[H^+]+K_a}t\right) \quad (5)$$

M' and N' are constants independent of t, which are

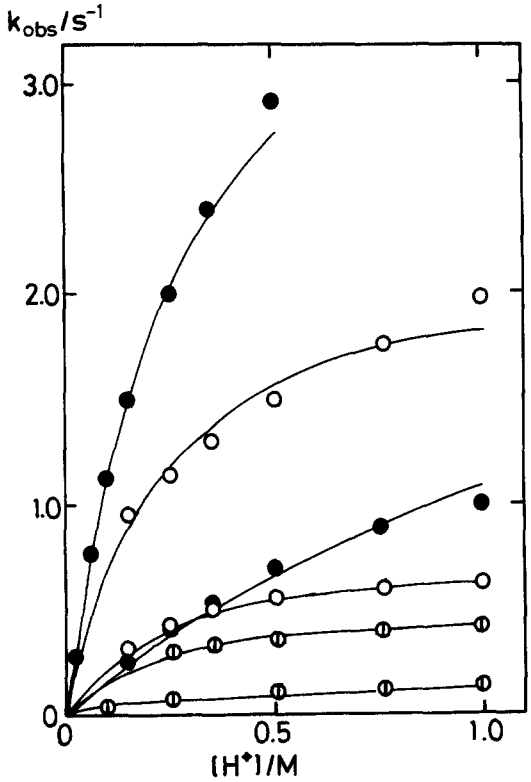

Fig. 2. Plots of k_{obs} (k_{fast} and k_{slow}) versus [H$^+$] for the acid hydrolysis of *fac*(*N*)-[Co(CO$_3$)(5-dptma)] (Φ), *mer*(*N*)-[Co(CO$_3$)(i-dtma)] (○) and *trans*(*O*)-[Co(aeida)(CO$_3$)]$^-$ (●) in aqueous solutions at 25°C and I = 2.0 (NaClO$_4$). The lines show the k_{calc} (see text).

given by the M'' (eqn (11)) and N'' (eqn(12)) to be mentioned later respectively with the neglection of the K_b value. K_a is the acidic dissociation constant of the species **3**. Eqn (5) involves two acidity dependent pseudo first-order rate constants, but the correspondence between these and the k_{fast} or the k_{slow} is not a priori clear. Therefore, we consider two possible correspondences: one with eqns (6) and (7); and the other with eqns (8) and (9).

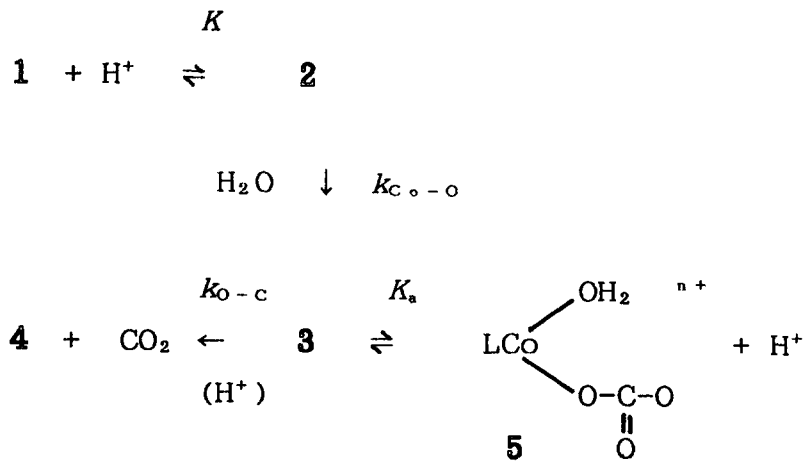
$$k_{fast} = \frac{k_{Co\text{-}O}K[H^+]}{1+K[H^+]} \tag{6}$$

$$k_{slow} = \frac{k_{O\text{-}C}[H^+]}{[H^+]+K_a} \tag{7}$$

$$k_{slow} = \frac{k_{Co\text{-}O}K[H^+]}{1+K[H^+]} \tag{8}$$

$$k_{fast} = \frac{k_{O\text{-}C}[H^+]}{[H^+]+K_a} \tag{9}$$

We derive the magnitudes of $k_{Co\text{-}O}$, K, $k_{O\text{-}C}$ or K_a according to these equations: the linear relations between the $1/k_{fast}$ or the $1/k_{slow}$ and the $1/[H^+]$. In the case of *fac*(*N*)-[Co(CO$_3$)(5-dptma)], K is derived as 6.7 and 2.2 M^{-1} by eqns (6) and (8), respectively. The latter value agrees satisfactorily with the K = 1.6 M^{-1} alternatively derived by eqn (4). Therefore, we prefer eqn (8) and derive K_a = 0.15 M by eqn (9). In the case of *mer*(*N*)-[Co(CO$_3$)(5-dptma)], K is derived as 0.75 M^{-1} by eqn (6). This value agrees well with the K = 1.0 M^{-1} by eqn (4). The k_{slow} is approximately constant and we cannot estimate the K_a value by eqn (7). In the case of *fac*(*N*)-[Co(CO$_3$)(i-dtma)], the K = 2.9 M^{-1} by eqn (6) agrees well with the K = 1.2 M^{-1} by eqn (4). The k_{slow} is again approximately constant and we cannot estimate the K_a value. In the case of *mer*(*N*)-[Co(CO$_3$)(i-dtma)], both the K = 4.9 M^{-1} by eqn (6) and the K = 4.6 M^{-1} by eqn (8) are comparable to the K = 1.4 M^{-1} by eqn (4). We tentatively prefer eqn (8) and derive K_a = 0.2 M by eqn (9). In the case of *mer*(*N*)-[Co(CO$_3$)(i-2,3-ma)], the K = 0.51 M^{-1} by eqn (6) agrees well with the K = 0.91 M^{-1} by eqn (4). The k_{slow} is again approximately constant and



Scheme 2. Modified mechanism I for reaction 1.

we cannot estimate the K_a value. In the case of *cis*(*O*)-[Co(aeida)(CO_3)]$^-$, the $K = 0.48$ M^{-1} by eqn (8) agrees well with the $K = 1.3$ M^{-1} by eqn (4) and we tentatively estimate $k_{O\text{-}C} \fallingdotseq 2$ s^{-1}. In the case of *trans*(*O*)-[Co(aeida)(CO_3)]$^-$ the K is derived as 3.5 M^{-1} by eqn (6) and as 0.7 M^{-1} by eqn (8). The latter value agrees well with the $K = 1.0$ M^{-1} by eqn (4). We derive $K_a = 0.3$ M by eqn (9). In the case of *mer*(*N*)-[Co(CO_3)(5-dptma)], the k_{slow} is approximately independent of the acidity as mentioned above. However, this case cannot be explained by the current mechanism (Scheme 1) on account of the following observation. In certain limited acidity range, the whole trace of the absorbance at 306.8 or 290 nm is well approximated as a curve for a single first-order process, whereas it deviates from this beyond such acidity range. In the current mechanism, the K_a is negligibly small and the whole trace should reduce to a curve for a single first-order process at the isosbestic wavelength between the species **3** and **4** irrespective of the acidity. On close examination, it can be noticed that the k_{slow} for this complex changes slightly with the acidity and attains a flat maximum around $[H^+] = 0.2$ M. This suggests an amphoteric character of the species **3**; a deprotonation from **3** giving rise to the inert complex **5** and a protonation to **3** giving rise to the inert carbonic acid complex **6** as shown in Scheme 3. According to this modified mechanism II (Scheme 3), the time course of the absorbance is given by eqns (10)–(12).

$$|A_t - A\infty| = M'' \exp\left(-\frac{k_{Co\text{-}O}K[H^+]}{1+K[H^+]}t\right) + N'' \exp\left(-\frac{k_{O\text{-}C}[H^+]}{(K_h/K_w)[H^+]^2+[H^+]+K_a}t\right) \quad (10)$$

$$M''/[Co]_T = \frac{\varepsilon_1 - \varepsilon_4 + K[H^+](\varepsilon_2 - \varepsilon_4)}{1+K[H^+]} + \beta\left\{\frac{K_a(\varepsilon_5 - \varepsilon_4)}{[H^+]} + \varepsilon_3 - \varepsilon_4 + (K_h/K_w)[H^+](\varepsilon_6 - \varepsilon_4)\right\} \quad (11)$$

$$N''/[Co]_T = \beta\left\{\frac{K_a(\varepsilon_4 - \varepsilon_5)}{[H^+]} + \varepsilon_4 - \varepsilon_3 + (K_h/K_w)[H^+](\varepsilon_4 - \varepsilon_6)\right\} \quad (12)$$

$$\beta \equiv \frac{k_{Co\text{-}O}\alpha K[H^+]}{k_{O\text{-}C}\alpha(1+K[H^+]) - k_{Co\text{-}O}K[H^+]}$$

$$\alpha \equiv \frac{[H^+]}{(K_h/K_w)[H^+]^2+[H^+]+K_a}$$

The ε_1, ε_2, ε_3, ε_4, ε_5 and ε_6 are the extinction coefficients at the relevant wavelength due to the complex species **1**, **2**, **3**, **4**, **5** and **6**, respectively. $[Co]_T$ is the total concentration of the Co(III) complex in the solution. K_h is the equilibrium constant for

$$\mathbf{3} + H_2O \rightleftharpoons \mathbf{6} + OH^-$$

and K_w is the autoprotolysis constant of water. Comparing eqn (3) with eqn (10), we interpret the k_{slow} for *mer*(*N*)-[Co(CO_3)(5-dptma)] by eqn (13)

$$k_{slow} = \frac{k_{O\text{-}C}[H^+]}{(K_h/K_w)[H^+]^2+[H^+]+K_a} \quad (13)$$

and estimate the relevant constants by the quadratic relation between the $[H^+]/k_{slow}$ and the $[H^+]$ (Table 2). In the case of *fac*(*N*)-[Co(CO_3)(i-dtma)], the k_{slow} also changes slightly with the acidity with a flat maximum at $[H^+] \sim 0.7$ M. This may also be explained by the modified mechanism II, but we keep from the estimation of the constants because of the scarcity of the k_{slow} data. We assume that for this complex the $k_{O\text{-}C}$ is close to the mean k_{slow} value on account of the proximity between the estimated value of $k_{O\text{-}C}$ and the mean k_{slow} for *mer*(*N*)-[Co(CO_3)(5-dptma)]. Similarly, we assume that for *mer*(*N*)-[Co(CO_3)(i-2,3-ma)] $k_{O\text{-}C}$ is close to the mean k_{slow} value. The equilibrium and the rate constants thus derived for our seven carbonato complexes are summarized in Table 3 with those given previously by Buckingham *et al.* for nine carbonato complexes [3,6]. In Table 3, the following may be noticed. The K values are surprisingly independent of the variation of the L ligand and are about 1 M^{-1} for these sixteen carbonato complexes. This may be explained that the protonation occurs at a site well removed from the Co(III) center and therefore not influenced by the coordination environment around the Co(III). This magnitude of the K remarkably differs from the previously presumed magnitude 10^{-6} M [4]. In contrast, the values of $k_{Co\text{-}O}$ depend significantly on the variation of the L ligand and cover a reactivity range of 10^4. The $k_{Co\text{-}O} = 126$ s^{-1} with L = *mer*(*N*)-5-dptma is the greatest among hitherto reported $k_{Co\text{-}O}$ values. This may be explained that this bond cleavage occurs between the LCo(III) moiety and the bicarbonato ligand and therefore is much influenced by the variation of the L or the coordination environment around the Co(II). However, we cannot find any general trend between the magnitude of the $k_{Co\text{-}O}$ and the charge or the constitution of the L ligand. It ranges 0.008–9.7 s^{-1} for the neutral L; 0.2–126 s^{-1} for the uninegative L; and 3–4.1 s^{-1} for the dinegative L. The *mer*(*N*)-[Co(5-dptma)(O_2COH)]$^+$ ring-opens much faster than the *fac*(*N*) congener, whereas the *mer*(*N*)-[Co(i-dtma)(O_2COH)]$^+$ ring-opens rather slower than its *fac*(*N*) congener. The *cis*(*O*) and the *trans*(*O*)-[Co(aeida)(O_2COH)] ring-open with essentially the same half life. In this bond cleavage, the trans-effect should be operative. As can be understood in Fig. 1, the two Co—O(bicarbonato) bonds in the bidentate bicarbonato complex **2** are inequivalent and the weaker

trien = 1,8-diamino-3,6-diazaoctane; tren = tris(2-aminoethyl)amine; cyclen = 1,4,7,10-tetraazacyclododecane; *N*-mecyclen = 1-methyl-1,4,7,10-tetraazacyclododecane; H(gly) = glycine; H_3(nta) = nitrilotriacetic acid.

one should cleave. The most interest point may be that we have found in the case of certain our carbonato complexes that both of the k_{fast} and the k_{slow} depend on the acidity, whereas Buckingham *et al.* have considered that in the case of their carbonato complexes one between the k_{fast} and the k_{slow} is independent of the acidity [3,6]. In this connection, we have reinvestigated reaction 1 with L of $(en)_2$ or α-trien at 25°C

and $I = 2.0$ ($NaClO_4$) [11]. With L = $(en)_2$, Buckingham *et al.* have assumed the acidity independent $k_{fast} = 0.93\ s^{-1}$ at lower acidity [3], whereas we have found that the k_{fast} increases significantly with the increasing acidity, for example with $[Co]_T = 0.7$ mM and $\lambda = 278$ or 280 nm; $k_{fast} = 0.51\ s^{-1}$ at $[H^+] = 0.15$ M and $1.08\ s^{-1}$ at $[H^+] = 1.00$ M, we have estimated that $k_{O\text{-}C} = 1.3\ s^{-1}$ and $K_a = 0.23\ M^{-1}$ according to eqn (9). With L = α-trien, Buckingham *et al.* have reported essentially acidity independent $k_{slow} = 0.62\ s^{-1}$ at $[H^+] = 0.2$–1.0 M [6], whereas we have found that the k_{slow} changes with the acidity with a maximum around $[H^+] = 0.2$ M. For example, with $[Co]_T = 0.8$ mM and $\lambda = 284$ nm; $k_{slow} = 0.16\ s^{-1}$ at $[H^+] = 0.02$ M, $0.81\ s^{-1}$ at $[H^+] = 0.20$ M and $0.57\ s^{-1}$ at $[H^+] = 1.00$ M, we have estimated that $k_{O\text{-}C} = 0.94\ s^{-1}$ and $K_a = 0.06$ M and $K_b/K_w = 1.6\ M^{-1}$ according to eqn (13). We consider that the acidity independent k_{slow} or k_{fast} reported by Buckingham *et al.* for reaction 1 with L = $(NH_3)_4$, β-trien, tren $(gly)_2$ and nta may also be explained by the amphoteric character of the complex **3** with the $k_{O\text{-}C}$ value close to the mean value of the corresponding k_{slow} or k_{fast} [6]. Thus, the $k_{O\text{-}C} = 0.2$–$4\ s^{-1}$ in Table 3 are again almost independent of the variation of the L ligand. This may be explained that the O—C bond cleavage occurs at the bicarbonato ligand coordinating to Co(III) and therefore is not influenced by the variation of the coordination environment around the Co(III). The $K_a = 0.006$–0.3 M for *cis*-$[CoL(OH_2)(O_2COH)]^{n+1}$ (**3**) are somewhat dependent on the variation of the L ligand, which is rather unexpected in consideration of the deprotonation site apart from the Co(III) center. These K_a values are incompatible with the reported equilibrium constant 4×10^{-7} M (25°C, $I = 0.5$) for an analogous acid dissociation eqn (14) from the pentaammine-bicarbonatocobalt(III) complex [12].

$$(H_3N)_5Co\,O{-}\overset{\overset{O}{\|}}{C}{-}OH^{2+} \rightleftharpoons (H_3N)_5Co\,O{-}\overset{\overset{O}{\|}}{C}{-}O^{+} + H^{+} \quad (14)$$

However, considering that the metal center moiety $CoL(OH_2)$ may correspond to a proton, the acid dissociation from *cis*-$[CoL(OH_2)(O_2COH)]^{n+1}$ may be reasonably compared with the first dissociation from carbonic acid.

$$HO{-}\overset{\overset{O}{\|}}{C}{-}OH \rightleftharpoons HO{-}\overset{\overset{O}{\|}}{C}{-}O^{-} + H^{+}$$

Our $K_a = 0.006$–0.3 M do not differ so drastically from the equilibrium constant 1.7×10^{-4} M (25°C, $I = 0$) of the latter [4]. The $K_b/K_w = 0.12$ and $1.6\ M^{-1}$ means very weak basicity $K_b = 10^{-15}$–10^{-14} M of *mer*(*N*)-$[Co(5\text{-dptma})(OH_2)(O_2COH)]^+$ or of α-$[Co(trien)(OH_2)(O_2COH)]^{2+}$. Since we have no precedent value of the equilibrium constant for this type of basicity, we have studied the acid hydrolysis of the monodentate carbonato complex $[Co(CO_3)(NH_3)_5]^+$ at 25°C and $I = 2.0$ ($NaClO_4$); with $[H^+] = 0.02$–1.01 M, $[Co]_T = 1.9$ mM and $\lambda = 278$ nm [11]. The whole trace was well regarded as a curve for a single first-order process with the experimental rate constant decreasing monotonically with the increasing acidity: for example $1.28\ s^{-1}$ at $[H^+] = 0.02$ M and $0.99\ s^{-1}$ at $[H^+] = 1.01$ M. From this result, we can estimate the equilibrium constant $0.3\ M^{-1}$ for the equilibrium

$$(H_3N)_5Co{-}O{-}\overset{\overset{O}{\|}}{C}{-}OH^{2+} + H^{+} \rightleftharpoons (H_3N)_5Co{-}\underset{\underset{H}{|}}{O}{-}\overset{\overset{O}{\|}}{C}{-}OH^{3+} \quad (15)$$

although we cannot estimate a reliable equilibrium constant for the above mentioned equilibrium 14. Equilibrium 15 is analogous to our proposed equilibrium

$$\mathbf{3} + H^+ \rightleftharpoons \mathbf{6}$$

and the proximity of the above estimated constant $0.3\ M^{-1}$ for equilibrium 15 to the $K_b/K_w = 0.12$ or $1.6\ M^{-1}$ for the latter is quite reasonable. In conclusion, we consider that the general mechanism of reaction 1 is given by our modified mechanism II (Scheme 3) with the magnitudes of K_a being rather dependent on the variation of the L ligand. In the cases of *fac*(*N*)-$[Co(CO_3)(5\text{-dptma})]$, *mer*(*N*)-$[Co(CO_3)(i\text{-dtma})]$ and *trans*(*O*)-$[Co(aeida)(CO_3)]^-$, we cannot estimate reliable K_b/K_w values from our kinetic data, since in our acidity range the k_{fast} increases monotonically with the increasing acidity or the effect of the basicity is dormant.

(Received 25 August 1997; accepted 2 October 1997)

Abstract—The nickel(II) complexes of two isomeric cyclohexylcyclams were prepared by employing a nickel template reaction. The cyclohexylcyclams were synthesized from the nickel(II) complexes and then the copper(II) complexes were prepared from the free ligands and copper(II) perchlorate. The nickel(II) and copper(II) complexes exhibit clusters of ions corresponding to $[M-ClO_4]^+$ and $[M-2ClO_4+2H]^+$ which is the base peak in FAB mass spectra. A strong band observed at ca 3200 cm^{-1} is assigned to the N—H stretching mode and the band is slightly shifted to lower frequency on metal coordination, indicating freshly strong bands due to ClO_4^- stretching mode at ca 1090 and ca 620 cm^{-1}. The molar conductances for the complexes are 1:2 electrolytes in *N,N*-dimethylformamide and the perchlorate anions are ionized on dissolution in the solvent. The nickel(II) and copper(II) complexes of the two isomers are subjected to the square-planar ligand-field, but the ligand-field band for the nickel(II) complex of isomer L_t^3, *trans*-cyclohexylcyclam, shows the distorted octahedral form in coordinating solvent. ESR spectra for the copper(II) complexes of the two isomers also give the spin Hamiltonian parameters of the square-planar coordination. ^{13}C-NMR spectral results are comparable with those of another spectra. © 1998 Elsevier Science Ltd. Keywords: macrocycle; cyclohexylcyclam; two isomers; nickel(II) complex; copper(II) complex; spectrum.

Substantial effort has been expended on the investigation of cyclam (1,4,8,11-tetraazacyclotetradecane) complexes and *N*-substituted cyclam complexes [1]. These are rare examples of cyclam complexes substituted by cyclohexyl groups at the 2-, 3-, 9- and 10-positions. Since the complexes have been synthesized on the basis of the structural interest, the spectral research has not been advanced satisfactorily. Kobiro *et al.* presented only the synthesis and molecular structures of nickel(II) complexes with cyclohexylcyclams and dicyclohexylcyclams (1,2,3,4,5,6,7,8,9,10,11,12,13,14,15,16,17,18,19,20,21,22-docosahydrodibenzo[*b,i*]-[1,4,8,11]tetraazacyclotetradecine) without the study of the spectral properties [2]. We have already reported the syntheses, the spectral properties and the kinetic data of cobalt(III), nickel(II), copper(II) and zinc(II) complexes with dicyclohexylcyclams [3].

In the present work, we employed the nickel(II) and copper(II) complexes with cyclohexylcyclams, namely

2,3-*cis*-cyclohexano-1,4,8,11-tetraazacyclotetradecane (L_c^3, *cis*-cyclohexylcyclam) and 2,3-*trans*-cyclohexano-1,4,8,11-tetraazacyclotetradecane (L_t^3, *trans*-cyclohexylcyclam), to make a further exploration into the influence on the cyclohexyl group in the dicyclohexylcyclam complexes. We report here the spectral properties and characterization of the nickel(II) and copper(II) complexes of cyclohexylcyclams, as examined by electronic, vibrational, mass, NMR and ESR spectroscopy. The characteristic behavior of the cyclohexylcyclam complexes is discussed by reference to that of cyclam and dicyclohexylcyclam complexes.

EXPERIMENTAL

Physical measurements

All melting points were observed on a Yanaco MP-500D micro melting point apparatus (hot-plate type). Elemental analyses were determined with a Yanaco CHN corder MT3. EI mass spectra (at 70 eV) for cyclohexylcyclams and their intermediates and FAB mass spectra (in a matrix of 3-nitrobenzyl alcohol) for the complexes were carried out with a JEOL JMS-DX 300 gas chromatograph-mass spectrometer. Conductivity measurements were made on *N,N*-dimethylformamide solutions of the complexes kept at 25.0 ± 0.1°C with a Coolnics Thermo-Bath (model CTE-310). Conductivities were measured with a TOA Electronics Ltd, CM-20E. Infrared spectra covering the 400–4000 cm^{-1} range were obtained on a Hitachi 260-30 spectrophotometer at room temperature with neats and potassium bromide disks. Electronic spectra were taken on a Shimadzu UV 200S double beam spectrophotometer for *N,N*-dimethylformamide solutions at room temperature in the range 12,500–37,000 cm^{-1}. Proton and carbon-13 NMR spectra were recorded on a JEOL JNM-A500 spectrometer in chloroform-*d*, methanol-d_4, dimethyl sulfoxide-d_6 and/or trifluoroacetic acid-*d* at room temperature and the chemical shifts are reported in ppm relative to tetramethylsilane as an internal reference standard. ESR spectra were measured on a JEOL JES-RE2X X-band spectrometer equipped with a 100 kHz field modulation unit. The copper(II) complexes were run in *N,N*-dimethylformamide at room temperature with a capillary tube and at 77 K. The manganese ions diffused into magnesium oxide were utilized to gain the standard reference signals for measurements.

Separation of cis-*cyclohexane*-1,2-*diamine* (cis-*dac*) *and* trans-*cyclohexane*-1,2-*diamine* (trans-*dac*)

The method of Saito and Kidani was modified for the separation of *cis*-dac and *trans*-dac [4]. To a solution of cyclohexane-1,2-diamine (*cis*- and *trans*-mixtures) (Aldrich Chemical Co. Inc., 25.0 g, 0.22 mol) in methanol (160 ml) was added in limited amounts a solution of nickel(II) chloride hexahydrate (26.0 g, 0.11 mol) in methanol (440 ml) at room temperature with stirring. After 3 h, the precipitates deposited were separated by filtration, washed sufficiently with methanol, and vacuum dried to give 11.9 g (30%) of fine yellow crystals (*cis*-dac nickel(II) complex). The yellow crystals (7.90 g, 0.022 mol) were decomposed by adding 6 N sulfuric acid (15 ml). The solution was evaporated under reduced pressure and ethanol (80 ml) was added to the oil residue. The colorless precipitates deposited were collected by filtration and recrystallized from water to obtain colorless plates (*cis*-dac H_2SO_4 salt). The yield was 8.72 g (93%) (lit. [5] mp 304–309°C), mp 308–311°C (dec). IR (KBr): 3100–2000 (N—H), 1610, 1530 (N—H), 1150, 620 (S—O) cm^{-1}.

After the separation procedure of the above yellow *cis*-dac nickel(II) complex, water (100 ml) was added to the filtrate, which was allowed to stand for a week in a refrigerator. The resulting deposits were isolated by filtration and washed with water to afford 22.5 g (52%) of violet needles (*trans*-dac nickel(II) complex). The reaction of the violet needles (8.6 g, 0.022 mol) with 6 N hydrochloric acid (15 ml), following the above procedure, gave colorless prisms (*trans*-dac 2HCl salt). The yield was 6.54 g (80%) (lit. [4] mp 321–326°C), mp 318–323°C (dec). IR (KBr): 3000–2100 (N—H), 1610, 1520 (N—H) cm^{-1}.

Preparation of cyclohexylcyclams and their complexes

N,N′-*Bis*(2-*cyanoethyl*)-cis-1,2-*diaminocyclohexane* (1c). After sodium (1.07 g, 46.8 mmol) was dissolved in methanol (200 ml), *cis*-dac H_2SO_4 salt (5.15 g, 24.3 mmol) was added to it at room temperature with stirring. To the reaction solution was added dropwise at 0°C a solution of freshly distilled acrylonitrile (2.23 g, 42.1 mmol) in methanol (3.0 ml). The reaction mixture was stirred for 1 h at 0°C and heated under reflux for 5 h with stirring. After being cooled down at room temperature, the excess acrylonitrile was evaporated *in vacuo* to yield 4.76 g (89%) of a colorless viscous liquid (1c). An analytical sample was recrystallized from *n*-hexane-ethyl ether at −60°C to obtain colorless prisms. IR (KBr): 3320, 3270 (N—H), 2230 (C≡N) cm^{-1}. EIMS *m/z* (relative intensity): 221 (21.9), 220 (95.8), 180 (69.6), 166 (23.5), 151 (45.1), 150 (60.4).

N,N′-*Bis*(2-*cyanoethyl*)-trans-1,2-*diaminocyclohexane* (1t). The reaction of *trans*-dac 2HCl salt (4.08 g, 24.3 mmol), sodium (1.07 g, 46.8 mmol) and acrylonitrile (2.08 g, 39.2 mmol) in methanol (200 ml), following the above procedure, gave colorless prisms (1t) using tetrahydrofuran instead of ethyl ether. The yield was 4.18 g (87%). IR (KBr): 3315, 3280 (N—H), 2230 (C≡N) cm^{-1}. EIMS *m/z* (relative intensity): 221 (10.1), 220 (100), 180 (68.8), 166 (20.2).

5,6-cis-*Cyclohexano*-4,7-*diazadecane*-1,10-*diamine* (L_c^1). To a mixture of lithium aluminum hydride (1.51

g, 39.8 mmol) and anhydrous ethyl ether (40 ml) was added a solution of aluminum chloride (5.31 g, 39.8 mmol) in anhydrous ethyl ether (40 ml) at room temperature with stirring under argon atmosphere. To the mixture was added anhydrous tetrahydrofuran (70 ml) and to it was added a solution of 1c (3.52 g, 15.9 mmol) in anhydrous tetrahydrofuran (10 ml) at 40°C over 20 min with stirring. After being refluxed for 2 h and being cooled at room temperature, methanol (10 ml) was added dropwise to the reaction mixture and then a 20% aqueous potassium sodium tartrate solution (100 ml) was added. The organic solvent was taken off by diminished pressure and a 25% aqueous sodium hydroxide solution (100 ml) was added to the residue. The aqueous mixture was extracted three times with dichloromethane (100 ml). The organic layer was dried over anhydrous sodium sulfate overnight and distilled under nitrogen atmosphere at 150°C (1 torr) to give a colorless viscous liquid (L_c^1) (lit. [2b] bp 152°C (1 torr)). The yield was 3.10 g (86%). IR (neat): 3260 (N—H), 1600 (N—H) cm^{-1}. EIMS *m/z* (relative intensity): 228 (13.3), 182 (12.9), 155 (27.7), 154 (100). ^{1}H-NMR (chloroform-*d*): δ 1.0–2.0 (m, 18H), 2.5–3.0 (m, 10H).

5,6-trans-*Cyclohexano*-4,7-*diazadecane*-1,10-*diamine*(L_t^1). The reaction of 1t (3.51 g, 15.9 mmol) and lithium aluminum hydride (1.51 g, 39.8 mmol) in an anhydrous mixed solvent composed of ethyl ether (65 ml) and tetrahydrofuran (70 ml), following the above procedure, gave a colorless viscous liquid of bp 157°C (2 torr) (lit. [2b] bp 159°C (2 torr)). The yield was 3.13 g (86%). IR (neat): 3265 (N—H), 1600 (N—H) cm^{-1}. EIMS *m/z* (relative intensity): 228 (32.0), 156 (21.6), 155 (100). ^{1}H-NMR (chloroform-*d*): δ 1.13 (q, 4H, J = 8.9 Hz), 1.5–1.9 (m, 12H), 2.1 (s, 4H), 2.3–3.0 (m, 8H).

(5, 6-cis-*Cyclohexano*-4, 7-*diazadecane*-1, 10-*diamine*) *nickel(II) diperchlorate* ($NiL_c^1(ClO_4)_2$). A mixture of L_c^1 (3.02 g, 13.2 mmol) and methanol (5.0 ml) was added into nickel(II) perchlorate hexahydrate (4.83 g, 13.2 mmol), which was dissolved in methanol (10 ml), at room temperature for 3 h with stirring. The precipitates deposited were collected by filtration and vacuum dried to give 3.13 g (49%) of fine orange crystals; mp 207.7–208.2°C (dec). IR (KBr): 3280, 3220 (N—H), 1610 (N—H), 1090, 615 (Cl—O) cm^{-1}. FABMS *m/z* (relative intensity): 487 (1.55), 485 (1.64), 387 (66.6), 385 (90.9), 286 (100).

(5,6-trans-*Cyclohexano*-4,7-*diazadecane*-1,10-*diamine*)*nickel(II) diperchlorate* ($NiL_t^1(ClO_4)_2$. The reaction of L_t^1 (2.81 g, 12.3 mmol) and nickel(II) perchlorate hexahydrate (4.49 g, 12.3 mmol) in methanol (15 ml), following the above procedure, gave fine orange crystals. The yield was 1.85 g (31%); mp 224.8–226.7°C (dec). IR (KBr): 3320, 3235 (N—H), 1595 (N—H), 1100, 610 (Cl—O) cm^{-1}. FABMS *m/z* (relative intensity): 487 (1.73), 485 (1.83), 387 (85.3), 385 (100), 286 (100).

(2,3 - cis - *Cyclohexano* - 1,4,8,11 - *tetraazacyclotetradecane*)*nickel(II) diperchlorate* ($NiL_c^3(ClO_4)_2$). To a stirred solution of $NiL_c^1(ClO_4)_2$ (0.51 g, 1.06 mmol) in water (50 ml) was added to a 40% glyoxal solution (0.27 g, 1.72 mmol) during 10 min and then the mixture was heated at 50°C for 5 h with stirring. The resulting slurry was cooled to 5°C and treated with sodium borohydride (0.08 g, 2.12 mmol), which was added in small portions over 1 h. The reaction mixture was heated at 90°C for 30 min, and then the hot solution was filtered rapidly through a glass filter. The filtrate was acidified with a 60% perchloric acid and permitted to stand overnight at room temperature. The product deposited was separated by filtration and recrystallized from water to afford fine orange crystals. The yield was 0.41 g (75%); (lit. [2b] mp > 290°C) mp 225.6–226.1°C (dec). IR (KBr): 3205 (N—H), 1605 (N—H), 1090, 615 (Cl—O) cm^{-1}. FABMS *m/z* (relative intensity): 510 (2.94), 411 (29.9), 312 (36.7), 311 (42.4), 277 (100).

(2,3 - trans - *Cyclohexano* - 1,4,8,11 - *tetraazacyclotetradecane*)*nickel(II) diperchlorate* ($Ni_t^3(ClO_4)_2$). The reaction of $Ni_t^1(ClO_4)_2$ (0.51 g, 1.06 mmol), 40% glyoxal (0.25 g, 1.70 mmol) and sodium borohydride (0.08 g, 2.12 mmol) in water (50 ml), following the above procedure, gave fine orange crystals. The yield was 0.34 g (63%); (lit. [2b] mp > 275°C (dec)), mp 237.8–239.1°C (dec). IR (KBr): 3200 (N—H), 1610 (N—H), 1100, 620 (Cl—O) cm^{-1}. FABMS *m/z* (relative intensity): 510 (7.61), 411 (100), 312 (47.2), 311 (88.3).

2,3 - cis - *Cyclohexano* - 1,4,8,11 - *tetraazacyclotetradecane*(cis-*Cyclohexylcyclam*, L_c^3). The method of Kobiro *et al.* was modified for the preparation of *cis*-Cyclohexylcyclam [2b]. To a stirred solution of $Ni_c^3(ClO_4)_2$ (1.47 g, 2.87 mmol) in water (10 ml) was added sodium cyanide (0.94 g, 14.4 mmol) over 10 min at room temperature. The mixture was kept under reflux for 3 h with stirring. After the resulting mixture was cooled to room temperature, sodium hydroxide (100 mg, 2.5 mmol) was added and the reaction mixture was extracted three times with dichloromethane (10 ml). The organic layer was separated and dried over anhydrous sodium sulfate overnight. The solvent was evaporated *in vacuo*, and then the resulting crude solid was recrystallized from acetonitrile to give fine white crystals. The yield was 0.44 g (61%), (lit. [2b] mp 137.5–138°C), mp 133.2–134.7°C (dec). IR (KBr): 3250, 3180 (N—H), 2900, 2800 (C—H) cm^{-1}. FABMS *m/z* (relative intensity): 255 (5.88), 254 (39.4), 253 (7.16), 210 (15.3), 196 (18.5), 182 (28.5), 180 (41.6), 168 (35.7), 167 (100).

2,3 - trans - *Cyclohexano* - 1,4,8,11 - *tetraazacyclotetradecane* (trans-*Cyclohexylcyclam*, L_t^3). The reaction of $Ni_t^3(ClO_4)_2$ (0.70 g, 1.37 mmol) and sodium cyanide (0.45 g, 6.85 mmol) in water (10 ml), following the above procedure, was obtained as fine white crystals which was recrystallized from a blended solvent of chloroform and ethyl ether. The yield was 0.24 g (69%) (lit. [2b] mp 218–219°C), mp 216.0–217.9°C. IR (KBr): 3260, 3170 (N—H), 2920, 2800 (C—H) cm^{-1}. FABMS *m/z* (relative intensity): 255 (10.2), 254

(80.8), 253 (8.91), 210 (13.4), 196 (21.3), 182 (43.9), 180 (51.2), 168 (49.2), 167 (100).

(2,3 - cis - *Cyclohexano* - 1,4,8,11 - *tetraazacyclotetradecane)copper(II) diperchlorate* ($CuL_c^3(ClO_4)_2$). To a stirred solution of L_c^3 (0.09 g, 0.36 mmol) in methanol (3.0 ml) was added a solution of copper(II) perchlorate hexahydrate (0.14 g, 0.36 mmol) in methanol (1.0 ml) at room temperature. The reaction mixture was heated at 50°C for 2 h and cooled to room temperature. The precipitates deposited were isolated by filtration and recrystallized from water to obtain claret prisms. The yield was 0.14 g (73%), mp 285–288°C (dec). IR (KBr): 3220 (N—H), 2940, 2860 (C—H), 1610 (N—H) 1100, 610 (Cl—O) cm^{-1}. FABMS *m/z* (relative intensity): 518 (1.54), 515 (0.53), 418 (77.2), 416 (100), 317 (45.6), 315 (58.0), 254 (51.5).

(2,3 - trans - *Cyclohexano* - 1,4,8,11 - *tetraazacyclotetradecane)copper(II) diperchlorate* ($CuL_t^3(ClO_4)_2$). The reaction of L_t^3 (0.05 g, 0.21 mmol) and copper(II) perchlorate hexahydrate (0.08 g, 0.21 mmol) in methanol (4.0 ml), following the above procedure, gave claret needles. The yield was 0.07 g (65%), mp > 300°C. IR (KBr): 3240 (N—H), 2940, 2860 (C—H), 1600 (N—H), 1090, 620 (Cl—O) cm^{-1}. FABMS *m/z* (relative intensity): 518 (1.04), 515 (0.42), 418 (68.4), 416 (89.2), 317 (36.4), 315 (50.4), 259 (24.7).

RESULTS AND DISCUSSION

Synthesis of cyclohexylcyclams and their complexes

Cis-Cyclohexane-1,2-diamine (*cis*-dac) and *trans*-cyclohexane-1,2-diamine (*trans*-dac) were separated from a mixture according to a modification of the procedure reported by Saito and Kidani [4]. The cyclam with bulky substituents at *cis*-positions on one side of cyclam ring, namely *cis*-cyclohexylcyclam L_c^3, was synthesized according to a modification of the method described by Kobiro *et al.*, as shown in Scheme 1 [2b]. The *trans*-cyclohexylcyclam L_t^3 was also synthesized in a similar procedure as L_c^3. Reaction of diamine (*cis*-dac and *trans*-dac) and acrylonitrile followed by lithium aluminum hydride reduction gave tetraamine (L_c^1 and L_t^1). The nickel(II) templated reaction of the tetraamine with glyoxal followed by sodium borohydride reduction led to the cyclohexylcyclam nickel(II) complexes, $NiL_c^3(ClO_4)_2$ and $NiL_t^3(ClO_4)_2$. The template cyclization was achieved at 50°C, while the reduction was performed at 90°C. The nickel(II) complexes are obtained as fine orange crystals. Cyclohexylcyclams were liberated by the treatment of the nickel(II) complexes with sodium cyanide in water. *cis*-Cyclohexylcyclam and *trans*-cyclohexylcyclam were synthesized with a maximum overall yield of 28 and 15%, respectively. The cyclohexylcyclams easily yielded the claret copper(II) diperchlorate complexes by reaction with copper(II) perchlorate hexahydrate in methanol at 50°C. The analytical data for the cyclohexylcyclams and their complexes are summarized in Table 1. The elemental analyses of these crystalline samples were in good agreement with compounds of these expected compositions.

Mass spectra

The EI mass spectra of cyclohexylcyclams and their intermediates exhibit molecular ions, respectively. The nickel(II) and copper(II) complexes reveal clusters of ions corresponding to $[M-ClO_4]^+$ and $[M-2ClO_4+2H]^+$ which is the base peak in FAB

mass spectra. When the complexes are analyzed with FAB and FD technique, the molecular ions are not observed.

Molar conductivity

The molar conductances for the nickel(II) and copper(II) complexes are listed in Table 2. The complexes, $[ML](ClO_4)_2$ (M = Ni(II) or Cu(II); L = L_c^3 or L_t^3), are 1 : 2 electrolyte in *N,N*-dimethylformamide (DMF) at 25°C and are tetra-coordinated in this solvent. Therefore, the perchlorate anions are ionized on dissolution in the solvent. This result is consistent with the corresponding infrared and electronic spectral behavior.

Infrared spectra

The characteristic IR bands for the present discussion are collected in the Experimental section. The

Table 2. Molar conductances for the complexes at 25°C in *N,N*-dimethylformamide[a]

Complex	$\Lambda_M(\Omega^{-1}\,cm^2\,mol^{-1})$	Type of electrolyte
$NiL_c^3(ClO_4)_2$	155	3 (1 : 2)
$NiL_t^3(ClO_4)_2$	161	3 (1 : 2)
$CuL_c^3(ClO_4)_2$	160	3 (1 : 2)
$CuL_t^3(ClO_4)_2$	153	3 (1 : 2)

[a] For ca 10^{-3} mol dm^{-3} solution. Assignment of the type of electrolyte presented in solution was made on the basis of the conductance data compiled by Geary [6].

metal-free cyclohexylcyclams show strong bands at ca 3250 cm^{-1} which are associated with N—H stretching modes. The nickel(II) and copper(II) complexes also indicate only one strong band near 3200 cm^{-1} owing to secondary amine stretching vibrations. It is clear that this vibrational modes shift slightly to lower frequency upon complex formation. Intense broad bands are newly observed in the 1090–1100 cm^{-1} region with the formation of the nickel(II) and copper(II) complexes and can be attributed to the stretching vibration modes of perchlorate ions [7]. This band is most sensitive to metal-coordination among the absorption peaks appearing in the NaCl range. The perchlorate group in these metal complexes may be present not as a coordinated group but as a simple isolated anion, judging from the vibrational frequency [8]. This result is supported by the conductance data. An other band based upon the perchlorate group is observed at about 620 cm^{-1} that may be attributable to its bending vibration [8].

Electronic spectra

The two copper(II) complexes, $CuL_c^3(ClO_4)_2$ and $CuL_t^3(ClO_4)_2$, show only one broad band in the range appearing below 34,000 cm^{-1} as shown in Fig. 1. The general feature of the spectra for the complexes is similar to each other. This suggests that the coordination structure of the copper(II) complexes is almost analogous. The absorption band observed at about 19,100 cm^{-1} is attributed to a ligand-field transition, because the molar extinction coefficient of the band is similar to that commonly assigned to a ligand-field transition [9]. The spectral behavior is comparable with that of square-planar copper(II) complexes [9] and with that of the copper(II) complexes derived from dicyclohexylcyclams [3a]. Hence, the copper(II) complexes are square-planar coordination.

The two nickel(II) complexes are different from each other on the ligand-field spectra in coordinating solvent. $NiL_c^3(ClO_4)_2$ complex exhibits only one broad ligand-field band at 22,400 cm^{-1} as shown in Fig. 2. Analogous ligand-field spectra have been observed for $Ni(DMG)_2$ and $Ni(4\text{-}N)(ClO_4)_2$ [3a,10]. This seems to

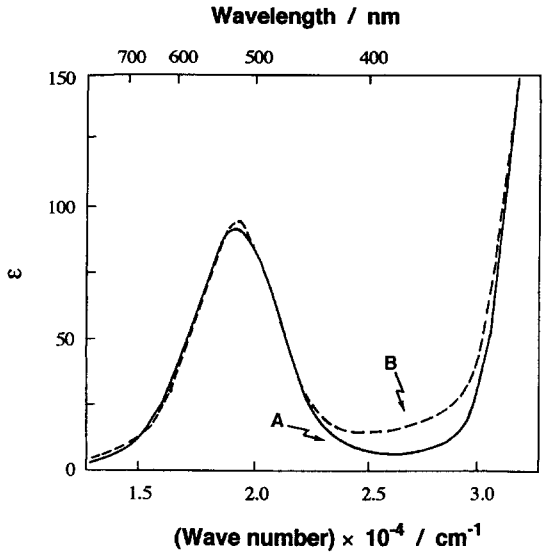

Fig. 1. Electronic spectra for the copper(II) complexes of cyclohexylcyclams at room temperature in *N,N*-dimethylformamide; A, $CuL_c^3(ClO_4)_2$; B, $CuL_t^3(ClO_4)_2$.

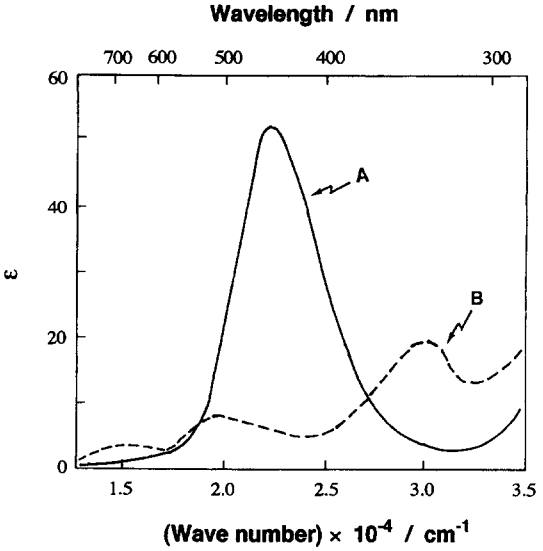

Fig. 2. Electronic spectra for the nickel(II) complexes of cyclohexylcyclams at room temperature in *N,N*-dimethylformamide; A, $NiL_c^3(ClO_4)_2$; B, $NiL_t^3(ClO_4)_2$.

indicate that the structure of $NiL_c^3(ClO_4)_2$ complex is a square-planar configuration [9]. On the other hand, $NiL_t^3(ClO_4)_2$ complex reveals three ligand-field bands in coordinating solvent such as DMF, as shown in Fig. 2. This spectrum suggests that the complex is an octahedral configuration [3a,9]. When the coordinating ability of the solvent is very poor, $NiL_t^3(ClO_4)_2$ complex assumes a square-planar configuration.

Table 3. Electronic absorption bands for the nickel(II) and copper(II) complexes of cyclohexylcyclams[a]

Complex	Ligand-field transition in cm^{-1} (ε)
$NiL_c^3(ClO_4)_2$	22300 (52)
$NiL_t^3(ClO_4)_2$	14800 (3.5), 19600 (8.0), 29700 (19)
$CuL_c^3(ClO_4)_2$	19100 (92)
$CuL_t^3(ClO_4)_2$	19200 (95)

[a] Measured in *N,N*-dimethylformamide at room temperature.

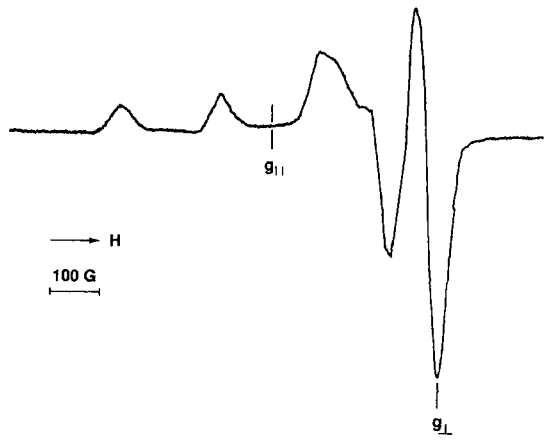

Fig. 3. ESR spectrum of the copper(II) complex, $CuL_c^3(ClO_4)_2$, in *N,N*-dimethylformamide at 77 K.

Hence, the coordination structure of the nickel(II) complexes is determined with their spectra in coordinating solvent. A similar phenomenon has been observed for $Ni(4\text{-}P)(ClO_4)_2$ complex [3a]. It is very interesting to note that $Ni(4\text{-}P)(ClO_4)_2$ complex containing two cyclohexyl groups, $NiL_t^3(ClO_4)_2$ complex bearing one cyclohexyl group and $Ni(cyclam)^{2+}$ complex having no cyclohexyl group show the distorted octahedral forms in coordinating solvent in contrast to square-planar forms of $Ni(4\text{-}N)(ClO_4)_2$ and $NiL_c^3(ClO_4)_2$ complexes [11]. Accordingly, the magnitude of ligand-field for $NiL_c^3(ClO_4)_2$ complex is approximately similar to that for $Ni(4\text{-}N)(ClO_4)_2$ complex. The ligand-field transition bands of the complexes are summarized in Table 3.

ESR spectra

In the ESR spectra of the copper(II) complexes measured in *N,N*-dimethylformamide at room temperature, a set of four hyperfine lines were observed by the magnetic interaction between an unpaired electron and a copper nucleus ($I = 3/2$), but superhyperfine lines based upon the nitrogen nuclei ($I = 1$) do not turn up. The ESR spectrum of $CuL_c^3(ClO_4)_2$ complex in *N,N*-dimethylformamide at 77 K is shown in Fig. 3. The general feature of the spectrum is in accord with that of square-planar coordination. A set of four copper hyperfine lines on the parallel component of the *g*-tensor ($g_{\parallel}$) in the low field region are observed, while such hyperfine lines are not obvious on the perpendicular component of the *g*-tensor ($g_{\perp}$) which lies in the higher field region. Superhyperfine lines based upon the nitrogen nuclei do not appear on the $g_{\parallel}$ and $g_{\perp}$ components. The general features of the spectra for $CuL_c^3(ClO_4)_2$ and $CuL_t^3(ClO_4)_2$ complexes are analogous to each other. The spin Hamiltonian parameters observed in this work are very similar to those for porphyrin, phthalocynaine, cyclam and dicyclohexylcyclam copper(II) complexes as given in Table 4 [3a,12,13,14]. Consequently, the present copper(II) complexes are of square-planar coordination.

NMR spectra

Definitive assignments for the cyclohexylcyclams (L_c^3, L_t^3) and their nickel(II) complexes are very difficult because of giving several peaks of a multiplet in the ^{1}H-NMR spectra. Therefore, ^{1}H-NMR spectra of these compounds cannot be utilized to distinguish between two isomers.

^{13}C-NMR data of *cis*-dac, *trans*-dac, L_c^3, L_t^3 and the nickel(II) complexes are compiled in Table 5. The carbon signals of L_c^3, L_t^3 and their nickel(II) complexes indicate seven lines, respectively. $NiL_t^3(ClO_4)_2$ complex do not give a well-resolved ^{13}C-NMR spectrum in dimethyl sulfoxide-d_6 and pyridine-d_5 which are strong coordinating solvents. This shows that these solvents coordinate the axial positions of the complex, which becomes an octahedral configuration in the solvents and is a paramagnetism. The ^{13}C-NMR spectra are scarcely susceptible to solvent effect in a solvent of which the coordinating power is very poor. The peaks of C(3), C(4) and C(6) positions adjacent to amines are shifted downfield by 1.8–7.7 ppm upon formation of the nickel(II) complexes. The magnitude of the downfield for $NiL_c^3(ClO_4)_2$ complex is larger than that for $NiL_t^3(ClO_4)_2$ complex. The downfield shift can be attributable to the deshielding effect due to the positive charge provided by the nickel ion in the complexes. The deshielding effect for $NiL_c^3(ClO_4)_2$ complex is greater than that for $NiL_t^3(ClO_4)_2$ complex. This seems to indicate that the coordinated structure of the two nickel(II) complexes is somewhat different. The magnitude of the shifts for C(1) and C(2) positions is smaller than that for C(3) and C(4) positions. This is mainly due to the fact that the C(1) and C(2) positions are placed further from the positive charge of the nickel(II) ion which affords the deshielding effect.

(Received 4 August 1997; accepted 1 October 1997)

Abstract—Lanthanide complexes of P,P′-di(2-ethylhexyl) methanediphosphonic acid, $H_2DEH[MDP]$, were prepared and investigated by infrared spectroscopy. Qualitative information about the nature of the phosphonate binding in the complexes was obtained by measuring the asymmetric and symmetric POO^- stretching frequencies of the ligand. These vibrational modes appear at lower energy in the complexes than in the sodium salt. This indicates symmetrical coordination of the phosphonate groups through chelate and/or bridging interactions. The frequency difference between the POO^- stretching bands $\Delta\nu$ becomes smaller as the ionic potential e/r of the metal ion increases. The correlation is valid when both oxygen atoms are involved in the bonding and no other absorption bands interfere with the POO^- vibrations. The origin of this empirical correlation is the change in the P—O bond order which arises from a change in the strength of the metal–diphosphonate interaction. The far-infrared spectra of the lanthanide complexes, an ^{54}Fe-labelled compound, and the sodium salt of $H_2DEH[MDP]$ were measured to provide insight into the nature of the metal–ligand interaction. The appearance of metal–oxygen stretching bands in the iron compound indicates that the iron–diphosphonate interaction has a substantial covalent component whereas the absence of metal–oxygen stretching bands in the lanthanide complexes indicates the binding is predominantly ionic. © 1998 Elsevier Science Ltd. Keywords: lanthanide complexes; metal diphosphonates; infrared stretching frequencies.

Alkyl-substituted diphosphonic acids are of considerable interest as solvent extraction reagents for metal ions [1–3]. These molecules are powerful complexing agents and the strong acidity of the diphosphonic acid functionality permits the formation of metal complexes of high stability under very acidic conditions [4–6]. We recently reported that qualitative information about the coordination mode of the phosphonate groups in metal complexes of P,P′-di(2-ethylhexyl) methanediphosphonic acid ($H_2DEH[MDP]$) may be obtained by comparing the energies of the asymmetric and symmetric POO^- stretching modes of the ligand in the complexes to their corresponding values in the sodium salt [7]. Interpretation of the vibrational data uses bonding arguments developed for analogous complexes of carboxylic acids where relationships between the COO^- stretching frequencies and the type of carboxylate coordination are well established [8].

While investigating the complexation chemistry of $H_2DEH[MDP]$, we observed that the frequency difference $\Delta\nu$ between the POO^- stretching bands in the metal compounds becomes smaller as the ionic potential e/r of the metal ion increases [7]. This type of correlation had been reported previously by Peppard and Ferraro for ionic complexes of organ-

ophosphoric acids of the type $(RO)_2PO(OH)$ and $(RO)(R)PO(OH)$ [9,10] and was subsequently observed for metal complexes of P,P′-di(2-ethylhexyl) ethanediphosphonic acid, $H_2DEH[EDP]$ [11]. Similar correlations between the ionic potential of the metal ion and anion stretching vibrations have been demonstrated for nitrate [12,13] and carboxylate [14,15] compounds. In the present study, lanthanide complexes of $H_2DEH[MDP]$ were prepared and characterized to test the general validity of this correlation for diphosphonate complexes. The far-infrared spectra of the lanthanide complexes, an ^{54}Fe-labeled compound, and the sodium salt of $H_2DEH[MDP]$ were measured to provide information about the nature of the metal-diphosphonate interaction.

EXPERIMENTAL

Materials

Reagent grade $La(NO_3)_3 \cdot 6H_2O$, $Pr(NO_3)_3 \cdot 5H_2O$, $Gd(NO_3)_3 \cdot 5H_2O$, and $Yb(NO_3)_3 \cdot 5H_2O$ obtained from Aldrich Chemical Co. were used without further purification. Reagent grade $Nd(NO_3)_3 \cdot 6H_2O$ from GFS Chemical Co. was used as received. Iron-54 wire, 96.4% isotopically pure, was obtained from Cambridge Isotope Laboratories, Inc., dissolved in 1 M HNO_3, and used to prepare an ^{54}Fe-labeled $H_2DEH[MDP]$ complex. Aqueous solutions were prepared using Ultrex reagent nitric acid (J. T. Baker Chemical Co.) and water obtained from a Milli-Q2 purification system.

Measurements

Infrared spectra in the 4800–400 cm^{-1} region were obtained on a Nicolet 510P PC/IR Fourier transform spectrometer. Solid samples were run as KBr pellets with air as the background. The spectra were checked as nujol mulls supported on KBr plates. Spectra in the 650–150 cm^{-1} range were obtained by collecting 128 scans at 4 cm^{-1} resolution on a Bruker 98 vacuum FT-IR interferometer using a globar source, a DTGS detector, and a mylar beam splitter. Solid samples were run as CsI pellets referenced against a blank CsI pellet. The reproducibility of the spectra was checked by multiple scans on at least two different samples over the desired frequency range. The uncertainty in the measured frequencies for the absorption bands is 1 cm^{-1}.

Elemental analyses were performed by Galbraith Laboratories, Inc., Knoxville, TN. Metal ion analyses for the compounds were performed by the Analytical Chemistry Division of ANL using ICP-AES. Solid samples were weighed into a platinum crucible and ignited in air at 1100°C. The residue was fumed with concentrated H_2SO_4 and made up to the final volume with dilute nitric acid. The relative uncertainty in the metal ion analysis is estimated to be ~5%.

Preparation of compounds

P,P′-di(2-ethylhexyl) methanediphosphonic acid. $H_2(C_{17}H_{36}O_6P_2)$ was prepared by the reaction of two equivalents of 2-ethylhexanol with methanediphosphonic acid in dry THF as previously described [7]. $Na_2(DEH[MDP])$, $Fe_2(DEH[MDP])_3$, and $Eu_2(DEH[MDP])_3$ were prepared as reported earlier [7].

$La_2(C_{17}H_{36}O_6P_2)_3 \cdot 2H_2O$, $Pr_2(C_{17}H_{36}O_6P_2)_3 \cdot 3H_2O$, $Nd_2(C_{17}H_{36}O_6P_2)_3 \cdot 2H_2O$, $Gd_2(C_{17}H_{36}O_6P_2)_3 \cdot 5H_2O$, $Tb_2(C_{17}H_{36}O_6P_2)_3 \cdot 2H_2O$, and $Yb_2(C_{17}H_{36}O_6P_2)_3 \cdot 2H_2O$. The lanthanide complexes were prepared by slow addition of a methanol solution of $H_2DEH[MDP]$ to an equivalent amount of metal nitrate in methanol solution which had been acidified with 2 drops of 0.1 M HCl. The flocculent precipitate which formed upon concentrating the reaction mixture was collected by filtration, washed with water and methanol, and dried overnight at 60°C. Typical yields were in the 70–90% range. The infrared spectra of the solids indicated that the salts were isolated as hydrates. The stoichiometry of the hydrate was established by drying to constant weight at 120°C. Anal. for $La_2C_{51}H_{112}O_{20}P_6$. Found: C, 40.42, H, 7.79, La, 19.34, H_2O, 2.30; Calc. RESULTS AND DISCUSSION

The spectra of the lanthanide compounds prepared in this study in the mid-infrared region are very similar to the spectrum previously reported for the Eu(III)-$H_2DEH[MDP]$ complex [7]. In all cases, the compounds exhibit absorption bands in regions characteristic for water of hydration (*vide infra*). The stretching and bending vibrations of the 2-ethylhexyl group appear in conventional regions characteristic of alkyl groups. The frequencies and tentative assignments of the absorption bands in the 1250–950 cm^{-1} region are listed in Table 1. These assignments have been discussed in detail for the Eu(III) complex [7] and need no further explanation. The frequency of the asymmetric and symmetric POO^- stretching modes of the diphosphonate ligand are lower in the lanthanide compounds than in the sodium salt, i.e. 1246 and 1144 cm^{-1}, respectively. The shift of both $\nu_{asym}(POO^-)$ and $\nu_{sym}(POO^-)$ to lower energy in the lanthanide com-

plexes is similar to that observed for other $H_2DEH[MDP]$ compounds [7].

The decrease in $\nu_{asym}(POO^-)$ observed upon complexation essentially rules out monodentate coordination of the phosphonate groups. Coordination of a single oxygen of a $>PO_2^-$ group would result in considerably different P—O bond orders and increase the frequency of the asymmetric POO^- stretching vibration. The asymmetric COO^- stretching mode in analogous monodentate carboxylate complexes generally appears at frequencies that are significantly higher than values characteristic for ionic salts or bidentate and bridged complexes [8]. The separation between the COO^- stretching frequencies also generally is larger in monodentate carboxylate complexes than is characteristic for other types of bonding [8]. Symmetrical coordination of the $>PO_2^-$ groups on the other hand can reduce the bond order of both P—O bonds by the same amount and cause both stretching modes to decrease in energy. Symmetrical coordination of diphosphonate ligand can occur through chelation and/or bridging arrangements. Several recently reported lanthanide complexes of 1-hydroxyethane-1, 1-diphosphonic acid have structures in which both coordination modes are utilized by the ligand to complex the metal ion [16]. In the Nd(III) and Eu(III) complexes, the diphosphonate ligand simultaneously bridges two different metal ions through the $>PO_2^-$ groups and coordinates in a bidentate fashion to form 6-member chelate rings [16].

The frequency difference $[\nu_{asym}(POO^-)-\nu_{sym}(POO^-)]$ between the asymmetric and symmetric POO^- stretching modes of the phosphonate group are sensitive to the lanthanide ion present in the complex. The difference $\Delta\nu$ becomes progressively smaller as the ionic potential of the metal ion increases. Figure 1 shows a plot of the ionic potential, e/r (charge/ionic radius for coordination number 6) [17] vs $\Delta\nu$ for the complexes reported in this study. This correlation which was previously observed with other $H_2DEH[MDP]$ and $H_2DEH[EDP]$ compounds [7,11] thus appears to be generally valid for diphosphonate complexes when both oxygen atoms of the $>PO_2^-$ groups are involved in complexing the metal ion. The correlation should be useful for identifying changes in metal-ligand bonding across a series of complexes containing similar metal ions such as lanthanides [16] or actinides and with changes in metal oxidation state.

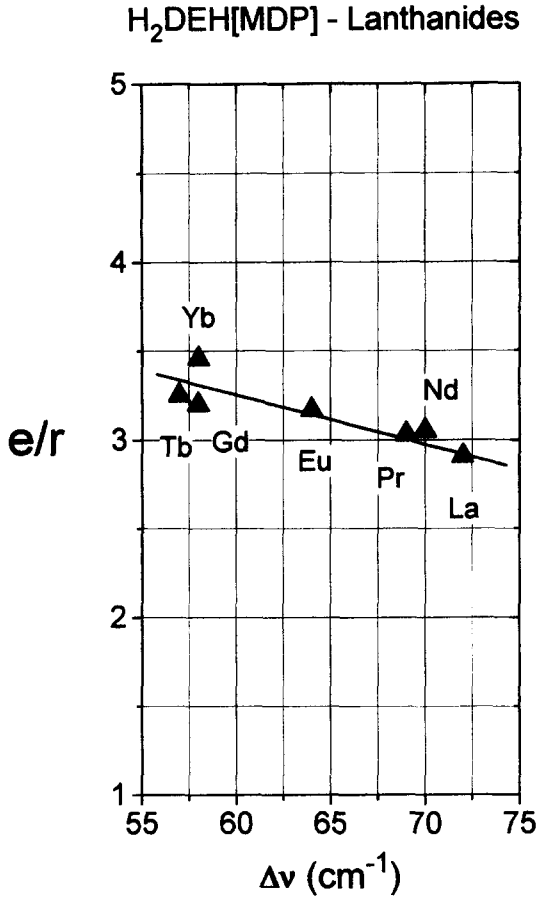

Fig. 1. A plot of e/r, the ionic potential of the metal ion, versus the difference $\Delta\nu$ between $\nu_{asym}(POO^-)$ and $\nu_{sym}(POO^-)$ for lanthanide complexes of $H_2DEH[MDP]$, where e = ion charge and r = Shannon ionic radius.

The frequency difference between the asymmetric and symmetric COO^- stretching bands in hydrated lanthanide acetates has been reported [15] to show a decrease with decreasing metal ion radius that is analogous to the correlation observed for the lan-

thanide diphosphonates in the present study. The crystal structure of $Er(CH_3COO)_3(H_2O)_4$ reveals that the carboxylate ion in this lanthanide complex is coordinated to the metal as a chelating ligand as well as in an arrangement involving both chelation and bridging [18]. Bands at 260 cm^{-1} and 196 cm^{-1} in the far-infrared spectrum of the erbium complex have been assigned to Er—O stretching modes on the basis of a normal coordinate analysis [19].

A vibrational analysis by Kumamoto indicates that the P—O bond order within alkyl-phosphate anions plays a major role in determining the frequency of the P—O stretching vibrations [20]. Since this is undoubtedly true for diphosphonate anions as well, the variation of $\Delta\nu$ with e/r is a reflection of a change in the P—O bond order which results from a change in the strength of metal–diphosphonate interaction [21]. Changes in the P—O bond order that result from changes in the metal–ligand bond strength could arise from P—O bond polarization due to purely electrostatic effects, covalence in the metal–oxygen interaction, or a combination of both effects. We suggested earlier that changes in the nature of the metal–ligand interaction might be involved since the smallest $\Delta\nu$ values are observed for the diphosphonate compounds where the metal–oxygen electronegativity difference is the least [11].

The far-infrared spectra of the lanthanide complexes prepared in this study, the iron complex, and the sodium salt of H_2DEH[MDP] were measured to provide insight into the nature of the metal-diphosphonate interaction. Figure 2 shows the spectra for Na_2(DEH[MDP]), Fe_2(DEH[MDP])$_3$, and Eu_2(DEH[MDP])$_3$. All of the compounds investigated have two bands in the 550–450 cm^{-1} region where the POO^- deformation, δ(POO), and POC deformation, δ(POC), modes generally appear [22,23]. The higher energy band in this region was tentatively assigned earlier as δ(POO) on the basis of its metal sensitivity [7]. The iron complex also has a strong absorption band at 256 cm^{-1} that is not present in the spectrum of H_2DEH[MDP] or any of the other compounds listed in Table 2. This band was initially assigned as a metal–oxygen stretching mode, ν(M—OP), by comparison with related iron(III) complexes [24]. A metal–oxygen stretching mode will become IR active if the metal–oxygen bond is sufficiently covalent. Depending upon the actual symmetry of the iron complex at least two Fe–O stretching bands are expected to be infrared active.

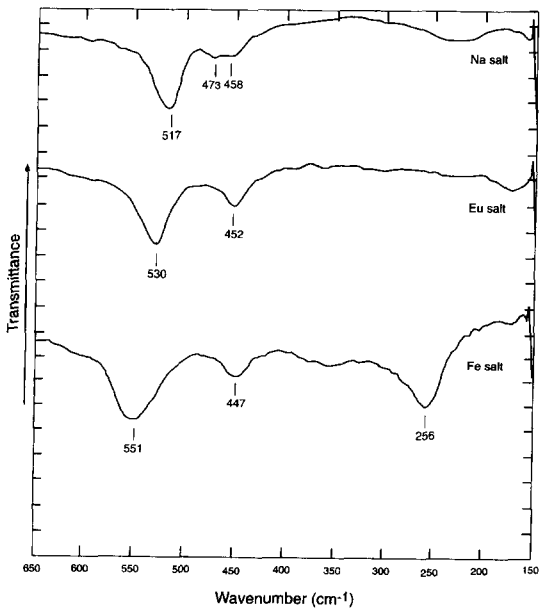

Fig. 2. The far-infrared spectra of the sodium-, europium-, and iron-H_2DEH[MDP] compounds in the 650–150 cm^{-1} region.

The metal isotope technique developed by Nakamoto [25] provides a unique method to identify metal–ligand vibrations since only vibrations involving motion of the metal atom are shifted by metal isotope substitution. The frequency of the absorption bands in the far-infrared for the ^{54}Fe-labeled H_2DEH[MDP] complex are compared in Table 2 with those for the compound prepared from the natural iron isotopic mixture, i.e. 91.5% ^{56}Fe. (The spectra for the two samples were identical in the mid-infrared region). The 256 cm^{-1} absorption band shifts to higher frequency upon substitution with the lighter isotope. The magnitude and direction of this isotopic shift are similar to that reported for Fe—O stretching modes in the tris(acetylacetonato)iron(III) complex [26].

The 551 cm^{-1} band also shifts to higher energy upon isotopic substitution. This band is relatively broad and asymmetric in the iron complex and most likely does not represent a pure vibrational mode. A small isotopic shift is expected for the δ(POO) band which is strongly metal sensitive since POO^- bending involves some metal motion and the vibration should be coupled with the metal–oxygen stretching mode [27]. The 4 cm^{-1} shift, however, is larger than expected. The large isotopic shift indicates that the 551 cm^{-1}

*This band has a substantial metal–oxygen stretching component, *vide infra*.

band has a substantial iron–oxygen stretching component. A band at nearly this frequency in the infrared spectrum of the tris(oxalato)ferrate(III) complex has been identified on the basis on a normal coordinate analysis as an iron–oxygen stretching mode [27]. The frequency of the δ(POC) mode is unaffected by isotopic substitution as expected.

The appearance of metal–oxygen stretching bands in the anhydrous iron-H_2DEH[MDP] complex indicates that the iron-diphosphonate interaction has a substantial covalent component. The absence of these bands in the lanthanide complexes indicates that the binding is predominantly ionic in these compounds. Thus, based on these findings, it appears that changes in the P—O bond order in metal-diphosphonate complexes arise from a combination of bond polarization and covalence effects. This conclusion is consistent with the physical properties of the compounds, the results from our solvent extraction and aggregation studies [1,7], and small angle neutron scattering measurements [28]. The absence of metal–oxygen stretching bands in the lanthanide complexes further indicates that the water in these ionic compounds is not coordinated to the metal ion. This inference is in agreement with the observed structural results for analogous lanthanide complexes of 1-hydroxyethane-1,1-diphosphonic acid [16].

Acknowledgements—The authors wish to thank Paul G. Rickert for preparing the P,P′-di(2-ethylhexyl) methanediphosphonic acid and Ken L. Nash for helpful discussions and suggestions. We also wish to thank Marcos H. Grimsditch and S. Uram for use of the Bruker 98 vacuum FT-IR interferrometer and help in recording the spectra. The support provided for this work by the Department of Energy, Office of Basic Energy Sciences (BES) is acknowledged. One of us (J.A.G.) also wishes to acknowledge support from the U.S. Department of Education under the GAANN Fellowship Program.

(Received 21 July 1997; accepted 1 October 1997)

Abstract—The template reactions of 2,6-diacetylpyridine with 1,12-diamine-4,9-dioxadodecane in the presence of yttrium and lanthanide ions produce the pentadentate macrocyclic complexes with N_3O_2 set of donor atoms as a result of [1 + 1] Schiff base condensation. The complexes were characterized by spectral data (IR, UV–vis, ^{1}H NMR, FAB-MS), thermogravimetric and elemental analysis. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: Schiff bases; Macrocyclic complexes; Template synthesis; Yttrium; Lanthanides.

The design and synthesis of macrocyclic lanthanide complexes is currently attracting considerable attention since they can be used as supramolecular devices and sensors [1,2], contrast agents in magnetic resonance imaging [3–5], potential radiopharmaceuticals [6], as possible bioinorganic models for the active sites in metallobiomolecules [7,8], as synthetic nucleases for *in vivo* application [9]. The conjugation of macrocyclic complexes of yttrium and lanthanide radioisotopes to monoclonal antibodies results in agents for radioimmunotherapy and other medical applications [10]. In all of these situations the metal complex must be sufficiently stable *in vivo*, inert to metal release under physiological conditions in order to avoid the damage to nontarget cells. The Schiff base macrocyclic yttrium and lanthanide complexes fulfill these requirements, because they are extremely inert with respect to release of the metal ion, whereas the exocyclic ligands (anion or water molecules) are labile and easy to change.

Many of the synthetic routes to macrocyclic ligands involve the use of the metal ion template to orient the reacting groups of the ligand in the desired conformation for optimum ring closure. The favorable enthalpy for the formation of the metal–ligand bonds overcomes the unfavorable entropy from the ordering of the multidentate ligand around the metal ion and thereby promotes the cyclization reaction [11–13].

In searching for new stable complexes of the rare earth elements in view of their potential applications and continuing our studies on the effectiveness of metal ions of varying radius and electron configuration in the synthesis of macrocyclic and macroacyclic compounds we have recently reported the template action of yttrium and heavier (smaller) lanthanide(III) ions (dysprosium, erbium, thulium and lutetium) in the synthesis of 15-membered pentadentate Schiff base macrocyclic ligand derived from 2,6-diacetylpyridine and 3,6-dioxaoctane-1,8-diamine [14,15]. The higher lanthanide(III) ions (lanthanum, samarium and europium) have been found to be ineffective as templates in the synthesis of this macrocycle under similar conditions. These results have prompted us to investigate the template action of the lanthanides in the synthesis of related macrocyclic ligand with greater ring size. The preparation and characterization of new 19-membered macrocyclic Schiff base complexes formed in the lanthanide-promoted condensation reactions between one molecule of 2,6-diacetylpyridine and one molecule of 1,12-diamine-4,9-dioxadodecane is the subject of this paper. We have also found that under different experimental conditions these ions may act as effective templates in the synthesis of the dinuclear octadentate macroacyclic complexes of podate type with terminal

* Author to whom correspondence should be addressed.

acetylpyridyl groups and N_4O_4 set of donor atoms as a result of [2+1] Schiff base partial condensation of two molecules of 2,6-diacetylpyridine with one molecule of 1,12-diamine-4,9-dioxadodecane [16].

EXPERIMENTAL

The hydrated lanthanide(III) salts were prepared by dissolving the 99.99% oxides (Fluka) in a slight excess of appropriate acid. The solutions were evaporated and precipitates recrystallized from methanol. 2,6-Diacetylpyridine and 1,12-diamine-4,9-dioxadodecane (Aldrich Chemical Company) were used without further purification.

Preparation of the complexes. General procedures

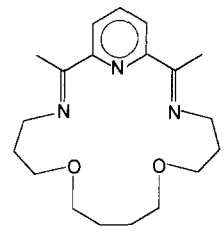
All complexes were performed under similar conditions. To a mixture of appropriate metal salt (0.1 mmol) in methanol (10 cm^3) and 2,6-diacetylpyridine (0.1 mmol) in methanol (10 cm^3), 1,12-diamine-4,9-dioxadodecane (0.1 mmol) in methanol (10 cm^3) was added dropwise with stirring. The reaction was carried out for 4 h. The solution volume was then reduced to 10 cm^3 by roto-evaporation and an orange precipitate formed on addition of a small amount of diethyl ether. This was filtered off, washed with ether, and dried *in vacuo*. Yields: 76–81%. The results of elemental analysis of the complexes are listed in Table 1.

Measurements

IR spectra were recorded using CsI pellets in the range 4000–200 cm^{-1} on a Perkin-Elmer 580 spectrophotometer. Electronic spectra were measured on a Shimadzu UV-160 spectrophotometer. ^1H NMR spectra were run in DMSO-d_6 on a Varian Gemini 300 spectrometer using TMS as an internal reference. FAB-mass spectra were obtained on a AMD-604 mass spectrometer with the glycerol as matrix. Thermogravimetric measurements were performed using Shimadzu TGA-50 derivatograph.

RESULTS AND DISCUSSION

The lanthanide(III) ion complexes of the new macrocyclic ligand **L**-product of a Schiff base cyclocondensation of one molecule of 2,6-diacetylpyridine with one molecule of 1,12-diamine-4,9-dioxadodecane were prepared by the reaction of appropriate metal salts acting as template agents with diketone and diamine in the 1 : 1 : 1 molar ratio of starting materials.



L

The formulations of these complexes as $LnL(H_2O)_nX_3 \cdot mH_2O$, where L is $Me_2pyo[19]triene\text{-}N_3O_2$, Ln = Y^{3+}, La^{3+}, Eu^{3+}, Gd^{3+}, Dy^{3+}, Ho^{3+}, Er^{3+}, Tm^{3+}, Yb^{3+}, Lu^{3+}, X = NO_3^- or Cl^-, n = 0–4, m = 0–4, follow from spectral data (IR, UV–vis, ^1H NMR, FAB-MS) and thermogravimetric and elemental analyses. The complexes are orange air stable solids, moderately soluble in CH_3CN and DMSO.

The infrared spectra of these complexes taken in the region 4000–200 cm^{-1} are all very similar except for anion vibrational modes (Table 2) and provide some information regarding the bonding in the complexes. They confirm the formation of the macrocyclic compounds by the absence of bands characteristic of

carbonyl and amine groups of the starting materials. An important feature is the occurrence of a strong band at 1650–1620 cm^{-1} attributable to C=N stretching modes indicating the Schiff base condensation. The spectra exhibit medium to strong bands at 1598–1570 cm^{-1} as expected for the high energy ring vibrations of the coordinated pyridine. The bonding of the pyridine nitrogen atom is also shown by the presence of the band at 1030–1010 cm^{-1} and 668–630 cm^{-1} attributable to the ring breathing frequency and the low energy pyridine ring vibrations, respectively [17]. The C—O—C stretching mode occurs at 1095–1085 cm^{-1} indicating ether oxygen coordination [18]. The complexes show the broad diffuse band centered at ca 3450–3400 cm^{-1} due to the stretching and bending modes of lattice and/or coordinated water. In addition, weak bands are detectable at 860–815 cm^{-1} region (except for yttrium) which may be assigned to rocking or wagging modes of water molecules interacting with the metal ion [19]. The presence of water bound in two different ways is confirmed by the results of thermogravimetric analysis. The complexes lose the water molecules in two steps: below 100°C and/or above 150°C corresponding to the lattice and/or coordinated water molecules, respectively. The amount of these two kinds of water molecules per mol of metal ion was calculated from the weight loss observed for the complexes at these two temperature ranges. Information about the bonding mode of the counterions in these complexes may also be obtained from IR spectra [20]. In the spectra of the nitrate complexes ν(N—O) stretching frequency is observed as a very strong broad band centered at 1380 cm^{-1}. In addition medium bands at 825–816 cm^{-1} are also detectable. Comparison with the infrared spectral data of the various nitrate complexes with known X-ray crystal structures reveals that the broadening or splitting of these bands is characteristic of the presence of both coordinated and ionic nitrates [21–24]. The spectrum of the chloride complex shows medium absorption band at 225 cm^{-1} attributable to the M—Cl frequency indicating the interaction of at least part of the chloride counterions with the metal. The IR spectra of the perchlorate complexes exhibit the strong absorption band centered at 1080 cm^{-1} typical of the asymmetric Cl—O stretching mode and a weak band at 625 cm^{-1} associated with the asymmetric Cl—O bending mode. The considerable broadening (1200–900 cm^{-1}) of the higher energy band suggests, similarly to the nitrate complexes, that the perchlorate counterions are partially involved in the coordination sphere of the metal ion [20,21]. However the C—O—C stretching mode of the polyether chain also falls in this region.

The FAB mass spectrum of the lanthanum nitrate complex provides strong evidence for the formation of the macrocyclic complex with the ligand **L** as a product of the template condensation of one molecule of diketone with one molecule of diamine and confirms the presence of nitrate anions in both inner and outer spheres of the complex. The highest peak of the spectrum observed at m/z 599.1 corresponds to the $[LaL(NO_3)_2]^+$. This species loses the nitrate group resulting in the formation of the fragment $[LaL(NO_3)]^{2+}$ at m/z 536.0. The spectrum also exhibits a peak due to the free ligand at m/z 470.

The electronic spectra of the complexes for solutions in acetonitrile show similar features, containing intense and medium bands with maxima at 207–220 and 266–276 nm which may be assigned to the transition of the $\pi \rightarrow \pi^*$ type of the coordinated macrocycle.

The ^1H NMR spectra of DMSO-d_6 solution of the diamagnetic yttrium and lutetium complexes exhibit three multiplets in a ratio 1:1:2: the protons α to nitrogen give raise to a triplet (4H) at δ 2.85 ($J = 7.6$) for the yttrium complex and at δ 2.81 ($J = 6.9$) for the lutetium complex, the protons β to nitrogen to quintet (4H) at δ 1.77 ($J = 7.3$) for the yttrium complex and at δ 1.76 ($J = 6.2$) for the lutetium complex and the protons adjacent to the oxygen to the triplet (8H) at δ 3.43 ($J = 6.1$) for the yttrium complex and δ 3.42 ($J = 5.5$) for the lutetium complex. The remain-

ing protons of the —$OCH_2CH_2CH_2CH_2O$— chain (4H) occur at δ 1.54 and 1.52 for the yttrium and the lutetium complex, respectively. The pyridine protons are observed at δ 8.3–7.8 (6H) and the methyl protons of the two CH_3CN groups (6H) at δ 2.53 for the yttrium complex and at δ 2.51 for the lutetium complex. The integrated relative intensities of the above signals are in good agreement with the required ratios consistent with the proposed formulations of the complexes.

On the basis of available evidence it can be concluded that the yttrium and lanthanide ions are effective templates for the synthesis of new Schiff base macrocyclic complexes, in which the new ligand with N_3O_2 set of donor atoms acts as pentadentate chelator. The 19-membered macrocyclic product of the template process, contrary to the 15-membered coronand with similar set of donor atoms [14,15], appears to be large enough to encapsulate all the lanthanides irrespective of the ionic radius size of the central atoms. The high coordination number characteristic of these ions is achieved by the incorporation of water molecules and/or counterions in the coordination sphere of the complexes. Since there is no ligand field stabilization energy effect in the yttrium and lanthanide(III) ions (d^0 configuration) their coordination environment is determined mainly by the chelating power of the ligand (preferred conformation, nature and disposition of donor atoms). Thus these ions can be accommodated by the particular stereochemical constraints enforced by the template process. Efforts to prepare free macrocycle in the reaction of the 2,6-diacetylpyridine with 1,12-diamine-4,9-dioxadodecane in the absence of metal ion were unsuccessful and resulted in the formation of insoluble yellow compound of polymeric character terminated with carbonyl functions. The failure of this system to undergo complete condensation and cyclization confirms the importance of metal ion in directing the steric course of the condensation process, which ultimately ends with ring closure.

(Received 17 July 1997; accepted 1 October 1997)

Abstract—The synthesis and some spectroscopic properties of the new palladium(II) complexes with monoethyl 2-quinolylmethylphosphonate (2-mqmp) have been reported. It was shown that the molecular or the ionic complexes could be isolated by reaction of 2-mqmp with PdX_4^{2-} (X = Cl, Br) depending on the acidity of the aqueous reaction solution. The square planar dihalide complexes *trans*-$Pd(2\text{-mqmp})_2X_2$ with monodentate N-bonded ligand through the quinoline nitrogen were obtained at pH ~ 3.5. Under acidic conditions at pH < 3 the ion-pair salt complexes [2-mqmp H^+][Pd(2-mqmp)X_3^-] containing the protonated quinoline ligand as cation and the quinoliniummethylphosphonatetrihalopalladate complex as anion were isolated. These ionic complexes by heating in methanol were decomposed: the chloro complex to the molecular dichloropalladium adduct $Pd(2\text{-mqmp})_2Cl_2$, while its bromo analogue gave a mixture of the dibromopalladium adduct $Pd(2\text{-mqmp})_2Br_2$ and the ion-pair hexabromodipalladium salt complex [2-mqmp H^+]$_2$[$Pd_2Br_6^{2-}$]. The chelate complex Pd(2-mqmp-H)$_2\cdot 2H_2O$ was isolated at pH > 6. In this compound 2-mqmp acts as a bidentate ligand through the quinoline nitrogen and the phosphonic acid oxygen. The new complexes were identified and characterized on the basis of elemental and thermogravimetric analysis, magnetic and conductance measurements, as well as by infrared and positive/negative-ion FAB-mass spectroscopic studies. © 1998 Elsevier Science Ltd. Keywords: palladium(II) complexes; quinolylmethylphosphonate complexes; infrared study; mass spectroscopy.

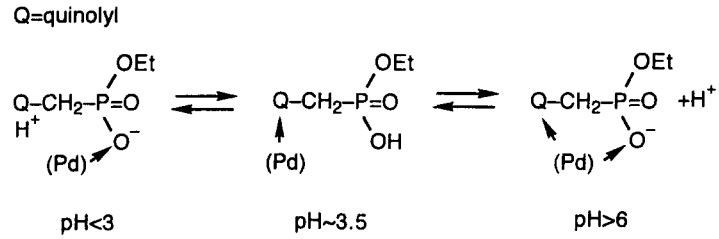
Organophosphorus compounds such as derivatives of various aminophosphonic acids, have currently attracted considerable interest not only because of their complexation capability towards numerous metal ions that enable application of the selected derivatives as catalysts, extractants, ion-exchangers etc [1–6], but also of their occurrence in living organisms and bioactivity [7–9]. The investigation of their interaction with metal ions, both in the solid state and in solution, may contribute to a better understanding of the biological activity of these compounds which is mainly displayed through their metabolic regulation and ability to inhibit various metalloenzymes having an amino acid as substrate. The differences in size, shape and basicity of the carboxylate and phosphonate groups might reflect in differences in the enzyme-substrate interactions.

As a part of our systematic investigation on coordination behaviour of various aminophosphonic acid derivatives with respect to Pd(II) ion, especially of those derived from quinoline and aniline which might be of interest as anticancer and antiviral agents [10–12], we describe here the preparation and characterization of new palladium complexes with monoethyl 2-quinolylmethylphosphonate (2-mqmp). In our earlier papers we studied Pd(II) halide complexes with diethyl 2-quinolylmethylphosphonate (2-dqmp), the ligand which appeared to coordinate metal ion in a monodentate and bidentate manner via only the quinoline nitrogen or both the quinoline nitrogen and the phosphoryl oxygen atoms [10,13]. Monoester 2-mqmp containing the phosphonic acid group has shown different complex-forming behaviour, since depending on the acidity of the reaction solution either the zwitterion, molecular or anionic form of this organophosphonate ligand can coordinate to the metal ion.

* Author to whom correspondence should be addressed.



Dihalide adducts containing mutually *trans*-bonded ligand via the quinoline nitrogen are formed at pH ~ 3.5, at higher acidity this ligand acts in a zwitterion form yielding salt complexes with the protonated quinolylmethylphosphonate ligand as cation and the quinoliniummethylphosphonatetrihalopalladate complex as its counterion, while at lower acidity the phosphonate monoanion coordinates to metal through the quinoline nitrogen and the deprotonated phosphonic acid group. Ionic trihalopalladium salt complexes upon heating in methanol are decomposed to the molecular dihalopalladium complexes. The bromo complex along the dibromo adduct gave also the quinolinium salt of the hexabromodipalladate anionic complex without direct Pd-organophosphorus ligand bonding.

EXPERIMENTAL

Materials

Monoethyl 2-quinolylmethylphosphonate (2-mqmp) and sodium monoethyl 2-quinolylmethylphosphonate, prepared as previously described [14], were purified by recrystallization from absolute ethanol prior to use. Dichloro-bis(acetonitrile)-palladium(II) and dibromo-bis(benzonitrile)palladium(II) complexes were prepared according to literature methods [15]. All other reagents and solvents were analytical grade products and were used without purification.

Preparation of complexes

$Pd(2\text{-mqmp})_2Cl_2$ (**1**). For the preparation of this complex few general procedures could be used, either reaction of 2-mqmp with $K_2[PdCl_4]$ in aqueous solution, or with $Na_2[PdCl_4]$ in methanolic solution, reaction of 2-mqmp with dichloro-bis(acetonitrile) palladium(II) complex in dichloromethane, or it could be obtained from the ionic quinolinium trichloropalladium complex **3**.

(a) Addition of a concentrated aqueous solution of $K_2[PdCl_4]$ (0.135 g, 0.41 mmol) to a stirred solution of 2-mqmp (0.205 g, 0.82 mmol) in water (5 ml) gave a solution with pH ~ 3.5. The reaction mixture was continuously stirred for 24 h at room temperature. The yellow precipitate formed was filtered off, washed with cold water and methanol, and dried *in vacuo* over P_2O_5. Yield: 0.180 g (65%).

(b) A mixture of 2-mqmp (0.200 g, 0.80 mmol) and $Na_2[PdCl_4]$ (0.117 g, 0.40 mmol) in methanol (10 ml) was stirred for 12 h at r.t. The precipitate which formed was separated and dried as described. Yield 0.101 g (78%). Alternatively, refluxing the reaction mixture under a stream of N_2, complex **1** precipitated with the same yield after only 3 h of vigorous stirring.

(c) $Pd(CH_3CN)_2Cl_2$ (0.120 g, 0.45 mmol) was dissolved in hot dichloromethane (10 ml), filtered to remove any impurities, and added to a stirred solution of 2-mqmp (0.222 g, 0.88 mmol) in dichloromethane (5 ml). After heating the reaction mixture under reflux for 4 h with continuous stirring, the precipitate formed was separated by filtration of the hot suspension. Yield: 0.201 g (67%).

(d) Heating the trichloropalladium complex **3** in methanol at reflux temperature under inert atmosphere gave rise to the precipitation of **1** in an almost quantitative yield.

$Pd(2\text{-mqmp})_2Br_2$ (**2**). Efforts to prepare pure complex **2** according to the same synthetic procedures as that used for preparation of **1**, by reaction of 2-mqmp with $K_2[PdBr_4]$ either in aqueous or methanolic solution, were unsuccessful. A mixture of complexes **2** and **5** were obtained. However, two other methods could be used, the reaction of 2-mqmp with dibromo-bis(benzonitrile)palladium(II) complex and decomposition of the ionic quinolinium tribromopalladium complex **4** in the methanolic solution.

(a) A suspension of $Pd(PhCN)_2Br_2$ (0.150 g, 0.32 mmol) in hot dichloromethane (10 ml) was added to a stirred solution of 2-mqmp (0.150 g, 0.60 mmol) in the same solvent (5 ml). The reaction mixture was refluxed with vigorous stirring for 4 h. The orange precipitate formed was immediately separated by filtration, washed with cold dichloromethane and ether, and dried *in vacuo* overnight at r.t. Yield: 0.090 g (39%).

(b) By refluxing in methanol for 12 h under an inert atmosphere complex **4** was almost completely converted into complex **2**.

[2-mqmp H][Pd(2-mqmp)Cl_3] (**3**). To a concentrated solution of 2-mqmp (0.252 g, 1.0 mmol) in water under stirring was added dropwise a mixture of $K_2[PdCl_4]$ (0.165 g, 0.51 mmol) and 1 : 1 HCl (0.6 cm^3)

in water (3 ml). An addition constant stirring for 12 h at +4°C yielded a hazel precipitate (0.180 g, 50%) which was washed with the minimum ice-cold water and methanol, and dried *in vacuo* at r.t. This complex could be prepared also by reaction of 2-mqmp with a mixture of $PdCl_2$ and HCl under the similar reaction conditions.

[2-mqmp H][Pd(2-mqmp)Br_3] (**4**). This complex could be prepared by reaction of 2-mqmp with $K_2[PdBr_4]$ in water (pH ~3.5) or by reaction of the same reactants in the HBr acidic medium (pH <3).

(a) A concentrated aqueous solution of $K_2[PdBr_4]$ (0.210 g, 0.42 mmol) was added dropwise to a stirred solution of 2-mqmp (0.200 g, 0.80 mmol) in water (5 ml). The reaction mixture was continuously stirred for 6 h at r.t. Complex **4** obtained as a brown precipitate was separated by filtration, washed with ice-cold water and methanol, and dried in desicator over P_2O_5. Yield 0.140 g (42%). After long standing from the mother aqueous solution complex **2** was gradually formed as an ochre precipitate. Yield: 0.090 g (29%).

(b) A mixture of $K_2[PdBr_4]$ (0.267 g, 0.53 mmol) and concentrated HBr (0.5) in water (5 ml) was slowly added to a stirred solution of 2-mqmp (0.252 g, 1.0 mmol). After an additional stirring of 6 h at +4°C only complex **4** precipitated. Yield: 0.711 g (74%).

[2-mqmp H]$_2$[Pd_2Br_6] (**5**). The quinolinium tribromopalladium complex **4** was refluxed for 15 min in methanol under a stream of nitrogen. The hot solution was filtered to remove any impurities and the brown crystal precipitate obtained gradually on cooling was isolated, washed with cold methanol and dried overnight *in vacuo* at r.t. The longer heating afforded a mixture of the complexes **2** and **5**, which were separated under the microscope.

Pd(2-mqmp-H)$_2 \cdot 2H_2O$ (**6**). Two methods were applied for preparation of this complex.

(a) A concentrated aqueous solution of $K_2[PdCl_4]$ (0.125 g, 0.38 mmol) was added dropwise to a stirred solution of sodium salt of 2-mqmp (0.209 g, 0.77 mmol) in water (5 ml). The reaction mixture was continuously stirred for 48 h at r.t. The yellow precipitate formed was filtered off, washed with minimum cold water and absolute ethanol, and dried *in vacuo* over P_2O_5. Yield: 0.150 g (61%).

(b) A concentrated aqueous solution of $K_2[PdCl_4]$ (0.147 g, 0.45 mmol) was slowly added to a stirred solution of 2-mqmp (0.210 g, 0.84 mmol) in water (5 ml). The pH was adjusted to pH ~6 with dilute sodium hydroxide. An additional stirring of 48 h yielded a precipitate which was separated, washed and dried as described. Yield: 0.184 g (68%).

Physical measurements and analyses

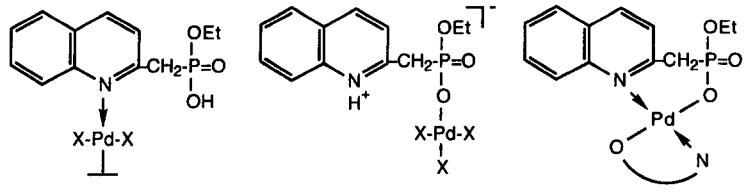
Melting points were determined on a hot stage microscope and are uncorrected. Infrared spectra were recorded on a Perkin Elmer 580 B spectrophotometer using KBr pellets (4000–250 cm^{-1}) and Nujol mulls in polyethylene (400–200 cm^{-1}). Mass spectrometric measurements were performed on a double-focusing reverse-geometry VG ZAB 2F instrument operating under FAB conditions using the 8 keV Xe atoms. Glycerol or 3-nitrobenzyl alcohol were employed as the matrix for recording the positive-ion mass spectra. Negative-ion spectra were obtained with the 3-nitrobenzyl alcohol liquid matrix. Metastable transitions were detected by mass-analysed ion kinetic energy (MIKE) spectrometry [16]. Expected natural abundance isotope clusters patterns for various ion clusters were calculated with the Isotopic Distribution Program (IDS) contained in the FTMS 7.01 application program of the NICOS operating system using polynomial expansion based on natural abundances of the isotopes. Conductance measurements were carried out at room temperature using a CD 7A Tacussel conductance bridge for 10^{-3} mol l^{-1} solutions in methanol and dimethylformamide. Magnetic susceptibilities in the solid state were measured at r.t. by the standard Gouy method using a Cahn-Ventron RM-2 balance and $CuSO_4 \cdot 5H_2O$ as the susceptibility standard. Elemental analyses were performed by the standard analytical methods in the Ruđer Bošković Institute.

RESULTS AND DISCUSSION

Synthesis and properties

Investigations of the complex-forming behaviour of monoethyl 2-quinolylmethylphosphonate towards palladium(II) ion have shown that this ligand under different reaction conditions can act in a monodentate manner either through the quinoline nitrogen or the phosphonic acid oxygen, forming *trans*-square dihalide adducts (**1** and **2**) in the first case, and the ion-pair salt complexes with the protonated quinolylmethylphosphonate ligand as cation and the quinoliniummethylphosphonatetrihalopalladium(II) complex as anion (**3** and **4**) in the second one. The bonding mode of 2-mqmp also include the bidentate coordination through both the quinoline nitrogen and the deprotonated phosphonic acid group giving chelate complex Pd(L—H)$_2$ (**6**). It may be presumed that 2-mqmp in aqueous medium over a wide pH range exhibits either the molecular, zwitterion or the anionic form and therefore according to the acidity of the reaction solution three types of complexes have been obtained (Fig. 1).

The molecular dichloride complex **1** could be obtained either by reaction of 2-mqmp with K_2PdCl_4 in water or with Na_2PdCl_4 in methanol. Under the same reaction conditions 2-mqmp by reacting with K_2PdBr_4 gave a mixture of the corresponding bromo complex **2** and the ion-pair quinoliniumtribromopalladium salt complex **4**. In addition, dihalide adducts **1** and **2** could be obtained by reaction of



trans-Pd(2-mqmp)$_2$X$_2$ X=Cl (**1**); X=Br (**2**)

[2-mqmp H$^+$][Pd(2-mqmp)X$_3^-$] X=Cl (**3**); X=Br (**4**)

Pd(2-mqmp–H)$_2$ (**6**)

Fig. 1. Proposed chemical structures of palladium complexes with monoethyl 2-quinolylmethylphosphonate (2-mqmp).

2-mqmp with dichloro-bis(acetonitrile)palladium(II) and dibromo-bis(benzonitrile)palladium(II) complex, respectively, under refluxing in dichloromethane. In HX acidic medium (pH <3) 2-mqmp reacts in a zwitterion form with PdX_4^{2-} (X = Cl, Br) forming anionic complexes $PdLX_3^-$ with palladium ion bonded at the phosphonic acid moiety, while the quinoline nitrogen is remained protonated. The isolated quinolinium salt complexes $[LH^+][PdLX_3^-]$ are stable in the solid phase but unstable in solution. By heating in methanol the chloro complex **3** was converted into the dichloropalladium adduct **1**, while the corresponding bromo complex **4** gave a mixture of the dibromo adduct **2** and the quinolinium hexabromodipalladium salt complex **5** with two cationic quinolinium moieties and dimeric bromobridged dianionic complex $Pd_2Br_6^{2-}$. In neutral and basic media the phosphonate acid group is deprotonated and 2-mqmp acts as chelate ligand giving very stable complex **6** with two six-membered {N,O} chelate rings.

Physical properties, analytical and conductance data of the novel palladium complexes are reported in Table 1, while the most important spectral data (IR and FAB-mas) are summarized in Tables 2–4. The prepared complexes are microcrystalline, coloured yellow to red, and are stable under normal laboratory conditions. Their diamagnetic behaviour suggests the square-planar stereochemistry around the palladium(II) ion. The molar conductance measurements are consistent with the proposed structure of the complexes and their stoichiometry. The molar conductance of complexes **1** and **2** ($\Lambda_M = \sim 20$ S cm^2 mol^{-1} in dmf) corresponds to those of non-electrolyte compounds and is comparable with that obtained for the free monoester ligand, which confirms that these complexes are true molecular addition compounds. The ionic complexes **3** and **4** exhibit conductivities as expected for 1 : 1 electrolytes ($\Lambda_M = \sim 45$ in dmf), while complex **5** behaves as a 2 : 1 electrolyte in dimethylformamide and methanol solution ($\Lambda_M = 89.2$ and 189.2, respectively). The very low conductance value obtained for complex **6** ($\Lambda_M = 0.5$ in dmf) confirms the presence of deprotonated phosphonic acid groups in this chelate compound. In general, complexes are only slightly soluble or insoluble in all common solvents, and slightly soluble or soluble in dimethylformamide and dimethylsulfoxide. In general, palladium bromide complexes are more soluble than the corresponding chloride analogues, as are ionic complexes with respect to the molecular complexes. Because of the insolubility of the prepared complexes in suitable solvents or their instability, we could not grow crystals for the X-ray crystal analysis. The structures of the complexes were deduced mainly from their infrared and mass spectroscopic studies.

Infrared spectra

The IR frequencies associated with the main and characteristic functional groups of the free 2-mqmp and its palladium(II) complexes are summarized in Table 2. As a general remark we must emphasize that some vibrational modes are coupled giving rise to a great complexity of the spectra as was shown in Fig. 2. Infrared spectrum of the free 2-mqmp clearly indicates zwitterion structure of this organophosphorus ligand in the solid phase, similarly as was determined for a large number of various aminophosphonic acids and their monoesters both by infrared and X-ray crystallographic studies [17–20]. The absorption attributed to the protonated quinoline nitrogen appears as a strong band at 1652 cm^{-1} and two very broad bands of medium intensity around 2450 and 2000 cm^{-1} [10], while the ionized PO_2^- group gives strong absorption bands between 1245–1200 cm^{-1} characteristic of the antisymmetric stretching and between 1070–1025 cm^{-1} of the symmetric stretching vibration of this group [21]. In the latter frequency range the ν[P—O—(Et)] absorption is superimposed upon that of the symmetric PO_2^- vibration [22]. The position and complexity of the $\nu(NH^+)$ and $\nu(PO_2^-)$ bands indicate a strong hydrogen bonding in this organophosphorus compound. In going from the free ligand to the complexes the significant differences may be noticed in the bands arising from various modes of donor groups which are involved in bonding to palladium.

In dihalopalladium complexes **1** and **2** the ligand molecule is coordinated in a molecular form through the quinoline nitrogen what was supported by missing of the $\nu(NH^+)$ absorption as well as by changes

noticed in the 1600–1500 cm^{-1} region where occur bands arising from the stretching modes of the C=C and C=N vibrations of the quinoline ring. These bands show a small higher frequency shift and the lowest band that appeared at 1514 cm^{-1} also marked an intensity increase with respect to the corresponding absorptions in the free 2-mqmp. Furthermore, these complexes show bands attributed to the (P)—O—H and P—O—(H) absorptions. There is no evidence of band at about 3500 cm^{-1} normally ascribed to the OH stretching because of the very strong hydrogen bonding between the P—O—H and the P=O group. There are instead three typical broad shallow bands in the 2800–1600 cm^{-1} region that are appeared to be characteristic of the P—OH group whole rather than of the OH group alone. The highest band at 2620 cm^{-1} could be assigned to an OH vibration perturbed by strong intermolecular hydrogen bonding, the second one at 2320 cm^{-1} is a combination band of the P—O—(H) stretching and O—H deformation vibrations, and the lowest band at 1660 cm^{-1} is also a combination band involving the P=O vibration. The similar bands were found for a number of various acidic phosphorus esters [21,23]. The P—O—(H) stretching vibration is superimposed on the P—O—(C) stretching vibration giving broad and complex bands around 1000 cm^{-1}. The ligand bands attributed to the ν[C—O—(P)] and ν[P—C] vibrations between 1160–1140 cm^{-1} and at 774 cm^{-1}, respectively, remain almost at the same position as in the free ligand.

The ionic complexes **3**, **4** and **5** similarly as the uncoordinated ligand show three characteristic bands for the protonated quinoline $\nu(NH^+)$ vibration. Because of the weaker hydrogen bonding in complexes than in the free ligand, these bands are displayed in spectra of complexes at higher frequencies. The presence of both the bonded and the non-bonded phosphonate acid group in complexes **3** and **4** gives rise to considerably complicated spectra in the region of

1250–950 cm^{-1}, so the proposed assignments must be regarded as approximate description of the vibrations.

The spectrum of complex **6** is much simpler with respect to spectra of the other complexes. There is no evidence of the NH^+ and P—O—H bands what is consistent with the assumption that 2-mqmp in this complex is deprotonated and that acts as chelate ligand in the anionic form. This is confirmed by the characteristic changes in the stretching vibrations of the quinoline-ring caused by coordination of the quinoline nitrogen as well as by the presence of the $\nu(PO_2^-)$ absorption as two strong bands at 1230 and 1218 cm^{-1} for the asymmetric and a very strong band at 998 cm^{-1} for the symmetric mode of this vibration. The bands attributed to the P—O—C and P—C groups are slightly shifted to lower frequencies due to metal bonding through the deprotonated phosphonic acid group. The presence of the lattice water in this complex is indicated by the medium and very broad ν(OH) absorption around 3420 cm^{-1}.

The far-IR spectra of complexes give insight into the metal-ligand vibrations which are very useful for determining the modes of ligand coordination. Dihalide complexes PdL_2X_2 show one band for the Pd—X stretching in the expected range for terminal halides in a *trans*-square planar D_{2h} stereochemistry [24], and one band for the Pd—N stretching at about 270 cm^{-1} characteristic for the coordinated quinoline ring [10,25]. In the case of the ionic quinolinium trihalopalladium complexes the position and multiplicity of the palladium-halide stretching bands are in agreement with those obtained for complexes having the form $[Pd(Pt)LX_3^-]$, X = Cl, Br [26,27]. The C_{2v} symmetry is a reasonable approximation for this type complexes. The absorption at 409 cm^{-1} in complex **3** and that at 376 cm^{-1} in complex **4** may be attributed to ν(Pd—O) vibration. This band was found to increase in frequency with the decrease in the ionic radii of the halogen ion. The metal-oxygen bond is stronger when palladium(II) is bonded to chloride since it is more electronegative than bromide and the amount of positive charge on palladium(II) ion is greater [28]. The lower value obtained for the bromide complex also agrees with the *trans*-influence [29]. Only one ν(Pd—Br) band is found in the examined range for the hexabromodipalladium complex **5**, as the other bands for this complex containing both the terminal and bridged bromide ligands are expected to be below 200 cm^{-1} [30]. The {N,O} chelation in complex **6** of two ligand molecules in a *trans*-orientation is confirmed by the presence of one ν(Pd—O) and one ν(Pd—N) band.

Mass spectra

The positive/negative fast atom bombardment mass spectrometric investigations of 2-quinolylmethylphosphonate (2-mqmp) and its palladium(II) complexes give valuable structural information of these compounds. Their fragmentation pathways including possible structures of fragment ions have been proposed on the basis of the accurate mass measurements, metastable ion studies and some high-resolution results. The fragment ions containing palladium and halide atoms are identified by the presence of the characteristic clusters of isotopic peaks corresponding to the relative abundances of the palladium and halide isotopes. The theoretical isotopic mass distributions of Pd and Pd_nX_m (X=Cl, Br; $n = 1, 2$; $m = 1$–6) clusters were also calculated to justify the ion assignments. The major structurally informative fragment ions observed in the positive-ion mode of complexes **1–6** are summarized in Table 3, while those obtained in the negative-ion mode of the ionic complexes **3–5** are given in Table 4. The *m/z* values of the mass ions are referred to ^{106}Pd, ^{35}Cl and ^{79}Br isotope-containing species. m-Nitrobenzyl alcohol (NBA) or glycerol (G) were used as matrix for recording the positive- and NBA for the negative-ion mass spectra.

The results related to decomposition behaviour of the free organophosphorus ligand provides a basis for interpreting its palladium neutral and ionic complexes. The predominant pathway for the ligand ion fragmentation is the dissociation or complete loss of the phosphonate ester group as is shown in Scheme 1. The dissociation mechanism is dominated by six-membered McLafferty-type rearrangement of the protonated molecular ion [31], which is the base peak at *m/z* 252, resulting in the protonated quinolylmethylphosphonic acid $[QCH_2P(OH)_3]^+$ at *m/z* 224.

The further loss of a water molecule yields the $[QCH_2PO(OH)]^+$ ion at *m/z* 206. The MIKE analysis of the protonated parent ligand shows that the initial

dissociation routes involve also a loss of a water molecule as well as the ethanol loss, a process often observed in mass spectrometry of the ethyl esters [32,33]. Further fragmentations include direct cleavage of the C—P and Q—C bonds giving ions at *m/z* 143 and *m/z* 130, respectively. In addition, FAB-induced dimerization of the organophosphorus ligand as well as of its quinolylmethyl fragment gives rise to ions at *m/z* 503 and *m/z* 284, respectively. In the high-mass region there are also few characteristic peaks obtained by interaction with the glycerole matrix [34]. The most abundant addition products of glycerol to ligand molecule or its fragments, ranged about 10%, are detected at *m/z* 292 $(PO_2(OEt)+2G)^+$, *m/z* 314 $(QH+2G)^+$ and *m/z* 344 $(MH+G)^+$.

In the positive-ion FAB mass study of the palladium complexes it has been found that the protonated ligand ion at *m/z* 252 represents the major fragment ion and that the other most intense fragment ions correspond to the fragments of the free non-coordinated ligand molecule. The ions based on organophosphorus or halide loss from the parent complex molecule as well as ligand exchange or addition of the matrix molecules could also be detected, which is in agreement with the FAB mass results obtained for various coordination compounds of transition metals [35–38]. The first point to be noted is that the relative abundance of the protonated molecular ion in the spectra of the halide complexes is either very small (<1% in complex **1**) or absent (in complexes **2**–**5**) and the highest mass ions in principle originate from the halide loss from the parent molecular ion. Only complex **6** exhibits the moderate intense protonated molecular ion indicating the great stability of this complex with ligand bonded in a bidentate manner forming six-membered chelate ring.

Decomposition of palladium dihalide complexes **1** and **2** goes under two fragmentation routes: those in which the parent molecular ion sequentially loses hydrogen halides and those corresponding to loss of the phosphonate ester group or its fragments. The most important fragmentation pathway is the loss of two HX molecules, which may be assumed to give rise to ion at *m/z* 607 corresponding to the protonated chelate complex **6** $[Pd(L—H)_2+H]^+$ (Scheme 2). This was supported by the presence of the identical fragmentation patterns to those obtained for complex **6** in the metastable ion studies (Fig. 3). The most important fragmentation reactions for this complex are outlined in Scheme 3. The initial decompositions are the same to those described for the free ligand related to losses of H_2O, C_2H_4, EtOH and PO(OEt)OH, respectively. The most interesting fragmentation pathways are the loss of the one or both phosphonate ester group giving mono- and dimetallated complexes at *m/z* 498 and *m/z* 390, respectively. Further fragmentation is considered to involve the loss of the whole quinolylmethylphosphonate ligand molecule accompanied by its fragmentation. The most abundant palladium containing fragment ions are those at *m/z* 357 and *m/z* 248. The former contains one bidentate N,O-bonded organophosphorus ligand, while in the latter the quinolylmethyl fragment undergoes palladation at the quinoline nitrogen and the quinolylmethyl carbon atom. The high stability of such metallated systems is in agreement with the general assumption of high stability of the cyclopalladated complexes with the nitrogen donor ligands [39,40]. Glycerine adducts are the same as in the spectrum of free ligand at *m/z* 266, 292, 314 and 344.

In the positive-ion mass spectra of all ionic complexes **3**–**5** it could be observed that the protonated ligand molecule as the intact cation is the major fragment ion and that the diagnostic fragment ions of the palladium halide complex anions are very poor. Only complex **3** contains structurally relevant fragment ions that allow also the anion characterization. Structure-specific fragment ions are formed by the successive losses of three chloride ions from the qui-

noliniummethylphosphonatetripalladium complex, giving the small abundant fragment ions at m/z 680, m/z 645 and m/z 610, respectively, as is shown in Fig. 4. Increasing dehalogenation is evident specially in the case of bromide complexes which did not produce any palladium halide fragment ion. Predominant peaks corresponding to ions containing palladium are those with metal bonded to one or two ligand molecules or their fragments, identically as in the non-ionic complexes. It may be presumed that the very low stability of the palladium halide containing fragment ions in positive-ion mass spectroscopy in addition to high ligand abundance in the ionic source contribute to formation of these palladium adduct ions. Such reaction might occur in a matrix solution by the FAB-induced condensed phase reaction.

Mass spectra of halide complexes **1**–**5** were recorded by using matrix 3-nitrobenzyl alcohol (NBA) containing sodium chloride, which leads to more complex spectra because of incorporation of the Na^+ into some fragment ions. It is known that cations present with sample undergoing FAB perturb the distribution of desorbed molecular adduct ions [41]. Thus almost all halide containing fragments as well as ligand mono-

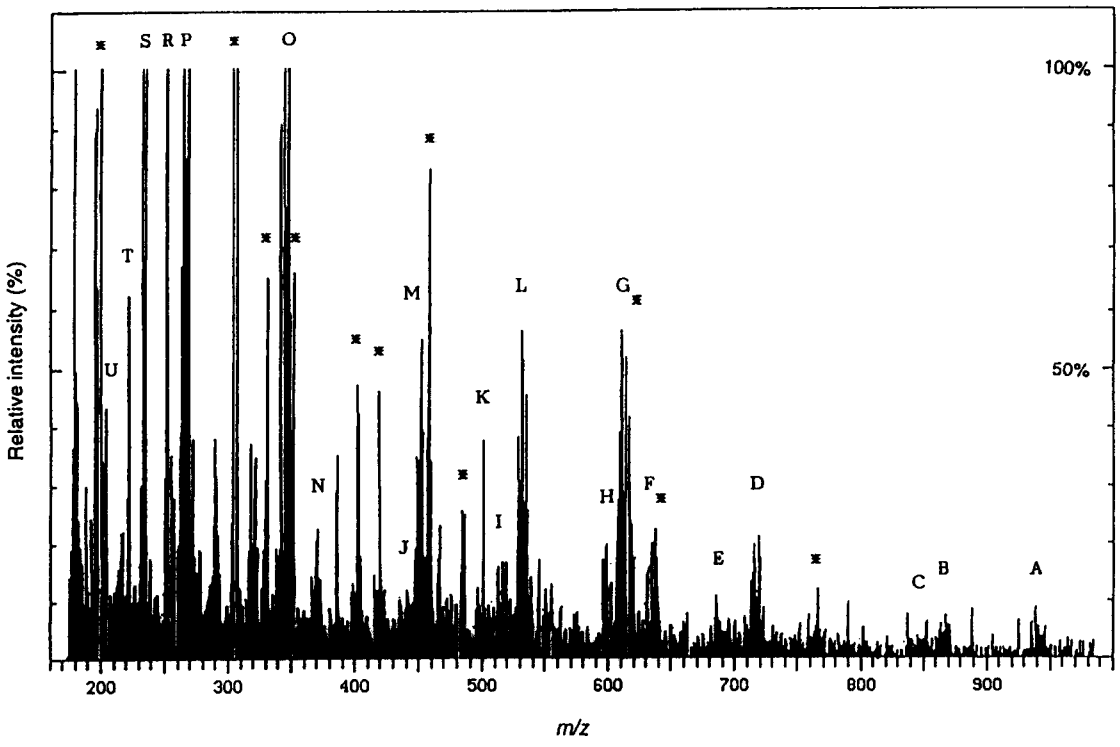

Fig. 5. Negative-ion FAB mass spectrum of complex **5** with NBA as matrix. Matrix ions are indicated by an asterix.

mer and ligand dimer molecules form sodium adduct ions as was shown in Table 3. The potential sites for binding of sodium ion are halides and phosphonate oxygen atoms. Furthermore, besides numerous matrix ions and their sodium adducts, in each spectrum there are also present adduct ions obtained by reaction with NBA matrix or its fragments (e.g. NO_2, N, O). Among them the most abundant are those at *m/z* 404 $(LH+NBA)^+$ and *m/z* 414 $(2Q+NBA+H)^+$.

In order to get more structural information of the ionic complexes **3**–**5**, especially of their anionic part, these compounds have been investigated also by spectrometric measurements carried out under negative-ion FAB conditions, Generally, in negative-ion mass spectrometry the palladium halide fragment ions are more stable and abundant than in the positive-ion mode [42]. The major fragment ions are summarized in Table 4. The initial fragmentation pathway of trihalide palladium complexes **3** and **4** is similar to that described for chloride complex **3** in the positive-ion mass study, consisting of sequential loss of three halide radicals from the deprotonated molecular ion. It should be pointed out that the most important fragment ions are those related to the intact complex anion $[PdLX_3]^-$ at *m/z* 462 and *m/z* 594, respectively, and those obtained by subtracting one and two halide radicals from these ionic species. In addition, simple palladium trihalide and dihalide adduct ions are present also in a high abundance. It is further noteworthy that bromide complex **4** shows a more complicated fragmentation pattern than its chloride analogue complex **3**. This is specially related to the presence of dipalladium bromide adduct ions $[Pd_2Br_n]^-$, $n = 2$–6, indicating that this complex is converted partly into the hexabromodipalladium complex **5** in the gas phase under FAB conditions, similarly as does also by heating in solution. The most abundant and extensive fragmentation patterns could be observed in the case of dimeric bromobridged complex **5**, where a spectrum with fragment ion assignation is presented in Fig. 5. All intense metal-containing peaks reveal multiplet structures corresponding to the relative abundances of the palladium and halide isotopes. The fragmentation pattern of the organophosphorus ligand in ionic complexes is similar to that obtained in the positive-ion mode including C_2H_4, H_2O, EtOH and PO(OEt)OH loss from the deprotonated ligand molecular ion. It could be concluded that a combination of the ion-positive/negative FAB mass spectrometry investigation gives a very useful information on either the stability of the product ions or the reactivity of the ionic species.

(Received 21 July 1997; accepted 29 September 1997)

Abstract—The crystal and molecular structure of $[Cu(phen)_2(HL)] \cdot (phen)_{0.5} \cdot 7H_2O$ (H_3L = 1,3,5-triazine-2,4,6(1H,3H,5H)-trione) has been determined by X-ray diffraction methods. The structure is built up of neutral $[Cu(phen)_2(HL)]$ entities (which are associated to form dinuclear units through hydrogen bonds involving the cyanurate ions), uncoordinated phenanthroline and crystallisation water molecules. The copper atom is involved in a CuN_5 chromophore, with an stereochemistry near to a compressed trigonal bipyramid (TBP) but with a significant degree of distortion towards the square pyramidal (SP) topology. The EPR spectrum is indicative of a mixed $d_{z^2}/d_{x^2-y^2}$ ground state for the copper(II) ions in agreement with the structural data. No exchange coupling has been detected down to 4.2 K by means of magnetic susceptibility measurements. This feature is discussed on the basis of the bridging network. © 1998 Elsevier Science Ltd. Keywords: crystal stucture; copper complexes; cyanurate; hydrogen bonds; epr spectroscopy.

A continuing effort has been focused in the last years towards the characterisation of binuclear and polynuclear transition metal complexes comprising two or more metal centres bridged by extended polyatomic ligands [1,2]. In such a context, the role played by nitrogen heterocyclic systems, both non-chelating (i.e. azines and azoles) and chelating as bridging ligands, has been recently investigated. In contrast, what occurs with azoles and the coordinating behaviour of higher azines (triazines and tetraazines) is relatively unexplored [3]. The cyanuric acid (1,3,5-triazine-2,4,6(1H,3H,5H)-trione, hereinafter H_3L), a related system, may be considered as a potential candidate to construct extended arrays involving metal centres. Therefore, the cyanurate(2-) anion could behave as a bridging ligand and simultaneously take part in stabilising interactions, such as hydrogen bonds, due to its functionality as both hydrogen-donor and acceptor [4]. By taking advantage of these features, the cyanurate(2-) ions could be used to synthesise metal complexes linked by hydrogen bonds. These types of system have been explored in the development of synthetic strategies for the construction of molecular precursor compounds [5] and ordered supramolecular aggregates [6].

In the last years, the preparation of several cyanurato complexes have been described [7–9] but only a few have been structurally characterised [4,10–13]. Therefore, the coordination behaviour of the cyanuarate anion is not sufficiently explored. In this paper we report the synthesis, crystal structure and electronic properties of a new phenanthroline-containing copper(II) cyanurate complex. As far we are aware, it is the first compound structurally characterised containing bisdeprotonated cyanuric acid as ligand.

EXPERIMENTAL

Preparation of the complex

A solution of phenanthroline (2.2 mmol) in water–ethanol (25 ml) was added to an aqueous solution of copper(II) nitrate (1 mmol in 25 ml), then, an aqueous solution of Na_2HL (1 mmol in 20 ml) was added. The resultant blue-green solution (pH = 10.8) was left at room temperature and after two weeks prismatic blue crystals appeared, which were separated by filtration, washed and dried. Found C, 51.9; Cu 8,2; N 14.4; Calc. for $C_{33}H_{35}CuN_8O_{10}$: C, 51.6; Cu 8.3; N 14.6%.

Physical measurements

The IR spectrum (KBr pellets) was recorded on a Pye Unicam SP2000 spectrophotometer. Diffuse reflectance spectrum was obtained using a Perkin–Elmer Lambda 9 UV/VIS/IR spectrophotometer. Polycrystalline powder EPR spectra were recorded at room temperature on a Bruker ESP-300 spectrometer working at Q-band. Magnetic susceptibility measurements were carried out on polycrystalline samples with a pendulum-type apparatus equipped with a helium cryostat. The experimental susceptibilities were corrected both for the diamagnetic contributions using the Pascal constants [14] and for the temperature independent paramagnetism of the Cu(II) ion estimated to be 6×10^{-5} cm^3 mol^{-1} per copper(II) ion.

Crystal structure

A blue prismatic crystal of the title compound with approximate dimensions ($0.2 \times 0.3 \times 0.4$ mm^3) was mounted on a Enraf–Nonius CAD-4 diffractometer. Intensity data and the 25 reflections for the unit cell determination (least squares fit with $8° < \theta < 14°$) were measured at room temperature using Mo–K_α radiation with a graphite monochromator. The technique used was $\omega/2\theta$ scan, variable speed, width $(0.7 + 0.35 \tan\theta)°$ in ω, and θ limits $1° < \theta < 25°$ in the range $0 < h < 12$, $0 < k < 38$, $-12 < l < 12$. No intensity decay was detected. From the 6009 independent reflections 3319 with $I > 2\sigma(I)$ were considered to have been observed. Absorption correction was not applied.

The structure solution by direct methods with the program SIR92 [15] revealed the presence, in each asymmetric unit, of one complex unit, several water molecules and one half of non-copper-coordinated phenanthroline molecule, disordered across an inversion centre as shown in Scheme 1. C(34) and C(35) atoms were refined with occupancy factors of 0.5 and the atom pairs C(33)/N(33) and C(31)/N(31) included with 0.5 individual occupancy and linked parameters.

On the other hand, two water molecules—O(10) and O(11)— were also refined with 0.5 occupancy factors. The hydrogen atoms of the phenanthrolines were geometrically calculated and those of O(4) to O(9) water molecules and that of N(7)—from the cyanurate anion—were found in the Fourier map. We were not able to find the hydrogen atoms of the O(10) and O(11) water molecules. Once placed, all H-atoms were included in the refinement as isotropic fixed contributors with a common thermal parameter (those of C(34) and C(35) with a 0.5 occupancy factor). This chemical model—all non-hydrogen atoms with anisotropic thermal motion—was refined by least squares on F using the XRAY76 System [16] (487 parameters). In the final stages an empirical weighting scheme was chosen in order to give no trends in $\langle w\Delta^2 F \rangle$ vs $\langle F_o \rangle$

and vs $\langle \sin\theta/\lambda \rangle$ using the program PESOS [17]. Geometric calculations were made with PARST [18].

All calculations were done with a VAX6410 computer and atomic scattering factors, and anomalous dispersion corrections were taken from Ref. 19. Other relevant parameters of the crystal structure analysis are listed in Table 1.

RESULTS AND DISCUSSION

Crystal structure description

The crystal structure of the title compound is built up of neutral $[Cu(phen)_2(HL)]$ entities—which are associated to form dinuclear units through hydrogen bonds involving the cyanurate ions—uncoordinated phenanthroline molecules and molecules of water of crystallisation. Figure 1 shows a perspective view of the $[Cu(phen)_2(HL)]$ entity with the atomic numbering scheme and Fig. 2 shows a view of the unit cell contents. Selected bond distances and angles are listed in Table 2.

The structure of the molecule involves five-coordinated CuN_5 chromophores, which exhibit compressed trigonal bypiramid (TBP) coordination geometry, similar to those reported for several $[Cu(N—N)_2X]$ entities [20–22]. Such a stereochemistry for five-coordinated copper(II) systems is slightly stabilised if significant steric hindrances are present [23]. Three nitrogen atoms define the equatorial plane: one of each phenanthroline molecule—N(1) and N(3)—and the third, N(5), from the cyanurate anion. The deviation of the copper(II) ion from this plane is of ca 0.03 Å towards the N(2) atom. The angles in the equatorial plane are considerably distorted from the ideal trigonal angle of 120°, with one small angle of 99.4° between the Cu—N(phen) equatorial bonds. On the other hand, despite that the N(2) and N(4) atoms being slightly removed from the ideal axial positions (due to a small bite angle of the rigid bidentate phenanthroline ligands) none of the out-of-plane N_{ax}—Cu—N_{eq} angles can be considered as unusual ($90 \pm 10°$). The Cu—N_{ax} distances are shorter than Cu—N_{eq}(phen) which is usual for this type of system [19,20]. In the equatorial plane the two Cu—N(phen) bond distances are not significantly different (mean value of 2.130(5) Å) and larger (by ca 0.16 Å) than Cu—N(cyanurato) the latter being similar to those reported for other cyanurato-containing copper(II) complexes [10,13]. All these features clearly indicate a significant distortion in the

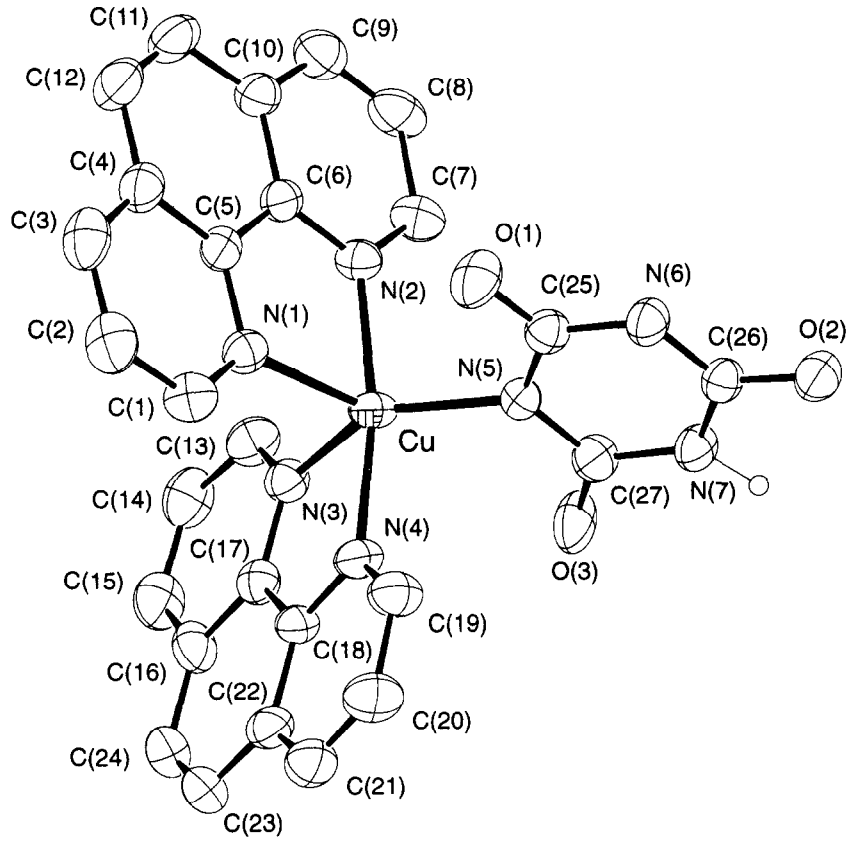

Fig. 1. View of the $[Cu(phen)_2(HL)]$ units, showing the atom labelling. For clarity, the hydrogen atoms of the phenanthroline molecules have been omitted.

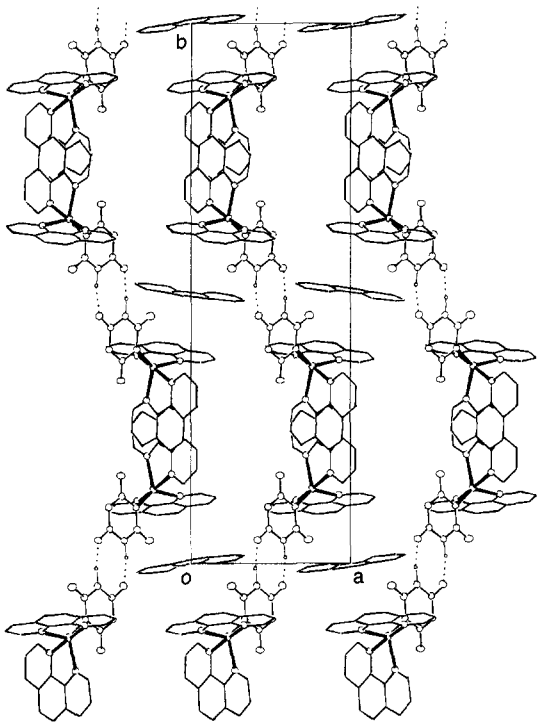

Fig. 2. Crystal packing as projected along *c* axis. Water molecules and hydrogen atoms of phenanthroline molecules have been omitted.

coordination polyhedron; we have quantified this distortion—from an ideal TBP geometry ($\Delta = 0$) towards a square pyramidal one (SP, $\Delta = 1$)—by application of the method of Muetterties and Guggemberger [24] using the analytical formula proposed by Galy [25]. The obtained value of $\Delta = 0.19$ indicates the predominance of the TBP form, but with a significant degree of distortion towards the SP topology.

Both coordinated phenanthroline molecules are essentially planar and are located nearly perpendicular to the equatorial plane (dihedral angles of 89.3 and 92.9°). On the other hand, the whole of bond distances and angles compares well with those reported for related $[Cu(phen)_2X]$ complexes [20,26].

The cyanurate ring is essentially planar and it is located nearly parallel to the equatorial plane (dihedral angle of 13.6°). The whole of angle and bond distances compares well with those reported for other cyanurato-complexes (see Table 3). As usual, the cyanurate ion coordinates through a nitrogen atom (in only a few cases has the presence of coordinated O-cyanurate ions been postulated, based on vibrational spectroscopic data [8b,8d] but no structural confirmation has been provided). The most striking feature is the low value of the δ parameter ($\delta = \Sigma|120-\alpha_i|$, being α_i the C—N—C and N—C—N angles in the C_3N_3 nucleus) compared with those calculated for other cyanurato-complexes as well as the cyanuric free molecule (see Table 3) making evident that in the title compound the ring is not greatly distorted from a regular hexagon. The all six C—N bonds are alike (see Table 2), the mean value indicating an appreciable double bond character. This mean value is similar to those observed in cyanuric acid as well as other cyanurate copper(II) compounds. On the other hand, the three C—O bond distances are also similar to those reported for related compounds and slightly longer than those in free cyanuric acid (see Table 4). With regard to the coordinating behaviour displayed by the cyanurate(2-) groups in this compound, it may be outlined that its potential functionality as a bridging ligand could be blocked by steric hindrance factors as well as by the propensity for aggregation of the cyanurate [4]. In this sense, it must be stressed that the nitrogen atom N(7) acts as protonic donor towards the oxygen atom O(2) of a centrosymmetrically related $[Cu(phen)_2(HL)]$ molecule, thus linking two complex units by means of double N—H···O interactions forming dimeric entities $[Cu(phen)_2(HL)]_2$ (intradimer Cu—Cu distance of ca 12.11 Å) which are aligned parallel to the *b* axis (see Fig. 2).

All water molecules are involved in moderate hydrogen bonds as indicated by the intermolecular O···X distances and the corresponding O—H···X angles (X = O, N) listed in Table 4. Molecules O(4), O(5), O(6) and O(9) connect two cyanurate ions of different dimeric entities forming infinite zig-zag chains along the *c* axis with a Cu—Cu distance of 9.13 Å. Finally, the free phenanthroline molecules are located along the *b* axis (see Fig. 2) stacked between two coordinated ones belonging to adjacent dimeric entities related by an inversion centre.

Vibrational and electronic spectra

The vibrational spectrum of $[Cu(phen)_2(HL)]\cdot(phen)_{0.5}\cdot 7H_2O$ shows several bands in the 4000–2000 cm^{-1} region, varying from 3600 to 2800 cm^{-1} assigned to stretching of the NH groups and water molecules implied in hydrogen bonds. In the 1700–400 cm^{-1} there are several bands from phenanthroline molecules and cyanurate anions. Despite its complexity, in comparing the spectra reported for several cyanurate derivatives [8–10], some absorptions were tentatively assigned. So, the set of bands observed between 1740 and 1600 cm^{-1} are assigned to ν(C=O) and ν(C=N) vibrations, the higher wavenumber corresponding to those of ν(C=O). On the other hand, the doublet observed at ca 420 cm^{-1} is tentatively attributed to the Cu—N stretching vibrations [10].

The electronic reflectance spectrum of the studied compound exhibits a broad absorption band centred at ca 14,500 cm^{-1} with a shoulder at ca 13,000 cm^{-1}. These features are in good agreement with the stereochemistry observed around the copper(II) ions [28]. If the non-equivalence of the bond lengths in the CuN_5 chromophores is neglected, the point group symmetry

of the coordination polyhedron is close to C_{2v}, with the shorter Cu—N bond defining the direction of the two-fold axis. Taking into account these considerations, it may be assumed that the *d–d* band structure arises from the overlap of the

$$^2B_2(d_{xy}) \rightarrow {}^2A_1(d_{z^2}/d_{x^2-y^2}),$$
$$^2A_2(d_{yz}) \rightarrow {}^2A_1(d_{z^2}/d_{x^2-y^2})$$
and
$$^2B_1(d_{xz}) \rightarrow {}^2A_1(d_{z^2}/d_{x^2-y^2})$$

transitions. In addition to the *d–d* band structure, the spectrum displays one more intense band centred at ca 22,500 cm^{-1}, assignable to metal ligand ($e_g \rightarrow \pi^*$) transitions [29].

EPR spectroscopy and magnetic behaviour

The room-temperature X-band EPR powder spectrum of the title compound shows wide features corresponding to orthorhombic symmetry with no possibility of extracting accurate g values. Hyperfine coupling is observed in the low field part of the spectrum with a line separation of 118 G. However, a clear signal corresponding to $\Delta Ms = \pm 2$ (at about 1600 G) is observed with increasing the gain of the spectrometer, indicating some degree of interaction between the different chromophores. In the Q-band spectrum three signals are clearly defined giving g values of 2.017, 2.125 and 2.235 ($g_{av} = 2.125$). Again, hyperfine coupling is well resolved on the largest g value giving $A = 124 \cdot 10^{-4}$ cm^{-1}. These values are very similar to those found in the complexes Cu(terpy)X_2 (X = Br, I, NCS) [30]—which contain pentacoordinate CuN_3X_2 chromophores having a coordination geometry close to C_{2v}—and $[Cu(bipy)_2(NH_3)](BF_4)_2$ (with CuN_5 chromophores intermediate between the ideal square pyramidal, C_{4v}, and trigonal bipyramidal, D_{3h}) [28]. As discussed above, in our compound the local symmetry is nearly C_{2v}. Following the vibrational model proposed by Reinen [23], the ground-state wave function of a five-coordinated copper(II) complex can be expressed as follows:

$$\varphi_g = (1+c^2)^{-1/2}[d_{z^2} + cd_{x^2-y^2}]$$

The mixing coefficient c is zero for the trigonal bipyramid (d_{z^2} ground state) and is $1/\sqrt{3}$ for the square pyramid ($d_{z^2-y^2}$ ground state). The corresponding expressions for the g values are:

$$g_z = g_o + 8[c^2/(1+c^2)]u_z$$
$$g_y = g_o + 2[c^2/(1+c^2)][1-\sqrt{3}/c]^2 u_y$$
$$g_x = g_o + 2[c^2/(1+c^2)][1+\sqrt{3}/c]^2 u_x$$

where u_i is the orbital contribution. Taking u_i as 0.032 ($g_{av} = g_o + 4u_i$), the experimental g values can be sufficiently reproduced with c values of 0.33 ± 0.03, and very close to that of 1/3 expected for an actual C_{2v} geometry, thus implying a ground state for the Cu(II) ions between d_{z^2} (TBP) and $d_{x^2-y^2}$ (SP). Hence, there is a full agreement between the structural and spectroscopic results. Moreover, from the well-resolved hyperfine coupling in the g_z component, we can estimate the mixing coefficient of the copper(II) ground state function in the whole molecular orbital containing the unpaired electron, by application of well known equations relating the MO and EPR parameters [31]. A value of 0.80 results, which is similar to that observed for other Cu—N bonded complexes indicating an important amount of covalency.

The magnetic study of the title compound shows that in the temperature range (4.2–300 K) the $\chi_M T$ product is nearly constant and the whole susceptibility data can be fitted to the Curie–Weiss expression $\chi_M = C/(T-\theta)$ affording $C = 0.429$ cm^3 mol^{-1} ($g = 2.14$) and $\theta = +0.35$ K. The small absolute value of the Weiss correction could suggest a very weak ferromagnetic interaction between the copper(II) ions. Notwithstanding, this interaction if present, could only be detected unambiguously at very low temperatures. Therefore, this result indicates that the copper(II) ions may be viewed as essentially magnetically non-coupled. In all cases, very small values of $|J|$ would be expected due the large exchange distance (both the intradimer and interdimer pathways). According to the limit function proposed by Coffman and Buetter [32] for long-range exchange interactions, $|J|$ values less than 10^{-2}–10^{-3} cm^{-1} would be expected for the title compound.

Acknowledgements—We thank Drs F. Lloret and L. Lezama for their assistance with susceptibility measurements and Q-band EPR experiences, respectively. We also thank Dr M. Martínez-Ripoll and the U.E. de Cristalografía at the Instituto Rocasolano (CSIC, Madrid) for providing access to computing facilities in the crystal structure determination.

New aliphatic and aromatic thiolato-bridged complexes of palladium(II) and platinum(II)

José Ruiz, Consuelo Vicente, Venancio Rodríguez and Gregorio López*

Departamento de Química Inorgánica, Universidad de Murcia, 30071 Murcia, Spain

(Received 4 June 1997; accepted 29 September 1997)

Abstract—The hydroxo binuclear complexes $[NBu_4]_2[\{M(C_6F_5)_2(\mu\text{-}OH)\}_2]$ (M = Pd or Pt) react with thiols in methanol at room temperature to give the binuclear di-μ-thiolato complexes $[NBu_4]_2[\{M(C_6F_5)_2(\mu\text{-}SR)\}_2]$ (M = Pd, R = Et **1**, t-Bu **2**, C_6H_5 **3**, and *p*-MeC_6H_4 **4**; M = Pt, R = Et **5**, t-Bu **6**, C_6H_5 **7** or *p*-MeC_6H_4 **8**). The trinuclear palladium complexes $[NBu_4]_2[(C_6F_5)_2Pd(\mu\text{-}SEt)_2Pd(\mu\text{-}SEt)_2Pd(C_6F_5)_2]$ **9** or $[NBu_4]_2[(C_6F_5)_2Pd(\mu\text{-}1,2\text{-}S_2C_6H_4)Pd(\mu\text{-}1,2\text{-}S_2C_6H_4)Pd(C_6F_5)_2]$ **10** have been obtained by reaction of the binuclear hydroxo palladium complex $[NBu_4]_2[\{Pd(C_6F_5)_2(\mu\text{-}OH)\}_2]$ with an excess of EtSH in refluxing methanol or with an excess of $C_6H_4(SH)_2$-1,2 in methanol at room temperature, respectively. The mixed hydroxo-azolate bridged complexes $[\{M(C_6F_5)_2\}_2(\mu\text{-}OH)(\mu\text{-}L)]^{2-}$ [M = Pd, L = pyrazolate (pz); M = Pt, L = pyrazolate (pz) or 3,5-dimethylpyrazolate (dmpz)] react with thiols (1:1 molar ratio) in methanol to give the corresponding mixed thiolato-azolate bridged palladium or platinum complexes $[\{M(C_6F_5)_2\}_2(\mu\text{-}SR)(\mu\text{-}L)]^{2-}$ (M = Pd, L = dmpz, R = C_6H_5 **11**, *p*-MeC_6H_4 **12**; M = Pt, L = pz, R = C_6H_5 **13**, *p*-MeC_6H_4 **14**, Et **15**, t-Bu **16**; L = dmpz, R = C_6H_5 **17**, R = *p*-MeC_6H_4 **18**, Et **19**]. The complexes have been characterized by partial elemental analyses, conductance measurements and spectroscopic (IR and ^1H and ^{19}F NMR) methods. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: palladium; platinum; thiolate complexes.

There has been recent interest in platinum and palladium μ-thiolato complexes due to their possible use in homogeneous catalysis [1–4]. Thus, for example, the systems of the type $[Pt_2(\mu\text{-}SR)(\mu\text{-}Cl)Cl_2(PR'_3)_2]/SnCl_2\cdot 2H_2O$ have a high catalytic activity in the hydrogenation of styrene [5].

We have reported on the synthesis of $[NBu_4]_2[\{M(C_6F_5)_2(\mu\text{-}OR)\}_2]$ (M = Ni, Pd and Pt; R = H, Me or Ph) and we have used them as precursors in synthetic work, based on the considerable nucleophility of the bridging OR groups [6–10]. Thus the hydroxo complexes react with protic acids HL to give mono- or bi-nuclear complexes [6–13] depending on the chelating or bridging nature of the L^- ligand. We report here the reactions of $[NBu_4]_2[\{M(C_6F_5)_2(\mu\text{-}OH)\}_2]$ (M = Pd or Pt) and $[NBu_4]_2[\{M(C_6F_5)_2\}_2(\mu\text{-}OH)(\mu\text{-}L)]$ (L = pyrazolate-type ligand) with aliphatic and aromatic thiols RSH. The synthesis of the related bi- and tri-nuclear nickel(II) complexes have been reported recently [14].

EXPERIMENTAL

The C, H, N, S analyses were performed with a Carlo Erba model EA 1108 microanalyzer. Decomposition temperatures were determined with a Mettler TG-50 thermobalance at a heating rate of 5°C min^{-1} and the solid samples under nitrogen flow (100 ml min^{-1}). The NMR spectra were recorded on a Bruker AC 200E or Varian Unity 300 spectrometer. Infrared spectra were recorded on a Perkin–Elmer 16F PC FT-IR spectrophotometer using Nujol mulls between polyethylene sheets. Conductance measurements were performed with a Crison 525 conductimeter (solvent acetone; $c \approx 5\times10^{-4}$ mol l^{-1}). Solvents were dried by the usual methods. The precursors $[\{MC_6F_5)_2(\mu\text{-}OH)\}_2]^{2-}$ and $[\{M(C_6F_5)_2\}_2(\mu\text{-}OH)(\mu\text{-}L)]^{2-}$ (M = Pd or Pt; L = pz or dmpz) were prepared by procedures described elsewhere [6,8,9].

Preparation of the complexes

Complexes **1–4**. The appropriate thiol RSH (0.143 mmol) was added to a solution of $[NBu_4]_2$

$[\{Pd(C_6F_5)_2(\mu\text{-}OH)\}_2]$ (0.10 g, 0.071 mmol) in methanol (10 cm^3). The resulting solution was stirred at room temperature for 1 h and then concentrated under reduced pressure. Addition of water caused the precipitation of the title complexes as yellow solids, which were filtered off and air-dried.

Complexes **5–7**. The corresponding thiol RSH (0.127 mmol) was added to a solution of $[NBu_4]_2[\{Pt(C_6F_5)_2(\mu\text{-}OH)\}_2]$ (0.0635 mmol) in methanol (10 cm^3). The solution was boiled under reflux for 7 h and then concentrated under reduced pressure. Addition of water caused the precipitation of the complexes as yellow solids, which were filtered off and air-dried.

Complex **8**. *p*-MeC_6H_4SH (0.127 mmol) was added to a solution of $[NBu_4]_2[\{Pt(C_6F_5)_2(\mu\text{-}OH)\}_2]$ (0.0635 mmol) in benzene (8 cm^3). The solution was boiled under reflux for 7 h and then concentrated under reduced pressure. Addition of hexane caused the precipitation of complex **8** as a yellow solid which was filtered off and air-dried.

Complex **9**. EtSH (0.571 mmol) was added to a solution of $[NBu_4]_2[\{Pd(C_6F_5)_2(\mu\text{-}OH)\}_2]$ (0.10 g, 0.071 mmol) in methanol (12 cm^3). The solution was boiled under reflux for 6 h, whereupon the yellow complex **9** precipitated. It was collected by filtration and air-dried.

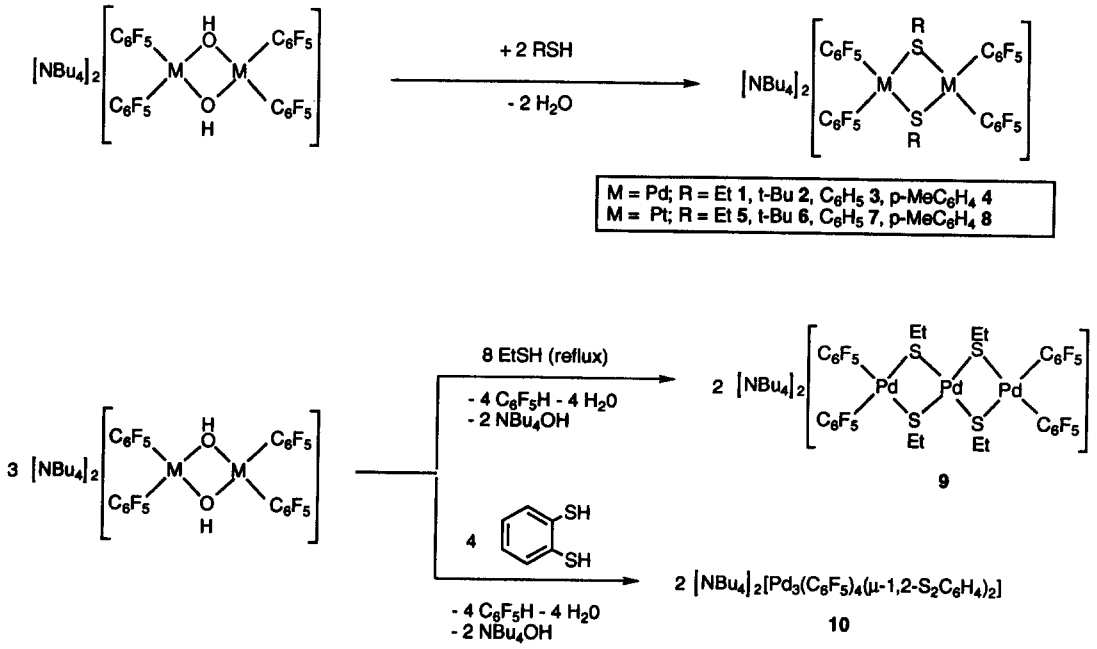
Complex **10**. To a solution of $[NBu_4]_2[\{Pd(C_6F_5)_2(\mu\text{-}OH)\}_2]$ (0.10 g, 0.071 mmol) in methanol (12 cm^3) was added $C_6H_4(SH)_2$-1,2 (0.286 mmol). The resulting deep yellow solution was stirred at room temperature for 1.5 h, whereupon the yellow complex **10** precipitated. The complex was collected by filtration and air-dried.

Complexes **11** *and* **12**. The appropriate thiol RSH (0.067 mmol) was added to a solution of $[NBu_4]_2[\{(C_6F_5)_2Pd\}_2(\mu\text{-}OH)(\mu\text{-dmpz})]$ (0.067 mmol) in methanol (6 cm^3). The resulting solution was stirred at room temperature for 1 h, during which time the white binuclear complexes precipitated spontaneously, and then the solvent was partly evaporated under reduced pressure. The complexes were collected by filtration and air-dried.

Complexes **13–19**. The corresponding thiol RSH (0.060 mmol) was added to a solution of $[NBu_4]_2[\{(C_6F_5)_2Pt\}_2(\mu\text{-}OH)(\mu\text{-L})]$ (L = pz or dmpz) (0.060 mmol) in methanol (8 cm^3). The solution was boiled under reflux for 7 h and then concentrated under reduced pressure until complexes **13, 14, 17** or **18** precipitated as white solids, which were filtered off and air-dried. For complexes **15, 16** and **19**, the resulting solutions were vacuum-evaporated to dryness and the residues treated with isopropanol. The complexes were collected by filtration and air-dried.

RESULTS AND DISCUSSION

The reactions of the hydroxo-complexes $[NBu_4]_2[\{M(C_6F_5)_2(\mu\text{-}OH)\}_2]$ (M = Pd and Pt) with thiols RSH in methanol at room temperature in the 1 : 2 molar ratio yield the new binuclear di-μ-thiolato complexes $[NBu_4]_2[\{M(C_6F_5)_2(\mu\text{-}SR)\}_2]$ **1–8** (Scheme 1). The acidic proton of the thiol is abstracted by the corresponding hydroxo-complex generating the



Scheme 1.

anionic ligand RS^- which is subsequently trapped by the organometallic moiety $M(C_6F_5)_2$ to form complexes **1–8** and the concomitant release of water.

Partial elemental analyses and decomposition temperatures for all the complexes are given in Table 1. In acetone solution, they behave as 2:1 electrolytes [15], in agreement with the proposed formulae. The new complexes show IR absorptions characteristic of the C_6F_5 group (1630 m, 1490 vs, 1050 s, 950 vs and 810–770 cm^{-1}) [16]. The IR absorption at approx. 800 cm^{-1} is a split band which is the so-called X-sensitive mode and is characteristic of the *cis* geometry of the $M(C_6F_5)_2$ fragment [17,18].

The ^1H and ^{19}F NMR spectra (Table 2) are consistent with the proposed formulae. The ^{19}F NMR spectra show the presence of four equivalent freely rotating C_6F_5 rings giving three resonances with relative intensities of 8:4:8 due to the *ortho*-, *para*-, and *meta*-F atoms, respectively. As expected, the *ortho*-F signals of complexes **5–8** are flanked by the satellites due to the coupling to ^{195}Pt.

The reaction of $[\{Pd(C_6F_5)_2(\mu\text{-}OH)\}_2]^{2-}$ with an

[a] Additional peaks of $[NBu_4]^+$ are found at δ ca 3.43 (t, NCH_3), 1.80 (m, NCH_2CH_2), 1.40 (m, CH_2CH_3) and 0.95 (t, CH_3), the relative intensities being 16 : 16 : 16 : 24 respectively.

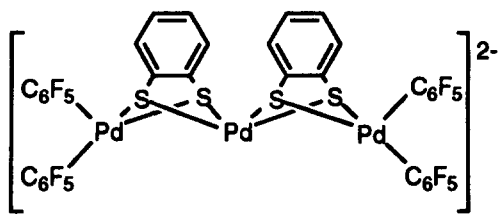
[b] In $CDCl_3$.

[c] Obscured by $[NBu_4]^+$ peaks.

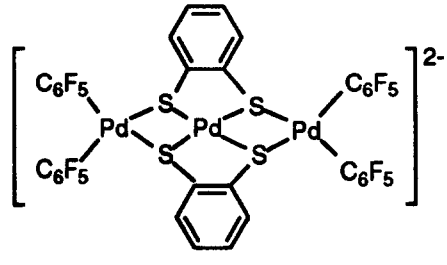
excess of EtSH in refluxing methanol yields the formation of the tetrakis(μ-thiolato) tripalladium complex $[NBu_4]_2[(C_6F_5)_2Pd(\mu\text{-SEt})_2Pd(\mu\text{-SEt})_2Pd(C_6F_5)_2]$ **9** (Scheme 1). The analytical, conductance (Table 1) and ^{1}H NMR (2 $[NBu_4]^+$: 4 EtS^-) data for **9** are consistent with the proposed formula. This reaction implies cleavage of two Pd—C_6F_5 bonds leading to the likely formation of the homoleptic thiolato complex $[Pd(SEt)_4]^{2-}$, which in turn acts as a ligand to two $[Pd(C_6F_5)_2]$ moieties. The ^{1}H NMR spectrum of complex **9** indicates that the SEt groups are equivalent and the SEt resonances are found at lower field than in the spectrum of the binuclear complex **1**, as previously observed in the analogous trinuclear nickel complex $[NBu_4]_2[(C_6F_5)_2Ni(\mu\text{-SEt})_2Ni(\mu\text{-SEt})_2Ni(C_6F_5)_2]$, the structure of which was confirmed by X-ray diffraction [14]. The syntheses of pentafluorobenzenethiolato trinuclear palladium or platinum complexes $[(C_6F_5)_2M(\mu\text{-}SC_6F_5)_2M(\mu\text{-}SC_6F_5)_2M(C_6F_5)_2]^{2-}$, by reaction of $[M(C_6F_5)_2(thf)_2]$ (thf = tetrahydrofuran) with $[M(SC_6F_5)_4]^{2-}$ (M = Pd or Pt) [19], and the tetrakis (μ-thiolato) palladium complex $Pd_3(\mu\text{-SCy})_4Cl_2(PMe_3)_2$, from $[\{PdCl(PMe_3)(\mu\text{-Cl})\}_2]$ [1], have also been recently described.

On the other hand, the reaction of the binuclear hydroxo palladium complex $[NBu_4]_2[\{Pd(C_6F_5)_2(\mu\text{-OH})\}_2]$ with an excess of 1,2-benzenedithiol $C_6H_4(SH)_2$-1,2 in methanol at room temperature affords the trinuclear complex $[NBu_4]_2[Pd_3(C_6F_5)_4(\mu\text{-}1,2\text{-}S_2C_6H_4)_2]$ **10**. The ^{19}F NMR spectrum of complex **10** shows a single resonance for the *p*-fluorine atoms, in agreement with the presence of four equivalent C_6F_5 rings. The presence of two 1 : 1 resonances in the *o*-fluorine region, and two additional 1 : 1 resonances in the *m*-fluorine region, suggests restricted rotation around the Pd—C bonds. The NMR data of complex **10** are consistent with the structures A and B given below.

Examples of 1,2-dithiolate-bridged complexes such as $[Ru_2(CO)_4(\mu\text{-}1,2\text{-}S_2C_6H_4)(PPh_3)_2]$ [20] or $[Rh_2\{\mu\text{-}S(CH_2)_3S\}(cod)_2]$ (cod = cycloocta-1,5-diene) [21] are known in the literature. It is noteworthy that the



A



B

binuclear $[NBu_4]_2[(C_6F_5)_2Pd(\mu\text{-}1,2\text{-}S_2C_6H_4)Pd(C_6F_5)_2]$ was not obtained when the reaction of the binuclear hydroxo palladium complex $[NBu_4]_2[\{Pd(C_6F_5)_2(\mu\text{-}OH)\}_2]$ with 1,2 benzenedithiol $C_6H_4(SH)_2$-1,2 in a 1 : 1 molar ratio was tried, a mixture containing the trinuclear complex **10** together with starting material was detected instead.

The hydroxo-azolate bridged complexes $[\{(C_6F_5)_2M\}_2(\mu\text{-}OH)(\mu\text{-}L)]^{2-}$ (M = Pd or Pt, L = pyrazolate-type ligand) were also treated with thiols, RSH, in a 1 : 1 molar ratio to give the heterobridged complexes $[\{(C_6F_5)_2M\}_2(\mu\text{-}SR)(\eta\text{-}L)]^{2-}$ **11–19** (Scheme 2). These reactions imply protonation of the hydroxo group and replacement by μ-thiolates. Palladium and platinum heterobridged binuclear complexes containing the central core $[M_2(\mu\text{-}SR)(\mu\text{-}X)]$ (X = Br, O_2CMe or pyrazolato) have been reported [22–25].

The ^1H NMR spectra of complexes **11–19** are consistent with the proposed formulae. Thus the dimethylpyrazolate ligand (dmpz) in complexes **11, 12** and **17–19** gives one singlet (H^4) and another singlet (for the Me group), with relative intensities of 1 : 6, as expected for a bridging dmpz ligand [6,9,22]. For the pyrazolate ligand (pz) in complexes **13–16** one triplet (H^4) and one doublet (H^3 and H^5), with relative intensities of 1 : 2, are observed.

The ^{19}F NMR spectra of **11–19** (Table 2) should exhibit six resonances for the C_6F_5 rings, in accordance with the presence of two equivalent C_6F_5 rings *trans* to S and two equivalent C_6F_5 rings *trans* to N, but overlapping of some signals is observed in some cases. Furthermore, also in some cases, at room temperature some of the resonances of the *o*-F or *m*-F atoms are broad, which suggests some restriction on the rotation around the M—C bonds. For example, only a very broad resonance at 20°C is observed in the *o*-fluorine region of the NMR spectrum of **18** (δ −114.8 ppm), whereas the low temperature spectrum (−70°C) shows four 2 : 2 : 2 : 2 sharp resonances in the *o*-fluorine region (δ −113.2, −114.3, −116.9 and −117.0 ppm).

(Received 7 July 1997; accepted 26 September 1997)

Abstract—The preparation of the polymeric chain complex, $\{[Mn(bic)(H_2O)]_2 \cdot 2Br \cdot 2H_2O\}_n$ (**2**) is reported. Characterization is made by single X-ray structure, IR and magnetochemistry data. Each seven-coordinate manganese ion has a slightly distorted pentagonal bipyramidal coordination geometry. Bicine is a hexadentate ligand using one nitrogen, three oxygen and one μ_2-oxygen atom from the carboxylate group to coordinate to two Mn^{II} ions. The two hydroxyl groups are not deprotonated, and the μ_2-oxygen atom of the carboxylate moiety of the bic^- ligand is a bridge leading to a polymeric chain. One water molecule coordinates to the Mn^{II} ion, and also forms a strong hydrogen bond with other non-coordinated water molecules. Both non-coordinated water and counter Br^- ion are located between the zigzag chains. Weak pairwise antiferromagnetic exchange interactions ($J = -1.42\ cm^{-1}$) are found within the chain complex due to antiparallel geometry orientations of neighboring Mn^{II} centers. © 1998 Elsevier Science Ltd. Keywords: bicine; manganese; magnetic exchange; one-dimensional; polymer.

The use of polydentate ligands with deprotonatable hydroxyl groups as bridging ligands has led to the formation of Co_{24} [1], Fe_{19}, Fe_{17} [2], Fe_{10} [3], Fe_6 [4], Mn_{13} [5], Mn_{10} [6], Mn_7 [7] polynuclear metal complexes. Interesting structural and magnetic properties have been reported for several of these complexes. *N,N-bis*(2-hydroxyethylglycine) (bicine) is one of these polydentate ligands that is widely used as a buffer substance in biochemical studies [8]. In solution bicine reacts with various transition metal ions [9]; the X-ray structures of only a few of these bicinate metal complexes have been determined [10]. In the structurally characterized complexes it is found that bicine is a versatile ligand and functions either as a tetradentate ligand to form mononuclear metal complexes or as a pentadentate ligand to form polymeric chain complexes [9,10].

Recently we employed bicine as a ligand to prepare a polynuclear manganese complex. A linear polymeric complex of Mn^{II}, $\{[Mn(bic)Cl]_2 \cdot 2H_2O\}_n$ (**1**), was formed by the reaction of $MnCl_2 \cdot 6H_2O$ with bicine in a basic methanol solution [11]. Each Mn^{II} ion is six coordinate, the bicinate (bic) ligand is a pentadentate ligand, and the Cl^- ion is coordinated to the Mn^{II} ion. In this paper we report the synthesis and characterization of $\{[Mn(bic)(H_2O)]_2 \cdot 2Br \cdot 2H_2O\}_n$ (**2**), a zigzag chain of seven coordinate Mn^{II} ions that have pentagonal bipyramidal geometry.

EXPERIMENTAL

Instrumentation and materials

A room-temperature infrared spectrum was obtained on a Nicolet 550 Magna FTIR spectrophotometer. Variable-temperature magnetic susceptibility data were collected for a polycrystalline sample of complex **2** on a Quantum Design MPMS5 SQUID susceptometer equipped with a 55 kG magnet and operating in the range of 1.8–400 K. Diamagnetic corrections were estimated using Pascal's constants and were subtracted from the experimental molar susceptibility to obtain the paramagnetic molar susceptibilities [12]. Solvents and reagents were used as purchased.

Synthesis

Equal equivalents of $MnBr_2 \cdot 6H_2O$ (2.00 g, 8.25 mmol) and bicine (1.34 g, 8.25 mmol) were dissolved

* Author to whom correspondence should be addressed.

in 30 cm^3 deionized water. A 4.0 ml 25% methanolic solution of $[(CH_3)_4N]OH$ (9.50 mmol) was added dropwise to give a solution with pH $\approx$ 8. The solution was warmed to boiling for 10 mins, and the color of the solution gradually changed from colorless to brown. X-ray quality crystals were obtained by slow evaporation over several days. Found: C, 21.70; H, 4.64; N, 4.18; Calc. for $\{[Mn(bic)(H_2O)]_2 \cdot 2Br \cdot 2H_2O\}_n$ (**2**): C, 21.64; H, 4.84; N, 4.20. The yield was 68.80% based on $MnBr_2$.

X-ray crystallography

Data were collected at room temperature on a Siemens R3m/v four circle diffractometer, employing Mo K_α ($\lambda = 0.71073$ Å) radiation with a graphite crystal monochromator. Data were measured by using Wyckoff omega scans. Crystallographic data and other pertinent information are given in Table 1. Selected bond distances and angles are listed in Table 2. Lorentz and polarization corrections were applied and direct methods (SHELXTL PC) revealed the structure. The structure was refined in the monoclinic space group $C2/c$ system using anisotropic thermal parameters for all non-hydrogen atoms and isotropic ones for the hydrogen atoms. The positional parameters of all hydrogen atoms were included in the least-squares refinement cycles. The discrepancy indices $R = (\Sigma||F_o| - |F_c||)/\Sigma|F_o|$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$ are listed in Table 1.

RESULTS AND DISCUSSION

Compound preparation

The goal of this research was to prepare a polynuclear manganese complex that incorporates Mn ions and the bicinate anion. In order to prepare a high nuclearity Mn complex, a *basic* aqueous solution containing Mn^{II} and bicine was allowed to react in air. It is clear that some of the Mn^{II} was oxidized, for the color of the solution changed from colorless to dark brown. Two products were isolated: light brown crystals that analyzed as $\{[Mn(bic)(H_2O)]_2 \cdot 2Br \cdot 2H_2O\}_n$ (**2**) and a dark brown solid. Efforts are continuing to characterize the dark brown solid. In the following is given a characterization of the light brown crystals of complex **2**.

Structural description

The polymeric structure of complex **2** is comprised of a dimeric $[Mn(bic)(H_2O)]_2^{2+}$ repeating unit with two counter bromide ions and two hydrogen bonded H_2O molecules. The one-dimensional structure is shown in Fig. 1 together with the atom-numbering scheme. The carboxylate moiety of the bicinate ligand acts as a tridentate group where one carboxylate oxygen atom bridges two Mn^{II} ions, yielding a chain that runs parallel to the b axis as depicted in Fig. 2. Each Mn^{II} ion is seven coordinate, and coordination geometry is that of a slightly distorted pentagonal bipyramid. Within the chain the dimeric units are arranged head to tail, and all pentagonal plane atoms of Mn^{II} are co-planar, making a *zigzag* chain. A water molecule is hydrogen bonded to the coordinated water, and each water molecule only forms one strong hydrogen bond: the distances and angles of the O(5)—H···O(6) interaction are 2.690 Å, 171.1°, respectively. The bromide ion is only 3.040 Å away from the O(3) atom of the bicinate ligand, and there is probably a weak Br···H—O hydrogen bond. Both non-coordinated water molecules and the bromide ions fill the void between the chains. There are two pairs of anti-parallel chains running through each unit cell. If one assumes the O(2) atom in Fig. 1 is the head of a chain, then in Fig. 2(a) the two top chains run out of the paper, whereas the two bottom chains run into the paper. The intra-chain distance between neighboring Mn^{II} ions are 7.87, 7.98, and 11.59 Å. The intra-chain distance between two neighboring Mn^{II} ions is 4.41(3) Å, and it is shorter than that in complex **1** (4.987 Å), because the bridge in complex **2** is a single oxygen atom, whereas in complex **1** the bridging is by a CO_2^-.

Each Mn^{II} ion in complex **2** has a distorted hepta coordination comprised of two hydroxyl-oxygen

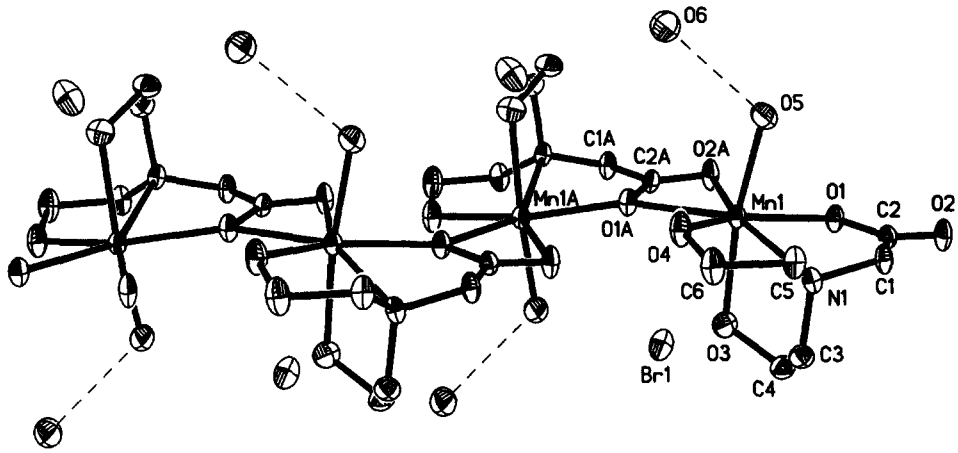

Fig. 1. X-ray structural representation of the linear chain in $\{[Mn(bic)(H_2O)]_2 \cdot 2Br \cdot 2H_2O\}_n$ (complex **2**). Atoms are represented by their 50% probability ellipsoids. Hydrogen atoms on carbon atoms are omitted for clarity. Hydrogen-bonding contacts between coordinated H_2O and uncoordinated H_2O molecules are indicated by dashed lines.

atoms O(3) and O(4), one nitrogen atom N(1), one oxygen atom O(5) from a water molecule, one carboxylate oxygen atom O(1) and another two oxygen atoms O(1A), O(2A) from a second bicinate ligand. The Mn—N bond length (2.356 Å) is significantly longer than the Mn—O bond distances to the carboxylate and hydroxyl oxygen atoms that are about 2.20 Å. This is different from what was found [10] in the bicinate copper complexes. For all copper complexes, at least one Cu—O bond (hydroxyl oxygen) is longer than Cu—N bond. This difference is likely the result of the different coordination geometry. In the case of complex **2**, since it is hepta-coordinate, this requires the five-membered chelate rings associated with the bic^- ligand to be more distorted from the conformation observed in the five-coordinate Cu^{II} complexes and in the six-coordinate complex **1**. There is an appreciable bond length difference for the μ_2-oxygen atom in the carboxylate coordinate to two Mn^{II} centers [2.213 and 2.346 Å for Mn(1)—O(1A), Mn(2)—O(1A), respectively]. The origin of these differences is probably due to the steric effects from the unusual bridging mode for the carboxylate ligand in complex **2**.

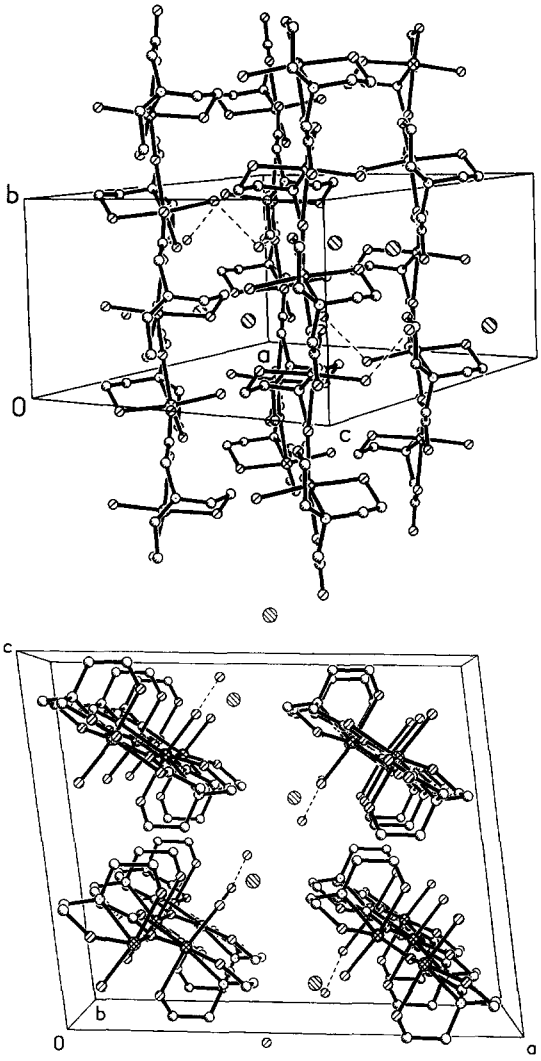

Fig. 2. Drawing showing the unit cell arrangement in two different views (a) and (b) of $\{[Mn(bic)(H_2O)]_2 \cdot 2Br \cdot 2H_2O\}_n$ (complex **2**).

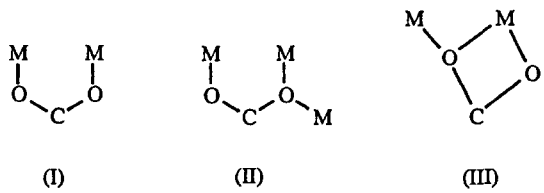
A carboxylate moiety can bridge between metal ions in different ways. The most common bridging mode is shown in (I).



In bridging mode (II) one oxygen atom of the CO_2^- unit interacts with one metal ion, whereas the other oxygen atom bridges between two other metal ions. There have been several examples of carboxylate bridging mode (II) reported [13] for polynuclear manganese complexes. The less commonly encountered bridging mode (III) is found in complex **2**. Both O(1A) and O(2A) coordinate to Mn(1) forming an unusual four-membered ring. Steric effects keep these two oxygen atoms somewhat removed from the normal bond length of Mn—O (~2.20 Å) in manganese carboxylate complexes [13a].

Small deviations from an idealized pentagonal bipyramid are found at the Mn^{II} center. The best equatorial pentagonal plane is defined by atoms O(1), O(1A), O(2A), O(1), N(1), O(4) and Mn(1). The five angles in this plane are approximately evenly distributed, except for the small angle from the unusual four-membered ring of the carboxylate moiety [73.67(1), 73.94(1), 78.78(1), 56.18(1), 80.76(1)° for O(1)—Mn(1)—N(1), N(1)—Mn(1)—O(4), O(4)—Mn(1)—O(1A), O(1A)—Mn(1)—O(2A), O(2A)—Mn(1)—O(1), respectively]. The atoms O(3) and O(5) are found at apical sites with nearly equal bond lengths (Table 1); the O(3)—Mn(1)—O(5) angle is 168.34(1)°. The polydentate structure of the bicinate ligand and unusual coordination mode of the carboxylate moiety contribute to the distortion from pentagonal bipyramidal geometry.

A few hepta-coordinate manganese complexes have been reported [14–16]. Macrocyclic ligands or rigid, resonance-stabilized planar ligands have been employed to enforce pentagonal planar coordination. Bicine is neither macrocyclic nor rigid, however it can adopt a conformation in which it acts as hexadentate ligand with extremely unusual μ_2-bridging oxygen atom from the carboxylate moiety. The bicinate ligand uses four atoms to coordinate to the Mn^{II} ion to form three five-membered chelate rings, leaving appreciable space to accommodate three other atoms. Then, two oxygen atoms of a carboxylate from another bic^- insert to form a four-membered ring. The last position is taken by an H_2O molecule. The versatility of the bic^- ligand is fully manifested in complex **2** with three five-membered rings and one four-membered chelate ring.

Oxygen atoms from the deprotonated ethyl hydroxyl group in the ligand heidi [N(2-hydroxyethyl)iminodiacetic acid] serve as a μ_3-oxo bridge in the formation of Fe_{17} and Fe_{19} clusters [2]. Deprotonated hydroxy groups are not seen for bicine, even though both ligands are structurally similar. It is likely that the ethyl hydroxyl group of heidi is more acidic than that in bicine because the former has two strong electron withdraw carboxylic groups, and there is only one carboxylic group in bicine. In the case of complex **2**, the most remarkable structural features are the hepta coordination and the unusual coordination mode of the carboxylate moiety leading to the formation of the first chain complex with hepta coordinate metal centers.

Complexes **1** and **2** were obtained by the same reaction in different solvents. The formation of complex **1** could be related to the limited amount of water in methanol and the excess of Cl^- used in the reaction.

In this case the Cl^- ion coordinates to the Mn^{II} ion; each Mn^{II} has a distorted octahedral coordination geometry, and the bic^- ligand is pentadentate. Complex **2** was formed in aqueous solution. The Br^- ion is apparently too large to bind together with the bic^- ligand.

Infrared spectroscopy

Four strong broad bands are found in the KBr-pellet IR spectrum for complex **2** at energies above 3000 cm^{-1}; they are at 3470, 3411, 3369, and 3217 cm^{-1}. The two bands at 3369 and 3217 cm^{-1} are reasonably assigned to OH stretching vibrations [10d], and the two higher frequency bands (3470, 3411 cm^{-1}) are attributable to coordinated and non-coordinated H_2O molecules. That both bands appeared at lower frequencies than seen in complex **1** [11] could be due to the stronger hydrogen bonding between two water molecules present in complex **2**.

The bands at 1567 and 1446 cm^{-1} are assigned to the COO^- antisymmetric and symmetric stretching vibrations, respectively. The frequency separation of these two bands is only 121 cm^{-1}, which is much smaller than that of free ligand, and also smaller than in copper complexes which have carboxylate bonding mode I [10]. This could be attributed to the unusual coordination mode of the carboxylate group.

Magnetochemistry

Variable-temperature dc magnetic susceptibility data were collected in a 10 kG field for a powdered sample of complex **2** constrained in parafilm. A plot of the effective magnetic moment (μ_{eff}) per molecule or unit in the temperature range of 2.0–320 K is shown in Fig. 3 (circles). The effective magnetic moment per Mn decreases gradually from 5.65 μ_B at 320 K to 5.75 μ_B at 70.0 K, and then more rapidly to 0.96 μ_B at 2.00 K. A weak antiferromagnetic exchange interaction between Mn^{II} centers is evident.

The data were analyzed assuming an isotropic Heisenberg pairwise interaction between Mn^{II} ions in a linear chain. The spin Hamiltonian is given in eqn (1). Wagner and Friedberg [17] derived the equation for the magnetic susceptibility for a linear chain with S = 5/2 ions in

$$H = -2J \sum_{i=1}^{n} S_i \cdot S_{i-1} \quad (1)$$

$$\chi_M = \{Ng^2\mu_B^2 S(S+1)/3kT\}\{(1+U)/(1-U)\} \quad (2)$$

eqn (2), where $U = \coth(K - 1/K)$ and $K = 2JS(S+1)/kT$. The parameters are **J** for the magnetic exchange interaction and an isotropic g value. The solid curve (circles) in Fig. 3 represents the least-squares fit of the data to eqn (2) to give the parameters

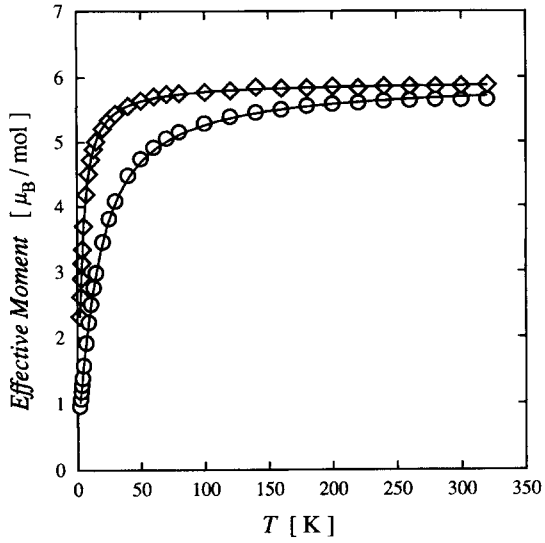


Fig. 3. Plot of the effective magnetic moment versus temperature for a powder sample of $\{[Mn(bic)Cl]_2 \cdot 2(H_2O)\}_n$ (**1**) and $\{[Mn(bic)(H_2O)]_2 \cdot 2Br \cdot 2H_2O)\}_n$ (**2**) (diamonds for complex **1** and circles for complex **2**). Data were collected in a 10.0 kG field. The solid lines represent the best fit of the data to eqn (2).

$J = -1.42(2)$ cm^{-1} and $g = 2.00(1)$. It can be seen that the agreement between the theory and experimental data is quite satisfactory.

The data and fitting results for complex **1** (diamonds) are also shown in Fig. 3. In this complex, the magnetic exchange coupling constant **J** was found to be $-0.30(1)$ cm^{-1}. The stronger antiferromagnetic interaction in complex **2** compared to that in complex **1** probably results from the fact that the magnetic exchange in complex **2** is supported by the μ_2-oxygen bridge atom from the carboxylate group, whereas in complex **1** it is supported by the three atoms of a bridging carboxylate group.

Much effort has been spent to synthesize and characterize Mn^{II} linear chain complexes [17–22]. Three types of bridging ligands have been found that support weak antiferromagnetic interactions: carboxylate, phosphinate and chloride ions. The magnetic exchange parameter **J** varies from -9.3 cm^{-1} for the chloro bridge to -0.2 cm^{-1} for the carboxylate and phosphinate bridges [17–22]. The **J** values for complexes **1** and **2** are within this range.

Spectroscopic and theoretical study of aromatic α–hydroxy hydrazones and their copper(II) complexes in dioxane–water mixtures

Gabriela N. Ledesma, Manuel Gonzalez Sierra and Graciela M. Escandar*

Facultad de Ciencias Bioquímicas y Farmacéuticas, Universidad Nacional de Rosario, Suipacha 531 (2000) Rosario, Argentina

(Received 12 April 1997; accepted 26 September 1997)

Abstract—Two aromatic α-hydroxy hydrazones, *N*-phenyl-*N'* (2-hydroxy-1-phenylmethylene hydrazine) and *N*-phenyl-*N'* (2-hydroxy-1-naphthylmethylene hydrazine), and their copper(II) complexes have been studied in both 30% and 70% dioxane–water (v/v) systems. Structural analysis of the anionic forms of the free compounds has been performed using ^{13}C NMR and electronic absorption spectroscopies and semiempirical MO calculations. The equilibrium constants for the deprotonation reactions of the hydrazones and for their coordination with Cu(II) ion were studied by spectrophotometric titration. Coordination binding sites and stereochemistry of the chelates were inferred from NMR spectroscopy. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: spectroscopy; coordination chemistry; aromatic α-hydroxy hydrazones.

Hydrazones are compounds with wide applications in several areas such as organic, analytical and industrial chemistries. The electronic structure of certain hydrazones allows their use as hole-transporting agents in organic layered photoconductors, employed in the electrophotographic process in copiers and printers [1]. From a biological point of view, they have both herbicide and insecticide activities, and are components of several drugs for the treatment of diseases such as cancer and schizophrenia [2]. Pyridoxal hydrazone derivatives have been utilized as chelating agents for mobilizing iron during the therapy of iron overload, in order to replace the commonly used desferrioxamine [3]. At present, there is an increasing interest in the coordination chemistry of suitable ligands for biomedical objectives. However, little information is known in the literature about metal equilibrium constants and complexation behavior of hydrazones. The present investigation was undertaken in view of this and of the potential biological use of complexes formed with this type of ligand.

In the present work, we focus our study on the evaluation of the coordination ability of aromatic α-hydroxy hydrazones with copper(II) ion, as part of a general program devoted to the analysis of prototropic and binding properties of aromatic compounds containing conjugated heterocycles [4]. Specifically, the ligands studied are: *N*-phenyl-*N'*(2-hydroxy-1-phenylmethylene hydrazine) (PHPH) and *N*-phenyl-*N'*(2-hydroxy-1-naphthylmethylene hydrazine) (PHNH) (Scheme 1). These ligands and their metal complexes are not soluble in water but in mixtures of water with dioxane. The use of such solvent mixtures has the advantage of allowing the study of the metal–ligand interaction in a medium with a dielectric constant which is lower relative to pure water, resembling to a certain degree, the interaction in biological media (e.g. active-site cavities of enzymes) [5]. On the other hand, since water–dioxane mixtures are compatible with the membrane glass electrode, a simple relationship between the formed complexes and the pH of the media can be established. The studies are performed by a combination of spectroscopy and semiempirical-molecular mechanics calculations. The relationship of both the tautomeric and isomeric properties of the

studied compounds to their acid-base and chelating behaviors is investigated.

EXPERIMENTAL

Reagents and solvents

A stock solution of Cu(II) (0.010 M) was prepared from $Cu(NO_3)_2.3H_2O$ (Mallinckrodt) and the exact concentration was volumetrically determined with ethylenediaminetetraacetic acid and murexide as indicator [6]. Solutions of carbonate-free NaOH in 30% dioxane–70% water (v/v) and 70% dioxane–30% water (v/v) were standardized with the use of the Gran's plots [7]. 1,4-Dioxane (p.a.) was obtained from Merck. The water employed was purified by ion exchange and distilled.

Synthesis of the ligands

The ligands were prepared using standard procedures [8]. Briefly, an aqueous solution of phenylhydrazine hydrochloride was allowed to react with the corresponding ethanolic aldehyde solution (salicylaldehyde or 2-hydroxynaphthalene-1-carbaldehyde) in the presence of sodium acetate. This mixture was warmed and shaken. After cooling, the obtained solid was recrystallized from water/ethanol. Elemental analysis was performed by Atlantic Microlab Inc. for C, H and N, and was in agreement with the calculated values: for PHPH, found: C, 73.54; H, 5.73; N, 13.06; $C_{13}ON_2H_{12}$ requires C, 73.56; H, 5.70; N, 13.20%; for PHNH, found: C, 77.76; H, 5.37; N, 10.71; $C_{17}ON_2H_{14}$ requires C, 77.54; H, 5.36; N, 10.64%. The purity was also checked by thin layer chromatography using different solvent systems.

The stability of the ligands at both acid and alkaline pH was checked by chromatography and ^{13}C NMR, in the solvents and at usual concentrations.

pH determinations

pH values were obtained with a Metrohm 713 pH meter fitted with a glass and reference electrodes. In order to read $-\log [H^+]$, the pH meter–electrode system was calibrated with buffer solutions at 0.10 M ionic strength ($NaNO_3$). The effect of the solvent composition in the pH measurements was taken into account by correcting each meter reading with a conversion factor [9]. This factor was obtained, prior to each experiment, by titration of both 30% and 70% v/v dioxane–water solutions of standard HNO_3 with successive quantities of standard NaOH in the corresponding solvent mixture. In these latter titrations, the ionic strength was also adjusted to 0.10 M with $NaNO_3$ and the temperature was maintained at 20.0°C. The water hydrolysis constants, in our conditions of ionic strength and temperature, were found to be $10^{-14.2}$ and $10^{-15.7}$ for 30% and 70% v/v dioxane–water, respectively. The latter value is in accordance with that found by Motekaitis *et al.* [$K_w = 10^{-16.00}$, 25.00°C, $\mu = 0.100$ M (KCl)] [10].

Equilibrium constant determinations

Due to the low solubility of both ligands and their complexes, the equilibrium constant determinations were performed in diluted solutions using spectrophotometric techniques. The measurements were made at 20.0°C and $\mu = 0.10$ M ($NaNO_3$) using a Beckman DU640 spectrophotometer in 1.00 cm quartz microcells. Conformity to Beer's law in the concentration range used was verified prior the determinations. The initial concentrations of hydrazone in the experimental solutions were in the interval of $2–8 \times 10^{-5}$ M. The PHPH system could be evaluated in both solvent systems, whereas the PHNH system was only investigated in 70% v/v dioxane–water solvent for solubility reasons. Although 1:2 systems were

evaluated in addition to 1:1 metal–ligand systems, only 1:1 complexes were found. A typical spectrophotometric experiment was previously described in the literature [4]. Concisely, profiles of absorbances (at selected wavelengths) vs pH are obtained according to the following procedure: small increments of NaOH solution (made up in 30 or 70% v/v dioxane–water) are added to the solution containing hydrazone or hydrazone and metal in the corresponding solvent system. For each pH point (in the range 5–12.5) a known aliquot of solution is extracted and the absorption spectrum is read. Equilibrium conditions, determined by constant pH meter and absorbance readings, is obtained before proceeding with the next step. Each run was done in triplicate. The data processing for the computation of the equilibrium constants and of the species distribution diagram were performed using the EPSILON program [11].

^{13}C NMR measurements

Carbon-13 NMR spectra were recorded on a Bruker AC-200 NMR spectrometer operating at a nominal frequency of 50.3 MHz. The samples were ca 0.2 M in hydrazones, dissolved in acetone-d_6: water 90% v/v. This ratio of solvents was adequate to keep both the ligands and the complexes in solution at the high concentrations required in these experiments. The alkaline medium was obtained by adding 3 M NaOH. The metal ion was introduced as an appropriate aliquot of 0.1 M $Cu(NO_3)_2$ solution. Since increasing the Cu(II) ion concentration beyond 4×10^{-3} M causes complex precipitation, only a small metal concentration range was used (1×10^{-3}–4×10^{-3} M). The ^{13}C resonances were referenced against the CD_3 signal of acetone-d_6 (30.2 ppm) and converted to the TMS scale.

Molecular orbital and molecular mechanics calculations

Semiempirical MO (AM1) calculations (geometry optimization and calculation of heats of formation) and molecular mechanics (MM+) calculations were performed by using the Hyperchem package of programs on an Pentium-150 microcomputer.

RESULTS AND DISCUSSION

Structural analysis of the ligands

We have previously studied the proton transfer process in the ground state of PHPH and PHNH [12]. The results showed that the enolic tautomers (Scheme 1) are favored in both ligands, and that no aromaticity transfer occurs in the PHNH ligand from the ring containing the OH to the adjacent aromatic ring. In the present paper, structural information about the anionic forms of these compounds is obtained. When the −OH proton is released from the compounds, the C(7)—N(1) and C(9)—N(1) bonds in PHPH and PHNH respectively, are able to acquire single bond character. This may allow a rotation about these bonds, leading to the presence of two possible isomeric structures, A and B (Scheme 2). The heats of formation (ΔH_f°) calculated by AM1 indicate that B isomers are more stable than A forms (Table 1). Whereas in the protonated hydrazones the possibility of hydrogen bond between the OH group and N(1) stabilizes a six-membered ring structure (Scheme 1), in the anionic forms the hydrogen bond takes place between the oxygen and N(2)—H, favoring a structure with a seven membered-ring. Seven and eight membered hydrogen bonded rings have been previously characterized as being very stable [13].

Table 2 collects the complete ^{13}C NMR assignments for the studied compounds in alkaline media. These assignments were based on those previously reported for the protonated structures in $CDCl_3$ [12]. It should be noted that at the high concentration of hydrazones and due to their very low acidity constants in the solvent used, it is not possible to increase the alkali concentration to produce complete deprotonation with no undesirable side reactions. Therefore, the ^{13}C NMR spectra provide evidence for the behavior of deprotonated forms, albeit with a contribution of the protonated forms. The results show that there exist a contribution of the keto structures in the anions, as can be judged from the chemical shifts for the C—O carbon, which are displaced toward higher frequencies. Recall that the typical chemical shifts of C—O(H)

moieties are in the range 150–155 ppm, whereas those corresponding to carbonylic groups are around 180 ppm.

Semiempirical MO (AM1) calculations (Table 1) are also in agreement with the NMR findings. Geometry optimization of the deprotonated ligands shows bond lengths about the N—N—C—C—C—O moiety corresponding to structures as shown in Scheme 2.

In contrast to the PHPH anion, the anionic form of PHNH is in principle able to suffer aromaticity transfer. However, the C—C bond lengths corresponding to the aromatic ring adjacent to that containing the oxygen show no significant aromaticity transfer, as in the case of the protonated hydrazone. As shown in Table 1, calculated bond lengths around the six-membered ring show alternation between formally double and single bonds. This result leads to the conclusion that the addition of an aromatic ring in going from PHPH to PHNH does not produce major structural changes. This differs from previous observations for related azo compounds and Schiff bases [4,14–16], and may have an influence on the values of deprotonation constants and complex formation.

Deprotonation constants

Tables 3 and 4 show, respectively, the spectral characteristics and deprotonation constant values of the ligands under study. Figure 1 shows the spectra of PHPH in 30% v/v dioxane–water at selected pH values (for clarity only some spectra are illustrated). As shown in this picture, the λ_{max} of 344 nm detected at acid pH, and in accordance with an enolic structure for the protonated ligand, shifts slightly towards a longer wavelength (366 nm) at high pH. This fact could indicate a contribution of the quinoid structure to the deprotonated ligand form. The comparability between the deprotonation constants (within experimental error) of both ligands in 70% dioxane–water could be attributed to the similar structures in both protonated and deprotonated forms, contrary to the case of related azocompounds [4]. The deprotonation constant values of PHPH in aqueous 30% and 70% dioxane could indicate that the solvent effect on the apparent acidity is significant.

Copper(II) complexes

The spectra of the complex solutions resemble those of the free compounds. Therefore, the determinations in the complex systems were performed at wavelengths similar to those used in the deprotonation constants calculations and keeping fixed the molar extinction coefficients and deprotonation constants of the free compounds. As an example of the spectrophotometric titration curves, Fig. 2 shows the profile for the Cu (II)—PHNH system in 70% dioxane–water solvent.

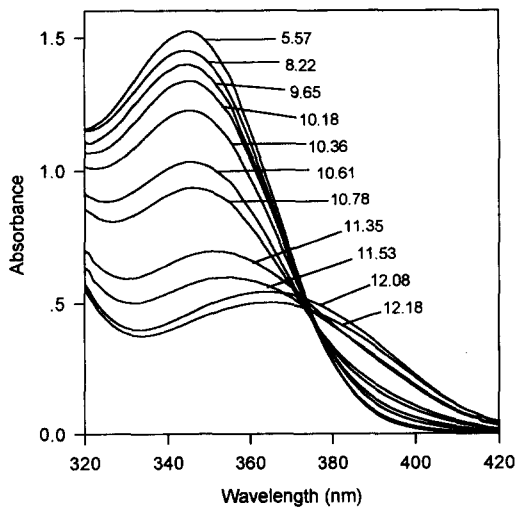

Fig. 1. Absorbance at different pH values of PHPH in 30% v/v dioxane–water; initial $C_{PHPH} = 7.37 \times 10^{-5}$ M, $\mu = 0.10$ M ($NaNO_3$), $t = 20.0$°C.

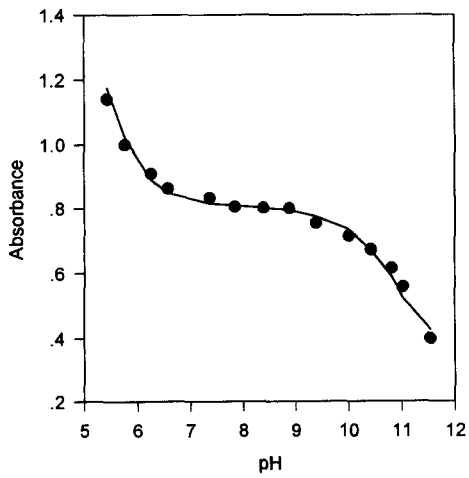

Fig. 2. Experimental (•) and calculated (—) absorbance values vs pH in the Cu(II)–PHNH system in 70% dioxane–water solvent; initial $C_{PHNH} = 6.14 \times 10^{-5}$ M, initial $C_{Cu} = 5.98 \times 10^{-5}$ M, $\mu = 0.10$ M ($NaNO_3$), $t = 20.0$°C.

The spectrophotometric curves of both ligand systems were processed and the best fit involved the formation of the $[CuLH_{-1}]$ and $[CuLH_{-2}]^-$ species. In the latter formula, L represents the ligands in their deprotonated forms and H_{-n} indicates the protons released in the complex formation, in addition to the ligand OH proton. The latter can be ascribed to the water molecules coordinated to the metal center. Hydrolytic species of the Cu(II) ion were not found.

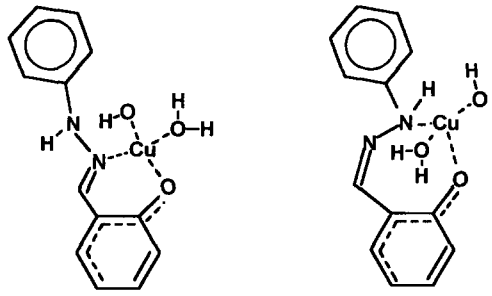
The molar extinction coefficients and the equilibrium constant values for the Cu(II) complexes are listed in Tables 3 and 4, respectively. From the latter magnitudes the species distribution curves were calculated for each system. The species distribution diagram in Fig. 3 points out the interplay of the Cu (II)-containing species for the same system of Fig. 2.

Since no significant changes in the absorbance vs pH in the alkaline zone for the Cu(II)—PHPH system in 70% dioxane were observed, the equilibrium constant for the $[CuLH_{-2}]^-$ complex could not be determined. This fact is ascribed to the possible similarity between the molar extinction coefficients of the two equilibrating complexes.

The complex equilibrium constant values for both hydrazones are similar and this fact can be attributed to the absence of aromaticity transfer in the PHNH molecule, which leads both hydrazones to have similar electronic structures and therefore comparable abilities for coordination.

Structural analysis of complexes

Both A and B anionic forms of the studied hydrazones (Scheme 2) may coordinate the metal ion. In the first case, the donor groups of the ligands include the oxygen and N(1) (through its lone pair of electrons). Thus, six membered-ring chelates can be formed. On the other hand, with B anionic forms, the metal coordination may involve the lone pair electrons of N(2) and the oxygen atom, with seven membered-ring chelates formation. Due to the fact that a high coordination of the metal center would involve severe steric strain, a tetracoordinated copper(II) ion is suggested in both cases. The other binding positions could be fulfilled with hydroxyl groups. Both types of structures are represented in Scheme 3. Unfortunately, both the low concentrations of the complexes in the working solutions and the interference of the ligand's color prevented obtaining unambiguous conclusions from the *d-d* spectra of the complexes regarding the complex geometries.



Scheme 3.

With the purpose of comparing the relative steric strain of the complexes involving the proposed spatial arrangements shown in Scheme 3, molecular mechanics calculations were carried out [17,18]. The obtained strain energies for the neutral $[CuLH_{-1}]$ complexes with either type of coordination (12.9 kcal mol^{-1} for both PHPH complexes with rings of six and seven members, and 13.6 and 13.1 kcal mol^{-1} for the PHNH complexes with rings of six and seven members, respectively) do not reflect significant differences. However, more rigorous structural information can be obtained from ^{13}C NMR experiments [19,20]. Upon addition of Cu(II) solution to an alkaline solution of PHPH dissolved in acetone-d_6, selective peak broadening in the ^{13}C NMR spectrum was observed. The affected signals in the complex spectrum are those corresponding to C(2) and C(7) (see Scheme 2). This result suggests that the more stable complex structure is that where the metal ion is bound to the oxygen of C(2) and to the lone pair electrons of N(1), forming a six-membered ring.

Since solid formation occurs even at very low metal ion concentration, the ^{13}C NMR spectrum corresponding to the Cu(II)–PHNH system could not be performed.

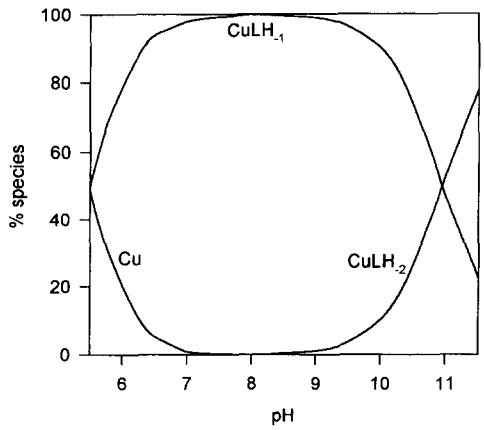


Fig. 3. Distribution of species as a function of pH in a Cu(II)–PHNH system in 70% dioxane–water solvent; initial $C_{PHNH} = 6.14 \times 10^{-5}$ M, initial $C_{Cu} = 5.98 \times 10^{-5}$ M, $\mu = 0.10$ M ($NaNO_3$), $t = 20.0$°C.

CONCLUSIONS

By using spectroscopic methods and semiempirical MO calculations the preferred isomeric and resonant forms of potential ligands as the anions of α-hydroxy hydrazones have been established. Thus, both the

anionic form of PHPH as well as that corresponding to PHNH have a contribution of the keto structures. These structures exist primarily as the isomers with hydrogen bond between the oxygen and the N(2) proton, forming a structure with a seven-membered-ring. No aromaticity transfer occurs in PHNH and this fact is related to the magnitude of the complex equilibrium constants. Both the deprotonation constants of the compounds and their copper(II) complexes were evaluated, confirming the existence of chelates with different degrees of deprotonation. The more probable complex structures would involve a metal coordination with the oxygen, nitrogen N(1) and hydroxyl groups.

(Received 5 June 1997; accepted 25 September 1997)

Abstract—The reaction of $[Ru(tpy)Cl_3]$ with pap has afforded $[Ru(tpy)(pap)Cl]^+$ which has been isolated and characterized as the perchlorate salt. Treatment of $[Ru(tpy)(pap)Cl]^+$ with Ag^+ in aqueous solution gives $[Ru(tpy)(pap)(H_2O)]^{2+}$. This aquo-complex has been reacted with three monodentate ligands (L′ = CH_3CN, 4-picoline and N_3^-) to afford complexes of type $[Ru(tpy)(pap)(L')]^{n+}$. Structure determination of $[Ru(tpy)(pap)(CH_3CN)](ClO_4)_2$ by X-ray crystallography shows that tpy is coordinated to ruthenium in the usual meridional fashion and the pap ligand is bound to ruthenium with the azo-nitrogen trans to CH_3CN. All these complexes except $[Ru(tpy)(pap)(H_2O)]^{2+}$ show a Ru(II)-Ru(III) oxidation in the range 1.11–1.50 V vs SCE and three ligand(pap/tpy)-based reductions on the negative side of SCE. The aquo-complex shows a $Ru^{II}—OH_2/Ru^{IV}=O$ couple in aqueous solution (pH = 1–4), the E° of this oxidation is estimated to be 0.82 V vs SCE. Attempt to chemically oxidize the aquo-complex by Ce^{4+} in aqueous solution (1 M $HClO_4$) results in the catalytic oxidation of water to dioxygen. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: ruthenium; 2-(phenylazo)pyridine; synthesis; characterization; structure; reactivities.

There has been much current interest [1] in the chemistry of $[Ru(tpy)(L)Cl]^{n+}$ type of complexes (where tpy = 2,2′6′,2″-terpyridine, L = bidentate ligand, n = 0 or 1) primarily due to the dissociation of the Ru—Cl bond and the reactivities resulting thereof (Scheme 1). One particularly interesting aspect of this chemistry is the generation of oxo-ruthenium complex via the formation of aquo-complex. The oxo-ruthenium complexes are receiving continuous attention because of their usefulness as catalysts in different oxidation reactions [2]. As water is a rather labile ligand, the aquo-complexes are known to function as excellent staring materials for the synthesis of mixed ligand complexes and thus they can display quite interesting chemistry as well [3]. Efforts are being made to modulate the reactivities of such complexes by varying the nature of the ligand L. In the present study, we have chosen 2- (phenylazo)pyridine (pap, **1**) as the bidentate ligand. The 2-(phenylazo)pyridine ligand is a strong π-acid, stronger than 2,2′-bipyridine (bby) and other familiar N—N donor ligands, and is a recognized stabilizer of the lower oxidation states of ruthenium [4]. Oxo-ruthenium complexes containing

the 2-(phenylazo)pyridine ligand are therefore expected to be strong oxidizing agents. We report here the chemistry of chloro-, aquo-, and oxo-complexes of ruthenium incorporating terpyridine and 2-(phenylazo)pyridine.

EXPERIMENTAL

Materials

Commercial ruthenium trichloride, purchased from Arora Matthey, Calcutta, India, was converted to $RuCl_3 \cdot 3H_2O$ by repeated evaporation to dryness with concentrated hydrochloric acid. [Ru(tpy)Cl_3] and 2-(phenylazo)pyridine were synthesized using literature procedures [5,6]. 4-Picoline (pic), sodium azide and sodium perchlorate were purchased from Aldrich. All other chemicals and solvents were reagent grade commercial materials and used as received. Purification of acetonitrile and preparation of tetraethylammonium perchlorate (TEAP) for electrochemical work were performed as reported in the literature [7].

Physical measurements

Microanalyses (C, H, N) were performed using a Perkin–Elmer 240C elemental analyser. IR spectra were obtained on a Perkin–Elmer 783 spectrometer with samples prepared as KBr pellets. Electronic spectra were recorded on a Hitachi U 3400 spectrophotometer. Magnetic susceptibilities were measured using a PAR 155 vibrating sample magnetometer. ^{1}H NMR spectra were obtained on a Varian Gemini 300 MHz NMR spectrometer using TMS as the internal standard. Solution electrical conductivities were measured using a Philips PR 9500 bridge with a solute concentration of 10^{-3} M. The pH measurements were made with a Systronics 361 pH meter. Electrochemical measurements were made using a PAR model 273 electrochemistry system. A platinum disc working electrode, a platinum wire auxiliary electrode and an aqueous saturated calomel reference electrode (SCE) were used in a three-electrode configuration. All electrochemical data were collected at 298 K and are uncorrected for junction potentials.

X-ray structure determination of [Ru(tpy) (pap) (CH_3CN)](ClO_4)$_2$ complex

Single crystals of the complex were grown at 298 K by slow diffusion of benzene into an acetonitrile solution of the complex. Selected crystal data and a data collection parameters are collected in Table 1. The unit cell parameters were determined by a least-squares fit of 30 machine-centered reflections ($14^\circ < 2\theta < 28^\circ$). Data were collected on a Siemens R3m/V diffractometer using graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å) and were corrected for Lorentz and polarization factors. The data set was corrected for absorption emperically on the basis of azimuthal scans [8]. Two standard reflections monitored after 98 reflections showed no significant intensity variation.

Systematic absence led to the identification of space group $P2_1/c$. The structure was solved by the heavy-atom method, the positions of the metal ion being determined from a Patterson map and the remaining non-hydrogen atoms by successive Fourier-difference syntheses. The structure was then refined by full-matrix least-squares procedures. All non-hydrogen atoms excluding the disordered perchlorate oxygen atoms were refined anisotropically. Hydrogen atoms were included at their respective calculated positions with fixed isotropic thermal parameters (0.08 Å^2) at the final cycle of refinement. Final residuals are given in Table 1. All computations regarding data collection, structure solution and refinement were carried out on a Micro Vax II computer using the SHELXTL-PLUS programme package [9].

Preparation of the complexes

Warning: Perchlorate salts are hazardous because of the possibilities of explosion. They should be prepared in small amount and handled with care.

$[Ru(tpy)(pap)Cl]ClO_4$

$[Ru(tpy)Cl_3]$ (200 mg, 0.45 mmol) and pap (125 mg, 0.68 mmol) were gently refluxed for 1 h in 30 cm^3 of 3 : 1 ethanol-water containing LiCl (200 mg) and triethylamine (0.06 cm^3). The hot solution was filtered to remove any insoluble material. The filtrate was cooled to room temperature and to it was added a saturated aqueous solution of $NaClO_4$ (10 cm^3). Upon standing pinkish-red microcrystalline solid separated out which was collected by filtration, washed with little cold water and dried *in vacuo* over P_4O_{10}, yield 230 mg, 78%.

$[Ru(tpy)(pap)(H_2O)](ClO_4)_2$

$[Ru(tpy)(pap)Cl]ClO_4$ (200 mg, 0.31 mmol) and $AgNO_3$ (53 mg, 0.31 mmol) were gently refluxed for 1 h in 30 cm^3 of 1 : 5 acetone-water. After being cooled to room temperature, the mixture was filtered to remove AgCl. To the filtrate was added a saturated aqueous solution of $NaClO_4$ (10 cm^3) and the solution was chilled overnight in a refrigerator to give microcrystalline red precipitate of $[Ru(tpy)(pap)(H_2O)](ClO_4)_2$ which was collected by filtration, washed with a minimum volume of cold water and dried *in vacuo* over P_4O_{10}, yield 157 mg, 70%.

$Ru(tpy)(pap)(CH_3CN)]ClO_4)_2$

$[Ru(tpy)(pap)(H_2O)](ClO_4)_2$ (200 mg, 0.27 mmol) was dissolved in acetonitrile (30 cm^3) and gently heated for 30 min with continuous stirring. The volume of the solution was then reduced to ~5 cm^3 and a saturated aqueous solution of $NaClO_4$ (10 cm^3) was added. Upon cooling the solution in an ice bath $[Ru(tpy)(pap)(CH_3CN)](ClO_4)_2$ precipitated as a dark crystalline solid. This was collected by filtration, washed with little cold water and dried *in vacuo* over P_4O_{10}, yield 175 mg, 85%.

$[Ru(tpy)(pap)(pic)](ClO_4)_2$

A solution of $[Ru(tpy)(pap)(H_2O)](ClO_4)_2$ (200 mg, 0.27 mmol) and pic (0.03 cm^3, 0.28 mmol) in 30 cm^3 of ethanol was gently refluxed for 2 h. The volume of the solution was reduced to ~5 cm^3 and a saturated aqueous solution of $NaClO_4$ (10 cm^3) was added to it. Upon cooling to 0°C a red microcrystalline precipitate separated out which was collected by filtration, washed with a little cold water and dried *in vacuo* over P_4O_{10}, yield 175 mg, 80%.

$[Ru(tpy)(pap)(N_3)]ClO_4$

$[Ru(tpy)(pap)(H_2O)](ClO_4)_2$ (200 mg, 0.27 mmol) was dissolved in 30 cm^3 of 3 : 1 methanol-water and to it was added NaN_3 (18 mg, 0.28 mmol). The solution was refluxed for 1 h on a water bath. The volume of the solution was reduced to ~10 cm^3. Upon cooling the solution in an ice-bath $[Ru(tpy)(pap)(N_3)]ClO_4$ separated out as a deep pink microcrystalline solid which was isolated by filtration, washed with little ice-cold water and dried *in vacuo* over P_4O_{10}, yield 147 mg, 82%.

RESULTS AND DISCUSSION

Synthesis and characterization

$[Ru(tpy)(pap)Cl]^+$ has been synthesized by the smooth reaction of pap with $[Ru(tpy)Cl_3]$ in refluxing ethanol in the presence of NEt_3 and LiCl. In this reaction NEt_3 functions as a reducing agent to help the dissociation of Cl^- from $[Ru(tpy)Cl_3]$, whereas LiCl is used to prevent any dissociation of Cl^- from the product. The complex cation has been isolated as perchlorate salt in the solid state and its composition has been confirmed by microanalytical data (Table 2). As pap is an unsymmetrical bidentate ligand, $[Ru(tpy)(pap)Cl]^+$ may exist in two geometrical isomeric

forms, **2** and **3**. We assign structure **3** to this complex in analogy to the structurally characterized [Ru(tpy)(pap)(CH_3CN)]$(ClO_4)_2$ complex (*vide infra*). Infrared spectrum of this complex shows many vibrations of different intensities below 1600 cm^{-1} and is therefore complex in nature. Attempts have not been made to assign each individual band. However, a sharp vibration observed at 325 cm^{-1} is assigned to ν(Ru—Cl) stretching mode. Another intense band at 1310 cm^{-1} is attributed to the ν(N=N) vibration [10]. Two intense vibrations are observed at 1100 cm^{-1} and 620 cm^{-1} due to the presence of ClO_4^-. Magnetic susceptibility measurement shows that [Ru(tpy)(pap)Cl]$^+$ is diamagnetic which is in accordance with the +2 state of ruthenium (low-spin d^6, S=0) in this complex. ^{1}H NMR spectrum of [Ru(tpy)(pap)Cl](ClO_4), recorded in CD_3CN solution, shows many sharp resonances (Fig. 1). In total thirteen resonances may be expected for the twenty hydrogens present in the [Ru(tpy)(pap)Cl]$^+$ complex, seven signals for the nine hydrogens of pap ligand and six signals for the eleven hydrogens of tpy ligand (because a plane of symmetry splits the tpy ligand into two equal halves). Actually eleven resonances are experimentally observed (Fig. 1) because of overlap of signals. Integration of the signals corresponds to the twenty hydrogens present in the complex. Assignment of all the observed signals to specific hydrogens has not been attempted. However, the two doublets (1-H each) observed at 9.86 and 8.73 ppm are respectively assigned to the 6-H and 3-H of the pyridine ring in the pap ligand.

Electronic spectrum of [Ru(tpy)(pap)Cl]ClO_4 recorded in acetonitrile solution, shows four absorptions in the visible region (Table 2). The low-intensity absorption observed at 680 nm is assigned to the *d-d* transition ($^1A_1 \rightarrow {}^1T_1$) ([11]. The other possible *d-d* transition ($^1A_1 \rightarrow {}^1T_2$) [11] could not be detected due to the presence of intense absorption at higher energies. The other three intense absorptions are probably due to allowed metal-to-ligand charge-transfer transitions. Multiple charge-transfer transitions in such complexes may result from lower symmetry splitting of the metal level, the presence of different acceptor orbitals and from the mixing of singlet and triplet configurations in the excited state through spin-orbit coupling [12]. Conductivity measurement in acetonitrile solution shows that [Ru(tpy)(pap)Cl]ClO_4 behaves as a 1 : 1 electrolyte (Table 2), as expected.

Reaction of $[Ru(tpy)(pap)Cl]^+$ with Ag^+ in 1 : 5 acetone-water solution results in the deposition of AgCl leaving $[Ru(tpy)(pap)(H_2O)]^{2+}$ in solution, which has been subsequently precipitated as the red perchlorate salt. Elemental analytical data (Table 2) agree well with the composition of this complex. [Ru(tpy)(pap)(H_2O)](ClO_4)$_2$ is diamagnetic, as expected and is assumed to have a stereochemistry similar to **3** with H_2O replacing Cl^-. Infrared spectrum of this aquo-complex is very similar to that of the precursor chloro-complex, except that the ν(Ru—Cl) vibration, observed in the chloro-complex at 325 cm^{-1}, is absent in the aquo-complex. Besides that, an additional broad band centered around 3450 cm^{-1} is observed in the aquo-complex due to the coordinated water molecule. [Ru(tpy)(pap)(H_2O)](ClO_4)$_2$ behaves as a 1 : 2 electrolyte in aqueous solution (Table 2), as expected. Electronic spectrum recorded in aqueous solution shows two intense metal-to-ligand charge-transfer transitions at 485 nm and 350 nm together with a weak *d-d* ($^1A_1 \rightarrow {}^1T_1$) transition at 650 nm (Table 2).

Electronic spectrum of the aquo-complex is characteristically different in acetonitrile solution indicating coordination of CH_3CN. To investigate and utilize this lability of the aquo ligand, the aquo-complex has been reacted with three monodentate *N*-donor ligands [viz. acetonitrile, 4-picoline (pic) and azide (N_3^-)] and three complexes of type $[Ru(tpy)(pap)(L')]^{n+}$ are obtained in decent yields. Compositions of these three complexes have been verified by their elemental analytical data (Table 2). All three complexes are diamagnetic and show sharp ^1H NMR signals in $CDCl_3$ solution. These spectra are mostly similar to the spectrum of $[Ru(tpy)(pap)Cl]^+$, the differences observed are due only to the new ligand L′. For example in the acetonitrile complex (L′ = CH_3CN), the acetonitrile methyl signal is observed at 2.78 ppm. Infrared spectra of the $[Ru(tpy)(pap)(L')]^{n+}$ species are complex in nature, as expected, and they are very similar to one another with minor differences due to the difference in L′. Conductivity measurements of the three $[Ru(tpy)(pap)(L')]^{n+}$ complexes in acetonitrile solution show that the L′ = CH_3CN and pic complexes (n = 2) are 1 : 2 electrolytes and L′ = N_3^- (n = 1) complex is a 1 : 1 electrolyte (Table 2), as expected. Electronic spectra of these complexes in acetonitrile solution show several intense absorptions in the visible region (Table 2) which are probably due to metal-to-ligand charge-transfer transitions.

Crystal structure of [Ru(tpy)(pap)(CH_3CN)] (ClO_4)$_2$

A perspective view of the complex cation is shown in Fig. 2 and selected bond distances and angles are listed in Table 3. The coordination sphere around ruthenium is N_6 with varying Ru—N distances. The tpy ligand is coordinated in the usual fashion with the central nitrogen (N3) being closest to ruthenium [2(i),13]. The pap ligand is bound to ruthenium with the azo nitrogen (N6) *trans* to the coordinated CH_3CN. The Ru—N6 (azo) distance is much shorter than the Ru—N4 (py) distance which is attributed to the better π-backbonding [$d\pi$(Ru) $\rightarrow \pi^*$(azo)] power of the azo function [14]. Accordingly the azo N6-N5 distance is longer than that in the uncoordinated ligand [14]. The CH_3CN molecule is coordinated in the usual manner [13] with slight deviation from linearity around C27 and N7. The other three [Ru(tpy)(pap)(L′)]$^{n+}$ complexes are assumed to have similar structure with the L′ replacing CH_3CN.

Cyclic voltammetric studies

Cyclic voltammograms of all the complexes except $[Ru(tpy)(pap)(H_2O)]^{2+}$ have been recorded in acetonitrile solution. Voltammetric data are presented in Table 4 and selected voltammograms are shown in Fig. 3. All these complexes show a reversible one-electron oxidation in the range 1.1–1.5 V (all poten-

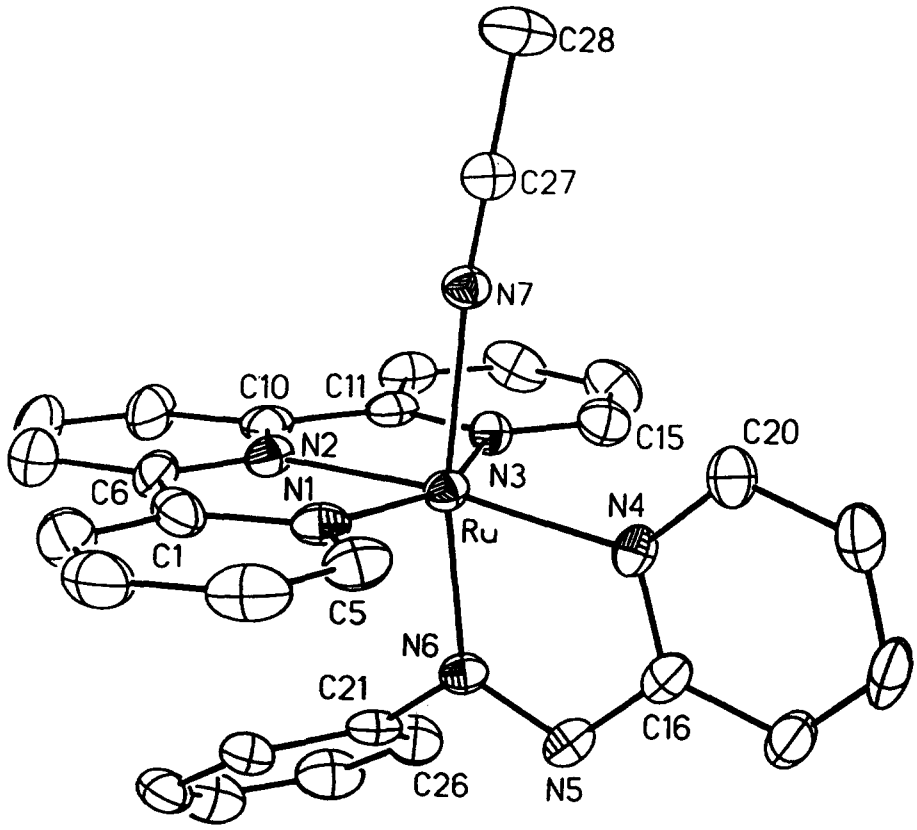

Fig. 2. An ORTEP plot and atom-labelling scheme for the cation of $[Ru(tpy)(pap)(CH_3CN)](ClO_4)_2$.

Table 4. Cyclic voltammetric data

Complex	Voltammetric data[a] Ru^{II}-Ru^{III}	E^0_{298}/V(ΔE_p/mV) Ligand reductions
$[Ru(tpy)(pap)Cl]ClO_4$	1.21(60)	−0.72(60); −1.21(100); −1.40(100)
$[Ru(tpy)(pap)(CH_3CN)](ClO_4)_2$	1.29(80)	−0.51(70); −1.29(60); −1.45(100)
$[Ru(tpy)(pap)(pic)](ClO_4)_2$	1.50(80)	−0.31(60); −1.04(80); −1.48(80)
$[Ru(tpy)(pap)(N_3)]ClO_4$	1.11(80)	−0.60(80); −1.27(80); −1.60(80)

[a] Condition: solvent, acetonitrile; supporting electrolyte, TEAP (0.1 M); working electrode, platinum; reference electrode, SCE; solute concentration, $\sim 10^{-3}$ M; $E^0_{298} = 0.5(E_{pa} + E_{pc})$, where E_{pa} and E_{pc} are anodic and cathodic peak potentials, $\Delta E_p = E_{pa} - E_{pc}$; scan rate, 50 mV s^{-1}.

tials are referenced to SCE) which is assigned to the ruthenium(II)-ruthenium(III) oxidation. The one-electron nature of this oxidation has been established by comparing its current height with that of standard ferrocene/ferrocenium couple under identical experimental condition. The ruthenium(II)-ruthenium(III) oxidation potential is ~400 mV more positive in $[Ru(tpy)(pap)Cl]^+$ than that in $[Ru(tpy)(bpy)Cl]^+$ [2(i)] which is due to the stronger π-acidity of pap than bpy. The ruthenium(II)-ruthenium(III) oxidation potential in $[Ru(tpy)(pap)Cl]^+$ appears to be the highest among the $[Ru(tpy)(N\text{-}N)Cl]^+$ complexes reported so far. The ruthenium(II)-ruthenium(III) oxidation potential in the other three $[Ru(tpy)(pap)(L')]^{n+}$ (L′ = CH_3CN, 4-picoline and N_3^-) complexes is observed to be sensitive to the nature of L′, as expected. For L′ = 4-picoline it is highest and lowest for L′ = N_3^- in this series.

Each complex shows three one-electron reductive responses on the negative side of SCE (Table 4). 2-(Phenylazo)pyridine is known to accept two electrons in its lowest unoccupied molecular orbital which is largely azo in nature [3(d)]. Polypyridine ligands are also capable of accepting electrons [13]. However it is

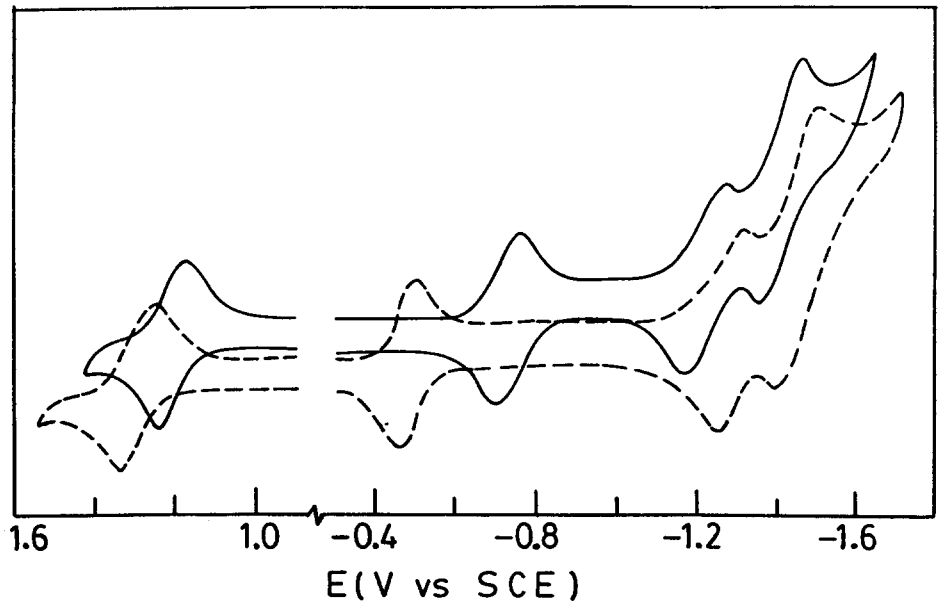

Fig. 3. Cyclic voltammograms of $[Ru(tpy)(pap)Cl]ClO_4$ (—) and $[Ru(tpy)(pap)(CH_3CN)](ClO_4)_2$ (- - -) in acetonitrile solution (0.1 M TEAP) at a scan rate of 50 mV s^{-1}. The solute concentration was $\sim 10^{-3}$ M.

well documented in literature that the azopyridine ligands are better acceptors and undergo easier reductions than the polypyridine ligands [3(d),15]. Hence the first two reductions observed in the $[Ru(tpy)(pap)(L')]^{n+}$ complexes are assigned to pap (eqn (1) and (2)) and the third one is assigned to tpy (eqn (3)).

$$[Ru^{II}(tpy)(pap)(L')]^{+/2+} + e^- \rightleftharpoons [Ru^{II}(tpy)(pap^{\bullet})(L')]^{0/+} \quad (1)$$

$$[Ru^{II}(tpy)(pap^{\bullet})(L')]^{0/+} + e^- \rightleftharpoons [Ru^{II}(tpy)(pap^{\bullet})(L')]^{-/0} \quad (2)$$

$$[Ru^{II}(tpy)(pap^{\bullet})L')]^{-/0} + e^- \rightleftharpoons [Ru^{II}(tpy^{\bullet})(pap^{\bullet})(L')]^{2-/-} \quad (3)$$

Cyclic voltammetry of $[Ru(tpy)(pap)(H_2O)]^{2+}$ in aqueous solution (pH 1–4) shows a single step two-electron oxidation (eqn 4). The two-electron nature of this oxidation has been established by comparing

$$[Ru^{II}(tpy)(pap)(H_2O)]^{2+} \rightarrow [Ru^{IV}(tpy)(pap)(O)]^{2+} + 2H^+ + 2e^- \quad (4)$$

its current height with that of $[Fe(CN)_6]^{4-}/[Fe(CN)_6]^{3-}$ couple under identical (pH = 7) experimental condition. This oxidation potential is sensitive to the pH of the solution and it decreases linearly with the increase in pH with a slope of 60 mV per unit pH. This, according to eqn 5

$$E = E^{\circ} - 0.059(m/n)pH \quad (5)$$

(where E = observed potential, E^0 = formal potential, m = number of proton transfer and n = number of electron transfer) [2(i)], indicates the loss of two protons along with two electrons. The formal potential of this oxidation, calculated from the intercept of the linear plot at pH = 0 (eqn 5), is found to be 0.82 V.

Synthesis of the oxo-ruthenium complex, $[Ru^{IV}(tpy)(pap)(O)]^{2+}$, has been attempted by chemical oxidation of the aquo-complex by Ce^{4+} in 1 M $HClO_4$. This reaction has been monitored spectrophotometrically and the results are shown in Fig. 4. Addition of a ten fold excess of Ce^{4+} to the aquo-complex initially brings about the expected oxidation (eqn 6), characterized by an instantaneous colour change from red to orange. Accordingly the intense absorption at 480 nm

$$[Ru^{II}(tpy)(pap)(H_2O)]^{2+} + 2Ce^{4+} \rightleftharpoons [Ru^{IV}(tpy)(pap)(=O)]^{2+} + 2Ce^{3+} + 2H^+ \quad (6)$$

(ε = 12 400 M^{-1} cm^{-1}) due to the aquo-complex disappears and a new absorption at 390 nm (ε = 11 700 M^{-1} cm^{-1}), characteristic of the oxo-complex, develops. However, with time this new absorption gradually disappears and the original absorption at 480 nm is restored slowly with an isosbestic point at 438 nm. This clearly indicates regeneration of the aquo-complex from the oxo-complex (eqn 7). This

$$[Ru^{II}(tpy)(pap)(O)]^{2+} + H_2O \rightarrow [Ru(tpy)(pap)(H_2O)]^{2+} + 1/2O_2 \quad (7)$$

reduction reaction is found to be pseudo-first-order

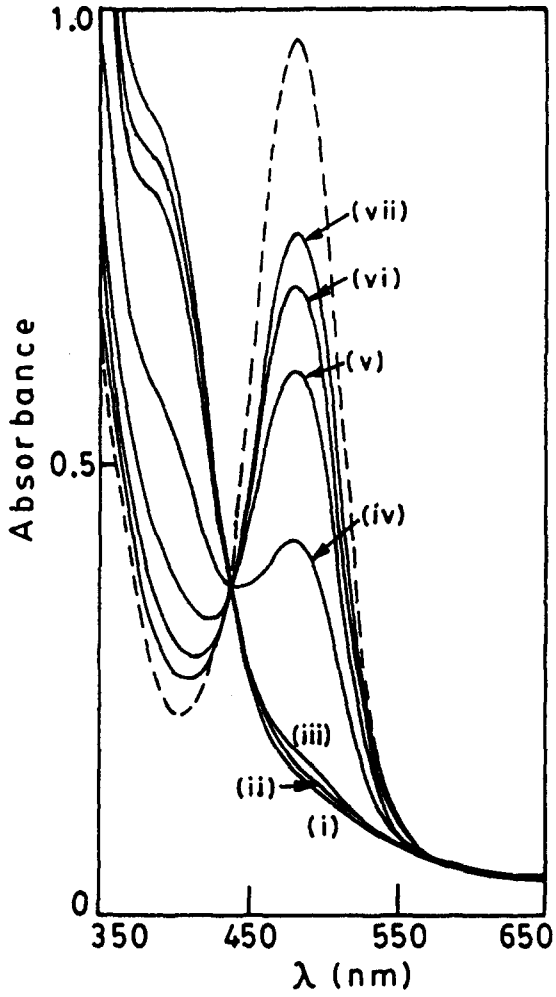

Fig. 4. Electronic spectrum of $[Ru(tpy)(pap)(H_2O)]^{2+}$ in 1 M $HClO_4$ (---) and the time dependent electronic spectra of $[Ru(tpy)(pap)(H_2O)]^{2+}$ with ten-fold excess of Ce^{4+} in 1 M $HClO_4$ (i–vii): (i) 5 min, (ii) 10 min, (iii) 15 min, (iv) 25 min, (v) 35 min, (vi) 45 min and (vii) 60 min.

with respect to the oxo-complex and the rate constant for this reaction has been found to be 4.6×10^{-4} sec^{-1}. If more Ce^{4+} is added to the reaction mixture, the same sequence of reactions is repeated. The net result is therefore the catalytic oxidation of water to dioxygen by $[Ru(tpy)(pap)(H_2O)]^{2+}$ in presence of Ce^{4+} (Scheme 2). The generation of dioxygen has been established by its characteristic cyclic voltammetric reduction at -0.3 V. Whether dioxygen is generated directly from water or via the formation of hydrogen peroxide is not known. Similar catalytic oxidation of water to dioxygen by aquo-complex of ruthenium is reported in the literature [16].

The pK_a of $[Ru(tpy)(pap)(H_2O)]^{2+}$, determined by pH-metric titration of the aquo-complex with standard alkali solution, is found to be 8.4. Comparison with the acidity of some similar $[Ru(tpy)(N\text{-}N)(H_2O)]^{2+}$ complexes (Table 5) shows that the *N-N* = pap complex is the strongest acid in this family, which is due to the better π-acidity of the pap than the other *N-N* ligands. The $[Ru(tpy)(pap)(H_2O)]^{2+}$ complex is the only example of its type which can catalyze the oxidation of water to dioxygen. The single-step two-electron two-proton transfer reaction (eqn 4) at high potential and the low pK_a of this aquo-complex are attributed to the observed catalytic activity. Utilization of the Ru^{II}—OH_2/Ru^{IV}=O couple for the catalytic oxidation of different organic substrates is under investigation.

(Received 28 April 1997; accepted 19 September 1997)

Abstract—The reaction of Ni(oxen) [oxen = *N*,*N*′-bis(2-aminoethyl)oxamido dianion], $NiCl_2$ and the disodium salt of EDTA (ethylenediamine tetraacetic acid) in 1 : 1 : 1 molar ratio gave the trinuclear complex $[Ni_3(oxen)_2(en)][ClO_4]_2$ (en = 1,2-ethylenediamine), where en came from the partial decomposition of oxen. The complex exhibits a curved Ni_3 metal arrangement with the angle Ni(2)—Ni(1)—Ni(2a) of 119.0°. The structure consists of a Ni_3^{II} unit with three nickel(II) atoms chelated and bridged by two oxamidato (oxen) groups in *cis*-conformation. The central nickel atom has a distorted octahedral geometry whereas the two on the sides have square-planar surroundings. The complex is paramagnetic and its magnetic behaviour can be interpreted by single-ion anisotropy with $D = 5.22\ cm^{-1}$ and $m_s = 0$ singlet ground state. © 1998 Elsevier Science Ltd

Keywords: crystal structure; magnetism; oxamidate; nickel(II) complex; trinuclear complex.

N,*N*′-disubstituted oxamides are multifunctional ligands which can chelate as well as bridge metal ions to form polynuclear and low-dimensional complexes. The versatility of these ligands (Scheme 1) is based on: (i) the variety of substituted derivatives, which can afford different numbers of chelate rings with different donor atoms [1], (ii) the bidentate character of the mononuclear compounds in *cis*-conformation which can chelate and bridge other metal ions to form polynuclear species [2–6] (Scheme 2), and (iii) the bisterdentate character of these ligands in the *trans*-conformation allowing the formation of *trans*-oxamidato-bridged metal dimers which can be linked by a second bridging ligand such as azide [7–9], cyanate [10], carboxylate [11–13], cyanide [14], pyrimidine [15,16], and 4,4′-bipyridine [15] to form 1D or 2D homo- or heterometallic complexes (Scheme 2).

The mononuclear nickel(II) compounds of oxamidates are diamagnetic due to the square-planar coordination with the strong-field amide N atoms [6], in contrast to the paramagnetic mononuclear copper(II) complexes, and polynuclear ones with oxamidate bridges which usually exhibit strong antiferromagnetic exchange interactions [7–17]. It is known that copper(II) complexes have been actively investigated due to the strong tendency of formation of *trans*-oxamidato-bridged copper(II) dimers which can be linked by a second bridging ligand to form low-dimensional magnetic coupling system [7–17], while the difficulty in the formation of nickel(II) analogues explains the lack of magnetic studies concerning these complexes. In an attempt to obtain oxamidato-bridged polynuclear [16] and low-dimensional nickel(II) complexes, a trinuclear nickel complex with *N*,*N*′-bis(2-aminoethyl)oxamide (H_2oxen) in *cis*-conformation was isolated and characterized by X-ray crystallography. We describe here the synthesis, structure together with its magnetic properties.

EXPERIMENTAL

Preparation

The ligand H_2oxen and its mononuclear nickel(II) compound Ni(oxen) were obtained according to the literature [18].

$[Ni_3(oxen)_2(en)][ClO_4]_2$. To an aqueous solution of Ni(oxen) (1.0 mmol, 0.23 g) was added an aqueous solution of $NiCl_2 \cdot 2H_2O$ (1.0 mmol, 0.24 g) with stirring for 5 min to yield a yellow-green solution. An aqueous solution of disodium salt of EDTA (1.0 mmol, 0.37 g) was then added to the above solution to give a green solution which after standing at room temperature for two weeks gave well shaped green crystals. Yield: 42%. Found: C, 21.50; H, 4.08; N, 17.90. Calc. for $C_{14}H_{32}Cl_2N_{10}Ni_3O_{12}$: C, 21.56; H, 4.13; N, 17.96 %. IR (KBr, cm^{-1}): 3360 (m), 3318

(m), 3289 (m), 3149 (w), 2952 (w), 2896 (w), 2853 (w), 1672 (s), 1647 (s), 1574 (m), 1454 (m), 1377 (m), 1328 (w), 1284 (w), 1089 (s), 1011 (m), 969 (w), 871 (w), 723 (w), 660 (w), 625 (w), 540 (w), 470 (w), 435 (w). UV [λ_{max}, nm; (ε, $L \cdot mol^{-1} \cdot cm^{-1}$)]: 412.9 (255.5), 325.0 (2855.5), 300.1 (4759.1).

Crystal structure determination

A single crystal with suitable dimensions was mounted on a glass fiber and data collection was performed on a Siemens P4 diffractometer by ω-scan technique using graphite-monochromated Mo-K_α radiation ($\lambda = 0.71073$ Å). The crystal data, data collection and refinement parameters are summarized in Table 1.

The coordinates of the metal atoms were determined by direct methods and the remaining non-hydrogen atoms were located from successive Fourier difference syntheses. The structure was refined by full-matrix least-squares techniques with anisotropic thermal parameters for all the non-hydrogen atoms. The positions of the hydrogen atoms were isotropically added to the structure factor calculations but not refined. All calculations were performed on an IBM PC/486 computer with the Siemens SHELXTL-P4/PC program package [19].

Physical measurements

IR spectrum was obtained from a Perkin–Elmer 577 spectrophotometer as KBr pellets. UV spectrum was recorded on a Beckman DU-8B spectrophotometer with the sample dissolved in DMF. Variable-temperature magnetic susceptibilities in the temperature range 1.6–260 K were measured on a model CF-1 superconducting extracting sample magnetometer at a magnetic field of 5.0 T with the powdered sample kept in capsule for weighing. The temperature was raised gradually from 1.6 to 260 K. Data were recorded at an applied field gradient $H(dH/dX)$ of 1.4×10^7 Oe × Oe/cm. An interval of 30 s was kept between data collections and each measurement took 10 s.

RESULTS AND DISCUSSION

In an attempt to synthesize oxamidato-bridged polynuclear or low-dimensional nickel(II) complexes, the reaction of Ni(oxen), $NiCl_2 \cdot 6H_2O$ and Na_2EDTA was carried out in an equimolar ratio, on the assumption that oxamidato-bridged nickel(II) dimers can be connected via the carboxylate groups of EDTA to yield polymeric structure, where the oxamidato frequently changes conformation from *cis* into *trans* as observed in Cu(II) complexes [7–17]. Unexpectedly, the product isolated was a trinuclear complex bridged only by *cis*-oxamidate without involving EDTA. The co-ligand en may have been formed through the partial decomposition of oxen as that found in the reaction of Ni(oxen) with KSCN [6]. Ni(oxen) is more easily decomposed in aqueous solution as compared with Cu(oxen), especially when other acidic or basic reagents are present in the reaction system. The presence of nickel chloride and EDTA in the system may exert some influence on the decomposition, but it is believed that Ni(oxen) is stable enough in the absence of other acidic or basic species. Undoubtedly, Cu(oxen) is much more stable than Ni(oxen) as when Cu^{2+} is introduced into the aqueous solution of Ni(oxen), Cu(oxen) is formed immediately as the solution turned into violet-red from the yellow colour of Ni(oxen). Moreover, the *cis* conformation of the oxamidato-bridged nickel(II) dimer was unchanged even if a second bridging ligand was added. This behaviour is different from that of the copper(II) species in which *cis*-oxamidato-bridged dimers are easily linked by a second ligand to form *trans*-oxamidato-bridged polynuclear [17,20,21] or polymeric [7–17] structure.

The molecular structure with atom-labelling scheme and the packing in the unit cell are depicted in Figs 1 and 2, respectively. Selected atomic distances and bond angles are presented in Table 2. The structure consists of one cation $[Ni_3(oxen)_2(en)]^{2+}$ and two anions ClO_4^-. The trinuclear cation, which possesses a C_2 axis through atom Ni(1) and the

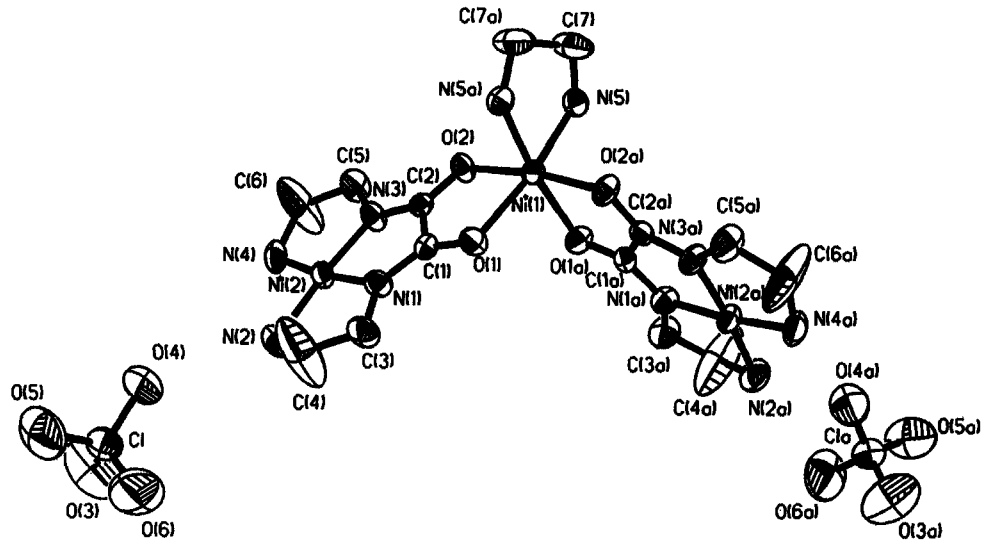

Fig. 1. Thermal ellipsoid plot (50%) showing the atom-labelling scheme of the complex $[Ni_3(oxen)_2(en)][ClO_4]_2$.

middle of the C(7)—C(7a) bond, can be viewed as a $Ni(en)^{2+}$ fragment, to which the two Ni(oxen) units with oxen in *cis* conformation are *cis* oriented. The arrangement of Ni_3 is curved with the angle of Ni(2)—Ni(1)—Ni(2a) being 119.0°, different from other Ni_3 complexes reported in literature with quasi-linear [22,23] or equilateral triangular [24,25] metal assembly.

The three metal centers exhibit alternating square-planar and octahedral coordination environments. The repeating asymmetric unit contains two nickel centers of non-identical geometries. Atom Ni(1) possesses a distorted octahedral environment with N_2O_4 core with the equatorial plane of Ni(1) defined by two N atoms of 1,2-ethenediamine and two O atoms from *cis*-oxen, while the axial coordination sites are occu-

pied by the other two O [O(2) and O(2a)] atoms from *cis*-oxen. Atom Ni(2) affords an approximately square-planar surroundings with N_4 donors [N(1), N(2), N(3) and N(4)] of amide and amine, and Ni(2) is displaced out of the plane by only 0.002 Å. There are only a few examples [22,26] of trinuclear nickel(II) complexes reported to date, in which three nickel(II) centers exhibit alternating square-planar and octahedral geometries.

The deprotonated oxen ligand in *cis* conformation forms one five-membered chelate ring for Ni(1) and three for Ni(2). The deprotonated amide N(1) and its symmetry-related N(1a) are sp^2-hybridized and the three atoms [Ni(2), C(1) and C(3)] around N(1) lie in a plane with the sum of the three angles C(1)—N(1)—Ni(2) [115.3(4)°], Ni(2)—N(1)—C(3) [116.6(4)°] and C(1)—N(1)—C(3) [128.1(5)°] close to 360°. The bridging group O(1)N(1)C(1)C(2)N(3)O(2) is planar within experimental error, with Ni(1) displaced by 0.045 Å and Ni(2) by 0.009 Å, from this plane. The dihedral angle between the five-membered chelate rings O(1)—C(1)—C(2)—O(2)—Ni(1) and O(1a)—C(1a)—C(2a)—O(2)—Ni(1a) is 88.0°. The Ni···Ni separation through the *cis*-oxamidate bridge is 5.25 Å.

The temperature-dependences of the molar magnetic susceptibility χ_M and of magnetic moment μ_{eff} are shown in Fig. 3. The susceptibility increases continuously down to the lowest measured temperature 1.6 K. However, fitting the experimental data with

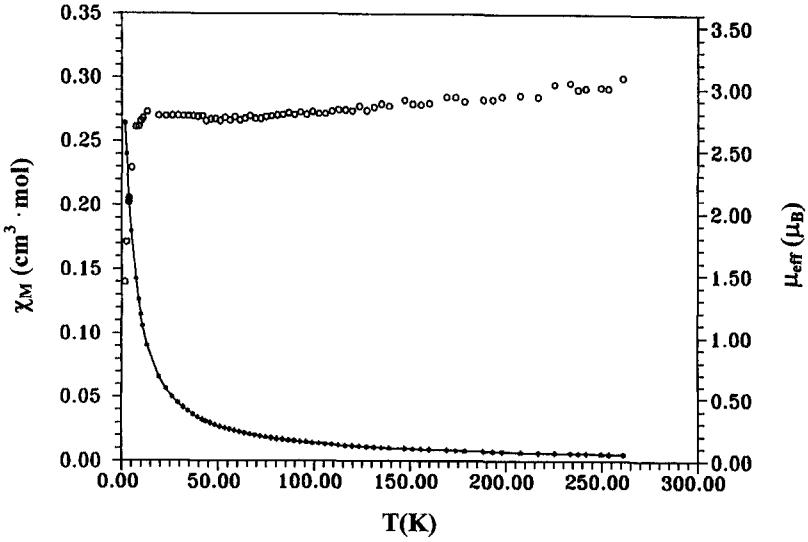

Fig. 3. Plots of the temperature dependences of the molar susceptibilities χ_M (*) and of the effective magnetic moments μ_{eff} (o) for the complex $[Ni_3(oxen)_2(en)][ClO_4]_2$. The solid line represent the best calculated curve.

the Curie–Weiss equation indicates that the deviation from Curie-like behaviour is obvious. The Curie–Weiss parameters are $C = 1.28\ cm^3 \cdot K \cdot mol^{-1}$ and $\theta = -3.2$ K. The value of the Curie constant shows the $g = 2.37$.

The effective magnetic moment μ_{eff} decreases slowly from 3.35 μ_B at 270 K to 3.04 μ_B at 8.7 K. Below this temperature, μ_{eff} drops rapidly to 2.58 μ_B at 4 K, and to 1.57 μ_B at 1.6 K. As shown in the trinuclear nickel(II) compound $[Ni_3(OC_6H_4S)_2(HOC_6H_4S)_2(PBu^n_3)_2]\cdot 2EtOH$ [22] with a similar structure, the slow decrease of μ_{eff} in the temperature range 270–9 K may originate from antiferromagnetic exchange and/or dipolar interaction between the nickel(II) ions, and the rapid decrease at very low temperature may result from single-ion anisotropy of octahedrally coordinated nickel(II) ion with the high-spin state S = 1. Hence, the experimental data can be fitted in terms of a model of single-ion zero-field splitting with the intermolecular exchange interaction in a molecular field approach. The expression of magnetic susceptibility [6,20] is shown as follows:

$$\chi_M = \frac{2Ng^2\mu_B^2}{3k(T-\theta)} \frac{2x^{-1} - 2e^{-x}x^{-1} + e^{-x}}{1 + 2e^{-x}} \qquad (1)$$

where $x = D/kT$. A least-squares fitting of the experimental data was carried out, allowing D, θ and g to vary. A set of the best fitting parameters gave $g = 2.37$, $D = 5.22\ cm^{-1}$ and $\theta = -1.45$ K with the deviation factor defined by $R = \Sigma(\chi_M^{obs} - \chi_M^{calc})^2/\Sigma(\chi_M^{obs})^2$ being 9.3×10^{-4}. A positive value of the parameter D means that the $m_s = 0$ state which lies below the $m_s = \pm 1$ state is the ground state.

(Received 22 April 1997; accepted 18 September 1997)

Abstract—A series of lanthanide polyoxoanions $[LnAs_4W_{40}O_{140}]^{25-}$ (Ln = La, Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy or Yb) have been prepared from the cryptate anion $[NaAs_4W_{40}O_{140}]^{27-}$ and lanthanides and characterized by elemental analysis, ^{183}W NMR, emission spectra. A number of evidences indicate that the lanthanides occupy the central site in the complexes. The title complexes display anti-tumor activity *in vitro* and *in vivo*.

Keywords: polyoxometalates; lanthanide polyoxoanions; heteropoly-tungstoarsenates; antitumor activity.

A crystallographic investigation [1] of $[NaAs_4W_{40}O_{140}]^{27-}$ anion revealed it to be a cryptate containing an encapsulated central sodium cation. The close match between the ionic radii of Na^+ and Ln^{3+} suggested that the latter cations might be similarly incorporated into the polyanion skeleton. Because of their higher charge the lanthanide complexes would be expected to be even more stable than that of Na^+. This paper describes the synthesis and characterization of the novel polyanions $[LnAs_4W_{40}O_{140}]^{25-}$ (Ln = La, Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy or Yb) and their biological activity.

EXPERIMENTAL

Materials

The heteropolymetallates employed $Na_{27}[NaAs_4W_{40}O_{140}]\cdot XH_2O$, $K_{27}[KAs_4W_{40}O_{140}]\cdot XH_2O$ and $[K_{21/19}[KAs_4W_{40}O_{140}M_2]\cdot XH_2O$ ($M = Mn^{2+}$, Ni^{2+}, Cu^{2+} or Co^{2+}) (abbreviated as $NaAs_4W_{40}$ and $KAs_4W_{40}M_2$, respectively) were prepared according to literature method [2] and were identified by vis spectra, IR spectra and polarography. Other chemicals were reagent grade.

Preparation of $K_{23}H_2[LaAs_4W_{40}O_{140}]\cdot 45H_2O$

$Na_{27}[NaAs_4W_{40}O_{140}]$ (25 g, 2.2 mmol) was dissolved in water (100 cm^3) and to this solution a solution of $La(NO_3)_3$ (2.2 mmol) in H_2O (10 cm^3) was added dropwise with vigorous stirring. After the addition was complete stirring was continued for a further 30 min and solid KCl (4.5 g) was then added. Upon standing at 0°C an oil formed, which subsequently crystallized. The product was dissolved in water, which was passed through a cation exchange column (Dowex 50, potassium form, 20 mesh, flow rate 0.5 $cm^3\ min^{-1}$). The eluate was concentrated, producing a precipitate which was filtered off and recrystallized from hot water twice. Yield of the crude product was about 60% and the pure product was 30% (based on $NaAs_4W_{40}$).

* Author to whom correspondence should be addressed.

The other lanthanide complexes were prepared using a similar procedure as described above.

Preparation of $K_{21}[LaAs_4W_{40}O_{140}M_2]\cdot XH_2O$ ($M = Mn^{2+}$, Ni^{2+}, Cu^{2+} or Co^{2+})

$K_{23}H_2[LaAs_4W_{40}O_{140}]\cdot 45H_2O$ (12 g, ca 1 mmol) was dissolved in H_2O (50 cm^3) and to this solution a solution of $M(NO_3)_{2/3}$ (2.0×10^{-3} mol) in H_2O (10 cm^3) was slowly added, whilst stirring vigorously. After the addition was complete the mixture was then stirred for a further 30 min. Solid KCl (2.5 g, 3.3×10^{-2} mol) was then added to the mixture and the resulting precipitate, removed by filtration, was then dissolved and precipitated twice, in order to obtain a sodium-free potassium salt. The latter was recrystallized from warm H_2O. Yield ca 75%.

Analytical procedure

Tungsten was weighed as WO_3 after precipitation by 8-hydrooxyquinoline and ignition at 750°C. The lanthanides were determined volumetrically (back-titration of an excess of EDTA with $ZnSO_4$). Arsenic(III) was titrated with I_2. Potassium and transition metals were determined by atomic absorption spectroscopy. The water content was determined by thermogravimetry.

Elemental analyses of part samples were performed by E+R Microanalytical Laboratory, Inc., Corona, NY.

Physical measurements

UV–vis spectra were recorded on a Beckman DU-8B spectrophotometer. IR spectra were obtained on an Alpha Centauri IR Spectrometer with KCl pellets. Emission spectra were recorded with a P-E MPE-6 spectrofluorometer. Atomic absorptions were recorded with a P-E 1030 atomic absorption spectrometer. ^{183}W NMR spectra were recorded at 12.50 MHz on a Bruker WM 300 spectrometer using quadraphase detection.

RESULTS AND DISCUSSION

Analytical results and formulations

Chemical analyses of the potassium salts of the title anions leads to the formulae indicated in Table 1, showing that the lanthanides give $[LnAs_4W_{40}O_{140}]^{25-}$ type of complexes with $[NaAs_4W_{40}O_{140}]^{27-}$, while addition of transition metal cations to $[LaAs_4W_{40}O_{140}]^{25-}$ gave complexes of the type $[LaAs_4W_{40}O_{140}M_2]^{n-}$. ($M = Mn^{2+}$, Ni^{2+}, Cu^{2+} or Co^{2+}).

The magnetic susceptibilities of the complexed lanthanides were determined by the Faraday method at room temperature and from these data the effective magnetic moments were calculated; $K_{23}H_2[LaAs_4W_{40}O_{140}]$ was used for diamagnetic correction. The results are given in Table 2. The observed magnetic moments are very close to those given by Van Vleck, showing that the lanthanides in the complexes remain in the +3 oxidation state.

Emission spectrum

An X-ray structural investigation of $(NH_4)_{23}[NH_4As_4W_{40}O_{140}(CoOH_2)_2]\cdot$ca $20H_2O$ [1] revealed that the polytungstate is constructed from four B-type AsW_9O_{33} units and four WO_6 octahedra. The unshared oxygens of the latter defined an eight-coordinate site (S_1) occupied by an ammonium ion and four five-coordinate sites (S_2), each defined by four oxygen atoms and an arsenic central unshared electron pair.

In order to throw light on the coordination site problem for La in the complex the emission spectrum of $K_{21}H_4[EuAs_4W_{40}O_{140}]$ was recorded. Figure 2 shows the spectrum of the solid sample at 295 K; it consists of $^5D_0$—^7F_J bands split by the local crystal field, whose transition frequencies are listed in Table 3. It can be seen that the emission spectrum of $EuAs_4W_{40}$ is very similar to those of $Eu(SiW_{11})_2$, $Eu(GeW_{11})_2$ and $Eu(AsW_{11})_2$ in terms of both the number of peaks and transition frequencies, showing that they have similar local site symmetry. According to Blasse *et al.* [3], in $K_{13}[Eu(SiW_{11}O_{39})_2]$ structure. Eu is coordinated by eight oxygen atoms forming a distorted archimedean antiprism, like U in $[U(GeW_{11}O_{39})_2]^{12-}$ [4]. By comparing the emission spectra of these complexes we conclude that the Eu^{3+} ion is coordinated by eight oxygen atoms in the $[EuAs_4W_{40}O_{140}]^{25-}$ complex, i.e. the Eu^{3+} ion occupies the S_1 site in the complex.

^{183}W NMR spectra

The previously determined structure of $(NH_4)_{23}[NH_4As_4W_{40}O_{140}(CoOH_2)_2]\cdot$ca $20H_2O$ [1] revealed that the cobalt-free heteropolyanion had D_{2d} symmetry, and therefore contained six structurally distinct types of tungsten atoms. The ^{183}W NMR spectra of the lanthanide derivatives consist of six lines and similar to that of the sodium derivatives (Table 4).

From the emission spectrum of $EuAs_4W_{40}$ and the ^{183}W NMR spectra of $LaAs_4W_{40}$ or $EuAs_4W_{40}$ we conclude that the structure of both $NaAs_4W_{40}$ and $LnAs_4W_{40}$ are isostructural and that Ln^{3+} ion replaces Na^+ ion in the structure. This result is consistent with that of the other cryptate polyanions $[NaSb_9W_{21}O_{86}]^{18-}$ or $[NaP_5W_{30}O_{110}]^{14-}$, in which the Na^+ can be substituted by the lanthanide cation [7,8]. This conclusion is reinforced by strong similarities between reaction stoichiometry, IR spectra, visible spectra and redox properties.

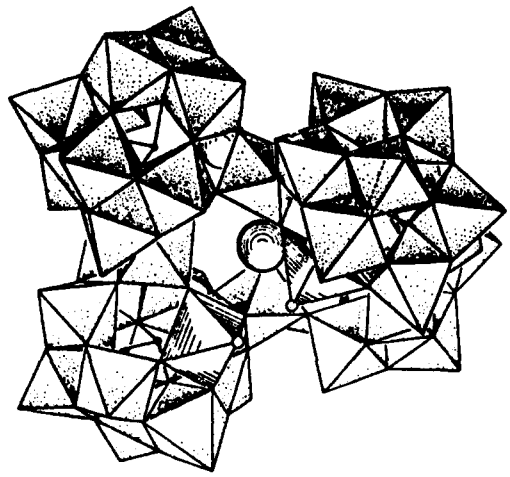

Fig. 1. $[(NH_4)As_4W_{40}O_{140}(CoOH_2)_2]^{23-}$. The aquocobalt ions, shown as shadowed square pyramide with small open circles (H_2O molecules), occupy two of the S_2 sites. A tightly bound ammonium ion (large circle) occupies the S_1 site at the center of the structure.

Reactions with transition metal ions

The stoichiometry for the $LaAs_4W_{40}$ and transition metal ion reactions were studied by conductivity measurements; the conductimetric titrations are shown in Fig. 3. Figure 3(a) shows an equivalent point for $M^{2+}/LaAs_4W_{40} = 2$(M = Co, Cu or Ni), corresponding to the reaction:

$$(LaAs_4W_{40}O_{140})^{25-} + 2M^{2+} \rightleftharpoons (LaAs_4W_{40}O_{140}M_2)^{21-}$$

Figure 3(b) shows an equivalent point for $Ag^+/LaAs_4W_{40}Co_2 = 2$. Since the visible spectrum of $LaAs_4W_{40}Co_2$ does not change during the titration, Ag^+ ions do not replace Co^{2+} ions, and therefore react according to:

Table 3. Transition frequencies in the emission spectra of some tungstoeuropates (nm)

(Received 9 June 1997; accepted 10 September 1997)

Abstract—Complexes of cobalt(II), nickel(II), copper(II), zinc(II) and cadmium(II) with the anion of the Schiff base 2-tosylamino(2′-pyridyl)aniline (HL) have been prepared by using an electrochemical procedure. These compounds were characterized by elemental analysis, IR, UV and NMR spectroscopy, and in the case of $[CoL_2]$ by X-ray diffraction methods. In this compound the cobalt(II) atom is in a distorted tetrahedral environment, each Schiff base anion acting as a bidentate ligand with the pyridine nitrogen atom un-coordinated. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: electrochemical synthesis; 2-tosylamino(2′-pyridyl)aniline; Schiff base complexes; crystal structure.

INTRODUCTION

This work continues studies of neutral complexes [1–11] of Schiff bases such as I and II where X = O, S, Se and Het = an heterocyclic ring. In these compounds, the pyridine nitrogen atom is un-coordinated although for the complexes of cobalt(II) [10] with ligand II (where X = S and Het = thiophene) and zinc(II) [11] with ligand I (where X = O) X-ray studies show a weak intramolecular secondary bond between the metallic atom and the $N_{pyridine}$ atoms.

We have now synthesized by an electrochemical procedure Co, Ni, Cu, Zn and Cd complexes containing the ligand L, derived from I with X = NHTs. The crystal structure of bis-[2-tosylamino(2′-pyridyl)anilinato]cobalt(II) is also reported.

EXPERIMENTAL

Materials

The metals (Ega Chemie) were used in the form of ca 2 × 2 cm plates. All solvents, 2-aminopyridine and other reagents except 2-tosylaminobenzaldehyde are commercially available and were used without further purification. 2-Tosylaminobenzaldehyde was prepared following a method previously described [12]. The Schiff base was prepared by addition of 10 ml of a solution of freshly distilled 2-aminopyridine (0.47 g, 0.005 mol) to a solution of 2-tosylaminobenzaldehyde (1.38 g, 0.005 mol) in 50 ml of dry toluene. The mix-

ture was heated in a Dean-Stark trap until the calculated amount of water was removed. After the reaction was completed, toluene was distilled off *in vacuo* on a water bath, and 30 ml of boiling methanol was added to the residue. The crystals precipitated upon cooling were filtered off, and washed twice with 5 ml of methanol. Recrystallized from a (1 : 1) methanol-benzene mixture, yielding light-yellow crystals with m.p. 112–113°. Anal: Calc. for $C_{19}H_{17}N_3O_2S$: C, 64.96; H, 4.84; N, 11.97; S, 9.12. Found: C, 64.71; H, 4.63; N, 11.89; S, 9.44.

Electrochemical synthesis

The electrochemical method used for the synthesis of the complexes was similar to that described by Tuck [13]. The cells were of the general type:

$$Pt_{(-)}/CH_3CN + HL/M_{(+)}$$

$$M = Co, Ni, Cu, Zn \text{ or } Cd$$

The solution was placed in a 100 ml tall form beaker, the anode was suspended into the solution by a platinum wire, and another platinum wire was used as the cathode. The ligand was dissolved in ca 50 ml of acetonitrile and a small amount of tetramethylammonium perchlorate (ca 10 mg) was added to the solution as the supporting electrolyte. **Caution!** Perchlorate salts solutions are potentially explosive. They should be handled in small quantity and with caution. As the electrolysis proceeded, hydrogen gas was evolved at the cathode. In the case of the zinc and cadmium complexes the yellow solids precipitated during the electrolysis; they were collected by filtration, washed twice with hot acetonitrile and diethylether and dried *in vacuo*. In the case of the nickel, cobalt and copper complexes, concentration of the reaction mixture by evaporation at room temperature was required to obtain solid products, which were purified as before. The crystals of $[CoL_2]$ obtained were suitable for X-ray diffraction studies. Details of the solution composition and the electrochemical conditions are given in Table 1.

Crystal structure determination

A yellow prismatic crystal of approximate dimensions $0.45 \times 0.20 \times 0.05$ mm was mounted on a glass fiber and used for data collection on a Nicolet P3 diffractometer. The monoclinic space group $P2_{1/c}$ was assumed due to extinctions observed. Data were collected at 293 K using Cu–K_α radiation ($\lambda = 1.54178$ Å) and the $\omega/2\theta$ scan technique. The data were corrected for Lorentz and polarization effects. An empirical absorption correction was made. The crystal data and a summary of the data collection and structure refinement for the compound are given in Table 2.

The structure was solved by direct methods [14] and refined on F^2 by full-matrix least squares method with unit weight and anisotropic displacement parameters for the non-hydrogen atoms. Hydrogen atoms were

located from geometrical considerations (C—H = 0.95 Å), and added to the structure factor calculations as fixed contributions (B_{iso} = 4.0 Å^2) and their positional parameters were not refined. The maximum difference density at final cycle 0.733; minimum −0.805. The crystal was strongly twinned, we managed to extract a correct lattice. That is the reason for the rather high R-factor and esd values. Two independent molecules differ in the region of p-tolylsulfonyl groups, one molecule has pseudosymmetry C_2, another is unsymmetrical.

Atomic scattering factors from International Tables for X-ray Crystallography [15]. Computations were performed on a DECMicroVAX 3500 computer. Atom positions, bond lengths and bond angles have been deposited as supplementary material.

RESULTS AND DISCUSSION

The anodic oxidation of the metal in an electrochemical cell containing a solution of the ligand LH in acetonitrile allows the isolation of compounds of composition $[ML_2]$, where L is the anion resulting of the deprotonation of the amide group of Schiff base.

For the cobalt, nickel, zinc and cadmium complexes, the electrochemical efficiency, defined as moles of metal dissolved per Faraday of charge, E_f, was close to 0.5 mol.F^{-1}, which is compatible with the following reaction scheme

$$\text{Cathode:}\quad 2HL + 2e^- \rightarrow H_{2(g)} + 2L^-$$

$$\text{Anode:}\quad 2L^- + M \rightarrow [ML_2] + 2e^-$$

$$M = Co, Ni, Zn \text{ or } Cd$$

For copper, E_f, was close to 1 mol.F^{-1}. This value shows that the anodic oxidation leads initially to Cu(I) species followed by further oxidation in solution to Cu(II).

$$\text{Cathode:}\quad HL + e^- \rightarrow 1/2H_{2(g)} + L^-$$

$$\text{Anode:}\quad L^- + Cu \rightarrow [CuL] + e^-$$

$$[CuL] + HL \rightarrow 1/2H_{2(g)} + [CuL_2]$$

The products obtained were characterized analitically and by IR, and NMR spectroscopies. The crystal structure of $[CoL_2]$ has been determined by X-ray diffraction.

Structure of $[CoL_2]$

The unit cell contains two crystallographically distinct but chemically equivalent molecules (molecules A and B). Figure 1 shows the structure of molecule A with the atom numbering system used. Selected bond distances and angles for both molecules are listed in Tables 4 and 5, respectively.

The complex consists of mononuclear units with a tetracoordinate cobalt atom bound to the nitrogen atoms of two bidentate monoanionic ligands. However, the two molecules A and B are slightly different and show some variation in bond distances and angles. Thus, A has N—Co—N angles in the range 93.6(5)–123.2(5)° and distances Co—N 1.981(13)–2.031(11) Å; in B the range of N—Co—N angles is 93.3(6)–131.9(6) and that of distances Co—N are 1.958(13)–1.999(13) Å. The tetrahedral environment of the cobalt atom is distorted due to the small bite required by N—Co—N = 93.0(6)–93.6(6)°, which also results in secondary deviation of the other perinuclear angles from the ideal values of 109°.

The Co—N_{imine} bond lengths [1.981(13), 2.000(12) Å] in A and [1.999(13) Å] in B are very similar between them, but they are shorter than the value found in another complex containing tetrahedral cobalt(II) and a Schiff base; for example, 2.066(8) Å in bis(tert-butylpyrrole-2-carboxaldimino)cobalt(II) [16]. However, the Co—N_{amide} bond lengths are substantially different in both molecules. Thus, whereas in the symmetric molecule B the Co—N_{amide} distance is 1.959(13) Å, in A those distances [1.982(12) and 2.031(11) Å] are different and larger than that of B.

The C—N bond length is in agreement with the value of 1.30 Å proposed for a C=N bond [17] and the pyridine nitrogen atom is not coordinated to the cobalt.

Spectroscopic and magnetic data

The ν(N—H) broad band of the free Schiff base in the 2800–3000 cm^{-1} region, characteristic of NH groups involved in intramolecular hydrogen bonds NH···N=C, is absent from the IR spectra of the complexes, consistent with the coordination of the

[a] Calculated values in parentheses.

deprotonated ligand. The band attributable to ν(C=N) shifts to lower frequencies in all the complexes as a consequence of coordination through the imine nitrogen. On the other hand, the pyridine ring stretching band observed between 1600 and 1400 cm^{-1} and the ring deformation bands which appear at about 600 and 400 cm^{-1} are shifted to higher frequencies in the complexes. This behaviour has been proposed as a probe of pyridine nitrogen atom coordination to the metal. However, the structural data for $[CoL_2]$ show that the pyridine is not bound to the metal. We believe that the observed shift can be due to the change in the conjugation between the heterocyclic ring and the rest of the ligand as a result of the coordination of the imine nitrogen to the metal. This behaviour has been previously observed in other similar systems. Therefore, these results show that the Schiff base coordinates through the imine and amide nitrogen atoms in all complexes, with a coordination number of four for the metals, in agreement with the structure of $[CoL_2]$ elucidated by X-ray diffraction.

The proton NMR data of the zinc and cadmium complexes are in accord with the above conclusions. The spectrum of the free ligand shows a peak at 12.5

ppm, assignable to the amide hydrogen, which is absent in the spectra of the complexes. The peak for the imine hydrogen atom (9.3 ppm in the free ligand) undergoes a shift towards higher field in the compounds, 9.1 ppm, and the peak for the 6-hydrogen of the pyridine ring is practically at the same field in the spectra of complexes and free ligand.

The solid state electronic spectrum in the near IR-visible region of the cobalt(II) complex, shows two *d-d* transition bands, one at 16,800–18,800 cm^{-1} and the other in the range 6600–8400 cm^{-1}; of the type expected for distorted tetrahedral cobalt(II) compounds [18]. The band in the visible region has been assigned to a $^4T_1(P) \leftarrow {}^4A_2$ (ν_3) transition, and the multicomponent one in the near IR region to $^4T_1(F) \leftarrow {}^4A_2$ (ν_2) transition. The $^4T_2 \leftarrow {}^4A_2$ (ν_1) tran-

sition has not been observed, but its position at ca 4520 cm^{-1} has been calculated as described by Lever. The values obtained for 10 Dq (4520 cm^{-1}), β (0.83) and B (804 cm^{-1}) are also in the range expected for pseudotetrahedral cobalt(II) complexes. The magnetic moment for this complex is 4.65 B.M. is in the range expected for tetrahedral cobalt(II) compounds.

The value of the magnetic moment of the copper complex (1.8 B.M.) corresponds to one unpaired electron. The solid state electronic spectrum shows two bands at around 10,700 and 18,100 cm^{-1}, and is consistent with an approximately square-planar stereochemistry. The band that appears at 27,000 cm^{-1} may be assigned to a charge transfer transition. The magnetic moment of the nickel(II) complex (3.18 B.M.) and its solid reflectance spectrum are consistent with a tetrahedral geometry for the complex. The bands observed at ca 8200 and 14,200 cm^{-1} are assigned to the two highest of the three expected spin allowed transitions, $^3A_2 \leftarrow {}^3T_1$ (ν_2) and $^3T_1(P) \leftarrow {}^3T_1(F)$ (ν_3), respectively.

Abstract—Copper-based transition metal complexes which perform single-strand scission of DNA in a site-specific manner have been designed. The complexes $Cu(dpg)^+$ and $Cu(dpgt)Cl^+$ (H(dpg) and (dpgt) represent bis(2-pyridylmethyl) derivatives of glycylglycine and glycylglycylglycine, respectively), were prepared in this study and its crystal structures were determined. We have found that $Cu(dpgt)Cl^+$ and $Cu(dpg)^+$ complexes convert supercoiled plasmid DNA into a mixture of nicked and linear forms in the presence of hydrogen peroxide, whereas related Cu(II) complexes, which lack a peptide group, produce complete degradation of DNA under the same experimental conditions. © 1998 Elsevier Science Ltd. Keywords: DNA cleavage; copper(II) and hydrogen peroxide; tripodal-ligands containing peptide group; supercoiled DNA.

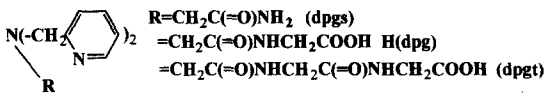
Reagents that bind sequence selectively to single- or double-strand DNA are of significant interest in molecular biology and medical chemistry as they may be developed into gene-targeted drugs for diagnostic and therapeutic application, and to provide tools for sequence specific modification of DNA [1,2]. Generally the metal complexes have at most a low level of specificity for different DNA sequence or structures, however one can transform them into probes for single sites on genomic DNA by tethering them to sequence-selective DNA binding moieties [3–5]. Recently copper(II) polypeptide complexes have been successfully used to functionalize sequence-specific DNA-binding molecules [6]. Functional metal complexes of polypeptides are an exciting area of research, especially in the generation of site-selective prove for DNA structure.

In this study we have prepared two copper(II) compounds with the ligands (H(dpg) and dpgt)) shown below, and determined the structures of the complexes, a polypeptide group is included in the ligand, (dpgt). We have examined the activities of these complexes for relaxation of supercoiled Form I DNA (pBR322) in the presence of hydrogen peroxide, in order to investigate the effect of the polypeptide group for site-specific degradation of DNA. Preparation and crystal structure of the $Cu(dpgs)ClClO_4$ was already reported by us [7].



EXPERIMENTAL

Materials

The ligands, H(dpg) and (dpgt) were obtained according to the general methods as described in the previous paper [8]. Copper(II) compounds were obtained by mixing $CuCl_2 \cdot 2H_2O$ and methanol solution of the ligand, and also by the addition of $NaClO_4$ or NH_4PF_6. Yields of the compounds of $H(dpg)/ClO_4$, $H(dpg)/PF_6$, and (dpgt) complexes are 25, 30 and 60%, respectively. $Cu(dpgt)ClClO_4 \cdot 0.5H_2O$; Calcd C, 37.42; H, 3.66; N, 12.12%. Found: C, 37.34; H,

3.49; N, 11.87%. Cu(dpg)PF_6; Calcd C, 36.83; H, 3.28; N, 10.74%. Found: C, 37.27; H, 3.46; N, 10.68%. Cu(dpg)$ClO_4 \cdot 3H_2O$; Calcd C, 36.23; H, 4.37; N, 10.56%. Found: C, 35.79; H, 4.10; N, 10.41%.

Crystal structure determination

The compounds used in the structure determination were recrystallized from a methanol/water mixture, and the crystal data of the compounds are listed in Table 1. X-ray diffraction intensities were measured up to $2\theta = 55^\circ$ using Mo–K_α radiation ($\lambda = 0.71073$ Å) on a Rigaku AFC-5 four-circle diffractometer, and absorption corrections were carried out by a numerical integration method. The structures were refined using CRYSTAN-GM software, and details have been deposited as Supplementary Materials.

Relaxation of pBR322 DNA

DNA (supercoiled pBR322) was purchased from Wako Chemicals. In a typical run, a copper(II) complex solution (4 μl of 0.1 mM solution), DNA (4 μl of 0.1 mg ml solution), Tris buffer (3 μl of 0.1 M solution, pH = 7.8) and hydrogen peroxide (4μl of 10 mM solution) were mixed and kept to stand for 1 h at 298 K. The extent of DNA cleavage was assessed by analysis on 0.9% agarose gel containing ethidium bromide [9]. The bands were photographed with Polaroid 667 film.

RESULTS AND DISCUSSION

Crystal structure

ORTEP drawing of two compounds illustrated in Figs 1 and 2, and the structural properties of Cu(dpgs)Cl^+ is also depicted in Fig. 3 [7]. In the Cu(dpgs)Cl^+ complex, the geometry around the copper(II) ion is that of a tetragonal pyramid with the oxygen atom of the amide-group at the apical position. Three nitrogen atoms (two pyridine nitrogen and one aliphatic amine) and the chloride ion are located in the basal plane of the complex. The structural properties of the Cu(dpgt)Cl^+ and Cu(dpg)$^+$ are essentially the same as those reported for the (dpgs)-complex, as shown in Figs 1–2 and Table 2, except for the polymeric structure of the (dpg)-complex in the solid state; in this case, carboxylic oxygen at the terminal peptide group (O(4), see Fig. 1) is also coordinating another copper(II) ion, forming a polymeric structure. However, the conductance data in the water solution indicates that this complex exists as a monomeric one in an aqueous solution, maybe Cu(dpg)$(H_2O)^+$ as illustrated below.

DNA scission chemistry

In this study, the copper(II) complex with (tpa), Cu(tpa)Cl^+ was also examined for DNA degradation, where (tpa) represents tris(2-pyridyl-methyl)amine. As shown in Fig. 4, it is clear that the degradation of

pBR322 DNA is highly dependent on the structure and concentration of the copper(II) compounds used.

In the concentration range of 0.5–1.0 mM of the copper(II) ion, all the complexes including (tpa) and compounds prepared in this study are competent to effect DNA strand scission. At 0.1 mM copper(II) ion concentration, the (dpgs)-complex gives Form II DNA, nicked from (relaxed circular) [9] (see lane 5), the (tpa)-complex gave both the Form II and Form III DNA (linear duplex) [9] (see lane 7 in Fig. 4), but the other two (dpg) and (dpgt)-compounds gave no effect for degradation (see lane 3, for example). At 0.5 mM, the (dpgs)-complex exhibited high efficiency for degradation, producing fragments with no supercoiled, nicked, and linear DNA (see lane 11). However, compounds with (dpg) and (dpgt) converted supercoiled plasmid to a mixture of nicked and linear DNA at 0.5 mM concentration, and even at 1.0 mM concentration (see lanes 9, 13, 15).

It is well known that metal complexes bind to DNA through both covalent and non-covalent modes. In the present cases, all the used copper(II) complexes with cationic charge may bind to the sugar-phosphate backbone electrostatically [10]. The high efficiency of DNA cleavage by the compounds with (dpgs) and (tpa) may indicate that these complexes bind to DNA with higher affinity than those of the (dpg) or (dpgt) complexes, however the details on this problem is unclear at present. Alternatively, it may be likely that the complexes with (dpg) and (dpgt) may bind to DNA in site-specific manner due to the presence of peptide group in the ligand.

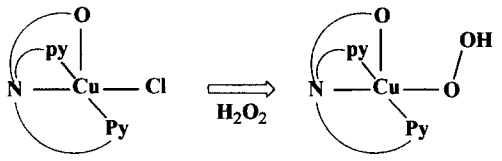
Active species for strand scission

In the previous paper, we have reported that a peroxide adduct formation occurs in the solution containing a copper(II) complex and hydrogen peroxide, as shown below [7];



Copper, in the presence of oxygen donor species, is thought to be able to form different oxidative intermediates, depending on the specific complex and conditions. A nondiffusable copper-oxene intermediate has been invoked in some cleavage reactions, [11] while for others, Fenton-type chemistry, which involves release of diffusable hydroxyl radical, has been suggested [5]. The formation of the hydroxyl radical ($OH^\bullet$) has been investigated by the use of spin-trapping reagents, such as DMPO [13], however, its validity has been doubted by several authors [14–16]. Thus, at present it seems most likely that the most reliable method to produce and to detect $OH^\bullet$ should be the X-ray irradiation of N_2O-saturated aqueous solution, and evaluation of formation of 8-hydroxy derivative of guanosine or 2′-deoxyguanosine in the solution [17]. We already reported that formation of 8-hydroxydeoxyguanosine occurs in the solution of copper(II) chloride/hydrogen peroxide system in which no degradation of DNA was detected, however, little formation of 8-hydroxydeoxyguanosine was detected in the solutions of $Cu(tpa)Cl^+$/hydrogen peroxide and other copper(II) chelates used in this study [12]. We could not detect the formation of PBN—OH in the $Cu(tpa)Cl^+$ and $Cu(dpgs)Cl^+$/hydrogen peroxide solutions containing PBN(α-phenyl-N-*t*-butylnitrone), one of the

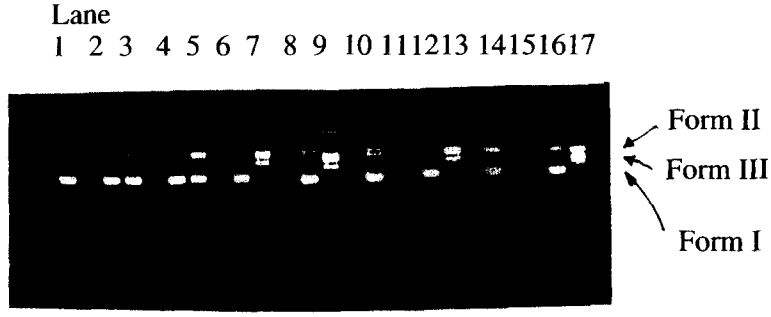


Fig. 4. Relaxation of pBR322 DNA by copper(II) complexes in the presence of hydrogen peroxide. spin-trapping reagents [18]. Based on the above discussion, and also on the fact that the copper(II) complexes with (tpa) or (dpgs) have not activity for decomposition of hydrogen peroxide [7,19], i.e., a redox reaction between a copper(II) complex and hydrogen peroxide does not occur, it seems reasonable to assume that an active species for DNA cleavage is neither a hydroxy radical nor a copper-oxene species in the present cases. Above discussion may support the idea that an active species for DNA strand scission in the present cases should be a peroxide adduct as shown above.

Thus, we would like to propose that DNA strand scission by the copper(II) complexes should proceed via formation of a peroxide intermediate, as shown below; the peroxide adduct attacks the carbon atom of C4′-position, and activation of the peroxide ion in the intermediate is greatly enhanced as suggested [8], and this may induce degradation of the sugar ring, leading to facile strand scission of the DNA. Above proposal may be supported by the facts that (1) the copper(II)-peroxide adduct with end-on coordination mode exhibits an electrophilic nature, tending to interact with an organic moiety [7,8,20], and (2) the tetrahydrofuran-ring can facilely interact with a metal-peroxide ion [21,22].

(Received 6 June 1997; accepted 20 August 1997)

Abstract—Two new polymeric mixed ligand complexes of copper(II) azide with 2-chloropyridine (**1**) and 3-benzoylpyridine (**3**) have been prepared and characterized by crystallographic and spectroscopic methods. The 1:1 complex of 2-chloropyridine features penta-coordinate copper centers and two $\mu(1,1)$ bridging azido ligands forming chains of polyhedra along the *a*-axis of the unit cell. In the 1:2 complex, **2**, two copper atoms are located at different inversion centers. The coordination geometries of both copper atoms may be described as distorted tetragonal bipyramids and both azides serve as $\mu(1,3)$ bridging ligands giving rise to chains of polyhedra. The IR and Raman spectra are reported and vibrational bands of diagnostic values compared with those of parent ligands and correlated with the structures of the complexes. The solid and solution electronic spectra of **1** and **2** display strong absorptions due to $N_3^- \rightarrow Cu^{II}$ charge transfer transitions. The EPR spectra of powder samples and DMF solutions are recorded at both room temperature and 77 K. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: copper(II) azide complexes; 2-chloropyridine; 3-benzoylpyridine; crystal structure; molecular vibrations; EPR spectra.

Copper(II) azide systems have been of considerable interest due to the broad range of their structural and magnetic properties [1]. In particular, azide can act as a bridging ligand giving rise to ferromagnetic exchange interactions and antiferromagnetic ones, depending upon its mode of coordination; $\mu(1,1)$ and $\mu(1,3)$, the Cu—N_3—Cu angle as well as the geometry of the copper center [2–8]. The azido ligand, therefore represents a good choice for the design of new magnetic systems. For this ligand, it is also important to note the great versatility in the coordination modes giving rise to high nuclearity systems [9, 10].

It has been reported that the interaction between copper(II) azide and pyridine produces different modifications of a polymeric 1:2 complex and the products described as brown, brownish-green or green [11–13]. X-ray structure determinations, however, have shown that while the green and brownish-green modifications contain distorted octahedral copper(II) atoms, the two azide groups are crystallographically distinct with different structural environments. In the green form of the 1:2 complex, one azide ligand is monodentate whereas the other coordinates asymmetrically to three different metal centers [14]. In the brownish-green form, each pair of copper atoms are simultaneously bridged by $\mu(1,1)$ and $\mu(1,3)$ azido ligands [15]. These different modifications reflect the versatile nature of the azido ligand. Such versatility manifests itself in the substantial array of copper(II)

azide complexes of monosubstituted pyridine ligands that have been prepared, structurally characterized and shown to have a wide variety of stoichiometries, solid state stereochemistries and varying degrees of oligomerization [15–20]. In this paper we report the synthesis and characterization of two new polymeric complexes of copper(II) azide with 2-chloropyridine and 3-benzoylpyridine (hereafter abbreviated as 2-Clpy and 3-Bzpy, respectively), in order to appraise the influence of the substituent in the pyridine ring upon the mode of bonding of the azido ligand, as elucidated by X-ray crystallographic and spectroscopic methods.

EXPERIMENTAL

2-Chloropyridine and 3-benzoylpyridine were purchased from Aldrich company and other chemicals were of analytical grade quality.

Preparation of polymeric $[Cu(2\text{-chloropyridine})(N_3)_2]_n$ *complex* (**1**)

Copper(II) nitrate trihydrate (0.72 g, 3 mmol) dissolved in acetone (ca 40 cm^3) and 2-Clpy (1.13 g, 10 mmol) were mixed together, followed by addition of an aqueous solution of NaN_3 (0.52 g, 8 mmol). The green solution mixture was boiled for about 15 min and filtered. The filtrate was allowed to stand over three weeks in an open place, after which it separated into two layers. This final mixture was further allowed to stand over two months to produce black needles like crystals of the complex. Yield: 30%. Found: C, 23.1; H, 1.6; N, 37.4; Cu, 24.1. Calc.: C, 23.0; H, 1.55; N, 37.5; Cu, 24.3%.

Preparation of polymeric $[Cu(3\text{-benzoylpyridine})_2(N_3)_2]_n$ *complex* (**2**)

Copper(II) nitrate trihydrate (0.72 g, 3 mmol) and 3-benzoylpyridine (1.83 g, 10 mmol) were mixed together in 50 cm^3 acetone. To this mixture, an aqueous solution (ca 5 cm^3) of NaN_3 (0.48 g, 7.5 mmol) was added with continuous stirring. The green precipitate was filtered off and then dissolved in DMF. The final solution was filtered off and the filtrate boiled for ca 15 min, and allowed to stand in a refrigerator for ca two months until black crystals of the complex separated. Yield: 50%. Found: C, 56.3; H, 3.7; N, 21.6; Cu, 12.1. Calc.: C, 56.1; H, 3.5; N, 21.8; Cu, 12.4%.

Physical measurements

Raman spectra were obtained using a Perkin–Elmer System 2000 NIR FT-Raman spectrometer. Both compounds are very sensitive to the power of the laser beam. Below 100 mW, either no spectrum or a noisy spectrum obtained whereas above 100 mW the sample decomposed gradually and immediately at 200 mW. In order to obtain good spectrum the sample was ground with KBr and measured at a power of 200 mW. The experimental procedures and instruments used for other measurements are as described previously [20].

X-ray crystallography

A modified STOE four circle diffractometer was used for single crystal X-ray measurements. Orientation matrix and lattice parameters were obtained by least-squares refinement of the diffraction data from 28 (compound **1**) and 36 (compound **2**) reflections in the 2θ range 10–27°. Data were collected at 295(2) K using graphite crystal monochromatized Mo–K_α radiation ($\lambda = 0.71069$ Å) and the ω-scan technique. The intensities were corrected for Lorentz-polarization effects, intensity decay and for absorption [21]. Crystallographic data are collected in Table 1.

The structures were solved by heavy atom methods and subsequent Fourier analyses. Anisotropic displacement parameters were applied to the non-hydrogen atoms in full-matrix least-squares refinements based on F^2. The hydrogen atoms were assigned with common isotropic displacement factors and included in the final refinement cycles by use of geometrical restraints. Analytical expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated. The programs DIFABS [21] and SHELXTX/PC [22], were used for computations. Selected bond distances and angles are given in Tables 2 and 3. Positional parameters, anisotropic displacement parameters, hydrogen atom coordinates, a full list of bond lengths and angles and F_o/F_c tables have been deposited as supplementary material.

Caution: Both compounds are very sensitive to grinding and explode upon heating and friction.

RESULTS AND DISCUSSION

The reaction of copper(II) ions and 2-chloropyridine and 3-benzoylpyridine in presence of azide ions in acetone media afforded the title complexes. In case of 2-Clpy, only 1 : 1 complex is formed whatever the ratio of the reactants. Indeed, all other 2-substituted pyridines, e.g. 2-picoline [17], 2-bromopyridine [19] and 2-aminopyridine [6], form only 1 : 1 complexes with copper(II) azide indicating that the steric hindrance of the substituent group in position 2 in pyridine ring plays the important role in the synthesis of their copper(II) azido complexes. Both complexes (**1**) and (**2**) are insoluble in many non-polar solvents as well some polar solvents, e.g. acetone, chloroform, methyl and ethyl alcohols indicating their polymeric nature. They are, however, quite soluble in DMSO and DMF giving rise to non-conducting solutions, although the color of complex (**2**) changes

to brown immediately in both solvents. The color change from green to brown in DMF and DMSO could be associated with the partial reduction of Cu(II) to Cu(I) leading to mixed-valence compounds which are well known to exhibit such brownish color.

Structure

Figures 1 and 2 illustrate the principle structural features of complex (**1**) for which selected bond lengths and bond angles are collected in Table 2. In the structure, $\mu(1,1)$ azido groups [N(11)—N(12)—N(13) and N(11a)—N(12a)—N(13a)] bridge a pair of copper centers, Cu(1) and Cu(1a), whereas $\mu(1,1)$ azido ligands [N(21)—N(22)—N(23) and N(21a)—N(22a)—N(23a)] bridge the pair of copper atoms, Cu(1) and Cu(1b), giving rise to chains of polyhedra along the *a*-axis of the unit cell. Each pair of copper centers is related by an inversion center forming a planar Cu_2N_2 ring. The coordination of copper(II) atom by 2-Clpy and azido ligands may be described as distorted trigonal bipyramid with N(21) and N(11a) at the axial sites and N(1), N(11) and N(21b) in the equatorial positions.

It is of interest to compare the structure of **1** with other 1 : 1 mixed ligand complexes of copper(II) azide with 2-substituted pyridines; 2-bromopyridine (**3**) [19], 2-methylpyridine (**4**) [17], 2-aminopyridine (monodentate and accompanied by H_2O) (**5**) [6] and 2-benzoylpyridine (**6**) [18]. Common structural features of this series of complexes are five coordination about the copper atom (trigonal bipyramidal in **1** and square pyramidal in the others) and a planar Cu_2N_2 ring. The dimeric nature of **6** arises from the fact that the three coordination sites around each metal atom are taken up by a terminal azide and a chelating bidentate 2-Bzpy molecule. Complex **5** is likewise binuclear, but the structure is further modified by the formation of intramolecular O···H—N (amine) acceptor and intermolecular O—H···N (terminal azide) donor hydrogen bonds [18]. The organic ligands is mondentate in **1**, **3** and **4**, and unsaturation in the copper(II) coordination sphere is satisfied by converting the remaining azide from terminal to $\mu(1,1)$ in **1** and **3** and $\mu(1,3)$ in **4**, thereby resulting in the formation of polymeric chains. The Cu—N(L) distance reported in these complexes is 2.076(8), 1.992(2) and 2.001(2) for **3**, **4** and **5**, respectively, and therefore it increases in the order 2-Mepy < 2-ampy < 2-Clpy < 2-Brpy.

A plot and atom numbering scheme of complex (**2**) are given in Fig. 3. In the asymmetric unit, two copper atoms are located at different inversion centers. Each

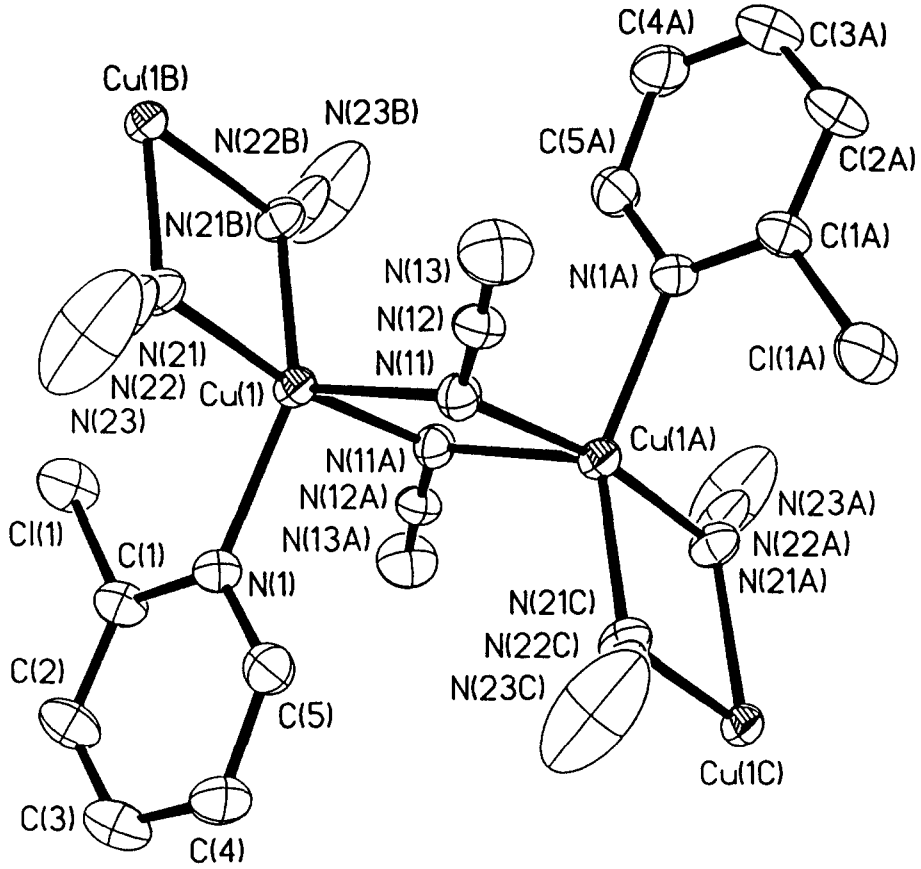

Fig. 1. Molecular geometry and atom labelling scheme of $[Cu(2\text{-chloropyridine})(N_3)_2]_n$, **1**. Hydrogen atoms are omitted.

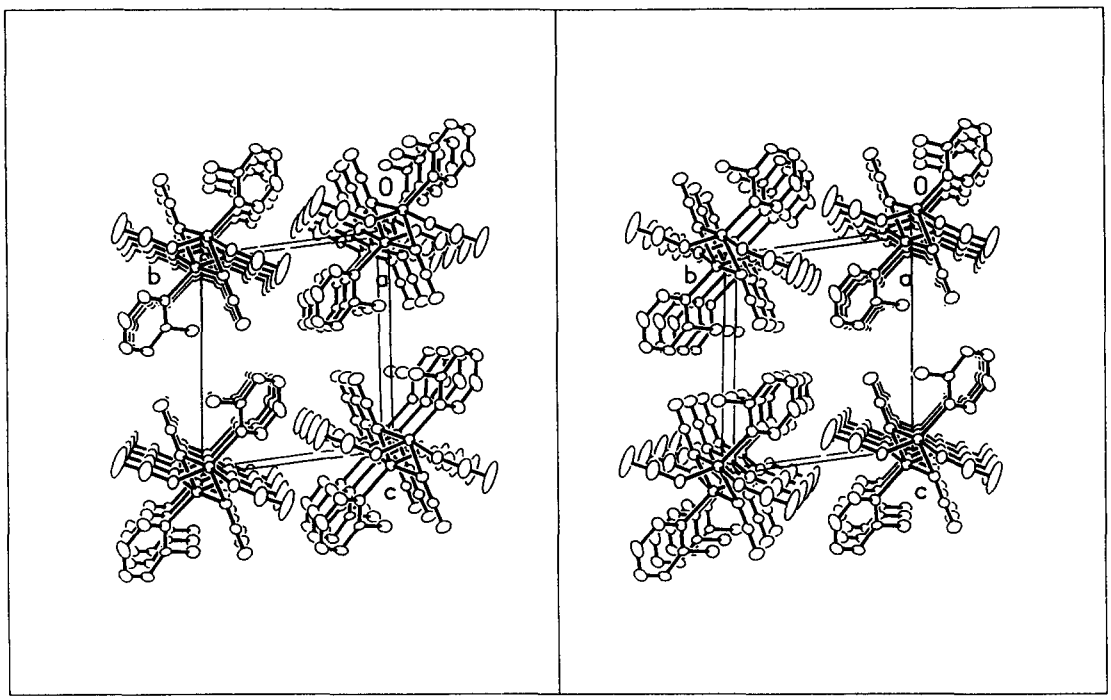

Fig. 2. Packing plot (stereo) of $[Cu(2\text{-chloropyridine})(N_3)_2]_n$, **1**, viewed along the *a*-axis of the unit cell.

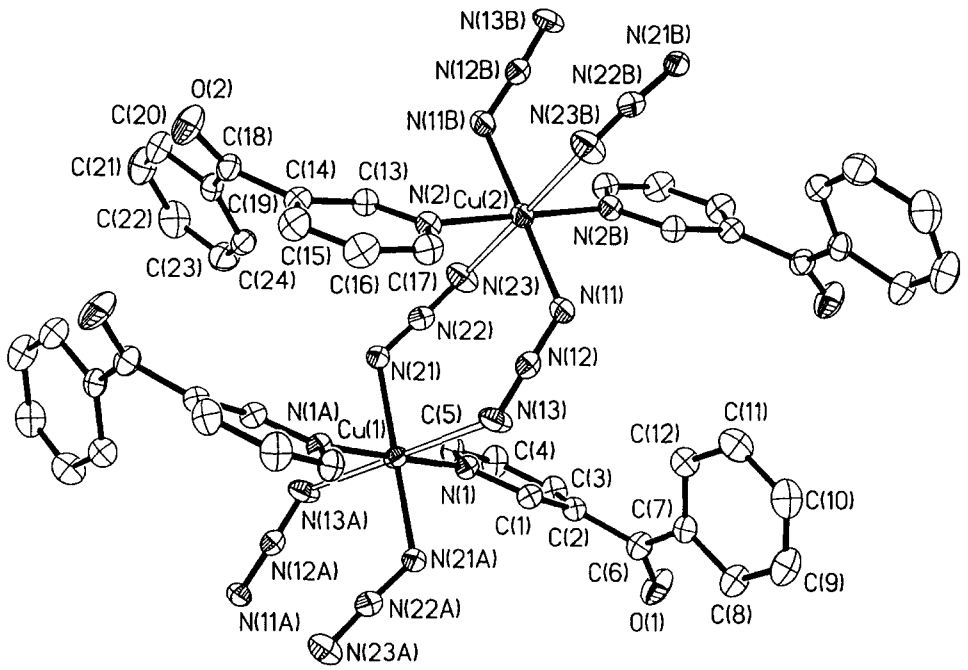

Fig. 3. Molecular geometry and atom labelling scheme of $[Cu(3\text{-benzoylpyridine})_2(N_3)_2]_n$, **2**. Hydrogen atoms are omitted for clarity.

copper center, however, is coordinated by two organic ligands and the end nitrogens of two di-$\mu(1,3)$ bridging azido groups. The coordination polyhedra of both copper atoms may be described as distorted tetragonal bipyramids with N(13) and N(13a) in case of Cu(1) and N(23) and N(23a) in case of Cu(2) at the axial site forming chains of polyhedra (Fig. 4). The Cu—$N(N_3)$ bond lengths vary from 1.981(4) to 2.552(4) Å, and the Cu—N(3-Bzpy) distances are 2.007(3) and 2.042(3) Å.

The di-$\mu(1,3)$ mode of azide bridging has previously been found in the discrete dinuclear complexes $[Cu(PPh_3)_2(N_3)_2]$ [23], $[Ni_2(tren)_2(N_3)_2]^{2+}$ where tren = tris(2-aminoethyl)amine [24], $[Cu(Me_4en)_2(N_3)_2]$ [25] and polymeric complex $[Cd(py)_2(N_3)_2]_n$ [26]. The structure of the title complex (**2**) differs from those of manganese(II) complexes of the same general formula $[MnL_2(N_3)_2]_n$ for L = ethyl isonicotinate [27], 3-acetyl pyridine [28], 4-cyanopyridine [28] and ethyl nicotinate [29]. In all of these complexes the manganese atom is located in a *trans*-octahedral environment and bonded to four azido ligands and two axial organic molecules. The four azido ligands behave differently; two azido groups are coordinated in the $\mu(1,1)$ fashion between two manganese atoms giving rise to a planar Mn_2N_2 units, and the other two azides bonded in the $\mu(1,3)$ mode.

The Cu···Cu distances of 3.112(2) and 3.233(2) within the cyclic Cu_2N_2 units in structure **1**, which are comparable with those found in the structure of $[Cu(2\text{-methyl-5-ethylpyridine})(N_3)_2]_n$ (3.131(1) and 3.236(1) Å) [30], are shorter than corresponding values found in $[Cu(3\text{-pic})(N_3)_2]_n$ (3.546(2) Å) [6] and $CuL'(N_3)_2$ (3.78 Å) L' = (2-aminoethyl)pyridine) [31], but longer than those found in $[Cu(py—NO)—(N_3)_2]_n$ (3.07 Å) [32]. The Cu···Cu distance of 5.092(2) Å, found in complex (**2**) within the eight-membered ring $Cu_2(N_3)_2$, are comparable with corresponding values of 5.004(2) Å and 5.227(7) Å reported in $[Cu(tmen)(N_3)_2]_2$ (tmen = tetramethylenediamine) [25] and $[Cu_2(Me_5\text{-dien})_2(N_3)_2]^{2+}$ [33], respectively.

IR and Raman spectra

The IR and Raman spectral results of the complexes are collected in Table 4. Raman spectra of good quality were obtained for free ligands and complex (**2**) only (see the experimental section). The IR spectrum of **1** exhibits two bands due to the $\nu_{as}(N_3)$ mode which are consistent with the presence of two azides of different degrees of asymmetry. Although the positions of these bands are not consistent with the $\nu_{as}(N_3)$ vs δd (δd is the difference between N—N distances in an azide group) relationship reported earlier [34], the higher frequency band may be assigned to the N(21)—N(22)—N(23) azide with δd of 0.089 Å whereas the 2020 cm^{-1} is related to the N(11)—N(12)—N(13) ligand with δd of 0.045 Å. The asymmetric nature of both azido ligands is strongly evidenced by the appearance of the $\nu_s(N_3)$ vibration bands in the range 1350–1270 cm^{-1}. For a symmetrical N_3^- ion, the ν_s mode (ν_1) is not IR active but

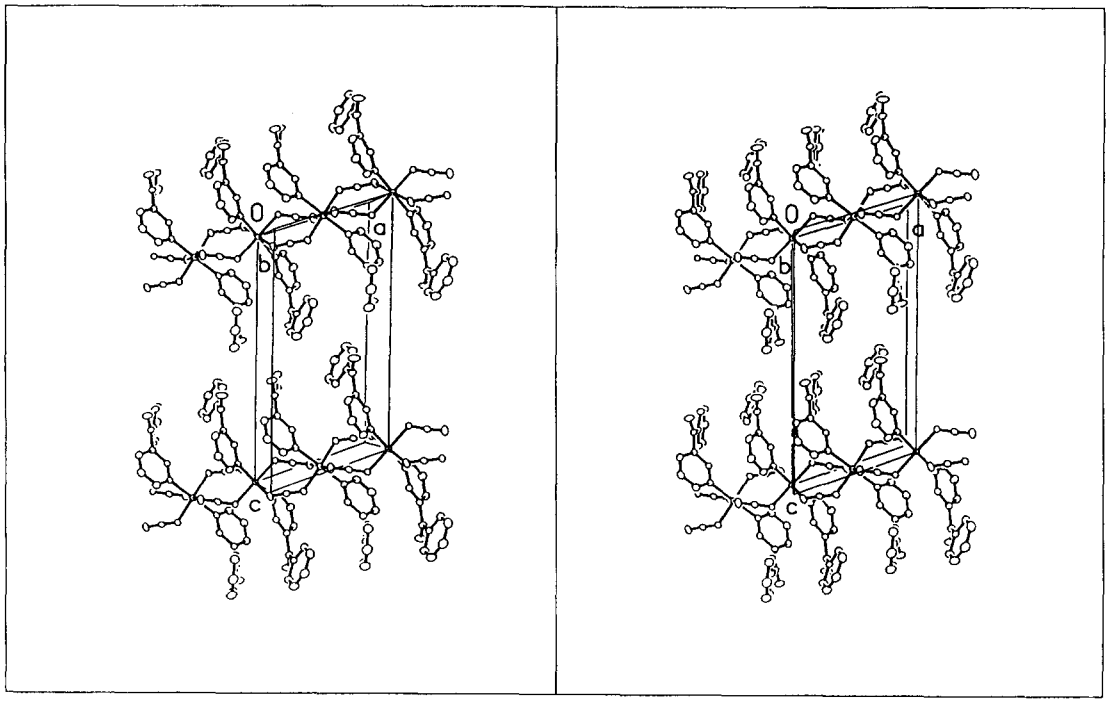

Fig. 4. Packing plot (stereo) of $[Cu(3\text{-benzoylpyridine})_2(N_3)_2]_n$, **2**, viewed along the *b*-axis of the unit cell.

Raman active, whereas $\nu_{as}(N_3)$ (ν_3) and $\delta(N_3)$ (ν_3) modes are IR active and Raman inactive. In accordance with this, the IR spectrum of **2** shows a very strong band at 2030 cm^{-1} due to ν_{as} and no band due to ν_s could be located in the range 1350–1270 cm^{-1}. This result strongly supports the symmetrical nature of both azido ligands in **2**. Other support comes from the Raman spectrum of **2**, which exhibits only a medium peak at 1327 cm^{-1} due to ν_s. The disappearance of the ν_{as} (N_3) and $\delta(N_3)$ vibration peaks suggests that the mutual exclusion rule is valid for such polymeric complex although it contains two metal atoms at two different inversion centers.

Electronic spectra

The electronic absorption spectra of complexes **1** and **2** measured as Nujol mulls are given in Table 5 and Fig. 5. These spectra exhibit *d–d* transitions as a broad band centered around 13888 cm^{-1} and 15870 cm^{-1}, suggesting five- and six-coordination geometries around metal atoms for **1** and **2**, respectively. The position of the *d–d* in **1** is very similar to that reported (See Fig. 1, ref. 5) for the polymeric 1 : 1 copper(II) azide complex of 3-picoline in which copper(II) atoms have a trigonal bipyramidal geometry. The spectrum of complex **1** also show a very strong band around 23,255 cm^{-1} along with a moderate band around 18,518 cm^{-1}. These bands are due to $N_3^- \rightarrow Cu^{II}$ LMCT transitions. While two and four azide-to-copper(II) CT transitions have been predicted on theoretical bases for terminal and (μ-1, 1) or (μ-1, 3) bridging azides, only one and two bands have been reported for monomers and $\mu(1,3)$ or $\mu(1,1)$ dimers, respectively [35]. Complex **2** which contains only $\mu(1,3)$ bridging azides shows a very broad and strong N_3^--MCT band around 21,300 cm^{-1}. As a distinct absorption band is usually observed in the range 17,000–21,000 cm^{-1} for copper(II) azide complexes containing di-$\mu(1,1)$ bridging azides, and as no band is observed in the above region of the spectrum of **2**, the 18,518 cm^{-1} band is evidently due to the di-$\mu(1,1)$ azide-to-copper CT transitions. The appearance of such a moderate band in copper(II) azido complexes, therefore may be taken as strong evidence for the presence of di-$\mu(1,1)$ azido system. In DMF and DMSO solution of **1**, however, only one broad and very strong band observed corresponds to the main $N_3^- \rightarrow$ MCT transition in the solid complex, whereas the *d–d* band remains at almost the same position. The DMF solution of **2** shows the CT band shifted to higher wave number whereas the *d–d* band appears at lower wave number suggesting five coordinate copper geometry in this solvent. It is possible that one of the two organic ligand molecules washed out and the solution contains only the 1 : 1 complex as the spectrum is very similar to that of **1**.

EPR spectra

The room temperature EPR spectrum of a polycrystalline sample of **1** is a well defined typical spec-

trum of copper(II) system of axial type with $g_{\parallel} = 2.26$ and $g_{\perp} = 2.08$. At 77 K, the spectrum displays the same signals at 2.27 and 2.08, overlapped with a wide isotropic signal. In fact many 1 : 1 copper(II) azide solid complexes of similar ligands frequently exhibit such a broad isotropic signal [5,6]. In DMF, compound **1** is not freely soluble, and the room temperature spectrum of the filterate, however, consists of a half field signal at $g = 4.28$ (Fig. 6) indicating that dimeric units are present in this solution. The main signal at $g = 2.13$ is broad and poorly defined. At 77 K, the DMF solution does not show the half field signal. Instead, the spectrum shows very well hyperfine coupling with the copper nucleus of the g parallel, giving four peaks with hyperfine constant $A = 143$ G (average) and $g_{\perp} = 2.05$. The room temperature EPR spectrum of a polycrystalline sample of **2** is almost of axial type copper(II) systems, exhibiting a poor hyperfine coupling with the copper nucleus of the $g_{\parallel}$ with $A = 81$ G (average). At 77 K, the spectrum displays the same features except that the hyperfine constant A becomes 32.6 G (average).

Abstract—The title compound, $[\Delta,\Lambda\text{-Ni(en)}_2(NCS)_2]_2[\Delta,\Lambda\text{-Ni(en)}_3][PF_6]_2$ (**1**) (en = ethylenediamine) has been synthesised via a molecular rearrangement reaction of *trans*-$Ni(en)_2(NCS)_2$. **1** consists of $[Ni(en)_2(NCS)_2]_2$ (**1a**), $[Ni(en)_3]^{2+}$ (**1b**) and $[PF_6]^-$ (**1c**) molecular units in a 2:1:2 ratio, such that both **1a** and **1b** crystallise in an ordered racemic sequence of Λ and Δ chiral units. Extensive intermolecular hydrogen bonding is observed between amine protons of the en chelate rings and the fluorine atoms of the $[PF_6]^-$ counteranions, as well as between the amine protons and sulfur atoms of the NCS ligands. The en chelates display ring conformations of $\Lambda\lambda\lambda$ for **1a** and $\Lambda\delta\delta\delta$ for **1b**. © 1998 Published by Elsevier Science Ltd. All rights reserved

Keywords: hydrogen bonding; amine protons; co-crystallisation.

The absolute configurations of optically active coordination compounds has been of long-standing interest to chemists. Since the structure and absolute configuration of the $[Co(en)_3]^{3+}$ (en = ethylenediamine) cation were determined in 1955 by Saito *et al.* [1], numerous studies of structurally related compounds have been made. Where such compounds contain five-membered chelating ethylenediamine (en) rings, two possible enantiomeric configurations (Δ or Λ) and two possible ring conformations (δ and λ) may be formed. In the case of the *tris*-chelating pseudo-octahedral complex, $[M(en)_3]^{n+}$, combination of these ring conformations and configurations leads to eight possible different isomers ($\Lambda\delta\delta\delta$, $\Lambda\delta\delta\lambda$, $\Lambda\delta\lambda\lambda$, $\Lambda\lambda\lambda\lambda$, $\Delta\delta\delta\delta$, $\Delta\delta\delta\lambda$, $\Delta\delta\lambda\lambda$ or $\Delta\lambda\lambda\lambda$); while for *bis*-chelating molecules, *cis*-$[M(en)_2]X_2$, there may be six different isomeric forms ($\Lambda\delta\delta$, $\Lambda\delta\lambda$, $\Lambda\lambda\lambda$, $\Delta\delta\delta$, $\Delta\delta\lambda$ or $\Delta\lambda\lambda$) [2]. In the solid state both complexes usually occur as racemic mixtures, crystallising in centrosymmetric space groups that lead to an equal number of Λ and Δ metal centres.

As part of a continuing study into polymetallic complexes of linearly coupled paramagnetic metal ions, we have focused on the synthesis and structural characterisation of systems based on the *trans*-$Ni(en)_2X_2$ monomeric unit; where X typically is a N- or O-donor ligand or a non-coordinated counteranion. More specifically, we have been investigating the reactivity of linear di-nitrogen bridging ligands such as pyrazine and 4,4′-bipyridine with *trans*-$Ni(en)_2(NCS)_2$. In the case of pyrazine, we observed that the bridging ligand was not sufficiently reactive under the conditions used to form a polymeric species. Rather, a molecular rearrangement reaction takes place whereby one monomer unit loses its thiocyanato ligands to another chelating en ligand and two other monomer units *trans*-/*cis*- isomerise. Together these three molecular units co-crystallise along with PF_6^- counterions to form a complex salt. Here we present the synthesis and structural analysis of this new tri-nickel complex salt: $[\Delta,\Lambda\text{-Ni(en)}_2(NCS)_2]_2[\Delta,\Lambda\text{-Ni(en)}_3](PF_6)_2$.

EXPERIMENTAL

$Ni(NCS)_2^1/_2H_2O$, ethylenediamine, NH_4PF_6 and pyrazine were obtained from commercial sources and used as received. Methanol was of A.R. grade and was used without further purification.

Preparation of Δ,Λ-$[Ni(en)_2(NCS)_2]_2$-Δ,Λ-$[Ni(en)_3](PF_6)_2$

trans-$Ni(en)_2(NCS)_2$ was prepared from $Ni(NCS)_2^1/_2H_2O$ and ethylenediamine in the manner reported by Brown and Lingafelter [3]. The absolute configuration of this compound was confirmed as *trans*- by X-ray diffraction of a single crystal. To an aqueous solution of *trans*-$Ni(en)_2(NCS)_2$ (1 mmol, 30 ml) and NH_4PF_6 (2 mmol) was added a methanolic solution of pyrazine (1 mmol, 10 ml) with rapid stirring. No immediate precipitate resulted. Upon reducing the volume to ~20 ml on a hotplate and allowing the solution to stand in air for 3 weeks pale purple crystals of (**1**) suitable for X-ray diffraction were formed, along with a number of dark purple crystals of $[Ni(en)_2(\mu_{N,S}\text{-}NCS)]_2[PF_6]_2$ (**2**). The physical and structural characterisation of **2** is reported elsewhere [4].

Crystal structure determination

Measurements were made on Rigaku AFC7R diffractometer at ambient temperature using monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å). A pale purple single crystal of **1** was placed at the end of a glass fibre. Cell constants were obtained by least-squares analysis of 25 strong reflections in the range $22.04° < 2\theta < 24.90°$. Details of crystal data, data collection and structure refinement are summarised in Table 1. The intensity data were corrected for Lorentz and polarisation effects and an empirical absorption correction based on azimuthal scans of several reflections was also applied. The structure of **1** was solved by direct methods and developed by alternating cycles of difference Fourier syntheses and full matrix least-squares refinements. The positions of the non-hydrogen atoms were determined unequivocally. The non-hydrogen atoms were refined anisotropically, while the hydrogen atoms were placed at calculated positions for the final refinement and their thermal parameters refined isotropically. Neutral atom scattering factors were taken from Ref. 5 and anomalous dispersion corrections were taken from Ref. 6. Crystallographic calculations were carried out with a teXsan crystallographic software package of Molecular Structure corporation (1985 & 1992).

RESULTS AND DISCUSSION

Molecular and crystal structure

The compound $[\Delta,\Lambda\text{-}Ni(en)_2(NCS)_2]_2[\Delta,\Lambda\text{-}Ni(en)_3](PF_6)_2$ (**1**) crystallises in the monoclinic space group C_2/c (No. 15) with $a = 24.715(3)$ Å, $b = 12.806(2)$ Å, $c = 17.328(2)$ Å, $\beta = 124.532(6)°$, $V = 4518(1)$ Å^3 and $Z = 4$. The arrangement of the three distinct molecules *cis*-$[Ni(en)_2(NCS)_2]$ (**1a**), $[Ni(en)_3]^{2+}$ (**1b**) and the counteranion $[PF_6]^-$ (**1c**) in the asymmetric unit of **1** is shown in Fig. 1. Selected bond lengths are given in Table 2 and selected bond angles in Table 3. The *bis*-chelate molecule (**1a**) is centred at a general (x,y,z) 8-fold crystallographic site; while the *tris*-chelate molecule (**1b**) and the counteranions (**1c**) occupy 4-fold sites at $(\frac{1}{2}, y, \frac{1}{4})$, $(0, y, \frac{1}{4})$ and $(\frac{1}{4}, \frac{1}{4}, 0)$ respectively, leading to a ratio of 2 : 1 : 2 in the unit cell. Numerous uni-metallic [7–19] complex salts containing the optically active $[Ni(en)_2X_2]$ or $[Ni(en_3)]^{2+}$ structural units have been studied; as have a number of di-nickel salts containing one or the other of these structural units [20–23]. To our knowledge, there has only been one other report of a co-crystallised salt containing both of these elements, notably $[Ni(en)_2(benzoyl\text{-}hydrazine)][Ni(en)_3]I_4 \cdot H_2O$ [24].

The $Ni(en)_2(NCS)_2$ *structural motif* (**1a**)

The structure of **1a** is in itself noteworthy. As an isolated molecule $Ni(en)_2(NCS)_2$ has only been detected in the solid state as a *trans*-isomer; although, two different structural modifications have been reported [3,25]. To our knowledge, this is the first

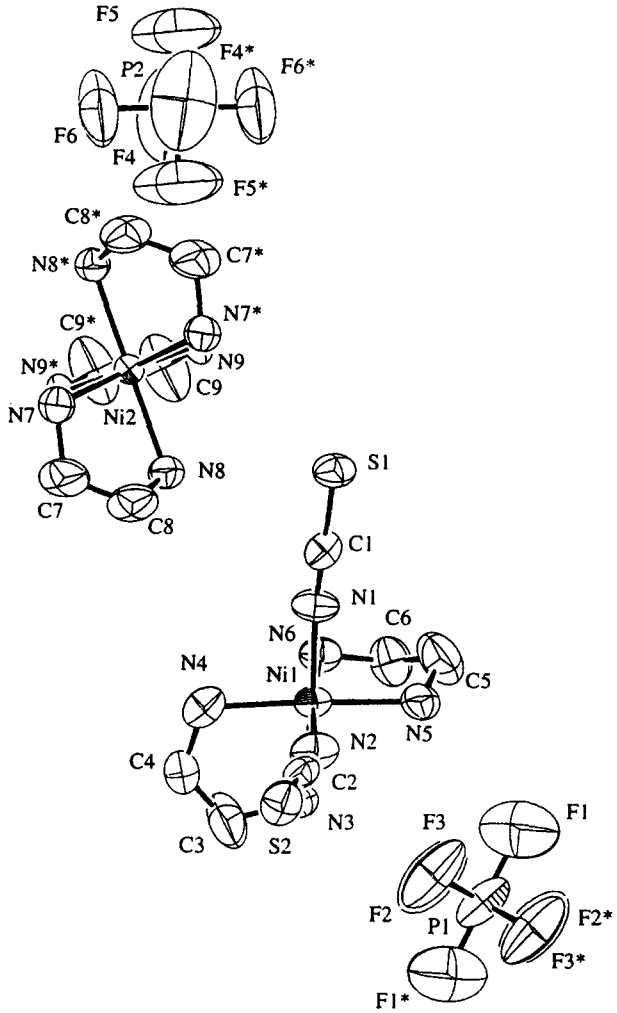

Fig. 1. An ORTEP drawing of the asymmetric unit of $[Ni(en)_2(NCS)_2]_2[Ni(en)_3](PF_6)_2$ (**1**). Hydrogen atoms have been omitted for clarity. All atoms are represented by the thermal ellipsoids at 50% probability.

report of an optically active Ni(II) centre containing *bis*-chelating en rings as well as two monodentate N-donor thiocyanato ligands in a *cis*-arrangement. Monomeric molecular structures of the type $Ni(en)_2(NCS)X$ have been reported where $X = Cl^-$, Br^- or NO_3^- [18]; while dimeric structures $[Ni(en)_2(\mu_{N,S}\text{-}NCS)]_2X_2$ have been characterised for $X = I^-$ or ClO_4^- [19]. As a part of our own study, the dimeric species $[Ni(en)_2(\mu_{N,S}\text{-}NCS)]_2[PF_6]_2$ (**2**) has also been isolated [4]. Recently, the 1-dimensional polymeric Ni(II) complex $\{catena\text{-}(\mu_{N,S}\text{-}NCS)[Ni(en)_2]\}(PF_6)$ has been reported [26]. Polymeric structures with bridging nitrito groups have also been noted for $\{catena\text{-}(\mu\text{-}NO_2)[Ni(en)_2]\}X$ where $X = BF_4^-$ [27], ClO_4^- [28], and I_3^- and PF_6^- [29].

The Ni1—N bond lengths of the thiocyanato ligands of **1a** (2.083(6) Å (Ni1 – N1) and 2.070(6) Å (Ni1 – N2)) are significantly shorter than that found in the case of the *trans*-isomer (2.15 Å) [3], and slightly longer than that reported for *cis*-$Ni(en)_2(NCS)Cl$ (2.01 Å) [18]. The N1—Ni1—N2 bond angle between the NCS ligands is 92.2(2)°, while the average bond angle between the Ni1—N(en) bonds and the Ni1—N(NCS) bonds are 90.2(3)° and 174.8(3)°. The average N—Ni1—N bond angle within the en rings of 82.4(3)° is characteristic of deviations away from regular octahedral geometry that have been observed for other chelating systems [7–13,20,21]. Ni1—N(en) bond lengths are typical of those found in other uni-metallic $Ni(en)_2(X)_2$ complexes; although in **1a**, a clear trans effect is observed relative to the thiocyanato ligands (Table 2). This feature has also been observed by Poraj-Kosic in the case of the compounds $Ni(en)_2(NCS)Cl$ and $Ni(en)_2(NCS)(NO_3)$ [18]. The bond lengths (Table 2) and bond angles (Table 3) of the en and NCS ligands of **1a** are characteristic of those found in other coordination complexes.

The ring pucker of the chelate rings in **1** can be quantified by the dihedral angle (ω) between the planes defined, for example, by N3—C3—C4 and C3—C4—N4. The values of ω for the N3—N4 and N5—N6 rings were found to be 14(1)° and 48(1)° respectively; the former being substantially smaller than usually found (~50°) in tri-chelating en complexes [9,11] This atypical ring pucker of the N3—N4 chelate may be a consequence of the strong hydrogen bonds that form between amine protons and acceptor sites on the counteranions (see below).

The $[Ni(en)_3]^{2+}$ *structural motif* (**1b**)

While the $[Ni(en)_3]^{2+}$ (**1b**) moiety displays C_3 pseudo-symmetry typical of *tris*-chelating molecular units, it is noteworthy that the true site symmetry in this crystal is C_2. The average Ni2—N bond length of 2.128(7) Å in **1b** is characteristic of those found in other uni-metallic $[Ni(en)_3]^{2+}$ complex salts [7–13]. N—Ni2—N bond angles within the en chelate rings of 81.9(3)° (N7—Ni2—N8) and 81.7(4)° (N9—Ni2—N9*) also show the usual deviations away from regular octahedral geometry that have been observed in other systems [7–13]. The average values for N—Ni2—N bond angles between adjacent chelate rings are 92.9(3)° and 171.5(3)°; being consistent with the above compounds. In general, the other bond lengths and bond angles within the chelate rings of **1b** are consonant with those observed in other

$[Ni(en)_3]^{2+}$ complex salts [7–13]. Dihedral angles (ω) of 43(1)° and 38(1)° for the N7—N8 and N9—N9* chelates indicate moderate ring pucker.

Hydrogen bonding

Extensive hydrogen bonding is observed in **1** between the amine protons and Lewis base (acceptor) sites. Table 4 contains selected intra- and intermolecular hydrogen bonding distances and angles. Figure 2 shows intermolecular hydrogen bonding (dashed lines) and partial packing of the unit cell, projected along the *b*-axis between $-0.28 \leqslant y \leqslant 0.28$. Both chiral elements **1a** and **1b** show strong intermolecular hydrogen bonding, particularly between amine donor protons and the fluorine atoms of **1c**; forming a 3-dimensional network within the crystal. In the case of **1a,** the majority of strong hydrogen bonds occur between amine protons that are parallel to the pseudo-C_3 axis. The converse is true in the case of **1b,** where strong hydrogen bonds are formed almost exclusively by amine protons that present oblique angles to the pseudo-C_3 axis of the molecule. Weaker intermolecular hydrogen bonds are also observed between amine protons and Lewis base sites at S atoms of the thiocyanato ligands and N atoms of other en groups.

Intermolecular hydrogen bonding is a feature commonly observed in compounds containing chelating en rings. In the case of *bis*-chelating molecules, strong intermolecular bonds have been observed between amine protons and coordinated NO_2 ligands [18], and ClO_4^- counteranions [28]. While not specifically mentioned by the authors Monfort *et al.* in the case of

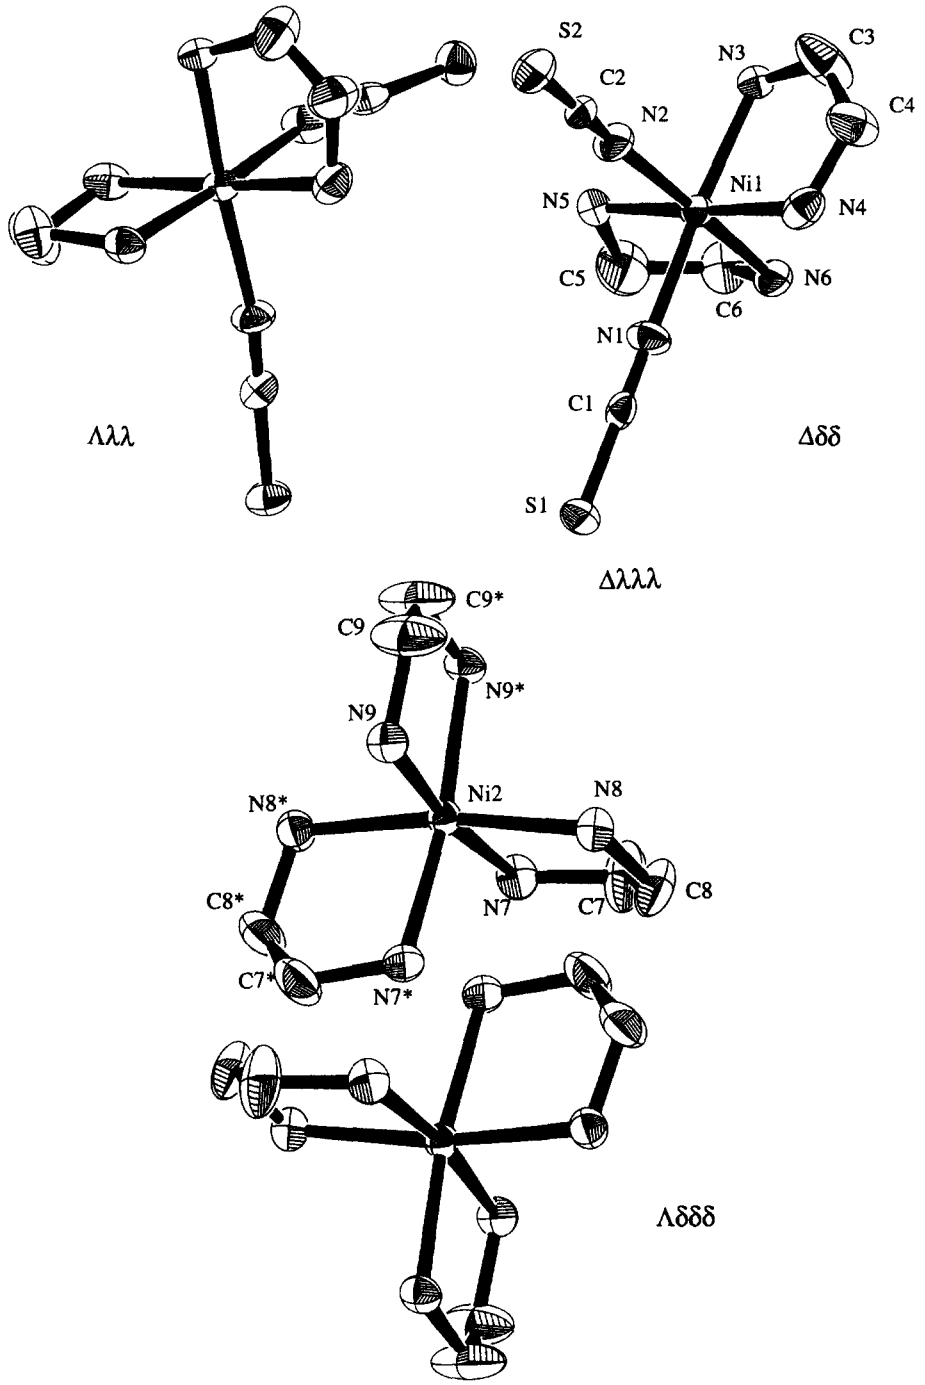

Fig. 3. Isomeric mirror image forms of (**a**) $\Lambda\lambda\lambda$ and $\Delta\delta\delta$ for **1a** and; (**b**) $\Lambda\delta\delta\delta$ and $\Delta\lambda\lambda\lambda$ for **1b**. Hydrogen atoms have been omitted for clarity.

{*catena*-($\mu_{N,S}$-NCS)[Ni(en)$_2$]}(PF_6) [26], it seems likely that hydrogen bonding interactions should also play a significant role in stabilising this compound. Strong intermolecular hydrogen bonding has also been observed in many *tris*-chelating molecules between amine protons and oxygen atoms of nitrate [7]; sulfate [9]; acetate [11] and tartrate [12] counterions.

Absolute configurations of **1a** *and* **1b**

Both molecular species **1a** and **1b** form chiral entities; however, due to the constraints of crystal symmetry presented by the centrosymmetric C_2/c space group, both Λ and Δ forms are present in equal quantities and ordered in the unit cell. The $\Lambda\lambda\lambda$ and $\Delta\delta\delta$ forms of **1a** are displayed in Fig. 3(a); while the $\Lambda\delta\delta\delta$

and $\Delta\lambda\lambda\lambda$ forms of **1b** are given in Fig. 3(b). The following discussion will relate to the Λ configuration only, keeping in mind that for racemic systems, these arguments hold equally true for their respective mirror images having the Δ configuration.

Much debate has centred around which chemical effects cause any of the four isomers ($\Lambda\delta\delta\delta$, $\Lambda\delta\delta\lambda$, $\Lambda\delta\lambda\lambda$, $\Lambda\lambda\lambda\lambda$) to be the most stable. Factors that have been considered include anion size [20], hydrogen bonding [30] and crystal packing forces [11]. Gollogly *et al.* [31] argued that entropy effects would cause the $\Lambda\delta\delta\lambda$ isomer to have the lowest free energy, and structural characterisation of compounds containing very few hydrogen bonds has lent weight to this proposal [13,32]. It has been observed that the most common configuration is $\Lambda\delta\delta\delta$, presumably because it is the one most easily stabilised by hydrogen bonds. Cramer and Huneke [13] proposed that this isomer should have the second lowest energy; while the rarely observed $\Lambda\lambda\lambda\lambda$ configuration which also has a strong tendency to from hydrogen bonds should be the isomer with the highest energy. As was observed for **1b**, Cramer and Huneke [13] found that in the case of the $\Lambda\delta\delta\delta$ configuration, the strongest or greatest number of hydrogen bonds were formed to amine protons that had oblique angles to the pseudo-C_3 axis. The converse was observed for λ rings; where a majority or the strongest bonds were formed with amine protons that were parallel to the pseudo-C_3 axis.

The conformations of *bis*-chelating en rings have received less attention; however, the absolute configuration of $\Lambda\lambda\lambda$ for **1a** is again consistent with a majority of strong hydrogen bonds being formed between counteranions and "parallel" amine protons.

(Received 25 June 1997; accepted 14 August 1997)

Abstract—A series of functionally substituted cyclopentadienyl MNiFeS clusters $(\eta^5\text{-}RC_5H_4)(\eta^5\text{-}C_5H_5)MNiFeS(CO)_5$ (**1**, M = Mo, R = CHO; **2**, M = W, R = CHO; **3**, M = Mo, R = CH_3CO; **4**, M = W, R = CH_3CO; **5**, M = Mo, R = CH_3O_2C; **6**, M = W, R = CH_3O_2C) were successfully synthesized by isolobal displacement reactions of corresponding functional cyclopentadienyl MCoFeS clusters $\eta^5\text{-}RC_5H_4MCoFeS(CO)_8$ with nickelocene in THF at reflux. Further treatment of clusters **1**–**4** with reducing agent $NaBH_4$ at r.t. in MeOH yielded primary and secondary alcohol cluster derivatives (**7**, M = Mo, R = CH_2OH; **8**, M = W, R = CH_2OH; **9**, M = Mo, R = $CH(OH)CH_3$; **10**, M = W, R = $CH(OH)CH_3$), which could react with the alkylating reagent Et_3OBF_4 to give ether cluster derivatives (**11**, M = Mo, R = $CH(OC_2H_5)CH_3$; **12**, M = W, R = $CH(OC_2H_5)CH_3$). Although reactions of clusters **1** and **2** with an aqueous acid solution of 2,4-dinitrophenylhydrazine at r.t. led to almost complete decomposition of the starting clusters, the reactions of clusters **3** and **4** under similar conditions afforded phenylhydrazone cluster derivatives (**13**, M = Mo, R = 2,4-$(NO_2)_2C_6H_3NHN$; **14**, M = W, R = 2,4-$(NO_2)_2C_6H_3NHN$). All these novel cluster products have been characterized by elemental analysis and spectroscopic techniques, as well as for cluster **1** by X-ray crystallographic study. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: functional cyclopentadienyl ligands; MoNiFeS clusters; WNiFeS clusters; isolobal displacement; crystal structure.

Transition metal clusters containing functionally substituted cyclopentadienyl ligands have been recently receiving considerable attention in our laboratory [1–9]. This is largely because (i) these can be potentially used as homogeneous catalysts or as models for adsorbed substrates or their fragments on the solid surface of heterogeneous catalytic processes [10–13]; (ii) the functionally substituted cyclopentadienyls of these clusters can undergo transformation reactions to give numerous novel transition metal cluster derivatives, which could be difficultly or even not prepared by other methods [2–5]. As a continuation of this project we undertook a study on the synthesis and structural characterization of tetrahedral MNiFeS clusters with a general formula $(\eta^5\text{-}RC_5H_4)(\eta^5\text{-}$

* Author to whom correspondence should be addressed.

C_5H_5)MNiFeS(CO)$_5$ (M = Mo, W; R = CHO, CH_3CO etc.) and herein report the interesting results concerning this study.

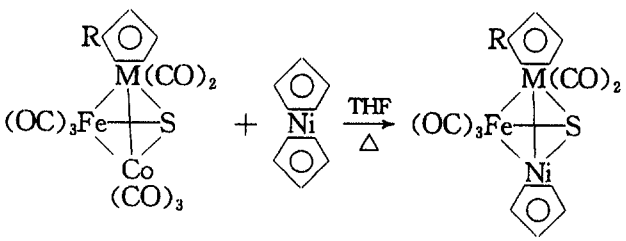
RESULTS AND DISCUSSION

It was found that the tetrahedral MCoFeS clusters containing functionally substituted cyclopentadienyl ligands η^5-$RC_5H_4MCoFeS(CO)_8$ [2,8,9] reacted with nickelocene in THF at reflux to give corresponding functionally substituted cyclopentadienyl MNiFeS clusters (η^5-RC_5H_4)(η^5-C_5H_5)MNiFeS(CO)$_5$ (**1–6**), as shown in Scheme 1.

Clusters **1–6** were actually derived from isolobal displacement of $Co(CO)_3(d^9ML_3)$ in starting clusters η^5-$RC_5H_4MCoFeS(CO)_8$ by η^5-$C_5H_5Ni(d^9ML_3)$ generated *in situ* from thermal decomposition of nickelocene [14,15]. Although η^5-$RC_5H_4M(CO)_2(d^5ML_5)$ is also isolobal with η^5-$C_5H_5Ni(d^9ML_3)$, no products derived from isolobal displacement of the former by η^5-C_5H_5Ni were found under such conditions. It follows that the isolobal fragment $Co(CO)_3$ is a much better leaving group than η^5-$RC_5H_4M(CO)_2$ in such isolobal displacement reactions. Among these products except **3** being previously reported [8], all are new and have been characterized by elemental analysis, IR, ^{1}H NMR and MS spectroscopy. IR spectra of these new clusters showed four absorption bands at 2065–1844 cm^{-1} and one absorption band at 1713–1631 cm^{-1}, characteristic of the CO ligands attached to transition metals and the carbonyl groups of the functional substituents, respectively. ^{1}H NMR spectra of these new clusters exhibited one singlet between 5.28–5.34 ppm and two multiplets between 5.40–6.20 ppm, which were assigned to five protons of the cyclopentadienyl ring and four protons of the substituted cyclopentadienyl ring, respectively. Since those functional substituents are electron-withdrawing, the upfield multiplet was attributed to H^3 and H^4 protons of the substituted cyclopentadienyl ring and the downfield multiplet attributed to H^2 and H^5 protons. In addition, for **1** and **2** the ^{1}H NMR spectra displayed one singlet at about 9.65 ppm for the proton of formyl group, whereas for **4–6** the ^{1}H NMR spectra showed one singlet at 2.36 ppm for the acyl proton and one singlet at about 3.87 ppm for carbomethoxy protons, respectively. The mass spectra of all new clusters exhibited not only their respective molecular ion (M^+) peaks, but also the corresponding fragment ion peaks such as those of $(M-nCO)^+$ and $MoNiFeS^+$ or $WNiFeS^+$.

Although reactions of the functional group of a cyclopentadienyl ring in mononuclear transition metal complexes, such as ferrocene derivatives [16] and group 6 monometallic compounds [17] have been extensively studied, the investigations of this kind of reactions involved in cluster systems are quite few [2,3]. In order to know the influence of the cluster core upon transformation reactions of the functional group of a cyclopentadienyl ring and to prepare a series of new functional cyclopentadienyl clusters, we explored some of functional transformation reactions of cluster **1–4**. It was found that clusters **1–4** could be reduced by $NaBH_4$ in methanol at room temperature to give primary and secondary alcohol cluster derivatives **7–10**. Further treatment of **9** and **10** with alkylating reagent Et_3OBF_4 in CH_2Cl_2 at room temperature gave rise to ether cluster derivatives **11** and **12**. It is worth noting that although clusters **1** and **2** reacted in ethanol with an aqueous acid solution of 2,4-dinitrophenylhydrazine at room temperature to lead almost complete decomposition of the clusters, the reactions with clusters **3** and **4** under similar conditions afforded the expected phenylhydrazone cluster derivatives **13** and **14**. All the reactions mentioned above are shown in Scheme 2.

The clusters **7–14** are all new functionalized cyclopentadienyl MNiFeS clusters, which have been char-



1—6

clusters	1	2	3	4	5	6

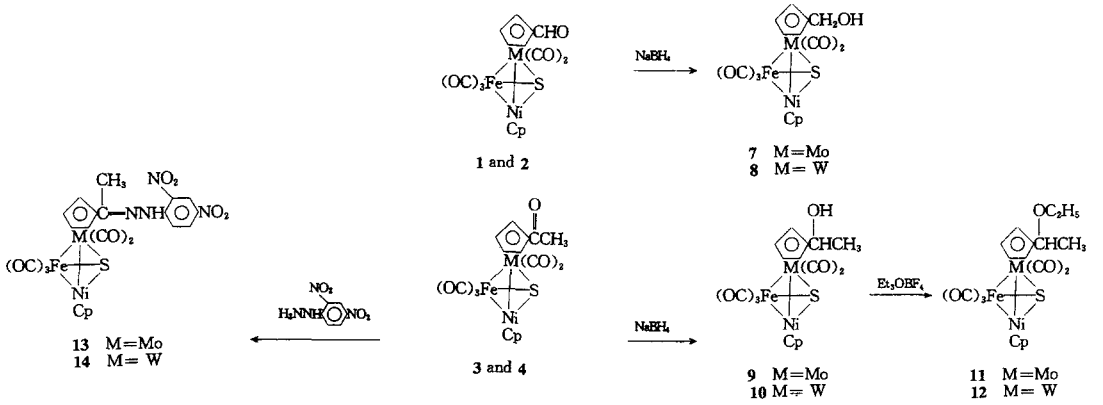

Scheme 2.

acterized by elemental analysis, IR and ^{1}H NMR spectroscopy. In IR spectra of **7–14** there were three to five absorption bands between 2065–1860 cm^{-1}, which are characteristic of the CO ligands bound to transition metals. In addition, IR spectra of **7–10** exhibited hydroxyl absorption bands between 3400–3440 cm^{-1}, whereas those of **11–12** showed C—O—C absorption bands at about 1021 cm^{-1} and those of **13–14** showed the C=N absorption bands at about 1612 cm^{-1}, respectively. ^{1}H NMR spectra of **7–14** indicated all their protons present in these molecules, such as the protons of hydroxyl groups of **7–10** between 1.46–2.14 ppm and imino groups of **13–14** at about 11.2 ppm. It is noteworthy that the four protons of the substituted cyclopentadienyl of **7–14** showed one or two multiplets in the range of 4.6–6.1 ppm. Except for **13** and **14**, the singlet for **7–12** caused by five protons of cyclopentadienyl ring coordinated to Ni atom were mingled together with their corresponding multiplets caused by four protons of the substituted cyclopentadienyl ring.

It is worth noting that during the separation of the products yielded from reactions mentioned above we usually observed several small continuous bands appeared on the TLC plates. The formation of these bands, which are difficult to be separated and might consist of both unreacted starting materials and some byproducts, causes the low yields of the isolated products.

In order to unambiguously confirm the structure of cluster **1**, an X-ray diffraction analysis was undertaken. The molecular structure of **1** is shown in Fig. 1. The selected bond lengths and angles are listed in Table 1. As shown in Fig. 1, cluster **1** consists of a distorted tetrahedral core MoNiFeS, which carries two carbonyls on Mo atom and three on Fe atom, one cyclopentadienyl ligand attached to the Ni atom and one formylcyclopentadienyl ligand coordinated to the Mo atom. For this molecule, the bond lengths involving the cluster core, the distance from Ni to centroid of cyclopentadienyl ring (denoted as Ni—Cp_{cent}), the distance from Mo to centroid of substituted cyclopentadienyl ring (Mo—Cp_{cent}) and the dihedral angle between two cyclopentadienyl rings (Z) are very close to the corresponding analog **3** [8], as shown in Table 2.

Finally, it should be noted that while the three carbonyls attached to Fe atom are terminal, one carbonyl bound to Mo atom C(12)—O(4) is terminal and the other C(13)—O(5) is semi-bridging. This is because the asymmetry parameter α (0.35) of C(13)—O(5) is well within the range for semi-bridging carbonyls, whereas that (0.61) of C(12)—O(4) falls out of the range [18]. The coexistence of both terminal and semi-bridging carbonyls are in good agreement with the IR spectrum of cluster **1** showing several strong absorption bands from 2032 cm^{-1} to 1844 cm^{-1}.

EXPERIMENTAL

All reactions were carried out under a prepurified nitrogen atmosphere using vacuum-line techniques. THF and diethyl ether were distilled from sodium benzophenone ketyl. Dichloromethane, methanol and ethanol were bubbled with nitrogen for 10 min prior to use. While $NaBH_4$ and 2,4-dinitrophenylhydrazine are of commercial origin, η^5-$RC_5H_4MCoFeS(CO)_8$ (M = Mo, W; R = CHO, CH_3CO, CH_3O_2C) [2,8,9], $(\eta^5$-$C_5H_5)_2Ni$ [19] and Et_3OBF_4 [20] were prepared according to literature methods. Preparative TLC was carried out on glass plates (26 × 19 cm) coated with silica gel G (10–40 μm). IR and ^{1}H NMR spectra were recorded on a Nicolet FT-5DX spectrophotometer and a Jeol FX 90Q spectrometer. C/H analyses, MS and melting points were performed by a Perkin–Elmer 240C analyzer, an HP 5988A spectrometer and a Yanaco MP-500 instrument, respectively.

Preparation of **1**

To a 100 cm^3 three-necked flask fitted with a magnetic stir-bar, a rubber septum and a reflux condenser

MS (EI, ^{184}W, ^{58}Ni), *m/z* (relative intensity): 628 (M^+, 7.9), 572 [$(M-2CO)^+$, 8.6], 544 [$(M-3CO)^+$, 26.0], 488 [$(M-5CO)^+$, 100.0], 571 [$(M-CO-CHO)^+$, 5.2], 543 [$(M-2CO-CHO)^+$, 9.8], 487 [$(M-4CO-CHO)^+$, 43.3], 459 [$(M-5CO-CHO)^+$, 9.3], 395 ($C_5H_5NiSFeW^+$, 13.1), 394 ($C_5H_4NiSFeW^+$, 11.2), 330 ($NiSFeW^+$, 2.0).

Preparation of **3**

To the flask described above were added 1.00 g (1.70 mmol) of η^5-$CH_3COC_5H_4MoCoFeS(CO)_8$, 0.740 g (3.90 mmol) of Cp_2Ni and 20 cm^3 of THF. The mixture was refluxed for 10 h. Solvent was removed at reduced pressure and the residue was extracted with CH_2Cl_2. The extracts were subjected to TLC separation using 1:1 CH_2Cl_2/petroleum ether as eluent. Several small bands with a major one were developed. From the fourth main green band was obtained 0.385 g (40%) of **3** as a deep-green solid, which has been identified by comparison of its IR and ^1H NMR spectra with those of an authentic sample previously reported [8].

Preparation of **4**

To the flask described above were added 0.990 g (1.50 mmol) of η^5-$CH_3COC_5H_4WCoFeS(CO)_8$, 0.650 g (3.44 mmol) of Cp_2Ni and 20 cm^3 of THF. The mixture was refluxed for 30 h. The same workup as that for **3** was used to give 0.185 g (19.2%) of **4** as a black solid. M.p. 69–70°C. Anal. Found: C, 32.14; H, 1.85. Calc. for $C_{17}H_{12}FeNiO_6SW$: C, 31.77; H, 1.88%. IR (KBr, disk): $\nu_{(C\equiv O)}$ 2032 (vs), 1991 (s), 1959 (vs), 1852 (s) cm^{-1}; $\nu_{(C=O)}$, 1672 (s) cm^{-1}. ^1H NMR ($CDCl_3$): δ 2.36 (s, 3H, CH_3), 5.28 (s, 5H, C_5H_5), 5.44–5.80 (m, 2H, H^3, H^4), 5.88–6.16 (m, 2H, H^2, H^5) ppm. MS (EI, ^{184}W, ^{58}Ni), *m/z* (relative intensity): 642 (M^+, 9.6), 586 [$(M-2CO)^+$, 7.4], 558 [$(M-3CO)^+$, 22.0], 530 [$(M-4CO)^+$, 4.9], 502 [$(M-5CO)^+$, 100.0], 395 ($C_5H_5NiFeSW^+$, 7.1), 394 ($C_5H_4NiFeSW^+$, 11.2), 330 ($NiFeSW^+$, 4.3), 123 ($C_5H_5Ni^+$, 19.0).

Preparation of **5**

To the flask described above were added 1.160 g (1.97 mmol) of η^5-$CH_3O_2CC_5H_4MoCoFeS(CO)_8$, 0.840 g (4.43 mmol) of Cp_2Ni and 25 cm^3 of THF. The mixture was refluxed for 18 h. The same workup as that for **4** was used to give 0.330 g (29.4%) of **5** as a deep-green solid. M.p. 71–72°C. Anal. Found: C, 35.61; H, 2.12. Calc. for $C_{17}H_{12}FeMoNiO_7S$: C, 35.77; H, 2.12%. IR (KBr, disk): $\nu_{(C\equiv O)}$ 2041 (vs), 1991 (s), 1967 (vs), 1885 (s) cm^{-1}; $\nu_{(C=O)}$ 1713 (s) cm^{-1}. ^1H NMR ($CDCl_3$): δ 3.86 (s, 3H, CH_3), 5.28 (s, 5H, C_5H_5), 5.40–5.68 (m, 2H, H^3, H^4), 5.96–6.20 (m, 2H, H^2, H^5) ppm. MS (EI, ^{98}Mo, ^{58}Ni), *m/z* (relative intensity): 572 (M^+, 1.2), 516 [$(M-2CO)^+$, 0.9], 488 [$(M-3CO)^+$, 3.2], 460 [$(M-4CO)^+$, 1.0], 432 [$(M-5CO)^+$, 6.4], 373 ($C_5H_4MoFeSC_5H_5Ni^+$, 7.1), 309

($C_5H_5NiFeSMo^+$, 1.3), 308 ($C_5H_4MoFeSNi^+$, 1.8), 244 ($MoFeSNi^+$, 4.6), 123 ($C_5H_5Ni^+$, 6.8).

Preparation of **6**

To the flask described above were added 1.07 g (1.58 mmol) of η^5-$CH_3O_2CC_5H_4WCoFeS(CO)_8$, 0.650 g (3.44 mmol) of Cp_2Ni and 20 cm^3 of THF. The mixture was refluxed for 30 h. The same workup as that for **5** was used to give 0.130 g (12.5%) of **6** as a black solid. M.p. 75–76°C. Anal. Found: C, 31.28; H, 1.80. Calc. for $C_{17}H_{12}FeNiO_7SW$: C, 31.00; H, 1.84%. IR (KBr, disk): $\nu_{(C\equiv O)}$ 2032 (vs), 1991 (s), 1959 (vs), 1877 (s) cm^{-1}; $\nu_{(C\equiv O)}$ 1713 (s) cm^{-1}. ^1H NMR ($CDCl_3$): δ 3.88 (s, 3H, CH_3), 5.34 (s, 5H, C_5H_5), 5.50–5.76 (m, 2H, H^3, H^4), 5.92–6.20 (m, 2H, H^2, H^5) ppm. MS (EI, ^{184}W, ^{58}Ni), *m/z* (relative intensity): 658 (M^+, 4.2), 630 [$(M\text{-}CO)^+$, 0.7], 602 [$(M\text{-}2CO)^+$, 3.3], 574 [$(M\text{-}3CO)^+$, 11.6], 546 [$(M\text{-}4CO)^+$, 3.7], 518 [$(M\text{-}5CO)^+$, 21.5], 459 ($C_5H_4WFeS\text{-}C_5H_5Ni^+$, 13.5), 395 ($C_5H_5NiWFeS^+$, 4.7), 394 ($C_5H_4WFeSNi^+$, 4.7), 330 ($WFeSNi^+$, 1.2), 123 ($C_5H_5Ni^+$, 9.2).

Preparation of **7**

To a solution of 0.374 g (0.69 mmol) of **1** dissolved in 20 cm^3 of MeOH was added 0.026 g (0.69 mmol) of $NaBH_4$ and stirred for 20 min at room temperature. Solvent was removed at reduced pressure and the residue was extracted with CH_2Cl_2. The extracts were subjected to TLC separation using CH_2Cl_2 as eluent. Several small bands with a major one were developed. From the main green band was obtained 0.075 g (20.0%) of **7** as a deep-green solid. M.p. 128–129°C. Anal. Found: C, 36.02; H, 2.24. Calc. for $C_{16}H_{12}FeMoNiO_6S$: C, 35.40; H, 2.23%. IR (KBr, disk): $\nu_{(O\text{-}H)}$ 3400 (m) cm^{-1}; $\nu_{(C\equiv O)}$ 2032 (vs), 1983 (vs), 1950 (vs), 1918 (s), 1844 (s) cm^{-1}. ^1H NMR ($CDCl_3$): δ 1.46–1.88 (m, 1H, OH), 4.28–4.58 (m, 2H, CH_2), 5.12–5.72 (m, 9H, C_5H_5, C_5H_4) ppm.

Preparation of **8**

The same procedure as that for **7** was followed, but 0.434 g (0.69 mmol) of **2** instead of **1** to give 0.089 g (20.5%) of **8** as a deep-green solid. M.p. 133–134°C. Anal. Found: C, 30.80; H, 1.45. Calc. for $C_{16}H_{12}FeNiO_6SW$: C, 30.47; H, 1.92%. IR (KBr, disk): $\nu_{(O\text{-}H)}$ 3419 (m) cm^{-1}; $\nu_{(C\equiv O)}$ 2065 (m), 2032 (vs), 1959 (vs), 1860 (s) cm^{-1}. ^1H NMR ($CDCl_3$): δ 1.60–1.88 (s, 1H, OH), 4.20–4.60 (m, 2H, CH_2), 5.00–5.88 (m, 9H, C_5H_5, C_5H_4) ppm.

Preparation of **9**

To the flask described above were added 0.400 g (0.72 mmol) of **3**, 0.027 g (0.72 mmol) of $NaBH_4$ and 10 cm^3 of MeOH. The mixture was stirred overnight at room temperature. Solvent was removed at reduced pressure and the residue was extracted with 2:1 CH_2Cl_2/petroleum ether. The extracts were subjected to TLC separation using 2:1 CH_2Cl_2/petroleum ether as eluent. From the main blue band was obtained 0.300 g (75%) of **9** as a black oil. Anal. Found: C, 36.96; H, 2.39. Calc. For $C_{17}H_{14}FeMoNiO_6S$: C, 36.74; H, 2.36%. IR (KBr, disk): $\nu_{(O\text{-}H)}$ 3427 (m) cm^{-1}; $\nu_{(C\equiv O)}$ 2033 (vs), 1967 (vs), 1923 (s), 1860 (s) cm^{-1}. ^1H NMR ($CDCl_3$): δ 1.46 (d, J = 7.2 Hz, 3H, CH_3), 1.76–2.04 (m, 1H, OH), 4.48–4.80 (m, 1H, CH), 5.12–5.76 (m, 9H, C_5H_5, C_5H_4) ppm.

Preparation of **10**

The same procedure as that for **9** was followed, but 0.400 g (0.62 mmol) of **4** was added instead of **3** to give 0.311 g (78%) of **10** as a black oil. Anal. Found: C, 31.76; H, 1.79. Calc. For $C_{17}H_{14}FeNiO_6SW$: C, 31.72; H, 2.04%. IR (KBr, disk): $\nu_{(O\text{-}H)}$ 3440 (m) cm^{-1}: $\nu_{(C\equiv O)}$ 2020 (vs), 1950 (vs), 1860 (s) cm^{-1}. ^1H NMR ($CDCl_3$): δ 1.48 (d, 3H, J = 7.2 Hz, CH_3), 1.90–2.14 (m, 1H, OH), 4.50–4.92 (m, 1H, CH), 5.00–5.74 (m, 9H, C_5H_5, C_5H_4) ppm.

Preparation of **11**

To the flask described above were added 0.400 g (0.72 mmol) of **9**, 0.370 g (1.95 mmol) of Et_3OBF_4 and 15 cm^3 of CH_2Cl_2. The mixture was stirred at room temperature for 8 h. Solvent was removed at reduced pressure and the residue was extracted with 2:1 CH_2Cl_2/petroleum ether. The extracts were subjected to TLC separation using 2:1 CH_2Cl_2/petroleum ether as eluent. From the main blue band was obtained 0.054 g (13%) of **11** as a black solid. M.p. 144°C (dec.). Anal. Found: C, 39.07; H, 2.76. Calc. for $C_{19}H_{18}FeMoNiO_6S$: C, 39.08; H, 2.93%. IR (KBr, disk): $\nu_{(C\equiv O)}$ 2032 (vs), 1975 (vs), 1950 (vs), 1885 (s) cm^{-1}; $\nu_{(C\text{-}O)}$ 1023 (w) cm^{-1}. ^1H NMR ($CDCl_3$): δ 1.32–1.60 (m, 6H, $2CH_3$), 3.60–4.08 (m, 2H, CH_2), 4.60–5.52 (m, 10H, CH, C_5H_5, C_5H_4) ppm.

Preparation of **12**

The same procedure as that for **11** was followed, but 0.311 g (0.48 mmol) of **10** was used instead of **9** to give 0.048 g (15%) of **12** as a black solid. M.p. 170°C (dec.). Anal. Found: C, 34.19; H, 2.52. Calc. for $C_{19}H_{18}FeNiO_6SW$: C, 33.97; H, 2.55%. IR (KBr, disk): $\nu_{(C\equiv O)}$ 2068 (m), 2030 (vs), 1955 (vs), 1883 (vs) cm^{-1}; $\nu_{(C\text{-}O)}$ 1020 (m) cm^{-1}. ^1H NMR ($CDCl_3$): δ 1.31–1.60 (m, 6H, $2CH_3$), 3.80–4.20 (m, 2H, CH_2), 4.68–5.76 (m, 10H, CH, C_5H_5, C_5H_4) ppm.

Preparation of **13**

To the flask described above were added 0.300 g (0.54 mmol) of **3**, 10 cm^3 of ethanol and 3 cm^3 of 2,4-dinitrophenylhydrazine solution, prepared by dissolving 2.00 g (10.0 mmol) of 2,4-dinitrophenylhydrazine in 10 cm^3 of 98% concentrated H_2SO_4 followed by diluting with 14 cm^3 of distilled water and 46 cm^3 of 95% ethanol. The reaction mixture was stirred at room temperature for 3 h. The precipitate was filtered out and washed with ethanol. The washed precipitate was extracted with CH_2Cl_2. The extracts were subjected to TLC separation using 1 : 1 CH_2Cl_2/petroleum ether as eluent. From the main blue band was obtained 0.300 g (76%) of **13** as a black solid. M.p. 164°C (dec.). Anal. Found: C, 37.83; H, 2.26; N, 7.82. Calc. for $C_{23}H_{16}FeMoN_4NiO_9S$: C, 37.59; H, 2.19; N, 7.62%. IR (KBr, disk): $\nu_{(C\equiv O)}$ 2032 (vs), 1959 (vs), 1877 (s) cm^{-1}; $\nu_{(C=N)}$ 1614 (s) cm^{-1}. ^1H NMR ($CDCl_3$): δ 2.18 (s, 3H, CH_3), 5.23 (s, 5H, C_5H_5), 5.58 (t, 2H, H^3, H^4), 6.06 (t, 2H, H^2, H^5), 7.84–8.16 (m, 1H, H^6 of benzene ring), 8.24–8.56 (m, 1H, H^5 of benzene ring), 9.20 (s, 1H, H^3 of benzene ring), 11.29 (s, 1H, NH) ppm.

Preparation of **14**

The same procedure as that for **13** was followed, but 0.160 g (0.26 mmol) of **4** was used instead of **3** to give 0.080 g (37%) of **14** as a black solid. M.p. 105°C (dec.). Anal. Found: C, 33.35; H, 1.95; N, 6.84. Calc. For $C_{23}H_{16}FeN_4NiO_9SW$: C, 33.57; H, 1.96; N, 6.81%. Single-crystal structure determination of **1**

Crystals of **1** suitable for X-ray diffraction were obtained by slow evaporation of CH_2Cl_2/petroleum ether solution. A single-crystal measuring $0.20 \times 0.20 \times 0.50$ mm was mounted on a glass fiber and placed on a Rigaku AFC7R diffractometer with graphite monochromated Mo–K_α radiation and a 12 kW rotating anode generator. A total of 3006 independent reflections was collected at 293 K by ω-2θ scan mode, of which 2697 with $I \geqslant 3\sigma(I)$ were considered to be observed and used in subsequent refinement. The data was corrected for Lp factors. Details of crystal parameters, data collections and structure refinement of **1** are given in Table 3.

The structure was solved by direct methods and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included but not refined. Final refinement by full-matrix least-squares method for non-hydrogen atoms converged to give the unweighted and weighted agreement factors R and Rw. The highest peak on the final difference Fourier map has a height of 1.15 $eÅ^{-3}$. All calculations were performed on Micro Vax II computer using the TEXSAN program system.

Synthesis and magnetic properties of copper(II)—cobalt(II) complexes of *N,N′*—oxamidobis (benzoato) cuprate(II)

Guang-Ming Yang, Juan Shi, Shi-Ping Yan, Dai-Zheng Liao,* Zong-Hui Jiang and Geng-Lin Wang

Department of Chemistry, Nankai University, Tianjin 300071, P. R. China

(Received 19 June 1997; accepted 14 August 1997)

Abstract—Four heteronuclear metal complexes $[Cu(obbz)Co(L)_2]\cdot nH_2O$ (L = 2,2′-bipyridine (bipy), 4,4′-dimethyl-2,2′-bipyridine (Me_2bipy), 1,10-phenanthroline (phen) or 5-nitro-1,10-phenanthroline (NO_2phen)), have been prepared by the reaction of sodium *N,N,′*-oxamidobis(benzoato)cuprate(II) quadrihydrate, $Na_2[Cu(obbz)]\cdot 4H_2O$, with a divalent metal ion and L. The complexes $[Cu(obbz)Co(bipy)_2]\cdot 5H_2O$ (**1**) and $[Cu(obbz)Co(phen)_2]\cdot 5H_2O$ (**3**) were characterized by variable-temperature magnetic susceptibility measurements, indicating that an antiferromagnetic spin-exchange interaction operates between the copper(II) and cobalt(II) ions. © 1998 Elsevier Science Ltd. Keywords: binuclear complexes; copper(II)—cobalt(II); magnetic properties.

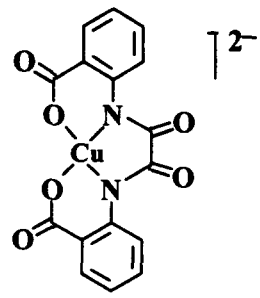
Binuclear metal complexes containing two different metal ions are of current interest in connection with spin-exchange and charge-transfer between metal ions and in the domain of metallo-enzymes and homogeneous catalysis [1]. Some years ago Kahn reported two alternating bimetallic chain compounds, of formula $MnCu(obbz)\cdot 5H_2O$ and $MnCu(obbz)\cdot H_2O$ and one binuclear compound, of formula $NiCu(obbz)\cdot 6H_2O$ where obbz stands oxamidobis(benzoato). These compounds were obtained by reaction of the copper(II) precursor $[Cu(obbz)]^{2-}$, shown below



with the manganese(II) ion or nickel(II) ion [2]. However, to our knowledge, no other binuclear complexes of this kind have been reported till now. In this paper, we describe synthesis and magnetic properties of four novel heterobinuclear complexes $[Cu(obbz)]Co(L)_2]\cdot nH_2O$ (L = bipy, Me_2bipy, phen, NO_2phen).

EXPERIMENTAL

Materials

Oxalyl chloride and anthranilic acid were purchased from Aldrich and were of reagent grade. $Na_2[Cu(obbz)]\cdot 4H_2O$ was prepared by the literature method [2].

Synthesis of $[Cu(obbz)]Co(L)_2]\cdot nH_2O$ (L = *bipy, Me_2bipy, phen, NO_2phen*)

The methods used to prepare the four complexes $[Cu(obbz)]Co(L)_2]$ were virtually identical and are exemplified by $[Cu(obbz)Co(bipy)_2]\cdot 5H_2O$ (**1**). To a solution of bipy (62.4 mg, 0.4 mmol) and $Co(NO_3)_2\cdot 6H_2O$ (29.1 mg, 0.1 mmol) were stirred in H_2O (20 cm^3), was successively added a solution of $Na_2[Cu(obbz)]\cdot 4H_2O$ (51.0 mg, 0.1 mmol) in H_2O (20

cm^3). After 12 h stirring the microcrystals thus obtained were filtered off, washed several times with H_2O and MeOH. The compounds were recrystallized from DMF, and dried *in vacuo*. Analytical data are given in Table 1.

Measurements

Elemental analyses of carbon, hydrogen and nitrogen were performed with a Perkin–Elmer Model 240 elemental analyser. Metal contents were determined by EDTA titration. IR spectra were measured on a Shimadzu Model 480 IR spectrophotometer, using KBr pellets. Variable temperature (77–300 K) magnetic susceptibility was measured on a Cahn 2000 microbalance. Diamagnetic correction were made with Pascal's constants for all the constituent atoms, and the magnetic moments were calculated using the equation $\mu = 2.828(X_M T)^{1/2}$.

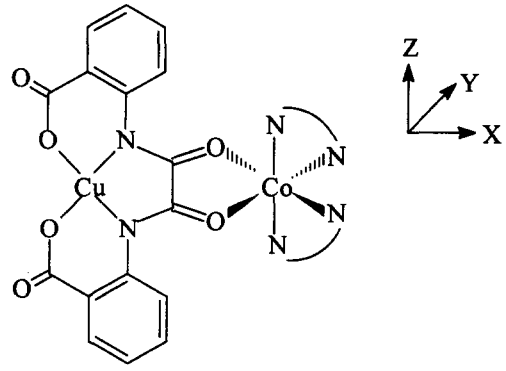

Fig. 1. Proposed chemical structures of complexes (L = bipy, Me_2bipy, phen, NO_2phen).

RESULTS AND DISCUSSION

General characterization

The elemental analysis (Table 1) and IR and magnetic measurements indicated that the reaction of $Na_2[Cu(obbz)]\cdot 4H_2O$ with $Co(NO_3)_2\cdot 6H_2O$ and bipy, Me_2bipy, phen or NO_2phen yielded the binuclear complexes, which are presumed to be chemical structures, as shown in Fig. 1. In the IR spectra, the characteristic bands attributed to the starting complex $Na_2[Cu(obbz)]\cdot 4H_2O$ and terminal ligands are present. The most characteristic features are the very strong and wide band centred at 1600 cm^{-1} and the strong and sharp band centred at ca. 800 cm^{-1}, due to the presence of oxamido group. On the other hand, a very strong and wide band attributable to water appears at 3400 cm^{-1}.

Magnetic properties

The temperature dependences of the susceptibility and magnetic moment for (1) and (3) are shown in Figs 2 and 3, the effective magnetic moments per molecule are 3.07 B.M (1) and 3.46 B.M. (3) at room temperature, respectively, which are slightly lower than the spin-only value 4.24 B.M., implying the operation of antiferromagnetic spin-exchange interaction. Variable temperature susceptibility data were collected for (1) and (3) (Figs 2 and 3). Cobalt(II) ion under O_h-symmetry possesses the $^4T_{1g}$ ground state. Therefore, the magnetic susceptibility for a copper(II)—cobalt(II) ($S = 3/2$) binuclear complex with cobalt(II) under O_h-symmetry is difficult to explain. However, for the present complexes the configuration around the cobalt(II) ion is somewhat distorted from O_h-symmetry. According to Sinn [3], it is likely that the Heisenberg model is applicable to the explanation for the magnetism of the present copper(II)—cobalt(II) complexes. Based on this model ($\hat{H} = -2J\hat{S}_1\hat{S}_2$), the molar magnetic susceptibility for a copper(II)—cobalt(II) ($S = 3/2$) binuclear complex is represented by eqn (1) [3].

$$X_M = \frac{2N\beta^2}{K(T-\theta)}\left[\frac{5g_2^2+g_1^2\exp(-4J/KT)}{5+3\exp(-4J/KT)}\right] \quad (1)$$

where $g_1 = (5g_{Co}-g_{Cu})/4$, $g_2 = (3g_{Co}+g_{Cu})/4$ and each symbol has its usual meaning.

As shown in Figs 2 and 3, good least-squares fits to the experimental data were attained with eqn (1). The magnetic parameters and the agreement factor $F = \Sigma[X_M)_{obs}-(X_M)_{calc}]^2/\Sigma((X_M)_{obs}$ thus determined

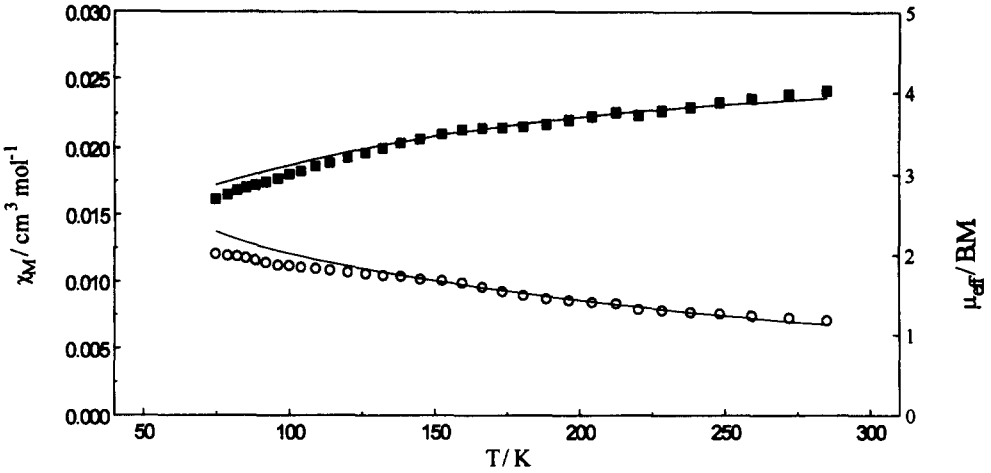

Fig. 2. X_M versus T plots for [Cu(obbz)Co(bipy)$_2$]. The curve is drawn based on eqn (1) with the magnetic parameter given in the text.

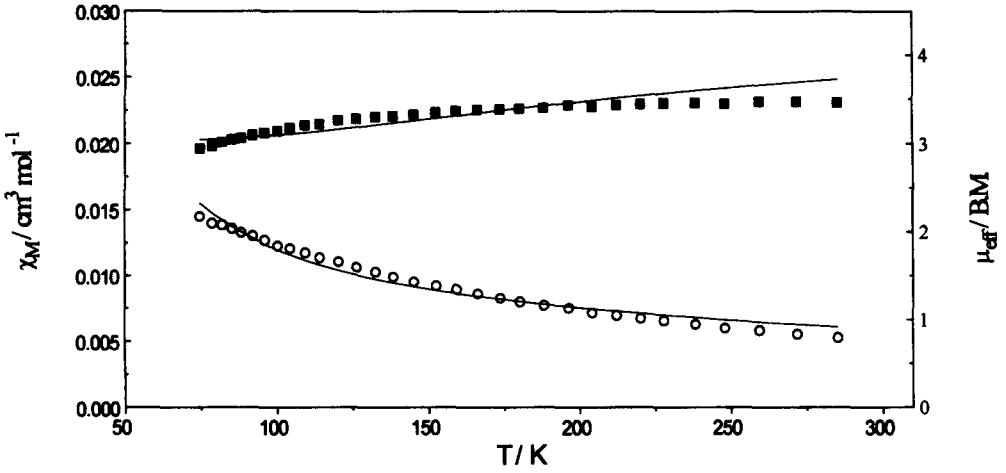

Fig. 3. X_M versus T plots for [Cu(obbz)Co(phen)$_2$]. The curve is drawn based on eqn (1) with the magnetic parameter given in the text.

are $\theta = -8$, $J = -48$ cm^{-1}, $g_{Cu} = 2.01$, $g_{Co} = 2.12$, $F = 2.8 \times 10^{-5}$ for (**1**) and $\theta = 0$, $J = -73$ cm^{-1}, $g_{Cu} = 2.01$, $g_{Co} = 2.11$, $F = 2.4 \times 10^{-5}$ for (**3**). These results ($J < 0$) indicate that the complexes undergo an antiferromagnetic spin-exchange interaction, between Cu(II) and Co(II) ions.

To describe the mechanism of the exchange interaction, several models have been proposed [4,5]. According to these models, strict orbital orthogonality results in ferromagnetism, otherwise an antiferromagnetic coupling should be expected. For the present complexes, if the whole molecular symmetry is considered to be C_{2v} and the coordinates used is shown by Fig. 1, the 3d metallic orbitals of copper(II) and cobalt(II) ions transform as $a_1(d_{z^2}, d_{x^2-y^2})$, $a_2(d_{yz})$, $b_1(d_{xy})$ and $b_2(d_{zx})$. Around the copper(II) ion there is just one unpaired electron which occupies the b_1(Cu) orbital. Around the cobalt(II) ion the unpaired electron has some distribution in b_1(Co) [6]. Because there is no orthogonality between the b_1 magnetic orbitals centred on the copper(II) and cobalt(II) ions, the antiferromagnetic interaction should be observed.

(Received 8 April 1997; accepted 30 June 1997)

Abstract—Several mercury(II) complexes with 2-pyridinecarboxylic and 6-methyl-2-pyridinecarboxylic acids as well as with corresponding esters have been obtained and some of them structurally characterized by X-ray diffraction. $[HgC_5H_4NCOO)_2]$ consists of one-dimensional chains of octahedrally coordinated mercury atoms linked by means of the oxygen atoms of the carboxylate groups. The structure of the isomorphous complexes $[HgX_2(C_5H_4NCOOPr^i)]$, X = Br or I, consists of isolated centrosymmetric dimers with unsymmetrical μ-X bridges, where mercury atoms are in a distorted square pyramidal coordination. Complex $[Hg(Cl_2(Me-C_5H_3NCOOEt)]$ has a polymeric chain structure formed by loosely bound formula units through a unique non-planar bis(chloride) asymmetric $Hg(\mu\text{-}Cl)_2Hg$ bridge. In all cases picolinate ligands behave as chelates. The crystal structures are compared with those found for the related family $[HgCl_2(C_5H_4NCOOR)]$, R = Me, Et, Pr^n or Pr^i. © 1998 Published by Elsevier Science Ltd. All rights reserved

Keywords: mercury complexes; picolinate complexes; chelate complexes; crystal structures; FAB mass spectra.

A significant number of 1:1 adducts of mercury(II) halides, particularly with tertiary phosphines, have been structurally characterized [1,2]. Although the structure most frequently encountered consists of discrete centrosymmetric halide-bridged dimers, other more highly associated structures also occur [3]. However, the small amount and great diversity of structural data currently available thwart any attempt at a systematic catalogue.

We have recently reported the synthesis and X-ray crystal structure of $HgCl_2$ adducts with esters of 2-pyridinecarboxylic acid, which, unlike tertiary phosphines, behave as bidentate ligands. Accordingly, the structures of $[HgCl_2(C_5H_4NCOOR)]$ complexes have shown a great variety ranging from different one-dimensional chains for R = Me and Et, through well separated tetramers for R = Pr^i, to discrete dimers for

* Author to whom correspondence should be addressed.

R = Pr^n [4]. This remarkable diversity prompted us to extend the previous work to other halide ions and to ligands related to esters of 2-pyridinecarboxylic acid. As a result we now report the synthesis of $[HgX_2(C_5H_4NCOOPr^i)]$, X = Br (**5**), I (**6**), and $[HgCl_2(MeC_5H_3NCOOR)]$, R = Me (**7**), Et (**8**) complexes. The structural features observed for the isomorphous complexes **5** and **6** are similar to those already reported for $[HgCl_2(C_5H_4NCOOPr^n)]$, all three being discrete centrosymmetric dimers with unsymmetrical bis(μ-halide) bridges. Complex **8** consists of an infinite one-dimensional chain, which can be compared to that found in complex $[HgCl_2(C_5H_4NCOOEt)]$ [4], although the geometrical parameters of the linking —Hg(μ-Cl)$_2$Hg— units in both compounds are markedly different. Several mercury(II) complexes with 2-pyridinecarboxylic and 6-methyl-2-pyridinecarboxylic acids in anionic form are also reported. The X-ray structure of $[Hg(C_5H_4NCOO)_2]$ (**1**) shows that it consists of a one-dimensional chain where carboxylate groups bridge consecutive mercury atoms. A preliminary report on this structure has already been given [5].

EXPERIMENTAL

Preparations

The compound 6-methyl-2-pyridinecarboxylic acid was synthesized as previously described [6]. Its ester derivatives as well as the isopropyl ester of the commercially available 2-pyridinecarboxylic acid were obtained by the usual esterification procedure in acidic medium with an excess of the corresponding alcohol [7].

The same general procedure was used in all syntheses of complexes. A 4.10^{-2} M solution (25 cm^3) containing the mercury(II) salt was slowly added to the same volume of a solution of the ligand. In all cases a white solid formed after 30 min of stirring, which was filtered off, washed with diethyl ether and dried *in vacuo*. The solvent, the mercury(II) salt and the Hg^{II} to ligand molar ratio used in each synthesis, the yield of the reaction and the elemental analysis of each complex together with the corresponding label are given in Table 1. Transmission FT-IR were recorded from KBr discs at room temperature on a Perkin–Elmer 2000 spectrometer (2 cm^{-1} resolution) in the region 4000–400 cm^{-1}. The ^{1}H NMR spectra at room temperature were obtained in D_2O or CD_3OD solution in a Bruker AC-250 MHz instrument and externally referred to TMS. Positive-ion fast atom bombardment (FAB) mass spectra were obtained with a VG Quattro quadruple mass analyser.

Single crystals of **1** were obtained from a methanolic solution of $C_5H_4NCOOMe$ and $Hg(AcO)_2$ in a 1:1 molar ratio. Crystals of **5, 6** and **8** were obtained by recrystallization of the corresponding solid in ethanol for **5** and **6** and methanol for **8**.

X-ray crystallography

Crystal data and selected information on data collection and structure determination are given in Table 2. Data for **5** and **6** were collected on an Enraf–Nonius CAD4 diffractometer at room temperature; cell parameters were refined from an initially found set of reflections, and intensities were measured by $\omega/2\theta$ scan, using standard control software. Data for **8** were collected on a Siemens SMART CCD area detector diffractometer with nitrogen gas cooling; cell parameters were refined from the observed setting angles of all strong reflections in the complete data set, and intensities were integrated from series of narrow-frame exposures (0.3° in ω), using standard Siemens SMART and SAINT software. Graphite-monochromated Mo-$K\alpha$ radiation (λ = 0.71073 Å) was employed in all cases. Absorption corrections were applied semi-empirically, based on azimuthal scans and symmetry-equivalent reflections.

The structures were solved by direct methods [8] and refined by full-matrix least-squares on F^2 for all unique measured data [9], with weighting $w^{-1} = \sigma^2(F_0^2) + (aP)^2 + (bP)$, where $P = (F_0^2 + 2F_c^2)/3$. Hydrogen atoms were included with riding model constraints, and other atoms were refined anisotropically. In agreement with the ^{1}H-NMR spectrum, compound **8** was found to contain a disordered mixture of the ethyl and methyl ester ligands; the relative proportions are 0.47:0.53(3), and the terminal methyl group of the ethyl substituent is poorly defined.

Atomic coordinates, complete bond lengths and angles, and displacement parameters have been deposited as supplementary material at the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Synthesis, infrared and ^{1}H NMR results

Reactions of $Hg(AcO)_2$ with 2-pyridinecarboxylic acid at 1:2 or 1:1 metal to ligand molar ratio lead to complex **1**. However, the same reaction with 6-methyl-2-pyridinecarboxylic acid leads to complex **2** if the molar ratio used is 1:2 but to complex **3** if it is 1:1 (Table 1). Conductivity data for **2** and **3** indicate that none of them gives rise to ions in solution and thus it is likely that acetate ions in the solid are bound to mercury atoms. The slight solubility of **1** in most solvents has not allowed conductivity measurements and has precluded formation of single crystals from recrystallization of the corresponding solid. These have been obtained after leaving undisturbed for several weeks a methanolic solution of $Hg(AcO)_2$ and 2-pyridinecarboxylic acid methyl ester at 1:1 molar ratio.

According to infrared data, the pyridine nitrogen atom is coordinated to mercury in all the complexes, as shown by the two strong absorptions at 1350 and

[a] The solvent used for the synthesis of complexes **1, 3, 7** and **8** was methanol, for complexes **2, 5** and **6,** ethanol and for complex **4,** a 1:1 MeOH/EtOH mixture.

[b] 4×10^{-2} M salt solutions have been used.

[c] Required values are given in parentheses.

[d] 10^{-3} M in methanol. Absence of data indicates insoluble complexes.

[e] A 1:1 ratio leads to the same complex.

[f] Synthesis are given in ref. [4]. As there reported, a 1:2 molar ratio affords the 1:1 adduct, $HgX_2(L)$, exclusively.

650 cm^{-1} [10,11]. Moreover, the difference between the symmetric and asymmetric stretching vibrations of the carboxylate group, $\Delta = [\nu(COO)_{as} - \nu(COO)_s]$, can provide information on the possible behaviour of anionic carboxylate ligands in complexes **1–4** as well as on that of the acetate group in complex **3**. Unfortunately, a Δ value cannot be easily established for complexes containing carboxylate groups of ester ligands. Comparison of the Δ values found for complexes **1–3** together with the proposed behaviour of the corresponding carboxylate group based on the literature data [12,13] is given in Table 3. A good agreement is found for complex **1** of known structure. According to the literature a Δ value in the range 200–270 is indicative of COO^- behaving as a unidentate ligand. For mercury–carboxylate complexes, this range would also be compatible with bidentate bridging carboxylate groups with two different mercury oxygen distances. This is the case for complex **1** of known structure (description of the structure below), where Hg—O bond lengths are 2.470 and 2.756 Å. Complexes **2** and **3** show essentially the same Δ value, which is close to that of **1** and thus the same behaviour of the COO^- group for 6-methyl-2-pyridinecarboxylate ligand in **2** and **3** as that of 2-pyridinecarboxylate in **1** could be proposed.

Overlapping of bands has not allowed prediction of the behaviour of carboxylate and nitrate groups in complex **4**. In this case the bands at 1720 and 1618 cm^{-1} can be assigned to the $\nu_{as}(COOH)$ and $\nu_{as}(COO)$ vibrations, respectively. The simultaneous presence of COOH and COO^- groups in metal complexes is not unusual; examples of complexes related to those reported here are: $[M(C_5H_4NCOOH)(C_5H_4NCOO)X]$, X = Cl, Br, SCN and M = Co, Ni, Cu [14,15] or X = Cl and M = Zn [16], $[Mn(C_5H_4NCOOH)(C_5H_4NCOO)Cl]_2$ [17] and $[Ag(C_5H_4NCOOH)(C_5H_4NCOO)]\cdot H_2O$ [18]. Although the X-ray structure for $[Ag(MeC_5H_3NCOOH)(MeC_5H_3NCOO)]$ is known, the correlation between infrared data and ligand behaviour remains difficult.

Table 3. Proposed behaviour of the carboxylate group in complexes **1–3**, based on infrared data

Complex	$\Delta = [\nu(COO)_{as} - \nu(COO)_s]$	Proposed behaviour for COO^- group[a]
1	196	Unidentate
2	205	Unidentate
3	206 ($MeC_5H_3NCOO^-$)	Unidentate
	167 ($MeCOO^-$)	Bidentate bridging or chelating[b]

[a] Literature data (ref. [12]) allow the following assignments: Δ = 200–270, unidentate; Δ = 160–172, chelating or bridging.

[b] In most examples (CSD, ref. [33]) of mercury complexes with acetate group, it behaves as bidentate bridging rather than chelating ligand.

The production of complexes **5–8** irrespective of the ester to metal molar ratio parallels the behaviour found for the series $[HgCl_2(C_5H_4NCOOR)]$, R = Me, Et, Pr^n and Pr^i, of known structure [4]. Conductivity and infrared data for complexes with esters of 2-pyridinecarboxylic acid (**5**, **6**) or 6-methyl-2-pyridinecarboxylic acid (**7**, **8**) are in good agreement with those observed for this series of $[HgCl_2(C_5H_4NCOOR)]$ complexes. This, together with the X-ray data for **5**, **6** and **8**, shows that the behaviour of chloride ions and ester ligand in complex **7** is probably similar to that in the other complexes.

^1H NMR spectra were recorded for all complexes except for **1** and **4** owing to their very low solubility in common solvents. Data for complexes **2**, **3** and **5–8** are shown in Table 4. The observed chemical shifts for the complexed ligands have very close values to those of the uncoordinated pyridinecarboxylate compounds. The spectrum of a solution of crystals of **8**, in contrast to those for complexes **5–7**, gave evidence that a partial trans-esterification reaction had occurred during its recrystallization from methanol. The X-ray crystal structure of **8** fully confirmed this observation. Integration of peaks for **3** indicated the presence of acetate and 6-methyl-2-pyridinecarboxylate anions in a 1:1 ratio.

FAB mass spectra

Positive-ion FAB mass spectra have been recorded for complexes **5** and **6** in glycerol and *p*-nitrobenzyl alcohol matrix, respectively. In both cases, the dinuclear nature of the corresponding complex species is fully confirmed by a molecular ion (MH^+) peak at *m/z* 1052 (**5**) and 1240 (**6**). Three most intense peaks can be attributed to the successive loss of one isopropyl group, then one halogen atom (Br for **5** and I for **6**) and finally one whole ester ligand. These peaks are observed at *m/z* 1018, 938 and 775 for complex **5** and 1204, 1077 and 912 for complex **6**. The spectrum of **6** is shown in Fig. 1 as representative of both complexes.

The molecular ion peak has not been observed in the FAB mass spectrum of complexes **1–4**, this is probably due to the low solubility of **2** and **3** and the practical insolubility of **1** and **4** in common organic solvents. The spectra of both **7** and **8**, feature fragmentation peaks corresponding to the breakdown of the complex with the loss of one chlorine atom.

Description of the structures of $[Hg(C_5H_4NCOO)_2]$ (**1**), $[HgBr_2(C_5H_4NCOOPr^i)]$ (**5**), $[HgI_2(C_5H_4NCOOPr^i)]$ (**6**) *and* $[HgCl_2(MeC_5H_3NCOOEt)]$ (**8**)

The structure of complex **1** consists of an infinite one-dimensional chain of mercury atoms linked by 2-pyridinecarboxylate ligands, which behave as chelates

and simultaneously bridge two consecutive mercury atoms (Fig. 2). Selected bond lengths and angles are given in Table 5. The chain could be considered as formed by centrosymmetric units of formula $[Hg(C_5H_4NCOO)_2]$, where both ligands chelate the metal centre *via* the pyridine nitrogen and one carboxylate oxygen atom. The other oxygen of the same group is responsible for chain formation with the next mercury. The single crystallographically independent mercury atom completes the distorted octahedral coordination [73.15(14)–106.85(14)°] to the two chelating ligands with two additional oxygen atoms of neighbouring units. Because of the inversion centre on the mercury atom here are only one Hg—N and two different Hg—O distances; that within the chelating ligand [Hg—O(1), 2.470(5) Å] is significantly shorter than that with the oxygen atom of the neighbouring unit [Hg—O(2A), 2.756(4) Å], and both are greater than the sum of corresponding covalent radii, 2.22 Å [19]. Consistent with the two different Hg—O

distances, the two C—O bond lengths in the carboxylate group also differ: C(6)—O(1) is 1.268(6) Å and C(6)—O(2) is 1.232(7) Å. The polymer chains run parallel to the *c* axis and are linked only by normal van der Waals interactions.

Mercury complexes with carboxylate ligands show for the COO^- group a wide variety of coordination modes. The one where each carboxylate oxygen is singly coordinated to a different mercury atom is the most common. However, with this restriction, complexes with carboxylate ligands containing an additional amine-nitrogen donor atom reduce to [MeHg($PhCH_2CH_2CH(NH_2)COO$)] [20], [MeHg($MeSCH_2CH_2CH(NH_2)COO$)] [21] and [$Hg_2\{Me_2NCH_2CH_2NMe_2CH_2CO_2\}_2Cl_4$] [22]. None of these three structures is comparable to that found for [Hg($C_5H_4NCOO)_2$], which has main structural features analogous to those observed in [Cu(C_5H_4N-$COO)_2$] [23].

The structure of complexes **5** and **6** consists of isolated centrosymmetric dimers with unsymmetrical μ-X bridges, X = Br or I, respectively; five-coordination at each mercury is completed by a terminal halogen and a chelating picolinate ester ligand, $C_5H_4NCOOPr^i$ (Fig. 3). The most significant bond lengths and angles are given in Table 6. The bridging Hg_2X_2 unit is strictly planar owing to a crystallographic inversion centre in the middle of the Hg(μ-X)$_2$Hg ring. The mercury-bridging halogen distances are, as expected, longer than the mercury-terminal halogen distances. They all are within the sum of the van der Waals radii and agree well with literature values for complexes containing centrosymmetric Hg(μ-X)$_2$Hg units in which the mercury atoms are pentacoordinated and linked by highly unsymmetric μ-bromo [24–27] and μ-iodo bridges [28–31]. Complexes **5** and **6** show a similar structure to that found in [$HgCl_2(C_5H_4NCOOPr^n)$] rather than that of [$HgCl_2(C_5H_4NCOOPr^i)$], which consists of isolated tetramers [4]. It is noteworthy that the angles about mercury in the first three vary over a wide range. Accordingly, the approach of Reedijk *et al.* [32] has been used to assign a specific coordination geometry. The values obtained for the trigonality index, τ (zero or one if the geometry is perfect square pyramidal or trigonal bipyramidal, respectively) are given in Table 7 and indicate that a distorted square-based pyramidal geometry should be assigned in the three complexes. Comparison with τ values for related complexes found in the literature is also included in the Table.

Complex **8** has a polymeric chain structure con-

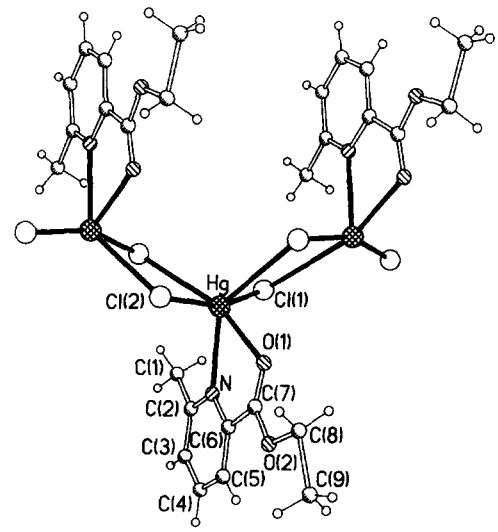

Fig. 4. Part of the polymeric chain structure of compound **8**, with unique atoms labelled.

sisting of $[HgCl_2(MeC_5H_3NCOOEt)]$ adducts, which are linked by means of secondary long range interactions between covalently bonded Hg–Cl pairs; the $Hg(\mu\text{-}Cl)_2Hg$ bridging unit thus formed is highly unsymmetrical (Fig. 4). Selected bond lengths and angles are given in Table 8. The primary coordination of the single crystallographically independent Hg atom is 4-fold by Cl(1), Cl(2) and one chelating ester ligand. On this basis the coordination geometry about mercury is very distorted with angles ranging between 158.72(7) and 64.86(19)°. Each $[HgCl_2(MeC_5H_3NCOOEt)]$ molecule links to two neighbouring units by means of a unique non-planar bis(chloride) asymmetric $Hg(\mu\text{-}Cl)_2Hg$ bridge with four different Hg—Cl distances varying from 2.3381(19) to 3.3844(19) Å and a dihedral angle between Hg—Cl(1)—Cl(2A) and Hg(A)—Cl(1)—Cl(2A) planes of 14.25°. Two of the four Hg—Cl distances are close and agree well with the expected value for mercury-terminal chlorine bonds; the sum of corresponding covalent radii is 2.43 Å. The other two are much longer but also close to each other and lie within the sum of van der Waals radii, 3.45 Å. Consideration of these long range interactions allows Hg to achieve an effective six coordination. The chain formed by the weak interaction of consecutive $[HgCl_2(MeC_5H_3NCOOEt)]$ units runs parallel to the c axis. Each unit is related to the next one by glide-plane symmetry, so that each unit is exactly one unit cell displaced from the next unit by one. Examination of the packing arrangements shows that the chains are well separated.

The X-ray structures of the series of adducts $[HgCl_2(C_5H_4NCOOR)]$, recently determined, have shown that complexes with R = Me and Et adopt polymeric chain structures, both different from complex **8**, while those with R = Pr^n or Pr^i comprise only discrete centrosymmetric dimers and tetramers,

respectively [4]. Comparison of the one-dimensional chains found for the $[HgCl_2(C_5H_4NCOOR)]$, R = Me, Et, complexes with that of complex **8** indicates that the main difference lies in the geometric parameters of the corresponding $Hg(\mu\text{-}Cl)_2Hg$ building units. That of complex **8**, unlike the other two, allows a description of the chain as formed by loosely bound monomeric $[HgCl_2(MeC_5H_3NCOOEt)]$ molecules. These data indicate that not only the nature of the alkyl group R in $[HgCl_2(C_5H_4NCOOR)]$ complexes but an increase in the steric effects of the picolinate ester ligand, as happens in $[HgCl_2(MeC_5H_3NCOOEt)]$, have a strong influence on the geometry of the constituent $Hg(\mu\text{-}Cl)_2Hg$ bridging units, which probably play a significant role in influencing the structure of the corresponding $HgCl_2$ adducts. Moreover, while complexes **5** (X = Br) and **6** (X = I) of general formula $[HgX_2(C_5H_4NCOOPr^i)]$ are isostructural and consist of discrete dimers, the structure of the Cl analogue is formed by well separated tetramers. Thus, it is likely that the smaller size of the chlorine atom allows an increase in the nuclearity of the corresponding complex species.

Acknowledgments—We thank DGICYT (PB94-0695) and EPSRC for financial support. R.M. is grateful for a grant from Ministerio de Educación y Ciencia. Dr M. Seco is thanked for his help in recording the FAB mass spectra and for interesting discussions.

Cyclic voltammetric studies on *N,N*-disubstituted *N'*-ferrocenoylthioureas and their transition metal complexes

O. Seidelmann and L. Beyer*

Institute of Inorganic Chemistry, Department of Chemistry and Mineralogy, University of Leipzig, D-04103 Leipzig, Germany

(Received 7 October 1997; accepted 14 November 1997)

Abstract—The Fe(II)/Fe(III) redox potentials of *N,N*-disubstituted *N'*-ferrocenoylthioureas and the respective ferrocene-1,1'-dicarbonic acid-di- *N,N*-dialkyl-thioureids are shifted cathodically by complexation of Ni(II), Cu(II), Co(III), Mn(II), Pt(II) and Pd(II). The extent of the shift is more pronounced in the latter ligand class and reaches values up to −0.32 V. The *N,N*-disubstituted *N'*-ferrocenoylthioureas exhibit two redox processes in dichlormethane. A mechanistic scheme is proposed. Ferrocene-1,1'-dicarbonic acid-di- *N,N*-dialkyl-thioureids decompose after oxidation in dichlormethane. In contrast, complexes of both ligand types contain quasireversibly oxidisable ferrocene subunits. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: ferrocene; thiourea; cyclic voltammetry; coordination compound; redox switch; transition metal.

Heterobimetallic compounds are being investigated intensively [1,2]. Their desired molecular features like catalysis, optical behaviour, conductivity and magnetism [3] are predominantly determined by the oxidation state of the metals involved and by metal–metal communication [4]. In order to increase this intermetal interaction, efforts are aimed to synthesise molecules in which metals are bound in close proximity and/or being connected by a conjugated pathway [5,6,7].

Ferrocene can be used as one part in heterobimetallic compounds. There is evidence that, owing to orbital geometry, interaction between the embedded iron and a second metal bound on sidechains of the cyclopentadienyl rings is poor [8]. Nevertheless, a rising number of ferrocene derivatives has been created capable of complexing additional metal ions. The ferrocene subunit itself meets a lot of basic requirements essential for a wide application like stability, large-scale availability, safe handling and ease of derivatisation. The reversible Fe(II)/Fe(III) redox behaviour may be the most useful feature of this compounds. On the one hand monitoring of these potential allows us to detect binding of an other (metal) ion [9–11], on the other hand the binding strength of this ion can be "tuned" by switching the ferrocene oxidation state [12–15].

Because of their biological importance, emphasis of many research activities has been placed on complexation of alkaline metals within ferrocene containing frameworks [16,17]. However, binding of transition metal ions on mainly nitrogen, nitrogen and oxygen or sulphur of ferrocenyl sidechains has been studied as well [18–20]. In many cases, electrochemical behaviour revealed a moderate anodic shift of the Fe(II)/Fe(III) redox couple after complexation [21].

N,N-disubstituted *N'*-acylthioureas are easily accessible, well investigated ligands [22] obtaining excellent chelating properties for a wide range of transition metal ions. They posses a hard and a softer donor atom and the possibility of compensating positive charges by deprotonation [23–25].

Introduction of the ferrocene moiety into this ligand class has been accomplished recently, heterobimetallic complexes have been synthesised [26,27]. In these compounds a conjugated link between the two metals is combined with their quite close proximity—especially concerning coordination compounds of the ferrocene-1,1'-dicarbonic acid-di- *N,N*-dialkyl-thi-

oureids. Therefore, cyclic voltammetric studies should show distinct effects resulting from electronic changes by complexation of a second transition metal.

The following complex compounds have been employed.

EXPERIMENTAL

Synthesis of the compounds

Compounds **1**–**5**; (**1**–**4a**–**f**) and (**5**–**7**)**b** have been prepared according to literature methods [26,27]. Chelates (**5**–**7a**) have not been isolated but were only obtained in solution by mixing of stoichiometric amounts of ligand (dissolved in 20 cm^3 dichlormethane) and the respective metal acetate (dissolved in 0.5 cm^3 ethanol) at room temperature immediately prior voltammetric measurements.

Compounds **6** and **7** have been prepared as follows. The respective *N*,*N*-disubstituted thiourea (15 mmol = 1.95 g for **6**; 2.19 g for **7**) [28] was suspended in 30 cm^3 dry toluene and 15 mmol (1.2 g) dry pyridine under argon. At a temperature of 90°C 1,1′-ferrocene dicarbonylchloride (7.5 mmol = 2.33 g), dissolved in 30 cm^3 toluene, was added dropwise to the vigorously stirred suspension over a period of 45 min. After 5 h stirring at this temperature, the residue was filtered off and washed three times with 20 cm^3 hot toluene. The united dark brown toluene solution was washed twice with 20 cm^3 cold water, dried using sodium sulphate and evaporated to dryness. The dark paste was treated with hot *n*-hexane until it solidified. Recrystallisation in toluene yielded orange brown crystals.

Analytical data of the new compounds are to be found in Table 1.

Cyclic voltammetry

Cyclic voltammetry was performed using a conventional three-electrode system. The working electrode was a glassy carbon disc (Metrohm, number: 6.1204.000, ϕ = 3 mm), polished with an Al_2O_3 suspension prior every experiment. The counter electrode was a platinium disc (Sensortechnik Meinsberg, Germany). A double junction Ag/AgCl electrode was used as reference (Metrohm, number: 6.0726.110). The inner chamber was filled with a saturated solution of LiCl in ethanol, the outer chamber contained a 0.1 M TBAPC solution in dichlormethane. Dichlormethane was of p.a. grade and saturated with nitrogen. The concentration of supporting electrolyte (Bu_4NClO_4) was 0.1 M. The concentration of compounds investigated was 0.5 mM, 1 mM and 5 mM. The number of electrons involved in oxidation processes was determined by coulometry. All compounds were investigated at 25°C. Cyclic voltammograms of ligands **1**–**4** also were measured at 0°C. The estimated error of measured voltage is about 0.01 V. All data represent the average of five measurements.

Voltammograms (v = 1–50 mV s^{-1}) were recorded with the electrochemical interface (SI 1280, Solartron-Schlumberger) under application of the software CORRWARE (Scribner, Charlottesville VA). Voltammograms (v = 100–1000 mV s^{-1}) were recorded with a "AUTOLAB PGSTAT -10". "Digi Sim 2.0" by Bioanalytical Systems, Inc., was used to simulate cyclic voltammograms.

Potentiometric titration in dioxan/water 75 : 25 was employed to determine pK_s values.

RESULTS AND DISCUSSION

Ferrocenoyl-thioureas of the types L1H and L2H2

As an example of the ligand centred redox processes, the cyclic voltammogram (CV) of **4** in dichlormethane is shown in Fig. 1. Each CV recorded of **1–4** reveals the displayed shape. Two one-electron redox couples, the first at a potential of about 780 mV (I), the second at 900 mV (I), occur (Table 2). This is quite an unexpected result because the respective benzoylthiourea do not show any redox process without initial oxidation in a potential range of 1.1 V to −0.5 V [29] and the ferrocene subunit should only give rise to one such process (Fe(II)/Fe(III)). A third reduction peak occurs only at fast scan rates at about −0.2 V (III).

As side chain centred quasireversible redox processes are not expected, both redox couples should be caused by the ferrocene moiety. An anodic shift of the Fe(II)/Fe(III) couple compared with ferrocene/ferrocenium is expected because of the electron withdrawing effect of the carbonyl function attached to ferrocene in **1–4**. The shift extent of I (about +0.25 V) corresponds with comparable substituted compounds [21]. Therefore, we attribute this one electron step to this process. The redox potential is only slightly influenced by different -NR_2 (Table 2). Parallel to

our work, the redox behaviour of *N*-ferrocenoyl-*N'*-monosubstituted thiourea has been investigated [30]. A comparable influence of the amine substituents on the redox potential is attributed there to an intramolecular hydrogen bonding ring. As compounds **1**–**4** do not form hydrogen bridges, this effect cannot be explained in this way. The magnitude of the amine dependent redox shift corresponds with that of the experimental error. Therefore, we do not venture an explanation.

In order to investigate the nature of the redox processes, further CV experiments were carried out. They included repeated potential cycling, initial 200 s electrode polarisation at various potentials, varying of scan rate, temperature and concentration. The following results have been obtained.

(i) Adsorption could be excluded as a reason for one of the peaks because of their concentration independent height relation; (ii) Varying of concentration (0.5 up to 5 mmol l^{-1}) shows no effect on the redox potentials or CV shape; (iii) Oxidation peaks I and II are diffusion-controlled ($i \sim v^{1/2}$) (Fig. 2.); (iv) Reduction current III decreases to zero at scan rates < 10 mV s^{-1} (Fig. 1.); (v) Process III is only detectable after initial oxidation at II; (vi) During repeated potential cycling I disappears, the oxidation peak of II broadens, its reduction peak is shifted to more cathodic potentials and increases. Potential cycling within a potential window of 0.5 V and 0.9 V (redox couple I) results in quite reproducible CVs without any change of the peaks. Even an initial electrode polarisation at 0.9 V for 200 s does not affect the CV shape remarkably (Fig. 3.). This allows the conclusion of a comparatively stable oxidation product; (vii) Potential cycling beyond the anodic peak of I (0.75–1.2 V) covering both electrochemical processes of II leads to irreversible destruction of the chemical species involved. Similar effects are observable after

electrode polarisation beyond 0.95 V; (viii) Current of II is temperature dependent. At 0°C its magnitude is only 70% of that measured at 25°C while I seems to be unaffected.

These effects and the earlier drawn conclusion concerning the ferrocene centred character of II give rise to the assumption that this process involves the Fe (II)/Fe(III) couple of a product of I_{ox} which lost its positive charge by a chemical reaction. A similar CV behaviour has been observed recently [31]. There, the oxidised ferrocene subunit was immediately reduced by a phosphino substituent which led to a second Fe(II)/Fe(III) redox process. Here, the reaction following the first oxidation is supposed to be fast as well, because various v (1–1000 mV s^{-1}) do only have a slight effect on the current ratio II_{ox}/I_{ox}. Considering the weak but detectable acidity of ligands **1–4** [27] and its known enhancement by oxidation of ferrocene bearing acids [33]—due to the repulsive effect of positive charges—we propose to attribute II to the Fe (II)/Fe(III) redox couple of oxidised and deprotonated compounds **1–4**. The oxidation product of II seems to be chemically unstable and causes unidentified decomposition products. One of which gives rise to the reduction peak at −0.2 V if the scan rate is fast enough. The two broad redox peaks remaining after prolonged potential cycling and the increase of the reduction peak indicate an electrode surface coating which can also be seen visually.

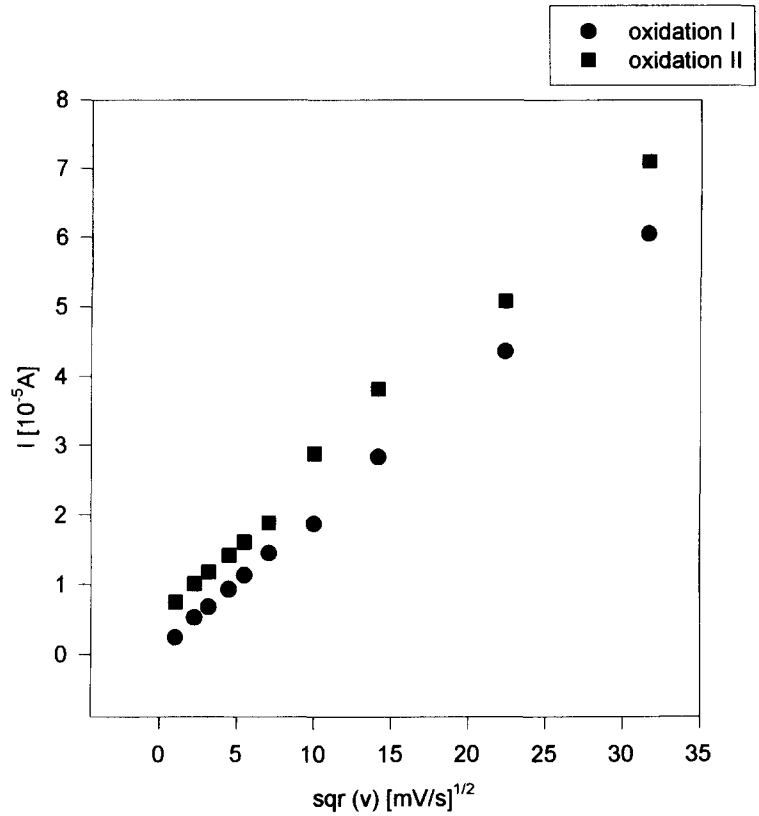

Fig. 2. Oxidation current of processes I and II vs sqr (v) (v: 1 mV s^{-1}–1000 mV s^{-1}, c = 1 mM).

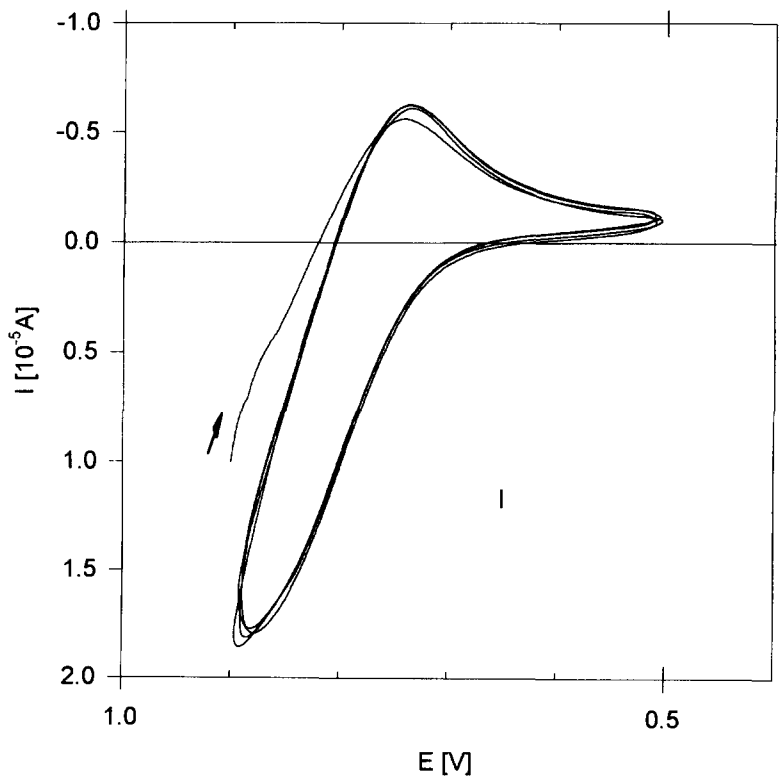

Fig. 3. Cyclic voltammogram of **4** (1 mM) in dichlormethane. Cycles without interim electrode polish. Scans: 200 s electrode polarisation at 0.9 V then 10 cycles, 0.9 V to 0.5 V and return.

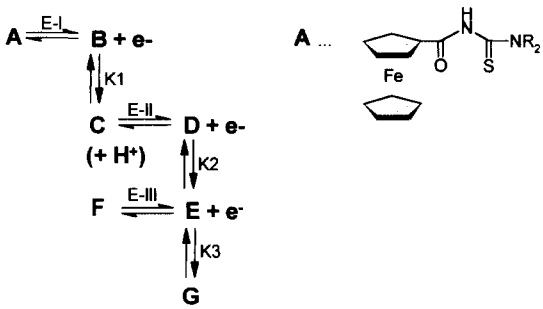
The following scheme sums up chemical and electrochemical processes we assume to take place during CV studies on **1–4**.



As indicated by the temperature dependence of II, a chemical reaction (K1) should be neccessary to form C. Reduction III is not detectable without initial oxidation II. Therefore, E should result from D and not from C. Obviously, stability of E is limited. Decomposition to the electrochemically inert G can be assumed.

To strengthen the theory of this mechanism the cyclic voltammograms were computer-simulated. According to the measured CVs, the curves were simulated for various scan rates and concentrations using one set of parameters. It cannot be expected that simulated CVs of such a complex mechanism resemble the measured ones in all characteristics. The mathematical software model is too simple to reflect the complex reality correctly. The estimation and variation of 23 independent parameters belonging to 8 mostly unknown species should give the true values only in exceptional cases. Nevertheless, one set of parameters yields CVs which resemble the experimentally recorded fairly well (Fig. 4). Accept from the absolute values of the current, the main charactristics are displayed correctly within a scan rate range of 1 mV s^{-1} to 1 V s^{-1}. Especially, the general shape and its relative changes are simulated adequately. At least, one can conclude from the simulations that there is no general contradiction between the proposed mechanism and the experimental data.

(Used parameter set: $E0_1 = 0.77$ V [$\alpha = 0.5$, $k_{s1} = 0.002$], $E0_2 = 0.97$ V [$\alpha = 0.5$, $k_{s2} = 0.01$], $E0_3 = -0.12$ V [$\alpha = 0.5$, $k_{s3} = 0.1$]; $K_{eq1} = 20$ [$k_f = 3$ s^{-1}, $k_b = 0.15\,s^{-1}$], $K_{eq2} = 50$ [$k_f = 100\,s^{-1}$, $k_b = 2\,s^{-1}$], $K_{eq3} = 60$ [$k_f = 0.01$ s^{-1}, $k_b = 0.000167$ s^{-1}]; D [cm^2 s^{-1}]: $D_A = 2 \cdot 10^{-5}$, $D_B = 0.0002$, $D_C = D_D = D_E = D_F = D_G = 1 \cdot 10^{-5}$.)

Ligands **5–7** show a different and less complex redox behaviour. Only one oxidation peak occurs in dichlormethane. As expected the extent of anodic shifting is about twice as large as measured at the monosubstituded ligands **1–4**, compared with ferrocene/ferrocenium. The influence of -NR_2 is negligible (Table 2). Repeated potential cycling reveals irreversibility of the oxidation process.

The two pK_s values of **5–7** lie in a narrow range around $pK_s1 = 11.1$ and $pK_s2 = 12.6$. So, compared with **1–4** [27], their first deprotonation step is slightly more enhanced. Therefore, a proton loss and further reactions following the oxidation is imaginable here as well. More probable, however, is a total destruction of the electron lacking ferrocene moiety which lost here the "electron buffer" capacity of the unsubstituted cyclopentadienyl ring [31].

Heterobimetallic coordination compounds

Cyclic voltammograms of (**1–4a–f**) reveal only one ferrocene centred redox couple representing a two electron transfer (Fig. 5). Hence, an interaction between the two ferrocenes can be excluded [21]. This redox process is shifted to more cathodic potentials compared with the free ligands (Table 3). Considering the positive charge of the coordinated metal ions, an anodic shift might be expected as it is reported in most papers dealing with comparable compounds. In [32] the first example of a cathodic shifted redox potential is reported. There and here deprotonation accompanies complexation and the entering transition metal has to "compensate" the electron withdrawing effect of the leaving, "hard" proton. This is done incompletely in general and means an increase in complex stability of the oxidised coordination compound compared with the neutral one [34]. As can be seen from the data of Table 3, the different metal ions investigated have only a modest metal specific influence on the Fe(II)/Fe(III) redox couple leading to comparable shifts of about −0.15 V with −0.05 V (**4d**) and −0.19 (**1c**) as most extreme values.

Whereas no general trend can be deduced from the data, the following order going parallel with increasing shift extents is valid within a compound class resulting from one ligand: Mn(II)Pd(II)Pt(II)Ni(II) Cu(II)Co(III). A reason for this order could be the charge/radius ratio. The smaller it is the more negative shifts should be detected. However, this approach does only apply to the order of Mn(II)—Ni(II)—Cu(II). Especially the large shift of the "hard" Co(III) can not be explained in this way. Therefore an other aspect should be taken into consideration. The cathodic shift could be caused by a a π-donation effect of the oxygen. Mn(II) is the best a π-acceptor of the ions mentioned above and Co(III) the worst. So the ferrocenium state is more stabilized by the a π-electron withdrawing Mn(II) ion than by Co(III).

In most cases the redox processes are more reversible here than those of the free ligands. A comparable repulsion of the bound metal ion followed by chemical reactions and compound destruction could not be observed during potential cycling. In all coordination compounds, except the palladium chelates, further electrochemical processes occur in addition to the ferrocene bound redox couple, especially the quasi reversible Cu(II)/Cu(I) is easily detectable (Fig. 5).

Nearly all CVs reveal another oxidation or redox process beyond 0.9 V. It does not show much metal

specificy. The lowest values are measured for manganese chelates (0.96 V), the highest for platinium complexes (1.5 V). They could be attributed to certain metal bound redox processes, i.e. Cu(II)/Cu(III) [35], Mn(II)/(III) or Ni(II)/Ni(III), but there is no certainty about it. Comparative measurements on benzoylthiourea revealed ligand oxidation beginning beyond 1.1 V [29].

Cyclic voltammograms of (**5–7a,b**) show at least one quasi reversible two electron redox step (Table 3). Compared with the free ligand it is shifted cathodically as well but more emphasised than observed at the monosubstituted ferrocene derivatives. A compound destruction does not occur during potential cycling. According to the cathodic shift, the complex stability is enhanced by oxidising the ligand. Obviously the extended conjugated chelate system is more capable of distributing the positive charge. Additionally the side chain electron withdrawing has been lowered by substitution the proton for "softer" metals.

As mentioned in [27] the nickel chelates **5–7** tend to polymerisation. Ten minutes after addition of the nickel acetate the CV peak began to decrease and the solution became clouded, indicating the beginning polymerisation process.

CONCLUSIONS

The Fe(II)/Fe(III) redox potential of *N,N*-disubstituted *N'*-ferrocenoylthioureas and the respective ferrocene-1,1'-dicarbonic acid-di- *N,N*-dialkylthioureids displays a distinct cathodic shift upon coordination of transition metal ions. Therefore they could be used as amperometric detectors or as pH-controlled "reversed" redox switches [36] as they tend to enhance metal bonding in their oxidised state by liberating protons. Limits are set by the low metal specificity and the polymerisation tendency of **5–7**—

chelates which up to now only allows to form definite copper complexes.

Ligand destruction following the oxidation step is generally avoided by complexation. Nevertheless, investigation of the destruction mechanism and its products might be promising in order to prove the proposed reaction scheme.

(Received 10 September 1997; accepted 11 November 1997)

Abstract—The dihydroperchlorate salt of the tetra-aza macrocycle C-*meso*-5,12-diethyl-7,14-dimethyl-tetra-azacyclotetradeca-4,11-diene (L) has been prepared by the reaction of ethylenediamine monohydroperchlorate with 4-hexen-3-one in methanol solution. A variety of *trans*-$[CoLX_2]^+$ complexes (X = Cl^-, Br^-, NCS^-, N_3^-, OAc^- and NO_2^-) have been prepared and characterised as their perchlorate salts. Infrared and visible spectra are reported. Copper(II), nickel(II) and zinc(II) complexes have also been prepared and characterised. © 1998 Published by Elsevier Science Ltd. All rights reserved

Keywords: tetra-azamacrocycle; synthesis; copper(II); nickel(II); cobalt(III); zinc(II) complexes.

The reaction of ethylenediamine monohydroperchlorate with α,β-unsaturated ketones gives a range of macrocyclic tetra-azacyclotetradecadienes (Scheme). The reaction involves Michael addition of the amine monohydroperchlorate to the α,β-unsaturated ketone to give the β-aminoketone; two moles of which can then cyclise to give the macrocyclic 14-membered diimine. The reaction appears to be stereospecific giving only the *trans*-diimine with no evidence for the *cis*-isomer. The present paper describes the reaction of ethylenediamine monohydroperchlorate with 4-hexen-3-one to give the dihydroperchlorate salt (**1**). Reduction of (**1**) with $NaBH_4$ gives the saturated ligand L_A. The crystal structure [1] of $[NiL_A](ClO_4)_2$ establishes that the complex has the C-*meso* configuration (**2**) with a *trans* III (RSSR) chiral *sec*-NH configuration, confirming that the macrocyclic diene does indeed have the expected *trans*-diimine stereochemistry.

In a previous paper [2] one of us has described the facile preparation of cobalt(III) complexes of a range of tetra-aza macrocyclic dienes using cobalt(II) precursor complexes and oxidation by dioxygen. We have now extended this synthetic approach to the preparation of a range of cobalt(III) complexes of the ligand (**1**) = L. Copper(II), nickel(II) and zinc(II) complexes of the ligand have also been prepared and characterised.

EXPERIMENTAL

Synthesis

C-*meso*-5,12-diethyl-7,14-dimethyl-tetra-azacyclotetradeca-4-11-diene dihydroperchlorate. Perchloric acid (72%, 8.3 cm^3, 0.102 mol) was added to a cooled 10% methanolic solution of ethylenediamine (6.12 g, 0.102 mol). The reaction mixture was cooled to −10°C and 4-hexen-3-one (10.0 g, 0.102 mol) in methanol (10 cm^3) added dropwise. After stirring for 30 min a white precipitate began to form. Stirring was continued for 3 h then the ligand dihydroperchlorate salt was filtered off, washed with methanol, then diethyl ether and dried *in vacuo*. A second crop was obtained by allowing the filtrate to stand at room temperature for several hours. The crude product was

Scheme 1.

recrystallised from hot methanol. (**CARE!** *perchlorate salts of amines are hazardous materials and can explode on excessive heating.*) Yield: 15.1 g (61%), mp 108–109°C. Found: C, 40.0; H, 7.2; N, 11.7. Calc. for $C_{16}H_{34}Cl_2N_4O_8$, C, 39.9; H, 7.1; N, 11.6%. The infrared spectrum (KBr disc) has ν NH 3184, ν C=N 1668 and perchlorate bands at 1110 and 626 cm^{-1}.

$[CuL](ClO_4)_2$. An excess of basic copper(II) carbonate (0.36 g, 1.5 mmol) and the ligand dihydroperchlorate (0.5 g, 1.0 mmol) were slurried together in water and the mixture heated on a steam bath for 30 min. The unreacted carbonate was filtered off and the purple complex crystallised on cooling the filtrate. The complex was filtered off, washed with water then dried *in vacuo*. Yield: 0.20 g. Found: C, 35.5; H, 6.1; N, 10.3. Calc for $C_{16}H_{32}Cl_2CuN_4O_8$: C, 35.4; H, 5.9; N, 10.3%. The infrared spectrum (KBr disc) has ν NH 3238, ν C=N 1673 and perchlorate bands at 1103 and 635 cm^{-1}. The complex has λ_{max} 517 nm (ε = 87 $dm^3\ mol^{-1}\ cm^{-1}$) in aqueous solution.

$[NiL(H_2O)_2](ClO_4)_2$. This complex was prepared essentially as described above replacing basic copper(II) carbonate with nickel(II) carbonate. On cooling in ice the purple octahedral nickel(II) complex crystallised. The complex was filtered off, washed with water then dried *in vacuo*. Yield: (0.1 g). Found: C, 33.2; H, 6.3; N, 9.6. Calc. for $C_{16}H_{36}Cl_2NiN_4O_{10}$: C, 33.5; H, 6.3; N, 9.8%. The infrared spectrum (KBr disc) has ν NH bands at 3344, 3292 and 3254, ν C=N 1688 and perchlorate bands at 1089 and 624 cm^{-1}. The visible spectrum has λ_{max} at 550 and 870 nm (ε = 11 and 17 $dm^3\ mol^{-1}\ cm^{-1}$ respectively) in aqueous solution.

$[ZnL(H_2O)_2](ClO_4)_2$. Zinc(II) perchlorate hexahydrate (2.60 g, 7.0 mmol) and the ligand dihydroperchlorate salt (3.36 g, 7.0 mmol) were separately dissolved in water (ca 10 cm^3). The solutions were mixed and heated on a steam bath for 30 min. On cooling in ice very pale yellow crystals formed and were filtered off, washed with water and dried *in vacuo*. Yield: 0.95 g. Found: C, 33.1; H, 6.5; N, 9.6. Calc. for $C_{16}H_{36}Cl_2ZnN_4O_{10}$: C, 33.1; H, 6.25; N, 9.65%. The infrared spectrum has ν NH 3265; ν C=N 1670 and perchlorate bands at 1070 and 637 nm.

Trans-$[CoLCl_2]ClO_4 \cdot H_2O$. Cobalt(II) chloride hexahydrate (0.37 g, 1.55 mmol) and the ligand dihy-

droperchlorate (0.75 g, 1.56 mmol) were separately dissolved in hot methanol (10 cm^3). The solutions were mixed and heated on a steam bath for 10 min. During this time the colour changed from blue to green. On cooling in ice, the green complex crystallised and was filtered off, washed with methanol then diethyl ether and dried *in vacuo*. A second crop was obtained by reduction of the filtrate on a steam bath to ca 5 cm^3 followed by cooling in ice. Total yield: 0.75 g (91%). Found: C, 36.3; H, 6.5; N, 10.7. Calc. for $C_{16}H_{34}Cl_3CoN_4O_5$, C, 36.3; H, 6.9; N, 10.6%. Infrared spectrum ν H_2O 3418, ν NH 3205, ν C=N 1659 and perchlorate bands at 1090 and 623 cm^{-1}.

Trans-[CoLBr$_2$]ClO$_4$. Methanolic solutions of $CoBr_2 \cdot 6H_2O$ (0.51 g, 1.56 mmol) and the ligand dihydroperchlorate (0.75 g, 1.56 mmol) were treated as described above for the dichloro complex. Total yield of the green crystalline complex 0.8 g (86%). Found: C, 32.7; H, 5.6; N, 9.4. Calc. for $C_{16}H_{32}Br_2ClCoN_4O_4$: C, 33.0; H, 5.55; N, 9.6%. Infrared spectrum, ν NH 3196, ν C=N 1654 with perchlorate bands at 1084 and 623 cm^{-1}.

Trans-[CoL(NO$_2$)$_2$]ClO$_4 \cdot$ H$_2$O. *Trans*-[CoLCl$_2$]ClO$_4 \cdot H_2O$ (0.15 g, 0.28 mmol) was dissolved in hot methanol (10 cm^3). On addition of sodium nitrite (0.08 g, 1.16 mmol) dissolved in methanol (10 cm^3) the colour of the solution changed from green to yellow. After heating on a steam bath for 15 min, the solution was cooled to 4°C and diethyl ether (2 cm^3) added. On standing for several hours the yellow complex crystallised, and was filtered off, washed with diethyl ether and dried *in vacuo*. Yield: 0.10 g (65%). Found: C, 35.0; H, 5.9; N, 15.3. Calc. for $C_{16}H_{34}ClCoN_6O_9$: C, 35.0; H, 6.3; N, 15.3%. Infrared spectrum, ν H_2O 3458, ν NH 3202, ν C=N 1656, ν NO_2^- 1403, 1303, 821 and perchlorate bands at 1085 and 623 cm^{-1}.

Trans-[CoL(CH$_3$CO$_2$)$_2$]ClO$_4 \cdot$ 2H$_2$O. *Trans*-[CoLCl$_2$]ClO$_4 \cdot H_2O$ (0.10 g, 0.19 mmol) and sodium acetate (0.06 g, 0.73 mmol) were separately dissolved in hot methanol (10 cm^3). On addition of the sodium acetate solution to the cobalt complex the colour of the solution changed from green to wine red. The solution volume was reduced to ca 5 cm^3 on a steam bath and then allowed to stand for several days at 4°C. The red crystalline solid which precipitated was filtered off, washed with ethanol then diethyl ether and dried *in vacuo*. Yield: 0.8 g (71%). Found: C, 40.5; H, 6.5; N, 9.5. Calc. for $C_{20}H_{42}ClCoN_4O_{10}$: C, 40.50; H, 7.15; N, 9.45%. Infrared spectrum, ν H_2O 3440, ν C=N 1659, ν NH 3080, ν $CH_3CO_2^-$ 1577, 1388, 1329, 924, 685 with perchlorate bands at 1092 and 623 cm^{-1}.

Trans-[CoL(NCS)$_2$]ClO$_4 \cdot$ H$_2$O. *Trans*-[CoL(NCS)$_2$]ClO$_4 \cdot H_2O$ (0.15 g, 0.28 mmol) and sodium thiocyanate (0.09 g, 1.11 mmol) were separately dissolved in hot methanol (10 cm^3). On addition of the sodium thiocyanate solution the colour changed from green to deep red. The solution volume was reduced to ca 5 cm^3 and on cooling diethyl ether (2 cm^3) added. On standing for several days at 4°C a red crystalline solid deposited, which was filtered off, washed with cold methanol then diethyl ether and dried *in vacuo*. Yield: 0.07 g (44%). Physical measurements

Infrared spectra were recorded as KBr discs on a Shimadzu IR-435 instrument. Electronic absorption spectra were obtained using a Perkin–Elmer Lambda 5 spectrophotometer. Magnetic susceptibility measurements were made using a Johnson Matthey magnetic susceptibility balance using $Hg[Co(NCS)_4]$ as calibrant.

RESULTS AND DISCUSSION

The reaction of ethylenediamine monohydroperchlorate with 4-hexen-3-one in methanol solution gives good yields (ca 60%) of the dihydroperchlorate salt of 5,12-diethyl-7,14-dimethyl-tetra-azacyclotetradeca-4,11-diene (**1**) which has the centrosymmetric C-*meso* configuration (**3**). The dihydroperchlorate salt reacts with cobalt(II) chloride in methanol solution in the presence of air to give the green *trans*-$[CoLCl_2]^+$ cation which can be crystallised in high yield as the perchlorate salt. The complex has an electronic spectrum typical [3,4] of a *trans*-$[CoN_4Cl_2]$ chromophore with bands at 617 nm (ε = 46 dm^3 mol^{-1}) with a shoulder on the charge transfer band at ca 440 nm, Table 1. Thus the trans-dichlorocobalt(III) complex of C-*meso*-5,12-Me_2 [14]diene has λ_{max} 624 nm (ε = 33) with a shoulder at 450 nm (ε = 39) [3].

The green bromo-complex can be similarly prepared by replacing cobalt(II) chloride by the bromide salt. Metal complexes of this type have two chiral *sec*-NH centres so that N-*meso* and N-*racemic* diastereoisomers can occur. This aspect of the stereochemistry was not investigated in detail, but the complexes normally have a single NH band suggesting that the N-*meso* stereochemistry (4) is preferred, Table 2.

Two bands are normally observed in the *d-d* spectra of cobalt(III) complexes the $^1A_{1g} \rightarrow {}^1T_{1g}$ and the $^1A_{1g} \rightarrow {}^1T_{2g}$. If the ligand field is sufficiently high the higher energy $^1A_{1g} \rightarrow {}^1T_{2g}$ transition is frequently obscured by the high intensity ligand-to-metal charge transfer band. As a result only the lower energy band is observed in the complexes $[CoLX_2]^+$ where X = NO_2^-, N_3^- and NCS^-. Two bands are observed in the dichloro complex and the diacetato complex due to the relatively weak ligand field exerted by these monodentate ligands. The spectrum of the acetato complex is shown in Fig. 1. The higher energy band in the bromo complex is obscured due to the lower energy of the Co^{III}–Br charge transfer transition which moves into the visible region.

The nickel(II) complex was obtained as the purple octahedral species $[NiL(H_2O)_2]^{2+}$ which was readily isolated as the perchlorate salt. The visible spectrum has λ_{max} 550 nm (ε = 11) and 870 nm (ε = 15 dm^3 mol^{-1} cm^{-1}) fully consistent with an octahedral stereochemistry. Normally such nickel(II) complexes are square planar and exhibit in some cases a planar $\rightleftharpoons$ octahedral equilibrium. It appears that the ligand field provided by this macrocycle is insufficient to lead to the square planar stereochemistry. The purple copper(II) complex has a single *d-d* band at 517 nm (ε = 87) which is quite characteristic of copper(II) complexes of tetra-aza macrocyclic dienes of this type. For example, the copper(II) complex of 5.6.12.13-tetramethyl-1,4,8,11-tetra-azacyclotetradeca-4,11-diene [4] has a *d-d* band at 513 nm (ε = 82).

The infrared spectra confirm that the complex $[CoL(NO_2)_2]$ has the isonitrito structure with N-bonded NO_2^- and the NCS^- derivative the N-bonded isothiocyanato structure. In isothiocyanato complexes the strength of the C—S bond increases while that of the N=C remains almost unchanged [5]. In the NCS^- ion ν C—S occurs at 749 cm^{-1} and ν C=N at 2049 cm^{-1}. In $[CoL(NCS)_2]ClO_4$ bands are seen at 2103 and 845 cm^{-1} fully consistent with the N-bonded structure. The acetato complex contains both monodentate acetate and anionic acetate and bands typical of these groups are seen in the spectrum.

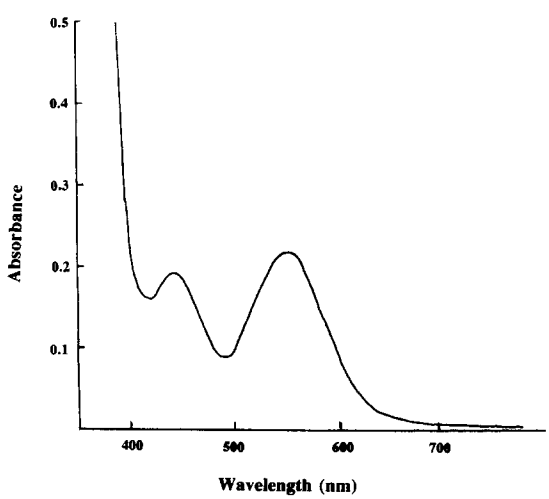

Fig. 1. The UV-vis spectrum of the complex $[CoL(OAc)_2]ClO_4 \cdot H_2O$ in nitromethane solution. The complex has λ_{max} 552 nm (ε = 42 dm^3 mol^{-1} cm^{-1}) and 440 nm (ε = 37 dm^3 mol^{-1} cm^{-1}).

Electronic spectrum and crystal structure of *fac*-$MoOCl_3$(dppe)

Ralph A. Isovitsch, Frank R. Fronczek and Andrew W. Maverick*

Department of Chemistry, Louisiana State University, Baton Rouge, LA 70803-1804, U.S.A.

(Received 4 August 1997; accepted 10 November 1997)

Abstract—X-ray analysis of the oxomolybdenum(V) complex $MoOCl_3$(dppe) (dppe = 1,2-bis(diphenylphosphino)ethane) shows that it is the facial isomer. ($C_{26}H_{24}Cl_3MoOP_2$, space group $P2_1/n$, $a = 13.217(1)$, $b = 12.8935(8)$, $c = 16.0578(9)$ Å, $\beta = 99.967(5)°$, $V = 2695.1(6)$ Å^3, $Z = 4$, $R = 0.038$ for 6228 data with $I > 1\sigma(I)$.) The electronic absorption spectrum of the title compound is also compared with those of other oxomolybdenum(V) complexes. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: crystal structure; molybdenum oxo complex; phosphine complex; electronic absorption spectrum.

Many oxomolybdenum(V) complexes are green in color; a simple example is *trans*-$MoOCl_4(H_2O)^-$, which shows maxima in its electronic absorption spectrum at 712 and 445 nm in HCl(aq.) [1]. Closely related species such as the square-pyramidal $MoOCl_4^-$ [2], and a variety of ligand-substitution products [3], are also green. We have recently studied the photochemistry of oxomolybdenum(V) in the presence of phosphines [4]. Although the initial solutions in these experiments, which are believed to contain $MoOCl_4L^-$ (L = PEt_2Ph, $PEtPh_2$, PPh_3), are also green, they turn deep red-brown on visible and near-UV irradiation. We proposed that this color is due to complexes of the type $MoOCl_3L_2$, but we were unable to isolate the products in pure form, and there are few data on this type of complex in the literature. We now report the identification of the dppe (dppe = $Ph_2PCH_2CH_2PPh_2$) example, $MoOCl_3$(dppe), as the facial isomer by X-ray crystallography; its electronic spectral properties are also discussed herein.

EXPERIMENTAL

Reagents and chemicals

$MoOCl_3$(dppe) was prepared as a microcrystalline brick-red powder according to the method used for the red form of the complex by Butcher and Chatt [6]. Wedge-shaped crystals suitable for X-ray analysis were isolated by layering a saturated CH_2Cl_2 solution of $MoOCl_3$(dppe) with diethyl ether. These crystals appeared orange-brown in transmitted light. Thinner crystals were deep red in one polarization and lighter orange-brown in the other polarization. IR: 944 cm^{-1} (ν_{MoO}). Anal: Calcd for $C_{26}H_{24}Cl_3OMoP_2$: C, 50.64; H, 3.92; Cl, 17.25. Found: C, 50.50; H, 4.18; Cl, 17.51.

Instrumentation

A Perkin–Elmer 1760X spectrometer was used to record FT-IR spectra; samples were thin films or KCl pellets. Electronic absorption spectra were recorded on an Aviv 14DS spectrophotometer. Fluorescence measurements utilized a Spex Fluorolog 2 Model F112X instrument, with Hamamatsu R406 (S-1) PMT.

X-ray crystallography

Diffraction data were collected on an Enraf-Nonius CAD4 diffractometer fitted with Mo-$K\alpha$ source and graphite monochromator, using the θ-2θ scan method. The intensities were corrected for absorption using ψ scan data for five reflections. The MoLEN [5] set of programs was used for structure solution and refinement. Selected bond distances and angles are presented in Table 1.

RESULTS AND DISCUSSION

$MoOCl_3(dppe)$ was first reported by Butcher and Chatt in 1971 [6]. Its magnetic moment was close to the value for one unpaired electron, suggesting a simple monomeric structure. They isolated red and brown forms of $MoOCl_3(dppe)$, with the red form turning brown on refluxing in 2-propanol for 3 h. The properties of these two forms were reported to be similar, the major difference being that the ν_{MoO} of the red isomer was 941 cm^{-1} and that of the brown was 952 cm^{-1}. Levason *et al.*, in their study of oxomolybdenum(IV) and -(V) complexes with diphosphine, diarsine and arsine-phosphine ligands, first reported the solution and solid state electronic absorption spectrum of the red form of $MoOCl_3(dppe)$ as well as those of other $MoOCl_3(L\text{-}L)$ complexes [7]. They did not prepare the brown form of $MoOCl_3(dppe)$, but they did isolate red and brown forms of a similar complex, $MoOCl_3(cis\text{-}Ph_2PCH{=}CHPPh_2)$, and noted that the differences in IR and electronic absorption spectra of these two forms were small. Herbowski reported an alternative procedure for the brown isomer of $MoOCl_3(dppe)$ and reported its IR and electronic absorption spectra [8]. His reported value for ν_{MoO} was in accord with that of Butcher and Chatt, but his electronic absorption data disagreed with those of Levason *et al.* [7]. Dziegielewski and Filipek [9] studied the red isomer of $MoOCl_3(dppe)$, but their electronic absorption data were also different from those of Levason *et al.* We find that the IR and UV-vis spectral properties of the compound agree closely with those originally reported by Levason and co-workers.

$MoOCl_3(dppe)$ is stable to dry air and light in the solid state and as a solution in CH_2Cl_2, $CHCl_3$ and CH_3CN. The infrared spectrum of this complex shows ν_{MoO} at 944 cm^{-1}, which corresponds well to the value reported by Butcher and Chatt [6] and Levason *et al.* [7] (941 cm^{-1}). We attempted to prepare the brown form of $MoOCl_3(dppe)$ by the literature method [6], but we obtained only material that was spectroscopically identical to that of the red form.

The deep red color of $MoOCl_3(dppe)$ in the solid and in solution is mainly due to an intense band in the middle of the visible region. Solutions in CH_3CN (Fig. 1) show this absorption at 495 nm ($\varepsilon = 1670$ M^{-1} cm^{-1}), and also a shoulder at ca 670 nm ($\varepsilon \sim 45$). The lower-energy band is likely to be due to a simple *d-d* transition similar to that in the "molybdenyl" ion [1]. The intensity of the 495-nm band suggests substantial charge-transfer character. For example, LMCT transitions are expected to occur at lower energy in Mo(V) than in Re(V), since the d_{xy} orbital in Mo(V) is half-occupied (vs fully occupied in Re(V)).

The distinctive absorption spectrum for $MoOCl_3(dppe)$ as compared to other oxomolybdenum(V) complexes, and discrepancies in the literature data for the compound, led us to an interest in confirming its structure. We were also interested in the compound as a model for the photochemical processes we were investigating in the Mo(V)/PR_3 systems. (Interestingly, although a number of other Mo(V) complexes $MoOCl_4L^-$ [L = H_2O and CH_3CN

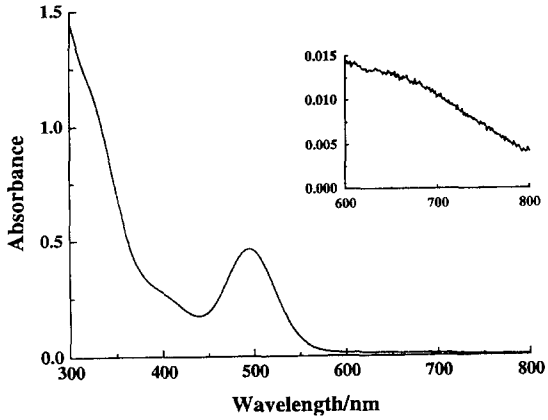

Fig. 1. Electronic absorption spectrum of a 0.0013 M solution of $MoOCl_3$ (dppe) in CH_3CN. Inset shows expanded view of 600–800 nm region.

[3a], and several phosphines [4] are fluorescent in solution at room temperature, we were unable to detect fluorescence from either solid $MoOCl_3$(dppe) or its solutions.)

Figure 2 is an ORTEP [10] drawing of $MoOCl_3$(dppe), which has the facial geometry. Molecules of $MoOCl_3$(dppe) show equatorial Mo—Cl bond lengths (see Table 1) that are indistinguishable from those observed in $(AsPh_4)[MoOCl_4(H_2O)]$ (2.359(3) Å) [11]. One of the characteristic features of metal-oxo complexes, a longer bond trans to the oxo group, is followed here (Mo—Cl1, 2.4790(6) Å). (For example, in the structure of $K_2[MoOCl_5]$, the axial Mo—Cl distance is ca 0.20 Å longer than the equatorial [12].) The two Mo—P bond lengths (Mo—P1 and Mo—P2) are similar. The Mo≡O bond length, 1.674(2) Å, falls into the normal range for terminal Mo≡O bonds in six-coordinate complexes (1.65–1.70 Å) [13].

As far as we are aware, only two *fac*-MOX_3L_2 (L = monodentate phosphine) complexes have been structurally characterized: *fac*-$ReOCl_3(PEt_2Ph)_2$ and the isostructural bromide. A search of the Cambridge Structural Database [15] yielded only one example of a MOX_3L_2 complex with M = group 6 metal: $WOCl_3(PEt_3)_2$, which has the *trans-mer* geometry [16]. The other examples are all rhenium complexes: *fac*-$ReOCl_3$(dppe) (which is isostructural with the present complex) [17], *trans-mer*-$ReOCl_3(PEt_2Ph)_2$ [18], *trans-mer*-$ReOCl_3(PPh_3)_2$ [19], and $ReOI_2Cl(PPh_3)_2$ (also *mer*, with I *trans* and PPh_3 *trans*) [20].

The present work establishes that $MoOCl_3$(dppe), like $ReOCl_3$(dppe), has the facial geometry. This is one of the two geometries that have been observed for analogous complexes $MOX_3(PR_3)_2$ of monodentate phosphines, the other being *trans-mer*. The product of the Mo(V)-PPh_3 photochemical reaction may be *fac*-$MoOCl_3(PPh_3)_2$, as suggested by the strong spectral similarities between it and $MoOCl_3$(dppe), but the *trans-mer* isomer cannot be ruled out. What is clear, on the other hand, is that simple substitution *trans* to the oxo group in *trans*-$MoOCl_4L^-$ cannot account for the formation of either *fac*- or *trans-mer*-$MoOCl_3(PPh_3)_2$. Instead, the phosphines in $MoOCl_3(PPh_3)_2$ are likely to be *cis* to the oxo group. This makes it likely that the initial photosubstitution reaction of Mo(V) with PPh_3 is also *cis*.

A structural comparison can be made between these MOX_3L_2 complexes and the quadrivalent MOX_2L_3 (L = phosphine) complexes. The only structurally characterized examples in the latter group appear to be of Mo(IV) and W(IV), all with the *cis-mer* geometry: $MoOCl_2(PMe_2Ph)_3$ [21], $MoOCl_2(PEt_2Ph)_3$ [22], $MoOCl_2(PMe_3)_3$ [23], and $MoOCl_2(PMePh_2)_3$ and $MoO(NCO)_2(PEt_2Ph)_3$ [24]; and $WOCl_2(PMe_3)_3$ [25], $WOCl_2(PMe_2Ph)_3$ [26], and $WOBr_2(PMe_2Ph)_3$ and $WOBr_2(PMePh_2)_3$ [27]. Although the nomenclature is different for the preferred products in $M^VOX_3L_2$ (*fac* and *trans-mer*) and

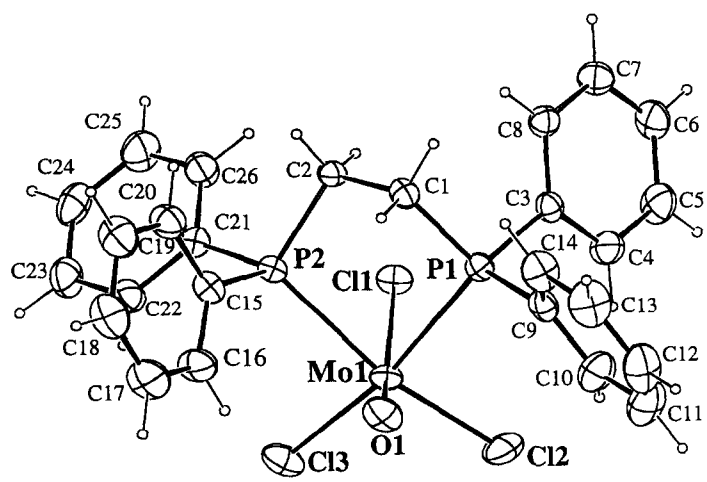

Fig. 2. ORTEP [10] drawing of $MoOCl_3$(dppe). Hydrogen atoms omitted for clarity.

$M^{IV}OX_2L_3$ (*cis-mer*), this is mainly because different ligands are used to identify the isomer (O and two L in M(V); O and two X in M(IV)). There is an important structural feature in common between the two oxidation states: in all of the crystallographically characterized examples so far, only the X ligand binds trans to the oxo group. (This is as expected if the best arrangement in both cases is with the stronger-field phosphine ligands *cis* to the oxo group, and a halide ligand in the *trans* position.)

Both the homogeneity of the title compound (as judged by its color and IR spectrum) and the previously published X-ray data (which include no examples of *cis-mer*-$M^{V}OX_3$(phosphine)$_2$ complexes) suggest that our samples of $MoOCl_3$(dppe) contain only the facial isomer.

Summary

The molybdenum(V) oxo complex $MoOCl_3$(dppe) has been determined by X-ray analysis to contain the facial isomer. Its electronic spectrum is very similar to that previously reported by Levason and co-workers [7] for the "red form" of the compound. It is also similar to those produced on irradiation of oxomolybdenum(V) in the presence of PEt_2Ph, $PEtPh_2$, and PPh_3 [4].

(Received 21 July 1997; accepted 10 November 1997)

Abstract—Homogeneous catalysis of the water-gas shift reaction has been accomplished by the use of solutions of $CuCl_2 \cdot 2H_2O$ in aqueous pyridine and other substituted pyridine (methyl pyridines or dimethylpyridine) solutions. This system is stable, low active catalyst displaying turnover frequencies for hydrogen production ($TF(H_2)$) of about 6 moles H_2 per mole Cu per day for [Cu] = 20 mM, P(CO) = 1.9 atm and $T = 120°C$.

Keywords: WGSR; homogeneous catalysis; copper complexes.

The water-gas shift reaction (WGSR, eqn (1)) $\Delta G^{\circ} = -28.5$ kJ mol^{-1} (298°K) is an important chemical transformation that find industrial applications in hydrogen production, carbon monoxide removal, and adjustment of CO : H_2 ratios in synthesis gas [1].

$$CO + H_2O \rightleftarrows CO_2 + H_2 \quad (1)$$

Previous studies by different groups have demonstrated WGSR catalysis by different soluble transition metal complexes [2–23]. For example $RhCl_3 \cdot 3H_2O$ dissolved in pyridine and other methylpyridines have been reported as stable and moderately active WGSR catalyst displaying turnover frequencies for hydrogen production ($TF(H_2)$) of about 10^2 moles of H_2 per mole Rh per day for [Rh] = 10 mM, P(CO) = 0.9 atm and $T = 100°C$ with Ea = value ~ 11.5 kcal mol^{-1} deg^{-1}. This studies was conducted in both, batch reactor [16,22] and continuous flow reactor [18]. In the course of continuing to explore similar system in these laboratories it became matter of interest to study an homogeneous copper system because is known that the most commercial active heterogeneous catalyst for the WGSR contained a mixture of copper and zinc oxide [1]. Described here is a study of the WGSR catalysis by a system formed by dissolving $CuCl_2 \cdot 2H_2O$ in aqueous solutions of pyridine and other substituted pyridines.

EXPERIMENTAL

Materials

Pyridine, methylpyridines (4-picoline, 3-picoline and 2-picoline) and dimethylpyridine (2,6-lutidine) were obtained from Aldrich and distilled over KOH. Copper(II) dichloride was obtained from Merck. All gases and gas mixtures CO, N_2, He/H_2 (91.4/8.6%), CO/CH_4 (94/6%), $CO/CH_4/CO_2/H_2$ (84.8/5.1/5.3/4.8%) were purchased from BOC Gases and used as received. Water was doubly distilled.

Instrumentation

Infrared spectra were recorded on a Perkin–Elmer 1769X-FT spectrophotometer using NaCl for solutions samples. UV-visible spectra were recorded on a Perkin–Elmer 533 spectrophotometer in 1.0 cm (Precision) quartz cell. EPR experiments were carried out in a conventional Varian E-line X-band spectrometer, using a rectangular cavity operating in the TE 102 mode. Analysis of gaseous reactants and products were carried out on a Hewlett-Packard 5890 Series II programmable (ChemStation) gas chromatograph fitted with a thermal conductivity detector. The column used was Carbosieve-B, 80–10 mesh, (Hewlett-Packard). The column temperature was programmed from 60–175°C at a flow rate of 50 ml min^{-1} using a He/H_2 (91.4/8.6%) mixture as carrier gas. Calibration curves were prepared periodically for H_2, CO, CO_2, and CH_4. The individual analysis were found to be accurate and reproducible within $< \pm 10\%$.

Batch reactor procedures

Catalytic runs were conducted in all-glass reactor vessels consisting of round bottom flask (100–200 ml) connected to an "O" ring sealed joint to a two-way Rotoflow Teflon stopcock attached to the vacuum line [16,21]. In a typical catalytic run, copper salt and solvent system were added to the glass reactor vessel, then the solution was degassed by three freeze-pump-cycles. The reaction vessel was charged with CO/CH_4 (94/6%) mixture at the P(CO) = 1.5 atm at R.T. (equaled 1.9 atm at 120°C) and placed in a thermostatted glycerol oil bath at 120 ± 0.5°C. Gas samples of 1.0 ml were periodically removed from the reaction vessel at bath temperature, analyzed by gas chromatography and corrected for small background signals. Methane was used as internal standard, thus allowing the calculation of absolute quantities of consumed CO and produced H_2 and CO_2. The reaction vessel was periodically flushed and loaded with the CO/CH_4 mixture as described above.

RESULTS AND DISCUSSION

Catalysis studies of the WGSR

Catalysis runs were carried out for [Cu] = 20 mM prepared from $CuCl_2 \cdot 2H_2O$ with P(CO) = 1.9 atm in various aqueous/pyridine or substituted pyridine solutions (8/2 v/v amine/water) over temperature of 120°C. Quantitative analysis of gas samples taken after the reaction solution reached working temperature, indicated that production of H_2 and CO_2 and consumption of CO follow the stoichiometry shown in eqn (1). The active solutions have undergone some buffering owing to CO_2 produced and the subsequent formation of carbonates. The shift in basicity was probed by determining the resulting solution pH with a Denver model Acumet Basic pH-meter. A freshly prepared solution of $CuCl_2 \cdot 2H_2O$ in 80% aqueous 4-picoline gave a pH of 8.00 while aged catalytic solution gave lower pH value 7.48 ± 0.05. Figure 1 displays the production of H_2 for catalytic runs in different amines over a period of several hours. These plots show no discontinuities which means that catalytic activity is constant for the aged solutions. This activities defined as turnover frequency (TF = moles of product H_2 or CO_2/(g-atom. wt. of Cu)/(24 h)) are summarized in Table 1. The TF values for this copper/amine system proved to be dependent of the nature of the amine. The TF values were measured for different copper-substituted pyridine, in order to show the dependence of the catalytic activity on the nature of the organic cosolvent. Slight differences were noted for those pyridine monomethylated in β or γ positions and relative high differences were observed for the systems with α-substituted amine. A plot of log of $TF(H_2)$/day values vs pK_a of the protonated bases is shown in Fig. 2.

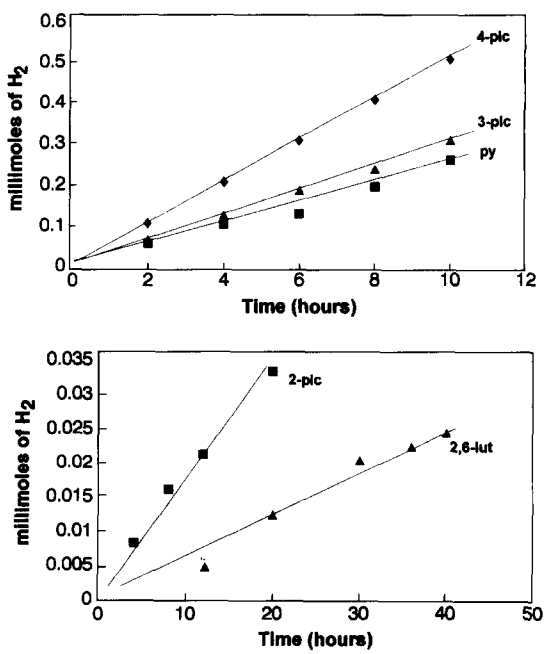

Fig. 1. Total H_2 produced as a function of time by a solution prepared from 0.2 mmol $CuCl_2 \cdot 2H_2O$ in 10 ml substituted pyridine/water solutions (8/2) under 1.9 atm CO at 120°C. Upper figure: reactions in sterically unhindered pyridines; lower figure: reactions in 2-picoline and 2,6-lutidine.

Table 1. WGSR activities by $CuCl_2 \cdot 2H_2O$ in aqueous pyridine and substituted pyridine[a]

Amine	pK_a[b]	TF(H_2)day[c]
4-picoline	6.00	6.1
3-picoline	5.52	4.1
pyridine	5.27	3.1
2-picoline	5.97	2.0
2,6-lutidine	6.75	1.2

[a] P(CO) = 1.9 atm, T = 120°C; [Cu] = 20 mM; 10 ml of solution amine/water, 8/2, v/v.

[b] From [24].

[c] Mol H_2/(g-atom. wt of Cu)/(24 h). Experimental uncertainty is about ± 10%.

Linearity is approximately followed in the case of nonhindered bases; also the slope indicates a minor basicity effects on catalytic activity. However, increasing steric effects effectively lower the reaction rates. Since methyl substitution in α position on the heterocyclic amine lowers the catalytic activity, coordination of the amine to the copper apparently plays an important role in determining the activity of these catalysts. Thus, it appears likely that in these media the hetero-aromatic amine behaves as a ligand as well as Brönsted base. These results suggest a critical steric parameter which can be viewed as the effects of competition for binding to the catalytic metal center, which is affected more by steric constraints than by electronic effects. The above observations are in agreement with earlier report on the depression of catalytic activity of $RhCl_3 \cdot 3H_2O$/amine system was depressed by the presence of a methyl substituent on the nitrogen of the amine.

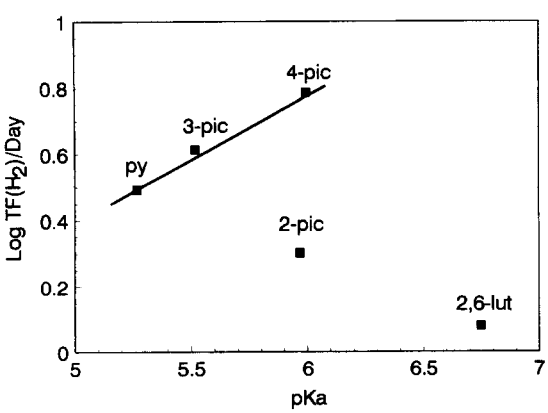

Fig. 2. Plot of log of TF(H_2)/day values vs pK_a of the protonated base for the sterically and nonsterically hindered pyridines.

Spectroscopic studies of catalyst solutions

Dissolution of $CuCl_2 \cdot 2H_2O$ (0.034 g, 0.20 mmol) in 10 ml of 80% aq. amine (amine = 4-picoline, 3-picoline, 2-picoline, pyridine or 2,6-lutidine) at room temperature leads to the gradual formation of a blue solution due to the formation of $CuCl_2(amine)_2$ and/or $CuCl_2(amine)_4$ [25,26]. After charging Cu/4-picoline blue solution with CO (1.5 atm) and heating the reaction vessel in a 120°C glycerol bath, this solution first changed to a green color, then (over 1–5 min) to a final red-brown color characteristic of a mature catalyst solution. Very similar color changes were seen when the solvent was 80% aqueous 2-picoline or 2,6-lutidine, but some differences were seen with pyridine or 3-picoline, which gave a final orange color solutions after similar treatment. For the Cu/aq. 4-picoline, the electronic absorption spectra of the red-brown solution noted above displayed a broad rinsing absorption from > 500 nm with a well defined shoulder at approximately 450 nm (Table 2). The electronic spectra of the red-brown solution of 2-picoline system displayed a similar shoulder shifted ~21 nm to longer wavelength, but also a weaker band at ~498 nm. The IR spectrum of the red-brown mature solution of the $CuCl_2 \cdot 2H_2O$/aq. 4-picoline or 2-picoline, systems displayed only a single peak in the CO stretching region, attributable to terminally coordinated CO (Table 2), indicating the presence of copper carbonyls complexes. These observations are similar to those of Gagne *et al.* [27]. who reported that IR spectra both in solution and in the solid state of the carbonyl adduct $Cu(LBF_2)(CO)$ (LBF = difluoro-3,3′-(trimethylenedinitrilo)*bis*(2-butanoneoximate)borate) show only one band in the ν_{CO} region (2080 cm^{-1}), characteristic of COs terminally coordinated to Cu. Similar observation was made for the compound $Cu(h^5\text{-}C_5H_5)(CO)$ which has a ν_{CO} at 2093 cm^{-1} [28]. Air exposure of the catalytic solution of the Cu/4-picoline system for several hours yields the formation of a blue color solid and a red-brown solution. The IR spectra of the blue solid and the remnant solution, each one showed no bands in the ν_{CO} region. These results reflect the non stability of the catalytic solutions to the air; that it, the copper carbonyls species present in the catalytic solutions are only stable in CO atmosphere. When the above heterogeneous system is charged with feed gases mixture, CO/CH_4, and heated to 120°C, it is observed the total dissolution of the blue solid and formation of the red-brown solution. However, catalytic activity of this recovered solution decreased by 50%. Figure 3 shows the EPR spectra of solution of $CuCl_2 \cdot 2H_2O$ in 95% aq. 4-picoline (A), and mature catalytic solution of the same system (B) in presence of CO. Calibration was made using the Varian Strong Pitch (g = 2.0028), and a diluted Mn^{2+} aq. solution. In both spectra, special care was taken in having the same amount of Cu atoms of the solutions in the cavity. The area of spectrum (A) is 4.0 times the area of (B). This indicates

Table 2. Infrared and visible spectra data of solutions resulting from reactions of $CuCl_2 \cdot 2H_2O$ in 80% aq. 4-picoline or 2-picoline solutions under CO[a]

Amine	Solution color	IR bands in the ν_{CO} region[b] (cm^{-1})	Electronic absorption bands[c] (nm)
4-picoline	red-brown	2067 (m)	451 (sh, 2343)
2-picoline	red-brown	2070 (m)	498 (sh, 72), 470 (sh,115)

[a] solvent = amine/water, 8/2, v/v, P(CO) = 1.5 atm, room temperature.
[b] (m) = medium.
[c] sh = shoulder, values in parentheses are approximate extinction coefficient in $M^{-1}\ cm^{-1}$.

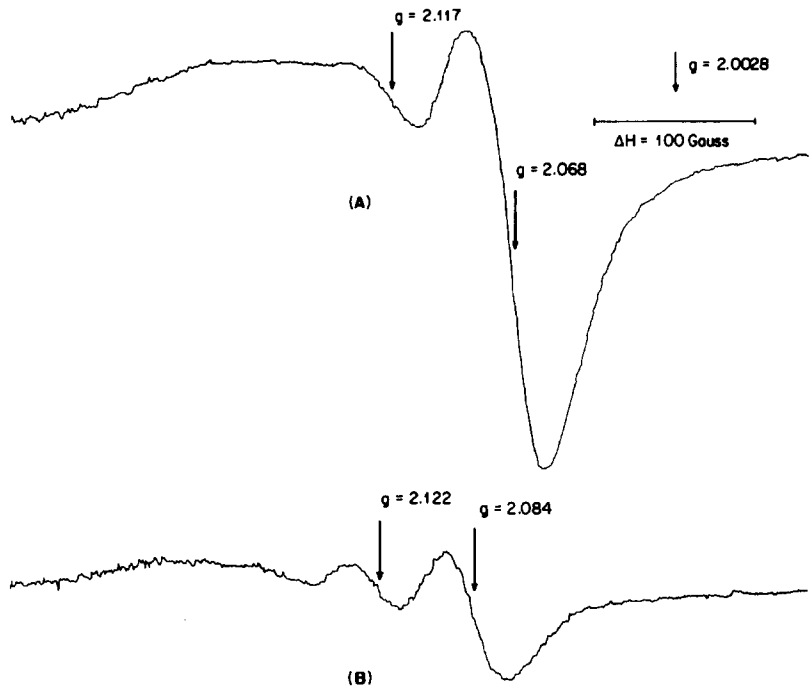

Fig. 3. EPR spectra for: (A) solution of 20 mM $CuCl_2 \cdot 2H_2O$ in 95% aq. 4-picoline (B) and mature catalytic solution of 20 mM of $CuCl_2 \cdot 2H_2O$ 95% aq. 4-picoline under P(CO) = 1.5 atm at 25°C.

the presence of copper(II) d^9 species in both solutions, but the copper(II) concentration is diminished in the mature solution. It is probably due to the reduction of Cu(II) to Cu(I) by the CO/H_2O couple. Similar results were observed for the other Cu/aq. amine systems mentioned above. Line shape and *g*-value differences between both spectra, are due to different molecular environments, and will be discussed in a forthcoming paper.

Summary

It was found that $CuCl_2 \cdot 2H_2O$ in 80% aq. amine under CO atmosphere formed a low active catalyst system for the WGSR. Among the catalyst systems studied, Cu/aq. 4-picoline was the most active. Finally the presence of terminal carbon monoxide indicated by the IR spectrum of $CuCl_2 \cdot 2H_2O$ in 80% aq. 4-picoline or 2-picoline solutions with CO under WGSR conditions as well as the EPR studies, provide strong experimental evidence of the formation of the Cu(I)—CO complex as a reaction intermediate.

Evidence for formation of the $FeSbO_4$ phase at the surface of poreless silica

Edilson V. Benvenutti[a]* and Luci I. Zawislak[b]

[a]Instituto de Química, UFRGS, CP 15003, 91501-970, Porto Alegre, RS, Brazil

[b]Instituto de Física, UFRGS, CP 15051, 91501-970, Porto Alegre, RS, Brazil

(Received 27 May 1997; accepted 10 November 1997)

Abstract—A possible $FeSbO_4$ phase was detected at a poreless silica surface using Mossbauer spectroscopy and infrared absorption of pyridine adsorbed on the surface. The phase was obtained from $Fe(CO)_5$ as starting material, without calcination treatment. Attempts to synthesizing the $FeSbO_4$ phase using a porous silica gel, under these conditions failed. The influence of the pores on the support is discussed. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: iron antimony; poreless silica; Mossbauer effect; infrared.

The $FeSbO_4$ phase produced by calcination of antimony and iron oxides at high temperatures is known to be very active in the allylic oxidation and ammoxidation of alkenes [1–8].

Recently, the synthesis and characterization of $FeSbO_4$ phases grafted onto a silica gel surface have been described as the product from an immersion of Sb/SiO_2 (antimony(V) oxide grafted onto a silica gel surface) in acid aqueous solution of iron III followed by heat treatment at 150°C [9,10], or an immersion of Sb/SiO_2 in a solution of $Fe(CO)_5$ in CCl_4 followed by hydrolysis and heat treatment at 800°C [10]. In the first case, the $FeSbO_4$ phase was formed at 150°C. This fact was explained by antimony(V) migration through the pores, from the internal to the external surface of the matrix, induced by acid medium. This mechanism was supported by XPS and Mossbauer analyses. The use of $Fe(CO)_5$ in CCl_4 has demonstrated that the $FeSbO_4$ phase is not detected at 150°C, but it appears after the heat treatment at 800°C. In this case, the high temperature treatment induces the Fe^{III} and Sb^{V} ions reaction.

In order to gain a better understanding of the mechanism involved in the $FeSbO_4$ phase formation on silica gel surface, the Sb/SiO_2 was synthesized using a poreless silica (aerosil). In this case, the $FeSbO_4$ phase formation will not depend on the migration mechanism of Sb^{V} ions through the pores, so this phase is expected to be formed from a solution of $Fe(CO)_5$ in CCl_4, at 150°C. Evidence for the formation of the $FeSbO_4$ phase were detected using FT-IR spectroscopy with pyridine as probe molecule, and by Mossbauer spectroscopy.

EXPERIMENTAL

Sb/SiO_2 (*Antimony oxide grafted on SiO_2*)

Fumed silica (aerosil) was activated at 150°C *in vacuo* (10^{-1} Pa). The $SbCl_5$ (Carlo Erba) (1 cm^3), previously distilled in a Schlenk apparatus, was dissolved in CCl_4 (Merck) (50 cm^3), dried above 0.4 nm molecular sieves. The activated silica (8.5 g) was then added. The mixture was stirred for 6 h under argon at solvent-reflux temperature. The resulting modified silica was filtered under argon in a Schlenk apparatus, washed with CCl_4 to eliminate unreacted $SbCl_5$ and trapped HCl, and finally degassed. The hydrolysis of the grafted $SbCl_5$ was carried out under a flux of wet air for 16 h, then washed with twice-distilled water and finally dried for 5 h under vacuum (10^{-1} Pa) at 150°C.

* Author to whom correspondence should be addressed.

The equations describing the reaction can be written as

$$n{\equiv}SiOH + SbCl_5 \rightarrow ({\equiv}SiO)_nSbCl_{5-n} + (5-n)HCl$$

$$({\equiv}SiO)_nSbCl_{5-n} + (5-n)H_2O \rightarrow ({\equiv}SiO)_nSb(OH)_{5-n} + (5-n)HCl,$$

where ≡SiOH represents a free silanol group on the silica surface. The resultant material $({\equiv}SiO)_n Sb(OH)_{5-n}$, obtained by this procedure was designated as Sb/SiO_2.

$Fe/Sb/SiO_2$ (*Iron^{III} oxide dispersed on* Sb/SiO_2). Approximately 4 g of Sb/SiO_2 and 0.5 cm^3 of $Fe(CO)_5$ were added to 30 cm^3 of CCl_4. The mixture was refluxed for 4 h under argon atmosphere. The subsequent solid was filtered off and washed with CCl_4 under argon atmosphere and degassed at 150°C. The resulting black material was exposed to water vapour from the air for 1 day giving the yellow Iron^{III} oxide dispersion and washed with water. The resulting material was dried 5 h at 150°C *in vacuo* (10^{-1} Pa).

IR analyses. The sorption of pyridine vapour by $Fe/Sb/SiO_2$ was studied by IR spectroscopy. Reagent-grade pyridine (Merck) was previously dried over 0.4 nm molecular sieves and submitted to various freeze–pump–thaw cycles. A self supporting disk of $Fe/Sb/SiO_2$ with an area of 5 cm^2 and weight of 50 mg, was prepared. The cell used was connected to a greaseless vacuum line and the system was pumped for 1 h at a pressure of 10^{-3} Pa at 150°C. After this treatment the pyridine was introduced into the cell at a pressure of 1.6 Pa at room temperature. The FT-IR equipment used was a Mattson, model 3020. The spectra were obtained after 100 scans, with a resolution of 4 cm^{-1}.

Mossbauer analyses The Mossbauer spectra were obtained in a standard transmission geometry, using a constant acceleration electromechanical drive system with a multichannel analyzer for collecting and storing the data. A source of ^{57}Co in a rhodium matrix was used at room temperature. The velocity scale and magnetic field were calibrated using metallic iron. Measurement at 4.2 K were done with the sample immersed in liquid helium.

Chemical analyses The antimony and iron analyses were carried out on a Rigaku RIX 2000 X-Ray Fluorescence Spectrometer. The quantities of Sb and Fe determined were (in wt%) Sb = 2.3% ; Fe = 3.0%.

RESULTS

IR analyses

The spectra of $Fe/Sb/SiO_2$ submitted to 1.6 kPa of pyridine are shown in Fig. 1. The bands at 1595 and 1444 cm^{-1} (Fig. 1a) are due to the 8a and 19b modes of pyridine bonded to the free silanol ≡SiOH groups through hydrogen bonds [11–13]. These bands were also observed in the pure silica and disappear after heating the disk *in vacuo*. Figure 1b shows the infrared spectrum after having pumped off the material for 1 h at 100°C with two bands at ca 1600 cm^{-1} (broad) and 1447 cm^{-1}, respectively, in consistency with the 8a and 19b modes of pyridine coordinated to Lewis acid sites in the $FeSbO_4$ phase supported on silica surface [10]. After further pumping (2 h) at the same temperature (100°C) it can be observed that the broad band at ca 1600 cm^{-1} resolves into two bands (1600 and 1612 cm^{-1}) (Fig. 1c). The band at 1612 cm^{-1} becomes more defined after heating the disk at 200°C *in vacuo* (10^{-3} Pa) for 1 h (Fig. 1d). The bands 1612 and 1451 cm^{-1} that remain in the spectrum (Fig. 1d), were assigned to the 8a and 19b modes of pyridine coordinated to iron^{III} oxide [14] (see Table 1). The band at ca 1489 cm^{-1} is due to the 19a mode and always present for all kinds of pyridine adsorption [15].

Mossbauer analyses

The Mossbauer spectrum of poreless $Fe/Sb/SiO_2$, obtained at room temperature, reveals a broadened quadrupole doublet, with an isomer shift, relative to α-Fe, of 0.38 mm s, a linewidth of 0.47 mm s and a quadrupole splitting of 0.74 mm s. These values are very close to the results already obtained for the $FeSbO_4$ phase [4,16–18].

At liquid helium temperature the Mossbauer spectrum shows two partially resolved hyperfine patterns. Site 1 with a hyperfine field of 469 (3) kOe and site 2 with 524 (3) kOe contributing with 70% and 30%, respectively, to the final spectrum. The hyperfine parameters obtained by a least-squares fit are shown in Table 2.

The site 1 data are comparable to the data for the $FeSbO_4$ phase, although the broad linewidth demonstrates the existence of hyperfine magnetic field distribution. This component of the spectrum was fitted to a field distribution with an average hyperfine field of 473 (3) kOe, a difference between the maximum and minimum values of 32 kOe and a linewidth fixed at 0.30 mm s^{-1}. The hyperfine parameters of site 1 fitted to a field distribution are quite similar to those published for the $FeSbO_4$ phase [10,17] (see Table 2).

The presence of two hyperfine fields (two sites) can be explained taking into account that the ratio Fe/Sb is 1.3, so there is an excess of iron on the sample that remains as iron^{III} oxide. The site 2 data are very close to the ones related to Fe^{III} oxide dispersed on silica surface [19] (531 kOe).

DISCUSSION

The Fe—Sb oxide system exhibits a behavior that strongly depends on the Sb/Fe ratio. The formation of α-Fe_2O_3 along with $FeSbO_4$ has been reported [4], even for the stoichiometric ratio of Sb/Fe = 1.0. In the Sb rich side (Sb/Fe ratio greater than one) $FeSb_2O_6$,

$FeSb_2O_4$ or $Fe_2Sb_2O_7$ may be formed. However, in this case, Fe^{II} and Sb^{III} species would be present [1,4,16]. Our spectra do not exhibit traces of Fe^{II}.

The Mossbauer spectra at room temperature indicate that the only phases present are $FeSbO_4$ and α-Fe_2O_3. Both, values for isomer shift and for the quadrupole splitting at room temperature, indicating the existence of high spin Fe^{III} in distorted octahedral environment, are in very good agreement with those reported earlier for $FeSbO_4$ [4,16,18]. Moreover the spectrum recorded at liquid helium temperature exhibits the existence of hyperfine magnetic field distributions with hyperfine parameters similar to those published by F. J. Berry *et al.* [17]. The Sb/Fe ratio used in the preparation of the sample, minor than one, is also responsible for the non existence of Fe^{II}.

The hyperfine magnetic field of the Mossbauer spectrum at liquid helium temperature, shows unambiguously two sites of Fe^{III}, which we assign to α-Fe_2O_3 and $FeSbO_4$.

It is known [9–10], when the support is porous silica gel, that Sb^V ions prefer the internal position on the pores (internal surface), where the contact with iron-pentacarbonyl is very difficult. In this case, the reaction is possible only with calcination at 800°C. The $FeSbO_4$ phase is detected on the silica gel surface, at 150°C only, when the synthesis is carried out using $FeCl_3$ in acid medium.

In this work, the $FeSbO_4$ phase was evidenced before the calcination using $Fe(CO)_5$ as starting material, because the reaction was carried out on the fumed silica surface modified with antimony(V). The used support, has only external surface (poreless), so the Sb^V ions on the surface are directly exposed to iron and the possible $FeSbO_4$ phase can be detected at temperature of 150°C.

The $FeSbO_4$ phase formed on the surface in this condition consists in high dispersed form, and X-Ray Diffraction pattern is not possible to be obtained. However it is known [20] that monocrystals structures including two dimensional crystals for other systems has been obtained.

The synthesis carried out with low temperature treatment avoids agglomerates on the highly dispersed phase of the catalyst and changes in the morphology of support caused by calcination.

CONCLUSIONS

The important $FeSbO_4$ phase that is potentially a selective catalyst for oxidation and ammoxidation of alkenes might be obtained on poreless silica surfaces modified with antimony(V) ions at low temperatures (150°C) using $Fe(CO)_5$ deposition synthesis. This result confirms that, on the porous silica gel surface modified with antimony(V), this phase could be detected only if supported by the mechanism of migration of Sb^V ions by acid medium, in this case using acid aqueous solution of $iron^{III}$.

(Received 24 September 1997; accepted 6 November 1997)

Abstract—Four new binuclear complexes of the type $[(Cu(L)_x)_2ox](ClO_4)_2$ (L = 1,3-diaminopropane (1,3-pn), $x = 1.5$ (**1**); L = 1,3-diaminopropane, $x = 1$ (**2**); L = *N*-(2-aminoethyl)-1,3-propanediamine (ept), $x = 1$ (**3**)) or $[(Ni(L)_2)_2ox](ClO_4)_2$ (L = 1,2-diaminopropane (1,2-pn) (**4**)) have been prepared and studied by elemental analysis, IR and electronic spectroscopies. Spectroscopic data are consistent with oxalate-bridged structures between five-coordinate (N_3O_2) Cu(II) (compounds **1** and **3**), four coordinate (N_2O_2) Cu(II) (**2**) and six-coordinate (N_4O_2) Ni(II) (**4**). Magnetochemical measurements (72–300 K) show (**2**) and (**4**) are antiferromagnetic ($J = -254$ and -33 cm^{-1} respectively ($H = -JS_1S_2$)). © 1998 Elsevier Science Ltd. All rights reserved

Keywords: copper(II) complexes; nickel(II) complex; μ-oxalato complexes; magnetic properties; antiferromagnetism.

Dinuclear oxalate-bridged copper(II) complexes are known in a range of metal coordination geometries from four to six [1–11]. Oxalate provides an efficient superexchange pathway to give antiferromagnetism of varying extents in these complexes. The theory initiated by Hoffmann and coworkers [12] and developed by Kahn and colleagues [13,14] has shown that there is a correlation between coordination geometry and magnitude of the singlet-triplet separation, $-J$. Values up to 400 cm^{-1} can be found. Indeed there is the above mentioned theory on the structure vs magnetism correlation of copper(II) binuclear compounds, but as it happens, the experimental verification came first, then theoretical work to rationalize the observations [15–18].

For nickel(II), oxalato bridging has been found with NiN_4O_2 octahedral chromophores [2,3,11–14,19–21]. The nitrogen donors are tetra-aza macrocycles, linear tetramines or two diamine molecules. Magnetostructural data concerning the oxalato-bridged nickel(II) complexes have revealed that the magnetic coupling J ($H = -JS_1S_2$), which varies from -22 to -40 cm^{-1}, is strongly dependent on the nature of the donor atoms of terminal ligands [22].

The aim of this work was the preparation and physicochemical study of new binuclear μ-oxalato complexes of copper(II) or nickel(II) with 1,3-diaminopropane (1,3-pn), *N*-(2-aminoethyl)-1,3-propanediamine (ept) or 1,2-diaminopropane (1,2-pn) of compositions $[(Cu(1,3\text{-pn})_{1.5})_2ox](ClO_4)_2$ (**1**), $[(Cu(1,3\text{-pn}))_2ox](ClO_4)_2$ (**2**), $[(Cu(ept))_2ox](ClO_4)_2$ (**3**) and $[(Ni(1,2\text{-pn})_2)_2ox](ClO_4)_2$ (**4**) and comparison with analogous known μ-oxalato complexes. Above mentioned three amines were chosen intentionally: 1,2-diaminopropane is an example of bidentate ligand which forms five-membered cycle in the complex, 1,3-diaminopropane as bidentate ligand forms six-membered cycle and *N*-(2-aminoethyl)-1,3-propanediamine is tridentate ligand which forms both five-membered cycle and six-membered cycle in the complex. The compounds prepared were characterized by elemental analysis, IR and UV-vis spectroscopies and variable temperature magnetic susceptibility measurements.

EXPERIMENTAL

Chemicals and methods

The starting materials $Cu(ClO_4)_2 \cdot 6H_2O$ and $Ni(ClO_4)_2 \cdot 6H_2O$ were obtained by the reaction between basic copper and nickel carbonates and aqueous $HClO_4$. 1,3-Diaminopropane and 1,2-diaminopropane (racemic mixture) (Fluka), *N*-(2-aminoethyl)-1,3-propanediamine (Aldrich) and sodium oxalate (Lachema Brno) were used without further modification.

Elemental analyses of carbon, hydrogen and nitrogen were performed on a Fisons Instruments EA1108 CHN instrument. Nickel was determined gravimetrically using dimethylglyoxime. Electronic absorption spectra in water solution were run on a SPECORD M40. IR spectra were obtained as Nujol mulls on a SPECORD IR 80 using the Nujol technique. Temperature-dependent magnetochemical data were obtained by the Faraday method in the 72–300 K range as described previously [23]. Diamagnetic corrections were made with Pascal's constants for all the constituent atoms and magnetic moments were calculated using the equation $\mu_{eff} = 2.828(\chi_M T)^{1/2}$.

Syntheses

$[(Cu(1,3\text{-pn})_{1.5})_2ox](ClO_4)_2$ (**1**). A solution of 0.18 g (1.34 mmol) of sodium oxalate in 20 cm^3 water was added to a solution of 1.00 g (2.70 mmol) of $Cu(ClO_4)_2 \cdot 6H_2O$ and 0.34 cm^3 (4.10 mmol) of 1,3-diaminopropane in 30 cm^3 water. The reaction mixture was concentrated by heating to 15 cm^3 and then was allowed to stand overnight. The solid was filtered off and then recrystallized from water to give dark blue microcrystals. The crystals were filtered off, washed with small amount of water and dried at 40°C. The yield was 0.1 g (12%).

$[(Cu(1,3\text{-pn}))_2ox](ClO_4)_2$ (**2**). A solution of 0.18 g (1.34 mmol) of sodium oxalate in 20 cm^3 water was added to a solution of 1.00 g (2.70 mmol) of $Cu(ClO_4)_2 \cdot 6H_2O$ and 0.17 cm^3 (2.05 mmol) of 1,3-diaminopropane in 30 cm^3 water. A small amount of solid formed was discarded. The reaction mixture was concentrated by heating to 15 cm^3 and then was allowed to stand overnight. The solid was filtered off and then recrystallized from water to give light blue microcrystals. The crystals were filtered off, washed with a small amount of water and dried at 40°C. The yield was 0.1 g (13%).

$[(Cu(ept))_2ox](ClO_4)_2$ (**3**). A solution of 0.18 g (1.34 mmol) of sodium oxalate in 20 cm^3 water was added to a solution of 1.00 g (2.70 mmol) of $Cu(ClO_4)_2 \cdot 6H_2O$ and 0.34 cm^3 (2.70 mmol) of *N*-(2-aminoethyl)-1,3-propanediamine in 25 cm^3 water. The reaction mixture was concentrated by heating to 15 cm^3. After cooling a blue product was obtained. The solid was filtered off and then recrystallized from hot water to give blue microcrystals. The crystals were filtered off, washed with water and dried at 40°C. The yield was 0.60 g (68%).

$[(Ni(1,2\text{-pn})_2)_2ox](ClO_4)_2$ (**4**). A solution of 0.18 g (1.34 mmol) of sodium oxalate in 20 cm^3 water was added to a solution of 1.00 g (2.73 mmol) of $Ni(ClO_4)_2 \cdot 6H_2O$ and 0.47 cm^3 (5.51 mmol) of 1,2-diaminopropane in 25 cm^3 water. The reaction mixture was concentrated by heating to 20 cm^3. After cooling a violet product was obtained. The substance was filtered off and then recrystallized from hot water to give violet microcrystals. The product was filtered off, washed with water and dried at 40°C. The yield was 0.65 g (69%).

RESULTS AND DISCUSSION

The chemical composition of the complexes are given in Table 1. The data from physicochemical studies are given in Table 2 and 3 and Figs 1, 2, 3 and 4.

The new coordination compounds were prepared by the reaction of the metal perchlorate with the appropriate polyamine and sodium oxalate in aqueous solution.

The IR spectra were not studied in detail; only characteristic vibrations for $\nu_3(ClO_4)$, $\nu_4(ClO_4)$, $\nu_{asym}(CO_2)$, $\nu_{sym}(CO_2)$ and $\delta(CO_2)$ were interpreted. The values given in Table 2 are consistent with tetradentate oxalate [21,24] and perchlorate [25].

In the electronic absorption spectrum of Cu(II) complexes we can find a strong band corresponds to a *d-d* transition in the range 13,000–18,000 cm^{-1} [26]. In the present compounds bands at 16,300, 15,900 or 16,400 cm^{-1}, respectively, may be ascribed to *d-d* transitions of copper(II). In the octahedral complexes of Ni(II) we can find three bands which are due to a *d-d* transitions ($\nu_1 = {}^3T_{2g}(F) \Leftarrow {}^3A_{2g}(F)$, $\nu_2 = {}^3T_{1g}(F) \Leftarrow {}^3A_{2g}(F)$, $\nu_3 = {}^3T_{1g}(P) \Leftarrow {}^3A_{2g}(F)$); for $[Ni(en)_3]^{2+}$ $\nu_2 = 18{,}350$ cm^{-1}, $\nu_3 = 29{,}000$ cm^{-1}) [26]. In the present complex bands at 17,900 cm^{-1} and 28,700 cm^{-1}, respectively, may be assigned as ν_2 and ν_3, respectively.

The spectroscopic data described above are consistent with oxalate-bridged dimeric structures for all four complexes. Square planar four coordination is proposed for (**2**), and octahedral geometry for the nickel complex (**4**). For compounds (**1**) and (**3**) five-coordination is suggested, but there are various possibilities for isomerism, and we are not able to distinguish between the possibilities for the 5-coordinate structure.

A magnetochemical study of each compound has been made in the temperature range 70–300 K. The results are shown graphically in Figs 1–4. Complexes (**1**) and (**3**) are essentially magnetically dilute, with very little sign of antiferromagnetic exchange. It will be seen that for both these compounds the magnetic moment per copper dimer does not fall below the spin-only value. The slight falls in magnetic moment with

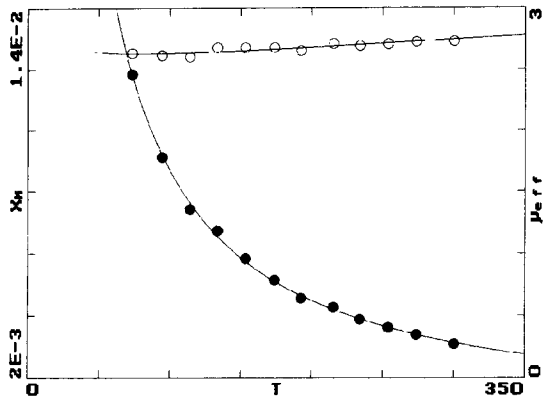

Fig. 3. The paramagnetic susceptibility (●-in cgs) and effective moment (○-μ_B) vs temperature curves for [(Cu(ept))$_2$ox](ClO$_4$)$_2$. The circles are the experimental points.

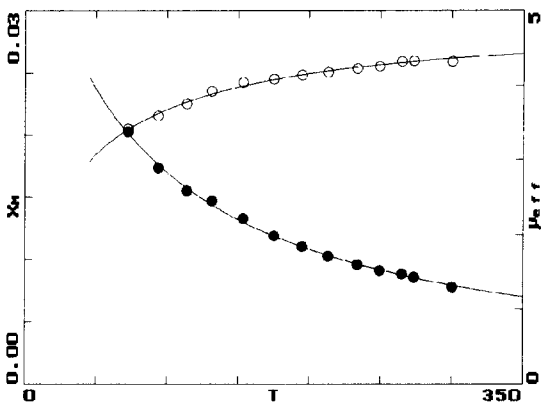

Fig. 4. The paramagnetic susceptibility (●-in cgs) and effective moment (○-μ_B) vs temperature curves for [(Ni(1,2-pn)$_2$)$_2$ox](ClO$_4$)$_2$. The circles are the experimental points, the solid lines are theoretical lines.

temperature are barely significantly outside the experimental error of +2% and +1.2% for compounds (**1**) and (**3**) respectively. Plots of reciprocal susceptibility against temperature give slightly antiferromagnetic Weiss constants of 16.4 and 11.1 K respectively. We conclude that it is not meaningful, for which a more extended temperature range of data is required. The analogous compound [(Cu(dien))$_2$ox](ClO$_4$)$_2$ (dien = diethylenetriamine) does not exhibit significant exchange down to 4 K [27].

Complex (**2**) behaves like a classical copper(II) dimer. The data follow the Bleaney-Bowers eqn [28]:

$$\chi_M = \left(\frac{2\mu_o N g^2 \beta^2}{kT}\right)[3+\exp[(-J)/(kT)]]^{-1} + N_\alpha \quad (1)$$

Using the usual value of the second order paramagnetic molar susceptibility N_α of 60 cgs units per copper and a fixed value of g, J is found [29] to be -254 cm^{-1} ($H = -JS_1S_2$, $S_1 = S_2 = 1/2$). If g is allowed to vary, the best fit to data is unrealistically found to be 1.85, with J equal to -234 cm^{-1}; if N_α is ignored, also unrealistically, the best value of g is 2.1, with $J = -260$ cm^{-1}. Because of the weak paramagnetism of this strongly coupled system there is a large experimental error of +4% on the data, which makes the fit of data to theory acceptable.

This strong antiferromagnetism can be explained by the proposed square planar coordination for copper. The [(1,3-pn)Cu(μ-ox)Cu(1,3-pn)] unit is planar, so that the x^2-y^2 magnetic orbitals on Cu will be ideally directed for overlap with the oxalate σ orbitals and the antiferromagnetic exchange will be maximized [13,14].

The effective magnetic moment of 3.06 μ_B at 299.8 K per Ni(II) ([Ni(1,2-pn)$_2$)$_2$ox](ClO$_4$)$_2$) is typical for octahedrally coordinated nickel(II). The variable-temperature magnetic moment and magnetic susceptibility in the range 72–300 K for a solid sample of the title compound is shown in Fig. 4. The magnetic moment is temperature dependent and decreases from 4.33 μ_B/mol (3.06 μ_B per Ni^{2+}) at 300 K to 3.43 μ_B at 72.3 K. This proves that there is antiferromagnetic coupling across the oxalate bridge (Weiss constant is 73.0 K). The magnetic behaviour of the title complex could be interpreted using isotropic spin Hamiltonian $H = -JS_1S_2$, where $S_1 = S_2 = 2/2$ and J is the exchange integral. The experimental data have been fitted to the expression [3]

$$\chi_M = \left(\frac{\mu_o N g^2 \beta^2}{3kT}\right)\frac{30\exp(3J/kT)+6\exp(J/kT)}{5\exp(3J/kT)+3\exp(J/kT)+1} + N_\alpha \quad (2)$$

by using of Klička's program [29] for HDVV-dimer model and using the usual value of the second order paramagnetic molar susceptibility N_α of 100 cgs units per nickel. The best fit parameters obtained are: $J = -33$ cm^{-1}, $g = 2.25$. ($H = -JS_1S_2$, $S_1 = S_2 = 2/2$) For Ni(II) complexes in octahedral geometry, the metal x^2-y^2 orbital is half occupied and is aligned to allow overlap with the oxalate σ-orbitals. For present complex, the observed J-value of -33 cm^{-1} is similar to those of [Ni$_2$(1,3-pn)$_4$ox](ClO$_4$)$_2$ [30] ($J = -36$ cm^{-1}) or [Ni$_2$en$_4$ox](NO$_3$)$_2$ (en = ethylenediamine) ($J = -32$ cm^{-1}) [19].

In conclusion, it can be seen that this group of four oxalate-brigded complexes clearly demonstrated the effect of varying coordination on the magnitude of exchange interactions.

(Received 25 August 1997; accepted 6 November 1997)

Abstract—A crystal structure determination of $Cu(phpyH)ClClO_4 \cdot CH_3OH$ revealed that the protonated phenolic oxygen atom lies at the apex of a square pyramidal CuN_4O arrangement with Cu(II)—O(phenolic) distances of 2.46 and 2.57 Å; this is a novel copper(II) model compound for galactose oxidase where the Cu(II)–phenolic oxygen (Tyrosine-495) distance is rather long, 2.69 Å, and the present results may provide chemical evidence for possible participation of Tyrosine-495 in the oxidation of galactose. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: long Cu(II)–phenol bond; galactose oxidase model; Tyrosine residue.

Galactose oxidase (GO) is a secreted mononuclear copper enzyme, which has been isolated from the cultured media of a number of fungal species [1]. Even though it contains only a single copper atom, the enzyme catalyzes the two-electron oxidation of the position-6 hydroxy group of galactose to the corresponding aldehyde, concurrent with the reduction of O_2 to H_2O_2 as follows.

$$RCH_2OH + O_2 \rightarrow RCHO + H_2O_2$$

An unusual property of GO, which distinguishes it from simple mononuclear copper enzymes, is that the protein has three well-defined and stable oxidation levels. Of these three, only the intermediate or one-electron oxidized from, shows a Cu(II) electron paramagnetic resonance (EPR) signal, and this is typical of the "Type-2" or normal class [2,3]. A recent X-ray absorption edge study by Clark *et al.* has established that galactose oxidase copper is cupric in the enzyme's highest oxidation level [4]. The fact that this form is EPR-silent indicates that the Cu(II) is anti-ferromagnetically coupled to a second $S = 1/2$ species. As GO contains no other metal besides the redox-active copper center, the paramagnetic species to which it is coupled is likely to be an organic radical, and that this organic radical should be phenol group of Tyrosine-495, or -272 [5], the possible participation of the latter (Tyr-272) being proposed by several authors [6].

Until now, many copper(II) complexes with phenolic oxygen atom are prepared and characterized; in almost all the cases, phenolic oxygen atom is located at the corner of the square plane containing the copper(II) ion; this situation corresponds to that of Tyr-272 in GO. There are few reports that phenoxo radical formation occurs in the reaction with dioxygen molecule for these compounds containing copper(I) or copper(II) ion [7], and this should be due to lowering of the occupied orbital energy of phenolic anion through coordination to a copper atom. Only in exceptional case, phenolic oxygen is at the apical position of the square pyramide in the complex with (2-hydroxy-5-nitrobenzyl)bis(2-pyridylmethyl)amine [8], however in this case copper(II)–phenolic oxygen atom is 2.268 Å, which is much shorter than that in the enzyme [5]. In this study we have succeeded in preparing the copper(II) complex with long copper(II)–phenolic oxygen distance, this may give useful information to elucidate origin and mechanism of radical formation in GO.

Scheme 1

EXPERIMENTAL

Synthesis of copper(II) complexes

The schematic illustration of ligand synthesis is given above.

By adding $NaBH_4$ (2 g) to methanol solution (40 ml) containing 2-aminomethyl-pyridine (0.01 M) and salicylaldehyde (0.01 M), white *N*-(*o*-hydroxybenzyl)-2-aminomethylpyridine, **1** was obtained. Compound **1** was reacted with 2-picolychloride to give H(phpyH) (see scheme above) in an aqueous solution [9]. The aqueous solution was evaporated, and ligand, H(phpyH) was extracted by methanol, and the methanol solution was used for copper(II) complex synthesis without further purification. By adding $NaClO_4$ or NH_4PF_6 (500 mg) to a methanol solution (20 ml) containing a ligand, which was derived from **1** (0.004 M) and 2-picolychlorode (0.004 M), copper(II) chloride (0.004 M), the desired copper(II) compound was obtained as green crystals. The corresponding 5-Br derivative was synthesized according to the similar ways as described for the H(phpyH)-complex. Yields of the copper(II) compounds are in the range 50–60% based on the copper(II) chloride used. Anal: Calcd for Cu(phpyH)$ClClO_4$: C, 45.30; H, 3.80; N, 8.34. Found: C, 45.77; H, 4.31; N, 8.23%. Calc. for Cu (5-Br-phpyH)$ClClO_4 \cdot H_2O$: C, 38.96; H, 3.44; N, 717. Found: C, 38.74; H, 3.14; N, 7.11%.

Crystal structure determination

The compounds in the crystal structure determination were recrystalized from a methanol/water solution. The structures of two new compounds were determined in this study, and the crystal data of the complexes are summarized in Table 1. X-ray diffraction intensities were measured up to $2\theta = 55°$ using Mo-K_α radiation ($\lambda = 0.71073$ Å) on a Rigaku AFC-5 four-circle diffractometer, and the absorption corrections were carried out by a numerical integration method. The structures were refined using CRYSTAN-GM software, and the details have been deposited as a supplementary data.

Molecular orbital calculations

MO calculations for *N,N*-dimethyl-*o*-hydroxy-benzylamine and its 5-bromo derivative (neutral form, see the figure at the top of next page) were performed by the use of AM1 method [10].

RESULTS AND DISCUSSION

There are two independent molecules in unit cell of $Cu(phpyH)ClClO_4 \cdot CH_3OH$. In Fig. 1, the ORTEP drawing of one of the two $Cu(phpyH)Cl^+$ molecules is shown, and the projections along the Cl—Cu—N bonding are illustrated in Fig. 2, and the selected bond distances and angles are listed in Table 2. The structural property of the compound is essentially the same as that of the $Cu(mopy)Cl^+$ compound [10]. Copper(II) complex is of a square pyramid and square plane is occupied by three nitrogen atoms (two pyridine and one aliphatic amine) and chloride ion. It should be noted here that the apical position is occupied by the phenolic oxygen atom with protonated form, and the distances between copper and oxygen atom are 2.457(5) and 2.565(4) Å, which is much longer than that in the 5-nitro derivative [8], and is very similar to that in GO (2.69 Å) [5]. In Fig. 3 The ORTEP drawing of the corresponding 5-bromo-derivative is shown, and the selected bond distances and angles are also summarized in Table 3. The structural properties of the compound are essentially the same as that of the (phpyH)-complex, but the distance between the copper(II) ion and phenol oxygen is 2.363(5) Å, which is much shorter than that in the (phpyH)-ligand.

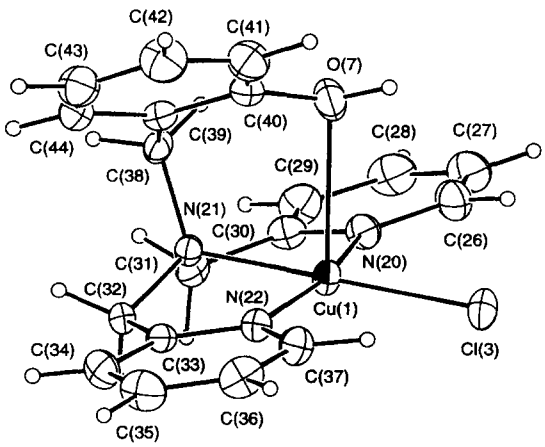

Fig. 1. ORTEP drawing of $Cu(phpyH)Cl^+$-(a), Cu(1) complex.

In Table 4, the energies of HOMO and LUMO of the two compounds, *N,N*-dimethyl-*o*-hydroxy-benzylamine and its 5-bromo-derivative are shown; it is clear that these two orbitals are consisted of *p*-orbitals of π-type, and that the energies of both HOMO and LUMO of the former compound are higher than those of the 5-bromo derivative. This suggests that the introduction of electron-withdrawing group on the phenolic ring induces the shortening of distances between the copper(II) ion and phenolic oxygen atom.

In the square pyramidal copper(II) compounds with (phpyH) and (5-Br-phpyH), HOMO of the ligand which contains *p*-orbital of phenol oxygen of π-type (see Table 4) approaches to a copper(II) atom along the *z*-axis (see Fig. 2 and Fig. 4 (A)), leading to interaction with d_{z^2}-orbital; angle between the phenol plane and the plane which contains the copper(II) coordination site is 39, 37, and 41° for Cu(1) and Cu(2) in the $Cu(phpyH)Cl^+$, and $Cu(5\text{-Br-phpyH})\,l^+$, respectively. In this case, since the d_{z^2}-orbital is doubly occupied (see Fig. 4 (B)), the interaction between the HOMO (π-type, containing phenolic oxygen) and the d_{z^2}-orbital does not contribute to the stabilization of the system, rather to induction of destabilization.

This may explain the shorter Cu(II)–oxygen atom distance observed for the corresponding 5-bromo derivative than that of the (phpyH)-complex. This may also support that radical formation (oxidation of phenolic ring) is more favorable for the system with long copper(II)–phenolic oxygen distance as observed in the native GO. Based on the above discussion, present results may suggest that the higher energy of HOMO of the phenolic group may lead to the longer the copper(II)–phenolic oxygen atom distance, and this makes the phenol ring to be more oxidizable, and that an ESR-silent state of GO (not necessarily diamagnetic) may be written as,

Cu(II)–phenoxo radical (Tyr 495)

and this may reacts as a two-electron acceptor in the reaction.

Table 4. Energies of HOMO and LUMO of *N*,*N*-dimethyl-*o*-hydroxy benzylamine and its derivatives (in the calculation, benzene ring is placed in *x*-*y* plane)

	HOMO/eV	LUMO/eV
X = H	−8.94[a]	0.37[b]
5-Br	−9.02	0.07
3,5-Br_2	−9.17	−0.23
5-NO_2	−9.80	−0.94

[a] HOMO is written as $-0.39p_z(O)-0.21p_z(C6)-0.51p_z(C5)+0.33p_z(C4)-0.19p_z(C3)+0.47p_z(C2)+0.39p_z(C1)$.

[b] LUMO is written as $0.07p_z(O)+0.55p_z(C6)-0.13p_z(C5)-0.37p_z(C4)-0.41p_z(C3)-0.22p_z(C2)+0.53p_z(C1)$.

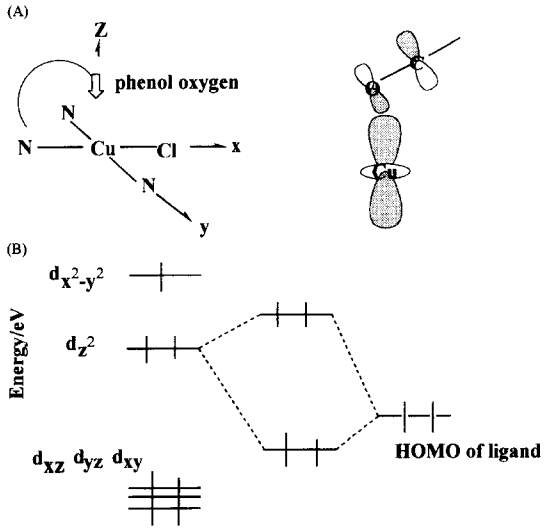

Fig. 4. (A) Interaction between HOMO of ligand and d_{z^2}-orbital of copper(II) ion. (B) Schematic illustration of relative energies of orbitals concerned. Bars (perpendicular) show an electron. As d_{z^2}-orbital is doubly occupied, this interaction induce destabilization of the complex, because HOMO of the ligand is also occupied by two electrons. Thus, the higher the energy of the HOMO, the longer the bond distance between copper(II) and phenol oxygen becomes.

(Received 21 July 1997; accepted 5 November 1997)

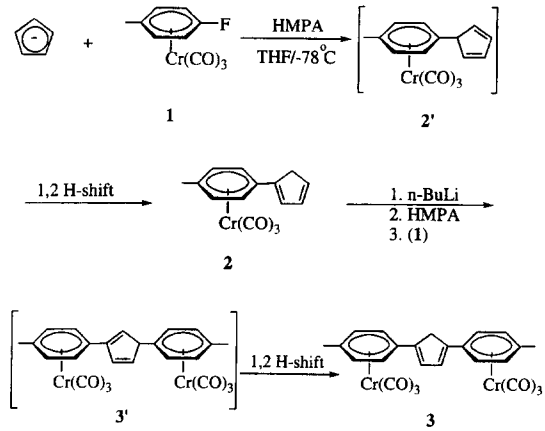
Abstract—1-[Tricarbonyl(η^6-4-toluene)chromium]-3-[tricarbonyl(η^6-4-anisole)chromium]indene (**7**) and 3-[tricarbonyl(η^6-4-toluene)chromium]-1-[tricarbonyl(η^6-4-anisole)chromium]indene (**7′**) were obtained as an isomeric mixture from the nucleophilic substitution of tricarbonyl(η^6-4-fluoroanisole)chromium (**6**) by deprotonated 3-[tricarbonyl(η^6-4-toluene)chromium]indene (**4**). Presumably, a 1,3-shift of a benzylic proton takes place during the formation of (**7**). The ratio of the two isomers is close to 1 : 1. 1-[Tricarbonyl(η^6-4-toluene)chromium]-3[tricarbonyl(η^6-4-anisole)chromium]-3-methylindene (**9**) was obtained as the only isolable product from the nucleophilic substitution of deprotonated 3-[tricarbonyl(η^6-4-toluene)chromium] methylindene (**8**) and 1-[tricarbonyl(η^6-4-toluene)chromium]methylindene (**8′**) with tricarbonyl(η^6-4-fluoroanisole)chromium (**6**). No proton shift was observed. Presumably, the nucleophilic substitutions take place directly on the fluorine-bearing carbon in all these cases. The new compounds were characterized by mass, infrared, ^{1}H, and ^{13}C NMR spectra. The molecular structure of (**9**) has been determined by an X-ray diffraction study. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: nucleophilic substitution; hydride shift; diaryl bimetallic compounds.

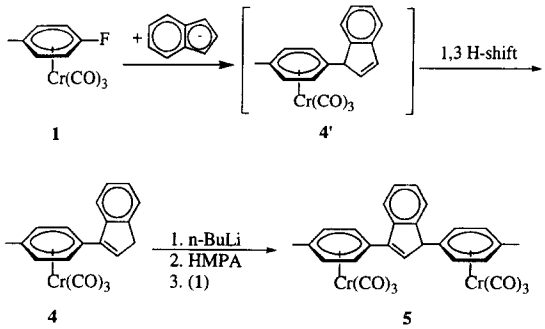
The thermal, suprafacial vs antarafacial, sigmatropic 1,3- and 1,5-shifts of alkyl groups in geminally substituted cyclopentadienes is known to take place at elevated temperatures [1]. Our previous work provided some examples of 1,2- or 1,3-hydride migration around the cyclopentadienyl ring during the nucleophilic substitution of tricarbonyl (η^6-4-fluorotoluene)chromium (**1**) by cyclopentadienyl and related compounds at much lower reaction temperature (Schemes 1, 2) [2]. The reactions were carried out in tetrahydrofuran (THF) and hexamethylphosphoric triamide (HMPA) as cosolvent [3].

* Author to whom correspondence should be addressed.

It is known that the arene protons and the benzylic protons become more acidic in (arene)$Cr(CO)_3$, due to the strong electron-withdrawing ability of the $Cr(CO)_3$ fragment, and are thereby more easily removed [4]. Therefore, it was speculated that in the above reactions the benzylic protons of the presumably intermediates, (**2′**) or (**3′**) or (**4′**), were first pulled out by basic solvent forming their corresponding anionic species. Then, these anionic species abstracted protons from various sources and formed the corresponding neutral products, 1-tricarbonyl[(η^6-4-toluene)chromium]cyclopentadiene (**2**) or 1,4-bis[tricarbonyl(η^6-4-toluene)chromium] cyclopentadiene (**3**) or 3-[tricarbonyl(η^6-4-toluene)chromium]indene (**4**). The observed 1,2-



Scheme 1.



Scheme 2.

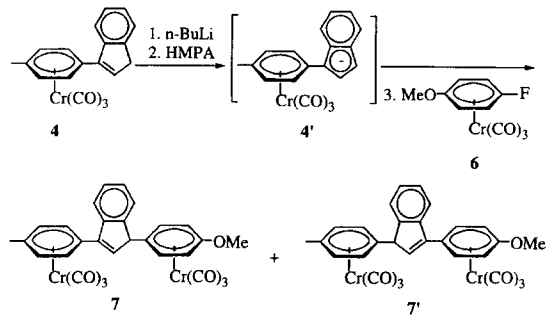
or 1,3-hydrogen shift at the end of the reaction resulted.

The fact that two distinct $-CH_3$ peaks were observed for 1,3-bis[tricarbonyl(η^6-4-toluene) chromium]indene (**5**) in one ^{1}H NMR spectrum is noteworthy (Scheme 2) [2b]. It implies that the benzylic proton does not become detached reversibly from compound **5** on the NMR timescale at room temperature as might be suggested. Otherwise, the molecule would be fluxional and it would not be possible to distinguish between the two $-CH_3$ groups [5]. It also suggests that the observed hydride shift must take place during the reaction not after it. It was therefore of interest to examine the factors which cause the hydrogen shift during the nucleophilic substitution reaction.

We also report the preparations and characterizations of some diaryl bimetallic compounds which have gained attention recently [6].

RESULTS AND DISCUSSION

The nucleophilic substitution of tricarbonyl(η^6-4-fluoroanisole)chromium (**6**) by deprotonated 3-[tricarbonyl(η^6-4-toluene)chromium] indene (**4**) was carried out in tetrahydrofuran first at $-78°C$ after which the reaction temperature was raised gradually to 25°C. A mixture of presumably 1-[tricarbonyl



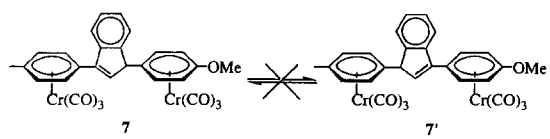
Scheme 3.

(η^6-4-toluene)chromium]-3-[tricarbonyl(η^6-4-anisole) chromium]indene (**7**) and 3-[tricarbonyl(η^6-4-toluene) chromium] - 1 - [tricarbonyl(η^6 - 4 - anisole)chromium] indene (**7′**) was yielded (Scheme 3). There were two sets of $-CH_3$ and $-OCH_3$ peaks observed in the ^{1}H NMR spectrum. Each set of peaks corresponds to one of the isomers, (**7**) or (**7′**). The ratio of these two isomers is close to 1 : 1 judging from the integration of their corresponding peaks in the ^{1}H NMR spectrum. It was further characterized by mass spectroscopy. Unfortunately, attempts to grow crystals were fruitless. The fact that two distinct sets of $-CH_3$ and $-OCH_3$ peaks were observed in the ^{1}H NMR spectrum was consistent with the previous observations on (**5**). It indicates that the conversion of these two isomers does not take place on the NMR timescale at room temperature.

A variable temperature ^{1}H NMR experiment was carried out for (**7**) and (**7′**) [7]. Since the structures of (**7**) and (**7′**) are very close and the benzylic proton is acidic, it was speculated that the conversion from (**7**) to (**7′**) or vice versa might be achieved simply by raising the temperature. The variable temperature ^{1}H NMR experiment for the isomers was conducted over the range 20°C to 70°C. Each measurement was taken at increments of 10°C. (Diagram 1). There was no significant change judging by the appearance of the spectra. This indicates that the conversion between (**7**) and (**7′**) on the NMR timescale cannot be achieved, at least below 70°C. The conversion did not happen when a small amount of THF, which was used as the solvent in the above reactions, was added to the solution.

A mixture of 3-[tricarbonyl(η^6-4-toluene)chromium] -1-methylindene (**8**) and its isomers, (**8′**) and (**8″**), was prepared by the procedures described in the Experimental Section (Scheme 5).

The nucleophilic substitution of tricarbonyl(η^6-4-fluoroanisole)chromium (**6**) by the deprotonated (**8**)



Scheme 4.

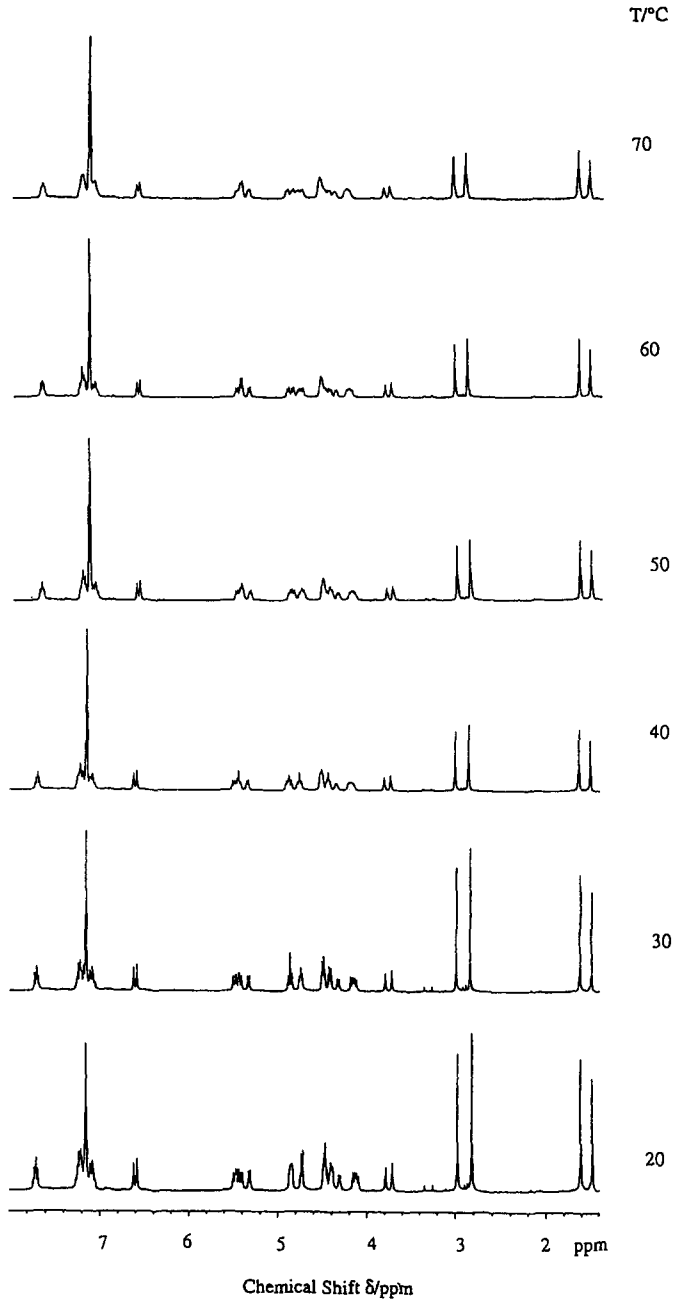


Diagram 1. Variable temperature ^{1}H NMR experiment for (**7**) and (**7′**)

and (**8′**) was carried out using similar reaction procedures to those described above (Scheme 6). Only one product, 1-[tricarbonyl(η^6-4-toluene)chromium]-3-[tricarbonyl(η^6-4-anisole)chromium]-1-methylindene (**9**), was obtained in this case.

Compound (**9**) was characterized by mass, infrared, and by ^{1}H and ^{13}C NMR spectra as well as by an X-ray crystal structure determination (Fig. 1). This shows that the two $Cr(CO)_3$ fragments are on opposite

faces of the bridging ligand; this could be a result of packing effects in the solid state. The two (arene) $Cr(CO)_3$ fragments might actually rotate freely in solution. The bond lengths of C(21)—C(20) and C(21)—C(13) are 1.340 and 1.510 Å, respectively. Accordingly, the former is a typical double bond and the latter is a single bond (Table 2). The dihedral angles between the phenyl rings and the indenyl ring are 84° and 28°, respectively. The orientation of the $Cr(CO)_3$ in (arene)$Cr(CO)_3$ complexes has been the subject of extensive studies [8]. In our case, a staggered orientation was observed for the (methyl-arene) $Cr(CO)_3$ fragment, while an eclipsed orientation was observed for the (methoxy-arene)$Cr(CO)_3$ fragment.

The formation of (**9**) was a result of direct nucleophilic substitution. There was no alkyl group or 1,3-hydrogen shift observed after the substitution this contrasting with the result from the reaction shown in Scheme 2. Therefore, it is clear that the benzylic proton is necessary for the hydrogen shift. The methyl group could not be removed and further migration did not take place under these reaction conditions.

The organic moiety of (**9**), 1-(4-toluene)-3-(4-anisole)-1-methylindene, was obtained by exposing a CH_2Cl_2 solution of the complex to air. The metal free organic part was further purified and the conversion was shown to be almost quantitative. This demonstrates a pathway for making quaternary carbon which might be difficult to do in another way.

1-[Tricarbonyl(η^6-4-anisole)chromium]-3-[tricarbonyl(η^6-4-toluene)chromium]-1-methylindene, (**9′**), a structural isomer of (**9**), can be prepared and separated as the only product by the pathway shown in Scheme 7. However, an isomeric mixture of (**9**) and (**9′**) was obtained in a ratio of 1 : 1 from the reaction of deprotonated (**7**) and methyl iodide. This indicates that the observation of the single product (**9**) in Scheme 6 and (**9′**) in Scheme 7 is because of the different reaction pathways rather than being due to an energetic factor.

It seems reasonable to propose that the removal of the benzylic proton from the product of the nucleophilic substitution reaction is the key to the observed hydrogen shift. The reaction mechanism proposed is as follows. Firstly, the benzylic proton of the neutral product is removed by strong base(s) to form the anionic species. Then, this anionic species picks up a proton and forms the most stable structure(s). The end result is a hydrogen shift. There are, at least, two proton abstracting reagents capable of achieving the

deprotonation. The first one is *n*-BuLi. The benzylic proton might be abstracted by the excess *n*-BuLi. Secondly, the proton might be removed by an already deprotonated species such as deprotonated (**4**) or (**7**) in each case. The first possibility was examined as shown in Scheme 8. The isomeric mixture of (**7**) and (**7′**) was placed in a reaction flask this being followed by addition of *n*-BuLi and then by excess MeI [9]. The reaction mixture was allowed to stir for 2 h. The products, (**9**) and (**9′**), were characterized. It was shown that the benzylic proton had been replaced by a methyl group. This indicates that the *n*-BuLi is capable of removing the benzylic proton from the reactant(s). There was no reaction if *n*-BuLi was absent.

Another proton abstractor might be the deprotonated species obtained from the neutral species by addition of *n*-BuLi. This newly deprotonated species might abstract a benzylic proton from another neutral compound thereby forming a neutral species itself. This is demonstrated in Scheme 9. It shows that (**7a**), the deprotonated mixture of (**7**) and (**7′**), abstracts a benzylic proton from (**7**). The dissociated proton might attack (**7a**) at any available position and has an equal chance of forming (**7**) or (**7′**). This mechanism is capable of explaining why there are two isomers formed via the nucleophilic substitution reaction in Scheme 3 but only one product in Scheme 6.

The possibility that the deprotonated species is able to remove a benzylic proton is also supported by the following experiment (Scheme 10). In this experiment, the deprotonated (**4**) pulled out the benzylic proton of (**7**) and (**7′**) and resulted in the formation of (**9**) and (**9′**).

Another possible mechanism, modified from that proposed by Pauson and Brookhart, involving hydrogen migration via the metal would be consistent with our observed results, as demonstrated in Scheme 11

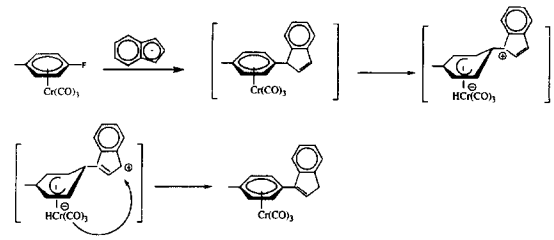
Scheme 10.

[10]. However, this is unlikely because of the long distance between the metal hydride and the positive charged carbon atom to be attacked.

In summary, it has been shown that both *n*-BuLi and the deprotonated product have the capacity to bring about the deprotonation which causes the



Scheme 11.

observed hydrogen shift. If *n*-BuLi is the only proton abstractor, the reaction will stop quickly after the total consumption of *n*-BuLi. It might not happen at all if the mole ratio of *n*-BuLi to the compound to be deprotonated is less than one mole equivalent. However, when less than one equivalent of *n*-BuLi was used in the reaction, the reaction still proceeded, even though, in lower yield. Therefore, it is very likely that the *n*-BuLi starts the reaction and the deprotonated species then takes over as the proton abstractor being itself converted to the product(s). Therefore, we propose that the deprotonated product abstracts the benzylic proton from the product of the direct nucleophilic substitution and itself forms the neutral compound(s). When the abstracted proton coordinates back to the deprotonated product forming the neutral product(s), it chooses to form the energetic favored structure(s). In this case, the favored structure(s) is the one with more and better conjugated double bonds in the molecule(s).

We have also been able to prepare diaryl bimetallic compounds through consecutive nucleophilic substitution and the structure of one of these compounds has been determined. We have also demonstrated that the organic moiety in the bimetallic compound (**9**), which might be difficult to make by a mere conventional method, can be obtained easily under mild oxidation conditions.

EXPERIMENTAL

Apparatus and materials

All operations were performed in a nitrogen-flushed glove box or in a vacuum system. Freshly distilled solvents were used. All processes of separation of the products were performed by Centrifugal Thin-Layer Chromatography (CTLC, Chromatotron, Harrison model 8924). ^1H and ^{13}C NMR spectra were recorded (Varian-300 spectrometer) at 300 and 75.46 MHz, respectively; chemical shifts are reported in ppm relative to internal TMS. IR spectra of solutions in $CHCl_3$ were recorded on a Hitachi 270-30 spectrometer. Mass spectra were recorded on a JOEL JMS-SX/SX 102A GC/MS/MS spectrometer.

Preparation of **7** *and* **7′**

Into a 40 cm^3 flask was placed (η^6-4-fluoroanisole)chromium (**4**) (0.214 g, 0.626 mmol), and the flask was then evacuated under reduced pressure for 10 min and finally filled with nitrogen. Anhydrous tetrahydrofuran (3 cm^3) was added to the reaction flask which was then cooled to −78°C (acetone-$N_{2(l)}$bath). Next, *n*-BuLi (1.6 M, 0.47 ml, 0.75 mmol) was added dropwise to the cold reaction flask. The deprotonation process was carried out at that temperature for 1.2 h and then HMPA (0.54 ml, 3.12 mmol) was added. Thirty minutes later, a solution of tricarbonyl(η^6-4-fluoroanisole)chromium (**6**) (0.20 g, 0.763 mmol) in 3 cm^3 of anhydrous THF was added slowly to the cold reaction mixture. The reaction was stirred at −78°C for another 3 h and gently warmed to 20°C during the next 16 h.

Subsequently, the resulting yellow solution was filtered through a small amount of silica gel. The filtrate was evaporated under reduced pressure to yield the crude product. On purification by centrifugal thin layer chromatography, a yellow band of 1-[tricarbonyl(η^6-4-anisole)chromium]-3-[tricarbonyl(η^6-4-toluene)chromium]indene (**7**) and 1-[tricarbonyl(η^6-4-toluene)chromium]-3-[tricarbonyl(η^6-4-anisole)chromium]indene (**7′**) was isolated (0.212 g, 58%).

Characterization of **7** *and* **7′**

Synthesis of **9**

The experimental procedures were similar to those given above. A mixture of **8** and **8′** (0.215 g, 0.604 mmol) was first deprotonated by *n*-BuLi (1.6 M, 0.45 ml, 0.72 mmol) then a solution of tricarbonyl(η^6-4-fluoroanisole)chromium (**6**) (0.190 g, 0.772 mmol) was added slowly to the reaction mixture. Purification of the resulting yellow solution was carried out on CTLC. A yellow band of 1-methyl-1-[tricarbonyl(η^6-4-anisole)chromium]-3-[tricarbonyl(η^6-4-toluene)chromium]indene (**9**) was isolated (0.125 g, 35%). In addition, a small amount of unreacted (**8**) and (**8′**) were recovered.

Characterization of **9**

^{1}H NMR ($CDCl_3$): δ 1.67 (3H, —CH_3 in indenyl), 2.27 (3H, —CH_3 in (toluene)$Cr(CO)_3$), 3.68 (3H, —OCH_3 in (anisole)$Cr(CO)_3$), 4.94, 5.08, 5.36, 5.82 (4H, (anisole)$Cr(CO)_3$), 5.36, 5.82 (4H, (toluene)$Cr(CO)_3$), 6.63 (1H, indenyl), 7.37, 7.62 (4H, arene in indenyl); ^{1}H NMR (C_6D_6): δ 1.39 (3H, —CH_3 in indenyl), 1.60 (3H, —CH_3 in (toluene)$Cr(CO)_3$), 2.81 (3H, —OCH_3 in (anisole)$Cr(CO)_3$), 4.13, 4.48, 5.34, 5.54 (4H, (anisole)$Cr(CO)_3$), 4.41, 5.16 (4H, (toluene)$Cr(CO)_3$), 6.53 (1H, indenyl), 7.71, 7.02 (4H, arene in indenyl); ^{13}C NMR ($CDCl_3$): δ 20.516 (1C, Me), 21.388 (1C, Me), 53.062 (1C, quaternary carbon in indenyl), 55.614 (1C, —OCH_3), 77.231, 93.549 (2C, (toluene)$Cr(CO)_3$), 92.659, 93.006, 93.237, 94.171 (4C, (anisole)$Cr(CO)_3$), 100.396, 105.838, 108.230 (3C, *ipso* of (arene)$Cr(CO)_3$), 121.417, 122.831, 126.859, 127.828, 138.544, 139.717, 143.585, 144.199 (8C, indenyl), 152.496 (1C, *ipso* of (anisole)$Cr(CO)_3$), 233.042, 233.495 (6CO); IR($CHCl_3$); $\nu_{(CO)}$ 1965.0, 1886.6 cm^{-1}; MS *m/z* 598 (P^+).

Characterization of **9′**

^{1}H NMR ($CDCl_3$): δ 1.69 (3H, —CH_3 in indenyl), 2.16 (3H, —CH_3 in (toluene)$Cr(CO)_3$), 3.77 (3H, —OCH_3 in (anisole)$Cr(CO)_3$), 4.94, 5.10, 5.33, 5.69 (4H, (toluene)$Cr(CO)_3$), 5.27, 5.98 (4H, (anisole)$Cr(CO)_3$), 6.67 (1H, indenyl), 7.36, 7.62 (4H, arene in indenyl); ^{13}C NMR ($CDCl_3$): δ 20.143 (1C, Me), 21.176 (1C, Me), 53.224 (1C, quaternary carbon in indenyl), 55.791 (1C, —OCH_3), 77.268, 79.031 (2C, (anisole)$Cr(CO)_3$), 91.090, 91.788, 93.530, 93.625 (4C, (toluene)$Cr(CO)_3$), 93.773, 94.186, 96.612 (3C, *ipso* of (arene)$Cr(CO)_3$), 110.194, 121.361, 122.954, 126.949, 127.951, 138.564, 142.400, 143.864 (8C, indenyl), 152.622 (1C, *ipso* of (anisole)$Cr(CO)_3$), 233.251, 234.048 (6CO); IR($CHCl_3$): $\nu_{(CO)}$ 1964.2, 1886.2 cm^{-1}; MS *m/z* 598 (P^+).

Preparation of **11** *and* **12**

Into a 50 cm^3 flask was placed (**9**) (0.10 g) and 20 cm^3 of CH_2Cl_2. The solution was exposed to air and sunlight for about 20 min. The green precipitate was separated and the filtrate was passed through a small amount of silica gel. The filtrate was evaporated under reduced pressure to yield the crude product. On purification by centrifugal thin-layer chromatography (eluent: hexane), a colorless band of (**11**) was isolated. The conversion to **11** from **9** is almost quantitative.

The experimental procedures for the preparation of **12** from **9′** were similar.

Characterization of **11**

^{1}H NMR ($CDCl_3$): δ 1.77 (3H, -CH_3 in indenyl), 2.41 (3H, —CH_3 in toluene), 3.77 (3H, —OCH_3 in anisole), 6.53 (1H, indenyl), 6.80, 7.24, 7.54 (m, 12H, arene in indenyl and toluene and anisole); ^{13}C NMR ($CDCl_3$): δ 21.290 (1C, Me), 23.068 (1C, Me), 54.894 (1C, quaternary carbon in indenyl), 55.223 (1C, —OCH_3), 113.725, 127.215, 127.544, 129.242 (8C toluene and anisole), 120.866, 123.026, 125.730, 126.503, 141.380, 142.100, 143.194, 154.603 (8C, indenyl), 132.684, 134.898, 137.485, 158.160 (4C, *ipso* of anisole and arene)); MS *m/z* 326 (P^+).

Characterization of **12**

^{1}H NMR ($CDCl_3$): δ 1.78 (3H, —CH_3 in indenyl), 2.30 (3H, —CH_3 in toluene), 3.87 (3H, —OCH_3 in anisole), 6.50 (1H, indenyl), 7.02–7.60 (m, 12H, arene in indenyl and toluene and anisole); ^{13}C NMR ($CDCl_3$): δ 20.785 (1C, Me), 22.848 (1C, Me), 55.075 (1C, quaternary carbon in indenyl), 55.266 (1C, —OCH_3), 114.065, 123.205, 126.188, 128.949 (8C, toluene and anisole), 113.589, 128.250, 140.147, 159.445 (4C, *ipso* of anisole and arene), 120.920, 125.89, 125.632, 129.231, 141.230, 142.436, 142.753, 154.681 (8C, indenyl); MS *m/z* 326 (P^+).

Crystal structure determination of **9**

A crystal of dimensions $0.21 \times 0.22 \times 0.45$ mm for $C_{30}H_{22}Cr_2O_7$ was selected for indexing and intensity data collection on a Seimens Smart-CCD diffractometer equipped with a normal focus, 3 kW sealed tube X-ray source. Intensity data were collected in 1271 frames with increasing ω (width of 0.3° per frame). Unit cell dimensions were determined by a least-squares fit of 8192 reflections with $5 < 2\theta < 50°$. Absorption correction was based on 10465 symmetry-equivalent reflections using the SHELTL-PC program package ($T_{min,max}$ = 0.821, 0.912). On the basis of systematic absence, statistics of intensity distribution, and successful solution and refinement of the structure, the space group was determined to be $P2_1/c$ (No. 14).

(Received 11 September 1997; accepted 3 November 1997)

Abstract—The reaction of [$Pt_2Me_4(\mu$-$SMe_2)_2$] (**1**) with the imine 3-(CF_3)C_6H_4CH=NCH_2Ph (**2a**) yields the cyclometallated compound [PtMe{3-(CF_3)C_6H_3CH=NCH_2Ph}(SMe_2)] (**3a**) by selective metallation at the less hindered of the two *ortho* positions of the aryl ring followed by loss of methane. A similar reaction for imine 2-(CF_3)C_6H_4CH=NCH_2Ph (**2c**) yields the cyclometallated compound [PtMe{2-(CF_3)C_6H_3CH=NCH_2Ph}(SMe_2)] (**3c**). The reactions of these compounds with triphenylphosphine in (1 : 1) ratio produce compounds [PtMe{3-(CF_3)C_6H_3CH=NCH_2Ph}(PPh_3)] (**4a**) and [PtMe{2-(CF_3)C_6H_3CH=NCH_2Ph}(PPh_3)] (**4c**). The X-ray structure of **4a** is reported. An excess of triphenylphosphine produces metallacycle cleavage and [PtMe{3-(CF_3)C_6H_3CH=NCH_2Ph}(PPh_3)$_2$] (**5a**) is formed with the imine acting as a [C^-] unidentate ligand. Oxidative addition of methyl iodide to compounds **4a** and **4c** gives cyclometallated platinum(IV) complexes. Imines 3,5-(CF_3)$_2C_6H_3$CH=NCH_2Ph (**2b**) and 2-F-6-(CF_3)C_6H_3CH=NCH_2Ph (**2d**) fail to react with [$Pt_2Me_4(\mu$-$SMe_2)_2$] (**1**). © 1998 Elsevier Science Ltd. All rights reserved

Keywords: selective metallation; N-benzylidenebenzylamine; trifluoromethyl.

There has been considerable interest in cyclometallated platinum(II) compounds due to their photochemical, photophysical and electrochemical properties [1]. The most convenient way to prepare cyclometallated compounds is the initial coordination of the heteroatom followed by metallation [2]. In particular, polyfunctional Schiff bases such as N-benzylidenebenzylamines, are suitable ligands to study these reactions, and the ease of such processes depends on the basicity of the N-donor atom and the nature of the substituents adjacent to the C-donor atom.

We are currently studying the influence of different substituents in the carbon atom adjacent to the metallation position on the formation of platinacycles from N-benzylidenebenzylamines. While metallation at the position adjacent to a small electron-withdrawing fluorine atom is favoured [3], electron-donating groups such as methyl or methoxy groups inhibit the metallation process [4]. For chlorinated N-benzylidenebenzylamines, metallation at a position adjacent to a chlorine atom has been achieved; however, metallation at the less hindered position is preferred for 3-ClC_6H_4CH=NCH_2Ph [5]. These results indicate a subtle balance between the favourable electron-withdrawing ability and the unfavourable size of the chlorine substituent.

We now report the results obtained for analogous imines bearing trifluoromethyl groups adjacent to the metallation positions such as 3-(CF_3)C_6H_4CH=NCH_2Ph (**2a**) and 3,5-(CF_3)$_2C_6H_4$CH=NCH_2Ph (**2b**). The trifluoromethyl group was chosen as a substituent because its approximate electronegativity (3.2) is similar to the electronegativities of chlorine (3.2) or flu-

orine (4.0) [6] although it is considerably larger. A comparison of the stereo-electronic parameters of different substituents is presented in Table 1 [7].

Furthermore, the presence of CF_3 groups in the *ortho* positions of the aryl ring such as for ligands 2-$(CF_3)C_6H_4CH{=}NCH_2Ph$ (**2c**) and 2-F-6-$(CF_3)C_6H_3CH{=}NCH_2Ph$ (**2d**), may lead to activation of C(aliphatic)—F bonds upon reaction with the platinum substrate.

RESULTS AND DISCUSSION

The reactions of $[Pt_2Me_4(\mu\text{-}SMe_2)_2]$ (**1**) with iminic ligands $ArCH{=}NCH_2Ph$ containing trifluoromethyl groups (**2a–2d**) were carried out in acetone and the results are shown in Scheme 1.

For imine 3-$(CF_3)C_6H_4CH{=}NCH_2Ph$ (**2a**), formation of cyclometallated compound $[PtMe\{3\text{-}(CF_3)C_6H_3CH{=}NCH_2Ph\}(SMe_2)]$ (**3a**) by *ortho*-metallation with loss of methane was achieved. As we have reported for analogous imines 3-$XC_6H_4CH{=}NCH_2Ph$ (X = Me, OMe, Cl), metallation occurred selectively at the less hindered of the two non-equivalent *ortho* positions of the benzal ring.

When imine 3,5-$(CF_3)_2C_6H_3CH{=}NCH_2Ph$ (**2b**) was exposed to **1** no reaction occurred. Previous results for analogous imines with different substituents in the carbon atoms adjacent to the metallation positions indicate that, although formation of platinacycles is achieved for F [3] or Cl [5] substituents, no reaction takes place for Me or MeO groups [4]. The failure to produce metallation can be related to an unfavourable combination of steric and electronic effects. For the highly electron-withdrawing trifluoromethyl group, steric effects alone account for the results observed.

The reaction of imine 2-$(CF_3)C_6H_4CH{=}NCH_2Ph$ (**2c**) with **1** produced compound $[PtMe\{2\text{-}(CF_3)C_6H_3CH{=}NCH_2Ph\}(SMe_2)]$ (**3c**) by C—H bond activation with loss of methane. Activation of the C(aliphatic)—F bond to yield a six-membered metallacycle was not observed.

In order to attempt the activation of a C(aliphatic)—F bond, imine 2-F-6-$(CF_3)C_6H_3CH{=}NCH_2Ph$ (**2d**) was tested. Activation of the C(aliphatic)—F bond was not observed upon reaction with **1**. This result is not unexpected since it has been reported that imine 2,6-$F_2C_6H_3CH{=}NCH_2Ph$ fails to react, and C—F activation is less likely for an aliphatic than for an aromatic carbon atom.

In contrast to the results observed for imines containing methyl or methoxy groups, coordination of the imine ligand to platinum through the nitrogen atom was not detected when the reaction of imines **2a–2d** with **1** was monitored by ^1H NMR spectroscopy. This result suggests that the metallation step is fast for **2a** and **2c**; for **2b** and **2d**, the electron-withdrawing ability of the CF_3 groups decreases the basicity of the nitrogen atom and prevents the formation of coordination compounds.

The reaction of compound **3a** with one equivalent of triphenylphosphine in acetone yielded the cyclometallated compound $[PtMe\{3\text{-}(CF_3)C_6H_3CH{=}NCH_2Ph\}(PPh_3)]$ (**4a**). When the reaction was carried out using a large excess of triphenylphosphine, the displacement of both the SMe_2 and the iminic nitrogen for two PPh_3 produced the cleavage of the metallacycle and the formation of compound $[PtMe\{3\text{-}(CF_3)C_6H_3CH{=}NCH_2Ph\}(PPh_3)_2]$ (**5a**). The formation of analogous compounds with the imine acting as a $[C^-]$ unidentate ligand has been previously reported for compounds containing a chlorine [5] or a fluorine [8] atom at C^5, and this has been attributed to unfavourable steric effects between the halogen atom and the methyl group. However, the result obtained for compound **3a** could only be explained on electronic grounds by assuming that a weaker Pt—N bond in *cis* may result from the electron-withdrawing ability of the CF_3 group.

The reaction of compound **3c** with triphenylphosphine in acetone yielded the cyclometallated compound $[PtMe\{2\text{-}(CF_3)C_6H_3CH{=}NCH_2Ph\}(PPh_3)]$ (**4c**) and, in this case, cleavage of the metallacycle was not observed even when a large excess of PPh_3 was used.

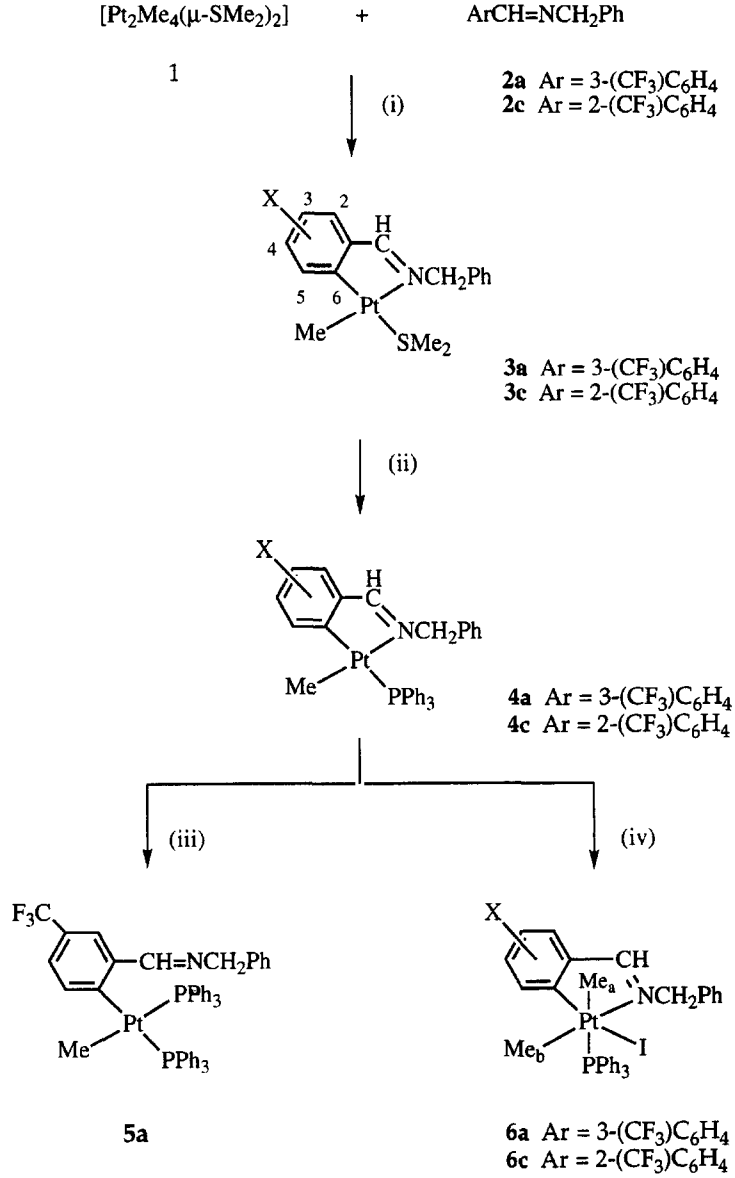
The reactions of **4a** and **4c** with methyl iodide were also studied. Oxidative addition of alkyl halides to square-planar platinum(II) complexes is well documented; in particular, studies concerning compounds $[PtMe_2(NN)]$ (where NN is a bidentate nitrogen donor ligand) have been reported and experimental evidence points to *trans* stereochemistry in the resulting platinum compounds [9,10]. This process is inhibited by the presence of highly electron-withdrawing groups, as in $[Pt(4\text{-}CF_3C_6H_4)_2(bipy)]$ or by steric hindrance as in $[Pt(2\text{-}MeC_6H_4)_2(bipy)$ [11]. In the latter case, the presence of the *ortho*-substituent may prevent attack at the platinum by blocking the coordination sites above and below the plane.

Upon addition of an excess of methyl iodide to

Table 1. Electronic and steric parameters for several substituents[a]

	σ_I	σ_R	E_S
F	0.50	−0.31	−0.46
Me	−0.05	−0.13	−1.24
OMe	0.27	−0.42	−0.55
Cl	0.46	−0.18	−0.97
CF_3	0.42	0.08	−2.4

[a] σ_I, σ_R, and E_S are inductive (*para*), mesomeric (*para*) and steric parameters, respectively, taken from Ref. [7]. H is taken as a standard, with a value 0. Positive σ values indicate electron-withdrawing groups, negative σ values indicate electron-donating groups and negative E_S values indicate unfavourable steric effects.



Scheme 1. (i) Acetone, room temperature, 16 h, C—CH_4 1 ; (ii) $+PPh_3$ (1 : 1), acetone, room temperature, 16 h ; (iii) $+PPh_3$ (5 : 1), acetone, room temperature, 16 h ; (iv) +HeI, acetone, room temperature, 2 h.

solutions of compounds **4** in acetone, the colour of the solution faded and compounds $[PtMe_2I\{(CF_3)C_6H_3CH{=}NCH_2Ph\}(PPh_3)]$ (**6**) were isolated. Thus, in this system, the presence of the electron-withdrawing group CF_3 does not prevent the oxidative addition; a similar result has been reported for fluorinated cyclometallated compounds [12]. Moreover, oxidative addition of methyl iodide takes place even when the bulky CF_3 group is in an *ortho* position of the aryl group as in **6c**.

Compounds **3a**, **3c**, **4a**, **4c**, **5a**, **6a** and **6c** were characterized by elemental analysis and ^1H and ^{19}F NMR spectra, together with ^{31}P NMR spectra for the phosphine derivatives. In the ^1H NMR spectra, the resonance for the methyl-platinum group, in all cases coupled to ^{195}Pt, appears as a singlet for compounds **3a** and **3c**, as a doublet due to coupling with one phosphorus atom for **4a** and **4c**, and as a doublet of doublets due to coupling with two non-equivalent phosphorus atoms for **5a**. For the latter compound, the coupling constant of the iminic hydrogen to platinum is much lower than that of cyclometallated compounds **3a** and **4a**. Two methyl-platinum resonances, coupled with ^{195}Pt and ^{31}P, appear for compounds **6**. The small value for the coupling constant of the axial methyl with platinum suggest a *trans* arrangement of

the axial methyl and the PPh_3, as previously observed for analogous compounds [13]. For all the compounds, the ^{19}F NMR spectra consist of a single resonance; the lack of platinum satellites for **3a** confirms that metallation occurred at position C^6. The ^{31}P NMR spectra consist of a single resonance for compounds **4** and **6**, and of a doublet of doublets for **5a**, in all cases with platinum satellites. Reduced coupling constants to platinum are observed for platinum(IV) compounds **6a** and **6c**.

Compound **4a** was also characterized crystallographically. Suitable crystals of **4a** were grown in acetone solution. The crystal structure is composed of discrete molecules separated by van der Waals distances. The structure is shown in Fig. 1 and the molecular dimensions are listed in Table 2. The coordination sphere of platinum is square-planar. The metallacycle is approximately planar; the largest deviation from the mean plane determined by the five atoms is 0.059 Å for C(6). The metallacycle is nearly coplanar with the coordination plane, the dihedral angle being 8.16°. The angles between adjacent atoms in the coordination sphere of platinum lie in the range 78.93(13)–98.97(9)°, the smallest angles corresponding to the metallacycle. Bond lengths in the coordination sphere of platinum are in the range expected for cyclometallated platinum compounds [4,8,13].

The results reported in this paper for N-benzylidenebenzylamines bearing trifluoromethyl groups indicate that the bulk of the CF_3 substituent inhibits the metallation at the adjacent positions. Thus, in contrast to the result obtained for chlorine substituents, the electron-withdrawing ability of the CF_3 group does not overcome its unfavourable steric effect. However, oxidative addition of methyl iodide to the obtained cyclometallated compounds is not prevented by the bulk of the CF_3 group due to the nearly coplanar arrangement of the metallacycle and the coordination plane.

EXPERIMENTAL

^1H and ^{31}P-$\{^1H\}$ NMR spectra were recorded by using Varian Gemini 200 (^1H, 200 MHz), Bruker WP80SY (^{31}P, 32.4 MHz), and Varian XL 300FT (^{19}F, 282.2 MHz; ^{31}P, 121.4 MHz) spectrometers, and referenced to $SiMe_4$ (^1H), H_3PO_4 (^{31}P) and CCl_3F (^{19}F). δ values are given in ppm and J values in Hz. roanalyses were performed by the Serveis Científico-Tècnics de la Universitat de Barcelona. Decomposition points were obtained with a Buchi 510 melting point instrument.

Preparation of the compounds

The complex $[Pt_2Me_4(\mu\text{-}SMe_2)_2]$ (**1**) was prepared by the method reported in the literature [14]. Compounds **2** were prepared by the reaction of 5 mmol of the corresponding aldehyde with 0.53 g (5 mmol) of the benzylamine in 25 ml of ethanol. The mixture was refluxed for 2 h and the solvent was removed in a rotary evaporator to yield yellow oils or white solids [15].

3-$(CF_3)C_6H_4CH{=}NCH_2Ph$ (**2a**). Yield: 1.0 g (76%). ^1H NMR ($CDCl_3$), $\delta = 4.86$ [s, CH_2], {7.35 [m], 7.56 [d, 1H], 7.66 [d, 1H], 7.96 [d, 1H], 8.07 [s], aromatics}, 8.43 [s, CHN]. ^{19}F NMR (acetone-d^6), $\delta = -69.29$ [s, CF_3].

3,5-$(CF_3)_2C_6H_3CH{=}NCH_2Ph$ (**2b**). Yield: 1.4 g (85%). ^1H NMR ($CDCl_3$), $\delta = 4.89$ [s, CH_2], {7.33 [m], 7.92 [s, 1H], 8.24 [s, 2H], aromatics}, 8.46 [s, CHN]. ^{19}F NMR (acetone-d^6), $\delta = -69.61$ [s, CF_3].

2-$(CF_3)C_6H_4CH{=}NCH_2Ph$ (**2c**). Yield: 1.1 g (84%). ^1H NMR ($CDCl_3$), $\delta = 4.87$ [s, CH_2], {7.34 [m], 7.53 [t, 1H], 7.66 [d, 1H], 8.26 [d, 1H], aromatics}, 8.77 [s, CHN]. ^{19}F NMR (acetone-d^6), $\delta = -63.82$ [s, CF_3].

2-F-6-$(CF_3)C_6H_3CH{=}NCH_2Ph$ (**2d**). Yield: 1.3 g (93%). ^1H NMR ($CDCl_3$), $\delta = 4.91$ [s, CH_2], {7.34 [m], 7.50 [m]}, 8.61 [s, CHN]. ^{19}F NMR (acetone-d^6), $\delta = -64.64$ [s, CF_3], -119.07 [s, F].

Compounds **3** were prepared by reaction of 100 mg (0.17 mmol) of $[Pt_2Me_4(\mu\text{-}SMe_2)_2]$ (**1**) with 0.35 mmol of the corresponding imine in acetone (25 ml). The mixture was stirred for 16 h and the solvent was removed in a rotary evaporator. The residue was washed with hexane (3 × 5 ml) and recrystallized in acetone (2 ml)/hexane (10 ml) to yield yellow-orange solids, which were filtered and washed with hexane (3 × 5 ml).

$[PtMe\{3\text{-}(CF_3)C_6H_3CH{=}NCH_2Ph\}(SMe_2)]$ (**3a**). Yield: 138 mg (74%) m.p. 115–118°C (d). Anal: calc. for $C_{18}H_{20}F_3NSPt$: C, 40.45; H, 3.77; N, 2.62. Found: C, 40.85; H, 3.93; N, 2.66. ^1H NMR (acetone-d^6), $\delta = 0.89$ [s, ^2J(HPt) = 83, Me], 1.97 [s, ^3J(HPt) = 27, SMe_2], 5.26 [s, ^3J(HPt) = 12, CH_2], {7.31 [m], 7.75 [m], aromatics}, 8.98 [s, ^3J(HPt) = 56, CHN]. ^{19}F NMR (acetone-d^6), $\delta = -63.96$ [s, CF_3].

$[PtMe\{2\text{-}(CF_3)C_6H_3CH{=}NCH_2Ph\}(SMe_2)]$ (**3c**). Yield: 140 mg (75%) m.p. 123–127°C (d). Anal: calc. for $C_{18}H_{20}F_3NSPt$: C, 40.45; H, 3.77; N, 2.62. Found: C, 40.85; H, 3.77; N, 2.62. ^1H NMR (acetone-d^6), $\delta = 0.89$ [s, ^2J(HPt) = 83, Me], 1.98 [s, ^3J(HPt) = 27, SMe_2], 5.38 [s, ^3J(HPt) = 10, CH_2], {7.32 [m], 7.90 [d, J(HPt) = 61, J(HH) = 8, 1H], aromatics}, 9.15 [s, ^3J(HPt) = 54, CHN]. ^{19}F NMR (acetone-d^6), $\delta = -59.97$ [s, ^5J(FPt) = 7, CF_3].

Compounds **4** were prepared by reaction of 50 mg (94 mmol) of the corresponding compound **3** with 25 mg (95 mmol) of PPh_3 in acetone (10 ml). The mixture was stirred at room temperature for 16 h. On addition of hexane (15 ml), yellow crystals were formed, and they were collected by filtration, washed with hexane (3 × 5 ml) and dried *in vacuo*.

$[PtMe\{3\text{-}(CF_3)C_6H_3CH{=}NCH_2Ph\}(PPh_3)]$ (**4a**). Yield: 50 mg (73%) m.p. 148°C (d). Anal: calc. for $C_{34}H_{29}F_3NPPt$: C, 55.59; H, 3.98; N, 1.91. Found: C, 55.72; H, 4.13; N, 2.12. ^1H NMR (acetone-d^6), $\delta = 0.74$ [d, ^2J(HPt) = 83, ^3J(HP) = 7, Me], 4.41 [s, ^3J(HPt) = 10, CH_2], {6.9 [m], 7.2 [m], 7.45 [m], 7.68 [m], aromatics}, 8.71 [s, ^3J(HPt) = 55, CHN]. ^{19}F

NMR (acetone-d^6), $\delta = -64.03$ [s, CF_3]. ^{31}P NMR (acetone), $\delta = 29.33$ [s, ^1J(PPt) = 2237].

[PtMe{2-(CF_3)C_6H_3CH=NCH_2Ph}(PPh_3)] (**4c**). Yield: 55 mg (80%) m.p. 145°C (d). Anal: calc. for $C_{34}H_{29}F_3NPPt$: C, 55.59; H, 3.98; N, 1.91. Found: C, 55.59; H, 4.01; N, 1.97. ^{1}H NMR (acetone-d^6), $\delta = 0.70$ [d, ^2J(HPt) = 82, ^3J(HP) = 7, Me], 4.47 [s, ^3J(HPt) = 9, CH_2], {6.8 [d, 2H], 7.21 [m], 7.43 [m], 7.61 [m], 8.05 [m, 1H], aromatics}, 8.83 [s, ^3J(HPt) = 58, CHN]. ^{19}F NMR (acetone-d^6), $\delta = -59.55$ [s, CF_3]. ^{31}P NMR (acetone), $\delta = 29.05$ [s, ^1J(PPt) = 2236].

Compound **5a** was prepared by reaction of 50 mg (94 mmol) of the corresponding compound **3a** with 120 mg (0.458 mol) of PPh_3 in acetone (10 ml). Within 1 h, the colour of the solution faded and a white precipitate was formed. After addition of hexane (10 ml), the white solid was collected by filtration, washed with hexane (3 × 5 ml) and dried *in vacuo*.

[PtMe{3-(CF_3)C_6H_3CH=NCH_2Ph}(PPh_3)$_2$] (**5a**). Yield: 80 mg (86%) m.p. 178°C (d). Anal: calc. for $C_{52}H_{44}F_3NP_2Pt$: C, 62.65; H, 4.45; N, 1.40. Found: C, 62.68; H, 4.62; N, 1.39. ^{1}H NMR (acetone-d^6), $\delta = 0.29$ [dd, ^2J(HPt) = 67, $^3J(HP_a)$ = 8, $^3J(HP_b)$ = 6, Me], {4.74 [d], 4.88 [d], ^2J(HH) = 13, *AB* pattern, CH_2], {6.5 [m], 6.7 [m], 7.2 [m], aromatics}, 9.52 [s, ^4J(HPt) = 10, CHN]. ^{19}F NMR (acetone-d^6), $\delta = -63.92$ [s, CF_3]. ^{31}P NMR (acetone), $\delta = 25.84$ [d, ^1J(PPt) = 1949, ^2J(PP) = 14], 26.18 [d, ^1J(PPt) = 1916, ^2J(PP) = 14].

Compounds **6** were prepared by reaction of 50 mg (68 mmol) of the corresponding compound **4** with an excess of methyl iodide (0.1 ml) in 10 ml of acetone. The mixture was stirred at room temperature for 2 h. On addition of hexane (15 ml), light yellow crystals were formed, and they were collected by filtration, washed with hexane (3 × 5 ml) and dried *in vacuo*.

[$PtMe_2$I{3-(CF_3)C_6H_3CH=NCH_2Ph}(PPh_3)] (**6a**). Yield: 50 mg (84%). Anal: calc. for $C_{35}H_{32}F_3INPPt$: C, 47.96; H, 3.68; N, 1.60. Found: C, 48.7; H, 4.0; N, 1.7. ^{1}H NMR (acetone-d^6), $\delta = 1.10$ [d, ^2J(HPt) = 60, ^3J(HP) = 8, Me_a], 1.59 [d, ^2J(HPt) = 70, ^3J(HP) = 8, Me_a], {4.74 [m], 5.65 [m], J(HH) = 16, *AB* system}, {6.7 [d, J(HH) = 8, J(HPt) = 43, 1H], 7.2 [m, 2H], 7.3 [m], 7.5 [m], aromatics}, 8.31 [s, ^3J(HPt) = 49, CHN]. ^{19}F NMR (acetone-d^6), $\delta = -65.18$ [s, CF_3]. ^{31}P NMR (acetone), $\delta = -9.63$ [s, ^1J(PPt) = 1021].

[$PtMe_2$I{2-(CF_3)C_6H_3CH=NCH_2Ph}(PPh_3)] (**6c**). Yield: 45 mg (75%). Anal: calc. for $C_{35}H_{32}F_3INPPt$: C, 47.96; H, 3.68; N, 1.60. Found: C, 47.9; H, 3.8; N, 1.7. ^{1}H NMR (acetone-d^6), $\delta = 1.08$ [d, ^2J(HPt) = 60, ^3J(HP) = 8, Me_a], 1.58 [d, ^2J(HPt) = 70, ^3J(HP) = 8, Me_a], {4.93 [m], 5.72 [m], J(HH) = 16, *AB* system}, {7.4 [m], 7.5 [m], aromatics}, 8.31 [s, ^3J(HPt) = 50, CHN]. ^{19}F NMR (acetone-d^6), $\delta = -61.02$ [s, CF_3]. ^{31}P NMR (acetone), $\delta = -9.85$ [s, ^1J(PPt) = 1015].

X-ray structure analysis, data collection

A prismatic crystal of **4a** was selected and mounted on an Enraf-Nonius CAD4 diffractometer. Unit cell parameters were determined from automatic centreing of 25 reflections ($12° < \theta < 21°$) and refined by least-squares method. Intensities were collected with graphite monochromatized Mo–K_α radiation, using $\omega/2\theta$ scan-technique. 8435 reflections were measured in the range $2.38° < \theta < 29.96°$, and 7202 were assumed as observed applying the condition $I > 2\sigma(I)$. Three reflections were measured every 2 h as orientation and intensity control, significant intensity decay was not observed. Lorentz-polarization and absorption corrections were made. Further details are given in Table 3.

Structure solution and refinement

The structure was solved by direct methods, using SHELXS Computer Program [16], and refined by the full-matrix least-squares method, with the SHELX93 computer program [17] using 8435 reflections. The function minimized was $\Sigma w\|F_o|^2-|F_c|^2|^2$, where $w=[\sigma^2(I)+(0.0462P)^2]^{-1}$ and $P=(|F_o|^2+2|F_c|^2)/3$.f, f' and f'' were taken from International Tables of X-Ray Crystallography [18]. Fluorine atoms of CF_3 groups were located in disorder positions. An occupancy factor of 0.5 was assigned according to the height of Fourier synthesis. 19 hydrogen atoms were located from a difference synthesis and 10 hydrogen atoms were computed and refined with an overall isotropic temperature factor using a riding model. The final R factors, the number of refined parameters, and the maximum and minimum peaks in the final difference synthesis are given in Table 3.

(Received 25 August 1997; accepted 3 November 1997)

Abstract—Two novel mixed-valent tellurium(II and IV) dithiocarbamate complexes have been prepared and their structures determined by X-ray diffraction studies. Complex **1**, $[Te^{IV}(S_2CNEt_2)_3]_2[Te^{II}(S_2CNEt_2)_2](PF_6)_2$, was obtained from the metathesis reaction of $[Te^{IV}(S_2CNEt_2)_3ClO_4]$ with KPF_6 due to the partial reduction of the primary product $[Te^{IV}(S_2CNEt_2)_3]PF_6$, which is thermodynamically unstable. The preparation of tellurium(IV) dithiocarbamate in dilute perchloric acid medium results in complex **2**, which has a composition $[Te^{IV}(S_2CNEt_2)_3][Te^{II}(S_2CNEt_2)_2](ClO_4)$. These two complexes represent the first examples of mixed valent complexes of tellurium consisting only the sulphur ligands. Their structural investigation shows that these complexes are stabilized primarily due to the supramolecular Te···Te interaction, the distance of which is shorter than the earlier known complex. While $Te^{II}(S_2CNEt_2)_2$ is sandwiched between two $Te^{IV}(S_2CNEt_2)_3$ molecules in **1**, two such Te(II) molecules are sandwiched in complex **2**. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: tellurium-dithiocarbamate complexes; mixed-valent; supramolecular interactions; crystal structures.

One of the most interesting aspects in studies involving tellurium complexes with sulphur containing ligands, in both Te^{II} and Te^{IV} oxidation states, is their stereochemical activity and supramolecular associations [1]. Tellurium, in the aforementioned oxidation states, is known to exhibit a wide range of coordination geometries. Complexes with monodentate sulphur ligands, particularly thiourea and its derivatives, have been characterized structurally relatively well [2]. The geometry around tellurium in these complexes reflects the bonding ability of tellurium. However, bidentate 1,1-dithiolate ligands, such as dithiocarbamates, xan-

thates and dithiophosphates exhibit a greater structural diversity in their tellurium coordination chemistry owing to their small bite. Apart from being excellent chelating agents, these ligands produce strong distortion in the coordination geometries around the central tellurium, compared to the monodentate ligands. Another important aspect which determines the coordination geometry in the tellurium complexes is presence of the lone pair(s) of electrons, which in some cases are stereochemically active, occupying the vertices of the coordination polyhedra, while in many other cases they are stereochemically inactive.

The neutral dithiocarbamate complexes of tellurium in both +II and +IV oxidation states are very well known [3]. Our earlier work in the mixed halide-dithiocarbamate complexes, combined with the results from other groups shows the diverse nature in the geometry exhibited by tellurium [4]. In mixed iodide-dithiocarbamate complexes of tellurium(II and IV), when the number of ligand atoms cannot satisfy the preferred coordination number, then bridging through the iodide results leadings to dimeric or polymeric structures [4a–c]. Despite the structural characterization of many tellurium complexes with sulphur ligands, their structures still remain largely unpredictable. Moreover, when the preferred coordination number of tellurium cannot be satisfied by the ligands of the specific molecular composition, then organization of the molecules in the crystal takes place in such a way as to have supramolecular interaction, which results in an extended coordination. This provides a strong motivation for our continuing studies in the chemistry of the dithiocarbamate complexes of tellurium.

Here we report the preparation and the characteristic structural features observed in two such complexes. In order to see what could be the geometrical features in the six-coordinated tris(dithiocarbamato)tellurium(IV) complex, if we are able to isolate that species with the non-coordinating PF_6^- anion, we obtained complex **1** of composition $[Te^{IV}\{(C_2H_5)_2NCS_2\}_3]_2Te^{II}\{(C_2H_5)_2NCS_2\}_2](PF_6)_2$. Complex **2** was obtained from the reaction of sodium tellurite with diethyldithiocarbamate in 4N perchloric acid.

RESULTS AND DISCUSSION

Syntheses and general properties

Complex **1** resulted from an attempted isolation of the $Te(S_2CNEt_2)_3PF_6$ species by reaction of $Te(S_2CNEt_2)_3ClO_4$ with KPF_6 in methanol–dichloromethane mixture. However the resultant compound, crystallized from dichloromethane with few drops of ethylacetate, conformed to the composition $[Te(S_2CNEt_2)_3]_2[Te(S_2CNEt_2)_2](PF_6)_2$. The reaction of sodium tellurite in 4N perchloric acid with sodium diethyldithiocarbamate resulted in **2**. Recrystallization in dichloromethane–ethylacetate mixture afforded black crystals. Both the compounds were characterized by elemental analyses. The infrared spectra exhibits the characteristic bands of the dithiocarbamate and that due to PF_6 and ClO_4 anions in their respective complexes. The complexes **1** and **2** are the first examples of a mixed-valent complex of tellurium containing only the sulphur ligands.

When a dichloromethane solution of $[Te(S_2CNEt_2)_3ClO_4]$ was reacted with the methanolic solution of KPF_6, immediate precipitation of $KClO_4$ takes place. The resultant $[Te(S_2CNEt_2)_3]PF_6$, due to its inherent instability undergoes a partial reduction and hydrolysis to yield **1** as one of the products. The most probable mechanistic pathway for such a reaction is given in Scheme 1.

$$2[Te^{IV}(S_2CNEt_2)_3]PF_6 \rightleftharpoons Te^{II}(S_2CNEt_2)_2 + [Te^{IV}(S_2CNEt_2)_2](PF_6)_2 + Et_2NC(S)SSC(S)NEt_2$$

$$[Te^{IV}(S_2CNEt_2)_2](PF_6)_2 + 2H_2O \rightarrow TeO_2 + 2(Et_2NCS_2)^- + 4H^+ + 2PF_6^-$$

$$[Te^{IV}(S_2CNEt_2)_2](PF_6)_2 + (Et_2NCS_2)^- \rightarrow [Te^{IV}(S_2CNEt_2)_3]PF_6 + PF_6^-$$

the overall reaction is,

$$10[Te^{IV}(S_2CNEt_2)_3]PF_6 + 2H_2O \rightarrow 3[Te^{IV}(S_2CNEt_2)_3]_2[Te^{II}(S_2CNEt_2)_2(PF_6)_2 + TeO_2 + 3Et_2NC(S)SSC(S)NEt_2 + 4HPF_6$$

Scheme 1.

The coordinatively unsaturated $[Te^{IV}(S_2CNEt_2)_3]PF_6$ first undergoes a partial autoreduction, as shown in Scheme 1, to $Te^{II}(S_2CNEt_2)_2$, tetraethylthiuramdisulphide, which is the oxidation product of the dithiocarbamate, and $[Te^{IV}(S_2CNEt_2)_2](PF_6)_2$. The resultant bis(diethyldithiocarbamato)tellurium(IV) dication is very unstable and as a result hydrolyzes slowly in the presence of water in methanol to tellurium oxide. The liberated dithiocarbamate combines with the dication and stabilizes it from further hydrolysis. The $Te^{II}(S_2CNEt_2)_2$ forms an adduct with tris(diethyldithiocarbamato)-tellurium(IV) cation, to give **1**. The final products formed are **1**, tellurium oxide, disulphide and HPF_6.

The reaction of aqueous sodium tellurite with the dithiocarbamate ligand in acidic conditions is used for the preparation of tetrakis(diethyldithiocarbamato)tellurium(IV). In 4N perchloric acid medium, and when methanol was used for dissolving the dithiocarbamate, $[Te^{IV}(S_2CNEt_2)_3(ClO_4)]$ was obtained as the sole product [5]. The structural study of this complex shows that the two oxygen atoms of the perchlorate anion are also coordinated to tellurium, so that the tellurium(IV) attains its pre-

ferred coordination number of 8, which is responsible for the stability of this complex. If water is used for dissolving the dithiocarbamate, the product obtained is **2**, representing an adduct of $[Te^{IV}(S_2CNEt_2)_3](ClO_4)$ and $Te^{II}(S_2CNEt_2)_2$ in 1:1 molar ratio. The tellurium(IV) is partially reduced by the dithiocarbamate to tellurium(II). This reduced tellurium(II) complexes with the dithiocarbamate and this complex stabilizes the already formed tris-(diethyldithiocarbamato)tellurium(IV) cation to yield adduct **2** as shown in equation 1.

$$2Na_2Te^{IV}O_3 + 12HClO_4 + 7NaS_2CNEt_2 \rightarrow \mathbf{2} + Et_2NC(S)SSC(S)NEt_2 + 11NaClO_4 + 6H_2O \quad (1)$$

Compound **2** undergoes hydrolytic decomposition very easily. In the presence of trace amount of water, the tellurium(IV) species undergoes hydrolysis to give tellurium oxide, while at the same time liberating the free dithiocarbamate. For each mole of $[Te^{IV}(S_2CNEt_2)_3]^+$ converting to TeO_2, three moles of the free dithiocarbamate are released, which in turn complexes with the unhydrolysed $[Te^{IV}(S_2CNEt_2)_3]^+$ to give $Te^{IV}(S_2CNEt_2)_4$. Thus the products of hydrolysis are $Te^{IV}(S_2CNEt_2)_4$, $Te^{II}(S_2CNEt_2)_2$ and TeO_2. This clearly shows that the driving force for the formation of the adduct is the presence of the coordinatively unsaturated $[Te^{IV}(S_2CNEt_2)_3]^+$ species. Once the saturation of coordination occurs by complexing with the fourth dithiocarbamate, the tellurium(II) complex is freed as shown in Scheme 2.

$$\mathbf{2} + H_2O \rightarrow [Te^{IV}(S_2CNEt_2)_3OH] + Te^{II}(S_2CNEt_2)_2 + HClO_4$$

$$[Te^{IV}(S_2CNEt_2)_3OH] + H_2O \rightarrow Te^{IV}O_2 + 3Et_2NCS_2^- + 3H^+$$

$$\mathbf{2} + (Et_2NCS_2)^- \rightarrow Te^{IV}(S_2CNEt_2)_4 + Te^{II}(S_2CNEt_2)_2 + ClO_4^-$$

the overall reaction is,

$$4[Te^{IV}(S_2CNEt_2)_3][Te^{II}(S_2CNEt_2)_2]ClO_4 + 2H_2O \rightarrow Te^{IV}O_2 + 3Te^{IV}(S_2CNEt_2)_4 + 4Te^{II}(S_2CNEt_2)_2 + 4HClO_4$$

Scheme 2.

In $[Te(S_2CNR_2)_3]X$ (where X = I, Br, Cl or SCN) [6], Te has a distorted pentagonal bipyramid geometry with the X atom occupying one of the axial positions, where the seventh coordination site is occupied by X. However, the isolation of the species, $[Te(S_2CNEt_2)_3]^+$, as such is difficult. In the perchlorate salt of this complex, the two oxygen atoms of the perchlorate are coordinated to Te, so that it was eight-coordinated with a distorted dodecahedron geometry. In the present instance the isolation of $[Te(S_2CNEt_2)_3]^+$ has become possible due to its adduct formation with $Te^{II}(S_2CNEt_2)_2$ through weak Te(II)···Te(IV) interaction. The complexes **1** and **2** differ only in the ratio of the Te(IV) and Te(II).

Structural characterization

The detailed structural study of title complexes show some very interesting features. The structure of **1** can be described as consisting of two independent tellurium complexes, $[Te^{IV}(S_2CNEt_2)_3]PF_6$ and $Te^{II}(S_2CNEt_2)_2$ in the ratio of 2:1 (Fig. 1), with the $Te^{II}(S_2CNEt)_2$ moiety sandwiched between two $Te^{IV}(S_2CNEt_2)_3$ molecules as shown in the crystal packing diagram (Fig. 2). This sandwich type structure is held together by means of short Te···Te and weak Te---S interactions. Each Te(IV) is seven-coordinated; six primary coordinations, by the S atoms of three dithiocarbamate ligands, and one secondary coordination, to Te(II), if the short Te···Te interaction is also taken into account. The Te(II), on the other hand, has a coordination number of six. It is coordinated by the four S atoms of the two dithiocarbamates and by the two Te(IV) atoms in the axial positions.

The tetravalent tellurium Te(1) is in a general position, whereas the divalent tellurium Te(2) sits on a two-fold axis (0, *y*, 1/4). The six primary coordination sites of Te(1) are occupied by the sulphur atoms of the three dithiocarbamate ligands. The Te—S bond distances ranges between 2.434–2.804 Å, with all the three dithiocarbamates bound in anisobidentate manner to the tellurium. The occurrence of such long distances Te—S bonds for these complexes have been explained on the basis of the three-centre four-electron bond concept [7]. All the Te—S distances and S—Te—S angles are similar to that observed in other $[Te(S_2CNR_2)_3]X$ compounds. In the $Te^{II}(S_2CNEt_2)_2$ moiety, the tellurium atom sits on a crystallographic special position and only one dithiocarbamate forms a part of the asymmetric unit. The two dithiocarbamates are coordinated in an anisobidentate manner (the Te—S distances being 2.487 and 2.859 Å) and the two axial positions are occupied by the Te(IV) atoms. In the previously known examples of $Te^{II}(S_2CNR_2)_2$ [8], the geometry around the tellurium atom is planar trapezoidal with one of the S—Te—S angles being very large (about 145°). Hence it could be interpreted as a planar pentagonal, with one of the corners missing. As Te(2) is on a two-fold axis, the $Te^{II}(S_2CNR_2)_2$ in **1** is symmetrically disposed. With two Te(1) atoms above and below, the geometry around Te(2) can be described as a distorted octahedron with the angle axial Te(1)—Te(2)—Te(1′) angle being 161.43°.

The shortest Te(IV)—S distance of 2.434 Å in the present instance, is incidentally, of that of axial sul-

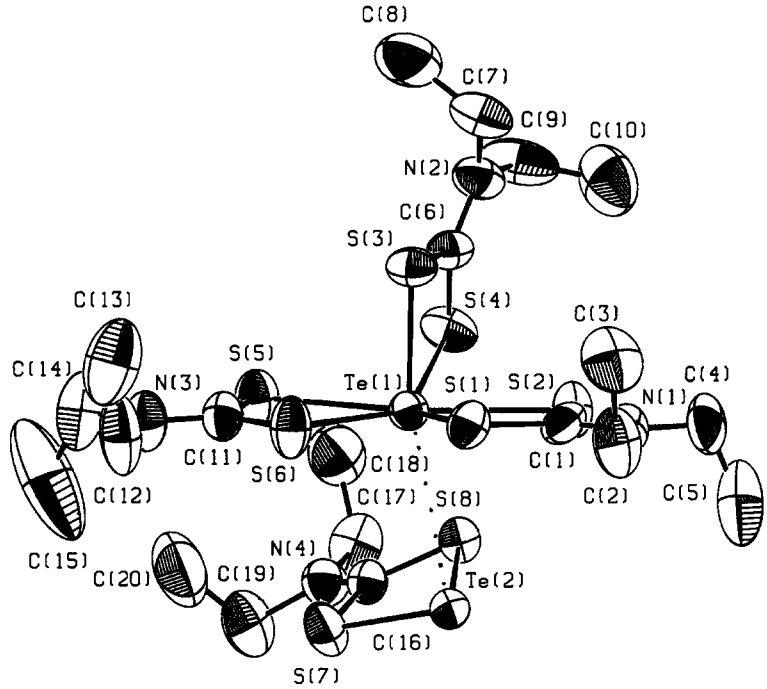

Fig. 1. An ORTEP plot of the cationic complex $\{[Te^{IV}\{S_2CN(C_2H_5)_2\}_3]\ 0.5[Te^{II}\{S_2CN(C_2H_5)_2\}_2]^+\}$ of **1** present in the asymmetric unit, drawn with 50% probability ellipsoids. Te^{II} is present on a crystallographic two-fold axis. The symmetry related half of the molecule and the hydrogen atoms are omitted for clarity.

phur atom (S3). This axial Te—S bond is *trans* to the Te···Te interaction and hence produces a *trans* bond lengthening effect on the Te—Te bond. The Te···Te distance of 3.390 Å is greater than the sum of the covalent radii of tellurium atoms (2.72 Å) [9] but close to the sum of the atomic radii of Te (3.28 Å), if the three-centre four-electron radii of Te is taken into account [7]. However in the latter case the radii was computed based on the square planar tellurium(II) complexes with monodentate ligands. This distance is also considerably shorter than the distance of 3.542 Å observed in the only previous known example [10] of a mixed valent Te(IV)—Te(II) complex $[I(Pr^i_2NCS_2)Te^{II}(\mu\text{-}I)Te^{IV}(S_2CNPr^i_2)_2I]$ containing the sulphur ligands. However in the already known example, iodide bridges the two tellurium atoms and the Te···Te interaction is only secondary. The one other known example [11] containing a Te—Te bond, with sulphur ligands coordinated to Te, is TeL_2-TeLSCN, and the distance observed there is 3.221 Å. However, both the telluriums here are in +II oxidation state.

Apart from the Te···Te interaction, the crystal structure is stabilized by Te---S secondary interactions. Te(1) has weak interaction with S(8), the sulphur atom bound to Te(2) at a distance of 3.500 Å. However, Te(II) has four such interactions, with

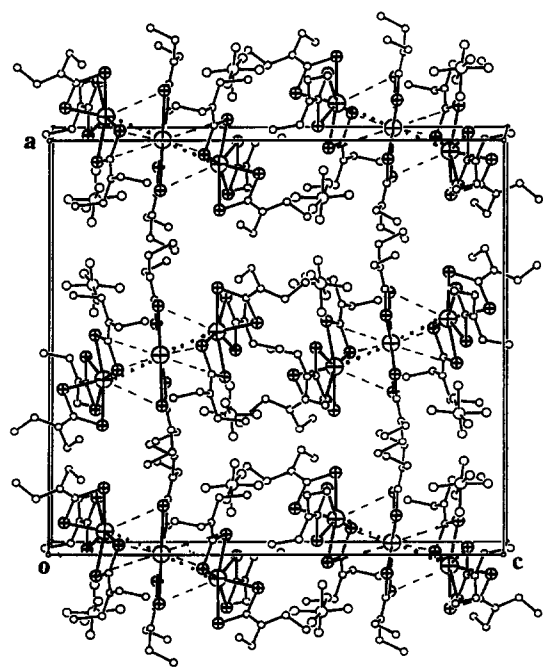

Fig. 2. The packing of the molecules of **1** in the unit cell illustrating the Te···Te interaction, the secondary Te---S interactions and the sandwich type arrangement.

two symmetry related S(1) and S(2) atoms at distances of 3.885 and 3.890 Å.

In complex **2** also there are two independent Te(IV) and Te(II) dithiocarbamate complexes $[Te^{IV}(S_2CNEt_2)_3]ClO_4$ and $Te^{II}(S_2CNEt_2)_2$ (Fig. 3), however in the ratio of 1 : 1. The structural difference with **1** arises basically due to the interleaving of another Te(II)-dithiocarbamate between the Te(II) and Te(IV) complexes, the two $Te^{II}(S_2CNEt_2)_2$ molecules being sandwiched between two $[Te^{IV}(S_2CNEt_2)_3]$ moieties as shown in Fig. 4.

The $Te^{IV}(S_2CNEt_2)_3$ moiety in this complex also is made of three anisobidentate dithiocarbamates and with almost similar geometrical features as that of **1** (Te—S distances ranges between 2.474–2.805 Å). Te(1) has six primary coordinations, with a pentagonal pyramidal geometry. When the secondary Te···Te interaction is also taken into account the geometry becomes pentagonal bipyramidal. The Te—S(3) bond distance (2.473 Å) in **2** is a bit longer than that in **1**, which again reflects in the Te···Te interaction, *viz.* shortening by almost similar magnitude. Thus, the Te···Te interaction of 3.347 Å is shorter than in **1**. There is a secondary interaction between Te(1) and S(8) of distance 3.601 Å, which essentially shows that the geometry around the Te(IV) centre is conserved as in **1**.

The main difference between the crystal structures of **1** and **2** lies around the Te(II) centre. The geometry around Te(2) in **2** is unlike in **1**. But it is similar to

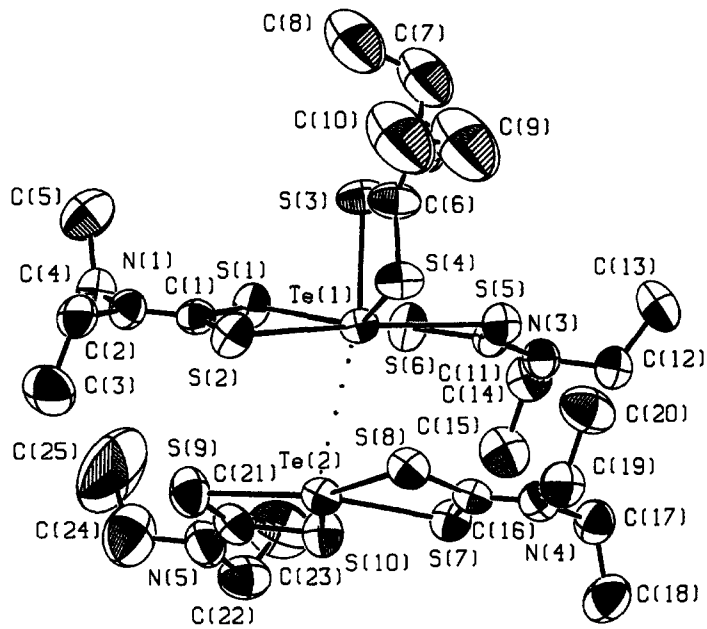

Fig. 3. An ORTEP plot of the cationic complex $\{[Te^{IV}\{S_2CN(C_2H_5)_2\}_3]\ [Te^{II}\{S_2CN(C_2H_5)_2\}_2]^+\}$ of **2** drawn with 50% probability ellipsoids. N(2) is hidden behind the atoms C(9) and C(10). The hydrogen atoms are omitted for the sake of clarity.

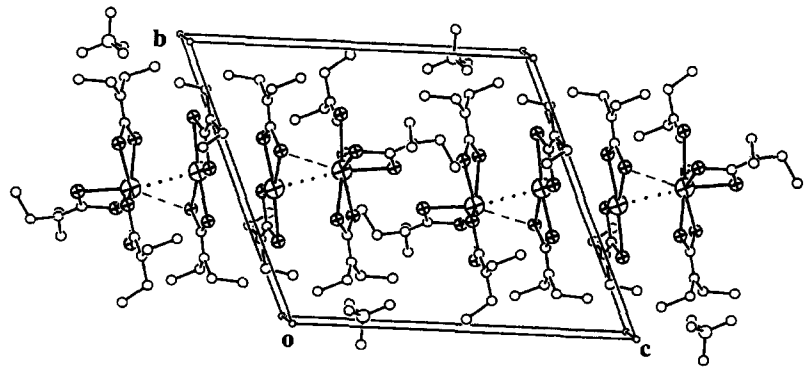

Fig. 4. The packing diagram of the molecules of **2** in the unit cell illustrating the Te···Te interaction, the secondary Te---S interactions and the double sandwich type arrangement.

that observed in the other structures, with one small and one large interligand S—Te—S angles (79.5 and 147.8°). If the Te···Te interaction is also taken into consideration, then the geometry becomes capped trapezoid. The Te(II)···Te(II) distance is rather large, and is close to the sum of the van der Waal's radii of the tellurium atoms (4.40 Å) [12], to be thus considered as a secondary interaction. There is just one more Te---S secondary interaction involving Te(II), which is with S(2) at a distance of 3.853 Å.

EXPERIMENTAL

Tellurium dioxide, sodium diethyldithiocarbamate and potassium hexafluorophosphate were used as obtained commercially. Dichloromethane, methanol and ethylacetate were distilled and stored over molecular sieves before use. The complex $Te\{(C_2H_5)_2NCS_2\}_3ClO_4$ was prepared as described previously [5]. The C, H and N analyses of the complexes were performed using a Heraeus CHN-O-RAPID analyser.

Preparation of $[Te^{IV}\{S_2CN(C_2H_5)_2\}_3]_2[Te^{II}\{S_2CN(C_2H_5)_2\}_2](PF_6)_2$ (**1**)

$Te\{(C_2H_5)_2NCS_2\}_3ClO_4$ (0.134 g, 0.2 mmol) was dissolved in dichloromethane (10 cm^3). A methanol solution (10 cm^3) of KPF_6 (0.076 g, 0.4 mmol) was then added to it with stirring. The white precipitate of $KClO_4$ was filtered off and the clear solution kept aside for solvent evaporation at room temperature. The gummy residue obtained was recrystallized in 10:1 *v/v* mixture of dichloromethane–ethylacetate, which yields small brown crystals of **1** (yield 70%). Found: C, 25.9; H, 4.2; N, 6.1. Calc. for $C_{40}H_{80}N_8S_{16}P_2F_{12}Te_3$: C, 25.9; H, 4.3; N, 6.0%.

Preparation of $[Te^{IV}\{S_2CN(C_2H_5)_2\}_3][Te^{II}\{S_2CN(C_2H_5)_2\}_2](ClO_4)$ (**2**)

Tellurium dioxide (0.040 g, 0.25 mmol) was dissolved in 1M NaOH (10 cm^3) in a beaker. This solution was then acidified by 4N perchloric acid (25 cm^3). To the clear solution, sodium diethyldithiocarbamate (0.281 g, 1.25 mmol) dissolved in water was added at room temperature with constant stirring. A red precipitate of **2** was formed and was filtered immediately. The precipitate was then air dried, dissolved in dichloromethane and washed thrice with 1N perchloric acid (10 cm^3). The clear red solution was then dried over anhydrous sodium sulphate to remove any moisture. The solvent was evaporated and the red residue washed repeatedly with CCl_4 (10 cm^3). Recrystallization in 10:1 *v/v* mixture of dichloromethane and ethylacetate yield dark black crystals of **2** (yield 60%). Found: C, 27.4; H, 4.7; N, 6.4. Calc. for $C_{25}H_{50}N_5S_{10}ClO_4Te_2$: C, 27.4; H, 4.6; N, 6.4%. The red gummy residue obtained along with it was identified as a mixture of $Te^{IV}\{S_2CN(C_2H_5)_2\}_4$ and $Te^{II}\{S_2CN(C_2H_5)_2\}_2$, formed as a result of hydrolysis of **2**. They were removed by a rapid washing with methanol. Small amounts of insoluble tellurium dioxide formed was discarded.

X-ray crystallography

The X-ray diffraction experiments were carried out at room temperature on automated Siemens P4 diffractometer (complex **1**) and Enraf-Nonius CAD4 (complex **2**) diffractometers with graphite monochromator. Cell constants and the orientation matrix for the data collection were obtained by least squares refinement of 25 carefully chosen high angle reflections. The crystal data and pertinent details of the experimental conditions are summarized in Table 1. The intensity data were collected by θ–2θ and ω–2θ scan modes, respectively, for **1** and **2**. Three standard reflections from different zones of the reciprocal space were measured periodically, with no significant variation in the intensity. Absorption correction based on ψ-scans was applied to the data of complex **1** ($T_{min} = 0.690$ and $T_{max} = 0.959$) while for data of complex **2** no corrections were employed.

The crystal structures were solved by direct methods (SHELXS-86) [13]. Their refinement were carried out by full-matrix least-squares method using SHELXL-93 [14]. The refinement calculations were based on F^2; the hydrogen atoms were introduced at calculated positions. In both the cases the refinements converged at a reasonably low *R*-value (Table 1), allowing a reliable description of the atomic parameters and of the intermolecular interactions involving tellurium and dithiocarbamate sulphurs. The weighting schemes employed during refinement were $w = 1/[\sigma^2|F_o| + (0.1517P)^2]$ and $1/[\sigma^2|F_o| + (0.0488P)^2 + 3.76P]$ where $P = [\max(F_o^2, 0) + 2|F_c|^2]/3$ for **1** and **2**, respectively. However some difficulties were encountered in the refinement procedure, similar to those typically observed in these types of compounds. The $(PF_6)^-$ anion of **1** was disordered and no correct model could be assigned for the disorder. All the fluorine atoms were refined isotropically and significant residual electron density was found around this anion, which does not in any way affect our observations in the positively charged tellurium complex. In **2**, the atoms N2, C7, C8, C9 and C10 of one of the dithiocarbamates was highly disordered, apart from the $(ClO_4)^-$ anion. No satisfactory model could be ascribed to the disorder and hence these atoms were refined isotropically. The highest residual electron density of 1.7 electrons per $Å^3$ in the final difference map is also around this disordered fragment with no apparent effect on the precise location of the other atoms.

The selected bond lengths and angles are given in Table 4. Complete sets of the atomic coordinates,

Abstract—Novel zinc(II) and cadmium(II) derivatives of 1-methyl- (L′) and 1-benzyl-imidazole (L″) of the type 1 : 1 $[(L)MX_2]$ (L = L″, M = Zn, X = 4-acetyl-1-phenyl-3-methylpyrazolonato (Q″), 4-benzoyl-1-phenyl-3-methylpyrazol-5-onato (Q′) or 4-benzoyl-1,3-dimethylpyrazol-5-onato (Q*); L = L″, M = Cd, X = Q′ or Q*), 2 : 1 $[(L)_2MX_2]\cdot y(H_2O)$ (L = L′, M = Zn, X = Cl, Br, I, CH_3CO_2, Q′, Q″ or Q*; L = L′, M = Cd, X = I, CH_3CO_2, Q′ or Q*; L = L″, M = Zn, X = Cl, Br, I; L = L″, M = Cd, X = I or Q″), 3 : 1 $[(L'')_3MX_2]\cdot y(H_2O)$ (M = Zn, X = CF_3CO_2, NO_3 or BF_4; M = Cd, X = NO_3), 4 : 1 $[(L')_4Zn]X_2\cdot y(H_2O)$ (X = NO_3 or BF_4), 5 : 1 $[(L')_5Zn]X_2\cdot y(H_2O)$ (X = ClO_4 or CF_3CO_2) 6 : 1 $[(L')_6Zn]X_2\cdot y(H_2O)$ (L = L′, M = Zn, X = CF_3SO_3; L = L′, M = Cd, X = NO_3, ClO_4 or BF_4; L = L″, M = Cd, X = ClO_4 or BF_4), 4 : 3 $[(L'')_4(CdX_2)_3]$ (X = Cl or Br) and finally 5 : 3 $[(L')_5(CdBr_2)_3]$ have been prepared and characterized by IR and far-IR data, conductivity, ^1H NMR and in some cases also with ^{113}Cd NMR spectroscopy. The 4,7-dimethyl-1,10-phenanthroline (Me_2Phen) and 2,2′-bipyridine (Bipy) displace all the 1-methylimidazole donors from $[(L')_5Zn](ClO_4)_2\cdot H_2O$ or $[(L')_6Cd(ClO_4)_2$ diethyl ether suspension, yielding the trischelate complexes $[(Me_2Phen)_3M](ClO_4)_2$ and $[(Bipy)_3M](ClO_4)_2$ (M = Zn or Cd). On the other hand, 2-benzoylpyridine (Bzpy) and 4,7-diphenyl-1,10-phenanthroline (Ph_2Phen) react with $[(L')_5Zn](ClO_4)_2\cdot H_2O$ yielding the mixed ligands complexes $[(Bzpy)_2(L')_2Zn](ClO_4)_2$ and $[(Ph_2Phen)_2(L')Zn](ClO_4)_2$ respectively. From the reaction of Ph_2Phen with $[(L')_6Cd(ClO_4)_2$ the ionic compound $[(Ph_2Phen)_3Cd](ClO_4)_2$ is obtained. The structure of $[(L'')_3Cd(NO_3)_2]$ was determined by X-ray single crystal diffraction: the Cd atom exhibited a distorted trigonal bipyramidal geometry, involving two O-monodentate nitrato groups in axial position and three 1-benzylimidazole ligand in the equatorial positions. ^{113}Cd NMR solution data carried out on selected soluble pyrazolonato, carboxylato and nitrato derivatives indicated five- or six-coordinate N_3CdO_2, N_4CdO_2, N_2CdO_4 and $NCdO_4$ species in solution.

Keywords: Zn(II) and Cd(II) complexes; imidazoles; phenanthroline; bipyridine; ^{113}Cd; crystal structure; pyrazolonate.

Imidazole is a molecule of considerable interest as versatile donor and potential fungicide [1] and also of great biochemical importance [2]: this five-membered nitrogen heterocycle in fact occurs in proteins as part of the side chain of the amino acid histidine [3], in nucleic acid structures as part of the purine moiety [4] of adenine and guanine, and in the vitamin B_{12} cohenzime as benzimidazole [5].

It has also been found that its conjugate base, the imidazolate ion (Im^-) acts as a bridging ligand between Cu(II) and Zn(II) centres in bovine heritrocyte superoxide dismutase (BESOD) [6].

Many studies have appeared in literature which describe the synthesis and characterization of imidazole-metal ion derivatives [7] as model compounds in order to obtain indirect knowledge of the nature of the interactions involved in a proposed enzyme-metal-ion-substrate complex, but generally the simple imidazole heterocycle has been employed.

L' L''

Fig. 1. Structure of the imidazole donors employed in this work.

We have recently started to investigate the behaviour of variously substituted monoalkyl- and monoaryl-imidazoles with Hg(II) [8], Au(I) [9], Cu(I) [10] and Sn(IV) [11].

The purpose of this paper is to extend the knowledge of the modes of action of N-substituted imidazoles towards zinc and cadmium acceptors. In fact the presence of different R groups at the 1-position of the imidazolic ring may affect the coordination properties of the pyridinic nitrogen atom through steric and electronic effects. Here we report the synthesis and spectroscopic characterization of new zinc(II) and cadmium(II) derivatives of 1-methyl- (L') and 1-benzyl-imidazole (L'') (Fig. 1), two heterocyclic donors with different basicities [12]. The factors affecting the stoichiometry and the coordination number are discussed and rationalized on the basis of steric and electronic arguments. The X-ray crystal structure of $[(L'')_3Cd(NO_3)_2]$ has also been determined and compared with other imidazole complexes.

EXPERIMENTAL

The samples for microanalysis were dried *in vacuo* to constant weight (20°C, ca 0.1 Torr). Elemental analyses (CHNS) were carried out in the house with a Carlo Erba model 1106 instrument. IR spectra were recorded from 4000 to 100 cm^{-1} and from 4000 to 600 cm^{-1} with a Perkin–Elmer instrument System 2000 FT-IR and a 1600 Series FT-IR instrument, respectively. ^1H- and ^{113}Cd NMR spectra were recorded on a VX-300 Varian spectrometer operating at room temperature (300 MHz for ^1H and 66.55 MHz for ^{113}Cd). Melting points were taken on an IA 8100 Electrothermal instrument. The electric resistance of solutions was measured with a Crison CDTM 522 conductometer at room temperature. The osmometric measurements were carried out at 37° over a range of concentrations with a Knauer KNA0280 vapour pressure osmometer calibrated with benzil. The solvent was Baker Analyzed Spectrophotometric grade chloroform or acetone. The results were reproducible to ±2%.

Reagents

Preparation of the proligands 4-acetyl- *and* 4-benzoyl-1-phenyl-3-methylpyrazol-5-onato (HQ' *and* HQ''), *and* 1,3-dimethyl-4-benzoylpyrazol-5-onato (HQ*). The proligands 4-acetyl- and 4-benzoyl-1-phenyl-3-methylpyrazol-5-onato and 1,3-dimethyl-4-benzoylpyrazol-5-onato (HQ', HQ'' and HQ*) were prepared according to Jensen's procedure [13]. Their analytical and spectroscopic data are in accordance with those reported in literature [13,14].

Preparation of bis(1-methylimidazole)dichlorozinc(II) **1**. Compound **1** precipitated out upon mixing $ZnCl_2$ (1.0 mmol, 0.136 g) in diethyl ether (20 ml) with 1-methylimidazole (L') (2.0 mmol, 0.164 g) in the same solvent (20 ml) and recrystallized from chloroform/ether. Compounds **2–5** and **21–24** were prepared similarly, while EtOH was used for compounds **7–9, 13–17, 26** and **30–34**.

The adducts **18** and **35** (50% aqueous cadmium fluoroborate was employed), **6** and **25** were prepared by addition of an ether suspension of the salt to a stirred ether solution of the ligand.

Preparation of [*bis*(1-methylimidazole)*bis*(1-phenyl-3-methyl-4-benzoylpyrazol-5-onato)zinc(II)] **10**. An ethanolic solution (60 cm^3) of the proligand HQ' (2.0 mmol, 0.556 g) was added to an ethanolic solution (30 cm^3) of zinc(II) acetate dihydrate (1.0 mmol, 0.219 g). A pale-rose precipitate was formed immediately. The reaction mixture was set aside overnight and the solid product was filtered off, washed with ethanol, recrystallized with chloroform/diethyl ether and shown to be complex $[(Q')_2Zn(H_2O)]$ by analysis and spectral data. Furthermore, $[(Q')_2Zn(H_2O)]$ (1.0 mmol, 0.638 g) was added to a diethyl ether solution (50 cm^3) of L' (2.0 mmol, 0.163 g). The reaction mixture slowly changed to a clear yellow solution. This was refluxed for 6 h, then the volume was reduced on the rotary evaporator until formation of a yellow powder, which was filtered off, washed with diethyl ether (ca 20 cm^3) and shown to be compound **10** by analysis. Compounds **11, 12** and **27–29** were obtained similarly. Compounds **19, 20** and **36–38** were obtained similarly using Cd(II) acetate dihydrate as starting material.

Preparation of [(1-methylimidazole)*bis*(4,7-diphenyl-1,10-phenanthroline)zinc(II)]diperchlorate **40**. [Pentakis(1-methylimidazole)Zn(II)(aquo)]diperchlorate (1.0 mmol, 0.690 g) was added to a 1 : 1 diethyl ether/ethanol solution (60 cm^3) of 4,7-diphenyl-1,10-phenanthroline (2.0 mmol, 0.664 g).

The suspension was set aside for about 3 h. The colorless precipitate formed was filtered off, washed with diethyl ether and shown to be compound **40** by analysis. Compounds **39** and **41–45** were obtained similarly.

CAUTION. The perchlorate derivatives reported in this paper may explode by shock or heating when dry. Small quantities (≤0.5 g) of the dry products should be handled.

Crystal structure determination of $[(L'')_3Cd(NO)_3)_2]$ **33**.

Crystals of **33** were grown from ethanol/diethyl ether solution. A colorless crystal with dimension $0.6 \times 0.3 \times 0.2$ mm was mounted on a glass fibre. Diffraction data were collected on an Enraf-Nonius CAD-4 diffractometer using Mo–K_α radiation. To record the intensities of reflections θ–2θ scan method were used. The crystallographic calculations were performed using the SHELXS-86 for structure solution [15] and SHELXL-93 for structure refinement [16]. The position of cadmium atom was found by Patterson method. Successive Fourier syntheses gave the coordinates of other atoms. The structure was anisotropically refined by full-matrix least-squares for all non-hydrogen atom to $R = 0.037$. The hydrogen atoms were refined isotropically. The crystallographic data are given in Table 1, selected bond lengths and angles are presented in Table 2.

RESULTS AND DISCUSSION

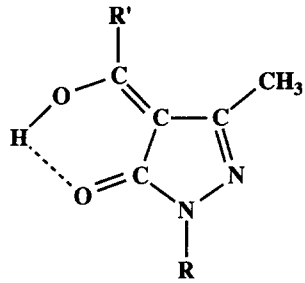
Synthesis of 4-acyl-5-pyrazolonato-metal precursors $[(Q)_2M(H_2O)_x]$ ($x = 1$ or 2)

The β-diketones 4-acyl-5-pyrazolone proligands HQ (Fig. 2) (HQ′ = 1-phenyl-3-methyl-4-benzoyl-pyrazol-5-one, HQ″ = 1-phenyl-3-methyl-4-acetyl-pyrazol-5-one, HQ* = 1,3-dimethyl-4-benzoyl-pyrazol-5-one) react in ethanol with $[(CH_3CO_2)_2M]\cdot 2H_2O$ (M = Zn or Cd), giving the compounds $[(Q)_2M\cdot(H_2O)_y]$ in accordance with the following eqn (1):

$$2HQ + [(CH_3CO_2)_2M]\cdot 2H_2O \xrightarrow{EtOH/H_2O} 2CH_3COOH + [(Q)_2M\cdot(H_2O)_y]$$

(M = Cd or Zn; HQ = HQ′, HQ″ or HQ*, $y = 1$ or 2) (1)

These bis(β-diketonato) complexes are air and solution stable, generally soluble in acetone, DMSO and in chlorinate solvents, insoluble in alcohol, water and



HQ': R = R' = Ph
HQ'': R = Ph, R' = Me
HQ*: R = Me, R' = Ph

Fig. 2. Structure of the proligands HQ', HQ'' and HQ*.

diethyl ether. According to literature [14a] and on the basis of spectral and analytical data [14b], the donors (Q) are coordinated to metal in the O_2-bidentate anionic form.

Synthesis of 1-methyl *and* 1-benzylimidazole *complexes*

1-Methylimidazole (L') and 1-benzylimidazole (L'') react in ethanol or diethyl ether solution/suspension with MX_2 acceptors (M = Zn, Cd; X = Cl, Br, I, NO_3, ClO_4, CF_3SO_3, BF_4, CH_3COO, CF_3COO, Q', Q'' or Q_M) affording the derivatives **1–38**:

$$nL + mMX_2(H_2O)_x \rightarrow (L)_n(MX_2)_m(H_2O)_x \quad (2)$$
$$\mathbf{1\text{–}38}$$

Some of the zinc(II) carboxylate, nitrate and perchlorate retain or absorb one or two water molecules. Derivatives **4, 5** and **6** are amorphous below 30°C and liquid up to 30°C, whereas all the other compounds are air stable microcrystalline solids with sharp melting points (Table 3). They are generally soluble in acetone and DMSO, insoluble in alcohols and diethyl ether. The derivatives of 1-methylimidazole show appreciable solubility also in chlorinated solvents.

The ligand/metal ratio $m:n$ has been found to vary in a wide range: 1 : 1 in the case of 4-acylpyrazolonato derivatives **27–29, 36** and **38** (Fig. 3a); 2 : 1 in the case of dihalide, *bis*(acetato) or *bis*(pyrazolonato) derivatives (Fig. 3b) **1–4, 10–12, 14, 15, 19–23, 32** and **37**; 3 : 1 in the case of nitrato, tetrafluoroborato e trifluoroacetato derivatives of L'' **24–26** and **33**; 4 : 1 in the case of $[(L')_4Zn(NO_3)_2]\cdot(H_2O)_2$ and $[(L')_4Zn(BF_4)_2]$ derivatives **6** and **8**; 5 : 1 in the case of derivatives $[(L')_5Zn](CF_3COO)_2\cdot(H_2O)$ **5** and $[(L')_5Zn](ClO_4)_2\cdot(H_2O)$ **9**; 6 : 1 in the case of derivatives **7, 16–18, 34** and **35**; finally from the reaction of dibromocadmium with L' and of dichloro- and dibromocadmium acceptors with L'' we have obtained poor soluble compounds with lower m/n ratio, i.e. 5 : 3 in **13** and 4 : 3 in **30** and **31**.

Several interesting trends emerge: in our conditions the dihalide give generally pseudotetrahedral 2 : 1 adducts. However, polynuclear 5 : 3 and 4 : 3 adducts were isolated when a sparingly soluble halo-bridged polymeric CdX_2 (X = Cl or Br) was employed as acceptor. 5 : 1 or 6 : 1 adducts are found only with good acceptors such as the perchlorate, tetrafluoroborate and trifluoroacetate and also with $Cd(NO_3)_2$, when the more basic and less hindered L' was employed as donor. No adduct has been isolated for zinc or cadmium cyanide, fluoride or cadmium sulphate, even when the reaction was performed under more forcing conditions, i.e. strong excess of the ligand and in refluxing solvents.

Reactivity of derivatives 1–3, 9, 14 *and* 17

The donor 4,7-dimethyl-1,10-phenanthroline and 2,2'-bipyridine react with compounds **9** and **17** yielding the *tris*-chelate complexes **39, 41, 44** and **45** upon complete displacement of the azole from the coordination sphere of the zinc, whereas the less basic 4,7-Ph_2-Phen and Bzpy displace respectively four and three molecules of the L' donor, yielding the mixed ligand derivatives $[(Ph_2Phen)_2(L')Zn](ClO_4)_2$ and $[(Bzpy)_2(L')_2Zn](ClO_4)_2$ **40** and **42** respectively. On the other hand 4,7-Ph_2-Phen and Bzpy are able to displace all the six molecules of L' from the adduct $[(L')_6Cd](ClO_4)_2$ **17**.

No reaction occurred in diethyl ether between the P-donors PR_3 (R = phenyl, benzyl or cyclohexyl) and the adducts **9** and **17**.

When the reaction between 4,7-Me_2-Phen, 4,7-Ph_2-Phen, Bipy or Bzpy and $[(L')_2ZnX_2]$ **(1–3)** or $[(L')_2CdI_2]$ **(14)** was carried out under the same conditions, the starting materials were always recovered.

Conductivity data

Conductivity measurements have been performed in dichloromethane or acetone solution for all the compounds **1–45** (Table 4).

Derivatives **1–5, 10–12, 15, 19, 20, 22, 27–29, 36–38** are non electrolytes. Derivatives **13, 14, 21, 23–25** and **30–32** for which a non-ionic structure has been observed in the solid state (see below the IR data section) show low conductance values in acetone, in accordance with ionic partial dissociation in this solvent. The dissociation seems to be dependent upon concentration of the solutions.

In the case of derivatives **6, 8, 9, 26** and **42,** which show conductance values typical of 1 : 1 electrolytes, an ionic structure in solution $[(L)_n(MX)_m(H_2O)]^+[X]^-$ can be hypothesized: on the basis of preliminar molecular weight determinations (r = ratio between experimental and theoretic molecular weight being in the range 0.50–0.70) carried out on selected derivatives we also suggest that these complexes undergo in solution ligand dissociation. The derivative

$[(L')_6Zn](CF_3SO_3)_2$ **7,** which is ionic in the solid state, shows a value typical of a 1 : 1 electrolyte: in this case partial dissociation of the 1-methylimidazole donors and coordination of one CF_3SO_3 group is likely. However, in the case of compounds **7, 8, 9, 40** and **42** which show in dichloromethane a conductance value typical of a 1 : 1 electrolyte, we cannot exclude in this solvent the possibility of ion-pairing effects which cause a much lower value of conductivity with respect to that observed in acetone for analogous compounds.

Finally, in the case of derivatives **17, 18, 34, 35, 39–41** and **43–45,** 2 : 1 ionic species can be postulated in solution, with both the counterions (BF_4^- or ClO_4^-) out of the inner coordination sphere of the metal.

^1H NMR data

The proton NMR spectra of derivatives **1–45** have been recorded in deuterated chloroform or acetone (Table 5). The choice of the solvent was dictated by the solubility of the compounds. The signals of the azole ring protons of L′ and L″ have been found shifted to lower field upon coordination. The same trend has been observed for the proton signals of the R groups bonded to pyrrolic nitrogen (R = Me or Bz). However, the deshielding observed is attenuated at a position remote from the metal. The Δ observed is likely due to a σ-charge donation from the N-donor to zinc(II) or cadmium(II) acceptor and is evidence of the existence of the complexes in solution.

Also if one would expect in many of these compounds the existence in solution of more than one isomer, or the presence of non identical ligands, in all the ^1H NMR spectra of **1–45** we found only one set of signals for each equivalent proton group. This is likely due to a rapid exchange between free and bound ligand or between different metal coordination sites. This rapid exchange is operating also at low temperature: in fact the spectra of derivatives **1, 4, 7, 10** and **16** remain unchanged also at −70°C.

In the case of derivatives **4, 10–12, 15, 19, 20, 27–29** and **36–38** the integration of the absorptions due to the acetato groups or the acylpyrazolonato ligands

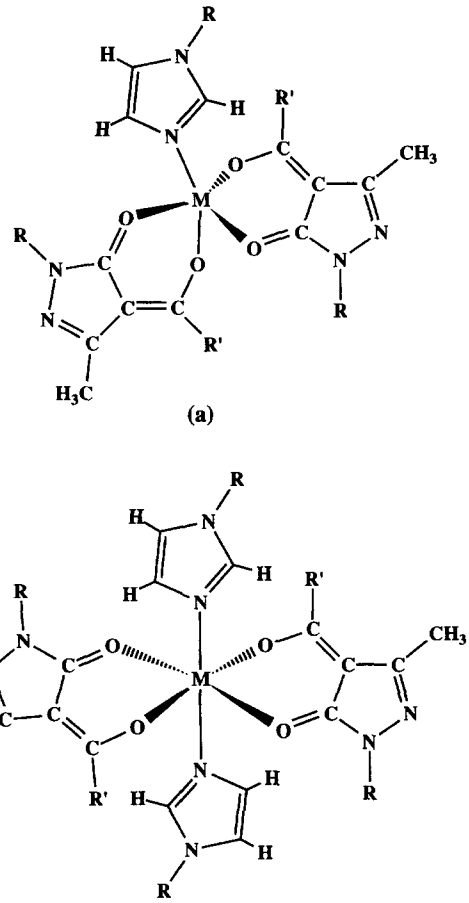

Fig. 3. Structures possible for the mixed ligand complexes 1 : 1 $[(L)M(Q)_2]$ and 2 : 1 $[(L)_2M(Q)_2]$.

and that of imidazoles is in accordance with the ligand/metal ratio *m*/*n* proposed in the empirical formula.

In the spectra of **39–45** all the expected signals of protons of bidentate and monodentate nitrogen donors have been detected. In the *tris*(chelate) derivatives the signals of the donor are generally downfield shifted upon coordination, whereas only a small displacement was observed in the mixed-ligand complexes.

^{113}*Cd NMR data*

We have carried out ^{113}Cd NMR spectra of deuterated acetone or chloroform solutions of several cadmium derivatives (Table 6). In the case of derivatives **15, 16, 19, 20, 33, 34** and **36–38** only a small resonance has been found in the range +59/+99 ppm, which is typical of five- or six-coordinate N_3CdO_2, N_4CdO_2, N_2CdO_4 and $NCdO_4$ species. Accordingly with the conductance value the derivative **16** likely possesses in solution an N_4CdO_2 core, differently from that observed in the solid state; it likely undergoes partial ligand L′ dissociation with consequent nitrato re-association. The presence in all the spectra of only a single absorbance is indicative of absence of isomers in solution or shows that a fluxional mechanism is operating at room temperature. It is well-known that ligands that bond to cadmium through oxygen cause increased shielding [17]. In fact the presence of only two oxygens bonded to cadmium in **15** and **16** is confirmed by their downfield shifted (+95.9 and +98.6 ppm, respectively) with respect to the other complexes containing four oxygens. In the case of derivatives **17** and **34** the absorption at ca +190/+200 ppm indicate a CdN_6 central core [18], as hypothesized also by conductance values. In the latter derivatives the cadmium nucleus is deshielded with respect to the former compounds due to the presence in the metal environment of only nitrogen atoms, poorer shielding donor than oxygens.

IR and far-IR data

Selected IR and far-IR data of derivatives **1–45** are reported in Table 7. The spectra are recorded in Nujol mull and some ones also in chloroform.

Besides the expected bands over 3000 cm^{-1}, due to ν(C—H) of the azoles, other absorptions in the range 1700–1500 cm^{-1} and below 600 cm^{-1} give additional information about the geometry of the derivatives.

In the case of di-halo-metal adducts **1–3, 14, 21–23** and **32** two M—N and two M—X stretching vibrations are expected to be IR active for pseudo-tetrahedral (C_{2v} symmetry) complexes. In our case, the assignments of the M-halogen symmetric and asymmetric stretching vibrations are unambiguous, well-distinguishable strong absorptions being present under 350 cm^{-1}, which are red-shifted on going from M—Cl (310–290 cm^{-1}) to M—Br (250–230 cm^{-1}) and to M—I (230–190 cm^{-1}) [19]. The medium absorptions in the range 230–250 cm^{-1} can be assigned to ν(M—N) stretching modes [19]: in the di-chloro- and di-iodo-zinc derivatives the ν(M—N) modes can be assigned without much ambiguity, but for the di-bromo-zinc derivatives they lie close to the ν(Zn—Br) region and coupling must be appreciable.

Derivatives **13, 30** and **31** likely possess a polynuclear nature, owing to their analytical formula and low solubility in all solvents. In fact the ν(M—X) vibrations are found at very low frequencies, in accordance with the presence of bridging metal-halogen bonds [20]. In these adducts the metal should be five- or six-coordinate, surrounded by four bridging halogens and one or two azoles.

Derivatives **7, 16–18, 34, 35, 39, 41** and **43–45** contain octahedral MN_6^{2+} ions. An ideally octahedral MN_6 species (O_h symmetry) should present only two asymmetric (M—N) modes (ν_3 and ν_4, whereas the symmetric ν_1 and ν_2 are Raman active) [20]. The existence of octahedral MN_6^{2+} species is supported by the

and ν_4) [22], which have been found in the solid state spectrum of **16** at ca 1390, 830 and 720 cm^{-1}, together with an unsplitted $(\nu_1+\nu_4)$ combination band at 1740 cm^{-1}, in accordance with an ionic formulation of nitrato groups [23].

The β-diketonato derivatives **10, 11, 12, 19, 20, 27–29** and **36–38** show the typical ν(C···O) absorption bands in the range 1550–1650 cm^{-1} [24]. It can be noted that the higher frequency band shifts the blue of 10–20 cm^{-1} with respect to that of $(Q)_2M\cdot(H_2O)$ reactants, due to the lengthening of the M—O bonds upon increasing of the coordination number. They generally show two or three ν(M—O) absorptions between 370–440 cm^{-1} and one or two strong bands in the range 180–220 cm^{-1} due to ν(M—N). In the case of six-coordinate derivatives a *trans*-N_2MO_4 geometry (D_{4h} symmetry) is likely, whereas for five coordinate NMO_4 derivatives we are not able to indicate the preferred geometry.

In the case of carboxylate derivatives it is generally accepted [25] that it is possible to distinguish between ionic, unidentate, chelating bidentate or bridging bidentate groups on the basis of Δ value [where $\Delta = \nu_a(COO)—\nu_s(COO)$]. The following trend should be found:

$$\Delta_{unidentate} > \Delta_{ionic} > \Delta_{bridging\ bidentate} > \Delta_{chelating\ bidentate}$$

where Δ_{ionic} is ca 160–170 for acetates and ca 220–230 for trifluoroacetates [25]. In our 1-substituted imidazole derivatives **4, 5, 15** and **24** we predict a unidentate coordinating behaviour of $RCOO^-$: $\Delta = 213$ in derivative **4**, in accordance with a pseudo-tetrahedral geometry and an N_2ZnO_2 central core. Compound **15** is likely to be pseudo-tetrahedral, notwithstanding $\Delta = 165$ likely due to the possibility of H-bonded water to uncoordinated carbonyl, which should lower the $\nu_a(COO)$ [25]. Besides two strong absorptions at ca 170–190 cm^{-1} caused to ν(M—N) modes, we have also found a new band at ca 280 cm^{-1} likely due to ν(M—O). In the spectra of trifluoroacetates **5** and **24** the Δ value are 273 and 248 respectively, in accordance with a unidentate formulation of these groups. The derivative **5** could be hepta-coordinated while derivative **24** probably possesses a five-coordinate geometry. The difference in stoichiometry can be ascribed to the higher steric hindrance of L'' with respect to L'. A similar difference can also be observed between the nitrates **6** and **24** and tetrafluoroborates **8** and **26**. The electron-withdrawing power of CF_3 should be responsible for the higher coordination numbers found in the trifluoroacetates with respect to acetates. In the spectra of **5** and **24** we have also found a strong absorption at ca 280 cm^{-1} due to ν(M—O). No differences have been observed in the solution (chloroform) spectra of **4** and **5**, the $\Delta = [\nu_a(COO)—\nu_s(COO)]$ values being 209 and 260 cm^{-1}, respectively.

The zinc-nitrate derivative **6** should possess in the solid state a tetragonally distorted trans-octahedral N_4ZnO_2 central core: in fact two ν(Zn—N) and one ν(Zn—O) [26] have been identified in the far region. The nitrate behaviour is not well identified, due to the presence in the solid and in solution spectra of several overlapped absorptions in the region 1100–1500 cm^{-1}.

We assign a six-coordinate geometry to derivative **8** in the solid state, with both BF_4^- groups unidentate: in fact ν_3 mode is split into two broad bands (1100 and 1024 cm^{-1}). We observed also two bands at 775 and 521 cm^{-1} due to ν_1 and ν_4 respectively [27]. Moreover, the absorptions at 250–270 cm^{-1} could be tentatively assigned to ν(Zn—F) modes. In chloroform solution the derivative **8** shows a conductance value typical of 1:1 ionic species (see Conductivity data section), but in the IR spectrum in chloroform solution it is not possible to distinguish between the unidentate and the ionic BF_4^- group [28].

Derivative **9** should have a six-coordinate N_5ZnO core, both in the solid and in the solution state, in fact the spectra recorded in Nujol and in chloroform are almost identical and show several absorptions due to perchlorate groups: that centered at 1070 cm^{-1} (ν_3 mode) present a splitting likely due to lowering of symmetry from T_d (ionic) to C_{3v} (unidentate), together with bands at 959 (ν_1 mode, IR-inactive for ionic ClO_4^-), 654 and 622 cm^{-1} (ν_5 and ν_3 modes, respectively) [21].

Derivatives **25** and **26** possess a five-coordinate geometry in the solid state with both the counterions unidentate; in the case of derivative **33** the X-ray crystal structure (see below) shows a trigonal bipyramidal (or seven-coordinated) environment of cadmium: the IR data are in accordance with this evidence, in particular the combination band $\nu_1+\nu_4$ is split (1760 and 1744 cm^{-1}) with $\Delta = 16$, typical of unidentate or strongly asymmetric bidentate nitrates (C_s symmetry) [22,23]. A very similar spectroscopic behaviour has been found in the IR spectrum of compound $[(L'')_3Zn(NO_3)_2]\cdot(H_2O)$ **25**. In the spectrum of compound **26** the ν_3 band of BF_4^- is split into three absorptions (1100, 1055 and 1015 cm^{-1}) as expected for unidentate groups [21].

Finally, derivatives **40** and **42** possess ZnN_5^{2+} and

Table 7. Selected IR data (4000–100 cm^{-1})[a] of the donors and their derivatives **1–45**

[a] Nujol mull. [b] Chloroform solution.

$O_2ZnN_4^{2+}$ cations, respectively, with ionic perchlorate groups [21].

Structure description of derivative **33**

According to the X-ray analysis the compound $[(L'')_3Cd(NO_3)_2]$ **33** (Fig. 4) has a molecular structure. The cadmium atom is coordinated by three monodentate 1-benzylimidazole molecules and two unsymmetrically bidentate nitrate-groups situated in *trans* position (O(1)—Cd—(O4) = 159.7°). Taking into account two shortest Cd—O bonds, the coordination polyhedron could be described in a first approximation as a strongly distorted trigonal bipyramid, with two oxygen atoms situated in apexes and three nitrogen atoms of imidazoles occupying equatorial positions. The average Cd—N (imidazole) distance is 2.25 Å that corresponds to those in cadmium *bis*(1-ethylimidazole)thiolate (2.28 Å, [29]) and in $\{\eta^3$-HB(3-Bu^t-5-Mepz)$_3\}$Cd(η^2-O_2NO) (2.24 Å, [30]). In the crystal structures of hexakis (1-methylimidazole)cadmium nitrate [31] and [*tris*(3,5-dimethypyrazol-1-ylmethyl)-amine]Cd(η^2-O_2NO)(η^1-ONO_2) [32] average Cd—N (imidazole) distances are longer (2.35 Å and 2.36 Å, respectively) due to larger coordination number (CN) of Cd (CN = 6 and 7 respectively). The larger contrast between the molecular structure of derivative **33** and that of analogous $Cd(py)_3(NO_3)_2$ (py = pyridine [33]) lies in the difference of Cd—O(NO_3) distances within the same nitrate group: in our compound the shorter Cd—O distances (2.45, 2.46 Å) are in good accordance with the four bond distances found in $Cd(py)_3(NO_3)_2$ [33] (2.44, 2.49 Å) where the nitrate group acts as symmetrically bidentate ligand. Whereas the longer Cd—O distances (2.70 Å (O2) and 2.67 Å (O5)) are of the same order of magnitude as the longer one found (2.885(4) Å) in the derivative [*tris*(3,5-dimethypyrazol-1-ylmethyl)-amine]Cd(η^2-O_2NO)(η^1-ONO_2) [32]. The additional weak coordination of both nitrate group produces a marked distortion from the regular trigonal bipyramidal geometry: the O1—Cd—O4 angle is decreased to 159.7° (instead of 180°) and the N7—Cd—N5 is increased to 147.2° (instead of 120°) due to the repulsion from additional atoms O2 and O5. The bidentate coordination of the nitrate groups results in a slight distortion of O—N—O angles (118.1, 120.1, 121.9 for one NO_3 and 119.1, 119.9, 120.9° for the other) to compare with bidentate nitrate in $Cd(py)_3(NO_3)_2$ [33] (115.5, 121.9, 122.6°).

Bond distance and angles for 1-benzylimidazole are substantially similar to the values found in several N-alkylsubstituted imidazole derivatives of group 8–14 metals [34].

CONCLUSION

The combined evidence from measurements carried out in solid state and in solution (IR, molecular weight determinations, conductivity, NMR spectra, X-ray crystal structure determination) gives here a picture which is different from that obtained when other acceptors were considered.

The 1-R-imidazole (R = methyl or benzyl) seems to be a very good donor: in the derivatives here described the ligand/metal ratio, frequently a measure of the donating ability, is generally higher than 1 with the exception of sterically hindered derivatives **27–29**. The ratio is also higher than 4 with good acceptors such as MX_2 where X is a good leaving group such as ClO_4^-, NO_3^-, BF_4^-, $CF_3SO_3^-$ and $CF_3CO_2^-$. We have found a marked difference between the behaviour of 1-methyl and 1-benzylimidazole: the donating ability can be easily correlated to basicity and steric hindrance of the heterocyclic ring: the 1-methylimidazole which is more basic and less sterically hindered than 1-benzylimidazole, is also the best donor ligand.

Polynuclear derivatives are also possible in the case of cadmium halide acceptors: this behaviour is analogous to that found in the poly(pyrazolyl)alkane chemistry [35].

The 1-R-imidazole can be completely displaced

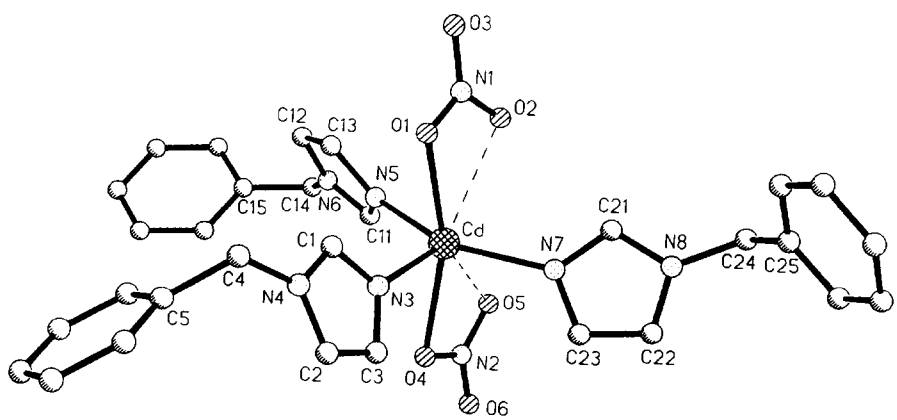

Fig. 4. Molecular structure of **33**, with H atoms omitted.

from the coordination environment of its zinc complexes only if very basic (such as 4,7-dimethylphenanthroline and 2,2′-bipyridil) chelating donors are employed (derivatives **39** and **41**). On the other hand when the less basic 2-benzoylpyridine and 4,7-diphenylphanthroline are used in the displacement reaction, mixed ligand complexes such as **40** and **42** are obtained.

Supplementary material— Tables of atomic coordinates and isotropic equivalent thermal parameters, tables of structure factors, a full list of bond lengths and angles, tables of anisotropic displacement parameters are available on request from one of the authors.

Kinetics and mechanism of hydrazine oxidation by a tri-bridged manganese(IV,IV) dimer in weakly acidic media

Anath Bandhu Mondal, Anup Kumar Bhattacharya, Dilip Maji and Rupendranath Banerjee*

Department of Chemistry, Jadavpur University, Calcutta-700 032, India

(Received 23 July 1997; accepted 29 October 1997)

Abstract—The complex ion $[Mn_2^{IV}(\mu\text{-}O)_2(\mu\text{-}MeCO_2)(bipy)_2(H_2O)_2]^{+3}$ $\{\mathbf{1}\}^{3+}$ (bipy = 2,2′-bipyridine) and its aqua derivatives, $[Mn_2(\mu\text{-}O)_2(bipy)_2(H_2O)_4]^{+4}$ $\{\mathbf{2}\}^{4+}$ and $[Mn_2(\mu\text{-}O)_2(\mu\text{-}MeCO_2)(bipy)(H_2O)_4]^{+3}$ $\{\mathbf{3}\}^{3+}$ coexists in rapid equilibria in aqueous buffers ($MeCO_2^-$ + bipy; pH, 4.5–5.5). The solutions are reasonably stable and react with hydrazine to produce manganese(II) and N_2. The reactions follow simple first-order kinetics in the presence of excess hydrazine. The rate determining steps are one-electron reductions of $\{\mathbf{2}\}^{4+}$ and $\{\mathbf{3}\}^{3+}$ to $\{\mathbf{2}\}^{3+}$ and $\{\mathbf{3}\}^{2+}$ respectively. The 1e-reduced products rapidly produce $[(bipy)_2Mn^{III}(\mu\text{-}O)_2\text{-}Mn^{IV}(bipy)_2]^{3+}$ in the presence of excess bipy and deficit hydrazine. Kinetic activity of $\{\mathbf{1}\}^{3+}$ is insignificant compared to $\{\mathbf{2}\}^{4+}$ and $\{\mathbf{3}\}^{3+}$. Rate of reduction increased with increase in the concentration of hydrazine and ethanoate, but it decreased with increase in [bipy]. Increase in rate at higher pH indicates inner-sphere coordination and deprotonation of $N_2H_5^+$. The mild oxidising character of $\{\mathbf{2}\}^{4+}$ and $\{\mathbf{3}\}^{3+}$ along with major structural changes associated with one-electron oxidation of hydrazine disfavours an outer-sphere pathway. © 1998 Elsevier Science Ltd. Keywords: manganese; hydrazine; binuclear complex; kinetics; redox.

A large number of multinuclear manganese complexes have been synthesised in the recent past [1]. They are well characterised and contain different types of ligands. These synthetic manganese complexes are quite attractive as biological models and as novel oxidants [2]. Their reactivity and kinetic studies, though limited in number, produced interesting results. The present kinetic investigation on the oxidation of hydrazine by the $[Mn_2^{IV}(\mu\text{-}O)_2(\mu\text{-}MeCO_2)(bipy)_2(H_2O)_2]^{+3}$ ion, [$\{\mathbf{1}\}^{3+}$; bipy = 2,2′-bipyridine] was initiated to further explore the reaction mechanism by which the multinuclear, high-valent manganese complexes are reduced. The dimanganese(IV,IV) complex, $\{\mathbf{1}\}(ClO_4)_3 \cdot H_2O$ is the first to include simultaneously a bridging ethanoate ligand, bis(μ-oxo) bridge and two water molecules, each coordinated to manganese(IV) ion [3]. Three of its structural features appear noteworthy: (1) a bending of the $Mn^{IV}(\mu\text{-}O)_2Mn^{IV}$ unit in the presence of ethanoate bridge, (2) elongation of the equatorial Mn—N bonds due to trans-influence of the bridging oxygen atom, and (3) presence of fully protonated water molecules in the coordination sphere of each manganese(IV). Features (1) and (2) significantly affects the solution chemistry of $\{\mathbf{1}\}^{3+}$. For example, the bridging ethanoate and one of the bipy ligands are labile and in solution $\{\mathbf{1}\}^{3+}$ coexists with its aqua derivatives. Spectrophotometric studies [4] indicated rapid solution equilibrium but no deprotonation of the coordinated water molecules at least up to pH 5.5. The rate-pH profile also suggested no kinetic contribution from any deprotonated $\{\mathbf{1}\}^{3+}$.

Though the facts are interesting, we could not so far ascertain whether the intimate mechanism of electron transfer is inner-sphere or outer-sphere. The present investigation attempts to explore this aspect.

EXPERIMENTAL

Materials

Hydrazinium nitrate was prepared by mixing dilute hydrazine hydrate (G.R., E. Merck) with dilute nitric

* Author to whom correspondence should be addressed.

acid in equivalent proportions. The resulting solution was standardised with KIO_3 in the presence of concentrated HCl [5]. Solutions of hydrazinium nitrate are stable [6] and did not loose in strength for at least a week at ~27°C. *p*-Dimethylamino benzaldehyde (G.R., E. Merck) was recrystallised from alcohol. All other materials including the complex $\{\mathbf{1}\}^{3+}$ and $[(bipy)_2Mn^{III}(\mu\text{-}O)_2Mn^{IV}(bipy)_2]^{+3}$ were described earlier [4,7b]. Doubly distilled water was used throughout.

Physical measurements and kinetics

Kinetics was determined spectrophotometrically at 420 nm [4b] in aqueous buffers (ethanoate + bipyridine; pH, 4.0–5.5) at $I = 1.0$ mol dm^{-3} ($NaNO_3$). Total concentration of 2,2′-bipyridine ($c_{bipy} = [bipy] + [Hbipy^+]$) and ethanoate ($c_{ea} = [MeCO_2^-] + [MeCO_2H]$) were in the ranges 5–35 and 5–20 mmol dm^{-3} respectively. Solution pH (Orion 710A pH meter), absorbance and electronic spectra (Shimadzu UV-1601 PC) were measured as stated earlier [4]. Pseudo first-order conditions were maintained with 20–50 times of hydrazine over total complex (0.1 mmol dm^{-3}). The first-order rate constant k_o was evaluated as usual from the least-squares slope of the ln $(A_t - A_\infty)$ vs time (t) data.

Stoichiometric measurements

Mixtures of hydrazine and the complex $\{\mathbf{1}\}^{3+}$ in different ratios (6.0–2.0) were allowed to react (pH, 4.0–5.5) until the solution turned colourless. Hydrazine content in the spent solution was estimated colorimetrically [8] at 458 nm, after developing a yellow colour with *p*-dimethylaminobenzaldehyde, dissolved in a mixture of ethanol and concentrated HCl. The final hydrazine concentrations used for calibration were $(2\text{–}85) \times 10^{-6}$ mol dm^{-3}. Gas evolved during the reaction was collected in a 5 ml microburette by downward displacement of water. The measured volume was corrected to NTP as usual. Stoichiometric measurements were carried out on a larger scale (total volume, 100 ml; complex, 1.0 mmol dm^{-3}) than used in kinetics. The very small volume of the gas evolved in the kinetic experiments had no effect on the absorbance, which did not change by time-to-time shaking of the spectrophotometer cell. Nessler's reagent [alkaline potassium iodomercurate(II)] was used to test qualitatively for ammonia. The test can detect 500 μg dm^{-3} of NH_3.

RESULTS AND DISCUSSION

Stoichiometry and reaction products

Measurements at different pH and different hydrazine : complex ratio yielded Δ[complex] : Δ[hydrazine] = 1.05 ± 0.1. Qualitative analysis of the reaction mixture for NH_3 gave negative results, though (0.98 ± 0.02) mole of a gas evolved per mole of the complex consumed. Hence, the most likely oxidation product of $N_2H_5^+$ is dinitrogen according to the stoichiometric eqn (1).

$$[Mn_2(\mu\text{-}O)_2(\mu\text{-}MeCO_2)(bipy)_2(H_2O)_2]^{3+} + N_2H_5^+ \rightarrow 2\,Mn^{II} + MeCO_2H + 2\,bipy + 4\,H_2O + N_2 \quad (1)$$

The reaction involves a net 4e-change and must be a multistep process. It is likely that all steps in (1) are 1e-changes and all manganese species except manganese(II) are binuclear in line with the evidences (a)–(c). (a) Electrochemical reduction of the (IV,IV) dimer $[Mn_2(\mu\text{-}O)_2(\mu\text{-}HPO_4)(bipy)_2(H_2PO_4)_2]$ yields the $Mn^{III}Mn^{IV}$ derivative, $[(bipy)_2Mn^{III}(\mu\text{-}O)_2Mn^{IV}(bipy)_2]^{+3}$. Electrochemical [9,10] and chemical [7] reduction of this and several other $Mn^{III}Mn^{IV}$ complexes with a $\{Mn_2O_2\}^{3+}$ core in turn, produce $(Mn^{III})_2$ dimer and then a mixture of Mn^{III} and Mn^{II} species. (b) Different oxidation-levels of the binuclear catalase enzyme models [11] preserve nuclearity. (c) The various oxidation levels (*S*-states) [12] of the manganese clusters in PS II [13] also apparently retain bond connectivity. (d) Manganese has a high tendency [14] for the generation and retention of the di(μ-oxo) bridged unit $\{Mn_2O_2\}^{n+}$.

In an attempt to detect any intermediate manganese complex, we mixed $\{\mathbf{1}\}^{3+}$ with less than stoichiometric amounts of hydrazine and recorded the spectra. Typically, with complex : hydrazine = 4 : 1; pH 4.5; c_{bipy}, 0.035 mol dm^{-3}; and $c_{ea} = 0.1$ mol dm^{-3}, we observed the growth and decay of a broad band at the longer wavelengths and a narrower band at 684 nm (Fig. 1). Both the bands are fingerprints [10c] for

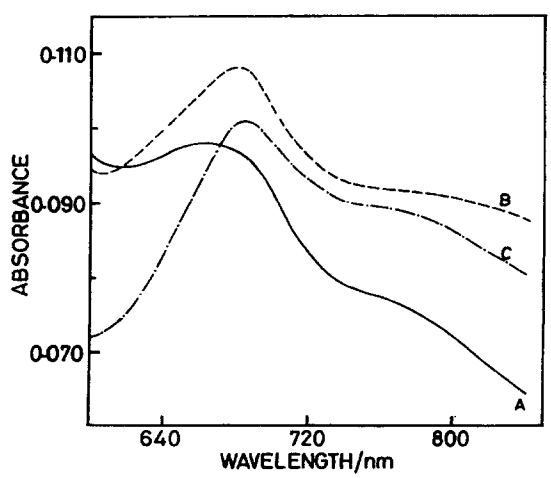

Fig. 1. (A): Spectra of 0.20 mmol dm^{-3} complex. Spectra of a mixture of (A) with hydrazine (4 : 1) after 2 min (B), and after 5 min (C) of mixing. (C) undergoes no further change with time. $c_{bipy} = 0.035$ mol dm^{-3}, $c_{ea} = 0.1$ mol dm^{-3}, pH = 4.50, $I = 1.0$ mol dm^{-3}, temp. = 25.0°C.

$[(bipy)_2Mn^{III}(\mu\text{-}O)_2Mn^{IV}(bipy)_2]^{3+}$, a complex which forms by 1e-reduction [4a] of $\{\mathbf{1}\}^{3+}$ by $S_2O_3^{2-}$ and in the electrochemical reduction [9] of $[Mn_2(\mu\text{-}O)_2(\mu\text{-}HPO_4)\text{-}(bipy)_2(H_2PO_4)_2]$. It appears very much likely that hydrazine also reduces complex $\{\mathbf{1}\}^{3+}$ by one-electron steps and that all the intermediates are binuclear.

Kinetics

At a fixed pH, c_{bipy} and c_{ea}, the first-order rate constant, k_o (Table 1) increases linearly with increase in hydrazine concentration. It also increases with increase in $[MeCO_2^-]$, but saturates at high $[MeCO_2^-]$ (>0.054 mol dm^{-3}) (Fig. 2A). Again at a fixed pH and c_{ea}, k_o decreased with increasing [bipy] and tends to a minimum value at high [bipy] (Fig. 2B). The results along with previous equilibrium studies [4a] indicate rapid ligand dissociation equilibria (2) and (3) and prominent kinetic activities for the hydrolytic derivatives $\{\mathbf{2}\}^{4+}$ and $\{\mathbf{3}\}^{3+}$.

$$[Mn_2(\mu\text{-}O)_2(\mu\text{-}MeCO_2)(bipy)_2(H_2O)_2]^{3+} \{\mathbf{1}\}^{3+} + 2H_2O \overset{K_{12}}{\rightleftharpoons} [Mn_2(\mu\text{-}O)_2(bipy)_2(H_2O)_4]^{4+} \{\mathbf{2}\}^{4+} + MeCO_2^- \quad (2)$$

$$\{\mathbf{1}\}^{3+} + 2H_2O \overset{K_{13}}{\rightleftharpoons} [Mn_2(\mu\text{-}O)_2(\mu\text{-}MeCO_2)(bipy)(H_2O)_4]^{3+} \{\mathbf{3}\}^{3+} + bipy \quad (3)$$

Increase in pH at fixed c_{bipy} and c_{ea} increases both [bipy] and $[MeCO_2^-]$. At $[MeCO_2^-] > 0.054$ mol dm^{-3} therefore one expects decrease in k_o with increasing pH provided only equilibria (2) and (3) are present. However, at all values of [bipy] and $[MeCO_2^-]$, k_o increases with increase in pH (Fig. 2C). It is necessary therefore that a deprotonation equilibrium involving either the reducing agent or the substrate complex

[a] Temp., 25.0°C; I, 1.0 mol dm^{-3}; [complex], 0.1 mmol dm^{-3}. The values were not affected significantly ($\leqslant 4\%$) by stray light, variation in complex concentration (0.05–0.3 mmol dm^{-3}) or when purified dinitrogen was passed through the solutions prior to kinetic measurements. Parenthetical values are k_o calculated using eqn (9).

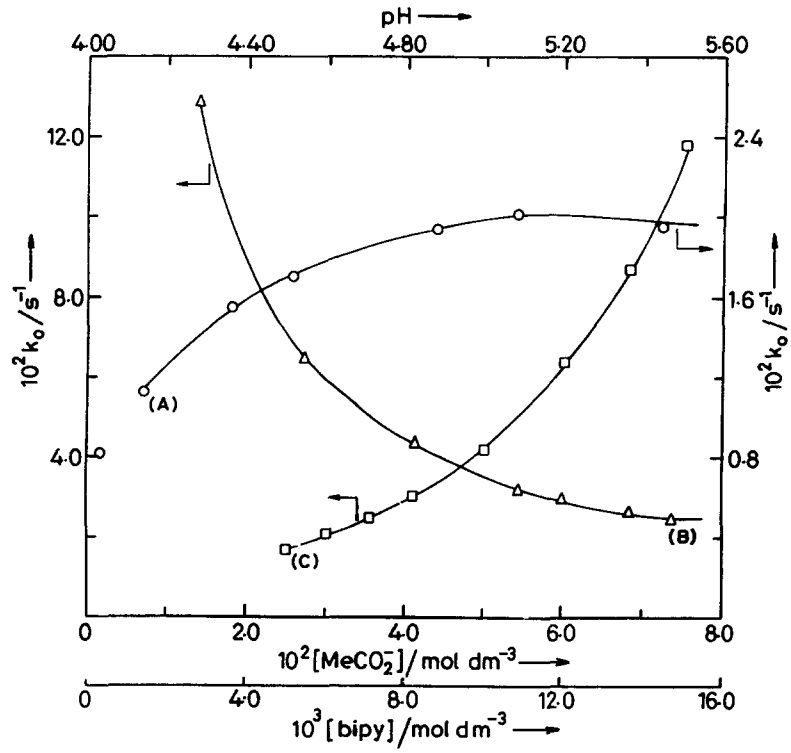

Fig. 2. Variation of k_o with $[MeCO_2^-]$ (A), [bipy] (B) and pH (C) at 25.0°C, I = 1.0 mol dm^{-3}. For (A): [bipy] = 0.0191 mol dm^{-3}, pH = 4.50. For (B): $[MeCO_2^-]$ = 0.073 mol dm^{-3}, pH = 4.50. For (C): c_{bipy} = 0.035 mol dm^{-3}, c_{ea} = 0.10 mol dm^{-3}.

must be considered in addition to equilibria (2) and (3). Previous equilibrium and kinetic studies [4] suggested inappreciable deprotonation of the oxidant. Hence deprotonation of the reducing agent seems logical. However, $N_2H_5^+$ is a weak acid (pK_a = 8.06) [15a] and, as such, an unlikely source for the observed proton dependence. We, therefore, presume that the deprotonation of $N_2H_5^+$ occurs after its coordination to a manganese(IV) centre (eqns (4) and (5)). A similar coordination of $N_2H_5^+$ to $[Mn(cydta)(H_2O)]^-$ (cydta is cyclohexyl-edta) and subsequent inner-sphere redox reaction is known [16]. Scheme 1 is therefore proposed.

The scheme presupposes a negligible kinetic activity for $\{\mathbf{1}\}^{3+}$ in line with our earlier kinetic observations. Analysis of observed dependence of k_o on different reagent concentrations supports this presumption (see later).

As discussed earlier, eqns (6) and (7) are likely to be multi-step, one-electron processes. Therefore, the immediate product of oxidation of N_2H_4 should be $N_2H_4^+$. This weak acid (pK_a = 7.1) [15b] is oxidized to N_2 via N_2H_2, detected [17] as an intermediate in the oxidation of $N_2H_5^+$ by $[IrCl_6]^{2-}$. The pathway for the conversion of N_2H_2 to N_2 is uncertain [18a] but in the present case the required oxidising equivalents are

$$\{\mathbf{2}\}^{4+} + N_2H_5^+ \overset{K_{2N}}{\rightleftharpoons} \underset{\mathbf{2N}}{[Mn_2(\mu\text{-}O)_2(bipy)_2(H_2O)_3(N_2H_4)]^{4+}} + H^+ + H_2O \quad (4)$$

$$\{\mathbf{3}\}^{3+} + N_2H_5^+ \overset{K_{3N}}{\rightleftharpoons} \underset{\mathbf{3N}}{[Mn_2(\mu\text{-}O)_2(\mu\text{-}MeCO_2)(bipy)(H_2O)_3(N_2H_4)]^{3+}} + H^+ + H_2O \quad (5)$$

$$\mathbf{2N} \overset{k_1}{\longrightarrow} \text{products } (Mn^{II}, N_2, \text{bipy}) \quad (6)$$

$$\mathbf{3N} \overset{k_2}{\longrightarrow} \text{products } (Mn^{II}, N_2, MeCO_2^-) \quad (7)$$

Scheme 1.

available from the high-valent manganese species. Dimerisation of N_2H_3 leads [18b] to NH_3, but this was absent in the present reactions. Presumably, $[N_2H_3]$ is very low and the rates of oxidation of $N_2H_4^+$ and its conjugate base N_2H_3 by the high-valent manganese species are very fast. Accumulation and dimerisation of N_2H_3 is thus disfavoured. The complex $[Mn_2(\mu\text{-}O)_2(\mu\text{-}HPO_4)(bipy)_2(H_2PO_4)_2]$ {**4**} is a close analogue of **3N**. Its electrochemical reactions [9] in phosphate buffer produces first the dimanganese(III,IV) complex $\{\mathbf{4}\}^-$. However, $\{\mathbf{4}\}^-$ is not stable and immediately changes to the dimer $[(bipy)_2Mn^{III}(\mu\text{-}O)_2\text{-}Mn^{IV}(bipy)_2]^{+3}$ $\{\mathbf{5}\}^{3+}$ (eqn (8)), which may undergo further reduction. We know that different reducing agents reduces $\{\mathbf{5}\}^{3+}$ to (Mn_2^{III}) and

$$\{\mathbf{4}\} + e \rightarrow \{\mathbf{4}\}^- \tag{8a}$$

$$\{\mathbf{4}\}^- + 2\,bipy + H^+ \rightarrow \{\mathbf{5}\}^{3+} + 3\,H_2PO_4^- \tag{8b}$$

subsequently to Mn^{II} under conditions similar to the present ones [7]. Equations (7a)–(7e) account for the reaction shown in eqn (7):

$$\mathbf{3N} \xrightarrow{k_3} \{\mathbf{3}\}^{2+} + N_2H_4 \tag{7a}$$

$$\{\mathbf{3}\}^{2+} + 3\,bipy \xrightarrow{fast} \{\mathbf{5}\}^{3+} \tag{7b}$$

$$\{\mathbf{5}\}^{3+} + R \xrightarrow{fast} (Mn_2^{III}) \tag{7c}$$

$$(Mn_2^{III}) + R \xrightarrow{fast} Mn^{II} + Mn^{III} \tag{7d}$$

$$Mn^{III} + R \xrightarrow{fast} Mn^{II} \tag{7e}$$

Here R represents a reducing equivalent, provided by $N_2H_5^+$ or any of its radicals.

A $[Mn^{III}Mn^{IV}(\mu\text{-}O)_2(\mu\text{-}MeCO_2)]^{2+}$ core analogous to that in $\{\mathbf{3}\}^{2+}$ has been isolated [19,20] and it is known that deaquation of $Mn^{III}Mn^{IV}$ dimers by bipy is fast in bipy-Hbipy$^+$ buffer [7b]. We also have verified that steps (7c) and (7d) are much faster compared to the step (7a). Pathways similar to (7a)–(7e) is expected for **2N** also.

Scheme 1 leads to eqn (9):

$$k_o = \left[\frac{k_1K_{2N}K_{12}[bipy]}{P[H^+]} + \frac{k_2K_{3N}K_{13}[MeCO_2^-]}{P[H^+]}\right] \tag{9}$$

The hydrazinium cation forms very weak complexes with metal ions and both K_{2N} and K_{3N} are likely to be very small. Therefore, from the known [4a] values of K_{12} $[(1.0\pm0.1)\times10^{-2}$ mol dm$^{-3}]$ and K_{13} $[(1.0\pm0.09)\times10^{-3}$ mol dm$^{-3}]$ one finds that under the experimental conditions,

$$P \approx [MeCO_2^-][bipy] + K_{12}[bipy] \tag{10}$$

Hence, eqn (9) transforms to (11):

$$(k_o\{[MeCO_2^-][bipy] + K_{12}[bipy]\}[H^+])/[N_2H_5^+] = k_1K_{2N}K_{12}[bipy] + k_2K_{3N}K_{13}[MeCO_2^-] \tag{11}$$

The known proton dissociation equilibrium constants for ethanoic acid ($K_{ea} = 1.8\times10^{-5}$) and Hbipy$^+$ ($K_{Hbipy} = 3.8\times10^{-5}$) give $[MeCO_2^-]$ and [bipy]:

$$[MeCO_2^-] = \frac{c_{ea}K_{ea}}{\{[H^+] + K_{ea}\}};$$

and

$$[bipy] = \frac{c_{bipy}K_{Hbipy}}{\{[H^+] + K_{Hbipy}\}}$$

Hence we get,

$$\frac{k_o(c_{ea}c_{bipy}K_{ea}K_{Hbipy} + K_{12}c_{bipy}K_{Hbipy}[H^+] + K_{12}c_{bipy}K_{Hbipy}K_{ea})[H^+]}{[N_2H_5^+]} = (k_1K_{2N}K_{12}K_{ea}c_{bipy}K_{Hbipy} + k_2K_{3N}K_{13}c_{ea}K_{ea}K_{Hbipy}) + (k_1K_{2N}K_{12}c_{bipy}K_{Hbipy} + k_2K_{3N}K_{13}c_{ea}K_{ea})[H^+] \tag{12}$$

Plots of left hand side of eqn (11) vs $[MeCO_2^-]$ at constant [bipy], and vs [bipy] at constant $[MeCO_2^-]$ were excellent straight lines. Their slopes yielded $k_1K_{2N} = (1.11\pm0.14)\times10^{-4}$ s^{-1} and $k_2K_{3N} = (6.33\pm0.23)\times10^{-3}$ s^{-1} at 25.0°C, $I = 1.0$ mol dm^{-3} using known K_{12} and K_{13} values. Excellent linear plots of left hand side of eqn (12) vs $[H^+]$ further supports the scheme. The k_1K_{2N} and k_2K_{3N} values can reproduce the k_o data within 5% (parenthetical values in Table 1). The agreement justifies exclusion of $\{\mathbf{1}\}^{3+}$ from the kinetic scheme, and the order of kinetic activity appears as: $\{\mathbf{1}\}^{3+} \ll \{\mathbf{2}\}^{4+} < \{\mathbf{3}\}^{3+}$. A similar order was observed earlier in the reactions of the complex $\{\mathbf{1}\}^{3+}$ with nitrite and thiosulphate and one finds that the rate of oxidation increases with increasing number of aqua ligands attached to a manganese centre. This trend is, however, not a speciality for the binuclear complexes, it is also well documented for higher valent mononuclear manganese complexes [21]. The probable reasons have been discussed earlier in details [4,7(a–c)].

The constants k_1K_{2N} and k_2K_{3N} should be replaced by k_1K_a and k_2K_a respectively, in case the reactions involve outer-sphere electron transfer with N_2H_4. Using the proton dissociation constant for $N_2H_5^+$, $K_a = 8.7\times10^{-9}$ mol dm^{-3} [15a], the outer-sphere rate constants are, $k_1 = 1.3\times10^4$ dm^3 mol^{-1} s^{-1} and $k_2 = 7.3\times10^5$ dm^3 mol^{-1} s^{-1}. Of these k_1 is comparable to the rate constant, 2.01×10^4 dm^3 mol^{-1} s^{-1} for the outer-sphere oxidation [22] of hydrazine by $[IrCl_6]^{2-}$ while k_2 exceeds it. The E° value for the $[IrCl_6]^{2-/3-}$ couple is 0.892 vs NHE [23]; its self exchange rate (2×10^5 dm^3 mol^{-1} s^{-1}) [24] is expected to

exceed those for the more rigid molecules, $\{2\}^{4+}$ and $\{3\}^{3+}$. Again, an estimated upper limit for the self-exchange rate constant for the $N_2H_4/N_2H_4^+$ couple is $k_{22} = 0.3$ mol^{-1} dm^3 s^{-1}. Its $E^\circ \sim (-0.73$ V). Assuming simple Marcus relation (13) for outer-sphere reactions, [25] and the same self exchange rates for $\{2\}^{4+}$, $\{3\}^{3+}$ and

$$k_{12} = (k_{11}k_{22}K_{12})^{1/2} \quad (13)$$

$[IrCl_6]^{2-}$, one can calculate a lower limit of E° for $\{2\}^{4+}$ and $\{3\}^{3+}$ as ~ 1 V. However, cyclic voltametry of $\{1\}^{3+}$ in CH_3CN shows an irreversible wave at 0.33 V vs SCE corresponding to the (IV,IV)/(III,III) reduction [3b]. Hence, the high E° value calculated from eqn (13) speaks against an outer-sphere mechanism. Stated simply, the low self-exchange rate of the $N_2H_4^+/N_2H_4$ couple and a moderately weak reducing character of $N_2H_5^+$ in weakly acidic solution disfavours outer-sphere reactions. In the present case, an additional barrier to outer-sphere reactions may be present. The highest occupied orbital of manganese ions in $\{2\}^{3+}$ and $\{3\}^{3+}$ is π^* but that in the reducing agent is σ. An outer-sphere electron transfer would thus be expected to be slow.

Synthesis of high surface area silica by solvent exchange in alkoxy derived silica gels

S. Rajesh Kumar, P. Krishna Pillai and K. G. K. Warrier*

Structural Ceramics Unit, Regional Research Laboratory (CSIR), Trivandrum—695019, India

(Received 25 August 1997; accepted 28 October 1997)

Abstract—Silica gels have been prepared by the hydrolysis of tetraethyl orthosilicate at pH 9.5 with a high water: TEOS ratio. The gels were exchanged with different solvents such as ethanol, methanol, isopropanol and acetone. The resultant gels were calcined at 500°C for 3 h at heating rate of 3°C min^{-1}. The surface area and total pore volume of the calcined gels measured using nitrogen adsorption show much dependence with the nature of the liquid used for the exchange. The gel washed with ethanol under the conditions of present investigation shows maximum surface area. The adsorption isotherm of this gel also shows the characteristics of Type IV behaviour. Other gels usually show Type II behaviour. Solvents of low vapour pressure and high molecular volume favour the formation of gels with high pore volume. The method of exchange of solvents also influences the characteristics of the final gel precursor in terms of surface area and pore volume. Repeated washing of the gels with solvents and subsequent removal result in high surface area, while evaporating the gels with solvents results in relatively less porous gels. © 1998 Elsevier Science Ltd. Keywords: solvent exchange; silica; surface area.

High purity silica is well known for a variety of industrial applications. It is used as catalytic supports, fillers, fused silicawares, optical glasses and waveguides [1]. Silica gels are also used as thermal and accoustic insulators. One of the methods for obtaining pure silica is by the controlled hydrolysis of silicon alkoxides [2–4]. Sol gel silica has been used as membranes, coatings and also to prepare low temperature glasses [5,6]. When the alcogels are dried at ambient pressures under moderate temperatures, xerogels are obtained. Supercritical conditions of drying result in aerogels which are characterised by low densities and extremely high porosities [7–8]. However, the porosities and other characteristics of the resultant silica gel depend primarily on the conditions of hydrolysis of the alkoxides, such as the nature of catalysts [9], the alkoxide/alcohol and alkoxide/water ratio [10], pH [9], presence of other solvents [11] and interaction with additives as well as gel modifiers [12]. Use of surfactant media involving inverse micelle and lamellar phase systems resulted in silica gels having cylindrical pores of controlled size [13]. Once a precursor gel having a desired structure is arrived at, the most important step for obtaining a porous ceramic is the removal of the solvent and volatiles. Usual drying methods lead to considerable shrinkage of the gel and this introduces stresses which result in the collapse of the gel structure. A gel having small pore radius containing solvent of high surface tension undergoes considerable shrinkage on drying. The capillary pressure exerted during drying by solvent evaporation is counteracted by the bulk modulus of gel which in turn is related to its skeletal strength. One of the solutions is to strengthen the gel walls or to allow the escape of the solvents with least disturbance which has been well achieved by drying under supercritical conditions [14]. However alternative simpler methods are being looked for in view of the expensive nature of this technique. Recently a few novel methods are reported to prepare aerogel like materials at ambient pressures. Smith *et al.* [15] achieved this by introducing hydrophobic groups in the gel network. Brinker *et al.* reported the silation technique by introduction of $Si(CH_3)_3$—O group in place of surface hydroxyl groups of the gel for preparing aerogel membranes [16]. Recently yet another simple method has been reported based on strengthening the gel structure by aging and using *n*-heptane as the liquid for drying [17].

* Author to whom correspondence should be addressed.

Therefore in the present investigation silica gels with identical skeletal strength are synthesised and have been exchanged with liquids of different chain lengths and molecular sizes and subsequently dried under identical conditions. The resultant gels are then calcined at 500°C and are characterised by specific surface area and pore volume data measured using BET nitrogen adsorption technique.

EXPERIMENTAL PROCEDURE

The gels were prepared by the hydrolysis of the tetraethyl orthosilicate (TEOS, Alfa chemicals, U.S.A., 99% purity). 15 ml of TEOS was mixed slowly with 60 ml of ethanol kept under stirring and this solution was added dropwise to 75 ml of double distilled water, pH being maintained at 9.5 by adding dilute ammonia [Qualigens, India]. The mixture was kept under stirring for 24 h. Further, this mixture was heated at refluxing conditions and then aged for 24 h before drying in an air oven at 50°C and designated as NS. To another batch of the above gel 20 ml ethanol was added, refluxed at 50°C for 3 h, cooled and the solvent was separated by filtration. The process was repeated 5 times. The gel was then dried in air oven at 50°C over a period of 3 h and designated as WE. The same procedure was adopted with other liquids such as methanol, isopropanol, acetone and are designated as WM, WI, WA respectively.

Another set of studies were done on similar precursor gel by adding 20 ml methanol and refluxing for 3 h at 50°C. The free methanol was evaporated by heating the gel at 50°C for 10 min. Such steps were repeated 5 times. The same procedure was also followed with isopropanol. The gels treated with methanol and isopropanol were designated as EM and EI respectively. All dried gels were calcined at 500°C for 3 h at heating rate of 3°C min^{-1}. The BET specific surface area and pore volume of the calcined gels were measured at liquid nitrogen temperature after degassing for 5 h at 200°C in flowing nitrogen in BET surface area analyser (Micromeritics, U.S.A., Model No. 2360). The dehydroxylation patterns of selected gel samples were studied using Schimadzu TGA 50H Thermogravimetric Analyser.

RESULTS AND DISCUSSION

In the present investigation, the silica gels were prepared under high water/alkoxide ratio in order to result in porous silica gels having high surface area. A high pH of 9.5 was maintained for the medium in order to achieve a gel with high permeability. The gels were also aged under refluxing conditions in order to enhance the skeletal strength. Since all the conditions of formation of the gels are kept constant, the gel structure is assumed to be similar. The dehydroxylation patterns presented in Fig. 1. indicate two steps of weight loss, one less than 100°C and the other at higher temperatures. The weight loss associated with the removal of free solvent as well as the dehydroxylation step of WM is found to be the least. In the dehydroxylation pattern of WE there are two distinct regions of weight loss. The treatment with solvents appears to effect the initial weight loss considerably. However, the second dehydroxylation step is more influenced only in the case of ethanol, the effective total loss increased considerably. This indicates that all the solvents are not influencing the gel structure.

The surface areas and pore volumes of the calcined gels are presented in Table 1. The surface area values of the gels treated with solvents and calcined follow the order WM < NS < WA < WI < WE. The pore volumes are in the order WM < WA < NS < WE < WI. On the other hand the surface areas of the evaporated samples are in general, much less than the corresponding washed samples. The surface area and pore volume values of both methanol washed and evaporated gels are much lower than others. In general WI and WE appear to be most promising in terms of specific surface area and also pore size distribution. The nitrogen adsorption isotherms of calcined gels are represented in Figs 2 and 3. The adsorption behaviour of the gels is highly influenced by the nature of the solvent used for exchange. However, the gels evaporated with solvents show considerable non porous behaviour.

Earlier studies [11] reported that the solvents present during hydrolysis of alkoxides have much importance on the final properties of the precursor gels especially on the surface area and pore volume. Effect of diols, drying control chemical additives, long chain alcohols and branched alcohols were studied in detail [11–13]. Alcohols with long hydrocarbon chains having very low vapour pressure as solvent for the hydrolysis medium of alkoxides give gels with high surface area and porosity. In the present study, exchange of water and ethanol mixture from the gel skeleton by extraction with different liquids and subsequently using them as drying liquids give large specific surface area and porosity.

Figure 4 shows the relation between the vapour pressure of the drying liquid and resultant properties such as surface area and pore volume of the calcined gels. Earlier studies show that as the vapour pressure of the liquid used in the hydrolysis of silicon alkoxides increases the surface area and pore volume of the resultant gel decreases. In the present case out of the many solvents used, methanol having the higher vapour pressure probably results in gels having least porosity. Acetone, with vapour presssure higher than methanol results in gel having higher surface area and pore volume than methanol counterpart. Probably factors other than vapour pressure of the drying liquid also influence these properties. Figure 5 relates the surface area and pore volume values of the calcined gel with the relative dielectric constants of the liquids

with which the gels were washed. Dielectric constant is frequently used as a measure of the reactions involving solvents, and it is accepted that ions are present more stably in a solvent having a higher dielectric constant [11]. Therefore with increase in relative dielectric constant of the drying liquids the surface area and pore volume values of the resultant gel decrease. This trend is followed generally in the present case with exception to ethanol. Figure 6 relates the surface area and pore volume values of the calcined gels with molecular volumes of the liquids used. Alcohols of long hydrocarbon chains are indicated to result in high surface area and pore volume in precursor gels. Generaly a similar trend is followed in the present case also. Acetone is an exception and might be due to its high vapour pressure.

The shrinkage in the gel is related much on the surface tension of the drying liquid as evidenced from the equation: $P_c = -2\gamma_{LV}/(r_p - t)$ [17] where P_c is the capillary pressure which causes the shrinkage. γ_{LV} = surface tension of the pore liquid, r_p = pore radius and t = thickness of the adsorbed layer. Here in the present work, the gels were prepared at identical conditions and hence we can take all the parameters constants except γ_{LV} for all the gels. The surface tension values of the drying liquids are in the order: isopropanol < ethanol < acetone < methanol. The pore volume values of the resultant gels are just in the reverse order i.e. as the surface tension of the pore liquid increases shrinkage also increases and hence

lower pore volumes for the resultant gels. Surface area of the gels are also in the same order except in the case of ethanol. It appears therefore that solvents with low values of vapour pressure, surface tension, relative dielectric constant, and higher molecular volumes as the drying liquids favour high porosity in the resultant xerogels.

The surface area and pore volume of methanol washed gel are found to be much lower than even that of the parent gel NS. Methanol has high vapour pressure, high dielectric constant, high surface tension and low molecular volume and is indicated to produce gels of low surface area and pore volume. The surface tension of 50% methyl alcohol with water at 50°C (32.95 dynes cm^{-1}) is much higher than that of ethyl alcohol-water mixture. On washing and drying, methanol evaporates much faster leaving behind residual water in the gel structure, hence causes high shrinkage and collapse of the gel structure during drying. On the contrary ethanol and isopropanol form azeotropic mixtures with water and carry increasing quantity of water on drying.

The procedure adopted for exchange of liquids is also an important criterion which determines the final properties of the dried gel. The method based on repeated washing does not disturb the gel structure or skeletal strength appreciably and hence higher surface area and pore volume values result. On the other hand the evaporation with solvents weakens the gel structure. The process appears to be promising with isopropanol, which forms an azeotropic mixture with water.

The adsorption isotherms of the gels generally show Type II behaviour. However, the patterns differ much from the starting gel to that washed with different solvents. Gels washed repeatedly with acetone and methanol are fairly non porous in nature compared

to other gels as evidenced from the Fig. 2. The gel washed with ethanol shows higher adsorption at low relative pressures is more microporous than the other gels. At higher relative pressures the gel washed with isopropanol shows more adsorption. The starting gel with micropores might have changed to macropores due to washing with isopropanol is reflected in the lower surface area and higher pore volume than the one washed with ethanol. This can be attributed to the larger molecular volume of isopropanol than ethanol. The volume of nitrogen adsorbed by these two gels in the partial pressure range 0.4–0.8 is much higher than the other gels which shows the mesoporous nature of the gels. These two gels appear to possess a combination are having some characteristics of Type II and IV adsorption isotherms. Fig. 2 shows the adsorption isotherms of the gels evaporated with isopropanol and methanol. Both show non-porous nature.

CONCLUSION

The present investigation ascertains that the nature of pore liquid in precursor gels is one of the major factors which decides the pore structure during drying. Liquids of low surface tension, low vapour pressure, low dielectric constant and high molecular volume favour the production of gels having high surface area and pore volume. Out of the various solvents investigated for solvent exchange ethanol and isopropanol appear to be most interesting and this method is simple. The exchange of solvents by other methods such as evaporation after soaking the gel with solvents has not been effective. As a result of repeated exchange it has further been possible to convert micropore-rich precursor to one having mesopore structure. In any case, in order to obtain porous gel, the gel structure has to be strengthened prior to solvent exchange.

(Received 25 August 1997; accepted 28 October 1997)

Abstract—The new podand ligand S=P(pzpy)$_3$ [L^1; pzpy = 3-(2-pyridyl)-pyrazol-1-yl], containing three bidentate pyrazolyl-pyridine arms linked to an apical P=S group via the pyrazolyl N^1 atoms, was prepared and crystallographically characterised. Reaction with Cu(II) or Cu(I) resulted in complexes of the partially-hydrolysed ligand $[OSP(pzpy)_2]^-$ (L^2), containing two bidentate chelating arms linked by a thiophosphinate fragment. $[Cu_2(L^2)_2(\mu\text{-pzpy})_2]$ contains a planar dinuclear copper(II) core with two pyrazolate bridges linking the metal centres, and one L^2 ligand attached to each metal by one bidentate arm with the other arm pendant. In $[Cu_2(L^2)_2]$ each ligand L^2 acts as an *N,N*-donor to one metal ion and an *N,S*-donor to the other with a non-coordinated pyridyl group, such that each metal ion has an N_3S donor set; this complex is achiral with a "side-by-side" disposition of bridging ligands. For comparison purposes we also crystallographically characterised $[Cu_2(L^3)_2]$, where L^3 is $[O_2P(pzpy)_2]^-$, an analogue of L^2 but with a phosphinate rather than thiophosphinate group. This complex is a dinuclear double helicate in which each ligand acts as an *N,N*-bidentate chelate to each metal ion. Comparison of this with the structure of $[Cu_2(L^2)_2]$ shows that it is the involvement of the thiophosphinate S atom of L^2 in coordination that prevents helication from occurring. © 1998 Elsevier Science Ltd. Keywords: double helicates; copper; crystal structures; dinuclear complexes.

We have been interested in the preparation and coordination chemistry of new multidentate ligands which contain two or three chelating arms linked to a central spacer [1–7]. Some examples are in Scheme 1. The coordination behaviour of these ligands is characterised by a large degree of variability in the structures of their complexes, because the ligands generally have the ability to donate all of their chelating arms to one metal ion if it is large enough, or alternatively to act as a bridge between different metal ions in other cases. The former type of coordination behaviour is exemplified by the mononuclear lanthanide complexes of the podand $[HB(pzpy)_3]^-$ [pzpy denotes the fragment 3-(2-pyridyl)-pyrazol-1-yl] which we have studied in some detail [1,2]; the latter type of behaviour affords a variety of unusual structures such as tetranuclear [3] and trinuclear [4] complexes with $[HB(pzpy)_3]^-$, dinuclear double helicates with $[H_2B(pz\text{-}bpy)_2]^-$ [5], infinite one-dimensional helicates with $[O_2P(pzpy)_2]^-$ [6], and an octanuclear helical molecular ring with $[H_2B(pzpy)_2]^-$ [7].

In seeking to extend this type of chemistry we recently attempted to prepare the podand O=P(pzpy)$_3$, as a neutral analogue of the hexadentate podand $[HB(pzpy)_3]^-$ in which the three bidentate arms were linked by a P=O head-group rather than by a borohydride. However, this compound proved

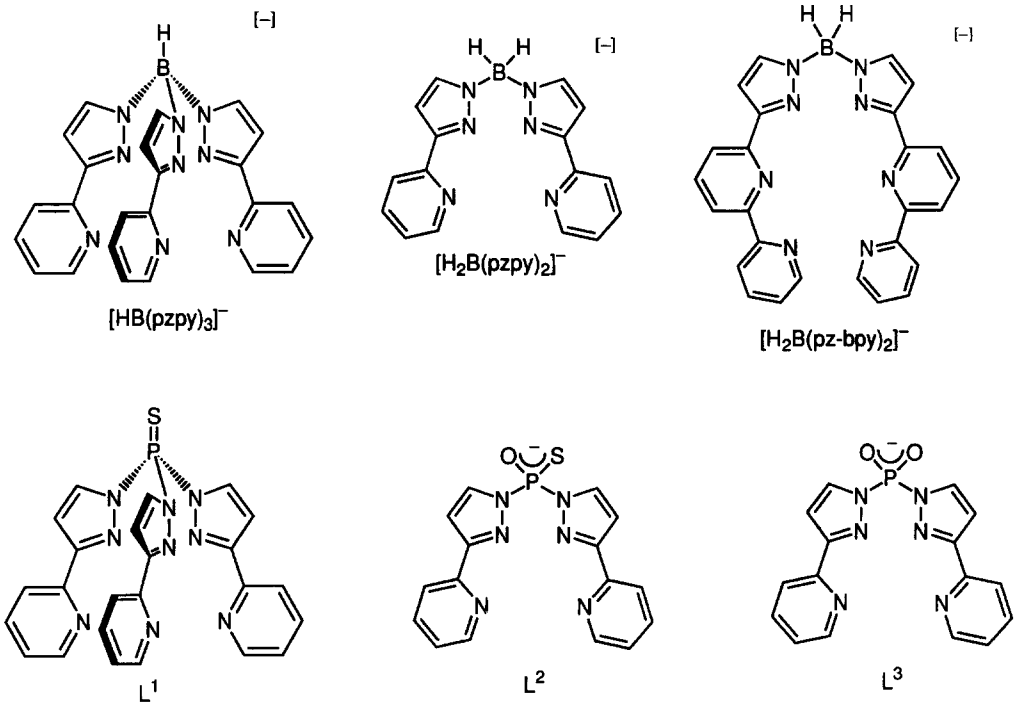

Scheme 1.

too reactive to isolate, giving instead the hydrolysis product $[O_2P(pzpy)_2]^-$ (hereafter L^3) whose coordination behaviour has been examined [6]. We have now prepared the related podand ligand $S{=}P(pzpy)_3$ (L^1), reasoning that replacement of the oxo-substituent by its less electronegative sulfur analogue might render the resulting ligand less susceptible to hydrolysis. In this we were partly correct, as L^1 has been successfully prepared and crystallographically characterised; however, attempts to prepare copper(I) and copper(II) complexes with L^1 have resulted in decomposition of the ligand to give complexes of $[OSP(pzpy)_2]^-$ (L^2), an analogue of L^3 but with one of the oxygen atoms of the phosphinate group replaced by sulfur to give a thiophosphinate. In this paper we describe the synthesis and characterisation of L^1, its reactions with Cu(II) and Cu(I) salts to give complexes of L^2, and a related double-helical Cu(I) complex of L^3.

EXPERIMENTAL

3-(2-Pyridyl)-pyrazole [8] and $[Cu(MeCN)_4][PF_6]$ [9] were prepared according to the published methods; other reagents were obtained commercially and used as received. Instrumentation used for routine spectroscopic analyses has been described previously [1].

Preparation of L^1

A mixture of 3-(2-pyridyl)pyrazole (2.90 g, 20 mmol) was suspended in a mixture of toluene (30 cm^3) and dry Et_3N (2.83 g, 28 mmol). This was cooled to 0°C, and a solution of $PSCl_3$ (0.83 g, 4.9 mmol) in toluene (5 cm^3) was added dropwise; the mixture was then heated to reflux for 18 h to give a clear solution. On cooling to room temperature, $Et_3N \cdot HCl$ separated and was filtered off to leave a clear yellow solution which was evaporated to dryness to give a waxy yellow solid. Trituration with MeCN gave white solid which was filtered off, washed with MeCN and then Et_2O, and dried *in vacuo*. Yield of L^1: 1.98 g (82%). Found: C, 58.0; H, 3.7; N, 25.3. Required for $C_{24}H_{18}N_9PS$: C, 58.2; H, 3.6; N, 25.5%. EI MS: $m/z = 495$ (M^+).

Reaction of L^1 *with copper(II) acetate hydrate*

To a blue-green solution of $[Cu(MeCO_2)_2 \cdot H_2O]$ (0.061 g, 0.31 mmol) in MeOH (10 cm^3) was added L^1 (0.153 g, 0.31 mmol) and the mixture was stirred at room temperature for 1 h. During this time the colour of the solution became dark green, and then a bright turquoise solid precipitated. This was filtered off, washed with MeOH and Et_2O, and dried *in vacuo*. Yield: 75 mg, 42%. Found: C, 48.7; H, 3.6; N, 20.5. Required for $[Cu_2(L^2)_2(\mu\text{-pzpy})_2] \cdot 2H_2O$: C, 48.6; H,

3.4; N, 21.2%. Recrystallisation from MeCN/ether gave X-ray quality crystals of $[Cu_2(L^2)_2(\mu\text{-pzpy})_2]$.

Reaction of L^1 *with* $[Cu(MeCN)_4][PF_6]$

To a solution of $[Cu(MeCN)_4][PF_6]$ (0.174 g, 0.47 mmol) in dry CH_2Cl_2 (10 cm^3) under N_2 was added L^1 (0.232 g, 0.47 mmol), resulting immediately in a bright orange solution which was stirred for 2 h at room temperature, during which time a yellow suspension formed. After addition of hexane (10 cm^3), the suspension was filtered under N_2, washed with a CH_2Cl_2/hexane mixture, and dried *in vacuo* to give $[Cu(L^1)][PF_6]$ in 65% yield. Found: C, 40.2; H, 2.7; N, 17.6. Required for $[Cu(L^1)][PF_6]$: C, 40.9; H, 2.6; N, 17.6%. Recrystallisation under N_2 by cooling a saturated MeCN solution afforded X-ray quality crystals of a decomposition product which proved to be $[Cu_2(L^2)_2]$ (see Results and Discussion section).

Preparation of $[Cu_2(L^3)_2]$

$[Et_3NH][L^3]$ (0.22 g, 0.50 mmol) and $[Cu(MeCN)_4][PF_6]$ (0.19 g, 0.50 mmol) were added to dry MeCN (10 cm^3) under N_2 with stirring. The solution turned orange, and on standing overnight (under N_2) small orange crystals grew. The orange product $[Cu_2(L^3)_2]$ was extremely air-sensitive, reacting rapidly to give a green tetranuclear Cu(II) complex of pzpy (arising from both oxidation of the metal and decomposition of the ligand) which has been previously characterized [10]. Consequently, an elemental analysis of $[Cu_2(L^3)_2]$ could not be obtained.

Crystal structure determinations

Suitable crystals were quickly transferred from the mother liquor to a stream of cold N_2 at $-100°C$ on a Siemens SMART diffractometer fitted with a CCD-type area detector. In all cases data were collected at $-100°C$ using graphite-monochromatised Mo–K_α radiation. A detailed experimental description of the methods used for data collection and integration using the SMART system has been published [1]. For triclinic crystals a full sphere of data was collected to allow a good absorption correction using SADABS; for all other crystal systems a hemisphere is sufficient. Table 1 contains a summary of the crystal parameters, data collection and refinement. In all cases the structures were solved by conventional heavy-atom or direct methods and refined by the full-matrix least-squares method on all F^2 data using the SHELXTL 5.03 package on a Silicon Graphics Indy computer [11]. Non-hydrogen atoms were refined with anisotropic thermal parameters; hydrogen atoms were included in calculated positions and refined with isotropic thermal parameters riding on those of the parent atom.

In all cases data were collected in the first instance to a 2θ limit of 55° (the default setting for our area detector). For the three copper complexes the data were in every case weak and for the final refinement were truncated at a 2θ value above which no significant diffracted intensity was observed. Including of data above this 2θ threshold in the refinement resulted in substantially poorer R indices with no noticeable improvement in the precision of the structures. In every case the data-to-parameter ratio is, however, reasonable.

Crystals of L^1 were stable and diffracted well, and the structural determination presented no problems. There is no imposed symmetry within the molecule.

In $[Cu_2(L^2)_2(\mu\text{-pzpy})_2]$ the crystals were well-formed and stable, but the weak high-angle data and modest level of refinement ($R_1 = 10.8\%$) is ascribable to the high degree of thermal motion of the non-coordinated pendant arm of L^2 which is not constrained by coordination to a metal ion. These atoms consequently have particularly high thermal parameters, but could not be separated into disordered components. The molecule is centrosymmetric, with half of it constituting an asymmetric unit.

Crystals of $[Cu_2(L^2)_2]\cdot 6$ MeCN were rather small and lost solvent rapidly on removal from the mother liquor, resulting in partial decomposition in the few seconds it took to coat the crystals in paraffin oil and transfer them to the cold stream of N_2 on the diffractometer; consequently the data were weak. The complex lies astride an inversion centre, so the asymmetric unit corresponds to $Cu(L^2)\cdot 3$ MeCN. One of the MeCN molecules is well-behaved. The other two are disordered over two positions by swivelling about the methyl carbon atoms, such that the methyl carbon atom is fixed in each case and the other C and N atoms are disordered over two sites with 50:50 site occupancies.

Crystals of $[Cu_2(L^3)_2]\cdot 3$MeCN were likewise small (that used had dimensions $0.20\times 0.10\times 0.05$; the larger ones were not single) and not only lost solvent rapidly but were unstable with respect to aerial oxidation. Again partial decomposition occurred during transfer to the diffractometer and the data were very weak. The complex lies astride a C_2 axis, which runs through the two independent Cu atoms and which therefore have 50% site occupancy. The asymmetric unit therefore corresponds to $Cu(L^1)\cdot 1.5$ MeCN, with one unique acetonitrile molecule and one across an inversion centre. The data was too weak to allow complete resolution of the disorder; the atoms of the solvent molecules were therefore modelled just as carbon atoms and hydrogen atoms were not included in the refinement. The space group $P2_12_12$ is very unusual and is non-centrosymmetric: spontaneous resolution of the helicates has therefore occurred on crystallisation. The absolute structure parameter was zero within experimental error, indicating that the optical configuration was chosen correctly.

RESULTS AND DISCUSSION

Synthesis and structure of L^1

Reaction of three equivalents of 3-(2-pyridyl) pyrazole (Hpzpy) with $PSCl_3$ in toluene/Et_3N, according to a published method for reaction of other pyrazoles with $PSCl_3$ [12], afforded L^1 in good yield. The crystal structure is shown in Fig. 1 and confirms the formulation. Each of the three bidentate pzpy arms has a *transoid* conformation to allow the nitrogen lone pairs to avoid each other. Two of the arms are directed away from the capping S atom towards the region of space where metal-ion binding would occur; the third arm is directed away from this area, presumably for steric reasons, by rotation about the P(1)—N(51) bond. The increased length of the P—N bonds (ca 1.70 Å) compared to the B—N bonds of the tris(pyrazolyl)borate analogue $[HB(pzpy)_3]^-$ (ca 1.53 Å) suggest that the cavity of L^1 would be slightly larger than that of $[HB(pzpy)_3]^-$ if it coordinated all of its donor arms to the same metal ion.

Reaction of L^1 *with* Cu(II) *and* Cu(I) *salts to give complexes of* L^2

Reaction of L^1 with copper(II) acetate dihydrate in methanol rapidly resulted in formation of a turquoise precipitate whose elemental analysis did not correspond to any obvious combination of metal, ligand (L^1) and counter-ion.

The crystal structure of the product is in Fig. 2, and showed it to be in fact $[Cu_2(L^2)_2(\mu\text{-pzpy})_2]$ (consistent with the elemental analysis) in which partial solvolysis of L^1 has occurred to give L^2, with two bidentate pzpy arms attached to a thiophosphinate head-group. This results in liberation of one equivalent of the bidentate ligand Hpzpy into the medium *per* molecule of L^2, and both L^2 and (deprotonated) pzpy are coordinated in the dinuclear Cu(II) complex. Each pzpy fragment bridges the two Cu(II) centres, with the bidentate chelating site (pyridyl N and pyrazolyl N^2 atoms) coordinated to one Cu(II) ion, and the pyrazolyl N^3 atom coordinated to the other. The result is a planar $\{Cu_2(\mu\text{-pzpy})_2\}$ fragment of the type we have previously seen in the grid-like tetranuclear Cu(II) complex $[Cu_4(pzpy)_6(dmf)_2]^{2+}$ [10]. Each ligand L^2 is terminally bound to one Cu(II) ion via one of the two chelating arms; the second arm is pendant with a *transoid* conformation of the heterocyclic rings to minimise the lone pair/lone pair repulsion. Each Cu(II) ion is formally five-coordinate in a square-pyramidal geometry, with the axial Cu(1)—N(21) bond [2.358(11) Å] being considerably longer than the four equatorial bonds which all lie in the range 1.96–2.05 Å. The sixth coordination site of each Cu(II) ion is involved in a weak pseudo-axial interaction to the oxygen atom of the thiophosphinate

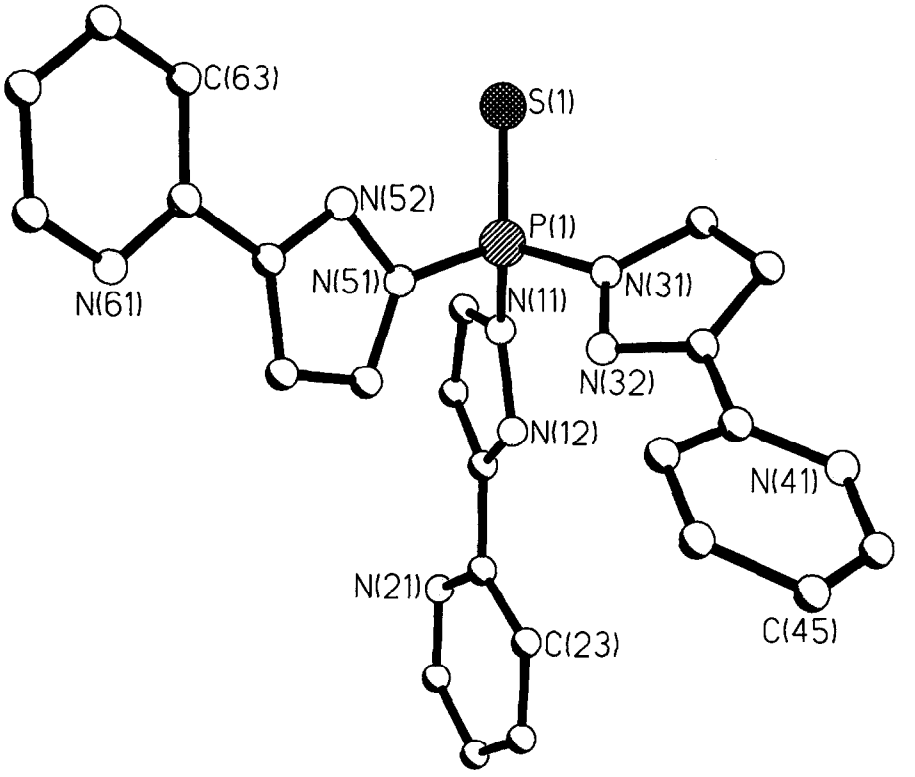

Fig. 1. Crystal structure of L^1.

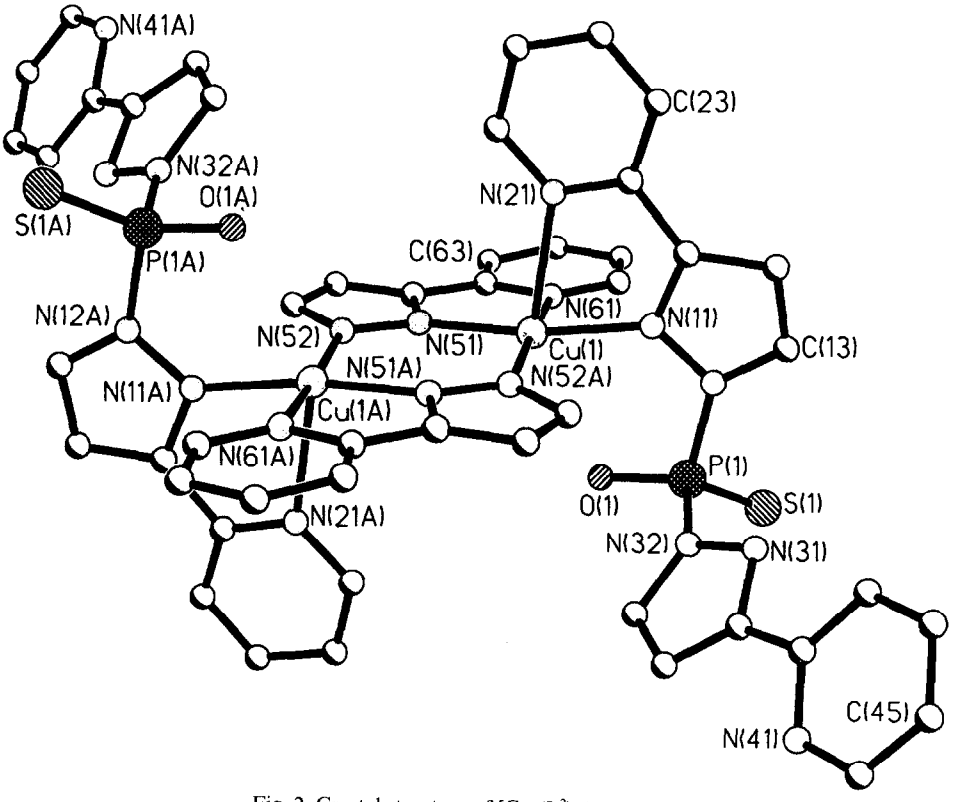

Fig. 2. Crystal structure of $[Cu_2(L^2)_2(\mu\text{-pzpy})_2]$.

group of L^2, with the Cu(1) $\cdots$ O(1) separation being 2.79 Å. Several other planar dinuclear Cu(II) complexes with pyrazolate bridges are known, and they invariably display strong antiferromagnetic exchange [13].

We thought that the hydrolysis of L^1 in the above reaction probably arose from the presence of water of crystallisation in copper(II) acetate. Accordingly we performed the reaction of L^1 with $[Cu(MeCN)_4][PF_6]$ in distilled acetonitrile under N_2. This afforded a yellow solid whose elemental analysis suggested the formulation $[Cu(L^1)][PF_6]$, i.e. a mononuclear complex of the intact ligand L^1. The IR spectrum contained the characteristic hexafluorophosphate bands. X-ray quality crystals were obtained by cooling a saturated MeCN solution of the crude material, still under N_2. In the IR spectrum of the crystals, however, the stretches due to the hexafluorophosphate ion were no longer present, and the structure (Fig. 3) shows again that partial decomposition of the ligand has occurred to give $[Cu_2(L^2)_2]$, despite the use of distilled solvents and an N_2 atmosphere for handling the material at all times.

In $[Cu_2(L^2)_2]$ both ligands are bridging both metal ions, in a centrosymmetric "face to face" (rather than helical) manner. Each ligand coordinates to one Cu ion as a bidentate *N,N*-donor chelate in the usual way via the pyrazolyl and pyridyl groups of one arm, but coordinates to the other Cu ion as an *S,N*-donor chelate via the thiophosphinate S and pyrazolyl groups. The pyridyl group of this ligand arm is therefore pendant, although the N atom is directed towards the Cu ion [non-bonded Cu(1) $\cdots$ N(21) separation, 3.29 Å] indicating a weak residual interaction. Each ligand therefore acts as an N_3S donor with one non-coordinating pyridyl group. The affinity of Cu(I) for thiolate and thioether donors is well known and therefore results in a somewhat unexpected binding mode for L^2 in this structure. The dihedral angle between the CuNN and CuNS planes of each chelating fragment is 83°, consistent with the common preference of Cu(I) for pseudo-tetrahedral geometry.

The double-stranded helicate $[Cu_2(L^3)_2]$

Given coordination of the S atom of L^2 in $[Cu_2(L^2)_2]$, we were interested to see what would happen if the S atom were replaced by an O atom (as in L^3), since the more electronegative O atom would be less likely to coordinate to the "soft" Cu(I) ions. The ligand L^3 is therefore more likely to coordinate solely via its N atoms in its Cu(I) complex, and we found recently that complexes of Ag(I) and Tl(I) with L^3 have unusual infinite one-dimensional helical structures [6].

Reaction of L^3 with $[Cu(MeCN)_4][PF_6]$ in distilled MeCN under N_2 afforded a yellow-orange material which was very air sensitive; exposure to air rapidly gave the green tetranuclear Cu(II) complex of pzpy [10], following hydrolysis of L^3 and oxidation of Cu(I) to Cu(II). This is in strong contrast to the Ag(I) complex with L^3 which is completely stable in air and actually crystallises with water molecules in the lattice [6]. Small crystals of the orange product could be isolated which were just suitable for X-ray diffraction studies, and the crystal structure (Fig. 4) shows the complex to be $[Cu_2(L^3)_2]$.

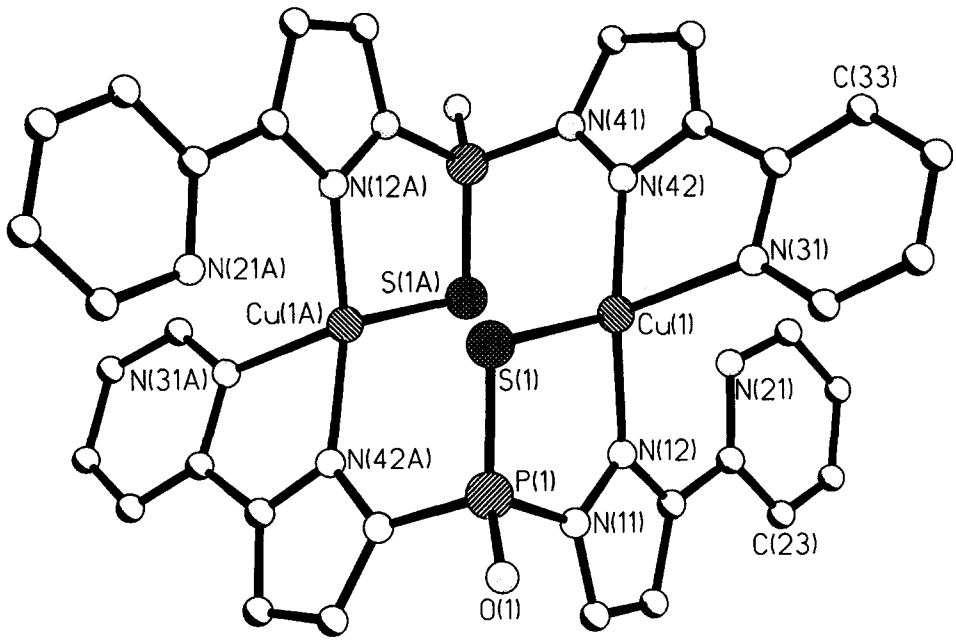

Fig. 3. Crystal structure of $[Cu_2(L^2)_2]$.

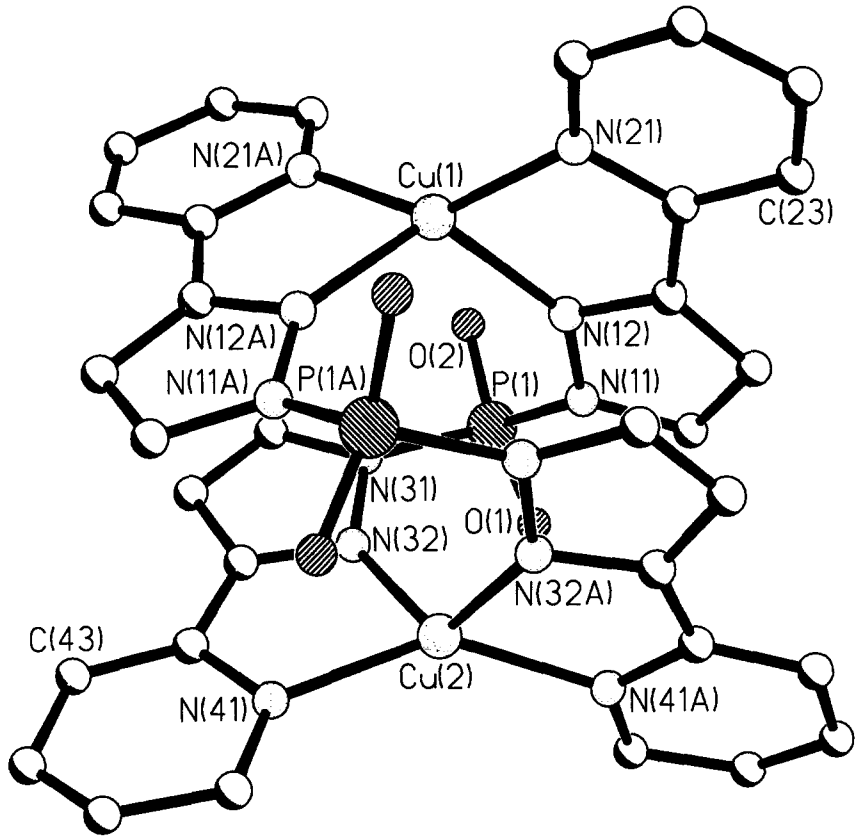

Fig. 4. Crystal structure of $[Cu_2(L^3)_2]$.

The structure is a double-stranded helix, with each Cu(I) ion coordinated by two *N,N*-bidentate chelating fragments, one from each ligand, and the phosphinate group not involved in coordination. As is normal in helicate structures there are π-stacking interactions between overlapping sections of the two ligands, and this is emphasised in Fig. 5; the mean-plane separations of the overlapping areas are in the range 3.2–3.5 Å. The two CuNN planes at each metal ion are approximately mutually perpendicular [79° at Cu(1) and 77° at Cu(2)], and the bond lengths and angles of the metal-ion coordination spheres are entirely typical of Cu(I) complexes with chelating diimine ligands [14]. The Cu(1)···Cu(2) separation is 4.63 Å. Constable and co-workers have prepared a variety of double-helical dinuclear copper(I) complexes with 2,2′:6′,2″:6″,2‴-quaterpyridine and various substituted derivatives in which they showed that the "pitch" of the helix and hence the metal–metal separation depended on the nature of the substituents on the ligand [15]. In the case of $[Cu_2(L^3)_2]$ the $\{PO_2\}^-$ spacer group separating the bidentate fragments results in a greater metal–metal separation than observed in the quaterpyridine complexes.

The structure of $[Cu_2(L^3)_2]$ is of interest not only in comparison to the related quaterpyridine helicates, but in relation to the non-helical, "side-by-side" structure of $[Cu_2(L^2)_2]$, in which the high affinity of the sulfur ligand for Cu(I) precludes a helical conformation. Figure 4 shows clearly that the helical ligand arrangement in $[Cu_2(L^3)_2]$ results in the phosphinate oxygen atoms being directed away from the metal ions and not participating in coordination. If $[Cu_2(L^2)_2]$ were helical it would therefore not be possible for the S atoms to coordinate. We also note that the chemical stability of $[Cu_2(L^2)_2]$ with respect to aerial oxidation, in marked contrast to $[Cu_2(L^3)_2]$, presumably arises from stabilisation of the Cu(I) state by coordination of the sulfur atom.

CONCLUSIONS

The desired podand ligand L^1 could be made easily in high yield and has been crystallographically characterised, but so far we have not been able to isolate complexes of the intact ligand. Reaction with Cu(I) and Cu(II) salts afforded in each case complexes of the thiophosphinate ligand L^2 on recrystallisation, arising from partial hydrolysis of the ligand. The Cu(II) complex $[Cu_2(L^2)_2(\mu\text{-pzpy})_2]$ has a planar dicopper(II) core with two bridging pyrazolate groups, and hypodenate L^2 ligands in which one bidentate arm is pendant. In the Cu(I) complex $[Cu_2(L^2)_2]$ each ligand

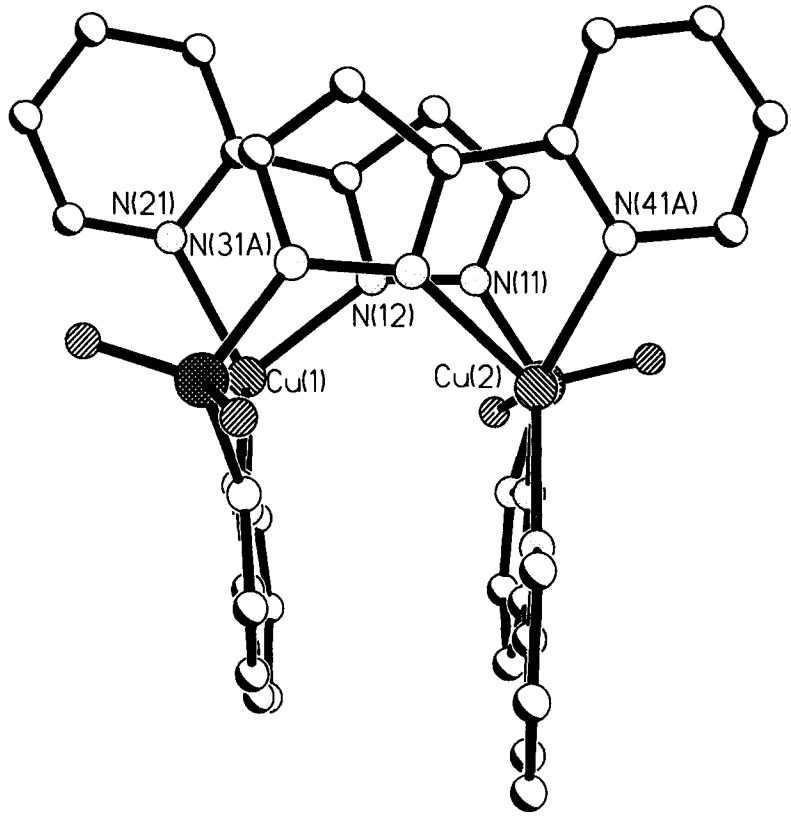

Fig. 5. Alternative view of the crystal structure of $[Cu_2(L^3)_2]$ emphasising the inter-ligand aromatic π-stacking.

L^2 is bridging in an asymmetric manner, acting as an *N,N*-donor to one metal and an *N,S*-donor to the other resulting in an achiral centrosymmetric structure. In contrast $[Cu_2(L^3)_2]$, in which the S atom of the thiophosphinate is replaced by an O atom which no longer coordinates to Cu(I), is a double-stranded helicate in which each ligand bridges symmetrically as an *N,N*-chelate to each metal ion.

(Received 21 July 1997; accepted 28 October 1997)

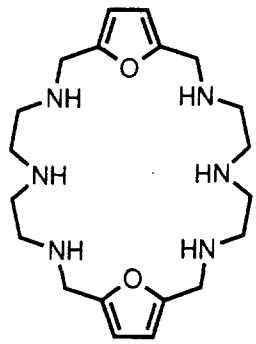
Abstract—The hexaaza macrocyclic ligand 3,6,9,17,20,23-hexaazatricyclo[23.3.1.1]triaconta-1(29),11(30),12,14,25,27-hexaene (L), forms strong dinuclear complexes, as well as several protonated and hydroxo chelates, with Cu(II) ions. The host–guest interactions between the dinuclear copper(II) complexes of L and malonate, maleate, fumarate, pyrophosphate and orthophosphate anions were investigated by potentiometric conventional pH-metry as well as by spectrophotometric titrations in 2 : 1 : 1 molar ratio for Cu(II), L and guest. Several ternary complexes are found in aqueous solution as a result of coordinate bonding, hydrogen bond formation and Columbic attraction between the host and guest. The stability constants for all the species found are reported. The dinuclear copper(II) complex of L shows stronger complexation with the maleate anion than with malonate and fumarate anions. It is suggested that the presence of the double bond in maleate offers a more favourable geometry for coordination to the Cu_2L host. Complexation with pyrophosphate and orthophosphate anions show little difference in stability. The big, flexible, pyrophosphate anion probably coordinates outside the macrocycle. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: host–guest; hexaaza macrocyclic ligand; dinuclear complexes.

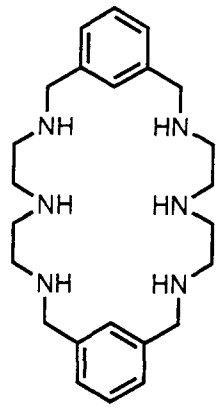
The chemistry of large polyazamacrocyclic ligands is of considerable interest since the addition to complexing cationic species [1–6], the dinuclear metal complexes are also capable of coordinating anions [7–10]. The study of macrocyclic ligands and their metal complexes can add to a better understanding of certain biological functions as well as to new catalysts of value in chemical synthesis. Recently Martell and coworkers have reported that the macrocyclic hexaamine ligand 3,6,9,16,19,22-hexaaza-27,28-dioxatricyclo[22.2.1.1] - octacosa - 1(26),11,13,24 - tetraene (BFBD, Formula I), is capable of forming mono- through hexaprotonated cationic species as well as both mono- and dinuclear Cu(II) complexes which in turn recognize oxalate, malonate and pyrophosphate anions. Crystal structures confirmed that the binding of anionic substrates to the protonated macrocyclic ligand BFBD is through electrostatic forces and hydrogen bonds [11].

For the ternary Cu(II) complexes it is described that the strength of the coordinate bonds and electrostatic attractive forces all contribute to their stabilities. The binding strength increases with the charge of both hosts and guests, as well as with the basicity of the donor groups of the guests. The ligand L (Formula

* Author to whom correspondence should be addressed.



Formula I. BFBD



Formula II. L

II), consisting of two diethylenetriamine units separated by m-xylyl bridges, is also capable of forming dinuclear metal complexes, whereby each metal ion is coordinated by three amino nitrogen atoms leaving additional coordination sites available. In aqueous solution these coordination sites could be occupied by H_2O, OH^- or anionic substrates [12].

In this paper we report the formation of dinuclear Cu(II) complexes with L as well as their interaction with malonate, maleate, fumarate, pyrophosphate and orthophosphate anions since only one account of additional substrate binding by these complexes has been described [13].

Potentiometric equilibrium methods and spectrophotometric data are employed to elucidate the nature of the ternary species formed in solution.

EXPERIMENTAL

Reagents

The ligand L was synthesized as described previously [14], but with some minor modifications and was separated as its hexahydrochloride salt ($L \cdot 6HCl.H_2O$). All other reagents were of analytical grade and used as received. Distilled and deionized water (Milli-Q quality, specific conductance < 0.05 $\mu S\ cm^{-1}$) was used throughout for all solutions.

Solutions

Carbonate-free sodium hydroxide solutions (ca 0.500 mol dm^{-3}) were prepared from Titrisol ampoules and were standardized by titration with HCl. The HCl solution was standardized by argentometry. The metal ion stock solution was prepared from metal perchlorate and was standardized by titration with the disodium salt of ethylenediaminetetraacetic acid (EDTA) in the presence of a small amount of the Hg (EDTA) complex using appropriate conditions and electrodes (mercury and calomel electrode) [15]. All final solutions for the potentiometric and spectrophotometric titrations were made up to an ionic strength of 0.1 mol dm^{-3} with sodium perchlorate.

Equipment

The potentiometric measurements were carried out with an automatic titration system, equipped with a Radiometer PHM84 pH meter and a Schott T-100 burette (total volume 5 cm^3). The pH meter was fitted with a Schott H2680 glass electrode and a Schott B3410 calomel electrode with a second salt bridge filled with 0.1 mol dm^{-3} NaCl. A Schott titration assembly was used with a thermostatted vessel (80 cm^3) and a magnetic stirrer. All titrations were performed at 25°C ± 0.1°C under an atmosphere of nitrogen, presaturated with water vapour by bubbling through a 0.1 mol dm^{-3} $NaClO_4$ solution. The program Titrate, slightly modified, was used to monitor the titration [16].

The electrode system was calibrated as a hydrogen ion concentration probe ($pH = -\log[H^+]$) by titrations of hydrochloric acid 40 cm^3 0.0359 mol dm^{-3}) with NaOH(aq). The concentration of HCl was determined by argentometry. The titration data were processed using Gran's method in order to calculate the standard cell potential (E°), the dissociation of water (K_w), together with the correction terms for changes in the liquid junction potential in strong acid medium, a_j ($-\log[H^+] < 2.5$), and for the non-linear electrode response in a strong alkaline medium, b_j ($-\log[H^+] > 11.5$) [17]. The pK_w value was found to be 13.78 in accord with literature values, $a_j = 420$ mV $dm^3\ mol^{-1}$ and $b_j = -90$ mV $dm^3\ mol^{-1}$ [18]. The electromotoric force readings were converted into pH values using eqn (1); pH values were obtained by successive approximations taking $[H^+]$ as zero at the start.

$$pH = (E^\circ - E + a_j[H^+] + b_j K_w[H^+]^{-1})/S \quad (1)$$

The value for the Nernst slope, S, was obtained as the slope of the plot pH_{calc} vs $E_{measured}$ for

$2.4 < pH_{calc} < 3.3$ and was 59.0 ± 0.05 mV. Calibration parameters remained fairly constant with time. Titrations were performed with 0.5302 mol dm^{-3} and with C_M to C_L to C_G ratios of 2 : 1 : 1, G being the guest ligand. Equilibrium times of up to 10 min were required.

The electronic absorption spectra were recorded at 25°C on a Hewlett Packard 8451A diode array spectrophotometer in the wave length region 190 to 820 nm. Spectra were obtained from titrations similar to those in the potentiometric experiments; for each titration point a small amount of the titration solution was injected into a cell of appropriate length and re-injected in the titration vessel after recording the spectrum [19].

Calculations

The calculations of the stability constants of the various species formed in aqueous solution were obtained from numerical analysis of all experimental emf data from the potentiometric titrations using Superquad [20,21]. Titration data were evaluated by testing chemically acceptable complexation models. The best models were selected after successive attempts according to the best agreement between observed and calculated data and by means of an accurate statistic analysis of the global σ-value for the refinement, and goodness of fit (χ^2) and the standard deviation of each formation constant as calculated by Superquad. In addition, the program Equil [22] was used to calculate simulated titration curves for each given set of species and stability constants, and to calculate the species distribution curves relative to total Cu^{2+} present. Due to data entry limitations of this program, no smooth curves were obtained for some complexes at pH ranges corresponding to inflection points.

The protonation as well as the complexation constants of the guest ligands with Cu^{2+} were used as found in the literature at 25°C and ionic strength 0.10 mol dm^{-3} [23].

RESULTS AND DISCUSSION

Protonation constants

The pH titration profile of the ligand has a 4 equivalent buffer region for pH 8–11 ($2 < a < 6$ with a being the number of moles base added to the total number of moles ligand), indicating the presence of four moderately to strong basic amino groups. These amino groups are the ones closest to the benzene ring and their basicities are little influenced by Coulombic effects. The remaining two amino groups have low basicity. It is clear that the central amino groups of the diethylenetriamine moieties in the macrocycle are involved here as their basicities will be strongly influenced by the Coulombic effects of two adjacent (positive) protonated amino groups. These observations are in agreement with the calculated protonation constants given in Table 1.

Copper(II) complexes

The ligand L forms both mononuclear (1 : 1) and binuclear (2 : 1) complexes [24]. The titration conditions were chosen in that way that only the Cu_2L complex was present as final complex.

This complex is formed maximally at pH 6. The calculated stability constants are presented in Table 2 together with values in the literature.

It can be seen that fairly close agreement is obtained for the stability constants of these species that are common to both studies. The small differences may result from the use of different supporting electrolytes.

The species distribution curves are presented in Fig. 1. It is seen that the mononuclear copper complex $CuLH_2$, appears only at low pH. In the region pH 4–7 the Cu_2L complex is dominant, while at higher pH the hydroxo species $Cu_2L(OH)$ and $Cu_2L(OH)_2$ are formed owing to the deprotonation of the water mol-

Table 1. Individual and cumulative protonation constants of the ligand L at 25°C and I = 0.10 mol dm^{-3} $NaClO_4$

Equilibrium[a]	log K
$L + H \Leftrightarrow HL$	9.57
$L + 2H \Leftrightarrow H_2L$	18.41
$L + 3H \Leftrightarrow H_3L$	26.49
$L + 4H \Leftrightarrow H_4L$	33.73

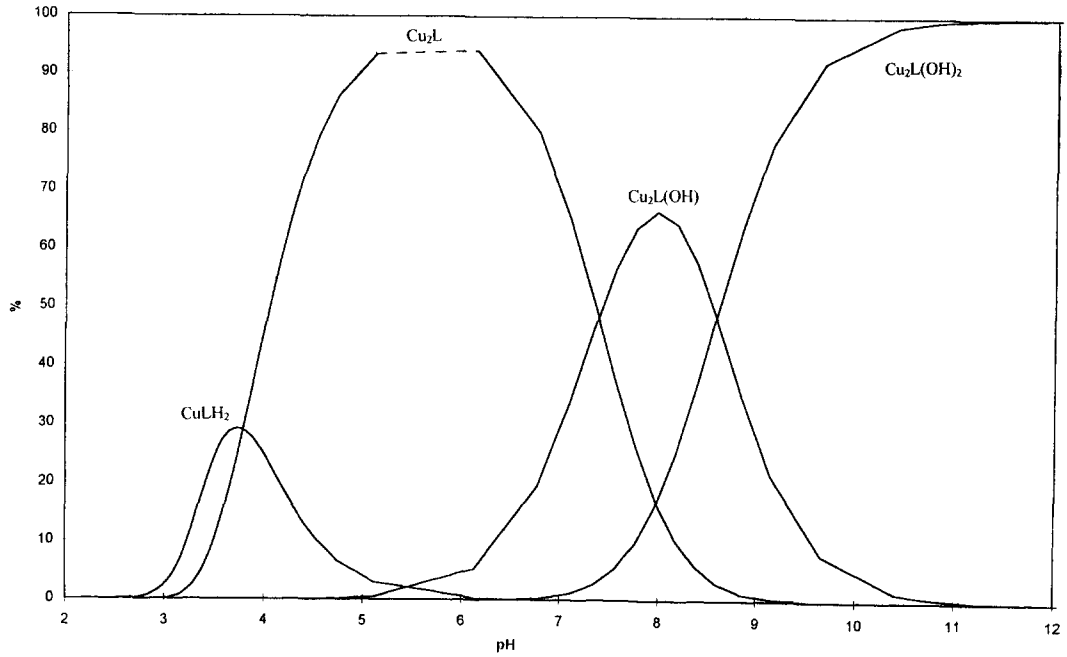

Fig. 1. Species distribution diagram showing the species formed as a function of pH when L and Cu(II) are equilibrated at 25°C and $I = 0.10$ mol dm^{-3} $NaClO_4$ in 1 : 2 molar ratio.

ecules which coordinate the Cu(II) centra in the Cu_2L complex.

The spectrophotometric titration up to $a = 6$ shows the formation of one chromophore with $\lambda_{max} = 645$ nm ($\nu_{d\text{-}d} = 15.530$ cm^{-1}). Beyond $a = 6$ the absorbance decreases while λ_{max} shifts to 630 nm ($\nu_{d\text{-}d} = 15.873$ cm^{-1}) as the $Cu_2L(OH)_2$ complex is formed as final species.

Binding of malonate anion by Cu(II) complexes of L

The titration curve shows two inflection points at $a = 8$ and $a = 10$ corresponding to the formation of Cu_2LMa and $Cu_2L(OH)_2$ complexes. Refinement of the model necessitated the introduction of $CuLMaH_2$ as additional complex. The stability constants obtained for the binding of the malonate anion to the dinuclear Cu(II) complexes are presented in Table 3. Calculated equilibrium constants for the equilibrium of malonate with the host complexes $CuLH_2$ and Cu_2L are also given. The dinuclear ternary complex Cu_2LMa is the most stable among these three species.

In the species distribution diagram (see Fig. 2) it is seen that the Cu_2LMa complex is formed up to 100% and that the mononuclear ternary complex $CuLMaH_2$, which appears only at low pH, only reaches 20% of total metal. Thus the guest complexes $CuLH_2$ and Cu_2L stabilize the malonate anion to the same extent as their individual procentual formation (see Fig. 1).

At the point of the mononuclear ternary complex

Table 3. Stability constants for the ternary complexes formed in the Cu(II)-L-malonate system ($I = 0.10$ mol dm^{-3} $NaClO_4$; 25°C)

Equilibrium[a]	log K
$Cu + L + Ma + 2H \Leftrightarrow CuLMaH_2$	35.13
$2Cu + L + Ma \Leftrightarrow Cu_2LMa$	29.94
$2Cu + L + Ma + OH \Leftrightarrow Cu_2LMa(OH)$	20.26
$CuLH_2 + Ma \Leftrightarrow CuLMaH_2$	5.59
$Cu_2L + Ma \Leftrightarrow Cu_2LMa$	5.77
$Cu_2L(OH) + Ma \Leftrightarrow Cu_2LMa(OH)$	3.47

[a] Charges are omitted for clarity.

$CuLMaH_2$, it is interesting to know where the two protons are located. In the species distribution diagrams (Fig. 1 and 2) it is found that the maximum of the $CuLH_2$ complex is reached at pH 3.6 which is just the same for the $CuLMaH_2$ complex. This indicates that the two protons must be on amino groups of the macrocycle L.

The malonate anion is then coordinated to Cu(II) at one side and hydrogen bonded to the protonated amino groups at the other side of the macrocycle. The suggested binding mode is shown in Chart 1 [25].

At higher pH the hydroxo species $Cu_2LMa(OH)$ is formed. Finally at sufficiently high pH the malonate anion is replaced by hydroxide ions and the $Cu_2L(OH)_2$ becomes the final complex.

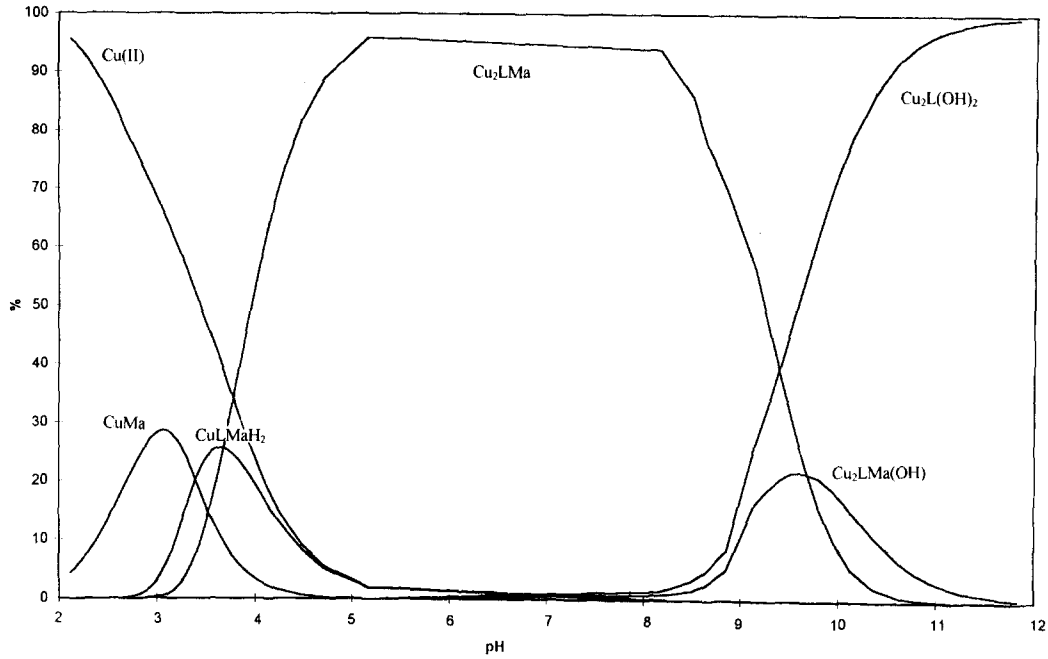

Fig. 2. Species distribution diagram showing the species formed as a function of pH when Cu(II), L and malonate are equilibrated at 25°C and $I = 0.10$ mol dm^{-3} $NaClO_4$ in 2 : 1 : 1 molar ratio.

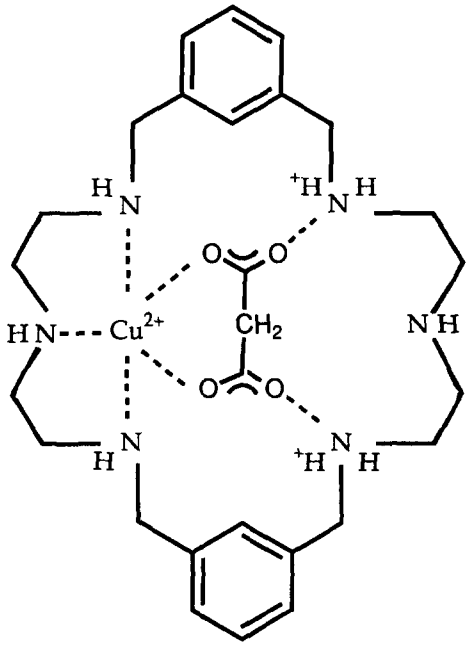

Chart 1. Possible binding mode in $CuLMaH_2$.

It is also noteworthy that at very low pH there is an appreciable interaction between the Cu(II) ion and malonate anion resulting in the CuMa complex. This is not surprising as malonate is a much weaker base than the ligand L.

The spectrophotometric titration shows the build-up of one chromophore to $a = 8$ with $\lambda_{max} = 662$ nm ($\nu_{d\text{-}d} = 15.106$ cm^{-1}) corresponding to the formation of the Cu_2LMa species. After $a = 8$ the absorbance drops and λ moves to lower wavelength. A new maximum is reached by $a = 10$ with $\lambda_{max} = 630$ nm ($\nu_{d\text{-}d} = 15.873$ cm^{-1}) proving that the $Cu_2L(OH)_2$ complex is the final complex.

Binding of maleate anion by Cu(II) complexes of L

The two inflection points in the titration curve correspond to the formation of the following complexes: Cu_2LMale ($a = 8$) and $Cu_2L(OH)_2$ ($a = 10$). Refinement of the model necessitated the introduction of $CuLMaleH_2$ as additional complex. The stability constants obtained for the 2 : 1 : 1 molar ratio of Cu(II) : L : Maleate system are presented in Table 4. These results show the formation of three ternary species in the region pH 2–12, which are the same for the previous system except that the equilibrium constants of this system for the host–guest complexation are higher than for malonate. The distribution diagram for the maleate ternary system (not shown) is similar to that for the malonate system. The following remarks are of interest: (i) the mononuclear ternary complex $CuLMaleH_2$ only appears at low pH and reaches up to 20% of total metal; (ii) the least important species are CuMale and Cu_2L indicating the larger affinity of the maleate anion for Cu(II) ions and its minor affinity for the Cu_2L-complex; (iii) the Cu_2LMale complex is the only important species in solution in the region pH

Table 4. Stability constants for the ternary complexes formed in the Cu(II)-L-maleate system ($I = 0.10$ mol dm^{-3} $NaClO_4$; 25°C)

Equilibrium[a]	log K
$Cu + L + Male + 2H \Leftrightarrow CuLMaleH_2$	38.41
$2Cu + L + Male \Leftrightarrow Cu_2LMale$	30.75
$2Cu + L + Male + OH \Leftrightarrow Cu_2LMale(OH)$	21.98
$CuLH_2 + Male \Leftrightarrow CuLMaleH_2$	8.87
$Cu_2L + Male \Leftrightarrow Cu_2LMale$	6.58
$Cu_2LMale(OH) + Male \Leftrightarrow Cu_2LMale(OH)$	5.19

[a] Charges are omitted for clarity.

5–8.5; (iv) at higher pH the monohydroxo complex $Cu_2LMale(OH)$ is formed, followed by the replacement of the maleate anion by a second hydroxide ion.

It is also interesting to note that this maleate anion forms more stable complexes with Cu_2L than the malonate anion does. This is probably due to the fact that the double bond in the maleate anion causes enhanced rigidity and that the geometry of the rigid anion is more favourable for complexation. In the spectrophotometric titration it is seen that the absorbance steadily rises up to $\lambda_{max} = 630$ nm ($\nu_{d\text{-}d} = 15.873$ cm^{-1}) corresponding to the formation of the Cu_2LMale complex. Then the absorbance drops and also λ_{max} moves up to lower values. A new maximum is reached with $\lambda_{max} = 615$ nm ($\nu_{d\text{-}d} = 1626$ cm^{-1}) probably corresponding to the formation of the $Cu_2L(OH)_2$ species.

Binding of fumarate anion by Cu(II) complexes of L

The pH profile of this system shows two inflection points corresponding to the Cu_2LFum ($a = 8$) and the $Cu_2L(OH)_2$ complex ($a = 10$). Refinement of the model necessitated the introduction of $CuLFumH_2$ as additional complex. The equilibrium constants obtained for the binding of the fumarate anion to the dinuclear Cu(II) complexes are listed in Table 5.

Table 5. Stability constants for the ternary complexes formed in the Cu(II)-L-fumarate system ($I = 0.10$ mol dm^{-3} $NaClO_4$; 25°C)

Equilibrium[a]	log K
$Cu + L + Fum + 2H \Leftrightarrow CuLFumH_2$	35.02
$2Cu + L + Fum \Leftrightarrow Cu_2LFum$	29.14
$2Cu + L + Fum + OH \Leftrightarrow Cu_2LFum(OH)$	18.84
$CuLH_2 + Fum \Leftrightarrow CuLFumH_2$	5.48
$Cu_2L + Fum \Leftrightarrow Cu_2LFum$	4.97
$Cu_2L(OH) + Fum \Leftrightarrow Cu_2LFum(OH)$	2.05

[a] Charges are omitted for clarity.

The species found are the same as the ones found with the malonate and the maleate anion but they are less stable. From Table 5 it is clear that fumarate stabilizes the mononuclear complex more than the dinuclear one. Moreover, comparison with corresponding data in Table 4 shows that the host–guest complexation is stronger with maleate than with fumarate. This observation must be related to the *cis*-position of the carboxylate group on the double bond in maleate, offering a more favourable orientation for interaction with both Cu^{2+} ions in the Cu_2L complex than the trans-orientation in fumarate. The malonate anion which has no double bond is very flexible and can arrange itself in a favourable conformation for coordination.

The distribution diagram for the fumarate ternary system (not shown) is similar to that for the malonate system. The following remarks are of interest: (i) the formation of the mononuclear ternary complex $CuLFumH_2$, reaches a maximum of 30% of total metal only at low pH; (ii) the amount of the Cu_2LFum species rapidly increases to 90% in the pH range 5–9.5; (iii) the monohydroxo complex $Cu_2LFum(OH)$ is formed at high pH while a second hydroxide ion replaces the fumarate anion at pH 10.5.

The spectrophotometric titration indicates the formation of one chromophore to $a = 8$ with $\lambda_{max} = 630$ nm ($\nu_{d\text{-}d} = 15.873$ cm^{-1}). This corresponds to the formation of the Cu_2LFum complex in the titration curve. Further titration causes a decrease in absorbance and λ. A new maximum is reached at $\lambda_{max} = 615$ nm ($\nu_{d\text{-}d} = 1626$ cm^{-1}) at $a = 10$ which corresponds to the $Cu_2L(OH)_2$ species formed at $a = 10$.

Binding of pyrophosphate anion by Cu(II) complexes of L

Table 6 gives the stability constants for the ternary complexes formed for the interactions of two equivalents of Cu(II) with L and the pyrophosphate anion. Six ternary complexes are formed of which two mononuclear and four dinuclear complexes. This greater number of complexes was expected considering the fact that pyrophosphate is a poly-acid. The formation of these ternary complexes can be understood as (i) host–guest interaction between the hosts $CuLH_2$, Cu_2L or $Cu_2L(OH)$ and pyrophosphate (H_2Py or Py) (see Table 6, equilibriums 8, 10 and 15), and (ii) protonation of these ternary complexes (Table 6, equilibriums 9, 11 and 12).

Firstly, the host–guest interactions in the former group of ternary complexes are based on electrostatic attraction since the stability constants of these complexes increase with increasing charges on both positive host and negative guest.

Secondly, if one compares the protonation constants of Cu_2LPy and of Cu_2LPyH (Table 6, equilibriums 11, and 12, respectively) with the first, respectively the second protonation constant of pyro-

Table 6. Stability constants for the ternary complexes formed in the Cu(II)-L-pyrophosphate system ($I = 0.10$ mol dm^{-3} $NaClO_4$; 25°C)

Equilibrium[a]		log K
$Cu + L + Py + 4H \Leftrightarrow CuLPyH_4$	(1)	50.64
$Cu + L + Py + 5H \Leftrightarrow CuLPyH_5$	(2)	53.25
$2Cu + L + Py \Leftrightarrow Cu_2LPy$	(3)	34.85
$2Cu + L + Py + H \Leftrightarrow Cu_2LPyH$	(4)	41.80
$2Cu + L + Py + 2H \Leftrightarrow Cu_2LPyH_2$	(5)	46.36
$2Cu + L + Py + OH \Leftrightarrow Cu_2LPy(OH)$	(6)	25.05
$2Cu + L + Py + 2OH \Leftrightarrow Cu_2LPy(OH)_2$	(7)	10.67
$CuLH_2 + H_2Py \Leftrightarrow CuLPyH_4$	(8)	6.56
$CuLPyH_4 + H \Leftrightarrow CuLPyH_5$	(9)	2.61
$Cu_2L + Py \Leftrightarrow Cu_2LPy$	(10)	10.68
$Cu_2LPy + H \Leftrightarrow Cu_2LPyH$	(11)	6.95
$Cu_2LPyH + H \Leftrightarrow Cu_2LPyH_2$	(12)	4.56
$Cu_2L + HPy \Leftrightarrow Cu_2LPyH$	(13)	9.16
$Cu_2L + H_2Py \Leftrightarrow Cu_2LPyH_2$	(14)	7.65
$Cu_2L(OH) + Py \Leftrightarrow Cu_2LPy(OH)$	(15)	8.26

[a] Charges are omitted for clarity.

phosphate ($\log K_1^H = 8.47$ and $\log K_2^H = 6.07$ for pyrophosphate) [26], a constant difference of -1.50 log K-units is found. It is likely that protonation takes place at the remaining free O^- sites of pyrophosphate since the Cu_2L^{4+}-unit in the ternary complex will lower the basicity of the bound pyrophosphate unit. On the other hand, the protonation constant for the formation of $CuLPyH_5$ (see Table 6, equilibrium 9) is 0.70 log units higher than the $\log K_3^H (= 1.92)$ of pyrophosphate. This indicates that the proton added is shared between an O^- site of pyrophosphate and an amino group of L.

Finally, the higher stability of Cu_2LPy relative to Cu_2LMa, Cu_2LMale and Cu_2LFum prevents the replacement of pyrophosphate by a hydroxide anion in alkaline medium.

The species distribution diagram depicted in Fig. 3 shows the presence of the Cu_2LPyH_2 complex at low pH. By increasing the pH, the Cu_2LPyH complex becomes the only important species in solution till pH 6.5. After that, the Cu_2LPy species becomes more important till pH 10 where the $Cu_2LPy(OH)$ complex becomes the only species in solution. In contrast with the previous observations, the pyrophosphate anion is not replaced by a hydroxide ion at high pH.

Chart 2 shows a possible coordination mode for Cu_2LPy.

The spectrophotometric titration shows a steadily rising absorbance with $\lambda_{max} = 666$ nm ($\nu_{d\text{-}d} = 15.015$ cm^{-1}) corresponding to the formation of the Cu_2LPyH complex in the titration curve. Between pH 6 and 8 the absorbance further increases with a new maximum at $\lambda_{max} = 680$ nm ($\nu_{d\text{-}d} = 14.706$ cm^{-1}). This is in accordance with the formation of the Cu_2LPy species.

Binding of orthophosphate anion by Cu(II) complexes of L

The pH profile of this titration shows an inflection point at $a = 8$ corresponding to the Cu_2LPH complex and a second inflection point at $a = 10$ which corresponds to the $Cu_2LP(OH)$ species. The stability constants for the system Cu(II) : L : Orthophosphate in 2 : 1 : 1 molar ratio are listed in Table 7. Five ternary species are formed of which one mononuclear and four dinuclear complexes. The distribution diagram for the orthophosphate ternary system (not shown) is similar to that for the pyrophosphate system. The following remarks are of interest: (i) the Cu_2LPH_2 complex is the only important species in solution in the low pH region; (ii) the only species found in the pH range 5–8 is Cu_2LPH; (iii) further increase of pH increases the share of the Cu_2LP complex till pH 9 whereafter the $Cu_2LP(OH)$ species becomes important.

The difference in stability values for the dinuclear species can again be explained in terms of electrostatic attractions. If the Cu_2LP, Cu_2LPH and Cu_2LPH_2 complexes are compared (Table 7, equilibriums 7, 10 and 11), it can be seen that the charge on the dinuclear complex remains the same but that the negative charge of the phosphate anion decreases with increasing protonation, thus lowering the electrostatic attraction between the reacting species. It is clear that addition of one proton to the Cu_2LP and Cu_2LPH species (Table 7, equilibriums 8 and 9) must necessarily decrease the strength of coordinate bonding and lead to a decrease in stability. The same explanation can be given for the comparison of Cu_2LP and $Cu_2LP(OH)$ species (Table 7, equilibriums 8 and 12).

A possible binding mode for Cu_2LP is shown in Chart 3.

It can be seen in spectrophotometric titration that the absorbance steadily rises up to $a = 8$ with $\lambda_{max} = 645$ nm ($\nu_{d\text{-}d} = 15.504$ cm^{-1}) corresponding the formation of the Cu_2LPH complex in the titration curve. After $a = 8$ the absorbance and λ_{max} drop to lower values. A new maximum is reached at $a = 10$ with $\lambda_{max} = 615$ nm ($\nu_{d\text{-}d} = 1626$ cm^{-1}) corresponding to the formation of the $Cu_2LP(OH)$ species.

CONCLUSION

Considering the host–guest systems Cu^{2+} : L : G in 2 : 1 : 1 molar ratio, it is noticed that both the $CuLH_2$ and Cu_2L species appear as host while G and protonated forms of G act as guest. The most important species is the dinuclear Cu_2LG complex (90%).

The binding with malonate, maleate and fumarate anions compared well but a preference for the maleate anion was observed. This was caused by the enhanced

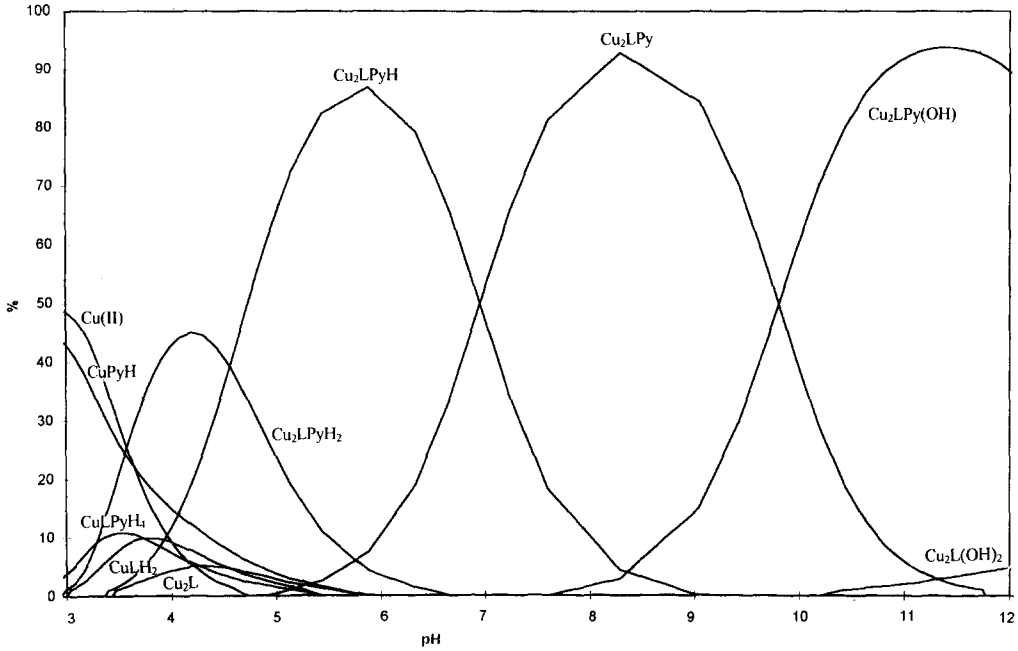

Fig. 3. Species distribution diagram showing the species formed as a function of pH when Cu(II), L and pyrophosphate are equilibrated at 25°C and $I = 0.10$ mol dm^{-3} $NaClO_4$ in 2 : 1 : 1 molar ratio. The $Cu_2LPy(OH)_2$ complex appears only for a little percentage and is not shown.

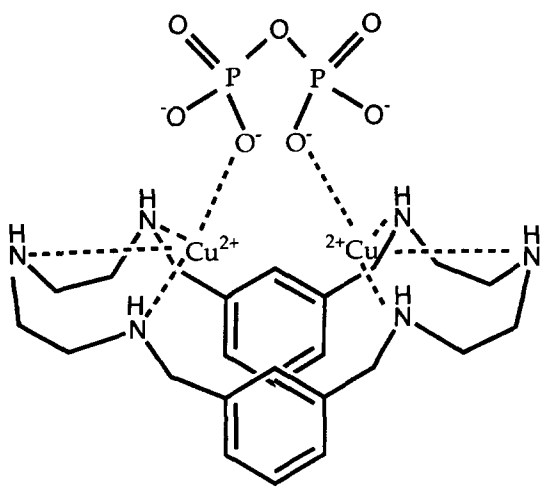

Chart 2. Possible binding mode in Cu_2LPy.

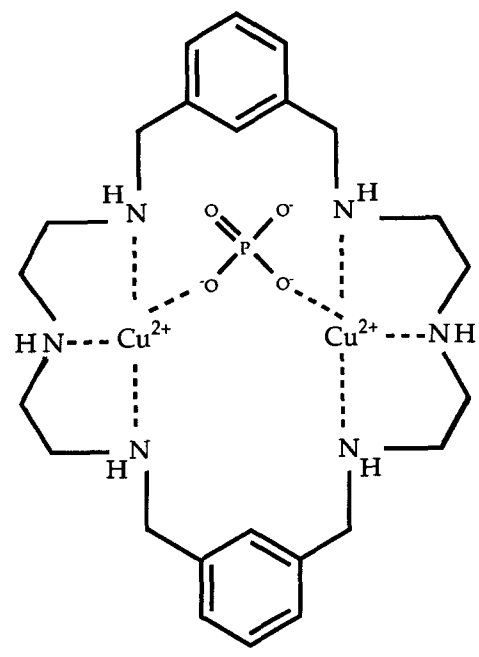

Chart 3. Possible binding mode in Cu_2LP.

rigidity (in comparison with malonate anion) and the favourable *cis*-coordination for complexation (in comparison with fumarate anion).

The complexes obtained with pyrophosphate and orthophosphate anions were also comparable with a slight preference for the former. From log K values a greater stability was expected for pyrophosphate considering the greater number of O^- groups. The loss in stability is caused by the necessarily coordination of the big anion outside the macrocycle.

^{195}Pt NMR spectra of ferrocenylketimine complexes of platinum(II)

Li Ding, Yang Jie Wu* and Da Peng Zhou

Department of Chemistry, Zhengzhou University, Zhengzhou 450052, P.R. China

(Received 25 August 1997; accepted 27 October 1997)

Abstract—The ^{195}Pt NMR spectra of two series of 18 ferrocenylketimine complexes of platinum(II) which include 9 cycloplatinated derivatives [σ-Pt{(η^5-C_5H_3CMe=NAr)Fe(η^5-C_5H_5)}(DMSO)Cl] (**1**) and 9 coordinated compounds [*trans*-$PtCl_2$(DMSO){(η^5-C_5H_4CMe=NAr)}Fe(η^5-C_5H_5)] (**2**) (Ar = substituted phenyl groups) have been recorded. The ^{195}Pt chemical shifts are regularly affected by the substituents in the N-phenyl rings, and satisfactory to excellent linear relationships are found to exist between the ^{195}Pt shifts (δ) and Hammett substituent constants in both series. The directions of the substituent effect on δ(^{195}Pt) are the same in both series, i.e., electron-donating substituents cause shifts to higher frequency, and the coordinated compounds have a better linear relationship. These ^{195}Pt NMR features support the existence of intramolecular coordination between the imino nitrogen atom and the platinum(II) and n-π conjugation between the nitrogen and the N-phenyl ring. © 1998 Elsevier Science Ltd. Keywords: ^{195}Pt NMR spectra; ferrocenylketimine complexes of platinum(II); substituent effect; intramolecular coordination.

The chemistry of platinum spans a gap which includes heterogeneous catalysts for automobiles [1], homogeneous catalysts for organic synthesis [2], and cancer drugs [3]. Consequently an increasing number of chemists express an interest in ^{195}Pt nuclear magnetic resonance and the number of reports containing ^{195}Pt data on organometallic complexes has steadily increased. To the best of our knowledge, so far none of the ^{195}Pt NMR studies has described the linear correlations between ^{195}Pt shifts (δ) and Hammett substituent constants (σ_p or σ_m). There are only two reports of ^{195}Pt NMR involving ferrocenyl platinum complexes [4]. Herein we report the ^{195}Pt chemical shift in solution and the linear correlations between δ(^{195}Pt) values and Hammett substituent constants σ_p or σ_m for the following ferrocenylketimine derivatives of platinum(II).

RESULTS AND DISCUSSION

^{195}Pt NMR spectra

The ferrocenylketimine complexes of platinum(II) **1** and **2** were synthesized according to the published procedure [5], based on the reaction of the free ligands with stoichiometric amounts of *cis*-Pt(DMSO)$_2$Cl$_2$ in refluxing toluene. The ^{195}Pt chemical shifts for compounds **1** and **2** are listed in Table 1.

Table 1. ^{195}Pt NMR chemical shifts δ for compounds **1** and **2**

Compounds	δ_1 (ppm)	Compounds	δ_2 (ppm)
1a	−3790.1	**2a**	−2966.1
1b	−3797.7	**2b**	−2966.9
1c	−3802.7	**2c**	−2968.8
1d	−3804.6	**2d**	−2975.9
1e	−3805.0	**2e**	−2976.1
1f	−3819.7	**2f**	−2988.2
1g	−3800.7	**2g**	−2967.9
1h	−3808.3	**2h**	−2978.0
1i	−3815.0	**2i**	−2985.3

For the *trans* derivatives **2**, the ^{195}Pt chemical shift falls within the range of −2966.1 to −2988.2 ppm, characteristic of a $PtNSX_2$ donor set. An analogue is *trans*-$PtCl_2(NH_3)$(DMSO) for which $\delta(^{195}Pt)$ is −3067 ppm [6]. A $PtNOX_2$ donor set is expected to give values in the range of −1600 to −1800 ppm [4a]. The results obtained confirm that the DMSO is S-bound in solution. Cycloplatination results in a large lower frequency shift to a range of −3790.1 to −3819.7 ppm, making easy identification of this type of product. A closely comparable shift in the literature [4a] was −3899 ppm for compound [σ-Pt{(η^5-$C_5H_3CH(Me)NMe_2$)Fe(η^5-C_5H_5)}(DMSO)Cl].

It is usually convenient to discuss the magnetic shielding of the heavier nuclei principally in terms of local "paramagnetic" and "diamagnetic" contributions σ^p and σ^d. Metal chemical shifts are dominated by changes in the paramagnetic screening contribution, σ^p, to the total shielding [6a]. This term depends upon (a) the asymmetry of the electronic distribution within the valence *5d* and *6p* orbitals of the platinum atom, (b) the mean inverse cube of the distance between these electrons and the platinum nucleus, and (c) the inverse of the energy separations between the ground and excited states for these electrons.

A decrease in halide content normally causes a ^{195}Pt shift to lower frequency on the basis of electronegativity differences and changes in electronic asymmetry [6b], so the lower frequency shift of cycloplatination is a direct consequence of σ-Pt—C bond formation. The higher frequency shift of compounds **2** may be tentatively ascribed to a strong *trans* effect, which makes a difference in σ^p due to the change in electronic excitation energy. This phenomenon is in accordance with that noted elsewhere [6b]: for $[PtCl_2(PR_3)_2]$ and $[PtCl_2(AsR_3)_2]$ types, the shift of the *cis* complex is at lower frequency than that of its *trans* analogue by 400–500 ppm.

Effects of substituents of N-phenyl ring

Electronic withdrawal by a substituent connected to the platinum atom modifies the electronic unbalance among its valence orbitals, and will result in a change in σ^p [7]. As shown in Table 1, the ^{195}Pt shifts show obvious dependence on the nature of the substituents in the N-phenyl ring, with lower frequency shifts resulting from electron-withdrawing groups and with higher frequency shifts resulting from electron-donating groups. Such a trend has also been found in the ^{199}Hg NMR spectra of ferrocenylimine derivatives of mercury [8]. Satisfactory to excellent linear correlations between ^{195}Pt shifts (δ) and Hammett substituent constant σ_p or σ_m [9] were obtained for both series (Eqns (1) and (2) for compounds **1** and **2**, respectively).

$$\delta_1 = -3800.2 - 23.3\sigma \quad n = 9 \quad r = -0.975 \quad (1)$$

$$\delta_2 = -2970.5 - 21.7\sigma \quad n = 9 \quad r = -0.991 \quad (2)$$

However, no obvious correlation with substituent effect has been found for the *meta*- and *para*-substituted arylplatinum cyclooctadiene compounds [7].

It is noteworthy that the ^{195}Pt chemical shifts of compounds **2** are less sensitive to the change of the substituents in the N-phenyl ring in comparison with compounds **1** (see slope in Eqn (1) which is larger than that in Eqn (2)). The X-ray crystal structures [5] (Fig. 1) have shown that Pt—N bond length of compound **2c** is shorter than that of compound **1c**, and the angle between the N-phenyl ring and the plane of C—C=N—C in **2c** is larger than that in **1c** (68.24° and 87.43° for **1c** and **2c**, respectively). If only *n*-π conjugation involving the *n*-electrons of the imino nitrogen and π-electrons of the N-phenyl group is considered, the substituents in the N-phenyl ring should have a much stronger effect on platinum for compounds **2** than that for compounds **1**. A possible explanation is that the substituents affect the platinum of compounds **1** not only by means of the N → Pt interaction, but also via part transmission of electronic effects through the C=N bond and the substituted Cp ring, though the nonplanarity of the N-phenyl ring and the plane C—C=N—C destroys the π-π conjugation between the C=N bond and the N-phenyl group to some extent. As for compounds **2**, there is only N → Pt interaction.

It is believed that there is an interaction between the *n*-electrons and unoccupied *5d* and *6p* orbital of the platinum atom [10]. In this way, the electron-donating groups should enhance the unbalance of electron distribution in the unoccupied orbital of the platinum, thus leading to an increase in the paramagnetic shielding term σ^p with observed higher frequency shift while the electron-withdrawing groups have an opposite effect.

EXPERIMENTAL

The details for the synthesis and characterization of compounds **1** and **2** have been described previously [5].

(Received 23 August 1997; accepted 27 October 1997)

Abstract—Novel mono- and didentate ferrocenylphosphines containing complexes, $[Mo_2(CO)_6(dfpp)_2(\mu\text{-pa})]$ (dfpp = diferrocenylphenylphosphine) and $[Mo_2(CO)_6(\mu\text{-dppf})(\mu\text{-pa})]$, have been isolated and characterized by infrared and electronic spectroscopy, and cyclic voltammetry. For the $[Mo_2(CO)_6(\mu\text{-dppf})(\mu\text{-pa})]$ complex a single crystal X-ray structure analysis evidences its double bridge nature and the asymmetry of the bridging ligands due to steric constraints. In the visible region, the new compounds show strong solvatochromic bands and this effect has been evaluated by using the E^*_{MLCT} parameter. The redox behaviour of the complexes involves molybdenum and ferrocene-based oxidations and pa-based reductions. The results are compared to the previously characterized analogous complexes based on the related ligands triphenylphosphine and 1,2-*bis*(diphenylphosphino)ethane. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: molybdenum; carbonyl; ferrocenylphosphines; polypyridine complexes.

In a recent article we have reported [1] the reaction chemistry of the novel dinuclear acetonitrile derivated $[Mo_2(CO)_6(NCMe)_2(\mu\text{-pa})]$ (pa = pyridine-2-carbaldehyde azine, Fig. 1) towards the monodentate phosphine PPh_3 and the didentate phosphine 1,2-*bis*(diphenylphosphino)ethane (dppe). The labile MeCN groups of the acetonitrile complex are readily replaced by PPh_3 and dppe to yield the *bis*(PPh_3) compound $[Mo_2(CO)_6(PPh_3)_2(\mu\text{-pa})]$ and the dppe-bridged complex $[Mo_2(CO)_6(\mu\text{-dppe})(\mu\text{-pa})]$, respectively. These homobimetallic species are characterized by strong solvatochromic bands in the visible region (MLCT, pa(π^*) ← Mo(d)) and by molybdenum centered (oxidation) and pa centered (reduction) redox processes. The single crystal X-ray structure of the double bridge complex $[Mo_2(CO)_6(\mu\text{-dppe})(\mu\text{-pa})]$ shows an asymmetric bridging pa ligand because of the shortness of the —CH_2CH_2— chain of the dppe ligand linking the molybdenum atoms.

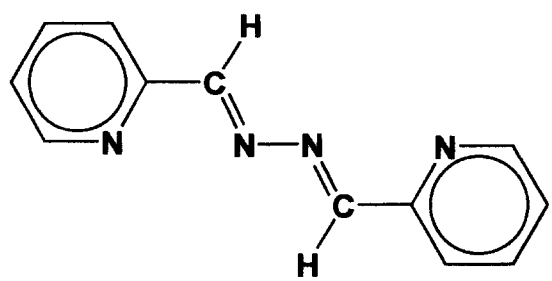

Fig. 1. Structure of the pa ligand.

In this work, we further extend the study of the aforementioned synthetic avenue to mono- and didentate ferrocenylphosphines to obtain multinuclear compounds. In this regard, by using the redox-active P-donor metalloligands diferrocenylphenylphosphine (dfpp) and 1,1′-*bis*(diphenylphosphino)ferrocene (dppf) the heterometallic complexes $[Mo_2(CO)_6(dfpp)_2(\mu\text{-pa})]$ and $[Mo_2(CO)_6(\mu\text{-dppf})(\mu\text{-pa})]$ were isolated. The spectroscopic, electrochemical and structural properties of these new ferrocenylphosphine complexes are reported herein.

EXPERIMENTAL

Reagent grade solvents were used for all preparations. Diferrocenylphenylphosphine (dfpp) and 1,1′-*bis*(diphenylphosphino)ferrocene (dppf) were purchased from Aldrich Chemical Co. $[Mo_2(CO)_6(NCMe)_2(\mu\text{-pa})]$ was obtained following similar methods to those described in the literature [1].

Synthesis of $[Mo_2(CO)_6(\mu\text{-dppf})(\mu\text{-pa})]\cdot 1.25(CH_3)_2CO$

Into a solution of 0.125 g (0.192 mmol) of just prepared $[Mo_2(CO)_6(NCMe)_2(\mu\text{-pa})]$ in 40 cm^3 of CH_2Cl_2 were added 0.106 g (0.192 mmol) of dppf and stirred for 3 h under nitrogen. The dark green coloured solution was then filtered. To this filtrate 20 cm^3 of MeOH were added and on standing for 1 h a dark green precipitate was formed, which was filtered off and washed with 3 portions of MeOH (10 cm^3). The resultant crude precipitate was dissolved in Me_2CO (100 cm^3), filtered, and the filtrate was evaporated to ca 10 cm^3 at room temperature. The dark green crystals were separated by filtration and washed with Me_2CO (5 cm^3). Yield: 0.095 g (41%). Anal. Found: C, 55.90; H, 3.80; N, 4.60%. Calc. for $C_{52}H_{38}FeMo_2N_4O_6P_2\cdot 1.25(CH_3)_2CO$: C, 55.84; H, 3.83; N, 4.68%. IR (KBr, disc): $\nu_{C\equiv O}$, 1918 s, 1825 s and 1801 s cm^{-1}.

Synthesis of $[Mo_2(CO)_6(dfpp)_2(\mu\text{-pa})]\cdot 3CH_3OH$

The same procedure for the above dppf complex $[Mo_2(CO)_6(\mu\text{-dppf})(\mu\text{-pa})]$ was followed, but the crude dark green precipitate was dissolved in hot CH_2Cl_2 instead of Me_2CO. After the addition of equal volume of MeOH the solution was concentrated *in vacuo* to half of the volume. The concentrated solution was stored at room temperature (2 h). The needle like dark green crystals were washed with CH_2Cl_2–MeOH (1 : 1). Anal. Found: C, 53.60; H, 4.20; N, 3.40%. Calc. for $C_{73}H_{68}Fe_4Mo_2N_4O_9P_2$: C, 54.04; H, 4.22; N, 3.45%. IR (KBr, disc): $\nu_{C\equiv O}$, 1906 s, 1815 s and 1798 s cm^{-1}.

Instruments

IR spectra were registered as solid KBr samples on a Bruker Model IFS-66V FTIR instrument. The electronic spectra were obtained on a Spectronic 3000 diode array spectrophotometer. Cyclic voltammograms were obtained in CH_2Cl_2 containing 0.10 M $TBAPF_6$ as supporting electrolyte. The three electrode measurements were carried out with a Wenking Potentioscan POS-73 and a X-Y recorder. A platinum-disk working electrode, a platinum wire auxiliary electrode, and a AgCl/Ag reference electrode (with internal reference ferrocenium/ferrocene) were used in the cyclic voltammetry experiments.

X-ray crystal structure of $[Mo_2(CO)_6(\mu\text{-dppf})(\mu\text{-pa})]\cdot 1.25(CH_3)_2CO$

A brownish single crystal suitable for the X-ray diffraction study, measuring $0.50\times 0.16\times 0.08$ mm, was fixed with epoxy resin to a glass fibre and mounted onto a Siemens R3m/V single crystal diffractometer. Intensity data were collected using graphite monochromatized Mo–K_α radiation ($\lambda = 0.71073$ Å). A total of 50 independent reflexions in the range $15 \leqslant 2\theta \leqslant 25^\circ$ were used for crystal system and cell parameters determination. Crystal data: Monoclinic, $P2_1$, $a = 10.925(9)$, $b = 11.070(7)$, $c = 24.15(2)$ Å, $\beta = 102.43(2)^\circ$, $Z = 2$. Data collection and structure determination: 5664 reflections collected in an angle span of $2 \leqslant 2\theta \leqslant 50^\circ$, within index ranges $-13 \leqslant h \leqslant 12, 0 \leqslant k \leqslant 13, 0 \leqslant l \leqslant 28$. Of them, 5332 were independent ($R_{int} = 0.045$), and 4119 considered observed ($I > 2\sigma(I)$). No absorption correction was applied. The structure was partially solved by routine application of direct methods and completed through the iterative use of difference Fourier synthesis. Least squares refinement using F^2 of 679 parameters and 11 soft restraints led to the final indices $R_1 = 0.042$, $wR_2 = 0.099$ [$I = 2\sigma(I)$], $R_1 = 0.069$, $wR_2 = 0.203$ [all data], and the goodness of fit on F^2 is 1.00, max. and min. $\Delta\rho$: 0.50 and -0.38 eÅ^{-3}. Hydrogen atoms were included at their calculated positions and allowed to ride. In the course of the structure resolution, 1.25 acetone molecules per formula unit were found in the form of solvate and split into two different positions with occupancy factors of 0.60 and 0.65, respectively. Programs used: Data reduction, structure solution by direct methods, structure refinement by full matrix least squares on F^2, molecular graphics: SHELXTL-Plus package, version 5.03 (Sheldrick, 1994) [2].

RESULTS AND DISCUSSION

Treatment of $[Mo_2(CO)_6(NCMe)_2(\mu\text{-pa})]$ with dfpp (1 : 2 molar ratio) or dppf (1 : 1 molar ratio) in dichloromethane at room temperature, afforded the new heterometallic complexes $[Mo_2(CO)_6(dfpp)_2(\mu\text{-pa})]$ and $[Mo_2(CO)_6(\mu\text{-dppf})(\mu\text{-pa})]$, respectively. These

dark-green coloured products are air stable. The dppf derivative is soluble in organic solvents such as dichloromethane, chloroform or benzene, but unsoluble in alcohols and light petroleum. The dfpp based complex shows a lower solubility than that of the dppf-based compound in all the solvents.

The molecular structure of the dppf complex $[Mo_2(CO)_6(\mu\text{-dppf})(\mu\text{-pa})]$ is shown in the Fig. 2 with the atomic numbering scheme. The solid state structure is characterized by the two molybdenum atoms, Mo1 and Mo2, bridged by the pa and dppf ligands, and, in addition, each metal centre is coordinated by a set of tricarbonyl groups in a facial arrangement. The ligand geometry around the Mo atoms is distorted octahedral as is inferred from the smaller N1—Mo1—N2 [72.0(3)°] and N3—Mo2—N4 [72.4(3)°] angles, due to the constrain imposed by the five-membered ring of the bonded pa ligand. In spite of this distortion, the lack of planarity around each Mo centre is not strong [the best mean plane defined by N2, N1, C47 and C49 deviate by 0.019(7), −0.024(8), 0.031(9) and −0.038(11) Å, and the homologous one defined by N3, N4, C50 and C52 deviate by 0.014(8), −0.013(8), 0.027(11) and −0.030(11) Å]. All the Mo—N and Mo—CO distances are in accord with the values of other molybdenum carbonyl derivatives [1]. The Mo1—P1 [2.588(3) Å] and Mo2—P2 [2.596(3) Å] lengths are comparable with those observed in the related Mo-dppf compounds $[Mo(CO)_4(dppf)]$ [3] [2.560(16) Å] and $[Mo_2(CO)_{10}(\mu\text{-dppf})]$ [4] [2.532(1) Å]. The pa ligand is forced to be non-planar and to acquire an approximately *trans* configuration by the steric requirements of the dppf ligand [the torsion angle C40—N2—N4—C46 is 140.6(9)°]. The pyridyl rings are rather planar with a maximal deviation of 0.012(12) Å for C42 and of 0.015(13) Å for C37, the dihedral angle between them is 144.3(3)°. The notorious enlargement of the P—Mo—N(hidrazinic) angles in the $[Mo_2(CO)_6(\mu\text{-dppf})(\mu\text{-pa})]$ complex [average P1—Mo1—N2 and P2—Mo2—N4 angles of 97.7(7)°] in comparison with the analogous angles in the dppe complex $[Mo_2(CO)_6(\mu\text{-dppe})(\mu\text{-pa})]$ [89.39(14)°] [1], makes evident the bulkier nature of the ferrocenyl group with respect to the aliphatic $—CH_2CH_2—$ chain. The two cyclopentadienyl rings of the ferrocenyl unit do not deviate significantly from the planarity [maximal deviations on each ring are 0.012(11) Å for C27 and 0.010(9) Å for C31], but they are slightly displaced from a coplanar position as is evidenced by the dihedral angle of 1.1(4)° between both planes. The Fe—cp [cp = centroid of the C_5 ring] distances [P1 ring, 1.647(1) Å; P2 ring, 1.637(1) Å] are in agreement with that found in the literature [5] and the iron atom is slipped from each cyclopentadienyl ring by 0.018(2) and 0.048(3) Å, respectively. The phosphorous atoms of the phosphocyclopentadiene rings, which virtually do not suffer displacement from their respective C_5 ring planes [0.058(3) Å for P1 and 0.013(2)Å for P2], are rotated relative to one another giving a dihedral angle P1—cp1—cp2—P2 of 116.4(4)° and, besides, the two C_5 rings of the ferrocenyl moiety reach a nearly staggered conformation [the angle to get the nearby perfectly staggered situation is approximately 11.0°].

The solid state IR spectra of the $[Mo_2(CO)_6(dfpp)_2(\mu\text{-pa})]$ and $[Mo_2(CO)_6(\mu\text{-dppf})(\mu\text{-pa})]$ complexes have a pattern similar to other molybdenum(0) tricarbonyl species. They present three strong carbonyl stretching bands, the two at lower

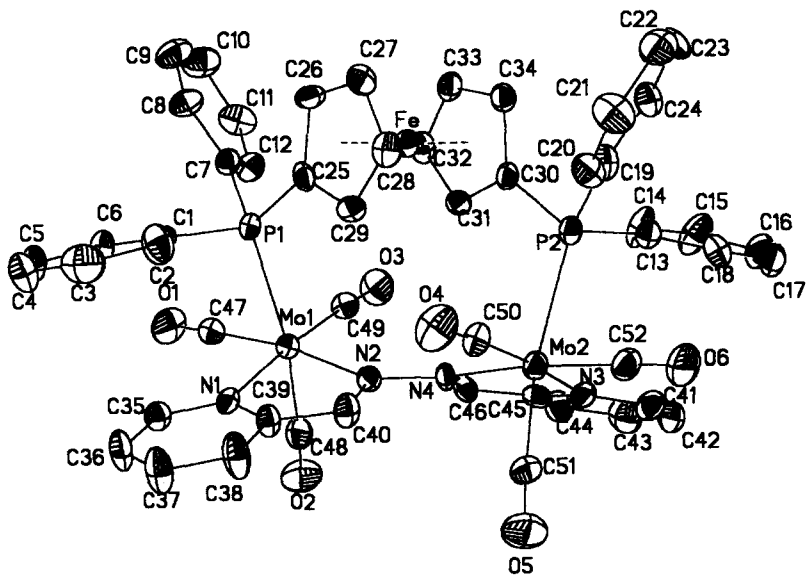

Fig. 2. Schematic view of the complex $[Mo_2(CO)_6(\mu\text{-dppf})(\mu\text{-pa})] \cdot 1.25(CH_3)_2CO$ showing the atomic labelling used and the thermal ellipsoids, drawn at a 50% level (the acetone molecules have been omitted).

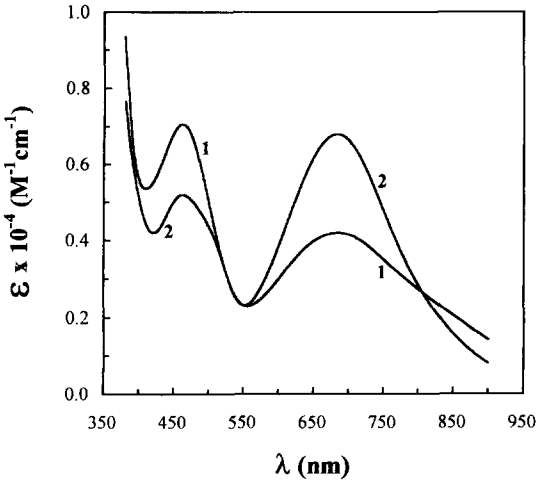

Fig. 3. Electronic spectra recorded in dichloromethane for (**1**) $[Mo_2(CO)_6(dfpp)_2(\mu\text{-pa})]$ and (**2**) $[Mo_2(CO)_6(\mu\text{-dppf})(\mu\text{-pa})]$.

frequency are superimposed. This characteristic pattern has been shown to belong to the *fac* isomers [6].

The electronic absorption spectra in the visible region of the $[Mo_2(CO)_6(dfpp)_2(\mu\text{-pa})]$ and $[Mo_2(CO)_6(\mu\text{-dppf})(\mu\text{-pa})]$ complexes were measured in dichloromethane solution (Fig. 3). Both complexes show two strong solvatochromic absorption bands. Previous work [1] has assigned these bands as MLCT transitions from the Mo t_{2g} orbitals to the first and the second LUMO of the π^* orbitals of the pa ligand, MLCT(1) and MLCT(2) respectively. The longest wavelength MLCT(1) transition of the dfpp complex (690 nm, $\varepsilon = 4200\ M^{-1}\ cm^{-1}$) appears slightly red-shifted with respect to that of the dppf-bridged species (682 nm, $6800\ M^{-1}\ cm^{-1}$). Nevertheless, in the highest energy side the effect works in the opposite way; the MLCT(2) transition of the dfpp compound (462 nm, $7100\ M^{-1}\ cm^{-1}$) is blue-shifted in comparison with the analogue of the dppf-bridged complex (468 nm, $5200\ M^{-1}\ cm^{-1}$). This behaviour is expected considering the existence of different conformations of the pa ligand on each one of these complexes. More specifically, theoretical calculations [1] (extended-Hückel MO calculations with charge iteration) predict a planar conformation (*trans*) for the azine in complexes with monodentate ligands (*viz.*, the dfpp complex) and, besides, if the structure is distorted from the planar situation (*viz.*, the dppf complex) the first and second LUMOs of the pa π^* system become closer in energy (comparatively the changes of energy in the metal orbitals are not significant).

The solvatochromism of the MLCT(1) and MLCT(2) transitions of the dppf complex $[Mo_2(CO)_6(\mu\text{-dppf})(\mu\text{-pa})]$ was evaluated (the low solubility of the dfpp compound precluded this evaluation) by plotting the respective charge-transfer energies MLCT(1) and MLCT(2) vs the E^*_{MLCT} parameter [7] (Table 2). The linear correlations obtained are described by the equation $\bar{\nu}_{MLCT} = A + B \cdot E^*_{MLCT}$ (MLCT(1): $A = 13{,}676$, $B = 1481\ cm^{-1}$, $r = 0.987$; MLCT(2): $A = 20{,}852$, $B = 1128\ cm^{-1}$, $r = 0.993$). The slope B, i.e. the solvent sensitivity, of the MLCT(1) transition is comparable, within the experimental error, to that calculated for the related double bridge complex $[Mo_2(CO)_6(\mu\text{-dppe})(\mu\text{-pa})]$ ($B = 1634\ cm^{-1}$ using the solvents of Table 2) [1], showing that the introduction of the ferrocenyl moiety in place of the aliphatic chain $—CH_2CH_2—$ has no great inci-

[a] Solvent parameters (E^*_{MLCT}) from Ref. 7.

dence on the interaction with the solvent. The solvent sensitivities of the MLCT(2) transitions seem to be different; the slope B in the dppf complex results lower than that of the dppe ($B = 1692$ cm^{-1}) species. But, this difference is apparent, since it can be attributed to the uncertainty in the measurements of the respective λ_{max}; these bands occur as shoulders of the strong absorptions coming from the UV region.

The cyclic voltammetry studies for the $[Mo_2(CO)_6(dfpp)_2(\mu\text{-pa})]$ and $[Mo_2(CO)_6(\mu\text{-dppf})(\mu\text{-pa})]$ complexes were carried out in CH_2Cl_2 solution. The doubly bridged dppf complex $[Mo_2(CO)_6(\mu\text{-dppf})(\mu\text{-pa})]$ shows an irreversible oxidation wave at $E_p = 0.28$ V followed for a quasi-reversible couple at $E_{1/2} = 0.63$ V. The first wave compares well with that of the molybdenum(0/+1) oxidation of the dppe species $[Mo_2(CO)_6(\mu\text{-dppe})(\mu\text{-pa})]$ [1]. Then, the quasi-reversible remaining couple, absent in the dppe species, is assigned straightforwardly to the one electron ferrocene/ferrocenium oxidation in the dppf ligand [8]. For the *bis*(dfpp) compound was not possible to determine with exactitude the expected anodic processes involving the ferrocenyl groups [9], they appear overlapped with the irreversible Mo(0/+1) wave (the superimposed waves were observed at about 0.3 V). The reduction side for the doubly bridged dppf complex, is characterized by two reversible one electron waves centred on the pa ligand [1] ($E^1_{1/2} = -1.44$ V; $E^2_{1/2} = -1.94$ V). By contrast, in the *bis*(dfpp) system the first one is reversible ($E^1_{1/2} = -1.45$ V) and the more catodic is irreversible ($E_p = -2.04$ V). Probably, this difference is due to the bridge nature of dppf ligand which blocks a following reaction that could occur if two monodentate phosphine dfpp ligands were the coordinating species.

Abstract—The reaction of $Ni(ClO_4)_2.aq$, ethylenediamine (en) and KSeCN afford mononuclear $[Ni(en)_3][Ni(en)_2(NCSe)_2]_2(ClO_4)(SeCN)$ (**1**) complexes. The same reaction starting with $Ni(NO_3)_2.aq$ with or without KPF_6 affords two different compounds: $[Ni(en)_3][Ni(en)_2(NCSe)_2]_2(PF_6)_2$ (**2**) and $[Ni(en)_2(NCSe)_2]$ (**3**). The structures of the three compounds were determined by X-ray crystallography. The structures of compounds (**1**) and (**2**) were very similar, consisting of two discrete mononuclear Ni(II) complexes, one *tris*-chelate and the other *cis bis*-chelate with the two selenocyanato ligands linked by the nitrogen atoms. The structure of complex (**3**) is different and consisted of a discrete neutral mononuclear Ni(II) complex *trans bis*-chelate with the two selenocyanato ligands also linked by the nitrogen atoms. Structures, synthetic trends and magnetic behaviour are discussed. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: selenocyanato complexes; mononuclear Ni(II) complexes; magnetism.

Magnetic interactions propagated by pseudohalide bridging ligands between paramagnetic centers have attracted great interest in the past few years. The most comprehensive literature refers to N_3^- bridging ligands: The end-to-end bridging mode creates antiferromagnetic coupling [1] and the end-on mode, ferromagnetic coupling [2]. With cyanato bridging ligands this behaviour is not so clear and the number of reported complexes that have been fully characterized is too low to permit magneto-structural correlations [3]. The literature on thiocyanato ligand is more abundant: the bridge mode usually involves both nitrogen and sulphur, and thus an M—NCS—M linkage occurs [4]. Focusing our attention on Ni(II) polynuclear complexes [5], the Ni—SCN and Ni—NCS angles are almost constant and they all show ferromagnetic behaviour [6]. With the selenocyanato anion only one *bis*(μ-selenocyanato)nickel(II) 1-D complex [7], and one *bis*(μ-selenocyanato)nickel(II) dinuclear complex [8] are reported: both also show ferromagnetic coupling [9]. Owing to the reduced number of selenocyanate derivatives we tried the synthesis of new Ni(II) complexes with $SeCN^-$ as bridging ligand, using the ethylenediamine as terminal ligand. Unfortunately, with nitrate, perchlorate and hexafluorophosphate as counteranion and maintaining an Ni(II): amine: selenocyanato ratio 1:2:1 yield the monomers (**1**), (**2**), (**3**) instead of the desired dimeric product $[Ni_2(en)_4(\mu\text{-}SeCN)_2]X_2$ as the ratio could be expected to furnish.
