(Received 30 September 1997; accepted 11 November 1997)

Abstract—$RhCl_3\cdot 3H_2O$ reacts with ca six molar equivalents of PPh_2H or PCy_2H in EtOH solution under a N_2 atmosphere and in the presence of excess NH_4PF_6 to yield $[RhCl_2(PPh_2H)_4]PF_6$ or $[RhCl_2(PCy_2H)_4]PF_6$ respectively as yellow solids. $^{31}P\{^1H\}$ NMR spectroscopy shows the presence of the *trans* isomer only in chlorocarbon solutions, with J_{RhP} ca 80 Hz. Upon standing a solution of *trans*-$[RhCl_2(PPh_2H)_4]PF_6$ in a MeCN/thf mixture results in the production of yellow crystals of $[(PPh_2OH)(PPh_2O)Cl(NCMe)Rh(\mu\text{-}Cl)_2Rh(PPh_2OH)(PPh_2O)Cl(NCMe)]\cdot 2thf$, the structure of which shows an edge-bridged bioctahedral arrangement with d(Rh···Rh) = 3.74 Å. The NCMe ligands lie *trans* to the terminal Cl ligands, while the PPh_2OH and PPh_2O ligands are *trans* to the bridging Cl ligands. The crystal structure of the triply-bridged dimer $[(PPh_2OH)_2(PPh_2O)Rh(\mu\text{-}Cl)_3Rh(PPh_2OH)(PPh_2O)_2]$ has also been determined, showing a face-sharing bioctahedral arrangement, with d(Rh···Rh) = 3.39 Å. Both dinuclear species show significant P—O—H···O—P hydrogen-bonding interactions. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: rhodium; phosphine; X-ray structure; phosphinite.

In contrast to tertiary phosphines, the coordination chemistry of primary and secondary phosphines has been largely neglected. This is in part due to the fact that coordination to a metal ion leads to the P-bound proton becoming very acidic and hence these species are liable to deprotonate yielding phosphido derivatives [1]. We have been investigating the chemistry of primary and secondary phosphines with the platinum group metals with a view to using these as neutral formally two-electron donors [2–5]. In our recent work we have isolated the stable cationic species $[MCl(PCy_2H)_3]^+$ (M = Pd, Pt) [2], and the neutral complexes $[M'X_2(L)_4]$ (X = Cl or Br, M' = Ru: L = PPh_2H, $PPhH_2$; M' = Os: L = PPh_2H, $PPhH_2$, PCy_2H). $^{31}P\{^1H\}$ NMR spectroscopic studies, together with X-ray crystallographic studies on several of these, confirm the *trans*-dihalo arrangement, with the four neutral phosphine ligands occupying the equatorial plane. The Ru and Os compounds exhibit reversible M(II)/(III) redox couples [3,4]. We now report the preparation and spectroscopic characterisation of the Rh(III) species *trans*-$[RhCl_2(PR_2H)_4]PF_6$ (R = Ph, Cy), together with single crystal X-ray structure determinations on two unusual chloro-bridged bioctahedral dimers $[(PPh_2OH)_2(PPh_2O)Rh(\mu\text{-}Cl)_3Rh(PPh_2OH)(PPh_2O)_2]$ and $[(PPh_2OH)(PPh_2O)Cl(NCMe)Rh(\mu\text{-}Cl)_2Rh(PPh_2OH)(PPh_2O)Cl(NCMe)]\cdot 2thf$, isolated as decomposition products.

Several Rh(I) and Ir(I) complexes with secondary phosphines have been reported previously, including $[M(PR_2H)_4]^+$ (M = Rh, Ir; R = Cy, Ph, Et) and $[Rh(PBu^t_2H)_3Cl]$ [6]. Also, in an early paper Hayter reported the preparation of the neutral Rh(III) complexes $[RhCl_3(PPh_2H)_3]$ and $[RhCl_3(PEt_2H)_3]$ by reaction of $RhCl_3\cdot 3H_2O$ with three molar equivalents of

* Author to whom correspondence should be addressed.

the phosphine in EtOH, although the characterisation of these species was very limited [7].

RESULTS AND DISCUSSION

Reaction of $RhCl_3 \cdot 3H_2O$ with six molar equivalents of PPh_2H or PCy_2H in degassed EtOH solution affords a colour change to yellow. In the presence of NH_4PF_6 concentration of the solution *in vacuo* gives the complexes $[RhCl_2(PPh_2H)_4]PF_6$ or $[RhCl_2(PCy_2H)_4]PF_6$ respectively as yellow solids. IR spectroscopy confirms the presence of the phosphine ligands and ν(P—H) occurs as a weak absorption at ca 2370 cm^{-1}. In addition, strong peaks around 840 and 555 cm^{-1} are assigned to $\nu(PF_6^-)$ and $\delta(PF_6^-)$ respectively, confirming the presence of the non-coordinating anion. The electrospray mass spectra reveal peaks with the correct isotopic distributions at $m/z = 883$ and 847 for the former, corresponding to $[RhCl(PPh_2H)_4]^+$ and $[Rh(PPh_2H)_4]^+$, and 965 and 767 for the latter, corresponding to $[RhCl_2(PCy_2H)_4]^+$ and $[RhCl_2(PCy_2H)_3]^+$. There was no evidence for other Rh-containing species such as dimers at higher m/z.

The $^{31}P\{^1H\}$ NMR spectrum of $[RhCl_2(PPh_2H)_4]PF_6$ reveals a doublet at +1.2 ppm indicative of a *trans*-dichloro geometry with four equivalent PPh_2H ligands coordinated in the equatorial plane, $J_{RhP} = 83$ Hz; typical of Rh(III) phosphine couplings. A septet at −146.3 ppm is also observed due to the PF_6^- and these signals integrate as 4 : 1. Similarly, for $[RhCl_2(PCy_2H)_4]PF_6$ a doublet at −5.0 ppm and septet at −146.3 ppm are observed, $J_{RhP} = 74$ Hz. In both cases the proton coupled ^{31}P NMR spectrum shows a distinctive second order pattern due to the coordinated secondary phosphines (Fig. 1), as expected given the direct one-bond P—H coupling, coupling to the P—H protons from *cis* and *trans* phosphine ligands and coupling to the phenyl or cyclohexyl ring protons. These data, together with ^1H NMR spectroscopy and microanalyses, confirm the products to be the Rh(III) tetrakis-phosphine complexes *trans*-$[RhCl_2(PPh_2H)_4]PF_6$ and *trans*-$[RhCl_2(PCy_2H)_4]PF_6$.

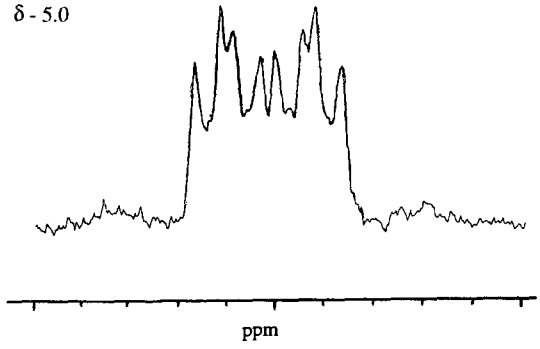

Fig. 1. ^{31}P NMR spectrum of *trans*-$[RhCl_2(PCy_2H)_4]PF_6$ showing the coordinated phosphine region.

In an attempt to grow crystals suitable for a single crystal X-ray structure analysis, a solution of *trans*-$[RhCl_2(PPh_2H)_4]PF_6$ in MeCN/thf was allowed to stand for several days at ca −15°C. This resulted in the formation of a few yellow columnar crystals, along with phosphine oxide. A structure analysis performed on one of these crystals showed them in fact to be the unusual $(\mu\text{-Cl})_2$ edge-bridged bioctahedral species $[(PPh_2OH)(PPh_2O)Cl(NCMe)Rh(\mu\text{-}Cl)_2Rh(PPh_2OH)(PPh_2O)Cl(NCMe)] \cdot 2thf$, formed by oxidation of the secondary phosphine complex. The structure shows (Fig. 2, Table 1) a centrosymmetric dinuclear species in which each Rh(III) centre is coordinated to two bridging Cl ligands, one terminal Cl ligand, one PPh_2OH, one PPh_2O^- and one NCMe ligand, giving a distorted octahedral arrangement, Rh—P(1) = 2.267(3), Rh—P(2) = 2.268(3), Rh—Cl(1) = 2.321(3), Rh—Cl(2) = 2.493(2), Rh—N(1) = 2.015(8) Å. The bridging Cls are *trans* to the diphenylphosphinous acid and diphenylphosphinite ligands, leaving the terminal Cl and NCMe ligands mutually *trans*. The phosphinous acid proton was located in the difference map, and the position of this between the two O atoms, together with the O(1)···O(2) distance of 2.38 Å, suggests a significant H-bonding interaction involving the P—O—H···O—P fragments. This type of H-bonding arrangement has been observed previously in several species including for example $[(PPh_2OMe)_2(PPh_2OH)Ru(\mu\text{-}Cl)_3Ru(PPh_2OH)_2(PPh_2O)]$ [8], $[PtH(PPh_2O^nBu)(PPh_2OH)(PPh_2O)]$ [9], $[Pd(S_2PMe_2)(PPh_2O)(PPh_2OH)]$ [10] and $[(PPh_2OH)(PPh_2O)ClRh(\mu\text{-}Cl)_3RhCl(PPh_2O)(PPh_2OH)]^-$ [11]. The Rh···Rh distance is 3.74 Å in our product, indicating non-interacting metal centres. This compares with an Rh···Rh distance of 3.745(15) Å for $[(Rh_2(PBu^n_3)_4Cl_6]$ [12].

Since only a few crystals of this material were produced, a full spectroscopic study was not possible. Importantly however, an electrospray mass spectrum of these did not reveal the same peaks as observed for $[RhCl_2(PPh_2H)_4]PF_6$ (above), showing instead peaks with the correct isotopic distributions at $m/z = 1122$ and 582, assigned to $[Rh_2Cl_3(PPh_2OH)_2(PPh_2O)_2]^+$ and $[RhCl(PPh_2OH)(PPh_2O)(MeCN)]^+$ respectively.

In a separate experiment, upon standing an ethanol solution containing $RhCl_3 \cdot 3H_2O$ and three molar equivalents of PPh_2H, a few orange prism crystals of a second dinuclear species, $[(PPh_2OH)_2(PPh_2O)Rh(\mu\text{-}Cl_3)Rh(PPh_2OH)(PPh_2O)_2]$, were produced (together with phosphine oxide and other decomposition products). The crystal structure of this material shows (Fig. 3, Table 2) a $(\mu\text{-Cl})_3$ confacial bioctahedral geometry, in which one Rh(III) centre is formally ligated to two PPh_2OH and one PPh_2O^- ligands and three bridging Cl's, while the other formally has one PPh_2OH, two PPh_2O^- and three bridging Cls. The phosphinous acid protons were not identified in the difference map in this case, however they are again implicated by the

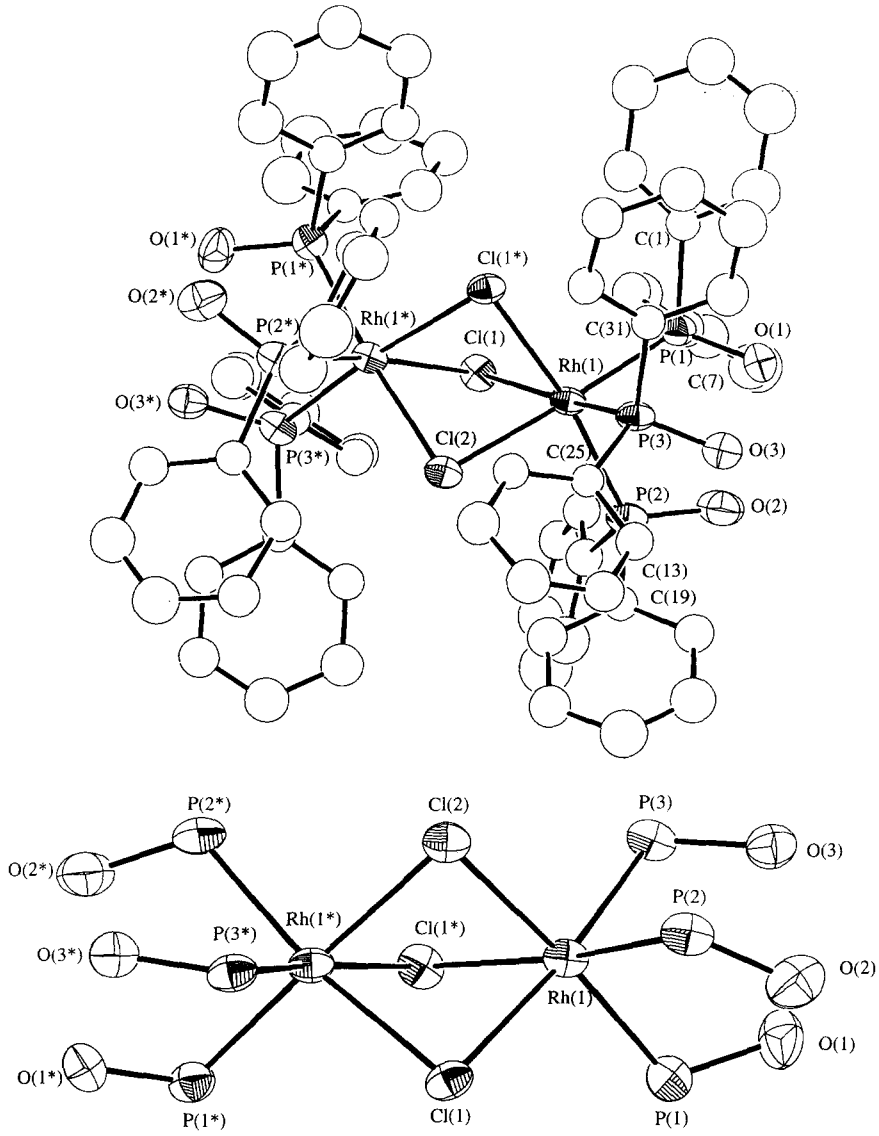

Fig. 3. View of the structure of $[(PPh_2OH)_2(PPh_2O)Rh(\mu\text{-}Cl)_3Rh(PPh_2OH)(PPh_2O)_2]$ (a) with the numbering scheme adopted and (b) showing the chloro-bridged core. Atoms marked * are related by a crystallographic 2-fold axis.

O···O distances, O(1)···O(2) = 2.55, O(1)···O(3) = 2.54, O(2)···O(3) = 3.01 Å. Hence these interatomic distances suggest that the most plausible arrangement is for O(1) to be deprotonated, since this allows a significant H-bonding interaction of O(1) with both the proton on O(2) and O(3). The third phosphinous acid proton is disordered across a crystallographic two-fold axis and must be associated with either O(2) or O(3) and only on one half of the molecule. However, there is little doubt over its presence since otherwise, counting charges would imply a Rh(II)/Rh(III) dimer which is highly unlikely, and further, there was no evidence for any other species in the difference map. Stephenson and co-workers reported a similar disorder problem in the structure of the Ru(II)/Ru(II) dimer $[(PPh_2OEt)_2(PPh_2OH)Ru(\mu\text{-}Cl)_3Ru(PPh_2OH)_2(PPh_2O)]$, which also crystallises in the space group F_{ddd} with a half-molecule in the asymmetric unit. In this case there was substantial disorder of the PPh_2O^- and PPh_2OEt ligands about a two-fold axis or centre of symmetry [8]. They also reported a full structure determination on the related confacial bioctahedral Ru(II)/Ru(II) dimer $[(PPh_2OMe)_2(PPh_2OH)Ru(\mu\text{-}Cl)_3Ru(PPh_2OH)_2(PPh_2O)]$, formed by pyrolysis of $[PPh_2OMe)_3Ru(\mu\text{-}Cl)_3Ru(PPh_2OMe)_3]Cl$ for 12 h at 120°C [8]. The Rh···Rh distance in $[(PPh_2OH)_2(PPh_2O)Rh(\mu\text{-}Cl)_3Rh(PPh_2OH)(PPh_2O)_2]$ is 3.39 Å. The only previously reported dinuclear Rh(III) complex which involves similar phosphinito ligation is the anionic dimer $[(PPh_2OH)(PPh_2O)ClRh(\mu\text{-}Cl)_3RhCl(PPh_2O)(PPh_2OH)]^-$ for which d(Rh···Rh) is 3.2262(16) [11].

A mass spectrum of the remaining crystals showed peaks around $m/z = 1487$ corresponding to loss of one Cl from the neutral dimer, and once again there was no evidence for any rhodium species involving PPh_2H ligands. Furthermore, an IR spectrum showed peaks due to the PPh_2OH and PPh_2O^- ligands as well as a weak absorption at 253 cm^{-1} assigned to $\nu(Rh—Cl_{bridging})$.

These results show that while PPh_2H and PCy_2H react readily with Rh(III) to give the tetrakis phosphine cations $[RhCl_2(L)_4]^+$, the diphenylphosphine complex is not very stable in solution, readily undergoing oxidation and dimerisation. This is in contrast to the behaviour of the Ru(II) and Os(II) species *trans*-$[MX_2(L)_4]$ (X = Cl or Br; L = PPh_2H, PCy_2H, $PPhH_2$) which are apparently much more stable [3,4]. The dinuclear species reported here presumably precipitate out of solution due to their poor solubilities. Prior to this work there was only one reported Rh(III) chloro-bridged dimer involving phosphinite ligands [11]. Current work is aimed at finding alternative, more direct, synthetic routes to these and other rhodium phosphinite derivatives.

EXPERIMENTAL

Infrared spectra were measured as KBr or CsI discs or as Nujol mulls using a Perkin–Elmer 983G spectrometer over the range 180–4000 cm^{-1}. Mass spectra were run by positive electrospray (ES) using a VG Biotech Platform. ^1H NMR spectra were recorded using a Bruker AM300 spectrometer operating at 300 MHz. $^{31}P\{^1H\}$ NMR spectra were recorded in 10 mm o.d. tubes containing ca 10% deuterated solvent, using a Bruker AM360 spectrometer operating at 145.8 MHz and are referenced to external 85% H_3PO_4 [$\delta(^{31}P) = 0$]. Microanalyses were performed by the Imperial College microanalytical service. PCy_2H was purchased from Strem and PPh_2H was prepared by the literature procedure [13].

PREPARATIONS

trans-$[RhCl_2(PPh_2H)_4]PF_6$

$RhCl_3 \cdot 3H_2O$ (0.106 g, 0.40 mmol), PPh_2H (0.45 ml, 2.4 mmol) and a small excess of NH_4PF_6 (0.08 g,

0.5 mmol) were added to stirring, degassed EtOH (30 cm^3) under a N_2 atmosphere. This solution was stirred at room temperature for 1 day during which time a light yellow precipitate was deposited. This was collected by filtration, washed with Et_2O and dried *in vacuo* (Yield: 0.41 g, 95%). Calc. for $C_{48}H_{44}Cl_2F_6P_5Rh$: C = 54.2, H = 4.1%; Found: C = 53.8, H = 3.8%. Electrospray mass spectrum (MeCN): found $m/z = 883$, 847; Calc. for $[^{103}Rh^{35}Cl(PPh_2H)_4]^+$ $m/z = 882$, $[^{103}Rh(PPh_2H)_4]^+$ $m/z = 847$. $^{31}P\{^1H\}$ NMR spectrum ($CH_2Cl_2/CDCl_3$, 300 K): $\delta + 1.2$ (*d*, PPh_2H, 4P, $J_{RhP} = 83$ Hz), -146.3 (*spt*, PF_6^-, 1P). ^1H NMR spectrum (300 MHz, $CDCl_3$, 300 K): δ 7.1–7.4 (*m*, Ph), 5.7 (*m*, P*H*). IR spectrum (CsI disk): 3051 w, 2372 w, 1460 m, 1375 m, 1308 m, 1182 m, 1161 m, 1071 m, 923 m, 840 vs, 735 m, 557 s, 504 m, 477 w, 448 m, 420 w, 365 w cm^{-1}.

trans-$[RhCl_2(PCy_2H)_4]PF_6$

$RhCl_3 \cdot 3H_2O$ (100 mg, 0.38 mmol) dissolved in a minimum volume of H_2O was added to deoxygenated EtOH (20 cm^3). Excess PCy_2H (0.45 cm^3, 2.3 mmol) was added to the solution and the mixture was refluxed under N_2 for 3 h, yielding a yellow solution. Addition of excess NH_4PF_6 gave a yellow solid which was collected by filtration, washed with Et_2O and dried *in vacuo* (Yield: 0.22 g, 52%). Calc. for $C_{48}H_{88}Cl_2F_6P_5Rh$: C = 51.9, H = 8.3%; Found: C = 51.6, H = 8.1%. Electrospray mass spectrum (MeCN): found $m/z = 965$, 767; calculated for $[^{103}Rh^{35}Cl_2(PCy_2H)_4]^+$ $m/z = 965$, $[^{103}Rh^{35}Cl_2(PCy_2H)_3]^+$ $m/z = 767$. $^{31}P\{^1H\}$ NMR spectrum ($CH_2Cl_2/CDCl_3$, 300 K): δ -5.0 (*d*, PCy_2H, 4P, $J_{RhP} = 74$ Hz), -146.3 (*spt*, PF_6^-, 1P). IR spectrum (CsI disk): 2921 s, 2851 sm, 2362 w, 2321 w, 1460 m, 1375 m, 1290 w, 1263 w, 1226 w, 1199 w, 1175 w, 1075 m, 1048 w, 1002 m, 936 w, 920 w, 836 vs, 722 m, 559 s 513 wm 478 m, 449 w, 432 w, 389 w, 343 m, 281 w cm^{-1}.

X-RAY CRYSTALLOGRAPHY

$[(PPh_2OH)(PPh_2O)Cl(NCMe)Rh(\mu\text{-}Cl)_2Rh(PPh_2OH)(PPh_2O)Cl(NCMe)] \cdot 2thf$

Yellow, columnar crystals of $[(PPh_2OH)(PPh_2O)Cl(NCMe)Rh(\mu\text{-}Cl)_2Rh(PPh_2OH)(PPh_2O)Cl(NCMe)] \cdot 2thf$ were obtained from a solution of *trans*-$[RhCl_2(PPh_2H)_4]PF_6$ in MeCN/thf. The selected crystal ($0.30 \times 0.20 \times 0.15$ mm) was coated with mineral oil and mounted on a glass fibre under a cold stream of N_2 gas.

Crystal data. $C_{60}H_{56}Cl_4N_2O_6P_4Rh_2$, $M = 1372.6$, triclinic, space group P_1 (#2), $a = 13.056(2)$, $b = 13.920(3)$, $c = 9.276(4)$ Å, $\alpha = 107.50(2)$, $\beta = 100.50(2)$, $\gamma = 103.32(2)^\circ$, $V = 1504.4(8)$ Å^3 [from 2θ values of 20 reflections measured at $\pm\omega$], $\lambda = 0.71073$ Å, $Z = 1$, $D_{calc} = 1.515$ g cm^{-3}, $\mu = 8.82$ cm^{-1}, $F(000) = 696$.

Data collection and processing. Data collection used a Rigaku AFC7S diffractometer equipped with an Oxford Systems cryostream operating at 150 K, using graphite monochromated Mo-K_α radiation, (ω-2θ scan technique), 5542 data collected ($2\theta_{max}$ 50.0°), 5290 unique data ($R_{int} = 0.063$ based on F^2). As there were no identifiable faces an empirical absorption correction was applied using ψ-scans (min. and max. transmission factors were 0.738 and 1.000 respectively).

Structure solution and refinement. The structure was solved by direct methods [14] and expanded using Fourier techniques to locate all non-H atoms in the half-molecule in the asymmetric unit (related to the other half by a centre of symmetry) [15]. During refinement one fully occupied THF solvent molecule was also identified in the asymmetric unit. All non-H atoms were refined anisotropically and hydrogen atoms were included in fixed calculated positions [with d(C—H) = 0.96 Å] but not refined. The H atom associated with the PPh_2OH ligands was located in the difference map and included but not refined. The final cycle of full-matrix least-squares refinement (on *F*) was based on 2859 observed reflections with ($I > 2.5\sigma(I)$) and 352 variable parameters and converged with $R = 0.053$, R_w 0.059, using the weighting scheme $w^{-1} = \sigma^2(F)$. The maximum residual peak and minimum residual trough corresponded to $+1.33$ and -1.45 eÅ^{-3}. Selected bond lengths and angles are given in Table 1.

$[(PPh_2OH)_2(PPh_2O)Rh(\mu\text{-}Cl)_3Rh(PPh_2OH)(PPh_2O)_2]$

Orange prisms of $[(PPh_2OH)_2(PPh_2O)Rh(\mu\text{-}Cl)_3Rh(PPh_2OH)(PPh_2O)_2]$ were obtained from a solution of $RhCl_3 \cdot 3H_2O$ (0.094 g, 0.36 mmol) and three molar equivalents of PPh_2H (1.08 mmol) in EtOH (20 cm^3), which was refluxed for one hour to give an organge solution, and then maintained at ca -15°C over several days. The selected crystal ($0.55 \times 0.40 \times 0.30$ mm) was coated with mineral oil and mounted on a glass fibre under a cold stream of N_2 gas.

Crystal data. $C_{72}H_{63}Cl_3O_6P_6Rh_2$, $M = 1522.30$, orthorhombic, space group F_{ddd}, $a = 25.861(6)$, $b = 43.002(5)$, $c = 23.924(5)$ Å, $V = 26605(7)$ Å^3 [from 2θ values of 20 reflections measured at $\pm\omega$], $\lambda = 0.71073$ Å, $Z = 16$, $D_{calc} = 1.520$ g cm^{-3}, $\mu = 8.13$ cm^{-1}, $F(000) = 12384$.

Data collection and processing. Data collection used a Rigaku AFC7S diffractometer equipped with an Oxford Systems cryostream operating at 150 K, using graphite monochromated Mo-K_α radiation. Using the ω scan technique 6235 data were collected ($2\theta_{max}$ 50.0°). As there were no identifiable faces an empirical absorption correction was applied using ψ-scans (min.

and max. transmission factors were 0.910 and 1.000 respectively).

Structure solution and refinement. The structure was solved by direct methods [14] and expanded using Fourier techniques to locate all non-H atoms in the half-molecule in the asymmetric unit (related to the other half by a crystallographic two-fold axis) [15]. The Rh, Cl, P and O atoms were refined anisotropically and hydrogen atoms were included in fixed calculated positions [with d(C—H) = 0.96 Å] but not refined. The H atoms associated with the PPh_2OH ligands were not located in the difference map, and were therefore omitted from the final structure factor calculation. The final cycle of full-matrix least-squares refinement (on F) was based on 2461 observed reflections with ($I > 2.5\sigma(I)$) and 222 variable parameters and converged with $R = 0.076$, R_w 0.104, using the weighting scheme $w^{-1} = \sigma^2(F)$. The maximum residual peak and minimum residual trough corresponded to +2.19 (attempts were made to refine this as a partially occupied O atom e.g. from a H_2O solvent molecule, but without success) and −0.78 e $Å^{-3}$. Selected bond lengths and angles are given in Table 2.

Atomic coordinates, anisotropic thermal parameters and bond lengths and angles for the two structures have been deposited at the Cambridge Crystallographic Data Centre (CCDC).

Acknowledgements—We thank the EPSRC for a studentship (S.J.A.P.) and for provision of the X-ray diffractometer. We also thank Johnson Matthey plc for loans of $RhCl_3 \cdot 3H_2O$.

(Received 12 May 1997; accepted 10 November 1997)

Abstract—On heating, milling and sonication, cadmium ferricyanide decomposes and reduces to cadmium ferrocyanide. Two compositions were studied, pure cadmium ferricyanide and mixed potassium–cadmium ferricyanide. The role of reducing agent is played by the CN^- anions liberated during the decomposition process. The solid decomposition product is composed by several phases of cadmium ferrocyanide, an Fe^{3+} phase and also potassium ferrocyanide in the case of the mixed complex salt. The decomposition process was monitored using DTA, XRD, IR and Mössbauer techniques. No occurrence of linkage isomerization in cadmium ferricyanide was detected. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: cadmium ferricyanide; reducing agent; decomposition.

Transformation of hexacyanometallates through linkage isomerization was predicted and observed approximately 30 years ago [1–3]. The phenomena have been well established for ferrous chromicyanide and manganicyanide which transform spontaneously into the corresponding ferrocyanides [2–5]. The change in the structural chain M—NC—M′ can be envisaged as a flipping of the CN ligands through an unstable intermediate ferric salt produced by an electron transfer which reduces the inner cation to Cr^{II} and Mn^{II} [5]. Other results such as the isomerization of cobaltous chromicyanide [2] and silver cobalticyanide [6] have been contested [5,7]. House *et al.* have reported the isomerization of $KCd[Fe(CN)_6]\cdot 5H_2O$ on heating at above 110°C [8] and on sonication [9]. In this report we present evidence that $Cd_3[Fe(CN)_6]_2\cdot 12H_2O$ and $KCd[Fe(CN)_6]\cdot 5H_2O$ undergo reduction to ferrocyanides when heated, milled or sonicated, without linkage isomerization. The processes were followed by DTA, XRD, IR and Mössbauer techniques.

EXPERIMENTAL

Cadmium ferricyanide was prepared in two different compositions: $Cd_3[Fe(CN)_6]_2\cdot 12H_2O$ and $KCd[Fe(CN)_6]\cdot 5H_2O$; in the following, $Cd_3Fe_2^{III}$ and $KCdFe^{III}$, respectively. The former composition was obtained mixing five-fold excess of cadmium chloride with potassium ferricyanide as aqueous solutions. The precipitate was filtered, washed several times with distilled water and dried in a desiccator over silica gel. $KCdFe^{III}$ was prepared in the same manner but using a large excess of potassium ferricyanide. By the same procedure cadmium ferrocyanide ($Cd_2[Fe(CN)_6]\cdot xH_2O$) and mixed potassium–cadmium ferrocyanide ($CdK_2[Fe(CN)_6]\cdot xH_2O$), which we will label Cd_2Fe^{II} and CdK_2Fe^{II}, were also prepared. In the preparation of Cd_2Fe^{II} and CdK_2Fe^{II}, ferrocyanic acid and potassium ferrocyanide, respectively, were used. Mixed potassium–cadmium ferrocyanide was also obtained by mechanochemical reduction of $Cd_3Fe_2^{III}$ and $KCdFe^{III}$ by milling with KBr [10,11]. These last two complexes together with manganous ferrocyanide ($Mn_2[Fe(CN)_6]\cdot 8H_2O$), in the following Mn_2Fe^{II}, were used as reference compounds. The preparation of Mn_2Fe^{II} is reported elsewhere [12]. The compositions

suggested by the above abbreviations were confirmed by chemical analysis. Hydration degree was determined using thermogravimetry.

The nature and transformations of $Cd_3Fe_2^{III}$, $KCdFe^{III}$, Cd_2Fe^{II}, CdK_2Fe^{II} and Mn_2Fe^{II} were followed by IR spectroscopy in Nujol mulls between CaF_2 plates and in KBr disks, using an ATI Mattson (Genesis Series) FT-IR spectrometer, in the frequency range of 4000–400 cm^{-1}. The structural characterization was performed through XRD with monochromated CuK_α and CoK_α radiations in a HZG-4 diffractometer (Carl Zeiss). Thermal analysis was carried out in a MOM Q-1500 equipment.

The Mössbauer spectra were recorded at room temperature with a Co^{57} in Rh source, using a constant acceleration spectrometer (from Mosstec). All spectra were fitted using an iterative least-squares minimisation algorithm and pseudo-Lorentzian line shapes to obtain the values of isomer shift (δ), quadrupole splitting (Δ), linewidth (Γ) and relative area (A). The isomer shift values are reported relative to sodium nitroprusside.

Isothermal heating of samples was carried out in air in the temperature range of 100–150°C using a sand-bath regulated at ± 3°C and heating times from some minutes to 100 h. Samples were also heated in vacuum at a pressure of 10^{-6} Torr. Irradiation with microwaves was performed using a domestic oven (from Sanyo) operated at 500 watts. For sonication experiments 0.1 g of sample was mixed with 20 ml of dioxane in a glass container and then irradiated up to 2 h using a laboratory ultrasound apparatus (homemade). The effect of milling on the compounds was studied grinding the samples at room temperature and at 80°C in an agate mortar. Samples were also milled in a micronizer (ZM-1 Retsch) at 20,000 rpm.

RESULTS AND DISCUSSION

Characterization of the initial compounds and standards

As far as we know, the crystalline structure of Cd_2Fe^{II} and CdK_2Fe^{II} have not been previously reported. We have found these compounds tetragonal and orthorhombic, respectively, their crystal data are given in Tables 1 and 2. Some of the reported XRD powder patterns for cadmium ferrocyanide [13–15] can be indexed using these two unit cells. The structural refinement of these compounds will be reported elsewhere. According to their XRD powder patterns, both $Cd_3Fe_2^{III}$ and $KCdFe^{III}$ crystallise in the fcc crystal cell (Fm3m) of Prussian Blue analogs [16–18] with slightly different cell edges (a_0); see Fig. 1a. As the structural model for $Cd_3Fe_2^{III}$ can be used, the reported structure for divalent transition metal hexacyanometallates(III) [19–26], where 33% of the complex anions positions are left vacant. The vacant sites are occupied by water molecules which replace some CN ligands of the outer Cd^{2+} cations. The structure of $KCdFe^{III}$ has a cubic framework of Fe^{III}—CN—Cd^{2+} chains with potassium cations occupying half of the small cubic voids of the network, similar to that of soluble Prussian Blue $KFe[Fe(CN)_6]\cdot xH_2O$ [17].

The IR spectra of Cd_2Fe^{II} and CdK_2Fe^{II}, both in anhydrous and hydrated forms, are similar, with a strong ν(CN) band at 2063 cm^{-1} and a weak band at 2030 cm^{-1}; see Fig. 2a and Table 3. The origin of that weak band at 2030 cm^{-1} will be discussed below. Their δ(Fe—C≡N) and ν(Fe—C) vibrations fall at 595 cm^{-1} and 450 cm^{-1}, respectively. The IR spectra of $Cd_3Fe_2^{III}$ and CdK_2Fe^{III} are also similar with ν(CN), δ(Fe—C≡N) and ν(Fe—C) at 2152 cm^{-1}, 528 cm^{-1} and 415 cm^{-1}, respectively; see Fig. 2b and Table 3.

Mössbauer spectra of Cd_2Fe^{II} and CdK_2Fe^{II} are single lines, while for $Cd_3Fe_2^{III}$ and $KCdFe^{III}$ they are quadrupole doublets, see Fig. 3 and Table 4. No sig-

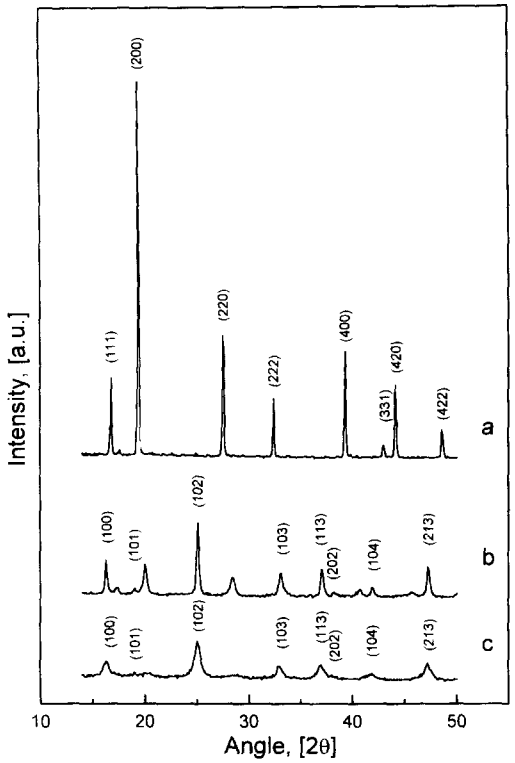

Fig. 1. XRD powder patterns of (a) cadmium ferricyanide; (b) cadmium ferricyanide heated for 50 h in air at 120°C; (c) cadmium ferricyanide milled for 2 h in agate mortar at 80°C. The decomposition products (b) and (c) are of low crystallinity, however their main reflections correspond to $Cd_2[Fe(CN)_6]\cdot xH_2O$.

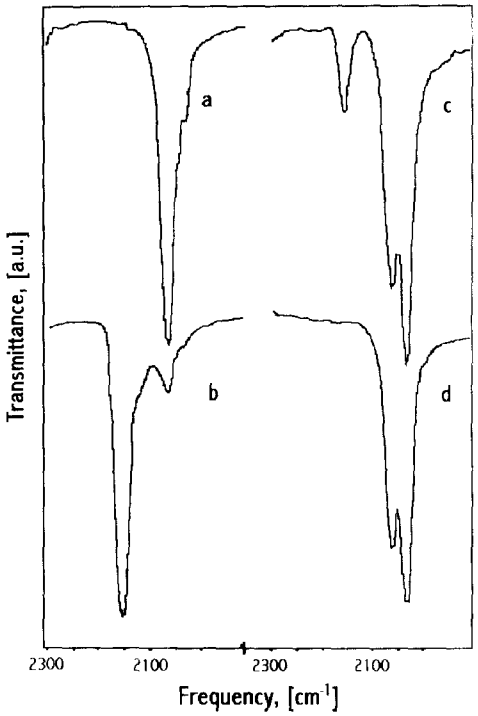

Fig. 2. IR spectra (CN stretching region) of (a) cadmium ferrocyanide; (b) cadmium ferricyanide with impurities of cadmium ferrocyanide; (c) cadmium ferricyanide heated for 20 h in air at 120°C; (d) cadmium ferricyanide heated for 50 h in air at 120°C.

nificant differences in Mössbauer parameters between pure and mixed salts are observed.

Transformations of $Cd_3[Fe(CN)_6]_2\cdot 12H_2O$

We have carried out a parallel study of the two compositions of cadmium ferricyanide. With minor differences, which will be discussed below, their behaviour on the different treatments is similar. In the following we will discuss in detail the results concerning $Cd_3Fe_2^{III}$ which is a simple salt.

Isothermal and microwave heating

When $Cd_3Fe_2^{III}$ samples are isothermally heated above 100°C, chemical processes take place. Thermal analysis shows an endothermic effect with loss of weight due to a dehydration process, which begins at about 70°C, followed at a higher temperature by a strong exothermic peak with its maximum at 150°C. Most ferricyanides decompose on heating with initial reduction as the first step, with loss of CN ligands. The free CN^- reduces the ferricyanide to ferrocyanide and at the end an oxidised phase of Fe^{3+} remains [27–32]. The heated product shows a decrease in the intensity of the 2152 cm^{-1} band until its total disappearance. New bands appear at 2063 cm^{-1} and 2030 cm^{-1}; see Fig. 2c,d and Table 3. The 2063 cm^{-1} band corresponds to Cd_2Fe^{II}. When the heating is performed in vacuum, the 2030 cm^{-1} is the main band in the decomposition product. Equal result is obtained by microwave heating; see Fig. 4a,b. Four bands at 611 cm^{-1}, 595 cm^{-1}, 456 cm^{-1} and 450 cm^{-1} appear in the low frequency region ; see Fig. 5b. The bands at 595 cm^{-1} and 450 cm^{-1} correspond to δ(Fe—C≡N) and ν(Fe—C) vibrations of Cd_2Fe^{II}. Since the pair at 611cm^{-1} and 456 cm^{-1} is dominant when the band at 2030 cm^{-1} is the most intense CN vibration (samples heated in vacuum), obviously these three bands can be assigned to a reduction product, which we interpreted as an anomalous cadmium ferrocyanide phase; in the following labelled as $Cd_2Fe^{II}(A)$. The well defined set of ν(CN), δ(Fe—C≡N) and ν(Fe—C) vibration modes supports the interpretation of that anomalous species as a metal hexacyanometallate.

XRD powder patterns confirm the decomposition of $Cd_3Fe_2^{III}$ on heating and the formation of products of low crystallinity; see Fig. 1. Samples with strong IR absorption bands at 2063 cm^{-1} and 2030 cm^{-1} have XRD powder patterns which can be interpreted

Table 3. ν(CN) frequencies of some selected samples of cadmium hexacyanoferrates and manganous ferrocyanide

as normal Cd_2Fe^{II} (see Fig. 1b and Table 1) and minor diffraction peaks of non-identified decomposition products, probably phases of Fe^{3+} and Cd^{2+}. According to these results, Cd_2Fe^{II}(A) is amorphous since in spite of being the majority phase it does not produce an XRD powder pattern.

Mössbauer spectra of totally reduced $Cd_3Fe_2^{III}$ samples can be fitted as a superposition of two quadrupole doublets plus a singlet; see Fig. 3c and Table 4. According to its isomer shift value ($\delta = 0.16$ mm/s) the singlet was assigned to normal Cd_2Fe^{II}. The doublet with larger Δ value has an isomer shift ($\delta = 0.61$ mm/s) typical of high spin Fe^{3+} [33,34]. This ferric phase results from the decomposition process of $Cd_3Fe_2^{III}$ on heating. The other doublet with $\delta = 0.08$ mm/s and $\Delta = 0.20$ mm/s was assigned to Cd_2Fe^{II}(A). The high spin Fe^{3+} phase was not identified because it does not produce a reliable XRD pattern. However, it is probably a ferric oxide phase with very low particle size, which is in accordance with its Mössbauer spectra. Fe^{3+} oxide and oxihydroxide of low particle size have Mössbauer spectra at room temperature consisting in broad doublets due to their superparamagnetic behaviour [35–38].

Effect of mechanical milling and irradiation with ultrasound

Mechanical milling in an agate mortar or in a micronizer has the same effect on $Cd_3Fe_2^{III}$ that heating. In this process the rupture of metal–ligand bonds takes place induced by the mechanical deformation originated in the milling process and/or by the local heating generated in the colliding points of the crystals [39–41]. When the grinding is carried out at room temperature, to reach a 100% decomposition one must mill several hours in the agate mortar and always the resulting product shows the two CN absorption bands at 2063 cm^{-1} and 2030 cm^{-1} with approximately the same intensity. However, if the grinding process is performed at above 70°C the decomposition is fast with formation of mainly the Cd_2Fe^{II}(A) species with CN band at 2030 cm^{-1}; see Fig. 4c.

By hot-milling it is possible to obtain a decomposition product of $Cd_3Fe_2^{III}$ practically free of normal Cd_2Fe^{II}. A typical XRD powder pattern of totally reduced $Cd_3Fe_2^{III}$ sample by milling is shown in Fig. 1c. In that pattern the diffraction peaks corresponding to normal Cd_2Fe^{II} are weak and broaded. The

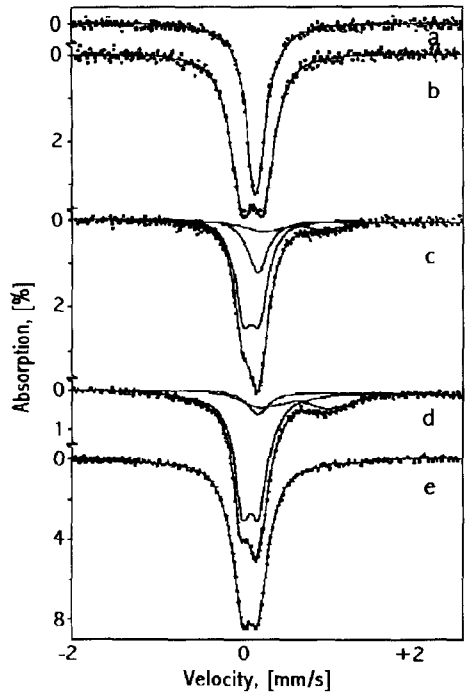

Fig. 3. Mössbauer spectra at room temperature of (a) cadmium ferrocyanide; (b) cadmium ferricyanide; (c) cadmium ferricyanide heated for 50 h in air at 120°C; (d) cadmium ferricyanide milled for 2 h in an agate mortar at 80°C; (e) anhydrous manganous ferrocyanide obtained by vacuum dehydration at 140°C.

observed broadening of the diffraction peaks can be explained as due to the preparation method. The milling process produces a material with very low particle size and deformed micro-crystals. In the Mössbauer spectra of hot-milled $Cd_3Fe_2^{III}$ samples it is also dominant the doublet corresponding to $Cd_2Fe^{II}(A)$ with about a 70% of the relative area and only a contribution of about a 9% from normal Cd_2Fe^{II}; see Fig. 3d and Table 4. The low frequency region of IR spectra is simple with the absorption bands corresponding to δ(Fe—C≡N) and ν(Fe—C) at 612 cm^{-1} and 455 cm^{-1}, respectively.

Irradiation with ultrasound in essense is similar to mechanical milling [42]. When a slurry of crystalline material is sonicated the collapse of acoustic bubbles originates the collision of particles at high speed causing their fracture [43–45] and probably also an increase of the local temperature. Our results of sonication of $Cd_3Fe_2^{III}$ samples reproduce those previously reported for $KCdFe^{III}$ submitted to similar treatment [9]. On sonication $Cd_3Fe_2^{III}$ decomposes but the decomposition product is practically free of $Cd_2Fe^{II}(A)$; see Fig. 5d and Table 3. However, we interpreted the absorption at 2063 cm^{-1} as due to normal ferrocyanide and not as occurrence of linkage isomerization in $Cd_3Fe_2^{III}$, as reported by House *et al.* [9]. With ultrasound the decomposition rate is low and even after several hours of treatment in the IR spectra of sonicated $Cd_3Fe_2^{III}$ samples the most intense band falls at 2152 cm^{-1}, corresponding to the starting compound. The absence of $Cd_2Fe^{II}(A)$ in this process could be related with that low decomposition rate. In contrast, heating and milling are more drastic processes which favour the formation of amorphous phases, like $Cd_2Fe^{II}(A)$.

Decomposition products of $CdK[Fe(CN)_6]\cdot 5H_2O$

Mixed potassium–cadmium ferrocyanide decomposes by reduction as does the pure cadmium complex ($Cd_3Fe_2^{III}$) when it is submitted to the above discussed processes. However, in the case of $CdKFe^{III}$ the IR spectra of the decomposition product are very complex with new absorption bands in the range of 2020–2100 cm^{-1}. When this product is washed with water the solid precipitate shows the CN absorption bands characteristic of the two species of Cd_2Fe^{II} while from the filtrate potassium ferrocyanide, $K_4[Fe(CN)_6]$ which we will label KFe^{II}, can be crystallised by evaporation. Potassium ferrocyanide in its anhydrous form has six CN absorption bands at 2027, 2042, 2047, 2064, 2071 and 2093 cm^{-1} [46,47]. This explains why in the IR spectra of decomposed $CdKFe^{III}$ several additional CN absorption bands are observed. During the decomposition of $CdKFe^{III}$ the formation of anhydrous KFe^{II} also takes place. The formation of single complex salts from mixed hexacyanoferrates is also observed in oxidation processes of hexacyanometallates in solid state [12].

XRD corroborates the IR results. In XRD powder patterns of decomposed $CdKFe^{III}$ samples diffraction peaks of KFe^{II} and normal Cd_2Fe^{II} can be detected. Similar information is derived from the Mössbauer spectra where also the doublet corresponding to $Cd_2Fe^{II}(A)$ is observed.

Another important peculiarity of the decomposition process of $CdKFe^{III}$ compared with $Cd_3Fe_2^{III}$ is related with their decomposition rate. Parallel heating of $Cd_3Fe_2^{III}$ and $CdKFe^{III}$ samples shows that the mixed complex presents higher stability. This could be explained by the role of crystallisation water. In alkali ferricyanides hydration water catalyses the decomposition process [31]. This fact could also explain the higher stability observed for $Cd_3Fe_2^{III}$ when it is heated in vacuum or by microwave irradiation compared with its conventional heating in air.

On the nature of anomalous cadmium ferrocyanide

In a first attempt to understand the nature of $Cd_2Fe^{II}(A)$, normal Cd_2Fe^{II} was submitted to the above discussed processes (heating, milling and sonication), however, no significant changes were observed in its IR and Mössbauer spectra; see Tables 3 and 4.. Since $Cd_2Fe^{II}(A)$ is amorphous, Cd_2Fe^{II} was

Table 4. Mössbauer parameters at room temperature of some selected samples of cadmium hexacyanoferrates and manganous ferrocyanide

Starting compound	Sample history	δ^a	Δ	Γ	A	Assignment
		(%)	(mm/s)

amorphized by very prolonged milling but the resulting amorphous Cd_2Fe^{II} has IR and Mössbauer spectra very different to those observed for Cd_2Fe^{II}(A). The CN absorption of amorphous Cd_2Fe^{II} is a broad band at 2063 cm^{-1}; see Fig. 6a. The milling process partially removes the degeneration of the allowed F_{1u} triplet [17,48,49] which is observed as a broadening in the CN

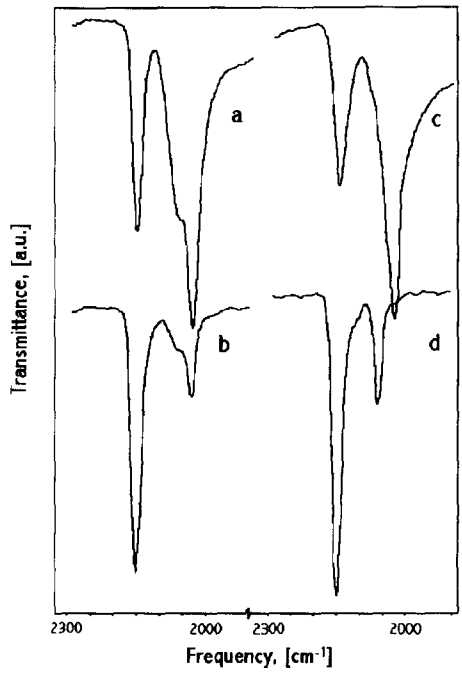

Fig. 4. IR spectra (CN stretching region) of cadmium ferricyanide (a) heated for 20 h in vacuum at 140°C; (b) irradiated with microwaves for 1 h at 500 watts; (c) milled for 30 min in agate mortar at 80°C; (d) sonicated for 1 h at room temperature.

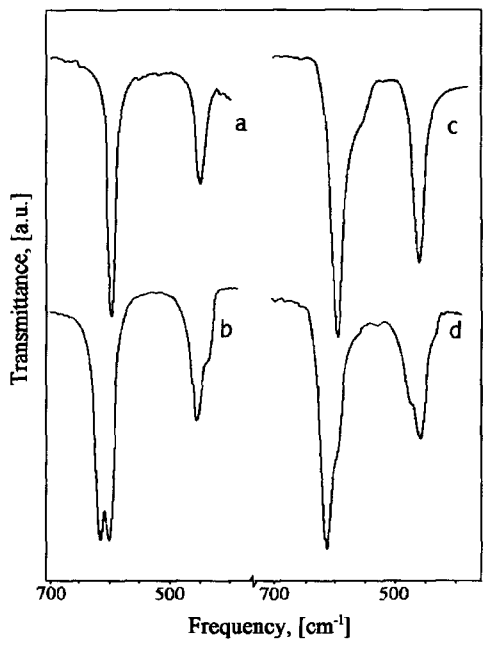

Fig. 5. IR spectra (low frequency region) of (a) cadmium ferrocyanide; (b) cadmium ferricyanide heated for 50 h in air at 120°C; (c) manganous ferrocyanide hydrate; (d) partially dehydrated manganous ferrocyanide (mixture of anhydrous and hydrated phases).

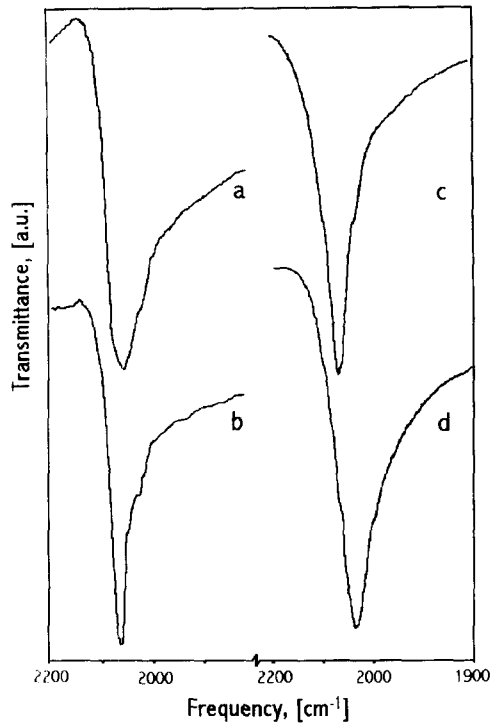

Fig. 6. IR spectra (CN stretching region) of (a) amorphous cadmium ferrocyanide (obtained by prolonged milling of ordered cadmium ferrocyanide); (b) cadmium ferrocyanide pyrolized for 1 h in vacuum at 400°C; (c) manganous ferrocyanide hydrate; (d) anhydrous manganous ferrocyanide.

absorption. The Mössbauer spectra of this amorphous Cd_2Fe^{II} can be fitted as a broad singlet or an unresolved doublet (see Table 4) which is also different to the resolved doublet observed for $Cd_2Fe^{II}(A)$.

An insight to the nature of $Cd_2Fe^{II}(A)$ can be obtained by comparing to the behaviour of manganous ferrocyanide. When Mn_2Fe^{II} is dehydrated the ν(CN) band changes from 2066 cm^{-1} to 2032 cm^{-1}; see Fig. 6c,d. This frequency shift of 34 cm^{-1} is analogous to that observed in Cd_2Fe^{II} species, of 32 cm^{-1}. The analogy is also valid for the low frequency region where the frequency shift of δ(Fe—C≡N) and ν(Fe—C) vibrations of Mn_2Fe^{II} on dehydration is 16 cm^{-1} and 5 cm^{-1}, respectively, similar to the corresponding shift observed in Cd_2Fe^{II} species; see Fig. 5c,d. In the structure of Mn_2Fe^{II} the structural $Mn_2[Fe(CN)_6]$ units are linked by three water molecules and three CN ligands [50]. On dehydration the water bridges are eliminated and these structural units remain linked by only three CN ligands, resulting in a complex where a 50% of the Fe^{II}—CN—Mn^{2+} chains are unlinked. From this point of view, $Cd_2Fe^{II}(A)$ can be imaged as a complex with many Fe^{II}—CN—Cd^{2+} chains unlinked. This picture is in accordance with the observed release of CN^- ligands during the decomposition process of $Cd_3Fe_2^{III}$ and with the amorphous character of the resulting $Cd_2Fe^{II}(A)$. A random loss of CN^- ligands must destroy the skeletal structure of the complex giving an amorphous material. The Mössbauer results also support this hypothesis. The Mössbauer spectrum of hydrated manganous ferrocyanide is a single absorption line typical of metal ferrocyanide [51–53] while in its anhydrous state the Mössbauer absorption is a doublet with δ and Δ values close to those found for $Cd_2Fe^{II}(A)$ [35]; see Fig. 2e and Table 4. The value of $\Delta \neq 0$ in this case is sensing an asymmetrical environment for Fe^{II} (lattice contribution) since low spin ferrous cation does not have electronic contribution to Δ [34,35].

Metal ferrocyanides decompose at higher temperature than the corresponding ferricyanides but also lossing CN ligands. From this fact $Cd_2Fe^{II}(A)$ could be obtained pyrolizing $CdFe^{II}$ in vacuum. When Cd_2Fe^{II} was pyrolized in vacuum above 400°C, in the resulting product appears the CN absorption at 2030 cm^{-1}, characteristics of $Cd_2Fe^{II}(A)$; see Fig. 6b.

Anomalous metal ferrocyanides are also observed in decomposition products of other metal hexacyanoferrates (II and III). A detailed study of these anomalous complexes is now in progress.

Expected Mossbauer and IR spectra for isomerized cadmium ferricyanide

Cd^{2+} forms di- and tetracyano complexes with CN ligands [17,54,55]. In consequence, a maximum of two thirds of the Fe^{3+}—CN—Cd^{2+} chains could be converted to Fe^{3+}—NC—Cd^{2+}. In an isomerized cadmium ferricyanide Fe^{3+} cations must have a mixed coordination sphere formed by four N and two C of CN ligands. Since Fe^{3+} forms low spin complexes when coordinated with CN ligands at the C end and adopts the high spin electronic configuration when the coordination takes place at the N end [34,56–60], there are two possibilities for Fe^{3+} cation in an isomerized cadmium ferricyanide: it remains in low spin state or it passes to the high spin configuration. In both possibilities the Mössbauer spectra of the isomerized species and of the initial compounds must be very different. In the former possibility a larger quadrupole splitting must be expected since in addition to the electronic contribution to the value of Δ now a lattice contribution is also present (due to the mixed coordination sphere). In the second possibility the most significant variation must be observed in the value of δ, changing from about 0.10 mm/s for the low spin configuration to about 0.64 mm/s in the high spin one [59–61].

The changes in IR spectra on isomerization of cadmium ferricyanide must also be significant and very different from those reported for thermal-treated and sonicated $KCdFe^{III}$ samples [8,9]. In $KCdFe^{III}$ or $Cd_3Fe_2^{II}$ the symmetry around the central cation (Fe^{3+}) is O_h type and only a CN absorption band is observed (degenerated F_{1u} vibrational state) but in

partially isomerized samples the point symmetry around the new central cation (Cd^{2+}) will be C_{4v} or less; in consequence the degeneration must be removed and several CN absorption bands will be observed [48,62]. Furthermore, the CN absorption corresponding to the chains Fe^{3+}—NC—Cd^{2+} must fall above 2140 cm^{-1} since this is the frequency of the anion $[Cd(CN)_4]^{2-}$ [48]. Isomerized cadmium ferricyanide should present a CN triplet near 2160 cm^{-1} [63,64].

The processes which take place in heated and sonicated cadmium ferricyanides are the normal decomposition and reduction observed in metal ferricyanides and not linkage isomerization as reported [8,9].

CONCLUSIONS

When cadmium ferricyanide or mixed potassium–cadmium ferricyanide are heated in air or in vacuum above 100°C, or irradiated with microwaves or ultrasound, or milled in a mortar or in a micronizer, the decomposition of these compounds take place with formation of several phases of cadmium ferrocyanide. In this transformation the role of reducing agent is played by the CN^- anions liberated in the decomposition process. The CN absorption bands at 2030 cm^{-1} and at 2063 cm^{-1} in the decomposition products are assigned to anomalous and normal cadmium ferrocyanides, respectively. The appearance of these two CN absorptions cannot be interpreted as occurrence of a linkage isomerization process in cadmium ferricyanide when this compound is heated or sonicated as have been reported [8,9].

(Received 6 August 1997; accepted 27 October 1997)

Abstract—The enthalpies of protonation of 12-(2′-hydroxy-5′-bormo-benzyl)-1,4,7,10-tetraazacyclotridecane-11,13-dione(HBTADO) have been determined in aqueous solution at 25.0 ± 0.1°C and ionic strength 0.1 mol dm^{-3} KNO_3 by means of model RD-1 automatic conduction calorimeter. The enthalpies of coordination of the binary complex compounds of this ligand with copper(II) and the ternary complex compounds of this ligand copper(II)-5-substituted 1,10-phenanthrolines have also been determined under identical conditions of the ternary complex compounds of the type Cu(II)-α-aminoacids-HBTADO have been evaluated through "overall calculation". Linear enthalpy relationships, linear enthalpy-entropy relationships have been found to exist between the enthalpies of formation of ternary complex compounds Cu(II)-R′Phen-HRTADO and the enthalpies, entropies of protonation of ligands HRTADO. In addition, linear enthalpy relationships have been found to exist between the enthalpies of formation of ternary complex compounds Cu(II)-α-aminoacids-HRTADO and the enthalpies of formation of binary complex compounds $Cu(II)H_{-1}A$ and linear entropy relationships have been found to exist between the entropies of formation of ternary complex compounds Cu(II)-α-aminoacids-HRTADO and the entropies of formation of binary complex compounds $Cu(II)H_{-1}A$.

Keywords: enthalpy of protonation; enthalpy of coordination; HBTADO.

Macrocyclic oxopolyamines are unique metal chelators, their structure bearing the dual features of macrocyclic polyamines and oligopeptides [1–4]. Because of their important biological functions and some unusual properties, oxopolyamines have been extensively studied, and structural features for their biological significance are well recognized [1–11]. A calorimetric study of the coordination reaction in aqueous solution for these macrocyclic dioxotetraamines with metal ions can provide useful information, in particular, in understanding the high stability of these complex compounds formed from these macrocyclic polyamines with metal ions arises from enthalpy effect or entropy effect and if Linear Enthalpy Relationships (LERs) exist in these systems. In previous papers [12–15], we reported the calorimetric measurements of the enthalpies of protonation of 12-(2′-hydroxy-3′,5′-dibromobenzyl)-1,4,7,10-tetraazacyclo-tridecane-11,13-dione (HDBTADO), 12-(2′-hydroxy-benzyl)-1,4,7,10-tetraazacyclotridecane-11,13-dione(HTADO), 12-(2′-hydroxy-3′-methoxy-benzyl)1,4,7,10-tetraazacyclotridecane-11,13-dione(HMTADO), 1,4,7,10-tetraazacyclo-

tridecane-11,13-dione(TADO) and of the enthalpies of coordination of the bianary complex compounds of Cu(II)-HDBTADO, -HTADO, -HMTADO and -TADO and of the ternary complex compounds of Cu(II)-5-substituted phenanthrolines(R′Phen)-HDBTADO, -HTADO, -HMTADO and -TADO and of Cu(II)-α-aminoacids-HDBTADO, -HTADO, -HMTADO and -TADO. In order to understand how the substituents of benzyl of these macrocyclic dioxotetraamines with pendant group influence their enthalpies of coordination and entropies of coordination, in this paper, we report the study on the thermodynamical properties of protonation of 12-(2′-hydroxy-5′-bromo-benzyl)-1,4,7,10-tetraazacyclotridecane-11,13-dione(HBTADO) and of coordination of its binary complex compounds with Cu(II) as well as its ternary complex compounds with Cu(II)-R′Phen and Cu(II)-α-aminoacids.

THEORETICAL

The two amido groups in macrocyclic dioxotetraamines are equivalent upon coordination to a 3d metal ion and both are deprotonated simultaneosly [11]. The following two eqns (1) and (2) must be considered in addition to those eqns for the calculation reported earlier [16].

$$Cu + A = CuH_{-2}A + 2H$$

$$\beta_{CuH_{-2}A} = [CuH_{-2}A][H]^2/[Cu][A] \quad (1)$$

$$Cu + A = CuH_{-1}A + H$$

$$\beta_{CuH_{-1}A} = [CuH_{-1}A]/[Cu][A] \quad (2)$$

where A denotes HBTADO; H denotes hydrogen ion. Charges omitted for clarity.

EXPERIMENTAL

HBTADO was prepared and its structure determined by means of elemental analysis, IR, NMR and MS as reported earlier [17]. The rest of all chemical reagents, the experimental conditions were reported previously [12]. The methods for the measurement of all heat effects were the same as reported previously [16]. A model RD-1 automatic conduction calorimeter with a precision of ±0.5% has been used to measure the heat effect [18].

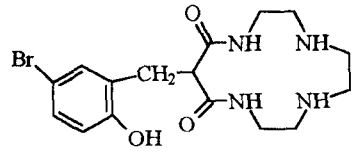

Fig. a.

RESULTS AND DISCUSSION

The experimental results of the protonation study of ligand HBTADO are presented in Table 1. The values of the enthalpies of coordination of the binary systems Cu(II)-HBTADO and of the ternary systems Cu(II)-R′Phen-HBTADO and Cu(II)-α-aminoacids-HBTADO are collected in Tables 2, 3, and 4, respectively. Thermodynamic functions of coordination of binary systems Cu(II)-HRTADO(12-(2′-hydroxy-3′,5′-substituted benzyl)-1,4,7,10-tetraazacyclotridecane-11,13-dione) (and of protonation of ligands HRTADO) and ternary systems Cu(II)—R′Phen-HRTADO and Cu(II)-α-aminoacids-HRTADO are summarized in Tables 5, 6 and 7, respectively.

As can be seen from Table 1, the enthalpy of first protonation ligand HBTADO, i.e., the enthalpy of coordination of proton to oxygen atom of pendant group, is -29.3 ± 0.2 kJ mol^{-1}. This value is slightly larger than that of phenol, -25.5 kJ mol^{-1} [19]. As can be seen from Table 2, the enthalpies of coordination of binary complex compounds $CuH_{-2}A$ and $Cu(II)H_{-1}A$ are -12.7 ± 0.2 and -13.8 ± 0.5 kJ mol^{-1}, respectively.

These values are negative, indicating that the overall enthalpy effects of coordination of Cu(II) to ligand HBTADO are exothermic. Because the coordination of Cu(II) with the four nitrogen atoms of the HBT-

Fig. c.

ADO ligand would simultaneously release two hydrogen ions from the amido groups, a certain amount of energy was consumed, but an oxygen atom on the phenol group of HBTADO ligand binding with Cu(II)(for $CuH_{-2}A$) or hydrogen ion (for $CuH_{-1}A$) will give out a certain amount of energy which is larger than the consumed energy ($\Delta H_{CuH_{-2}TADO}$ = 13.85±0.43 kJ mol^{-1} [15]).

As can be seen from Table 3, the values of the enthalpies of coordination of ternary complex compounds CuR′PhenA are −6.51±0.26(CH_3Phen), −8.71±0.26(Phen), −11.2±0.3(ClPhen) and −14.2±0.3(NO_2Phen) kJ mol^{-1}, respectively. As the tendency of Cu(II) to coordinate R′Phen is very strong, the CuR′Phen complex does not dissociate in the pH range 2–7 and it may be regarded as a stable series. Therefore, CuR′Phen can coordinate with only two nitrogen atoms of the amindo groups of HBTADO and it cannot form a planar structure with four nitrogen atoms of the ligand HBTADO. Thus, the bond of CuR′Phen with HBTADO may bend, with energy expenditure, but the oxygen atom of phenol group takes part in the coordination with Cu(II) of Cu(II)-R′Phen by releasing of certain amount of energy to exceed the energy consumed. Therefore, enthalpies of coordination of ternary systems Cu(II)-R′Phen-HBTADO are negative values. Furthermore, a d-p back π bonding takes place between the 3d electron cloud of Cu(II) and p-orbital of R′Phen; this decreases the electron density at Cu(II), strengthens the bonding between Cu(II)-R′Phen and HBTADO, and increases the enthalpies of coordination of Cu(II)-R′Phen to HBTADO. When the substituents R′on Phen vary from CH_3 to NO_2 the coordination tendency increases, while the enthalpies of protonation of ligands R′Phen decrease with substituents varying from CH_3 to NO_2. By plotting of the enthalpies of coordination of CuR′Phen with ligand HBTADO against the enthalpies of protonation of the ligands R′Phen ($\Delta H_{HR'Phen}$ CH_3: −16.7; H: −15.1; Cl: −11.6; NO_2: −8.4 kJ mol^{-1}) [20], a straight line is obtained with a negative slope.

The regression equation is as follows:

$$\Delta H_{CuR'Phen} = -21.65-0.8874\Delta H_{HR'Phen}$$

$$\gamma = -0.9947$$

The linear enthalpy relationship indicates that the enthalpies of coordination of ligand HBTADO to CuR′Phen strongly depend on the enthalpies of protonation of ligands R′Phen.

It is apparent from Table 4 that the enthalpies of coordination ternary complex compounds Cu(II)-α-aminoacids-HBTADO(CuAB) have values ranging from −(60–69) kJ mol^{-1}. These values were larger than the enthalpies of coordination of binary complex compound $CuH_{-2}A$(−12.7±0.2 mol^{-1}) and $CuH_{-1}A$(−13.8±0.5 kJ mol^{-1}).

In forming these ternary complex compounds, the ligand HBTADO will simultaneously release two protons from the amido groups. When the α-aminoacid coordinated to Cu(II) with its carboxyl oxygen, one of the protons released from amido groups of ligand HBTADO would combine with the amino group nitrogen of α-aminoacid. When the stability constants of the ternary complex compounds Cu(II)-HBTADO-α-aminoacids were calculated with TITFIT [21], only the model $\log\beta_{CuAB}$ was simulated and the result of calculation was convergent. Judging from the released heats and the colour of final solutions, both the binary system Cu(II)-HBTADO and the ternary systems Cu(II)-HBTADO-α-aminoacids appear to have been formed.

The absorption maximum is at 510 nm for Cu(II)-HBTADO binary system and at 600–620 nm for Cu(II)-α-aminoacids-HBTADO ternary systems. This indicates that the α-aminoacids take part in the coordination with Cu(II)-HBTADO in the ternary complex systems Cu(II)-HBTADO-α-aminoacids.

In Table 4 also reported the pH values of the solutions before the reaction are in the range of 9.4–9.9 (the α-aminoacids thus exist in deprotonation form) while after reaction the pH values of the solutions are in the range 4.9–5.8; the α-aminoacidic carboxyl group cannot accept a proton under these conditions. One of the two protons released from the amido groups of HBTADO must therefore bind to the nitrogen atom of the amino group of the α-aminoacids and the oxygen atom of the carboxyl group of the the α-aminoacids would coordinate to the Cu(II) of Cu(II)-HBTADO. The crystal structures of the five coordination compounds of Cu(II) with the 4-(quinolin-8-ylmethyl)-1.4.7.10-tetraazacyclotridecane-11.13-dione and with 4,7-bis(quinolin-8-ylmethyl)-1,4,7.10-

HDBTADO	−104.9 [28]	−46.7±0.5 [12]	195

tetraazacyclotridecane-11,13-dione have been obtained [22]. Furthermore, five coordination compounds, in which the water molecule coordinates with the Cu(II) of Cu(II)-TADO, have been crystallographically established [23]. These crystal structure determinations indicated that the five coordination structures proposed for the mixed complex compounds Cu(II)-HBTADO-α-aminoacids (CuAB) are reasonable. According to the above assumption, for the Cu(II)-HBTADO-α-aminoisobutyric acid ternary complex compound, the enthalpy of coordination of HBTADO to Cu(II) with concomitant double deprotonation of amido groups is −13.8 kJ mol^{-1}, the enthalpy of protonation of the nitrogen atom of amino group of α-aminoisobutyric acid −51.9±0.1 kJ mol^{-1} [16], the enthalpy of coordination of oxygen atom of carboxyl group of α-aminoisobutyric acid to copper(II) (i.e. the difference between the enthalpy of first coordination of α-aminoisobutyric acid to copper(II), −25.8±0.3 kJ mol^{-1} [16], and the enthalpy of first coordination of ammonia with copper(II), −23 kJ mol^{-1} [19]) is about −2.8 kJ mol^{-1}. Thus, the total amount of these enthalpies is −68.5 kJ mol^{-1}, which approximately equals the enthalpy of coordination of the ternary complex compound Cu(II)-HBTADO-α-aminoisobutyric acid, −69.7 kJ mol^{-1}. For Cu(II)-HBTADO-proline the calculated value is −59.9 kJ mol^{-1},

the experimental one is -60.7 kJ mol^{-1}. For Cu(II)-HBTADO-isoleucine the calculated value is -65.1 kJ mol^{-1}, the experimental one is -65.9 kJ mol^{-1}. For Cu(II)-HBTADO-glycine the calculated value is -64.3 kJ mol^{-1}, the experimental one is -65.3 kJ mol^{-1}. For Cu(II)-HBTADO-valine the calculated value is -63.9 kJ mol^{-1}, the experimental one is -65.3 kJ mol^{-1}. For Cu(II)-HBTADO-serine the calculated value is -62.1 kJ mol^{-1}, the experimental one 63.0 kJ mol^{-1}.

These findings again show that the enthalpy of coordination of ternary complex compounds are approximately the sum of the enthalpy of coordination of the corresponding parent binary complex compounds provided no d-p back π bonding exists in the ternary system [16]. However, a linear enthalpy relationship was found to exist between the enthalpies of coordination of ternary complex compounds CuAB and the enthalpies of protonation of ligand α-aminoacids (ΔH_{HB}: Pro, -43.3 ± 0.1; Aib, -51.9 ± 0.1; iLe, -48.5 ± 0.1; Gly, -47.7 ± 0.2; Val, -47.3 ± 0.1; Ser, -45.5 ± 0.1 kJ mol^{-1}) [16] with the following correlation equation:

$$\Delta H_{CuAB} = -15.28 + 1.049\Delta H_{AB}$$
$$r = 0.9974$$

The linear enthalpy relationship indicates that the enthalpies of coordination of ternary complex compounds Cu(II)-α-aminoacids-HBTADO strongly depend on the enthalpies of protonation of ligands α-aminoacids. The slope of the line is approximately unity.

It is found from Table 5 that the protonation of these macrocyclic ligands, HRTADO(12-(2′-hydroxy-3′,5′-substituted benzyl)-1,4,7,10-tetraazacyclotridecane-11,13-dione) has three steps. Enthalpies of first protonation (i.e. the enthalpies of protonation of oxygen atom of phenol group, ΔH_{HA} values decrease with the change of substituents from methoxyl to dibromo. Because the values of enthalpies of first protonation depended on the densities of electron cloud on the oxygen atom of phenol group. Furthermore, due to the stacking effect [24,25], the oxygen atom of the phenol group is drawn near to nitrogen atom of amino group of macrocyclic ring. When first proton coordinated to the oxygen atom of the phenol group, it may be bridged to two nitrogen atoms of two amino group of HRTADO ligands. This effect will increase the enthalpies of first protonation of the macrocyclic ligands HRTADO. Therefore, the enthalpies of the first protonation of HMTADO, HTADO ligands (-35.6 ± 0.3, -32.7 ± 0.3 kJ mol^{-1}) much exceed -25.5 kJ mol^{-1}, the enthalpy of protonation of phenol. Although Br atom, two Br atoms on phenyl ring decrease the electron density on oxygen atom of phenol group for HBTADO, HDBTADO ligands, respectively, but the enthalpies of first protonation of HBTADO, HDBTADO still are -29.7 ± 0.2, -25.1 ± 0.3 kJ mol^{-1}. When the second and the third protons coordinate to two nitrogen atoms of two amino groups of HRTADO ligands, first must break the bridged bond of first proton with two nitrogen atoms of two amino groups. This need consumes certain energy and this consumed energy decreased with varying of substituents from CH_3 to 2Br. Therefore, ΔH_{H_2A} and ΔH_{H_3A} are -19.1 ± 0.1, -22.8 ± 1.1, -24.4 ± 0.3, -17.0 ± 0.7 and -18.4 ± 0.4, -19.6 ± 1.4, -24.4 ± 0.3, -13.8 ± 1.0 kJ mol^{-1}, respectively. These values all are smaller than -36.8 ± 0.2 and -30.2 ± 0.2 kJ mol^{-1} (see ΔH_{HA} and ΔH_{H_2A} of TADO in Table 5). But ΔH_{H_2A} and ΔH_{H_3A} of HDBTADO appear out of the ordinary. Again see ΔS_{H_2A} and ΔS_{H_3A} of HDBTADO in Table 5, we find that ΔS_{H_2A} is ordinary and ΔS_{H_3A} appear special large. (A substance of this phenomenon is not understood and further investigation needs to be done.) Above factors cause that ΔG_{H_2A} and ΔG_{H_3A} of HDBTADO are out of the ordinary. This phenomenon also is found to exist in the binary and ternary complexes.

It is also seen from Tables 5 and 6 that the linear enthalpy relationships have been found to exist between the enthalpies of coordination of ternary complex compounds Cu(II)—R′Phen-HRTADO(A) and the enthalpies of protonation of the first step of ligands A, ΔH_{HA}, with correlation equations as following:

Cu(II)-CH_3Phen-A ternary system:
$\Delta H_{CuCH_3Phen} = 53.78 + 2.058\Delta H_{HA}$ $\quad r = 0.9929$
Cu(II)-Phen-A ternary system:
$\Delta H_{CuPhenA} = 51.96 + 2.054\Delta H_{HA}$ $\quad r = 0.9944$
Cu(II)-ClPhen-A ternary system:
$\Delta H_{CuClPhen} = 48.10 + 2.020\Delta H_{HA}$ $\quad r = 0.9960$
Cu(II)-NO_2Phen-A ternary system:
$\Delta H_{CuNO_2PhenA} = 46.85 + 2.073\Delta H_{HA}$ $\quad r = 0.9926$

It is seen from Tables 5 and 6 that some linear enthalpy-entropy relationships have been found to exist between the enthalpy of coordination of ternary complex compounds Cu(II)—R′Phen-A and the entropy of protonation of ligands A with correlation equations as follows:

Cu(II)-CH_3Phen-A ternary system:
$\Delta H_{CuCH_3Phen} = -108.7 + 1.156\Delta S_{HA}$ $\quad r = 0.9920$
Cu(II)-Phen-A ternary system:
$\Delta H_{CuPhenA} = -110.0 + 1.151\Delta S_{HA}$ $\quad r = 0.9919$
Cu(II)-ClPhen-A ternary system:
$\Delta H_{CuClPhen} = -111.3 + 1.134\Delta S_{HA}$ $\quad r = 0.9946$
Cu(II)-NO_2Phen-A ternary system:
$\Delta H_{CuNO_2PhenA} = -116.7 + 1.163\Delta S_{HA}$ $\quad r = 0.9906$

This existence of these two linear relationships has its internal correlation. Since the benzyl hydroxy group of macrocyclic ligands can take part not only in combing with hydrogen ion but also can take part in coordination with Cu(II)-R′Phen. When the substituents on the benzyl group are different the enthalpies of coordination of ternary complex compounds Cu(II)-R′Phen-A and the enthalpy and entropy of

protonation of macrocyclic ligands A vary accordingly. As can be seen from Tables 5 and 7, some linear enthalpy relationships also exist between the enthalpies of coordination of ternary complex compounds Cu(II)-HRTADO(A)-α-aminoacids(B) and the enthalpies of coordination of the binary complex compounds Cu(II)H-1A with correlation equations as the following (except the Cu(II)-α-aminoacids-TADO ternary systems):

Cu(II)-Pro-A ternary system:
$\Delta H_{CuProA} = -47.42 + 1.025\Delta H_{CuH_{-1}A}$ $\gamma = 0.998$
Cu(II)-Aib-A ternary system:
$\Delta H_{CuAibA} = -56.08 + 0.993\Delta H_{CuH_{-1}A}$ $\gamma = 1.000$
Cu(II)-iLe-A ternary system:
$\Delta H_{CuiLeA} = -52.49 + 0.992\Delta H_{CuH_{-1}A}$ $\gamma = 1.000$
Cu(II)-Gly-A ternary system:
$\Delta H_{CuGlyA} = -51.88 + 0.997\Delta H_{CuH_{-1}A}$ $\gamma = 1.000$
Cu(II)-Val-A ternary system:
$\Delta_{HCuValA} = -51.50 + 0.987\Delta H_{CuH_{-1}A}$ $\gamma = 1.000$
Cu(II)-Ser-A ternary system:
$\Delta_{HCuSerA} = -49.80 + 0.987\Delta H_{CuH_{-1}A}$ $\gamma = 1.000$

As can be seen also from Tables 5 and 7 that some linear entropy relationships have been found to exist between the entropies of coordination of the ternary complex compounds Cu(II)-HRTADO(A)-α-aminoacids (B) and the entropies of coordination of the binary complex compounds Cu(II)H-1A with correlation equations as follows(except the Cu(II)-TADO-α-aminoacids ternary system):

Cu(II)-Pro-A ternary system:
$\Delta S_{CuProA} = 41.66 + 1.662\Delta S_{CuH_{-1}A}$ $\gamma = 0.991$
Cu(II)-Aib-A ternary system:
$\Delta S_{CuAibA} = 17.07 + 1.556\Delta S_{CuH_{-1}A}$ $\gamma = 0.997$
Cu(II)-iLe-A ternary system:
$\Delta S_{CuiLeA} = 32.01 + 1.467\Delta S_{CuH_{-1}A}$ $\gamma = 0.999$
Cu(II)-Gly-A ternary system:
$\Delta S_{CuGlyA} = 31.62 + 1.468\Delta S_{CuH_{-1}A}$ $\gamma = 0.995$
Cu(II)-Val-A ternary system:
$\Delta S_{CuValA} = 34.70 + 1.467\Delta S_{CuH_{-1}A}$ $\gamma = 0.997$
Cu(II)-Ser-A ternary system:
$\Delta S_{CuSerA} = 44.00 + 1.374\Delta S_{CuH_{-1}A}$ $\gamma = 0.986$

The existence of these linear relationships indicates that the values of enthalpies and entropies of coordination of the ternary complex compounds Cu(II)AB strongly depend on the values of enthalpies and entropies of coordination of the binary complex compounds Cu(II)H$_{-1}$A. As reported above the enthalpies of coordination of ternary complex compounds, Cu(II)AB can be related to additivity effect to the parent binary complex compounds, i.e. the enthalpies of ΔH_{CuAB} are equivalent to the sum of the enthalpies of protonation of nitrogen atom on the amino group of α-ammoniac's, the enthalpies of coordination of oxygen atom on carboxyl group of α-aminocids with Cu(II) of binary complex compounds Cu(II)H$_{-1}$A and the enthalpies of coordination of the binary complex compounds Cu(II)H$_{-1}$A.

It is seen from Table 6 that the values of enthalpies of coordination of ternary complex compounds Cu(II)-R′Phen-A are rather small, the range of 2 to -2.8 kJ mol^{-1}, but the values of entropies of coordination of ternary complex compounds Cu(II)-R′Phen-A are larger, about 120 to 170 kJ^{-1} mol^{-1}, i.e. the values of $-T\Delta S_{CuR'PhenA}$ of ternary complex compounds Cu(II)-R′Phen-A are -32 to -50 kJ mol^{-1}. It means that the high stability of ternary complex compounds Cu(II)-R′Phen-A mainly arises from their entropy effects, which might be resulted from the stacking effect of aromatic ring of 5-substituted phenanthrolines with the macrocyclic ring and phenyl ring of HRTADO ligands [24–26].

(Received 1 July 1997; accepted 9 October 1997)

Abstract—MCl_2 (4,2′-6′,4″-terpyridine) compounds, where M = Mn(II), Co(II), Ni(II), Cu(II) or Zn(II), have been synthesized and characterized by IR and electronic spectroscopy and susceptibility magnetic measurements. Crystalline structure of the Zn(II) complex has been determined by X-ray diffraction. The Zn(II) atom shows to be in a highly distorted tetrahedral environment, defined by two Cl atoms and two N atoms of two ligand molecules, that act as bridges bound through the N atoms of the external pyridine rings. The structure is made of chains that do not interact among them. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: coordination compounds; MCl_2(4,2′-6′,4″-terpyridine) compounds; *catena*-poly [(dichlorozinc)-μ-(4,2′-6′,4″-terpyridine)].

INTRODUCTION

The different relative position of the N atoms in the terpyridine isomers leads to different coordination behaviour.

4,2′-6′-4″-terpyridine(I) possesses three pyridinic N-atoms with donor character. However, due to its relative position, they cannot coordinate to the same metallic cation as it happens with the 2,2′-6′-2″-terpyridine(II) isomer.

2,2′-6′,4″-perpyridine(III) is a bidentate ligand through the two nearest N atoms or a cyclometalling ligand, with N_2C donor set, with Ru [1], possessing a non-chelating pyridine ring which is protonated.

No reference related to the isomer (I) complex formation has been found. However it seems likely that it can behave as a bridge ligand coordinated through the N-atoms of the external rings.

In the present work we describe the synthesis and characterization of the complexes [MCl_2 (4,2′-6′,4″-terpyridine)], M = Mn(II), Co(II), Ni(II), Cu(II) and Zn(II). For the Zn(II) complex we were able to determine its crystalline structure. The ligand behaves as a bridge through the N-atoms of the external rings.

EXPERIMENTAL

Preparation of complexes

All complexes were synthesized by adding, with stir and at room temperature, an ethanolic solution of the ligand (0.5 mmol in 5 ml) to an aqueous solution of the metal chloride (0.5 mmol in 3 ml), in stoichiometric

quantities. The resulting precipitate was washed with ethanol and air dried.

Table 1 collects analytical results and yields of complexes preparation.

By evaporation of a solution of Zn(II) complex in DMS some translucent and colourless crystals were obtained.

Physical measurements

C, H and N were analysed using a Perkin–Elmer 240C Elemental Analyzer. Conductivity measurements were made using a Metrhom E518 conductimeter with a Metrhom 6.0901.110 cell (constant = 0.74 cm^{-1}). IR spectra were recorded in the 4.000–65 cm^{-1} region, on a Nicolett 740 FT-IR spectrometer, with KBr pellets in the middle range and with Nujol on a polyethylene film under 650 cm^{-1}. Electronic spectra, as diffuse reflectance, were registered on a Schimadzu UV-265 FW instrument, in the 900–190 nm range. Magnetic susceptibilities were determined with a DSM8 susceptometer, with a Drusch M 1119 power source and an Oxford ITC4 temperature controller. Diamagnetic corrections were applied [2].

X-ray crystal structure determination

A colourless crystal of needle-like shape and dimensions $0.10 \times 0.10 \times 0.25$ mm^3 was mounted on a Nonius CAD-4 diffractometer and used for the structure determination. Table 2 collects the main crystal data and the refinement parameters for $ZnC_{15}N_3H_{11}Cl_2$. Graphite monochromated Mo-K_α ($\lambda = 0.71069$ Å) was used in the data collection carried out at 295 K. The unit cell parameters were determined by least-square refinement of the 2θ values of 25 strong well

centered reflections in the angular range $13° < 2\theta < 35°$. The intensities were measured in the angular range $1° < 2\theta < 60°$ (hkl range, 9,0,0 to 9,19,23) using the $\omega/2\theta$ scan technique. There was no appreciable change in the intensities of three standard reflections periodically monitored. The raw data were corrected for Lorentz and polarization effects. Scattering factors for neutral atoms were taken from the "*International Tables for X-Ray Crystallography*" [3].

The heavy atoms (Zn and Cl) were located using the Patterson function while the other non-hydrogen atoms (N and C) positions were determined by subsequent Fourier syntheses. Since no trends in ΔF vs F_o or $\sin\theta/\lambda$ were observed, unit weights were assigned. Due to the crystal size and to the low absorption coefficient, no absorption correction was applied. A final refinement was undertaken with anisotropic thermal motion for the non-hydrogen atoms with the hydrogen atoms at the positions determined by the molecular geometry and keeping the isotropic thermal parameters constant and equal for all of them. Full-matrix least-square refinement minimized $\Sigma w(|F_o|-|F_c|)^2$. The maximum and average shift-to-error ratios were 0.001 and 0.0004 respectively, while the maximum residual electron density, located near the Zn atom, was 0.6 $e\text{Å}^{-3}$. Most of the calculations were carried out with the XRAY80 program [4].

RESULTS AND DISCUSSION

Due to the insolubility of most complexes in the habitual solvents, it was not possible to carry out conductivity measurements. However zinc complex, which was soluble in DMSO, showed to be no-conductor.

Crystalline structure of $ZnCl_2$(4,2′-6′,4″-terpy)

Table 3 collects the main interatomic distances (Å) and angles (degrees). The compound consist of infinite zigzag chains of composition $ZnCl_2$(4,2′-6′,4″-terpy) running parallel to the *b*-axis. Figure 1 shows an ORTEP view of the molecule and Fig. 2 depicts the molecular packing in the crystal.

The zinc atoms are coordinated to two chlorine atoms and to two nitrogen atoms, N(1) and N(3′), of two different terpy ligands. These atoms are arranged in a very distorted tetrahedron with two long Zn—Cl distances, 2.214 Å and 2.192 Å, and to two Zn—N shorter bonds, 2.051 Å and 2.071 Å. These distances

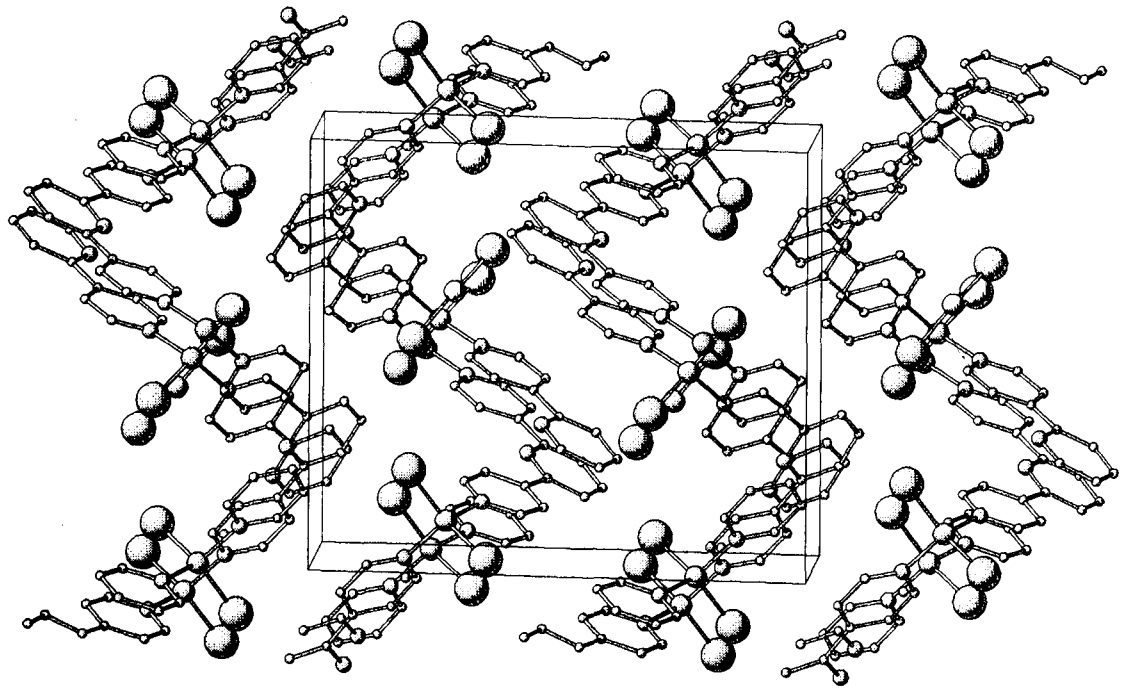

Fig. 2. Molecular packing in the crystal of $Zn(4,2'\text{-}6',4''\text{-terpy})Cl_2$

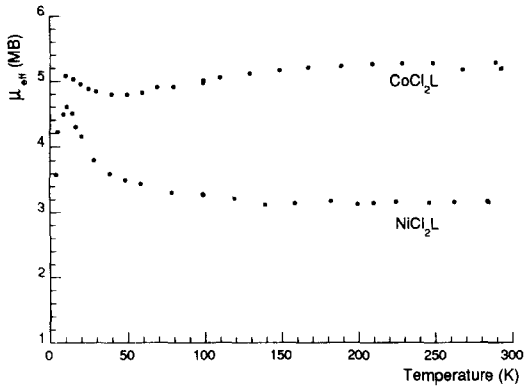

Fig. 3. Magnetic moment vs temperature for Co(II), and Ni(II) complexes.

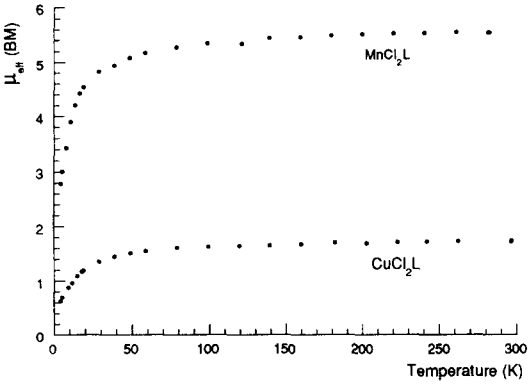

Fig. 4. Magnetic moment vs temperature for Mn(II) and Cu(II) complexes.

are similar to that observed in other monomeric complexes: d(Zn—Cl) = 2.22 Å and 2.23 Å, d(Zn—N) = 2.05 Å in $ZnCl_2(py)_2$ [5], and d(Zn—Cl) = 2.26 Å, d(Zn—N) = 2.09 Å, 2.18 Å and 2.14 Å in $ZnCl_2$(2,2′-6′,2″-terpy) [6]. The angles Cl(1)—Zn—Cl(2) (121.9°) and N(1)—Zn—N(3′) (98.6°) are very different from the value of a regular tetrahedron (109.5°); this is probably a steric requirement of the large chlorine atoms bonded to the zinc. The rest of the tetrahedral angles are much closer to their ideal value. The zinc atoms of neighbouring chains are at a distance of 6.649 Å, the length of the *a*-axis. The shortest distance between a zinc and a chlorine atom of neighbouring chains is at least of 5.8 Å. These long distances exclude any type of interchain interactions.

The molecules of the ligand are coordinated to two different metallic atoms by the nitrogen atoms of both the terminal rings, N(1) and N(3), acting as bridges, while the central ring is not coordinated. Every pyridine ring of the ligand keeps its planarity. However, the terpy molecule as a whole is not planar: the angle is defined by rings containing the N(1) and N(2) atoms is only 9.0° while the angle between the central ring and that containing the N(3) atom is 106.8°. This is necessary to allow the tetrahedral coordination of the metallic atoms.

X-ray diffraction of the other complexes

Powder diffractograms of Mn(II), Co(II), Ni(II) and Cu(II) complexes showed them to be analogues. However they are different to the Zn(II) complex diffractogram, denoting that they have structural differences.

We suppose for those cations, an octahedral environment in the solid state, in accordance with the other experimental results.

Infrared spectra

Complexes infrared spectra reproduce basically that of the ligand with some modifications due to its coordination. The ligand shows a band at 1593 cm^{-1}, related to pyridine ring vibrations that shifts to higher frequencies in the metal complexes with an increase of 15 to 22 cm^{-1}, depending on the metal.

The assignation of the far infrared bands is not feasible due to the many peaks that the ligand itself shows in this area. Around 340 cm^{-1} there is a clear band that is not present in the ligand, and it is assigned to the stretching frequency of M—Cl.

Electronic spectra

Only diffuse reflectance spectra were recorded due to the insolubility of most of the complexes. The ligand shows a band in the ultraviolet region centered at 290 nm with a shoulder that starts under 450 nm, assigned to a π-π^* transition. All the five complexes clearly show this shoulder.

In Table 4 are summarized the bands and their assignation on the bases of an octahedral environment for the metallic cation.

The $CuCl_2L$ complex shows a very broad band at 700 nm (14,200 cm^{-1}) that is assigned to the $^2E_g \rightarrow {}^2T_{2g}$ transition, from which a 10 Dq value of 14,200 cm^{-1} is estimated. The complex of Ni(II) presents two bands, one at 700 nm assigned to the $^3A_{2g} \rightarrow {}^3T_{1g}(F)$ transition and other around 23,800 cm^{-1} assigned to the $^3Ag_{2g} \rightarrow {}^3T_{1g}(P)$ transition. From these two bands a 10 Dq value of 9,000 cm^{-1} and a *B* value of 740 cm^{-1} are obtained. The band corresponding to the $^3Ag_{2g} \rightarrow {}^3T_{2g}$ transition is not observed, as it should appear at lower frequencies.

The Co(II) complex also shows two bands centered at 620 and 530 nm (16,100–18,900 cm^{-1}), assigned to $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ and $^4T_{1g}(F) \rightarrow {}^4A_{2g}$ transitions, respectively. The values of 10 Dq = 10,500 and B = 712 cm^{-1} are deduced from these bands.

The complexes of Zn(II) and Mn(II) showed only

Table 4. Assignation of the found bands and calculated values of 10 Dq and *B*

Compound	ν (cm^{-1})	Assignation	10 Dq (cm^{-1})	B (cm^{-1})
$CoCl_2L$	16,100 cm^{-1}	$^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$		
	18,900 cm^{-1}	$^4T_{1g}(F) \rightarrow {}^4A_{2g}(F)$	10,500	712
$NiCl_2L$	14,200 cm^{-1}	$^3A_{2g} \rightarrow {}^3T_{1g}(F)$		
	23,800 cm^{-1}	$^3A_{2g} \rightarrow {}^3T_{1g}(P)$	9,000	740
$CuCl_2L$	14,200 cm^{-1}	$^2E_g \rightarrow {}^2T_{2g}$	14,200	

the ligand bands, as it was expected, due to their d^{10}–d^5 configurations.

Using Jørgensen's expression 10 Dq = f(ligand)·g(cation)·10^3 cm^{-1} it is possible to calculate a 10 Dq value for the complexes, estimating, from the Co(II) complex results, a value of $f = 1.13$ for both ligands and accepting the parameter g for the cations Cu^{2+} (12) and Mn^{2+} (8.5) [7]. The resulting values for 10 Dq are 13,560 cm^{-1} for $CuCl_2L$, and 9,600 cm^{-1} for $MnCl_2L$.

Magnetic measurements

Table 5 shows the magnetic values for the temperature range in which the Curie-Weiss law is obeyed.

$ZnCl_2L$ complex is diamagnetic as it was expected for a d^{10} configuration.

Table 5. Magnetic results

Compound	T (°K)	θ (°K)	μ (BM)[a]	
$MnCl_2L$	100–295	−14.0	5.69	(d^5, high spin)
$CoCl_2L$	100–295	−9.1	5.31	(d^7, high spin)
$NiCl_2L$	100–295	3.4	3.13	(d^8)
$CuCl_2L$	100–295	−22.8	1.79	(d^9)

[a] Calc. from the Curie constant value.

For Mn^{2+} and Co^{2+} complexes the μ_{eff} value is in agreement with a high spin value for d^5 and d^7 configurations, respectively.

The representation of μ vs T at low temperatures shows an antiferromagnetism interaction in the cases of Mn and Cu complexes, and a ferromagnetic interaction for the Ni complex. This result agrees with the sign of θ. As the solid structures are unknown it is not possible to make an adjustment of the found data.

(Received 30 June 1997; accepted 6 October 1997)

Abstract—The complex of the *bis*(triphenylphosphine)gold(I) cation and the radical anion of 2,2′-(2,5-cyclohexadiene-1,4-diylidene)bispropanedinitrile, (TCNQ), has been prepared and characterized by spectroscopic and X-ray crystallographic methods. The solid state structure consists of the linear (P—Au—P) cation *bis*(triphenylphosphine)gold(I) and the approximately planar radical anion of TCNQ. The bond lengths are: Au—P 2.300(2); P—C 1.800(11), 1.789(11), 1.800(11); C≡N 1.175(16), 1.128(16). The infrared spectrum of the complex exhibits bands at 2176 and 2150 cm^{-1} in the nitrile region. The electron spin resonance spectrum of this compound, in benzene, is consistent with a structure in which the TCNQ radical anion is symmetrically oriented about the *bis*(triphenylphosphine)gold(I) cation. The hyperfine coupling constants are: $a^N = 0.981$, $a^H = 1.379$, $a^P = 0.095$ gauss. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: TCNQ; spectroscopy; X-ray crystallography.

Recent interest [1–4] in the radical anion salts of *bis*(triphenylphosphine)gold(I)$^+$ prompted a reexamination of research previously conducted in our laboratory [5]. The initial interest in this class of compounds was aroused by the potentially unique electrical and magnetic properties of the radical anion salts of TCNQ and TCNE. Since certain aspects of our initial study differ from those recently reported [2,4] we have redetermined the crystal structure and reinvestigated the ESR spectrum of the *bis*(triphenylphosphine)gold(I)$^+$ TCNQ$^-$ salt and report the results here.

EXPERIMENTAL

Preparation of chloro(triphenylphosphine)gold(I)

To a solution of hydrated chloroauric acid (0.97 g, 2.58 mmol) in ethanol (20 cm^3) was added triphenylphosphine (1.27 g, 4.84 mmol). The solution was stirred for 15 min during which time the yellow color of the gold(III) dissipated and a white crystalline product separated. The product was recovered by filtration, washed with ethanol (5 cm^3) and finally with diethyl ether (5 cm^3). The product was recrystallized from ethanol: m.p. 239–241°. Calc. for $C_{18}H_{15}PAuCl$: C, 43.70; H, 3.06. Found: C, 43.54; H, 2.70.

Preparation of bis(triphenylphosphine)gold(I)$^+$ TCNQ$^-$

A mixture of triphenylphosphine (1.80 g, 6.86 mmol) and chloro(triphenylphosphine)gold(I) (3.26 g, 6.59 mmol) was suspended in ethanol (75 cm^3) and the mixture heated until the solution cleared (about 10 min). Potassium hydroxide (0.40 g, 7.13 mmol) was added and the solution refluxed an additional fifteen minutes. The resulting hot red solution was filtered into a suspension of TCNQ (1.56 g, 7.64 mmol) in ethanol (30 cm^3). The solution turned green and dark green crystals separated from the mixture. The product may be purified by dissolution in benzene and reprecipitation by the addition of pentane. Calc.: C, 62.30; H, 3.67; N, 6.05. Found: C, 62.24; H, 3.52; N, 5.96.

Infrared spectra

The infrared spectrum of TCNQ was recorded in a KBr pellet, Nujol and chloroform. Where the medium does not absorb, the features of these spectra are identical. A medium intensity, sharp single band at 2220 cm^{-1} is assigned to the nitrile stretching frequency and a medium intensity band at 1540 cm^{-1} is assigned to the C=C stretching frequency. The frequencies correspond to the assignments reported by Acker and Hertler [6].

The infrared spectrum of *bis*(triphenylphosphine)gold(I)$^+$ TCNQ$^-$ was recorded in Nujol, benzene and a KBr pellet. Where the solvent does not absorb, the features of the spectrum are identical in Nujol and benzene. The nitrile frequencies are assigned to the bands at 2176 and 2150 cm^{-1}. The spectrum observed in the KBr pellet appears to be a composite of the spectrum of bromo (triphenylphosphine)gold(I) and potassium TCNQ.

Electron spin resonance spectrum

The electron spin resonance spectrum of *bis*(triphenylphosphine)gold(I)$^+$ TCNQ$^-$ was recorded at a concentration of 1×10^{-4} in benzene. The solvent was deoxygenated by introducing it into a vacuum line (which had been pumped down to a pressure of 10^{-5} torr), and freezing it to liquid nitrogen temperature. The cycle of freezing and thawing was repeated several times. After the solvent was deoxygenated it was transferred on the vacuum line to the sample holder. The sample holder consisted of a compartment for the solvent, a compartment for the sample and an ESR tube. These compartments were connected by a common junction which was fitted with a vacuum stopcock and an O-ring joint. The device could be attached to the vacuum system via the O-ring connector and in this manner the sample and solvent could be handled in a vacuum and mixed just prior to recording the spectrum. The hyperfine components resulting from four equivalent nitrogen, hydrogen and carbon atoms and two equivalent phosphorus atoms have been resolved. The hyperfine coupling constants are: $a^N = 0.981$, $a^H = 1.379$, $a^P = 0.095$ and $a^{C\text{-}13}$ for four equivalent, nitrile carbon atoms was estimated to be 0.19.

A g-value of 2.0113(2) was calculated by comparing the spectrum of the gold complex with that of Fremeys salt by use of a dual cavity and dual channel recorder. The center of the spectrum of Fremeys salt was estimated to be 3390 gauss.

A spin concentration experiment was performed in order to show that the observed spectrum was that of the gold compound and not that of an impurity. A solution of the gold complex of known concentration was placed in one section of the cavity and a sample of DPPH in the other section. Suitable signal levels and modulation amplitudes were chosen such that only the envelopes of the two curves were apparent. The spectra of both samples were recorded; then a sample of pitch in KCl was substituted for the sample containing the gold compound. The number of spins in the sample of DPPH was then calculated by comparison of the curves. The DPPH was used as a secondary standard because of experimental difficulties in observing the spectrum of pitch in KCl at an intensity sufficient to compare it directly to the gold complex. A value of 9.75×10^{16} spins was calculated from this experiment compared to the calculated value of 7.9×10^{16} from the solution concentration.

X-ray crystallography

Bis(triphenylphosphine)gold(I)$^+$ TCNQ$^-$ forms dark green parallelepipeds elongated along the a axis. Crystals suitable for structural analysis were obtained from an ethanol solution.

The lattice constants were determined on a Picker four circle automated diffractometer using Ni-filtered $CuK_{\alpha 1}$ radiation ($\lambda_{\alpha 1} = 1.54051$ Å). The constants are: $a = 10.937(2)$, $b = 13.267(2)$, $c = 9.2299(7)$, $\alpha = 107.48(1)$, $\beta = 100.34(1)$, $\gamma = 119.73(2)$ at 295°K. The intensity data were determined on a Picker four circle diffractometer using Zr-filtered Mo–K_α radiation ($\lambda = 0.7107$). The intensity measurements utilized the step scan method detailed elsewhere [7] and were corrected for absorption [9]. Further experimental details are given in Table 1.

The calculated X-ray density is 1.52 g cm^{-3} ($Z = 1$, $M.W. = 925.76$). A measured density of 1.49 g cm^{-3} was determined psychometrically using iosoctane.

Precession photographs revealed that the crystal either belonged to the space group $P\bar{1}$ or $P1$. Examination of the Patterson map and subsequent refinement revealed that the compound belonged to the triclinic space group $P\bar{1}$.

The crystal used for structural analysis was mounted along the a axis and data collected to $\theta = 25°$.

Structure determination and refinement

The structure of *bis*(triphenylphosphine)gold(I)$^+$ TCNQ$^-$ was solved using heavy atom techniques, employing a program previously developed at the University of Iowa. The atom scattering factors were taken from "International Tables for X-ray Crystallography" [13]. All atoms were assumed to be neutrally charged. Both real and imaginary dispersion corrections were applied for gold and phosphorus during all stages of the refinement.

The progress of the refinement was followed using the relation:

$$R_2 = [\Sigma w(\Delta F)^2 / \Sigma w(F_o)^2]^{1/2}$$

where $\Delta F = F_o - F_c$. The function minimized was $\Sigma w(\Delta F)^2$. In the final refinement step, anisotropic ther-

mal displacement factors were used for all non-hydrogen atoms. Hydrogen atoms were included at fixed positions, 0.95 Å, with isotropic thermal displacement factors. The phenyl groups were constrained to be idealized planar groups with exact distances of 1.40 Å.

RESULTS AND DISCUSSION

The synthesis of *bis*(triphenylphosphine)gold(I)$^+$ TCNQ$^-$ differs from the previously reported procedure, involving the reaction of lithium salt of TCNQ$^-$ and *bis*(triphenylphosphine)gold(I) perchlorate, and consists of the formation of an intermediate gold cluster compound and the oxidation of this compound by TCNQ to yield the green crystalline unsolvated product. The intermediate solution of the polygold compound was not isolated but is similar to that reported by Malatesta [10] from which polygold compounds have been previously isolated.

The infrared spectrum in the nitrile region (2176 and 2150 cm^{-1}) corresponds to the values reported for the solvated species [2,4].

The electron spin resonance spectrum of the titled compound is shown in Fig. 1a along with the simulated spectrum of the compound, 1b, and the spectrum of the TCNQ radical anion, 1c, reported by Fischer and McDowell [12]. In contrast to the spectra of the solvated species the unsolvated form displays extensive hyperfine interactions.

The spectrum was recorded in benzene at a concentration of 10^{-4} M. The hyperfine components resulting from four equivalent nitrogen, hydrogen,

and carbon-13 atoms and two equivalent phosphorus atoms were resolved. The hyperfine coupling constants are: $a^N = 0.981$, $a^H = 1.379$, $a^P = 0.095$, and $a^{C\text{-}13}$ for one set of four equivalent, nitrile, carbon atoms was estimated to be 0.19, with an average line width of 0.0716 gauss. The g-value was found to be 2.0113(2). It should be noted that no splitting due to the gold atom was observed which may be due to the fact that the hyperfine coupling constant for gold is probably very small and thus this component was not resolved.

The fact that there are four equivalent nitrogen atoms, four equivalent hydrogen atoms, and two equivalent phosphorus atoms indicates that the cation is symmetrically arranged with respect to the anion, $TCNQ^-$, in a solvent cage of benzene. One cannot exclude the possibility of two equivalent hydrogen atoms on the triphenylphosphine accounting for the additional splitting instead of the phosphorus atoms. It would, however, be a very fortuitous situation if only two triphenylphosphine hydrogens were involved in the splitting and if this were the case then one would anticipate a^H to be much larger.

Table 1 lists the crystallographic data and processing parameters and intermolecular distances and bond angles are listed in Table 2. Figure 2 illustrates the molecular configuration and atom numbering scheme. Figure 3 is a stereoplot viewed perpendicular to the a, c face, and Fig. 4 is a packing diagram featuring the a, c face.

The crystals belong to the triclinic, centrosymmetric space group $P\bar{1}$ in contrast to the arrangement of the solvated form which has been assigned to the noncentrosymmetric, monoclinic space group $C2$. The geometry about the gold atom is linear with a P—Au—P bond angle of 180°. The TCNQ anion is slightly distorted from planarity with a center of symmetry located at the center of the anion. The planes containing the TCNQ anions are separated by the cations at a distance of 12.78 Å. The bond distances and bond angles of the phenyl groups were fixed and refined as a group. With the exception of the nitrile groups the distances within the anion were close to normal values as reported in Table 2.

Abstract—The first transition metal-carbonyl complex containing iodoacetamido function, $CpFe(CO)_2$[η^1-*N*(1)-4-iodoacetamidophthalimidato] was synthesized and used for labeling of two drugs: phenytoin and ethosuximide. © 1998 Published by Elsevier Science Ltd. All rights reserved

Keywords: metal-carbonyl; iodoacetamido; phenytoin anion; ethosuximide anion

Transition metal carbonyl complexes having substituents able to react selectively with functional groups present in molecules of biological and pharmacological interest, currently attract considerable interest as IR-detectable labeling reagents [1]. The detection of the bioconjugates is feasible in a pico- or subpicomole scale by virtue of very strong absorption bands corresponding to the ν(CO) modes, appearing at 2100–1850 cm^{-1} i.e. in the region which is generally free from other interferring absorptions, even in aqueous solutions and biological systems [2,3]. This approach was successfully applied for the labeling of haptens in immunoassays (CMIA-carbonylmetalloimmunoassay) [2], for labeling of steroid hormones for the study of hormone-receptor interaction [4], and labeling of oligonucleotides [5,6]. Most of the labeling procedures described up to now is based on organometallic complexes containing active *N*-hydroxysuccinimide ester function which reacts with the amino group present in the biomolecule and forming the amido bond. Another approach uses organometallic complexes having pyrylium system [7], or iminoester [8], as a reactive function (target function-NH_2).

We have recently reported the synthesis of $CpFe(CO)_2$(η^1-N-maleimidato), which contains a maleimide system reactive towards thiol groups and can be used for labeling of e.g. cysteine-containing peptides or proteins [9]. However, we have demonstrated that it can also label histidine and (in basic medium) lysine residues [10]. Another approach developed recently in our laboratory in collaboration with the Prof. Jaouen's group is the use of the $CpFe(CO)_2$– complexes of phthalimide containing in the 3- or 4-position isothiocyanato functions reactive towards amino groups [11].

In this communication we report the synthesis of the first metallocarbonyl marker containing the $CpFe(CO)_2$(η^1-N-phthalimidato) system and iodoacetamido group as the reactive function. This function is believed to be specific for thiols (cysteines), although it can also react with methionines (MeS-), histidines (imidazole) and lysines (NH_2) [12,13]. However, prompted by recent interest in the development of organometallic tracers for immunoassays of antiepileptic and sedative drugs [2,14,15], we decided to study the reactivity of our reagent toward anions of two important representants of this group of drugs: phenytoin (5,5-diphenylhydantoin) and ethosuximide (2-methyl-2-ethylsuccinimide).

We synthesized the bioconjugates of these products which are of interest as potential markers in carbonylmetalloimmunoassays (CMIA).

Experimental

All reactions were carried out under argon. Dichloromethane was distilled from CaH_2. $CpFe(CO)_2[\eta^1$-*N*(1)-4-aminophthalimidato] (**1**) was prepared according to the earlier published procedure [11]. All reagents and other solvents (reagent grade) were used as received from Aldrich or Fluka. Column chromatographies were carried out using Kieselgel 60 (230–400 mesh ASTM) purchased by Merck. Instrumentation: IR-Specord 75 IR; ^{1}H NMR: Varian Gemini 200BB (200 MHz); FAB MS: Finnigan MAT 95. IR spectra were recorded in $CHCl_3$, ^{1}H-NMR in $CDCl_3$ and referenced to internal TMS, FAB spectra in m-nitrobenzyl alcohol matrices.

$CpFe(CO)_2(\eta^1$-*N*(1)-4-*iodoacetamidophthalimidato*) (**2**)

To a solution of **1** (310 mg, 0.92 mmol) in CH_2Cl_2 (5 ml) DCC (206 mg, 1.0 mmol) and iodoacetic acid (186 mg, 1.0 mmol) were added. After 1 h stirring at r.t. the solid formed was filtered off and the filtrate evaporated to dryness. Column chromatography (eluent $CHCl_3$) and crystallization (CH_2Cl_2-ether) gave **2** as yellow solid. Yield 386 mg (83%). IR (cm^{-1}): 2050 and 1995 cm^{-1} (Fe–CO), 1690 cm^{-1} (CO–amide), 1655 (CO–phthalimide), 1535 (amide-II). ^{1}H NMR ($CHCl_3$): 8.10, b, 1H, NH; 7.76, d ($J = 8.0$ Hz), 1H and 7.58, d ($J = 8.0$ Hz), 1H, H-5 and H-6; 7.69, s, 1H, H-3; 5.12, s, 5H, Cp; 3.90, s, 2H, CH_2. Residual ether (0.2 molecule) shows signals at 3.49, q and 1.22, t.

Analysis: Found: C, 40.61, H, 2.37; N, 5.83, I, 24.75. Calc. for $C_{17}H_{11}N_2O_5IFe \times 0.2\ C_4H_{10}O$: C, 40.35; H, 2.19; N, 5.54; I, 25.08.

Reaction of **2** *with Na-phenytoin*

A solution of **2** (102 mg, 0.20 mmol) and phenytoin (51 mg, 0.20 mmol) in 0.05 M NaOMe in MeOH (4 ml) was incubated at 50°C for 24 h, cooled to r.t. and poured to water (20 ml). The yellow precipitate was filtered off, dried under vacuum and recrystallized from CH_2Cl_2- pentane. Yield 107 mg (85%). IR (cm^{-1}): 2045, 1990 (Fe–CO); 1780, 1725 (phenytoin and amide CO); 1645 (phthalimide CO); ^{1}H-NMR: 9.11, bs, 1H (NH); 7.3–7.8, m, 13H (aromatic Hs); 5.07, s, 5H (Cp); 4.34, s, 2H (CH_2); FAB MS [positive ions, m/e (intensity)]: 631 (24%), M + H; 575 (56%), M + H-2CO. Elemental analysis: Found: C 61.08; H 3.72; N 8.82. Calc. for $C_{32}H_{22}N_4O_7Fe$: C 60.97; H 3.52; N 8.89.

Reaction of **2** *with Na-ethosuximide*

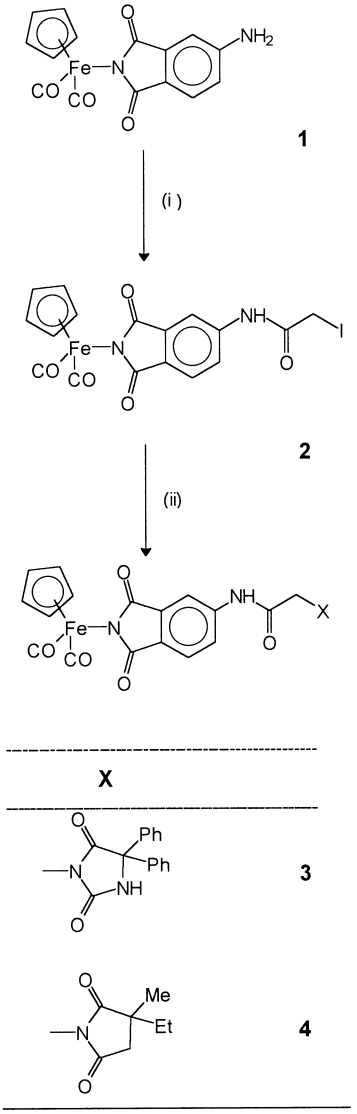
A solution of **2** (102 mg, 0.20 mmol) and ethosuximide (30 mg, 0.21 mmol) in 0.05 M NaOMe in MeOH (4 ml) was incubated at 50°C for 2 d, cooled to r.t., poured to water (20 ml) and extracted with dichloromethane (3×5 ml). The combined extracts were dried with sodium sulphate and evaporated to dryness to give yellow oil. The oil was dissolved in ether ($\sim$20 ml), diluted with hexanes and slowly concentrated *in vacuo* to give an yellow solid (53 mg, 51%). IR (cm^{-1}): 2045, 1990, (Fe–CO); 1775, 1720 (amide and succinimide CO); 1645 (phthalimide CO); ^{1}H-NMR: 8.32 bs, 1H, NH; 7.72, d ($J = 8$ Hz), 1H and 7.54, d ($J = 8$ Hz), 1H, H-5 and H-6; 7.67, s, 1H, H-3; 5.12, s, 5H, Cp; 4.38, s, 2H, $COCH_2$; 2.77, d ($J = 18$ Hz) 1H and 2.54, d ($J = 18$ Hz), 1H, succinimide ring CH_2, 1.82 m, 2H CH_2 (in Et); 1.38, s, 3H, Me; 0.94, t ($J = 7$ Hz), 3H, CH_3 (in Et); FAB MS [positive ions, m/e (intensity)]: 520 (26%), M + H; 464 (51%), M + H-2CO. Elemental analysis: Found: C 55.68; H 4.12; N, 8.32. Calc. for $C_{24}H_{21}N_3O_7Fe$: C 55.51; H 4.08; N, 8.09.

RESULTS AND DISCUSSION

Our results are summarized in Scheme 1.

We have found that readily accessible 4-aminophthalimidato complex **1** [11] readily reacts with iodoacetic acid and *N*,*N*′-dicyclohexylcarbodiimide (DCC) in dichloromethane at room temperature to give the 4-iodoacetamido derivative **2** in high yield. Its structure was confirmed by spectroscopic as well as elemental analyses data. The amino group in **1** can be therefore acylated under mild conditions and **1** is a potential labeling reagent for biomolecules containing carboxylic functions. This possibility, however, will be a subject of further studies.

The iodoacetamido complex **2** readily reacts with sodium salts of phenytoin and ethosuximide (prepared by dissolving of the corresponding NH acids in methanol containing the equimolar amount of sodium methoxide) to afford conjugates **3** and **4,** respectively. The structures of these complexes were confirmed by spectroscopic and elemental analysis data. Their FAB mass spectra (*meta*-nitrobenzyl alcohol as a matrix) display, in the positive ions mode, peaks corresponding to M + H and M + H-2CO ions and in the negative ions mode to M-H and M-H-2CO ions. ^{1}H NMR spectra of conjugates **3** and **4** show characteristic singlet of —$COCH_2N$— protons (4.44 ppm for **3** and 4.38 ppm for **4**), shifted downfield in comparison to the signal of the —$COCH_2I$ protons in **2** (3.90 ppm). The complexes **3** and **4** are yellow air-stable microcrystalline solids, soluble in polar organic



Scheme 1. (i) ICH_2COOH—DCC; (ii) phenytoin (ethosuximide)-CH_3ONa-CH_3OH.

solvents (ethanol, dimethylsulfoxide, dimethylformamide), in chloroform, and practically insoluble in water. Their IR spectra show very strong absorption bands at around 2050 cm^{-1} and 1990 cm^{-1} i.e. in the region where the detection is particularly sensitive [2,3].

Compound **2** as containing the iodoacetamido function is also a potential label for biomolecules containing HS-groups [12,13]. Feasibility of such labeling is currently under study in our laboratory.

Syntheses and characterization of diamine complexes of nickel(II) trifluoroacetate : thermochromism and X-ray single crystal structure analyses of $[Ni(pren)_2(CF_3CO_2)_2]$ and $[Ni(ipren)_2(CF_3CO_2)_2]$ (pren = N-propylethane-1,2-diamine and ipren = N-isopropylethane-1,2-diamine)

(Received 11 June 1997 ; accepted 15 August 1997)

Abstract—The complexes, $[NiL_2(CF_3CO_2)_2]$ [L = N-methylethane-1,2-diamine (meen), N-ethylethane-1,2-diamine (eten), N-propylethane-1,2-diamine (pren) and N-isopropylethane-1,2-diamine (ipren)] have been prepared and X-ray single crystal structures of $[Ni(pren)_2(CF_3CO_2)_2]$ **3** and $[Ni(ipren)_2(CF_3CO_2)_2]$ **4** are determined. Both **3** and **4** have slightly distorted *trans*-octahedral geometry with N_4O_2-chromophore around nickel(II). The crystals are stabilized by H-bonds and this interaction is higher in **4** due to close proximity of methyl H-atoms of isopropyl group with oxygen atoms of trifluoroacetate groups. The complexes **3** and **4** exhibit blue to light-violet, irreversible discontinuous thermochromism. $[Ni(meen)_2(CF_3CO_2)_2]$ **1** also shows thermochromism, blue-violet to blue but reverts on keeping in humid atmosphere. On the other hand, $[Ni(eten)_2(CF_3CO_2)_2]$ **2** undergoes decomposition without showing any phase transition. However, thermochromism here is considered to be due to a decreased in-plane ligand field strength resulting from the conformational changes in diamine chelate rings. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: thermochromism ; N-propylethane-1,2-diamine ; N-isopropylethane-1,2-diamine ; X-ray single crystal analysis of nickel(II) ; nickel(II) trifluoroacetate ; conformational isomerism

Thermochromic phenomenon in diamine complexes of nickel(II) is well documented in the literature [1–12]. This usually takes place with (i) change in geometry/chromophore or (ii) retention of geometry/chromophore. The former is known from the inception of nickel-amine chemistry. It is observed that X-ray single crystal analyses are not usually essential to characterize the thermochromic isomers of the first kind as the routine physico-chemical measurements (magnetic susceptibility, electronic spectra etc.) are often enough to do the same and even help to interpret the mechanism of such thermochromism. On the other hand, thermochromism of the latter kind which was first reported by Pfeiffer *et al.* [13] in 1938, became popular in the early 1960s when some workers studied $M(diamine)_2X_2$ [M=Cu(II)/Ni(II) and X an anion]. It is evident that such thermochromism can only be characterized by X-ray single crystal analyses as in general the changes observed in magnetic, electronic

* Author to whom correspondence should be addressed.

spectral etc. measurements are not so detectable and the syntheses of suitable single crystals specially of high-temperature phase species are extremely difficult. However, Grenthe *et al.* [5] reported for the first time the X-ray single crystal analyses of both the low- and high-temperature phase species of bis-(*N*,*N*-diethylethane-1,2-diamine)copper(II) perchlorate and concluded that thermochromism of this kind was due to a decreased strength of in-plane ligand field, the mechanism which was first proposed by Hatfield *et al.* [14] in 1963. From the reports presented so far one can conclude that this type of thermochromism largely depends on the nature of the diamine as well as on the counter anion. Easily polarizable anions like I^-, Br^- etc. are observed to exhibit continuous thermochromism, whereas less easily polarizable anions like ClO_4^-, BF_4^- etc. show discontinuous thermochromism. However, studies on thermochromism with a less easily polarizable anion, $CF_3CO_2^-$ are scanty. Moreover, the thermochromic phenomena exhibited by nickel(II) complexes of $RNHCH_2CH_2NH_2$ (R = alkyl group) are not investigated systematically. In this context, studies of N-alkyl substituted diamine complexes of nickel(II) trifluoroacetate are relevant and here we report the syntheses and characterization of N-alkyl substituted diamine complexes of nickel(II) trifluoroacetate; X-ray single crystal structure analyses of $[NiL_2(CF_3CO_2)_2]$ (L = N-propyl/isopropylethane-1,2-diamine) and their thermochromism in the solid phase.

EXPERIMENTAL

Materials

High-purity N-methylethane-1,2-diamine (meen), N-ethylethane-1,2-diamine (eten), N-propylethane-1,2-diamine (pren) and N-isopropylethane-1,2-diamine (ipren) were purchased from Aldrich Chemical Company Inc. and used as received. All other chemicals were of analytical reagent grade.

Physical measurements

The thermal analyses (TG-DTA) were carried out using a Shimadzu DT-30 thermal analyser under a flow of nitrogen (flow rate : 30 $cm^3\ min^{-1}$). The sample (particle size of 150–200 mesh) was heated in a platinum crucible at a rate of 10°C min^{-1} with inert alumina as reference. The changes of phase transitions were calculated by a Perkin–Elmer DSC-7 differential scanning calorimeter using indium metal as calibrant (rate of heating/cooling, 10°C min^{-1}). Elemental analyses, IR-spectra (KBr, 4000–400 cm^{-1}), electronic spectra (Nujol mull), magnetic susceptibility and X-ray powder diffraction were done by a Perkin–Elmer 240C elemental analyser, a Perkin–Elmer IR 783, a Shimadzu UV 2100, an EG and G PAR 155 vibrating sample magnetometer and a Seifert XRD 3000P, respectively.

Syntheses of the complexes

$[Ni(meen)_2(CF_3CO_2)_2]$ **1** was prepared as reported earlier [15]. Analytical data were in well agreement with the previous report. All attempts to prepare single crystals suitable for X-ray analysis failed.

$[Ni(eten)_2(CF_3CO_2)_2]$ **2** was synthesized by adding the diamine (2 mmol) to nickel(II)trifluoroacetate hexahydrate dissolved in acetonitrile-butanol (1 : 1) mixture. The resulting solution was kept in a $CaCl_2$-desiccator and after a few days crystalline complex was separated out. It was filtered, washed with butanol and dried in a $CaCl_2$-desiccator. (Yield : 71% ; Found : C, 31.1 ; H, 5.2 ; N, 12.0 ; Ni, 12.7. Calc. for $C_{12}H_{24}N_4O_4F_6Ni$: C, 31.2 ; H, 5.2 ; N, 12.1 ; Ni, 12.7%) ; μ_{eff}, 3.11 B.M. ; λ_{max}(Nujol) 1088, 785, 565 and 352 nm). Here also no suitable single crystal for X-ray analysis was obtained.

$[Ni(pren)_2(CF_3CO_2)_2]$ **3** was prepared following the procedure adopted for complex **2** (Yield : 68% ; Found : C, 34.4 ; H, 5.7 ; N, 11.2 ; Ni, 12.0. Calc. for $C_{14}H_{28}N_4O_4F_6Ni$: C, 34.4 ; H, 5.7 ; N, 11.4 ; Ni, 12.0%) ; μ_{eff}, 3.14 B.M. ; λ_{max}(Nujol) 1135, 825, 562 and 358 nm. Single crystals suitable for X-ray analysis were obtained on crystallization of **3** from acetonitrile.

$[Ni(ipren)_2(CF_3CO_2)_2]$ **4** was obtained by adopting the same procedure as of complex **2** (Yield : 64% ; Found : C, 34.4 ; H, 5.7 ; N, 11.2 ; Ni, 12.0. Calc. for $C_{14}H_{28}N_4O_4F_6Ni$: C, 34.4 ; H, 5.7 ; N, 11.4 ; Ni, 12.0%) ; μ_{eff}, 3.13 B.M. ; λ_{max} (Nujol) 1167, 783, 578 and 383 nm. Single crystals suitable for X-ray measurement were prepared by following the procedure adopted for complex **3**.

Crystallography

Suitable single crystals of complexes **3** and **4** were mounted on a Rigaku/AFC 7 diffractometer. Setting angles for 25 accurately centred reflections were measured for both cases and lattice constants were obtained by least squares refinements. Crystal data were summarized in Table 1. Intensity data were collected using graphite monochromated Mo-K_α radiation ($\lambda = 0.7107$ Å) with ω-2θ scan mode. The stability of the crystal was measured during X-ray exposures by monitoring three standard reflections at a regular interval. In both cases all data were corrected for Lorentz and polarization effects. Empirical absorption corrections were made for both crystals using the ψ-scan method (T_{min}/T_{max} 0.857/0.999 for **3** and T_{min}/T_{max} 0.965/0.998 for **4**). The structures were solved by Patterson methods followed by Fourier syntheses. Anisotropic full-matrix least-squares refinements based on F were carried out on the non hydrogen atoms (TEXSAN) [16]. During the refinement both the crystal structures were found to be

disordered. In complex **3,** the three fluorine atoms of the trifluoroacetate group were distributed over a pair of three positions (F1, F2, F3; F1A, F2A, F3A) with equal site occupancy factor 0.5. In complex **4,** the following cases of disorder were observed: oxygen atom (O2) distributed over two positions O2 and O2A, with site occupancy ratio 0.75/0.25; the three fluorine atoms of the trifluoroacetate group distributed over two pairs of three positions (F1, F2, F3; F1A, F2A, F3A) with equal occupancy factor 0.5; each of the two diamine carbon atoms distributed over two positions (C2, C2A; C3, C3A) with site occupancy ratio 0.6/0.4 in each case. Hydrogen atoms were included in fixed calculated positions. Complex neutral scattering factors were used. All calculations were carried out using TEXSAN [16], PARST [17] and ORTEP-II [18] programs. Selected bond distances and angles are in Table 2.

Additional materials available from the Cambridge Crystallographic Data Centres comprises of lists of structure factors, all bond lengths and angles, coordinates and occupancy factors, thermal parameters and H-atom coordinates.

RESULTS AND DISCUSSION

The composition of the complexes were confirmed by elemental analyses. The complexes exhibit IR bands comparable to those of the diamine systems whose chelate character has been established by X-ray single crystal analyses [10,19]. The magnetic and electronic spectral data of the complexes are in good agreement with octahedral nickel(II), indicating that nickel(II) is surrounded by N_4O_2-chromophore in each complex. The Near-IR spectrum of each complex shows three bands suggesting D_{4h}-symmetry. Thus, the complexes are in the *trans*-configuration [20]. The solid state thermal property of $[Ni(meen)_2(CF_3CO_2)_2]$ **1** is found to be in good agreement with the work reported by us. Earlier [15], we omitted to observe the thermochromism, blue-violet-to-blue phenomenon associated with this phase transition. However, $[Ni(eten)_2(CF_3CO_2)_2]$ **2** upon heating does not show any phase transition before decomposition (initial temperature of decomposition, Ti = 122°C). On the other hand, blue complexes $[Ni(pren)_2(CF_3CO_2)_2]$ **3** and $[Ni(ipren)_2(CF_3CO_2)_2]$ **4** exhibit irreversible endo-

thermic phase transition (86–112°C; $\Delta H = 13.2$ kJ mol^{-1} for **3** and 155–174°C; $\Delta H = 12.2$ kJ mol^{-1} for **4**) yielding light-violet species **3a** and **4a,** respectively (Figs 1 and 2). The species **3a** and **4a** retain their identity in solid state and revert only on crystallization from $CH_3OH/C_2H_5OH/CH_3CN$ etc. The complexes **3a** and **4a** on further heating undergo melting (190–200°C; $\Delta H = 23.6$ kJ mol^{-1} for **3a** and 208–216°C; $\Delta H = 21.8$ kJ mol^{-1} for **4a,** respectively) (Fig. 1). The melted species on cooling show exotherm with equal enthalpy changes as are observed during heating. Thus, the meltings are reversible in nature. It is evident from the thermal data that the temperature ranges and the value of enthalpy changes associated with phase transitions as well as melting for **3** and **4** have noticeable differences. This probably arises due to steric factors. However, the magnetic data of **3a** and **4a** do not differ from **3** and **4,** respectively. But there is a slight shift in the electronic band position on the thermochromic phase transitions to a shorter wavelength region [λ_{max}(Nujol) 1056, 818, 555 and 355 nm for **3a** and 1095, 765, 560 and 365 nm for **4a,** *vide supra*]. All these suggest that the *trans*-octahedral configuration is retained in **3a** and **4a**. Thus, it may be inferred that these phase transitions (**3** → **3a** and **4** → **4a**) are not associated with any change in geometry/chromophore around nickel(II). However, the IR-spectra of the pairs [(**3, 3a**) and (**4, 4a**)] show marked differences in the regions of 3300–3100, 3000–2800, 1400–1350, 1330–1000 and 1000–430 cm^{-1}, where the vibration of $\nu(NH_2)$, $\nu(CH_2)$, $\rho_w(CH_2)$, $\tau(NH_2)+\tau(CH_2)+\rho_w(NH_2)$ and $\rho_r(NH_2)+\nu$(M—N) appear. It is well documented that the five membered chelate rings formed by ethane-1,2-diamine (en) and its derivatives are not planar and due to this non-planarity they exist in either of two conformations delta (δ) or lambda (λ) in a chelate complex causing the existence of different conformational isomers [21]. As for example, in a *trans*-bis(en) complex, the (en) ring can form three conformational isomers $\delta\lambda$, $\delta\delta$ and $\lambda\lambda$ (of which the latter two are a mirror image to each other and identical in energy). We reported earlier two conformational isomers of $NiL_2(NCS)_2$ (L = *N,N′*-dimethylethane-1,2-diamine) [10] and characterized them by X-ray crystallography. They showed noticeable differences in IR-spectra in the regions as stated above. So it may be assumed that the members of the respective pair [(**3, 3a**) and (**4, 4a**)] are conformational isomers to each other.

The ORTEP views of the complexes **3** and **4** are given in Figs 3 and 4 showing the atom numbering scheme. Since the crystal structure of both the complexes are very similar, a general description of the structures is given. In both complex units of **3** and **4,** the nickel atom occupies a centre of inversion and displays slightly distorted octahedral coordination. Two trifluoroacetate groups are bonded to metal atom in *trans* positions. The four ligand nitrogen atoms (N1, N2 and their centrosymmetrically related ones) define the equatorial plane. The ligand moieties are monometallic, bidentate, resulting in a distorted octahedral coordination around Ni atom. The distortions of the coordination octahedra are due to the slight differences between equatorial Ni—N1 [2.100(3) Å for **3** and 2.089(2) Å for **4**] and Ni—N2 [2.109(4) Å for **3** and 2.175(2) Å for **4**] lengths as well as between endocyclic N1—Ni—N2 [83.9(1)° for **3** and 82.7(1)° for **4**] and exocyclic N1—Ni—N2 [96.1(1)° for **3** and 97.3(1)° for **4**] angles and slight deviation of the O1—Ni—O1* axis from orthogonality [range 86.3(1)° to 93.7(1)° for **3** and 86.9(1)° to 93.2(1)° for **4**] to equatorial plane. The Ni—N, Ni—O bond distances are consistent with the corresponding values of other analogous octahedrally coordinated Ni-complexes [10,22,23]. However, it is interesting to note that in complex **3** Ni—N2 distance is 2.109(4) Å, whereas, in complex **4** Ni—N2 distance is 2.175(2) Å. This reflects the differences in the electronic effects of the chain attached to metal atom via N2. The C—F distances and the large librational motion of F for both crystals call for comment. The mean C—F distance is 1.29(2) Å for complex **3** and 1.292(9) Å for **4**. Angles in CF_3 vary widely from the expected threefold symmetry. These values agree with CSD data base survey of trifluoroacetate group by Gleghorn *et al.* [24]. The large librational motion of F atom may be due to fairly free rotation of CF_3. In complex **3,** the five membered chelate rings display an open envelope geometry with the flap atom C2, 0.555(5) Å away from the least-square plane through the remaining endocyclic atoms. The chelate rings in complex **4** also

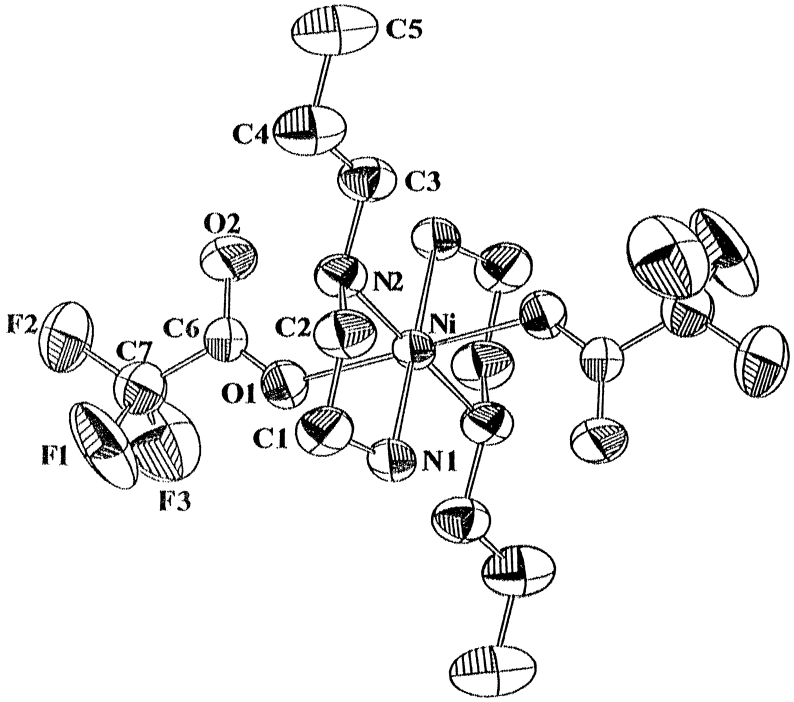

Fig. 3. An ORTEP[18] view of complex **3**.

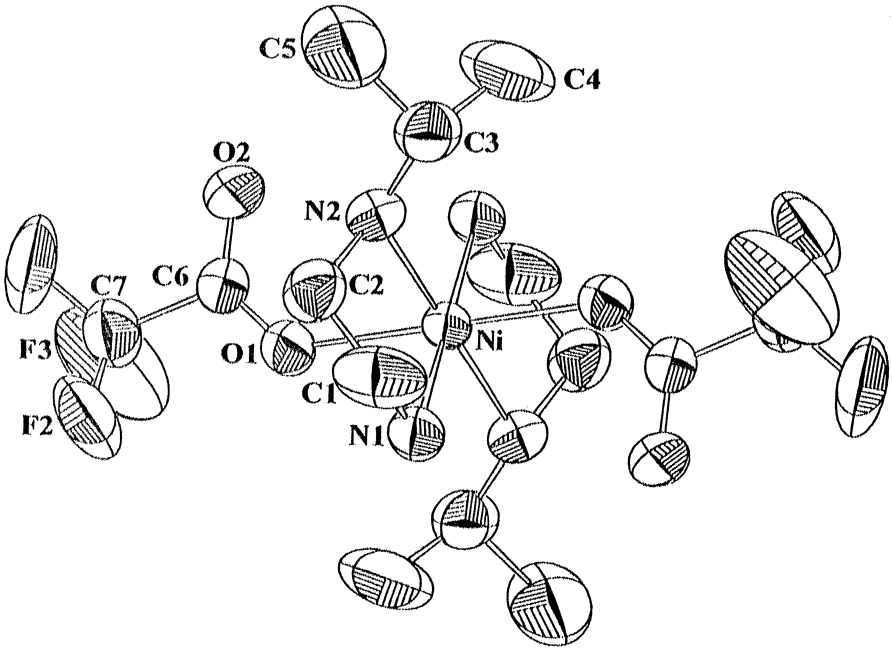

Fig. 4. An ORTEP[18] view of complex **4**.

display the pen envelope geometry with the flap atom C2 and C2A, 0.571(9) Å and 0.550(6) Å, respectively, away from the least square planes through the remaining atoms of the chelate rings. The dihedral angle of the planar parts of the two orientations of the chelate rings is 0.02°.

Crystal packing and hydrogen bonds

Both complexes **3** and **4** are stabilized mainly by intermolecular hydrogen bonds N—H···O which control the overall chelate ring conformations. The O2 atom of trifluoroacetate group of both **3** and **4** provides a potential hydrogen bond acceptor site (H···O2, 2.172(6) Å for **3** and 2.223(10) Å and H···O2A, 2.22(3) Å for **4**) in addition to amine N1 atoms. Other moderate intermolecular hydrogen bonds C4—H···O1, C4—H···N1, N2—H···O2 occur in complex **4**. Possible hydrogen bonds are listed in Table 3 with the widely accepted criteria that hydrogen bonds should be less than the sum of van der Waals radii of H and the acceptor atom.

The molecular packings of both crystals are dominated by strings of molecules along the *b* direction. The strings are held together by several intermolecular hydrogen bonding network. From the comparison of hydrogen bonding networks (Table 3) one may envisage that the hydrogen bonding system of complex **4** is much more extensive than that of complex **3**. This discrepancy is a consequence of bulky isopropyl groups in complex **4,** so that both C4 and C5 take part in hydrogen bonding. This may explain the higher temperature ranges for phase transition as well as melting exhibited by complex **4**.

Several attempts were made to obtain suitable single crystals of complexes **3a** and **4a** but they crystallized to **3** and **4,** respectively from solution. Thus we examined the complexes **3a** and **4a** by X-ray powder diffraction. Accurate d_{hkl} spacings (Å) were obtained from the powder patterns recorded on a Seifert XRD 3000P diffractometer at 30 kv and 30 mA with 2° min^{-1} scan rate. The initial cell parameters have been determined from powder diffraction data and accurate lattice parameters were obtained by least-squares refinements [25] (Table 1). Though it is difficult to comment on the mechanism of phase transition from X-ray powder data (deposited) the following observations are noteworthy. 0*k*0 data containing lines of both **3a** and **4a** show systematic absences with *k* odd but all *h*01 reflection types are present. The likely space group for both **3a** and **4a** is therefore $P2_1$. There are no drastic changes in the cell volume apart from a slight decrease (Table 1) and the systems remain monoclinic. Crystals of **3** and **4** with space group $P2_1/c$, $Z = 2$ and the molecules being centrosymmetric, the Ni-atoms assume the special positions. But with space group $P2_1$ the two molecules have to be distributed over two general equivalent positions.

Table 3. Hydrogen bonding geometry (Å, °)

Complex **3**			
D—H···A	D···A	H···A	<D—H···A

C4—H20···F2A(6)	3.19(1)	2.48(1)	132.1(4)
C5—H25···F1(8)	3.38(2)	2.58(2)	142.0(5)

Symmetry codes:
(1) x,y,z; (2) $-x,-y,-z$; (3) $-x,+y-1/2,-z-1/2$; (4) $x,-y+1/2,+z-1/2$; (5) $x,+y-1,+z$; (6) $x,-y+1/2,+z+1/2$; (7) $x,-y+1/2,z-1/2$; (8) $-x+1,-y,-z$.

Then the molecules are no longer centrosymmetric. This may be explained as follows. In the lower temperature phase N—H···O and C—H···N bonds would be expected to hinder the bond rotation of trifluoroacetate group and the alkyl groups of the ligand moieties. In the transition to the high-temperature phases the H-bonds are weakened upon onset of hindered rotation and lead to a different molecular conformations. Due to the decrease of cell volume, the high-temperature molecular framework of both the crystals are more compact, making the transition irreversible.

CONCLUSIONS

The anion, $CF_3CO_2^-$, like other less easily polarizable anions ClO_4^-, BF_4^- etc. exhibits discontinuous thermochromism due to conformational changes of the diamine chelate rings. N-methylethane-1,2-diamine yields discontinuous thermochromism which is found to be time dependent reversible in nature, whereas N-propyl and N-isopropylethane-1,2-diamine exhibit irreversible thermochromism and N-ethylethane-1,2-dimine does not show any thermochromism likely to be due to overlapping with its decomposition temperature range. Thus, it may be concluded that steric and inductive effect exerted by *n*-propyl and isopropyl alkyl groups are optimum to exhibit irreversible discontinuous thermochromism in the nickel(II) trifluoroacetate system.

(Received 28 October 1996; accepted 5 May 1997)

Abstract—A new V^{III} vanadium phosphate, $(H_3NCH_2CH_2NH_3)[V(OH)(HPO_4)_2]\cdot H_2O$ (**1**), with a novel 1-D polymeric chain structure was prepared hydrothermally and its structure determined by X-ray diffraction. The structure consists of infinite $\{V(OH)(HPO_4)_2\}^{2-}$ chains, ethylenediammonium dications and lattice water molecules. The $\{V(OH)(HPO_4)_2\}^{2-}$ chains contain an infinite $\{V^{3+}—OH—V^{3+}\}$ backbone bridged by $(HPO_4)^{2-}$ groups. Each V^{3+} atom has a quite regular octahedral configuration containing four phosphate oxygens and two trans positioned OH groups. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: vanadium phosphates; hydrothermal synthesis; X-ray crystal structure

The V/O/phosphate or arsenate system is dominated by three dimensional (3-D) and two dimensional (2-D) structures. Examples of lamellar vanadium phosphates include $VO(PO_4)\cdot 2H_2O$ [1], $VO(HPO_4)\cdot nH_2O$ [2,3], and a series compounds with the compositions of $M_{0.5}[VOPO_4]\cdot nH_2O$ [4–6] (M = Na, Ca, Sr, Pb, Co, Ni, Cu; $n = 2$, and M = K; $n = 1.5$). Among the known 3-D vanadium phosphates are the compounds $Ni_{0.5}[VOPO_4]\cdot 1.5H_2O$ [7], $Pb_{0.5}[VOPO_4]$ [8], and M_nVOPO_4 [9–15] (M = Li, Na, K, $n = 1$, and M = Ca, Ba; $n = 0.5$), while known examples of 1-D polymers of vanadium phosphates are provided by $NH_4(VO_2)(HPO_4)$ [15] and $VO(HPO_4)\cdot 4H_2O$ [16]. We have synthesized several novel vanadium phosphates with 2-D and 3-D framework structures through the introduction of organic templates or by the combination of both organic and inorganic cations in the reaction mixtures [17–20]. In addition, two organically templated 1-D vanadium arsenate polymers, $(H_2NC_4H_8NH_2)[(VO)_2(HAsO_4)_2(H_2AsO_4)_2]$ and $(H_3NCH_2CH_2NH_3)[V^{III}(HAsO_4)_2(H_2AsO_4)]\cdot H_2O$, have recently been isolated [21]. The structural diversity of the vanadium system results from the variation in the vanadium oxidation state and in the vanadium to phosphate or arsenate ratio. While V^{IV}-containing phosphates are very common, phosphates containing exclusively V^{III} are rare [22–25]. We report here the hydrothermal synthesis and single crystal structure of a V^{III} phosphate, $(H_3NCH_2CH_2NH_3)[V(OH)(HPO_4)_2]\cdot H_2O$ (**1**), which contains a novel polymeric chain structure.

EXPERIMENTAL

Synthesis of $(H_3N(CH_2)_2NH_3)[V(OH)(HPO_4)_2]\cdot H_2O$, (**1**)

The synthesis of the title compound was carried out in a polytetrafluoroethylene-lined stainless steel container under autogeneous pressure. The greenish plate-like crystals were obtained as a minor product ~5%) from hydrothermal reaction of VO_2, CuO, H_3PO_4, $H_2NCH_2CH_2NH_2$ and H_2O in a mole ratio of

1.0 : 0.7 : 6.9 : 3.6 : 265 at 160°C for 4 days with $(H_3N(CH_2)_2NH_3)_4[(V(H_2O)_2(VO)_6(OH)_2(HPO_4)_3(PO_4)_5]\cdot 3H_2O$ [26] as the major product. A higher yield of the title compound was obtained from the hydrothermal reaction of VO_2, H_3PO_4, $FeSO_4\cdot 7H_2O$, $H_2NCH_2CH_2NH_2$ and H_2O in the mole ratio of 1.0 : 7.3 : 0.5 : 3.7 : 256 at 160°C for 5 days. Under the latter reaction conditions, greenish needle-shaped crystals were isolated in about 50% yield based on vanadium. Small amounts of tiny black crystals (<5%), whose EDS analysis showed the presence of V (but not P), were also present as an impurity phase. Some of the needle-shaped crystals from this prep contained iron in varying amounts as indicated by EDS analysis, but there was no evidence of iron substitution at the vanadium sites in the final crystal structure solution. Although not completely understood, the presence of $FeSO_4\cdot 7H_2O$ seems to be necessary for the high yield synthesis of phosphate (**1**). Reactions done under similar conditions, but without $FeSO_4\cdot 7H_2O$, yielded different products.

Crystallography

A greenish plate-like crystal of the title compound having approximate dimensions of $0.2\times 0.2\times 0.05$ mm was mounted on a glass fiber. All measurements were made on a Rigaku AFC7R diffractometer with graphite monochromated Mo-K_α radiation and an 18 kW rotating anode generator. Cell constants and an orientation matrix for data collection, obtained from a least-squares refinement using the setting angles of 25 reflections in the range $20.53 \leqslant 2\theta \leqslant 26.78°$, corresponded to a triclinic cell. Based on the statistical analysis of intensity distribution, and the successful solution and refinement of the structure, the space group was determined to be $P\bar{1}$. The data were collected out to 60° in 2θ using the ω–2θ scan technique at a speed of 16°/min in ω. A total of 2223 reflections were measured of which 2022 were unique ($R_{int} = 0.039$). The intensities of three representative reflections were measured after every 150 reflections and remained constant throughout data collection. An empirical absorption correction based on ψ scans was applied to the data, and the data were corrected for Lorentz and polarization effects. The structure of (**1**) was solved by direct methods using the *teXsan* crystallographic software package from Molecular Structure Corporation [27]. All the non-hydrogen atoms were refined anisotropically, and no attempt was made to locate the hydrogen atoms. A high thermal parameter was observed for the water molecule in the structure of (**1**), and is likely indicative of partial occupancy. The final cycle of full-matrix least-squares refinement was based on 1329 observed reflections ($I \geqslant 3\sigma(I)$) and 157 variable parameters, and converged with unweighted and weighted agreement factors of $R = \Sigma\|F_o - |F_c\|/\Sigma|F_o| = 0.051$ and $R_w = (\Sigma\omega(|F_o| - |F_c|)^2/\Sigma\omega F_o^3)^{1/2} = 0.058$. Further details of the X-ray structural analysis are given in Table 1.

RESULTS AND DISCUSSION

Our continued investigation into the vanadium phosphate system has resulted in the synthesis of an unusual 1-D $\{V^{+3}—OH—V^{3+}\}$ polymeric chain material. The structure of $(H_3N(CH_2)_2NH_3)[V(OH)(HPO_4)_2]\cdot H_2O$ (**1**) consists of infinite $\{V(OH)(HPO_4)_2\}^{2-}$ chains, ethylenediammonium dications and lattice water molecules, which are all clearly visible in the unit cell view depicted in Fig. 1. The corner-shared hydroxide group (O(8)) is at nearly equal distances to the two V^{3+} centers with a V—O—V angle of 131.3(3)°, thus forming an infinite zig-zag {V—OH—V} chain which runs down the crystallographic c axis. As can also be seen in Fig. 1, there is an extensive hydrogen bonding scheme in this structure. The $\{V(OH)(HPO_4)_2\}^{2-}$ chains are hydrogen bonded to each other via the pendant P—OH groups along the crystallographic a axis with a short O(3)···O(6) contact of 2.605(8) Å. The lattice water molecule, O(10), is in contact with O(9) and the hydroxide group, [O(8)], with distances in the range of 2.77–2.86 Å. The chains are also hydrogen bonded to the NH_3^+ groups of the ethylenediammonium cations with all N···O distances less than 3 Å. Other bond distances and angles of interest can be found in Table 2.

The infinite $\{V(OH)(HPO_4)_2\}^{2-}$ chains of $(H_3N(CH_2)_2NH_3)[V(OH)(HPO_4)_2]\cdot H_2O$ (**1**) are more clearly depicted in Fig. 2. Each chain contains an

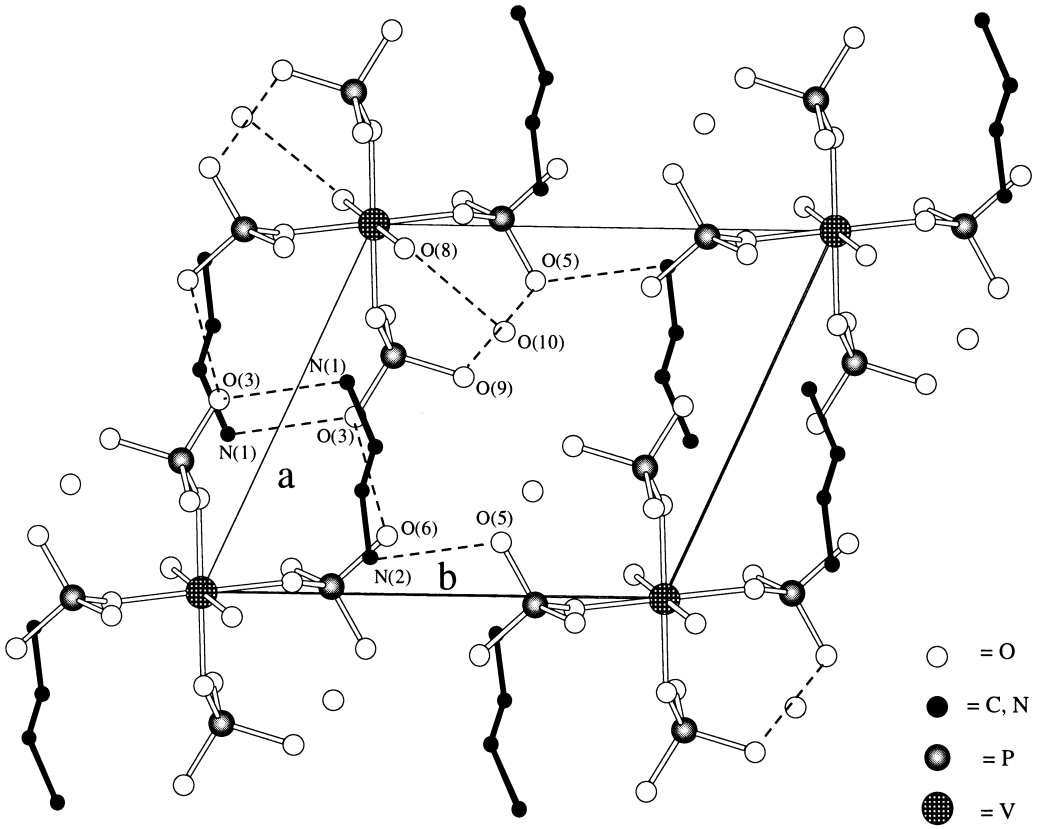

Fig. 1. A projection of the structure of $(H_3NCH_2CH_2NH_3)[V(OH)(HPO_4)_2]\cdot H_2O$ down the crystallographic c axis showing the ethylenediamine molecules, lattice water molecules, and the infinite chains of corner sharing VO_6 octahedra.

infinite $\{V^{3+}—OH—V^{3+}\}$ backbone bridged by $(HPO_4)^{2-}$ groups. As can be seen in this figure, only two of the four oxygen atoms of each $(HPO_4)^{2-}$ group are bridged to two V^{3+} centers. Also, since each V^{3+} atom resides on an inversion center, it has a quite regular octahedral configuration containing four phosphate oxygens and two trans positioned OH groups. The six V—O bond distances for V(1) in the chains are in the range of 1.979(5)–2.032(5) Å, and the V—O bond distances for V(2) are in the range of 1.986(5)–2.029(5) Å. Such a regular octahedral coordination is indicative of V^{3+}, and this $+3$ oxidation state has in fact been confirmed by valence sum calculations.

It is interesting to note that the finite $\{V^{3+}—OH—V^{3-}\}$ chains in (**1**) are different from those in the structures of $(H_3NCH_2CH_2NH_3)[V^{III}(HAsO_4)_2(H_2AsO_4)]\cdot H_2O$ (**2**) and $(H_2C_4H_8NH_2)[(VO)_2(HAsO_4)_2(H_2AsO_4)_2]$ (**3**) [21]. While the infinite chains in arsenate (**2**) contain $V^{III}O_6$ octahedra bridged into 1-D chain *via* $(HAsO_4)$ and (H_2AsO_4) groups, these chains contain isolated VO_6 octahedra with no covalent $\{V—O—V\}$ intrachain connections. In (**2**), the two free vertices in the octahedra are compensated by two oxygen atoms from an additional bridging $\{AsO_4\}$ group. Similar chains to those in (**2**) are also found in the structure of a strontium vanadium phosphate $Sr_2[V^{III}(PO_4)_2(H_2PO_4)]$ [22]. The infinite chains in arsenate (**3**) are composed of corner sharing $V^{IV}O_6$ octahedra and $(HAsO_4)$ and (H_2AsO_4) tetrahedra. The backbone of these chains consists of $\{V^{4+}{=}O\cdots V^{4+}\}$ chains containing alternating short V=O vanadyl contacts of 1.627 Å and longer $V\cdots O$ distances of 2.248 Å *trans* to the vanadyl oxygen positions. Such corner sharing 1-D chains of $V^{IV}O_6$ octahedra are also found in the 3-D structures of $(NH_4)[(VO)(V_2O_3)(AsO_4)_2(HAsO_4)]$ [28] and $NH_4[VOPO_4]$ [29].

The $\{M^{3+}—OH—M^{3+}\}$ (M = Al, Fe) type chains found in (**1**) are fairly common in naturally occurring

minerals. Examples include sideronatrite $Na_2[Fe(SO_4)_2(OH)]\cdot 3H_2O$ [30], metasideronatrite $Na_2[Fe(SO_4)_2(OH)]$ [31], tancoite $LiNa_2H[Al(PO_4)_2(OH)]$ [32] and overite $Ca_2Mg_2[Al(PO_4)_2(OH)]_2\cdot 8H_2O$ [33]. The synthetic compound $Na_4[Al(PO_4)_2(OH)]$ [34] also contains chains of {Al—OH—Al} which are similar to those found in mineral tancoite.

Using the same organic template, ethylenediamine, but under different reaction conditions and with different vanadium sources, two open framework vanadium phosphates with very large tunnels in which protonated ethylenediamine molecules reside have been made [19,26]. In these reactions, ethylenediamine acts not only as a templating agent, but also as a reducing agent, which is responsible for the reduction of V^{5+} to V^{4+} under the hydrothermal conditions. In case of phosphate (**1**), however, it is not clear whether ethylenediamine is solely responsible for the reduction of V^{4+} to V^{3+}. Since EDS analysis showed that some of the crystal obtained from reactions with the presence of $FeSO_4\cdot 7H_2O$ contained small amounts of iron, it is possible that the presence of Fe^{2+} may have played a role in the reduction processes. Also, the fact that the content of iron differs from one crystal to another indicates that isomorphous substitution of iron for V^{3+} may have taken place. This kind of substitution is not unusual and has been observed in many compounds. In fact, the $\{Fe^{3+}—OH—Fe^{3+}\}$-type chains have been found in the layered structures of phosphate minerals like jahnsite. $CaMnMg_2[Fe(PO_4)_2(OH)]_2\cdot 8H_2O$ [35] and segelerite $Ca_2Mg_2[Fe(PO_4)_2(OH)]_2\cdot 8H_2O$ [33].

In summary, the isolation of $(H_3NCH_2CH_2NH_3)[V(OH)(HPO_4)_2]\cdot H_2O$ (**1**) provides another demonstration of the dramatic expansion of the structural and compositional range of the phosphate materials resulting from the incorporation of organic templates.

Acknowledgements—The work at Texas A&M University was supported by the National Science Foundation under grant No. DMR-9107715 for which grateful acknowledgement is made. We thank Professor A. K. Cheetham for providing us with the information on $Na_4[Al(PO_4)_2(OH)]$ before publication.

Supplementary materials available— Tables of atomic coordinates, bond lengths and angles, anisotropic displacement coefficients (16 pages), and observed and calculated structure factors (10 pages) for (**1**) are available on request.

BOOK REVIEW

Gmelin Handbook of Inorganic and Organometallic Chemistry, 8th Edition, Supplement Volume B 9. Ternary and Quaternary Si(H)F—O, Si(H)F—N, and SiF(—O)—N Compounds, Derivatives Substituted at O and N, and Fluorosilicate Salts of O- and N-Based Cations. Springer-Verlag, Berlin, 1997. 289 + xv pages. Price DM 1740. (ISBN 3-540-93750-1).

This volume is the third and last instalment of Gmelin Supplements dealing with silicon-fluorine compounds. Binary Si—F species were the subject of Volume B 7 and ternary Si—F—H compounds of Volume B 8. Now it is the turn of compounds which all contain silicon linked to fluorine and also to nitrogen, to oxygen or to both nitrogen and oxygen; such compounds which additionally have Si—H bonds are also included. This definition is taken to include not only adducts of Si—F_x species with N- and O-donors, such as $SiF_4 \cdot 2NH_3$, but also those salts in with an SiF_x^{n-} anion is associated with an ammonium or substituted ammonium cation, such as $(PhNH_3)_2^+(SiF_6)^{2-}$. Because of the classification system used in Gmelin, no compounds with Si—C bonds are included. This explanation of the actual contents may reassure those worried by the length of the volume's title. The literature coverage effectively dates from 1959 to 1995, although some papers published up to November 1996 have been considered; this represents commendably rapid publication, given the complexity of a book of this type.

Perhaps a volume of Gmelin does not always suggest itself as ideal bedtime reading, yet here may be found many intriguing nuggets of information and pointers to further research. For example, $(NH_4)_2SiF_6$ can be found as a crystalline mineral, resulting from volcanic activity or burning coal mines—unsuitable experimental conditions for the laboratory, however. Also a polymer of claimed composition $(FSiN)_x$, first prepared over 20 years ago, has recently appeared in a patent as a protective semiconducting layer in the manufacture of LCD devices. Another patent describes how a substituted pyridyldiazonium salt $(RN_2)_2SiF_6$ may be used in the synthesis of pharmaceuticals. The major areas of coverage relate to adducts of SiF_4 with N-bases, fluorosiloxanes such as $SiF_3O(SiF_2O)_nSiF_3$ ($n = 0, 1, 2, \ldots$), alkoxysilanes $SiF_n(OR)_{4-n}$ ($n = 1$–3), corresponding aminosilanes $SiF_n(NR^1R^2)_{4-n}$ ($n = 1$–3; R^1 = H or organyl), cyclosilazanes $[F_2SiNR]_2$, *Si*-fluorosilatranes, and salts of SiF_5^- and SiF_6^{2-} with $[(N\text{-Base})H]^+$ cations. Besides these main categories, however, there is a miscellany of other compounds, some of which were reported in the 1960s and 1970s and could helpfully be reinvestigated using modern techniques. The theoreticians have been active in this whole field, too; here there are calculations which provide structures, thermodynamic data, bond dissociation energies, and likely reaction paths for small molecules such as $F_2Si{=}O$, $FSi{\equiv}N$, and F_3SiNH and even large molecules like $H_3SiNSiF_2N(SiH_3)SiF_2$. Practical applications are not forgotten: the fluoroalkoxysilane $SiF(OC_2H_5)_3$, for instance, can act as a precursor for chemical vapour deposition of Si/O/F thin films, and also enters into sol-gel processes for making special glasses or preceramic polymers.

This volume is written by a group of Gmelin staff, together with U. Klingebiel (Göttingen), and edited overall by R. Haubold and F. Schröder. It fully maintains the high reputation of these volumes for meticulous accuracy, completeness and critical appraisal of the extensive literature.

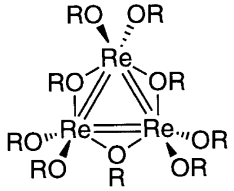
(Received 22 March 1997; accepted 12 June 1997)

Abstract—Rhenium(III) chloride reacts with sodium isopropylthiolate to give the homoleptic rhenium thiolate cluster $Re_3(\mu\text{-}SPr^i)_3(SPr^i)_6$ in moderate yield. Proton and ^{13}C NMR spectra indicate the cluster has virtual C_s symmetry in solution due to the high barrier to inversion for the three-coordinate sulfur atoms at the bridging sites. The Re–Re bond distances are longer than those in analogous alkoxide clusters. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: rhenium ; cluster ; thiolate.

INTRODUCTION

We recently reported the synthesis of the homoleptic rhenium alkoxide clusters $Re_3(\mu\text{-}OPr^i)_3(OPr^i)_6$ and $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6$ (**I**) [1–3]. Both act as



I

sources of terminal monohydride clusters, $Re_3(\mu\text{-}OR)_3H(OR)_5$, from which an extensive Re–H insertion chemistry can be generated [1–5]. The homoleptic neopentoxide cluster also reacts with ethyne to give $Re_3(\mu\text{-}HCCH)(\mu\text{-}OCH_2Bu^t)_2(OCH_2Bu^t)_7$, an unusual cluster in which the Re–Re multiple bonds appear to be involved in the Re–ethyne bonding [5, 6]. The extensive reactivity observed for the alkoxide clusters prompted us to attempt the synthesis of a thiolate analog. Surprisingly, the only structurally characterized homoleptic rhenium thiolate complexes in the literature are the trigonal prismatic chelate complexes $Re(SC(Ph)=C(Ph)S)_3$ and $[Re(MeC(CH_2S)_3)_2]^-$ [7, 8]. Other structurally characterized metal–organic rhenium compounds with exclusively sulfur coordination include $[Re(1,4,7\text{-trithiacyclononane})_2]^{2+}$ [9], $[Re(S)(SCH_2CH_2S)_2]^-$ [10], $[Re_2(\mu\text{-}S\text{-}S_2CNMe_2)_2(S_2CNMe_2)_3]^+$, $[Re(\eta^2\text{-}S_2CNMe_2)_4]^+$, and $[Re(\mu\text{-}S)(\eta^2\text{-}S_2CNBu^i_2)_2]_2$ [11].

We report here the synthesis, solution characterization and X-ray crystal structure determination of $Re_3(\mu\text{-}SPr^i)_3(SPr^i)_6$.

EXPERIMENTAL

All manipulations were carried out in a nitrogen-filled glove box or by using standard Schlenk techniques. Solvents were purified by standard techniques and then stored in the glovebox over molecular sieves until they were needed. Rhenium metal was purchased from Cleveland Refractory Metals and $Re_3(\mu\text{-}Cl)_3Cl_6(THF)_3$ was prepared as described in the literature [12–14]. Proton and ^{13}C NMR spectra were referenced internally to solvent proton and carbon-13 resonances, respectively. The spectra were collected on a 300-MHz instrument. Elemental analyses were performed by Oneida Research Services, Whitesboro, NY.

Synthesis of $Re_3(\mu\text{-}SPr^i)_3(SPr^i)_6$

Sodium isopropylthiolate (1.6 g, 16 mmol) was added to a red solution of $Re_3Cl_9(THF)_3$ (2.0 g, 1.8 mmol) in THF (140 cm^3). The mixture was refluxed for 2 days, and the solvent was then removed under reduced pressure. The residue was extracted with hexanes ($5 \times 20\ cm^3$), and the extracts were combined and filtered through Celite. The filtrate was taken to dryness *in vacuo* and the residue was dissolved in a mixture of CH_2Cl_2 and CH_3CN (5:1). The solution was concentrated to about 5 cm^3 and the flask was then transferred to a freezer ($-35°C$) where red crystals formed over a period of 2 days (yield 0.65 g, 58%). Found: C, 26.4; H, 5.0. Calc. for $Re_3S_9C_{27}H_{63}$: C, 26.7; H, 5.1%.

^1H NMR ($CDCl_3$): δ 1.06 (d, 6, $J_{HH} = 6.9$ Hz, SCHMe_2), 1.09 (d, 6 $J_{HH} = 7.2$ Hz, SCHMe_2), 1.25 (d, 6, $J_{HH} = 6.9$ Hz, SCHMe_2), 1.31 (d, 6, $J_{HH} = 6.9$ Hz, SCHMe_2), 1.39 (d, 6, $J_{HH} = 6.9$ Hz, SCHMe_2), 1.50 (d, 6 $J_{HH} = 6.6$ Hz, SCHMe_2), 1.69 (d, 6, $J_{HH} = 6.6$ Hz, SCHMe_2), 1.75 (d, 6, $J_{HH} = 6.6$ Hz, SCHMe_2), 1.84 (d, 6, $J_{HH} = 6.6$ Hz, SCHMe_2), 3.27 (septet, 1 $J_{HH} = 6.6$ Hz, SC*H*Me_2), 3.84 (septet, 3, $J_{HH} = 6.6$ Hz, SC*H*Me_2), 4.01 (septet, 2, $J_{HH} = 6.6$ Hz, SC*H*Me_2), 4.50 (septet, 1, $J_{HH} = 6.6$ Hz, SC*H*Me_2), 4.57 (septet, 2 $J_{HH} = 6.6$ Hz, SC*H*Me_2), $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 25.6 (2, SCHMe_2), 25.9 (2, SCHMe_2), 26.7 (2, SCHMe_2), 27.4 (2, SCHMe_2), 28.0 (2, SCHMe_2), 28.3 (2, SCHMe_2), 28.4 (4, SCHMe_2), 28.7 (2, SCHMe_2), 32.5 (1, S*C*HMe_2), 37.5 (2, S*C*HMe_2), 38.0 (1, S*C*HMe_2), 44.2 (2, S*C*HMe_2), 44.3 (2, S*C*HMe_2), 47.1 (1, S*C*HMe_2). IR (Nujol, KBr, cm^{-1}): 1306 w, 1304 w, 1236 s, 1150 s, 1040 m, 984 w, 914 m, 799 w, 723 m, 594 w.

Crystal structure determination

The crystals for study were grown from a concentrated CH_2Cl_2/MeCN solution at $-35°C$ over a period of one month.

Crystal data. $C_{27}H_{63}S_9Re_3 \cdot CH_2Cl_2$, $M = 1319.97$, monoclinic, space group $P2_1/n$, $a = 13.327(3)$, $b = 16.868(6)$, $c = 21.352(6)$ Å, $\beta = 102.62(2)°$, $U = 4684$ Å^3, $T = -50°C$, Mo-K_α ($\lambda = 0.71073$ Å), $Z = 4$, $D_c = 1.87\ g\,cm^{-3}$, $F(000) = 2544$, $\mu = 83.61\ cm^{-1}$. Crystal size: $0.30 \times 0.50 \times 0.60$ mm.

Data collection. The magenta-colored irregular blocks were manipulated under mineral oil. Nicolet R3m/V diffractometer equipped with a low-temperature device, ω mode with scan width $\Delta\theta = 1.30 + (K\alpha_2 - K\alpha_1)°$, scan speed range 1.5–15.0° min^{-1}, graphite-monochromated Mo-K_α radiation; 6615 reflections measured ($4° \leqslant 2\theta \leqslant 45°$, h, k, $\pm l$), 4567 independent with $I > 3\sigma(I)$. Lorentz and polarization corrections were applied as well as semi-empirical absorption corrections based on psi scans of ten reflections having chi angles between 70 and 90°. Two standard reflections were measured every two hours or after every 100 data collected, and these showed no significant variation.

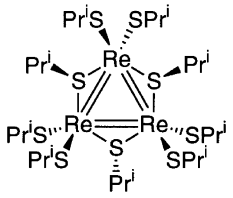
Structure solution and refinement. The Laue symmetry was determined to be 2/m and the space group was shown to be $P2_1/n$. The structure was solved by interpretation of the Patterson map, which revealed the positions of the three independent Re atoms. Remaining nonhydrogen atoms were found in subsequent difference Fourier syntheses. The hydrogen atoms were placed in calculated positions and constrained to riding motion, with a single variable isotropic temperature factor for all of them. Two of the isopropyl groups (C4 and C13) were found to be significantly disordered, and these were treated by substituting two ideal rigid bodies having 50% occupancy at each site and allowing them to rotate independently. Additionally, a heavily disordered molecule of methylene chloride solvent was located, and eventually it was refined as three ideal rigid bodies each having 1/3 occupancy. After all shift/esd ratios were less than 0.1 (except for the rigid bodies) convergence was reached with R, $R_w = 0.048$, 0.049. The weighting scheme was $w = [\sigma(F)]^{-2}$ (GOF = 2.18). No unusually high correlations were noted between any of the variables in the last cycle of full-matrix least squares refinement except between variables in the disordered methylene chloride solvent. The final difference density map showed a maximum peak of about 1.50 e/Å^3 located near Re. All calculations were made using Nicolet's SHELXTL PLUS (1987) package of programs [15].

Tables of final atomic coordinates, bond distances, bond angles, torsion angles, anisotropic thermal parameters, least-squares planes and calculated H-atom positions, as well as a packing diagram, have been deposited with the Editor.

RESULTS AND DISCUSSION

The halide $Re_3(\mu\text{-}Cl)_3Cl_6(THF)_3$ reacts with $NaSPr^i$ in refluxing THF to give $Re_3(\mu\text{-}SPr^i)_3(SPr^i)_6$ as red crystals in moderate yield after a workup that includes crystallization from CH_2Cl_2/MeCN. Attempted preparations of other derivatives, including phenyl thiolate and substituted phenyl thiolate derivatives, failed to give clean products.

The room temperature ^1H NMR spectrum of $Re_3(\mu\text{-}SPr^i)_3(SPr^i)_6$ consists of nine sharp equal-intensity doublets and five septets in a 3:2:2:1:1 ratio arising, respectively, from the methyl and methine protons. The septet of relative intensity 3 consists of two accidentally degenerate septets. Proton NMR spectra recorded for a toluene-d_8 solution at temperatures up to 90°C were not significantly different from room temperature spectra. These data are consistent with a static structure that has a bridging isopropyl groups locked into a configuration with one group antifacial to the other two (**II**). The same structure is observed in the solid state (see next page).



II

The bridging isopropyl thiolates are locked into one configuration as a consequence of the relatively large barrier to inversion at sulfur [16]. This is in contrast to the analogous isopropoxide cluster $Re_3(\mu\text{-}OPr^i)_3(OPr^i)_6$, which has rapid inversion at oxygen for the bridging alkoxide sites and a ^1H NMR spectrum consisting of only four peaks, two 2:1 methyl doublets and two 2:1 methine septets.

The high temperature stability of $Re_3(\mu\text{-}SPr^i)_3(SPr^i)_6$ in solution contrasts sharply with the behavior of $Re_3(\mu\text{-}OPr^i)_3(OPr^i)_6$. In solution, the homoleptic isopropoxide cluster exists in equilibrium with $Re_3(\mu\text{-}OPr^i)_3(H)(OPr^i)_5$ and free acetone even at room temperature ($K_{eq} = 6 \times 10^{-4}$ M at 23°C) [2]. The equilibrium presumably does not exist for $Re_3(\mu\text{-}SPr^i)_3(SPr^i)_6$ because the C═S bond in Me_2C═S is weaker than C═O in Me_2C═O [E(C═O) = 191 kcal/mol vs E(C═S) ≈ 137 kcal/mol] [17] and the difference in these bond energies is not compensated for by the stronger Re–OR bond in comparison to Re–SR. Also, greater stabilization is expected for release of Me_2C═O from the more sterically crowded alkoxide cluster in comparison to release of Me_2C═S from the thiolate cluster. The alkoxide cluster is more sterically crowded than the thiolate cluster because the Re–O and O–C bonds are shorter than the Re–S and S–C bonds.

To confirm the structure of $Re_3(\mu\text{-}SPr^i)_3(SPr^i)_6$ an X-ray crystallographic study was carried out. A thermal ellipsoid plot is shown in Fig. 1 and selected bond distances and angles are given in Table 1. The Re–Re bond distances [2.475(1)–2.494(1) Å] are significantly longer than the distances observed in trirhenium(III) clusters with alkoxide bridges, such as $Re_3(\mu\text{-}OCH_2Bu^t)_3(OCH_2Bu^t)_6$ [2.365(1)–2.372(1) Å] [3], and for the chloride-bridged Re–Re bonds in $Re_3(\mu\text{-}Cl)_3(OBu^t)_6$ [2.436(3)–2.439(3) Å] and $Re_3(\mu\text{-}Cl)(\mu\text{-menthoxo})_2Cl(menthoxo)_5$ [2.422(3) Å]. The Re–$S_{terminal}$ distances [av. 2.28 Å] are shorter than the Re–S_{bridge} distances [av. 2.40 Å], and both sets of distances are normal; for example, the Re–S distances [8, 10] in $[Re(MeC(CH_2S)_3)_2]^-$ and $[Re(S)(SCH_2CH_2S)_2]^-$ range from 2.285(2) to 2.345(5) Å and the Re–S_{bridge} distances in $[Re(\mu\text{-}SEt)Cl(3,6\text{-dithiaoctane})]_2$ are 2.330(6)–2.371(6) Å] [18].

The angles at sulfur for the terminal ligands, 113–121°, are normal [19]. The $S_{terminal}$–Re–$S_{terminal}$ angles are all very close to 124° but at each Re site one of the two terminal sulfurs is closer to being perpendicular to the Re_3 plane than the other. The most pronounced difference involves S(5) and S(6) for which the centroid [Re(1)–Re(2)]–Re(3)–S angles are 129.6 and 106.6°, respectively. The differences may be due to the configurations of the bridging thiolates. The isopropyl

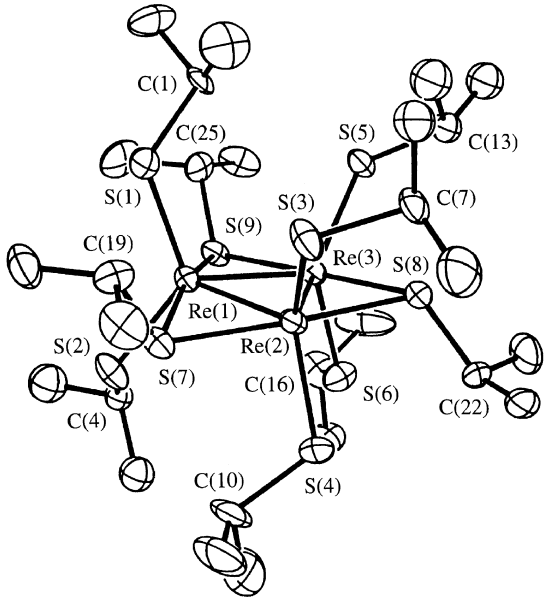

Fig. 1. Molecular structure of $Re_3(\mu\text{-}SPr^i)_3(SPr^i)_6$ (40% probability ellipsoids). Only one orientation of each disordered group is shown.

groups of the S(7) and S(9) bridging thiolates are bent to the same side of the Re_3 plane as the S(3) and S(5) terminal thiolates. This causes the terminal ligands to bend away from the Re_3 plane and consequently the S(4) and S(6) terminal ligands move towards being perpendicular to the plane. The positions of the S(4) and S(6) ligands apparently force the S(2) thiolate away from the plane, which in turn brings S(1) closer to the perpendicular position.

CONCLUSION

The halide $Re_3(\mu\text{-}Cl)_3Cl_6(THF)_3$ reacts with $NaSPr^i$ to give the homoleptic trirhenium(III) thiolate cluster $Re_3(\mu\text{-}SPr^i)_3(SPr^i)_6$ in moderate yield. In solution the cluster has virtual C_s symmetry because of the high barrier to inversion for the three-coordinate sulfurs at the bridging sites. The Re–Re bond distances are longer than those in analogous alkoxide clusters. $Re_3(\mu\text{-}SPr^i)_3(SPr^i)_6$ appears to be the first structurally characterized homoleptic rhenium thiolate cluster.

*Acknowledgements*Acknowledgement for support is made to the Robert A. Welch Foundation. We are grateful to Dr James Korp for his technical assistance with the X-ray crystallographic analysis.

(Received 24 July 1997 ; accepted 28 October 1997)

Abstract—The preparation and characterisation of [Os(η^5-C_5Ph_5)$(CO)_2$Br] (**1**) are described ; this complex is the first reported $C_5Ph_5^-$ derivative of osmium. A single crystal X-ray diffraction study of (**1**) (refined to $R = 0.040$, $R_w = 0.043$) is also reported. The related complexes, [Os{η^5-C_5Ph_4(p-^{t}BuC_6H_4)}$(CO)_2$Br] (**2**) and [Os{η^5-C_5(p-MeC_6H_4)$_5$}$(CO)_2$Br] (**3**), have also been prepared. Carbonyl substitution of (**1**) in tetrahydrofuran following treatment with Me_3NO afforded [Os(η^5-C_5Ph_5)(CO)(L)Br] (L = PMe_2Ph (**4**), $P(OEt)_3$ (**5**), $P(OCH_2)_3CCH_3$ (**6**) and ^{t}BuNC (**7**)). A single crystal X-ray diffraction study of (**6**) (refined to $R = 0.066$, $R_w = 0.073$) is described. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: osmium ; cyclopentadienyl ; pentaphenylcyclopentadienyl ; crystal structure.

Relatively few cyclopentadienyl or substituted cyclopentadienyl complexes of osmium have been described and the number of structurally characterised derivatives is correspondingly small [1–22]. Previously, the half-sandwich compounds [Os(η^5-C_5H_5)$(CO)_2$Br] and [Os(η^5-C_5H_5)$(CO)_2$H] have been prepared from the reactions of $Os(CO)_4Br_2$ with $(C_5H_6)_2$ in decane and Tl(C_5H_5) in heptane, respectively [23]. In addition, [Os(η^5-C_5Me_5)$(CO)_2$Br] has been synthesised by reacting $Os(CO)_4Br_2$ with C_5Me_5H in decane [23] ; [Os(η^5-C_5Me_5)$(CO)_2$I] from a one-pot reaction of $Os_3(CO)_{12}$, I_2 and C_5Me_5H in benzene [6], and [Os(η^5-C_5Me_5)$(CO)_2$H] from $Os_3(CO)_{12}$ and C_5Me_5H in heptane [23]. More recently, [Os(η^5-C_5Me_5)Br(μ-Br)]$_2$ has been synthesized in good yield from H_2OsBr_6 and C_5Me_5H [20]. This dimer proved to be a convenient intermediate in the synthesis of a wide variety of [Os(C_5Me_5)L_n] complexes.

The formal oxidative addition of $C_5R_{5-n}H_nX$ (n = 0–5) to a transition metal precursor is an alternative synthetic route to cyclopentadienyl and substituted cyclopentadienyl complexes. This route has not been widely exploited because of the lack of ready availability of most of the necessary $C_5R_{5-n}H_nX$ precursors. However, 1-bromo-1,2,3,4,5-pentaarylcyclopentadienyl species are readily prepared in high yield and their reactions with organometallic precursors provide convenient routes to pentaarylcyclopentadienyl complexes [24–26]. A potentially wide range of ligands with varying electronic and steric properties is accessible in this way.

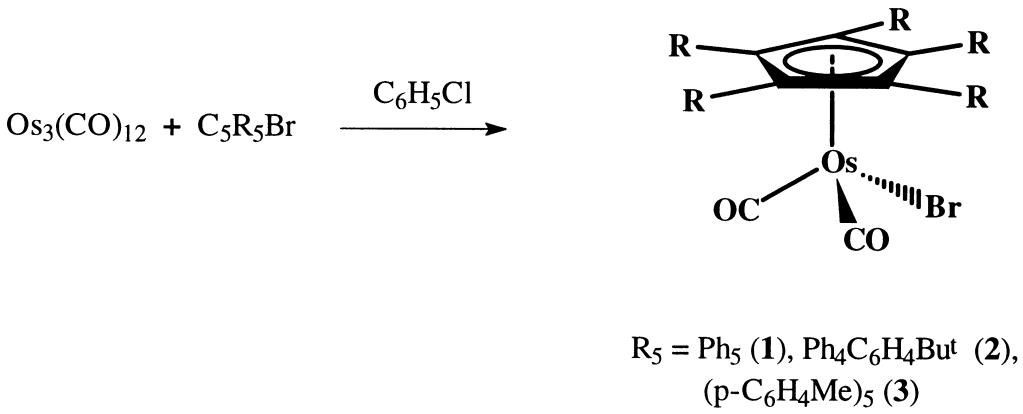
Although pentaphenylcyclopentadienyl complexes of many metals are known and several of these have been structurally characterised [27–56], no pentaphenylcyclopentadienyl complex of osmium has been reported.

Herein we describe the preparation of [Os(η^5-C_5Ph_5)$(CO)_2$Br] by the formal oxidative addition of C_5Ph_5Br to $Os_3(CO)_{12}$. The similar complexes [Os{η^5-C_5Ph_4(p-^{t}BuC_6H_4)}$(CO)_2$Br] and [Os{η^5-C_5(p-MeC_6H_4)$_5$}$(CO)_2$Br] have also been prepared. The crystal structure of [Os(η^5-C_5Ph_5)$(CO)_2$Br] and the preparation of several derivatives of the mono (pentaphenylcyclopentadienyl)osmium moiety are also reported.

RESULTS AND DISCUSSION

[Os(η^5-C_5Ph_5)$(CO)_2$Br] (**1**) was prepared by refluxing a mixture of $Os_3(CO)_{12}$ and C_5Ph_5Br in chloro-

* Author to whom correspondence should be addressed.



Scheme 1.

benzene. The complex was isolated as an air-stable pale yellow solid after purification on a silica gel column and crystallisation from dichloromethane/*n*-hexane, and was characterised by elemental analysis, and mass, infrared and ^{1}H and ^{13}C NMR spectra. Small amounts of the new complex [Os(η^5-C_5Ph_5)$(CO)_2$H] (similarly characterised), and of C_5Ph_5H and $Os_3(CO)_{10}Br_2$ were also obtained in variable amounts and were isolated after column chromatography of the reaction mixture. The analogous osmium compounds, [Os{η^5-C_5Ph_4(*p*-^{t}BuC_6H_4)}$(CO)_2$Br] (**2**) and [Os{η^5-C_5(*p*-MeC_6H_4)$_5$}$(CO)_2$Br] (**3**) have also been prepared by reacting the corresponding perarylcyclopentadienyl bromide with $Os_3(CO)_{12}$ in chlorobenzene (Scheme 1). Although the yields of (**2**) and (**3**) were considerably lower than that of (**1**), they have not been optimised. The analytical and spectroscopic data of (**1**)–(**3**) were consistent with the formulation of the products as [Os(η^5-ligand)$(CO)_2$Br]. The mass spectra of (**1**)–(**3**) show that the main fragmentation pathway is via the loss of the two carbonyl ligands although all exhibit an (often intense) ion assigned to [Os(ligand)$_2$ − H]$^+$.

A single crystal X-ray diffraction study of (**1**) was undertaken for comparison with those of the iron [30] and ruthenium [46] analogues. [Os(η^5-C_5Ph_5)$(CO)_2$Br] crystallises in the orthorhombic space group PBCA and is isostructural with [Fe(η^5-C_5Ph_5)$(CO)_2$Br] [30] and [Ru(η^5-C_5Ph_5)$(CO)_2$Br] [46]. The crystal structure of [Os(η^5-C_5Ph_5)$(CO)_2$Br] consists of discrete molecules in the solid state and no intermolecular contacts of significance were observed in the solid. The closest intermolecular contact is 3.44 Å between O(1) on molecule (x, y, z) and C(22) on molecule ($1/2-x$, $1/2+y$, $+z$). The closest intermolecular non-bonding approaches to osmium are greater than 4 Å. Final atomic positional coordinates, with estimated standard deviations, bond lengths and angles and anisotropic thermal parameters are deposited.* Selected interatomic bond distances and angles, with standard deviations derived from the refinement, are given in Tables 1 and 2. The atomic nomenclature is defined in Fig. 1. Figures 1 and 2 illustrate the molecular geometry viewed along, and perpendicular to, the normal to the C_5 plane of the $C_5Ph_5^-$ ligand, respectively.

The [Os(η^5-C_5Ph_5)$(CO)_2$Br] *molecule*

Coordination by the η^5 pentaphenylcyclopentadienyl group, the bromine atom and the two carbonyl groups creates a "piano stool" environment about the osmium atom. The Os-(ring centroid) distance is 1.90 Å and the average Os—C distance of 2.27 Å may be compared with 2.214 Å for [Os(η^5-

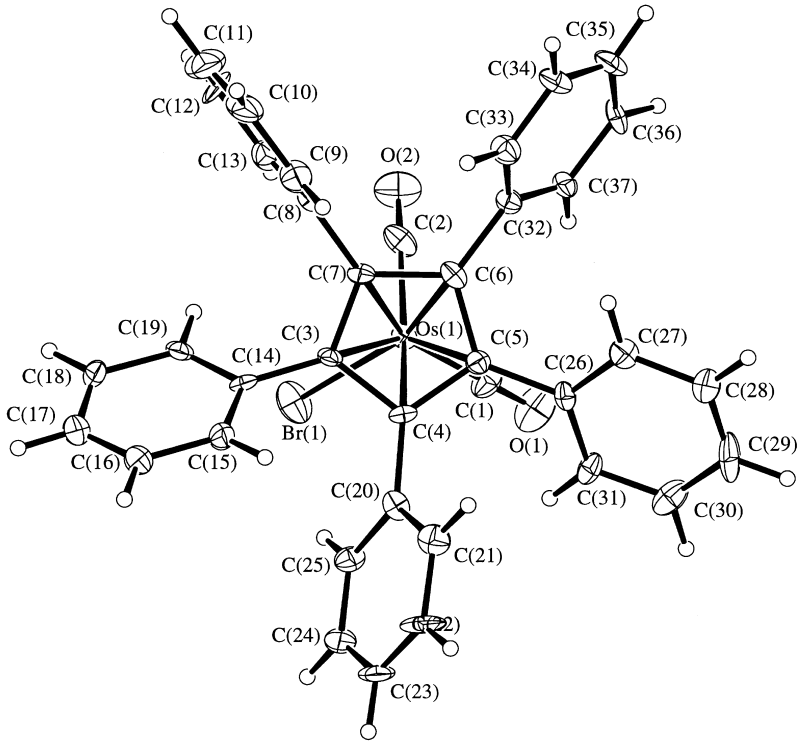

Fig. 1. ORTEP [69] (25% probability) illustration of the molecular structure of [Os(η^5-C_5Ph_5)$(CO)_2$Br] (**1**) showing the atom numbering. Viewed along the normal to the C_5Ph_5 plane.

C_5H_5)$(PPh_3)_2$Cl] [3], 2.177 Å for [Os(η^5-C_5H_5)$(PPh_3)_2$Br] [22], 2.25 Å for [Os(η^5-C_5H_5)$(PMe_3)_2(NO)]^+$ [1], 2.247 Å for [Os_2(η^5-$C_5Me_5)_2(CO)_2$(μ-H)$_2$] [2] and 2.223 and 2.261 Å for the two isomeric forms of [Os(η^5-C_5H_5)(η^2-CH_2═CH-$C_6H_4PPh_2$)Br] [4]. The Os—CO distances (1.87(2) and 1.93(2) Å) are indistinguishable and may be compared, for example, with a bond length of 1.833(9) Å in [Os_2($\eta^5C_5Me_5)_2(CO)_2$(μ-H)$_2$] [2], 1.879(5) Å in [Os(η^5-C_5Me_5)(CO)(PPh_3)(═C═C(^{t}Bu)H][BF_4] [6]

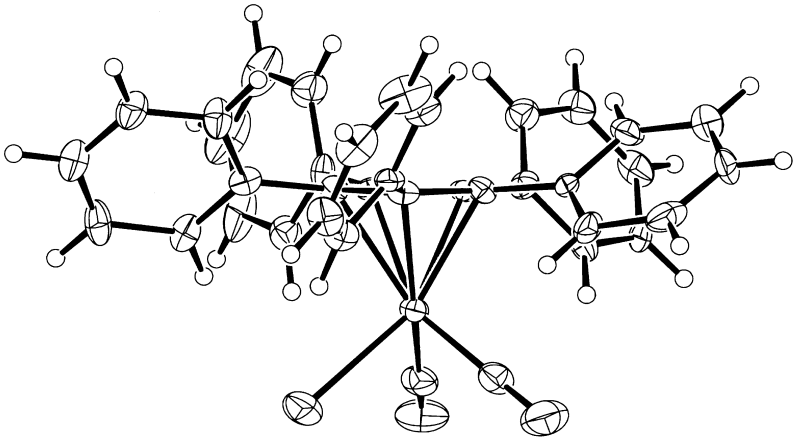

Fig. 2. ORTEP [69] (25% probability) illustration of the molecular structure of $[Os(\eta^5\text{-}C_5Ph_5)(CO)_2Br]$ (**1**) viewed perpendicular to the normal to the C_5Ph_5 plane.

and 1.919(14), 1.961(15) and 1.929(15) Å in $[Os(\eta^4\text{-}C_4Ph_4CO)(CO)_3]$ [57]. The C═O bond lengths in (**1**) are equivalent. The Os—Br distance is 2.530(2) Å and may be compared with values of 2.5438(9) Å for $[Os(\eta^5\text{-}C_5H_5)(PPh_3)_2Br]$ [22], 2.545(2) and 2.510(2) Å in two molecules of $[Os(\eta^5\text{-}C_5H_5)(\eta^2\text{-}CH_2{=}CH\text{-}C_6H_4PPh_2)Br]$ [4] and 2.559(1) Å for $[Os(\eta^5\text{-}C_5Me_5)Br(\mu\text{-}Br)]_2$ [20].

The C_5 nucleus of the pentaphenylcyclopentadienyl ligand is planar to within 0.02 Å. The C—C bond lengths of the C_5 ring range from 1.42(2)–1.48(2) Å, the average C—C bond length being 1.45 Å, which is consistent with C_5Ph_5 rings in other metal complexes. The *ipso*-carbon atoms of each of the phenyl rings are displaced slightly from the C_5 plane by between 0.07 and 0.25 Å, with the average distance being 0.16 Å. The *ipso*-carbon atoms of all phenyl rings are on the opposite side of the C_5 plane to the osmium atom. The phenyl rings are all also planar to within 0.02 Å and are canted at between 39.5 and 88.0° to the C_5 ring in a paddle wheel arrangement. The phenyl ring defined by C(8) is almost perpendicular to the C_5 ring.

Table 3 compares some bond length data determined for $[Os(\eta^5\text{-}C_5Ph_5)(CO)_2Br]$ and its iron (**8**) and ruthenium (**9**) analogues. As expected, it is evident that differences between the compounds of the three metals are generally small. For all three compounds the view of the coordination sphere of the metal as a distorted octahedron is supported by the angles subtended at the metal atom by the bromine atom and the two carbonyl carbon atoms (C(1)—M(1)—Br(1) = 86.6(1)°, 86.8(2)° and 88.1(5)°; C(1)—M(1)—C(2) = 89.8(2)°, 87.9(3)° and 88.6(7)°; C(2)—M(1)—Br(1) = 86.6(1)°, 85.5(3)° and 87.4(5)° for M = Fe (**8**), Ru (**9**) and Os (**1**), respectively). The average deviation of the phenyl rings from coplanarity with the C_5 ring is 59.9° in (**1**), which is similar to that of (**8**) (58.7°) [30] and (**9**) (62.0°) [46], while both (**8**) (87.4°) and (**9**) (87.4°) also contain a phenyl ring almost perpendicular to the C_5 ring.

Mono-carbonyl substitution of (**1**) in tetrahydrofuran using Me_3NO and appropriate ligands, L, afforded $[Os(\eta^5\text{-}C_5Ph_5)(CO)(L)Br]$ (L = PMe_2Ph (**4**), $P(OEt)_3$ (**5**), $P(OCH_2)_3CCH_3$ (**6**) and ^{t}BuNC (**7**)) (Scheme 2), which have been characterised by elemental analysis, and mass, infrared and ^{1}H and ^{31}P NMR

Table 3. Comparisons of selected metrical data between $[M(\eta^5\text{-}C_5Ph_5)(CO)_2Br]$ (M = Fe (**8**), Ru (**9**), Os (**1**))

Scheme 2.

spectra. The mass spectra of compounds (**4**)–(**7**) all exhibit a molecular ion, although the dominant ion is $[M\text{-CO-L}]^+$. A single CO stretching vibration is observed in the IR spectrum in CH_2Cl_2 solution. As observed in the solid state IR spectrum of $[Fe(\eta^5\text{-}C_5Ph_5)(CO)(PMe_3)Br]$ [58], the spectra of (**4**)–(**6**) in KBr show a splitting of the CO stretching absorptions observed in solution. This is thought to be due to the presence of two diastereoisomers derived from the opposite canting modes of the five phenyl groups around the C_5 rings [58]. The observation of one set of NMR signals in CD_2Cl_2 suggest, however, that in solution the five phenyl groups around the ring rotate rapidly on the NMR time scale. In none of these reactions, even when an excess of ligand and Me_3NO were used, did we observe the loss of two carbonyl ligands.

A single crystal X-ray diffraction study was undertaken on $[Os(\eta^5\text{-}C_5Ph_5)(CO)\{P(OCH_2)_3CCH_3\}Br]$. The compound crystallises in the monoclinic space group $P2_1/n$ (#14). The pentaphenylcyclopentadienyl ligand is once again coordinated in the η^5 mode with coordination completed by the $P(OCH_2)_3CCH_3$ ligand, one carbonyl ligand and the bromide ligand, the latter two of which are disordered between two sites. Final atomic positional coordinates, with estimated standard deviations, bond lengths and angles and anisotropic thermal parameters are deposited.* Selected interatomic bond distances and angles, with standard deviations from the refinement are given in Tables 4 and 5. The atomic nomenclature is defined in Fig. 3, which illustrates the molecular geometry viewed perpendicular to the normal to the C_5 plane of the $C_5Ph_5^-$ ligand.

Again no intermolecular contacts of significance were observed in the solid. The closest intermolecular contact is 3.13 Å between O(1a) on molecule (x, y, z) and C(29) on molecule ($-1/2-x$, $y-1/2$, $1/2-z$). The closest intermolecular non-bonding approaches to osmium are greater than 4 Å.

The $[Os(\eta^5\text{-}C_5Ph_5)(CO)\{P(OCH_2)_3CCH_3\}Br]$ *molecule*

The Os-(ring centroid) distance is 1.92 Å and the average Os—C distance is 2.28 Å. Disorder in the carbonyl and bromine ligands precludes any comment on the Os—CO bond distances and the C—O distances. The Os—Br distances appear to be shorter than that of (**1**).

The C_5 nucleus of the pentaphenylcyclopentadienyl ligand is planar to within 0.02 Å. The C—C bond lengths of the C_5 ring range from 1.43(1)–1.46(1) Å, the average being 1.45 Å. The *ipso*-carbon atom of each of the phenyl rings is displaced from the C_5 plane by between 0.11–0.35 Å, with the average being 0.18 Å. Again the *ipso* carbons of all phenyl rings are on the opposite side of the C_5 plane to the osmium atom. The phenyl rings are all planar to within 0.03 Å with normal dimensions and are canted at between 44.6 and 56.3° to the C_5 ring in the usual paddlewheel arrangement, with an average deviation from coplanarity of 52.6°.

EXPERIMENTAL

All manipulations were performed at atmospheric pressure under an atmosphere of dinitrogen by using conventional Schlenk techniques. Chlorobenzene (Merck) was dried, distilled and stored over calcium hydride. Tetrahydrofuran (thf) (Merck) was pre-dried over sodium wire and distilled from sodium benzophenone ketyl. *n*-Hexane (BDH) was distilled from sodium wire. Dichloromethane (Ajax) was distilled from calcium hydride. C_5Ph_5Br, [59] $C_5Ph_4(p\text{-}^tBuC_6H_4)Br$ [59] and $C_5(p\text{-}MeC_6H_4)_5Br$ [25] were prepared as described previously. $Os_3(CO)_{12}$ (Aldrich), $P(OEt)_3$ (Merck), PMe_2Ph (Fluka) and ^{t}BuNC (Aldrich) were used as received. Trimethylamine *N*-oxide dihydrate (Aldrich) was dehydrated by sublimation prior to use. Flash silica (240–400 mesh) was obtained

from Merck. Elemental analyses (C, H, N, Br) were performed by the Australian Microanalytical Service. Melting points were recorded on a Reichert hot platform in air and are uncorrected. Fourier transform infrared spectra were recorded on a Digilab FTS-40 spectrometer. ^1H and ^{13}C NMR spectra were recorded

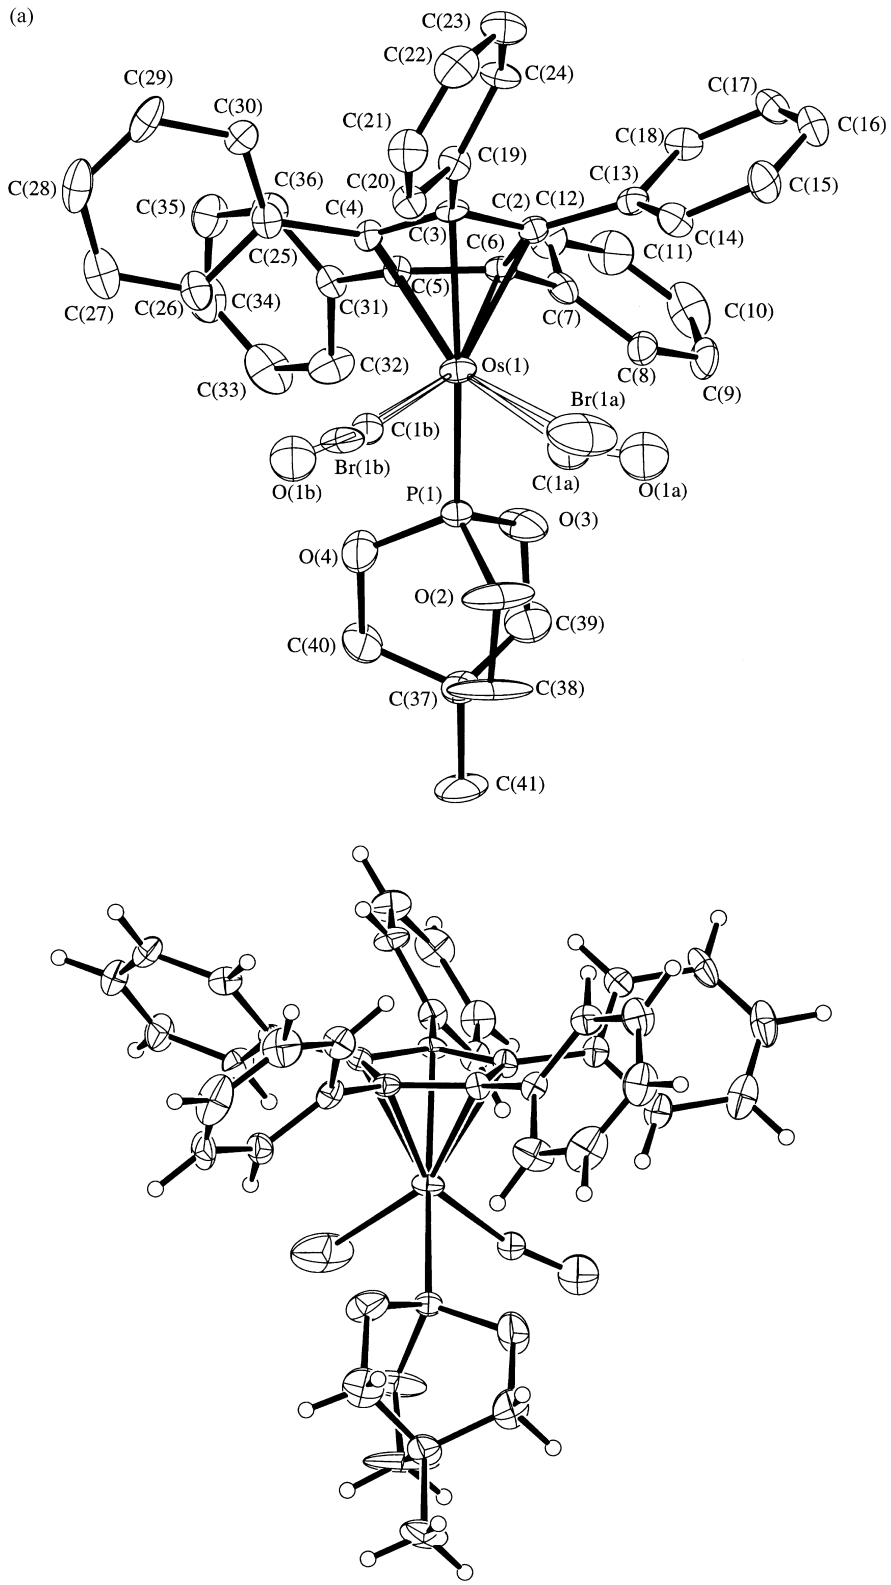

Fig. 3. ORTEP [69] (25% probability) illustration of the molecular structure of [Os(η^5-C_5Ph_5)(CO){P(OCH$_2$)$_3$CCH$_3$}Br] (**6**) viewed approximately perpendicular to the normal to the C_5Ph_5 plane (a) illustrating the disorder and (b) with the disorder now shown, for clarity.

on Bruker AC200F (^{1}H NMR 200.13 MHz, ^{13}C NMR 50.33 MHz) or Bruker AMX400 (^{1}H NMR 400.21 MHz) spectrometers. The spectra were referenced internally to TMS or to residual solvent resonances (CD_2Cl_2, ^{1}H δ 5.30 ppm, ^{13}C δ 53.8 ppm). ^{31}P NMR spectra were recorded on a Bruker AMX400 spectrometer operating at 162.0 MHz and were referenced with respect to 85% H_3PO_4 as standard reference, with an external reference of neat trimethylphosphite (δ 140.85 ppm). Electron impact mass spectra were obtained using a Kratos MS 9 geometry mass spectrometer with a direct insertion probe, a 280°C source temperature, 70 eV ionisation voltage and 4 kV acceleration voltage.

Preparation of [Os(η^5-C_5Ph_5)$(CO)_2$Br] (**1**)

A mixture of $Os_3(CO)_{12}$ (219 mg, 0.242 mmol) and C_5Ph_5Br (402 mg, 0.765 mmol) in chlorobenzene (90 ml) was heated at reflux for 18 h. The solvent was removed *in vacuo*, then column chromatography was performed. Elution with *n*-hexane afforded a small amount of $Os_3(CO)_{10}Br_2$. (Found: C 12.1, H < 0.1, Br 17.5. $C_{10}Br_2O_{10}Os_3$ requires C 11.9, Br 15.8%). IR (cyclohexane): *v* (CO) 2114 w, 2080 s, 2069 s, 2026 vs, 2012 s, 1993 w, 1989 w cm^{-1} [lit. [60]: *v* (CO) 2113 w, 2080 s, 2069 s, 2026 s, 2012 s, 1991 sh, 1987 w cm^{-1}]. A small amount of C_5Ph_5H (identified on the basis of IR (KBr) and m.p.) was similarly obtained by elution with 20% CH_2Cl_2/80% *n*-hexane. Elution with 30% CH_2Cl_2/70% *n*-hexane and evaporation to dryness (rotary evaporator) afforded a white solid which was crystallised from CH_2Cl_2/*n*-hexane to give colourless crystals of [Os(η^5-C_5Ph_5)$(CO)_2$H] m.p. > 140°C (dec.). (Found: C 64.3, H 3.6. $C_{37}H_{26}O_2Os$ requires C 64.2, H 3.8%). ^{1}H NMR ($CDCl_3$, 200.13 MHz): δ 7.10–7.03 (m, 25H, Ar-*H*), −13.19 (s, 1H, Os-*H*) ppm. Mass spectrum: EI (*m*/*e*) 694 ([*M*]$^+$, 100%). IR (KBr) ν_{max} 3110 vw, 3087 vw, 3061 w, 3040 vw, 3031 vw, 2077 w, 1998 vs, 1984 w, 1938 vs, 1907 w, 1734 vw, 1717 vw, 1700 vw, 1684 vw, 1653 w, 1602 w, 1577 w, 1559 w, 1540 w, 1505 w, 1457 vw, 1446 w, 1412 w, 1182 vw, 1157 vw, 1073 w, 1029 w, 922 vw, 803 w, 783 w, 758 w, 741 m, 709 (sh), 698 m, 607 w, 575 w, 562 w, 518 w, 509 w cm^{-1}. IR (CH_2Cl_2): *v* (Os—H) 2087 vs, *v* (CO) 2008 vs, 1945 vs, cm^{-1}. Further elution with 70% CH_2Cl_2/30% *n*-hexane afforded a yellow solution which after evaporation and crystallisation of the solid from CH_2Cl_2/*n*-hexane gave yellow crystals of [Os(η^5-C_5Ph_5)$(CO)_2$Br] (**1**) (365 mg, 65%) m.p. > 205°C (dec.). (Found: C 57.2, H 3.3, Br 10.5. $C_{37}H_{25}BrO_2Os$ requires C 57.6, H 3.3, Br 10.4%). ^{1}H NMR (CD_2Cl_2, 200.13 MHz): δ 7.25–7.00 (m, 25H, Ar-*H*) ppm. ^{13}C NMR (CD_2Cl_2, 50.33 MHz): δ 178.0 (*C*O), 132.9 (quaternary Ar-*C*), 129.7, 128.9, 128.3 (Ar-*C*H), 104.9 (Cp-*C*) ppm. Mass spectrum: EI (*m*/*e*) 1081 ([Os(η^5(C_5Ph_5)$_2$—H]$^+$, 3%), 772 ([*M*]$^+$, 1%), 744 ([*M*]—CO]$^+$, 1%), 716 ([*M*—2CO]$^+$, 100%), 446 (HC_5Ph_5, 12%), 445 (C_5Ph_5, 10%). IR (KBr) ν_{max}: 3111 vw, 3090 w, 3059 w, 3046 (sh), 2028 vs, 1973 vs, 1602 w, 1579 vw, 1502 w, 1446 w, 1419 w, 1398 vw, 1379 vw, 1184 vw, 1158 vw, 1076 w, 1030 w, 1002 vw, 921 vw, 841 vw, 802 w, 782 w, 767 vw, 738 m, 707 m, 697 m, 676 vw, 593 w, 581 w, 571 w, 562 w, 544 w, 518 vw, 501 vw, 493 vw, 465 w cm^{-1}. IR (CH_2Cl_2): *v* (CO) 2033 vs, 1978 vs cm^{-1}.

Preparation of [Os{η^5-C_5Ph_4(*p*-^{t}BuC_6H_4)}$(CO)_2$Br] (**2**)

A similar reaction of $Os_3(CO)_{12}$ (111 mg, 0.122 mmol) and C_5Ph_4(*p*-^{t}BuC_6H_4)Br (223 mg, 0.383 mmol) in chlorobenzene (50 ml) afforded after column chromatography, elution with 50% CH_2Cl_2/50% *n*-hexane and crystallisation from CH_2Cl_2/*n*-hexane, a pale yellow powder identified as [Os{η^5-C_5Ph_4(*p*-^{t}Bu-C_6H_4)}$(CO)_2$Br] (**2**) (110 mg, 36%) m.p. > 210°C (dec.). (Found: C 59.2, H 4.2, Br 9.9. $C_{41}H_{33}BrO_2Os$ requires C 59.5, H 4.0, Br 9.7%). ^{1}H NMR (CD_2Cl_2, 200.13 MHz): δ 7.25–6.90 (m, 24H, Ar-*H*), 1.24 (s, 9H, ^{t}Bu) ppm. Mass spectrum: EI (*m*/*e*) 1193 ([Os(C_5Ph_4(*p*-^{t}BuC_6H_4))$_2$—H]$^+$, 37%), 772 [*M*—2CO]$^+$, 100%). IR (KBr) ν_{max} 3110 vw, 3091 vw, 3058 w, 3042 (sh), 2965 w, 2936 vw, 2905 vw, 2870 vw, 2026 vs, 1971 vs, 1684 vw, 1653 vw, 1602 vw, 1578 vw, 1559 vw, 1540 vw, 1520 vw, 1506 vw, 1502 vw, 1473 vw, 1457 vw, 1441 w, 1420 vw, 1396 vw, 1364 vw, 1269 vw, 1200 vw, 1185 vw, 1120 vw, 1108 vw, 1076 vw, 1027 vw, 1018 vw, 919 vw, 842 w, 797 vw, 756 w, 749 w, 737 w, 705 m, 699 m, 596 w, 581 w, 569 w, 558 w, 547 w, 501 vw, 493 vw, 464 w cm^{-1}. IR (CH_2Cl_2): *v* (CO) 2033 vs, 1977 vs cm^{-1}.

Preparation of [Os{η^5-C_5(*p*-MeC_6H_4)$_5$}$CO)_2$Br] (**3**)

Similarly, reaction of a mixture of $Os_3(CO)_{12}$ (235 mg, 0.259 mmol) and C_5(*p*-MeC_6H_4)$_5$Br (460 mg, 0.772 mmol) in chlorobenzene (60 ml) afforded after column chromatography, elution with 70% CH_2Cl_2/30% *n*-hexane and crystallisation from CH_2Cl_2/*n*-hexane, a pale yellow powder identified as [Os{η^5-C_5(*p*-MeC_6H_4)$_5$}$(CO)_2$Br] (**3**) (60 mg, 9%) m.p. > 210°C (dec.) (Found: C 60.1, H 4.1. $C_{42}H_{35}BrO_2Os$ requires C 59.9, H 4.2%). ^{1}H NMR (CD_2Cl_2, 200.13 MHz): δ 6.90 (m, 20H, Ar-*H*), 2.27 (s, 15H, Me) ppm. Mass spectrum: EI (*m*/*e*) 1221 ([Os(C_5(*p*-MeC_6H_4)$_5$)$_2$—H]$^+$, 100%), 786 ([*M*—2CO]$^+$, 97%), 515 (C_5(*p*-MeC_6H_4)$_5$, 88%). IR (CH_2Cl_2): *v* (CO) 2030 vs, 1974 vs cm^{-1}.

Preparation of $[Os(\eta^5\text{-}C_5Ph_5)(CO)(PMe_2Ph)Br]$ (**4**)

A portion of Me_3NO (18 mg, 0.24 mmol) was added to a mixture of $[Os(\eta^5\text{-}C_5Ph_5)(CO)_2Br]$ (141 mg, 0.183 mmol) and PMe_2Ph (0.030 ml, 0.21 mmol) in thf (25 ml) giving a colour change from yellow to orange-yellow. After stirring at room temperature for 1 h spot TLC (CH_2Cl_2/*n*-hexane 1 : 1) and solution IR (CH_2Cl_2) showed that no starting material remained. The reaction mixture was evaporated *in vacuo* and then column chromatography was performed. Elution with 50% CH_2Cl_2/50% *n*-hexane afforded an orange solution which after evaporation and crystallisation of the solid from CH_2Cl_2/*n*-hexane afforded orange crystals of $[Os(\eta^5\text{-}C_5Ph_5)(CO)(PMe_2Ph)Br]$ (**4**) (135 mg, 84%) m.p. $> 250°C$ (dec.). (Found: C 59.7, H 4.1, Br 8.7. $C_{44}H_{36}BrOOsP$ requires C 59.9, H 4.1, Br 9.1%). ^1H NMR (CD_2Cl_2, 200.13 MHz): δ 7.71–7.61, 7.31–7.26 (2 × m, 5H, P-Ar-*H*), 7.15–6.85 (m, 25H, Ar-*H*), 2.04 (d, *J* (PH) = 10 Hz, 3H, Me), 1.97 (d, *J* (PH) = 10 Hz, 3H, Me) ppm. ^{31}P $\{^1H\}$ NMR (CD_2Cl_2, 162.0 MHz): δ 100.3 ppm. Mass spectrum: EI (*m*/*e*) 882 ($[M]^+$, 95%), 854 ($[M—CO]^+$, 62%), 716 ($[M—CO—PMe_2Ph]^+$, 100%), 138 (PMe_2Ph, 89%). IR (KBr) ν_{max} 3154 vw, 3106 vw, 3085 vw, 3058 (sh), 3053 w, 3039 vw, 3031 (sh), 3006 vw, 2988 vw, 2915 vw, 1928 s, 1919 vs, 1600 w, 1580 vw, 1502 w, 1481 vw, 1445 w, 1436 w, 1415 vw, 1378 vw, 1317 vw, 1298 vw, 1284 vw, 1265 vw, 1181 vw, 1154 vw, 1099 vw, 1076 w, 1028 w, 1004 vw, 944 w, 914 w, 842 w, 799 w, 782 w, 747 (sh), 740 m, 707 m, 701 s, 682 w, 620 vw, 598 w, 592 w, 565 w, 561 w, 550 w, 533 vw, 514 w, 493 w, 434 w cm^{-1}. IR (CH_2Cl_2): *v* (CO) 1928 vs cm^{-1}.

Preparation of $[Os(\eta^5\text{-}C_5Ph_5)(CO)\{P(OEt)_3\}Br]$ (**5**)

A similar reaction and workup of $[Os(\eta^5\text{-}C_5Ph_5)(CO)_2Br]$ (112 mg, 0.145 mmol), $P(OEt)_3$ (0.030 ml, 0.173 mmol) and Me_3NO (15 mg, 0.20 mmol) in thf (22 ml) afforded yellow crystals of $[Os(\eta^5\text{-}C_5Ph_5)(CO)\{P(OEt)_3\}Br]$ (**5**) (97 mg, 74%) m.p. $> 230°C$ (dec.). (Found: C 55.9, H 4.6, Br 9.2. $C_{42}H_{40}BrO_4OsP$ requires C 55.4, H 4.4, Br 8.8%). ^1H NMR (CD_2Cl_2, 400.21 MHz): δ 7.14–7.00 (m, 25H, Ar-*H*), 4.23–3.98 (m (32 peaks), 6H, CH_2), 1.07 (t, 2*J* (HH) = 7 Hz, 9H, CH_3) ppm. ^{31}P $\{^1H\}$ NMR (CD_2Cl_2, 162.0 MHz): δ 214.0 ppm. Mass spectrum: EI (*m*/*e*) 910 ($[M]^+$, 11%), 882 ($[M—CO]^+$, 6%), 716 ($[M—CO—P(OEt)_3]^+$, 100%). IR (KBr) ν_{max} 3110 vw, 3087 vw, 3057 w, 3041 vw, 3033 vw, 2977 w, 2928 vw, 2905 vw, 2867 vw, 1947 (sh), 1936 vs, 1890 vw, 1602 w, 1503 w, 1445 w, 1392 w, 1319 vw, 1286 vw, 1183 vw, 1159 w, 1093 w, 1061 w, 1028 s, 955 m, 936 w, 849 vw, 801 w, 783 w, 765 w, 744 m, 711 m, 703 s, 678 vw, 668 vw, 622 vw, 591 w, 565 w, 559 w, 549 w, 537 w, 517 w, 482 vw cm^{-1}. IR (CH_2Cl_2): *v* (CO) 1940 vs cm^{-1}.

Preparation of $[Os(\eta^5\text{-}C_5Ph_5)(CO)\{P(OCH_2)_3CCH_3\}Br]$ (**6**)

A mixture of $[Os(\eta^5\text{-}C_5Ph_5)(CO)_2Br]$ (228 mg, 0.295 mmol), $P(OCH_2)_3CCH_3$ (125 mg, 0.844 mmol) and Me_3NO (37 mg, 0.49 mmol) in thf (30 ml) was stirred at room temperature for 24 h after which time column chromatography was performed. Elution with 50% CH_2Cl_2/50% *n*-hexane, evaporation of the solvent and crystallisation of the solid from CH_2Cl_2/*n*-hexane afforded $[Os(\eta^5\text{-}C_5Ph_5)(CO)_2Br]$ (**1**) (80 mg, 35%). Subsequent elution with 100% CH_2Cl_2 and crystallisation of the solid from CH_2Cl_2/*n*-hexane afforded bright yellow crystals of $[Os(\eta^5\text{-}C_5Ph_5)(CO)\{P(OCH_2)_3CCH_3\}Br]$ (**6**) (128 mg, 49%) m.p. $> 270°C$. (Found: C 55.1, H 3.7, Br 9.4. $C_{41}H_{34}BrO_4OsP$ requires C 55.2, H 3.8, Br 9.0%). ^1H NMR (CD_2Cl_2, 200.13 MHz): δ 7.19–7.03 (m, 25H, Ar-*H*), 4.23 (d, *J* (PH) = 5 Hz, 6H, CH_2), 0.76 (s, 3H, CH_3) ppm. ^{31}P $\{^1H\}$ NMR (CD_2Cl_2, 162.0 MHz): δ 216.7 ppm. Mass spectrum: EI (*m*/*e*) 892 ($[M]^+$, 26%), 864 ($[M—CO]^+$, 11%), 716 ($[M—CO—P(OCH_2)_3CCH_3]^+$, 100%). IR (KBr) ν_{max} 3108 vw, 3085 vw, 3055 w, 3037 vw, 3031 (sh), 2966 vw, 2960 (sh), 2943 vw, 2884 w, 1960 vs, 1952 (sh), 1912 vw, 1601 w, 1579 vw, 1501 w, 1484 vw, 1463 w, 1445 w, 1415 vw, 1395 w, 1184 w, 1174 w, 1155 vw, 1075 w, 1030 s, 988 vw, 959 w, 928 w, 860 w, 802 w, 795 m, 788 m, 742 w, 711 w, 700 m, 658 m, 621 vw, 587 w, 561 w, 547 w, 524 w, 516 w, 498 vw, 417 w cm^{-1}. IR (CH_2Cl_2): *v* (CO) 1963 vs cm^{-1}.

Preparation of $[Os(\eta^5\text{-}C_5Ph_5)(CO)(CNBu^t)Br]$ (**7**)

To a mixture of $[Os(\eta^5\text{-}C_5Ph_5)(CO)_2Br]$ (128 mg, 0.166 mmol) and ^{t}BuNC (0.030 ml, 0.27 mmol) in thf (25 ml) was added Me_3NO (16 mg, 0.21 mmol), giving a colour change from pale yellow to orange-yellow. After stirring at room temperature for 1 h, the solution IR *v* (CO) (CH_2Cl_2) showed that no starting material remained. The reaction mixture was evaporated to dryness (*in vacuo*) and column chromatography was performed. Elution with 70% CH_2Cl_2/30% *n*-hexane afforded a yellow-orange solution which after evaporation and crystallisation of the solid from CH_2Cl_2/*n*-hexane gave yellow crystals of $[Os(\eta^5\text{-}C_5Ph_5)(CO)(CNBu^t)Br]$ (**7**) (124 mg, 90%) m.p. $> 240°C$ (dec.). (Found: C 59.9, H, 4.1, Br 9.7, N 1.8. $C_{41}H_{34}BrNOOs$ requires C 59.6, H 4.1, Br 9.7, N 1.7%). ^1H NMR (CD_2Cl_2, 200.13 MHz): δ 7.20–7.05 (m, 25H, Ar-*H*), 1.40 (s, 9H, ^{t}Bu) ppm. Mass spectrum. EI (*m*/*e*) 827 ($[M]^+$, 26%), 799 ($[M—CO]^+$, 6%), 771 ($[M—C(CH_3)_2CH_2]^+$, 10%), 743 ($[M—CNBu^t—H]^+$, 67%), 716 ($[M—CO—CNBu^t]^+$, 100%). IR (KBr) ν_{max} 3110 vw, 3087 vw, 3084 vw, 3056 w, 3037 vw, 3033 vw, 2984 w, 2937 vw, 2147 m, 2072 (sh), 2024 vw, 1954 vs, 1905 vw, 1602 w, 1504 w, 1473 w, 1457 w, 1445 w, 1419 w, 1398 w, 1370 w, 1232 w, 1206 w, 1183 w, 1074 w, 1029 w, 919

w, 802 w, 783 w, 739 m, 698 vs, 587 w, 567 s, 555 w, 541 vw, 517 vw, 464 w cm^{-1}. IR (CH_2Cl_2): *v* (CN) 2156 m, *v* (CO) 1960 vs cm^{-1}.

Structure determinations

(a) $[Os(\eta^5\text{-}C_5Ph_5)(CO)_2Br]$ (**1**). Primitive orthorhombic cell constants were obtained from a least-square refinement against the setting angles of 25 reflections in the range $16.18 < 2\theta < 24.08^\circ$ measured and refined on an Enraf-Nonius CAD-4 four-circle diffractometer, employing graphite monochromated Mo–K_α radiation. The intensities of three representative reflections measured every hour did not change significantly during the course of the data collection. An analytical absorption correction was applied to the data and the data were also corrected for Lorentz and polarisation effects. All calculations were performed using the teXsan [61] crystallographic software package. The structure was solved in the space group PBCA (#61) by direct methods [62] and expanded using Fourier techniques [63]. Non-hydrogen atom sites were modelled anisotropically and hydrogen parameters were included in the full matrix least squares refinement with calculated positions and group temperature factors. Neutral atom scattering factors were taken from Cromer and Waber [64]. Anomalous dispersion effects were included in the structure factor calculation [65], and the values for $\Delta f'$ and $\Delta f''$ were those of Creagh and McAuley [66]. The values for the mass attenuation coefficients are those of Creagh and Hubbel [67].

Crystal data for $[Os(\eta^5\text{-}C_5Ph_5)(CO)_2Br]$ (**1**)

$C_{37}H_{25}BrO_2Os$, M = 771.71, orthorhombic, space group, PBCA (#61), $a = 18.028(3)$, $b = 14.921(2)$, $c = 21.718(3)$ Å, $U = 5842(1)$ Å^3, $D_c(Z = 8) = 1.76$ g cm^{-3}, $F(000) = 2992$, μ (Mo–K_α) = 57.67 cm^{-1}. Specimen: yellow blade, $0.525 \times 0.125 \times 0.012$ mm. $N = 4162$, $N_{unique} = 3976$, $N_o = 2249$, range of *hkl* $0 \to 15$, $0 \to 18$, $0 \to 22$, $R_{merge} = 0.166$, $R = 0.040$, $R_w = 0.043$, residual extrema -1.15 and 1.01 eÅ^3, $T_{min,max} = 0.27, 0.86$.

(b) $[Os(\eta^5\text{-}C_5Ph_5)(CO)\{P(OCH_2)_3CCH_3\}Br]$ (**6**). Lattice parameters at 21°C were obtained from a least squares refinement to the setting angles of 25 reflections in the range $19.77 < 2\theta < 113.36^\circ$, measured and refined on a Rigaku AFC7R diffractometer, employing graphite monochromated CuKα radiation, generated from a direct drive rotating anode. Intensity data were collected with $\omega/2\theta$ scans to a maximum 2θ value of 120.1°, with a scan width of $(1.1 + 0.35 \tan\theta)^\circ$. An empirical absorption correction based on azimuthal scans of three reflections was applied to the data. The data were corrected for Lorentz and polarisation effects and a small correction for secondary extinction applied (coefficient = 1.11 $\times 10^{-6}$). All calculations were performed using the teXsan structure determination software package [61]. The structure was solved by direct methods [68] and extended with Fourier maps [63]. The refinement weighting scheme was based on counting statistics. Generally the non-hydrogen atoms were refined anisotropically, and the hydrogen atoms were included in the full matrix least squares refinement at calculated positions with group temperature factors. The carbonyl and bromide ligands were found to be site disordered. Although the carbonyl groups could be located they could not be successfully refined; possibly because of orientation disorder or a consequence of the site disorder. Neutral atom scattering factors were taken from Cromer and Waber [64]. Anomalous dispersion effects were included in the structure factor calculation [65], and the values for $\Delta f'$ and $\Delta f''$ were those of Creagh and McAuley [66]. The values for the mass attenuation coefficients are those of Creagh and Hubbel [67].

Crystal data for $[Os(\eta^5\text{-}C_5Ph_5)(CO)\{P(OCH_2)_3CCH_3\}Br]$ (**6**)

$C_{41}H_{34}BrO_4OsP$, M = 891.80, monoclinic, space group, $P2_1/n$ (#14), $a = 12.230(3)$, $b = 16.135(9)$, $c = 18.331(3)$ Å, $\beta = 101.63(2)$, $U = 3543(1)$ Å^3, $D_c(Z = 4) = 1.672$ g cm^{-3}, $F(000) = 1752$, μ (Cu-K_α) = 88.89 cm^{-1}. Specimen: yellow prism, $0.260 \times 0.250 \times 0.140$ mm. $N = 5787$, $N_{unique} = 5496$, $N_o = 4242$, range of *hkl* $0 \to 13$, $0 \to 18$, $-20 \to 20$, $R_{merge} = 0.0327$, $R = 0.066$, $R_w = 0.073$, residual extrema -2.75 and 2.31 eÅ^3, $T_{min,max} = 0.48, 0.98$.

CONCLUSION

The preparation and crystal structure of $[Os(\eta^5\text{-}C_5Ph_5)(CO)_2Br]$, the first osmium complex of the pentaphenylcyclopentadienyl ligand, has been described. This completes the preparation and characterisation of the iron-triad $[M(\eta^5\text{-}C_5Ph_5)(CO)_2Br]$ series of this ligand. The crystal structure of the osmium complex is isostructural with those of its iron and ruthenium analogues. The osmium complex is stable in air and readily undergoes monocarbonyl substitution with a variety of ligands. The crystal structure of one such resultant complex, $[Os(\eta^5\text{-}C_5Ph_5)(CO)\{P(OCH_2)_3CCH_3\}Br]$, is also reported.

Acknowledgements—We thank the Australian Research Council for financial support and Dr M. J. Aroney for the gift of $P(OCH_2)_3CCH_3$.

(Received 16 June 1997; accepted 24 September 1997)

Abstract—The hydrothermal reaction of $RbVO_3$, $(NH_4)_2B_4O_7\cdot 4H_2O$, ethylenediamine (en), and H_2O in a mole ratio of 1:8:2:135 heated at 170°C for 5 days produces pale green crystals of the novel polyoxovanadium borate cluster compound $Rb_4[(VO)_6\{B_{10}O_{16}(OH)_6\}_2]\cdot 0.5H_2O$ (**1**) which contains $[V_6B_{20}O_{38}(OH)_{12}]^{4-}$ clusters, each cluster comprising a nearly hexagonal ring of six *trans*-edge-sharing VO_5 square pyramids capped on each side by a $B_{10}O_{16}(OH)_6^{8-}$ triangle. The $[V_6B_{20}O_{38}(OH)_{12}]^{4-}$ clusters are separated in the solid state by Rb^+ cations. Magnetic susceptibility and valence sum calculations indicate that all six of the vanadium atoms in the cluster are in the 4+ oxidation state. © 1998 Elsevier Science Ltd. Keywords: hydrothermal synthesis; polyoxovanadium borates; polyoxometalates; X-ray structures.

INTRODUCTION

The chemistry of polyoxometalates incorporates a rich and diverse agglomeration of compounds unique in their topological and electronic properties, making them applicable in fields ranging from analytical and clinical chemistry, to catalysis (including photocatalysis), biochemistry (electron transport inhibition), medicine (antitumoral and antiviral), and solid state devices [1]. Metal-metal interactions in the oxo clusters range from very weak (virtually none) to very strong (metal-metal bonding) and can be controlled by choice of metal (3d, 4d, 5d), electron population (degree of reduction), and extent of protonation. It has been observed that mixed-valence vanadates, in particular, show highly variable capacities for unpaired electrons, and many form clusters containing highly symmetrical core assemblies of VO_x units that can adopt quasi-spherical structures [2]. Although the chemistry of the polyoxovanadates (a subset of the polyoxometalates) is very diverse, only a few structural motifs, which are based largely on edge and corner sharing VO_5 square pyramids, are actually observed [3]. The polyoxovanadium borates (a subset of the polyoxovanadates) remain largely unexplored, and although a large number of borate mineral structures are known [4], synthetically prepared and structurally characterized examples are rare [5]. Having recently isolated the polyoxovanadium borates $(enH)(enH_2)_4[(VO)_{12}B_{17}O_{38}(OH)_8]\cdot H_2O$ (en = ethylenediamine) and $(enH_2)_5[(VO)_{12}O_6\{B_3O_6(OH)\}_6]\cdot H_2O$ [6], which were prepared by hydrothermal synthetic techniques, we were encouraged to further explore this potentially rich and structurally diverse system. We report herein the synthesis of a novel polyoxovanadium borate cluster species, $Rb_4[(VO)_6\{B_{10}O_{16}(OH)_6\}_2]\cdot 0.5H_2O$ (**1**), containing a hexavanadate core and polyborate ligands of unprecedented structure.

EXPERIMENTAL

General

Compound (**1**) was prepared by the hydrothermal reaction of $RbVO_3$ (0.114 g) $(NH_4)_2B_4O_7 \cdot 4H_2O$ (1.30 g), ethylenediamine (0.074 g), and H_2O in a 1:8:2:135 molar ratio heated at 170°C for 5 days. The syntheses were conducted in 23 mL polytetrafluoroethylene-lined acid digestion bombs filled to ca. 8% at room temperature. In all cases, the borate was added first, followed by the vanadium source, water, and finally the amine. This preparation gave a nearly single phase of pale green plate-shaped crystals of $Rb_4[(VO)_6\{B_{10}O_{16}(OH)_6\}_2] \cdot 0.5H_2O$ (**1**) which were isolated in approximately 45% yield with a minor phase (ca. 1–2%) of orange crystals. An X-ray structural analysis of the orange crystals revealed that they contained the previously characterized $[(VO)_{12}O_6\{B_3O_6(OH)\}_6]^{10-}$ cluster [6]. The role of the ethylenediamine (en) in the preparation is currently under investigation as this species appears to be needed in the syntheses (perhaps to adjust the pH of the reactions which are typically in the 8–9 range) although it is not incorporated in the final structure. Indeed, experiments using equimolar amounts of 1,3-diaminopropane (DAP) in place of en resulted in nearly the same yield of (**1**), but if neither en nor DAP are used, no crystals are obtained [7].

Crystallography

A single crystal of (**1**) having approximate dimensions of $0.17 \times 0.12 \times 0.11$ mm was mounted on a glass fiber. A total of 14,207 reflections were collected on a Siemens SMART system equipped with a CCD detector at 293 K in the θ range of 2.08° to 28.25°, of which 5390 ($R_{int} = 0.0456$) were considered observed [($I \geq 3.0\sigma$ (I)] and 5384 were used in the final refinement. The structure was solved by direct methods and refined by full-matrix least-squares on F^2 using SHELXTL. All of the non-hydrogen atoms were refined with anisotropic displacement parameters. The Rb^+ atoms were disordered and refined with 50% occupancy factors. The final cycle of least-squares using 421 variable parameters converged with $R(R_w) = 0.0366(0.0472)$ and a goodness-of-fit value of 1.021. The largest (smallest) peak in the final difference map was 0.947(−0.582) eÅ^{-3}. Further details of the X-ray structural analysis are given in Table 1, and some selected bond lengths and angles are given in Table 2. A complete listing of atomic coordinates, thermal parameters and F_{obs}/F_{calc} values have been deposited at the Cambridge Crystallographic Data Centre.

Magnetic Susceptibility

Magnetic susceptibility measurements were done on a Quantum Design MPMS SQUID magnetometer.

Table 1. Crystallographic Data for $Rb_4[(VO)_6\{B_{10}O_{16}(OH)_6\}_2] \cdot 0.5H_2O$

Formula	$Rb_4V_6B_{20}O_{50.5}H_7$
FW	1678.28
Crystal Color, Habit	Green, Plate
a(Å)	11.9932(3)
b(Å)	12.74480(10)
c(Å)	14.9514(2)
β(°)	95.7320(10)
V(Å^3)	2273.85(4)
Z	2
Space Group	$P\,2_1/n$ (No.14)
D_{calc}(ġcm^{-3})	2.452
μ (mm^{-1})	5.574
Crystal Size (mm)	0.17x0.12x0.11
θ range for Data Collection (°)	2.08 to 28.25
No. of Data Collected	14207
Data $I \geq 3\sigma(I)$	5390
No. of Variables	420
Final R/R_w	0.0366/0.04572

The data from 100 to 300 K were fit to the Curie–Weiss law and gave an effective moment per vanadium atom of 1.71 μ_B. This agrees well with the theoretical value of 1.73 μ_B for a free spin d^1 (V^{4+}) system.

RESULTS AND DISCUSSION

The $V_6B_{20}O_{50}$ clusters in $Rb_4[(VO)_6\{B_{10}O_{16}(OH)_6\}_2] \cdot 0.5H_2O$ (**1**) can be visualized most easily as being composed of a nearly hexagonal ring of six *trans*-edge-sharing VO_5 square pyramids (Fig. 1) capped on each side by a $B_{10}O_{16}(OH)_6^{8-}$ triangle (Fig. 2). All six of the terminal vanadyl (V=O) groups in this hexagonal vanadate, whose toroid structure is unprecedented among polyoxometalate species, radiate outwardly from the cluster, and have V–O bond distances ranging from 1.612(2)–1.624(2) Å. The $B_{10}O_{16}(OH)_6^{8-}$ caps are composed of three fused $B_3O_5(OH)_3^{4-}$ FBB's (fundamental building blocks) [8] that share oxygen atoms with a central tetrahedral BO_4 group. This tetrahedral BO_4 group possesses a terminal B–O$^-$ bond that is collinear with the pseudo $\bar{3}$ axis of the cluster, and the two $B_{10}O_{16}(OH)_6^{8-}$ caps are related by twofold symmetry about one of the three two-fold axes bisecting the vanadium ring. Of the six-OH groups that radiate out from the triangular $B_{10}O_{16}(OH)_6^{8-}$ units, three are bonded to trigonal planar boron atoms and have B–O bond distances ranging from 1.385(4)–1.378(4) Å, while the other three (which were identified using valence bond calculations) [9] are shared between adjacent tetrahedral boron atoms having B–O bond distances ranging from 1.425(4)–1.439(4) Å. The central tetrahedral BO_4 group has three internal B–O bond distances of 1.495(4), 1.493(4), and 1.488(4) Å, and a significantly shorter terminal B–O bond distance of 1.424(4) Å

Symmetry transformations used to generate equivalent atoms: #1 $-x, -y+1, -z$.

(which is consistent with its assignment as an O^- group). The assignment of the O^- group to the central tetrahedral boron atom (and not one of the trigonal boron atoms) is also reasonable given the fact that one would expect an oxygen atom bonded to a tetrahedral boron to be more acidic than an oxygen atom bonded to a corresponding trigonal boron. This assignment is also consistent with valence bond calculations [9], and the charge balancing requirements of the cluster.

As can be seen in Figs 3 and 4, the $[(VO)_6\{B_{10}O_{16}(OH)_6\}_2]^{4-}$ cluster, as a whole, displays approximate $\bar{3}$ symmetry about an axis running through the center of the vanadium ring perpendicular to the plane of the six vanadium atoms. The cluster has an approximate diameter of 6 Å (V–V) at the vanadium ring and a height of 5.9 Å (O–O of the nearest oxygens of the central boron in each cap). Unlike the previously characterized $V_{12}B_{17}O_{58}$ and $V_{12}B_{18}O_{60}$ clusters [6], which contain ethylenediamine template molecules and water molecules that reside between the clusters, the intercluster space in (**1**) is filled only with Rb^+ cations, and the intracluster space contains electron density corresponding to a partially occupied water molecule. In comparing the structures

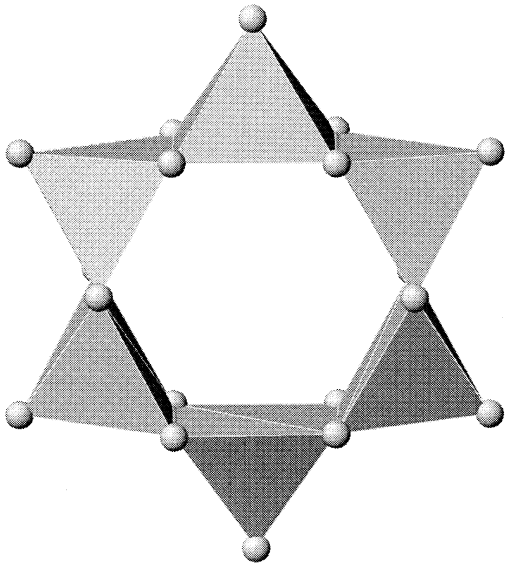

Fig. 1. A polyhedral representation of the hexagonal ring of six *trans*-edge-sharing VO_5 square pyramids present in the structure of (**1**).

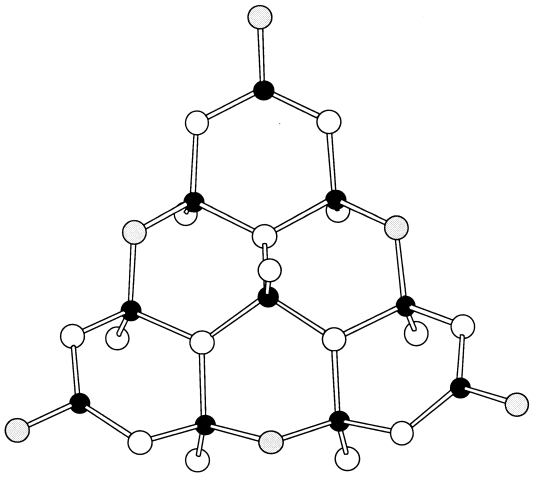

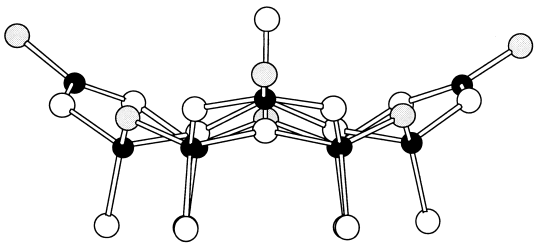

Fig. 2. Two views of the $B_{10}O_{16}(OH)_6^{8-}$ triangular polyborate caps that are present in the structure of (**1**). The central tetrahedral boron atom has a B–O$^-$ bond which is collinear with the pseudo $\bar{3}$ axis of the cluster, while the other six tetrahedral boron atoms have oxygen atoms pointing in the opposite direction that are part of the hexavanadate ring.

of these unusual polyoxovanadate borate clusters, it is interesting to note that each has a very specific polyborate ligand which is associated with a very specific vanadate moiety. The $V_{12}B_{18}O_{60}$ cluster, for example, comprises a puckered $B_{18}O_{36}(OH)_6$ ring sandwiched between two triangular rings of six alternating *cis* and *trans* edge-sharing vanadium atoms. The $V_{12}B_{17}O_{58}$ cluster, on the other hand, comprises a contorted vanadium oxide ring in which two semicircles of five *trans* edge-sharing VO_5 square pyramids interpenetrate forming clefts which are occupied by $B_8O_{17}(OH)_4$ and $B_9O_{18}(OH_4)$(enH) chains. Obviously,

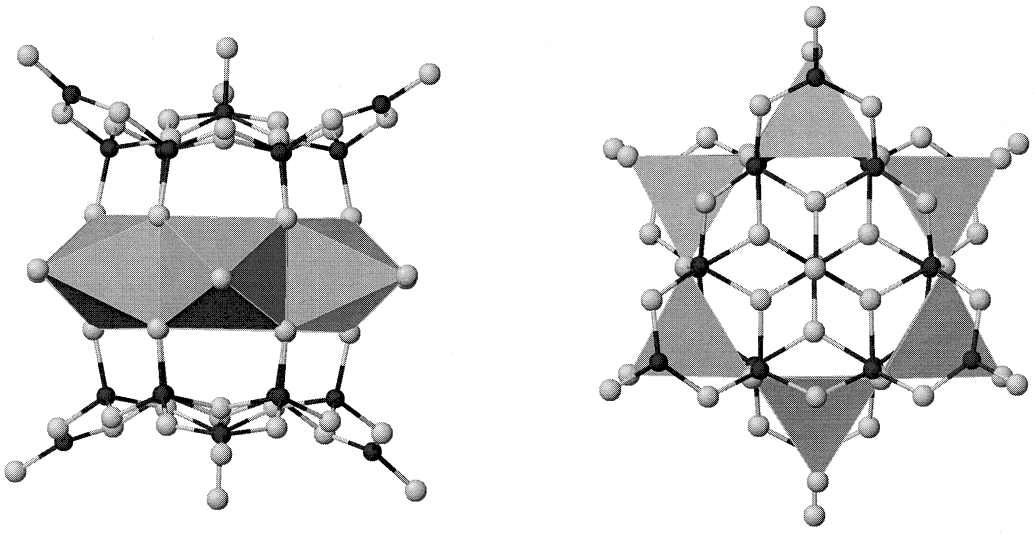

Fig. 3. Two views of the structure of the $[V_6B_{20}O_{38}(OH)_{12}]^{4-}$ cluster in $Rb_4[(VO)_6\{B_{10}O_{16}(OH)_6\}_2]\cdot 0.5H_2O$ (**1**).

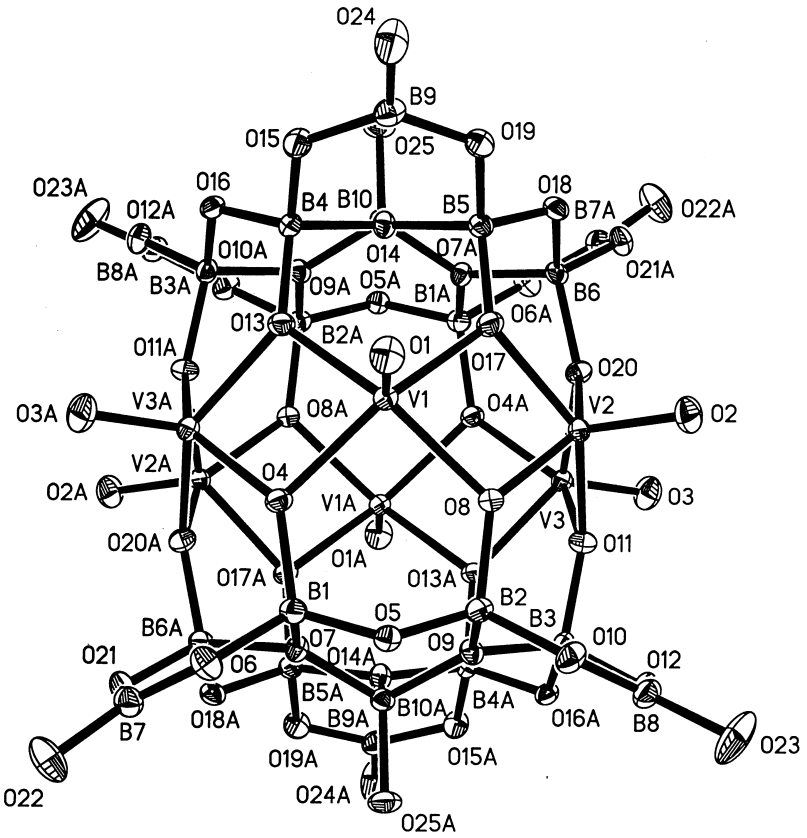

Fig. 4. ORTEP view of the structure of the $[V_6B_{20}O_{38}(OH)_{12}]^{4-}$ cluster in $Rb_4[(VO)_6\{B_{10}O_{16}(OH)_6\}_2]\cdot 0.5H_2O$ (**1**) showing the 50% probability thermal ellipsoids and atomic numbering scheme.

very sensitive relationships exist between the polyborate and vanadate moieties, and these relationships are clearly dependent on synthetic conditions which will require further study.

The +4 oxidation state of the vanadium atoms in (**1**) satisfies the charge requirements of the cluster and has been confirmed by valence bond calculations [9]. This oxidation state has also been verified by magnetic susceptibility experiments. The pale green color of the crystals also suggests that (**1**) contains only V^{IV}, and not mixed V^{IV}/V^{V} sites as are observed in the orange or dark red compounds containing $V_{12}B_{17}O_{58}$ and $V_{12}B_{18}O_{60}$, respectively.

The facile, high yield, synthesis of this and other structurally and compositionally unprecedented vanadium borate clusters [7] continues to point to hydrothermal synthesis as a particularly useful, and increasingly important, method for preparation of new compounds.

Monomeric Cu(II) complexes with tetradentate bis(benzimidazole) ligand ; synthesis, EPR, spectral and electrochemical studies

Rajesh and Pavan Mathur*

Department of Chemistry, University of Delhi, Delhi—110 007, India

(Received 27 June 1997 ; accepted 21 October 1997)

Abstract—A series of 1 : 1 copper(II) complexes with the tetradentate ligand 1,2*bis* (2 benzimidazolyloxamethyl) benzene (L) have been prepared with stoichiometry of $Cu(L)X_2 \cdot nH_2O$ ($X = Cl^-$, NO_3^-, OAc^- and $HCOO^-$). X-band EPR spectra of the above complexes examined as a frozen DMSO/DMF solution indicate $g_\parallel > g_\perp > 2.0$ and show four or less than four $g_\parallel$ lines and a broadening of the $g_\perp$ component suggesting a lowered site symmetry for the copper(II) ion. The $g_\perp$ component of all the complexes show nitrogen superhyperfine structure. A clear five line pattern is found in the $g_\perp$ region with $B_N \simeq 15G \pm 1$ for $Cu(L)\ X_2 \cdot nH_2O$ complexes indicating that two nitrogen from the benzimidazole ring are coordinated to the central Cu^{II} in the equatorial basal plane while the other two positions in the sphere are occupied by the anionic ligand (X). Interestingly with ClO_4^- as the anion, a 1 : 2 complex results with stoichiometry of $[Cu(L)_2]\ (ClO_4)_2$.

The X-band EPR spectra of $[Cu(L)_2](ClO_4)_2$ complex shows a clear nine line SHF structure on the $g_\perp$ component indicating the presence of four nitrogen atoms coordinated to the central Cu^{II} atom ; this confirms the retention of two ligands around Cu^{II} in solution. Molecular orbital coefficients β_1 and β_1' have been evaluated from the expression used by Manoharan and Rogers. The trends of β_1 and β_1' indicate increasing electron delocalization on nitrogen atom as we change the exogenous ligand from formate/acetate-chloride to nitrate. The covalency parameter, α^2, has also been evaluated and reflects the decreasing trend of covalency in the order, nitrate > chloride ⩾ acetate > formate for complexes containing these ligands. This trend of order is in conformity with that obtained from MO coefficients. All the complexes exhibit a visible band with λ_{max} in the 625–690 nm region, in DMF ; suggesting a distorted geometry for copper(II) ion in the present series of complexes. Cyclic voltammetric studies of copper(II) complexes reveal that the $E_{1/2}$ for the Cu^{II}/Cu^{I} couple shifts to most negative value with $HCOO^-$ and OAc^- anionic ligands implying that these anion stabilize the Cu^{II} state whereas $E_{1/2}$ data for NO_3^- reveals that this anion destabilizes the Cu^{II} state. A plot of visible band energy vs $E_{1/2}$ shows that as the energy of the $d_{x^2-y^2}$ orbital decreases, an anodic shift in $Cu^{II} \rightarrow Cu^{I}$ reduction potential is observed. © 1998 Elsevier Science Ltd. All rights reserved

Copper in a biological system is utilized, primarily in redox reactions associated with the reduction of oxygen to water, and oxygenation reactions. A copper containing superoxide dismutase has the specific but important role of removing the highly reactive superoxide anion (dismutation), and in these oxygenation reactions copper is active as the biological catalyst in the reaction [1]. The second major biological role of copper is in the transport of copper around the human body controlling its uptake and excretion [2]. The uptake of copper(II) by brain tissue was found to be facilitated by complexation using histidine in a study of the uptake of complexed copper-67 by brain hypothalamic tissue [3].

Galactose oxidase, an extracellular enzyme secreted by the fungus Dactylum dendroides, is among the few known copper containing enzymes that have a built in secondary co-factor. The copper site has a square planar coordination, comprises one tyrosine oxygen atom, two histidine nitrogen atoms and an acetate oxygen atom, providing an N_2O_2 donor array to the copper site with an axial tyrosine [4,5].

Since protein structure imparts a distortion in coordination geometry around the metal ion, which is an important factor in controlling the redox properties of the particular protein and imidazole group of histidine being a ligand apparently present in many proteins [6–8] ; a logical step to synthetic models should be to

* Author to whom correspondence should be addressed.

design and synthesize ligands containing one or two imidazole groups and so might impose a distorted coordination around the Cu^{II}. In an effort to simulate low symmetry metal environment as can be imposed by the protein structure, numerous septadentate [9], hexadentate [10], tetradentate [11], and tridentate [12], benzimidazole based ligands have been utilized to synthesize model compounds.

For the present study we have synthesized a series of copper(II) complexes by utilizing a tetradentate 1,2*bis* (2 benzimidazolyloxamethyl) benzene (L) ligand. These complexes are expected to have the following: (a) having a nearly square planar ($Cu^{II}N_4$) and $Cu^{II}N_2O_2$ chromophore as is observed in the bovine dismutase and galactose oxidase; (b) having a high affinity for an exogenous ligand in the cupric; (c) exhibiting at least quasi-reversible redox behaviour. Earlier we have utilized this ligand to synthesize some manganese(III) complexes [13].

EXPERIMENTAL

Starting materials

1,2-Diaminobenzene was recrystallized before use. Solvents and reagents (A.R. Grade) were used without purification.

Synthesis of ligand 1,2bis(2-*benzimidazolyl oxa methyl*)*benzene* (*L*)

1,2 phenylene dioxy diacetic acid (20.3 g, 90 m mol) was combined with 1,2-diaminobenzene (19.5 g, 180 m mol) and powdered. The mixture was heated for 3 h at a temperature of 150–160°C on an oil bath until all effervescence ceased. The resulting red blue glasslike solid after cooling was powdered and was added to 4MHCl (250 cm^3). Upon scratching the sides of the flask a grey white precipitate was obtained. This was filtered out and washed by slurrying in acetone several times. The above hydrochloride was dissolved in distilled water (220 cm^3) and the resulting filtrate was then neutralized with 1 : 1 ammonia until a white precipitate was formed. The white precipitate was collected, washed with ether and dried over P_2O_5 *in vacuo* (yield 70%). The procedure is similar to that reported by Reed *et al.* [14]. The ligand was characterized by ^1H NMR.

^1H NMR L δ_H (DMSO-d_6); 12.6 (NH 2H,S), 7.6 (aArH 4H,m), 7.2 (bArH + cArH 6H,m), 7.0 (dArH 2H,S), 5.3 (Aliph. 4H,S).

Elemental analysis and UV spectra of the ligand are reported in Table 1.

Synthesis of complexes

The coordination compounds of general formulae $Cu(L)X_2 \cdot nH_2O$ ($X = Cl^-$, NO_3^-, OAc^- and $HCOO^-$) were prepared by dissolving the appropriate hydrated metal salt (1 m mol) in methanol (10 cm^3) and adding this solution to the ligand (1 m mol) in warm methanol (20 cm^3). The reaction mixture was then left stirring. After 1 h of stirring bluish green precipitates of the desired compounds were obtained. These were collected by filtration, washed with methanol and dried over P_2O_5 *in vacuo*. The $[Cu(L)_2](ClO_4)$ (**5**) was prepared by the similar procedure as above except that crystallized precipitate was obtained on slow evaporation of the reaction mixture upon standing at room temperature.

CAUTION: Although no accident occurred with the present copper(II) perchlorate complex during the experimental work, it should be remembered that perchlorates are potentially explosive.

Physical measurements

Elemental analyses were obtained from microanalytical laboratory of RSIC, University of Punjab, Chandigarh, India. Metal was estimated by shimadzu model AA 640-13 atomic absorbance spectrophotometer.

Infrared spectra of the samples in Nujol mulls were recorded on a Perkin–Elmer model 1710 FT-IR spectrometer, solution electronic spectra were obtained on a Perkin–Elmer DU-260 spectrophotometer, ^1H NMR spectra on a Bruker 300 MHz FT-NMR spectrometer and EPR spectra on a varian E 112 X-band

spectrometer calibrated with diphenyl picrylhydrazyl (dpph), at liquid nitrogen temperature (77 K).

Cyclic voltammetric (c.v.) measurements were carried out using a BAS model CV-50W electrochemical analysing system. A 3 : 7 DMSO : MeCN solvent system was employed for c.v. studies with 0.1 M $NaClO_4$ as supporting electrolyte. A three electrode configuration was used, comprising a Pt disc working electrode (~ 3.1 mm^2 area), Pt wire counter electrode and an $Ag/AgNO_3$ (0.01 M $AgNO_3 + 0.1$ M TBAP/MeCN) reference electrode. The electrode performance was monitored by observing the ferrocenium/ferrocene (Fc^+/Fc) couple in the above solvent system. Experiments were carried out at room temperature (25°C) under dry N_2.

RESULTS AND DISCUSSION

EPR spectroscopy

Figure 1a–c represents the X-band EPR spectra of copper(II) complexes at 77 K, examined as a frozen dimethyl formamide solution. In general the EPR spectra reveal the presence of a distorted tetragonal copper site in the complexes. This is evident from the trend of their respective $g_\parallel$ and $g_\perp$ values which in all cases show $g_\parallel > g_\perp > 2$ (Table 2). All the complexes show four or less than four $g_\parallel$ components and a broadening of $g_\perp$ component. Such a broadening [15] of $g_\perp$ component is indicative of lowered symmetry.

The EPR spectra of all the complexes show nitrogen superhyperfine structure in the perpendicular region, arising from the interaction of the copper(II) odd electron with nitrogen atom, as can be seen from their spectra in Fig. 1a–c. The clear five line pattern in the perpendicular region for $Cu(L)X_2 \cdot nH_2O$ ($X = Cl^-$, NO_3^-, OAc^- and $HCOO^-$) indicates that two imine nitrogen from the two benzimidazole rings are coordinated to Cu atom in the equatorial basal plane. The other two positions in the plane are occupied by the anionic ligand (X) as supported by the IR spectra and further by the crystal structure of a related compound Cu(L) Br_2 [L = 1,6*bis* (benzimidazole-2yl)-2,5 dioxahexane] where Cu atom is bounded strongly to two benzimidazole N atoms of benzimidazole ligand and two anionic Br atoms are bounded in the basal plane with a rhombus shape [16].

The spin Hamiltonian parameters of some $Cu(L)X_2 \cdot nH_2O$ ($X = NO_3^-, OAc^-, HCOO^-$) complexes are very similar to the EPR X-band spectral parameters observed for galactose oxidase ($g_\perp = 2.04$, $g_\parallel = 2.28$) [17]; this indicates that the above complexes may have potential relevance to mononuclear copper site in the galactose oxidase.

Cryogenic frozen EPR spectra of $[Cu(L)_2]$ $(ClO_4)_2$ complex shows superhyperfine structure (SHF) on the $g_\perp$ component, having a clear nine line pattern with $B_N \simeq 15\text{G} \pm 1$. The appearance of clear nine SHF lines on the perpendicular copper hyperfine component indicates the presence of four nitrogen atoms coordinated to Cu^{II} atom, thus confirming the retention of

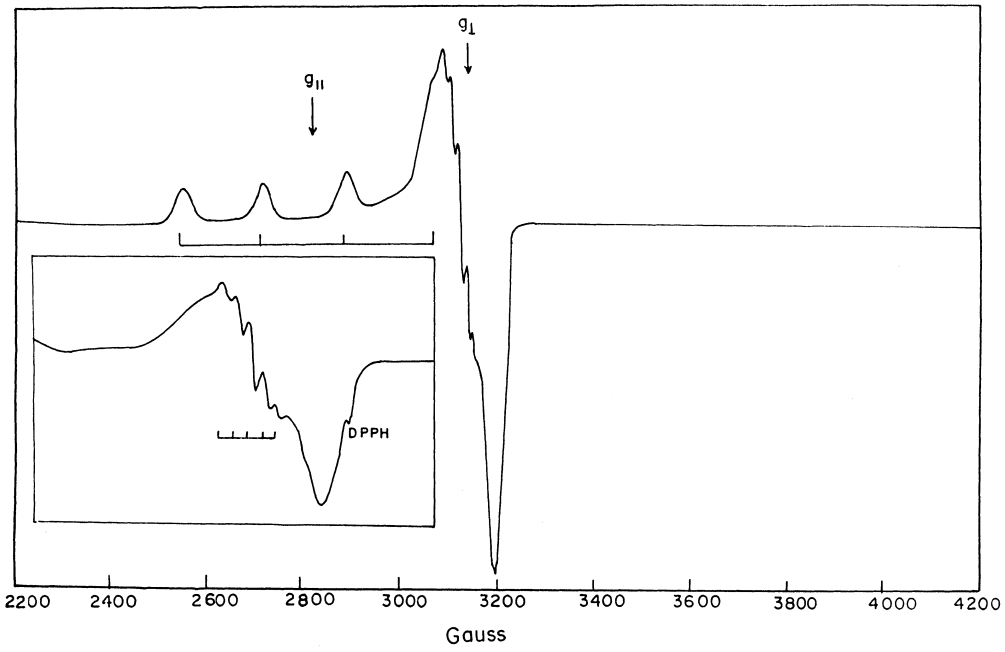

Fig. 1a. 2000 G Scan of frozen DMF solution of $Cu(L)(NO_3)_2$. Conditions: receiver gain = 2.0×10^2 G; microwave power 20 mW; microwave frequency 9.01 GHz; modulation amplitude 2.5 G; $T = 77$ K at X-band.

two ligands around Cu in a square planar array in solution. The $g_\parallel$ and $A_\parallel$ values of the complex lies on the $g_\parallel$ vs $A_\parallel$ map [18] and is typical for planar CuN_4 chromophore [19]. The value of $g_\parallel/A_\parallel$ quotient 132.0 cm^{-1} supports the square planar geometry with no appreciable tetrahedral distortion [20–22].

We have made an attempt to calculate the MO coefficients for the b1g orbital, i.e. β_1 and also the ligand coefficient β_1' in the b1g MO, from the superhyperfine structure in the $g_\perp$ region. The SHF coupling constant (B_N) could be related to β_1' and the contribution from the 2*s* and 2*p* functions [23] (with $\phi^2(2s) = 33.4 \times 10^{24}$ cm^{-3} for the 2*s* function and $<r^{-3}>_p = 21.1 \times 10^{24}$ cm^{-3} for the 2*p* function following Maki and McGarvey [24]). Once β_1' is known, β_1 could be calculated by the relation $\beta_1^2 + \beta_1'^2 - 2\beta_1\beta_1' s = 1$ where *s* is the overlap integral. The values of β_1 and β_1' are in keeping with those calculated for Cu^{II} TPP complex, and provide proof that there is considerable covalent bonding particularly in plane σ bonding. The relative trend of β_1 and β_1' with respect to exogenous ligand (X = Cl^-, NO_3^-, OAc^-, $HCOO^-$) shows that there is greater unpaired electron delocalization on benzimidazole nitrogen atom as we move from formato/acetato-chloride to nitrato complex.

Electronic and electrochemistry

Figure 2 shows the electronic spectra of copper(II) complexes; their band positions and extinction coefficients are reported in Table 3. Several prominent bands are obtained in the UV region and are assigned to the benzimidazolyl group π-π^* transition. These bands show a slight blue shift in their respective complexes and support binding of the benzimidazolyl ring imine nitrogen to the metal centre, this being the preferred nitrogen atom for coordination [13–15,25]. New bands arise in the visible part of the spectrum in the region of 625–690 nm, and are assigned to *d-d* transition. The energy of the *d-d* transition suggests distorted tetragonal copper(II) complexes [15] and follows the order nitrate (**2**) <chloride (**1**) <acetate (**3**) <formate (**4**). A square N_2O_2 donor array is expected to produce a *d-d* transition in the region of 500–550 nm [26]; the considerably longer wavelength observed in our complexes is a clear indication of the weakened equatorial ligand field, due to the lowered basicity of the imine N-atom of the benzimidazole. We have calculated the covalency parameter, α^2, using a simple relationship: $g_\parallel = 2.0023 - 8\lambda\alpha^2/xy$ [27]. The smaller the value of α^2, the more the covalency of copper-ligand bond in the complex; thus on the basis of α^2 value, the order of decreasing covalency is nitrate > chloride $\geqslant$ acetate > formate for copper(II) complexes containing these ligands. This trend is in conformity with that obtained from MO coefficients.

The order of energies is in keeping with the above covalency order found from EPR parameters. The decreasing order of covalency reflects the increasing order of visible band energy, i.e. the higher the covalency, the lower the energy of the $d_{x^2-y^2}$ orbital and correspondingly the energy of the $d_{xy} \rightarrow d_{x^2-y^2}/d_{xz}, d_{yz} \rightarrow d_{x^2-y^2}$ transition is also lowered.

Figure 3a–d and Fig. 4 shows the cyclic voltammogram and differential pulse voltammogram of the copper(II) complexes taken in 3:7 DMSO: MeCN solvent system. The reversible one electron Fc^+/Fc couple in the above solvent system has an $E_{1/2}$ of 0.27 V vs $Ag/AgNO_3$. The electrode potentials of the copper(II) complexes are given in Table 4.

All complexes exhibit a quasi-reversible reduction wave in the range of +0.12V to −0.24V region, with peak to peak width much larger than that observed for the one electron couple Fc^+/Fc ion in the same solvent system. Larger peak width for the one-electron $Cu^{II} \rightarrow Cu^I$ couple in their respective complexes is not an uncommon observation [28]. We therefore assign this cathodic wave to the reduction of $Cu^{II} \rightarrow Cu^I$ couple. $E_{1/2}$ data for this couple (Table 4) indicates that the most negative potential is for formate/acetato complex followed by chloride and nitrato. We there-

fore conclude that the binding of the formato/acetate anion stabilizes the Cu^{II} centre, while the binding of the nitrate anion tends to stabilize the Cu^{I} state in comparison to the Cu^{II} state.

The stabilization of Cu^{II} state by exogenous ligand can be well understood by making a correlation between the covalency factor, α^2, *d-d* energy bands and redox potentials ($E_{1/2}$) in the respective complexes. An increase in covalency in the Cu^{II}—N equatorial bond leads to a decrease in repulsion between the $d_{x^2-y^2}$ orbital and the equatorial ligands, causing a concomitant decrease in the energy of this orbital and also an anodic shift in the $Cu^{II} \rightarrow Cu^{I}$ reduction potential [28]. This parameter will also be affected by other equatorial ligands (x) in the complexes. This is evident from a plot of *d-d* band energy (ν_{max}) vs $Cu^{II} \rightarrow Cu^{I}$ redox potential ($E_{1/2}$) (Fig. 5).

Infrared spectroscopy

In the IR spectra of the free ligand (in Nujol), a strong band in 1460 cm^{-1} is attributed to stretching

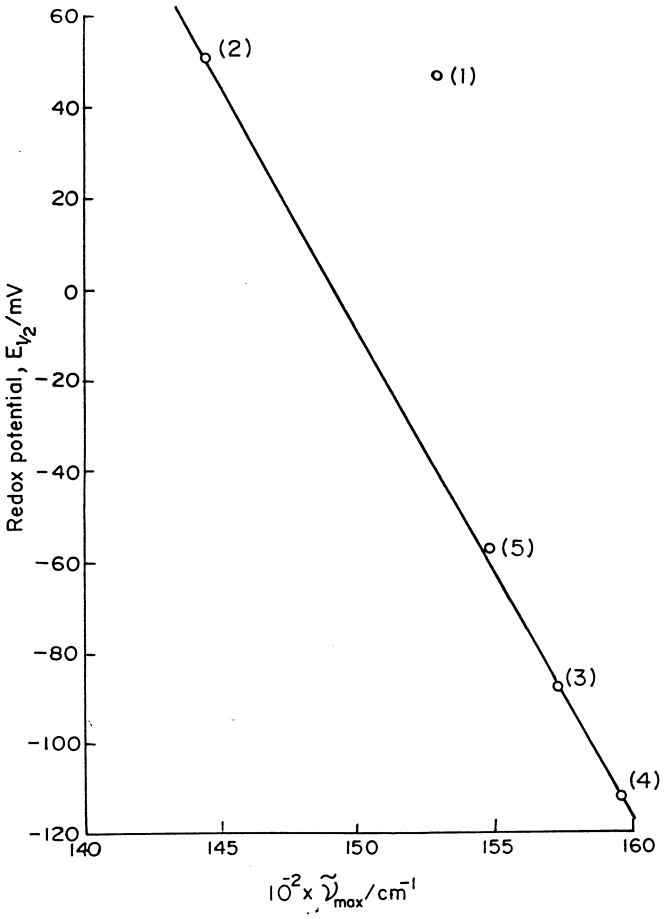

Fig. 5. Plot of visible band energy (ν_{max} cm^{-1}) vs redox potential $E_{1/2}$ (mV) for $Cu(L)Cl_2 \cdot H_2O$ (**1**), $Cu(L)(NO_3)_2$ (**2**), $Cu(L)(OAc)_2 \cdot 2H_2O$ (**3**), $Cu(L)(HCOO)_2 \cdot H_2O$ (**4**) and $Cu(L)_2(ClO_4)_2 \cdot 2H_2O$ (**5**).

mode for [—C═N—C═C—]. In the present case we find that the shift in 1460 cm^{-1} is 10–20 cm^{-1} for the copper complexes. This implies direct coordinates of all the imine nitrogen atoms to Cu^{II}. This is a preferred nitrogen atom for coordination as found in other metal complexes with benzimidazole [25]. The acetato and formato complexes show additional band at 1600–1610 cm^{-1} and 1320–1340 cm^{-1} respectively. These suggest the presence of coordinated acetate/formate and are assigned to a unidentate mode of binding of acetato/formato group [29]. In the nitrato complex new bands appear at 1420, 1320, and 1020 cm^{-1} are assigned to $\nu_{asym}(NO_2)$, $\nu_{sym}(NO_2)$ and $\nu_{asym}(NO)$ respectively, suggesting a unidentate mode of binding of nitrate group [30], whereas in the copper(II) perchlorate complex appearance of strong bands at 1080 and 910 cm^{-1}, suggests the presence of ionic perchlorate [31].

Solid state metathesis routes to Group IIIa nitrides : comparison of Li_3N, NaN_3, Ca_3N_2 and Mg_3N_2 as nitriding agents

I. P. Parkin* and A. M. Nartowski

Department of Chemistry, University College London, 20 Gordon Street, London WC1H OAJ, U.K.

(Received 15 July 1997 : accepted 31 October 1997)

Abstract—Reaction of MCl_3 (M = Sc, Y, La) with Li_3N, NaN_3, Ca_3N_2 and Mg_3N_2 at 380–800°C in sealed glass or Pyrex ampoules for 1–2 h produces MN in good yield. The metal nitrides were characterised by X-ray powder diffraction, electron probe analysis, FT-IR and microanalysis. Variations in reaction initiation temperatures, nitride composition and crystallinity were correlated with nitriding agent. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: nitride ; solid-state ; metathesis.

Metal nitrides are man made materials that have found applications in a wide variety of industrial processes. Early transition metal nitrides are hard, refractory materials which show good electrical and thermal conductivity similar to metals but with better wear resistance. Titanium and zirconium nitride are used as hard phases in steel manufacture and also as coatings for tool bits [1]. Surprisingly, metal nitrides are also utilised in solar control coatings for windows where their particular reflectance and transmission properties can be used in environmental management [2]. Nitrides have also been used in high temperature crucibles, electronic circuits, catalysts and jewellery [3]. Nitrides of the Group I and II elements are salt like with metal cations and nitride anions [4]. Transition metal nitrides are interstitial compounds with nitrogen filling vacancies within a close packed metal lattice. The interstitial nature of the materials means that non-stoichiometries are common [5,6], for example, tantalum nitride has known phases from Ta_3N_5 to $TaN_{0.01}$.

Nitrides have been made by a number of methods. Conventionally combination of metal with ammonia, nitrogen or nitrogen/hydrogen mix has allowed nitride formation [7]. These routes can suffer from incomplete reaction and require prolonged elevated temperatures (1000°C). High temperature combination of the metal halide with ammonia has also yielded metal nitrides [8]. Disalvo and co workers have synthesised a range of new ternary metal nitrides by reactions in liquid sodium at 750°C [9]. Russian scientists have developed self propagating routes to metal nitrides by reacting metal powders with nitrogen under high pressure [10]. Kaner *et al.* [11,12] and ourselves [13–17] have shown that it is possible to form metal nitrides by solid state metathesis reactions (SSM) of anhydrous metal halides with lithium nitride and sodium azide eqn (1).

$$Li_3N + TiCl_3 \rightarrow TiN + 3\,LiCl \qquad (1)$$

These reactions are self propagating requiring no heat other than to initiate them. They are rapid (over in 2–3 s) with dramatically fast heating (up to 1400°C) and cooling rates. The reactions are very exothermic driven by the lattice energy of the coproduced lithium chloride. Removal of the coproduced chloride is relatively straight-forward simply by washing the product with water.

In this paper we outline the synthesis of Group IIIa nitrides using various nitriding sources. This was undertaken both to extend the range of metathesis reactions to Group IIIa nitrides and more importantly to see how changes in nitriding reagent altered ease of reaction initiation and product crystallinity and composition. The air sensitivity of the nitrides was also probed.

EXPERIMENTAL

All reagent manipulations were carried out under nitrogen or argon atmospheres using either glove box or Schlenk line techniques. Glass ampoules (greater than 35 cm^3 internal volume) were annealed prior to use and thoroughly flame dried under vacuum. Anhydrous metal chlorides and NaN_3, Li_3N, Ca_3N_2 and Mg_3N_2 were obtained from Aldrich Chemical Co. and Strem chemicals and used as supplied. Methanol was dried over 3 Å molecular sieves and degassed with nitrogen prior to use. Infra-red spectra were recorded on a Nicolet 205 FT-IR spectrometer using KBr discs. Powder XRD measurements were performed on a Siemens Diffractometer D5000 in transmission mode using Ge monochromated Cu-$K_{\alpha 1}$ ($\lambda = 1.5406$ Å) radiation. SEM profiles and energy dispersive X-ray analyses (EXDA) were obtained on a Jeol JSM 820 instrument using a Kevex detector and software. EDXA was performed on various regions across the sample surface, using point analyses to determine regional homogeneity. Electron probe analysis were performed on a Jeol EMA microprobe. A Lenton Thermal Designs programmable tube furnace was used to initiate the bulk reactions. Point source reactions were initiated by electrically heated nicrome wire filament at 800°C. Microanalysis was determined by the departmental service at UCL.

Reaction of NaN_3 *with* MCl_3 (M = Sc, Y, La)

The same general reaction scale and procedure was utilised for all reactions outlined below for sodium azide and lanthanum trichloride.

Sodium azide (0.050 g, 0.77 mmol) and $LaCl_3$ (0.504 g, 0.22 mmol) were carefully ground together and sealed under vacuum in a large pyrex ampoule. The ampoule was placed into a tube furnace and the temperature ramped at 10°C per minute from room temperature until a reaction was observed (380°C) by a thermal flash and the appearance of material at the end wall of the ampoule. After cooling, the ampoule was broken open and the material was washed with methanol (4×7 ml) and dried *in vacuo*. The residual black materials were analysed by powder XRD (Table 1), SEM/EDXA and FT-IR. Microanalysis LaN ; calculated N = 9.1%, observed N = 5.8% (implying non-stoichiometry and formation of $LaN_{0.61}$; nitrogen stoichiometry as determined by electron probe indicated that the nitride products were in the range $MN_{0.9}$–$MN_{0.7}$ (M = Y, La) also indicating non-stoichiometry).

Reactions involving Ca_3N_2 and Mg_3N_2 with MCl_3 were conducted in quartz ampoules and the oven temperature raised up to 800°C maintained at this temperature for 1 h and allowed to cool to room temperature.

Reactions involving Li_3N and MCl_3 initiated at 500°C with an orange thermoflash. Reactions can be made to occur with these reagents at 400°C for 3 h, however a very poorly crystalline product is produced.

Isolated yields for the Li_3N, Mg_3N_2 and Ca_3N_2 reactions were typically 70–90%. Sodium azide reactions gave yields from 20–30%.

Filament initiation ; reactions did not initiate in the filament mode (nichrome wire, 800°C).

Caution! These reactions are extremely exothermic and can produce large quantities of nitrogen (especially the NaN_3 reactions). Large ampoules should be used to minimise the risk of pressure explosions and reactions should be conducted behind a safety screen.

RESULTS AND DISCUSSION

Synthesis and characterisation

Reactions of Group IIIa anhydrous chlorides with a number of different nitriding agents (Li_3N, Mg_3N_2, Ca_3N_2 and NaN_3) were investigated. Mixtures of the preground elements were heated in sealed glass or quartz ampoules. At certain temperatures (Table 1) a thermal flash was observed and the solid material was spread over the ampoule walls. In the Ca_3N_2 and Mg_3N_2 reactions the ampoules were heated further for 1 h at 750°C and then allowed to cool to room temperature. All reactions afforded a (dark) powder which was purified by washing with methanol and dried briefly *in vacuo*. Both the washed and as prepared powders were analysed by SEM/EDAX, X-ray powder diffraction, microanalysis, electron probe and FT-IR.

The as prepared materials showed by powder XRD a mixture of Group IIIa metal nitride and main Group chloride. Metal chloride was removed by trituration to leave just the diffraction patterns for either ScN, YN (Fig. 1) or LaN. Patterns indexed well and correlated with literature measurements [18]. However a small variation in the observed *a* parameter was noted depending on the nitriding source (Table 1). This may correspond to some nitrogen substoichiometry, especially as cubic transition metal nitrides are known to tolerate wide ranges in composition ($MN_{1.0}$–$MN_{0.7}$). Differences in the degree of crystallinity of the powders were noted dependent on nitriding agent. This is commented on below. SEM measurements of the as prepared powders revealed a smooth morphology, whilst EDAX showed the presence of Group IIIa metal, main group metal and chlorine (nitrogen was below the threshold of the EDAX system used). This corresponds to the formation of Group IIIa nitride with main group metal chloride on the surface. Trituration of the material produced small (ca 1 μm) aggregates with sharp angles and faces by SEM and only Group IIIa metal by EDAX. Surprisingly little variation in morphology was observed for different reaction temperatures (Table 1), although the highest temperature reactions did show slightly

Table 1. Reaction conditions and XRD data for the products from reactions of MCl_3 (M = Sc, Y, La) with Li_3N, NaN_3, Mg_3N_2 and Ca_3N_2

Reagents	Synthesis	Colour	Phase observed	Observed *a* parameter (Å)	Literature [18] *a* parameter (Å)

larger agglomerates after washing. Electron probe measurements showed predominantly the presence of metal and nitrogen with elemental ratios in the range $MN_{0.9}$–$MN_{0.7}$ across many surface spots. Notably little oxygen was detected, indicating that the products are not metal oxynitrides. FT-IR analysis of the nitride powders showed just a single broad absorption band centred at 650 cm^{-1} (LaN) corresponding to a metal nitrogen stretch [19]. Elemental combustion analysis also showed a nitrogen deficient nitride of formula $LaN_{0.61}$. This low value maybe due to the refractory nature of the nitride (making combustion analysis difficult). Although as stated above it is likely that the Group IIIa nitrides formed are sub-stoichiometric in nitrogen. It should also be noted that some nitrogen loss may occur prior to analysis (see later).

Overall the reactions can be summarised as indicated in eqns (2)–(5).

$$MCl_3 + 3NaN_3 \rightarrow MN + 3NaCl + 4N_2 \quad (M = Sc, Y, La) \quad (2)$$

$$MCl_3 + Li_3 \rightarrow MN + 3LiCl \quad (M = Sc, Y, La) \quad (3)$$

$$2MCl_3 + Ca_3N_2 \rightarrow 2MN + 3CaCl_2 \quad (M = Sc, Y, La) \tag{4}$$

$$2MCl_3 + Mg_3N_2 \rightarrow 2MN + 3MgCl_2 \quad (M = Sc, Y) \tag{5}$$

Initiation temperatures

Reactions with sodium azide all initiated at 380°C (NaN_3 dec 365°C) [19]. A bright white thermoflash occurred at the initiation temperature and the products were spread throughout the ampoule due to nitrogen evolution eqn 2. Crystallinity of the product was much lower than with other nitriding agents as the product is spread throughout the ampoule allowing for less self annealing. Reactions of other nitriding agents with anhydrous metal chlorides formed a partly fused solid, eqns 3–5. In general use of Li_3N produced the most crystalline product. In this case the reactions initiated at 550°C with an orange thermal flash and produced a dark partly fused product. It was possible to get a reaction between Li_3N and MCl_3 at 400°C below the thermal flash temperature if the reaction was left for 3 h, however the product was notably less crystalline and more unstable readily losing nitrogen. No reaction was observed between calcium or magnesium nitrides and Group IIIa metal halides at temperatures up to 600°C.

However heating to 750°C for 1 h in a quartz ampoule did promote reaction. In this case no thermoflash was observed and a darkening of the solid was noted at 700–750°C (Table 1). For comparable reactions calcium nitride tended to give more crystalline products than magnesium nitride.

The temperature required for initiation of the solid state metathesis reaction is very dependent on the nitriding reagent. This can be directly related to the ease in which the solid state diffusion barrier is overcome. Sodium azide decomposes at ca 365°C [12]. This allows the lowest temperature initiation of any of the nitriding agents studied. Presumably the sodium released on decomposition can react with chloride of the metal halide and allow partial reduction of the metal halide and formation of molten NaCl in which the reaction can propagate. This reaction is probably of the reduction-oxidation mechanism as described by Kaner [12]. Lithium nitride reactions were observed to initiate at ca 550°C with Group IIIa chlorides. This is below the melting points of both Li_3N (810°C) [12] and MCl_3 (850°C M = Sc, Y, La) [21]. Interestingly an early report noted that Li_3N starts to lose some nitrogen at 550°C prior to melting [22]. This temperature corresponds to the initiation temperatures observed. Thus either the partial loss of nitrogen is important in initiating the reaction, or at this temperature the rate of solid state diffusion between reacting grains (possibly promoted by some free Li generated on loss of nitrogen) has become sufficient for the exothermic combination reaction to become self propagating. The reactions of magnesium and calcium nitrides and MCl_3 do not show a thermal flash. Notably the decomposition points of Mg_3N_2 and Ca_3N_2 at 1500°C and 900°C [21] (note 1150°C is also quoted for Ca_3N_2 [22]) are above the decomposition points of the metal halides.

Thermodynamic considerations

Reactions of Group IIIa anhydrous chlorides and the various nitriding agents were studied by point source filament initiation. This was achieved by placing a glowing filament (800°C) onto a preground mixture of the reacting powders. No solid flame was observed and all the reactions failed to propagate. Some reaction was observed at the tip of the filament for the reactions involving sodium azide and lithium nitride, probably corresponding to partial reaction or decomposition. It has been shown previously [12,17] that the ease of reaction propagation can be related to $T_{ad,s}$ (the adiabatic reaction temperature for the reaction assuming salt formation only i.e. $LaCl_3 + Li_3N \rightarrow La + N + 3LiCl$) and the melting points of the co-produced metal halides. This model has been built up by empirical argument stating that the reaction can only propagate if sufficient reaction energy is available to melt the co-produced salt, the reaction proceeding between intervening layers with the melt; thereby overcoming the solid state diffusion barrier. In the reactions outlined for Group IIIa elements $T_{ad,s}$ for La and Y is below the melting point of the co-produced salts, the reaction between $ScCl_3$ and Li_3N is at the cross over point for propagation.

Heats of reaction for eqns 2–5 as assessed by Hess's Law show a decrease in exothermicity with nitriding agent in the order NaN_3, Li_3N, Ca_3N_2, Mg_3N_2 (ca -650 kJ mol^{-1} NaN_3 and $ScCl_3$ to -260 kJ mol^{-1} Mg_3N_2 and $LaCl_3$). The most exothermic reactions did not correspond to the most crystalline sample. However the Mg_3N_2 prepared nitrides showed the least crystallinity (ca 200 Å from the Scherrer equation [1]) and these reactions were also the least exothermic. The sodium azide prepared nitrides also showed limited crystallinity [1] (ca 250 Å) probably because of the excess gas produced in the reaction and spread of product within the ampoule, thus limiting self annealing [17]. The lithium nitride reactions showed the greatest crystallinity (ca 450 Å) [1] probably as a fused product was obtained and the reaction was also very exothermic. It may also be possible that the coproduced LiCl acts as a template for the formation of cubic nitrides [13,15].

Changes in nitridation

It was observed that the nitridation level of the metal nitrides was adversely effected by the use of vacuum drying. In the case of YN prepared from

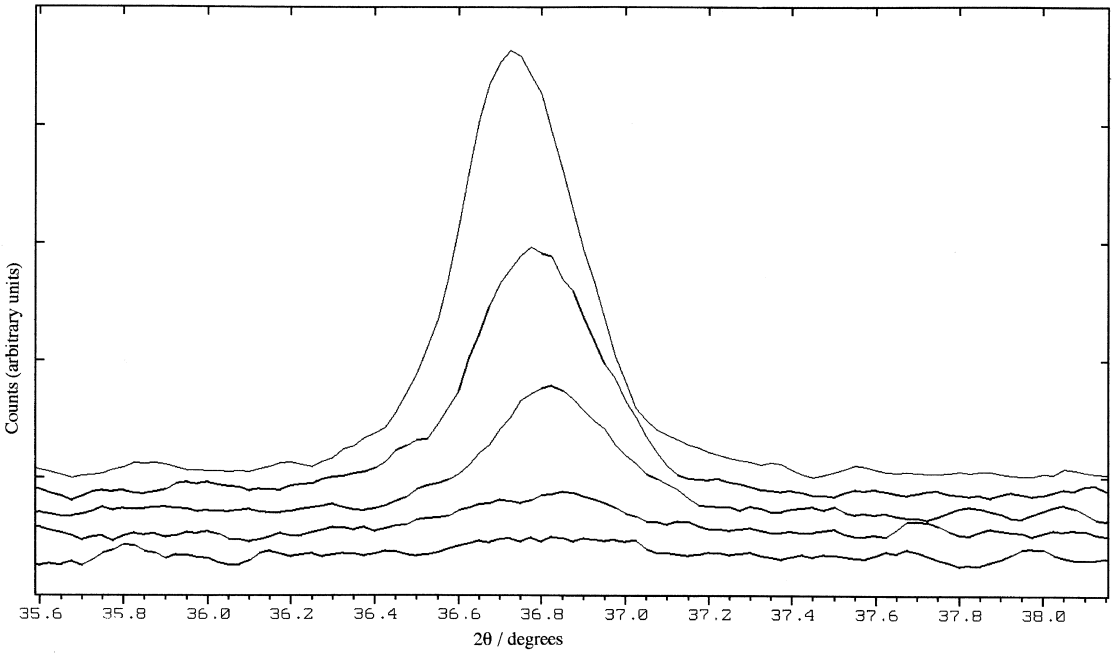

Fig. 2. Changes in the YN (1 1 1) reflection with time after storage in air (patterns recorded at 10 min intervals).

Ca_3N_2 and YCl_3 the *a*-parameter shifted from 4.897 Å to 4.886 Å, this was also accompanied by a change in colour from brown to navy green. Goldschmidt [23] determined that the lattice parameter is sensitive to degree of nitridation. The *a* value of cubic nitrides decreases as the amount of nitrogen in the product goes down, until a critical point is reached and the material ceases to have a cubic structure. Changes in nitride lattice parameter can often be correlated with Vegards law [24]. We would have liked to correlate the observed low levels of nitridation in the Group IIIa nitrides ($MN_{0.8}$ by electron probe) with the lower *a* parameter, however to our knowledge no Vegard like compositional range for Group IIIa nitrides has been published. However it is probably fair to note that a decrease in *a*-value corresponds to lower nitridation levels. Additionally a decrease in lattice parameter is noticed upon short vacuum drying of the product. It also appears that the loss of nitrogen from the structure *in vacuo* is fast initially at high levels of nitridation, but slows dramatically as the nitrogen content decreases.

Nitride samples prepared by SSM reactions also appear to be sensitive to the presence of oxygen, far more so than nitrides prepared by conventional means. This may be due to the high defect concentrations and relatively high surface areas generating quite a porous material. It was noted that diffraction peaks for YN when measured in air decreased in intensity with time for the same sample. A new set of diffraction lines appeared with oxidation corresponding to Y_2O_3, however these only grew in initially and did not continue to increase as the nitride peaks diminished. In addition to the nitride peaks going down in intensity they also shifted position (Fig. 2) ($a = 4.883$ Å over a period of 1 h in air) corresponding to loss of nitrogen. Such nitride materials must be handled and stored in a nitrogen atmosphere.

Attempts at forming solid solutions of Y_xSc_yN using mixtures of the metal chlorides and Li_3N were unsuccessful forming a mixtures of phases that could be assessed as the individual nitrides.

CONCLUSIONS

Reaction of Li_3N, Na_3N, Ca_3N_2 and Mg_3N_2 with anhydrous Group IIIa chlorides offer a convenient one step high yield route to metal nitrides MN. Crystallinity is dependent on the nitriding reagent with Li_3N and Ca_3N_2 producing the most crystalline products. Ease of reaction initiation is related to the ease in which the solid state diffusion barrier is overcome, this can be correlated to decomposition points of the nitride reagents. Group IIIa nitrides formed via SSM reactions are air and vacuum sensitive losing nitrogen.

(Received 26 August 1997 ; accepted 6 December 1997)

Abstract—The crystal structure of the neutral, *pseudo*-octahedral *mono* phenanthroline iron(III) complex $Fe(phen)Cl_3H_2O$ is reported, which surprisingly is the first well-characterized $Fe(phen)Cl_3$ complex (space group $P\bar{1}$; $a = 10.224(4)$ Å, $b = 10.603(3)$ Å ; $c = 6.628(2)$ Å ; $\alpha = 100.70(2)^\circ$, $\beta = 108.17(2)^\circ$, $\gamma = 92.06(2)^\circ$; $R = R_w = 0.033$). Of the three unidentate chloride ions, two are coplanar with phenanthroline ligand while the third is out of plane and is *trans* to the water molecule. The metal environment is distorted from regular octahedral due to the non-equivalent ligand donor set. The N–Fe–N bite angle of 75.6° is compressed below right-angular with a corresponding opening of the other bond angles around the iron in this plane. The Fe—Cl bonds are inequivalent, ranging from 2.25 to 2.35 Å, the axial Fe—Cl bond being elongated. The axial aquo group is tilted towards the phenanthroline ring, making an angle of 83.8° with N(1) and 81.8° with N(2), respectively. Comparison with the Mn(III) analog yields the effect of changing from a high spin d^5 to a high spin d^4 center. © 1997 Elsevier Science Ltd

Keywords: iron(III) ; phenanthroline ; DNA intercalator.

1,10-phenanthroline (phen) is a popular ligand, extensively studied for the DNA cleaving activity of its copper compounds [1] and the DNA intercalating properties of the ruthenium compounds [2]. The screw-chain structure of 1,10-phenanthroline · H_2O [3] forms via a H-bonding network. Phen complexes with many metals exhibiting 1 : 1, 1 : 2, and 1 : 3 metal to ligands stoichiometries. Numerous X-ray crystal structures have been reported for bis-phen [4–8] and tris-phen [9–12] complexes, while complexes containing a solitary phen ligand are scarce [14–16]. Attempts to prepare the species with the empirical formula $Fe(phen)Cl_3$ have been described [17–19] but the correct composition of the product has not been clearly established and several formulae have been proposed. For example, the action of phen on $FeCl_3$ in acetone was recently shown to yield $[Fe(phen)_2Cl_2][FeCl_4]$ [4].

EXPERIMENTAL

$Fe(phen)Cl_3 \cdot H_2O$ was prepared by mixing an aqueous solution of iron chloride with 1,10-phenanthroline solution in 10 M HCl in the mole ratio of 1 : 1 and recrystallizing the resulting compound from a water : methanol (1 : 1) mixture. The yield of the compound is very low. Elemental Analysis : Found C, 41.23% ; H, 2.76%, Fe, 14.84% ; Calcd C, 39.99% ; H, 2.80%, Fe, 15.49%.

Data collection and processing

Measurements were made as previously described [31] using a Rigaku AFC6S diffractometer with

* Author to whom correspondence should be addressed.

graphite monochromated MoKα radiation on a red crystal fragment of [Fe(phen)(H_2O)Cl_3], $C_{12}H_{10}ON_2FeCl_3$, dimensions $0.50 \times 0.40 \times 0.30$ mm, on a glass fibre. Cell dimensions were $a = 10.224(4)$ Å, $b = 10.603(3)$ Å; $c = 6.628(2)$ Å; $\alpha = 100.70(2)^\circ$, $\beta = 108.17(2)$, $\gamma = 92.06(2)^\circ$; V = 667.4(4) Å [3]. For Z = 2 and F.W. = 360.4, the calculated density is 1.79 g/cm [3]. Based on packing considerations, a statistical analysis of intensity distribution, and the structure solution, the space group was determined to be $P\bar{1}$. Data were collected at 20°C using ω–2θ scans. Scans of $(1.37 + 0.33 \tan\theta)^\circ$ were made at 4.0°/min (in ω). Stationary background counts were made on both sides of each reflection. Of the 3409 reflections collected, 3232 were unique ($R_{int.} = 0.043$); equivalent reflections were averaged. Of these, 2172 reflections and $F_0^2 > 3\ \sigma(F_0^2)$, where $\sigma(F_0^2)$ was estimated from counting statistics [31,32]. Lorentz-polarization and absorption [33] corrections were applied. The intensities of three standard reflections measured after every 150 reflections showed no greater variation than those expected from Poisson statistics.

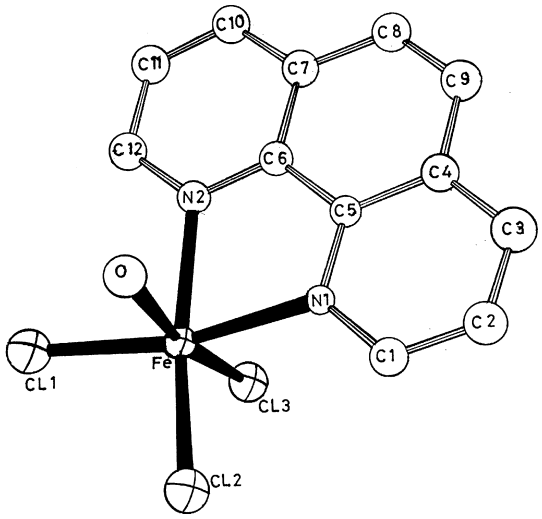

Fig. 1. Molecular structure of [Fe(phen)Cl_3(H_2O)]. Selected bond distances (Å): Fe—Cl(1) 2.282(1), Fe—Cl(2) 2.250(1), Fe—O 2.188(3), Fe—Cl(3) 2.342(1), Fe—N(1) 2.167(3), Fe—N(2) 2.182(3); bond angles (°): Cl(3)—Fe—O 169.13(7), Cl(2)—Fe—Cl(3) 98.71(5), O—Fe—N(1) 83.8(1), O—Fe—N(2) 81.8(1), N(1)—Fe—N(2) 75.6(1).

Structure solution and refinement

The metal and halogen position were determined from a 3-D Patterson which phased the data sufficiently to locate the other atoms from difference Fourier maps. Non-hydrogen atoms were refined anisotropically. Full-matrix least-squares refinement [34] using the TEXRAY [35] program set gave unweighted and weighted agreement factors of $R = (\Sigma||F_o| - |F_c||)/\Sigma|F_o| = 0.033$, $R_w = [(\Sigma w(|F_o| - |F_c|)^2/\Sigma w(F_o^2))]^{1/2} = 0.033$. The standard deviation of an observation of unit weight [36] was 1.66. The weighting scheme was based on counting statistics and included a factor ($p = 0.015$) to downweight the intense reflections. Neutral atom scattering factors were taken from Cromer and Waber [37]. Anomalous dispersion effects were included in F_{calc} [38], the values for $\Delta f'$ and $\Delta f''$ were those of Cromer [39].

RESULTS AND DISCUSSION

Here we report the crystal structure of [Fe(phen)Cl_3(H_2O)] which is a distorted octahedral compound an ORTEP [20] of which is shown in Fig. 1. The N_2Cl_2 equatorial plane exhibits slightly unequal bond distances for the Fe–N linkages at 2.167 and 2.182 Å. The shorter of these is balanced by a slightly longer (2.282 Å vs 2.250 Å) Fe—Cl bond on the opposite side. Metal ligand bond lengths can be used to determine the spin state and further that the effect of counterions is relatively small when a spin equilibrium is not present [21–30]. The comparison with the tris (phen) complex (Table 1) shows the present complex to be unambiguously high spin d^5. The iron–nitrogen distances observed in the present complex are significantly greater than those found for the tris phenanthroline compounds (Table 1) while the Fe—Cl distances are slightly greater than those in bis derivatives. The remaining chloro group is axial at a greater distance (Fe—Cl = 2.342 Å) compared with the 2.282 Å and 2.250 Å values for the in-plane Fe—Cl bonds. The aquo group, *trans* to the axial chloro group, at 2.188 Å and is slightly tilted away from the halogens and towards the plane of the phen ring, making angles of 83.82° and 81.8° with N1 and N2 atoms, respectively. The bond angle N1—Fe—N2 atoms is fairly compressed (75.6°) due to the constraint exercised by the solitary chelate ring and is compensated by opening of the other bond angles around iron in the N_2Cl_2 plane.

The molecules link together via a weak hydrogen bonding network. The coordinated water links to the axial chloride of the neighbouring molecule (3.265(3) Å progressing along the *b* axis), and also to an equatorial Cl(1) through the crystallographic inversion centre (3.258(3) Å progressing along the *a* axis). The closest Fe–Fe separation is 5.555(2) Å.

A manganese(III) analog of the present complex has been reported and this provides an opportunity to compare d^4 and d^5 configurations in the same ligand environment (Table 1). The overall average metal–ligand bonds are similar, 2.235 Å for Fe and 2.240 Å for Mn, the trend reflecting the expected slightly smaller size of the Fe^{3+} ion. However, the individual bonds show far greater differences. The manganese ion lies closer to the phen ligand, with Mn—N distances 2.067, 2.074 Å, vs 2.167, 2.182 Å for Fe, which opens up the N—Mn—N angle (79.8° vs 75.6° for Fe). The equatorial Mn—Cl bonds show the same trend at

Table 1. Summary of averaged bond distances and bond angles of some phen complexes

Compound	⟨M-N⟩ (Å)	M-Cl (Å)	N-M-N(°)	Spin state	Ref.
$[Fe(III)(phen)Cl_3H_2O]$	2.174(3)	2.276[b] 2.276[b]	75.6(1)	HS[d]	*a*
$[Fe(III)(phen)_2Cl_2][FeCl_4]$	2.250(11)	2.246(4)	—	HS[d]	4
$[Fe(III)(phen)_3](ClO4)_3]H_2O$	1.973(8)	—	83.0(3)	LS[e]	10
$[Mn(III)(phen)Cl_3(H_2O)]$	2.971(2)	2.233[b] 2.527[c]	79.82	HS[d]	14

[a] Present work.
[b] Equatorial.
[c] Axial.
[d] High spin.
[e] Low spin.

2.225, 2.240 Å vs 2.250, 2.282 Å for Fe. The most dramatic difference occurs in the axial bonds which show the manganese complex to be dramatically distorted in the Jahn-Teller sense : there is dramatic elongation in the bond to the axial oxygen (2.306 Å for Mn vs 2.189 Å for Fe) and the axial Cl (2.527 Å for Mn vs 2.306 Å for Fe).

(Received 3 September 1997; accepted 5 January 1998)

Abstract—Reaction of 3,3-$(CO)_2$-4-SMe_2-3,1,2-*closo*-$RhC_2B_9H_{10}$ with iodine results in the formation of 3-(CO)-3,3-$(I)_2$-4-SMe_2-3,1,2-*closo*-$RhC_2B_9H_{10}$, **1**. Reaction between **1** and PPh_3 results in substitution of the carbonyl group to afford 3-PPh_3-3,3-$(I)_2$-4-SMe_2-3,1,2-*closo*-$RhC_2B_9H_{10}$, **2**. Both new compounds have been fully characterised by multinuclear NMR spectroscopy and also by a single crystal X-ray diffraction studies.

Keywords: carbaborane; rhodium; synthesis; structure.

We [1] and others [2], have recently been interested in the synthesis and chemistry of "charge-compensated" carbaboranes and carbametallaboranes derived from them, particularly those based upon [9-SMe_2-7,8-*nido*-$C_2B_9H_{10}]^-$, $[carb']^-$, and its derivatives. Such compounds are of interest due to the formal analogy that exists between the monoanionic $[carb']^-$ and $[\eta^5$-$C_5H_5]^-$, Cp^-, exemplified by, amongst others, the compounds *commo*-[3,3′-Fe-{4-SMe_2-1,2-$C_2B_9H_{10}\}_2$] [2c], an analogue of the ubiquitous organometallic species $FeCp_2$, 3-(η^5-C_5Me_5)-4-SMe_2-3,1,2-*closo*-$MC_2B_9H_{10}$, M = Fe [2d], Ru [1g], and 3,3,3-$(CO)_3$-4-SMe_2-3,1,2-*closo*-$MnC_2B_9H_{10}$ [1c], an analogue of $CpMn(CO)_3$. Although it has been shown [2c], for example, that *commo*-[3,3′-Fe-{4-SMe_2-1,2-$C_2B_9H_{10}\}_2$] can readily be oxidised to *commo*-[3,3′-Fe-{4-SMe_2-1,2-$C_2B_9H_{10}\}_2]^+$, paralleling the oxidation of ferrocene to ferrocinium, relatively little derivative chemistry of charge-compensated carbametalloboranes has so far been reported.

The compound $CpRhI_2(CO)$ has been known for nearly 30 years [3], being formed by simple oxidation of $CpRh(CO)_2$ with iodine. Moreover the carbonyl group of $CpRhI_2(CO)$ is readily displaced by phosphine ligands. We report here the synthesis, characterisation and reactivity of analogous compounds in which the cyclopentadienyl group had been replaced by the formally isolobal carb′ ligand.

EXPERIMENTAL

General

All experiments were carried out under a dry, oxygen-free dinitrogen atmosphere, with the new compounds reported being stable as solids to the ambient atmosphere and slightly sensitive as solutions. All solvents were stored over the appropriate drying agents and distilled immediately prior to use: CH_2Cl_2; CaH_2: 60–80°C light petroleum fraction; Na wire: diethylether; Na wire/benzophenone ketyl. Microanalyses were performed by the departmental service. The compound 3,3-$(CO)_2$-4-SME_2-3,1,2-*closo*-$RhC_2B_9H_{10}$ [1e] was prepared as previously described.

NMR spectroscopy

^1H NMR spectra were recorded on Brüker AC200 and DPX 400 (NOESY spectra) spectrometers. ^{11}B and ^{31}P spectra were recorded on the DPX 400 spectrometer. Unless otherwise stated, measurements were made at 297 K from $CDCl_3$ solutions. Proton chemical shifts are reported relative to residual protio solvent

* Author to whom correspondence should be addressed.

in the sample, ^{11}B shifts (at 128.4 MHz) are relative to external $BF_3 \cdot OEt_2$, and ^{13}P shifts (at 162.0 MHz) are relative to external H_3PO_4.

IR spectroscopy

IR spectra were recorded on a Nicolet Impact 400 spectrometer from CH_2Cl_2 solutions in 0.1 mm solution cells.

3-(CO)-3-$(I)_2$-4-SMe_2-3,1,2-*closo*-$RhC_2B_9H_{10}$, **1**. To a stirring, ice-cooled solution of 3,3-$(CO)_2$-4-SMe_2-3,1,2-*closo*-$RhC_2B_9H_{10}$ (0.055 g, 0.16 mmol) in Et_2O (15 cm^3) was added, dropwise over 10 min, a soln of iodine (0.045 g, 0.18 mmol). Over the addition period a fine black precipitate formed. The solution was warmed to room temperature, with stirring, over 30 min and then allowed to settle. The dark supernatant liquid was decanted via syringe, and the resulting solid washed with Et_2O (2×10 cm^3) and dried *in vacuo* to afford 0.063 g (68%) of black 3-(CO)-3-$(I)_2$-4-SMe_2-3,1,2-closo-$RhC_2B_9H_{10}$, **1**. Diffraction-quality crystals were obtained from the slow diffusion of a CH_2Cl_2 soln of **1** and light petroleum (1 : 4) at room temp. $C_5H_{16}B_9I_2ORhS$ requires C 10.4, H 2.79%. Found for **1** C 10.3, H 2.56%. IR (cm^{-1}): 2581 (*br m*, B-H), 2079 (*s*, CO). NMR (δ ppm): ^1H; 5.15 (*br s*, 1H, C_{cage}—H), 4.89 (*br s*, 1H, C_{cage}—H), 2.77 (*s*, 3H, SMe), 2.58 (*s*, 3H, SMe): $^{11}B\{^1H\}$; 11.84 (1B), 8.08 (1B), 1.13 (2B), −0.05 (1B), −5.18 (1B), −6.09 (1B), −8.83 (1B), −21.34 (1B).

3-PPh_3-3-$(I)_2$-4-SMe_2-3,1,2-*closo*-$RhC_2B_9H_{10}$, **2**. Compound **1** (0.070 g, 0.12 mmol) was dissolved in CH_2Cl_2 (15 cm^3) and PPh_3 (0.032 g, 0.12 mmol) added as a solid. The soln was stirred for 50 min after which time IR spectroscopy indicated that all of **1** had been consumed. The solvent was removed *in vacuo* and the resulting burgundy solid washed with Et_2O (15 cm^3) to afford 0.091 g (93%) of 3-PPh_3-3-$(I)_2$-4-SMe_2-3,1,2-*closo*-$RhC_2B_9H_{10}$, **2**. Crystals suitable for X-ray diffraction were obtained by slow diffusion of a concentrated CH_2Cl_2 soln of **2** and light petroleum (1 : 4) at 4°C. $C_{22}H_{31}B_9I_2PRhS$ requires C 32.5, H 3.85%. Found for **2** C 32.1, H 3.70%. IR (cm^{-1}): 2572 (*br*, B-H). NMR (δ ppm): ^1H; 7.95 (*m*, 2H, C_6H_5), 7.82 (*m*, 2H, C_6H_5), 7.71 (*m*, 2H, C_6H_5), 7.46–7.20 (*m*, 9H, C_6H_5), 5.62 (*br s*, 1H, C_{cage}—H), 2.78 (*s*, 3H, SMe), 2.58 (*s*, 3H, SMe), 2.26 (*br s*, 1H, C_{cage}—H): $^{11}B\{^1H\}$; 9.16 (1B), 8.10 (1B), 0.93 (1B), −2.37 (2B), −5.09 (1B), −12.21 (1B), −18.20 (2B): $^{31}P\{^1H\}$; 34.78 [*d*, *J*(RhP) 124 Hz].

Crystallographic studies

Measurements on single crystals of **1** and **2** were carried out at room temperature on a Siemens P4 diffractometer with graphite-monochromated Mo–K_α X-radiation ($\lambda = 0.71073$ Å) using ω scans. Crystallographic computing was performed using the XSCANS [4] and SHELXTL [5] systems, the latter on a Pentium 90 MHz PC.

Table 1 lists details of unit cell data, intensity data collection and structure refinement. The unit cell parameters and orientation matrix for data collection were determined by the least-squares refinement of the setting angles of 18 and 28 centred reflections, for **1** and **2** respectively, with 2θ ranging from 10.67–24.93° for **1** and 10.67–16.49 for **2**. Data were collected to 2θ max of 50° for **1** and 45° for **2**. Standard reflections were re-measured every 100 data and crystal decay detected (5 and 26% for **1** and **2** respectively) for which subsequent correction was made. Data were further corrected for absorption by psi scans. Both structures were solved by direct and difference Fourier methods and refined by full-matrix least-squares against F^2. Cage C atoms were identified by a combination of refined (as B) isotropic thermal parameters and interatomic distances. Phenyl and methyl H atoms were set in calculated positions, allowed to ride on their respective C atom, and cage B—H atoms were similarly treated. Cage C—H atoms were located in difference Fourier maps and refined subject to a fixed C—H distance of 1.15 Å. All H atoms were assigned (riding) isotropic thermal parameters set at $1.2 \times U_{iso}$ of the attached "heavy" atom, except for methyl H atoms ($1.5 \times U_{C\text{-methyl}}$). Refinement of the structure of compound **1** was routine, but the quality of the data for **2** did not justify anisotropic refinement of C or B atoms.

Complete atomic co-ordinates, thermal parameters and bond lengths and angles have been deposited with the Cambridge Crystallographic Data Centre. See Instructions for Authors, *Polyhedron*, 1998, Issue 1.

RESULTS AND DISCUSSION

Reaction between 3,3-$(CO)_2$-4-SMe_2-3,1,2-*closo*-$RhC_2B_9H_{10}$ and one equivalent of I_2 in ether solvent affords the new compound 3-(CO)-3,3-$(I)_2$-4-SMe_2-3,1,2-*closo*-$RhC_2B_9H_{10}$, **1,** as a black solid in good yield. The IR spectrum of compound **1** (in CH_2Cl_2) demonstrates that one carbonyl ligand has been lost in the reaction, since only a single CO stretching band is observed, at 2079 cm^{-1}. In **1** ν(CO) is 33 cm^{-1} to high frequency of that found in the precursor, reflecting the change from a formal Rh^I metal centre to a formal Rh^{III} centre and the change in the metal-ligand set. The ^1H NMR spectrum of **1** displays resonances due to the inequivalent cage-carbon bound hydrogen atoms as two, integral one, singlets, at 5.15 and 4.89 ppm, at unusually high frequency for a carbametallaborane [6], and shifted by ca 2 ppm to high frequency relative to the precursor [1e]. The inequivalent SMe groups are seen as the expected two, integral three, singlets at 2.77 and 2.58 ppm. The $^{11}B\{^1H\}$ NMR spectrum shows eight resonances between 11.84 and −21.34 ppm, in the ratio 1 : 1 : 2 : 1 : 1 : 1 : 1 : 1 (high frequency to low frequency), the integral two

resonance representing a 1 + 1 coincidence. To confirm the molecular architecture of compound **1** a single-crystal diffraction study was undertaken.

Figure 1 shows a perspective view of compound **1,** demonstrating the atomic numbering scheme employed, whilst Table 2 gives selected interatomic distances and angles. Compound **1** displays the *closo*-MC_2B_9 molecular architecture predicted by empirical electron counting rules [7]. The $\{Rh(I)_2(CO)\}$ fragment is oriented such that the carbonyl group lies effectively *trans* to the cage carbon atoms, reflecting the fact that the frontier molecular orbitals of *nido*-C_2B_9 carbaborane ligands are localised on the facial boron atoms [8]. The rhodium atom is essentially *pseudo* octahedrally coordinated, I(1)—Rh(3)—I(2) 86.44(2)°, I(1)—Rh(3)—C(30) 88.8(2)°, and I(2)—Rh(3)—C(30) 82.9(2)°. Whilst the Rh—C(30) distance, 1.869(6) Å, is slightly longer than found in other formal Rh^{III}—CO species [9], it nevertheless lies within the range reported for other *closo* carbarhodaboranes bearing a carbonyl ligand [10]. The C_{cage}—C_{cage} connectivity, 1.591(8) Å, is essentially the

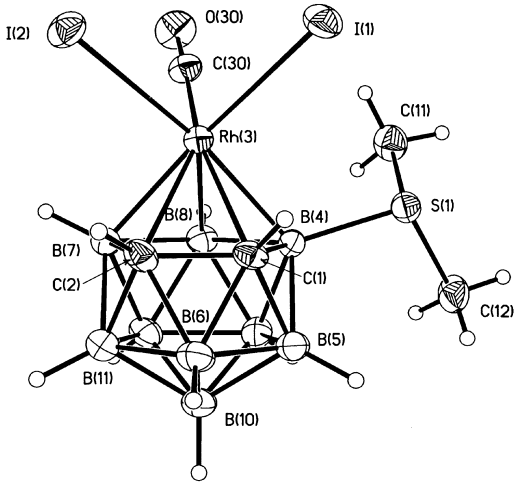

Fig. 1. Perspective view of compound **1** demonstrating the numbering scheme used. Thermal ellipsoids are drawn at the 40% probability level, except for H atoms which have an artificially small radius for clarity.

same length as that found in the precursor species 3,3-$(CO)_2$-4-SMe_2-3,1,2-*closo*-$RhC_2B_9H_{10}$ [1e], 1.596(4) Å, and in 3,3,3-$(CO)_3$-4-SMe_2-3,1,2-*closo*-$MnC_2B_9H_{10}$ [1c], 1.585(3) Å, whilst all other bond lengths and angles in the cage are in the ranges normally associated with such polyhedra.

The orientation of the SMe_2 ligand is conveniently measured by τ, the calculated torsion angle

C(1)—B(4)—S(1)—S(lone pair). In **1** τ is -25.5° (the minus sign representing a clockwise rotation about the S—B bond when viewed from S for the enantiomer shown in Fig. 1), at the upper end of the range generally found (ca -3° to -21°) in carb′H and its uncrowded derivatives [1a–1e], possibly due to a minimisation of steric interactions between I(1) and the methyl group C(11).

In $CpRhI_2(CO)$ the high value of ν(CO), 2065 cm^{-1} (Nujol), implies a relatively weakly bound CO ligand. Consistent with this, $CpRhI_2(CO)$ reacts with PPh_3, via loss of CO, to afford $CpRhI_2(PPh_3)$ [3]. Similarly, treatment of a CH_2Cl_2 soln of compound **1** with one equivalent of PPh_3 results in the disappearance of the CO stretch in the IR spectrum and the isolation of the new compound 3-(PPh_3)-3,3-$(I)_2$-4-SMe_2-3,1,2-*closo*-$RhC_2B_9H_{10}$, **2,** in good yield. The ^1H NMR spectrum of compound **2** shows resonances due to the triphenylphosphine ligand as an unusual set of three, integral two, multiplets, centred on 7.95, 7.82 and 7.71 ppm, and an integral nine multiplet, between 7.46 and 7.20 ppm. The cage-carbon hydrogen atoms are observed at 5.62 ppm and 2.26 ppm, the former frequency comparable to those in **1** but the latter shifted significantly to low frequency. Peaks due to the inequivalent SMe groups are essentially unchanged from their positions in **1**. In the $^{11}B\{^1H\}$ NMR spectrum there are seven resonances (1 : 1 : 1 : 2 : 1 : 1 : 2, high frequency to low frequency) between 9.16 and -18.20 ppm. In the $^{31}P\{^1H\}$ NMR spectrum is observed a doublet at 34.78 ppm with the expected rhodium coupling, J(RhP) 124 Hz.

To establish a firm stereochemistry for compound **2** a single crystal X-ray structural determination was performed. Unfortunately, and despite repeated recrystallisations, only small, weakly diffracting crystals of compound **2** could ever be obtained. Although the eventual structural solution is characterised by a relatively poor residual (conventional R factor ca 0.14) we are confident that the C_{cage} atoms identified in Fig. 2, a perspective view of a single molecule, are correctly positioned for the following reasons: the 1–2 distance is 1.60 Å, cf the 7–8 distance of 1.88 Å; all R indices and the goodness-of-fit parameter are worse if C(1) and C(2) are interchanged with B(7) and B(8); the PPh_3 ligand lies approximately *trans* to the C_{cage} positions in Fig. 2, as would be expected by analogy with the structure established for compound **1**. Steric crowding between the PPh_3 and SMe_2 units results in the latter adopting a conformation defined by $\tau = 77.7^\circ$, i.e. rotated ca 90° from its position in **1**.

A ^1H-^1H NOESY NMR experiment on compound **2** demonstrated that only one of the cage carbon hydrogen atoms, that which resonates at 5.62 ppm, shows a strong contact with (one of) the SMe signals, whilst the other, at 2.26 ppm, shows contact with the 5.62 ppm signal and with the three, integral two, aromatic signals. Thus the resonance at 5.62 ppm is ascribed to H(1) and that at 2.26 ppm to H(2). Overall this data implies that, whilst rotation of the Ph rings

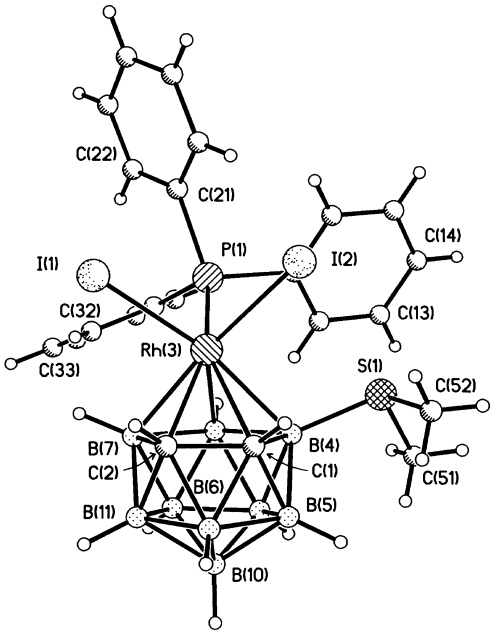

Fig. 2. Molecular structure and atomic numbering scheme for compound **2**.

about the P—C bonds must be rapid on the NMR timescale (affording equivalence of the *ortho* protons on each ring), rotation of the PPh_3 groups about the Rh-P bond is slow on the NMR timescale (three integral two signals observed) but rapid on the NOESY timescale [allowing each pair of *ortho* protons contact with H(2)]. Moreover, given the conformation of **2** determined crystallographically, some sort of dynamic process must be operating in solution that allows the *ortho* phenyl protons to contact with H(2). The factors affecting the rotation of metal-fragment vertices in carbametallaboranes have been discussed previously [11], and in the case of fragments of local C_s symmetry bound to asymmetric carbaborane cages large rotational barriers are generally observed. This might imply that in **2** the $\{RhI_2(PPh_3)\}$ fragment merely undergoes substantial libration about the Rh(3)···B(10) axis on the timescale of the NOESY experiment.

CONCLUSIONS

We have shown here that the chemistry of 3,3-$(CO)_2$-4-SMe_2-3,1,2-*closo*-$RhC_2B_9H_{10}$ parallels that of $CpRh(CO)_2$ in as much as both compounds undergo oxidation with elemental iodine to afford species in which one carbonyl ligand has been replaced by two iodide ligands. Additionally, reaction of this new bis-iodo-carbarhodaborane with triphenylphosphine results in substitution of the remaining carbonyl ligand by phosphine, again paralleling the behaviour of the analogous cyclopentadienyl compound.

(Received 25 August 1997; accepted 5 January 1998)

Abstract—STM images of aqueous solutions of L-ascorbic acid containing Gd^{3+} ions at pH values of 2, 6 and 12 have been recorded periodically after drying the samples on gold coated mica. The results have revealed that the organisations of the AA molecules and metal ions show different features throughout the conversion of Gd-ascorbate complexes to Gd-oxalates. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: STM; vitamin C; decomposition.

Vitamin C, being a constituent of the cell, and a good reductant, has momentous biological functions. The recent findings of Hallis *et al.* [1] on the antitumor activities of several platinum diammine ascorbate compounds and Cardin and Roy [2], on the anticancer properties of some organometallic titanium and tin ascorbate complexes have added more attention to the biochemistry of this sugar molecule.

The aqueous chemistry of L-ascorbic acid (AA) is of essential importance in understanding the characteristics of this water-soluble vitamin. Among the numerous reactions studied are those involving its efficient reduction of many transition metal ions and complexes at moderately low to low pH values [3–8]. In alkaline solutions, the rate of autooxidation of AA and the effect of catalytic impurities increase significantly [9]. It is also known that *in vitro* decomposition of dehydroascorbic acid (DHA), the stable oxidation product of AA, leads to the formation of CO_2, oxalic acid, trihydroxybutyric acid and other products, depending on the reaction conditions [10–12]. DHA, diketogulonic acid, ascorbate sulfate, oxalate, methyl ascorbate and 2-ketoascorbitol have been identified as the AA metabolites in human urine [13]. However, the chemical redox behavior, metabolism and enzymatic behavior, such as for ascorbate oxidase, of the acid are not fully realized and the research concerning particularly the degradation details are somewhat limited.

Recently, we reported the decomposition of AA in the presence of nonoxidizing metal ions from low to high pH values providing that the metal ions do not hydrolyze or precipitate extensively [14]. We studied with Co^{2+} and Gd^{3+} ions specifying transition and rare earth metals and observed the pH-independent formation of metal oxalates via ascorbate complexes by IR spectroscopic and X-ray crystallographic analyses. In this paper, we present the images of the interaction of AA with Gd^{3+} to gain a molecular-level structural information by Scanning Tunneling Microscopy (STM), which is a novel technique successfully employed for the examination of biological samples [15–20].

EXPERIMENTAL

General

Reactions were conducted in deionized/deoxygenated water at a AA to metal ratio of 10 : 2. 0.0013 g of AA (Merck) was dissolved in 95 ml of water and the pH of this solution was adjusted to the desired value (6 and 12) by the controlled addition of

* Author to whom correspondence should be addressed. Fax : (0312) 299 2163. E-mail : bkaran@eti.cc.hun.edu.tr

NaOH solution and to 2 by adding HCl. The solution containing Gd^{3+} was prepared by dissolving the appropriate quantity of $Gd(NO_3)_3 \cdot 6H_2O$ (prepared from Gd_2O_3) in 5 ml of water. Each experiment was started from freshly prepared solutions and oxygen-free conditions were provided by passing nitrogen gas through the system. The reaction mixtures obtained by the addition of the metal solution to the acid solutions at different pH values were kept at closed vessels and 10 μl samples were withdrawn for STM tests after each time interval.

STM studies

The STM used in this work was constructed in our laboratory [21]. Mechanically, it consists of two main modules : a scanner and a course positioner. The scanner part is constructed with a PZT tube (EBL #PZT-5H, Staveley Sensors Inc., CT) glued to an aluminum body. Electrical connections to the PZT are through a special connector. The tip holder is glued to the interior of the PZT tube but isolated electrically. The course positioner is magnetically driven slider which is fastened to the scanner. The whole system is mounted on a vibration isolation stage.

In order to obtain the STM images, 10 μl of AA solution (0.1 mg ml^{-1}) was deposited on the Au (111) which was grown epitaxially on mica [22]. The deposit was dried at room temperature under atmospheric pressure in a clean room with a relatively slow drying rate. The STM was operated in air at atmospheric pressure with a tip-to-substrate bias of 200–400 mV and a tunnelling current of 50 pA. Etched tips of Pt/Ir (80 : 20) wires (0.5 mm in diameter, Digital Instruments, Santa Barbara, CA) were used in constant current mode. The average sizes of the species have been determined by use of about 50 different STM images at a scan speed of image/1.40 s.

RESULTS AND DISCUSSION

Our previous findings had revealed that AA complexes with Co^{2+} and Gd^{3+} ions in aqueous solutions and these complexes subsequently decompose to the metal oxalates irrespective of the pH of the solution [14]. The acidity of the medium had almost no effect on the composition of the cobalt oxalates. In all investigated cases, providing pH > 3, the final products obtained with Co^{2+} had been defined as $CoC_2O_4 \cdot 2H_2O$, which were stable in solution but not in the solid state to accumulate X-ray data. On the other hand, the oxalates produced with Gd^{3+} had shown variations in their water content depending on the pH of the solution.

In this study, we attempted to correlate the structures of both vitamin C (Fig. 1). and its interaction with Gd^{3+} ions by a novel technique, the so-called "scanning tunnelling microscopy". A home-made STM was used, which was successfully employed in our previous studies for imaging of various biological molecules, e.g. nucleic acids [23], tRNA [24]. Gold coated mica was used as the basic substrate. Au (111) grown epitaxially on mica has atomically flat terraces and is a suitable substrate for organic material to be used under ambient conditions [25]. The direct tip-surface interaction is relatively weak and the structure of the substrate is not visible in the presence of the adsorbate. In order to eliminate the "gluing" effect, humidity of the STM chamber was kept around 35%, at which reliable images were taken, by a humidity control unit. For the same reason, and also to get images with high resolution, bias voltage was kept relatively high (in the range of 200–400 mV), and the tunneling current was 50 pA.

STM images under constant current mode permit topographic and the so-called "chemical contrast" images to be obtained. Figure 2 gives the STM micrographs of vitamin C on gold coated mica at a constant current mode. Figure 2(A) shows the two dimension image with scan area of 2×2.1 nm, the enlarged image given on the right hand corner more clearly shows the AA molecule. Figure 2(B) shows the three dimensional image of this molecule with scan area of 0.43×0.75 nm. STM images always involve both topographic and electronic contributions which can be difficult to separate and theoretical approaches are needed to relate the images to the structure of the molecule. We adopted the CACAO program to calculate the molecular orbitals of the isolated AA molecule [26]. Figure 3(A, B) shows the charge density contour plots that we obtained using this program. The energy gap between the HOMO and LUMO is 3.1 eV. The most significant contribution to the image is known to come from the frontier orbitals (HOMO and LUMO) for small molecules [27]. The experimental image of the AA molecule looks similar to the HOMO orbital and this is inconsistent with the fact that tunneling is through the unoccupied states with positive sample bias in the free molecule. Considering the possibility that AA molecule changes its geometrical structure on the Au layer due to a keto-enol tautomerism, calculations were also done for the corresponding enol tautomer. The contour plots are almost identical for both tautomeric forms concluding that the image corresponds to the HOMO orbital. The calculations were also repeated for the ascorbate anion and the same results were obtained. So, the missing agreement between the expected structure and the STM image is mainly due to the substrate effect. The interaction of the molecule with the surface states near the Fermi level might have caused shifts and broadenings in the energy levels. It is also possible that other orbitals neighbouring HOMO and LUMO contribute to the observed image. The topographic image is brighter in the vicinity of the carbon–carbon double bond because this bond is more readily conductive to tunneling current. The hydroxyl groups and the saturated aliphatic backbone are less conductive to tunneling and they give darker images.

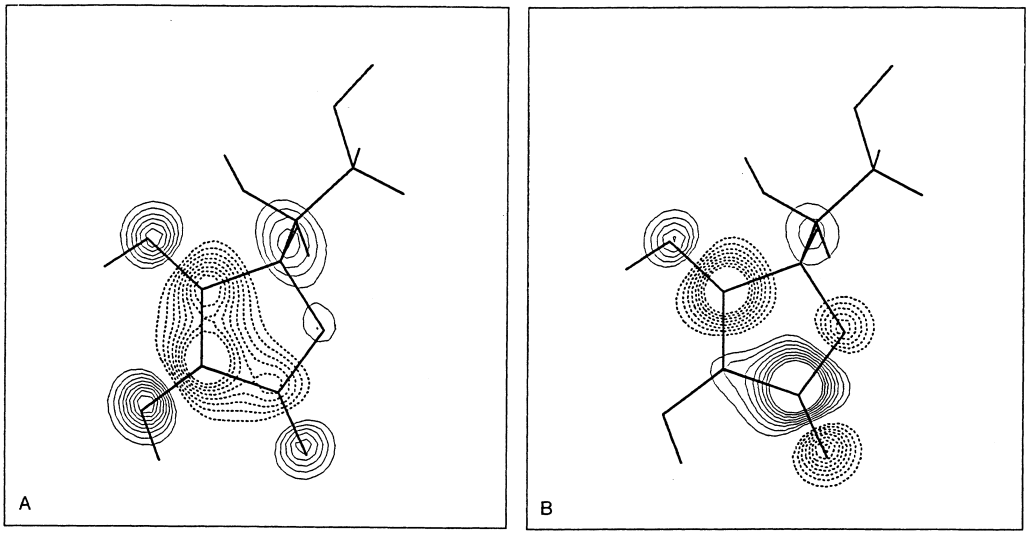

Fig. 3. (A) Contour plot of charge density of HOMO (B) Contour plot of the charge density of LUMO.

The results obtained by STM analysis of some biological molecules have been successfully used for direct comparison with the information provided by X-ray crystallography [28]. Since AA is well-characterized by X-ray [29], we attempted to correlate the topographic image with its X-ray data. The STM ring width of AA measured as approximately 4 Å is larger than that predicted by crystallography which is 2.2 Å. This disagreement is not very surprising since molecules can adopt various orientations and binding modes at the surfaces and the radius of the molecule is known to increase upon adsorption [30].

The images recorded periodically from solutions containing AA and Gd^{3+} ions at pH values of 2, 6 and 12 are given in Fig. 4. As shown in Fig. 4(A), the lighter parts that look like blobs indicate the Gd^{3+} ions with diameters of 2.5 ± 0.2 Å (experimental value is 2.5 Å) [31]. The gray (darker) parts indicate the AA molecules in contact with the metal ions. This image taken after two days in acid solutions shows the AA molecules organizing to some extent with some structural modifications. After four days (B), the vitamin molecules and Gd^{3+} ions seemed to be arranged in a periodic array with a 28.5 Å spacing between the rows. After twelve days of standing (C), a highly symmetrical polymeric structure was observed. Concerning our previous experimental results, we assume that this polymeric matrix corresponds to the oxalate structure.

Fig. 4(D) and Fig. 4(G) represent the images from solution of pH = 6 and 12, respectively, after two days from the start of the experiments. AA molecules came into sight as clusters with individual Gd^{3+} ions around. The micrographs taken in the following intervals Fig. 4(E, H), represented almost the same features. Figure 4(F, I) denote to the images obtained after twelve days which are notably different than the final image at pH = 2. A structural organization was not recognized in these samples prepared at high pH values. This is in agreement with our previous results that the stable, crystalline gadolinium oxalate could be obtained only at pH = 2. No significant change was noted in the images during the period between the fourth and twelfth days.

Image interpretation is still the most serious limitation on useful application of STM. However, our qualitative analysis agrees with the experimental results and this promotes us to propose the following mechanism. When AA molecules contact with the metal ions, the first interaction is supposed to occur over the ring part. AA coordinates metal ions forming chelates $[MHL^{+(n-1)}]$ at low and intermediate pH values and unprotonated chelates $[ML^{+(n-2)}]$ at high pH, however the complexes are suggested to be weak in aqueous solution [9]. It is quite reasonable to suggest that the lactone ring is opened to give chain-like structures and then the chains collapse and grow in an anisotropic way to build up the oxalate structures. Major variations in the ring stretching and deformation vibrations of the ascorbate complexes had been noted before in their IR spectra upon decomposition to the oxalates [14]. Nevertheless, evidence to the proposed decomposition scheme using the STM images is speculative and requires high resolution studies and advanced theoretical calculations.

CONCLUSIONS

There seems to be a commonality in the chemistry of decomposition of AA in the presence of nonoxidizing metals. The experimental results reveal that the decomposition products are metal oxalates irrespective of the pH of the solution. However, the path-

ways, the rate of decomposition and the structures of the final oxalates are governed by the pH to some extent. STM analyses have displayed that during the formation of the oxalate structures, the organization of the molecules at different pH values proceeds in different manners.

(Received 11 November 1997; accepted 6 January 1997)

Abstract—Three tetrakis(μ_2-carboxylate)-bridged dicopper(II) complexes of betaines, $[Cu_2(pybet)_4(H_2O)_2](NO_3)_2(ClO_4)_2\cdot 2H_2O$ (pybet = pyridinioacetate, $C_5H_5N^+CH_2CO_2^-$, pybet) (**1**), $[Cu_2(pybet)_4(H_2O)Cl](ClO_4)_3\cdot 2H_2O$ (**2**) and $[Cu_2(ppbet)_4Cl_2](ClO_4)_2$ (ppbet = pyridiniopropionate, $C_5H_5N^+CH_2CH_2CO_2^-$) (**3**), have been synthesized and characterized by X-ray crystallography. These complexes all comprise $[Cu_2(\mu_2\text{-carboxylate})_2]$ structures (Cu···Cu = 2.677(1)–2.760(1) Å) with each copper(II) atom being coordinated in a square-pyramidal CuO_4L environment, in which the axial ligands (L) are two aqua molecules (Cu—O = 2.093(2) Å), one aqua molecule and one chloride ion (Cu—O = 2.130(8), Cu—Cl = 2.358(4) Å) and, two chloride ions (Cu—Cl = 2.454(2) Å) in complexes **1, 2** and **3,** respectively. The intramolecular Cu···Cu distance may correlate to the mutual repulsion between the axial and basal metal-ligand bonds. Temperature-dependent magnetic susceptibility data of the powder samples of the complexes have been fitted, yielding the intramolecular coupling constant $2J$ values of -340, -321 and -301 cm^{-1} for **1, 2** and **3,** respectively. The magnitudes of $2J$ may be inversely correlated to the displacement of the metal atom from the basal plane. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: copper(II); carboxylate; dimeric; crystal structure; magnetic properties.

Since the first report of the crystal structure of copper(II) acetate monohydrate, $[Cu_2(MeCO_2)_4(H_2O)_2]$ [1], a large number of copper(II) carboxylates of this type, generally formulated as $[Cu_2(RCO_2)_4L_2]$ (L denotes the axial ligand), have been structurally established [2–4] where the R groups include a variety of small and bulky organic groups [1–8]. The intramolecular Cu···Cu distance can vary from 2.563(4) Å in $[Cu_2(EtCO_2)_4(dioxane)_2]$ [9] to the longest 2.886(2) Å in $[Cu_2(F_3CCO_2)_4(quinoline)_2]$ [10]. On the other hand, anionic compounds are rarely established as the axial ligands in this type of dimeric compounds, two known complexes contain SCN^- anions [8]. While only one example of the two axial positions occupied by two different ligands has been very recently uncovered, in which the two axial ligands are one water and one methanol molecules [11].

More interesting is the fact that the nature of the structural variation and the magnetic properties is not yet clear and has provoked considerable controversy after the very extensive investigation. The structural results and magnetic studies have confirmed that the insensitivity of the coupling constants $2J$ to the Cu···Cu separation. Therefore the idea that the spin coupling exchange proceeds predominantly by the superexchange through the carboxylate bridges has become increasingly favoured [5,8,10,12]. Nevertheless, no concrete conclusion has been drawn for the magneto-structural relation [5,12].

Recently we took advantage of the zwitterionic characteristics of betaines to prepare metal carboxylate complexes containing anionic ligands [13]. Particularly, we have synthesized several dimeric copper(II) complexes of betaines, and exhibited the very important effect of the axial ligands on the Cu···Cu separations [14]. Encouraged by this fact, we have attempted to synthesize new dimeric copper(II) car-

boxylate complexes containing different kind of carboxylate bridges as well as different kind of axial ligands to provide structural models of trivial differences for magneto-structural investigation, and we report herewith the syntheses, crystal structures and magnetic properties of three new dimeric copper(II) carboxylate complexes bridged by betaine derivatives, namely $[Cu_2(pybet)_4(H_2O)_2](NO_3)_2(ClO_4)_2 \cdot 2H_2O$ (pybet = pyridinioacetate, $C_5H_5N^+CH_2CO_2^-$, pybet) (**1**), $[Cu_2(pybet)_4(H_2O)Cl](ClO_4)_3 \cdot 2H_2O$ (**2**) and $[Cu_2(ppbet)_4Cl_2](ClO_4)_2$ (ppbet = pyridiniopropionate, $C_5H_5N^+CH_2CH_2CO_2^-$) (**3**), in which the axial ligands are two aqua ligand, one aqua and one chloride ligands and, two chloride ligands, respectively.

EXPERIMENTAL

Materials

Pyridinioacetate (pybet) and pyridiniopropionate (ppbet) were synthesized with the literature method [15]. All other reagents were commercially available and used as received.

Caution. Metal perchlorate containing organic ligands are potentially explosive. Only a small amount of material should be prepared and handled carefully.

Syntheses

$[Cu_2(pybet)_4(H_2O)_2](NO_3)_2(ClO_4)_2 \cdot 2H_2O$ (**1**). A mixt. of pybet (0.412 g, 3 mmol) and $Cu(NO_3)_2 \cdot 6H_2O$ (0.362 g, 1.5 mmol) was dissolved in distilled water (8 ml) and heated at 50°C for 10 min, an aq. soln (2 ml) of $NaClO_4 \cdot H_2O$ (0.106 g, 1.5 mmol) was then added with stirring for 20 min. The soln was allowed to evap. slowly at room temp. After about a week greenish blue polyhedral crystals began to appear, and the product was collected within one month in 70% yield (Found: C, 31.3; H, 3.5; N, 7.8. Calcd for $C_{28}H_{34}Cl_2Cu_2N_6O_{26}$ **1**: C, 31.4; H, 3.4; N, 7.9%). IR data (ν/cm^{-1}): 3409 s (br), 3135 m, 3085 m, 3057 m, 1637 s (br), 1489 s, 1384 vs, 1307 s (br), 1215 w, 1194 w, 1114 s, 1117 s, 1082 s, 983 w, 934 w, 828 w, 779 w, 716 m, 674 w, 625 m.

$[Cu_2(pybet)_4(H_2O)Cl](ClO_4)_3 \cdot 2H_2O$ (**2**). A mixt. of pybet (0.412 g, 3 mmol) and $CuCl_2 \cdot 2H_2O$ (0.256 g, 1.5 mmol) was dissolved in distilled water (8 ml) and heated at 60°C for 10 min, after that an aq. soln (2 ml) of $NaClO_4 \cdot H_2O$ (0.106 g, 1.5 mmol) was added with stirring for 20 min. The soln was allowed to evap. slowly at room temp. After about 4 days light blue polyhedral crystals began to appear. The product was collected within one week (50% yield) (Found: C, 31.3; H, 3.1; N, 5.1. Calcd for $C_{28}H_{32}Cl_4Cu_2N_4O_{23}$ **2**: C, 31.6; H, 3.2; N, 5.3%). IR data (ν/cm^{-1}): 3550 m (br), 3430 m (br), 3135 m, 3085 m, 2980 w, 1672 vs, 1637 vs, 1489 s, 1449 m, 1398 vs, 1314 m, 1222 m, 1194 m, 1145 vs, 1117 vs, 1084 vs, 967 w, 934 w, 850 w, 779 w, 716 s, 674 m, 625 s, 584 w. A small quantity of a deep blue crystalline compound was also isolated as a minor product, which has been carefully separated under microscope, and characterized as a monomeric complex $[Cu(pybet)_2(H_2O)_2Cl]ClO_4$, and the structure of which will be published elsewhere.

$[Cu_2(ppbet)_4Cl_2](ClO_4)_2$ (**3**). A mixt of ppbet (0.454 g, 3 mmol) and $CuCl_2 \cdot 4H_2O$ (0.256 g, 1.5 mmol) was dissolved in distilled water (8 ml) and heated at 60°C for 10 min, an aq. soln (2 ml) of $NaClO_4 \cdot H_2O$ (0.106 g, 1.5 mmol) was then added with stirring for 20 min. The soln was allowed to evap. slowly at room temp. After about 10 days greenish blue polyhedral crystals began to appear. The product was collected within one month, and the yield was 55% (Found: C, 38.2; H, 3.5; N, 5.4. Calcd for $C_{32}H_{36}Cl_4Cu_2N_4O_{16}$ **3**: C, 38.4; H, 3.6; N, 5.6%). IR data (ν/cm^{-1}): 3128 w, 3085 w, 2973 w, 2924 w, 2853 w, 1630 vs, 1581 w, 1489 s, 1433 s, 1405 s, 1306 w, 1328 w, 1300 m, 1215 w, 1160 m, 1096 vs, 990 w, 962 w, 878 w, 779 m, 681 s, 625 s, 596 m.

Physical measurements

The C, H and N microanalyses were carried out with a Perkin–Elmer elemental analyzer. The FT-IR spectra were recorded from KBr pellets in range of 4000–400 cm^{-1} on a Nicolet 5DX spectrometer.

Magnetic susceptibility measurements were carried out on microcrystalline samples in the temp. range 100–300 K and in an applied field of 1000 G with a Quantum Design MPMS SQUID magnetometer. The data were corrected for the diamagnetic contributions, which were estimated from the Pascal constants [16].

X-ray crystallography

A summary of selected crystallographic data for the three complexes is given in Table 1. Intensity data collections for complexes **1** and **3** were carried out on a Siemens P4 diffractometer using graphite-monochromated Mo–K_α (λ = 0.71073 Å) radiation at 294 K, while the intensity data for complex **2** were collected on an Enraf-Nonius CAD4 diffractometer using graphite-monochromated Mo–K_α radiation at 294 K. For all complexes, determinations of the crystal class, orientation matrix, and cell dimensions were performed according to the established procedures; the intensity data were collected using the ω-scan mode. The data processing was made with SHELXTL-PC program package [17] for complexes **1** and **3,** and with the NRCVAX program package [18] for complex **2**. Lp corrections and absorption corrections have been applied [19].

Most of the non-hydrogen atoms in the crystal structures were located with the direct methods of SHELXTL-PC program package and subsequent Fourier syntheses were used to derive the remaining non-hydrogen atoms. All the non-hydrogen atoms

were refined anisotropically except the two-fold disordered oxygen atoms of one perchlorate anion in complex **2,** which were subjected to geometric restraints. Hydrogen atoms of water molecules were located from the difference maps; hydrogen atoms of the betaine ligands were generated geometrically (C—H 0.96 Å), assigned isotropic thermal parameters, and ride on their parent carbon atoms. All the hydrogen atoms were held stationary and included in the final stage of full-matrix least-squares refinement using SHELXTL-PC program package. Analytical expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated [20]. The selected bond lengths and bond angles are listed in Table 2. Additional crystallographic data are available as supplementary materials.

RESULTS AND DISCUSSION

Crystal structures

The crystal structure of complex **1** contains discrete $[Cu_2(pybet)_4(H_2O)_2]^{4+}$ cations, nitrate and perchlorate anions, and lattice water molecules. The dimeric $[Cu_2(pybet)_4(H_2O)_4]^{4-}$ cation, as shown in Fig. 1, has a centrosymmetrically tetrakis(μ_2-carboxylate)-bridged structure, which is analogous to that of the copper(II) acetate complex [1]. In the dimeric cation, each copper(II) atom is coordinated in a distorted square-pyramidal environment by four oxygen atoms of the μ_2-carboxylate groups at the basal plane (mean Cu—O = 1.982 Å) and by an aqua ligand at the axial position with a markedly longer Cu—O distance of 2.093(3) Å. The Cu···Cu separation (2.677(1) Å) in the dimeric structure of complex **1** is very similar to the analogous complex containing the same dimeric cation [14], and slightly longer than that (2.614(3) Å) in the acetate complex [1]. The displacement of the metal atom from the basal plane in the square-pyramid (designated as δ hereafter) is 0.214 Å with the mean Cu—O—C angle being 121.2°.

Complex **2** is composed of a dinuclear $[Cu_2(pybet)_4(H_2O)Cl]^{3+}$ cation, perchlorate anions and lattice water molecules. The $[Cu_2(pybet)_4(H_2O)Cl]^{3+}$ cation, as illustrated in Fig. 2, has a similar tetrakis(μ_2-carboxylate)-bridged dinuclear structure as found for other compounds of the type of copper(II) acetate monohydrate [1]. Noteworthy is that the two axial positions of this dinuclear cation are occupied by one water molecule and one chloride ion, respectively. So far very few tetrakis(μ_2-carboxylate)-bridged dimeric or dinuclear copper(II) complexes with both of the axial positions ligated by anionic ligands, such SCN^- and Cl^-, have been documented [8, 14], and only one dinuclear copper(II) complex comprising two different axial ligands, namely one aqua and one methanol molecules, has been reported very recently [11]. No example of such tetrakis(μ_2-carboxylate)-bridged dicopper(II) complex composed of one neutral and

Symmetry codes: for **1,** (a) $-x, 1-y, -z$; (b) $-x, y, z$; (c) $x, 1-y, -z$; for **2** (a) $x, 0.5-y, z$; for **3,** (a) $2-x, -y, 1-z$.

one anionic axial ligands has been documented. Thus complex **2** may present a novel structural variety among the tetrakis(μ_2-carboxylate)-bridged copper(II) complexes. It is also of interest to compare the geometries of the two crystallographically independent copper(II) atoms in the dinuclear structure. The Cu(1) atom is ligated by a chloride atom at the axial position, the δ (0.279 Å), Cu—O—C (mean 123.4°), and Cu—O(basal) (mean 1.990 Å) values for the Cu(1) atom are significantly larger than the corresponding values (0.198 Å, 121.5, 1.977 Å) for the Cu(2) atom which is ligated by an aqua ligand at the axial position. These observations can be rationalized on the base that with ligation of a larger and anionic axial ligand Cl^-, there will be a greater repulsion between the Cu—Cl and Cu—O(basal) bonds resulting in larger Cl—Cu—O(basal) bond angles, ''moving'' of the Cu(1) atom toward the axial ligand, and/or lengthening the Cu—O(basal) bond distance [14]. Thus displacement of the Cu(1) atom from the basal plane of the square-pyramid is much greater than that of the Cu(2) atom.

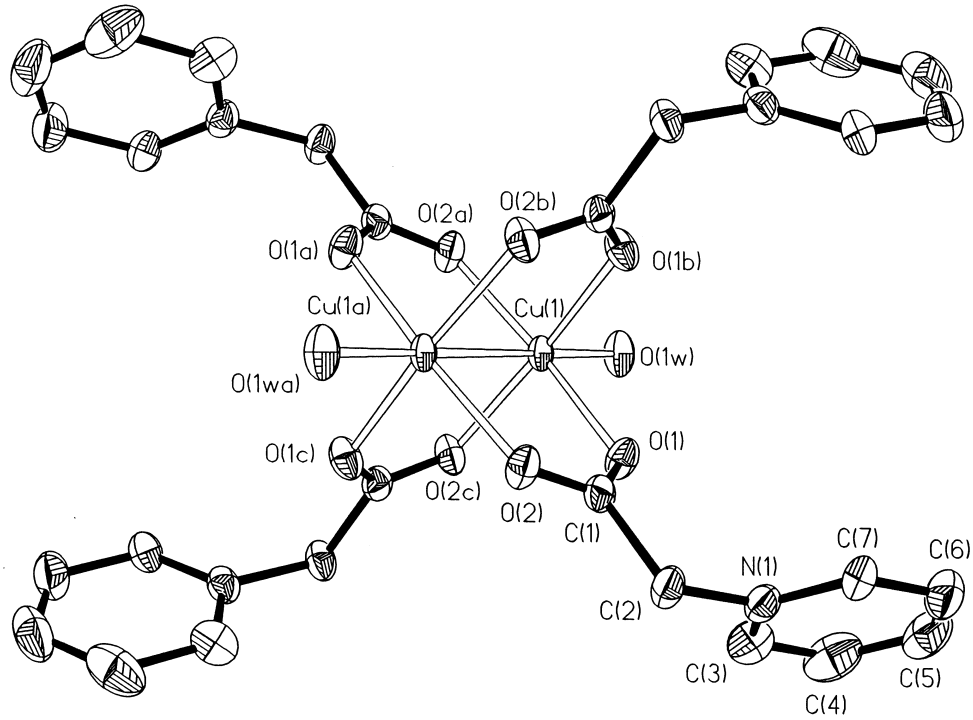

Fig. 1. ORTEP drawing (at 35% probability) of the dimeric cation in complex **1**. Symmetry codes are given in Table 2.

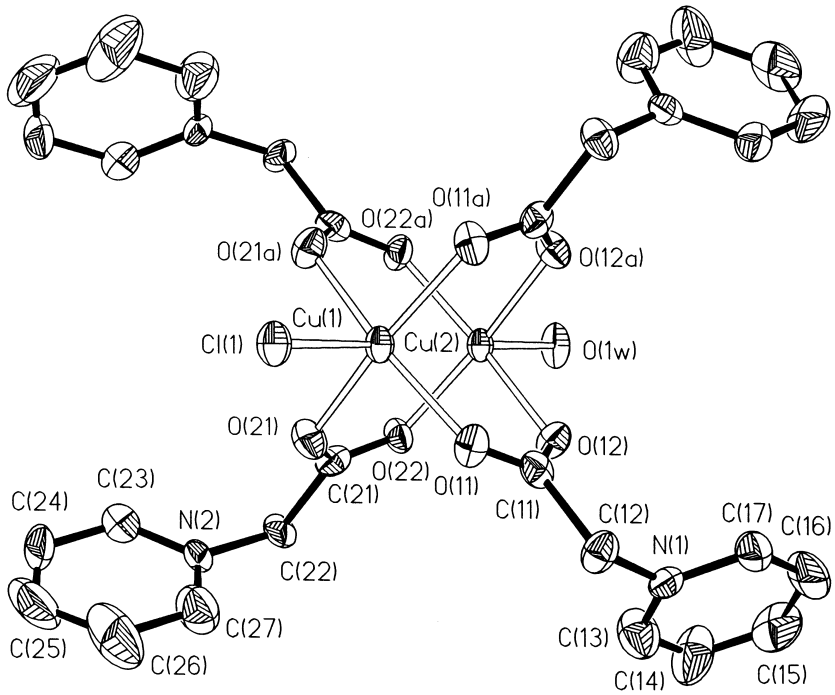

Fig. 2. ORTEP drawing (at 35% probability) of the dinuclear cation in complex **2**. Symmetry code: (a) x, $0.5-y$, z.

Complex **3** is composed of a dimeric $[Cu_2(ppbet)_4Cl_2]^{2+}$ cation and two perchlorate anions. The $[Cu_2(ppbet)_4Cl_2]^{4+}$ cation, as illustrated in Fig. 2, has a similar centrosymmetrically tetrakis(μ_2-carboxylate)-bridged dimeric structure as found for other compounds of the type of copper(II) acetate monohy-

drate. Since the axial positions are both occupied by chloride ligands, the greater repulsion between the Cu—Cl and Cu—O(basal) bonds in complex **3** affords larger Cl—Cu—O(basal) bond angles, a very large intramolecular Cu···Cu separation (2.760(1) Å), a larger δ (0.269 Å), a larger Cu—O(basal) bond lengths (mean 1.982 Å), as well as very large Cu—O—C angles (mean 124.9°). Similar tetrakis(μ_2-carboxylate)-bridged dimeric copper(II) complexes with both axial chloride ligands have been reported in our previous work, where the μ_2-carboxylate groups are betaine ($Me_3N^+CH_2CO_2^-$) and pybet [14].

Magnetic properties

Temperature-dependent magnetic susceptibility data for the three complexes have been measured from 300 K down to 100 K. The μ_{eff} values are plotted versus temp. in Fig. 4 for the three complexes. At room temp., the μ_{eff} values are ca 2.0 μ_B for these complexes. Upon cooling down from room temp., the μ_{eff} values decreases continuously for all three complexes, thus indicating a strong antiferromagnetic interaction between the copper(II) atoms in the dimeric or dinuclear structures. Assuming isotropic exchange, the exchange Hamiltonian is $H = -2JS_1 \cdot S_2$ with $S_1 = S_2 = 1/2$, and the magnetic susceptibility per cation is given by the eqn (1) [21]

$$\chi_M = \frac{2Ng^2\beta^2}{3kT}\left[1+\tfrac{1}{3}\exp\left(\frac{2J}{kT}\right)\right]^{-1}(1-\rho)+\frac{Ng^2\beta^2}{2kT}\rho \qquad (1)$$

where N, g, β, k are Avogadro's constant, g factor, Bohr magneton, and Boltzman constant, respectively and $2J$ is the exchange coupling constant. The best least-squares fitting results are illustrated in Fig. 4 and are listed in Table 3, exhibiting that the magnitudes of the intramolecular magnetic coupling are greater than 300 cm^{-1} for all three complexes, which are compatible to those found for the acetate analogues (-285 to -325 cm^{-1}) [2,3,22,23].

Discussion

We have suggested that [14], the Cu···Cu separation in the $[Cu_2(RCO_2)_4L_2]$ structures may be generally correlated to the electronic repulsion of the metal-ligand bonds, especially in the case of less sterically demanding ligands, and to the steric interaction between the bulky axial and bridging carboxylate ligands in the case of bulky ligands. Our current observations in this work are in accord with this assumption. With different axial ligands, we demonstrate the effect of the axial ligands on the geometrical variation such as the Cu···Cu separation and δ value. With one axial position occupied by chloride ligand in complex **2,** the Cu···Cu separation and mean δ value become larger in comparison to those in complex **1,** while these values are more larger in complex **3,** in which both axial positions are occupied by chloride ligands. Particularly, complex **2** is a nice example demonstrating the mutual repulsion between the axial and the basal coordination bonds. Hence we may conclude that the structural variation in the $[Cu_2(RCO_2)_4L_2]$ structures is mainly dictated by the mutual repulsion between the basal and axial metal-ligand bonds [14].

There have been several attempts to correlate the magnitudes of $2J$ with structural parameters in the $[Cu_2(RCO_2)_4L_2]$ structures, but no success has been achieved [2,3,5,11,12,21]. One may also notice that the ideal of the spin coupling by superexchange through the carboxylate bridges is favoured by both experimental [5,8,22,23] and theoretical [24] investigations.

Table 3. Parameters deduced from magnetic data

Complex	$2J$, cm^{-1}	g	ρ	10^3 R^a
1	340	2.23	3.0	8.7
2	321	2.19	5.5	4.9
3	301	2.05	4.9	6.0

[a] $R = [\Sigma(\chi_{obs}T - \chi_{obs}T)^2/(\chi_{obs}T)^2]^{1/2}$

Inspection of the structural data and the magnetic parameters for the three complexes (see Table 4) shows that the intramolecular coupling constants may apparently be correlated to the Cu···Cu distances, δ values or the mean Cu—O—C bond angles, and are not very sensitive to the Cu—O(basal) bond lengths. On the other hand, previous studies have shown that the direct interaction between the pair of copper(II) atoms should be very weak or even negligible [12]. Therefore it may be reasonable to correlate the magnetic coupling magnitudes to the δ values, since the δ value geometrically reflects both the Cu—O bond lengths and the O—Cu—L bond angles, and hence is indicative of the molecular orbital overlap between the metal atom and the carboxylate groups. As shown in Table 4, a smaller δ value represents a stronger magnetic coupling. It should be pointed out that due to lack of detailed structural parameters and/or magnetic results, we could not examine this deduction on other related quadruply μ_2-carboxylate-bridged dicopper(II) complexes.

Conclusion

This work presents three new dimeric (or dinuclear) copper(II) carboxylates, among which one has two aqua molecules, one has an aqua molecule and one chloride ion, and one has two chloride ions, as axial ligands, respectively. The structural variations in the dimeric structures may be correlated to the mutual repulsion of the basal and axial metal-ligand bonds in the square-pyramidal environment around the copper(II) atom. The current results demonstrate that the magnitudes of the intramolecular antiferromagnetic coupling between the two copper(II) atoms may be

(Received 24 October 1997: accepted 6 January 1998)

Abstract—Two chloranilate-bridging dinuclear Mn(II) compounds with different lattice solvate molecules, $[Mn_2(TPA)_2(CA)](ClO_4)_2 \cdot 3H_2O$ (compound **1**) and $[Mn_2(TPA)_2(CA)](ClO_4)_2 \cdot 2CH_3CN$ (compound **2**), were synthesized and their crystal structures were determined by single-crystal X-ray diffraction. In the cation $[Mn_2(TAP)_2(CA)]^{2+}$, each Mn^{2+} ion is coordinated by four nitrogen atoms from TPA and two oxygen atoms from chloranilate and the chloranilate bridges two Mn^{2+} ions in a bis bidentate fashion. The temperature-dependent magnetic susceptibility data of compound **1** were fitted based on $H = -JS_1S_2$, yielding the intramolecular coupling constant J value of -0.12 cm^{-1}. The electrochemical properties and catalase-like activity of compound **1** were studied. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: manganese complexes; dinuclear complexes; crystal structures; magnetism; cyclic voltammetry; catalase activity.

The study of Manganese complexes with various nuclearities and various oxidation states has received considerable attention in the past few years. The research interests are mainly centred on two aspects, one is in the field of molecular magnetism aimed at the investigation of exchange-coupling interactions between adjacent metal ions in the polynuclear complexes of Mn, another is the endeavour to model the structures, properties and functions of the active sites of Mn-containing enzymes in biological systems, such as the oxygen-evolving complex of photosystem II, [1,2] manganese catalases [3,4], Mn-SOD and manganese ribonucleotide reductase [5].

Manganese catalases catalyse the disproportionation of hydrogen peroxide to dioxygen and water very efficiently and this process is important for cell detoxification. Manganese catalases all appear to have a binuclear manganese active site and it is generally believed that the disproportionation reaction is catalysed by the interconversion of the two oxidation states $Mn^{III}Mn^{III}$ and $Mn^{II}Mn^{II}$. However, the core structure in manganese catalases has not been established yet and the exact mechanism of H_2O_2 disproportionation is still unknown [6]. In order to gain insight into the structure and catalytic mechanism of manganese catalase, it is of value to synthesize and characterize dinuclear manganese complexes in various oxidation states to unravel the more complex behavior of the biological sites by serving as models of the structural, spectral, or functional properties [7–10].

* Author to whom correspondence should be addressed.

In this study on dinuclear manganese complexes we used tripod ligand TPA as ending ligand and chloranillic acid as bridging ligand and succeeded in synthesizing and characterizing compounds **1** and **2**. It is especially interesting that our efforts to synthesize the dinuclear manganese(III) complex is in vain, because the Mn(II) dimer is always obtained whether the starting material is divalent manganese salt or trivalent manganese salt. Chloranilic acid can be capable of bridging metal ions by their four, partically negatively charged oxygen atoms. Previous reports on oligomeric or polymeric Cu, Ni, Fe, Mo complexes bridged by the anion of chloranilic acid are known [11–14]. But no Mn complexes containing chloranilic acid ligand has been reported until now. Thus compounds **1** and **2** are the first examples of chloranilate-bridged manganese(II) complexes. The present work will report the syntheses and crystal structures of these two compounds, together with the magnetic properties, the electrochemical properties and the catalase-like activity of the compounds.

EXPERIMENTAL

Preparations

$TPA \cdot 3HClO_4$ was synthesized according to literature procedure [15]. Tetra-*n*-butylammonium perchlorate (TBAP) was twice recrystallized from absolute ethanol and dried *in vacuo* at 40°C prior to use. Acetonitrile (MeCN) was purified as previously described [16]. All other chemicals were purchased commercially and used as received.

$[Mn_2(TPA)_2(C_6Cl_2O_4)](ClO_4)_2 \cdot 3H_2O$ (compound **1**) was prepared by mixing $TPA \cdot 3HClO_4$ (0.118 g, 0.2 mmol) and Et_3N (0.081 g, 0.8 mmol) in 30 ml of methanol and $Mn(ClO_4)_2 \cdot 6H_2O$ (0.0724 g, 0.2 mmol) in 10 ml of methanol and after stirring for about 10 min, a methanolic solution (10 ml) of chloranilic acid (0.021 g, 0.1 mmol) was added to the reacting mixture. The resulting red solution was stirred for another half an hour and was then allowed to stand at room temperature. Dark red prismatic single crystals suitable for X-ray crystallography were obtained after ten days (0.07 g, yield 61%). Anal: Calcd for $C_{42}H_{42}Cl_4Mn_2N_8O_{15}$: C, 43.84; H, 3.68; N, 9.74; Mn, 9.55. Found: C, 43.72; H, 3.76; N, 9.84; Mn, 9.26%.

$[Mn_2(TPA)_2(C_6Cl_2O_4)](ClO_4)_2 \cdot 2CH_3CN$ (compound **2**) was prepared as follows. A methanolic solution (10 ml) of chloranilic acid (0.021 g, 0.1 mmol) was added to a stirring mixture of $TPA \cdot 3HClO_4$ (0.118 g, 0.2 mmol) in 20 ml of methanol and Et_3N (0.081 g, 0.8 mmol) and $Mn(CH_3COO)_2 \cdot 6H_2O$ (0.049 g, 0.2 mmol) in 10 ml of methanol. After stirring for half an hour the resulting red solution was allowed to stand at room temperature and one week later the black red microcrystalline material was obtained by filtration and then redissolved in MeCN. The black red single crystals were recovered by the vapour diffusion of Et_2O into the MeCN solution for several days (0.038 g, yield 32%). Anal: Calcd for $C_{46}H_{42}Cl_4Mn_2N_{10}O_{12}$: C, 46.88; H, 3.59; N, 11.89; Mn, 9.32. Found: C, 46.70; H, 3.52; N, 12.24; Mn, 9.25%.

CAUTION: Although we experienced no difficulties with the compounds isolated as their perchlorate salts, the unpredictable behaviour of perchlorate salts necessitates extreme caution in their handling.

Physical measurements

Elemental analyses were performed on a Perkin–Elmer 240c analytical instrument. Magnetic susceptibility data on powder samples were measured over a temperature range of 75–300 K at a measuring 6000 G by using a CAHN-2000 Faraday-type magnetometer. The apparatus was calibrated with $[Ni(en)_3]S_2O_3$ (en = ethylenediamine). Diamagnetic corrections were made using Pascal's constants. Electrochemical analysis by cyclic voltammetry were performed on a BAS-100B electrochemical analyzer, in conjunction with a conventional three-electrodes fitted with a purged dinitrogen gas inlet and outlet, a glassy-carbon working electrode, Ag/AgCl electrode as the reference electrode and a platinum auxiliary electrode. All electrochemical experiments were carried out under dry and purified dinitrogen atmosphere at 298 K. The Fc^+/Fc couple was used as an external standard ($E_{1/2} = 0.43$ V).

Crystal structure determination and refinement

The relevant crystal data and structural parameters for compounds **1** and **2** are summarized in Table 1. The intensities were collected at 294 K on a Siemens P_4 four-circle diffractometer with monochromated Mo–K_α ($\lambda = 0.71073$A) radiation using $\theta/2\theta$ scan mode with a variable scan speed 5.0–50.0° min^{-1} in ω. The data were corrected for Lorentz and polarization effects during data reduction using XSCANS [17].

The structure was solved by direct method and refined on F^2 by full-matrix least squares methods using SHELXTL version 5.0 [18]. The O atoms of perchlorate in compound **1** (sof (site occupancy factor) = 0.7 for O(11), O(12), O(13) and O(14); sof = 0.3 for O(11′), O(12′), O(13′) and O(14′)), as well as O(2w) (sof = 0.5) are found disordered. All the non-hydrogen atoms were refined anisotropically, except the water and perchlorate oxygen atoms in compound **1** which are isotropic. All the hydrogen atoms were placed in calculated positions (C—H, 0.96; N—H, 0.90 and O—H, 0.85Å) assigned fixed isotropic thermal parameters at 1.2 times the equivalent isotropic U of the atoms to which they are attached (1.5 times for the O—H and methyl groups) and allowed to ride on their respective parent atoms.

The contributions of these hydrogen atoms were included in the structure-factors calculations.

All computations carried out on a PC-586 computer using the SHELXTL-PC Program Package [18]. Analytical expressions of neutral-atom scattering factors employed and anomalous dispersion corrections were incorporated [19].

RESULTS AND DISCUSSION

Structure description

ORTEP representations of the two compounds **1** and **2** are shown in Fig. 1 and Fig. 2, respectively. Selected bond distances and bond angles for **1** and **2** are listed in Table 2.

Compound **1** crystallizes in the monoclinic space group $C2/c$, and consists of discrete $[Mn_2(TPA)_2(CA)]^{2+}$ cations, two perchlorate and three lattice water molecules. The cation is centrosymmetric and the asymmetric unit thus consists of half of the cation. The chloranilate ligand bridges two Mn^{2+} ions in a bis bidentate fashion with fairly small chelating bond angles (73.84(6)° for O(1)—Mn(1)—O(2)). The Mn···Mn distance in the dimer is 8.151(6) Å. The C_6 ring entity is planar and the largest deviation of the atoms from the least-squares plane, defined by the ring atoms (C(19), C(20), C(21), C(19A), C(20A), C(21A) is 0.001(7) Å for C(21), C(21A). The largest deviation for the oxygen atoms is 0.054(7) Å for O(2). The Mn ions is protruding out by 0.317(5) Å of the defined plane. The C(19)—C(20) distance (1.542(3) Å) is comparable to C—C single bond length, whereas the significantly shorter C(20)—C(21) distance (1.411(4) Å) are close to a C=C double bond length. The C(19)—O(1) length and C(20)—O(2) length are 1.252(3) Å and 1.251(3) Å, respectively. These structural features of the bridging chloranilate ligand indicate it has a partially delocalized, quinoid structure which is true of the free dianion [20] and are similar to those for reported chloranilate-bridging dinuclear Cu(II) or Ni(II) complexes [21].

Six coordination of the manganese atom are completed by the four nitrogen atoms (N(1), N(2), N(3) and N(4) from TPA. The tripodal ligand TPA causes a characteristic coordination geometry in metal complexes. The Mn(1)—N(1) (amine) bond is the longest (2.358(2) Å) among the Mn(1)—N bonds. The bonds between Mn(1) and N (pyridine) atoms (N(2), N(3) and N(4)) lie in the range of 2.205(2)–2.242(2) Å and the average Mn—N (pyridine) bond length is 2.226(4) Å. The average N(amine)—Mn(1)—(pyridine) bond angle is 74.04(6)°. These observations agree well with those reported for other Mn(II) complexes of TPA [22]. The Mn—O lengths of 2.155(2) Å and 2.214(2) Å are similar to the Mn—O lengths of oxalate-bridged Mn(II) complexes [23]. The resulting manganese (II) coordination is quite severely distorted due to the

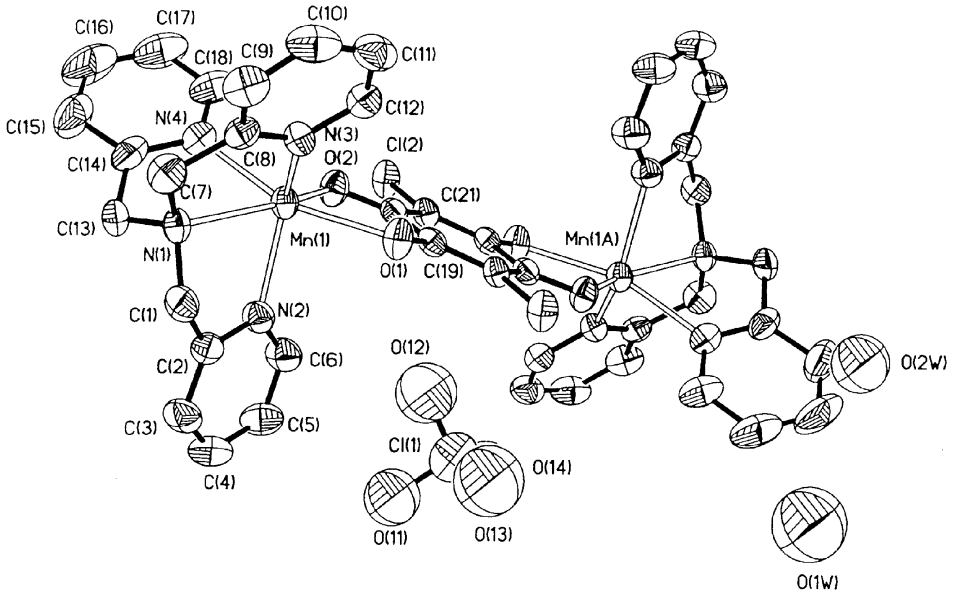

Fig. 1. Molecular structure and atom numbering of the cation of compound **1**. Thermal ellipsoids are drawn at the 30% probability level.

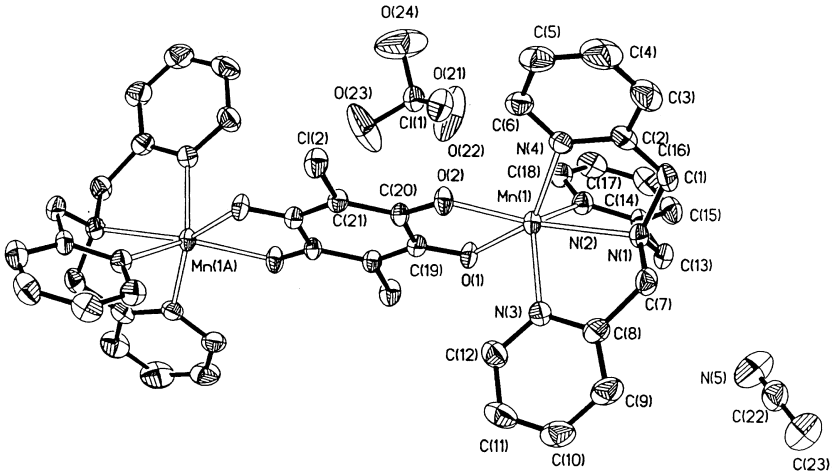

Fig. 2. Molecular structure and atom numbering of the cation of compound **2**. Thermal ellipsoids are drawn at the 30% probability level.

small bite angles formed by the TPA ligands and the chloranilate ligands. The perchlorate groups have their expected tetrahedral geometry.

Compound **2** crystallizes in the space group ($P\bar{1}$). Three lattice water molecules in compound **1** were replaced by two MeCN molecules. The cation also possess a center of symmetry. The C_6 entity of bridging chloranilate ligand is also planar and the largest deviation of the atoms from the least-squares plane, defined by the ring atoms C(19), C(20), C(21), C(19A), C(20A), C(21A)) is $-0.023(7)$ Å for C(21), C(21A). The largest deviation for the oxygen atoms is 0.054(7) Å for O(2). The Mn ion is 0.031(5) Å out of this plane and this deviation is much smaller than that in compound **1**. The Mn$\cdots$Mn separation is 8.231(7) Å. The Mn—N bond lengths and Mn—O bond lengths show little differences compared with those in compound **1**. (*cf.* Table 2) which confirm that Mn atoms in compound **2** are indeed divalent as in compound **1**. The chelating bond angles (72.65(12)° for O(1)—Mn(1)—O(2)) formed by the bridging chloranilate and the average N(1)(amine)—

Mn(1)—N(pyridine) bond angle (73.07(6)°) are both slightly smaller than the relevant angles (73.90(5)° and 74.05(6)°) in compound **1**.

Magnetic properties

Temperature dependent magnetic susceptibility for compound **1** have been measured down to 75 K and χ_M values are plotted vs temperature (Fig. 3), where χ_M is the molar magnetic susceptibility. The effective magnetic moment at 300.30 K is 8.34 B.M. which is close to the spin-only value of 8.36 B.M. expected for two uncoupled high-spin Mn^{II} ions. Upon cooling, the magnetic moment value decrease slowly from 8.34 B.M. at 300.2 K to 7.92 B.M. at 75 K, showing the presence of extremely weak antiferromagnetic exchange interaction. Assuming isotropic exchange, the exchange Hamiltonian is $H = -2JS_1 \cdot S_2$ with $S_1 = S_2 = 5/2$, and the magnetic susceptibility per mole of the dimer is given by eqn (1) [24]

$$\chi_M = 2Ng^2\beta^2/ kT[(e^x + 5e^{3x} + 14e^{6x} + 30e^{10x} + 55e^{15x})/ (1 + 3e^x + 5e^{3x} + 7e^{6x} + 9e^{10x} + 11e^{15x})] \quad (1)$$

where N, g, β, x are Avogadro's constant, g factor, Bohr magneton, and $x = J/kT$, respectively, and J is the exchange coupling constant for the manganese dimer. Using eqn (1), the least-squares fit to the magnetic susceptibility data gives the parameters: $g = 1.991$, $J = -0.12$ cm^{-1}. the discrepancy factor defined as $R = \Sigma(\chi_{calc} - \chi_{obs})^2]/\Sigma(\chi_{obs})^2$ is 1.5×10^{-4}. The magnetic susceptibility calculated by using the fit parameters is shown as the solid line in Fig. 3.

The magnetic exchange interaction through bridging chloranilate ligand is very weak. The J value is slightly smaller than those of other Mn^{II} complexes bridged by terephthalate, isophthalate or *trans* butaene diacid salt ligands ($J = -1.04$–-0.53) [25,26].

Cyclic voltammetry

Cyclic voltammogram of compound **1** in degassed and deaerated acetonitrile solution containing 0.1 mol cm^{-3} TBAP is shown in Fig. 4. Compound **1** undergo three quasireversible one-electron redox processes [27], suggesting the formation of $[Mn_2(TPA)_2(CA)]^{n+}$ species, with $n = 1$–4. The first quasireversible electron-transfer process ($E_{1/2} = -0.95$ V vs Ag/AgCl

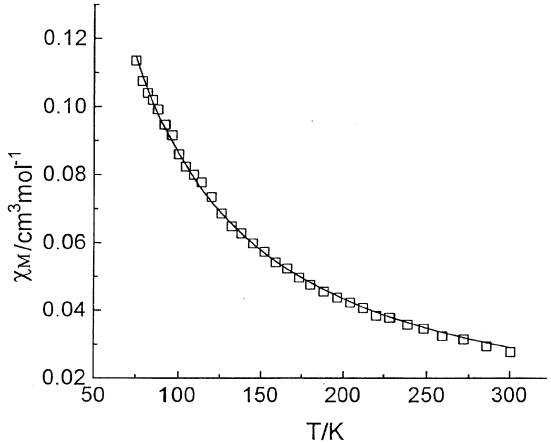

Fig. 3. The plot of X-T for compound **1**. The solid line represents best fit of data according to eqn (1).

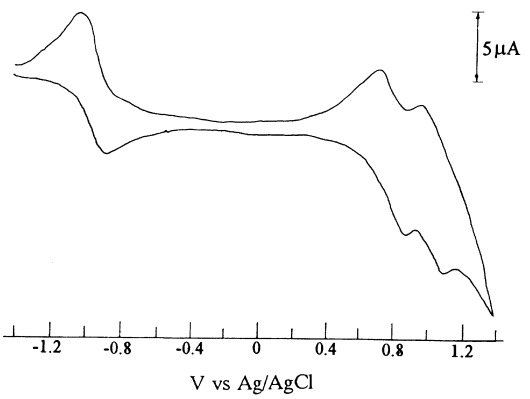

Fig. 4. Cyclic voltammogram of compound **1** in MeCN, 0.1 mol dm^{-3} TBAP. Scan rate is 0.1 V s^{-1}.

and $\Delta E = 100$ mV) which can be suggested to be associated with a ligand-centered electron-transfer reaction (CA^{2-}/CA^{3-}). Another two quasireversible one-electron redox processes observed at more positive potentials ($E_{1/2} = 0.8$ V vs Ag/AgCl and $\Delta E = 105$ mV; $E_{1/2} = 1.0$ V vs Ag/AgCl and $\Delta E = 100$ mV can be assigned to the couples, $Mn_2^{III}/Mn^{III}Mn^{III}$ and $Mn^{I}{}^{I}Mn^{III}/Mn^{II}Mn^{II}$. It is noticeable that the difference between the two redox steps is small (0.2 V), so that the disproportionation constant associated with the equilibrium

$$2[Mn_2(TPA)_2(CA)]^{3+} \leftrightharpoons [Mn_2(TPA)_2(CA)]^{4+} + [Mn_2(TPA)_2(CA)]^{2+} \quad (2)$$

is ca 10^{-3}. This result strongly suggested that the cation $[Mn_2(TPA)_2(CA)]^{3+}$ is not stable [28] and gives a reasonable explanation to the phenomenon observed that $[Mn_2(TPA)_2(CA)]^{2+}$ is obtained in spite of Mn(III) salt being used as starting material. The cyclic voltammetry of compound **2** was also measured and exact same C.V. diagram was obtained (not shown).

Reaction with hydrogen peroxide

Hydrogen peroxide decomposes catalytically in the presence of compound **1**. To a solid sample (10 mg, 8.7×10^{-3} mmol) of compound **1** was added aqueous H_2O_2 (7.9 M, 2 ml, 15.8 mmol). The mixture was stirred and thermostated at 25°C and the evolved O_2 was measured volumetrically [7]. The total amount of O_2 evolved corresponded to half the equivalent of H_2O_2 added, indicating that all the H_2O_2 disproportionated into O_2 and H_2O [eq. (3)]. The time courses of dioxygen

$$2H_2O_2 \rightarrow O_2 + 2H_2O \quad (3)$$

evolving are shown in Fig. 5. During the first minute of the reaction each mol of compound **1** disproportionated 890 mol of H_2O_2. This model catalyst is approximately five orders of magnitude less reactive than the metalloproteins from *L. plantarum* or *T. album* and is close to another model compound reported earlier [7,8]. Besides, we tested the catalase activity of manganese(II) perchlorate and manganese(III) acetate under the identical conditions as in the case of compound **1** (not shown). During the first minute of the reaction each mol of manganese(II) perchlorate and manganese(III) acetate can only disproportionate 0.12 and 1.16 mol of H_2O_2, respectively [8]. It is obvious that compound **1** can act as an effective catalyst for the disproportionation of H_2O_2.

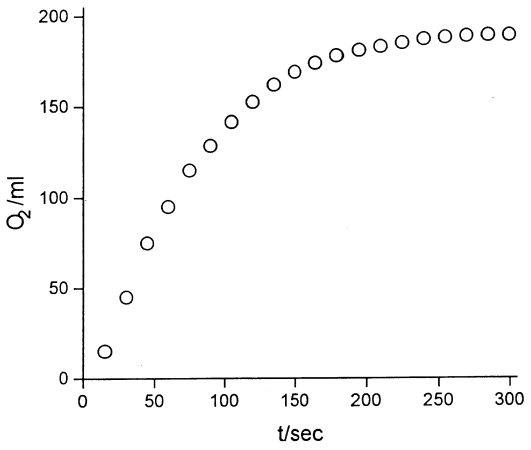

Fig. 5. Time course of dioxygen evolution in H_2O_2 disproportionation by compound **1**. Conditions: **1** (10 mg, 8.7×10^{-3} mmol), H_2O_2 (7.9 M, 2 ml, 15.8 mmol), at 298 K.

(Received : 17 November 1997 ; accepted 6 January 1998)

Abstract—Eleven antimony compounds $RSb[(CH_2)_3]_2$ NR′ and eight germanium compounds $R_2Ge[(CH_2)_3]_2$ NR′ (some combinations of R = Cl, I, NCS, $OSiPh_3$, Ph, and NR′ = NMe, NBz, NBu^i) have been synthesized by diGrignard reactions and subsequent treatment with AgSCN, Ph_3SiONa or PhLi. The compounds were compared to 14 Sn, 1 As, 5 Sb and 4 Bi analogues taken from the literature. Evidence is provided for 1,5-chelation Sb···N via crystal structure determinations (5 + 1 (lit) Sb compounds), ^{13}C- and ^{29}Si-NMR chemical shifts, ^{121}Sb and ^{127}I Mössbauer data (11 and 3 Sb compounds, respectively), cyclic voltammetry (9 Sb compounds) and semi-empirical MO calculations on the Extended Hückel level (8 present compounds and 4 models). The ligand sequence (Cl < I < NCS) holds for an increasing approach N···Sb. The effect of electronegativity and the effect of *n*- or $\pi \rightarrow \sigma^*$ charge transfer into the LUMO at Sb are counteractive. The intramolecular donor strength increases in the following order : NBu^i < NBz < NMe. Simultaneously a decrease of the absolute value of the ^{121}Sb quadrupole coupling constant from Mössbauer spectroscopy occurs. The postulation of a control of the Sb···N chelation by frontier orbital interactions is supported by the CV results in CH_2Cl_2 at a Au/Hg electrode. It is proved by scan rate dependence that the observed reversible reduction/oxidation process is diffusion controlled, and by coulometry that the reduction takes place by transfer of one electron. © 1998 Elsevier Science Ltd. Keywords: antimony ; hypervalency ; frontier orbitals ; Mössbauer spectroscopy ; cyclic voltammetry ; coulometry ; NMR.

Recently we have created a novel view about the bonding scheme of the long-known phenomenon of hypervalency at tin(IV) [2]. This view arose from systematic experimental investigations in some series of heterocycles which contained a potential intramolecular donor and the axial/equatorial ligands Cl, Br, I and Me [2]. The sequences of interaction (donor)···Sn showed that, with regard to the ligands

at Sn, their electronegativity and a $n \rightarrow \sigma^*$ charge transfer into the LUMO at Sn^{IV} are counteractive. The geometric impetus for this view came from the method of structure correlation of Bürgi and Dunitz [3a] and from papers of van Koten [3b], whereas the theoretical portions build on papers of Musher [3c] and of Noyori [3d].

In this work our ideas shall be extended to antimony(III) as a central atom, and the question of the influence of the lone pair of electrons in a ψ-trigonal bipyramidal geometry arises [4]. We synthesized a series of compounds **4** with Sb^{III} and, in addition, the compounds **1** with Ge^{IV} as a central atom (Scheme 1) [5–7]. Structural, spectroscopic and electrochemical data and semi-empirical MO calculations for these compounds will be compared to the analogous data of the rings **2, 3** and **5,** which contain Sn^{IV} [6b], As^{III} [6a] and Bi^{III} [6a] as central atoms (Scheme 1).

RESULTS

Synthetic aspects

The Cl_2, ClPh, Cl and I substituted heterocycles **1** and **4** were obtained by reaction of the diGrignard reagent $R'N[(CH_2)_3MgCl]_2$ with $GeCl_4$ [2d], $PhGeCl_3$, $SbCl_3$ or SbI_3. To obtain the NCS substituted compounds, $R'N[(CH_2)_3]_2SbI$ was reacted with AgSCN in CH_2Cl_2. The heterocycles substituted with ($OSiPh_3$) or Ph have been obtained from those with Cl_2 or Cl substitution by reaction with Ph_3SiONa in toluene or with PhLi in *n*-hexane.

Molecular structures

Five structure determinations have been carried out in this paper; the data for the compound **4** (NMe/Cl) were taken from Ref. [6a]. Bond distances at antimony and axial and equatorial bond angles are given in Table 1. The cores of all six molecular structures are similar. Figures 1 and 2 show exemplarily plots of the compounds **4** (NMe/NCS) and **4** (NBu^i/I).

In order to get an idea about the goodness of the ψ-trigonal bipyramidal geometry around antimony, angle differences have been included in Table 1. Distances between atoms of different kinds were transformed into Pauling bond orders BO [8] in order to obtain comparability. All six structures have similar conformations, and no short intermolecular contacts disturb the distances given in Table 1.

Spectroscopic data

Table 2 contains the ^{13}C NMR chemical shifts of the α-CH_2 groups in equatorial position at Ge, Sn [6b], As [6a], Sb, or Bi [6a] for all compounds of Scheme 1. In addition, the ^{29}Si NMR chemical shifts of the $OSiPh_3$ groups are given. A full set of the ^{13}C NMR chemical shifts of the compounds **1** and **4** has been deposited with the Editor as supplementary material.

Table 3 contains the ^{121}Sb and ^{127}I Mössbauer parameters of the compounds **4**. Figure 3 gives exemplarily the ^{121}Sb Mössbauer spectra of the compounds **4** (NMe/Cl,Br,I). The asymmetric shape of the

absorption peaks shows that the sign of the quadrupole coupling constant (e^2qQ) is obviously negative [12b].

Extended Hückel calculations

To support the bonding scheme of hypervalency which had been introduced in Ref. [2], semi-empirical MO calculations on the Extended Hückel level have been performed for the six compounds **4** whose geometry is known from the crystal structure analyses [13a,14]. Figure 4 shows in graphical form the energetical sequence of the MO's for the compound **4** (NMe/Cl) and the distribution of three filled and one empty orbital over the atoms of the molecule. Table 4 summarizes some typical results and contains also results for the compounds **1** (NBu^i/Cl_2) and **2** (NBu^i/

Cl_2) [6c] with Ge and Sn as central atoms [13a,14]. In addition, Table 4 gives the results for the four hypothetical molecules $Cl_2Ge/SnBu^n{}_2$ and ClAs/$SbBu^n_2$, for which a perfect tetrahedral/ψ-tetrahedral geometry had been optimized by means of a force-field calculation prior to the Extended Hückel calculation [13b,14].

Cyclic voltammetry in CH_2Cl_2 *solution*

To get an experimental support of the calculated HOMO (lone pair σ) and LUMO (3-center $^3\sigma^*$) of Fig. 4, cyclic voltammetric experiments with nine from the sixteen available Sb compounds **4** have been performed [15]. After considerable optimization the proper conditions for reproducible results in both initial sweep directions (oxidative electron transfer from the HOMO into the reference electrode and reductive electron transfer from the reference electrode into the LUMO) were found. The results are summarized in Table 5, and two examples of the cyclic voltammograms obtained are shown in Fig. 5.

With regard to the initial anodic sweep direction, all nine investigated Sb compounds show an oxidative peak E_{ox} between +0.55 and +1.25 V. The peaks are generally small and broad. After inversion of the applied potential at +1.5 V, a decomposition of the compounds occurs in most cases. Only for **4** (NBz/I) (Fig. 5a) and for **4** (NBu^i/I) a quasi-reversible reduction peak E_{red} was found.

With regard to the initial cathodic sweep direction, three of the investigated Sb compounds (**4** (NBu^i/Cl), **4** (NBz/I) (borderline case, see footnote *d* of Table 5) and **4** (NMe/$OSiPh_3$)) decompose immediately under the influence of the reductive potential. The six other investigated compounds result in reversible cyclic voltammograms with $E_{red} - E_{ox}$ between 0.10 and 0.14

V (Fig. 5b). The voltammograms are comparable to those of the used standard ferrocene ($E_{red} - E_{ox} = 0.13$ V). The solution diffusion control of the process was established by measuring the peak currents for both reduction (i_c) and oxidation (i_a) for **4** (NMe/I) and **4** (NMe/NCS) and plotting i_c and i_a against the square root of the scan rate over three decades of speed (10–1000 mV s^{-1}) and using ferrocene as a standard [15a].

Bulk electrolysis in CH_2Cl_2 *solution*

To ascertain the number of electrons involved in the reversible redox process, controlled potential electrolysis (coulometry) [16b] was performed for the compound **4** (NMe/I). The results are given in Table 6. After extensive optimization of the experimental conditions (applied potential, cooling) it was concluded definitely that the process is a one-electron-transfer.

DISCUSSION

Investigation in the solid

The X-ray data of Table 1 demonstrate the order (1) for the intramolecular nucleophilic attack of the donor R′N at the σ-Lewis acidic Sb on a path to a four-electron three-center interaction R′N···Sb—R(ax).

$$d(\text{R′N}\cdots\text{SbCl}) > d(\text{R′N}\cdots\text{SbI}) > d(\text{R′N}\cdots\text{SbNCS}) \quad (1)$$

Geometrically, a continuous change from a ψ-tetrahedral three-coordination to a ψ-trigonal-bipyramidal four-coordination occurs. The order (1) is not governed by the electronegativity of the ligands R (influence of the HOMO). An enhanced $n \rightarrow \sigma^*$ or $\pi \rightarrow \sigma^*$ charge transfer from R(ax) into the LUMO of the π-acidic Sb promotes the path [2]. With regard to the HOMOs, the negative sign of the ^{121}Sb coupling constant e^2qQ (Table 3) suggests a larger population of

[a] Counter electrode Pt; scan rate 100 mV s^{-1}; evaluation of the voltammograms according to Ref. [16a].
[b] Working electrode Pt; sweep range 0.0 to +1.5 to −1.5 to 0.0 V.
[c] Working electrode Au/Hg; sweep range −0.2 to −1.7 (or −2.0) to −0.2 V.
[d] Scan rate 300 mV s^{-1}, at lower scan rates immediate decomposition; result not fully reproducible.

the antimony 5p electrons in the equatorial plane (6 electrons) compared to those in the axial direction (< 4 electrons).

With regard to the donor group R′N, Table 1 demonstrates the order (2) of increasing interaction, i.e. increasing σ-donor strength.

$$d(Bu^iN\cdots SbI) > d(BzN\cdots SbI) > d(MeN\cdots SbI) \quad (2)$$

The absolute value e^2qQ of ^{121}Sb (Table 3) decreases for all three investigated ligands, Cl, I and NCS, identically to order (2). This decrease suggests a simultaneous increase in the electron density of the axial three-center interaction R′N···Sb—R(ax).

In Fig. 6 the bond orders of the ligands at antimony BO(Sb—R(ax)) are plotted versus BO(Sb···N) for the five halide substituted cases. The familiar structural trans influence (shorter N···Sb and longer Sb—R(ax)) is valid for pairs of identical donor groups (NBz and NMe). It inverts or becomes zero at an interchange of the donor groups (NBu^i into NBz, NBz into NMe; compounds **4** (NBu^i/I) → **4** (NBz/I): d(Sb···N) 2.420 (5) → 2.391 (7) Å and d(Sb-I) 2.994 (1) → 2.982 (1) Å; for similar results in three series of tin compounds and in one series of silicon compounds

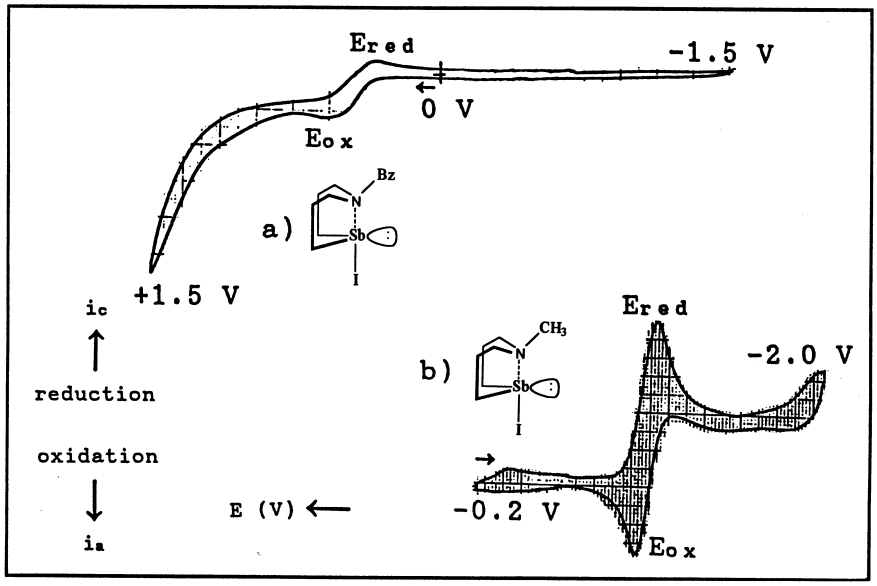

Fig. 5. Cyclic voltammograms of the compound **4** (NBz/I) a) (oxidative sweep direction, Pt electrode) and **4** (NMe/I) b) (reductive sweep direction, Au/Hg electrode).

Table 6. Controlled potential electrolysis of **4** (NMe/I) (30–40 mg/60 ml CH_2Cl_2) at $-10°C$

Reductive potential[a] (mV)	No. of electrons	Reductive potential[a] (mV)	No. of electrons
−1260	0.44	−1340	b

−1320	1.00		

[a] Ag/AgCl reference electrode different from that used in Table 5: CV peaks (scan rate 100 mV s^{-1}) for ferrocene E_{ox}/E_{red} +368/+190 mV, for **4**(NMe/I) E_{red}/E_{ox} −1309/−1122 mV.

[b] Decomposition into colorless, insoluble Sb(III) material; without cooling, elementary antimony precipitates.

[c] Amalgamation of the precipitated elementary antimony with the mercury pool cathode.

see Ref. [2d]). This behaviour supports the assumption of a charge flow from the ligands into the LUMO at Sb.

With regard to the charges on ^{127}I (Townes-Dailey treatment [12a] in Table 3), the order (3) mirrors the structural finding (4). Compounds with a longer Sb-I distance own a more negative charge on the iodine atom, i.e. the Sb-I bond seems to be more ionic.

$$|Z(I)|(MeN\cdots SbI) \geqslant |Z(I)|(Bu^tN\cdots SbI) > |Z(I)|(BzN\cdots SbI) \quad (3)$$

$$d(Sb—I)\,2.995(1) \geqslant d(Sb—I)\,2.994(1) > d(Sb—I)\,2.982(1)Å \quad (4)$$

HOMO and LUMO by cyclic voltammetry and coulometry

The oxidation of the compounds **4** at a positive potential is followed in most cases by decomposition. The two cases of quasi-reversible oxidation/reduction suggest that no full oxidation of Sb(III) to Sb(V)

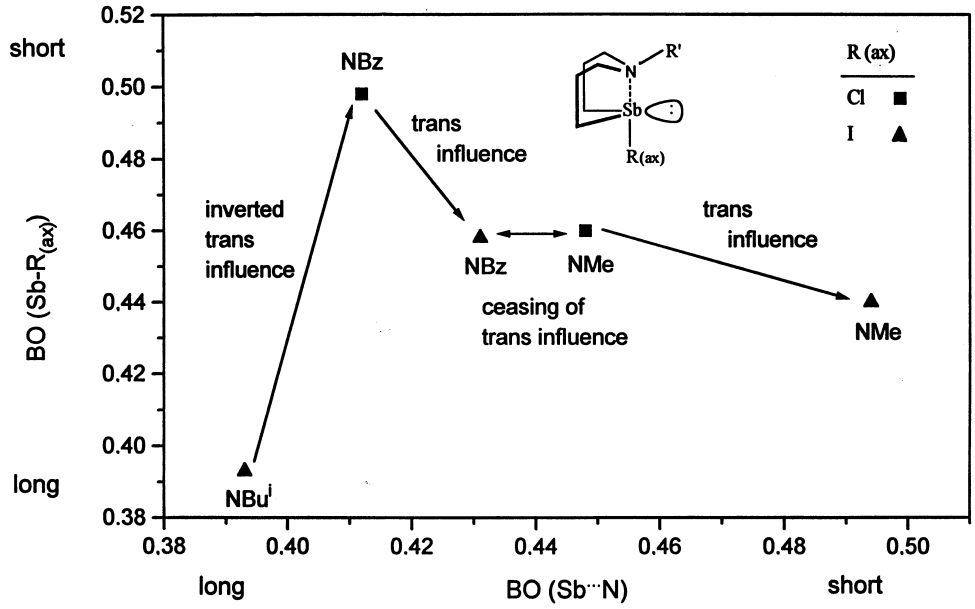

Fig. 6. Related *trans* bond orders of the four-electron three-center interaction N · · · Sb-Hal.

occurs. The signals are broad ; for a two-electron process narrow signals should be expected [15b].

The reversibility of the redox potentials E_{red} and E_{ox} in the reductive mode, the proof of a diffusion controlled molecular process in solution and the proof of a one-electron reduction for **4** (NMe/I) support experimentally the likelihood of a charge flow from the ligands into the LUMO mostly associated with the central Sb atom. The similarity of all CVs and their peak voltage positions indicate that for all these Sb compounds a transfer of one electron into an equivalent molecular orbital eventuates. Because of the extended time frame of the bulk electrolysis compared to the cyclic voltammetry in the former, restricted experimental conditions are involved while in the latter no such decomposition occurred due to the brevity of the experiment.

In view of the qualitative nature of the kinetically controlled method cyclic voltammetry [17], and with regard to the approximations of the Extended Hückel method, no direct numerical comparison of the potentials of Table 5 (units V) to the calculated LUMO energies of Table 4 (units eV) can be made.

^{13}C NMR *chemical shifts in* $CDCl_3$ *solution*

Figure 7 summarizes the chemical shifts of the α-methylene groups in the rings of Scheme 1. The overall sequences of the ^{13}C deshielding ($CH_2Ge \geqslant CH_2Sn$ and $CH_2Bi > CH_2As > CH_2Sb$) suggest sequences of electronegativity of the central atoms ($EN(Ge) \geqslant EN(Sn)$ and $EN(Bi) > EN(As) > EN(Sb)$), respectively (for a detailed discussion of this aspect see Ref. [6a]). For each element individually, the ligand Ph induces a distinct up-field shift. The special kind of donor group NR′ has no influence on $\delta(^{13}C)$.

For the three Sb—NCS compounds $\delta(^{13}C)$ is slightly deshielded (= 135 ppm) in comparison to Me—NCS (= 128.5 ppm [18]). This deshielding is in accordance with the assumed charge-giving power of the isothiocyanate ligand into the LUMO at Sb. On the other hand, the bonding isomerism Sb—NCS (compound **4** (NMe/NCS), is confirmed also for the two other compounds ($\delta(^{13}C$(Et—SCN) 112 ppm [18]).

^{29}Si NMR *chemical shifts in* $CDCl_3$ *solution*

The values of $\delta(^{29}Si)$ for the (—$OSiPh_3$) ligand in the compounds **1, 2, 4** and in the tetrahedral analogue $Ph_3SiOSiPh_3$ are sterically determined : −18.5, −19.5 and −(24 to 26) ppm for the ligand in tetrahedral, equatorial and axial trigonal bipyramidal position, respectively. In two cases, the (—$OSiPh_3$) ligands exchange at room temperature on the NMR time scale. With regard to axial (—$OSiPh_3$) bound to Sn or Sb, no difference in $\delta(^{29}Si)$ exists.

EXPERIMENTAL

General considerations

The starting ligands $R'N[(CH_2)_3Cl]_2$ and the related diGrignard reagents were prepared as described previously [6a]. Grignard iniators were CCl_4 for the chlorine substituted compounds and I_2 for the iodine

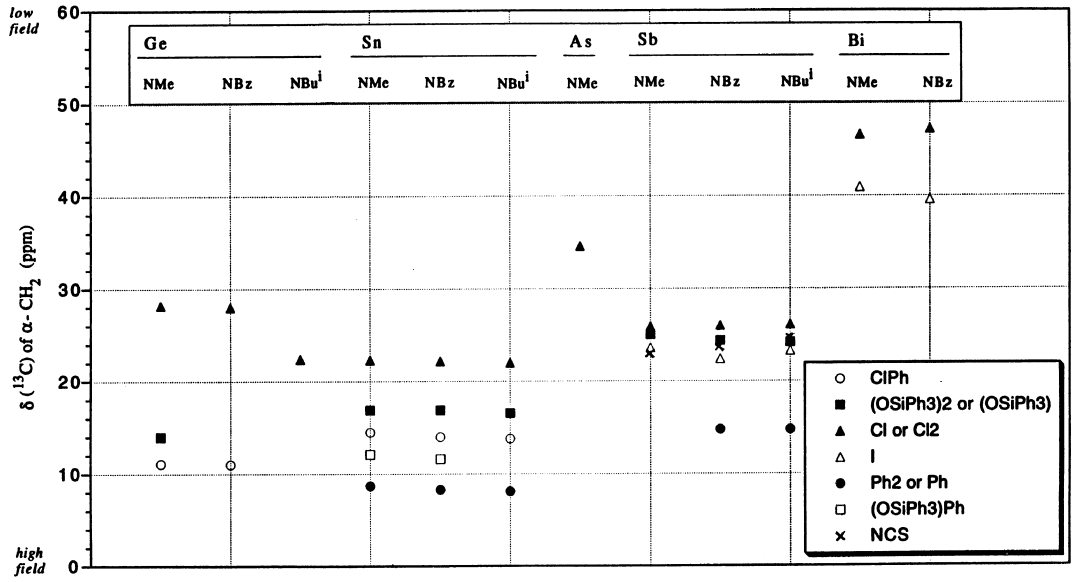

Fig. 7. Sequence of $\delta(^{13}C)$ for the equatorial α-methylene groups in the rings **1** to **5** in $CDCl_3$ solution.

substituted ones. The reagent AgSCN was precipitated from an aqueous solution of KSCN with $AgNO_3$, washed with cold acetone and dried *in vacuo*. The reagent Ph_3SiONa was obtained by reaction of Ph_3SiOH with sodium in toluene. Melting points were determined in glass capillaries in a Kofler block. Elemental analyses were carried out by the Microanalytical Laboratory of the Institut für Organische Chemie, Universität Mainz. NMR spectra were recorded on a Bruker WP-80/DS spectrometer (^{13}C/20.15, ^{29}Si/15.92 MHz; solvent $CDCl_3$; ambient temperature; external standard $SiMe_4$). Mass spectra were recorded using a Finnigan 8230 spectrometer.

Preparations of **1** *and* **4**

The syntheses of the Cl substituted compounds were carried out as described previously [6a]. Detailed procedures follow for the compounds **4** (NMe/I) and **4** (NBz/NSC). Under the exclusion of light and air and under vigorous stirring, 0.08 mol of the diGrignard reagent $MeN[(CH_2)_3MgCl]_2$ in 150 ml THF and 0.08 mol SbI_3 as a solid were added simultaneously into 1.5 l toluene (three-necked 2 l flask) over a period of 1.5 h. Stirring was continued at room temperature for 24 h. The dark-reddish reaction mixture was filtered twice to remove MgI_2. The solvent was removed under vacuum and moderate temperature, and the crude product was recrystallized from ethanol. A colorless solid was obtained. A suspension of 0.005 mol of freshly prepared and dried AgSCN and 0.005 mol **4** (NBz/I) were stirred in 150 ml CH_2Cl_2 for 24 h at room temperature. The reaction mixture was filtered off and the solvent removed under vacuum. The resulting crude product was recrystallized from ethanol to obtain a colorless solid. Table 7 summarizes the yields and the analytical data for the 19 synthesized compounds. For some of the Ge compounds **1** the analytical data are not satisfying. All these compounds **1** were obtained in low yields and the separation from oligomeric by-products was difficult. Repeated chromatographic purifications resulted in no better analytical data. Nevertheless, the identities of the compounds are not in doubt. The compound **1** (O/Cl_2) was not obtained in a pure state at all.

Mössbauer spectroscopy

^{121}Sb Mössbauer spectra were measured with an Austin Science S-600 Mössbauer spectrometer using a $Ca^{121m}SnO_3$ source (16 MBq) and a pure germanium detector [19a]. ^{127}I Mössbauer spectra were recorded in the same way as described previously by using a $Mg_3{}^{127m}TeO_6$ source instead of a $Zn^{127m}Te$ source [19b]. The Mössbauer source (1.6 GBq) was prepared by a high flux neutron irradiation of $Mg_3{}^{126}TeO_6$ (193 mg) at a reactor core of JRR-3M of the Japan Atomic Energy Research Institute. Both the corresponding sources and the samples [(15 mg Sb)/cm^2 or (30 mg I)/cm^2 were kept at 20 K in a cryostat incorporating a closed-cycle refrigerator [19c]. The Doppler velocity was measured with an Austin Science LC-9 laser interferometer and calibrated by measuring the ^{57}Fe Mössbauer spectrum of an iron foil at 20 K using a $^{57}Co(Rh)$ source. The spectra were fitted to twelve-line quadrupole-split lines by using a transmission integral method [19d].

[j] Traces of Cl, see X-ray crystallography.

Electrochemistry

The CV measurements of Table 5 were performed with a BAS CV 27 Voltammograph coupled with a Houston Instruments Series 2000 Omnigraph X-Y recorder. The scan rate dependence and the coulometry were done with a BAS 100 B/W electrochemical analyser coupled to a PC.

Conventional disk gold electrodes (2.5 mm diameter) were amalgamated by dipping in triple distilled mercury until a good coating of mercury completely covered the gold surface, and used immediately. To renew the Au surface, the electrode was dipped in nitric acid and washed with water, polished on a cloth pad which was exclusively used for these electrodes and then again washed with water, acetone and finally with dry CH_2Cl_2, and the Hg amalgamating procedure was repeated. Auxiliary electrodes were of 1 mm diameter Pt wire. Reference electrodes were Ag/AgCl filled with CH_2Cl_2 (saturated LiCl) and were separated from the test solution by a fritted salt bridge containing CH_2Cl_2 and the electrolyte. Measurements were made in a conventional three electrode cell, from quiescent solutions blanketed with N_2, which were previously sparged with dry high purity N_2.

The bulk electrolysis was performed in a cylindrical glass cell equipped with a separate fritted anode compartment (Pt basket anode) and a magnetically stirred

Table 8. Summary of crystal data, intensity data collection (Mo radiation, ambient temperature) and refinement for the compounds **4**

mercury pool cathode. The solution was continually sparged with N_2 during the coulometric measurement. The electrolysis was stopped if no further current decrease occurred (15 to 5% of the initial current, about 1 h).

The CH_2Cl_2 (anal. gr. BDH) was passed through activity 1 alumina which had been previously preheated to 600°C. The supporting electrolyte, Bu$^n{}_4$NPF$_6$, was stored over P_2O_5 for 48 h prior to usage and solutions of this in CH_2Cl_2 (0.1 M) were made up just prior to the measurements. Ferrocene (Riedel-de Haën) was used as a standard.

X-ray crystallography

Colorless single crystals were obtained from ethanol (**4**(NMe/I, NMe/NCS, NBu^i/I, NBz/Cl)) or from ethanol/toluene 1 : 1 (**4**(NBz/I)). A summary of the crystal data, of the intensity data collections and of the refinements is given in Table 8. The densities were determined by flotation in aqueous polytungstate solution. The quality of the crystals was examined by Laue exposures. Integrated intensities were measured by means of $\omega/2\theta$ scans on an Enraf-Nonius CAD4 diffractometer. The structures were solved by Patterson syntheses and completed by Fourier syntheses (program package SHELXTL). The refinements resulted in good convergences and in even distributions of the variances. Hydrogen atoms were calculated and refined as riding on their carbon atoms. Two atoms of the compound **4** (NMe/NCS) are severely disordered (N(2) and the ring atom C(2)); all attempts to resolve this disorder failed. The space group is unambiguously Pnam (no. 62 : C_s symmetric molecule). Refinements in the space group Pna2$_1$ resulted in a severely distorted molecule and in many correlations. The crystal of **4** (NBu^i/I) contained traces of Cl from the Grignard reagent (residual 4.0 e$^-$/Å^3, D_{calcd}/D_{exptl} 1.94/1.87 g cm^{-3}, the analytical iodine content in Table 7 is low) which crystallographically could not be refined. Details of crystal data and structure determinations, ORTEP views, tables of positional and thermal parameters, bond lengths, bond angles and torsion angles have been deposited with the Editor as supplementary material.

CONCLUSIONS

All experimental data (structure determinations, Mössbauer spectroscopy, electrochemistry, NMR spectroscopy) and the Extended Hückel calculations are in a rough agreement with the assumed bonding scheme of hypervalency: four-electron three-center interaction and its main control by a partial charge transfer from the ligands into the three-center LUMO. In view of the fact that the Extended Hückel method is a very first approximation, a state of the art ab initio calculation is needed for a fully consistent interpretation of the experimental findings. Such calculations are in preparation.

(Received 8 October 1997 : accepted 9 January 1998)

Abstract—A series of mononuclear complexes $[M(H_2L)](ClO_4)_2$ (**1**–**6**) [M = Mg^{II}, Cu^{II}, Ni^{II}, Co^{II}, Fe^{II}, Mn^{II}], homo-/hetero-dinuclear complexes $[M_ALM_B](ClO_4)_2$ (**7**–**11**) [$M_A = M_B = Cu^{II}$, Ni^{II}; $M_A = Ni^{II}$, $M_B = Cu^{II}$, Co^{II}; $M_A = Mn^{II}$, $M_B = Cu^{II}$], and a tetranuclear complex $[\{Ni^{II}LFe^{III}(H_2O)\}_2(\mu\text{-}O)](ClO_4)_4$ (**12**) derived from an asymmetric tetraiminodiphenol macrocyclic ligand H_2L have been synthesized and characterized. The dinucleating ligand is formally the condensation product of 2 equiv. of 2,6-diformyl-4-methylphenol and 1 equiv. each of 1,2-diaminoethane and 1,3-diaminopropane. In the complexes $[Ni(H_2L)](ClO_4)_2$ (**3**), $[NiLCu](ClO_4)_2$ (**9**) and $[NiLCo(H_2O)_2](ClO_4)_2$ (**10**), the Ni^{2+} ion is located at the site having the ethylene chain and has a square planar geometry, while the second metal centre in **9** or **10** is either of square planar or pseudo octahedral geometry. The nickel(II) centre continguous to the propylene chain in $[NiLNi(H_2O)_2](ClO_4)_2$ (**8**), however, has octahedral configuration. Variable-temperature magnetic susceptibility data for $[MnLCu(H_2O)](Cl)(ClO_4)$ (**11**) reveal antiferromagnetic spin-exchange interaction ($\mathbf{H} = -2J\ S_1 \cdot S_2$) with $J = -31$ cm^{-1}. The cyclic voltammograms of $[CuLCu](ClO_4)_2 \cdot 2H_2O$ (**7**) and $[NiLNi(H_2O)_2](ClO_4)_2$ (**8**) show the occurrence of two stepwise reduction couples $M^{II}M^{II}/M^{II}M^{I}$ and $M^{II}M^{I}/M^{I}M^{I}$ and the corresponding comproportionation constants are 2.4×10^{12} and 1.7×10^{4}, respectively. The heterodinuclear complexes also undergo stepwise reduction, e.g. $[NiLCu]^{2+}$ with $E^1_{1/2} = -0.25$ V and $E^2_{1/2} = -1.45$ V, and $[NiLCo(H_2O)_2]^{2+}$ with $E^1_{1/2} = -1.10$ V and $E^2_{1/2} = -1.30$ V. In the hetero-tetranuclear complex $[\{Ni^{II}LFe^{III}(H_2O)\}_2(\mu\text{–}O)](ClO_4)_4$ (**12**) the electron transfer reactions take place in three steps at −0.04, −0.40 and −1.20 V. © 1998 Elsevier Science Ltd. Keywords: macrocylic complexes; phenolate bridged Schiff base; homo- and hetero-dinuclear complexes; dissimilar dicompartmental complexes; magnetochemistry; electrochemistry.

Studies on dinuclear metal complexes of Schiff base type dicompartmental tetraazadiphenol macrocyclic ligands have contributed significantly to the understanding of chemical behaviour of coupled systems [1–15]. Recently [16–20] there has been increasing attention in homo- and hetero-dinuclear complexes with different donor compartments to understand mutual influence of two metal ions upon their physiochemical properties. Metal complexes of dinucleating macrocyclic ligands with dissimilar coordination sites are of special importance because of their unprecedented electronic, magnetic and redox

* Author to whom correspondence should be addressed.

properties. Furthermore, it is possible to control properties of such systems by matching the size of the ligand hole and metal ions. Of particular interest is studying the effect of cavity size of the ligand compartment on redox potential of the complexes and stability of mixed-valence species.

The dinucleating macrocycles derived from 2 : 2 condensation of 2,6-diformyl-4-methyphenol and 1,3-diaminopropane was first studies by Pilkington and Robson [21]. Nag *et al.* [20] and Okawa *et al.* [16] have reported the synthesis of tetraaminodiphenol macrocylic ligands with different lateral chains. Herein, we report the synthesis, spectroscopic, magnetic properties and electrochemistry of homo- and hetero-dinuclear metal complexes having asymmetric compartments derived from a precursor magnesium complex $[Mg(H_2L)](NO_3)_2 \cdot 2H_2O$ (**1**).

EXPERIMENTAL

Materials

All reagents and solvents were purchased from commercial sources and used as such unless stated otherwise. 2,6-diformyl-4-methylphenol was obtained as described in the literature [22].

Preparation of the complexes

All the cobalt(II), iron(II) and manganese(II) complexes were prepared under oxygen-free dry nitrogen. The solvents were thoroughly degassed before use.

$[Mg(H_2L)](NO_3)_2 \cdot 2H_2O$ (**1**). This compound was prepared by slight modification of the method reported earlier [20a]. To a boiling solution of a mixture of $Mg(NO_3)_2 \cdot 6H_2O$ (2.56 g, 10 mmol), $Mg(OAc)_2 \cdot 4H_2O$ (2.14 g, 10 mmol) and 2,6-diformyl-4-methylphenol (3.28 g, 20 mmol) in methanol (150 cm^3) was added a solution (50 cm^3) of 1,2-diaminoethane (0.6 g, 10 mmol) over a period 2 h. After additional reflux for 1 h, a second solution (50 cm^3) of 1,3-diaminopropane (0.74 g, 10 mmol) in methanol was added again over a period of 2 h. The solution was refluxed for a total period of 6 h, which on concentration on a rotary evaporator gave orange-red crystals of the magnesium iminomethyl-diprotonated complex. This was filtered off and air dried. Yield : 5.25 g, 92%.

General procedure for the synthesis of the complexes $[M(H_2L)](ClO_4)_2$ (**2**–**6**) [M = Cu^{II}, Ni^{II}, Co^{II}, Fe^{II} or Mn^{II}].

A solution of complex **1** (0.57 g, 1 mmol) and the metal salt $M(ClO_4)_2 \cdot xH_2O$ (2 mmol) in methanol (30 cm^3) was stirred for 10 min, during which time the compound was separated as microcrystals. This was collected by filtration, washed with methanol and air dried. Yield : 70–80%.

$[CuLCu](ClO_4)_2 \cdot 2H_2O$ (**7**). A suspension of $[Cu(H_2L)](ClO_4)_2$ (**2**) (0.33 g, 0.5 mmol), $Cu(ClO_4)_2 \cdot 6H_2O$ (0.18 g, 0.5 mmol) and Et_3N (0.101 g, 1 mmol) in methanol (30 cm^3) was stirred for ca. 0.5 h when a clear green solution was obtained. The solution was kept at room temperature for overnight period, during which time green crystals deposited. The compound was recrystallized from MeOH–MeCN (1 : 1) mixture ; Yield : 0.34 g, 90%.

$[NiLNi(H_2O)_2](ClO_4)_2$ (**8**). To a solution of $[Ni(H_2L)](ClO_4)_2$ (**3**) (0.32 g, 0.5 mmol) in acetonitrile (50 cm^3) were added $Ni(ClO_4)_2 \cdot 6H_2O$ (0.18 g, 0.5 mmol) and Et_3N (0.101 g, 1 mmol) and refluxed for 0.5 h. The deep red solution was rotary evaporated to ca 20 cm^3, which on cooling (5°C) deposited bright red crystals. These were collected by filtration and recrystallized from MeOH ; Yield : 0.30 g, 82%.

$[NiLCu](ClO_4)_2$ (**9**). To a solution of **3** (0.32 gm, 0.5 mmol) in acetonitrile (50 cm^3) were successively added a solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.185 gm 0.5 mmol) in methanol (10 cm^3) and Et_3N (0.101 gm 1 mmol). The solution was stirred at room temperature for 0.5 h and allowed to undergo slow evaporation. The brown crystalline compound that deposited on standing was filtered and washed with cold MeOH ; Yield : 0.24 gm 68%.

$[NiLCo(H_2O)_2](ClO_4)_2$ (**10**). To a boiling solution of **3** (0.32 gm, 0.5 mmol) in acetonitrile (40 cm^3) were added sequentially $Co(ClO_4)_2 \cdot 6H_2O$ (0.18 g, 0.5 mmol) and Et_3N (0.101 g, 1 mmol). After refluxing for 0.5 h, part of the solvent (ca 20 cm^3) was removed in a stream of nitrogen and the solution kept in a refrigerator for several hours. The orange crystalline compound that deposited was collected by filtration and washed with MeOH ; Yield : 0.23 g, 62%.

$[Mn(H_2O)LCu(Cl)](ClO_4)$ (**11**). $[Mn(H_2L)(H_2O)_2](ClO_4)_2$ (**6**) (0.30 g, 0.5 mmol) in 1 : 1 MeCN–MeOH (30 cm^3) solution was first treated with a solution of $CuCl_2 \cdot 2H_2O$ (0.085 g, 0.5 mmol) in methanol (10 cm^3) and then Et_3N (0.101 g, 1 mmol). The solution was stirred for 1 h, concentrated (ca 10 cm^3) and cooled. The product that deposited in crystalline form was collected by filtration and dried in vacuum ; Yield : 0.19 g, 60%.

$[\{Ni^{II}LFe^{III}(H_2O)\}_2(\mu\text{-}O)](ClO_4)_4 \cdot 2H_2O$ (**12**). A mixture of **3** (0.65 g, 1 mmol), $Fe(ClO_4)_2 \cdot 6H_2O$ (0.36 g, 1 mmol) and Et_3N (0.202 g, 2 mmol) in acetonitrile (70 cm^3) was kept exposed to air and refluxed for 1 h. The deep red solution was filtered, concentrated (ca 30 cm^3) and set aside for several hours. The compound that deposited as red crystal was filtered and recrystallized from acetonitrile ; Yield : 0.48 g, 65%.

CAUTION! All the perchlorate salts reported here are potentially explosive and therefore should be handled with care.

Physical measurements

IR spectra were recorded on a Perkin–Elmer 783 spectrophotometer using KBr discs. Electronic spec-

tra were obtained with Shimadzu UV-160 and Hitachi U 3400 spectrophotometers over the UV–vis and near IR regions. The electrochemical data were obtained with a BAS 100B assembly (BAS) comprising a glassy carbon or a Pt working electrode, a Pt auxiliary electrode and a Ag-AgCl reference electrode. The concentration of the supporting electrolyte tetraethylammonium perchlorate (TEAP) was maintained to 0.1 mol dm^{-3}. The reference electrode was separated from the bulk solution with a salt bridge having a Vycor plug. IR compensation was achieved before each CV was recorded. The ferrocene/ferrocenium couple was used to monitor the reference electrode and was observed at 0.36 V. Room temperature and variable-temperature magnetic susceptibility measurements were made with a PAR model 155 vibrating sample magnetometer employing $[HgCo(NCS)_4]$ as a calibrant. Carbon, hydrogen and nitrogen analysis were carried out on a Perkin–Elmer 240 C elemental analyzer.

RESULTS AND DISCUSSION

Synthesis

The asymmetric macrocyclic magnesium complex $[Mg(H_2L)](NO_3)_2 \cdot 2H_2O$ (**1**) was synthesized by the sequential addition of 1 equiv. each of 1,2-diaminoethane and 1,3-diaminopropane to a boiling methanol solution containing $Mg(NO_3)_2 \cdot 6H_2O$, $Mg(OAc)_2 \cdot 4H_2O$ and 2,6-diformyl-4-methylphenol (2 equiv.) over a period of several hours. The conversion of the Mg-complex (**1**) to the mononuclear complexes $[M(H_2L)](ClO_4)_2$ (**2**–**6**; M = Cu^{II}, Ni^{II}, Co^{II}, Fe^{II} and Mn^{II}) by transmetallation reaction was achieved in good yield. The homo- and hetero-dinuclear complexes (**7**–**11**) were obtained by reacting an appropriate mononuclear complex with its complimentary metal salt and triethylamine. However, when $[Ni(H_2L)](ClO_4)_2$ was reacted with $Fe(ClO_4)_2 \cdot 6H_2O$ in open air a heterotetranuclear complex $[\{Ni^{II}LFe^{II}(H_2O)\}_2(\mu\text{-}O)](ClO_4)_4$ (**12**) was obtained. The formation of the different types of metal complexes are illustrated in Scheme 1.

Characterization

The analytical data of the compounds (Table 1) are consistent with the proposed compositions. The characteristic band(s) due to $\nu_{C=N}$ in all the complexes are observed between 1640 and 1620 cm^{-1}. Moreover, all the dinuclear complexes (**7**–**11**) show a group of structured bands in the range 1100–1200 cm^{-1}, and at ca 630 cm^{-1} due to either metal-bound or hydrogen bonded perchlorates.

Magnetic properties

The room temperature magnetic moments of the complexes are given in Table 1. The diamagnetic behaviour of the mononuclear nickel(II) complex **3** is indicative of the square-planar geometry of the metal ion. The location of the low-spin nickel(II) centre in the smaller ligand compartment provided by the —$(CH_2)_2$— chain in preference to that having the —$(CH_2)_3$— chain can be concluded on the basis of earlier studies [16a,20a]. In retrospect, this also leads to conclude that the magnesium ion in the precursor complex **1** is positioned in the smaller ligand compartment.

The room temperature diamagnetic nature of the dicopper(II) complex **7** is indicative of strong intramolecular antiferromagnetic spin-exchange interaction. The magnetic moment of the dinickel(II) complex $[NiLNi(H_2O)_2](ClO_4)_2$ (**8**) at room temperature (3.18 μ_B) is consistent with the value expected for a combination of a low-spin ($S = 0$) and a high-

Table 1. Analytical data and magnetic moments for the complexes

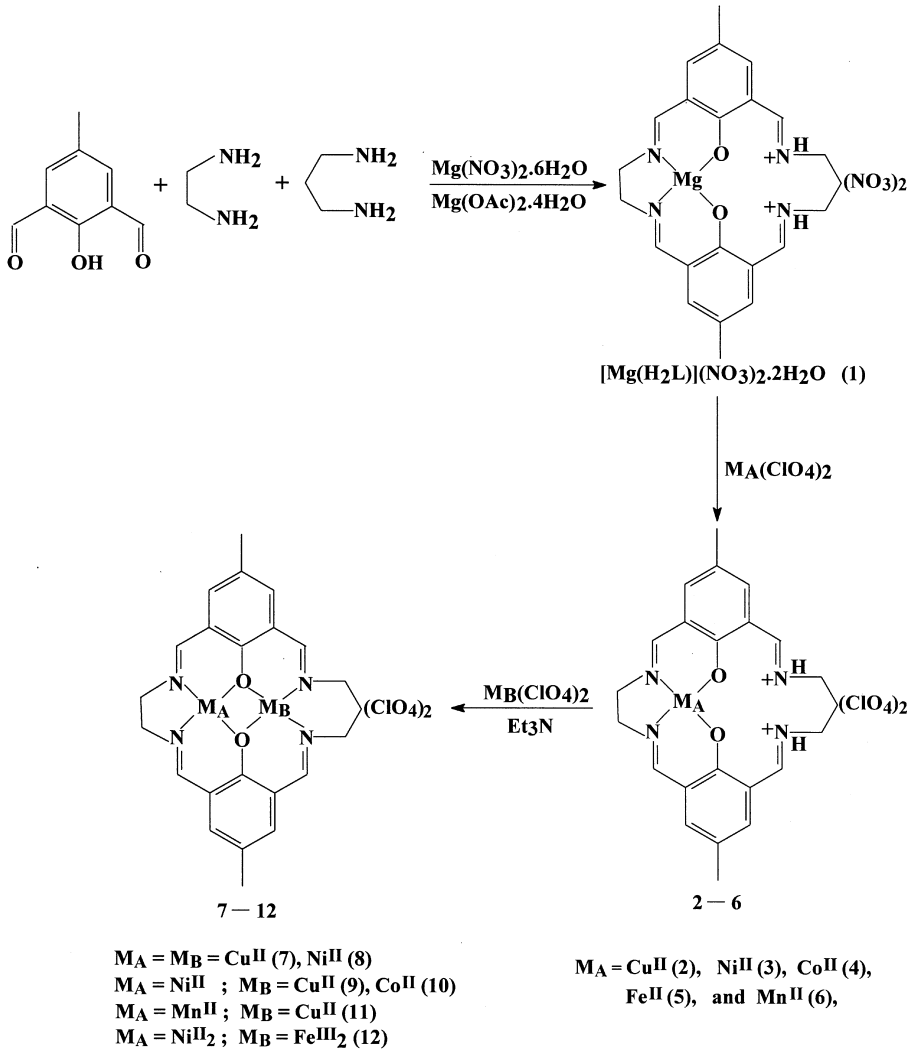

Scheme 1.

spin ($S = 1$) nickel(II) centers. It should be noted that similar magnetic behaviour was observed for the structurally characterized analogous dinickel(II) complex [20a] derived from the saturated macrocyclic ligand version of H_2L. The room temperature magnetic moment of the heterodinuclear $Ni^{II}Cu^{II}$ complex **9** (1.75 μ_B) is again in agreement with the value expected for a compound in which the nickel(II) ion is spin-paired. In the case of $Ni^{II}Co^{II}$ complex **10,** however, the observed moment (4.84 μ_B) is considerably higher than the expected value (3.87 μ_B for $S = 2$ and $g = 2.0$), presumably due to the significant contribution of orbital magnetic moment of the cobalt(II) centre. The tetranuclear complex $[\{NiL\text{-}Fe(H_2O)\}_2(\mu\text{-}O)](ClO_4)_4$ (**12**), on the other hand, shows a magnetic moment 2.07 μ_B (at 300 K), which is indicative of a strong intramolecular (Fe^{III}—O—Fe^{III}) antiferromagnetic spin-exchange interaction.

Variable temperature magnetic susceptibility measurement has been carried out for the $Mn^{II}Cu^{II}$ complex **11** between the temperature range 85 and 293 K (Fig. 1). The susceptibility data have been analyzed using the isotropic Heisenberg-Dirac-van Vleck model with the spin Hamiltonian $\mathbf{H} = -2JS_1 \cdot S_2$. Nonlinear least-squares fitting of the theoretical expression (1)

$$\chi_M = \frac{N\beta^2 g^2}{kT}\left[\frac{10 + 28e^{6J/kT}}{5 + 7e^{6J/kT}}\right] \qquad (1)$$

to the experimental data has been made by varying J and g. In eqn (1) the symbols have their usual meanings. Since the measurements were limited up to 85 K, additional terms due to temperature independent paramagnetism and contribution of the mononuclear paramagnetic impurity were not considered. The room temperature magnetic moment of **11** is lower than the spin-only value and decreases with decreasing temperature. The observed behaviour is indicative of

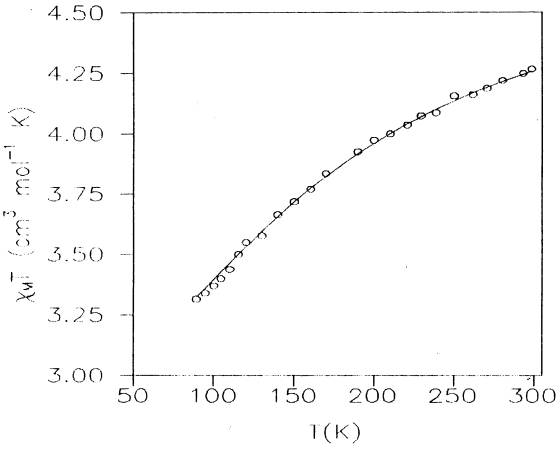

Fig. 1. Thermal variations of the product of the molar magnetic susceptibility with temperature (o) for the complex **11**. The solid lines represent the calculated values using the best-fit parameters given in the text.

intramolecular antiferromagnetic spin exchange interaction. Figure 1 shows that the $\chi_M T$ vs T data for complex **11** can be satisfactorily fitted to eqn (1) with $J = -31$ cm^{-1} and $g = 2.04$. The exchange integral of **11** is similar to the values ($-J = 30$–36 cm^{-1}) reported for several $Cu^{II}Mn^{II}$ complexes derived from related macrocyclic ligands [13c,23].

Electronic spectra

The electronic spectral data for the complexes are given in Table 2. The mononuclear complexes (**2**–**6**) show the azomethine π–π^* band at ca 410 nm whereas for the dinuclear complexes (**7**–**11**) it occurs at shorter wavelengths (360–385 nm). Furthermore, the extinction coefficients of the π–π^* band of the dinuclear complexes **7**–**11** (9000–10000 dm^3 mol^{-1} cm^{-1}) are significantly lower than those of the mononuclear complexes (13000–14000 dm^3 mol^{-1} cm^{-1}). This probably indicates that the uncoordinated protonated azomethine moieties act as a strong chromphore.

9 $[NiLCu](ClO_4)_2$	670(49), 375(9770)
10 $[NiLCo(H_2O)_2](ClO_4)_2$	960(10), 540(sh), 380(9880)
11 $[MnL(H_2O)Cu(Cl)](ClO_4)$	540(145), 365(12810)
12 $[\{NiLFe(H_2O)\}_2(\mu\text{-}O)](ClO_4)_4 2H_2O$	655(38), 370(9150)

The dicopper(II) complex (**7**) exhibit a copper-based d–d band in the visible region at ca 560 nm. The spectral feature of the dinickel(II) complex (**8**) shows three bonds at ca 990, 525 and 385 nm, which can be attributed to the octahedral nickel(II) centre with the transitions due to $^3A_{2g} \rightarrow {}^3T_{2g}$, $^3A_{2g} \rightarrow {}^3T_{1g}$ and $^3A_{2g} \rightarrow {}^3T_{1g}(P)$, respectively. The extinction coefficient of the band at 385 nm ($\varepsilon = 9760$ M^{-1} cm^{-1}) indicates that the $^3A_{2g} \rightarrow {}^3T_{1g}(P)$ transition must be admixed with the intraligand π–π^* transition. In the visible range the $Ni^{II}Cu^{II}$ complex (**9**) exhibits a d–d band due to the copper(II) centre at 670 nm, while in the $Ni^{II}Co^{II}$ complex (**10**) two d–d bands are observed at ca 960 and 540 nm due to the octahedral cobalt(II) centre. It may be noted that in square planar mononuclear nickel(II) complex only an ill-defined shoulder is observed at ca 530 nm, which apparently gets obscured in the heterodinuclear complexes **8**–**10**. Finally, the $Mn^{II}Cu^{II}$ complex (**11**) which shows a band at 540 nm ($\varepsilon = 145$ M^{-1} cm^{-1}) is clearly due to the d–d transition of the copper(II) centre because spin-forbidden d–d transition due to manganese will be too weak.

Electrochemistry

The electrochemical properties of the complexes have been studies by cyclic voltammetric and differential pulse voltammetric measurements. For oxidation acetonitrile solution and a Pt electrode was used, while for reduction DMSO solution and a glassy carbon electrode was used. The electrochemical data of the complexes are given in Table 3.

Of the five mononuclear complexes **2**–**6,** $[Cu(H_2L)](ClO_4)_2$ (**2**) and $[Ni(H_2L)](ClO_4)_2$ (**3**) do not show any electrochemical response during oxidation up to 1.5 V. On the other hand, the complexes of cobalt(II), iron(II) and manganese(II) undergo nearly reversible or quasireversible oxidation reaction. In the case of $[Co(H_2L)(H_2O)_2](ClO_4)_2$ (**4**) the Co^{II}/Co^{III} couple has the $E_{1/2}$ value of -0.03 V whose peak to peak separation (ΔE_p) increases from 140 to 200 mV with the increase of scan rate from 50 to 500 mV s^{-1}. The behaviour of $[Mn(H_2L)(H_2O)_2](ClO_4)_2$ (**6**) is quite similar to that of **4** with $E_{1/2} = -0.00$ V and ΔE_p changes from 120 to 180 mV as the scan rate (v) is varied from 50 to 500 mV s^{-1}. By contrast, the variation of ΔE_p for $[Fe(H_2L)(H_2O)_2(ClO_4)_2$ (**5**) occurs in a narrow range 70–90 mV from $v = 50$–500 mV s^{-1}, and the $E_{1/2}$ of the Fe^{II}/Fe^{III} couple occurs at -0.20 V. The facile oxidation of the iron(II) complex at a negative potential is noteworthy. The criteria

[a] Scan rate, 100 mV s^{-1}.
[b] Irreversible peak potential from DPV.

of quasireversibility viz (i) a linear relation between current height (i_{pa} or i_{pc}) and square root of scan rate (v); (ii) the ratio of i_{pa} to i_{pc} almost unity; and (iii) the invariance of $E_{1/2}$ with variation of scan rate have been verified for all the three compounds. Furthermore, one electron transfer that occurs during oxidation $M^{2+} = M^{3+} + e^-$ has been established by coulometric measurements carried at a potential more positive to $E_{1/2}$ by 0.2 V.

As compared to oxidation, the electrochemical reduction of the mononuclear complexes lack well defined features. They either undergo irreversible reduction or following electron transfer dissociation of the metal ion from the macrocyclic ring takes place. Thus, while **3** and **4** get irreversibly reduced at −0.95 and −1.0 V, respectively, the behaviour of complexes **2, 5,** and **6** are complicated by demetallation.

The cyclic voltammogram of [CuL-Cu]$(ClO_4)_2 \cdot 2H_2O$ (**7**) exhibits two redox couples at −0.40 and −1.15 V with their peak to peak separation (ΔE_p at $v = 100$ mV s^{-1}) of 70 and 85 mV, respectively, indicating that both the couples are practically reversible in nature. Differential pulse voltammetric measurements also revealed the occurrence of two waves with equal pulse heights at the indicated potentials. Coulometric analyses have established that each of the redox couples are associated with one electron transfer process, that is, $Cu^{II}Cu^{II}/Cu^{II}Cu^{I}$ and $Cu^{II}Cu^{I}/Cu^{I}Cu^{I}$. The wave at −0.40 V seems to be due to the reduction of the Cu^{II} centre located at the —$(CH_2)_3$— chain and the wave at −1.15 V to the reduction of the Cu^{II} centre located at the —$(CH_2)_2$— site. This assignment seems reasonable [24] because the greater flexibility of the —$(CH_2)_3$— chain (with respect to the more rigid —$(CH_2)_2$— chain) makes it easier for the copper(II) ion go get reduced and undergo reorganization to the pseudotetrahedral geometry of copper(I).

It is of interest to compare the redox potentials $E^1_{1/2}$ and $E^2_{1/2}$ of the present dicopper(II) complex (designated as *2*,*3*-derivative for the lateral chains —$(CH_2)_2$— and —$(CH_2)_3$—) with the analogous (*2*, *2*) [−0.55 and −1.10 V] and (*3*, *3*) [−0.50 and −0.95 V] macrocyclic complexes [24]. Clearly, the $E^1_{1/2}$ value of the (*2*, *3*) complex (−0.40 V) is greater than those of the (*2*, *2*) [−0.55 V] and (*3*, *3*) [−0.50 V] complexes, whereas the $E^2_{1/2}$ value of the (*2*, *3*) [−1.15 V] is lower than those of the (*2*, *2*) [−1.10V] and (*3*, *3*) [−0.95 V] complexes. The easier reduction of the first copper(II) centre in the (*2*, *3*) complex indicates greater stability of its mixed-valence species. The equilibrium constants (K_c) for the comproportionation reaction $2M^{II}M^{I} = M^{II}M^{II} + M^{I}M^{I}$ is obtained using eqn (2)

$$K_c = 10^{\Delta E/0.059} \quad (2)$$

where $\Delta E = [E^1_{1/2} - E^2_{1/2}]$ in volt. The values of K_c are: 2.4×10^{12} (for *2*, *3*), 3.8×10^9 (for *2*, *2*) and 5.1×10^7 (for *3*, *3*) [24].

Figure 2 shows that the two nickel(II) centres in $[NiLNi(H_2O)_2](ClO_4)_2$ (**8**) undergo stepwise reduction. In the first step one electron transfer reaction of $Ni^{II}Ni^{II}$ to $Ni^{II}Ni^{I}$ takes place almost reversibly since for this couple i_{pc}/i_{pa} ratio remains unity and ΔE_p varies only to a small extent from 70 to 110 mV with the increase of scan rate from 50 to 500 mV s^{-1}, while the $E_{1/2}$ value (−0.95 V) remains unchanged. Moreover, the linear dependence of i_{pc} on $\sqrt{v}$ has been observed. By comparison to the reduction potential ($E_{pc} = -0.95$ V) of the mononuclear nickel(II) complex (**3**), the first electron transfer reaction in **8** can be attributed to the square-planar nickel(II) site. The second couple involving $Ni^{II}Ni^{I}/Ni^{I}Ni^{I}$ is quasireversible in nature with $E_{1/2} = -1.20$ V and $\Delta E_p = 140$ mV at $v = 100$ mV s^{-1}. However, as may be noted in Fig. 2, in the case of the reoxidation peak relative to the most cathodic step is rather high and the ratio of i_{pc} to i_{pa} is ca 0.8. When the scan rate is

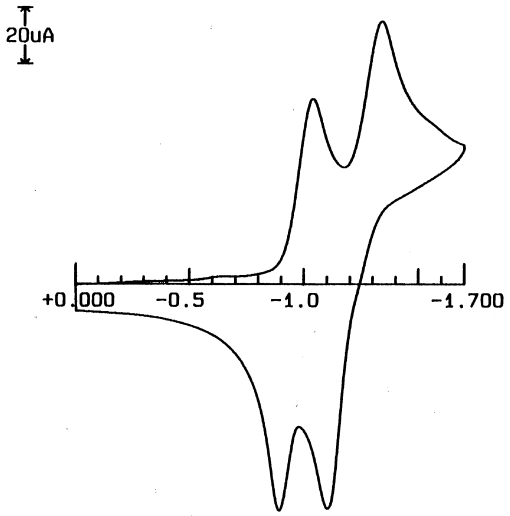

Fig. 2. Cyclic voltammogram of **8** in CH_3CN with a glassy carbon electrode at a scan rate of 100 mV s^{-1}. Concentration of the complex: 1.0×10^{-3} mol dm^{-3}; concentration of supporting electrolyte $[Et_3N](ClO_4)$: 0.1 mol dm^{-3}.

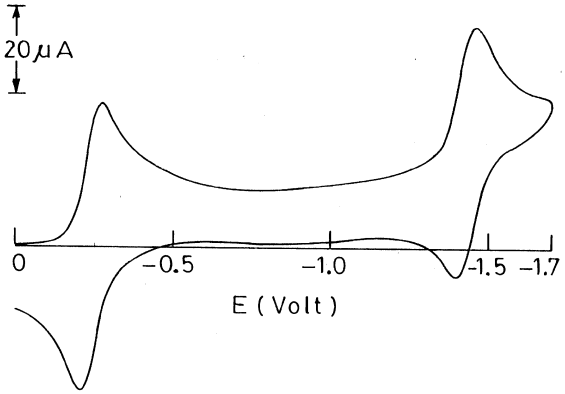

Fig. 3. Cyclic voltammogram of **9** in CH_3CN with a glassy carbon electrode at a scan rate of 100 mV s^{-1}. Concentration of the complex: 1×10^{-3}; concentration of supporting electrolyte $[Et_4N](ClO_4)$: 0.1 mol dm^{-3}.

increased, the augmentation in height of the anodic peak occurs to a greater extent relative to that of the cathodic peak. This indicates that the reduced $Ni^{I}Ni^{I}$ species is weakly adsorbed on the electrode surface [25]. From the difference in potentials ($\Delta E_{1/2}$) of the two redox couples in **8** (0.25 V) the comproportionation constant K_c is estimated to be 1.7×10^4.

The electrochemistry of the heterodinuclear [NiL-Cu]$(ClO_4)_2$ complex **9** (Fig. 3) shows two well-separated reversible redox couples with their $E_{1/2}$ values of -0.25 and -1.45 V. For each couples ΔE_p value (60 mV) remains invariant with the change of scan rate. The first redox couple is evidently due to Cu^{II}/Cu^{I} [13,26], while the second is due to Ni^{II}/Ni^{I} [13b,16d]. It may be noted that in **9** the $E^1_{1/2}$ value for the copper(II) centre is shifted to a more positive potential (-0.25 V) relative to that of **7** (-0.40 V), while the value of $E^2_{1/2}$ for the nickel(II) centre is more negative in **9** (-1.45 V) relative to that of **8** (-1.20 V). The observed differences in potentials of the heterodinuclear complex *vis-à-vis* the homodinuclear complexes must be related to their structures. Although crystallographic data for these complexes are not available at this stage, it is reasonable to assume that in the $Ni^{II}Cu^{II}$ complex (**9**) the square-planar nickel(II) centre located at the smaller cavity has shorter Ni—O and Ni—N distances relative to the Cu—O and Cu—N distances located at the larger cavity. As a result, the nickel(II) centres is more electron-rich compared to copper(II) centre. Consequently, it will be easier to add an electron to the copper(II), while it will be more difficult to reduce the nickel(II) centre.

Figure 4 shows the cyclic voltammogram of the heterodinuclear $Ni^{II}Co^{II}$ complex (**10**) which undergoes stepwise reversible reductions at potentials -1.10 V ($\Delta E_p = 70$ mV at $v = 100$ mv s^{-1}) and -1.30 V ($\Delta E_p = 75$ mV at $v = 100$ mv s^{-1}). By taking into consideration the reduction potentials of the relevant mononuclear complexes **3** or **4,** the redox couple at -1.10 V for **10** is tentatively assigned to Ni^{II}/Ni^{I} and the other couple at -1.30 V to Co^{II}/Co^{I}.

The oxo-bridged $Ni^{II}_2Fe^{III}_2$ complex (**12**) exhibits complex electrochemical responses in the potential range 0.2 to -1.17 V. Figure 5 shows three stepwise reductions at the potentials -0.04, -0.40 and -1.20 V, of which the first and second steps are one electron transfer processes whereas the third one is a two electron transfer reaction. The differential pulse voltammogram shows that the height of third step is almost double of the other two steps. The ΔE_p value for the third couple ($\Delta E_p = 75$ mV at $v = 100$ mV s^{-1}) is indicative of a quasireversible electron transfer process. In the light of a previous study [27] the overall electron transfer reactions may be tentatively considered in the following way

$$Ni^{II}Fe^{III}—O—Fe^{III}Ni^{II} \xrightarrow[-0.04\,V]{e^-} Ni^{II}Fe^{II}—OH—Fe^{III}Ni^{II}$$

$$e- \Big| \; -0.40\,V \downarrow$$

$$2Ni^{I}Fe^{II} \underset{-1.20\,V}{\overset{2e^-}{\rightleftharpoons}} 2Ni^{II}Fe^{II}$$

(Received 20 October 1997; accepted 12 January 1998)

Abstract—The reaction between $[Mn(CO)_5]Br$ and $Na[(OPPh_2)_2N]$ in argon atmosphere affords the preparation of $Mn(CO)_4[(OPPh_2)_2N]$ as a white powder. During attempts to grow X-ray diffraction quality crystals the tetracarbonylmanaganese(I) complex was oxidized and deep purplish-blue crystals were isolated. An X-ray diffractometry analysis has revealed the identity of the new product, i.e. the manganese(III) derivative, $Mn[(OPPh_2)_2N]_3 \cdot CH_2Cl_2$. The compound crystallizes in the triclinic space group *P*-1 and the crystal contains discrete, monomeric molecules of $Mn[(OPPh_2)_2N]_3$. The imidodiphosphinato groups are coordinated through both oxygen atoms of a ligand moiety to the central manganese atom. The resulted coordination octahedron exhibits a tetragonally elongated distortion as reflected by the Mn—O bond lengths [av. 2.130(16), 1.945(6) Å] and *cis* O—Mn—O bond angles [endocyclic (av.) 90.5(0.6)°; exocyclic (range) 87.2(0.1)–92.7(0.1)°]. The structure of the title compound is compared with those of other monomeric manganese(III) derivatives containing MnO_6 cores with various degrees of distortion. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: manganese(III) complexes; imidodiphosphinato.

Recently we have described the synthesis and the molecular structure of the monomeric complex $Mn(CO)_4[(SPPh_2)_2N]$ [1]. Our interest in the investigation of metal complexes containing such ligands prompted us to attempt the preparation of the dioxo analog in order to establish structural changes which might be produced by changes in the chalcogen atoms attached to phosphorus. Several previous studies using phosphorus ligands have proved that modification in the organic groups or chalcogen atoms at phosphorus may result in dramatic structural changes [2] not only in the case of Main Group metal compounds [e.g. lead compounds, $Pb(S_2PR_2)_2$ [3,4], inorganic and organoantimony(III) and antimony(V) compounds [5], but also for transition metal compounds [e.g. $Ni[(SPR_2)_2N]_2$, R = Me [6], Ph [7,8] exhibit a tetrahedral NiS_4 core, $Ni[(SPMe_2)(SPPh_2)N]_2$, has a square-planar NiS_4 core [8], while the dinuclear $\{Ni_2[(OPPh_2)_2N]_4(H_2O)\}$ contains two different octahedral NiO_6 cores [9].

We wish to report here the molecular structure of the manganese(III) complex, $Mn[(OPPh_2)_2N]_3 \cdot CH_2Cl_2$, produced via aerial oxidation during recrystallization of the product isolated by reacting $[Mn(CO)_5]Br$ and $Na[(OPPh_2)_2N]$. It should be noted that the oxygen-donor ligands are known to stabilize manganese(III) species [10].

EXPERIMENTAL

$[Mn(CO)_5]Br$ [11] was obtained according to literature. IR spectra were obtained in KBr disk (4000–200 cm^{-1}) using a Perkin–Elmer 283B spectrometer. ^1H, ^{13}C and ^{31}P NMR spectra were recorded using Varian

* Author to whom correspondence should be addressed.

Gemini 200 and Varian VXR 300S instruments. The chemical shifts are reported in ppm relative to TMS and H_3PO_4 85%, respectively.

Preparation of tetraphenylimidodiphosphinic acid, $(OPPh_2)_2HN$ [12]

A slight excess of H_2O_2 30% (14 ml) was added dropwise to a suspension of $(PPh_2)_2NH$ (20 g, 0.05 mol) in 200 ml THF, and the reaction mixture was stirred over night. The resulting white, solid product was filtered, washed with THF and dried in air. Yield: 21 g (97%), m.p. = 275–277°C (lit. [12] 268–269°C). IR (KBr, cm^{-1}): ν(PO) 1120 s, 1105 s; $\nu_{as}(P_2NH)$ 920 s. ^{1}H NMR ($CDCl_3$, 200 MHz): 7.35 m (3H, C_6H_5-meta + para), 7.80 ddd [2H, C_6H_5-ortho, ^3J(PH) 12.8, ^3J(HH) 7.5, ^4J(HH) 1.5 Hz]. ^{13}C NMR ($CDCl_3$, 50 MHz): 128.24 m [C_m, ^3J(PC) 13.0 Hz], 131.96 s (C_p), 131.96 m [C_o, ^2J(PC) 10.9 Hz], 134.33 d [C_i, ^1J(PC) 101.6 Hz]. ^{31}P NMR ($CDCl_3$, 121.4 MHz): 19.4 s.

Preparation of sodium tetraphenylimidodiphosphinate, $Na[(OPPh_2)_2N]$ [13]

$(OPPh_2)_2NH$ (4.5 g, 10.8 mmol) and NaOMe (0.6 g, 11 mmol) in 100 ml ethanol were stirred for 6 h, at room temperature. The insoluble solid product was filtered, and the solvent was removed from the clear filtrate in a rotary evaporator to dryness. The remaining white solid was extracted several times in a Soxhlet apparatus using MeCN as solvent. The white crystals of the title compound which deposited from the MeCN extract were filtered and dried *in vacuo*. Yield: 3.3 g (70%), m.p. = 335–338°C. IR (KBr, cm^{-1}): $\nu_{as}(P_2N)$ 1260 vs, 1220 vs; ν(PO) 1140 vs, 1120 s. ^{1}H NMR (CD_3OD, 300 MHz): 7.18 m (3H, C_6H_5-meta + para), 7.72 ddd (2H, C_6H_5-ortho, ^3J(PH) 12.3, ^3J(HH) 7.7, ^4J(HH) 1.9). ^{13}C NMR (CD_3OD, 75 MHz): 128.52 m [C_m, ^3J(PC) 12.7 Hz], 130.64 s (C_p), 132.50 t [C_o, ^2J(PC) 9.8 Hz], 140.86 d [C_i, ^1J(PC) 134.5 Hz]. ^{31}P NMR (CD_3OD, 121.4 MHz): 11.3 s.

Reaction of $[Mn(CO)_5]Br$ *with* $Na[(OPPh_2)_2N]$

A stoichiometric amount of $Na[(OPPh_2)_2N]$ (1.1 g, 2.55 mmol) was added to a solution of $[Mn(CO)_5]Br$ (0.7 g, 2.55 mmol) in 100 ml anhydrous THF. The reaction mixture was stirred under reflux until the IR spectrum of the crude solution remained unchanged in the region characteristic for CO stretching vibrations. After 0.5 h the formation of a white solid was noted. The NaBr was filtered off and the removal of the solvent from the clear filtrate under vacuum resulted in an oily product. Recrystallization of this material from a THF/*n*-hexane (1 : 1) solvent mixture resulted in isolation of $Mn(CO)_4[(OPPh_2)_2N]$ as a white solid. Yield: 0.53 g (36%), m.p. = 170–175°C (dec.). IR (KBr, cm^{-1}): $\nu_{as}(P_2N)$ 1243 vs; ν(PO) 1126 vs, 1097 s; ν(CO) 2035 vs, 2008 vs, 1983 vs, 1924 vs.

X-ray crystal determination of $Mn[(OPPh_2)_2N]_3$

Empirical formula $C_{72}H_{60}N_3O_6P_6Mn{\cdot}CH_2Cl_2$, M = 1388.9, triclinic, $a = 13.572(1)$, $b = 13.852(1)$, $c = 18.761(2)$ Å, $\alpha = 95.44(2)$, $\beta = 98.50(2)$, $\gamma = 97.08(2)^\circ$, $U = 3438.7(5)$ Å^3, $F(000) = 1436$, $Z = 2$, $D_C = 1.341$ g cm^{-3}, space group P-1, μ(Cu–K_α) = 4.031 mm^{-1}, crystal size $0.28 \times 0.26 \times 0.24$ mm.

Purplish blue prisms of $Mn[(OPPh_2)_2N]_3$. [Anal. Calc. for $C_{72}H_{60}N_3O_6P_6Mn{\cdot}CH_2Cl_2$: C, 63.1; H, 4.5; N, 3.0; Found: C, 62.8; H, 4.4; N, 2.8%; ES (CH_2Cl_2, cm^{-1}): 32,570, 18,250] were obtained from CH_2Cl_2/*n*-hexane solution. Data were collected at room temperature (293 K) on a Siemens P4/PC four-circle diffractometer with parallel-graphite crystal monochromator (Cu–K_α radiation, $\lambda = 1.54178$ Å), for 9660 reflections of which 9194 were independent reflections [$R_{int} = 6.20\%$] and 7287 ($F^2 > 2.0\sigma(F^2)$) were used in the full-matrix least-squares refinement with the SHELXL-97 program system [14]. The structure was solved by Patterson methods [15] and difference Fourier synthesis revealed the positions for the other non-hydrogen atoms. All non-hydrogen atoms were refined anisotropically, and hydrogen atoms were calculated as a riding model with isotropic U. Semi-empirical absorption correction was applied based on ψ-scan (transmission: min. 0.0128, max. 0.7645). The CH_2Cl_2 solvent molecule was distorted and was modeled [14] in two positions for each atom; the site occupation factors were 0.30/0.70 for C(1a)/C(1b), Cl(1)/Cl(1a) and Cl(2)/Cl(2a), respectively. The final R values are $R_1 = \Sigma|F_o - F_c|/|\Sigma|F_o| = 6.24\%$ and $wR_2 = [\Sigma(w|F_o - F_c|)^2/\Sigma w|F_0|^2]^{1/2} = 15.83\%$ with weights $w^{-1} = \sigma^2(F_o^2) + (0.1003P)^2 + 2.8031P$, where $P = (F_o^2 - 2F_c^2)/3$; goodness-of-fit 1.009. The residual electron density from a final difference Fourier synthesis was in the range of 0.523, -0.753 eÅ^{-3}.

RESULTS AND DISCUSSION

The tetraphenylimidodiphosphinic acid and its sodium salt were prepared using previously described procedures [12,13], and were characterized by IR and multinuclear NMR spectroscopy. The resonance signals observed in the ^{1}H and ^{13}C NMR spectra of both compounds exhibit the expected pattern due to the proton–proton and proton–phosphorus, and carbon–phosphorus couplings, respectively. A significant increase in the ^1J(PC) coupling constant from 101.6 Hz in the free acid to 134.5 Hz in the sodium salt was noted. In addition, when the ^{13}C NMR spectrum of $Na[(OPPh_2)_2N]$ was recorded in DMSOd_6, the resonance for the *ipso* carbon was further split due to the coupling to the second phosphorus atom of the ligand unit [^1J(PC) = 129.0 Hz, ^3J(PC) = 4.3 Hz]. However, ^{31}P NMR spectra show only one broad resonance for

both phosphorus atoms, in the sodium salt the signal being shifted about 10 ppm to lower field due to delocalization of the electrons over the OPNPO fragment.

The carbonylmanganese(I) complex, $Mn(CO)_4[(OPPh_2)_2N]$, was prepared by methatesis according to eq (1) and isolated as a white solid:

$$[Mn(CO)_5]Br + Na[(OPPh_2)_2N] \rightarrow Mn(CO)_4[(OPPh_2)_2N] + CO + NaBr \quad (1)$$

Its IR spectrum shows a strong absorption assigned to $\nu_{as}(P_2N)$ stretching vibration at about 1243 cm^{-1} which is consistent with the coordination of the ligand in its deprotonated form (cf $\nu_{as}(P_2NH)$ 920 cm^{-1} in $(OPPh_2)_2NH$, and $\nu_{as}(P_2N)$ 1260, 1220 cm^{-1} in $Na[(OPPh_2)_2N]$). In the carbonyl stretching region the expected four bands were observed (2035 vs, 2008 vs, 1983 vs, 1924 vs cm^{-1}, in KBr pellet, and 2051 vs, 2012 vs, 1980 m, and 1932 m cm^{-1}, in *n*-hexane solution), corresponding to non-degenerate ν(CO) vibrations $(2A_1 + B_1 + B_2)$ [16]. This behavior is characteristic of psuedooctahedral complexes with a carbonyl C_{2v} local symmetry, and is consistent with the coordination of the imidodiphosphinato ligand through both oxygen atoms.

A monomeric structure (**a**) might be proposed for this carbonylmanganese complex in solid state, similar to that established for the dithio analog [1]. However, a dimeric structure of type (**b**) cannot be ruled out.

Several attempts to grow X-ray quality crystals of $Mn(CO)_4[(OPPh_2)_2N]$ were performed using $CHCl_3$/hexane and CH_2Cl_2/hexane solutions but always decomposition of the starting material was achieved. The initial colorless solution became violet within few days and deposited purplish-blue crystals of the manganese(III) complex $Mn[(OPPh_2)_2N]_3$ (as proved by X-ray diffractometry—see below) together with an amorphous brown solid (probably MnO_2). The decomposition process might be described by eqn (2):

$$3\,Mn(CO)_4[(OPPh_2)_2N] + 2\,O_2 \rightarrow Mn[(OPPh_2)_2N]_3 + 2\,MnO_2 + 12\,CO \quad (2)$$

Attempts to obtain the same manganese(III) compound by oxidizing the manganese(II) complex, $Mn[(OPPh_2)_2N]_2$ [17], with hydrogen peroxide both in water suspension or chloroform solution have failed. No color change was observed when air was bubbled about out 6 h through a $CHCl_3$ solution of $Mn[(OPPh_2)_2N]_2$. However after a long period of time during which the solvent was slowly evaporated a purplish-blue solid was finally obtained. This was soluble in chloroform and was proved to be the corresponding manganese(III) complex. The compound was very stable and no decomposition was observed after several weeks in open atmosphere.

Table 1 contains selected bond distances and angles in $Mn[(OPPh_2)_2N]_3$ and Fig. 1 shows the ORTEP-like view [15] of the molecular structure with the atom numbering scheme.

The crystal contains discrete molecules of the manganese(III) complex, in which the imidodiphosphinato ligands act as bidentate moieties. As expected the PNP fragment, which in the free acid has a linear orientation, becomes now angular [av. 124.6(6)°] to allow the coordination of both oxygen atoms to the metal. Although significant differences in the manganese–oxygen bond lengths are noted (see below), the corresponding phosphorus–oxygen distances are equivalent [av. 1.518(9) Å] as are the phosphorus–nitrogen bonds [av. 1.587(7) Å]. These values might be considered of intermediate magnitude between single and double phosphorus–oxygen [cf $Ph_2P(=S)OMe$ [18]: P—O 1.60(2) Å; $Ph_3P(=O)$ [19]: P=O 1.487(2) Å] and phosphorus-nitrogen bonds [cf $Me—S—PPh_2=N—Ph_2P=S$ [20]: P—N 1.610(4), P=N 1.568(4) Å]. However the considerable double bond character of both bond types is evident.

The six-membered MnO_2P_2N inorganic rings thus formed are not planar despite the averaging in bond lengths due to some delocalization of π-electrons over the OPNPO fragment. They exhibit a twisted boat conformation as reflected by the torsion angles and the deviations from the MnO_2 planes within a MnO_2P_2N ring, respectively (Table 2).

For 6-coordinate complexes the octahedral geometry is the most common. However in many cases different degrees of distortion from the octahedron have been established [21], and this is the case for various manganese(III) complexes with chelating oxo ligands, MnL_3, resulting in a MnO_6 core (Fig. 2). A first type of distortion is the tetragonal distortion, that is either elongation or compression along one of the fourfold rotational axes of the octahedron, resulting in a reduction of symmetry from O_h to D_{4h}. This is the case of the previously reported β- and γ-forms of Mn(acetilacetonato)$_3$ and the distortion has been

[a] Esds for average bond length are calculated from the equation $\sigma = \left\{\left[\sum_{i=1}^{i=N}(x_i - x)^2/(N-1)\right]\right\}^{1/2}$, where x_i is ith bond length and x is the mean of the N equivalent bond lengths. An analogous formula is used for the calculation of esds for average bond angles [25].

[e] Calculated from published atomic coordinates.

discussed in connection with the Jahn-Teller effect. The title compound, $Mn[(OPPh_2)_2N]_3$, exhibits a similar tetragonal elongation of the MnO_6 octahedral core (for comparative molecular parameters see Table 3): the axial Mn—O bond distances [av. 2.130(16) Å] are about 0.18 Å longer than the equatorial Mn—O bond distances [av. 1.946(7) Å]. The distortion of the oxygen atom arrangement around the metal is also reflected in the magnitude of the O—Mn—O angles. An elongation or compression along one of the three-fold rotational axes of the octahedron might also be expected and results in a trigonal antiprism (D_{3h}). The Mn(tropolonato)$_3$ complex shows an unusual feature, i.e. there are two crystallographically independent molecules: one is tetragonal elongated, while the other one was described as orthorhombical distorted with three pairs of different Mn—O distances [24]. It should be mentioned here that Keppert has considered an orthorhombical distortion of β-$Mn[(OCMe)_2CH]_3$, while the two independent molecules in the unit cell of the Mn(tropolonato)$_3$ complex were both described as exhibiting different degrees of tetragonal elongation (4% and 10%) [21].

Another possibility of distorsion might be considered for complexes containing MX_6 cores the coordination polyhedron being intermediate between a perfect octahedral symmetry and a trigonal prismatic coordination. For M(bidentate ligand)$_3$ complexes this type of distortion is completely defined by the normalized bite of the bidentate ligand b and the twist angle θ between two opposite triangular faces [21]: the shorter the bite distance, the smaller the twist angle. For manganese(III) complexes containing bidentate dioxo ligands (Table 3), if any Jahn-Teller distortions are ignored and the O—Mn—O bond angles are averaged assuming a three fold axis, then the calculated values of b and θ are consistent with the repulsion-energy calculations [21]. The flexibility of the OPNPO skeleton can allow smaller or larger O···O bite values as required by the coordination geometry around the metal atom. Therefore the tetragonal elongation observed in the case of $Mn[(OPPh_2)_2N]_3$ adds further evidence that the distortion of the molecular structure of Mn(III) complexes is due to the Jahn-Teller effect.

(Received 13 November 1997; accepted 11 January 1998)

Abstract—Two one dimension copper(II) polymer chain complexes with an identical molecular formula, $[Cu(dien)(OAc)]_n(ClO_4)_n$, but different stuctural features were synthesized through the reaction of $Cu_2(OAc)_4 \cdot 2H_2O$ with $M(dien)_2(ClO_4)_2$ ($M = Cu^{2+}$, Ni^{2+} and Zn^{2+}; dien = diethylenetriamine). In complex **1,** the geometry at each Cu(II) ion is a distorted octahedron (4+2) (D. K. Towle, *et al*. *Inorg*. *Chem*. 1988, **27,** 394–399); while in complex **2,** that is pentacoordinate and best described as a distorted trigonal bipyramid. The acetate groups act as monodentate bridging mode in **1,** but as single *syn-anti* bridging fashion (Cu—O = 2.008(10) and 2.062(11) Å) in **2**. These provide a good example for the suggested pathway in the "carboxylate shift". The isomer can also be diagnosed by FT-IR and FT-Raman spectroscopies, and X-ray powder diffraction. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: copper complex; diethylenetriamine; acetate; coordination polymer; carboxylate shift; one dimension.

A plethora of dinuclear or polynuclear carboxylates of a variety of transition metal ions have been prepared and structurally characterized in recent years. The increasing interest in this coordination chemistry is due to several reasons. Firstly, the carboxylate groups from aspartate and glutamate side chains play a crucial role as ligands in many metalloenzymes involving mono- or polymetallic active sites [1], and the synthesis and characterization of discrete dinuclear and polynuclear carboxylates is one of the major objectives of bioinorganic model chemistry [2]. Secondly, carboxylate metal complexes are good catalyst in some reactions and widely applied in industrial and laboratorial catalyses [3]. Thirdly, carboxylate anions have a versatile coordination behavior, generating various and sometimes surprising molecular architectures [4]. Lastly, polynuclear carboxylates are very good candidates for the investigation of exchange-coupling interactions between adjacent metal ions [5].

Though a number of carboxylate-bridged copper(II) complexes have been synthesized and characterized, only a few mono(μ-carboxylate)-bridged copper(II) chain complexes were obtained [6]. Of these few examples, the geometry at each Cu(II) ion in the chain complex $[Cu(dien)(OAc)]_n(ClO_4)_n$ (**1**) is a distorted 4+2 octahedron [6a]. Every Cu(II) ion is connected to two others in the chain through acetate bridges, and the acetate groups act as monodentate bridging mode which is an important intermediate between other carboxylate binding modes [1b,7]. The movement from monodentate bridging to other binding modes is termed the "carboxylate shift" [7]. This phenomenon could be kinetically important in carboxylate containing metalloproteins.

Such observations have prompted us to further investigate the "carboxylate shift" from the monodentate bridging to other binding fashion using the diethylenetriamine as a tridentate ligand in the synthesis of carboxylate Cu(II) complexes. In this paper, we report the syntheses and structural characterization of two one dimension polymer chain com-

* Author to whom correspondence should be addressed.

plexes with an identical molecular formula $[Cu(dien)(OAc)]_n(ClO_4)_n$. They are good example for the suggested pathway in the "carboxylate shift" [1b].

EXPERIMENTAL

Starting materials were purchased from commercial sources and were used without further purification. The complex $[Cu(dien)_2](ClO_4)_2$, $[Zn(dien)_2](ClO_4)_2$ and $[Ni(dien)_2](ClO_4)_2$ were preparated according to the procedure described [8]. (**CAUTION**: No problems were encountered during the preparation of the perchlorate derivatives described above. However, suitable care and precautions must be taken when handling such potentially explosive compounds.) Elemental analyses (C, H and N) were performed on a Perkin–Elmer 240Q Elemental analyzer. FT-IR spectra were recorded on a Bruker IFS-66 spectrometer as KBr pellets (4000–400 cm^{-1}). FT-Raman spectra were collected on a Brucker RFS-100 spectrometer with an excited source 1064 nm. UV–visible spectra were measured on a Milton Roy Spectronic 3000 spectrophotometer in methanol solution at room temperature. X-ray powder diffraction was recorded by a Philips MPD-1880I diffractiometer at room temperature using Cu–K_α (1.540562 Å) radiation, 40 kV anodic voltage and 50 mA current. The samples were scanned for 2θ angles from 4 to 64° at a scanning rate of 0.02° per min.

Synthesis

Hexacoordinated $[Cu(dien)(OAc)]_n(ClO_4)_n$ (**1**). Method A. $Cu_2(OAc)_4 \cdot 2H_2O$ (0.199 g, 0.5 mmol) was added to a methanol solution (20 ml, methanol : water = 9 : 1) containing $Cu(dien)_2(ClO_4)_2$ (0.468 g, 1 mmol) with stirring. The solution was stirred at 50°C for 3 h. A blue precipitate was produced, filtered off after cooling to room temperature and washed with ethanol and acetone and dried in air. The blue colour product was recrystallined with water and methanol. Yield: 0.62 g, 95.0%. Found: C, 22.31; H, 3.43; N, 12.75%. Calc. for $C_6H_{11}N_3O_6ClCu$: C, 22.15; H, 3.38; N, 12.92%. FT-IR data (cm^{-1}): 3222 m, 3130 s, 2937 m, 1603 vs, 1572 vs, 1430 m, 1402 vs, 1335 m, 1144–1086 vs, 1034 m, 687 m, 636 m, 626 s. FT-Raman data (cm^{-1}): 1601 w, 1563 w, 1464 s, 1257 m, 1144 m, 1122 m, 932 vs, 914 m, 625 m, 463 vs, 388 m, 348 w, 320 m, 276 m, 224 s. Electronic spectrum in water, λ_{max}, nm (ε, M^{-1} cm^{-1}): 610 (195), 246(3400). A single crystal suitable for X-ray analysis was obtained by slow evaporating a methanol and water mixture solution of compound **1**.

Method B. $Cu_2(OAc)_4 \cdot 2H_2O$ (0.199 g, 0.5 mmol) was added to a stirring methanol solution (20 ml, methanol : water = 3 : 1) containing $Ni(dien)_2(ClO_4)_2$ (0.462 g, 1 mmol). The solution was stirred at 50°C for 5 h. A blue precipitate was produced, filtered off after cooling to room temperature and washed with ethanol and acetone and dried in air. The product was recrystallined with water and methanol. Yield: 0.28 g, 86.1%. The product was identified by FT-IR spectra (*vide infra*).

Pentacoordinated $[Cu(dien)(OAc)]_n(ClO_4)_n$ (**2**). Method A. Complex **1** (0.325 g, 1 mmol) and $NaOAc \cdot 3H_2O$ (0.136 g, 1mmol) were added to an ethanol solution (30 ml, ethanol : water = 1 : 1), and the solution was stirred at 60°C for 5 h. The solution was filtered off, and the filtrate was stayed in air to evaporate slowly to get crystals. The pale blue crystals were collected, washed with cold ethanol-diethyl ether (1 : 1) and dried in air. Yield: 0.13 g, 40%. Found: C, 22.42; H, 3.50; N, 12.80%. Calc. for $C_6H_{11}N_3O_6ClCu$: C, 22.15; H, 3.38; N, 12.92%. FT-IR data (cm^{-1}): 3317 s, 3262 s, 2923 m, 1608 m, 1562 vs, 1458 m, 1427 s, 1338 w, 1142–1065 vs, 1014 m, 938 s, 675 m, 633 s, 627 s, 507 m. FT-Raman data (cm^{-1}): 1602 w, 1471 s, 1458 s, 1254 m, 1128 m, 1063 m, 959 m, 931 vs, 911 m, 625 m, 457 m, 423 m, 304 w, 229 w. Electronic spectrum in water, λ_{max}, nm (ε M^{-1} cm^{-1}): 613 (176), 249 (3350). A single crystal suitable for X-ray analysis was obtained by slow evaporating a methanol and water mixture solution of compound **2**.

Method B. $Cu_2(OAc)_4 \cdot 2H_2O$ (0.199 g, 0.5 mmol) was added with stirring to an ethanol solution (20 ml ethanol : water = 1 : 1) containing $Zn(dien)_2(ClO_4)_2$ (0.469 g, 1 mmol). The solution was stirred at 60°C for 5 h. The solution was filtered off after cooling to room temperature. The blue precipitate was washed with cool ethanol and acetone and dried in air. Yield: 0.15 g, 46.1%. The product was identified by FT-IR spectra (*vide infra*), and it displays an almost same spectrum of hexacoordinate **1**. The filtrate was stayed in air to evaporate the solvent to get crystals after 3 days. The product was collected by filter, washed with cold ethanol-diethyl ether (1 : 1) and dried in air. Yield: 0.1 g, 30.7%. The identification of the product was deduced by FT-IR spectra comparison with method A (*vide infra*).

Crystallographic measurements and structure resolution

Crystal data for **2**: $C_6H_{11}ClN_3O_6Cu$, orthorhombic, space group *P*nma, $a = 8.3130(10)$, $b = 8.642(2)$, $c = 17.727(2)$ Å, $V = 1273.6(3)$ $Å^3$, $Z = 4$, $D_{calc} = 1.670$ Mg/m^3, $\mu = 1.943$ mm^{-1}, $T = 294$ K.

A pale blue single crystal of complex **2** having approximate dimension of $0.08 \times 0.25 \times 0.30$ mm was mounted on a glass fiber and placed on a Siemens R3m/V diffractometer using graphite-monochromated Mo–K_α X-radiation ($\lambda = 0.71073$ Å). Cell constants and orientation matrix for data collection, obtained from a least-squares refinement using the setting angles of 25 carefully centered reflections with $12 \leqslant 2\theta \leqslant 23°$. 1201 independent reflections were collected in the range $7.0 \leqslant 2\theta \leqslant 45.0°$ ($0 \leqslant h \leqslant 9$,

$0 \leqslant k \leqslant 10$, $0 \leqslant l \leqslant 20$) with the variable-speed ω-scan technique. Crystal stability was monitored by recording three check reflections at intervals of 97 data measurements, and no significant variation was detected. The structure was solved by direct methods using the SHELXTL-PC program package [9]. All the non-hydrogen atoms were refined anisotropically. Hydrogen atoms of the ligands were generated in their idealized positions (C—H = 0.96 Å), assigned isotropic thermal parameters. The structure was refined in full-matrix least-squares where the function minimized was $\Sigma w(F_o - F_c)^2$ and the weighting scheme $w = [\sigma^2 (F) + 0.0001F^2]^{-1}$. The final cycle of refinement was based on 807 observed reflections and 92 variable parameters and converged with unweighted and weighted agreement factors of $R = \Sigma([F_o] - [F_c])/\Sigma[F_c] = 0.0712$ and $R_w = [\Sigma w(F_o - F_c)^2/\Sigma w(F_o)^2]^{1/2} = 0.0780$, GOF = 0.92. The largest difference peaks and hole were 1.14 and -0.71 eÅ^{-3}, respectively. The unit cell of **1**: monoclinic, space group $P2_1/n$ with $a = 10.124(2)$ Å, $b = 8.082(3)$ Å, $c = 15.512(2)$ Å, $\beta = 99.02\ (2)^\circ$, $V = 1254.6$ Å^3, $Z = 4$, and is the same as the reported [6a], and its structure was not refined.

RESULTS AND DISCUSSION

Syntheses and spectra properties

The synthesis of the complex formulated as $[Cu(dien)(OAc)]_n(ClO_4)_n$ was first reported by Towle and his coworker in 1988 [6a], because of its interesting magnetic properties. The present syntheses differ from that reported and result in the formation of a novel isomer. The reactions of the copper(II) acetate with $M(dien)_2(ClO_4)_2$ ($M = Cu^{2+}$, Ni^{2+} and Zn^{2+}) were carried out in methanol-water solution, and a dark blue polymer copper(II) complex $[Cu(dien)(OAc)]_n(ClO_4)_n$, **1,** was precipitated from the solution. On the other hand, the filtrate of the reaction solution from $Zn(dien)_2(ClO_4)_2$ and $Cu_2(OAc)_4 \cdot 2H_2O$ was left in air to evaporate the solvent and pale blue crystals were obtained. These observations have prompted us to further examine what differences in their geometries and how we can obtain the desired product under the reaction conditions. We notice that the counterion ClO_4^- is essential to obtain the desired product under this reaction condition. Efforts to obtain a polymeric structure analogous to **1** or **2** using Cl^- anion displacing the counterion ClO_4^- was not successful. We have tried to expand this synthetic procedure to prepare other polymer compounds containing Zn^{2+} or Ni^{2+} ion. We found that an isostructural complex $[Zn(dien)(OAc)]_n(ClO_4)_n$ was produced, however, trying to prepare an analogous complex containing Ni^{2+} ion was not successful under this condition [10].

Complexes **1** and **2** display quite different on their FT-IR and FT-Raman spectra, though they have an identical molecular formula. The IR spectra of both complexes **1** and **2** exhibit very strong bands around 1100 and 625 cm^{-1}, which were assigned to $v_3(T_2)$ and $v_4(T_2)$ modes of the uncoordinated perchlorate anion. The v(NH) stretching vibration in the free dien ligand at 3360 and 3295 cm^{-1} bands were assigned to primary and second amine groups, respectively, which were down-shift to 3317 and 3262 cm^{-1} for **2,** 3222 and 3130 cm^{-1} for **1,** respectively. These shifts are strong evidence that the ligand is coordinated in a tridentate mode [11]. A number of geometric isomers of hexacoordinate dien complexes $M(dien)L_3$ have been prepared and the ligand conformation has been studied by IR spectroscopy. It has been concluded that the facial (*fac*) and meridional (*mer*) isomers for monodien complexes may be distinguished by their IR spectra [11,12]. The presence of a band at ca 933 cm^{-1} in the recorded spectrum is taken as evidence for the *fac* conformation of dien [12b]. However, the spectrum of complex **2** displays an intense peak at 938 cm^{-1} while it is absent in complex **1**. Thus, our results also seem to support that this band could be used as a diagnostic tool for the dien conformation. On the other hand, the v(COO) stretching vibrations also display significant differences in the spectra of **1** and **2**. The v_{as}(COO) and v_s(COO) bands are located at 1572 and 1402, and 1562 and 1427 cm^{-1} in the spectra of **1** and **2,** respectively. The difference values of v_{as}(COO) and v_s(COO) are 170 and 137 cm^{-1} for **1** and **2,** respectively. These are consistent with the geometries of acetate groups adopted as monodentate bridging mode in **1** and *syn-anti* mode in **2** [13].

Complex **1** shows a band at 1563 cm^{-1} in FT-Raman spectrum; however, this peak was absent in complex **2**. But the strong band at 1464 cm^{-1} in **1** was split into a doublet at 1471 and 1459 cm^{-1} with 12 cm^{-1} apart in **2**. These were also strong evidence that the acetate groups adopted as distinct fashions in **1** and **2,** consistenting with the results from FT-IR and single crystal diffraction experiments. X-ray powder diffraction experiments also display significant differences between **1** and **2** (seen Fig. 1).

Crystal structure

The crystal structure of **2** reveal that the complex has an extended structure, forming infinite μ-OAc chain. A labelled diagram is shown in Fig. 2. Selected bond distances and angles are collected in Table 1. The Cu(II) ions are connected through single *syn-anti* acetate bridges, forming infinite zig-zag chains running along the *a* crystallographic axis. The average distance between the two chains is 9.953 Å. Though a number of copper(II)-carboxylate complexes were prepared, complexes exhibiting a single *syn-anti* carboxylate bridge are not very common in the literature [6], due to the fact that the *anti* lone pair of the carboxylate groups have a lower basicity than the *syn* ones [14].

The geometry of each copper(II) ion is five coor-

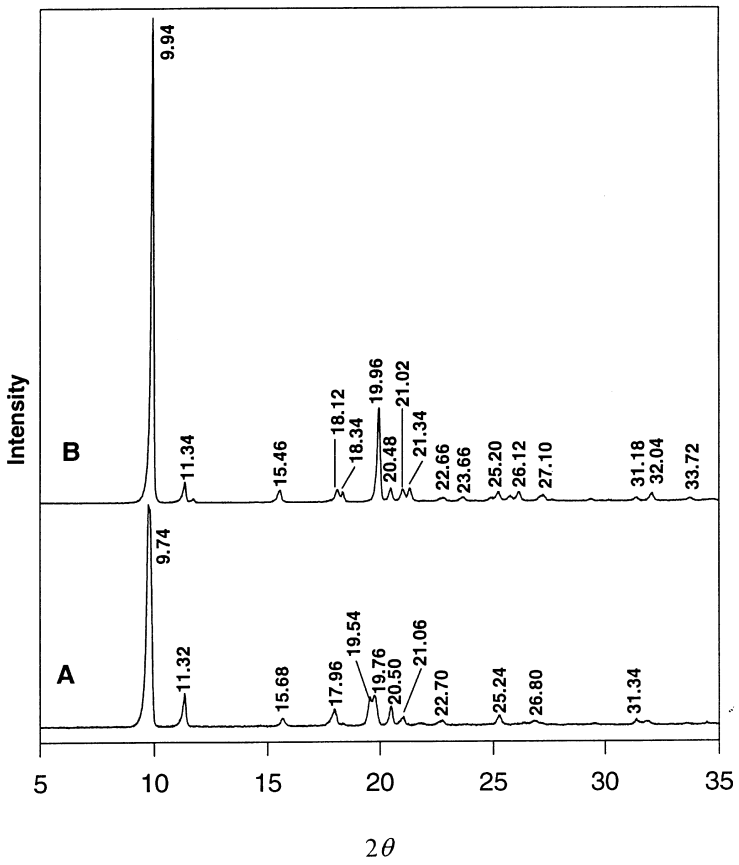

Fig. 1. X-ray powder patters for (A) complex **2** and (B) complex **1** at room temperature with 0.02° per min rate using Cu–K_α (1.540562 Å) radiation, 40 kV anodic voltage and 50 mA current.

dinate with C_{2v} symmetry, the structure being best described as a distorted trigonal bipyramid in which N(2) and N(2a) are axial while N(1), O(1) and O(2) are in the trigonal plane. As expected for a trigonal bipyramid, Cu(II) ion lies in the trigonal plane (average deviation from the four-atom plane is 0). This plane is coplanar with the two adjacent carboxylate planes, and perpendicular with the plane consisting of three nitrogen atoms and Cu(II) (the largest deviation from the four-atom plane is 0.075 Å). The principal distortion from trigonal pyramidal geometry is the angles in the trigonal plane; in the idealized case these should all be 120°, but in complex **2** they range from 93.3(3)–139.2(6)°. Obviously, there is an alternate description of the complex **2** as a distorted tetragonal pyramid, where one oxygen atom from the acetate is axial while the other oxygen atom from another acetate and the three nitrogen atoms from the dien ligand are equatorial. But the distortions from idealized tetragonal pyramidal geometry are severe. The structure of the infinite chain resembles those found in $[Cu(dien)(HCOO)]_n(HCOO)_n$ [6b] and $[Cu(1,1\text{-}Me_2\text{-}dien)(OAc)]_n(ClO_4)_n$ [6e], which contain similar carboxylate bridges. It is interesting that there are several differences between the molecular structure of **2** and **1,** although they have an identical molecular formula $[Cu(dien)(OAc)]_n(ClO_4)_n$. In complex **1,** the coor-

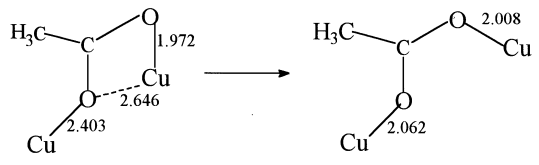
dination around the Cu(II) ion is a distorted octahedron (4+2), due to the implication of both *syn* and *anti* lone pairs of the bridging oxygen atom [6a]. The coordination mode of the acetate groups in **1** can best be described as monodentate bridging, the "dangling" oxygen [1b] occupying one of the equatorial positions at 1.972(4) Å. In complex **2,** however, the distances between O(2b) (*anti*) and two neighbouring Cu(II) ions within the chain are 2.062(11) and 2.701 Å, whereas in **1** they are 2.403(4) and 2.646(4) Å [6a]. As a consequence, the Cu···Cu distance in **2** (4.440 Å) is significantly longer than that found in **1** (4.210 Å). The differences between **1** and **2** arise mainly from the coordination modes adopted by the acetate groups. These can be realized through the "carboxylate shift" (see Scheme 1). In complex **1,** the acetate groups act as monodentate bridging mode which would be considered as an important intermediate towards other carboxylate binding modes [1b]. The *syn* electron pair of the second carboxylate oxygen, called the "dangling" oxygen atom, would play an important role by interacting with one of the bridged metallic centers. The gradual change from monodentate bridging to other binding modes was termed the "carboxylate shift" [1b]. The shift from monodentate bridging to the classical *syn-syn* bidentate bridging would occur through *syn-anti* bidentate bridging attachment of the carboxylate ligand, such as observed in complex **2**.



1
Monodentate bridge

2
Syn-anti bridge

Scheme 1. The carboxylate shift from monodentate bridge (**1**) to *syn-anti* bridge (**2**) with different Cu—O distances (angstrom).

Therefore, the different geometries of acetate groups adopted in **1** and **2** illustrate well the suggested pathway in the "carboxylate shift".

Supplementary materials—List of atomic coordinates and isotropic temperature factors, anisotropic temperature factors, hydrogen coordinates, bond distances and angles, and observed and calculated amplitudes have been deposited with the Cambridge Crystallographic Data Center.

(Received 2 June 1997 ; accepted 12 January 1998)

Abstract—The heteronuclear complex of tetraphenylantimony(V) with anion of *bis*(oximino-cyanoacetamidato(2-)-*N*,*N*)nickelate(II) $[(Ph_4Sb)_2\{Ni(NCC(NO)C(O)NH)_2\}]$ **1** was synthesized and investigated by single crystal X-ray analysis. **1** was isolated as a result of the reaction between tetraphenylantimony(V) chloride and nickel(II) complex with (hydroximino)cyanoacetamide (H_2aco) $Na_2\{Ni(aco)_2\}$ obtained by reaction of $Ni(Haco)_2$ with NaOH. The crystal comprises heterometal centrosymmetric molecules $(Ph_4Sb)_2\{Ni(aco)_2\}$. The Ni atom is in a slightly distorted square planar surrounding formed by the four nitrogen atoms of deprotonated hydroximino and amide groups (Ni—N_{oxime} 1.890(4), Ni—N_{amide} 1.862(4) Å). The ligands are situated in *trans* positions with respect to each other. The coordination environment of the antimony atom in the Ph_4Sb^+ cation is somewhat distorted trigonal bipyramidal [SbC_4O], Sb—C_{eq} 2.084(5)–2.108(5) Å. All angles C_{eq}—Sb—O_{ax} are less than 90°. Ph_4Sb^+ coordinates to the oxygen atom of C═O group (Sb—O 2.647(3) Å). The geometrical parameters of the CNO group indicate that it exists in the nitroso-form. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: heteronuclear complex ; oximes ; tetraphenylantimony(V) ; nickel(II) complex ; crystal structure.

The last decade is marked by the increasing interest to the design and synthesis of new homo- and heteropolynuclear metal assemblies. These compounds often possess unusual structural, spectral and magnetic properties and represent an evident interest in the field of molecular electronics and magnetism. Bi- and polynuclear metal complexes were also successfully used in bioinorganic chemistry as models of active centers of some metalloproteins (*e.g.*, superoxidedismutase) [1]. Another possible application of the mentioned compounds in this field is connected with their bioactivity which may be quite different as compared to that indicated by mononuclear complexes. The compounds containing potentially anti-cancer ions : diorganotin(IV) [2], organoantimony(V) [3], platinum(II), palladium(II) [4–6], ruthenium(III,IV) [7,8] together with 3d-metals ions having remarkable biological activity [9] are of special interest.

One possible approach for synthesis of heteropolynuclear complexes with desirable structure is usage of mononuclear complexes as ligands. The suitable ligands for obtaining of such "building blocks" should form rather stable mononuclear complexes and not undergo the rearrangement of the coordination sphere upon interaction with the additional metal ions. Chelating ligands possessing strong field donor groups such as oxamide derivatives [10] and dioximes [11] were used for these purposes. Earlier we reported the oxime analogues of aminoacids and peptides which were shown to be specific and efficient

* Authors to whom correspondence should be addressed.

ligands for Cu^{2+} and Ni^{2+} ions [12,13]. These ligands contain adjacent oxime and amide groups and was established to form stable anionic complexes with ($[MN_4]$, $2N_{oxime}$, $2N_{amide}$) coordination (M=Cu^{2+}, Ni^{2+}) at pH 7 and higher. These species can form additional coordination bonds by means of the oxygen atoms of oxime (C=NO) and carbamoyl (C=O) group. The former coordination mode is the most likely and was observed recently in homobinuclear complexes of (hydroximino)propanamide (H_2pox): $[Cu\{Cu(Hpox)(pox)\}]^{+}$[11] and (hydroximino)cyanacetamide (H_2aco): $[Cu\{Cu(aco)_2\}]$[12] formed in aqueous solution, while the latter one was not known up to date.

In this work the crystal and molecular structure of the first heteronuclear complex containing doubly deprotonated (hydroximino)cyanacetamide $[(Ph_4Sb)_2[Ni(aco)_2]$ is reported.

EXPERIMENTAL

All chemicals were commercial products of reagent grade and used without further purification. Ni(H-aco)$_2 \cdot 2H_2O$ was synthesized according to [14].

^{13}C and 1H NMR spectra were recorded on a JEOL-400 GSX FT-NMR spectrometer. UV–VIS spectra were obtained on a Cary-14 spectrometer. IR spectra were recorded on a 2020 Galaxy Series FT-IR spectrometer.

Synthesis of $[(Ph_4Sb)_2\{Ni(NCC(NO)C(O)NH)_2\}]$ **1**

To the suspension of 0.103 g (0.323 mmol) of Ni(H-aco)$_2 \cdot 2H_2O$ in 25 ml of water 0.16 ml of 2M NaOH solution was added. The obtained mixture was heated at 80°C upon continuous stirring until complete dissolution of solid. 0.301 g of Ph_4SbCl (0.626 mmol) was added to the resulting solution, and the formed precipitate after 2 h was filtered off and washed with a small amount of ice water. The product **1** may be purified by recrystallization from water or acetonitrile. Yield: 0.282 g (76.5%). Found: C, 55.9; H, 3.1; N, 7.8; Ni, 5.5. Calc. for $C_{54}H_{42}N_6O_4NiSb_2$: C, 56.2; H, 2.9; N, 7.5; Ni, 5.9 %. ^{1}H NMR ($CDCl_3$), ppm δ 7.696 (d, $J = 7.2$ Hz, 16H), 7.496 (m, 24H), 3.010 (s, 2H); ^{13}C NMR ($CDCl_3$), ppm δ 170.0167 (**C**(O)NH_2), 135.36, 133.57, 131.62, 129.88 (Ph), 124.57 (**C**≡N), 113.34 (**C**NO); UV–vis, cm^{-1} 17600 ($\varepsilon = 130$), 18800 ($\varepsilon = 70$); IR, cm^{-1} ν(C≡N) 2199, ν(C=O) 1561, ν(N—O) 1163.

The crystal suitable for X-ray analysis was obtained by slow isothermal (298 K) evaporation of acetonitrile solution of **1**.

Crystallographic data collection and structure determination

Crystal data and experimental details are presented in Table 1. The accurate unit cell parameters and the orientation matrix were calculated from the setting angles of 24 reflections using the least-square technique. Intensities were collected using an Enraf-Nonius CAD-4 diffractometer in the ω-2θ scan mode using graphite-monochromated Cu–K_α radiation. The intensities of three standard reflections, monitored every 100 intensity scans showed no evidence of crystal decay. Corrections for Lorentz and polarization effects as well as an empirical correction for absorption using DIFABS [15] were applied; minimum and maximum absorption corrections were 0.974 and 1.020.

The structure was solved by direct methods using SHELXS-86 [16] and refined by full-matrix, least-squares on all F_o^2 using SHELXL-93 [17]. Neutral atom scattering factors and anomalous dispersion terms used in the refinement were taken from reference [18], real and imaginary components of anomalous dispersion were included for all non-H atoms. The position of the N—H hydrogen atom was determined from difference Fourier synthesis and refined in isotropic approximation. The C—H hydrogen atoms of the phenyl groups were added at calculated positions and included in the calculation of structure factors as the fixed contributions. Correction for extinction was taken into account in the course of refinement. A weighting scheme of the form $w = 1/\sigma^2(F_o^2) + (0.0813xP)^2 + 3.35\ P$ [where P is defined as $(F_o^2 + 2F_c^2)/3$] was applied. Observed and calculated structure factors, anisotropic thermal parameters, atomic coordinates, full list of interatomic distances, bond angles and torsion angles are given in supplementary material. The selected bond distances and angles are listed in Table 2.

RESULTS AND DISCUSSION

The crystal comprises centrosymmetric molecules $(Ph_4Sb)_2\{Ni(aco)_2\}$ having no close contacts between each other (Fig. 1). The closest intermolecular contacts in the crystal packing are 3.565(3) Å (C(12)—O(1) $(1-x,1-y,-z)$) that is equal to the sum of the Van der Waals radii [19].

In the complex anion the nickel atom occupies a center of symmetry. The coordination environment of the central atom is slightly distorted square planar formed by the four nitrogen atoms belonging to the deprotonated hydroximino and amide groups. The ligands are two-charged anions of (hydroximino)cyanacetamide. They are situated in *trans* position with respect to each other. The Ni—N(oxime) and Ni—N(amide) distances are 1.890(4) and 1.862(4) Å, respectively. The angular distortions around the Ni atom are connected with formation of five-members chelate ring: the bite angle N(1)—Ni—N(2) is decreased to 83.7(2)°, the N(1)—Ni—N(2)$(-x+2, -y+2, -z)$ angle is increased to 96.3(2)°. The mentioned chelate ring is in fact planar.

[b] $x-1, y-1, z$.

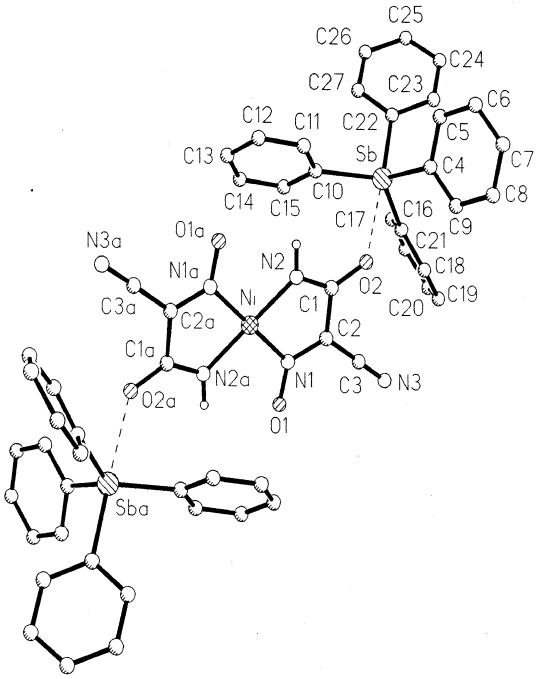

Fig. 1. Structure and numbering scheme for complex **1**.

The antimony atom of Ph_4Sb^+ cation is in somewhat distorted trigonal bipyramidal surrounding. Equatorial positions are occupied by the carbon atoms of phenyl rings which are situated in the most sterically favorable propeller-like conformation and slightly inclined to the oxygen atom occupying the axial position. All the angles C_{eq}—Sb—O_{ax} are less than 90° (Table 2). The second apical position is occupied by the carbon atom of the phenyl ring, the Sb—C_{ax} distance is slightly increased as compared to Sb—C_{eq} (2.120(5) Å, Table 2). According to relative electronegativity of oxygen and carbon atoms, the oxygen atom of carbamoyl group occupies the axial position. The distance Sb—O(2) ($x-1$, $y-1$, z) 2.647(3) Å is relatively long, which indicates its ionic character. For comparison, the distances Sb—O observed in five-coordinated tetraphenylantimony(V) complexes lie in the range 2.20–2.35 Å [20]; the longest Sb—O contact reported for tetraphenylstibonium benzenesulfonate monohydrate 2.506 Å [21]. Such elongation of the Sb—O bond length in (1) leads to an increase of the tetrahedral distortion in the Ph_4Sb moiety; C_{eq}—Sb—O_{ax} 77.6(2)–82.3(2)° for **1,** 80.59(7)–84.76(7)° for Ph_4Sb(Haco) and 82.8(2)–86.6(2)° for Ph_4Sb(dco) [22].

Ph_4Sb^+ coordinates to oxygen atom of C═O group forming O═C—C═N(oxime) bridges between two metal centers. As a result the electron density in the frame of the ligand is significantly disturbed. Thus the C═O and C═N(oxime) bond lengths (Table 2) are increased as compared to the values observed in $\{(H_3C)_4N)_2[Cu(aco)_2]\}$ [13] (1.237(3) and 1.302(3) Å, respectively), whereas the C—N(amide) and N—O bond lengths (Table 2) are decreased (in $\{(H_3C)_4N)_2[Cu(aco)_2]\}$ [13] 1.313(3) and 1.289(3).

The angular parameters of the present ligand are similar to those observed for the other ligands having deprotonated oxime and amide groups [12,13]. The geometrical parameters of CNO group (Table 2) indicate that this moiety exists in the nitroso-form.

(Received 24 October 1997 ; accepted 23 January 1998)

Abstract—The spin state of iron(III) in substituted *N*,*N*′-ethylenebis(salicylidenaminato) complexes of type [Fe(5-X-salen)L_2]Y, where X = CH_3O, H and Cl, L = Im and 2-MeIm and Y = Cl^-, ClO_4^- and BPh_4^- was determined using X-ray structures, magnetic susceptibility and variable temperature EPR studies. X-ray data of [Fe(5-CH_3O-salen)$(Im)_2$]Y, where Y = ClO_4^- (**1**) and Cl^- (**2**) are as follows : **1**, $C_{24}H_{26}N_6O_8ClFe$, monoclinic $P2_1/n$, a = 10.516(4) Å, b = 13.752(3) Å, c = 19.227(3) Å, β = 102.14(2)°, V = 2718(11) Å^3, Z = 4, R = 0.097 (R_w = 0.084) ; **2**, $C_{24}H_{26}N_6O_4ClFe$, monoclinic $P2_1/n$, a = 11.709(3) Å, b = 12.746(2) Å, c = 17.388(4) Å, β = 106.15(2)°, V = 2493(15) Å^3, Z = 4, R = 0.062 (R_w = 0.065). Metal-ligand bond distances are consistent with a HS state for iron(III) which has a tetragonally distorted octahedral geometry. Imidazole planes are coplanar and bisect the N—Fe—O bond angle in **2** while they are oriented by 77.3° apart in **1** almost coinciding with the N—Fe—O direction. Counterions showed significant effect on the overall molecular geometry and FeN_2C_2 ring. Methanolic solutions of all the complexes showed spin crossover whereas only salen and 5-Cl-salen complexes exhibited this phenomenon in solid state. EPR investigations revealed, for the first time, two types of interconvertible low spin species (LS1 and LS2) in solution ; the former was characterized by an almost axial g tensor with lower g anisotropy (2.238–1.937) while the latter with a rhombic tensor with larger g anisotropy (2.382–1.911). Ground state wave functions and distortion parameters were calculated. Structure-spin state-reactivity correlations are proposed. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: Iron(III) complexes ; salen ; spin crossover ; structures ; EPR.

Spin crossover in iron complexes has been extensively studied to understand the mechanisms and various factors influencing the phenomenon, to explore its implications in metalloproteins e.g., myoglobin, hemoglobin and cytochromes and to examine the spin state-reactivity correlation [1–5]. Recently, molecules with labile electronic ground state are attracting more attention due to their potential application as sensors and memory devices [6,7]. Factors like substitution, axial ligands, counterions, solvent of crystallization etc, influence the nature of spin state crossover [5,8]. Interestingly, the orientation of axial imidazole and pyridine ligands in porphyrinato complexes also control the electronic ground state [4,9]. Variable temperature X-ray structural studies have revealed that the electron transfer rate is coupled to intermolecular solid state effects and the onset of dynamic motions of a solvent molecule in the lattice. The dynamic disorders in the lattice lead to rapid spin interconversion rates and reversible abrupt transition while static order leads to slow rates and gradual spin crossover behavior [10].

Spin crossover in salen type complexes was observed initially by Nishida *et al.* [11] and later Kennedy and co-workers have reported a detailed study

*Author to whom all correspondence should be addressed : Special Instruments Laboratory, National Chemical Laboratory, Pune 411 008, India.

on the influence of uncoordinated anion on the spin state interconversion dynamics [12]. With a view to understand further the structure-spin state-reactivity correlations we report here structure and variable temperature ESR investigations on some Fe(III) substituted quadridentate salen complexes of type [Fe(5-X-salen)L_2]Y, where X = CH_3O, H and Cl; L = substituted imidazole (Im) and Y = Cl^-, ClO_4^- and BPh_4^-. Ligand field strength is systematically varied by introducing varying donacity substituents in salen as well as in axial imidazole ligands.

EXPERIMENTAL

Synthesis

The Schiff base ligands, *N*,*N*′-ethylenebis(5-methoxysalicylidenamine) (5-CH_3O-salenH_2), *N*,*N*′-ethylenebis(salicylidenamine) (salenH_2) and *N*,*N*′-ethylenebis(5-chlorosalicylidenamine) (5-Cl-salenH_2), were prepared as condensation products of the respective aldehyde (2 mmol) and en (1 mmol) in absolute alcohol [13]. Iron(III) complexes with these ligands, Fe(5-X-salen)Cl were prepared following the method of Gerloch *et al*. [14].

[Fe(5-X-salen)L_2]Cl

The complexes were synthesized by adding the ethanolic soln (10 ml) of axial ligand L (Im or 2-MeIm, 5 mmol) in small frs to a hot suspension of Fe(5-X-salen)Cl in ethanol (1 mmol, 25 ml). The reaction mixt was refluxed for ~1 h under inert atmosphere, filtered and kept for slow evaporation. Microcrystals were obtained overnight.

[Fe(5-X-salen)L_2]Y

The complexes with counterion Y (ClO_4^- or BPh_4^-) were prepared by adding freshly prepared $NaClO_4$ and $NaBPh_4$ (1 mmol) in ethanol to the above hot ethanolic solns of [Fe(5-X-salen)L_2]Cl. Microcrystals were obtained overnight by slow evaporation.

In the case of salen and 5-Cl-salen the products were isolated by using a rotary evaporator as slow evaporation always yielded products contaminated with an orange red μ-oxo compound. **Caution!** Perchlorato salts can potentially explode during drying and grinding, so proper care should be exercised while handling such compounds. So far we have not experienced any problems during sample preparation.

Physical measurements

Microanalyses of complexes were done using a CHN Carlo Erba 1106 elemental analyzer. The IR spectra were measured for KBr pellets (1% *w*/*w*) at 298 K on a Carl Zeiss Specord M-80 spectrophotometer. Electronic spectra were recorded for ethanolic solns on a Shimadzu UV–vis spectrophotometer in the range 200–1100 nm. Magnetic susceptibilities of the complexes were measured by the Faraday method; $Hg[Co(SCN)_4]$ was used as a calibrant. Effective magnetic moments (μ_{eff}) were calculated after applying diamagnetic correction.

EPR investigations were carried out on a Bruker ESP 300 X-band spectrometer with a 100 kHz field modulation. DPPH was used as a field marker ($g = 2.0036$). Samples were taken in quartz tubes as glass tubes in general contained iron(III) ion impurity which gave signal at $g \cong 4.2$ overlapping with the compound signals. The spectra were measured in the temperature range 77–298 K for both polycrystalline samples and solns. Measurements at 77 K were performed using a quartz inserting Dewar while variable temperature studies were done with a Bruker ER4111 set-up.

X-ray crystallography

Crystallographic data for complexes **1** and **2** are summarized in Table 1. Both the structures were solved by the heavy-atom method and refined by the full-matrix least-squares procedure as described in Table 1. The oxygen atoms of perchlorate ion in complex **1** show very high thermal anisotropic vibrations, a possible factor for a rather high R value for this complex. Hydrogen atom positions were mostly obtained from difference Fourier synthesis, a few (belonging to the methyl group) were fixed stereochemically at appropriate geometries. The H-atoms were included only for the structure factor calculation and were not refined in the least-squares. All computations were performed on a PDP-11/73 computer using the Structure Determination Package (SDP) available from Enraf-Nonius [16].

Analysis of EPR data

The EPR spectra for Fe(III) complexes have been extensively studied by several workers [17]. The spectrum for a high spin complex ($t_{2g}^3\ e_g^2$, $S = 5/2$) is described by the following spin Hamiltonian.

$$\mathcal{H} = D[S_z^2 - S(S+1)/3 + (E/D)(S_x^2 - S_y^2)] + \beta_e \mathrm{H}.g.S \quad (1)$$

Here D and E are the tetragonal and rhombic zero-field splitting parameters for $^6A_{1g}$. If the electron Zeeman energy is greater than the zero-field terms, one observes resonances from all the $(2S+1)$ fine structure levels at free spin g value. On the other hand, if $D > g\beta_e$H and the system is tetragonal ($E = 0$), the three Kramers' doublets are well separated and only transitions are allowed within the ground state doublet $|\pm 1/2>$ resulting in resonances at $g\perp \cong 6.0$ and $g\| \cong 2.0$. However, in the case of extreme rhombic

symmetry ($E/D = 1/3$) the resonances corresponding to each doublet occur at

$$E_3 : g_x \cong g_y \cong 0.6, g_z \cong 9.6 \quad \text{highly anisotropic}$$

$$E_2 : g_x = g_y = g_z \cong 4.286 \quad \text{almost isotropic}$$

$$E_1 : g_x = g_z \cong 0.6, g_y \cong 9.6 \quad \text{highly anisotropic}$$

Inclusion of cubic field terms further deviate these values. In the case of polycrystalline samples the spectrum corresponds to an ensemble average of all the orientations and consists a strong signal at $g \cong 4.3$.

In the case of low spin Fe(III) complexes, if the appropriate one electron orbitals for the t_{2g}^5 configuration ($S' = 1/2$) are employed with the following Hamiltonian

$$\mathscr{H} = \zeta 1.s - \Delta[1_z^2 - 1(1+1)/3] - V(1_+^2 + 1_-^2)/2 \quad (2)$$

then a set of three secular equations result for the ground state Kramers' doublet [18]. Here ζ is the one electron spin-orbit coupling constant, Δ is the axial distortion and V is the low symmetry rhombic distor-

tion. The secular equations can be solved to give wave functions which upon application of a Zeeman Hamiltonian operator gives the following expressions for the g values.

$$g_z = -2[a^2 - b^2 + c^2 + K(a^2 - c^2)]$$
$$g_x = 2[2ac - b^2 + \sqrt{2}Kb(c - a)]$$
$$g_y = -2[2ac + b^2 + \sqrt{2}Kb(c + a)] \quad (3)$$

Here K is the orbital reduction parameter or covalency parameter; a, b and c are the MO coefficients describing the ground state Kramers' doublet

$$\psi = a|+1^+> + b|\xi^-> + c|-1^+>$$
$$\psi' = a|-1^-> - b|\xi^+> + c|+1^-> \quad (4)$$

where $|+1>$, $|-1>$ and $|\xi>$ $\{= (|+2> - |-2>)/\sqrt{2}\}$ are the one electron orbitals. A computer program was written to evaluate a, b, c and K by least squares fitting the experimental g values to the above g value expressions and the normalization condition given by eqn (5)

$$a^2 + b^2 + c^2 = 1 \quad (5)$$

In addition the energy separations of the three Kramers' doublets of $^2T_{2g}$ ($\Delta E_1/\lambda$ and $\Delta E_2/\lambda$) and distortion parameters (Δ/λ and V/λ) were obtained by solving the secular equations. In the absence of information about the sign and orientation of g values, as usually happens for powder samples, 48 combinations were considered. The best fit values were selected on the basis of physically reasonable values of K, Δ and V. These values for all the complexes are listed in Table 3.

RESULTS AND DISCUSSION

Spectral characterization

The IR spectra for solids showed intense peaks in the range 1608–1650 cm^{-1} attributable to the stretching modes of azomethine and phenyl groups. Upon complexation these peaks shifted to lower frequency side by ~ 10 cm^{-1}, compared to that for free ligands. The absence of a broad band around 3460 cm^{-1} due to ν(O—H) indicated the coordination of salen as a dianionic ligand. The presence of axial ligands was confirmed by their characteristic peaks. Perchlorate ion gave strong peaks around 1148, 1116, 1086 and 630 cm^{-1}. Methanolic solutions of the complexes showed intense charge transfer bands of ligand origin in the UV-visible spectra around 249, 305 and 375 nm. In the case of the complexes with 5-CH_3O-salen, moderately intense bands were observed additionally at 450 and 567 nm due to MLCT transitions. However, for salen and 5-Cl-salen these bands have shifted to ~ 460 nm revealing the effect of substituents on the ligand field strength.

Effects of counterion and substitution on the chelate geometry. Structures of [Fe(5-CH_3O-salen)$(Im)_2$]Y, *where* Y = ClO_4^- (**1**) *and* Y = Cl^- (**2**)

ORTEP [19] views of **1** and **2** are shown in Fig. 1 along with the atom numbering. Selected bond distances and angles are given in Table 2. The Fe atom is in a tetragonally distorted octahedral coordination in **1**, with the Fe—O bond distances being the shortest (1.923(6), 1.869(6) Å), Fe—N(salen) distances being intermediate (2.109(7), 2.117(6) Å) and axial Fe—N(Im) being the longest (2.15(1), 2.21(1) Å). The Fe—N(salen) and Fe—O distances are comparable with those of the high spin complex [Fe(salen)$(Im)_2$]PF_6 [12]. The five membered FeN_2C_2 (ethylenediamine) ring has the *meso* conformation in **1** with the displacements of atoms C8 and C9 being 0.25 Å and 0.40 Å from the FeN_2 plane, in opposite directions. The planar sal1 and sal2 units are symmetrically bent in opposite directions form the N_2O_2 plane, making almost equal angles (~ 13–14°) with it. The overall conformation of **1** is very much like the one observed for [Fe(salen)$(Im)_2$]PF_6 complex [12]. This type of conformation is observed to lock up the Fe atom in a high spin state, which is indeed the case with complex **1** in solid state.

The Fe—O distances in **2** are identical (1.913(4), 1.914(3) Å), Fe—N(Im) distances are much shorter (2.112(7), 2.132(7) Å) compared to **1** and Fe—N-(salen) distance (Fe—N2 = 2.150(4) Å) is the longest in the Fe-coordination polyhedron reflecting a weaker coordination probably due to the thermal agitation of the ring atoms. The conformation of salen framework in **2** shows a marked difference from that of **1**. Here, the ethylenediamine ring appears to be planar as opposed to the *meso* form in **1**. However, rather long thermal ellipsoids (Fig. 1) of carbon atoms C8 and C9 with their longest axes perpendicular to the FeN_2 plane indicate a disorder of C8 and C9 implying the equilibrium of the two opposite *meso* conformations, whether it is static or dynamic in nature cannot be resolved by one temperature X-ray structure alone. Similar observation has also been reported for Co(II) complexes [20]. This makes the overall conformation (Fig. 2) of the molecule quite different from **1**. The sal1 and sal2 units are bent towards the same side with respect to the N_2O_2 plane by unequal amounts (13.1° and 6.99°, respectively), giving a shallow "umbrella like" shape to the molecule.

The complex molecule adopts two different conformations as seen best in Fig. 2, which could be attributed to the presence of different anions resulting in different packing forces. The extreme influence of the anions on the solid state conformations is seen in the case of [Fe(salen)$(Im)_2$]Y structures; the molecule has a "stepped" conformation exhibiting spin tran-

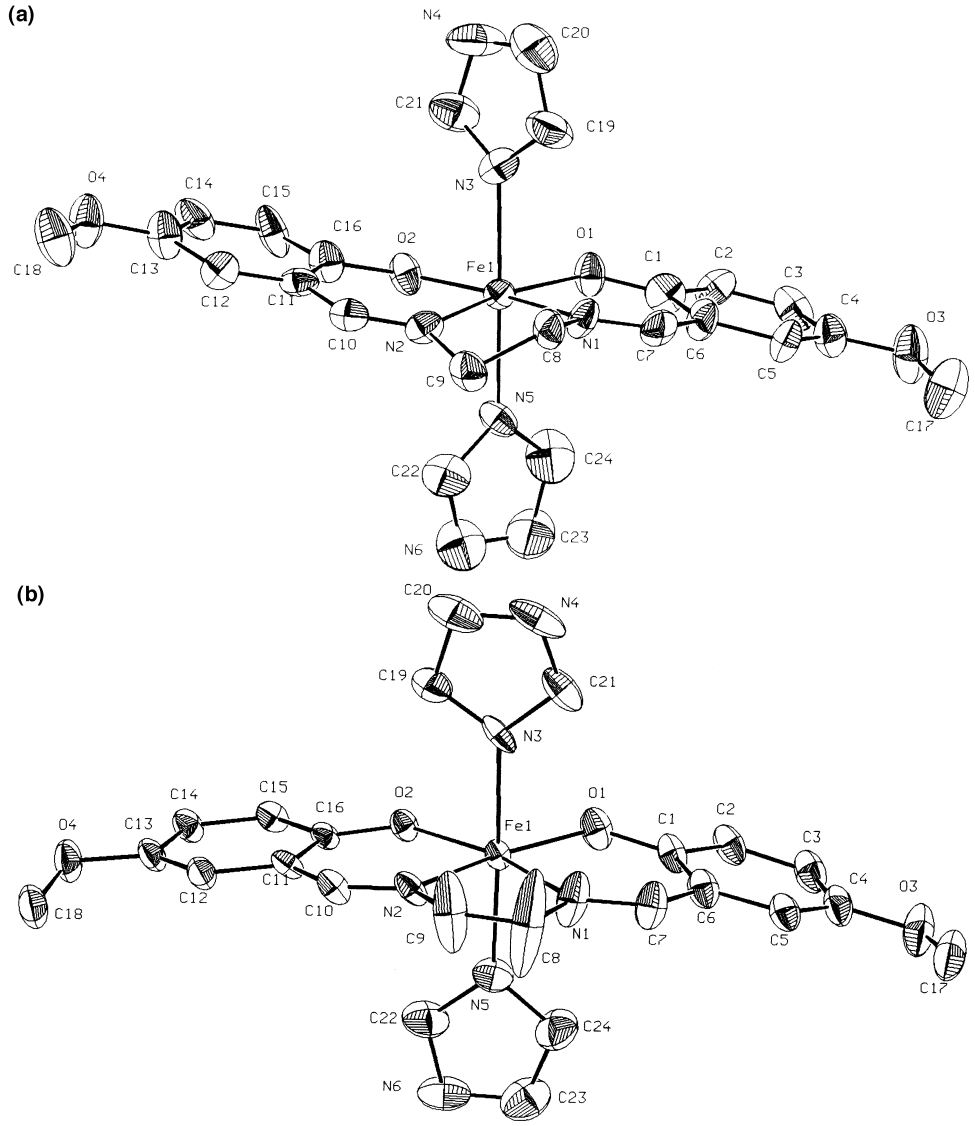

Fig. 1. Molecular Structure (ORTEP diagrams) of the cation $[Fe(5\text{-}CH_3O\text{-}salen)]^+$ in (a) **1**, Y = ClO_4^-, 50% probability surfaces and (b) **2**, Y = Cl^-, 40% probability surfaces.

sition (ST) behavior when Y = ClO_4^- whereas the molecule is planar showing no ST when Y = PF_6^- [12].

The orientation of the imidazole rings in **1** and **2** is best seen looking approximately down in the perpendicular direction to the FeN_2 plane of 5-CH_3O-salen (fig. 3). In **1**, the imidazoles are aligned almost along the O—Fe—N bond directions, thus making an angle of 77.3° with each other. In **2**, both the planes of imidazole rings are almost along the direction bisecting the O—Fe—N angles, the angle between the planes is 175.1°. In **1**, the imidazole ring containing N4 does not show any H-bonding interaction of N—H···O type with ClO_4^- oxygens, the other imidazole ring N5, C22, N6, C23, C24 shows a weak (N6H)···O5 hydrogen bond (3.08 Å, 128°) whereas in **2**, both the imidazole N—H make good H-bonding interactions with the Cl^- anion (N4—H···Cl1 = 3.15 Å, 158°; N6—H···Cl1 = 3.08 Å, 142°).

Spin crossover in polycrystals-magnetism and EPR studies

All the complexes are paramagnetic and μ_{eff} values at 298 K vary in the range 5.54–5.96 μ_B corresponding to a high spin electronic ground state with five unpaired electrons. The salen and 5-Cl-salen complexes with Cl^- and ClO_4^- ions however, showed interesting spectral changes due to spin crossover as the temperature was lowered to 77 K. A typical variation for polycrystals of $[Fe(salen)(2\text{-}MeIm)_2]ClO_4$ is depicted in Fig. 4. In fact, several resonances were observed at

ambient temperatures with g values being 19.26, 10.72, 8.29, 7.14, 4.32, 3.7, 3.43 and 2.87. As discussed in the experimental section (*vide supra*), higher limit of g for high spin species in a rhombically distorted zero-field (if $D \geqslant 0.15\ cm^{-1}$) is ~ 10. The signals with $g \sim 19.26$

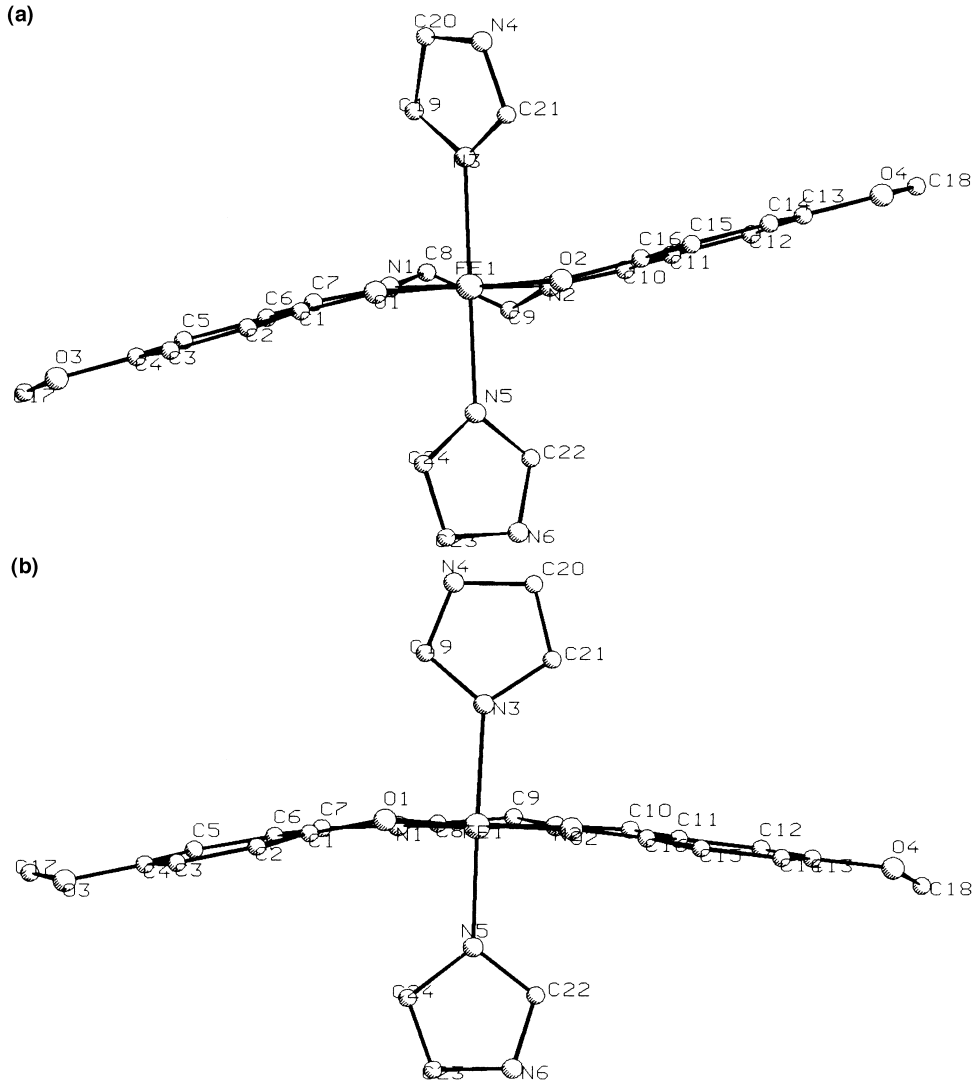

Fig. 2. Diagrams showing the effect of counterion on the conformational flexibility of 5-CH_3O-salen moiety in (a) **1** and (b) **2**.

and 10.72, prevalent only at ambient temperatures, cannot be accounted for an isolated high spin ferric ion but are attributed to those originating through exchange interactions between weakly antiferromagnetically coupled nearest neighbors [21]. As the temperature of the sample was lowered the intensity of these signals decreased and around 230 K a new signal ($g \sim 2.1$) appeared, the intensity of which increased with further lowering of temperature. Finally, an axial spectrum was observed at 77 K with $g\| = 2.107$ and $g\perp = 2.067(3)$ corresponding to a low spin configuration for Fe(III). But for complexes with Im as an axial ligand, the low spin species was characterized by a rhombic spectrum. Complexes with BPh_4^- as the counter anion showed two resonances ($g \sim 8.6$ and 4.3) at 298 K. However, at 77 K additional weak signals appeared around $g \sim 2$ corresponding to spin equilibrium ($5/2 \rightleftharpoons 1/2$). It is important to note that the observation of distinct high and low spin resonances implies that the spin state conversion rates are slower than the EPR time scale ($\sim 10^{10}$ s^{-1}).

Unlike those of salen and 5-Cl-salen, the complexes with 5-CH_3O-salen showed very broad signals in the range 800–4000 G at 298 K. Cooling the sample to 77 K has moderately reduced the line widths. These features indicate that 5-CH_3O-salen complexes are of high spin type throughout the temperature range and are consistent with the structural parameters. X-ray structure of **2** indeed revealed the intermolecular interactions through counterion (Cl^-) making N3(H)—Cl—(H)N6 bonds. We believe that these H-bonds are probably the pathway for exchange interactions resulting in broad signals.

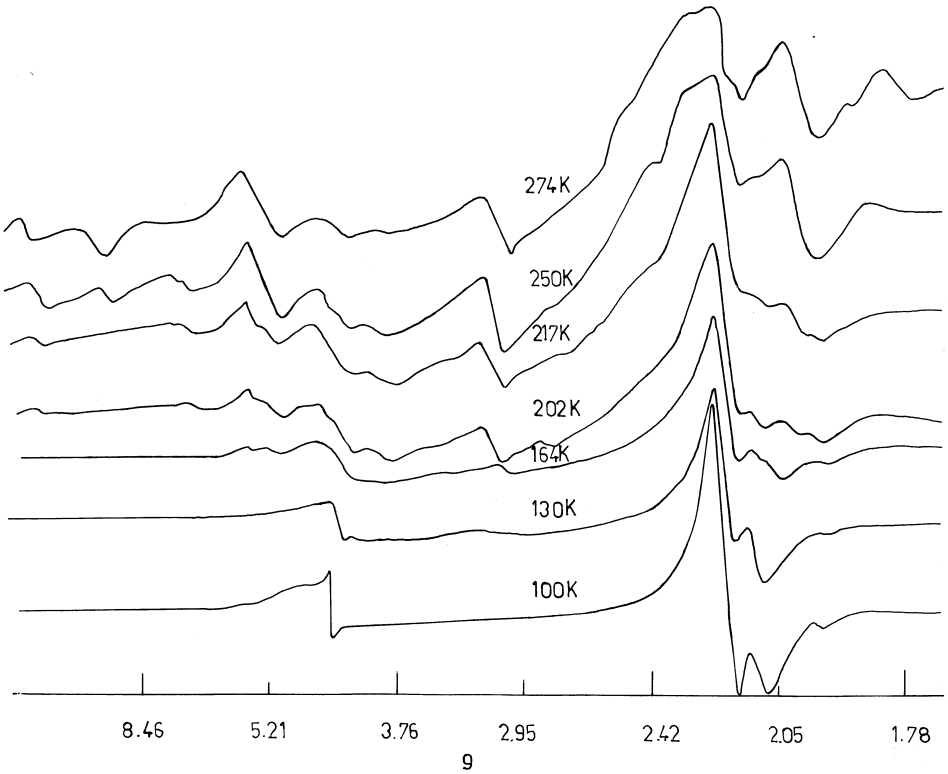

Fig. 4. Variable temperature EPR spectra for polycrystals of $[Fe(salen)(2\text{-}MeIm)_2](ClO_4)$. Experimental conditions 9.47 GHz microwave frequency, 2 mW power, 3.15-G modulation and 2×10^4 gain.

EPR of solutions

Methanolic and DMF solutions of the complexes did not show EPR at ambient temperatures, probably due to short electron spin lattice relaxation times. However, upon cooling a sharp signal due to high spin state (at $g \cong 4.3$) and around 220 K, a signal for a low spin state (at $g = 2.1$) appeared. As the temperature was further lowered the intensity of the signal due to low spin state gradually increased while that of high spin state decreased. For salen and 5-Cl-salen complexes the spectrum at 77 K could be attributed solely to a low spin state (Fig. 5). Spin crossover in these complexes is gradual and complete. 5-CH_3O-salen complexes are high spin in solid state whereas their methanolic solutions exhibit spin crossover behavior. The spectrum at 77 K (Fig. 5) contains signals due to both high and low spin states. In other words, spin crossover in 5-CH_3O-salen complexes is not complete above 77 K. It is clear from Fig. 5 that the intensity ratio of HS to LS state signals varies linearly with the donacity of the substituents in the order $CH_3O > H > Cl$.

Variable temperature spectra for Salen and 5-Cl-salen complexes with Im as axial ligand and Cl^- and ClO_4^- as counterions showed the presence of two types of low spin (LS1 and LS2) species. Around 220 K, methanolic solutions showed an almost "axial" spectrum with g anisotropic being 2.22–1.95 corresponding to LS1. As the temperature was lowered, the intensity of signals for LS1 decreased and a rhombic type spectrum with higher g anisotropy (2.44–1.89) corresponding to LS2 appeared. The intensity of signals for the latter species increased with further lowering of temperature. The transition from LS1 to LS2 is reversible and Fig. 6 depicts the variable temperature spectra for [Fe(5-Cl-salen)$(Im)_2$]Cl. As far as we are aware, this is the first report showing the existence of two types of low spin species.

Complexes with 2-MeIm as axial ligand showed spectra characteristic of LS1 species only. The intensity ratio of the HS to LS signals at 77 K varied with counter ions in the order $BPh_4^- > ClO_4^- > Cl^-$. While the methanolic solutions of the complexes exhibited spin crossover behavior, their DMF solutions were high spin throughout the temperature range. It may be possible that the highly coordinating solvents may not allow changes in the chelate conformation and restrict the breathing modes of the salen ligand responsible for the spin crossover phenomenon. Indeed such solvent and Schiff base interactions were observed in our earlier studies on Cu(II) complexes [22] and by others [23]. The g values for low spin state are listed in Table 3.

Methanolic solutions of the complexes showed remarkable thermochromism, with the colour changing from reddish brown to bluish violet or green. Interesting to note that reddish brown is associated

[a] Two types of low spin species LS1 and LS2.

with the HS state while bluish violet to LS1 and green to LS2 states. Such colour isomerism with spin crossover was also observed in some related Fe(III) complexes and this phenomenon probably associates with changes in the ligand geometry.

Ground state wave function, distortion parameters and excitation energies for low spin configuration

The EPR data for the low spin configurations (Table 4) were least squares fitted to the g value expressions given by eqns (5)–(7) and the MO coefficients for the ground state Kramers' doublet (a, b and c), orbital reduction parameter (K), distortion parameters (axial, Δ and rhombic, V) and energy separations of the two excited doublets are listed in Table 3. It is obvious that the ground state has a "predominant" d_{xy} character with a little admixture from the d_{xz} and d_{yz} orbitals ($b > a$ and c). The orbital reduction parameter (K) varies in accordance with the donacity of the substituent in the order 5-CH_3O > H > Cl and suggests more covalent bonding in salen and 5-Cl-salen complexes compared to 5-CH_3O-salen complexes. The V/Δ values, a measure of rhombicity, are higher for 5-Cl-salen and salen than for 5-CH_3O-salen complexes. A considerable variation in these values is observed for LS1 and LS2 configurations (LS2 > LS1). Taking the value of spin-orbit coupling constant (λ) to be 460 cm^{-1} for a free Fe(III) ion, the separation of the two excited Kramers' doublets (ΔE_1 and ΔE_2) were calculated to lie in the range 1485–2736 and 2800–4774 cm^{-1}, respectively. These values indicate that the three doublets are well separated and resonances occur from the ground state Kramers' doublet only. Interestingly X-ray structures indicate that Fe—N and Fe—O bond distances are shorter for spin crossover $[Fe(salen)(Im)_2](ClO_4)$ [12] compared to $[Fe(5\text{-}CH_3O\text{-salen})(Im)_2]Y$, where $Y = ClO_4^-$ (**1**) and Cl^- (**2**) and complement the EPR results confirming higher covalency for salen than for 5-CH_3O-salen.

Structure-spin state-reactivity correlations

For complexes with ligand field strength in the crossover region, a change in the physical parameters (temperature, pressure etc.) alters the molecular geometry and thereby causes spin state conversion. According to Scheidt and Reed [4] upon crossover from a HS to a LS state the iron atom in porphyrin complexes moves more into the plane of the macrocyclic ligand and Fe—N bond lengths decrease from ~2.14 Å for a high spin to ~1.99 Å for a low spin configuration; as a consequence of this the size of the porphyrin core reduces. Kennedy *et al.* have reported similar structural changes in Fe—N bond lengths for a related $[Fe(salen)(Im)_2](ClO_4)$ complex [12] and Hendrickson *et al.* [10] for $[Fe(3\text{-OEt-salAPA})_2]ClO_4 \cdot C_6H_6$, where 3-OEt-salAPA = Schiff base condensate of 3-ethoxysalicylaldehyde and N-(3-aminopropyl)aziridine. X-ray structural data and molecular geometries of various related Fe(III) Schiff base complexes are listed in Table 5. These results and those of our on analogous Cu(II) complexes [22] reveal that salen ligand is conformationally flexible like the heme environment in metalloproteins and adopts an overall "stepped, umbrella or planar" conformation. Also the FeN_2C_2 ring containing the ethylene back-

bone takes up geometries like "envelope, planar or *meso*" conformations. X-ray structures in the present investigation indicate a considerable effect of the counterion on ligand geometry. The chloro complex (**2**) has an "umbrella" type overall chelate conformation with a "planar" geometry for FeN_2C_2 whereas the perchlorato complex (**1**) possesses an overall "planar" conformation with a "*meso*" arrangement for the FeN_2C_2 ring. The bond lengths of Fe—N(salen/Im) and Fe—O fall within the range for high spin complexes consistent with EPR results for solid complexes. The comparative study (Table 4) clearly indicates and agrees well with the report by Kennedy *et al*. [12] that the "envelope" geometry is essential for spin crossover while "*meso*" is for high spin configuration. Probably shortening of Fe—N bonds without much alterations in the geometry of the molecule is possible only with the "stepped" conformation. Although 5-CH_3O-salen complexes are high spin in solid state, their methanolic solutions exhibit spin crossover behavior. This observation suggests that in solid state the molecule is fixed in a high spin type "umbrella or planar" geometry due to packing or intermolecular interactions while in solutions it undergoes conformational changes to a "stepped" conformation with a certain degree of "envelope" geometry for the FeN_2C_2 ring which is responsible for spin crossover.

The axial ligands (Im) in **1** and **2** adopt two types of conformations "syn" for (Cl^-) and "gauche" (for ClO_4^-), but their orientations unlike for porphyrin complexes [4,9] have little effect on the spin state of Fe(III). However, the "syn" orientation results in higher symmetry at the site of Fe(III) and an axial spectrum for LS1. Steric hindrance due to CH_3 groups in complexes with 2-MeIm probably allows only the "syn" arrangement for the axial ligands whereas in complexes with Im, the axial ligands undergo orientational changes with lowering of temperature resulting in a "gauche" arrangement corresponding to LS2 and a rhombic EPR spectrum (Table 3). Effect of solvent on spin crossover suggests that DMF molecules probably involve in H-bonding interactions with the Schiff base ligand and does not allow the molecules to take up the "stepped" conformation responsible for spin transition. These results reveal that a flexible ligand geometry providing required ligand field strength is essential for the central metal ion Fe(III) to exhibit spin crossover behavior.

During the preparation it was observed that the spin crossover complexes 5-Cl-salen and salen were highly reactive towards molecular oxygen and readily forms orange red μ-oxo Fe(III) species. It is pertinent to note that a similar reactivity towards molecular oxygen also by Co(II) [24,26], Ni(III) [28] and Mn(II) [29] salen type complexes. Interestingly the bioinorganic catalysts, hemoproteins involved in several physiological functions also exhibit conformational flexibility of the surrounding protein macrostructure *vis-a-vis* labile spin states. All these factors tempt us to conclude that there exists an interesting correlation between the structure-spin state and functionality of the molecules. The energy liberated by electronic structural rearrangement would enhance the functionality of spin crossover complexes.

CONCLUSIONS

Substituents on salen ligand and counterion showed significant effect on the chelate geometry, spin state and reactivity of iron(III) in [Fe(5-X-salen)$(Im)_2$]Y complexes. A "stepped" conformation for salen is essential for spin crossover. Finally, it is believed that spin crossover associated with changes in the chelate conformation aids the reactivity of the molecules.

Copper(II) complexes of two new oxamidate bis-tetradentate Schiff-base ligands

Jose M. Dominguez-Vera,* Natividad Galvez, Jose M. Moreno and Enrique Colacio

Departamento de Química Inorgánica, Facultad de Ciencias, Universidad de Granada, 18071 Granada, Spain

(Received 17 November 1997; accepted 21 January 1998)

Abstract—Two novel symmetrical bis-tetradentate Schiff base ligands, H_2L^1 and H_4L^2, have been prepared from the condensation of *N*,*N*′-bis(3-aminopropyl)oxamide with pyridine-2-carbaldehyde and pyrrol-2-carbaldehyde, respectively. The ligands react with copper(II) nitrate in basic medium to yield the dinuclear complexes $[Cu_2L^1](NO_3)_2$ and $[Cu_2L^2]$. $[Cu_2L^1](NO_3)_2$ reacts with sodium azide to yield the neutral dinuclear complex $[Cu_2L^1(N_3)_2]$, which was structurally characterized by X-ray diffraction. The complex crystallizes in the monoclinic system, space group $P2_1/c$ with cell constants: $a = 7.916(2)$ Å, $c = 20.110(4)$ Å, $\beta = 95.20(3)^\circ$, $V = 1255.4(4)$ Å^3, $Z = 2$. The structure consists of neutral quasi-planar centrosymmetric dinuclear copper(II) molecules, where two crystallographically equivalent copper(II) ions are bridged by an oxamidate group in *trans* conformation, resulting in a copper-copper distance of 5.271 Å. Each copper(II) ion occupies the N_3O inner site of the doubly-deprotonated L^1 ligand with bond distances of ca 2.0 Å, whereas a nitrogen atom from the azide group completes the coordination polyhedron with a longer bond distance of 2.340(4) Å. All the dinuclear complexes exhibited strong antiferromagnetic exchange interaction. The magnetic data were analyzed by using the Bleaney-Bowers equation ($H = -JS_1S_2$) leading to singlet-triplet energy values (J) of 425.5 cm^{-1} for $[Cu_2L^1](NO_3)_2$, 427.9 cm^{-1} for $[Cu_2L^2]$ and 424.1 cm^{-1} for $[Cu_2(L^1)(N_3)_2]$. These J values are a consequence of the ability of the oxamidate-bridge to propagate the antiferromagnetic exchange interaction between metal ions which allow a large overlap of the $d_{x^2-y^2}$ magnetic orbitals centered on each copper(II) ion. © 1998 Elsevier Science Ltd. Keywords:

N,*N*′-bis(substituted)oxamides (scheme) have played a key role in the design of polymetallic ligands due to their versatility and remarkable ability to mediate strong exchange interactions when acting as bridging ligands between paramagnetic centers. The versatility of these ligands is based on (i) the wide variety of derivatives which can be prepared by changing the substituents of the amino groups, thus leading to different chelate rings and/or donor atoms and (ii) their easy *cis-trans* conformational isomerization.

Most *N*,*N*′-bis(substituted)oxamides reported up to date contain an amino moiety (primary, secondary to tertiary) as a terminal group X and an aliphatic chain of two or three carbon atoms. From this type of ligands, a lot of structures, including di- [1–13], tri [13], tetra- [14] and infinite polynuclear [1,15] copper(II) complexes have been reported and their magnetic properties studied. When X is NH_2, it has been recently shown that the oxamide reacts with aldehydes, such as salicylaldehyde [16] or imidazole-2-carbaldehyde [17] to yield new binucleating ligands. This latter fact adds a new perspective that increases the interest of this type of ligands, since by choosing the appropriate aldehyde reagent, one can obtain new polynucleating ligands designed for particular problems.

Following this line, condensation of *N*,*N*′-bis(3-aminopropyl)oxamide with pyridine-2-carbaldehyde or pyrrol-2-carbaldehyde leads to two new symmetric ligands, H_2L^1 and H_4L^2 (scheme). In both ligands, the *trans* conformation become more likely due to steric hindrance from the pyridyl or pyrrol groups. In the *trans* conformation, both ligands display two identical

H_2L^1 H_4L^2

Scheme 1.

N_3O coordination sites and then, the ligand can simultaneously accommodate two copper(II) ions. In fact, H_2L^1 and H_4L^2 readily react with copper(II) nitrate hydrate to afford homodinuclear complexes of formula $[Cu_2L^1](NO_3)_2 \cdot 2H_2O$ and $[Cu_2L^2] \cdot 2H_2O$, respectively. In the complex $[Cu_2L^1](NO_3)_2 \cdot 2H_2O$, each copper(II) ion can accept one donor atom in axial position. Thus, by reaction of $[Cu_2L^1](NO_3)_2 \cdot 2H_2O$ with sodium azide we succeeded in obtaining the neutral dinuclear complex $[Cu_2L^1(N_3)_2]$, which was structurally characterized by X-ray diffraction. All the dinuclear complexes exhibited strong antiferromagnetic exchange interaction.

EXPERIMENTAL

Preparation of the ligands

N,*N*′-bis(3-aminopropyl)oxamide (hereafter H_2oxpn) was prepared as previously reported [17]. H_2L^1 and H_4L^2 were synthesized by following a general procedure we recently reported [17]. Pyridine-2-carbaldehyde or pyrrol-2-carbaldehyde was directly added to a methanolic suspension of H_2oxpn. After one hour of heating at 50°C, the resulting yellow soln was kept at 0°C for one day. H_2L^1 and H_4L^2 were obtained in good yield as yellow pale and white powders, respectively. Analytical data (C, H, N) were according to the anhydrous ligands. ^{1}H NMR [$(CD_3)_2SO$] of H_2L^1: δ 1.84 (q, 4H, CCH_2C), δ 3.23 (m, 4H, CH_2NH), δ 3.63 (t, 4H, NCH_2), δ 7.44 (dd, 2H, CH), δ 7.85 (pst, 2H, CH), δ 7.97 (psd, 2H, CH), δ 8.33 (s, 2H, HC═N), δ 8.62 (psd, 2H, CH) and δ 8.80 (t, 2H, NH). ^{1}H NMR [$(CD_3)_2SO$] of H_4L^2: δ 1.77 (q, 4H, CCH_2C), δ 3.23 (m, 4H, CH_2NH), δ 3.48 (t, 4H, NCH_2), δ 6.11 (m, 2H, CH), δ 6.43 (dd, 2H, CH), δ 6.85 (pst, 2H, CH), δ 8.06 (s, 2H, HC═N), δ 8.97 (t, 2H, NH).

Preparation of the complexes

$[Cu_2L^1](NO_3)_2 \cdot 2H_2O$. H_2L^1 (2 mmol, 760 mg) was dissolved in 50 ml of a methanol/water (4 : 1) mixt. containing potassium hydroxide (4 mmol, 224 mg). Then, solid copper nitrate hydrate (4 mmol, 750 mg) was directly added with stirring. After a few minutes a dark-blue soln was obtained, which was filtered to remove any amount of insoluble material. Slow evaporation at room temp. afforded green crystals which were filtered off, washed with methanol and diethyl ether and air-dried; yield 78% (Found: C, 36.1; H, 4.1; N, 16.6. Calc. for $C_{20}H_{26}N_8O_{10}Cu_2$: C, 36.1; H, 3.9; N, 16.8).

$[Cu_2L^2] \cdot 2H_2O$. H_4L^2 (2 mmol, 708 mg) was dissolved in 50 ml of methanol containing potassium hydroxide (8 mmol, 448 mg). Addition of any copper(II) salt (2 mmol) such as nitrate, acetate or chloride leads after a few minutes of stirring to the precipitation of the complex as a brown powder, which was filtered off, washed with methanol and diethyl ether and air-dried; yield 70%. (Found: C, 42.0; H, 4.4; N, 16.3. Calc. for $C_{18}H_{22}N_6O_4Cu_2$: C, 42.1; H, 4.3; N, 16.4).

Both complexes $[Cu_2L^1](NO_3)_2 \cdot 2H_2O$ and $[Cu_2L^2] \cdot 2H_2O$ can also be prepared from the condensation of the complex $[Cu_2(trans\text{-oxpn})(NO_3)_2]$ [1] with pyridine-2-carbaldehyde or pyrrol-2-carbaldehyde, respectively in basic medium.

$[Cu_2(L^1)(N_3)_2]$. Sodium azide (3 mmol, 195 mg) was added to a methanolic soln of $[Cu_2L^1](NO_3)_2 \cdot 2H_2O$ (1 mmol, 665 mg). The resulting blue soln was filtered to remove any amount of insoluble material and

allowed to stand at room temp. After one day, blue crystals suitable for X-ray diffraction were obtained in good yield, 76%. (Found : C, 40.9 ; H, 3.5 ; N, 28.6. Calc. for $C_{20}H_{20}N_{12}O_2Cu_2$: C, 40.9 ; H, 3.4 ; N, 28.6).

Physical measurements

Elemental analyses were carried out at the Technical Services of the University of Granada on a Fisons-Carlo Erba analyzer model EA 1108. IR spectra were recorded on a Perkin–Elmer 983 G spectrometer using KBr pellets and NMR spectra, ^{1}H, on a Bruker AM-300 using dmso-d_6 as solvent. Variable-temperature magnetic susceptibility data were collected on powdered samples of the compounds with use of a pendulum type magnetometer (MANICS DSM8) equipped with a helium continuous flow cryostat working in the temperature ranges 300–4 K for $[Cu_2(L^1)(N_3)_2]$ and $[Cu_2L^2]\cdot 2H_2O$ and 300–60 K for $[Cu_2L^1](NO_3)_2\cdot 2H_2O$ with a Drusch EAF 164E electromagnet. The magnetic field was approximately 15,000 G. Data were corrected for the diamagnetism of the ligands using Pascal's constants.

X-Ray data collection and structure determination of the complex $[Cu_2(L^1)(N_3)_2]$

Single crystal data collection was performed at 293 K with a Siemens R3m/V diffractometer using graphite monochromatized Mo–K_α ($\lambda = 0.71073$ Å) radiation. A prismatic blue crystal of dimensions $0.28 \times 0.40 \times 0.24$ mm was used.

The unit cell parameters were calculated by least-squares refinement of 25 well centred reflections in the range $15 < 2\theta < 45°$. A total of 4193 reflections ($5 < 2\theta < 60°$) were collected and of those 2399 unique reflections with $I > 2.5\sigma(Io)$ were considered as observed. The data were corrected for Lorentz-polarization effects and for absorption (empirical Ψ scan). Crystallographic data are listed in Table 1.

The structure was solved by direct methods and subsequent Fourier syntheses with the SHELXTL-PC V.5 program [18]. All non-hydrogen atoms were refined anisotropically, except the C(10) atom which was refined isotropically in two disordered positions. The hydrogen atoms were generated at their ideal positions and included in the calculations riding on their carrying atoms. Neutral atomic scattering and dispersion factors were those included in the SHELXTL-PC package.

RESULTS AND DISCUSSION

The ability of H_2oxpn to react with imidazole-2-carbaldehyde has been recently shown [17]. In this paper we extend such method with other aldehyde reagents in order to prepare two new bis-tetradentate schiff-base ligands. The ligands H_2L^1 and H_4L^2 are easily obtained by condensation of one mol of H_2oxpn with two moles of pyridine-2-carbaldehyde or pyrrol-2-carbaldehyde, respectively. ^{1}H NMR spectroscopy provides a good characterization of both ligands. The assignments (see experimental section) are based on the chemical shift, intensity and multiplicity values and they are supported by comparison between themselves with literature data for similar compounds [16,17].

The complexes $[Cu_2L^1](NO_3)_2\cdot 2H_2O$ and $[Cu_2L^2]\cdot 2H_2O$ can be prepared either from the respective ligands, by direct reaction with copper(II) nitrate or by making use of the template effect, by reacting the complex $[Cu_2(trans\text{-oxpn})(NO_3)_2]$ [1] with pyridine-2-carbaldehyde or pyrrol-2-carbaldehyde. In this second way, as for other similar reactions previously reported [17], a basic medium is needed to carry out the formation of the Schiff-base.

The IR spectra of both ligands show the characteristic sharp and intense ν(N—H) vibrations at 3303 and 3298 cm^{-1} and ν(C═O) amide bands at 1653 and 1648 cm^{-1} for H_2L^1 and H_4L^2, respectively. In addition, for H_4L^2, a small band corresponding to the ν(N—H) of the pyrrol ring is observed at 3190 cm^{-1}.

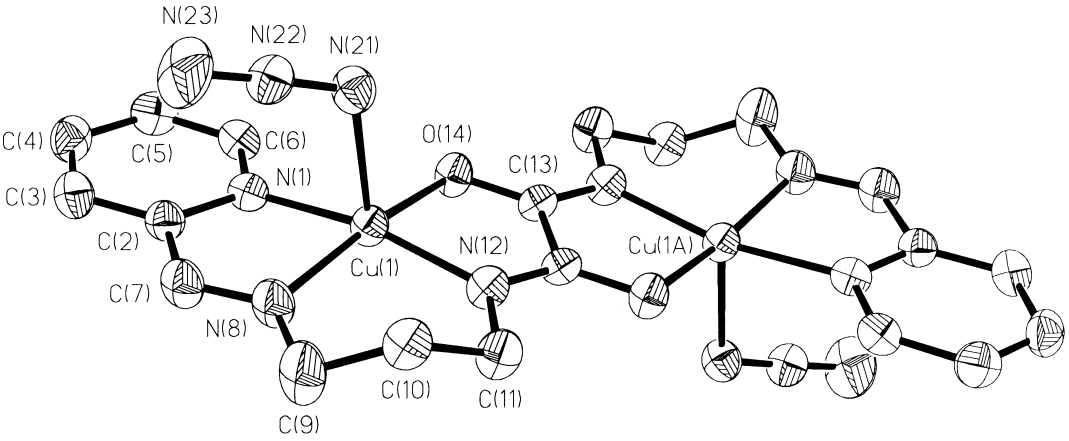

Fig. 1. A perspective view of the dinuclear $[Cu_2L^1(N_3)_2]$ molecule.

Likewise, a comparative study of the IR spectra of the ligands and their complexes reveals some details of the coordinating behaviour of the H_2L^1 and H_4L^2 ligands. Thus, in the IR spectra of all the copper(II) complexes NH absorption are absent, which confirms that the oxamidate group in H_2L^1 and the oxamidate and pyrrol groups in H_4L^2 coordinate the copper(II) ion in a deprotonated form. Moreover, the IR spectra of the copper(II) complexes of H_2L^1exhibit bands of the corresponding copper salt anion. These spectral features are in accord with the molecular structure proposed for $[Cu_2L^1](NO_3)_2 \cdot 2H_2O$ and $[Cu_2L^2] \cdot 2H_2O$, in which two copper(II) ions occupy the two symmetric N_3O inner sites of the di- and tetradeprotonated L^1 and L^2 ligands, respectively.

In $[Cu_2L^1](NO_3)_2 \cdot 2H_2O$, each copper(II) ion can accept one donor atom, such as the nitrogen atom from an azide anion, giving rise to the neutral complex $[Cu_2L^1(N_3)_2]$, that can be obtained as blue crystals suitable for X-ray diffraction. The structure of this complex consists of neutral centrosymmetric dinuclear copper(II) molecules. A perspective view of the molecular structure together with the atomic numbering scheme is shown in Fig. 1. Selected intramolecular bond distances and angles are listed in Table 2.

Within the dinuclear molecules, the crystallographically equivalent copper(II) ions are bridged by an oxamidate group in *trans* conformation, resulting in a copper-copper distance of 5.271 Å. A centre of inversion is located at the middle of the C(13)—C(13)^{i} bond of the oxamidate group (i: $-x$, $-y$, $-z+1$). Each copper(II) ion occupies the N_3O inner site of the doubly-deprotonated L^1 ligand with bond distances of ca 2.0 Å. The N(21) atom from the azide group completes the coordination polyhedron. The copper ion environment can be considered as CuN_4O square-pyramidal, $\tau = 0.02$ (according to the procedure proposed by Addison *et al.* [19], τ is 1 for the regular trigonal bipyramid and 0 for the square pyramid), with the basal plane defined by the N_3O coordination site of L^1 and the apical position being occupied by the azide N(21) atom at a longer bond distance of 2.340(4) Å. The coordination basal plane is almost

Table 2. Selected bond lengths (Å) and angles (°) for $[Cu_2L^1(N_3)_2]$

Cu(1)—N(12)	1.971(4)	Cu(1)—O(14)	1.999(3)

N(22)—N(21)—Cu(1)	114.4(3)	N(23)—N(22)—N(21)	176.9(5)

planar with maximum deviation of 0.0076 Å for the atom N(8). As usual in this geometry, the copper(II) ion deviates (0.2085 Å) from the coordination basal plane toward the apical position.

The bis-tetradentate behaviour of the ligand gives rise to one six- and two five-membered chelate rings on each copper(II) ion. The coordination basal plane and the oxamidate bridging group are almost planar and form a dihedral angle of 8.8°. The deviation of the copper(II) ion from the $C_2N_2O_2$ plane is very small (0.0139 Å), so that the dinuclear $[Cu_2L^1]^{2+}$ skeleton is not far from planarity.

The azide fragment is quasi-linear, with a N(21)—N(22)—N(23) angle of 176.9(5)°, and asymmetric with N(21)—N(22) and N(22)—N(23) distances of 1.199(6) and 1.155(7) Å, respectively. The angle Cu—N(21)—N(22) is of 114.4(3)° which agrees with a sp^2-hybridization of the N(21) atom.

There are no hydrogen bonds or close contacts between the dinuclear molecules, indicating that these are well isolated in the structure.

Magnetic properties

The temperature dependence of the χT product per copper atom for $[Cu_2L^1](NO_3)_2\cdot 2H_2O$, $[Cu_2L^2]\cdot 2H_2O$ and $[Cu_2L^1(N_3)_2]$ are shown in Fig. 2. The room-temperature χT values for the three compounds are lower than that expected for non-interacting copper(II) ions (0.375 $cm^3\ mol^{-1}$ K with $g = 2.0$). This fact together with the decreasing of χT with T over the explored temperature range, clearly indicate that strong antiferromagnetic exchange couplings operate between copper(II) ions in the three compounds.

In keeping with their dinuclear structures, the magnetic data of the complexes were analyzed by the Bleaney-Bowers equation ($H = -JS_1S_2$). A parameter, ρ, was included into the equation to consider the mononuclear magnetic impurity and in the case of the complex $[Cu_2L^1(N_3)_2]$, a Weiss constant, θ, was also included to take phenomenologically into account the decrease of χT at low temperature. The g values were those obtained from the polycrystalline EPR spectra at room temperature. The best fit of the magnetic data by this equation was found with $J = 425.5\ cm^{-1}$, $g = 2.05$, $\rho = 5.8\%$ for $[Cu_2L^1](NO_3)_2\cdot 2H_2O$, $J = 427.9\ cm^{-1}$, $g = 2.04$ and $\rho = 6.1$ for $[Cu_2L^2]\cdot 2H_2O$ and $J = 424.1\ cm^{-1}$, $g = 2.09$, $\rho = 2.1$ and $\theta = -9.2$ K for $[Cu_2L^1(N_3)_2]$.

The singlet-triplet energy values (J) obtained are close to other structurally characterized *trans*-oxamidate-bridged dinuclear copper(II) complexes [1–8] and they are a consequence of the ability of the oxamidate-bridge to propagate the antiferromagnetic exchange interaction between metal ions, which allows a large overlap of the $d_{x^2-y^2}$ magnetic orbitals centered on each copper(II) ion [20]. The high bridging site planarity also contribute to the large J values observed for these complexes.

(Received 26 November 1997; accepted 21 January 1998)

Abstract—The reaction of $[(dien)Cu(ONO_2)]NO_3$ and [(dien)CuBr]Br with Guanosine(Guo) gave the compounds $[(dien)Cu(Guo\text{-}N^7)(ONO_2)]NO_3$ [dien = diethylenetriamine and [(dien)Cu(Guo)(Br)]Br, respectively. The reaction of $[(dien)Cu(ONO_2)]NO_3$ with Adenine(A) afforded the compound $[(dien)Cu(A)(ONO_2)]NO_3$. The complexes have been characterized by elemental analyses, molar conductance and magnetic measurements, as well as by electronic and IR spectral studies. According to the spectral data the ligands (Guo and A) bind to the copper atom via N^7. The crystal structure of the $[(dien)Cu(Guo\text{-}N^7)(ONO_2)]NO_3$ complex has been determined by X-ray diffraction. Copper(II) is five coordinated with three nitrogen atoms from the dien molecule [2.015(6) Å, 2.007(4) Å, 2.038(6) Å], the N^7 atom from guanosine [2.006(4) Å] and an oxygen atom from a nitrato group [2.251(6) Å]. The five donor atoms form a distorted square pyramid with the four nitrogen atoms on its basal plane and the oxygen atom at the apical position. All the complexes are electrolytes as indicated by their molar conductance in methanol or water. The magnetic moments are consistent with monomeric copper(II) units. © 1998 Elsevier Science Ltd. Keywords: Copper(II) complexes; dien; guanosine; adenine; crystal structure; absolute configuration.

The antitumour activity of inorganic compounds was reported more than 25 years ago [1]. It is well known that the most famous antitumour drug *cis*-DDP reacts with cellular components such as DNA and proteins [2,3]. The formation of metal complex-DNA adduct is expected to have a significant impact on the biological function of DNA. NMR and X-ray structural studies showed that the metals prefer as binding sites on DNA the N^7 atoms of guanine and adenine [4,5], the N^1 atom of adenine [6,7] and the N^3 atom of cytosine [8]. In some cases the preference of the metals for other coordination sites of the bases, is governed by the reaction conditions [9, 10], such as solvent, pH, etc; it is also associated with the stronger basicity of certain nitrogen atoms, the hydrogen bonds, the steric hindrance and unpredictable factors.

Although the Pt(II) complexes seem to be the major pharmacological tool in chemotherapy, some inorganic compounds of Re [11], Ru [12], Rh [13], Cu(I) and Cu(II) [14] have also been documented to exhibit carcinostatic activity. These metal centres with polyamine ligands, could be the key for future studies, owing to their lower toxicity to humans as compared to that of platinum [15, 16].

In a previous study [17] we found that the antiproliferative activity of copper(II) compounds with triamines (dien, dpt and their derivatives) is related with their electronic structure and is independent of the additional counter-ion (e.g. NO_3^-, SO_4^{2-}, etc.). Taking into account that the square planar or square pyramidal Cu(II) compounds exhibit the tendency for axial ligation [18] and in order to extend our knowledge on the coordination chemistry of the above complexes, we carried out reactions of $[(dien)Cu(ONO_2)]NO_3$ and [(dien)Cu(Br)]Br with DNA com-

ponents, such as guanosine and adenine and studied the reaction products. The results of this work are presented in this paper.

EXPERIMENTAL

Starting materials

Adenine and guanosine were purchased from P-L Biochemicals Inc., copper(II) nitrate trihydrate and copper(II) bromide were obtained from Merck Chemicals and used as received. [(dien)Cu(ONO_2)]NO_3 and [(dien)Cu(Br)]Br were prepared as previously described elsewhere [19,20]. The solvents were reagent grade and were used without further purification.

Preparation of complexes

The new complexes were prepared by mixing a methanolic suspension of guanosine and a methanolic or aqueous solution of [(dien)Cu(ONO_2)]NO_3 or [(dien)Cu(Br)]Br in 1 : 1 molar ratio. The same products were also formed in a different molar ratio (1 : 2).

Compound **1**. [(dien)Cu(Guo-N^7)(ONO_2)]NO_3 (**1**) was prepared by mixing a methanolic suspension of guanosine (2 mmol in 20 cm^3 of MeOH) and a methanolic solution of [(dien)Cu(ONO_2)]NO_3 compound (2 mmol in 10 cm^3 of MeOH). The reaction mixture became clear after 1 h stirring at 45°C, and it was then left for slow evaporation at room temperature. After 10 days blue crystals formed. The crystals were isolated by filtration and dried under vacuum. The yield of the reaction was 65%.

Anal. (**1**) Calcd for $C_{14}H_{26}N_{10}O_{11}Cu$: C, 29.29; H, 4.57; N, 24.49; Cu, 11.07. Found: C, 29.35; H, 4.55; N, 24.45; Cu, 11.08. UV–vis bands; 596 nm ($\log\varepsilon = 1.93$), 266 nm ($\log\varepsilon = 3.97$) (MeOH), 613 nm ($\log\varepsilon = 1.93$), 208 nm ($\log\varepsilon = 4.58$), 250 ($\log\varepsilon = 4.54$), 274 sh, (in H_2O), $\Lambda\mu = 130$ μS cm^{-1} (in MeOH), $\Lambda\mu = 242$ μS cm^{-1} (in H_2O).

Compound **2**. The [(dien)Cu(Guo-N^7)Br]Br (**2**) compound was prepared by the reaction of [(dien)Cu(Br)]Br with guanosine. An aqueous solution of [(dien)Cu(Br)]Br (2 mmol in 3 cm^3 H_2O) was mixed with a suspension 2 mmol of guanosine in methanol (20 cm^3). The Guo reacted slowly with [(dien)Cu(Br)]Br and after 2 h stirring a light blue solid was formed. The solid was isolated by filtration and recrystallized from water-methanol (1 : 1). The yield of the reaction was 52%.

Anal. (**2**) Calcd for $C_{14}H_{26}N_8O_5Br_2Cu$: C, 27.57; H, 4.27; N, 18.38; Cu, 10.43. Found: C, 27.60; H, 4.25; N, 18.40; Cu, 10.40. UV–vis bands; 608 nm, 276 nm, 254 nm, 209 nm (MeOH), 619 nm ($\log\varepsilon = 1.86$), 282 nm ($\log\varepsilon = 3.34$), 227 nm ($\log\varepsilon = 3.35$) (in H_2O), $\Lambda\mu = 240$ μS cm^{-1} (H_2O), $\Lambda\mu = 128$ μS cm^{-1} (MeOH).

Compound **3**. [(dien)Cu(A)(ONO_2)]NO_3 (**3**) was prepared by mixing a methanolic suspension of adenine (2 mmol in 20 cm^3 of MeOH) and a methanolic solution of [(dien)Cu(ONO_2)]NO_3 (2 mmol in 10 cm^3 of MeOH). The resulting mixture was refluxed for 1 h and cooled at room temperature. The light blue product was isolated by filtration, washed with diethylether and dried under vacuum. The yield of the reaction was 70%.

Anal. (**3**) Calcd for $C_9H_{18}N_{10}O_6Cu$: C, 25.38; H, 4.23; N, 32.89; Cu, 14.93. Found: C, 25.40; H, 4.23; N, 32.77; Cu, 14.89. UV–vis bands; 619 nm ($\log\varepsilon = 1.99$), 259 nm ($\log\varepsilon = 4.41$), 216 ($\log\varepsilon = 4.38$) (MeOH), 622 nm ($\log\varepsilon = 1.83$), 259 nm ($\log\varepsilon = 4.45$), 208 nm ($\log\varepsilon = 4.64$) (in H_2O), $\Lambda\mu = 207$ μS cm^{-1} (in H_2O), 120 μS cm^{-1} (in MeOH).

Physical methods

C, H and N microanalyses were carried out with a Perkin–Elmer 2400 elemental analyser and copper was determined by atomic absorption spectroscopy. IR spectra were recorded with a Perkin–Elmer 1650 FT-IR instrument in the 200–4000 cm^{-1} region, using KBr pellets and calibrated against polystyrene. Electronic spectra were obtained in solution on a Shimadzu UV-160A spectrophotometer in the 200–1100 nm region. Molar conductivities were run on a WTW conductivity bridge and a calibrated dip type cell. Magnetic susceptibilities of powdered samples were determined by employing the Faraday method with a home-made balance against $Hg[Co(SCN)_4]$ as a calibrant. Diamagnetic corrections were estimated from Pascal constants.

X-ray structure determination of [(dien)Cu(Guo-N^7)(ONO_2)]NO_3

A blue crystal prism of dimensions $0.63 \times 0.22 \times 0.18$ mm was mounted on a modernized Philips PW1100 single-crystal diffractometer. Cell parameters were calculated by least squares refinement of the setting angles of 29 reflections [$25.09° < 2\theta < 31.34°$, Mo–$K_\alpha$ radiation]. From systematic absences the space group $P2_12_12_1$ was unequivocally determined. Intensity data were collected up to $2\theta = 55°$ with graphite monochromated Mo–K_α radiation using the learnt profile method [21] (scintillation counter, $2\theta/\omega$ scan mode, three standard reflections monitored every 120 min). Two independent sets of reflections were measured, which were corrected for Lorentz and polarization effects but not for absorption. They were finally reduced to 2987 unique ones of which 2458 were considered as observed [$F_o > 4\sigma(F_o)$] and were used in the subsequent calculations. Crystal data for [(dien)Cu(Guo-N^7)(ONO_2)]NO_3 are given in Table 2. For the solution, refinement and analysis of the structure the PC version of the XTAL 3.2 system of crystallographic programmes was used [22].

The structure was solved by direct methods and difference Fourier syntheses. Neutral atomic scattering factors and anomalous dispersion corrections were taken from Ref. [23]. The structure refinement was performed by the full-matrix least-squares method, in which the function minimized was $\Sigma w(F_o - F_c)^2$. All hydrogen atoms, except H(O5A) (see Fig. 1), could be located in a difference Fourier map. Non-hydrogen and hydrogen atom parameters were refined in alternate cycles. In the final stage of refinement anisotropic displacement parameters were introduced for all the non-hydrogen atoms and isotropic ones for the hydrogen atoms. Also, bond length restraints for the hydrogen atoms attached to the nitrogen atoms of the dien group were applied. Atoms H1(C5A) and H2(C5A), which showed a tendency to move to chemically unrealistic positions, were kept fixed. The weighting scheme used was $w = 1/\sigma^2(F_o)$, where $\sigma^2(F_o) = \sigma^2(F_{statistics}) + \sigma^2(F_{mod})$ and $\sigma^2(F_{mod})$ is the so called "ignorance factor" [22]. An extinction correction was deemed as not necessary. At convergence R was 0.049 and Rw 0.036. A separate refinement of the enantiomorph structure resulted in final R and Rw values of 0.060 and 0.041, respectively. The application of the $\mathscr{R}$ test [24] indicates that the first enantiomorph is correct at a significance level much lower than 0.005.

RESULTS AND DISCUSSION

The reaction of [(dien)Cu(ONO$_2$)]NO$_3$ with guanosine(Guo) and adenine(A) yielded coloured, air stable, microcrystalline or crystalline compounds of the general formula [(dien)CuBX)]X; [B = guanosine(Guo), adenine(A) and X = NO$_3$, Br]. The complexes **1** and **3** are soluble in methanol and water, whereas the [(dien)Cu(Guo)(Br)]Br is soluble in water and slightly soluble in methanol. The prepared complexes are all insoluble in common organic solvents and their elemental analysis fit the proposed stoichiometry well. The magnetic moments of the Cu(II) complexes, at room temperature, were found to be 1.73–1.85 BM (Table 1). These values are in accordance with the d^9 electronic configuration of copper(II) and confirm the monomeric nature of the compounds under investigation. The $\Lambda\mu$ values of all complexes in methanol and water are indicative of 1 : 1 and 2 : 1 electrolytes, respectively [25]. The conductivities of the complexes were again measured after 24 and 48 h.

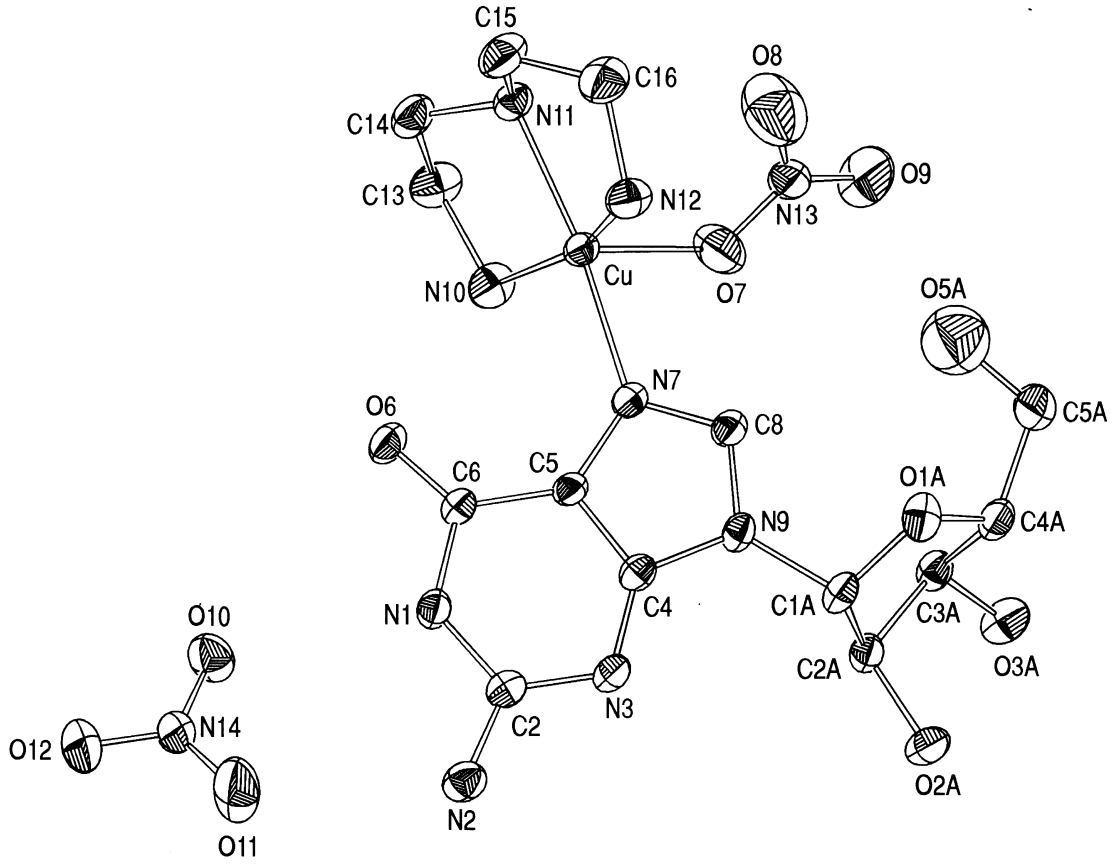

Fig. 1. ORTEP plot of the symmetric unit of the structure of [(dien)Cu(Guo-N^7)(ONO$_2$)](NO$_3$) with the atomic numbering scheme. Hydrogen atoms are omitted for clarity and atomic thermal ellipsoids are at 30% probability level.

	3144	1489	1384			

The results were almost identical suggesting that the complexes are stable in solution. Attempts to react $[(dien)Cu(ONO_2)]NO_3$ with guanine or adenosine failed to give the expected product. Also, the reactions of [(dien)Cu(Br)]Br with the previous ligands plus adenine were not successful.

IR spectral studies

The most important IR bands of the ligands and their complexes are displayed in Table 1. In the infrared spectra of the ligands guanosine, adenine and the starting complexes $[(dien)Cu(ONO_2)]NO_3$ and [(dien) Cu(Br)]Br, the medium intensity bands in the 3350–3100 cm^{-1} range, could be assigned to primary and secondary amino groups, respectively. Some of these bands are shifted upon complexation to higher and some others to lower frequencies. Although these shifts are strong evidence that the dien ligand is coordinated in a tridentate mode, an accurate assignment of these bands seems to be impossible, since some of them are obscured by others coming from guanosine or adenine. In the IR spectra of **1** and **2** complexes, the bands 3423 and 3453 cm^{-1} are attributed to the ν(O—H) vibration of the sugar moiety and are shifted to lower frequencies by 46 and 16 cm^{-1}, respectively. This shift may be due to the effect of hydrogen bonding between the protons of O—H groups and the counterions (NO_3^-) for **1** and Br^- for **2**. The band assigned as $\nu(C^6{=}O^6)$ for guanosine (1732 cm^{-1}), upon coordination shows a negative shift of 58 and 42 cm^{-1} for **1** and **2,** respectively. Considering that the $C^6{=}O^6$ group does not participate in coordination via its oxygen atom or in any other mode, the observed shift of the respective band is probably attributed to a rearrangement of the intraligand hydrogen bonding of the ligands, caused by the metallation of N^7. Support for the above argument is provided by the X-ray data (*vide infra*). The strong $\nu(C{=}N^7)$ bands of the ligands occurring at 1693 (Guo) and 1672 (A) cm^{-1}, appear at 1619, 1620 and 1656 cm^{-1} in the spectra of the respective complexes **1, 2, 3,** i.e. they are all shifted to lower wave numbers. The observed negative shifts strongly suggest that coordination of the ligands to the copper(II) atom occurs via the N^7, in agreement with its marked basicity [26]. In the IR spectra of **1** and **3** complexes, the weak band at ca 1750 cm^{-1} and the strong bands at 1410 and 1384 cm^{-1} indicate the existence of a free [27] NO_3^- and a unidentate [28] nitrato group, respectively. This observation is in accordance with molar conductivities and X-ray data. Finally, the weak or medium intensity bands in the regions 461–439 and 390–332 cm^{-1} are due to the stretching vibrations of Cu—N and Cu—O bonds, respectively [29]. These bands, as expected, shift to lower wave numbers by 19–8 cm^{-1} for Cu—N and 28–10 cm^{-1} for Cu—O bonds, in respect to those of the starting material $[(dien)Cu(ONO_2)]NO_3$. Finally,

[a] $R = \Sigma\|\|F_o| - |F_c\|| / \Sigma|F_o|$,
[b] $R_w = [\Sigma_w(|F_o| - |F_c|)^2 / \Sigma w|F_o|^2]^{1/2}$
[c] $S = [\Sigma w(|F_o| - |F_c|)^2 / (N_{ref}\text{-}N_{param})]^{1/2}$

the complex **2** displays a single band at 284 cm^{-1}, which is due to the Cu—Br stretching vibration.

In view of our IR, magnetic and conductivity data, it can be concluded that the metal in compounds **1** and **3** is five coordinated, the four coordination sites being occupied by nitrogen atoms [three from dien and one from guanosine (**1**) or adenine (**3**)] and the fifth one by one oxygen atom from the nitrato group. The complex **2** is also five coordinated with the three nitrogen atoms of dien and the N^7 atom from guanosine, while the fifth site is occupied by the bromine atom.

Electronic spectral studies

The electronic spectra of the complexes taken in methanol and water were recorded between 1100 nm and 200 nm. The bands in the UV–vis spectra of the new complexes may be related either to the ligands guanosine, adenine or to the starting materials [(dien)Cu(ONO$_2$)]NO$_3$ and [(dien)Cu(Br)]Br. The band at 615 nm and 618 nm of the starting materials [(dien)Cu(ONO$_2$)]NO$_3$ and [(dien)Cu(Br)]Br, respectively can be considered as a crystal field band on the basis of its low intensity. It is very broad and possibly represents a spectral envelope covering several *d-d* transitions [30]. The bands of **1, 2** and **3** in methanol, occurring at 596–608 nm region, are shifted to higher energies as compared to the analogous ones of the starting materials. It is reasonable to assume that the ligands (guanosine and adenine) influence appreciably the energy levels of *d* orbitals of the metal ion. This *d-d* separation is the result of transformation of [CuN_3O_2] and [CuN_3Br] chromophores of [(dien)Cu(ONO$_2$)]NO$_3$ and [(dien)Cu(Br)]Br to [CuN_4O] and to [CuN_4Br], respectively in the new complexes. Furthermore, the crystal field bands of **1, 2** and **3** complexes in aqueous solution are shifted to lower energies, implying ligand (NO_3, Br) replacement by one or two water molecules. The above change in the coordination sphere is further supported by molar conductivity measurements, indicating transformation from 1 : 1 (methanol) to 2 : 1 electrolytes (water). The intense absorption band at 251 nm of the [(dien)Cu(ONO$_2$)]NO$_3$ complex is tentatively attributed to a $\pi^* \leftarrow n$ intraligand transition. This band also occurs in the spectra of **1** and **3** complexes, but is slightly shifted towards lower energy. The bands at 254 nm and 260 nm in the spectra of the free guanosine and adenine, respectively, is attributed to an intraligand transition of $\pi^* \leftarrow \pi$ type, located possibly on the C=N group. This band is shifted to higher wave numbers, in the **1, 2** and **3** complexes, a fact further supporting the idea of the coordination of the guanosino and adenosino ligands via the N^7.

Crystal structure of [(dien)Cu(Guo-N^7)(ONO_2)]NO_3

An ORTEP view of the asymmetric unit of the structure of [(dien)Cu(Guo-N^7)(ONO_2)]NO_3 is shown in Fig. 1, while selected bond lengths and angles along with the established hydrogen bonds are given in Table 3.

Copper is bonded to the Guo ligand through N(7) and to the dien ligand through N(10), N(11) and N(12) with the terminal atoms N(10) and N(12) being in *trans* position to each other. Moreover, one of the NO_3 groups is linked to copper through O(7), thus completing a distorted square pyramidal (SP) arrangement with O(7) occupying its apex and with atoms N(7), N(10), N(11) and N(12) lying on the basal plane. The compound may be thus formulated as $[(dien)Cu(Guo\text{-}N^7)(ONO_2)]^+(NO_3)^-$. The same atomic arrangement around the copper atom may

Symmetry operations: [a] $x+1, y, z$; [b] $x+1, y+1, z$; [c] $1-x; -1/2+y, 1/2-z$; [d] $1-x, 1/2+y, 1/2-z$.

be described as distorted trigonal bipyramidal (TBP) with atoms N(7) and N(11) at axial positions. The degree of distortion of the coordination polyhedron from the ideal SP arrangement may be defined as $\tau = (\beta - \alpha)/60$ [31]. For an ideal square pyramid it is $\alpha = \beta = 180^\circ$ and $\tau = 0$, while for an ideal trigonal bipyramid it is $\beta = 180^\circ$, $\alpha = 120^\circ$ and $\tau = 1$. In our case is $\alpha = 162.9^\circ$, $\beta = 169.9^\circ$ and $\tau = 0.12$, which indicates a geometry very close to square pyramidal. The maximum deviation from the best plane through the four basal atoms occurs for N(11) [0.061(9) Å], while the metal atom is 0.213(1) Å distant from that plane. The geometry of the dien moiety is as expected [32,19,33]. The N^PCuN^S valence angles (N^P from primary and N^S from secondary amino group) are lower than 90° [85.0(3)° and 84.7(2)°] and N^PCuN^P is much lower than 180° [162.9(2)°], indicating a slight strain in the coordinated dien ligand.

The pyrimidine and imidazole rings of the Guo group are planar within experimental error ($3\sigma_{combined}$) forming an angle of 1.3(2)° between them, so that the whole purine nucleus appears essentially as planar. This value is substantially smaller than the corresponding ones of similar compounds, e.g. 4.0° in the complex of cadmium(II) with guanosine 5′-phosphate [34]. The best plane through the purine ring makes an angle of 66.0(1)° with the basal plane of the copper coordination polyhedron. This value may be compared with the corresponding values of 63.4° for [Pd(diethylenetriamine)(guanosine)]$(ClO_4)_2$ [33], of 65.9° for $\{[(dien)Pt]_2G\text{-}N^1,N^7)\}(ClO_4)_3 \cdot 2H_2O$ (Pt1 coordination plane) [35] and of 61.7° and 69.6° for *cis*-$[(NH_3)_2Pt(U\text{-}N^3(G\text{-}N^1,N^7)Pt(dien)](ClO_4)$. $2.5H_2O$ (coordination planes of Pt1 and Pt2, respectively [35]). The geometry of the purine ring is as expected, with the bond lengths lying in the range 1.313(7)–1.383(7) Å for the imidazole and 1.331(8)–1.416(8) Å for the pyrimidine rings, respectively, while the corresponding valence angles ranges are 105.5(5)°–111.5(5)° and 111.7(5)°–128.1(5)°. The general observation that the internal ring angle at N(1) is greater than at N(3), the latter having no extra-annular attachment, is also confirmed by the present study [33,36]. The deviations of the substituents N(2) and O(6) from the purine best plane are significant [0.08(1) Å and 0.065(7) Å, respectively], which may be attributed to the involvement of these atoms in the hydrogen bonding system of the structure (see Table 3).

The valence angles in the ribose ring are close to tetrahedral values ranging between 101.1(4)° and 109.9(4)°. Atoms C(1A), C(2A), C(4A) and (O(1A) are coplanar within experimental error, while C(3A) is 0.584(9) Å distant from that plane, on the same side as C(5A) and N(9). This corresponds to the C(3A) *endo* conformation. The angle formed by the ribose and purine rings is 105.7(2)° The orientation of the C(5A)—O(5A) bond relative to the ribose ring is *gauche-gauche*, the torsional angles $\phi_{O\text{–}O}$ and $\phi_{C\text{–}O}$ being −47(1)° and 68.4(9)° respectively.

Both NO_3 groups have normal geometry, the mean N—O distances being 1.204(6) Å and 1.221(5) Å, and the mean O—N—O valence angles being 120.0(5)° and 120.0(4)° for the coordinated and the uncoordinated NO_3 groups, respectively.

As can be seen from Table 3, hydrogen bonding plays a predominant role in the stabilization of the structure. Intermolecular hydrogen bonds occur between neighbour [(dien)Cu(Guo-N^7)(ONO_2)]$^+$ cations as well as between [(dien)Cu(Guo-N^7)(ONO_2)]$^+$ cations and (NO_3^- anions. Furthermore, three intramolecular hydrogen bonds [N(10)—H(10)···O(6), N(12)—H(12)···O(8) and O(5A)—H(O5A)···O(1A)] are possible, as can be deduced from the short donor-acceptor contact distances 3.098(8) Å, 3.21(1) Å and 2.666(1) Å, respectively. The shortening of the C(5A)—O(5A) bond distance to 1.30(1) Å may be attributed to the latter mentioned hydrogen bond [37,38].

CONCLUSION

In conclusion, the present study showed that the reaction of [(dien)CuX]X, (X = NO_3, Br) with guanosine or adenine (B) gave compounds of the general formula [(dien)CuBX]X. In all these compounds, spectral data indicated that the ligands bind to the copper atom through N7. This has also been confirmed in one case, [(dien)Cu(Guo)(ONO_2)]NO_3, by X-ray analysis. Lastly, the inability of [(dien)Cu(ONO_2)]NO_3 complex to react with guanine and adenosine and that of [(dien)Cu(Br)]Br complex with guanine, adenine and adenosine, which may be due to their electronic and molecular parameters, should indicate lower anticancer activity than that of diethylenetriamine-Pt complexes.

(Received 5 January 1998 : accepted 15 January 1998)

Abstract—The 1,3,5-triaza-7-phosphaadamantane [TPA] complexes of the type $[MCl_2(TPA)_2]$ (where M = Ni, Pd, Pt), $[Ni(CN)_2(TPA)_3]$ and $[PtCl(TPA)_3](BPh_4)$ have been synthesized and characterized by ^1H, $^{31}P\{^1H\}$ NMR, Laser-Raman spectroscopy and elemental analyses. The reactivity of the complexes $[MCl_2(TPA)_2]$ with water to produce the oxide of TPA follows the order Pt > Pd > Ni. The structure of the complex $[Ni(CN)_2(TPA)_3] \cdot 4.3H_2O$ was determined by single crystal X-ray diffraction methods. The structure determination shows that the nickel atom has a trigonal-bipyramidal geometry with the cyanide ligands in the apical positions. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: group 10 complexes ; 1,3,5-triaza-7-phosphaadamantane ; crystal structure.

Considerable attention has been focused in recent years on the complexes of the water-soluble air-stable phosphine 1,3,5-triaza-7-phosphaadamantane [TPA] with transition metal ions [1,2]. Studies by Darensbourg and co-workers have shown that certain rhodium and ruthenium complexes have high catalytic activity towards the hydrogenation of olefins and the conversion of unsaturated aldehydes to saturated aldehydes or unsaturated alcohols in aqueous two-phase solvent systems [1]. Furthermore, the small steric size, greater basicity and non-ionic nature of TPA makes it an attractive alternative to the commonly employed sulphonated phosphines such as tris-*meta*-sulphonatophenylphosphine(TPPTS) [1f,3]. Hence, since group 10 complexes are well established as homogeneous hydrogenation catalysts, it is of great interest to also develop the chemistry of TPA with these metal ions. Although we explored the synthesis of Ni, Pd and Pt complexes in an earlier preliminary survey of TPA metal complexation behaviour [2a], to this date only two papers concerning group 10 complexes of TPA have been reported ; they describe the crystal structures of $[Pt(TPA)_3Cl]Cl \cdot MeOH \cdot H_2O$ [2c] and *trans*-$[Pt(TPA)_2(CN)_2$ [4]. In continuation of our research on the chemistry of transition metal ions with this interesting ligand [2], we report here the syntheses and characterization of some complexes of the TPA ligand with group 10 metals, including the X-ray structural determination of a pentacoordinate nickel cyanide complex.

RESULTS AND DISCUSSION

The reaction of TPA with $NiCl_2 \cdot 2H_2O$, $Na_2[Ni(CN)_4]$, $PdCl_2$ or $MCl_2(PhCN)_2$ (M = Pd or Pt) yielded molecular complexes of the type $[MCl_2(TPA)_2]$ (where M = Ni, Pd, Pt), $[Ni(CN)_2(TPA)_3]$ or $[(PtCl(TPA)_3)]Y$ (Where M = Pt, Y = Cl or BPh_4). Most of the syntheses were effected in methanolic solution because of the unexpectedly [1,2] low solubility of the complexes in water and their reactivity with water (*vide infra*). NMR spectroscopic data were therefore collected for dimethylsulphoxide (DMSO) solutions.

The Laser Raman spectra of the complexes $[MX_2(TPA)_2]$ (M = Ni, Pd or Pt) show that the complexes exist exclusively in the *cis* isomeric form. The $^{31}P\{^1H\}$ NMR spectra of these square-planar complexes show single broad resonances for the nickel(II) (also variable with concentration and time) and palladium(II) complexes and a sharper resonance with the expected Pt-195 satellites for the platinum(II) complex. The ^1J(Pt-P) value shows that the chlorine atom is *trans* to the phosphine group as its magnitude (3305 Hz) confirms the *cis*- nature of the complexes. Broadening of the $^{31}P\{^1H\}$ NMR signal occurred when excess TPA was added to a solution of the palladium complex, indicating that phosphine exchange was responsible for the broadness of the resonance. Decomposition of the complexes in the presence of water was also evident, as will be discussed later.

The $^{31}P\{^1H\}$ NMR spectrum of the complex $[PtCl(TPA)_3]BPh_4$ in CH_3CN/D_2O solution shows two resonances (1 : 2 ratio) with platinum satellites. The coupling constant of ^1J(Pt—P) = 3300 Hz (for the smaller peak) corresponds to the TPA trans to the chlorine atom whereas the other value of ^1J(Pt—P) = 2211 Hz corresponds to a TPA trans to another TPA group. In the case of $[Ni(CN)_2(TPA)_3]$, the $^{31}P\{^1H\}$ NMR spectrum in CD_3OD/H_2O solution showed a broad peak at −49.1 ppm together with a weak sharp one at −1.7 ppm that shows the presence of some TPA oxide.

The $^{31}P\{^1H\}$ NMR spectra of the complexes $[Ni(CN)_2(TPA)_3]$ and $[PtCl(TPA)_3]BPh_4$ in DMSO-d_6 display broad peaks (with the disappearance of satellites for the platinum complex). In the former case, the peak due to TPA oxide is more intense than it was in CD_3OD/H_2O solution. These observations may be a consequence of coordination of DMSO with the nickel or platinum atoms giving a hexacoordinated nickel(II) complex $[Ni(CN)_2(TPA)_3(DMSO)]$ or pentacoordinated $[PtCl(DMSO)(PTA)_3(BPh_4)$ or tetracoordinated $[Pt(DMSO)(TPA)_3]Cl(BPh_4)$ platinum(II) complexes. Due to the small size of the TPA ligand (the Tolman cone angle is only 102°), these solvated complexes might easily exchange the coordinated DMSO with free DMSO and exhibit fluxionality and/or TPA exchange leading to the observed broad $^{31}P\{^1H\}$ peak with the disappearance of satellites. In contrast, as mentioned above, the corresponding palladium and platinum complexes *cis*-$[PdCl_2(TPA)_2]$ and *cis*-$[PtCl_2(TPA)_2]$ show sharper $^{31}P\{^1H\}$ NMR spectra under similar conditions, indicating that there is no coordination of DMSO with the central metal ion that might lead to TPA exchange or fluxionality. The structure determination of crystals of the $[PdCl_2(TPA)_2]$ complex prepared in aqueous solution [method (a)] has shown that the asymmetric unit contains two molecules of the square-planar complex linked by a water molecule of solvation [2g].

The ^1H NMR spectra of all the complexes show the expected peaks and integrations [1,2]. The —CH_2— protons nearer to the phosphorus atom are much more deshielded than the —CH_2— protons nearer to the nitrogen atoms. This confirms the coordination of the phosphorus atom rather than any nitrogen atom of the TPA ligand; in contrast, it was shown earlier that one (only) nitrogen atom of TPA is more readily protonated, with the pK_a being near 6.0 [2d].

The red colored $[NiCl_2(TPA)_2]$ complex is insoluble in most organic solvents (sparingly soluble in DMSO, giving a very broad ^1H or $^{31}P\{^1H\}$ NMR spectrum) but dissolves readily in water giving first a dark blue color, then immediately turning to an orange color, and finally giving a colorless solution. This solution on slow evaporation yielded colorless crystals of TPA oxide. The ^1H NMR spectra of the complexes $[NiCl_2(TPA)_2]$, $[PdCl_2(TPA)_2]$ and $[PtCl_2(TPA)_2]$ in water observed over different intervals show that all three complexes undergo reaction with water and give TPA oxide. This observation is similar to that reported for a Rh(I)—TPA complex $[RhCl(TPA)_3]$ [1f]. For the present group 10 complexes we observed, on a qualitative basis only, that the reactivity follows the order Pt > Pd > Ni and that the formation of TPA oxide is very much less when an excess of free TPA is in solution.

In order to probe the probable mechanism and to isolate any resulting species after the reaction, the $[PtCl_2(TPA)_2]$ complex was dissolved in a CH_2Cl_2/methanol (20 ml) solution, to which 10 ml of water was added, and the solution was kept to allow slow evaporation during a few weeks. The resulting crystalline product was filtered off, washed with water (to remove a soluble compound identified by NMR and IR spectroscopy as TPA oxide) and analyzed by a single crystal X-ray diffraction analysis. The preliminary X-ray data showed that the isolated complex was $[PtCl(TPA)_3]Cl$, previously characterized by crystallography [2c]. As suggested for a Rh-TPA complex [1f], the probable mechanism for this reaction involving group 10 metal ions may be the oxidative addition of water to form an hydriohydroxo M(IV) species, which allows TPA to be oxidized; subsequent TPA and chloride exchange could then lead to the isolated products of TPA oxide and $[MCl(TPA)_3]Cl$. The observed relative rate of the reaction agrees well with the order of the M^{2+}/M^{4+} oxidation potentials of these ions, i.e. the tendency for oxidative addition, though other mechanisms (especially for Ni) can not

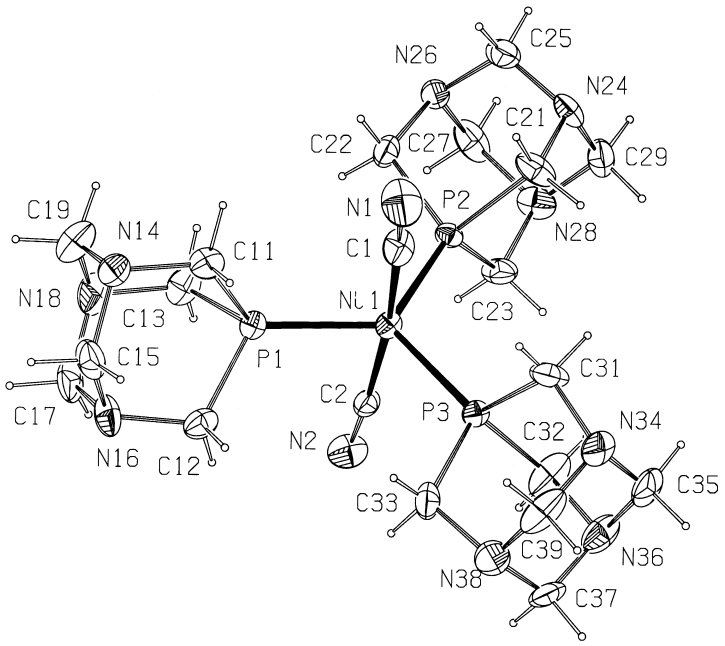

Fig. 1. A view of the $[Ni(CN)_2(TPA)_2]$ molecule showing our numbering scheme. Anisotropic displacement ellipsoids are drawn at the 30% level.

be ruled out. The propensity of group 10 metal ions to form tris-TPA complexes may be a strong factor in lowering the barriers to TPA oxidation. In a separate experiment, $[PtCl(TPA)_3]BPh_4$ was readily isolated in high yield (Experimental); the corresponding palladium complex apparently formed as a yellow complex (giving two very broad ^{31}P NMR signals in D_2O) but its purification was not pursued due to its ease of decomposition.

Structure of $[Ni(CN)_2(TPA)_3]$,4.3(H_2O); (**1**),4.3 (H_2O)

An ORTEP plot of (**1**) is shown in Fig. 1; selected dimensions are given in Table 1. The nickel atom is bonded to three equatorial TPA ligands and two axial cyanide groups giving a trigonal bipyrimidal geometry. A search of the April 1997 release of the Cambridge Structural Database [5] revealed several

X-ray analyses for $Ni(CN)_2(PR_3)_3$ species. Those complexes involving $PPh(OEt)_2$ [6], $C_{13}H_{11}P$ (5-methyl-dibenzophosphole) [7] and $P(CH_2OH)Ph_2$ [8] were best described as having square-pyramidal geometries, while those with $PPhMe_2$ [9] and $C_{14}H_{13}P$ (5-ethyl-dibenzophosphole) [7] as the phosphine ligands had geometries that were closer to being trigonal-bipyramidal in shape. Comparison of the structural data shows clearly that the present TPA species has a structure only slightly distorted from the ideal trigonal-bipyramidal shape.

The Ni—P bond distances in **1** (ave. 2.226(3) Å) are not significantly different from each other or from those found in $[Ni(CN)_2(PPhMe_2)_3$ (**2**) (ave. 2.235(3) Å) [9] and in $[Ni(CN)_2(C_{14}H_{13}P)_3$ (**3**) (ave. 2.253 Å) [7]. Similarly, the Ni—CN bond distances of 1.852(15) and 1.855(15) Å in **1** are comparable to those in **2** (1.836(11) and 1.860(12) Å) and in **3** (1.820 and 1.855 Å). The C—Ni—C bond angle in **1** is significantly less, at 173.6(6)°, than those found in **2** (176.5(4)°) and **3** (176.7)°. This angle departs considerably from 180° for analogous $Ni(CN)_2(PR_3)_3$ species with greater distortions toward the square-pyramidal shape; for example, C—Ni—C is 163.8(4) for the species with $P(CH_2OH)Ph_2$ [8]. Another indication of distortion is the range of C—Ni—P angles. These are 86.0(4)–91.4(4)° in **1,** 88.6(3)–92.4(3)° in **2** and 85.8–93.7° in **3**, signifying that these three complexes undergo similar small distortions. This is not surprising even though the phosphines differ considerably in their cone angles because steric hindrance is minimized with all three phosphine ligands occupying equatorial sites. In **1** the presence of water molecules in the crystal lattice may contribute to the small observed distortions from idealized trigonal-pyramidal geometry. As observed in previous TPA structures [1], extensive hydrogen-bonding occurs between the water molecules and nitrogen atoms of various TPA ligands. No H atoms were located on water molecules (some of which are disordered with partial occupancy) but the various O···N distances (supplementary material) are in the ranges normally associated with O—H···N hydrogen bonds. Other bond distances and angles observed in **1** for the TPA ligands are comparable to those previously reported [1,2,4].

EXPERIMENTAL

$NiCl_2 \cdot 2H_2O$, $NiCl_2 \cdot 6H_2O$, NaCN, $PdCl_2$ and $PtCl_2$ were obtained from commercial sources. The $[PdCl_2(CH_3CN)_2]$, $[PdCl_2(PhCN)_2]$, $[PtCl_2(PhCN)_2]$ [10] and TPA [11] were prepared according to the reported methods. All the solvents were distilled and dried prior to use. The $^{31}P\{^1H\}$ NMR spectra were recorded on a Varian Unity-400 MHz instrument operating at 161.8 MHz whereas ^1H NMR spectra were recorded on a Varian-Gemini-200 spectrometer operating at 200 MHz. The chemical shifts are relative to external 85% H_3PO_4 and internal chloroform or DMSO peaks respectively for the $^{31}P\{^1H\}$ and ^1H resonances. The IR spectra were recorded on a Nicolet DXC-20 FTIR instrument using KBr discs (4000–400 cm^{-1}). The Raman spectra were recorded on a Bruker FRA 106 FT-Raman module interfaced to a Bruker IFS-66 FT-IR bench; the incident radiation was at 943.4 nm.

Synthesis of $[NiCl_2(TPA)_2] \cdot 2H_2O$

To a methanolic solution of $NiCl_2 \cdot 2H_2O$ (106 mg, 0.64 mmol), a methanolic solution of TPA (200 mg, 1.28 mmol) was added under a nitrogen atmosphere. The solution immediately turned to a dark blue color and on stirring, deposited a red colored powder leaving a colorless solution. The red powder was filtered, washed with methanol and dried (50 mg, 18%; Anal: Calcd for $C_{12}H_{24}H_6P_2NiCl_2 \cdot 2H_2O$: C, 30.4; H, 5.8; N, 17.5. Found: C, 30.0; H, 5.9; N, 17.6. mp, 220°C (dec); ^1H NMR (δ ppm, DMSO): very broad (4.1–5.2); Laser Raman (ν_{Ni-Cl}): 272, 305 cm^{-1}).

The supernatant on slow evaporation yielded colorless crystals (120 mg; $^{31}P\{^1H\}$ NMR (δ ppm, CD_3OD/H_2O): −1.2; ^1H NMR (δ ppm, D_2O): 3.85 (d, ^2J(P—H) = 10 Hz, PCH_2, 6H); 4.15 (q, NCH_2, 6H, ^2J(H—H) 14 Hz).

Synthesis of $[Ni(CN)_2(TPA)_3] \cdot 4.3H_2O$

To an aqueous solution of $NiCl_2 \cdot 6H_2O$ (200 mg, 0.83 mmol), NaCN (82 mg, 1.67 mol) solid was added and stirred for 10 min. To this suspension, excess of TPA (450 mg, 2.8 mmol) was added and the clear red solution was stirred for 30 min. The solution was evaporated in vacuum, and the residue washed with methanol, filtered off and dried. It was recrystallized from a water/ethanol mixture. Since the crystallized product was contaminated with some TPA-oxide (colorless crystals), the red coloured crystals of the titled compound were picked out from the mixture. (Mp, 230°C (dec); FTIR (ν in cm^{-1}): 3565 [br, NH, OH, st]; 2096 [CN, st]; 1613 [br, NH, OH, bend]: $^{31}P\{^1H\}$ NMR (δ ppm): (CD_3OD/H_2O): −49.1; (DMSO): very broad spectrum at −49.7; ^1H NMR (δ ppm, CD_3OD): 4.23 (br, PCH_2, 18H); 4.62 (m, NCH_2, 18H).

Synthesis of cis- $[PdCl_2(PTA)_2]$

Method (*a*). To a water solution of TPA (excess) (543 mg, 3.4 mmol), $PdCl_2$ solid (104 mg, 0.587 mmol) was added and the mixture was stirred for 10 min. By that time all the $PdCl_2$ dissolved to give a clear greenish yellow solution. After filtration, the solution on slow evaporation yielded a greenish yellow crystalline product (Yield: 250 mg, 87%), mp 235°C (dec): Anal: Calcd for $C_{12}N_{24}N_6P_2PdCl_2 \cdot 0.5\ H_2O$: C, 28.79,; H, 5.03; N, 16.79. Found: C, 28.8; H, 4.9; N,

16.7. Laser Raman (ν_{Pd-Cl}): 273, 302 cm^{-1}; $^{31}P\{^1H\}$ (δ ppm, DMSO): −18.3; ^1H (δ ppm, DMSO); 4.35–4.55 (m, PCH_2, NCH_2).

Method (*b*). To a hot acetonitrile solution of $[PdCl_2(CH_3CN)_2]$ (202 mg, 0.77 mmol), a water/methanol solution of TPA (300 mg, 1.9 mmol) was added and stirred for 3 h. The greenish yellow colored product that had precipitated was filtered off and dried (Yield 250 mg, 66%). $^{31}P\{^1H\}$ NMR (δ ppm, DMSO): −18.5.

Method (*c*). To a dichloromethane solution of $[PdCl_2(PhCN)_2]$ (170 mg, 0.44 mmol), a water/methanol solution of TPA (157 mg, 1.0 mmol) was added and stirred for 2 h. The resulting precipitate was filtered and washed with methanol and dried (Yield: 160 mg, 74%). $^{31}P\{^1H\}$ NMR (δ ppm, DMSO): −18.1.

Synthesis of cis-$[PtCl_2(TPA)_2]$

To a dichloromethane solution of $[PtCl_2(PhCN)_2]$ (300 mg, 0.64 mmol), a methanolic solution of TPA (200 mg, 1.28 mmol) was added and stirred for 3 h. The resulting colorless precipitate was filtered, washed with methanol and dried (Yield: 300 mg, 81%, mp,

Crystallography

Details of the cell data, data collection and refinement for $[Ni(CN)_2(TPA)_2]\cdot 4.3H_2O$ are summarized in Table 2. There was 14% decay of standard intensities during data collection and this was allowed for by appropriate scaling. In the final refinement cycles, all non-H atoms except those of the partially occupied water molecules (O4, O51, O52) were allowed anisotropic displacement parameters; water O atoms O4, O51, O52 were refined isotropically. All H atoms on the TPA ligands were treated as riding atoms. The final positional and displacement parameters, structure factors, full list of dimensions involving all non-H atoms have been deposited with the Cambridge Crystallographic Data Centre and are also available from the authors in CIF format.

CONCLUSIONS

The reaction of the small water-soluble phosphine TPA with group 10 metal(II) chlorides yielded the corresponding *cis*-$[MCl_2(TPA)_2]$ complexes. These complexes are unstable (except in the presence of excess of TPA) in water producing TPA oxide, apparently via a $[MCl(TPA)_3]$ cation intermediate, in the reactivity order of Pt > Pd > Ni. The complex $[Ni(CN)_2(TPA)_3]\cdot 4.3H_2O$ was shown to have a slightly distorted *trans*-trigonal bipyramidal geometry by X-ray analysis.

New mono- and di-nuclear mixed complexes of cyanides and 2,3-bis(2′-pyridyl)pyrazine with ruthenium

Mónica E. García Posse, Florencia Fagalde, Mónica M. Vergara and Néstor E. Katz*

Instituto de Química Física, Facultad de Bioquímica, Química y Farmacia, Universidad Nacional de Tucumán, Ayacucho 491, (4000) San Miguel de Tucumán, Argentina

(Received : 9 July 1997 ; accepted 15 January 1998)

Abstract—The synthesis and spectroscopic, electrochemical and emissive properties of a new mononuclear mixed complex, of formula $[Ru(dpp)(CN)_4]^{2-}$ (dpp = 2,3-bis(2′-pyridyl)pyrazine are reported. The spectroscopic (IR, UV-visible, and emission) results demonstrate that dpp has a π-acceptor capacity intermediate between bpy and bpz (bpy = 2,2′-bipyridine, bpz = 2,2′-bipyrazine), when coordinated to ruthenium cyanides. The redox potential of the Ru^{II}/Ru^{III} couple and the observed luminiscence at room temperature imply its possible use as a photosensitizer. Since dpp has also the extra ability, when compared to bpy, to form supramolecular complexes, new dinuclear complexes with dpp bridging $Ru(CN)_4{}^{n-}$ (n = 1,2) moieties can also be obtained. The corresponding mixed-valent complex, $[(CN)_4Ru^{II}(dpp)Ru^{III}(CN)_4]^{3-}$, has the characteristics of a Class (II) species, as disclosed by the weak interaction between both metallic centres. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: polypyridine complexes ; dpp ; ruthenium ; π-backbonding ; mixed valence.

Polypyridyl complexes of ruthenium(II) have been extensively investigated due to their interest in photocatalysis and energy conversion [1–3]. The prototype of all inorganic photosensitizers, the ion $Ru(bpy)_3{}^{2+}$ (bpy = 2,2′-bipyridine) presents severe photochemical drawbacks, since the presence of low-lying *d-d* excited states gives rise to photodecomposition [4–6]. Thus, the use of auxiliary non-chromophoric ligands with strong ligand fields, such as cyanide groups, is necessary to inhibit these undesirable side reactions in the design of new photosensitizers, such as $[Ru(bpy)(CN)_4]^{2-}$ [7], $[Fe(bpz)(CN)_4]^{2-}$ [8], $[Os(bpy)(CN)_4]^{2-}$ and $[Ru(bpz)(CN)_4]^{2-}$ (bpz = 2,2′-bipyrazine) [9]. In this work, we report the synthesis and structural properties of the new mononuclear complex $[Ru(dpp)(CN)_4]^{2-}$ (dpp = 2,3-bis(2′-pyridyl)pyrazine) and some dinuclear complexes derived from it. We aim to compare the π-backbonding ability of the ligands bpy, bpz and dpp, shown in Scheme 1, in the same chemical environment. Both bpz and dpp have the additional capacity (absent in bpy) to incorporate other metallic centres by coordinating through their remote N atoms, so that supramolecular systems can be obtained [10–23].

EXPERIMENTAL

Syntheses

$Na_2[Ru(dpp)(CN)_4].4H_2O$ (**I**). It was prepared in a similar way to that previously described for the corresponding complex of bpz [9]. 0.5 g of $K_4[Ru(CN)_6].3H_2O$ and 0.25 g of dpp were dissolved in a 3 : 1 v/v mixture of H_2O/MeOH (34 cm^3). The solution was irradiated under constant stirring with a UV lamp at λ = 254 nm for 52 h, and then filtered. The filtrate was evaporated to dryness. The violet solid was dissolved in 11 cm^3 of water and filtered to eliminate the excess of dpp. Upon addition of MeOH (200 cm^3), the unreacted $K_4[Ru(CN)_6]$ was separated

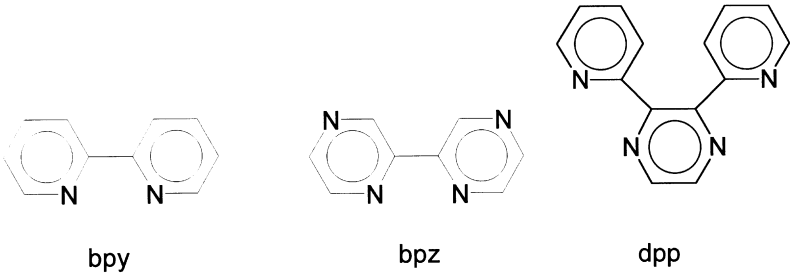

Scheme 1.

from the mixture and the filtrate was evaporated to dryness. The solid was redissolved in 10 cm^3 of water, reprecipitated with 200 cm^3 of acetone, filtered off and dried *in vacuo* over P_4O_{10}. The solid was then sorbed onto an SP-Sephadex A-25 column and eluted with 0.2 M NaI, rotoevaporated to 8 cm^3, cooled to room temperature, and precipitated with EtOH (100 cm^3). The orange powder was filtered, washed with EtOH and dried *in vacuo* over P_4O_{10}. Yield: 80 mg (13%). Anal. Calcd: C, 38.78; H, 3.26; N, 20.10%. Found: C, 38.41; H, 3.75; N, 21.43%.

$Na_4[(CN)_4Ru(dpp)Ru(CN)_4].4NaI.12H_2O$ (**II**). This complex was obtained as a by-product of the synthesis of **I**. It was eluted from the Sephadex column with 0.4 M NaI, rotoevaporated, cooled to room temperature, and precipitated with acetone (100 cm^3). It was then filtered off, washed with acetone and dried *in vacuo* over P_4O_{10}. Yield: 32 mg (4%). Anal. Calcd: C, 17.02; H, 2.21; N, 10.82%. Found: C, 16.48; H, 2.53; N, 11.32%. The tetrabutylammonium salts of (**I**) and (**II**) were obtained by exchanging Na^+ ions by Bu_4N^+ ions in a SP-Sephadex C-25 column previously equilibrated with $Bu_4{}^nNBr$.

Materials, instrumentation and techniques

MeCN was distilled from $KMnO_4$ and dried over molecular sieves. *Tetrakis*(*n*-butyl)ammonium hexafluorophosphate (TBAH) was recrystallized four times from EtOH and dried at 150°C for 72 h. All other chemicals were reagent grade and used without further purification.

Chemical analyses were performed at INQUIMAE (University of Buenos Aires, Argentina).

IR spectra were recorded as KBr or CsI pellets on a Perkin-Elmer 983G spectrophotometer. UV–vis spectra were obtained with a Shimadzu UV-160A spectrophotometer. Electrochemical measurements were performed with an EQMAT-Sl potentiostat in a standard H-type three-electrode cell with platinum wires as working and auxiliary electrodes and Ag/AgCl (3 M) as a reference electrode. Emission spectra were obtained with a Shimadzu RF-5301 PC spectrofluorometer at room temperature (23 ± 1°C). Emission quantum yields were determined by comparing the integrated emission spectra of the complexes relative to that of an isoabsorbative solution of $Ru(bpy)_3{}^{2+}$ ($\varphi_{em} = 0.042$).

RESULTS AND DISCUSSION

Figure 1 shows the IR spectrum of (**I**). Four bands are observed in the cyanide stretching frequency (ν_{CN}) zone, as expected for a cyanometalate of C_{2v} symmetry [8]. As shown in Table 1, the values of ν_{CN} for this complex are intermediate between those of the corresponding complexes of bpy and bpz. Since these frequencies are sensitive to the extent of $d_\pi(Ru) \rightarrow \pi^*(CN)$ backbonding and considering the competition between the cyanide groups and the polypyridyl ligand for the π-electron density of Ru, the following order of π-acceptor capacity towards the $Ru(CN)_4{}^{2-}$ moiety is disclosed:

$$bpy < dpp < bpz.$$

In complex (**II**), only 3 bands are detected in the ν_{CN} zone (at 2097, 2064 and 2047 cm^{-1}), as expected from the higher symmetry of a dinuclear species. These values are similar to those of (**I**), indicating small interaction between both metallic centres in (**II**).

Figure 2 shows the UV–vis spectrum of (**I**) in aqueous solution. Ligand(dpp)-centered π-π^* transitions are observed at 248, 272 and 302 nm. Three metal-to-ligand charge-transfer transitions (MLCT) are observed at 220 nm [$d_\pi(Ru) \rightarrow \pi^*(CN)$], 380 nm, [$d_\pi(Ru) \rightarrow \pi_2^*(dpp)$] and 447 nm [$d_\pi(Ru) \rightarrow \pi_1^*(dpp)$]. The energy value for the lowest-lying MLCT excited state ($E_{op} = 2.77$ eV) is intermediate between those

bpz	2105	2073	2066	2052	9

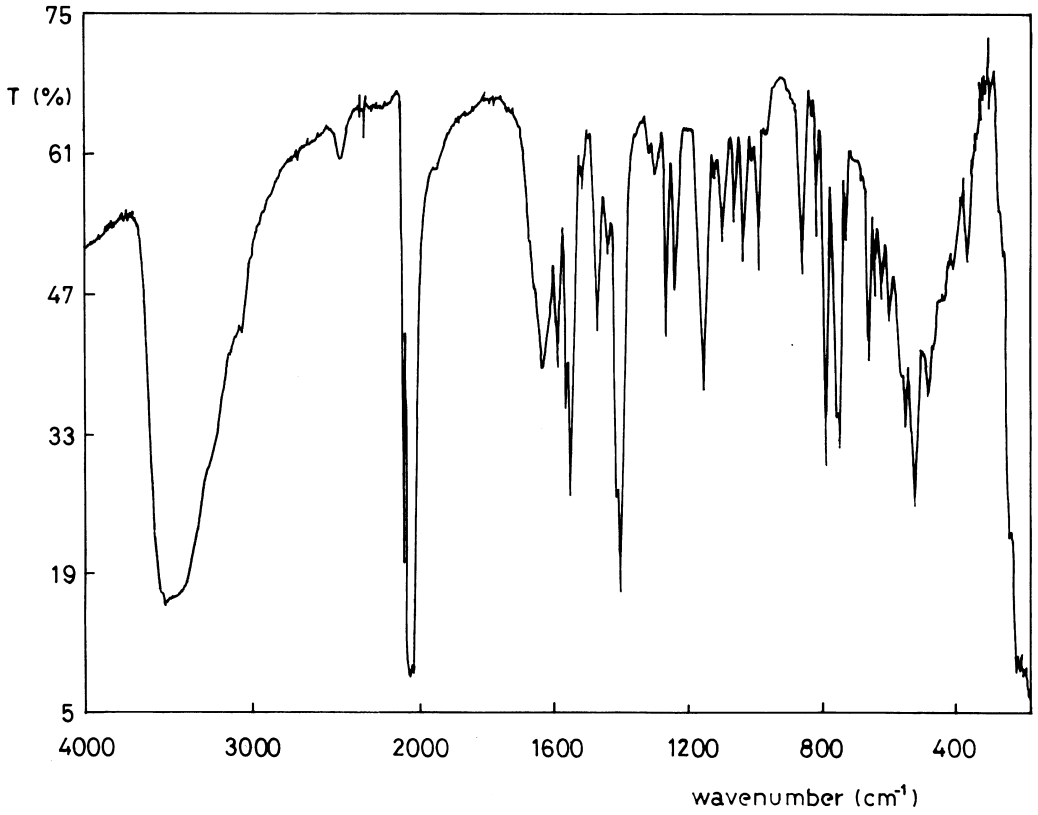

Fig. 1. IR spectrum of $Na_2[Ru(dpp)(CN)_4].4\ H_2O$ (as a KBr pellet).

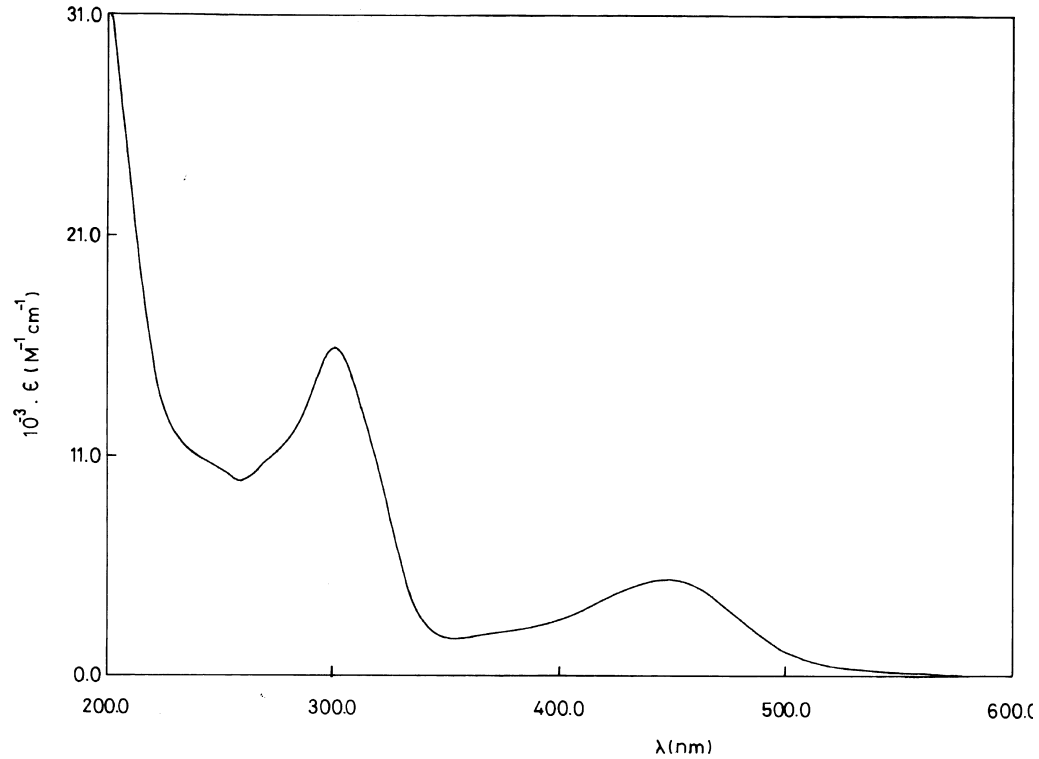

Fig. 2. UV–vis spectra in aqueous solution of $[Ru(dpp)(CN)_4]^{2-}$.

corresponding to the bpy (3.10 eV) and bpz (2.68 eV) complexes of $Ru(CN)_4^{2-}$ [7,9], in agreement with the IR results, since these energy values connote the extent of $Ru \rightarrow L$ π-backbonding (with L = polypyridyl ligand). On the other hand, this value of E_{op} for complex (**I**) is higher than the corresponding values for $[Ru(dpp)(bpy)_2]^{2+}$ (2.58 eV) and $[Ru(dpp)(NH_3)_4]^{2+}$ (2.27 eV) [10,12], indicating that the extent of π-backbonding Ru $\rightarrow$ dpp is strongly diminished when cyanides are used as co-ligands. For the Bu_4N^+ salt of (**I**), spectra in different solvents can be obtained. The correlation between E_{op} for the MLCT $d_\pi(Ru) \rightarrow \pi_1^*(dpp)$ and the acceptor number (AN) of the solvent, as shown in Fig 3, is similar to those encountered in analogous complexes [9], and can be accounted for by the specific interactions of the electron-donating cyanides with the solvents.

Complex (**II**) has a value of $\lambda_{max} = 474$ nm, corresponding to the MLCT transition of minimum energy. The small shift in E_{op}, when compared to the mononuclear species (**I**) ($\Delta E_{op} = 0.14$ eV) is equivalent to introducing a weak electron-withdrawing substituent in the periphery of dpp; this small interaction can be attributed to steric restrictions in the bridging ligand [10].

Figure 4 shows a spectrophotometric titration of complex (**II**) performed by adding stoichiometric amounts of $S_2O_8^{2-}$ in $HOAc/AcO^-$ aqueous buffer. A new band is observed at $\lambda_{max} \approx 1100$ nm, corresponding to a metal-to-metal charge transfer (MMCT) transition in the mixed-valent complex $[(CN)_4Ru^{II}(dpp)Ru^{III}(CN)_4]^{3-}$. The electronic coupling is rather weak ($H_{AB} \approx 550$ cm^{-1}), pointing to a Class (II) species [24]. By contrast, no MMCT band was detected for the mixed-valent analogue $[(bpy)_2Ru(dpp)Ru(bpy)_2]^{5+}$, a fact explained by the little metal-metal interaction appearing in this latter complex as a consequence of the steric constraints imposed by the dpp bridging ligand [10]. We conclude that steric effects are less demanding when replacing bipyridines by cyanides as co-ligands.

The redox potentials determined by cyclic voltammetry are typical for cyanometalates [9]. In the Bu_4N^+ salt of the mononuclear complex $[Ru(dpp)(CN)_4]^{2-}$, the Ru^{III}/Ru^{II} redox potential is $E_{ox} = 0.44$ V (vs $Ag^+/AgCl$, in MeCN, 0.1 M TBAH), while the ligand reduction potential appears at $E_{red} = -1.59$ V (in the same conditions). The difference $E_{ox} - E_{red}$ is lower than the corresponding values for the bpy and bpz analogues [9]. For complex (**II**), two oxidative waves are observed, as expected for both Ru^{III}/Ru^{II} couples, with a difference in redox potentials of 0.23 V (in aqueous solution). This value indicates that the coupling of both metallic centers in this dinuclear species is intermediate between that of $[(NH_3)_4Ru(dpp)Ru(NH_3)_4]^{4+}$ ($\Delta E_{1/2} = 0.36$ V) and that of $[(bpy)_2Ru(dpp)Ru(bpy)_2]^{4+}$ ($\Delta E_{1/2} = 0.19$ V) [10,12]. This last result is consistent with the detection of a MMCT band in the mixed-valent derivative of (**II**).

Complex (**I**) emits in aqueous solution at room temperature. Figure 5 shows the emission spectra at

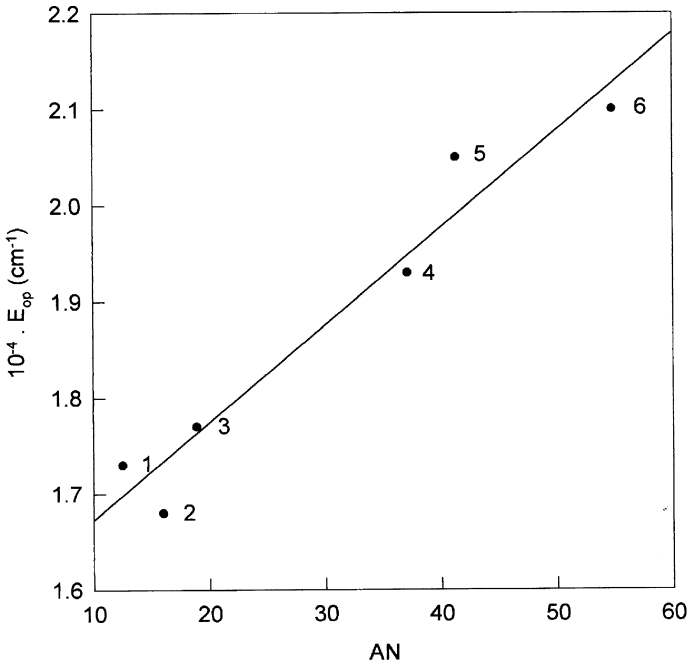

Fig. 3. Plot of E_{op} for the lowest-lying MLCT in $[Ru(dpp)(CN)_4]^{2-}$ vs the solvent acceptor number (AN). **1** = acetone; **2** = *N*,*N*-dimethylformamide; **3** = acetonitrile; **4** = ethanol; **5** = methanol; **6** = water.

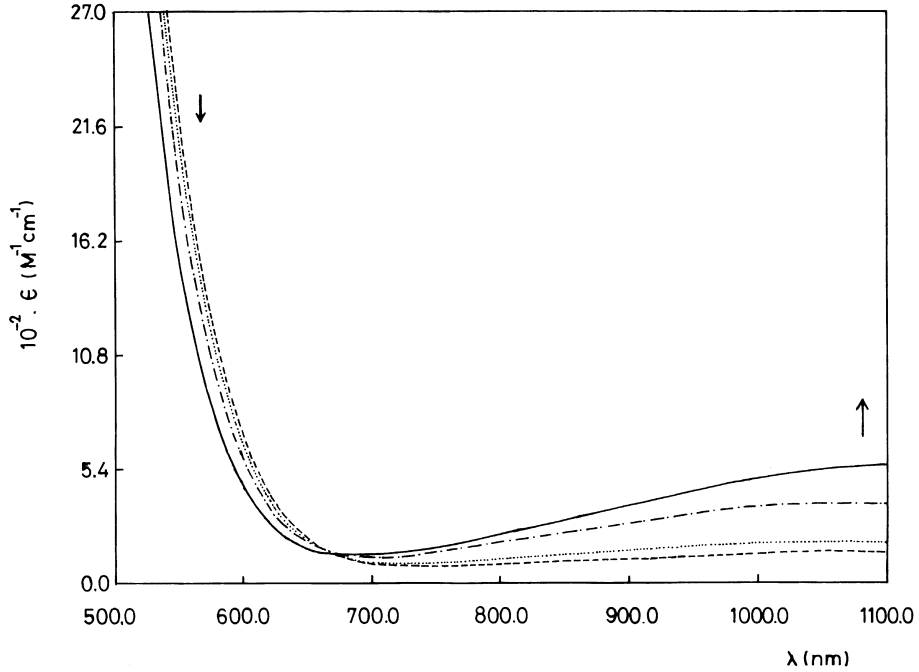

Fig. 4. Visible spectrophotometric titration of $[(CN)_4Ru^{II}(dpp)Ru^{III}(CN)_4]^{4-}$ with increasing amounts of $S_2O_8^{2-}$, in water, at pH = 4.

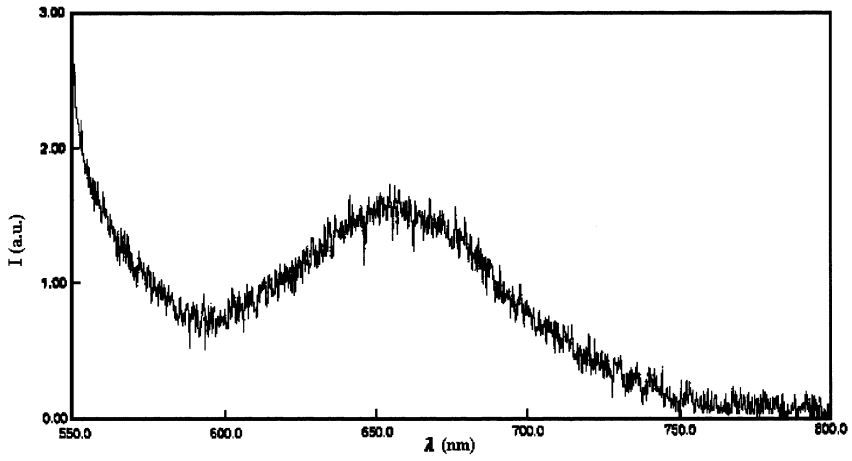

Fig. 5. Emission spectrum of $[Ru(dpp)(CN)_4]^{2-}$ in aqueous solution (λ_{ex} = 450 nm).

λ_{ex} = 450 nm. The obtained value of $\lambda_{em} = (652 \pm 2)$ nm is almost solvent independent and the corresponding energy value (E_{em} = 1.91 eV) is intermediate between those of the analogous complexes of bpy (E_{em} = 2.03 eV [7]) and bpz (E_{em} = 1.76 eV [9]), in agreement with the IR and UV–vis results. The quantum yield is $\phi_{em} < 0.001$. We can then deduce that complex (**I**) can be used as a photosensitizer in aqueous solution. Complex (**II**) does not emit in water at room temperature, contrasting to the behaviour of $[(bpy)_2Ru(dpp)Ru(bpy)_2]^{4+}$, which is emissive at room temperature [10]. This result points to a stronger metal-metal interaction in the complex described in this work as compared to $[(bpy)_2Ru(dpp)Ru(bpy)_2]^{4+}$, in accord with their optical and electrochemical properties.

It can be concluded that the new mono- and di-nuclear mixed complexes of dpp and ruthenium cyanides synthesized and characterized in this work allow us to classify dpp as a ligand whose electronic π-accepting ability is intermediate between bpy and bpz. While the mononuclear complex $[Ru(dpp)(CN)_4]^{2-}$

can be used as a photosensitizer in aqueous solution, the electronic interactions disclosed in the dinuclear species $[(CN)_4Ru(dpp)Ru(CN)_4]^{4-}$ seem to be lower than those found in similar bpz-bridged complexes [25], but stronger than in $[(bpy)_2Ru(dpp)Ru(bpy)_2]^{4+}$ [10]. The electronic coupling between metallic centers can thus be tuned by using bridging ligands with some steric restrictions, such as dpp, and co-ligands with no steric constraints, such as cyanides.

(Received 21 January 1998 ; accepted in revised form 26 January 1998)

Abstract—The oxidation of D-galactono-1,4-lactone by Cr^{VI} yields D-lyxonic acid, carbon dioxide and Cr^{3+} as final products when an excess of sugar acid over Cr^{VI} is used. The redox reaction occurs through $Cr^{VI} \rightarrow Cr^{III}$ and $Cr^{VI} \rightarrow Cr^{V} \rightarrow Cr^{III}$ paths. The complete rate law for the Cr^{VI} oxidation reaction is expressed by $-d[Cr^{VI}]/dt = (k_0 + k_H\,[H^+])\,[gal][Cr^{VI}]$, where $k_0 = (31 \pm 3) \times 10^{-4}\ M^{-1}\ s^{-1}$ and $k_H = (99 \pm 5) \times 10^{-4}\ M^{-2}\ s^{-1}$, at 40°C. Cr^{V} is formed in a rapid step by reaction of the $CO_2^{\cdot-}$ radical with Cr^{VI}. Cr^{V} reacts with the substrate faster than does Cr^{VI}. The Cr^{V} oxidation follows the rate law: $-d[Cr^{V}]/dt = (k'_0 + k'_H\,[H^+])\,[gal]$, where $k'_0 = (15 \pm 2) \times 10^{-3}\ M^{-1}\ s^{-1}$ and $k'_H = (34 \pm 4) \times 10^{-3}\ M^{-2}\ s^{-1}$, at 40°C. The EPR spectra show that several intermediate $[Cr(O)(gala)_2]^-$ linkage isomers are formed in rapid pre-equilibria before the redox steps.

Keywords: galactonolactone ; chromium ; oxidation ; kinetics ; mechanism ; Cr^{V} ; Cr^{VI}.

Hexavalent chromium, in many different compounds, is a well established carcinogen and mutagen [1–5]. The observation of Cr^{V} and Cr^{IV} intermediates in the selective oxidation of organic substrates by Cr^{VI} and their implication in the mechanism of Cr-induced cancers [6–8] has generated a considerable amount of interest in their chemistry and biochemistry [9–12]. The biological reduction of Cr^{VI} to lower states has been observed with a wide variety of naturally occurring cellular reductants [13–15]. Ligands that possess two oxygen atoms able to form five-membered rings about the metal ion, such as 1,2-diols and α-hydroxyacids, are effective as non enzymatic reductants and complexation agents towards hypervalent chromium and can stabilise the labile oxidation states of chromium [12, 16–19]. For this reason sugars, or their derivatives, may play an important role in the chemistry of Cr^{VI}. Aldonic acids (or their lactones) have been found as metabolic intermediates in animals and plants, as products of the action of micro-organisms on carbohydrates and as constituents of acidic polysaccharides [20]. Cr^{VI} oxidation of α-hydroxyacids has been extensively studied [21–29]. These oxidations may yield products coming from either C—C [21–22,25–27,29] or C—H [23–24,28,29] cleavage, depending on the particular molecular characteristics of the organic substrate, through mechanisms involving either two-electron or three-electron initial oxidation of substrate by Cr^{VI}. Polyhydroxyacids offer additional binding sites to form the Cr^{VI} (Cr^{V}) ester precursor of slow electron-transfer steps and provide helpful information about stereoelectronic effects affecting the reaction course [28]. In previous work we have found that the number and arrangement of hydroxyl groups of aldoses affect the Cr^{VI} and Cr^{V} oxidation rates and mechanism [30–34]. At present, we are interested in correlating the stereochemistry of aldonic acids with their ability for reducing and co-

† The present work was presented at the X Meeting on Physical-Chemistry, Tucumán, Argentina, April 21, 1997.

ordinating Cr^{VI} and Cr^{V}, as well as determining the preferred donor sites of these polyhydroxyacids. In this paper we report our results on the chromic oxidation of D-galactono-1,4-lactone (Scheme 1) and we present structural evidences for the intermediate Cr^{V} complexes formed in acid and neutral aqueous solutions.

EXPERIMENTAL

Materials

D-Galactono-1,4-lactone (Sigma grade), D-gluconic acid (Sigma grade), potassium dichromate (BDH), sodium perchlorate (Fluka grade), acrylonitrile (Aldrich grade) and perchloric acid (P. A. Merck) were used without further purification. Water was purified by deionisation, followed by double distillation from a potassium permanganate solution. $Na[Cr(O)(ehba)_2]\cdot H_2O$ was synthesised from 2-ethyl-2-hydroxybutanoic acid (Aldrich grade) and sodium dichromate (Merck) in acetone (Merck, A. R. grade) according to the literature method [35].

The stability of the organic substrate under conditions used in the kinetic studies was tested. The acid (gala) : lactone (galL) proportion of the reductant in the starting solution was calculated by optical rotation measurements at given hydrogen ion concentrations [36] and the composition of the substrate solution at different perchloric acid concentrations is shown in Table 1. The equilibrated solutions are stable over the time required for the kinetic measurements. In the text that follow gal refers to the total reductant concentration ([gal] = [galL] + [gala]).

For experiments performed in the 2–8 pH range, the pH of the solutions was adjusted by addition of 0.5 M NaOH and 0.5 M $HClO_4$.

Spectrophotometric measurements

Most kinetics measurements were made at 350 nm, by monitoring the absorbance changes on a Guilford Response II spectrophotometer with fully thermostated cell compartments. Mixtures of sodium perchlorate and perchloric acid were used to maintain a constant ionic strength (I) of 1.0 M. Reactant solutions were previously thermostated and transferred into a cell of 1 cm path length immediately after mixing and disappearance of Cr^{VI} was followed until at least 80% conversion. Experiments were performed at 40°C unless otherwise mentioned. In most experiments the concentration of Cr^{VI} was kept constant at 3.6×10^{-4} M while the gal concentration was varied from 0.018 to 0.122 M. The first-order dependence of the rate upon $[Cr^{VI}]$ was verified. The pseudo-first-order rate constants were calculated at various $[Cr^{VI}]_0$, but at constant temperature, $[gal]_0$, $[H^+]$ and I. As expected on the basis of a $-d(\ln[Cr^{VI}])dt = k_{obs}$ rate law where $k_{obs} = f([gal][H^+])$, k_{obs} was found to be essentially constant with increasing $[Cr^{VI}]_0$.

Cr^{V} was monitored by following the absorbance growth and decay at 750 nm of mixtures of Cr^{VI} (3.6×10^{-3} M) and excess gal (0.18–0.57 M) at fixed perchloric acid concentrations. The formation of Cr^{III} was monitored at 570 nm ($[Cr^{VI}]_0 = 1.8\times10^{-2}$ M and ratios of gal to Cr^{VI} from 10 : 1 to 20 : 1, at $[HClO_4]$ in the 0.25–0.75 M range). At the end of the reaction the two *d–d* bands ascribed to Cr^{III} were observed at

Table 1. Proportion of D-galactonolactone (galL) and D-galactonic acid (gala) in the starting solution[a]

[HClO4]/M	$10^2\ C_T$[b]/M	R[c]	galL (%)	gala (%)
0.25	6.60	−0.760	78.9	21.1
0.38	5.00	−0.539	72.2	27.8

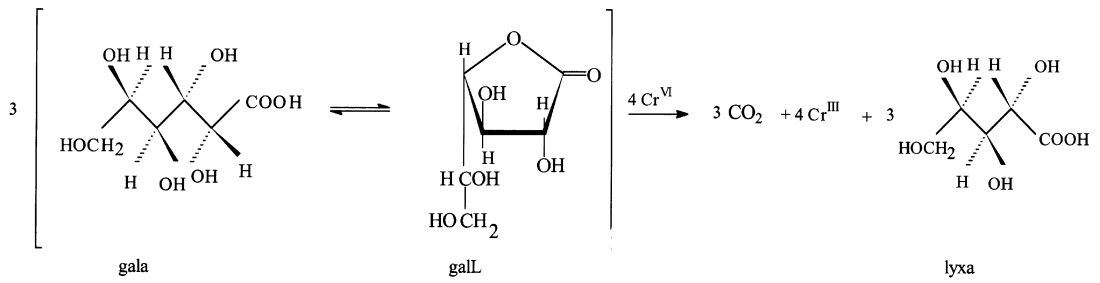
[a] Values used in calculations: molar rotations: −13.84 (galL); −2.84 (gala), +0.805 (gal^-); $K = [H^+][gal^-]/([gala]+[galL]) = 2.25\times10^{-5}$.

[b] $C_T = [gala]+[galL]+[gal^-]$, where gal^- refers to galactonate and represents <0.02% of C_T.

[c] Optical rotation.



Scheme 1.

$\lambda_{max} = 410$ ($\varepsilon = 33$) and 566 nm ($\varepsilon = 27.5$ dm^3 mol^{-1} cm^{-1}) ([$HClO_4$] = 0.25 M). Both, visible and UV spectral maxima and intensities, are in close agreement (*vide infra*) with those observed for the acid solutions of the K[Cr(OH)(gala)(lyxa)] (lyxa = D-lyxonic acid) ternary complex, independently synthesised [37] according to a literature method [38]. These *d–d* bands changed with time toward bands of lower intensity at $\lambda_{max} = 408$ ($\varepsilon = 19.7$) and 573 nm ($\varepsilon = 15$ dm^3 mol^{-1} cm^{-1}), characteristic of the $[Cr(H_2O)_6]^{3+}$ ion.

Products analysis

Under the conditions used in the kinetic measurements (ratios of gal to Cr^{VI} from 50 : 1 to 340 : 1), qualitative identification of D-lyxonic acid as the reaction product was carried out by paper chromatography. D-lyxonic acid was identified against an authentic sample using *n*-butanol/acetic acid/water (4 : 1 : 5) as eluent. Paper chromatograms were visualised by two kinds of development reagents : a three-stage dip of silver nitrate, sodium hydroxide and sodium thiosulphate [39] and *p*-anisidine reagent [40]. D-lyxonic acid identification as the only reaction product was also made by ^{13}C NMR. A mixture of gal (7.64×10^{-3} mmol) and potassium dichromate (1.66×10^{-3} mmol) in 1 M $HClO_4$ (10 cm^3) was allowed to react at 40°C. After the reaction had proceeded to completion the mixture was stirred with a Dowex 50W-X8 cation exchange resin until all the Cr^{III} was removed from the solution and a concentrated sample was analysed by ^{13}C NMR. Lyxonic acid and unreacted galL and gala were identified by comparing against authentic samples.

Under all these experimental conditions (large to moderate excess of organic substrate) a quantitative yield of carbon dioxide was observed.

The presence of free radicals was tested for in the reaction of gal with Cr^{VI}. A solution of potassium dichromate (4×10^{-4} mmol) in 2 cm^3 of 0.5 M $HClO_4$ was added to a mixture of 4×10^{-2} mmol gal and acrylonitrile (0.25 cm^3) in 0.5 M $HClO_4$ (0.25 cm^3) at 40°C. After 1 h a white precipitate appeared. Control experiments (without potassium dichromate or reductant present) did not show the formation of a precipitate. Besides, the addition of an excess of acrylonitrile on the reaction mixture results in the complete suppression of the carbon dioxide evolution.

EPR spectroscopy

The EPR spectra were obtained on a Bruker ESP 300 spectrometer. The microwave frequency was generated with a Bruker 04 ER (9–10 GHz) and measured with a Racal-Dana frequency meter. The magnetic field was measured with a Bruker NMR-probe gaussmeter. A least-squares EPR spectrum-fitting program, e23new, was used to estimate the spectral parameters and relative concentrations of the Cr^{V} complexes, using Lorentzian line shapes [41,42].

RESULTS AND DISCUSSION

Rate studies

The absorbance vs time curves at 350 nm exhibit a monotonic decrease of absorbance which cannot be described by a single exponential decay. At this wavelength, kinetic traces show an initial deviation from first-order decay over short time periods. These kinetic profiles could be adequately described by the set of consecutive first-order reactions of Scheme 2 :

It is known that Cr^{V} species absorb strongly at 350 nm and may superimpose Cr^{VI} absorbance yielding the wrong interpretation of spectrophotometric absorbance decay values [29]. Thus, considering the Cr^{V} absorption superimposition, the absorbance at 350 nm, at any time during the reaction, is given by

$$Abs^{350} = \varepsilon^{VI}[Cr^{VI}] + \varepsilon^{V}[Cr^{V}] \quad (1)$$

Combining the eqn (1) with rate expressions [43] derived from scheme 2, yields :

$$Abs^{350} = Abs_0 e^{-k6t} + k_6 \varepsilon^{V}[Cr^{VI}]_0 (e^{-k5t} - e^{-2k6t})/(2k_6 - k_5) \quad (2)$$

In this equation, ε^{V} refers to the molar absorptivity of Cr^{V} at 350 nm and was assumed to be the same as for the complex $[Cr^{V}(O)(ehba)_2]^-$ [35]. Parameters k_6 and k_5 refer to the rate of disappearance of Cr^{VI} and Cr^{V}, respectively, and were evaluated from a non-linear iterative computer fit of eqn (2). It must be noted that in eqn (2), k_6 appears in the numerator of the pre-exponential term and $2k_6$ appears in the denominator and in the exponential terms because, according to the proposed reaction scheme, only half of the Cr^{VI} reaches Cr^{III} through a Cr^{V} intermediate.

Figure 1(a) shows a typical curve for one run at 350 nm and the curve fit according to eqn (2). The calculated kinetic parameters, k_6 and k_5, for various concentrations of gal at fixed concentrations of $HClO_4$, are summarised in Table 2. In multiple measurements, the reproducibility of the two rate constants is better than 10%.

Values of k_5 and k_6 may also be obtained from absorbance data at 750 nm. At this wave length, only Cr^{V} absorbs and the experimentally observed intermediate Cr^{V} growth and decay curve could be fitted by eqn (3)

$$Abs^{750} = k_6[Cr^{VI}]_0 \varepsilon^{V}(e^{-k5t} - e^{-2k6t})/(2k_6 - k_5) \quad (3)$$

where ε^{V} refers here to Cr^{V} molar absorptivity at 750 nm. A good fit of data is obtained with $\varepsilon^{V} = 38$ M^{-1} cm^{-1} [26], as shown in Fig. 1(b). Since at least tenfold higher initial Cr^{VI} and gal concentrations were necessary to follow absorbance changes at 750 nm, $k_5/10$ and $2k_6/10$ values calculated by eqn (3) are coincident

with those obtained from eqn (2), when the same gal/Cr^{VI} ratio and [$HClO_4$] were employed. For gal and Cr^{VI} concentrations used in the kinetic measurements, either at 350 or 750 nm, the calculated maximum Cr^{V} concentrations ($[Cr^{V}]_{max}$) represent up to 8% of the total chromium concentration.

The Cr^{III} formation was followed at 570 nm. At this wave length, changes in Cr^{III} concentration can be described by the pair of consecutive reactions shown in the Scheme 3 and the experimental absorbance can be fitted by eqn (4)

$$\begin{aligned} Abs^{570} &= Abs([Cr^{III}]) + Abs(Cr^{3+}) \\ &= [Cr^{VI}]_0 k_1 (e^{-k1t} - e^{-k3t})(\varepsilon_1^{III} - \varepsilon_2^{III})/ \\ &\quad (k_3 - k_1) + Abs_\infty (1 - e^{-k1t}) \end{aligned} \quad (4)$$

where k_1 and k_3 refer to the rates of Cr^{VI} and [Cr^{III}] disappearance, and ε_1^{III}, ε_2^{III} are the molar absorptivities of the Cr^{III} complex formed at the end of the redox reaction and $[Cr(H_2O)_6]^{3+}$, respectively. A typical fit of experimental data at 570 nm by using eqn (4) is shown in Fig. 1(c). Here, we have considered that the rate of Cr^{III} complex formation equals the rate of Cr^{VI} decay, without taking into account Cr^{V}. This is consistent with the observation of an isosbestic point at 525 nm under conditions employed to follow Cr^{III} at 570 nm (Fig. 2) and the low $[Cr^{V}]_{max}$ (up to 8%) observed at 750 nm (Fig. 1), for the same oxidant and reductant concentration range. Values of k_1 calculated by eqn (4) are coincident with $2k_6$ values obtained by using either eqn (2) or (3). On the other hand, k_3 depends strongly on [H^+] and a more detailed study is required for the complete description of the hydrolysis mechanism.

Cr^{VI} *oxidation of gal*

In the proton concentration range studied, plots of $2k_6$ vs [gal] gave good straight lines from which values of k were determined (Table 3). A plot of k vs [H^+] gave a straight line with a positive intercept, showing that the second-order rate constant may be expressed as consisting of an acidity independent and an acidity dependent term:

$$k = k_0 + k_H[H^+] \quad (5)$$

where $k_0 = (31 \pm 3) \times 10^{-4}$ M^{-1} s^{-1} and $k_H = (99 \pm 5) \times 10^{-4}$ M^{-2} s^{-1}

The complete rate law is then given by

$$-d[Cr^{VI}]/dt = 2k_6[Cr^{VI}]_T = (k_0 + k_H[H^+])[gal][Cr^{VI}]_T \quad (6)$$

where $[Cr^{VI}]_T$ represents the total Cr^{VI} concentration.

The two terms in the rate law (eqn (6)) results from the fact that there are at least two transition states, differing in composition but similar in energy, through which the reduction of Cr^{VI} can proceed. Thus, the oxidation of gal by Cr^{VI} should occur through two parallel slow steps leading to the redox products. Besides, in the range of substrate concentrations employed, only substrate first-order dependence was observed and D-lyxonic acid and carbon dioxide were the only detected reaction products, clearly showing that the C—C scission is preferred to the C—H cleavage at the α-carbon. A mechanism taking account of these facts is proposed in Scheme 4.

In this mechanism we have assumed that the open carboxylic acid is the reactive form of the organic substrate. This assumption is based on previous findings showing the enhanced ability of hydroxyacids to bind Cr^{VI} and Cr^{V} [13,25–28]. In any case, a possible mechanism involving the lactone may not be discarded. However, if the lactone was the reactive form of the organic reductant, co-ordination of Cr^{VI} should be favoured at a pair of adjacent hydroxyl groups of the molecule [44]. The intermediate complex formed in this way might be present in the equilibrium mixture but should not be a direct precursor of the slow redox steps. Opening of the lactone ring and rearrangement should be required for the slow electron transfer steps to take place within a complex with the carboxylate bound to Cr^{VI}. On the other hand, in the [H^+] range studied, Cr^{VI} exists mainly as $Cr_2O_7^{=}$ [45,46]. Thus, the first step of the proposed mechanism may be interpreted as the formation of a monochelate with gala acting as a bidentate ligand bound to Cr^{VI} at Cl—O and C2—O to yield the anionic species A^{2-}. This intermediate, or its monoprotonated form (AH^-), may decompose to the products. The rate law corresponding to this mechanism may be expressed as in eqn (7):

$$-d[Cr^{VI}]/dt = (k_1K_1 + k_2K_1K_2[H^+])[gala][Cr^{VI}] \quad (7)$$

Equation (7) may be expressed as a function of the total organic substrate concentration as in eqn (8):

$$-d[Cr^{VI}]/dt = (k_1K_1 + k_2K_1K_2[H^+])[gal]K_h[Cr^{VI}]/(1 + K_h) \quad (8)$$

We propose that redox paths, involving either A^{2-} or AH^- intermediate complexes, are three electron steps, just as observed for the chromic oxidation of mandelic [25], 2-hydroxy-3-methylbutanoic [21] and D-ribonic [22] acids, and Cr^{III} is formed with the oxidation products. The alternative path corresponding to the sequence $Cr^{VI}/Cr^{IV}/Cr^{III}$ was discarded on the basis of the complete CO_2 suppression after addition of excess

$$Cr^{VI} \xrightarrow{k_1} [Cr^{III}] \xrightarrow{k_3} Cr^{3+}$$

Scheme 3. [Cr^{III}] = Cr^{III}-gala-lyxa ternary complex

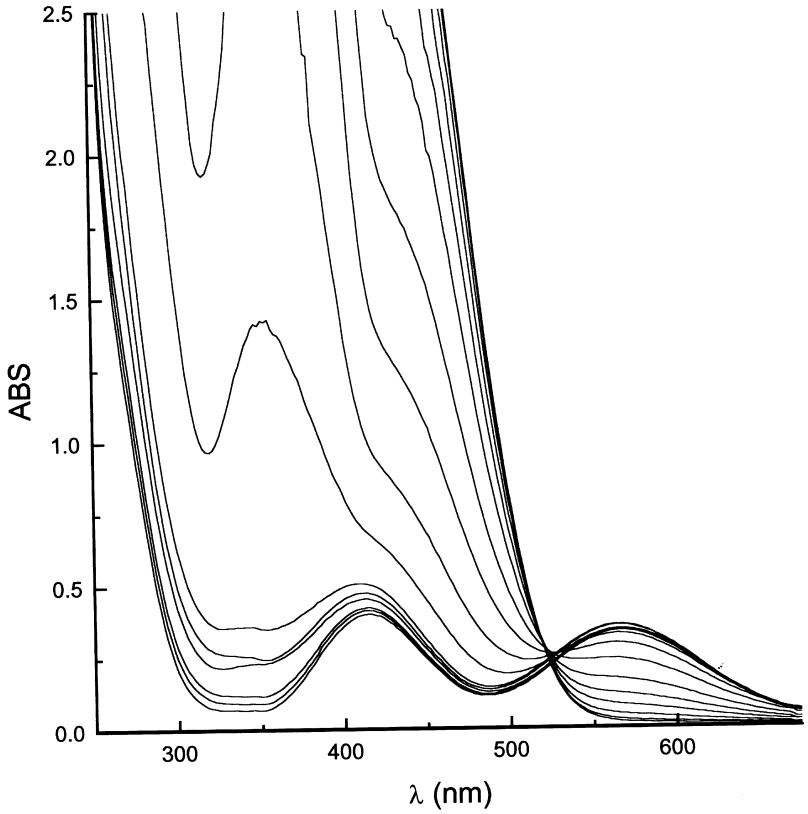

Fig. 2. Time evolution of the UV–vis spectrum of a mixture of gal (0.75 M) and Cr^{VI} (1.8×10^{-2} M). [$HClO_4$] = 0.5 M; $T = 25^{\circ}C$, over a period of ca 45 min.

Table 3. Values of k and k' for different [$HClO_4$]

[$HClO_4$/M	0.25	0.38	0.5	0.75	1.0
$10^3\,k/M^{-1}\,s^{-1}$	5.20	7.24	8.22	10.5	12.9
$10^3\,k'/M^{-1}\,s^{-1}$	20.6	29.7	33.8	39.2	48.2

acrylonitrile on the reaction mixture and the fact that the 2-ketoacid was not observed over the whole set of conditions used here. Besides, Cr^{II} formation was not proposed since CrO_2^{2+}, which is taken as evidence that Cr^{II} is an intermediate product of the reaction, was not observed as we did for the oxidation of homoserine by Cr^{VI} [24]. $CO_2^{\cdot-}$ radicals formed in the slow steps may react with Cr^{VI} in a subsequent fast step to yield Cr^{V} and carbon dioxide. Polymerisation after addition of acrylonitrile support the formation of these radicals. Cr^{V} can further oxidise gala as will now be discussed.

Cr^{V} *oxidation of gal*

At the [$HClO_4$] used in the kinetics measurements, the reaction of Cr^{VI} with excess gal generates an EPR spectrum dominated by a single detectable signal at $g_{iso} = 1.9781$ (Fig. 3 Inset) with the four weak ^{53}Cr (9.55% abundance, $I = 3/2$) hyperfine peaks at 18 G spacing, typical of five-co-ordinate oxochromate(V) complexes [47,48].

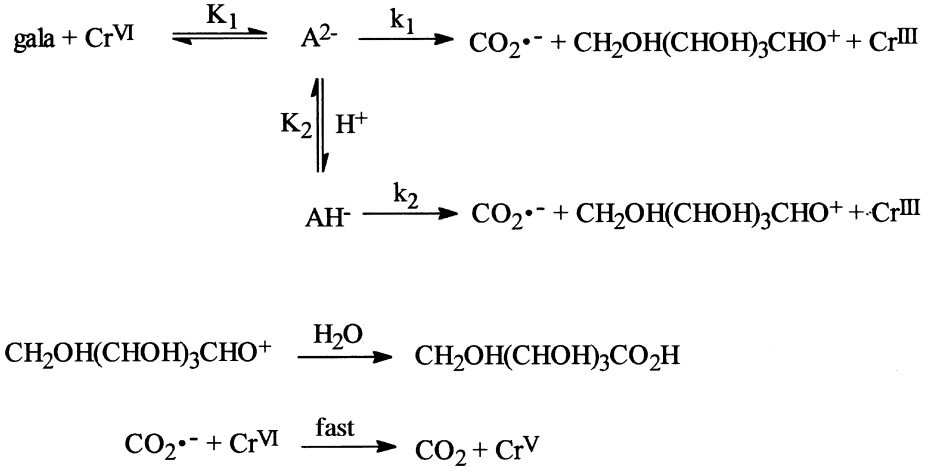
The rate of formation and disappearance of the intermediate Cr^{V} calculated from the peak-to-peak heights (and/or areas) of the EPR signals as a function of time (Fig. 3) are consistent with values obtained from the spectrophotometric measurements. The delayed t_{max} observed by this technique, account for the lower temperature (25°C, instead of 40°C) used in the EPR measurements.

In the 0.25–1 M proton concentration range, plots of k_5 vs [gal] gave good straight lines from which values of k' were determined (Table 3). A plot of k' vs [H^+] gave a straight line with a positive intercept, showing that the second-order rate constant may be expressed as consisting of an acidity independent and an acidity dependent term. The rate constant for the disappearance of Cr^{V} then may be expressed as:

$$k_5 = (k'_0 + k'_H[H^+])[gal] \quad (9)$$

where $k'_0 = (15 \pm 2) \times 10^{-3} M^{-1} s^{-1}$

and $k'_H = (34 \pm 4) \times 10^{-3} M^{-2} s^{-1}$ (10)



Scheme 4. $A^{2-} = [(galaH_{-2})(O)_2(OH_2)CrOCrO_3]^{2-}$

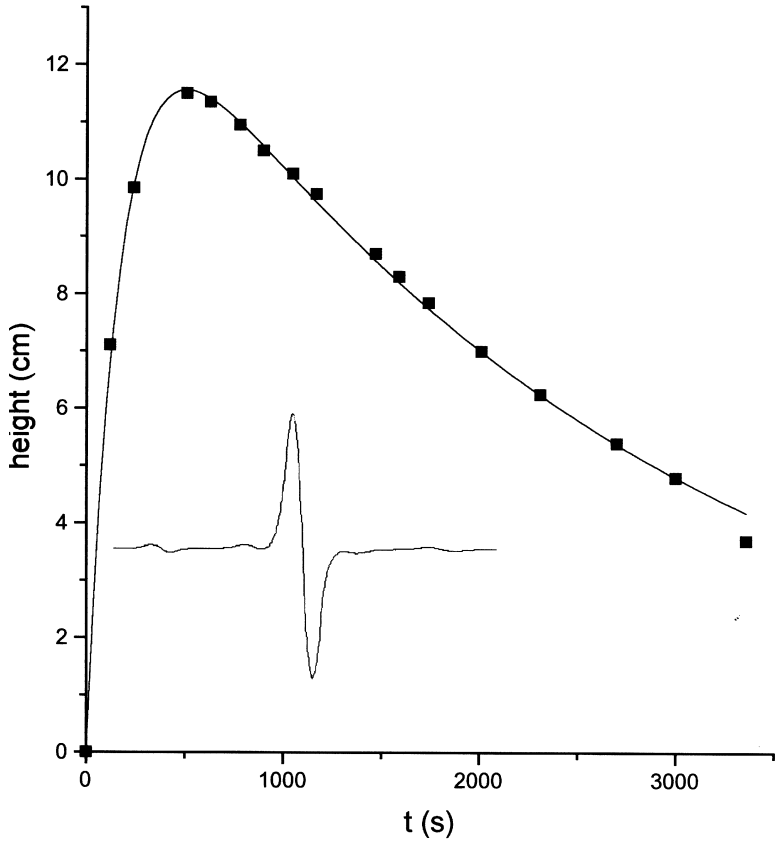


Fig. 3. Peak-to-peak heights of Cr^{V} EPR signals vs time. [gal] = 0.144 M; $[Cr^{VI}] = 3.6 \times 10^{-3}$ M; $[H^+] = 0.5$ M; $I = 1$ M; $T = 25°C$. $T_{max} = 508$ s. Inset: EPR signal recorded at $t = 15$ min.

This means that the Cr^{V} intermediate decays to the product directly or through an acid-catalysed step. Since the latter is of the same order as the non-catalysed step, at low acid concentration (i.e. neutral pH) the oxidation occurs mainly through the non-acid-catalysed path. In this way, the intermediate Cr^{V} is consumed faster than observed for the reaction of Cr^{VI} with sugars for which the non-acid catalysed path is extremely slow and the Cr^{V} intermediates remain in solution after several weeks [30–32].

A mechanism taking into account the structural evidence for the Cr^V intermediate complex and the kinetics results is given in Scheme 5.

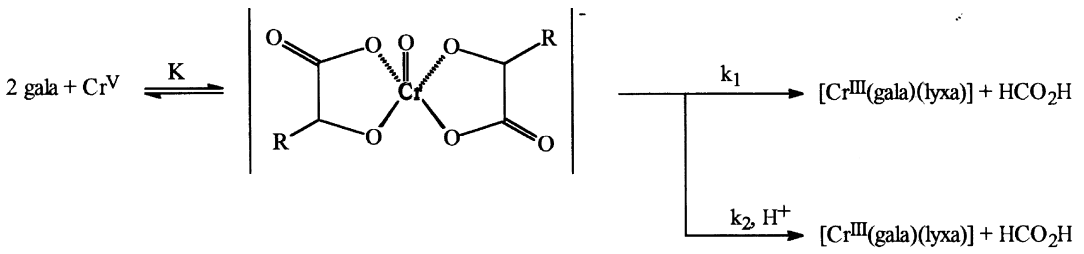
In this mechanism, only one of the two gala molecules involved in the Cr^V complex formation is oxidised to D-lyxonic acid through the two-electron intramolecular redox path, in accordance with the observed first-order rate on [gala]. Possibly, several linkage isomers might be formed by co-ordination of gala with Cr^{VI} via any pair of properly disposed hydroxyl group (see discussion below). However, since D-lyxonic acid is the only reaction product observed in the solution, the Cr^V complex, precursor of the redox steps, must be one with at least one gala molecule bound to Cr^V at the carboxylate group. Besides, the g_{iso} and A_{iso} values observed for the Cr^V intermediate are close to those of $[Cr(O)(ehba)_2]^-$. Since the g_{iso} and, specially, A_{iso} values are very sensitive to the Cr^V co-ordination environment, our assumption seems to be a reasonable one.

It must be noted that, in Scheme 5, the two-electron substrate C—C cleavage affords formic acid. However, under our experimental conditions, we have never detected formic acid. This fact may be explained if, under conditions used here, formic acid is oxidised faster than gal. Effectively, Cr^{VI} oxidation of formic acid to carbon dioxide is faster than gal oxidation [49], affording the observed quantitative yield of carbon dioxide.

The proton superhyperfine (shf) coupling has been shown to be useful in determining the binding of 1,2-diolate moieties of sugars to the Cr^V centre [30,44]. We found that performing the reaction at pH > 2, the single broad (linewidth ~ 2 G) signal observed at higher $[H^+]$ sharpens and the shf pattern resolves, thus providing new insights about the gala co-ordination sites.

The reaction of Cr^{VI} with an excess of 5–20 times of gal, in the 2–6 pH range, at 25°C, results in the formation of a Cr^V EPR spectrum which is a composite of at least two EPR signals at $g_1 = 1.9781$ and $g_2 = 1.9788$. The relative proportion of the signals depends on the pH, but is independent of the gal/Cr^{VI} ratio employed and the reaction time (the signals were deconvoluted by fitting the spectra by Lorentzian derivatives). Figure 4(a) shows the spectrum of a reaction mixture at pH = 5 with the simulated spectrum, for which a g_1/g_2 ratio = 0.41 was obtained. The best fit of the spectrum yields the spectral parameters summarised in Table 4. The g_{iso} values obtained for the two signals are those expected for five-co-ordinate oxochromate(V) complexes; while the different shf patterns indicate that they are linkage isomers [50]. In this way, the shf splitting of the signal at g_1 arises from the coupling of two equivalent protons and may be attributed to a complex with two ligand molecules bound to Cr^V at Cl—O/C2—O. The shf splitting of the signal at g_2 may be assumed to arise from two different binding modes of the two ligand molecules co-ordinated to Cr^V, via a 1,2-diolate and the α-hydroxocarboxylate donor sites, respectively. In the oxidation of D-gluconic acid (glca) with Cr^{VI}, in this pH range, only one species is detected. Interestingly, the g_{iso} value (1.978) and the shf pattern (Fig. 5) reveal the same chelation mode of glca as for gala in the complex giving rise to the signal at g_2. For the same gal/Cr^{VI} ratios, in the 6–8 pH range, the spectra are dominated by a signal at 1.9795 with a shf splitting value of 0.92 G. The g_{iso} and shf pattern clearly indicate that CrO^{3+} co-ordinates two gala molecules via a 1,2-diolate moiety and that the shf structure derives from the coupling with the four equivalent protons. In this pH range, the minor signal ($g_{iso} = 1.978$) can be attributed to the isomer with the ligand acting through a 1,2-diolate and the α-hydroxocarboxylate donor sites. Figure 4(b) shows the spectrum of a reaction mixture at pH = 7.4 with the simulated spectrum, for which the major Cr^V species represents the 92% of the Cr^V in solution.

A last point to consider is that, at each pH, the



$$[Cr^{III}(gala)(lyxa)] \longrightarrow Cr^{3+} + gala + lyxa$$

Scheme 5. R = $CH_2OH(CHOH)_3$

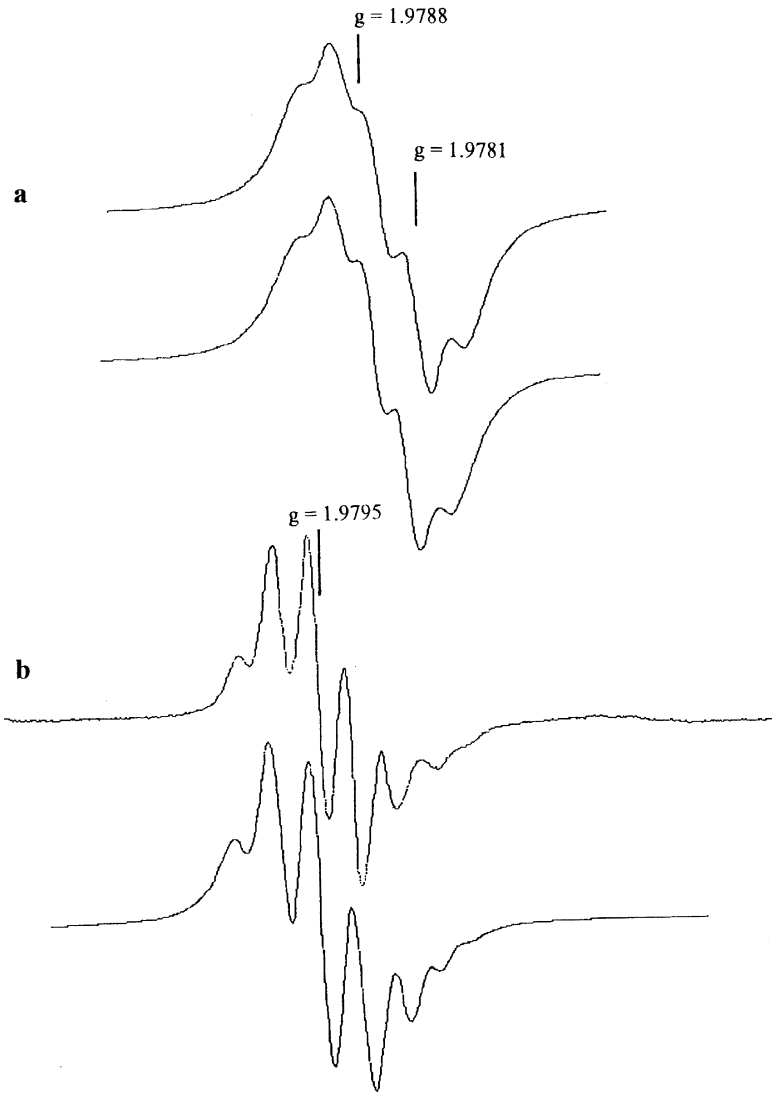


Fig. 4. X-band EPR signal of a mixture of gal and Cr^{VI} (5 : 1 mole ratio) at (a) pH = 5.4, 2 h after mixing, (b) pH = 7.4, 1 day after mixing, and the corresponding simulated spectra (linewidth = 0.8 and 0.6 G, respectively) ; $T = 25^{\circ}C$, modulation amplitude = 0.63 G, centre field = 3555 G ; frequency = 9.84 GHz.

Table 4. EPR spectral parameters

	g_{1iso} (m)	a_{1iso}/G	g_{2iso} (m)	a_{2iso}/G
[H+] > 0.1 M	1.9781	—		
pH = 2–6	1.9781 (t)	0.75	1.9788 (dt)	0.75, 0.92
pH = 6–8	1.9795 (quint)	0.92	1.978 (dt)	0.7, 0.9

m = multiplicity ; t = triplet ; dt = double-triplet ; quint = quintet

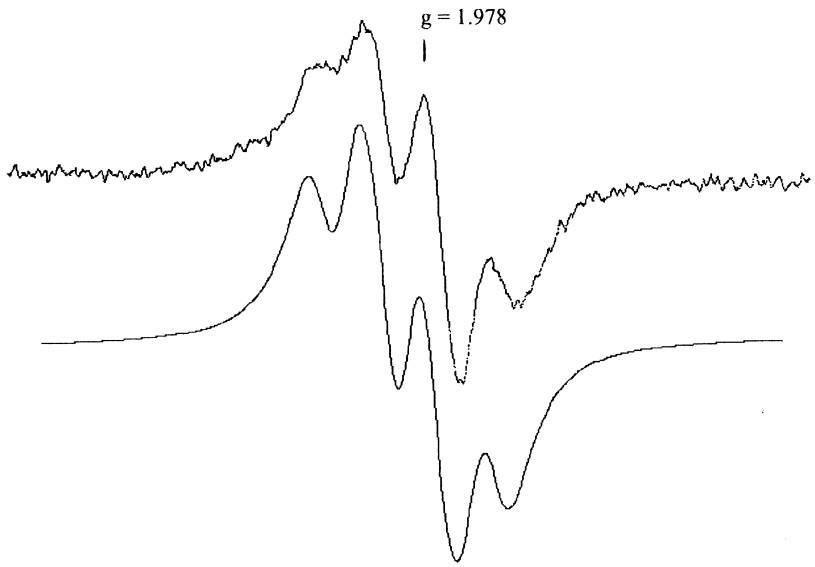

Fig. 5. X-band EPR signal of a mixture of D-gluconic acid and Cr^{VI} (10 : 1 mole ratio) at pH = 4, 1 day after mixing and the corresponding simulated spectrum (linewidth = 0.55); $T = 25°C$; modulation amplitude = 0.515 G; centre field = 3530 G; frequency = 9.77 GHz.

relative proportion of the intermediate Cr^{V} complexes remains constant over the reaction time, meaning that these Cr^{V} intermediates are in rapid equilibria compared to the time scale of their subsequent reduction to Cr^{III}.

(Received 21 January 1998; accepted 26 January 1998)

Abstract—Nickel(II), copper(II) and palladium(II) complexes of 1-phenylglyoxal bis{N(3)-diethylthiosemicarbazone}, H_2Pg4DE, have been prepared, studied spectroscopically and their crystal structures solved. H_2Pg4DE and the three complexes have been characterized by IR, electronic, ^{1}H NMR (Ni, Pd) and ESR (Cu) spectra. Upon formation of these complexes, loss of the N(2)H hydrogens from both thiosemicarbazone moieties occurs, and the ligands coordinate to the metal centers as dianionic, tetradentate N_2S_2 ligands. The nickel(II) and copper(II) complexes, [M(Pg4DE)], coordinate in the expected 5-5-5-chelate ring system, but [Pd(Pg4DE)] coordinates with 5-6-4-membered chelate rings. The thiosemicarbazone moiety attached to the phenyl keto carbon in [Pd(Pg4DE)] forms the 4-membered chelate ring coordinating via N(2) rather than the azomethine nitrogen, N(1). © 1998 Elsevier Science Ltd. All rights reserved

Keywords: 1-phenylglyoxal; bis(thiosemicarbazone); nickel(II); copper(II); palladium(II); N(3)-diethylthiosemicarbazone.

The synthesis and spectral characterization of metal complexes with 1-phenylglyoxal bis{N(3)-substituted thiosemicarbazone} ligands have been reported previously [1]. The copper(II) and nickel(II) complexes of the bis{N(3)-methyl-, N(3)-dimethyl- and piperidylthiosemicarbazones} were included in that study. Because of the antitumor activity of α-diketone and α-ketoaldehyde bis(thiosemicarbazones) [2], as well as their metal complexes [3], and the considerable dependence of the biological activity on the nature of the N(3)-substituent attached to the thiosemicarbazone moiety in other series of thiosemicarbazones [4], a series of copper(II) and nickel(II) complexes of 2,3-butanedione [5], pyruvaldehyde [6] and glyoxaldehyde [7] bis{N(3)-substituted thiosemicarbazones} have also been studied. We have now prepared and spectrally characterized 1-phenylglyoxal bis{N(3)-diethylthiosemicarbazone}, H_2Pg4DE, and its nickel(II), copper(II) and palladium(II) complexes. The crystal structures of the three complexes have been solved and are included here. Because of the bulkiness of the phenyl group, the two thiosemicarbazone moieties may not be on opposite sides of the carbon-carbon backbone, as was found with 2,3-butanedione thiosemicarbazones [5]. Thus, they are shown on the same side of the carbon-carbon backbone for H_2Pg4DE in Fig. 1.

EXPERIMENTAL

Preparation of phenylglyoxal bis{N(3)-diethylthiosemicarbazone}

1-Phenylglyoxal bis{N(3)-diethylthiosemicarbazone}, H_2Pg4DE, was obtained by stirring 1-phenylglyoxal monohydrate (Aldrich) and N(3)-diethylthiosemicarbazide for several hours in a molar ratio of 1 : 2 in absolute ethanol with a few drops of concentrated sulfuric acid added to catalyze the reaction. N(3)-diethylthiosemicarbazide was prepared by the

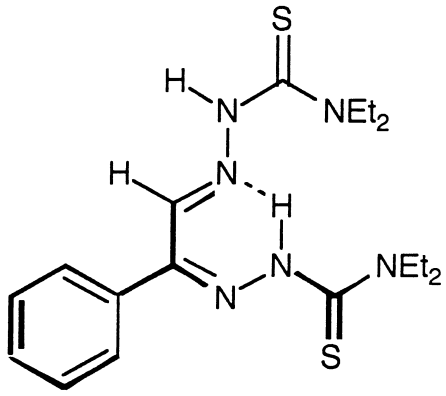

Fig. 1. Intramolecularly hydrogen bonded H_2Pg4DE.

method described by Scovill [8]. H_2Pg4DE has been characterized by IR, UV–vis, ^1H and ^{13}C NMR spectra and has a melting point of 158–159°C.

Preparation of metal complexes

The metal complexes were prepared by refluxing a solution of H_2Pg4DE and an equimolar amount of the metal acetate (Ni, Cu) in ethanol for 4–5 h (aqueous-methanol mixture of K_2PdCl_4 with triethylamine added for the preparation of [Pd(Pg4DE)]. The resulting solids, which formed on cooling, were filtered, washed with diethyl ether and dried at 35°C. Found: Calcd for [Ni(Pg4DE)]·$1/2H_2O$: %C = 47.0 (47.2); %H = 5.5 (5.9) and %N = 18.3 (18.3); for [Cu(Pg4DE)]·H_2O: %C = 45.7 (45.8); %H = 5.3 (6.0).

Partial elemental analyses were performed by National Chemical Consulting, Inc. of Tenafly, NJ. The magnetic susceptibilities were measured with a Johnson Matthey Magnetic Susceptibility balance. Infrared spectra were recorded with Perkin–Elmer 783 and Bruker Model IFS 66V Spectrometers using Nujol mulls between Csl plates; electronic spectra were acquired as Nujol mulls impregnated on filter paper and as dimethylsulfoxide (DMSO) solutions in 1 cm cells with a Perkin–Elmer 330 spectrometer and NMR spectra were obtained with a Varian 300 MHz Gemini spectrometer using d^6-DMSO as the solvent with tetramethylsilane as reference. ESR spectra were recorded with a Varian E104 Spectrometer in an insert Dewar with DPPH as reference.

X-ray data collection and reduction

A brown prismatic crystal of [Ni(Pg4DE)], a violet prismatic crystal of [Cu(Pg4DE)] and a garnet prismatic crystal of [Pd(Pg4DE)] were mounted on a glass fiber and used for data collection. Cell constants and an orientation matrix for data collection were obtained by least-squares refinement of the diffraction data from 25 reflections in the range $5.563° < \theta < 11.993°$, $21.424° < \theta < 42.274°$ and $8.817° < \theta < 18.090°$ for [Ni(Pg4DE)], [Cu(Pg4DE)] and [Pd(Pg4DE)], respectively, with an ENRAF-NONIUS MACH3 automatic diffractometer [9]. Data were collected at 293° using Mo–K_α radiation ($\lambda = 0.71073$ Å) for [Ni(Pg4DE)] and [Pd(Pg4DE)] and Cu–K_α ($\lambda = 1.54184$ Å) for [Cu(Pg4DE)] and the ω scan technique, and the data corrected for Lorentz and polarization effects [10]. An empirical absorption correction was made [11].

Structure solution and refinement

The structure was solved by direct-methods [12], which revealed the position of all non-hydrogen atoms, and refined on F^2 by a full-matrix least-squares procedure using anisotropic displacement parameters [13]. The hydrogen atoms were located in their calculated positions (C—H, 0.93–0.97 Å) and refined using a riding model. Atomic scattering factors were taken from the *International Tables for X-ray Crystallography* [14]. Molecular graphics are from ZORTEP [15]. A summary of the crystal data, experimental details and refinement results are listed in Table 1.

RESULTS AND DISCUSSION

NMR results

The ^1H and ^{13}C NMR spectral results are shown in Table 1 for both H_2Pg4DE and the metal complexes, [Ni(Pg4DE] and [Pd(Pg4DE)]. Because the two thiosemicarbazone moieties are attached to carbon centers with different environments, the ^1H resonances for the individual hydrogens are different in the two moieties. For H_2Pg4DE one of the N(2)Hs is found at $\delta = 12.898$ and the other at $\delta = 10.784$. The former, based on X-ray crystal studies of related bis(thiosemicarbazones) of 1-phenylglyoxal [16], is attached to the "phenyl arm" which is hydrogen bonding to the azomethine nitrogen of the "aldehyde arm" as depicted in Fig. 1. In d^6-DMSO the "phenyl arm" N(2)H is found at $\delta = 13.151$ and the "aldehyde arm" at $\delta = 10.990$ with a weaker resonance at 11.200, which is likely due to the aldehyde arm's N(2)H hydrogen bonding with DMSO. Both N(2)Hs are lost on formation of the nickel(II) and palladium(II) complexes {and copper(II) complex} so that neither spectrum has resonances at low field.

The aldehyde hydrogen attached to C(11) (*vide infra*) shifts up field from $\delta = 8.310$ in the spectrum of H_2Pg4DE to $\delta = 7.256$ and 7.135 in the spectra of [Ni(Pg4DE)] and [Pd(Pg4DE)], respectively. The greater covalency of the C—H bond accompanies the donation of electron density by the azomethine nitrogen to the metal centers. Two resonances are assignable to the ethyl group's CH_2 protons because of the two different thiosemicarbazone moieties. The shifts

[a] Numbers in parentheses are log ε; [b] the intensity of these bands indicates that some n–π* charge transfer and/or intraligand character must also be involved, particularly since H_2Pg4DE has a band at 18,590 cm^{-1}.

on coordination are not as great as the aldehyde hydrogen because of their greater distance from the coordinating thiolato sulfurs. Even smaller shifts of the ethyl groups' CH_3 protons occurs on coordination. The magnetic susceptibility for the violet [Cu(Pg4DE)] is 1.73 B.M., which is consistent with minimal spin orbit coupling of the unpaired electron, as well as weak/no coupling between copper(II) centres.

Crystal structures of [*Ni*(*Pg*4*DE*)], [*Cu*(*Pg*4*DE*)] *and* [*Pd*(*Pg*4*DE*)]

The crystal data for [Ni(Pg4DE)], [Cu(Pg4DE)] and [Pd(Pg4DE)] are shown in Table 2, selected bond lengths in Table 3 and selected bond angles in Table 4. A complete list of bond distances and angles, as well as the positional parameters, equivalent isotropic temperature factors and lists of F_o/F_c values are included in the supplementary material deposited with the Editor. Perspective views of [Ni(Pg4DE)], [Cu(Pg4DE)] and [Pd(Pg4DE)] are shown in Figs 2, 3 and 4, respectively.

Based on other thiosemicarbazones [17] the mode of coordination for [Ni(Pg4DE)] and [Cu(Pg4DE)] is as expected with the two azomethine nitrogens and the two thiolato sulfurs bonding, on loss of N(2)H from both moieties, to give approximately planar, 4-coordinate complexes. The M—S bonds for these two complexes {and for [Pd(Pg4DE)]} are significantly longer than the M—N bonds so that the coordination geometry about the metal ions is more rectangular than square; the *cis* bond angles in [Cu(Pg4DE)] range from 81.12(14)°, N(21)—Cu—N(11) to 108.36(5)°, S(1)—Cu—S(2). Also, the bonds within the two thiosemicarbazone moieties of [Ni(Pg4DE)] and [Cu(Pg4DE)] have different distances which are conveniently listed in Table 5. Significant differences are found for both Ni, Cu—N and Ni, Cu—S for the two moieties with the "phenyl arm" having the longer Ni, Cu—N bond, but the shorter Ni, Cu—S bond. In the thiosemicarbazone moieties of [Ni(Pg4DE)] there are significant differences for the N—N, the N═C and C—N bonds along the thiosemicarbazone moiety, but not for C═N where the two moieties would be expected to be most different. The bond angles involving the nickel(II) center are not significantly different among the two moieties, nor are there significant difference in the bond angles within the two moieties. Surprisingly, the bond distances and angles for the two arms of [Cu(Pg4DE)] are not very different.

In contrast the two "arms" of [Pd(Pg4DE)] coordinate in a different manner; the "aldehyde arm" coordinates in the expected fashion like both arms of [Ni(Pg4DE)] and [Cu(Pg4DE)], but the "phenyl arm" coordinates via the thioamide nitrogen, rather than the azomethine nitrogen, forming a four-membered chelate ring with the thiolato sulfur donor. Thus, the coordination about the nickel and copper in their complexes is 5-5-5 in terms of the number of atoms in the three chelate rings, but for [Pd(Pg4DE)] it is 5-6-4. This results in the coordination for [Pd(Pg4DE)] being even less square than [Ni(Pg4DE)] and [Cu(Pg4DE)]; the *cis* bond angles range from 70.3(3)°, N(21)—Pd—S to 110.94(11)°, S(1)—Ni—S(2). However, the N(21)—M—S(1) trans angle is 178.7(3)° for [Pd(Pg4DE)], but 166.69(11)° for [Cu(Pg4DE)] and 171.4(3)° for [Ni(Pg4DE)].

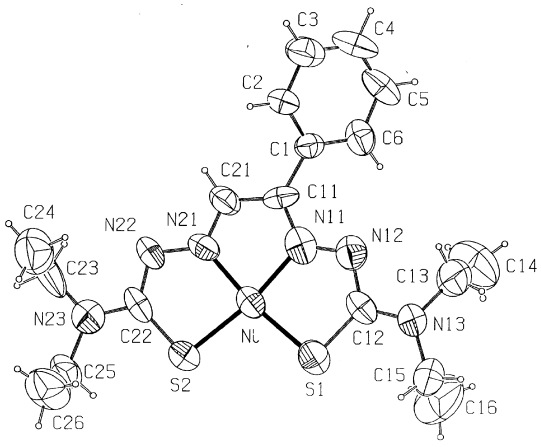

Fig. 2. A perspective view of [Ni(Pg4DE)].

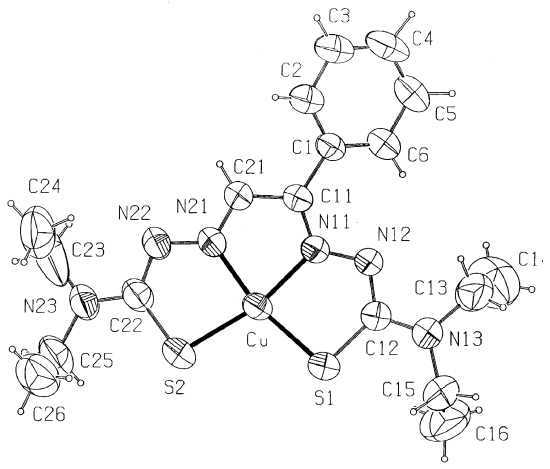

Fig. 3. A perspective view of [Cu(Pg4DE)].

In addition, the two "arms" of [Pd(Pg4DE)] would be expected to have different bond distances and angles between their thiosemicarbazone moieties, as well as in coordination to the palladium(II) center. Somewhat surprisingly the two Pd—N bonds are not significantly different, but the two Pd—S bonds, 2.257(3) for the "phenyl arm" and 2.344(3) for the "aldehyde arm" are very different. In the two thiosemicarbazone moieties of [Pd(Pg4DE)], the greatest difference occurs for the N—N bond, but its difference is nearly equal to the combination of estimated standard deviations. The bond angles involving sulfur coordination as well as the thiosemicarbazone moiet-

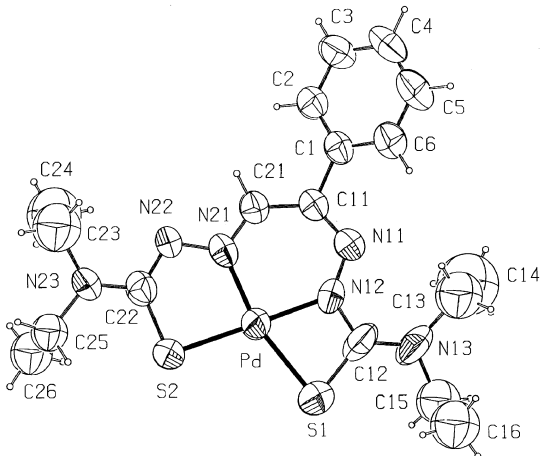

Fig. 4. A perspective view of [Pd(Pg4DE)].

ies, however, do show significant differences with the largest being as follows (phenyl arm listed first): Pd—S—C, 78.1(4)°, 94.6(4)°; N—N—C(S), 127.9(9)°, 111.2(9)°; N—C(S)—NEt_2, 126.4(11)°, 115.6(10)° and S—C—NEt_2, 108.6(8)°, 118.2(8)°. The latter two bond angle comparisons show that the NEt_2 function's position in the two "arms" is rather different. Even though the chelate ring sizes are different, the N(12)—C(12)—S(1) angle of 125.0(9)° of the phenyl arm (i.e., 4-membered chelated ring) and the corresponding N(22)—C(22)—S(2) bond angle, 126.17(9)° (i.e., 5-membered chelated ring), are within combined estimated standard deviations.

As would be expected, the metal-ligand bond distances are significantly longer for [Pd(Pg4DE)] than for [Ni(Pg4DE)], and those of [Cu(Pg4DE)] are more similar to [Pd(Pg4DE)]. Also, a comparison of the bond distances of the "aldehyde arms" of the three complexes shows that they are not significantly different. There is somewhat more variation in the bond angles of [Pd(Pg4DE)] compared to [Ni(Pg4DE)] and [Cu(Pg4DE)]: C(21)—N(21)—Pd is 120.5(7)° compared to ca 114.6°; C(21)—N(21)—N(22) is 116.0(4)° for [Pd(Pg4DE)] compared to ca 120.6° and C(25)—N(23)—C(23) is 112.5(9)° for [Pd(Pg4DE)] compared to ca 115.4°.

For [Ni(Pg4DE)] there is only a very small mean plane deviation of 0.0186 Å for the donor atom plane, S1—N11—N21—S2, and the two nitrogens deviate from the plane to the greatest extent {i.e., N11 = −0.0208(31) Å and N21 = 0.0214(32) Å}. There is even less deviation from planarity of the planes involving the thiosemicarbazone moieties, and these planes are almost coplanar with the S1—N11—N21—S2 plane, the angles for the various planes being in the 1–2° range. For [Cu(Pg4DE)] there is a somewhat larger mean plane deviation of 0.0390 Å for the donor atom plane, S1—N11—N21—S2, and again the two nitrogens deviate from the plane to the greatest extent {i.e., N11 = −0.0447(17) Å and N21 = 0.0455(18) Å}. The planes involving the thiosemicarbazone moieties are again nearly coplanar with the S1—N11—N21—S2 plane, the angles for the various planes being in the 1–2° range. For [Pd(Pg4DE)], S1—N11—N21—S2 has a mean plane deviation of 0.199 with the two nitrogens showing the largest deviation. The angles with the thiosemicarbazone moiety planes are less than 1°.

IR, UV–vis and ESR spectral results

The assignments of IR spectral bands useful for determining the bis(thiosemicarbazone's) mode of coordination are listed in Table 1. The ν(C=N) bands of H_2Pg4DE (1546, 1540 cm^{-1}) shift to slightly lower

[a] M—N—N for the "phenyl arm".

frequencies in the spectra of the complexes indicating coordination of the azomethine nitrogen {N(1)}. A second band due to ν\{C(3)=N(2)\} (which formally becomes a double bond in the complexes) is often observed in this same range in the complexes' spectra, but is not resolved in these spectra. The uncomplexed H_2Pg4DE's spectrum shows the thioamide IV band, which possesses considerable contribution from ν(CS), at 793 cm^{-1}. This band, which is a single band in the spectra of H_2Pg4DE and its complexes, shifts to lower energy by 50–90 cm^{-1} on coordination in agreement with previous studies [5–7]. Bands in the 350 cm^{-1} region are assigned to ν(M—S) and those in the 450–470 cm^{-1} region to ν(M—N) vibrations, supporting the coordination of the ligands as tetradentate N_2S_2 chelating agents [18].

Also included in Table 1 are the band maxima of solution ($CHCl_3$) electronic transitions for H_2Pg4DE and its complexes. The high energy π–π* transition (ca 40,000 cm^{-1}) is not significantly altered on complex formation except that the molar absorptivity is larger in the complexes because of overlap of the blue shifted n–π* transition, which also has a higher molar absorptivity in the spectra of the complexes. The two n–π* transitions at 31,650 and 28,410 cm^{-1} primarily associated with the azomethine functions of the two thiosemicarbazone moieties are shifted to higher energy for the complexes and merged into one band at about 34,500 cm^{-1}. The thioamide functions cause the lower energy bands in the spectrum of H_2Pg4DE, and these also shift to higher energy (ca 27,000 cm^{-1}) in the spectra of the three metal complexes. Bands below 25,000 cm^{-1} in their spectra are assignable to S–M(II) charge transfer bands [19], and the bands below 20,000 cm^{-1} also probably possess some charge transfer character since the molar absorptivities are in excess of 10^3.

The powder ESR spectrum of [Cu(Pg4DE)] at room temperature does not allow resolution of the lowest field feature, which often occurs for copper(II) centers having one or more soft donors such as sulfur. At liquid nitrogen temperature the $g_\parallel$ feature appears to be at 2.118 and $g_\perp = 2.038$ resulting in a g_{av} of 2.065 which is comparable to recently studied bis(thiosemicarbazone) complexes of copper(II) [1,5–7]. The familiar 4-line pattern due to copper(II) hyperfine occurs in DMF solution with 5 lines in 1 : 2 : 3 : 2 : 1 ratio due to nitrogen superhyperfine (2 nearly equivalent nitrogens) resolved on the two highest field hyperfine lines. The ESR solution parameters are $g_o = 2.058$, A_o(Cu) = 88 G and A(N) = 15 G. The frozen DMF solution ESR clearly shows the first two parallel features and the third parallel is at essentially the same field as the perpendicular feature. The frozen solution parameters are as follows: $A_\parallel = 195$ G, $g_\parallel = 2.109$, $g_\perp = 2.025$ and $g_{av} = 2.053$. The region of the spectrum containing the third parallel feature and the perpendicular feature is nicely resolved (>11 lines) and has a splitting of ca 17 G. Assuming $2A_\perp + A_\parallel/3 = 76$ G should be about the same as A_o (solution), 88 G, suggests that the splitting is better assigned to nitrogen superhyperfine than $A_\perp$(Cu).

New dithiocarbamate compounds of manganese carbonyl and a zinc polymer

Richard D. Adams* and Mingsheng Huang

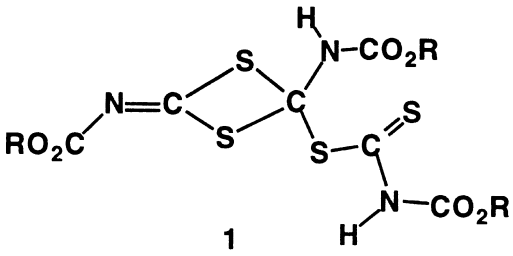
Department of Chemistry and Biochemistry, University of South Carolina, Columbia, SC 29208, U.S.A.

(Received 13 November 1997; accepted 26 January 1998)

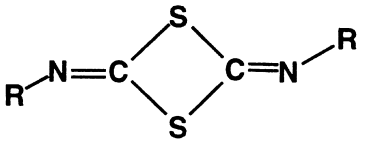
Abstract—The reaction of $[EtO_2CN{=}CS_2C\{N(H)CO_2Et\}\{S_2CN(H)CO_2Et\}]$, **1** with $Mn_2(CO)_9NCMe$ yielded the dithiocarbamate complex $Mn(CO)_4[S_2CN(H)CO_2Et]$, **2** which was characterized structurally in the form of its phosphine derivative $Mn(CO)_3(PMe_2Ph)[S_2CN(H)CO_2Et]$, **3**. Compound **3** was found to contain a chelating dithiocarbamato ligand with a *cis*-positioned phosphine ligand. Compound **1** also reacts with zinc acetylacetonate to yield the zinc dithiocarbamate complex $Zn(\mu\text{-}S,S\text{-}S_2CN(H)CO_2Et)(\mu\text{-}O,S\text{-}S_2CN(H)CO_2Et)$, **4**. Compound **4** forms a helical polymer in the solid state with the zinc ions linked by bridging dithiocarbamate ligands. Compound **1** appears to be a good source of the ethoxycarbonylthiocarbamate ligand. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: dithiocarbamate ligand; manganese; zinc; polymer.

We have recently obtained the new compound $\{EtO_2CN{=}CS_2C[N(H)CO_2Et][S_2CN(H)CO_2Et]\}$, **1** from the reaction of water with ethoxycarbonylisothiocyanate [1]. Compound **1** can be viewed as an adduct of a dimer **A** of the isothiocyanate



1



A

and the dithiocarbamic acid, EtO_2CNHCS_2H. Isothiocyanates are effective ligands for the transition metals [2,3]. They have been shown to coordinate in η^2-C—S, **B** and bridging μ-η^2-C—S, **C** and μ-η^3-N—C—S, **D** bonding modes between two metal atoms. Dithiocarbamate anions are also good ligands for the transition metals and a large number of complexes have been made by employing them [4].

In this report we describe reaction of the compound **1** with $Mn_2(CO)_9(MeCN)$ and zinc acetylacetonate. We have found that compound **1** readily transfers its dithiocarbamate grouping to the metal atoms to yield new metal compounds.

EXPERIMENTAL

Unless specified otherwise, all reactions were performed under an atmosphere of nitrogen. All solvents were appropriately dried and degassed prior to use. Zinc acetylacetonate was purchased from Strem and was used without further purification. TLC separations were performed in air by using silica gel (60 Å, F_{254}) on plates (Whatman, 0.25 mm). Elemental analyses were performed by Desert Analytics, Tucson, AZ. Mass spectra were carried out on a VG Model

70SQ mass spectrometer (direct inlet, electron impact ionization). {$EtO_2CN{=}CS_2C[N(H)CO_2Et][S_2CN(H)CO_2Et]$}, **1** which contains one equivalent of cocrystallized $EtO_2CN{=}C{=}S$ was prepared as previously described [1]. $Mn_2(CO)_9(MeCN)$ was prepared by the reported method [5].

Reaction of **1** *with* $Mn_2(CO)_9(MeCN)$

An 89.0 mg amount (0.159 mmol) of **1** · ($EtO_2CN{=}C{=}S$) was added to a soln of a 25.0 mg amount (0.062 mmol) of $Mn_2(CO)_9(MeCN)$ in 10 ml of hexane. The mixt was stirred at room temp. for 4 days. The volatiles were removed under vacuum, and the residue was separated by TLC using a 3/1 hexane/CH_2Cl_2 solvent mixt. This yielded $Mn_2(CO)_{10}$, (1.7 mg) and yellow $Mn(CO)_4[S_2CN(H)CO_2Et]$, **2** (18.6 mg, 45% yield). Spectral data for **2**: IR (ν_{CO} in hexane, cm^{-1}): 2092 (m), 2014 (s), 2003 (s), 1966 (s), 1777 (w, br), 1759 (w, br). ^1H NMR (δ in C_6D_6, ppm): 7.45 (s, br, 1H, NH), 3.63 (q, $^3J_{H-H} = 7.2$ Hz, 2H, OCH_2Me), 0.73 (t, $^3J_{H-H} = 7.1$ Hz, 3H, CH_3). MS: parent ion m/e = 331 plus ions corresponding to the loss of each of the four carbonyl ligands.

Reaction of **2** *with* PMe_2Ph

A 19.1 mg amount (0.058 mmol) of **2** and 9.0 ml amount (0.116 mmol) of dimethylphenylphosphine were dissolved in 25 ml of hexane. The soln was heated to reflux for 30 min. After the solvent was removed via rotary evaporation, the residue was separated by TLC using a 1/1 hexane/CH_2Cl_2 solvent mixt. This yielded a yellow band of $Mn(CO)_3(PMe_2Ph)[S_2CN(H)CO_2Et]$, **3** (22.1 mg, 87% yield). Spectral data for **3**: IR (ν_{CO} in hexane, cm^{-1}): 2026 (vs), 1947 (s), 1917 (s), 1773 (w, br), 1751 (w, br). ^1H NMR (δ in $CDCl_3$, ppm): 8.05 (s, br, 1H, NH), 7.42 (m, 5H, C_6H_5), 4.20 (q, $^3J_{H-H} = 7.0$ Hz, 2H, OCH_2Me), 1.82 (d, $^3J_{H-H} = 8.1$ Hz, 6H, $P(CH_3)_2$), 1.29 (t, $^3J_{H-H} = 7.0$ Hz, 3H, OCH_2CH_3). Anal: Calc. (found): C, 40.82 (40.77); H, 3.88 (3.51); N, 3.17 (3.20).

Preparation of $Zn(S_2CNHCO_2Et)_2$, **4**

(a) To a 15 ml three necked flask was added a 50.0 mg amount (0.089 mmol) of **1** · ($EtO_2CN{=}C{=}S$), a 50.0 mg amount (0.186 mmol) of $Zn(acac)_2$ and 5 ml of CH_2Cl_2. The mixt was stirred at room temperature for 18 h. The mixt was filtered and washed with 2×0.5 ml of ethylacetate. The filtrate and the washings were combined and the solvent removed. The resulting residue was separated by TLC using silica gel thin plates without fluorescent indicator and a 1/3 hexane/CH_2Cl_2 solvent mixt. This yielded 11.2 mg of Zn (μ-*S*,*S*-$S_2CN(H)CO_2Et$)(μ-*O*,*S*-$S_2CN(H)CO_2Et$), **4** (57% yield based on **1**). Spectra data for **4**: ^1H NMR (δ in $CDCl_3$, ppm): 9.05 (s, br, 2H, NH), 4.30 (q, $^3J_{H-H} = 7.1$ Hz, 4H, OCH_2Me), 1.33 (t, $^3J_{H-H} = 7.1$ Hz, 6H, CH_3). Anal: Calcd (found): C, 24.40 (24.45); H, 3.07 (2.86); N, 7.11 (7.01).

(b) A 30.0 mg amount (0.054 mmol) of **1** · ($EtO_2CN{=}C{=}S$) was dissolved in a minimum amount of CH_2Cl_2. The soln was loaded on TLC plates (silica gel with Zn_2SiO_4 fluorescent indicator). A pale yellow band was eluted with a 3/1 CH_2Cl_2/hexane solvent mixt to yield 4.8 mg of **4** (45% yield).

Crystallographic analyses

Crystals of **3** suitable for X-ray diffraction analysis were obtained by slow evaporation of solvent from a hexane soln at $-4°C$. Crystals of **4** suitable for X-ray diffraction analysis were obtained by slow evaporation of solvent from a 1/3 acetone/acetonitrile soln at 25°C. The crystals used in intensity measurements were mounted in thin-walled glass capillaries. Diffraction measurements for **3** were made on a Rigaku AFC6S fully automated four-circle diffractometer using graphite-monochromated Mo–K_α radiation. Diffraction measurements for **4** were made on a Rigaku AFC5R fully automated four-circle diffractometer using graphite-monochromated Cu–K_α radiation. The unit cells were determined and refined from 15 randomly selected reflections obtained by using the AFC6S or AFC5R automatic search, center,

[a] $R = \Sigma_{hkl}(\|F_{obs}| - |F_{calc}\|)/\Sigma_{hkl}|F_{obs}|$; $R_w = [\Sigma_{hkl}w(|F_{obs}| - |F_{calc}|)^2/\Sigma_{hkl}wF^2_{obs}]^{1/2}$, $w = 1/\sigma^2(F_{obs})$; GOF $= [\Sigma_{hkl}w(|F_{obs}| - |F_{calc}|)^2/(n_{data} - n_{vari})]^{1/2}$.

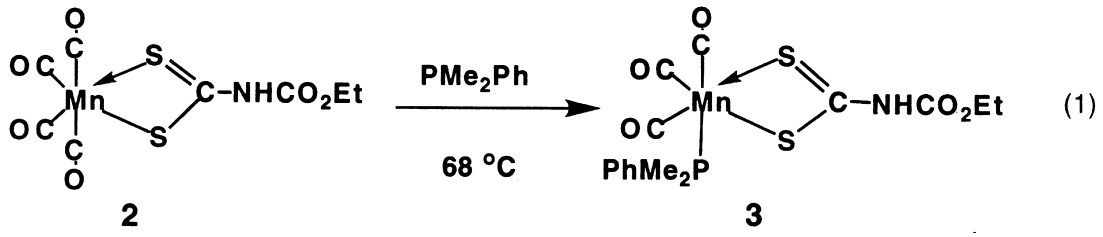
index, and least-squares routines. Crystal data, data collection parameters, and results of these analyses are listed in Table 1. All data processing was performed on a Silicon Graphics Indigo^2 computer by using the TEXSAN structure solving program library obtained from the Molecular Structure Corp., The Woodlands, TX. Neutral atom scattering factors were calculated by the standard procedures [6a]. Anomalous dispersion corrections were applied to all non-hydrogen atoms [6b]. Lorentz-polarization (Lp) and absorption corrections were applied in each analysis. Full matrix least-squares refinements minimized the function: $\Sigma_{hkl}w(|F_o| - |F_c|)^2$, where $w = 1/\sigma(F)^2$, $\sigma(F) = \sigma(F_o^2)/2F_o$, and $\sigma(F_o^2) = [\sigma(I_{raw})^2 + (0.02\cdot I_{net})^2]^{1/2}/\mathrm{Lp}$.

Compounds **3** and **4** crystallized in the monoclinic crystal system. The patterns of systematic absences observed during the collection of intensity data identified the space group uniquely as $P2_1/c$ for compounds **3** and **4**. For **3** the hydrogen atom (H) on the nitrogen atom N was located and refined with isotropic thermal parameters. The positions of all other hydrogen atoms were calculated by assuming idealized geometries with all C—H distances at 0.95 Å. Their contributions were added to the structure factor calculations, but their positions were not refined. For **4** the hydrogen atoms H(1) and H(2) on the nitrogen atoms N(1) and N(2) were located and refined with isotropic thermal parameters. The positions of all other hydrogen atoms were calculated by assuming idealized geometries with all C—H distances at 0.95 Å. Their contributions were added to the structure factor calculations, but their positions were not refined. One equivalent of MeCN from the crystallization solvent was found cocrystallized in the lattice. This was included in the calculations and was satisfactorily refined with 100% occupancy.

RESULTS AND DISCUSSION

When compound **1** was allowed to react with $Mn_2(CO)_9(MeCN)$ in a hexane soln at 25°C for 4 days, the compound **2** was formed in 45% yield. A manganese pentacarbonyl grouping was eliminated in the process, presumably as $HMn(CO)_5$. $HMn(CO)_5$ is relatively unstable and was not recovered from the reaction. The formula of compound **2** was established by a combination of IR, ^{1}H NMR, mass spectral and elemental analyses. The structure proposed for **2** is based largely on a single crystal X-ray diffraction analysis of the PMe_2Ph derivative *fac*-$Mn(CO)_3$(P-Me_2Ph)[$S_2CN(H)CO_2Et$], **3** that was obtained by the reaction of **2** with PMe_2Ph. Compound **3** is obtained in 87% yield after 30 min at reflux in a hexane soln, eqn (1).

Compound **3** was characterized crystallographically and an ORTEP diagram of the molecular structure is shown in Fig. 1. Compound **3** is a six coordinate complex. It contains three COs, one PMe_2Ph and one $S_2CN(H)CO_2Et$ ligand. The three CO ligands are arranged in a *fac*-form. This is consistent with three strong absorptions in the IR spectrum in solution, 2026 (vs), 1947 (s), 1917 (s) cm^{-1}. The dithio-



(1)

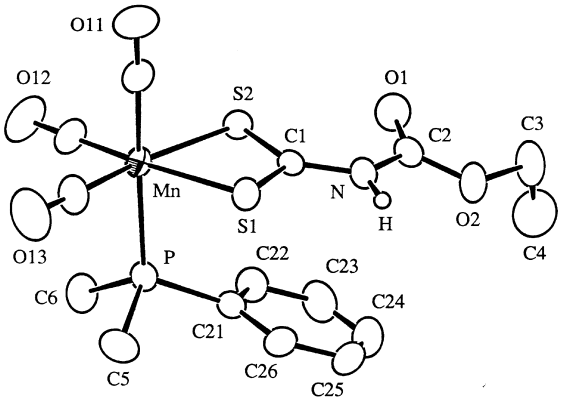


Fig. 1. An ORTEP diagram of $Mn(CO)_3(PMe_2Ph)(S_2CNHCO_2Et)$, **3**. Selected interatomic distances (Å) and angles (°) are: Mn—S(1) = 2.3882(8), Mn—S(2) = 2.3851(9), Mn—P = 2.3554(9), S(1)—C(1) = 1.704(3), S(2)—C(1) = 1.678(3), C(1)—N = 1.363(4), C(2)—N = 1.390(4), C(2)—O(1) = 1.191(4), C(2)—O(2) = 1.337(4); S(1)—C(1)—S(2) = 114.2(2), N(1)—C(1)—S(1) = 118.9(2), N(1)—C(1)—S(2) = 126.8(2), C(1)—N(1)—C(2) = 127.1(3).

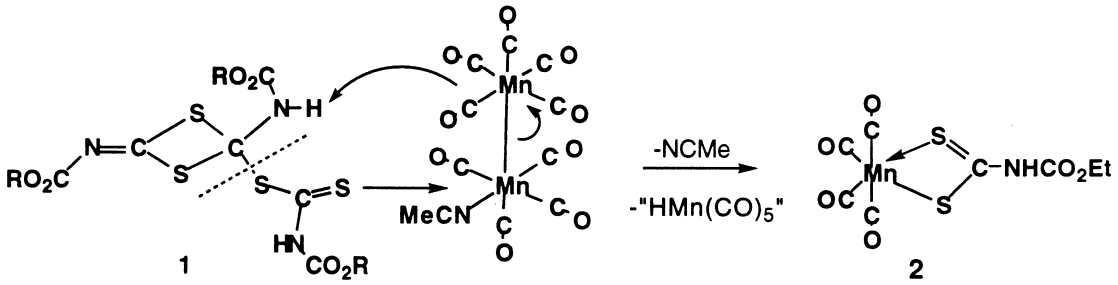
carbamato ligand is chelated to the metal atom via the two sulfur atoms. The Mn—S distances are essentially identical, Mn—S(1) = 2.3882(8) Å, Mn—S(2) = 2.3851(9) Å, and are similar to those found in the related complex $Mn(CO)_3(PPh_3)(S_2CNMe_2)$, **5,** 2.373–2.385 Å [7]. The carbon–sulfur distances are very similar in length C(1)—S(1) = 1.704(3) Å, C(1)—S(1) = 1.678(3) Å and are similar to those found in compound **5,** 1.646–1.706 Å. The hydrogen atom on the nitrogen atom was located crystallographically and its resonance was observed in the ^1H NMR spectrum as a broad singlet at $\delta = 8.05$ ppm.

We anticipate that the formation of **2** has occurred by the transfer of the dithiocarbamate ion from **1** to the $Mn_2(CO)_9(NCMe)$ through cleavage of the carbon–sulfur bond and a nucleophilic displacement of the NCMe ligand from the manganese complex by the dithiocarbamate. Although this could occur via a mechanism involving radicals, we prefer a mechanism based on two electron processes as shown in the Scheme which culminates with a protonation of a transient $Mn(CO)_5$ anion formed by cleavage of the Mn—Mn bond to yield $HMn(CO)_5$.

Compound **1** was also found to react with $Zn(acac)_2$ in CH_2Cl_2 solvent at 25°C over a period of 18 h to produce a new compound $Zn(\mu\text{-}S,S\text{-}S_2CN(H)CO_2Et)(\mu\text{-}O,S\text{-}S_2CN(H)CO_2Et)$, **4** in 57% yield. It is even formed (45% yield) simply by eluting **1** over TLC plates containing the $Zn_2(SiO_4)$ fluorescent indicator. Compound **4** was characterized by a single-crystal X-ray diffraction analysis. The compound exists in a polymeric form in the solid state. An ORTEP diagram showing a portion of one polymeric chain of the structure is shown in Fig. 2. The ZnSCS linkage of the polymer is indicated by the solid bonds. In compound **4,** one dithiocarbamato ligand is chelated to the zinc atom via the two sulfur atoms S(1) and S(2). This ligand is not involved in the polymeric linkage. The Zn—S(1) distance of 2.671(2) Å is significantly longer than the Zn—S(2) distance, 2.345(2) Å. This may be related to the coordination geometry and bonding about the zinc ion, see below. The polymeric chain is formed via the coordination of the second dithiocarbamate ligand. The sulfur atom S(4) is bonded to one zinc atom, Zn—S(4) = 2.342(2) Å, while the other sulfur atom S(3) is bonded to another zinc atom, Zn*—S(3) = 2.326(2) Å. This coordination leads to the formation of an helical infinite chain along *b*-direction of the unit cell. In addition, the carbonyl oxygen atom O(3) of the carboxylate group is also coordinated to zinc. This results in the formation of a six membered metallocycle, Zn—S(3)—C(3)—N(2)—C(4)—O(3). The zinc atom has a five-coordinate distorted trigonal bipyramidal geometry. The equatorial sites are occupied by the sulfur atoms S(2), S(3) and S(4). The axial sites are occupied by the atoms S(1) and O(3). Both zinc-ligand axial bonds are unusually long, Zn—S(1) = 2.671(2) Å and Zn—O(3) = 2.154(2) Å. Zinc has been found in distorted trigonal bipyramidal environments in the related five coordinate dithiocarbamate complexes $Zn(S_2CNEt_2)_2$ [8] and $Zn(py)(S_2CNMe_2)_2 \cdot 0.5C_6H_6$ [9]. In both cases the axial Zn—S bond distances are significantly longer than the equatorial Zn—S bond distances. The Zn—O(3) bond distance is significantly longer than those found in related carboxylate complexes $[NBu^n_4[Zn(S_2CNEt_2)_2(O_2CMe)]$, 1.979(6) Å [10] and $Zn(O_2CCH_2CH_3)_2$, 1.95 Å [11]. In the solid state, the two dithiocarbamato ligands in **4** are inequi-



Scheme 1.

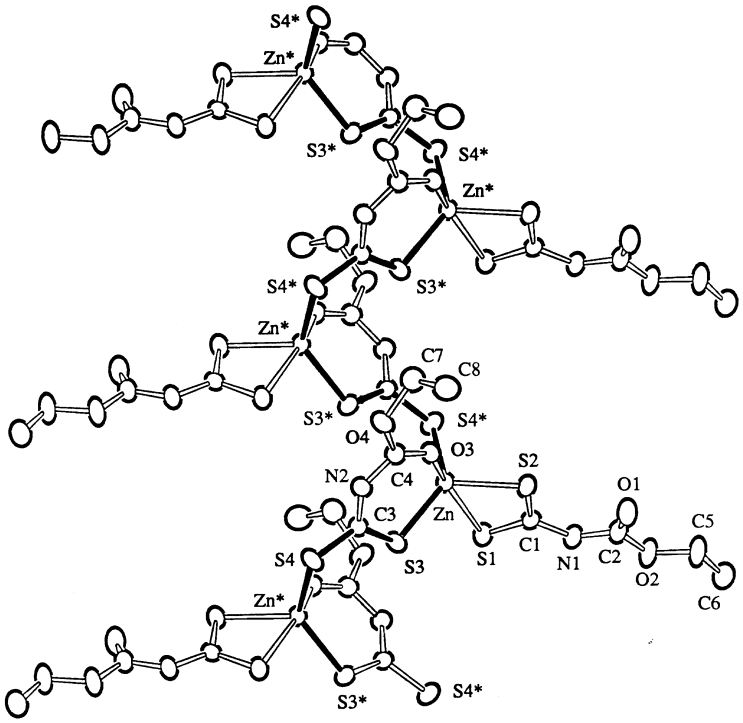


Fig. 2. An ORTEP diagram showing a portion of the polymeric chain Zn(μ-*S*,*S*-$S_2CN(H)CO_2Et$)(μ-*O*,*S*-$S_2CN(H)CO_2Et$), **4**. The connectivity of the ZnSCS polymer is indicated by the solid bonds. Selected interatomic distances (Å) and angles (°) are: Zn—S(1) = 2.671(2), Zn—S(2) = 2.3451(2), Zn—S(3) = 2.326(2), Zn—S(4) = 2.342(2), Zn—O(3) = 2.154(4), S(1)—C(1) = 1.678(6), S(2)—C(1) = 1.704(5), S(3)—C(3) = 1.682(5), S(4)—C(3) = 1.691(5), C(1)—N(1) = 1.371(7), C(2)—N(1) = 1.405(7), C(3)—N(2) = 1.365(7), C(4)—N(2) = 1.379(7), C(4)—O(3) = 1.212(6); S(1)—Zn—S(2) = 71.64(5), S(1)—Zn—S(3) = 90.06(5), S(1)—Zn—S(4) = 90.63(5), S(1)—Zn—O(3) = 161.4(1), S(2)—Zn—S(3) = 121.43(6), S(2)—Zn—S(4) = 107.28(6), S(2)—Zn—O(3) = 94.4(1), S(3)—Zn—S(4) = 107.68(7), S(3)—Zn—O(3) = 86.9(1), S(4)—Zn—O(3) = 105.6(1), S(1)—C(1)—S(2) = 121.3(3), S(3)—C(1)—S(4) = 121.9(3).

valent, however, only one set of resonances for the ethyl groups and only one for the hydrogen atom bonded to two nitrogen atoms, 9.05 (s, br, 2H, NH), are observed in the ^{1}H NMR spectrum in solution. This suggests that compound **4** depolymerizes when dissolved in chloroform solvent, and the two dithiocarbamato ligands are either structurally equivalent or are dynamically averaged on the NMR time scale in solution. Other zinc dithiocarbamates, $Zn(S_2CNEt_2)_2$ [8] and $Zn(S_2CNMe_2)_2$ [12] have been found to form dimeric units in solid state, but they exist in monomeric forms in solution.

The formation of compound **4** also appears to be the result of transfer of the dithiocarbamate grouping of **1** to a zinc ion. Zinc and other dithiocarbamates have been used for a variety of purposes ranging from

pesticides to rubber vulcanization accelerators [13]. In summary it appears that **1,** which is very easily obtained from ethoxycarbonylisothiocyanate, is a convenient source of the ethoxycarbonyldithiocarbamate.

Supplementary material: Tables of final atomic positional parameters, bond distances, bond angles and anisotropic thermal parameters are available for the structural analysis of **3** and **4** (11 pages) have been deposited with the Cambridge Crystallographic Data Centre. Support for an upgrade of the NMR facilities at the University of South Carolina was provided by an NSF ARI grant, Grant No. CHE-9601723.

Acknowledgments—These studies were supported by the Division of Chemical Sciences of the Office of Basic Energy Sciences of the U.S. Department of Energy. The authors wish to thank Prof. F. A. Cotton and Dr Lee Daniels for measurement of the diffraction intensity data for compound **4**.

(Received 2 December 1997; accepted 3 February 1998)

Abstract—The reaction of pyridine-2-carbonitrile (2-CNpy) with 2-amino-2-hydroxymethyl-1,3-propanediol (AL^1), 2-amino-2-methyl-1,3-propanediol (AL^2) and 2-amino-2-methyl-1-propanol(AL^3) in ethanolic solutions of Cu(II) and Co(II) salts led to the formation of solid complexes containing 2-(2-pyridinyl)-4,4-bis (hydroxymethyl)-2-oxazoline (pyoxaL^1), 2-(2-pyridinyl)-4-hydroxymethyl-4-methyl-2-oxazoline (pyoxaL^2) and 2-(2-pyridinyl)-4,4-dimethyl-2-oxazoline (pyoxaL^3), respectively. Their stereochemistry and the mode of ligand coordination have been determined by spectral, magnetic and conductometric measurements. The crystal structure of [CuBr(2-(2-pyridinyl)-4,4-bis(hydroxymethyl)-2-oxazoline)$_2$]Br·0.5H_2O was determined by X-ray diffraction technique. The influence of Cu(II) and Co(II) salts on the formation of 2-pyridinyl-2-oxazolines is briefly compared with that of Ni(II) salts. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: 2-pyridinyl-2-oxazoline; nucleophilic reaction; copper(II) complexes; cobalt(II) complexes; crystal structure.

The activation of molecules containing the nitrile group upon their coordination to a metal atom has been exploited in addition reactions of nucleophiles such as water, alcohols and amines yielding amide [1,2], iminoether [3,4] or amidine [3,5] complexes. The reaction of pyridine-2-carbonitrile with water or an alcohol in the presence of some metal(II) salts leads to the formation of complexes which contain pyridine-2-carboxamide or O-alkylpyridine-2-carboximidate [6–11]. However, several nickel(II) complexes of 2-pyridinyl-2-oxazolines have been isolated [12] from the aqueous or ethanolic solutions of pyridine-2-carbonitrile in the presence of some amino alcohols (Scheme 1).

This paper describes the synthesis and the structural characterization of some copper(II) and cobalt(II) solid complexes which contain 2-pyridinyl-2-oxazolines (denoted as pyoxaL^1, pyoxaL^2 and pyoxaL^3). These complexes were prepared by the reaction of pyridine-2-carbonitrile with 2-amino-2-hydroxymethyl-1,3-propanediol, 2-amino-2-methyl-1,3-propanediol, or 2-amino-2-methyl-1-propanol in the presence of Cu(II) or Co(II) salts. Dry or wet ethanol was usually used as a solvent. The X-ray crystal structures of [CuCl(pyoxaL^1)$_2$]Cl·0.5H_2O [13] and [CuBr(pyoxaL^3)$_2$]Br·H_2O [14] have been recently determined. In order to help solve the problem of oxazoline ring coordination in complexes with

pyoxaL, the crystal structure of complex $[CuBr(pyoxaL^1)_2]Br \cdot 0.5H_2O$ was also solved in our research.

EXPERIMENTAL

Chemical reagents

All the chemicals used were of reagent grade. Hydrates and anhydrous copper(II) and cobalt(II) salts were prepared according to previously described procedures [15,16]. Ethanol was dried by the standard method [17]. Solid pyridine-2-carbonitrile (2-CNpy) was purified by distillation under reduced pressure. 2-Amino-2-hydroxymethyl-1,3-propanediol (AL^1), 2-amino-2-methyl-1,3-propanediol (AL^2) and 2-amino-2-methyl-1-propanol (AL^3) were used without further purification.

Analysis and physical measurements

Copper and cobalt were determined by EDTA titration; carbon, hydrogen and nitrogen by micro-analytical methods (Carlo Erba Instruments EA 1108).

Magnetic moments were measured with a Gouy balance for the powdered solid at 293 K. Electronic spectra of the powdered samples in Nujol mulls and diffuse reflectance spectra in MgO were recorded at room temperature on a Specord M40 and a Magna 750 spectrophotometer, respectively. A Radelkis OK 104 conductometer was used for conductivity measurements of complexes (concentration 1.0×10^{-3} M) in acetonitrile, nitromethane and nitrobenzene at 298 K. Analytical data, magnetic moments, electronic spectral data and molar conductivity values of complexes are given in Tables 1 and 4. IR spectra were recorded on a Philips Analytical PU 9800 FTIR spectrometer at room temperature with 4 cm^{-1} resolution. The spectra of solid samples were obtained in mulls (Nujol and hexachlorobutadiene) as well as in KBr pellets (1 wt%).

X-ray structure determination

Crystallography. The diffraction intensities for complex $[CuBr(pyoxaL^1)_2]Br \cdot 0.5H_2O$ (complex **IV**) were collected with a KUMA KM 4 diffractometer using a graphite-monochromated Mo-K_α radiation. A summary of crystal, experimental and refinement data are listed in Table 2. The space group $C2/c$ was assumed throughout the structure analysis and was confirmed by the successful refinement of the structure. All data were collected at room temperature with a variable-speed ω–2θ scan technique to a maximum 2θ value 54.28°. The unit-cell parameters were derived from least-squares refinement of 25 well-centered reflections. The intensities of three representative reflections, which were measured after 100 reflections, remained constant throughout data collection. Lorentz and polarization corrections were applied, but not absorption. For the determination of the structure a total of 4353 reflections were measured of which 3851 reflections were unique with $F_o \geqslant 4\sigma(F)$.

Structure solution and refinement. The positions of copper and bromine atoms were located from the Patterson method by program SHELXS-86 (Sheldrick, 1985) [18] and the remaining non-hydrogen atoms were located subsequently via Fourier methods [19]. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms, except those in water, were placed in geometrically calculated positions. Atomic scattering factors were taken from *International Tables for X-ray Crystallography* [20]. Selec-

ted interatomic distances and angles are listed in Table 3. Additional data for the structure are included in the Supplementary material available (see later).

Preparation of complexes

Most of the complexes were formed in reaction mixtures containing metal(II) salts, pyridine-2-carbonitrile, amino alcohols and ethanol (dry or wet). The complex $[Co(NCS)_2(pyoxaL^1)_2]$ (**X**) was, however, prepared in ethanolic as well as in aqueous solutions. On the other hand, complex $[Co(H_2O)_2(pyoxaL^1)_2](ClO_4)_2$ (**IX**) can only be prepared in an aqueous solution of appropriate reagents.

The complexes can be obtained in high yields (from 65% to 80%) under mild reaction conditions. Reaction mixtures were first heated at 330 K for 20 min or under reflux for several hours and then slowly cooled to room temperature. While some complexes started to precipitate during heating of mixtures, the others deposited from final solutions over several minutes or days. Some special conditions used in investigated complexes are described in the following text.

Copper(II) complexes

For the synthesis of all complexes, anhydrous copper(II) salts and ethanol as a solvent were used. To achieve higher yields and well-shaped crystalline products, however, wet ethanol appears to be more suitable for the preparation of complexes **I**–**VI**.

$[CuCl(pyoxaL^1)_2]Cl \cdot 0.5H_2O$ (**I**),

$[CuCl(pyoxaL^2)_2]Cl \cdot 0.5H_2O$ (**II**) and

$[CuCl(pyoxaL^3)_2]Cl \cdot H_2O$ (**III**).

A filtered solution of copper(II) chloride (5 mmol) in ethanol (40 cm^3) was mixed with an ethanolic solution (20 cm^3) containing pyridine-2-carbonitrile and an appropriate amino alcohol in equimolar quantities (10 mmol). The mixture was heated for 20 min at about 330 K. Immediately formed precipitates were gradually dissolved to produce the final reaction solutions. Blue-green complexes **I** and **II** started to crystallize from these solutions after several days. When the final reaction solution prepared from amino alcohol AL^3 was cooled to room temperature, a powder-like green compound with a composition close to $[CuCl_2(NH_3)_2]$

was first obtained in a small amount. After standing the filtrate for several weeks, during which time most of the solvent evaporated, acetone (1 : 1) was added to the resulting oil and blue green crystals of complex **III** were obtained. All of the solid complexes **I**–**III** were collected by filtration, washed with ethanol and finally, dried *in vacuo*.

$[CuBr(pyoxaL^1)_2]Br \cdot 0.5H_2O$ (**IV**), $[CuBr(pyoxaL^2)_2]Br$ (**V**) and $[CuBr(pyoxaL^3)_2]Br \cdot H_2O$ (**VI**)

Ethanolic solutions of reagents were prepared in the same way as described above. However, the reaction mixtures were refluxed for 1h, 3h and 6h, respectively, for the preparation of complexes **IV, V** and **VI**. Well-shaped green crystals of complexes **IV, V** and **VI** were obtained when the resulting solutions were left to crystallize at room temperature for several days.

Cobalt(II) complexes

To prepare pure solid complexes **VII**–**XII** in good yields it was necessary to use various solvents (water, dry or wet ethanol). Anhydrous cobalt(II) salts, except of $Co(ClO_4)_2 \cdot 6H_2O$, were used for the synthesis of the appropriate complexes.

$[CoCl_2(pyoxaL^1)_2]$ (**VII**) and

$[CoBr_2(pyoxaL^1)_2]$ (**VIII**).

Complexes **VII** and **VIII** were prepared in dry ethanolic solutions by the reaction of equimolar quantities of 2-CNpy and AL^1 (10 mmol) with 5 mmol of $CoCl_2$ and $CoBr_2$, respectively.

The mixture was heated under reflux for 3 h. Both complexes started to deposit during refluxing the reaction solutions. Pink crystals were filtered, washed with dry ethanol and finally dried *in vacuo*.

$[Co(H_2O)_2(pyoxaL^1)_2](ClO_4)_2$ (**IX**) and

$[Co(NCS)_2(pyoxaL^1)_2]$ (**X**).

Both complexes were prepared in the similar way as described above, but as a solvent water was used. The reaction mixture was refluxed only for 1 h. While pink complex **X** was precipitated upon being heated under reflux, pink crystals of complex **IX** were deposited after several hours from the filtrate.

Complex **X** can also be prepared in wet ethanolic solution.

$[Co(NCS)_2(pyoxaL^2)_2]$ (**XI**) and

$[Co(NCS)_2(pyoxaL^3)_2]$ (**XII**).

Pink complexes **XI** and **XII** were prepared only when wet ethanol was used. The other reaction conditions for the production of both solid complexes were identical with those of complex **X** synthesis.

RESULTS AND DISCUSSION

Synthesis

The reaction of 2-CNpy with amino alcohol (AL^1–AL^3) in ethanolic solution of Cu(II) and Co(II) salts leads to the formation of solid complexes containing respective 2-pyridinyl-2-oxazolines ($pyoxaL^1$–$pyoxaL^3$) in good yields. To achieve higher yields and well-shaped crystalline product, however, wet ethanol appears to be more suitable for the preparation of Cu(II) complexes (**I**–**VI**). Only perchlorato (**IX**) and thiocyanato (**X**) Co(II) complexes with $pyoxaL^1$ were prepared in aqueous solution by the analogous reaction of 2-CNpy with AL^1 as described [12] for the preparation of all Ni(II) complexes. All other pure Co(II) complexes (**VII, VIII, XI** and **XII**) were synthesized only from dry ethanolic solution. Study of the different reaction products formed by the reaction of 2-CNpy with AL^1, as well as by the hydrolysis of $pyoxaL^1$ in aqueous solution of Ni(II), Co(II) and Cu(II) salts, is in progress and will be reported [21] later.

Crystal structure description of complex **IV**

Composition and structure of two prepared bromo copper(II) complexes, namely $[CuBr(pyoxaL^1)_2]Br \cdot 0.5H_2O$ (**IV**) and $[CuBr(pyoxaL^3)_2]Br \cdot H_2O$ (**VI**) [14], were determined by single crystal X-ray diffraction technique. The crystal structure of the complexes consists of $[CuBr(pyoxaL)_2]^+$ (where pyoxaL is equal to $pyoxaL^1$ or $pyoxaL^3$) cations, Br^- counter-anions and water of crystallization linked by hydrogen-bonding interactions. Perspective view and atomic numbering of $[CuBr(pyoxaL^1)_2]^+$ are shown in Fig. 1. Selected bond distances and angles for cation are listed in Table 3. Moreover, the X-ray crystal structure of the chloro complex $[CuCl(pyoxaL^1)_2]Cl \cdot 0.5H_2O$ (**I**) has been previously determined [13] and is very similar to that of bromo complex **IV**. The copper(II) atom is five-coordinated. The molecules of 2-pyridinyl-2-oxazoline are coordinated to copper(II) atom via the N1 and N3 (the nitrogen atom of the pyridine ring) as well as via the N2 and N4 (the nitrogen atom of the oxazoline ring) as *N*,*N*-coordinated chelates. Formation of other five-membered chelate ring (contain hydroxymethyl group in 4 position of the oxazoline ring) by coordination of the oxygen atom of hydroxymethyl group is not observed in any case. The fifth coordination site of the copper(II) atom is occupied by the halogenide anion. The value of τ parameter for complexes **I, IV** and **VI** ($\tau = 0.48$) shows that the coordination polyhedron around Cu(II) is best described as an intermediate between trigonal bipyramidal and square pyramidal [22]. This finding is in good agreement with interpretation of their electronic spectra (see later).

The Cu—Br(1) interatomic distances in the coordination polyhedron of bromo complexes **IV** (2.401 Å) and **VI** (2.403 Å) are nearly equal. The average value of bond distances Cu—N(1) and Cu—N(3) (nitrogen atoms of pyridine ring) for complex **IV** (Table 3) is 2.010 Å. Similarly, the average value of bond distances Cu—N(2) and Cu—N(4) (nitrogen atoms of the oxazoline ring) is 2.147 Å. Therefore, the bond distances of copper(II) atom to nitrogen atoms

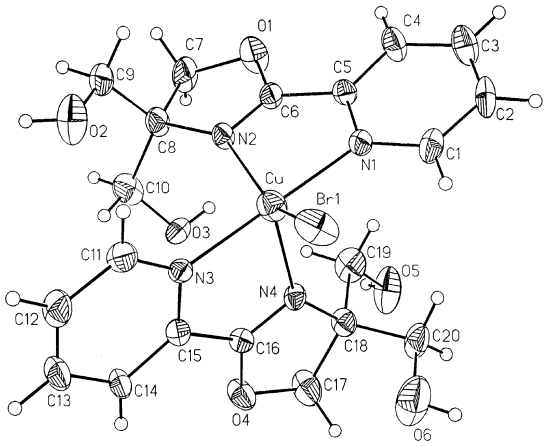

Fig. 1. PLUTO plot of $[CuBr(pyoxaL^1)_2]^+$ cation in complex **IV** (thermal ellipsoids are shown at 50% probability level).

of the oxazoline ring are rather longer than bond distances to nitrogen atom of pyridine rings. The Cu—N bond distances in bromo complex **VI** and chloro complex **I** are in the same range as for complex **IV**. The angle between five-membered planar chelate ring formed by Cu—N1—C5—C6—N2 and Cu—N3—C15—C16—N4 atoms for [CuBr(pyoxaL^1)$_2$]Br·0.5H$_2$O (**IV**) is equal to 89.2(1)°.

Stereochemistry of complexes

All of the complexes contain two molecules of *N*,*N*-coordinated 2-pyridinyl-2-oxazoline ligands (see IR spectra). In agreement with this finding and based on the values of magnetic moments, molar conductivities and electronic spectral data (Table 4), the composition and stereochemistry were assigned to the complexes under investigation.

Copper(II) complexes. Molar conductivity values in nitromethane and in acetonitrile show that all of the copper complexes are univalent compounds [23], i.e. one halogenide anion is coordinated to the central atom (copper has coordination number five), the other acts as a counter-ion. The main reasons for some lower value (in acetonitrile for chloro and nitrobenzene for bromo complexes) would seem to be solvent interactions and the low ionic mobilities of some of the ions involved [23].

For five coordinate copper(II) complexes there are two extreme structures, the square pyramid and the trigonal bipyramid, but not unexpectedly, many distorted intermediates are known. Copper(II) complexes (**I**–**VI**) exhibit peaks in electronic spectra extending from 9000 to 13,500 cm^{-1} (usually, the higher peak maximum energy, the higher molar absorptivity), which is rather typical for square pyramidal Cu(II) complexes. However, the reflectance

Table 4. Magnetic moments, electronic spectral data and molar conductivities of complexes

[c] In nitromethane.
[d] In nitrobenzene.

electronic spectra do not allow us to safely distinguish the regular square pyramids from the regular trigonal bipyramids and the data should be interpreted with care [24]. The suggested composition and stereochemistry of these complexes, namely

$[CuCl(pyoxaL^1)_2]Cl \cdot 0.5H_2O$ [**I**] [13],

$[CuBr(pyoxaL^1)_2]Br \cdot 0.5H_2O$ (**IV**) and

$[CuBr(pyoxaL^3)_2]Br \cdot H_2O$ [**VI**] [14]

are also in a good agreement with their crystal structure determined by single crystal X-ray diffraction.

Cobalt(II) complexes. The electronic spectra of cobalt(II) complexes (**VII**–**XII**) contain a broad band in the near infrared region from 7900 to 9700 cm^{-1}. Second band, present in the visible near 20,000 cm^{-1}, has a shoulder or fine structure to it. Therefore, the electronic spectra of cobalt(II) complexes are clearly consistent with a tetragonally distorted octahedral structure [24]. Similarly, the magnetic moments values of these complexes are within the range usually found for distorted octahedral cobalt(II) complexes [15]. The molar conductivities of all complexes (except of **IX**) in acetonitrile and nitrobenzene are typical for those of non-electrolytes [23]. Molar conductivities for complex **IX** in acetonitrile as well as in nitrobenzene suggest that compound **IX** is a 1 : 2 electrolyte with non-coordinated perchlorate anions [23].

IR spectra

The IR spectra of 2-pyridinyl-2-oxazolines under study ($pyoxaL^1$–$pyoxaL^3$) and their Ni(II) complexes have been published [12]. The IR spectral data of all complexes **I**–**XII** that are diagnostic of the coordinating groups are available as supplementary material. Now the crystal and molecular structure of complexes **I, IV** and **VI** fully confirms the formation of the new organic ligand, i.e. the conversion of the nitrile to the 2-oxazoline. Thus both the knowledge of the crystal structure of complexes **I, IV** and **VI** and IR spectral data confirm *N*,*N*-coordination of 2-pyridinyl-2-oxazolines molecules in all solid complexes. The IR spectra of the other complexes, when compared with those of complexes **I, IV** and **VI,** provide evidence that all the complexes contain *N*,*N*-coordinated 2-pyridinyl-2-oxazolines molecules as the only organic ligands.

Thiocyanate complexes **X**–**XII** show a very strong and broad band in the region 2090–2070 cm^{-1}. The position of this band due to $\nu(C{\equiv}N)$ indicates the presence of monodentate NCS groups which are coordinated through the nitrogen atoms only [25].

The coordination mode of the perchlorate groups in solid complex **IX** was established mainly on the basis of their IR spectra. The spectrum of complex show a very broad band with maximum at about 1080 cm^{-1} which correspond to the non-coordinated perchlorate group [25].

Supplementary material available—The atomic positional parameters and isotropic thermal parameters, anisotropic thermal parameters, H atom parameters, observed and calculated structure factors, equations of planes and full listings of bond distances and angles for complex **IV** have been deposited with the Editor as supplementary data. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

Foreword

The word "cluster" takes on many implications in various areas of chemistry. To the inorganic chemist the definition most commonly recognized was provided by F. A. Cotton some three decades ago: "a finite group of metal atoms that are held together mainly or at least to a significant extent, by bonds directly between metal atoms, even though some nonmetal atoms may also be intimately associated with the cluster" [1]. A word is but a word and in any language its meaning is continually changing, being influenced by its heritage and its common usage and so an inorganic chemist of 1998 would, if composing a dictionary, have to extend the meaning of cluster to include complexes where metal ions contained within an aggregate show strong cooperative electronic or magnetic interactions. This extension of Cotton's original definition has been modified by its common usage in bioinorganic chemistry. Metalloenzymes that have strongly coupled metal centers, such as the Fe_4S_4 cubanes, are referred to as clusters. However, *the moving finger writes and having writ moves on* and so from bioinorganic "clusters" have emerged abiological clusters. These have neither biological relevance nor metal-metal bonds but show fascinating magnetic properties—single molecular magnets. So in the current language of inorganic chemistry a "cluster" may take on many meanings but it is still distinct from a polynuclear aggregate such as a polyoxometallate or polymeric alkoxide of aluminum or yttrium. Inorganic clusters may be neutral molecules, complex ions or may exist as subunits in extended lattice structures.

In organometallic chemistry the beginning of cluster chemistry can be traced to that of metal carbonyl chemistry with the early work of Dewar [2] ($Fe_2(CO)_9$, $Fe_3(CO)_{12}$) and Mond [3] ($Co_2(CO)_8$) which was followed by the pioneering work of the great German chemist Walter Hieber [4]. The field of metal carbonyl cluster chemistry did not fully flourish until the advent of routine ^{13}C NMR spectroscopy and single crystal X-ray diffraction by automated diffractometers. This led to the general recognition of so many issues that we now take for granted: fluxionality and stereochemical non-rigidity; ligands such as carbide and hydride; unique modes of ligand binding and, indeed, hydrocarbyl ligands that could not be supported by a single metal center. The field developed so fast with each new finding fueling further intensive study. The concepts of organometallic surface chemistry became intertwined with cluster chemistry and heterogeneous catalysis [5]. The range of ligands supporting organometallic cluster chemistry became more and more extensive: cyclopentadienes, tertiary phosphines, alkoxides, thiolates, halides [6]. Complementary ligands such as π-donors and π-acceptors were shown to relate early and late transition metal cluster compounds through isolobal relationships [7]. As the size of some metal clusters increased, they impinged on colloidal and nanoparticles. When would the size of a metal cluster be large enough that certain metallic properties would persist in the cluster?

With this brief and simplistic background, it has been my pleasure to edit this symposium-in-print which traverses a wide variety of topics in the general field of inorganic cluster chemistry. It is also particularly appropriate to do so in the year that Lord Lewis enters his eighth decade, for without any doubt his group at Cambridge will long be remembered for their pioneering work on high nuclearity clusters. Professor Lewis' work, spanning now over four decades, has contributed greatly to numerous areas of inorganic chemistry and he and his coworkers, in particular, Brian Figgis and Malcolm Gerloch, also pioneered the field of ligand field theory and magnetism. It thus seems particularly appropriate that this special issue on clusters and magnetism within clusters is effectively a tribute to Jack Lewis as a man who has given so much to chemistry and, at the same time, has given so much of himself in the service of science and higher education. He has been and still is an ambassador for chemistry and science in the public arena and in setting public policy on environmental matters.

On behalf of the chemical community, I express our genuine appreciation and admiration for his achievements to date and, on this the celebration of his 70th birthday, wish him well in all his endeavors in the coming years.

New compounds with extended structure lattices from the reactions of cuprous iodide with cyclic polydisulfides†

Richard D. Adams*, Mingsheng Huang and Sherida Johnson

Department of Chemistry and Biochemistry, University of South Carolina, Columbia, SC 29208, U.S.A.

(Received 23 May 1997; accepted 3 July 1997)

Abstract—The reactions of CuI with 1,2,5,6-tetrathiacyclooctane, **1** $\overline{SCH_2CH_2SSCH_2CH_2S}$ and 1,2,5,6,9,10-hexathiacyclododecane, **2** $\overline{SCH_2CH_2SSCH_2CH_2SSCH_2CH_2S}$ in acetonitrile solvent have yielded the new compounds $[Cu_2I_2(\mu\text{-}\overline{SCH_2CH_2SSCH_2CH_2S})]_\infty$, **3** and $[CuI(\mu\text{-}\overline{SCH_2CH_2SSCH_2CH_2SSCH_2CH_2S}]_\infty$, **4** in yields of 75 and 61%, respectively. Both products were characterized crystallographically. Compound **3** contains a network of CuI double chains with step ladder-like structures. The chains are linked by bridging η^2-tetrathiacyclooctane ligands to form 2-dimensional sheets through coordination of the disulfide groups to the copper atoms. Compound **4** contains isolated Cu_2I_2 groups which are linked by two bridging η^2-hexathiacyclododecane ligands to form 1-dimensional chains along the crystallographic *b*-direction. © 1998 Elsevier Science Ltd

Keywords: cyclic polydisulfides; copper iodide.

In recent studies we have shown that the thiirane complex $W(CO)_5(\overline{SCH_2CH_2})$ is an effective catalyst for the transformation of thiirane into cyclic polydisulfides, eq. (1) [1]. 1,2,5,6-tetrathiacyclooctane, **1** $\overline{SCH_2CH_2SSCH_2CH_2S}$ and 1,2,5,6,9,10-hexathiacyclododecane, **2** $\overline{SCH_2CH_2SSCH_2CH_2SSCH_2CH_2S}$ are the principal products. Polythioether macrocycles have been demonstrated to be an important class of ligands [2], but the coordination properties of cyclic polydisulfides have not yet been investigated.

Coordination complexes of simple aliphatic organic disulfides have been prepared with copper [3], rhenium [4], silver [5], mercury [6] and manganese [7] without inducing rupture of the disulfide S—S bond. However, the reaction of **1** with $Ru_3(CO)_{12}$ leads to the formation of two isomers of $Ru_3(CO)_7(\mu\text{-}SCH_2CH_2S)_2$ which contain bridging ethanedithiolate ligands formed by cleavage of both of the disulfide S—S bonds [8]. In an effort to prepare complexes of **1** and **2** without cleavage of the S—S bond, we proceeded to investigate their reactions with CuI. We have observed the formation of two new compounds that exhibit interesting extended structures in the solid state that are created by the formation of bridging ligands involving η^2-coordination of the cyclic disulfides. The results of this study are reported herein.

EXPERIMENTAL

General data

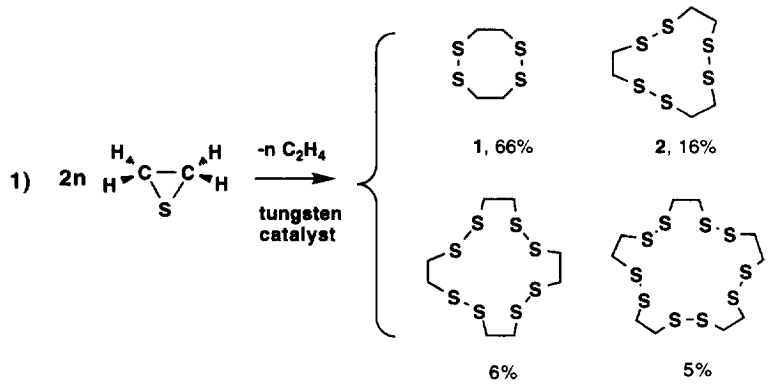
Reagent grade acetonitrile was used as purchased. All reactions were performed in air. The products do not appear to be air sensitive. The cyclic disulfides **1** and **2** were prepared by our previously reported procedure [1]. CuI was purchased from Strem and was used without further purification. ^{1}H NMR spectra were taken at 300 MHz on a Bruker AM-300 spectrometer. Elemental analyses were performed by Desert Analytics, Tucson, AZ.

Synthesis of $[(CuI_2(\mu\text{-}\overline{SCH_2CH_2SSCH_2CH_2S}))]_\alpha$, **3**

A solution of 114.0 mg (0.60 mmol) of CuI in 10 cm^3 of acetonitrile was combined with a solution of

* Author to whom correspondence should be addressed.

† Dedicated to Lord Lewis on the occasion of his 70th birthday.



50.0 mg (0.27 mmol) of **1** in 5 cm^3 of acetonitrile in a small vial. The solution was stirred at room temperature for 1 h and then filtered to remove any undissolved particles. The filtrate was allowed to stand at room temperature in open air for 3 days. 123.1 mg of colorless crystals of $[Cu_2I_2(\overline{SCH_2CH_2SSCH_2CH_2S})_\infty]$, **3** formed and was collected (yield 75% based on **1**). Spectral data for **3**: ^1H NMR (δ in CD_3CN, ppm): 3.14 (s, 8H, $4CH_2$). Anal. calc (found): C, 8.55 (8.50); H, 1.27 (1.43).

Synthesis of $[CuI(\mu\text{-}\overline{SCH_2CH_2SSCH_2CH_2SSCH_2CH_2S})]_\infty$, **4**

A solution of 31.0 mg (0.16 mmol) of CuI in 12 cm^3 of acetonitrile was combined with a solution of 13.0 mg (0.047 mmol) of **2** in 10 cm^3 of CH_2Cl_2 in a small vial. The mixture was stirred at room temperature for 30 min and then filtered to remove any undissolved particles. The filtrate was allowed to stand at room temperature in open air for 3 days. 27.0 mg of colorless crystals of $[CuI(\mu\text{-}\overline{SCH_2CH_2SSCH_2CH_2SSCH_2CH_2S}]_\infty$, **4** formed and was collected (yield 61% based on the **2**). Spectral data for **4**: ^1H NMR (δ in CD_3CN, ppm): 3.21 (s, 12H, $6CH_2$). Anal. calc (found): C, 15.43 (15.40); H, 2.59 (2.36).

Crystallographic analyses

Crystals of **3** and **4** suitable for X-ray diffraction analysis were obtained simply by slow evaporation of solvent from solutions of CuI and the appropriate ligand, **1** or **2**, in acetonitrile solvent at 25°C. The crystals used in intensity measurements were mounted in thin-walled glass capillaries. Diffraction measurements were made on a Rigaku AFC6S fully automated four-circle diffractometer using graphite-monochromated Mo-K_α radiation. The unit cells were determined and refined from 15 randomly selected reflections obtained by using the AFC6S automatic search, center, index, and least-squares routines. Crystal data, data collection parameters, and results of these analyses are listed in Table 1. All data processing was performed on a Silicon Graphics Indigo^2 computer by using the TEXSAN structure solving program library obtained from the Molecular Structure Corp., The Woodlands, TX. Neutral atom scattering factors were calculated by the standard procedures [9a]. Anomalous dispersion corrections were applied to all non-hydrogen atoms [9b]. Lorentz-polarization (Lp) and absorption corrections were applied in each analysis. Full matrix least-squares refinements minimized the function: $\Sigma_{hkl}w(|F_o|-|F_c|)^2$, where $w = 1/\sigma(F)^2$, $\sigma(F) = \sigma(F_o^2)/2F_o$, and $\sigma(F_o^2) = [\sigma(I_{raw})^2 + (0.02I_{net})^2]^{1/2}/\text{Lp}$.

Compound **3** crystallized in the triclinic crystal system. The space group $P\bar{1}$ was assumed and confirmed by the successful solution and refinement of the structure. The structure was solved by a combination of direct methods (MITHRIL) and difference Fourier syntheses. All nonhydrogen atoms were refined with anisotropic thermal parameters. The positions of all hydrogen atoms were calculated by assuming idealized geometries with all C—H distances at 0.95 Å. Their contributions were added to the structure factor calculations, but their positions were not refined.

Compound **4** crystallized in the monoclinic crystal system. The patterns of systematic absences observed during the collection of intensity data were consistent with either of the space groups $C2/c$ or Cc. The structure was solved and successfully refined in the higher symmetry centrosymmetric space group $C2/c$. The structure was solved by a combination of direct methods (MITHRIL) and difference Fourier syntheses. All nonhydrogen atoms were refined with anisotropic thermal parameters. The positions of all hydrogen atoms were calculated by assuming idealized geometries with all C—H distances at 0.95 Å. Their contributions were added to the structure factor calculations, but their positions were not refined.

RESULTS AND DISCUSSION

When a solution of CuI and **1** in acetonitrile was allowed to evaporate in the open air, the compound

$[Cu_2I_2(\overline{SCH_2CH_2SSCH_2CH_2S})]_\infty$, **3** was formed in a crystalline form in a 75% yield. The crystals which formed were suitable for single crystal X-ray diffraction analysis and the product was therefore promptly characterized by this method. An ORTEP drawing of a section of the solid state structure of **3** is shown in Fig. 1. Selected interatomic distances and angles are listed in Tables 2 and 3, respectively. The solid state structure of **3** consists of a double chain arrangement of CuI in a 'step ladder-like' structure that runs parallel to the a-axis of the unit cell. Each copper atom is coordinated to three iodide ligands in the chain and one sulfur atom of one disulfide group of the $\overline{SCH_2CH_2SSCH_2CH_2S}$ ligand. The second disulfide group is coordinated by one of its sulfur atoms to the copper atom of a neighboring CuI double chain. This pattern is repeated indefinitely along the length of the chain. Moreover, the chains are linked in such a way as to form a 2-dimensional sheet. The Cu(1)—S(1) distance is slightly longer than the Cu(2)—S(3) distance, 2.374(2) *vs* 2.342(2) Å. The difference must

be attributed to packing effects. Each copper ion has an approximate tetrahedral geometry. The conformation of the $\overline{SCH_2CH_2SSCH_2CH_2S}$ ligand has a crown type structure which differs from that of the free molecule which has been described as a 'twist-boat-chair' [10]. There are many examples of ladder-like CuX double chain structures in the literature [11], but there are very few in which the chains are linked together to form 2-dimensional sheets [12]. The reaction of CuI with EtSSEt has been reported to yield the complex CuI(μ-η^2-EtSSEt) that contains isolated CuI double chains in which the η^2-EtSSEt ligand bridges adjacent Cu atoms in the same chain [3].

When **3** is dissolved in CD_3CN, only one resonance is observed in the ^1H NMR spectrum at $\delta = 3.14$ ppm. This is not consistent with the solid state structure. This resonance is not significantly different from that of the free molecule **1**; therefore, it is concluded that the $\overline{SCH_2CH_2SSCH_2CH_2S}$ ligand is displaced from the copper atoms when **3** is dissolved.

When a solution of CuI and **2** in acetonitrile was allowed to evaporate in the open air, the compound **4** was formed in a crystalline form in a 61% yield. The crystals which formed were suitable for single crystal X-ray diffraction analysis and the product was thus characterized by this method. An ORTEP drawing of a section of the solid state structure of **4** is shown in Fig. 2. Selected interatomic distances and angles are listed in Tables 4 and 5, respectively. The solid state structure of **4** consists of isolated Cu_2I_2 groups which are linked by two bridging η^2-hexathiacyclododecane ligands to form 1-dimensional chains that run parallel to the crystallographic *b*-direction of the unit cell. The two independent copper atoms lie on special positions on the *b*-axis and the chain has a 2-fold rotational symmetry. Each copper atom is coordinated to two iodide ligands in the chain and two sulfur atoms: one from a disulfide group of two separate

$\overline{SCH_2CH_2SSCH_2CH_2SSCH_2CH_2S}$ ligands. A second disulfide group is coordinated by one of its sulfur atoms to the copper atom of an adjacent Cu_2I_2 group. The Cu—S distances are similar to those in **3**: Cu(1)—S(1) = 2.379(2) Å and Cu(2)—S(3) = 2.433(2)Å. Each copper ion has an approximate tetra-

[a] Distances are in angstroms (Å). Estimated standard deviations in the least significant figure are given in parentheses.

hedral geometry, but the two copper atoms are different. As can be seen in the figure, Cu(2) is coordinated to the two sulfur atoms of the S_2 grouping, S(3) and S(3*), that lie closest to the Cu—Cu axis, while Cu(1) is coordinated to the two sulfur atoms of the S_2 grouping, S(1) and S(1*), that lie farther from the Cu—Cu axis. As a result, the S(3)—Cu(2)—S(3*) angle is much smaller than the S(1)—Cu(1)—S(1*) angle, 85.87(9) *vs* 101.24(9)°. These distortions produce an opposite but smaller counter effect on the I—Cu—I angles, that is, the I—Cu(2)—1* angle is significantly larger than the I—Cu(1)—1* angle, 116.32(5) *vs* 113.80(5)°. The conformation of the ring of the $\overline{SCH_2CH_2SSCH_2CH_2SSCH_2CH_2S}$ ligand is similar to that of the free molecule [13], except for some minor twisting in the conformation at the sites of coordination. There are a number of reports of ligated CuI dimers in the literature [14], but there are a very few examples of chain structures formed by the head-to-tail ligation of dimeric CuI groupings by bidentate ligands [12a,15]. CuX dimers form 1-dimensional chains with tetrahydrothiophene by using the sulfur atom as a single atom bridge [16].

When **4** is dissolved in CD_3CN, only one resonance is observed in the ^1H NMR spectrum at $\delta = 3.21$ ppm. This is not consistent with the solid state structure. This resonance is not significantly different from that of the free molecule **2**, and therefore, as with **3**, it is concluded that the $\overline{SCH_2CH_2SSCH_2CH_2SSCH_2CH_2S}$ ligand in **4** is displaced from the copper atoms when the compound is dissolved.

Two new compounds, **3** and **4**, were obtained from reactions of CuI with the cyclic disulfides **1** and **2**, respectively. Each case only one of the two sulfur atoms in the disulfide group is engaged in coordination to copper. Interestingly, in both cases the cyclic disulfide ligands have adopted bridging bidentate coordination modes by employing coordination of two disulfide groupings. In **3** the copper iodide assembled itself in the well known double chain, step-ladder structure. The interesting feature of the solid state structure is that the bridging disulfide ligands serve as links between the chains together to form 2-dimensional sheets.

For **4** the copper iodide formed in groups no larger than dimers, Cu_2I_2. The dimers are then linked by two bridging ligands of **2** to form 1-dimensional chains. At this time, one can only speculate as to why the two different structural types have formed from these two similar ligands. Steric bulk and geometry of the ligands are two factors which distinguish them. For example, for **1** the disulfide groups lie on opposite sides of the ring. It is easy to arrange a regular repeating pattern of the ligands in a way that can allow a chain of copper atoms to be coordinated to one of the disulfide groups and a second chain to be coordinated to the second disulfide group, etc. to form a sheet. Seemingly, it would be possible to arrange an extended lattice of two bridged CuI chains by using **2** as well, but extending this into a sheet would be more difficult and would probably require considerable folding which might be energetically unfavorable.

(Received 22 September 1997; accepted 12 November 1997)

Abstract—Three complexes from the reaction of bis(diphenylphosphino)ethane (dppe), water and acetonitrile have been structurally characterized. Reaction of the quadruply M—M bonded complex $[Mo_2(CH_3CN)_8(ax\text{-}CH_3CN)][BF_4]_4$ (**1a**), with dppe produces $[Mo_2(\mu,\eta^2\text{-}CH_3CN)(\mu,\eta^1\text{-}NC(CH_3)P(Ph_2)CH_2CH_2PPh_2)(CH_3CN)_7][BF_4]_4$ (**2**), in which an acetonitrile molecule is bound to both Mo atoms in a perpendicular mode. A new chelating ligand, namely $NC(CH_3)P(Ph_2)CH_2CH_2PPh_2$, is formed by coupling of a dppe to an acetonitrile molecule. It bridges both Mo atoms with its **N** atom and chelates to one of the Mo atoms with both **N** and **P** atoms. When a trace amount of water is introduced into **2** at low temperature, the compound $[Mo_2(\mu,\eta^2\text{-}CH_3CNBF_3)(\mu,\eta^1\text{-}N(H)COCH_3)(CH_3CN)_8][BF_4]_3$ (**3**), is obtained. It has a crosswise bridging acetonitrile moiety; the nitrogen atom of this bridging acetonitrile is also coordinated to a BF_3 group in the solid state. An acetamidate ligand, instead of the coupled dppe group, bonds to both Mo atoms symmetrically using only the N atom. Hydrogen bonding is observed between the amide NH group and one F atom of one of the BF_4^- counteranions. Both compounds **2** and **3** have edge-sharing bioctahedra and elongated Mo—Mo distances. By adding an excess of water to the solution of **2**, complex $[Mo_2(\mu\text{-}N(H)COCH_3)_2(CH_3CN)_4][BF_4]_2$ (**4**) is produced. The crystal structure of **4** shows two *cis* bridging acetamidate ligands. The N and O atoms of each acetamido group coordinate to the Mo atoms and they are evenly distributed on two positions. The results are rationalized as nucleophilic attacks of dppe or water molecules on coordinated acetonitrile ligands on the dimolybdenum complexes. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: dimolybdenum compounds; crosswise bridging; iminophosphine; acetamidate; crystal structure.

Among the large family of metal to metal bonded complexes of molybdenum [1], dinuclear complexes in which all the ligands coordinated to the $[Mo_2]^{4+}$ core are labile are rare, although there are a few [2]. Several years ago we reported an efficient synthesis of an acetonitrile complex of this type, namely, $[Mo_2(CH_3CN)_8(ax\text{-}CH_3CN)_2][BF_4]_4 \cdot 2CH_3CN$ [3], $\mathbf{1} \cdot 2CH_3CN$ and anticipated its use in the preparation of other molybdenum compounds [4]. However, the isolated products are extremely dependent on the reaction conditions. We have observed recently not only ligand substitution reactions, but also transformations of the nitrile molecules. In two cases, products having perpendicular bridging (**I**) instead of end-on coordination (**II**) of acetonitrile molecules have been observed, namely, $[Mo_2(\mu,\eta^2\text{-}CH_3CN)(\mu\text{-dppa})(\mu\text{-}NC(CH_3)P(C_6H_5)_2NP(C_6H_5)_2)(CH_3CN)_5][BF_4]_3$ and $[Mo_2(\mu,\eta^2\text{-}CH_3CN)(\mu\text{-}O)(\mu\text{-dppa})_2(CH_3CN)_4][BF_4]_2$, where dppa is bis(diphenylphosphino)amine [5]. The first compound of any kind with a crosswise bridging acetonitrile ligand $W_2Cl_4(\mu\text{-dppm})_2(\mu,\eta^2\text{-}$

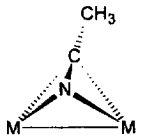
† Dedicated to Lord Lewis on the occasion of his 70th birthday.

CH_3CN), had been reported only about a year earlier by Eglin and coworkers [6]. Though nitrile complexes of this kind are still uncommon, isostructural and isoelectronic alkyne complexes are well established [7].



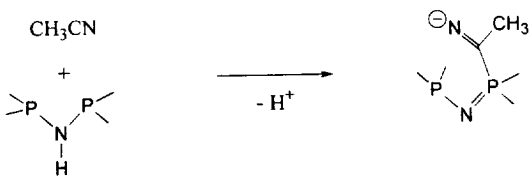
crosswise bridging

I

end-on coordination

II

In addition to the formation of a crosswise bridging acetonitrile molecule, the reaction of **1** with dppa led to another unusual result: a deprotonated dppa became linked to one acetonitrile molecule, as shown in Scheme 1. This dppa—CH_3CN coupled ligand (**III**) is monoanionic. It forms a six-membered ring with one of the Mo atoms as the result of a nucleophilic attack of the phosphine on the acetonitrile molecule.



III

A practical problem with compound $\mathbf{1}\cdot 2CH_3CN$ is that it easily loses some acetonitrile and is thus difficult to handle in the crystalline form. Here we first report the structure of a more stable crystalline form of this compound, namely $[Mo_2(CH_3CN)_8(ax\text{-}CH_3CN)][BF_4]_4$ (**1a**). We have also characterized three compounds obtained from the reaction of **1a** with nucleophiles. With dppe, a dimolybdenum complex $[Mo_2(\mu,\eta^2\text{-}CH_3CN)(\mu\text{-}NC(CH_3)P(C_6H_5)_2CH_2CH_2P(C_6H_5)_2)(CH_3CN)_7][BF_4]_4$ (**2**), is produced. It contains a μ,η^2-CH_3CN ligand perpendicular to the metal-metal bond, and a new chelating ligand NC$(CH_3)P(Ph)_2CH_2CH_2\mathbf{P}(Ph)_2$ (**IV**) as well, which is formed by linking of dppe to acetonitrile, as shown in Scheme 2. When a trace amount of water is added to **2** at low temperature, the compound $[Mo_2(\mu,\eta^2\text{-}CH_3CNBF_3)(\mu,\eta^1\text{-}N(H)COCH_3)(CH_3CN)_8][BF_4]_3$ (**3**), is formed. Compound **3** has a BF_3 group bound to the N atom of the crosswise bridging μ,η^2-CH_3CN ligand. In addition, there is an acetamidate ligand, CH_3CONH^-, bridging both Mo atoms through the amide N atom in a μ,η^1 coordination mode. The bridging CH_3CNBF_3 ligand in **3** can also dissociate partially in solution to give $[Mo_2(\mu,\eta^2\text{-}CH_3CN)(\mu,\eta^1\text{-}N(H)CO\text{-}CH_3)(CH_3CN)_8][BF_4]_3$, (**3a**), and BF_3. When more than one equivalent of water is present, further hydrolysis of acetonitrile gives two acetamidate ligands and the complex $[Mo_2(\mu\text{-}N(H)COCH_3)_2(CH_3CN)_4][BF_4]_2$ (**4**) is formed. In this compound an Mo_2^{4+} core is supported by two acetamido ligands that bind in the previously known syn way [1] with the remaining four positions occupied by CH_3CN molecules.

EXPERIMENTAL

Materials and methods

All operations were carried out under an argon atmosphere using standard Schlenk or drybox techniques. Solvents were purified by conventional methods and distilled under nitrogen from CaH_2 or Na/K, as appropriate. Published procedures were used to synthesize **1** in amorphous form by drying it under vacuum [3]. Single crystals of $[Mo_2(CH_3CN)_8(ax\text{-}CH_3CN)][BF_4]_4$ (**1a**) were obtained by slow diffusion of a layer of toluene into an acetonitrile solution. Other chemicals, including dppe were purchased from Aldrich and were used as received. Infrared spectra were recorded in the range 4000–400 cm^{-1} on a Perkin–Elmer 16-PC spectrophotometer using KBr pellets. Nuclear magnetic resonance spectra were recorded on a Unity plus 300 spectrometer at 300 MHz for ^1H, 282 MHz for ^{19}F, and 121.4 MHz for ^{31}P. Reference standards were: ^1H, CH_3CN (1.95 ppm); ^{19}F, CCl_3F (0.00 ppm); ^{31}P, H_3PO_4 (0.00 ppm).

Preparation of $[Mo_2(\mu,\eta^2\text{-}CH_3CN)(\mu\text{-}NC(CH_3)P(C_6H_5)_2CH_2CH_2P(C_6H_5)_2)(CH_3CN)_7][BF_4]_4$ (**2**)

A mixture of **1a** (0.23 g, 0.25 mmol) and dppe (0.10 g, 0.25 mmol) was dissolved in acetonitrile (20 cm^3) to give a bright blue solution. After the solution was stirred for a few minutes, it turned dark green. Stirring was continued for 2 h and then toluene (20 cm^3) was injected underneath the resulting solution. Slow diffusion of the two layers gave green crystals of $[Mo_2(\mu,\eta^2\text{-}CH_3CN)(\mu\text{-}NC(CH_3)P(C_6H_5)_2CH_2CH_2P(C_6H_5)_2)(CH_3CN)_7][BF_4]_4\cdot 3$toluene, $\mathbf{2}\cdot 3$toluene, which were separated by filtration. Yield: 0.080 g, 20%. Another crop of **2**, namely $\mathbf{2}\cdot CH_3CN$, was isolated by layering the concentrated filtrate with diethylether (20 cm^3). Yield: 0.138 g, 41%. ^1H-NMR (300 MHz, CD_3CN, 20.0°C) δ (ppm): 7.12–8.14 (m, 20H, aromat. H), 3.63 (s, 3H, bridging CH_3CN), 3.35, 2.75 (m, 4H, coupled CH_3CN-dppe C_2H_4), 2.29 (s, 3H, coupled CH_3CN-dppe CH_3), 1.95 (s, terminal $NCCH_3$); $^{31}P\{^1H\}$-NMR (121.4 MHz, CD_3CN, 20.0°C) δ (ppm): 16.06, 13.96; $^{19}F\{^1H\}$-NMR (282.2 MHz, CD_3CN, 20.0°C) δ (ppm): −150.17 (NMR lines are generally broad.); IR (KBr) (cm^{-1}): 2963 (m), 2925 (m), 2320 (m), 2292 (m), 1638 (m), 1522 (w), 1485 (w), 1438 (m), 1370 (w), 1300 (w), 1262 (m), 1083 (vs), 803 (m), 742 (w), 693 (w).

Preparation of $[Mo_2(\mu,\eta^2\text{-}CH_3CNBF_3)(\mu\text{-}N(H)CO\text{-}CH_3)(CH_3CN)_8][BF_4]_3$ (**3**)

A mixture of **1a** (0.23 g, 0.25 mmol) and dppe (0.10 g, 0.25 mmol) was dissolved in acetonitrile (15 cm^3).

The solution was stirred for 1 h. At this stage, one equivalent of H_2O in 10 cm^3 acetonitrile (made by adding 4.5×10^{-2} cm^3 H_2O to 100 cm^3 CH_3CN) was added with a syringe and stirring was ceased after 30 min. Toluene (20 cm^3) was then injected underneath the resulting solution. Slow diffusion of the two solvent layers at −20°C gave purple crystals of $[Mo_2(\mu,\eta^2\text{-}CH_3CNBF_3)(\mu\text{-}N(H)COCH_3)(CH_3CN)_8][BF_4]_3 \cdot 2CH_3CN$, **3**·$2CH_3CN$. Yield: 0.257 g, 25%. ^{1}H-NMR (300 MHz, CD_3CN, 20.0°C) δ (ppm) 9.81 (br, 1H, acetamido NH), 3.37 (s, 3H, bridging $N(BF_3)CCH_3$), 2.81 (s, 3H, acetamido CH_3), 1.95 (s, terminal CH_3CN); $^{19}F\{^1H\}$-NMR (282.2 MHz, CD_3CN, 20.0°C) δ (ppm): −138.90 (br, bridging CH_3CNBF_3), −150.27 (s, BF_4^-); IR (KBr) (cm^{-1}): 3387 (s), 2317 (m), 2290 (m), 1375 (vw), 1701 (sh), 1636 (m), 1370 (m), 1300 (w), 1216 (m), 1084 (vs), 694 (w), 534 (m), 521 (m).

Preparation of $[Mo_2(\mu\text{-}N(H)COCH_3)_2(CH_3CN)_4][BF_4]_2$ (**4**)

A bright blue solution was obtained after **1a** (0.24 g, 0.26 mmol) and dppe (0.11g, 0.27 mmol) were dis solved in acetonitrile (20 cm^3). It became dark green after being stirred for 1 h. At this stage, H_2O (1.0×10^{-2} cm^3, 5.5 mmol) was added by a microsyringe. The green solution was stirred until the color changed to red, in about 10 h. Toluene (20 cm^3) was then injected underneath the resulting solution, and slow diffusion of the two layers at room temperature gave crystals of $[Mo_2(\mu\text{-}N(H)C(O)CH_3)_2(CH_3CN)_4][BF_4]_2 \cdot 2CH_3CN$, **4**·$2CH_3CN$. Yield: 0.153 g, 81%. ^{1}H-NMR (300 MHz, CD_3CN, 20.0°C) δ (ppm): 7.69 to 7.19 (br, 2H, bridging acetamidate NH), 2.13 (s, 6H, bridging acetamido ligands CH_3), 1.95 (s, terminal CH_3CN); $^{19}F\{^1H\}$-NMR (282.2 MHz, CD_3CN, 20.0°C) δ (ppm): −150.57 (s, BF_4^-); IR (KBr) (cm^{-1}): 3425 (m), 2939 (m), 2321 (m), 2292 (m), 1658 (s), 1578 (m), 1437 (m), 1262 (w), 1066 (vs), 804 (w), 748 (w), 697 (m), 521 (m).

Crystallographic studies

Crystals of each compound, **1a**, **2**·CH_3CN, **3**·$2CH_3CN$, and **4**·$2CH_3CN$, were mounted on the tips of glass fibers and cooled under a nitrogen stream on the Nonius FAST area-detector diffractometer at −60°C. Unit cell dimensions were obtained by indexing 250 strong reflections in the 2θ range of 18.0° to 41.8° and confirmed by taking axial images. Details of the use of the FAST diffractometer in our laboratory have been previously described [8]. The highly redundant data sets were corrected for Lorentz and polarization effects. The absorption corrections were based on fitting a function to the empirical transmission surface as sampled by the multiple equivalent measurements inherent in area detector data [9].

In each case the structure was solved by direct methods and refined using the SHELXTL programs

[10]. Disorder of the BF_4^- ions was encountered during structural refinement for **1a**, **2**·CH_3CN and **4**·$2CH_3CN$. Atoms of the disordered anions were refined isotropically. Final residuals and figures of merit and other crystallographic details for all structures are reported in Table 1.

The structure of the $[Mo_2(CH_3CN)_8(ax\text{-}CH_3CN)]^{4+}$ core of **1a** was refined anisotropically and all hydrogen atoms were placed in calculated positions. Careful consideration was given to the choice of the chiral space group *I*4. The molecule is incompatible with any other space group, but there was some evidence that the crystals were enantiomeric twins. Inclusion of the inversion twin law in the refinement resulted in successful refinement of the model. Selected bond distances and angles are listed in Table 2.

Two crystalline forms for compound **2** have been obtained. Crystals of the toluene solvate, **2**·3toluene, were very thin plates, from which only a weak data set was collected.* Crystals of the acetonitrile solvate, **2**·CH_3CN, were of better quality for single crystal X-ray analysis. During refinement, one of the four independent phenyl groups of the dppe ligand was found to be disordered with the two orientations being slightly displaced from each other and having occupancies of 0.7 and 0.3. Displacement parameters in the disordered group were refined isotropically. Hydrogen atoms were included in calculated positions. Selected bond distances and angles are listed in Table 3.

Compound **3**·$2CH_3CN$ crystallized in the chiral monoclinic space group $P2_1$. The absolute structure of **3**·$2CH_3CN$ was determined from the Flack parameter [$x = -0.13(5)$] [11]. All non-hydrogen atoms of the metal complex were refined with anisotropic displacement parameters, and hydrogen atoms were included in calculated positions. Selected bond distances and angles are listed in Table 4.

Compound **4**·$2CH_3CN$ crystallizes in the centered orthorhombic space group *Aba*2. Both acetamido ligands are disordered; the O and N atoms are best refined as distributed evenly on each side of the monoanionic ligand. Hydrogen atoms were included in calculated positions during final refinement. Selected bond distances and angles for **4**·$2CH_3CN$ are listed in Table 5.

Other crystallographic data, including that for **2**·3toluene, are given as supplementary material. Supplementary data have been deposited with the Cambridge Crystallographic Data Centre.**

RESULTS AND DISCUSSIONS

Compound **1a**

Published procedures [3b] were used to prepare **1** as an amorphous powder material. It was then recrystallized by allowing toluene to diffuse into a concentrated acetonitrile solution giving a nonaacetonitrile species (**1a**) instead of the crystalline decaacetonitrile complex reported earlier [3].

A perspective view of the $[Mo_2(CH_3CN)(ax\text{-}CH_3CN)]^{4+}$ core of compound **1a** is shown in Fig. 1. It consists of a discrete $[Mo_2]^{4+}$ unit with Mo—Mo distance of 2.180(1) Å. Both Mo atoms and the axially coordinated CH_3CN ligand reside on a crystallo-

*Compound **2**·3toluene crystallizes in orthorhombic space group $P2_12_12$ with the following unit cell parameters: $a = 22.710(3)$ Å, $b = 25.976(5)$ Å, $c = 11.4213(8)$ Å, $V = 6738(2)$ Å^3, and $Z = 4$. Data were collected on a Nonius FAST area detector system with Mo–K_α radiation. Because the data set had a low data to parameter ratio, (4.2 : 1 for $I > 2\sigma(I)$), we did not attempt a complete refinement of the structure. However, the chemical composition was clear from the preliminary study. Further crystal data and atomic coordinates for **2**·3toluene have been deposited with the Cambridge Crystallographic Data Centre.

Supplementary material available: Table of positional parameters for **1a, **2**·CH_3CN, **2**·3toluene, **3**·$3CH_3CN$, **4**·$2CH_3CN$, full tables of displacement parameters and molecular dimensions (50 pages).

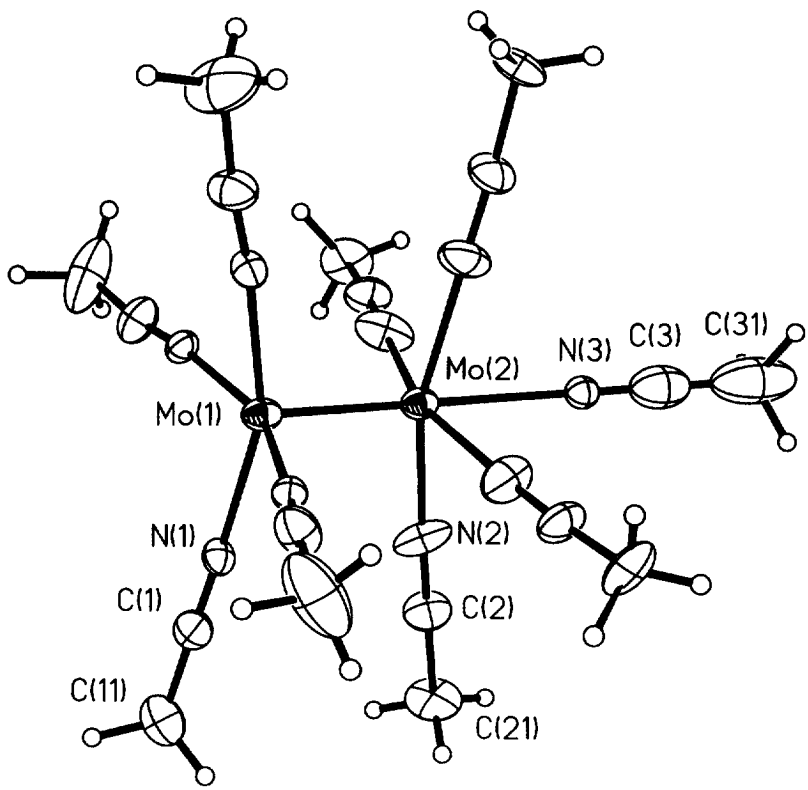

Fig. 1. The $[Mo_2(CH_3CN)_8(ax\text{-}CH_3CN)]^{4+}$ cation in **1a**. Thermal displacement ellipsoids are shown at the 30% probability level; hydrogen atoms are omitted.

CH_3CN ligands are labile and undergo rapid exchange with the solvent; a similar result was previously observed for complex **1** [3a]. In solution **1a** is very sensitive to its environment. It is important that only freshly distilled acetonitrile be used for the reactions, otherwise decomposition of **1a** gives a brown solution in less than one day.

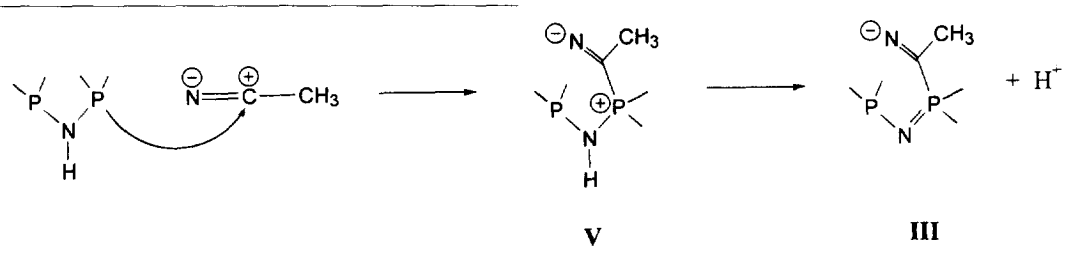
Compound **2**

The reaction of **1a** with bis(diphenylphosphino)ethane, dppe, in acetonitrile at room temperature produces compound **2** (eqn (1)).

$$[Mo_2(CH_3CN)_8(ax\text{-}CH_3CN)][BF_4]_4 + dppe \xrightarrow[CH_3CN]{} [Mo_2(\mu,\eta^2\text{-}CH_3CN)(\mu\text{-}NC(CH_3)PPh_2\text{-}CH_2CH_2PPh_2)(CH_3CN)_7][BF_4]_4 \quad (1)$$

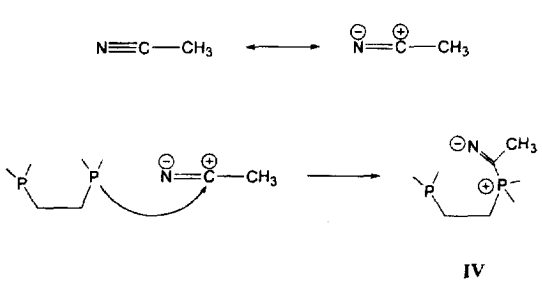
The reaction takes place quickly as an obvious color change from bright blue to dark green occurs within a few minutes.

The bonding of the newly formed ligand **IV** is unusual. It forms a seven-membered ring with one of the Mo atoms. Though the $NC(CH_3)P(Ph_2)CH_2CH_2PPh_2$ ligand itself is neutral, formally there is a partial charge distribution that makes the coupled phosphorus atom P(2) of dppe positive (i.e. it is effectively quaternized) and the acetonitrile nitrogen atom N(8) negative. As shown in Table 3, the bonds from the formally charged P atom to its adjacent atoms are about 0.01 to 0.03 Å shorter than those for the phosphine atom P(1). Thus the CH_3CN-dppe coupled ligand **IV** can be considered as consisting of a four electron donor imino group bridging the Mo atoms. As shown in Fig. 2, atom N(8) bridges both Mo atoms with Mo—N distances of 2.034(5) Å and 2.049(5) Å with a very acute Mo(1)—N(8)—Mo(2) angle of 75.1(2)°. This seven membered ring differs from that of the previously reported dppa compound [5], where a nitrogen to phosphorus double bond produces a coplanar six membered ring. Nevertheless, they are chemically related as shown in Scheme 3.



V **III**

The structure of the cation in $2 \cdot CH_3CN$ is shown in Fig. 2. Two important features merit comment. First, there is a μ,η^2-CH_3CN ligand which is perpendicular to the Mo—Mo bond. This coordination mode is well known for alkyne complexes but there are only a few examples for nitrile compounds [5]. Coordination of the CH_3CN molecule to the dinuclear system increases the N—C bond distance to 1.269(8) Å and decreases the N—C—CH_3 angle to 136.2(6)°. Second, a new chelating ligand $NC(CH_3)P(Ph_2)CH_2CH_2PPh_2$, **IV**, is formed as shown in Scheme 2. One of the P atoms of the dppe group is bonded to the carbon atom of an acetonitrile molecule; the formal oxidation state of this P atom changes from +3 to +5.



IV

The monoanionic CH_3CN-dppa coupled ligand **III** is formed by deprotonation of the neutral intermediate **V**, which is less stable than that formed by dppe and CH_3CN. The dimolybdenum unit changes from a paddlewheel structure in the starting material to an edge-sharing one in **2**. As a consequence the Mo—Mo distance increases from 2.180(1) to 2.488(1) Å, which is in the range found for double bonded edge-sharing dimolybdenum compounds [12].

Spectroscopic data are also consistent with the formation of **2**. The methyl group of the μ,η^2 acetonitrile molecule shows a peak at 3.63 ppm in ^1H NMR. The complex multiplets centered at 3.35 and 2.75 ppm are in agreement with the unsymmetrical environment of the C_2H_4 group in the coupled CH_3CN-dppe ligand **IV**; a singlet at 2.29 ppm corresponds to the CH_3 group of the CH_3CN-dppe ligand. The $^{31}P\{^1H\}$ NMR spectrum of compound **2** shows two signals of equal intensity at 16.06 and 13.96 ppm which is consistent with the two P atoms of the modified dppe moiety being chemically different. The $^{19}F\{^1H\}$ NMR spectrum exhibits a single peak for the BF_4^- counter anions at −150.17 ppm. An IR band at 1638 cm^{-1} is assigned to the μ,η^2-CH_3CN ligand; the terminal acetonitrile stretching vibrations are at 2317

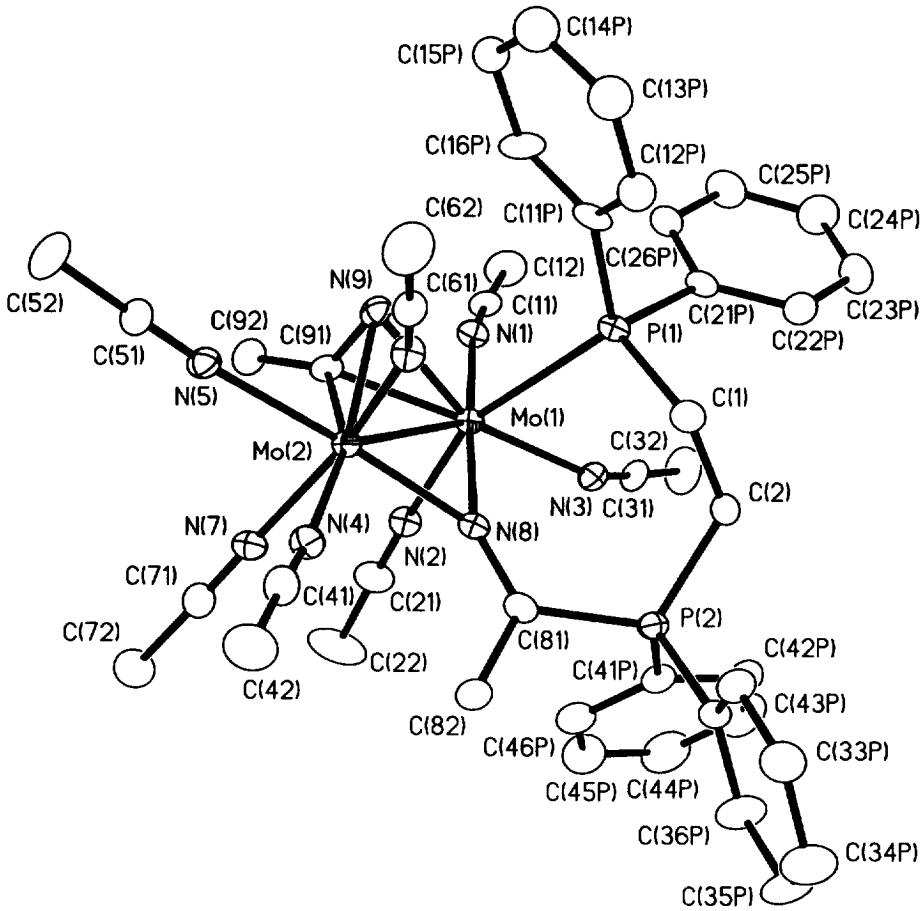


Fig. 2. The $[Mo_2(\mu,\eta^2\text{-}CH_3CN)(\mu\text{-}NC(CH_3)P(C_6H_5)_2CH_2CH_2P(C_6H_5)_2)(CH_3CN)_7]^{4+}$ cation in compound **2** · CH_3CN. Atoms are represented by their thermal displacement ellipsoids at the 30% probability level; hydrogen atoms are omitted.

and 2290 cm^{-1}. All of the features are fully consistent with the solid state structure.

Solutions of compound **2** are extremely sensitive to impurities. Thus, it is critical that freshly distilled acetonitrile be used for the reaction in order to isolate the described product. If even traces of water are present, decomposition of **2** occurs and the color of the reaction solution changes from green to purple. Materials isolated from such a reaction mixture show a broad signal at 9.8 ppm in the ^1H NMR, which is consistent with the existence of an amido NH group. Unfortunately, crystals of the isolated purple material are badly twinned preventing a detailed investigation of the solid-state structure [13], and we have made no further attempt to characterize this substance. Further comments on it will be found in the section entitled Conclusions.

Compound **3**

To understand the chemistry of the highly reactive CH_3CN-dppe coupled compound **2**, the result of careful, deliberate hydrolysis of **2** was studied. When a trace amount of water is introduced into the reaction system at low temperature, a reaction takes place that leads to the formation of an isolable acetamidate-coordinated compound **3** (eqn (2)).

$$[Mo_2(\mu,\eta^2\text{-}CH_3CN)(\mu\text{-}NC(CH_3)PPh_2CH_2CH_2PPh_2)(CH_3CN)_7][BF_4]_4 + H_2O \xrightarrow[CH_3CN]{} [Mo_2(\mu,\eta^2\text{-}CH_3CNBF_3)(\mu\text{-}N(H)COCH_3)(CH_3CN)_8][BF_4]_3 + HF + dppe \quad (2)$$

The structure of the cation of **3** · $2CH_3CN$ is shown in Fig. 3. There is a bridging acetonitrile moiety perpendicular to the M—M bond. A BF_3 group is also bound to the N atom of the bridging acetonitrile with a B—N distance of 1.59(1) Å. The crosswise bridged acetonitrile moiety has an N—C distance of 1.30(1) Å and an N—C—CH_3 angle of 133.7(6)° similar to that in **2**. Introducing a trace amount of water forms the acetamidate ligand $^-HNCOCH_3$; no coupling is

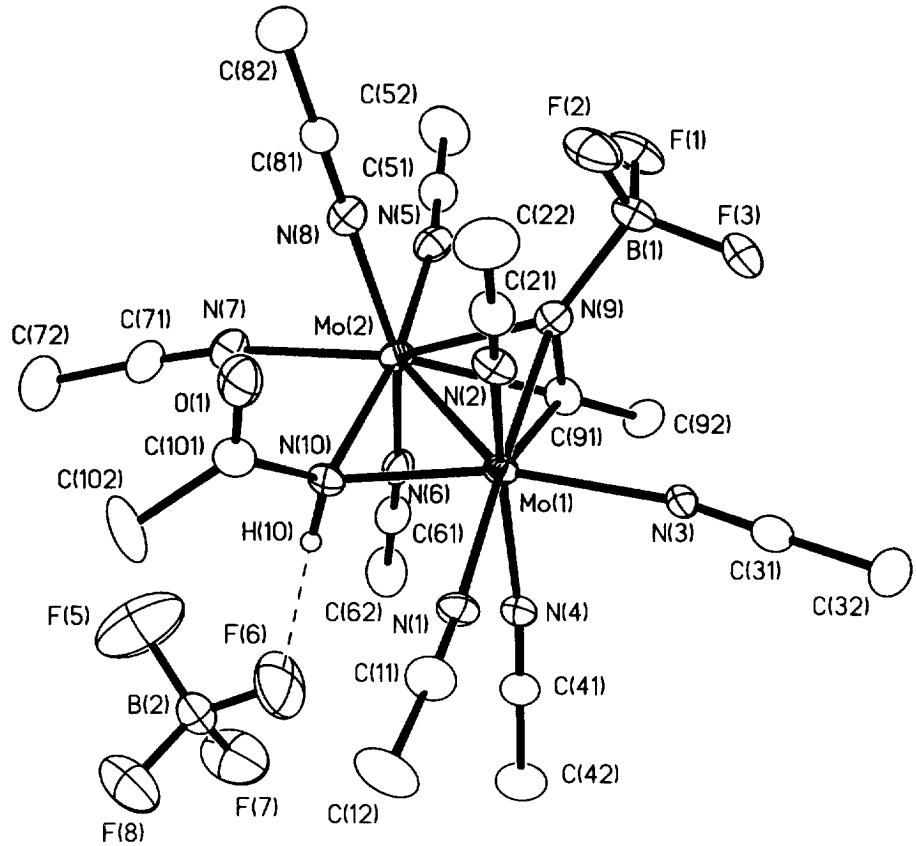

Fig. 3. The cation in $3 \cdot 2CH_3CN$, together with one hydrogen-bonded BF_4^- ion. Atoms are represented by their thermal displacement ellipsoids at the 30% probability level; hydrogen atoms are omitted.

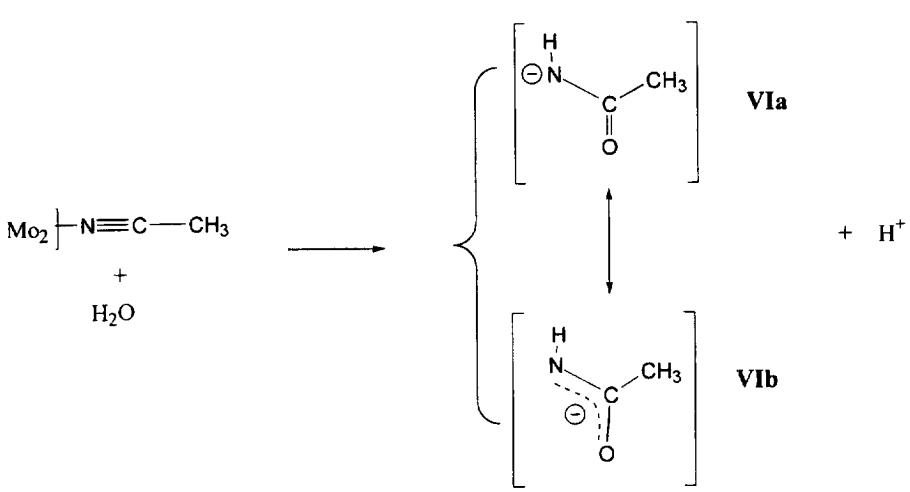
observed. The N atom of the acetamidate ligand binds to both Mo atoms with Mo—N distances of 2.100(6) and 2.103(6) Å. The existence of an amidate NH^- group also leads to hydrogen bonding to one of the BF_4^- counter anions, as shown in Fig. 3. The N(10)—F(6) distance is 2.98(1) Å and the N(10)—H(10)—F(6) angle is 174.6(3)°. It is interesting to notice that the monodentate resonance form **VIa** (Scheme 4) is stabilized in this compound instead of the bidentate form **VIb**, in which the electronic structure of the ligand is delocalized.

The proton NMR spectrum for **3**, Fig. 4(a), shows



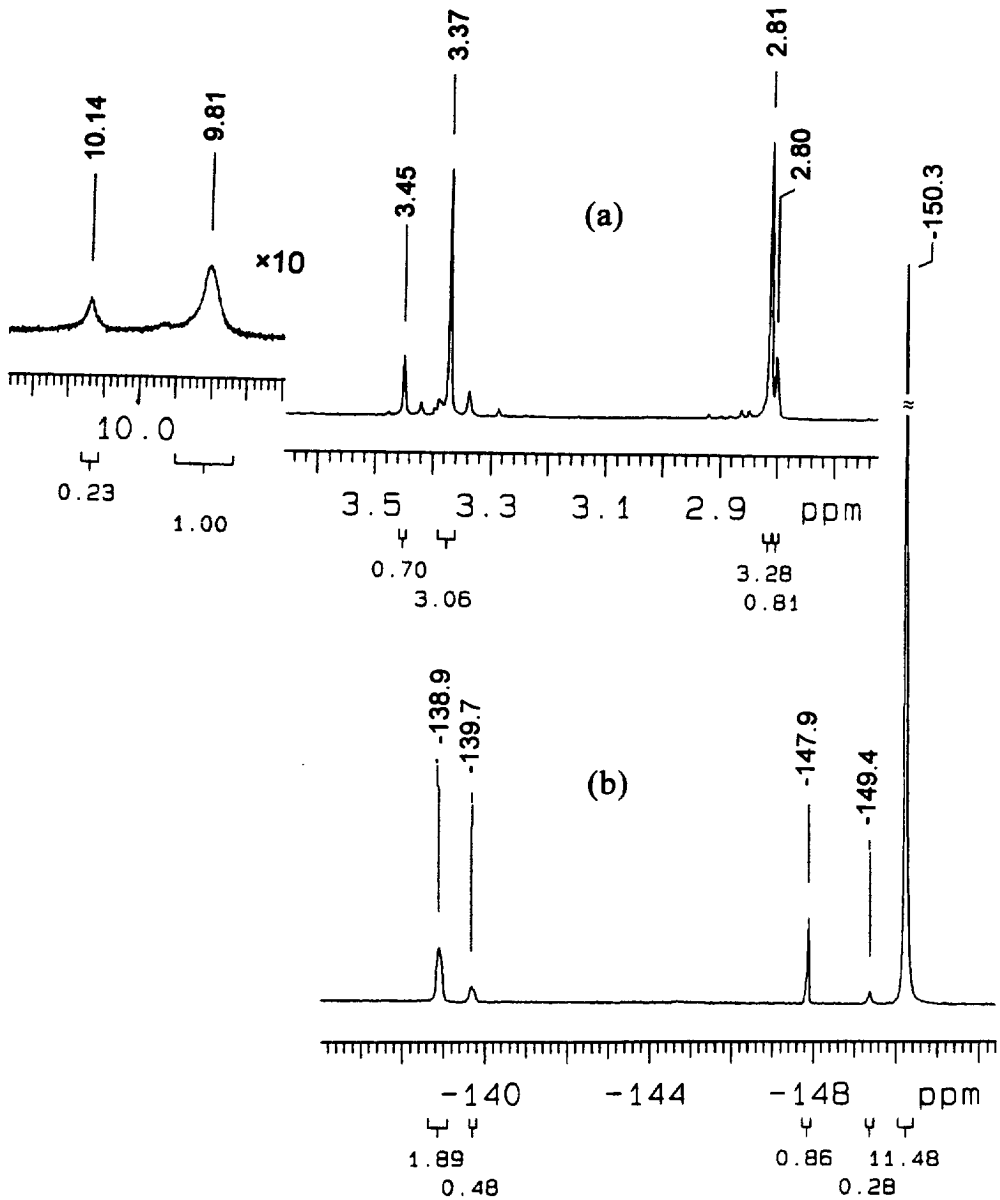


Fig. 4. (a) Proton NMR spectrum of **3** in CD_3CN showing the existence of two sets of N—H and CH_3 groups. One set of resonances with higher intensities corresponds to the bridging CH_3CNBF_3 and acetamidate ligands in **3**; the other set is for the bridging CH_3CN and acetamidate ligands in **3a**. (b) The $^{19}F\{^1H\}$ NMR spectrum of **3** in CD_3CN.

that the molecule persists in solution but that it partly dissociates to release the BF_3 group, giving **3a**. For **3** and **3a** there are broad signals at 9.81 and 10.14 ppm due to the N—H protons, with an intensity ratio of about 4 : 1. Upfield, in the aliphatic C—H region there are signals at 2.81 ppm for the amidate CH_3 group and 3.37 ppm for the CH_3 group in CH_3CNBF_3 in **3**. Signals that correspond to the amidate and μ,η^2—CH_3CN groups in **3a** are seen at 3.45 and 2.80 ppm, respectively at about 0.25 the intensity.

Turning now to the ^{19}F spectrum, Fig 4(b), we found a strong signal at −150.3 ppm for the BF_4^- ions. The peaks at −138.9 and −139.7 can be assigned to the BF_3 moieties, the former ones bound in the μ,η^2—CH_3CNBF_3 group and the latter being free CH_3CNBF_3 molecules arising from the dissociation. The assignments of the signals at −147.9 and −149.4 ppm are uncertain. A possible assignment of the signal at −147.9 is to $B_2F_7^-$ [14]. If this is correct, we get a fairly good fit to the relative intensities. The intensity of the signal would be apportioned in a prorata way to its formal components, $BF_3 + BF_4^-$. Thus the "total" BF_3 intensity would be 1.89 + 0.48 + 0.37 = 2.74 and the "total" BF_4^- inten-

sity would be 11.48+0.49 = 11.97. The ratio 11.97/2.74 = 4.37 is in fair agreement with the ideal ratio of 4.0.

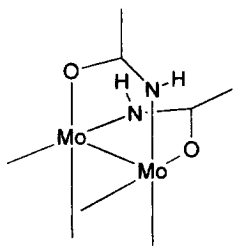
The formation of acetamide by hydrolysis of coordinated acetonitrile is well known [15].

Compound **4**

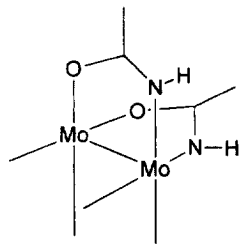
Compound **4** is formed by adding an excess of water to the acetonitrile solution of **1a** and dppe. As the reaction proceeds, the color of the mixture changes gradually from green to purple to red (eqn (3)).

$$[Mo_2(CH_3CN)_8(ax\text{-}CH_3CN)][BF_4]_4 + 2H_2O \xrightarrow[CH_3CN]{dppe} [Mo_2(\mu\text{-}N(H)COCH_3)_2(CH_3CN)_4][BF_4]_2 + 2HBF_4 \quad (3)$$

Compound $4 \cdot 2CH_3CN$ has a paddlewheel structure with two bidentate amidate ligands *cis* to each other as shown in Fig. 5. Though it is possible that a *trans* isomer may be produced from the hydrolysis of **1a**, it is not seen in the solid state. In this bisacetamidate-bridged complex, the positions of the N and O atoms are best described as evenly occupied by both N and O atoms. This disorder could be due to "head to tail" (**VIIa**) or "head to head" molecules (**VIIb**) pointing in both directions or to a random mixture of "head to tail" and "head to head" molecules. The X-ray results do not discriminate among these possibilities. Perhaps a disorder of "head to tail" molecules is most likely.



VIIa



VIIb

Distances from the O or N atoms of the acetamidate ligands to the Mo atoms are in the range of 2.07(1) to

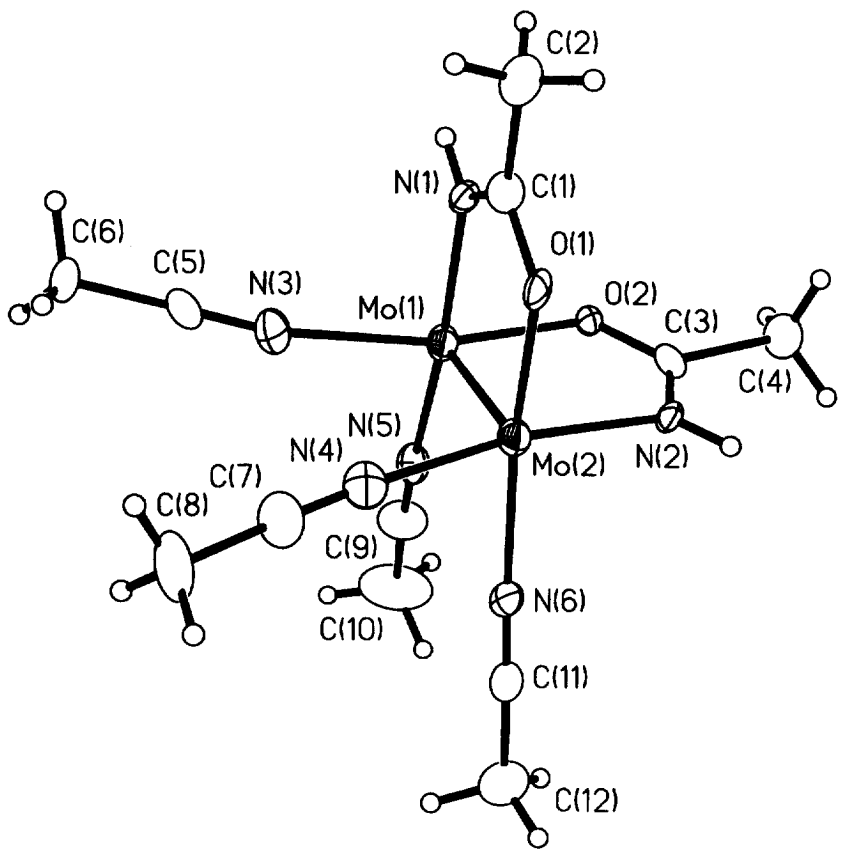


Fig. 5. The cation in $4 \cdot 2CH_3CN$. Atoms are represented by their thermal displacement ellipsoids at the 30% probability level. Hydrogen atoms are drawn as spheres of arbitrary size.

2.09(1) Å. The Mo—Mo bond distance is 2.144(2) Å; it is shorter than that of the starting material $[Mo_2(CH_3CN)_8(ax\text{-}CH_3CN)][BF_4]_4$ (**1a**) and similar to that of the closely related bisacetate acetonitrile cation $[Mo_2(O_2CCH_3)_2(CH_3CN)_4]^{2+}$, in which the Mo—Mo distance is 2.133 Å [16].

Both acetamidate ligands adopt the delocalized electron structure **VIb** shown in Scheme 4, as they are bidentate. The fact that **4** exhibits only a broad peak at 2.13 ppm for the acetamidate CH_3 group in the ^1H NMR spectrum is in agreement with the observation that only the *cis* isomer exists in the solid state. The broad signals that appear between 7.69 and 7.19 ppm for the amido NH groups of the bridging acetamidate ligands might indicate the coexistence of "head to tail" or "head to head" configurations in the *cis* isomer. The $^{19}F\{^1H\}$ NMR spectrum of **4** has a single resonance at −150.57 ppm for the BF_4^- ions. The existence of two BF_4^- counteranions in the crystal structure of **4** also implies that the Mo atoms are in an oxidation state of +2.

CONCLUSIONS

The genesis of this work was the observation made many years ago in this laboratory that treatment of a solution of **1** with a phosphine (with the intention, originally, of simply replacing coordinated CH_3CN ligands by phosphines) led to the formation of a purple product. Crystals of this purple product have been obtained several times, but the structure was not cleanly determined because of disorder and/or twinning. This crystallographic problem has never been overcome.

As far as could be determined, the purple product consists of a tetrapositive dimolybdenum cation with an edge-sharing bioctahedral structure and four BF_4^- ions. The eight terminal ligands in this cation are clearly seen as end-coordinated CH_3CN molecules, but the bridging ligands could not be cleanly resolved. No phosphine is present in this product. The present investigation was undertaken to see what leads up to this purple product, and we have, indeed, gained much insight into that aspect of the chemistry.

Three dimolybdenum compounds that contain ligands which result from the transformation of acetonitrile molecules have been prepared and structurally characterized. The common feature of these ligands is that they result from nucleophilic attacks on the cyanide carbon atom of the acetonitrile by phosphine and water. Depending on the reaction conditions, crosswise bridging acetonitrile, coupled CH_3CN-dppe, μ,η^1 and μ,η^2 coordinated acetamidate ligands have been observed.

The single crystal X-ray structures of compounds **2** and **3** confirmed an edge-sharing bioctahedral geometry. The bonding of the crosswise bridging acetonitrile molecules to the Mo atoms in both compounds are similar: the bridging acetonitrile ligands bend upon coordination and their C—N distances are close to the ideal value for sp^2-hybridized carbon atoms. In compound **3**, the bridging acetonitrile ligand also coordinates to a BF_3 molecule which is labile and can dissociate in acetonitrile solution to produce **3a**.

In addition to the formation of bridging acetonitrile molecules, there is a CH_3CN-dppe coupled chelating ligand $NC(CH_3)P(Ph_2)\,CH_2CH_2PPh_2$ in compound **2**. Although the ligand is neutral, there is a formally localized negative charge on the N atom and a positive charge on the neighboring P atom. According to the valence structure, this negatively charged N atom can be considered as a four electron donor. The difference between the coupled CH_3CN-dppe ligand and the previously reported coupled CH_3CN-dppa ligand is that the amine NH group in dppa can be readily deprotonated to give a monoanionic ligand. These two compounds provide examples of nucleophilic attacks by phosphine molecules on a nitrile carbon atom.

Hydrolysis then produces acetamidate ligands, which coordinate in a manner that depends on reaction conditions. By introducing a trace amount of water to a cold solution of compound **2**, compound **3** is obtained. When two equivalents of water are added at ambient temperature, compound **4** is isolated in which neither coupled dppe nor a bridging acetonitrile ligand is observed. Instead, there are two acetamidate ligands bridging both Mo atoms in **4**.

We now believe that the purple compound is an intermediate between **2** and/or **3** and the ultimate hydrolysis product **4**, but exactly what it is still remains uncertain.

Acknowledgments—We are grateful to the Robert A. Welch Foundation for their financial support of this work.

(Accepted 19 November 1997)

Abstract—Reactions between $Ru_5(\mu_5\text{-}C_2)(\mu\text{-}SMe)_2(\mu\text{-}PPh_2)_2(CO)_{11}$ (**1**) and $Co_2(CO)_8$ give the octanuclear cluster $Co_2Ru_6(\mu_7\text{-}C_2)(\mu_3\text{-}SMe)_2(\mu\text{-}PPh_2)_2(\mu\text{-}CO)_4(CO)_{13}$ (**4**) and the nonanuclear $Co_4Ru_5(\mu_8\text{-}C_2)(\mu_3\text{-}SMe)_2(\mu\text{-}PPh_2)_2(\mu\text{-}CO)_7(CO)_{11}$ (**5**), both characterised by single crystal X-ray structure determinations. The core of **4** consists of a Co_2Ru_3 square pyramid sharing a basal edge with a $CoRu_3$ square; the seventh Ru atom bridges the outer edge of the square pyramid. In **5**, two of the metal atoms are disordered (M = Co/Ru = 1 : 1). In this complex, two square pyramids (Co_2MRu_2 and Co_2M_2Ru) share a non-bonded edge [3.22 Å], with the ninth atom (Ru) bridging an outer edge. In both complexes, the μ_3-SMe groups and three of the Ru atoms they bridge form an almost planar $SRuSRu_2$ ring. The C_2 ligands hold the two square faces at dihedral angles of 85.75(3) (**4**), 87.8° (**5**) and are attached to seven metal atoms in **4**, eight metal atoms in **5**. © 1998 Elsevier Science Ltd. Keywords: cobalt; ruthenium; carbido cluster; crystal structure.

Earlier, we have described reactions of the open cluster $Ru_5(\mu_5\text{-}C_2)(\mu\text{-}SMe)_2(\mu\text{-}PPh_2)_2(CO)_{11}$ (**1**) with iron and ruthenium carbonyls to give the hexa- and heptanuclear clusters $MR\mu_5(\mu_6\text{-}C_2)(\mu\text{-}SMe)_2(\mu\text{-}PPh_2)_2(CO)_{14}$ (**2**) and $M_2Ru_5(\mu_6\text{-}C_2)(\mu_3\text{-}SMe)_2(\mu\text{-}PPh_2)_2(\mu\text{-}CO)(CO)_{15}$ (**3**) (M = Fe, Ru) (Scheme 1) [1]. In these reactions, the C_2 ligand acts as a centre around which further metal atoms may be added and it also serves to hold apart the square faces of the clusters. At the time of our communication [1], we also reported briefly on one of the products obtained from similar reactions of **1** with $Co_2(CO)_8$. This paper describes these reactions in detail together with the structures of the two heteronuclear complexes obtained.

RESULTS AND DISCUSSION

The reaction between **1** and $Co_2(CO)_8$ was carried out in toluene for 2 h at 110°C in a Carius tube. The black solution was separated into a major and a minor product by preparative thin-layer chromatography followed by crystallisation from methanol-dichloromethane. The two complexes were characterised by single crystal X-ray structure determinations as $Co_2Ru_6(\mu_7\text{-}C_2)(\mu_3\text{-}SMe)_2(\mu\text{-}PPh_2)_2(\mu\text{-}CO)_4(CO)_{13}$ (**4**) (black, 60% yield) and $Co_4Ru_5(\mu_8\text{-}C_2)(\mu_3\text{-}SMe)_2(\mu\text{-}PPh_2)_2(\mu\text{-}CO)_7(CO)_{11}$ (**5**) (orange, 32% yield) (Scheme 2).

Molecular structure of $Co_2Ru_6(\mu_7\text{-}C_2)(\mu_3\text{-}SMe)_2(\mu\text{-}PPh_2)_2(\mu\text{-}CO)_4(CO)_{13}$ (**4**)

Figure 1 shows a plot of a molecule of **4** and selected bond parameters are given in Table 1 The Co_2Ru_6

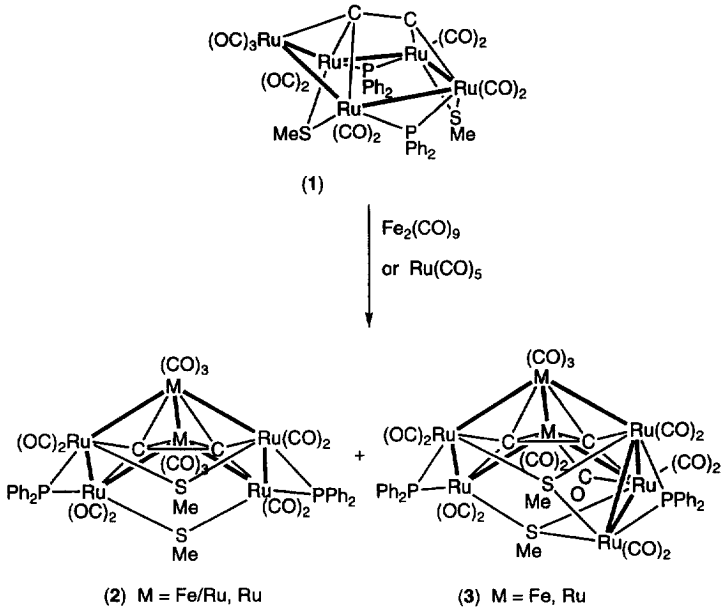
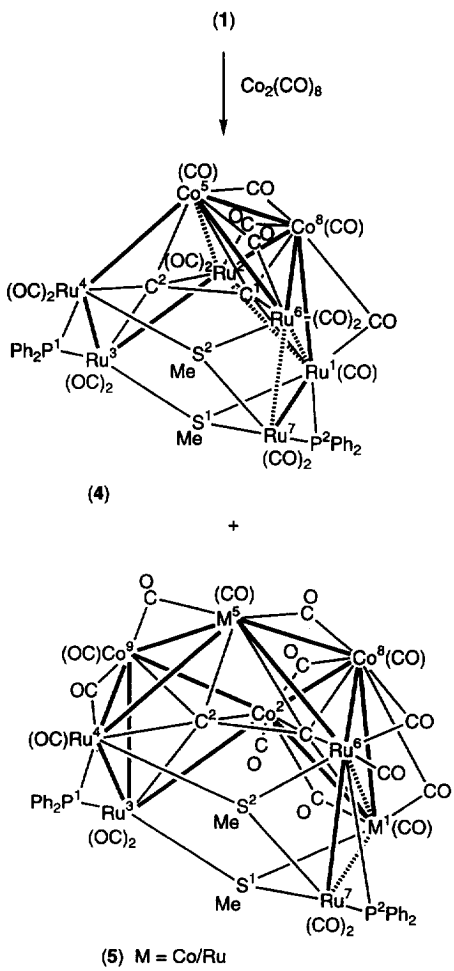


Scheme. 1.



Scheme. 2.

core consists of a permetallabicyclo[2.2.0]hexane skeleton, of which the outer Ru(1)—Ru(6) edge is bridged by Ru(7), with a geometry resembling that found for complexes **3**. The central hinge atoms are Co(5) and Ru(2). The eighth atom, Co(8), caps the square face [Co(5)Ru(1,2,6)] containing the non-bridged outer edge. The C_2 ligand [C(1)—C(2) 1.36(2) Å] links the two square faces and is also close enough to the capping Co(8) atom for there to be a significant bonding interaction with C(1). Only the edge-bridging Ru(7) atom is not attached to the C_2 ligand. The two SMe groups bridge non-bonded Ru···Ru vectors [Ru—S 2.412–2.416(3) and 2.431–2.458(3) Å], while the PPh_2 ligands bridge Ru(1)—Ru(7) and Ru(3)—Ru(4) edges [Ru—P 2.295–2.348(4) Å]. Atoms S(1)Ru(3,4)S(2)Ru(7) form a nearly planar ring [χ^2 2654; maximum deviation, S(1) 0.131(3) Å] as found in complexes **3**. There are also 17 carbonyl groups which complete the coordination of the various metal atoms; of these, four are found associated with the Co(5)—Co(8) [CO(53), bridging], Co(8)—Ru(1) [CO(12), semi-bridging], Co(8)—Ru(2) [CO(23), bridging] and Co(5)—Ru(6) [CO(52), bridging] edges.

The metal–metal bond distances fall into the following groups. The unique Co(5)—Co(8) distance is 2.517(3) Å, which may be compared with the Co—Co separation in $Co_2(CO)_8$ (2.52 Å) [2]. There are two cobalt–ruthenium separations longer than 2.9 Å [Co(5)—Ru(2), Co(8)—Ru(6)] and four others are between 2.610(2) [Co(8)—Ru(2)] and 2.867(2) Å [Co(8)—Ru(1)]. Typical Co—Ru separations are found in $Co_2Ru(\mu\text{-CO})(CO)_{10}$ [2.720(5) Å] [3], $Co_2Ru(\mu_3\text{-}RC_2R')(\mu\text{-CO})(CO)_8$ [non-bridged 2.699(1), 2.690(6) Å; CO-bridged 2.591(2), 2.568(1) Å for R, R′ = H, Bu^t and Ph, Ph, respectively] [4], and

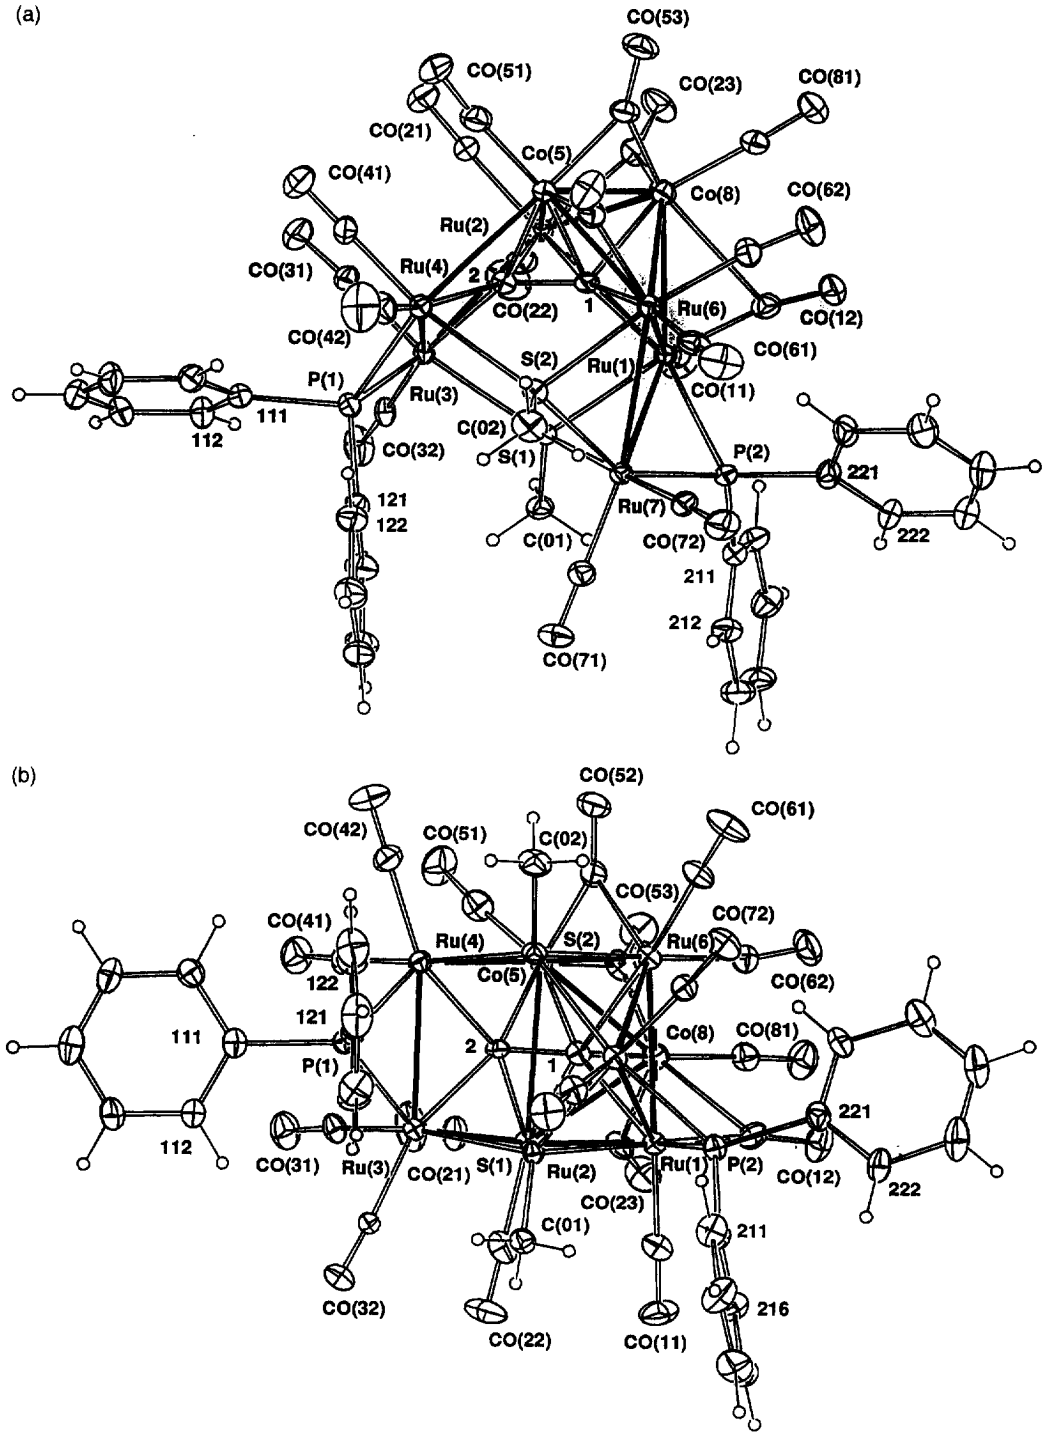


Fig. 1. Plots of two orientations of a molecule of $Co_2Ru_6(\mu_7\text{-}C_2)(\mu_3\text{-}SMe)_2(\mu\text{-}PPh_2)_2(\mu\text{-}CO)_4(CO)_{13}$ (**4**), showing the atom numbering scheme. In this figure and Fig. 2, non-hydrogen atoms are shown with 20% thermal envelopes; hydrogen atoms have arbitrary radii of 0.1 Å.

$Co_2Ru_3(\mu_5\text{-}PhC_2C_2Ph)(\mu\text{-}CO)_2(CO)_{12}$ [2.587, 2.598(1) Å, CO-bridged; 2.643, 2.730(1) Å, non-bridged] [5]. Three Ru—Ru separations are between 2.841(2) [Ru(3)—Ru(4)] and 2.952(2) Å [Ru(1)—Ru(7)] and three exceed 3.0 Å [Ru(1)—Ru(2,6) and Ru(6)—Ru(7)].

The interactions of the C_2 ligand with the metal atoms are similar to those found for carbido clusters,

e.g. Ru—C 2.12(1)–2.200(9) Å and Co—C 2.039(8)–2.05(1) Å, which may be compared with values of about 2.04 Å for the Ru—C(carbide) bonds in $Ru_5C(CO)_{15}$ [6] and of about 1.87(2) Å for the stronger Co—C(carbide) bonds in (trigonal prismatic) $[NEt_4]_2[Co_6C(CO)_{13}]$ [7].

Molecular structure of $Co_4Ru_5(\mu_8\text{-}C_2)(\mu_3\text{-}SMe)_2(\mu\text{-}PPh_2)_2(\mu\text{-}CO)_7(CO)_{11}$ (**5**).

The structure of **5** was reported briefly in our original communication [1], but no extended discussion of the molecular structure has been given until now. Figure 2 gives a plot of a molecule of **5** and selected bond distances and angles are collected in Table 1. The metal cluster consists of two edge-sharing square pyramids, which are also linked by the C_2 ligand in the same fashion as found for **4**. In this complex, atoms Co(8) and Co(9) cap the square faces on opposite sides to the C_2 ligand. Both of these metal atoms are within bonding distance [1.94(3) Å] of the appropriate carbon atoms, with separations which more closely resemble those found for other Co—C(carbide) distances [7].

Disorder is found in the two atom sites M(1,5), with M(1) and M(5) refining to 1/1 Co/Ru in each case. It is interesting that whereas the disorder found in the $FeRu_5$ and Fe_2Ru_5 complexes (**2-Fe** and **3-Fe**) involves the hinge atoms [1], in the present structure only one such atom [M(5)] is disordered, with M(1) being in the opposite corner across the square base. Atom Ru(7) bridges the M(1)—Ru(6) edge. The two SMe groups are in the μ_3 bridging mode, linking atoms M(1)—Ru(3)—Ru(7) and Ru(4)—Ru(6)—Ru(7); here the S(1)Ru(3)Ru(4)S(2)Ru(7) ring is also nearly planar [χ^2 250; maximum deviation, S(1) 0.127(9) Å]. The two PPh_2 ligands bridge Ru(3)—Ru(4) and Ru(6)—Ru(7). Of the 18 carbonyl groups, seven are found bridging various Co—Ru and Ru—Ru bonds.

The spectroscopic properties of the two complexes are in accord with their solid-state structures. The IR ν(CO) spectra contain both terminal and bridging CO absorptions. The ^{1}H NMR spectrum of **4** contains a singlet at δ 1.74 and a doublet at δ 2.85 from the SMe groups, the ^{31}P coupling to the latter signal suggesting that it arises from SMe(2). For **5**, both SMe groups give rise to singlets at δ 1.87 and 1.93. We did not record a ^{13}C NMR spectrum for **4** because of its low solubility; that for **5** contains a low-field resonance at δ 254.9 which is coupled to one of the ^{31}P nuclei, and assigned to the carbons of the C_2 ligand.

These two clusters have interesting electron counts, which can be related in part to the unusual metal separations found in the core; the dicarbon ligand is considered to be a six-electron donor. The skeleton may be derived from a trigonal prism by breaking two M—M bonds to give the permetallabicyclohexane structure. For **4**, where one square is capped by Co and one edge is bridged by Ru, the cluster condensation rules of Mingos [9] predict a C.V.E. count of 118 [square (64) + square pyramid (74) − edge (34) + triangle (48) − edge (34) = 118], or four fewer than found [2 × Co (18) + 6 × Ru (48) + 17 × CO (34) + 2 × SMe (10) + 2 × PPh_2 (6) + C_2 (6) = 122]. For **5**, in which both squares are open [no M—M bond is assumed between M(2) and Co(5) (3.22 Å), as sup-

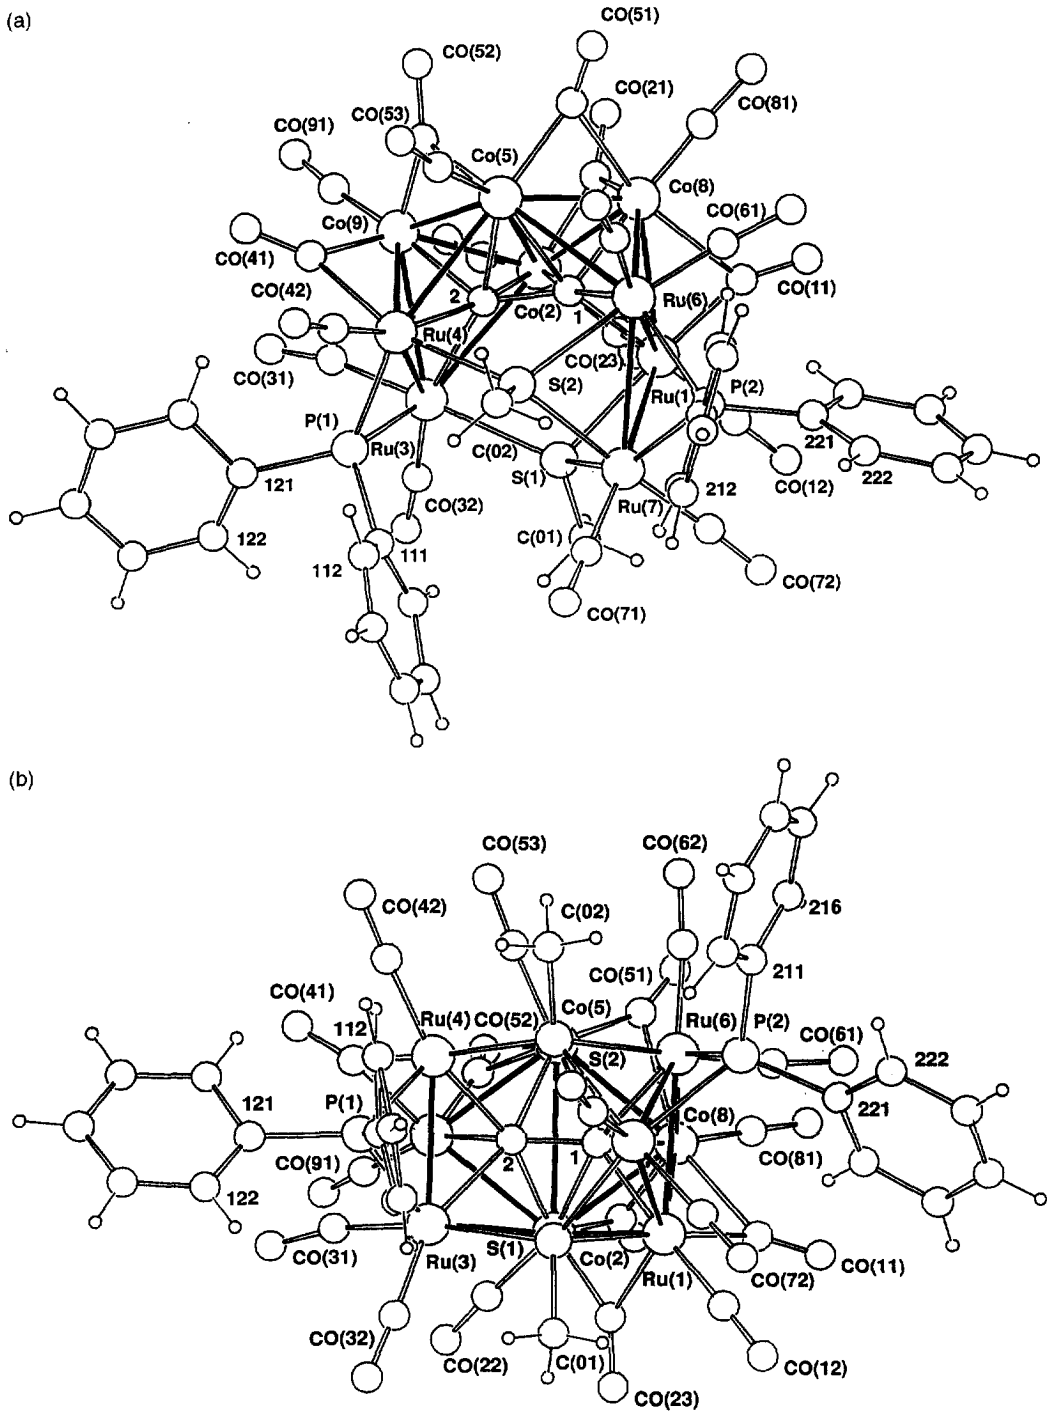

Fig. 2. Plots of two orientations of a molecule of $Co_4Ru_5(\mu_8\text{-}C_2)(\mu_3\text{-}SMe)_2(\mu\text{-}PPh_2)_2(\mu\text{-}CO)_7(CO)_{11}$ (**5**), showing the atom numbering scheme.

ported by EH MO calculations (see below)] and capped by Co atoms, with an edge bridged by the fifth Ru atom, the expected C.V.E. count is 130 [2 × open square pyramid (152) − 2 × shared atoms (36) + triangle (48) − edge (34) = 130]. The observed C.V.E. count for **5** is 134 [4 × Co (36) + 5 × Ru (40) + 18 × CO (36) + 2 × SMe (10) + 2 × PPh_2 (6) + C_2 (6) = 134], which is four more than expected, as found for **4**.

Detailed consideration of these molecular structures shows that several of the M—M separations are longer than 3.0 Å. In these clusters the excess of electron density is considered to be accommodated in

M—M anti-bonding orbitals, delocalised over several metal centres, as found with earlier examples of 50 C.V.E trinuclear clusters [10]. This is confirmed by EH MO calculations in the case of **5**, for instance, which indicate that molecular orbitals in the HOMO region are rather heavily weighted towards the metal atoms (>85%) and slightly M—M anti-bonding [8]. Rather weak M—M overlap populations are computed for **5** overall compared with those computed in smaller M_nC_2 species which obey the Mingos rules [8]. Note that the overlap population for the $M(2)\cdots Co(5)$ separation is slightly negative (−0.01), clearly indicating no bonding interaction. A small but still significant HOMO/LUMO gap (0.60 eV) is calculated for **5**. Further, the interactions of the C_2 ligand with the capping Co atoms weaken the electron density in the C—C bond, leading to a lengthening of this bond [cf 1.36 Å in **4** (with one capping Co), further lengthened to 1.41 Å in **5** (two capping Co atoms)]. This is reflected in the atomic net charges, which show that the two carbons in **5** are less negatively charged than in smaller M_nC_2 species (−1.7/−0.19 vs −0.32 in complex **2-Fe**, for instance) [8].

The C_2 ligand appears to be too large to fit into a trigonal prism, so that the open arrangements found in **4** and **5** (which can be derived from a trigonal prism by cleavage of two M—M bonds) are the most suitable. Larger clusters containing a fully encapsulated C_2 ligand have been described, such as $[NEt_4]_2[Co_6Ni_2(C_2)(\mu\text{-}CO)_8(CO)_8]$ [11] and $[PPh_4]_2[Co_3Ni_7(C_2)(\mu\text{-}CO)_{10}(CO)_6]$ [12]. However, the role of the bridging SMe groups in preventing the clusters in **4** and **5** from closing further cannot be discounted.

The mechanism of formation of **4** and **5** is not easy to discern. We note that there is a good mass balance in its reaction, a total isolated yield of 92% of the two complexes being obtained. Formally, addition of the $Co(CO)_3$ fragment to **1** may proceed in a manner similar to that proposed for the formation of **3** and **4** [13]. However, an additional reaction involving some disproportionation of the ruthenium cluster must occur to allow the sixth Ru atom to be incorporated into **4**.

CONCLUSION

Reactions of **1** with metal substrates have proved to be a rich source of unusual cluster architectures as a result of the C_2 ligand acting as a partial template around which the novel cores can be constructed. In addition, the ability of the SMe groups to act as μ_2 or μ_3 bridging units gives a facility for incorporation of extra metal atoms. Our original MO calculations [14] pointed to localisation of a high lying MO on one of the bridging SMe groups of **1**. The potential for this group to enter into further reactions has been amply demonstrated by the formation of larger clusters such as **2–5**, and points to further exciting chemistry to be derived from **1**.

EXPERIMENTAL

General conditions

All reactions were carried out under dry, high purity nitrogen using standard Schlenk techniques. Solvents were dried and distilled before use. Elemental analyses were by the Canadian Microanalytical Service, Delta, B.C., Canada V4G 1G7. Preparative T.L.C. was carried out on glass plates (20 × 20 cm) coated with silica gel (Merck 60 GF_{254}, 0.5 mm thick).

Reagents. Complex **1** was prepared as described earlier [15]. $Co_2(CO)_8$ (Strem) was used as received.

Instrumentation. IR: Perkin–Elmer 1700X FT IR; 683 double beam, NaCl optics; NMR: Bruker CXP300 or ACP300 (^{1}H NMR at 300.13 MHz, ^{13}C NMR at 75.47 MHz). FAB MS: VG ZAB 2HF (FAB MS, using 3-nitrobenzyl alcohol as matrix, exciting gas Ar, FAB gun voltage 7.5 kV, current 1 mA, accelerating potential 7 kV).

Reaction of **1** *with* $Co_2(CO)_8$

A solution of **1** (75 mg, 0.051 mmol) and $Co_2(CO)_8$ (300 mg, 0.88 mmol) in toluene (10 ml) was heated in a Carius tube at 110°C for 22 h. Solvent was removed and the residue purified by preparative T.L.C. (light petroleum/acetone 10/3).

The major black band (R_f 0.3) was recrystallised from CH_2Cl_2/MeOH to yield black crystals of $Co_2Ru_6(\mu_7\text{-}C_2)(\mu_3\text{-}SMe)_2(\mu\text{-}PPh_2)_2(\mu\text{-}CO)_4(CO)_{13}$ (**4**) (52 mg, 60%). Anal. Found: C, 31.83; H, 1.57%; M, 1690, (mass spectrometry). $C_{45}H_{26}Co_2O_{17}P_2Ru_6S_2$. Calcd C, 32.00; H, 1.55%; M, 1690. IR: ν(CO) (cyclohexane) 2066 m, 2040 s, 2029 vs, 2007 m, 2001 m, 1983 m, 1974 m, 1965 w, 1960 w, 1854 m, 1827 w cm^{-1}. ^{1}H NMR ($CDCl_3$): δ 1.74 (3H, s, SMe), 2.85 (3H, d, J_{HP} 1.7 Hz, SMe), 6.73–7.91 (20H, m, Ph). FAB MS (m/z): 1690 M^+; 1662–1186, $[M-n\text{CO}]^+$ (n = 1–17).

An orange band (R_f 0.6) was recrystallised (CH_2Cl_2/MeOH) to give orange crystals of $Co_4Ru_5(\mu_8\text{-}C_2)(\mu_3\text{-}SMe)_2(\mu\text{-}PPh_2)_2(\mu\text{-}CO)_7(CO)_{11}$ (**5**) (24 mg, 32%). Anal. Found: C, 31.75; H, 1.58%; M, 1735 (mass spectrometry). $C_{46}H_{26}Co_4O_{18}P_2Ru_5S_2$. Calcd C, 31.83; H, 1.50%; M, 1735. IR (cyclohexane): ν(CO) 2065 m, 2041 vs, 2031 s, 2024 s, 2010 m, 2006 (sh), 1995 m, 1988 (sh), 1976 m, 1968 w, 1962 (sh), 1950 vw, 1876 m, 1856 m, 1843 w, 1839 (sh), 1832 w, 1824 w, 1816 (sh) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ 1.71, 2.81 (2 × 3H, s, SMe), 6.85–7.68 (20H, m, pH). FAB MS (m/z): 1735, M^+; 1707–1231, $[M-n\text{CO}]^+$ (n = 1–18).

CRYSTALLOGRAPHY

Unique data sets were measured at ca 295 K within the specified $2\theta_{max}$ limits using an Enraf-Nonius CAD4 diffractometer ($2\theta/\theta$ scan mode; mono-

chromatic Mo–K_α radiation, λ 0.7107$_3$ Å); N independent reflections were obtained, N_o with $I > 3\sigma(I)$ being considered "observed" and used in the full matrix least squares refinement after gaussian absorption correction. Anisotropic thermal parameters were refined for the non-hydrogen atoms; $(x, y, z, U_{iso})_H$ were included constrained at estimated values. Conventional residuals R, R' on $|F|$ are quoted, statistical weights derivative of $\sigma^2(I) = \sigma^2(I_{diff}) + 0.0004\sigma^4(I_{diff})$ being used. Computation used the XTAL 2.6 program system [16] implemented by S. R. Hall; neutral atom complex scattering factors were employed. Pertinent results are given in the figures and tables.

Abnormal features/variations in procedure

(**4**). The solvent molecule as modelled had very high "thermal motion".

(**5**). Possibly consequent on mixed site occupancy in M(1,5), data were weaker and more limited in extent than in **4**, supporting meaningful anisotropic thermal parameter refinement for Ru, Co, S, P only.

Acknowledgements—We thank the Australian Research Council for financial support and Johnson Matthey Technology Centre of a generous loan of $RuCl_3 \cdot nH_2O$. Continuing discussions with Professor J.-F. Halet, Université de Rennes 1, France, are acknowledged.

Structural and bonding trends in rhenium carbonyl cluster chemistry: metal–metal and metal–ligand bond lengths and calculated strengths*

Katherine M. Hillary, Andrew K. Hughes, Karen L. Peat and Ken Wade†

Department of Chemistry, University Science Laboratories, South Road, Durham, DH1 3LE, U.K.

(Received 6 October 1997; accepted 24 November 1997)

Abstract—The published Re—Re bond lengths, d(Re—Re), of neutral and anionic rhenium carbonyl clusters, including those containing hydride ligands and core carbon atoms, $[Re_x(CO)_yH_z]^{c-}$ and $[Re_xC(CO)_yH_z]^{c-}$, have been converted into rhenium–rhenium bond enthalpies, E(Re—Re), using $E(Re—Re) = A\,d(Re—Re)^{-4.6}$ where $A = 2.118 \times 10^{13}$ for d(Re—Re) in picometres and E(Re—Re) in kJ mol^{-1}. Values for the total metal–metal bond enthalpies, ΣE(Re—Re), have been calculated for each cluster. Trends in ΣE(Re—Re) are explored as a function of the cluster nuclearity, x, and the number of electrons donated by the ligands. Trends in ΣE(Re—Re) are also explored as a function of the number of electron pairs involved in cluster bonding, determined by both localised (EAN) and delocalised (PSEPT) models. For the rhenium clusters containing core carbon atoms the total metal–metal bond enthalpy is consistently higher than for other species of similar electron counts, indicating that the metal atoms in such clusters are pulled closer together by the core carbon atoms, which have an effective radius of ca 0.622 Å. Moreover, the addition and removal of ligands from core carbon clusters does not alter ΣE(Re—Re) as greatly as in smaller clusters devoid of core atoms. The $[ReH(CO)_4]_n$ ($n = 2, 3, 4$) clusters are compared and contrasted with the isolobal cycloalkanes, $(CH_2)_n$, and the requirements of octahedral $Re(CO)_4X_2$ fragments and bent Re—H—Re 3c—2e bonds are shown to favour the 6-membered $(ReH)_3$ ring as the strain-free ring. © 1998 Elsevier Science Ltd. Keywords: rhenium; carbonyls; clusters; bond-enthalpies; bond-lengths.

Many fundamental and commercially important reactions of small organic molecules (CO, H_2, alkenes) are catalysed by metal surfaces, and there is a need to understand the thermodynamics and kinetics of these processes. Whilst the overall reaction may involve the conversion of one organic species into another, and the thermodynamics of such species are well understood, the thermodynamics of individual steps at a metal surface are less well defined. Metal carbonyl clusters containing hydride ligands are models of CO and H_2 on metal surfaces, and studies of the thermodynamics of $M_x(CO)_yH_z$ clusters will lead to data for M—CO and M—H bond energies which can be applied to metal-surface processes. In the present paper we focus on the ways in which the attachment of carbonyl and hydride ligands to small rhenium clusters affects the metal–metal bonding therein, as revealed by a detailed study of their metal–metal distances.

In two recent papers [1,2], we have explored the implications of a relationship, $E = A\,d^{-k}$, between the length (d) and strength (E) of metal–metal bonds in transition metal carbonyl clusters, in conjunction with the available experimental thermodynamic data, and shown how one could assess the relative thermodynamic stabilities of osmium carbonyl clusters, $Os_x(CO)_y$, and their hydride and anionic derivatives, from their structures. Our approach assigned bond enthalpies, E(Os—Os), to the individual pairwise (though not necessarily electron pairwise) metal–metal bonding interactions they contained. For the binary osmium carbonyls, we found that the osmium–

† Author to whom correspondence should be addressed.

carbonyl bond enthalpy, E(M—CO), increased slightly, but consistently, as the cluster nuclearity, x, increased, and as the proportion of ligand molecules to metal atoms, y/x, decreased [1]. In examining a wider range of osmium carbonyl clusters, including neutral and anionic species containing hydride ligands, we explored trends in the total metal–metal bond enthalpy, ΣE(Os—Os), as a function of ligand to metal ratio, number of hydride ligands, and the number of electrons formally available to bond the metal atoms [2]. We also estimated limiting values for Os—H bond enthalpies, and drew attention to a relationship between cluster nuclearity and the Os—C and CO bond lengths.

We are now extending the application of our bond length–bond enthalpy relationship to other metals, with the aims of exploring the validity of this relationship, and of utilising the total metal–metal bond enthalpies of clusters to explore and illustrate trends in cluster bonding and geometry. We are also attempting to elucidate values for bond enthalpies E(M—CO) and E(M—H) for a wide range of transition metals. The metal—metal bond enthalpy of the binary rhenium carbonyl, $Re_2(CO)_{10}$, was discussed by us previously [3]. In the current work we consider a wide range of carbonyl clusters of rhenium, including some containing interstitial carbon atoms.

Rhenium clusters pose some contrasts with those of osmium, although the differences between the clusters of these two metals are not as great as those between osmium and other metals. Since rhenium has one electron fewer than osmium, the ligands in a cluster need to provide relatively more electrons in order to achieve electronic saturation. However, this can be difficult without causing steric congestion. As a result, there are few very high nuclearity rhenium clusters, and the majority of pentanuclear and larger clusters contain interstitial carbon atoms, which provide four electrons to the cluster electron count without occupying surface coordination sites. In common with the carbonyl clusters of osmium, the clusters of rhenium tend to have terminal carbonyl ligands. The need to achieve electronic saturation without reaching coordinative saturation means that there are many rhenium clusters which contain formal Re—Re double bonds, a feature to which we shall return. There are series of rhenium clusters having different electron counts for the same number of metal atoms, also a series of similar composition, $[HRe(CO)_4]_n$, but differing nuclearity, n, and these provide opportunities to explore and illustrate trends in the metal–metal bonding.

The basis of our approach is that the metal–metal bonds in metal carbonyl clusters resemble those in the bulk metal sufficiently to permit use of the same bond length–bond enthalpy relationship. The metal–metal bonds in question are relatively weak, much weaker than the metal–ligand bonds, which is why adsorption of ligands such as carbon monoxide molecules on metal surfaces can cause drastic rearrangement of the metal surface atoms [4]. However, despite the relative softness of the metal–metal bonding potential energy well, we consider the use of the bond length–bond enthalpy relationship to be justified, particularly because we focus on the total bond enthalpy, ΣE(M—M), rather than on individual bonds. We feel that the important feature of our method is that we use a single parameter to characterise all the small bond length changes which accompany a chemical change (protonation, ligand addition) to a cluster, and in the case of large clusters this single parameter is easier to interpret than a list of many bond lengths.

RESULTS AND DISCUSSION

It is the basis of our method that the length, d, and enthalpy, E, of individual M—M bonds are described by $E = Ad^{-k}$, where $k = 4.6$ for all transition metals, and the constant A is determined from the atomisation enthalpy and the interatomic distances in the bulk metal. For rhenium $A = 2.118 \times 10^{13}$ for d in picometres and E in kJ mol^{-1}. As in our earliest papers [3,5], we include only nearest neighbour (polyhedron edge) interactions in calculating the total metal–metal bond enthalpy, ΣE(Re—Re) for the Re clusters considered here.

For the crystallographically characterised neutral binary osmium carbonyls we were able to estimate the gas-phase enthalpies of formation from the enthalpy of disruption to gaseous metal atoms and CO, the enthalpy of atomisation of the bulk metal, and the enthalpy of formation of carbon monoxide [1]. This method is based on a knowledge of the experimental enthalpies of formation of some simple binary carbonyls including $Os_3(CO)_{12}$ and $Re_2(CO)_{10}$ [6]. To extend such a study to clusters containing hydride ligands it would be necessary to include E(M—H) terms, and for a cluster containing an interstitial carbon atom, we require knowledge of the enthalpy change associated with the release of a carbon atom from such a site, or of the relationship between M—C distances and associated E(M—C) bond enthalpies. Studies are in progress to investigate these relationships [7]. For the present we consider only the total rhenium–rhenium bond enthalpy, ΣE(Re—Re), for clusters containing interstitial atoms as a function of the electrons they contribute, and investigate patterns and trends in this parameter.

Three main ways of predicting or rationalising the shapes of metal clusters have been explored. One, the treatment of metal clusters as fragments of the bulk metal [8], has evident merit for large clusters, although it is exceedingly difficult to estimate the ligand-bonding capacity of the metal atoms on the fragment surfaces and anyway rhenium is not known to generate high nuclearity clusters. A second approach is to assume that each metal atom obeys the 18 electron rule, by using all nine valence shell orbitals either to bond ligands, to accommodate lone pair electrons,

or to participate in 2-centre 2-electron metal–metal bonds. This approach works well for small clusters such as $[Re_4(CO)_{16}]^{2-}$, indeed for rationalising the metal networks in most of the carbonyls of rhenium, but has limited use for certain important species such as $[Re_6H_7(CO)_{18}]^-$, for which there is an electron pair too many to explain the 12 edges of the octahedron as 2c2e bonds. The 2c2e approach to cluster electron counting, though often helpful in understanding connectivities, is not readily able to predict cluster geometries. The third method of treating the bonding in osmium carbonyl and similar metal clusters, Polyhedral Skeletal Electron Pair Theory, PSEPT [9], exploits the analogy with borane clusters [10]. This too assumes that each metal atom uses all nine valence shell atomic orbitals, six for bonding to carbonyl ligands or accommodating lone pair electrons, the remaining three orbitals being available for metal–metal bonding use. This approach allows many structures to be rationalised or even predicted, including some important systems that appear anomalous in localised bond terms, like the octahedral cluster referred to above. However, it should be noted that PSEPT classifies as skeletal electron pairs some electrons that contribute little or not at all to the actual metal–metal bonding, even though the presence of these (effectively lone pair) electrons does influence the molecular shape. In our discussion of metal–metal bond energies below, we draw attention to some of these features, and analyse the effectiveness with which the available electrons, counted by each of these latter two schemes, are used for metal–metal bonding.

Since the important features of the clusters that we wish to discuss, apart from the metal–metal bond distances, are their polyhedral shapes, the structures of the rhenium carbonyl clusters discussed here are presented in figures in a way that draws attention to the polyhedral shape defined by the metal atoms, the numbers of bonding contacts (polyhedron edge lengths) therein, the numbers and distribution of the carbonyl ligands, and the locations of bridging carbonyl ligands and hydrides. All of these clusters have been structurally characterised by diffraction techniques, the majority using X-ray diffraction, so although the hydrogen atoms have not been located directly, their positions have been deduced by potential energy calculations [11].

Figure 1 shows the structurally characterised examples of neutral rhenium carbonyls, $[Re_x(CO)_y]$, rhenium carbonyl anions, $[Re_x(CO)_y]^{c-}$, and both neutral and anionic rhenium carbonyl hydride clusters, $[Re_x(CO)_yH_z]^{c-}$. We indicate in Table 1 the total metal–metal bond enthalpies, $\Sigma E(Re—Re)$, calculated for these clusters using eqn (1), including all first coordination sphere contacts. The Table also shows the number of skeletal electron pairs according to PSEPT (S_p), the number of electron pair bonds according to a localised (18 electron or EAN) bond model (S_{lb}), and the total metal–metal bond enthalpy per osmium, per PSEPT electron pair and per localised electron pair bond. Several of the anionic rhenium clusters have been characterised as salts with more than one counter-ion. These are indicated in the Table, and the data for only one of these salts are discussed in later sections. The salt $[Re_4H_4(CO)_{15}][NEt_4]_2$ has been crystallographically characterised in three polymorphs, described as Forms I, II and III in Ref. 12. These three polymorphs give very similar $\Sigma E(Re—Re)$ values, as indicated in the Table.

The most informative way to represent the total metal–metal bond enthalpy is to plot the total metal–metal bond enthalpy per rhenium atom, $\Sigma E(Re—Re)/x$, as a function of the number of ligand electrons per rhenium atom, as shown in Fig. 2. As in the case of similar graphs plotted for osmium and rhodium clusters, the data in Fig. 2 fall on or close to a curve, which can be approximately fitted by a second order polynomial showing that the metal–metal bonding becomes stronger as the clusters become larger and the ratio of ligand electrons to metal atoms becomes smaller. The data for Re are more scattered than those for Os and Rh, and large rhenium clusters are only known with multiple hydride ligands, which utilise some of the metal–metal bonding electrons for M—H—M bonding and so reduce the value of $\Sigma E(Re—Re)$. Both of these factors mean that a fit to the data in Fig. 2 extrapolates to give a value for the atomisation enthalpy of bulk Re metal (when the number of electrons per metal equals seven) which is lower than the experimental value (770 kJ mol^{-1}).

We have included examples of crystallographically characterised rhenium carbonyl clusters containing interstitial carbon atoms. Their structures are shown in Fig. 3. We have chosen at this stage to consider only clusters containing interstitial atoms entirely surrounded by metal atoms, where it is clear that all the valence shell electrons of the interstitial atom are involved in cluster bonding. We wish to exclude from the current discussion clusters where heteroatoms bridge surface metal atoms, when some of the valence electrons may be counted as lone pairs. The $[Re_5C(CO)_{16}H]^{2-}$ cluster has been included, since all the valence electrons of the carbon atom are involved in cluster bonding. Table 2 lists the rhenium clusters containing interstitial carbon atoms which have been examined in this study, along with the $\Sigma E(Re—Re)$ value, and the total number of ligand electrons donated to the cluster, where the core carbon atom contributes all of its four valence electrons to the cluster electron count. In the PSEPT bonding model all of the rhenium carbide clusters in the current work formally contain seven skeletal electron pairs, and are thus based on the *nido* square pyramid for the Re_5 cluster, or the *closo* octahedron for Re_6 clusters, with the addition of capping atoms in the case of Re_7 and Re_8 clusters. Figure 2 includes these core carbide systems.

In Fig. 2, the core carbon containing clusters fall on a line approximately parallel with, but above, the line through the non core carbon clusters. This indi-

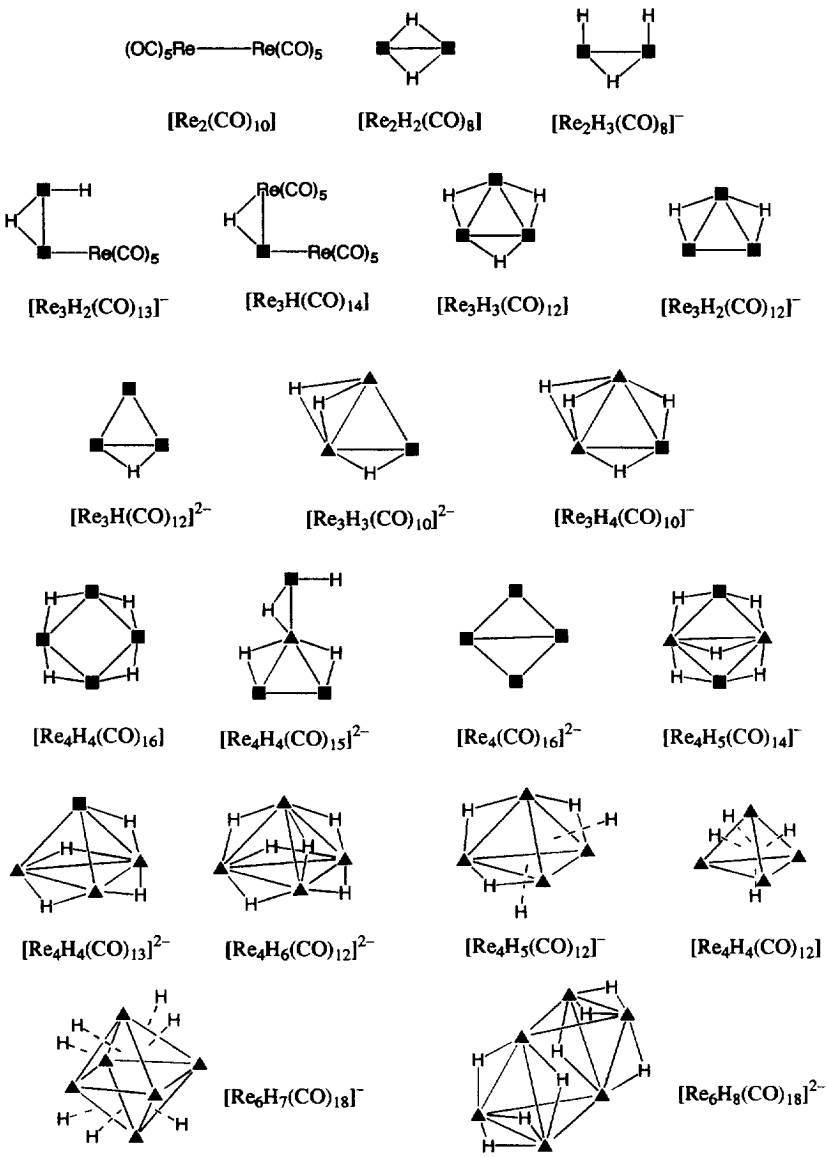

Fig. 1. The structures of the rhenium carbonyl clusters discussed in this work. Lines are drawn to indicate connectivity, and do not imply the presence of single bonds. cates that the metal–metal bonding in the core carbon clusters is stronger than the metal–metal bonding in non core carbon clusters. This trend can be interpreted by considering the structural and electronic effects of introducing a core atom into a rhenium cluster. As indicated in the introduction, there are no examples of large rhenium clusters such as $[Re_6(CO)_{21}]^{2-}$ that do not contain either hydride or core carbon ligands, but if we consider the hypothetical octahedral cluster $[Re_6(CO)_{21}]^{2-}$, and assume that the Re—Re distances will be of the same length or shorter than those in $Re_2(CO)_{10}$ [3.042 Å, E(Re—Re) = 80 kJ mol^{-1}], then the total metal–metal bond enthalpy, ΣE(Re—Re) for $[Re_6(CO)_{21}]^{2-}$ will be $\geqslant$960 kJ mol^{-1}. Replacement of two CO ligands by a core carbon atom gives the known $[Re_6C(CO)_{19}]^{2-}$ cluster, which has ΣE(Re—Re) = 1015 kJ mol^{-1}. This suggests that in the case of octahedral rhenium clusters the introduction of a core carbon atom pulls the rhenium atoms closer together, increasing metal–metal bonding. The transformation of $[Re_6(CO)_{21}]^{2-}$ into $[Re_6C(CO)_{19}]^{2-}$ removes two ligands from the crowded outside of the cluster, and compensates for the electron count by adding a core carbon atom.

The mean Re—Re distance in $[Re_6C(CO)_{19}]^{2-}$ is 3.006 Å, implying a radius for the rhenium atoms of

1. Two molecules in the asymmetric unit, ΣE(Re—Re) = 57.2 kJ mol^{-1} for the second molecule.

2. Data are for $[Re_2H_2(CO)_8]$ co-crystallised with $[Re_3H_3(CO)_{12}]$. An older structure of $[Re_2H_2(CO)_8]$ gives ΣE(Re—Re) = 100.4 kJ mol^{-1}.

3. Data for $[Ph_3PNPPh_3][Re_3H_4(CO)_{10}]$; $[Et_4N][Re_3H_4(CO)_{10}]$ gives ΣE(Re—Re) = 243.2 kJ mol^{-1}.

4. Three polymorphs of $[Re_4H_5(CO)_{15}][NEt_4]_2$ are known, data are given for Form II (EAREHC02), for Form I (EAREHC01) ΣE(Re—Re) = 268.0 kJ mol^{-1}; for Form III (EAREHC) ΣE(Re—Re) = 264.9 kJ mol^{-1}.

5. Although the structure of $[Re_4(CO)_{16}][Et_4N]_2 \cdot 0.5\{(NEt_4)[trans\text{-}ReH_2(CO)_4]\}$ is disordered, the structure is of better quality than $[Bu_4N]_2[Re_4(CO)_{16}]$, for which ΣE(Re—Re) = 431.4 kJ mol^{-1}.

6. Data are for $[BzMe_3N]_2[Re_4H_6(CO)_{12}]$; $(Ph_4As)_2[Re_4H_6(CO)_{12}]$ gives ΣE(Re—Re) = 403.0 kJ mol^{-1}.

7. Data for $[Ph_4As]_2[Re_4H_4(CO)_{13}]$; for $(Et_4N)_2[Re_4H_4(CO)_{13}]$ ΣE(Re—Re) = 449.1 kJ mol^{-1}.

8. Two half-molecules in the asymmetric unit, ΣE(Re—Re) = 489.5 kJ mol^{-1} for other half molecule.

9. $[Re(CO)_3(DMF)_3][Re_3H_4(CO)_9]$ exists as a monomer in solution, the solid-state structure contains the $[Re_6H_8(CO)_{18}]^{2-}$ ion, data are given for the dimer. The three Re—Re bonds of the Re_3 fragment give ΣE(Re—Re) = 222.6 kJ mol^{-1}.

1.503 Å and a radius for the core carbon atom of 1.503×0.414 Å = 0.622 Å, which is rather smaller than the single bond covalent radius of carbon (0.77 Å). Mason has correlated the effective carbon radius for a number of core-carbon metal clusters with the ^{13}C NMR chemical shift [13], and interpreted the strongly deshielded shifts in terms of a "compression" of the interstitial carbon atoms. We note that density-functional theory calculations by Kaupp have proposed an alternative interpretation [14]. Our bond-enthalpy data do not suggest that the core carbon atom is "compressed" to fit into the hole in an octahedral rhenium cluster such as $[Re_6C(CO)_{19}]^{2-}$. Instead we suggest that it should be regarded as a $C^{\delta+}$ ion, with a radius $\leqslant$0.622 Å, which pulls the metal atoms towards it. Furthermore, the idea of a strong "pull" between core carbon atom and the surrounding metal atoms equates to a strong metal-carbon bond enthalpy. We will explore likely values for E(M—C) bond enthalpies in a future paper.

For the clusters in Table 1 the total metal–metal bond enthalpy per localised bond pair ranges from 45 to 85 kJ mol^{-1}. Such a wide range of values indicates that it would be difficult to interpret the thermodynamics of these clusters with a model using a single value for the metal–metal bond enthalpy in rhenium clusters. For the core carbon-containing clusters, the total metal–metal bond enthalpy per localised bond pair covers a very much narrower range of values, providing a further illustration of the influence of the core carbon atoms "pulling" the metal atoms together, giving a metal–metal bond enthalpy which is influenced much less by the ligands around the cluster.

For all of the rhenium carbonyl clusters, we have

1. Data are taken for one of the molecules in the asymmetric unit of VOSLEU, $[Re_6C(CO)_{19}][Ph_4P]_2$; for the other molecule ΣE(Re—Re) = 1008 kJ mol^{-1}; for JOCXAA, $[Re_6C(CO)_{19}][Ph_3PNPPh_3]_2$ ΣE(Re—Re) = 1036.6 kJ mol^{-1}.

2. Data are taken for GEGFUT, $[Re_7C(CO)_{21}H][Et_4N]_2$; for GEGAA, $[Re_7C(CO)_{21}H][Et_4N][C_7H_7]$, ΣE(Re—Re) = 1287 kJ mol^{-1}.

explored correlations between the total metal–metal bond enthalpy and the number of skeletal electron pairs formally available to bond the metal atoms, using a delocalised (PSEPT = Polyhedral Skeletal Electron Pair Theory) bonding model. Table 3 presents the total metal–metal bond enthalpy per PSEPT skeletal electron pair, tabulated as a function of the number of skeletal electron pairs and the cluster structural type (capped-*closo*, *closo*, *nido*, *arachno*, or *hypho*). The metal–metal bond enthalpy per skeletal electron pair increases as the cluster structural type becomes less open (upwards in Table 3), and the available electrons are used for metal–metal bonding, rather than as metal-based lone pairs. Within a given cluster structural type, the metal–metal bond enthalpy increases as the number of skeletal electron pairs or vertices increases.

There are two features of rhenium carbonyl cluster chemistry which we wish to explore using the total

[a] The structure of $[Re_4H_4(CO)_{16}]$ is a square of Re atoms, the $[Re_4H_4(CO)_{15}]^{2-}$ cluster has the alternative spiked triangle geometry.

metal–metal bond enthalpy to quantify structural changes. The first is the presence of series of clusters which have the same empirical formula, namely the $[ReH(CO)_4]_n$ (n = 2–4) series, which are three of the clusters which have 16 valence electrons per metal (or nine ligand electrons per metal), the other examples being $[Re_4H_4(CO)_{15}]^{2-}$, $[Re_3H_2(CO)_{12}]^-$ and $[Re_3H(CO)_{12}]^{2-}$, the latter two being obtained by successive deprotonations of $[ReH(CO)_4]_3$. The second feature is the presence of two series of clusters containing three and four metal atoms, with varying electron counts, and hence structures which vary between very open clusters and unsaturated closed clusters.

As in our previous discussion of hydride-containing osmium carbonyl clusters, we note that the "hydride" ligand in a general mono-hydride cluster $[Re_xH(CO)_y]^{c-}$ can be formally regarded as an H^+ ion protonating the hydride-free $[Re_x(CO)_y]^{(c+1)-}$ cluster. Terminal hydrides may be regarded as resulting from the protonation of metal-based lone pairs, whereas (μ_2-H) ligands may be regarded as resulting from protonation of a 2c2e metal–metal bond, converting the two centre Re—Re bond pair into a three-centre two-electron Re(μ-H)Re system. Triply-bridging hydride ligands on a cluster face result from the protonation of a three-centre two-electron Re_3 bond. In such a formalism, the doubly hydride-bridged bonds of $[Re_2H_2(CO)_8]$ can be regarded as resulting from the addition of two H^+ ions to $[Re_2(CO)_8]^{2-}$ (cf B_2H_6 derivable from $[B_2H_4]^{2-}$: these systems are both analogues of C_2H_4). Each protonation converts one electron pair of the double bond into a three-centre two-electron bond*.

The photochemical and thermal interconversion of the three rhenium clusters $[ReH(CO)_4]_n$ (n = 2–4) has been described together with their solid-state structures, and these clusters have been described as organometallic analogues of the $(CH_2)_n$ molecules ethene, cyclopropane and cyclobutane, possessing respectively four, six and eight skeletal electron pairs according to PSEPT, although the analogy also holds in a localised bond description. In fact, given the presence of bridging hydrides in these rhenium clusters, they might be better described as analogues of B_2H_6, B_3H_9 and B_4H_{12}, though the latter boranes are only postulated as reactive intermediates in borane reactions. The anionic spiked-triangular cluster $[Re_4H_4(CO)_{15}]^{2-}$ is formally an analogue of methylcyclopropane; the spiked triangle presents a structure with four Re—Re bonds, three of which are protonated/bridged by hydride ligands, the final hydride is terminally located on the spike atom. Studies of the thermochemistry of cyclopropane, cyclobutane and cyclopentane show that these cycloalkanes have a measurable ring-strain [15], associated with their bond angles deviating from the ideal tetrahedral angle (109°) since their structures require eclipsed C—C—C fragments, with bond angles of 60°, 90° and 108°, respectively. Cyclohexane is strain-free, since the chair conformation allows staggered bonds and angles of 109°. In contrast, the structures of the cyclic rhenium clusters $[ReH(CO)_4]_n$ (n = 3 and 4) are based on octahedral metal fragments, and so the preferred angle for a strain-free structure would appear to be 90°. A further feature is that three centre two electron M—H—M bonds are bent at the hydrogen. Figure 4 shows the equatorial projections (the axial CO ligands are omitted) of the hypothetical hydride-free clusters $[Re_3(CO)_{12}]^{3-}$ and $[Re_4(CO)_{12}]^{4-}$ constructed using strictly octahedral metal geometries. For the cluster $[Re_3(CO)_{12}]^{3-}$, (a), the Re_3 ring will be strained, since the Re—Re—Re angles will be 60° rather than 90°, but the protonation to form $[Re_3H_3(CO)_{12}]$ (b), with bent 3c—2e bonds will relieve the strain. By contrast, for the cluster $[Re_4(CO)_{12}]^{4-}$ a square geometry, (d), would be strain-free, and the addition of four protons along the Re—Re edges to give bent at hydrogen 3c—2e bonds will introduce strain, minimised by placing two protons inside the ring and two outside, (e). The published structure of $[Re_4H_4(CO)_{16}]$ resembles (e). Although the hydrogen atoms were not located in electron density maps, their locations were deduced from potential energy calculations. The crystal structure of $[Re_4H_4(CO)_{16}]$ does present the short and long non-bonded carbonyl contacts suggested by Fig. 4e. The conclusion that can be drawn is that the combination of octahedral metal coordination and bent 3c—2e bonds makes the $[Re_3H_3(CO)_{12}]$ cluster strain-free, whilst the non-bonded contacts in $[Re_4H_4(CO)_{16}]$ make this a strained ring. This conclusion is borne out by the fact that the total metal–metal bond enthalpy for the four bonds of $[Re_4H_4(CO)_{16}]$ (182 kJ mol^{-1}) is barely greater than that for the three bonds of $[Re_3H_3(CO)_{12}]$ (179.5 kJ mol^{-1}). There are thus different trends in ring-strain as a function of ring size in the $(CH_2)_n$ and $[ReH(CO)_4]_n$ systems, a consequence of the differences between tetrahedral and octahedral coordination together with the nonlinear nature of M—H—M bonds.

Progressive deprotonation of $[Re_3H_3(CO)_{12}]$ would be expected to introduce progressively greater ring-strain, so reducing ΣE(Re—Re) for this trinuclear cluster, whereas deprotonation of $[Re_4H_4(CO)_{16}]$ would be expected to increase ΣE(Re—Re) as ring strain, and non-bonded repulsions are reduced. A corollary is that $[Re_4H_4(CO)_{16}]$ should be a stronger Brönsted acid than $[Re_3H_3(CO)_{12}]$.

It is worth noting that $[Re_4H_4(CO)_{15}]^{2-}$ has the spiked triangular skeleton that is more suited to its degree of protonation than a square skeleton would be.

The total metal–metal bond enthalpies for the rhenium carbonyl clusters containing three and four rhenium atoms are presented in Tables 4 and 5 listed according to the number of cluster valence electrons.

*Many textbooks and papers draw a structure for complexes such as $[Re_2H_2(CO)_8]$ with a double bond and two bridging hydrides, which is misleading.

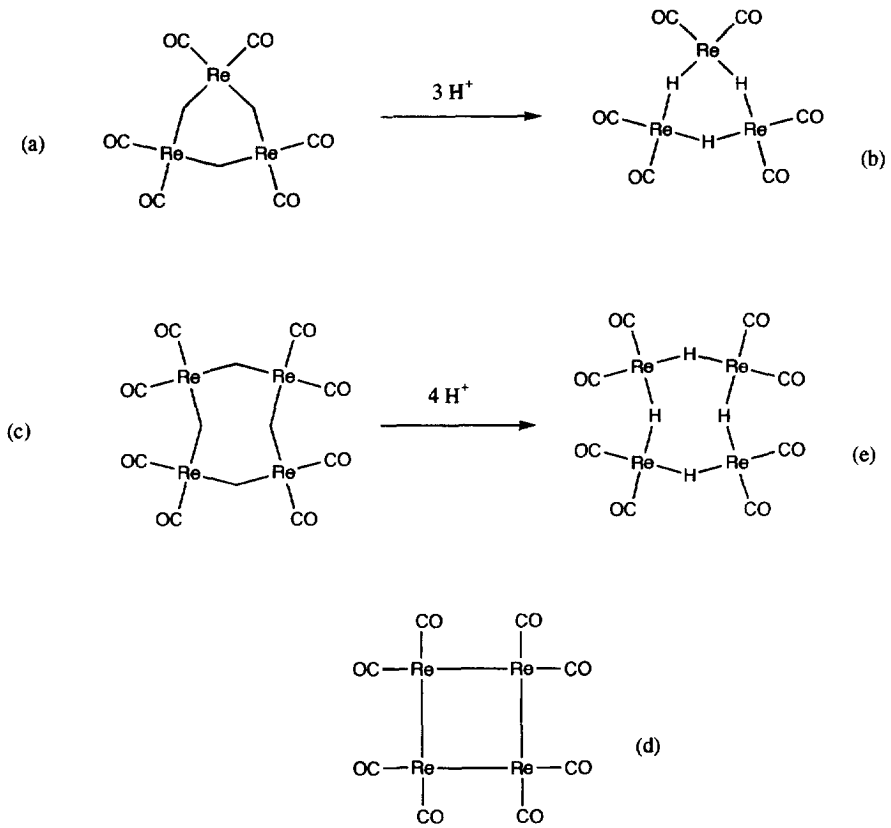

Fig. 4. The clusters $[Re_3(CO)_{12}]^{3-}$ and $[Re_4(CO)_{16}]^{4-}$ constructed using octahedral metal fragments, with all angles 90°. As shown, addition of protons forming bent Re—H—Re bonds gives the known $[Re_3H_3(CO)_{12}]$ and $[Re_4H_4(CO)_{16}]$ clusters. Only the equatorial planes of the clusters are drawn, the axial carbonyl ligands are omitted.

Table 4. The Re_3 clusters studied in this work and the calculated total metal–metal bond enthalpy, ΣE(Re—Re) in kJ mol^{-1}, for each cluster, tabulated as a function of electron count, and the departure of cluster formula from the parent $[Re_3H_3(CO)_y]$ clusters. Those parent clusters in italics are not structurally known, but are included for the purposes of constructing the table. The Tables show the equivalent number of PSEPT skeletal electron pairs and number of formal Re—Re bonds required to satisfy the 18 electron rule. The structures of the clusters are presented in the form of the connectivities and bond orders of the underlying metal cores, although the clusters are more delocalised than the representation given by the figures, thus, there are two bonds of formal bond order 1.5 in $[Re_4H_5(CO)_{12}]^-$, but the bonds in $[Re_4H_4(CO)_{12}]$ all have the same bond order. The vertical layout of the

data for the Re_3 clusters is centred about the $[Re_3H_3(CO)_y]$ ($y = 11$–13) clusters, only one of which is known, with vertical steps representing the formal reactions shown at the left. The Re_4 clusters are presented as based on $[Re_4H_4(CO)_y]$ ($y = 12$–16), although only the most open cluster, $[Re_4H_4(CO)_{16}]$, and the most closed example, $[Re_4H_4(CO)_{12}]$, are known. For both the Re_3 and Re_4 series there is the expected trend for the total metal–metal bond enthalpy to decrease as the number of skeletal electron pairs increases and the cluster becomes more open. For the Re_4 clusters there is a steady trend in the total metal–metal bond enthalpy of the most hydride-rich clusters. When presented as a function of the number of formal localised Re—Re bonds, as in Table 1, it becomes clear that the total metal–metal bond enthalpy per formal metal–metal bond is also not constant, indicating that any analysis of the thermodynamics of metal carbonyl clusters using a model which has fixed metal–metal bond enthalpies will be flawed.

There are three classes of clusters which are related by reactions which formally involve the loss or gain of ligands. Thus there are pairs of rhenium carbonyl clusters which are related by the addition or loss of a proton, there are also pairs of clusters which are formally related by the reductive elimination of H_2 followed by the addition of CO to maintain the same number of electrons, and there are clusters where formally a CO ligand is removed and two electrons added. These cluster interconversion reactions are listed in Table 6 together with the total metal–metal bond enthalpies of the pairs of clusters, and the change in $\Sigma E(Re—Re)$ for the formal reaction. A number of features can be noted from the data in Table 6. All ligand interchange reactions involving clusters containing interstitial carbon atoms result in much smaller changes in the metal–metal bonding enthalpies than similar reactions involving clusters which do not contain interstitial atoms. This suggests that the metal–metal bond distances in core carbon containing clusters are not very sensitive to ligand exchange, and may be largely determined by the bonding or steric requirements of the core carbon atom. The addition of a proton to the small clusters produces a loss in metal–metal bonding between 25 and 32 kJ mol^{-1}, all three examples involving the protonation of a metal–metal bond pair. The loss in metal–metal bonding will be compensated for by the E(cluster-H) bond enthalpy (on which there are at present no thermochemical experimental data). Similarly, replacement of two hydride ligands (as H_2) by CO produces a gain in metal–metal bonding as 3c—2e Re—H—Re bonds are replaced by two centre Re—Re and Re—CO bonds.

The gold phosphine fragment, $Au(PPh_3)^+$, is isolobal with the proton, so the mixed-metal rhenium gold cluster $\{Re_7C(CO)_{21}[Au(PPh_3)]\}^{2-}$ is a direct analogue of $[Re_7C(CO)_{21}H]^{2-}$. The total metal–metal bond enthalpy for the gold cluster is 28 kJ mol^{-1} less than the metal–metal bond enthalpy of $[Re_7C(CO)_{21}]^{3-}$, indicating that some metal–metal bonding is lost on introduction of the gold vertex, which is presumably compensated for by Re—Au bonding. However, whilst the hydride ligand in $[Re_7C(CO)_{21}H]^{2-}$ bridges an edge, the gold fragment in $\{Re_7C(CO)_{21}[Au(PPh_3)]\}^{2-}$ is located in a triply bridging mode on the face opposite the capping Re atom.

Earlier we discussed the replacement of two CO ligands in the hypothetical $[Re_6(CO)_{21}]^{2-}$ by a core

Table 6. Pairs of rhenium carbonyl clusters which are related by addition and removal of ligands and or electrons. (c) Replacement of a CO ligand by two electrons ($-CO+2e^-$)		
$[Re_4H_4(CO)_{16}] \rightarrow [Re_4H_4(CO)_{15}]^{2-}$	182.2 → 264.3	+82.1
$[Re_7C(CO)_{22}]^- \rightarrow [Re_7C(CO)_{21}]^{3-}$	1291 → 1302	+11

carbon to give $[Re_6C(CO)_{19}]^{2-}$, and estimated the total metal–metal bond enthalpy of $[Re_6(CO)_{21}]^{2-}$ to be $\geqslant 960$ kJ mol^{-1}. Alternatively removal of one H^+ [$\Delta\Sigma$(Re—Re) = 30 kJ mol^{-1}] and replacement of three H_2 groups by CO ligands [$\Delta\Sigma$(Re—Re) $\geqslant 3 \times 40$ kJ mol^{-1}] will convert $[Re_6H_7(CO)_{18}]^-$ [ΣE(Re—Re) = 774.5 kJ mol^{-1}] into $[Re_6(CO)_{21}]^{2-}$ giving an alternative estimate of ΣE(Re—Re) $\geqslant 925$ kJ mol^{-1} for $[Re_6(CO)_{21}]^{2-}$.

The highly unsaturated cluster $[Re_3H_4(CO)_9]^-$ is interesting in that it formally contains two Re—Re double bonds (which are protonated) [16] and is thus an analogue of the unknown cyclopropadiene. Although conductivity data indicate that this cluster exists as a monomer in solution, in the solid state the electronic unsaturation is relieved by the formation of a dimer $[Re_6H_8(CO)_{18}]^{2-}$, the structure of which is a trigonal antiprism, or octahedron elongated along one of the S_3 axes. The four Re—Re bonds which are broken on converting the dimer into the monomer provide a metal–metal bond enthalpy of 175 kJ (mol of dimer)$^{-1}$. This substantial bond enthalpy is lost on forming the monomer in solution, suggesting that dissociation of the dimer is likely to be a process favoured by entropy, and the likelihood that the three Re—Re bonds in the monomer are shorter, and stronger, than the same bonds in the solid-state dimer. In analysing the data, we have considered this cluster in its dimeric form, and the data in Fig. 2 relate to $[Re_6H_8(CO)_{18}]^{2-}$.

CONCLUSIONS

We have shown that the total metal–metal bond enthalpy of a rhenium carbonyl cluster provides a single parameter to characterise the metal–metal bonding. Changes in bond lengths on the addition of protons and carbonyl ligands can be quantified through the total metal–metal bond enthalpy. We have investigated trends in the metal–metal bond enthalpy of rhenium carbonyl clusters as a function of the number of electrons available for bonding in both localised (18 electron or EAN) and delocalised (PSEPT) bonding models. For rhenium clusters containing core carbon atoms the metal–metal bond enthalpy is higher than for clusters with similar electron counts devoid of core carbon atoms, and we interpret this as a consequence of the attractive pull of a cationic core carbon, $C^{\delta+}$, on its surrounding metal atoms. A core carbon atom apparently requires less space (radius 0.622 Å) than octahedral rhenium carbonyl clusters held together by seven skeletal electron pairs would normally make available.

EXPERIMENTAL

Fractional atomic coordinates for $[Re_2(CO)_{10}]$ [17], $[Re_2H_3(CO)_8][Et_4N]$ [18], $[Re_3H(CO)_{14}]$ [19], $[Re_3H(CO)_{12}][Et_4N]_2$ [20], co-crystallised $[Re_2H_2(CO)_8]$ $[Re_3H_3(CO)_{12}]$ [21], $[Re_4H_4(CO)_{16}]$ [21], $[Re_3H_2(CO)_{12}][Ph_4As]$ [22], $[Re_4H_5(CO)_{14}][Et_4N]$ [23], $[Re_3H_4(CO)_{10}][Ph_3PNPPh_3]$ [24], $[Re_4H_6(CO)_{12}][BzMe_3N]_2$ [25], $[Re_4H_4(CO)_{13}][Ph_4As]_2$ [26], $[Re_4(CO)_{16}][Bu_4N]_2$ [27], $[Re_4H_5(CO)_{12}][Et_4N]$ [28], $[Re_6H_7(CO)_{18}][Et_4N]$ [29], $[Re_4H_4(CO)_{12}]$ [30], $[Re_6C(CO)_{18}H][Et_4N]_3$ [31], $[Re_5C(CO)_{16}H][Et_4N]_2$ [32], $[Re_7C(CO)_{21}H][Et_4N]_2$ and $[Re_7C(CO)_{21}H]$ $[Et_4N][C_7H_7]$ [33], $[Re_7$

$C(CO)_{21}H_2][Et_4N]$ [34], $[Re_7C(CO)_{21}][Ph_4P]_3$ [35], $[Re_6C(CO)_{19}H][Et_4N]$. CH_2Cl_2 [36], $[Re_6C(CO)_{19}][Ph_4As]_2$ [36], $[Re_7C(CO)_{22}]$ $[Et_4N]$ [37] and $\{Re_7C(CO)_{21}[Au(PPh_3)]\}[Ph_4As]_2$ [38] were retrieved from the Cambridge Structural Database [CSD April 1997 release, version 5.11 on the University of Durham UNIX network) [39] using QUEST and metal–metal distances were evaluated using BABEL [40]. The fractional atomic coordinates for Forms I and II of $[Re_4H_4(CO)_{15}][Et_4N]_2$ were retrieved from the CSD [12], the Re—Re bond lengths of Form III were also retrieved from Ref. 12. Fractional atomic coordinates for $[Re_2H_2(CO)_8]$ [41], $[Re_4(CO)_{16}][Et_4N]\cdot 0.5\{[NEt_4]$-*trans*-$ReH_2(CO)_4\}$ [20], $[Re_3H_4(CO)_{10}][Et_4N]$ [43], and $[Re_3H_3(CO)_{10}][NEt_4]_2$ [43], $[Re_4H_6(CO)_{12}]$ $[Ph_4As]_2$ [44], $[Re_4H_4(CO)_{13}][Et_4N]_2$ [45], $[Re_6C(CO)_{18}H_2][MePh_3P]_2$ [46], $[Re_6C(CO)_{19}]$ $[Ph_3PNPPh_3]_2$ [47], and $[Re_8C(CO)_{24}][Et_4N]_2$ [48], are not available in either the CSD or the Inorganic Crystal Structure Datafile (ICSD) or in the original publications, and metal–metal distances were retrieved directly from figures or tables in the publications. The structures of $[Re_3H_2(CO)_{13}][NEt_4]$ [49], and $[Re(CO)_3$ $(DMF)_3]_2[Re_3H_4(CO)_9]_2$ [15] were published whilst this work was in progress, and data is not available from the CSD at the time of writing this manuscript; for these clusters metal–metal distances were retrieved from the publications.

Kaleidagraph running on a Mac LCII was used to draw Fig. 2, relating the total Re—Re bond enthalpy per metal atom $\Sigma E(Re—Re)/x$, to the number of ligand electrons per metal atom.

The Re—Re distances used in this work are without e.s.d.s since they were derived from fractional atomic coordinate data available from the Cambridge Structural Database which does not contain e.s.d.s, and in many cases complete lists of Re—Re distances are not available in the original publication, so we are unable to extract e.s.d.s from that source; as indicated previously [1], we feel that the crystallographic contribution to the errors in $\Sigma E(Re—Re)$ is less than 1 kJ mol^{-1}. In contrast the e.s.d.s on M—C and C—O distances are typically larger, reflecting the lighter atomic masses of these elements and libration of carbonyl ligands, and mean that any attempt to estimate Re—C and C—O bond enthalpies from current crystallographic data will result in large estimated errors.

(Received 27 September 1997; accepted 3 December 1997)

Abstract—*Para*-cymene ruthenium dichloride dimer reacts in aqueous solution with sodium molybdate or sodium vanadate to give the amphiphilic clusters $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)_4Ru_4Mo_4O_{16}]$ (**1**) and $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)_4Ru_4V_6O_{19}]$ (**4**) respectively. The analogous reaction of hexamethylbenzene ruthenium dichloride dimer with sodium vanadate gives $[(\eta^6\text{-}C_6Me_6)_4Ru_4V_6O_{19}]$ (**5**). The mixed-metal clusters $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)Ru(\eta^5\text{-}C_5Me_5)_3Rh_3Mo_4O_{16}]$ (**2**) and $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)_2Ru_2(\eta^5\text{-}C_5Me_5)_2Rh_2Mo_4O16]$ (**3**) are accessible from a mixture of *para*-cymene ruthenium dichloride dimer and pentamethylcyclopentadienyl rhodium dichloride dimer with sodium molybdate in aqueous solution. The crystal structure analyses of **1** and **4** reveal different framework geometries of the metal oxygen skeletons. ^{17}O NMR spectroscopy and partial charge calculations confirm the presence of three different types of oxygen atoms in **1**. © 1998 Elsevier Science Ltd. Keywords: arene; ruthenium; molybdenum; vanadium; oxo clusters; X-ray structure.

The past two decades have witnessed a steadily growing interest in molecules containing both, organometallic groups and oxometallic entities [1]. Such clusters are accessible by metathesis reaction between an organometallic halide and an oxometallic anion.

$$(\eta^5\text{-}C_5H_5)TiCl_3 + [H_3PW_{11}O_{39}]^{4-} \rightarrow [(\eta^5\text{-}C_5H_5)Ti(PW_{11}O_{39})]^{4-} + 3HCl$$

Since the discovery of $[(\eta^5\text{-}C_5H_5)Ti(PW_{11}O_{39})]^{4-}$ in 1978 by W. G. Klemperer and co-workers [2], a large number of organometallic oxide complexes have been prepared, in particular by W. G. Klemperer [3], K. Isobe [4] and R. G. Finke [5]. This type of compound contains soft as well as hard metal centers and hydrophobic as well as hydrophilic ligands. The combination of low- and high-valent transition metals and the amphiphilic character predispose these molecules also as homogeneous catalysts for oxidation reactions; the catalytic potential of these compounds has been reviewed recently [6]. Furthermore organometallic oxo clusters provide molecular models for heterogeneous catalysts derived from organometallic complexes adsorbed at metal oxide surfaces [7].

Recently, in a preliminary communication, we reported the neutral amphiphilic cluster $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)_4Ru_4Mo_4O_{16}]$ (**1**) which was found to present a unique framework geometry [8]. In this paper we extend our study to hexamethylbenzene ruthenium and pentamethylcyclopentadienyl rhodium units as well as to vanadate. Thus, the synthesis and characterisation of $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)Ru(\eta^5\text{-}C_5Me_5)_3$

$Rh_3Mo_4O_{16}$] (**2**) [(η^6-*p*-$MeC_6H_4iPr)_2Ru_2(\eta^5$-$C_5Me_5)_2Rh_2Mo_4O_{16}$] (**3**), [(*p*-$MeC_6H_4iPr)_4Ru_4V_6O_{19}$] (**4**) and [($\eta^6$-$C_6Me_6)_4Ru_4V_6O_{19}$] (**5**) are reported; in addition we describe the characterisation of the three different types of oxygen atoms in **1** by ^{17}O NMR spectroscopy and by electron-density calculations.

RESULTS AND DISCUSSION

The *para*-cymene complex [(η^6-*p*-$MeC_6H_4iPr)_2Ru_2Cl_4$] reacts with Na_2MoO_4 in aqueous solution at room temperature to give the neutral organoruthenium oxomolybdenum cluster [(η^6-*p*-$MeC_6H_4iPr)_4Ru_4Mo_4O_{16}$] (**1**) only. Complex **1** is sparingly soluble in water and aromatic hydrocarbons, and well soluble in polar organic solvents such as dichloromethane or methanol.

$$2[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)_2Ru_2Cl_4] + 4Na_2MoO_4 \rightarrow [(\eta^6\text{-}p\text{-}MeC_6H_4iPr)_4Ru_4Mo_4O_{16}] + 8NaCl \quad (1)$$

Single-crystal X-ray structure analysis of **1**·2 C_6H_5Me (orange, rod-like crystals) revealed the molecule to contain a unique $Ru_4Mo_4O_{12}$ framework which can be described as a central Mo_4O_4 cube with four folded ORuO flaps resembling the sails of a windmill. The molecular structure of **1** is depicted in Fig. 2. Important bond lengths and angles are presented in Table 1. The distortion [Mo(2)—O(2)—Mo(1) 106.04(12)°, O(12)—Mo(1)—O(2) 71.37(10)°] with respect to the idealized cubic representation is due to the geometry of the oxygen atoms of the central cube which is more tetrahedral than octahedral. Eight of the twelve framework oxygen atoms are doubly bridging, while four are quadruply bridging. Each ruthenium atom is coordinated to an η^6-*p*-cymene ligand [Ru(1)—C6 ring centroid 1.627 Å], and each molybdenum atom carries a terminal oxo ligand [Mo(1)—O(7) 1.706(3) Å].

A calculation of the charge distribution in **1**, based on the application of the partial charge model [9], to the structural data of **1** gave the following results: The partial charge on the four ruthenium atoms is +1.093, and on the four molybdenum atoms +1.737, reflecting the electronegativity difference between ruthenium and molybdenum. The four *p*-cymene ligands have a partial charge of −0.412, whereas there is a clear differentiation of the different oxo ligands: The terminal oxo ligands (O_4, O_7, O_8 and O_{14}) have a partial charge of −0.492, the doubly bridging oxo ligands (O_1, O_3, O_5, O_6, O_{10}, O_{11}, O_{13} and O_{16}) −0.578, and the quadruply bridging oxo ligands (O_2, O_9, O_{12} and O_{15}) −0,769. Thus, the electronic density driven from the metal atoms has flown mainly onto oxo atoms, but also onto the aromatic ligands. It is interesting to note the strong discrimination among the oxygen atoms due to their relative structural environment, with the lowest electronic structural density found on the terminal oxygen atoms.

The three different types of oxygen atoms in **1** are also confirmed by ^{17}O NMR spectroscopy: A sample of **1**, enriched in ^{17}O, prepared from enriched Na_2MoO_4, gives rise to three completely resolved signals, in addition to the signal of the MoO_4^{2-} anion at δ 748 ppm. These signals can be easily assigned on the basis of a qualitative correlation between the shift of ^{17}O signal and the decreasing number of metal centres bound to the oxygen atom [10]. Thus, the signal at δ 783 ppm corresponds to the four terminal (μ_1) oxygen atoms in **1**, while the eight doubly bridging (μ_2) and the four quadruply bridging (μ_4) oxygen atoms give rise to a resonance at δ 21 and −7 ppm, respectively.

Sodium molybdate reacts with a 1:1 mixture of *para*-cymene ruthenium dichloride dimer and pentamethylcyclopentadienyl rhodium dichloride dimer

in aqueous solution to yield a mixture of mixed ruthenium-rhodium complexes, from which $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)Ru(\eta^5\text{-}C_5Me_5)_3Rh_3Mo_4O_{16}]$ (**2**) and $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)_2Ru_2(\eta^5\text{-}C_5Me_5)_2Rh_2Mo_4O_{16}]$ (**3**) can be isolated by thin-layer chromatography.

$$1/2[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)_2Ru_2Cl_4] + 3/2[(\eta^5\text{-}C_5Me_5)_2Rh_2Cl_4] + 4Na_2MoO_4Na_2 \rightarrow [(\eta^6\text{-}p\text{-}MeC_6H_4iPr)Ru(\eta^5\text{-}C_5Me_5)_3Rh_3Mo_4O_{16}] + 8NaCl \quad (2)$$

$$[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)_2Ru_2Cl_4] + [(\eta^5\text{-}C_5Me_5)_2Rh_2Cl_4] + 4Na_2MoO_4Na_2 \rightarrow [(\eta^6\text{-}p\text{-}MeC_6H_4iPr)_2Ru_2(\eta^5\text{-}C_5Me_5)_2Rh_2Mo_4O_{16}] + 8NaCl \quad (3)$$

The two mixed ruthenium-rhodium clusters **2** and **3** have a very similar infrared spectrum which, however, differs significantly from that of **1** but resembles the Mo—O absorption pattern of the known [4a] rhodium cluster $[(\eta^5\text{-}C_5Me_5)_4Rh_4Mo_4O_{16}]$. Both **2** and **3** show two strong bands at 925, 898 cm^{-1} and 927, 901 cm^{-1} respectively, which can be assigned to the vibrations of the terminal Mo=O bonds. Characteristic absorptions at 689, 642, 584, 538 cm^{-1} (**2**) and 692, 641, 587, 538 cm^{-1} (**3**) are attributed to the Mo—O vibrations of the internal oxygen atoms, in line with the assignment proposed by K. Isobe *et al.* for $[(\eta^5\text{-}C_5Me_5)_4Rh_4Mo_4O_{16}]$ [4a]. On the basis of the infrared spectra, it can be concluded that the mixed ruthenium-rhodium clusters **2** and **3** do not adopt the structure of the windmill-like ruthenium cluster **1**, but the triple cube-like structure of the rhodium cluster $[(\eta^5\text{-}C_5Me_5)_4Rh_4Mo_4O_{16}]$. Accordingly, the ^1H NMR spectrum of **2** shows a 1 : 3 ratio of the *p*-cymene and pentamethylcyclopentadienyl signals. However, there are three possibilities of replacing two $(C_5Me_5)Rh$ units in $[(\eta^5\text{-}C_5Me_5)_4Rh_4Mo_4O_{16}]$ by two $(\eta^6\text{-}p\text{-}MeC_6H_4iPr)Ru$ fragments, so that three isomers can be expected for **3**. Indeed, the ^1H NMR spectrum reveals **3** to be a mixture of at least two isomers, because, instead of one CH_3 doublet of the isopropyl substituent of the *p*-cymene ligand, two doublet signals centrered at $\delta = 1.38$ and 1.37 ppm are observed.

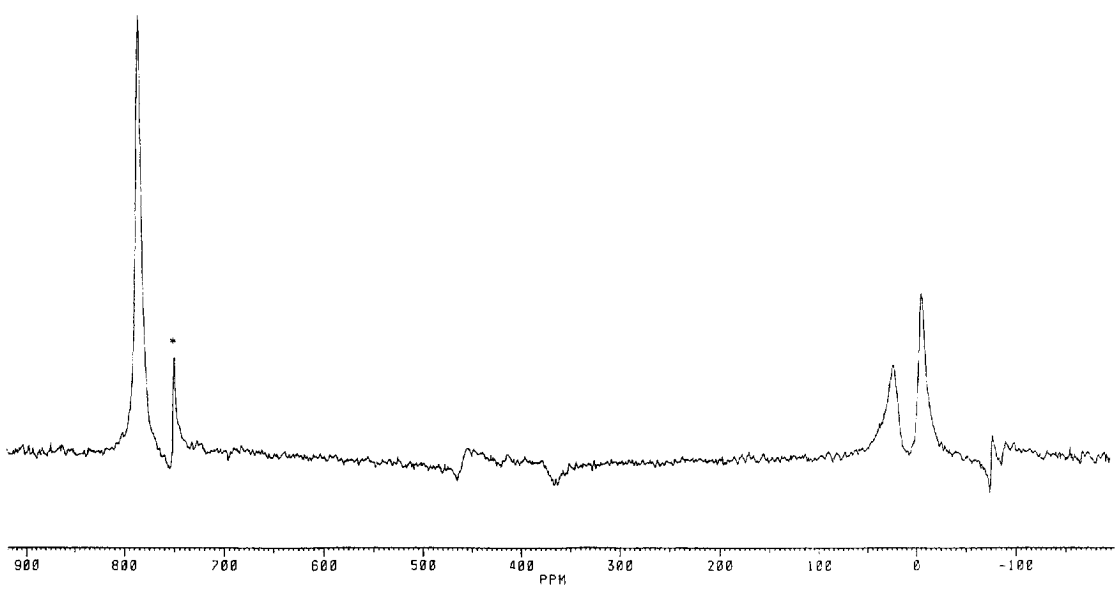

Fig. 3. ^{17}O NMR spectrum of $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)_4Ru_4Mo_4O_{16}]$ (**1**) in $CDCl_3$ (*excess of MoO_4^{2-}).

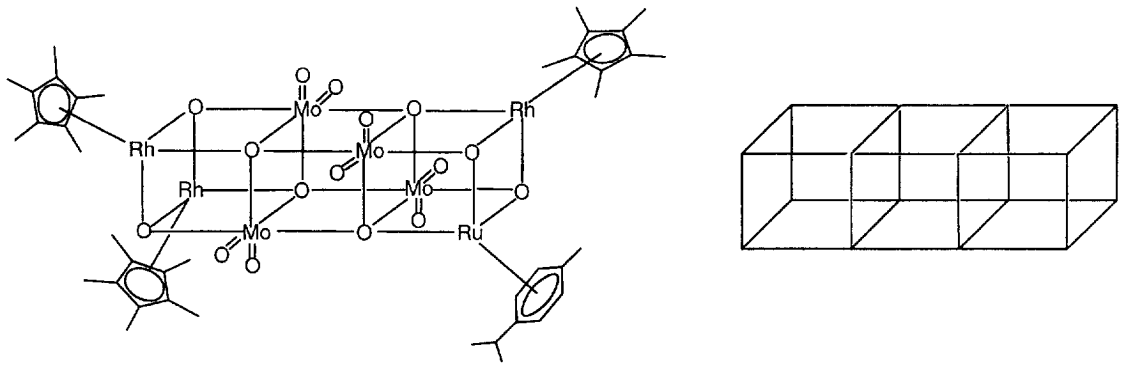

Fig. 4. Proposed molecular representation of $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)Ru(\eta^6\text{-}C_5Me_5)_3Rh_3Mo_4O_{16}]$ (**2**) with the triple-cube geometry of the $RuRh_3Mo_4O_8$ framework.

With sodium vanadate, *p*-cymene ruthenium dichloride dimer reacts in aqueous solution to give organoruthenium oxovanadium cluster $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)_4Ru_4V_6O_{19}]$ (**4**). Complex **4** is also soluble in both, dichloromethane and water.

$$2[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)_2Ru_2Cl_4] + 6NaVO_3 + H_2O \rightarrow [(\eta^6\text{-}p\text{-}MeC_6H_4iPr)_4Ru_4V_6O_{19}] + 6NaCl + 2HCl \quad (4)$$

The ^1H NMR spectrum of **4** shows the four *p*-cymene ligands to be equivalent, since there is only one set of signals for the methyl, isopropyl and aromatic protons with correct integral ratio. In the IR spectrum of **4**, the absorptions at 1089, 1037, and 944 cm^{-1} correspond to the stretching vibration of the terminal V=O bonds. Bands at 677 and 568 cm^{-1} can be assigned to the vibrations of bridging (μ_3) oxygen atoms, while an absorption at 493 cm^{-1} is attributed to the vibration of a central (μ_6) oxygen atom.

The structure analysis of a single crystal of **4** reveals a $Ru_4V_6O_{13}$ framework which can be described as a quadruple-cube with a μ_6-oxygen atom at the centre. This structure can be derived from that of the hypothetical $V_6O_{19}^{8-}$ anion, isostructural with the well-known $Nb_6O_{19}^{8-}$ [11], $Ta_6O_{19}^{8-}$ [12], $Mo_6O_{19}^{2-}$ [13] and $W_6O_{19}^{2-}$ [14] anions. It is also found in the known clusters $[(C_5Me_5)_4Rh_4V_6O_{19}]$ and $[(C_5Me_5)_4Ir_4V_6O_{19}]$ reported by K. Isobe *et al.* [4c,15]. The structure of **4** is shown in Fig. 5. Selected bond distances and angles are listed in Table 4. The cluster presents a quadruple-cube framework that contains four RuV_3O_4 cubic units alternatively fitted through V—O bonds at the three edges of the cube. The central oxygen atom of the V_6O_{19} group is common to all four RuV_3O_4 units, thus all oxygen atoms of the V_6O_{19} group, except for the terminal oxygen atom, participate in the quadruple-cube cluster. Each vanadium atom carries a terminal oxygen atom [O(6)—V(4) 1.607(4) Å], and each ruthenium atom is coordinated to a η^6-*p*-cymene ligand. In an alternative view, **4** can be considered as comprising one $V_6O_{19}^{8-}$ unit and four $(\eta^6\text{-}p\text{-}MeC_6H_4iPr)Ru^{2+}$ groups, sitting on alternating faces of the octahedron formed by the hexavanadate unit through oxygen bridges. The vanadium atoms can be described as octahedrally coordinated. The ruthenium atom in the $(\eta^6\text{-}p\text{-}MeC_6H_4iPr)Ru^{2+}$ group is bound to three adjacent bridging O atoms [Ru(4)—O(8) 2.103(4) Å].

Whereas sodium molybdate does not react with the hexamethylbenzene analogue $[(\eta^6\text{-}C_6Me_6)_2Ru_2Cl_4]$ to give a complex analogous to **1**, sodium vanadate reacts to give $[(\eta^6\text{-}C_6Me_6)_4Ru_4V_6O_{19}]$ (**5**), analogous to **4**. Like **4**, complex **5** is soluble in both water and organic solvents, but it forms blue crystals, while **4** has a violet colour. The IR, MS and ^1H NMR data of **5** suggest the compound to have the same structure as the *p*-cymene analogue **4**.

EXPERIMENTAL

The following chemicals were purchased from commercial sources and used without further purification: $RuCl_3 \cdot n\ H_2O$ (Johnson Matthey); $RhCl_3 \cdot 3H_2O$ (Métaux Précieux); (R)-(−)-5-Isopropyl-2-methyl-1,3-cyclo-hexadiene (Merck); hexamethyldewarbenzene (Aldrich); hexamethylbenzene (Lancaster), $Na_2MoO_4 \cdot 2\ H_2O$ (Fluka); $NaVO_3$ (Fluka). The organic solvents were refluxed over appropriate desiccants, distilled, and saturated with nitrogen. The bidistilled water degassed and saturated with N_2 prior to use. The ^1H NMR spectra were recorded on a Varian Gemini 200 BB instrument. ^{17}O NMR spectra were measured on a Bruker AM 360 spectrometer working at 48.82 MHz and using 10 mm o.d. sample tubes, the solvent was CD_2Cl_2. Total spectral width of 55.6 kHz with 8 K data points for the FIDs (10^4–10^5 transients added) were used. ^{17}O chemical shift were measured with respect to bulk water (external reference, 0 ppm). To flatten the baseline larger pre-scan-delay values (DE) were used causing some first order phase errors. The IR spectra were recorded on a Perkin–Elmer FTIR 1720 X spectrophotometer (4000–400 cm^{-1}) as KBr pellets. The mass spectra (FAB)

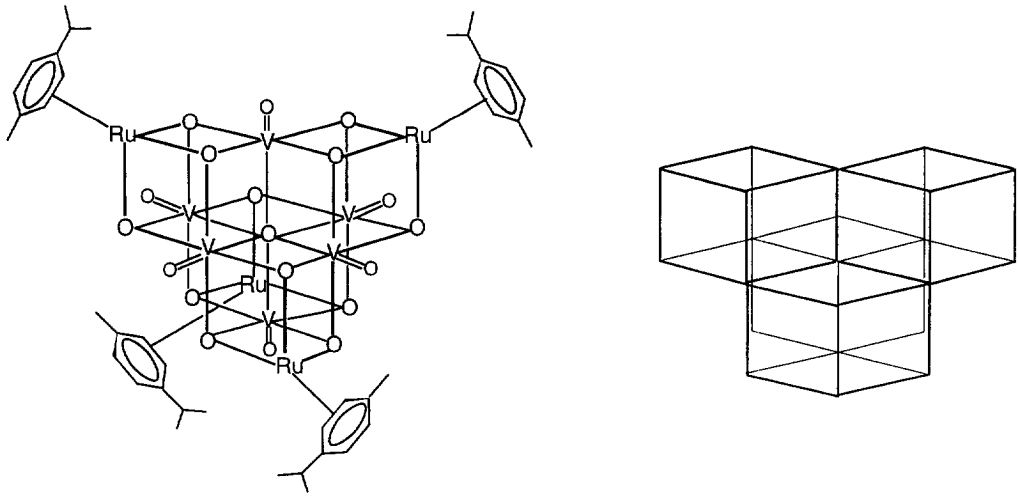

Fig. 5. Molecular representation of $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)_4Ru_4V_6O_{19}]$ (**4**).

were performed by Prof. Titus A. Jenny, University of Fribourg. Microanalytical data were obtained from the Mikroelementaranalytisches Laboratorium ETH Zürich. The starting materials $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)_2Ru_2Cl_4]$ [16], $[(\eta^6\text{-}C_6Me_6)_2Ru_2Cl_4]$ [16] and $[(\eta^5\text{-}C_5Me_5)_2Rh_2Cl_4]$ [17] were synthesised according to the literature procedures.

Preparation of $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)_4Ru_4Mo_4O_{16}]$ (**1**)

A suspension of $[(p\text{-}MeC_6H_4iPr)_2Ru_2Cl_4]$ (200 mg, $3.27 \cdot 10^{-4}$ mol) in 20 cm^3 of water was added dropwise to an aqueous solution (10 cm^3) of $Na_2MoO_4 \cdot 2H_2O$ (790 mg, $3.3 \cdot 10^{-3}$ mol). The mixture was stirred for 4 h at 25°C. After evaporation of the water, the product was extracted with CH_2Cl_2 (20 cm^3) and dried over $MgSO_4$. (**1**) was recrystallised from a mixture of dichloromethane and toluene (1:1) to give analytically pure orange crystals (155 mg, 60% yield). IR (KBr): ν[cm^{-1}] = 921, 874 (terminal oxygen atom); 785, 739, 642 and 602 (bridging oxygen atom). MS (FAB+): *m/z*: 1581 (^{101}Ru, ^{96}Mo). ^{1}H NMR (200 MHz, CD_2Cl_2): δ = 1.39 (d, 6H, $CH(CH_3)_2$), 2.27 (s, 3H, $C_6H_4CH_3$), 2.97 (sp, ^{1}H, $CH(CH_3)_2$), 5.30 (d, 2H, C_6H_4), 5.37 (d, 2H, C_6H_4). Found: C, 30.33; H 3.51. Calc. for $C_{40}H_{56}Mo_4O_{16}Ru_4$: C, 30.39; H, 3.57%.

Preparation of $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)Ru(\eta^5\text{-}C_5Me_5)_3Rh_3Mo_4O_{16}]$ (**2**) and $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)_2Ru_2(\eta^5\text{-}C_5Me_5)_2Rh_2Mo_4O_{16}]$ (**3**)

$[(\eta^5\text{-}C_5Me_5)_2Rh_2Cl_4]$ (200 mg, $3.24 \cdot 10^{-4}$ mol) and $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)_2Ru_2Cl_4]$ (200 mg, $3.27 \cdot 10^{-4}$ mol) were suspended in 50 cm^3 of water and treated with an aqueous solution of $Na_2MoO_4 \cdot 2H_2O$ (1.57 *g*, $6.5 \cdot 10^{-3}$ mol) in 20 cm^3 of water. The mixture was stirred for 12 h. The resulting red-orange solution was extracted with 30 cm^3 of dichloromethane, then the organic layer was collected and dried with $MgSO_4$, giving a crude red-orange powder product on evaporation of the solvent. The crude product was dissolved in a minimum of dichloromethane and separated by thin-layer chromatography on silica (CH_2Cl_2/acetone/methanol, 5:10:3). The products **2** and **3** were isolated from the two main bands by elution with CH_2Cl_2/aceton/methanol (5:10:3) and evaporation to dryness after filtration of $MgSO_4$. Preparation of $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)_4Ru_4V_6O_{19}]$ (**4**)

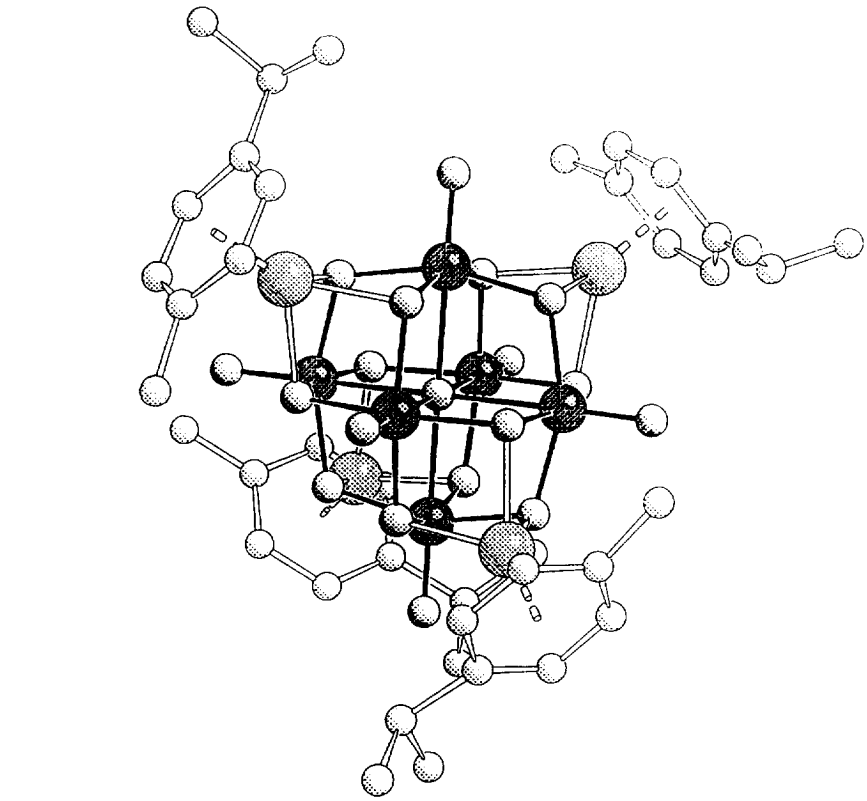
A suspension of $[(p\text{-}C_6H_4iPrMe)_2Ru_2Cl_4]$ (200 mg, $3.27 \cdot 10^{-4}$ mol) in 20 cm^3 of water was added dropwise to an aqueous solution (35 cm^3) of $NaVO_3$ (398 mg, $3.27 \cdot 10^{-3}$ mol). The mixture was stirred for 4 h at 25°C. After evaporation of the water, the solid was extracted with CH_2Cl_2 (20 cm^3). The dichloromethane solution was dried over $MgSO_4$, and evaporated to



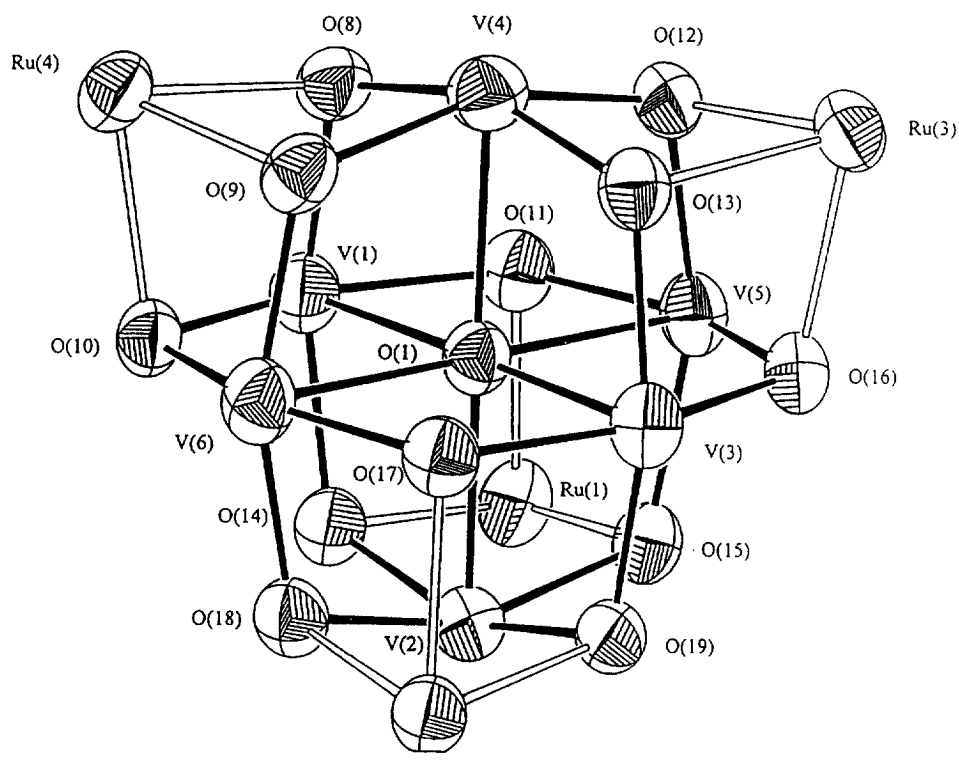


Fig. 6. Molecular structure of $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)_4Ru_4V_6O_{19}]$ (**4**). (a) Hydrogen atoms and two water molecules have been omitted for clarity. (b) $Ru_4V_6O_{13}$ framework with labelling scheme.

Preparation of $[(\eta^6\text{-}C_6Me_6)_4Ru_4V_6O_{19}]$ **(5)**

A suspension of $[(\eta^6\text{-}C_6Me_6)_2Ru_2Cl_4]$ (100 mg, $1.49 \cdot 10^{-4}$ mol) in 25 cm^3 of water was added dropwise to an aqueous solution (20 cm^3) of $NaVO_3$ (181 mg, $1.49 \cdot 10^{-3}$ mol). The mixture was stirred for 4 h at 25 C. After evaporation of the water, the solid was extracted with CH_2Cl_2 (20 cm^3). The dichloromethane solution was dried over $MgSO_4$, and evaporated to dryness to give the product as a dark blue powder (95 mg, 68% yield). IR (KBr): $\nu[cm^{-1}] = 1075, 1024, 939$ (terminal oxygen atom), 675, 567 (bridging oxygen atom), 492 (central oxygen atom). ^1H NMR (200 MHz, CD_2Cl_2): $\delta = 2.29$ (s, 18H, $C_6(CH_3)_6$), MS (FAB+): *m/z*: 1663 (^{101}Ru, ^{51}V). Found: C, 31.11; H, 3.97. Calc. for $C_{48}H_{72}O_{19}Ru_4V_6 \cdot 4CH_2Cl_2$: C, 31.19; H, 4.03%.

^{17}O-enrichment procedure

A solution of $Na_2MoO_4 \cdot 2\ H_2O$ (395 mg, 1.63 10^{-3} mol) in 1 cm^3 of 10% enriched $H_2{}^{17}O$ (Yeda, Israel) was heated to 90°C for 3 h with stirring and cooled to 25°C. To the resulting solution, containing ^{17}O-enriched MoO_4^{2-}, 200 mg ($3.27 \cdot 10^{-4}$ mol) of $[(\eta^6\text{-}p\text{-}MeC_6H_4iPr)_2Ru_2Cl_4]$ were added, then the mixture was heated to 95°C with vigorous stirring during 3 h. Then the solvent was removed, the residual orange solid was extracted with dichloromethane (25 cm^3) and crystallised from a mixture of dichloromethane and toluene (1 : 1).

X-ray structure determination of **1** *and* **4**

Suitable crystals of **1** and **4** were obtained as indicated in the synthetic section. Selected experimental crystallographic details of the structure determination of **1** and **4** are given in Tables 3 and 4. For **1**, single-crystal X-ray diffraction data were collected at −50 C on a Stoe-Siemens AED2 4-circle diffractometer using Mo–K_α graphite monochromated radiation ($\lambda = 0.71073$ Å; $\omega/2\theta$ scans), whereas for **4**, the X-ray diffraction data were collected at room temperature on a Stoe Imaging Plate Diffractometer System (Stoe and Cie 1995) equipped with a one-circle goniometer and a graphite Mo–K_α monochromated

[a] $R_1 = \Sigma \| F_o | - | F_c \| / \Sigma | F_o |$.
[b] $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2 / \Sigma w(F_o)^4]^{1/2}$.
[c] $S = [\Sigma w(F_o^2 - F_c^2)^2 / (n-p)]^{1/2}$ (n = number of reflections, p = number of parameters).

radiation ($\lambda = 0.71073$ Å, φ oscillation). Data were collected in one stage: 120 exposures (3 min per exposure) were obtained at 80 mm with $0 \leqslant \varphi \leqslant 120°$ and with the crystal oscillated through 1° in φ. The structure of **1** was solved by Patterson methods and that of **4** by direct methods using the program SHELXS 86 [18]. For both compounds, **1** and **4**, the structure refinement, using weighted full-matrix least-square on F^2, was carried out using the program SHELXL 93 [19]. During the refinement of **1**, two molecules of toluene were located. Two partially occupied H_2O positions were found for **4** (occupancies 0.33 and 0.5). For compound **1**, an empirical absorption correction was applied using DIFABS (PLATON) [20]. Non-H atoms were refined anisotropically, and hydrogen atoms were included in calculated positions and refined as riding atoms using the SHELXL 93 default parameters. The figures were drawn using the programs ZORTEP [21] (thermal ellipsoides, 50% probability level) and SCHAKAL [22]. Complete tables of bond lengths and angles and lists of thermal parameters have been deposited at the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ (U.K.).

Application of the partial charge model

The partial charge model [9] was applied to the crystallographic data of **1**, using the following parametrization: Electronegativities (Mulliken scale, values in eV): $\chi(H) = 7.176$; $\chi(C, sp^2) = 8.876$; $\chi(C, sp^3) = 8.148$; $\chi(O) = 9.630$; $\chi(Ru) = 4.11$ and $\chi(Mo) = 8.876$. Atomic sizes (covalent radii in Å): $r(H) = 0.37$; $r(C) = 0.77$; $r(O) = 0.73$; $r(Ru) = 1.25$; $r(Mo) = 1.30$. Total electrical charge = 0.0 (neutral complex). The program calculated the minimum interatomic distance to be 0.94

Structural systematics in penta- and hexanuclear metal clusters containing carbocyclic ligands†

Paul R. Raithby* and Gregory P. Shields

Department of Chemistry, Lensfield Road, Cambridge CB2 1EW, U.K.

(Received 3 October 1997; accepted 16 December 1997)

Abstract—This article describes the structural chemistry of penta- and hexanuclear ruthenium and osmium carbonyl clusters which contain one or more arene (η^6-Ar) or cyclopentadienyl (η^5-Cp) groups, and compares and contrasts their structures with those of related binary carbonyl and carbonyl hydride clusters. The pentanuclear structures described are based on the trigonal bipyramidal metal framework, or on frameworks derived from this by the cleavage of one or more metal–metal edges. The steric and electronic factors which determine the position of the M(η^6-Ar) or M(η^5-Cp) units in the framework are discussed. For the hexanuclear clusters two basic metal core geometries are observed, the bicapped tetrahedron, comprising three fused tetrahedra, and the octahedron. The two series of compounds exhibit quite different structural chemistries. The bicapped tetrahedral structures exhibit quite extensive isomerism for the carbocyclic ligand substituted complexes, the positions of the M(η^6-Ar) or M(η^5-Cp) being dependent on both steric and electronic factors. For the octahedral carbocyclic ligand substituted complexes isomerism is less prevalent, but an analysis of the ligand polyhedra in these systems shows that low energy transformations, consistent with the fluxional properties of these complexes, are possible. The metal core geometries and ligand polyhedral geometries of related series of hexanuclear clusters are analysed statistically using half-normal probability plots and scatter plots. © 1998 Elsevier Science Ltd. Keywords: osmium; ruthenium; carbocyclic ligands; X-ray structures; statistical analysis.

The last four decades have seen the development of cluster chemistry from its infancy to one of the major areas of research within the discipline of "organometallic chemistry" [1]. Lewis and his co-workers have been instrumental in the expansion of the subject, from early studies, which confirmed the existence of metal–metal bonds between transition metals [2], to the recent characterisation of high nuclearity metal clusters which form the link between conventional organometallic complexes and the bulk metal [3].

One of the key areas of transition metal cluster research has concerned the nature of the interaction between the metal cluster core and arene and cyclopentadienyl ligands. These carbocyclic ligands are of great importance in many catalytic processes, and establishing the nature of the bonding between the carbocyclic ring and the surface of the metal catalyst is fundamental to the understanding of the reaction [4]. Cluster complexes, which can be probed by conventional spectroscopic and structural techniques, are useful as models for investigating these processes. In 1968, Lewis and Johnson synthesised $Ru_6C(CO)_{14}(\eta^6$-$C_6H_3Me_3)$, the first structurally characterised cluster to exhibit the η^6-bonding mode for the arene [5], and in 1985 they reported the synthesis and characterisation of the clusters $Os_3(CO)_9(\mu_3$-$\eta^2:\eta^2:\eta^2$-$C_6H_6)$ and $Ru_6C(CO)_{14}(\mu_3$-$\eta^2:\eta^2:\eta^2$-$C_6H_6)$ [6], in which an arene ring lies parallel to a triangular face of the cluster; a bonding mode predicted for the interaction of an arene ring with the Rh{111} surface of the bulk metal. These and related studies have led to the development of an extensive chemistry of this class of complex which has been the subject of several recent reviews [7].

The arene and cyclopentadienyl-substituted clusters may be prepared by a number of synthetic routes. These include: (i) the coupling of a mononuclear carbocyclic metal-containing cation, a capping reagent, with a pre-formed anionic carbonyl cluster [8]; (ii) the thermolysis or pyrolysis of a carbocyclic

* Author to whom correspondence should be addressed.

† Dedicated to Professor Lord Lewis on the occasion of his 70th birthday, with sincere thanks for his support and friendship over the years.

compound with a binary carbonyl complex [6,9]; and (iii) the reaction of the carbocyclic ligand with an Me_3NO-activated cluster which leads to the transfer of the ligand to the cluster [10].

The carbocycle-substituted clusters have been shown by crystallographic studies to adopt a range of metal framework geometries and ligand distributions. The structures have been interpreted both in terms of the established electron counting rules, such as the Effective Atomic Number Rule (E.A.N.) [11] and the Polyhedral Skeletal Electron Pair Theory (P.S.E.P.T.) [12], and in terms of the Ligand Polyhedral Model (L.P.M.) [13]. The electron counting rules deal only with the metal framework geometry, in either a predictive or interpretative mode, and give no guide to the distributions of the ligands around the cluster core. In contrast, the L.P.M. approach considers the cluster in terms of a metal core enclosed in a polyhedron of carbonyl ligands, the arrangement of which is dependent on their mutual non-bonded interactions, and little information can be gleaned concerning the metal core geometry. The role of the intermolecular interactions in the crystal packing arrangements of arene-substituted clusters has also been investigated, with particular reference to arene-arene π-stacking [14] and C(arene)—H $\cdots$ O(carbonyl)/M—H $\cdots$ O(carbonyl) hydrogen bonding [15]. Such interactions will perturb the ligand polyhedron and hence, indirectly, the metal core structure, since the metal–metal bonding interactions are relatively "soft", i.e. not strongly distance dependent.

These approaches to rationalizing the structures of carbocycle-substituted clusters are complementary, but do not give the complete picture regarding the structure and reactivity of these complexes. In this review, where we concentrate on the extensive chemistry of penta- and hexanuclear osmium and ruthenium carbocycle clusters, we aim to consider both the steric and electronic components that determine the structures of this class of complex, including the nature of the reaction by which they were formed, and draw general conclusions concerning the structures adopted.

We commence our study by considering pentanuclear clusters which contain a terminally bound carbocyclic ligand, and compare them with related binary carbonyls and binary carbonyl hydrides. These clusters may be considered as the simplest case, where a carbocyclic-substituted metal complex caps a preformed tetrahedral metal cluster core, and forms the first series of compounds where not all the metal atoms form the same number of connections to the other metal atoms in the core. In the trigonal bipyramid, the five-vertex deltahedron (a polyhedron with all triangular faces), the two apical metal atoms have a metal connectivity of (3) while the equatorial ones have a metal connectivity of (4) as shown in Fig. 1.

We then expand the study to consider hexanuclear systems, and emphasise the structural differences between the series of clusters which have metal core structures based on fused tetrahedral and on octahedral geometries.

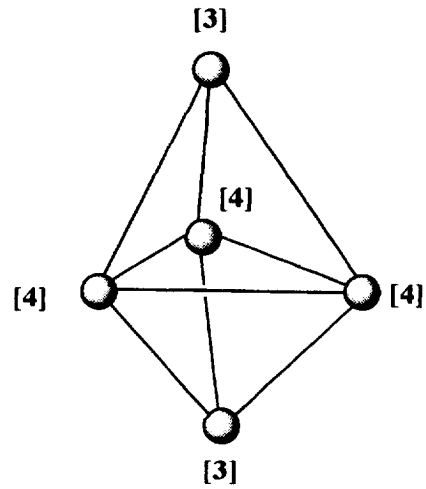

Fig. 1. Metal–metal connectivities in the trigonal bipyramid.

OBSERVATIONS AND DISCUSSION

Trigonal bipyramidal clusters

The archetypal pentanuclear cluster with a trigonal bipyramidal metal core is $Os_5(CO)_{16}$ **1** [16,17] (Fig. 2a). The two apical Os atoms are connected to three equatorial Os atoms and to three terminal carbonyls. Two of the equatorial Os atoms are connected to two equatorial and two axial Os atoms and to three carbonyls, while one equatorial Os atom is connected to two axial and two equatorial Os atoms and to *four* carbonyls [18]. The two carbonyl groups in the equatorial plane bonded to the latter Os atom form very asymmetric ("incipient") bridges to the other two equatorial Os atoms, while the two axial carbonyls are linear. The Os—Os bond lengths involving the eight co-ordinate, formally $20e^-$ metal centre are considerably longer (by ca 0.1 Å) than the other Os—Os distances in the cluster. This observation may be attributed to steric or electronic effects, or both. Mingos and Evans [19] have shown that the replacement of one $Os(CO)_3$ by an $Os(CO)_4$ unit in an electron-precise or deltahedral cluster does not change the electron count, but is accompanied by a decrease in the M—M bond strength due to differences in the frontier orbitals of the two units. The carbonyl ligand polyhedron, expressed in Föppl notation, is essentially 1 : 6 : 3(3) : 3 in form, one of several found to have approximately equal lowest energy, although it is distorted quantitatively due to the asphericity of the trigonal bipyramidal metal core [20].

Metal–metal bond lengths for all the trigonal bipyramidal structures discussed in this section are presented in Table 1. A common numbering scheme, as illustrated in the table, is adopted in which the two

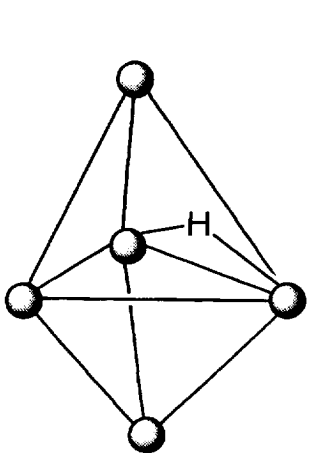
axial sites are denoted M_1 and M_5, and the equatorial carbocyclic ligand-substituted site is denoted M_4.

The mixed-metal cluster $Os_4Ru(CO)_{13}(\eta^6\text{-}C_6H_6)$ **2** may be synthesised via the ionic coupling reaction shown in eqn (1) [21,22]:

$$[Os_4(CO)_{13}X]^- \xrightarrow{K^+/Ph_2CO^-} [Os_4(CO)_{13}]^{2-} \quad X = Cl, Br, I$$

$$\xrightarrow{[Ru(C_6H_6)(MeCN)_3]^{2+}} Os_4(CO)_{13}Ru(C_6H_6) \quad (1)$$

The molecular structure (Fig. 2b) has approximate C_s symmetry with one CO ligand bridging the equatorial edge between the Ru and an Os centre. The shortest bonds are between the formally $17e^-$ axial Os and $18e^-$ equatorial Os vertices. In the equatorial plane the shortest edge is the Os—Os bond and the longest the carbonyl bridged Os—Ru edge, although the differences are only the order of 0.02 Å or less, and the capping group is bonded essentially symmetrically. There is no structural evidence for an isomer with the Ru in the axial position, only the thermodynamic



$Os_5(CO)_{15}]^-$ (3)

Fig. 3. The molecular structure of the anion 3.

product with the arene in the equatorial position is observed. The greater donor character of the metal-arene M(η^6-Ar) [Ar = arene] or M(η^5-Cp) [Cp = η^5-C_5H_5] fragment compared to an $M(CO)_3$ or $M(CO)_4$ unit enhances electron donation from the formally $20e^-$ to the $17e^-$ sites, stabilising the cluster, and hence, where steric constraints permit, the M(η^6-Ar) or M(η^5-Cp) group should occupy the "electron rich" centre. The replacement of an $M(CO)_3$ or $M(CO)_4$ fragment by an M(η^6-Ar) or M(η^5-Cp) fragment is always associated with the presence of a bridging CO group, bridging the M(η^6-Ar) or M(η^5-Cp) fragment and an adjacent metal. The bridging CO is better able to distribute the addition electron density in the cluster core which originates from the "electron rich" M(η^6-Ar)/M(η^5-Cp) fragment.

The dihydrido cluster $H_2Os_5(CO)_{15}$ has not been characterised crystallographically, although the related dianion $[HOs_5(CO)_{15}]^-$ **3** [23] has been studied as its PPN^+ [$PPN^+ = [N(PPh_3)_2]^+$] salt [24]. The anion (Fig. 3) has ideal C_{2v} symmetry, although the metal core is somewhat distorted from this. The μ-H ligand bridges an equatorial edge, and this Os—Os edge is the longest metal–metal contact in the structure, between the Os atoms of highest connectivity. As in $Os_5(CO)_{16}$ **1**, the axial-equatorial distances between $Os(CO)_3$ units are the shortest in the structure. Other distances are comparable, given the deviations of ca 0.04 Å between chemically equivalent distances, indicating considerable deformation of the soft metal core with intermolecular interactions.

The arene derivatives have been prepared by the reaction of the reduction product of $H_2Os_4(CO)_{13}$ with K^+/Ph_2CO^- with $[M(\eta^6\text{-}C_6H_6)(MeCN)_3]^{2+}$ (M = Ru, Os) or $Os(\eta^6\text{-}C_6H_5Me)(CF_3SO_3)_2$ (Scheme 1) [25]. In each case, the initial kinetic products $H_2Os_4(CO)_{12}M(\eta^6\text{-Ar})$ [M = Ru, Ar = C_6H_6 **4**, M = Os, Ar = C_6H_6 **5**, Ar = C_6H_5Me **6**] are unstable and a structure with the arene in an axial site, i.e. a simple face-capping product, has been postulated [25]. The Os complexes **5** and **6** convert, at room temperature, to the equatorial isomers **7** and **8**, respectively, in ca 40% yield. The crystal and molecular structure of **8** has been determined, and the $Os(C_6H_5Me)$ group occupies an equatorial site in the trigonal bipyramid (Fig. 4). The hydride ligands bridge two adjacent axial-equatorial edges. These are the shortest in the metal core, involving the formally $17e^-$, equatorial Os atom bound to only two terminal CO ligands, while the longest edge Os—Os is bridged by a carbonyl ligand which is again associated with the arene-substituted metal centre.

Two possible mechanisms for the formation of the equatorial isomers **7** and **8** exist. The first involves the "clipping" of the M(η^6-Ar) fragment onto a face of the pre-formed metal tetrahedron, to give the axial isomer, followed by a Berry pseudo-rotation mech-

Fig. 6. The molecular structure of **10**.

anism involving a trigonal bipyrimidal-square based pyramid-trigonal bipyramid cluster rearrangement to give the observed equatorial isomer (Fig. 5). This type of mechanism has been suggested in order to account for the formation of related thermodynamic products in other systems [26]. The second mechanism would involve the opening out of one edge of the metal tetrahedron, and the insertion of the M(η^6-Ar) fragment into that edge to form the trigonal bipyramid to give the isomer with the M(η^6-Ar) unit in the equatorial site. In view of the observation of the clusters **4**, **5** and **6**, although not their complete characterisation, it is probable that the first mechanism is the correct one for both the hydrido and non-hydrido clusters.

Deprotonation of initial axial products **4** and **5** with NEt_3 followed by ionic coupling with excess $[AuPPh_3]^+[NO_3]^-$ produces $HOs_4M(CO)_{12}(\eta^6\text{-}C_6H_6)AuPPh_3$ (M = Ru **9**, Os **10**) (Scheme 1) which have similar IR and ^1H NMR spectra [26]. The solid state structure of **10** (Fig. 6) has the Os(η^6-Ar) group in the electronically and sterically (with respect to $AuPPh_3$) favoured equatorial site; it is unclear whether this results from a metal core rearrangement in the anion or in the final product. The parent cluster $HOs_5(CO)_{15}AuPPh_3$ **11** [27] has a similar $AuPPh_3$-capped trigonal bipyramidal geometry and the hydride ligand also bridges an equatorial edge.

However, the M—M bond distances differ significantly in detail between the structures of **10** and **11**. All bonds involving the arene-substituted Os atom in **10** are substantially shorter by (0.03 Å or more) than the corresponding distances for the $Os(CO)_3$ group in **11** and the H-bridged bond is shorter than the Au-bridged bond in **10** whereas they are approximately equal in **11**. The $AuPPh_3$ moiety caps asymmetrically in each. Whilst some of these differences can be attributed to the greater donor ability of the Os(η^6-Ar) group as compared to $Os(CO)_3$, some may be a consequence of distortions imposed on the metal core by intermolecular interactions.

Tetra-hydrido clusters may also be prepared by the similar ionic coupling route (eqn (2)) [28]:

$$Os_4H_4(CO)_{12} \xrightarrow{K^+/Ph_2CO^-} [Os_4H_4(CO)_{11}]^{2-}$$

$$\xrightarrow[M=Ru,Os]{[M(C_6H_6)(MeCN)_3]^{2+}} H_4Os_4(CO)_{11}M(C_6H_6) \quad (2)$$

M = Ru **12**, Os **13**

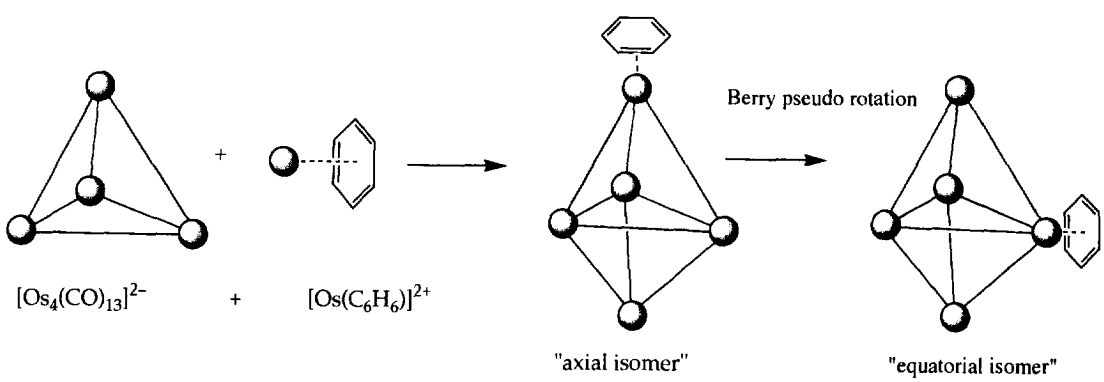

Fig. 5. A possible mechanism for the formation of clusters **7** and **8**.

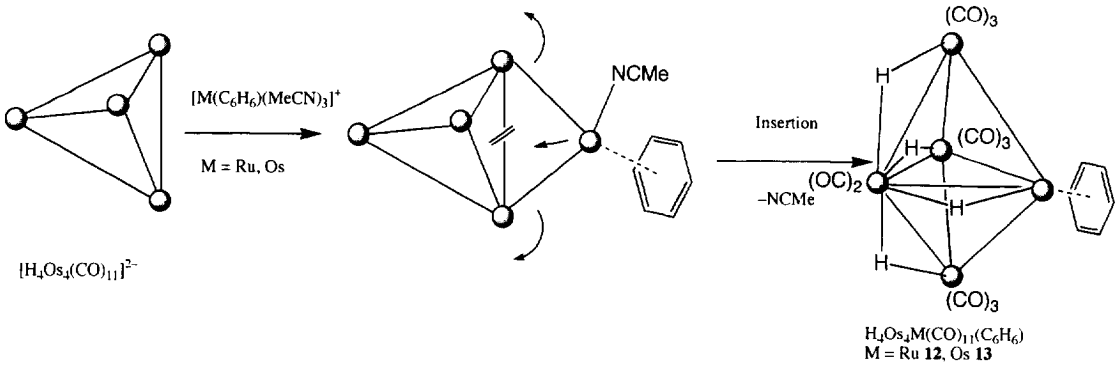

Fig. 7. A possible mechanism for the formation of **12** and **13**.

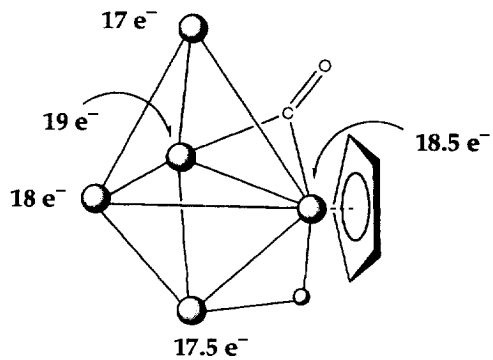
In this reaction there was no evidence for the existence of axially-capped derivatives and both $H_4Os_4M(CO)_{11}(\eta^6\text{-}C_6H_6)$ [M = Ru **12**, Os **13**] have the benzene ligand in the favoured equatorial site in the solid state. Clusters **12** and **13** are isomorphous and their core bond lengths are similar, with no clear trends apparent on substituting Os with Ru. With regard to the formation of **12** and **13**, an edge-bridged tetrahedral intermediate which retains one acetonitrile ligand has been postulated, the $M(\eta^6\text{-Ar})$ unit then inserts into the edge-bridged Os—Os bond with loss of MeCN to generate the product (Fig. 7) [28,29]. In contrast to the di-hydrido structure **8**, the longest axial-equatorial bonds in **12** and **13** are those bridged by hydrides, as the equatorial Os atom coordinated to two terminal carbonyls is now ten-coordinate and has a higher formal electron count. Similarly, the unbridged equatorial edge is the shortest, the presence of the equatorial ligands causing the $Ru(\eta^6\text{-}C_6H_6)$ unit to bond asymmetrically in the equatorial plane. The M—Os(axial) bonds involving the $M(\eta^6\text{-}C_6H_6)$ unit are the shortest axial-equatorial distances (cf **10**).

Cyclopentadienyl-substituted pentanuclear clusters are also known, and the $[Os_4RuCp(CO)_{13}]^-$ anion **14** has been synthesised in a similar manner to $Os_4(CO)_{13}Ru(\eta^6\text{-}C_6H_6)$ **2** using $[RuCp(MeCN)_3]^+$ as the capping group. It has not been characterised in the solid state, although spectroscopic data are consistent with a structure similar to that of **2** [21]. The anion **14** may also be produced by deprotonation of $HOs_4(CO)_{13}RuCp$ **15**, which is formed when $[RuCp(MeCN)_3]^+$ is treated with $[Os_4(CO)_{13}Cl]^-$ in the absence of an additional reducing agent [18,30]. In the solid state, the cluster has the expected trigonal bipyramidal metal core with the Cp-bound Ru atom in an electronically favoured equatorial site, and coordinated to a semi-bridging CO ligand (Fig. 8). The bond parameters in **15** follow the same trends as those in $H_2Os_5(CO)_{12}(\eta^6\text{-}C_6H_5Me)$ **8**. The two independent molecules in the asymmetric unit of **15** have similar bond parameters; the longest distances involve the Ru atom, which has the highest connectivity and electron count. The semi-bridged edge is longer than other



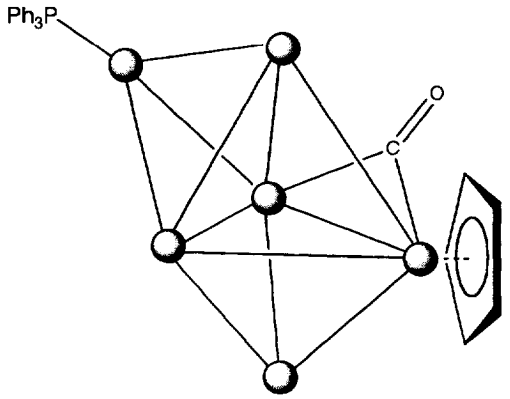
$HOs_4(CO)_{13}Ru(C_5H_5)$ **(15)**

Fig. 8. The molecular structure of **15**.

Ru—Os equatorial edges, an effect more marked than in **8**, i.e. the cap is less symmetric.

The anion **14** may be capped with $[AuPPh_3]^+[NO_3]^-$ to produce the cluster $Os_4(CO)_{13}RuCp(AuPPh_3)$ **16** (Fig. 9) which has a similar structure to the $AuPPh_3$-capped, arene-substituted clusters **9** and **10** [21]. It is interesting to note that in both the case of **16** and of the gold-containing, arene-substituted clusters the "$AuPR_3$" fragment clips on to a triangular face of the preformed Os_5 or Os_4Ru cluster, and there is no indication of the core rearrangement that must take place when either the $M(\eta^6\text{-Ar})$ or $M(\eta^5\text{-Cp})$ fragment is added to the tetrahedral Os_4 unit. In **16** the $AuPPh_3$ group caps asymmetrically, in a manner dissimilar to that in either **10** or **11**. This capping Au atom has the effect of increasing axial-equatorial distances, whereas the absence of a μ-H decreases the coordination number of the Ru atom such that its bonds are much shorter than those in $HOs_4(CO)_{13}RuCp$ **15**, and are comparable to the unbridged Os—Os axial-equatorial distances.

Having seen that metal framework rearrangements occur when an $M(\eta^5\text{-Cp})$ or an $M(\eta^6\text{-Ar})$ fragment is added to a tetrahedral cluster core, and that in the final



$Os_4(CO)_{13}Ru(Cp)AuPPh_3$ **(16)**

Fig. 9. The molecular structure of **16**.

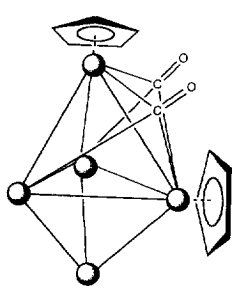
product obtained from these syntheses the trigonal bipyramidal metal core always has the M(η^5-Cp) or M(η^6-Ar) unit occupying an equatorial site, it is of interest to see what core geometry is obtained if two carbocyclic-substituted metal units are added to a trinuclear cluster core.

Bicapped clusters derived from trinuclear precursors may be prepared readily. If the dianion $[Os_3(CO)_{11}]^{2-}$ is reacted with two equivalents of $[RuCp(MeCN)_3]^+[PF_6]^-$, $Os_3(CO)_{11}Ru_2Cp_2$ **17** is produced (Fig. 10). Alternatively, deprotonation of $Os_3RuH(CO)_{11}Cp$ followed by addition of one equivalent of the capping reagent is equally effective [21,30,31]. Cluster **17** has crystallographic C_s symmetry in the solid state and the metal framework is again a trigonal bipyramid. However, in this case, while one of the Ru(η^5-Cp) units occupies the favoured "electron rich" equatorial site, as seen for the mono-carbocyclic ligand-substituted systems, the second Ru(η^5-Cp) unit occupies an axial site. Another important feature of the structure is that it has two μ_3-CO ligands which cap the two $OsRu_2$ triangular faces of the trigonal bipyramid. In this bonding mode CO ligands are better π-acceptors than terminal or μ_2-CO ligands and serve to reduce electron density on the metal core introduced by two adjacent Ru(η^5-Cp) units. This feature perhaps balances out the additional electron density being pushed into the cluster core by the Ru(η^5-Cp) fragment occupying an electronically less favoured axial site. There is no evidence for cluster rearrangement since the product could be derived by repeated capping of the triangular precursor (as could an axial-axial isomer, although the equatorial position is the preferred site, since, as has been discussed previously, the enhanced electron-donating ability of Cp ligands, compared to carbonyl groups, enhancing donor bonds to the axial sites). The Ru—Ru bond is shortest metal–metal contact in the structure, and Ru—Os bonds are generally longer than Os—Os bonds.

Edge-bridged and spiked tetrahedral clusters

Two crystallographic modifications of $H_2Os_5(CO)_{16}$ **18,** both of which have the edge-bridged tetrahedral metal core (Fig. 11) and essentially similar bond lengths have been studied; one has crystallographic C_s symmetry (II) [32,33]. The longest edges are those bridged by hydrido ligands, each having three terminal CO ligands associated with each Os atom, and distances to the edge bridging Os atom are longer than the other unbridged edges. Selected bond lengths for all the structurally characterised edge-bridged and spiked tetrahedral clusters discussed in this section are listed in Table 2; a common numbering scheme for the metal core is adopted, as illustrated in Table 2, with the edge-bridging metal atom denoted M_5.

The clusters $Os_4MH_2(CO)_{13}(\eta^6\text{-}C_6H_6)$ [M = Ru **19,** Os **20**] with an edge-bridged tetrahedral metal core, with benzene bound to the edge-bridging metal, are produced by CO scavenging from the initially produced trigonal bipyramidal axial isomers of $Os_4MH_2(CO)_{12}(\eta^6\text{-}C_6H_6)$ [M = Ru **4,** Os **5**] in yields of 15% and 40%, respectively [25]. This demonstrates that the trigonal bipyramidal cluster is activated to nucleophilic substitution by arenes in axial sites compared to $H_2Os_5(CO)_{15}$ [34]. The Ru complex **19** has



$[Os_3(CO)_9(\mu_3\text{-}CO)_2Ru_2(C_5H_5)_2]$ **(17)**

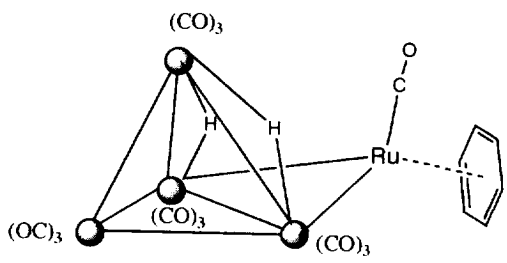
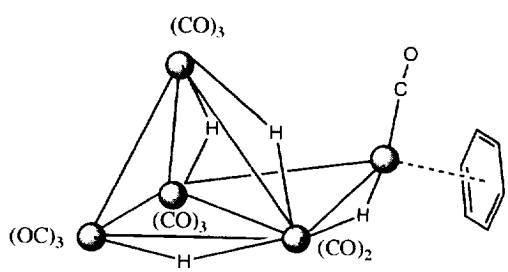
been characterised structurally (Fig. 12), and has bond lengths which are similar to those in $H_2Os_5(CO)_{16}$ **18** except that the Ru—Os bridge bonds are shorter, and the Os—Os bridged edge is substantially so (by ca 0.05 Å). This suggests that the benzene ligand increases the M—M bond strength on the bridged edge (or reduces crowding) as in $HOs_5(CO)_{15}AuPPh_3$ **11** vs $HOs_5(CO)_{12}(\eta^6\text{-}C_6H_6)AuPPh_3$ **10**.

Similarly, reaction of **4** and **5** with H_2 is accompanied by edge cleavage and the generation of $H_4Os_4M(CO)_{12}(\eta^6\text{-}C_6H_6)$ (M = Ru **21**, Os **22**) (Fig. 13) [26]. The pentaosmium compound **22** had been characterised previously as a product of the capping of $[Os_4H_4(CO)_{11}]^{2-}$ with $Os(\eta^6\text{-}C_6H_6)(MeCN)_3$, accompanied by CO scavenging [28]. It was suggested that **22** was formed from an MeCN-substituted edge-bridged intermediate, as the equatorial benzene cluster $H_4Os_5(CO)_{11}(\eta^6\text{-}C_6H_6)$ **13** is inactive towards CO addition and **22** could not be decarbonylated to give **13**. This indicates that equatorial arene substitution deactivates trigonal bipyramidal clusters to nucleophilic addition since the greater donor ability of the arene increases the electron density on the axial metal atoms. In the solid state, it can be seen, by reference to Table 2, that the hydrido-bridged edges in **22**



$H_2Os_4Ru(CO)_{13}(C_6H_6)$ **(19)**

Fig. 12. The molecular structure of **19**.



$H_4Os_5(CO)_{12}(C_6H_6)$ **(22)**

Fig. 13. The molecular structure of **22**.

involving M_2 are shorter than the corresponding edges in $H_2Os_5(CO)_{16}$ **18,** whilst those involving M_1 are longer. This is probably a consequence of reduced steric crowding at M_2 which bears only two CO ligands, as in the trigonal bipyramidal cluster $H_2Os_5(CO)_{12}(\eta^6\text{-}C_6H_5Me)$ **8**.

A Rh(CO)Cp*-bridged cluster [Cp* = η^5-C_5Me_5] has been synthesised by a similar route (eqn (3)) [35]:

$$Os_4H_4(CO)_{12} \xrightarrow{K^+/Ph_2CO^-} \begin{matrix}[Os_4H_4(CO)_{11}]^{2-} \\ + \\ [Os_4H_2(CO)_{12}]^{2-}\end{matrix} \xrightarrow{[RhCp^*(MeCN)_3]^{2+}} Os_4H_2(CO)_{13}RhCp^* \quad (3)$$

24

The edge-bridged tetrahedral core in $H_2Os_4(CO)_{13}RhCp^*$ **24** has crystallographic C_s symmetry (Fig. 14). The Cp analogue **23** had been prepared previously as a minor product (3.5% yield) in the thermolysis of $H_2Os_3(CO)_{10}$ and $CpRh(CO)_2$ [36]. The bond lengths in **23** and **24** (Table 2) are broadly similar to those in $H_2Os_4Ru(CO)_{13}(\eta^6\text{-}C_6H_6)$ **19,** although the bonds to edge-bridging rhodium atoms are shorter.

Similar edge-bridged tetrahedral structures have been suggested as the initial products of the reaction of $H_2Os_4(CO)_{12}M(\eta^6\text{-}C_6H_6)$ [M = Ru **4,** Os **5**] with phosphines and phosphites. In the reaction of **5** with PPh_2Me, substitution occurs at an equatorial site on the tetrahedron, adjacent to the edge-bridging $Os(CO)(C_6H_6)$ group, to yield $H_2Os_5(\eta^6\text{-}C_6H_6)(CO)_{12}PPh_2Me$ **25** (Fig. 15) [25]. Consideration of IR and ^1H NMR spectral data indicate that the $P(OMe)_3$ derivative is structurally analogous to **25** [25]. The phosphine has an edge-lengthening effect in **25** compared to $H_2Os_4Ru(CO)_{13}(\eta^6\text{-}C_6H_6)$ **19.** Most notably the *cis* Os—Os edge involving the edge-bridging Os atom is considerably longer (by ca 0.08 Å) than the other bond to the edge-bridging Os atom which is supported by an incipient CO bridge (Fig. 15).

For the axial isomer of $H_2Os_4Ru(CO)_{13}(\eta^6\text{-}C_6H_6)$ **4,** spectroscopic data suggest that the initial products are different from those obtained with **5,** with substitution occurring preferentially at the Ru centre **26** [25,37].

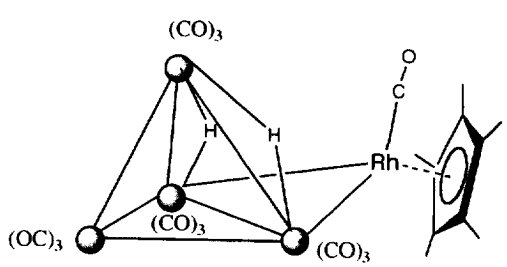


Fig. 14. The molecular structure of **24**.

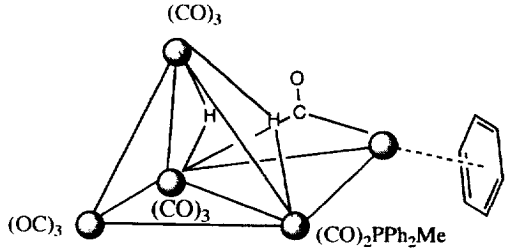

Fig. 15. The molecular structure of **25**.

These products are unstable and convert irreversibly to the clusters $H_2Os_4Ru(CO)_{12}(\eta^6\text{-}C_6H_6)(PPh_2Me)$ **27** and $H_2Os_4Ru(CO)_{12}(\eta^6\text{-}C_6H_6)(P\{OMe\}_3)$ **28,** respectively, in which orthometallation of the benzene ring and metal–metal bond cleavage has occurred to provide a spiked tetrahedral core geometry (Fig. 16). This transformation may be induced by the bulk and σ-donor properties of the phosphine at the Ru centre and the C—H cleavage driven by the formation of additional M—H and M—C bonds. Both complexes have similar core geometries in the solid state (Table 2), and three hydride ligands bridge the longest edges, of which the spike bond is the longest. The PPh_3 derivative and toluene analogue of **27** have been prepared and characterised spectroscopically, and the ^1H NMR spectrum suggests that the methyl group is *para* to the orthometallated carbon of the arene ring [26]. A similar orthometallation of a Cp ligand occurs in the related reaction (eqn (4)) [21]:

$$Os_3(CO)_{11}P(OMe)_3 \xrightarrow{K^-/Ph_2CO^-} [Os_3(CO)_{10}P(OMe)_3]^{2-} \xrightarrow{[RuCp(MeCN)_3]^+} Os_3Ru_2Cp_2(CO)_{11}P(OMe)_3 \xrightarrow{\downarrow heat, 2h} HOs_3Ru_2Cp(C_5H_4)(CO)_{11}P(OMe)_3 \; \mathbf{29} \quad (4)$$

In this instance, thermal activation is required to affect orthometallation. The final product **29** has been characterised structurally (Fig. 17, Table 2). In this cluster, the orthometalled cyclopentadienyl ring is π-bonded to the capping Ru(3) atom with C(1) bridging the spiked edge, Ru(5) possessing an η^5-Cp ligand. The geometry about the triply-bridging carbon atom C(1) is more asymmetric than in the arene-substituted clusters, with the shortest bond to the spike atom Ru(5) and longest to Os(1), such that the π-bond to Ru(3) is shorter than the latter. The spiked edge is also bridged, essentially symmetrically, by a CO ligand rather than a hydride as in **27** or **28** and the Os(1)—Ru(5) distance is thus considerably shorter (by ca 0.2 Å). The spike bond is bent towards Os(3) and Os(4) compared to geometry of **27** or **28** in order to accommodate the different position of the carbocyclic ligand, although the Ru(5)—Os(1)—Os(2) angle is essentially unchanged. Attempts to synthesise

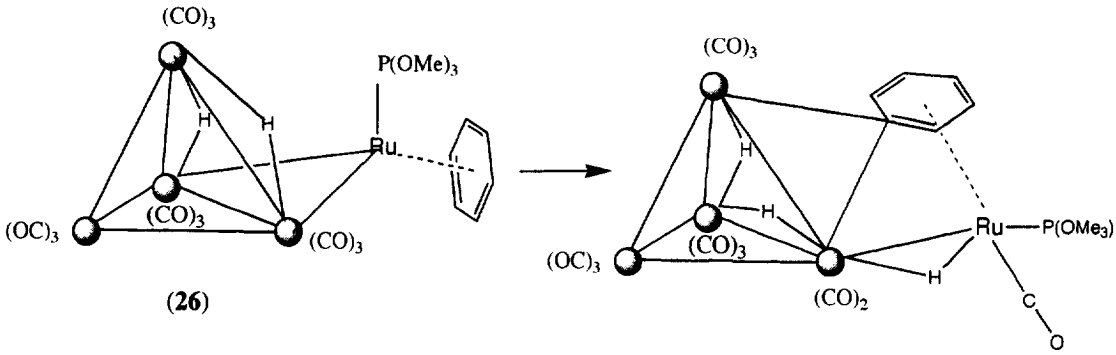

Fig. 16. The formation of **28** from **26**.

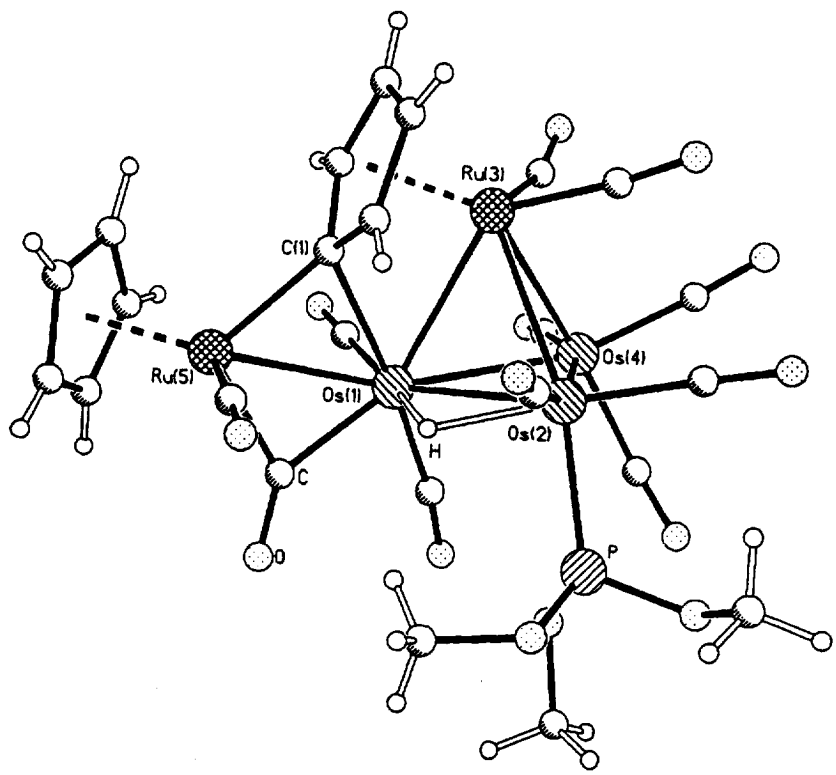

Fig. 17. The molecular structure of **29**.

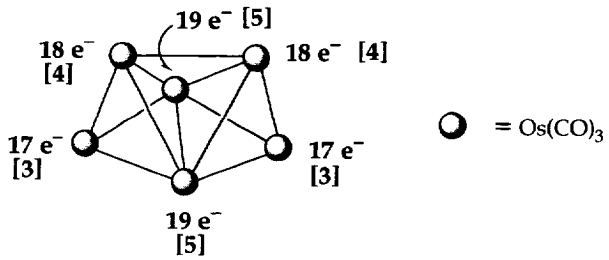
the PPh_3 derivative by a similar route failed to produce an analogous complex [21].

The isolation of the spiked tetrahedral clusters **27–29**, when stabilised by strongly electron donating phosphines or phosphites, may suggest that these are intermediates either for the metal framework rearrangements postulated for the formation of the trigonal bipyramidal pentanuclear clusters, described above, or for carbocyclic ring migration over the cluster surface. However, the reaction chemistry of these systems does not lead either to the formation of trigonal bipyramidal clusters, or to clusters in which the arene or cyclopentadienyl ring has migrated from one metal to another.

Bicapped and bis *edge-bridged tetrahedral clusters*

The archetypal bicapped tetrahedral cluster $Os_6(CO)_{18}$ **30** [16] has been characterised in the solid state alone [38] and as a $CHCl_3$ solvate (in which there are some solvent-carbonyl interactions) [39]. Each



$Os_6(CO)_{18}$ **(30)**

Fig. 18. The metal–metal connectivities and the metal atom electron counts in **30**.

metal has three terminal CO ligands, giving formal electron counts of 17, 18 and 19e⁻ for (3), (4) and (5) metal-connected vertices, respectively (Fig. 18). The (4)–(4) and (5)–(5) distances are shortest, i.e. those between metals of the same formal electron count [38]. Large variations, due to intermolecular interactions, in chemically equivalent distances prevent elucidation of trends in the other Os—Os lengths. The carbonyl polyhedron around the aspherical metal core is shown in Fig. 19 for the solvate **30**·$CHCl_3$; the ligand arrangement is somewhat distorted from ideal C_{2v} symmetry. As with the pentanuclear clusters, selected bond parameters for the bicapped tetrahedral clusters discussed in this section are presented in Table 3, and follow a common numbering scheme as illustrated by the diagram in Table 3.

Whilst the $Ru_6(CO)_{18}$ is unknown, the related cluster $(\mu_3\text{-H})_2Ru_6(CO)_{17}$ **31** (Fig. 20) has been characterised structurally [40]. It has two faces bridged by H ligands and one (somewhat asymmetric) bridging carbonyl between the two four-connected (4) vertices. The pattern of bond lengths is clearer and follows the trend M(4)—M(4) < M(4)—M(3) < M(5)—M(5) < M(5) —M(3) < M(4)—M(5), where shortening of M(4)—M(3) and M(4)—M(4) connections is attributable to reduced steric crowding and μ-CO on the M(4)—M(4) edge. The lengthening of M(4)—M(5) edges with respect to M(3)—M(5) edges is related to the presence of face-bridging hydrides.

Bicapped tetrahedral clusters in which three carbonyl ligands are replaced, formally, by an arene ligand may be produced by the ionic coupling reaction (eqn (5)) [41,42]:

$$[Os_5(CO)_{15}]^{2-} \xrightarrow{[M(\eta^6\text{-}C_6H_6)(MeCN)_3]^{2+}[BF_4]_2^-} [Os_5(CO)_{15}M(\eta^6\text{-}C_6H_6)]$$

$$\{M = Os\ \mathbf{32}, Ru\ \mathbf{33}\}$$

$$\xrightarrow{[Os(\eta^6\text{-}C_6H_5CH_3)(CF_3SO_3)_2]} [Os_6(CO)_{15}(\eta^6\text{-}C_6H_6)]\ \mathbf{34} \quad (5)$$

For these arene-substituted clusters there is good evidence that more than one isomer exists but one isomer has been crystallised and structurally characterised for **32**–**34**. Whereas the arene is bound to a metal atom in an 18e⁻ (4) site in $Os_6(CO)_{15}(\eta^6\text{-}C_6H_6)$ **32**, it adopts

the $17e^-$ (3) site in **33** and **34** (Fig. 21). Electronic factors would be expected to favour the sites in the order (5) > (4) > (3) with respect to metal–metal connectivity (since, at a simplistic level, the presence of better donor ligands in sites of higher formal electron count will enhance the strength of the formal donor bonds). However, the reverse would be expected on steric grounds, i.e. (3) > (4) > (5). Thus the observed geometries are a compromise between these two opposing influences. For **33** and **34,** solution studies identify the existence of a (4) substituted isomer which does not interconvert with the (3) isomer in the temperature range studied; there is also some evidence for a second isomer of **32** ((3)) in solution in addition to the major (45%) (4) product [30]. Only one isomer of $Os_6(CO)_{15}(\eta^6\text{-}C_6H_3Me_3)$ **35** is found in solution, with the bulky mesitylene ligand in the sterically-favoured (3) site [43]. The precise details of the mechanism leading to the (4) isomers remain unclear, although ^{13}C labelling experiments suggest that the related "capping" of $[Os_{15}(CO)_{15}]^{2-}$ with $[Ru(CO)_3(MeCN)]^{2+}$ proceeds via an edge-cleavage process [43]. Alternatively, $Os_6(CO)_{15}(\eta^6\text{-}C_6H_6)$ **34** may be synthesised in low yield from the reaction of $Os_6(CO)_{18}$ with three equivalents of Me_3NO in the presence of benzene.

Metal core geometries of the (3) isomers of **33** and **34** are strictly comparable in the solid state, given relatively large E.S.D.s for the Ru compound **33** (Table 3). The most striking feature of these molecules is the short metal–metal bond (ca 2.6 Å) which is associated with a semi-bridging CO ligand that is coordinated to the arene-substituted metal atom. The latter is more incipient in character in **33,** which has been attributed to the decreased electronegativity of Ru cf Os [42], but this may not be significant given the relatively poor quality of the Ru structure. This shortening is accompanied by considerable lengthening of the other bonds to arene-substituted metal (Table 3) compared to those in $Os_6(CO)_{18}$ **30**. The central tetrahedron is also twisted, such that M_1—M_3 and M_2—M_4 are shorter and M_1—M_4 and M_2—M_3 are longer (see labelling scheme in Table 3); this twist is associated with an elongation of the (4)—(4) bond M_3—M_4. This may be a consequence of intramolecular distortions in the ligand polyhedron introduced by the semi-bridging CO ligand or subtle changes in the electronic distribution in the molecule. Distances in $Os_6(CO)_{15}(\eta^6\text{-}C_6H_6)$ **32** do not differ as much from the $Os_6(CO)_{18}$ **30,** although there is a significant shortening of the M_3—M_4 and, especially, M_4—M_6 (by 0.09 Å) bonds; these changes are accompanied by small (ca 0.025 Å) decreases in distances M_2—M_3 and M_1—M_3.

If the capping reaction with $[Os_5(CO)_{15}]^{2-}$ is repeated using $[RhCp^*(MeCN)_3]^{2+}$ as the cationic reagent, three isomers are obtained from the one reaction [41]. The isomer that is produced in highest yield has been characterised structurally as $[Os_5Rh(CO)_{15}Cp^*]$ **36,** with the $Rh(\eta^5\text{-}C_5Me_5)$ group occupying one of the 17 electron, (3) connectivity centres; the sterically favoured product. The three isomers interconvert readily (on the ^1H NMR time scale) and samples of each revert to a mixture of isomers [41,44]. It is probable that the other isomers are (4) and (5) substituted products [41] and it is possible that the (5) isomer opens out to give the *bis* edge-bridged tetrahedral structure with $\mu_4\text{-}\eta^2$-CO ligands as in the Ru_5Rh analogue, $Ru_5(CO)_{12}(\mu\text{-}CO)(\eta^2\text{-}\mu_4\text{-}CO)_2RhCp^*$ **46** (Fig. 26) [45].

The anion $[Os_5(CO)_{15}RuCp]^-$ **37** may be prepared in a similar manner by the reaction of $[RuCp(MeCN)_3]^+$ with $[Os_5(CO)_{15}]^{2-}$ [30,46]. The ^1H NMR spectrum shows two singlets in the Cp region indicating that two isomers (probably with the RuCp in the (3) and (4) positions) are present in solution. Addition of one equivalent of $[AuPPh_3]^+[NO_3]^-$ yields the Au-capped species $Os_5(CO)_{15}RuCp(AuPPh_3)$ **38** [21] which has been studied crystallographically (Fig. 22). The asymmetric unit comprises two independent molecules, which although similar differ subtly in their ligand arrangements. These differences are reflected in variations in corresponding bond lengths (some of more than 0.05 Å) which are highly significant statistically, whereas the differences in light atom positions are of marginal significance.

Fig. 21. The molecular structures of **32, 33** and **34**.

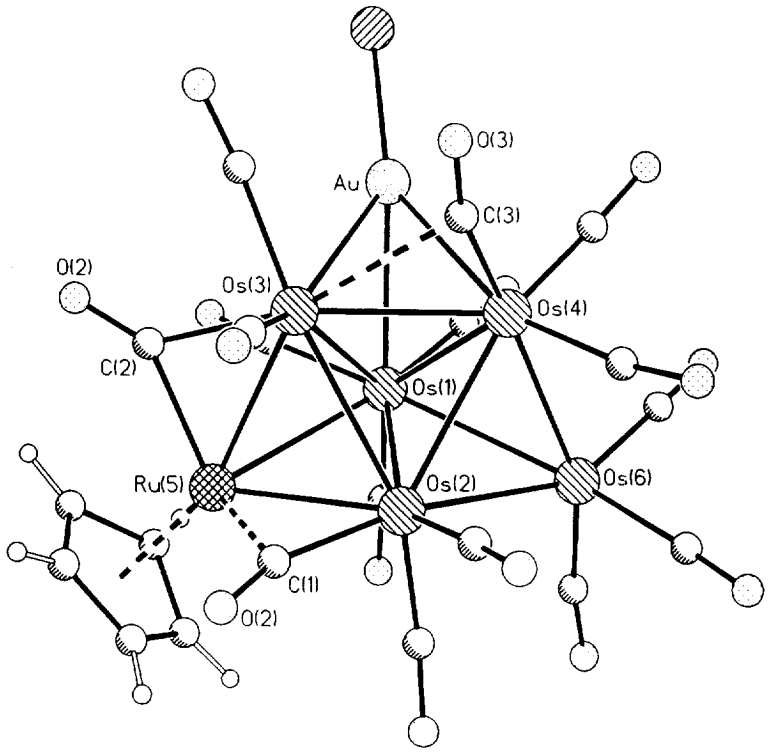

Fig. 22. Molecular structure of **38** with the phenyl rings omitted for clarity.

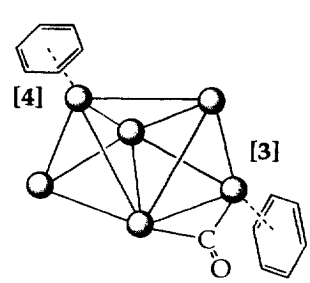
The reaction could be considered as a simple face-capping addition of the $[AuPPh_3]^+$ cation to the anion $[Os_5(CO)_{15}RuCp]^-$ **37**, since the RuCp moiety in $Os_5(CO)_{15}RuCp(AuPPh_3)$ **38** adopts the (3) position. However, ^1H and ^{31}P NMR spectra demonstrate the existence of other isomers in solution, which may have different positions of the Ru or Au centres (or both) compared to the solid-state structure [21]. The Au ligand caps one of the (5)(4)(4) faces Os(1)—Os(3)—Os(4) asymmetrically, with a considerably shorter bond to Os(1) in both independent molecules; this causes an elongation of the Os(1)—Os/Ru(3) and Os(1)—Os(4) bonds to distances of ca 2.9 Å or greater. The addition of the Au atom on this face necessitates a rearrangement of the ligand polyhedron around the Os(3)—Os(4) edge; one of the CO ligands forming a bridge to Ru(5) and another semi-bridging from Os(4) to Os(3). In both molecules, the Os(3)—Os(4) bond is ca 0.15–0.20 Å shorter than the other edges capped by the Au atom.

Having seen that it is possible to obtain the three possible isomers of the bicapped tetrahedral structures via the capping of dianionic pentanuclear clusters with dicationic mononuclear metal carbocyclic ligand fragments, it is logical to attempt to obtain bicapped tetrahedral structures in which two metal arene/cyclopentadienyl units replace two metal tricarbonyl units, and to investigate which isomers predominate in this situation. *Bis*-arene clusters $Os_4MM'(CO)_{12}(\eta^6\text{-Ar})(\eta^6\text{-Ar}')$ [Ar = Ar′ = C_6H_6, M = M′ = Os **39**; M = Os, M′ = Ru **40**; M = M′ = Ru **41**; Ar = C_6H_6, Ar′ = C_6H_5Me, M = M′ = Os **42**] may be prepared from the axially-substituted pentanuclear intermediates $H_2Os_4(CO)_{12}M(\eta^6\text{-Ar})$ (M = Ru **4**, Os **5**) by deprotonation and subsequent capping with dicationic reagents [25,47]. In all the structurally characterised products **39–42**, one arene ligand substitutes in a (3) and the other in a (4) site (Fig. 23), and there is no evidence for (4), (4) or (3), (3) isomers in solution or in the solid state. The (4), (4) isomer may be disfavoured electronically (too much electron density on adjacent metal atoms) and/or sterically. The isomer of $Os_5Ru(CO)_{12}(\eta^6\text{-}C_6H_6)_2$ **40** with Ru in the (3) position and Os in (4) position is produced irrespective of



$[Os_4(CO)_{12}MM'(arene)(arene')]$ **(39–42)**

Fig. 23. The structures of clusters **39–42**.

whether the Ru(η^6-Ar) fragment originates from the cluster anion or the capping anion. The toluene ligand occupies a (3) site in **42,** probably for steric reasons. Since simple capping products ((3), (3)) are not observed, metal core rearrangement must occur to generate the thermodynamically favoured product. It should be noted that rearrangement of the pentanuclear anion would not be sufficient to account for the formation of **40** by both routes. No evidence was found for arene migration in these studies, the arene remaining bound to the capping metal atom where this could be distinguished, i.e. in **40** and **41**.

The bond lengths in all four compounds are similar, and the *bis*(benzene) compounds **39–41** are isomorphous. Given that a series of closely related, independently measured structures is available, it is instructive to compare the bond parameters across the series by analytical methods. This can be achieved by means of a half-normal probability plot which shows whether systematic differences exist between the sets of parameters being compared [48]. In the case of the series of arene-substituted clusters, comparison of coordinates on half-normal probability plots (Fig. 24) indicates that there are significant differences in dimensions of the metal–metal core at level of nominal E.S.D.s, reflecting subtle differences in electronic behaviour of Os and Ru in these systems. However, CO and arene ligand positions are consistent with random error underestimated by factors of ca 1.5–1.6, indicating that the limited precision of light atom positions precludes detailed structural investigation of differences in the ligand polyhedra.

Distances involving the capped metal atom M(5) in compounds **39–42** (Table 4) have a similar asymmetry to those in **33** and **34** and the geometry of the semi-bridging CO is strictly comparable to that in **34,** although elongation of the M_1—M_5 bond is less marked. The same shortening of the M_6—M_4 edge is apparent as in $Os_6(CO)_{15}(\eta^6\text{-}C_6H_6)$ **32**; M_3—M_4 is longer than in either **30** or **32** but shorter than in **33–38**. The central tetrahedron is twisted as in **33–34,** although bonds to M_2 are considerably shorter (by $\geqslant 0.04$ Å). Similarly, M_2—M_6 is shorter than in either the (3) or (4) mono-arene isomers and may reflect, in part, reduced crowding with μ-CO at M_2. It should be noted that these changes will not be independent of each other, as changes in electron distribution and the ligand polyhedron will influence the entire cluster core.

Whilst the isomer with Cp or arene in the (5) site are unknown, compounds formally derived from this in which the metal core has opened out to provide a *bis* edge-bridged structure have been observed (Fig. 25). These contain carbonyl ligands in the uncommon μ_4-η^2-CO bonding mode, with the C=O π-bond donating two electrons to the bridging metal atoms after having "inserted" into the M_1—M_5 and M_1—M_6 bonds.

The $Ru_6(CO)_{15}(\eta^6\text{-}C_6Me_6)$ **43** and $Ru_6(CO)_{15}(\eta^6\text{-}1,3,5\text{-}Me_3C_6H_3)$ **44** clusters with this geometry are produced in the thermolysis of the respective arene with $Ru_3(CO)_{12}$ [49,50,51]. The central core structures are very similar (Table 4 and Fig. 25), with the shortest bond being M_3—M_4 which bears a μ-CO ligand. Within the central tetrahedron, the next shortest bonds are M_2—M_3 and M_2—M_4, between metal atoms with the (5) and (4) metal–metal connections. Edge bridge bonds to the (4) metals, M_3 and M_4 are shorter than those to M_2 which has connections to five metal atoms. Thermolysis of $Ru_3(CO)_{12}$ with cyclohexene leads to ring closure and production of an η^5-C_5H_4Me ligand which is bound to the apical atom M_1 in a similar structure **45,** although replacement of a $6e^-$ with a $5e^-$ donor is accompanied by a contract of the bonds to M_1 [52]. A μ_3-H ligand caps the basal face of the tetrahedron, causing these bonds to be elongated.

The heterometallic cluster $Ru_5(CO)_{15}RhCp^*$ **46** has been synthesised recently via an ionic coupling reaction accompanied by loss of $Ru(CO)_3$ group, as shown in (eqn (6)) [45]:

$$[Ru_6(CO)_{18}]^{2-} \xrightarrow[-\text{"}[Ru(CO)_3]\text{"}]{[RhCp^*(MeCN)_3]^{2+}} Ru_5(CO)_{12}(\mu\text{-}CO)(\eta^2\text{-}\mu_4CO)_2RhCp^* \quad (6)$$

The crystal structure comprises two independent molecules of $Ru_5(CO)_{15}RhCp^*$ **46** (Fig. 26) in the asymmetric unit, each lying on a mirror plane. Bond lengths in the metal core and those involving μ_4-CO ligands are broadly similar to those in **43–44**. The opening of the structure may serve to decrease steric congestion at the formally $19e^-$ site and/or reduce electron density at this site with the formation of face-capping CO ligands with enhanced π-acceptor character [45]. However, the fact that this type of structure is observed does suggest that "electron rich" donor groups, such as RhCp*, would be expected to occupy the $19e^-$ site.

Octahedral clusters

Theoretically, clusters based on an octahedral core could be formed by the ionic coupling of an anionic square-based pyramidal cluster with a cationic metal fragment. Such ionic coupling has been achieved when the square based pyramidal dianion is stabilised by a semi-interstitial carbido ligand, as in the anion $[Ru_5C(CO)_{14}]^{2-}$. However, unlike all the previous examples discussed for penta- and hexanuclear clusters, all six metal sites in the octahedral are electronically equivalent, with the same number of metal connections, and the opportunity for isomerism, in terms for the ligand positions, is severely limited. Again, unlike the bicapped tetrahedral clusters, there are not the appropriate number of electrons to describe the octahedral core geometries, even formally, in terms of localised two-centre two-electron metal–metal bonds, but applying Wade's Rules, all the octahedral carbo-

(46)

Fig. 26. The molecular structure of **46**.

cyclic ligand-substituted clusters have seven electron pairs for cluster framework bonding.

Since the structural chemistry of the central octahedral core of octahedral metal carbonyl clusters is fairly straightforward much attention has been focused on polymorphism and intermolecular interactions in Ru_6C systems [53,54,55], with packing energies being estimated for different arrangements. These species are characterised by a relatively flexible ligand polyhedron (which may be attributed to the inherent asymmetry in an $Ru_6(CO)_{17}$ structure with six metal vertices and 17 ligands, there being no unique low-energy manner in which to arrange them). It has been remarked previously [55,56,57] that the observed structures represent different compromises between conformational energies and crystal energy, i.e. the potential energy surface is relatively flat and conformation can be controlled at the intermolecular level [55]. Furthermore, there is a great variation in metal–metal bond lengths in different polymorphs and between crystallographically independent molecules in the lattice, i.e. M—M bonds are "soft" and adaptable to the electronic and steric demands of the ligands and packing arrangements [55]. This is expected because there is a greater delocalisation of the bonding electron density in the O_h core than in the lower symmetry (C_{2v}) bicapped tetrahedral systems, and the bonding in the octahedron cannot be rationalised in terms of a localised bonding description.

This flexibility should allow a greater part of the ligand conformational surface to be investigated, since it allows more local minima to be observed in the solid state. However, these polyhedra themselves have not been investigated in any detail previously, although three possible conformers were identified for $Ru_6C(CO)_{17}$ **47**, those with $(CO)_3$ units *cis-cis*, *cis-trans* and *trans-trans*

to the most symmetric bridging CO ligand (Fig. 27) [55]. In the two polymorphs reported [55,58], I is essentially *cis-trans* (I) while II has 11/2 molecules in the asymmetric unit, one on a 2-fold axis, with approximately *cis-cis* arrangements (IIA and IIB).

The ligand polyhedra are shown in Fig. 28, the carbonyl ligands being represented by the centroid of the C—O bond. I has an essentially 3 : 4 : 3 : 4 : (3) polytopal form (Fig. 28a) based on a tricapped trapezoidal prism with two triangles above and below the trapezoidal faces. In the solid state structure, the upper *trans* triangle (shaded spheres) is tilted with respect to the trapezoidal face (dotted spheres) and the *trans* CO ligand (denoted t) causes a significant lengthening of the uncapped rectangular face. A bridging CO ligand on an adjacent molecule "locks" into the irregular pentagonal hole thus generated in the ligand polyhedron [55]. The C_2-symmetric molecules IIb also pack in a similar "head-to-tail" manner, into the uncapped square face. The $(CO)_3$ units deviate subtly from an ideal *cis* arrangement, in that the CO ligands associated with the uncapped edges are twisted such that one CO (denoted a) lies over one of the long edges of the trapezia (black spheres), interactions with the semi-bridging CO ligands causing a complementary tilt of the central triangle (denoted b and t) (Fig. 28b). This provides two voids in the coordination polyhedron, which may interlock with the other (crystallographically independent) molecules. In IIa (Fig. 28c), one $(CO)_3$ group is in the symmetric *cis* conformation whilst the other is twisted as in IIb. In both the "*cis-cis*" variants, the bridging CO ligand is in a six-connected environment in the ligand polyhedron.

One way to display and compare ligand polyhedra is to produce a plot in which the positions of the centroids of the carbonyl ligands are converted to spherical polar coordinates, which are defined in terms of two angles θ and ϕ, and show the orientation of the ligands with respect to a common origin. These conformations for the polymorphs of **47** are represented in the symmetry-expanded spherical polar coordinate plot (Fig 29) which shows the angular disposition of the centroids of the C—O bonds with respect to the centroid of the Ru_6 octahedron as defined in Section 4.2 (each circle representing the position of a carbonyl ligand in one of the polymorphic structures). It can be seen that there is little variation in the positions of the bridging and semi-bridging CO ligands in the equatorial plane (these lying at positions close to ϕ 0°, 120° and 240° for the *cis-cis* form), whilst a preferred orientation for the $M(CO)_3$ units (circles lying close to the centre of the plot) is not apparent.

Mono-arene derivatives which contain an octahedral metal core may be prepared by a variety of routes. In addition to ionic coupling, these routes include the thermolysis of the arene with $Ru_3(CO)_{12}$ and reaction of $Ru_6C(CO)_{17}$ **47** with 1,3 or 1,4 hexadiene in presence of excess Me_3NO, and these methods of synthesis are summarised in a recent review [59]. Two polymorphs of $Ru_6C(CO)_{14}(\eta^6\text{-}1,4\text{-}C_6H_4Me_2)$ **48** have been synthesised recently by a different route [60].

Scatter plots can be used to show that the carbonyl ligands in the polymorphs of **48** adopt similar arrangements to those in $Ru_6C(CO)_{17}$ **47**, by comparison of Fig. 30 to Fig. 29, in particular the central 4 : 3 : 4 unit is maintained. The variations in the precise positions of the CO ligands in this central girdle of the ligand polyhedron may be attributed to differences in the nature of the arene and orientation of the terminal $M(CO)_3$ unit. These three ligands show no clear orientational preference, as in **47**. This has important consequences for the interpretation of fluxional processes in these molecules since it indicates that the $M(CO)_3$ unit could rotate independently of the other 14 CO ligands; whilst perturbing them to some extent, a complete polytopal rearrangement would not be required.

Scatter plots can also be used to analyse the orien-

tation of the arene rings with respect to the carbonyl polyhedron. With three substituents in the 1,3,5 positions on the benzene ring in $Ru_6C(CO)_{14}(C_6H_3R_3)$ [$C_6H_3Me_3$ **49** [54,58], $C_6H_3Et_3$ **50** [53]], one substituent lies parallel to the bridging CO ligand (0° position in ϕ) and the other two over the long sides of the trapezoidal face ($\pm 120°$ positions), minimising ligand–ligand interactions (Fig. 30b). Similar orientations are observed with 1,3-xylene (**51**): in one of the crystallographically independent molecules, and in the co-crystal with $[Ru_6C(CO)_{11}(\eta^6\text{-}1,3\text{-}C_6H_4Me_2)_2]$ **61,** one Me group is parallel to the μ-CO ligand, whereas in the other independent molecule, both Me groups are in the $\pm 120°$ positions [52,61]. In $Ru_6C(CO)_{14}(\eta^6\text{-}C_6H_5Me)$ **52** [62] and $Ru_6C(CO)_{14}(\eta^6\text{-}C_6H_5\{(CH_2)_2Ph\})$ **53** [63], the α-carbon lies parallel to the bridging CO (0° position) whilst with η^6-biphenyl the free Ph is in the 120° orientation [63]. With such bulky ligands, intermolecular interactions will be even more important in determining the conformation, given difficulties in ensuring an efficient packing motif.

A quite different orientation is displayed by *para*-substituted arenes, as exemplified by the *p*-xylene polymorphs **49** I and **49** II. The structure of **49** I was determined at room temperature and shows high thermal motion in some of the CO ligands which was modelled as two-fold disorder (Fig. 31, the dotted spheres and the dashed lines showing the second orientation). The carbonyl polyhedron of **49** II, determined at 153 K, is not disordered thermally. Scatter plots show that in both

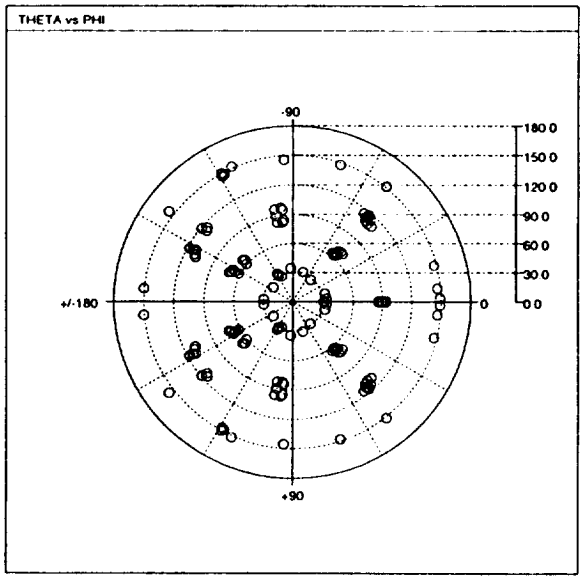

Fig. 29. Polar scatterplot of CO centroid distribution in the polymorphs of **47**.

polymorphs, the Me groups lie parallel to the bridged Ru—Ru edge (90° positions) such that the C_6 ring is rotated by 30° compared to those in **50–54**.

The arene conformation in $Ru_6C(CO)_{14}(\eta^6\text{-}1,4\text{-}C_6H_4Ph_2)$ **54** [64] is similar (although somewhat twisted) and the single CH_2Ph subsistent in $Ru_6C(CO)_{14}\{\eta^6\text{-}C_6H_5(CH_2Ph)\}$ **55** adopts the same position [63]. The benzene ligand in $Ru_6C(CO)_{14}(\eta^6\text{-}C_6H_6)$ **56**, which would not be expected to have a strong orientational preference, has one H aligned approximately parallel to the bridging CO [65]. The preference for substituents to adopt 0°, ±90° and ±120° is a common feature of all these clusters (Fig. 30b), the reluctance of the substituents to lie over the short edge of the trapezium (180° position) being due to the steric crowding with the two CO ligands at these vertices. In these structures, the carbido C atom is displaced from the centroid of the Ru_6 octahedron (mean 0.084(6) Å) towards the arene-bonded vertex to compensate for the greater donor ability of the arene [54,62].

Capping of $[Ru_5C(CO)_{14}]^{2-}$ with one equivalent of the monocation $[RuCp(MeCN)_3]^+[PF_6]^-$ produces the octahedral anion $[Ru_6C(CO)_{14}Cp]^-$ **57** as one product which has been characterised structurally as the $[(Ph_3P)_2N]^+$ salt [30,66]. The structure of this anion is similar to that of the arene complexes and the related cluster $[Ru_6C(CO)_{14}(\eta^5\text{-}C_5H_4PPh_3)]$ **58** [67]. The carbonyl polyhedra of **57** and **58** are similar, showing a similar scatter plot distribution (Fig. 30a), and scatter plots of the Cp rings show that they are tilted in both complexes away from the semi-bridging CO as this ligand occupies the position at θ and ϕ of zero (as defined earlier) (Fig. 32a).

Similarly, coupling of $[Ru_5C(CO)_{14}]^{2-}$ with $[RhCp^*(MeCN)_3]^{2+}$ yields the octahedral cluster $Ru_5RhCp^*(CO)_{14}$ **59** [68,69]. As in the homonuclear mono(arene) structures, the carbido C atom is displaced slightly toward the carbocycle-bound metal atom (by ca 0.01 Å). Although this displacement is not highly significant statistically, it is apparent in two independent determinations of this structure [68,69], and has also been observed in the structure determinations for all the arene-substituted Ru_6C cores [61–64]. The carbonyl ligand arrangement is similar to that in **48–58**; the orientation of the Cp* ligand (Fig. 32b) differs from that of the Cp ligand in complexes **57** and **58** by comparison to the orientation shown in the scatter plot for these complexes (Fig. 32a).

So far, only mono-carbocyclic-substituted octahedral carbonyl clusters have been considered. With di-substituted octahedral clusters isomers are again possible. *Bis*(arene) octahedral clusters exhibited three principal coordination modes: *cis*-η^6,η^6; $\eta^6,\mu_3\text{-}\eta^2:\eta^2:\eta^2$ and *trans*-η^6,η^6 (Fig. 33), but the structural chemistry of these systems has not yet been extensively exploited [59]. On steric grounds, with the arene rings at opposite ends of the cluster, the *trans*-η^6,η^6 coordination mode is the most common. The CO distribution is similar to that in $Ru_6C(CO)_{17}$ **47** in the *trans*-η^6,η^6 only, the central 4 : 3 : 4 layers being maintained (Fig. 34a). In some examples, the central triangle is tilted and the short edges of the trapezia are mutually skewed (Fig. 34b); such an arrangement maintains C_2 symmetry although the mirror planes are lost. This effect can also be seen in the polar scatter plot (Fig. 35a), angle ϕ for the CO ligands at $\phi \approx \pm 150°$ spanning a 30° range.

In the *bis*(mesitylene) cluster $Ru_6C(CO)_{11}(\eta^6\text{-}C_6H_3Me_3)_2$ **60** [70,71], the methyl groups adopt the same configuration as in **49** and are mutually staggered; the CO polyhedron adopts the less twisted form (Fig. 34a). The mixed arene cluster $Ru_6C(CO)_{11}(\eta^6\text{-}1,3\text{-}C_6H_4Me_2)(\eta^6\text{-}C_6H_5Me)$ **61** is similar [72], with an Me

group of each arene lying parallel to μ-CO ligand ($\phi = 0°$ position). Whereas in the co-crystal of $Ru_6C(CO)_{11}(\eta^6\text{-}1,3\text{-}Me_2C_6H_4)_2$ **62** with **51** all methyl groups are mutually staggered, the structure of **62** alone has crystallographic C_2 symmetry and the CO ligands adopt the more twisted arrangement (Fig. 34b) with only the Me groups at 0° being staggered [61]. This serves to decrease the distance between the CO ligands and H atoms of the methyl groups, consistent with some intramolecular attraction.

The *bis*(benzene) complex **63** [73] has the same CO arrangement and precise C_2 symmetry; benzene ligands are twisted slightly from staggered conformation, concomitant with distortion of CO arrangement. It is apparent from Fig. 35b that substituents on the arene adopt the $\phi = 0°$, $\pm 120°$ positions, no examples with *para* substituents having been characterised structurally.

CONCLUSIONS

From the range of structures reviewed above it is apparent that metal clusters, where the metal framework structures can, at least formally, be rationalised in terms of localised bonding schemes (those penta- and hexanuclear clusters based on fused tetrahedral metal core geometries), do exhibit a structural chemistry which retains remnant of localised metal–metal bonding. In cation/anion coupling reactions between tetrahedral cluster anions and mononuclear carbocyclic-coordinated metal cations the resulting pentanuclear clusters offer more than one possible site for the cationic capping group to attach itself to the cluster. In trigonal bipyramidal structures, the carbocyclic ligand-coordinated metal unit occupies the $20e^-$ equatorial site, i.e. the thermodynamic product with the "electron-rich" group in the site of higher metal coordination number, and this product may be thought to be produced by a metal framework rearrangement. Generally, the "electron rich" metal is associated with (semi-)bridging CO or H ligands. The initial kinetic product may be the simple axially-capped derivative in some cases, although these are susceptible to nucleophilic attack to generate edge-bridged structures, in which the metal arene or metal cyclopentadienyl fragment invariably adopts the bridging site. When phosphines are present, such edge-bridged structures may rearrange to spike-tetrahedral clusters in which orthometallation of the arene or cyclopentadienyl ligand has occurred.

By contrast, coupling reactions between tetrahedral cluster anions and $[AuPR_3]^+$ fragments, give products in which the gold-containing fragment just clips on to an edge or a face of the existing metal carbonyl polyhedron, and no metal framework rearrangement necessarily occurs.

Three distinct sites with formal electron counts of 17, 18 and $19e^-$ are available for substitution in bicapped tetrahedral clusters. No clear preferences emerge, since steric and electronic factors are opposed, and several isomers exist for a number of compounds in solution. The presence of the arene has a greater effect on the geometry of the metal core in the (3) $17e^-$ isomers, one bond to this cap being shortened significantly and associated with a semi-bridging carbonyl interaction. Where two arene fragments are present, one adopts a $17e^-$ and the other an $18e^-$ site, presumably for steric reasons. No clusters with an arene or Cp ligand in the $19e^-$ site are known. However, when good electron donor fragments, such as "$Ru(C_6H_3Me_3)$" or "$Rh(C_5Me_5)$" are introduced into the cluster, the core opens

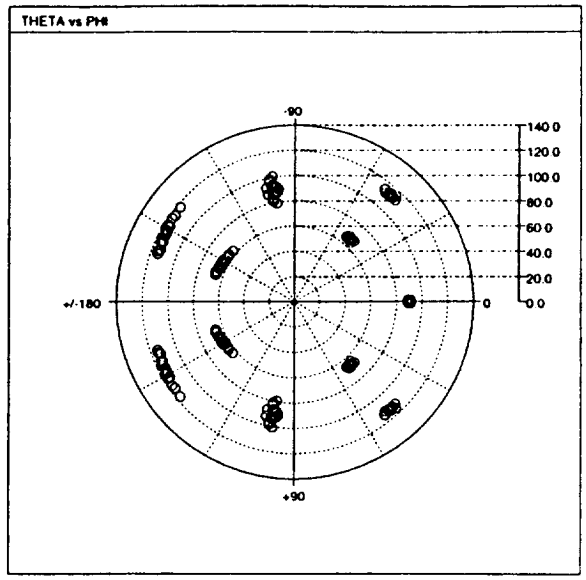
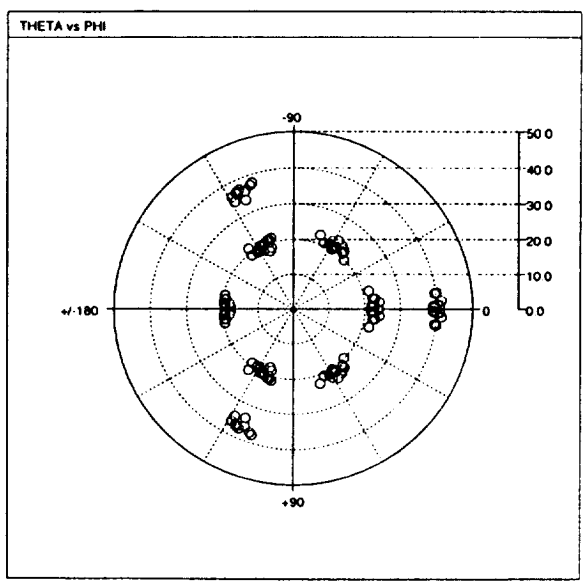
out to a *bis* edge-bridged tetrahedral arrangement with two μ_2-η^4-CO ligands, and the "electron rich" metal-carbocyclic ligand fragment occupies the previously $19e^-$ site.

The M_6 octahedral clusters exhibit delocalised metal framework bonding, and coupling reactions between metal–arene and metal–cyclopentadienyl cationic fragments and carbido-stabilised square-base pyramidal cluster anions afford simple octahedral coupled products. The octahedral carbido clusters that have been structurally studied display essentially the same ligand arrangement which is highly flexible. This is reflected in the M—M distances which follow no clear trend. Since, in an octahedron all the metal sites are equivalent, there are no favoured positions for the metal carbocyclic ligand units in the mono-substituted clusters. The orientational preferences of arene ligands with different substituents may be rationalised by analysing the CO ligand polyhedra. One clear electronic effect in these structures is the tendency for the interstitial carbido ligand to be displaced towards the arene-bearing metal vertex and is reminiscent of the behaviour of the alkyne-bridged tetranuclear clusters [74].

Half-normal probability plots for isomorphous structures demonstrate that while errors in light-atom positions are too large to make any comparison of their positions, differences in metal coordinates are significant. However, the significance of M—M bond distances will



(a)



(b)

Fig. 35. Polar scatter plots of (a) CO distribution and (b) arene orientation in **60–63**.

also be dependent on the accuracy and precision of the unit cell parameters, the uncertainties in which may be seriously underestimated in some cases [75]. Furthermore, comparison of differences in chemically-equivalent M—M bond distances, within the same molecule or between independent molecules in the same or different crystal structures using the χ^2 test, indicates that they are significant at the 99% probability level, based on the nominal E.S.D.s. In the solid state, these differences reflect the softness of the M—M parameters and may be attributed to a variety of intra- and intermolecular interactions, and give cause for caution in their interpretation.

METHODOLOGY

Half-normal probability plots

Atomic coordinates and E.S.D.s were obtained from the original refinements where these had been performed in the Department of Chemistry, Uni-

versity of Cambridge. Otherwise, coordinates were downloaded from the CSD and E.S.D.s were entered manually from the original publications (although coordinate E.S.D.s have been stored in the CSD from a certain date, it is not possible to obtain them using the currently available software). The deviations $|\delta_i|$ were calculated by a FORTRAN-77 program written by the author, incorporating an ordering subroutine based on the delayed-exchange shellsort [76] procedure. The expected order statistics were derived using subroutine G01DAF in the NAG FORTRAN library [77]. The actual and expected order statistics, scaled by a factor of 100, were output in the form of a CSD.tab file [78] and imported into the program VISTA [79] for scatter plotting and gradient calculation. In some cases, E.S.D.s were only available to one significant figure; the consequent rounding errors being manifested as undulations on the half-normal plots.

Polar scatter plots for Ru_6C *clusters*

Atomic coordinates were obtained from the original refinements, where these were available, or from the CSD. The Ru_6 octahedra were fitted by a least-squares procedure to an ideal O_h geometry (Fig. 36) with Ru—Ru bond lengths of 2.89 Å (mean length in 2 polymorphs of $Ru_6(CO)_{17}$) using the program XP [80] and mass-weighted centroids of the C—O bonds calculated. The x axis was taken as bisecting the Ru—Ru bond bridged most symmetrically by a CO ligand and the coordinates of the metal and ligand atoms were output as Cartesian coordinates. The deviation of the carbido C atom from the centroid of the ideal octahedron and the spherical polar coordinates of the CO centroids, C atoms in arene/Cp rings and α C atom of any substituents were calculated using a program developed by the author for the purpose and exported in .tab format. The coordinates of the $Ru_6(CO)_{17}$ and $Ru_6(CO)_{11}L_2$ structures were four-fold permuted to take into account their ideal C_{2v} symmetry, whereas the $Ru_6(CO)_{14}L$ structures were two-fold permuted to represent their ideal $C_{s(v)}$ symmetry. Histograms and polar scatter plots were produced using the program VISTA.

(Received 8 October 1997; accepted 17 December 1997)

Abstract—Variable temperature, MAS and wide-line solid state NMR measurements have been carried out on $H_4Ru_4(CO)_{12}$ and $H_4Ru_4(CO)_{11}\{P(OMe)_3\}$. The variation of spin-lattice relaxation time (T_1) and linewidth at half intensity ($\Delta\nu_{1/2}$) of the hydride resonance with temperature for both samples are very similar and suggests that a common hydride movement occurs with $E_a = 17 \pm 2$ kJ mol^{-1}. We attribute this movement to a 2-site H-flip about H-occupied Ru—Ru edges which preserves the site symmetry of the crystals. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: cluster carbonyls; solid state NMR; hydride; ruthenium.

There is now a large number of transition metal carbonyl clusters containing hydride ligands but the *exact* H-location in the solid state is difficult without the benefit of a neutron diffraction structure [1]. It is sometimes possible in solution to obtain the limiting low temperature spectrum which can distinguish between terminal, edge-, face-bridging, pseudo-interstitial and interstitial site occupancy when the metal has a spin (e.g. ^{103}Rh [2–4]) or through other two bond spin-spin coupling data as exemplified by $H_4Ru_4(CO)_{11}\{P(OMe)_3\}$, *vide infra* [5]. In solution, H is notoriously labile and variable temperature NMR measurements show that it can undergo a variety of fluxional processes including migration within the metallic skeleton [4] and migration over the periphery of the metallic skeleton [2,5]. Comparative H-migrational studies between the behaviour found in the solid state and in solution are much less numerous. However, initial comparative studies on $H_2Ru_2Rh_2(CO)_{12}$ [6], $[H_xRh_{13}(CO)_{24}]^{(5-x)-}$ ($x = 2, 3$) [6] and $H_4Ru_4(CO)_{12}$ [7] in all cases suggest that there is much more restricted H-movement in the solid compared to the solution state. Following our recent work on $H_2Ru_2Rh_2(CO)_{12}$ [6], and in order to gain further insight into H-migration in tetranuclear carbonyl clusters in the solid state, we now report solid state NMR measurements on $H_4Ru_4(CO)_{12-x}L_x$ ($x = 0$, 1; $L = P(OMe)_3$) which give an activation energy for H-motion in $H_4Ru_4(CO)_{12}$ that is significantly different to the previously reported value [7].

The structures of $H_4M_4(CO)_{12-x}L_x$ (M = Ru, Os; $x = 0$–4; L = PR_3 or $P(OR)_3$) have been reviewed [8]. For this series of compounds, neutron diffraction data is only available on $H_4Os_4(CO)_{11}\{P(OMe)_3\}$ [9] and $H_4Ru_4(CO)_8\{P(OMe)_3\}_4$ [10]. In both cases the hydrides occupy the four long edges of the M_4-tetrahedron and HYDEX [11] has been used to indirectly locate the hydrides from X-ray diffraction studies of related clusters. In this family of derivatives, all adopt a pseudo-D_{2d} H_4M_4-core (see Fig. 1) and progressive carbonyl substitution by other ligands occurs on different metals *trans* to the non-H-bridged metal–metal vector and *transoid* to each other in a step-wise

† This paper is dedicated to Professor Lord Lewis FRS for his outstanding contributions to inorganic chemistry and particularly his contributions to furthering the greater understanding of metal carbonyl clusters.

manner. In all these cases, the carbonyls are approximately ccp and each of the CO's in the $M(CO)_3$ unit is oriented over a M_3-face (see Fig. 2).

Solution NMR studies show that there is rapid intramolecular hydrogen-exchange for the substituted derivatives $H_4Ru_4(CO)_{12-x}\{P(OMe)_3\}_x$ ($x = 1, 2, 3, 4$) [5]. Thus, at room temperature, there is only one hydride chemical shift with a time-averaged coupling to phosphorus; on cooling to 149 K, the monosubstituted cluster has two equally intense hydride resonances at -17.55 ppm (singlet) and -18.10 ppm (doublet) (^2J(P—H) 12.5 Hz) which is entirely consistent with the solid state neutron diffraction structure of the analogous cluster, $H_4Os_4(CO)_{11}\{P(OMe)_3\}$ [9]. The activation energy for the H-exchange over the Ru_4-tetrahedron in $H_4Ru_4(CO)_{11}\{P(OMe)_3\}$ in solution is 14.2 kJ mol^{-1} and involves concerted H-movement from occupied to unoccupied Ru—Ru edges [13]. Solution measurements on $H_4Ru_4(CO)_{12}$ show that there is just one ^{13}C resonance (198.0 ppm) and one ^1H resonance (-17.98 ppm) down to 153 K and recently variable temperature ^{13}C-$\{^1H\}$ CP/MAS, ^1H MAS and ^1H wide-line NMR spectra of $H_4Ru_4(CO)_{12}$ have been reported [7]. These data were used to obtain an activation energy (67.2 ± 8 kJ mol^{-1}) for a motional process which does not involve the carbonyl ligands and was attributed to a dynamic process involving either the H_4Ru_4-core as a whole about the approximate C_2 axis which incorporates the midpoints of the non H-bridged Ru—Ru edges or a concerted motion of the hydrides over the surface of the Ru_4-tetrahedron between the four equivalent positions. From their T_1 data, Aime *et al.* [7] report the value of E_a of 59.2 kJ mol^{-1} but our calculations using their data shows that the value of E_a should be 32.3 kJ mol^{-1}. In order to resolve this discrepancy, we have repeated the solid state NMR measurements on $H_4Ru_4(CO)_{12}$. In addition, we now also report analogous measurements on $H_4Ru_4(CO)_{11}\{P(OMe)_3\}$.

RESULTS AND DISCUSSION

Variable temperature solid state ^1H NMR measurements have been carried out on $H_4Ru_4(CO)_{12-x}L_x$ ($x = 0, 1$; L = $P(OMe)_3$) together with ^{13}C CP/MAS measurements on the unsubstituted derivative. Room temperature ^{31}P-$\{^1H\}$ MAS measurements on H_4Ru_4

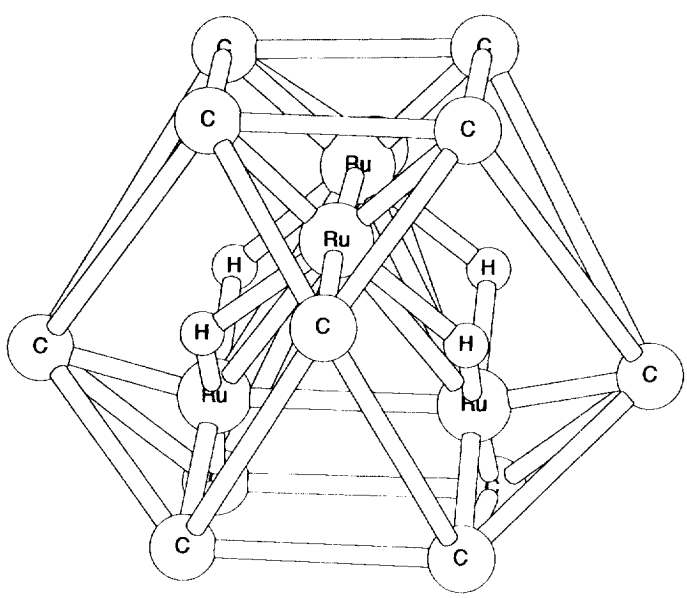

Fig. 2. Schematic representation of the H_4Ru_4-group within the CO-polyhedron of $H_4Ru_4(CO)_{12}$.

$(CO)_{11}\{P(OMe)_3\}$ have also been carried out and the spectrum consists of a single ^{31}P resonance at $\delta_{iso} = 145.7$ ppm with spinning sidebands. The observed spectrum can be simulated by using the parameters of $\delta_{11} = 256$, $\delta_{22} = 205$, and $\delta_{33} = -24$ ppm, and is entirely consistent with the presence of a single isomer (see Fig. 1) analogous to $H_4Os_4(CO)_{11}\{P(OMe)_3\}$ characterized by neutron diffraction [9]. Our room temperature ^{13}C CP/MAS NMR measurements on $H_4Ru_4(CO)_{12}$ are entirely in agreement with those reported previously [7] but our T_1 and wide-line ^1H NMR measurements on $H_4Ru_4(CO)_{12}$ differ significantly from those reported previously [7]. In addition, we now also report new ^1H NMR measurements on $H_4Ru_4(CO)_{11}\{P(OMe)_3\}$.

Variable temperature ^1H MAS spectra of $H_4Ru_4(CO)_{12}$ are shown in Fig. 3. The peaks between 0–5 ppm are due to residual solvent (octane and dichloromethane) and the centre of the hydride resonance appears at ca -18 ppm. It is to be noted that the relative ratio of solvent : hydride is much lower in our spectra than found previously [7] thus allowing us to obtain better data from wide-line measurements, *vide infra*. In agreement with earlier ^1H MAS measurements [7], there is only one hydride resonance. The observed sharpening of this peak above room temperature corresponds to the line-narrowing of the wide-line spectra as shown in Fig. 3 (at 200 MHz : 290 to ca 350 K; at 270 MHz [7]: 310 to ca 360 K). Crystallographically [12], because of the slight distortion of the Ru_4-core from T_d symmetry, we could expect up to four hydride resonances in the solid state but, in wide-line NMR measurements these resonances will be severely broadened due to dipole-dipole interactions. Thus, the lack of variation in $\Delta\nu_{1/2}$ of the hydride resonance at low temperature is consistent with the rigid-lattice structure but at higher temperatures some H-movement must occur in the solid state and, in order to obtain the activation energy (E_a) for this motion without MAS effects, we have measured wide-line ^1H NMR spectra (Fig. 4). Below 280 K, we can recognize the typical powder pattern (so-called "Pake doublets"), in which the peak separation is approximately given by [14,15]

$$\Delta\nu_{p-p} \approx \frac{3}{4\pi}\gamma^2 h d^{-3}. \quad (1)$$

Using eqn (1) and d(H—H) = 2.8 Å (obtained using HYDEX [11]) we obtain $\Delta\nu_{p-p} = 16.4$ kHz compared

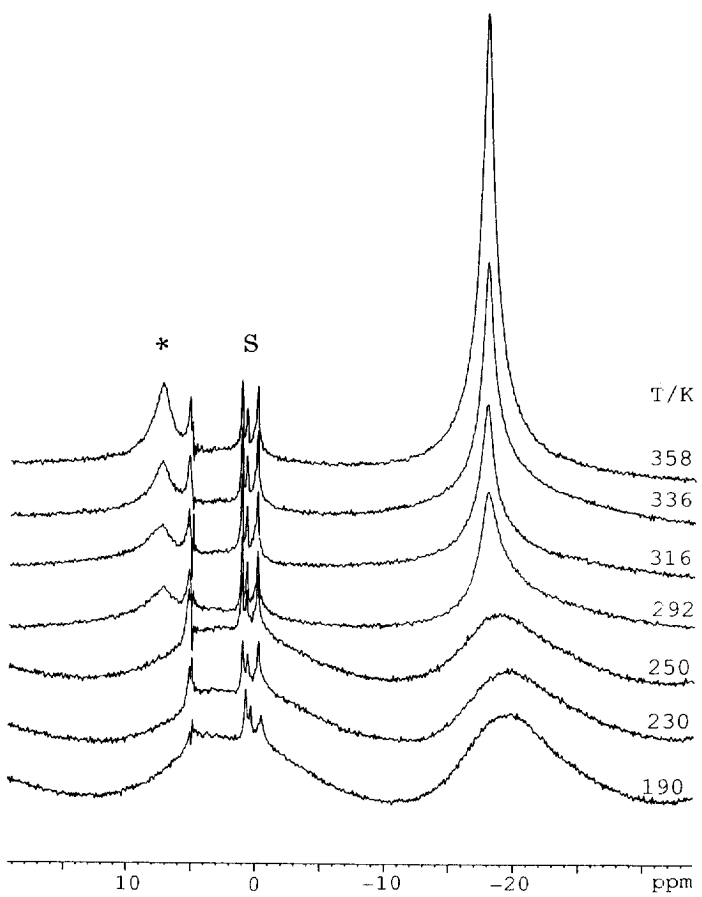

Fig. 3. Variable-temperature ^1H MAS NMR of $H_4Ru_4(CO)_{12}$ at a spinning rate of 5 kHz. * : sideband, S : solvent.

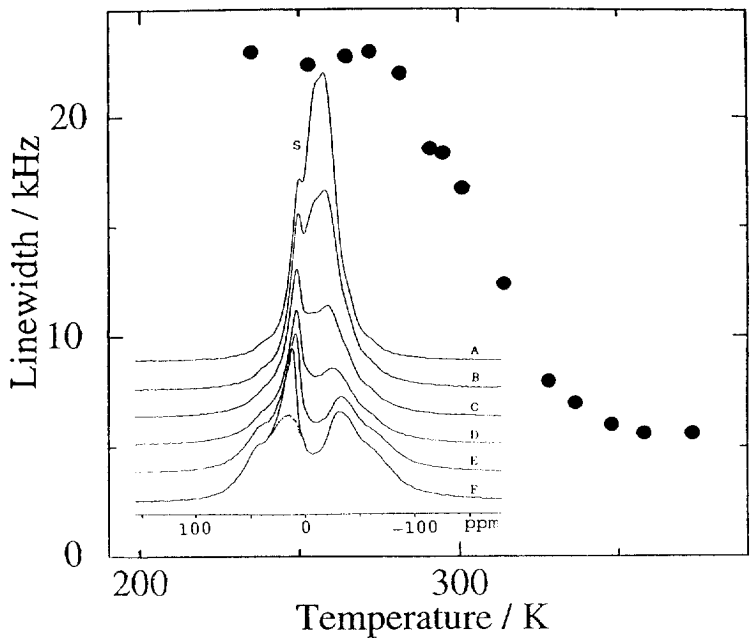

Fig. 4. Temperature dependence of the linewidth ($\Delta\nu_{1/2}$) of wide-line ^{1}H NMR spectra for $H_4Ru_4(CO)_{12}$. The spectra in the insert were measured at (A) 336, (B) 328, (C) 314, (D) 301, (E) 280, (F) 230 K, respectively. S: solvent.

with the peak-to-peak width, 14.5 ± 1.5 kHz, in the observed spectrum at 230 K (Fig. 4). It is, therefore, obvious that below 280 K $\Delta\nu_{1/2}$ assumes the rigid lattice value (23 kHz) which is much larger than the one (12 kHz) reported by Aime *et al.* [7]. Above 280 K, a distinct narrowing of the resonance was observed. The variation in $\Delta\nu_{1/2}$ of the hydride resonance with temperature allows us to calculate an activation energy of $E_a = 18.5 \pm 2$ kJ mol^{-1} which is much smaller than previously reported (75.1 kJ mol^{-1}) [7].

Figure 5 shows the temperature variation in the spin-lattice relaxation time (T_1) at 200 MHz for solid $H_4Ru_4(CO)_{12-x}L_x$ ($x = 0, 1$; L = $P(OMe)_3$) together with the data from previous measurements at 270 MHz on $H_4Ru_4(CO)_{12}$ [7]. These data and the variation in $\Delta\nu_{1/2}$ with temperature as described above indicate that the correlation time τ_c of the hydride motion in all these samples must be in the slow-motion region where $\omega_0\tau_c \gg 1$. It is interesting to compare our T_1 values for $H_4Ru_4(CO)_{12}$ with those reported in Ref. 7: as the dipolar T_1 is proportional to ω_0^2 in the slow-motion region, the T_1 values measured at 270 MHz must be longer than those measured at 200 MHz if there is no specific relaxation mechanism at high frequency. However, inspection of Fig. 5 shows that this is obviously not the case. It is possible that this results from an averaging of the intrinsic hydride relaxation with the very short relaxation of a large amount of solvent protons present in Aime *et al.*'s sample [7]; this would result in a shorter T_1 reported in Ref. 7 compared to the T_1 observed in the present study.

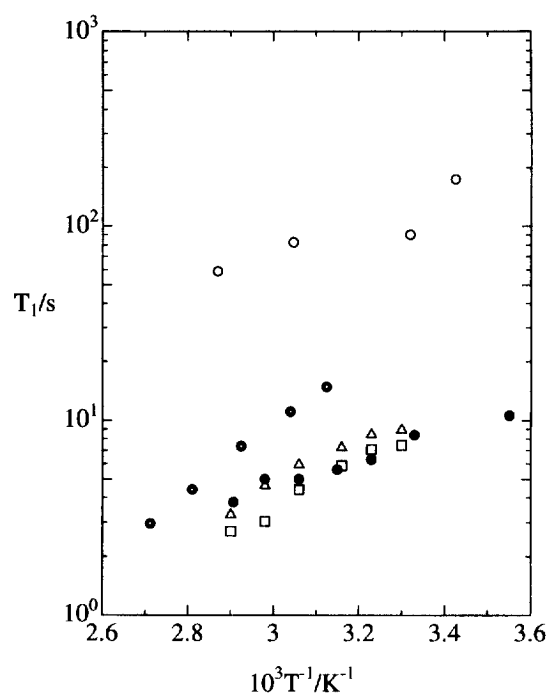

Fig. 5. Temperature dependence of the ^{1}H spin-lattice relaxation time (T_1) for: ○ $H_4Ru_4(CO)_{12}$ (from wide-line measurements); ◎ $H_4Ru_4(CO)_{12}$ (from wide-line measurements) [7]; ● $H_4Ru_4(CO)_{11}\{P(OMe)_3\}$ (from hydride resonance); □ $H_4Ru_4(CO)_{11}\{P(OMe)_3\}$ (from CH_3 resonance); △ $H_4Ru_4(CO)_{11}\{P(OMe)_3\}$ (from wide-line measurements).

We calculate E_a to be 16.1 ± 0.5 kJ mol^{-1} using our static T_1 data for $H_4Ru_4(CO)_{12}$ as shown in Fig. 5; this is in close agreement with the value calculated from the variation in $\Delta\nu_{1/2}$ with temperature, *vide supra* but significantly different from that reported by Aime *et al.* [7] ($E_a = 59.2$ kJ mol^{-1}); our recalculation, using their data, shows that their value of E_a should be 32.3 kJ mol^{-1} which is still much larger than the E_a value obtained from our measurements (see Table 1).

We have also measured the temperature dependence of the wide-line ^{1}H NMR spectra for the monosubstituted derivative [see Fig. 6(a)]. In this case, although $\Delta\nu_{1/2}$ of the hydride resonance was expected to change with temperature, it was not possible to obtain quantitative linewidth variations at half height for the hydride resonance because of the close proximity of the intense resonance from the phosphite ligand and residual solvent. However, comparison of the lineshape at 145 K with that at 344 K shows that there is some evidence for motional narrowing.

Figure 6(b) shows the variable temperature ^{1}H MAS spectra of $H_4Ru_4(CO)_{11}\{P(OMe)_3\}$ which consists of a broad and intense resonance due to the methyl groups at ca 3 ppm together with a high field resonance at -18 ppm due to the hydrides. In contrast to the solution NMR spectrum at low temperature [13], the hydride resonance consists of a single broad line due to the dipolar couplings of the four inequivalent hydrides (chemical shift difference is probably less than 0.6 ppm) in the solid state. Analysis of the lineshape reveals that there is a slight variation in the hydride resonance from 180 to 355 K when compared with the unsubstituted cluster (see Fig. 3). In other words, motional narrowing in the monosubstituted cluster occurs at a higher temperature than that observed for the unsubstituted cluster.

The T_1 values for both the hydride and methyl resonances, obtained with MAS, show a similar temperature dependence between 300 and 345 K (see Fig. 5). The hydride T_1 in $H_4Ru_4(CO)_{11}\{P(OMe)_3\}$ is shorter than in $H_4Ru_4(CO)_{12}$ as a result of the dipolar coupling between the hydrides and methyl protons, but the temperature dependence of the hydride T_1 gives a similar value of E_a (15.8 ± 0.5 kJ mol^{-1}) to those we obtained for $H_4Ru_4(CO)_{12}$ over the same temperature range. Usually at room temperature the correlation time of the CH_3-reorientation with such an activation energy is considered to be in the fast-motion region where $\omega_0\tau_c \ll 1$ [16.17]. Thus, it is probable that the same type of hydride motion with similar values of E_a (17 ± 2 kJ mol^{-1}) takes place in both unsubstituted and monosubstituted clusters, although the correlation times for this motion are different for both compounds.

Previous work on $H_2Ru_2Rh_2(CO)_{12}$ shows that the lowest activation energy H-movement in solution involves the Ru—H—Rh hydrogen moving to the unoccupied Ru—Rh vector [18]. In order for this to occur, the hydrogen on the Ru—Rh vector must initially flip about this edge so that it changes from being coplanar with the Ru—Rh_2-face to become coplanar with the Ru_2Rh-face (see Fig. 7 in Ref. 6), before traversing the $RuRh_2$-face to the previously unoccupied Ru—Rh edge. Solid state NMR studies on $H_2Ru_2Rh_2(CO)_{12}$ show that the H-movement is much more restricted than in solution [6]. In order to account for the low value of E_a (ca 1 kJ mol^{-1}) *and* the T_1 value for $H_2Ru_2Rh_2(CO)_{12}$ in the solid state, it has been suggested that both these values can be accommodated by a H-movement which only involves a flip-flop about the occupied Ru—Rh edge (see Fig. 7) [6]. Such ideal extreme positions have been suggested to be adopted in transition metal hydride clusters [19] and a flip-flop about a single Ru—Rh edge would give rise to a flipping angle of the H—H vector of $<$ca 16°. It is suggested that our present solid state NMR data can be accommodated by a similar H-movement involving all the H's in $H_4Ru_4(CO)_{12}$. This would give rise to an extreme fluctuation of the H—H vector of $<$ca 32° and calculations, using d(H—H) = 2.8 Å and the same procedure as reported previously [6], gives a minimum T_1 value of 6.6 s at 200 MHz. However, since this calculation neglects the variation in d(H—H) and the inter-H—H-vector interaction, the value of T_1 (min) could be even shorter for this H-flipping model which is consistent with the data reported in Fig. 5. If the concerted motion pro-

posed by Aime *et al.* [7] is considered, the calculated T_1 (min) would be much shorter (<1.5 s) which is inconsistent with the available T_1 data. Because of the similar value of E_a found for H-movement in both the unsubstituted and monosubstituted clusters, it seems probable that a similar H-movement is involved in both clusters although it is presently not possible to be sure whether *all* the hydrides in $H_4Ru_4(CO)_{11}L$ ($L = P(OMe)_3$) are involved. Nevertheless, it is worth noting that a H-flipping mechanism might induce the phase transition found for $H_4Ru_4(CO)_{11}\{P(OMe)_3\}$ [10].

It is concluded that $H_4Ru_4(CO)_{12-x}L_x$ ($x = 0, 1$; $L = P(OMe)_3$) both undergo the same type of hydride motion (2-site flip about the occupied edge) in the solid state and the following summarises the supporting evidence:

(1) The values of E_a from our temperature dependent wide-line measurements involving T_1 and $\Delta\nu_{1/2}$ are in close agreement and the similarity of E_a (17 ± 2 kJ mol^{-1}) suggests a common mechanism for the H-movement.

(2) The calculated T_1 (min) value for the H-movement involving H-flipping about an edge is in the same region as that experimentally observed in $H_4Ru_4(CO)_{12}$.

(3) The value for the concerted hydride motion from occupied to unoccupied edges was found to be 14.2 kJ mol^{-1} [13] and for an analogous motion in the solid state, would be expected to be much higher than the value of E_a found in the present solid state NMR measurements.

EXPERIMENTAL

Solid state NMR measurements were carried out on a Bruker DSX200 spectrometer operating at 200 MHz using a 7 mm diameter rotor for MAS experiments and using a sealed 5 mm diameter glass ampoule for wide-line measurements. ^1H T_1 values were obtained using the inversion recovery technique. The ^1H and ^{31}P-$\{^1H\}$ chemical shifts were referenced to TMS and H_3PO_4 85% aq. solution respectively. The temperature of the MAS probe was calibrated by the method reported previously [20] and the wide-line probe was calibrated using a CA thermocouple before the NMR measurements were carried out.

$H_4Ru_4(CO)_{12}$ and $H_4Ru_4(CO)_{11}\{P(OMe)_3\}$ were prepared as described previously [21,22] and recrystallised from dichloromethane/octane. Prior to NMR measurements all samples were dried for a minimum of 12 h under high vacuum (10^{-3} mm Hg) at a temperature of 70°C. Purity of all samples was checked by IR and solution ^1H NMR before and after NMR measurements.

When the solvent was not completely removed from $H_4Ru_4(CO)_{11}\{P(OMe)_3\}$, a very sharp component of the hydride resonance appeared above room temperature which was observed to be reversible on cooling. This narrow component has a much shorter T_1 (ca 1.2 s at 345 K) than the broad component. We also found that the relative intensity of this narrow component decreases after heating the sample several times. The appearance of this very sharp resonance is typical of the isotropically averaged "solution-state behaviour" of molecules; we propose that this arises due to a process which is as yet not well understood but may involve the partial dissolution of the compound in the residual solvent trapped in the crystal lattice.

(Received 10 October 1997; accepted 30 December 1997)

Abstract—The monosubstituted compound $[Ir_4(CO)_{11}(PPh_2Cl)]$ reacts on silica gel to give $[HIr_4(CO)_{10}(\mu\text{-}PPh_2)]$ and the novel compounds $[Ir_4(CO)_{11}(PPh_2OH)]$ and $[Ir_6(\mu\text{-}CO)(CO)_{12}(\mu\text{-}PPh_2)_2]$ whose relative yields (up to 75, 10 and 40%, respectively) depend on cluster loading and the polarity of the eluent. The molecular structure of the hexanuclear compound was established by an X-ray analysis and consists of an octahedron of iridium atoms with two diphenylphosphido groups symmetrically bridging two non consecutive edges. Thermolysis of $[HIr_4(CO)_{10}(\mu\text{-}PPh_2)]$ in THF results in the formation of the same hexanuclear compound (up to 40%), together with $[Ir_7(\mu\text{-}CO)(CO)_{13}(\mu\text{-}PPh_2)(\mu_3\text{-}PPhC_6H_4)]$ (10%) and $[Ir_8(\mu\text{-}CO)_2(CO)_{14}(\eta^1\text{-}Ph)(\mu\text{-}PPh_2)(\mu_4\text{-}PPh)]$ (40%), depending on the reaction conditions; their molecular structures were determined by X-ray analyses. The heptanuclear compound exhibits a capped octahedral metal frame with a diphenylphosphido and a phenyl orthometallated phosphido ligands bridging two opposite equatorial edges of the octahedron; the octanuclear cluster exhibits a fused octahedron-square based pyramid metal atom arrangement with the phosphinedene ligand bonded to the square face of the pyramid and the phosphido group to one of the edges of the octahedron. Possible mechanisms for the formation of these high nuclearity clusters are discussed. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: high nuclearity clusters; iridium; synthesis; thermolysis.

Surface mediated cluster synthesis has emerged in recent years as an extremely efficient and selective alternative to the established synthetic routes [1] involving vacuum pyrolysis, thermolysis and reduction of preformed carbonyls [2]. The selectivity of surface mediated syntheses is controlled by the choice of the inorganic oxide that plays the role of the solvent in conventional syntheses. A number of high nuclearity iridium clusters, which were previously obtained from the reduction of $[Ir_4(CO)_{12}]$, e.g. $[Ir_6(CO)_{15}]^{2-}$ [3,4], $[Ir_8(CO_{22}]^{2-}$ [5], have been produced by reductive carbonylation of $[Ir_4(CO)_{12}]$ adsorbed on MgO surfaces [6,7]. Similarly, neutral carbonyl Ir, Rh, Os and Ru clusters have been synthesized from the reductive carbonylation of supported halide precursors on SiO_2 [1].

Transformations of cluster compounds on silica gel

or alumina during purification have been described [8] and are certainly much more common than suggested by literature reports. To our knowledge, however, not a single case involving cluster build-up has been reported so far. This report describes our studies involving the synthesis and transformation of $[Ir_4(CO)_{11}(PPh_2Cl)]$ on silica gel plates to give the novel compound $[Ir_6(\mu\text{-}CO)(CO)_{12}(\mu\text{-}PPh_2)_2]$, and an alternative route to this compound and to $[Ir_7(\mu\text{-}CO)(CO)_{13}(\mu\text{-}PPh_2)(\mu_3\text{-}PPhC_6H_4)]$ (10%) and $[Ir_8(\mu\text{-}CO)_2(CO)_{14}(\eta^1\text{-}Ph)(\mu\text{-}PPh_2)\text{-}(\mu_4\text{-}PPh)]$ (up to 40%), via thermolysis of $[HIr_4(CO)_{10}(\mu\text{-}PPh_2)]$.

RESULTS AND DISCUSSION

Synthesis and characterisation of $[Ir_4(CO)_{11}(PPh_2Cl)]$, **3a**

The cluster compound $[Ir_4(CO)_{12}]$, **1**, reacts with equivalent amounts of Bu_4NBr and PPNCl in refluxing THF to yield $Bu_4N[Ir_4(CO)_{11}Br]$, **2a**, and $PPN[Ir_4(CO)_{11}Cl]$, **2b**, respectively, in quantitative yields [9]. The reactions of **2a** and **2b** with 1 equivalent of PPh_2Cl in CH_2Cl_2 or acetone at room temperature lead to an immediate colour change from orange to yellow, and formation of $[Ir_4(CO)_{11}(PPh_2Cl)]$, **3a**, as evidenced by IR and ^{31}P NMR spectroscopies. If these reaction mixtures are left stirring, however, precipitation of **1** starts to occur, after 10 min. These reactions were monitored by $^{31}P\{^1H\}$ NMR spectroscopy in $CH_2Cl_2/CDCl_3$, for 4 h under atmospheres of Ar and CO. The spectra of the mixtures under Ar, just after the addition of PPh_2Cl to **2a** and **2b**, showed only a very strong peak at δ 35.2 (s) attributed to **3a** and a weak broad peak at δ −33.3, attributed to $[Ir_4(CO)_{10}(PPh_2Cl)_2]$, **4**. A decrease in the concentration of **3a**, concomitant with an increase in that of **4**, was noted during the first hour, but no substantial change was evidenced during the next 3 h. Furthermore, no additional peaks were observed in the spectra of the supernatants of either reaction mixtures. Under an atmosphere of CO, the process occurred more rapidly, and the $^{31}P\{^1H\}$ NMR spectra of the supernatants of both reaction mixtures showed only the presence of **4**, after 30 min. Further precipitation of **1** and darkening of the solutions were observed after longer periods of time, in the absence of CO, due to the decomposition of **4** into unidentified species.

In order to investigate whether the presence of PPNCl or Bu_4NBr was necessary for the formation of **1** and **4**, pure samples of **3a** were left stirring in $CH_2Cl_2/CDCl_3$ under Ar and under CO for 4 h, during which time precipitation of **1** was not noted and the $^{31}P\{^1H\}$ NMR spectrum of **3b** stayed unchanged. It is well known that PPNCl catalyses CO substitution by nucleophiles in ruthenium carbonyl clusters [10]. In our case, however, the halide seems to be catalysing the substitution, not only of a CO, but also of a PPh_2Cl ligand, according to the following equations:

$$[Ir_4(CO)_{11}(PPh_2Cl)],\mathbf{3a} + X^- \rightarrow \text{“}[Ir_4(CO)_{10}(PPh_2Cl)X]^-\text{”} + CO$$

$$[Ir_4(CO)_{11}(PPh_2Cl)],\mathbf{3a} + X^- \rightarrow \text{“}[Ir_4(CO)_{11}X]^-\text{”} + PPh_2Cl$$

$$\text{“}[Ir_4(CO)_{10}(PPh_2Cl)X]^-\text{”} + PPh_2Cl \rightarrow [Ir_4(CO)_{10}(PPh_2Cl)_2],\mathbf{4} + X^-$$

$$\text{“}[Ir_4(CO)_{11}X]^-\text{”} + CO \rightarrow [Ir_4(CO)_{12}],\mathbf{1} + X^-$$

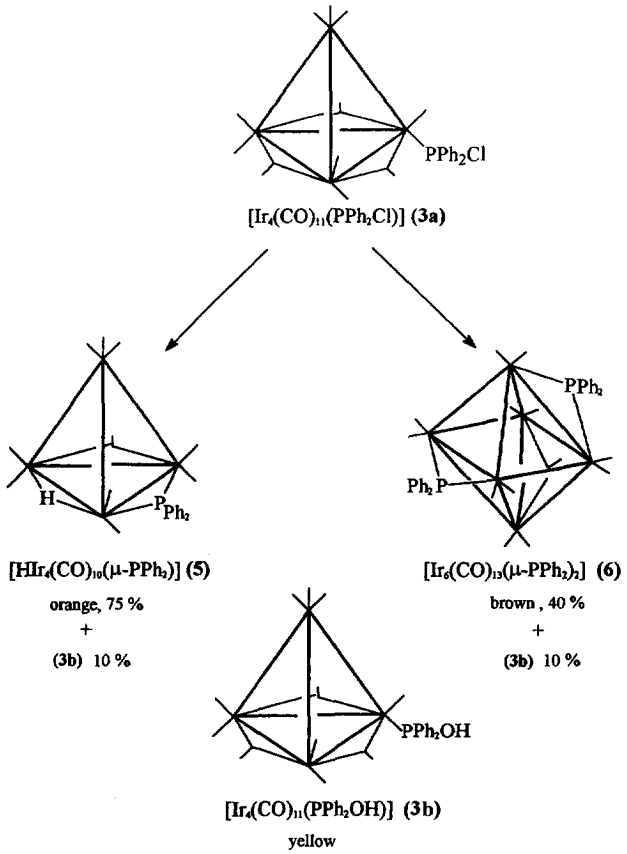
$$X = Br^- \text{ or } Cl^-$$

The process is driven by the precipitation of **1** and occurs, most probably, as a result of the high lability of the PPh_2Cl ligand. By comparison, reaction of the analogous compound $[Ir_4(CO)_{11}(PPh_2Me)]$ with PPNCl occurs only under much harsher conditions (THF, reflux, 3 h), to yield $PPN[Ir_4(CO)_{10}(PPh_2Me)Cl]$, and is readily reversed in the presence of CO, without formation of **1** [11]. In fact, labilization of ligands other than CO in the presence of halides has not yet been observed in tetranuclear iridium systems.

Study of the behaviour of **3a** *on TLC plates*

Purification of **3a** by TLC was only possible if performed under specific conditions, such as very low cluster loading, quick elution of the compound and extraction from the plates, as soon as it separates out from the base line. Under the chromatographic conditions normally employed for the purification of the PR_3, PR_2H and PRH_2 derivatives of **1** [12a] (~20 mg of the compound per plate, CH_2Cl_2 : hexane 1 : 4 as eluent), the mixture reacted on the silica gel to give three products, which separated out, and whose yields (based on **1**) were extremely sensitive to cluster loading and to the polarity of the eluent. Low cluster loading (10 mg/plate) and solvent polarity (CH_2Cl_2/hexane 1.5 : 8.5) yielded the novel yellow compound $[Ir_4(CO)_{11}(PPh_2OH)]$, **3b** (10%) and the known orange species $[HIr_4(CO)_{10}(\mu\text{-}PPh_2)]$ [12b], **5** in high yields (75%). This compound was previously obtained from $[Ir_4(CO)_{10}(PPh_2H)]$, **3c**, upon deprotonation and protonation of the resulting anion $[Ir_4(CO)_{10}(\mu\text{-}PPh_2)]^-$, in 85% yield, based on **1**. High cluster loading (40 mg/plate) and solvent polarity (CH_2Cl_2/hexane 3 : 7), however, resulted in the darkening of the reaction mixture on the plates and separation of **5** (10%), **3b** (10%) and of the dark brown species $[Ir_6(\mu\text{-}CO)(CO)_{12}(\mu\text{-}PPh_2)_2]$, **6** (40%), see Scheme 1.

Interestingly, compounds **3b**, **5** and **6** were formed in small amounts, when an excess silica gel for TLC was added to solutions of **3a** in $CH_2Cl_2/CDCl_3$, both



Scheme 1.

in the presence and in the absence of PPNCl or Bu_4NBr, and the mixtures were left stirring under Ar or in air for 1 h, as shown by ^{31}P NMR spectroscopy.

Quantitative formation of **3b** was shown to occur, by ^{31}P NMR spectroscopy, upon addition of degassed water to a solution of **3a** in $CH_2Cl_2/CDCl_3$. Furthermore, this compound is stable on TLC plates, and therefore, it must result from the reaction of **3a** with the silica gel surface water. This process is related to the previously reported hydrolysis of the aminophosphinidene ligand of $[Ru_4(CO)_{12}(\mu_3\text{-}P(NPr^i_2)_2)]$ absorbed onto silica that yields $[Pr^i_2NH_2]$ $[Ru_4(CO)_{12}(\mu_3\text{-}P{=}O)]$, possibly via formation of the hydroxyphosphinidene cluster $[Ru_4(CO)_{12}(\mu_3\text{-}POH)]$ [13].

The transformation of **3a** into **5** and **6** has not been investigated under conditions that would discount the importance of the water and oxygen in their formation, so we can only speculate about the possible reactions of **3a** on the silica gel surface that might be involved in the formation of these species. Thus, electrophilic attack of the silanol group at the P—Cl bond of the PPh_2Cl coordinated ligand in **3a** and elimination of HCl would result in the formation of the $[Ir_4(CO)_{11}(PPh_2OSi{\equiv})]$ species. Also, oxidative addition of surface silanol groups at an Ir—Ir bond, as with $[M_3(CO)_{12}]$ (M = Ru and Os), from which $[(\mu\text{-}H)M_3(CO)_{10}OSi{\equiv}]$ are formed on silica surface [14], would result in species such as $[(\mu\text{-}H)Ir_4(CO)_{10}(OSi{\equiv})(PPh_2Cl)]$. Both reactions are favoured on highly hydroxilated surfaces. In addition, oxidation of these species and of **3a** (and possibly **4**) may also occur, with the generation of reactive fragments, whose combination would be favoured by the high cluster concentration on the plates, to generate the hexanuclear cluster **6**.

Characterisation of $[Ir_4(CO)_{11}(PPh_2OH)]$, **3b**

The formulation of compound **3b** was based on spectroscopic and analytical data (see Table 1), as crystals suitable for an X-ray analysis could not be obtained. The hydroxil proton of **3b** appears at δ 3.1, $J_{P,H}$ = 13 Hz in the ^1H NMR spectrum, at 233 K. The $^{31}P\{^1H\}$ NMR spectrum of **3b** in CD_2Cl_2, at 295 K, consists of a broad singlet at δ 72.3. On cooling to 233 K, two signals are resolved at δ 68.8 and 65.5 in the

Table 1. ^{1}H and $^{31}P\{^{1}H\}$ NMR spectra of compounds **3b** and **6–8**

intensity ratio 1 : 0.03. These data indicate that **3b** exists in solution in the form of two inter-converting isomers which, by analogy with the $[Ir_4(CO)_{11}L]$ (L = PPh_3, PPh_2Me, PMe_3), compounds, are the C_{3v}axial and C_{3v}radial isomers [15].

Although to our knowledge this is the first report of a phosphinous acid derivative R_2POH stabilized by a carbonyl cluster, PH_2OH itself and some of its derivatives have been stabilized previously by P-complexation to "$W(CO)_5$" [16].

X-ray molecular structure of $[Ir_6(\mu\text{-CO})(CO)_{12}(\mu\text{-}PPh_2)_2]$, **6**

Compound **6** was characterized by analytical and spectroscopic methods (see Table 1 and Experimental) and by an X-ray analysis. Crystals of **6** suitable for X-ray crystallography were obtained from CH_2Cl_2/hexane. A perspective view of **6** is shown in Fig. 1, together with the labeling scheme. Selected bond distances and angles of **6** are listed in Table 2. The molecule contains an Ir_6 octahedral core, with eleven Ir—Ir bond distances falling in a fairly narrow range [from 2.729(1) to 2.791(1) Å]. Two diphenylphosphido ligands symmetrically bridge two non-consecutive edges belonging to two different equators of the octahedral frame. P—Ir bond distances average to 2.294(4) and 2.281(4) Å for the P(1)Ph_2 and P(2)Ph_2 ligands, respectively. Interestingly, the Ir—Ir edge, which is bridged by the closest PPh_2 group also shows the shortest metal-metal bond distance in the octahedron frame. Twelve CO ligands are terminally bound, two on each metal vertex, while the thirteenth CO group symmetrically bridges one edge of the octahedron equator not substituted by the PPh_2 ligands.

Cluster **6** possesses 86 valence electrons, and exhibits a remarkably similar molecular geometry to those of the dianionic $[Ir_6(\mu\text{-}CO)_3(CO)_{12}]^{2-}$ [17] and the monoanionic $[Ir_6(\mu\text{-}CO)_2(CO)_2(\mu\text{-}PPh_2)]^-$ [18] clusters. The latter compound was recently obtained from the oxidation of $[Ir_6(\mu\text{-}CO)_3(CO)_{12}]^{2-}$ with $[FeCp_2]^+$ in the presence of PPh_2H, followed by deprotonation of the coordinated phosphine. Two of the three bridging CO ligands in the dianionic compound are formally replaced by two 3-electron donor PPh_2 groups in **6**, whilst $[Ir_6(\mu\text{-}CO)_2(CO)_{12}(\mu\text{-}PPh_2)]^-$ results, formally, from the replacement of one μ-CO in the dianion by a μ-PPh_2 fragment. The steric arrangement of the remaining twelve CO ligands does not differ substantially in the three species. Average Ir—Ir bond distances compare well in **6**, $[Ir_6(\mu\text{-}CO)_2(CO)_{12}(\mu\text{-}PPh_2)]^-$ and $[Ir_6(\mu\text{-}CO)_3(CO)_{12}]^{2-}$ [av. Ir—Ir 2.776(1), 2.776(1) and 2.773(1) Å, respectively] and so do the metal-carbon bond lengths [av. $Ir—C_{(COt)}$ 1.86(2), 1.87(2) and 1.86(2); $Ir—C_{(COb)}$ 2.06(2), 2.05(2) and 2.04(2), respectively].

In spite of the lack of symmetry of compound **6** in the solid state, the $^{31}P\{^1H\}$ NMR spectrum showed a singlet at δ 127.7 from 295 to 183 K which indicates that it is fluxional at those temperatures.

Thermolysis of $[HIr_4(CO)_{10}(\mu\text{-}PPh_2)]$, **5**

In order to find out whether compound **6** would also be formed under thermolytic conditions, compound **5** was heated in THF under reflux. After 12 h, three compounds were isolated in sufficient yields to be fully characterized by analytical and spectroscopic data

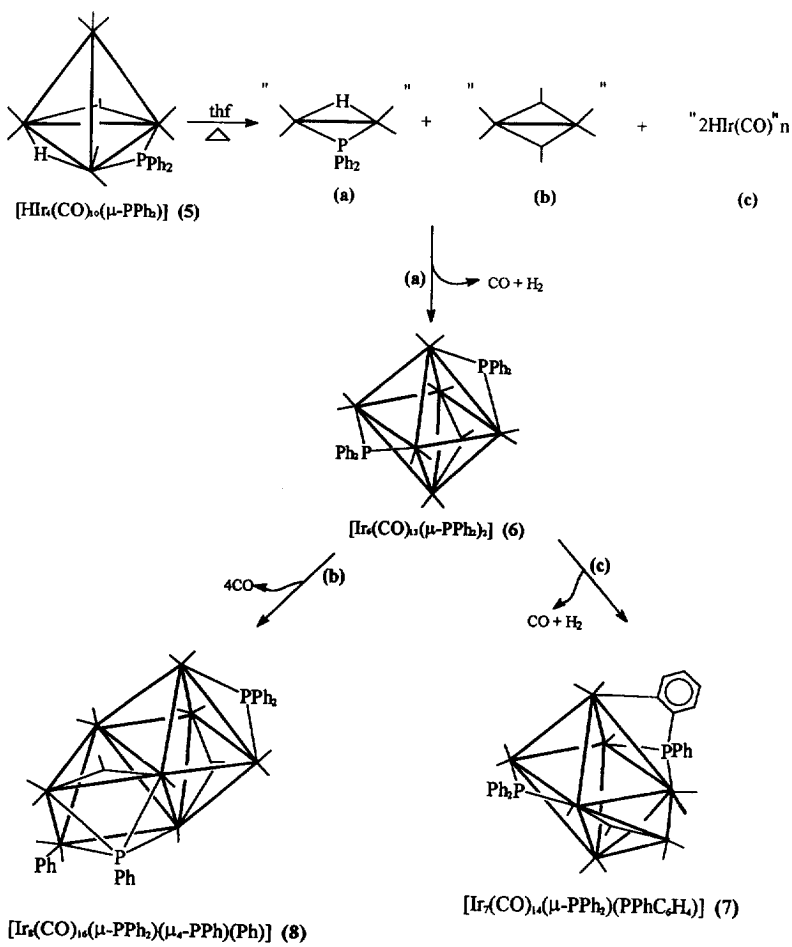
and by X-ray analyses: compound **6** (40%), $[Ir_7(\mu\text{-}CO)_2(CO)_{12}(\mu\text{-}PPh_2)(\mu_3\text{-}PPhC_6H_4)]$, **7** (10%) and $[Ir_8(\mu\text{-}CO)(CO)_{15}(\eta^1\text{-}Ph)(\mu\text{-}PPh_2)(\mu_4\text{-}PPh)]$ **8**, (18%), in addition to starting material **5** (18%). Heating compound **5** for an additional 12 h period did not lead to the formation of other products, but resulted in an increase in the yield of the octanuclear cluster **8** (40%) and a decrease in that of the hexanuclear compound **6** (14%), whilst that of **7** (10%) remained unchanged; some starting material **5** (9%) was also recovered under these conditions. Furthermore, thermolysis of **5** in THF for longer periods of time, or in refluxing toluene for 12 h led to larger amounts of decomposition material on the base line of the TLC plates.

Formation of **6** might be rationalized in terms of condensation of **5** with a reactive unsaturated hydrido-phosphido fragment with loss of H_2 and CO (See Scheme 2). Considering that heating compound **6** under reflux in THF for 12 h does not lead to cluster build up, it is possible that compounds **7** and **8** might result from further condensation of a monomeric and a dimeric unsaturated fragments, respectively, with **6**, accompanied by orthometallation and cleavage of a $P—C_{Ph}$ bond, respectively.

Formation of high nuclearity clusters from other phosphido compounds, such as $[HRu_3(CO)_{10}(\mu\text{-}PPh_2)]$, $[HRu_3(CO)_9(\mu\text{-}PPh_2)]$ [19,20], $[H_2Ru_3(CO)_8(\mu\text{-}PPh_2)_2]$ [20] and $[H_3Ru_3(CO)_7(\mu\text{-}PPh_2)_3]$ [20], has been shown to occur previously. Also in these cases, products resulting from the activation of $P—C_{Ph}$ and orthometallation were isolated. It is interesting, however, that heating $[HM_3(CO)_{10}(\mu\text{-}PPh_2)]$ (M = Ru [20] and Os [21]) under mild conditions leads to the formation of the unsaturated compound $[HRu_3(CO)_9(\mu\text{-}PPh_2)]$ and of the orthometallated product $[H_2Os_3(CO)_9(\mu\text{-}PPhC_6H_4)]$, respectively, whilst even under mild conditions, compound **5** undergoes cluster build up.

X-ray molecular structure of $[Ir_7(\mu\text{-}CO)(CO)_{13}(\mu\text{-}PPh_2)(\mu_3\text{-}PPhC_6H_4)]$, **7**

The molecular structure of **7** is shown in Fig. 2. Selected bond distances are listed in Table 2. The molecule possesses 98 valence electrons, and exhibits a capped octahedron arrangement of iridium atoms, with fifteen Ir—Ir bond distances falling in the range



Scheme 2.

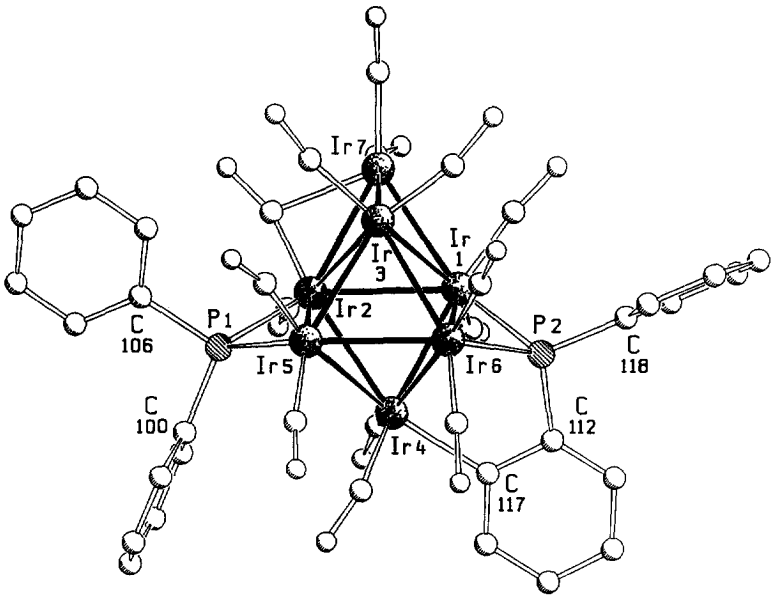


Fig. 2. Molecular structure of $[Ir_7(\mu\text{-CO})(CO)_{13}(\mu\text{-PPh}_2)(\mu_3\text{-PPhC}_6H_4)]$, **7**.

from 2.632(5) to 2.866(4) Å. A diphenylphophido and a phenyl orthometallated phosphido ligands bridge two opposite equatorial edges of the octahedron. Thirteen CO ligands are terminally bound, two on six metal vertex and one on the seventh metal atom, while the fourteenth CO group symmetrically bridges the edge formed by the capping iridium atom and the iridium atom bearing only one terminal CO. The only other known heptanuclear iridium cluster, $[Ir_7(\mu\text{-CO})(CO)_{11}(C_8H_{12})(C_8H_{11})(C_8H_{10})]$, which was obtained from the reaction of **1** with 1,5-cyclooctadiene in refluxing chorobenzene [22], exhibits a similar metal framework arrangement. The steric arrangement of the thirteen CO ligands does not differ substantially in the two species. Average Ir—Ir bond distances compare well in **7** and $[Ir_7(\mu\text{-CO})(CO)_{11}(C_8H_{12})(C_8H_{11})(C_8H_{10})]$ [av. Ir—Ir 2.767(5), and 2.763(1) Å, respectively] and the same can be said for the metal-carbon bond lengths [av. Ir—$C_{(CO_t)}$ 1.84(4) and 1.86(5); Ir—$C_{(CO_b)}$ 1.99(10) and 2.04(4), respectively].

X-ray molecular structure of $[Ir_8(\mu\text{-CO})_2(CO)_{14}(\eta^1\text{-Ph})(\mu\text{-PPh}_2)(\mu_4\text{-PPh})]$, **8**

Compound **8** was formulated on the basis of analytical and spectroscopic data (see Table 1 and Experimental) but an X-ray analysis experiment was necessary to establish its structure unambiguously. The molecular structure of **8** is shown in Fig. 3, together with the labeling scheme. Selected bond distances are listed in Table 2. The metal arrangement can be described as a fused polyhedron, formed by an octahedron and a square based pyramid (atoms Ir1—Ir5) sharing a triangular face. Ir—Ir bond distances range from 2.711(2) to 2.845(2) Å. The μ-PPh_2 ligand symmetrically bridges one of the edges of the octahedron. A second PPh_2 ligand has undergone P—C bond cleavage; the two resulting fragments, *viz* the phenyl ligand and the phenyl phosphinedene, bind in η^1-fashion to one of the basal atoms and in μ_4-fashion the four basal atoms of the square based pyramid, respectively. A similar kind of μ_4-coordination of a PPh ligand, which donates four electrons to the metal frame, has previously been observed in the pentanuclear iridium compounds $[Ir_5(\mu\text{-CO})_2(CO)_7L(\eta^5\text{-}C_5Me_5)(\mu_4\text{-PPh})]$ (L = CO, PPh_3) [23]. Fourteen carbonyls are terminally bound to the iridium atoms, while the remaining two CO ligands symmetrically bridge one of the basal square pyramids and one of the octahedron edges. The only two other octanuclear iridium clusters whose structures have been determined to date are $[Ir_8(CO)_{22}]^-$ [24] and $[Ir_8Au_2(CO)_{20}(PhPPPh)(PEt_3)]$ [25], which exhibit *bis*-tetranuclear frameworks linked by an Ir—Ir bond and by the PhPPPh ligand, respectively.

EXPERIMENTAL

General procedures and materials

Iridium trichloride (Johnson and Matthey), PPNCl and Bu_4NBr (Aldrich), diphenyl phosphine and chlorodiphenyl phosphine (Strem Chemicals) were used as purchased. The compounds $[Ir_4(CO)_{12}]$ **1** [26], $[Ir_4(CO)_{11}(PPh_2H)]$ **3c**, $[HIr_4(CO)_{10}(\mu\text{-PPh}_2)]$ **5** [12], $Bu_4N[Ir_4(CO)_{11}Br]$ **2a** and $PPN[Ir_4(CO)_{11}Cl]$ **2b** [9] were prepared by literature methods. Manipulations

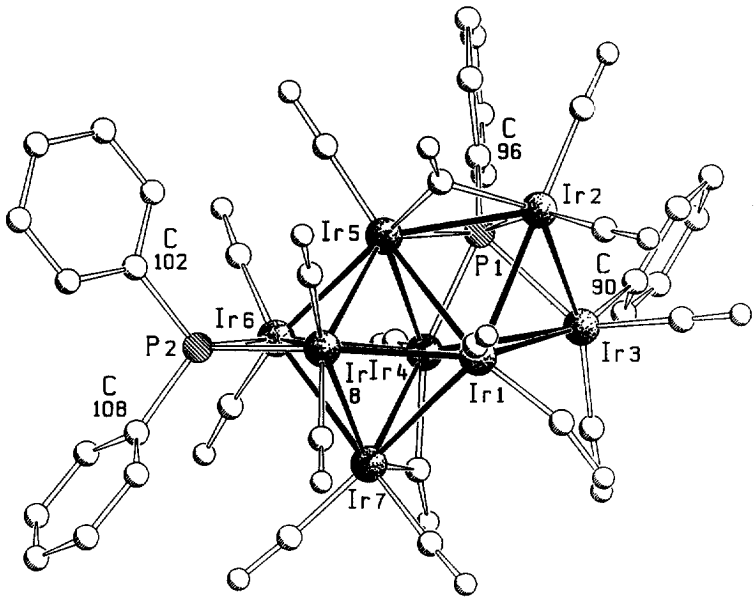

Fig. 3. Molecular structure of $[Ir_8(\mu\text{-}CO)_2(CO)_{14}(\eta^1\text{-}Ph)(\mu\text{-}PPh_2)(\mu_4\text{-}PPh)]$, **8**.

were performed in Schlenk tubes, under an atmosphere of dry Ar, unless otherwise specified. Solvents were dried as previously described [12] and freshly distilled under Ar and degassed before use. Preparative TLC was carried out in air by using *ca* 2 mm thick glass-backed silica gel plates (20 × 20 cm) prepared from silica GF_{254} Type 60, Fluka, and the compounds extracted from the silica with dichloromethane. All substituted Ir_4 cluster compounds were stored under an inert atmosphere for they were found to be slightly air sensitive in the solid state. FAB-MS were obtained on a VG AutoSpec using p-nitrobenzyl alcohol as a matrix at the University of Sussex, U.K. IR spectra on a JASCO IR 700 between 2200 and 1600 cm^{-1} using CaF_2 cells. ^1H and ^{31}P $\{^1H\}$ NMR data were obtained on a Bruker AC 300 instrument, using deuterated solvents as lock and reference [^1H $SiMe_4$; ^{31}P 85% H_3PO_4 (external)]. Microanalyses were performed at the Instituto de Química, UNICAMP, Brazil.

Preparation of $[Ir_4(CO)_{11}(PPh_2Cl)]$, **3a**

An orange solution of $PPN[Ir_4(CO)_{11}Cl]$ **2b** (37.1 mg, 0.023 mmol) in CH_2Cl_2 (2 cm^3) was cooled to −30°C and treated with PPh_2Cl (4.1 μl, 0.023 mmol). The yellow reaction mixture was warmed to 25°C. Quick purification of the reaction mixture by TLC, using CH_2Cl_2/hexane (3:7) as eluent, taking care to load each plate with a maximum of 3 mg of **3a**, and extracting the yellow compound from the plates, just after it had separated out from the base line, gave pure **3a** (17.3 mg, 60%), IR (ν_{CO} hexane): 2084 s, 2052 vs, 2040 vs, 2030 vs, 1955 m, 1885 w, 1845 m and 1824 m, cm^{-1}. Use of $Bu_4N[Ir_4(CO)_{11}Br]$ **2a**, instead of **2b**, gave similar yields of **3a**, under the same conditions.

Investigation of the stability of **3a** *in the presence of* PPNCl *or* Bu_4NBr

An orange solution of $PPN[Ir_4(CO)_{11}Cl]$ **2b** (148.5 mg, 0.09 mmol) in CH_2Cl_2 (5 cm^3) was cooled to −30°C and treated with PPh_2Cl (16.6 μl, 0.09 mmol). Quick warming of the reaction mixture to 20°C was followed by addition of 0.5 cm^3 of $CDCl_3$. A ^{31}P $\{^1H\}$ NMR spectrum was recorded immediately, and every 30 min thereafter. After 10 min stirring at room temperature **1** started to precipitate, and was decanted, before each sampling. Same procedure was followed in the reaction of $Bu_4N[Ir_4(CO)_{11}Br]$, **2a** with PPh_2Cl.

Investigation of the stability of **3a** *in the absence of* PPNCl *or* Bu_4NBr

Solutions of pure **3a** (20 mg, 0.016 mmol) in CH_2Cl_2:$CDCl_3$ (0.8 cm^3:0.5 cm^3) were left stirring under Ar and under CO for 4 h. No precipitation of **1** was observed and the ^{31}P $\{^1H\}$ NMR spectra of both solutions showed only the presence of **3a**.

Reaction of $[Ir_4(CO)_{11}(PPh_2Cl)]$ **3a** *on TLC plates*

Method 1: Low cluster loading (10 mg/plate), CH_2Cl_2/hexane (1.5:8.5), yielded the orange species **5** (83.5 mg, 75%), the yellow compound $[Ir_4(CO)_{11}(PPh_2OH)]$ **3b** (11.5 mg, 10%); R_f 0.79, IR (ν_{CO} hexane): 2084 s, 2052 vs, 2014 vs, 1974 vs, 1880 w,

1845 m and 1823 m cm^{-1} and the brown compound $[Ir_6(\mu\text{-}CO)(CO)_{12}(\mu\text{-}PPh_2)_2]$ **6** (8.5 mg, 5%) R_f 0.64, IR (ν_{CO} hexane): 2078 s, 2050 vs, 2040 vs, 2020 wsh, 2010 s, 1993 s, 1957 w and 1842 s cm^{-1}. Found: C, 23.2; H, 0.8. Calc. for $C_{37}H_{20}O_{13}P_2Ir_6$: C, 23.5; H, 1.0%. *Method* 2: High cluster loading (40 mg/plate), CH_2Cl_2/hexane (3:7), resulted in the separation of compounds **5** (11 mg, 10%), **3b** (11.5 mg, 10%) and **6** (68 mg, 40%).

Reactions of **3a** *with silica gel*

The following reactions were monitored by $^{31}P\{^1H\}$ NMR spectroscopy, after stirring for 1 h at 25°C under (a) Ar and (b) air. Addition of silica gel for TLC (excess, approximately 50 mg) to three solutions containing **3a** (20 mg, 0.016 mmol) and PPNCl (1 equiv.), **3a** and Bu_4NBr (1 equiv.) or pure **3a** in CH_2Cl_2: $CDCl_3$ (2 cm^3: 1 cm^3) led to the formation of compounds **3b, 5** and **6** in trace amounts.

Reaction of **3a** *with* H_2O

Addition of H_2O (50 μl, 2.85 mmol) to a solution of **3a** (10 mg, 0.008 mmol) in CH_2Cl_2: $CDCl_3$ (4 cm^3: 1 cm^3) led to quantitative formation of $[Ir_4(CO)_{11}(PPh_2OH)]$ **3b,** confirmed by $^{31}P\{^1H\}$ NMR spectroscopy.

Thermolysis of **5**

A solution of compound **5** (100 mg, 0.08 mmol) in THF (20 cm^3) was heated under reflux for 12 h. The solvent was evaporated, the mixture was dissolved in CH_2Cl_2 (2 cm^3) and purified by TLC with CH_2Cl_2/hexane (1:5) as eluent, to yield: compounds **6** (R_f 0.51, 60 mg, 40%); $[Ir_7(\mu\text{-}CO)_2CO)_{12}(\mu\text{-}PPh_2)(\mu_3\text{-}PPhC_6H_4)]$ **7** (R_f 0.58, 17 mg, 10%), IR (ν_{CO} hexane): 2074 m, 2046 s, 2040 vs, 2022 m, 2006 w, 1993 w and 1850 w, cm^{-1}; and $[Ir_8(\mu\text{-}CO)(CO)_{15}(\eta^1\text{-}Ph)(\mu\text{-}PPh_2)(\mu_4\text{-}PPh)]$ **8** (R_f 0.40, 28 mg, 15%): IR (ν_{CO} hexane): 2076 s, 2048 vs, 2038 vs, 2008 m, 1991 m, 1955 m and 1840 s, cm^{-1}; Found: C, 20.2; H, 0.6. Calc. for $C_{40}H_{20}O_{16}P_2Ir_8$: C, 20.4; H, 0.8%. FAB-MS m/z = 2362 (=M) [M-n(CO)] (n = 1–16); three brown species (R_f 0.24, 0.29, 0.62) in minute amounts and unreacted **5** (18 mg, 18%).

The thermolysis of compound **5** was repeated (a) under the same conditions but for 24 h, and gave the same three products, **6** (10 mg, 14%), **7** (8 mg, 10%) and **8** (37 mg, 40%), and unreacted **5** (4 mg, 9%); (b) in toluene under reflux for 12 h, and produced the

same products **6** (23 mg, 30%), **7** (5 mg, 6%) and **8** (27 mg, 32%), and unreacted **5** (4 mg, 9%).

Thermolysis of $[Ir_6(\mu\text{-}CO)(CO)_{12}(\mu\text{-}PPh_2)_2]$, **6**. A solution of compound **6** (20 mg, 0.01 mmol) in THF (10 cm^3) was heated under reflux for 12 h. The reaction was monitored by IR spectroscopy, which showed no changes in the ν_{CO} region. The solvent was evaporated, the mixture was dissolved in CH_2Cl_2 (1 cm^3) and purified by TLC with CH_2Cl_2/hexane (1.5:8.5) as eluent. Only compound **6** (16 mg, 84%) was recovered from the plates, which showed also some decomposition material on the base line.

Crystal structure determination. Crystal data and details of measurements for compounds **6, 7** and **8** are summarized in Table 3. Diffraction intensities were collected at room temperature on an Enraf-Nonius CAD-4 diffractometer equipped with a graphite monochromator (Mo–K_α, $\lambda = 0.71069$ Å). Intensity data were reduced to F_o^2. Crystals were obtained from CH_2Cl_2/hexane by slow evaporation. The structures were solved by direct methods, followed by least-squares refinements. For all calculations the crystallographic programs SHELX86 [27a] and SHELXL93 [27b] were used. Empirical absorption correction was applied for the three compounds by azimuthal scanning of reflections with $\chi > 80°$. Ir and P atoms and CO groups in **6**, Ir, P and O atoms in **7** and **8** were refined anisotropically. All phenyl rings (except for the orthometallated ring in **8**) were refined as rigid groups. Due to the scarce quality of data, constraints were applied for compound **7** on refining Ir—C_{CO} and C—O distances. The hydrogen atoms were added in calculated positions (C_{sp}^2—H 0.93 Å) and refined "riding" on the corresponding C atoms. For graphical representations the program SCHAKAL92 [27c] was used.

Acknowledgements—We thank FAPESP, PADCT and CNPq of Brazil (M.H.A. and M.D.V.) and the Ministero della Universitá e della Ricerca Scientifica e Tecnologica of Italy (D.B. and F.G.) for research grants, Johnson and Matthey plc for their generous loan of $IrCl_3$ and Prof. J. F. Nixon for the FAB-MS at the University of Sussex.

C-C coupling reactions on a flexible Ru_3Pt framework: X-ray crystal structures of $Ru_3Pt[\mu_4\text{-}C(Bu^t)C(H)C\{C(Bu^t)\}\{C(H)C(Bu^t)\}]\{\mu\text{-}\sigma\text{-}\pi\text{-}C(H)=C(H)(Bu^t)\}(CO)_7(dppe)$, $Ru_3Pt[\mu_3\text{-}C(Bu^t)CC(Bu^t)CH_2](CO)_8(dppe)$ and $Ru_3Pt\{\mu_4\text{-}C(Ph)CCC(H)(Bu^t)\}(\mu_4\text{-}Te)(\mu\text{-}TePr^i)(CO)_6(dppe)$‡

(Received 9 October 1997: accepted 2 January 1998)

Abstract—Reaction of $Ru_3Pt(\mu\text{-}H)\{\mu_4\text{-}C{\equiv}C(Bu^t)\}(CO)_9(dppe)$ (**1**) with excess $HC{\equiv}CBu^t$ afforded three C-C coupled products, $Ru_3Pt[\mu_4\text{-}C(Bu^t)C(H)C\{C(Bu^t)\}\{C(H)C(Bu^t)\}]\{\mu\text{-}\sigma\text{-}\pi\text{-}C(H)=C(H)(Bu^t)\}(CO)_7(dppe)$ (**3**), and an inseparable mixture of the *trans*- and *gem*-isomers of $Ru_3Pt[\mu_3\text{-}C(Bu^t)CC(Bu^t)\cdot CH_2](CO)_8(dppe)$ **4a**. Single crystal X-ray structure determinations of **3** and ***gem*-4a** were undertaken. Cluster **3** contains an Ru_3Pt chain-skeleton with three metal-metal bonds and incorporates three molecules of $HC{\equiv}CBu^t$ as a σ-π-vinyl ligand and an unusual C-C coupled ligand. Cluster ***gem*-4a** contains a tetrahedral Ru_3Pt skeleton with a C-C coupled vinyl-alkyne ligand. Reaction of **1** with $HC{\equiv}CR$, R=Ph and $SiMe_3$ gave similar products **4b** and **4c** respectively, with evidence for all three possible isomers *cis*-, *trans*-, and *gem*, while reaction of **1** with $PhC{\equiv}CPh$ gave the expected *cis*-, *trans* mixture of isomers of **4d**. Treatment of **1** with $Pr^iTeC{\equiv}CPh$ afforded two isomers of $Ru_3Pt\{\mu_4\text{-}C(Ph)CCC(H)(Bu^t)\}(\mu_4\text{-}Te)(\mu\text{-}TePr^i)(CO)_6(dppe)$ (**5**) as an inseparable mixture. A single crystal X-ray structure determination of the isomer ***trans*-5** was undertaken. The Ru_3Pt skeleton consists of a distorted square plane with a μ_4-capping tellurium atom. The C-C coupled ligand μ_4-$C(Ph)CCC(H)(Bu^t)$ is bonded in an unusual fashion to all four metal atoms, and can be thought of as a metallated vinyl-alkyne.

Keywords: ruthenium-platinum cluster; alkynyl ligand; acetylide ligand; C-C coupling reaction, tellurium; telluro-alkyne; crystal structure.

The hydrido-alkynyl cluster $Ru_3Pt(\mu\text{-}H)\{\mu_4\text{-}C{\equiv}C(Bu^t)\}(CO)_9(L_2)$ (**1**, L_2 = dppe), containing a spiked-triangular metal skeleton, undergoes an interesting tautomerisation to the vinylidene cluster $Ru_3Pt\{\mu_4\text{-}C{=}CH(Bu^t)\}(CO)_9(L_2)$ (**2**, L_2 = dppe) which has a butterfly metal skeleton [1]. This reaction is reversible, and shows an inverse kinetic isotope effect, and the first order rate constant also shows a marked dependence on the nature of the chelating diphosphine L_2 [2,3]. The H-atom migration between the Ru-Ru bond and the vinylidene CH position has been shown to be intra-molecular [1,2], and the change in geometry of the metal skeleton has been followed directly using EXAFS [4]. In view of the continuing interest in C_2 chemistry in metal clusters [5], and of earlier studies on C-C coupling reactions of alkynes at metal clusters [6], we report herein some reactions of **1** with alkynes. Aspects of this work have been previously communicated in a review [7].

EXPERIMENTAL

All reactions were carried out under nitrogen using Schlenk tube techniques and freshly distilled dried solvents as previously reported [1]. The complex $Ru_3Pt(\mu\text{-}H)\{\mu_4\text{-}C{\equiv}C(Bu^t)\}(CO)_9(dppe)$ (**1**) was prepared in situ, as previously described [1]. All the alkynes, except $Pr^iTeC{\equiv}CPh$, were obtained from Aldrich Chemicals, and used as received. The literature route [8] was used to prepare $Pr^iTeC{\equiv}CPh$, which was stored in the dark at 5°C.

Reactions of $Ru_3Pt(\mu\text{-}H)\{\mu_4\text{-}C{\equiv}C(Bu^t)\}(CO)_9(dppe)$ (**1**) *with* $RC{\equiv}CR^1$

(*a*) R = Bu^t, R^1 = H. To a solution of 0.262 g (0.213 mmol) of **1** in 20 ml THF was added a large excess of $HC{\equiv}CBu^t$ (0.2 ml, 1.6 mmol). The resulting orange solution was heated under gentle reflux for a period of 16 hours, after which time the colour changed to deep red. The solvent was removed *in vacuo* and chromatography (Florisil, 2·20 cm column, hexanes/CH_2Cl_2 mixtures as eluant) of the red solid residue afforded two bands. The first band (total weight 0.086 g) was bright red and contained complex **3** $Ru_3Pt[\mu_4\text{-}C(Bu^t)C(H)C\{C(Bu^t)\}\{C(H)C(Bu^t)\}]\{\mu\text{-}\sigma\text{-}\pi\text{-}C(H){=}C(H)(Bu^t)\}(CO)_7(dppe)$, and the essentially inseparable, non-interconverting *gem* and *trans*-isomers of complex **4a** $Ru_3Pt[\mu_3\text{-}C(Bu^t)CCC(Bu^t)](CO)_8(dppe)$. The second orange-red band (0.107 g, 41%) contained cluster **2**. Fractional recrystallisation of the first band from hot n-octane gave yellow crystals (0.008 g, 3%) of complex **3**, and an inseparable red crystalline mixture (~0.05 g) of the isomers of **4a**. The two isomers are formed in equal proportions. The relative proportions could be changed on further fractional recrystallisation, but we were unable to obtain spectroscopically pure bulk samples of either isomer. A few crystals of pure *gem*-**4a** were obtained, and examined by X-ray crystallography. The spectroscopic assignments were made on the basis of examining several samples with differing relative concentrations of the two isomers. A ^{31}P NMR spectrum of the crystal sample from the X-ray analysis was used to confirm the relative assignments of the isomers, and to demonstrate that the crystal sample was representative of the bulk sample. Satisfactory microanalyses were obtained for **3** and for all the isomer mixtures of **4**. Only those resonances which could be unambiguously assigned to individual isomers are listed below.

Spectroscopic data for **3**. IR (cyclo-C_6H_{12}) ν(CO) 2050 (s), 2009 (m), 2000 (s), 1976 (s), 1969 (m), 1932 (w), 1925 (w) cm^{-1}. ^1H NMR ($CDCl_3$, 298 K) 8.37 [d, 1H, H (10), J(H-H) = 13.6 Hz], 8.10–7.03 [m, 20H, Ph], 6.55 [s, 1H, H (15), J(P-H) = 11 Hz], 4.27 [d, 1H, H (11), J(H-H) = 13.6 Hz], 1.35 [s, 9H, Bu^t] 1.29 [s, 9H, Bu^t], 0.97 [s, 9H, Bu^t], 0.22 [s, 9H, Bu^t]. ^{31}P NMR ($CDCl_3$, 298 K) δ 51.9 [d, 1P, J(P-P) = 10.3, J(Pt-P) = 2304 Hz], 50.6 [d, 1P, J(P-P) = 10.3, J(Pt-P) = 3136 Hz]. The signal for H (17) could not be unambiguously assigned, and is presumably obscured by other resonances. In view of the shorter distance between P1 and the Pt atom (see Table 2), the ^{31}P resonance at δ 50.6 with the largest J(Pt-P) is tentatively assigned to this phosphorus atom.

Spectroscopic data for gem-**4a**. ^1H NMR ($CDCl_3$, 298 K) δ 8.13–7.10 [m, 20H, Ph], 3.30 [s, 1H, C=C(H)], 1.60 [s, 9H, Bu^t], 0.99 [s, 9H, Bu^t], 0.78 [s, 1H, C=C(H)]. ^{31}P NMR ($CDCl_3$, 298 K) δ 56.4 [d, 1P, J(P-P) = 28.5, J(Pt-P) = 3541 Hz], 43.4 [d, 1P, J(P-P) = 28.5, J(Pt-P) = 2540 Hz]. In view of the shorter distance between P1 and the Pt atom (see Table 3), the ^{31}P resonance at δ 56.4 with the largest J(Pt-P) is tentatively assigned to this phosphorus atom.

Spectroscopic data for trans-**4a**. ^1H NMR ($CDCl_3$, 298 K) δ 8.10–7.03 [m, 20H, Ph], 4.05 [dd, 1H, C=C(H), J(H-H) = 10, J(P-H) = 1.5 Hz], 2.72 [d, 1H, C=C(H), J(H-H) = 10 Hz]. ^{31}P NMR ($CDCl_3$, 298 K) δ 58.9 [d, 1P, J(P-P) = 27, J(Pt-P) = 3539 Hz], 43.8 [d, 1P, J(P-P) = 27, J(Pt-P) = 2520 Hz].

(*b*) R = Ph, R^1 = H. A solution of 0.236 g (0.19 mmol) of **1** in 20 ml THF was treated with 0.2 ml (1.8 mmol) of $PhC{\equiv}CH$. After heating under gentle reflux for 17 h, workup as before afforded a bright red band (0.114 g) containing three compounds inseparable by chromatography, *trans*-**4b**, *gem*-**4b** and *cis*-**4b** in the ratio 50 : 32 : 18 respectively on the basis of integration of the ^{31}P NMR peaks.

Spectroscopic data for gem-**4b**. ^1H NMR ($CDCl_3$, 298 K) δ 8.20–6.15 [m, 25H, Ph], 3.42 [s, 1H, C=C(H)], 3.24–1.92 [m, 4H, CH_2], 1.34 [s, 9H, Bu^t], 0.78 [s, 1H, C=C(H)]. ^{31}P NMR ($CDCl_3$, 298 K) δ

57.5 [d, 1P, J(P-P) = 28, J(Pt-P) = 3531 Hz], 44.4 [d, 1P, J(P-P) = 28, J(Pt-P) = 2524 Hz].

Spectroscopic data for trans-**4b**. ^{1}H NMR ($CDCl_3$, 298 K) δ 7.77–6.86 [m, 25H, Ph], 4.80 [d, 1H, C=C(H), J(H-H) = 9.2 Hz], 3.24 [d, 1H, C=C(H), J(H-H) = 9.2 Hz], 3.14–1.68 [m, 4H, CH_2], 1.55 [s, 9H, Bu^t]. ^{31}P NMR ($CDCl_3$, 298 K) δ 61.3 [d, 1P, J(P-P) = 26, J(Pt-P) = 3549 Hz], 45.7 [d, 1P, J(P-P) = 26, J(Pt-P) = 2523 Hz].

Spectroscopic data for cis-**4b**. ^{1}H NMR ($CDCl_3$, 298 K) δ 8.02–6.28 [m, 25H, Ph], 5.24 [d, 1H, C=C(H), J(H-H) = 7 Hz], 4.36 [d, 1H, C=C(H), J(H-H) = 7 Hz], 3.19–2.10 [m, 4H, CH_2], 1.70 [s, 9H, Bu^t]. ^{31}P NMR ($CDCl_3$, 298 K) δ 58.2 [d, 1P, J(P-P) = 31, J(Pt-P) = 3522 Hz], 46.7 [d, 1P, J(P-P) = 31, J(Pt-P) = 2573 Hz].

(*c*) R = Me_3Si, R^1 = H. A solution of 0.137 g (0.11 mmol) of **1** in 20 ml THF was treated with 0.2 ml (0.14 g, 1.4 mmol) of $Me_3SiC{\equiv}CH$. After heating under gentle reflux for 14 h, workup as before afforded three bands. The second red band afforded a bright red solid (0.056 g) containing three compounds inseparable by chromatography, *gem*-**4c**, *trans*-**4c** and *cis*-**4c** in the ratio 46 : 43 : 11 respectively on the basis of integration of the ^{31}P NMR peaks. In addition cluster **2** (third band) and $Ru_3(\mu$-H)(C≡CBu^t)(CO)$_9$ (first band) were also isolated.

Spectroscopic data for gem-**4c**. ^{1}H NMR ($CDCl_3$, 298 K) δ 8.22–6.76 [m, 20H, Ph], 3.24–1.93 [m, 4H, CH_2], 3.14 [s, 1H, C=C(H)], 1.54 [s, 9H, Bu^t], 0.98 [s, 1H, C=C(H)], −0.02 [s, 9H, Me_3 Si]. ^{31}P NMR ($CDCl_3$, 298 K) δ 57.1 [d, 1P, J(P-P) = 28, J(Pt-P) = 3539 Hz], 44.3 [d, 1P, J(P-P) = 28, J(Pt-P) = 2529 Hz].

Spectroscopic data for trans-**4c**. ^{1}H NMR ($CDCl_3$, 298 K) δ 8.24–6.18 [m, 20H, Ph], 4.04 [dd, 1H, C=C(H), J(H-H) = 11.3, J(P-H) = 1 Hz], 3.27–1.99 [m, 4H, CH_2], 1.55 [s, 9H, Bu^t], 1.38 [d, 1H, C=C(H), J(H-H) = 11.3 Hz])], 0.03 [s, 9H, Me_3Si]. ^{31}P NMR ($CDCl_3$, 298 K) δ 59.1 [d, 1P, J(P-P) = 27, J(Pt-P) = 3538 Hz], 44.4 [d, 1P, J(P-P) = 27, J(Pt-P) = 2530 Hz].

Spectroscopic data for cis-**4c**. ^{1}H NMR ($CDCl_3$, 298 K) δ 1.06 [s, 9H, Bu^t], 0.03 [s, 9H, Me_3Si]. ^{31}P NMR ($CDCl_3$, 298 K) δ 60.5 [d, 1P, J(P-P) = 26, J(Pt-P) = 3554 Hz], 45.7 [d, 1P, J(P-P) = 26, J(Pt-P) = 2522 Hz].

(*d*) R = R^1 = Ph. To a solution of 0.105 g (0.11 mmol) of **1** in 20 ml THF was added 0.23 mmol of PhC≡CPh. After heating under gentle reflux for 17 h, workup as before afforded a single red band, giving a bright red solid (0.085 g) containing two compounds inseparable by chromatography, *cis*-**4d** and *trans*-**4d** in the ratio 91 : 9 respectively on the basis of integration of the ^{31}P NMR peaks.

Spectroscopic data for trans-**4d**. ^{1}H NMR ($CDCl_3$, 298 K) δ 7.98–6.49 [m, 30H, Ph], 4.8 [s, 1H, C=C(H)], 3.15–1.64 [m, 4H, CH_2], 1.41 [s, 9H, Bu^t], 1.38 [d, 1H, C=C(H), J(H-H) = 11.3 Hz])],0.03 [s, 9H, Me_3Si]. ^{31}P NMR ($CDCl_3$, 298 K) δ 57.8 [d, 1P, J(P-P) = 34, J(Pt-P) = 3460 Hz], 44.2 [d, 1P, J(P-P) = 34, J(Pt-P) = 2580 Hz].

Spectroscopic data for cis-**4d**. ^{1}H NMR ($CDCl_3$, 298 K) δ 8.02–6.46 [m, 30H, Ph], 3.19–1.60 [m, 4H, CH_2], 3.10 [s, 1H, C=C(H)], 1.22 [s, 9H, Bu^t]. ^{31}P NMR ($CDCl_3$, 298 K) δ 57.0 [d, 1P, J(P-P) = 28, J(Pt-P) = 3532 Hz], 44.2 [d, 1P, J(P-P) = 28, J(Pt-P) = 2535 Hz].

(*e*) R = TePr^i, R^1 = Ph. To a solution of 0.097 g (0.10 mmol) of **1** in 20 ml THF was added 0.54 mmol of Pr^{i}TeC≡CPh. After heating under gentle reflux for 18 h the solution became deep red-purple. Workup as before afforded, in addition to unreacted alkyne and cluster **2**, a purple-red band. On recrystallisation of this band from hexanes/CH_2Cl_2, a dark red crystalline solid (0.026 g) was obtained, which contained two compounds inseparable by chromatography, *trans*-**5** and (tentatively) *cis*-**5** in the ratio 85 : 15 respectively on the basis of integration of the ^{31}P NMR peaks. A ^{31}P spectrum of the sample used for X-ray crystallography was used for the relative assignments of the isomers.

Spectroscopic data for trans-**5**. ^{1}H NMR ($CDCl_3$, 298 K) δ 8.18–6.42 [m, 25H, Ph], 5.67 [s, 1H, C=C(H)], 3.28–2.15 [m, 4H, CH_2], 2.88 [septet, 1H, $CHMe_2$ J(H-H) = 7 Hz] 1.52 [d, 6H, $CHMe_2$, J(H-H) = 7Hz], 1.35 [s, 9H, Bu^t]. ^{31}P NMR ($CDCl_3$, 298 K) δ 47.0 [d, 1P, J(P-P) = 10, J(Pt-P) = 4767 Hz], 25.1 [d, 1P, J(P-P) = 10, J(Pt-P) = 2614 Hz]. In view of the shorter distance between P1 and the Pt atom (see Table 4), the resonance at δ 47.0 with the largest J(Pt-P) is tentatively assigned to this phosphorus atom.

Spectroscopic data for cis-**5**. ^{31}P NMR ($CDCl_3$, 298 K) δ 44.0 [d, 1P, J(P-P) = 9, J(Pt-P) = 4739 Hz], 23.7 [d, 1P, J(P-P) = 9, J(Pt-P) = 2573 Hz].

Crystallographic studies on 3, gem-**4a** *and* trans-**5**

Single crystals of suitable size were attached to glass fibres using acrylic resin, and mounted on a goniometer head in a general position. Data were collected in bisecting mode using graphite monochromated X-radiation (λ = 0.71073 Å) on an Enraf-Nonius CAD4 diffractometer. All data sets were collected at ambient temperature (nominally 293 K). Details of data collection procedures and structure refinements are given in Table 1. Unit cell dimensions were determined by refinement of the setting angles of 25 reflections. Standard reflections were measured every 2 h during data collection, and an interpolated correction was applied to the reflection data where necessary. Lorentz-polarisation corrections, and absorption corrections by the method of Stuart and Walker [9] were also applied. The structures were solved by direct methods (MITHRIL [10]) and subsequent electron density difference Fourier maps. Anisotropic thermal parameters were used for all non-H atoms in complexes **3** and *trans*-**5**, and for the Pt, Ru, P and O atoms in

gem-**4a**. Hydrogen atoms were included in calculated positions with C-H = 0.96 Å, except for some of the hydrogens bonded to the coordinated carbons of the organo-ligands. Those on carbons C10, C11, C15 and C17 in cluster **3**, and on C13 in *trans*-**5** were included in calculated positions assuming sp^2 hybridisation at these centres. Those on C11 in *gem*-**4a** were observed from Fourier maps and were included at the observed positions. They were allowed to ride on the carbon atom C11 during refinement. The crystal quality for **3** and particularly *gem*-**4a** was poor, and this is reflected in the final residuals. In view of this, isotropic rather than anisotropic thermal parameters were used for the C-atoms in *gem*-**4a**. Nevertheless, the main structural features of all clusters were clearly defined by the X-ray analyses. Calculations using PLATON [11] showed that all three crystals displayed voids in the lattice, presumably containing solvent molecules. Although weak peaks were observed in the Fourier maps close to these voids, indicative of disordered, partially occupied solvent molecules, in no case was it possible to refine any realistic solvent molecules. For this reason, the SQUEEZE procedure of van de Sluis and Spek [12] was used to model this aspect of the electron density. Refinement (SHELXL-97 [13]) was by full-matrix least-squares on F^2, using all the unique data and the weighting scheme $W = [\sigma^2(F_o)^2 + (AP)^2 + BP]^{-1}$ where $P = [F_o^2/3 + 2F_c^2/3]$. All calculations were carried out on a Pentium P120 PC, and ORTEP [14] thermal ellipsoid plots were obtained using the program ORTEP-3 for Windows [15].

RESULTS AND DISCUSSION

The reaction of the hydrido-alkynyl cluster $Ru_3Pt(\mu\text{-H})\{\mu_4\text{-C}{\equiv}\text{C(Bu}^t\text{)}\}\text{-(CO)}_9\text{(dppe)}$ (**1**) with

excess HC≡CBu^t afforded on workup a modest yield of a bright red solid which contained three complexes which proved inseparable by chromatography. Under the conditions of the experiment cluster **1** slowly tautomerises to the vinylidene cluster $Ru_3Pt\{\mu_4$-C=CH-(Bu^t)$\}(CO)_9$(dppe) (**2**) [1–3], and in a test reaction cluster **2** was found to react with HC≡CBu^t in an identical fashion to **1**. It is not clear whether **1** or **2** (or indeed both) are the reactive clusters, since the reaction is reversible [1–3], but in all experiments reported here, the more readily available cluster **1** was used.

Fractional recrystallisation of the bright red solid from hot n-octane allowed the isolation of a small sample of pure yellow $Ru_3Pt[\mu_4$-C(Bu^t)C(H)C{C(Bu^t)}{C(H)C(Bu^t)}]$\{\mu$-σ-π-C(H)≡C(H)(Bu^t)$\}(CO)_7$(dppe) (**3**), but we were unable to obtain pure samples of the isomers of red $Ru_3Pt\{\mu_3$-C(Bu^{2t})CC(Bu^t)CH$_2$$\}(CO)_8$(dppe) **4a**. The complexes were characterised by spectroscopic means, and for complexes **3** and the *gem*-isomer of **4a** also by single crystal X-ray diffraction. The relative proportions of the two isomers of **4a** could be changed somewhat by fractional crystallisation. This was most easily followed by ^{31}P NMR spectroscopy, where the signals from both isomers were clearly distinguished. Most of the ^{1}H resonances from both isomers could be identified, though due to signal overlaps, not all expected resonances could be unambiguously assigned.

An ORTEP [14] view of the molecular structure of **3** is shown in Fig. 1, with important metrical parameters given in Table 2. The cluster contains an Ru_3Pt chain, with three metal-metal bonds. The Pt atom is formally a 16-electron centre, and is coordinated to the dppe ligand, to one Ru atom [Ru-Pt = 2.730(2)Å), and is σ-bonded to C14. A complex C-C coupled ligand C(Bu^t)C(H)C{C(Bu^t)}{C(H)C(Bu^t)} is bonded to all four metal atoms. The carbon atoms C14=C15 act as a σ-π-vinyl ligand across the Pt-Ru1 vector, and hence are formally doubly bonded. The C14=C15 distance of 1.45(3) Å indicates a degree of π-delocalisation with the ruthena-cyclopentadienyl group, which comprises the ring of atoms Ru3=C20=C16=C17=C18. The six central C-atoms C14=C18 and C20 and the ruthenium atom Ru3 are virtually coplanar, the maximum deviation from their mean plane being 0.05(2) Å for C16. The carbons C10, C11, C15 and C17 each bear one hydrogen atom. The central ruthenium atoms Ru1 and Ru2 carry two terminal CO ligands each, and are bridged by the C10=C11 atoms of a second σ-π-vinyl ligand CH=CH(Bu^t). The Ru2 atom is bonded to all four atoms C16=C17=C18=C20, with marginally shorter distances to the inner carbons C16 and C17. The terminal ruthenium atom Ru3 bears three terminal CO ligands.

The μ_4-C(Bu^t)C(H)C{C(Bu^t)}{C(H)C(Bu^t)} ligand is derived either by C-C coupling of two HC≡CBu^t groups with the original alkynyl ligand in **1** (or the vinylidene ligand in **2**) or of three HC≡CBu^t molecules with each other. Since the Bu^t substituents on the alkyne and alkynyl ligands are identical, it is

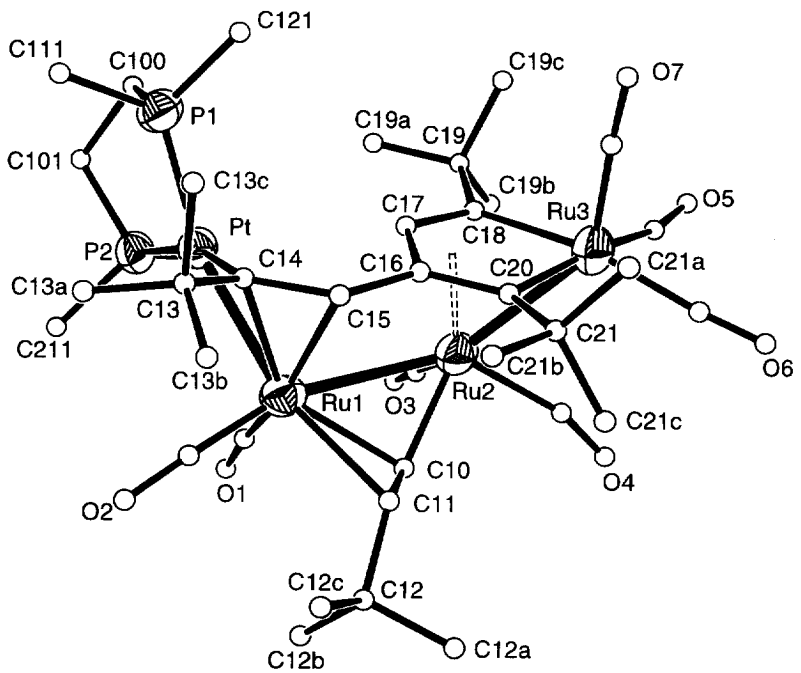

Fig. 1. Molecular structure and atomic labelling scheme for $Ru_3Pt[\mu_4$-C(Bu^t)C(H)C{C(Bu^t)}{C(H)C(Bu^t)}]$\{\mu$-σ-π-C(H)≡C(H)(Bu^t)$\}(CO)_7$(dppe) (**3**). Thermal ellipsoids are drawn at the 50% probability level, and C and O atoms are drawn as spheres of arbitary radius.

not possible to distinguish these possibilities. Unfortunately, we are unable to isolate any analogs of **3** using alkyne reagents with differing substituents (see below). Nevertheless, it is clear that a total of three $HC\equiv CBu^t$ molecules have been incorporated into the cluster. A search of the Cambridge Crystallographic DataBase revealed that the connectivity of the μ_4-$C(Bu^t)C(H)C\{C(Bu^t)\}\{C(H)C(Bu^t)\}$ ligand in cluster **3** is unique. There are numerous examples of metallocyclopentadienyl units coordinated to a second metal atom (i.e. the so called ferrole structure), but very few with ligating substituents on the 1-, or 2-positions. One rare example is $Ru_3(CO)_8$ [RCC(Ph)(Ph)CR] [R = C(H)=C(H)(Ph)] reported by Koridze *et al.* [16] where one of the 1-vinyl groups is coordinated to an Ru atom.

The total cluster valence electron (CVE) count in cluster **3** is 64, assuming the μ_4-$C(Bu^t)C(H)C\{C(Bu^t)\}\{C(H)C(Bu^t)\}$ ligand acts as a 9-electron donor. This is consistent with the presence of three metal-metal bonds and a 16-electron Pt centre [17].

The cluster $Ru_3Pt\{\mu_3\text{-}C(Bu^t)CC(Bu^t)CH_2\}(CO)_8$ (dppe) *gem*-**4a** was also characterised by X-ray crystallography. An ORTEP [14] view of the molecular structure is shown in Fig. 2, with important metrical parameters given in Table 3. The cluster contains a tetrahedral Ru_3Pt arrangement, with rather unsymmetrical Pt-Ru distances [2.697(3)–2.982(3) Å]. The dppe ligand remains coordinated to the Pt atom. This atom is on the opposite side of the Ru_3 triangle to the hydrocarbyl ligand, with which it forms no bonds. This is in contrast to the situation found in **1** and **2** [1,2], where the hydrocarbyl ligand is bonded to all four metals. Ruthenium atoms Ru1 and Ru2 each bear three CO ligands, the carbonyl CO(6) being semi-bridging towards the Pt atom [Ru2=C6 = 2.02(3), Pt=C6 = 2.31(3) Å]. The ruthenium atom Ru3 bears two terminal CO ligands, and is also coordinated to the allylic C_3 fragment C11=C12=C13.

The μ_3-$C(Bu^t)CC(Bu^t)CH_2$ ligand coordinated to the three Ru atoms is the result of a head-to-tail C-C coupling of the original alkynyl (or vinylidene) ligand with one molecule of $HC\equiv CBu^t$. One possible description of this ligand is that of a vinyl substituted alkyne $(Bu^t)C\equiv C{=}C(Bu^t){=}CH_2$, with the alkyne component coordinated to the Ru_3 in the classic $\{\mu_3\text{-}\eta^2\text{-}(\|)\}$-mode [6a], and with the vinyl group η^2-coordinated to Ru3. This would give carbons C13 and C14 an *sp* hybridisation, with sp^2 hybridisation for carbons C12 and C11. The angles at these carbons (see Table 2), and the C-C distances of C11=C12 = 1.44(4), C12=C13 = 1.35(3), C13=C14 = 1.49(3) Å indicate that this is a simplification. All three distances are intermediate between single and double bonds. Alternatively, one may view the C11=C12=C13 section as an allyl group, which is metallated at the carbons C13 and C14. An identical ligand, coordinated in an identical fashion, has been previously reported by Aime *et al.* [18a] in the cluster $Ru_3(CO)_6\{\mu_3\text{-}C(Bu^t)CC(Bu^t)CH_2\}\{\mu_3\text{-}C(H)C(Bu^t)COC(Bu^t)CH]$ (this compound exists as two isomers [18b]), and by Gervasio *et al.* [19] in the cluster $Ru_3(CO)_5\{\mu_3\text{-}C(Bu^t)CH_2\}\{\mu_3\text{-}C(H)C(Bu^t)COC(Bu^t)CHC(Bu^t)CH]$. A closely related species is $Ru_3(CO)_7\{\mu_3\text{-}C(Bu^t)CC(Ph)CH(Ph)\}(C_2Ph_2)$[20].

The total CVE count in cluster **4a** is 60, assuming that the μ_3-$C(Bu^t)CC(Bu^t)CH_2$ ligand acts as a 6-electron donor. This is consistent with the presence of six metal-metal bonds and an 18-electron Pt centre [17]. The ^{31}P NMR data indicates that the two P atoms are inequivalent, which is consistent with the crystal structure. There was no evidence for exchange broad-

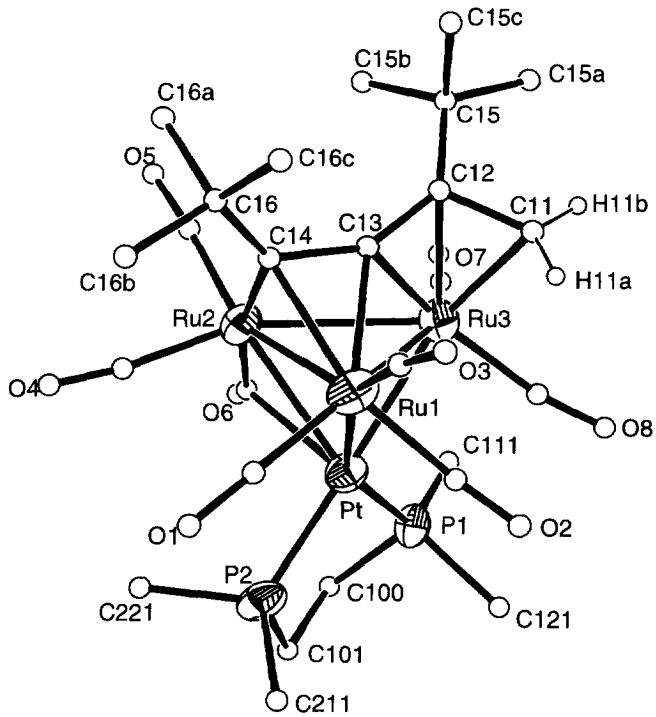

Fig. 2. Molecular structure and atomic labelling scheme for $Ru_3Pt\{\mu_3\text{-}C(Bu^t)CC(Bu^t)CH_2\}(CO)_8(dppe)$ (*gem*-**4a**). Thermal ellipsoids are drawn at the 50% probability level, and C, O and H atoms are drawn as spheres of arbitary radius.

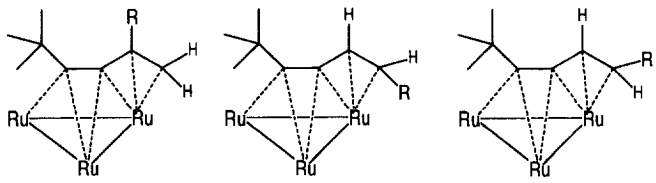
ening at room temperature, indicating that any rotation of the Pt(dppe) fragment [2] was slow on the NMR timescale. The values of $J(^{195}Pt\text{-}P)$ for the high and low frequency ^{31}P resonances are in the narrow ranges of 3535 ± 15 Hz and 2550 ± 30 Hz respectively for all the derivatives **4** and their isomers (see Experimental Section). In conjunction with the similarity of chemical shifts, this proves very strong evidence that they all have closely similar structures.

There are potentially three isomers of **4a** (shown in the Scheme), depending on the stereo-geometry of the H atoms in the C-C coupled ligand, namely *gem*-**4a** observed in the crystal structure, *trans*-**4a** and *cis*-**4a**. The first isomer arises from a "head-to-tail" C-C coupling, while the latter two result from a "head-to-head" coupling. Only two isomers were observed for **4a**, the second isomer being assigned to *trans*-**4a** on the basis of the significant H-H coupling. The lack of



Scheme 1.

observable quantities of *cis*-**4a** is attributed to the steric bulk of the Bu^t group, which would cause unacceptable steric strain were it substituted in the position of H11a, see Fig. 2 and the space-fill view in Fig. 3.

Reactions of **1** with PhC≡CH and $Me_3SiC{\equiv}CH$ gave mixtures of three inseparable isomers of **4b** and **4c** respectively, which had closely similar ^{31}P NMR spectra. The Ph and $SiMe_3$ groups are evidently less sterically demanding than the Bu^t group in these compounds, since the cis isomers are also formed, albeit in minor proportions. It is somewhat surprising that the $SiMe_3$ derivative forms a cis isomer, but this is attributed to the expected larger C-Si distance as compared with the corresponding C-C distance (~1.85 versus 1.54 Å), which means that the bulky methyl groups are further from the terminal C-atom (C11 in Fig. 2). No evidence for analogs of compound **3** was obtained for these alkynes. Reaction of **1** with PhC≡CPh afforded two isomers of **4d**, as expected, with the Ph groups cis (main isomer) and trans. Again, the ^{31}P NMR spectra were very similar to the above mentioned derivatives.

We have previously reported [3] that the reaction of **1** with the phosphino-alkyne $Ph_2PC{\equiv}CPPh_2$ afforded modest yields of the two phosphido species, $Ru_3Pt(\mu_4\text{-}C{\equiv}CBu^t)(\mu\text{-}PPh_2)(CO)_7(dppe)$ and $Ru_3Pt\{\mu\text{-}C{\equiv}C(H)Bu^t\}(\mu\text{-}PPh_2)_2(CO)_7(dppe)$, the former being characterised by an X-ray structure. We did not isolate any C-C coupled products from this reaction. In view of the extensive cluster chemistry of phosphino-alkynes, often involving P=C bond cleavage, [21] it was decided to investigate the reactivity of **1** with a related telluro-alkyne ligand $Pr^tTeC{\equiv}CPh$.

The synthesis of a series of alkyltelluro-alkynes was reported by Comasseto and Dabdoub [8], though very little coordination chemistry of these potentially interesting ligands has been reported. Apart from a few simple coordination complexes [22], we are only aware of one crystallographically characterised cluster complex containing such a ligand, *viz* $Co_2(CO)_6[C_6Me_3H_2$-

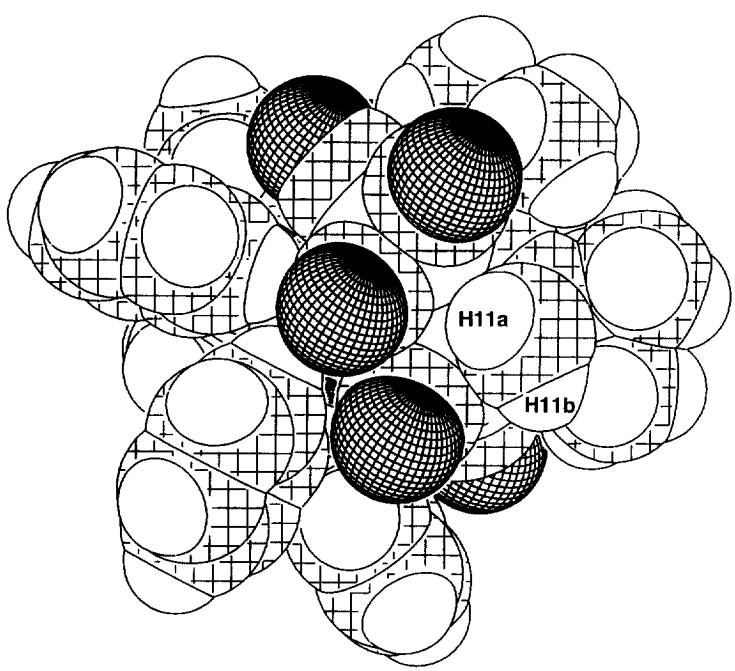


Fig. 3. Space-fill view of $Ru_3Pt\{\mu_3\text{-}C(Bu^t)CC(Bu^t)CH_2\}(CO)_8(dppe)$ (*gem*-**4a**). C atoms are shown as cross-hatched, O atoms are net-shaded globes and H atoms have no shading.

$TeC{\equiv}CSiMe_3$} [23]. The reaction of **1** with excess $Pr^iTeC{\equiv}CPh$ afforded modest yields of a crystalline mixture of two complexes in the ratio 85 : 15 which proved inseparable by chromatography. A single crystal X-ray structure of the major component showed it to have the composition $Ru_3Pt\{\mu_4\text{-}C(Ph)CCC(H)(Bu^t)\}(\mu_4\text{-}Te)(\mu\text{-}TePr^i)(CO)_6(dppe)$ (*trans*-**5**). In view of the similarity of the ^{31}P NMR spectra of both compounds (see Experimental Section), we tentatively assign the minor component as the isomer *cis*-**5**, with the alternate stereo-geometry at C13. Due to the small quantities available, we have not examined this minor product in any more detail.

The molecular structure of *trans*-**5** is shown in Fig. 4, and important bond lengths and angles are given in Table 4. The complex retains the Ru_3Pt skeleton, with four metal-metal bonds, though the Pt=Ru3 distance of 3.1289(9) Å is somewhat longer than Pt=Ru1 = 2.9834(9) Å, and is best considered as a weak interaction. The metal skeletal geometry is a distorted square plane. If the μ_4-Te atom is treated as a 6-electron donor, and each M=C interaction as a σ-interaction, this results in an 18-electron count at each metal atom, and a CVE count of 66. This is consistent with three metal-metal bonds. The alternate treatment of the μ_4-Te atom as a 4-electron donor, giving a CVE count of 64, with four metal-metal bonds and an 18-electron Pt centre is also reasonable. It is probably preferable to treat the μ_4-Te atom as a part of the cluster core. Cluster *trans*-**5** has 8 skeletal electron pairs and may be viewed as an arachno-pentagonal bipyramid, which is consistent with the long Pt=Ru3 bond. A few similar examples [24] of clusters containing the μ_4-Te atom are known. The cluster $Fe_2Ru_2(\mu_4\text{-}Te)_2(CO)_{11}$ [24b] provides an interesting comparison with *trans*-**5**, in that treating the μ_4-Te atoms as formal 6-electron donors gives a CVE count of 66, and the Fe=Fe distance of 2.872(4) Å is substantially longer than is normal for an Fe=Fe bond.

The μ_4-C(Ph)CCC(H)(Bu^t) ligand is derived from a heat to tail C-C coupling of the alkynyl ligand in **1** (or the vinylidene ligand in **2**) with a C≡CPh group resulting from cleavage of the ligand $Pr^iTeC{\equiv}CPh$. It may be thought of as a coordinated vinyl-alkyne, where the C_1 atom of the vinyl group (C12 in Fig. 4) is metallated. The bonding of the resultant C_4 fragment to a tetra-metallic skeleton is unique, though it is related to the bonding of the diyne in $Ru_4(CO)_{10}(\mu_4\text{-}PR)\{\mu_4\text{-}RC{\equiv}C{=}C{\equiv}CR\}$ (**6a** R = C≡CBu^t, R = Bu^t [25a], **6b** R = Me_3Si, R = Me [25b]. In *trans*-**5** the C_4 ligand is a 7-electron donor, while the diyne ligand in **6** is an 8-electron donor. In both cases the formalism describing the nature of the C_4 ligands is clearly simplistic, as may be judged from the C=C bond lengths. In both complexes *trans*-**5** and **6**, the central C=C bond is the shortest one, and Carty and coworkers [25a] have suggested the diyne ligand in **6a** may be considered as a bis(alkylidyne) dicarbide. The formation of the C-C coupled ligand in *trans*-**5** may be a further example of the activating influence of

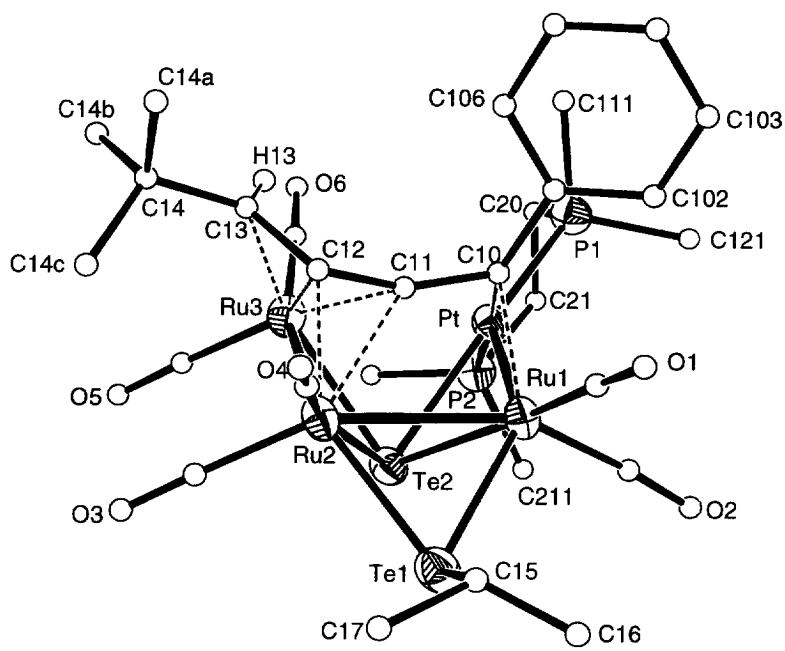

Fig. 4. Molecular structure and atomic labelling scheme for $Ru_3Pt\{\mu_4\text{-}C(Ph)CCC(H)(Bu^t)\}(\mu_4\text{-}Te)(\mu\text{-}TePr^i)(CO)_6(dppe)$ (*trans*-**5**). Thermal ellipsoids are drawn at the 50% probability level, and C, O and H atoms are drawn as spheres of arbitary radius.

main group elements [see reference 25b and references therein]. A related metallated alkynyl fuctionalised vinylidene ligand bonded to an Ru_2Pt cluster in $Ru_2Pt(CO)_6(\mu$-$PPh_2)(\mu_3$-C=C=C≡CBu^t) has also been reported recently [26].

CONCLUSIONS

Cluster **1** (or **2** or both) readily react with a variety of alkynes to undergo C-C coupling reactions under mild conditions. Modest to reasonable yields of these products were obtained. In cases where isomers of the C-C coupled ligand are possible, all isomers were observed except for **4a**. The Ru_3Pt skeleton remains intact throughout these reactions, although the number of metal-metal bonds in the products differs. These reactions provide further evidence for the flexibility of the metal skeleton in platinum-containing cluster compounds [7,17].

Supplementary material—Tables of atomic coordinates and equivalent isotropic thermal parameters, anisotropic thermal parameters and a complete listing of bond lengths and bond angles for complexes **3**, *gem*-**4a** and *trans*-**5**. Tables of observed and calculated structure factors are available from LJF on request.

(Received 6 November 1997; accepted 5 January 1998)

Abstract—The structures of [Crypt221-Na]$_2$[$H_2Ru_4(CO)_{12}$] and [Crypt222-K]$_2$[$Ru_4(CO)_{13}$] were determined from single crystal X-ray diffraction studies. A survey of the structures of tetranuclear carbonyl clusters of the Group 8 metals and their conjugate bases is presented. The cluster core of $[H_2Ru_4(CO)_{12}]^{2-}$ is a tetrahedron of Ru atoms with three edge bridging carbonyls arranged around the base. Two single edge bridging hydrogens reside between the apical Ru atom and two basal Ru atoms. Two terminal carbonyls are bound to each basal Ru atom and three terminal carbonyls are bound to the apical Ru atom. The apical Ru atom has three terminal carbonyls bound to it. In addition, two singly bridging hydrogens occur between apical and basal rutheniums. The $[Ru_4(CO)_{13}]^{2-}$ dianion structure consists of a tetrahedral Ru_4 core with three edge bridging carbonyls arranged around the base. Two semi-edge bridging carbonyls reside between the apical and two basal Ru atoms. Crystal data for [Crypt221-Na]$_2$[$H_2Ru_4(CO)_{12}$]: space group $P\bar{1}$, $a = 13.718(2)$ Å, $b = 20.997(6)$ Å, $c = 10.344(1)$ Å, $\alpha = 97.02(2)^\circ$, $\beta = 92.81(1)^\circ$, $\gamma = 77.80(2)^\circ$, $V = 2889.56$ Å^3. Crystal data for [Crypt222-K]$_2$[$Ru_4(CO)_{13}$]: space group $P2_1/c$, $a = 11.221(3)$ Å, $b = 22.951(6)$ Å, $c = 25.219(6)$ Å, $\beta = 97.61(2)^\circ$, V = 6427.74 Å^3. © 1998 Elsevier Science Ltd. While homonuclear and heteronuclear tetrahedral carbonyl hydride clusters of the iron subgroup and their conjugate anion Brönsted bases have been reported, gaps still remain with respect to structural information regarding arrangements of carbonyl groups as a function of charge on the cluster. In this respect we are interested in ligand arrangements in ruthenium carbonylate anions that were prepared earlier in this laboratory [1–3] as part of a program to develop systematic syntheses of such cluster complexes. The anion $[H_2Ru_4(CO)_{12}]^{2-}$ [1] is conveniently prepared by deprotonating $H_4Ru_4(CO)_{12}$ with KH (Reaction (1)). IR spectra and ^{13}C NMR spectra indicate that this anion contains bridging carbonyls and a structure was proposed [1]. Since the molecular structures of its conjugate Brönsted acids $H_4Ru_4(CO)_{12}$ [4], $[H_3Ru_4(CO)_{12}]^-$ [5,6], and its osmium cluster counterpart $[H_2Os_4(CO)_{12}]^{2-}$ [7] possess only terminal carbonyl groups, it was of interest to determine the solid state structure of $[H_2Ru_4(CO)_{12}]^{2-}$ to determine if the spectroscopic data accurately reflect the disposition of the carbonyl ligands.

$$H_4Ru_4(CO)_{12} + 2KH \xrightarrow{THF} K_2[H_2Ru_4(CO)_{12}] + 2H_2 \quad (1)$$

The anion $[Ru_4(CO)_{13}]^{2-}$ [2] is prepared by the stoichiometric reduction of $Ru_3(CO)_{12}$ according to the reaction shown below (Reaction (2)). This anion is highly fluxional in solution.

$$Ru_3(CO)_{12} + 3/2K(C_6H_5)_2CO \xrightarrow{THF} 3/4K_2[Ru_4(CO)_{13}] + 9/4CO \quad (2)$$

IR spectra suggest the presence of bridging carbonyls. Carbon-13 NMR spectra over the temperature range 20°C to −138°C display only a single resonace at 223.5 ppm, intermediate for bridge and terminal carbonyls. The conjugate acids of $[Ru_4(CO)_{13}]^{2-}$,

Dedication: To Lord Jack Lewis, a true scholar and gentleman.

$[HRu_4(CO)_{13}]^-$ [8] and $H_2Ru_4(CO)_{13}$ [9] contain one edge-bridging and two semibridging carbonyls, respectively. It was of interest to determine the structure of $[Ru_4(CO)_{13}]^{2-}$ in order to learn how the carbonyl ligands are disposed with increasing charge in the sequence $H_2Ru_4(CO)_{13}$, $[HRu_4(CO)_{13}]^-$, and $[Ru_4(CO)_{13}]^{2-}$. Furthermore, it was of interest to compare the structure of $[Ru_4(CO)_{13}]^{2-}$ with that of the known structure of $[Fe_4(CO)_{13}]^{2-}$ [10,11], especially since the structure of $[HFe_4(CO)_{13}]^-$ [12] differs markedly from that of $[HRu_4(CO)_{13}]^-$.

In the present report, we provide structural details for the $[H_2Ru_4(CO)_{12}]^{2-}$ and $[Ru_4(CO)_{13}]^{2-}$ anions based upon X-ray diffraction analyses and we summarize available crystallographic results on the structures of tetrahedral homonuclear and heteronuclear clusters of the iron subgroup.

EXPERIMENTAL

Materials

All manipulations were carried out on a standard high vacuum line or in a glovebox. Solvents were dried and degassed according to standard procedures [13]. $Na_2H_2Ru_4(CO)_{12}$ and $K_2Ru_4(CO)_{13}$ were prepared by the literature methods [1,2]. Kryptofix-2.2.2 and Kryptofix-2.2.1 were purchased from MCB Manufacturing Chemists Inc. and used as received.

$[Crypt222\text{-}K]_2[Ru_4(CO)_{13}]$. Kryptofix-2.2.2 (13 mg, 0.035 mmol, 12% molar excess) and $K_2Ru_4(CO)_{13}$ (13 mg, 0.015 mmol) were combined in a 10 ml flask under a dry, oxygen-free atmosphere. Dry THF (4 ml) was condensed into the flask and stirred for 4 hrs. The solution was then filtered to yield very fine red crystals of $[Crypt222\text{-}K]_2[Ru_4(CO)_{13}]$. Additional crystals suitable for X-ray analysis were obtained from the filtrate after 24 h at room temperature.

$[Crypt221\text{-}Na]_2[H_2Ru_4(CO)_{12}]$. $[Crypt221\text{-}Na]_2[H_2Ru_4(CO)_{12}]$ was prepared in analogous fashion as that described above using Kryptofix-2.2.1 and $Na_2[H_2Ru_4(CO)_{12}]$.

X-ray crystallography

For X-ray examination and data collection, each crystal was sealed in a glass capillary and mounted on a goniometer head. All X-ray data were collected on an Enraf-Nonius CAD4 diffractometer with graphite-monochromated Mo-K_α radiation. Unit cell parameters and standard deviations were obtained by least squares refinement from 24 reflections, well-distributed in reciprocal space and lying in the 2θ range 20–30°. Intensity data were collected at 25°C in the ω-2θ scan mode for the range $4 \leqslant 2\theta \leqslant 50°$. Six standard reflections were monitored and showed no significant decay. The data were corrected for Lorentz and polarization effects. The intensities were also corrected for absorption by using an empirical method based upon measured ψ scans.

The structures were solved using a combination of direct methods for $[Crypt222\text{-}K]_2[Ru_4(CO)_{13}]$ or the Patterson function for $[Crypt221\text{-}Na]_2[H_2Ru_4(CO)_{12}]$, difference Fourier and least squares refinement on F using SDP (Structure Determination Package) [14]. A final difference Fourier synthesis showed no significant features. Table 1 summarizes the crystallographic data for $[Crypt221\text{-}Na]_2[H_2Ru_4(CO)_{12}]$ and $[Crypt222\text{-}K]_2[Ru_4(CO)_{13}]$.

RESULTS

Structure of $[H_2Ru_4(CO)_{12}]^{2-}$.

The molecular structure of $[H_2Ru_4(CO)_{12}]^{2-}$ is shown in Fig. 1. Interatomic distances and angles are collected in Tables 2 and 3, respectively.

The Ru_4 core of the $[H_2Ru_4(CO)_{12}]^{2-}$ cluster is a tetrahedron with three edge-bridging carbonyls arranged around the base. Two terminal carbonyls are bound to each basal Ru atom while the apical Ru(4) binds to three terminal carbonyls. Although not located directly in the structure determination, two singly bridging hydrogens that span the Ru(1)—Ru(4) and Ru(3)—Ru(4) bonds are inferred as indicated by the long Ru—Ru distances (ave. 2.973 Å) compared to the Ru(2)—Ru(4) bond length of 2.820(1) Å. "Long" Ru—Ru distances that are hydrogen bridged (2.92–2.93 Å) and "short" Ru-Ru distances that are not hydrogen bridged (2.80 Å) have been observed in $[H_3Ru_4(CO)_{12}]^-$, the isomer of C_2 symmetry, for which the bridge hydrogens were located [5]. Other examples: $H_4Ru_4(CO)_{12}$ [4] and $H_2Ru_4(CO)_{13}$ [9] also have "long" and "short" Ru-Ru distances, with the long distances inferring the presence of bridge hydrogens and the short distances unbridged.

Carbonyl bridged Ru—Ru distances in $[H_2Ru_4(CO)_{12}]^{2-}$ are on the average 2.770 Å. The terminal carbonyls on the Ru(4) apex are staggered with respect to the three cluster faces with the common vertex Ru(4). The carbonyl that is staggered with respect to the Ru(1)—Ru(3)—Ru(4) face has a Ru(4)—C(43) distance of 1.917(3) Å and M—Ru(4)—C(43) angles where (M=Ru(1) or Ru(3) $\approx$ 113.5°) that are longer and more obtuse, respectively, than the remaining carbonyls on Ru(4) which have Ru—C distances of 1.88—1.89 Å and angles of 84.6–97.7°. This effect is attributed to the presence of hydrogen atoms that are situated along the Ru(4)—Ru(3) and Ru(4)—Ru(1) edges of the Ru(1)—Ru(4)—Ru(3) face.

Structure of $[Ru_4(CO)_{13}]^{2-}$. The molecular structure of $[Ru_4(CO)_{13}]^{2-}$ is shown in Fig. 1. Interatomic distances and angles are given in Tables 4 and 5, respectively. The $[Ru_4(CO)_{13}]^{2-}$ anion structure is based on a tetrahedral Ru_4 core. The apical ruthenium Ru(3) is

$[H_2Ru_4(CO)_{12}]^{2-}$ $[Ru_4(CO)_{13}]^{2-}$

Fig. 1. X-ray structures of $[Ru_4(CO)_{13}]^{2-}$ and $[H_2Ru_4(CO)_{12}]^{2-}$.

bound to four carbonyls, two of which are semibridging to the basal rutheniums Ru(2) and Ru(4). Distances of these ruthenium atoms to the carbonyl carbons are Ru(2)...C(32)=2.439(4) Å and Ru(4)...C(34)=2.592(4) Å, while the ruthenium–carbonyl bond angles are Ru(3)—C(32)—O(32)=153.6(4)° and Ru(3)—C(34)—O(34)=160.1(4)°. The semibridging carbonyls in the parent cluster, $H_2Ru_4(CO)_{13}$, have similar bonding distances and angles (2.31–2.47 Å, 144–154°) [9]. The distances of the Ru(3) atom to the carbons of the semibridging carbonyls are significantly longer than the distances of the Ru(3) atom to the terminal carbonyls: Ru(3)—C(32)=1.959(4) Å and Ru(3)—C(34)=1.941(4) Å as compared to Ru(3)—C(31)=1.882(5) Å and Ru(3)—C(33)=1.870(4) Å. Each basal ruthenium of the $[Ru_4(CO)_{13}]^{2-}$ anion has two terminal carbonyls bonded to it and is edge-bridged to each of the other rutheniums *via* a slightly asymmetric carbonyl bridge.

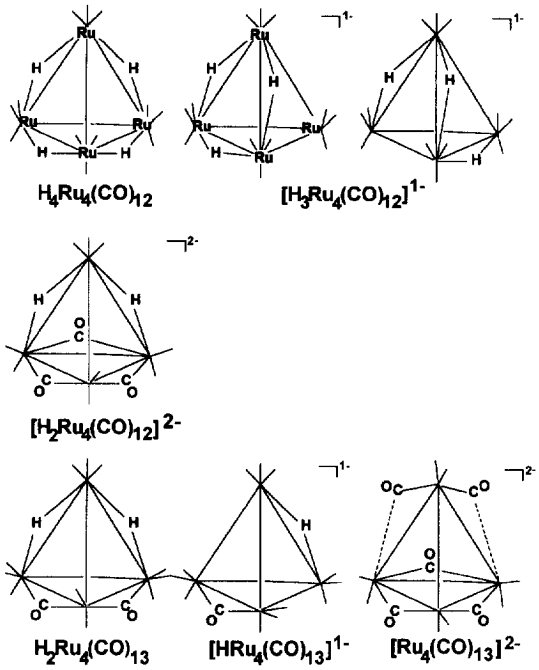

Fig. 2. Comparison of structures of $H_4Ru_4(CO)_{12}$ and $H_2Ru_4(CO)_{13}$ and their conjugate bases.

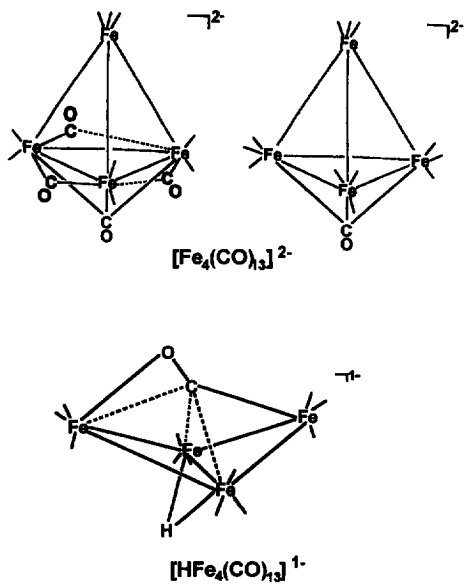

Fig. 3. Comparison of the structures of $[Fe_4(CO)_{13}]^{2-}$ and $[HFe_4(CO)_{13}]^{-}$.

The basal Ru—Ru bond lengths average 2.779 Å while the apical Ru bonds are somewhat longer (ave. 2.864 Å). Similar values are observed for the carbonyl bridged Ru—Ru and unbridged Ru—Ru distances in $[H_2Ru_4(CO)_{12}]^{2-}$ and $[HRu_4(CO)_{13}]^{-}$ [8].

DISCUSSION

Figure 2 depicts schematic arrangements of carbonyl groups and hydrogens in the known structures of $H_4Ru_4(CO)_{12}$ and $H_2Ru_4(CO)_{13}$ and their conjugate bases $[H_3Ru_4(CO)_{12}]^-$, $[H_2Ru_4(CO)_{12}]^{2-}$, $[HRu_4(CO)_{13}]^-$, and $[Ru_4(CO)_{13}]^{2-}$. In the series defined by $H_4Ru_4(CO)_{12}$ [4], the removal of one proton results in the formation of two structurally identified isomers [5,6] of $[H_3Ru_4(CO)_{12}]^-$ which differ solely by the placement of bridging hydrogen atoms. The removal of a second proton results in the formation of $[H_2Ru_4(CO)_{12}]^{2-}$. In this case the three terminal carbonyls have moved to edge-bridging sites. This structure is consistent with that proposed earlier by Inkrott and Shore [1] based upon NMR and IR spectra. This difference in carbonyl arrangement in $[H_2Ru_4(CO)_{12}]^{2-}$ compared to $H_4Ru_4(CO)_{12}$ and $[H_3Ru_4(CO)_{12}]^-$ is believed to be due to the larger negative charge on the dianion and reflects a mode of averaging charge distribution in the cluster framework. Chini [15] found a linear relationship between the fractions of terminal carbonyl groups and the average negative charge per carbonyl group for a series of isoelectronic octahedral carbonyl rhodium clusters. It appears that the ability of carbonyl ligands to disperse electron density on a metal cluster decreases in the order face-bridging > edge-bridging > terminal [15,16].

Table 6 compares the known structures of tetrahedral clusters of the Group 8 metals of the type $H_{4-n}M_4(CO)_{12}^{-n}$ ($n = 0, 1, 2$). All of the Ru_4 and Os_4 clusters are essentially isostructural with the exception of $[H_2Ru_4(CO)_{12}]^{2-}$ and $[H_2Os_4(CO)_{12}]^{2-}$ [7] which reflects the well-known fact that the tendency for carbonyls to occupy bridging sites diminishes down the Fe, Ru, Os group. While two isomers [5,6] of $[H_3Ru_4(CO)_{12}]^-$ have been structurally identified (Figure 2) only the structure of C_2 symmetry has been positively identified for $[H_3Os_4(CO)_{12}]^-$ [5].

Table 6 also compares the known structures of tetrahedral clusters of the Group 8 metals that have 13 carbonyls. The arrangements of carbonyl groups on the metal cores of the $[Ru_4(CO)_{13}]^{2-}$ and $[Fe_4(CO)_{13}]^{2-}$ are markedly different. In the case of the ruthenium cluster anion there are two semibridging carbonyls from the apical Ru atom to the basal Ru atoms and three bridging carbonyls around the base. In the case of the iron cluster with a PPN^+ counterion [10] (Fig. 3) a carbonyl group caps the basal Fe_3 triangle. The remaining 12 carbonyls in this anion are in terminal positions (Fe—C . . . Fe=2.67–2.82 Å, Fe—C—O=169–171°). On the other hand with a $[Fe(py)_6]^{2+}$ cation [11], three of the terminal carbonyls on the Fe_3 basal triangle move to semibridging positions (Fe—C . . . Fe = 2.24–2.33 Å, Fe—C—O = 151–158°), but the capping carbonyl remains in place.

In the case of the $[Ru_4(CO)_{13}]^{2-}$ dianion, we observed no significant difference in its structure when the counter ion is $[Crypt222\text{-}K]^+$ or $[PPh_4]^+$. The $[PPh_4]^+$ salt has a similar structure wherein the three basal edge-bridging carbonyls and the two apical semibridging carbonyls are maintained [17].

A further point of interest is that while the structure of $[Fe_4(CO)_{13}]^{2-}$ [10,11] and $[Ru_4(CO)_{13}]^{2-}$ have similar metal cores and differ principally in the fact that $[Fe_4(CO)_{13}]^{2-}$ contains a face-capping carbonyl group, the $[HFe_4(CO)_{13}]^-$ [12] and $[HRu_4(CO)_{13}]^-$ [8] ions have markedly different metal cores. A tetrahedral Ru_4 core exists in $[HRu_4(CO)_{13}]^-$ while a "butterfly" Fe_4 core accompanied by an oxocarbonyl bridge occurs in $[HFe_4(CO)_{13}]^-$.

Crabtree and Lavin [18] expanded upon the structural analyses of semibridging carbonyl bond angles first considered by Curtis [19]. At that time, however, structures for only three tetranuclear carbonyl clusters of the iron sub-group were known. We have examined the M_1CO (denoted as θ) and CM_1M_2 (denoted as ψ) angles for the clusters in the present study and from structures reported since Crabtree and Lavin's work was published. In general, the results reported here fall in the ranges of angles assigned by Crabtree and Lavin [18] to terminal ($\psi > 70°$, $\theta > 165°$), semibridging ($\psi \approx 50$–$75°$, $\theta \approx 145$–$165°$), edge-bridging ($\psi \approx 49°$, $\theta \approx 138°$) carbonyls.

Acknowlegement—We thank the National Science Foundation for support of this work.

Abstract—The clusters $Ru_3(CO)_{12}$, $Ru_6C(CO)_{17}$, $H_4Ru_4(CO)_{12}$ and $H_2Os_3(CO)_{10}$ react with the phosphine, $P(m\text{-}C_6H_4SO_3Na)_3$, to afford water soluble clusters which are catalyst precursors in the water gas shift reaction. Electrospray mass spectrometry provides an excellent means of characterising the clusters in solution from their negative ion spectra. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: clusters; phosphine; water soluble; ruthenium; osmium

There has been considerable interest over the last two decades in conducting organometallic reactions in an aqueous environment. This is partly because water is cheap and environmentally friendly, but also from a synthetic viewpoint, biphasic catalytic processes can be performed which allows separations to be achieved with considerable ease [1]. In this respect, much effort has been devoted to the synthesis of water soluble mononuclear catalysts and this area has been recently reviewed [2]. The most noteworthy complex of this type is perhaps the rhodium adduct $Rh(H)CO\{P(m\text{-}C_6H_4SO_3Na)_3\}_3$ which is employed in a biphasic system catalysing the conversion of propene to *n*-butyraldehyde [3], although a number of other catalytic systems have also been developed [4].

While cluster compounds are known to be effective catalysts for a large number of processes [5], the area of water soluble clusters is poorly developed. Süss-Fink and his coworkers have prepared several tetraruthenium-tetraarene clusters including the 58 electron species $[H_4Ru_4(\eta\text{-}C_6H_6)_4]^{2+}$ [6]. This cluster has been shown to catalyse the hydrogenation of various arenes to give the corresponding cyclohexanes under biphasic conditions [7].

There has also been a preliminary report describing the synthesis of several water soluble carbonyl clusters with the water soluble phosphine, $P(m\text{-}C_5H_4SO_3Na)_3$, but their use as catalysts was not investigated [8]. Since the reactivity of transition metal carbonyl clusters towards phosphine ligands is a mature area we decided to prepare further clusters, including some with hydride ligands, with the water soluble phosphine $P(m\text{-}C_6H_4SO_3Na)_3$. In this paper we describe the results of this study which includes their synthesis, characterisation, stability and catalytic activity in the water gas shift reaction. This is an important reaction in industry and if successful, could be used in biphasic hydrogenation reactions using water as the source of H_2 gas.

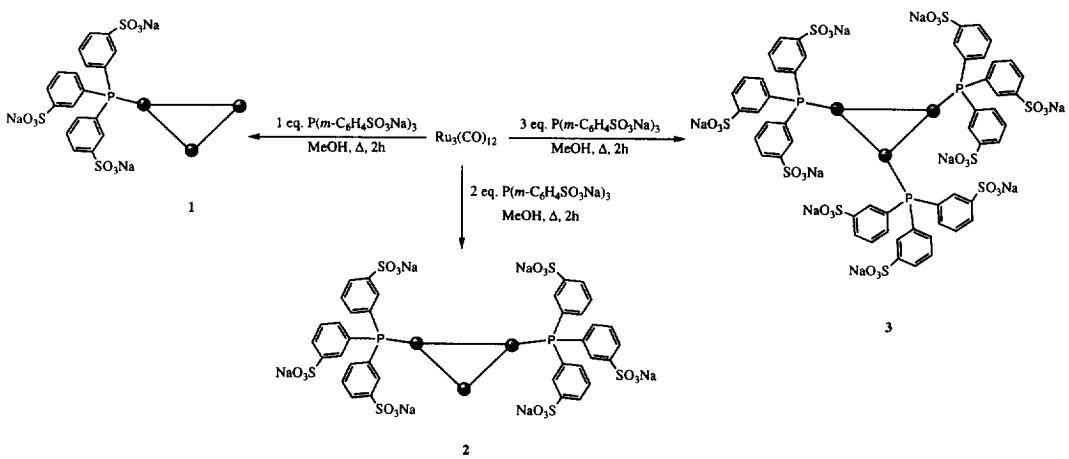
RESULTS AND DISCUSSION

The reaction of $Ru_3(CO)_{12}$ with one to three equivalents of the water soluble phosphine, $P(m\text{-}C_6H_4SO_3Na)_3$, in methanol for 2 h affords $Ru_3(CO)_{11}\{P(m\text{-}C_6H_4SO_3Na)_3\}$ **1**, $Ru_3(CO)_{10}\{P(m\text{-}$

* Author to whom correspondence should be addressed.

$C_6H_4SO_3Na)_3\}_2$ **2** and $Ru_3(CO)_9\{P(m\text{-}C_6H_4SO_3Na)_3\}_3$ **3** in quantitative yield (Scheme 1). In a related reaction, $Ru_6C(CO)_{17}$ was heated under reflux in methanol containing one equivalent of $P(m\text{-}C_6H_4SO_3Na)_3$ to afford $Ru_6C(CO)_{16}\{P(m\text{-}C_6H_4SO_3Na)_3\}$ **4** in quantitative yield (Scheme 2). The hydride cluster $H_4Ru_4(CO)_{12}$ has been reacted with one, two and four equivalents of $P(m\text{-}C_6H_4SO_3Na)_3\}$ to afford $H_4Ru_4(CO)_{11}\text{-}\{P(m\text{-}C_6H_4SO_3Na)_3\}$ **5**, $H_4Ru_4(CO)_{10}\{P(m\text{-}C_6H_4SO_3Na)_3\}_2$ **6** and $H_4Ru_4(CO)_8\{P(m\text{-}C_6H_4SO_3Na)_3\}_4$ **7** in high yield (Scheme 3). The unsaturated 46 electron hydride cluster $H_2Os_3(CO)_{10}$ undergoes addition reactions with phosphine ligands and also reacts with methanol [9]. Therefore, $H_2Os_3(CO)_{10}$ and $P(m\text{-}C_6H_4SO_3Na)_3$ were stirred in equimolar quantities in refluxing propanone for 2 h to afford $H_2Os_3(CO)_{10}\{P(m\text{-}C_6H_4SO_3Na)_3\}$ **8** in 43% yield (Scheme 4). The lower yield obtained from this reaction is attributed to the poor solubility of the phosphine ligand in the solvent and extending the reaction time did not improve the yield. Clusters **1–8** are all highly soluble in water and slightly soluble in methanol at room temperature. In deoxygenated water they are stable for several days but when exposed to air they slowly decompose. As solid materials they are stable for prolonged periods even when precautions to exclude air or moisture are not taken.

Compounds **1–8** were characterised by spectroscopy and full details are given in the experimental section. Clusters **1–3** have been reported previously and spectroscopic data is in good agreement with that obtained earlier [8]. Microanalytical data was obtained on all the compounds but was not very informative. It would appear that methanol and/or water contaminates the sample and even after prolonged periods under vacuum not all the solvent could be removed. Mass spectra were obtained using fast atom bombardment (FAB) ionisation in both positive and negative modes, and electrospray techniques (ESMS) to compare the older FAB method with the newer ESMS method which has only recently been applied to organometallic systems [10]. ESMS is particularly appropriate for ionic species such as those



Scheme 1. The synthesis of **1**, **2** and **3**; CO ligands have been omitted for clarity.

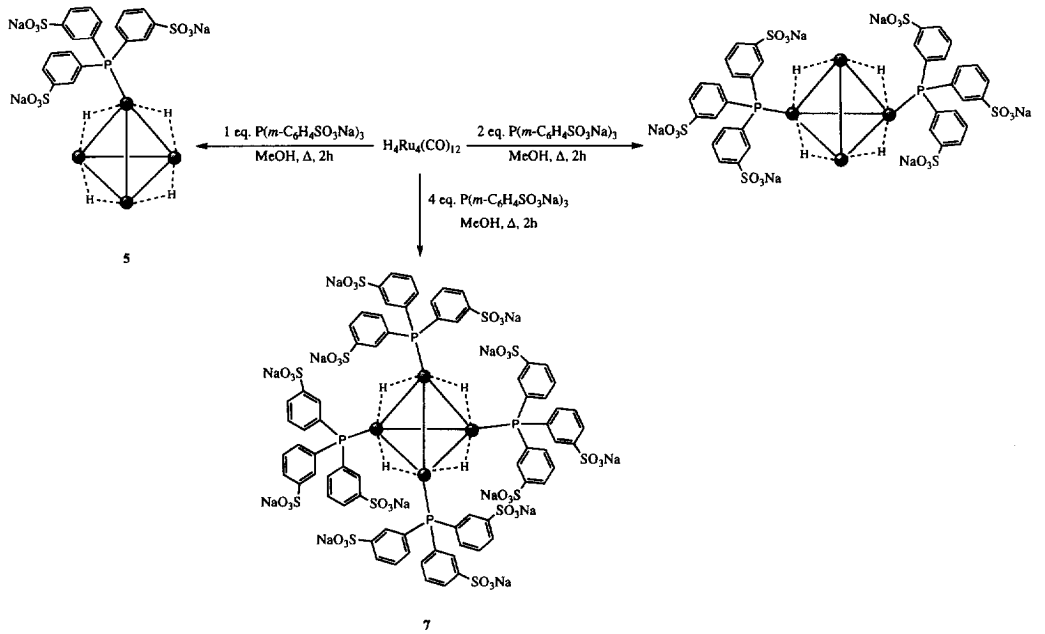
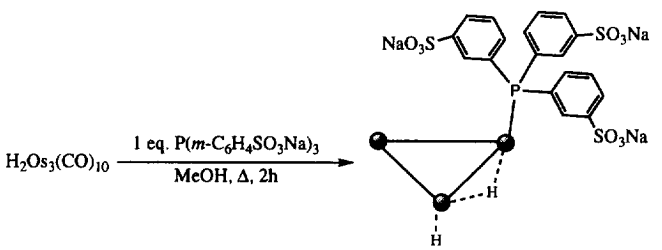


Scheme 3. The synthesis of **5**, **6** and **7**; CO ligands have been omitted for clarity.



Scheme 4. The synthesis of **8**; CO ligands have been omitted for clarity.

examined here and can be readily recorded from aqueous solutions. The ligand itself has been examined previously and gives clear peaks in the negative ion mode assignable to $[P(m\text{-}C_6H_4SO_3)_3Na_2]^-$, $[P(m\text{-}C_6H_4SO_3)_3Na]^{2-}$ and $[P(m\text{-}C_6H_4SO_3)_3]^{3-}$ [11]. However ESMS of complexes or clusters incorporating this ligand do not appear to have been reported before.

With FAB mass spectrometry it was only possible to obtain spectra for the mono-phosphine derivatives (**1**, **4**, **5** and **8**) as the more highly substituted clusters did not contain peaks at higher masses. In positive mode peaks were observed which either corresponded to the intact parent ion or that in which one carbonyl loss had taken place. In addition, peaks which may be assigned to further carbonyl loss and cluster fragmentation were also observed. Only **4** gave a negative mode spectrum corresponding to the intact parent cluster in which one sodium ion was lost. This was followed by peaks corresponding to the sequential loss of some of the carbonyl groups and peaks corresponding to lower nuclearity fragments were also observed.

Generally the ESMS spectra were more useful for characterisation and showed common features. As an illustration, we discuss the spectra of $Ru_6C(CO)_{16}\{P(m\text{-}C_6H_4SO_3Na)_3\}$ **4**, recorded with water as the mobile phase. At low cone voltages (10 V) there were essentially two peaks, one centred at m/z 523 which can be assigned to $[Ru_6C(CO)_{16}\{P(m\text{-}C_6H_4SO_3)_3\}]^{3-}$, and one centred about m/z 795 which is assigned to $[Ru_6C(CO)_{16}\{P(m\text{-}C_6H_4SO_3)_3 + Na]^{2-}$. In each case the assignment was confirmed by a comparison of the simulated isotope pattern with that recorded at high resolution (see inset, Fig. 1). As the cone voltage was increased, leading to more vigorous collisions in the source, a third peak at m/z at 1612 appeared, corresponding to $[Ru_6C(CO)_{16}\{P(m\text{-}C_6H_4SO_3)_3\} + 2Na]^-$, but this was always weak. At

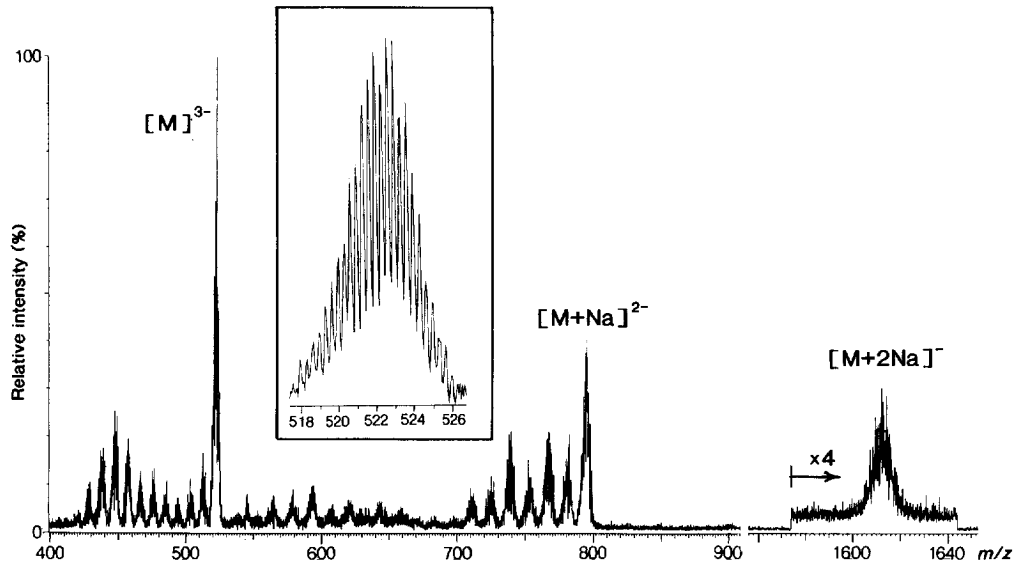


Fig. 1. The negative ion electrospray mass spectrum of $Ru_6C(CO)_{16}\{P(m\text{-}C_6H_4SO_3Na)_3\}$ **4** in aqueous solution, recorded with cone voltage of 40 V to induce some fragmentation. Peaks are assigned with [M] = $[Ru_6C(CO)_{16}\{P(m\text{-}C_6H_4SO_3)_3\}]^{3-}$. The charges on the ions are apparent from the separation in the isotope pattern (the inset is an enlargement of the peak at m/z 520, with mass separation of 0.33 mass units) and by the mass differences associated with CO loss (9.3 for the 3-ion and 14 for the 2-ion). The weak peaks between 540 and 660 mass units appear to arise from an impurity in the sample as they cannot be assigned as fragmentation ions.

the same time fragmentation by CO loss occurred from the 2− and 3− peaks. This is illustrated in Fig. 1, recorded at intermediate cone voltages. One interesting observation is that under these conditions the amount of fragmentation is markedly different for the different ions; the 1− ion at *m/z* 1612 shows no detectable fragmentation, the 2− ion at *m/z* 795 is flanked by peaks corresponding to the loss of up to six CO ligands, whereas the 3− ion at *m/z* 523 shows associated fragmentation peaks with up to ten CO groups eliminated. The reverse might have been expected since CO ligands are expected to be more tightly bound in species with higher negative charge, although in this case most of the charge is probably localised on the phosphine ligand. Presumably the higher charged species travel at higher velocity as they are accelerated across the skimmer cone voltage difference leading to more energetic collisions and hence greater fragmentation. A similar effect has been found with Cd-thiolate clusters [12]. Adding extra Na^+ ions to the solution under analysis had little effect on the relative amounts of the ions $[Ru_6C(CO)_{16}\{P(m\text{-}C_6H_4SO_3)_3\}+n\text{Na}]^{(3-n)-}$, but added Cs^+ suppressed the $[Ru_6C(CO)_{16}\{P(m\text{-}C_6H_4SO_3)_3\}+\text{Na}]^{2-}$ peak in favour of a $[Ru_6C(CO)_{16}\{P(m\text{-}C_6H_4SO_3)_3\}+\text{Cs}]^{2-}$ signal at *m/z* 849.5. Clearly ESMS could be used conveniently to assess the relative ion-pairing abilities of different cations with these cluster anions.

The spectra recorded for $H_4Ru_4(CO)_{11}\{P(m\text{-}C_6H_4SO_3Na)_3\}$ **5** followed the same pattern, with clear $[H_4Ru_4(CO)_{11}\{P(m\text{-}C_6H_4SO_3)_3\}]^{3-}$ and $[H_4Ru_4(CO)_{11}\{P(m\text{-}C_6H_4SO_3)_3\}+\text{Na}]^{2-}$ peaks dominating the spectra at lower cone voltages and these with their CO-loss analogues at higher voltages. No $[H_4Ru_4(CO)_{11}\{P(m\text{-}C_6H_4SO_3)_3\}+2\text{Na}]^-$ was observed at all for this example.

The doubly substituted species $Ru_3(CO)_{10}\{P(m\text{-}C_6H_4SO_3Na)_3\}_2$ **2** was expected to give higher charged ions, potentially up to 6−. At low cone voltages the peaks observed were assigned to [**2**-2Na]$^{2-}$, [**2**-3Na]$^{3-}$, [**2**-4Na]$^{4-}$, and [**2**-5Na]$^{5-}$, with the 4− ion being dominant. The fully dissociated 6− ion apparently has too high a charge density to be detected. The isotope patterns for the 4− and 5− ions could not be fully resolved but the charges on the anions were clear from the spacing between the CO-loss species (7 and 5.6 mass units respectively) at higher cone voltages. Even at the lowest cone voltages CO-loss species were observed for the 4− and 5− ions, confirming the observation that fragmentation increases for the higher charged species. As noted above, no sensible FAB mass spectra signals at all could be obtained for this cluster.

For $Ru_3(CO)_9\{p(m\text{-}C_6H_4SO_3Na)_3\}_3$ **3**, even higher-charged species are potentially possible. The ESMS spectrum of this cluster was less clean, but peaks corresponding to [**3**-4Na]$^{4-}$ and [**3**-3Na]$^{5-}$ were the main ones observed. There were competing signals from the disubstituted cluster **1**, but whether these arose from an impurity in the sample or from rearrangement in the spectrometer is not clear. The corresponding spectra of the samples were also recorded using MeOH as mobile phase, but there were no significant differences to those obtained from aqueous solutions.

For all of these examples, the overall quality of the ESMS spectra and the observation of a series of ions from varying degrees of association with Na^+ cations makes this the method of choice for analysing the $\{P(m\text{-}C_6H_4SO_3Na)_3\}$-substituted clusters.

The ^1H NMR clusters **1–8** showed multiplet resonances typical of phenyl ring protons between 7.2 and 8.2 ppm. In addition, clusters **5–8** afforded multiplet resonances at negative δ values due to the presence of hydride ligands. These were quite complicated signals and since the spectra were recorded in D_2O it was not possible to lower the temperature. The $^{31}P\text{-}\{^1H\}$ NMR spectra of clusters **1–4** and **8** all contained one singlet resonance in the region 34.5–37.3 ppm. The tetraruthenium clusters all gave rise to more than one resonance with the peaks lying in a slightly larger range, *viz.* 35.5–46.5 ppm. Clearly, this data is not very informative and as such the ESMS was the most useful technique available for the characterisation of these clusters.

It has not been possible to obtain single crystals of **1–8** suitable for X-ray diffraction studies. The structures shown in the Schemes for the $\{P(m\text{-}C_6H_4SO_3Na)_3\}$-containing clusters are based on those identified by single crystal X-ray diffraction analyses for related PPh_3 and other simple phosphine derivatives, as in most cases the IR spectra of the $\{P(m\text{-}C_6H_4SO_3Na)_3\}$ and PPh_3 or other simple phosphine species are quite similar [13].

The precursor clusters $Ru_3(CO)_{12}$, $H_4Ru_4(CO)_{12}$ and $H_2Os_3(CO)_{10}$ have all been shown to catalyse the water gas shift reaction (i.e. the conversion of H_2O and CO to H_2 and CO_2) [14]. We decided to test the water soluble derivatives of these aforementioned clusters, *viz.* **3, 7** and **8,** as potential catalysts in this process (see experimental for details). All these clusters were found to catalyse the formation of CO_2 and H_2. However, on recovery of the clusters after two cycles, only $H_4Ru_4(CO)_8\{P(m\text{-}C_6H_4SO_3Na)_3\}_4$ **7** remained unchanged. As yet it has not been possible to fully characterise the materials recovered from these reactions although the compound derived from cluster **3** which did not originally contain a hydride ligand was found to have peaks indicative of hydrides in the ^1H NMR spectrum.

EXPERIMENTAL

The synthesis of clusters was conducted under an atmosphere of nitrogen gas using degassed solvents. *Tris*-(3-sulphonatophenyl)phosphine tetrahydrate trisodium salt, $P(m\text{-}C_6H_4SO_3Na)_3 \cdot 4H_2O$, was purchased from Strem Chemicals and used as received. The clusters $Ru_3(CO)_{12}$ [15], $Ru_6C(CO)_{17}$ [16], $H_4Ru_4(CO)_{12}$ [17] and $H_2Os_3(CO)_{10}$ [17] were prepared according to the literature methods. The preparation of $Ru_3(CO)_{11}\{P(m\text{-}C_6H_4SO_3Na)_3\}$ and $Ru_3(CO)_{10}\{P(m\text{-}C_6H_4SO_3Na)_3\}_2$ have been reported previously using a method similar to that described herein [8]. Infrared spectra were recorded as KBr discs using a Mattson Research Series 1 FTIR instrument. $^{31}P\text{-}\{^1H\}$ and ^1H NMR spectra were recorded on a JEOL JNM-EX270 FT NMR instrument. FAB mass spectra were obtained using a Micromass autospec instrument. ESMS spectra were recorded on a VG Platform II mass spectrometer using water as the mobile phase at a flow rate of 0.1 ml min^{-1}. Nitrogen was used as the nebulising and drying gas. Samples were introduced as aqueous solutions, and spectra were recorded with skimmer cone voltages between 10 and 50 V. Theoretical isotope patterns were calculated using the *Isotope* program [18]. Values for *m/z* given in the experimental section are for the most intense isotopomer.

Preparation of $Ru_3(CO)_{11}\{P(m\text{-}C_6H_4SO_3Na)_3\}$ **1**

The cluster $Ru_3(CO)_{12}$ (60 mg) and $P(m\text{-}C_6H_4SO_3Na)_3$ (57 mg, 1 mol equiv.) was heated under reflux in methanol (20 ml) for 2 h during which time the reaction mixture turned deep red in colour. The solvent was removed under reduced pressure to afford a red solid which was washed with hexane (2×10 ml) and dried under vacuum. The compound was characterised by spectroscopy as $Ru_3(CO)_{11}\{P(m\text{-}C_6H_4SO_3Na)_3\}$ **1** (120 mg, quantitative yield). Compound **1** is soluble in water and stable for several days.

Spectroscopic data for **1**. IR: (KBr disc) ν_{CO}, 2102 (m), 2052 (s), 2009 (vs), 1957 (m, sh) cm^{-1}; $^{31}P\text{-}\{^1H\}$ NMR: (D_2O) 34.7 (s) ppm; ^1H NMR: (D_2O) 7.5–8.1 (m) ppm; FAB^+ mass spectrum: 1180 $[1]^+$. The spectroscopic data is in good agreement with that previously reported.

Preparation of $Ru_3(CO)_{10}\{P(m\text{-}C_6H_4SO_3Na)_3\}_2$ **2**

The cluster $Ru_3(CO)_{12}$ (100 mg) and $P(m\text{-}C_6H_4SO_3Na)_3$ (190 mg, 2 mol equiv.) was heated under reflux in methanol (20 ml) for 2 h during which time the reaction mixture turned deep red in colour. The solvent was removed under reduced pressure to afford a red solid which was washed with hexane (2×10 ml) and dried under vacuum. The compound was characterised by spectroscopy as $Ru_3(CO)_{10}\{P(m\text{-}C_6H_4SO_3Na)_3\}_2$ **2** (298 mg, quantitative yield). Compound **2** is soluble in water and stable for several days.

Spectroscopic data for **2**. IR: (KBr disc) ν_{CO}, 2072 (w), 2060 (w), 2047 (m), 2034 (s), 2024 (s), 1990 (s), 1968 (s), 1950 (m) cm^{-1}; $^{31}P\text{-}\{^1H\}$ NMR: (D_2O) 36.9 (s) ppm; ^1H NMR: (D_2O) 7.5–8.1 (m) ppm; FAB^+ and FAB^- mass spectra did not afford peaks which could be assigned to the cluster. ESMS spectrum (cone voltage 10 V) *m/z* 837 (3%) $[\mathbf{2}\text{-}2Na]^{2-}$, 550 (30%) $[\mathbf{2}\text{-}3Na]^{3-}$, 407 (100%) $[\mathbf{2}\text{-}4Na]^{4-}$, and 321 (25%) $[\mathbf{2}\text{-}5Na]^{5-}$.

Preparation of $Ru_3(CO)_9\{P(m\text{-}C_6H_4SO_3Na)_3\}_3$ **3**

The cluster $Ru_3(CO)_{12}$ (70 mg) and $P(m\text{-}C_6H_4SO_3Na)_3$ (200 mg, 3 mol equiv.) was heated under reflux in methanol (20 ml) for 2 h during which time the reaction mixture turned deep red in colour. The solvent was removed under reduced pressure to afford a red solid which was washed with hexane (2 × 10 ml) and dried under vacuum. The compound was characterised by spectroscopy as $Ru_3(CO)_9\{P(m\text{-}C_6H_4SO_3Na)_3\}_3$ **3** (242 mg, quantitative yield). Compound **3** is soluble in water and stable for several days.

Spectroscopic data for **3**. IR: (KBr disc) ν_{CO}, 2053 (s), 2017 (s, sh), 1995 (vs), 1943 (s), 1907 (m) cm^{-1}; $^{31}P\text{-}\{^1H\}$ NMR: (D_2O) 37.3 (s) ppm; ^1H NMR: (D_2O) 7.2–8.1 (m) ppm; FAB^+ and FAB^- mass spectra did not afford peaks which could be assigned to the cluster and the ESMS spectra were less clean than for other examples but peaks at *m/z* 542 $[\mathbf{3}\text{-}4Na]^{4-}$ and 429 $[\mathbf{3}\text{-}5Na]^{5-}$ were clear.

Preparation of $Ru_6C(CO)_{16}\{P(m\text{-}C_6H_4SO_3Na)_3\}$ **4**

The cluster $Ru_6C(CO)_{17}$ (50 mg) and $P(m\text{-}C_6H_4SO_3Na)_3$ (33 mg, 1 mol equiv.) was heated under reflux in methanol (20 ml) for 2 h. The solvent was removed under reduced pressure to afford a red solid which was washed with hexane (2 × 10 ml) and dried under vacuum. The compound was characterised by spectroscopy as $Ru_6C(CO)_{16}\{P(m\text{-}C_6H_4SO_3Na)_3\}$ **4** (77 mg, quantitative yield). Compound **4** is soluble in water and stable for several days.

Spectroscopic data for **4**. IR: (KBr disc) ν_{CO}, 2090 (m), 2055 (s, sh), 2023 (vs), 1986 (m, sh), 1838 (w) cm^{-1}; $^{31}P\text{-}\{^1H\}$ NMR: (D_2O) 36.2 (s) ppm; ^1H NMR: (D_2O) 7.7–8.2 (m) ppm; FAB^- mass spectrum: *m/z* 1613 $[\mathbf{4}\text{-}Na]^-$. ESMS (cone voltage 12 V) *m/z* 1612 (4%) $[\mathbf{4}\text{-}Na]^-$, *m/z* 795 (20%) $[\mathbf{4}\text{-}2Na]^{2-}$, *m/z* 522 (100%) $[\mathbf{4}\text{-}3Na]^{3-}$. (See also Fig. 1 for the spectrum at higher cone voltages).

Preparation of $H_4Ru_4(CO)_{11}\{P(m\text{-}C_6H_4SO_3Na)_3\}$ **5**

The cluster of $H_4Ru_4(CO)_{12}$ (39 mg) and $P(m\text{-}C_6H_4SO_3Na)_3$ (32 mg, 1 mol equiv.) was heated under reflux in methanol (20 ml) for 2 h during which time the reaction mixture became deep red in colour. The solvent was removed under reduced pressure to afford an orange-brown solid which was washed with hexane (2 × 10 ml) and dried under vacuum. The compound was characterised by spectroscopy as $H_4Ru_4(CO)_{11}\{P(m\text{-}C_6H_4SO_3Na)_3\}$ **5** (65 mg, 89% yield). Compound **5** is soluble in water and stable for several days.

Spectroscopic data for **5**. IR: (KBr disc) ν_{CO}, 2098 (m), 2070 (s), 2059 (vs), 2024 (s), 2017 (s), 1997 (m), 1958 (m) cm^{-1}; $^{31}P\text{-}\{^1H\}$ NMR: (D_2O) 41.0 (s, 1P), 46.5 (s, 1P) ppm; ^1H NMR: (D_2O) 7.2–8.1 (m), −31.0–−32.5 (m) ppm; FAB^+ mass spectrum: *m/z* 1284 $[\mathbf{5}]^+$. ESMS (cone voltage 10 V) *m/z* 620 (8%) $[\mathbf{5}\text{-}2Na]^{2-}$, *m/z* 406 (100%) $[\mathbf{5}\text{-}3Na]^{3-}$, (cone voltage 20 V) *m/z* 620 (30%) $[\mathbf{5}\text{-}2Na]^{2-}$, *m/z* 405.7 (100%) $[\mathbf{5}\text{-}3Na]^{3-}$, *m/z* 396.3 (80%) $[\mathbf{5}\text{-}CO\text{-}3Na]^{3-}$, *m/z* 387 (70%) $[\mathbf{5}\text{-}2CO\text{-}3Na]^{3-}$, *m/z* 377.7 (70%) $[\mathbf{5}\text{-}3CO\text{-}3Na]^{3-}$, *m/z* 368.3 (35%) $[\mathbf{5}\text{-}4CO\text{-}3Na]^{3-}$.

Preparation of $H_4Ru_4(CO)_{10}\{P(m\text{-}C_6H_4SO_3Na)_3\}_2$ **6**

The cluster $H_4Ru_4(CO)_{12}$ (32 mg) and $P(m\text{-}C_6H_4SO_3Na)_3$ (53 mg, 2 mol equiv.) was heated under reflux in methanol (20 ml) for 2 h during which time the reaction mixture became deep red in colour. The solvent was removed under reduced pressure to afford an orange-brown solid which was washed with hexane (2 × 10 ml) and dried under vacuum. The compound was characterised by spectroscopy as $H_4Ru_4(CO)_{10}\{P(m\text{-}C_6H_4SO_3Na)_3\}_2$ **6** (82 mg, 95% yield). Compound **6** is soluble in water and stable for several days.

Spectroscopic data for **6**. IR: (KBr disc) ν_{CO}, 2093 (w), 2059 (vs), 2107 (vs), 1996 (s), 1970 (m) cm^{-1}; $^{31}P\text{-}\{^1H\}$ NMR: (D_2O) 36.3 (s, 3P), 44.0 (s, 1P) ppm; ^1H NMR: (D_2O) 7.2–8.0 (m), −32.0–−33.0 (m) ppm; FAB^+ and FAB^- mass spectra did not afford peaks which could be assigned to the cluster.

Preparation of $H_4Ru_4(CO)_8\{P(m\text{-}C_6H_4SO_3Na)_3\}_4$ **7**

The cluster $H_4Ru_4(CO)_{12}$ (25 mg) and $P(m\text{-}C_6H_4SO_3Na)_3$ (83 mg, 4 mol equiv.) was heated under reflux in methanol (20 ml) for 2 h during which time the reaction mixture became deep red in colour. The solvent was removed under reduced pressure to afford an orange-brown solid which was washed with hexane (2 × 10 ml) and dried under vacuum. The compound was characterised by spectroscopy as $H_4Ru_4(CO)_8\{P(m\text{-}C_6H_4SO_3Na)_3\}_4$ **7** (75 mg, 75% yield). Compound **7** is soluble in water and stable for several days.

Spectroscopic data for **7**. IR: (KBr disc) ν_{CO}, 2080 (w), 2065 (m), 2059 (m), 2021 (s), 1967 (m) cm^{-1}; $^{31}P\text{-}\{^1H\}$ NMR: (D_2O) 35.5 (s, 1P), 36.9 (s, 2P), 39.1 (s, 1P) ppm; ^1H NMR: (D_2O) 7.4–8.0 (m), −31.7–−32.8 (m) ppm; FAB^+ and FAB^- mass spectra did not afford peaks which could be assigned to the cluster.

Preparation of $H_2Os_3(CO)_{10}\{P(m\text{-}C_6H_4SO_3Na)_3\}$ **8**

The cluster $H_2Os_3(CO)_{10}$ (50 mg) and $P(m\text{-}C_6H_4SO_3Na)_3$ (35 mg, 1 mol equiv.) was heated under reflux in acetone (20 ml) for 2 h during which time the reaction mixture changed from purple to an orange-brown colour. The solvent was removed under reduced pressure to afford an orange-brown solid which was washed with hexane (2 × 10 ml) and dried under vacuum. The compound was characterised by

spectroscopy as $H_2Os_3(CO)_{10}\{P(m\text{-}C_6H_4SO_3Na)_3\}$ **8** (50 mg, 43% yield). Compound **8** is soluble in water and stable for several days.

Spectroscopic data for **8**. IR: (KBr disc) ν_{CO}, 2082 (m), 2052 (s, sh), 2017 (vs), 2009 (vs), 1984 (s, sh), 1950 (m, sh) cm^{-1}; $^{31}P\text{-}\{^1H\}$ NMR: (D_2O) 34.5 (s) ppm; ^1H NMR: (D_2O) 7.4–8.2 (m), −31.5–−32.5 (m) ppm; FAB^- *m/z* 1373 [**8**-Na-CO]$^-$.

Catalytic runs

In a typical experiment the cluster (ca 25 mg) was dissolved in degassed water (30 ml) and placed in an autoclave under an atmosphere of CO. The solution was heated under reflux for 5 h and the gas tested qualitatively for the presence of CO_2. The autoclave was recharged with CO and heated under reflux for a further 12 h. The gas was again qualitatively tested for CO_2 after this time. The solvent was removed under reduced pressure and the cluster recovered.

(Received 27 October 1997; accepted 13 January 1998)

Abstract—The structures of $[Ru_5C(CO)_{14}L]$, where L = $P(4\text{-}C_6H_4OMe)_3$, **2a**, $P(4\text{-}C_6H_4F)_3$, **2b**, and PCy_3, **2c**, and of $[Ru_5C(CO)_{13}(etpb)_2]$ (etpb = $P(OCH_2)_3CEt$)), **3**, have been determined. The Ru—Ru and Ru—P bond distances of the $[Ru_5C(CO)_{15-n}L_n]$ clusters, **2a, 2b, 2c, 3**, $[Ru_5C(CO)_{14}(PPh_3)]$, and $[Ru_5C(CO)_{13}(PPh_3)_2]$, were analyzed and the results are compared with those reported elsewhere for the unsubstituted parent cluster, and for the clusters $[Ru_3(CO)_{12-n}L_n]$, $n = 1$ or 2. The Ru_5 clusters all maintain the square pyramidal arrangement of the parent cluster and the general arrangement of the ligands. The average Ru—Ru distances are remarkably constant but individual Ru—Ru distances vary widely. A clear feature is that the lengths of the Ru—Ru bonds in the basal plane that are *cis* to the axial Ru—P bonds are longer than any of the other Ru—Ru distances in all the $[Ru_5C(CO)_{15-n}L_n]$ clusters except **3**. The distance lengthens slightly with increasing cone angle of the substituent P-donor ligand but this effect may be at least partly due to crystal packing effects. The Ru—P distances in the Ru_5 and Ru_3 clusters increase significantly with increasing ligand cone angle and net electron donicity. The two effects cannot easily be separated due to the general correlation of the donicity and size of the P-donor ligands and both effects may apply. A distinctive feature of these changes in bond lengths is that they do not depend on whether $n = 1$ or 2, showing that the substituent effects are localized. The carbido atom out-of-plane distance increases in an approximately linear fashion with the basicity of the P-donor ligand.

Keywords: pentaruthenium complexes; carbonyl complexes; carbido clusters, P-donor substituent complexes; cluster complexes; X-ray crystal structure.

The reaction chemistry of $[Ru_5C(CO)_{15}]$, **1**, has been extensively studied since the cluster was first reported in 1973 [1]. Most reactions of **1** begin by the direct substitution of a CO ligand although this step is sometimes promoted by Me_3NO [2]. The substitution of the CO ligands in **1** by P-donor ligands has been reported and the structures of some of the derivatives have been characterized by X-ray crystallography [3].

The single crystal X-ray structure for the parent cluster $[Ru_5C(CO)_{15}]$, **1** has been reported [3b]. The five Ru atoms in **1** form the corners of a square pyramid, consistent with the prediction from cluster electron counting rules for a *nido*-octahedral structure [4]. The apical Ru atom is bound to four other Ru atoms, and the basal Ru atoms to three others. The carbido atom is situated equidistantly from the four basal Ru atoms and is slightly (0.11(2) Å) below the basal plane. The CO ligands surround the framework with three ligands terminally bound to each Ru atom. Studies of the adduct $[Ru_5C(CO)_{15}(NCMe)]$, formed when **1** is dissolved in acetonitrile, have shown that the addition of a ligand to **1** results in a structural change of the Ru_5 core to an *arachno*-pentagonal-bipyramid [3b]. The reaction of **1** with PPh_3 gives a substituted complex, $[Ru_5C(CO)_{14}(PPh_3)]$, in which a carbonyl ligand on one of the basal Ru atoms is replaced by the PPh_3 ligand [3b]. In the presence of an excess of PPh_3, two carbonyl ligands on opposite basal Ru atoms are replaced giving $[Ru_5C(CO)_{13}(PPh_3)_2]$.

† Dedicated to Jack Lewis on the occasion of his 70th birthday.

Kinetic studies on the substitution of a CO ligand in **1** by P-donor ligands shows a marked difference in the mechanism between smaller incoming nucleophiles and the larger ones [5a]. The substitution reactions of **1** with the smaller phosphine and phosphite nucleophiles proceed through two observable steps, and kinetic parameters were determined for both. The first step proceeds very quickly with an associative rate law characterized by a linear dependence of k_{obs} on the concentration of the incoming nucleophile. The carbonyl stretches in the infrared spectrum of the product of this first step have a similar pattern to the known acetonitrile adduct $[Ru_5C(CO)_{15}(NCMe)]$ [3b]. A second, much slower step, to form the monosubstituted product follows a dissociative rate law for which the rate law is independent of the concentration of the incoming nucleophile. For the larger nucleophiles, the initial adduct is not detected. Instead, the substitution reaction proceeds by a single observable step that follows an associative rate law with a first order dependence on the concentration of the incoming nucleophile.

The kinetic studies clearly demonstrate the important effects of the nature of the phosphorus donor nucleophile on the substitution reactions of **1**. The structures of a series of phosphine or phosphite substituted clusters, $[Ru_5C(CO)_{14}L]$ and $[Ru_5C(CO)_{13}L_2]$, were determined to complement the kinetic studies [5]. The trends of the bond distances in the core of these substituted clusters, when compared with the steric and electronic parameters of the ligands, can possibly give insight into the nature of the dynamic behaviour of these clusters.

RESULTS AND DISCUSSION

The structures of $[Ru_5C(CO)_{14}L]$, where L = $P(4\text{-}C_6H_4OMe)_3$, **2a**, $P(4\text{-}C_6H_4F)_3$, **2b**, and PCy_3, **2c**, and $[Ru_5C(CO)_{13}(etpb)_2]$, (etpb = $P(OCH_2)_3CEt$)) **3**, have been determined. Table 1 summarizes the crystallographic information. Atomic parameters for **2a**, **2b**, **2c** and **3** have been deposited as supplementary material. The molecular structures are depicted in Figs 1 through 7. The X-ray structure determinations for **2a**, **2b** and **3** were straightforward and for these three structures all non-H atoms were refined with anisotropic thermal parameters. The structure of **2c** was difficult to solve and refine, due to poor crystal mosaicity resulting in weak X-ray data, and the unusually large number of molecules in the asymmetric unit. Consequently, all the C atoms in **2c** were refined isotropically to increase the data to parameter ratio.

In the crystal structures, the Ru metal skeleton of the substituted clusters $[Ru_5C(CO)_{15-n}L_n]$ ($n = 1, 2$) **2a**, **2b**, **2c**, **3**, $[Ru_5C(CO)_{14}(PPh_3)]$, and $[Ru_5C(CO)_{13}(PPh_3)_2]$, are similar to that of the parent cluster $[Ru_5C(CO)_{15}]$ (see Table 2). Thus, the square pyramidal cluster framework is able to accommodate a vast range of sizes of ligands bound to the basal Ru atoms—from the small CO ligand to the bulky PCy_3—without any significant distortion of its basic geometry. The three ligands bound to the basal Ru atoms are all disposed in the same way in one axial and two equatorial positions, the latter being fairly symmetrical with respect to each of the Ru^a—Ru^b bonds, and the P-donor substituents are always in axial positions. (Ru^a and Ru^b are apical and basal Ru atoms, respectively.) There are therefore always two Ru^b—Ru^b bonds that are *cis* to each substituent. The three CO ligands attached to the apical Ru atom are necessarily less symmetrically bound because this Ru atom is connected to four basal metal atoms. One of the Ru^a—CO^b bonds always lies roughly above one of the Ru^a—Ru^b bonds while the other two are almost symmetrically disposed on either side of the Ru^a—Ru^b bond "*trans*" to the first and are roughly eclipsed with respect to the two equatorial CO ligands attached to the Ru^b atom. In no case are carbonyl ligands seen to adopt the "semi-bridging" arrangement reported in the related $[Ru_3(CO)_{10}(PPh_3)_2]$ cluster [6]. There are no discernable systematic differences in Ru—CO bond lengths between the unsubstituted cluster and any of the substituted ones showing that such substituent effects are dissipated over the whole of the cluster rather than being evident in any specific Ru—CO bond. This is also indicated by the small range of C—O stretching frequencies found in a large variety of substituted clusters. Thus plots of corresponding values of ν_{co} against χ [7a,8] are closely linear for all bands with gradients of only 0.1–0.2 [5a,9] in contrast to gradients of ca. 1 and 2 for the complexes $[Ru(CO)_4L]$ and $[Ru(CO)_3L_2]$, respectively [10]. (χ is a measure of the net electron donicity of the ligands based on the values of the C—O stretching frequencies in the complexes $[Ni(CO)_3L]$.) However, the Ru—P distances, presented in Table 3, vary widely from 2.217(3) Å to 2.407(9) Å.

If the arrangement of the ligands described above were completely symmetrical it would be expected that there would be three types of Ru^a—Ru^b bond in the parent cluster: one that is eclipsed by an Ru^b—CO bond, another "*trans*" to that bond and two "*cis*" to it. However, in most cases there are four quite distinct Ru^a—Ru^b bond lengths (Table 2), even in the unsubstituted cluster, and it seems likely that crystal packing effects lower the symmetry of all the individual molecules. The ranges of Ru^a—Ru^b bond lengths, presented in Table 2 and shown graphically in Fig. 8, do vary substantially, even within otherwise identical molecules. Thus the range in **2c**, II is only 0.049(6) Å whereas it is 0.177(6) Å in **2c**, III, indicating the ease of deformation of the framework. The Ru^b—Ru^b bond lengths show a comparable variation.

Since the X-ray crystallography data are sparse for the P-donor substituted clusters $[Ru_5C(CO)_{15-n}L_n]$, structural parameters of the related clusters $[Ru_3(CO)_{12-n}L_n]$, $n = 1$ or 2, will be considered as well [6,11] (Table 4). The Ru_3 metal framework is closely related to the triangular face of the Ru_5C cluster but

any substituents are situated in the Ru_3 plane rather than axially as in the Ru_5 clusters. This has the result that there are two sorts of Ru—Ru bonds when one Ru atom has a substituent attached, i.e. one *trans* to the substituent and another *cis* to it. The Ru—Ru and Ru—P bond lengths [6,11] of the P-donor substituted Ru_3 clusters are very similar to those of the corresponding Ru_5C clusters. A study of the variation of the Ru—Ru and Ru—P bond lengths within some of the Ru_3 clusters listed in Table 8 has been published [11b]. The results suggested that the length of the Ru—Ru bonds *cis* to the phosphorus ligand correlated with the ligand cone angles in a non-linear fashion, whereas the Ru—P bond lengths correlated linearly with substituent cone angles.

Ru—Ru *bonds*

The total variation of the Ru—Ru bond lengths in the $[Ru_5C(CO)_{15-n}L_n]$ (n = 0–2) clusters is quite large. The difference between the shortest and longest Ru—Ru distances listed in Table 2 is 0.199(5) Å, the shortest being a Ru^a—Ru^b in **2c,** III, and the longest a Ru^b—Ru^bL bond in **2c,** II and $[Ru_5C(CO)_{14}PPh_3]$. If all the Ru—Ru bonds in the substituted clusters are treated as random variations of a single bond length then the average of the 72 values is 2.8400(50) Å compared with an average of the unsubstituted clusters of 2.8404(66) Å. This shows that, if there are any changes in some of the bond lengths caused by substitution, they essentially cancel each other out. If

the Ru—Ru distances of each cluster are averaged, the largest variation between clusters is only 0.013 Å which again suggests that there are compensating effects of lengthening and shortening of bonds. Introduction of a large P-donor substituent might be expected to cause an expansion of the framework of the cluster due to the expansion of the ligand envelope. Metal–metal bonds are generally weaker than the

metal–CO bonds; the estimated contribution to the enthalpy of disruption of the $[Ru_3(CO)_{12}]$ cluster (into Ru and CO) has been estimated to be 117 kJ mol^{-1} for each Ru—Ru bond and 172 kJ mol^{-1} for each Ru—CO bond [12]. Thus, as a small carbonyl ligand is replaced by a larger P-donor ligand, the ligand

sphere would be expected to expand and the metal atoms would be correspondingly pulled apart. However, the average Ru—Ru distance within the clusters varies considerably less than the individual Ru—Ru distances, and this suggests that any expansion must be localized and is being counterbalanced by shortening elsewhere. It seems most likely that the expansion involves Ru—Ru bonds that are near the P-donor ligand. It is clear from Fig. 8, however, that the shortest Ru^b—Ru^bL bond is as long or much longer than the longest of any of the other distances in the same type of cluster so it is only the Ru^b—Ru^bL distances in the monosubstituted clusters and in $[Ru_5C(CO)_{13}(PPh_3)_2]$ that are being selectively lengthened. This effect is less pronounced in $[Ru_5C(CO)_{13}(etpb)_2]$ where the Ru^b—Ru^bL distances overlap with the others.

These observations were confirmed by a statistical analysis of the variation in Ru—Ru distances in both the Ru_5 and Ru_3 clusters which was approached in several stages [13]. (Details of the statistical procedures are given in the Supplementary Pages.) Firstly, the average Ru—Ru bond length was plotted against the separate stereo-electronic parameters for the phosphorus ligands. The ligand size was described by Tolman's cone angle θ [7] and the electronic donicity of the ligand was characterized by Tolman's χ parameter [7a], as modified by Bartik *et al.* [8] (see above). The resulting plots showed no obvious correlations. This was confirmed with a regression analysis; all correlations for average Ru—Ru bond distance against steric and electronic parameters had a $p > 0.05$ and usually $p > 0.35$ for both the F test of the analysis of the variation and for the probability of the t statistic. (p represents the probability that the correlation can be rejected.) The effect of the substitution of one or two carbonyl ligands with P-donor ligands shows no overall effect on the average Ru—Ru distance within the cluster.

Secondly, the effect of the P-donor ligand on the neighbouring Ru—Ru bonds in Ru_5C clusters was analyzed. The Ru—Ru bonds were grouped into Ru^a—Ru^b and Ru^b—Ru^b bonds which were subdivided according to whether the Ru atom had an attached P atom (Ru^a—Ru^bL or Ru^b—Ru^bL) or not (see Table 2). There were then four groups since no P atoms are bound to an apical Ru atom. The Ru—Ru bond distances were compared against each other using a one way analysis of variance. The test suggested that the groups were not equivalent. The groups were then compared against each other by the F-test for equivalence of variance and students' t-test for the equivalence of means. The statistical tests show conclusively that the basal Ru—Ru bond in which a P-donor ligand is bound to one of the Ru atoms (i.e. the Ru^b—Ru^bL bond) is longer than the others, which are statistically equivalent to each other. The lengthening of this Ru—Ru distance shows that the presence of the P-donor ligand only affects the Ru—Ru distance in the bond *cis* to the substituent. The other Ru—Ru

distances then must all shorten, on average, by approximately an equal amount, although individually the shortening will be quite small.

To see if the lengthening of the Ru^b—Ru^bL distance in the Ru_5 clusters, and the *cis* Ru—Ru distance in the Ru_3 clusters, depends on the nature of the P-donor ligands, the Ru^b—Ru^bL and *cis* Ru—RuL distances were plotted against the steric and electronic parameters of the substituents. All plots showed a wide scatter of the bond distances around the lines but trends can be seen. Generally, the Ru—Ru distances increase with increasing net electron donicity of the ligands (decreasing χ) and increase with increasing size (θ) of the substituent, the gradients of the linear least squares plots being $-(1.9 \pm 0.4) \times 4^{-4}$ Å cm and $(7.3 \pm 1.7) \times 10^{-3}$ Å deg^{-1}, respectively. The *F*-statistics are (1,41)23.6 and (1,43)19.4, respectively. The R^2 values are both very low (0.31 and 0.37) and this shows that features other than the electronic and steric properties of the individual substituents are accounting for 60–70% of the variations. These are likely to be due to intermolecular packing forces since the molecules generally packed in different ways for each structure. However, both correlations are nevertheless

statistically significant at $p \ll 0.05$ for both the F test of the analysis of the variation, and the t statistic, so the contribution of the electronic and/or steric effects to the trends is well established. The reason for the dual correlation may be that the electronic parameters correlate with the cone angles with $p \ll 0.05$, as the smaller ligands tended to be less basic. In an attempt to differentiate between the steric and electronic effects the compounds containing phosphine ligands with phenyl and substituted phenyl groups ($\theta = 145°$) were

selected and the Ru^b—Ru^bL distances of these Ru_5 clusters were plotted against the electronic parameter. The plots show no trend and a regression analysis shows no correlation. Unfortunately the range of basicities and number of ligands involved were both small but the result suggests that the changes in the Ru^b—Ru^bL distances (and possibly also the *cis* Ru—Ru distances) may depend more on the size of the ligands than on their basicity. If the lengthening of the Ru^b—Ru^bL distances is related to the size of the P-donor ligand, it might be expected that increasing the size of the P-donor ligand also would increase the angle between the Ru—P vector and the plane defined by the four basal Ru atoms. This is observed although the variation within chemically equivalent values, in **2c** and **3**, is large (~6°). The angles between the Ru—P vectors and the planes defined by the four basal Ru atoms in **2c** are over 10° larger than the corresponding angles in **3**. Since the size and shape of the P-donor ligands could influence the packing of the lattice even the statistically significant increase in the Ru^b—Ru^bL distance with cone angle might be accounted for by lattice effects if these were systematic enough, i.e. the trends would not be properties of the individual molecules. In this connection it should be noted that the trends observed include examples of both bis and mono substituted clusters. For instance the Ru^b—Ru^bL lengths are very close for the mono and *bis* PPh_3 clusters which shows that the effects of the substituents are limited to the neighbouring Ru—Ru bonds. If the P-donor ligands caused a general expansion of the cluster then it would have been expected that two substituents would have a greater influence than one. Also there are two Ru—Ru bonds that are lengthened by each substituent in the Ru_5 clusters whereas only one is lengthened by the Ru_3 clusters. In spite of these differences the correlations are still highly significant.

Ru—P *bonds*

The Ru—P bonds in Tables 3 and 4 were analyzed in the same manner as the Ru—Ru bonds, and the situation is considerably clearer. The bond lengths vary significantly more than the Ru—Ru distances discussed above and the Ru—P bond lengths correlate extremely well with both the θ and χ parameters of

the ligands individually, the lengths increasing with increasing size (by $(2.58 \pm 0.14) \times 10^{-3}$ Å deg^{-1} with $R^2 = 0.92$ and $F(1,29)^* = 321$) and net electron donicity of the P-donor ligands (by $-(6.1 \pm 0.5) \times 10^{-3}$ Å cm with $R^2 = 0.87$ and $F(1,27) = 181$) so the putative lattice effects contribute a great deal less to the variations in these bond lengths. Again the size and basicity effects cannot be easily partitioned and, indeed, both could affect the Ru—P distance. Larger P-donors could well have longer Ru—P bonds for steric reasons, but it is also true that the smaller ligands are generally phosphites. These are believed to be π-acids as well as σ-donors while the larger ligands are only σ-donors [4], and the smaller ligands could be more strongly bonded and shorter as a result. The correlation with χ would not otherwise make sense since more strongly σ-donating P-donors would be expected to be more strongly bound and shorter so that the correlation would be opposite to that expected. The possibility that electronic effects could influence the Ru—P distance has been demonstrated by Giering *et al.* [14]. They noted in a study of steric and electronic effects on Fe—P bond lengths in the complexes [(η-Cp)(L)(CO)FeCOMe] and [(η-Cp′)(L)(CO)FeCOMe] (Cp′ = MeC_5H_4) that the least basic P-donors, which they concluded to be π-acceptors, fell into a group with Fe—P distances that were shorter by about 0.1 Å than those in the complexes containing ligands that they classified as pure σ donors. However, the plot of Ru—P distances against χ does show a monotonic decrease and the ligands are not grouped in the manner noted for the Fe—P distances [14]. It should also be noted that the changes in the Ru—P bond lengths are the same irrespective of whether there are one or two substituents present, and this reemphasizes the fact that the effects of different substituents within the ligand envelope are localized.

The problem of correlations between the χ and θ parameters of the P-donor ligands was reduced, as before, by using the data for ligands with a constant θ ($\theta = 145°$). A $p > 0.05$ of the F- and t-tests for the linear least squares fit was obtained, and consequently no trend of the Ru—P distance with the value of χ is evident. This suggests that the substantial variations in the Ru—P lengths are more likely to be influenced by the ligand size though the qualifications noted above are equally applicable here.

Carbido atom out-of-plane distance

The distance that the carbido atom lies below the plane formed by the four basal Ru atoms varies by about 0.12 Å and appears to depend on the basicity of the P donors (Table 5). Theoretical calculations [15] on the cluster $[Fe_5C(CO)_{15}]$ predict that, if it were to gain two electrons, the carbido atom should move to the vertex position, about 0.84 Å below the plane. The carbido atom would then be required to donate only two electrons to the total of skeletal bonding electrons. Similarly, as the P-donor ligands donate more electron density to the Ru_5 framework, the carbido atom could move further from the basal plane to compensate for the extra electron density in the metal framework. To examine this hypothesis, the carbido out-of-plane distance is plotted in Fig. 9 against the net electron donicity of the ligands as measured by the value of $\delta(^{13}CO)$, the chemical shift of the ^{13}C atom in the complexes $[Ni(CO)_3L]$ referenced to that in $[Ni(CO)_4]$ [16]. Choice of this parameter rather than χ allows the data for the parent cluster to be included. The data for the monosubstituted clusters fall on a line that also goes close to the point for the parent cluster, and the point for the bis-substituted PPh_3 cluster would also fall on the line if the net electron donicity of the pair of ligands were assumed simply to be twice that indicated by the $\delta(^{13}CO)$ value for PPh_3. However, the data for the two forms of the *bis*-etpb cluster both lie below the line, even before an increased electron donicity due to the presence of two ligands is allowed for, and they are both less than the value for the parent cluster. Nevertheless the expected general trend with net electron donicity seems to be reasonably well established.

CONCLUSION

The Ru—Ru and Ru—P bond distances of the $[Ru_5C(CO)_{15-n}L_n]$ clusters were analyzed and the results combined with those reported for the clusters $[Ru_3(CO)_{12-n}L_n]$ [6,11]. The largest effect is the significant and linear increase of ca 0.2 Å in the Ru—P bond lengths with increasing basicity and/or size of the P-donor ligands. The effects of size and basicity

[a] Calculated from coordinate data from Ref. 3b.

*Two "outlying" data points were omitted from the analysis.

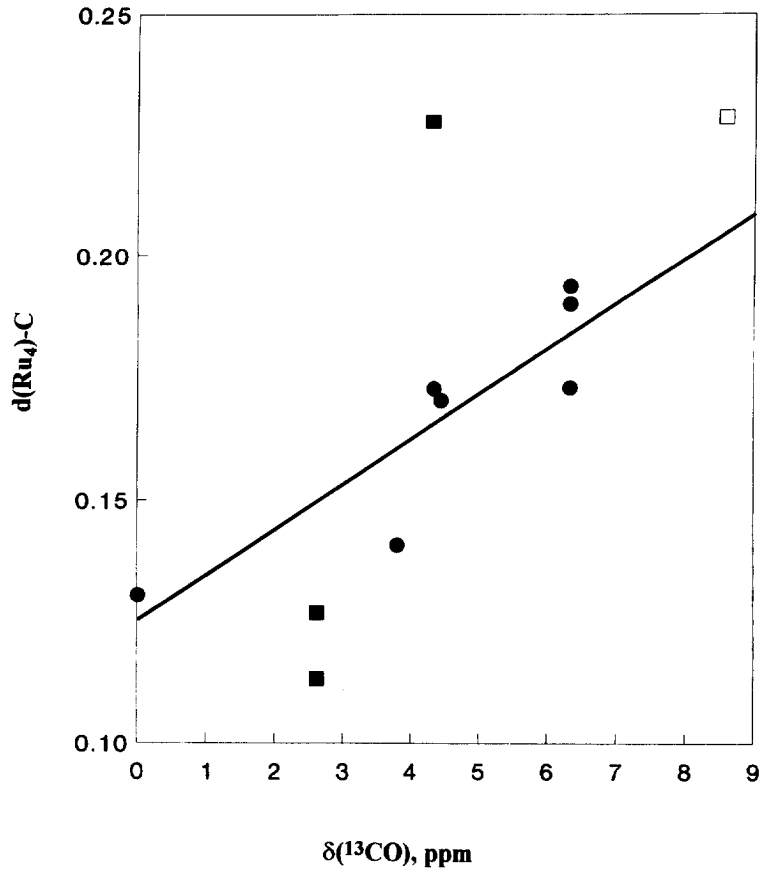

Fig. 9. Effect of net electron donicity of L (L = CO or P-donor ligands) on the distance that the C atom lies below the basal Ru_4 plane. ●: unsubstituted or monosubstituted clusters; ■: disubstituted clusters; □: the disubstituted cluster with L = PPh_3 and twice as much net electron donicity allowed for as in the monosubstituted PPh_3 substituted cluster.

cannot easily be separated, due to the correlation of the basicity and size parameters for most of the P-donor ligands, and both effects may be important. The Ru—Ru bonds are also significantly longer when a P-donor ligand is attached to one of the Ru atoms (a basal one) in all the $[Ru_5C(CO)_{15-n}L_n]$ clusters (except when L = etpb), and the Ru—Ru bonds *cis* to the Ru—P bonds are longer than the other Ru—Ru distances in the Ru_3 clusters. However, the dependence of these Ru—Ru bond distances on the nature of the P-donor substituents is quite small and can account for only 30–40% of the variations in the bond lengths. It seems probable that lattice effects account for the remaining 60–70% of the differences between the substituted and parent clusters. The effects on the Ru—Ru and Ru—P distances are not affected by whether there are one or two substituents present so the effects appear to be localized close to the substituents. As in the parent cluster, the carbido atoms in all the substituted Ru_5 clusters lie below the plane defined by the four basal Ru atoms and the extent of this distortion appears to be determined usually by the degree of electron donation from the substituents.

EXPERIMENTAL

The compound **2a, 2b, 2c** and **3** were prepared by literature methods [3b,5] and crystals were grown by slow evaporation of 1 : 1 hexane : CH_2Cl_2 solutions. Table 1 details the experimental data for the single crystal X-ray solution and refinement for the structures.

Accurate cell dimensions and crystal orientation matrix were determined on an Enraf-Nonius CAD-4 diffractometer by a least squares treatment of the setting angles of 25 high angle reflections [17]. Intensities of reflections were collected with variable scan speeds and widths of the ω-2θ type scans by using graphite monochromatized Mo–K_α radiation (0.70930 Å), at a temperature of 293(2) K. A scan of 25% of the full range on either side of each reflection was used for the background measurement. Three standard reflections were collected every 120 min to check the crystal orientation and intensity of the reflections. A linear correction was applied to correct for the variation of the standards. The structures were solved by direct methods [18]. Refinements were by full-matrix least-

squares calculations on F^2 using all data, initially with isotropic and then anisotropic thermal parameters for non-hydrogen atoms; the carbon atoms for **2c** were refined isotropically due to the low value of the data to parameter ratio. In the final rounds of calculations, the hydrogen atoms were positioned on geometric grounds (C—H 0.96 Å for —CH_3 groups, C—H 0.97 Å for CH_2 groups and 0.93 Å for aryl CH groups) and included as riding atoms in the structure factor calculation with refinement rotation of the methyl groups where possible; the isotropic displacement coefficients were refined on a per group basis. The refinement minimized $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2]/[\Sigma w(F_o^2)^2]$ for all reflections where $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$, where a and b are the first and second weighting scheme parameters, respectively and $P = [(\text{the maximum of } 0 \text{ or } F_o^2)/3 + 2F_c^2/3]$. The extinction coefficient, χ, where $F^* = F_c[1 + (\chi \times F_c^2 \times \lambda^3)/(1000 \times \sin 2\theta)]^{-1/4}$ was used. The data sets were corrected for absorption using a semi-empirical approach [19]. The absolute configuration for the non-centrosymmetric space group in the structure of **2c** was confirmed by the Flack parameter which refined to a value of $-0.2(1)$ [20]. Scattering factors for neutral atoms were used as stored in the programs. All calculations were carried out on a personal computer with SHELXTL PC, version 4.2 [18].

Homometallic octahedral boride cluster chemistry: Reactions of $[Ru_6(CO)_{17}B]^-$ with PPh_3 and $P(OMe)_3$, and the crystal structure of $[Ru_6(CO)_{16}\{P(OMe)_3\}B(AuPPh_3)]$†

(Received 14 October 1997; accepted 14 January 1998)

Abstract—The reaction between $[(PPh_3)_2N][Ru_6(CO)_{17}B]$ and PPh_3 leads to the formation of $[(PPh_3)_2N][Ru_6(CO)_{16}(PPh_3)B]$, the yield being dependent on reaction conditions. Treatment of $[Ru_6(CO)_{16}(PPh_3)B]^-$ with CF_3CO_2H or Ph_3PAuCl gives $[HRu_6(CO)_{16}(PPh_3)B]$ or $[Ru_6(CO)_{16}(PPh_3)B(AuPPh_3)]$ respectively; the latter cluster can also be prepared by PPh_3-for-CO substitution starting from $[Ru_6(CO)_{17}B(AuPPh_3)]$. When $[(PPh_3)_2N][Ru_6(CO)_{17}B]$ is treated with $P(OMe)_3$, followed by the addition of Ph_3PAuCl, the cluster $[Ru_6(CO)_{16}\{P(OMe)_3\}B(AuPPh_3)]$, **4** is obtained, but reaction of $[(PPh_3)_2N][Ru_6(CO)_{16}\{P(OMe)_3\}B]$ with CF_3CO_2H results in cleavage of one methoxy group and the formation of $[Ru_6(CO)_{16}\{\mu\text{-}P(OMe)_2\}B]$. Whereas multi-phosphine substitution in $[Ru_6(CO)_{17}B]^-$ was not achieved when the Lewis base was PPh_3, up to four $P(OMe)_3$ ligands could be introduced. An X-ray crystal structure determination of **4** confirms the retention of the octahedral Ru_6-cluster core with an interstitial boron atom; the gold(I) phosphine unit bridges an Ru—Ru edge causing significant elongation of the latter, and the $P(OMe)_3$ substituent occupies a terminal site on a ruthenium centre remote from the gold(I) fragment. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: boride; cluster; phosphine; phosphite; ruthenium.

Our studies of the reactivity of boride-containing homometallic ruthenium clusters with phosphines and phosphites have been confined to compounds containing three (triangular framework) or four (butterfly framework) metal centres [1–3]. The substitution behaviour of $[HRu_4(CO)_{12}BH_2]$ is significantly influenced by the nature of the Lewis base, and (for the range of ligands studied) high degrees of substitution were only achieved with the tertiary phosphite $P(OMe)_3$ [2]. In each of the homometallic ruthenaboranes studied, the boron atom was exposed, either residing in a vertex site or in a semi-interstitial position, and was attached to two or more H atoms.

In the present paper we extend our studies to the cluster $[Ru_6(CO)_{17}B]^-$, the conjugate acid $[HRu_6(CO)_{17}B]$ has been structurally characterized [4,5] and possesses an octahedral framework containing an interstitial boron atom. In the lower nuclearity clusters, some competition between B and Ru sites of attack are possible and have been observed [1]; this was also the case in the related ferraborane $[HFe_3(CO)_9BH_2R]^-$ (R = H; CH_3) [6,7]. The interstitially sited B atom in $[Ru_6(CO)_{17}B]^-$ is shielded from attack and substitution chemistry is expected to involve the ruthenium-bound carbonyl ligands. The anion $[Ru_6(CO)_{17}B]^-$ is isoelectronic with the neutral carbido cluster $[Ru_6(CO)_{17}C]$ for which both mono- and disubstituted PPh_3 derivatives have been reported [8]. With $P(OMe)_3$, up to four CO ligands in $[Ru_6CO)_{17}C]$ have been replaced [9], a result that parallels our

observation of multi-substitution by $P(OMe)_3$ in $[HRu_4(CO)_{12}BH_2]$ [2]. The aims of the present study were to explore the reactivity of $[Ru_6(CO)_{17}B]^-$ towards PPh_3 and $P(OMe)_3$, and to investigate the effects of protonation of the anionic products and the reactions of the latter with [PhPAuCl].

EXPERIMENTAL

General data

Fourier-transform NMR spectra were recorded on a Bruker WM 250 spectrometer, ^1H shifts are reported with respect to δ 0 for Me_4Si, ^{11}B NMR with respect to δ 0 for $F_3B \cdot OEt_2$ and ^{31}P NMR with respect to δ 0 for 85% H_3PO_4; downfield chemical shifts are positive. Solution infrared spectra were recorded on a Perkin–Elmer FT 1710 spectrophotometer, and fast ion bombardment (FIB) and fast atom bombardment (FAB) mass spectra using Kratos instruments (3-NBA matrix = 3-nitrobenzyl alcohol).

All reactions were carried out under argon by using standard Schlenk methods. Solvents were pre-dried and distilled under N_2. Separations were achieved by using thin layer plate chromatography with Kieselgel 60-PF-254 (Merck). PPh_3 and $P(OMe)_3$ were used as received (Aldrich); $[Ph_3PAuCl]$ [10], $[(Ph_3P)_2N][Ru_6(CO)_{17}B]$ [11] and $[Ru_6(CO)_{17}B(AuPPh_3)$ [11] were prepared according to literature methods. Yields were somewhat variable and typical values (with respect to starting cluster) are given.

Preparation of $[(Ph_3P)_2N][Ru_6(CO)_{16}(PPh_3)B]$, $[(Ph_3P)_2N][1]$

In a typical reaction, $[(Ph_3P)_2N][Ru_6(CO)_{17}B]$ (33 mg, 0.020 mmol) was dissolved in CH_2Cl_2 (5 ml), and to this was added PPh_3 (26 mg, 0.1 mmol). The solution was stirred at room temperature and was monitored by spot TLC until there was no apparent change in the number and relative quantities of the compounds present. The reaction time was 3 hr; solvent was removed *in vacuo*, and the products (two fractions) were separated by TLC (2 : 1 CH_2Cl_2 : hexane). The first fraction (orange, 5%) was unreacted $[(Ph_3P)_2N][Ru_6(CO)_{17}B]$, and the second (brown, $\approx$90%) was identified as $[(Ph_3P)_2N][Ru_6(CO)_{16}(PPh_3B]$, $[(Ph_3P)_2N][\mathbf{1}]$. If the stoichiometry is altered to 1 : 2 (cluster : phosphine), the yield of $[(Ph_3P)_2N][\mathbf{1}]$ is $\approx$70%, and in a 1 : 1 reaction, the yield falls to $\approx$35%. Photolysis of the CH_2Cl_2 solution containing a 1 : 5 cluster : PPh_3 mixture resulted in a greater product distribution (see text). $[Ph_3P)_2N][\mathbf{1}]$: ^1H NMR ($CDCl_3$, 298 K): δ 7.3–7.7 (m, Ph); ^{11}B NMR ($CDCl_3$ 298 K): δ 196.0, $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 185 K): δ 53.2 (1P, PPh_3), 21.0 (2P, cation). IR (CH_2Cl_2) ν(CO) 2058 m, 2025 s, 1999 vs, 1945 w cm^{-1}. MS (negative FIB): 1328 (P^-) with 2 CO loses, 1066 (P^-—PPh_3) with 3 CO losses.

Preparation of $[HRu_6(CO)_{16}(PPh_3)B]$

$[(Ph_3P)_2N][\mathbf{1}]$ (34 mg, 0.018 mmol) was dissolved in CH_2Cl_2 (5 ml) and 5 μl CF_3CO_2H was added. The solution was stirred at room temperature and the reaction was monitored by IR spectroscopy. After 10 min, solvent was removed *in vacuo*, and the products were separated by TLC (2 : 1 hexane : CH_2Cl_2). One fraction eluted and $[HRu_6(CO)_{16}(PPh_3)B]$ was isolated in $\geqslant$95% yield. ^1H NMR ($CDCl_3$, 298 K): δ 7.5–7.8 (m, Ph), −17.5 (s, Ru—H—Ru); ^{11}B NMR ($CDCl_3$, 298 K): δ 195.0; $^{31}P\{^1H\}$ NMR ($CDCl_3$, 298 K): δ 35.9. IR (CH_2Cl_2) ν(CO) 2087 w, 2052 vs, 2026 s, 2000 w sh, 1974 w sh cm^{-1}. MS (positive FAB): 1330 (P^+) with 3 to 15 CO losses.

Preparation of $[Ru_6(CO)_{16}(PPh_3)B(AuPPh_3)]$. Method 1

$[(Ph_3P)_2N][\mathbf{1}]$ (35 mg, 0.018 mmol) was dissolved in CH_2Cl_2 (5 ml) and to this were added solid $[Ph_3PAuCl]$ (18 mg, 0.036 mmol) and $Tl[PF_6]$ (4 mg, 0.01 mmol). The solution was stirred for 1 h at room temperature and then solvent was removed *in vacuo*. Product separation by TLC (2 : 1 hexane : CH_2Cl_2) gave one predominant orange-brown fraction identified as $[Ru_6(CO)_{16}(PPh_3)B(AuPPh_3)]$ (90% yield). ^1H NMR ($CDCl_3$, 298 K): δ 7.3–7.8 (m, Ph); ^{11}B NMR ($CDCl_3$, 298 K): δ 195. 9; $^{31}P\{^1H\}$ NMR ($CDCl_3$, 298 K): δ 71 (1P, $AuPPh_3$), 42 (1P, $RuPPh_3$). IR (CH_2Cl_2) ν(CO) 2071 m, 2030 vs, 1993 m, 1978 w sh, 1950 w sh, 1854 w, 1825 w cm^{-1}. MS (positive FIB): 1787 (P^+) with 16 CO losses.

Preparation of $[Ru_6(CO)_{16}(PPh_3)B(AuPPh_3)]$. Method 2

$[Ru_6(CO)_{17}B(AuPPh_3)$ [11] (104 mg, 0.067 mmol) was dissolved in CH_2Cl_2 (5 ml) and to this was added PPh_3 (88 mg, 34 mmol). The solution was stirred at room temperature for 1 h, solvent was removed *in vacuo*, and the products were separated by TLC (2 : 1 CH_2Cl_2 : hexane). One major fraction (orange-brown) was collected and identified as $[Ru_6(CO)_{16}(PPh_3)B(AuPPh_3)]$ yield $\approx$70%) with the same spectroscopic signatures as the product formed from method 1.

Preparation of $[(Ph_3P)_2N][Ru_6(CO)_{16}\{P(OMe)_3\}B]$, $[(Ph_3P)_2N][\mathbf{2}]$

In a typical reaction, $[(Ph_3P)_2N][Ru_6(CO)_{17}B]$ (33 mg, 0.020 mmol) was dissolved in CH_2Cl_2 (5 ml), and to this was added $P(OMe)_3$ (2 μl, 0.02 mmol). The reaction was monitored by IR spectroscopy, and after 10 min, the most intense absorption had shifted to 1999 cm^{-1}. Solvent was removed *in vacuo* and products were separated by TLC (2 : 1 CH_2Cl_2 : hexane).

Only one fraction eluted (orange-brown, typically ≈60% yield) and was identified as $[(Ph_3P)_2N][Ru_6(CO)_{16}\{P(OMe)_3\}B]$. ^1H NMR ($CDCl_3$, 298 K): δ 7.4–7.7 (m, Ph), 3.6 (d, J_{PH} 12 Hz, Me); ^{11}B NMR ($CDCl_3$, 298 K): δ 197.2; $^{31}P\{^1H\}$ NMR ($CDCl_3$, 298 K): δ 150.3 (1P, $P(OMe)_3$), 21.0 (2P, cation). IR (CH_2Cl_2) ν(CO) 2060 m, 2026 s, 2001 vs, 1914 m cm^{-1}. MS (negative FIB): 1190 (P^-) with 9 CO losses.

Preparation of $[Ru_6(CO)_{16}\{\mu\text{-}P(OMe)_2\}B]$, **3**. Method 1

$[(Ph_3P)_2N][\mathbf{2}]$ (21 mg, 0.012 mmol) was dissolved in CH_2Cl_2 (5 ml) and CF_3CO_2H (5 μl) was added. The solution was stirred for 5 min during which time it became red; IR spectroscopic monitoring indicated that the reaction was complete within this period. The solvent was removed *in vacuo* and the products were separated by TLC (2:1 hexane:CH_2Cl_2). One red-orange fraction eluted, and was identified as $[Ru_6(CO)_{16}\{\mu\text{-}P(OMe)_2\}B]$ (≥95% yield). ^1H NMR ($CDCl_3$, 298 K): δ 3.8 (d, J_{PH} 13 Hz, Me); ^{11}B NMR ($CDCl_3$, 298 K): δ 193.3; $^{31}P\{^1H\}$ NMR ($CDCl_3$, 298 K): δ 357.7. IR (CH_2Cl_2) ν(CO) 2089 w, 2080 m, 2065 m, 2055 s, 2039 vs, 2025 m sh, 1989 m cm^{-1}. MS (negative FIB): 1190 (P^-) with 9 CO losses.

Preparation of $[Ru_6(CO)_{16}\{\mu\text{-}P(OMe)_2\}B]$, **3**. Method 2

The advantage of this method over method 1 is that it does not involve the isolation of the intermediate anion **2**. In a typical reaction, $[(Ph_3P)_2N][Ru_6(CO)_{17}B]$ (98 mg, 0.06 mmol) was dissolved in CH_2Cl_2 (5 ml), and to this was added $P(OMe)_3$ (7μl, 0.06 mmol). The solution was stirred at room temperature, and IR spectroscopic monitoring showed the reaction to be complete in 10 min; the strongest absorption had shifted to 1996 cm^{-1}. Trifluoroacetic acid (10 μl) was added to the solution; it was stirred for 5 min at room temperature, after which time the strongest absorption in the IR spectrum had shifted to 2065 cm^{-1}. Solvent was removed *in vacuo* and the products were separated by TLC (2:1 hexane:CH_2Cl_2). The first (orange, 15%) fraction was $[H_2Ru_4(CO)_{13}]$, identified by its IR spectrum [12]; the second (red-orange, 30%)band was compound **3**, and the final fraction (brown, 40%) was unreacted $[(Ph_3P)_2N][Ru_6(CO)_{17}B]$.

Preparation of $[Ru_6(CO)_{16}\{P(OM)_3\}B(AuPPh_3)]$, **4**

In a typical reaction, $[(Ph_3P)_2N][Ru_6(CO)_{17}B]$ (49 mg, 0.03 mmol) was dissolved in CH_2Cl_2 (5 ml), and to this was added $P(OMe)_3$ (3.5 μl, 0.03 mmol). The solution was stirred at room temperature and the reaction monitored by IR spectroscopy; the strongest absorption shifted to 1998 cm^{-1}. After 10 min, $[Ph_3PAuCl]$ (30 mg, 0.06 mmol) and $Tl[PF_6]$ (4 mg, 0.01 mmol) were added, and the solution was stirred at room temperature for 30 min. Solvent was then removed *in vacuo*, and products were separated by TLC (2:1 hexane:CH_2Cl_2). Three fractions eluted the first band was non-boron containing and was not characterized further. The second and third fractions were $[Ru_6(CO)_{17}B(AuPPh_3)]$ [11] (orange, ≈15%), and $[Ru_6(CO)_{16}\{P(OMe)_3\}B(AuPPh_3)]$ (red, ≈40%) respectively. ^1H NMR ($CDCl_3$, 298 K): δ 7.4–7.7 (m, Ph, 15H), 3.6 (d, J_{PH} 12 Hz, Me, 9H); ^{11}B NMR ($CDCl_3$, 298 K): δ 195.6; $^{31}P\{^1H\}$ NMR ($CDCl_3$, 298 K): δ 140.8 (1P, $P(OMe)_3$), 72.2 (1P, $AuPPh_3$). IR (CH_2Cl_2) ν(CO) 2055 m, 2032 vs, 1989 s, 1983 s cm^{-1}. MS (positive FIB): 1651 (P^+) with 15 CO losses.

Preparation of $[Ru_6(CO)_{14}\{P(OMe)_3\}_3B(AuPPh_3)]$

In a typical reaction, $[(Ph_3P)_2N][Ru_6(CO)_{17}B]$ (38 mg, 0.023 mmol) was dissolved in CH_2Cl_2 (5 ml), and to this was added $P(OMe)_3$ (6μl, 0.058 mmol). The solution was stirred at room temperature and the reaction monitored by IR spectroscopy; after 10 min, the strongest absorption had shifted to 1986 cm^{-1} and the spectrum showed no further changes. $[Ph_3PAuCl]$ (23 mg, 0.046 mmol) and $Tl[PF_6]$ (4 mg, 0.01 mmol) were added to the reaction mixture, and the solution was stirred for 30 min. Solvent was then removed *in vacuo*, and the products were separated by TLC (1:1 hexane:CH_2Cl_2). Two fractions eluted; the first was identified as $[Ru_6(CO)_{16}\{P(OMe)_3\}B(AuPPh_3)]$ (≈10%) and the second fraction was $[Ru_6(CO)_{14}\{P(OMe)_3\}_3B(AuPPh_3)]$ (orange-brown, ≈80%). ^1H NMR ($CDCl_3$, 298 K): δ 7.4–7.7 (m, Ph, 15H), 3.6 (d, J_{PH} 11 Hz, Me, 9H), 3.5 (d, J_{PH} 12 Hz, Me, 18H); ^{11}B NMR ($CDCl_3$, 298 K): δ 197.8; $^{13}P\{^1H\}$ NMR ($CDCl_3$, 298 K): δ 144.4 (2P, $P(OMe)_3$), 137.0 (1P, $P(OMe)_3$), 69.9 (1P, $AuPPh_3$). IR (CH_2Cl_2) ν(CO) 2055 m, 2032 vs, 1989 s, 1983 s cm^{-1}. MS (positive FIB): 1841 (P^+) with 14 CO losses.

Preparation of $[Ru_6(CO)_{13}\{P(OMe)_3\}_4B(AuPPh_3)]$

$[(Ph_3P)_2N][Ru_6(CO)_{17}B]$ (49 mg, 0.03 mmol) was dissolved in CH_2Cl_2 (5 ml), and to this was added $P(OMe)_3$ (14 μl, 0.12 mmol). The solution was stirred, and the reaction monitored by IR spectroscopy; the reaction was deemed complete after 30 min, when the strongest absorption had shifted to 1976 cm^{-1} and showed no further change. $[Ph_3PAuCl]$ (30 mg, 0.06 mmol) and $Tl[PF_6]$ (4 mg, 0.01 mmol) were added, the solution was stirred for 30 min, and then solvent was removed *in vacuo*. Separation by TLC (1:2 hexane:CH_2Cl_2) yielded one major fraction, identified as $[Ru_6(CO)_{13}\{P(OMe)_3\}_4B(AuPPh_3)]$ (red-brown, ≈80%). ^1H NMR ($CDCl_3$, 298 K): δ 7.4–7.7 (m, Ph, 15H), 3.6 (d, J_{PH} 11 Hz, Me, 18H), 3.7 (d, J_{PH} 11 Hz, Me, 18H); ^{11}B NMR ($CDCl_3$, 298 K): δ 196.2; $^{31}P\{^1H\}$ NMR ($CDCl_3$, 298 K): δ 141.2 (2P,

$P(OMe)_3$), 137.5 (2P, $P(OMe)_3$), 68.0 (1P, $AuPPh_3$). IR (CH_2Cl_2) ν(CO) 2096 m, 2026 m, 1997 s sh, 1983 vs cm^{-1}. MS (positive FAB): 1937 (P^+) with 1 CO loss.

Crystal structure determination of **4**

Crystals suitable for X-ray diffraction were grown from a concentrated CH_2Cl_2 solution layered with hexane. Crystallographic data for $[Ru_6(CO)_{16}\{P(OMe)_3\}B(AuPPh_3)]$, **4**, are collected in Table 1. Crystals (deep red plates) were photographically characterized and determined to belong to the triclinic crystal system. The centrosymmetric alternative was initially selected and this choice was supported by the results of refinement. An empirical correction for absorption was applied to the diffraction data ($T_{max/min} = 1.41$). The structure was solved by direct methods, completed from difference Fourier maps, and refined with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atom locations were idealized. All computations used SHELXTL 4.2 software (G. Sheldrick, Siemens XRD, Madison, WI).

RESULTS AND DISCUSSION

Triphenylphosphine substitution

The reaction of $[Ru_6(CO)_{17}B]^-$ with PPh_3 was initially performed with the reagents in a 1 : 1 molar ratio. After one hour, $\approx$65% of $[Ru_6(CO)_{17}B]^-$ remained unreacted; only one new product was obtained and was identified as the monosubstituted product $[Ru_6(CO)_{16}(PPh_3)B]^-$, **1**. The FIB mass spectrum showed a parent ion at m/z 1328 and the isotopic distribution was in accord with the proposed formulation. The presence of one PPh_3 ligand was confirmed by the appearance in the ^{31}P NMR spectrum at 185 K of a singlet at δ 53.2 with a relative integral of half that of the signal assigned to the $[(Ph_3P)_2N]^+$ counter-ion; at 298 K, only the signal due to the cation was resolved. The ^{11}B NMR spectrum of $[(Ph_3P)_2N][\mathbf{1}]$ exhibited a broadened singlet at δ 196.0, shift which is characteristic of a boron atom encapsulated within an octahedral Ru_6-cage [13]. The yield of **1** can be increased to $\approx$70% by lengthening the reaction period to 2 h, or by altering the ratio of $[Ru_6(CO)_{17}B]^-$: PPh_3 to 1 : 5 and with a reaction time of 3 h (yield $\geq$90%). In each case, there was no evidence for the substitution of more than one CO ligand by PPh_3. In an attempt to facilitate multisubstitution, we photolysed the reaction mixture, irradiation with a mercury high-pressure lamp for 2 h, and using a 1 : 5 cluster : ligand ratio. Under these conditions, a range of products, most in very low yield, was formed; no attempt was made to characterize these compounds. The two main products of the photolysis reaction were $[(Ph_3P)_2N][\mathbf{1}]$ (35% yield) and a neutral material which was tentatively formulated from mass spectrometric data as a mixture of $[HRu_7(CO)_{19}B]$ and $[HRu_7(CO)_{18}(PPh_3)B]$. The +FAB mass spectrum showed two sets of fragmentation patterns arising from parent ions at m/z 1253 and 1484. Attempts to further separate these materials were unsuccessful; the mixture showed one broad signal in the ^{11}B NMR spectrum, at δ 191 indicative of an octahedral Ru_6B-environment, and the ^{31}P NMR spectrum exhibited a singlet at δ 27. In the ^1H NMR spectrum of the mixture, signals assigned to the Ph groups were observed (δ 7.3–7.8) but no highfield resonances due to metal-bound H atoms could be resolved. With the formulations of $[HRu_7(CO)_{19}B]$ and $[HRu_7(CO)_{18}(PPh_3)B]$, the products are 98 electron clusters, consistent with capped octahedral Ru_7-frameworks. Among homometallic ruthenium clusters, this geometry has been crystallographically confirmed for the 98 electron clusters $[HRu_7(CO)_{20}]^-$ [14] and $[HRu_7(CO)_{19}(\mu\text{-}CNMe_2]^-$ [15]. Interestingly, our attempts to achieve an analogous cluster expansion reaction using $[Ru_6(CO)_{17}B]^-$ as the starting material, in the absence of PPh_3 but under the same photolytic conditions as described above, were unsuccessful.

Anion **1** protonates readily when treated with CF_3CO_2H, and the conversion to $[HRu_6(CO)_{16}(PPh_3)B]$ is essentially quantitative (Fig. 1). In the mass spectrum of this product, the parent ion and its isotopic distribution are consistent with the formulation. Upon protonation, the shift in the ^{11}B NMR signal is negligible (δ 196.0 to 195.0) indicating that the octahedral cage around the boron atom is

retained. In the ^{31}P NMR spectrum of the product, the loss of the resonance due to $[(Ph_3P)_2N]^+$ is consistent with the formation of a neutral species; a singlet, observed at δ 35.9, was assigned to the ruthenium-bound PPh_3 ligand. In the ^1H NMR spectrum, the presence of the metal-bound hydride was confirmed by the appearance of a highfield singlet (δ −17.5), and the lack of ^{31}P-^1H spin-spin coupling indicated that the H and P atoms were not attached to the same Ru atom. We propose that the H atom bridges an Ru—Ru edge (as in $[HRu_6(CO)_{17}B]$ [4,5], and is remote from the ruthenium atom carrying the PPh_3 ligand.

Reactions of metal cluster anions with gold(I) phosphine fragments are well established pathways to heterometallic clusters [16], and the relative ease with which these derivatives often crystallize makes them useful targets for study. Anion **1** reacts with an excess of $[Ph_3PAuCl]$ in the presence of $Tl[PF_6]$ to give an orange-brown product in high yield. The parent ion in the mass spectrum suggested the formulation $[Ru_6(CO)_{16}(PPh_3)B(AuPPh_3)]$; in the ^{31}P NMR spectrum, two singlets of relative intensities 1 : 1 were observed. On going from **1** to $[Ru_6(CO)_{16}(PPh_3)B(AuPPh_3)]$, the ^{11}B NMR signal shows virtually no change in chemical shift, in keeping with there being no disruption of the octahedral Ru_6B-core. From the spectroscopic data, it is not possible

to give an unambiguous structural assignment for $[Ru_6(CO)_{16}(PPh_3)B(AuPPh_3)]$, but by analogy with the $P(OMe)_3$ analogue discussed below, we propose a structure as represented in Fig. 1. We have previously reported details of the compounds $[Ru_6(CO)_{17}B(AuPR_3)]$ (R = Ph or 2-MeC_6H_4) [11]; the gold(I) phosphine unit bridges an edge of the octahedral Ru_6-cage and this further supports the structural proposal in Fig. 1.

The compound $[Ru_6(CO)_{16}(PPh_3)B(AuPPh_3)]$ can also be prepared by replacing a CO ligand in $[Ru_6(CO)_{17}B(AuPPh_3)]$ by triphenylphosphine. The IR and NMR spectroscopic properties of this product are identical to those of that obtained from anion **1**, confirming that the same isomer is formed preferentially in both reaction paths.

Trimethylphosphite substitution: monosubstitution

In contrast to the predictable behaviour of the triphenylphosphine system described above, reaction of $[(Ph_3P)_2N][Ru_6(CO)_{17}B]$ with $P(OMe)_3$ followed by protonation or treatment with $[Ph_3PAuCl]$ provided contrasting results. The reaction between equimolar equivalents of $[(Ph_3P)_2N][Ru_6(CO)_{17}B]$ and $P(OMe)_3$ led to the formation of $[(Ph_3P)_2N][Ru_6(CO)_{16}\{P(OMe)_3\}B]$, $[(Ph_3P)_2N]$[**2**] as expected. Mass spectrometric data were in accord with the formulation, and the ^{31}P NMR spectrum exhibited two singlets (relative intensities 1:2), the chemical shifts of which were consistent with a terminally bound $P(OMe)_3$ group (δ 150.3) and $[(Ph_3P)_2N]^+$ (δ 21.0). In the ^1H NMR spectrum, in addition to Ph resonances, a doublet at δ 3.6 (J_{PH} = 12 Hz) was assigned to the Me groups of $P(OMe)_3$. There was no significant change in the signal in the ^{11}B NMR spectrum on going from $[Ru_6(CO)_{17}B]^-$ to **2**, indicating retention of the octahedral metal framework around the boron atom.

Anion **2** reacts with CF_3CO_2H under the same conditions that facilitated the conversion of **1** to its conjugate acid. However, simple protonation does not occur. The ^{31}P NMR spectroscopic signature of the product was particularly revealing, with the appearance of a downfield signal at δ 357.7. This is characteristic of a bridging phosphido group and suggested that reaction with CF_3CO_2H had resulted in the conversion of the terminal $P(OMe)_3$ ligand to a μ-$P(OMe)_2$ unit (Fig. 1). This was supported by a parent ion at m/z 1190 in the mass spectrum, and the product was formulated as $[Ru_6(CO)_{16}\{\mu\text{-}P(OMe)_2\}B]$. The ^{11}B NMR spectroscopic resonance indicated that the octahedral Ru_6B-core was not disrupted during the reaction, and in the ^1H NMR spectrum, only a doublet (δ 3.8, J_{PH} 13 Hz) was observed, in keeping with the fact that protonation was not accompanied by the formation of a direct Ru—H interaction. It is assumed that the MeO group cleaved from the $P(OMe)_3$ ligand leaves as MeOH (eqn (1)). The cluster conversion proceeds without a change to the electron count since the two electrons contributed by the terminal $P(OMe)_3$ ligand and the single electron provided by the charge are replaced by three electrons contributed by the bridging $P(OMe)_2$ group. Unfortunately, X-ray quality crystals could not be obtained to permit crystallographic confirmation of the formation of the phosphido derivative.

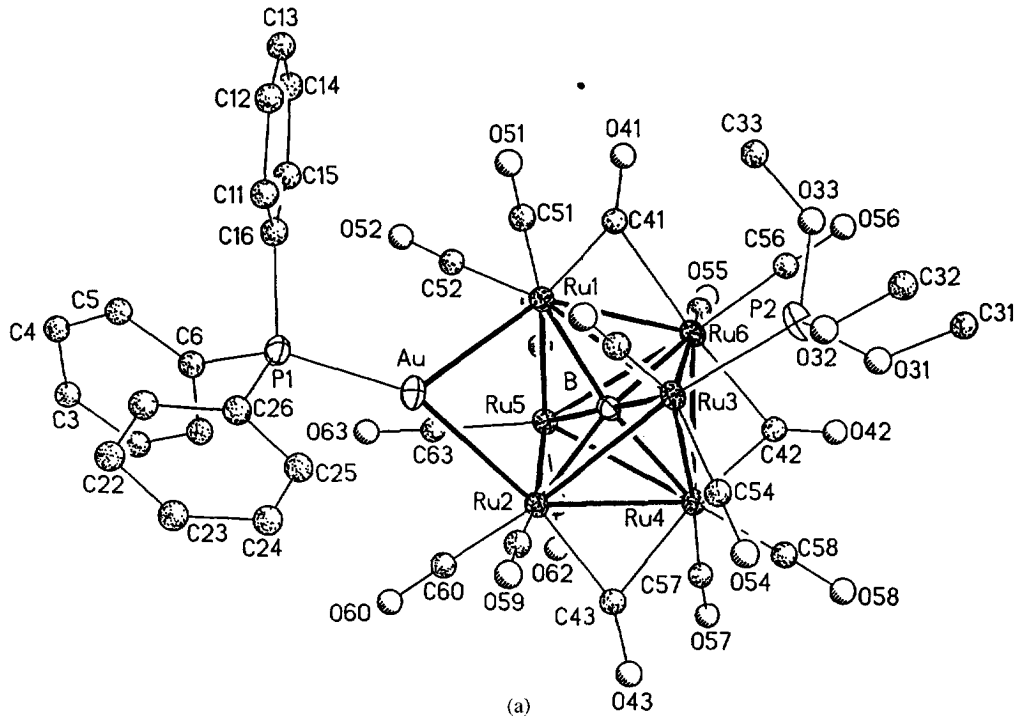
$$[Ru_6(CO)_{16}\{P(OMe)_3\}B]^- + H^+ \rightarrow [Ru_6(CO)_{16}\{\mu\text{-}P(OMe)_2\}B] + MeOH \quad (1)$$

These results are in contrast to the reaction between $[Ru_3(CO)_{10}\{P(OMe)_3\}_2]$ and CF_3CO_2H which leads to $[HRu_3(CO)_{10}\{P(OMe)_3\}_2]^+$ [17]. Although, the conversions of a terminal $P(OMe)_3$ ligand to μ_4-P(OMe) and bridging $OP(OMe)_2$ or OP(OMe)$OP(OMe)_2$ groups have previously been thermally promoted [18–20], the facile manner in which **2** converts to $[Ru_6(CO)_{16}\{\mu\text{-}P(OMe)_2\}B]$ upon protonation appears to be a novel observation. A related reaction has been reported by Süss-Fink and coworkers; the phosphido derivative $[Ru_3(CO)_9(PPh_3)(\mu\text{-}PPh_2)]^-$ was isolated as a product of the reaction between $[HRu_3(CO)_{11}]^-$ and PPh_3, and ^1H NMR spectroscopic data suggested that the reaction proceeded by the formation of $[HRu_3(CO)_{10}(PPh_3)]^-$ followed by $[HRu_3(CO)_9(PPh_3)_2]^-$ with consequent elimination of C_6H_6 [21].

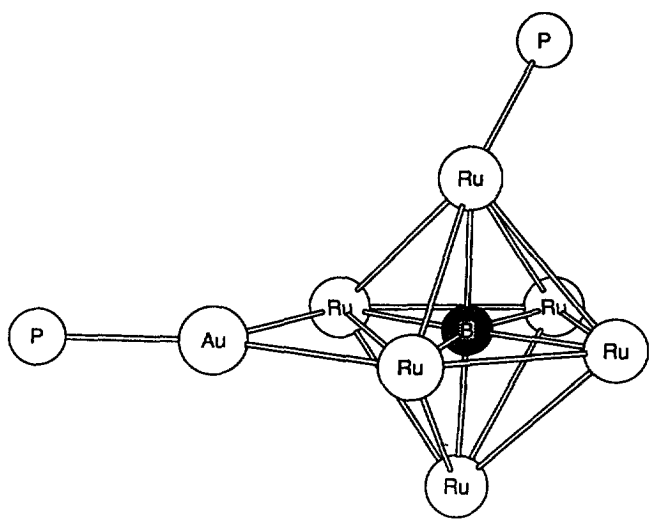
The 1:1 reaction of $[(Ph_3P)_2N][Ru_6(CO)_{17}B]$ with $P(OMe)_3$ followed by the addition of an excess of $[Ph_3PAuCl]$ gave the expected product $[Ru_6(CO)_{16}\{P(OMe)_3\}B(AuPPh_3)]$, **4**, as well as $[Ru_6(CO)_{17}B(AuPPh_3)]$ which clearly arose from direct combination of $[Ph_3PAuCl]$ with $[(Ph_3P)_2N][Ru_6(CO)_{17}B]$. Spectroscopic and mass spectrometric data for **4** were consistent with this formulation, and the boron-containing octahedral Ru_6-core suggested by the ^{11}B NMR spectroscopic shift (δ 195.6) was confirmed by the results of an X-ray structure determination.

Crystal structure of $[Ru_6(CO)_{16}\{P(OMe)_3\}B(AuPPh_3)]$

The structure of compound **4** is shown in Fig. 2a and a view of the cluster core showing the site of substitution is given in Fig. 2b. Selected bond distances and angles are listed in Table 2. The ruthenium atoms define a distorted octahedron, with the edge bridged by the gold(I) phosphine unit being significantly longer (3.299(2) Å) than the other eleven edges (see Table 2). The edge-bridging site adopted by the $AuPPh_3$ unit mimics that found for the $AuP(C_6H_4\text{-}2\text{-}Me)_3$ group in $[Ru_6(CO)_{17}B\{AuP(C_6H_4\text{-}2\text{-}Me)_3\}]$ [11]: here too, the bridged Ru—Ru edge is elongated (3.241(1) Å) but in both $[Ru_6(CO)_{17}B\{AuP(C_6H_4\text{-}2\text{-}Me)_3\}]$ and **4**, the long edges should be considered to contain ruthenium atoms within



(a)



(b)

Fig. 2. (a) The molecular structure of compound **4**, in an orientation that clearly illustrates the elongation of the edge Ru(1)—Ru(2); (b) a view of the cluster core including the P atoms of the $AuPPh_3$ and $P(OMe)_3$ groups.

bonding contact in order that the 86-electron Ru_6-core is consistent with the expected octahedral cage. The boron atom in **4** lies centrally within the Ru_6-cage, with Ru—B distances in the range 2.057(7) to 2.140(7) Å, the longer distances being associated with the two Ru atoms lying in the Ru_4Au equatorial plane but being remote from the gold atom. The $P(OMe)_3$ ligand occupies a terminal site, attached to an apical ruthenium atom (Ru(3)—P(2) = 2.260(2) Å); additionally, atom Ru(3) bears two terminal CO ligands, and the related ruthenium atom, Ru(5), bears three terminal carbonyls. Each ruthenium atom in the equatorial plane carries two terminal CO groups; of the remaining CO ligands, one is fully bridging along Ru(4)—Ru(6) (Ru(4)—C(42) = 2.015(7) and Ru(6)—C(42) = 2.118(7) Å), while edges Ru(1)—Ru(6) and Ru(2)—Ru(4) carry semi-bridging CO ligands (Ru(1)—C(41) = 1.981(7), Ru(6)—C(41) = 2.258(7), Ru(2)—C(43) = 1.960(7) and Ru(4)—C(43) = 2.316(7) Å).

Trimethylphosphite substitution: multisubstitution

The substitution behaviour of $P(OMe)_3$ in ruthenium carbonyl clusters has previously provided examples of relatively high degrees of substitution, for example in $[Ru_3(CO)_{12}]$ [22], $[H_4Ru_4(CO)_{12}]$ [23–25], $[HRu_4(CO)_{12}BH_2]$ [2], $[Ru_6(CO)_{17}C]$ [9] and $[HRu_3(CO)_{10}(NO)]$ [26]. One contributing factor is the relatively small cone angle of $P(OMe)_3$ (107°) compared with, for example, PPh_3 (145°) [27].

The reaction of $[(Ph_3P)_2N][Ru_6(CO)_{17}B]$ with 2.5 molar equivalents of $P(OMe)_3$ resulted in the formation of a product mixture, the IR spectrum of which contained a strong absorption at 1986 cm^{-1}, i.e. at lower wavenumber than the strongest absorption in the IR spectrum of $[Ru_6(CO)_{16}\{P(OMe)_3\}B]^-$ (2001 cm^{-1}). This observation suggested that a higher degree of substitution had been achieved. After the addition of $[Ph_3PAuCl]$ to the reaction mixture, two products were isolated: $[Ru_6(CO)_{16}\{P(OMe)_3\}B(AuPPh_3)]$ and $[Ru_6(CO)_{14}\{P(OMe)_3\}_3B(AuPPh_3)]$ were formulated on the basis of mass spectrometric and multinuclear NMR spectroscopic data. There was no evidence for $[Ru_6(CO)_{15}\{P(OMe)_3\}_2B(AuPPh_3)]$ being an isolable product. Three signals (relative integrals 2:1:1) were observed in the ^{31}P NMR spectrum of $[Ru_6(CO)_{14}\{P(OMe)_3\}_3B(AuPPh_3)]$, and that at δ 69.9 (relative integral 1) was assigned to the $AuPPh_3$ unit. Consistent with the remaining two ^{31}P NMR spectroscopic signals (the chemical shifts of which indicated terminally bound $P(OMe)_3$ ligands), the ^1H NMR spectrum showed two doublets (J_{PH} 11 and 12 Hz) of relative integrals 1:2. Two possible arrangements for the three $P(OMe)_3$ ligands, which take into account steric effects, are shown schematically in Fig. 3a and 3b. Although our data do not allow these two ligand dispositions to be distinguished, the arrangement shown in Fig. 3b has been proposed in the related carbido species $[Ru_6(CO)_{14}\{P(OMe)_3\}_3C]$ [9].

With a four-fold excess of $P(OMe)_3$, tetrasubstitution in $[Ru_6(CO)_{17}B]^-$ was achieved and the addition of $[Ph_3PAuCl]$ to the crude reaction mixture led to the formation of $[Ru_6(CO)_{13}\{P(OMe)_3\}_4B(AuPPh_3)]$ in ≈80% yield. The parent envelope in the mass spectrum was consistent with this formation, and the ^{31}P NMR spectrum exhibited signals in the 2:2:1; the latter signal (δ 68.0) was assigned to the $AuPPh_3$ group, while the remaining signals (δ 141.2 and 137.5) were indicative of terminally bound $P(OMe)_3$ ligands. Two equal intensity doublets in the ^1H NMR spectrum (δ 3.6 and 3.7) were assigned to the phosphite methyl groups. The most likely arrangement of the four $P(OMe)_4$ ligands is depicted in Fig. 3c, and is in keeping with the addition of a fourth ligand to either of the possible isomers proposed for $[Ru_6(CO)_{14}\{P(OMe)_3\}_3B(AuPPh_3)]$.

CONCLUSIONS

The borido anion $[Ru_6(CO)_{17}B]^-$ undergoes substitution with both PPh_3 and $P(OMe)_3$. Whereas monosubstitution of triphenylphosphine appears to be the limiting degree of reaction, up to four CO ligands can be replaced by $P(OMe)_3$ under facile reaction conditions. Protonation of $[Ru_6(CO)_{16}(PPh_3)B]^-$ is readily achieved, but treatment of $[Ru_6(CO)_{16}\{P(OMe)_3\}B]^-$ with H^+ results in the cleavage of one OMe group and the conversion of the terminal $P(OMe)_3$ ligand into a bridging $P(OMe)_2$ group.

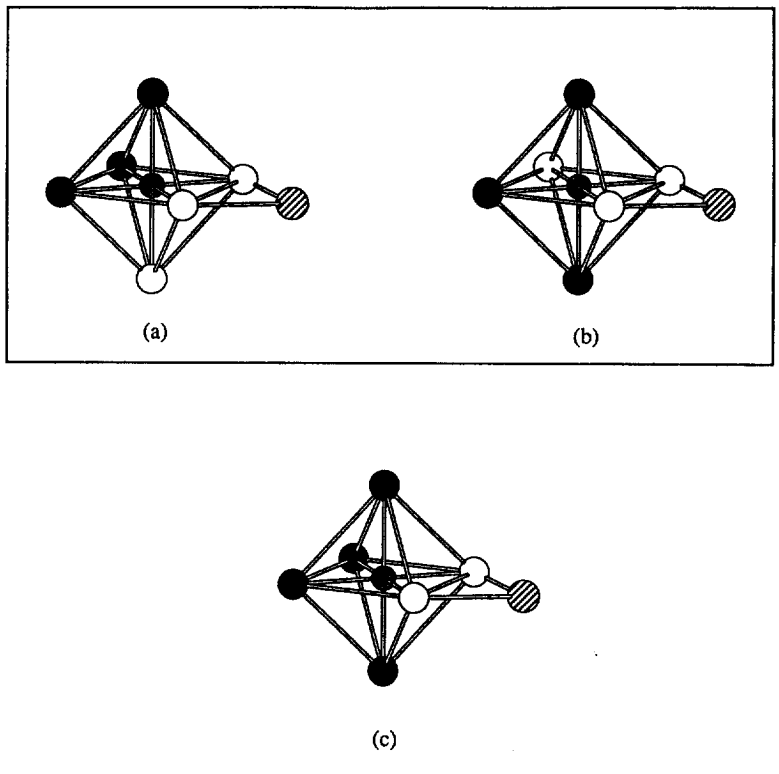

Fig. 3. Proposed arrangements of $P(OMe)_3$ ligands in (a) and (b) $[Ru_6(CO)_{14}\{P(OMe)_3\}_3B(AuPPh_3)]$, and (c) $[Ru_6(CO)_{13}\{P(OMe)_3\}_4B(AuPPh_3)]$.

Reactions of $[Ru_6(CO)_{16}(PPh_3)B]^-$ or $[Ru_6(CO)_{16}\{P(OMe)_3\}B]^-$ with $[Ph_3PAuCl]$ proceed as expected to produce $[Ru_6(CO)_{16}(PPh_3B(AuPPh_3)]$ or $[Ru_6(CO)_{16}\{P(OMe)_3\}B(AuPPh_3)]$ respectively. Crystallographic and ^{11}B NMR spectroscopic data provide evidence for the retention of the octahedral cluster core throughout the various transformations explored.

(Received 26 November 1997; accepted 1 February 1998)

Abstract—The photochemical reaction between $W_2(OCH_2{}^tBu)_6$ and P_4 has been studied by NMR spectroscopy in toluene-d_8 and those reactions have been complemented by studies on the bench top. A complex sequence of reactions is implicated by the formation of a variety of products, one of which has been observed previously in the thermal reaction between $W_2(OCH_2{}^tBu)_6L_2$ where L = py and $HNMe_2$ and P_4, namely $W_3(\mu_3\text{-}P)(OCH_2{}^tBu)_9$, while others must arise from degradation of OR ligands. A new compound $W_4(\mu_3\text{-}P)_2(\mu\text{-}OCH_2{}^tBu)_4(OCH_2{}^tBu)_6$ has been isolated and characterized. Crystal data at −165°C: $a = 19.955(4)$, $b = 25.222(3)$, $c = 12.775(2)$ Å, $Z = 4$ and space group *Pcab*. The centrosymmetric structure consists of a distorted rhombus of metal atoms having two different W—W edge distances 2.6938(8) and 2.7981(8) Å and a bonding W—W distance of 2.692(1) Å between the back-bone W atoms of the planar W_4 butterfly. The outer or wing-tip tungsten atoms are in a square based pyramidal environment with respect to the PWO_4 moiety with the W—P bond in the apical position. The O_4 basal plane involves two terminal and two bridging OR groups. The internal or back-bone tungsten atoms are also five coordinate, P_2WO_3, where two bridging OR groups occupy axial and the two W—P bonds and one W—OR terminal group occupy equatorial sites of a trigonal bipyramid. The cluster geometry is compared with those seen for $W_3(\mu_3\text{-}X)(OR)_9$, where X = CCH_3 and P, $W_4(O^iPr)_{12}$ and $W_4(OEt)_{16}$. The latter contains a central centrosymmetric W_4^{16-} cluster as does the present compound and the presence of the distorted rhomboidal geometry observed in both is proposed to arise from a second order Jahn-Teller distortion. © 1998 Elsevier Science Ltd. Keywords: tungsten; alkoxide; phosphide; cluster.

Previous work in this laboratory has shown that the thermal reaction between P_4 and $W_2(OCH_2{}^tBu)_6(L)_2$, where L = a labile neutral ligand such as $HNMe_2$ or pyridine, has led to the isolation and characterization of the compounds $(\eta^3\text{-}P_3)W(OR)_3L^1$ and $W_3(\mu_3\text{-}P)(OR)_9$.[2] Although it is possible to consider the formation of these two compounds by a reaction sequence wherein an initially formed tetranuclear $W_4(OR)_{12}(\mu\text{-}P_4)$ complex undergoes a disproportionation to give $W_3(\mu_3\text{-}P_3)(OR)_9$ and $(\eta^3\text{-}P_3)W(OR)_3$, we suggested that another reaction pathway was possible, namely one wherein a reactive $(RO)_3W{\equiv}P$ moiety was formed [along with $(\eta^3\text{-}P_3)W(OR)_3$] and that this underwent a conproportionation reaction of the type shown in eqn 1 [2].

$$(RO)_3W{\equiv}P + W_2(OR)_6 \rightarrow W_3(\mu_3\text{-}P)(OR)_9 \quad (1)$$

While we had no direct evidence for a reactive intermediate of the form $(RO)_3W{\equiv}P$ the conproportionation reaction of $(RO)_3W{\equiv}CMe$ with $M_2(OR)_6$ to give $M_2W(\mu\text{-}CMe)(OR)_9$ (M = Mo, W) were known [3] as were related reactions involving $(RO)_4W{=}E$ and $W_2(OR)_6$ to give $(RO)_{10}W_3(\mu_3\text{-}E)$ where E = O [4] and NH [5]. Subsequent to this work $L_3Mo{\equiv}P$ complexes were isolated from reactions between L_3Mo and P_4 by Cummins *et al.* [6] [L = $N(^tBu\text{-}d_6)(3,5\text{-}Me_2C_6H_3)$] and related $W{\equiv}P$

bonded complexes were prepared by Schrock and coworkers [7] employing the use of the bulky quadridentate trianionic ligand $N(CH_2CH_2NSiMe_3)_3^{3-}$.

We report here our studies of the reactions between P_4 and $W_2(OCH_2{}^tBu)_6$ in toluene under photolysis. Photolysis is known to lead to fragmentation of P_x moieties bound to metal atoms [8] and thus we expected that these reactions might proceed differently from those described earlier where the reactions were driven by heat.

RESULTS AND DISCUSSION

Syntheses and spectroscopic studies

The reaction between P_4 and $W_2(OCH_2{}^tBu)_6$ in toluene-d_8 under photolysis was carried out in a water cooled bath with the photolysis coming from the use of a Hanova Hg lamp. The reaction was monitored by $^{31}P\{^1H\}$ and ^1H NMR spectroscopy with time. These studies were complemented by bench top photolysis reactions in toluene. A number of products were seen to be formed in these reactions and the separation of the products proved exceptionally difficult. Column chromatography employing silica gel, which so commonly enjoys great success in metal carbonyl cluster chemistry, is not possible for these alkoxide clusters since Si—OH bonds present in the silica lead to permanent adsorption and subsequent decomposition of the clusters in the column. Silation of the silica with $(Me_3Si)_2NH$ does not prove to inhibit the decomposition. Consequently, we needed to rely on product analysis by spectroscopy (NMR) and by fractional crystallizations employing hydrocarbon solvents.

A major product in the reaction was the known compound $W_3(\mu_3\text{-}P)(\mu\text{-}OCH_2{}^tBu)_3(OCH_2{}^tBu)_6$ which was readily identifiable by $^{31}P\{^1H\}$ and ^1H NMR spectroscopy [2]. Notably, under photolytic conditions, no $(\eta^3\text{-}P_3)W(OCH_2{}^tBu)_3$ was observed [1]. Other products of ligand redistribution that were observed (and characterized) were $W_3(\mu_3\text{-}O)(OCH_2{}^tBu)_{10}$ and $W_3(\mu_3\text{-}O)(OCH_2{}^tBu)_9(O^tBu)$ [9]. Presumably here the oxo group arises from decomposition of alkoxide ligands and the structure of $W_3(\mu_3\text{-}O)(OCH_2{}^tBu)_{10}$ was seen to be akin to that previously reported for the related isopropoxide [10]. The occurrence of $W_3(\mu_3\text{-}O)(OCH_2{}^tBu)_9(O^tBu)$ reflects the presence of a rogue O^tBu ligand, present as a result of incomplete alcoholysis in the preparation of $W_2(OCH_2{}^tBu)_6$ from $W_2(O^tBu)_6$ and neopentanol.

By $^{31}P\{^1H\}$ NMR spectroscopy three other compounds were present in significant concentrations. One is possibly a P_6 complex (based on ^{31}P chemical shift) [11] which could have the form $(RO)_xW(\mu_1\text{-}\eta^6\text{-}P_6)W(OR)_x$. Regrettably we were unable to obtain this complex in single crystalline form. It is known that $Cp^*Mo(CO)_2(\eta^3\text{-}P_3)$ is converted by photolysis to $Cp^*Mo(\mu_1\text{-}\eta^6\text{-}P_6)MoCp^*$, for example [12]. This could explain the absence of $(\eta^3\text{-}P_3)W(OCH_2{}^tBu)_3$ in our photolysis. Furthermore, a singlet at 42.4 ppm with a $J_{W\,P}$ of 63 Hz is detected, so that—in comparison to other P_2 ligand complexes [13]—one could speculate on the existence of a $W_2(OR)_x(\mu,\eta^2\text{-}P_2)$ complex. The third compound, as we show below, is $W_4(\mu_3\text{-}P)_2(OCH_2{}^tBu)_{10}$. This compound must be formed by sacrificial OR group transfer—a process necessary to account for the formation of $W_3(\mu_3\text{-}O)(OCH_2{}^tBu)_{10}$.

$W_4(\mu_3\text{-}P)_2(OCH_2{}^tBu)_{10}$

An ORTEP drawing of the centrosymmetric $W_4(\mu_3\text{-}P)_2(OCH_2{}^tBu)_{10}$ molecule is given in Fig. 1 where the central $W_4P_2O_{10}$ core is numbered. A view perpendicular to that shown in Fig. 1 is given in Fig. 2. From these two views one can see that there is a central rhomboidal W_4 unit, or a flattened butterfly. The two μ_3-P ligands cap opposite triangular faces and each W atom is five coordinate with respect to ligand bonding. The outer W atoms, or wing-tip W atoms, W(1), are in a square based pyramid environment with the μ-P ligand in an apical position and the two terminal and two bridging OR ligands in the basal plane. The hinge or back-bone W atoms, W(2) are in a distorted trigonal bipyramidal environment with two bridging OR groups axial and the two μ-P and one terminal OR group in equatorial sites. Selected bond distances and angles are given in Tables 1 and 2, respectively.

The coordination about W(1) is similar to that seen in $W_3(\mu_3\text{-}P)(\mu\text{-}OCH_2{}^tBu)_3(OCH_2{}^tBu)_6$ [2] and one of the wing-tip Mo atoms in the butterfly Mo_4-complex anion $Mo_4(\mu_3\text{-}P)(OCH_2{}^tBu)_{10}^-$ [14]. By comparing these phosphido capped triangles it is also worthy to note that the M—M distances all fall within a narrow range from 2.7 to 2.8 Å. However, the oxidation states of the metal atoms and hence the electron count for cluster M—M bondings is different. For example, in $W_3(\mu_3\text{-}P)(OCH_2{}^tBu)_9$ and $Mo_4(\mu_3\text{-}P)(OCH_2{}^tBu)_{10}$ the oxidation state of the metal atoms is +4 and +3, respectively, and in the present complex of the formula $W_4(\mu_3\text{-}P)_2(OR)_{10}$ the central W_4^{16+} core gives W(4+) atoms. In this regard it is noteworthy that the planar rhomboidal structure is also seen in $W_4(OEt)_{16}$ [15] and in $W_4(O^iPr)_{12}$ [16] which represent clusters having W atoms in the +4 and +3 oxidation states, respectively. In each of these W_4 planar and centrosymmetric structures [$W_4(OEt)_{16}$, $W_4(O^iPr)_{12}$ and $W_4(P)_2(OCH_2{}^tBu)_{10}$] we observe two sets of edge distances differing by ca 0.1 Å. In other words the D_{2d} symmetrical structure with an M_4 diamond distorts to generate a C_{2h} structure with alternating short and long edges. The bonding in $W_4(O^iPr)_{12}$ [16] and $W_4(OEt)_{16}$ [17] have been investigated by computational methods and in both instances the distortion has been correlated with a second order Jahn-Teller effect. It seems that the same must be true in the present case for the W_4^{16+} core but calculations have as yet not been performed.

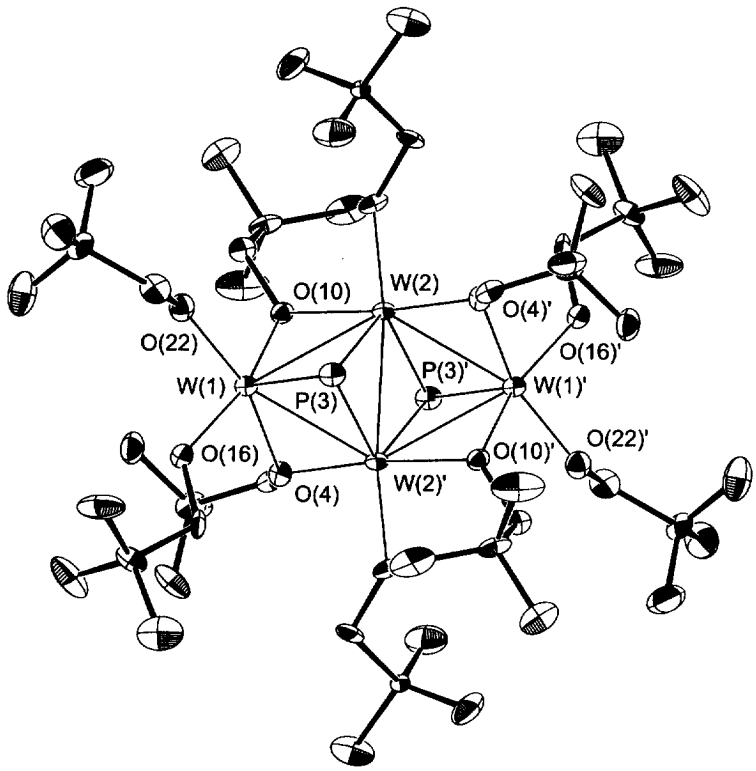

Fig. 1. An ORTEP drawing of the centrosymmetrical $W_4(\mu_3\text{-}P)_2(\mu\text{-}OCH_2{}^tBu)_4(OCH_2{}^tBu)_6$ molecule giving the atom number system used in the tables. This view emphasizes the rhomboidal W_4 unit and the two capping μ_3-P ligands.

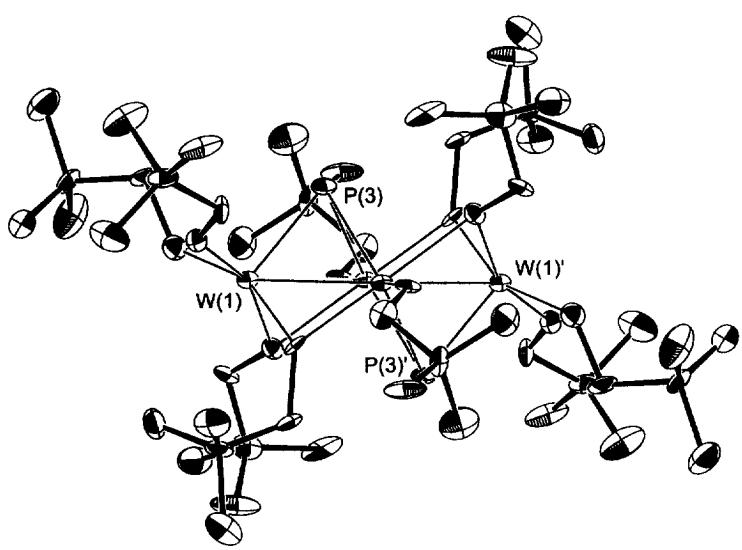

Fig. 2. An ORTEP view of the molecular structure of $W_4(\mu_3\text{-}P)_2(\mu\text{-}OCH_2{}^tBu)_4(OCH_2{}^tBu)_6$ viewed parallel to the W_4 plane. The square based pyramidal geometry of the wing-tip W atoms, W(1) and W(1)′ is clearly evident from this view.

EXPERIMENTAL SECTION

General

All solvents were dried, degassed and stored under N_2. All synthetic and handling procedures were carried out in a purified N_2 atmosphere using Schlenk techniques. P_4 was obtained from commercial sources and used after sublimation. The tungsten starting complex $[W_2(OCH_2{}^tBu)_6]$ was prepared from $[W_2(OCH_2{}^tBu)_6]$ and $^tBuCH_2OH$ as described in the literature [18]. ^{31}P NMR spectra were recorded on a Nicolet NT-360 (146.185 MHz) and the ^1H NMR data were obtained on a Bruker AM-500 (500.136 MHz).

Reaction of $W_2(OCH_2{}^tBu)_6$ *with* P_4*–Isolation of* $W_4(\mu_3\text{-}P)_2(\mu\text{-}OCH_2{}^tBu)_4(OCH_2{}^tBu)_6$

707 mg (0.79 mmol) $[W_2(OCH_2{}^tBu)_6]$ and 98.6 mg P_4 (0.79 mmol) in 150 ml toluene were radiated for 2 h in a UV apparatus (medium pressure mercury lamp, Hanovia 450-W) under internal water cooling to 15°C. The solvent was completely removed in vacuum. The resulting brown solid was purified from unreacted P_4 by sublimation of the latter in vacuum (10^{-3} Torr) at a bath temperature of 50°C. The ^{31}P NMR spectra of the crude reaction mixture revealed four phosphorus containing main products at 274.3 ppm ($J_{W\text{-}P} = 46$ Hz; ≈ 20 Mol.−%P), 224.8 ppm ($J_{W\text{-}P} \approx 60$ Hz, broad unresolved satellites; ≈ 5 Mol.−%P), 42.4 ppm ($J_{W\text{-}P} = 63$ Hz; ≈ 16 Mol.−%P) and −245.5 ppm ($J_{W\text{-}P} \approx 71$ Hz; ≈ 59 Mol.−%P). The residue was solved in 10 ml toluene. Fractional crystallization at 5°C give first 75 mg (10%) of $[W_3(\mu_3\text{-}P)(\mu\text{-}OCH_2{}^t\text{-}Bu)_3(OCH_2{}^tBu)_6]$ and after removal 20 mg (3%) of $[W_4(\mu_3\text{-}P)_2(\mu\text{-}OCH_2{}^tBu)_4(OCH_2{}^tBu)_6]$. Both other compounds could not be separated by fractional crystallization due to their low stability over a longer

(Received 17 October 1997; accepted 8 February 1998)

Abstract—The complexes $HRu_3(CO)_9\{C_2CR(OH)R'\}$ (**1**) have been obtained by reaction, in hydrocarbon solution, of $Ru_3(CO)_{12}$ with propargyl alcohols of general formula $HC_2CR(OH)R'$. In contrast, reaction of $Ru_3(CO)_{12}$ with the alcohols (R = R′ = Me; R = Me, R′ = Ph) in CH_3OH/KOH solution leads to formation of the corresponding allenylidene complexes $HRu_3(CO)_9\{HC_2C(R)R'\}$ (**2**). The ^1H and ^{13}C NMR fluxional behaviour of the complexes are discussed. The acetylide clusters are stable species and lose water only under drastic conditions (i.e. in the presence of strong acids or on TLC silica), to form vinylacetylide or allenylidene derivatives according to the nature of the acetylide substituents. The reverse hydration reactions occur with some difficulty.

The chiral cluster $HRu_3(CO)_9\{C_2CMe(OH)Ph\}$ (**1d**) reacts with dppm forming the "bridged" complex $HRu_3(CO)_7(dppm)\{C_2CMe(OH)Ph\}$ (**3**) which exists both in the solid state and in solution as two diastereoisomeric pairs of enantiomers. The X-ray structure and the NMR fluxionality of complex **3** is discussed. Protonation of complex **3** leads to loss of water and formation of $HRu_3(CO)_7(dppm)\{C_2C(=CH_2)Ph\}$ (**4**), the X-ray structure of which is also discussed. © 1998 Elsevier Science Ltd. All rights reserved

Propargyl alcohols have been used as synthons in organic reactions promoted by metal complexes since Reppe's time [1] and in recent times their synthetic potential has been extensively exploited [2]. For example, $HC_2CMe_2(OH)$ is a low cost starting material for the synthesis of both aryl- and diaryl-acetylenes [3] and of carbamates [4]. Propargyl alcohols have also been used in organic syntheses promoted by mononuclear ruthenium complexes [5], in olygomerization reactions [6] and, last but not least, $HC_2CR(OH)R'$ ligands have been used to form chiral $Co_2(CO)_6$(alkyne) derivatives [7].

Reactions of propargyl alcohols with metal carbonyl clusters have previously been reported and some examples will be discussed in this paper; for instance, with $M_3(CO)_{12}$ (M=Ru, Os) the ligands $HC_2CR(OH)R'$ undergo oxidative addition to form the hydrido-acetylide complexes $HM_3(CO)_9\{C_2CR(OH)R'\}$ (**1**) [8].

We have undertaken a systematic study of the reactions of propargyl alcohols with $Ru_3(CO)_{12}$ in either hydrocarbon or CH_3OH/KOH solutions; new complexes have been obtained together with improved yields of some known derivatives. Protonation (dehydration) and hydration reactions were performed on some of the products and followed using NMR spectroscopic techniques. Further, we have attempted to correlate the yields, protonation behaviour and acetylide ^{13}C NMR data with the donor properties of the cluster-bound ligands.

* R = R′ = Me, Ph; R = Me, R′ = Ph, Et, Pr^n.

† Author to whom correspondence should be addressed.

The chiral complex $HRu_3(CO)_9\{C_2CMe(OH)Ph\}$ (**1d**) has been reacted with dppm to give the "bridged" species $HRu_3(CO)_7(dppm)\{C_2CMe(OH)Ph\}$ (**3**). The solid state structure of monosubstituted **3** has been determined by X-ray diffraction while the fluxional nature of the complex has been investigated using multinuclear NMR spectroscopic techniques.

Protonation of **3** results in loss of water and formation of $HRu_3(CO)_7(dppm)\{C_2C[=CH_2)Ph\}$ (**4**), the structure of which has been confirmed using X-ray diffraction techniques.

EXPERIMENTAL

General materials and analysis of products

$Ru_3(CO)_{12}$ and alkynes are commercial products and were used as supplied. The propargyl alcohol $HC_2C(Ph)_2OH$ was synthesized using a slightly modified literature method [9] and characterized by ^1H and ^{13}C NMR spectroscopy [10].

Unless stated otherwise, the reactions were performed in conventional three-necked flasks equipped with gas inlet, reflux condenser and oil check valve. Analytically pure heptane, benzene, toluene or methanol were used as solvents, under dry nitrogen atmosphere. The reaction mixtures, filtered under N_2, were brought to small volume under reduced pressure and purified by means of preparative TLC plates (Kieselgel PF, Merck; eluants light petroleum 40–70°C and diethyl ether in variable v/v proportions according to the alkyne substituents). The products collected were crystallized, where possible, from heptane, heptane/$CHCl_3$, heptane/toluene or hexane/CH_2Cl_2 mixtures kept at low temperature for several days.

The products were analyzed by means of an F & M, C, H, N analyzer and a Perkin–Elmer AAS; some analyses were performed by F. Pascher Laboratories (Bonn, Germany). Satisfactory elemental analyses were obtained for all the complexes. The IR spectra were registered on a Perkin–Elmer 580 instrument using heptane or cyclohexane as solvent. The ^1H, $^{31}P\{^1H\}$ and $^{13}C\{^1H\}$ NMR data were collected on JEOL JNM 270/89 and EX 400 instruments and, unless otherwise specified, the spectra were run at room temperature, using $CDCl_3$ as solvent [11]. The EI and CI mass spectra were recorded with a Finnigan-Mat TSQ-700 mass spectrometer (Servizio di Spettrometria di Massa, Dipartimento di Scienza e Tecnologia del Farmaco, Università di Torino).

Reaction of $Ru_3(CO)_{12}$ with propargyl alcohols and related ligands, in hydrocarbon solvents

Complexes $HRu_3(CO)_9\{C_2Me(OH)R\}$ (R = Me, **1b**; R = Ph, **1d**; R = Et, **1e**) were obtained as previously reported [12,13] in 8%, 45% and 18% yields respectively.

Reaction with 2-diphenyl-1-propyn-2-ol $\{HC_2CPh_2(OH)\}$. A suspension of 400 mg (0.63 mmol) of $Ru_3(CO)_{12}$ and 700 mg (3.36 mmol) of ligand was heated at reflux in toluene for 4 min. A clear brown solution was obtained; TLC purification showed the presence of $Ru_3(CO)_{12}$ (5 mg, 1%), complex **1c** (100 mg, 21%), an orange product (complex **1c'**, 20 mg [15]) and decomposition. The reaction was repeated in refluxing benzene (10 min) with the same substrate/cluster ratio leading to an increase in the yield of **1c** to 200 mg (45%).

Complex **1c**. IR (ν_{CO}): 2101 w, 2075 s, 2055 s, 2025 vs, 1991 m, cm^{-1}. ^1H NMR [14]. ^{13}C NMR: (−40°C): 80.0, 105.9, 125.1, 127.6, 128.4, 145.7, 169.3, 186.6 s, 188.5 s, 192.8 s, 196.8 s, 199.1 s. EI mass spectrum. $P^+ = 768$ *m/z*, loss of 9 carbonyls and corresponding doubly charged ions.

Reaction with 3-methyl-1-hexyn-3-ol, $\{HC_2CMe(OH)Pr^n\}$. To a toluene suspension of 400 mg (0.63 mmol) of $Ru_3(CO)_{12}$ was added 1.0 cm^3 (6.4 mmol ca) of liquid alkyne and the mixture heated at reflux for 2 min. The orange-yellow solution was purified by TLC; small amounts of unreacted parent carbonyl, complex **1f** (80 mg, 20%), and considerable decomposition products were obtained.

Complex **1f**. IR: 2100 m, 2074 vs, 2058 vs, 2026 vs (b), 1991 m–s (b), cm^{-1}. ^1H NMR: 1.91 m (CH_2, Pr^n); 1.68 s (OH); 1.65 s (Me); 1.55 m (CH_2, Pr^n); 1.00 t (CH_3, Pr^n); −20.87 s (hydride). EI mass spectrum: P^+ 670 *m/z*, loss of 9 carbonyls.

Reaction with 1-pentyn-3-ol, $\{HC_2C(H)(OH)Et\}$. Treatment of a toluene solution of 0.5 g (0.79 mmol) of $Ru_3(CO)_{12}$ with 1.0 cm^3 (ca 9.5 mmol) of liquid alkyne and heating of the mixture at reflux for 5 min, gave a yellow-brown suspension; TLC showed the presence of a yellow (**Bg**) and a whitish-yellow (**Ag'**, ca 20%) product along with a red residue (ca 70%) [15].

Reaction with 3-methyl-1-butyne, $\{HC_2CMe_2H\}$. To a toluene suspension of 400 mg (0.63 mmol) of $Ru_3(CO)_{12}$ was added 0.6 cm^3 (ca 7.3 mmol) of liquid alkyne and the mixture heated at reflux for 2 min; after TLC purification. complex **1h** (60 mg, 15%) and several decomposition products were isolated.

Complex **1h**. IR: 2099 m, 2082 s, 2076 s, 2050 vs, 2024–2010 vs (b), 1994 m, cm^{-1}. ^1H NMR: 2.91 m (C—H), 1.12 d (CH_3), −20.95 s (hydride). EI mass spectrum: P^- 626 *m/z*, loss of 9 carbonyls.

Reaction with $\{HC_2C(=CH_2)CH_3\}$ [*isopropenylacetylene*]. A suspension of 400 mg of $Ru_3(CO)_{12}$ (0.62 mmol) and 0.5 cm^3 of alkyne (ca 7.6 mmol) in toluene was heated at reflux for 4 min. TLC separation showed the presence of yellow $HRu_3(CO)_9\{C_2C(=CH_2)CH_3\}$ (**1j**) (85 mg, 21%), orange-yellow $Ru_2(CO)_6L_2$ (**Aj**) (ca 20%) and orange $Ru_3(CO)_8L_2$ (**Cj**) [15].

Complex **1j**. ^1H NMR. [11] EI mass spectrum: P^+ 624 *m/z*, loss of 9 carbonyls.

Reaction of $Ru_3(CO)_{12}$ *with* $HC_2CR(OH)R'$ (R = R′ = Me; R = Me, R′ = Ph) *in* MeOH/KOH *solution*

To a methanolic solution (100 cm^3) of $Ru_3(CO)_{12}$ (200 mg; 0.32 mmol) was added 40 cm^3 of aqueous 1 M KOH solution and the mixture stirred until all of the ruthenium carbonyl was dissolved. A methanolic solution (15 cm^3) of either $HC_2Me(OH)Ph$ (462 mg; 3.20 mmol) or $HC_2CMe_2(OH)$ (2.5 cm^3; 28.5 mmol) was added to the mixture and the whole stirred for 2.5 h. After this time the solution was acidified by addition of H_2SO_4, the mixture filtered and the solid and liquid phases extracted separately with $CHCl_3$. Combination of the two fractions followed by TLC purification, eluting with pentane, led to isolation of yellow $HRu_3(CO)_9\{HC_2C(Me)Ph\}$ (**2c**), in 20% yield, or $HRu_3(CO)_9\{HC_2C(Me)Me\}$ (**2b**), in 35% yield respectively.

Complex **2c**. IR: 2094 m, 2083 s, 2065 s, 2060 m, 2053 w, 2043 s, 2038 w, 2028 s, 2021 s, 2010 s, 2001 m, 1991 m, 1989 m–sh, cm^{-1}. ^1H NMR: major isomer (−40°C), 8.45 s (1H, J = 1.86 Hz), 7.85–7.20 m (Ph), 2.22 s (Me); −20.20 s (hydride, J = 1.86 Hz). Minor isomer (−40°C); 8.57 s (1H); 7.85–7.20 m (Ph); 2.63 s (Me); −20.20 s (hydride).

Complex **2b**. IR: 2094.2 m, 2085.1 m, 2070.1 s, 2066.8 s, 2052.7 s, 2042.3 s, 2017.0 s, 2008.6 s, 2001.0 s, 1990.7 m, 1985.7 m–sh, cm^{-1}. ^1H NMR (CD_2CL_2) (−40°C); 8.13 d (1H, J = 1.86 Hz); 2.13 s (Me); 1.82 s (Me); −20.52 d (1H, J = 1.86 Hz).

Protonation, dehydration and hydration reactions in solution or on TLC plates

The protonation reactions of complexes **1b, 1c,** and **1d** were followed by NMR; these reactions were carried out via dropwise addition of concentrated H_2SO_4 (96%) to a $CDCl_3$ solution of the complex in a NMR tube. In some instances CF_3COOH was used [13] instead of sulphuric acid. The reactions were followed as a function of either time or concentration of H_2SO_4 and the yields of the products were evaluated by integration of the relevant NMR signals. Where possible, the nature of the products was confirmed by synthesizing them independently (e.g. complex **1j**). In some instances, the protonation reactions were performed in normal reaction vessels in order to isolate the products.

Protonation of $HRu_3(CO)_9\{C_2CMe_2(OH)\}$ (**1b**). Addition of three drops of H_2SO_4 resulted (after 10 min) in formation of the dehydration product $HRu_3(CO)_9\{C_2C(=CH_2)Me\}$ (**1j**) in 10% yield. The yield of **1j** was seen to increase slowly to a maximum of about 25% after 30 min. On leaving the mixture to stand for 12 h, however, total decomposition of the complex was found to have occurred.

Protonation of $HRu_3(CO)_9\{C_2CMe(OH)Ph\}$ (**1d**). Addition of 3 drops of H_2SO_4 resulted in the immediate formation of $HRu_3(CO)_9\{C_2C(=CH_2)Ph\}$ in 10% yield. After 20 min the yield reached ca 80% and after 30 min the reaction was nearly complete. It is worthy of note that, after 30 min, a hydridic signal at δ −11.3 (the intensity of which remained constant throughout the reaction) was observed; this may be due to the presence of $Ru_3(H)(OH)(C{=}C{=}C(Me)Ph)$ in the solution [16]. After protonation, TLC purification showed the presence of a yellow band which was collected and characterized as $HRu_3(CO)_9\{C_2(=CH_2)Ph\}$ (**1k**) [13].

Protonation of $HRu_3(CO)_9\{C_2CPh_2(OH)\}$ (**1c**). Addition of 50 μl of H_2SO_4 resulted in formation of a small amount (about 15%) of the corresponding dehydration product $Ru_3(H)(OH)(CO)_9(C{=}C{=}CPh_2)$ [16] (suggested by a decrease in the intensity of the OH signal at δ 2.64 and appearance of a hydridic signal at δ −11.37); no increase in the yield was noted after 15 min. Addition of a further 50 μl of acid resulted in the immediate formation of the allenylidene $Ru_3(H)(OH)(CO)_9(C{=}C{=}CPh_2)$ in 100% yield. Further addition of 50 μl of acid resulted in decomposition (gradual disappearance of the hydridic signal).

Dehydration—hydration reactions on TLC plates. These reactions are skimpily described in Ref. [17].

Synthesis and reactivity of $HRu_3(CO)_7(dppm)\{C_2CMe(OH)Ph\}$ (**3**) *and related compounds*

Reaction of $HRu_3(CO)_9[C_2Me(OH)Ph]$ *with dppm and* $Me_3NO\cdot 2H_2O$. $Ru_3(CO)_{12}$ (200 mg, 0.29 mmol), dppm (0.30 g, 0.78 mmol) and $Me_2NO\cdot 2H_2O$ (a few crystals) were dissolved in toluene (100 cm^3) and heated at reflux for 1 min during which time a colour change from yellow to red was observed. TLC, eluting with diethyl ether: petroleum ether (1:5), showed the presence of two bands; the first, yellow, provided $HRu_3(CO)_7(dppm)\{C_2C(Me)(Ph)OH\}$ (**3**) (70 mg, 24%, yellow crystals) and the second, red, provided an orange powder (70 mg), tentatively identified as $HRu_3(CO)_5(dppm)_2\{C_2CMe(OH)Ph\}$ (**D**).

Complex **3**. IR: 2064 vs, 2011 vs, 1995 vs, 1980 m, 1960 m, cm^{-1}.

^1H NMR ($CDCl_3$, −40°C): 8.21–6.47 m (Ph); 4.43 q (CH^a, J = 14 Hz); 4.29 q ($CH^{a'}$, J = 14 Hz); 3.41 q (CH^b, J = 14 Hz); 3.32 q ($CH^{b'}$, J = 14 Hz); 1.77 s (OH); 1.73 s (Me); −19.92 d (μ-H, J = 35 Hz); −20.04 d (μ-H, J = 35 Hz).

^{31}P NMR ($CDCl_3$, 0°C): 36.22 d (P^a, J = 53 Hz); 35.74 d ($P^{a'}$, J = 55 Hz); 30.27 d (P^b, J = 52 Hz); 29.60 d ($P^{b'}$, J = 52 Hz).

^{13}C NMR ($CDCl_3$, −20°C): 188.36 dd (d^1,$d^{1'}$); 191.45 d (d,d^1); 198.03 dd (a^1,$a^{1'}$); 199.00 dd (a,a′); 201 s (c,c′); 206.7 t (b,b′) [18].

Complex **D**. IR: 2061 m, 2052 m, 1998 s, 1975 m, cm^{-1}.

^1H NMR (−40°C): 7.84–6.09 m (Ph); 4.40 q

(CH_2), 3.35 q, 3.18 q (CH_2); 3.25 s (OH); 1.23 s (CH_3); −19.8/−20.5 dd (hydride).

^{31}P NMR (−40°C): 33.26, 33.01, 32.74, 32.48 q (J = 39.7, 44.2, 41.8); 19.91, 19.67 d (J = 39.7), 19.57, 19.33 d (J = 35.7) 24.67, 24.13 d (J = 86.9), 24.03, 23.68 q (J = 66.5).

Reaction of $Ru_3(CO)_{10}$(dppm) *with* $HC_2CMe(OH)Ph$ *in hydrocarbons.* A toluene solution (75 cm^3) of $Ru_3(CO)_{10}$(dppm) [19] (200 mg, 0.21 mmol) and $HC_2CMe(OH)Ph$ (120 mg, 0.82 mmol) was heated at reflux for 3 min: no colour change of the solution was observed. TLC purification, eluting with 50% diethyl ether, allowed the isolation of an orange band which ^1H NMR spectroscopy showed to be the starting complex.

Protonation of $HRu_3(CO)_7$(dppm){$C_2CMe(OH)Ph$} (**3**). Treatment of a $CDCl_3$ solution of complex **3** with 3 drops of H_2SO_4 led to formation of $HRu_3(CO)_7$(dppm){$C_2C(=CH_2)Ph$} (**4**). Purification of the complex was effected through chromatography on TLC plates, eluting with diethyl ether: petroleum ether (1 : 1) to give a yellow band (complex **4**).

Complex **4**. IR: 2007 s, 1983 s, 1975 s, 1945 s, 1932 s, 1889 w, cm^{-1}.

^1H NMR: 7.77–6.70 mm (Ph): 5.67 s (=CH_2); 4.37 q, 3.44 q (CH_2, dppm), 1.56 s (Me); −19.39, −19.47 d (hydride).

X-ray analyses of complexes **3** *and* **4**

Crystals of complex **3** were obtained by slow diffusion of hexane into a toluene solution of the complex. Crystals of complex **4** were formed through slow evaporation of dichloromethane at −20°C from a dichloromethane/hexane solution of the complex.

The data were collected on a Siemens P4 diffractometer using graphite-monochromated Mo–K_α radiation, in θ–2θ (complex **3**) and ω (complex **4**) scan mode, with a scan range of 2.2° (**3**) and 1.6° (**4**). The range of scan speed was 4–20° min^{-1}. Two standard reflections were measured every 50 reflections and they showed no decay. Cell constants were obtained from a least-squares refinement based on the setting angles of 35 reflections in the range $20° \leqslant 2\theta \leqslant 30°$. Empirical absorption corrections were performed for **3** and **4** according to the method of Ref. [20].

The structures were solved by direct methods and refined using the program SHELXTL PLUS (PC version 5.03).

Crystal data and refinement parameters are collected in Table 1.

The substitution of two equatorial CO groups by dppm on the two enantiomers of **1d,** deriving from the chiral alcohol, gives rise in complex **3** to a further asymmetry of the cluster and, consequently, to two pairs of enantiomers. During the refinement of complex **3** two diastereoisomers appeared superimposed in the asymmetric unit: they differ only in the chirality of the asymmetric C(10) and consequently in the orientation of its substituents. The two fragments corresponding to *R*- and *S*-C(10) were refined with occupancy factor 0.5. All non-hydrogen atoms, excluded those with occupancy factor 0.5, were anisotropically refined for both complexes.

The hydride atom was located for both complexes on the last Fourier difference maps and its refinement gave good results, obviously with high uncertainty; the other hydrogen atoms (except those of the OH groups which were not included, and those of C(11) of complex **4,** which were located on the experimental peaks) were calculated and refined according to the "riding" model, even if many of them appeared in the Fourier difference maps.

The weighting scheme was: $w = 1/[\sigma^2(F_o^2) + (0.0329 \cdot P)^2 + 1.30 \cdot P]$, $P = [\max(F_o^2) + 2F_c^2]/3$ for complex **3** and: $w = 1/[\sigma^2(F_o^2) + (0.0228 \cdot P)^2 + 2.27 \cdot P]$, $P = [\max(F_o^2) + 2F_c^2]/3$ for complex **4**. Tables of atomic coordinates and displacement parameters, lists of observed and calculated structure factors and complete lists of bond lengths and angles have been deposited with the Editor; atomic coordinates have been left with the Cambridge Crystallographic Data Centre.

RESULTS AND DISCUSSION

Synthesis of complexes $HRu_3(CO)_9${$C_2CR((OH)R'$} (**1**)

We obtained complexes **1** through a direct synthetic pathway consisting of oxidative addition of the propargyl ligands to $Ru_3(CO)_{12}$ as previously described for the range of alcohols $HC_2RR'(OH)$ [R = R′ = Me; R = Me, R′ = Et; R = Me, R′ = Ph) [13]; medium-low yields of complexes **1** were reported for M = Ru and higher yields for M = Os. For osmium it has also been shown that intact alcohols can coordinate first in a "parallel" fashion before undergoing oxidative addition to form complexes **1** [12].

Complexes **1** can also be obtained indirectly through C—C bond cleavage of diols to give complexes **1** and ketones [21]. Further, it has been shown that neither alkynes nor propargyl alcohols having hydrogen alpha to the alkyne C—C bond form complexes of type **1** [22] but instead lead to the formation of hydrido-allenyl or -allyl derivatives [23]. In accordance with this we have found during the course of our studies that no complexes of type **1** were isolated from reaction of $Ru_3(CO)_{12}$ with the series of alcohols $HC_2CR(OH)H$ (R = Me, Et, Ph). All of the complexes **1** reported or discussed in this paper are collected, along with their yields, in Table 2.

The yields of complexes **1a**–**1j** vary considerably according to the nature of the alkyne employed in the reaction and do not seem to bear any relation to the σ-Taft values. One general trend, however, is the increase in the yields of the complexes **1** when either

strong electron donor (i.e. those alkynes with highly positive σ-Taft values) or acceptor (i.e. those with highly negative σ-Taft values) ligands are present on the alkyne (although it should be noted that this rule does not apply to those alkynes having H alpha to the C≡C bond which, as mentioned above, do not give complexes of type **1**).

The ^{13}C NMR data for the acetylide units in complexes **1a**–**1j** (and related clusters) are presented in Table 3 [28–36]. The assignments are based on data in the literature [24–27].

In principle, the chemical shifts of the C_α and C_β should be affected directly by the electron donating ability of the acetylide substituents and the presence of substituents on the cluster frame.

Previously, it has been proposed that changes in the chemical shifts (δ) of the acetylide carbons may be associated with a change in their charges, although the observed chemical shifts are also dominated by paramagnetic terms of the screening constants. Further, it was suggested that the sum $\delta(C_\alpha) + \delta(C_\beta)$ ($\Delta+$) reflects any charge changes in the triple bond, while the difference $\delta(C_\alpha) - \delta(C_\beta)$ ($\Delta-$) can be used as a measure of the charge polarization in the triple bond [27].

For complexes **1** the $\Delta+$ and $\Delta-$ values show only slight differences from each other and are not sensibly affected by either different acetylide substituents or substitution of other ligands for CO, thus suggesting considerable "electronic rigidity" of the cluster frames. However, some small but regular trends can be discerned. For example, when metal fragments replace the bridging hydride group or when COs are substituted by Group XV donor ligands (in particular arsine and stibine) the $\Delta+$ values are always greater than that of $HRu_3(CO)_9(C_2Bu^t)$ (**1a**, arbitrarily taken as a reference) [8]. Further, the $\Delta-$ values are greater for the propargyl alcohols derivatives than for com-

plex **1a**; in particular, complexes **1c** and **1d** bearing phenyl groups give rise to higher values of $\Delta-$ than the other propargyl alcohols.

Protonation (dehydration) and attempted hydration reactions of complexes **1**

The behaviour observed for propargyl alcohols at an $M_3(CO)_{12}$ [M = Ru, Os] centre contrasts strongly with that seen at a tri-iron centre. The reactions of $Fe_3(CO)_{12}$ lead not to complexes of type **1** but, instead, facile dehydration of the ligands occurs in one or two different ways. The first requires the loss of the alcoholic OH and of a hydrogen from a methyl group on the same carbon atom, leading to a vinylacetylide or "ene-yne" ligand (route A). The second process (route B) requires loss of the OH and of the terminal alkynic hydrogen thus forming allenylidene derivatives. These two routes may occur competitively [37].

In addition, for the alkyne $HC_2CMe(OH)Ph$ "deoxygenation" of the ligand has also been observed [38]. Examples of routes A and B are given in Fig. 1a.

Propargyl alcohols do not readily undergo dehydration at an Ru_3 centre, the process only being effected under harsh reaction conditions (e.g. protonation with strong acids as discussed below). Some protonation reactions, using CF_3COOH, have been reported. For example, complexes **1d** and **1e** form eneyne ligands via "route A" [13] in yields of 20 and 55% respectively. In contrast, protonation of $HM_3(CO)_9\{C_2CPh_2(OH)\}$ allowed isolation (in the case of M = Os) of the allenylidene species $HM_3(CO)_9(OH)(C{=}C{=}CPh_2)$ which was proposed to be an intermediate in the dehydration of the parent complex via route B (see Fig. 1b). In the case of M = Ru, the corresponding allenylidene species could not be isolated but was intimated by the presence of signals in the ^1H NMR spectrum at 7.5 (10 H, m) and −11.27 (1H, s) ppm [16].

In this context it is interesting to note that reaction of ROH with $Cp^*WRe_2(CO)_9[C_2C(=CH_2)Me]$, containing a cluster bound isopropenyl-acetylide, has been shown to lead to the allenylidene complex $Cp^*WRe_2(CO)_8(\mu\text{-OMe})$ $(C{=}C{=}CMe_2)$ bearing a μ-OR moiety on an open cluster edge [39].

The protonation reactions described below were followed using ^1H NMR spectroscopic techniques varying either the reaction time or amount of acid added (see experimental section for details). The ^1H NMR data for the parent complexes and the dehydration products are presented in Table 4 together with the yields of the products (deduced through integration of the ^1H NMR resonances).

For complexes **1d** and **1c** when the concentration on acid was kept constant the yields of the protonated products increased steadily with time until the reaction was complete. In both cases, however, leaving the acidified solutions to stand at room temperature overnight resulted in decomposition of the products. Interestingly, for complex **1b** the yield was seen to reach a maximum of 25% after 30 min and then gradually decrease as the product started to decompose.

For each of the complexes **1b, 1c,** and **1d** the product yields were found to increase when the amount of acid used was increased. This observation is in accordance with the protonation mechanisms reported for surface reactions which are thought to proceed via direct attack of H^+ at the OH site of the alcohol [40].

There are several literature reports on the effect of supports in promoting hydration/dehydration reactions [41]. In particular, splitting and addition of

water [42] or of methanol [43] to ene-yne or allenylidene tri-iron derivatives occurs very easily on TLC silica.

In stark contrast to the above, the behaviour of complex **1d** on TLC silica plates indicates that the inorganic oxide has a very low hydration activity. Thus, adsorption of complex **1d** onto a TLC silica plate and heating in oven at 100°C for 15 min produced only trace amounts of the corresponding dehydration product $HRu_3(CO)_9[C_2C(=CH_2)Ph]$. Further, the failure of complex **1j** to react with "wet" TLC plates at room temperature, or a silica/water slurry at 55°C (see Ref. [17]) suggests that hydration of these complexes does not occur easily on silica. Hydration of **1j** to give $HRu_3(CO)_9(C_2CMe_2OH)$ (**1b**) was only effected under harsh reaction conditions (i.e. addition of acid to a chloroform solution of the complex followed by addition of water) and in low yield (< 10%).

In general, it would appear that dehydration of complexes **1** containing a methyl substituent on the same carbon as the OH unit leads to formation of the corresponding ene-yne product. However, during the protonation reactions described above, resonances in the ^{1}H NMR spectra were observed at about −11 ppm suggesting, perhaps, the formation of allenylidene products in minor yields (cf the hydride resonance seen for $HRu_3(CO)_9(OH)(C=C=CPh_2)$ at −11.27 ppm) [16]. Relationships between ene-ynes and allenylidene ligands have been demonstrated for dimolybdenum complexes [44]. In addition, as previously discussed, $Os_3(CO)_9(\mu$-CO)(HC≡CCMe$_2$OH) (containing a "parallel" alkyne unit) can either undergo oxidative addition forming complexes of type **1**, or can be protonated using CF_3COOH to form $HOs_3(CO)_9[C_2C(=CH_2)Me]$ via an allenylidene intermediate [12].

A summary of the synthetic pathways to complexes **1** and of the dehydration (rehydration) reactions is given in Scheme 1 below.

Most complexes of type **1** show fluxional behaviour of the carbonyls at room temperature [45]. Complex **1d** is no exception, however, a discussion of its fluxionality will be presented in a future publication.

Synthesis of complexes $HRu_3(CO)_9[HC_2C(Me)R]$ (**2**)

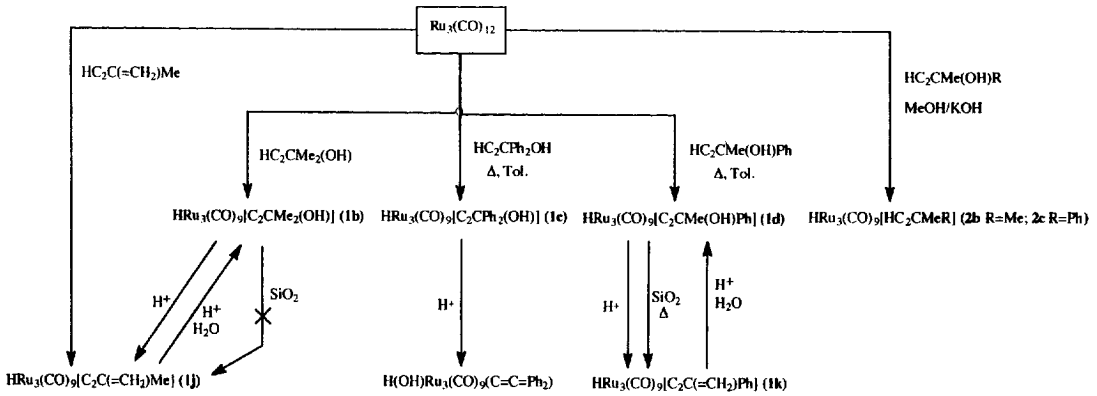
While reaction of $Ru_3(CO)_{12}$ with the propargyl alcohols $HC_2C(Me)_2OH$ and $HC_2C(Me)(OH)Ph$, in hydrocarbon solvents, led to formation of the corresponding alkylidine species $HRu_3(CO)_9[C_2C(Me)(OH)R]$ (**1b** R = Me, **1d** R = Ph), reaction of $Ru_3(CO)_{12}$ with the same alcohols in MeOH/KOH solution gave instead the allenylidene complexes $HRu_3(CO)_9[HC_2CMe_2]$ (**2b**) and $HRu_3(CO)_9[HC_2C(Me)(Ph)]$ (**2c**).

Characterization of the new complexes was relatively straightforward through comparison of the ^{1}H NMR and IR spectroscopic data with those of the directly analogous species $HRu_3(CO)_9[MeC_2CMe_2]$ [46] and $HRu_3(CO)_9[(C_2H_5)C_2C(Me)H]$ [23a].

The mechanism of the reaction is unclear. However, in keeping with the results seen earlier for the protonation of complexes **1b, 1d** etc, it may be that the loss of the OH group from the propargyl alcohol moiety is effected during acidification of the reaction mixture by addition of H_2SO_4 (see experimental section). A tempting alterative hypothesis (suggested by referees) could be the following; it is known that, under basic conditions, $Ru_3(CO)_{12}$ gives as the main product the anion $[HRu_3(CO)_{11}]^-$ [47]. This could react with the alkynes to form the allenyl complexes eventually via $H(\mu$-OH)$Ru_3(CO)_9$(allene) intermediates.

^{1}H NMR fluxionality of complexes **2**

The low temperature limiting ^{1}H NMR spectrum of **2b**, recorded at −40°C, shows two sharp resonances for the inequivalent methyl groups of the allenylidene ligand (see Fig. 2). At room temperature, however, the signals have started to broaden and col-



Scheme 1

lapse into the baseline indicating that some fluxional process is occurring.

Variable temperature ^1H and ^{13}C NMR studies have been carried out by Aime *et al.* [46] into the fluxionality of the related species $HRu_3(CO)_9[MeC_2CMe_2]$ and $HOs_3(CO)_9[MeC_2CMe_2]$ which both show identical behaviour in the ^1H NMR spectrum to complex **2b**. They proposed a mechanism for the fluxional process (see Fig. 2) in which the hydride migrates from the Ru(1)—Ru(2) edge to the Ru(1)—Ru(3) edge while the allenylidene unit undergoes a "wagging" motion, pivoting about the C(2) carbon, allowing the two methyl groups attached to C(3) to be seen as a single sharp resonance in the ^1H NMR spectrum at higher temperatures.

Interestingly, the ^1H NMR spectrum of complex **2c** at $-40°C$ shows it to exist as a mixture of two isomers in a ratio of ca 3 : 1. The fact that the same is not true for complex **2b** suggests that the isomerism is due to the presence of two different groups (methyl and phenyl) on the C(3) carbon of the allenylidene ligand and that the isomers differ only in the orientation of these two substituents (see below).

If this is the case then the fluxional process described above should allow interconversion between the two isomers to occur and, indeed, ^1H NMR spectrum of **2c** at room temperature shows broadening of the signals for the unique proton, the methyl and the hydride groups of each isomer (see Fig. 2).

Synthesis of $HRu_3(CO)_7(dppm)\{C_2C(Me)(OH)Ph\}$ **(3)**

It is perhaps surprising to note that substitution of cluster carbonyls on complex **1d** for dppm occurs under thermal conditions, without loss of water or re-orientation of the acetylide unit, to give $HRu_3(CO)_7(dppm)\{C_2C(Me)(OH)Ph\}$ **(1)** (see Scheme 2).

Re-orientation of alkynes on addition or removal of carbonyls from a complex has been observed in the past. For example, Lavigne and co-workers have shown that the complex $Ru_3(CO)_7(\mu\text{-}CO)(dppm)\{C_2Ph_2\}$, having an alkyne bound in a parallel fashion, loses CO reversibly to yield the perpendicular bound alkyne complex $Ru_3(CO)_7(dppm)\{C_2Ph_2\}$ [48]. Further, Smith *et al.*, have synthesized the complex $Os_3(CO)_7(dppm)\{C_2Ph_2\}$, having a perpendicular alkyne, which can also undergo reversible addition of CO resulting in a parallel arrangement of the alkyne on the complex [49].

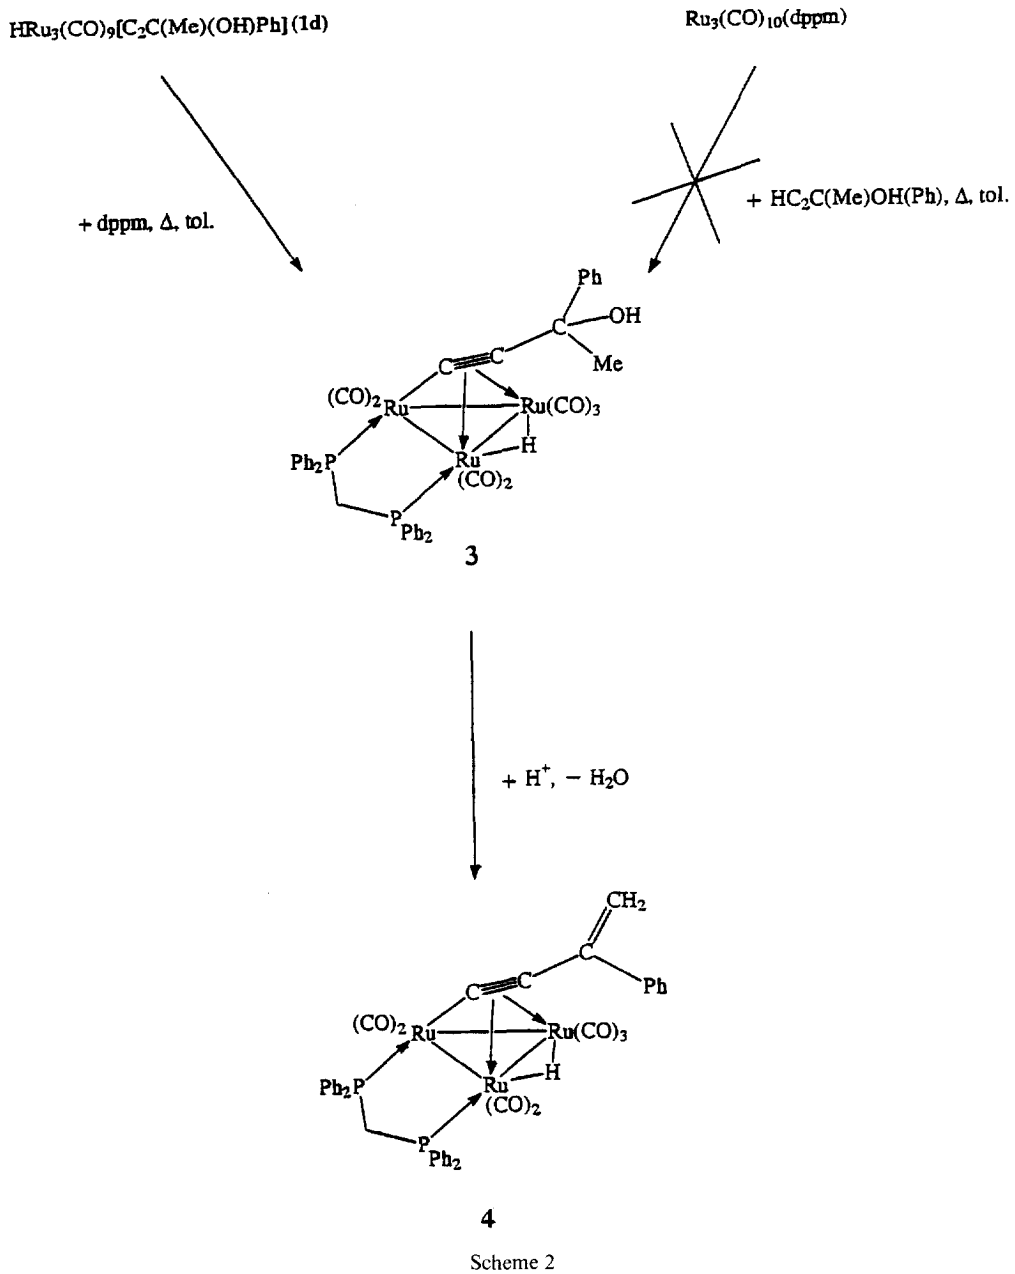
Interestingly, attempts at preparing complex **3** from reaction of $Ru_3(CO)_{10}(dppm)$ with $HC_2CMe(OH)Ph$ were unsuccessful; it may be that the already coordinated dppm does not favour oxidative addition of the alkyne. The structure of complex **3** has been determined by X-ray crystallography and is discussed later.

Protonation of complex **3**. Complex **3** has been protonated following the same procedure used for complexes **1**. Loss of water, via route A, to give $HRu_3(CO)_7(dppm)\{C_2C(=CH_2)Ph\}$ **(4)** was observed but no other major structural changes could be detected. The solid state structure of **4** has also been obtained through a single crystal X-ray analysis and is discussed in the following section along with that of complex **3**.

X-ray structures of $HRu_3(CO)_7(dppm)\{C_2C(Me)(OH)Ph\}$ **(3)** *and* $HRu_3(CO)_7(dppm)\{C_2C(=CH_2)Ph\}$ **(4)**

The structures of two superimposed diastereoisomers of complex **3** and the structure of complex **4** are shown in Figs 3 and 4 respectively. Relevant bond lengths and angles are reported in Table 5.

The framework of both clusters **3** and **4** consist of a triangle of ruthenium atoms, with Ru(1) and Ru(2) coordinated to two carbonyl groups and Ru(3) to three carbonyl groups. The Ru(1)—Ru(2) edge of the cluster is bridged by a dppm ligand held in an equatorial position and tilted towards the acetylide ligand, the angle between the Ru_3 and the Ru(1)P(1)P(2)Ru(2) planes being 15° **(3)** and 17° **(4)**, while



Scheme 2

the methylene group of the dppm molecule is out of the plane. A bridging hydride spans the Ru(2)—Ru(3) edge and is in a niche formed by the carbonyl groups (having a mean distance of 2.49 Å from the C atoms for both compounds). The hydride lies in the plane formed by the atoms C(3)C(4)C(5) and C(7) (having a mean deviation from the plane of 0.056 Å (**3**) and 0.038 Å (**4**)) but at an angle of 39° (**3**) and 38° (**4**) from the Ru_3 plane. The presence of the hydride atom causes a great tilt of the CO(6) group trans to it (26° with respect to the Ru_3 plane as opposed to the 0–14° range for the other equatorial CO groups); this arrangement of carbonyls leads to an octahedral coordination about Ru(2) and Ru(3) (if the Ru(2)—Ru(3) bond is not taken into account).

The acetylide is coordinated in a "perpendicular" fashion to all three metal atoms and is positioned across the Ru(2)—Ru(3) edge.

For complex **3** it is noteworthy that, in the solid state, two pairs of enantiomers (A/C and B/D) can be detected (see Scheme 5). These differ in orientation of the acetylide ligand with respect to the dppm unit (e.g.

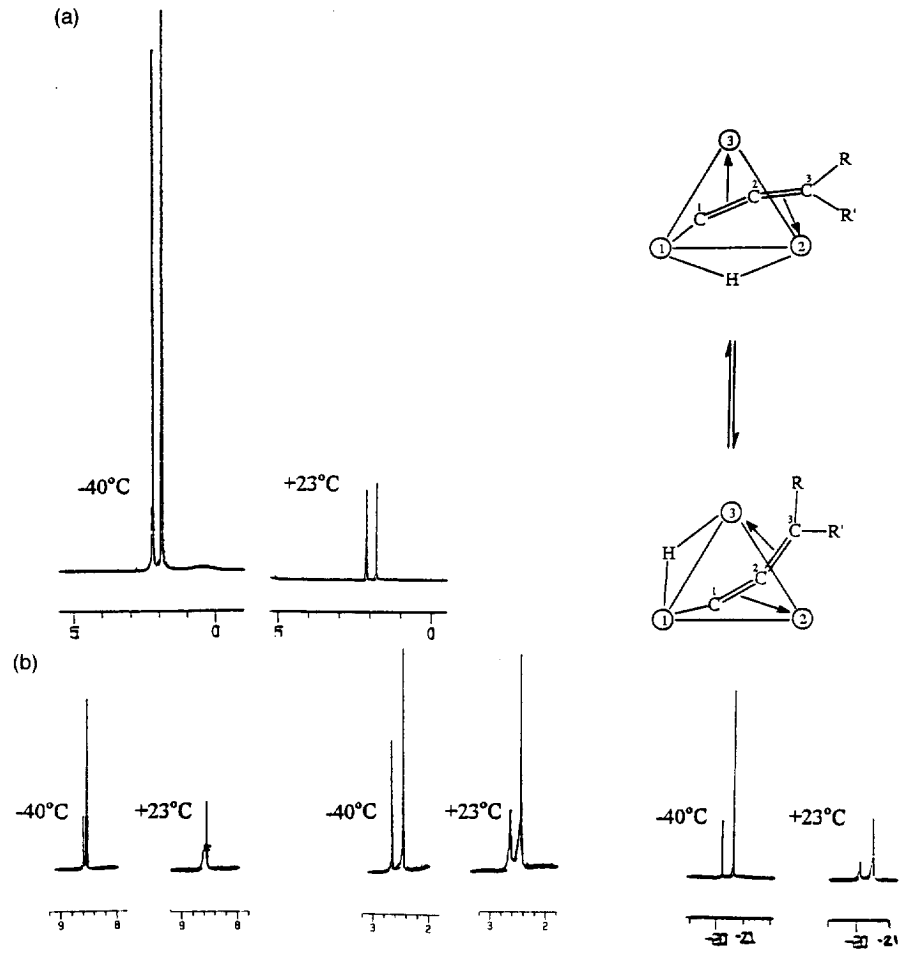


Fig. 2. (a) Variable temperature ^1H NMR spectra of $HRu_3(CO)_9(HC_2CMe_2)$ (**2b**) in CD_2Cl_2 solution; methyl region only; (b) Variable temperature ^1H NMR spectra of $HRu_3(CO)_9(HC_2CMe(Ph))$ (**2c**) in $CDCl_3$ solution; HC=C, methyl and hydride regions only.

pairs A/D and C/B) and in the chirality of C(10) (e.g. pairs A/B and C/D).

It appears that the phenyl group is always held away from the dppm ligand, presumably for steric reasons.

The complex $HRu_3(CO)_7(dppm)\{C_2Bu^t\}$ (**3a**) has been studied previously [35] using X-ray crystallography and has a structure similar to that of **3**. The main difference between **3** and **3a** stems from the fact that, whereas, complex **3a** exists as a mixture of two enantiomers due to the chirality induced on the metal frame by the dppm substitution, complex **3** contains, in addition, a chiral ligand giving rise to two pairs of enantiomers (four diastereoisomers).

Like complexes **3** and **4**, the t-butyl species **3a** has found to have the dppm bound in an equatorial manner to the cluster and so it seems likely that this is the arrangement most favoured for complexes of type **1**. This contrasts with the behaviour seen for dppe and other chelating ligands which may also give axial and/or chelated derivatives [36] but agrees well with the fact that these types of complexes have not previously been isolated from reaction of dppm with triruthenium acetylide derivatives [35,48].

Some important bonding parameters for the clusters **1a, 1k, 3, 3a, 4** and the chelate derivative $HRu_3(CO)_7(bpcd)\{C_2Bu^t\}$ (**3b**) (bpcd = 4,5-bis(diphenylphosphino)-4-cyclopenten-1,3-dione) [50], are presented in Table 6 below.

From the data listed in Table 6, one can see that the dppm substitution has no effect on the mean cluster dimensions; as expected, the Ru(1)—C(8) σ-bond is always significantly shorter than the other Ru-acetylide bonds. A close inspection of the data of Table 6 shows that the majority of the differences are within the e.s.d. values, thus rendering them insignificant. It seems, therefore, that the Ru_3C_2 core of the alkylidene clusters is "rigid" *vis-a-vis* substitution of dppm for CO; this agrees well with the ^{13}C NMR and σ-Taft data discussed earlier for these types of complexes.

Scheme 3

Fluxionality of complexes **3** *and* **4**

Complex **3** can exist as a mixture of two enantiomers due to the chirality of the cluster induced by the dppm group. In addition, the presence of a chiral centre on the acetylide unit allows each of the enantiomers to exist as two diastereoisomers having either an *R*- or *S*-configuration of the ligand chiral centre. These two centres of chirality on the cluster give rise to two sets of signals on the NMR spectra, each set corresponding to one of the two enantiomeric pairs of isomers. Thus, in the low temperature limiting ^{1}H NMR spectrum of **3** signals are observed in the hydride region at δ −19.31 (d, μ-H) and −19.35 (d, μ-H′) and in the methylene region at δ 3.41 (q, CH^a) and 4.43 (q, CH^b) and δ 3.32 (q, Ch$^{a'}$) and 4.29 (q, CH$^{b'}$) (see Fig. 5). This is in contrast with the analogous complex $HRu_3(CO)_7(dppm)\{C_2Bu^t\}$ (**3a**) which possesses only one centre of chirality (that on the cluster) and shows only one set of resonances in the ^{1}H NMR spectrum (i.e. having a doublet for the hydride group and two quartets corresponding to the inequivalent protons of the methylene group). Similarly, in the ^{31}P NMR spectrum of **3**, recorded at 0°C, four AB type resonances (corresponding to P^a, P$^{a'}$, P^b and P$^{b'}$) are seen as opposed to the two AB type resonances that were observed for complex **3a** at this temperature.

Variable temperature NMR studies on complex **3a** have shown it to undergo a fluxional process at higher temperatures [35]. The same process is found to occur for complex **3** and is best described as "rotation of the propargyl alcohol moiety concurrent with hydride migration" and leads to equivalence of P^a and P^b and Ru_1 and Ru_2, and so loss of the dppm induced chirality of the cluster (see Scheme 6).

Thus, in the hydride region of the ^{1}H NMR, as the temperature is increased from −80°C, the two

Scheme 6

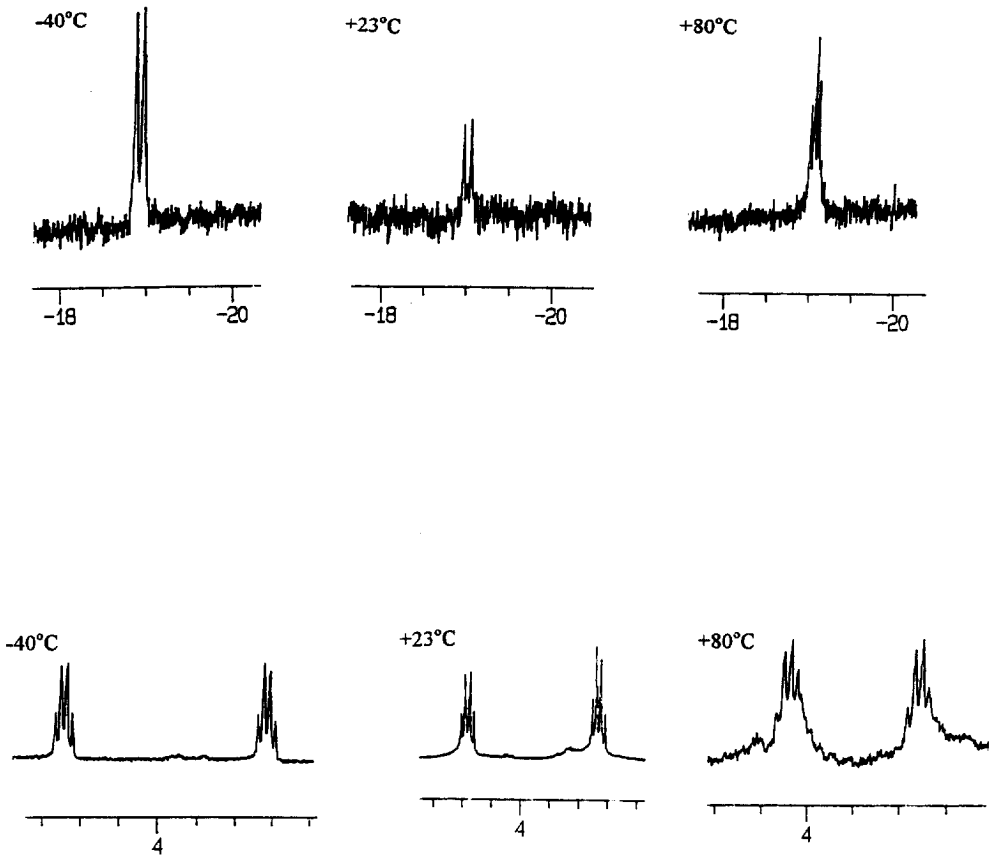

Fig. 6. Variable temperature ^{1}H NMR spectra of $HRu_3(CO)_7(dppm)(C_2C(=CH_2)Ph)$ (**4**) in d^8-toluene; methylene and hydride regions only.

doublets start to merge together as the chirality of the cluster is lost. At 40°C the remaining doublet has started to collapse into the baseline until at 80°C a triplet is observed corresponding to the A_2X system expected when rapid interconversion of the isomers is occurring on the NMR timescale.

Interestingly, for the methylene protons of the dppm ligand warming the solution leads to coalescence of the signals due to protons H^a and $H^{a'}$ and H^b and $H^{b'}$ until at 80°C two quartets are observed for the inequivalent protons H^a and H^b. That the fluxional process does not lead to equivalence of protons H^a and H^b confirms that the dppm ligand stays rigidly anchored to the Ru^1—Ru^2 edge throughout.

As expected, in the ^{31}P NMR spectrum the resonances start to coalesce and collapse into the baseline on warming until, at 58°C, the two phosphorous atoms appear as one broad hump centred at about 27 ppm suggesting that they are becoming chemically equivalent. Unfortunately, a higher temperature spectrum was not obtained.

The same fluxional process as described above for complexes **3** and **3a** is also found to occur for complex **4**. However, as complex **4** was obtained through dehydration of the propargyl alcohol unit of **3** the chirality of the acetylide ligand is lost and so the variable temperature NMR data mirror exactly those of complex **3a**. Thus, in the low temperature limiting ^{1}H NMR spectrum (−80°C) the hydride proton is observed as a doublet at δ −20.25 and the methylene protons H^a and H^b as quartets at δ 4.37 and 3.32 respectively (see Fig. 6).

On raising the temperature the doublet for the hydride tends to a triplet (A_2X system at 80°C) while the resonances for the methylene protons remain unchanged suggesting, once again, that the dppm ligand remains rigid throughout the fluxional process.

Comparable behaviour to that discussed above for complex **3** has been reported for the complex $(CpCo)_3$(1,1-diphenylethane) $[HC(Ph)_2CH_3]$ where one phenyl group is coordinated facially to the trico-

14. Complex **1c′**: IR (ν_{CO}): 2096 m, 2057 s, 2032 s, 2014 w, 1866 m, cm^{-1}. ^1H NMR: δ 8.51 s, 7.83–7.16 mm (Ph); 6.30 s; 1.57 s; −21.12 s (hydride). EI MS: $P^+ = 768$ *m/z* loss of 9 CO and doubly charged ions [see **1c**]. Tentatively identified as $H_2Ru_3(CO)_9[HC_2C(OH)Ph_2]$, $P^+ = 770$ *m/z*.
15. "Side reactions" occurring during the synthesis of complexes **1** often lead to metallacyclic complexes of the general formula $Ru_2(CO)_6(alkyne)_2$ formed through coupling of two alkynes (complexes A) or of one intact and one dehydrated propargyl

alcohol (complexes B). Other metallacyclic products include those of general formula $Ru_3(CO)_8(alkyne)_2$ (complexes C). Spectroscopic data for complexes of type A, B, or C obtained during the course of this work are given below.

Complex **Bg**: ^1H NMR: δ 11.4 s (H—C), 7.40 s (C—H), 3.05 qq (CH_2), 1.58 s (CH_3/OH), 1.26 m (CH_3/OH), 0.99 m (OH). EI-MS: $P^+ = 522$ *m/z* $[Ru_2(CO)_6X_2–H_2O]$.

Complex **Ag**: IR: 2079 ms, 2048 vs, 1997 s (b), cm^{-1}. ^1H NMR: δ 6.87 d ($J = 3.49$), 6.62 d ($J = 2.8$) (external Hs); 4.53 d ($J = 4.9$), 4.07 d (internal Hs); 1.93 s, 1.89 s (OH), 1.80 qq, 1.01 tt (Et). ^{13}C NMR: δ 32.8 d (CH_3, CH_2): 74.5 s, 79.6 s (C—OH); 98.4 s, 134.5 s, 141.7 s, 178.6 s (Cs of metallacycle); 194.9, 195.6, 196.4, 196.6, 198.7 {3 non equivalent and 3 equivalent COs}. EI-MS: $P^+ = 540$ *m/z*, loss of six CO $[Ru_2(CO)_6X_2$, isomers?].

Complex **Aj**: IR: 2083 s, 2053 vs, 2013 vs, 1996 s, 1987 m–s, cm^{-1}. ^1H NMR: δ 6.24 s (2H), 4.87 s, 4.71 s (CH_2), 1.90 s (CH_3). EI-MS: P^+ *m/z* = 504, loss of 6 CO, then complex fragmentation.

Complex **Cj**: IR: 2062 m–s, 2024 vs, 2000 ms, 1976 m–s, 1881 m, cm^{-1}. ^1H NMR: δ 8.87 s, 7.01 s, 5.48 s, 5.21 m, 3.40 s, 2.45 s, 2.02 s (CH_3). EI-MS: P^+ *m.z* = 664, loss of 8 CO and correspondingly doubly charged ions.

17. A chloroform solution of **1d** was deposited on a dry TLC plate at room temperature and then heated at 100°C for 15 min, after which time a mixture of parent **1d** and of the dehydration product $HRu_3(CO)_9\{C_2C(=CH_2)Ph\}$ in a ratio of ca 60 : 1 was obtained. Chromatography of complex **1j** on wet TLC plates, resulted in unaltered **1j**. Complex **1j** was dissolved in hexane and a slurry of silica and D_2O added; the suspension was heated at 55°C for 1 h, after which time only starting **1j** was recovered. To a chloroform solution of **1j** four drops of H_2SO_4 was added, then water; after 30 min, small amounts of the hydration product **1b** were obtained.
18. Throughout the NMR data the "superscript" refers to the two possible (*R* and *S*) configurations of the chiral propargyl alcohol ligand, see results and discussion section.

(Received 8 November 1997: accepted 11 February 1998)

Abstract—The reaction between $[(PPh_3)_2N][Rh_2Ru_4(CO)_{16}B]$ and five-fold excess of PPh_3, followed by addition of Ph_3PAuCl leads to the formation of $[Rh_2Ru_4(CO)_{15}(PPh_3)B(AuPPh_3)]$ and $[Rh_2Ru_4(CO)_{14}(PPh_3)_2B(AuPPh_3)]$. Phosphorus-31 NMR spectroscopic data were in accord with substitution at the Rh centres; and X-ray diffraction study of $[Rh_2Ru_4(CO)_{14}(PPh_3)_2B(AuPPh_3)]$ showed that the Rh atoms occupied *cis*-sites in the octahedral Rh_2Ru_4-cage. The reaction between $[(PPh_3)_2N][Rh_2Ru_4(CO)_{16}B]$ and a five-fold excess of PPh_3, followed by addition of CF_3CO_2H yielded $[HRh_2Ru_4(CO)_{15}(PPh_3)B]$, $[HRh_2Ru_4(CO)_{14}(PPh_3)_2B]$ and $[HRh_2Ru_4(CO)_{13}(PPh_3)_3B]$, their formations being dependent on reaction conditions. Treatment of $[(PPh_3)_2N][Rh_2Ru_4(CO)_{16}B]$ and $P(OMe)_3$ (1 : 1) followed by Ph_3PAuCl leads to the formation of $[Rh_2Ru_4(CO)_{16}B(AuPPh_3)]$ (for which an X-ray structural determination has been carried out), $[Rh_2Ru_4(CO)_{15}\{P(OMe)_3\}B(AuPPh_3)]$ and $[Rh_2Ru_4(CO)_{14}\{P(OMe)_3\}_2B(AuPPh_3)]$. By altering the cluster : phosphite ratio to 1 : 3, the major product was $[Rh_2Ru_4(CO)_{13}\{P(OMe)_3\}_3B(AuPPh)_3)]$. The addition of CF_2CO_2H in place of Ph_3PAuCl to the crude products of the reaction between $[(PPh_3)_2N][Rh_2Ru_4(CO)_{16}B]$ and $P(OMe)_3$ promoted cleavage of the P—O bond and results in the formation of $[Rh_2Ru_4(CO)_{14}\{P(OMe)_3\}\{\mu\text{-}P(OMe)_2\}B]$ and $[Rh_2Ru_4(CO)_{13}\{P(OMe)_3\}_2\{\mu\text{-}P(OMe)_2\}B]$. Products have been characterized by IR and multi-nuclear NMR spectroscopies and mass spectrometry, and evidence for *cis-trans* isomerization of the Rh_2Ru_4-framework is presented. © 1998 Elsevier Science Ltd. Keywords: Boride; cluster.

We have recently reported the results of a study of the reactions of the homometallic boride cluster anion $[Ru_6(CO)_{17}B]^-$ with PPh_3 and $P(OMe)_3$ and the subsequent reactions of the phosphine or phosphite substituted products with sources of Ph_3PAu^+ or H^+ [1]. In the present paper, we describe a complementary study which focuses on the reactivity of the heterometallic cluster $[Rh_2Ru_4(CO)_{16}B]^-$. The metal cluster core of this anion exhibits two isomers in which the Rh atoms are either adjacent (*cis* isomer) or apart (*trans* isomer), the latter being the preferred species [2]. We were interested in investigating how replacement of CO for phosphine or phosphite ligands might influence this *cis-trans* isomer distribution, and how the reactivity behaviour of $[Rh_2Ru_4(CO)_{16}B]^-$ differed from that of $[Ru_6(CO)_{17}B]^-$; for example, we were unable to introduce more than one PPh_3 group into $[Ru_6(CO)_{17}B]^-$, and, whereas $[Ru_6(CO)_{16}(PPh_3)B]^-$ protonated on an Ru—Ru edge, treatment of $[Ru_6(CO)_{16}\{P(OMe)_3\}B]^-$ with acid resulted in the cleavage

of one methoxy group and the formation of $[Ru_6(CO)_{16}\{\mu\text{-}P(OMe)_2\}B]$ [1].

EXPERIMENTAL

General data

Fourier-transform NMR spectra were recorded on a Bruker WM 250 spectrometer; ^1H shifts are reported with respect of δ 0 for Me_4Si, ^{11}B NMR with respect to δ 0 for $F_3B \cdot OEt_2$, and ^{31}P NMR with respect to δ 0 for 85% H_3PO_4; downfield chemical shifts are positive. Solution infrared spectra were recorded on a Perkin-Elmer FT 1710 spectrophotometer, and fast ion bombardment (FIB) and fast atom bombardment (FAB) mass spectra using Kratos instruments (3-NBA matrix = 3-nitrobenzyl alcohol). The isotopic patterns of the parent peaks reported were consistent with simulated isotope distributions.

Reactions were carried out under argon using standard Schlenk techniques. Solvents were pre-dried and distilled under N_2. Separation involved thin layer plate chromatography using Kieselgel 60-PF-254 (Merck). PPh_3 and $P(OMe)_3$ were used as received (Aldrich); $[Ph_3PAuCl]$ [3], and $[(Ph_3P)_2N][Rh_2Ru_4(CO)_{16}B]$ [2] were prepared according to literature procedures. Typical yields (with respect to starting cluster) from a series of reactions are given; yields tend to be variable.

Preparations of $[Rh_2Ru_4(CO)_{15}(PPh_3)B(AuPPh_3)]$ *and* $[Rh_2Ru_4(CO)_{14}(PPh_3)_2B(AuPPh_3)]$

In a typical reaction, $[(Ph_3P)_2N][Rh_2Ru_4(CO)_{16}B]$ (10 mg, 6.2 μmol) was dissolved in CH_2Cl_2 (3 ml) and to this solution was added PPh_3 (8.2 mg, 31 mmol). The solution was stirred at room temperature for 17 h, after which time $[Ph_3PAuCl]$ (an excess, ≈ 10 μmol) was added. The solution was stirred for 30 min, and then solvent was removed *in vacuo*. The products were separated by TLC (hexane: CH_2Cl_2 4:5); two green fractions were eluted, but the lower one converted quantitatively to another green fraction during elution. The first fraction (50%) was identified as $[Rh_2Ru_4(CO)_{15}(PPh_3)B(AuPPh_3)]$; the second (final $r_f \approx 0.7$, 45%) was $[Rh_2Ru_4(CO)_{14}(PPh_3)_2B(AuPPh_3)]$.

$[Rh_2Ru_4(CO)_{15}(PPh_3)B(AuPPh_3)]$. ^1H NMR (CD_2Cl_2, 298 K): δ 7.3–7.6 (m, Ph); ^{11}B NMR (CD_2Cl_2, 298 K); δ 199.1; $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ 70.9 (1P, s), 32.5 (1P, d, J_{RhP} 195 Hz); IR (CH_2Cl_2) ν(CO) 2071 w, 2038 vs, 2022 m sh, 1990 w, 1873 w, 1847 w cm^{-1}. MS (positive FAB): $^{12}C_{51}{}^1H_{30}{}^{197}Au{}^{11}B{}^{16}O_{15}{}^{31}P_2{}^{103}Rh_2{}^{101}Ru_4$ 1762 (P^+).

$[Rh_2Ru_4(CO)_{14}(PPh_3)_2B(AuPPh_3)]$. ^1H NMR (CD_2Cl_2, 298 K): δ 7.3–7.7 (m, Ph); ^{11}B NMR (CD_2Cl_2, 298 K): δ 188.5; $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ 65.9 (1P, s), 38.5 (2P, d, J_{RhP} 142 Hz); IR (CH_2Cl_2) ν(CO) 2055 w, 2034 vs, 1998 vs, 1942 w, 1832 w cm^{-1}. MS (positive FAB): $^{12}C_{68}{}^1H_{45}{}^{197}Au{}^{11}B{}^{16}O_{14}{}^{31}P_3{}^{103}Rh_2{}^{101}Ru_4$ 1996 (P^+).

Preparations of $[HRh_2Ru_4(CO)_{14}(PPh_3)_2B]$ *and* $[HRh_2Ru_4(CO)_{13}(PPh_3)_3B]$

In a typical reaction, $[(Ph_3P)_2N][Rh_2Ru_4(CO)_{16}B]$ (129 mg, 0.08 mmol) was dissolved in CH_2Cl_2 (10 ml) and to this solution was added solid PPh_3 (105 mg, 0.40 mmol). The solution was stirred at room temperature for 17 h, after which time the strongest absorption in the IR spectrum had shifted to 2009 cm^{-1}. CF_3CO_2H (10 μl) was added to the stirring solution and after 15 min, the strongest absorption in the IR spectrum had shifted to 2029 cm^{-1}. Solvent was removed *in vacuo*, and the products separated by TLC (hexane: CH_2Cl_2 2:1). The first fraction (orange, 25%) was identified as $[HRh_2Ru_4(CO)_{14}(PPh_3)_2B]$ and the second (orange-brown, 60%) as $[HRh_2Ru_4(CO)_{13}(PPh_3)_3B]$. A third fraction (red) was isolated in low yield and could not be sufficiently characterized.

$[HRh_2Ru_4(CO)_{14}(PPh_3)_2B]$. ^1H NMR ($CDCl_3$, 298 K): δ 7.3–7.7 (m, Ph), −14.9 (s, Ru—H—Ru); ^{11}B NMR ($CDCl_3$, 298 K): δ 186.5; $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 36.6 (d, J_{RhP} 150 Hz); IR (CH_2Cl_2) ν(CO) 2068 m, 2042 vs, 2022 s, 1992 m, 1845 w cm^{-1}. MS (positive FAB): $^{12}C_{50}{}^1H_{31}{}^{11}B{}^{16}O_{14}{}^{31}P_2{}^{103}Rh_2{}^{101}Ru_4$ 1538 (P^+) with 12 CO losses.

$[HRh_2Ru_4(CO)_{13}(PPh_3)_3B]$. IR ($CH_2Cl_2$) ν(CO) 2054 m, 2029 vs, 2009 s, 1958 m, 1833 w cm^{-1}. MS (positive FAB): 1774 (P^+) with 3 to 6 CO losses. The NMR spectroscopic data showed the presence of two isomers (see text):

Isomer **I**. ^1H NMR ($CDCl_3$, 298 K): δ 7.3–7.7 (m, Ph), −14.2 (d, J_{PH} 20 Hz, Ru—H—Ru); ^{11}B NMR ($CDCl_3$, 298 K): δ 188.6; $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 38.4 (1P, s), 33.9 (2P, d, J_{RhP} 154 Hz).

Isomer **II**. ^1H NMR ($CDCl_3$, 298 K): δ 7.3–7.7 (m, Ph), −15.3 (br, Ru—H—Ru); ^{11}B NMR ($CDCl_3$, 298 K): δ 194.5; $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 37.5 (1P, s), 36.8 (2P, d, J_{RhP} 153 Hz).

Preparation of $[HRh_2Ru_4(CO)_{15}(PPh_3)B]$

$[(Ph_3P)_2N][Rh_2Ru_4(CO)_{16}B]$ (48 mg, 0.03 mmol) was dissolved in CH_2Cl_2 (5 ml) and to this solution was added PPh_3 (8 mg, 0.03 mmol). The solution was stirred at room temperature and was monitored by IR spectroscopy; after 15 min the strongest absorption in the spectrum had shifted to 2010 cm^{-1}. CF_3CO_2H (5 μl) was added to the stirring solution and after 5 min, the IR spectrum exhibited the strongest carbonyl absorption at 2050 cm^{-1}. Solvent was removed *in vacuo*, and the products separated by TLC (hexane: CH_2Cl_2 2:1). Two fractions were eluted, the first (orange-brown, 50%) was $[HRh_2Ru_4(CO)_{15}(PPh_3)B]$ and the second $[HRh_2Ru_4(CO)_{14}(PPh_3)_2B]$ (30%).

$[HRh_2Ru_4(CO)_{15}(PPh_3)B]$. IR ($CH_2Cl_2$) ν(CO) 2087 m, 2050 vs, 1995 m, 1852 w cm^{-1}. MS (positive

FIB): $^{12}C_{33}{}^{1}H_{16}{}^{11}B^{16}O_{15}{}^{31}P^{103}Rh_2{}^{101}Ru_4$ 1301 (P^+) with 10 CO losses. The NMR spectroscopic data showed the presence of two isomers (see text).

Isomer **I**. ^{1}H NMR ($CDCl_3$, 298 K): δ 7.4–7.7 (m, Ph), −15.6 (td, J_{RhH} 13, J_{PH} 4Hz, Rh—H—Rh); ^{11}B NMR ($CDCl_3$, 298 K): δ 192.7 (triplet, J_{RhB} 30 Hz); $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 28.9 (dd, $^1J_{RhP}$ 148 Hz, $^2J_{RhP}$ 31 Hz).

Isomer **II**. ^{1}H NMR ($CDCl_3$, 298 K): δ 7.4–7.7 (m, Ph), −14.9 (s, Ru—H—Ru); ^{11}B NMR ($CDCl_3$, 298 K): δ 187.7; $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 36.7 (dd, $^1J_{RhP}$ 176 Hz, $^2J_{RhP}$ 31 Hz).

Preparations of $[Rh_2Ru_4(CO)_{16}B(AuPPh_3)]$, *cis- and trans-*$[Rh_2Ru_4(CO)_{15}\{P(OMe)_3\}B(AuPPh_3)]$ *and* $[Rh_2Ru_4(CO)_{14}\{P(OMe)_3\}_2B(AuPPh_3)]$

In a typical reaction, $[(Ph_3P)_2N][Rh_2Ru_4(CO)_{16}B]$ (48 mg, 0.03 mmol) was dissolved in CH_2Cl_2 (5 ml) and to this solution was added $P(OMe)_3$ (3.5 mmol, 0.03 mmol). The solution was stirred at room temperature for 15 min, the time taken for the strongest absorption in the IR spectrum to shift to 2009 cm^{-1}. Solid $[Ph_3PAuCl]$ (30 mg, 0.06 mmol) and $TlPF_6$ (4 mg, 0.01 mmol) were then added, and the solution stirred for 30 min; solvent was then removed *in vacuo*. Separation by TLC (hexane:CH_2Cl_2 1:1) gave four fractions; the first (green, 30%) was identified as $[Rh_2Ru_4(CO)_{16}B(AuPPh_3)]$ [2], the second (brown, 20%) was *cis*-$[Rh_2Ru_4(CO)_{15}\{P(OMe)_3\}B(AuPPh_3)]$, the third (green, 20%) was *trans*-$[Rh_2Ru_4(CO)_{15}\{P(OMe)_3\}B(AuPPh_3)]$, and the final band (brown, 20%) *cis*-$[Rh_2Ru_4(CO)_{14}\{P(OMe)_3\}_2B(AuPPh_3)]$. This latter compound was unstable with respect to (relatively slow) conversion into the green *trans*-isomer (see text).

cis-$[Rh_2Ru_4(CO)_{15}\{P(OMe)_3\}B(AuPPh_3)]$. This was unstable with respect to conversion to *trans*-$[Rh_2Ru_4(CO)_{15}\{P(OMe)_3\}B(AuPPh_3)]$, and could only be partially characterized: IR (CH_2Cl_2) ν(CO) 2070 m, 2032 vs, 1989 m, 1856 w cm^{-1}.

trans-$[Rh_2Ru_4(CO)_{15}\{P(OMe)_3\}B(AuPPh_3)]$. Two inseparable isomers: IR (CH_2Cl_2) ν(CO) 2056 m, 2038 vs, 1988 m, 1850 w cm^{-1}. MS (positive FAB): $^{12}C_{36}{}^{1}H_{24}{}^{197}Au^{11}B^{16}O_{18}{}^{31}P_2{}^{103}Rh_2{}^{101}Ru_4$ 1624 (P^+) with 13 CO losses.

Isomer **I**. ^{1}H NMR ($CDCl_3$ 298 K): δ 7.3–7.7 (m, Ph), 3.6 (d, J_{PH} 11 Hz); ^{11}B NMR ($CDCl_3$, 298 K): δ 200.6; $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 70.6 (1P, s), 133.9 (1P, s).

Isomer **II**. ^{1}H NMR ($CDCl_3$, 298 K): δ 7.3–7.7 (m, Ph), 3.7 (d, J_{PH} 11 Hz); ^{11}B NMR ($CDCl_3$, 298 K): δ 195.8; $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 67.5 (1P, s), 134.5 (1P, s).

cis-$[Rh_2Ru_4(CO)_{14}\{P(OMe_3\}_2B(AuPPh_3)]$. Two inseparable isomers: IR (CH_2Cl_2) ν(CO) 2058 m, 2021 vs, 2016 vs, 1839 m cm^{-1}.

Isomer **I**. ^{1}H NMR ($CDCl_3$, 298 K): δ 7.4–7.7 (m, Ph), 3.6 (d, J_{PH} 12 Hz); ^{11}B NMR ($CDCl_3$, 298 K): δ 187.0; $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 68.0 (s), 129.1 (d, J_{RhP} 227 Hz).

Isomer **II**. ^{1}H NMR ($CDCl_3$, 298 K): δ 7.4–7.7 (m, Ph), 3.8 (d, J_{PH} 12 Hz); ^{11}B NMR ($CDCl_3$, 298 K): δ 194.6; $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 68.0 (s), 134.5 (s).

trans-$[Rh_2Ru_4(CO)_{14}\{P(OMe)_3\}_2B(AuPPh_3)]$. ^{1}H NMR ($CDCl_3$, 298 K): δ 7.4–7.7 (m, Ph, 15H), 3.5 (d, J_{PH} 13 Hz, 18H); ^{11}B NMR ($CDCl_3$, 298 K): δ 201.6; $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 70.8 (s, 1P), 129.8 (s, 2P); IR (CH_2Cl_2) ν(CO) 2057 s, 2024 vs, 2002 vs, 1859 w, 1836 w cm^{-1}; MS (positive FAB): $^{12}C_{38}{}^{1}H_{33}{}^{197}Au^{11}B^{16}O_{20}{}^{31}P_3{}^{103}Rh_2{}^{101}Ru_4$ 1720 (P^+) with 11 CO losses.

Preparation of $[Rh_2Ru_4(CO)_{13}\{P(OMe)_3\}_3B(AuPPh_3)]$.

$[(Ph_3P)_2N][Rh_2Ru_4(CO)_{16}B]$ (80 mg, 0.05 mmol) was dissolved in CH_2Cl_2 (5 ml) and to this solution was added $P(OMe)_3$ (16 mmol, 0.15 mmol). The solution was stirred at room temperature for 10 min, after which time the strongest absorption in the IR spectrum had shifted to 1987 cm^{-1}. Solid $[Ph_3PAuCl]$ (49 mg, 0.10 mmol) and $TlPF_6$ (4 mg, 0.01 mmol) were added, and the solution stirred for 30 min; solvent was then removed *in vacuo*. Separation by TLC (hexane:CH_2Cl_2 2:1) gave four fractions; the two bands (brown) with lowest r_f values were not sufficiently well characterized for identification. The first fraction (brown, 20%) was identified as *cis*-$[Rh_2Ru_4(CO)_{13}\{P(OMe)_3\}_3B(AuPPh_3)]$ and the second (green, 30%) as *trans*-$[Rh_2Ru_4(CO)_{13}\{P(OMe)_3\}_3B(AuPPh_3)]$.

cis-$[Rh_2Ru_4(CO)_{13}\{P(OMe)\}_3B(AuPPh_3)]$. ^{1}H NMR ($CDCl_3$, 298 K): δ 7.4–7.7 (m, Ph, 15H), 3.6 (d, J_{PH} 12 Hz, 18H), 3.7 (d, J_{PH} 12 Hz, 9H); ^{11}B NMR ($CDCl_3$, 298 K): δ 188.7; $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 66.9 (s, 1P), 132.6 (d, J_{RhP} 236 Hz, 2P), 135.4 (s, 1P); IR (CH_2Cl_2) ν(CO) 2059 m, 2042 m, 1997 vs cm^{-1}; MS (positive FAB): $^{12}C_{40}{}^{1}H_{42}{}^{197}Au^{11}B^{16}O_{22}{}^{31}P_4{}^{103}Rh_2{}^{101}Ru_4$ 1816 (P^+) with 3 to 8 CO losses.

trans-$[Rh_2Ru_4(CO)_{13}\{P(OMe)_3\}_3B(AuPPh_3)]$. ^{1}H NMR ($CDCl_3$, 298 K): δ 7.4–7.7 (m, Ph, 15H), 3.4–3.8 (m, 27H); ^{11}B NMR ($CDCl_3$, 298 K): δ 203.2; $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 70.8 (s, 1P), 130.8 (s, 1P), 131.5 (s, 1P), 133.9 (d, J_{RhP} 324 Hz, 1P); IR (CH_2Cl_2) ν(CO) 2058 m, 2044 m, 1994 vs, 1846 w, 1821 w cm^{-1}; MS (positive FAB): $^{12}C_{40}{}^{1}H_{42}{}^{197}Au^{11}B^{16}O_{22}{}^{31}P_4{}^{103}Rh_2{}^{101}Ru_4$ 1816 (P^+) with 9 CO losses.

Preparations of $[Rh_2Ru_4(CO)_{14}\{P(OMe)_3\}\{\mu\text{-}P(OMe)_2B]$ *and* $[Rh_2Ru_4(CO)_{13}\{P(OMe)_3\}_2\{\mu\text{-}P(OMe)_2\}B]$

In a typical reaction, $[(Ph_3P)_2N][Rh_2Ru_4(CO)_{16}B]$ (56 mg, 0.035 mmol) was dissolved in CH_2Cl_2 (5 ml) and to this solution was added $P(OMe)_3$ (8 μl, 0.07 mmol). The solution was stirred at room temperature for 10 min, the time taken for the strongest absorption

in the IR spectrum to shift to 1998 cm^{-1}. CF_3CO_2H (5 μl) was added to the stirring solution and after 5 min, the strongest absorption in the IR spectrum had shifted to 2034 cm^{-1}. Solvent was removed *in vacuo*, and the products separated by TLC (hexane : CH_2Cl_2 1 : 1). Three fractions were eluted, leaving a brown residue on the baseline, identified as unreacted $[(Ph_3P)_2N][Rh_2Ru_4(CO)_{16}B]$. The first and third fractions were $[Rh_2Ru_4(CO)_{14}\{P(OMe)_3\}\{\mu\text{-}P(OMe)_2\}B]$ (orange-brown, 40%) and $[Rh_2Ru_4(CO)_{13}\{P(OMe)_3\}_2\{\mu\text{-}P(OMe)_2\}B]$ (orange, 10%). The second fraction, present in low yield, eluded full characterization.

$[Rh_2Ru_4(CO)_{14}\{P(OMe)_3\}\{\mu\text{-}P(OMe)_2\}B]$. Two inseparable isomers: IR (CH_2Cl_2) ν(CO) 2075 m, 2035 vs, 2015 s sh, 1971 m, 1872 w cm^{-1}. MS (positive FAB): $^{12}C_{19}{}^{1}H_{15}{}^{11}B^{16}O_{19}{}^{31}P_2{}^{103}Rh_2{}^{101}Ru_4$ 1230 (P^+) with 9 CO losses.

Isomer **I**. ^{1}H NMR ($CDCl_3$, 298 K): δ 3.66 (d, J_{PH} 13 Hz), 3.74 (d, J_{PH} 13 Hz); ^{11}B NMR ($CDCl_3$, 298 K): δ 190.3; $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 125.8 (dd, $^1J_{RhP}$ 243, $^2J_{RhP}$ 32 Hz, 1P), 352.5 (d, J_{RhP} 65 Hz, 1P).

Isomer **II**. ^{1}H NMR ($CDCl_3$ 298 K): δ 3.68 (d, J_{PH} 13 Jz), 3.69 (d, J_{PH} 13 Hz); ^{11}B NMR ($CDCl_3$, 298 K): δ 194.7 (dd, J_{RhB} 39, 21 Hz); $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 130.9 (dd, J_{RhP} 259, J_{PP} 65 Hz, 1P), 331.0 (dd, J_{RhP} 130, J_{PP} 65 Hz, 1P).

Crystal structure determinations of $[Rh_2Ru_4(CO)_{16}B(AuPPh_3)]$ *and* $[Rh_2Ru_4(CO)_{14}(PPh_3)_2B(AuPPh_3)]$

Crystallographic data are collected in Table 1. Crystals were photographically characterized and determined to belong to the monoclinic crystal system. For the *I*-centred monoclinic, the centrosymmetric alternative was initially selected, and this choice was supported by the results of refinement. Empirical corrections for absorption were applied to the diffraction data. The structures were solved by direct methods, completed from difference Fourier maps, and refined with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen-atom locations were idealized. All computations used SHELXTL 4.2 software (G. Sheldrick, Siemens XRD, Madison, WI).

RESULTS AND DISCUSSION

The starting cluster anion for the reactions described in this paper was $[Rh_2Ru_4(CO)_{16}B]^-$, and it is important to note that the octahedral cage exists in both the *trans* and *cis* forms (with respect the Rh positions), with the former being the preferred species in solution [2]. The structure of the *trans*-isomer has been confirmed by an X-ray diffraction study [4]. Thus, in any reaction of $[Rh_2Ru_4(CO)_{16}B]^-$, products may arise from the reaction of either isomer. In the discussion that follows, isomerism in respect of the

Rh_2Ru_4 will be termed "cage-isomerism" to distinguish it from isomers arising from substitution of the PPh_3 or $P(OMe)_3$ ligands.

Reaction of $[Rh_2Ru_4(CO)_{16}B]^-$ *with 5-fold* PPh_3 *and excess* Ph_3PAuCl. The reaction between $[(PPh_3)_2N][Rh_2Ru_4(CO)_{16}B]$ and a five-fold excess of PPh_3, followed by addition of an excess of Ph_3PAuCl yielded two green products, and during TLC separation, the lower fraction quantitatively converted to a new green compound. The mass spectrum of the first fraction was consistent with this being a monophosphine substitution product of $[Rh_2Ru_4(CO)_{16}B]^-$ with the addition of an $AuPPh_3$ fragment, i.e. $[Rh_2Ru_4(CO)_{15}(PPh_3)B(AuPPh_3)]$. This was supported by the $^{31}P\{^1H\}$ NMR spectrum which exhibited two signals in a 1 : 1 ratio; the singlet at δ 70.9 was assigned to the gold-bound PPh_3 group and a doublet at δ 3.25 (J 195 Hz) showed that the phosphine ligand had substituted at a Rh site (^{103}Rh, 100%, $I = \frac{1}{2}$). Although spectroscopic data indicate that only one cage-isomer is formed, it was not possible to confirm whether this was the *trans* or *cis* arrangement.

Mass spectrometric data for the second isolated product of the reaction indicated the formation of $[Rh_2Ru_4(CO)_{14}(PPh_3)_2B(AuPPh_3)]$, and the $^{31}P\{^1H\}$ NMR spectrum was consistent with this. Two signals in a 1 : 2 ratio were observed; a singlet at δ 65.9 was assigned to the $AuPPh_3$ group and a doublet at δ 38.5 (2P, J 142 Hz) revealed that both phosphine ligands were attached to rhodium. As in the monosubstituted case, spectroscopic data for $[Rh_2Ru_4(CO)_{14}(PPh_3)_2B(AuPPh_3)]$ indicated that only one cage-isomer was present in solution. Crystals suitable for an X-ray diffraction study were grown away from dichloromethane layered with hexane.

Crystal structure of $[Rh_2Ru_4(CO)_{14}(PPh_3)_2B(AuPPh_3)]$

Figure 1 shows the molecular structure of $[Rh_2Ru_4(CO)_{14}(PPh_3)_2B(AuPPh_3)]$, and selected bond distances and angles are given in Table 2. The presence of the phosphorus atoms (and using the ^{31}P NMR spectroscopic data described above) allow us to effectively label the Rh centres, thereby overcoming the problem of distinguishing the Rh and Ru atoms by X-ray crystallographic methods. The Rh atoms are mutually *cis* in an octahedral Rh_2Ru_4 cage, with the boron atom being fully interstitial (a fact that is also evident from the down field shift of δ 188.5 in the ^{11}B NMR spectrum). The gold(I) phosphine unit adopts an Ru—Ru edge-bridging position, with the Au and P atoms lying in the plane containing the Rh(1), Rh(2), Ru(1) and Ru(4) atoms. In related structures we have observed both edge-bridging and face-capping environments for AuL fragments [2,5], but the most relevant comparison is between the arrangements in $[Rh_2Ru_4(CO)_{14}(PPh_3)_2B(AuPPh_3)]$ and $[Ir_2Ru_4(CO)_{16}B\{AuP(C_6H_{11})_3\}]$ [2]. Both have the heteroatoms in adjacent sites in the octahedral framework, but in $[Ir_2Ru_4(CO)_{16}B\{AuP(C_6H_{11})_3\}]$, the $AuP(C_6H_{11})_3$] fragment bridges the Ir—Ir edge, whereas in $[Rh_2Ru_4(CO)_{14}(PPh_3)_2B(AuPPh_3)]$, $AuPPh_3$ bridges an Ru—Ru edge. In the iridium case however, we proposed [2] that a *trans* → *cis* isomerism of the Ir_2Ru_4 cage accompanied the addition of the $[AuP(C_6H_{11})_3]^+$ electrophile. In the reaction sequence for the preparation of $[Rh_2Ru_4(CO)_{14}(PPh_3)_2B(AuPPh_3)]$, phosphine substitution occurs prior to the addition of $AuPPh_3$, and it is likely that steric factors play in role directing the gold(I) unit to the ruthenium-centred site. However, it remains unproven at what stage in the reaction the dominance of a *cis*-Rh_2Ru_4 cage (in contrast to the starting anion $[Rh_2Ru_4(CO)_{16}B]^-$) prevails. The conversion observed on the TLC plate is, of course, a possibility, but it would seem more likely that this takes place in concert with the addition of Ph_3PAuCl, and that the former is a more facile process, perhaps associated with a rearrangement involving the gold fragment on the surface of the Rh_2Ru_4-framework. We report the solid state structure of $[Rh_2Ru_4(CO)_{16}B(AuPPh_3)]$ later in this paper.

Reaction of $[Rh_2Ru_4(CO)_{16}B]^-$ *with 5-fold* PPh_3 *and* CF_3CO_2H

The isolobal analogy between $[AuL]^+$ and H^+ has been exploited in cluster chemistry for many years [6,7]. The aim of carrying out the reaction of $[Rh_2Ru_4(CO)_{16}B]^-$ with a five-fold excess of PPh_3 followed by acidification was to compare as parallel a reaction as possible with that described above. Mass spectrometric data suggested that the products isolated from the reaction were $[HRh_2Ru_4(CO)_{14}(PPh_3)_2B]$ and $[HRh_2Ru_4(CO)_{13}(PPh_3)_3B]$. The ^{11}B and ^{31}P NMR spectra of $[HRh_2Ru_4(CO)_{14}(PPh_3)_2B]$ were consistent with the presence of one cage-isomer, and one arrangement of the PPh_3 ligands; a doublet (J 150 Hz) in the $^{31}P\{^1H\}$ NMR spectrum indicated that both PPh_3 groups were rhodium-bound. A singlet at δ −14.9 in the ^1H NMR spectrum showed the presence of a ruthenium-attached hydrido ligand. Two possible structures can be proposed for $[HRh_2Ru_4(CO)_{14}(PPh_3)_2B]$ with the Rh atoms either *trans* or *cis*; however, the similarity between the ^{11}B NMR chemical shifts [8] for $[HRh_2Ru_4(CO)_{14}(PPh_3)_2B]$ and $[Rh_2Ru_4(CO)_{14}(PPh_3)_2B(AuPPh_3)]$ strongly suggest that the Rh_2Ru_4 arrangements are the same and hence we propose that $[HRh_2Ru_4(CO)_{14}(PPh_3)_2B]$ is the *cis*-isomer with the hydrido ligand occupying the same site as the $AuPPh_3$ group in $[Rh_2Ru_4(CO)_{14}(PPh_3)_2B(AuPPh_3)]$ (Fig. 1).

The NMR spectroscopic data for $[HRh_2Ru_4(CO)_{13}(PPh_3)_3B]$ were consistent with the presence of two isomers, **I** and **II**, and we were able to separate these by thin layer chromatography. The ^{11}B NMR spectrum showed two broad signals at δ 188.6 (isomer

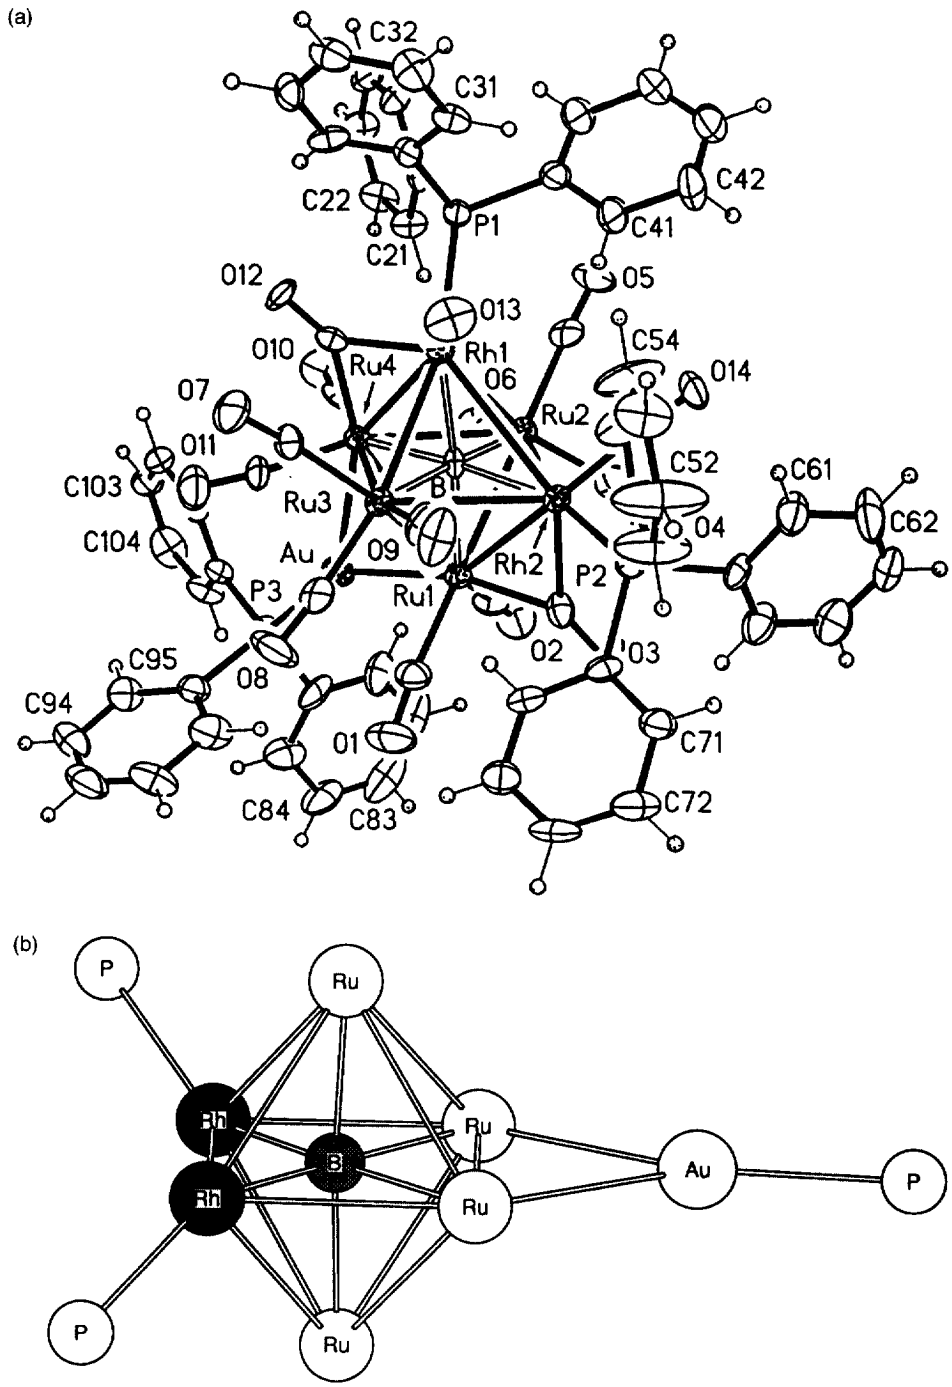

Fig. 1. (a) The molecular structure of $[Rh_2Ru_4(CO)_{14}(PPh)_3B(AuPPh_3)]$; (b) the $Rh_2Ru_4P_2B(AuP)$ core of $[Rh_2Ru_4(CO)_{14}(PPh)_3B(AuPPh_3)]$.

I) and 194.5 (isomer **II**) in a ratio $\approx 3:1$, while the $^{31}P\{^1H\}$ NMR spectrum exhibited four signals, which, on the ground of relative integrals, could be assigned as a singlet (1P) and doublet (2P, J_{RhP} 154 Hz) for isomer **I**, and a singlet (1P) and doublet (2P, J_{RhP} 153 Hz) for isomer **II**. In the highfield part of the ^1H NMR spectrum, two signals in a ratio $\approx 3:1$ were observed, a doublet at $\delta -14.2$ (J_{PH} 20 Hz) and a broad singlet at $\delta -15.3$ assigned to isomers **I** and **II** respectively. In proposing structures of isomers **I** and **II**, we have made the assumption that the trisubstituted derivative arises by PPh_3 substitution on the disubstituted product and that no skeletal rearrangement takes place. Figure 2 shows structures which are consistent with

the spectroscopic data for isomers **I** and **II** of $[HRh_2Ru_4(CO)_{13}(PPh_3)_3B]$. The presence of the bulky triphenylphosphine ligands should hinder cage-isomerization; however, our observations that both $[Rh_2Ru_4(CO)_{14}\{P(OMe)_3\}_2B(AuPPh_3)]$ and $[Rh_2Ru_4(CO)_{13}\{P(OMe)_3\}_3B(AuPPh_3)]$ undergo *cis* → *trans* cage-isomerization (see later) underline the fact that caution in making an assumption about cage-rearrangement is needed and in the absence of crystallographic data, we emphasize that these structures are likely, they are not unique possibilities.

Reaction of $[Rh_2Ru_4(CO)_{16}B]^-$ *with an equivalent of* PPh_3 *followed by* CF_3CO_2H

In an attempt to facilitate monosubstitution in $[Rh_2Ru_4(CO)_{16}B]^-$, we carried out a 1:1 reaction between this anion and PPh_3 with vastly reduced reaction time, followed by protonation. The desired product $[HRh_2Ru_4(CO)_{15}(PPh_3)B]$ was obtained in ≈50% yield, and its formation was accompanied by that of $[HRh_2Ru_4(CO)_{14}(PPh_3)_2B]$. The formulation of $[HRh_2Ru_4(CO)_{15}(PPh_3)B]$ was indicated by the mass spectrum of the compound, but solution NMR spectroscopic data showed the presence of two isomers (**I** and **II**); these were inseparable by TLC. The ^{11}B NMR spectrum exhibited two signals at δ 192.7 (with resolved ^{103}Rh—^{11}B coupling of 30 Hz) and 187.7, the former being more intense. The ^{31}P NMR spectrum of the isomer mixture showed two doublets of doublets, consistent with Rh—P bond formation in each isomer: isomer **I**, $^1J_{RhP}$ 148 Hz, $^2J_{RhP}$ 31 Hz, and isomer **II**, $^1J_{RhP}$ 176 Hz, $^2J_{RhP}$ 31 Hz. The fact that a ^2J coupling was observed indicated that the rhodium atoms were adjacent to each other, confirming a *cis*-Rh_2Ru_4 core. Two highfield signals in the ^1H NMR spectrum (δ −15.6 and −14.9 for isomers **I** and **II**, respectively) were indicative of protonation on the metal cage. For isomer **I**, a triplet of doublets was observed due to coupling to two ^{103}Rh centres (J 13 Hz) and to one ^{31}P nucleus, the value of 4 Hz being characteristic of a *cis* P—M—H arrangement. The hydride signal for isomer **II** was a singlet indicating an Ru—H—Ru environment, remote from the phosphine ligand. Figure 3 shows the proposed structures for the two isomers of $[HRh_2Ru_4(CO)_{15}(PPh_3)B]$; that for **I** is clearly assigned from the NMR spectroscopic data, while for isomer **II**, the particular edge chosen for the placement of the bridging hydrido ligand is not definitive.

Reaction of $[Rh_2Ru_4(CO)_{16}B]^-$ *with an equivalent of* $P(OMe)_3$ *followed by* Ph_3PAuCl

Our previous studies of the reactivity of $[Ru_6(CO)_{17}B]^-$ with $P(OMe)_3$ followed by treatment with either Ph_3PAuCl or acid had given contrasting results, with the proposed formation of a phosphido bridge in the second case [1]. We were therefore interested to investigate parallel reactions with $[Rh_2Ru_4(CO)_{16}B]^-$. As the discussion that follows shows, substitution by $P(OMe)_3$ appears to have the effect of giving species in which *cis* → *trans* isomerization of the Rh_2Ru_4 framework occurs relatively slowly.

The 1:1 reaction of $[Rh_2Ru_4(CO)_{16}B]^-$ with $P(OMe)_3$ yielded mono- and disubstitution products in addition to unreacted cluster anion. Each was isolated as the triphenylphosphine gold(I) derivative. The chromatographic separation of the products gave $[Rh_2Ru_4(CO)_{16}B(AuPPh_3)]$ as the first fraction; we return to this compound in the next section. The

second (brown) and third (green) fractions were identified as *cis*- and *trans*-$[Rh_2Ru_4(CO)_{15}\{P(OMe)_3\}B(AuPPh_3)]$ respectively. Over a period of time, the brown product converted quantitatively to the green compound, reminiscent of the *cis* → *trans* cage-isomerisms observed for related clusters [2]. The rate of isomerization was sufficiently rapid that the *cis*-isomer could not be well characterized. The mass spectrum of the green isomer was consistent with the formulation $[Rh_2Ru_4(CO)_{15}\{P(OMe)_3\}B(AuPPh_3)]$, but solution spectroscopic data showed the presence of two (inseparable by TLC) isomers. The ^{11}B NMR spectrum of the mixture exhibited two signals at δ 200.6 and 195.8 (relative integrals 3:2, assigned to isomers **I** and **II** respectively); although not unambiguous, these particularly downfield shifts (compared with ^{11}B shifts in the earlier discussions) are consistent with a *trans*-arrangement of the Rh_2Ru_4 cage [8]. Four singlets were observed in the $^{31}P\{^1H\}$ NMR spectrum, two were assigned to gold-bound PPh_3 groups and two to ruthenium-bound $P(OMe)_3$ ligands. Their relative integrals allowed assignments to appropriate isomers (see experimental section). The ^1H NMR spectroscopic data were consistent with the presence of two isomers, but provided no further structural information. Given that the data suggest (i) the Rh_2Ru_4 octahedral cage is retained in both isomers, (ii) that the Rh atoms are *trans* to each other, and (iii) that the $P(OMe)_3$ group is attached to a ruthenium atom, isomerism must be due to the location of the $AuPPh_3$ group. Since our previous studies of Rh_2Ru_4 and Ir_2Ru_4 borides, (supported by crystallographic data), have evidenced different bonding modes (edge-bridging, face-capping, association with Ru and/or rhodium or iridium) [2,5, this work], it is not possible to speculate on the distinction between isomers **I** and **II** of *trans*-$[Rh_2Ru_4(CO)_{15}\{P(OMe)_3\}B(AuPPh_3)]$ and we have not been able to obtain X-ray quality crystals to aid structural assignments.

The final fraction to be isolated was brown in colour, but on storage in either the solid state or in solution, underwent quantitative conversion to a green compound, suggesting a *cis* → *trans* cage-isomerization. However, this isomerization was sufficiently slow that both isomers could be independently characterized by mass spectrometry and IR and NMR spectroscopies. The mass spectra of both green and brown compounds were consistent with the formulation $[Rh_2Ru_4(CO)_{14}\{P(OMe)_3\}_2B(AuPPh_3)]$. The spectroscopic characteristics of the green compound indicated a single species, with the significantly downfield ^{11}B NMR shift of δ 201.6 consistent with a *trans*-arrangement of Rh atoms. The $^{31}P\{^1H\}$ spectrum exhibited singlets in a ratio 1:2, assigned to gold- and ruthenium-bound phosphorus atoms respectively. One doublet (for the methyl protons) in the ^1H NMR spectrum is also consistent with equivalent $P(OMe)_3$ groups. Two possible structures for *trans*-$[Rh_2Ru_4(CO)_{14}\{P(OMe)_3\}_2B(AuPPh_3)]$ are shown in Fig. 4; one has an edge-bridging $AuPPh_3$ unit. Alternatively, the gold(I) phosphine unit could be face-capping over one of the Ru_2Rh faces remote from the $RuP(OMe)_3$ units; this would give a structure analogous to that of $[Rh_2Ru_4(CO)_{16}B\{AuP(C_6H_{11})_3\}]$ which has been crystallographically confirmed [2]. A structure with the $P(OMe)_3$ ligands attached to *trans* rather than *cis* Ru atoms is also possible, but is considered less likely.

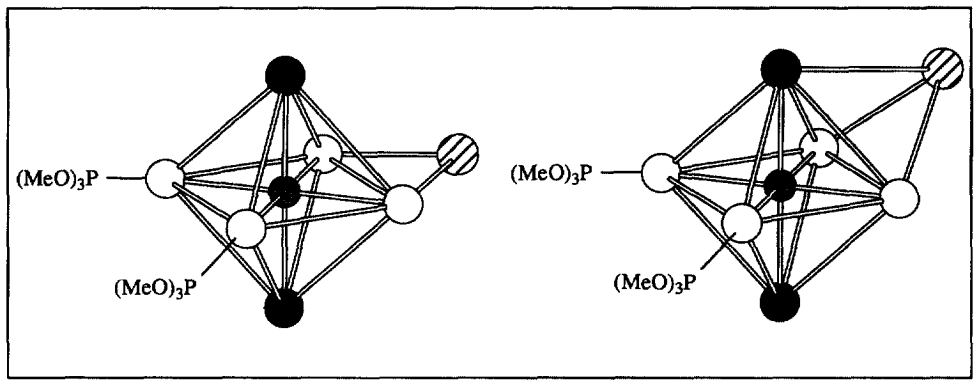
We now return to *cis*-$[Rh_2Ru_4(CO)_{14}\{P(OMe)_3\}_2B(AuPPh_3)]$, from which *trans*-$[Rh_2Ru_4(CO)_{14}\{P(OMe)_3\}_2B(AuPPh_3)]$ is formed. The spectroscopic data for the *cis*-isomer showed the presence of two structural isomers, **I** and **II** (inseparable by TLC), present in a 2:1 ratio respectively. In the $^{31}P\{^1H\}$ spectrum of the isomer mixture, only one signal was observed for the $AuPPh_3$ unit (δ 68.0), suggesting very similar environments in each isomer. The $P(OMe)_3$ ligands are attached to ruthenium in isomer **I** (^{31}P singlet) and to rhodium in isomer **II** (^{31}P, doublet, J_{RhP} 227 Hz). This observation is significant because it means that for isomer **II**, *cis* → *trans* cage-isomerization is accompanied by phosphite migration from rhodium to ruthenium. The structures that we propose for isomers **I** and **II** of *cis*-$[Rh_2Ru_4(CO)_{14}\{P(OMe)_3\}_2B(AuPPh_3)]$ are shown in Fig. 4b.

Crystal structure of $[Rh_2Ru_4(CO)_{16}B(AuPPh_3)]$

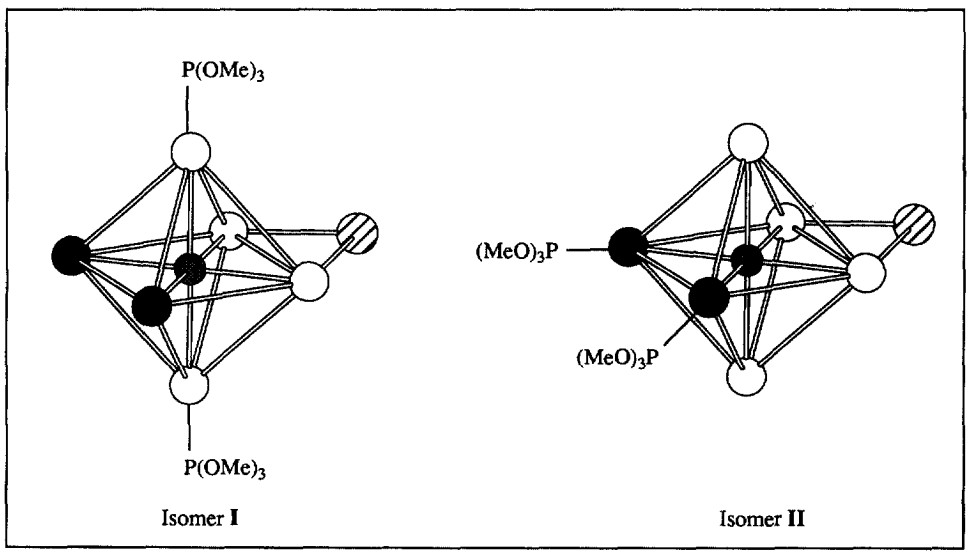
We have previously reported the synthesis and spectroscopic characterization of $[Rh_2Ru_4(CO)_{16}B(AuPPh_3)]$ [2]. The isolation of this compound in the present work gave crystals (grown from a CH_2Cl_2 solution layered with hexane) which were suitable for single crystal structural analysis. The molecular structure of $[Rh_2Ru_4(CO)_{16}B(AuPPh_3)]$ is shown in Fig. 5, and selected bond distances and angles are listed in Table 3. The results of the determination confirm the presence of the octahedral metal core around an interstitial boron atom. The structure is analogous to that found for $[Rh_2Ru_4(CO)_{16}B\{Au\{C_6H_{11})_3\}]$ [2]; as in that structure, it is not possible to unambiguously distinguish between Ru and Rh atoms by single-crystal X-ray diffraction techniques. However, in low oxidation state metal carbonyl clusters, the connectivity number of ruthenium to the CO ligands is generally greater than that of rhodium, and rhodium centres are more likely to be associated with bridging CO ligands than are ruthenium atoms. The allocation of the rhodium atoms in a *trans*-arrangement as shown in Fig. 5 follows from these guidelines. The gold(I) phosphine fragment caps the Ru(1)Ru(4)Rh(1)-face; the eight faces of the *trans*-Rh_2Ru_4 octahedron are, of course, equivalent.

Preparation and characterization of $[Rh_2Ru_4(CO)_{13}\{P(OMe)_3\}_3B(AuPPh_3)]$

Trisubstitution by $P(OMe)_3$ in $[Rh_2Ru_4(CO)_{16}B]^-$ was achieved by using a 1:3 stoichiometry, and neutral products were isolated after the addition of



(a)



(b)

Fig. 4. (a) Two possible structures for *trans*-$[Rh_2Ru_4(CO)_{14}\{P(OMe)_3\}_2B(AuPPh_3)]$; both are consistent with spectroscopic data; (b) proposed structures for isomers **I** and **II** of *cis*-$[Rh_2Ru_4(CO)_{14}\{P(OMe)_3\}_2B(AuPPh_3)]$.

$[Ph_3PAuCl]$. An extended reaction time was not required and 50% conversion to $[Rh_2Ru_4(CO)_{13}\{P(OMe)_3\}_3B(AuPPh_3)]$ (present as two cage isomers) was achieved in 10 min; two unidentifiable products were also formed. Mass spectrometric data for the two products isolated showed them both to be consistent with the formulation $[Rh_2Ru_4(CO)_{13}\{P(OMe)_3\}_3B(AuPPh_3)]$. The ^{11}B NMR spectrum of each compound exhibited one peak, but the different chemical shift values (δ 203.2 and 188.7) suggested that the products were *trans*- and *cis*-cage isomers, respectively. This was further supported by the fact that, over a period of days, the compound with δ ^{11}B 188.7 converted to that with δ ^{11}B 203.2. Significantly, this isomerization process was slower than that observed for *cis* → *trans* $[Rh_2Ru_4(CO)_{14}\{P(OMe)_3\}_2B(AuPPh_3)]$. Both isomers of $[Rh_2Ru_4(CO)_{13}\{P(OMe)_3\}_3B(AuPPh_3)]$ could therefore be spectroscopically characterized without problems associated with isomerization. The $^{31}P\{^1H\}$ NMR spectrum of *cis*-$[Rh_2Ru_4(CO)_{13}\{P(OMe)_3\}_3B(AuPPh_3)]$ showed, in addition to a signal at δ 66.9 assigned to the PPh_3 group, a double (J_{RhP} 236 Hz) and a singlet with relative integrals of 2:1. In the $^{31}P\{^1H\}$ NMR spectrum of *trans*-$[Rh_2Ru_4(CO)_{13}\{P(OMe)_3\}_3B(AuPPh_3)]$, three singlets and a doublet were observed; the singlet at δ 70.8 was assigned to the $AuPPh_3$ groups, and the lower field singlets (1:1, δ

130.8 and 131.5) denoted the presence of two inequivalent ruthenium-bound $P(OMe)_3$ ligands. The doublet (δ 133.9, J_{RhP} 324 Hz) showed that the third $P(OMe)_3$ was attached to rhodium. The proposed structures for *cis*- and *trans*-$[Rh_2Ru_4(CO)_{13}\{P(OMe)_3\}_3B(AuPPh_3)]$ are shown in Fig. 6; edge-bridging sites are shown for the gold(I) phosphine units, but we have not been able to obtain X-ray quality crystals of either isomer to confirm this. Even in the absence of definitive crystallographic data, the ^{31}P NMR spec-

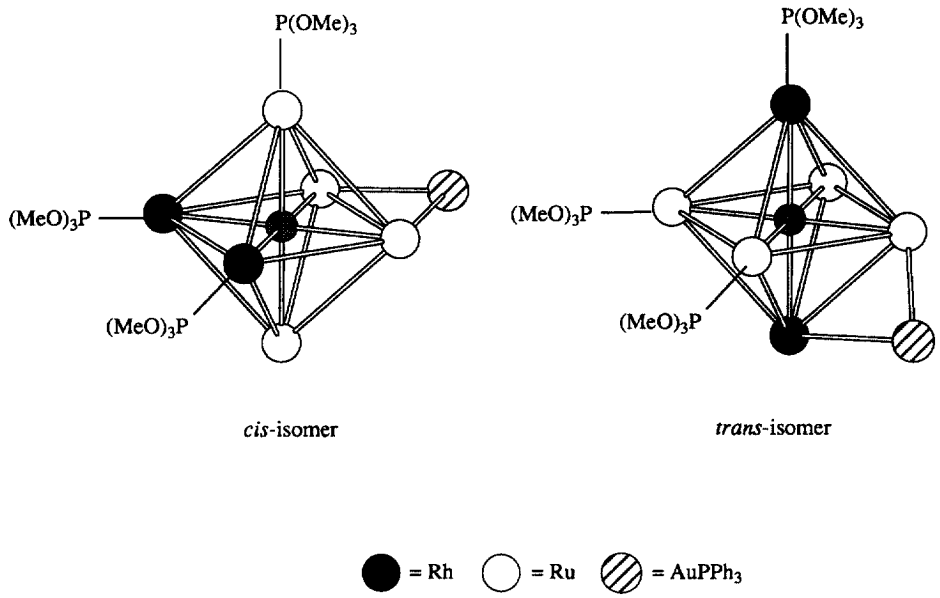

Fig. 6. The proposed structures for *cis*- and *trans*-$[Rh_2Ru_4(CO)_{13}\{P(OMe)_3\}_3B(AuPPh_3)]$.

troscopic results clearly reveal that *cis* → *trans* cage isomerism is accompanied by migration of one $P(OMe)_3$ ligand from rhodium to ruthenium.

The reaction of $[Rh_2Ru_4(CO)_{16}B]^-$ *with* $P(OMe)_3$ *followed by protonation*

The results of our investigations into the reaction of $[Ru_6(CO)_{17}B]^-$ with $P(OMe)_3$ followed by protonation were consistent with the initial substitution of one CO by $P(OMe)_3$ followed by cleavage of one methoxy group and the formation of $[Ru_6(CO)_{16}\{\mu\text{-}P(OMe)_2\}B]$. However, we were unable to confirm this by the determination of the solid state structure of the latter compound [1]. As the discussion below shows, similar results have now been obtained with $[Rh_2Ru_4(CO)_{16}B]^-$.

The reaction of $[Rh_2Ru_4(CO)_{16}B]^-$ with a two-molar equivalent of $P(OMe)_3$, followed by protonation with CF_3CO_2H, gave two isolable products, the mass spectra of which were consistent with the formula $[Rh_2Ru_4(CO)_{14}\{P(OMe)_3\}\{P(OMe)_2\}B]$ and $[Rh_2Ru_4(CO)_{13}\{P(OMe)_3\}_2\{P(OMe)_2\}B]$. The fact that each $P(OMe)_2$ group is in a bridging mode is supported by characteristic shifts in the ^{31}P NMR spectrum of each compound (see below) and is consistent with electron-counting schemes for the compounds in which the $P(OMe)_2$ group contributes three electrons. The ^{11}B NMR spectrum of $[Rh_2Ru_4(CO)_{14}\{P(OMe)_3\}\{\mu\text{-}P(OMe)_2\}B]$ showed two signals, δ 190.3 (isomer **I**) and 194.7 (isomer **II**) with relative integrals 3 : 1, indicative of two isomers, and this was consistent with both the $^{31}P\{^1H\}$ NMR and ^1H NMR spectroscopic data. Based upon signal integrals, the signals in the $^{31}P\{^1H\}$ NMR spectrum could be assigned to individual. For isomer **I**, the observation of a doublet of doublets (δ 125.8, $^1J_{RhP}$ 243, $^2J_{RhP}$ 32 Hz) and a lowfield doublet (δ 352.5, J_{RhP} 65 Hz) was interpreted in terms of a rhodium-bound, terminal $P(OMe)_3$ group and a Ru—Rh, edge-bridging $P(OMe)_2$ group. Moreover, the fact that $^2J\,^{103}Rh—^{31}P$ coupling was observed for the terminal phosphite ligand implied that the two Rh atoms in the metal cage were mutually *cis*. From our experience with these species, it is reasonable to assume that isomer **II** also possesses a *cis*-arrangement of Rh atoms in the metal cage; isomers **I** and **II** were inseparable by TLC, and there was no spectroscopic evidence for their interconversion. The $^{31}P\{^1H\}$ NMR spectrum of isomer **II**, exhibited two doublets of doublets. The higher field signal (δ 130.9) showed couplings of 259 Hz (characteristic of a rhodium-bound, terminal $P(OMe)_3$ ligand) and 65 Hz. The lower field signal (δ 331.0) exhibited couplings of 130 Hz (assigned to $^{103}Rh—^{31}P$ coupling) and 65 Hz. The common coupling (65 Hz) was assigned to $^{31}P—^{31}P$ spin-spin coupling, implying that the two phosphorus atoms were attached to the same Rh centre. Proposed structures for isomers **I** and **II** are shown in Fig. 7a.

Spectroscopic data showed that the second product of the reaction, $[Rh_2Ru_4(CO)_{13}\{P(OMe)_3\}_2\{P(OMe)_2\}B]$, existed in one structural form. The $^{31}P\{^1H\}$ NMR spectrum exhibited three signals (equal relative integrals), two (doublets of doublets) due to terminal $P(OMe)_3$ ligands (δ 126.8 and 129.2), and one (a doublet) due to a bridging $P(OMe)_2$ group (δ 354.7). The observation of $^2J_{RhP}$ coupling for the terminal ligands, suggested that the rhodium atoms in

Fig. 7. (a) The proposed structures of isomers **I** and **II** of $[Rh_2Ru_4(CO)_{14}\{P(OMe)_3\}\{P(OMe)_2\}B]$; (b) the proposed structure of $[Rh_2Ru_4(CO)_{13}\{P(OMe)_3\}_2\{P(OMe)_2\}B]$.

the cage were mutually *cis*, and the data are in accord with the structure shown in Fig. 7b. In this case, no $^{31}P_{terminal}$—$^{31}P_{bridge}$ coupling was observed. However, values of J depend upon the relative orientations of the ligands [9] and it is reasonable that the coupling was too small to be resolved.

Neither *cis*-$[Rh_2Ru_4(CO)_{14}\{P(OMe_3\}\{\mu\text{-}P(OMe)_2\}B]$ nor *cis*-$[Rh_2Ru_4(CO)_{13}\{P(OMe)_3\}_2\{P(OMe)_2\}B]$ showed a tendency for conversion to the *trans*-isomers over a period of storage of several days.

CONCLUSIONS

The behaviour of $[Rh_2Ru_4(CO)_{16}B]^-$ towards PPh_3 or $P(OMe)_3$ followed by protonation or reaction with Ph_3PAuCl shows general similarities to that of the homometallic boride $[Ru_6(CO)_{17}B]^-$ [1]. In particular, terminal $P(OMe)_3$ in the anionic cluster can be readily converted to a μ-$P(OMe)_2$ group by protonation with trifluoroacetic acid, presumably through loss of MeOH. We have previously commented upon related reactions: protonation of $[Ru_3(CO)_{10}\{P(OMe)_3\}_2]$ by CF_3CO_2H which gives $[HRu_3(CO)_{10}\{P(OMe)_3\}_2]^+$ [10] rather than a $P(OMe)_2$ bridge, thermally promoted conversions of terminal $P(OMe)_3$ to μ_4-P(OMe), bridging $OP(OMe)_2$ or $OP(OMe)OP(OMe)_2$ [11–13], and the formation of $[Ru_3(CO)_9(PPh_3)(\mu\text{-}PPh_2)]^-$ from $[HRu_3(CO)_{11}]^-$ and PPh_3 [14].

As anticipated, the presence of the heterometals in $[Rh_2Ru_4(CO)_{16}B]^-$ complicates the picture with respect to the behaviour of $[Ru_6(CO)_{17}B]^-$, but at the same time "labels" two sites in the cage with respect to the other four. Some general observations are that: (i) PPh_3 substitutes for CO at rhodium rather than ruthenium; (ii) introduction of two PPh_3 ligands (at Rh) is possible, whereas attempts to introduce two PPh_3 ligands into $[Ru_6(CO)_{17}B]^-$ failed [1]; (iii) cage isomerization (*cis* → *trans* Rh_2Ru_4) becomes less facile

across the series $[Rh_2Ru_4(CO)_{16-x}\{P(OMe)_3\}_xB(AuPPh_3)]$ for $x = 1$ to 3; (iv) migration of $P(OMe)_3$ from Rh to Ru accompanies *cis* → *trans* cage rearrangement in $[Rh_2Ru_4(CO)_{16-x}\{P(OMe)_3\}_xB(AuPPh_3)]$, $x = 2$ or 3.

(Received 19 December 1997)

Abstract—Reaction of the tungsten oxo acetylide complex $Cp^*W(O)_2CCPh$ with $Ru_4(CO)_{12-13}[PN(^iPr)_2]$ affords two oxo bridged metal clusters η^5-$Cp^*p^*W(\mu\text{-}O)Ru_4(CO)_9(\mu\text{-}CO)[\mu_3\text{-}\eta^2\text{-}OPN(^iPr)_2](\mu_4\text{-}\eta^2\text{-}CCPh)$ **2** and η^5-$Cp^*p^*W(\mu\text{-}O)_2Ru_4(CO)_{10}[\mu_3\text{-}PN(^iPr)_2](\mu_5\text{-}\eta^2\text{-}CCPh)$ **3**. X-ray analysis shows that **2** has a single W–O–Ru oxide bridge and contains a bridging diisopropylaminophosphinidoxo ligand while in **3** both oxide ligands bridge W–Ru bonds. © 1998 Elsevier Science Ltd. Keywords: Phosphinidoxo; oxo; acetylide; ruthenium; tungsten

The oxide (=O) group is normally considered to be a hard ligand in organometallic chemistry, principally associated with early, high oxidation state metal fragments [1]. However, recent developments suggest that oxides can play an important role as interfacial ligands, bridging early–high and late–low oxidation state metal centers to form mixed metal oxide clusters which may serve as models for oxide supported platinum metal catalysts [2, 3]. In this communication we report the synthesis of two new oxide bridged early–late organometallic clusters, one of which has W–O–Ru and W–O–P interactions and contains the rare phosphinidoxo ligand RPO [4], the other having two oxide ligands bridging Ru–W bonds.

A potentially powerful methodology for constructing oxide bridged mixed metal clusters consists of delivering an early metal oxo compound bearing an unsaturated hydrocarbyl ligand to a late metal which has a high affinity for unsaturated hydrocarbyl groups. Using this strategy, reaction of η^5-$Cp^*W(O)_2CCPh$ ($Cp^*=C_5Me_5$)(13.0 mg, 0.029 mmol) [5] in refluxing hexane for 3 h with the nido 62e-phosphinidene cluster $Ru_4(CO)_{13}[PN(^iPr)_2]$ **1** (25.0 mg, 0.028 mmol) [6], known to strongly coordinate acetylenes, afforded two new complexes η^5-$Cp^*W(\mu\text{-}O)Ru_4(CO)_9(\mu\text{-}CO)[\mu_3\text{-}\eta^2\text{-}OPN(^iPr)_2](\mu_4\text{-}\eta^2\text{-}CCPh)$ **2** [7] and η^5-$Cp^*W(\mu\text{-}O)_2Ru_4(CO)_{10}[\mu_3\text{-}PN(^iPr)_2](\mu_5\text{-}\eta^2\text{-}CCPh)$ **3** [8] in 57% and 32% yield respectively.

The molecular structure of **2** [9] (Fig. 1) consists of an almost planar Ru_4 butterfly (dihedral angle of 177.43°) with the Cp^*WC_2Ph fragment coordinated as a 6e-donor to the Ru(2)Ru(3)Ru(4) triangle as a μ_3-η^2-$\parallel$-acetylene and with the tungsten atom asymmetrically bridging the Ru(1)–Ru(2) bond (Ru(1)–W = 2.9248(3); Ru(2)–W = 2.7823(3)). The most interesting features of the cluster are associated with the oxide ligands derived from the $Cp^*W(O)_2$ moiety. One oxygen atom, O(2) acts as a bridge between tungsten and the phosphorus atom of the phosphinidene of **1** forming a μ_3-η^2 diisopropylaminophosphinidoxo $[O{=}PN(^iPr)_2]$ ligand on the Ru(1)–Ru(2)–W face. The P–O(2) bond length (1.570(1) Å) is comparable to that in the μ-diphenylphosphidoxo cluster $Fe_3(CO)_9(\mu_3\text{-}\eta^2\text{-}C_2{}^t\text{Bu})(\mu\text{-}OPPh_2)$ (P–O = 1.539(2) Å) [4] and in $Fe_3(CO)_{10}(\mu_3\text{-}O{=}P^t\text{Bu})$ (P–O = 1.532(4) Å) [4] and only slightly longer than the P=O distance in phosphine oxide complexes [10]. Although many examples of terminal phosphine oxides, μ–O=PR_2 (phosphidoxo) [11] and most recently, PO (phosphorus

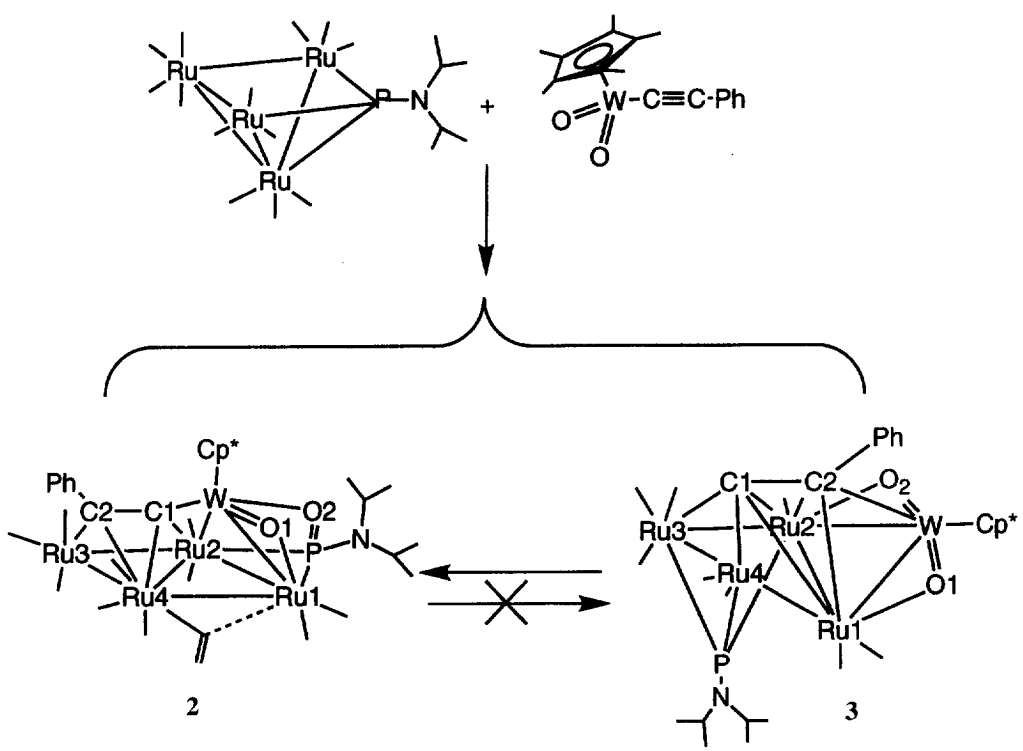
Selected bond lengths not mentioned in the text (Å): W–Ru(1) = 2.6910(5), W–Ru(2) = 3.0467(5), Ru(1)–Ru(2) = 2.8154(7), Ru(1)–Ru(4) = 2.8661(6), Ru(2)–Ru(3) = 2.7786(6), Ru(3)–Ru(4) = 2.8393(7) and Angles (°) O(1)–W–O(2) = 111.0(2).

monoxide) complexes [6] are known, clusters with oxidised phosphinidene ligands μ-O=PR are very rare. The only other examples are the $Fe_3(CO)_{10}(\mu_3$-O=PR) (R=^{t}Bu, ^{i}Pr) compounds synthesised in very low yields by Huttner and co-workers [4]. Together with the long W–O(2) distance (2.07(2) Å) indicative of a W–O single bond, the P=O bond length in **2** suggests a P=O→W interaction. Cluster **2** also has a W–O(1)–Ru(1) bridge (W–O(1) = 1.759(2); Ru(1)–O(1) = 2.227(2) Å) but, in this case, the oxide is double bonded to the tungsten atom and the interaction is best described as W=O→Ru. In this model tungsten is in a +4 oxidation state and one of the original oxo ligands has transferred to and oxidised the phosphinidene ligand. Overall **2** is electron precise (76 e-, 7 M–M).

In the second cluster **3** [12] (Fig. 2) the $Cp^*W(O)_2C_2Ph$ fragment is attached to a non-planar arrangement of four ruthenium atoms (4 Ru–Ru) via a μ_5-acetylide, two W–Ru bonds and two W–O–Ru oxide bridges. From the W–O and Ru–O bond lengths (W–O(1) = 1.815(4); W–O(2) = 1.783(4); Ru(1)–O(1) = 2.147(4); Ru(2)–O(2) = 2.191(4) Å), the metal–oxide interactions are best represented as W=O→Ru in both cases. In this case the tungsten atom is formally in a +6 oxidation state. Complex **3** is the first example of an early–late metal organometallic cluster with two oxide bridges to ruthenium [13].

In the tungsten oxo acetylide **1** and in the cluster **2** the alkynyl ligand is bound to tungsten via the Cα carbon atom. However in the conversion of **2** to **3** an apparent rotation of the alkynyl group has occurred such that in **3** Cβ, the carbon atom bearing the phenyl group, is attached to the tungsten atom. Although phenyl group migrations are known in organometallic chemistry [14], a reorientation of the acetylide on the cluster framework, similar to the rearrangement observed in other alkynyl clusters [15] is more likely.

On refluxing in heptane, **3** is converted solely to **2** whereas **2** remains unchanged under identical conditions. (Scheme 1). Thus **3**, with two W–O–Ru bridges is the kinetic product of the reaction of $Cp^*W(O)_2C_2Ph$ with **1** and **2** which formally results from oxidation of a phosphinidene ligand by a tungsten oxo functionality is the thermodynamic product. The high stability of complexes such as **2** in solution and in the solid state suggests, *inter alia* that oxide ligands may support novel combinations of early and late metals in disparate oxidation states and that oxidation of organophosphorus ligands may serve as a mechanism to reduce or mediate formal oxidation state differences between metal centers in clusters.



Scheme 1. *Synopsis* The new mixed early–late metal oxide bridged clusters $Cp^*W(\mu\text{-}O)Ru_4(CO)_9(\mu\text{-}CO)[\mu_3\text{-}\eta^2\text{-}OPN(^iPr)_2](\mu_4\text{-}\eta^2\text{-}CCPh)$ **2** and $Cp^*W(\mu\text{-}O)_2Ru_4(CO)_9[\mu_3\text{-}PN(^iPr)_2)(\mu_5\text{-}\eta^2\text{-}CCPh)$ **3** have been synthesised via the strategy of delivering an early metal oxo acetylide $Cp^*W(O)_2CCPh$ to a late metal alkyne acceptor $Ru_4(CO)_{13}(\mu_3\text{-}PN(^iPr)_2)$. Crystal structures reveal two W–O–Ru bridges in **3**, a single W–O–Ru Interaction in **2** and a novel W–O–P bridge to a μ_3-η^2-phosphinidoxo (O=PPh) ligand in **2**. The metals in **2** and **3** exist in disparate oxidation states.

In summary, new types of stable oxide bridged mixed metal organometallic clusters can be accessed via reaction of high oxidation state oxo acetylides with late metal carbonyl complexes. We are currently examining the potential of this methodology for the introduction of oxide ligands into other mixed oxidation state organometallic clusters and for the generation of new "oxidised" phosphido supporting ligands.

(Received 31 October 1997; accepted 14 March 1998)

Abstract—The coordination of ammonia and of aliphatic amines (RNH_2(R = Et, n-Bu, s-Bu, t-Bu, cyclohexyl) and Et_2NH) to the electron deficient clusters $Os_3(CO)_9(\mu_3\text{-}\eta^2\text{-}C_9H_6N)(\mu\text{-}H)$ (**1**) and $Os_3(CO)_9(\mu_3\text{-}\eta^2\text{-}XC_9H_5N)(\mu\text{-}H)$ (X = 5-NH_2, **4**; 3-NH_2, **5**; 6-NH_2, **6**; 5-Br, **7**; 5-CH_3, **8**) has been studied. The initially formed adducts of the amines with **1** gradually isomerize to give a mixture of two isomers whose ratio varies with the cluster, the solvent and the amine. Studies of the variation of the isomer ratio with temperature yield ΔH° and ΔS° values for the isomer equilibrium. The primary cause of the change in the isomer ratio is the variation in ΔS° which is rationalized as being due to solvation effects. The overall structure of the two isomers is assigned on the basis of NMR measurements to one where the amine occupies an axial position on the cluster and where the hydride and quinoline ring bridge different edges of the cluster. The equilibrium constant for amine complex formation is primarily determined by the steric bulk of the amine. The amine substituted complex **4** shows absolutely no tendency to coordinate amines and this is ascribed to relief of the electron deficiency at the metal core by the mesomeric effects of the *para*-amino group. The isomeric **5** and **6**, however, do undergo coordination of amines at the metal core. The 5-methyl substituted complex **8** does not complex amine either. Compounds **1**,**4**–**8** all undergo simple protonation with both coordinating (CF_3CO_2H) and non-coordinating acids (HBF_4) to give cationic dihydrido complexes whose solution structures are elucidated by NMR techniques. The chemistry of these electron deficient clusters is compared with related $\mu_3\text{-}\eta^2$ imidoyl complexes and can be understood in terms of the Hammett equation, at least for protonation. © 1998 Elsevier Science Ltd. Keywords: Amines; clusters; Osmium; Quinolines.

INTRODUCTION

We recently reported the synthesis and reactivity of a novel class of electron deficient triosmium clusters $Os_3(CO)_9(\mu_3\text{-}\eta$ [2]-$C_9H_6N)(\mu\text{-}H)$ (**1**) from the reaction of quinoline with $Os_3(CO)_{10}(CH_3CN)_2$ followed by thermolysis or photolysis of the initially formed decacarbonyl eq. (1) [1–3]. This type of compound can be synthesized in good yield with a wide range of substituents in the quinoline ring [1, 4].

The reaction of these complexes with soft nucleophiles such as phosphines results in ligand addition at the metal core along with rearrangement eq. (2) [1, 3]. On the other hand, reaction with hydride [1] or carbanions [4] results in nucleophilic attack at the 5-position of the quinoline ring. Subsequent protonation leads to a nucleophilic addition product eq. (3) [4] and hydride abstraction from the intermediate anion effects overall nucleophilic substitution eq. (4) [4]. In light of this diverse reactivity, we thought it would be useful to study the reactivity of **1** with amines

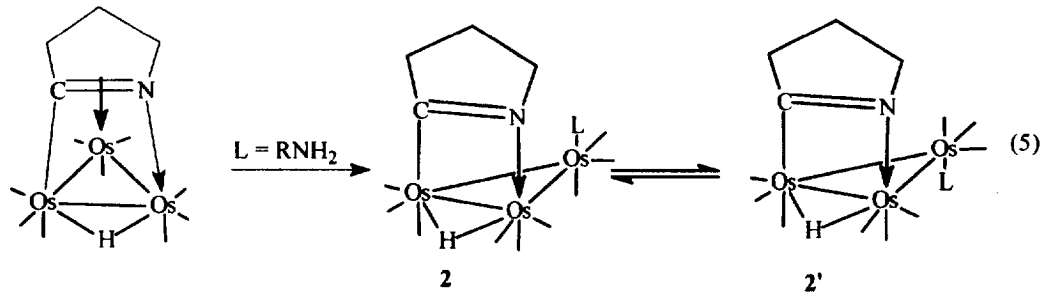
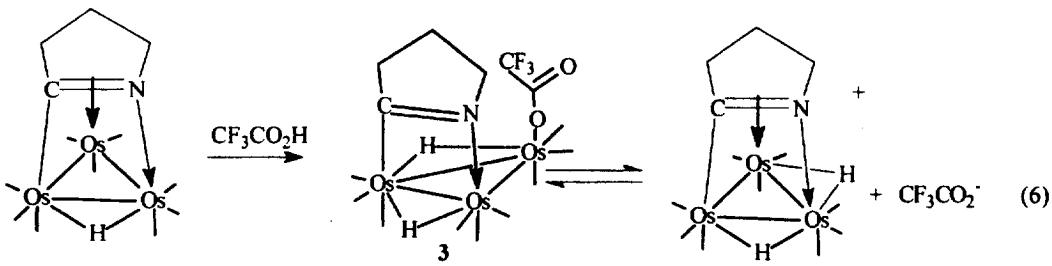
and carboxylic acids which are intermediate in nucleophilicity relative to phosphines and carbanions.

We recently completed detailed studies of the reaction of these ligands with the electron precise, but quite reactive μ_3 imidoyl complexes of the type, $Os_3(CO)_9(\mu_3\text{-}\eta^2\text{-}C{=}N(\text{-}CH_2\text{-})_3(\mu\text{-}H)$, where coordination was highly selective for primary amines and where the formation of two axially coordinated isomers, $Os_3(CO)_9(\mu\text{-}\eta^2\text{-}C{=}N(\text{-}CH_2\text{-})_3(\mu\text{-}H)L$ (**2** and **2'**) was observed eq. (5) [5]. The neutral adduct $Os_3(CO)_9(\mu\text{-}\eta^2\text{-}C{=}N(\text{-}CH_2\text{-})_3(\mu\text{-}H)_2(CF_3CO_2)$ (**3**), was the main product of the reaction of trifluoroacetic acid with the μ_3-imidoyl complexes but a small amount of a monoprotonated species was observed to be in equilibrium with the adduct eq. (6). In the case of non-coordinating anions such as BF_4^-, only simple protonation was observed [6, 7].

We report here the results of studies on the coor-



(5)



(6)

dination chemistry of ammonia, aliphatic amines, and protic acids with **1**, in an attempt to define the stereodynamics of its coordination sites and how these differ from those observed in **2** and **3** (eqs. (5–6)). One of our research goals in developing the chemistry of complexes such as **1** was to understand the degree of electronic communication between the quinoline ring and the metal core. Our initial efforts in this area have resulted in the synthesis of the compounds $Os_3(CO)_9(\mu_3\text{-}\eta^2\text{-}XC_9H_5N)(\mu\text{-}H)$ (X = 5-NH_2, **4**; 3-NH_2, **5**; 6-NH_2, **6**; 5-Br, **7**; 5-CH_3, **8**). We report here our initial results on the synthesis of these compounds according to the methods outlined in eqs. (1–4). Studies of their reactivity reveal the extraordinary impact of the electron deficient bonding mode of the cluster on the substituent in the 5-position and *vice versa*.

RESULTS AND DISCUSSION

Reactions with amines

The addition of a large excess (50 fold) of ammonia and various aliphatic amines to **1** results in an instant color change from green to orange and in the appearance of two new hydride peaks in the ^1H NMR in the range of −12 to −14 ppm (Table 1). The resonance at higher field (isomer I) is invariably in greater intensity (except in the case of NH_3) and the lower field resonance (isomer II) gradually increases in intensity until a final ratio (I/II), in the range of 0.5 to 4.8, is reached which does not change further (Table 1).

The ^{13}C NMR ($CDCl_3$, −60°C) of a ^{13}CO enriched sample of **1** treated with excess ammonia shows two sets of nine carbonyls (I: 187.3, 185.5, 185.6, 180.4, 179.8, 178.8 ($^2J^{13}C\text{-}^1H = 14$ Hz), 177.3($^2J^{13}C\text{-}^1H = 9$ Hz), 176.7, 176.2 ppm; II: 187.3, 186.7, 184.6, 182.0, 180.8, 177.8($^2J^{13}C\text{-}^1H = 12.5$ Hz), 177.5 ($^2J^{13}C\text{-}^1H = 9.6$ Hz), 176.8, 176.2 ppm). Significantly, the spectrum shows no resonances with ^{13}C satellites that, if present are indicative of a large *trans*-carbonyl coupling associated with the presence of an $Os(CO)_4$ group [5]. The previously reported amine complexes of triosmium clusters, **2** and **2'**, invariably have the amine (or ammonia) in an axial position eq. (5) [5]. Based on these facts alone, we can propose two alternative structures for the set of isomers formed from the interaction of amines with **1** eq. (7). One set has the hydride and the quinoline ring sharing a common edge while the amine occupies either axial site on the third, unbridged osmium atom (structures **A**, **A'**, eq. (7)). This structure is directly analogous to that observed related to μ_3 imidoyl complexes, **2** and **2'**, for which solid state structures are available eq. (5) [5].

On the other hand, coordination of the amine at the electron deficient osmium edge of **1** could lead to a structure where the quinoline ring and the hydride are on different edges with the amine occupying an axial position on the osmium atom bridged by the hydride but not by the quinoline ring structures **B**, **B'**, eq. (7)). This type of structure has been observed in the case of one imidoyl complex bearing ethyl and propyl groups on the imidoyl carbon and nitrogen atoms respectively eq. (8) [8]. We have also obtained indirect evidence for this structural type as a short-lived intermediate from the selective incorporation of

[a] only one isomer observed
[b] four hydride resonances observed

carbon monoxide into **1** [3]. In the case of phosphines reacting with **1**, such an intermediate is probably the initial product as well but goes on to rearrange as shown above eq. (2) [1, 3].

The initial formation of one isomer followed by the gradual appearance of a second has been shown to be an intermolecular process for the related μ_3-imidoyl complexes [5]. It would appear that this is also the case for **1** reacting with amines since the overall behavior of **1** towards amines is so similar [5]. The question of the structure of the amine adducts of **1** (**A** or **B**) still remains unanswered in the absence of a solid state structure.

The change in longitudinal relaxation time (T_1) of hydrides in metal clusters induced by proximal ligand protons can be used to qualitatively assess the distance between these two types of hydrogens [9]. Thus, for $Os_3(CO)_{10}(\mu\text{-}\eta^2\text{-}C_9H_6N)(\mu\text{-}H)$ (**9**) the T_1 of the hydride is 7.0 s while for **1** it is 4.0 s (Figure 1). We can attribute the shorter relaxation time in **1** to the proximity of the hydrogen of C(7) to the μ-hydride. If the amine adducts of **1** have a structure identical to their μ_3-imidoyl analogs then the T_1 of the μ-hydride would be expected to have a relaxation time similar to **9**. In fact, the T_1 of the ammonia adduct of **1** is 1.4 s which is consistent with a structure where the ammonia protons are proximal to the hydride; i.e., the structure resulting from addition of the ligand to the carbon bridged edge of the cluster without further rearrangement (structure **B**, eq. (7)).

$T_1 = 1.4$ s

Scheme 1.

This suggested structure is further supported by the ^{1}H NMR data obtained for the s-butyl adduct **1**. Here, four hydride resonances are observed. This is undoubtedly due to the presence of diastereomers induced by the presence of the chiral center on the s-butyl amine. In the structure proposed based on the T_1 measurements (structure B, eq. (7)), the environment on the osmium atom bound to the amine is quite asymmetric owing to the presence of the bridging hydride on one of the two edges of the triangle associated with the amine coordinated osmium atom. In the case of the structure adopted by the μ_3-imidoyl amine adducts (**2** and **2'** eq. (5)), the localized environment on the amine bound nitrogen is more symmetric and indeed only two hydride resonances are observed for the s-butyl complex [5].

Finally, the structure proposed is most consistent with a reversible amine coordination based on the principle of least motion since only the motion of the C(8) carbon pivoting on the coordinated nitrogen is required to reform **1** from its corresponding amine adduct. This motion is related to the reversible coordination of the C=N bond observed in the μ_3- to μ- to μ_3-imidoyl interconversions [5].

In our previous study of the imidoyl amine adducts, the initially formed isomer has the amine on the same face of the osmium triangle as the pyrrolidine ring (i.e., *syn*-) [5]. This isomer is more favored for the bulkier amines and this also appears to be the trend for the amine complexes of **1** Table 1. In fact, for the secondary amine Et_2NH only one isomer with a hydride chemical shift similar to the proposed *syn*-isomer is observed Table 1. Our initial thought for the imidoyl series was that the strictly sigma-bond framework of the pyrrolidine ring was less bulky than the carbonyl ligands which have π-electrons [5]. In light of the isomer ratios observed for the amine complexes of **1**, this cannot be the case since the quinoline ring also has π-electron density. Yet, the *syn*-isomer is still favored for bulkier ligands and the *anti*-isomer for the least bulky (ammonia). In order to further investigate this point, we measured the effect of temperature and solvent on the isomer ratio for three amine adducts of **1**. There are two obvious trends in the data (Table 2). First, it can be seen that the population of the *syn*-isomer is enhanced in the more polar solvent acetone Table 2. This, of course, is sensible in light of the expected greater polarity of the Os–

Table 2. ΔH° (kJ/mol) and ΔS° (J/mol K) for Amine Adducts of $Os_3(CO)_9(\mu_3\text{-}\eta^2\text{-}C_9H_6N)(\mu\text{-}H)$, **1**[a2]

[a] Values and errors obtained by taking the least squares fit to the function $\ln I/II = \Delta H^\circ - T\Delta S^\circ$ for at least ten temperatures between 233 and 298 K.

N bonds with the quinoline and amine relative to the Os–CO bonds. Overall, the ΔH° values hover around zero, ranging from -3 to $+2$ kJ/mole. The most significant differences between compounds and between solvents are in the ΔS° Table 2. Significantly, the ammonia complex is the only one with a negative ΔS°. This indicates that solvation, not steric effects, can account for the observed differences in the isomer ratios. Apparently, the more polar *syn-* isomers lead to more disordered solute–solvent interactions and this effect is enhanced by the presence of non-polar substituents on the amine. That the larger cyclohexyl group shows a less positive ΔS° than the ethyl group is difficult to rationalize but may relate to the mobility of this ligand in the adduct.

The trends in the equilibrium constants for the formation of amine complexes with **1** follow the trends observed for the related μ_3 imidoyl species, *n*-Bu > *s*-Bu > *t*-Bu. The absolute values for the equilibrium constants for **1** however, are much greater being 44.4, 2.7, and 0.39; and 1.25, 0.37, and 0.005 for **1** and the μ_3-imidoyls respectively [5]. This undoubtedly reflects the greater electron deficiency for the 46e$^-$ cluster relative to the reactive but electron-precise μ_3-imidoyls.

In order to assess the impact of an electron donating group on the coordination chemistry observed for **1**, we undertook the synthesis of the 3-, 5- and 6-amino analogs of **1**. The synthesis of these complexes proceeded in a straightforward manner. Significantly, the 5-amino derivative, $Os_3(CO)_9(\mu_3\text{-}\eta^2\text{-}5\text{-}NH_2C_9H_5)(\mu\text{-}H)$ (**4**) formed directly, at ambient temperatures, without requiring thermal or photochemical decarbonylation eq. (9) [1–3]. This undoubtedly reflects the impact of the strong π-electron donor in a position *para-* to the incipient three center, two electron band. The 3- and 6-amino derivatives **5** and **6** did require the usual decarbonylation procedure (eqs. (10–11)). In all of these reactions (eqs. (9–11)) no detectable competition for coordination of the quinoline nitrogen by the aniline amino groups is seen but the yields of **5** and **6** were significantly lower than for **4** and **1**.

The reaction of **4** with *n*-$BuNH_2$ in both CD_2Cl_2 and CD_3OD showed no sign of complex formation even in the presence of a 100-fold excess of *n*-$BuNH_2$. This can be attributed to the electron donating ability of the amino group which funnels electron density down to the electron deficient C(8)–Os_2 bonding framework by conventional benzenoid resonance.

The 3- and 6-amino derivatives **5** and **6** do coordinate *n*-$BuNH_2$, as **1**. The formation constants are of the same order of magnitude as for **1**, with **6** showing a significantly larger formation constant than **5** or **1** (Table 3). As for **1**, isomer I, presumably the more polar isomer is favored with the equilibrium ratios of I/II being two to three times larger than for **1** Table 3. One might have expected the K_f for **6** to be less than that of **5** since the electron donating amino group is on the carbocyclic ring, albeit in the meta position. Clearly, the magnitude of K_f and the I/II ratio depend on a subtle combination of factors which cannot be delineated at this time. The one firm conclusion that can be drawn from these studies is the profound influence that substitution at the 5-position of the quinoline ring has on the electron density at the metal core. This is born out by our studies of the $Os_3(CO)_9(\mu_3\text{-}\eta^2\text{-}(5\text{-}Br)C_9H_5N)(\mu\text{-}H)$ [4] (**7**) where the electron withdrawing bromine in the 5-position gives the largest K_f of all the derivatives of **1** investigated so far. In the case of $Os_3(CO)_9(\mu_3\text{-}\eta^2\text{-}(5\text{-}CH_3)C_9H_5N)(\mu\text{-}H)$ [4] (**8**), where there is only a weakly electron donating group in the 5-position amine complex formation was also not observed even in the presence of a large excess of n-$BuNH_2$.

Reactions with protic acids

In order to further probe the electron distribution in **1** and **4–8** we investigated their reactions with CF_3CO_2H and HBF_4. Addition of a six-fold excess of CF_3CO_2H to a CD_2Cl_2 solution of **1** results in complete conversion to a deep orange solution which exhibits two hydride resonances at -13.66 and -11.61 ppm in a 1:1 ratio. The aromatic resonances are all shifted downfield with respect to **1**. An equilibrium constant for protonation was calculated from a titration of **1** with CF_3CO_2H (Table 4). The ^{13}C-

NMR (CD_2Cl_2) of a ^{13}CO sample of **1** in the presence of the same excess gives a ^{13}C NMR in the carbonyl region showing nine resonances at 180.65, 175.20, 172.50, 172.45, 171.01, 167.93, 166.52, 159.84, and 159.99 ppm. The two resonances at 159.84 and 158.99 ppm appear as doublets of doublets in the proton coupled spectrum ($^2J^{13}C\text{-}^1H = 13.74$, 4.58 and 13.73, 6.10 Hz respectively) while the two at 180.65 and 172.45 ppm appear as doublets ($^2J^{13}C\text{-}^1H = 9.15$ and 7.63 Hz). Protonation with the non-coordinating acid, HBF_4 yields the virtually identical ^1H Table 4 and ^{13}C NMR (CD_2Cl_2) data (180.61, 175.78, 172.92, 172.36, 171.43, 168.13, 166.71, 159.94, 158.85 ppm with an identical coupling pattern). These data are consistent with simple protonation to give a dihydride cation eq. (12) as opposed to acid adduct formation

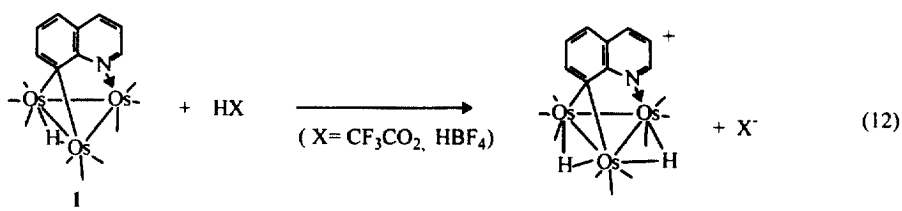
Table 4. Protonation Equilibria for Electron Deficient Quinoline Triosmium Clusters[a4]

Compound	K_{eq}	Acid	δ hydrides	Solvent
1	0.12	CF_3CO_2H	−13.66 −11.61	$CDCl_3$
1	12.2	HBF_4	−13.70 −11.65	$CDCl_3$
4	20.8	CF_3CO_2H	−14.35 −12.60	$CDCl_3$
5	0.72	CF_3CO_2H	−13.81 −11.73	$CDCl_3$
6	1.88	CF_3CO_2H	−13.72 −11.70	$CDCl_3$
7	0.05	CF_3CO_2H	−13.78 −11.50	$CDCl_3$
8	1.19	CF_3CO_2H	−14.00 −12.15	$CDCl_3$

[a] Measured by ^1H NMR ±10% at +22°C

eq. (6). The equilibrium constant for formation of the cation is considerably larger for the stronger acid, HBF_4 Table 4. The observation of well resolved carbonyl–hydride couplings indicates that the protonated species is rigid on the NMR time scale while the hydrides in the related cationic μ_3-imidoyl species are fluxional at ambient temperatures.

that the partially averaged acid/amine resonance is found between **5** and **6** ppm, suggesting a higher degree of amine protonation. The protonation equilibrium values (Table 4) obtained from these experiments are consistent with **4** having the greatest influence on the electron density at the metal core. A Hammett plot of the equilibrium data using standard



1 (12)

The protonation of **4** with aliquots of CF_3CO_2H reveals that the 5-amino derivative is considerably more basic at the metal core than **1** Table 4. After the first aliquot (slightly in excess of 1 equivalent) is added, **4** is completely converted to the dihydride cation and the resonance at 5.60 ppm attributable to the amino resonance is no longer observed. Instead, a broad resonance at 7.82 ppm is observed which is attributable to a partially averaged signal of the CF_3CO_2H and the amino group of **4**. The CF_3CO_2H proton resonance is observed at 8.00 ppm in the presence of **1**. As more CF_3CO_2H is added to the solution of **4**, the acid amine resonance shifts to lower fields and sharpens somewhat indicating more rapid exchange between the amine and the acid. Significantly, the amine resonances for **5** and **6** are found at considerably higher fields than for **4** at 4.14 and 4.79 ppm respectively. On treatment with CF_3CO_2H, the same overall behavior as for **4** is observed for **5** and **6** except

values of σ[10] yields a reasonably good straight line with a correlation coefficient of 0.93 and ρ value of −0.13 (Figure 1).

CONCLUSIONS

The electron deficient μ_3-η^2-quinoline triosmium clusters exhibit behavior towards amines similar to the related μ_3-η^2 pyrrolidine triosmium clusters [5]. Both show initial formation of a single isomer which then equilibrates to a mixture of two complexes. The equilibrium constants in both series depend on the steric bulk of the amine with the overall magnitudes being much greater for the quinoline series. Based on the NMR evidence accumulated to date, the actual structure of the amine–quinoline adducts is different from that of the imidoyls. However, definitive conclusions about the actual structures must await solid

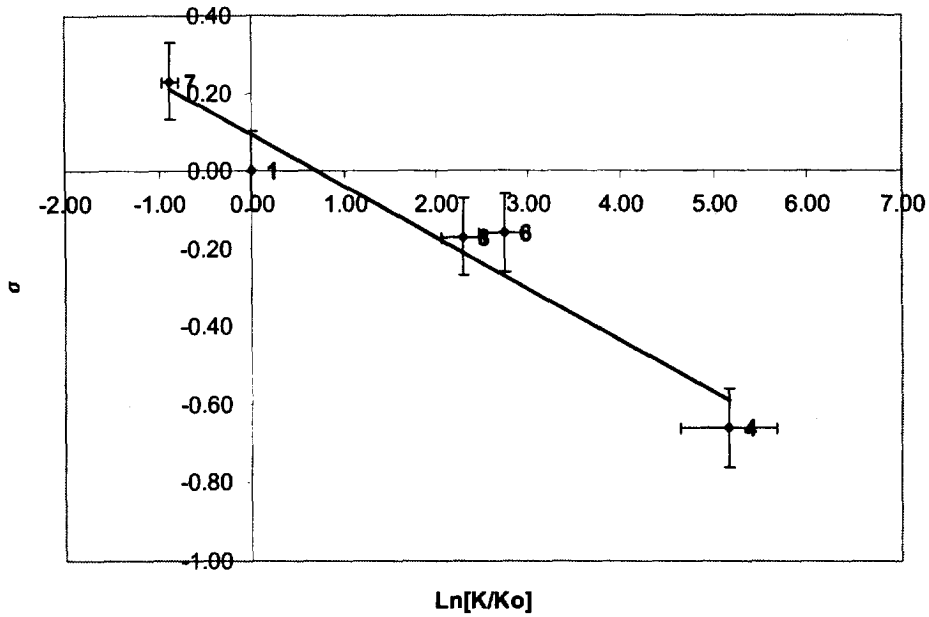


Fig. 1. Hammett, σ/ρ Plot of the Protonation Equilibria for Compounds **1**, **4**–**8** reacting with CF_3CO_2H (error bars for the σ values are from reference [10] and are $\pm 10\%$ for the K_{eq} values).

state structural determinations which have been difficult to obtain owing to the instability of the adducts as crystalline solids.

In sharp contrast to the μ_3-η^2-imidoyl clusters, the μ_3-η^2-quinoline clusters do not form acid adducts but simply undergo protonation in the presence of CF_3CO_2H.

The most interesting aspect of these studies is the profound influence that substituents in the 5-position have on the electronic properties of the metal core. That the simple free energy relationship normally applied to organic reactions can be used to rationalize the relationship between substitution on the carbocyclic ring and protonation at the metal core is reassuring in that it says that the relatively complex interactions (from an orbital point of view) between an organic moiety and two metal atoms can be understood in terms of a traditional physical organic chemistry model. The isomer I and II populations and the somewhat higher value of K_f for the 6-amino quinoline derivative, are less well understood, but seem to be dominated by solvation effects, at least from the data gathered so far.

EXPERIMENTAL

General: Compounds **1** [1], **7** [11] **8** [4], and 5-amino quinoline [11] and 5-bromo quinoline [11] were synthesized by known literature procedures. 3-Amino quinoline and 6-amino quinoline were purchased from Aldrich Chemical Co. and used as received. Methylene chloride was distilled from calcium hydride before use. Acetone-d_6, methylene chloride-d_2, and methanol-d_4 were purchased from Aldrich in single sample ampules and used as received. Chloroform-d_1 was dried over molecular sieves before use. NMR spectra were recorded on Jeol EX-400 or Varian Unity Plus 400 NMR spectrometers. Samples for T_1 measurement were previously degassed by three freeze thaw cycles. The non selective inversion recovery pulse sequence was used to obtain T_1 values. Infrared spectra were recorded on a Perkin–Elmer 1600 spectrometer and elemental analyses were performed by Schwarzkopf Microanalytical Laboratories, Woodside, New York.

Preparation of $Os_3(CO)_9(\mu_3\text{-}\eta^2\text{-}(5\text{-}NH_2)C_9H_5N)(\mu\text{-}H)$ ***4***. $Os_3(CO)_{10}(MeCN)_2$ (0.250 g, 0.268 mmol) was dissolved in CH_2Cl_2 (150 mL) and 5-amino quinoline (0.080 g, 0.5 mmol) was added. The reaction mixture was stirred for 16 h at room temperature. The resulting deep green solution was separated and filtered through a 14″ silica gel column eluted with hexane/CH_2Cl_2 (70:30), giving two bands. The first yellow band was a mixture of the isomers $Os_3(CO)_{10}(\mu\text{-}\eta^2\text{-}(5\text{-}NH_2)C_9H_5N)(\mu\text{-H})$ (less than 10%). The second fraction yielded (0.223 g, 0.219 mmol, 82.1% overall from $Os_3(CO)_{10}(CH_3CN)_2$) of the green major product, **4**, $Os_3(CO)_9(\mu_3\text{-}\eta^2\text{-}(5\text{-}NH_2)C_9H_5N)(\mu\text{-H})$ which gave green crystals from hexane/CH_2Cl_2 at -20C.

Analytical and spectroscopic data for $[Os_3(CO)_9(\mu_3\text{-}\eta^2\text{-}(5\text{-}NH_2)C_9H_5N)(\mu\text{-}H)]$ ***4***. Anal. calcd for $C_{18}H_8N_2O_9Os_3$: C, 22.38, H, 0.78; N, 2.76. Found: C, 22.37; H, 0.75; N, 2.83. IR (ν(CO) in hexane): 2080w, 2069m, 2040s, 2013s, 1981s, 1967w cm^{-1}. ^{1}H-NMR at 400 MHz in $CDCl_3$: δ 9.25 (dd, H(2)), 7.07 (t, H(3)), 8.00 (dd, H(4)), 8.16 (dd, H(6), 6.43 (d, H(7)), 5.60 (broad singlet, NH_2), -13.01 (s, hydride).

Synthesis of $Os_3(CO)_9(\mu_3\text{-}\eta^2\text{-}(n\text{-}X)C_9H_5N)(\mu\text{-}H)$, **5** (n = 3, $X = NH_2$), **6** (n = 6, $X = NH_2$), **7** (n = 5, $X = Br$). $Os_3(CO)_{10}(CH_3CN)_2$ (0.250–0.500 g, 0.27–0.54 mmol) was dissolved in 150–200 mL CH_2Cl_2 and a two-fold molar excess of the substituted quinoline was added by syringe. The solution was stirred for 16–20 h and then filtered through a small silica gel column to remove excess ligand and a small amount of brown decomposition product. The yellow methylene chloride solution was then photolyzed using a Rayonet photochemical reaction chamber equipped with 300 nm lamps for 2–4 h or until the infrared spectrum showed essentially complete conversion to the green nonacarbonyl derivative. The green methylene solution was then concentrated and purified by thin layer chromatography using 1:1 hexane/methylene chloride (for **5** and **6**) or 7:3 hexane/methylene chloride (for **7**). Yields for **5** and **6** ranged from 50–60% while those for **7** were 80–85%.

IR(ν(CO) in CH_2Cl_2): 2076w, 2050s, 2017s, 1989m, br cm^{-1}. ^1H NMR at 400 MHz in Acetone-d_6: δ 9.31(d, 1H), 8.68(dd, 1H), 8.61(dd, 1H), 7.41(d, 1H), 7.30(dd, 1H), 4.14(s, br, 2H), −12.23(s, 1H).

Analytical and spectroscopic data for $Os_3(CO)_9(\mu_3\text{-}\eta^2\text{-}(6\text{-}NH_2)C_9H_5N)(\mu\text{-}H)$ **6**. Calculated for $C_{18}H_8N_2O_9Os_3$: C, 22.38; H, 0.78; N, 2.76. Found: C, 22.49, H, 0.86; N, 2.71. IR (ν(CO) in CH_2Cl_2): 2076w, 2041s, 2018s, 1988m, br, 1973w, br cm^{-1}. ^1H NMR at 400 MHz in $CDCl_3$: δ 8.92(dd, 1H), 7.83(d, 1H), 7.79(dd, 1H), 7.36(d, 1H), 6.97(dd, 1H), 4.79(s, br 2H), −12.23(s, 1H).

Spectroscopic and analytical data for $Os_3(CO)_9(\mu_3\text{-}\eta^2\text{-}(5\text{-}Br)C_9H_5N)$ **7**. Calculated for $C_{18}H_6NO_9BrOs_3$: C, 20.97; H, 0.48, N, 1.36. Found: C, 20.84; H, 0.38; N, 1.37; IR(ν(CO) in CH_2Cl_2): 2077m, 2050s, 2020s, 1990s, 1977w, 1952w cm^{-1}. ^1H NMR at 400 MHz in $CDCl_3$: δ 9.32(dd, 1H), 8.49(dd, 1H), 8.39(d, 1H), 7.46(d, 1H), 7.19(dd, 1H), −12.07(s, 1H).

Evaluation of isomer ratios and equilibrium constants. Compounds **1** or **4–8**, were weighed directly into flame dried NMR tubes in 9–11 mg samples (~0.01 mmol). 0.60 mL of the NMR solvent was then added by syringe, followed by syringe addition of 2–20 μL of the amine or acid. The NMR tube was then capped and shaken and the proton or ^{13}C NMR monitored for at least 24 h after which time no further changes in the spectra were observed. The isomer ratios and equilibrium constants were evaluated by integration of the appropriate resonances. For formation constants, the equilibrium expression was:

$$K_f(\text{L/mol}) = \frac{[\text{cluster}-\text{amine adduct}]}{[\text{cluster}][\text{amine}]}$$

in most cases the equilibrium constant was evaluated at several concentrations of added amine and an average value is reported in Table 3. For the protonation equilibrium, the expression used was:

$$K_p = \frac{[\text{clusterH}^+][X^-]}{[\text{cluster}][HX]}$$

Again, the value of the equilibrium constant was evaluated at several acid concentrations in most cases.

(Received 20 January 1998)

Abstract—Cyclic voltammetry and *in situ* infrared spectroelectrochemistry and have been used to investigate the redox behaviour of $[Ru_6C(CO)_{17}]$ and $[NBu_4]_2[Ru_6C(CO)_{16}]$. Under strictly anaerobic conditions, the electrochemical reduction of $[Ru_6C(CO)_{17}]$ yields only $[Ru_6C(CO)_{16}]^{2-}$. However, in the presence of O_2, the reduction of $[Ru_6C(CO)_{17}]$ produces 1.1–1.3 mole of CO_2 per mole of cluster, in addition to $[Ru_6C(CO)_{16}]^{2-}$ and some cluster degradation products. Re-oxidation of electrogenerated $[Ru_6C(CO)_{16}]^{2-}$ results in the re-formation of $[Ru_6C(CO)_{17}]$. The conditions under which oxidation of chemically prepared $[Ru_6C(CO)_{16}]^{2-}$ leads to the formation of $[Ru_6C(CO)_{17}]$ have also been established. The oxidation of $[NBu_4]_2[Ru_6C(CO)_{16}]$ in the absence of a CO-source gives only ill-defined products, as does oxidation in the presence of CO_2, such that $[Ru_6C(CO)_{16}]^{2-}$ does not scavenge CO from other cluster molecules to form $[Ru_6C(CO)_{17}]$. The oxidation of a CO-saturated solution of $[NBu_4]_2[Ru_6C(CO)_{16}]$ produces near quantitative yields of $[Ru_6C(CO)_{17}]$. Mechanisms have been proposed to account for these interconversions.

The activation of polynuclear transition metal carbonyl clusters by oxidation or reduction has proven to be an effective means of initiating a variety of chemical reactions, and as a consequence clusters of this type have been the subject of extensive electrochemical investigations [1–9]. In the case of the hexanuclear carbide-centred octahedral cluster $[Ru_6C(CO)_{17}]$, two-electron reduction is known to induce ligand dissociation, producing $[Ru_6C(CO)_{16}]^{2-}$ which retains the octahedral $\{Ru_6C\}$ core geometry [10–12]. Recently, whilst reinvestigating the redox chemistry of $[Ru_6C(CO)_{17}]$ in non-aqueous media, CO_2 was observed to form, in addition to $[Ru_6C(CO)_{16}]^{2-}$, upon *reduction* of this cluster at a platinum electrode. The conversion of CO to CO_2 is a process that has attracted some attention within the chemical literature. This conversion can be achieved by a number of methods, including both homogeneous and heterogeneous catalysis§ [13–16] stoichiometric reaction of certain carbonyl and molecular oxygen complexes [17–20] electrochemical oxidation of adsorbed CO [21], and the action of oxygen-transfer reagents on transition metal carbonyl complexes [22]. The formation of CO_2 upon reduction of $[Ru_6C(CO)_{17}]$ was discovered when the electrolysis was performed in an infrared reflection-absorption spectroscopic (IRRAS) cell, which

* This paper is dedicated to Sir Jack Lewis on the occasion of his 70th birthday.

§ The water gas shift reaction is a well known example, where CO and H_2O are converted to CO_2 and H_2. See [13–15].

permits direct spectroscopic analysis of the redox products as they are formed. The details of this cell have been reported previously [23, 24] This observation prompted a detailed investigation of the redox behaviour of $[Ru_6C(CO)_{17}]$ and $[NBu_4]_2[Ru_6C(CO)_{16}]$ by voltammetric and infrared (IR) spectroelectrochemical techniques, in an effort to understand the apparent redox-activated transformation of coordinated CO to CO_2. The results from these studies are described herein.

EXPERIMENTAL

$[Ru_6C(CO)_{17}]$ and $[NBu_4]_2[Ru_6C(CO)_{16}]$ were prepared by standard procedures [11]. Voltammetric measurements were performed as described previously [25], using a Pt bead working electrode, Pt wire auxiliary electrode and a Ag/AgCl reference electrode, for which the ferrocene/ferrocenium couple was measured at +0.55 V. Infrared (IR) spectroelectrochemical measurements were conducted using an IRRAS cell [23, 24]. Freshly distilled solvents were used throughout with $[NBu_4][PF_6]$ electrolyte previously dried at 100°C under vacuum.

RESULTS AND DISCUSSION

2.1. *Reduction of* $[Ru_6C(CO)_{17}]$ *in the presence (or absence) of* O_2

Previous electrochemical studies of $[Ru_6C(CO)_{17}]$ have shown that this complex can be reduced in an irreversible two-electron process that leads to the formation of $[Ru_6C(CO)_{16}]^{2-}$ [12]. Cyclic voltammetry (CV) of $[Ru_6C(CO)_{17}]$ in 0.5 mol dm^{-3} $[NBu_4][PF_6]$ in CH_2Cl_2 (*vs.* Ag/AgCl reference electrode) confirmed these results. The irreversible reduction of $[Ru_6C(CO)_{17}]$, observed at $E_{pc} = -0.48$ V, gives rise to another irreversible process, at $E_{pa} = +0.52$ V, which can be attributed to the oxidation of $[Ru_6C(CO)_{16}]^{2-}$ (see below).

Through a series of IR spectroelectrochemical experiments, it has been established that the formation of CO_2 is dependent upon the presence of O_2 in solution, since the reduction of $[Ru_6C(CO)_{17}]$ under strictly anaerobic conditions yields $[Ru_6C(CO)_{16}]^{2-}$, with no CO_2 detected. The changes in the IR difference spectrum accompanying reduction in the absence of O_2 are shown in Fig. 1. The ν_{CO} bands for $[Ru_6C(CO)_{17}]$ at 2068 and 2048 cm^{-1} grow at negative absorbance, indicating depletion of the parent complex in the thin-layer, whilst new bands at 1978, 1918 and 1782 cm^{-1} grow at positive absorbance. The latter bands can be assigned to $[Ru_6C(CO)_{16}]^{2-}$, in accord with the voltammetric experiment. Free CO is thought to be produced when $[Ru_6C(CO)_{17}]$ is reduced under these conditions, although it was not detected (ν_{CO} expected at $\approx$2140 cm^{-1}) [26]. Low concentrations of free CO in solution are reportedly difficult to observe by IR spectroscopy due to the low absorption coefficient for ν_{CO} [26, 27].

O_2 itself does not react with the parent cluster $[Ru_6C(CO)_{17}]$ under the conditions of the voltammetric and spectroelectrochemical experiments, since the IR spectrum of a solution of $[Ru_6C(CO)_{17}]$ in 0.5 mol dm^{-3} $[NBu_4][PF_6]$ in CH_2Cl_2 remains unchanged in the presence of O_2. The CV of $[Ru_6C(CO)_{17}]$ in 0.5 mol dm^{-3} $[NBu_4][PF_6]$ in CH_2Cl_2 in the presence of O_2 is shown in Fig. 2(a). The CV is qualitatively similar to that recorded in the absence of O_2, the only differences being that the irreversible reduction wave at $E_{pc} = -0.48$ V is broadened somewhat and the magnitude of the peak current for the $[Ru_6C(CO)_{16}]^{2-}$ oxidation wave ($E_{pa} = +0.52$ V) is significantly reduced, indicating a diminished yield of this latter species on the CV timescale. The IR spectral changes accompanying the reduction of $[Ru_6C(CO)_{17}]$ in the presence of O_2 are shown in Fig. 3. Aside from the conversion of $[Ru_6C(CO)_{17}]$ to $[Ru_6C(CO)_{16}]^{2-}$, the reduction is accompanied by the formation of CO_2, as shown by the growth of the band in the IR spectrum at 2339 cm^{-1} [28].[4]* The voltammetry and spectroelectrochemistry of $[Ru_6C(CO)_{17}]$, both in the presence and absence of O_2, are unchanged at low temperature (210 K) and are similar in other solvents, *i.e.* acetonitrile and tetrahydrofuran.

QUANTIFICATION OF AMOUNT OF CO_2 FORMED

The quantity of CO_2 formed upon reduction of $[Ru_6C(CO)_{17}]$ can be established directly from the IR spectroelectrochemical experiments, using the ν_{CO} and ν_{CO_2} absorption coefficients for $[Ru_6C(CO)_{17}]$ and CO_2 respectively (Table 1) [29]. Qualitatively, the amount of CO_2 generated increases with increasing concentration of O_2, to a maximum level which corresponds to 1.1–1.3 mole of CO_2 per mole of cluster reduced, *i.e.* solutions pre-saturated with O_2 prior to electrolysis produce between 1.1–1.3 equivalents of

* The reduction of $[Ru_6C(CO)_{17}]$ on a preparative scale is most conveniently achieved using KOH/MeOH as the reductant. In this case the process is thought to involve the nucleophilic addition of OH^- to a CO ligand, forming a carboxylic acid intermediate, followed by the expulsion of CO_2 and then removal of H^+ by OH^- to form $[Ru_6C(CO)_{16}]^{2-}$. The possibility that adventitious H_2O is involved in the ligand transformation rather than O_2 is discounted since the concentration of H_2O (aside from being very low) will be approximately the same for all experiments. If adventitious H_2O were involved in the reaction, then CO_2 would still be liberated, even in the absence of O_2. The solvent/electrolyte solution is prepared in an identical manner just prior to each experiment, using freshly distilled solvent and electrolyte dried under high vacuum. Under these conditions, and with thorough purging of the cell, CO_2 is not liberated upon reduction of the cluster. Only upon the addition of O_2 was CO_2 observed to form.

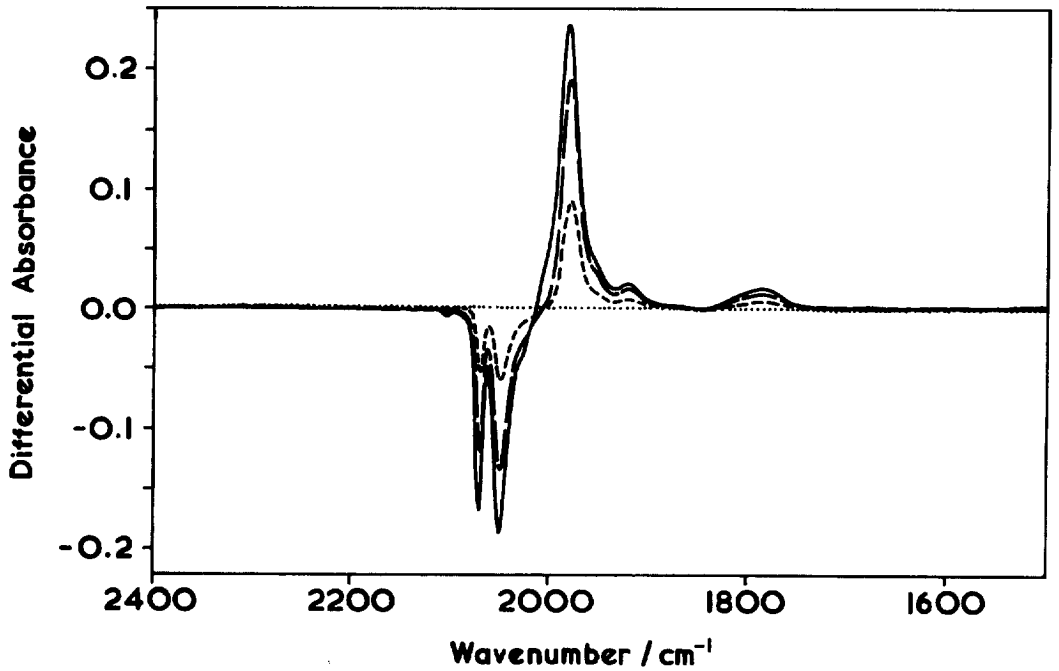

Fig. 1. Changes in the IR difference spectrum accompanying the reduction of $[Ru_6C(CO)_{17}]$ in an IRRAS cell in 0.5 mol dm^{-3} $[NBu_4][PF_6]$ in CH_2Cl_2 at room temperature. Following collection of the initial spectrum of $[Ru_6C(CO)_{17}]$, the potential of the Pt mirror working electrode (E_{app}) is stepped to −0.6 V and single scan spectra (1.0 cm^{-1} resolution) are then collected as a function of time. All spectra are ratioed against the initial $[Ru_6C(CO)_{17}]$ spectrum, such that the first spectrum prior to electrolysis is given by the horizontal line at zero absorbance. Those features that grow at negative absorbance correspond to the consumption of the parent complex, whilst those that grow at positive absorbance indicate formation of the redox product.

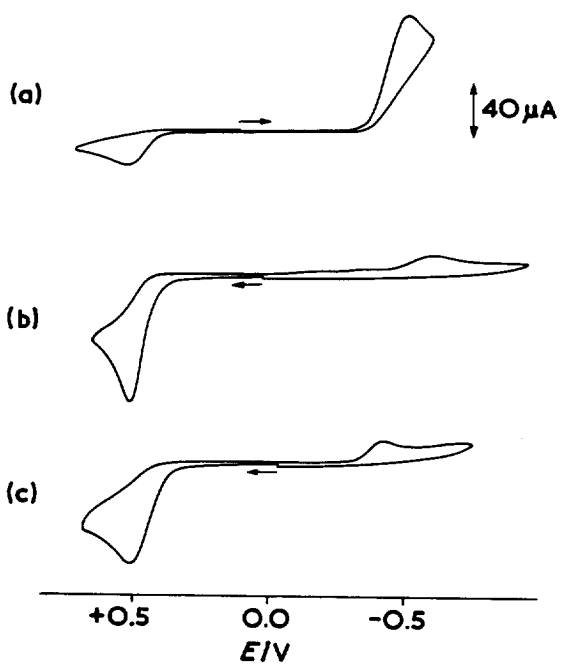

Fig. 2. Cyclic voltammetry in 0.5 mol dm^{-3} $[NBu_4][PF_6]$ in CH_2Cl_2 of (a) $[Ru_6C(CO)_{17}]$ in the presence of O_2, (b) $[NBu_4]_2$ $[Ru_6C(CO)_{16}]$ (c) $[NBu_4]_2[Ru_6C(CO)_{16}]$ in the presence of CO.

CO_2. The formation of greater than one equivalent of CO_2, in cases where the O_2 concentration is relatively high, indicates that the reduction of $[Ru_6C(CO)_{17}]$ in the presence of O_2 to form $[Ru_6C(CO)_{16}]^{2-}$ and CO_2 does not occur stoichiometrically. The conversion of additional CO groups of the active $\{Ru_6C\}$ species to CO_2 necessitates the formation of cluster degradation products and therefore less $[Ru_6C(CO)_{16}]^{2-}$. Comparing the final $[Ru_6C(CO)_{16}]^{2-}$ spectrum shown in Fig. 3 with that of chemically prepared $[Ru_6C(CO)_{16}]^{2-}$ (*e.g.* the first spectrum in Fig. 4) indicates the presence of additional carbonyl-containing species with ν_{CO} in the region 2000–2080 cm^{-1}. These features are attributed to CO-deficient $\{Ru_mC(CO)_n\}$ degradation products. In accord with these observations, the amount of $[Ru_6C(CO)_{16}]^{2-}$ formed, as compared with $[Ru_6C(CO)_{17}]$ initially present, is somewhat variable, depending upon the concentration of O_2 in solution.

REFORMATION OF $[Ru_6C(CO)_{17}]$

The spectral changes accompanying the re-oxidation of $[Ru_6C(CO)_{16}]^{2-}$, electrogenerated in the IRRAS cell as described above, occur in two distinct phases. The initial phase of the electrolysis involves the consumption of $[Ru_6C(CO)_{16}]^{2-}$ as shown by the collapse of the bands at 1978, 1918 and 1782 cm^{-1}, and

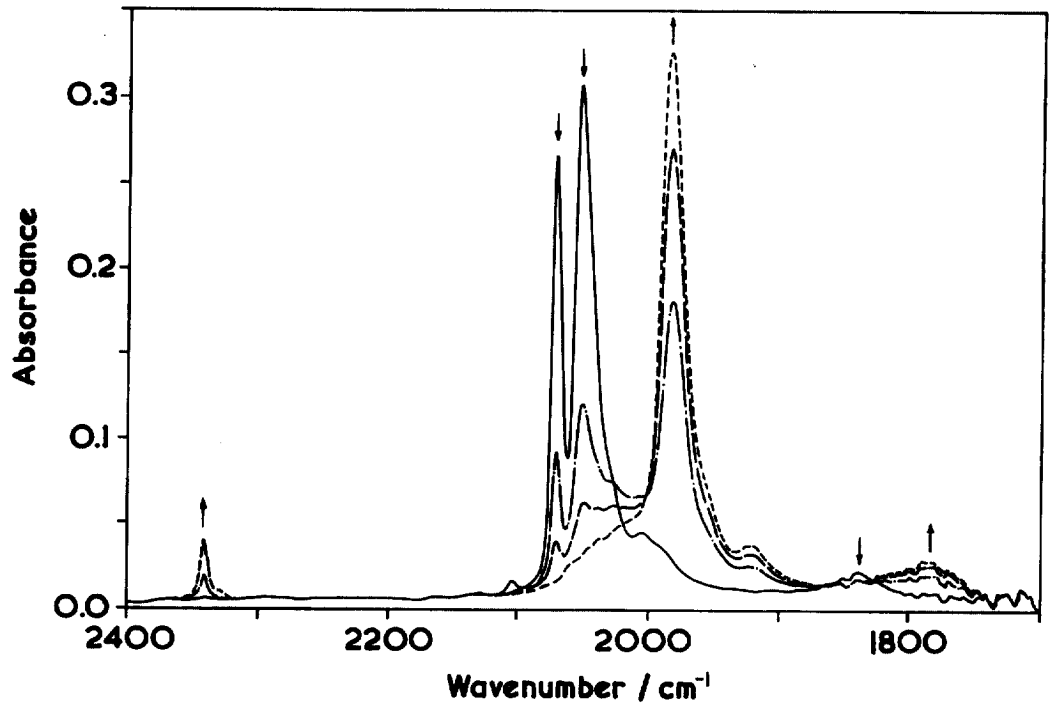

Fig. 3. IR spectral changes accompanying the reduction of $[Ru_6C(CO)_{17}]$ in an IRRAS cell in 0.5 mol dm^{-3} $[NBu_4][PF_6]$ in CH_2Cl_2 at room temperature, in the presence of O_2.

the formation of a species with $\nu_{CO} \approx 2030$–$2025\,cm^{-1}$. With most of the $[Ru_6C(CO)_{16}]^{2-}$ cluster consumed, the second phase of spectral changes occurs. The band(s) at ≈ 2030– $2025\,cm^{-1}$ decrease in intensity, ultimately producing a spectrum with sharp bands at 2068 and 2048 cm^{-1}, signifying the reformation of a considerable quantity of the parent cluster, $[Ru_6C(CO)_{17}]$.

The nature of the intermediate with $\nu_{CO} \approx 2030$–$2025\,cm^{-1}$ is of considerable interest, although its precise identity is uncertain. When the spectroelectrochemical experiment is conducted in tetrahydrofuran, similar spectral changes are observed, although the intermediate is distinctly more stable under these conditions. In this case it is proposed that an $[Ru_6C(CO)_{16}L]$ species is formed, where L is a weakly bound solvent molecule. For those experiments carried out in dichloromethane, where the solvent/electrolyte combination is considered to be non-coordinating medium, the stabilisation of a $[Ru_6C(CO)_{16}L]$ species may arise through an intermolecular interaction between two cluster molecules, or through the reorganisation of carbonyl ligands, *e.g.* end-bound CO (2 electron donor) becoming side-bound (4 electron donor). Another alternative for the intermediate species is the 84 electron-precise octahedral cluster $[Ru_6C(CO)_{16}]$, although given that the two-electron oxidation of $[Ru_6C(CO)_{16}]^{2-}$ is irreversible, even at low temperature (see below), this seems unlikely. The source of CO required for the reformation of $[Ru_6C(CO)_{17}]$, is discussed below.

OXIDATION OF $[Ru_6C(CO)_{16}]^{2-}$ IN THE ABSENCE OF POTENTIAL LIGANDS

Given the observation that the oxidation of electrogenerated $[Ru_6C(CO)_{16}]^{2-}$ leads to the reformation of a considerable amount of the starting cluster $[Ru_6C(CO)_{17}]$, the redox behaviour of chemically prepared $[NBu_4]_2[Ru_6C(CO)_{16}]$ was examined inde-

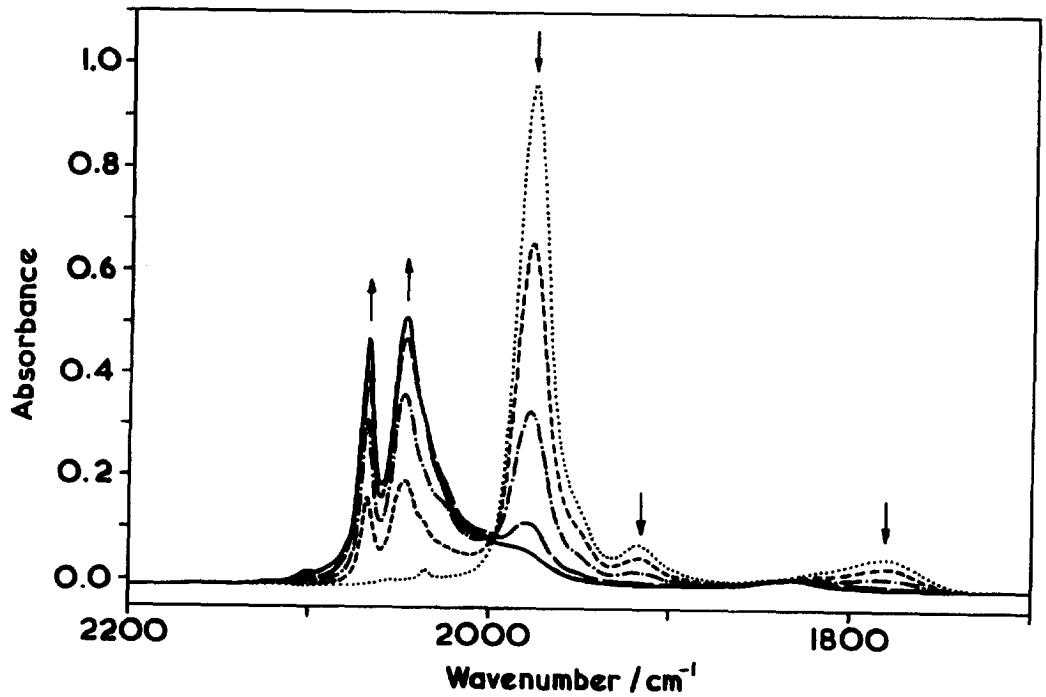

Fig. 4. IR spectral changes accompanying the oxidation of $[NBu_4]_2[Ru_6C(CO)_{16}]$ in an IRRAS cell in 0.5 mol dm^{-3} $[NBu_4][PF_6]$ in CH_2Cl_2 at room temperature, in the presence of CO.

pendently. The CV of $[NBu_4]_2[Ru_6C(CO)_{16}]$, dissolved in 0.5 mol dm^{-3} $[NBu_4][PF_6]$ in CH_2Cl_2, is shown in Fig. 2(b). An irreversible wave at $E_{pa} = +0.52$ V corresponds to the two-electron oxidation of $[Ru_6C(CO)_{16}]^{2-}$ [5] [12].* On the return scan several processes are detected in the region 0– −0.6 V, the most pronounced of which is that with $E_{pc} = -0.59$ V (*cf.* $E_{pc} = -0.48$ V for $[Ru_6C(CO)_{17}]$), in consequence of which $[Ru_6C(CO)_{17}]$ does not appear to re-form on the time-scale of the CV experiment. The species giving rise to the processes detected between 0– −0.6 V form as a result of oxidation of $[Ru_6C(CO)_{16}]^{2-}$, since they are not observed if the scan is switched prior to the irreversible wave with $E_{pa} = +0.52$ V. The CV of $[Ru_6C(CO)_{16}]^{2-}$ was also examined at low temperature (≈213 K), where the oxidation remained irreversible.

The oxidation of $[NBu_4]_2[Ru_6C(CO)_{16}]$ in the IRRAS cell, under conditions identical to those used in the voltammetric experiment, reveals a rapid series of spectral changes showing consumption of the parent cluster $[Ru_6C(CO)_{16}]^{2-}$ and the formation of product(s) with ν_{CO} in the region ≈2030–2025 cm^{-1}. With time, the ν_{CO} bands at 2030–2025 cm^{-1} also collapse, giving rise to a broad, ill-defined band(s) in the region 2110–2030 cm^{-1} with a maximum at ≈2082 cm^{-1}. At no stage of the electrolysis is there any evidence for the formation of $[Ru_6C(CO)_{17}]$, although a small quantity of this cluster may not necessarily be detected, given that the ν_{CO} bands diagnostic of $[Ru_6C(CO)_{17}]$ could be concealed under the broad band centred at 2082 cm^{-1}.

OXIDATION OF $[Ru_6C(CO)_{16}]^{2-}$ IN THE PRESENCE OF CO_2

The behaviour of $[Ru_6C(CO)_{16}]^{2-}$ in the presence of CO_2 was also examined by CV and IR spectroelectrochemistry. The CV of $[NBu_4]_2[Ru_6C(CO)_{16}]$ in 0.5 mol dm^{-3} $[NBu_4][PF_6]$ in CH_2Cl_2, pre-saturated with CO_2, is essentially identical to that recorded in the absence of CO_2. Upon oxidation of this solution in the IRRAS cell, those bands due to $[Ru_6C(CO)_{16}]^{2-}$ collapse with the growth of a slightly broad band at ≈2030–2025 cm^{-1}, during which time the intensity of the band due to CO_2 was unchanged. A further series of spectral changes occur with time, with the band(s) at ≈2030–2025 cm^{-1} decreasing in intensity and ultimately producing a spectrum with bands at 2158 and 2079 cm^{-1}. During the latter phase of the electrolysis some CO_2 is consumed, concomitant with the appearance of weak bands at 1714, 1587 and 1553 cm^{-1}. Although the product(s) of the oxidation of

* If the switching potential is made more positive, a further process is observed with $E_{pa} = +0.75$ V. This process, which has some reversibility in that there is evidence for a return wave ($i_{pc}/i_{pa} < 1.0$), arises as a consequence of oxidation of $[Ru_6C(CO)_{16}]^{2-}$, and may well be associated with the intermediate detected spectroscopically with $\nu_{CO} \approx 2030$–2025 cm^{-1}.

$[Ru_6C(CO)_{16}]^{2-}$ in the presence of CO_2 remain unidentified, in the context of this work the experiment serves to show that dissolved CO_2 does not function as a source of CO for the re-formation of $[Ru_6C(CO)_{17}]$ upon oxidation of electrogenerated $[Ru_6C(CO)_{16}]^{2-}$.

OXIDATION OF $[Ru_6C(CO)_{16}]^{2-}$ IN THE PRESENCE OF CO

The $[Ru_6C(CO)_{16}]^{2-}$ cluster is known to bind certain ligands upon oxidation to form clusters of general formula $[Ru_6C(CO)_{16}L]$ [12, 30]. The CV of $[NBu_4]_2[Ru_6C(CO)_{16}]$ in $0.5\,mol\,dm^{-3}$ $[NBu_4][PF_6]$ in CH_2Cl_2, pre-saturated with CO, is shown in Fig. 2(c). The irreversible oxidation at $E_{pa} = +0.52$ V gives rise to a product wave at $E_{pc} = 0.48$ V, which is consistent with the formation of $[Ru_6C(CO)_{17}]$. The oxidation of this solution in the IRRAS cell produces the spectral changes shown in Fig. 4. Those ν_{CO} bands due to $[Ru_6C(CO)_{16}]^{2-}$ at 1978, 1918 and 1782 cm^{-1} collapse with the growth of bands at 2068 and 2048 cm^{-1}, these being characteristic of $[Ru_6C(CO)_{17}]$. Under these experimental conditions, *i.e.* dry, non co-ordinating solvent and excess of CO, the conversion of $[Ru_6C(CO)_{16}]^{2-}$ to $[Ru_6C(CO)_{17}]$ appears to be quantitative, with no evidence for the production of other carbonyl-containing species. $[Ru_6C(CO)_{17}]$ has also previously been prepared, in nearly quantitative yield, by chemical oxidation of $[Ru_6C(CO)_{16}]^{2-}$ in a solution saturated with CO [31].

It is notable that the oxidative conversion of $[Ru_6C(CO)_{16}]^{2-}$ to $[Ru_6C(CO)_{17}]$ occurs quite quickly, and that there is no spectral evidence for the reaction proceeding *via* a long-lived intermediate, by contrast with the oxidations of electrogenerated $[Ru_6C(CO)_{16}]^{2-}$ or chemically prepared $[Ru_6C(CO)_{16}]^{2-}$. The spectral changes shown in Fig. 4 also give a good indication of the anticipated intensity ratios of ν_{CO} bands for the clean, stoichiometric interconversion of $[Ru_6C(CO)_{16}]^{2-}$ and $[Ru_6C(CO)_{17}]$. A comparison of Fig. 3 and Fig. 4 clearly shows that the reduction of $[Ru_6C(CO)_{17}]$ in the presence of O_2 does not produce a stoichiometric equivalent of $[Ru_6C(CO)_{16}]^{2-}$.

PROPOSED MECHANISM

A mechanism proposed to account for these observations is presented in Fig. 5. The reduction of $[Ru_6C(CO)_{17}]$ first gives the radical-anion $[Ru_6C(CO)_{17}]^{-\cdot}$. This species is probably present in low concentration only, given that the second reduction of the overall two-electron process is likely to be thermodynamically *easier* than the first. Whilst there is no IR spectral evidence for the formation of this thermodynamically unstable species, a previous study has reported its epr spectrum [32]. In the absence of O_2, $[Ru_6C(CO)_{17}]^{-\cdot}$ is reduced further to $[Ru_6C(CO)_{17}]^{2-}$, which is followed by chemical reaction involving CO ejection from the electron-rich cluster $[Ru_6C(CO)_{17}]^{2-}$ to yield $[Ru_6C(CO)_{16}]^{2-}$. Overall, the formation of $[Ru_6C(CO)_{16}]^{2-}$ from $[Ru_6C(CO)_{17}]$ under anaerobic conditions can be described in terms of the Testa and Reinmuth notation [33] as an EEC reaction. Should the $\{Ru_6C\}$ core of the proposed 87 and 88 electron intermediates ($[Ru_6C(CO)_{17}]^{-\cdot}$ and $[Ru_6C(CO)_{17}]^{2-}$ respectively) retain the octahedral geometry of $[Ru_6C(CO)_{17}]$, then $[Ru_6C(CO)_{17}]^{-\cdot}$ and $[Ru_6C(CO)_{17}]^{2-}$ are anticipated to be short-lived. In the presence of O_2 a somewhat different route is proposed. The first intermediate is likely to be the same as that formed under anaerobic conditions, *viz.* the radical-anion $[Ru_6C(CO)_{17}]^{-\cdot}$. Localisation of the odd electron onto a C-atom of a carbonyl ligand would render the radical ·CO group reactive towards O_2, thereby generating first a peroxy-carbonate ligand, $\cdot C(O)_2O$, which then undergoes decomposition either *via* a bimolecular interaction or *via* rearrangement through a carbonato ligand to generate CO_2 and $[Ru_6C(CO)_{16}]^{2-}$ (ECC). The radical-anion $[Ru_6C(CO)_{17}]^{-\cdot}$, although only present in low concentrations, is clearly highly reactive because small amounts of CO_2 are formed upon reduction of $[Ru_6C(CO)_{17}]$ unless extreme care is taken to exclude O_2, an efficient radical scavenger.

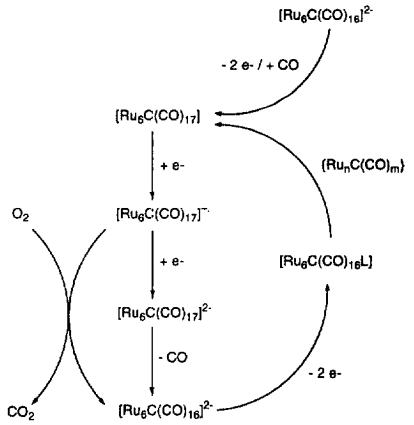

Fig. 5. Proposed Mechanisms. $\{Ru_mC(CO)_n\}$ refers to the cluster degradation products, formed during the initial reduction of $[Ru_6C(CO)_{17}]$ in the presence of O_2.

Through the experiments conducted with $[NBu_4]_2[Ru_6C(CO)_{16}]$, it can be concluded that the re-formation of $[Ru_6C(CO)_{17}]$ upon oxidation of electrogenerated $[Ru_6C(CO)_{16}]^{2-}$ does not occur through scavenging of CO from other $[Ru_6C(CO)_{16}]^{2-}$ species, nor through extraction of CO from CO_2. Instead, it is likely that the cluster degradation products, present in low concentration from the initial reduction of $[Ru_6C(CO)_{17}]$, are the source of CO.

The reaction of O_2 with a polynuclear carbonyl complex is not without precedent. In earlier work with the cluster anion, $[(\mu\text{-H})Os_3(CO)_{11}]^-$, it was dem-

onstrated that the reaction with O_2 led to the formation of the peroxy-formyl anion $[(\mu\text{-H})Os_3(CO)_{10}(\mu\text{-}CO_3)]^-$ which, in the presence of suitable electrophiles such as $[Os_6(CO)_{18}]$, yield CO_2-linked clusters [34]. The proposed peroxy-carbonate intermediate in the present system is clearly closely related to the osmium compound, $[(\mu\text{-H})Os_3(CO)_{10}(\mu\text{-}CO_3)]^-$.

(Received 15 September 1997; accepted 28 February 1998)

Abstract—Three alkyne-bridged dicobalt carbonyl complexes, $[Co_2(\mu\text{-RCCH})(CO)_6]$ (R = H **1a**, Me **1b**, CH_2OH **1c**) have been reacted with $Ph_2P(SPh)$ and with the new thiophosphine ligands, $Ph_2P(SR')$ (R′ = Bu^n, Bu^t), to give, initially, both mono-substituted $[Co_2(\mu\text{-RCCH})(CO)_5\{PPh_2(SR')\}]$ [(R′ = Ph; R = H **2a**, Me **2b**, CH_2OH **2c**), (R′ = Bu^n; R = H **3a**, Me **3b**, CH_2OH **3c**), (R′ = Bu^t; R = H **4a**, Me **4b**)] and bis-substituted $[Co_2(\mu\text{-RCCH})(CO)_4\{PPh_2(SPh)\}_2]$ [(R′ = Ph; R = H **5a**, Me **5b**, CH_2OH **5c**), (R′ = Bu^n; R = H **6a**, Me **6b**, CH_2OH **6c**), (R′ = Bu^t; R = H **7a**, Me **7b**)] products. Thermolysis of complexes **2–4** gives $[Co_2(\mu\text{-}PPh_2)\{\mu\text{-SR′C(O)CRCH}\}(CO)_4]$ [(R′ = Ph; R = H **8a**, Me **8b**, CH_2OH **8c**), (R′ = Bu^n; R = H **9a**, Me **9b**), (R′ = Bu^t; R = H **10a**, R = Me **10b**)] in which sulphur–phosphorus bond cleavage and sulphur–carbon bond formation at the dicobalt centre have occurred to generate SR′C(O)CRCH ligands incorporated into 5-membered ring metallacycles. The transformations are regiospecific with the bulky substituents (R = H) in all cases being located adjacent to the CO moiety of the metallacycle. Treatment of the complex $[Co_2(\mu\text{-}PPh_2)\{\mu\text{-SPhC(O)CHCH}\}(CO)_4]$ **8a** with ^{13}CO and monitoring of the reaction via $^{13}C\text{-}\{^1H\}$-NMR spectroscopy reveals the formation of a selectively labelled species, $[Co_2(\mu\text{-}PPh_2)\{\mu\text{-SPh}^{13}C(O)CHCH\}(^{13}CO)_2(CO)_2]$, in which the ketonic bridging carbonyl signal has been enhanced, while only two of the four signals due to the terminal carbonyl groups have been similarly enhanced. The mechanistic implications of this labelling study are discussed and pathways postulated for the reversible fragmentation of the SR′C(O)CRCH-bridged dicobalt systems. Single crystal X-ray diffraction studies have been performed on $[Co_2(\mu\text{-HCCH})(CO)_4\{PPh_2(SBu^n)\}_2]$ **6a**, revealing axially substituted thiophosphine groups and on $[Co_2(\mu\text{-}PPh_2)\{\mu\text{-SBu}^nC(O)CHCH\}(CO)_4]$ **9a**, in which an almost planar Co–S–C–C=C metallacycle-coordinated to the other cobalt is observed. © 1998 Elsevier Science Ltd. INTRODUCTION

Bimetallic transition metal complexes in which the metal centres are spanned by linked alkyne and carbonyl groups [μ-C(O)CRCR] have been thoroughly studied and a number of different bonding modes have been reported [1–3]. A common observation with these complexes is of the ease with which the alkyne–CO link can be cleaved, often to generate alkyne-bridged bimetallic species [2]. Notably, in the case of $[Rh_2(\mu\text{-CO})\{\mu\text{-C(O)CPhC}(C_6F_5)\}(\eta^5\text{-}C_5Me_5)_2]$, an equilibrium exists in the solid and in solution, with the isomeric alkyne-bridged species $[Rh_2\{\mu\text{-CPhC}(C_6F_5)\}(CO)_2(\eta^5\text{-}C_5Me_5)_2]$ [3].

As a consequence of our studies on the reactions of alkyne-hexacarbonyldicobalt complexes with ligands capable of undergoing intra-ligand bond cleavage, we have prepared a series of dicobalt complexes involving the C(O)CRCR structural motif incorporated into more elaborate bridging systems [4–7]. For example, dicobalt complexes with bridging ligands which incorporate linked alkyne, carbonyl and phosphide groups can be prepared from the reaction of $[Co_2(\mu\text{-CRCR})$

* To whom correspondence should be addressed.

$(CO)_6]$ **1** (R = H, alkyl, aryl or CO_2Me) with diphosphane, $Ph_2P(PPh_2)$, the ordering of the linked groups being influenced by the nature of the R groups [6]. As part of a preliminary communication, we reported that the reaction of $[Co_2(\mu\text{-HCCH})(CO)_6]$ **1a** with the thiophosphine, $Ph_2P(SPh)$, affords, as the sole product, $[Co_2(\mu\text{-}PPh_2)\{\mu\text{-SPhC(O)CHCH}\}(CO)_4]$ **8a**, in which the thiolate rather than the phosphide fragment is linked to the ketonic carbon of the C(O)CHCH moiety [7]. In order to examine the generality and regioselectivity of this reaction, we have sought to explore the role of the substituents on both the alkyne and on the thiolate group (Scheme 1). In addition, we describe the results of ^{13}CO labelling experiments undertaken in order to examine the rigidity of the bridging SRC(O)CRCR ligand in these dicobalt systems.

RESULTS AND DISCUSSION

Preparation of $Ph_2P(SR')$ ($R' = Bu^n$, Bu^t)

Two new thiophosphine ligands, $Ph_2P(SBu^n)$ and $Ph_2P(SBu^t)$, have been prepared in high yield from the reactions of the corresponding sodium thiolates with chlorodiphenylphosphine in THF (see Experimental). The FAB mass spectra of the compounds show their molecular ion peaks while the $^{31}P\text{-}\{^1H\}$ NMR spectra display resonances for the respective diphenylphosphide phosphorus atoms.

Reactions of **1** *with* $Ph_2P(SR')$

The reactions of $[Co_2(\mu\text{-RCCH})(CO)_6]$ (R = H **1a**, Me **1b**, CH_2OH **1c**) with $Ph_2P(SR')$ ($R' = Ph$, Bu^t, Bu^n) in toluene at 293 K afford $[Co_2(\mu\text{-RCCH})(CO)_5\{PPh_2(SR')\}]$ [($R' = Ph$; R = H **2a**, Me **2b**, CH_2OH **2c**), ($R' = Bu^n$; R = H **3a**, Me **3b**, CH_2OH **3c**), ($R' = Bu^t$; R = H **4a**, Me **4b**)] and $[Co_2(\mu\text{-RCCH})(CO)_4\{PPh_2(SR')\}_2]$ [($R' = Ph$; R = H **5a**, Me **5b**, CH_2OH **5c**), ($R' = Bu^n$; R = H **6a**, Me **6b**, CH_2OH **6c**, ($R' = Bu^t$; R = H **7a**, Me **7b**)] (Scheme 1). All of the complexes have been characterised by mass spectrometry, IR, ^1H, ^{31}P and ^{13}C NMR spectroscopy (see Table 1 and Experimental). In addition, the structure of complex **6a** has been the subject of an X-ray diffraction study.

The spectroscopic properties of the mono-substituted species, **2**, **3** and **4**, in solution are consistent with those found for analogous alkyne bridged dicobalt pentacarbonyl complexes with other phosphine substituents [8]. The $^{31}P\text{-}\{^1H\}$ NMR spectrum in each

[c] ^{31}P chemical shifts (δ) in ppm relative to external $P(OMe)_3$ (0.0 ppm) (upfield shifts negative), {^{1}H}-gated decoupled, measured in $CDCL_3$ at 293 K.

case shows the presence of a terminal $Ph_2P(SPh)$ ligand as a broad singlet resonance, assignable to the phosphorus atom of the ligand bound directly to a quadrupolar ^{59}Co atom. In the ^{13}C-$\{^1H\}$ NMR spectra, two carbonyl resonances of intensity ratio 3:2 suggest that the three carbonyl ligands residing on the unsubstituted cobalt are fluxional at room temperature on the NMR timescale and that the carbonyl ligands on the phosphine-substituted cobalt are either fluxional or are both coordinated pseudo-equatorially with the $Ph_2P(SR')$ group in a pseudo-axial position. X-ray studies of other reported alkyne-bridged pentacarbonyl–phosphinedicobalt complexes do show a preference for the phosphine ligands to be coordinated pseudo-axially [8].

The molecular structure of the bis-substituted complex $[Co_2(\mu\text{-HCCH})(CO)_4\{PPh_2(SBu^n)\}_2]$ **6a** complex has been determined by a single crystal X-ray diffraction study. The structure is illustrated in Fig. 1; Table 2 lists selected bond distances and angles.

The Co–Co bond [2.457(1) Å] in **6a** is bridged by an acetylene unit which lies almost perpendicular to the cobalt–cobalt bond [C(1)–Co(1)–Co(2) 50.5(2), C(1)–Co(2)–Co(1) 50.9(2), C(2)–Co(1)–Co(2) 51.3(2), C(2)–Co(2)–Co(1) 50.6(2)°]. Each cobalt atom is further bonded by two carbonyl ligands and a thiophosphine ligand which bonds *via* the phosphorus atom to complete a distorted octahedral arrangement about both metal centres. The two thiophosphine groups are orientated in a "sawhorse" configuration about the cobalt–cobalt bond occupying pseudo-axial sites on each each metal centre [Co(1)–P(1) 2.175(2) Å, P(1)–Co(1)–Co(2) 150.70(5)°; Co(2)–P(2) 2.169(2) Å, P(2)–Co(2)–Co(1) 147.82(5)°]. The configuration of $[Co_2(\mu\text{-HCCH})(CO)_4\{PPh_2(SBu^n)\}_2]$ **6a** is similar to that observed for the related complexes $[Co_2(\mu\text{-PhCCH})(CO)_4\{PPh_2(SPh)\}_2]$ [9] and $[Co_2(\mu\text{-HCCH})(CO)_4(PMe_3)_2]$ [10] with the phosphorus-containing ligands occupying pseudo-axial sites despite the resulting greater steric interactions with the bridging alkynes.

The spectroscopic properties of **6a** and the other bis-substituted complexes, **5–7**, are similar to those reported for analogous bis-substituted triorganophosphine complexes [8, 11]. The ^{31}P-$\{^1H\}$ NMR spectrum, in each case, exhibits one broad signal due to the phosphorus atoms being equivalent and directly coordinated to quadrupolar ^{59}Co atoms. In the complexes containing a symmetrical alkyne bridge (**5a**, **6a**, **7a**), one terminal carbonyl resonance is observed in the ^{13}C-$\{^1H\}$ NMR spectra. However, in the ^{13}C-$\{^1H\}$ NMR spectra of complexes containing an unsymmetrical alkyne bridge (**5b**, **5c**, **6b**, **6c**, **7b**), two terminal peaks are observed implying, either that the CO groups on each substituted cobalt atom are non-fluxional on the NMR timescale at room temperature, or that there is a fluxional process which leaves the CO groups inequivalent, such as the trigonal twist process which has been suggested elsewhere for related complexes [6].

Syntheses and properties of $[Co_2(\mu\text{-PPh}_2)\{\mu\text{-SR'C(O)CRCH}\}(CO)_4]$ **8–10**

Syntheses. The thermolysis of $[Co_2(\mu\text{-RCCH})(CO)_5\{PPh_2(SR')\}]$ [(R' = Ph; R = H **2a**, Me **2b**, CH_2OH **2c**), (R' = Bu^n; R = H **3a**, Me **3b**), (R' = Bu^t; R = H **4a**, Me **4b**)] in toluene at 313 K gives, in addition to the starting material, the complexes $[Co_2(\mu\text{-PPh}_2)\{\mu\text{-SR'C(O)CRCH}\}(CO)_4]$ [(R' = Ph; R = H **8a**, Me **8b**, CH_2OH **8c**), (R' = Bu^n; R = H **9a**, Me **9b**), (R' = Bu^t; R = H **10a**, R = Me **10b**)] in moderate yields (Scheme 1). These complexes have been characterised by ^1H, ^{13}C, ^{31}P NMR and IR spectroscopy, and by mass spectrometry and micro-

analysis. Complex **9a** has been the subject of a single crystal X-ray diffraction study.

Characterisation. The molecular structure of complex $[Co_2(\mu\text{-}PPh_2)\{\mu\text{-}SBu^nC(O)CHCH\}(CO)_4]$ **9a**, including the atom numbering scheme, is illustrated in Fig. 2. Table 3 lists selected bond distances and angles.

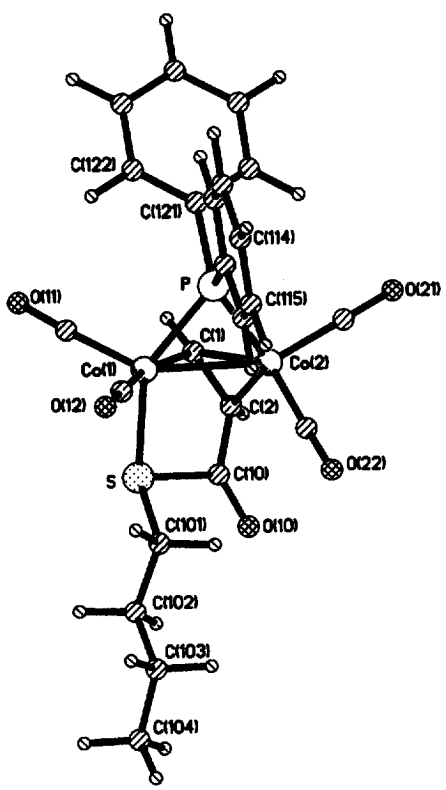

Fig. 2. Molecular structure of $[Co_2(\mu\text{-}PPh_2)\{\mu\text{-}SBu^n\text{-}C(O)CHCH\}(CO)_4]$ **9a** including the atom numbering scheme.

The single cobalt–cobalt bond [2.477(1) Å] is bridged by a diphenylphosphido group and the flyover ring [μ-SBu^{n}C(O)CHCH]. The latter is coordinated *via* S(1) and C(1) to Co(1) to form an almost planar [max. deviation from plane by C(1) 0.28 Å], five-membered metallacyclic ring [Co(1)–S–C(10)–C(2)=C(1)], in which the carbon–carbon double bond is π-coordinated to Co(2) *via* C(1) and C(2). The [μ-SBu^n-C(O)CHCH] ligand is attached to Co(1) such that S(1) and C(1) lie pseudo-*trans* and pseudo-*cis*, respectively, relative to the bridging phosphido group. The [μ-SBu^{n}C(O)CHCH] ligand is arranged in a similar manner to that of [μ-PPh_2C(O)CHCH] in $[Co_2(\mu\text{-}PPh_2)\{\mu\text{-}PPh_2C(O)CHCH\}(CO)_3(PPh_3)]$ [6] and shows very little structural deviation from the related complex, $[Co_2(\mu\text{-}PPh_2)\{\mu\text{-}SPhC(O)CHCH\}(CO)_4]$ **8a**, reported in an earlier communication [7]. The phosphido group bridges the two metal centres asymmetrically with Co(1)–P [2.202(2) Å] being considerably longer than Co(2)–P [2.136(2) Å]. This is presumably due to the better π-donation from Co(2) into the d-orbitals of the phosphorus [Co(2), zero oxidation state; Co(1), oxidation state II].

The spectroscopic properties of the metallacyclic ring complexes **8**–**10** are all very similar and, on this basis, can be considered to have related structures. In their IR spectra (in hexane), in addition to terminal ν_{CO} bands, weak bands at lower wavenumber (*region*: 1722–1653 cm^{-1}) corresponding to the presence of the inserted carbonyl in the [μ-SR′*C(O)*CRCH moiety] are observed.

The NMR spectra are particularly informative about the conformation of **8**–**10**. In the $^{31}P\text{-}\{^1H\}$ NMR spectra, one broad singlet resonance (*region*: 12.8–50.8 ppm), typical of a phosphido ligand bridging a single metal–metal bond [12] is observed for each complex. Similarly, in the ^1H NMR spectra, the orientation of the unsymmetrical olefinic moieties within the five-membered rings can be established unequivocally. When the olefinic moiety has only H sub-

stituents (**8a**, **9a**, **10a**) then, in addition to phosphido and thiolate group resonances, two signals both taking the form of double doublets and integrating as one proton each are seen. The downfield signal (*ca.* δ 6.2) is assigned to the [μ-SR′C(O)CHC*H*] protons, with the more upfield signal (*ca.* δ 4.3) being assigned to the [μ-SR′C(O)C*H*CH] protons. The spectra of the complexes containing an unsymmetrical olefinic fragment within the μ-SR′C(O)CRCH ligand [(R′ = Ph; R = Me **8b**, CH_2OH **8c**), (R′ = Bu^n; R = Me **9b**, CH_2OH **9c**), (R′ = Bu^t; R = Me **10b**)] display, in addition to the phosphido, thiolate and R′ group resonances, one further signal at *ca.* δ 6.2 taking the form of a doublet and integrating as one proton. The observation of only one olefinic hydrogen signal implies that the transformation is regiospecific, with the position of the signal indicating that the olefinic carbon to which the hydrogen is attached is σ-bonded to one of the cobalt atoms. It is noteworty that regiospecificity is not observed in the related thermolytic reaction of $[Co_2(\mu\text{-CRCH})(CO)_6]$ (R = Me **1b**, CH_2OH **1c**) with $Ph_2P(PPh_2)$ in which an approximately 1:1 mixture of $[Co_2(\mu\text{-}PPh_2)\{\mu\text{-}PPh_2C(O)CRCH\}(CO)_4]$ and $[Co_2(\mu\text{-}PPh_2)\{\mu\text{-}PPh_2C(O)CHCR\}(CO)_4]$ is obtained, although in this instance these are not the major products of the reactions [6].

In the $^{13}C\text{-}\{^1H\}$ NMR spectra of complexes **8–10**, in addition to upfield peaks corresponding to the olefinic carbon atoms, clearly identifiable signals are observed at lower fields for the terminal carbonyl [*range*: δ 207.8–198.8] groups and for the C(O) moieties [*range*: δ 184.2–178.8] of the bridging ligands. In most cases, all four of the terminal CO groups give rise to distinct resonances, suggesting the carbonyl ligands are non-equivalent at room temperature.

^{13}CO *labelling studies.* The facility with which the C(O)–CRCR link can be cleaved in a number of bimetallic complexes [1, 2] has prompted us to examine the possibility of similar cleavage within the SR′C(O)CRCH ligand using complex **8a** as a representative example.

Figure 3(a) shows the carbonyl region of the $^{13}C\text{-}\{^1H\}$ NMR spectrum at room temperature of ^{13}CO enriched **8a** $[Co_2(\mu\text{-}PPh_2)\{\mu\text{-}SPh^{13}C(O)CHCH\}(^{13}CO)_4]$, prepared by the reaction of a ^{13}CO enriched sample of **1a** with $Ph_2P(SPh)$. The enrichment is non-selective and five signals are seen; the four more downfield broader signals [δ 206.4, 202.3, 201.8, 198.9] correspond to the carbonyl groups bound to the quadrupolar cobalt atoms, while the sharper singlet resonance at δ 184.2 is due to the C(O) group incorporated into the bridging ligand. In Fig. 3(b) the ^{13}CO spectrum of complex **8a**, enriched by treating **8a** with ^{13}CO at 293 K, is shown. Two significant points emerge from a study of this latter spectrum: (i) the observed ^{13}CO enrichment of the ketonic C(O) group shows that this group exchanges rapidly with ^{13}CO gas at room temperature and (ii) only two of the four terminal carbonyl groups exchange. Accordingly the complex may be formulated as $[Co_2(\mu\text{-}PPh_2)\{\mu\text{-}SPh^{13}C(O)CHCH\}(^{13}CO)_2(CO)_2]$.

The substitution by ^{13}CO gas of the ketonic carbonyl group in solution at room temperature implies that, remarkably under these mild conditions, **8a** readily and reversibly undergoes both olefin–carbonyl and sulphur–carbonyl bond cleavage since these are both necessary for the labelling process. Scheme 2 shows a series of equilibria, the existence of which could account for the labelling process. Although we were unable to detect in solution by NMR spectroscopy any of the postulated intermediate species **A**, **B** or **C**, related complexes containing the proposed or similar bridging ligands have been isolated and shown to undergo carbonylation and/or decarbonylation reactions. Thus, examples of the reversible coupling of alkynes with CO groups on bimetallic centres have been well documented [1, 2, 3] although rare in dicobalt chemistry [13]. Dixneuf *et al.* have demonstrated the reversible decarbonylation reaction of the phosphide-containing metallacyclic ring species $[RuCo(\mu\text{-}CO)\{\mu\text{-}PPh_2C(O)CRCR'\}(CO)_5]$ to give $[RuCo(\mu\text{-}CO)\{\mu\text{-}PPh_2CRCR'\}(CO)_5]$ [14] which presumably proceeds via a similar set of equilibria. It should be noted that intermediate species **C** is not required for ^{13}CO exchange to take place but stable complexes containing a PhSCRCR bridging ligand are known

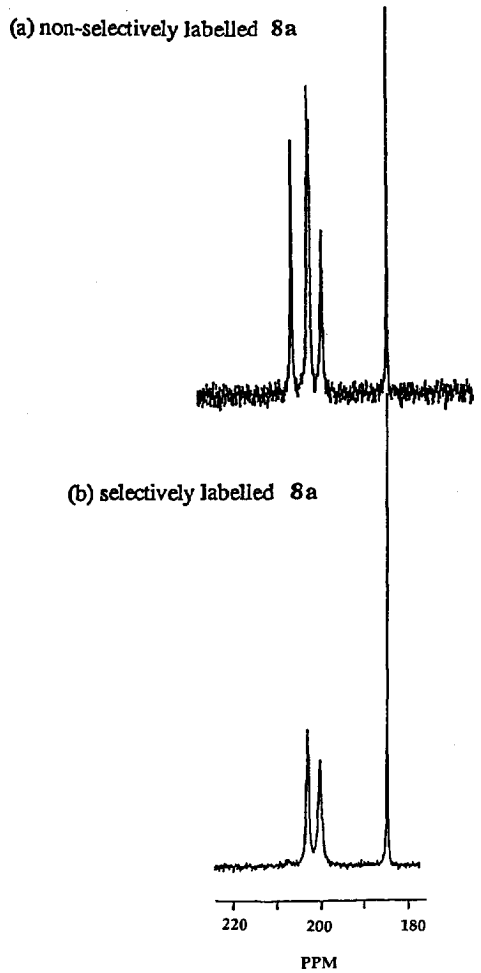

Fig. 3. Carbonyl regions of the ^{13}C-{^1H} NMR spectra of (a) non-selectivity labelled $[Co_2(\mu\text{-}PPh_2)\{\mu\text{-}SPH^{13}C(O)CHCH\}(^{13}CO)_4]$ **8a** and (b) selectively labelled $[Co_2(\mu\text{-}PPh_2)\{\mu\text{-}SPh^{13}C(O)CHCH\}(^{13}CO)_2(CO)_2]$ **8a**.

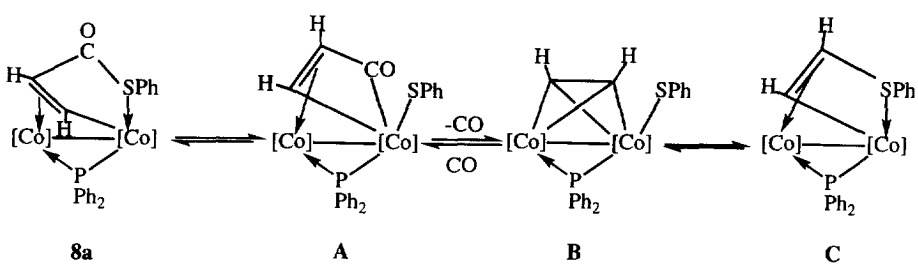
[15] and it seems likely that intermediate **B**, if it is formed, would be in equilibrium with a further intermediate of this type.

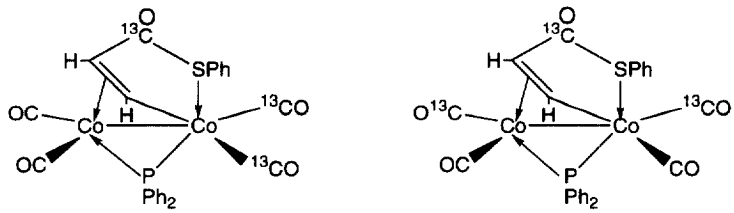
The other observation concerning the labelling, namely that only two of the four terminal carbonyl ligands in **8a** become labelled, is more difficult to explain and it is not clear which two are labelled. Two possible assigments are shown in Scheme 3; in (i) labelling of two carbonyl groups at one metal centre is proposed and in (ii) labelling has occurred at the axial sites of each metal centre. The observed spectra do not permit a distinction between these assignments. It is noteworthy, however, that substitution of carbonyl groups by phosphites or phosphines in complexes possessing the $(OC)_2Co\text{–}Co(CO)_2$ skeleton display a preference for sites axial to the metal–metal bond [4, 6, 7] and it may be that the ^{13}CO substitution favours only the axial sites.

CONCLUSIONS

In all cases, the reactions of thiophosphines with alkyne–hexacarbonyldicobalt complexes proceed by initial coordination of the intact $Ph_2P(SR')$ ligand, followed by phosphorus–sulphur bond cleavage and subsequent coupling of the thiolate fragment with a coordinated CO and CRCH group on the dicobalt complex. The transformations are regiospecific, such that the bulky substituent on the olefinic group is positioned adjacent to the ketonic group. In no case does the generated phosphide fragment couple with the alkyne or the CO groups, instead preferring to adopt a bridging mode between the metal centres. This result may be contrasted with the corresponding reactions of related molybdenum–cobalt alkyne-bridged systems which react with $Ph_2P(SR')$ to give products in which the PPh_2 fragment is linked to the alkyne moiety while the thiolate fragment bridges the metal centres [15]. This difference may be kinetic or thermodynamic in origin but the ready rearrangement of the SPhC(O)CHCH-bridged complex to a $PPh_2CHCHC(O)$-bridged species on bis-phosphine substitution [7], suggests that any kinetic barriers are low. This suggestion is supported by the results from the ^{13}CO labelling of **8a**, which shows that the SR′C(O)CRCH ligand fragments readily and reversibly under mild conditions. In the absence of phosphines therefore, the preference for the SR′ group to be coupled to the organic moiety and for the Ph_2P



Scheme 2. A possible pathway to account for the ^{13}CO labelling of the ketonic carbonyl group in **8a**. Terminal carbonyl groups have been omitted for clarity.



Scheme 3. Two possible assignments for the selectively ^{13}CO labelled terminal carbonyl groups in **8a**.

group to bridge the two metal centres is probably thermodynamically determined.

EXPERIMENTAL

All reactions were carried out under a nitrogen atmosphere using standard Schlenk techniques. Solvents were distilled under nitrogen from appropriate drying agents and degassed prior to use. Preparative thin-layer chromatography (TLC) was carried out on commercial Merck plates with a 0.25 mm layer of silica, or on 1 mm silica plates prepared at the University Chemical Laboratory, Cambridge. Column chromatography was performed on Kieselgel 60 (70–230 mesh) or (230–400 mesh). Products are given in order of decreasing R_f values.

The instrumentation used to obtain spectroscopic data has been described previously [17]. Unless otherwise stated, all reagents were obtained from commercial suppliers and the compounds $[Co_2(\mu\text{-RCCH})(CO)_6]$ (R = H **1a**, Me **1b**, CH_2OH **1c**) and $Ph_2P(SPh)$ were prepared by literature methods [18, 19, 20].

Synthesis of the ligands $Ph_2P(SR')$ ($R' = Bu^n$ *or* Bu^t)

To a solution of NaH (2.00 g, 0.08 mol) in THF (200 cm^3), was added R'SH ($R' = Bu^n$ or Bu^t, 8.8 cm^3, 0.08 mol) and the solution was left to stir. After 2 h, Ph_2PCl (15.0 cm^3, 0.08 mol) was added and the mixture was stirred for a further 3 h. The solvent was removed under reduced pressure and the residue was dissolved in hot toluene and filtered. Removal of the toluene from the filtrate gave $Ph_2P(SBu^n)$ (20.20 g, 92%) as a clear liquid, while pure $Ph_2P(SBu^t)$ (20.03 g, 92%) could be obtained by recrystallisation of the residue from hexane. Compound $Ph_2P(SBu^n)$: fast atom bombardment (FAB) mass spectrum, *m/z* 274 (M^+). ^1H NMR: δ 2.80[m, 2H, CH_2-S], 1.69[m, 2H, CH_2CH_2S], 1.49[m, 2H, $CH_2CH_2CH_2S$] and 0.95[m, 3H, $CH_3CH_2CH_2CH_2S$]. ^{31}P-{^1H} NMR: δ −113.0. ^{13}C-{^1H} NMR: δ 142–128[m, Ph], 32.5[s, CH_2S], 32.3[s, CH_2CH_2S], 20.0[s, $CH_2CH_2CH_2S$] and 11.1[s, $CH_3CH_2CH_2CH_2$]. Compound $Ph_2P(SBu^t)$: FAB mass spectrum, *m/z* 274 (M^+). ^{31}P-{^1H} NMR: δ −130.5.

Reactions of $[Co_2(\mu\text{-CRCH})(CO)_6]$ **1** *with* $Ph_2P(SR')$

(i) To a solution of $[Co_2(\mu\text{-HCCH})(CO)_6]$ **1a** (1.00 g, 3.21 mmol) in toluene (50 cm^3) was added $Ph_2P(SR')$ ($R' = Ph$, 0.944 g, 3.21 mmol; Bu^n, 0.881 g, 3.21 mmol; Bu^t, 0.881 g, 3.21 mmol) in toluene (50 cm^3). The solutions were stirred at 298 K for 24 h and, after removal of the solvent under reduced pressure, the mixtures were adsorbed onto a minimum amount of silica, added to the top of chromatography columns and purified by eluting with hexane–dichloromethane (10:1). This gave, in addition to a small amount of unreacted starting material, orange $[Co_2(\mu\text{-CHCH})(CO)_5\{PPh_2(SR')\}]$ [$R' = Ph$ **2a** (1.149 g, 62%); $R' = Bu^n$ **3a** (1.075 g, 60%); $R' = Bu^t$ **4a** (1.038 g, 58%)] and orange crystalline $[Co_2(\mu\text{-CHCH})(CO)_4\{PPh_2(SR')\}_2]$ [$R' = Ph$ **5a** (0.379 g, 14%); $R' = Bu^n$ **6a** (0.387 g, 15%); $R' = Bu^t$ **7a** (0.390 g, 15%)]. Complex **2a**: FAB mass spectrum, *m/z* 578 (M^+) and M^+-*n*CO (*n* = 1–5). ^{13}C NMR ($CDCl_3$, 293 K, ^1H composite pulse decoupled): δ 204.1(s, 2CO), 201.5(s, 3CO), 136–127(m, Ph) and 70.6(s, 2*C*H). Complex **5a**: FAB mass spectrum, *m/z* 844 (M^+) and M^+-*n*CO (*n* = 1–4). ^{13}C NMR ($CDCl_3$, 293 K, ^1H composite pulse decoupled): δ 206.0(s, 4CO), 136–128(m, Ph) and 70.9(s, 2*C*H). Complex **3a** (Found: C, 49.7; H, 3.8. $C_{23}H_{21}Co_2PSO_5$ requires C, 49.5; H, 3.8): FAB mass spectrum, *m/z* 558 (M^+) and (M^+-*n*CO) (*n* = 1–5). NMR ($CDCl_3$); ^{13}C(^1H composite pulse decoupled), δ 204.5[s, 2CoCO], 201.8[s, 3CoCO], 135–127[m, Ph], 70.7[s, *C*HCH], 32.4[s, CH_2], 31.7[s, CH_2], 21.7[s, CH_2] and 13.4[s, CH_3]. Complex **6a** (Found: C, 56.6; H, 5.0. $C_{38}H_{40}Co_2P_2S_2O_4$ requires C, 56.7; H, 5.0): FAB mass spectrum, *m/z* 804 (M^+) and (M^+-*n*CO) (*n* = 1–4). NMR ($CDCl_3$); ^{13}C(^1H composite pulse decoupled), δ 206.0[s, 4CoCO], 134–128[m, Ph], 70.7[s, *C*HCH], 32.5[s, CH_2], 32.0[s, CH_2], 22.7[s, CH_2] and 13.5[s, CH_3]. Complex **4a**: FAB mass spectrum, *m/z* 558 (M^+) and (M^+-*n*CO) (*n* = 1–5). NMR ($CDCl_3$); ^{13}C(^1H composite pulse decoupled), δ 205.0[s, 2CoCO], 201.9[s, 3CoCO], 137–127[m, Ph], 71.7[s, *C*HCH] and 32.6[s, Bu^t]. Complex **7a**: FAB mass spectrum, *m/z* 804 (M^+) and (M^+-*n*CO) (*n* = 1–4). NMR ($CDCl_3$); ^{13}C(^1H composite pulse decoupled), δ 206.1[s, 2CoCO], 205.9[s, 2CoCO], 135–127[m, Ph], 72.0[s, *C*HCH] and 32.5[s, Bu^t].

(ii) To a solution of $[Co_2(\mu\text{-MeCCH})(CO)_6]$ **1b** (1.00 g, 3.07 mmol) in toluene (50 cm^3) was added $Ph_2P(SR')$ (R′ = Ph, 0.902 g, 3.07 mmol; Bu^n, 0.841 g, 3.07 mmol; Bu^t, 0.841 g, 3.07 mmol) in toluene (50 cm^3). The solutions were stirred at 298 K for 24 h and after removal of the solvent under reduced pressure, the mixtures were adsorbed onto a minimum amount of silica, added to the top of chromatography columns and purified by eluting with hexane–dichloromethane (10:1). This gave, in addition to a small amount of unreacted starting material, orange $[Co_2(\mu\text{-CMeCH})(CO)_5\{PPh_2(SR')\}]$ [R′ = Ph **2b** (1.117 g, 63%); R′ = Bu^n **3b** (0.913 g, 52%); R′ = Bu^t **4b** (0.842 g, 48%)] and orange crystalline $[Co_2(\mu\text{-CMeCH})(CO)_4\{PPh_2(SR')\}_2]$ [R′ = Ph **5b** (0.342 g, 13%); R′ = Bu^n **6b** (0.352 g, 14%); R′ = Bu^t **7b** (0.251 g, 10%)]. Complex **2b** (Found: C, 52.8; H, 3.4; P, 5.3. $C_{26}H_{19}Co_2PSO_5$ requires C, 52.7; H, 3.2; P, 5.2): FAB mass spectrum, m/z 592 (M^+) and (M^+-nCO) (n = 1–5). NMR ($CDCl_3$); $^{13}C\{^1H$ composite pulse decoupled), δ 205.2[s, CoCO], 204.0[s, CoCO], 202.3[s, 3CO], 136–128[m, Ph], 89.8[s, *C*Me], 72.9[s, *C*H] and 19.4[s, Me]. Complex **5b**: FAB mass spectrum, m/z 858 (M^+) and (M^+-nCO) (n = 1–4). NMR ($CDCl_3$); $^{13}C\{^1H$ composite pulse decoupled), δ 206.2[s, 2CoCO], 205.9[s, 2CoCO], 136–127[m, Ph], 86.3[s, *C*Me], 72.5[s, *C*H] and 18.0[s, Me]. Complex **3b**: FAB mass spectrum, m/z 572 (M^+) and (M^+-nCO) (n = 1–5). NMR ($CDCl_3$); $^{13}C\{^1H$ composite pulse decoupled), δ 207.0[s, CoCO], 206.0[s, CoCO], 202.3[s, 3CoCO], 135–125[m, Ph], 88.8[s, *C*Me], 72.8[s, *C*H], 32.4[s, CH_2], 31.7[s, CH_2], 21.7[s, CH_2], 19.5[s, Me] and 13.4[s, CH_2CH_3]. Complex **5b**: FAB mass spectrum, m/z 818 (M^+) and (M^+-nCO) (n = 1–4). NMR ($CDCl_3$); $^{13}C\{^1H$ composite pulse decoupled), δ 206.0[s, 2CoCO], 205.9[s, 2CoCO], 136–128[m, Ph], 88.4[s, *C*Me], 72.1[s, *C*H], 32.3[s, CH_2], 31.9[s, CH_2], 21.8[s, CH_2], 18.1[s, Me] and 13.4[s, CH_2CH_3]. Complex **4b**: FAB mass spectrum, m/z 572 (M^+) and (M^+-nCO) (n = 1–5). NMR ($CDCl_3$); $^{13}C\{^1H$ composite pulse decoupled), δ 205.5[s, CoCO], 204.5[s, CoCO], 202.0[s, 3CoCO], 135–128[m, Ph], 89.0[s, *C*Me], 73.0[s, *C*H], 52.7[s, $C(CH_3)$], 32.6[s, $C(CH_3)_3$] and 19.3[s, Me]. Complex **7b**: FAB mass spectrum, m/z 818 (M^+) and (M^+-nCO) (n = 1–4).

(iii) To a solution of $[Co_2\{\mu\text{-}(CH_2OH)CCH\}(CO)_6]$ **1c** (1.00 g, 2.92 mmol) in toluene (50 cm^3) was added $Ph_2P(SR')$ (R′ = Ph, 0.860 g, 2.92 mmol; R′ = Bu^n, 0.801 g, 2.92 mmol) in toluene (50 cm^3). The solutions were stirred at 298 K for 24 h and after removal of the solvent under reduced pressure, the mixtures were adsorbed onto a minimum amount of silica, added to the top of chromatography columns and purified by eluting with hexane–ethylacetate (10:1). This gave, in addition to a small amount of unreacted starting material, orange $[Co_2\{\mu\text{-}(CH_2OH)CCH\}(CO)_5\{PPh_2(SR')\}]$ [R′ = Ph **2c** (1.134 g, 64%); R′ = Bu^n 3c (1.064 g, 62%)] and orange crystalline $[Co_2\{\mu\text{-}(CH_2OH)CCH\}(CO)_4\{PPh_2(SR')\}_2]$ [R′ = Ph **5c** (0.434 g, 17%); R′ = Bu^n **6c** (0.438 g, 18%)]. Complex **2c**: FAB mass spectrum, m/z 608 (M^+) and (M^+-nCO) (n = 1–5). NMR ($CDCl_3$); $^{13}C\{^1H$ composite pulse decoupled), Δ 205.7[s, br, 2CoCO], 205.1[s, 3CoCO], 135–128[m, Ph], 92.9[s, *C*(CH_2OH)CH], 70.1[s, C(CH_2OH)*C*H] and 62.8[s, C(*C*H_2OH)CH]. Complex **5c**: FAB mass spectrum, m/z 874 (M^+) and (M^+-nCO) (n = 1–4). NMR ($CDCl_3$); $^{13}C\{^1H$ composite pulse decoupled), δ 205.2[s, 2CoCO], 201.9[s, 2CoCO], 135–128[m, Ph], 91.2[s, *C*(CH_2OH)CH], 69.7[s, C(CH_2OH)*C*H] and 61.9[s, C(*C*H_2OH)CH]. Complex **3c**: FAB mass spectrum, m/z 588 (M^+) and (M^+-nCO) (n = 1–5). NMR ($CDCl_3$); $^{13}C\{^1H$ composite pulse decoupled), δ 206.0[s, CoCO], 203.5[s, CoCO], 201.0[s, 3CoCO], 134–128[m, Ph], 92.4[s, *C*(CH_2OH)CH], 70.8[s, C(CH_2OH)*C*H], 63.0[s, C(*C*H_2OH)CH], 32.4[s, CH_2], 31.7[s, CH_2], 21.7[s, CH_2] and 13.4[s, CH_3]. Complex **6c**: FAB mass spectrum, m/z 834 (M^+) and (M^+-nCO) (n = 1–4). NMR ($CDCl_3$); $^{13}C\{^1H$ composite pulse decoupled), δ 206.0[s, br, 4CoCO], 135–128[m, Ph], 92.0[s, *C*(CH_2OH)CH], 70.0[s, C(CH_2OH)*C*H], 62.9[s, C(*C*H_2OH)CH], 32.5[s, CH_2], 31.8[s, CH_2], 21.8[s, CH_2] and 13.4[s, CH_3].

Syntheses of $[Co_2(\mu\text{-}PPh_2)\{\mu\text{-}SR'C(O)CRCH\}(CO)_4]$ **8–10**

(i) Solutions of $[Co_2(\mu\text{-CHCH})(CO)_5\{PPh_2(SR')\}]$ (R′ = Ph **2a**, 0.289 g, 0.50 mmol; R′ = Bu^n **3a**, 0.300 g, 0.54 mmol; R′ = Bu^t **4a**, 0.300 g, 0.54 mmol) in toluene (50 cm^3) were thermolysed at 313 K for 5–8 h. After removal of the solvent under reduced pressure, the mixtures were purified using preparative TLC with hexane–dichloromethane (6:1) as eluent to give, in addition to a small amount of unreacted starting material, the red crystalline complexes $[Co_2(\mu\text{-}PPh_2)\{\mu\text{-}SR'C(O)CHCH\}(CO)_4]$ [R′ = Ph **8a** (0.173 g, 60%); R′ = Bu^n **9a** (0.168 g, 56%); R′ = Bu^t **10a** (0.159 g, 53%)]. Complex **8a** (Found: C, 51.6; H, 3.2; P, 5.5. $C_{25}H_{17}Co_2O_5PS$ requires C, 51.9; H, 3.0; P, 5.4): FAB mass spectrum, m/z 578 (M^+) and M^+-nCO (n = 1–5). ^{13}C NMR ($CDCl_3$, 293 K, ^1H composite pulse decoupled): δ 206.4(s, CO), 202.3(s, CO), 201.8(s, CO), 198.9(s, CO), 181.7[s, SPh*C*(O)CHCH], 142–128(m, Ph), 124.0[d, br, ^2J(PC) 30, SPhC(O)CH*C*H] and 63.1[s, br, SPhC(O)*C*HCH]. Complex **9a** (Found: C, 49.5; H, 3.8. $C_{23}H_{21}Co_2O_5PS$ requires C, 49.5; H, 3.8): FAB mass spectrum, m/z 558 (M^+) and M^+-nCO (n = 1–4). ^{13}C NMR ($CDCl_3$, 293 K, ^1H composite pulse decoupled): δ 206.6(s, CoCO), 202.9(s, CoCO), 202.0(s, CoCO), 199.0(s, CoCO), 184.2[s, SBu^n*C*(O)CHCH], 141–128(m, Ph), 124.0[d, ^2J(PC) 34, SBu^{n}C(O)CH*C*H], 62.7[s, SBu^{n}C(O)*C*HCH], 29.7[s, CH_2], 29.4[s, CH_2], 21.9[s, CH_2] and 13.6[s, CH_3]. Complex **10a**: FAB mass spectrum, m/z 558 (M^+) and M^+-nCO (n = 1–4).

(ii) Solutions of $[Co_2(\mu\text{-CMeCH})(CO)_5\{PPh_2(SR')\}]$ (R′ = Ph **2b**, 0.289 g, 0.50 mmol; R′ = Bu^n **3b**, 0.300 g, 0.54 mmol; R′ = Bu^t **4b**, 0.300 g, 0.54 mmol) in toluene

($50\,cm^3$) were thermolysed at 313 K for 5–8 h. After removal of the solvent under reduced pressure, the mixtures were purified using preparative TLC with hexane–dichloromethane (6:1) as eluent to give, in addition to a small amount of unreacted starting material, the red crystalline complexes $[Co_2(\mu\text{-}PPh_2)\{\mu\text{-}SR'C(O)CMeCH\}(CO)_4]$ [R′ = Ph **8b** (0.173 g, 60%); R′ = Bu^n **9b** (0.168 g, 56%; R′ = Bu^t **10b** (0.159 g, 53%)]. Complex **8b** (Found: C, 52.4; H, 3.4; P, 5.4. $C_{26}H_{19}Co_2O_5PS$ requires C, 52.7; H, 3.2; P, 5.2): FAB mass spectrum, *m/z* 592 (M^+) and M^+-*n*CO (*n* = 1–5). ^{13}C NMR ($CDCl_3$, 293 K, ^1H composite pulse decoupled): δ 207.8(s, CoCO), 202.7(s, CoCO), 202.0(s, CoCO), 199.4(s, CoCO), 178.8[s, SPh*C*(O)CMeCH], 142–127[m, Ph and SPhC(O)C-MeCH], 78.9[s, br, SPhC(O)*C*MeCH] and 23.6[s, Me]. Complex **9b**: FAB mass spectrum, *m/z* 572 (M^+) and M^+-*n*CO (*n* = 1–4). ^{13}C NMR ($CDCl_3$, 293 K, ^1H composite pulse decoupled): δ 207.4(s, CoCO), 207.0(s, 2CoCO), 198.8(s, CoCO), 181.3[s, SBu^n-*C*(O)CMeCH], 141–128(m, Ph), 126.6[d, ^2J(PC) 33, SBu^{n}C(O)CMe*C*H], 70.6[s, SBu^{n}C(O)*C*MeCH], 29.7[s, CH_2], 29.4[s, CH_2], 21.9[s, SBu^{n}C(O)C*Me*CH], 21.7[s, CH_2] and 13.6[s, CH_3]. Complex **10b**: FAB mass spectrum, *m/z* 572 (M^+) and M^+-*n*CO (*n* = 1–4).

(iii) Solutions of $[Co_2\{\mu\text{-}(CH_2OH)CCH\}(CO)_5\{PPh_2(SR')\}]$ (R′ = Ph **2a**, 0.289 g, 0.50 mmol; R′ = Bu^n **3a**, 0.300 g, 0.54 mmol; R′ = Bu^t **4a**, 0.300 g, 0.54 mmol) in toluene ($50\,cm^3$) were thermolysed at 313 K for 5–8 h. After removal of the solvent under reduced pressure, the mixtures were purified using preparative TLC with hexane–dichloromethane (6:1) as eluent to give, in addition to a small amount of unreacted starting material, the red crystalline complexes $[Co_2(\mu\text{-}PPh_2)\{\mu\text{-}SR'C(O)C(CH_2OH)CH\}(CO)_4]$ [R′ = Ph **8c** (0.173 g, 60%); R′ = Bu^n **9c** (0.168 g, 56%)]. Complex **8c** (Found: C, 50.9; H, 3.4. $C_{26}H_{19}Co_2O_6PS$ requires C, 51.3; H, 3.1): FAB mass spectrum, *m/z* 608 (M^+) and M^+-*n*CO (*n* = 1–4). ^{13}C NMR ($CDCl_3$, 293 K, ^1H composite pulse decoupled): δ 206.5(s, CoCO), 201.8(s, 2CoCO), 198.9(s, CoCO), 180.5[s, SPh*C*(O)C(CH_2OH)CH], 142–128[m, Ph], 126.2[d, ^2J(PC) 33 SPhC(O)C-(CH_2OH)*C*H], 66.3[s, SPhC(O)C(*C*H_2OH)CH] and 63.4[s, SPhC(O)*C*(CH_2OH)CH]. Complex **9c**: FAB mass spectrum, *m/z* 588 (M^+) and M^+-*n*CO (*n* = 1–4). ^{13}C NMR ($CDCl_3$, 293 K, ^1H composite pulse decoupled): δ 207.0(s, CoCO), 204.0(s, CoCO), 202.0(s, CoCO), 200.0(s, CoCO), 183.3[s, SBu^n-*C*(O)C(CH_2OH)CH], 142–128(m, Ph), 128.3[d, ^2J(PC) 33, SBu^{n}C(O)C(CH_2OH)*C*H], 66.5[s, SBu^n-C(O)C(*C*H_2OH)CH], 64.9[s, SBu^{n}C(O)*C*(CH_2OH)CH], 29.7[s, CH_2], 29.0[s, CH_2], 21.9[s, CH_2] and 13.5[s, CH_3].

Isotopic labelling experiments

Isotopic enrichment of **1a**. Complex $[Co_2(\mu\text{-}HCCH)(CO)_6]$ **1a** (1.00 g, 3.21 mmol) was dissolved in toluene ($50\,cm^3$). The solution was degassed under reduced pressure, back-filled with an atmosphere of ^{13}CO and left to stir at 293 K for 24 h. The reaction mixture was filtered and the solvent removed under reduced pressure to give the isotopically labelled species $[Co_2(\mu\text{-}HCCH)(^{13}CO)_n(^{12}CO)_n]$ (*n* = 1–6). NMR evidence shows a degree of enrichment >90% had been achieved.

Preparation of non-selectively labelled **8a**. The non-selectively labelled complex $[Co_2(\mu\text{-}PPh_2)\{\mu\text{-}SPh^{13}C(O)CHCH\}(^{13}CO)_4]$ **8a** was prepared using the procedure outlined in parts (b) and (c) above, starting from an isotopically enriched sample of **1a**.

Preparation of selectively labelled **8a**. Complex $[Co_2(\mu\text{-}PPh_2)\{\mu\text{-}SPhC(O)CHCH\}(CO)_4]$ **8a** (0.200 g, 0.35 mmol) was dissolved in toluene ($50\,cm^3$). The solution was degassed under reduced pressure, back-filled with an atmosphere of ^{13}CO and left to stir at 293 K for 24 h. The reaction mixture was filtered and the solvent removed under reduced pressure to give the selectively labelled species $[Co_2(\mu\text{-}PPh_2)\{\mu\text{-}SPh^{13}C(O)CHCH\}(^{13}CO)_2(CO)_2]$. NMR evidence shows a degree of enrichment of the labelled carbonyl groups to be >90%.

Crystal structure analysis of complexes **6a** *and* **9a**

Crystal data for $[Co_2(\mu\text{-}HCCH)(CO)_4\{PPh_2(SBu^n)\}_2]$ **6a**. $C_{38}H_{40}Co_2O_4P_2S_2$, M = 804.62, triclinic, space group $P\bar{1}$ (no. 2), a = 10.634(2), b = 13.563(3), c = 13.864(3) Å, α = 74.16(2), β = 82.46(2), γ = 81.26(2)°, U = 1892.8(7) Å^3, D_c = 1.412 g cm^{-3}, Z = 2, μ(Mo-K_α) = 11.0 cm^{-1}, $F(000)$ = 832.

Data collection for **6a**. An orange crystal of size 0.06 × 0.46 × 0.48 mm was used in data collection. Intensity data were collected on a Siemens R3m/V diffractometer at 295 K, using ω-2θ scan mode with graphite monochromated Mo-K_α radiation (λ = 0.71073 Å). No significant drift was encountered during data collection. 13271 reflections ($-12 \le h \le 12$, $-15 \le k \le 15$, $-16 \le l \le 16$) were collected in the range θ 1.5–25.0° with a scan width of 1.20°, to give 6636 (R_{int} = 0.0640) independent reflections with $I/\sigma(I) > 2.0$.

Structure solution and refinement for **6a**. All intensity data were corrected for Lorentz polarisation effects, and absorption corrections by the ψ-scan method; minimum and maximum transmission factors 0.3161 and 0.3804. Computations were performed using the SHELTXL PLUS package [21]. The structure was solved by a combination of Patterson synthesis (Co atoms) and Fourier-difference techniques. The structure was refined by full matrix least squares with all atoms assigned anisotropic displacement parameters [22]. Hydrogen atoms were placed in idealised positions and allowed to ride on the relevant carbon atoms. Residual electron densisty found after all atoms had been assigned, was successfully attributed to disorder of the butyl fragment of one of the PPh_2(S-

Bu^n) ligands and this was included in the final refinement. In the final cycles of refinement, a weighting scheme of the form $\omega^{-1}=\sigma^2(F)+0.010F^2$ gave satisfactory agreement analysis. The refinement converged to $R=0.0553$, w$R=0.1088$ and a goodness of fit = 1.002, with a final shift/esd of 0.019 and a residual electronic density of less than 1 e Å^{-3}.

Crystal data for [$Co_2(\mu$-$PPh_2)\{\mu$-SBu^n C(O)CHCH$\}(CO)_4$] **9a**. $C_{23}H_{21}Co_2O_5PS$, $M=558.29$, orthorhombic, space group $P2_12_12_1$, $a=10.240(3)$, $b=10.612(4)$, $c=22.160(4)$ Å, $U=2408.1(6)$ Å^3, $D_c=1.540$ g cm^{-3}, $Z=4$, μ(Mo–K_α) = 10.6 cm^{-1}, $F(000)=1136$.

Data collection for **9a**. A red crystal of size $0.25\times0.34\times0.29$ mm was used in data collection. Intensity data were collected on a 4 circle Philips diffractometer at 295 K, using ω-2θ scan modewith graphite monochromated Mo–K_α radiation ($\lambda=0.71073$ Å). No significant drift was encountered during data collection. 2438 reflections ($0\le h\le14$, $0\le k\le14$, $0\le l\le29$) were collected in the range θ 3–25°, with a scan width of 0.70°. Equivalent reflections were merged to give 1972 ($R_{int}=0.0644$) independent reflections with $I/\sigma(I)>3.0$.

Structure solution and refinement of **9a** [23]. The fractional coordinates of the metal atoms were obtained from a Patterson synthesis; remaining non-hydrogen atoms were located from subsequent Fourier-difference syntheses. The hydrogen atoms of this structure were included in geometrically idealised postions and constrained to ride on the relevant carbon atoms in calculated positions of C–H 1.080 Å with fixed thermal parameters of 0.08 Å^2, but were not refined. After initial refinement with isotropic thermal parameters for all atoms, empirical absorption correction were applied [24]. In the final stages of full matrix refinement the two metal atoms, the S and P atoms on the bridging ligands and the atoms of the CO groups were treated as anisotropically vibrating atoms. The final shift/esd was 0.032 and there was a residual electronic density of less than 1 e Å^{-3}. Refinement converged with reliability factors of $R=0.039$ and Rw = 0.042 and with weights of $1/\sigma^2F_o$ assigned to individual reflections [23].

Additional material, available from the Cambridge Crystallographic Data Centre, comprises H-atom coordinates, thermal parameters and remaining bond lengths and angles.

(Received 13 February 1998)

Abstract—An overview is provided of some recent developments in manganese carboxylate cluster chemistry. A variety of synthetic methodologies are described together with the structures of the resultant products, which span metal nuclearities of 4 to 18 and oxidation states of II to IV, including mixed-valency. The spins of the ground states of these products are often large and sometimes abnormally large, and in certain cases when this is coupled to a sufficiently large magnetoanisotropy, the clusters function as single-molecule magnets i.e., they can be magnetized by an external magnetic field below a critical temperature. These complexes display hysteresis in magnetization *vs.* magnetic field studies, and clear evidence for quantum tunnelling of magnetization. Such results establish single-molecule magnetism as a new magnetic phenomenon, and one that holds great promise for next-century technological applications. © 1998 Elsevier Science Ltd. INTRODUCTION

Over the last decade or so, manganese carboxylate cluster chemistry has proved to be a rich source of a variety of polynuclear species. To date, metal nuclearities of up to 18 have been encountered in discrete form, and the Mn oxidation states have spanned the range II–IV, including mixed valency. The metal ions are invariably bridged by combinations of O^{2-}, HO^- and RO^- ions, and occasionally by one or both oxygen atoms of carboxylate groups. The stimuli for these studies have been varied and have included (i) the search for models of Mn-containing proteins and enzymes, in which Mn nuclearities up to 4 have been identified [1]; and (ii) the realization that Mn clusters often possess large (and occasionally abnormally large) values of ground state spin (S) [2], leading to a desire to understand the factors that yield this property and, in turn, stimulating the development of synthesis methodologies that might yield such species on a regular basis.

In a previous report during the early years of our efforts in Mn carboxylate chemistry [3], we described how the trinuclear, oxide-centered complexes $[Mn_3O(O_2CR)_6L_3]^z$ ($z = 0$, Mn^{II}, $2Mn^{III}$; $z = +1$, $3Mn^{III}$) were an excellent starting point for the synthesis of species with nuclearities up to 12. In the intervening years, a number of new synthesis procedures have been developed, several of which will be summarized herein. We shall also describe the magnetic properties of selected species and show how the high spin value exhibited by some of them leads to these complexes displaying the new magnetic phenomenon of single-molecule magnetism, which was indeed initially identified in Mn carboxylate chemistry. For

[1] Dedicated to Professor Jack Lewis on the occasion of his 70th birthday.

* Author to whom correspondence should be addressed.

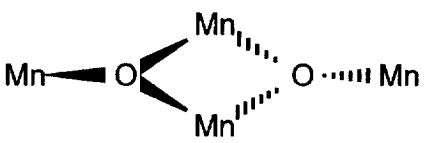
consistency with the theme of this Symposium-in-Print, we shall only describe complexes with nuclearities $\geqslant 4$.

SYNTHETIC METHODS

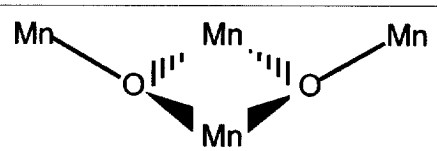
Aggregation of $[Mn_4O_2]^{8+}$ *butterfly complexes*

One family of complexes that had been frequently encountered in earlier work was that containing a $[Mn_4O_2]^{8+}$ core with a planar or butterfly-like Mn_4 unit and μ_3-O^{2-} ions. Thus, the species $[Mn_4O_2(O_2CR)_7(L\text{-}L)_2]^z$ had been prepared and characterized, and contain peripheral ligation provided by bridging RCO_2^- and chelating L-L (bipyridyl (bpy) [4], or the anions of picolinic acid (pic^-) [5], 8-hydroxyquinoline (hqn^-) [6], 2-hydroxymethylpyridine (hmp^-) [6] or dibenzoylmethane (dbm^-) [7]. These complexes were studied in detail by a variety of methods but did not represent good starting points to higher nuclearity species until the related complex $(NBu^n_4)[Mn_4O_2(O_2CPh)_9(H_2O)]$ (**1**; $4Mn^{III}$) was synthesized (Fig. 1) [7, 8]: the anion contains a $[Mn_4O_2]^{8+}$ butterfly unit with only H_2O and $PhCO_2^-$ peripheral groups, and it has consequently proven a superb stepping stone to other species. A few examples of its use for this purpose will be described.

Addition of Me_3SiCl destabilizes **1** by carboxylate abstraction and causes a nuclearity change to yield $(NBu^n_4)[Mn_8O_6Cl_6(O_2CPh)_7(H_2O)_2]$ (**2**; $8Mn^{III}$) [7, 9], whose anion is shown in Fig. 2. Such a transformation must clearly involve a complicated series of fragmentation/aggregation steps and equilibria, and the formation and isolation of **2** is undoubtedly facilitated by its low solubility that causes it to crystallize from solution. This is a common theme in many syntheses of higher nuclearity Mn species, and also rationalizes the often observed sensitivity of the product identity to the exact reaction conditions (i.e., carboxylate, solvent, etc.) which likely alter the relative solubilities of solution species in equilibrium. The structure of



planar



butterfly

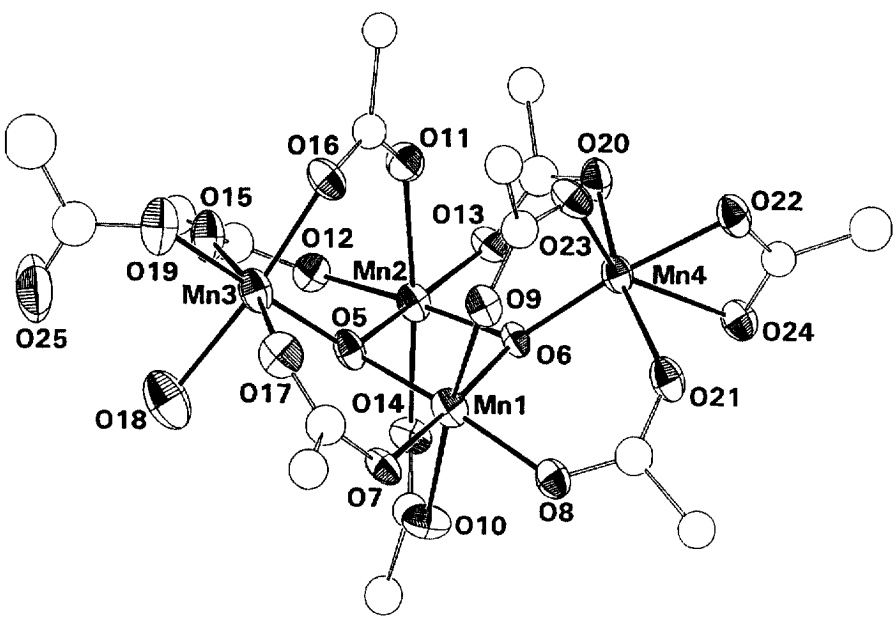


Fig. 1. The structure of the $[Mn_4O_2(O_2CPh)_9(H_2O)]^-$ anion of complex **1**.

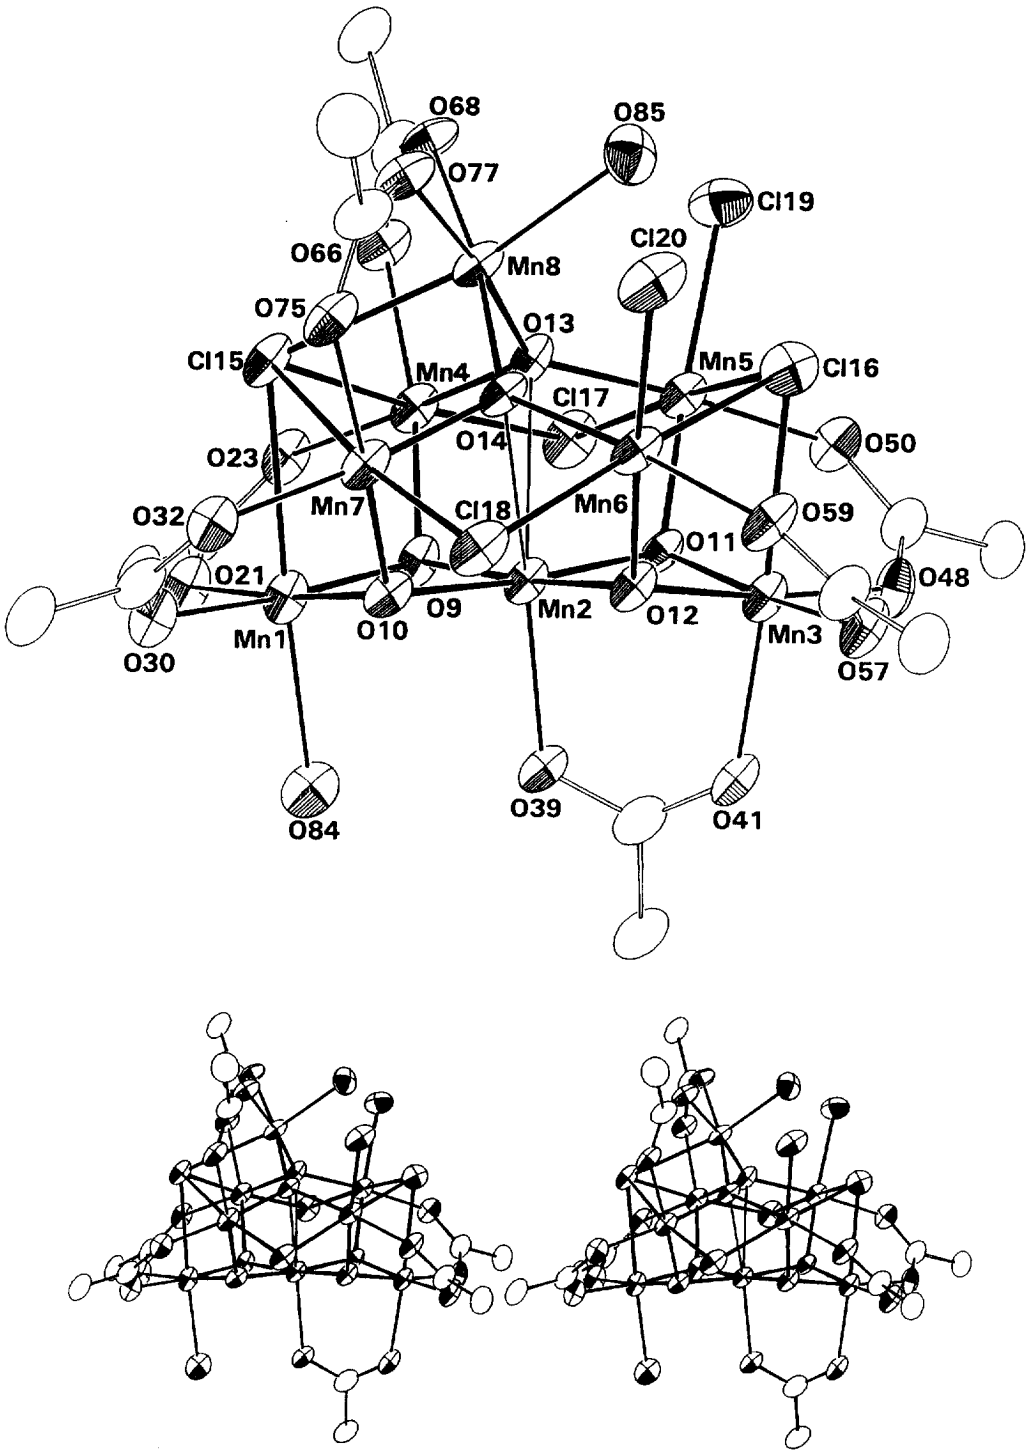

Fig. 2. The structure of the $[Mn_8O_6Cl_6(O_2CPh)_7(H_2O)_2]^-$ anion of complex **2**.

2 consists of two body-fused butterfly units sharing central Mn(2), and an eighth metal atom, Mn(8), is held to the four wingtip Mn atoms by oxide bridges O(13) and O(14).

Another way of destabilizing complex **1** to aggregation is addition of benzoyl peroxide $(PhCO_2)_2$, which again gives a higher nuclearity product $[Mn_9Na_2O_7(O_2CPh)_{15}(MeCN)_2]$ (**3**; $9Mn^{III}$) [9] but no increase in the Mn oxidation level (of the isolated product, at least). The structure (Fig. 3) again comprises two body-fused butterfly units as in **2**, but now with two additional Mn atoms attached to the wingtip

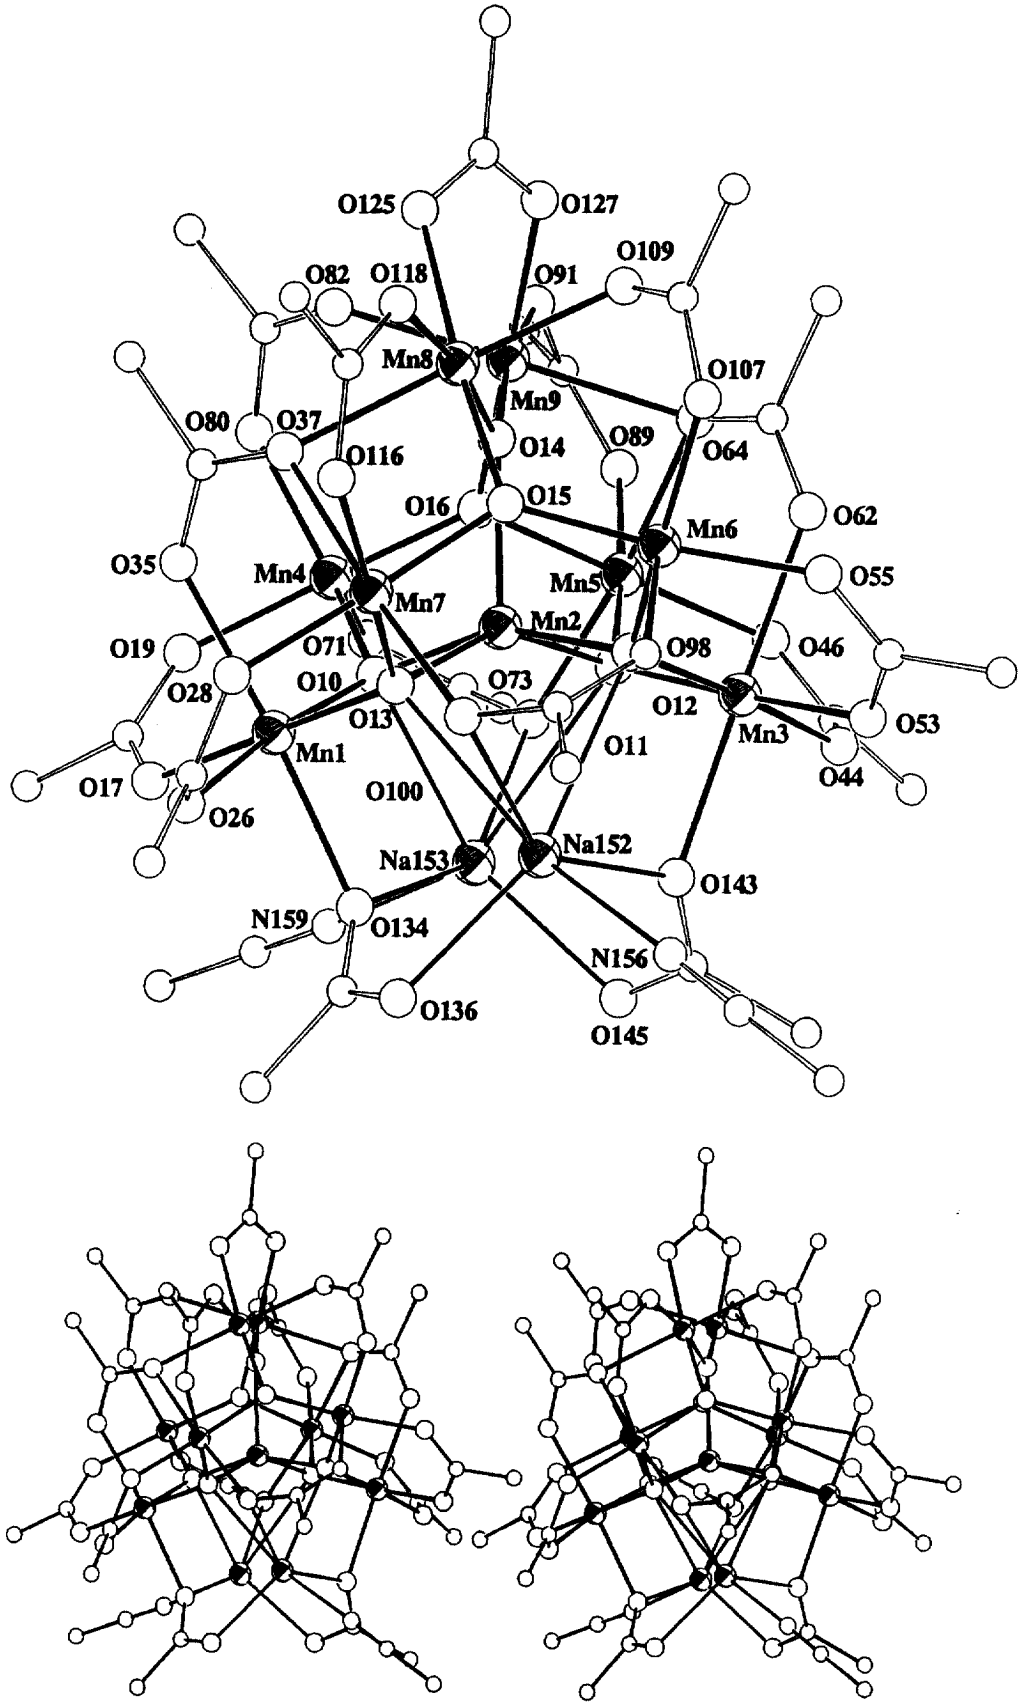

Fig. 3. The structure of $[Mn_9Na_2O_7(O_2CPh)_{15}(MeCN)_2]$ (**3**).

positions by three O^{2-} ions O(14)–O(16). The Na^+ ions are intimately attached to the $[Mn_9O_7]$ unit and the system is best described as a mixed-metal cluster. A related complex with the same core structure but without Na^+ ions, $[Mn_9O_7(O_2CPh)_{13}(py)_2]$, has been made by Armstrong and coworkers [10].

The reactions of complex **1** with appropriate dicarboxylates was envisaged as a potential way of bringing two or more $[Mn_4O_2]$ units into close proximity and thereby possibly triggering aggregation into a higher nuclear product. Two particularly interesting successes of this strategy can be described. The reaction of **1** with 2,2-diethylmalonate (Et_2mal^{2-}) gives $(NBu^n_4)_2[Mn_8O_4(O_2CPh)_{12}(Et_2mal)_2(H_2O)_2]$ (**4**; $2Mn^{II}$, $6Mn^{III}$) [8] whose structure (Fig. 4) clearly demonstrates that its $[Mn_8O_4]$ core can be described as two linked $[Mn_4O_2]$ butterfly units. The Et_2mal^{2-} groups provide additional inter-butterfly linkages and thus no doubt contribute to the formation and stabilization of an octanuclear species, presumably by initially forming a species in which two separate $[Mn_4O_2]$ complexes are bridged by a Et_2mal^{2-} group. In contrast, the reaction of complex **1** with KH(phth) (phth = phthalate) causes a transformation to the octadecanuclear cluster $[K_4Mn_{18}O_{16}(O_2CPh)_{22}(phth)_2(H_2O)_4]$ (**5**; $18Mn^{III}$) [11] shown in Fig. 5. This remarkable structure can nevertheless be considered as the result of the linkage of several $[Mn_4O_2]$ units, and the two $phth^{2-}$ groups are μ_4 and bridge a total of six Mn^{III} ions between them, no doubt a contributing factor to the high nuclearity of the product.

A final example of a high nuclearity product from a $[Mn_4O_2]$ complex is provided by the dissolution of $[Mn_4O_2(O_2CPh)_6(MeCN)_2(pic)_2]$ in Me_2NCOMe (DMA); black crystals of $[Mn_{10}O_8(O_2CPh)_6(pic)_8]$ (**6**; $10Mn^{III}$) slowly form (Fig. 6) [12]. This interesting transformation only occurs in DMA and is presumably caused by the good donor solvent destabilizing the $[Mn_4O_2]$ species to aggregation by partial or complete displacement of one or more carboxylate groups; again the low solubility of the product undoubtedly assists attainment of pure material.

Controlled potential electrolysis

The previous observation in our group that $[Mn_4O_2(O_2CMe)_6(py)_2(dbm)_2]$ ($4Mn^{III}$) would disproportionate to $[Mn_4O_3X(O_2CMe)_3(dbm)_3]$ ($X = Cl^-$ or Br^-; $3Mn^{III}$,Mn^{IV}) on treatment with

$$3[Mn_4O_2]^{8+} + 2X^- \rightarrow 2[Mn_4O_3X]^{6+} + 2Mn^{2+} + 2Mn^{3+} \quad (1)$$

Me_3SiX in CH_2X_2 (eq. (1)) [8, 13] prompted an investigation of the electrochemical oxidation of selected $[Mn_4O_2]^{8+}$ species as a potentially useful method of forming similar or related products. Controlled potential electrolysis (CPE) of $[Mn_4O_2(O_2CMe)_6(py)_2(dbm)_2]$ at 0.84 V *vs.* ferrocene in the presence of dbmH gave $[Mn_4O_3(O_2CMe)_4(dbm)_3]$ (**7**; $3Mn^{III}$, Mn^{IV}) [14]. Similarly, the CPE of $(NBu^n_4)[Mn_4O_2(O_2CPh)_7(dbm)_2]$ at 0.65 V gave $[Mn_4O_3(O_2CPh)_4(dbm)_3]$ (**8**; $3Mn^{III}$, Mn^{IV}) [15]. In both cases, the one-electron oxidation of the $[Mn_4O_2]^{8+}$ core has triggered incorporation of a third O^{2-} group, presumably from H_2O, and a change to a $[Mn_4(\mu_3\text{-}O)_3(\mu_3\text{-}O_2CR)]^{6+}$ core. This is summarized for **8** in eq. (2); a related equation summarizes the formation of **7**. The structures of **7**

$$[Mn_4O_2(O_2CPh)_7(dbm)_2]^- + dbmH - e^- + H_2O \rightarrow [Mn_4O_3(O_2CPh)_4(dbm)_3] + 3PhCO_2H \quad (2)$$

and **8** (Figs 7 and 8) are similar to those of $[Mn_4O_3X(O_2CMe)_3(dbm)_3]$ in possessing a trigonal pyramidal core with O^{2-} ions on three faces and the basal face of $3Mn^{III}$ ions capped by a μ_3-X^- or RCO_2^- ion. The R = Me (**7**) and Ph (**8**) species differ slightly, however, in that the former has a $\eta^1,\mu_3 - MeCO_2^-$ and the latter a $\eta^2,\mu_3 - PhCO_2^-$, the difference being assigned to the larger size of Ph *vs.* Me causing steric problems with the dbm Ph groups in a η^1, μ_3-bridging mode for the R = Ph case.

Access to complex **7** in particular has allowed site-selective ligand substitution reactions at the $\mu_3 - MeCO_2^-$ position to be developed, a process facilitated by the $\mu_3 - MeCO_2^-$ group lying at the intersection of the three Mn^{III} Jahn–Teller elongation axes and thus being more weakly bound and more susceptible to electrophilic attack by trimethylsilyl or related reagents than the other ligands in the molecule. Crystallographically confirmed products are shown in Fig. 9 [13–17], and others are currently being characterized.

Comproportionation reactions

A useful way of obtaining Mn_x products at the ~III oxidation level is the comproportionation between a Mn^{II} source and MnO_4^-. This was the original method used by Lis to access the dodecanuclear complex $[Mn_{12}O_{12}(O_2CMe)_{16}(H_2O)_4]\cdot 2H_2O\cdot 4MeCO_2H$ (**9**; $8Mn^{III}$, $4Mn^{IV}$) [18], the complex which has since initiated the field of Single-Molecule Magnetism (*vide infra*). Thus, the reaction of $Mn(O_2CMe)_2\cdot 4H_2O$ and $KMnO_4$ in 60% (v/v) $MeCO_2H/H_2O$ gives **9** *via* the comproportionation summarized in eq. (3). From **9** can now be made a variety of derivatives by

$$44Mn^{2+} + 16Mn^{7+} \rightarrow 5[Mn_{12}]^{40+} \quad (3)$$

ligand substitution reactions with other carboxylic acids eq. (4) [19, 20]; the R = Ph complex [19] is shown in Fig. 10. All these Mn_{12} complexes are trapped-valence and contain a central

$$[Mn_{12}O_{12}(O_2CMe)_{16}(H_2O)_4] + 16RCO_2H \rightarrow [Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4] + 16MeCO_2H \quad (4)$$

$[Mn^{IV}_4O_4]$ cubane around which is a non-planar ring

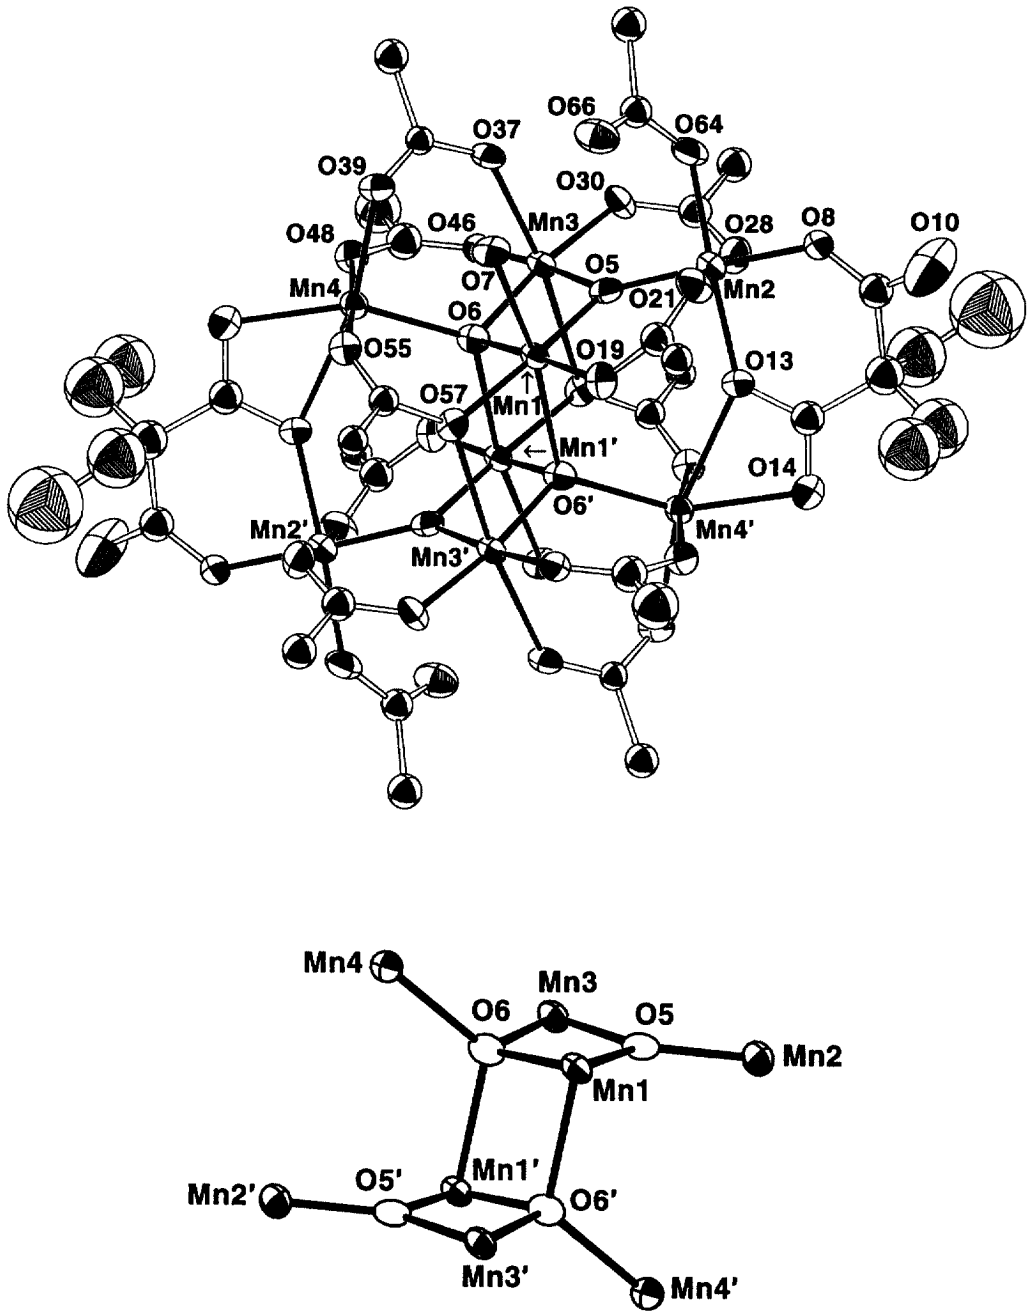

Fig. 4. The structure of $[Mn_8O_4(O_2CPh)_{12}(Et_2mal)_2(H_2O)_2]^{2-}$ anion and its $[Mn_8O_4]^{14+}$ core; the Mn^{II} ions are Mn4 and Mn4′.

of Mn^{III} ions held to the central cubane by eight O^{2-} ions.

The $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]$ complexes display a reversible one-electron reduction in the 0.00 to 0.50 V *vs.* ferrocene range, and this has allowed [20] isolation and characterization of the one-electron reduced clusters from reductions with I^-. Thus, for example, $(PPh_4)[Mn_{12}O_{12}(O_2CEt)_{16}(H_2O)_4]$ (**10**) can be prepared *via* eq. (5), a method that can readily be extended to other carboxylates [20].

$$[Mn_{12}] + PPh_4I \rightarrow (PPh_4)[Mn_{12}] + 1/2I_2 \qquad (5)$$

The comproportionation method has recently been employed to access a new Mn_7 complex. Treatment of $MnCl_2 \cdot 4H_2O$ with 2-hydroxymethylpyridine (hmpH) and NEt_4MnO_4 leads to $(NEt_4)[Mn_7(OH)_3Cl_3(hmp)_9]$

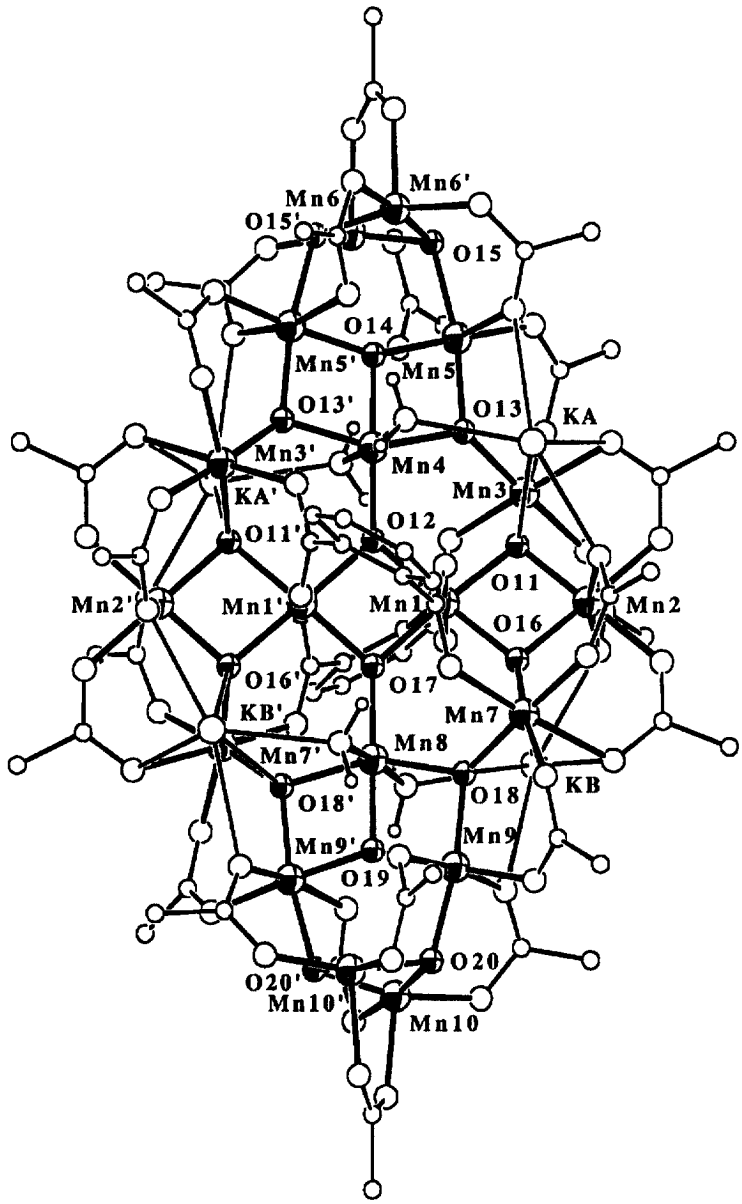

Fig. 5. The structure of $[K_4Mn_{18}O_{16}(O_2CPh)_{22}(phth)_2(H_2O)_4]$ **5**; the K^+ ions are labeled as KA and KB.

$(Cl)(MnCl_4)$ (**11**) [21], the Mn_7 anion of which (Fig. 11) contains $4Mn^{II}$, $3Mn^{III}$, the Mn^{III} ions being easily identified from structural parameters and Jahn–Teller distortions as Mn(2), Mn(4) and Mn(6). Use of $MnBr_2{\cdot}4H_2O$ leads to the corresponding Br derivative, which is isostructural. Interestingly, the reaction of hmpH with the Mn^{III} species $[Mn_3O(O_2CMe)_6(py)_3](ClO_4)$ leads to $[Mn_{10}O_4(OH)_2(O_2CMe)_8(hmp)_8](ClO_4)_4$ (**12**) [22], the cation of which (Fig. 12) is related to, but nevertheless distinctly different from that of **11**. Both **11** and **12** contain almost planar Mn_x cores held together by bridging O^{2-}/OH^- ions, with peripheral ligation provided by bridging hmp^- and (for **12**) $MeCO_2^-$ groups.

MAGNETIC PROPERTIES

Ground state spin value

It has become evident over the course of the last several years that small values of spin, S, in the ground states of Mn carboxylate clusters are almost the exception rather than the rule [2]. For example, in Table 1 are listed the S values for the Mn_x carboxylate species mentioned in this paper, and although clusters with $S = 0$ are present, noteworthy is the significant number of large S values in this list: for calibration, the largest S for a molecular species is currently the $S = 33/2$ for one of the clusters in cocrystallized Fe_{17}

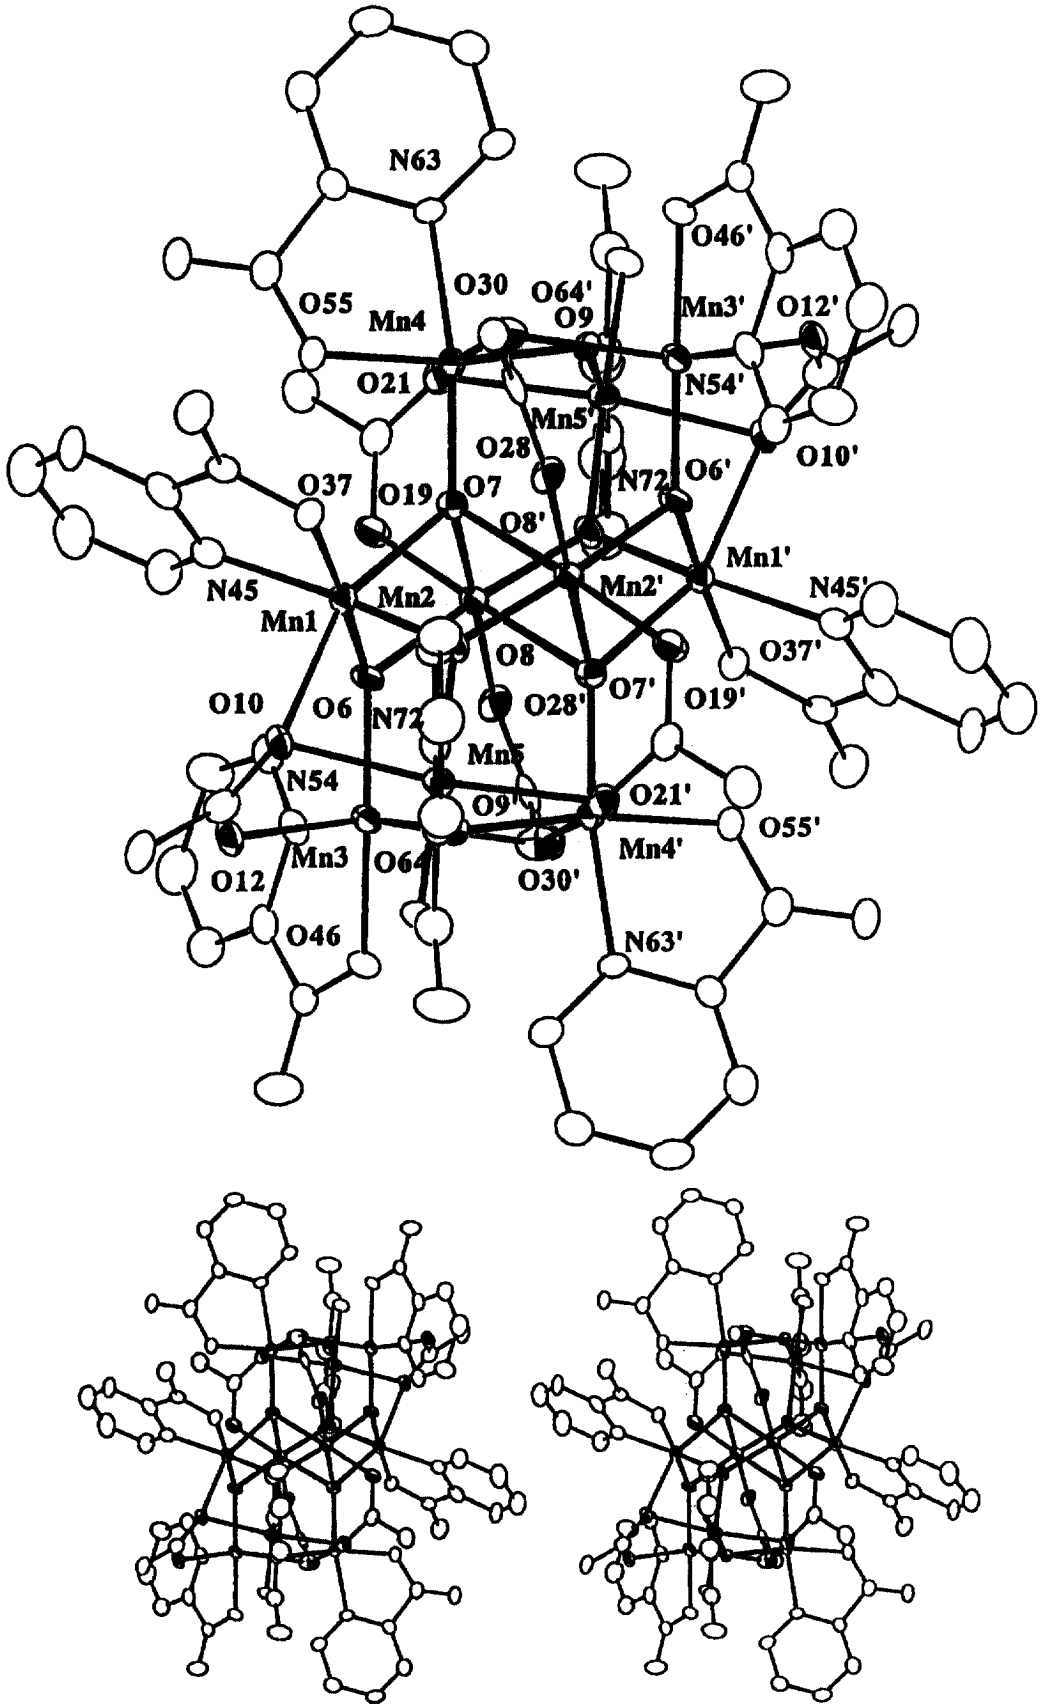

Fig. 6. The structure of $[Mn_{10}O_8(O_2CPh)_6(pic)_8]$ (**6**).

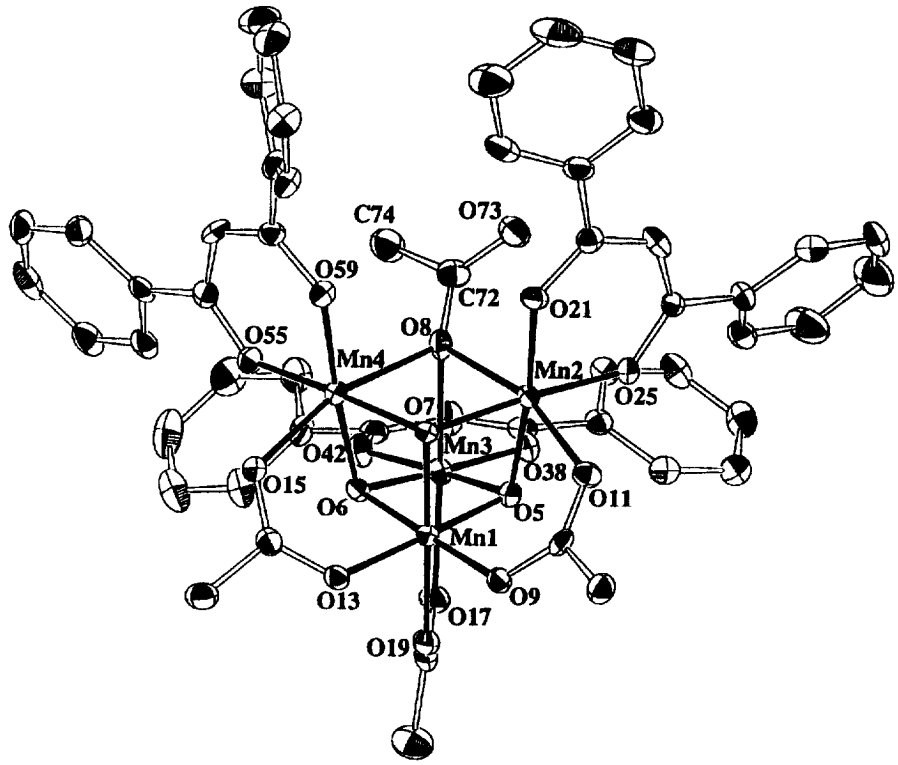

Fig. 7. The structure of $[Mn_4O_3(O_2CMe)_4(dbm)_3]$ (7).

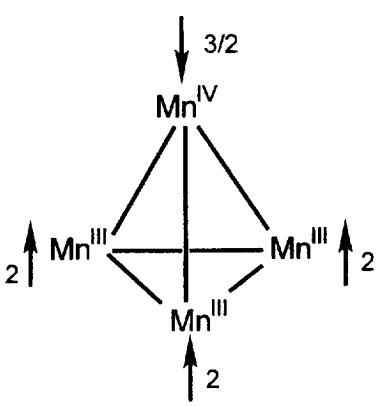
and Fe_{19} units [23]. The origin of the large S value is a result of the presence of (at least some) ferromagnetic exchange interactions and/or spin frustration [24, 25] effects arising from the presence in certain topologies of competing exchange interactions. The latter prevent (frustrate) the preferred spin alignments that would otherwise normally yield low spin species.

For smaller clusters such as some of those in Table 1, the individual pairwise exchange parameters can be



determined by fitting experimental molar magnetic susceptibility (χ_m) *vs.* T data to the appropriate theoretical equation derived for that topology and metal oxidation state(s) using the Kambe vector coupling methods [26]. In those cases, the ground state S value may be readily rationalized. In other clusters, their complexity (size, symmetry) precludes such an analysis and only the value of the ground state may be obtained (*via* magnetization *vs.* field studies). An example of the former is found in the $[Mn_4O_3X]^{6+}$ species, which contain a $3Mn^{III},Mn^{IV}$ pyramid of C_{3v} symmetry [13]. The Mn^{III}/Mn^{III} exchange interactions (J_{33}) are ferromagnetic ($+5$ to $+10\,cm^{-1}$) and the Mn^{III}/Mn^{IV} interactions (J_{34}) are antiferromagnetic (-20 to $-30\,cm^{-1}$), and the alignment of the individual Mn^{III} and Mn^{IV} spins (2 and 3/2, respectively) in the ground state are as shown, giving the molecular spin as $S = 6-3/2 = 9/2$, as is found experimentally.

An example of the latter approach is provided by the $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]$ clusters, which have $S = 10$ ground states, except for a few, such as the R = Et species, which have $S = 9$ [19, 20]. The ground state may be rationalized as resulting from ferromagnetic exchange interactions within the central $[Mn_4O_4]$ cubane and antiferromagnetic interactions between central Mn^{IV} and outer Mn^{III} ions (although none of the J values are actually known). This predicts a ground state of $S = 16-6 = 10$ since all the Mn^{IV} and Mn^{III} spins would be parallel and antiparallel, respectively. For complexes **2–6**, even this level of rationalization is not possible given the complex Mn_x topology. Many competing exchange interactions of comparable magnitude and resultant spin frustration effects are undoubtedly present, and the observed

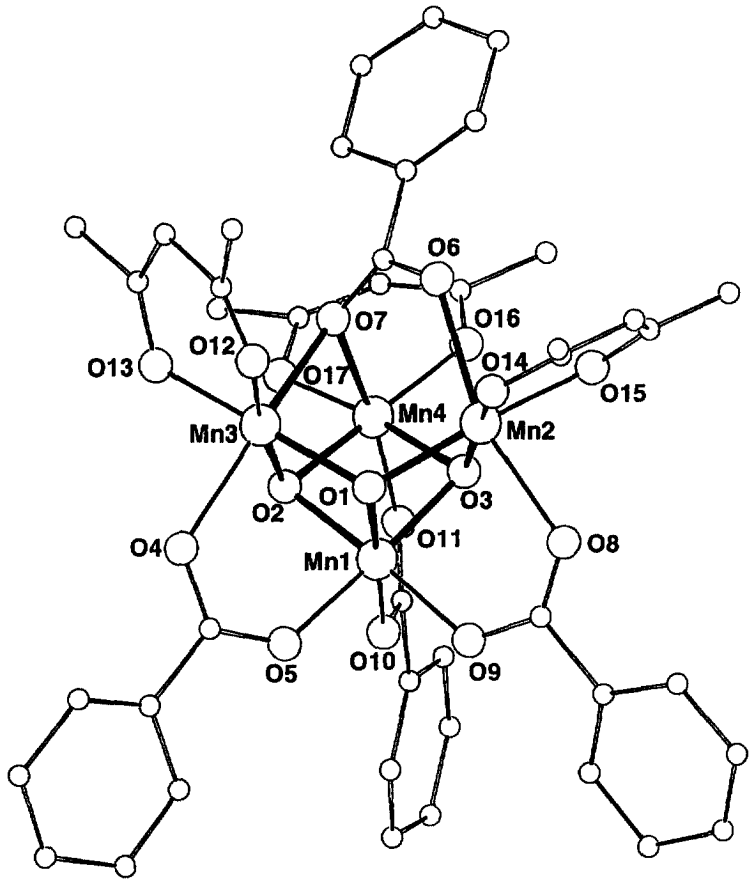


Fig. 8. The structure of $[Mn_4O_3(O_2CPh)_4(dbm)_3]$ (**8**).

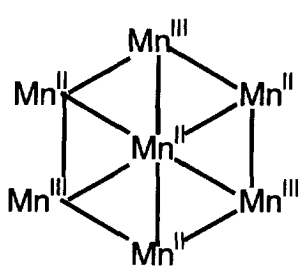
ground states must therefore be a delicate balance of several factors. The latter makes it extremely difficult, in general, to predict in advance what the ground state might be of a new structural type, although some rationalization of the measured value is usually possible with hindsight, and this can still be a very useful level of understanding to possess.

A case in point is provided by complex **11** [21], whose ground state $S = 10$ or 11 may be rationalized as due to competition between the various pairwise exchange interactions which all involve Mn^{II}/Mn^{II} (J_{22}) or Mn^{II}/Mn^{III} (J_{23}) pairs and are thus all expected



to probably be antiferromagnetic and very weak (and therefore of comparable magnitude). In particular, competition between J_{io} and J_{oo} (o = outer, i = inner), the former comprising both J_{22} and J_{23} and the latter only J_{23}, clearly prevents all spins aligning in an antiparallel arrangement. The resultant spin frustration thus gives a high spin ground state whose precise value must therefore be due to the relative magnitudes of the J values. The interesting prediction that follows from this argument is that removal of the central Mn should give a non-frustrated system with antiparallel spin alignments around the hexagonal ring and a $S = 15/2 - 6 = 3/2$ ground state. Such a $[Mn^{II}_3Mn^{III}_3]$ cyclic species is not yet available to test this prediction but we note that $[Fe_6Na(OMe)_{12}(dbm)_6]^+$ has a hexagonal ring of Fe^{III} ions, a central Na^+, and a $S=0$ ground state, as expected for a non-frustrated, antiferromagnetically-coupled system [27].

Single-molecule magnetism

In 1993, it was discovered that the $[Mn_{12}O_{12}(O_2CMe)_{16}(H_2O)_4]\cdot 2H_2O\cdot 4MeCO_2H$ (**9**) complex could function as a nanoscale magnet [19, 28]. This initiated the field of molecular nanomagnetism and such a molecule has since been termed a single-molecule mag-

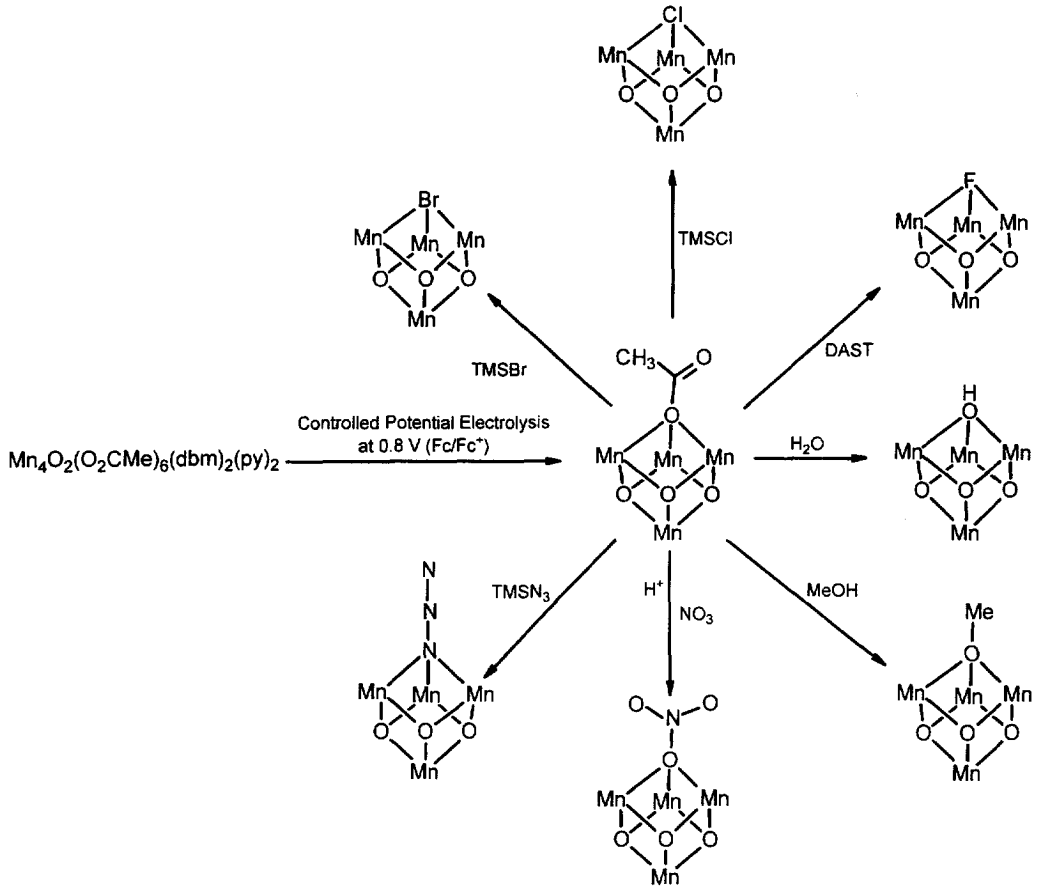


Fig. 9. Variation of X in structurally-characterized $[Mn_4O_3X]^{6+}$-containing products obtained from complex **7**. DAST is Et_2NSF_3; TMS is trimethylsilyl.

net (SMM) [29]. Nanoscale magnetic particles (nanomagnets) are typically of size 20–200 nm and are usually obtained by fragmenting bulk ferro- or ferrimagnets such as magnetite (Fe_3O_4), but this approach gives a distribution of particle sizes that complicates size *vs.* property studies and precludes a uniform response to an external influence such as an applied magnetic field. The discovery of SMMs in metal cluster chemistry represented an exciting breakthrough for a number of reasons: (i) metal clusters are normally prepared by solution methods and, once purified, such samples are composed of species of a

Table 1. state spin (S) values[1]

Complex[a]	Ox. state	S
$Mn_4O_3X(O_2CR)_3dbm)_3]$ (**7**,**8**)	$3Mn^{III}$, Mn^{IV}	9/2

single, sharply-defined size; (ii) they are readily amenable to variation in peripheral carboxylate ligation (small *vs.* bulky, hydrophilic *vs.* hydrophobic, etc.); (iii) they are normally soluble in common solvents providing advantages in potential applications, e.g., thin film formation (and removal); and (iv) they are, in fact, of sub-nanoscale dimensions—the $[Mn_{12}O_{12}]$ core of **9** has an approximate volume of only 0.1 nm^3. Points (i) and (iii) are major advantages of SMMs over conventional nanoscale magnetic particles, and point (iv) holds the promise of access to the ultimate high density memory device. Including the carboxylates, the volume of **9** is very approximately 2 nm^3, with a shape that can be described as a disc of circular surface area $\sim 2\,nm^2$ and thickness ~ 1 nm. Close packing could fit $\sim 5 \times 10^{13}$ clusters on a 1 cm^2 computer chip, at least four or five orders of magnitude greater than the highest density possible to date.

The SMM behavior of **9** and other carboxylate derivatives studied more recently is due to a combination of a large ground state spin S and negative magnetoanisotropy as gauged by a negative zero-field splitting parameter D. As a result, there is a significantly large barrier for the reorientation of the cluster's magnetization vector. Thus, if an applied magnetic field is used to orient all the molecular magnetization vectors in one direction, the temperature lowered below a critical (or "blocking") temperature (~ 3 K), and the field switched off, the magnetization vectors remain aligned and the sample is thus magnetized. The time scale of the magnetization relaxation is greater than two months.

More recently [20], the ionic species $(PPh_4)[Mn_{12}O_{12}(O_2CEt)_{16}(H_2O)_4]$ **10** and other carboxylate derivatives (such as the benzoate) have also been found to be SMMs, thus extending this new magnetic phenomenon to ionic species (i.e., "single-ion magnetism", although this alternate term has not been employed to date).

A characteristic signature of a magnet is hysteresis in the magnetization *vs.* magnetic field response, and representative examples are shown in Figs 13 and 14 for complex **10** [20, 30] and $[Mn_{12}O_{12}(O_2CC_6H_4\text{-}p\text{-}Me)_{16}(H_2O)_4]$ [31], respectively. Hysteresis of magnetization is clearly evident, confirming magnetic bistability and the appropriateness of the SMM description, but these figures also show two additional features that represent the focus of intense study at the present time. Considering Fig. 13 first, there are clear signs of steps on the hysteresis loop at regular intervals of magnetic field. Such steps were first seen for the $MeCO_2^-$ complex **9** [32] and are a signature of quantum tunnelling of the magnetization (QTM) i.e., instead of the cluster's magnetization relaxing from,

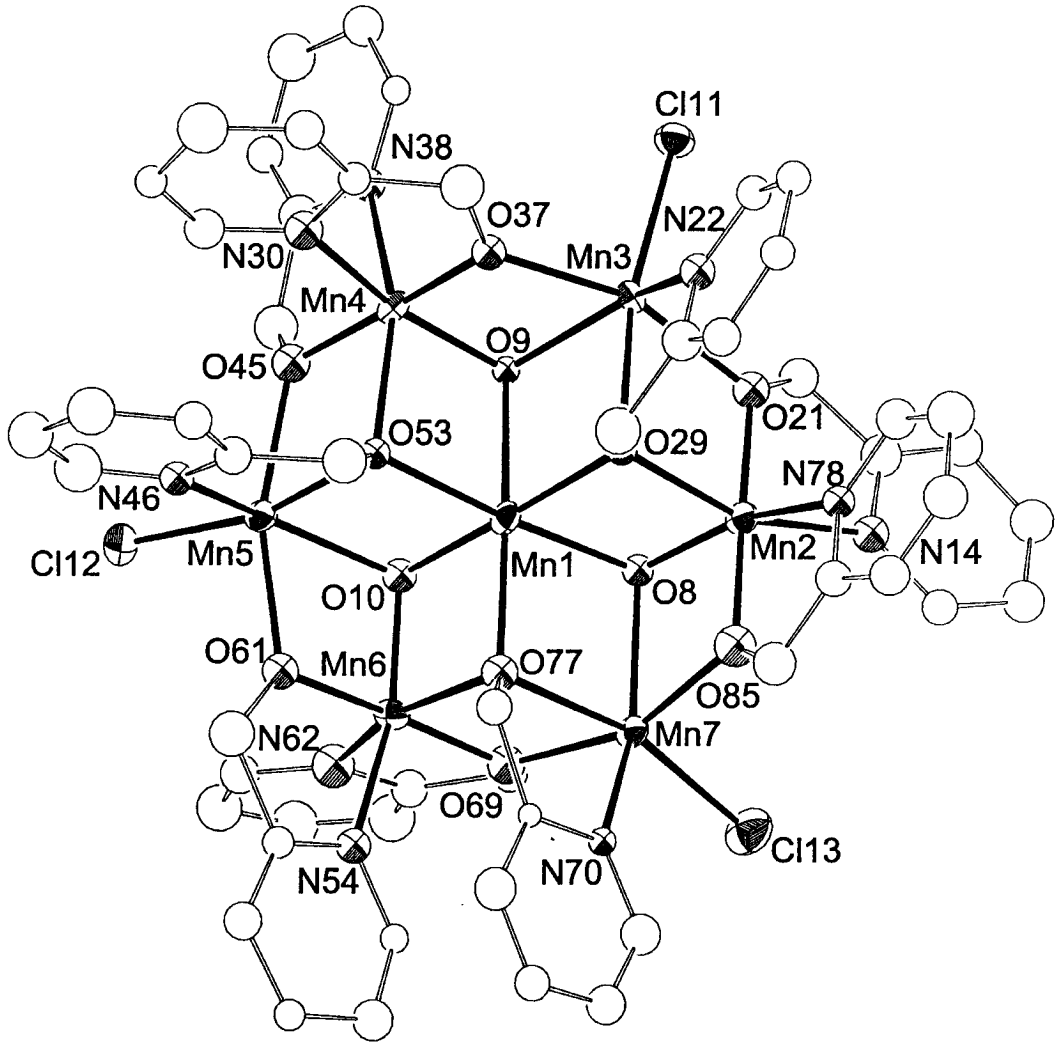

Fig. 11. The $[Mn_7(OH)_3Cl_3(hmp)_9]^{2+}$ cation of complex **11**.

say, "spin up" to "spin down" by going over the reorientation barrier, it instead tunnels through the barrier; more detailed discussion and analysis of the step behavior are available elsewhere [31–34]. In essence, these nanoscale clusters straddle the classical/quantum interface and thus allow study of how quantum mechanical behavior at the macroscopic scale underlies classical behavior at the macroscopic scale.

The hysteresis loops in Fig. 14 again show steps but also demonstrate a remarkable sensitivity of the hysteresis and QTM behavior to subtle differences resulting from two different crystal forms of the complex i.e., the $3H_2O$ solvate (space group $I2/a$) and the $HO_2CC_6H_4$-*p*-Me solvate (space group $C2/c$) [31]. The two crystal forms show significantly different step sizes, particularly the first step at zero field, which suggests that environmental differences in the two complexes have profound effects on the QTM rates. We have also found similar changes when the identity of the carboxylate is altered [34]. Such a significant sensitivity of the quantum behavior to readily-altered macroscopic parameters is important to understand and control, since this is likely to be important in future technological applications of SMMs.

One way to consider the Mn_{12} SMMs is as extremely small pieces of a metal oxide stabilized and solubilized by the carboxylate ligands. It is often contemplated how small a piece of a 3D extended solid such as a metal oxide can become and still retain the essential properties of the bulk material. With respect to magnetic properties, it would appear that as few as 12 metal ions in the $[Mn_{12}O_{12}]$-containing complexes will suffice! It should be added that the $[Mn_{12}O_{12}]$ core is not an exact, repeating unit within a known Mn oxide. In fact, an even smaller molecule can also be a SMM.

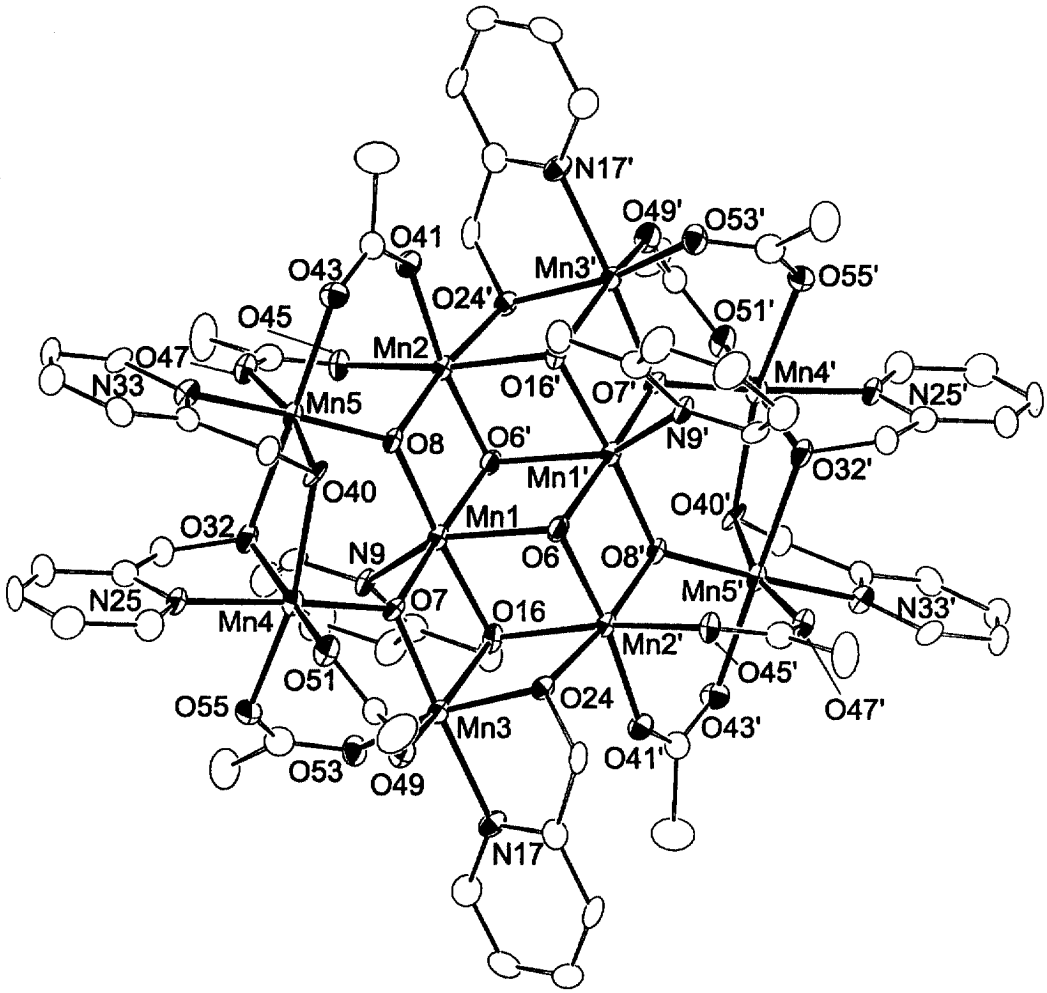

Fig. 12. The $[Mn_{10}O_4(OH)_2(O_2CMe)_8(hmp)_8]^{4+}$ cation of **12**.

The $[Mn_4O_3X]^{6+}$-containing clusters such as **7** have also been found to be SMMs, as reflected in the slow relaxation of magnetization [29], and the appearance [35] of a hysteresis loop *and* steps characteristic of QTM (Fig. 15). Lower temperatures are required, which is consistent with the smaller ground state spin of $S = 9/2$ for these clusters, as well as smaller D values than for the Mn_{12} species. Nevertheless, it firmly demonstrates that there is essentially no size minimum for the occurrence of SMM behavior; the $[Mn_4O_3X]$ core has a volume of $\sim 0.01\ nm^3$.

CONCLUSIONS

Manganese carboxylate cluster chemistry has proven to be an area that has something for everyone, from synthetic chemistry and structural aesthetics to high-spin ground states and novel magnetic properties. The SMM behavior could not of course have been anticipated, and this area is thus a perfect example of a curiosity-driven line of "pure" research that leads to results of potentially major technological application. The temperatures required for SMM behavior in this first generation of examples are very low (< 3 K) but in this regard the field is at the same stage as superconductivity was when it was discovered in elemental mercury at liquid helium temperatures i.e., the important point is the establishment of the phenomenon and it will be up to future efforts in the field of SMMs to push the critical temperature to higher, more useful values. Other examples of SMMs both outside and within Mn chemistry are being reported [36, 37], but they are all like the $[Mn_4O_3X]$ species in requiring lower temperatures than the $[Mn_{12}O_{12}]$ complexes. However, the search has only just begun.

24. To accommodate the comments of Kahn[25], expressions such as "spin frustration degeneracy" will be employed to describe the special case where competing exchange interactions lead to a degenerate ground state. In accord with our practice to date, we shall use "spin frustration" to describe the more general case where competing exchange interactions of comparable magnitude lead to the preferred spin alignments being prevented (frustrated).

(Received 24 November 1997; accepted 29 March 1998)

Abstract—Treatment of $[Au(MeCN)_2]SbF_6$ in acetonitrile with bis(diphenylphosphino)ethylamine (dppa) afforded a colourless crystalline material characterised as $[Au_2(\mu\text{-dppa})_2][SbF_6]_2$. An X-ray diffraction study confirmed that the two ligands bridge the two gold atoms with a Au···Au separation of 2.838(2) Å. The electronic absorption spectrum exhibits a band at 298 nm (ϵ_{max}, *ca.* 17000 $dm^3\,mol^{-1}\,cm^{-1}$) attributable to a $p_\sigma \Leftarrow d_\sigma^*$ transition. The compound luminesces strongly in acetonitrile (λ_{max} = 500 nm). Treatment of $HAuCl_4.2H_2O$ with 2,2′-thioethanol in methanol followed by the ligand afforded a colourless crystalline material characterised as $[Au_3Cl_2(\mu\text{-dppa})_2]PF_6$. A crystal structure determination revealed a cation of C_2 symmetry, comprising a bent chain of three gold atoms (Au···Au···Au = 167.5(8)°, Au···Au = 3.037(1) Å), with each pair of adjacent gold atoms bridged by a diphosphazane ligand and with the coordination at the outer gold atoms completed by a chloride ligand. This compound luminesces extremely weakly in acetonitrile but does emit strongly at 485 nm when irradiated in the solid state. The luminescence displayed by both compounds is attributed to the presence of a substantial intramolecular interaction between the gold atoms, but ligand effects appear to be more important in determining the emissive energies. © 1998 Elsevier Science Ltd. All rights reserved

Homoleptic digold(I) complexes, in which the gold atoms are bridged by two symmetric diphosphine ligands and in which each gold atom is two-coordinate, have been shown to be photoluminescent [1]. The best studied examples are salts of the dppm (dppm = $Ph_2PCH_2PPh_2$) ligand-bridged digold(I) cation, $[Au_2(\mu\text{-dppm})_2]^{2+}$. The BF_4^- salt is strongly phosphorescent in acetonitrile solution, the emission being observed at 593 nm at room temperature with a lifetime of 21 μs and a quantum yield of 0.31 [2]. The ClO_4^- salt also exhibits phosphorescence at room temperature in acetonitrile solution, but at 570 nm with a lifetime of 18 μs and a quantum yield of 0.15 [3, 4]. The room temperature emission spectrum of the BH_3CN^- salt has been recorded in the solid state, since this species decomposes on irradiation in solution; emission occurs at 490 nm in this case [2, 5]. In contrast, mononuclear bisphosphine complexes such as $[Au(PPh_3)_2]BPh_4$ are not luminescent [6]. This has led to the conclusion that the loss of centrosymmetric structure, brought about by the presence of an Au···Au interaction in the dinuclear species, is in some way responsible for the luminescence displayed by compounds of this type [6]. However, the intermetallic separation does not appear to play a significant role in determining the energy of the emission. For instance, Fackler *et al.* have shown that there is no direct correlation between the Au···Au separation and the emission wavelength (recorded in the solid state) for the following series of luminescent ligand-bridged digold(I) compounds: $[Au_2(\mu\text{-dppm})_2][BH_3CN]_2$, $[Au_2(\mu\text{-dppm})_2]Cl_2$, $[Au(CH_2)_2PPh_2]_2$, $[n\text{-}Bu_4N]_2$

‡ The late.

$[Au(S_2C{=}C(CN)_2)]_2$, $[Au(CH_2P(S)Ph_2)]_2$, and $[Au(S_2CNEt_2)]_2$ [2]. It has been suggested that this lack of correlation may be as a consequence of the HOMO having some ligand character and not being a purely metal orbital, with ligand changes affecting the energy of the HOMO, either directly or indirectly [2]. This being the case, the emissive properties of diphosphine ligand-bridged digold(I) complexes of the $[Au_2(\mu\text{-dppm})_2]^{2+}$ type may be more the property of the diphosphine ligand and, in particular, of the AuP_2 unit rather than of the intergold separation [1]. The diphosphazane ligand $Ph_2PN(Et)PPh_2$ (dppa) is closely related to the dppm ligand, the only difference being the presence of an ethylamino, rather than a methylene group, between the two phosphorus atoms. It was therefore of interest to compare the structure and emissive properties of the diphosphazane ligand-bridged chromophore, $[Au_2(\mu\text{-dppa})_2]^{2+}$, with those of the $[Au_2(\mu\text{-dppm})_2]^{2+}$ species. Accordingly, the SbF_6^- salt of the $[Au_2(\mu\text{-dppa})_2]^{2+}$ cation has been synthesised, its structure determined by means of X-ray diffraction, and its absorption and emission spectra in acetonitrile recorded.

Trigold(I) complexes stabilised by bidentate bridging ligands have received less attention, especially with regard to their photophysical properties. However, the syntheses and crystal structures of the $[AuCl(C_6F_5)_3]^-$ and chloride salts of the $[Au_3Cl_2(\mu\text{-dppm})_2]^+$ cation have been reported [7, 8]. In contrast to $[Au_2(\mu\text{-dppm})_2]^{2+}$, this cation does not appear to luminesce in solution, the authors only reporting the existence of an intense emission at 485 nm in the solid state for the chloride salt [8].

To establish whether $[Au_3Cl_2(\mu\text{-dppa})_2]^+$ has similar luminescent properties, its synthesis as the hexafluorophosphate salt was effected and its crystal structure and emission properties determined.

RESULTS AND DISCUSSION

Treatment of an acetonitrile solution of $[Au(MeCN)_2]^+$ with a molar equivalent of the solid $Ph_2PN(Et)PPh_2$ (dppa) ligand afforded a yellow solution from which $[Au_2(\mu\text{-dppa})_2][SbF_6]_2$ could be isolated in good yield as a colourless microcrystalline solid by precipitation with diethylether. Elemental analysis, the infrared spectrum recorded as a KBr pellet and the ^1H NMR spectrum are all consistent with the formulation of the compound as $[Au_2(\mu\text{-dppa})_2][SbF_6]_2$, as subsequently confirmed by means of a single crystal structure determination (see below). The $^{31}P\{^1H\}$ NMR spectrum recorded in CD_3CN exhibits a single sharp peak at 100.25 ppm, indicative of a phosphorus atom bonded to a gold atom; the phosphorus atoms of the free ligand resonate at 60.60 ppm. Interestingly, the phosphorus atoms of the diphosphazane ligand are considerably deshielded relative to those of the dppm ligand, the latter resonating at *ca.* 35 ppm in $[Au_2(\mu\text{-dppm})_2][ClO_4]_2$ [4]. This is to be expected in view of the stronger electron-withdrawing properties of the ethylamino as opposed to the methylene group. The compound is stable in the solid state but, if left to stand in solution in the presence of oxygen, it slowly degrades.

The procedure used for the preparation of $[Au_3Cl_2(\mu\text{-dppa})_2]PF_6$ is similar to one of two methods employed by Lin *et al.* for the preparation of $[Au_3Cl_2(\mu\text{-dppm})_2]Cl$ [8]. Thus, the compound is obtained in good yield by reacting $HAuCl_4.2H_2O$ with 2,2′-thioethanol in methanol before treating it with a slight excess of ligand. Isolation of the compound as a colourless microcrystalline solid was achieved by addition of NH_4PF_6 and crystallisation from the methanol solution. Elemental analysis, the infrared spectrum recorded as a KBr pellet and the ^1H NMR spectrum are all consistent with the formulation of the compound as $[Au_3Cl_2(\mu\text{-dppa})_2]PF_6$, as subsequently confirmed by means of a single crystal structure determination (see below). The $^{31}P\{^1H\}$ NMR spectrum recorded in CD_3CN exhibits a well-defined AA′BB′ pattern with the multiplets centred at 103.61 and 83.11 ppm. Such a pattern is also observed for the $[Au_3Cl_2(\mu\text{-dppm})_2]^+$ cation in its $[AuCl(C_6F_5)_3]^-$ salt [7]. On the other hand the $^{31}P\{^1H\}$ spectrum for the chloride salt is complicated by an exchange process driven by the reaction of the chloride counterion with the trinuclear gold cation. In this case, a AA′BB′ pattern is only observed in the presence of added $AgBF_4$, *i.e.*, when the potentially coordinating chloride counterion is replaced by the non-coordinating tetrafluoroborate anion [8]. As expected, the phosphorus atoms in the diphosphazane ligand-bridged trigold cation are deshielded relative to those in the analogous dppm ligand-bridged species; Uson *et al.* report an AA′BB′ pattern for $[Au_3Cl_2(\mu\text{-dppm})_2][AuCl(C_6F_5)_3]$ with the multiplets centred at 37.1 and 29.0 ppm [7]. As with the dinuclear diphosphazane ligand-bridged species, the trinuclear complex $[Au_3Cl_2(\mu\text{-dppa})_2]PF_6$ is stable in the solid state but, if left to stand in solution in the presence of oxygen, it slowly degrades.

Crystal structure and photophysical properties of $[Au_2(\mu\text{-dppa})_2][SbF_6]_2$

Crystals of the compound consist of well-separated $[Au_2(\mu\text{-dppa})_2]^{2+}$ cations and SbF_6^- anions, there being no unusual intermolecular contact distances. Figure 1 shows an ORTEP drawing of the cation, while selected interatomic distances and angles for the cation are given in Table 1.

The two gold atoms are bridged by the two diphosphazane ligands such that there is a crystallographically imposed centre of symmetry midway between them. The coordination at each gold atom is only approximately linear, as evidenced by a P(1)–Au–P(2′) angle of 167.5(8)°. As illustrated in Fig. 1, the deviation from linearity apparently results from

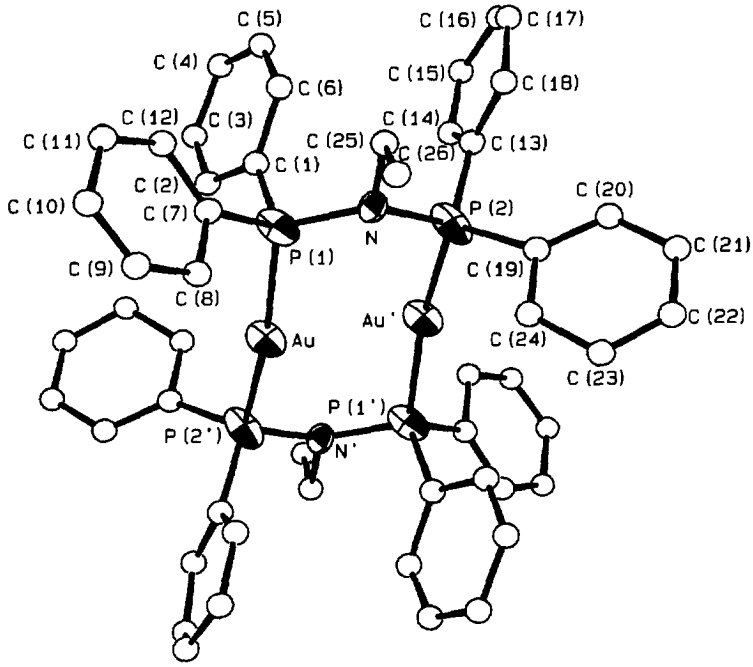

Fig. 1. ORTEP drawing of the $[Au_2(\mu\text{-dppa})_2]^{2+}$ cation in $[Au_2(\mu\text{-dppa})_2][SbF_6]_2$. The carbon atoms are drawn as spheres of arbitrary radius and the remaining atoms as 20% probability ellipsoids.

P(1)–N–C(25)	121.5(7)	P(2)–N–C(25)	116.9(7)

the two gold atoms being pulled towards each other by a substantial Au···Au interaction. This is reflected in an Au···Au distance of 2.838(2) Å that is significantly shorter than the Au···Au distances in $[Au_2(\mu\text{-dppm})_2][BH_3CN]_2{\cdot}2CH_2Cl_2$ (2.982 Å) [9], $[Au_2(\mu\text{-}Me_2PCH_2PMe_2)_2][ClO_4]_2$ (3.028 Å) [10], $[Au_2(\mu\text{-}Me_2PCH_2PMe_2)_2]Br_2{\cdot}H_2O$ (3.023 Å) [10], $[Au_2(\mu\text{-}Me_2PCH_2PMe_2)_2]Cl_2{\cdot}H_2O$ (3.010 Å) [11] and $[Au_2(\mu\text{-}Cy_2PCH_2PCy_2)_2][PF_6]_2$ (2.935 Å) [12]. It is also shorter than the Au···Au distance of 2.962 Å reported for $[Au_2(\mu\text{-dppm})_2]Cl_2$, but this comparison is not strictly valid since the gold atoms in the latter compound are formally three-coordinate, due to the close approach of the chloride anions [13]. In fact, the core structure of the $[Au_2(\mu\text{-dppa})_2]^{2+}$ cation is very similar in all respects to that observed for the other digold(I) ligand bridged species listed above, there being no evidence of a tendency for the gold atom to become three-coordinate by associating with the fluoride of the SbF_6^- anion. There is a slight twisting of the bridging ligands about the Au···Au vector, as reflected by a P(1)–Au···Au′–P(2) torsion angle of 12.4°. The Au–P bond lengths of 2.314(5) and 2.297(5) Å are somewhat shorter than the value of 2.400 Å given for eight compounds of the closely related dppm ligand with gold [14], but are very similar to the Au–P distance of

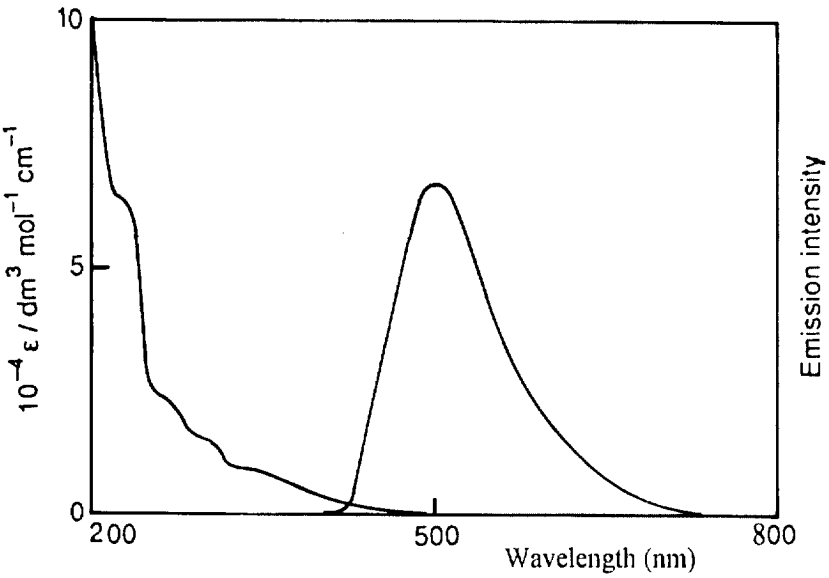

Fig. 2. Absorption and emission (340 nm excitation) spectra in CH_3CN of $[Au_2(\mu\text{-dppa})_2][SbF_6]_2$.

2.314(2) Å in $[Au_2(\mu\text{-}Cy_2PCH_2PCy_2)_2]^{2+}$ [12] and the Au–P distances of 2.311(4) and 2.317(4) Å in $[Au_2(\mu\text{-dppm})_2][BH_3CN]_2\cdot 2CH_2Cl_2$ [9].

The room temperature UV/vis absorption spectrum of $[Au_2(\mu\text{-dppa})_2][SbF_6]_2$ in acetonitrile is shown in Fig. 2. A very intense absorption band is observed as a shoulder at 226 nm which can be attributed to transitions within the phenyl rings [2]. Also observed are bands at 267 nm (ϵ_{max}, *ca.* 23000 dm^3 mol^{-1} cm^{-1}) and at 298 nm (ϵ_{max}, *ca.* 17000 dm^3 mol^{-1} cm^{-1}) while some lower energy and weaker absorptions are observed in the region 330–370 nm. Thus, the bands in the 250–400 nm region appear at positions very similar to those observed in the absorption spectrum of $[Au_2(\mu\text{-dppm})_2][ClO_4]_2$ recorded in acetonitrile [4], but with differences in the relative intensities of the bands and a generally lower resolution of the peaks in the absorption spectrum of $[Au_2(\mu\text{-dppa})_2][SbF_6]_2$. On this basis, we tentatively assign the absorption band at 298 nm to the spin-allowed $p_\sigma \Leftarrow d_\sigma^*$ transition, the equivalent band in the dppm-bridged cation being at 290 nm for the ClO_4^- salt [4] and at 293 nm for the BF_4^- salt [2]. Figure 2 also shows the emission spectrum of the $[Au_2(\mu\text{-dppa})_2]^{2+}$ cation measured at room temperature in acetonitrile, an intense and asymmetric emission band being observed at 500 nm. Thus, the $[Au_2(\mu\text{-dppm})_2]^{2+}$ and $[Au_2(\mu\text{-dppa})_2]^{2+}$ chromophores have in common the fact that they both emit strongly on irradiation in solution. This is unusual, as most ligand-bridged digold(I) species do not generally emit in solution, only displaying luminescence in the solid state [2]. For example, the diphosphine ligand-bridged species $[Au_2(\mu\text{-}Cy_2PCH_2PCy_2)_2]^{2+}$ does not emit at room temperature, only luminescing at 489 nm in the solid state at 77 K [12].

The emission maximum of 500 nm, recorded at room temperature in acetonitrile for the $[Au_2(\mu\text{-dppa})_2]^{2+}$ cation, occurs at a considerably lower wavelength, compared to the wavelengths recorded for the emission maxima observed under the same conditions for the $[Au_2(\mu\text{-dppm})_2]^{2+}$ cation; these occur at 570 and 593 nm for the ClO_4^- [3, 4] and BF_4^- salts [2] respectively. The difference of 23 nm in the emission wavelengths for the latter two salts has been ascribed to medium effects [1], but these seem unlikely to account for the decrease in emission wavelength of $\geqslant 70$ nm observed for the dppa ligand-bridged species. The emissive state for the dppm ligand-bridged cation is generally accepted as being phosphorescent [2–4], with the excited state being assigned as either $^3A_u(d\sigma^*)(p\sigma)$ [2–4] or $^3B_{1u}(d\delta^*)(p\sigma)$ [3, 4]. Assuming that one of these two assignments also applies to the dppa ligand-bridged chromophore, the expectation would be that a *decrease* in the Au···Au distance would lead to an increase in the interaction between the gold atoms and, hence, an *increase* in the emission wavelength. Exactly the opposite trend is observed when the Au···Au distances of the two cations are compared. Thus, although the Au···Au distance of 2.838(2) Å observed for $[Au_2(\mu\text{-dppa})_2]^{2+}$ is significantly shorter than the value of 2.982(2) Å reported for the BH_3CN^- salt of the $[Au_2(\mu\text{-dppm})_2]^{2+}$ cation [9], the wavelength of the emission is substantially *shorter*. It seems certain that effects intrinsic to the bridging ligands are responsible for the large difference in emission energy observed for the $[Au_2(\mu\text{-dppm})_2]^{2+}$ and $[Au_2(\mu\text{-dppa})_2]^{2+}$ chromophores. Such an effect could be caused by replacing a CH_2 group in the dppm ligand with an electron-withdrawing N(Et) group to give the dppa ligand,

resulting in less electron density on the donor phosphorus atoms in the dppa as compared to the dppm ligand. However, we are not in a position to quantify such an effect on the relative energies of the HOMO and LUMO in species of this type and, hence, to fully explain the differences in emission energy.

Crystal structure and photophysical properties of $[Au_3Cl_2(\mu\text{-}dppa)_2]PF_6$

Crystals of the compound consist of well-separated $[Au_3Cl_2(\mu\text{-dppa})_2]^+$ cations and PF_6^- anions, there being no unusual intermolecular contact distances. Figure 3 shows an ORTEP drawing of the cation while selected interatomic distances and angles for the cation are given in Table 2.

The cation comprises a bent chain of three gold atoms, each pair of adjacent gold atoms being bridged by a diphosphazane ligand and with the coordination at the two outer gold atoms being completed by a chloride ligand. Overall, the cation has C_2 symmetry. The deviation of the chain of gold atoms from linearity is reflected by a Au(2)···Au(1)···Au(2′) angle of 163.8(2)°. This is in marked contrast to the arrangement of gold atoms in $[Au_3Cl_2(\mu\text{-dppm})_2]^+$, where the Au···Au···Au angles are 74.2 and 74.6° for the $[AuCl(C_6F_5)_3]^-$ and Cl^- salts respectively [7, 8]. Each diphosphazane ligand is considerably twisted, as reflected by a P(1)–Au(1)···Au(2)–P(2) torsion angle of 46.9°. The equivalent torsion angles in the dppm-bridged trigold(I) cation are somewhat smaller, being 15.4 and 26.7° in the $[AuCl(C_6F_5)_3]^-$ salt and 23.6° in the chloride salt. It has been previously shown that diphosphazane ligands are very flexible in terms of twisting about the metal–metal vector which they bridge [15] and it may be that this is, in some way, responsible for the adoption of a near linear arrangement of gold atoms in the $[Au_3Cl_2(\mu\text{-dppa})_2]^+$ cation. The central gold atom is symmetrically coordinated by the phosphorus atoms of *trans* disposed diphosphazane ligands with a P(1)–Au(1) P(1′) angle of 175.4(6)°. The outer two gold atoms are asymmetrically coordinated, being bonded to the phosphorus atom of a diphosphazane ligand and to a chloride ligand; the P(2)–Au(2)–Cl angle of 177.1(1)° shows only a small deviation from linearity. The Au(1)···Au(2) distance of 3.037(1) Å is somewhat shorter than the Au···Au distances observed for the $[Au_3Cl_2(\mu\text{-dppm})_2]^+$ cation, these being 3.067 and 3.164 Å for the $[AuCl(C_6F_5)_3]^-$ salt and 3.076 Å for the chloride salt [7, 8]. This trend is consistent with the shorter Au···Au distance observed for the $[Au_2(\mu\text{-dppa})_2]^{2+}$ cation as compared to that reported for the $[Au_2(\mu\text{-dppm})_2]^{2+}$ cation (see above). The Au(1)–P(1) bond length of 2.313(2) Å is significantly longer than the Au(2)–P(2) bond length of 2.228(2) Å, presumably because of the greater *trans* influence of the diphosphazane as opposed to the chloride ligand. As might be expected, the Au–P(1) distance of 2.313(2) Å agrees well with that of 2.316 Å found for $[Au(PMePh_2)_2]^+$ [16] since, in both cases, the gold atom is symmetrically coordinated by phosphorus donor

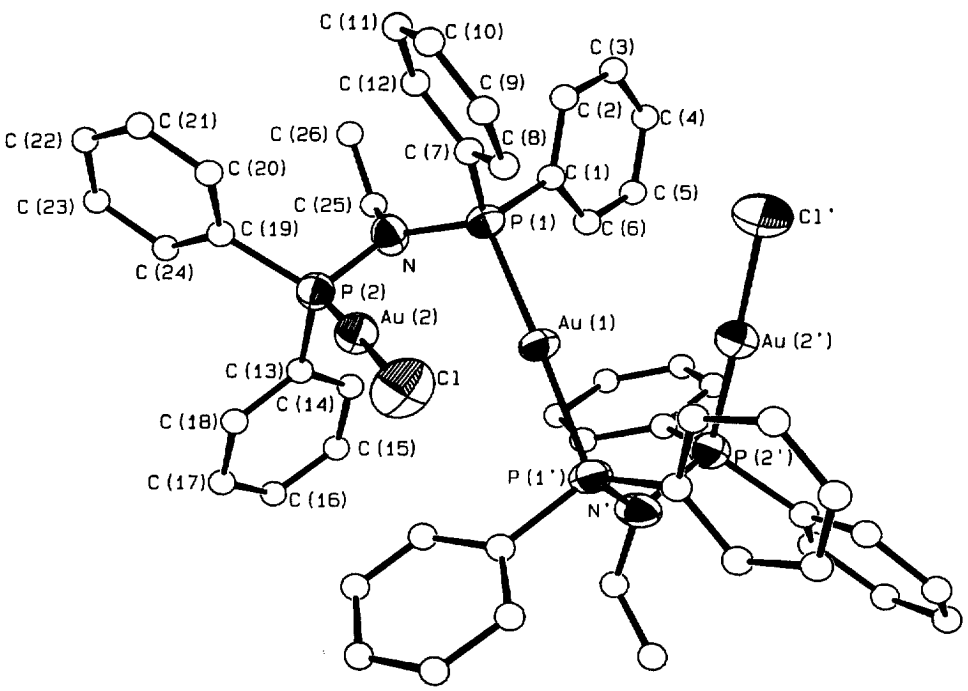

Fig. 3. ORTEP drawing of the $[Au_3Cl_2(\mu\text{-dppa})_2]^{2+}$ cation in $[Au_3Cl_2(\mu\text{-dppa})_2]PF_6$. The carbon atoms are drawn as spheres of arbitrary radius and the remaining atoms as 50% probability thermal ellipsoids.

Table 2. Selected interatomic distances (Å) and angles (°) for $[Au_3Cl_2(\mu\text{-dppa})_2]PF_6$

Au(1)···Au(2)	3.037(1)	Au(1)–P(1)	2.313(2)
Au(2)–Cl	2.282(2)	Au–P(2)	2.228(2)
P(1)–N	1.709(6)	P(1)–C(1)	1.807(7)
P(1)–C(7)	1.797(7)	P(2)–N	1.683(6)
P(2)–C(13)	1.780(13)	P(2)–C(19)	1.809(7)
N–C(25)	1.490(9)		

Au(2)···Au(1)···Au(2′)	163.8(2)	P(1)–Au(1)–P(1′)	175.4(6)
P(2)–Au(2)–Cl	177.1(1)	Au(1)–P(1)–N	109.4(2)
Au(1)–P(1)–C(1)	112.8(2)	Au(1)–P(1)–C(7)	113.3(2)
N–P(1)–C(1)	104.5(3)	N–P(1)–C(7)	107.6(3)
C(1)–P(1)–C(7)	108.7(3)	Au(2)–P(2)–N	110.8(2)
Au(2)–P(2)–C(13)	110.4(2)	Au(2)–P(2)–C(19)	116.7(2)
N–P(2)–C13	107.7(3)	N–P(2)–C(19)	104.5(3)
C(13)–P(2)–C(19)	106.2(3)	P(1)–N–P(2)	117.5(3)
P(1)–N–C(25)	123.3(5)	P(2)–N–C(25)	119.1(5)

ligands. Similarly, the Au(2)–P(2) distance of 2.228(2) Å corresponds closely with the Au–P distance of 2.238(5) Å in [ClAu(dppm)AuCl] [17] since the coordination environments of the gold atoms are the same. The Au(2)–Cl bond length of 2.282(2) Å is very similar to that observed in [ClAu(dppm)AuCl] [17] (2.288 Å) and those reported for the $[Au_3Cl_2(\mu\text{-dppm})_2]^+$ cation of 2.288 and 2.301 Å in the $[AuCl(C_6F_5)_3]^-$ salt and 2.290 Å in the chloride salt. In summary, although the arrangements of the gold atoms in $[Au_3Cl_2(\mu\text{-dppm})_2]^+$ and $[Au_3Cl_2(\mu\text{-dppa})_2]^+$ cations are different, the immediate coordination environments of the gold atoms are very similar.

The room temperature UV/vis absorption spectrum of $[Au_3Cl_2(\mu\text{-dppa})_2]PF_6$ in acetonitrile is shown in Fig. 4. The band at 230 nm, which is observed as a shoulder on the very intense peak in the ultraviolet region, can be attributed to transitions within the phenyl rings [2]. Also observed are a band at 295 nm ($\epsilon_{max} = ca.$ 20000 $dm^3 mol^{-1} cm^{-1}$) and a relatively weak absorption centred at 357 nm. The band at 295 nm is in a very similar position to that at 298 nm observed in the UV/vis spectrum of $[Au_2(\mu\text{-dppa})_2][SbF_6]_2$ measured in acetonitrile Fig. 2. On this basis, and for the same reasons as those discussed above, it is also tentatively assigned to a $p\sigma \Leftarrow d\sigma^*$

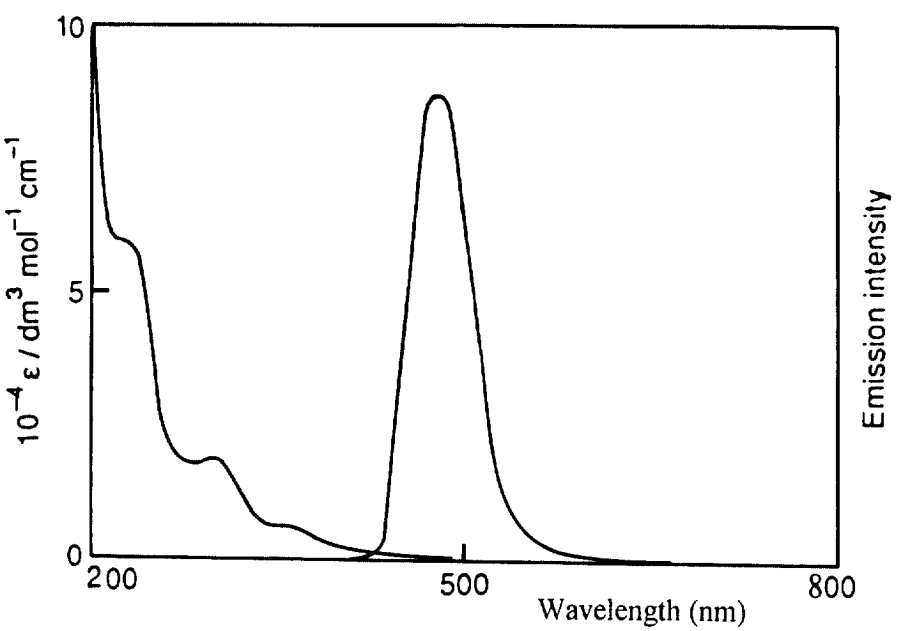

Fig. 4. Absorption in CH_3CN and solid state emission (340 nm excitation) spectra of $[Au_3Cl_2(\mu\text{-dppa})_2]PF_6$.

transition. Irradiation of an acetonitrile solution of $[Au_3Cl_2(\mu\text{-dppa})_2]PF_6$ at 340 nm only affords a very weak and indistinct emission band centred at about 560 nm. On the other hand, a powdered sample of the compound exhibits an intense blue emission as shown in Fig. 4 ($\lambda_{max} = 475$ nm). This emission is slightly blue-shifted compared to the emission maximum of 485 nm recorded in the solid state for $[Au_3Cl_2(\mu\text{-dppm})_2]Cl$ [8]. The origin of the emission is uncertain. However, solid $[AuCl(PPh_3)]$ has only a slight bluish-white emission, due to π–π^* transitions in the phenyl rings and bis(phosphine)gold(I) complexes such as $[Au(PPh_3)_2]BPh_4$ do not emit at all, neither in solution nor in the solid state [6]. It would therefore appear that the intramolecular gold–gold interactions present in the trinuclear $[Au_3Cl_2(\mu\text{-L-L})_2]^{2+}$ cations (L-L = dppm or dppa) are, in some way, responsible for the intense emission observed in the solid state for these compounds.

EXPERIMENTAL

General considerations

All manipulations were performed under nitrogen using a combination of vacuum and Schlenk techniques. Solvents were purified and degassed by standard procedures [18]. Infrared data were recorded as KBr pellets on a Shimadzu FTIR-4300 spectrophotometer. ^1H NMR spectra were recorded on a Varian Gemini-200 spectrometer with chemical shifts referenced to $SiMe_4$. $^{31}P\{H\}$ NMR spectra were recorded on a Varian FT80A spectrometer, chemical shifts being quoted relative to 85% H_3PO_4 (external, ^{31}P). Absorption spectra were recorded on a Shimadzu UV-2101PC UV-vis scanning spectrophotometer. Emission spectra were obtained on a Shimadzu RF-5000 recording spectrofluorophotometer. The C, H, and N analyses were performed by Galbraith Laboratories of Knoxville, Tennessee. The ligand $Ph_2PN(Et)PPh_2$ was prepared by a slight modification of the literature method [19].

Synthesis of $[Au_2(\mu\text{-dppa})_2][SbF_6]_2$

Excess gold powder (0.238 g, 1.208 mmol) was added with stirring to a solution of $NOSbF_6$ (0.134 g, 0.504 mmol) in acetonitrile (*ca.* 10 cm^3) at room temperature. Stirring was continued overnight to allow oxidation of gold to gold(I). The excess gold powder was removed by filtration through glass microfibre filter paper affording a clear colourless solution. Solid $Ph_2PN(Et)PPh_2$ (0.208 g, 0.504 mmol) was added with stirring following which the ligand dissolved and the solution turned yellow. After *ca* 1 h, the volume of the solution was reduced *in vacuo* and diethylether added. The product, which separated from the solution as a colourless microcrystalline solid, was isolated by filtration, washed with diethylether and dried *in vacuo*. Yield: *ca.* 0.77 g (90%). Found: C, 36.7; H, 2.9; N, 1.7; Calc. for $C_{52}H_{50}Au_2F_{12}N_2P_4Sb_2$: C, 36.9; H, 3.0; N, 1.6%. IR data (KBr pellet, cm^{-1}): 658 (vs) (SbF_6^-). ^1H NMR (CD_3CN): δ 7.64 (m, 40H, C_6H_5); 3.12 (q, 4H, CH_2); 0.35 (t, 6H, CH_3). $^{31}P\{^1H\}$ NMR (CD_3CN): δ 100.25.

Synthesis of $[Au_3Cl_2(\mu\text{-dppa})_2]PF_6$

Thiodiglycol (2,2′-thiodiethanol) (*ca.* 0.2 cm^3) was added, with stirring, to an orange-coloured solution of $HAuCl_4.2H_2O$ (0.211 g, 0.560 mmol) in methanol (*ca.* 15 cm^3) at room temperature. A slight excess of solid $Ph_2PN(Et)PPh_2$ (0.232 g, 0.560 mmol) was then added with stirring. After a period of *ca.* 30 min the ligand had dissolved to afford a solution of red-brown colour which subsequently turned yellow. After standing overnight, the solution became colourless. An excess of solid NH_4PF_6 (0.185 g, 1.140 mmol) was added and the solution stirred for 3–4 h. During this time, the product precipitated from the solution as a colourless microcrystalline solid. This was isolated by filtration through glass microfibre paper, washed with water followed by ether and finally dried *in vacuo*. Yield: *ca.* 0.70 g (80%). Found: C, 38.5; H, 3.2; N, 1.8; Calc. for $C_{52}H_{50}Au_3Cl_2F_6N_2P_5$: C, 38.3; H, 3.1; N, 1.7%. IR data (KBr pellet, cm^{-1}): 840 (vs) (PF_6^-). ^1H NMR (CD_3CN): δ 7.64 (m, 40H, C_6H_5); 3.12 (q, 4H, CH_2); 0.35 (t, 6H, CH_3). $^{31}P\{^1H\}$ NMR (CD_3CN): δ 103.61 and 83.11 (AA′BB′ pattern).

X-ray structure determinations of $[Au_2(\mu\text{-dppa})_2][SbF_6]_2$ *and* $[Au_3Cl_2(\mu\text{-dppa})_2]PF_6$

Crystal data, data collection and refinement parameters for $[Au_2(\mu\text{-dppa})_2][SbF_6]_2$ and $[Au_3Cl_2(\mu\text{-dppa})_2]PF_6$ are given in Table 3. Single crystals of the former compound were grown by slow diffusion of diethylether into a solution of the compound in dichloromethane, while single crystals of the latter compound were grown by slow diffusion of diethylether into an acetonitrile solution of the compound. Weissenberg photographs of the $[Au_2(\mu\text{-dppa})_2][SbF_6]_2$ crystals showed that the reflections were generally weak and rather diffuse, but repeated attempts to grow crystals which gave a better-defined diffraction pattern were unsuccessful. Diffractometer data were collected at 295 K with a Nonius CAD4 diffractometer using graphite monochromated Mo–$K\alpha$ radiation ($\lambda = 0.71073$ Å). Lattice parameters were obtained from the least-squares refinement of the setting angles of 25 reflections with $\theta > 12°$. Reflection intensities were measured by the variable-speed ω-2θ method in the range $3 \leqslant 2\theta \leqslant 46°$. Examination of three standard reflections, monitored after every 60 min, showed no evidence for crystal deterioration for either compound. Both data sets were corrected for Lorentz-polarisation effects and were also corrected for absorption using the psi-scan method [20]

(maximum and minimum transmission factors are 0.9999, 0.8936 and 0.9987, 0.8416 for $[Au_2(\mu\text{-dppa})_2][SbF_6]_2$ and $[Au_3Cl_2(\mu\text{-dppa})_2]PF_6$ respectively).

The structures of $[Au_2(\mu\text{-dppa})_2][SbF_6]_2$ and $[Au_3Cl_2(\mu\text{-dppa})_2]PF_6$ were solved by standard Patterson methods using the program SHELXS 86 [21] and subsequently completed by Fourier recycling and refinement using the program SHELX 76 [21]. The full-matrix least-squares refinements were based on $|F_o|$. The ethyl groups of the diphosphazane ligands in $[Au_2(\mu\text{-dppa})_2][SbF_6]_2$ are disordered such that they are not precisely related by the centre of symmetry midway between the two gold atoms. Various models for the disorder were tested but none gave a satisfactory solution. In the end, restrictions were placed on the N–C and C–C bond lengths with the methylene and methyl hydrogens not being included in the refinement. All the non-H atoms were assigned anisotropic temperature factors and the H-atoms a single common isotropic temperature factor; the latter were placed in calculated positions, except for the NEt hydrogens as noted above. Neutral-atom scattering factors were used with corrections for anomalous dispersion [22].

CONCLUSION

Two diphosphazane ligand-bridged complexes of gold have been synthesised, their crystal structures determined and their spectroscopic properties investigated, these being $[Au_2\{\mu\text{-}Ph_2PN(Et)PPh_2\}_2][SbF_6]_2$ and $[Au_3Cl_2\{\mu\text{-}Ph_2PN(Et)PPh_2\}_2]PF_6$. The cations of these compounds have in common Au···Au distances which are sufficiently short to indicate a substantial interaction between the gold atoms. This interaction is believed to be, in some way, responsible for the luminescence exhibited by the compounds, in solution for the dinuclear species and in the solid state for the trinuclear complex. However, we have not been able to establish a correlation between the Au···Au separation and the energy of the emission and, thus, conclude that the emission wavelength is determined more by the properties of the ligand. This conclusion is borne-out by a comparison of the emission properties of the diphosphazane ligand-bridged compounds with those reported for salts of the bis(diphenylphosphino)methane ligand-bridged cations, $[Au_2(\mu\text{-}Ph_2PCH_2PPh_2)_2]^{2+}$ and $[Au_3Cl_2(\mu\text{-}Ph_2PCH_2PPh_2)_2]^+$.

(Received 22 January 1998)

Abstract—Reaction of $[CuL_2]$ (LH: tfpbdH = 4,4,4-trifluoro-1-phenyl-1,3-butanedione; tropH = tropolone; or acacH = acetylacetone; Ph/Me-pdH = 1-phenyl-1,3-butanedione; Ph/Ph-pdH = 1,3-diphenyl-1,3-propanedione; or C_4H_3S/CF_3-pdH = 4,4,4-trifluoro-1-(2-thienyl-1,3-butanedione)) with benzotriazole (btaH) in CH_2Cl_2 yields the corresponding compound $[Cu_5(bta)_6L_4]$ (L = tfpbd, **1**; trop, **2**; acac, **3**; (Ph/Me-pd) **4**; (Ph/Ph-pd) **5**; (C_4H_3S/CF_3-pd) **6**). The structures of **1** and **2** have been determined by single crystal X-ray diffraction revealing a distorted tetrahedral arrangement of four Cu(II) centered on a fifth Cu(II). Each of the six bta ligands spans an edge of the Cu_4 tetrahedron and is ligated to the central Cu through its central nitrogen. Solid-state magnetic susceptibility studies from 2–300 K have been accomplished for **1**, **2** and **3** and reveal a weak antiferromagnetic intramolecular interaction between the five Cu(II) centres. The tridentate (μ_3-bridging) bonding motif of bta is well suited for the formation of a protective monolayer of bta^- ions on oxidised copper surfaces. Furthermore, the flexibility in this mode of coordination exhibited by bta^- ions, as manifest within the structures of **1**, **2**, and **3** (the structure of which was determined previously), is advantageous and would allow benzotriazolate to adapt to the various surface topographies which could well be presented by lightly oxidized copper surfaces. © 1998 Elsevier Science Ltd. Keywords: benzotriazole; β-diketonates; copper complexes; corrosion; crystal structures; magnetic properties.

INTRODUCTION

Specific ligands have been found to inhibit the corrosion of particular metals; benzotriazole (btaH) and substituted benzotriazoles are well established corrosion inhibitors for copper and its alloys [1]. It has been postulated that copper oxide films are prerequisites for successful corrosion inhibition [2] and practical use of btaH as a corrosion inhibitor involves application to copper surfaces which have undergone some degree of oxidation. We have investigated the mode of interaction of btaH with lightly oxidized copper surfaces by studying the coordination chemistry of this pro-ligand with complexes of Cu(II) bound to oxygen-donor ligands.

$[Cu_5(bta)_6(acac)_4]$, first reported by Marshall [3], is an attractive analogue for the structure of species formed by btaH in forming the protective barrier on the surface of copper and its alloys. Treatment of a CH_2Cl_2 solution of $[Cu(acac)_2]$ with solid btaH in a 1:5 ratio, followed by slow evaporation of the solvent yielded green, prismatic crystals of $[Cu_5(bta)_6(acac)_4].0.5CH_2Cl_2$. The structure of this cluster, wherein each bta ligand forms three η^1 Cu–N bonds in an "arrowhead" structural motif [4], is in accord with a

* Correspondence and proofs: Professor C. David Garner, FRS, Department of Chemistry, The University of Manchester, Manchester M13 9PL (UK).

model of the interaction of btaH with metal or metal oxide surfaces proposed on the basis of single crystal, UHV surface studies [5]. This relatively simple synthetic route to $[Cu_5(bta)_6(acac)_4]$ has permitted variation of the copper-containing starting material to produce other examples of this structural motif, as described herein. These systems allow further exploration of copper-bta interactions in an oxygen-rich metal environment. Not only are these clusters relevant to the corrosion inhibitive properties of btaH but also they are of chemical interest in their own right.

EXPERIMENTAL

General

All chemicals were reagent grade and were used as received. All preparations were carried out in air at ambient temperature.

Synthesis of $[CuL_2]$ (*L* = *tfpbd, trop, acac, (Ph/Me-pd), (Ph/Ph-pd), and* $(C_4H_3S/CF_3$-*pd)*

These compounds were prepared by an adaptation of a method described by Fernelius and Bryant [6] and crystallized from hot $CHCl_3$. Each compound had satisfactory elemental analysis (C,H,Cu) and the expected IR (KBr disk) and UV/Vis (CH_2Cl_2) spectroscopic properties.

Synthesis of $[Cu_5(bta)_6L_4]$ (*L* = *tfpbd* (*1*), *trop* (*2*), *acac* (*3*), *(Ph/Me-pd)* (*4*), *(Ph/Ph-pd)* (*5*), *and* $(C_4H_3S/CF_3$-*pd)* (*6*))

A solution of benzotriazole (0.143 g, 1.2 mmol) in CH_2Cl_2 (10 cm^3) was added to a solution of $[CuL_2]$ (1.0 mmol) in CH_2Cl_2 (75 cm^3). The resulting deep green solution was stirred for 2 h. at room temperature and the solvent left to evaporate in air. The resulting solid was crystallized by careful layering of a concentrated CH_2Cl_2 (or, for **4** $CHCl_3$) solution with a co-solvent (**1**, petroleum ether (40/60); **2**, **6** cyclohexane; **3**, **4** EtOH; **5** Et_2O) (1:4, v/v).

Microanalyses were carried out by the Microanalytical Laboratory of the Chemistry Department, The University of Manchester. IR spectra were recorded as KBr disks on an ATI Mattson Genesis Series FTIR spectrometer. UV/Vis spectra were recorded using a Varian Cary 1E UV/Vis spectrophotometer. Magnetic susceptibility measurements were performed on a Quantum Design MPMS-7 SQUID magnetometer at a field strength of 100 G (0.01 T) and over a temperature range of 2–300 K. Volume susceptibilities were measured on randomly oriented polycrystalline materials of **1** (23.6 mg), **2** (22.9 mg) and **3** (25.9 mg).

Crystallography

The crystallographic data for the structural determinations of **1** and **2** are summarized in Table 1; the X-ray structural determination of **3** has been previously published [4]. A single crystal of **1** or **2** was mounted in a glass capillary in the presence of some of the mother liquor. Data collection was carried out using a Rigaku AFC5R diffractometer which utilized graphite monochromated CuK_α radiation ($\lambda = 1.54178$ Å). The data were corrected for absorption [7], Lorentz-polarisation effects and, for **2**, a small linear intensity decay. The structures were solved by standard direct methods [8] and all refinements were performed using the teXsan crystallographic software package [9].

The asymmetric unit of **1**.$(C_6H_{14})_2C_6H_{12}$ consists of half a molecule, the second half being generated by rotation about a 2-fold axis. Also present are two solvent fragments considered to originate from the petroleum ether (40/60) used in the crystallization which were included as one hexane molecule and half a cyclohexane molecule, the second half being generated by inversion. The non-hydrogen atoms, except for carbon (C19–C38) atoms in the four bidentate oxygen donors, were refined anisotropically. A view of the $[Cu_5(bta)_6(tfpbd4]$ cluster of **1**, as viewed along the crystallographic two fold axis, is given in Fig. 1.

The asymmetric unit of **2**.H_2O consists of two $[Cu_5(bta)_6(trop)_4]$ and two H_2O molecules. In the second copper-containing molecule, one of the $C_7H_5O_2$ groups showed some disorder with two positions being identified for O10. Due to the large number of parameters involved in this structure, each molecule was refined separately. The non-hydrogen atoms, except for O17 and O18 of the water molecules, were refined anisotropically. A view of one of the copper clusters of **2**, with the carbon atoms of tropolonate omitted for clarity, is given in Fig. 2.

For both crystal structure determinations, the hydrogen atoms were included in calculated positions with fixed isotropic thermal parameters. Selected bond lengths, bond angles, non-bonding distances and non-bonding angles for the $[Cu_5(bta)_6(\beta\text{-diketonate})_4]$ cluster of **1**.$(C_6H_{14})_2C_6H_{12}$ and **2**.H_2O are presented in Tables 2 and 3, respectively.

RESULTS AND DISCUSSION

The previously employed synthetic methodology for the synthesis of $[Cu_5(bta)_6L_4]$ clusters [3, 4] has

been improved by the use of a stoichiometric amount of btaH in the preparation of the complexes **1**–**6**, resulting in the isolation of crystalline products in good yield.

The crystal and molecular structures of 1 and 2

As previously seen for **3** [4], the pentanuclear Cu(II) assemblies of **1** and **2** (see Figs. 1 and 2, respectively) each consist of a distorted tetrahedral arrangement of four Cu(II) centred on the fifth (see Figs. 3 and 4). Each benzotriazolate anion spans an edge of the tetrahedron and is ligated to the central Cu(II) *via* its central nitrogen atom. The coordination sphere at each apical Cu(II) is completed by a bidentate β-diketonate ligand. The central Cu(II) has a tetragonally distorted (4+2) octahedral coordination geometry, with (see Tabs. 2 and 3) average distances of Cu–N_{ax} = 2.29 Å, Cu–N_{eq} = 2.08 Å for **1** and Cu–N_{ax} = 2.41 Å, Cu–N_{eq} = 2.04 Å for **2**. Each apical Cu(II) is in an approximately square-based pyramidal $(Cu(N_2O_2)_{eq}(N)_{ax})$ environment, bound to three benzotriazolate nitrogen atoms and two oxygen atoms of the bidentate donor molecule. Average distances defining the geometry at the apical copper ions are Cu–N_{eq} = 1.97, Cu–N_{ax} = 2.20 and Cu–O = 1.94 Å for **1** and Cu–N_{eq} = 2.00, Cu–N_{ax} = 2.23 and Cu–O = 1.94 Å for **2**.

The distortion of the Cu^{II}_4 tetrahedral array can be measured by considering the Cu···Cu separations of the apical Cu(II) ions. For the Cu(II) bridged by axial benzotriazolate anions, (see Fig. 3), the average distance between apical coppers is 5.82 Å for **1** and 5.74 Å for **2**. This distance increases to *ca.* 6.05 Å for the Cu(II) bridged by equatorial benzotriazolate anions in **1** and *ca.* 6.16 Å for **2** and is accompanied by an increase in the $Cu_{(apical)}Cu_{(central)}Cu_{(apical)}$ bond angle (see Tabs. 2 and 3). The dihedral angles between opposite $Cu_{(apical)}Cu_{(central)}Cu_{(apical)}$ planes in **1** are 90.4° in the axial direction and 83.1 and 86.0° between planes in the equatorial direction. The corresponding angles in the two distinct molecules in the asymmetric unit of **2** are 90.6, 82.4 and 82.9° (Cu1–Cu5) and 90.1, 82.3 and 82.4° (Cu6–Cu10).

There are significant structural variations within each Cu^{II}_3–bta moiety of the structures **1**, **2** and **3**. The angles of inclination of the bta^- ions have been assessed by calculating the angle between the plane of the bta and that of the corresponding $Cu_{(apical)}Cu_{(central)}Cu_{(apical)}$ plane (Tab. 4). For the two axial bta^- ions of **1**, the angle is either 0 or 1.4°, whereas two of the equatorial bta^- ions are bonded at an angle of 7.9° and the other two at an angle of

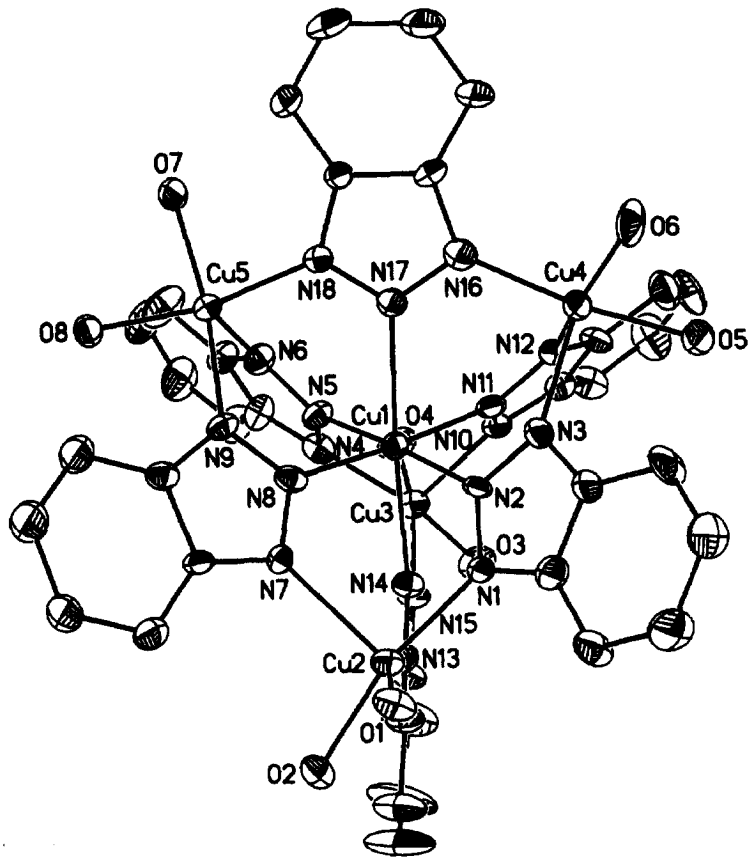

Fig. 2. ORTEP diagram showing the non-hydrogen atoms of $[Cu_5(bta)_6(trop)_4]$ (**2**); for clarity, the C atoms are not labelled and 30% probability thermal ellipsoids are given.

16.8°. This indicates that the two axial bta^- ions are bonded in a more upright orientation. In **2** the angle is 4.1 or 3.4° (Cu1–Cu5) and 4.3 or 2.9° (Cu6–Cu10) in the axial direction and in the equatorial direction the angle is 5.4, 7.4, 9.7 or 12.2° (Cu1–Cu5) and 3.0, 9.2, 12.1, 13.0° (Cu6–Cu10). The more irregular bonding of the equatorial bta^- ions could result from the square-based pyramidal geometry at the apical Cu(II). Thus, the longer Cu–N bond of the $(Cu(N_2O_2)_{eq}(N)_{ax})$ environment is found within each $Cu^{II}{}_3-bta_{eq}$ moiety and this asymmetry is reflected in the tilting of the bta^- ions. This situation does not occur in **3** since one of the longer Cu–N bonds is located in the $Cu^{II}{}_3-bta_{eq}$ moiety (Cu4, Cu1, Cu5).

Mass spectrometry

The $[Cu_5(bta)_6L_4]$ compounds were found to be amenable to characterisation by positive ion fast atom bombardment (+FAB) mass spectrometry and all exhibited a characteristic fragmentation pattern (Fig. 5). No parent ion was seen and, in each case, the first ion detected was $[Cu_5(bta)_5L_4]^+$. Each of these cluster cations fragment by losing two of the bidentate oxygen chelates, then a second bta, followed by the loss of the two remaining oxygen chelates. All of the mass spectra exhibited a characteristic "fingerprint" peak at $m/z = 789$, assigned to $[Cu_5(bta)_4]^+$. Loss of bta from this latter ion produced a second fingerprint peak at $m/z = 608$, corresponding to $[Cu_4(bta)_3]^+$. Other, less intense, peaks were present in each mass spectrum indicating other fragmentation routes; *e.g.*, a small peak was sometimes observed corresponding to the production of the $[Cu_5(bta)_6L_3]^+$.

Thus, in these mass spectra one of the tridentate μ_3-bridging bta is the first ligand to be lost by the cluster. With reference to the structural information available for these pentanuclear copper(II) clusters, the initial loss of bta may be explained by considering the Cu–N bonding at the central Cu(II) which is in a tetragonal ligand field-consistent with a Jahn-Teller distortion producing an elongation of the two Cu–N bonds to the axial bta. This lengthening of the bond between

the central Cu(II) and the central nitrogen atoms, from *ca.* 2.0 Å in the equatorial direction to *ca.* 2.4 Å in the axial direction, suggests that the axial bta ligands are more weakly bound than the equatorial ones.

IR spectroscopy

The IR spectra of the $[Cu_5(bta)_6L_4]$ compounds in KBr discs are dominated by bands attributable to the bidentate oxygen chelate and contain strong absorptions between *ca.* 1500 and 1600 cm^{-1} attributable to C···C and C···O stretching modes [10]. The coordinated benzotriazole in these complexes is considered responsible for the two bands at *ca.* 788 and 745 cm^{-1}; the stronger (at 745 cm^{-1}) is assigned as a C–H out-of-plane vibration and the weaker to a vibration involving both benzene and triazole in-plane bending [11].

UV/Vis spectroscopy

The $[Cu_5(bta)_6L_4]$ compounds, dissolved in CH_2Cl_2, exhibit a broad absorption profile in the visible region of the electromagnetic spectrum centred on *ca.* 670 nm (ε *ca.* 500 $dm^3\,mol^{-1}\,cm^{-1}$). This absorption accounts for the green colour of the compounds and is considered to arise from *d–d* transitions within each cluster.

The UV region of the spectra of the compounds $[Cu_5(bta)_6L_4]$ (where L = β-diketonates) contain two strong absorptions: the more intense band was observed at *ca.* 275 nm (ϵ *ca.* 8×10^4 to 1×10^5 $dm^3\,mol^{-1}\,cm^{-1}$) and the other between 300–

† Estimated standard deviations in the least significant figure are given in parentheses.

360 nm (ϵ *ca.* 5×10^4 to 8×10^4 $dm^3 mol^{-1} cm^{-1}$) depending on the nature of L. Each of these absorptions was usually accompanied by a low energy shoulder. The UV spectrum of bta^- (1.5×10^{-3} M btaH in an $NaOH/H_2O$ solution at pH = *ca.* 10) contains an absorption at 275 nm (ϵ = *ca.* 8.7×10^3 dm^3 mol^{-1} cm^{-1}), in agreement with the results reported by Xu *et al.* who assigned this absorption as a π–π^* transition in bta^- on the basis of the results of CNDO calculations [12].

Therefore, we assign the absorption of the band at *ca.* 275 nm in the UV spectra of the $[Cu_5(bta)_6L_4]$ compounds as a π-π^* transition of the bta ligands. The UV spectrum of $[Cu(acac)_2]$ (5.5×10^{-4} M in CH_2Cl_2) contains two absorptions at 245 and 296 nm ($\epsilon = 1.9 \times 10^4$ and 1.4×10^4 $dm^3 mol^{-1} cm^{-1}$, respectively). Investigation of the UV spectra of Cu(II) β-diketonates by Singh and Sahai led to the assignment of the former absorption as a L→M charge-transfer transition and the latter as a ligand π-π^* transition [13]. Therefore, the absorption at 300–360 nm is assigned as a π-π^* transition of L and the position of this band varies, as expected, with the nature of L. Thus, substitution of Me in L shifts the absorption from 301 nm (L = acac) to 335 nm (L = Ph/Me-pd), 336 nm (L = Ph/CF_3-pd), 363 nm (L = Ph/Ph-pd) and 348 nm (L = C_4H_3S/CF_3-pd), variations which parallel those observed in the spectra of $[CuL_2]$ compounds [13].

The UV spectrum of **2** contains absorptions at 245 and 332 nm and a broad absorption between 360 and 400 nm ($\epsilon = 1.2 \times 10^5$, 7.1×10^4 and 2.4×10^4 dm^3 mol^{-1} cm^{-1}, respectively). These absorptions, apart from the shoulder at *ca.* 275 nm, are also seen at lower intensity, in the UV spectrum of $[Cu(trop)_2]$ (3.4×10^{-4} M in CH_2Cl_2), λ/nm (ϵ/dm^3 mol^{-1} cm^{-1}) 390 (4.2×10^3), 332 (1.2×10^4), 251 (2.1×10^4). A shoulder was seen at *ca.* 275 nm which may cor-

Magnetic properties

The experimental data were corrected for inherent diamagnetism using Pascal's constants [14] and for the temperature independent paramagnetism (TIP) of 60×10^{-6} cm^3 mol^{-1} arising from four antiferromagnetically coupled Cu atoms [15]. TIP can arise in overall spin singlet systems resulting from mixing of the ground state wave function with non-thermally populated excited states [14]. The corrected $\chi_m T$ versus T plots for all three compounds exhibits the same general behaviour (as illustrated in Fig. 6). At high temperatures the curves have positive gradients. The $\chi_m T$ values at 300 K shown in Table 5 are comparable to the paramagnet limit of five isolated S = 1/2 spins (0.46875g^2 cm^3 K mol^{-1}). $\chi_m T$ decreases with a decreasing temperature, indicating that the antiferromagnetic contributions become more rel-

evant as thermal randomising energy is removed from the system. The $\chi_m T$ value for each of the compounds at 2 K equates to an $S = 1/2$ ground state. Plots of $1/\chi_m$ versus T give curves which could be fitted to a Curie–Weiss expression in the high temperature region (50–300 K). A least-squares fit gives the Weiss constants shown in the Table 5.

Magnetic modelling For the purposes of modelling the magnetic properties of the $[Cu_5(bta)_6L_4]$ systems, the geometry of the Cu_5 cluster was assumed to be that of a regular tetrahedron (T_d symmetry) with four equivalent spins at the vertices and an additional body-centred spin (Fig. 7). This geometry gives the energy levels:

$$E(S_{1234},S_T) = -J_1S_T(S_T+1)+J_1S_0(S_0+1) + (J_1-J_2)S_{1234}(S_{1234}+1)+4J_2S(S+1)$$

where: S_{1234} = algebraic sum of the spins for the outer Cu sites; S_T = total algebraic sum of all spins; S_0 = cen-

Table 5. Magnetic data observed, and magnetic parameters obtained, for **1**, **2** and **3**

Compound	J_1/cm^{-1}	J_2/cm^{-1}	g	$\chi_m T$ at 300 K/cm^3 K mol^{-1}	Weiss constant
1	−7.0	−7.3	2.39	2.61	−29.2
2	−6.5	−6.4	2.23	2.18	−19.9
3	−9.5	−9.4	2.14	2.00	−33.4

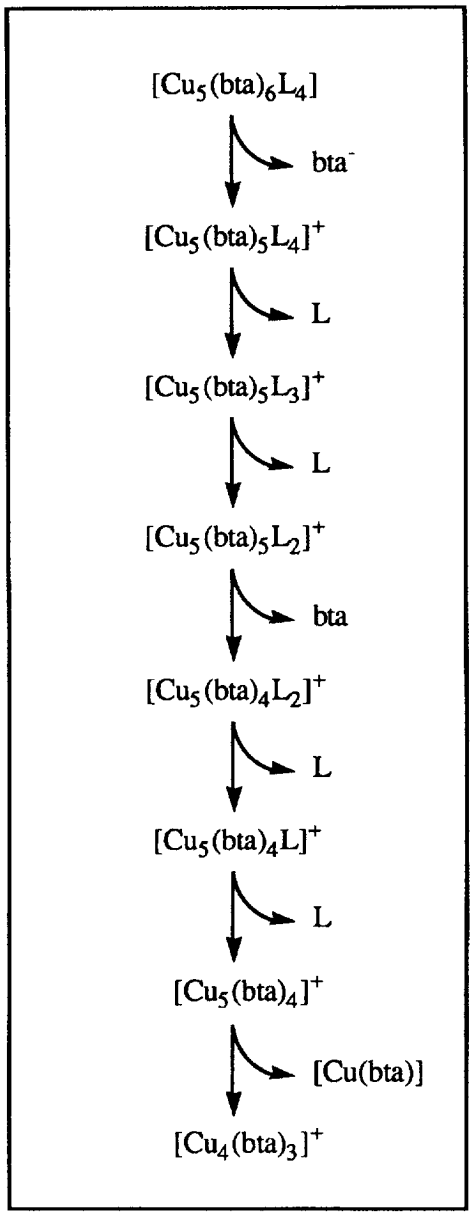

Fig. 5. Schematic diagram showing the observed fragmentation pattern of $[Cu_5(bta)_6L_4]$ under +FAB.

tral spin quantum number; J_1 = coupling constant between the central and outlying spins; J_2 = coupling constant between the outlying Cu sites [16]. The energy levels are applied to the Van Vleck equation summed over all possible combinations of the five spin sites.

$$\chi_m T = \frac{Ng^2\beta^2}{3k} \times \frac{\sum_{S_T} S_T(S_T+1)(2S_T+1)\exp(-E(S_T)/kT)}{\sum_{S_T}(2S_T+1)\exp(-E(S_T)/kT)}$$

Thus,

$$\chi_m T = (0.12505g^2)\frac{N}{D}$$

where:-

$$N = 52.5\exp([2J_1+3J_2]/kT) + 45\exp([J_1-J_2]/kT) + 3\exp(-3J_2/kT) + 15\exp([-3J_1+3J_2]/kT) + 4.5\exp([-2J_1-J_2]/kT)$$

$$D = 6\exp([2J_1+3J_2]/kT) + 12\exp([J_1-J_2]/kT) + 4\exp(-3J_2/kT) + 4\exp([-3J_1+3J_2]/kT) + 6\exp([-2J_1-J_2]/kT)$$

A least-squares fitting of this expression for $\chi_m T$ to the experimental results, using the Levenberg–Marquardt algorithm, gave the J_1, J_2 and g values presented in Table 5; these parameters were allowed full freedom in the model. The refined g-values are in the range 2.14 to 2.39 and are as expected for Cu^{II} centres, thereby giving added confidence to the use of this simple magnetic coupling model. Similar fits to the experimental data were also obtained for $J_1 \approx 3$ and $J_2 \approx 10$ cm^{-1} with a lower g-value; these were discounted because the fit at low temperatures (< 50 K) was significantly inferior to that with the values quoted above. Furthermore, the calculated g-values for these curves were lower than expected for spin-orbit coupled Cu(II). The values of J_1 and J_2 in Table 5 are low and this is not unexpected since most of the Cu(II)–Cu(II) couplings occur by a route which involves an axial and an equatorial nitrogen atom and, therefore, is quite long. $[Ni_5(OH)(bta)_5(acac)_4(H_2O)_4]$ [17] has a similar molecular structure to that of the compounds reported herein with bta ligands spanning five of the six edges of a Ni^{II}_4 tetrahedron centred on the fifth Ni^{II}. Magnetic studies have shown that the coupling constants between the Ni^{II} centres at the corners of the tetrahedron (J_2) are $-5\,cm^{-1}$ and $-10.7\,cm^{-1}$; the coupling constant between the central Ni^{II} and the outer Ni^{II} atoms (J_1) is $-6.1\,cm^{-1}$. These values are similar to those reported for the pentanuclear Cu^{II}-bta compounds described herein and indicate that the bta ligand propagates very weak antiferromagnetic exchange.

CONCLUSIONS

The tridentate (μ_3-bridging) bonding motif of bta^- ions is well suited for the formation of a protective monolayer on lightly oxidised copper surfaces. The flexibility in this mode of coordination exhibited within the clusters of **1**, **2**, and **3** is advantageous and would allow benzotriazolate to adapt to the various surface topographies which could well be presented by "real" oxidized copper surfaces.

Synthesis and structure of bis[2,2′-methylenebis(2,4-di-*t*-butylphenoxo)]niobium chloride

Lee Higham, Mark Thornton-Pett and Manfred Bochmann*

School of Chemistry, University of Leeds, Leeds LS2 9JT, U.K.

(Received 24 October 1997; accepted 5 January 1998)

Abstract—The addition of Li_2MTP [$MTPH_2$ = 2,2′-methylenebis(2,4-di-*t*-butylphenol)] to a suspension of $NbCl_5$ in toluene in either 1 : 1 or 2 : 1 ratios leads to the formation of a red powdery product from which deep red crystalline $NbCl(MTP)_2$ (**1**) can be obtained by sublimation. The structure of **1** was determined by single crystal X-ray diffraction. The compound is monomeric in the solid state, with a trigonal-bipyramidal $NbClO_4$ core and the chloride ligand in an equatorial position. The reaction of **1** with methyllithium affords yellow $NbMe(MTP)_2$. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: aryloxide complex; chelate complex; niobium; alkylation.

Aryloxide ligands of varying degrees of steric hindrance are well known to be able to stabilise early transition metals in a range of oxidation states and ligand environments. Examples include dimeric compounds of the type $Nb_2(OR)_{10}$ (R = Me [1], 4-MeC_6H_4 or 3,5-$Me_2C_6H_3$ [2]), as well as monomeric Nb(V) complexes with bulkier aryl substituents such as R = 2,6-$Me_2C_6H_3$. The niobium and tantalum complexes possess an extensive organometallic chemistry including their application as hydrogenation catalysts [3–5]. Early transition metal complexes with chelating aryloxide ligands are less well investigated but have received attention as alternatives to cyclopentadienyl ligands in homogenous polymerisation catalysts. For example, Miyatake *et al.* [6] reported that TiX_2(TBP) (X = Cl, OPr^i) activated with methylaluminoxane polymerised ethene with good activities. Related titanium and zirconium complexes were reported by Schaverien *et al.* [7] who found moderate polymerisation activity coupled with usually comparatively broad polymer molecular weight distributions. Other examples were provided by Floriani *et al.* [8] and Zubieta *et al.* [9] who isolated complexes such as $TiCl_2$(MMBP) and V(O)Cl (MMBP). A recent more systematic study of TiX_2(O—X—O)/MAO catalysts has highlighted the importance of the nature of X on the performance of such compounds as polymerisation catalysts [10].

As part of our interest in chelating ligands in Cp-free homogeneous alkene polymerisation systems [11] we became interested in the synthesis of complexes of the type (O—O)$NbCl_3$ and (O—O)$_2$NbCl (O—O = chelating bisphenolate). The recent report by Chisholm *et al.* [12] on related titanium, zirconium and tantalum complexes of the $[MMPB]^{2-}$ ligand prompts us to report the reaction of $NbCl_5$ with the chelating phenoxide ligand $[MTP]^{2-}$.

RESULTS AND DISCUSSION

Syntheses

In an attempt to prepare (MTP)$NbCl_3$, a suspension of $NbCl_5$ in toluene was treated at −78°C with a toluene solution of Li_2[MTP]. A viscous red solution resulted; there was no apparent further change on warming to room temperature. Filtration from precipitated LiCl and evaporation of the solvent left a red powder which, according to ^{1}H NMR data, contained coordinated MTP as well as free $MTPH_2$. Both the complex and the free ligand show similar solubility properties, being very soluble in diethyl ether but sparingly soluble in light petroleum, and efforts to achieved purification by recrystallisation were unsuccessful. Mass spectrometry indicated, however, that in spite of the chosen Nb/MTP ratio of 1:1 a volatile 1:2 complex of composition NbCl(MTP)$_2$ had been formed.

A crystalline product was obtained by the slow sublimation of the crude product through a plug of glass wool at 175 C/0.01 mm Hg. Some $MTPH_2$ sublimed as an off-white band. On raising the temperature to 275 C this was followed by the formation of dark-red crystalline blocks NbCl(MTP)$_2$ (**1**). The same product was obtained from the reaction of $NbCl_5$ and Li_2[MTP] in a 1:2 stoichiometry. Attempts to improve on the synthesis by varying the solvent were not successful. From THF solutions a yellow crystalline product was obtained which rapidly lost solvent of crystallisation and could not be fully characterised.

Compound **1** was characterised by single crystal X-ray diffraction. An ORTEP diagram is shown in Fig. 1. Selected bond distances and angles are collected in Table 1. The complex possesses trigonal-bipyramidal geometry, with an equatorial Cl ligand. Variable temperature NMR data indicate that this structure remains unchanged in solution; no interchange is observed between the diastereotopic hydrogen atoms of the bridging methylene group. In the solid state,

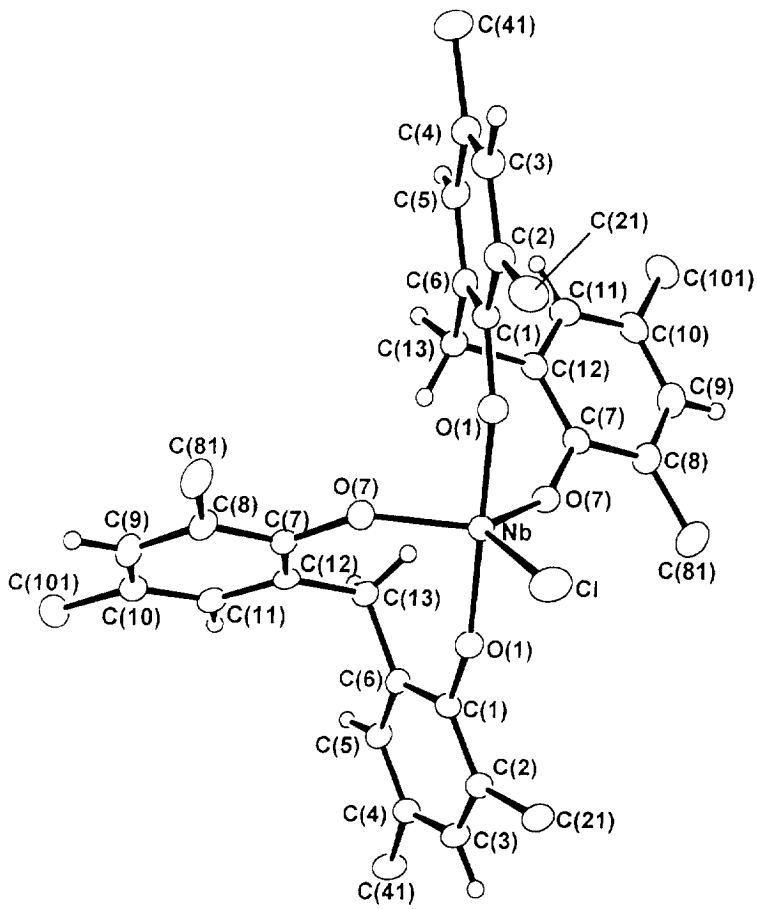

Fig. 1. ORTEP-type [20] diagram of the crystal structure of NbCl(MTP)$_2$. Thermal ellipsoids are shown at the 40% probability level. The molecule possesses crystallographic C_2 symmetry such that the C_2 axis runs along the Nb—Cl bond vector. In the interests of clarity, the methyl groups of the *t*-butyl substituents have been omitted.

Atoms marked * are related to their unmarked equivalents by the symmetry operator $-x$, y, $1/2+z$.

the (non-bonding) distance between the metal centre and one of these methylene-hydrogens (H13b) is 2.78 Å, while the other (H13b) is more remote, 4.34 Å.

The chloride ligand is in an equatorial position. The Nb—Cl distance of 2.3357(9) Å is slightly longer than the distances to terminal chloride ligands in Nb_2Cl_{10} [2.250(6) and 2.302(5) Å] [13] but significantly shorter than Nb—Cl bond lengths in the octahedral complex. $NbCl_3(OPr^i)_2\{O{=}P(NMe_2)_3\}$ [*trans*: 2.401(4) and 2.415 Å; *cis*: 2.452(3) Å] [14]. The Nb—O distances are typical for terminal alkoxo ligands in 5- and 6-coordinate niobium alkoxides; some comparative values are given in Table 2. Each chelate ring occupies an axial and an equatorial position of the NbO_4Cl core, with O—Nb—O angles of very close to 90° between the axial and equatorial oxygen atoms, while the O(1)—Nb—O(1*) moiety is strictly linear, 179.93(2)°.

In spite of the fact that the chelate rings might be expected to induce some angular distortions, the angles between the equatorial ligand atoms deviate only slightly from the ideal value of 120°, with

O(7)—Nb—O(7*) of 118.30(9)° and O(7)—Nb—Cl of 120.85(4)°. There is therefore no indication for ring strain in the 8-membered chelate rings. The Nb—O—C angles of, on average, 153.4° are significantly larger than tetrahedral, a typical feature in aryloxide complexes of electron deficient metals and are consistent with the partial M—O double bond character in these compounds, although these angles can vary significantly and those found in **1** are substantially larger than corresponding angles in related titanium and zirconium complexes [12].

There are a number of niobium and tantalum complexes with chelating ligands which adopt a similar structure, although in these cases the chelate ring formation is the result of C—H activation of ortho-substituents of the aryl rings. Pertinent examples are the Nb(V) alkyl (C—O)Nb(OAr)$_3$ [C—O = $OC_6H_4CMe_2CH_2-$] [3c] and a series of tantalum compounds such as (C—O)$_2$TaCl [15] and (C—O)$_2$TaMe [3b] (C—O = $-OC_6H_2X-2-Bu^t-6-CMe_2CH_2-$; X = H, Bu^t).

Complex **1** reacts with methyllithium in diethyl ether at −78°C to give (MTP)$_2$NbMe (**2**) as a yellow microcrystalline powder. The compound was characterised spectroscopically, and attempts to obtain X-ray quality crystals were unsuccessful. Characteristic are the set of two doublets for the bridging CH_2 group which are found in the ^{1}H NMR spectrum at δ 3.65 and 4.85, compared to chemical shifts of δ 3.50 and 5.42 in **1**, indicative of a structure very similar to that of **1**. The compound is sensitive to hydrolysis, with the evolution of methane, to give as yet uncharacterised products. Work exploring the reactivity of **1** and **2** is in progress.

CONCLUSION

Chelating aryloxo ligands strongly favour the formation of 2:1 complexes of the type (O—O)$_2$NbX, while 1:1 compounds (O—O)NbX$_3$ could not be isolated. The five-coordinate species strictly adhere to a trigonal-bipyramidal geometry. Fluxional processes which would lead to an interchange of the hydrogen atoms of the methylene groups in the two MTP ligands were not observed.

EXPERIMENTAL

All manipulations were carried out under a dry nitrogen atmosphere using vacuum line techniques. Solvents were dried over sodium (toluene), sodium-potassium alloy [diethyl ether, light petroleum (bp. 40–60°C)] or sodium-benzophenone (THf). Deuterated solvents were degassed by several free-thaw cycles and stored over 4A molecular sieve. NMR spectra were recorded on a Bruker DPX300 instrument. $NbCl_5$ was used as supplied. 2,2′-Methylenebis-(4,6-di-*t*-butylphenol) ($MTPH_2$) was prepared following a literature procedure [17].

Bis[2,2′-*methylenebis*(4,6-*di-t-butylphenoxo*)] *niobium chloride* (**1**).

A solution of $MTPH_2$ (6.86 g, 166 mmol) in toluene (100 cm^3) was cooled to −78°C and treated dropwise with *n*-butyllithium (13 cm^3, 1.6 M, 32 mmol). The solution was allowed to warm to room temperature, stirred for 1 h, and then transferred by cannula into a second flask containing niobium pentachloride (2.2 g, 8 mmol) in toluene (50 cm^3) at −78°C. The mixture turned red and was warmed to room temperature. Stirring was continued for 3 h. A white precipitate of LiCl was allowed to settle, and the somewhat viscous supernatant was filtered off. The filtrate was evaporated to dryness, leaving a dark-red powder, the NMR spectrum of which showed the presence of some free $MTPH_2$. Since both the niobium product and $MTPH_2$ are very soluble in diethylether and light petroleum and no purification could be achieved by recrystallisation, the solid product was transferred to a long sublimation tube, covered with a plug of glass wool and heated in a tube furnace to 175°C under reduced pressure (10^{-2} mm Hg). An off-white band of $MTPH_2$ appeared at the top of the sublimation tube. On raising the temperature to 275°C dark-red prisms of **1** were deposited half-way up the tube; these were collected (2.2 g, 2.27 mmol, 28%). ^{1}H NMR (C_6D_6, 25°C, δ): 7.31 (s, 8 H, Ar), 5.42 (d, 2 H, $^2J_{HH}$ = 14 Hz, CH*H*), 3.50 (d, 2 H, $^2J_{HH}$ = 14 Hz, C*H*H), 1.50 (s, 36 H, CMe_3), 1.30 (s, 36 H, CMe_3). ^{13}C NMR (C_6D_6, 25°C, δ): 158.6 (*ipso*-C), 145.7 (*p*-C), 137.9 (*o*-C), 135.9 (*o*-C), 125.2 (*m*-C), 122.4 (*m*-C), 35.9 (*C*Me$_3$), 35.6 (t, $^1J_{CH}$ = 127 Hz, CH_2), 34.6 (*C*Me$_3$), 31.5 (C*Me*$_3$), 30.4 (C*Me*$_3$). Anal. Found: C, 71.7; H, 8.8; Cl, 3.9. Calc. for $C_{58}H_{84}ClNbO_4$: C, 71.6; H, 8.7; Cl, 3.6%.

Bis[2,2′-*methylenebis*(4,6-*di-t-butylphenoxo*)] *methylniobium* (**2**).

A solution of **1** (0.9 g, 0.92 mmol) in diethylether (20 cm^3) was cooled to −78°C, and methyllithium (0.63 cm^3, 1.6 M, 0.92 mmol) was added via syringe. The reaction was allowed to warm slowly to room temperature. The colour changed from deep red to orange-yellow, and a white precipitate of LiCl formed. The filtrate was evaporated and the residue dissolved in light petroleum, and filtered again,leaving more LiCl. Concentration of the supernatant gave a yellow powder (0.70 g, 0.73 mmol, 88%). ^{1}NMR (C_6D_6, 25°C, δ): 7.34 (s, 8 H, Ar), 4.85 (s, 2 H, CH*H*), 3.65 (s, 2 H, C*H*H), 2.44 (s, 3 H, Nb-CH_3), 1.58 (s, 36 H, CMe_3), 1.32 (s, 36 H, CMe_3). ^{13}C NMR (C_6D_6, 25°C, δ): 157.9 (*ipso*-C), 143.5 (*p*-C), 136.3 (*o*-C), 134.6 (*o*-C), 125.1 (*m*-C), 122.0 (*m*-C), 53.8 (Nb-Me), 38.1 (CH_2), 35.6 (*C*Me$_3$), 34.3 (*C*Me$_3$), 31.8 (C*Me*$_3$), 30.5 (C*Me*$_3$). Anal. Found: C, 72.8; H, 8.6. Calc. for $C_{59}H_{87}O_4Nb$: C, 74.3; H, 9.2%.

X-ray crystallography

All crystallographic measurements were carried out at 160 K on a Stoe STADI4 4-circle diffractometer operating in the ω-θ scan mode using graphite monochromated Cu–K_α radiation ($\lambda = 1.54184$ Å). Cell dimensions were refined from the values of 40 reflections (together with their Friedel opposites) measured at $\pm 2\theta$ in order to minimise systematic error. Crystal data: $C_{58}H_{84}ClNbO_4$, red prism, $0.60 \times 0.44 \times 0.33$ mm, monoclinic, space group $C2/c$, $a = 14.7009(11)$, $b = 15.603(2)$, $c = 24.928(2)$ Å, $\beta = 98.093(8)°$, $Z = 4$, $V = 5661.1(11)$ Å^3. A total of 8915 reflections were measured in the range $3.58 \leqslant \theta \leqslant 64.55$ [$-17 \leqslant h \leqslant 17$, $-18 \leqslant k \leqslant 18$, $-26 \leqslant l \leqslant 28$] of which 4627 were unique ($R_{int} = 0.0402$). Data were corrected for absorption empirically using azimuthal ψ-scans (maximum and minimum transmission factors 0.675 and 0.506 respectively). The structure, which possesses crystallographic C_2 symmetry, was solved by heavy-atom methods using SHELXS-86 [18] and was refined by full-matrix least-squares (against all the unique F^2 data) using SHELXL-93 [19]. Non-hydrogen atoms were refined with anisotropic displacement parameters including those of a *t*-butyl substituent which was disordered over two positions; hydrogen atoms were constrained to idealised positions using a riding model with free rotation for methyl groups and fixed isotropic displacement parameters. Final $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma(F_o^2)^2]\}^{1/2} = 0.0890$, conventional $R = 0.0331$ for F values of 4512 reflections with $F_o^2 > 2\sigma(F_o^2)$. Weighting scheme $w = [\sigma^2(F_o^2) + (0.0409P)^2 + 8.5311P]^{-1}$ where $P = (F_o^2 + 2F_c^2)/3$, goodness of fit = 1.060 for all F^2 values and 334 parameters. Maximum and minimum residual electron density 0.47 and -0.89 eÅ^{-3} respectively.

Crystallographic data (consisting of atomic coordinates and full lists of bond lengths and angles) for the structure reported in this paper has been deposited with the Cambridge Crystallographic Data Centre. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. (fax: Int. code +(1223) 336-033; e-mail: teched@chemcrys.cam.ac.uk).

(Received 24 June 1997; accepted 7 January 1998)

Abstract—The complexation in ternary systems Ln-L-A (Ln—lanthanide ions Ln(III); L—acrylic, methacrylic, maleic acids; A—acetylacetone) have been investigated by pH-potentiometric titration technique and by NMR spectra lineshape analysis on the base of quantum-mechanical formalism of spin density matrix. Stability constants, NMR spectra, paramagnetic shifts, relaxation times and lifetimes of mixed-ligand complexes were determined. General conformities of the complexation according to the lanthanide row were revealed. The dependences of complex compounds stability on the lanthanide ionic radius are explained by joint influence of electrostatic and steric effects. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: mixed-ligand complexes; lanthanide ions; acetylacetone; organic unsaturated acids.

Crystal mixed-ligand complex compounds of lanthanides with acetylacetone and acrylic, methacrylic, maleic and fumaric acids of the composition $LnLA_2 \cdot H_2O$ (Ln(III)—Pr, Nd, Sm, Eu, Tb, Ho, Er, Yb; A—acetylacetone, L—unsaturated acids) have been synthesised earlier [1].

The aim of this work is the investigation of the composition and stability of mixed-ligand lanthanide complexes with acetylacetone and some organic unsaturated acids in aqueous medium by means of potentiometric titration and spectroscopic analysis of NMR line shape. The combination of two above-mentioned methods is interesting as far as NMR method enables us to determine the dynamics of the complexation process which is not available by potentiometric titration. So, having presumed some complexation model in NMR method we can approve the model if the results of two methods are proved to be similar. Moreover, a lot of publications on lanthanides complexation during the past years are focused more on X-ray structures. However, it is obvious that complex forms in solutions may be quite different.

RESULTS AND DISCUSSION

Such mixtures as organic acid—$LnCl_3$; acetylacetone—organic acid; acetylacetone—organic acid—$LnCl_3$ were titrated for determination of mixed-ligand complex stability constants.

The titration curves of ternary systems Ln-L-A (Ln—lanthanide ion Ln(III); L—acrylic, methacrylic, maleic acids; A—acetylacetone) are coincided with the titration curves of binary systems Ln-L at pH ~ 3.5–5.0, that confirms existence of binary lanthanide complexes with organic acids LnL at low pH values. Considerable divergence of titration curves is observed at pH ~ 5–8. The drop of buffer region of titration curves in ternary systems Ln-L-A witnesses the formation of mixed-ligand compounds.

Thus, stepwise rare earth metal complex formation with acetylacetone and unsaturated acids can be described by the following equations (the charges are omitted):

$$Ln + L \rightleftarrows LnL \quad (1)$$

$$LnL + A \rightleftarrows LnLA \quad (2)$$

$$LnLA + A \rightleftarrows LnLA_2 \quad (3)$$

The pH values of hydroxo species indicate the formation of mixed-ligand complex compounds in ternary systems Ln-L-A also (Table 1). It is interesting to note, that pH of the hydroxo species formation is higher in ternary systems than in binary ones. Saturation of lanthanide ions coordination sphere in pres-

Table 1. pH values of different complexes formation in the systems Ln-L-A

Complex	pH of complex formation	pH of hydroxocomplex formation
LnA_3	4.0–7.0	7.5–7.7
	Acrylic acid	
LnL	3.5–4.5	6.0–6.5
$LnLA_2$	5.0–7.5	7.8–8.0
	Methacrylic acid	
LnL	3.5–4.5	5.9 6.3
$LnLA_2$	5.0–7.5	7.7–8.0
	Maleic acid	
LnL	4.3–5.2	6.2 6.5
$LnLA_2$	5.5–8.0	>8.0

ence of mixed-ligand complex formation should interfere the formation of hydroxo species [2].

Reagent ratio in initial solutions was maintained constant ($C_{Ln}:C_L:C_A = 1:1:2$) in all studied systems, because the increase of C_L and C_A up to 3 and 5 accordingly did not lead to titration curves shape change.

The usage of diluted solutions prevented the formation of polymeric particles in investigated systems Ln-L-A [2]. The selected reagent ratio also prevented the formation of complexes LnL_2^+ and LnL_3 in given systems.

The ternary systems were also studied by NMR spectra lineshape function analysis [3–5], which based on quantum-mechanical method of spin density matrix [6]. Concentration reagent ranges in NMR investigation were selected by mathematical model on the base of appreciative stability constants values of binary complexes [7]. Reagent ratio was selected so that binary complex formation was enabled to neglect.

In development of spin density matrix formalism for the systems with three-positional ligand exchange, which can be accompanied by mixed-ligand LnLA and $LnLA_2$ complex formation, in work [8] the conditions which enable us to neglect the other complex formation in ternary systems were defined.

The description of NMR signal lineshape of isolated acetylacetone protons, which take place in three positional ligand exchange, must be examined. The condition of free A molecule in solution is described by spin density matrix $\rho^{(1)}$, but internal coordination sphere of paramagnetic ion—by spin density matrixes $\rho^{(2)}$ and $\rho^{(3)}$ in mixed-ligand complexes LnLA and $LnLA_2$ accordingly. We assumed, that spins in each molecule interact to each other inside one molecule only, and the interaction with the other nuclei of surrounding molecules and with paramagnetic centre may be taken into consideration by according relaxation parameters.

Under the assumption complex formation equilibria are given by:

$$\rho^{(2)} \leftarrow \rho^{(1)} \rightarrow \rho^{(3)} \quad \rho^{(1)} \leftarrow \rho^{(2)} \rightarrow \rho^{(3)} \quad \rho^{(1)} \leftarrow \rho^{(3)} \rightarrow \rho^{(2)} \tag{4}$$

The equations of spin density matrix motion in examined systems Ln-L-A in case of three-positional ligand exchange under the stable conditions are given by:

$$\frac{\rho^{(3)}-\rho^{(1)}}{\tau_{13}} + \frac{\rho^{(2)}-\rho^{(1)}}{\tau_{12}} + 2\pi i[\rho^{(1)}, \hat{H}^{(1)}] - \frac{\rho^{(1)}}{T_2^{(1)}} = 0$$

$$\frac{\rho^{(3)}-\rho^{(2)}}{\tau_{23}} + \frac{\rho^{(1)}-\rho^{(2)}}{\tau_{21}} + 2\pi i[\rho^{(2)}, \hat{H}^{(2)}] - \frac{\rho^{(2)}}{T_2^{(2)}} = 0$$

$$\frac{\rho^{(2)}-\rho^{(3)}}{\tau_{32}} + \frac{\rho^{(1)}-\rho^{(3)}}{\tau_{31}} + 2\pi i[\rho^{(3)}, \hat{H}^{(3)}] - \frac{\rho^{(3)}}{T_2^{(3)}} = 0$$

where τ_{ij} is the lifetime of i condition as related to transition to j condition, $T_2^{(i)}$—spin-spin relaxation time of nucleus to i condition.

Acetylacetone NMR signal lineshape in system Ln-L-A can be described by the following equation:

$$S(v) = \mathrm{Im}(P_A\rho_{12}^{(1)} + P_{LnLA}\rho_{12}^{(2)} + 2P_{LnLA_2}\rho_{12}^{(3)}) \tag{5}$$

where P_A, P_{LnLA}, P_{LnLA_2} are molar fractions of the according conditions.

NMR spectra lineshape depends on average lifetime values, as well as the resonance frequencies and relaxation times of examined ligand and complex nucleus. Correlation times τ_{ij} in the pseudo-first order reaction approximation are connected to each other by the equations:

$$\tau_{12}^{-1} = \tau_{21}^{-1} K_{LnLA}^{Ln}[Ln][L]; \quad \tau_{13}^{-1} = \tau_{32}^{-1} K_{LnLA_2}^{LnLA}[LnLA]$$

$$\tau_{23}^{-1} = \tau_{32}^{-1} K_{LnLA_2}^{LnLA}[L]; \quad \tau_{31} = \tau_{32}$$

Thus, the problem of theoretical NMR spectra calculation of acetylacetone, taking part in exchange (4), reduces to the solution of linear equations system with complex coefficients.

Iteration procedure of theoretical NMR spectra to experimental ones allows us to define the set of independent parameters that have influence on spectra shape. They are: NMR signals chemical shifts of acetylacetone methyl-protons (Table 2), relaxation times (Table 3) and stability constants of mixed-ligand complexes (Table 4).

Twenty to twenty five experimental S(v), values were used for optimisation of line shape for each NMR signal. The calculation of stability constants, chemical shifts, lifetimes and relaxation times were carried out by use of the program for theoretical NMR spectra calculation according to Binsch algorithm [6], which was supplied with minimising procedure on

least squares method. There is good agreement between the calculated lineshapes and the experimental NMR spectra. The error does not exceed 1%.

Obtained values of mixed-ligand lanthanide complexes stability constants by pH-potentiometric titration and NMR data are summarised in Table 4. The accuracy in determination of complex stability constants does not exceed ±0.02–0.19 logarithmic units. Results obtained by both methods coincide with accuracy up to 10%.

The dependencies of mixed-ligand stability constants on lanthanide's ionic radius (r) are presented on Fig. 1. The violation of monotonous change of $\lg\beta$ for mixed-ligand complexes might be due to stereochemical effects, covalent investment, structural changes in compounds along lanthanide row [4]. Slowing-down of increase in stability constants in cerium group at praseodymium–neodymium ($4f^3$–$4f^4$ configurations) and insignificant decrease of stability constants in yttrium group at erbium ($4f^{11}$ configuration) were observed within the general increase in complex stability with the decrease of lanthanide ionic radius. That variation in stability constants of binary and mixed-ligand complexes might be due to tetrad-effect [9,10].

Exceedingly high stability of lanthanide mixed-ligand complexes with maleic acid can be connected with strongly marked "chelate effect", which is due to entropy increase in system at ousting of water molecules by ligand from metal ion coordination sphere. Since maleic acid acts as bidentate ligand in complexes, "chelate effect" is more significant than in the case of monodentate binding acrylic and methacrylic acids. Moreover, the connection between complex stability and acidic properties of ligands (L) in these cases seems to be possible, which are increased as following: methacrylic < acrylic < maleic.

Complex stability of lanthanides with acetylacetone and unsaturated acids is less than stability of rare earth metal acetylacetonates in general. That fact can be connected with electrostatic and statistical effects [9,11].

Such destabilisation is explained by smaller compatibility of different ligands in coordination sphere of lanthanide ion and by lower symmetry of complexes when mixed-ligand compounds formation is taken place.

The diagrams of complex particles distribution as pH changes in ternary systems Ln-L-A, when mixed-ligand complexes were formed, have been plotted with the use of experimental values of complex stability constants.

The following reactions may be proceeded in examining systems (the charges are omitted):

$$Ln + L \rightleftarrows LnL$$

$$Ln + A \rightleftarrows LnA$$

$$LnA + A \rightleftarrows LnA_2$$

$$LnA_2 + A \rightleftarrows LnA_3$$

$$LnL + A \rightleftarrows LnLA$$

$$LnLA + A \rightleftarrows LnLA_2$$

from which that system of equations can be composed:

$$[LnL] = \beta^{Ln}_{LnL}[Ln][L]$$

$$[LnA] = \beta^{Ln}_{LnA}[Ln][A]$$

$$[LnA_2] = \beta^{Ln}_{LnA_2}[Ln][A]^2$$

$$[LnA_3] = \beta^{Ln}_{LnA_3}[Ln][A]^3$$

$$[LnLA] = \beta^{Ln}_{LnL}K^{LnL}_{LnLA}[Ln][L][A]$$

$$[LnLA_2] = \beta^{Ln}_{LnLA_2}[Ln][L][A]^2$$

$$C_L = [HL] + [L] + [LnL] + [LnLA] + [LnLA_2]$$

$$C_A = [HA] + [A] + [LnA] + 2[LnA_2] + 3[LnA_3] + [LnLA] + 2[LnLA_2]$$

$$C^{Ln} = [Ln] + [LnL] + [LnA] + [LnA_2] + [LnA_3] + [LnLA] + [LnLA_2]$$

The solution of this equation's system was held according to composed program. Plots of complex particles' distribution in ternary system Nd-L-A (L-acrylic acid) are presented in Fig. 2, which show that maintenance of binary acetylacetonates is negligible (<10%). Therefore, competitive reactions of lanthanide acetylacetonates complex formation do not occur actually under chosen experimental conditions ($C^{Ln}:C_L:C_A = 1:1:2$).

EXPERIMENTAL

Initial rare-earth metal chlorides were synthesised according to procedure [12] by dissolving corresponding lanthanide oxides in concentrated hydrochloric acid (P.C.) followed by the water evaporation. The stock solutions of 0.1 M of rare earth metal chlorides were prepared and their metal contents were estimated by complexometric titration with EDTA and xylenol orange as an indicator. Acetylacetone, acrylic, methacrylic acids were refluxed with reflux condenser at vacuum of $2 \cdot 10^3$ Pa. Maleic acid was recrystallised from water solution. All solutions were prepared in double-distilled carbonate free water. The solution of 1 M potassium hydroxide free of carbonates was used as a titrant. An I-130 digital pH-meter with glass elec-

trode and chlorine-silver electrode as comparative electrode were used for pH-titrations with accuracy of measurement ± 0.005 pH units. All pH-measurements of solutions were carried out at 25 ± 0.5° C.

The proton-ligand formation constants of acetylacetone and organic acids were determined by using Irving-Rossotti approach [13,14]. The calculations of rare-earth metal complex stability constants were per-

formed by Bjerrum [15,16] and Irving-Rossotti approach with the help of titration curves of such mixtures: organic acid-$LnCl_3$; acetylacetone-organic acid; acetylacetone-organic acid-$LnCl_3$ with the help of our developed computer program "Complex" with data calculation according to the least squares method.

The NMR spectra were obtained with 300 MHz Unity 300 spectrometer. Complex solutions were prepared in D_2O, TMS was used as an external standard.

(Received 20 October 1997; accepted 28 January 1998)

Abstract—Complexes of the type $[L_2PdCl_2]$, where L = $Ph_2PCH_2P(O)Ph_2$ (dppmO), $Ph_2P(CH_2)_2P(O)Ph_2$ (dppeO), $Ph_2P(CH_2)_3P(O)Ph_2$ (dpppO), $Ph_2P(CH_2)_4P(O)Ph_2$ (dppbO), and $Ph_2PC_5H_4FeC_5H_4P(O)Ph_2$ (dppfcO), were prepared in high yield from $Na_2[PdCl_4]$ and 2 equiv. of the corresponding L in dichloromethane-methanol. All complexes, except for $[(dppfcO)_2PdCl_2]$, can exist as the *cis* and *trans* isomers, or mixtures of both, with the *cis*/*trans* ratio decreasing in media of low polarity. The ferrocene containing complex, $[(dppfcO)_2PdCl_2]$, appeared to be exclusively *trans* in both the solid state and solution, as established by single crystal X-ray diffraction of its 1 : 3 benzene solvate. The ion exchange extraction of dichloromethane solutions of $[(dppmO)_2PdCl_2]$ and $[(dppeO)_2PdCl_2]$ with aqueous $NaBF_4$ furnished the corresponding cationic *P,O*-chelates, *cis*-$[(dppmO)_2Pd]^{2+}$ $(BF_4^-)_2$ and *cis*-$[(dppeO)_2Pd]^{2+}$ $(BF_4^-)_2$. Alternatively, these cations can be generated by the reaction between the chloro complexes, $[(dppmO)_2PdCl_2]$ and $[(dppeO)_2PdCl_2]$, with Ag^+. Single crystal X-ray diffraction of *cis*-$[(dppeO)_2Pd]^{2+}$ $(BF_4^-)_2$ revealed distinct conformations (a puckered chair and a distorted sofa) for the two chelate rings situated around each Pd atom. A polymeric, poorly soluble material, $\{[(dpppO)_2Pd]^{2+}$ $(BF_4^-)_2\}_n$, was isolated from the reaction between $[(dppO)_2PdCl_2]$ and $AgNO_3$/$NaBF_4$, with both coordinated and free phosphoryl groups being present in the product (IR). In dilute solutions of the $\{[(dpppO)_2Pd]^{2+}$ $(BF_4^-)_2\}_n$, depolymerization occurred, giving rise to the monomeric cationic chelate, *cis*-$[(dpppO)_2Pd]^{2+}$ $(BF_4^-)_2$. © 1998 Published by Elsevier Science Ltd. Keywords: bis-phosphine mono-oxides; palladium; chelates.

The coordination chemistry of bis-phosphine monoxides (BPMOs) of the general formula R_2P-X-$P(O)R_2$, where *X* = any divalent group, e.g. $(CH_2)_n$, is still insufficiently explored. Although some BPMO complexes with various metals have been reported [1–15], very little is known about palladium derivatives of BPMOs. Only two BPMO complexes of Pd have been described in the literature. One of them, $[(dppeO)_2PdCl_2]$ (dppeO = $Ph_2P(CH_2)_2P(O)Ph_2$), has been successfully used in catalyst [10]. However, no experimental procedure for the synthesis of this complex has been communicated. The other complex, $[(dppmO)_2PdCl_2]$ (dppmO = $Ph_2PCH_2P(O)Ph_2$), has been reported [6,13] but not characterized by any spectral or structural means. It is worth noting that studying solution behavior of such complexes is important because of their intriguing catalytic activity [10] and potential use in synthesis [13]. In the present paper we report, for the first time, the detailed preparation, full characterization, and some chemical reactions of a series of palladium complexes containing monoxides of bis(diphenylphosphino)methane (dppmO), 1,2-bis(diphenylphosphino)ethane (dppeO), 1,3-bis(diphenylphosphino)propane (dpppO), 1,4-bis(diphenylphosphino)butane (dppbO), and 1,1′-bis(diphenylphosphino)ferrocene (dppfcO).

RESULTS AND DISCUSSION

Synthesis of $[L_2PdCl_2]$ (L = dppmO, dppeO, dpppO, dppbO, *and* dppfcO)

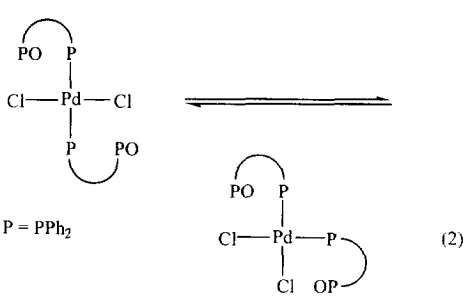
Adding methanolic $Na_2[PdCl_4]$ to a dichloromethane solution of a BPMO, L, (ca 2.1 equiv.) resulted in the formation of the corresponding $[L_2PdCl_2]$ in nearly quantitative yield (eqn (1)). The isolation and purification (if necessary) of the complexes is described in the Experimental Section.

$$Na_2[PdCl_4] + 2L \longrightarrow [L_2PdCl_2] + 2NaCl \quad (94\text{-}99\%) \quad (1)$$

All five compounds are stable crystalline solids which can be stored at room temperature in air for months with no sign of decomposition. All of them are soluble in dichloromethane and chloroform, slightly soluble in benzene, and insoluble in ether and alkanes. The complexes of dppmO and dppeO are soluble in methanol, whereas those containing dpppO and dppbO are only sparingly soluble in this solvent. The dppfcO complex was found to be insoluble in alcohols.

Solution behavior of $[L_2PdCl_2]$ (L = dppmO, dppeO, dpppO, dppbO, *and* dppfcO)

Like many square-planar Pd^{II} compounds of the general formula $[L_2PdCl_2]$ [16], complexes with L = dppmO, dppeO, dpppO, and dppbO exist in solution as mixtures of *cis* and *trans* isomers (eqn (2), Table 1). At room temperature, the isomers seem to equilibrate much more readily (seconds) than their monodentate tertiary phosphine counterparts. This remarkably facile *cis–trans* isomerization is likely due to the presence of the phosphoryl groups, whose oxygen atoms are capable of intramolecularly coordinating to the metal center. Clearly, this effect is similar to the free-ligand catalysis in the *cis–trans* isomerization reactions of Pd(II) and Pt(II) complexes [16]. As described below, firm evidence was obtained for such weak and reversible Pd—O interactions.



(2)

Structures of the isomers and their distribution in various solvents were studied by ^1H and ^{31}P NMR techniques. To assure reliable ^{31}P NMR integration measurements, the spectra of the first few samples were run with delay times D_1 = 1, 3, and 5 s. Since no changes in the integration ratios were noticed, the rest of the spectra were obtained with D_1 = 1 s. As anticipated [16], the *cis/trans* ratio for the equilibrated mixtures increased with solvent polarity (see Table 1).

$[(dppmO)_2PdCl_2]$. No NMR spectral characterization of this complex has appeared in the literature. According to our ^{31}P NMR data (Table 1), $[(dppmO)_2PdCl_2]$ in benzene is exclusively *trans*, whereas in methanol it is mostly *cis*, with the *cis–trans* ratio being 95 : 5. The resonances of both isomers are clearly seen in the ^{31}P NMR spectra obtained in CH_2Cl_2 and $CHCl_3$, solvents of intermediate polarity in comparison with benzene and MeOH. The small ^{31}P–^{31}P coupling constants did not allow us to immediately assign the observed resonances to the corresponding isomers. However, the proper assignment of the lines is easily made by comparison of the spectra of $[(dppmO)_2PdCl_2]$ with those of its dppeO analogue (see Table 1 and text below). In line with this assignment of the ^{31}P resonances are the patterns observed in the ^1H NMR spectra of the dppmO complex. The ^1H NMR spectrum of the $[(dppmO)_2PdCl_2]$ in $CDCl_3$, where the complex is 90% *trans* according to the ^{31}P NMR data, contains a doublet of virtual triplets ($J_{P\,H}$ = 11.4 Hz; $^2J_{P\,H}+{}^4J_{P\,H}$ = 7.4 Hz) at 3.9 ppm and a shoulder at 3.8 ppm due to the minor amount of the *cis* isomer. In methanol-d_4, the *cis* geometry prevails (ca 95%) and the resonance from the methylene protons appears at 4.3 ppm as a doublet of doublets with $J_{P\,H}$ = 13.5 and 10.5 Hz. This pattern was observed only for the freshly prepared sample, since the acidic CH_2 protons of the complex were found to undergo facile H/D exchange with the CD_3OD solvent. As a result, the methylene resonance soon began to diminish in intensity while transforming into a complex multiplet, and eventually disappeared altogether after a few days. As the H/D exchange occurred, a number of isotopomers (30.3–30.9 ppm) of varying intensities were observed for the P—Pd resonance in the ^{31}P NMR spectrum, due to the molecules containing the CH_2, CHD, and CD_2 groups.

$[(dppeO)_2PdCl_2]$. The ^{31}P NMR spectrum of a solid formulated as $[(dppeO)_2PdCl_2]\cdot 2H_2O$ was reported [3] to exhibit one singlet at 34.45 ppm. In another paper [10], two resonances (20.14 and 33.09 ppm) were observed in the ^{31}P NMR spectrum of $[(dppeO)_2PdCl_2]$ in chloroform-*d*, but no information was provided on the multiplicity of these signals. We found that solutions of $[(dppeO)_2PdCl_2]$ in chloroform-*d* contain both the *cis* and *trans* isomers, as can be clearly seen from the ^{31}P NMR spectrum. The *trans* isomer exhibits a doublet of doublets at 19.9 ppm for the P atom coordinated to the metal with $^3J_{P\,P}$ = 28.4 Hz and $^5J_{P\,P}$ = 25.9 Hz, and a virtual triplet at 33.2 ppm for the phosphoryl group with $^3J_{P\,P}+{}^5J_{P\,P}$ = 54.0 Hz. This spectral pattern exhibiting the remarkable long-range coupling is perfectly consistent with the *trans* geometry. Two doublets at 30.4 and 32.8 ppm ($J_{P\,P}$ = 56.1 Hz) were also found in the spectrum, obviously due to the *cis* isomer. Essentially the same pattern was observed for solutions of [(dppe-

$O)_2PdCl_2]$ in dichloromethane. It is worth noting that the coupling constant measured for the *cis* isomer is close to the values of 47.3–48.1 Hz obtained for the free ligand [17]. As anticipated, only the *trans* isomer was found in benzene solutions of the complex, whereas both the *cis* and *trans* isomers were present when methanol was used as the solvent (Table 1). The portionwise addition of water to the methanol solution lead to a noticeable increase in the *cis–trans* ratio.

$[(dpppO)_2PdCl_2]$ *and* $[(dppbO)_2PdCl_2]$. As the number of methylene groups separating the P^{III} and P^{V} atoms increases, the spectral behavior of the corresponding Pd complexes becomes less distinct. In fact, the ^{31}P NMR spectral patterns for the $[(dpppO)_2PdCl_2]$ and $[(dppbO)_2PdCl_2]$ are very similar, displaying almost identical parameters (Table 1). The chemical shift values provide information for the easy and unambiguous assignment of the resonances. Because of poor solubility no ^{31}P NMR spectra were obtained for solutions of $[(dpppO)_2PdCl_2]$ in benzene and $[(dppO)_2PdCl_2]$ in methanol. However, both isomers of $[(dppbO)_2PdCl_2]$ in approximately equal quantities were observed in a 1 : 10 chloroform–methanol solution of the complex.

$[(dppfcO)_2PdCl_2]$. Like the two preceding complexes, $[(dppfcO)_2PdCl_2]$ is a new compound. The ^{31}P NMR spectra of this complex suggest that in

benzene, chloroform, and dichloromethane it exists as only one isomer. In line with this is the ^{1}H NMR spectrum of the complex (see Experimental Section). Virtual insolubility of the $[(dppfcO)_2PdCl_2]$ in polar media, methanol included, prevented its characterization by NMR in such solvents.

As clearly seen from the above data, for the complexes $[L_2PdCl_2]$, where L = dppmO, dppeO, dpppO, and dppbO, the existence of both *cis* and *trans* isomers was reliably established by ^{31}P and ^{1}H NMR techniques. This was not the case, however, with the dppfcO complex, for which only one isomer was found to exist in various solvents. Due to the steric bulk of dppfcO ligand the *trans* geometry for the $[(dppfcO)_2PdCl_2]$ seemed to be more plausible. This conjecture was examined by X-ray analysis of the compound.

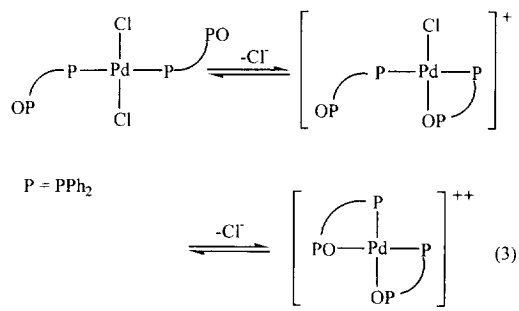
Single crystal X-ray diffraction study of $[(dppfcO)_2PdCl_2]$

As a new compound [18], the dppfcO ligand has been characterized by elemental analysis and NMR spectral data [19]. Although we had attempted a single crystal X-ray diffraction study of dppfcO twice, crystallographic disorder did not allow us to obtain accurate molecular parameters of the ligand. X-ray quality crystals of $[(dppfcO)_2PdCl_2]$ were obtained by diluting its saturated dichloromethane solution with benzene which caused slow precipitation of the complex as a 1 : 3 benzene solvate. Crystallographic parameters, data collection, and structure refinement summary are presented in Table 2. Table 3 lists the most important bond lengths and bond angles for the complex. As anticipated, the complex has a centrosymmetric *trans*-structure (Fig. 1) with almost ideal square-planar configuration around the Pd atom. One of the solvate benzene molecules occupies a general position in the crystal, whereas the second one lies on the center of symmetry. Both disubstituted ferrocene units possess slightly twisted conformation, often called "skew rings", which is dictated by steric requirements of diphenylphosphino and diphenylphosphoryl groups. The pseudo torsion angle P(1)–ring 1(center)–ring 2(center)–P(2) is equal to 133.7 , whereas at the ideal eclipsed conformation of the rings in ferrocene this angle is 144 . Both P(1) and P(2) slightly deviate from the mean planes of the corresponding 5-membered rings by 0.036 and 0.022 Å, respectively. The interplanar angle between the rings is 4.1 .

Although the dppfcO ligand is certainly bulkier than dppeO or PPh_3, the Pd—Cl and the Pd—P bond distances in $[(dppfcO)_2PdCl_2]$ are only slightly longer than those of *trans*-$[(dppeO)_2PdCl_2]$[11] and *trans*-$[(Ph_3P)_2PdCl_2$ [21,22]. Thus, the Pd—Cl bond length of 2.306 (1) Å was found in $[(dppfcO)_2PdCl_2]$, whereas the values of 2.292(1) Å [11] and 2.281–2.296(1) [21,22] have been reported for the dppeO [11] and triphenylphosphine [21,22] counterparts. The Pd—P bond in the dppfcO complex (2.347(1) Å) is ca 0.01 and 0.02 Å longer than those in the *trans*-$[L_2PdCl_2]$, where L = PPh_3 [21,22] and dppeO [11], respectively. This elongation may be due to the presence of the electron-rich, bulky ferrocene substituents on the coordinated phosphorus atoms. Among other features of the molecular geometry of the $[(dppfcO)_2PdCl_2] \cdot 3C_6H_6$ it is worth noting the small difference between the C—P (phosphine) and C—P (phosphoryl) bond lengths of 1.804–1.837(5) and 1.795–1.815(5) Å, respectively. No shortened intramolecular or intermolecular contacts were found in the structure of the complex.

Cationic palladium bis-chelates, $[(BPMO)_2Pd]^{2+}$

The literature [10–12] data and the data described above provide no firm evidence for any coordination of the phosphoryl group oxygen atoms to the metal center in complexes of the general formula $[(BPMO)_2PdCl_2]$ in the solid state or in solution. It was proposed [10] that such interactions between the phosphoryl oxygen atoms and the metal center might be responsible for the unique regioselectivity observed in the hydroxycarbonylation reaction of olefins catalyzed by $[(dppeO)_2PdCl_2]$. Higgins, Shaw, and Taylor [6] demonstrated that $[(dppmO)_2PdCl_2]$ can be forced to lose the chloro ligands when treated with 2 equiv. of $AgNO_3$. According to their ^{31}P NMR data, the resulting cationic complex, $[(dppmO)_2Pd]^{2+}$, is a *cis*-chelate with both oxygens of the phosphoryl groups coordinated to the metal [6]. Because of the ability of Ag^+ to trap Cl^- efficiently this result should not be regarded as evidence for the existence of equilibrium 3, either.



(3)

First evidence for equilibrium 3 was found in our work. Washing a dichloromethane solution of $[(dppmO)_2PdCl_2]$ with a few portions of 40% aqueous $NaBF_4$ at room temperature lead to the quantitative (^{31}P NMR) formation of $[(dppmO)_2Pd]$ $(BF_4)_2$ which was subsequently isolated in 74% yield. The ^{31}P NMR characterises of this complex were identical to those described for the cationic species obtained by the reaction between $[(dppmO)_2PdCl_2]$ and $AgNO_3$ [6]. The synthesis of $[(dppeO)_2Pd]$ $(BF_4)_2$ from the corresponding neutral dichloride and $NaBF_4$ was carried out in the same manner, furnishing the cationic complex in 96% isolated yield (eqn (4)).

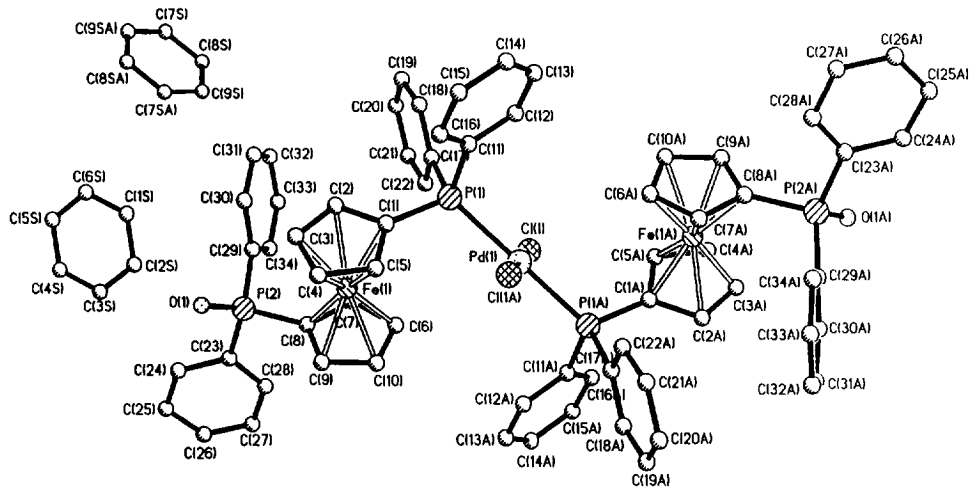

Fig. 1. Molecular structure of *trans*-$[(dppfcO)_2PdCl_2]$ with adopted numbering scheme. Hydrogen atoms are omitted for clarity.

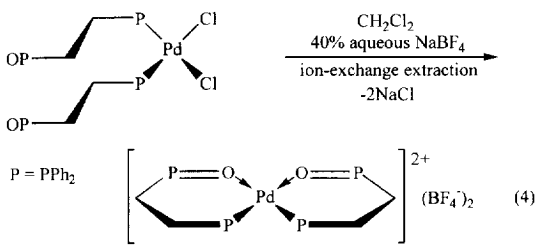

Both tetrafluoroborates, $[(dppeO)_2Pd]$ $(BF_4)_2$ and $[(dppmO)_2Pd]$ $(BF_4)_2$, are air-stable crystalline compounds soluble in dichloromethane and acetone, slightly soluble in chloroform, but insoluble in water, ether, and hydrocarbon solvents. Taking into account the poor affinity of the tetrafluoroborate anion for palladium(II) [23], it is reasonable to conclude that an intramolecular replacement of the chloro ligands by an oxygen of the coordinated BPMO takes place, followed by Cl^-/BF_4^- ion exchange.

The structure of the cationic bis-chelate, $[(dppeO)_2Pd]$ $(BF_4)_2$, was established by a single crystal X-ray diffraction study. Selected crystallographic data obtained, including experimental and structure refinement details, are given in Table 2. Some molecular geometry parameters are summarized in Table 4 and a general view of the dication is presented in Fig. 2. Although crystal disorder of the BF_4 anions and the single crystal's insufficient quality lowered accuracy of the structural results, the *cis* structure of the cation, $[(dppeO)_2Pd]^{2+}$, in the solid state was established beyond any doubt. The Pd atom and the four atoms constituting the first coordination sphere (P(1), P(2), O(1), and O(2)) are coplanar within 0.018 Å. However, a noticeable distortion from the ideal square-planar configuration is observed in the crystal structure, the O—Pd—O and P—Pd—P bond angles being 84.4(4)° and 97.3(2)°, respectively. It is remarkable that the two six-membered metallacycles appear to be in different conformations in the crystal state. For the PdP(1)C(49,50)P(2)O(1) ring a puckered chair conformation was established; the metal, oxygen, and both carbon atoms were coplanar within 0.011 Å, whereas P(1) and P(2) deviated from the plane by +0.84 and −0.70 Å, respectively. A distorted sofa conformation was observed for the other ring, PdP(3)C(51,52)P(4)O(2), with C(51) deviating by 0.77 Å from the mean plane formed by the other five atoms which are coplanar within 0.06 Å. It is worth noting the significant difference in the Pd—O—P bond angles, 124.1(6)° for Pd—O(1)—P(2) and 143.9(6)° for Pd—O(2)—P(4). Interestingly, the Pd—O bond distances (2.088(12) and 2.119(10) Å) are either comparable with or substantially shorter than the values reported for the Pd—O bond lengths in various palladium complexes containing hydroxo (2.07–2.28 Å) [24] and carboxylato (2.12–2.17 Å) [25] ligands. This suggests that the Pd—O coordination bonds are of considerable strength, despite the fact that they are *trans* to phosphine ligand whose *trans*-influence is normally significant. The Pd—P bond distances (2.240(4) and 2.247(5) Å) in the chelate are similar to those in *cis*-$[(dmpmO)_2PdCl_2]$ (2.254(1) and 2.248(1) Å) [12] but shorter by 0.08–0.09 Å than the Pd—P bond length in *trans*-$[(dppeO)_2PdCl_2]$ (2.327(1) Å) [11]. The Pd—P and Pd—O bond lengths measured suggest that the dication $[(dppeO)_2Pd]^{2+}$ is remarkably stable.

Among other structural characteristics of the chelate are shortened (3.27–3.28 Å) intramolecular C···C contacts due to the stacking interaction between the almost parallel C(1)—C(6) and C(31)—C(36) phenyl rings. Also, strong distortions are observed in the tetrahedral environment of P(1) and P(3), due to steric hindrance. Thus, Pd—P(1)—C(1) and Pd—P(3)—

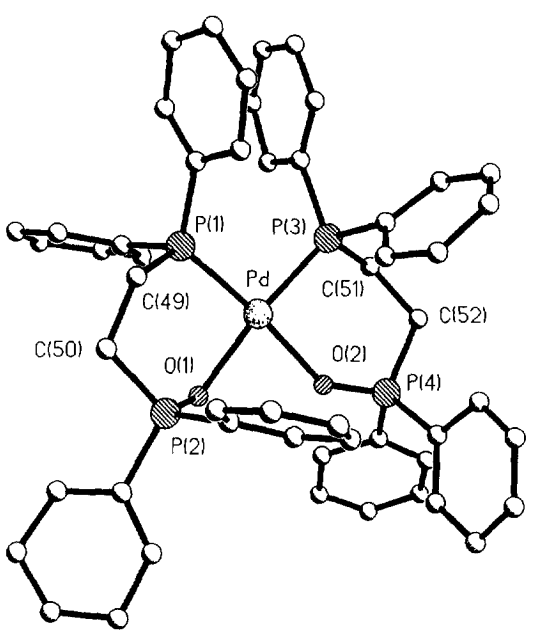

Fig. 2. Molecular structure of *cis*-$[(dppeO)_2Pd]^{2+}$ with adopted numbering scheme for the metallacycle atoms. Hydrogen atoms are omitted for clarity.

C(31) bond angles are increased to 122.7(6) and 120.1(7) degrees, whereas adjacent C(1)—P(1)—C(49) and C(25)—P(3)—C(31) bond angles are diminished to 98.1(8) and 103.5(8) degrees, respectively. On the contrary, P(2) and P(4) of the phosphoryl groups form tetrahedral bond angles of the almost ideal value, varying in the range of 107.1(8) to 112.1(7)°.

According to the room temperature ^{31}P NMR data, the $[(dppeO)_2Pd]\ (BF_4)_2$ remains *cis* in dichloromethane or methanol solutions, with both chelate rings undergoing conformational changes which are fast on the NMR time scale. Two sharp doublets of doublets at 36.5 and 48.2 ppm with $J_{P,P} = 10$ and 3 Hz were observed in the ^{31}P NMR spectrum of $[(dppeO)_2Pd]^{2+}$ in aqueous methanol, indicating that the geometry around the metal center is *cis*.

The dpppO counterpart of $[(dppeO)_2Pd]^{2+}$ and $[(dppmO)_2Pd]^{2+}$ was prepared by the reaction between $[(dpppO)_2PdCl_2]$ and $AgNO_3$ in dichloromethane/water, followed by the treatment of the reaction mixture with 40% $NaBF_4$ in water. Two broadened singlet resonances were observed in the ^{31}P NMR spectrum of the organic phase, with the chemical shifts of 30 ($\Delta\nu_{1/2} = 40$ Hz) and 55 ($\Delta\nu_{1/2} = 100$ Hz) ppm being indicative of a *P,O*-coordination mode for the dpppO ligands, as expected.

However, once precipitated by adding ether to the organic layer of the reaction mixture, the $[(dpppO)_2Pd]$ $(BF_4)_2$ appeared to be very poorly soluble in common organic solvents, dichloromethane and acetone included. In spite of this remarkably low solubility of the isolated crystalline compound, its ^{31}P NMR spectrum in CH_2Cl_2 was measured, exhibiting two *sharp doublets* ($J_{P\,P} = 7$ Hz) with virtually the same chemical shifts (30.4 and 55.6 ppm) as those observed before the complex was isolated. It is conceivable that in the concentrated solution formed upon reacting $[(dpppO)_2PdCl_2]$ with Ag^+ and then BF_4^-, the structure of the species obtained is somewhat different from that of the complex which has been isolated and consequently redissolved. The identical ^{31}P NMR chemical shifts suggest that both the P and O centers participate in coordinative interactions with the metal [6,14]. On the other hand, intermolecular Pd—O interactions of the type Pd—P—CH_2—CH_2—CH_2—PO—Pd might be pictured for the concentrated solution of the complex, resulting in the formation of oligometric/polymeric chains (Fig. 3). Facile ligand exchange in the oligomer is likely to be responsible for the line broadening in the ^{31}P NMR spectrum of the concentrated solution. It is noteworthy that the PO—Pd resonance was noticeably broader than the P—Pd signal, suggesting that the exchange processes involving the oxygen centers may be faster than those resulting in the cleavage and formation of the P—Pd bonds. In contrast, dilute solutions of the isolated complex contain the monomeric cation, $[(dpppO)_2Pd]^{2+}$, as indicated by the ^{31}P NMR data (see above).

Clearly, intramolecular vs intermolecular O—Pd coordination modes in the $[(dpppO)_2Pd]^{2+}$ system are strongly influenced by concentration effects which were not observed for the $[(dppmO)_2Pd]^{2+}$ and $[(dppeO)_2]^{2+}$ complexes. Furthermore, in the solid state both $[(dppmO)_2Pd]^{2+}$ and $[(dppeO)_2Pd]^{2+}$ are monomeric chelates, according to the solubility, X-ray, and also IR data. The IR spectra (KBr) of their tetrafluoroborate salts exhibited strong bands at 1102–1129 cm^{-1} due to the coordinated phosphoryl oxygens and no peaks in the range of 1180–1200 cm^{-1} where "free" phosphoryl P=O bonds normally absorb [6,14,15]. At the same time, two groups of bands were observed in the IR spectrum of the solid $[(dpppO)_2Pd]$ $(BF_4)_2$, at 1123–1105 cm^{-1} and 1195–1175 cm^{-1}. The former was obviously due to PO groups coordinated with the metal, whereas the latter pointed to the presence of free phosphoryls in the sample. It is clear that in order to contain both types of the phosphoryl groups while retaining square-planar geometry at the Pd centers, the solid $[(dpppO)_2Pd]$ $(BF_4)_2$ must possess polymeric or macrocyclic structure and should rather be formulated as $\{[(dpppO)_2Pd]$ $(BF_4)_2\}_n$. This is consistent with the ^{31}P NMR data obtained for the concentrated solution of oligomeric $[(dpppO)_2Pd]$ $(BF_4)_2$, prepared upon the exhaustive dechlorination of the $[(dpppO)_2PdCl_2]$ with Ag^+ (see above). The remarkable difference in the structure and behaviour of the three cationic complexes is definitely due to the substantial decrease in the magnitude of the chelate effect when going from the 5- and 6-membered metallacyles ($[(dppmO)_2Pd]^{2+}$ and $[(dppeO)_2Pd]^{2+}$, respectively) to the analogous, but much less stable, 7-membered rings ($[(dpppO)_2Pd]^{2+}$ [26]. For the same reason, the "silverless" synthesis of $[(dpppO)_2Pd]$ $(BF_4)_2$ from the corresponding dichloride requires many more ion-exchange extractions with aqueous $NaBF_4$, as compared with the above described similar preparation of $[(dppmO)_2Pd]$ $(BF_4)_2$ and $[(dppeO)_2Pd]$ $(BF_4)_2$. For instance, after a dichloromethane solution of $[(dpppO)_2PdCl_2]$ had been thoroughly washed with 40% aqueous $NaBF_4$ 12 times, the conversion to $[(dpppO)_2Pd]$ $(BF_4)_2$ was still incomplete (^{31}P NMR).

Attempted syntheses of $[(dppfcO)_2Pd]^{2+}$ and $[(dppbO)_2Pd]^{2+}$ from the corresponding dichloro complexes and aqueous $NaBF_4$ or $AgNO_3/NaBF_4$ were unsuccessful, and a complex mixture of unidentified products was obtained in both cases (^{31}P NMR). The metallacycles formed by the dppbO and dppfcO ligands are apparently too large in size to be

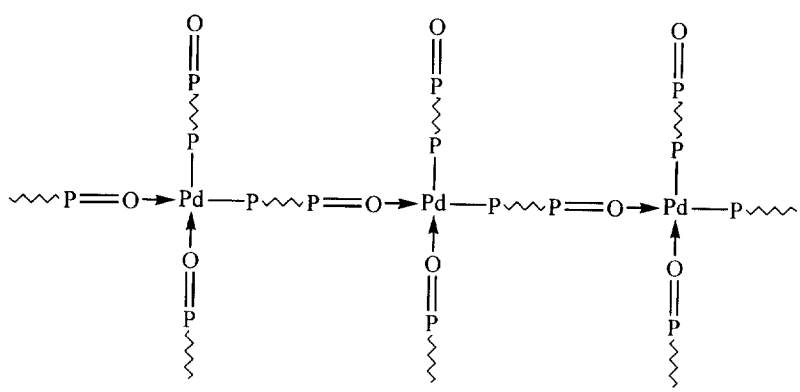

Fig. 3. Proposed structure for the $\{[(dpppO)_2Pd]^{2+}\}_n$ oligomer containing both coordinated and free phosphoryl groups.

sufficiently stable for successful isolation and characterization of the corresponding Pd chelates. Most likely, the generated compounds exist as mixtures of oligomeric species.

EXPERIMENTAL

NMR spectra were recorded on a Varian VXR-200 spectrometer. Chemical shifts are reported relative to TMS (^{1}H) and 85% H_3PO_4 (^{31}P). The BPMO ligands may be synthesized by the procedures reported in the literature [1b,3,6,27]. The phosphorus ligands, dppmO, dppeO, dpppO, dppbO, and dppfcO used in this work were prepared by the selective catalytic mono-oxidation of the corresponding bis-phosphines [18]. All other chemicals were purchased from Organometallics, Aldrich, and Strem and used as received. The synthesis, isolation, and purification of all complexes were conducted in air.

$[(dppmO)_2PdCl_2]$

A solution of $Na_2[PdCl_4]$ obtained by dissolving $PdCl_2$ (265 mg; 1.50 mmol) and NaCl (180 mg; 3.10 mmol) in hot methanol (20 ml) was added dropwise to a vigorously stirred solution of dppmO (1.459 g; 3.65 mmol) in CH_2Cl_2 (20 ml). The mixture was taken to dryness (rotary evaporation) and the residue was extracted with CH_2Cl_2 (30 ml). The dichloromethane solution was filtered, reduced in volume to ca 15 ml, diluted with ether (portionwise, 4 × 15 ml), and left at −15°C overnight. The yellow precipitate was separated, washed with ether, and dried under vacuum. The yield of $[(dppmO)_2PdCl_2]$ was 1.460 g (99%). The ^{31}P and ^{1}H NMR spectra of this complex in both chloroform-*d* and methanol-d_4 are described in the text and Table 1. In the ^{1}H NMR spectra, aromatic protons of the complex resonate as multiplets at 6.9–8.0 ppm and 7.0—8.0 ppm in $CDCl_3$ and CD_3OD, respectively.

$[(dppeO)_2PdCl_2]$

A solution of $Na_2[PdCl_4]$ obtained by dissolving $PdCl_2$ (498 mg; 2.81 mmol) and NaCl (361 mg; 6.22 mmol) in warm methanol (50 ml) was added dropwise to a vigorously stirred solution of dppeO (2.614 g; 6.23 mmol) in CH_2Cl_2 (30 ml). The mixture was evaporated to dryness and the residue was extracted with CH_2Cl_2. The combined dichloromethane extracts were filtered, reduced in volume, and treated with ether. The yellow precipitate was separated, washed with ether, and dried under vacuum. The yield of $[(dppeO)_2PdCl_2]$ was 2.677 g (95%). ^{1}H NMR ($CDCl_3$), δ: 2.6 (m, 8H, CH_2); 7.0–7.9 (m, 40H, C_6H_5).

$[(dpppO)_2PdCl_2]$

A solution of $Na_2[PdCl_4]$ obtained by dissolving $PdCl_2$ (520 mg; 2.94 mmol) and NaCl (385 mg; 6.64 mmol) in hot methanol (40 ml) was added dropwise to a vigorously stirred solution of dpppO (2.779 g; 6.49 mmol) in CH_2Cl_2 (30 ml). The mixture was taken to dryness (rotary evaporation) and the residue was extracted with CH_2Cl_2 (200 ml; the complex is only moderately soluble in dichloromethane [28]). The combined dichloromethane extracts were filtered, reduced in volume, and treated with ether to give a yellow microcrystalline solid which was separated, washed with ether, and dried under vacuum. The yield of $[(dpppO)_2PdCl_2]\cdot H_2O$ was 3.057 g (98%). Anal: Calcd for $C_{54}H_{54}Cl_2O_3P_4Pd$ ($C_{54}H_{52}Cl_2O_2P_4Pd\cdot H_2O$): C, 61.6; H, 5.2. Found: C, 61.7; H, 4.9. ^{1}H NMR ($CDCl_3$), δ: 1.8 (m, 4H, CCH_2C); 2.4 (m, 4H, CH_2PPd); 2.6 (m, 4H, CH_2PO); 7.0–7.8 (m, 40H, C_6H_5).

$[(dppbO)_2PdCl_2]$

A solution obtained by dissolving $PdCl_2$ (213 mg; 1.20 mmol) and NaCl (130 mg; 2.24 mmol) in hot methanol (50 ml) was added dropwise to a vigorously stirred solution of dppbO (1.216 g; 2.75 mmol) in CH_2Cl_2 (30 ml) [28]. Evaporation of the mixture gave a yellow oil which was dissolved in CH_2Cl_2 and the resulting solution was filtered, reduced in volume to ca 5 ml, and treated with ether (20 ml) to precipitate the complex. The crude solid product thus obtained (contaminated with ca 5% dppbO; ^{31}P NMR) was dissolved in dichloromethane (10 ml), the mixture was diluted with benzene (ca 30 ml), and the resulting yellow solution was slowly reduced in volume to ca 10 ml (rotary evaporation at room temperature). Upon standing for a few hours, yellow crystals of analytically and spectroscopically pure $[(dppbO)_2PdCl_2]\cdot 2C_6H_6$ precipitated, which was separated, washed with small quantities of benzene, and dried. The yield was 1.443 g (98%). Anal: Calcd for $C_{68}H_{68}Cl_2O_2P_4Pd$ ($C_{56}H_{56}Cl_2O_2P_4Pd\cdot 2C_6H_6$): C, 67.0; H, 5.6. Found: C, 67.4; H, 5.7. ^{1}H NMR ($CDCl_3$), δ: 1.6 (m, 8H, $C(CH_2)_2C$); 2.2 (m, 4H, CH_2PPd); 2.4 (m, 4H, CH_2PO); 7.1–7.8 (m, 40H + 12H, $C_6H_5 + C_6H_6$); an intense singlet at 7.3 ppm was observed due to the benzene present in the solid.

trans-$[(dppfcO)_2PdCl_2]$

A mixture of $PdCl_2$ (207 mg; 1.17 mmol) and NaCl (139 mg; 2.39 mmol) was stirred with methanol (40 ml) at ca 50°C until the solids dissolved. The resulting brown solution of $Na_2[PdCl_4]$ was added dropwise to a stirring solution of dppfoO [18,19] (1.477 g; 2.6 mmol) in CH_2Cl_2 (20 ml). After the dark red mixture was evaporated to dryness the residue was extracted

with CH_2Cl_2 (first 20 ml, then 4 × 5 ml), and the combined extracts were filtered, reduced in volume to ca 10 ml, and diluted with ether (portionwise, 4 × 5 ml). The orange-red crystals were separated, washed with ether, and dried. The yield of the *trans*-[(dppfcO)$_2$PdCl$_2$]·CH_2Cl_2 was 1.544 g (94%). Anal: Calcd for $C_{69}H_{58}Cl_4Fe_2O_2P_4Pd$ ($C_{68}H_{56}Cl_2Fe_2O_2P_4Pd \cdot CH_2Cl_2$): C, 59.1; H, 4.2. Found: C, 59.6; H, 4.2. ^{1}H NMR ($CDCl_3$), δ: 4.3 (s, 2H, C_5H_4); 4.4 (s, 2H, C_5H_4); 4.6 (s, 2H, C_5H_4); 4.9 (s, 2H, C_5H_4); 7.2–7.8 (m, 40H, C_6H_5).

cis-[(dppmO)$_2$Pd] (BF_4)$_2$

A solution of [(dppmO)$_2$PdCl$_2$] (202 mg; 0.21 mmol) in CH_2Cl_2 (5 ml) was vigorously stirred with 40% aqueous $NaBF_4$ (10 ml) for 15 min. The aqueous layer was separated by a pipette, another 10 ml of 40% $NaBF_4$ were added to the dichloromethane solution, and the mixture was stirred for another 15 min. This procedure was repeated five times. The organic phase was separated, filtered through cotton, and evaporated. The solid residue was recrystallized twice from CH_2Cl_2/ether to give 166 mg (74%) of white *cis*-[(dppmO)$_2$Pd] (BF_4)·H_2O. Anal: Calcd for $C_{50}H_{46}B_2F_8O_3P_4Pd$ ($C_{50}H_{44}B_2F_8O_2P_4Pd \cdot H_2O$): C, 54.7; H, 4.2. Found: C, 54.9; H, 4.2. ^{1}H NMR (acetone-d_6), δ: 4.8 (dd, 4H, $J_{P\,H}$ = 9.8 and 13.8 Hz, CH_2); 7.2–8.0 (m, 40H, C_6H_5). ^{31}P NMR (acetone-d_6), δ: 36.2 (d, 2P, $J_{P\,P}$ = 5.3 Hz, PPd); 59.7 (d, 2P, $J_{P\,P}$ = 5.3 Hz, POPd). IR (KBr), cm^{-1}: 1129, 1102 (PO).

cis-[(dppeO)$_2$Pd] (BF_4)$_2$

A solution of [(dppeO)$_2$PdCl$_2$] (204 mg; 0.21 mmol) in CH_2Cl_2 (5 ml) was vigorously stirred with 40% aqueous $NaBF_4$ (10 ml) for 15 min. The aqueous layer was separated by a pipette, another 10 ml of 40% $NaBF_4$, were added to the dichloromethane solution, and the mixture was stirred for another 15 min. This procedure was repeated five times. The organic phase was separated, filtered through cotton, and evaporated. The solid residue was recrystallized from CH_2Cl_2/ether (twice) and dried under vacuum to give 215 mg (96%) of pale-yellow *cis*-[(dppeO)$_2$Pd] (BF_4)$_2$. Anal: Calcd for $C_{52}H_{48}B_2F_8O_2P_4Pd$: C, 56.3; H, 4.4. Found: C, 56.1; H, 4.3. ^{1}H NMR (acetone-d_6), δ: 3.2 (m, 8H, CH_2); 7.2–8.2 (m, 40H, C_6H_5). ^{31}P NMR (MeOH), δ: 36.5 (dd, 2P, $J_{P\,P}$ = 10.0 Hz and 3.0 Hz, PPd); 48.2 (dd, 2P, $J_{P\,P}$ = 10.0 Hz and 3.0 Hz, POPd). ^{31}P NMR (acetone-d_6), δ: 37.8 (dd, 2P, $J_{P\,P}$ = 8.5 Hz and 4.6 Hz, PPd); 47.9 (dd, 2P, $J_{P\,P}$ = 8.5 H and 4.6 Hz, POPd). IR (KBr), cm^{-1}: 1125, 1103 (PO).

[(dpppO)$_2$Pd] (BF_4)$_2$

A solution of $AgNO_3$ (0.43 g; 2.5 mmol) in water (2 ml) was added to a vigorously stirred suspension of [(dpppO)$_2$PdCl$_2$] (1.00 g; 0.97 mmol) in CH_2Cl_2 (8 ml), causing an immediate precipitation of AgCl. Water (5 ml) and CH_2Cl_2 (7 ml) were added, and the mixture was stirred for another 5 min. The organic phase was separated, and the aqueous suspension of AgCl was washed with CH_2Cl_2 several times. The combined dichloromethane solutions were vigorously stirred with 40% $NaBF_4$ (2 × 20 ml, 30 min each), separated, filtered, reduced in volume, and treated with ether. The light-yellow precipitate was washed with ether and dried under vacuum. The yield of the cationic complex was 0.84 g (76%). Anal: Calcd for $C_{54}H_{52}B_2F_8O_2P_4Pd$: C, 57.0; H, 4.6. Found: C, 56.5; H, 4.6. ^{1}H NMR (acetone-d_6), δ: 2.8 (m, 4H, CH_2); 3.0 (m, 4H, CH_2); 3.2 (m, 4H, CH_2); 7.1–7.9 (m, 40H, C_6H_5). ^{31}P NMR (CH_2Cl_2), δ: 30.4 (d, 2P, $J_{P\,P}$ = 7.0 Hz, PPd); 55.6 (d, 2P, $J_{P\,P}$ = 7.0 Hz, POPd). IR (KBr), cm^{-1}: 1195, 1188, 1175, 1123, 1105 (PO).

X-ray diffraction studies

X-ray diffraction data were obtained with a Siemens P3/PC four-circle diffractometer with Mo–K_α-radiation and a graphite monochromator ($\theta/2\theta$ scan method) at 153 K and room temperature for single crystals of *trans*-[(dppfcO)$_2$PdCl$_2$] and *cis*-[(dppeO)$_2$Pd] (BF_4)$_2$, respectively. The diffraction quality of all examined crystal samples of the cationic complex was rather poor, displaying broad reflection peaks and irregular twinning. As all attempts to cool the samples led to an increase in the diffraction profiles, data collection was performed at room temperature. An empirical absorption correction was applied for the *trans*-[(dppfcO)$_2$PdCl$_2$], but not for the [(dppeO)$_2$Pd] (BF_4)$_2$ because of insufficient diffraction data quality. The structures were solved by direct methods and refined by the least squares techniques in the anisotropic (isotropic for disordered BF_4 anions) approximation. All H atoms were placed in geometrically calculated positions and included into refinement using a riding motion model. A PC SHELX PLUS program package was used for all calculations. Rotational disorder of the BF_4^- anions was detected in the difference Fourier maps for the cationic chelate, and therefore additional orientations of these anions were taken into account in the final refinement.

Acknowledgement—DuPont and the Science and Technology Endowment Program (STEP) Council at Wilfrid Laurier University are gratefully acknowledged for support.

Supporting information available—Full details of the X-ray diffraction studies of *trans*-[(dppfcO)$_2$PdCl$_2$] and *cis*-[(dppeO)$_2$Pd] (BF_4)$_2$, including crystallographic data, data collection, structure solution and refinement, ORTEP drawings, full tables of non-hydrogen atom coordinates with isotropic displacement parameters, full tables of bond lengths and bond angles, hydrogen atom coordinates, tables of anisotropic displacement parameters (22 pages), and two X-ray structure files in the CIF format. Ordering information is given on any current masthead page.

Synthesis, spectroscopic, photophysical and electrochemical properties of cyano-bridged copper(I)–ruthenium(II) complexes

Sudhir Ranjan and S. K. Dikshit*

Department of Chemistry, Indian Institute of Technology, Kanpur, (U.P.) 208016, India.

(Received 20 August 1997; accepted 12 February 1998)

Abstract—Complexes of the formula [(N–N)Cu($AsPh_3$)CN] (N–N = 2,2′–bipyridine, 1,10–phenanthroline) have been synthesized. $Ru(bpy)_2Cl_2.2H_2O$ and [(η^5–cp)$Ru(PPh_3)_2Cl$] react with [(N–N)Cu($AsPh_3$)CN] to give cyano-bridged compounds. IR spectral studies in the low frequency region (700–50 cm^{-1}) and 4000–400 cm^{-1} region reveal cyano bridging in the complexes. Luminescence measurements suggest oxidation of metal centres (Cu^I–Cu^{II} and Ru^{II}–Ru^{III}) on excitation at a charge transfer band. This has been substantiated with electrochemical studies of complexes which exhibit quasi-reversible reductions viz. Ru^{III}/Ru^{II} and Cu^{II}/Cu^I. The deposition of metallic copper is also observed at a potential of −1.55 V. Based on these data, a mechanism for photo-redox reaction of complexes has been presented. The properties of these bimetallic complexes are compared with those of parent complexes. © 1998 Elsevier Science Ltd. All rights reserved. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: synthesis; binuclear complexes; FTIR, quasi-reversible; luminescence; electron-transfer.

Solar energy is the largest energy source available to mankind but its utilization in comparison to its availability is negligible. The design of suitable chromophores to be used as sensitizers in this process is one of the aims of co-ordination chemists [1]. Mononuclear and binuclear Ru^{II} polypyridine complexes show remarkable sensitizing properties [2, 3]. Such systems are also involved in electron-transfer and energy transfer processes [4]. In recent years much work has been done on cyanobridged homo and hetero/polynuclear complexes [5] to explore the various photophysical properties, including sensitization.

There are some reports on heteronuclear cyanide [6] bridged complexes containing Ru^{II} and other metal centres. We have been interested in the properties of cyano bridged bimetallic complexes and our earlier studies on these systems have highlighted some of the interesting properties [7]. In continuation, in this paper we wish to report the electrochemical, photophysical and spectral studies on a variety of cyano-bridged Cu^I–Ru^{II} complexes. The stimulation for photophysical studies of bridged systems is based on the fact that Cu^I complexes independently exhibit luminescence [8].

1. EXPERIMENTAL

^1H NMR spectroscopy was carried out on a Bruker WP-80 and a Bruker DRX300 spectrometer in the range 0–10 ppm (δ) using TMS as an internal calibrant. A COSY two-dimensional experiment was carried out on the Bruker DRX 300. ^{13}C NMR spectroscopy was carried out on a Bruker WP-80 and a Bruker DRX300 spectrometer. IR spectra were recorded on a Shimadzu IR 420 Spectrophotometer as KBr pellets in the 4000–400 cm^{-1} range, FTIR spectra on a Perkin–Elmer FTIR 1700X Spectrophotometer in Nujol mull with polyethylene plates in the range 700–50 cm^{-1}. UV–Vis spectra were carried out on a Shimadzu double beam UV-160 spectrophotometer in acetonitrile. Melting points were obtained on a Fisher-John melting point apparatus and are uncorrected. Conductivity measurements were carried out in acetonitrile on a Toshniwal Conductivity Bridge. Microanalyses were performed at the RSIC, CDRI, Lucknow, India.

Emission spectra were recorded on a Perkin–Elmer

Luminescence Spectrophotometer LS50B. Correction of the luminescence intensity profile was performed by fluorescence data manager software. Luminescence quantum yields ϕ_s were evaluated by comparing areas under the corrected luminescence spectra on an energy scale and by using the following equation:

$$\frac{\phi_s}{\phi_r} = \frac{F_s.A_r}{F_r.A_s}$$

where the F_s and F_r are the integrated fluorescence intensities of the sample and $[Ru(bpy)_3]^{2+}$. A_s and A_r are the absorbance of the sample and $[Ru(bpy)_3]^{2+}$ at excitation of same wavelength. ϕ_r for $[Ru(bpy)_3]^{2+}$ is taken as 0.028.

For the lifetime measurements a coherent synchronously pumped cavity dumped dye laser (702-1) pumped by a coherent CW mode-locked Nd:YAG laser (Antares 76s) was used. The fundamental laser light at 600 nm was frequency doubled to produce exciting light at 300 nm. The emissions were detected at a magic angle of 54.7° polarisation using a Hamamatsu MCP photomultiplier tube (2809U). The response time of the setup is 50–60 ps.

The FAB mass spectra were recorded on a JEOL SX 102/DA-6000 system using Xenon (6 kV, 100 mA) as the FAB gas and *m*-nitrobenzyl alcohol as a matrix.

Cyclic voltammograms were recorded on a Bio-Analytical System-27 electrochemical analyser, utilizing a three electrode configuration, consisting of a glassy carbon working electrode, Pt wire auxiliary electrode and Ag/AgCl reference electrode. An omnigraphic model 100X-Y recorder was used to record the current-voltage output.

$RuCl_3.xH_2O$ was obtained from Loba Chemie and triphenylarsine, 2,2′-bipyridine and 1, 10-phenanthroline from E-Merck and used as received; Acetonitrile (Qualigens) used in electrochemical and spectroscopic studies was dried over molecular sieves. All other chemicals used were either AnalaR grade or chemically pure. Manipulations were invariably performed under oxygen free dry nitrogen atmosphere using standard schelnk line and other techniques [9]. The solvents were dried using standard procedures before use.

$Ru(bpy)_2Cl_2.2H_2O$ [10] and $[(\eta^5-cp)Ru(PPh_3)_2Cl]$ [11] were prepared according to methods in literature. CuCN, $Cu(AsPh_3)_2CN$ and their substituted analogues were prepared by modifying the literature procedures [7, 12].

1.1. *Syntheses*

1.1.1. *Cyanobis-(triphenylarsine)copper(I)*; $[Cu(AsPh_3)_2CN]$ [**1**] To a suspension of CuCN (0.895 g, 0.01 mole) in chloroform (50 cm^3) was added a solution of triphenylarsine (12.258 g, 0.04 mole) in chloroform (70 cm^3), and the reaction mixture was stirred constantly for an hour. During the course of the reaction the desired complex was precipitated. The volume of the reaction mixture was reduced in a rotatory evaporator. While removing the solvent, a white precipitate dissolved and a thick viscous liquid appeared. It was cooled and then treated with benzene (40 cm^3) which resulted in superfine white crystals. These were then filtered and washed with dry ether and then dried *in vaccuo*.

1.1.2. *Cyanobipyridine(triphenylarsine)copper(I)*; $Cu(AsPh_3)(bpy)CN$ [**2**] To a suspension of $Cu(AsPh_3)_2(CN)$ (0.701 g, 1 mmol) in benzene (30 cm^3) was added a solution of bipyridine (0.156 g, 1 mmol) in benzene (30 cm^3) with constant stirring. The resulting yellow solution was refluxed for 2–3 hours. The clear solution thus obtained was cooled, the volume was reduced to half and excess petroleum ether (60–80° C) was added, which resulted in the precipitation of a pale-yellow compound. It was filtered, washed several times with petroleum ether and dried *in vaccuo*. It was recrystalized from a $CHCl_3$–xylene mixture (1:1).

1.1.3. *Cyano1,10–phenanthroline(triphenylarsine) copper[I]*; $[Cu(AsPh_3)(phen)CN]$ [**3**] To a suspension of $Cu(AsPh_3)_2CN]$ (0.701 g, 1 mmol) in benzene (30 cm^3) was added a solution of 1,10. phenanthroline (0.198 g, 1 mmol) in benzene (30 cm^3) with constant stirring. Immediately an orange–red precipitate appeared, the resulting mixture was refluxed for an hour. After cooling, excess petroleum ether (60–80° C, 100 cm^3) was added to ensure complete precipitation of the complex. The complex was centrifuged and washed several times with petroleum ether and dried *in vaccuo*. It was recrystalized from a $CHCl_3$–xylene mixture (1:1).

1.1.4. *Bis–(triphenylarsine)copper(I)*(μ–cyano)-chlorobis–(2,2′–bipyridine)ruthenium(II)hexafluorophosphate; $[((AsPh_3)_2Cu–CN–Ru(bpy)_2Cl]PF_6$.[**4**] A mixture of $[Cu(AsPh_3)_2CN]$ (0.701 g, 1 mmol) and $Ru(bpy)_2Cl_2.2H_2O$ (0.512 g, 1 mmol) was suspended in ethanol (50 cm^3) and the suspension was refluxed for an hour. The solution was cooled and filtered. A highly concentrated solution of NH_4PF_6 in water (0.0064 g in 1 cm^3) was added, which caused the immediate precipitation of a complex. The precipitate was washed thoroughly with water and then with ether, and dried over P_4O_{10} for several hours. It was recrystalized from a $CHCl_3$–CH_3CN mixture (1:1).

1.1.5. *Bis–(triphenylarsine)copper(I)*(μ–cyano)-cyclopentadienylbis–(triphenylphosphine)rutherium (II)hexafluorophosphate; $[(AsPh_3)_2Cu–CN–Ru(\eta^5–cp)(PPh_3)_2]PF_6$ [**5**] $[Cu(AsPh_3)_2CN]$ (0.701 g, 1 mmol) and $(\eta^5-cp)Ru(PPh_3)_2Cl]$ (0.725 g, 1 mmol) were taken in methanol (50 cm^3) and the mixture was stirred vigorously. NH_4PF_6 (0.174 g, 1.2 mmol) was added to this solution and refluxed for an hour, which upon cooling gave a pale yellow precipitate. The solvent was evaporated to dryness *in vaccuo* and the residue was extracted with a small amount of dichloromethane and filtered. On addition of excess petroleum ether (60–80 C), a complex precipitated, which was centrifuged and washed several times with

petroleum ether and dried in vaccuo. It was recrystalized from $CHCl_3$.

1.1.6. *(1,10-Phenanthroline)(triphenylarsine) copper(I)*(μ-cyano)chlorobis-(2,2′-bipyridine)ruthenium(II)hexafluorophosphate; [(phen)($AsPh_3$)Cu-CN-Ru(bpy)$_2$Cl]PF_6 [6] [Cu($AsPh_3$)(phen)CN] (0.179 g, 0.2 mmol) and Ru(bpy)$_2Cl_2.2H_2O$ (0.104 g, 0.2 mmol) were dissolved in a 1:1 mixture of water and ethanol (50 cm^3), and the solution was refluxed for 5 hours. The resulting solution was cooled and filtered. To this filtrate was added a concentrated aqueous solution of NH_4PF_6 (0.0064 g/cm^3). A precipitate of maroon colour immediately appeared, which was centrifuged and washed several times with ether and dried over P_4O_{10} for several hours *in vaccuo*. It was recrystalized from a $CHCl_3$–CH_3CN mixture (1:1).

1.1.7. *(2,2′-Bipyridine)(triphenylarsine)copper(I)*(μ-cyano)chlorobis-(2,2′-bipyridine) ruthenium(II) hexafluorophosphate; [(bpy)($AsPh_3$)Cu-CN-Ru(bpy)$_2$ Cl]PF_6.[7] The same as in Section 1.1.6, except [Cu($AsPh_3$)(bpy)CN] was used in place of [Cu(As Ph_3)(phen)CN].

2. RESULTS AND DISCUSSION

The analytical data for the complexes are given in Table 1, which are consistent with the stoichiometries proposed. The conductivity data of the complexes [**1**], [**2**], and [**3**] show a non-electrolytic nature, whereas other cation complexes are 1:1 electrolytes [13]. All the complexes are diamagnetic at room temperature.

FAB mass spectral data are assigned in Table 2. The molecular ion peak usually is of a low intensity. All the complexes show a M–PF_6 peak. Other isotopic peaks are also observed and appear as bands. Some of these are summarized in Table 2. The variation in the m/z values is mainly due to presence of the heavier atom isotopes of ruthenium (96-104), Cu(63,65) and Cl(35,37). In Complex [**5**], M-PF_6 shows large variation. This may be due to the presence of seventy-eight carbon atoms. The effect diminishes as the number of carbons decreases in other complexes. The peak at m/z = 123.5 [**5**] indicates dissociation of $AsPh_3$ and facile rearrangement of counter anion at copper centre to produce neutral complex. This is also observed in complex [**7**].

Table 1. Analytical and Physical data of the Complexes

Complex	Colour	Analysis Found (Calc) (%)			mp*a* /t C	Yield*b* (%)	Ω^{-1} cm^2 mol^{-1} Conductivity
		C	H	N

2.1. *IR spectra*

The υ_{CN} stretching frequency data of the complexes [**1**]–[**7**] are given in Table 3. For complex [**1**], υ_{CN} at 2130 cm^{-1} (lit. value [14] 2125 cm^{-1}) indicates that the CN group is terminal. Lowering of υ_{CN} in complexes [**2**] and [**3**] may be due to an increase in coordination number [7, 15]. Further lowering of υ_{CN} stretching on bridging in complexes [**4**]–[**7**] is due to enhanced π-back donation from ruthenium and copper [7].

complexes [1]–[7] are given in Table 3. A representative FTIR spectra of complexes [1], [4] and [5] are shown in Fig. 1. The characteristics υ_{Ru-N}, υ_{Cu-C}, υ_{Cu-As} and δ_{Cu-CN} have been assigned according to literature data [16–22]. We find that similar spectral patterns also appear for new cyano bridged complexes. It is seen that some of the ligand vibrations which do not appear in the free ligand are activated by complex formation [20]. The splitting of some asymmetric bands are ascribed to lattice effect [22].

2.2. *NMR spectra*

The ^1H NMR and ^{13}C NMR spectral data are given in Table 3. The proton NMR of complex [5] having

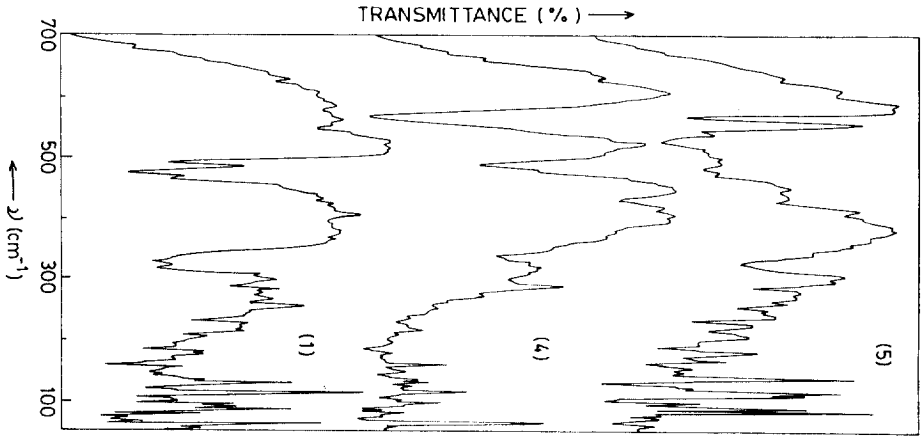

Fig. 1. Low Frequency IR spectra between 700 and 50 cm^{-1} of complexes [1], [4] and [5].

η^5–cp group shows a sharp singlet signal at 4.43 ppm (δ). The cp peak of a complex shifts slightly to higher δ in comparison to the parent complex $[(\eta^5-cp)Ru(PPh_3)_2Cl]$ [23]. The shift in δ value of cp protons in this complex suggests that the complex must be cationic in nature [24]. The proton signals of the phenyl groups appear in the region 7.0–8.0 as a broad multiplet [7].

Compound [4], [Fig. 2(a)], shows a complex pattern of resonance for which reliable assignment is not possible. To solve this problem spectra are assigned on the basis of a COSY two-dimensional experiment. Compound [4] is warmed to 120°C for a few minutes and then cooled before the spectrum was recorded. Two doublets are exhibited in the low-field area of the NMR spectrum and are found to be similar to the spectra reported in the literature [25, 26], whereas a multiplet is also observed in the region 7.0–8.8 ppm(δ) which cannot be assigned specifically [Fig. 2(b)]. These doublets are assigned as H^6 of bpy (A) and bpy (B) at 10.02 and 9.52 ppm (δ), respectively [Fig. 2(b)]. Appearance of these signals is due to different spatial interaction of the chloride ligand [26]. On further heating for one hour the spectra was recorded by suppressing phenyl protons. The spectrum indicated that the above multiplet has also fragmented into sharp signals [27] [Fig. 2(c)].

The ^{13}C NMR spectra of complex [1] exhibit NMR signals in the expected region of the phenyl group [28]. But in the case of complex [5], these signals were complicated and could not be specifically assigned. Nevertheless it can be said that the peak observed at 85.9 ppm (δ) for the cp group bound to ruthenium falls in the expected region [29].

2.3. *UV–Vis spectra*

Ground state absorption properties are summarised in Table 4, and the spectra of mononuclear and hetrobinuclear complexes are illustrated in Fig. 3. All the spectra were recorded in acetonitrile solution at room temperature. In cyanobridged complexes [4], [6] and [7] five bands are observed. These bands are characteristic bands of the $Ru(bpy)^{2+}_2$ chromophores [10, 30, 31]. Bands at 245, 246 and 244 nm in these complexes [4], [6] and [7] respectively are assigned as $\pi\rightarrow\pi^*$ (bpy) intraligand transition and $\pi\rightarrow\pi^*$ (phenyl) $AsPh_3$ transitions.

Small blue shifts are observed in comparison to $Ru(bpy)_2Cl_2.2H_2O$. A similar pattern of shifting has been observed for bands in the 280–290 nm range, which are characteristic of ligand-centred (LC) $\pi\rightarrow\pi^*$ (bpy) transitions. Assignment of bands at 346 nm [$d\pi(Ru)\rightarrow\pi^*$ (bpy)] and at 480 nm [$d\pi(Ru)\rightarrow\pi^*$ (bpy)] in complex [4] as metal-to-ligand charge transfer (MLCT) is based on literature reports [10, 30, 31]. Comparing these bands to corresponding values of $Ru(bpy)_2Cl_2.2H_2O$ ($\lambda_{max}=382$ nm and 551 nm), we infer that when the CN- ligand is attached to the $Ru(bpy)^{2+}_2$ moiety, there is an appreciable decrease in Ru→bpy π-backbonding. In this complex due to strong backbonding from Ru(II) to the cyano group, blue shift is observed, which is possible only when d-orbitals are increasingly stabilised. These bands predict the possibility of CN–Ru interaction. High energy bands, λ_{max} at 210 nm in [4], 213 nm in [6] and 209 nm in [7], are characteristics of [$d\pi(Ru)\rightarrow\pi^*(CN)$] MLCT transitions [32]. Thus, a possible explanation for the spectroscopic behaviour could be based on the fact that there are two types of Ru→Ligand MLCT transitions, one involving a terminal bpy ligand and the other involving a bridging CN- ligand. This has been supported by electrochemical results.

The absorption characteristics of [5] are similar to those of the well known analogue [7], $[(PPh_3)_2Cu-CN-Ru(\eta^5-cp)(PPh_3)_2]PF_6$. The MLCT transitions at 357.0 nm of complex $[(\eta^5-cp)Ru(PPh_3)_2Cl]$ is blue shifted which indicates the

Assignment of the multiplet in the range 7.5-8.8 could not be made because of the complexity of the multiplet.c) 300 MHz COSY ^{2}D-NMR spectrum of **[4]** recorded in DMSO-d^6. Assignment of all protons are given as follows: bpy (A); **6′** (10.02), **5′** (7.85), **4′** (8.23), **3′** (8.75), **3** (8.68), **4** (8.06), **5** (7.14), **6** (7.80), and bpy (B); 6′ (9.52), 5′ (7.98), 4′ (8.40), 3′ (8.83), 3 (8.68), 4(8.06), 5 (7.42), 6 (7.95) {ppm(δ)}.

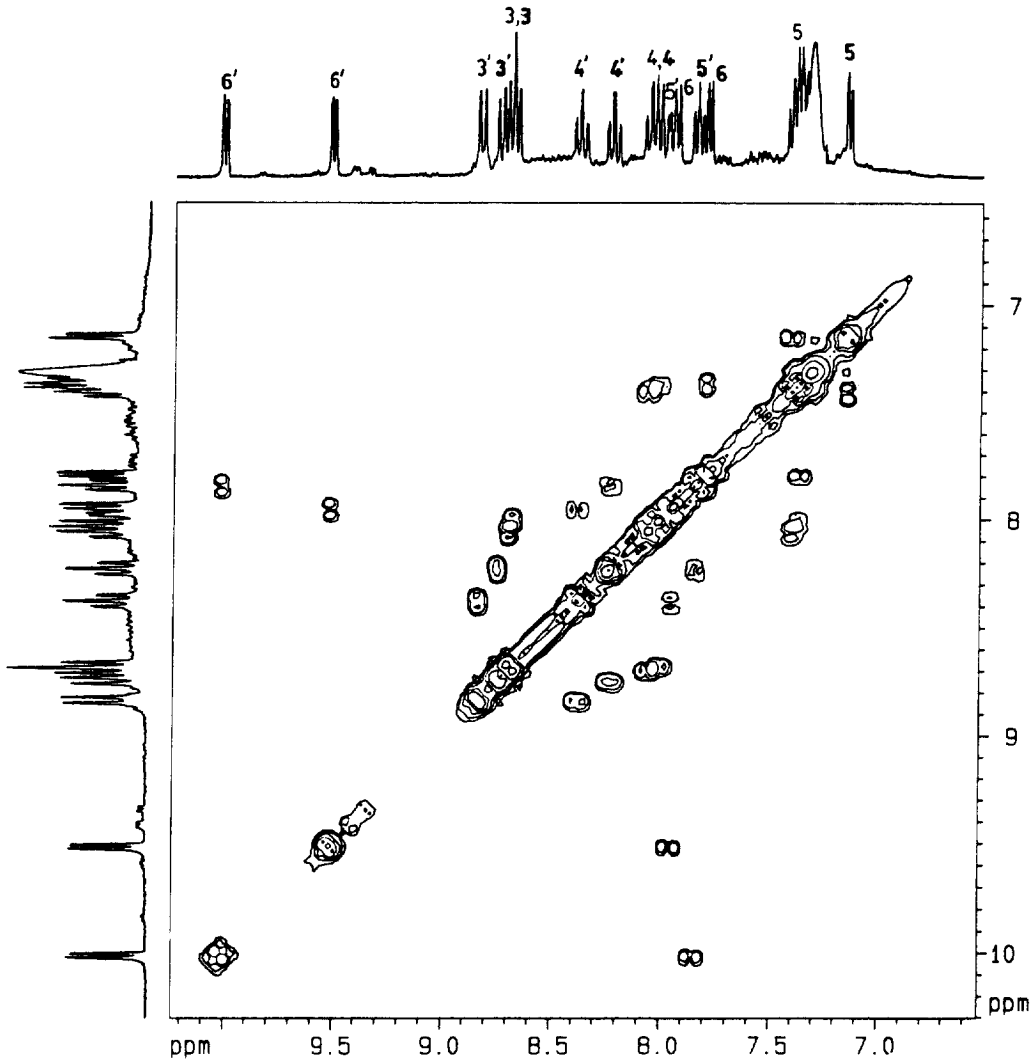

Fig. 2 — *continued.*

increasing stabilisation of ruthenium d-orbitals by backbonding from the ruthenium to the cyanide group. On bridge formation the MLCT transition at 246 nm in the complex becomes broad and appears as a shoulder. Such shifting is also observed in complexes [4]–[7], and is in good agreement with the shifting of υ_{CN} to low energy IR spectra. Complexes [2] and [3] give absorption bands at 357.5 nm and 363 nm respectively which are assigned as MLCT transitions and other bands are intraligand transitions [33]. The band at 269.0 nm of complex [3] appears as a shoulder on the band at 285.0 nm of complex [6]. Similarly the band at 284.0 nm of complex [2] appears as a shoulder on the band at 289.0 nm of complex [7]. No shoulder is observed in the electronic spectra of complex [4] because the band at 246.0 nm of [1] gets buried at the same λ_{max}.

2.4. *Electrochemical properties*

The electrochemical behaviour of a heterobinuclear cyano bridged system has been discussed previously [6], where ruthenium is one of the metal centres. Fig. 4 shows the voltammogram (*vs* Ag–AgCl in acetonitrile) of [6], at a scan rate of 100 mV/sec. $E_{1/2}$ values were obtained from the formula $E_{1/2}=\frac{E_{pa}+E_{pc}}{2}$. All of the waves with δE_p which are close to the values of δE_p for $[Ru(bpy)_3]^{2+}$ ($E_{1/2}=1.40$ V Vs Ag/AgCl [34], $\delta E_p=90$–120 mV at a scan rate of 100 mV/sec) are reversible. All the other waves can be regarded as quasi-reversible. This compound shows two quasi-reversible responses at 0.76 V ($E_{pa}=0.78$ V and $E_{pc}=0.73$ V) and 1.27 V ($E_{pa}=1.30$ V and $E_{pc}=1.24$ V) which are attributed to the processes

$Cu^I\rightarrow Cu^{II}$ and $Ru^{II}\rightarrow Ru^{III}$ corresponding to a phenanthroline bound copper metal centre and a bipyridine bound ruthenium metal centre respectively. The latter is consistent with literature values [32, 33]. The $E_{1/2}$ value for ligand reduction appears at -1.18 V which can be assigned to a copper bound phenanthroline reduction. Thus, the given ligand system can also stabilize the dinuclear cyano bridged com-

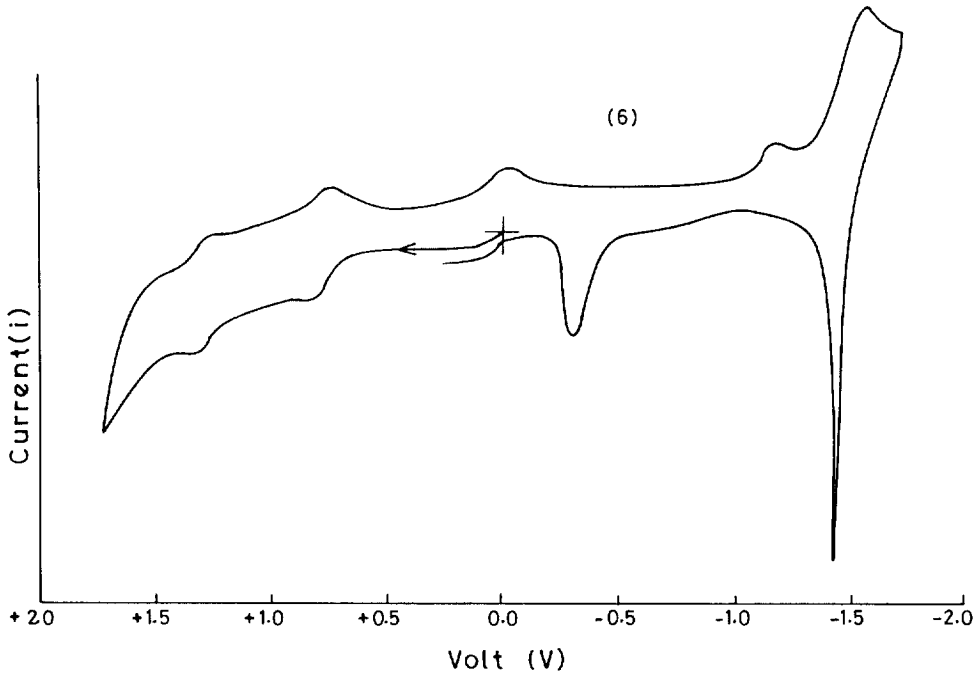

Fig. 4. Cyclic Voltammogram of complex [6] (vs Ag–AgCl in acetonitrile; 0.1 mol/dm^3 tetrabutylammonium hexafluorophosphate and scan rate 100 mV/sec; 25°C).

plexes in a higher oxidation state i.e., the Cu^{II}–CN–Ru^{III} form. Such a mechanism depends on the ability of the cyanide ligand to act as a conducting bridge and, moreover, it involves intramolecular electron transfer.

There is one irreversible reductive wave with $E_{red} = -1.55$ V attributable to the process $Cu^{I} \rightarrow Cu^{0}$ [35]. This shows the deposition of copper metal at the electrode. It is believed that the $E_{1/2}$ value for bipyridine ligand reduction has merged with Cu^{I}/Cu^{0} reduction value. The other $E_{1/2}$ value does not occur due to the narrow window range. A comparison of electrochemical data and previous investigations carried out on complexes of this type, has shown that Cu^{+} is oxidised at a potential less positive than Ru^{2+}, and Cu^{II} is interacting with Ru^{II} through a cyanide bridge. Complex [7] shows similar behaviour.

2.5. *Luminescence properties*

Room temperature emission band maxima, lifetimes and luminescence quantum yields are reported in Table 5. Representative luminescence spectra are shown in Fig. 5. The absorption spectra of cyano-bridged complexes are dominated by the $Ru(bpy)^{2+}_3$ chromophoric unit and the contribution of $[Cu(AsPh_3)(NN)]^{+}$ is negligible. Upon excitation performed at ~480 nm, these complexes exhibit emission band maxima at ~642 nm and are tentatively assigned as metal-to-ligand charge transfer transitions [36]. Besides these bands, emission bands appear at ~525–545 nm. The assignment of these electronic excited states poses an interesting problem. Probably the emission occurs from a copper sub-unit. Copper(I) centre, a d^{10} system is very electron rich in nature and can be stabilised by lignads having π-acid character, viz. PPh_3, bpy, phen, CO, CN- etc. Complexes having general formula $[Cu(PPh_3)_2(NN)]^{+}$, are known to exhibit emission properties both at low and room temperature. McMillin *et al* [33, 37], observed emissions at 608 and 575 nm in $[Cu(PPh_3)_2(phen)]^{+}$ and 620 nm in $[Cu(PPh_3)_2(bpy)]^{+}$. These emissions were tentatively assigned as metal-to-ligand charge transfers. However, a metal-centred $d \rightarrow s$ orbital transition was not ruled out. Moreover, there is extensive literature on the emission of poly nuclear copper(I) complexes. In the tri-nuclear copper(I) complex $[Cu_3(dpmp)_2(MeCN)_2(\mu-Cl)_2]^{+}$, where dpmp is bis(diphenylphosphinomethyl)methyl phosphine, an emission at 560 nm was assigned as a metal-centered $3d^9 4s^1 \rightarrow 3d^{10}$ transition [38]. In the bi-nuclear copper(I) complex $[PPh_3Cu_2Cl_2(py)]$ a similar type of assignment has been made by Jink *et al.*[39]. However, the possibility of a CT excited state was also predicted.

The emission bands at ~525–545 nm in the complexes [4], [6] and [7] have been assigned, based on a literature assignment of analogous compounds and our experimental observation. The complex [4] undergoes bi-exponential decay showing lifetimes at 0.201 ns ($A_1 = 0.67$) and 2.59 ns ($A_2 = 0.33$), [Fig. 6]. This confirms the presence of two species in the excited state, namely the copper and ruthenium sub-units.

Table 5. Luminescence Properties at 298 K

Complex	λ^{a}_{em}(nm)	τ (ns)	ϕ	K_r (s^{-1})	K_{nr} (s^{-1})
[4]	642	0.201	6.7×10^{-3}	33×10^{6}	4.9×10^{9}
[6]	644	0.118	7.5×10^{-4}	6.3×10^{6}	8.4×10^{9}
[7]	641	0.110	1.5×10^{-4}	1.3×10^{6}	9.0×10^{9}

a denotes Ru→bpy MLCT excited states, other λ_{em} values are ~525–545 nm for [4], [6] and [7] are assigned as metal-centered and metal-to-ligand charge transfer excited states.

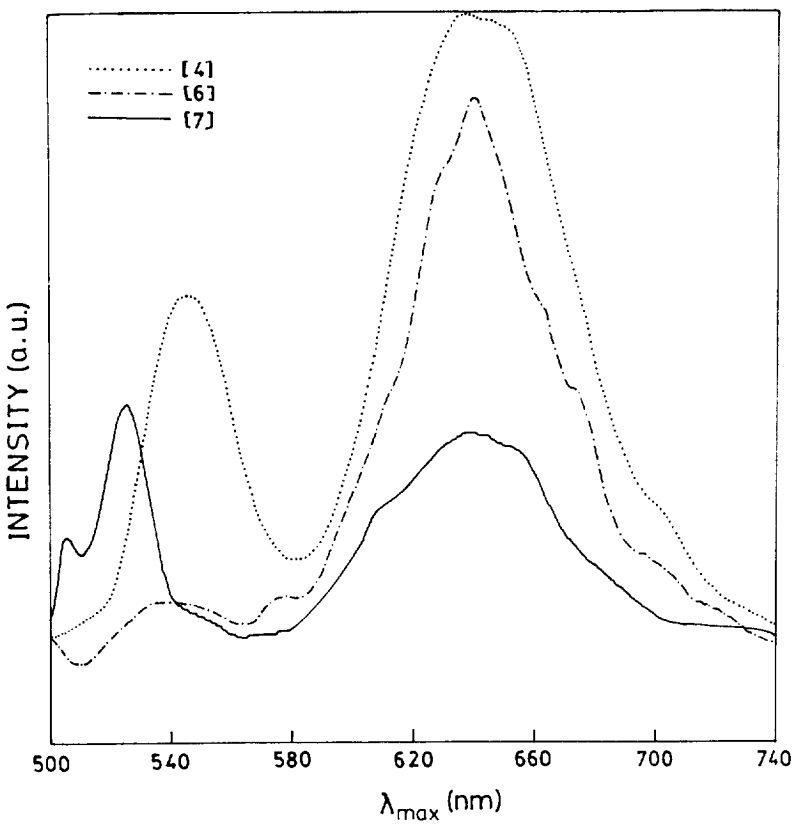

Fig. 5. Luminescence spectra of complexes [4], [6] and [7]; excitation were performed at $\lambda_{abs} \approx 480$ nm.

Hence the 525–545 nm emission bands have been assigned tentatively as metal-to-ligand charge transfers and metal-centred transitions. Thus the bridging between copper and ruthenium moieties introduces a new high energy state in the system. This proves that both the copper and ruthenium metal centres are emitters. It follows that energy transfer occurs from the ruthenium to the copper sub-unit due to ligand dissociation and the solvent (CH_3CN) takes the place of the copper coordination site [40]. Latimer type diagram of the complex [6] illustrate this inter-relationship using excited state redox potential in Fig. 7 in which oxidation of Cu(I) to Cu(II) occurs readily and hence the excited states of Cu(I)–polypyridyl sub-unit are potentially strongly reductant [33].

On the basis of the above facts, lifetimes and emission intensities decrease in the order $(AsPh_3)_2 >$ (phen)$(AsPh_3) >$ (bpy)$(AsPh_3)$ when $\lambda_{em} \approx 640$ nm, suggesting that non-radiative decay processes increase in efficiency along the same sequence and are significantly more effective in the bipyridine complex. These processes are also due to the favourable energetics of the bipyridine ligand bound to copper. The observation shows that the quantum efficiency of electron transfer is limited by the competing non-radiative decay process, which is quite rapid ($\approx 10^{9}$ s^{-1}).

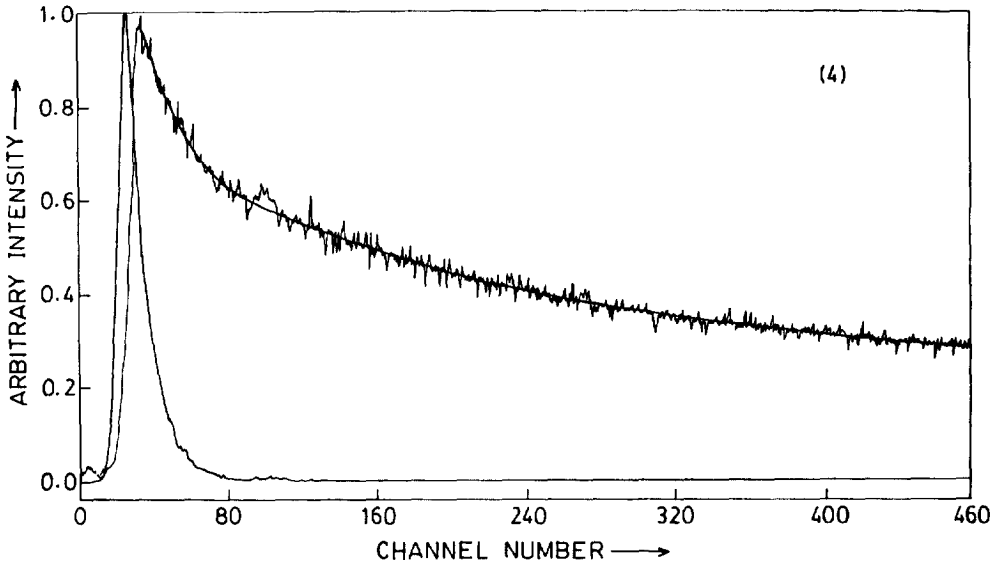

Fig. 6. Fluorescence decay curve of complex [4] at emission wavelength of 642 nm.

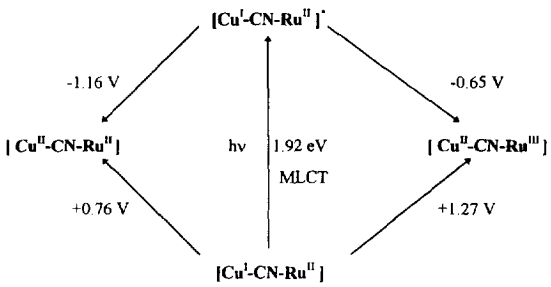

Fig. 7. Latimer type diagram showing ground and excited state potential of [6].

3. CONCLUSION

These studies show that the $[Ru(bpy)_2Cl]^+$ chromophore bound to copper moieties through a CN bridge cannot be easily functionalised. These moieties are redox active and ligand substitution usually causes a small change in excited state energy, but they can significantly change the excited state lifetime and the excited state redox potential. These excitations in the $[Ru(bpy)_2Cl]^+$ chromophore play a major role in determining the occurrence of specific intramolecular electron transfer processes.

Though the complexes exhibit relatively short lifetimes, compared to analogous complexes at room temperature, their desired properties may lead to the simple preparation of photochemical devices [41]. Studies in these directions are in progress.

(Received 19 September 1997: accepted 12 February 1998)

Abstract—The reaction of the 3,6-bis(2′-pyridyl)pyridazine(dppn) ligand, with one and two equivalents of $[Rh(CO)_2S_n](PF_6)$, (s = THF), yields respectively the mononuclear complex $[Rh(CO)_2(dppn)](PF_6)$ **1** and the binuclear complex $[Rh_2(CO)_4(dppn)](PF_6)_2$ **3**. Furthermore, the reaction of **1** with PPh_3 results in a substitution reaction to give $[Rh(CO)(dppn)(PPh_3)_2](PF_6)$ **2**. The unsaturated complex **3** reacts with the monodentate phosphine PPh_3 to yield a mixture of the known compound $[Rh(CO)_2(PPh_3)_2](PF_6)$ and of the mononuclear $[Rh(CO)(dppn)(PPh_3)](PF_6)$ **4**, the crystal structure of which was established by X-ray diffraction. Moreover, **3** reacts with the bis(diphenylphosphino)methane(dppm) ligand in a 1 : 2 ratio to form the binuclear A-frame complex $[Rh_2(CO)_2(dppn)(\mu\text{-dppm})_2](PF_6)_2$ **5**. However, the reaction of **3** with excess dppm (1 : 4 ratio) gives the known complex $[Rh(CO)(dppm)_2](PF_6)$ **6**. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: 3,6-bis(2′-pyridyl)pyridazine; bis(diphenylphosphino)methane; triphenylphosphine; carbonyl; rhodium; X-ray structure.

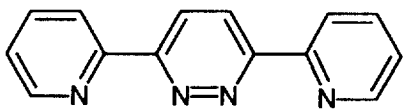
The heterocyclic 3,6-bis(2′-pyridyl)pyridazine ligand, hereafter dppn, is interesting in that it provides two adjacent chelating sites which are able to coordinate transition metals at an internuclear distance of approximately 3.5 Å. This can allow the two metals to interact via ligand bridges or electronically across the dppn planar framework. Such properties have been exploited in several ways to synthesise, for example: (i) a binuclear Ni(II) complex [1] in which the magnetic properties denote the presence of an exchange interaction between the two metal centres; (ii) several binuclear Cu(II) complexes [2] such as $[Cu_2(\mu\text{-}OH)Cl_3(H_2O)(dppn)]$, for which structural studies show that the hydroxy ligand bridges the two metal centres with a Cu(II) to Cu(II) separation of 3.376 Å. In $[Cu_2(\mu\text{-}OH)Br_3(dppn)]_n$, a polymeric stacking of binuclear units joined through bromide ligands is found; (iii) certain heterobinuclear complexes using two separate steps with a sequential addition of one equivalent of each of metal complexes [3]; (iv) a tetranuclear Cu(I) grid-like complex, $[Cu_4(dppn)_4]^{4+}$. It was seen that when one tetrahedral metal ion is incorporated into the dppn ligand, self-assembly of the monometallic units is possible to yield a complex in which the four copper atoms are coplanar and spanned by four dppn ligands. The X-ray structure determination shows that pairs of the quasi-planar dppn ligands align in parallel above and below the rhombic array of Cu_4 [4]. This principle has subsequently been expanded to the synthesis of a variety of fascinating self-assembled structures [5].

The presence of two metals held in close proximity is conceptually of great interest in homogeneous catalysts for several reasons. For example, a substrate may be activated by a simultaneous interaction with both

* Author to whom correspondence should be addressed.

metal centres. Alternatively, the two metals could serve to activate selectively different substrates, but their proximity would allow further interactions between the activated molecules. Heterobimetallic systems may be of particular interest for this type of reactivity.

In this paper we present the synthesis and characterisation of mononuclear and binuclear cationic Rh(I) complexes of the dppn ligand. Further reactions of the dirhodium complex of dppn with PPh_3 and $CH_2(PPh_2)_2$ were also studied. The single crystal X-ray structure of a monomeric dppn derivative of Rh(I) is also described.



dppn

EXPERIMENTAL

General

All reactions were carried out under an atmosphere of prepurified nitrogen or argon using standard Schlenk techniques or performed in a Vacuum Atmospheres Corporation glove box. Solvents such as Et_2O. THF and hydrocarbons were distilled from sodium and benzophenone and CH_2Cl_2 from CaH_2 under nitrogen. The 3,6-bis(2′-pyridyl)pyridazine(dppn)[6] and bis(diphenylphosphino)methane(dppm) ligands [7] as well as $[Rh(CO)_2Cl]_2$ [8] were prepared according to literature procedures. $RhCl_3 \cdot 3H_2O$. $AgPF_6$ and PPh_3 were respectively purchased from Johnson Matthey and Strem Chemicals and used as supplied.

IR spectra were recorded on a Perkin–Elmer 597 instrument. NMR spectra were run on a Bruker SY 200 spectrometer. Solvent peaks (^1H, ^{13}C NMR) served as internal references with the data fitted relatively to TMS. $^{31}P\{^1H\}$ NMR spectra were referenced to external 85% H_3PO_4 with downfield chemical shifts reported as positive. Attempts to record the mass spectra of these compounds by spectroscopic methods were unsuccessful.

Preparation of $[Rh(CO)_2(dppn)](PF_6)$ **1**

A solution of $[Rh(CO)_2S_n](PF_6)$(S = THF) prepared from a 2:1 reaction mixture of $AgPF_6$(0.215 mg, 0.850 mmol) and $[Rh(CO)_2Cl]_2$ (0.165 mg, 0.425 mmol) in THF (10 cm^3) was added dropwise to a solution of dppn (0.200 g, 0.850 mmol) in benzene (10 cm^3). The yellow-green precipitate which formed rapidly was separated and washed successively with THF (2 cm^3) and CH_2Cl_2(2 cm^3)(Yield: 85%). IR (Nujol mull, cm^{-1}) ν_{CO} 2100 (s), 2050 (s); ν_{P-F} 840 (br, s), 560 (s); $\nu_{(C=C\text{ or }C=N)}$ 1600 (mw), 1590 (w). Anal: Calcd for $C_{16}H_{10}N_4O_2F_6PRh$: C, 35.71; H, 1.87; N, 10.44; Rh, 19.12. Found: C, 36.54; H, 1.52; N, 9.58; Rh, 18.13.

Preparation of $[Rh(CO)(dppn)(PPh_3)_2](PF_6)$ **2**

Complex **1** (0.100 g, 0.185 mmol) in acetone (5 cm^3) was added to an acetone solution (5 cm^3) of PPh_3 (0.097 g, 0.370 mmol). The light brown precipitate was filtered, washed several times with Et_2O (3 × 5 cm^3) and dried under vacuum (Yield: 85%). IR (Nujol mull, cm^{-1}) ν_{CO} 1940. $^{31}P(^1H)$ NMR, ($(CD_3)_2CO$, δ_{ppm}), 41 (d, $I = 2$, $^1J_{Rh-P} = 113$ Hz, PPh_3), −143 (hept, $I = 1$, PF_6^-). Anal: Calcd for $C_{51}H_{40}N_4OF_6P_3Rh$: C, 59.20; H, 3.90; N, 5.41. Found: C, 58.15; H, 3.93; N, 5.41.

Preparation of $[Rh_2(CO)_4(dppn)](PF_6)_2$ **3**

A solution of dppn (0.100 g, 0.425 mmol) in benzene (5 cm^3) was added to a yellow solution of $[Rh(CO)_2S_n](PF_6)$(0.850 mmol) in THF (5 cm^3). The compound **3** precipitated out as an orange microcrystalline compound which was filtered and washed with THF (2 cm^3) and then CH_2Cl_2 (2 cm^3)(Yield: 90%). IR (Nujol mull, cm^{-1}) ν_{CO} 2100 (s), 2050 (s); ν_{P-F} 840 (br, s), 560 (s); $\nu_{(C=C\text{ or }C=N)}$ 1600 (mw). ^1H NMR ($(CD_3)_2CO$, δ_{ppm}) H arom: 9.35 (s, 2H), 9.22 (d, 2H), 8.89 (d, 2H), 8.67 (t, 2H), 8.16 (t, 2H). Anal: Calcd for $C_{18}H_{10}N_4O_4F_{12}P_2Rh_2$: C, 25.68; H, 1.20; N, 6.65; P, 7.36; Rh, 24.44. Found: C, 26.35; H, 1.28; N, 6.25; P, 7.25; Rh, 23.26.

Preparation of $[Rh(CO)(dppn)PPh_3)](PF_6)$ **4**

A solution of PPh_3 (0.093 g, 0.356 mmol) in CH_2Cl_2 (5 cm^3) was added dropwise to a slurry of the dimer **3** (0.100 g, 0.119 mmol) in CH_2Cl_2 (5 cm^3) under vigorous stirring for 1 h. The deep red solution was filtered over celite and evaporated to dryness. After recrystallisation from CH_2Cl_2/hexane, a mixture of yellow crystals of the known complex $[Rh(CO)_2(PPh_3)_2](PF_6)$ [9] and of red crystals of $[Rh(CO)(dppn)(PPh_3)](PF_6)$ **4** was obtained. For **4**: IR (Nujol mull, cm $^{-1}$) ν_{CO} 2000 (s); $^{31}P\{^1H\}$ NMR ($(CD_3)_2CO/CH_2Cl_2$, δ_{ppm}), 42.24 (d, $I = 1$, $J_{Rh-P} = 150$ Hz, PPh_3), −142 (hept, $I = 1$, PF_6^-). X-ray quality crystals of **4**·$(CH_3)_2CO$ were obtained from a 1:1 mixture of acetone/ethanol.

Preparation of $[Rh_2(CO)_2(dppn)(\mu\text{-dppm})_2](PF_6)_2$ **5**

To a suspension of **3** (0.100 g, 0.119 mmol) in CH_2Cl_2 (5 cm^3) was added dropwise a solution of dppm (0.091 g, 0.237 mmol) in CH_2Cl_2 (5 cm^3). The

reaction mixture was allowed to stir for 2 h during which a deep green colour developed. The green precipitate which formed after addition of Et_2O (40 cm^3) was filtered off, washed successively with C_6H_6 and Et_2O and dried under vacuum (Yield: 90%). IR (Nujol mull, cm^{-1}), besides specific absorptions due to dppn and PF_6^-, ν_{CO} 2000 (vs). $^{31}P\{^1H\}$ NMR (CD_2Cl_2, δppm), 24.5 (m, $I = 4$) and −143 (hept, $I = 2$). ^1H NMR (CD_2Cl_2, δ_{ppm}), 9.4–8 and 7.6–6.8 (m, H arom), 4.03 (m, —CH_2). Anal: Calcd for $C_{66}H_{54}N_4O_2F_{12}P_6Rh_2$: C, 50.99; H, 3.50; N, 3.60; P, 11.97; Rh, 13.24. Found: C, 49.50; H, 3.65; N, 3.70; P, 12.14; Rh, 12.80.

Reaction of **3** *with an excess of dppn to give* $[Rh(CO)(dppm)_2](PF_6)$ **6**

A solution of dppm (0.182 g, 0.473 mmol) in CH_2Cl_2 (5 cm^3) was added to a slurry of the dimer **3** (0.100 g, 0.119 mmol) in CH_2Cl_2 (5 cm^3). The mixture was stirred for 2 h at room temperature and the solvent evaporated to dryness under vacuum. A yellow product **6** was extracted with ether (Yield: 90%). IR (Nujol mull, cm^{-1}) ν_{CO} 1945 (s). $^{31}P\{^1H\}$ NMR (CD_2Cl_2, δ_{ppm}) −19.5 (d, $I = 4$, $J_{Rh-P} = 103$ Hz, dppm), and −143 (hept, $I = 1$, PF_6^-). ^1H NMR ($(CD_3)_2CO$, δ_{ppm}) 7.2–7.5 (m, H arom.), 4.5 ppm (m, —CH_2). Anal: Calcd for $C_{51}H_{44}OF_6P_5Rh$: C, 58.62; H, 4.21; P, 14.85; Rh, 9.86. Found: C, 58.24; H, 4.08; P, 14.13; Rh, 9.84.

X-ray crystal structure analysis of $[Rh(CO)(dppn)(PPh_3)](PF_6)\cdot$*acetone*, **4**·acetone

Suitable red single crystals for **4**·acetone were obtained by recrystallisation from an acetone-ethanol mixture at room temperature. One single crystal was cut out from a cluster of deep red crystals and mounted on a rotation-free goniometer head. A systematic search in reciprocal space using a Enraf-Nonius CAD4–F automatic diffractometer showed that crystals of **4**·acetone belong to the triclinic system. Quantitative data were obtained at room temperature. All experimental parameters used are given in Table 1. The resulting data set was transferred to a VAX computer, and for all subsequent calculations the Enraf-Nonius Molen package was used [10]. Three standard reflections were measured every hour during the entire data period showed no significant trend. The raw data were converted to intensities and corrected for Lorentz and polarisation factors. Absorption corrections derived from the Φ scans of 4 reflections were applied. The structure was solved using the heavy atom method. After refinement of the heavy atoms, a difference-Fourier map revealed maxima of residual electronic density close to the positions expected for hydrogen atoms; they were introduced in structure factor calculations by their computed coordinates (C—H = 0.95 Å) and isotropic temperature factors

The scattering factor coefficients and anomalous dispersion coefficients come respectively from [11]. Table 1 lists experimental details and final results.

RESULTS AND DISCUSSION

The deep yellow-green compound. $[Rh(CO)_2(dppn)](PF_6)$ **1**, was obtained in high yield by the reaction of equimolar amounts of $[Rh(CO)_2(THF)_n](PF_6)$ and dppn [6]. The IR spectrum of **1** displays two strong absorptions at 2100 and 2050 cm^{-1}, typical of terminal *cis* carbonyl ligands and similar to those reported for the analogous 2,2′-bipyridine of *o*-phenenthroline carbonyl complexes of Rh(I)[12,13]. Hence one chelating site of the dppn ligand is coordinated to the Rh(I) centre completing the square planar configuration for **1**. The reaction of **1** with PPh_3 (1 : 2 mol ratio) gives a brick red complex

which analyses as $[Rh(CO)(dppn)(PPh_3)_2](PF_6)$ **2**. The $^{31}P\{^1H\}$ NMR spectrum shows a doublet at 41 ppm [^1J(Rh—P) = 113 Hz] which suggests a trigonal bipyramid configuration for the pentacoordinated Rh(I) derivative [13] with two axial PPh_3 ligands and an equatorial CO ligand which is also revealed by the presence of a strong absorption band at 1940 cm^{-1} in the IR spectrum.

When two equivalents of $[Rh(CO)_2(THF)_n](PF_6)$ are added to one equivalent of dppn in a THF/C_6H_6 mixture, an orange dimeric complex **3**, corresponding to $[Rh_2(CO)_4(dppn)](PF_6)_2$, is obtained. Its ^1H NMR spectrum shows five aromatic resonances of equal intensity as one singlet, two doublets and two triplets indicating that both coordination sites of the dppn ligand are occupied by Rh(I) ions. Also, the IR spectrum in the carbonyl region shows only two terminal ν_{CO} absorptions at 2100 and 2050 cm^{-1}. Hence we can propose the symmetric binuclear structure shown in Scheme 1.

However, one Rh(I) in **3** can be relatively easily removed by ligands such as phosphines (Scheme 1). Treatment of **3** with PPh_3 gives $[Rh(CO)_2(PPh_3)_2](PF_6)$ [9] and $[Rh(CO)(dppn)(PPh_3)](PF_6)$ **4**, the formation of which can be followed by ^{31}P NMR. We have structurally characterised **4**·$(CH_3)_2CO$ by X-ray diffraction (Fig. 1), which enables us in part to understand the instability of the binuclear unit. The distorted square planar Rh(I) cation is quasi-symmetrically coordinated to the two nitrogen atoms (N1 and N12) by one chelating site of the dppn ligand. The two Rh—N distances (Rh—N1 = 2.090 (5) Å) and Rh—N12 = 2.096 (5) Å and the Rh—CO of 1.833 (7) Å as well as the Rh—P of 2.267 (2) Å are within the range of expected bond lengths for this type of Rh(I) cation. Selected bond distances and angles are given in Table 2. The unexpected feature of this structure is the coordination of PPh_3 to Rh(I) in a *trans* position to N12 of the pyridyl arm and *cis* to the *N*-pyridazine, whereas simple steric considerations might have placed the PPh_3 *cis* to N12. The result is that the phenyl groups of the phosphine block the free chelating site of dppn which may be responsible for the loss of Rh(I) from this site. We therefore sought to stabilise the bimetallic unit in **3** by use of the bis(diphenylphosphino)methane ligand (dppm), which is well known to form binuclear A-Frame structures (Scheme 2).

Treatment of the unsaturated dimer **3** with dppm in CH_2Cl_2 (1 : 2 molar ratio) gives a deep green compound isolated in reasonable yield, which analyses as $[Rh_2(CO)_2(dppn)(dppm)_2](PF_6)_2$ **5**. Its IR spectrum in Nujol mull displays a very strong absorption ν_{CO} at 2000 cm^{-1}), characteristic of terminal carbonyls, as well as absorption bands due to the coordinated ligands dppn and dppm and to the PF_6^- anion. The $^{31}P\{^1H\}$ NMR spectrum shows one signal due to coordinated dppm at δ = 24.5 ppm(m), indicating that **5** possesses only equivalent phosphorus environments, while the ^1H NMR spectrum reveals the presence of a symmetrically coordinated dppn. Therefore the spectroscopic features indicate the formation of a classical

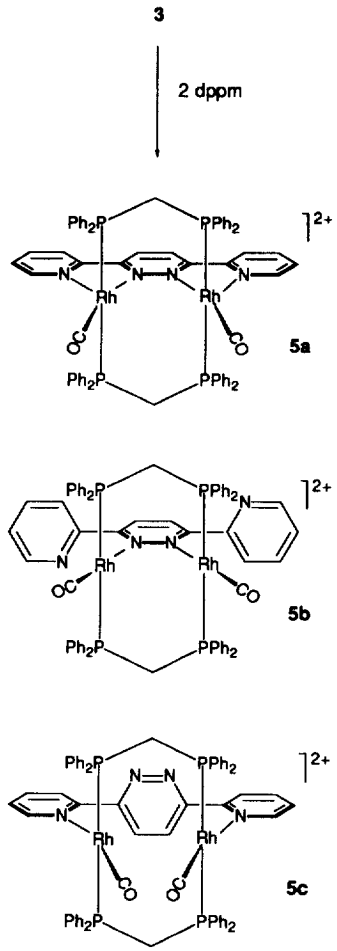
A-frame type structure as in **5a** with two bridging dppm units occupying mutually *trans* positions at the two Rh(I) centres and with the tetradentate dppn ligand as third bridge. Each Rh(I) would then possess a $18e^-$ configuration with a trigonal bipyramidal geometry (TBP) based on the CO ligand and a chelating site of the dppn ligand in the equatorial plane.

However we cannot exclude two other structural possibilities where only either the central pyridazine or the two pyridine end groups are coordinated to rhodium, as in **5b** and **5c** respectively; both Rh(I) atoms would then possess a $16e^-$ configuration. Such structures gain support from preliminary studies which show that this complex reacts rapidly with CO and H_2, more typical of an unsaturated Rh(I) centre. Further studies of this compound and its reactivity are in progress.

Finally, we found that the reaction of four equivalents of dppm with complex **3** in CH_2Cl_2 occurs with the total displacement of the dppn ligand, yielding a complex **6** having an analogous formulation to that already synthesised by another route $[Rh(CO)(dppm)_2]^+$[14]. Its spectroscopic features, including the IR spectrum (ν_{CO} at 1945 cm^{-1}) and the $^{31}P\{^1H\}$ NMR data in CD_2Cl_2 ($\delta = -19.5$ ppm (d), with $^1J_{Rh-P} = 103$ Hz), are closely similar to those previously reported.

CONCLUSION

The 3,6-bis(2′-pyridyl)pyridazine ligand, which possesses two contiguous binding sites for metal ions, has been found to form both mononuclear and binuclear complexes with Rh(I). However, the binuclear compounds were found to be relatively lab-



Scheme 2.

ile but their stability could be increased, in part, by the binding of further bridging ligands such as dppm.

(Received 29 January 1998; accepted 12 February 1998)

Abstract—Ruthenium(II) complexes of 2,2′:6′,2″:6″,2‴:6‴,2⁗-quinquepyridine ligands have been prepared and two series of complexes have been isolated. The first series consists of dinuclear double helical species of stoichiometry $[Ru_2L_2Cl_2][PF_6]_2$ in which one ruthenium centre is coordinated to two 2,2′:6′,2″-terpyridine domains of two 2,2′:6′,2″:6″,2‴:6‴, 2⁗-quinquepyridine ligands and the second is coordinated to the remaining 2,2′-bipyridine domains of ligands together with two chloride ligands. The second series consists of mononuclear $[RuL_2][PF_6]_2$ complexes which may be viewed as *prehelicates*. In essence they exhibit the same structural features as $[Ru_2L_2Cl_2][PF_6]_2$ with the exception that the $RuCl_2$ unit has been removed. The $[RuL_2][PF_6]_2$ complexes also exhibit a novel type of conformational isomerism leading to extremely interesting NMR behaviour. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: double-helicates; ruthenium complexes; metallosupramolecular chemistry; X-ray structure.

Self assembling supramolecules have attracted considerable recent attention and those processes in which the assembly is directed by metal-ligand interactions have proved to be particularly versatile and facile [1,2]. We and others have investigated the structural requirements of ligands which give rise to helical co-ordination compounds [3] and have demonstrated that the oligopyridines and molecules containing oligopyridine metal-binding domains are of particular utility for the assembly of multiple-helical species [4,5]. Our interest lies in the development of the co-ordination chemistry of the higher oligopyridines as the organic components of helical supramolecular systems. In previous papers in this series we have discussed the co-ordination behaviour of 2,2′:6′,2″:6″,2‴:6‴,2⁗-quinquepyridine (qpy) and a number of its derivatives with a variety of transition metal ions [6–21]. Following our initial studies, other authors have also discussed aspects of the co-ordination chemistry of qpy and substituted derivatives [22–32]. In this paper we report our detailed studies of ruthenium complexes of qpy ligands.

EXPERIMENTAL

Infrared spectra were recorded on Perkin-Elmer 1710, Philips PU9624 or Mattson Genesis Fourier-transform spectrophotometers with samples in compressed KBr discs. Proton NMR spectra were recorded on Brüker WM250, AM400 or Varian Gemini 300 MHz spectrometers. Fast atom bombardment (FAB) and electron-impact (EI) mass spectra were recorded on Kratos MS-50, Kratos MS-890, VG 70-250 or Kratos MS-902 spectrometers; for FAB or FIB spectra the sample was loaded using acetonitrile as a solvent and 3-nitrobenzyl alcohol as supporting matrix. Time of flight (Maldi) spectra were recorded using a PerSeptive Biosystems Voyager-RP Biospectrometry Workstation. Electrochemical measurements were performed with an Amel model 553 potentiostat connected to an Amel model 567 function generator and an Amel model 560/A interface or an Echo Chemie Autolab PGSTAT 20 system using platinum bead or glassy carbon working and auxiliary electrodes with an Ag/AgCl electrode as reference. The experiments were conducted using purified acetonitrile as solvent and freshly recrystallised 0.1 M $[Bu^n4N][BF_4]$ or $[Bu^n4N][PF_6]$ as supporting elec-

trolyte; ferrocene was added at the end of each experiment as an internal reference. The ligands 2,2′:6′,2″:6″,2‴:6‴,2⁗-quinquepyridine (qpy), 4′4‴-diphenyl-2,2′:6′,2″:6″,2‴:6‴,2⁗-quinquepyridine (dpqpy), and 4′,4‴-bis(4-chlorophenyl)-2,2′:6′,2″:6″,2‴:6‴,2⁗-quinquepyridine (dcqpy) were prepared as previously described [16]. All other chemicals were used as supplied. Hydrated ruthenium trichloride was purchased from Oxchem.

$[Ru_2L_2Cl_2][PF_6]_2$ (L = *qpy*, *dpqpy*, *dcqpy*)

The appropriate ligand (0.1 mmol) was added to a solution of commercial $RuCl_3 \cdot 3H_2O$ (0.20 g, 0.1 mmol) in ethane-1,2-diol (30 cm^3) containing *N*-ethylmorpholine (2 drops). The mixture was then heated to reflux for 45 min, after which time t.l.c. analysis showed a major red-purple spot. The reaction mixture was then filtered to remove any solids to give a clear red-purple solution. The solutions were then concentrated *in vacuo* and the products precipitated by the addition of methanolic ammonium hexafluorophosphate and water. The red-purple precipitates were then collected (yield ~ 40%) by filtration and recrystallised from methanol.

$[Ru_2(qpy)_2Cl_2][PF_6]_2$. Red-purple microcrystals. (Found: C, 44.3; H, 2.7; N, 10.4% $C_{50}H_{34}N_{10}Ru_2Cl_2P_2F_{12}$ requires C, 44.9; H, 2.6; N, 10.5%). IR (KBr): 1647 w, 1637 m, 1618 m, 1602 m, 1560 w, 1541 w, 1458 m, 1410 w, 1385 s, 1082 w, 1043 w, 1014 w, 847 s, 773 m, 559 s cm^{-1}. Mass spectrum (FAB) *m/z* 1193 $\{Ru_2(qpy)_2Cl_2(PF_6)\}$, 1048 $\{Ru_2(qpy)_2Cl_2\}$.

$[Ru_2(dpqpy)_2Cl_2][PF_6]_2$. Red-purple microcrystals. (Found: C, 54.0; H, 3.4; N, 8.3% $C_{74}H_{50}N_{10}Ru_2Cl_2P_2F_{12}$ requires C, 54.1; H, 3.1; N, 8.5%). IR (KBr): 1635 m, 1610 s, 1473 m, 1456 m, 1437 m, 1412 s, 1385 s, 1090 w, 1080 w, 1032 m, 1018 m, 845 s, 766 s, 557 s cm^{-1}. Mass spectrum (FAB) *m/z* 1501 $\{Ru_2(dpqpy)_2Cl_2(PF_6)\}$, 1352 $\{Ru_2(dpqpy)_2Cl_2\}$.

$[Ru_2(dcqpy)_2Cl_2][PF_6]_2$. Red-purple microcrystals. (Found: C, 50.9; H, 3.0; N, 8.4% $C_{74}H_{46}N_{10}Ru_2Cl_6P_2F_{12}$. MeCN requires C, 50.1; H, 2.7; N, 8.5%). IR (KBr): 1662 w, 1655 m, 1635 s, 1610 s, 1558 w, 1541 s, 1522 w, 1497 s, 1471 m, 1458 m, 1448 w, 1437 m, 1417 s, 1398 m, 1385 s, 1093 m, 1012 m, 847 s, 557 m cm^{-1}. Mass spectrum (FAB) *m/z* 1634 $\{Ru_2(dcqpy)_2Cl_2(PF_6)\}$, 1489 $\{Ru_2(dcqpy)_2Cl_2\}$.

$[RuL_2][PF_6]_2$, (L = *qpy*, *dpqpy*, *dcqpy*)

The appropriate ligand (0.2 mmol) was added to a solution of $RuCl_3 \cdot 3H_2O$ (0.020 g, 0.1 mmol) in *N*,*N*-dimethylformamide (DMF) (30 cm^3) containing *N*-ethylmorpholine (2 drops). The mixture was left to stand for 1.5 h during which time a green colour developed after which it was heated to reflux for 45 min. After this period, t.l.c. analysis showed one major orange spot. The mixture was then filtered and the clear orange filtrate was concentrated and methanolic ammonium hexafluorophosphate and water added. The orange precipitate was collected by filtration and dissolved in hot methanol. Upon cooling a small amount of purple $[Ru_2L_2Cl_2][PF_6]_2$ was precipitated and removed by filtration; the addition of a few drops of methanolic ammonium hexafluorophosphate to the orange filtrate and reduction in volume *in vacuo* gave the orange products in ~40% yield.

RESULTS AND DISCUSSION

2,2′:6′,2″:6″,2‴:6‴,2⁗-quinquepyridine complexes

2,2′:6′,2″:6″,2‴:6‴,2⁗-quinquepyridine is a versatile ligand which forms a wide range of mono-helical and multi-helical complexes upon coordination to appropriate transition metal ions. Detailed studies of the behaviour of qpy ligands with a range of metal ions have led to an understanding of the interplay between the ligand donor properties and the size and electronic requirements of the metal centre. The bulk of the studies reported have been concerned with labile metal centres which allow self-assembly processes to dictate the structure of the final product. However, the useful redox, photochemical and photophysical properties of ruthenium(II) oligopyridine complexes have prompted us [17,21] and others [25] to investigate the co-ordination behaviour of qpy ligands with this less labile metal centre.

Reactions of $RuCL_3$ with qpy ligands

The simplest ruthenium complex containing a qpy ligand would be the ruthenium(III) 1:1 adduct with ruthenium trichloride [Ru(L-*N*,*N*′,*N*″)Cl_3](here and throughout L denotes 2,2′:6′,2″:6″,2‴:6‴,2⁗-quinquepyridine or a substituted derivative). We have made a number of attempts to prepare species of this stoichiometry from the reaction of commercial ruthenium trichloride with a variety of qpy ligands under a range of conditions. Our studies are uniformly disappointing and may be summarised as having one of two results. When mild reaction conditions are used (methanol or ethanol as solvent) with the less soluble qpy ligands (qpy, dpqpy, dtqpy, dcqpy), essentially no reaction is observed. This almost certainly reflects the insolubility of the ligands in the protic reaction solvents. In contrast, if solubilised ligands were used (tbqpy, dfqpy) or if less soluble ligands were reacted under forcing conditions (hot DMF or ethane-1,2-diol solvent) mixtures of various ruthenium(II) compounds (see later) were obtained.

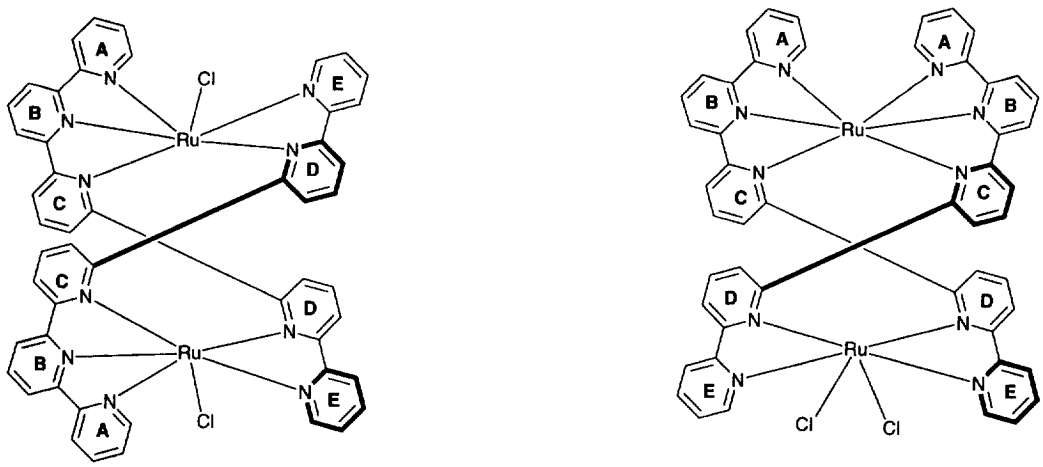
Accordingly, we decided to investigate the direct formation of ruthenium(II) complexes from the reactions of ruthenium trichloride with the ligands under reductive conditions., Once again, we found that the less soluble ligands did not react with ruthenium trichloride under mild conditions (refluxing methanol or ethanol containing *N*-ethylmorpholine). In contrast, dark coloured reaction solutions were obtained from the solubilised ligands in alcoholic solvents or upon reaction of all of the ligands in hot DMF or ethane-1,2-diol containing *N*-ethylmorpholine. We concentrate now on the reactions of qpy, dcqpy and dpqpy which may be regarded as typical in their co-ordination behaviour. Thin layer chromatographic (t.l.c.) analysis of the dark-coloured reaction mixtures (silica, 1:7 saturated aqueous KNO_3 solution: acetonitrile) indicated the presence of variable amounts of two close-running orange-red and red-purple products in each case.

Attempts to purify the orange-red and red-purple products by column chromatography (silica) using a variety of mobile phases met with mixed success. The R_f values of the two products are very similar and, although clean fractions could be obtained from the fore-run and the tail, complete separation of the bands was only rarely and irreproducibly achieved. As a result, pure red-purple and orange-red products could only be obtained in very low yields by chromatographic methods. However, we also noted that the red-purple products were significantly less soluble in cold methanol than the orange-red ones and that recrystallisation from methanol yielded the pure red-purple species. From the mother liquor, it was possible to isolate the pure orange-red species by chromatography.

Eventually we found reaction conditions which resulted in large excesses of one of the two products. After 2 h at reflux in ethane-1,2-diol, 1:1 mixtures of ruthenium trichloride and the qpy ligand yielded orange solutions which were shown by t.l.c. to contain predominantly the orange-red product. In contrast, reaction in DMF at room temperature for 1.5 h yielded a deep green solution. Subsequent heating of this green solution to reflux for 45 min gave a purple solution that was shown by t.l.c. to contain only the red-purple product. For each ligand, pure orange-red and red-purple compounds were isolated as their hexafluorophosphate salts after recrystallisation from methanol. Representative microanalytic results are given in the experimental section, although we repeat our previous comments that combustion analysis of ruthenium complexes of the higher oligopyridines frequently gives results with unacceptably low carbon figures.

The red-purple $[Ru_2L_2Cl_2][PF_6]_2$ complexes

In each case, the FAB mass spectra of the red-purple compounds exhibited peaks corresponding to $\{Ru_2L_2Cl_2(PF_6)\}^+$ and $\{Ru_2L_2Cl_2\}^+$ and microanalysis indicated a formulation $[Ru_2L_2Cl_2][PF_6]_2$. Assuming two six co-ordinate ruthenium(II) centres, a total of twelve donor atoms are required. The mass spectrometric results strongly suggest a dimeric formulation and, as we have previously discussed, such a formulation results in a dinuclear double-helical complex with qpy ligands. However, two double-helical structures are possible, as shown in Fig. 1. In one, the two ruthenium centres are equivalent and each is in a N_5Cl environment whilst in the other, one ruthenium is in a N_6 environment whilst the other has a N_4Cl_2 donor set. Electrochemical studies proved to be useful in distinguishing between these possibilities. For each of the compounds, the cyclic voltammogram of an acetonitrile solution exhibits processes in the



I II

Fig. 1. Possible structures of the complex $[Ru_2L_2Cl_2]^{2+}$.

region of +1.0 V (all potentials quoted vs $F_cF_c^+$: L = qpy, +1.1 V; L = dpqpy, +0.98 V; L = dcqpy, +0.99 V) together with additional processes in the ranges 0.70–0.72 V (L = qpy, +0.70 V; L = dpqpy, +0.74 V; L = dcqpy, +0.72 V) and 0.55–0.58 V (L = qpy, +0.58 V; L = dpqpy, +0.58 V; L = dcqpy, +0.55 V). The +1.00 V process is typical of a $\{Ru(tpy)_2\}$ centre whilst the process at +0.50 V is typical of a RuN_4Cl_2 centre [33]. We have previously shown that electrochemical oxidation of ruthenium(II) chloro complexes in acetonitrile leads to chloride loss and the formation of acetonitrile complexes, and we assign the +0.70 V process, which builds up with time, to a $RuN_4Cl(MeCN)$ centre [21]. In addition, each of the complexes exhibits reductions in the range −1.59 to −1.63 V and −1.76 to −1.80 V. These electrochemical data are only consistent with structure II in Fig. 1.

Further confirmation of the assignment of structure II to the complexes came from their ^1H NMR spectra, data for which are presented in Table 1. In both structures I and II, all of the pyridine rings of each ligand are non-equivalent and 17 resonances are expected in each case for the complex with qpy. The most noticeable features are doublets shifted to high and to low field of the bulk of the resonances; a typical spectrum for the complex $[Ru_2(dcqpy)_2Cl_2][PF_6]_2$ is presented in Fig 2. The following discussion will concentrate on the parent $[Ru_2(qpy)_2Cl_2][PF_6]_2$ complex. The coupling constants (5–6 Hz) unambiguously establish that both of these shifted resonances may be assigned to H^6 of a terminal pyridine ring. As mentioned earlier, the terminal pyridine rings of a given ligand are inequivalent in both of the possible structures presented in Fig. 1 although the large difference in chemical shifts argues indirectly in favour of structure II. The spectra were fully assigned by means of COSY (Fig. 3) and NOE experiments at 250, 400 and 500 MHz which lead to the assignments presented in Table 1. The unambiguous assignment to structure II follows from the H^6 resonances. The strong downfield shifting is a characteristic of H^{6A} of a 2,2′-bipyridine unit in which

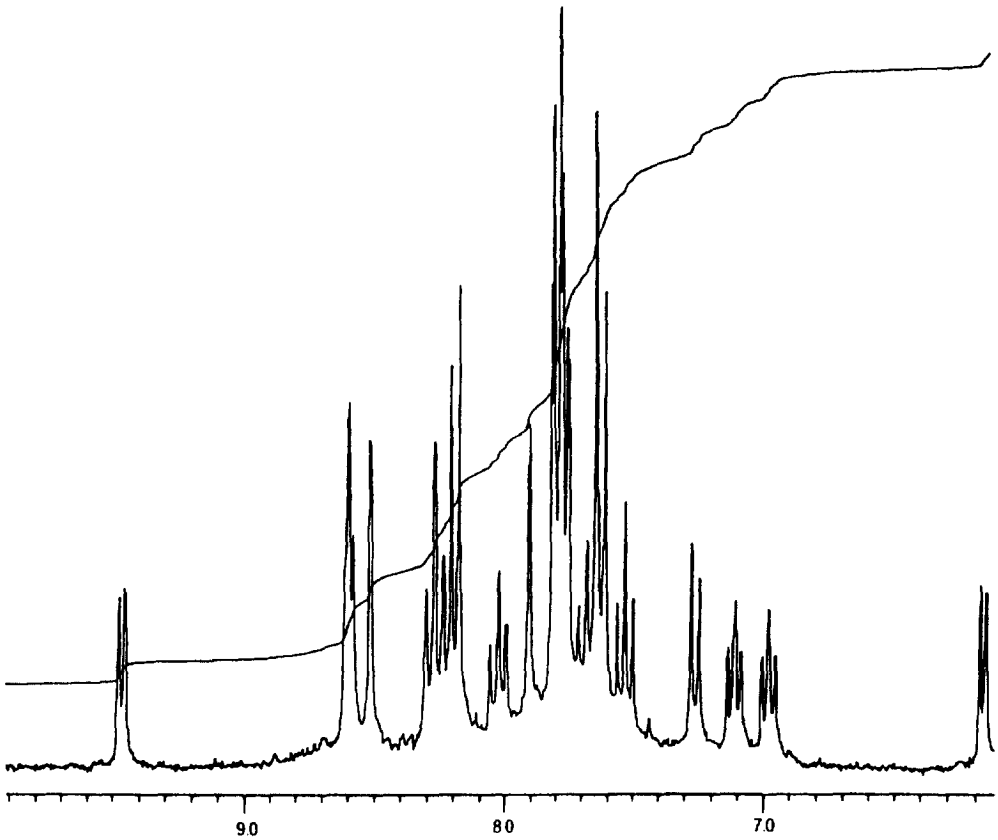

Fig. 2. 400 MHz ^{1}H NMR spectrum of a CD_3CN solution of $[Ru_2(dcqpy)_2Cl_2][PF_6]_2$.

ring A is *cis* and ring D is *trans* to a Ru—Cl bond (cf. δ 10.20 in $[Ru(tpy)(bpy)Cl]^+$). The upfield-shifted H^6 may also be unambiguously assigned to H^{6A} by comparison with the spectra of the $[Ru_2L(tpy)Cl][PF_6]_3$ complexes reported earlier [21]. The spectra of the complexes with the substituted ligands are exactly analogous, and the NMR experiments allow the unambiguous assignment of the structure $[Ru_2(\mu\text{-}\kappa^3N,N',N'':\kappa N''',N'''',\text{-L})_2Cl_2][PF_6]_2$ with a *cis* arrangement of the chloride ligands as presented in Fig. 1. Further support for the assignment of these structures to the complexes comes from the unambiguous solid state determination of the structure of the complex $[Ru_2(qpy)_2(O_2CCO_2)][CF_3SO_3]_2 \cdot 6H_2O$ which was prepared from $Ru_2(qpy)_2Cl_2][PF_6]_2$ [25]. In the complex cation $[Ru_2(qpy)_2(O_2CCO_2)]^{2+}$ the general double-helical dinuclear configuration of structure II is adopted, with the sties of the two chloride ligands being occupied by a didentate oxalate group.

The orange-red $[RuL_2][PF_6]_2$ *complexes*

We now turn to the orange-red compounds. The mass spectra of these compounds exhibit intense peaks corresponding to $\{RuL_2(PF_6)\}^+$ and $\{RuL_2\}^+$ whilst the microanalysis was consistent with a formulation $[RuL_2][PF_6]_2$. Each qpy ligand possesses a total of five nitrogen donors and ruthenium(II) centres are almost invariably six co-ordinate. We have shown previously, that if oligopyridine ligand arrays present more than six donors, that the consequence is the formation of complexes containing hypodentate ligands in which one or more pyridine is not +0.98 V together with reductions in the range −1.6 to −1.9 V. The +1.00 V process is typical of a $\{Ru(tpy)_2\}$ centre and is also remarkably consistent with the process assigned to the RuN_6 centre in the $[Ru_2L_2Cl_2][PF_6]_2$ compounds [33].

There are a three possible structures for such complexes, as shown in Fig. 4. In each structure, the two ligands present a tridentate tpy domain to the metal. In structure III, the two ligands are equivalent and a terminal tpy domain of each is involved, leaving a non-coordinated bpy domain. In structure IV, the two ligands are also equivalently partitioned, and each has two non-coordinated terminal pyridine residues. Finally, in structure V, one ligand has a non-coordinated bpy domain the other has two non-coordinated pyridine residues [34–36].

All of the chromatographic techniques that we used indicated that single isomers of the $[RuL_2][PF_6]_2$ compounds were formed. In particular, we expected dra-

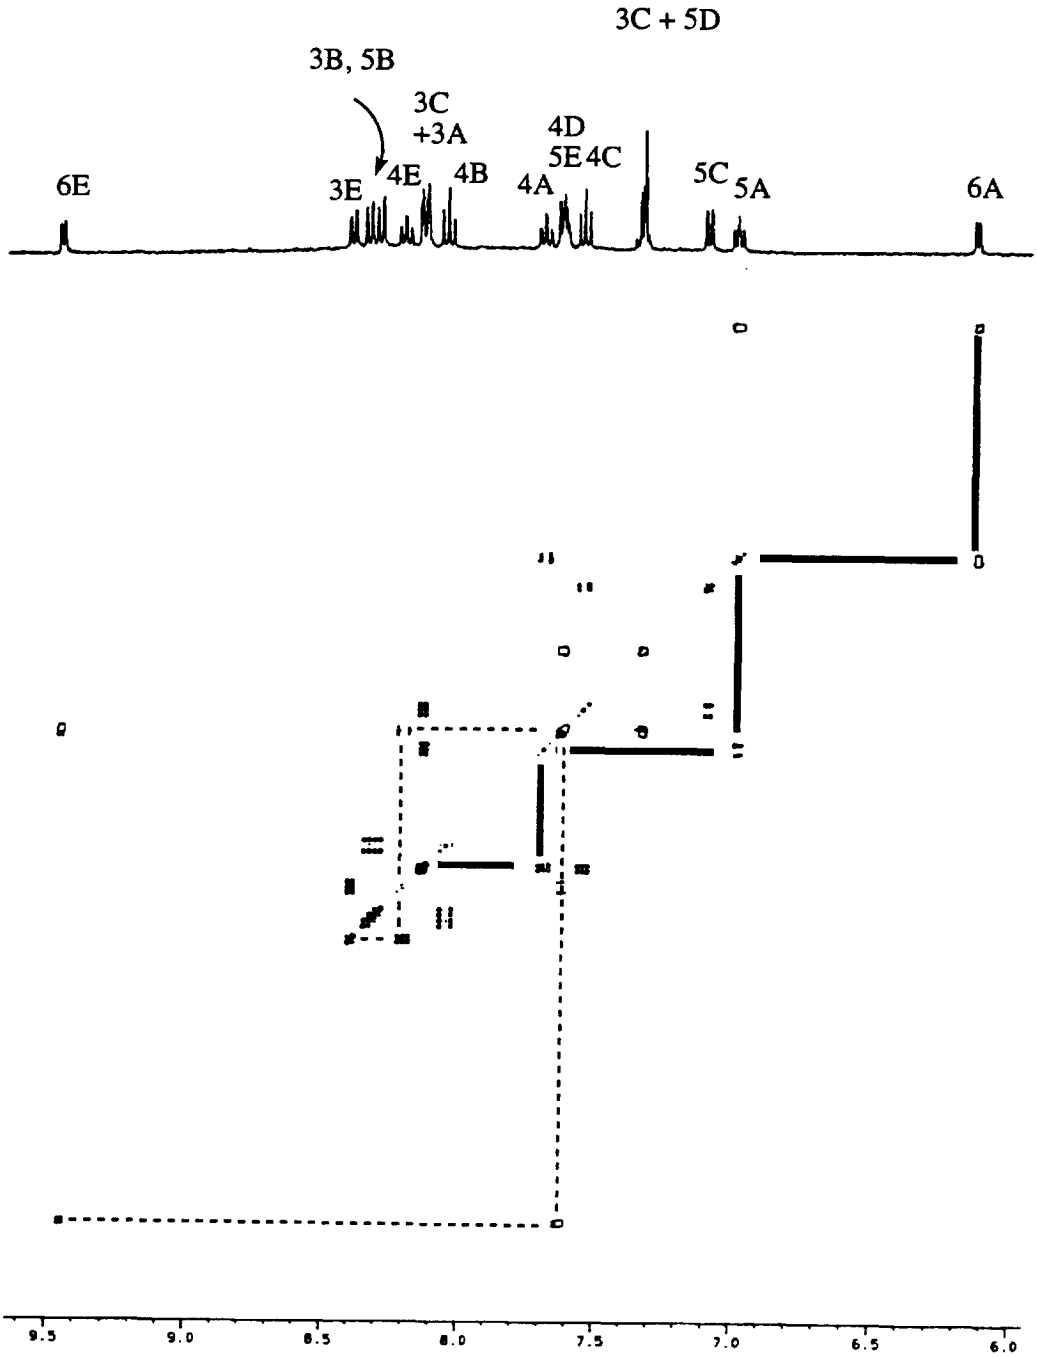

Fig. 3. 400 MHz ^{1}H COSY spectrum of $[Ru_2(qpy)_2Cl_2][PF_6]_2$ showing the connectivity of the two terminal rings and the assignment of the remaining resonances.

matically different behaviour on chromatography between complexes with four terminal pyridine rings non-coordinated and those with non-coordinated bpy domains. We also note, that 6,6″-diaryl-2,2′:6′,2″-terpyridine ligands exhibit severe steric interactions between the aryl groups and the complexes are significantly destabilised and also only formed in forcing conditions. These latter observations suggest that partitioning the ligand into a tpy and a bpy domain is more likely than the partitioning into a tpy and two pyridine domains. Structure IV is the most symmetrical of the various possibilities. The two ligands

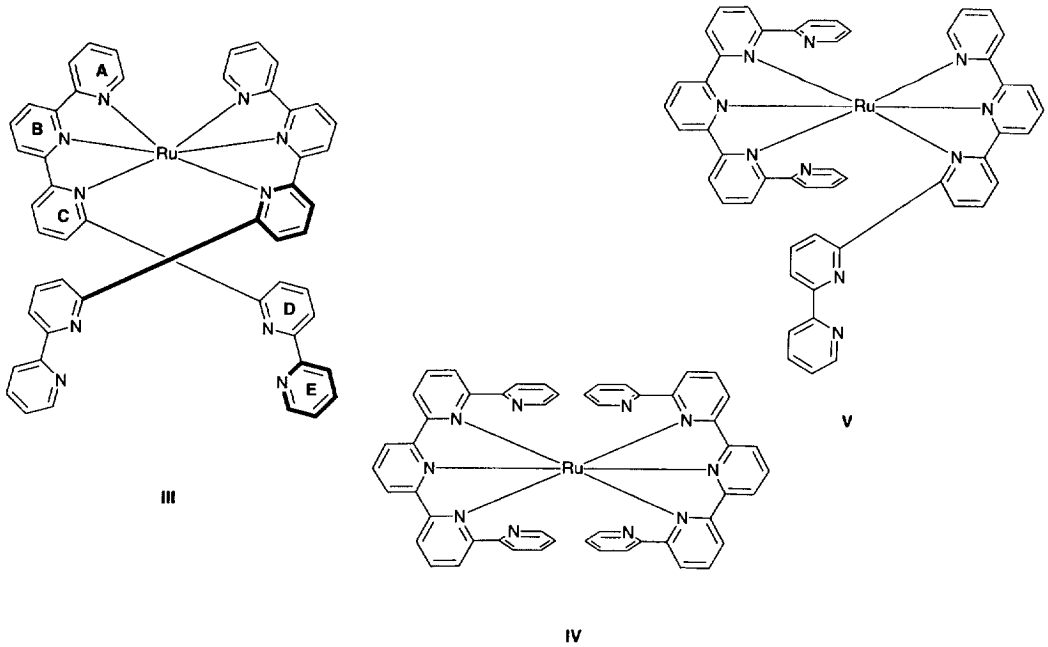

Fig. 4. Possible structures of the complex cations $[RuL_2]^{2+}$

are equivalent and each ligand is symmetrical about the central ring. Accordingly, structure IV would give rise to nine resonances for $[Ru(qpy)_2][PF_6]_2$. The 500 MHz ^1H COSY NMR spectrum of a CD_3CN solution of $[Ru(qpy)_2][PF_6]_2$ and is presented in Fig. 5. Without further analysis, it is immediately evident that the complexity of the spectra is not consistent with the symmetrical structure IV. This latter statement relies upon our previous comment that we are confident that only one of the structures III, IV or V is present.

Detailed analysis of this spectrum and the corresponding spectra for the complexes with dpqpy and dcqpy suggested that more than 17 (for qpy), 21 (for dpqpy) and 19 (for dcqpy) proton environments were present. We begin with a consideration of the spectrum of $[Ru(qpy)_2][PF_6]_2$. The most obvious feature is a low-field doublet at δ 8.9 with a coupling constant of 5.7 Hz which must be assigned to H^6 proton of a non coordinated ring. The COSY spectrum establishes the connectivity of this resonance (of intensity 1H) to three resonances of intensity 1/3 H at δ 7.6, 7.57 and 7.56. Subsequent analysis of the spectrum establishes the presence of three sub-spectra of very closely related compounds. The three subspectra consist of five separate connectivity systems in each case, although many of the expected 51 resonances are coincident and the connectivity is established through ^4J couplings. As was discussed earlier, the chromatographic behaviour argued strongly against the presence of mixtures of structures III, IV and V and the presence of a single H^6 proton of a non-coordinated ring is consistent only with structure III. Apparently three very similar isomers of structure III are present.

We have previously shown that in *N,N'*-bonded complexes of 6-phenyl-2,2';-bipyridine such as $[Ru(bpy)_2(Hpbpy)]^{2+}$ (Hpbpy = 6-phenyl-2,2'-bipyridine), the non-coordinated phenyl ring is stacked with one of the pyridine rings of a bpy ligand and cannot rotate freely about the interannular C—C bond to its directly bonded bipyridine unit [37]. We have also shown that related effects occur with hypodentate oligopyridine complexes [34–36]. Accordingly, each of the qpy ligands in $[Ru(qpy)_2][PF_6]_2$ can exist in two configurations related by the orientation of the non-coordinated bpy unit with respect to the coordinated tpy unit. This is illustrated for an archetypal $[Ru(qpy)(tpy)]^{2+}$ system in Fig. 6. In Fig. 6a, the non-coordinated bpy unit is oriented so that it faces forward and in Fig. 6b the corresponding isomer with it facing to the back is presented. The two cannot be interconverted without free rotation about the bond between the bpy and tpy components. If this were to occur, there would be serious steric interactions between the bpy unit and the other tpy ligand. Figure 6 also emphasises that in the parent $[Ru(qpy)(tpy)]^{2+}$ system, the two forms a and b are related as enantiomers. Figure 6c also introduces a notation which will simplify subsequent discussion . The tpy ligand is rotated so that it lies behind the plane of the paper and is represented as a hatched bar. The qpy ligand is oriented so that it lies in front of the plane of the paper and with the nitrogens of the terminal rings aligned vertically. The twisting about the C—C bond

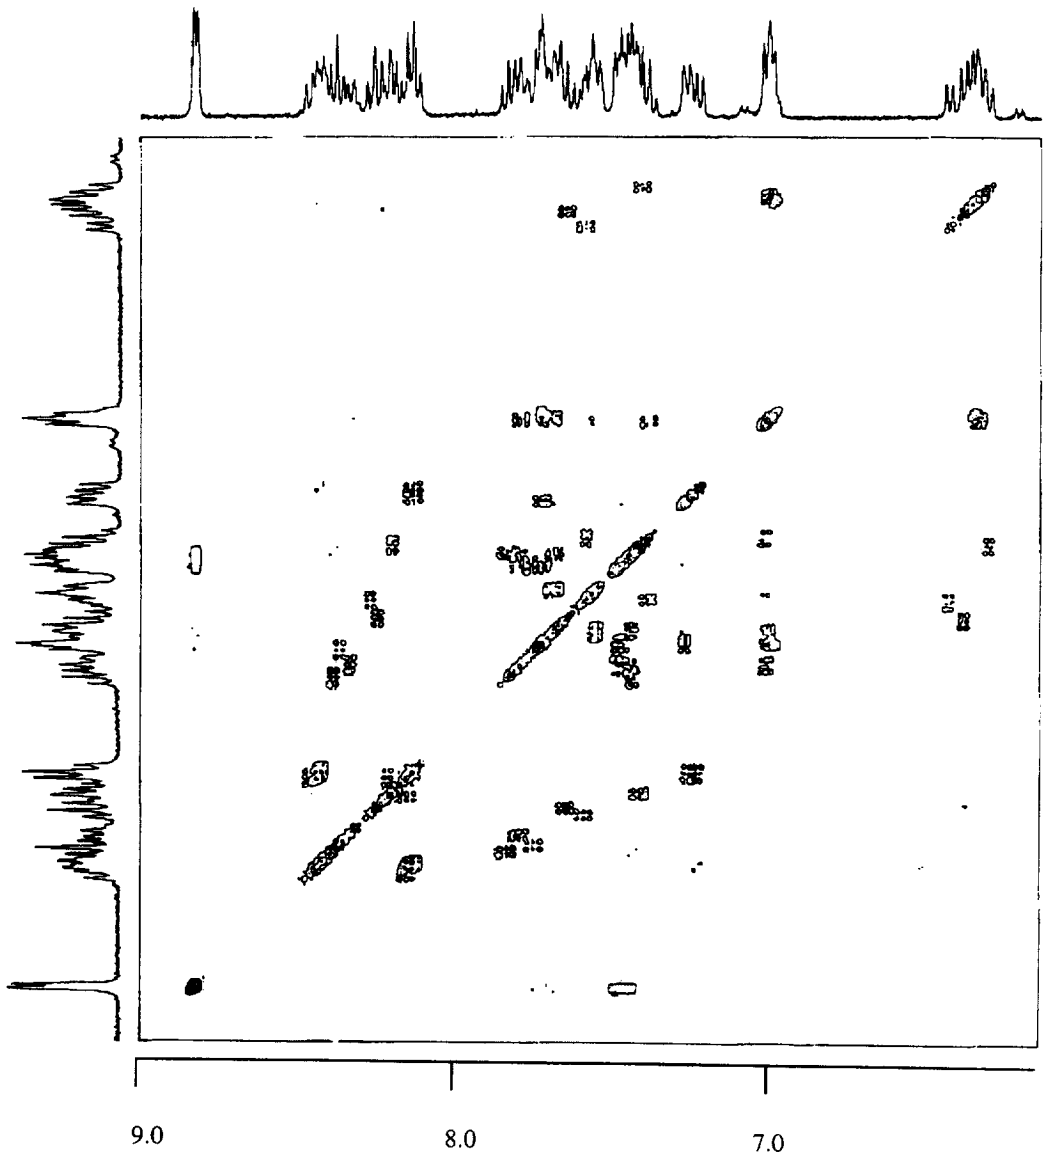

Fig. 5. 500 MHz ^{1}H COSY spectrum of $[Ru(qpy)_2][PF_6]_2$.

between the tpy and bpy domains of the qpy ligand is such that the two are near orthogonal. The qpy ligand is represented in solid black. Free rotation about the C—C bond of the two rings of the bpy domain is assumed.

The situation is more complicated when two such qpy ligands are present. Using the notation introduced in Fig. 6c, with the hatched ligand lying behind the plane of the paper, it is apparent that six isomers can exist, consisting of three enantiomeric pairs of conformers. Furthermore, these conformers cannot interconvert if free rotation about the bond between the tpy and bpy domains of each ligand is not possible. On the basis of this treatment we predict the three closely related species which occur in the spectrum of $[Ru(qpy)_2][PF_6]_2$ when it adopts the parent structure III. To conclude the discussion of the qpy complex, the experimental spectra are fully consistent with the presence of three conformers of structure III. The final assignments are given in Table 2, in which the sub-spectra IIIa, IIIb and IIIc are listed. The correlation of the individual rings to the individual sub-spectra is arbitrary—in other words, whilst the connectivity within the AIIIa ring of the BIIIa ring is absolutely certain, we do not know whether the AIIIa ring is bonded to the sub-spectrum for BIIIa, BIIIb or BIIIc nor can we, despite numerous attempts to deconvolute the high field NOESY spectra, unambiguously correlate the three sub-spectra a, b and c with the conformers α, β and γ.

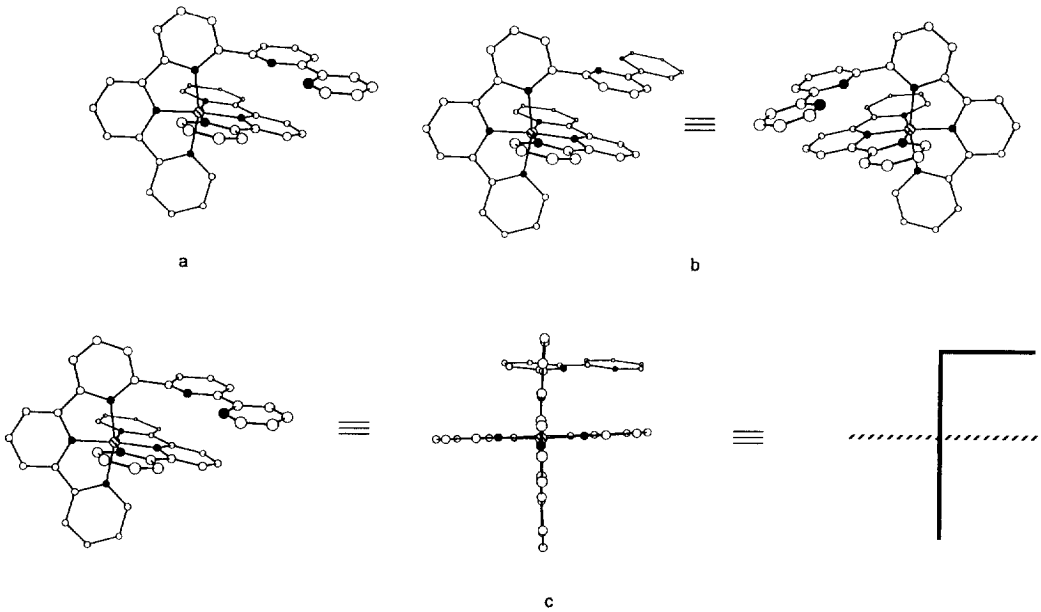

Fig. 6. Possible conformers of the complex cation $[Ru(tpy)(qpy)]^{2+}$. (a) One of the possible conformers is converted into (b) the other by rotation about the C—C bond between coordinated and non-coordinated rings. The new conformer is an enantiomer of the original conformer a. (c) A simple notation to describe the conformers of the $[Ru(tpy)(qpy)]^{2+}$ cation.

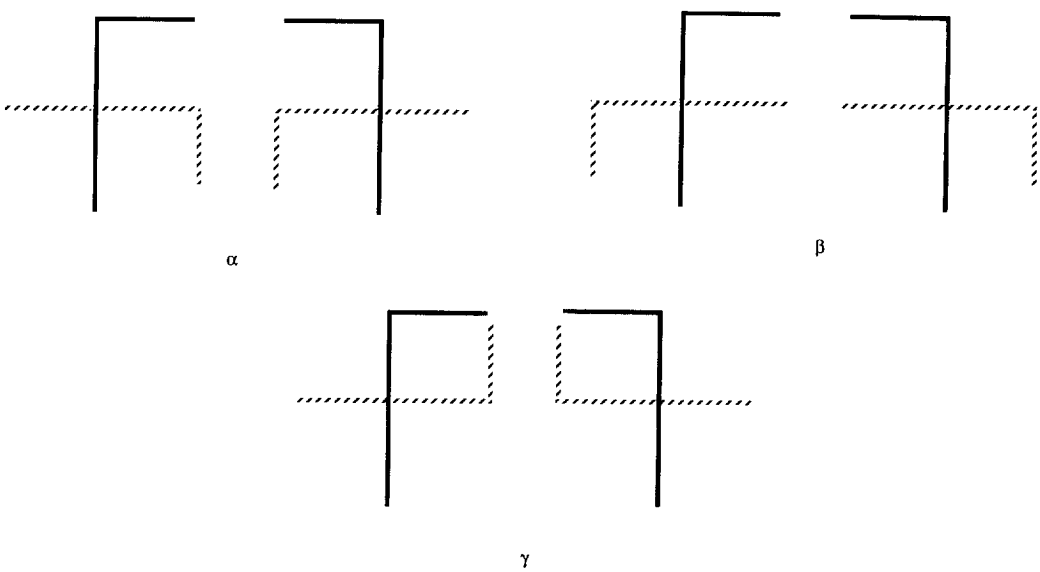

Fig. 7. Possible conformers of the complex cation $[Ru(qpy)_2]^{2+}$.

The introduction of additional substituents introduces more complexities to the system. Once again, all of the chromatographic analysis is consistent with the presence of just one of the isomers III, IV and V and a similar analysis to that discussed above leads to the conclusion that structure III represents the gross connectivity within the molecule. However, the presence of the additional aryl groups in the 4′ and 4‴-positions introduces new conformational possibilities. Returning to a simple model, Fig. 8a illustrates the effect of the introduction of a single phenyl substituent in a $[(4'\text{-Phqpy})(tpy)Ru]^{2+}$ complex. It is immediately apparent from Fig. 8a that the terminal non-coordinated pyridine ring and the aryl ring are spatially similar and that a conformer of type 8b will also exist. Figure 8c extends the earlier notation introducing a

dotted bar to represent the additional aryl ring. Moving directly to complexes with two substituted ligands, it follows that a total of three conformers are possible, each existing as a pair of enantiomers, as shown in Fig. 9. In the case of the α conformer, the two ligands are magnetically non-equivalent (most easily seen by considering the neighbours of the dotted aryl ring in Fig. 9) and will give rise to a separate sub-spectrum for each ligand. Accordingly, we predict a total of four sub-spectra corresponding to the three conformers α, β and γ from $[Ru(dpqpy)_2]^{2+}$ and it is extremely gratifying to find that the COSY spectrum reveals exactly this. Chemical shifts for the various sub-spectra, labelled a, b, c and d are presented in Table 2. Once again, the same provisos as discussed above for $[Ru(qpy)_2][PF_6]_2$ apply.

In conclusion, the ^{1}H NMR spectra of the $[RuL_2][PF_6]_2$ compounds are extremely complicated, but are fully compatible with the presence of only structure III complexes but with a number of non-interconverting conformers present in solution. Structure III is essentially very closely related to the structure II which was established for the $[RuL_2Cl_2][PF_6]_2$ complexes with the exception that the $RuCl_2$ unit is not present. This suggested that the $[RuL_2][PF_6]_2$ complexes could be viewed as precursors to $[RuL_2Cl_2][PF_6]_2$. The reaction of the $[RuL_2][PF_6]_2$ complexes with ruthenium trichloride in ethanol results in the quantitative conversion to $[RuL_2Cl_2][PF_6]_2$. Accordingly, we view these species as *prehelicates* or precursor complexes for the dinuclear double helicates.

CONCLUSIONS

We have shown that 2,2′:6′,2″:6″,2‴:6‴,2⁗-quinquepyridine ligands form mononuclear and dinuclear

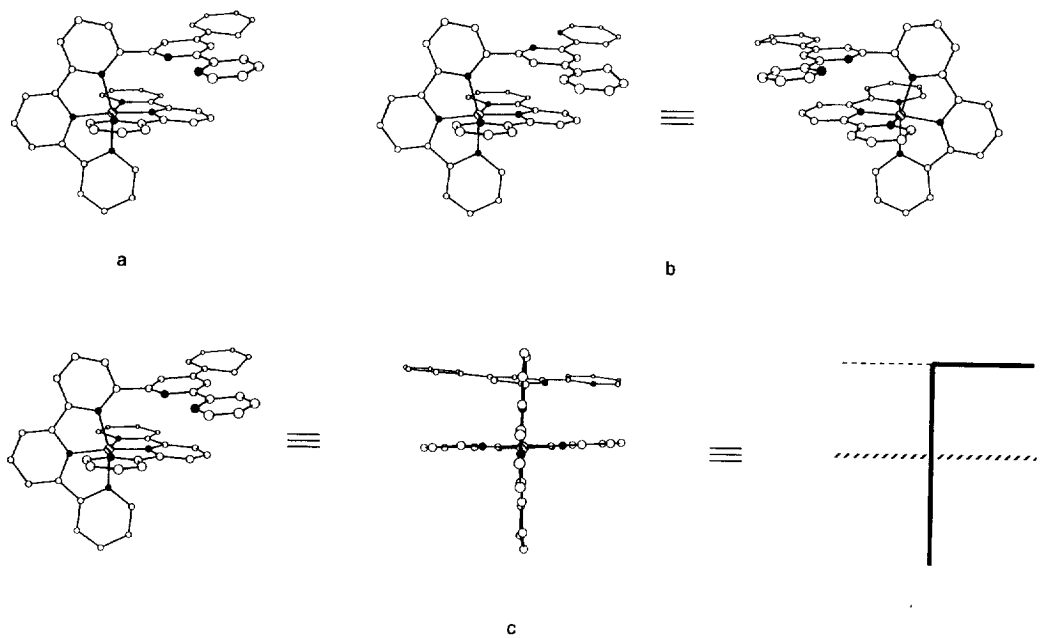

Fig. 8. (a, b) Possible conformers of the complex cation $[Ru(tpy)(4'\text{-Phqpy})]^{2+}$. (c) A simple notation to describe the conformers of the $[Ru(tpy)(4'\text{-Phqpy})]^{2+}$ cation.

ruthenium(II) complexes. The mononuclear complexes may be viewed as *prehelicates* in that they have a double helical ligand array with two non-coordinated bpy domains preorganised for coordination to a second metal centre. The dinuclear complexes are true double helicates and incorporate two six coordinate metal centres. We are currently investigating the extent of conformational effects in other hypodentate ligand systems are assessing the use of the *prehelicates* in the formation of heterodinuclear complexes.

(Received 13 October 1997; accepted 13 February 1998)

Abstract—Magnetically diluted systems of dithiocarbamate complexes of the type $^{63,65}Cu$/[Ni(II)—Me(II)—Dtc] (Me = Zn, Cd, Hg; Dtc = MDtc (dimethyl-) or EDtc (diethyldithiocarbamate)), which model the structural heterogeneity on the local, molecular and supramolecular levels, have been prepared and studied by means of ESR and solid state ^{13}C and ^{15}N CP/MAS NMR spectroscopy.

Three possible structures of these dithiocarbamate complexes were unambiguously identified in the composition of the samples under investigation: (i) the mononuclear square-planar, $Ni(Dtc)_2$; (ii) dinuclear with non-planar molecular configurations, $Me_2(Dtc)_4$ and (iii) heteropolynuclear complexes with a common composition of $Me_2(Dtc)_4 \cdot nNi(Dtc)_2$ (n = 1–4; Me = Zn, Cd, Hg). The latter is a newly proposed type of structure of dithiocarbamate complexes in the matrix of the model systems. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: dithiocarbamate complexes; structure; heteropolynuclear compounds; magnetically diluted systems; ESR spectroscopy; ^{13}C and ^{15}N CP/MAS NMR spectroscopy.

Dithiocarbamates play an important role in inorganic chemistry and technology, in rubber chemistry as vulcanizing agents, in the froth flotation process of sulphide minerals, in agriculture as fungicides and pesticides, in medicine as radioprotectors and for the treatment of the chronic alcoholism, as antioxidants and lubricants etc. Therefore studies of these compounds have attracted interest for about one hundred years.

Depending on experimental preparation conditions, some dithiocarbamate complexes of transition metals can adopt both mono- and binuclear types of molecular structures [1]. Monomeric molecules are square-planar while the dimeric species have non-planar configurations of the coordination polyhedra of the central atom (distorted tetrahedral, or trigonally-bipyramidal, or square-pyramidal). It is known that nickel(II) complexes have mononuclear square-planar molecular structures, $Ni(Dtc)_2$ [2–8], while zinc(II) [9–13], cadmium(II) [14,15] and mercury(II) [16] complexes have dimeric non-planar molecular configurations $Me_2(Dtc)_4$.

Depending on a sample preparation procedure interesting possibilities for structural organizations of these substances occur when both mono- and dinuclear complexes are present simultaneously: (i) Uniform distribution of monomeric and dimeric molecules (a "molecular mixture"); (ii) Phase microheterogeneity, when each species forms local spatial domains with a homogeneous molecular composition; (iii) Intermediate, between "i" and "ii".

In our previous publications [17–20] we have prepared copper(II)-doped samples of various dithiocarbamate complexes and studied their structural

* Author to whom correspondence should be addressed.

features by means of ESR spectroscopy. Unusual ESR spectra have been detected in samples consisting of both structural types discussed above. We have suggested that in many cases not only purely mononuclear or/and binuclear molecules, but also a new structural type could be identified. However, we failed to prepare this new structural model in the single crystal state and to elucidate its structure by means of X-ray diffraction data analysis: Two components (Ni and Zn; Ni and Cd; Ni and Hg) crystallize separately forming local spatial domains with a homogeneous molecular composition. Therefore, only indirect spectroscopic methods can be used to characterize this new structural type.

In this article we report the preparation procedure and spectroscopic ESR and solid state ^{13}C and ^{15}N CP/MAS NMR studies of dithiocarbamate complexes: [Ni(II)—Me(II)—Dtc](Me = Zn, Cd, Hg) which model this new structural situation. The main structural peculiarity of these dithiocarbamates is a simultaneous presence of both mononuclear and dinuclear molecules. In the present article we confirm the identification of a new structural type of dithiocarbamate complexes in the [Ni(II)—Me(II)—Dtc] systems and propose its molecular structure.

EXPERIMENTAL

Preparation of model systems

All chemicals were commercial materials and were used without further purification. Dimethyl- and diethyldithiocarbamate complexes of Ni, Zn, Cd and Hg were prepared according to the literature [2–16].

The model systems [Ni(II)—Me(II)—Dtc] were prepared at 363 K by mixing water solutions of nickel(II) salts and zinc(II), cadmium(II) or mercury(II) salts (with concentrations C = 0.5 M and experimental ratios Ni : Me = 1 : 9–9 : 1) with an excess (~10%) of sodium dimethyldithiocarbamate (MDtc) dihydrate, $Na(CH_3)_2NC(S)S \cdot 2H_2O$, or sodium diethyldithiocarbamate (EDtc) trihydrate, $Na(C_2H_5)_2NC(S)S \cdot 3H_2O$, as the ligands in aqueous solution. The full coagulation and final ageing were carried out at room temperature or at 363 K. Then the prepared dark green precipitates were collected, filtered off, washed with water and dried *in vacuo* over phosphorus pentoxide in a desiccator.

The above dithiocarbamate complexes and model systems are diamagnetic and small amounts of copper(II) (Cu : [Ni + Me] = 1 : 1000) were therefore added as spin-labels for ESR studies. Copper(II) salts with natural isotopic abundance and also isotopically highly enriched samples (^{65}Cu −99.2 at.%; ^{63}Cu −99.95 at.%) were used in the synthesis.

Physical measurements

ESR measurements were made at 298 and 77 K on a "RadioPAN" ESR spectrometer SE/X-2544 working at ~9.5 GHz. First and second derivatives of ESR signals were recorded, as well as the second derivative of the second harmonic (corresponding to the third derivative). The latter considerably improves the resolution of ESR spectra [21]. A microwave frequency was measured with microwavemeter MCM-101. The magnetic field was calibrated and measured using the NMR-gaussmeter JTM-246. The uncertainty of measurements was ±0.003 for g-values, and ±2% for the anisotropic hyperfine coupling (h.f.c.) constants: A_1^{Cu}, A_2^{Cu} and A_3^{Cu} (given in Gauss (G)).

Solid state natural abundance ^{13}C magic-angle-spinning (MAS) NMR spectra were recorded on a Chemagnetics Infinity CMX-200 (B_0 = 4.70 T) spectrometer using cross-polarization (CP) from the protons together with proton decoupling [22]. The ^{13}C operating frequency was 50.35 MHz. The proton $\pi/2$ pulse duration was 3.8 μs, CP mixing time 2 ms and the nutation frequency of protons during decoupling $\omega_{nut}/2\pi$ = 88 kHz. For different samples from 1536 to 18,432 transients with a relaxation delay of 2 s were accumulated. Powder samples (ca. 50 mg) were packed into zirconium dioxide standard double bearing 4.0 mm rotor systems. The spinning frequencies for all samples were 4000 and/or 6000 Hz and stabilized to ±3 Hz using an inbuilt stabilization device. All ^{13}C chemical shift data were externally referenced to the least shielded resonance of solid adamantane at 38.56 ppm relative to tetramethylsilane [23].

Natural abundance ^{15}N CP/MAS NMR spectra were recorded on a Chemagnetics Infinity CMX-360 (B_0 = 8.46 T) spectrometer. The ^{15}N operating frequency was 36.48 MHz. The proton $\pi/2$ pulse duration was 3.2 μs, CP mixing time 3.5 ms and the nutation frequency of protons during decoupling was 50 kHz. A total of 17,600 transients, spaced by relaxation delays of 2 s, were accumulated. Powder samples (ca. 350 mg, 7.5 mm rotors) were spun at the spinning frequencies of 6000 Hz. ^{15}N isotropic chemical shifts are given with respect to NH_4Cl powder (0 ppm, externally referenced) [24,25]. The drift of the ^{15}N frequency (B_0—drift) was 0.016 Hz h^{-1}.

All solid state ^{13}C and ^{15}N CP/MAS NMR spectra were recorded at room temperature (ca. 300 K).

RESULTS AND DISCUSSION

ESR measurements

Figure 1 shows ESR spectra (first derivative) of magnetically diluted systems of diethyldithiocarbamate Ni and Zn complexes. Minute quantities (Cu : Me = 1 : 1000) of the copper isotopes, ^{63}Cu or ^{65}Cu, were used as spin-labels for ESR measurements. As we already reported, copper(II) can substitute Ni(II), Zn(II), Cd(II) and Hg(II) in dimethyl-, diethyl-, dibutyl-, pentamethylene-, hexamethylene- and morpholinedithiocarbamate complexes without considerable distortions of an original structure of

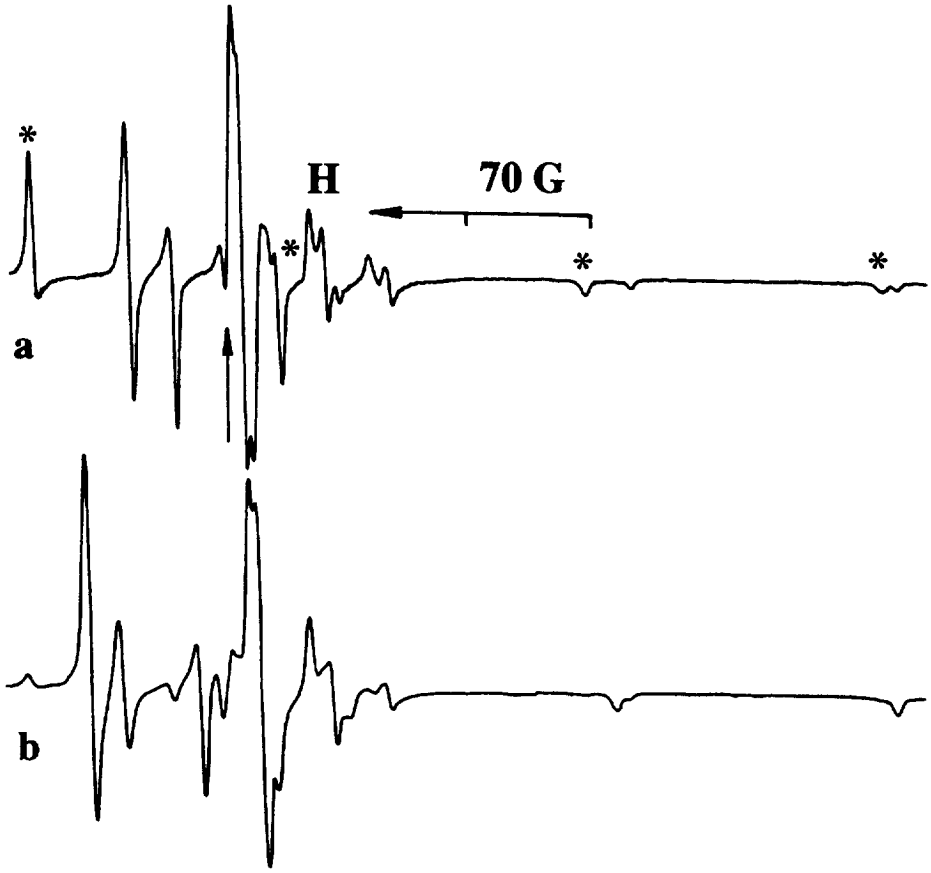

Fig. 1. ESR spectra of magnetically diluted systems with ratio Ni : Zn = 1 : 1 and ^{63}Cu : Me = 1 : 1000: (a) a mechanical mixture of ^{63}Cu(II)/[Ni(II)-EDtc] and ^{63}Cu(II)/[Zn(II)-EDtc]. Both the square-planar CuS_4 and the trigonal-bipyramidal CuS_5 chromophores are present. ESR components of the parallel orientation corresponding to the mononuclear complex (structural state **I**) are shown by asterisks (*). The other components correspond to the dinuclear complex (structural state **II**). The vertical arrow shows the position of DPPH signal; (b) ^{63}Cu(II)/[Ni(II)-Zn(II)-EDtc]. The square-pyramidal chromophore CuS_5 (structural state **III**) is dominated.

undoped complexes [17–20]. Therefore ESR signals from copper(II) can reveal structural features of these systems.

Figure 1a shows ESR spectrum of the mechanical mixture of ^{63}Cu(II)/[Ni(II)-EDtc] and ^{63}Cu(II)/[Zn(II)-EDtc]with the ratio of the metals Ni : Zn = 1 : 1. It is known that the dithiocarbamate nickel(II) complexes adopt the square-planar molecular structures[2–8] (structural state **I**), while Zn(II)-EDtc molecules are predominantly in the dinuclear states with a distorted trigonal bipyramidal or a distorted tetrahedral configurations of coordination polyhedra of the central atom [9–13] (structural state **II**). Therefore well-resolved hyperfine structures from both structural states of copper(II) are present simultaneously in the ESR spectrum. For each copper(II)-doped complex there is a quartet of resonance lines due to the hyperfine interaction of the unpaired electron with the ^{63}Cu or ^{65}Cu nuclear spin ($I = 3/2$) in each of the three principal orientations of the hyperfine coupling tensor. ESR parameters for various dithiocarbamate complexes, i.e. three different components of both g- and A-tensors, are summarized in Table 1. In this table data for dimethyldithiocarbamate complexes and for complexes of other metals (Cd, Hg) are also given (ESR spectra not shown).
