Both g- and A-tensors of the first structural state (**I**) are almost axially symmetric with large parallel and small perpendicular components. However, there is a slight rhombicity of the ESR parameters in the xy-plane. This type of anisotropy reflects a slight unequivalence of Me—S chemical bonds which can be connected with a small rhombic distortion of a square-planar chromophore. As we reported earlier ESR parameters of the structural state **I** are extreme compared to copper(II) complexes with S-homogeneous coordination spheres [21]. Namely, g_1, g_2 and g_3 have minimal while A_1^{Cu}, A_2^{Cu} and A_3^{Cu} constants maximal possible values. These features are characteristic for the square-planar chromophores CuS_4. Therefore, both the character of experimental spectra

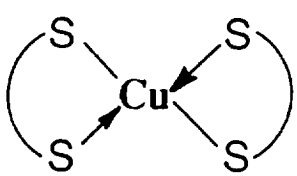
** Data from Ref. [28] for square-pyramidal adducts of bis-(diethyldithiocarbamato)copper(II) with axial coordination of organic sulphur bases (L-O-butyl-*N*-methyl- or O-butyl-*N*,*N*-diethylthionocarbamate; L'-cyclic organic sulphides: 2-methyltetrahydrothiophene, 2-hexylthiane, 3-amylthiane). Experimental conditions: toluene glasses at 77 K.

and ESR parameters can be used in the identification of the structural state **I**, Cu(Dtc)$_2$, with the square-planar mononuclear geometry (Scheme 1).

ESR-parameters of the second structure (II) reflect non-planar configurations of copper(II) coordination polyhedra: distorted tetrahedral, distorted trigonally-bipyramidal or distorted square-pyramidal (see Table 1) [17,18]. The stabilization of paramagnetic chromophores with unusual types of geometry: tetrahedral CuS_4, square-pyramidal and trigonally-bipyramidal CuS_5 can be explained by a formation of heterodinuclear complexes—CuMe(Dtc)$_4$ (Me = Zn, Cd, Hg) by means of a chemical interaction between the paramagnetic component and the diamagnetic matrix [26] The molecular structures of the corresponding zinc(II), cadmium(II), mercury (II) [9–16] and copper(II) [27] dithiocarbamate complexes are very similar. X-ray diffraction data show that all complexes are binuclear with two dithiocarbamate-bridged ligands. Scheme 2 shows the molecular structure of these heterobinuclear complexes.

Figure 1b shows ESR spectrum of a model Cu(II)/[Ni(II)-Zn(II)-EDtc] system with the Ni:Zn ratio 1:1. Components of the hyperfine structure corresponding to the square-planar molecules almost



Scheme 1. The main fragment of the molecular structure of mononuclear square-planar complexes: Cu(Dtc)$_2$.

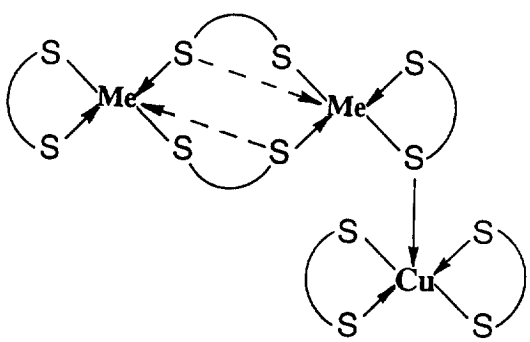
vanish in spite of the equal experimental ratio of the Ni and Zn metals. Instead, a high intensity "intermediate" ESR signal and the components of a moderate intensity from the dimeric form appear in the spectrum. Moreover, it was established that the "intermediate" is not an independent signal. It is a "satellite" of the signal of the dinuclear form. In fact it is not possible to observe the "intermediate" signal without the signal of a dinuclear complex in the experimental ESR spectra. This "intermediate" signal is assigned here to a new structural state (**III**) of copper(II) in the composition of magnetically diluted systems Cu/[Ni(II)-Me(II)-Dtc]. It is also tabulated in Table 1. A pertinent question arises, since nickel(II) and zinc(II) dithiocarbamate complexes adopt two different types of molecular structures, the mononuclear square-planar and the dinuclear with non-planar configurations respectively, what is a new structural state (**III**) detected in the model systems Cu(II)/[Ni(II)-Me(II)-Dtc]?

The third structural position of copper(II) is characterized by ESR parameters, which are typical for molecules with axial symmetry (see Table 1). Both

hyperfine coupling constants and g-values of the structural state **III** are very close to those formed by square-pyramidal adducts of bis(diethyldithiocarbamato) copper(II) with axially coordinated molecules of organic sulphur bases, $Cu(EDtc)_2L$, which have a homogeneous coordination sphere of sulphur atoms [28] (see Table 1). Therefore, it can be proposed that copper(II) in the structural state **III** forms the square-pyramidal chromophore CuS_5. The main reason for this deviation from the square-planar polyhedron towards the square-pyramidal one is the coordination of the terminal sulphur atom of the dinuclear molecule, $Me_2(Dtc)_4$, to the axial position of the mononuclear molecule—$Cu(Dtc)_2$ (Scheme 3).

Experimental data show that the square-planar structure of mononuclear complexes cannot be realized in the model systems [Ni(II)-Me(II)-Dtc]. This is because of a partial coordination unsaturation of copper(II) in $Cu(Dtc)_2$ in combination with a neighbouring environment of dimeric non-planar molecules $Me_2(Dtc)_4$. In this situation copper(II) occupies a new magnetic and structural position (**III**) which is readily revealed by ESR. One can also say that the formation of a new chemical bond is equivalent to the formation of a heterotrinuclear complex.

Important structural information can also be derived from the ratio of signal intensities of states **III** and **II**. For magnetically diluted trinuclear complexes a theoretical ratio of signal intensities **III/II** must be equal to 1:2 in accordance with a probability of a substitution of metal atoms by copper(II) in the "mononuclear" and "dinuclear" parts of trinuclear complexes. But in experimental spectra this ratio can vary from 1:2 to 2:1. This can be explained by a formation of new chemical bonds between a dinuclear and several mononuclear molecules: two (1:1), three (3:2) or four (2:1). Therefore, in principal, polynuclear complexes $Me_2(Dtc)_4 \cdot nNi(Dtc)_2$ (n = 1–4; Me = Zn, Cd, Hg) can be formed with almost identical ESR parameters of all square-pyramidal coordination polyhedrons in the corresponding copper(II)-doped systems.



Scheme 3. The main fragment of the molecular structure of trinuclear complexes: $Cu(Dtc)_2$ $Me_2(Dtc)_4$ (Me = Zn, Cd, Hg)

^{13}C and ^{15}N CP/MAS NMR measurements

In order to confirm the above conclusions and establish further information the model systems were also studied by means of solid state ^{13}C and ^{15}N CP/MAS NMR spectroscopy. Figure 2a shows ^{13}C NMR spectrum of bis(diethylditiocarbamato) nickel(II). There are three resonances which can be assigned to the three inequivalent ^{13}C sites of ligands: methyl, methylene and dithiocarbamate groups: CH_3—, —CH_2— and =NC(S)S—. Both chemical shifts and the corresponding ratios of integral intensities (2:2:1) were used in the assignment. Note that chemical shifts of these three resonances are in accordance with data for natrium diethyldithiocarbamate

Fig. 2. The 50.35 MHz ^{13}C CP/MAS NMR spectra of the following complexes: (a) $Ni(EDtc)_2$; (b) $Zn_2(EDtc)_4$; (c) the model system [Ni(II)-Zn(II)-EDtc]. The experimental ratio Ni:Zn = 1:1. The MAS frequency was 4 kHz.

powder (Table 2). Experimental splittings of the asymmetric doublets for methylene and dithiocarbamate groups (85 and 70 Hz, respectively) arise from the incomplete suppression of the dipolar interaction between ^{13}C ($I = 1/2$) and quadrupolar nucleus ^{14}N ($I = 1$) by the MAS experiment [29,30]. Figure 3a shows ^{15}N NMR spectrum of the nickel(II) complex. The single resonance reflects undoubtedly the magnetic equivalence of dithiocarbamate ligands. Both ^{13}C and ^{15}N NMR measurements of bis(diethylditiocarbamato)nickel(II) agree well with X-ray diffraction data showing the mononuclear centrosymmetrical molecule with two structurally equivalent chelating diethyldithiocarbamate ligands [8].

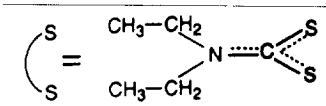
Figures 2b and 3b show ^{13}C and ^{15}N CP/MAS spectra of the dinuclear zinc(II) complex. Each of the three corresponding ^{13}C resonances (methyl, methylene and dithiocarbamate groups) and ^{15}N resonance are split distinctly in doublets. These splittings reflect a structural difference between pairs of diethyldithiocarbamate ligands in the zinc(II) complex. Indeed, there are two groups of ligands with heterogeneous structural functions in the dinuclear zinc(II) diethyldithiocarbamate as is also confirmed by X-ray data analysis [10]. Each of two terminal ligands form the four-membered chelate ring (as in the nickel(II) complex) and two bridged ligands are coordinated by two zinc atoms and form an extensive eight-membered ring.

In order to assign ^{13}C and ^{15}N resonances to the terminal or to the bridged ligands, dithiocarbamate N—C interatomic distances were examined in both nickel(II) and zinc(II) complexes. The X-ray data analysis shows that the dithiocarbamate group is planar practically in all known transition metal complexes [2–16]. This is due to a considerable contribution of the double-bond character to single bonds in the =NC(S)S— group. The double-bond contribution varies from small values for relatively ionic compounds [31,32] to rather large values for mainly covalent complexes [2–16]. In the latter case a considerable δ^+ charge is localized on the nitrogen atom, while a δ^- charge is delocalized on the four-membered metallochelate ring CS_2Me (Scheme 4).

It is known that an admixture of the sp^2-hybridized state leads simultaneously to the decrease of both the N—C interatomic distance and the degree of shielding of the nitrogen nucleus by electrons. Table 3 shows N—C and C—S interatomic distances in relevant complexes obtained from X-ray data analysis [8,10,33]. From these data we can conclude that the largest carbon-nitrogen partial-double-bond character is at the bridged dithiocarbamate ligands of the $Zn_2(EDtc)_4$ complex. It corresponds to the largest deshielding of nitrogen nucleus and to the largest ^{15}N chemical shift value (δ = 149.8 ppm.). The other resonance can be assigned to the ^{15}N sites at the therminal ligands (δ = 136.8 ppm, see Fig. 3b).

Table 2. ^{13}C and ^{15}N chemical shifts of diethyldithiocarbamate complexes (from TMS and NH_4Cl)

Complex	Chemical Shifts (ppm)				
	=NC(S)S—	—CH_2—	—CH_3	=N—	
	204.2 (70)*	46.2 (85)*	12.8	139.4	
	202.1 (72)* 199.5 (70)*	49.7 50.6	12.7 14.5	136.8 149.8	(terminal) (bridged)
	201.8	50.4	12.4	136.5	(terminal)
	199.5	50.4	14.5	149.5	(bridged)
	205.8 (82)*	43.9	12.4	131.6 133.9	
Na(EDtc)	206.5	48.6	13.2	139.0	



* ^{13}C–15N asymmetric doublets (in Hz).

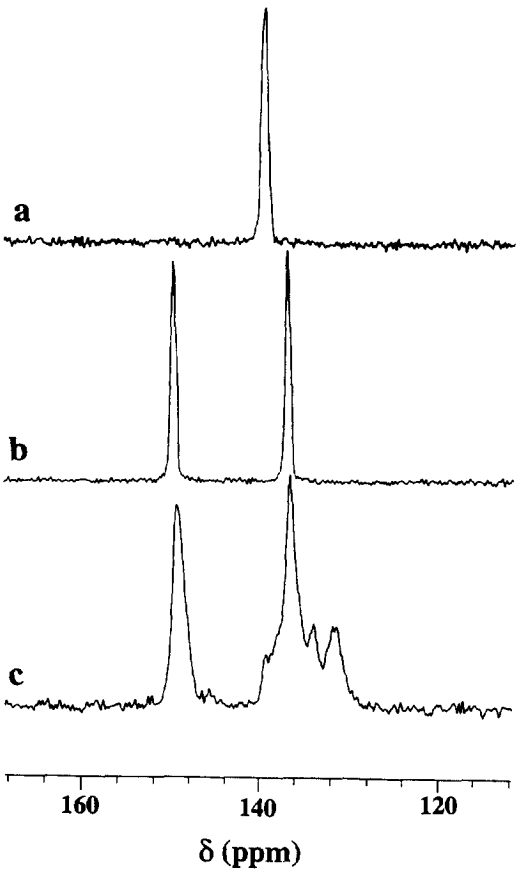


Fig. 3. The 36.48 MHz ^{15}N CP/MAS NMR spectra of $Ni(EDtc)_2$ (a), $Zn_2(EDtc)_4$ (b), and [Ni(II)-Zn(II)-EDtc](c) complexes. The MAS frequency was 6 kHz.

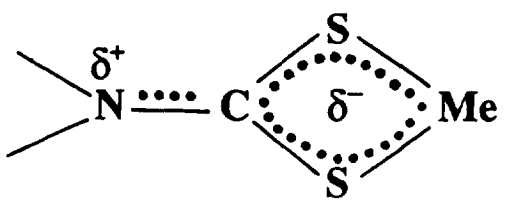


Scheme 4. The charge distribution in a dithiocarbamate group with the N—C partial-double-bond character.

Since the surplus charge δ^- is delocalized at the four-membered chelate ring CS_2Zn, the largest shielding of the ^{13}C sites is expected at the dithiocarbamate groups with the shortest N—C bond, i.e. at the bridged ligands of the $Zn_2(EDtc)_4$ complex. Owing similar arguments, we can assign the ^{13}C resonance at $\delta = 199.5$ ppm to the N—C site of the bridged ligands. It is also expected that the electron density is displaced from carbon atoms of methylene and methyl groups to the nitrogen atom which has the surplus charge δ^+. Therefore ^{13}C resonances at $\delta = 50.6$ and 14.5 ppm can be assigned to the methylene and methyl sites at the bridged ligands respectively.

The nickel(II) complex has an intermediate value for the N—C bond length and therefore also for an admixture of the sp^2-hybridized state at the nitrogen atom. Indeed, the ^{15}N chemical shift value for the nickel(II) complex is equal to 139.4 ppm which is between two ^{15}N resonances of the dinuclear zinc(II) complex. However, ^{13}C chemical shift value for the dithiocarbamate site at the nickel(II) complex fall out of these empirical correlations. In order to explain this an influence of the second factor, namely C—S bond lengths, was examined. Both C—S chemical bonds in the $Ni(EDtc)_2$ molecule are very short (see Table 3). Therefore, sulphur atoms which have a relatively high electronegative character cause an additional (compared to the zinc(II) complex) displacement of the electron density from the dithiocarbamate carbon atom, i.e. cause an additional deshielding of this site.

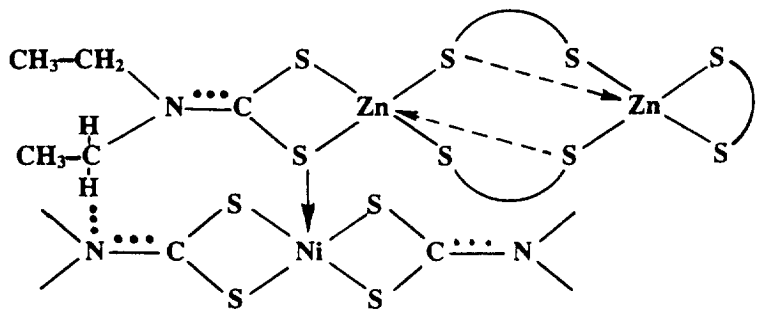
Even though the empirical correlations between chemical shifts and electron densities can be established for complexes discussed above, we stress here that theoretical calculations of chemical shifts are needed for more detailed structural elucidations. There has been recent progress in establishing correlations between calculated chemical shift values and structure both in small molecules and macromolecules such as peptides and proteins [34].

Figures 2c and 3c show ^{13}C and ^{15}N CP/MAS spectra of the model system [Ni(II)-Zn(II)-EDtc] (with Ni : Zn = 1 : 1) which consists of polynuclear complexes (**III**). It can be seen that both ^{13}C and ^{15}N sites of the "dinuclear" part of this polynuclear complex have chemical shifts which are very close to those of the corresponding sites of the zinc(II) complex (see Table 2). However, two new ^{13}C (see Fig. 2c) and two new ^{15}N resonances (Fig. 3c) of the above model system can not be assigned neither to the pure nickel(II) nor to the zinc(II) complexes. These four new resonances were assigned to ^{13}C and ^{15}N sites of dithiocarbamate groups and to ^{13}C sites of the methylene groups of diethyldithiocarbamate ligands in the square-planar molecules which are coordinated to the sulphur atoms in the terminal ligands of the dinuclear zinc(II) complex (see Table 2). It is known that an additional coordination of an electron donor atom to the axial position of a square-planar transition metal dithiocarbamates yields a decrease of the nitrogen-carbon partial-double-bond character and, as result of that, a displacement of the electron density from the carbon to the nitrogen atom in the metallochelate ring [35]. In our case the coordination of the sulphur atom to the axial position of the $Ni(EDtc)_2$ molecule leads to an increase of the ^{13}C chemical shift (by 1.6 ppm) and to a decrease of ^{15}N ones (by 6.7 ppm, in average) at the =NC(S)S— site. A decrease of the nitrogen δ^+ charge results in an enhanced shielding of methylene ^{13}C nuclei and therefore the decrease of the chemical shift (by 2.3 ppm) of these sites.

It is important to note the appearance of the two

Table 3. The interatomic distances in =NC(S)S— group of diethyldithiocarbamate compounds

Complex	$Ni(EDtc)_2$ [8]	$Zn_2(EDtc)_4$ [10]		$Na(EDtc)$ [33]
Distance N—C, Å:	1.324 (3)	1.340 (13) (terminal)	1.310 (12) (bridged)	1.339 (4)
Distance C—S, Å:	1.714 (3)	1.722 (10) (terminal)	1.723 (10) (bridged)	1.713 (3)
	1.715 (3)	1.725 (10)	1.737 (9)	1.729 (3)



Scheme 5. Scheme of interaction between "dinuclear" and "mononuclear" parts in the polynuclear complexes.

structurally unequivalent ^{15}N sites (131.6 and 133.9 ppm) of the "nickel part" of the heteropolynuclear complex. This means that nitrogen atoms of the two dithiocarbamate ligands have different electronic environments. The most probable explanation for this structural unequivalence is the formation of a hydrogen bond between one of nitrogen atoms of the Ni(II) complex and a methylene group of the terminal ligand of the dinuclear molecule (Scheme 5).

The result of this interaction is the increase of ^{15}N chemical shift by 2.3 ppm which reflects the decrease of shielding of the corresponding nitrogen atom compared to the other one. The hydrogen bond formation is sterically allowed since the four-membered chelate ring of the dinuclear Zn(II) molecule is perpendicular to the plane of the square-planar Ni(II) complex. The other nitrogen atom of the "nickel part" of the heteropolynuclear complex is in a different environment, since the dinuclear molecule is non-planar. The dihedral angle between planes of the eight- and four-membered chelate rings is close to 90 .

CONCLUSIONS

Dithiocarbamate complexes of the type [Ni(II)-Me(II)-Dtc] (Me = Zn, Cd, Hg; Dtc = MDtc (dimethyl-) or EDtc (diethyldithiocarbamate)), which model a structural heterogeneity on the local, molecular and supramolecular levels, have been prepared and studied by means of ESR and solid state ^{13}C and ^{15}N CP/MAS NMR spectroscopy.

Three possible structures of these dithiocarbamate complexes were unambiguously identified: (i) the mononuclear square-planar, $Ni(Dtc)_2$; (ii) dinuclear with non-planar molecular configurations, $Me_2(Dtc)_4$ and (iii) polynuclear (supramolecular) complexes with a common composition of $Me_2(Dtc)_4 \cdot nNi(Dtc)_2$ (n = 1–4; Me = Zn, Cd, Hg). The latter is a newly proposed type of structure of dithiocarbamate complexes in the matrix of the model systems. It was established that the simultaneous presence of mononuclear and dinuclear molecules of dithiocarbamates in the prepared samples can lead to the formation of the heteropolynuclear complexes.

(Received 17 December 1997: accepted 18 February 1998)

Abstract—The formation of the compounds $C_4H_7Br_2NSSe$ (**3**), $(C_4H_7BrNS)_2[SeBr_6]$ (**4**) and $C_8H_7Br_2NSSe$ (**5**) from the reaction of the title selenium donors (**1** and **2**) with molecular dibromine in CH_2Cl_2 and MeCN solutions has been investigated by ^{77}Se and ^{13}C NMR, UV-visible spectroscopies and by conductometric measurements. In the conductometric titrations of **1** or **2** with dibromine, the very low values of conductivity recorded up to the 1 : 1 Br_2/**1**(**2**) molar ratio indicate the formation of the non-conducting hypervalent selenium compounds **3** and **5**, as confirmed by UV–visible and NMR spectroscopies. Above this ratio, **1** and **2** behave differently; in fact, for both of them the conductivity values increase on increasing the amount of added dibromine, but the values recorded for **1**, that are much higher than those for **2**, are time-dependent. This indicates a kinetic transformation of **1** that has been shown to lead to the previously characterized **4**. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: *N*-methylthiazolidine-2(3H)-selone; *N*-methylbenzothiazole-2(3H)-selone; hypervalent selenium compounds with bromine; hexabromoselenate(2-); conductometric measurements; ^{77}Se and ^{13}C NMR and UV–visible spectroscopies.

In our investigations on the donor/acceptor interactions between heterocycles containing thionic and selonic groups and dihalogens or interhalogens [1–6], we have found that, besides the donor/acceptor adducts, a large variety of products can be obtained and that X-ray crystal structure determination plays a crucial role in their characterization. As a development of our research in this field, we have recently reported the results obtained by reacting *N*-methyl-1,3-thiazolidine-2(3H)-selone (**1**) and *N*-methylbenzothiazole-2(3H)-selone (**2**) with molecular dibromine in CH_2Cl_2 solution [6] (Scheme 1). Whatever the reagent molar ratio, **2** gives the hypervalent compound $C_8H_7Br_2NSSe$ (**5**), which bears the Br—Se—Br linear group. **1** gives the hypervalent compound $C_4H_7Br_2NSSe$ (**3**) when the reaction is carried out in 1 : 1 Br_2/**1** molar ratio, while by using the 2 : 1 or higher reagent molar ratios, the ionic compound $2[C_4H_7BrNS]^+ [SeBr_6]^{2-}$ (**4**) is obtained. Compounds **4** and **5** were characterized by X-ray crystal structure determination [6].

Since **4** represents the unique case reported in literature where oxidation of the selenium of a selonic group leads to hexabromoselenate(2-), we thought of investigating its formation in CH_2Cl_2 as well as MeCN solution by UV–visible, ^{77}Se and ^{13}C NMR, and conductometric titration techniques.

EXPERIMENTAL

Materials

N-methyl-1,3-thiazolidine-2(3H)-selone (**1**) was synthesized according to the procedure reported in Ref. [7]. *N*-methylbenzothiazole-2(3H)-selone (**2**), dibromine and the solvents (CH_2Cl_2 and MeCN) were purchased from Aldrich and used without further purification.

Conductometric titrations

Conductometric titrations were carried out at $T = 298$ K in CH_2Cl_2 solution in a standard-thermostatted cell with a Model 120 Microprocessor Conductivity Meter Analytical Control. The k cell (1.23 cm^{-1}) was determined by measuring at $T = 298$ K the conductivity of three bidistilled water solutions of KCl (0.1, 0.01 and 0.001 mol dm^{-3} respectively) previously kiln-dried for 12 h. Conductivity was recorded after 5 minutes from each Br_2 addition in order to allow the stabilization of the temperature. In the titration of **1**, since conductivity showed a continuous increase with time, the conductivity values were also recorded after 10 minutes from each addition. The CH_2Cl_2 solutions of Br_2 were titrated with a standard aqueous $Na_2S_2O_3$ solution (0.100 mol dm^{-3}) according to traditional methods.

Kinetic measurements and data treatment

The kinetic measurements ($T = 298$ K, CH_2Cl_2 solution, [**1**] = $1 \cdot 10^{-2}$ mol dm^{-3}) have been carried out in *pseudo*-first order conditions (large excess of dibromine) by mixing pre-thermostatted solutions of the reagents and recording the changes of conductivity with time. Straight lines have ben obtained by reporting $\ln(\sigma_t - \sigma_t)/(\sigma_t - \sigma_0)$ vs time (σ_0 and σ_t are the conductivity values in μS cm^{-1} at time 0 and ∞ respectively).

Ultraviolet spectra

Spectrophotometric measurements were carried out in CH_2Cl_2 and in MeCN solutions by using a Varian model Cary 5 UV–vis–NIR spectrophotometer equipped with a temperature controller accessory and connected with an IBM Personal System 2 Type 8513 TKQ S/N 55-DMR89. For both **1** and **2**, the spectra of 9 different solutions, with a Br_2/donor molar ratio ranging from 0.3 to 6 were recorded in the range 200–400 nm at the temperature of $T = 298$ K. Because of

the kinetic process for the reaction between **1** and Br_2, the spectra of their mixtures were recorded immediately after mixing the pre-thermostatted solutions of the reagents.

^{77}Se and ^{13}C NMR measurements

^{77}Se and ^{13}C NMR spectra were recorded at a temperature of 293 K by a Varian Unity 300 MHz spectrometer. Chemical shifts are quoted relative to Me_2Se ($\delta = 0$) for the ^{77}Se nucleus and TMS or DMSO-d_6, as the external reference, for the ^{13}C nucleus. For **1**, several solutions having the same donor concentration ($2.7 \cdot 10^{-2}$ mol dm^{-3}) and increasing amounts of dibromine (maximum value $[Br_2]/[\mathbf{1}]$ molar ratio 6) were prepared and their NMR spectra recorded some hours afterwards mixing the reagents. ^{77}Se spectra of compounds **3**, **4** and **5**, which have low solubility in CH_2Cl_2, were only recorded in MeCN solution at a concentration of approximately $2.7 \cdot 10^{-2}$ mol dm^{-3}.

RESULTS AND DISCUSSION

Depending on the reagent molar ratios, the reactions of *N*-methyl-1,3-thiazolidine-2(3H)-selone (**1**) and *N*-methylbenzothiazole-2(3H)-selone (**2**) with molecular dibromine in CH_2Cl_2 solution give the solid products, **3**, **4** and **5** [6, 8]. In fact, using a Br_2/donor 1 : 1 molar ratio, both donors yield the hypervalent selenium compounds **3** and **5**, bearing the Br—Se—Br linear group; with a 2 : 1 molar ratio, **2** gives **5** again, and **1** gives **4**.

In order to understand the different reactivity of **1** and **2** towards Br_2 and to ascertain whether **4** exists in solution or is formed only during the crystallization process, we prepared several solutions of **1** and **2** and Br_2 in different stoichiometric ratios and recorded their conductivities, ultraviolet absorption spectra and ^{77}Se and ^{13}C NMR chemical shifts.

Conductometric measurements

The conductometric titrations of **1** and **2** with Br_2, carried out in CH_2Cl_2 solution, show that the conductivity up to the 1 : 1 Br_2/**1**(**2**) molar ratio is constant and very low, for **2** lower than for **1** by about one order of magnitude. This indicates the formation of non-conducting species, which are very likely to be the hypervalent selenium compounds **3** and **5**.

Above the 1 : 1 molar ratio, **1** and **2** behave differently: while for **2**, conductivity does not vary after each addition of the Br_2 solution, for **1** it changes with time, and the drift continues beyond the titration until **4** starts precipitating. Moreover, the conductivity values for **2** still remain lower than for **1**.

It is important to remark once more that in the first part of the titration of **1** (up to the 1 : 1 Br_2/**1** molar ratio) the conductivity values are very low (but still higher than for **2**) and do not change in time; the low conductivity values indicate that the non-conducting species should be in equilibrium with some ions, and that this equilibrium should be almost completely shifted to the left (for **2** more than for **1**), towards the hypervalent compounds.

We have also carried out kinetic measurements, by recording the increase of the conductivity values in time (Fig. 1). In particular, six kinetic measurements ($T = 298$ K, $[\mathbf{1}] = 1 \cdot 10^{-2}$ mol dm^{-3}) have been carried out in *pseudo*-first order conditions, using concentrations of Br_2 from 30 to 80 times higher than that of **1**. In these conditions, the straight lines of $\ln(\sigma_t - \sigma_t)/(\sigma_t - \sigma_0)$ vs time (see Fig. 1) indicate that the reaction is of the first-order with respect to **1**. The k_{obs} are independent on the bromine concentration and a constant value of $(5.8 \pm 0.3) \cdot 10^{-4}$ s^{-1} is obtained for all kinetic experiments.

The conductometric results might be explained by hypothesizing the hypervalent selenium compounds in equilibrium with $[>CSeBr]^+$ and Br^- ions during the first part of the titration (Br_2/donor < 1 : 1) (see Scheme 2). The very low conductivity values recorded in this part of the titration for both **1** and **2** should be due to this equilibrium, which is prevalently shifted to the left. The addition of further amounts of dibromine (Br_2/donor > 1 : 1) shifts this equilibrium to the right as a consequence of the formation of the Br_3^- anion (step 3) and increases the conductivity values.

Under this hypothesis, it is possible to account for the different reactivity of **1** and **2** towards Br_2. In fact, the cation deriving from **2** should be more stable than that derived from **1**, because of a more efficient delocalization of the positive charge on the aromatic ring [9]. This justifies the fact that only compound **5** was obtained in the solid state [6] for both 1 : 1 and 2 : 1 Br_2/**2** molar ratios. In the case of **1**, further reactions lead to the formation of the ionic compound **4**. This causes an increase of the number of conducting species in time and, as a consequence, total conductivity increases.

Ultraviolet measurements

In order to support this hypothesis independently, we recorded the ultraviolet spectra of authentic samples of **1**–**5** dissolved in MeCN (Table 1), and of several mixtures of **1** (or **2**) and Br_2 in MeCN (see Figs 2 and 3). Since no kinetics occurs in the reaction between Br_2 and **2**, we start first with this case. Up to the 1 : 1 Br_2/**2** molar ratio (curves 1–4 of Fig. 3) the spectra show: (i) a decrease in the band at about 350 nm (which is the most intense of **2**); (ii) an increase in the absorption at around 235 nm (which is the most intense of **5**); and (iii) the presence of an isosbestic point at 329 nm; this should agree with an equilibrium between the two species **2** and **5**. However, a careful examination of the curves shows that other species in low concentrations (such as Br_3^- and $[>CSeBr]^+$)

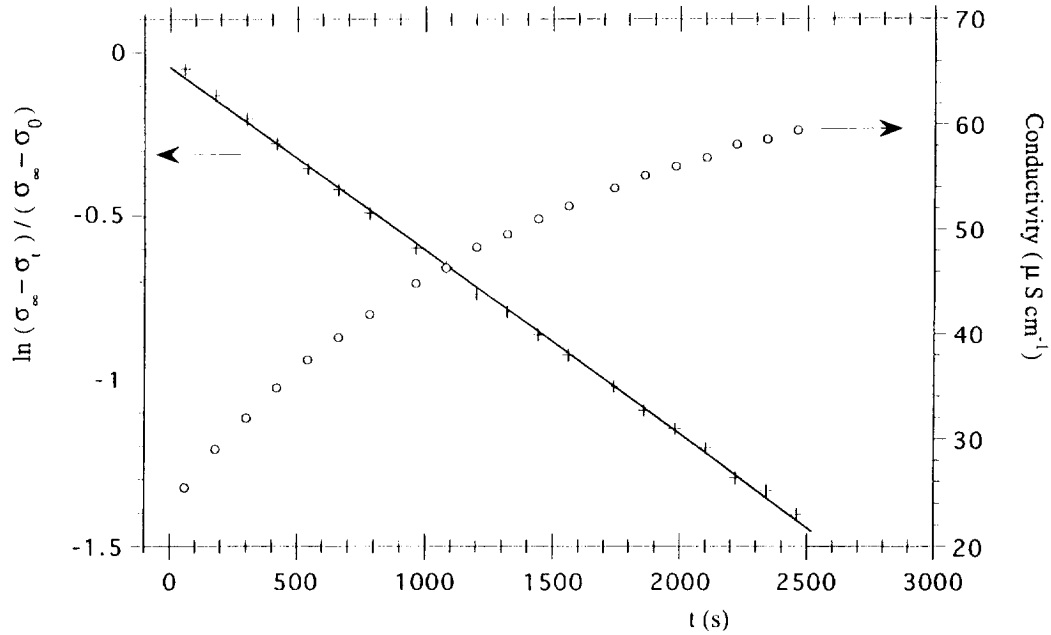

Fig. 1. Conductivity values (o; scale on the right) of the reaction between **1** and Br_2, recorded as a function of time (T = 298 K; CH_2Cl_2 solution; [**1**] = $1 \cdot 10^{-2}$ mol dm^{-3}; [Br_2]/[**1**] molar ratio = 50). The straight line obtained by reporting $\ln(\sigma_\infty - \sigma_t)/(\sigma_\infty - \sigma_0)$ (+; scale on the left) vs time has a slope of $5.6 \cdot 10^{-4}$ s^{-1} (correlation coefficient = 0.999) (σ_∞ and σ_0 are the conductivities at times ∞ and 0 respectively.

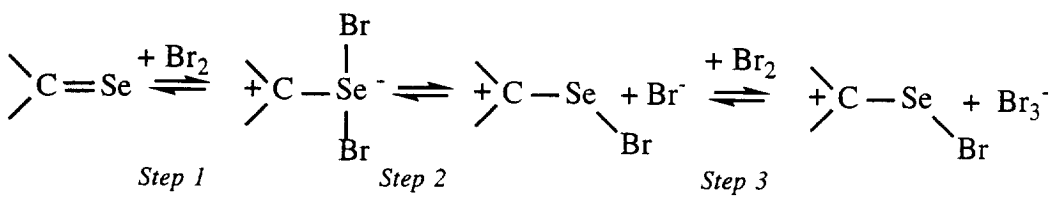

Scheme 2.

Table 1. UV–visible absorptions of all the species involved in the equilibria of **1** and **2** with Br_2 (log ε in parentheses) in MeCN

Compound	Absorption bands (nm)
1	227(3.73)253(3.68)302(4.01)
3	230(4.57)281(4.26)
4	204(4.48)216(4.40)270(4.90)
2	351(4.50)388(3.36)
5	200(4.41)236(4.50)306(4.05)
Br_3^-	269(4.75)[a]
Br_2	268(2.16)393(2.19)

[a] This value was measured on a freshly prepared solution of tetrabutylammonium tribromide ($4.0 \cdot 10^{-5}$ mol dm^{-3}) and is very close to the value of 4.74 reported by A. I. Popov [11].

should be present and might be responsible for the irregular trend around 260 cm^{-1}. By increasing the amount of Br_2 (curves 5–9), the spectra mainly show a continuous increase in the intensity of the band around 270 nm, due to the Br_3^- anion [11], as shown in step 3. As can be seen from an examination of the curves 6–9, the absorbance at 236 cm^{-1} does not increase any further above the 3 : 1 Br_2/**2** molar ratios, indicating that **2** has completely reacted to give **5**.

The spectra of freshly prepared mixtures of **1** and dibromine in MeCN solution were recorded immediately after temperature stabilization and look quite different. Again, the first four spectra (curves 1–4) show an increase in the absorption at around 230 nm (hypervalent selenium compound **3**), but neither a regular decrease of the band at 302 nm (which is the most intense of **1**) nor the presence of isosbestic points.

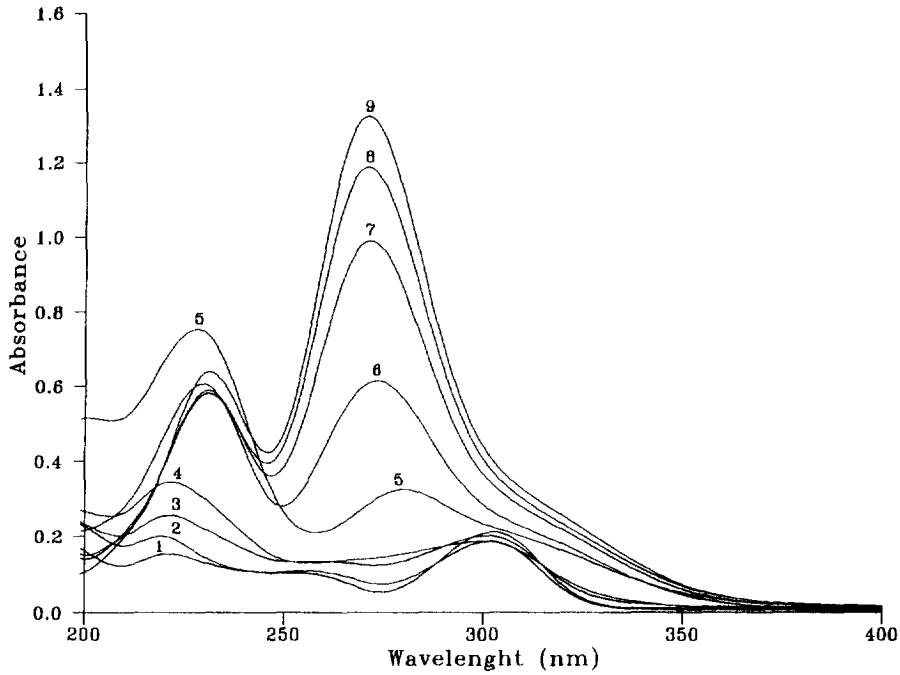

Fig. 2. Spectra of nine solutions having a constant concentration of **1** [$2.1 \cdot 10^{-5}$ mol dm^{-3}] and increasing amounts of Br_2 ($T = 298$ K; MeCN). The $[Br_2]/[\mathbf{1}]$ molar ratios are 0.24, 0.48, 0.71, 0.95, 2.02, 2.98, 4.05, 5.00 and 5.95 for 1–9 respectively.

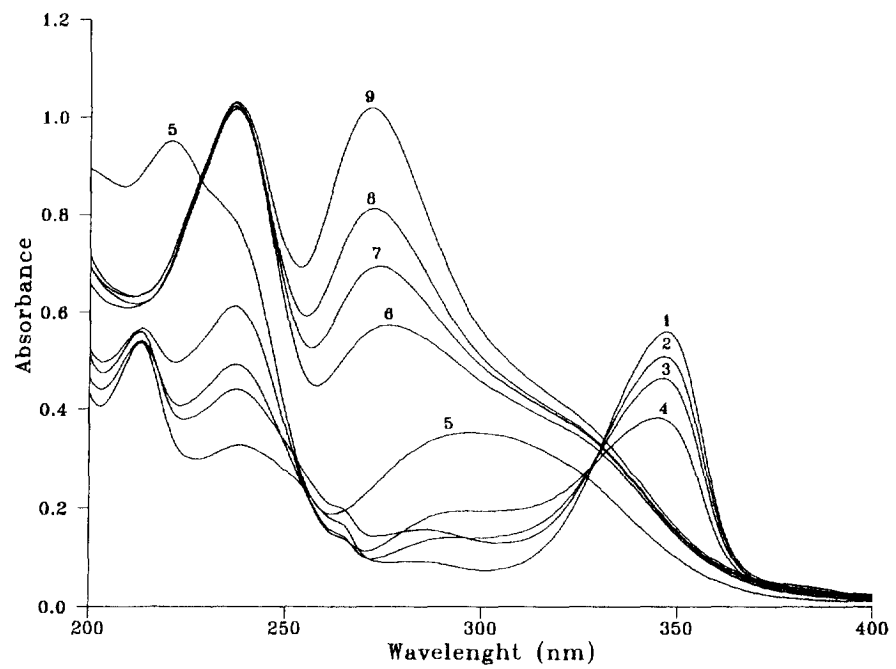

Fig. 3. Spectra of nine solutions having a constant concentration of **2** [$2.28 \cdot 10^{-5}$ mol dm^{-3}] and increasing amounts of Br_2 ($T = 298$ K; MeCN). The $[Br_2]/[\mathbf{2}]$ molar ratios are 0.27, 0.55, 0.68, 0.96, 1.92, 3.01, 3.97, 4.8 and 6.03 for 1–9 respectively. The spectra 1–4 show the presence of an isosbestic point at 329 nm.

The kinetic process and the presence of more than two species in solution should be responsible for this. For mixtures having Br_2/**1** molar ratios higher than 1 : 1 (curves 5–9), a band at around 270 nm, similar to that found in the case of **2**, increases on increasing Br_2 concentration, but in this case the band has a much higher intensity than the other bands in the spectrum, agreeing with the fact that both the Br_3^- and $SeBr_6^{2-}$ anions have very strong absorptions at this wavelength (see Table 1). Also these results confirm Scheme 2 and indicate the formation of **4** in solution on addition of Br_2 to **1** beyond the 1 : 1 Br_2/**1** molar ratio.

^{13}C and ^{77}Se NMR spectra

The titration of **1** with Br_2 has also been monitored by recording the ^{77}Se NMR chemical shifts of their mixtures in CH_2Cl_2 and MeCN solutions at the end of the reaction (Fig. 4) [12]. In both the solvents, the ^{77}Se NMR chemical shifts move to higher fields in presence of an equimolar amount of Br_2, from 420.4 to 374.5 ppm in CH_2Cl_2 and from 399.0 to 387.0 in MeCN, indicating shielding of the selenium atom. These values are very close to that recorded for an authentic sample of **3** (379.8 ppm) in MeCN (Fig. 4) [13]. All this indicates that **3** is forming during the first step of the titration in both solvents. By increasing the amount of added Br_2, the signal moves towards lower fields in both solvent, but, in MeCN solution, the ^{77}Se NMR chemical shifts (▲ in Fig. 4) show more deshielding with respect to that found in CH_2Cl_2 solution (+ in Fig. 4). The titration of **1** with Br_2 was also monitored by recording the ^{13}C NMR chemical shifts of C(4), C(5) and the methyl group (Fig. 5). The addition of Br_2 up to the 1 : 1 molar ratio linearly shifts the signals to low fields, indicating an increase in overall deshielding of the pentaatomic ring. After the 1 : 1 molar ratio, the signals of the carbons remain unchanged. This behaviour is quite different from that observed for the ^{77}Se chemical shifts. The comparison of the ^{13}C NMR spectra of **3** and **4** solves this puzzle. Apart from a signal at 167.6 ppm detected only for the $C_4H_7BrNS^+$ cation of **4** and attributed to the C(2) carbon atom, the values of all the other carbon resonances (61.3, 41.2, 31.1 ppm for **3** and 63.3, 43.3, 31.4 ppm for **4**) are very close. Then, the transformation of **3** into the $C_4H_7BrNS^+$ cation cannot be followed by the changes of the chemical shifts of the carbons, but by the changes of the conductivity values since it brings to charged species.

However, if **4** is forming during the kinetic process for a Br_2/**1** molar ratio higher than 1 : 1, as indicated

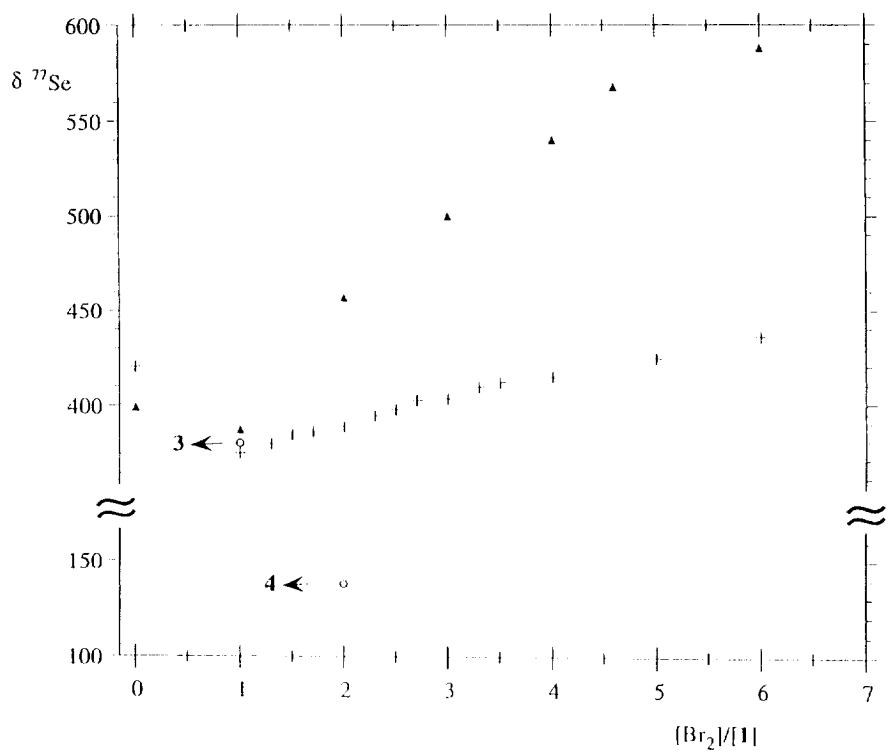

Fig. 4. ^{77}Se NMR chemical shifts of mixtures **1** and Br_2 in CH_2Cl_2 (+) and in MeCN (▲) as a function of $[Br_2]/[\mathbf{1}]$ molar ratios. The values recorded on authentic samples of **3** and **4** (o), dissolved in MeCN, are also reported. The value for **4** is reported at 2 on the abscissa, since **4** contains four bromine atoms for each pentaatomic ring. No values are reported in the first part of the titration for molar ratios intermediate between 0 and 1, since the ^{77}Se signal has not been detected.

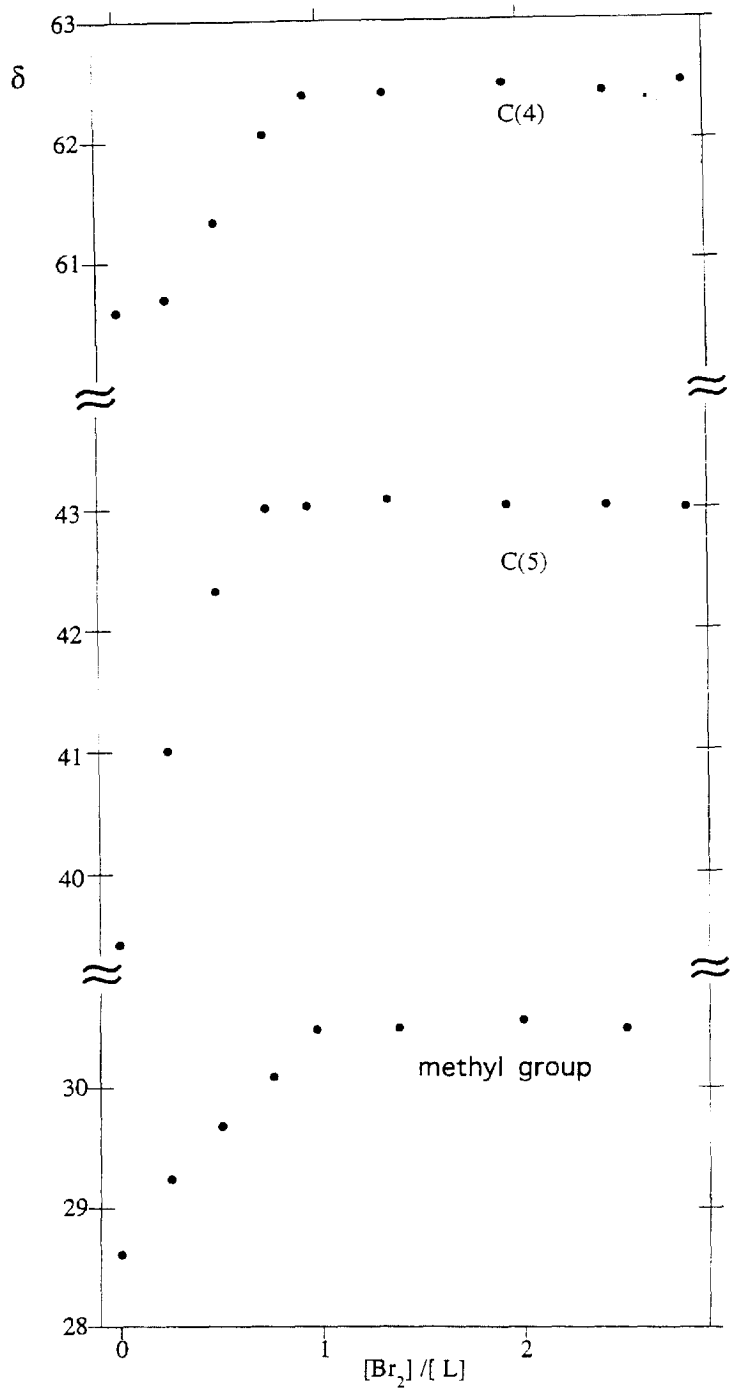

Fig. 5. ^{13}C NMR chemical shifts of C(4), C(5) and of the methyl group for mixtures of **1** [$2.7 \cdot 10^{-2}$ mol dm^{-3}] and Br_2 in CH_2Cl_2 as a function of $[Br_2]/[\mathbf{1}]$ molar ratios.

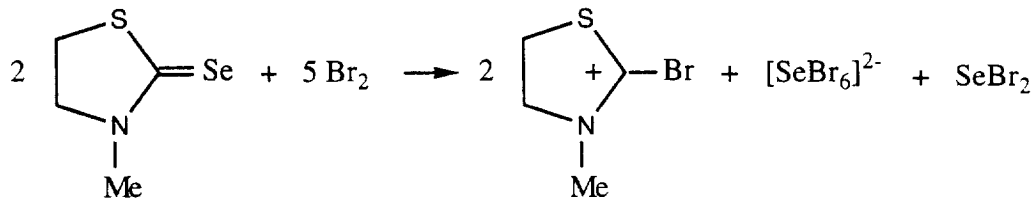
by conductometric measurements and UV–visible spectra, why does the ^{77}Se signal move in opposite direction compared with the value of 138.09 ppm (see Fig. 4) recorded in MeCN for pure **4**? [14]. This fact seems to be in contrast with the formation of $SeBr_6^{2-}$ ion in solution. In order to clarify this point and elucidate the stoichiometry of the reaction, in a typical experiment carried out in CH_2Cl_2 solution, we recorded the ^{77}Se NMR spectrum on the filtered solution after precipitation of **4**. A signal at 1368 ppm, which is not very different from the value of 1496 ppm reported for pure $SeBr_2$ [15], has been detected [16].



Scheme 3.

From this, it seems very likely that the reaction is that reported in Scheme 3 and the ^{77}Se NMR signal detected during the titration is mediated on the different selenium compounds present in solution. The value of 1368 ppm, which is different from that reported for $SeBr_2$, can easily be explained by taking into account further possible equilibria involving $SeBr_2$, bromide and $[SeBr_6]^{2-}$ ions.

In order to confirm this, an authentic sample of **4**, dissolved in MeCN, was reacted with approximately an equivalent amount of $SeBr_2$, obtained *in situ* by $SeBr_4$ and metallic selenium [15]. A signal of 373.5 ppm was detected for the mixture. The closeness of this value to those recorded during the titration confirms that it is precisely the $[SeBr_6]^{2-}$ ion that is forming in solution. The different values of the ^{77}Se NMR chemical shift of $[SeBr_6]^{2-}$, detected in presence and without $SeBr_2$, are the key to give a final explanation of all experimental data.

CONCLUSIONS

In this paper we investigate the different reactivity of **1** and **2** in the reaction with dibromine, using conductometric measurements, the UV–visible and ^{77}Se and ^{13}C NMR spectroscopies. The two donors give the corresponding 10-Se-3 [17] hypervalent compounds **3** and **5** by oxidative addition of Br_2 as a unique compound for the Br_2/**1**(or **2**) molar ratios $\leqslant 1:1$; this is in good agreement with conductometric and spectrophotometric measurements. In both cases, conductometric measurements show no formation of dications as intermediates in the oxidation reaction, unlike what has recently been found by us [9] for some 1,3-dimethylimidazoline-2-selone derivatives. For higher Br_2/**1**(or **2**) molar ratios, **1** and **2** behave very differently: **2** always gives the same hypervalent selenium compound **5**, while **1** gives the very unusual *N*-methyl-2-bromothiazolidium hexabromoselenate(2-) (**4**). In this case, the conductometric measurements have shown a measurable kinetic process of formation of **4**. The comparative spectrophotometric studies carried out on the two substrates in the same conditions, have allowed us to identify the different stability of the $[>CSeBr]^+$ cation [4], generated in the equilibrium reaction between the hypervalent compounds and Br_2, as the reason for the different behaviour of the two substrates. Finally, ^{77}Se NMR measurements have allowed to identify $SeBr_2$ as the species formed parallelly to **4**. According to the view that **3** and the cation of **4** may be regarded as adducts of nucleophilic carbene ligands (thiazolin-2-ylidene C_4H_7NS) with the acceptors $SeBr_2$ (**3**) and Br^+ (cation of **4**), it is interesting to point out that both groups affect the ^{13}C chemical shifts of the pentaatomic ring in the same manner.

9. In a recent paper [Bigoli, F., Deplano, P., Devillanova, F. A., Lippolis, V., Mercuri, M. L., Pellinghelli, A. M. and Trogu, E. F., *Eur. J. Inorg. Chem.*, 1998, **1**, 137, analogous titrations carried out on some imidazoline-2-selone derivatives have shown that conductivity values increase on addition of Br_2, reach a maximum for the 0.5 : 1 Br_2/imidazoline molar ratio, and subsequently decrease to the 1 : 1 molar ratio. Above the 1 : 1 molar ratio, conductivity increases and, as found

for **2**, is time independent. In those cases, it was shown that the reactions involve the formation of dications containing the Se—Se bridge as intermediates in the formations of the hypervalent 10-Se-3 selenium compounds. In the present case, however, the observed trends in the conductivity exclude the formation of the corresponding dications of **1** and **2** on the way to **3** and **5**. Very recently, S. Husebye [10] reported a scheme to collect the wide variety of compounds formed in reaction between chalcogen ligands and halogens, and showed different possible pathways for the formation of dications and hypervalent selenium compounds. On the basis of the results obtained with the imidazoline-2-selone derivatives, that scheme should be enlarged at least to include the direct formation of hypervalent selenium compounds from dications by addition of dihalogens.

Abstract—The reaction of $Ga(^tBu)_3$ with 1 molar equivalent of a carboxylic acid yields the carboxylate bridged dimeric compounds, $[(^tBu)_2Ga(\mu\text{-}O_2CR)]_2$, where R = Ph (**1**), C_6H_4-3-CN (**2**), and C_6H_4-3-Br (**3**), respectively. Similarly, reaction of $Ga(^tBu)_3$ with HSPh yields the thiolate bridged compound, $[(^tBu)_2Ga(\mu\text{-}SPh)]_2$ (**4**). The molecular structures of compounds **1**, **2**, and **4** have been determined by X-ray crystallography. The Ga···Ga and Ga-ligand inter-atomic distances for these compounds, as well as group 15 and 16 donor bridging ligands, are compared to the values for the surface of GaAs and cubic-GaS in order to determine their suitability as linkage groups for self-assembled monolayers. © 1998 Elsevier Science Ltd. INTRODUCTION

There has been increasing interest in the development of chemical sensors with enhanced sensitivity and selectively. Important applications for such sensors include clinical chemistry, such as alternative site and critical care measurements [1], environmental detection of hazardous and mutagenic substances [2], and in-line monitors for the food production industry [3]. Requirements for such sensors are their ability to provide a rapid and reversible response, parts per billion (ppb) level detection, compact packaging for *in-situ* detection, performance in either gaseous or liquid media, highly sensitive (molecular) detection, and low cost. The overall requirements for a selective ion or molecular sensor are an indicator molecule that reversibly interacts with a target molecule with a high degree of specificity (e.g., Fig. 1) and the presence of some detectable property that changes when the target molecule has interacted. A wide variety of changes and therefore suitable detection methods have been employed, including electrochemical methods [4], optical [5, 6], photoelectronic [7, 8], thermal [9], and electronic [10]. With regard to electronic detection one such device is the chemFET (chemically sensitive field effect transistor) in which the flow of electrons in the channel is controlled by the absorption of a target molecule into a chemically sensitive membrane [11]. However, this membrane has a drawback in its affinity for water and other chemical species that interfere with its function. Additionally, the SiO_2 dielectric layer is porous which allows for the diffusion of water through to the channel thus destroying the device. Ideally, in order to realize a chemFET the gate dielectric would need to be chemically stable, compatible with commercial production techniques in a close-packed arrangement to avoid contamination, and be able to be chemically modified. We have recently reported that through the use of cubic-GaS (c-GaS)

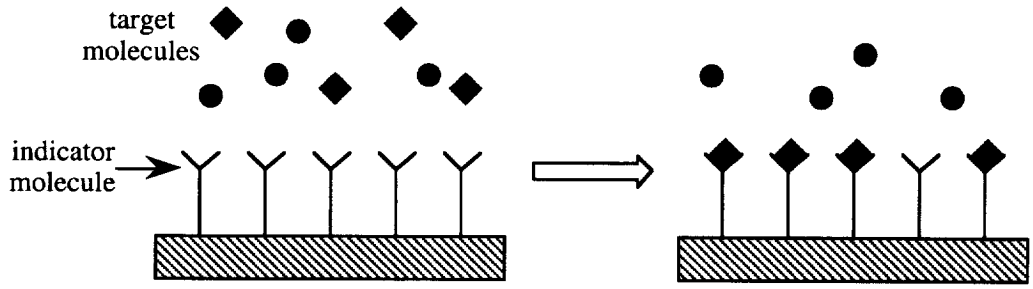

Fig. 1. Schematic representation of the selective interaction between a surface bound indicator molecule and a target molecule.

as the gate dielectric it is possible to fabricate a GaAs analog to the MOSFET (metal oxide semiconductor field effect transistor); a field effect transistor with an insulating sulfide heterojunction (FETISH) [12]. In contrast to SiO_2, c-GaS is non-porous and is chemically resistant to oxidation. Thus, we have proposed that a chemically responsive FETISH (chem-FETISH) should offer significant advantages over the traditional chem-FET.

The simplest method of fabricating a chem-FETISH would be to attach indicator molecules to the surface of the c-GaS gate dielectric. These could be bound via a spacer unit through chemical modification of the surface, e.g., Fig. 2. One key component is the use of a suitable linkage unit which will covalently bind to the surface and be stable in various solvent media. While suitable surface linkage moieties have been identified for such materials as gold [13], alumina [14], and zirconium oxide [15], there is little precedent for GaAs and none for c-GaS.

We have previously demonstrated that the strong binding of carboxylate groups to aluminum oxide surfaces is due to the topotactic nature of the reaction, i.e., no reconstruction (bulk reorganization) of the Al-O framework is required for the carboxylate group to bind to the surface [16]. We were able to show through the synthesis and characterization of model compounds that the carboxylate ligand is ideally suited to binding two aluminum atoms with a Al···Al distance of 3.11–4.46 Å, which encompasses the most accessible Al···Al distance present on the surface of aluminum oxides (3.70 Å). We propose to employ the same concept in rationalizing the best linkage units for binding to c-GaS (and GaAs). In this regard a variety of model compounds have been synthesized, and along with other model compounds previously reported [17–19], their Ga-to-Ga and Ga-to-ligand distances were compared to those of c-GaS and GaAs.

RESULTS AND DISCUSSION

Carboxylates

As noted in the Introduction we have previously shown that carboxylates are ideal ligands for complexation to aluminum oxide surfaces due to the topotactic nature of the reaction and the strength of the subsequent complex [16]. Since c-GaS and GaAs readily form native oxide layers through atmospheric oxidation/hydrolysis, a carboxylate linkage group is possible via the reaction of the surface with RCO_2H.

The reaction of $Ga(^tBu)_3$ [20, 21], with one molar equivalent of a carboxylic acids yields the di-*tert*-butylgallium carboxylates $[(^tBu)_2Ga(\mu\text{-}O_2CR)]_2$, eq. (1).

$$Ga(^tBu)_3 + RCO_2H \rightarrow {}^1/_2[(^tBu)_2Ga(\mu-O_2CR)]_2 + {}^tBuH \quad (1)$$

$$R = Ph(\mathbf{1}),\quad C_6H_4-3-CN(\mathbf{2}),\quad C_6H_4-3-Br(\mathbf{3})$$

In the case of compounds **2** and **3** the termini employed were chosen to provide suitable probes for XPS and/or IR characterization of surfaces. The ^1H and ^{13}C NMR spectroscopy and mass spectrometry of compounds **1**–**3** are consistent with dimeric structures, which have been confirmed for compounds **1** and **2** by X-ray crystallography.

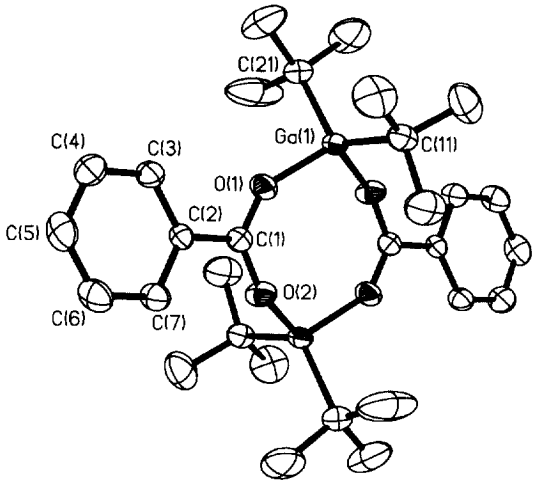

Fig. 3. The molecular structure of $[(^tBu)_2Ga(\mu\text{-}O_2CPh)]_2$ (**1**). Thermal ellipsoids are shown at the 30% level and hydrogen atoms are omitted for clarity.

The molecular structures of $[(^tBu)_2Ga(\mu\text{-}O_2CPh)]_2$ (**1**) and $[(^tBu)_2Ga(\mu\text{-}O_2CC_6H_4\text{-}3\text{-}CN)]_2$ (**2**) are shown in Fig. 3 and Fig. 4; selected bond lengths and angles are given in Tab. 1. The structures of both compounds consists of centro-symmetric dimers of two '$Ga(^tBu)_2$' units bridged by two carboxylate groups. This is consistent with other alkyl Group 13 carboxylates as shown from IR and Raman spectroscopy, mass spectrometry, and molecular weight measurements [22]. Additionally, the structure of compound **1** is isomorphous with its aluminum analog [16]. The Ga–O bond lengths to the carboxylate ligands in these dimeric systems [Ga–O = 1.957(3)–1.960(3) Å] are comparable to the bridging carboxylate interactions with the four-coordinate gallium in the polymeric $[MeGa(\mu\text{-}O_2CMe)_2]_x$ [1.899(3)–1.942(4) Å] [23], but significantly shorter than those observed in $Rb[(Me_3Ga)_2(\mu\text{-}O_2CMe)_2]$ [2.068(8), 2.070(8) Å] [24]. The carboxylate's O–C bond lengths in both compounds are similar (see Tab. 1), indicative of a symmetrically bound acid group that is unaffected by the carboxylate organic substituents. The bond lengths and angles within the carboxylate unit are typical of such moieties [25].

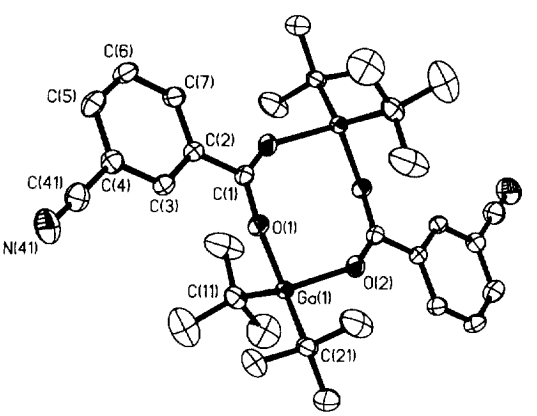

Fig. 4. The molecular structure of $[(^tBu)_2Ga(\mu\text{-}O_2CC_6H_4\text{-}3\text{-}CN)]_2$ (**2**). Thermal ellipsoids are shown at the 30% level and hydrogen atoms are omitted for clarity.

The $Ga_2O_4C_2$ cycles in $[(^tBu)_2Ga(\mu\text{-}O_2CR)]_2$ are examples of eight-membered ring compounds of the group 13 metals [18, 26]. The eight membered $Ga_2O_4C_2$ rings in compounds **1** and **2** adopt a chair-like structure, see Fig. 5. A similar confirmation is adopted by the aluminum carboxylates, $[(^tBu)_2Al(\mu\text{-}O_2CR)]_2$ [16]. The puckering of the $Ga_2O_4C_2$ ring may be considered to be as a result of folding of the eight-membered ring along the two inter-ligand O···O vectors. The extent of folding (θ_{ring}) is defined as the angle between the GaO_2 planes and the O_4C_2 plane. For the aluminum carboxylates, $[(^tBu)_2Al(\mu\text{-}O_2CR)]_2$, the geometrical result of the planar $Al_2O_4C_2$ core is that the Al···Al intra-molecular distance is maximized, and consequently so are the inter-substituent distances (i.e., $^tBu\cdots R$), resulting in a correlation between θ_{ring} and the steric bulk of the carboxylate substituent (**R**) as defined by Tolman's cone angle (θ) [27]. In this regard, the agreement in the θ_{ring} for the $Ga_2O_4C_2$ ring: $\theta_{ring} = 155.2°$ (**1**) and 154.1° (**2**) is consistent with the similarity of the steric bulk of the carboxylate groups in compounds **1** and **2**.

Benzenethiolate

The reaction of $Ga(^tBu)_3$ with one molar equivalent of PhSH yields the di-*tert*-butylgallium thiolate, eq. (2).

$$Ga(^tBu)_3 + RSH \rightarrow {}^1/_2[(^tBu)_2Ga(\mu\text{-}SR)]_2 + {}^tBuH \quad (2)$$
(4)

The molecular structure of one of the independent molecules of $[(^tBu)_2Ga(\mu\text{-}SPh)]_2$ (**4**) is shown in Fig. 6; selected bond lengths and angles are given in Tab. 2.

The Ga–S and Ga–C bond distances are within the range expected (Ga–S = 2.33–2.46 Å [28–31], Ga–C = 1.96–2.16 Å [25]). Furthermore, within each independent molecule the two Ga–S distances to each sulfur are essentially the same, suggesting the presence of a symmetrically bridging thiolate ligand. As has been reported for Group 13 thiolate [32, 33] selenolate [34, 35] and tellurolate [36] compounds the geometry about the sulfur is pyramidal (i.e., Fig. 7), i.e., Σ(X-E-X) = 333(2)°, not planar as is found in their oxygen analogs $[(^tBu)_2M(\mu\text{-}OR)]_2$ [17]. As consequence of the non-planar geometry of the sulfur there is significant distortion of the gallium center from ideal tetrahedral, with a distinct asymmetry in the C–Ga–S angles, see Fig. 7.

Model compounds for surface binding to c-GaS and GaAs

Both c-GaS and GaAs have *fcc*-Zinc Blende structures and although both {100} and {111} oriented crystals are employed in GaAs devices, the Ga···Ga distances are irrespective of orientation. Thus, for simplicity only the {100} face will be considered.

Complexation of any ligand to either a c-GaS or GaAs surface may occur via monodentate terminal, bidentate (e.g., bridging), or multidentate (e.g., cap-

ping) ligation. Each of these binding modes is depicted schematically in Fig. 8. Terminal and chelating coordination should be independent of the structure of the surface, however, we have shown that the stability of bridging (and presumably capping) ligands is dependent on the distance over which they bridge [16]. A consideration of the possible Ga···Ga distances on the {100} face of c-GaS shows that two inter-gallium distances are possible, 3.89 and 5.50 Å [37]. Similarly, for GaAs these distances are 3.997 and 5.653 Å [38]. Table 3 summarizes the Ga-X and Ga···Ga distances observed for compounds **1**, **2** and **4** as well as those in complexes of selected Group 15 and 16 donor ligands. A graphical representation is given in Fig. 9, from which it can be seen that while carboxylate ligands are ideal for alumina surfaces they are not suitable for c-GaS and GaAs. In contrast, ER (E = S, Se, Te), ER_2 (E = P, As) and $O_{4-n}PR_2$ (n = 1, 2) all form complexes in which the Ga···Ga distance covers a range including those required to bind to the (100) surface of both GaAs and c-GaS. In fact, the thiolate ligand is nearly ideal to act as a bridging ligand across the Ga···Ga distance of either the (100) or (111) faces and it is interesting to speculate, with hindsight, that this observation provides a rationalization for the suitability of thiols to form self assembled monolayers on GaAs [39]. We propose that the reaction of thiols with the surface of c-GaS or GaAs be considered a topotactic reaction, since no reconstruction (bulk reorganization) of the Ga-E (E = S, As) framework is

required for the ligand to bind. Our surface binding studies will be reported elsewhere.

EXPERIMENTAL

All operations were carried out using Schlenk techniques or in an argon atmospheric VAC glovebox. ^1H and ^{13}C NMR analysis was carried out on a Bruker WM-250 MHz spectrometer. Mass spectrometry was performed using a Finnegan MAT95 mass spectrometer with an electron beam energy of 70 eV for EI mass spectra. IR analysis was carried out on Nicolet 760 and Perkin Elmer 1600 FT-IR spectrometers using Nujol mulls. The synthesis of $Ga(^tBu)_3$ was carried out by literature methods [20, 21]. The carboxylic acids were purchased from Aldrich and used without further purification.

$[(^tBu)_2Ga(\mu\text{-}O_2CPh)]_2$ (*1*)

A solution of benzoic acid (0.51 g, 4.2 mmol) was slurried in hexane (10 cm^3) and to this was added a solution of $Ga(^tBu)_3$ (0.80 g, 3.3 mmol) in hexane (10 cm^3). This addition was done slowly dropwise with continuous stirring. The reactant mixture became warm throughout the addition, and the solution appeared to be clear afterward, with only a small amount of white powder left at the bottom of the flask. The reaction mixture was allowed to stir for 40 h., and the resultant slurry was filtered. The volatiles were removed from the filtrate to reveal a white powder. Recrystallization in toluene gave small, block crystals. Yield *ca.* 80%. Mp: 203–205°C. EI-MS (*m/z*; %) 449 ($2M^+ - {}^t$Bu-OCPh + H, 5), 304 (M^+, 12), 247 (M^+-^{t}Bu, 40), 191 (M^+-2 ^{t}Bu, 100), 105 (COPh, 40), 57 (^{t}Bu, 60). Crystallographic studies

Crystals of compounds **1**, **2** and **4** were sealed in a glass capillary under argon and mounted on the goniometer of a Enraf-Nonius CAD-4 automated diffractometer. Data collection and cell determinations were performed in a manner previously described [64], using the $\theta/2\theta$ scan technique. Pertinent details are given in Tab. 4. The structures were solved by direct methods (SHELX86) [65]. The models were refined using full-matrix least squares techniques. Ga, N, and O atoms were refined anisotropically for compound **2**, while all non-hydrogen atoms were refined anisotropically for compound **1** and **4**. Hydrogen atoms were included and constrained to 'ride' upon the appropriate atoms [d(C-H) = 0.95 Å, U(H) = 1.3 B_{eq}(C)]. All computations other than those specified were performed using MolEN [66]. A summary of cell parameters, data collection, and structure solution is

Anatase to rutile transformation in sol-gel titania by modification of precursor

C. Suresh, V. Biju, P. Mukundan and K. G. K. Warrier*

Structural Ceramics Unit, Regional Research Laboratory (CSIR), Trivandrum-695019, India

(Received 2 December 1997; accepted 18 February 1998)

Abstract—The effect of pH on the formation of high temperature phases in titanium oxide, derived by hydrolysis of modified titanium isopropoxide has been reported. The anatase to rutile phase transformation is delayed in the case of acetic acid modified gel precursor at pH 3 and 4, showing the presence of anatase phase even at 1000°C. On the other hand, in the sample precursor prepared at pH 6, anatase to rutile transformation is complete at 800°C, under identical conditions of heat treatment. The transformation has been followed by thermal analysis and X-ray powder diffraction data. Impedance spectroscopy has been attempted as a useful and effective tool in identifying the anatase and rutile phases as well as transformation temperatures. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: sol-gel titania; impedance spectroscopy; anatase; rutile phases; transformation termperatures.

Titania has been well recognised as a pigment in paints, as a filler material and also in enamels and glazes for ceramics [1,2]. More recently the application of titania has spread to catalysts, catalyst supports and membranes [3–7]. Suitably modified titania has also been found to respond electrically in different humidity environments and has therefore found application as humidity sensors [8,9]. However these applications demand high purity titania with controlled particle size, definite phase composition and surface properties. Sol-gel methods have been widely investigated with advantage over conventional methods in controlling the properties of titania [10,11]. Further, titania normally undergoes anatase-rutile phase transformation in the temperature range 600–700°C [12]. For high temperature applications of titania as catalyst, membranes and sensors, a stable anatase phase is necessary [1,2]. Usually this is achieved to some extent by incorporating other metal oxides as dopants in small quantities. Y_2O_3 and SiO_2 have been found to shift the anatase-rutile transformation to higher levels [13,14]. Modifying the precursor characteristics by involving different solvents and by introducing gel modifiers [15,16] have been the other approaches attempted earlier to arrive at titania having specific properties. However, there has been no systematic data reported on the effect of pH condition in presence of modifiers on precursor and subsequent phase development on calcination. The anatase-rutile transformation is usually detected using X-ray powder diffraction analysis. Differential thermal analysis of the precursor gel has limited success in detecting this transformation since energy change involved is very small. Therefore other simple techniques where the change can be detected in bulk would be more useful. Sensitive electrical measurements can be effectively employed to characterise the phase change in TiO_2. Conventional electrical measurements are time consuming and limited to certain fixed frequencies but the impedance spectral method has been found to cover a large range of frequencies. This method has been successfully applied earlier to analyse doped and undoped zinc oxide varistors [16], solid state powder reactions of oxide superconductors [17] and also to study the role of microstructure in the electrical behaviour of sensor materials based on anatase [18].

Titania powders were prepared by sol-gel process in this study with acetic acid as a modifier at different pH conditions. The phase transformation during heat treatment was investigated by impedance spectroscopic measurements and the data are compared with those obtained from thermal analysis and X-ray powder diffraction. Impedance spectral measurement carried out on bulk samples is a novel and effective tool for detecting the anatase-rutile transformation,

which has also been found to be dependent on the pH of the precursor.

EXPERIMENTAL

The titania samples were prepared by hydrolysis of titanium isopropoxide (Aldrich Chemicals, U.S.A.). In a typical experiment, 25 ml titanium isopropoxide was dissolved in 48 ml acetic acid (S.D. Fine Chemicals, India) and was stirred for 0.5 h. To this solution 150 ml double distilled water was added dropwise under continuous stirring for 1 h. The pH was adjusted to 3 by adding 10% ammonium hydroxide. The mixture was heated to 70°C in an air oven to get a gel. Similar procedures were followed to prepare titania samples at pH values 4, 5, and 6.

Thermal analysis of the gels were carried out in flowing nitrogen gas (DTA/TGA Shimadzu 50H) at a rate of 10°C/min. The IR spectra of gels dried at 80°C was recorded in Nicolet Impact 400 D FTIR Spectrometer in the range 4000–500 cm^{-1}as powders dispersed in KBr pellets. The dried gels were further calcined at 400, 600, 800 and 1000°C for 3 h, and X-ray powder diffraction patterns were recorded in a Philips Diffractometer PW 1710. The gels prepared at pH 4 and 6 were pelletised and heated at 400, 600, 800 and 1000°C and the parallel surfaces were coated with silver on to which copper leads were attached. Impedance spectral measurements on these samples were carried out using HP 4192A Impedance analyser and data measured were analysed using EQUIVCRT software.

RESULTS AND DISCUSSIONS

X-ray powder diffraction results are given in Table 1. Samples heated at 400°C show only anatase at all pH conditions. The same trend continues up to 600°C. When heated at 800°C samples at pH 3 and 4 show presence of anatase and traces of rutile, but the intensity of anatase peaks are greater in samples prepared at pH 3 and 4 than at 5. For the samples prepared at pH 6, only rutile phase is present (Fig. 1A and 1B). Samples prepared at pH 3 and 4 heat treated at 1000°C still show the presence of anatase phase but those prepared at pH 5 and 6 show rutile phase only.

A-Anatase, R-Rutile.

The thermogravimetric curves of gels prepared at pH 4 and 6 (Fig. 2) indicates nearly identical pattern of decomposition with a total loss of 25.81 and 35.54% respectively. The decomposition is nearly complete below 400°C. Greater weight loss in the sample prepared at pH 6 indicates the presence of a larger amount of hydroxyls in the gel as free water, since the low temperature decomposition curve has larger weight loss as compared to the sample prepared at pH 4. Further, the thermogravimetric curve of the precursor at pH 4 indicates a larger loss above 300°C, which is due to the larger amount of bonded hydroxyls. Differential thermal analysis curves of the gels prepared at pH 4 and 6 are shown in Fig. 3. The endothermic peak below 100°C which is assigned to the expulsion of free water from the gel, is more prominent in the sample prepared at pH 6. This is in conformation with the TGA analysis which shows a greater weight loss ~ 14% in the sample prepared at pH 6 as compared to the weight loss ~ 8% in the sample prepared at pH 4 up to 100°C. An endothermic peak at 266°C, which is prominent in the DTA curve of gel prepared at pH 4, is associated with the removal of water from the gel network. However this peak is very weak for the sample prepared at pH 6 indicating a lesser amount of bound water in the gel due to a more open structure at higher pH. The broad exothermic peak around 350°C present in the DTA curves of both the samples correspond to the removal of organics. The exothermic peak indicates the onset of anatase phase formation near 400°C in both the samples. It also appears that the formation of anatase for gel prepared at pH 4 is extended over a larger range of temperature compared to its counterpart at pH 6.

Analysis of the infra red spectra of the dried gels was done based on the results published earlier [19,20]. Bands corresponding to 1384 and 1407 cm^{-1} in the spectra of samples prepared at pH 3 and 4 are due to free acetic acid present in the system and these bands are not present in samples at pH 5 and 6. The band corresponding to 1530 cm^{-1} is due to the chelated acetate group [20] which is strong at pH 3 and weakens with increasing pH and no such band is observed in samples prepared at pH 6 (Fig. 4). This indicates that as the pH of the precursor increases the chelating effect of acetic acid decreases. The bands at 2913, 3103, 2990 and 3107 cm^{-1} are due to $-CH_3$ and $-CH_2$-stretching. The peaks corresponding to 653, 650, 673 and 676 cm^{-1} in the spectra of samples prepared at pH 3, 4, 5 and 6 respectively are due to Ti—O stretching vibration [19]. The shifting of the peak corresponding to Ti—O stretching to a higher wavenumber side with an increase of pH indicates an increase in the strength of Ti—O bond. It could be

concluded that the extent of chelation of acetate group decreases with an increase of pH.

The room temperature impedance measurements indicate that in all the samples, irrespective of pH, the bulk resistance increases with increase in calcination temperature. Impedance curves of the calcined gels prepared at pH 4 and pH 6 are presented in (Fig. 5) and the resistivity values measured on the same samples are shown in Table 2. At 400°C, the impedance curves of both the samples are similar. This is in conformation with the X-ray powder diffraction results. However, at 600°C, the impedance curves, as well as resistivity values show marked differences between samples at pH 4 and 6 even though the X-ray powder diffraction patterns are identical. The greater bulk resistivity value for the samples at pH 6 is due to the starting of anatase to rutile transformation which is beyond the detection limits of X-ray powder diffraction. This conclusion is based on our earlier studies [13,21], which indicated that anatase has a preferentially conducting and rutile insulating nature. The relatively low value of the bulk resistivity for the sample prepared at pH 4 indicates that anatase to rutile

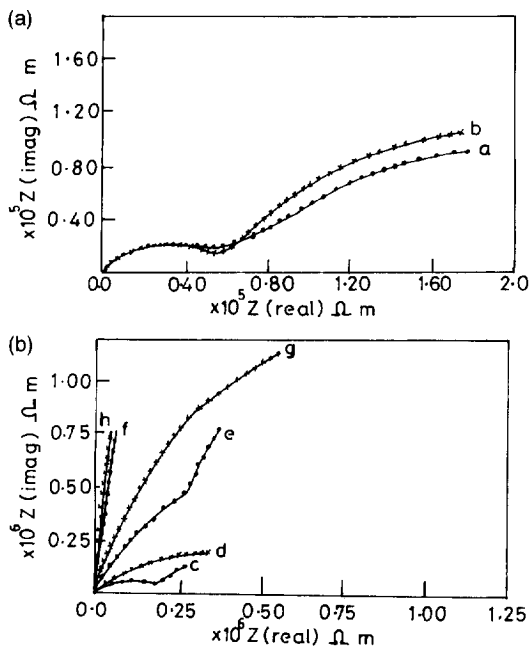

Fig. 5. A. Impedance spectra of calcined samples at (a) pH4 400°C; (b) pH6 400°C. B. Impedance spectra of calcined samples at (c) pH4 600°C; (d) pH6 600°C; (e) pH4 800°C; (f) pH6 800°C; (g) pH4 1000°C; (h) pH6 1000°C.

transformation has not yet started. At 800°C the samples prepared at pH 6 is highly resistive. This shows the presence of only rutile phase which is in conformation with X-ray powder diffraction analysis. The bulk resistivity of the samples prepared at pH 4 and calcined at 800°C is relatively low due to the low concentration

Table 2. Resistivity values of the samples calcined at different temperatures

	Resistivity (ohm-m) of the samples calcined at			
	400°C	600°C	800°C	1000°C
pH4	6.89×10^4	2.25×10^5	2.19×10^6	3.37×10^6
pH6	6.81×10^4	5.62×10^5	1.04×10^7	1.85×10^7

of rutile phase. The bulk resistivity of the samples calcined at 1000°C is very high. This is due to the rutile phase present. The greater value of bulk resistivity for the sample prepared at pH 6 is due to presence of only rutile phase. For the sample prepared at pH 4 the bulk resistivity is comparatively less due to the presence of appreciable quantities of anatase phase, easily detected by X-ray powder diffraction patterns which causes considerable decrease in resistivity values.

Acetic acid used here is to modify the hydrolysis and condensation reactions in the precursor gels since gel modifiers are known to control the size and shape of pore distributions [22]. As the pH is increased the chelated acetate group becomes weak facilitating early hydrolysis to form high temperature phases.

At low pH, condensation reaction is slow compared to hydrolysis because of charge-charge repulsion between protonated hydrated metal cations which allows branching to occur before particle growth to produce strongly cross linked gel. Further, increase in pH may alter the highly cross linked network structure. This is clearly seen from FTIR results where the bands corresponding to chelated acetate group that are strong at pH 3 becomes weaker with increase of pH and nearly disappears at pH 6. The gel having polymeric chains with little branching and cross linking, and also a smaller void region, is structurally weak and thus collapses rapidly on calcination [22]. Hence the strengthening of the gel network by modification through acetic acid and the associated structural changes have been evident in extending the anatase rutile transformation to higher temperatures. Thus the present study indicates that control of the precursor structure could be quite effective in increasing the stability of anatase phase, which is an important requirement for many of the high temperature applications of titania.

CONCLUSION

This study has shown the strong dependence of precursor history on the formation characteristics of various high temperature phases in sol-gel titania. Acetic acid in the pH range up to 4 is a very effective modifier to extend the thermal stability of anatase phase by about 100°C, compared to unmodified one. This approach has been significant since it may help to a considerable extent, in dispensing with the con-

ventional use of oxide dopants. Further, the use of impedance spectral measurement is seen to be a very simple tool to identify the anatase-rutile transformation in bulk specimens and the results are confirmed by X-ray powder diffraction data. Thus a novel approach is presented where on one hand, suitably modified gel precursor could be a simple source for anatase titania stable at high temperature which, on the other, could further be detected by a simple technique of impedance spectroscopy.

Platinum(II) and palladium(II) complexes derived from the anion of sulfathiazole [4-amino-N-(thiazol-2-yl)benzenesulfonamide, stzH]; crystal structure of *cis*-$[Pt(stz)_2(PPh_3)_2]\cdot 3CHCl_3$

(Received 10 October 1997; accepted 18 February 1998)

Abstract—Reaction of the complexes *cis*-$[PtCl_2L_2]$ [L = PPh_3 or L_2 = 1,1′-bis(diphenylphosphino)ferrocene (dppf)], or $[PdCl_2(phen)]$ [phen = 1,10-phenanthroline] with two mole equivalents of sulfathiazole (stzH) in methanol with excess triethylamine yields the complexes *cis*-$[M(stz)_2L_2]$ in good yields. The complexes have been characterised by elemental microanalysis, together with infrared, ^1H and ^{31}P NMR spectroscopies. A single-crystal X-ray structure determination on the complex *cis*-$[Pt(stz)_2(PPh_3)_2]$ **3a** shows that both stz ligands coordinate via the thiazole nitrogen atoms. Using positive-ion electrospray mass spectrometry (ESMS) all complexes yield strong molecular ions $[M+H]^+$ at low cone voltages. At higher cone voltages, loss of one stz ligand occurs, giving $[L_2M(stz)]^+$ ions. The complex *cis*-$[PtCl(stz)(PPh_3)_2]$ **4** was also prepared using a 1:1 mole ratio of reactants. Functionalisation of both primary arylamine groups of **3a** can be accomplished using either acetic anhydride or trifluoroacetic anhydride, in pyridine solvent, and the derivatives **5** were characterised by ^{31}P NMR spectroscopy, elemental analysis and ESMS. © 1998 Elsevier Science Ltd. Keywords: platinum; palladium; sulfathiazole; electrospray; crystal structure.

Sulfonamide compounds, including sulfanilamide **1** and sulfathiazole **2** have been long known for their antibacterial properties [1]. The presence of relatively acidic N—H protons in these compounds (activated by the adjacent electron-withdrawing sulfonyl moiety) suggested that these sulfa drugs should readily form complexes with platinum group metal complexes, bonding as their monoanions. Metal complexes of such ligands are of importance since the polymeric silver(I) complex of the related compound sulfadiazine, which contains silver–amide linkages, is widely used clinically for the treatment of severe burns [2]. We are interested in the general properties of platinum-group metal–amide complexes [3], particularly for ligands which have biological activity [4,5]. Studies on metal complexes of sulfa drugs is an area which has attracted interest in recent years. While a number of complexes of first-row transition metals have been described [6–8], few platinum or palladium complexes of sulfathiazole have been reported. However, some complexes of platinum(II) have been found to be effective bactericides against sulfa-drug resistant bacteria [9], and a platinum(II) complex of the related sulfa drug sulfadiazine has been found to show antitumour activity [10]. A palladium(II) complex of sulfathiazole has been used in the quantitative analysis of the ligand [11] and stability constants for a number of metal complexes, including palladium(II) have been determined [12]. Platinum and palladium complexes of other sulfonamide ligands are known [13,14].

In this paper we describe the synthesis of some new platinum(II) and palladium(II) derivatives containing

deprotonated sulfathiazole ligands. The application of electrospray mass spectrometry to the study of this type of complex is also described.

RESULTS AND DISCUSSION

Syntheses and X-ray crystal structure

Reaction of the complexes *cis*-$[PtCl_2L_2]$ [L = PPh_3 or L_2 = 1,1′-bis(diphenylphosphino)ferrocene (dppf)], or $[PdCl_2(phen)]$ [phen = 1,10-phenanthroline] with two mole equivalents of sulfathiazole (stzH) **2** with excess triethylamine in hot methanol yields, after precipitation with water, filtration, washing and drying, the complexes *cis*-$[M(stz)_2L_2]$ (**3a–c**). The complexes are air-stable solids, poorly soluble in chlorinated organic solvents, and insoluble in water. However they are generally more soluble in dimethyl sulfoxide, allowing partial NMR characterisation of the complexes. Electrospray mass spectrometry was also used to characterise these complexes, this being a particularly useful technique for the analysis of complexes of low solubility, and where the reaction centre (in this case the NH_2 groups) is remote from the metal centre. The attempted synthesis of **3a** using milder reaction conditions (excess triethylamine in refluxing dichloromethane for 4 h) gave a mixture of **3a** and the mono stz complex **4**, identified by $^{31}P-\{^1H\}$ NMR spectroscopy. Subsequent reaction of *cis*-$[PtCl_2(PPh_3)_2]$ with one equivalent of stzH in CH_2Cl_2–MeOH with triethylamine gave crude complex **4** in 76% yield. The product also contained a small amount of **3a**.

The NH_2 groups of the platinum complex **3a** can be acetylated (acetic anhydride/pyridine) or trifluoroacetylated (trifluoroacetic anhydride/pyridine) to give the derivatised products **5a** and **5b**, respectively. Attempted sulfonylation of **3a** using *p*-toluenesulfonyl chloride in pyridine gave a mixture of products, as shown by ESMS (see below). The derivatised products **5** are somewhat more soluble in dichloromethane and chloroform than **3a**.

Unambiguous characterisation of the complexes **3–5** by NMR spectroscopy (*vide infra*) was not easily achieved, and thus a single-crystal X-ray diffraction study was carried out on one derivative. The majority of the complexes did not crystallise well, however crystals of **3a** suitable for a structure determination were obtained on allowing a saturated chloroform solution to stand at room temperature for several weeks. Figure 1 shows the molecular structure together with the atom numbering scheme, and the caption gives selected bond lengths and angles.

The complex contains the expected approximately square-planar platinum(II) centre, with two stz ligands coordinated through their thiazole nitrogen atoms, in a *cis*-arrangement. The structure determination is the first of a platinum-group metal sulfathiazole complex bonded via the thiazole nitrogen.

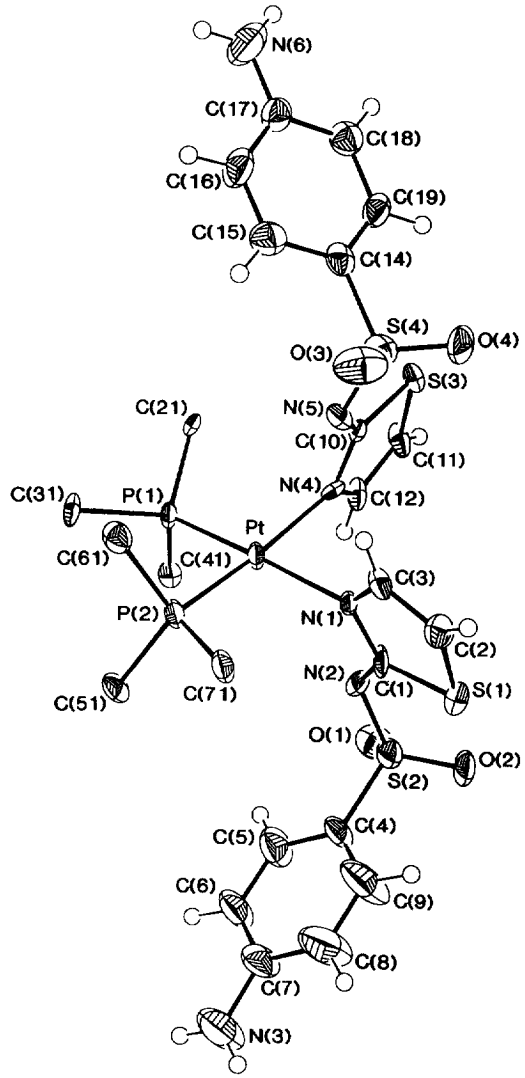

Fig. 1. Molecular structure of the complex *cis*-$[Pt(stz)_2(PPh_3)_2]$ **3a**, showing the atom numbering scheme. Only the phosphorus-bonded triphenylphosphine carbon atoms are shown for clarity, and the three chloroform molecules of solvation have also been omitted.
Selected bond lengths (Å) *and angles* (°): Pt(1)—N(4) 2.095(7); Pt(1)—N(1) 2.110(7); Pt(1)—P(2) 2.278(2); Pt(1)—P(1) 2.290(2); N(1)—C(1) 1.349(13); N(1)—C(3) 1.358(13); N(4)—C(10) 1.346(12); N(4)—C(12) 1.385(12); N(4)—Pt(1)—N(1) 85.0(3); N(1)—Pt(1)—P(2) 90.9(2); N(4)—Pt(1)—P(1) 89.5(2); P(2)—Pt(1)—P(1) 96.33(9).

There are only three other reported structures of transition-metal (copper and zinc) complexes containing solely thiazole nitrogen bonded stz ligands [7,8]. The thiazole moieties are roughly perpendicular to the platinum coordination plane, as shown in Fig. 2, resulting in a *trans*-disposition of the remainder of the stz ligands, presumably to minimise steric interactions. The coordination plane is twisted so that the

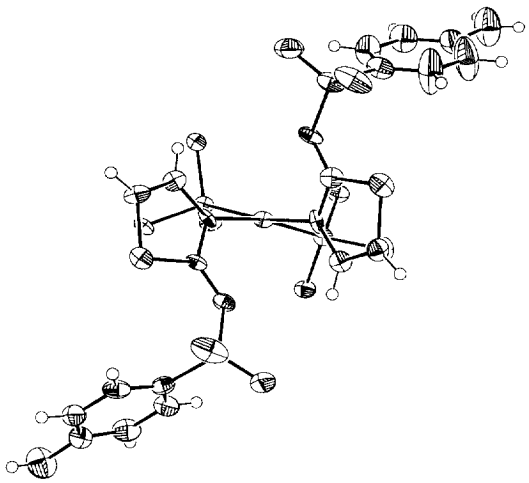

Fig. 2. View of complex **3a** along the N—Pt—N plane, showing the coordination of the thiazole moieties perpendicular to the platinum coordination plane, resulting in the disposition of the bulk of the stz ligands above and below the plane.

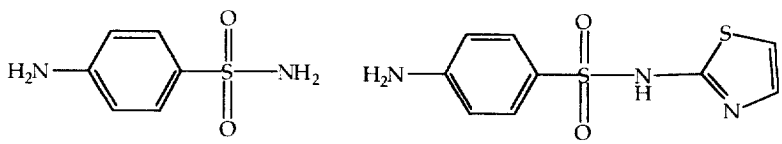
N—Pt—N plane is at 14.2° to the P—Pt—P one (Fig. 2).

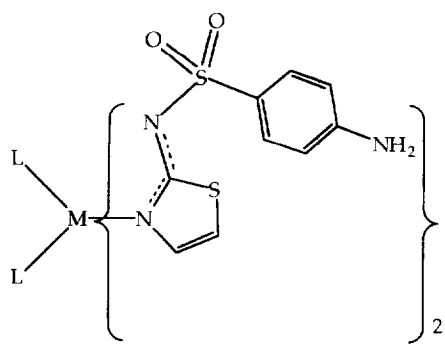
NMR spectroscopy

The $^{31}P-\{^1H\}$ NMR spectra of the phosphine complexes **3a** and **3b** show a single resonance, consistent with two equivalent phosphine ligands. The values of $^1J(Pt,P)$ are indicative of the presence of phosphine ligands *trans* to relatively low *trans*-influence nitrogen donor ligands. Thus, for the triphenylphosphine complex **3a**, the value of $^1J(Pt,P)$ is 3444 Hz, which is in the range expected for nitrogen donor ligands, and compares well with the $^1J(Pt,P)$ values of 3054, 3454 and 3284 Hz found for the amide complexes *cis*-$[Pt(NCH_2CH_2CO)_2(PPh_3)_2]$ [5], $[Pt\{NHS(O)_2NH\}(PPh_3)_2]$ [13] and the isatin-derived complex *cis*-$[Pt(isat)_2(PPh_3)_2]$ (isatH = isatin, indole-2,3-dione) [15], respectively.

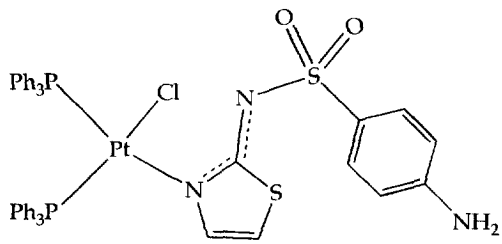
The ^1H and $^{13}C-\{^1H\}$ NMR spectra of the phosphine complexes **3a** and **3b** are relatively uninformative, due to the large number of overlapping signals in the aromatic region. However, unam-



1 **2**



Complex	M	L or L_2
3a	Pt	PPh_3
3b	Pt	dppf
3c	Pd	phen



4

5b: R = $C(O)CF_3$
5c: R = $S(O)_2C_6H_4Me$-*p*

biguous NMR assignment of the complex **3a** was achieved using HMBC [Heteronuclear Multiple Bond Correlation (long-range ^{13}C-^1H correlation, optimised for ^2J and ^3J coupling)] and HMQC [Heteronuclear Multiple Quantum Correlation (short-range ^{13}C-^1H, optimised for ^1J coupling)] inverse 2D experiments. The aromatic region of the ^1H NMR spectrum of **3a** is illustrated in Fig. 3. The assignment of hydrogen atoms 2″ and 3″ (which cannot be easily distinguished by standard methods) was made using known assignments of the thiazole group in the literature [16]. No $^2J_{C,Pt}$ or $^3J_{C,Pt}$ couplings could be observed for this complex, even with overnight acquisition periods on a relatively concentrated solution. The addition of D_2O to a d_6-DMSO solution of compound **3a** resulted in complete exchange of the NH_2 protons at δ 5.64, confirming their assignment.

Complex **4** gives the expected AB pattern in the ^{31}P NMR spectrum, with resonances at δ 13.4 and 5.2, showing coupling of ^{195}Pt of 3850 and 3254 Hz, respectively, consistent with PPh_3 ligands *trans* to chloride and *N*-donor ligands. For the related complex *cis*-[PtCl(debarb)$(PPh_3)_2$] (debarb = anion of 5,5-diethylbarbituric acid) comparable values of ^1J(Pt,P) of 3950 and 3337 Hz were observed for the phosphines *trans* to chloride and amide ligands [4]. The difference in coupling constants is larger for the asymmetric complex **4** when compared to the symmetrical species *cis*-[$PtCl_2(PPh_3)_2$] [^1J(Pt,P) 3673 Hz] and the complex **3a** [^1J(Pt,P) 3444 Hz], and this effect has been reported previously [15,17].

The ^{31}P NMR spectra of the derivatised complexes **5** show little change in the ^1J(Pt,P) coupling constant [**5a** 3449 Hz, **5b** 3450 Hz] from the parent complex **3a** [3444 Hz]. This is not unexpected given the remoteness of the reactive site from the Pt—P moiety.

Electrospray mass spectrometry

The sulfathiazole complexes **3**–**5** have been investigated by electrospray mass spectrometry (ESMS). This relatively new technique, which was originally developed by Fenn and co-workers for the analysis of large biomolecules, is finding increased use in the characterisation of inorganic complexes [18]. ESMS is particularly well-suited for complexes having only low solubilities and volatilities, such as those described in this paper. Additionally, the rather complicated ^1H and ^{13}C NMR spectra yielded by such complexes containing multiple aromatic ring systems, coupled with remote NH_2 functional groups, makes a simple mass spectrometric technique the method of choice for the initial characterisation of complexes of this type.

ESMS data for complexes **3**–**5** are summarised in Table 1, and the complex *cis*-[$Pt(stz)_2(PPh_3)_2$] **3a** is taken as a representative example for the purposes of the following discussion. At a cone voltage of 20 V the complex yields a strong protonated ion peak $[M+H]^+$ at *m/z* 1229. Excellent agreement was observed between the observed and calculated isotope distribution patterns. Additional small peaks were observed due to $[M+Na]^+$ and $[M+K]^+$, formed from traces of the alkali metal cations present in the system. Such adducts from trace cations are well-known in electrospray mass spectra. No higher aggregates of the type $[2M+H]^+$ or $[3M+H]^+$ were observed. Upon increasing the cone voltage to 30 V, an additional species, having major peaks at *m/z* 973 and 974 is observed, and is assigned to the species $[Pt(stz)(PPh_3)_2]^+$, i.e. $[M-stz]^+$, formed by loss of a sulfathiazole anion ligand. Upon further increasing the cone voltage, the relative proportion of the $[M-stz]^+$ species increases at the expense of $[M+H]^+$ and $[M+Na]^+$. At still higher cone voltages, the species $[(o\text{-}C_6H_4PPh_2)Pt(PPh_3)]^+$ (*m/z* 718), containing an orthometallated PPh_3 ligand, and its solvated analogue $[(o\text{-}C_6H_4PPh_2)Pt(PPh_3)(NCCH_3)]^+$, are observed. We have previously observed such cyclometallation in studies of a wide range of platinum(II) complexes [4,5,15].

The other stz complexes show generally similar ESMS behaviour to the triphenylphosphine complex

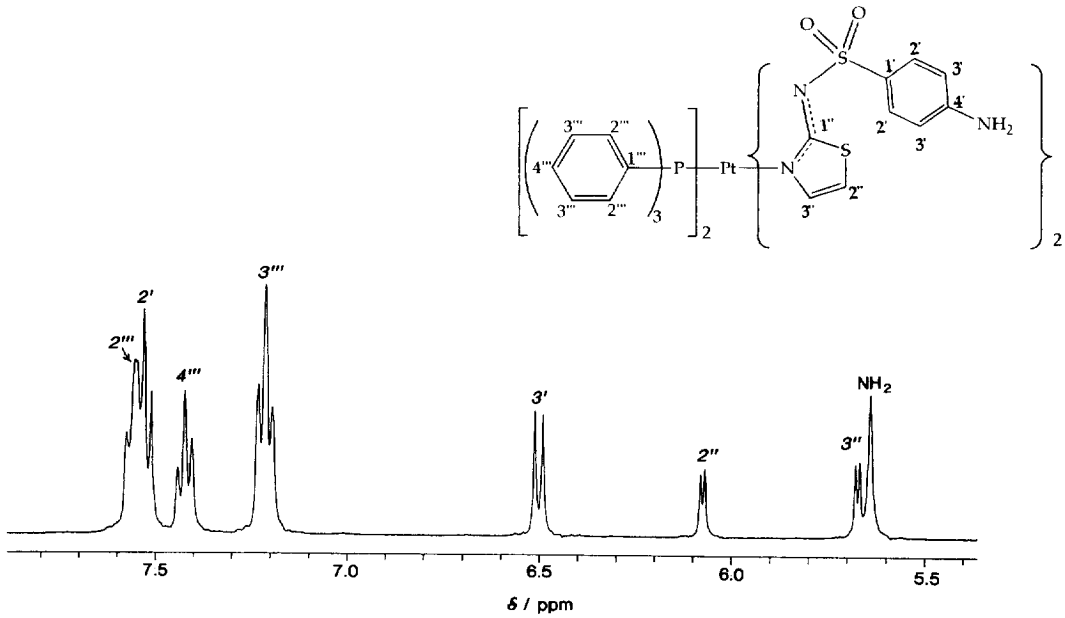

Fig. 3. ^{1}H NMR spectrum (400 MHz, d_6-DMSO solution) of the aromatic region of the platinum–triphenylphosphine complex *cis*-[Pt(stz)$_2$(PPh$_3$)$_2$] **3a**, showing the assignment of the various aromatic and NH_2 protons. The inset shows the atom numbering scheme.

5b	20	$[M+H]^+$ (1422, 100%)
	50	$[M-stzCOCF_3]^+$ (1069, 100%), $[M+H]^+$ (1422, 100%)

[a] Identification of ions is by means of the most intense peak or peaks in the isotope distribution pattern.
[b] Weak ions also observed due to the small amount of impurity **3a** present in this sample.

3a. All complexes yield a strong $[M+H]^+$ molecular ion, though different propensities to form the $[M(stz)L_2]^+$ ion were observed. The observation of $[M-stz]^+$ ions up to high cone voltage suggests that the platinum-amide bond in the monocationic species possess considerable stability, though cyclometallation of the PPh_3 ligands provides an apparent route for fragmentation. In contrast, loss of the first stz^- ligand appears to provide an alternative ionisation process (to protonation) at moderate cone voltages.

For complex **4** containing one chloride and one stz ligand, the ESMS spectrum of a freshly prepared solution showed a large $[M+H]^+$ peak at m/z 1010. The presence of both multi-isotopic platinum and di-isotopic chlorine leads to a highly distinctive isotope

distribution pattern for this species, and excellent agreement was found between observed and calculated patterns. The aromatic amine group present in the complex is expected to be the most basic in the complex, and is thus the likely site of protonation.

The acetylated complex **5a** shows a strong $[M+H]^+$ ion at *m/z* 1313 in the 20 V ESMS spectrum, confirming acetylation of both primary amine groups. When the cone voltage is increased to 50 V, one of the acetylated sulfathiazole ligands (stzAc) is lost, giving $[M-stzAc]^+$ (*m/z* 1015) as the base peak, thus paralleling the behaviour of the parent **3a**. Identical behaviour was shown by the trifluoroacetylated complex **5b**. However, the product (**5c**) from the attempted reaction of **3a** with *p*-toluenesulfonyl chloride (Tol-SO_2Cl) in pyridine was shown by ESMS to be a mixture of products, with both mono- and di-sulfonylated complexes giving their respective $[M+H]^+$ ions in the 20 V positive-ion spectrum. The major peak, at *m/z* 1207, is assigned as $[Pt(stz\text{-}SO_2Tol)(pyridine)(PPh_3)_2]^+$ apparently formed by loss of one stz ligand and coordination of a pyridine ligand, the solvent used in the synthesis of this product. However, $^{31}P\text{-}\{^1H\}$ NMR of this mixture of products yielded only a single resonance [δ 2.7, ^1J(PtP) 3450], suggesting that the neutral complexes **3a** and **5c** (and the mono-derivatised complex) have a lower ionisation efficiencies than the cationic $[Pt(stz\text{-}SO_2Tol)(pyridine)(PPh_3)_2]^+$. The NH_2 group is located some distance from the PPh_3 ligands, and ^{31}P NMR is therefore insensitive to changes at this position. Despite the lack of success of the synthesis of **5c**, the study demonstrates that ESMS provides a valuable characterisation technique for rapid identification of reaction products in this system, where ^1H and ^{13}C NMR is of limited diagnostic value.

In conclusion, a number of platinum(I) and palladium(II) complexes containing deprotonated sulfathiazole ligands have been prepared; a structure determination of the bis(triphenylphosphine) platinum complex **3a** shows the ligands to be coordinated through the thiazole nitrogen atoms. Electrospray mass spectrometry is demonstrated to be a useful technique for investigating the chemistry of this class of compound.

EXPERIMENTAL

The compound $[PdCl_2(phen)]$ [19] was synthesised via the literature procedure. The complexes *cis*-$[PtCl_2(PPh_3)_2]$ and $[PtCl_2(dppf)]$ were prepared by ligand substitution [20] of the cyclo-octa-1,5-diene (cod) ligand of the complex $[PtCl_2(cod)]$ [21]. The following compounds were either prepared via the literature procedure or used as supplied from commercial sources: PPh_3 (Pressure Chemical Company), dppf and trifluoroacetic anhydride (Aldrich), sulfathiazole **2** and *p*-toluenesulfonyl chloride (BDH). Methanol was of LR grade and used without any prior purification, while triethylamine was distilled from KOH pellets prior to use.

Melting points were recorded on a Reichert hot-stage apparatus and are uncorrected. Elemental analyses were performed by the Campbell Microanalytical Laboratory, University of Otago. IR spectra were recorded as KBr disks on a Perkin-Elmer 1600 Series or BioRad FTS-40 FTIR spectrophotometers. $^{31}P\text{-}\{^1H\}$ NMR spectra were recorded (unless otherwise stated) in $CDCl_3$ solution, to which ca 20% of DMSO was added, either on a JEOL JNM-FX90 spectrometer, at 36.23 MHz, or on a Bruker AC300P spectrometer at 121.51 MHz. Spectra were recorded with external 85% H_3PO_4 as the reference (δ 0.0). ^1H NMR spectra were recorded in d_6-DMSO solution on a Bruker DRX spectrometer at 400.13 MHz, or on a Bruker AC300P instrument at 300.13 MHz, chemical shifts being relative to $SiMe_4$ (δ 0.0). $^{13}C\text{-}\{^1H\}$ NMR spectra were recorded on a Bruker AC300P spectrometer at 75.47 MHz.

Electrospray mass spectra were obtained in positive-ion mode with a VG Platform II mass spectrometer, with MeCH–H_2O (1 : 1) as the mobile phase. Cone voltages were typically varied from 10 to 100 V, in order to investigate the effect of higher voltages on fragmentation of the parent ions. Excellent agreement between observed and calculated isotope distribution patterns was observed for all major ions. Theoretical isotope patterns were calculated using the *Isotope* program [22].

Melting point, microanalytical and IR spectroscopic data for complexes **3**–**5** are presented in Table 2.

Synthesis of cis-$[Pt(stz)_2(PPh_3)_2]$ **3a**

A suspension of *cis*-$[PtCl_2(PPh_3)_2]$ (200 mg, 0.253 mmol) and stzH **2** (133 mg, 0.521 mmol) was heated to reflux in methanol (20 cm^3) with triethylamine (0.4 cm^3) for 1.5 h to give a white suspension. The mixture was cooled and water (30 cm^3) added. The product was filtered, washed with water (5 cm^3) and dried *in vacuo* to yield **3a** (260 mg, 84%). NMR: $^{31}P\text{-}\{^1H\}$ (121.5 MHz), δ 3.48 [s, ^1J(Pt,P) 3444]. $^{13}C\text{-}\{^1H\}$: ($CDCl_3$) δ 168.5 (s, 1″), 151.4 (s, C-4′), 133.8 (d, C-2‴, 6‴), 133.2 (s, C-2″), 131.1 (d, C-4‴), 130.2 (s, C-1′), 128.3 (d, C-3‴, 5‴), 127.4 (d, C-2′, 6′), 126.9 [s, (dd, second-order, $^1J_{C,P}$ 68.53, $^3J_{C,P}$ 5.87), C-1‴], 112.3 (d, C-3′,5′), 105.8 (d, C-3″).

Synthesis of cis-$[Pt(stz)_2(dppf)]$ **3b**

A suspension of $[PtCl_2(dppf)]$ (101 mg, 0.123 mmol) and stzH **2** (63 mg, 0.247 mmol) in methanol (30 cm^3) with triethylamine (1 cm^3) was refluxed for 1.5 h. The yellow suspension was cooled to room temperature, and the product filtered, washed with methanol (5 cm^3) and dried *in vacuo* to give **3b** (118

mg, 76%). ^{31}P-$\{^1H\}$ NMR (121.5 MHz), δ 3.8 [s, ^1J(Pt,P) 3535].

Synthesis of [Pd(stz)$_2$(phen)] **3c**

The complex [PdCl$_2$(phen)] (125 mg, 0.350 mmol) with stzH **2** (179 mg, 0.701 mmol) in methanol (30 cm^3) with added triethylamine (1 cm^3) was refluxed for 16 h to give an orange suspension. Complex **3c** was filtered off, washed with methanol (5 cm^3), acetone (5 cm^3) and dried *in vacuo* to give an orange powder (244 mg, 88%).

Synthesis of cis-[PtCl(stz)(PPh$_3$)$_2$] **4**

To a solution of *cis*-[PtCl$_2$(PPh$_3$)$_2$] (143 mg, 0.181 mmol) and stzH **2** (47 mg, 0.184 mmol) in methanol (10 cm^3) and dichloromethane (20 cm^3) was added triethylamine (1 cm^3), and the mixture stirred overnight at room temperature. The resulting colourless solution was rotary evaporated to dryness at 40°C to afford a white solid, which was found to be complex **4**, with a small quantity (ca 3%) of the bis(stz) complex **3a**. The solid was washed with isopropanol (20 cm^3) to remove triethylammonium chloride, and dried *in vacuo* to give crude **4** (139 mg, 76%). ^{31}P-$\{^1H\}$ NMR (36.2 MHz), δ 13.4 [s, ^1J(Pt,P) 3850, ^2J(P,P) 17] and 5.2 [s, ^1J(Pt,P) 3254].

Reaction of ***3a*** *with acetic anhydride, trifluoroacetic anhydride and* p-*toluenesulfonyl chloride*

General method. To a stirred solution of complex **3a** (ca 150 mg, 0.122 mmol) in pyridine (5 cm^3) was added acetic anhydride or trifluoroacetic anhydride (40 drops) or *p*-toluenesulfonyl chloride (100 mg), and stirred for 60 min. The mixture was poured onto crushed ice and allowed to warm to room temperature. The resulting solid was filtered, washed with water (10 cm^3) and ether (10 cm^3) and dried *in vacuo*.

Complex **5a**. Reaction of **3a** (164 mg, 0.133 mmol) with acetic anhydride gave **5a** (108 mg, 62%) as a white powder. ^{31}P-$\{^1H\}$ NMR (121.5 MHz), δ 3.3 [^1J(Pt,P) 3449].

Complex **5b**. Reaction of **3a** (160 mg, 0.130 mmol) with trifluoroacetic anhydride gave **5b** (129 mg, 70%) as a pale pink powder. ^{31}P-$\{^1H\}$ NMR (121.5 MHz, $CDCl_3$), δ 2.2, ^1J(Pt,P) 3450.

Complex **5c**. Reaction of **3a** (154 mg, 0.125 mmol) with *p*-toluenesulfonyl chloride gave **5b** (96 mg) as a white powder, which was shown to be a mixture of products by ESMS. ^{31}P-$\{^1H\}$ NMR (121.5 MHz, $CDCl_3$) showed a single major peak at δ 2.7 [^1J(Pt,P) 3450].

Crystal structure determination of **3a**

Crystals of **3a** suitable for an X-ray structure determination were obtained by allowing a saturated $CHCl_3$ solution of the complex to stand at 4°C for several weeks. Unit cell dimensions and intensity data were obtained on a Seimens SMART diffractometer. The data collection nominally covered over a hemisphere of reciprocal space, by a combination of three sets of exposures: each set had a different ϕ angle for the crystal and each exposure covered 0.3° in ω. The crystal to detector distance was 5.0 cm. The data set was corrected using SADABS [23], including an empirical absorption correction ($T_{max,min}$ 0.83, 0.39).

Crystal data. $C_{54}H_{46}N_6O_4P_2S_4Pt.3CHCl_3$, Mr = 1586.34 (including solvent of crystallisations), triclinic, $P\bar{1}$, a = 11.0997(1), b = 14.7197(2), c = 21.3011(2) Å, α = 78.349(1), β = 77.424(1), γ = 71.016(1)°, U = 3179.43(6) Å^3, D_{calcd} 1.657 g cm^{-3}, Z = 2, $F(000)$ = 1580, Mo—K_α X-rays (λ = 0.71073 Å), μ(Mo-K_α) = 2.82 mm^{-1}, crystal 0.40 × 0.11 × 0.10 mm^3.

A total of 31,057 reflections in the range $2° < \theta < 28°$ were collected at 203 K, with 13,802 unique (R_{int} 0.087). The structure was solved by Patterson methods (SHELXS-96 [24]) and developed routinely. One of the three $CHCl_3$ molecules in the lattice was partially disordered with two of the chlorine atoms each distributed over two sites, while another showed high temperature factors suggesting at least partial disorder/occupancy. In the final cycles of least-squares refinement based on F^2 (SHELXL-96 [24]) all non-hydrogen atoms were anisotropic and hydrogen atoms were included in calculated positions. The refinement converged with $R_1 = 0.0854$ for 9727 data with $I > 2\sigma(I)$, 0.1230 for all data, $wR_2 = 0.1950$ $\{w = [\sigma^2(F_o^2) + 0.1143P^2]^{-1}$ where $P = (F_o^2 + 2F_c^2)/3\}$ and GoF 1.047. A final difference map showed somewhat large residual features of +7.21 and −3.66 e Å^{-3}, within 1 Å of the platinum atom, which could not be improved upon by reprocessing the data. This, together with the higher than usual *R* factors, suggests that the data were not of the best quality, a problem exacerbated by the disorder in the $CHCl_3$ molecules in the crystal. Detailed discussion of bond parameters is therefore deemed inappropriate.

Further details of the structure investigation, together with lists of final atomic coordinates, thermal parameters, and complete bond distances and angles, and structure factors may be obtained from the Cambridge Crystallographic Data Centre, or from the authors on request.

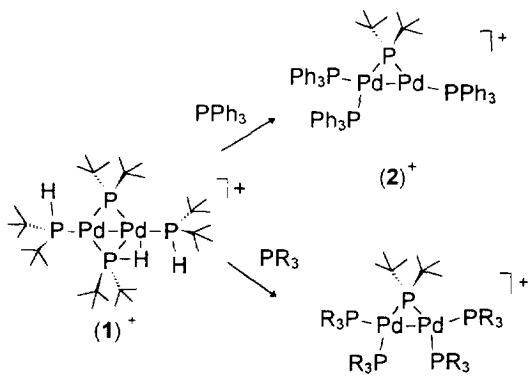
(Received 2 December 1997; accepted 24 February 1998)

Abstract—New mono-phosphido-bridged cationic derivatives of dipalladium(I) have been prepared by reacting $[Pd_2(\mu-PBu^t_2)(PPh_3)_3]BF_4$ (**2**)BF_4, with $P(OR)_3$ (R = Me, Et, Ph). Under a large excess of the entering phosphite, all the PPh_3 molecules terminally bonded to the central $Pd_2(\mu-PBu^t_2)$ core can be substituted, yielding $[Pd_2(\mu-PBu^t_2)\{P(OR)_3\}_4]BF_4$, [(**4a**)$BF_4$, R = Me; (**4b**)$BF_4$, R = Et and (**4c**)$BF_4$, R = Ph]. The intermediate mixed-ligand complex $[Pd_2(\mu-PBu^t_2)(PPh_3)\{P(OPh)_3\}_2]BF_4$, (**5**)$BF_4$, was isolated in the reaction with $P(OPh)_3$. Moreover, the reactions of the new complexes with CO, isoprene and CS_2 were investigated and compared to the corresponding reactions of the phosphine-substituted complexes. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: dinuclear; phosphido-bridges; palladium(I); phosphite; cationic.

The chemistry of phosphido-bridged palladium(I) dinuclear derivatives was rather unexplored until a few years ago [1]. Our group is involved in a systematic study of this field [2–7], and has shown that the secondary phosphine-bridged $[Pd_2(\mu-PBu^t_2)(\mu-PBu^t_2H)(PBu^t_2H)_2]BF_4$, (**1**)$BF_4$ [3], can be employed as the precursor of a series of mono-phosphido-bridged cationic derivatives of general formula $[Pd_2(\mu,PBu^t_2)(PR_3)_n]BF_4$, [4] with n depending on the steric demand of the phosphine ligand ($n=3$, R = Ph [(**2**)BF_4]; $n=4$, R = Me [(**3a**)BF_4], R = Et [(**3b**)BF_4] or $R_3 = Cy_2H$, [(**3c**)BF_4]; see Scheme 1). Both (**1**)BF_4 and its derivatives with other phosphines have shown an interesting reactivity; they can be used as a source of still rare examples of terminally bonded Pd(I) carbonyls [3b, 5] or show cooperation of the two metal centers in the coordination of polyunsaturated molecules as isoprene [5, 6] or CS_2 [4b, 7]. We now report the synthesis of new members of this family, bearing phosphites terminally bonded to the central $[Pd_2(\mu-PBu^t_2)]^+$ core, and compare their reactivity with that given by their phosphine analogues.



Scheme 1

EXPERIMENTAL

General and instrumental

All reactions were performed under an atmosphere of purified nitrogen or carbon monoxide by using standard Schlenck techniques. Solvents were dried by

* Address to whom correspondence should be addressed.

standard procedures and distilled under nitrogen prior to use. Deuterated solvents were used as purchased and stored on molecular sieves under an inert atmosphere. $[Pd_2(\mu-PBu^t_2)(PPh_3)_3]BF_4$, **(2)**$BF_4$, was prepared as previously described [4b]. IR spectra were recorded with a Perkin-Elmer FT-IR 1725X spectrophotometer and NMR spectra with a Varian Gemini 200BB spectrometer, frequencies were referenced to the residual signal of the deuterated solvent (^1H, ^{13}C) and to external 85% H_3PO_4 (^{31}P). The progress of the reactions was monitored by means of $^{31}P\{^1H\}$ NMR spectroscopic analyses of small samples of a reaction mixture, after adding a few drops of C_6D_6 for the lock signal capture and the field homogeneity optimization operations.

Preparation of $[Pd_2(\mu-PBu^t_2)\{P(OMe)_3\}_4]BF_4$, ***(4a)****BF*$_4$. Trimethyl phosphite (0.16 mL, 1.44 mmol) was added to a red acetone (10 mL) solution of **(2)**BF_4 (179 mg, 0.145 mmol). The solution turned quickly orange; after 15 min most of the solvent was evaporated and *n*-hexane (20 mL) was added, causing the precipitation of a yellow powder which was filtered off, washed with *n*-hexane, and *vacuum* dried (95 mg, 70% yield).

Elem. Anal. Calcd for $C_{20}H_{54}BF_4P_5Pd_2$: C, 25.5, H, 5.78. Found: C, 25.6, H, 5.80%. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 298 K): δ (ppm) 345.5 (tm, $^2J_{PP} \approx 282$, 46 Hz, $\mu-PBu^t_2$), 136.2 (dm, $^2J_{PP} \approx 280$ Hz, $P(OMe)_3$ *trans* to μ-P), 127.2 (m, $P(OMe)_3$ *cis* to μ-P). ^1H NMR ($CDCl_3$, 298 K): δ (ppm) 3.65 (m, 36 H, OCH_3), 1.35 (d, $^3J_{HP} = 14.2$ Hz, 18 H, $PC(CH_3)_3$). IR (Nujol, KBr): 1028 s, br (ν_{BF}) cm^{-1}.

Preparation of $[Pd_2(\mu-PBu^t_2)\{P(OEt)_3\}_4]BF_4$, ***(4b)****BF*$_4$. Triethyl phosphite (0.37 mL, 2.16 mmol) was added to a red acetone (15 mL) solution of **(2)**BF_4 (266 mg, 0.216 mmol). The solution turned quickly orange; after 30 min most of the solvent was evaporated after which *n*-hexane (25 mL) was added, causing the precipitation of a yellow powder. The suspension was left overnight at -30 C, the solid filtered off, washed with *n*-hexane, and *vacuum* dried (158 mg, 66% yield).

Elem. Anal. Calcd for $C_{32}H_{78}BF_4O_{12}P_5Pd_2$: C, 34.6, H, 7.09. Found: C, 34.8, H, 6.99. $^{31}P\{^1H\}$ NMR (Acetone-d_6, 298 K): δ (ppm) 345.6 (tm, $^2J_{PP} \approx 280$, 50 Hz, $\mu-PBu^t_2$), 137.2 (dm, $^2J_{PP} \approx 280$ Hz, $P(OEt)_3$ *trans* to μ-P), 123 (m, $P(OEt)_3$ *cis* to μ-P). ^1H NMR ($CDCl_3$, 298 K): δ (ppm) 3.9 (br s, 24 H, OCH_2CH_3), 1.3 (overlapping m, 54 H, $OCH_2CH_3 + PC(CH_3)_3$). IR (Nujol, KBr): 1034 s, br (ν_{BF}) cm^{-1}.

Preparation of $[Pd_2(\mu-PBu^t_2)\{P(OPh)_3\}_4]BF_4$, ***(4c)****BF*$_4$. Triphenyl phosphite (1.71 mL, 6.52 mmol) was added to a red CH_2Cl_2 (15 mL) solution of **(2)**BF_4 (80 mg, 0.065 mmol). The color of the solution turned quickly orange; after 15 min 2/3 of the solvent were evaporated and Et_2O (20 mL) was added, causing the precipitation of an orange powder which was filtered, washed with Et_2O, and *vacuum* dried (88 mg, 80% yield).

Elem. Anal. Calcd for $C_{80}H_{78}BF_4O_{12}P_5Pd_2$: C, 57.0, H, 4.66. Found: C, 57.6, H, 4.66. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 298 K): δ (ppm) 360.0 (tt, $^2J_{PP} \approx 240$, 46 Hz, $\mu-PBu^t_2$), 118.0 (dm, $^2J_{PP} = 240$ Hz, $P(OPh)_3$ *trans* to μ-P), 103 (m, $P(OPh)_3$ *cis* to μ-P). ^1H NMR ($CDCl_3$, 298 K): δ (ppm) 7.2 (m, 60 H, OC_6H_5), 1.3 (d, $^3J_{HP} = 15$ Hz, 18 H, $PC(CH_3)_3$). IR (Nujol, KBr): 1055 s, br (ν_{BF}) cm^{-1}.

Preparation of $[Pd_2(\mu-PBu^t_2)(PPh_3)\{P(OPh)_3\}_2]BF_4$, ***(5)****BF*$_4$. Triphenyl phosphite (4.07 mL, 15.5 mmol) was added to a red CH_2Cl_2 (10 mL) solution of **(2)**BF_4 (327 mg, 0.26 mmol). The color of the solution turned quickly orange; after 15 min most of the solvent was evaporated and Et_2O (30 mL) was added, causing the precipitation of an orange powder which was filtered, washed with Et_2O, and *vacuum* dried (220 mg, 64% yield).

Elem. Anal. Calcd for $C_{62}H_{63}BF_4O_6P_4Pd_2$: C, 56.1, H, 4.78. Found: C, 58.5, H, 5.05. $^{31}P\{^1H\}$ NMR (acetone-d_6, 298 K): δ (ppm) 374.2 (ddd, $^2J_{PP} = 195$, 102, 70 Hz, $\mu-PBu^t_2$), 124.2 (ddd, $^2J_{PP} = 102$, 37 Hz, $^3J_{PP} = 363$ Hz, $P(OPh)_3$), 113.6 (ddd, $^2J_{PP} = 70$, 14 Hz, $^3J_{PP} = 363$ Hz, $P(OPh)_3$), 26.8 (ddd, $^2J_{PP} = 195$, 37 Hz, $^3J_{PP} = 14$ Hz), the spectrum shows other minor signals (see Results and Discussion) due to other compounds which justify the low purity found in elemental analysis, attempted purification by column chromatography led to decomposition. ^1H NMR ($CDCl_3$, 298 K): δ (ppm) 7.1 (m, 45 H, $PC_6H_5 + OC_6H_5$), 1.4 (d, $^3J_{HP} = 14.6$ Hz, 18 H, $PC(CH_3)_3$). IR (Nujol, KBr): 3040 ($\nu_{=CH}$), 1588, 1486 ($\nu_{C=C}$), 1055 s, br (ν_{BF}) cm^{-1}.

Reactions of ***(4a,b)****BF*$_4$ with CS_2 A 10-fold excess of CS_2 was added by syringe to a $CDCl_3$ solution (0.5 mL) of **(4a)**BF_4 (15 mg, 0.0159 mmol) or **(4b)**BF_4 (18 mg, 0.0162 mmol). The orange solutions turned quickly yellow and were analyzed by $^{31}P\{^1H\}$ NMR spectroscopy (see Results and Discussion).

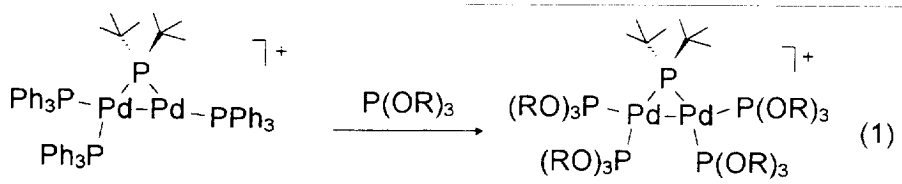
Reactions of ***(4a,b)****BF*$_4$ with isoprene A 10-fold excess of isoprene was added by syringe to a $CDCl_3$ solution (0.5 mL) of **(4a)**BF_4 (16 mg, 0.017 mmol) or **(4b)**BF_4 (19 mg, 0.0171 mmol). The orange solutions turned quickly yellow and were analyzed by $^{31}P\{^1H\}$ NMR (see Results and Discussion).

Reactions of ***(4a,b)****BF*$_4$ with *CO* Carbon monoxide was bubbled into orange $CDCl_3$ solutions of complex **(4a)**BF_4 or **(4b)**BF_4 (*ca* 30 mg/mL). A faint bleaching of the starting colour was observed and the solutions were analyzed by $^{31}P\{^1H\}$ NMR spectroscopy which exhibited only the resonances of the reagents. The IR spectra of the solutions exhibited medium-weak ν_{CO} absorptions around 2070 cm^{-1}.

RESULTS AND DISCUSSION

The unsaturated triphenylphosphine derivative $[Pd_2(\mu-PBu^t_2)(PPh_3)_3]BF_4$, **(2)**$BF_4$ [4b], proved to be a suitable precursor to phosphite substituted complexes. When acetone or methylene chloride solu-

tions of (**2**)BF_4 were reacted at room temperature with an excess of the appropriate phosphite, the corresponding persubstituted derivatives (eq 1) were formed and isolated as yellow microcrystalline solids in satisfactory to good yields (67–80%). The reactions were fast and clean when at least a 10-fold excess of the alkyl phosphite was employed; in the case of triphenyl phosphite a higher excess of the ligand was necessary. The new complexes analyzed nicely for the composition $[Pd_2(\mu-PBu^t_2)\{P(OR)_3\}_4]BF_4$, [(**4a**)$BF_4$, R = Me; (**4b**)$BF_4$, R = Et and (**4c**)$BF_4$, R = Ph] and, as inferred by the analysis of ^{31}P NMR spectra (see below), retain the usual [4a] structure exhibited by the analogous phosphine derivatives, with two palladium centers in a distorted square planar geometry sharing a bridging phosphido ligand and the metal-metal bond.



(**2**)$^+$

(**4a**)$^+$: R = Me
(**4b**)$^+$: R = Et
(**4c**)$^+$: R = Ph

The $^{31}P\{^1H\}$ NMR spectrum of (**4b**)BF_4 is shown in Scheme 1, with the numbering scheme.

This particular framework of phosphorus atoms (Pd_2P_5 planar core with C_{2v} symmetry) constitutes an AA′BB′X spin system where A and B are, respectively, the P-nuclei *trans* and *cis* to X, the bridging phosphorus. Due to the magnetic non-equivalence of the couples AA′ and BB′, the spectrum cannot be interpreted with simple first order approximations, and can be quite complex. In general, the lines within the multiplets are no longer directly correlated to the values of $^2J_{AX}$, $^2J_{BX}$ and $^2J_{AB}$, but to combinations of these coupling constants and of $^3J_{AA'}$, $^3J_{BB'}$ and $^3J_{AB'}$. When the differences (in Hertz) between the values of δ_A, δ_B and δ_X are much larger than coupling constants values, as in the case of the phosphine derivatives [4a], the spectrum is still relatively simple and easily simulated. The large downfield shift of δ_A and δ_B which occurs when phosphites are employed in place of the phosphines (around 100 ppm) approaches them to δ_X; the spin system is better defined as AA′BB′C and give rise to an extreme complication of the spectra; none of the nine independent variables of the spin system can be easily extracted from the spectrum. Due to this difficulty only some spectral features were reproduced in the simulation with a satisfactory approximation. This is particularly true for the low

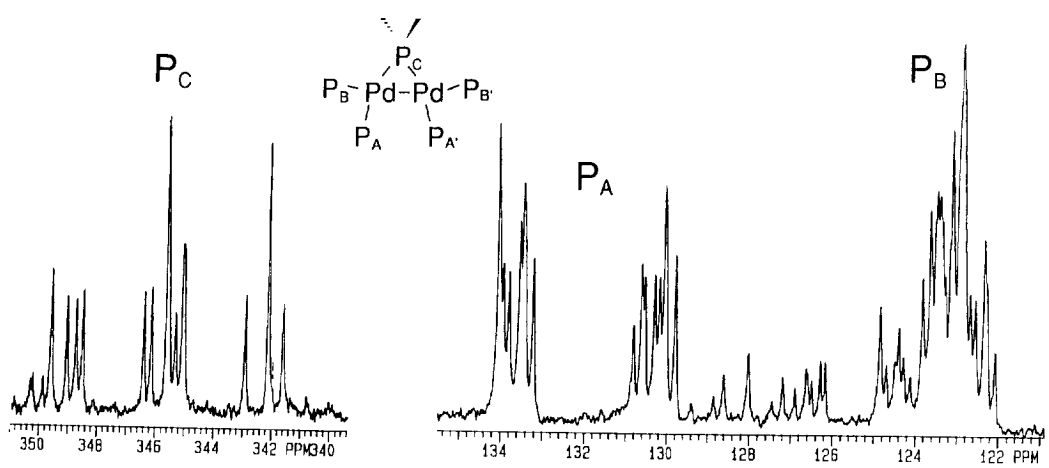


Fig. 1. $^{31}P\{^1H\}$ NMR spectrum (acetone-d_6, 293 K) of $[Pd_2(\mu-PBu^t_2)\{P(OEt)_3\}_4]BF_4$ (**4b**)BF_4, with the numbering scheme.

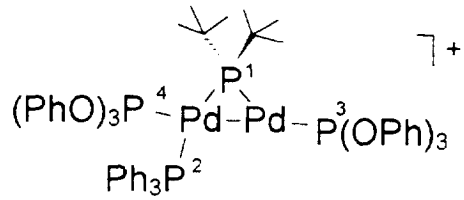
field signal due to μ-P, which highly resembles the signal given by the corresponding phosphorus [4a] of $[Pd_2(\mu-PBu^t_2)(PR_3)_4]BF_4$ (R = Me, Et), and allows an approximate evaluation of δ_C, $^2J_{AC}$ and $^2J_{BC}$, respectively found at *ca* 345.5 ppm, 282 and 46 Hz for (**4a**)BF_4, *ca* 345.6 ppm, 280 and 50 Hz for (**4b**)BF_4 and *ca* 360 ppm, 240 and 46 Hz for (**4c**)BF_4. These values confirm the approximately planar disposition of the $Pd_2(\mu$-P)P_4 core, with two *pseudo-trans* and two *pseudo-cis* (compared to μ-P) phosphite ligands.

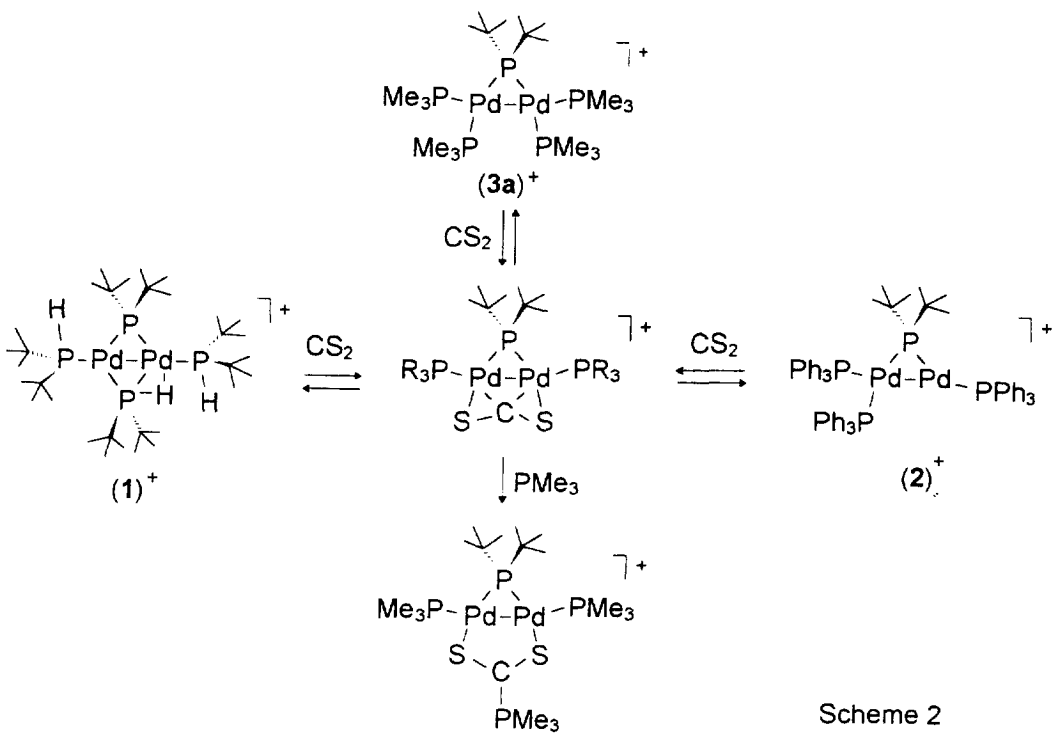
^{1}H NMR spectra are easily interpreted and give the expected integral ratio between the various types of nuclei.

With lower $P(OR)_3$/(**2**)BF_4 ratios we observed the formation of mixtures of products arising from the progressive stepwise substitution of the three triphenylphosphine molecules contained in (**2**)$^+$. The number of observed intermediates, of general formula $[Pd_2(\mu-PBu^t_2)(PPh_3)_{(3-n)}\{P(OPh)_3\}_n]BF_4$, is generally high, since different geometrical isomers were observed for a given value of n. Therefore very complex mixtures were formed in most cases but one. In fact, when (**2**)BF_4 was reacted with a 10-fold excess of $P(OPh)_3$ one of these intermediates can be isolated sufficiently pure and readily identified as $[Pd_2(\mu-PBu^t_2)(PPh_3)\{P(OPh)_3\}_2]BF_4$, (**5**)$BF_4$. Its $^{31}P\{^1H\}$ NMR spectrum is quite simple and shows a doublet of doublets of doublets ($^2J_{PP}$ = 195, 70, 102 Hz) at 374.2 ppm for the bridging phosphide (P_1); the remaining three P nuclei give resonances at 26.8 ppm (ddd, J_{PP} = 195, 37, 14 Hz), assigned to the phosphorus (P_2) of a PPh_3 molecule(for its high field position) *trans* to μ-P (for the large J_{PP} = 195) and at 124.2 (J_{PP} = 363, 37, 102 Hz) and 113.6 (J_{PP} = 363, 70, 14 Hz), respectively assigned to P_3 of the phosphite on the tricoordinated palladium center and to P_4 of the phosphite *cis* to the phosphine molecule.



(**5**)$^+$

The assignment of the latter two resonances has been made by considering that the coupling to P_1 should be minor (70 Hz) when the angle P–Pd–P1 approaches 90° (P_4), and increase (102 Hz) when this angle becomes wider (P_3). Larger values of J_{PP} were observed for phosphite-phosphite or phosphite-phosphine couples with respect to the corresponding phosphine-phosphine couples of the structurally related cation (**2**)$^+$. The exceedingly high value of $^3J_{P3P4}$ = 363 Hz is probably due to a nearly linear dis-



Scheme 2

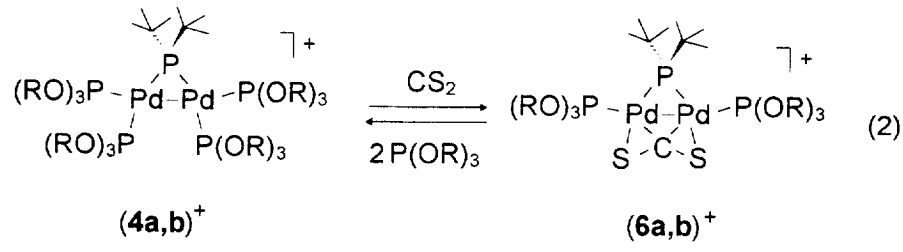
position of the $(PhO)_3P$–Pd–Pd–$P(OPh)_3$ fragment; the corresponding constant was found at 135 Hz in $(\mathbf{2})^+$ [4b].

The purity of the samples of $(\mathbf{5})BF_4$ is not high (*ca* 80%) and small amounts of other intermediates were observable in the spectrum but not identified due to severe overlapping of the weak signals. Well separated signals were observed only in the phosphide region, where two weak ddd appear at 369.8 ($^2J_{PP}$ = 155, 52, 98 Hz) and 355.5 ppm ($^2J_{PP}$ = 220, 75, 61 Hz) suggesting for these derivatives the same type of skeleton assigned to $(\mathbf{5})^+$.

Reactivity of the cations $(\mathbf{4a,b})^+$. The availability of the new complexes allowed us to investigate the influence of the substitution with phosphites on the reactivity of this class of derivatives. We decided to use as tests the reactions with CS_2, isoprene and carbon monoxide, which had previously been investigated for the corresponding phosphine substituted derivatives [3b, 4–7].

Reactions with CS_2. We knew that carbon disulfide reacts with the cations $(\mathbf{1})^+$-$(\mathbf{3})^+$ yielding the corresponding adducts (see Scheme 2) [4b]; these exhibited an unprecedented coordination mode of the CS_2 molecule, with a central planar $Pd_2P_3(CS_2)$ core. One or two phosphine molecules are displaced from the starting complex; in one case (PMe_3) this can behave as a nucleophile toward the metal bonded carbon disulfide molecule [8].

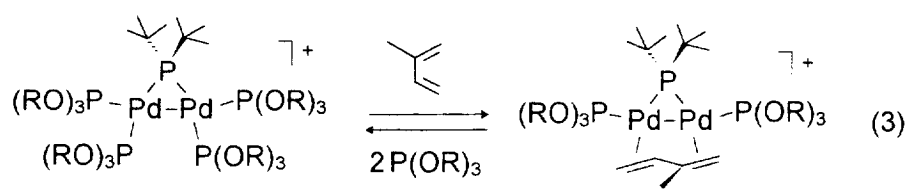
An orange $CDCl_3$ solution of the alkyl phosphite derivatives $(\mathbf{4a})BF_4$ or $(\mathbf{4b})BF_4$ turns immediately yellow when reacted with a 10-fold excess of CS_2. The $^{31}P\{^1H\}$ NMR spectra of the solutions show that in both cases the same type of equilibrium given by the cations $(\mathbf{1})^+$ and $(\mathbf{2})^+$ has established, yielding the CS_2 adducts $(\mathbf{6a})BF_4$ and $(\mathbf{6b})BF_4$ (eq 2). The spectra of these species are very simple, as those given by the corresponding phosphine derivatives [4b], and consist of a high field triplet and a low field doublet coupled by a small $^2J_{PP(cis)}$; these parameters were found at 417.6, 130.1 ppm and 27 Hz for $(\mathbf{6a})BF_4$ and 354.2, 133.5 ppm and 24 Hz for $(\mathbf{6b})BF_4$.



$(\mathbf{4a,b})^+$ $(\mathbf{6a,b})^+$ (2)

A significant difference between the reactions given by $(\mathbf{4a})BF_4$ and $(\mathbf{4b})BF_4$ concerns the position of the equilibrium. In the former case this is shifted toward the reagents: with also larger amounts of CS_2 the resonances of the cation $(\mathbf{4a})^+$ are well visible in the spectrum, although severely broadened by exchange processes. On the contrary, the reaction with $(\mathbf{4b})BF_4$ is shifted toward $(\mathbf{6b})BF_4$ and, with a 10-fold excess of CS_2, the resonances assigned to $(\mathbf{4b})^+$ have nearly completely disappeared from the spectrum.

Reactions with isoprene. Isoprene is another potentially bidentate ligand which was shown to react with the phosphine cations $(\mathbf{1})^+$ – $(\mathbf{3})^+$ yielding the corresponding isoprene derivatives $[Pd_2(\mu\text{-}PBu^t_2)(\mu,\eta^2,\eta^2\text{-isoprene})(PR_3)_2]^+$, as BF_4 or triflate salts [5, 6]. The cooperation between the two metal centers in the coordination of the bidentate ligand was demonstrated also in these cases. The diene molecule, with the two double bonds in a *trans* configuration, was in fact shown to simultaneously coordinate to both metals of the $[Pd_2(\mu\text{-}PBu^t_2)(PR_3)_2]^+$ fragment. The same type of reaction is given by the phosphite cations $(\mathbf{4a})^+$

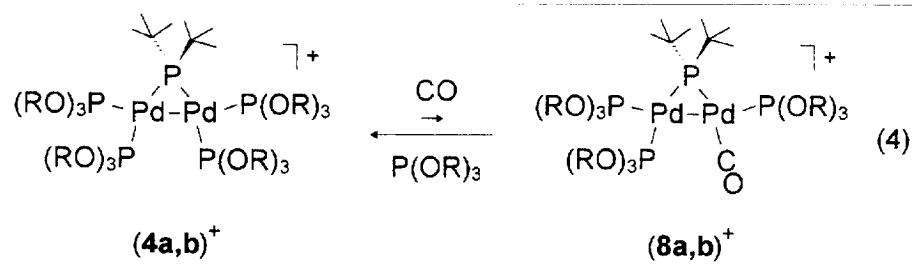


(3)

$(\mathbf{7a})^+$: R = Me
$(\mathbf{7b})^+$: R = Et

and $(\mathbf{4b})^+$ (eq. 3). In fact, after the addition of a 10:1 molar excess of isoprene, a $CDCl_3$ solution of $(\mathbf{4a})BF_4$ (or $(\mathbf{4b})BF_4$) exhibited in the $^{31}P\{^1H\}$ NMR spectrum new resonances assigned to the diene derivatives $(\mathbf{7a})BF_4$ and $(\mathbf{7b})BF_4$, together with the resonances of the starting complexes, considerably broadened. Analogously to the reactions with CS_2 described above, the equilibrium (eq. 3) is greatly shifted to the left when the phosphite is $P(OMe)_3$ and to the right when the phosphite is $P(OEt)_3$. As shown earlier for the corresponding phosphine complexes, the spectrum of $(\mathbf{7a})^+$ (or $(\mathbf{7b})^+$) is due to an ABX spin system, where X is the bridging phosphorus and A and B are the similar, but unequivalent, phosphite P-nuclei (δ_A, δ_B, δ_X and $J_{AX} \approx J_{BX}$ were respectively found at 134.2, 132.8, 381.9 ppm and 53 Hz for $(\mathbf{7a})BF_4$ and at 129.2, 127.4, 379.9 ppm and 51 Hz for $(\mathbf{7b})BF_4$).

Reactions with CO Carbon monoxide was bubbled into orange solutions of complexes $(\mathbf{4a,b})BF_4$. An immediate, hardly perceptible, bleaching of the solutions, together with the appearance of weak to medium ν_{CO} absorptions around 2070 cm^{-1} in the IR spectra, was observed. The $^{31}P\{^1H\}$ NMR spectra of the solutions exhibited broad signals practically in the same positions of those due to the starting materials. These results can be explained by the substitution of a phosphite ligand by a CO molecule, giving $[Pd_2(\mu-PBu^t_2)(CO)\{P(OR)_3\}_3]BF_4$ [$(\mathbf{8a})BF_4$, R = Me; $(\mathbf{8b})BF_4$, R = Et], as shown in eq. 4.



Equilibrium 4 should be far shifted to the left since the NMR resonances are not significantly shifted with respect to those of $(\mathbf{4a,b})BF_4$; their severe broadening is assignable either to the rate of the direct and forward reactions of eq. 4 or to exchange equilibria between coordinated and released $P(OR)_3$ molecules. An equilibrium analogous to that shown in eq. 4 was observed when studying the reaction of the trimethylphosphine derivative $(\mathbf{3a})BF_4$ with carbon monoxide, yielding $[Pd_2(\mu-PBu^t_2)(CO)(PMe_3)_3]BF_4$, this equilibrium is completely shifted to the right under 1 Atm of CO, but is easily reverted by reducing P_{CO} [5].

CONCLUSIONS

The new complexes $(\mathbf{4a–c})BF_4$, with a central $Pd_2(\mu-PBu^t_2)$ core binding four terminal phosphite ligands have been prepared in good yields and purity. At least with the phosphites employed in this work, electronically unsaturated derivatives bearing only three phosphite ligands proved to be too unstable to be isolated or even observed as transient species. The corresponding derivatives bearing phosphine ligands were shown to be isolable when the bulkier phosphines [as in complex $(\mathbf{2})BF_4$] are employed, or when at least one of the phosphines is secondary, and can saturate the electronic deficiency of the tricoordinated palladium center by donating the electrons of the P-H bond [as in the phosphine-bridged $(\mathbf{1})BF_4$]. It was instead possible to isolate, although not pure, a stable derivative with three mixed phosphine-phosphite terminal ligands, complex $(\mathbf{5})BF_4$. This is probably stable due to the presence of a PPh_3 molecule, bulkier than $P(OPh)_3$, which was in fact found to be adjacent to the unsaturated palladium center.

The results observed by studying the reactivity of $(\mathbf{4a,b})BF_4$ parallel those reported previously for their phosphine analogues, in fact both react with CO, CS_2 and isoprene equilibrating, respectively, with the corresponding derivatives $(\mathbf{6–8a,b})BF_4$.

As expected, the reactivity of these systems is highly dependent upon the dimensions of the ligands, since equilibria involving the trimethyl phosphite derivative $(\mathbf{4a})BF_4$, compared to those involving the triethyl phosphite analogue $(\mathbf{4b})BF_4$, are much more shifted towards the reactants. Since solution NMR spectra showed that the reactivity of the phosphite complexes towards CO, CS_2 and isoprene does not differ significantly from that of the phosphine derivatives we did not proceed further in the isolation of the products of these reactions.

(Received 6 January 1998; accepted 26 February 1998)

Abstract—The reactions of $ReOCl_3(Me_2S)(OPPh_3)$ with monodentate $P(OMe)_3$ (P) and bidentate $(OCMe_2CMe_2O)POCMe_2CMe_2OP(OCMe_2CMe_2O)$, (P–P) phosphites afford *fac*-$ReOCl_3P_2$ (**1**) and *fac*-$ReOCl_3$(P–P) (**2**) respectively. Both blue–violet **1** and **2** have been characterized by NMR, IR and UV–Vis spectroscopies as well as by X-ray crystallography. Crystal data of $ReOCl_3P_2$ (**1**): crystal class triclinic, space group $P\bar{1}$ (No 2), $a=8.558(2)$, $b=8.921(2)$, $c=12.617(3)$ Å; $\alpha=74.42(3)$, $\beta=81.81(3)$, $\gamma=63.43(1)$; $V=829.6(3)$ Å^3, $Z=2$. Crystal data of $ReOCl_3$(P–P) (**2**): monoclinic, space group $P2_{1/n}$, ($P2_{1/c}$ No 14), $a=9.615(2)$, $b=16.424(3)$, $c=17.395(3)$ Å; $\beta=99.81(3)$; $V=2706.8(9)$ Å^3, $Z=4$. There is 72:28 orientational disorder in **2** between the mutually *trans*-oxo and chloride ligands. In both **1** and **2**, the rhenium atoms are six coordinate with triply bonded terminal oxo ligands (**1** Re–O = 1.654(4) Å). (**2** Re–O = 1.692(15) Å) and chlorides in facial arrangements. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: oxo-rhenium; phosphite ligands; crystal structures; orientational disorder.

The chemistry of the phosphite metal complexes is still less recognized than that of respective phosphine congeners also including rhenium compounds [1]. A great variety of the electronic and steric properties [2, 3] of readily accessible phosphite ligands make them attractive to examine the influence of these properties on the structure and reactivity of the metal phosphite complexes [4]. There are rather few oxo-rhenium(V) complexes containing phosphite ligands, exemplified by $ReOX_3(PPh_3)L$ where X=Cl or Br; L=$[P(OMe)_3]$, $[P(OCH_2)_3CMe]$ or $[P(OCH_2)_3CEt]$ [5](a) and $ReOCl_3[P(OEt)_3]_2$ [5](b). $ReOCl_2[P(O)(OMe)_2](PPh_3)_2$ complex, containing phosphonato ligand which derives from phosphite has also been obtained [5](c). Nevertheless, there has been no information about the synthesis and geometry of oxo-rhenium(V) complexes of the $ReOCl_3P_2$ or $ReOCl_3$(P–P) type (where P and P–P indicate mono and bidentate phosphite ligands respectively). However, the analogs of phosphine complexes are well described [6]. In the present paper, we report on the synthesis and structural characterization of oxo-rhenium(V) complexes containing phosphite ligands: $P(OMe)_3$ (P) and chelating sterically encumbered $(OCMe_2CMe_2O)POCMe_2CMe_2OP(OCMe_2CMe_2O)$ (P–P) [7] (abbreviated also as pinacop) [4](c). While the phosphine congeners of $ReOCl_3P_2$ complexes usually adopt *trans-mer* geometry [6], both phosphite analogs exhibit the *cis-fac* arrangement of the ligands. These complexes are most interesting, especially because of their potential catalytic properties in the oxygen atom transfer (OAT) [8] or olefin metathesis reactions [9].

EXPERIMENTAL

All preparations were performed in an dry, oxygen-free argon atmosphere using the conventional Schlenk technique. Solvents were carefully dried and deoxygenated by standard methods [10]. $ReOCl_3(PPh_3)_2$ [11]

*Corresponding author. Tel.: (4871)204-254; Fax: (4871)204-420; E-mail: rybak@ichuwr.chem.uni.wroc.pl

and $ReOCl_3(Me_2S)$-$(OPPh_3)$ [12, 13] were obtained according to the procedures previously described. Trimethyl phosphite (Fluka) was distilled in vacuo from CaH_2 and stored in argon. The known method [4](c) was used for the preparation of bidentate phosphite ligand pinacop: $(OCMe_2CMe_2O)POCMe_2CMe_2OP(OCMe_2CMe_2O)$. The IR and FIR measurements were made in KBr pellets or in Nujol with Nicolet FTIR Impact 400 or Brucker IFS 113V. Spectra of ^1H, ^{13}C and ^{31}P NMR were obtained on a Brucker AMX (300 MHz for H NMR). The chemical shifts, δ, are given in ppm towards the TMS and H_3PO_4, respectively, using deuterated solvents as lock and reference. UV–VIS spectra in CH_2Cl_2 solution were obtained on HP 8452A. Elemental analyses were performed on a Perkin–Elmer 2400 CHN in the Laboratory of Elemental Analyses of our Department. Molecular weights were measured in dichloromethane solutions using the Molecular Weight Apparatus Model 115 (Perkin Elmer). The physical data for the complexes here obtained are reported in the experimental or results and discussion segments herewith.

fac-$ReOCl_3[P(OMe)_3]_2$ (**1**)

A mixture of $ReOCl_3(Me_2S)(OPPh_3)$ (0.64 g, 1 mmol), THF (40 cm^3) and $P(OMe)_3$ (0.35 cm^3, 3 mmol) was stirred in a slow stream of argon at room temperature until the starting rhenium compound reacted (30 min) and the navy-blue solution appeared. The volatile components of the homogeneous reaction mixture were stripped in vacuo. The dry residue was extracted with diethyl ether. The blue solid of **1** and a yellow solution containing $ReCl_3[P(OMe_3]_3$ as a by-product were obtained. Pure **1** was recrystallized from dichloromethane/ethyl ether solution as blue–violet crystals, in yield, 80% (0.44 g). These crystals were found to be suitable for X-ray structure determination. Anal. for $C_6H_{18}O_7Cl_3P_2Re$ (mol.wt.calc.: 556.9, found: 550); calc: C, 12.93; H, 3.23%; Found: C, 12.94; H, 2.90%; ^1H NMR (CD_2Cl_2, 25 C): δ 3.93 (d, $J_{PH} = 7.0$ Hz, CH_3). $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 25 C): δ (*vs.* H_3PO_4) 61.35s. IR(KBr, cm^{-1}) 1170m, 1040br.vs, ν(C–O–P) 980s ν(Re–O). FIR (nujol, cm^{-1}) 326vs, 296vs, 270sh, 234m ν(Re–Cl) and ν(Re–P).

fac-$ReOCl_3$*pinacop* (**2**)

Here we report on the details of synthesis of **2** [14], which provided crystals suitable for X-ray structure determination. A mixture of $ReOCl_3(Me_2S)(OPPh_3)$ (0.68 g, 1 mmol) and pinacop ligand (0.4 g, 1 mmol) in toluene (40 cm^3) was stirred and boiled, until the starting rhenium compound reacted (2 h) and the blue solid obtained. The crude solid was recrystallized from absolute ethanol which afforded blue–violet crystals of **2** (86% yield). Anal. for $C_{18}H_{36}O_7Cl_3P_2Re$ (mol.wt.calc.: 718.5, found: 800); calc: C, 30.07; H, 5.04%; Found: C, 29.58; H, 4.95%. ^1H NMR (CD_2Cl_2, 25 C): δ 1.57, 1.60, 1.63, 1.64, 1.65, 1.73 (s's, 1 each, CH_3). $^{13}C\{^1H\}$ NMR (CD_2Cl_2, 25 C): δ 25.1, 25.14, 25.79, 25.86, 26.11, 26.54 (s's, CH_3), 90.16, 91.92, 93.19 (s's, CCH_3). IR (KBr, cm^{-1}) 1140vs, 1040vs 1000s, ν(C–O–P) 980s ν(Re–O). FIR (nujol, cm^{-1}) 329vs, 300vs, 284s, 220m ν(Re–Cl) and ν(Re–P).

Crystal structure determination of complexes **1** *and* **2**

Table 1 summarizes the relevant data for the structure analyses. The diffraction data were collected on a Kuma KM-4, computer controlled, κ-axis diffractometer which was equipped with graphite monochromated MoKα radiation. The stability of intensities was monitored by the measurement of three standards every 100 reflections. Intensity data were corrected for Lorentz and polarization effects. The structures were solved with the heavy atom method, using SHELXS-86, and later refined by the full matrix, least square method using SHELXL-93 procedures [15]. Since **2** was found to be axially disordered, both orientations as well as the occupancy ratio were refined independently. All hydrogen atoms in both compounds were positioned based on the idealized geometry of the methyl group.

RESULTS AND DISCUSSION

Synthesis and characterization of the oxo-rhenium(V) complexes

A simple ligand substitution reaction of the labile compound $ReOCl_3(Me_2S)$-$(OPPh_3)$ [12] affords the preparations of complexes $ReOCl_3P_2$ (**1**) and $ReOCl_3P$–P (**2**), according to Scheme 1, where P=$P(OMe)_3$ and P–P=pinacop=$(OCMe_2CMe_2O)P$–$OCMe_2CMe_2OP(OCMe_2CMe_2O)$.

Complex **1** can be obtained at room temperature in THF solution. **2** can also be afforded at ambient temperature in THF solution. However, the ease of its separation from the reaction mixture was the reason for using the boiling toluene solution. In the previous attempts for preparation of **1**, using $ReOCl_3(PPh_3)_2$ as a starting compound, $ReOCl_3(PPh_3)[P(OMe)_3]$ has been obtained instead [5](a). The blue–violet oxo-rhenium complexes **1** and **2** are readily soluble in CH_2Cl_2, sparingly in ethanol or toluene and insoluble in ethyl ether. **1** and **2** are stable, both in solution and solid state, in the presence of dry air. Table 2 summarizes the spectroscopic data of several oxo-rhenium(V) complexes containing phosphorus ligands. Complexes **1** and **2** display two weak absorptions in the visible region of the electronic spectra, which are assigned to nd-π^*d transitions. A similar absorption maximum show complexes with the oxo-metal arrangement and 4–5d^2 electronic configuration [16]. The energetically higher and more intensive bands in UV correspond to CT transitions. The IR

[a] Evaluated as result of substraction spectra of **2** and ReCl$_3$(pinacop)[P(OMe)$_3$] obtained in oxygen transfer reaction with P(OMe)$_3$.

spectra of **1** and **2** show bands characteristic for coordinated phosphite ligands and strong bands corresponding to ν(Re–O) stretching vibrations in the range 950–1000 cm^{-1}. In the spectrum of **2**, the band at 980 cm^{-1} is obscured by a very intensive ligand absorption. FIR spectra in the range of ν(Re–Cl) stretching vibrations (200–400 cm^{-1}) show four bands. But in the same region, ν(Re–P) vibrations also occur [17]. This precludes unequivocal assignment of ν(Re–Cl) stretches and the anticipation of geometry of **1** and **2**. The ^1H and ^{31}P NMR spectra of **1** and **2** are more informative. The spectra of **1** show a doublet in ^1H NMR at δ 3.93, $^3J(PH) = 7.0$ Hz and one singlet in $^{31}P\{^1H\}$ NMR δ 61.35, indicating the equivalence of both phosphite ligands. Two possible arrangements *cis-fac* and *trans-mer* are consistent with these data. The ^1H NMR spectra of **2**, obtained at low temperature (213 K), exhibit ten signals of nonequal intensity which are due to twelve unequivalent methyl groups, Fig. 1. As the temperature is raised these signals broaden and coalesce to give, at room temperature, six single sharp resonances at δ 1.57, 1.6, 1.63, 1.64, 1.65, 1.73 ppm, indicating that the species is fluxional on the ^1H NMR time scale. The variable temperature ^1H NMR spectra shown in Fig. 1 reveal a rather complicated pattern. Hence, it appears that, in our system, there are several dynamic processes exhibiting different coalescence temperatures for chelating metallacycle and two phosphorus cycles. This is consistent with the molecular C_1 symmetry of **2** in solution and expected *cis-fac* geometry of the donor atoms with phosphorus placed mutually in *cis* positions. Thus, this obviously rules out both *cis-mer* and *trans-mer* arrangements. The striking similarity of the spectroscopic data in Table 2 points to the *cis-fac* geometry for both **1** and **2**, as well as other complexes from the Table. The *cis-fac* geometry was also found for some other oxo-rhenium(V) complexes containing less sterically demanding phosphine ligands [6]. Interestingly, phosphine oxo-rhenium(V) complexes, $ReOCl_3P_2'$ (where $P' = PEt_3$ and PEt_2Ph), exist in two geometric forms or isomerize readily from *cis-fac* to *trans-mer*. By contrast, phosphite complexes **1** and previously obtained $ReOCl_3[P(OEt)_3]_2$ [5](b) do not undergo isomerization, even under vigorous conditions (in boiling toluene for 24 h). It may suggest that other bisphosphite oxo-rhenium complexes should be available, preferably in *cis-fac* geometry. Presumably, the reason for this is in the origin of a better π-acceptor capability of phosphite *vs.* phosphine ligands [2, 3]. Both **1** and **2** readily undergo reduction with $P(OMe)_3$ to corresponding rhenium(III) complexes *via* common oxygen atom transfer reaction [8]. Furthermore, the phosphite oxo-rhenium compounds, **1** and **2**, appear quite inert to the substitution reactions. This is in agreement with the inertness of isostructural *cis*-$ReOCl_3(CNCMe_3)_2$ in substitution reactions [12]. Indeed, **1** and **2** do not react noticeably either with pyridine or methanol under mild reaction conditions. The analogous phosphine complexes are rather labile, e.g., *trans*-$ReOCl_3(PPh_3)_2$ in reaction with pyridine or methanol yields either $ReOCl_3py_2$ or $ReOCl_2(OMe)(PPh_3)_2$, respectively.

Crystal structure determination

It has recently been suggested that the *cis-fac* geometry of Chatt's blue $ReOCl_3(PEt_2Ph)_2$ compound is responsible for the unusually long Re–O bond, 1.869(11) Å, resulting from "*trans*-influence isomerism" [18]. It is worthwhile to note that there is no response in decrease of ν(Re–O) stretches in the IR spectra of the latter compound, as one may expect, for a long Re–O bond. There are many controversies concerning the structure and composition of Chatt's "violet complex" formulated as *trans*-$ReOCl_3(PEt_2Ph)_2$ [6](a)[19]. Mentioned above, the "*trans*-influence isomerism" of Chatt's blue *cis* isomer [18] as well as the blue–violet colour of both our complexes prompted us to undertake X-ray crystal structure determination of **1** and **2**.

A view of the molecular structure of complex **1**, along with the atom labeling scheme used in the crystal structure determination, is shown in Fig. 2. Selected bond distances and angles are given in Table 3. Complex **1** has a distorted octahedral geometry with the central rhenium atom bonded to one terminal oxygen atom, two mutually *cis* phosphite phosphorus and three chlorides in facial arrangement. The Re–O_t bond length of 1.654(4) Å is in the usual range of multiply bonded mono-oxo group [20]. A considerable *trans*-influence exerted by the Re=O fragment, lengthens the Re–Cl_1 bond by ca. 0.04 Å, in comparison to Re–Cl_2 and Re–Cl_3 distances, and bends away *cis* chloride ligands, yielding obtuse bond angles O_t–Re–Cl_2 and O_t–Re–Cl_3 above 100°. No extraordinary structural features, either unusual length of the Re–O_t bond or crystallographic disorder for **1** has been found. By contrast, compound **2** exhibits remarkable orientational crystallographic disorder which, when not recognized, led to unusual and erroneous results. Thus, the Re–O_t bond was unusually long at 1.891(9) Å, and the Re–Cl_1 bond *trans* to terminal oxygen atom O_t was shortened at 2.276(5) Å. Other relevant rhenium–donor atom distances for this false model were in their usual ranges (Re–Cl_2 = 2.351(4), Re–Cl_3 = 2.348(4), Re–P_1 = 2.410(4), Re–P_2 = 2.405(4) Å). Furthermore, a large difference of electron densities in proximity to rhenium atoms (peak/hole = 6.72/−5.81 e$Å^3$) also suggested the disordered structure of **2**. The structure of **2**, with the atom labeling scheme used in the structure determination, is shown in Fig. 3. In the crystal state, **2** shows molecular symmetry near C_1. Some molecules in the crystal adopt an orientation inverted by 180° to the one adopted by the majority as is shown in Fig. 4. This is manifested by virtual lengthening of the Re–O_t bond to an extent depending on the occupancies of the two

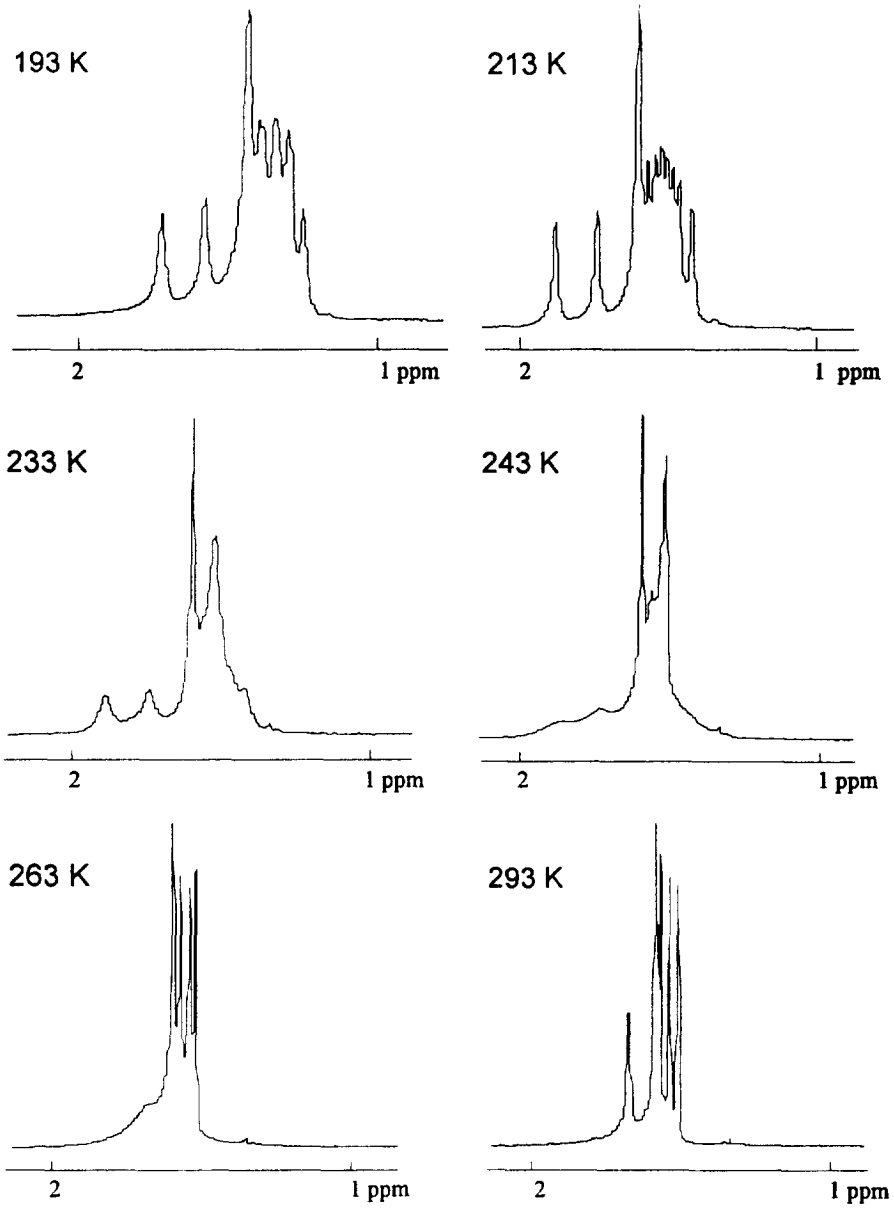

Fig. 1. Selected variable temperature ^{1}H NMR spectra of compound $ReOCl_3$pinacop (**2**)

orientations. The distance between disordered rhenium atom (Re_1–Re_2) is 0.505(6) Å, yet between disordered O_t–Cl_1, it is equal to 0.378(19) Å. The discerning data refinements gave the occupancy ratio 72:28 for the two vertical orientations. Finally, the separation of one orientation from another provides a correct set of structural parameters for **2** and its molecular structure. Selected bond distances and angles are given in Table 3. The seven membered ring COPRePOC is puckered and adopts a distorted chair conformation with two bridging phosphite oxygen atoms in opposite apical positions. In solution, a certain flexibility of the ring can be expected. Apart from orientational disorder and symmetry features, the molecular structure of **2** is quite similar to that of **1**. The Re–O_t bond length of 1.692(15) Å fits well to the triple rhenium oxygen bond distances [21]. A weak *trans*-influence, if any, is more likely pronounced by obtuse bond angles (O_t–Re–Cl_2 105.2° and O_t–Re–Cl_3 105.8) than by Re–Cl bond distances. Examples of other transition metal-oxo complexes that were suspected for unusually long Re–O bond or bond-stretch isomerism and appeared to be crystallographically disordered have been recently reviewed [22].

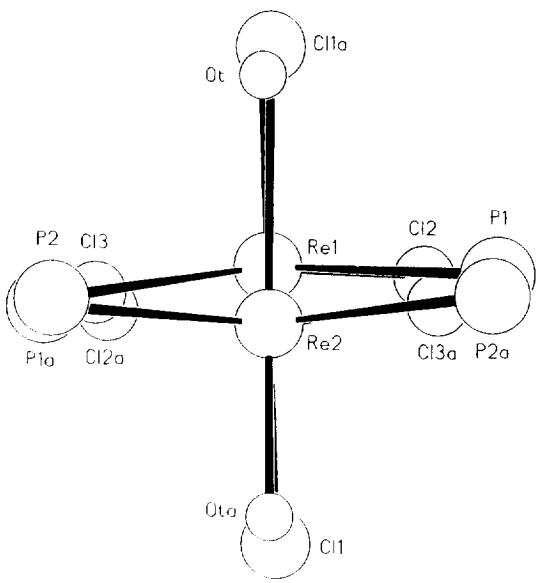

Fig. 4. View of disordered structure of (**2**)

This study has demonstrated that phosphite ligands may promote coordination chemistry distinct from that exhibited by phosphine congeners. This diversity was revealed in the geometry of quite inert *cis-fac*-$ReOCl_3P_2$ (**1** and **2**) complexes.

(Received 21 November 1997; accepted 26 February 1998)

Abstract—Two complexes $[Co(phen)_2TATP]^{3+}$ and $[Co(bipy)_2TATP]^{3+}$, where TATP is the planar ligand 1,4,8,9-tetra-aza-triphenylene, were synthesized and characterized. The binding of Co(III) polypyridyl mixed-ligand complexes to calf thymus DNA was investigated using absorption spectroscopy, fluorescence spectroscopy, viscosity measurement, and DNA cleavage assay. The absorption spectroscopic studies showed that the two new complexes $[Co(phen)_2TATP]^{3+}$ and $[Co(bipy)_2TATP]^{3+}$ exihibited apparently higher intercalating efficiency to DNA base pairs than $[Co(phen)_3]^{3+}$ and $[Co(bipy)_3]^{3+}$. The fluorescence of DNA helix was quenched by Co(III) complexes very strongly. From the viscosity experiment, we inferred that the binding of $[Co(phen)_3]^{3+}$ to DNA may be not by classical intercalation. When irradiated at 302 nm, $[Co(phen)_2TATP]^{3+}$ induced single-strand scissions and $[Co(bipy)_2TATP]^{3+}$ induced double-strand scissions in supercoiled DNA.

Keywords: Co(III) mixed-ligand complex; DNA; voltammetry; spectroscopy; viscosity; cleavage.

Considerable attention has been given to the design of small molecules that bind to DNA with site selectivity so as to develop new therapeutics and chemical probes for nucleic acid sites and structure, as well as novel diagnostic agents targeted to double-helical DNA [1]. Small molecules serve as analogues in studies of protein-nucleic acid recognition, provide site-specific reagents for molecular biology, and yield rationales for new drug design. The effect of size, shape, hydrophobicity and charge on the binding of the complex to DNA has been analyzed by changing the type of heteroaromatic ligand or metal center.

In the past decades, the interaction of Ru(II) polypyridyl coordination compounds have been studied extensively as structural probes and mediators of DNA cleavage reaction [2–4]. We have chosen to concentrate this work on complexes of Co(III), which have not received as much attention as the Ru(II) systems but possess the same interesting characteristics of metallointercalation and DNA cleaving properties [5–8]. In this paper, two Co(III) complexes, $[Co(phen)_2TATP](ClO_4)_3 \cdot 2H_2O$ and $[Co(bipy)_2TATP](ClO_4)_3 \cdot 3H_2O$ have been synthesized and identified the mode of binding with B-DNA by use of absorption spectroscopy, fluorescence spectroscopy, viscosity measurements, and DNA cleavage assay. The results should be valuable in understanding the mode of the complexes binding to DNA, as well as laying the foundation for the design of new probes for helical conformations and antitumor drugs.

EXPERIMENTAL

Materials and methods

All starting materials were commercially available and of analytical grade quality. TATP [9], cis-$[Co(phen)_2Cl_2]Cl \cdot 3H_2O$ [10], cis-$[Co(bipy)_2Cl_2]Cl \cdot 3H_2O$ [11], $[Co(phen)_3]Cl_3$ and $[Co(bipy)_3]Cl_3$ [12] were prepared and purified by methods described pre-

* Author to whom correspondence should be addressed.

viously, where bipy, phen and TATP stand for 2,2′-bipyridine, phenanthroline and 1,4,8,9-tetra-aza-triphenylene, respectively. The structures of ligands are showed in Fig. 1.

All the experiments involving the interaction of the Co(III) complexes with DNA were conducted in a pH 7.2 Tris buffer containing 5 mM tris (hydroxymethyl)aminomethane (Tris), 50 mM NaCl in doubly distilled water. Solution of calf thymus DNA gave ratios of UV absorbance at 260 nm and 280 nm, A_{260}/A_{280}, of ca. 1.8 ~ 1.9, indicating that the DNA was sufficiently free of protein [13]. DNA concentration per nucleotide was determined by $\epsilon_{260} = 6600\ M^{-1}cm^{-1}$ [14].

Cyclic voltammetry was performed by a Princeton Applied Research (PAR) Model 175 universal programmer with a three electrode system: the Au disk electrode (d = 4.0 mm) as the working electrode, saturated calomel electrode (SCE) as the reference electrode and Pt wire as the counter electrode. Supporting electrolytes were Tris buffer (pH = 7.2). Before each experiment, the supporting electrolytes were deaerated *via* purging pure N_2 for 15 min and nitrogen atmosphere was kept over the solution during the experiments.

The ^{1}HNMR spectra were recorded on a Bruker AM × 500 HNMR, Me_4Si as internal reference. IR spectra were recorded on Nicolet 170X-FT spectrophotometer with KBr pellets. UV spectra were obtained on a Shimadzu MPS-2000 UV-vis spectraphotometer. The fluorescence intensity measurements were carried out by a Shimadzu RF-5000 spectrofluorimeter.

Viscosity experments used a Ubbelodhe viscometer, immersed in a thermostated water bath maintained at 28(±0.1)°C. Data were presented as $(\eta/\eta)^{1/3}$ *versus* the concentration of Co(III) complexes, where η is the viscosity of DNA in the presence of complexes and η is the viscosity of DNA alone. Viscosity values were calculated from the observed flow times of DNA-containing solutions (t), corrected for the flow time of buffer alone (t), $\eta = t - t$ [15].

Photoactivated cleavage of 100 μM pBR322 DNA with 20 μM Co(III) complexes after irradiation at 302 nm (10 W-UV lamp) in 10 μL of 50 mM Tris, 18 mM NaCl, and pH 7.0 solution. Samples were subjected to electrophoresis on 0.8% agarose gels followed by staining with ethidium bromide. The photographs under UV light were taken.

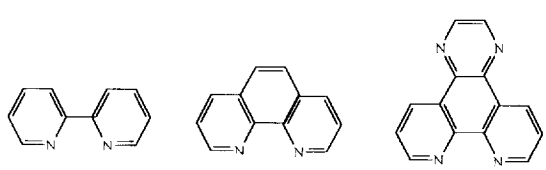

Fig. 1. Structures of the ligands.

Synthesis of $[Co(phen)_2TATP](ClO_4)_3 \cdot 2H_2O$

A mixture of cis-$[Co(phen)_2Cl_2]Cl \cdot 3H_2O$ (0.54 g, 0.001 mol) and TATP (0.26 g, 0.0011 mol) in water-methanol (20 cm^3, 1:1, v:v) was warmed on a water bath below 60°C for 2.5 hours. After filtration, the filtrate was treated with excess 8 M $NaClO_4$ solution, an orange precipitate formed. The precipitate was chromatographed over neutral Al_2O_3 column using a mixture of acetonitrile and toluene (1:1, v:v) solution as eluent to obtain a yellow solution. After concentration, a yellow solid was precipitated by adding ether into the solution. The precipitate was washed with ether and then dried under vacuum. Yield 44%. Anal. Calcd for $C_{38}H_{28}N_8CoCl_3O_{14}$: C, 46.29; H, 2.86; N, 11.36. Found: C, 46.25; H, 2.37; N, 11.27 (%). IR data (cm^{-1}): 1518 s, 1384 m, 1082 vs, 850 s, 723 s, 632 vs. UV λmax nm (log ε): 272.7 (4.85);217.7 (5.03). ^{1}HNMR (500 MHz, CD_3CN):δ 9.88(*t*, 2H), 9.46(*s*, 2H), 9.20(*t*, 2H), 8.60 (*d*, 2H), 8.16(*dd*, 2H), 7.99(*t*, 2H), 7.86(*t*, 2H), 7.72(*d*, 2H).

Synthesis of $[Co(bipy)_2TATP](ClO_4)_3 \cdot 3H_2O$

$[Co(bipy)_2TATP](ClO_4)_3 \cdot 3H_2O$ was prepared in a similar way with $[Co(phen)_2TATP](ClO_4)_3 \cdot 2H_2O$ Yield 35%. The eluent is acetonitrile and toluene (2:1, v:v) solution. Anal Calcd for $C_{34}H_{30}N_8CoCl_3O_{15}$: C, 42.71; H, 2.53; N, 11.72. Found: C, 42.71; H, 2.53; N, 11.51(%). IR data (cm^{-1}): 1574 m, 1447 s, 1384 m, 723 m, 625 s. ^{1}HNMR(400 MHz, d^6-DMSO $CDCl_3$)δ 9.85(m, 2H), 9.34(*s*, 2H), 9.06(*d*, 2H), 9.01(*d*, 2H). UV λmax nm (log ε): 304.7(4.50), 254.7(4.85), 220.7(4.92).

RESULTS AND DISCUSSION

Voltammetric studies

There are a couple of redox peaks corresponding to $[Co(phen)_2TATP]^{3+}$ and $[Co(bipy)_2TATP]^{3+}$, respectively. The E_{pc} and E_{pa} are 0.196 V and 0.121 V for $[Co(phen)_2TATP]^{3+}$, and 0.055 V and 0.128 V for $[Co(bipy)_2TATP]^{3+}$. The half-wave potentials $E_{1/2}$, taken as $(E_{pc} + E_{pa})/2$, are 0.159 V and 0.092 V for above two complexes, respectively. The separations of the anodic and cathodic peak potentials (ΔE_p) are 75 mV and 73 mV. In the range of 20 ~ 200 mv/s, all the peak potentials are independent of scan rates (v) and the i_{pc} and i_{pa} are proportional to symbol $v^{1/2}$. It indicates that this process may be a quasi-reversible, 1-electron redox reaction.

Electronic absorption spectra

In the UV region, the intense absorption bands observed in the Co(III) complexes are attributable to internal π to π* transition of the coordinated groups. The absorption spectra of the complexes in the

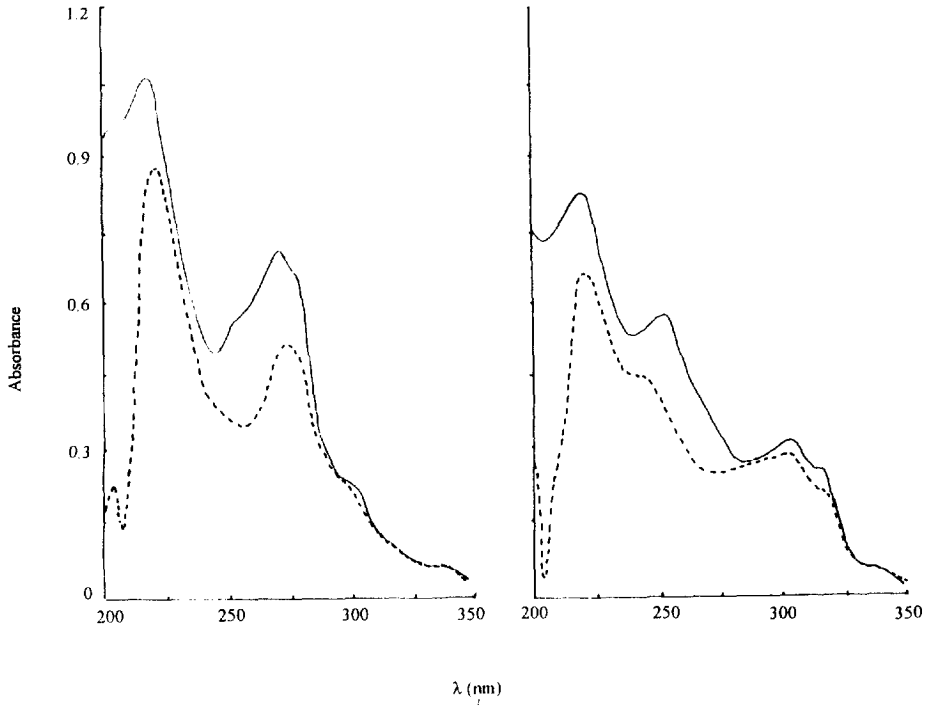

Fig. 2. Electronic absorption spectra of $[Co(phen)_2TATP]^{3+}$ (left) and $[Co(bipy)_2TATP]^{3+}$ (right) with no DNA (———) and [DNA]:[Co] = 40:1(- - -) with subtraction of the DNA absorbance.[Co] = 10 μM.

absence and the presence of calf thymus DNA (with subtraction of the DNA absorbance for the latter) are illustrated in Fig. 2. According to the data in Table 1, $[Co(phen)_2TATP]^{3+}$ and $[Co(bipy)_2TATP]^{3+}$ show the largest changes in absorption in the presence of DNA, hence, these two complexes appear to bind strongly to DNA, whereas $[Co(phen)_3]^{3+}$ and $[Co(bipy)_3]^{3+}$ bind more weakly and give smaller hypochromic effects. This is just the expected result on the basis that TATP possesses a greater planar area and hence higher hydrophobicity than that of phen and bipy, which would lead to TATP intercalating more deeply into the DNA base pairs [16, 17]. For $[Co(phen)_2TATP]^{3+}$, $[Co(bipy)_2TATP]^{3+}$ and $[Co(phen)_3]^{3+}$, a spectral shift to lower energy is found, which supports an electronic stacking interaction of the TATP and phen ligands with the base pairs of the helix.$[Co(bipy)_3]^{3+}$ shows weak hypochromism and no spectral red shift, because it only electrostatically binds with DNA [18].

Flourescence spectroscopic studies

Binding of Co(III) complexes to the DNA helix was found to quench the DNA flourescence very strongly.

Table 1. Absorption spectroscopic properties of the Co(III) complexes on binding to DNA

Complex[a]	Absorption λ_{max}(nm) free	bound	$\Delta\lambda$	Hypocromicity(%)
$[Co(phen)_2TATP]^{3+}$	218	222	4	17
	273	275	2	26
$[Co(phen)_3]^{3+}$	219	223	4	9
	274	276	2	15
$[Co(bipy)_2TATP]^{3+}$	221	222	1	20
	305	305	0	8
$[Co(bipy)_3]^{3+}$	222	222	0	5
	306	306	0	0

a.[Co] = 10 μM at [DNA]/[Co] = 40

For Co(III) complexes, no detectable emission is observed in aqueous solution. Fig. 3 reveals that the fluorescence intensity of DNA decreases rapidly with increasing concentration of Co(III) complexes with excitation at 320 nm. These quenching processes occur by electron and energy transfer. The data in Table 2 show that $[Co(phen)_2TATP]^{3+}$ exhibits higher quenching efficiency to DNA than that of $[Co(phen)_3]^{3+}$ and $[Co(bipy)_2TATP]^{3+}$ exhibits higher quenching efficiency than that of $[Co(bipy)_3]^{3+}$, which is consistent with the stronger binding ability of these two new Co(III) complexes with DNA. Besides, $[Co(bipy)_2TATP]^{3+}$ possesses the highest quenching efficiency to DNA because for non-intercalated coligands, steric interaction will influence the intercalating degree between the TATP and DNA base pairs; the reduced size of non-intercalated co-ligand bipy may increase the binding affinity of complexes with DNA [19].

Viscosity studies

The effect of Co(III) complexes on the viscosity of DNA is shown in Fig. 4. Hydrodynamic data provide perhaps the most critical test for intercalative binding in the absence of X-ray crystallographic or NMR structural data [20]. For complexes $[Co(phen)_2TATP]^{3+}$ and $[Co(bipy)_2TATP]^{3+}$, the viscosity of DNA increases with the increase of the concentration of the complexes, which is similar to that of proven DNA intercalator, $[Ru(phen)_2DPPZ]^{2+}$ [21]. Both complexes increase the relative viscosity of DNA in a manner consistent with binding by classical intercalation. This result parallels with the pronounced hypochromism and a large spectral red shift of the two new complexes.$[Co(phen)_3]^{3+}$ and $[Co(bipy)_3]^{3+}$ have no effect on the viscosity of DNA. Weak hypochromism, no spectral red shift and viscosity measurement support that $[Co(bipy)_3]^{3+}$ binds to DNA only by electrostatic force. Although Barton et al. proposed that $[Co(phen)_3]^{3+}$ intercalated into double-strandad DNA [18], but this viscosity experiment shows that $[Co(phen)_3]^{3+}$ may be a 'nonclassical' DNA intercalating agent.

Photoactivated cleavage of pBR322 DNA by Co(III) complexes

Figure 5 shows the gel electrophoretic separations of plasmid pBR322 DNA after incubation with Co(III) complexes and irradiation at 302 nm. DNA cleavage is followed by monitoring the conversion of supercoiled (form I) closed circular plasmid DNA to

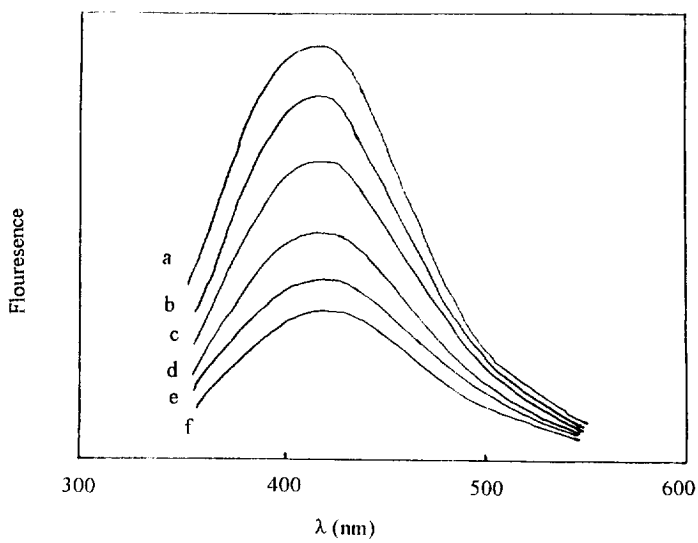

Fig. 3. Fluoresence quenching of DNA (2 mM) by increasing concentration of $[Co(phen)_2TATP]^{3+}$ [Co] = 0, 20, 40, 60, 80, 100 μM for a ~ f, respectively.

Table 2. The data for DNA fluoresence quenching by Co(III) complexes

Complex[a]	$[Co(phen)_2TATP]^{3+}$	$[Co(phen)_3]^{3+}$	$[Co(bipy)_2TATP]^{3+}$	$[Co(bipy)_3]^{3+}$
I_0/I	1.86	1.07	4.12	2.86

a.[DNA] = 2 mM, [Co] = 60 μM, Emission was monitored at 416 nm with excitation at 320 nm.

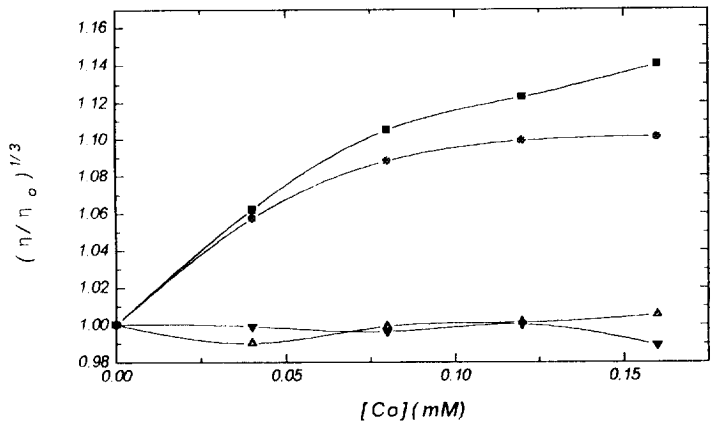

Fig. 4. Effect of increasing amounts of Co(III) complexes on the related viscosity of calf thymus DNA. (■), $[Co(phen)_2TATP]^{3+}$; (●), $[Co(bipy)_2TATP]^{3+}$; (▲), $[Co(phen)_3]^{3+}$; (▼), $[Co(bipy)_3]^{3+}$.

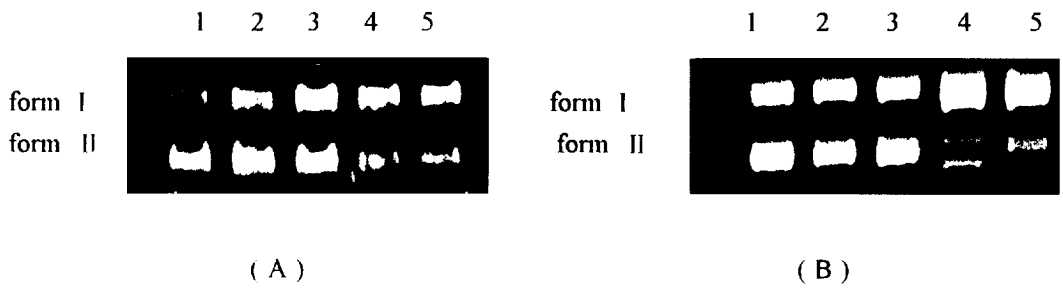

(A) (B)

Fig. 5. (A) Cleavage of pBR322 DNA in the presence of $[Co(phen)_2TATP]^{3+}$ and light. The 0.8% agarose gel shows the distribution of DNA forms initially without coblt (lane 1) and after irradiation at 302 nm in the presence of $[Co(phen)_2TATP]^{3+}$ for 0, 10, 20, and 30 min(lane 2 ~ 5, left to right). (B) Photoactivated cleavage of pBR322 DNA after 40 min irradiation at 302 nm with 1 = no complexes, 2 = $[Co(bipy)_3]^{3+}$, 3 = $[Co(phen)_3]^{3+}$, 4 = $[Co(bipy)_2TATP]^{3+}$, 5 = $[Co(phen)_2TATP]^{3+}$

the nicked circular (form II) species. Fig. 5A reveals the almost complete conversion of form I to II after 30 min irradiation in the presence of $[Co(phen)_2TATP]^{3+}$. Neither irradiation of the DNA at these low intensities without Co(III) nor incubation with Co(III) without light yielded significant strand scission. Fig. 5B examines the different binding mode of Co(III) complexes to the helix.$[Co(phen)_2TATP]^{3+}$ and $[Co(bipy)_2TATP]^{3+}$ cleave DNA to a much larger extent than $[Co(phen)_3]^{3+}$ and $[Co(bipy)_3]^{3+}$, which is consistent with their stronger intercalating ability to DNA base pairs. While $[Co(phen)_2TATP]^{3+}$ induced single-strand scissions in supercoiled DNA, $[Co(bipy)_2TATP]^{3+}$ induced the double-strand scissions. The higher strand scission efficiency of $[Co(bipy)_2TATP]^{3+}$ is related to the more intense absorption at 302 nm and the stronger quenching ability to DNA. The photoreduction of Co(III) complexes with concomitant hydroxide oxidation may be the important step in the DNA cleavage reaction [22]. Further study is necessary to clarify the reaction mechanism.

(Received 8 December 1997; accepted 26 February 1998)

Abstract—Reaction between diquat (dq = 6,7-dihydrodipyrido-[1,2-a:2′,1′-c]pyrazinediium) and $[M(CN)_8]^{4-}$ (M = Mo or W) led to the isolation of $(dq)_2[M(CN)_8]\cdot 5H_2O$ salts. Both salts were found to be isomorphic. The $[M(CN)_8]^{4-}$ anion has an approximately dodecahedral D_{2d} configuration. The structure consists of a three dimensional hydrogen bonded network. The intensely coloured solids (hydrated and anhydrous) show ion-pair charge-transfer (IPCT) interaction which is discussed in terms of their structure. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: octacyanomolybdate (IV); octacyanotungstate (IV); diquat; ion pair charge transfer; crystal structure; IR spectra.

The structure of octacyanometallates depends strongly on the nature of cation and other species, such as water of crystallization, capable of formation of hydrogen bonds. Considering cation-anion interaction several salts were synthesized and structurally characterized [1, 2]. Previously we have studied salts with bipyridinium cations of the following formulae: $(bpyH)_3(H_3O)[M(CN)_8]\cdot 2H_2O$ (bpy = 2,2′-bipyridyl) [3] and $(4,4'\text{-bpyH}_2)_2[M(CN)_8]\cdot 4.5H_2O$ (4,4′-bpy = 4,4′-bipyridyl) [4]. All these salts show the ion-pair charge-transfer (IPCT) phenomenon due to electron shift from anion to cation.

The structural data available for the 4,4′-bipyridinium salt show that there are several possibilities of charge dissipation through different types of hydrogen bonds in which the nitrogen end of cyano ligands, water molecules and the nitrogen atoms of pyridine rings participate [4]. It was also found that the electron can be transferred through the π stack systems of pyridine rings. To gain more information about the nature of electron transfer we extended our study to cover cases in which a direct hydrogen bond between anion and pyridine nitrogens cannot be formed. In this paper we present the synthesis and structure of octacyanometallates with the N,N′-alkylated derivative of 2,2′-bipyridinium, diquat (dq = 6,7-dihydrodipyrido-[1,2-a:2′,1′-c]pyrazinediium), as cation.

EXPERIMENTAL

Materials

The initial molybdenum (IV) and tungsten (IV) complexes $K_4[M(CN)_8]\cdot 2H_2O$ were prepared by methods described in the literature [5, 6]. The aqueous solutions of acids, $H_4[M(CN)_8]$, were obtained from potassium salts using ion exchange techniques (IR 120 ion exchange resin in H^+ form) [7]. $dqBr_2$ was purchased as a crude product-'Reglone' (Imperial Chemical Industries, ab. 20% $dqBr_2$ content) and refined by column chromatography in reverse-phase system on modified silica gel (RP 18) with methanol as a solvent, and then recrystallized twice from hot methanol. The purity of the product was checked by

* Correspondence to: fax: (48 12) 6340515, e-mail: samotus@ trurl.ch.uj.edu.pl.

measuring the UV spectrum and melting point ($\lambda_{max} = 308$ nm, mp. 320 C) [8]. Other reagents and solvents of analytical grade (POCh, Poland) were used as supplied.

Syntheses

Bis(6,7 - *dihydrodipyrido*[1,2 - *a*:2′,1′ - *c*]*pyrazi* - *nediium*) *octacyanomolybdate* (*IV*) *pentahydrate*, $(dq)_2[Mo(CN)_8]\cdot 5H_2O$ (**1**). 2.35 mmol (0.851 g) of $dqBr_2\cdot H_2O$ was dissolved in 100 ml of the aqueous solution containing 1.28 mmol (0.394 g) of $H_4[Mo(CN)_8]$ and then 300 ml of acetone was carefully added to form a separate top layer. The mixture was allowed to stand for 3 days at room temperature. The resulting precipitate was filtered off, washed with 1:2 water-acetone mixture and dried in air *via* suction. Yield: 0.89 g (91.0%). Found: C, 50.47; H, 4.49; N, 22.04; H_2O, 13.8%. Calc. for $C_{32}H_{34}N_{12}O_5Mo$: C, 50.40; H, 4.49; N, 22.04; H_2O, 13.8%.

Bis(6,7-*dihydrodipyrido*[1,2-*a*:2′,1′-*c*]*pyrazinediium*) *octacyanotungstate* (*IV*) *pentahydrate*, $(dq)_2[W(CN)_8]\cdot 5H_2O$ (**2**). The salt was obtained in a similar way to (**1**), except that 1.28 mmol (0.521 g) of $H_4[W(CN)_8]$ was used instead of the molybdenum compound. Yield: 0.89 g (81.5%). Found: C, 45.28; H, 3.78; N, 19.66; H_2O, 10.4%. Calc. for $C_{32}H_{34}N_{12}O_5W$: C, 45.19; H, 4.03; N, 19.76; H_2O, 10.6%.

The anhydrous salts $(dq)_2[Mo(CN)_8]$ (**3**) and $(dq)_2[W(CN)_8]$ (**4**) were obtained from (**1**) and (**2**) respectively by thermal dehydration at 90 C for about two hours (till the weight was constant).

Analytical methods and physical measurements

Carbon, nitrogen and hydrogen were determined by organic microanalysis. The content of water was determined by thermogravimetric analyses (t.g.). These analyses as well as differential thermal analyses (d.t.a.) were performed under argon within the temperature range 25–400 C, with a heating rate of 2.5 C/min on a MOM-Q 1500 thermoanalyser (Hungary). Uv-vis absorption and reflectance spectra (Shimadzu 2101 PC spectrometer with ISR-260 device) and e.s.r. spectra (Se/X-25, Poland) were recorded in the normal manner at room temperature. Infrared spectra were measured in KBr pellets (hydrated salts) and as nujol mulls (anhydrous salts) on a Brüker IFS 48 spectrometer. Raman spectra in water solution were recorded on a Cary 82 spectrometer (Varian USA).

Structures

Crystal structure analysis of $(dq)_2[Mo(CN)_8]\cdot 5H_2O$ (**1**), M = 762.65, orthorhombic, space group Pbca, a = 13.209(2), b = 14.639(4), c = 35.325(4) Å, $\alpha = \beta = \gamma = 90$ °, U = 6831(2) Å^3, $D_c = 1.483$ g cm^{-3}, Z = 8, $\lambda = 0.71073$ Å, T = 293 K, $\mu = 0.444$ mm^{-1}, dark purple blocks, crystal dimensions $0.51 \times 0.44 \times 0.27$ mm.

Data were collected with a Siemens P4 four-circle diffractometer using omega scans. Maximum 2θ was 50 with scan range ±1.2 around the $K_{\alpha 1} - K_{\alpha 2}$ angles, scan speed 3–30 min^{-1}, depending on the intensity of a 2-s pre-scan. Three standard reflections were monitored every 100 reflections, showing only slight changes during data collection. Unit-cell dimensions and standard deviations were obtained by least-squares fit to 33 reflections ($4.6 < \theta < 12.5$ °). The intensities of 5151 unique reflections were collected; 3484 were considered observed [$I/\sigma(I) > 2.0$). Reflections were corrected for Lorentz, polarization and absorption effects, the last by psi scans: maximum and minimum transmission factors were 0.8767 and 0.6907. Systematic absences were consistent with the space group Pbca, which was confirmed by successful refinement. Heavy atoms were located by the Patterson interpretation section of SHELXTL ver. 5.0 and the light atoms then found on successive Fourier syntheses, including H_2O. Anisotropic thermal parameters were used for all non-H atoms. Hydrogen atoms for the water molecules were located from difference Fourier maps then allowed to ride on the bonded oxygen atom; all other hydrogen atoms were included in calculated positions and not refined. Hydrogen atoms were given fixed isotropic thermal parameters, U = 0.08 Å^2. Final refinement was on F by least-squares methods with 458 parameters. Largest positive and negative peaks on a final difference Fourier synthesis were of height +0.409 and −0.364 eÅ^3. A weighting scheme of the form $w = 1/[\sigma^2(F_o^2) + (0.0384P)^2 + 6.18P]$ was used and shown to be satisfactory by weight analysis. Final R1 = 0.0445, ωR2 = 0.112 for all data. Maximum shift/error in final cycle 0.07. Computing was with SHELXTL ver. 5.0 [9]. Scattering factors in the analytical form and anomalous dispersion factors were taken from ref. [9].

Crystal structure analysis of $(dq)_2[W(CN)_8]\cdot 5H_2O$ (**2**), M = 850.52. The structure was determined in a similar manner. The tungsten salt (**2**) was found to be isomorphous with the molybdenum compound (**1**): orthorhombic, space group Pbca, a = 13.208(2), b = 14.642(3), c = 35.325(3) Å, $\alpha = \beta = \gamma = 90$ °, U = 6832(2) Å^3, $D_c = 1.646$ g/cm^3, Z = 8, dark green blocks, crystal dimensions $0.62 \times 0.38 \times 0.16$ mm.

Selected bond lengths and angles are given in Tables 1 and 2.

Additional materials available from the Cambridge Crystallographic Data Centre comprise atomic co-ordinates and equivalent isotropic displacement parameters, H-atom co-ordinates, displacement parameters, and the remaining bond lengths and angles.

Table 1. Selected bond lengths [Å] for $(dq)_2[Mo(CN)_8]\cdot 5H_2O$ (**1**) and $(dq)_2[W(CN)_8]\cdot 5H_2O$ (**2**) with estimated standard deviations (e.s.d.s.) in parentheses

RESULTS AND DISCUSSION

Characterization of the complexes

When the diquat dibromide is added to an aqueous solution of $H_4[M(CN)_8]$, the originally yellow colour changes to brownish-red (Mo) or green (W). (**1**) and (**2**) crystallize in the form of intensely coloured purple (**1**) or green (**2**) needles. They are soluble in water and insoluble in common organic solvents. Both salts are photosensitive as solids and in solution, but in diffused light they remain unaltered for a long period.

The thermograms show that dehydration takes place in two steps. The weight loss measurements indicate that in the first step at *ca.* $t_{max} = 90$ °C (**1**) or 70 °C (**2**) four water molecules are released. The remaining strongly bonded water molecule leaves at $t_{max} = 120$ °C (**1**) or 115 °C (**2**). The anhydrous salts are stable up to about 250 °C (**3**) and 280 °C (**4**), at which temperatures endothermal decomposition processes occur without separated steps.

The anhydrous salts (**3**) and (**4**) can be obtained by thermal dehydration of (**1**) and (**2**) at 100 °C for about two hours. They differ in colour from their hydrated analogues: (**3**) is green and (**4**) is brown. Exposed to humid air they gather moisture and return to their original colour and composition. This suggests that the water of crystallization fills structural cavities and becomes zeolitic in nature.

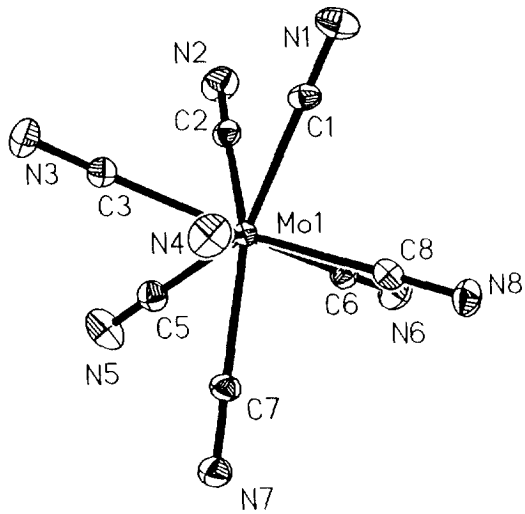

Fig. 1. The structure of $[Mo(CN)_8]^{4-}$ anion.

Structure

The crystal structure determination of (**1**) and (**2**) show that both salts are isomorphic. The metal atom is bonded to eight CN^- ligands (Figure 1) with coordination geometry close to dodecahedral (D_{2d} symmetry). An ideal dodecahedron is characterized by a set of shape parameters (Figure 2). There are two models proposed for the dodecahedral symmetry: the purely geometrical hard sphere model (HSM with parameters: $\theta_A = 36.9$, $\theta_B = 69.5$, a = m = g = 1.20, b = 1.50) and the so-called most favourable polyhedron (MFP: $\theta A = 35.2$, $\theta_B = 73.5$, a = m = 1.17, g = 1.24, b = 1.49), which includes the ligand-to-ligand repulsion energy minimalization [10]. The second approach results in two interpenetrating bispheroids and two symmetry-equivalent sets of metal-ligand bonds: longer M-L_A ('elongated' tetrahedron) and shorter M–L_B ('flattened' tetrahedron). The two groups of ligands with different bond lengths can be identified in the structure of (**1**) and (**2**), with the average metal-nitrogen distances: Mo–N_A = 3.322 Å, W–N_A = 3.327 Å (N2, N4, N5, N8) and Mo–N_B = 3.303 Å, W–N_B = 3.301 Å (N1, N3, N6, N7) Table 1. Such two sets of bonds were found for the anion of approximated D_{2d} symmetry in $(C_6H_6NO_2)_4[Mo(CN)_8]$ [11], $Rb_4[Mo(CN)_8]\cdot 3H_2O$ [12] and $K_5[Nb(CN)_8]$ [13], but no significant differences in bond lengths were observed for $(n\text{-}Bu_4N)_3[M(CN)_8]$ [14] and $K_4[M(CN)_8]\cdot 2H_2O$ [15] (M = Mo or W) (also approximated to D_{2d}). The values of shape parameters for (**2**) ($\theta_A = 36.4°$, $\theta_B = 73.3°$, a = 1.19, m = 1.16, g = 1.24, b = 1.47) are in good agreement with those calculated for the most favourable polyhedron model. Thus the $(dq)_2[M(CN)_8]\cdot 5H_2O$ structure belongs to the group of the best dodecahedrons known for molybdenum and tungsten octacyano complexes. (**1**) and (**2**) are also the first $[M(CN)_8]^{4-}$ salts with a high content of water of crystallization which exhibit D_{2d} symmetry of anion [1].

The M–C≡N chain is nearly linear, with bond angle differing from 180° by no more than 3°.

The diquat cations (Figure 3) are in preferred cis conformation with the angle between the pyridine rings equal to 22.9°. The bond lengths and bond angles Table 2 are almost the same as in the dibromide salt [16].

The $[M(CN)_8]^{4-}$ anions and the dq^{2+} cations form a three-dimensional net connected by hydrogen bonds (Figure 4). There are two non-equivalent locations of diquat in that net. A set of cations in positions parallel

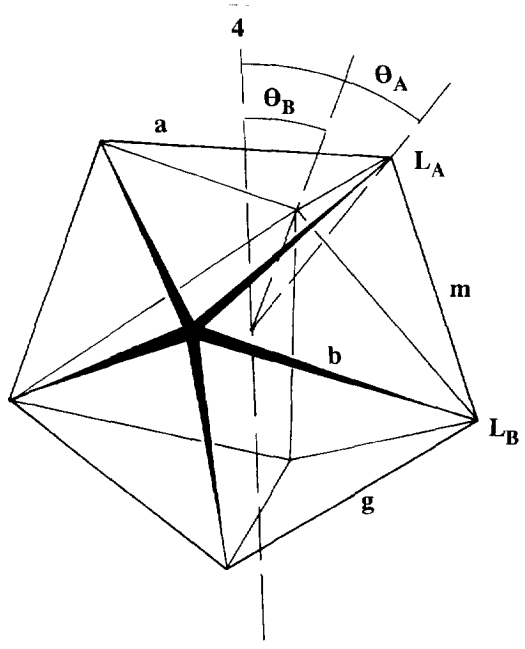

Fig. 2. Ideal dodecahedron with shape parameters.

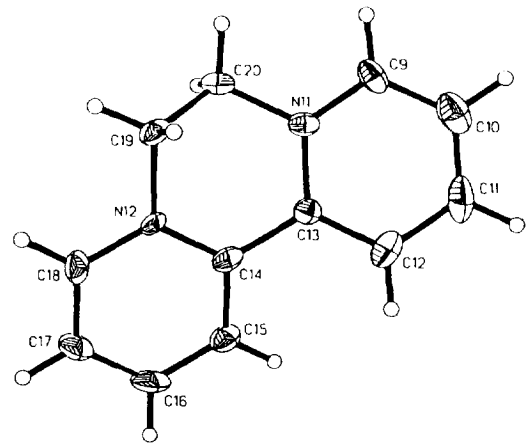

Fig. 3. The structure of diquat cation.

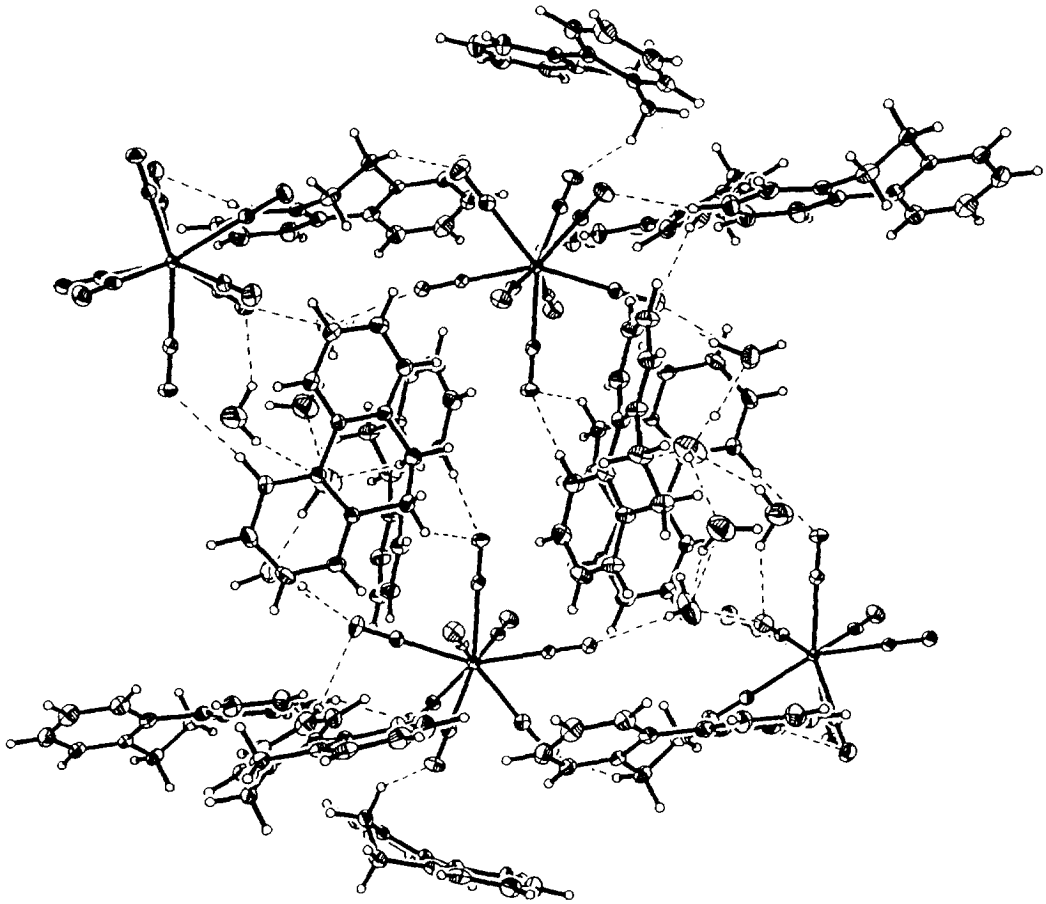

Fig. 4. The structure of $(dq)_2[Mo(CN)_8]\cdot 5H_2O$ (**1**).

to the z axis (central part of Fig. 4) separates layers containing cations perpendicular to the z axis (top and bottom part of Fig. 4).

The net is stabilized by strong hydrogen bonds (Figure 5) between cyanide nitrogens and water molecules (e.g. N1-O1 = 2.83 Å, N4-O1 = 2.88 Å) and water molecules (O1-O2 = 2.79 Å). In contrast to other similar species, there are also weak hydrogen bonds including cyanide nitrogen and cation aromatic carbon (e.g. N3-C21 = 2.97 Å), cyanide nitrogen and cation ethylene carbon (N5-C31 = 3.25 Å), and cation ethylene carbon and water molecule (C19-O5 = 3.26 Å).

The water molecules are close to each other linked through hydrogen bonds and form a column that fills a tunnel along the x axis (Figure 6). The distances between water oxygens and the bond angles are very close to those in ice, indicating weak interaction with ions. This is consistent with the zeolitic character of the water of crystallization shown by reversible dehydration at relatively low temperature. The differences in water molecule environments account for the two-step dehydration: the strongest bonded water molecule O1, linked *via* hydrogen bonds to two anions and to two other water molecules can be identified as the one released at higher temperature.

Spectra

In comparison to analogous potassium salts the visible spectra of (**1**) and (**2**) in aqueous solution show new absorption band in the 500–650 nm region (Figure 7) assigned to optical charge transfer (IPCT) from complex anion to diquat cation. Similarly to other polypyridinium octacyanometallates [3, 4] the tungsten compound absorbs light of lower energy than its molybdenum analogue ($\lambda_{max} = 545$ (Mo) and 625 nm (W)), due to the lower reduction potential of tungsten in the $[M(CN)_8]^{3-}/[M(CN)_8]^{4-}$ couple (0.78 V (Mo), 0.51 V (W) in water solution). In diluted solution, where ion-pairing is incomplete, the IPCT bands have low intensity. In the solid state they become stronger than $[M(CN)_8]^{4-}$ d-d transitions and shift to longer wavelength (592 for (**1**) and 710 nm for (**2**)). This bathochromic shift is justified by the Marcus-Hush theory [17, 18], according to which the energy of

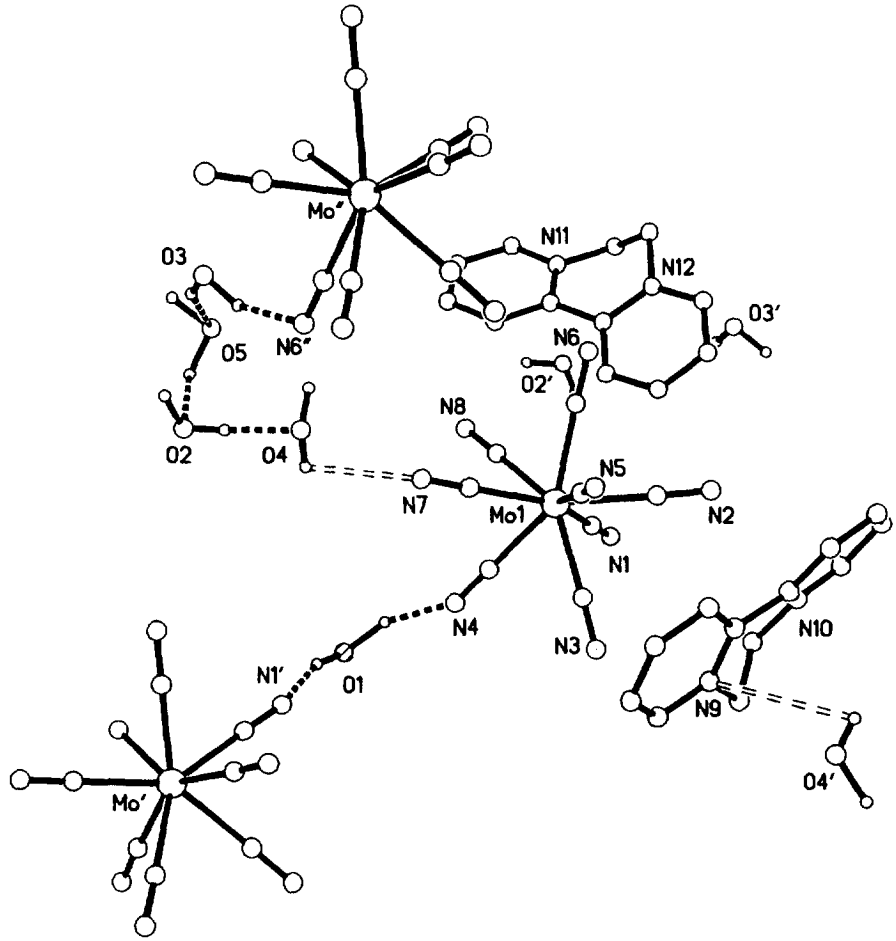

Fig. 5. Hydrogen bonds (broken filled line) and weak interactions of hydrogen-bond type (broken empty line) in the structure of (**1**).

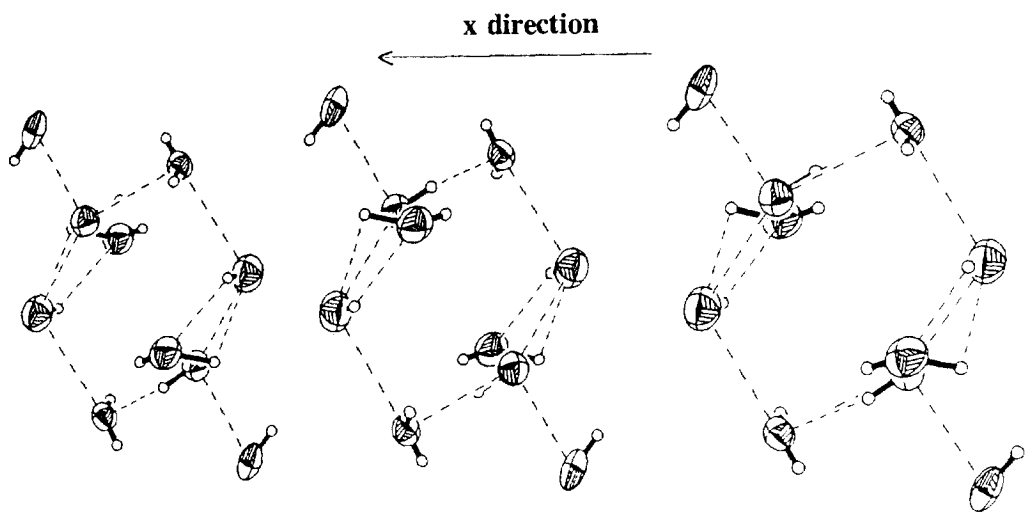

Fig. 6. The arrangement of water molecules in (**1**).

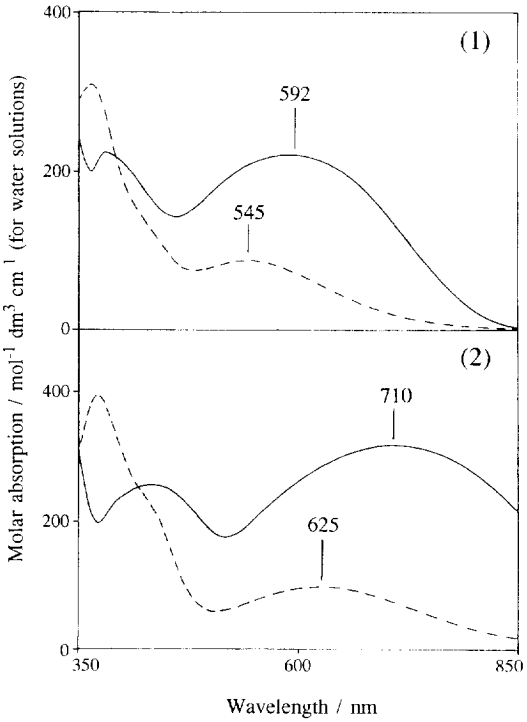

Fig. 7. Electronic absorption spectra in water solutions (broken line) and reflectance spectra (solid line) of $(dq)_2[Mo(CN)_8]\cdot 5H_2O$ (**1**) and $(dq)_2[W(CN)_8]\cdot 5H_2O$ (**2**).

optical electron transfer decreases as the distance between reacting moieties becomes shorter. The values of the shift, equal to 1500 (Mo) and 1900 cm^{-1} (W), fall between those observed for other bipyridinium octacyanomolybdates and tungstates [3, 4], so it seems that neither the extremely short distance between ions nor direct hydrogen bonding of the anion to cation carbons affect the process of optical electron transfer.

In the case of tungsten salts (**2**) and (**4**) the presence of the IPCT band in the electronic spectra is accompanied by 'real' electron transfer from anion to cation. The metal configuration changes from diamagnetic d^2 to paramagnetic d^1, so that an ESR signal due to this transition can be observed. The amount of paramagnetic (d^1) M(V) centres in (**2**) and (**4**) (0.67% and 2.19%) are of the same order of magnitude as for other salts [3, 4]. The increased paramagnetism observed for the anhydrous salt is connected with the shorter distance between ions. Molybdenum compounds (**1**) and (**3**) remain diamagnetic, which corresponds to the lower oxidation potential of molybdenum (IV) octacyanide.

The IR spectra of (**1**), (**2**), (**3**) and (**4**) (Table 3) are dominated by the bands of cation origin which change their position and intensity slightly in comparison to $dqBr_2\cdot H_2O$. This can be explained by the hydrogen bonding to anion. The differences are easily recognizable in the C–H stretching mode region (2950–3100 cm^{-1}).

The strong absorption near 2100 cm^{-1} is associated with C≡N stretching. This region is considered indicative of $[M(CN)_8]^{4-}$ local symmetry. Group theory predicts 2 IR and 3 Raman vibrational modes for D_{4d} and 4 IR and 6 Raman for D_{2d} symmetry [19, 20]. The number of absorption bands alone cannot be used to estimate geometry, because real structures are hardly ever ideal polyhedra. However the shape of the band (Figure 8) is a very characteristic feature, and provides enough information for rough symmetry estimation to be made.

CONCLUSIONS

It was found that i) isomorphic salts (**1**) and (**2**) have anions of approximately D_{2d} symmetry, providing one of the best dodecahedrons known for molybdenum and tungsten octacyanides; ii) cation and anion are directly linked *via* hydrogen-bonds between cyanide nitrogens and diquat carbons; iii) the water of crystallization fills linear cavities in the structure and has a zeolitic character shown by reversible dehydration; iv) the electronic spectra in both solids and solutions show new band characteristic for outer-sphere charge-transfer within the ion pair; v) there is no significant connection between direct hydrogen bonding between ions and the character of optical and thermal electron transfer; this problem needs further investigation.

Synthesis and characterization of cyanohydroisocyanoborates. Reactivity of the isocyano group towards nucleophiles

Béla Győri*, Zoltán Berente and István Lázár

Department of Inorganic and Analytical Chemistry, Lajos Kossuth University, P.O. Box 21., H-4010, Debrecen, Hungary.

(Received 27 January 1998; accepted 26 February 1998)

Abstract—$AgCNBH_2CN$ and $AgCNBH(CN)_2$ were synthesized with AgCN in Me_2S from $Me_2S{\cdot}BH_2CN$ and 4-cyanopyridine·$BH(CN)_2$, respectively. These silver complexes were transformed into $Na[BH_2(CN)NC]$ and $Na[BH(CN)_2NC]$ salts. In these hydrolytically very stable borates the isocyano group proved to be the most reactive site. This observation was demonstrated by reactions with nucleophiles, namely H_2S, NH_4N_3 and NH_4SCN. In the first two cases isocyano group underwent transformation into $-N(H)-C(H)=S$ and -1-(5H)tetrazolyl groups, respectively, which remarkably increase the stability of hydroborates towards acidic hydrolysis. Unlike alkyl- or arylisocyanides, isocyano groups here do not form ring in reaction with NH_4SCN, but most probably transform into $-N=C(H)-NCS$ groups. All compounds, including the *E*- and *Z*-isomers (where appropriate), were characterized by IR, ^1H, ^{11}B and ^{13}C NMR spectroscopy. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: cyanohydroisocyanoborates; cyanohydrothioformamidoborates; cyanohydrotetrazolylborates; *E,Z*-isomerism; multinuclear NMR.

A large number of cyanoboron compounds, containing B-CN units, have become known so far and sodium cyanoborohydride play a distinguished role in organic and organometallic syntheses. However, the number of isocyanoboron compounds, with B-NC units, prepared in the last two decades is quite limited. Several amine-isocyanoboranes ($A{\cdot}BH_2NC$) have been synthesized from the corresponding iodoborane complexes with transition metal cyanides or cyano complexes [1–4]. Moreover, their silver [1, 2], manganese [1] and nickel [4] complexes have also been reported. Chemical properties of amine-isocyanoboranes have not been extensively studied yet, however, in comparison with alkyl isocyanides $Me_3N{\cdot}BH_2NC$ appeared similar [5] but somewhat stronger in basicity [3].

Likewise, only a few representatives of isocyanoborates have been reported so far. The formation of $Na[BH_3NC]$ [6] was disproved based on our detailed investigations [7]. Nevertheless, silver complexes and sodium salts of bis- and tris-isocyanohydroborates could be obtained in pure form and proved rather stable towards both isomerisation and acidic hydrolysis [8]. Furthermore, borate ions with composition $[BX_2(NC)_2]$ (X=F,Br,Ph) are known also, but exclusively as ligands in cyclopentadienyl-carbonyl-μ-(bisisocyano-dihydroborate) complexes [9].

Hydrolytic stabilities of $Na[BH_2(NC)_2]$ and $Na[BH(NC)_3]$ are markedly lower than those of corresponding cyanohydroborates [8]. In reactions with HCl, amine hydrochlorides or bromine, the desired borane $BH(NC)_2$ or its amine complexes could not be obtained, apart from pyridine·$BH(NC)_2$, which was synthesized in low yield [8]. Studying the possibilities of chemical transformations to be made on the isocyano group (with H_2S, NH_4N_3 or NH_4SCN), we found that reactions generally led to decomposition, accompanied by extensive isomerization into cyanohydroborates, particularly in the case of $Na[BH_2(NC)_2]$. In order to obtain more stable isocyanoborates, we attempted to synthesize

compounds, which, besides isocyano group, contain strong electron-withdrawing cyano group(s) attached to boron. Here we report the preparation of two cyanohydroisocyanoborates and some reactions they are involved in.

EXPERIMENTAL

General comments

All reactions, except those involving water or noted otherwise, were performed under an oxygen and water free N_2 atmosphere using the general Schlenk techniques in flamed or oven dried glassware with absolutized solvents freshly distilled prior to use.

Me_2S was dried with sodium, then fractionally distilled. MeCN was dried over CaH_2, then distilled from P_2O_5. Ether and dioxane were distilled from Na–benzophenone. Acetone was distilled from a 1.5 m Raschig packed column. Pentane was fractionally distilled.

$(BH_2CN)_n/Me_2S$ [8, 10], 4-CN-py·$BH(CN)_2$ [8] and NH_4N_3 [11] were prepared by known methods. AgCN, NH_4Cl (Reanal), $Na_2S·9H_2O$, H_2S and NaN_3 (Merck) were used as received.

NMR spectra were recorded on a Bruker AM 360 instrument in 5 mm o.d. tubes. ^1H spectra were referred to DSS in D_2O and TMS in acetone. ^{13}C (90.5 MHz) spectra were referred to deuterated solvent signals in acetone-d_6 (29.9 ppm) and DSS in D_2O (0.00 ppm) as external reference. The measurements were run with quite concentrated solutions (≈ 1 M) and relatively long relaxation delays (usally 12 s) to approach quantitativity. Where assigning the spectra necessitated, homonuclear decoupling and *J*-modulated experiments were carried out. ^{11}B (115.5 MHz) spectra were referred to $Et_2O·BF_3$ in a capillary inserted into the tube. The coupling constants, unless otherwise noted, were measured between adjacent nuclei.

IR spectra were recorded on a Perkin Elmer Paragon PC 1000 FT-IR spectrometer.

The boron content of the samples was determined with acid-base titration in the presence of mannitol after fusion with NaOH and KOH.

Syntheses

$AgCNBH_2(CN)$ (*1*). A methyl sulfide solution of cyanodihydroborane (50.0 ml 1.876 M, 93.8 mmol) was added dropwise to the stirred methyl sulfide solution (30 ml) of silver cyanide (12.56 g, 93.81 mmol). At the beginning the solution turned black, due to the appearance of a small amount of silver, and later some precipitate fell out. This mixture was kept stirred at r.t. for 20 h, then filtered, and the filtrate was evaporated *in vacuo* to obtain a mixture of a solid and an oil. Acetonitrile (5 ml) was added to this residue, which completely solidified upon thorough evaporation *in vacuo*. The solid was redissolved in acetonitrile (40 ml), the insoluble parts were filtered off. The filtrate was evaporated to dryness *in vacuo*, the solid residue was suspended in ether (30 ml) and the suspension was filtered. The product was washed with ether (3 × 10 ml) and dried in a N_2-stream to give a light brown powder. Yield: 13.52 g (83%). Anal. Calcd for $C_2H_2AgBN_2$: B, 6.26. Found: B, 6.09%. IR (KBr, cm^{-1}): ν(B-H) 2422, 2405; ν(C≡N) 2223, 2198. ^{11}B NMR (CH_3CN):δ −27.2 (t, $J_{BH} = 98$ Hz).

$AgCNBH(CN)_2·CH_3CN$, $AgCNBH(CN)_2$ (*2*). Silver cyanide (16.07 g, 120 mmol) was added to the methyl sulphide suspension (80 ml) of 4-cyanopyridine-dicyanoborane (10.09 g, 60.07 mmol), and the mixture was refluxed for 48 h. The insoluble parts were filtered off and evaporation of the filtrate *in vacuo* gave a solid of constant weight. This solid was placed on a filter and 4-cyanopyridine was removed by extraction with acetone (50 ml) 25 times. The residue was dried with a N_2-stream and extracted with acetonitrile (60 ml) five times to separate the product from excess silver cyanide. The extract was evaporated *in vacuo* to leave a few mls of acetonitrile besides the solid residue. Ether (25 ml) was added to the residue, the product was filtered, washed with ether (3 × 10 ml) and dried in a N_2 stream to obtain 10.66 g (74%) $AgCNBH(CN)_2·CH_3CN$. This was in turn suspended in water (60 ml), the slurry was vigorously stirred for 2 h, filtered, the solid residue was washed with water (3 × 10 ml) and dried in a N_2 stream. Yield: 8.77 g (74%). Anal. Calcd for: B, 5.47. Found: B, 5.32%. IR (KBr, cm^{-1}): ν(B-H) 2453, ν(C≡N) 2212. ^{11}B NMR (CH_3CN):δ −27.9 (d, $J_{BH} = 108$ Hz).

$Na[BH_2(CN)NC]$ (*3*). To a stirred aqueous suspension of $AgCNBH_2(CN)$ (10.12 g, 58.59 mmol in 10 ml) was added an aqueous solution of $Na_2S·9H_2O$ (6.85 g, 28.5 mmol in 10 ml) in 5 min. Na_2S solution (0.300 M) was then added in small (0.1 − 0.2 ml) portions until a sample of the supernatant caused browning of approx. the same extent with Na_2S and lead(II) acetate solutions on a filter paper. Silver sulfide was separated on a filter and washed with water (3 × 15 ml). The washings were combined with the filtrate and evaporated *in vacuo* under r.t. to obtain a viscous resin. (In the final period of the evaporation blackening and precipitation of a gelly solid may occur.) The residue was dissolved in ether (40 ml), evaporated *in vacuo*, redissolved in ether and evaporated again. The residue was mixed with ether (40 ml) to give a two-phase system, and in case it was not clear, it was filtered. The filtrate was evaporated and the residue was kept under vacuum for 2 h. Pentane (25 ml) was added, the product was collected on a filter, washed with pentane (10 ml) and dried in a N_2 stream. Yield: 4.53 g, 88%. Anal. Calcd for $C_2H_2BN_2Na$: B, 12.31. Found: B, 12.14. Na[BH(CN)$_2$NC] (**4**). To a stirred aqueous suspension of AgCNBH(CN)$_2$·CH$_3$CN (5.10 g, 21.4 mmol in 5 ml) was added Na_2S solution (34.50 ml, 0.300 M, 10.4 mmol) in 5–10 min. The addition of this solution was continued by 0.1 ml portions until the supernatant over silver sulfide became clear, and then administered by 50 μl portions until addition of a new portion caused no opalescence at the spot of instillation. After 0.5 h stirring silver sulfide was filtered off, washed with water (3 × 5 ml) and the filtrate combined with the washings was evaporated *in vacuo* under 40 C to yield a viscous resin. The residue was triturated with ether (20 ml), which was in turn removed with a N_2 stream and the residue was kept under vacuum for 1 h. The remaining solid was suspended in ether (20 ml), collected on a filter, washed with ether (2 × 5 ml) and dried in a N_2 stream. Yield: 2.37 g, 98%. Anal. Calcd for C_3HBN_3Na: B, 9.58. Found: B, 9.40%. IR (KBr, cm^{-1}): ν(B-H) 2445; ν(C≡N) 2224; ν(N≡C) 2167. ^{1}H NMR (D_2O):δ 2.3 (br q, BH). ^{11}B NMR (D_2O):δ −30.3 (d, $J_{BH}=108$ Hz). ^{13}C $\{^1H\}$ NMR (D_2O):δ 167.13 (s, 1C, BNC), 132.6 (br q, 2C, BCN, $J_{BC}=64$ Hz).

Na[BH$_2$(CN)(N(H)C(H)=S)] (**5**). To an aqueous suspension of AgCNBH$_2$(CN) (1.55 g, 8.97 mmol in 3 ml) was added Na_2S solution (14.55 ml 0.300 M, 4.37 mmol) in 3–5 min. The addition of Na_2S solution was continued dropwise until a sample of the supernatant caused browning of approx. the same extent with Na_2S and lead(II) acetate solutions on a filter paper. Hydrogen sulfide was bubbled through the vigorously stirred solution for 30 min. Silver sulfide was filtered off, the filtrate was evaporated and acetonitrile (5 ml) was added to the residue. It was then evaporated, the residue was redissolved in acetonitrile (8 ml), the insoluble parts were filtered off, the filtrate was evaporated *in vacuo* until the solidification was complete. Ether (10 ml) was added to the product, it was then collected on a filter, and dried in a N_2 stream.

Yield: 0.93 g (85%). Anal. Calcd for $C_2H_4BN_2NaS$: B, 8.87. Found: B, 8.97%. Na[BH(CN)$_2$(N(H)C(H)=S)]·C$_4$H$_8$O (**6**). To a stirred aqueous suspension of AgCNBH(CN)$_2$·CH$_3$CN (1.202 g, 5.03 mmol in 1 ml) was added Na_2S solution (8.00 ml, 0.300 M, 2.40 mmol) in 5–10 min. The addition of this solution was continued by 50 μl portions until the supernatant over silver sulfide became clear, and then administered by 25 μl portions until addition of a new portion caused no opalescence at the spot of instillation. Hydrogen sulfide was bubbled through the vigorously stirred solution for 80 min. Silver sulfide was filtered off, the filtrate was evaporated and the yellowish resinous residue was dissolved in acetonitrile (6 ml). The insoluble parts were filtered off, and the filtrate was evaporated *in vacuo*. Ether (5 ml) and then dioxane (0.7 ml) were added to the resinous residue, which solidified upon trituration in minutes. The product was collected on a filter, washed with an ether-dioxane (10:1) mixture (2 × 3 ml), then with ether (1 × 3 ml) and dried in a N_2 stream. Yield: 1.13 g (96%). Anal. Calcd for $C_7H_{11}BN_3NaO_2S$: B, 4.60. Found: B, 4.49%. Na[BH(CN)$_2$(1-(5H)-tetrazole)] (**8**). To an aqueous solution of Na[BH(CN)$_3$NC] (0.480 g, 4.25 mmol in 5 ml) ammonium azide (0.511 g, 8.50 mmol) was added. The reaction mixture was kept at 85 C for 1.5 h, then evaporated to dryness *in vacuo* in a 75–80 C bath. Ether (10 ml) was added to the residue, the suspension was filtered, and the product was extracted with the filtrate five times, then dried in a N_2 stream. Yield: 0.58 g, 88%. Anal. Calcd for $C_3H_2BN_6Na$: B, 6.94. Found: B, 7.08%. IR (KBr, cm^{-1}): ν(C-H) 3155; ν(B-H) 2460; ν(C≡N) 2231. ^{1}H NMR (D_2O):δ 8.99 (s, 1H, CH), 3.15 (br q, 1H, BH). ^{11}B NMR (D_2O):δ −25.1 (d, $J_{BH}=108$). ^{13}C $\{^1H\}$ NMR (D_2O):δ 150.59 (s, 1C, CH), 132.2 (br q, 2C, BCN).

RESULTS AND DISCUSSION

Synthesis of cyanohydroisocyanoborates (**1–4**)

In the methyl sulfide solution of BH_2CN, which is an equilibrium mixture of $Me_2S·BH_2CN$ and $(BH_2CN)_n$

(n = 5,6) [8], AgCN slowly expels Me_2S to form $AgCNBH_2CN$, according to eq. (1). Similarly, 4-cyanopyridine, a weak base, can be displaced from its complex with dicyanoborane in a similar but even slower reaction, using excess AgCN in methyl sulfide solution, as described in eq. (2).

$$Me_2S{\cdot}BH_2CN + AgCN \xrightarrow[\text{r.t., 20h}]{Me_2S} \underset{\mathbf{1}}{AgCNBH_2CN} \quad (1)$$

$$4\text{-CN-py}{\cdot}BH(CN)_2 + AgCN \xrightarrow[\text{reflux 48h}]{Me_2S} \underset{\mathbf{2}}{AgCNBH(CN)_2} + 4\text{-CN-py} \quad (2)$$

Reaction (1) is accompanied by the reduction of a small amount of Ag(I) into finely divided elementary silver. The extent of this side reaction became considerable at higher temperatures or in not satisfactorily absolutized solvents. Reaction (2) was carried out using 100% excess of AgCN and the product could be separated from the remaining AgCN with acetonitrile in the form of an adduct $AgCNBH_2CN{\cdot}CH_3CN$. Acetonitrile could be removed by stirring in aqueous suspension.

1 and **2** could be transformed into their sodium salts with sodium metal in THF in the presence of 10 mol% benzophenone, or with Na_2S in water.

$$AgCNBH_n(CN)_{3-n} \xrightarrow[\text{(i) Na, } Ph_2CO/THF\quad \text{(ii) } Na_2S/H_2O]{\text{(i) or (ii)}} \underset{\substack{\mathbf{3}\ (n=2)\\ \mathbf{4}\ (n=1)}}{Na[BH_n(CN)_{3-n}(NC)]} \quad (3)$$

In reactions with Na-benzophenone silver occasionally fell out in colloid form and the isomerization of B-NC group can also take place to a small extent. Transformation of **2** with Na_2S could be carried out with no problem, while after the transformation of **1**, **3** could be obtained with small amount of silver as impurity. Transformation was attempted using NaI in both water and acetone, but no pure material could be obtained this way, because of formation of silver isocyano-iodo mixed complexes.

The presence and number of hydrogens attached to boron was confirmed by ^{11}B NMR spectra. Accordingly, **1** gave a triplet and **2** showed a doublet in acetonitrile solution. Binding mode of CN groups could not be determined from IR spectra, since in solid phase both B-CN and B-NC groups can coordinate to silver, resulting two nearby $\nu(C\equiv N)$ bands in the case of **1** and one broad $\nu(C\equiv N)$ band for **2** in the 2198–2223 cm^{-1} region. This is in agreement with the fact, that B-CN and B-NC groups give rise to similar $\nu(C\equiv N)$ frequencies (2190–2218 cm^{-1}) in the silver complexes of $[BH_n(NC)_{4-n}]^-$ and $[BH_n(CN)_{4-n}]^-$ ions (n = 1,2) [8]. The presence of cyano and isocyano groups in **3** and **4**, obtained from the silver complexes as described in (3, ii), was confirmed by their IR and ^{13}C NMR spectra. Both compounds show IR resonances in the regions characteristic to both cyanoborates (2200–2230 cm^{-1}) and isocyanoborates (2150–2170 cm^{-1}) [8]. ^{13}C NMR spectroscopy is an excellent tool for the determination of the binding mode of CN groups, since carbons directly attached to boron give broad quartets, due to the nuclear spin of 3/2 and the quadrupolar moment of ^{11}B nuclei, while carbons in B-NC groups show sharp singlets 22–24 ppm downfield from B-CN signals.

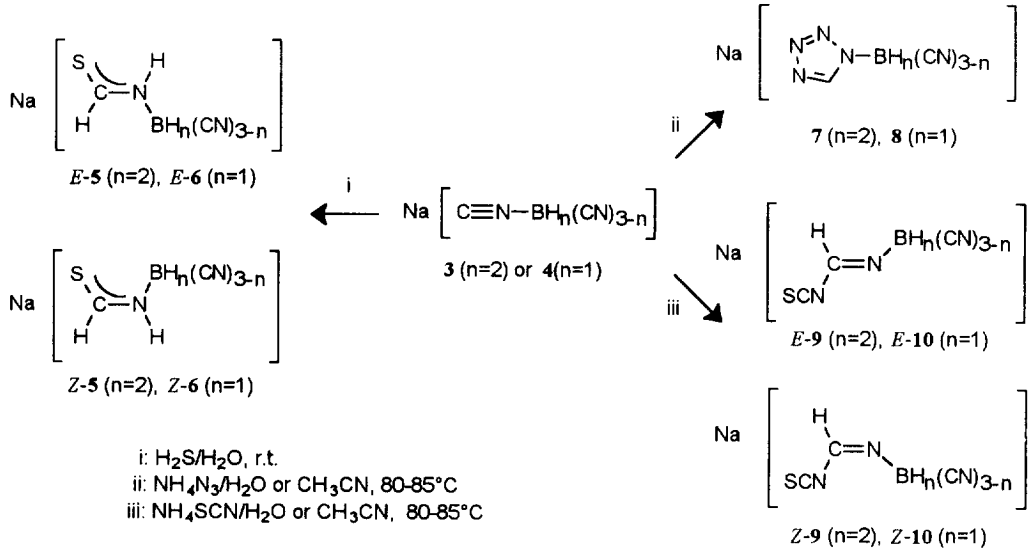
Hydrolytic stabilities of **3** and **4** are similar to those of cyanotrihydroborate [12] and dicyanodihydroborate [8], respectively. ^{11}B NMR monitoring of their 1 M aqueous solutions showed 18% hydrolysis into H_3BO_3 in the case of **3** after 48 h at 50 °C, while **4** showed no detectable decomposition of this kind. Simultaneously, 39% of **3** underwent isomerization into dicyanodihydroborate, while the similar conversion of **4** did not reach 1 mol%. The remarkable difference between the rates of isomerization is in accordance with our earlier experience, namely the rate increases as the number of hydrogens attached to boron increases [7, 8].

Isocyano group is described quite reactive, however, undergoes electrophilic rather than nucleophilic attack [13]. Nevertheless, we found that isocyano groups in these compounds readily react with certain nucleophiles, namely H_2S, NH_4N_3 and NH_4SCN (Scheme 1), under mild conditions.

*Reactions of **3** and **4** with hydrogen sulfide*

Cyanohydroisocyanoborates do not react with H_2S neither in Me_2S, nor in MeCN, even at 1–5 bar. On the other hand, the addition of H_2S to isocyano group took place with ease in water at ambient conditions, leading to the formation of a thioformyl group on the nitrogen, analogously to isocyano groups attached to carbon [13]. The products **5** and **6** were obtained in high yields, **6** as a dioxane adduct.

Like secondary thioformamides, **5** and **6** appeared in the reactions as a mixture of *E*- and *Z*-isomers in *Z*/*E* proportions of 15.4 for **5** and 1.59 for **6**. The isomers could be distinguished by either their ^1H, ^{11}B or ^{13}C NMR signals and identified by the coupling constants ($^3J_{HH}$) between NH and CH protons [14]. This constant could not be observed in D_2O, as NH protons are in a fast exchange equilibrium with the solvent, but in acetone-d_6 they appeared 16 Hz for *E*- and undetectably small for *Z*-isomers, due to the significant line width of these signals at room temperature. From both mixtures pure *E*-forms could be obtained after isomerization in acetone at 55 °C for 10 h (**5**) and 1 h (**6**). The isomerization could not be completed in water, where a *Z*/*E* proportion of 0.63



Scheme 1.

appeared to be equilibrial for **6** both at 50°C and 85°C. *Z*- and *E*-isomers show differences in their IR spectra as well, particularly the ν(N-H), thioformamide B (ν(CN) + NHR bending) and ν(CS) bands.

Both compounds are very stable towards acidic hydrolysis. Decomposition of **5**, accompanied by the simultaneous evolution of H_2 and H_2S, reached a considerable extent only in concentrated HCl. Decomposition of **6** was slow even in cc. HCl at boiling temperature, and the evolving gas could be identified as H_2S only. Of these experiences the former is more informative concerning the electronic effect of *N*-thioformamido group, since cyanotrihydroborate ion decomposes very quickly in 1 M HCl [12], while dicyanodihydroborate could be demolished only in cc. sulfuric acid at 100–120°C [8]. Thus, *N*-thioformamido group has a considerable electron-attracting effect which decreases the hydridic character of the hydrogen on the boron.

It should be noted, that the reaction of $Na[BH_2(NC)_2]$ with H_2S in water resulted in vigorous H_2 evolution and the formation of a red resin, which solidified upon treatment with ether. This product did not contain B-H group, but significant amount of NaSCN, identified by its intensive IR band at 2080 cm^{-1}.

Reactions of 3 and 4 with ammonium azide

Reactions between isocyanides and HN_3, producing 1-substituted tetrazoles, are rather slow in the absence of catalysts [15]. Azide ion could be added to isocyano groups in cyanohydroisocyanoborates also, to form 1-(5H)-tetrazolyl groups (Scheme 1) in relatively fast reactions.

Transformations of **3** could be accomplished with HN_3 in ether/THF, with NH_4N_3 (or NaN_3 and NH_4Cl) in acetonitrile or in water, or with NaN_3 in water in the presence of HCl. Yields, depending on the conditions, fall in a narrow range (46–65%). These reactions were accompanied by more or less isomerization of the isocyano groups, particularly in acidic aqueous medium, but the byproduct ($Na[BH_2CN)_2]$) could be separated from tetrazolylborate.

4 underwent an analogous reaction with NH_4N_3 either in acetonitrile or in water at 50–80°C. The transformation proceeded through intermediate of composition $[BH(CN)_2\text{-}N{=}C(H)\text{-}N_3]^-$ the *E*- and *Z*-isomers of which gave distinct signals both in ^1H and ^{11}B NMR spectra [*E*: δ(^1H, D_2O): 7.51 (s, CH), δ(^{11}B, D_2O): around −25.0 (d), under the signal of the endproduct; *Z*: δ(^1H, D_2O): 7.70 (s, CH), δ(^{11}B, D_2O): −28.8 (d)]. This intermediate accumulated to a remarkable extent (20–35 mol% depending on the conditions) in acetonitrile. In water the reaction was considerably faster, and the amount of the intermediate remained under 3–5% during the whole course of the reaction. Consequently, the ring closure, the second step of the reaction, seems to be favoured in water in comparison with acetonitrile.

Both tetrazolylborates are extremely stable towards acidic hydrolysis. Evolution of H_2 could be observed in cc. HCl solution of **7** only upon heating above 40–50°C. Decomposition of **8** is very slow in cc. HCl even at boiling temperature.

Contrary to **3** and **4**, in the reaction between $Na[BH_2(NC)_2]$ and HN_3 in ether/THF the presence of only a small amount of $[BH_2(CHN_4)_2]^-$ could be rendered likely by the appearence of IR bands at 3142

and 3136 cm^{-1} and a singlet at 8.98 ppm (D_2O) in ^1H NMR spectrum, but it could not be obtained in pure form.

Reactions of **3** *and* **4** *with ammonium thiocyanate*

Alkyl- and arylisocyanides react with two molar equivalents of HSCN to form 1-alkyl- or 1-aryl-2,4-dithioxo-1,2,3,4-tetrahydro-1,3,5-triazole rings [16]. In contrast, both **3** and **4** in both water and acetonitrile react with one molar equivalent of NH_4SCN exclusively. The reactions, monitored by means of ^{11}B NMR spectoscopy, were found considerably slower than those with NH_4N_3 and accompanied by decomposition into H_3BO_3 and isomerization of the isocyano group, particularly in the case of **3**. ^1H, ^{11}B and ^{13}C NMR spectra of the reaction mixtures strongly suggest that the main products of the reactions were most probably the mixtures of *E*- and *Z*-isomers of **9** [δ(^1H, D_2O): 7.61 s, (*Z*)-CH; 7.37 s, (*E*)-CH; δ(^{11}B, D_2O): -28.4 t, $J_{BH}=100$ Hz, (*Z*); -23.8 t, $J_{BH}=101$ Hz, (*E*)] and **10** [δ(^1H, D_2O): 7.69 s, (*Z*)-CH; 7.50 s, (*E*)-CH; δ(^{11}B, D_2O): -28.8 d, $J_{BH}=105$ Hz, (*Z*); -25.0 d, $J_{BH}=96$ Hz, (*E*)]. This assumption is based on the similarity to spectral patterns shown by **5**, **6** and the open-chain intermediates in the reactions between **3**, **4** and NH_4N_3. ^{13}C NMR spectra [δ(NCS) in D_2O: around 136 ppm] clearly confirmed that the products in question are isothiocyanates and not thiocyanates [17]. Despite our meticulous efforts, neither isothiocyanate derivative could be prepared in pure form.

CONCLUSION

Facile reactivity of isocyano group in cyanohydroisocyanoborates towards H_2S, NH_4N_3 and NH_4SCN implies the possibility of further versatile transformations. Anions in **3** and **4**, which possess exceptional hydrolyitic stability, can be regarded as potential ligands for transition metals, having three different possible coordinative sites. Indeed, platinum complexes of $[BH_2(CN)NC]^-$ ion have been recently reported formed in a reaction of coordinated cyanide [18]. With respect to the analogy between tetrazolyl and carboxyl groups [19], biological studies of **7** and **8** seems promising, in the light of the biological and pharmacological activities of carboxyboron compounds [20]. **5** and **7** are hydrolytically much more stable than **3**, consequently, *N*-thioformamido- and 1-(5H)-tetrazolyl groups appear to efficiently decrease the hydridic character of hydrogen in boron hydrides.

(Received 20 October 1997; accepted 26 February 1998)

Abstract—A new unsymmetrical (μ-oxo)diiron(III) complex $[Fe_2O(OAsPh_3)_4Cl_3]_2[Fe_2OCl_6].2CH_3CN$ (I), where $OAsPh_3$ is triphenylarsine oxide, has been prepared by several ways and characterized by X-ray structural analysis, elemental analysis, spectral and magnetic methods. The complex (I) is formed simultaneously with another two complexes of the composition $[Fe_2O(OAsPh_3)_4Cl_3][FeCl_4].CH_3CN$ (II) and $[Fe(OAsPh_3)_4Cl_2][FeCl_4]$ (III). In compound (I) the complex cation has one Fe atom coordinated by four $OAsPh_3$ which form a plane, and the oxo-bridged ligand occupies an apex and form a square pyramid configuration about the second iron atom. In the complex anion each Fe atom is tetrahedrally coordinated by three chlorine atoms and the oxo bridge. The magnetic properties have been investigated in the 4.2–300 K temperature range and these data correspond to the EPR spectra. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: iron(III) complexes; unsymmetrical oxo-bridged complexes; triphenylarsine oxide; magnetism; spectroscopic data; structure.

We are interested in the formation of iron complexes with triphenylphosphine oxide ($OPPh_3$) by autocatalytic oxidation of PPh_3 by dioxygen to $OPPh_3$ in the presence of some iron salts and corresponding anions [1–5]. In spite of the simplicity of the PPh_3-system we have explored the $AsPh_3$-system, too. How-

ever, in the later case we have found that besides the monomeric Fe(III) complex there are also formed the diiron(III) complexes. The monomeric $[Fe(OAsPh_3)_4Cl_2][FeCl_4]$ salt is known which was prepared by direct reaction of $FeCl_3$ with $OAsPh_3$ in ethanol [6] or toluene under anaerobic conditions [7]. Two oxo-bridged diiron salts: $[Fe_2O(OAsPh_3)_4Cl_3]_2[Fe_2OCl_6].2CH_3CN$ (I) and $[Fe_2O(OAsPh_3)_4Cl_3][FeCl_4].CH_3CN$ (II) have different anions. The $[(OAsPh_3)_4FeOFeCl_3]^+$ cation is the first nonbiological unsymmetrical oxo-bridged Fe(III) complex ion with penta- and tetracoordinated iron atoms. However, until to-date, in all the known oxo-bridged Fe(III) complexes both Fe(III) atoms are tetracoordinated [8–20], pentacoordinated [21–37], hexacoordinated [38–48] or even heptacoordinated [49]. There are examples [50–53], in which two non-equivalent Fe(III) atoms, (viz. hexa- and tetra- coordinated) are bridged by a single O atom. It is known [54] that unsymmetrical Fe–O–Fe bridge angle is present in a class of dinuclear iron proteins. The (μ-oxo)-diiron(III) complexes have been prepared by several ways and are characterized by spectral and magnetic methods as well as by X-ray analysis. (The compound (II) has been characterized by us previously [55]).

EXPERIMENTAL

Preparations of the compounds

Complexes of the composition, $[Fe_2O(OAsPh_3)_4Cl_3]_2[Fe_2OCl_6].2CH_3CN$ (I) $[Fe_2O(OAsPh_3)_4Cl_3][FeCl_4].CH_3CN$ (II) and $[Fe(OAsPh_3)_4Cl_3][FeCl_4]$ (III) are formed simultaneously and amounts of the individual complexes are dependent on the reaction conditions. These complexes were prepared by several ways:

Method 1

Solution of $OAsPh_3$ (2.575 g, 8.0 mmol) in ethanol (ca. 70 ml) or toluene (ca. 100 ml) was added to $FeCl_3$ (0.648 g, 4.0 mmol) at room temperature and the resulting mixture stirred for 2 h. The yellow product which precipitated was filtered out and recrystallized from acetonitrile. The individual complexes were separated by fractional crystallization using acetonitrile, yielding the following three products:

1. $[Fe_2O(OAsPh_3)_4Cl_3]_2[Fe_2OCl_6].2CH_3CN$ (I) as the least soluble complex (dark yellow sticks). Found: C, 51.56; H, 3.60; Cl, 12.90; Fe, 9.65. Calcd. for $C_{148}H_{126}As_8Cl_{12}Fe_6N_2O_{11}$: C, 51.3; H, 3.7; Cl, 12.3; Fe, 9.7%.
2. $[Fe_2O(OAsPh_3)_4Cl_3][FeCl_4].CH_3CN$ (II) as more soluble complex (yellow needles). Found: C, 50.76; H, 3.59; N, 0.83; Cl, 14.22; Fe, 9.46. Calcd. for $C_{74}H_{63}As_4Cl_7Fe_3NO_5$: C, 50.45; H, 3.60; N, 0.80; Cl, 14.09; Fe, 9.51%.
3. $[Fe(OAsPh_3)_4Cl_2][FeCl_4]$ (III) as the most soluble complex (light yellow plates). Found: C, 53.58; H, 3.78; Cl, 13.41; Fe, 6.67. Calc. for $C_{72}H_{60}O_4As_4Cl_6Fe_2$: C, 53.60; H, 3.75; Cl, 13.18; Fe, 6.92%.

When the reaction mixture is kept under argon, the complex (III) is a major fraction. However, when the raw product is slowly recrystallized from hot CH_3CN in the presence of O_2, both dimeric complexes (I + II) are formed in larger amounts.

Method 2

Solutions of acetonitrile (ca. 30 ml) and 0.70 ml of a 36% solution (by weight) of aqueous HCl (8.0 mmol) ($T = 333$ K) containing excess iron powder (0.33 g, 5.9 mmol) and $AsPh_3$ (1.23 g, 4.0 mmol) were stirred for about 2 days under a dioxygen atmosphere. The completion of the oxidation of $AsPh_3$ to $OAsPh_3$ was ascertained by comparing the electronic absorption spectrum of the reaction solution with the spectrum of pure $OAsPh_3$ which exhibits four absorption bands with the maxima at 252, 259, 262 and 270 nm. The resulting mixture was filtered (mainly from Fe_2O_3) and separated by fractional crystallization using CH_3CN by the same procedure of *Method* 1. In this case complex (III) was a minor fraction. Both dimeric complexes were obtained in equally amounts.

Method 3

$AsPh_3$ (0.61 g, 2.0 mmol) dissolved in ca. 40 ml CH_3CN was transfered to $FeCl_3$ (0.17 g, 1.0 mmol) in the reaction vessel. The contents were stirred and heated to a temperature of ~ 333 K under a O_2 atmosphere for ca. 2 days. Monitoring of the reaction course and fractional crystallization were done in the manner as mentioned above. In this case the dimers were obtained in larger amounts than complex (III) and were suitable for X-ray analyses.

Method 4

$Fe_2(SO_4)_3.7H_2O$ (1.10 g, 2.1 mmol) and KCl (0.60 g, 8.0 mmol) were placed into a thermostated vessel, the acetonitrile solution (ca. 30 ml) of $AsPh_3$ (1.23 g, 4.0 mmol) was added and the mixture was stirred under O_2 for about 2 days. The course on this reaction was monitored according to the manner mentioned above. After the oxidation, the K_2SO_4 as a by-product was filtered out. The crude product was separated by fractional crystallization, too. The complex (II) was the major product.

Method 5

The acetonitrile solution (30 ml) of complex (III) (0.41 g, 0.25 mmol) was stirred for about 10 h under

O_2 in a thermostated vessel ($T = 323$ K). The dark-yellow solution containing all the complexes was separated by fractional crystallization (see *Method* 1). The amount of (II) was larger than that of (I).

Elemental analyses confirm the composition of the separated complexes (*Method* 2 to 5). Elemental analyses were carried out using a Carlo-Erba C,H,N,S-O (EA 1108) analyser.

Spectroscopic studies

Infrared spectra were recorded using Philips Analytical PU 9800 FTIR spectrometer in Nujol mulls on KBr plates over 4000–200 cm^{-1} range. Electronic spectra were recorded on Specord M 40 spectrophotometer by Carl Zeiss. Resonance Raman spectra were recorded on a Bruker ER 200 E-SRC spectrometer. Electron paramagnetic resonance (EPR) spectrum was measured with X-band Radiopan SE/X spectrometer for powder. Solid sample of Mn(II) in MgO was used as the reference and the magnetic field was calibrated with a nuclear magnetometer MJ 110R.

Magnetic measurements

Magnetic susceptibility of the polycrystalline samples of the compounds were measured by the Faraday method in the temperature range 4.2–293 K, using a sensitive Sartorius M-25D electrobalance. Susceptometer was equipped with Oxford Instruments CF-1200 continuous-flow cryostat and an electromagnet operating at 6.25 kG. The calibrant employed was $HgCo(NCS)_4$ [56], for which the magnetic susceptibility taken as 16.44×10^{-6} $cm^3 g^{-1}$. The correction for diamagnetism of the constituent atoms was calculated using Pascal's constants [57] and found to be -928×10^{-6} cm^3 mol^{-1} and -1820×10^{-6} cm^3 mol^{-1} per molecule of complexes I and II, respectively. The value $N\alpha = 0$ ($cm^3 mol^{-1}$) was used for the temperature independent paramagnetism of the compounds. The effective magnetic moment was calculated from the equation, $\mu_{eff} = 2.83 \times (\chi_M \times T)^{1/2}$ (B.M.). The value of the exchange parameters were determined by least-square procedure, and the minimization of the function:

$$R = \sum_{i=1}^{n} (\chi_i^{exp\,tl} - \chi_i^{calcd})^2 / (\chi_i^{exp\,tl})^2$$

was the criterion used to determine the best fit.

X-ray structure determination

$[Fe_2O(OAsPh_3)^4Cl_3]_2[Fe_2OCl_6].2CH_3CN$ (I) A well-formed dark yellow crystal was affixed to the end of glass fiber using silicone grease and transferred to the goniostat where it was cooled to 120 K for data collection ($4^\circ < 2\Theta < 44^\circ$) (Table 1). Standard inert atmosphere techniques were used. A systematic search of a limited hemisphere of reciprocal space located no symmetry or systematic absences indicating a triclinic space group. Subsequent solution and refinement of the structure confirmed the proper space group to be $P\bar{1}$. The structure was solved by direct methods and refined by SHELXL-93 program [58]. The phenyl ring H-atoms were included in geometrically calculated positions and the acetonitrile H-atoms were not determined from final difference map. No absorption correction was applied. A final difference map was essentially featureless, the largest peaks being in the vicinity of the As atoms. The high values of anisotropic temperature factors for acetonitrile molecules may suggest partially disorder of these molecules. Bond lengths and angles, atomic coordinates, displacement parameters and lists of structure factors for (I) are deposited.

RESULTS AND DISCUSSION

Anhydrous $FeCl_3$ and $OAsPh_3$ interact rapidly in several solvents (e.g. ethanol [6], toluene [7], acetonitrile) to afford yellow solutions. When the interaction is carried out under anaerobic conditions, the complex (III) is formed as a major product. However, in the presence of oxygen the I and II complexes are also formed, (*Method* 1). A similar mixture of these 3 complexes were also obtained when the following reactants were used as the starting compounds:

$Fe–HCl–AsPh_3–O_2$	(*Method* 2)
$FeCl_3–AsPh_3–O_2$	(*Method* 3)
$Fe_2(SO_4)_3.7H_2O–KCl–AsPh_3–O_2$	(*Method* 4)
$[Fe(OAsPh_3)_4Cl_2][FeCl_4]–O_2$	(*Method* 5)

Autocatalytic oxidation of $AsPh_3$ to $OAsPh_3$ by O_2, which has taken place in the Methods 2, 3 and 4, were used for the preparation of mainly diiron complexes. During oxidation of $AsPh_3$ mentioned reaction systems consumed O_2, what was demonstrated by measurements of dioxygen uptake on the apparatus described previously [1].

Both the complexes (I) and (II) are built with identical cationic forms (Fig. 1), different anions ($FeCl_4^-$ [55] and $Fe_2OCl_6^{2-}$ (Fig. 2)) and acetonitrile solvate molecules. Selected bond distances and angles of the complex (I) are given in Tables 2 and 3, respectively. The complex cations of (I) and (II) have similar structures. They contain two unsymmetrical iron(III) μ-oxo species (Fig. 1). The Fe(1) atom is coordinated by four $OAsPh_3$ ligands which form a distorted square pyramide configuration about the Fe(1). The Fe(2) is tetrahedrally coordinated by three chlorine atoms and the oxo bridge. They differ significantly with Fe–O–Fe bond angle of 161.0(3) in (II) and of 170.3(3) in (I). The Fe(2)–O(5) bonds of 1.759(4) Å in (II) and 1.776(4) Å in (I) are slightly shorter than the Fe(1)–O(5) bonds (1.784(4) Å in (II) and 1.779(4) Å in (I)), as expected. Both lengths, as well as the Fe–O–Fe angle, fall in the range of values observed for the diiron(III) μ-oxo analogues (Table 5). The bond lengths for Fe(2)–Cl in (II) (average 2.204(3) Å) are identical with those observed in the $[(n5)FeOFeCl_3]^-$ cation (average 2.203(3) Å) [52] and they are the slightly shorter than Fe(2)–Cl bond lengths in (I) (average 2.218(4) Å). To our knowledge, the Fe–

distorted tetrahedral ligand environment. The bond distances of the anion agree with those of the compounds investigated so far. The Fe–O–Fe angle is relatively large (Table 5).

Table 4 summarized infrared spectroscopic data of three Fe(III)–$OAsPh_3$ complexes. In the IR spectra of these complexes showed that ν(As–O) bands are shifted to lower energies compared with the free $OAsPh_3$, as the result of $OAsPh_3$ coordination. The dimeric complexes I and II have a strong new absorption at 849 cm^{-1} and 841 cm^{-1}, respectively. It is attributed to the asymmetric Fe–O–Fe stretching vibration (ν_{as}). Intense absorption in the region 800–860 cm^{-1} is commonly used as diagnostic criterion for identification of the oxo-monobridged Fe(III) complexes [8, 52]. The bands assigned to the symmetric Fe–O–Fe stretching vibration (ν_s) observed at 415 (I) and at 411 cm^{-1} (II) are within the range expected for these monobridged structures [60]. The Fe–O–Fe vibrations of I and II correlate with bond angles: the Fe–O–Fe angles can be predicted within 10° from knowledge of ν_s and ν_{as} [60]. In the infrared spectrum the Fe–O–Fe frequencies are nearly identical with those observed in the Raman spectrum. Whereas ν_{as}(Fe–O–Fe) are stronger and ν_s(Fe–O–Fe) are weaker in the IR spectra of I and II, in the Raman spetra the stretching vibration intensities are opposite. Infrared bands at

Table 4. Characteristic IR data (cm^{-1}) for the Fe(III)–$OAsPh_3$ complexes

Compound	ν(As–O)	ν(FeOFe)		ν($FeCl_4^-$)	ν($FeCl_3$)	
		ν_{as}	ν_s		ν_{as}	ν_s
III	869s 828s	—	—	380s		
II	860s 828s	841s	411m	382s	369m	307m
I	881s 830vs	849vs	415m	—	363vs	314m

363 (I) and 369 cm^{-1} (II) are assigned to the respective Fe–Cl_3 asymmetric stretch by comparison with $[Fe_2OCl_6]^{2-}$ and bands at 314 (I) and 307 cm^{-1} (II) are assigned similarly to the symmetric $FeCl_3$ mode in agreement with literature data [51]. IR spectra of II and III show a characteristic strong band at 383 and 380 cm^{-1} (ν_3) of $FeCl_4^-$, respectively [8].

In Table 5 are summarized selected structural data for μ-oxo-bridged dimeric Fe(III) compounds. As can be seen, the mean Fe–O(bridge) bond distance increases with increasing coordination number in the sequence: 1.754 Å (tetra coordinated) < 1.771 Å (penta coordinated) < 1.786 Å (hexa coordinated), as expected. The Fe–O–Fe bridge angles in the series of tetra-, penta- and hexa-coordinated species are well comparable, i.e. they are in the range of 147.7 to 180°, of 142.7 to 180° and of 146.6 to 180°, respectively. There are relationships between the Fe–O–Fe bridge angle and Fe–Fe distances. When the former closses the latter is shortened.

The anion $FeCl_4^-$ is a strong paramagnet with $S=5/2$ spin, but the $Fe_2OCl_6^{2-}$ ion is a molecular antiferromagnet. Using the theoretical equation [61]

$$\chi_M = \left(\frac{N_g^2\mu_B^2}{kT}\right) \times \left(\frac{2e^{2x}+10e^{6x}+28e^{12x}+60e^{20x}+110e^{30x}}{1+3e^{2x}+5e^{6x}+7e^{12x}+9e^{20x}+11e^{30x}}\right)$$

(where χ_M was corrected for diamagnetism, and $TIP=0$ and $\chi=J/kT$) and X-ray data (this work) for $Fe_2OCl_6^{2-}$ in the crystal lattice of the complex (I), the relation $\chi_{Fe_2OCl_6^{2-}} = f(T)$ was prepared (Fig. 3). The magnetic interaction in a dimer is expressed by the Heisenberg–Dirac-van Vleck Hamiltonian. $H_{HDVV} = -2J_{S_aS_b}$, where $\hat{S}_a$ and $\hat{S}_b$ are the spins of the magnetically interacting iron(III) ions ($\hat{S}_a = \hat{S}_b = 5/2$).

The cationic forms observed in both the complexes indicate lack of any symmetry and a difference in the bridging angle Fe–O–Fe, 170.3° and 161.0° for the complexes I and II, respectively.

In the crystal lattice of the complex II two magnetically isolated paramagnetic forms exist, which confirms the absence of the maximum on the experimental curve $\chi_M = f(T)$ up to 4.2 K. A weak anomaly observed in the region 4.2–20 K and the value $\Theta \sim -2.5$ K may suggest weak antiferromagnetic superexchange interaction. The relation between

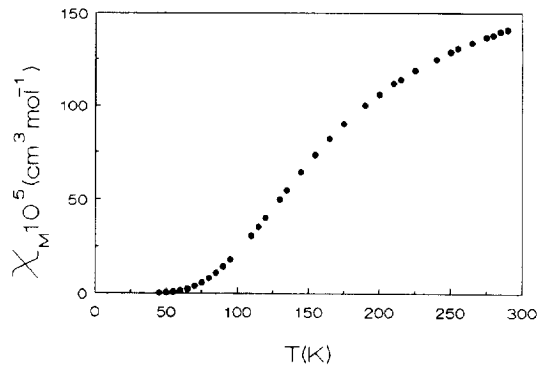

Fig. 3. Plots of the magnetic susceptibility versus T for $Fe_2OCl_6^{2-}$ anions calculated for $g=2$, $J=-170$ cm^{-1}, diamagnetic correction $= -188.10^{-6}$ cm^3 mol^{-1}.

molar magnetic susceptibility and the magnetic moment for both the complexes as a function of temperature enables us to compare their properties (Fig. 4; magnetic data are given for whole molecular system.). Both the complexes indicate a relation typical for a paramagnet, although the magnetic effect for the complex (II) is stronger (Table 6).

In the EPR spectrum of the complex (II) only one

[a] Where more than one chemically equivalent distance or angle present, the mean value is tabulated. The first number in parenthesis is e.s.d., the second is maximum deviation from the mean value.

[b] The chemical identity of coordinated atom/ligand is specified in these columns.

[c] There are two crystallographically independent molecules.

[d] It indicates that the distance was calculated trigonometrically [60].

Table 6. Magnetic data

Compound	Temperature $T(K)$	Magnetic susceptibility $\chi_M \times 10^6$ ($cm^3\ mol^{-1}$)	Magnetic moment μ_{eff} (B.M.)
$[Fe_2O(OAsPh_3)_4Cl_3][FeCl_4].CH_3CN$	4.2 292	894000 18700	5.48 6.62
$[Fe_2O(OAsPh_3)_4Cl_3]_2[Fe_2OCl_6].2CH_3CN$	4.2 290	319000 25800	3.28 6.06

single line is present, with $g = 2.04$ (room temperature and 77 K).

The EPR spectrum of the cation of complex (I) presents one single line with $g = 2.06$ and two additional weak lines with $g = 4.34$ and 6.08 at room temperature. It suggests a doublet ground state $< \pm 1/2$ I with admixture of $< \pm 3/2$ I and $< \pm 5/2$ I states.

The magnetic data for the $[(Ph_3AsO)_4FeOFeCl_3]^+$ cation, indicated only one unpaired electron per every Fe(III) centre, in a core of Fe(III) [D_{4h} deformed]–O–Fe(III) [T_d deformed]).

Further, the magnetic data at temperatures lower than 20 K are identical with the expected magnetism exclusively for the cation and indicate a singlet ground state and upper triplet state.

However, for complex II calculation of the magnetic moment of the cation was found to be impossible because we have not any possibility to estimate magnetism of the isolated $FeCl_4^-$ anion. It was imposible, too, to compare magnetic properties of $[(Ph_3AsO)_4FeOFeCl_3]^+$ cations from crystal lattice of the complexes I and II.

We also prepared another unsymmetrical oxo-bridged diiron(III) complexes with $[(Ph_3AsO)_4FeOFeBr_3]^+$ cation and study of their properties is in progress.

Atomic coordinates, displacement factor coefficients, full list of bond length and angles and lists of F_o/F_c values have been deposited as supplementary data with the Editor, from whom copies are available on request. Atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre.

(Received 18 December 1997; accepted 27 February 1998)

Abstract—A new compound $[Cu(Him)_2(ox)]_2[Cu(Him)_2(H_2O)]_2$ (Him = imidazole, ox = dianion of oxalic acid) has been prepared and structurally determined. The structure consists of quasi-one-dimensional chains built from two different neutral $[Cu(Him)_2(ox)]_2$ and $[Cu(Him)_2(H_2O)(ox)]_2$ units linked by hydrogen bonds. Two centrosymmetrically related copper ions in the former unit are five-coordinated by two nitrogen atoms from the imidazole ligands and two oxygen atoms from the oxalate anion occupying the basal plane and the oxygen atom of another chelating oxalate situated at the apical position with a weak contact of 2.837(2) Å. The coordination environment of the other two copper ions connected by O–H · · · O hydrogen bonds in the other unit can be described as a distorted square pyramid, with two oxygen atoms of the oxalate ion and two nitrogen atoms from the imidazole ligands in the basal plane and one oxygen atom of the coordinated water molecule in the apical position. The (Him)N–H · · · O(ox) hydrogen bonds connect the adjacent units to give rise to a quasi-one-dimensional structure. The room-temperature ESR study gives a $g_\perp$ value of 2.07 and a $g_\parallel$ value of 2.23. From magnetic susceptibility measurements the compound was found to exhibit a weak antiferromagnetic interaction ($J = -2.64\,cm^{-1}$) between the copper(II) ions through the Cu–O–Cu pathways. © 1998 Elsevier Science Ltd. All rights reserved. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: crystal structure; copper(II) complex; hydrogen bonding; magnetic behaviour; oxalate bridges; tetranuclear complex.

The oxalate has been proven to be a bridging ligand to propagate magnetic interactions and the exchange interaction between the copper ions through this bridge was found to vary from $J = -340\,cm^{-1}$ to $-0.5\,cm^{-1}$ [1–6]. To date, two different bridging modes (Scheme 1a and 1b [7]) have been observed for the oxalato group, of which the former mode is commonly seen.

In the present paper, we describe a new copper(II) compound $[Cu(Him)_2(C_2O_4)]_2[Cu(Him)_2(C_2O_4)(H_2O)]_2$ which has an unusual oxalate-bridged copper pair and a hydrogen-bonded copper pair (Him = midazole). Its dimeric arrangement and the presence of novel oxalate bridges (Scheme 1c) make this compound of considerable interest.

EXPERIMENTAL

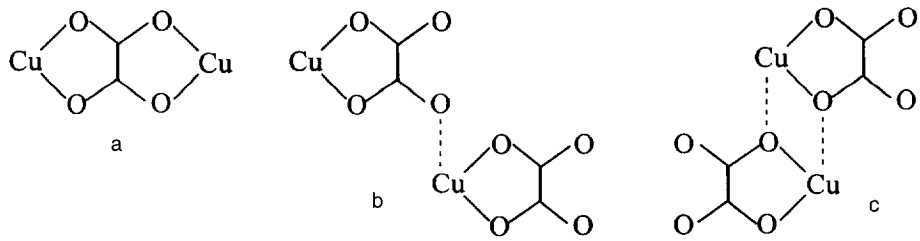
Copper nitrate trihydrate, sodium oxalate and Him were of analytical grade. $K_3[Cr(ox)_3] \cdot 3H_2O$ (ox^{2-} = dianion of oxalic acid) were prepared by the literature method [8].

Synthesis

The compound $[Cu(Him)_2(C_2O_4)]_2[Cu(Him)_2(C_2O_4)(H_2O)]_2$ was prepared by two different procedures.

Method 1: To $Cu(NO_3)_2 \cdot 3H_2O$ (241.6 mg, 1 mmol)

*Author to whom correspondence should be addressed.



Scheme 1. Different bridging modes for oxalate ligands.

and Him (136.2 mg, 2 mmol) in an aqueous solution (10 cm^3) was added Na_2ox (134 mg, 1 mmol) in water (5 cm^3). Blue microcrystals were obtained from the resulting solution upon standing for several hours. Yield: 50%. Found: C, 32.5; H, 3.1; N, 18.8. Calcd. for $C_{16}H_{18}Cu_2N_8O_9$: C, 32.4; H, 3.0; N, 18.9%. Method 2: To $Cu(NO_3)_2 \cdot 3H_2O$ (241.6 mg, 1 mmol) in 10 cm^3 of water was added an aqueous solution of $K_3[Cr(ox)_3] \cdot 3H_2O$ (487.4 mg, 1 mmol) in 10 cm^3 of H_2O. Then, to the resulting mixture was added Him (136.2 mg, 2 mmol) and the dark blue solution was stirred for 10 min and then filtered. The filtrate was left to stand at ambient temperature. After 3 d, prismatic blue crystals were obtained in 40% yield. Found: C, 32.5; H, 3.2; N, 19.3. Calcd. for $C_{16}H_{18}Cu_2N_8O_9$: C, 32.4; H, 3.0; N, 18.9%.

Physical measurements

Elemental analyses of carbon, hydrogen and nitrogen were carried out with a Perkin–Elmer analyzer model 240. The electronic spectrum was measured with a Perkin Elmer Hitachi-240 spectrophotometer. The powder ESR spectrum was recorded on a JES-FE1XG ESR spectrometer using an X-band and Mn^{2+} (MgO) reference. IR spectra on KBr pellets were performed on a Shimadzu IR-408 infrared spectrophotometer in the 4000–600 cm^{-1} region. Magnetic susceptibility measurement of a crystalline sample was carried out in the temperature range 2–290 K on a vibrating sample magnetometer, model CF-1. The experimental susceptibilities were corrected for the diamagnetism of the constituent atoms (Pascal' Tables).

Crystallographic data collection and structure determination

Data were measured at 299(1) K with a CAD-4 diffractometer using the ω-2θ scan technique with ω-scan width = $(0.65 + 0.35 \tan\theta)^\circ$, scan speed = 0.92–5.49° min^{-1}, graphite-monochromated M-Kα radiation; 2978 independent reflections $2 < \theta < 23^\circ$; hkl, h = −8–8, k = −8–8, l = 0–20, giving 2792 observed reflections ($I > 3\sigma(I)$). Intensity data were corrected for Lorentz-polarization factors and empirical absorption correction was made during processing.

The structure was solved by direct method (MULTAN 82). All non-hydrogen atoms were refined anisotropically by full-matrix least squares method. Atomic scattering factors were taken from ref.[9]. The weighting scheme w = 1 for all of observed reflections gave satisfactory agreement analyses. Calculations were performed with the SPD-PLUS program system [10] on a PDP11/44 computer.

RESULTS AND DISCUSSION

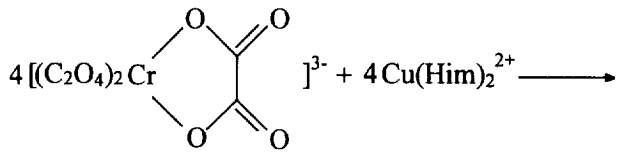
Preparation of $[Cu(Him)_2C_2O_4][Cu(Him)_2(C_2O_4)(H_2O)]_2$

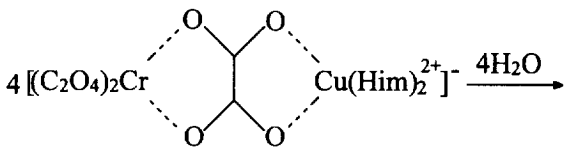
The oxalate as a multidentate anionic ligand has been proven to have the tendency to bridge two transition metal centres to give rise to dinuclear complexes. We initially investigated the reaction of equimolar amounts of $Cu(Him)_2^{2+}$ and Na_2ox in an aqueous solution and found that no crystals but microcrystals were obtained. The electrophilic attack of the CuL^{2+} complexes on the coordinated oxalate ligands in $Cr(ox)_3^{3-}$ ion has commonly been used to synthesize oxalate-bridged copper complexes [3–6]. In order to obtain the single crystals of the present compound suitable for X-ray structure analysis, we adopted the same way by employing the reaction between $Cu(Him)_2^{2+}$ and $Cr(ox)_3^{3-}$ in a 1:1 molar ratio. The result shows that an oxalate-bridged copper(II) compound is obtained. It may be accounted for if the following reaction (Scheme 2) is assumed. In addition, it follows that the preparation method 2 possesses a slower reaction so as to afford larger crystals with respect to the method 1.

Crystal structure of $[Cu(Him)_2(C_2O_4)]_2$ $[Cu(Him)_2(C_2O_4)(H_2O)]_2$

Crystal data, selected interatomic bond distances and bond angles and the intermolecular contacts are given in Tables 1, 2 and 3, respectively. The molecular structure and the view of the cell are shown in Figs 1 and 2, respectively.

The structure consists of quasi-one-dimensional chains built from two different binuclear units $[Cu(Him)_2(ox)]_2$ and $[Cu(Him)_2(H_2O)(ox)]_2$ linked by hydrogen bonds (Fig. 2). The Cu(1) and Cu(1a) (a:





$$[Cu(Him)_2(C_2O_4)]_2[Cu(Him)_2(C_2O_4)(H_2O)]_2 + 4\ Cr(C_2O_4)_2(H_2O)_2^-$$

Scheme 2. The representation of the mechanism of the electrophilic attack of $Cu(Him)_2^{2+}$ on $Cr(C_2O_4)_3^{3-}$.

$1+x$, $1+y$, $2+z$) ions of the centrosymmetrically related $[Cu(Him)_2(ox)]_2$ unit are five-co-ordinated (Fig. 1a) by two nitrogen atoms from the imidazole ligands and two oxygen atoms from the oxalate anion forming the basal plane and the square pyramidal is completed by the apical oxygen atom of another oxalate ligand at a distance of 2.837(2) Å from the copper ion, which is comparable with the Cu–O distances found previously in other copper(II) compounds [7, 11, 12, 13]. The bond angles of O(1a)–Cu(1)–O(3) and O(1a)–Cu(1)–O(1) are 106.8° and 76.4° which deviate remarkably from 90°. This apparently suggests some interaction between the O(1a) atom and Cu(1) atom. The largest deviations from the least-squares plane for Cu(1) defined by N(11), N(21), O(1) and O(3) are 0.1862 Å at O(1) and −0.1848 Å at O(3) and Cu(1) lies 0.0948 Å out of this plane toward O(1a). The Cu(1)···Cu(1a) separation is 5.879(5) Å.

The co-ordination environment of Cu(2) can be described as a distorted square pyramid, with two oxygen atoms of one oxalate ion and two nitrogen atoms from the imidazole ligands in the equatorial plane and one oxygen atom of the coordinated water molecule in the apical position. The oxygen and nitrogen atoms are alternatively below and above the plane with the deviations being N(41) 0.0967 Å, N(31) −0.0944 Å, O(5) 0.1052 Å and O(7) −0.1075 Å. The Cu(2) atom lies out of this plane by −0.0976 Å toward the coordinated O(9) atom. The centrosymetric copper groups are linked by the O(9)–H···O(5b) hydrogen bonds with the O(9)···O(5b) distance of 2.906(5) Å to give rise to another binuclear unit (Fig. 1b).

The Cu–N(Him) bond distances of both entities are similar, ranging from 1.948(3) to 1.981(3) Å, which are approximately equal and similar to corresponding lengths found in other imidazole copper complexes [14, 15]. Each imidazole ring is almost planar with deviations from the least-squares planes less than 0.0087 Å. The two imidazole planes in each neutral moiety are not coplanar with the dihedral angles of 108.5° and 100.5°, respectively.

As usual, the chelating oxalate possesses two pairs of C–O bonds with different bond lengths [7, 13, 16]: the coordinated oxygen atoms invariably possess longer C–O bonds which can be considered as single with respect to the short terminal C–O bonds. The difference observed is 0.055 Å (average value) excluding that between C(2)–O(3) and C(2)–O(4) of 0.016 Å, which is due to the existence of O(4d)···N(44) hydrogen bonding (d = x, y, $1+z$) undermining the C(2)–O(4) bond strength.

The O(4d)···N(44) hydrogen bonds of 2.879(6) Å (d = x, y, $1+z$) connect the adjacent units to give rise to a quasi-one-dimensional structure (Fig. 2).

Spectroscopic and magnetic properties

The infrared spectra display features characteristic of the chelating modes of oxalate and coordinated imidazole. The band at 3110 cm^{-1} can be attributed to the N-H vibration of Him. the broad band at 2900 cm^{-1} indicates the presence of hydrogen bond in the present complex. In the 1720–1630 cm^{-1} range the strong bands are characteristic of C–O stretch of the

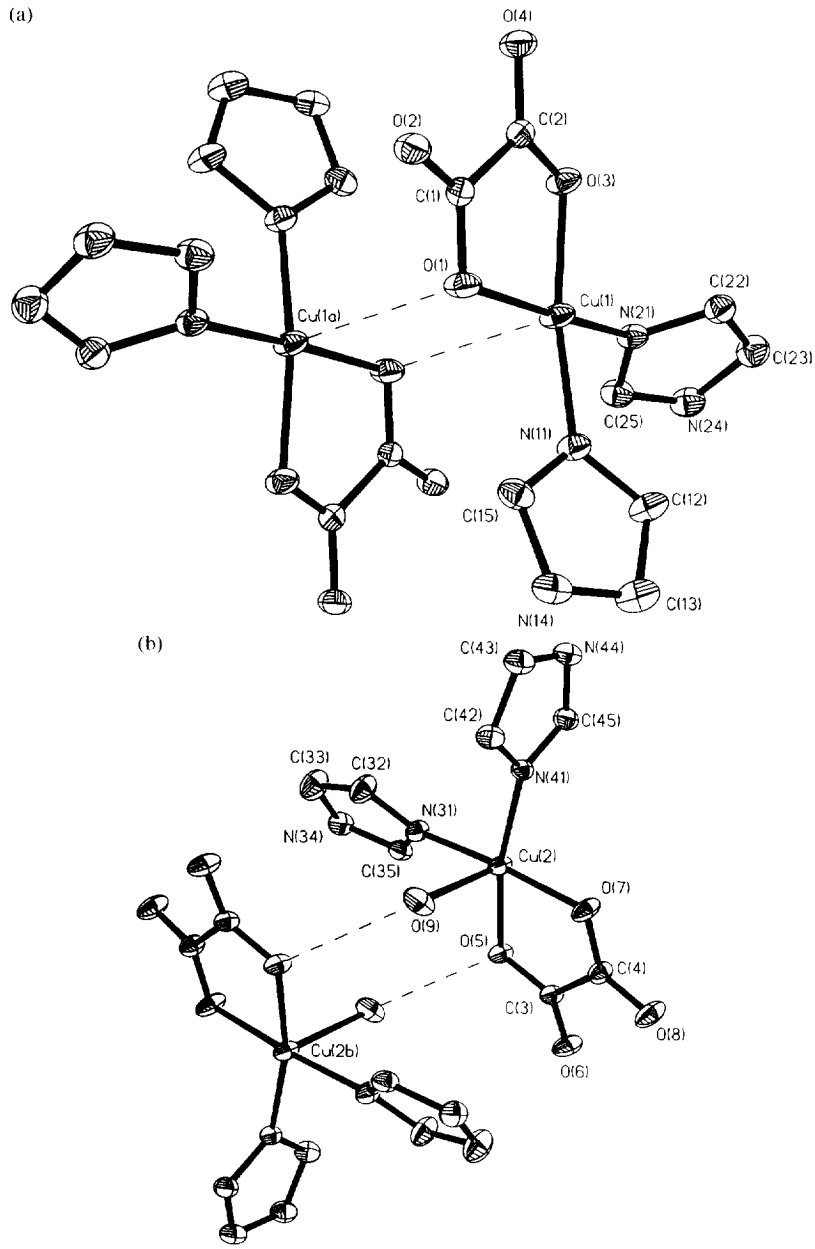

Fig. 1. The ORTEP [18] drawing of $[Cu(Him)_2(C_2O_4)]_2[Cu(Him)_2(C_2O_4)(H_2O)]_2$, showing thermal ellipsoids drawn at the 30% probability level: (a) $[Cu(Him)_2(C_2O_4)]_2$; (b) $[Cu(Him)_2(C_2O_4)(H_2O)]_2$.

oxalate ligand. Four bands at 1710, 1695 and 1670 cm^{-1} are observed which is in good agreement with the presence of chelating oxalate ligands [17] determined by the crystal structure analysis.

The solid-state reflectance electronic spectrum shows a broad band at 640 nm of medium-intensity which is assigned to d-d transition of copper ions in square pyramidal surroundings.

The powder X-band ESR spectrum at room temperature is anisotropic having a $g_\perp$ parameter value of 2.07 and a g value of 2.23. No half-field transition was observed.

Magnetic susceptibility data were collected on a crystalline sample in the temperature range 2–290 K. The variations of X_m and μ_{eff} is represented in Fig. 3 from 150 to 2 K. From 290 to 150 K, μ_{eff} remains practically constant and equal to 3.8 μ_B, which is the value expected for four isolated copper(II) ions with a g value of 2.17. Upon further lowering the temperature, μ_{eff} decreases, reaching a value of 2.6 μ_B at 2 K, which indicates the presence of an antiferromagnetic interaction between the copper(II) ions at low temperature.

The quasi-one-dimensional chain, formed by alter-

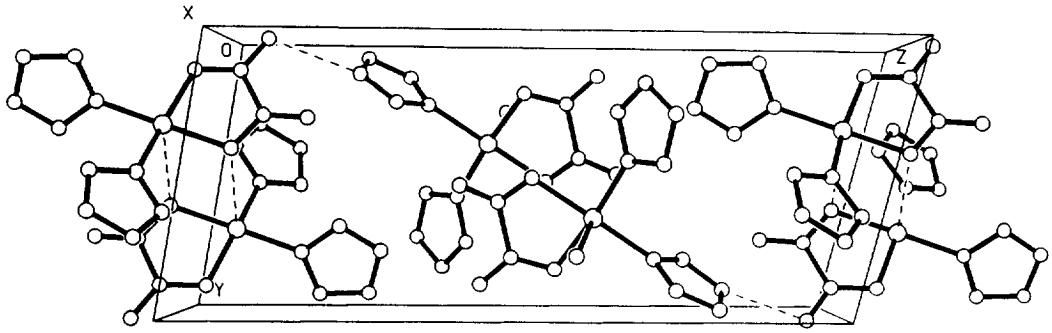

Fig. 2. View of the crystal cell of the compound showing the hydrogen bonds connecting the binuclear units.

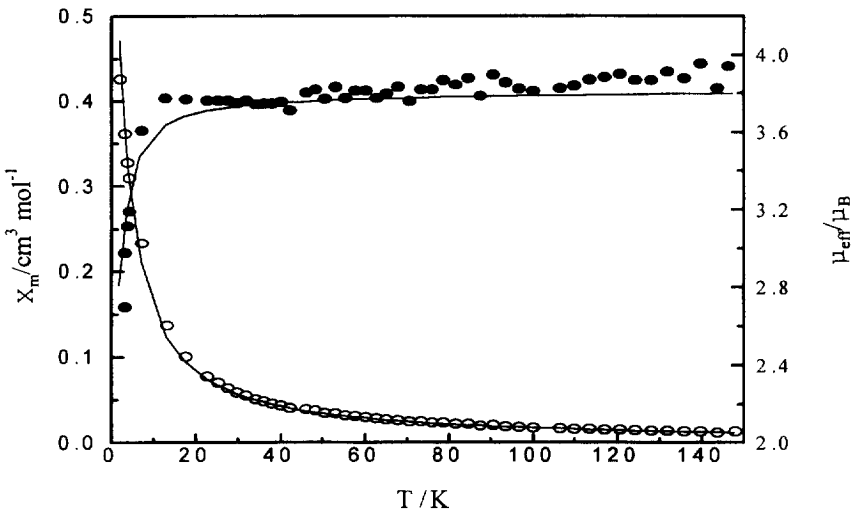

Fig. 3. Plots of μ_{eff} and X_m vs temperature for $[Cu(Him)_2(C_2O_4)]_2[Cu(Him)_2(C_2O_4)(H_2O)]_2$. The solid lines represent the theoretical values.

nation of (Cu_1–Cu_1) and (Cu_2–Cu_2) binuclear units through hydrogen bonds, can be schemtized as hereunder:

$$\cdots Cu_1 \overset{J}{\text{——}} Cu_1 \cdots Cu_2 \text{——} Cu_2$$

$$\cdots Cu_1 \overset{J}{\text{——}} Cu_1 \cdots Cu_2 \text{——} Cu_2 \cdots$$

Upon neglecting the very weak interactions through all of the hydrogen bonds, the magnetic susceptibility of the present compound can be generated by eqn (1) considering Cu_1–Cu_1 as a binuclear unit and Cu_2–Cu_2 as two temperature-independent copper ions.

$$X_m = \frac{2N\beta^2g^2}{KT}[3 + \exp(-2J/KT]^{-1} + 2 \times \frac{N\beta^2g^2}{4KT} + N\alpha \quad (10)$$

where X_m is the mole susceptibility per Cu_4 unit, J the exchange integral between the Cu_1 ions ($\hat{H} = -2J\hat{S}_1\hat{S}_2$) and the other symbols have their usual meanings. As shown in Fig. 3, a good least-square fit with the experimental data was attained with eqn (1), giving magnetic parameters $g = 2.17$, $J = -2.64\,cm^{-1}$, and the agreement factor defined as $R = \Sigma(X_{obs}\text{-}X_{calc})^2/\Sigma(X_{obs})^2$ equal to 8.8×10^{-4}. The small negative J value suggests that the Cu1a–O–Cu1 pathway within the present compound is unfavourable to achieve an effective overlap between magnetic orbitals of the copper ions. On the basis of the molecular structure of the compound, we see that the unpaired electron of the copper ion with a square pyramidal configuration can be described by a magnetic orbital built from the $d_{x^2-y^2}$ orbital with little contribution from the d_{z^2} orbital, and localized basically in the basal plane. Hence, two parallel magnetic orbitals unfavour the magnetic exchange and the weak coupling must be due to the slight delocalization of the magnetic orbitals towards the apical position occupied by the bridging oxygen atoms [19].

(Received 7 January 1998)

Abstract—Reaction of $Ag(NO_3)$ with 1 equiv of $K[HB(3,5\text{-}Me_2pz)_3]$ (pzH = pyrazole) and 1 equiv of PR_3 (R=OPh or C_6F_5) in methanol provides two new air stable derivatives $\{[HB(3,5\text{-}Me_2pz)_3]Ag(PR_3)\}$. When the interaction between $Ag(O_3SCF_3)$, CNR (R=Bu^t or cyclohexyl), and $K[HB(3,5\text{-}Me_2pz)_3]$ was carried out in CH_2Cl_2 at 0°C the air stable neutral compounds $\{[HB(3,5\text{-}Me_2pz)_3]Ag(CNR)\}$ were obtained. The borderline monodentate imidazole (ImH) reacts with the dinuclear $\{[HB(3,5\text{-}Me_2pz)_3]Ag\}_2$ yielding the mixed-ligand complex $\{[HB(3,5\text{-}Me_2pz)_3]Ag(ImH)\}$. On the other hand when the soft donor 1-methyl-2-mercaptoimidazole (Hmimt) was employed, no stable compound was obtained. We also synthesized $[Phen_2Ag](O_3SCF_3)$ (Phen = 1,10-phenanthroline) and its reaction with $K[HB(3,5\text{-}Me_2pz)_3]$ yielded the complex $\{Phen[HB(3,5\text{-}Me_2pz)_3]Ag\}$, which is not fluxional in solution. Instead only unmanageable material was obtained from the reaction between $(Hmimt)_2Ag(O_3SCF_3)$ and $K[HB(3,5\text{-}Me_2pz)_3]$. Finally, the gold(I) complex $[HB(3,5\text{-}Me_2pz)_3]Au(PPh_3)_2$ was obtained when the reaction between PPh_3AuCl and $[HB(3,5\text{-}Me_2pz)_3]$ was carried out in presence of 1 equiv of PPh_3. The solid state structures of $\{[HB(3,5\text{-}Me_2pz)_3]Ag(PPh_2Me)\}$ and $\{[HB(3,5\text{-}Me_2pz)_3]Ag(P\text{-}o\text{-}tolyl_3)\}$, show that the silver(I) atoms are in a strongly distorted tetrahedral environment, with the $[HB(3,5\text{-}Me_2pz)_3]^-$ donor acting in the tridentate form. The Ag–P and Ag–N bond distances in $\{[HB(3,5\text{-}Me_2pz)_3]Ag(PPh_2Me)\}$ are 2.336(2) Å and 2.316(6), 2.336(5) and 2.329(6) Å, respectively; they are shorter than in the more sterically hindered $\{[HB(3,5\text{-}Me_2pz)_3]Ag(P\text{-}o\text{-}tolyl_3)\}$ (Ag–P: 2.375(2) Å; Ag–N: 2.361(4) Å). The ligand bite N–Ag–N ranges from 82.1(2)° to 84.8(2)°, whereas the N–Ag–P angle ranges from 125.1(1) to 134.1(1)°. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: hydrotris dimethylpyrazol borate; spectroscopic; structural characterization; donor ligands.

The chemistry of poly(pyrazol-1-yl)borate complexes containing group 12 metals has recently attracted much interest [1–4]. In the case of copper(I) stable carbonyl complexes, such as $Cu(CO)[HB(pz)_3]$ [5], and triorganophosphine derivatives, such as $Cu(PR_3)[HB(pz)_n]$ (R = aryl or cyclohexyl; $n = 2$, 3 or 4) [6–8], have been obtained and characterized with analytical, spectral and X-ray data. The solid state and solution properties of the dinuclear $Cu_2[HB(pz)_3]_2$ and $Cu_2[HB(3,5\text{-}Me_2pz)_3]_2$ have also been described [9]. These two compounds show significative differences ascribed to steric influence of the methyl groups in the latter complex.

More recently, silver(I)poly(pyrazol-1-yl)borate derivatives have received great interest [10]. This is likely due to the fact that complex formation of silver(I) cations by ammonia, amines and other N-donor

*Author to whom correspondence should be addressed.

ligands has been well established in analytical and chemical technology of silver(I) for more than a century [11, 12], and it has been shown that this kind of compounds can have potential application in photography [13] or silver plating by electrochemical processes [14].

However to date the majority of these studies involves the use of polyfluorinated tris(pyrazol-1-yl)borate ligand [10]. These compounds can be used as new silver precursors: they possess a good combination of thermal stability and volatility and so promise to be excellent precursors for CVD of silver.

We have previously reported the synthesis, structural and spectroscopic characterization of several new silver{poly(pyrazol-1-yl)}borates(triorganophosphine) complexes [15, 16], and have indicated some relevant molecular and spectroscopic features. For example, it has been shown that the behavior in solution of $[Ag(PR_3)(HB(pz)_3]$ species is very different from that in solid state: the stability in solution is strongly dependent on the Tolman cone angle and pK_a of PR_3 [17], whereas in the solid state the bonding of $HB(pz)_3$ to $Ag(PR_3)$ is similar, despite the steric and electronic features of the N- and P-donor ligand.

In order to fully understand the coordination chemistry of poly(pyrazolyl)borates towards silver(I) acceptors, we now report the synthesis and reactivity of six new complexes containing the N_3-donor tris(3,5-dimethylpyrazol-1-yl)borato. Comparison was made with the results previously obtained and also with the new [gold(I){triphenylphosphine}tris(3,5-dimethylpyrazol-1-yl)borato] complex. The reactivity of silver(I)tris(3,5-dimethylpyrazolyl)borate derivatives towards N- and S- donor was also investigated.

We also report the crystal and molecular structure of tris(3,5-dimethylpyrazol-1-yl)boratosilver(I){tri-*o*-tolylphosphine} and tris(3,5-dimethylpyrazol-1-yl)boratosilver(I){methyldiphenylphosphine}, two compounds previously synthesized by us [15]. The present structural study was performed in order to support some of the hypotheses previously indicated.

EXPERIMENTAL

General comments.

All reactions were carried out under an atmosphere of dry, oxygen-free dinitrogen using standard Schlenk techniques. Solvents were freshly distilled over an appropriate drying agent and further degassed before use where necessary. In some cases the reactions were protected from light by covering reaction vessels with aluminium foil. Concentration was always carried out *in vacuo* (water aspirator). The samples for microanalysis were dried *in vacuo* to constant weight (20°C, *ca* 0.1 Torr). Elemental analyses (C,H,N) were performed in-house with a Carlo–Erba model 1106 instrument. IR spectra were recorded from 4000 to 100 cm^{-1} with a Perkin–Elmer System 2000 FT-IR instrument. ^1H, ^{13}C and ^{31}P NMR spectra were recorded on a VXR-300 Varian spectrometer operating at room temperature (300 MHz for ^1H, 75 MHz for ^{13}C and 121.4 MHz for ^{31}P). The electrical resistance of acetone solutions was measured with a Crison CDTM 522 conductimeter at room temperature.

Syntheses

The donor $K[HB(3,5\text{-}Me_2pz)_3]$ was prepared in accordance with the procedure reported in literature [18]. KBH_4, P-(*o*-tolyl)$_3$, $PMePh_2$, $P(C_6F_5)_3$, $P(OPh)_3$, 3,5-Me_2pzH, Hmimt, RNC (R=Bu^t or cyclohexyl), $Ag(O_3SCF_3)$, 1,10-phenanthroline, $(PPh_3)AuCl$ were purchased (Aldrich) and used as received.

Synthesis of $\{[HB(3,5\text{-}Me_2pz)_3]Ag\}_2$ (**1**). A mixture of $K[HB(3,5\text{-}Me_2pz)_3]$ (0.34 g, 1 mmol) in CH_3OH (30 ml) was added to $AgNO_3$ (0.17 g, 1 mmol) in CH_3OH (20 ml) at room temperature. A pale rose precipitate was immediately formed which was stirred ca. 30 min and then filtered off. The precipitate (**1**) was washed with CH_3OH and diethyl ether (0.283 g, yield 70%). Mp: 210°C dec. ^1H NMR($CDCl_3$), δ: 1.91 (s, 9H, 3 or 5-CH_3), 2.31 (s, 9H, 3 or 5-CH_3), 4.0 (br, 1H, B-*H*), 5.77 (s, 3H, 4-C*H*). $^{13}C\{^1H\}$ NMR ($CDCl_3$), δ: 13.9 (s, CH_3), 14.8 (s, CH_3), 105.3 (s, 4-*C*H), 146.8 s, 150.0 s (5-*C*-CH_3 and 3-*C*-CH_3). IR, cm^{-1}: 3119 w (CH) 2508 m (BH), 1538 s (ring). Anal. Calcd for $C_{15}H_{22}BN_6Ag$; C, 44.5; H, 5.5; N, 20.7. Found: C, 44.2; H, 5.6; N, 20.6%.

Synthesis of $[HB(3,5\text{-}Me_2pz)_3]Ag\{CNBu^t\}$ (**2**). A CH_2Cl_2 (10 ml) suspension of $Ag(O_3SCF_3)$ (0.26 g, 1.0 mmol) was treated with a CH_2Cl_2 solution of $K[HB(3,5\text{-}Me_2pz)_3]$ (0.34 g, 1.0 mmol) by slow cannula transfer. The solution became homogeneous and was stirred 1 h in the dark before addition of Bu*t*NC (8.3 ml of a 0.01 g/ml hexane solution, 1.0 mmol). The reaction mixture was stirred overnight. The volatile materials were removed under reduced pressure and the residue was extracted into benzene. Filtration through Celite followed by the removal of benzene from the filtrate gave **2**, which was purified from benzene/ethyl acetate (1:1) (0.391 g, yield 80%). Mp: 148°C dec. ^1H NMR($CDCl_3$), δ: 1.59 (s, 9H C_4H_9), 2.21 (s, 9H, CH_3), 2.35 (s, 9H, CH_3), 3.8 (br, 1H, B*H*), 5.66 (s, 3H, 4-C*H*); $^{13}C\{^1H\}$ NMR ($CDCl_3$), δ: 13.4 (s, CH_3), 14.8 (s, CH_3), 30.8 (s, C_4H_9), 104.2 (s, 4-*C*H), 116.6 (*C*N), 144.3 s, 147.5 s (5-*C*-CH_3 and 3-*C*-CH_3). IR, cm^{-1}: 3113 w (CH), 2506 m (BH), 2178 s (CN), 1536 m (ring). Anal. Calcd for $C_{20}H_{31}BN_7Ag$; C, 49.2; H; 6.4. N, 20.1. Found: C, 48.8; H, 6.5; N, 19.8%.

Synthesis of $[HB(3,5\text{-}Me_2pz)_3Ag\{CNCy\}$ (**3**). Compound **3** was prepared similarly to compound **2** by using $K[HB(3,5\text{-}Me_2pz)_3]$ (0.34 g, 1 mmol), CyNC (0.11 g, 1 mmol) and $Ag(O_3SCF_3)$ (0.26 g, 1 mmol) in CH_2Cl_2 (50 ml) at room temperature. Compound **3** was purified from acetonitrile/diethyl ether (1:1) (0.334 g, yield 65%). Mp: 218°C dec. ^1H NMR($CDCl_3$), δ: 2.21 (s, 9H, CH_3), 2.34 (s, 9H, CH_3),

1.49–1.60, 1.70–2.10 (m br, 11H C_6H_{11}), 3.9 (br, 1H, B*H*), 5.65 (s, 3H, 4-C*H*); $^{13}C\{^1H\}$ NMR ($CDCl_3$), δ: 12.9 (s, CH_3), 14.3 (s, CH_3), 22.6 s, 24.8 s, 32.2 s, 53.3 s (C_6H_{11}), 116.1 (*C*N), 103.7 (s, 4-*C*H), 143.8 s, 147.0 s (5-*C*-CH_3 and 3-*C*-CH_3). IR, cm^{-1}: 3111 w (CH), 2503 m (BH), 2191 m (CN), 1537 s (ring). Anal. Calcd for $C_{22}H_{33}BN_7Ag$; C, 51.4; H; 6.5, N, 19.1. Found: C, 51.3; H, 6.5; N, 18.7%.

Synthesis of [$HB(3,5\text{-}Me_2pz)_3$]Ag{$P(OPh)_3$} (**4**). A mixture of K[$HB(3,5\text{-}Me_2pz)_3$] (0.34 g, 1.0 mmol) in CH_3OH (30 ml) and $P(OPh)_3$ (0.310 g, 1.0 mmol) was added to $Ag(O_3SCF_3)$ (0.26 g, 1 mmol) in CH_3OH (20 ml). After the addition the solution was stirred 2 h at room temperature. The volatile materials were removed under reduced pressure, and the residue was extracted into CH_2Cl_2. Filtration through Celite, followed by the removal of CH_2Cl_2 from the filtrate gave **4** (0.572 g, yield 80%). Mp: 184 C dec. ^1H NMR($CDCl_3$), δ: 1.82 (s, 9H, CH_3), 2.35 (s, 9H, CH_3), 4.0 (br, 1H, B*H*), 5.62 (s, 3H, 4-C*H*), 7.10–7.40 (m br, 15H C_6H_5); ^{31}P NMR ($CDCl_3$, 293 C), δ: −38.5 dd ($J^{107}Ag\text{–}^{31}P = 845.9$ Hz, $J^{109}Ag\text{–}^{31}P = 977.6$ Hz); ($CDCl_3$, 223 C), δ: −36.1 dd ($J^{107}Ag\text{–}^{31}P = 847.7$ Hz, $J^{109}Ag\text{–}^{31}P = 978.2$ Hz). IR, cm $^{-1}$: 3100 w (CH), 2518 br (BH), 1587 s, 1540 s (ring). Anal. Calcd for $C_{33}H_{37}BN_6O_3PAg$; C, 55.5; H; 5.2, N, 11.8. Found: C, 55.3; H, 5.4; N, 11.6%.

Synthesis of [$HB(3,5\text{-}Me_2pz)_3$]Ag{$P(C_6F_5)_3$} (**5**). Compound **5** was prepared similarly to compound **4** by using K[$HB(3,5\text{-}Me_2pz)_3$] (0.34 g, 1.0 mmol), $P(C_6F_5)_3$ (0.532 g, 1.0 mmol) and $Ag(O_3SCF_3)$ (0.26 g, 1 mmol) in CH_3OH at room temperature. Compound **5** was purified from acetonitrile/benzene 1/1 (0.843 g, yield 90%). Mp: 210 C dec. ^1H NMR($CDCl_3$): δ 1.92 (s, 9H, CH_3), 2.31 (s, 9H, CH_3), 4.1 (br, 1H, B*H*), 5.77 (s, 3H, 4-C*H*); ^{31}P NMR ($CDCl_3$, 293 C), δ: −73.8 m ($J^{19}F\text{–}^{31}P = 35.4$ Hz); ($CDCl_3$, 223 C), δ: −74.0 m, −63.1 dd of multiplet ($J^{107}Ag\text{–}^{31}P = 572.4$ Hz, $J^{109}Ag\text{–}^{31}P = 658.5$ Hz, $J^{19}F\text{–}^{31}P = 31.1$ Hz). ^{19}F NMR ($CDCl_3$, 303 C) δ: −158.9 m [relative intensity ratio: 20], −156.8 m [1], −147.0 [20], −143.3 [1], −129.9 [20], 128.5 [1]. ^{19}F NMR ($CDCl_3$, 223 C) δ: −156.8 m, −143.3, 128.5. IR, cm^{-1}: 3118 w (CH), 2507 m (BH), 1643 m, 1537 s, 1518 s (ring). Anal. Calcd for $C_{33}H_{22}BF_{15}N_6PAg$; C, 42.3; H; 2.4, N, 9.0. Found: C, 42.5; H, 2.5; N, 9.1%.

Synthesis of [bis(1,10-phenanthroline)Ag]O_3SCF_3 (**6**). Compound **6** was prepared by adding a methanol solution (25 ml) of 1,10-phenanthroline (0.36 g, 2.0 mmol) to a stirred methanol solution of $Ag(O_3SCF_3)$ (0.26 g, 1.0 mmol). A colorless precipitate formed immediately. The reaction mixture was stirred 2 h. This material was then collected on a filter, washed with methanol and dried under vacuum to give **6** (0.376 g, yield 61%). Mp: 375 C dec. ^1H NMR(DMSO-d_6): δ 8.0 (pq, 4H, Phen), 8.2 (s, 4H, Phen), 8.8 (d, 4H, Phen), 9.2 (d, 4H, Phen). IR, cm^{-1}: 3120 w, 3060 w (CH), 1619 w, 1605 w, 1589 w, 1572 w, 1512 m (ring). Anal. Calcd for $C_{25}H_{16}F_3N_4O_3SAg$; C, 48.6; H, 2.6; N, 9.1; S, 5.2. Found: C, 48.2; H, 2.6; N, 9.0; S, 5.1%.

Synthesis of [$HB(3,5\text{-}Me_2pz)_3$]Ag(1,10-phenanthroline) (**7**). To a methanol solution of compound **6** (0.308 g, 0.5 mmol) K[$HB(3,5\text{-}Me_2pz)_3$] (0.17 g, 0.5 mmol) was added. After 2 days, the suspension was filtered and the precipitate washed with *n*-hexane and diethyl ether and shown to be compound **7** (0.438 g, yield 75%). Mp: 92–93 C. ^1H NMR($CDCl_3$): δ 2.0(s br, 9H, CH_3), 2.21 (s, 3H, CH_3), 2.23 (s, 3H, CH_3), 2.35 (s, 3H, CH_3), 5.29 (s, 1H, 4-C*H*), 5.60 (s, 1H, 4-C*H*), 5.68 (s, 1H, 4-C*H*), 7.65 (dd, 2H, Phen), 7.81 (s, 2H, Phen), 8.28 (d, 2H, Phen), 9.16 (d, 2H, Phen). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 12.1 (s, CH_3), 13.2 (s, CH_3), 13.9 (s, CH_3), 15.1 (s, CH_3), 104.5 (s, 4-*C*H), 105.2 (s, 4-*C*H), 144.5 s, 144.8 s, 146.6 s, 148.3 s (5-*C*-CH_3 and 3-*C*-CH_3), 123.6 s, 127.0 s, 129.1 s, 136.6 s, 144.8 s, 150.9 s (C_{Phen}). Synthesis of [$HB(3,5\text{-}Me_2pz)_3$]Ag(imidazole) (**8**). A solution of imidazole (0.068 g, 1.0 mmol) in CH_2Cl_2 (20 ml) was added to a solution of {[$HB(3,5\text{-}Me_2pz)_3$]Ag}$_2$ (0.40 g) in CH_2Cl_2 (20 l) at room temperature. After the addition the solution was stirred 2 h. The volatile materials were removed under reduced pressure and the residue was washed with diethyl ether (0.374 g, yield 75%). Mp: 124 C dec. ^1H NMR ($CDCl_3$, 293 C): δ 1.92 (s br, 9H, CH_3), 2.30 (s br, 3H, CH_3), 4.00 (br, 1H, B*H*), 5.76 (s, 3H, 4-C*H*), 7.10 (s, 2H, 4- and 5-C*H*), 7.67 (s, 1H, 2-C*H*); ($CDCl_3$, 193 C): δ 1.85 (s, 3H, CH_3), 2.08 (br, 6H, CH_3), 2.29 (s, 9H, CH_3), 4.7 (br, 1H, B*H*), 5.65 (s, 1H, 4-C*H*), 5.71 (s, 2H, 4-C*H*), 6.97 (s, 2H, 4- and 5-C*H*), 7.53 (s, 1H, 2-C*H*), 13.0 (br, 1H, N*H*). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 13.0 (s, CH_3), 13.3 (s, CH_3), 14.2 (s, CH_3), 104.7 (s, 4-*C*H), 121.7, 122.1 (s, 4- and 5-*C*H), 135.4 (s, 2-*C*H) 1146.1, 149.3 br (5-*C*-CH_3 and 3-*C*-CH_3). IR, cm^{-1}: 3118 w, 3060 w (CH), 2507 m (BH), 1534 s (ring) Anal. Calcd for $C_{18}H_{26}BN_8Ag$; C, 45.7; H, 5.5; N, 23.7 Found: C, 45.6; H, 5.5; N, 23.5%.

Synthesis of [bis(1-methyl-2-mercaptoimidazole)Ag]O_3SCF_3 (**9**). Compound **9** was prepared by adding an ethanol solution of $Ag(O_3SCF_3)$ (0.26 g, 1.0 mmol) to a stirred ethanol solution of 1-methyl-2-mercaptoimidazole (0.230 g, 2.0 mmol). A pale rose precipitate was formed immediately. The reaction mixture was stirred 2 h. This material was then collected on a filter, washed with ethanol and diethyl ether and dried to vacuum to give **9** (0.291 g, yield 60%). Mp: 182–183 C dec. ^1H NMR (DMSO-d_6, 293 C): δ, 3.6 (s, 6H, CH_3), 7.2 (d, 2H, 4- or 5-C*H*), 7.3 (d, 2H, 4- or 5-C*H*), 12.9 (s br, 2H, N*H*). IR cm^{-1}: 3200 br (NH), 3136 w (CH), 1574 m (ring). Synthesis of [$HB(3,5\text{-}Me_2pz)_3$]Au{PPh_3}$_2$ (**10**). A CH_2Cl_2 solution of K[$HB(3,5\text{-}Me_2pz)_3$] (0.71 g, 1.0 mmol) was added to a stirred solution of

PPh_3AuCl (0.49 g, 1.0 mmol) and PPh_3 (0.26 g, 1.0 mmol) in CH_2Cl_2. The mixture was stirred for ca. 3 h. Filtration through Celite followed by the removal of CH_2Cl_2 from the filtrate gave **10** as a pure colorless solid, which was washed and purified with diethyl ether and n-heptane (0.865 g, yield 85%) M.p. 128°C dec. ^{1}H NMR ($CDCl_3$, 293°C): δ 1.82 (s, 9H, CH_3), 2.33 (s, 9H, CH_3), 4.6 (br, 1H, BH), 5.66 (s, 3H, 4-CH), 7.37 (m br, 20H C_6H_5), 7.51 (m br, 10H C_6H_5); ($CDCl_3$, 193°C): δ 1.82 (s, 6H, CH_3), 2.29 (s, 3H, CH_3), 2.35 (s, 9H, CH_3), 4.6 (br, 1H, BH), 5.68 (s, 2H, 4-CH), 5.78 (s, 1H, 4-CH), 7.40–8.10 (m br, 30H C_6H_5); ^{31}P NMR ($CDCl_3$, 298°C): 0.7 br, 31.5 br; ($CDCl_3$, 193°C): 31.9 s, 32.4 s, 37.0 br, 39.0 br. IR, cm^{-1}: 3070 w, 3052 (CH), 2503 br (BH), 1538 s (ring). Anal. Calcd for $C_{51}H_{52}BN_6P_2Au$; C, 60.2; H, 5.2; N, 8.2. Found: C, 60.1; H, 5.4; N, 8.3%.

Synthesis of [hydrotris(3,5-dimethylpyrazol-1-yl)borate]Ag(PMePh$_2$) (**11**) *and [hydrotris(3,5-dimethylpyrazol-1-yl)borate]Ag(P-o-tolyl$_3$)* (**12**). Compounds **11** and **12** were prepared according to literature [15], and were recrystallized from acetonitrile/ethyl acetate.

X-ray data collection and solution and refinement of structures

Crystal data and a summary of data collection parameters for compounds **[Hydrotris(3,5-dimethylpyrazol-1-yl)borate]Ag(PMePh$_2$) (11)** and **[Hydrotris(3,5-dimethylpyrazol-1-yl)borate]Ag(P-o-tolyl$_3$) (12)** are summarized in Table 1. Data were collected on a Philips PW 1100 diffractometer by using Mo–Kα radiation in the range $4.1° < 2\theta < 56.0°$ and $4.5° < 2\theta < 56.0°$. Data were corrected for the Lorentz and polarization effects. The structures were solved by SHELXS 86 or SHELXL-93 direct methods [19]. Full-matrix least-squares refinement on F was computed and the function $\Sigma w[|F_o| - |F_c|]^2$ minimized. The non-hydrogen atoms were refined anisotropically. The position of the hydrogen atoms in **11** was calculated and in **12** was partially calculated, but all were refined. Selected bond lengths and bond angles for **11** and **12** are listed in Tables 2 and 3, respectively. The ORTEP plots of **11**, and **12** together with the numbering scheme are displayed in Figs 1 and 2, respectively.

RESULTS AND DISCUSSION

Synthesis

From the interaction between silver(I) nitrate and the potassium salts of tris(3,5-dimethylpyrazol-1-yl)borate $[HB(3,5\text{-}Me_2pz)_3]^-$ (pzH = pyrazole) in methanol at room temperature, complex **1** is obtained in accordance with the following general equations **1**:

$$2AgNO_3 + 2K[HB(3,5-Me_2pz)_3] \xrightarrow{CH_3OH,\,r.t.} [HB(3,5-Me_2pz)_3]Ag_2 + 2KNO_3 \quad (1)$$

1

The analytical and spectral data of **1** are in accordance with those reported in literature [20]. For this

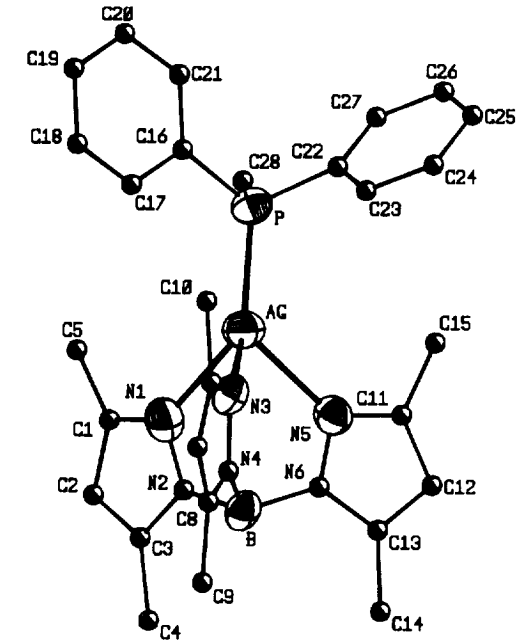

Fig. 1. ORTEP drawing of the molecular structure of **11**, with H atoms omitted.

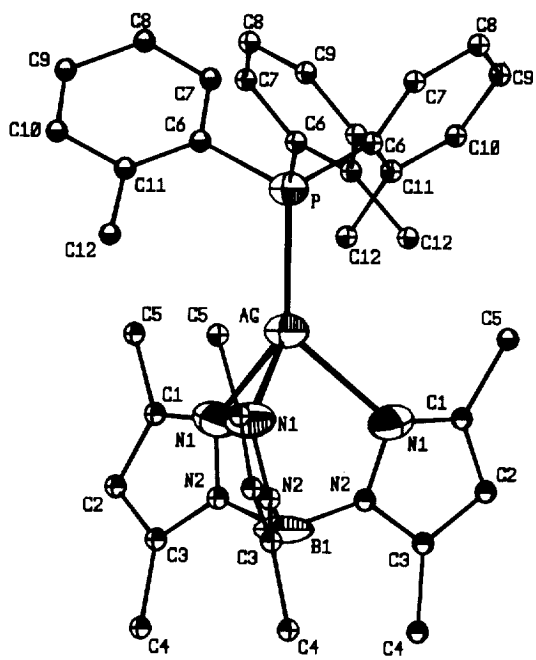

Fig. 2. ORTEP drawing of the molecular structure of **12**, with H atoms omitted.

compound a dinuclear structure such as in Fig. 3, has been previously hypothesized on the basis of vaporimetric molecular weight measurements and also on the basis of the similarity with the analogous copper complex [9].

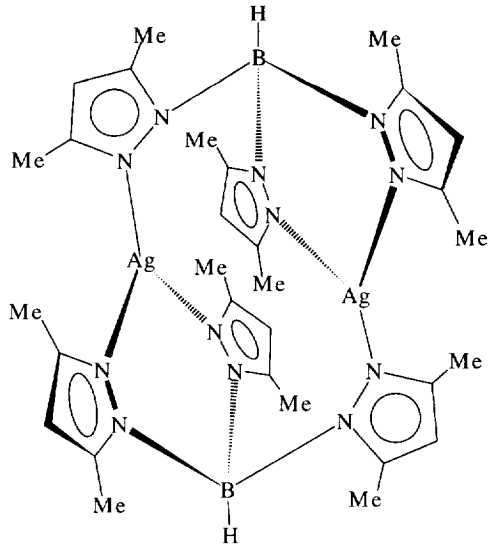

Fig. 3. Dinuclear structure proposed for derivative **1**.

The stable four-coordinate complexes [HB(3,5-$Me_2pz)_3$]Ag(CNBu*t*) (**2**) and [HB(3,5-$Me_2pz)_3$]Ag(CNCy) (**3**) were prepared upon addition of 1 molar equiv of *tert*-butyl- and cyclohexyl-isocyanide to a CH_2Cl_2 suspension of K[HB(3,5-$Me_2pz)_3$] and $Ag(O_3SCF_3)$ (equation **2**).

$$CNR + Ag(O_3SCF_3) + K[HB(3,5-Me_2pz)_3] \xrightarrow{CH_2Cl_2} [HB(3,5-Me_2pz)_3](RNC)Ag + KCF_3SO_3 \quad (2)$$

2: R=Bu^t
3: R=Cy

P(OPh)$_3$ and $P(C_6F_5)_3$ react with $AgNO_3$ and K[HB(3,5-$Me_2pz)_3$] in methanol at room temperature yielding the 1:1 adduct {[HB(3,5-$Me_2pz)_3$]Ag(P(OPh)$_3$)} (**4**) and {[HB(3,5-$Me_2pz)_3$]Ag(P(C_6F_5)$_3$)} (**5**).

From the reaction between 1,10-phenanthroline (Phen) and $Ag(O_3SCF_3)$ the 2:1 complex [(Phen)$_2$Ag]O_3SCF_3 (**6**) was obtained. Compound **6** reacts with K[HB(3,5-$Me_2pz)_3$] yielding, upon displacement of one of the Phen ligands, the neutral derivative {[HB(3,5-$Me_2pz)_3$](Phen)Ag} (**7**) (Fig. 4) in accordance with eqn (3):

$$[(Phen)_2Ag](O_3SCF_3) + nK[HB(3,5-Me_2pz)_3] \longrightarrow \underset{7}{\{[HB(3,5-Me_2pz)_3](Phen)Ag\}} + Phen + KCF_3SO_3 \quad (3)$$

Instead, the derivative {[HB(3,5-$Me_2pz)_3$]Ag(ImH)} (**8**) was obtained when complex **1** reacted with the neutral imidazole (ImH) in CH_2Cl_2 solutions.

The 1-methyl-2-mercapto-imidazole (Hmimt) is able to coordinate the Ag(I)O_3SCF_3 salts, yielding the derivative [(Hmimt)$_2$Ag]O_3SCF_3 (**9**). As expected, a ligand-to-metal ratio greater than 2-to-1 could not be obtained by addition of strong excess of Hmimt: the

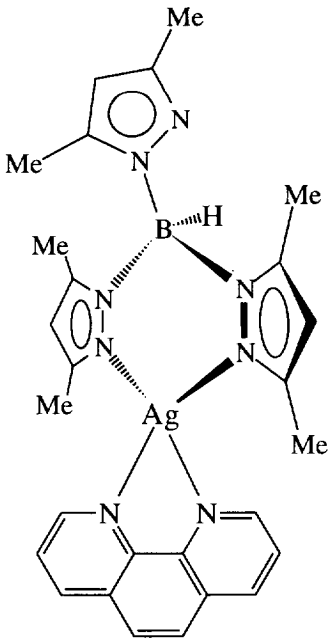

Fig. 4. Structure proposed for derivatives **7**.

steric hindrance of the methyl substituent at the 1 position of the ring blocks the formation of this ligand's product. From the reaction of complex **9** with $K[HB(3,5\text{-}Me_2pz)_3]$ only unmanageable material was obtained.

Finally, the gold(I) complex $\{[HB(3,5\text{-}Me_2pz)_3]Au(PPh_3)_2\}$ (**10**) was synthesized only when $K[HB(3,5\text{-}Me_2pz)_3]$ reacted with PPh_3AuCl in presence of 1 equiv. of PPh_3. It was not possible to obtain the 1:1 $\{[HB(3,5\text{-}Me_2pz)_3]Au(PPh_3)\}$ when the reaction was carried out in the same conditions in absence of PPh_3, the starting materials being always recovered.

With the exception of **6** and **9**, the electrical conductivity values show that none of the compounds are electrolyte both in acetone and dichloromethane. Derivatives **6** and **9** are soluble only in DMSO, in which they show conductance values typical of 1:1 electrolytes. All the complexes **1**–**10** are air stable yet decompose slowly when exposed to light.

In the IR spectra (see experimental section) of compounds **1**–**5**, **7**, **8**, and **10**, we always found the absorptions required by the presence of the tris(pyrazolyl)borate donor: amongst these, there are weak vibrations at ca. 3100 cm^{-1}, typical of ν(C–H) and other more intense absorption between 1550 and 1500 cm^{-1}, characteristic of the breathing of the heterocyclic ring, which may be taken as diagnostic of this type of ligand [21]. In addition, in these derivatives, the ν(B–H) generally appears as a single peak at ca. 2500 cm^{-1}. This absorption seems not to be dependent on the nature and basicity of the P-, N- and C-donor linked to silver(I).

In the IR spectra of **2** and **3** the ν(CN) stretching vibration of the isonitrile ligand falls at ca. 2190 cm^{-1}. This value is higher than that in the free CNBu^t (2138 cm^{-1}) [22] and CNCy (2137 cm^{-1}) [23] and suggests that also in these complexes the bonding is dominated by σ-donation [24]. There is no significant difference between the ν(CN) stretching frequency in the $[HB(3,5\text{-}Me_2pz)_3]$ derivatives with respect to $[HB(3,5\text{-}Ph_2pz)_3]$ and $[HB(3,5\text{-}(CF_3)_2pz)_3]$ ones. This fact also seems to indicate that bonding to RCN is similar despite the difference in the tris(pyrazol-1-yl)borate ligand.

In the spectra of derivatives **3**, **4** and **10**, it is impossible to assign the ν(Ag–P) and ν(Au–P) since these complexes exhibit a number of ligand vibrations in the low frequency region, whereas in the spectra of all the compounds **1**–**5** and **7** there are some bands between 350 and 240 cm^{-1}, absent in the spectrum of the potassium salt of $[HB(3,5\text{-}Me_2pz)_3]$ and of all the other donors, which can be tentatively assigned to ν(Ag–N) stretching vibration [25].

The IR spectra of derivatives **6** and **9** are characteristic for free uncoordinating O_3SCF_3 [26]; in fact, in the stretching regions $\nu[SO_3(E)]$ and $\nu[SO_3(A_1)]$ were assigned at ca. 1280 and 1030 cm^{-1}, respectively, with $\nu[CF_3(A_1)]$ and $\nu[CF_3(E)]$ at 1230 and 1160 cm^{-1}, respectively. The absence of absorptions due to Ag–O and Ag–S stretching vibrations confirm the cationic structure proposed for these complexes also on the basis of conductivity data.

The ^1H NMR spectra of **1**–**5**, **7**, **8**, and **10** were obtained using chloroform as solvent, whereas in the case of the slightly soluble derivatives **6** and **9**, the spectra were obtained in DMSO-d_6.

In most cases, the boron-hydrogen resonance is a broad signal due to interaction with the ^{11}B quadrupole.

The magnitude of Δ (=difference between the chemical shift related to the same type of proton in the silver(I) derivatives with respect to potassium salt of [hydrotris(3,5-dimethylpyrazolyl)borate]) suggests the existence of the complexes **2**, **3**, **4**, **8**, and **10** in weak donor solvent such as chloroform.

If a dinuclear structure such as that proposed in Fig. 3 is assumed for complex **1**, in the ^1H NMR spectrum at least two different sets of signals should be found for each equivalent group of protons; however, at room temperature the ^1H NMR spectrum of **1** exhibits only three sharp singlets at ca. 1.91, 2.31, and 5.77 ppm, suggesting equivalence of the three 3-Me, 5-Me, and 4-CH resonances. These results indicate that compound **1** is fluxional in solution, likely with a complete dissociation and reassociation of the pyrazolyl nitrogen occurring rapidly at 293 K. The fluxional behavior of **1** is also operative at low temperature. No change was observed on cooling the sample until 223 K.

In $CDCl_3$ at 293 K, the ^1H NMR spectrum of compound **5** is similar to that of derivative **1**. At the same temperature, the ^{31}P coordination chemical shift of **5** ($\delta(^{31}P)$ of $P(C_6F_5)_3$: −73.8 ppm) is ca. 0.01 ppm, in

accordance with the extensive dissociation (4) in chloroform:

$$2[HB(3,5-Me_2pz)_3]AgP(C_6F_5)_3 \longrightarrow \underset{\mathbf{5}}{} \underset{\mathbf{1}}{\{[HB(3,5-Me_2pz)_3]Ag\}_2} + 2P(C_6F_5)_3 \quad (4)$$

At 223 C, the spectrum of **5** is constituted by two different resonances, a sharp multiplet due to the free phosphorous donor and a double doublet of multiplet due to the silver(I)tris(pyrazolyl)borate complex, in which the separate coupling of ^{31}P to the ^{107}Ag, ^{109}Ag and ^{19}F nuclei are resolved. Also at this temperature, the coordination chemical shift is the smallest with respect to those previously observed [10, 15, 16]; however, the value of the silver–phosphorous coupling constants is typical of tetracoordinate silver(I) derivatives [27].

The ^{19}F resonances due to $P(C_6F_5)_3$ also shifted downfield upon coordination. At room temperature, three different multiplets due to ortho-, meta-, and para-F substituents in the complex were respectively observed, together with analogous resonances due to the free P-donor. The relative intensity ratio of complex/free donor is *ca.* 1/20. At *ca.* 203 K, the resonances due to the free P-donor disappear.

In the ^1H NMR spectra of **8** and **10**, two different sets of signals for each equivalent group of protons were also found at room temperature. On the basis of previous reports in literature [15] and of the well-known preference of analogous silver(I) [28] and gold(I) systems [29] for tetracoordination, we suggest that the donor $[HB(3,5\text{-}Me_2pz)_3]$ coordinates in this case in the bidentate form.

The ^{31}P NMR data of compounds **4** and **10** show several interesting features. The ^{31}P NMR spectrum of **4** at room temperature appears as a double doublet, owing to coupling with ^{107}Ag and ^{109}Ag nuclei, centered at -38.5 ppm. The signal is downfield shifted by ca 90 ppm with respect to the signal of the free P-donor $P(OPh)_3$. The coordination chemical shift (Δ) is the greatest with respect to those recorded to date for tris(pyrazolyl)borate-silver(I) complexes [10, 15, 16]. $P(OPh)_3$, in fact, is a stronger π-acceptor ligand than those investigated to date: in this case, an important π-contribution to bonding cannot be excluded. The magnitude of the $^{109}/^{107}Ag$–^{31}P coupling constants indicates that exchange processes and/or equilibria of dissociation of the phosphorous donor are not operative in these conditions. This fact is also confirmed by the negligible shift of the ^{31}P resonance on going from 313 K to 203 K.

The ^{31}P NMR spectrum of the gold(I) complex **10** is typical of a tetracoordinate species containing two triorganophosphine ligands [30]. The Δ is greater than those reported for similar complexes of rhodium(I) [31] and silver(I) acceptors [10, 15, 16], but is in the range reported for gold(I) derivatives [32, 33].

Description of the molecular structure of {[*hydrotris*(3,5-*dimethylpyrazol*-1-*yl*)*borate*]*Ag*(*PPh*$_2$Me)} (**11**)

The cell content consists of eight discrete molecules of {[hydrotris(3,5-dimethylpyrazol-1-yl)borate]Ag(PPh_2Me)} (**11**). Selected bond lengths and angles are listed in Tables 2 and 3 respectively. For clarity, only one molecule is displayed in the ORTEP plot of Fig. 1.

The molecules do not have significant intermolecular interaction within 3.5 Å.

The silver(I) atom adopts a strongly distorted tetrahedral coordination owing to the steric hindrance of both P- and N_3-donors.

The Ag–P and Ag–N bond distances are 2.336(2) and 2.316(6), and 2.336(5), and 2.329(6) Å, respectively. These values are similar to those found in the derivative {[hydrotris(3,5-dimethylpyrazol-1-yl)borate]Ag(P-*p*-tolyl$_3$)} [15] and slightly shorter than those found in {[hydrotris(pyrazol-1-yl)borate]Ag(PBenzyl$_3$)} [15] and {[hydrotris(pyrazol-1-yl)borate]Ag(P-*o*-tolyl$_3$)} [15], which contain a more hindered P-donor, and also than those in {[hydrotris(3,5-diphenylpyrazol-1-yl)borate]Ag(PPh_3)} [16] which contains a more sterically hindered N_3-donor.

The three P–Ag–N bond angles are markedly different from each other. This feature was not observed in the parent derivative {[hydrotris(3,5-dimethylpyrazol-1-yl)borate]Ag(P-*p*-tolyl$_3$)}. The N–Ag–N bond angles are of the same order of magnitude as those found in the silver(I)phosphinotris(pyrazolyl)borate complexes structurally characterized [10, 15, 16], and smaller than those found in analogous copper poly(pyrazolyl)borate complexes [6–8].

There is another interesting difference with respect to silver(I) poly(pyrazolyl)borates described in literature [10, 15, 16]. In complex **11** one of the three pyrazolyl ring shows a reliable distortion upon coordination: the N–N bond distance is significantly longer than those found in the other two azole rings, whereas the N–C and C–C ones are shorter. Analogously in the former ring the C–N–N bond angle corresponding to larger Ag–P–N bond angle is smaller than those in the latter ring, whereas that corresponding to smaller Ag–P–N is the largest.

Description of the molecular structure of {[*hydrotris*(3,5-*dimethylpyrazol*-1-*yl*)*borate*]*Ag*(*P-o*-tolyl$_3$)} (**12**)

The cell content consists of six discrete molecules of {[hydrotris(3,5-dimethylpyrazol-1-yl)borate]Ag(P-*o*-tolyl$_3$)} (**12**). Selected bond lengths and angles are listed in Tables 2 and 3 respectively. For clarity only one molecule is displayed in the ORTEP plot of Fig. 2.

The molecules do not have significant intermolecular interaction within 3.5 Å.

Also in complex **12**, the silver(I) atom adopts a strongly distorted tetrahedral environment: the Ag–N (2.361(4) Å and Ag–P (2.375(2) Å) bond lengths are longer than those found in other silver(I)phosphino derivatives containing the same donor. This is due to greater steric hindrance of P-*o*-tolyl$_3$ (cone angle = 194°) with respect to PPh_2Me and P-*p*-tolyl$_3$ (cone angle of 136 and 145°, respectively). This is also evident in the lengthening of the P–C bonds, which in **12** are longer with respect to P–C distances in analogous complexes. No remarkable effects were produced on the N–Ag–N and N–Ag–P angles by the coordination of the hindered P-*o*-tolyl$_3$. Instead the Ag–P–C and C–P–C are smaller with respect to those previously reported.

The weighted least-squares pyrazolate plane (N1–N2–C1–C2–C3) and the phenyl plane (C6–C11) do not deviate significantly from planarity and their dihedral angle is 119.1(1)°.

CONCLUSIONS

We prepared and characterized a series of new silver(I)phosphino complexes of the anionic donor tris(3,5-dimethylpyrazolyl-1-yl)borate, and used X-ray crystallography and NMR spectroscopy to examine how the silver(I) complexes properties are dependent on the electronic and steric properties of the azolate donor and/or of the neutral supporting P-, N or S-donor. We found that the behavior in solution can be very different from that in solid state: for example, comparison between the Ag–N and Ag–P bond lengths in the structures here solved and those in analogous complexes previously described suggests that bonding of [HB(pz)$_3$] to the AgPR$^t_3$ fragment is similar despite the steric and electronic differences of the P-donor ligands. On the other hand, the magnitude of the Ag–^{31}P coupling constant and ^{31}P chemical shift indicates that the structure and stability of complexes in solution are strongly dependent on the Tolman cone angle and pK_a of PR_3.

It has been noted that mixed ligand complexes can be synthesized starting from the dinuclear {[HB(3,5-Me$_2$pz)$_3$]Ag}$_2$ or [(Phen)$_2$Ag]O$_3$SCF$_3$, but it is not possible to displace the P-donor, for example from compound **4**, with a neutral N-donor mono or bidentate ligand such as imidazole or ortho-phenanthroline, even if it is more basic. On the other hand, the donor [HB(3,5-Me$_2$pz)$_3$] is not able to displace Hmimt or to substitute the O$_3$SCF$_3$ group in [(Hmimt)$_2$Ag]O$_3$SCF$_3$ (**9**).

It has been observed that 1:1 triorganophosphine complexes of gold(I) containing tris(pyrazolyl)borate cannot be synthesized, but that it is possible to obtain stable tris(pyrazolyl)borate compounds only if a 2:1 PR_3/gold ratio was used. However, more structural and spectroscopic studies, including bis- and tetrakis-(pyrazolyl)borates, bidentate diphosphine and different anionic and neutral donors, will be required to see whether these results are general and to develop the coordination chemistry of poly(azol-1-yl)borato donors with respect to Ag^I and Au^I metal centers.

Supporting information available

Tables listing anisotropic displacement parameters of non-hydrogen atoms, derived hydrogen coordinates and isotropic displacement parameters, and bond lengths and angles are available on request from one of the authors.

(Received 8 December 1997; accepted 27 February 1998)

Abstract—Mono- and binuclear Ni^{II}, Pd^{II}, and Pt^{II} complexes of cis- or trans-1,2-bis(diphenylphosphino)ethene (cis- or trans-dppen) have been prepared and characterized by X-ray diffraction methods, ^{195}Pt ^{1}H and ^{31}P ^{1}H NMR spectroscopy, FAB mass spectrometry, IR spectroscopy, elemental analyses and melting points. The X-ray structures of some rare examples of cis-dicyanide complexes of the type $[M(CN)_2(cis\text{-}dppen)]$ (M=Ni (**1**), M=Pd (**2**), M=Pt (**3**)) are given for the first time. All three crystal lattices are isomorphous and allow comparison of the radii of Ni, Pd, and Pt atoms. In **1**–**3** the coordination is square planar. In all cases the ethene bridges are nearly coplanar with the coordination planes, which can be explained by π-bonding interactions. Due to the isomorphous crystal lattices, **1**–**3** show analogous shortest intermolecular repulsive C–H···M contact approaches leading to small deviations from coplanarity.

The removal of one coordinated chloride in $[NiCl_2(cis\text{-}dppen)]$ by $AgBF_4$ followed by subsequent treatment with bis(diphenylphosphino)amine, $NH(PPh_2)_2$ (dppam), leads to the novel complex $[NiCl(cis\text{-}dppen)(dppam)](BF_4)$ (**4**). However, the analogous abstraction of both chlorides in $[MCl_2(cis\text{-}dppen)]$ (M=Pd, Pt) and reaction with dppam produces $[M(cis\text{-}dppen)(dppam)](BF_4)_2$ (M=Pd (**5**), M=Pt (**6**)). In the case of trans-dppen, the reaction with $Pd(CN)_2$ leads to another novel cis-dicyanide complex of the type $[Pd_2(CN)_4(\mu\text{-}trans\text{-}dppen)_2]$ (**7**). Substitution of chloride in $[Pt_2Cl_4(\mu\text{-}trans\text{-}dppen)_2]$ by cyanide leads to the analogous Pt^{II} compound $[Pt_2(CN)_4(\mu\text{-}trans\text{-}dppen)_2]$ (**8**). It is believed, that the unsaturated nature of cis- or trans-dppen leading to π-bonding interactions with the metal-ligand bonds, is responsible for the unusual stability of cis-dicyanide complexes. For dppam the presence of electronic delocalization is well-known. These effects are discussed in view of the X-ray structures of **1**–**3** and related compounds. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: crystal structures; nickel complexes; palladium complexes; platinum complexes; cyanide complexes; diphosphine complexes.

Though cyanide complexes of the d^8 metals Ni^{II}, Pd^{II}, and Pt^{II} are well-known [1], no X-ray structure analyses of the rare square planar cis-dicyanides containing phosphines have been reported. The given crystal structures include square planar trans-dicyanides [2], five-coordinate dicyanides [3] and dinuclear complexes containing square planar trans-dicyanide units [4]. In this work the first X-ray structures of the cis-dicyanide compounds $[M(CN)_2(cis\text{-}dppen)]$ (M=Ni (**1**), M=Pd (**2**), M=Pt (**3**), structure type (A) in Scheme 1, where cis-dppen is cis-1,2-bis(diphenylphosphino)ethene, are presented. These three structures fulfil the criteria of the same ligands, the same coordination number and geometry, isomorphous crystal lattices and equal experimental conditions, and therefore allow comparison of the radii of Ni, Pd, and Pt atoms [5]. Ni shows the smallest radius, but Pt is

Scheme 1. Structure types observed in the compounds **1**–**8**. The P-M-P (M = Ni, Pd, Pt) angles of chelating cis-dppen or dppam are constrained to values below 90°. Structure (A) occurs in $[M(CN)_2(\text{cis-dppen})]$ (M = Ni (**1**), M = Pd (**2**), M = Pt (**3**)), structure (B) in $[NiCl(\text{cis-dppen})(\text{dppam})](BF_4)$ (**4**), structure (C) in $[M(\text{cis-dppen})(\text{dppam})](BF_4)_2$ (M = Pd (**5**), M = Pt (**6**)) and structure (D) in $[M_2(CN)_4(\mu\text{-trans-dppen})_2]$ (M = Pd (**7**), M = Pt (**8**)).

smaller than Pd. Furthermore, in **1**–**3** the ethene bridges are nearly coplanar with the coordination planes due to π-bonding interactions. This effect has been observed earlier in several related compounds [1](b),[1](c),[6]. Interestingly, all three structures show analogous repulsive intermolecular C–H···M(d^8) contact approaches, where the presence of these structural anomalies has been emphasized only recently [7].

Furthermore, several novel d^8 metal complexes containing both cis-dppen and bis(diphenylphosphino)amine, $NH(PPh_2)_2$ (dppam), are presented. The transition metal chemistry of dppam, which is isoelectronic with bis(diphenylphosphino)methane, $CH_2(PPh_2)_2$ (dppm), has received widespread attention [8]. These complexes are of interest because of their potential as catalysts for the oligomerization and polymerisation of alkenes [9]. $[NiCl(\text{cis-dppen})(\text{dppam})](BF_4)$ (**4**, structure type (B) in Scheme 1), shows five-coordinate square pyramidal coordination, whereas the compounds $[M(\text{cis-dppen})(\text{dppam})](BF_4)_2$ (M=Pd (**5**), M=Pt (**6**), structure type (C) in Scheme 1) are square planar. The stability of halide-associated species containing dppam is well-known [10]. The replacement of $(BF_4)^-$ in **6** by Cl^- leads to the typical shift of ν(N–H) towards lower energies due to Cl ···H-N< hydrogen-bridging [11]. Furthermore, it is of great interest to combine the observed electronic delocalization in complexes of neutral or deprotonated dppam [12] with similar effects in compounds of cis-dppen.

$[Pd_2(CN)_4(\mu\text{-trans-dppen})_2]$ (**7**), where trans-dppen is trans-1,2-bis(diphenylphosphino)ethene, is a novel rare example of a trans-dppen-bridged dimer containing cis-dicyanide groups (structure type (D) in Scheme 1). The analogous Pt^{II} complex $[Pt_2(CN)_4(\mu\text{-trans-dppen})_2]$ (**8**) shows the same structure. A comparable trans-dppen-bridged dimer of the type rac-$[Pt_2Cl_2(\mu\text{-Cl})(\mu\text{-trans-dppen})P4]Cl$, where P4 is 1,1,4,7,10,10-hexaphenyl-1,4,7,10-tetraphosphadecane (tetraphos-1, P4), has already been reported [13].

There is continuing interest in ligands like cis-or trans-dppen, since they are heteroatom compounds that are isolobal with unsaturated hydrocarbon fragments [14].

EXPERIMENTAL

Reagents and chemicals

Reagent-grade chemicals were used as received unless stated otherwise. cis-1,2-Bis(diphenylphosphino)ethene (cis-dppen) and trans-1,2-bis(diphenylphosphino)ethene (trans-dppen) were purchased from Aldrich. Bis(diphenylphosphino)amine (dppam) was obtained from Strem. All other reagents and solvents were obtained from Fluka. Solvents used for NMR measurements and crystallization purposes were of purissimum grade quality. $NiCl_2 \cdot 6H_2O$, $PdCl_2$, $Na_2PtCl_4 \cdot 4H_2O$, $Pd(CN)_2$, and $Pt(CN)_2$ were also received from Fluka.

Instrumentation

Fourier-mode ^{195}Pt ^1H and ^{31}P ^1H NMR spectra were obtained by use of a Bruker AC-200 spectrometer (internal deuterium lock) and were recorded at 43.02 and 80.96 MHz, respectively. Positive chemical shifts are downfield from the standards, where 1.0 M Na_2PtCl_6 and 85% H_3PO_4 were used as standards, respectively.

Synthesis of Ni^{II}, Pd^{II}, and Pt^{II} complexes

A Schlenk apparatus and oxygen-free, dry Ar were used in the synthesis of all complexes. Solvents were degassed by several freeze-pump-thaw cycles prior to use. All reactions were carried out at room temperature unless stated otherwise.

[Ni(CN)$_2$(cis-dppen)] (1) and [Pd(CN)$_2$(cis-dppen)] (2)

Compounds **1** and **2** were prepared as described earlier [1](b),[1](c). Samples for X-ray diffraction studies were crystallized from CH_3NO_2/DMF (v/v = 1:1).

[Pt(CN)$_2$(cis-dppen)] (3)

$Pt(CN)_2$ (0.20 mmol, 0.049 g) was suspended in DMF (7 cm^3). Then cis-dppen (0.20 mmol, 0.079 g) was added with stirring. The reaction mixture was stirred at 75 C until a clear, colourless solution was obtained. The volume of the solvent was reduced and Et_2O was added. A white precipitate was filtered off, washed with Et_2O and dried in vacuo. A white powder was recrystallized from CH_3NO_2/DMF (v/v = 1:1): yield 0.103 g (80%); m.pt > 310 C. IR (KBr, cm^{-1}) CN: 2142 ν. Found: C, 52.1; H, 3.5; N, 4.3. Calc. for $C_{28}H_{22}N_2P_2Pt$: C, 52.3; H, 3.4; N, 4.4%. A sample for X-ray diffraction study was crystallized from CH_3NO_2/DMF (v/v = 1:1).

[NiCl(cis-dppen)(dppam)](BF$_4$) (4)

[$NiCl_2$(cis-dppen)] (0.15 mmol, 0.079 g) was dissolved in CH_2Cl_2/DMF (v/v = 5:1, 5 cm^3). Then $AgBF_4$ (0.15 mmol, 0.029 g) was added with stirring. The reaction mixture was stirred for 30 min, the formed AgCl was filtered off and a greenish solution was obtained. To this solution, dppam (0.15 mmol, 0.058 g) dissolved in CH_2Cl_2 was added slowly with vigorous stirring. After 2 h an orange-yellow solution formed. The volume of the solvent was reduced, EtOH was added and a yellow precipitate immediately formed. The precipitate was filtered off and dried in vacuo. A yellow powder was recrystallized from DMF: yield 0.056 g (39%); m.pt = 222–224 C. IR (KBr, cm^{-1}) N–H: 3239 ν, 2510 2δ. FAB mass spectrum: m/z 875.9 [NiCl(cis-dppen)(dppam)]$^+$, 840.45 [Ni(cis-dppen)(dppam)]$^+$. Found: C, 62.2; H, 4.6; N, 1.7. Calc. for $C_{50}H_{43}BClF_4NP_4Ni$: C, 62.4; H, 4.5; N, 1.5%.

[Pd(cis-dppen)(dppam)](BF$_4$)$_2$ (5)

[$PdCl_2$(cis-dppen)] (0.18 mmol, 0.103 g) was dissolved in CH_2Cl_2/DMF (v/v = 5:1, 6 cm^3). Then $AgBF_4$ (0.36 mmol, 0.070 g) was added with stirring. The reaction mixture was stirred for 2 h, the formed AgCl was filtered off and the solvent completely removed. The residue was dissolved in CH_2Cl_2 and dppam (0.18 mmol, 0.069 g) was added slowly with vigorous stirring. After 3 h a white precipitate was filtered off, washed with CH_2Cl_2 and dried in vacuo. A white powder was recrystallized from DMF: yield 0.172 g (90%); m.pt = 272–274 C dec. IR (KBr, cm^{-1}) N–H: 3237 ν, 2524 2δ. FAB mass spectrum: m/z 888.2 [Pd(cis-dppen)(dppam)]$^+$, 502.8 [Pd(cis-dppen)]$^+$. Found: C, 56.5; H, 4.3; N, 1.4. Calc. for $C_{50}H_{43}B_2F_8NP_4Pd$: C, 56.6; H, 4.1; N, 1.3%.

[Pt(cis-dppen)(dppam)](BF$_4$)$_2$ (6)

Compound **6** was prepared in an analogous manner to **5**, where after addition of dppam the reaction mixture was stirred for 20 h. A white powder was recrystallized from DMF/EtOH: yield 0.166 g (80%); m.pt = 291–293 C. IR (KBr, cm^{-1}) N–H: 3243 ν, 2520 2δ. FAB mass spectrum: m/z 976.9 [Pt(cis-dppen)(dppam)]$^+$, 899.8 [Pt(cis-dppen)(dppam)-Phenyl]$^+$. Found: C, 52.0; H, 3.9; N, 1.1. Calc. for $C_{50}H_{43}B_2F_8NP_4Pt$: C, 52.2; H, 3,8; N, 1.2%.

[Pd$_2$(CN)$_4$(μ-trans-dppen)$_2$] (7)

$Pd(CN)_2$ (0.20 mmol, 0.032 g) was suspended in DMF (7 cm^3). Then trans-dppen (0.20 mmol, 0.079 g)

was added with stirring and prevention of light. The reaction mixture was stirred at 45 C for 48 h and a white precipitate formed. The solvent was completely removed, the white residue was filtered off in CH_2Cl_2, washed with CH_2Cl_2 and dried in vacuo. A white powder was recrystallized from DMF: yield 0.077 g (69.5%); m.pt > 310 C. IR (KBr, cm^{-1}) CN: 2130 *v*. Found: C, 60.4; H, 4.1; N, 5.2. Calc. for $C_{56}H_{44}N_4P_4Pd_2$: C, 60.6; H, 4.0; N, 5.0%.

$[Pt_2(CN)_4(\mu\text{-}trans\text{-}dppen)_2]$ (**8**)

$[Pt_2Cl_4(\mu\text{-trans-dppen})_2]$ (0.080 mmol, 0.106 g) was dissolved in DMF. To this solution, NaCN (0.32 mmol, 0.016 g) was added with vigorous stirring and prevention of light. The reaction mixture was stirred for 4 h and then the solvent was completely removed. The residue was filtered off in H_2O, washed with H_2O and dried in vacuo. A white powder was recrystallized from CH_2Cl_2: yield 0.093 g (90%); m.pt > 310 C. IR (KBr, cm^{-1}) CN: 2130 *v*. Found: C, 52.1; H, 3.6; N, 4.4. Calc. for $C_{56}H_{44}N_4P_4Pt_2$: C, 52.3; H, 3.4; N, 4.4%.

X-ray crystallography

Crystal data. $C_{28}H_{22}N_2P_2Ni$ (**1**), M = 507.14, yellow crystal (prismatic; 1.0 × 0.5 × 0.4 mm), monoclinic, a = 8.463(2), b = 14.267(3), c = 19.994(4) Å, β = 90.89(3)°, V = 2413.82 Å^3, Z = 4, space group $P2_1/n$, D_c = 1.395 Mg m^{-3}, F(000) = 1048, μ(Mo-K$_\alpha$) = 0.955 mm^{-1}; $C_{28}H_{22}N_2P_2Pd$ (**2**), M = 554.84, colourless crystal (prismatic; 0.6 × 0.4 × 0.2 mm), monoclinic, a = 8.654(2), b = 14.222(3), c = 20.206(4) Å, β = 90.35(3)°, V = 2486.85 Å^3, Z = 4, space group $P2_1/n$, D_c = 1.482 Mg m^{-3}, F(000) = 1120, μ(Mo-K$_\alpha$) = 0.893 mm^{-1}; $C_{28}H_{22}N_2P_2Pt$ (**3**), M = 643.53, colourless crystal (prismatic; 1.0 × 0.6 × 0.4 mm), monoclinic, a = 8.665(2), b = 14.273(3), c = 20.063(4) Å, β = 90.79(3)°, V = 2481.07 Å^3, Z = 4, space group $P2_1/n$, D_c = 1.723 Mg m^{-3}, F(000) = 1248, μ(Mo-K$_\alpha$) = 5.803 mm^{-1}.

Data collection. Unit-cell dimensions and intensity data were obtained at 213 K using a Siemens P4 diffractometer and graphite monochromated Mo-K$_\alpha$ radiation. 2θ range = 4.0–55.0°, scan type = ω, scan speed = variable (2.0–29.3 min^{-1} in ω). Index ranges = $-1 \leqslant h \leqslant 10$, $-1 \leqslant k \leqslant 18$, $-25 \leqslant l \leqslant 25$ (**1**); $-1 \leqslant h \leqslant 11$, $-1 \leqslant k \leqslant 18$, $-26 \leqslant l \leqslant 26$ (**2**, **3**). No decay in the intensities of three standard reflections was observed during the course of each data collection. The data were corrected for Lorentz and polarization effects. In each case the empirical absorption correction was based on ψ-scans of nine reflections [range of transmission factors: 0.825–1.00 (**1**), 0.830–1.00 (**2**), 0.447–1.00 (**3**)] [15]. A total of 6995 (**1**), 7304 (**2**), and 7242 (**3**) reflections were measured, of which 5454 (**1**, R_{int} = 0.026), 5670 (**2**, R_{int} = 0.035), and 5629 (**3**, R_{int} = 0.036) were unique and 3973 (**1**), 3557 (**2**), and 4199 (**3**) satisfied the condition $I > 3\sigma(I)$.

Structure solution. All structure determination calculations were carried out on 80486- and Pentium-PCs using the PC-version of SHELXTL PLUS and SHELXL93 [16]. The positions of the nickel, palladium and platinum atoms were found by the Patterson method. Other atom positions were located from successive difference-Fourier maps.

In all three cases the non-hydrogen atoms have been refined with anisotropic thermal parameters. In **1** the hydrogen atoms were isotropically refined with fixed isotropic U. In **2** and **3** the hydrogen atoms were included using a riding model with isotropic U values depending on U_{eq} of the adjacent carbon atoms. The final R values of 0.030 (R′ = 0.030) (**1**), 0.032 (R′ = 0.032) (**2**), and 0.027 (R′ = 0.027) (**3**) were computed for 364 (**1**) and 298 (**2**,**3**) parameters, respectively. The largest features on the final difference maps were 0.39 eÅ^{-3} (**1**) [GOF = 1.05, largest Δ/σ = −0.005, weighting scheme: $w^{-1} = \sigma^2(F^2) + (0.0445P)^2 + 0.12P$], 0.38 eÅ^{-3} (**2**) [GOF = 0.99, largest Δ/σ = 0.001, weighting scheme: $w^{-1} = \sigma^2(F^2) + (0.0237P)^2$], and 0.83 eÅ^{-3} (**3**) [GOF = 1.02, largest Δ/σ = −0.001, weighting scheme: $w^{-1} = \sigma^2(F^2) + (0.0312P)^2 + 0.75P$].

Final atomic fractional coordinates and other relevant data have been deposited.

RESULTS

The X-ray structures of $[M(CN)_2(cis\text{-dppen})]$ (M=Ni (**1**), M=Pd (**2**), M=Pt (**3**)) show several interesting common features: π-bonding interactions leading to nearly coplanar coordination planes and ethene bridges, intermolecular repulsive C–H···M contact approaches, and isomorphous crystal lattices allowing comparison of the radii of Ni, Pd, and Pt atoms. All three structures show one discrete $[M(CN)_2(cis\text{-dppen})]$ molecule per asymmetric unit. Views of **1**, **2**, and **3** demonstrating the identical conformations including the orientations of the phenyl rings are given in Fig. 1; Table 1 contains selected bond distances and bond angles.

Figure 2 reveals the nearly coplanar arrangements of the coordination planes and the ethene bridges in **1**, **2**, and **3**. **1** shows the largest mean deviation of 0.036 Å from a least-squares plane through the metal, the phosphorus and the cyanide carbon atoms, which has to be compared with the corresponding values of 0.024 and 0.023 Å in **2** and **3**, respectively. In all three cases these deviations stem from very slight tetrahedral distortions of the coordination planes. Furthermore, also the five-rings are nearly planar, where the mean deviations from least-squares planes through the metal, the phosphorus and the carbon atoms of the ethene bridges are 0.017 (**1**), 0.016 (**2**), and 0.015 Å (**3**), respectively. These planar five-rings

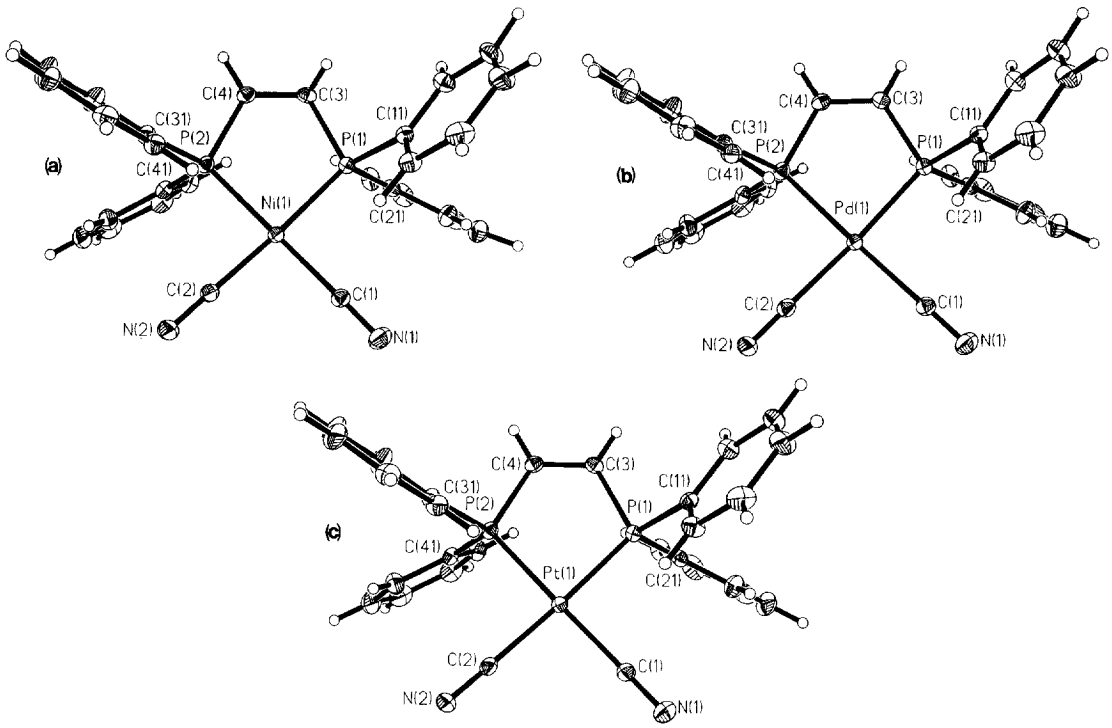

Fig. 1. Views of $[M(CN)_2(cis\text{-}dppen)]$ with the coordination planes through the metal atoms, the P atoms and the cyanide carbon atoms in the projection planes and showing the atom labelling scheme. (a) M=Ni (**1**); (b) M=Pd (**2**); (c) M=Pt (**3**). The coordination geometries including the orientations of the phenyl groups are identical.

have now been observed in several square planar d^8 metal complexes containing cis-dppen [1](b), [1](c), [6](a), [7](b) and are due to an enhancement of M-to-P π-bonding as a consequence of the unsaturated nature of cis-dppen. However, Fig. 2 also shows, that the most significant deviations from a coplanar arrangement of the coordination planes and the ethene bridges in **1**, **2**, and **3** are caused by a bowing of the C(2)N(2) cyanide groups away from these planes. A careful analysis of all three crystal structures indicates, that the only relevant intermolecular contact approaches are phenyl group C–H $\cdots$ M interactions of 2.850 (**1**), 2.781 (**2**), and 2.807 Å (**3**), as depicted in Fig. 2. These approaches cause the following deviations from least-squares planes through the phosphorus atoms, the carbon atoms of the ethene bridges, and the C(1)N(1) cyanide groups: Ni(1): −0.069, C(2): −0.189, N(2): −0.255 Å (**1**); Pd(1): −0.056, C(2): −0.120, N(2): −0.136 Å (**2**); Pt(1): −0.053, C(2): −0.122, N(2): −0.133 Å (**3**). Therefore, these C–H $\cdots$ M interactions are clearly repulsive (Fig. 2). The presence of these C–H $\cdots$ $M(d^8)$ contacts with H $\cdots$ M distances of 2.65–3.5 Å has been found only recently [7](a), where the nature of these interactions remained unclear. However, the X-ray structures of the two crystal modifications of $[PtCl_2(cis\text{-}dppen)]$ [7](b) also confirm, that these C–H $\cdots$ $M(d^8)$ interactions are repulsive: in one modification the coordination plane and the ethene bridge are strictly coplanar, whereas in the second the coordination plane of one molecule is tilted away from the incoming C–H group of a second molecule (C–H $\cdots$ Pt = 2.833 Å) leading to deviations from complete coplanarity.

Fig. 1 and Fig. 2 clearly show, that the three X-ray structures allow comparison of the radii of Ni, Pd, and Pt atoms [5]. There are three common trends, which indicate the same order of atomic radii: the mean M–P bond lengths of 2.1652(6) Å (**1**) < 2.2688(9) Å (**3**) < 2.2759(7) Å (**2**); the mean M–C bond lengths of 1.879(1) Å (**1**) < 2.010(4) Å (**3**) < 2.029(2) Å (**2**); the five-ring chelate angles of 87.57(3)° (**1**) > 86.06(4)° (**3**) > 85.82(3)° (**2**). All parameters significantly show the smallest radius for Ni. For Pd and Pt the differences of the mean M–C bond lengths and the five-ring chelate angles are at the margin of statistical significance, the values indicating that the platinum radius is slightly smaller than that for palladium. However, the mean M–P bond length is significantly smaller for Pt than for Pd. Assuming a covalent radius of tetra-coordinate phosphorus as $r(P)_{cov} = 1.11$ Å [17], the covalent radii of square planar d^8 Ni, Pd, and Pt are estimated as 1.06, 1.17, and 1.16 Å, respectively. The results presented here are in full agreement with the recently given smaller covalent radius for Au than for Ag, a phenomenon

which is generally referred to as the 'relativistic or Lanthanide contraction' [5](a).

Due to the presence of π-bonding interactions throughout the coordination planes and the ethene bridges of **1**–**3**, the aliphatic double-bond lengths of 1.312(3) Å (**1**), 1.330(4) Å (**2**), and 1.326(6) Å (**3**) are shortened compared with the ideal value of a simple double bond of 1.337(6) Å [18]. Interestingly, also the double-bond lengths of **1**–**3** reflect the above trend of covalent radii of Ni < Pt < Pd, since a smaller covalent radius facilitates the overlap of orbitals necessary for π-bonding interactions between the metal and the phosphorus atoms, which after some degree of rehy-

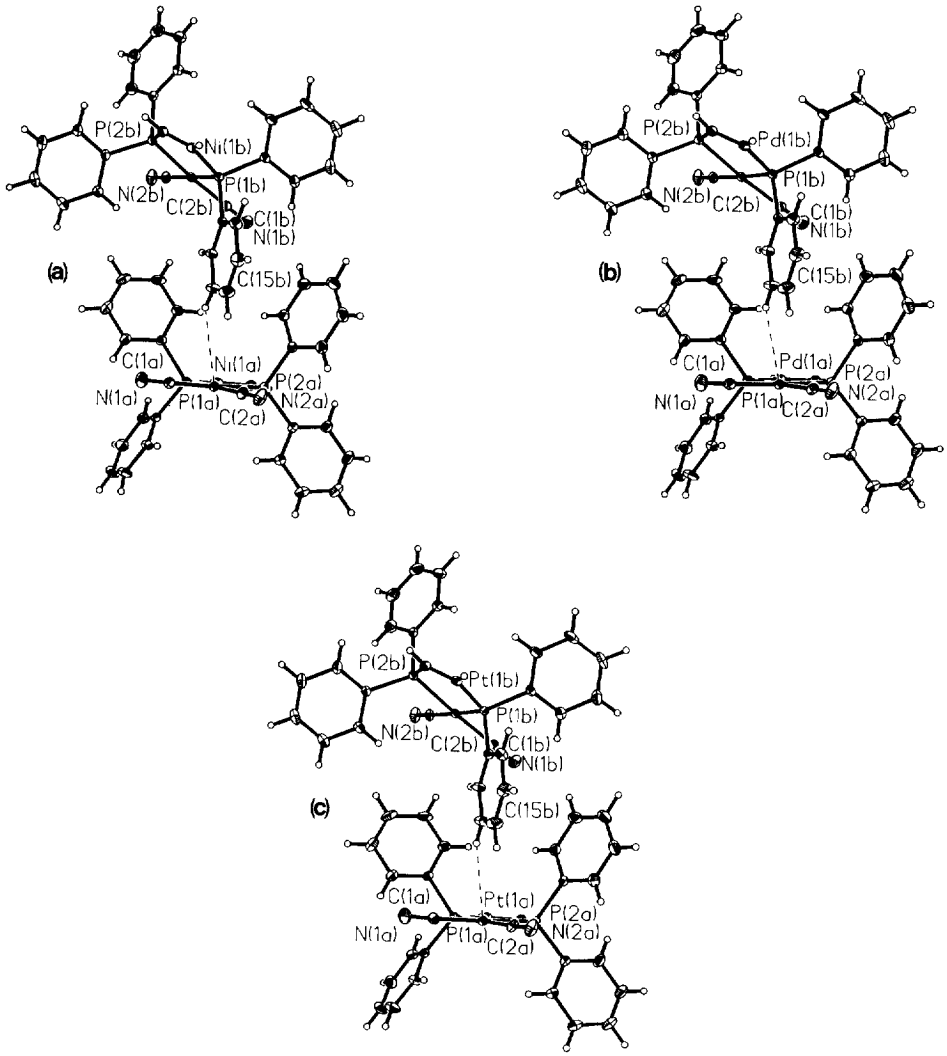

Fig. 2. Packing plots of $[M(CN)_2(cis\text{-}dppen)]$ showing the repulsive contact approaches between the hydrogen atoms attached to C(15b) and the metal atoms. (a) M=Ni (**1**); (b) M=Pd (**2**); (c) M=Pt (**3**). The largest deviations from coplanarity of the coordination planes and the ethene bridges occur in the case of (a).

bridization are responsible for the reduction of the double-bond lengths [1](c),[19]. Smaller than normal double-bond lengths have now been observed in several comparable d^8 complexes containing cis-dppen [1](b),[1](c),[7](b). The mean values of the CN bond lengths of 1.140(2) Å (**1**), 1.143(3) Å (**2**), and 1.147(4) Å (**3**) are within the usual range of 1.11–1.16 Å [2](a),[2](b),[3](a),[3](c),[4](c),[4](d).

In the syntheses of the complexes **4** and **5** the removal of chloride from $[MCl_2(cis\text{-}dppen)]$ (M=Ni, Pd) by precipitating AgCl with a silver salt leading to cationic intermediates was necessary for the completion of the reactions. However, in $[NiCl_2(cis\text{-}dppen)]$, also in the case of an excess of $AgBF_4$, only one chloride can be abstracted. It seems likely, that a chloride-bridged dimer of the composition $[Ni_2(\mu_2\text{-}Cl)_2(cis\text{-}dppen)_2](BF_4)_2$ is formed, since it has been found, that these species play an important role for chloride abstractions [20]. In the case of Pd both chlorides are removed and $[Pd(cis\text{-}dppen)(DMF)_2](BF_4)_2$ is produced [1](c). For Pt and compound **6** the same is true and an analogous intermediate occurs [1](c). However, it is also possible to treat $[PtCl_2(cis\text{-}dppen)]$ with dppam without chloride abstraction and $[Pt(cis\text{-}dppen)(dppam)]Cl_2$ is formed as indicated by its ^{31}P ^{1}H NMR parameters which are nearly identical with **6**.

The ^{195}Pt ^{1}H and ^{31}P ^{1}H NMR data for the complexes **3**–**8** are summarized in Table 2. δP of 52.6 in $[Pt(CN)_2(cis\text{-}dppen)]$ (**3**) shows the typical downfield five-ring contribution of chelating cis-dppen [21], which has also been observed in $[M(CN)_2(cis\text{-}dppen)]$ (M=Ni (**1**), Pd (**2**)) [1](b),[1](c). The $^{1}J(Pt,P)$ value of 2450 Hz indicates the strong trans influence of cyanide

Table 2. ^{195}Pt ^{1}H and ^{31}P ^{1}H NMR data for **3**–**8**[a]

Compound	δP	^{1}J(Pt,P)	^{2}J(P,P)$_{trans}$	^{2}J(P,P)$_{cis}$ + ^{4}J(P,P)
3	52.6	2450

	18.3d	2095	317	
7	16.8			
8	17.4	1577		

[a] *J* values in Hz. d = doublet, dt = doublet of triplets. Spectra were run at 298 K. The following solvents were used: DMF (**3**–**7**) and CH_2Cl_2 (**8**). [b] $\delta Pt = -4912$tt (tt = triplet of triplets).

[1](d),[22], in full agreement with the X-ray structure of **3** given above. The stronger trans influence of cyanide versus chloride can be directly observed in the elongated M–P bond lengths in **1** and **3** compared with [$NiCl_2$(cis-dppen)] [1](b) and [$PtCl_2$(cis-dppen)] [1](c),[7](b).

The ^{31}P ^{1}H NMR spectra of compounds **4**–**6** are of the AA′XX′ type, where A,A′ represent the dppam phosphorus nuclei and X,X′ the cis-dppen chelate. In [NiCl(cis-dppen)(dppam)](BF_4) (**4**) δP of 72.7 also stems from a downfield five-ring effect, which is only possible for cis-dppen (see structure (B) in Scheme 1). Therefore, the signal at 43.7 is attributed to dppam showing no upfield four-ring contribution [21], since δP for free dppam is 42.2 [11](b). Together with the small ^{2}J(P,P)$_{trans}$ value of only 162 Hz [22], this is consistent with the distorted square pyramidal coordination shown in structure (B) of Scheme 1, where the central Ni atom deviates from the basal plane. The m/z value of the molecular ion peak in the FAB mass spectrum is also in agreement with the five-coordinate species [NiCl(cis-dppen)(dppam)]$^{+}$. Comparable five-coordinate complexes containing bis(diphenylphosphino)methylamine have already been reported [10].

In [Pd(cis-dppen)(dppam)](BF_4)$_2$ (**5**) δP of 70.7 indicates the typical five-ring contribution of bidentate cis-dppen, whereas the signal at 27.2 shows a four-ring upfield effect and is therefore attributed to chelating dppam in a square planar coordination [21]. Together with the ^{2}J(P,P)$_{trans}$ value of 361 Hz in the usual range [22] this is consistent with structure (C) of Scheme 1. The presence of ^{2}J(P,P)cis + ^{4}J(P,P) of 34 Hz leads to virtually coupled triplets further split by ^{2}J(P,P)$_{trans}$. Comparable virtual couplings have been observed in complexes with dppm which is isoelectronic with dppam [1](a). In contrast to **4** the m/z value of the molecular ion peak in the FAB mass spectrum of **5** shows no chloride-associated species and is in agreement with [Pd(cis-dppen)(dppam)]$^{+}$. In a similar square planar Pd^{II} complex containing chelating dppam, [$Pd(C_6F_5)_2$(dppam)] [11](c), the presence of an upfield shift for δP of 28.73 is also indicative of a pure square planar coordination.

For [Pt(cis-dppen)(dppam)](BF_4)$_2$ (**6**) δPt of −4912 is in line with the corresponding value of −4765 in [Pt(dppe)(dppam)]Cl_2 (**9**) [9], where dppe is 1,2-bis(diphenylphosphino)ethane. In **6** the δP parameters of 61.6 for cis-dppen and 18.3 for dppam again show the downfield five-ring and upfield four-ring contributions, respectively. Also the ^{1}J(Pt,P) values of 2359 and 2095 Hz, which are typical for the relative strong trans influence of phosphorus [23], and the usual magnitude of ^{2}J(P,P)$_{trans}$ of 317 Hz [22] are in agreement with structure (C) of Scheme 1. In both **6** and **9** [9] the ^{1}J(Pt,P) parameters for the five-rings exceed ^{1}J(Pt,P) for the four-rings by about 250 Hz. The reduction in ^{1}J(Pt,P) for the phosphorus atoms of the dppam chelates stems from an increase in the proportion of p character in the Pt–P bond at the expense of s character. Also in **6** like in **5** the m/z value of the molecular ion peak in the FAB mass spectrum is consistent with [Pt(cis-dppen)(dppam)]$^{+}$, showing no chloride-association.

The ν(N–H) bands in the IR spectra of **4**–**6** at 3239, 3237, and 3243 cm^{-1}, respectively, are slightly shifted toward higher energies relative to that for the free ligand at 3230 cm^{-1} [11](c). This effect has been observed earlier and attributed to weak N–H···N- or N–H···P-bridges in the solid state of free dppam [11](b). However, no hydrogen bridges have been observed in the X-ray structure of free dppam [24]. Therefore it seems likely, that metal-phosphorus dπ-dπ back bonding in the case of coordinated dppam leads to an enhanced electron density at the nitrogen atom thus strengthening the N–H bond. A comparable effect is present in complexes of 1,2-bis(diphenylphosphino)acetylene (dppa) [6](b). It has generally been observed for complexes containing dppam, that there is significant reduction in ν(N–H) in the case of hydrogen bridging interactions of the NH group [9],[11](a),[11](c),[12](a). The replacement

of the $(BF_4)^-$ anions in **6** by chlorides leads to a shift of ν(N–H) to 2817 cm^{-1} certainly due to a N–H $\cdots$ Cl^- bridge. Comparable to this, ν(N–H) of $[Pt(dppe)(dppam)]Cl_2$ (**9**) occurs at 2801 cm^{-1}. The lack of this shift of ν(N–H) toward lower energies in $[NiCl(cis\text{-}dppen)(dppam)](BF_4)$ (**4**) (see above), clearly confirms the presence of coordinated chloride.

The compounds $[M_2(CN)_4(\mu\text{-}trans\text{-}dppen)_2]$ (M=Pd (**7**), M=Pt (**8**)) are two further rare examples of d^8 metal cis-dicyanide complexes. The δP values of 16.8 (**7**) and 17.4 (**8**) clearly indicate a normal coordination shift without any ring contribution, since it is impossible for trans-dppen to chelate. Together with the single $^{31}P\{^1H\}$ NMR resonances in both cases, this is in agreement with the symmetrical binuclear structure type (D) in Scheme 1 containing two trans-dppen bridges. Furthermore, the cis-dicyanide structure is clearly confirmed by the ^1J(Pt,P) value of 1577 Hz in **8** indicating the strong trans influence of cyanide [1](d),[22]. Analogous binuclear complexes with dppa have been described only recently [6](b).

DISCUSSION

It seems likely, that the easy formation of the otherwise rare d^8 metal cis-dicyanide complexes in **1**–**3**, **7**, and **8** is a consequence of the unsaturated nature of the diphosphines cis- and trans-dppen. In the case of d^8 metal complexes containing both the electron rich anions of β-diketones and cis-dppen, the above described π-bonding between the metals and cis-dppen stabilizes these compounds by decreasing the electron density at the metal atoms [25]. Furthermore, it has been shown by numerous X-ray structures that the linkage isomerism in $[Pd(SCN)_2(cis\text{-}dppen)]$ and [Pd(SCN)(NCS)(cis-dppen)] cannot be explained by a strictly steric model and also concurrent electronic effects have to be considered [26]. In **1**–**3** containing the also electron rich cyanides, the coordination planes and the ethene bridges are nearly coplanar clearly showing this π-bonding interaction. In **7** and **8** π-bonding between the coordination units and the trans-dppen bridges should also be present, since several X-ray structures of the analogous binuclear complexes with dppa clearly indicate π-bonding [6](b),[27]. Therefore, the lack of the π-bonding stabilization of cis-dicyanides leads to the preference of square planar trans-dicyanides [2], five-coordinate dicyanides [3] or binuclear complexes with square planar trans-dicyanide units [4]. Comparable to the cis-dicyanides a cooperative stabilization effect could be present in the compounds **4**–**6**, since it has been shown, that like cis-dppen also dppam is able to accept π-electron density from a metal centre producing a reduced P–N bond length [12](a).

The slight distortions in the X-ray structures of **1**–**3** as a consequence of the repulsive C–H $\cdots$ M contact approaches are in agreement with the flexibility of complexes in crystals [28]. With respect to the unclear nature of these C–H $\cdots$ M(d^8) interactions [7](a), an attractive weak hydrogen bond can now be ruled out [7](b),[29]. The distortions could be a result of the general trend in molecular crystals to produce closest packings [30] and a repulsive Coulomb interaction between the positive partial charges on the d^8 metals and the aryl protons.

The above given trend of 1.06, 1.17, and 1.16 Å for the covalent radii of square planar d^8 Ni, Pd, and Pt, respectively, is in agreement with the trend of the corresponding ionic radii in crystals for the square planar d^8 metals Ni of 0.44, Pd of 0.64, and Pt of 0.60 Å [31]. A similar tendency for the same d^8 metals has been found only recently in the X-ray structures of another isomorphous series of complexes comparable to **1**–**3** [5](b). Together with a reduction in radius of as much as 6% from Ag to Au [5](a), this could be a general result of the 'relativistic contraction' [32] from 4d to 5d metals. Further work on this is in progress.

(Received 15 December 1997)

Abstract—Coordination of 2,3-diphenyltetrazolium-5-thiolate (tet) to an Ru(trpy)(bpy)$(OH_2)^{2+}$ (trpy = 2,2′:6′,2″-terpyridine; bpy = 2,2′-bipyridine) centre resulted in the formation of [Ru(trpy)(bpy)(tet)]$(ClO_4)_2$. Single-crystal X-ray analysis revealed that the tet ligand is bound through the sulfur atom to a somewhat distorted-octahedral ruthenium centre. The Ru–S bond distance is 2.393(2) Å, and the Ru–S–C bond angle is 115.1(2)°; the tet N–N bonded distances [1.306(10) Å–1.316(9) Å] are essentially equal. These data, as well as spectroscopic and electrochemical evidence, suggest that the tetrazolium ring exhibits delocalized, mesoionic character with some thiolate character on the sulfur atom. © 1998 Elsevier Science Ltd. Keywords: ruthenium; tetrazolium-5-thiolate; terpyridine; bipyridine; synthesis; structure.

In spite of uncertainty about its composition and stability [1], dithizone has been used for years as a ligand in colourimetric determination of metals such as lead, mercury, copper, and silver [2]. Our interest in potential sulfur-nitrogen bidentate ligands for polypyridyl ruthenium complexes has led to the preparation of polypyridyl ruthenium complexes containing dithizone [3], dtz (I), and to the consideration of redox products of dithizone as ligands. In particular, 2,3-diphenyltetrazolium-5-thiolate, tet (II), is readily prepared by oxidation of dithizone and can be reduced back to dithizone [4].

In considering that there may be interesting relationships between the coordination of dithizone and tet to metal centres, we have prepared complexes of each using polypyridyl ruthenium moieties as the coordination centres. Dithizone often acts as a bidentate ligand, binding through the sulfur and a nitrogen atom to form a five-membered ring. NMR studies [3] indicate that this is the case also with $Ru(bpy)_2(dtz)^+$ (bpy-2,2′-bipyridine). Tet has not, however, been extensively studied as a ligand, and thus its coordination characteristics are poorly defined. In general, tetrazoles can coordinate to metal centres through either the 1 or 4 nitrogen [5–12], through the 2 or 3 nitrogen [13–18], or through two nitrogens as a bridging ligand [19, 20]. The tin complex, $Sn(CH_3)_2(phen)L_2$ (phen = 1,10-phenanthroline; L = 1-phenyl-5-thione-1,2,3,4-tetrazolate), contains one tetrazolate unit bound through nitrogen and another bound through sulfur [21]. In $[HgCl_2(tet)]$, the tet sulfur atom acts as a bridging ligand in a polymeric structure [22]. Because of the limited reports of characterization of tet complexes, especially structural characterization of classical transition metal complexes involving this ligand, we have performed a single crystal X-ray analysis of the tet complex reported here.

EXPERIMENTAL

The complex [Ru(trpy)(bpy)Cl]Cl [23] and tet [1] were prepared according to literature procedures. Other substances were of reagent grade quality and

were used as received. Spectrophotometric measurements were made with a Varian DMS-100 spectrophotometer. Electrochemical measurements were made with a Bioanalytical Systems Model CS-1087 Electrochemical Analyzer.

Synthesis

Preparation of $[Ru(trpy)(bpy)(tet)](ClO_4)_2$. A mixture of 0.300 g (0.535 mmol) of $[Ru(trpy)(bpy)Cl]Cl$ and 0.241 g (1.07 mmol) of $AgClO_4.H_2O$ was placed in a 100 cm^3 flask and 40 cm^3 of 75/25 acetone/water was added. The solution was flushed with nitrogen and refluxed for 1.5 h and then cooled. After filtration, 0.200 g (0.79 mmol) of tet was added to the filtrate. The solution was flushed with nitrogen and refluxed for 6 h. After cooling, the solution volume was reduced to 10 cm^3 by rotary evaporation. After cooling overnight, the solution was filtered to collect a brown precipitate. The precipitate was chromatographed on an alumina column using dichloromethane/acetone as eluent. Reprecipitation of the red-brown band gave 0.164 g (0.174 mmol) of product (33% yield). Anal. Calcd for $RuC_{38}H_{29}Cl_2N_9O_8S$: C, 48.36; H, 3.10; N, 13.36. Found: C, 46.77; H, 3.08; N, 12.88.

Crystal structure determination

Crystals of $[Ru(trpy)(bpy)(tet)](ClO_4)_2 \cdot H_2O$ were grown by slow evaporation of solvent from a 2:1:1 acetone:ethanol:water solution of $[Ru(trpy)(bpy)(tet)](ClO_4)_2$.

A crystal of dimensions *ca.* $0.06 \times 0.06 \times 0.60$ mm was mounted on the end of a thin glass fibre. Oscillation and Weissenberg photographs yielded preliminary unit-cell parameters and space group information. An Enraf–Nonius CAD-4 diffractometer (Cu-$K\alpha$ radiation, graphite monochromator) was used for all other measurements. Refined unit-cell parameters were derived from the diffractometer setting angles for 25 reflections ($36 < \theta < 40$) widely separated in reciprocal space. Intensity data were corrected for the usual Lorentz and polarization effects; an empirical absorption correction [T_{max}:T_{min}(rel.) = 1.00:0.93], based on the ϕ-dependency of the intensities of several reflections with χ *ca.* 90°, was also applied. Laue symmetry indicated that the crystals belonged to the trigonal system. The systematic absences ($00l$ when $l \neq 3n$) were consistent with the space group $P3_1$ and its enantiomorph $P3_2$.

The crystal structure was solved by direct methods (MULTAN11/82) [24] assuming at the outset that the space group was $P3_1$. Approximate non-hydrogen atom coordinates were derived in part from an *E*-map and from a series of weighted F_o and difference Fourier syntheses phased successively by an increasing number of atoms. One of the perchlorate ions and the water molecule are disordered over two sites, with the alternative location of the latter being masked by a perchlorate ion; moreover, the perchlorate ion at one of these sites is further disordered over two orientations. Non-hydrogen atom positional and temperature factor parameters (first isotropic and then anisotropic), with hydrogen atoms incorporated at their calculated positions in the later cycles, were adjusted by means of several rounds of full-matrix least-squares calculations. An extinction correction was included as a variable during the later iterations. The parameter refinement converged at $R = 0.0495$ ($R_w = 0.0637$). The chirality of the crystal used for data collection was established at this stage by introducing the imaginary contributions to the anomalous dispersion corrections into the structure-factor calculations. For parameters in space group $P3_1$, R was 0.0522 while R_w was 0.0692, whereas when those for the enantiomer were used in space group $P3_2$, the values were $R' = 0.0578$ and $R_w = 0.0782$. These differences are significant at the 0.005 level [25] when R'_w/R_w (0.0782/0.0692 = 1.130) equals to or exceeds 1.0012 and indicated that $P3_1$ was the correct choice. Continuation of the least-squares parameter refinement led to convergence at $R = 0.048$ ($R_w = 0.062$). A final difference Fourier synthesis contained no unusal features.

Crystallographic calculations were performed on PDP11/44 and MicroVAX computers by use of the Enraf–Nonius Structure Determination Package (SDP 3.0) [26]. For all structure-factor calculations, neutral atom scattering factors and their anomalous dispersion corrections were taken from ref. [27]. Further information concerning data collection and refinement are provided in Table 1. Atomic coordinates, thermal parameters, least-squares planes, and a listing of observed and calculated structure ampli-

RESULTS AND DISCUSSION

The complex $[Ru(trpy)(bpy)(tet)](ClO_4)_2$ was prepared by direct reaction of tet with $Ru(trpy)(bpy)Cl^+$ in aqueous ethanol solution. The intensely red-coloured complex exhibits properties consistent with the tet binding as a monodentate ligand through the sulfur atom. An MLCT absorption band at 480 nm ($\epsilon = 7200\ M^{-1}cm^{-1}$) is similar to those of Ru(trpy)(bpy)X^+ (X = anion) complexes [28]. The cyclic voltammogram of $Ru(trpy)(bpy)(tet)^{2+}$ in acetonitrile exhibits a pseudoreversible wave at 0.86 V vs. SSCE ($\Delta Ep = 80$ mV), consistent with $Ru^{III\,II}$ potentials for Ru(trpy)(bpy)X^+ complexes. However, bulk oxidation at a potential just above 0.86 V leads to complete loss of the wave. The foregoing evidence suggests that tet binds through the sulfur atom which possesses significant thiolate character, consistent with the mesoionic character of the free ligand. Thioether or thione ligands [29, 30] exhibit higher energy MLCT bands and higher $Ru^{III\,II}$ redox couples.

Single-crystal X-ray analysis of $[Ru(trpy)(bpy)(tet)](ClO_4)_2 \cdot H_2O$, Fig. 1 [31], confirms that the six-coordinate ruthenium centre binds to the sulfur atom of the tetrazolium ligand. Important bond distances and angles are listed in Table 2. Distortions from an octahedral arrangement around the ruthenium centre may be ascribed to constraints imposed by the bite angles of the bpy and trpy ligands, and are probably little influenced by the tet ligand. Distances and angles within the trpy ligands are close to the average values in related species [32–37] such as $Ru(bpy)_3^{2+}$ and $Ru(trpy)L_3^{2+}$ complexes. The Ru–N distances and angles are also in accord with expected values. The short Ru–N(7) distance [1.957(6) Å] and the N(1)–Ru–N(13) angle of only 158.5(2) are the result of the restricted bite angle of the trpy. Likewise, the bpy bite angle is only 78.4(2) .

Comparison of the structure of the bound tet to that of the free ligand [38, 39] reveals very little difference. In particular, the C(41)–S(46) and N(43)–N(44)

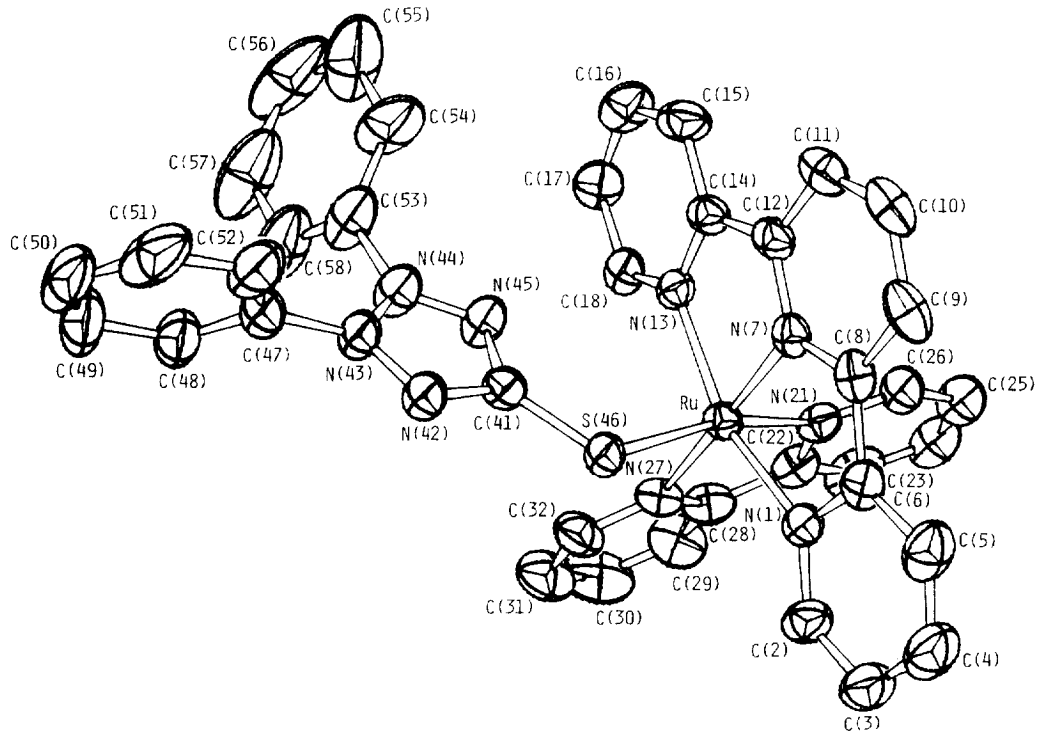

Fig. 1. ORTEP diagram (30% probability ellipsoids) showing the crystallographic atom numbering scheme and solid-state conformation of the $[C_{35}H_{29}N_9RuS]^{2+}$ ion; hydrogen atoms have been omitted.

bond lengths in the coordinated tet [1.686(8) Å and 1.316(9) Å, respectively] do not differ significantly from those in the free ligand {1.692(4) Å and 1.328(4) Å [38], and 1.687(5) Å and 1.313(4) Å [39], respectively, from two independent determinations}. The tetrazolium ring is essentially planar and its

* 
directly bonded substitutents lie close to the ring plane [Δ(Å): S(46) 0.008, C(47) 0.110, C(53) 0.035] as does the Ru atom [Δ 0.062 Å; N(45)–C(41)–S(46)–Ru torsion angle = 2(1)°]. Dihedral angles between the tetrazolium and phenyl ring planes are 63.1° and 70.8°, while that between the latter is 85.7° [torsion angles: N(44)–N(43)–C(47)–C(48) = 70(1)°, N(43)–N(44)–C(53)–C(58) = −72(2)°]. The bent geometry at the sulfur atom [C(41)–S(46)–Ru = 115.1(2)°] and the Ru–S distance [2.393(2) Å] are comparable to those observed in species like $Ru(CO)_2(pyridine)_2$(mercaptobenzothiazole)$_2$ [40] where the corresponding values are 109.0(1)° and 2.406(4) Å.

Table 3 lists bond distances in a number of tetrazoles. Distances in the coordinated and free tet are consistent with a mesoionic tetrazole structure. Thus, very similar N–N bond lengths are observed for tet [22, 38, 39] and related species [41]. Other tetrazoles [6–18, 41–43] typically exhibit longer N_1-N_2/N_3-N_4 than N_2-N_3 bond lengths indicative of greater double bond localization in the N_2-N_3 bond. These observations are consistent with considerable electron delocalization within the tetrazole ring of tet [44].

Even though considerable anionic character is anticipated for the sulfur atom of tet (and spectral and electrochemical properties are consistent with that character), the C–S bond length at 1.686(8) Å in the coordinated tet is significantly shorter than that usually observed for thiolato C–S species. For example, thiolato ligands in ruthenium complexes have C–S bond lengths ranging from 1.769(3) Å in *cct*-RuH$(SC_6H_4p\text{-}Me)(CO)_2(PPh_3)_2$ [45], 1.778(8), 1.788(7) Å in *cct*-$Ru(SC_6H_4p\text{-}Me)_2(CO)_2(PPh_3)_2$ [45], 1.77(2)–1.83(2) Å in (η^6-arene)$Ru(SAr)_2$ complexes [46], 1.77(1), 1.79(1) Å in *trans*-Ru-(2,6-$C_6H_3Me_2S)_2$$(CN^tBu)_4$ [46], to 1.848(5), 1.852(5) Å in Cp*Ru(NO)$(SCMe_3)_2$ [47]. The C–S bond length found here is also shorter than that at 1.711(8) Å in [Ru(4-methylpyrimidine-2-thionate)$(bipy)_2]^{2+}$ [48], but it is slightly longer than that of 1.632(5) Å in the coordinated thione [Cp(dppe)RuSCHC$_6$H$_4$OMe$)^+$] [49].

(Received 18 November 1997; accepted 12 March 1998)

Abstract—A new functionalized macrocyclic ligand 2,13-bis(2′-pyridylmethyl)-5,16-dimethyl-2,6,13,17-tetraazatricyclo[16.4.0.^{1,18}O^{7,12}]docosane (L^2) containing two 2-pyridylmethyl pendant arms has been prepared by the one-step reaction of 3,4-dimethyl-2,6,13,17-tetraazatricyclo[16.4.0.^{1,18}O^{7,12}]docosane (L^1) with 2-(chloromethyl) pyridine. The octahedral complexes $[NiL^2](ClO_4)_2$ and $[CuL^2](ClO_4)_2$, in which two pyridyl groups are coordinated to the metal ion, have been prepared and characterized. The crystal structure of $[CuL^2](ClO_4)_2$ shows that the complex is centrosymmetric and the metal center has a tetragonally distorted octahedral geometry. In concentrated $HClO_4$ solutions, the coordinated pyridyl groups of $[CuL^2]^{2+}$ are protonated and are removed from the coordination sphere. However, those of $[NiL^2]^{2+}$ are not protonated but are coordinated to the metal ion even in 3.0 *M* $HClO_4$. The macrocycle L^2 reacts more slowly with copper(II) ion than does L^1. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: tetraaza macrocycle; functionalized macrocycle; nickel(II) complex; copper(II) complex; crystal structure.

The synthesis of polyaza macrocyclic ligands and their metal complexes containing additional functional pendant arms is of growing importance to various fields of coordination chemistry, since the introduction of functional groups into a polyaza macrocyclic compound causes a considerable change in chemical properties and structures [1–14]. The structures and chemical properties of such compounds are also influenced by various factors, such as the type and number of the functional groups. For example, the fully N-hydroxyethylated macrocycle L^6 forms 1:1 metal–ligand complexes [6]. However, the macrocycle L^5, containing four N-pyridylmethyl pendant arms, generally acts as a binucleating ligand [7, 8]. Recently, we reported the preparation of di-N-hydroxyethylated macrocycle L^3 from the reaction of L^1 with an excess of 2-bromoethanol [9]. Interestingly, L^3 reacts with the Cu^{2+} ion more slowly than the unsubstituted macrocycle L^1, indicating that the reaction is retarded by the N-hydroxyethyl groups of L^3. This result contradicts those for various N-functionalized macrocycles, such as L^6, L^7, and L^8; the complexation reaction of L^6, L^7, and L^8 with Cu^{2+} ion is much faster than that for L^4 or the fully N-methylated derivative of L^4 [6, 10]. It has been also observed that, although the hydroxyl groups of $[CuL^3]^{2+}$ are not involved in coordination, those of $[NiL^3]^{2+}$ and $[CuL^6]^{2+}$ are coordinated to the metal ion [7, 9]. However, the origins of the differences are not thoroughly understood. To further investigate the effects of the nature of functional pendant arms on the coordination behaviors, we have been interested in the synthesis of new polyaza macrocycles containing various types of functional pendant arms.

In this work, we have prepared a new macrocyclic

* Author to whom correspondence should be addressed.

ligand L^2, containing two 2-pyridylmethyl pendant arms, from the one-step reaction of L^1 with an excess amount of 2-(chloromethyl)pyridine. This paper reports the synthesis and chemical properties of L^2 and its copper(II) and nickel(II) complexes. Crystal structure of $[CuL^2](ClO_4)_2$ is also determined. A number of studies have reported on the properties of tetraaza macrocyclic compounds containing 2-pyridylmethyl pendant arms [7, 8, 11, 12]. However, to our knowledge, examples of saturated 14-membered tetraaza macrocyclic compounds containing two N-(2-pyridylmethyl) pendant arms are not reported to date.

1. EXPERIMENTAL

1.1. *Materials and Measurements*

All chemicals used in syntheses were of reagent grade and were used without further purification. The macrocyclic ligand L^1 was prepared as described previously [15].

Electronic spectra were obtained using a Shimadzu UV-160 spectrophotometer. IR spectra were recorded as either Nujol mulls or KBr pellets on a Shimadzu IR-440 spectrophotometer, conductance measurements with a Metrohm Herisau Conductometer E518, and NMR spectra with a Bruker WP 300 FT NMR spectrometer. Mass spectra and elemental analyses were performed at the Korea Basic Science Institute, Seoul, Korea. Magnetic moments were calculated from magnetic susceptibility data obtained using a Johnson Matthey MK-1 magnetic susceptibility balance. Cyclic voltammograms were recorded using a Yanaco Voltammetric Analyzer p-1000 equipped with a FG-121B function generator and a Watanabe X–Y recorder. The electrochemical measurements were conducted in oxygen free 0.1 *M* $(n\text{-Bu})_4NClO_4$ acetonitrile solutions at 20 C.

Kinetic measurements of the formation of the copper(II) complexes of L^1 and L^2 were carried out in acetate buffer solutions (pH 5.4) of methanol–water (1:1) mixture at 20 C. The initial concentrations of the ligands and the metal ion in the reaction mixtures are 1.0×10^{-3} and 2.0×10^{-2} *M*, respectively. The reaction was monitored using the absorbance increase at 520 (L^1) or 553 nm (L^2).

1.2. *Synthesis of the Compounds*

1.2.1. L^2. A toluene (50 mL) suspension of L^1 (2.0 g, 6.0 mmol), 2-(chloromethyl)pyridine hydrochloride (3.0 g, 18 mmol), and KOH (4.0 g, 71 mmol) was heated to reflux over 30 h. The reaction mixture was filtered, and the filtrate was evaporated to dryness. The residue was dissolved in a minimum volume of chloroform. The chloroform solution was filtered and then the filtrate was re-evaporated to dryness. After methanol (20 mL) had been added to the resulting residue, the mixture was allowed to stand overnight. The white solid formed was filtered, washed with methanol and dried in air. Yield: >60%. Mass (*m/z*): 519 (M^+). Found: C, 73.94; H, 9.74; N, 16.30. Calc. for $C_{32}H_{50}N_6$: C, 74.09; H, 9.71; N, 16.20%. IR: 3260 (νN–H), 1600 (νC=N), and 1580 cm^{-1} (νC=C). ^{13}C-NMR ($CDCl_3$): 20.5 (Me), 22.0, 25.5, 26.5, 31.2, 33.8, 46.6, 50.5, 53.8, 55.9, 61.1, 121.9 (Py), 136.5 (Py), 136.8 (Py), 148.6 (Py), and 162.8 (Py) ppm.

1.2.2. $[NiL^2](ClO_4)_2$. A methanol suspension (30 cm^3) of $Ni(OAc)_2\cdot4H_2O$ (2.0 g, 8 mmol) and L^2 (2.0 g, 5 mmol) was heated to reflux for 30 min and then cooled at room temperature. After adding an excess of $HClO_4$, the mixture was stored in a refrigerator until the purple precipitates formed. The product was filtered and recrystallized from a hot water–acetonitrile (1:1) mixture. Yield: ~90%. Found: C, 49.34; H, 6.38; N, 10.75. Calc. for $C_{32}H_{50}N_6NiCl_2O_8$: C, 49.51; H, 6.49; N, 10.82%. IR: 3240 (νN–H), 1620 (νC=N), and 1580 cm^{-1} (νC=C). Magnetic moment (μ_{eff}): 2.88 μB.

1.2.3. $[CuL^2](ClO_4)_2$. The blue–purple complex was prepared by a method similar to that for the nickel(II) complex $[NiL^2](ClO_4)_2$, except that $Cu(OAc)_2.H_2O$ (2.0 g, 8 mmol) was reacted instead of $Ni(OAc)_2\cdot4H_2O$. Yield: ~90%. Found: C, 48.96; H, 6.42; N, 10.69. $C_{32}H_{50}N_6CuCl_2O_8$: C, 49.20; H, 6.45; N, 10.76%. IR: 3240 (νN–H), 1620 (νC=N), and 1580 cm^{-1} (νC=C).

1.3. *Crystallographic analysis of* $[CuL^2](ClO_4)_2$

A well-shaped crystal was mounted in a thin-walled glass capillary on an Enraf–Nonius CAD-4 diffractometer with graphite-monochromated Mo–Kα radiation ($\lambda=0.71073$ Å) at room temperature. Unit cell parameters were obtained by least-squares analysis of 25 well centered reflections ($10<\theta<13$). Reflection data were collected using $\omega/2\theta$ scan mode in θ range of 1.92–24.98 and monitored every 1 h using two standard reflections ($h, k, l = -4, 6, 0; 3, 7, -3$). The data were corrected for Lorentz-polarization effects and decay (less than 0.03% variation). Empirical absorption correction with 3ψ scans was carried out in the correction range of 0.80–1.00. The structure in C2/c was determined with Patterson method as well as difference Fourier techniques and refined on F^2 by using a full-matrix least-squares method with SHELXS-97 and SHELXL-97 [16]. All non-hydrogen atoms were refined by using anisotropic thermal factors and all hydrogen atoms were located geometrically by means of a riding model with 1.2 times isotropic thermal factors of the attached non-hydrogen atoms. Oxygen atoms on one of two ClO_4 anions were refined with half occupancies due to the disorder. The final cycle of the refinement gave the error indices, $R=0.040$ and $R_w=0.095$. The mean value of shift/esd. is 0.01 and the remaining largest peak is 0.39 e/Å^3 at 0.89 Å from Cl atom. Crystal data, details of the data

collection and refinement of the structure are listed in Table 1.

2. RESULTS AND DISCUSSION

2.1. *Synthesis*

The di-N-functionalized macrocycle L^2, in which two 2-pyridylmethyl groups are attached to the less sterically hindered nitrogen atoms, can be readily prepared by the direct reaction (*see* Experimental) of L^1 with an excess of 2-(chloromethyl)pyridine in the presence of KOH. It has been reported that the reaction of L^4 with 2-(chloromethyl)pyridine in a 1:4 molar ratio produces the fully N-pyridylmethylated macrocycle L^5 in high yield [7]. However, all efforts to introduce the pyridylmethyl groups into the secondary nitrogen atoms of L^2 were unsuccessful in the similar experimental conditions; the only compound isolated was the di-N-substituted macrocycle L^2 even after prolonged (6 days) heating of the mixture of L^1 or L^2 and 2-(chloromethyl)pyridine in a 1:8 molar ratio. It has also been reported that the reaction of L^1 with an excess of 2-bromoethanol produces only the di-N-substituted macrocycle L^3 as a main product [9]. However, the present result is different from the reported result that all secondary amino groups of L^1 are readily alkylated by the reaction of the macrocycle with an excess amount of bromoethane or 1-bromopropane [17]. No further substitution of the secondary amino groups of L^2 or L^3 may be attributed to the interactions between the amino groups and the pyridyl or hydroxyl groups, such as hydrogen bonding, which prevent the reaction, in addition to the steric hindrance caused by the C-substituents.

The new macrocycle L^2 readily dissolves in chloroform but slightly dissolves in methanol at room temperature. The mass spectrum of L^2 gives a m/z of 518, which is in accordance with the molecular weight of the macrocycle containing two 2-pyridylmethyl pendant arms. In the infrared spectrum of the macrocycle, νC=N and νC=C of the pendant pyridylmethyl groups are observed at *ca.* 1640 and 1580 cm^{-1}. One peak at 3260 cm^{-1}, corresponding to νN–H of the secondary amino groups, was also observed. The ^{13}C NMR spectrum of L^2 shows 16 peaks (see Section 1, Experimental), indicating that the macrocycle is a single isomer with a symmetrical arrangement of the carbon atoms. The above spectral data, together with the elemental analyses, are consistent with the structure of L^2; the structure was confirmed by the crystal structure of its copper(II) complex (see below).

The octahedral complexes, $[NiL^2](ClO_4)_2$ and $[CuL^2](ClO_4)_2$, in which two 2-pyridylmethyl groups are coordinated to the metal ion, are prepared by the reaction of each metal ion with L^2, followed by addition of an excess amount of perchloric acid or sodium perchlorate.

[b] $R=\Sigma||F_o|-|F_c||/\Sigma|F_o|$. $R_w=[\Sigma w(F_o^2-F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$, where $w=1/[\sigma^2(F_o^2)+0.0431P]^2+8.11P]$; $P=[\max(F_o^2,0)+2F_c^2]/3$.

2.2. *Crystal structure of* $[CuL^2](ClO_4)_2$

The ORTEP drawing (Fig. 1) of the complex cation $[CuL^2]^{2+}$ shows that the two 2-pyridylmethyl groups are attached to the less sterically hindered nitrogen atoms of the macrocyclic ligand. The nitrogen atoms of the pendant pyridyl groups are coordinated to the metal ion and the ligand serves as a hexadentate ligand. The complex has a tetragonally distorted octahedral coordination geometry, with an inversion center at the copper(II) ion; the metal atom and the four nitrogen atoms (N(1), N(2), N(1)′, N(2)′) are exactly in a plane. The macrocyclic ligand adopts the *trans*-III sterochemistry.

Selected bond distances and angles of the complex are summarized in Table 2. The Cu–N(1) and Cu–N(2) bond distances are in the normal range for Cu–N (amine) distances of six-coordinate copper(II) complexes with 14-membered tetraaza macrocyclic ligands [18, 19]. As expected from the Jahn–Teller effect, the apical Cu–N(3) (pyridine) distance (2.565(3) Å) is *ca.* 0.5 Å longer than the Cu–N(1) and Cu–N(2) distances. Somewhat interestingly, the Cu–N(3) distance is longer than the apical Cu–O (carboxylate group) distances (2.20–2.35 Å) of $[CuL^9]$ or various related macrocyclic copper(II) complexes containing coordinated acetate groups [18, 19]. The long Cu–N(3) distance is due to the steric hindrance between the N(3) atom and the methyl group at the six-membered chelate ring; the N(3)—C(10)′ distance was found to be 3.400(6) Å, which is shorter than the summation of Van der Waals radii of the nitrogen atom (1.55 Å) and methyl group (2.00 Å) [20]. The N(3)–Cu–N(3)′ angle is 180°, indicating that the three atoms are in a line. The Cu–N(3) bond is not perpendicular to the NiN_4 (N(1), N(2), N(1)′, N(2)′) plane with N(1)–Cu–N(3) and N(2)–Cu–N(3) angles of 77.3(2) and 80.2(2), respectively. The angle of Cu–N(3)–C(12) (103.1(2)°) is much smaller than that of Cu–N(3)–C(16) (133.3(2)°). The distorted angles about the coordinated N(3) atom may be due to the rigid structure of the pendant pyridylmethyl group and/or to the steric hindrance of the methyl group and the pyridyl group.

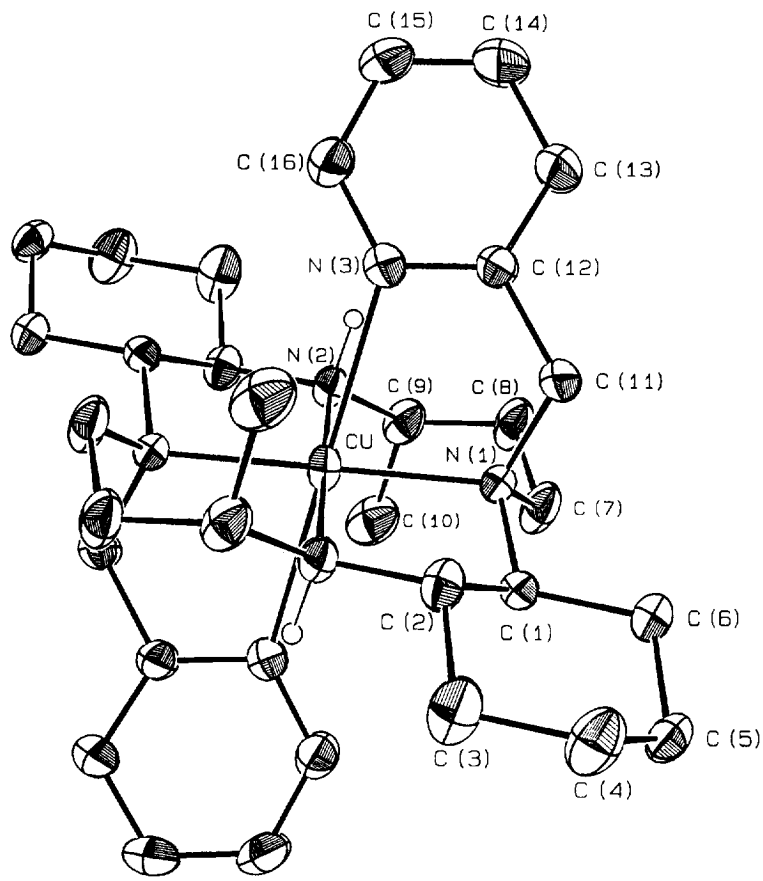

Fig. 1. Structure of $[CuL^2]^{2+}$ cation with atomic numbering scheme. Hydrogen atoms, except those attached to nitrogen atoms, are omitted for clarity.

2.3. *Characterization of the nickel(II) and copper(II) complexes*

The complexes $[NiL^2](ClO_4)_2$ and $[CuL^2](ClO_4)_2$ are soluble in acetonitrile and nitromethane, but are nearly insoluble in water at room temperature. They are extremely stable in the solid state and in the solutions. The infrared spectra of the complexes are similar to that of the free ligand L^2, except that $\nu(ClO_4)$ of the counter anions is observed at *ca.* 1100 cm^{-1}. The molar conductance values of the complexes measured in acetonitrile (*ca.* 270 $\Omega^{-1}mol^{-1}cm^2$) and nitromethane (*ca.* 180 $\Omega^{-1}mol^{-1}cm^2$) indicate that the complexes are 1:2 electrolytes.

The magnetic moment (2.88 μ_B at 20° C) of $[NiL^2](ClO_4)_2$ in the solid state is consistent with a d^8 electronic configuration in octahedral geometry. Visible absorption spectra (Table 3) of the nickel(II) complex in various solvents show d–d bands at *ca.* 530 nm. The wavelength and molar absorption coefficient of the band are comparable with those reported for the octahedral complex $[NiL^3]^{2+}$, in which two oxygen atoms of the pendant arms are coordinated to the metal ion [9]. The visible spectra and the magnetic moment clearly show that the metal ion of the nickel(II) complex is in an octahedral environment; the nitrogen atoms of the pendant pyridyl groups are coordinated to the metal ion. The visible spectrum of $[CuL^2]^{2+}$ measured in nitromethane shows a d–d band at 554 nm ($\epsilon = 111\ M^{-1}cm^{-1}$). The spectra measured in coordinating solvents, such as acetonitrile, are quite similar to that measured in nitromethane, indicating that the solvent molecules are not involved in coordination in the solvents. The wavelength of the band for $[CuL^2]^{2+}$ is *ca.* 30 nm longer than those for the square-planar complex $[CuL^3]^{2+}$ in which the oxygen atoms of the hydroxyethyl groups are not involved in coordination [9]. This is attributed to the coordination of the pendant pyridyl groups to the metal ion.

Cyclic voltammetric data of the complexes of L^2 are listed in Table 4. The redox potentials for $[ML^2]^{2+}$ ($M=Ni^{2+}$ or Cu^{2+}) are more positive than those for $[ML^1]^{2+}$. This agrees with the widely observed trend that substitution of coordinated secondary amino groups by tertiary ones in a polyaza macrocyclic nickel(II) or copper(II) complex makes the oxidation more difficult and the reduction easier [9, 17, 21, 22]. As expected from the electronic spectra, the potentials for $[NiL^2]^{2+}$ are comparable with those for $[NiL^3]^{2+}$ in which the hydroxyl groups are coordinated to the

Table 3. Electronic spectral Data[a]

[d] Ref.[9].

metal ion. However, in the case of the copper(II) complex $[CuL^2]^{2+}$, the redox potentials are distinctly less positive than those for $[CuL^3]^{2+}$. This is attributed to the coordination of the pyridyl groups; coordination of the pendant arms of a macrocyclic M(II) complex makes the oxidation to M(III) state easier and the reduction to M(I) more difficult [9, 13, 22]. The above results, together with the crystal structure, clearly show that the pendant pyridyl groups of $[CuL^2]^{2+}$ are coordinated to the metal.

2.4. *Kinetic and solution behaviors*

In order to investigate the effects of the pyridylmethyl groups of L^2 on the complex formation reaction, pseudo-first order rate constants (k) for the reaction of Cu^{2+} with L^1 and L^2 were determined in sodium acetate buffer solutions (pH 5.7) at 25 °C. The approximate k value for L^2 was found to be $1.6 \times 10^{-3}\,sec^{-1}$, which is lower than that for L^1 (*ca.* $1.7 \times 10^{-1}\,sec^{-1}$) under the same conditions, indicating that the introduction of 2-pyridylmethyl groups into L^1 to give L^2 reduces the rate. We could observe that the present result is similar to those reported for L^3 [9] and L^9 [19], in which two functional pendant arms are attached to diagonally related nitrogen atoms (not neighboring nitrogen atoms); the complexation reaction is retarded by the presence of the functional groups. However, this trend contradicts those reported for L^7 and L^8, in which two hydroxyethyl groups are attached to adjacent nitrogen atoms; in the cases of L^7 and L^8, the pendant hydroxyl groups enhance the rate of metal ion entry into the macrocycle by binding the metal ion outside the ring [10]. The present results and the above discussion strongly support the belief that the roles of functional pendant arms of a macrocyclic compound are strongly affected by the position of the pendant arms [10, 14]. It is likely that the diagonally substituted pyridylmethyl groups of L^2 cannot effectively bind the metal ion outside the macrocyclic ring and is insufficient to cause rate enhancement; the promoting effect of the functional pendant arms may be more than counterbalanced by their steric effect.

The complexes $[NiL^2](ClO_4)_2$ and $[CuL^2](ClO_4)_2$ are decomposed very slowly even in concentrated acid solutions, in analogy with the complexes of L^1 and L^3 [9, 15]. Visible spectra of the complexes ($1.0 \times 10^{-3}\,M$) in 0.5 M $HClO_4$ acetonitrile–water (1:1) indicated that only less than 3% of the complexes are decomposed in 20 h at 25 °C. The visible spectra of $[NiL^2]^{2+}$ measured in 0.1–3.0 M HCl CH_3CN–H_2O (1:1) solutions were found to be essentially the same as those observed in neutral and 0.1–2.0 M NaOH solutions. This result indicates that, somewhat unexpectedly, the pyridyl groups of the nickel(II) complex are not protonated even in concentrated acid solutions and that the hydroxide ion is not involved in coordination even in 2.0 M NaOH solution. In the case of the copper(II) complex $[CuL^2]^{2+}$, the spectra measured in 0.1–2.0 M NaOH solutions were quite similar to that in pure solvent. The spectrum of $[CuL^2]^{2+}$ measured in 0.1 M $HClO_4$ solution is also essentially the same as that obtained in pure solvent. However, further addition of the acid to the resulting solution increases the absorption at *ca.* 550 nm (Fig. 2), in contrast to the

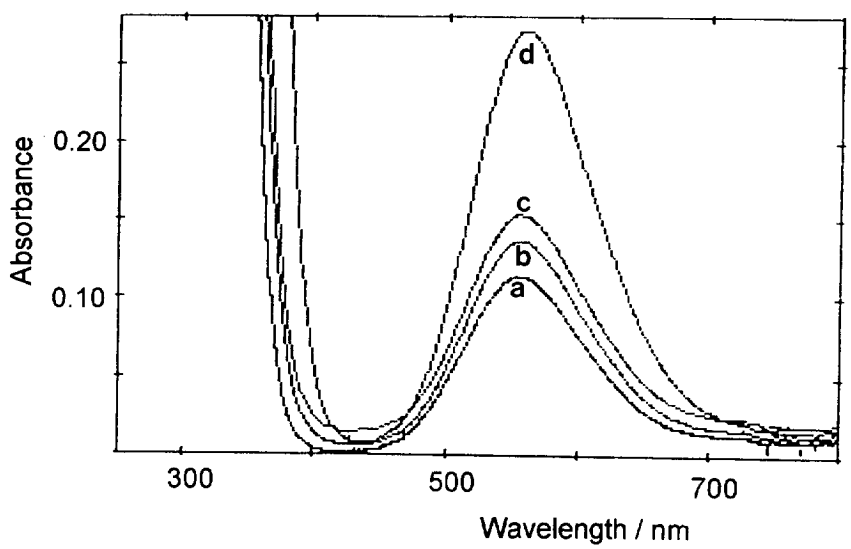

Fig. 2. Visible absorption spectra of $[CuL^2](ClO_4)_2$ ($1.0 \times 10^{-3}\,M$) in $HClO_4$ acetonitrile–water solution.$[HClO_4] = 0.0$ (a), 0.5 (b), 1.0 (c), and 2.0 M (d). The spectrum measured in 0.1 M $HClO_4$ solution is overlapped with curve (a). No apparent spectral change was observed in 2.0–4.0 M $HClO_4$ solutions.

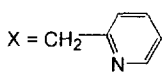

Scheme 1.

corresponding nickel(II) complex; the molar absorption coefficient ($270\ M^{-1}cm^{-1}$) of the band measured in 2.0 *M* $HClO_4$ is more than twice that in pure solvent. Such a marked spectral change indicates that the addition of the acid changes the coordination geometry and/or the degree of the solvation of the copper(II) complex. It is likely that, in the presence of the acid (>0.1 *M*), the pyridyl groups of the copper(II) complex are protonated and removed from the coordination sphere and then solvent molecules are coordinated to the metal ion. The easy protonation of $[CuL^2]^{2+}$, compared to that of $[NiL^2]^{2+}$, can be attributed to the weaker apical Cu–N interactions caused by the Jahn–Teller distortion.

3. CONCLUSION

The di-N-functionalized macrocycle L^2 is prepared in high yield by the direct reaction of L^1 and an excess of (2-chloromethyl)pyridine. The macrocycle L^2 reacts with nickel(II) and copper(II) ions to form stable octahedral complexes $[NiL^2]^{2+}$ and $[CuL^2]^{2+}$, respectively, in which the pyridyl groups are axially coordinated to the metal ions. The pyridyl groups of $[CuL^2]^{2+}$ are protonated in concentrated $HClO_4$ solutions, whereas those of $[NiL^2]^{2+}$ are not, even in 3.0 *M* $HClO_4$ solution. This work strongly suggests that two functional groups, attached to diagonally related nitrogen atoms of a 14-membered tetraaza macrocyclic ligand, reduce the formation of the copper(II) complex, in contrast to those attached to neighboring nitrogen atoms.

The reaction of $P_3N_3Cl_5NH_2$ with $SOCl_2$: the crystal structures of $P_3N_3Cl_5NSO$ and $Cl_5N_3P_3OP_3N_3Cl_5$

Josef Břínek, Milan Alberti, Jaromír Marek, Zdirad Žák and Jiří Toužín†

Department of Inorganic Chemistry, Masaryk University, 611 37 Brno, Czech Republic

Received 3 April 1998; accepted 2 June 1998

Abstract—Depending on reaction conditions, the reaction of $P_3N_3Cl_5NH_2$ with $SOCl_2$ gives four compounds: $P_3N_3Cl_5NSO$, $P_3N_3Cl_5NSNP_3N_3Cl_5$, $P_3N_3Cl_5NSCl_2$ and $P_3N_3Cl_5OP_3N_3Cl_5$. The reaction course and the composition of the reaction mixture can be easily monitored by ^{31}P NMR spectroscopy. $P_3N_3Cl_5NSO$ and $P_3N_3Cl_5OP_3N_3Cl_5$ were isolated in the form of single crystals and their structures have been determined by X-ray structure analysis. The vibrational spectra of $P_3N_3Cl_5NSO$, $P_3N_3Cl_5NSNP_3N_3Cl_5$ and $P_3N_3Cl_5NSCl_2$ are also briefly discussed. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: Cyclotriphosphazene; thionylchloride; X-ray structural analysis; NMR spectra; vibrational spectra.

INTRODUCTION

The reactivity of NH_2- and NSO-group in partly substituted halogeno-*cyclo*-triphosphazenes was studied mainly on pentafluoroderivatives. $P_3N_3F_5NH_2$ reacts with $SOCl_2$ to give $P_3N_3F_5NSO$ (yield >80%) and $P_3N_3F_5NSNP_3N_3F_5$ (yield <5%). For the preparation of pure $P_3N_3F_5NSNP_3N_3F_5$ the thermal condensation of $P_3N_3F_5NSO$ in the presence of pyridine as an acceptor of SO_2 is recommended [1]. Reaction of $P_3N_3F_5NH_2$ with SF_4 yields $P_3N_3F_5NSF_2$ contaminated by small amounts of $P_3N_3F_5NSNP_3N_3F_5$ [1]. $P_3N_3F_5NPCl_3$ is available by the reaction of $P_3N_3F_5NH_2$ with PCl_5 [2].

$P_3N_3F_5NCO$ can be prepared either by the reaction of $P_3N_3F_5NH_2$ with $ClSO_2NCO$ [3] or $P_3N_3F_5NSO$ with $(COCl)_2$ [4]. $P_3N_3F_5NCS$ was obtained by the reaction of $P_3N_3F_5Cl$ with AgSCN. Under UV-light excitation it reacts with Cl_2 giving $P_3N_3F_5NCCl_2$ [3]. $P_3N_3F_5NCO$ or $P_3N_3F_5NCS$ reacts with dimethylamine yielding N-substituted derivative of urea or thiourea $P_3N_3F_5NHCON(CH_3)_2$ and $P_3N_3F_5NHCSN(CH_3)_2$, respectively [3]. Substituted amides $P_3N_3F_5NHCOR$ were obtained by the reaction of $P_3N_3F_5NSO$ with carbonic acids [4]. Reactions of $P_3N_3F_5NH_2$ with $(COCl)_2$ [5] and BCl_3 [6] lead to $(P_3N_3F_5NHCO)_2$ and $(P_3N_3F_5NH)_3B$, respectively. $P_3N_3F_5NSCl_2$ in high yield and purity arises from the reaction of $P_3N_3F_5NSO$ and PCl_5 [1]. However, the formation of -$NPCl_3$ derivative, which was observed in the reaction of C_6H_5NSO with PCl_5 [7], was not detected.

Surprisingly, from all possible reactions of $P_3N_3Cl_5NH_2$ with halides of non-metals only that with PCl_5 leading to $P_3N_3Cl_5(NPCl_3)$ was studied [8]. This contribution comprises the results of our study of the reaction of monoaminopentachloro-*cyclo*-triphosphazene, $P_3N_3Cl_5NH_2$ (**1**), with $SOCl_2$ which yields, besides expected $P_3N_3Cl_5NSO$ (**2**) and $P_3N_3Cl_5NSNP_3N_3Cl_5$ (**3**), two other compounds $P_3N_3Cl_5NSCl_2$ (**4**) and $P_3N_3Cl_5OP_3N_3Cl_5$ (**5**).

EXPERIMENTAL

All manipulations were carried out by using standard Schlenk techniques under dry air atmosphere. The solvents were purified and dried by common methods. $P_3N_3Cl_5NH_2$ was prepared by reaction of $P_3N_3Cl_4(NH_2)_2$ with gaseous HCl in acetonitrile [9]. $P_3N_3Cl_4(NH_2)_2$ was prepared according to the method [10] modified in [11]. $SOCl_2$ was received from Aldrich and purified by distillation before use. For reactions

†Author to whom correspondence should be addressed.

the fraction with the boiling point 76 C was used. IR spectra were measured with Bruker IFS 28 spectrometer in nujol mulls between KBr or AgCl discs. Raman spectra were recorded at Spex Ramalog 3 spectrometer. The samples were measured in sealed glass capillary tubes, the spectra were excited by the 488 nm line of a Spectra Physics Model 165-03 argon laser (100–200 mW). Emission lines of the Ar^+ plasma were employed for the spectral calibration. MS spectra were obtained on HP 5970 MSD spectrometer (70 eV, EI) connected with gas chromatograph GC 5890 HP. ^{31}P NMR spectra were recorded in thionylchloride solution on a Bruker 500 DRX spectrometer at 202.5 MHz with respect to 85% H_3PO_4 as an external standard for ^{31}P measurement and without solvent at 50.7 MHz with respect to liquid NH_3 as an external standard for ^{15}N measurement of liquid (**3**). The samples were sealed in Simax tubes and inserted in original Wilmad tubes (diameter 5 mm) filled with D_2O as an external lock.

X-ray structure analysis[1]

The intensity data were collected on a KUMA KM4 four-circle κ-axis diffractometer [12] equipped with a modified Nonius low-temperature device with ω–2ϑ scan ($2\vartheta_{max} = 50^\circ$) and a variable scan speed using graphite-monochromatized MoK_α ($\lambda = 0.70930$ Å) radiation. The stability of the crystal was checked by remeasuring of three reference reflections after every 60 measurements, no significant decrease in their intensities was observed. An empirical absorption correction based on psi-scan was applied for (**2**) during the data reduction process. Because the shape of crystals of (**5**) can be described as thin plate, empirical absorption correction (DIFABS [13]) was applied. T_{max} and T_{min} are 1.000 and 0.473 and 1.000 and 0.276 for (**2**) and (**5**), respectively. The structures were solved by direct methods and refined anisotropically by a full-matrix least-squares procedure on F^2. Details of the data collection and structure refinement both structures are presented in the Table 1. The lists of the structure factors can be obtained upon request from the authors Z. Ž (**2**) or J. M. (**5**). The structures were solved by SHELXS-86 [14] and refined by SHELXL-93 [15].

Preparation of $P_3N_3Cl_5NSO$ (2)

1.0 g (3.0 mmol) of $P_3N_3Cl_5NH_2$ was dissolved in 10 ml of $SOCl_2$ at laboratory temperature and the reaction mixture was heated under reflux for 3.5 h at atmospheric pressure. After the reaction mixture was cooled to laboratory temperature and the excess of thionylchloride was removed *in vacuo*, a white crystalline compound was obtained.

Yield: 1.1 g (2.94 mmol) 96.4%. M.p.: 71.5°C (in sealed capillary). MS: $m/z = 374$ ($P_3N_3Cl_5NSO^+$, 65.8%), 339 ($P_3N_3Cl_4NSO^+$, 100%), 337 ($P_3N_3Cl_4NSO^+$, 65.8%), 326 ($P_3N_3Cl_5N^+$, 7.9%), 312 ($P_3N_3Cl^+_5$, 60.5%), 258 ($P_3N_3Cl_3O^+$, 15.8%), 242 ($P_3N_3Cl^+_3$, 13.2%). RA: 215 s, 227 m, 237 sh, 266 vw, 293 vw, 339 sh, 345 s, 373 vs, 404 vs, 420 sh, 520 bvw, 579 w, 659 m, 687 w, 764 w, 787 w, 872 vw, 970 vw, 1146 s, 1165 bvw, 1264 w. IR: 542 sh, 528 m, 585 w, 602 m, 649 w, 687 vw, 865 vw, 875 sh, 975 vw, 1148 sh, 1160 m, 1207 vs, 1216 sh, 1272 m, 1342 w.

Preparation of $P_3N_3Cl_5NSNCl_5N_3P_3$ (3)

(a) 1.0 g (3.0 mmol) of $P_3N_3Cl_5NH_2$ was dissolved in 10 ml of $SOCl_2$ at laboratory temperature and was heated in a sealed Schlenk tube at 120°C for 24 h. The reaction mixture was then cooled to laboratory temperature and an excess of $SOCl_2$ and released gases were removed *in vacuo* and a yellow clear oil was obtained. Yield: 0.93 g (1.36 mmol); 89%.

(b) 1.0 g (2.67 mmol) of $P_3N_3Cl_5NSO$ was dissolved in 15 ml of dichloromethane and 0.56 g (2.67 mmol) of PCl_5 was added. The reaction mixture was shaken at laboratory temperature until complete dissolution of PCl_5. After removal of the solvent and volatile reaction products ($POCl_3$ and $SOCl_2$), a yellow clear oil was obtained.

Yield: 0.87 g (1.45 mmol); 94.8%. Analysis: $P_3N_3Cl_5NSNCl_5N_3P_3$ (684.490): P 26.17 (calc. 27.15), S 5.60 (4.68), C 51.30 (51.80)%. RA: 128 s, 150 vs, 169 vs, 197 vs, 205 sh, 221 s, 254 w, 300 vw, 313 sh, 321 w, 337 w, 355 sh, 369 s, 385 m, 415 s, 433 m, 465 sh, 497 vw, 526 vw, 569 bvw, 603 vw, 657 w, 697 w, 748 sh, 756 vw, 797 w, 812 vw, 822 vw, 1139vw, 1170 w, 1202 vw, 1271 bvw. IR: 417 w, 436 w, 472 vw, 528 vs, 539 sh, 563 s, 592 vs, 598 vs, 651 s, 692 w, 741 bvw, 794 vw, 878 w, 973 bvw, 1179 vs, 1263 s, 1342 sh.

Preparation of $P_3N_3Cl_5NSCl_2$ (4)

1.0 g (2.67 mmol) of $P_3N_3Cl_5NSO$ was dissolved in 15 ml of dichloromethane and 0.6 g (2.88 mmol) of PCl_5 was added. The reaction mixture was shaken at laboratory temperature until complete dissolution of PCl_5. By removing the solvent and evasive reaction products ($POCl_3$ a $SOCl_2$) a yellow oil was obtained from which microcrystalline product precipitated within 48 h at laboratory temperature. The crude product was washed twice with pentane and dried *in vacuo* yielding white microcrystals.

Yield: 0.11 g (0.26 mmol); 9.6%. M.p.: 154.5–155°C (in sealed capillary). MS: $m/z = 429$ ($P_3N_3Cl_5NSCl^+_2$, 36.4%), 393 ($P_3N_3Cl_5NSCl^+$, 72.7%), 358 ($P_3N_3Cl_5NS^+$, 18.2%), 312 ($P_3N_3Cl^+_5$, 77.3%), 254

RESULTS AND DISCUSSION

In analogy with $P_3N_3F_5NH_2$, (**1**) reacts with $SOCl_2$ yielding $P_3N_3Cl_5NSO$ (**2**). ^{31}P NMR spectroscopy showed that in boiling $SOCl_2$ at atmospheric pressure the conversion is quantitative in 3.5 h. Single crystals of (**2**) suitable for X-ray analysis can be obtained directly from the reaction mixture after partial removal of thionylchloride *in vacuo* at laboratory temperature.

If the reaction was performed in a sealed system at 80–120°C, compounds (**3**) and (**4**) were also detected by ^{31}P NMR spectroscopy. Heating of the reaction mixture to 120°C for 24 h leads practically to pure (**3**) formed probably by the condensation reaction of (**1**) with (**2**) and/or (**2**) with (**4**). The alternative way to preparation of (**3**) is the reaction of (**2**) with PCl_5 in dichlormethane which is finished at laboratory temperature in a few minutes. If an excess of PCl_5 is used, a small amount of (**4**) as an intermediate product of reaction can be detected and isolated. Thermal condensation, used for the preparation of $P_3F_5N_3P_3NSNP_3N_3F_5$ from liquid $P_3N_3F_5NSO$, is not applicable for solid (**2**) and has not been observed in its boiling dichlormethane solution yet.

Up to now, (**5**) was always detected as one of the products of controlled hydrolysis of $P_3N_3Cl_6$ [16, 17]. We isolated (**5**) during the attempts to separate (**4**) from the reaction mixture containing also (**1**), (**2**) and (**3**) after removal of $SOCl_2$ by extraction with pentane. Apparently, the formation of (**3**) is connected with condensation of (**1**) with (**2**) under the release of water, which can react further with some of the phosphazene derivatives presented in the reaction mixture to give (**5**). The formation of (**5**) is not possible in the reaction mixture containing $SOCl_2$, which gives SO_2 and HCl with water.

NMR spectroscopic data

^{31}P NMR data for compounds (**1**)–(**4**) together with the data for $P_3N_3Cl_4(NH_2)_2$ [8] and $P_3N_3Cl_4NH_2NCO$ [18] are presented in Table 2. Only ^{19}F NMR data are available for $P_3N_3F_5NSO$, $P_3N_3F_5NSCl_2$ and $P_3N_3F_5NSNP_3N_3F_5$. The ^{31}P NMR spectra of (**2**), (**3**) and (**4**) have always the character of simple AB_2 systems and consist of a doublet of the PCl_2 group in the range between 22.77 and 22.11 ppm and a triplet for PClX (X = NSO, $NSCl_2$ and $NSNP_3N_3Cl_5$) with

Table 2. ^{31}P NMR spectroscopic data for (**1**)–(**4**) and related compounds

Compound		^{31}P chem. shift (ppm)	$^{2}J(^{31}PN^{31}P)$ (Hz)

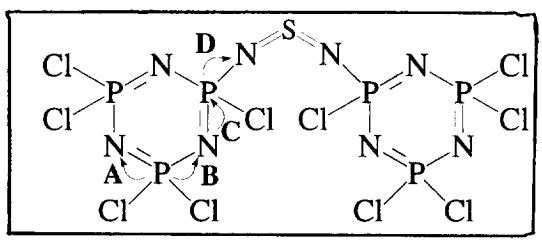
	$PClNH_2$	20.23 (t)	49.62
$P_3N_3Cl_5NSO$ (**2**)	PCl_2	22.77 (d)	
	PClNSO	0.84 (t)	53.35
$P_3N_3Cl_5NSNP_3N_3Cl_5$ (**3**)	PCl_2	22.11 (d)	
	PClNSN	8.06 (t)	53.97
$P_3N_3Cl_5NSCl_2$ (**4**)	PCl_2	22.55 (d)	
	$PClNSCl_2$	7.08 (t)	51.48
$P_3N_3Cl_4(NH_2)_2$ [8]	PCl_2	18.3 (d)	
	$P(NH_2)_2$	9.03 (t)	48.45
$P_3N_3Cl_4NH_2NCO$ [18]	PCl_2	21.50 (d)	
	PNH_2NCO	−3.20 (t)	59.00

chemical shifts from 8.06 to 0.84 ppm and coupling constants slightly over 51 Hz. Substitution of the amino group of (**1**) by -NSO or -$NSCl_2$ group in (**2**) or (**3**) and -$NSNP_3N_3Cl_5$ fragment in (**4**) results in a down-field shift of substituted phosphorus atom. Similar dependence was already reported [18].

The molecular structure of (**3**) has been confirmed



by 2D HETCOR ^{31}P–^{15}N NMR study. The obtained data suggests the presence of three NMR spectroscopic non-equivalent nitrogen atoms in the molecule, two of them making phosphazene cycle only. The ^{15}N NMR spectrum of (**3**) consists of a multiplet with chemical shift 112.0 ppm belonging to the $^{15}N_{endo}PClN_{exo}$ group, the multiplet at 123.0 ppm of $^{15}N(PCl_2)_2$ group and the multiplet at 185.5 ppm corresponding to the exocyclic ^{15}N atom. Observed ^{31}P–^{15}N coupling constants are $J(A) = 33$ Hz, $J(B) = 18$ Hz, $J(C) = 22$ Hz and $J(D) = 17$ Hz, respectively. Used experimental conditions are detailed in Ref. [19].

Available ^{31}P NMR data of (**5**) are summarized in Table 3. From the presence of the doublet for the PCl_2 group at 22.51 ppm and the triplet for the PClO group at 8.11 ppm a simple AB_2 spin system can be inferred from our ^{31}P NMR spectrum of (**5**). A simple character of this spectrum is in accordance with that reported in Ref. [16], although the published value of δ(PClO) seem to be somewhat high. On the other hand, the value of the chemical shift for the PClO group obtained in our study is in better agreement with results reported for (**5**) or similar P–O–P bridged phosphazene compounds (δ(PClO) in the range from 10 to −2.5 ppm) in Refs. [17, 20, 21]. However, second order spin systems were postulated in this papers. The relatively high value of J_{PNP} (58.93 Hz) suggests [21], in agreement with X-ray analysis, that (**5**) is a neutral molecule.

Vibrational spectra

The stretching vibrations of multiple bonds in -NSO, -$NSCl_2$ and -NSN-groups together with the antisymmetric stretching vibration of the phosphazene P_3N_3 cycle appear [1, 22–24] in the region 1100–1300 cm^{-1}. In Raman spectra the intensity of

Table 3. ^{31}P NMR spectroscopic data for (**5**)

Type	^{31}P chem. shift PCl_2 (ppm)	^{31}P chem. shift PClO (ppm)	$^{2}J(^{31}PN^{31}P)$ (Hz)	Refs.

AB_2	22.7 (d)	15.0 (t)	62.3	[16]
$AA'B_2B_2'$	21.8 (t)	2.9 (t), 2.3 (t)	not reported	[17]
	21.2 (t)	1.7 (t)		

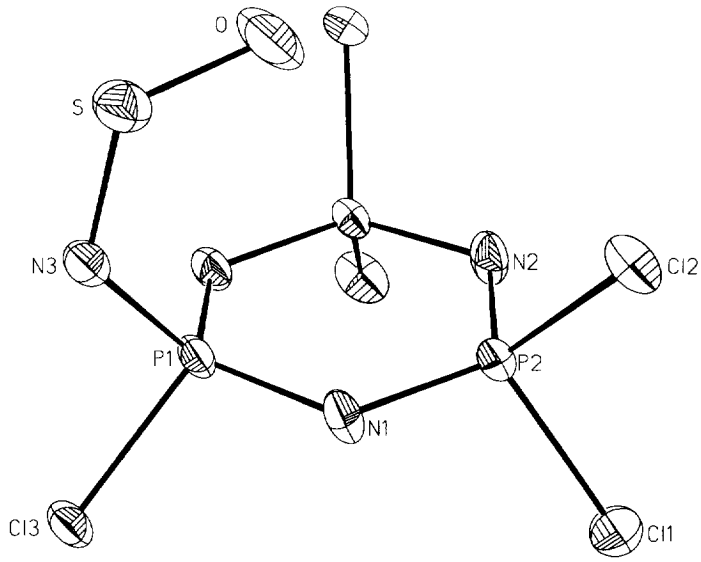

Fig. 1. View of the molecule of $P_3N_3Cl_5NSO$. The atoms are drawn as thermal ellipsoids at 50% probability level.

bands attached to ν (S=N) and ν (S=O) stretching vibrations are high, whereas in IR spectra these bands are weak. The ratio of intensities becomes reverse with bands of antisymmetric stretching vibrations of P_3N_3 cycle.

More bands than were expected for fundamental vibrations only were observed in the discussed region of all spectra. It can be explained for solid samples (**2**) and (**4**) as a consequence of crystal lattice arrangement. For example, in the Raman spectrum of (**4**) we observed the splitting of bands of ν N=S (1127 and 1169 cm^{-1}) and ν_{as} P_3N_3 (1226 and 1237 cm^{-1}), respectively. On the other hand, in the spectra of liquid sample (**3**) similar splitting was detected. Therefore the presence of bands of overtones or combination vibrations in the discussed region must be admitted [for example weak band at 1139 cm^{-1} in Raman spectrum of (**3**)].

Comparison of the vibrational spectra of (**1**)–(**4**) shows that stretching vibrations ν (P–N_{exo}) in (**2**) and (**4**) correspond to the bands with wavenumbers close to 870 cm^{-1}. In the case of (**3**) with two such bonds the corresponding pair of bands was observed at 794 and 878 cm^{-1}. In the Raman spectra of (**4**) the bands with wavenumbers 430 and 494 cm^{-1} can be assigned to the stretching vibrations ν_s and ν_{as} SCl_2, in agreement [1] with the results for $P_3N_3F_5NSCl_2$.

Description of the structures

The ORTEP [25] drawing of (**2**) is in Fig. 1 and bond lengths and angles are listed in Table 4. The

comparison of crystal data of (**1**) [9] and (**2**) shows that the substitution of -NH_2 by an -NSO group causes slight extension of the exocyclic P–N bond and contraction of endocyclic P–N bonds at the substituted phosphorus atom. A decrease in the value of the angle $N_{exo}PCl$ [100.2(2)° in (**2**) compared to 108.20(14)° in (**1**)] can be explained by the steric effect of the -NSO group. The six-membered ring P_3N_3 of (**2**) is deviated more significantly from planarity as in (**1**), the deviations of the P_1, N_1, P_2, N_2, P_{2A} and N_{1A} atoms from the least-squares plane fitted to P_3N_3 ring are −0.0695, 0.0113, 0.0114, −0.0390, 0.0113 and 0.0114 Å, respectively, which suggests a boat conformation of the P_3N_3 ring. The plane of the sulfinyl group is perpendicular to the plane formed by P and N atoms of the ring and thus the molecular symmetry of (**2**) is C_s. Bond lengths in the -NSO fragment of (**2**) agree very well with those found in organic -NSO derivatives [26–28] and their values [1.506(6) Å for S–N and 1.441(7) Å for S–O] suggest an important π-bond part (for single S–N and S–O bonds the lengths 1.76 and 1.69 Å were assigned [29]). The value of the angle [117.9(4)°] in the -NSO group of (**2**) is somewhat lower in comparison with those established in the compounds mentioned above.

Figure 2 shows the ORTEP [25] drawing of (**5**), bond lengths and angles are listed in Table 5. The crystal structure of the other crystal modification of (**5**) has already been published [17]. Both structures are monoclinic with the same space group ($P2_1/c$ and $P2_1/a$, respectively), but with different lattice parameters and Z: $a = 11.037$ Å, $b = 9.044$ Å, $c = 21.337$ Å, $\alpha = \gamma = 90°$, $\beta = 104.88°$, $Z = 4$ (our structure) and $a = 15.563$ Å, $b = 12.771$ Å, $c = 21.302$ Å, $\alpha = \gamma = 90°$, $\beta = 107.64°$, $Z = 8$ [17]. Comparison of both structures shows that values of bond lengths and angles in phosphazene rings are close. Significant differences were found for values of angles and bond lengths in the POP fragment when the POP angle [122.9(2)°] is smaller than those reported in Ref. [17] (128.8° and 135.6°). On the other hand, distances between bridged oxygen atom and adjacent phosphorus atoms are substantially longer, 1.663(4) and 1.650(4) Å, respectively (mean value reported in Ref. [17] is 1.594 Å).

BOOK REVIEW

Comprehensive Organometallic Chemistry Edition Pergamon, 1997. 14 Volumes.

It is hard to know where to start when reviewing superlative compendia like COMC. This set of 14 volumes covering the literature from 1982–1994 was edited by Abel, Stone and Wilkinson and is a great testament to their (and many authors') diligence and effort. Volumes covering all of the elements compile an excellent source of primary information. Furthermore, vol. 10 (M–M bonds), vol. 11 (main group organometallics in synthesis) and vol. 12 (transition metal organometallics in synthesis) provide excellent outlines of the usefulness of organometallic reagents. Volume 13 is a compendium of organometallic structures and vol. 14 provides a good culumative index.

It would be unfair to cite individual chapters for special mention. Dipping into individual volumes always provides some interesting chemistry which will doubtless spark new ideas. This is a super achievement and should be in every chemistry library. Individuals may find the price just a little bit taxing, though.

(Received 14 October 1997 : accepted 13 February 1998)

Abstract—Eleven mixed-ligand chelates of Ni(II) containing a molecule of *N*,*N*-di-, *N*,*N*,*N*′-tri-, or *N*,*N*,*N*′,*N*′-tetramethylethylenediamine, and a tropolonate (trop) or hinokitiolate (hino) ligand, were prepared, and their electronic spectra in solid state and in various organic solvents were studied. Most systems studied were green, containing octahedral chelate species $[Ni(trop/hino)(diamine)(H_2O/Solvent)_2]^+$ or $[Ni(NO_3)(trop/hino)(diamine)]$, but some were red, containing square planar $[Ni(trop/hino)(diamine)]^+$, and an equilibrium between the octahedral and square planar species was sometimes observed in solutions. Strong spectral resemblances with the corresponding diamine-β-diketonate chelates of Ni(II) could be pointed out. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: nickel(II) chelates; tropolonate; hinokitiolate; solvatochromism.

It is known that β-diketonates (β-dike) and *N*- or *N*,*N*′-alkylated ethylenediamines ($R_n$en) react with Ni(II) or Cu(II) to produce the mixed-ligand chelates, [M(β-dike)($R_n$en)]X (X is a univalent anion such as ClO_4^-), which are soluble both in polar and non-polar solvents exhibiting pronounced solvatochromic behaviors [1–3]. Such chelates may serve as visual indicators to estimate the polarities of organic solvents, with which their electronic spectra regularly vary [3].

We have recently reported on the solvatochromic properties of the mixed-ligand chelates of Cu(II) with *N*,*N*-/*N*,*N*′-di-, *N*,*N*,*N*′-tri-, or *N*,*N*,*N*′,*N*′-tetramethylethylenediamine and a tropolonate (trop) or hinokitiolate (hino; 4-isopropyltropolonate) ligand [4]. In continuation of the study, we tried to prepare similar chelates of Ni(II) and investigate their spectral behaviors. As was the case with the Cu(II) chelates, a close resemblance was found between the chelates obtained in this study and the corresponding diamine-β-diketonate chelates, in particular with respect to their solvatochromic behaviors, which will now be reported in this paper.

EXPERIMENTAL

Preparation of the chelates

All the reagents, including the solvent molecules, used for preparing the mixed nickel(II) chelates were commercial reagent grade chemicals and used without further purification. Tropolone and hinokitiol were supplied by Tokyo Chem. Ind. Co.

(i) $[Ni(trop)(tetmen)(H_2O)_2]ClO_4$ (**a**): Nickel(II) perchlorate hexahydrate (2 mmol, 0.73 g) was dissolved in a small amount of water, and an ethanolic solution (5 cm^3) containing equimolar amounts of *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (tetmen, 0.23 g) and tropolone (trop, 0.25 g) was added to it with

* Author to whom correspondence should be addressed.

stirring. After sodium carbonate (1 mmol, 0.11 g) was added to neutralize the solution, it was gently heated for 1 h and filtered. The filtrate was kept in a refrigerator for several days, and the green crystals precipitated were recrystallized from nitromethane. Yield : 0.56 g, 65%.

(ii) [Ni(trop)(tetmen)]$B(C_6H_5)_4$(**b**) : An excess amount of sodium tetraphenylborate (1.5 mmol, 0.51 g) was added to the suspension of **a** (1 mmol, 0.43 g) in 1,2-dichloroethane (10 cm^3) with stirring and gentle heating. After the insoluble residue was removed, the solution was kept in a refrigerator for several days to precipitate the red crystals. Yield : 0.26 g, 43%.

(iii) [$Ni(NO_3)$(trop)(tetmen)] (**c**) : Nickel(II) nitrate hexahydrate (2 mmol, 0.58 g) was dissolved in ethanol (5 cm^3), and a chloroform solution (15 cm^3) containing equimolar amounts of trop and tetmen was added to it with stirring. After an aqueous solution (0.5 cm^3) of sodium carbonate (1 mmol) was added to the solution, it was gently heated for an hour and filtered. The resulting solution was kept in a refrigerator for a week to precipitate the deep green crystals. Yield : 0.51 g, 71%.

(iv) [Ni(trop)(trimen)$(H_2O)_2$]ClO_4 (**d**) : Nickel(II) perchlorate hexahydrate (2 mmol), trop (2 mmol) and *N*,*N*,*N*′-trimethylethylenediamine (trimen, 3 mmol, 0.31 g) were mixed successively in acetone (5 cm^3). The resulting solution was evaporated to dryness on a hot plate and the residue was suspended in diethyl ether. The green powder obtained from the suspension was further treated with 1,2-dichloroethane (10 cm^3). After the insoluble residue was filtered off, the deep green crystals separated out immediately from the filtrate. Yield : 0.29 g, 35%.

(v) [Ni(trop)(trimen)]$B(C_6H_5)_4 \cdot H_2O$ (**e**) : This complex was prepared from **d** by the same method as that used for **b** ; 1.5 mmol of sodium tetraphenylborate was added to the suspension of **d** (1 mmol, 0.42 g) in 10 cm^3 of 1,2-dichloroethane. Yield : 0.15 g, 24%.

(vi) [$Ni(NO_3)$(trop)(trimen)] (**f**) : Nickel(II) nitrate hexahydrate (2 mmol) was mixed with trop (2 mmol) and trimen (3 mmol) in acetone (5 cm^3), and the solution was evaporated to dryness. The green powder obtained was extracted with 1,2-dichloroethane (5 cm^3), and the insoluble residue was removed. The resulting solution was evaporated to dryness again. The crude gummy product was suspended in diethyl ether (20 cm^3), and the green crystalline powder obtained was washed with diethyl ether thoroughly. Yield : 0.51 g, 74%.

(vii) [Ni(trop)(*NN*-dmen)$(H_2O)_2$]NO_3 (**g**) : An acetone solution containing the reaction mixture of nickel(II) nitrate hexahydrate (2 mmol), trop (2 mmol) and *N*,*N*-dimethylethylenediamine (*NN*-dmen, 3 mmol, 0.26 g) was evaporated to dryness. The green powder obtained was extracted with 1,2-dichloroethane (10 cm^3), and the oily residue was filtered off. The resulting solution was concentrated slowly at room temperature to precipitate the green crystals after a few days. Yield : 0.37 g, 51%.

(viii) [Ni(hino)(tetmen)$(H_2O)_2$]ClO_4 (**h**) : Hinokitiol (hino, 1.5 mmol, 0.25 g) and tetmen (1.5 mmol, 0.17 g) were added to a methanolic solution (10 cm^3) of nickel(II) perchlorate hexahydrate (1.5 mmol, 0.55 g), successively. The resulting suspension became a deep green solution by adding sodium carbonate (0.8 mmol, 0.08 g) with gentle heating. The solution was evaporated to dryness, and the green powder obtained was dissolved in 1,2-dichloroethane (10 cm^3) and filtered. The filtrate was kept in a refrigerator for several days. The green crystals which separated out were recrystallized from 1,2-dichloroethane. Yield : 0.42 g, 59%.

(ix) [Ni(hino)(tetmen)]$B(C_6H_5)_4 \cdot H_2O$ (**i**) : This complex was prepared from **h** by the same method as that used for **b** ; 1.5 mmol of sodium tetraphenylborate was added to the suspension of **h** (1 mmol, 0.47 g) in 10 cm^3 of 1,2-dichloroethane. Yield : 0.22 g, 32%.

(x) [$Ni(NO_3)$(hino)(tetmen)] (**j**) : Nickel(II) nitrate hexahydrate (1.5 mmol, 0.44 g) was mixed with hino (1.5 mmol) and tetmen (2.3 mmol, 0.27 g) in acetone (5 cm^3), and the solution was gently heated to dryness. The resulting solid was dissolved in 1,2-dichloroethane (10 cm^3) and then the insoluble residue was filtered off. After the filtrate was evaporated to dryness again, the green powder was extracted with three 10 cm^3 portions of diethyl ether. The combined ether solution was let stand for a day at room temperature to precipitate the deep green crystals which were recrystallized from diethyl ether. Yield : 0.24 g, 40%.

(xi) [Ni(hino)(*NN*-dmen)$(H_2O)_2$]NO_3 (**k**) : Nickel(II) nitrate hexahydrate (1.5 mmol) dissolved in methanol (5 cm^3), and a methanolic solution (5 cm^3) containing hino (1.5 mmol) and *NN*-dmen (1.5 mmol, 0.13 g) were mixed together, and sodium carbonate (0.8 mmol) was added to it with stirring and gentle heating. The solution was concentrated on a hot plate, and the oily product obtained was suspended in 1,2-dichloroethane (10 cm^3). The pale green powder isolated from the suspension was recrystallized from 1,2-dichloroethane. Yield : 0.51 g, 83%.

Attempts to prepare the mixed chelates containing hino and trimen in a pure form always failed in spite of many efforts.

Measurements

The visible and near-UV spectra of the chelates were recorded with a JASCO V-570 spectrophotometer at room temperature (ca 20°C). Solvents used for the spectral studies were GR or Spectro Grade products and were stored over molecular sieves (5 Å). The IR spectra were measured with a HORIBA FT-210 infrared spectrophotometer by the KBr disk and Nujol mull methods. The effective magnetic moments were evaluated from the susceptibilities measured by a Sherwood magnetic balance MSB-MKI. Thermogravimetry was carried out with a Seiko SSC/580

TG/DTA-30 apparatus. Each run was performed under a constant flow of nitrogen (0.2 $dm^3\ min^{-1}$) at a heating rate of 2°C min^{-1}; about 20 mg of sample was used.

RESULTS AND DISCUSSION

Structures of the chelates in solid state

Table 1 summarizes the solid-state properties and analytical data of the eleven mixed nickel(II) chelates obtained, and Fig. 1 shows the solid-phase (powder reflection) electronic spectra of some trop chelates. It can be seen that there are two types of chelates: the red diamagnetic ones with square planar geometry, which show a strong *d–d* band at ca 21×10^3 cm^{-1}, and the green paramagnetic ones with octahedral geometry, which show two weaker bands at ca 9×10^3 cm^{-1} (Band I) and 16×10^3 cm^{-1} (Band II), respectively [1,3,5,6]. All the tetraphenylborates belong to the former, while all the hydrated perchlorates, hydrated nitrates, and anhydrous nitrates (or nitrato chelates; cf. below) belong to the latter.

Among the chelates containing an NO_3^- ion, the spectrum of an anhydrous chelate is characteristically different from that of a hydrated chelate: (1) the Band II is notably stronger than the Band I in the former spectrum, while both are of comparable strength in the latter; (2) the Band I in the former is much broader than that in the latter, and is apparently split, indicating a stronger deformation of its geometry from octahedral symmetry. The case of **c** and **g** is compared in Fig. 1.

In this connection, it is also noted that hydrated nitrates (**g** and **k**) show a single IR band (a weak combination band of NO_3^-) at ca 1760 cm^{-1}, while anhydrous nitrates (**c, f** and **j**) show two such bands with a large separation (ca 50 cm^{-1}). These data imply that the nitrate ion in the hydrated nitrates is outside of the coordination sphere, while that in the anhydrous nitrates is a chelating nitrate ligand [7], which forms a 4-membered chelate ring with an anomalously small O—Ni—O angle [8].

The presence of two water molecules in chelates **a, d, g, h** and **k,** and one water molecule in **e** and **i** was also confirmed thermogravimetrically. Among the anhydrous chelates obtained by thermal dehydration, those from **a, d** and **h** are red, so that they should be formulated as square planar [Ni(trop/hino)(diamine)]ClO_4-type chelates. The anhydrous chelates from **g** and **k** are green, on the other hand, and their IR spectra show two bands around 1750 cm^{-1} with a large separation (42 and 33 cm^{-1}, respectively), implying that they are nitrato chelates [$Ni(NO_3)$(trop/hino)(*NN*-dmen)] like **c, f** and **j**.

All these considerations lead to the formulations of the obtained chelates given in Table 1.

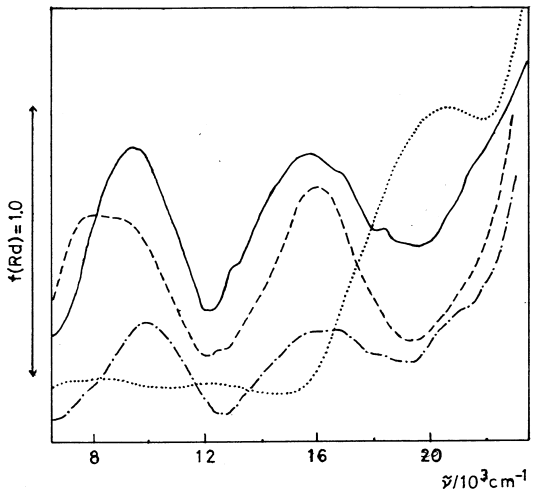

Fig. 1. Reflectance spectra of [Ni(trop)(tetmen)$(H_2O)_2$]ClO_4 (—), [Ni(trop)(tetmen)]$B(C_6H_5)_4$ (···), [$Ni(NO_3)$(trop)(tetmen)] (– –) and [Ni(trop)(*NN*-dmen)$_2(H_2O)_2$]NO_3 (— · —).

Structures of the chelates in solutions

The chelates obtained are, in most cases, slightly soluble in water, but they are fairly soluble in most organic solvents. Typical data of the electronic spectra of trop and hino chelates in various solvents are summarized in Tables 2 and 3, respectively. It can be seen that the red square planar species predominate in some solutions, but the green octahedral species (of the hydrated-chelate type spectra; *vide supra*) predominate in most others, and equilibrium mixtures of the two species occur in certain cases.

Figures 2 and 3 show the spectra of **a** and **b** in 1,2-dichloroethane (DCE), nitromethane (NM), THF and DMSO, respectively. In strongly polar and coordinating solvents like DMF, DMSO, and pyridine, the spectra of the two chelates are nearly identical, showing that the same octahedral species, most probably [Ni(trop)(tetmen)(Solvent)$_2$]$^+$, predominate in every case. In weakly polar and poorly coordinating solvents like DCE and NM, on the other hand, their spectra are that of the square planar species [Ni(trop)(tetmen)]$^+$ (so the chelate cation in **a** is readily dehydrated in such a solvent), whereas the very weak absorption in the red-to-IR region indicates that small amounts of octahedral species coexist in equilibrium with it. In solvents of intermediate coordinating power, such as alcohols, acetone and THF, the solutions are green, and their spectra are similar to those in strongly coordinating solvents; however, on heating they become yellowish to orange (thermochromism), and their absorption band around 21×10^3 cm^{-1} sensibly increases, forming a shoulder or hump at the skirt of the strong band of trop which appears at the blue end of the visible spectrum (this hump is most

clearly seen in THF even at room temperature; cf. Fig. 3). The equilibrium

$$[Ni(trop)(tetmen)]^+ + 2Solvent \rightleftharpoons [Ni(trop)(tetmen)(Solvent)_2]^+ \quad (1)$$

which is predominant in these solutions is thus shifted to the left hand side with the rise of temperature.

All these spectral behaviors are quite similar to those observed in the corresponding chelates with a β-diketonate ligand, in particular in those with an acetylacetonate (acac) ligand [1,3,7] of which trop is a vinylog [9], even with respect to the numerical values of $\tilde{\nu}_{max}$ of the individual case. A closer spectral comparison of **a** with that of its acac analogue [Ni(acac)(tetmen)$(H_2O)_2$]ClO_4 indicates however that, in solvents (ethanol, butanol, acetone and THF) where the equilibrium (1) is established, the relative concentration of the red species seems to be considerably lower in the case of **a,** although its reliable estimate is hindered by the strong blue band of trop which overlaps with its band too severely [10].

Figure 4 shows the spectra of **c** in the same solvents as those in Fig. 2. Here the predominating species is always green and octahedral, but there are evidently two kinds of them. The species formed in a strongly coordinating solvent (e.g. pyridine, DMF, DMSO, and now alcohols) shows nearly the same spectrum as that of **a** and **b** in the same solvent, i.e. [Ni(trop)(tetmen)$(Solvent)_2]^+$. The species formed in a less coordinating solvent shows a different spectrum, where the ε_{max} of the Band II is notably higher than that of the Band I, which is very broad with a somewhat split appearance. This latter species is most probably the undissociated nitrato chelate [Ni(NO_3)(trop)(tetmen)], in view of its spectral analogy with the solid chelates and, here again, with the corresponding β-diketonate chelates [1,3,6,8]. The pre-

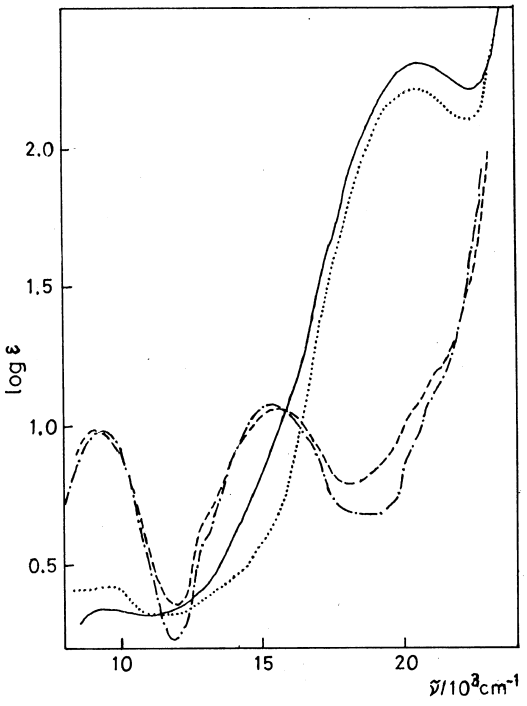

Fig. 2. Electronic spectra of $[Ni(trop)(tetmen)(H_2O)_2]ClO_4$ in DCE (—), NM(···), THF (– –) and DMSO (— · —).

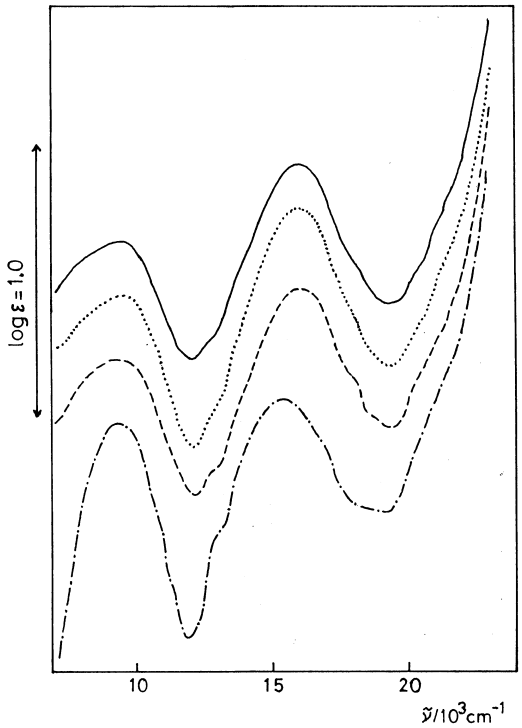

Fig. 4. Electronic spectra of $[Ni(NO_3)(trop)(tetmen)]$ in DCE (—), NM (···), THF (– –) and DMSO (— · —).

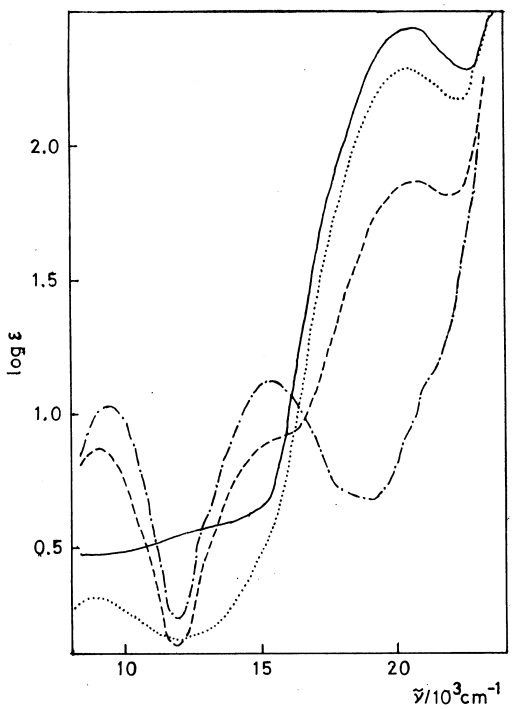

Fig. 3. Electronic spectra of $[Ni(trop)(tetmen)]B(C_6H_5)_4$ in DCE (—), NM (···), THF (– –) and DMSO (— · —).

dominating equilibrium in these solutions is, therefore, that of the dissociation/solvation of nitrato chelate, i.e.

$$[Ni(NO_3)(trop)(tetmen)] + 2Solvent \rightleftharpoons [Ni(trop)(tetmen)(Solvent)_2]^+ + NO_3^- \quad (2)$$

The spectra of the tetmen chelates of hino (**h, i** and **j**) are quite similar to those of the corresponding trop chelates (**a, b** and **c**). In addition, the solvatochromic behaviors of the trimen chelates of trop (**d, e** and **f**) can be understood similarly; even the change from tetmen to trimen does not alter the apparent solvatochromic changes of the chelates seriously, unlike the case of the Cu(II) chelates where the extent of solvatochromism depends sensitively on the structures of the diamine ligands [4]. On the other hand, the spectra of the hydrated nitrates with *NN*-dmen, **g** and **k,** which are probably formed as the result of decreased hydrophobicity of *NN*-dmen, show that they are readily dehydrated and dissolved as $[Ni(NO_3)$-(trop/hino)(*NN*-dmen)] in most solvents (even in DCE or NM, unlike the hydrated perchlorates **a, d** and **h** which are merely dehydrated into [Ni(trop/hino)(diamine)]$^+$ in them), and are converted into $[Ni(trop/hino)(NN\text{-dmen})(Solvent)_2]^+$ only in strongly coordinating solvents [11], as in the case of **c** and **j**.

A problem which still remains unsolved is whether the $[Ni(trop/hino)(diamine)(H_2O/Solvent)_2]^+$-type

chelate cations are *cis* or *trans*. Recent X-ray crystal structural studies of the corresponding acac-diamine chelates [12–14] proved that they are always *cis*, suggesting that the trop/hino-diamine chelates are also *cis*; there is still no direct evidence for it, however, and the reason why this structure is favored among these chelates is by no means clear. Further structural studies are now going on along these directions.

Structural characterization by ESR of copper complexes with unsymmetrical S,O or S,N bidentate thiourea derivative ligands

Emmanuel Guillon, Isabelle Déchamps-Olivier and Jean-Pierre Barbier*

G.R.E.C.I., Université de Reims Champagne-Ardenne, BP1039, 51687 Reims, Cédex 2, France

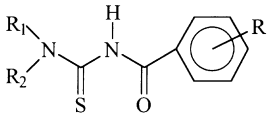
(Received 22 September 1997; accepted 12 March 1998)

Abstract—ESR spectra show the simultaneous presence of a planar *trans* and a nearly planar *cis* isomers in the 1:2 ratio for all "S,O" compounds $Cu(R_1R_2N\text{-}CS\text{-}N\text{-}COR)_2$ whereas an only isomer is present with the analogous "S,N" compounds. A strong tetrahedral distortion is observed when a bulky substituent is present on the nitrogen donor atom. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: thiocarbamide copper complexes; benzamidine copper complexes; ESR copper complexes.

In preceding papers [1–3], we have reported on the coordination of copper, nickel and cobalt with unsymmetrical bidentate ligands as:

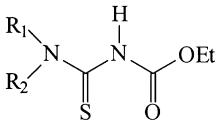
"S,O substituted" ligand
with R = H, Cl, Br, OCH_3 or NO_2
in *ortho, meta* or *para* position



$R_1 = R_2 = Et$ or $R_1,R_2N =$

Et_2R btu H morphR btu H

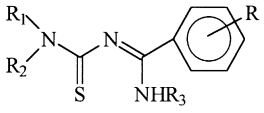
"S,O ethoxy" ligand



$R_1,R_2N =$ or

morph OEttu H or pyrro OEttu H

"S,NH_2" or "S,NHPh" ligand
if R_3 = H or Ph
with R = H or Cl



$R_1 = R_2 = Et$ or $R_1,R_2 =$

Et_2 tcR b H or { morph tcR b H ; morph tcPhR b H }

Whereas the configuration of diamagnetic cobalt complexes has been determined by ^1H and ^{13}C NMR spectroscopy, the geometry of the other complexes has not. The bis (*N*,*N*-diethyl,*N'*-benzoylthioureato) copper (II) has been investigated by Beyer *et al.* [4,5]: this compound can crystallize in three monoclinic forms. The crystal structure of one of these forms indicates that the S and O atoms are arranged in *cis* position in a slightly tetrahedrally distorted square geometry [4]. A single-crystal ESR study of this compound diluted in the corresponding *cis* nickel (II) chelate is in good agreement with this structure [5].

* Author to whom correspondence should be addressed.

Moreover, an X-ray structure analysis on the isosteric bis (*N*,*N*-diethyl-2-benzoylthioacetamidato) copper (II) has shown a simultaneous presence of two *cis* and one *trans* molecules in the unit cell [6]. In this paper, we report on the ESR study of the copper complexes in order to determine the influence of all substituents on their configuration.

EXPERIMENTAL

The "S,O" ligands were prepared as before by condensation of the morpholine or diethylamine with the benzoyl chloride or ethylformiate substituted by the ammonium thiocyanate [1, 2]. The "S,N" ligands were obtained from the nickel complexes with "S,O" ligands by substitution of the oxygen donor atom by chloride and then by ammoniac or a primary amine [3].

All the complexes were synthesized as described before, using copper (II) acetate or tetraethylammonium tetrachlorocuprate [1–3]. The ESR spectra of these complexes solutions (5×10^{-3} mol dm^{-3}) in chloroform-ethanol mixture (80–20) were obtained in the X-band at 77 K and at room temperature with a Varian E 109 spectrophotometer. The g values were measured relative to DPPH.

RESULTS AND DISCUSSION

The room-temperature solution ESR spectra show the typical four-lines patterns expected for coupling of the electron to the spin 3/2 copper (II) nucleus. ESR spectra of frozen solutions at 77 K are characterized by axial g and A tensors with $g_\parallel$ values $> g_\perp$ values. Three of the four parallel hyperfine features are well resolved while the fourth one at high field is overlapped in the broad $g_\perp$ signal. The g_0, $|A_0|$, $g_\parallel$ and $|A_\parallel|$ values could be readily determinated from spectra. As chloroform is a non coordinating solvent, dg_0/dT may be presumed negligible over the range 77–300 K, the $g_\perp$ and $|A_\perp|$ values could be calculated via the relationships $g_0=(g_\parallel+2\ g_\perp)/3$ and $|A_0|=(|A_\parallel|+2|A_\perp|)/3$ [7]. However, a possible small temperature dependence of $|A_0|$ renders approximate the values of $|A_\perp|$ derived from the room temperature $|A_0|$ values.

ESR spectra are similar for all the *N*,*N*-disubstituted, *N'*-benzoyl thioureas copper (II) complexes. At 77 K and at room temperature they show the presence of two four-line patterns. The two systems observed at room temperature involve the presence of two species and exclude the fact that the two four-lines systems arise from the isotopes ^{63}Cu and ^{65}Cu. Although the highest field $g_\parallel$ copper lines for the two isomers are superimposed on the $g_\perp$ copper lines, the partially resolved low field lines permit the determination of ESR parameters (Figure 1). The ESR parameters obtained from a single crystal of the *cis* $Cu(Et_2N\text{-}CS\text{-}N\text{-}CO\text{-}Ph)_2$ complex [5] are very close to our values for one system. By analogy with the isosteric $Cu(Et_2N\text{-}CS\text{-}CH\text{-}CO\text{-}Ph)_2$ complex, which present two *cis* and one *trans* molecules in the unit cell, the other system can be assigned to the *trans* isomer. All the EPR parameters are given in the Table 1. The $g_\parallel$ and $|A_\parallel|$ values indicate a square planar coordination geometry for the CuS_2O_2 moiety. All the spectra are almost superimposable. Whatever the electron-withdrawing or donor power and the *ortho*, *meta* or *para* position of the substituent on the aromatic ring, the consonant variation observed in $g_\parallel$ value is only of the same magnitude as the experimental error. In fact, the ESR parameters which relate to electron density in CuS_2O_2 plan are relatively insensitive to the substitution in these ligands aryl groups. Moreover the ratio $g_\parallel/|A_\parallel|$ is an indication of the stereochemistry of the copper (II) complexes. Addison has suggested that this ratio may be an empirical indication of the tetrahedral distortion of a square-planar geometry [8]. The values lower than 135 cm are observed for square-planar structures and those higher than 150 cm for tetrahedrally distorted complexes.

The lowest values of the ratio $g_\parallel/|A_\parallel|$ for the *trans* species are indicative of a planar *trans* arrangement whereas the slightly higher values of the ratio $g_\parallel/|A_\parallel|$ for the *cis* compounds indicate only a nearly planar *cis* arrangement as it is shown for the isosteric $Cu(Et_2N\text{-}CS\text{-}CH\text{-}COPh)_2$ compounds. It is noteworthy that the substitution of the aryl group by an ethoxy generates a small distortion around the metallic ion. These spectra were simulated with the following parameters $|A_0|=88\times10^{-4}$ cm^{-1}, $g_0=2.088$ for *cis* compounds and $|A_0|=76\times10^{-4}$ cm^{-1}, $g_0=2.097$ for *trans* compounds, with a line width equal to 10G. The sum of simulated spectra in the ratio *cis* 66% and *trans* 33% is in good agreement with the experimental spectra.

On the other hand, the ESR spectra of "$Cu(S,NH)_2$" compounds have only shown a nearly planar species in solution. The two bands at high field are well resolved and show five $(2nI_N+1)$ superhyperfine lines due to the interaction of the two nitrogen donor atoms ($I_N=1$) (Figure 2). Moreover, the spectra at 77 K which present, at high field, nine lines (eight and a shoulder), indicate unambigously a superhyperfine structure characteristic of an interaction with the two nitrogen donor atoms (Figure 3). The four supplementary lines can arise either from the two other non coordinated nitrogen atom or from the $g_\perp$ signal. All data are given in Table 2. The presence of a bulky substituent as phenyl on the nitrogen donor atom involves a tetrahedral geometry, the ratio $g_\parallel/|A_\parallel|$ being neighbouring 150 cm, with an important reduction of $|A_0|$ values.

The plot of $|A_\parallel|$ *vs* $g_\parallel$ (Figure 4) shows a linear relationship between $g_\parallel$ and $|A_\parallel|$ for each chro-

mophore. The $|A_\parallel|$ and $g_\parallel$ values are relatively insensitive to the inductive effect of the phenyl ring substituents and chiefly depend on the stereochemical factors as the redox properties. The $g_\parallel$ values are weaker in the "S,N" compounds in agreement with the more electron donating character of the nitrogen atom.

This study has shown the simultaneous presence of *cis* and *trans* isomers in the ratio 2:1 for all the "S,O" compounds as in the isosteric $Cu(Et_2N\text{-}CS\text{-}CH\text{-}CO\text{-}Ph)_2$ compound, whereas an only configuration seems present in the "S,N" complexes. The ratio $g_\parallel/|A_\parallel|$ is an empirical index of the tetrahedral distortion and the studied compounds can be arranged in the order square planar *trans* $Cu(S,O\ substituted)_2 \approx Cu(S,NH)_2 <$ *cis* $Cu(S,O\ substituted)_2 \approx$ *trans* $Cu(S,O\ ethoxy)_2 <$ *cis* $Cu(S,O\ ethoxy)_2 <$ strong tetrahedrally distorted $Cu(S,NPh)_2$.

(Received 21 October 1997; accepted 3 March 1998)

Abstract—Two isomeric complexes, $[CuL_2](NO_3)_2 \cdot 2H_2O$, (**1**, red) and $[CuL_2](H_2O)](NO_3)_2 \cdot H_2O$, (**2**, blue) (L = N^1-isopropyl-2-methyl-1,2-propanediamine) have been synthesised and their X-ray crystal structures have been determined. Both the isomers possess the same space group, $P2_1/n$. However, **1** is square planar and **2** is square pyramid having N_4 and N_4O chromophore, respectively around copper(II). The red isomer (**1**) upon heating loses water molecules yielding a violet dehydrated species, **1a** which on further heating undergoes an exothermic phase transition accompanied by thermochromism, violet (**1a**) to blue-violet (**1b**) in the solid state. (**1a**) and (**1b**) are probably conformational isomers and they revert to **1** in humid atmosphere. The blue isomer (**2**) upon heating transforms to blue-violet species on dehydration, which reverts immediately after cooling in open atmosphere. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: copper(II) nitrate; N^1-isopropyl-2-methyl-1,2-propanediamine; thermochromism; single crystal structure; isomer.

Thermochromism phenomena in nickel(II) and copper(II) complexes with N,N-diethyl-1,2-ethanediamine having counter anion as ClO_4^- and BF_4^- were studied extensively [1–5]. It was established that the sudden colour change in these compounds is due to the onset of dynamic disorder of diamine chelate rings. Later, a similar kind of thermochromism has been observed with other diamines (C-substituted [6, 7] and N-substituted [8]) with NO_3^- as counter anion which is coordinated in both the phases. In those studies it was found that the nature of substitution and the counter anion are very crucial for the thermochromic phase transition. Recently, we reported novel thermochromic phenomenon of nickel(II) salts using N^1-isopropyl-2-methyl-1,2-propanediamine [9, 10]. In these studies it was observed that slight variation of the experimental condition yielded different species. In the present paper we report the syntheses of two isomers of N^1-isopropyl-2-methyl-1,2-propanediamine copper(II) nitrate, their crystal structures and thermochromism in the solid state.

EXPERIMENTAL

General details

All the chemicals used were of A.R. grade. High-purity N^1-isopropyl-2-methyl-1,2-propanediamine

Non-SI unit employed: $\mu_B \approx 9.27402 \times 10^{-24}\,JT^{-1}$.

† Corresponding author.

(Aldrich) and $Cu(NO_3)_2 3H_2O$ (Merck) were available commercially. Analyses (C, H and N) were made by a 2400 (Series II) Perkin-Elmer elemental analyser. IR (in KBr and in nujol) and electronic spectra (in nujol) were recorded on a Perkin-Elmer IR (model 783) and Hitachi UV-VIS-NIR (model U-3410) spectrophotometer, respectively. The effective magnetic moments were evaluated from magnetic susceptibility measurements with an EG and G PAR 155 vibrating magnetometer. The thermal analyses (TG–DTA) were carried out on a Shimadzu DT-30 thermal analyser in dynamic atmosphere of dinitrogen (flow rate: 30 $cm^3 min^{-1}$). The sample (particle size within 150–200 mesh) was heated in a platinum crucible at a rate of 10°C min^{-1} with inert alumina as reference. The enthalpy changes of phase transformations were calculated using a Perkin-Elmer (model DSC-7) differential scanning calorimeter with indium metal as a calibrant (rate of heating 10°C min^{-1}).

Preparation of $[CuL_2](NO_3)_2 \cdot 2H_2O$ (**1**)

This was prepared by adding N^1-isopropyl-2-methyl-1,2-propanediamine (2 mmol) dropwise to copper(II) nitrate trihydrate (1 mmol, 241.6 mg) dissolved in ethanol-water (9:1) (10 cm^3) on stirring. The resulting violet solution on slow evaporation in a desiccator yielded the desired red crystalline complex. The crystals were separated, washed with ethanol and dried in a desiccator. Found: C, 34.8; H, 8.4; N, 17.3; Cu, 13.2. Calc. for $C_{14}H_{40}N_6O_8Cu$: C, 34.7; H, 8.3; N, 17.4; Cu, 13.1% μ_{eff} 1.64 μ_B, λ_{max} (nujol) 481 nm. Single crystals suitable for X-ray single crystal analysis were obtained by the diffusion technique from methanol and diethylether layer.

Preparation of $[CuL_2(H_2O)](NO_3)_2 \cdot H_2O$ (**2**)

N^1-isopropyl-2-methyl-1,2-propanediamine (3 mmol) was added dropwise to copper(II) nitrate trihydrate (1 mmol, 241.6 mg) dissolved in methanol on stirring. The resulting violet solution on slow evaporation in a desiccator yielded the desired blue crystalline complex. The crystals were separated, washed with methanol and dried in a desiccator. (Found: C, 34.7; H, 8.3; N, 17.4; Cu, 13.1. Calc. for $C_{14}H_{40}N_6O_8Cu$: C, 34.7; H, 8.3; N, 17.4; Cu, 13.1%) μ_{eff} 1.72 μ_B, λ_{max} (nujol) 652 and 580 nm. Recrystallisation from methanol yielded a mixture of blue and red crystals. The blue crystals were separated carefully and used for X-ray analysis.

X-ray data collection and structure refinement

Crystallographic data for complexes **1** and **2** are summarised in Table 1. Both the structures were solved by the heavy-atom method and refined by the full-matrix least-squares procedures. The H-atom positions were mostly found from the difference Fourier maps, the remaining were fixed at appropriate geometries. The refinement parameters are given in Table 1. All computations were carried out on a PDP-II/73 computer using Structure Determination Package (SDP) available from Enraf Nonius [11]. The selected bond distances and angles of complexes **1** and **2** are listed in Table 2. Recognised strong hydrogen bonds are given in Table 3. Table 4–13 containing the final positional parameters of non-hydrogen atoms, along with their isotropic equivalent temperature factors, complete bond distances and bond angles, anisotropic thermal parameters, H-atom coordinates, and list of observed and calculated structure factors for **1** and **2** are parts of supplementary materials.

RESULTS AND DISCUSSION

The red species, $CuL_2(NO_3)_2 \cdot 2H_2O$ (**1**) is generated on mixing copper(II) nitrate trihydrate and diamine in exactly 1:2 ratio in ethanol-water (9:1). Addition of excess ligand to the Cu-salt (*ca.* 3:1 ratio) in the same solvent yields a mixture of red and blue isomers. The pure blue species (**2**) is produced in presence of excess diamine when methanol is used as solvent. However, on recrystallisation either from methanol and ethanol-water, the blue species yields a mixture of red and blue isomers. The water molecules in complex **2** which is synthesised from methanol, comes from the hydrated Cu-salt as there is no other apparent source.

Structures of (**1**) *and* (**2**)

ORTEP [12] view of the complex molecules **1** and **2** with the two NO_3^- ions and water molecules are shown in Figs 1 and 2. Both the isomers (**1** and **2**) possess space group $P2_1/n$ but they differ in geometry. In structure **1** four nitrogen atoms from the two diamine molecules provide the tetra coordination which has a bias towards tetrahedral distortion, the deviation of N(1), N(2), N(3) and N(4) from the best plane through them is ± 0.08 Å. An additional long axial coordination from O(1w) (Cu(1)...O(1w) = 2.205(5) Å) makes the Cu(II) environment as square-pyramidal in **2**, the base of the pyramid is much more distorted tetrahedral than in **1**, the deviations of N(1), N(2), N(3) and N(4) are ± 0.11 Å from the least square plane and the displacement of Cu atom is 0.31 Å towards O(1w) from this plane. Average of Cu–N(primary amine) distances Cu(1)–N(2) and Cu(1)–N(3) is 1.987(3) Å for **1** and 2.003(3) Å for **2**, whereas average of Cu to secondary amine bonds Cu(1)–N(1) and Cu(1)–N(4) is more, 2.028(3) Å and 2.129(3) Å for **1** and **2**, respectively. The tendency of metal-nitrogen (primary) lengths shorter than the metal-nitrogen (secondary) lengths is noticed in N-substituted amines [13], and particularly reported for copper complexes of this ligand, with different anions [13, 14]. Bite angles N–Cu–N vary from the ideal value of 90°, which are

$R = \Sigma \| F_0 | - | F_c \| / \Sigma | F_o |$, $wR = [\Sigma w(F_0^2 - F_c^2) / \Sigma w(F_0^2)^2]^{1/2}$, $w = 1/[\sigma^2(F_0) + p(F_o)^2]$

slightly larger in **1** (average 84.8(1)°) than in **2** (average 83.5(2)°) (Table 3). Bond lengths and bond angles in the ligand moiety of **1** and **2** are similar except for the presence of a rather long bond C(3)–C(11) = 1.567(8) Å in **1**, which is also reported in the structure of Ni, Cu, Zn and Cd complexes of the same ligand [10, 14, 15, 16]. Conformations of N^1-isopropyl-2-methyl-1,2-propanediamine chelate ring are envelopes in both the structures (Figs 1 and 2); the deviations of the flap atoms C(2) and C(3) are 0.51 Å and 0.71 Å, respectively in **1** and 0.60 Å and 0.63 Å, respectively in **2**. The isopropyl groups in **2** are rotated about the N(1)–C(7) and N(4)–C(12) bonds in such a way that positions of C(8) and C(13) are essentially same as in **1** but the C(9) and C(14) are rotated away from the incoming water O(1w) to avoid the steric hindrance. This is clearly reflected in the torsion angles C(1)–N(1)–C(7)–C(8) and C(1)–N(1)–C(7)–C(9) are 52.6(1)° and −72.6(1)°, respectively in **1**, whereas these values are 57.6(1)° and 179.7(1)°, respectively in **2**. Similarly torsion angles C(4)–N(4)–C(12)–C(13) and C(4)–N(4)–C(12)–C(14) are 54.2(1)° and −72.5(1)°, respectively in **1** but 55.8(1)° and 178.0(1)°, respectively in **2**.

Intermolecular interaction

In both the structures, NO_3^- anions present in the crystal lattice take part only in the hydrogen bonding interactions with the amine nitrogens of the ligand, but do not coordinate to the metal ion directly. However, the role of anions is very significant in governing the intermolecular interactions that influence the thermochromic behaviour in solid state. It may be mentioned here that the ClO_4 [13] and NO_3 [14] salts

of Cu-complexes with the ligand under investigation are nonthermochromic. There are extensive hydrogen bonding network between the oxygens of the nitrates, water molecules and the N–H groups of the ligand (Table 3). Remarkably, the two nitrate groups have their H-bond attachments with the ligand conserved in both the structures a strong H-bond N(3)–H(2)N(3)...O(1) (from the nitrate group N(5), O(1), O(2), O(3)) and N(3)–H(1)N(3)...O(5) (from the nitrate group N(6), O(4), O(5), O(6)) are retained in the two isomers (Table 3). The hydrogen bonding interactions of the two water molecules are in a sense

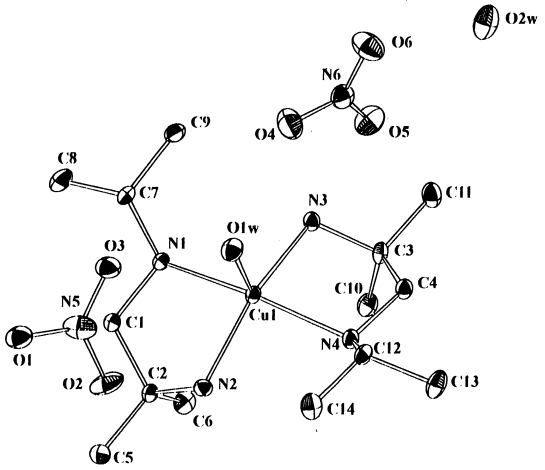

Fig. 2. ORTEP view of $[CuL_2(H_2O)](NO_3)_2 \cdot H_2O$ **2**.

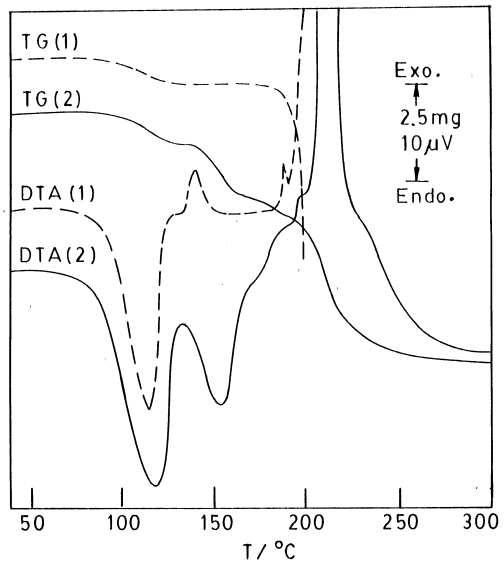

Fig. 3. TG and DTA curves of $[CuL_2](NO_3)_2 \cdot 2H_2O$ **1** (weight taken = 8.32 mg - - -) and $[CuL_2(H_2O)](NO_3)_2 \cdot H_2O$ **2** (weight taken = 10.14 mg ———).

complementary in the two structures, O(1w) makes H-bonding interactions with N(2), O(4) and O(2w) makes only single interactions with N(4) in **1**; O(1w) upon coordination to the Cu(II) ion in **2** retains only the interactions with O(4), the H-bond lost with N(2) and O(6) are provided by the water molecule O(2w). It is worth noting that the thermal anisotropies of the water molecules O(1w) and O(2w) are higher in **1** compared to **2.** It is tempting to surmise that free water molecules and anions upon heating would enhance their thermal vibrations furthermore, creating a dynamic situation for the thermochromic phase transition to take place.

Thermal analysis and thermochromism

The simultaneous thermogravimetric analyses and differential thermal analysis (TG–DTA) of complexes of **1** and **2** are shown in Fig. 3. The weight loss observed in the TG curves in the temperature regions (80–120°C and 80–130°C, for **1** and **2**, respectively) corresponds to the liberation of two molecules of water. In complex **1** (red), the dehydration proceeds endothermally resulting in a violet species (**1a**). **1a** on further heating undergoes an exothermic phase transformation (138–160°C; $\Delta H = -6.4\,kJ\,mol^{-1}$) and transforms to **1b** associated with a colour change, violet to blue-violet. The species, **1b** is metastable and transforms to **1** on keeping in a humid atmosphere for a few h. In a P_4O_{10}-desiccator, however, it slowly reverts to **1a** and the reversion completes in several days. The dehydrated species of complex **2** is extremely hygroscopic and transforms to **2** immediately on exposure to open atmosphere. Moreover, complex **2** starts to decompose (140°C) immediately after dehydration. Therefore, isolation and characterisation of the dehydrated species of **2** in pure form is difficult.

Electronic spectra and magnetic moments

The electronic spectrum (Fig. 4) of the red species **1** shows a broad band at 481 nm and that of the blue species shows a broad band at 580 nm and a shoulder at 653 nm consistent with the square planar geometry in the former and the axial interaction of the water molecule in the later [4]. The band position of higher

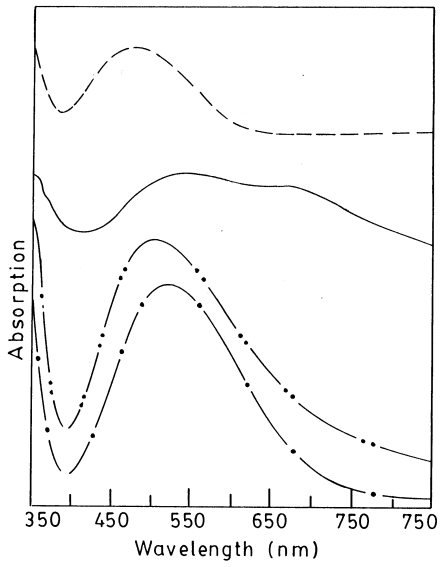

Fig. 4. Electronic spectra (nujol) of $[CuL_2](NO_3)_2 \cdot 2H_2O$ **1** (—-), $[CuL_2](NO_3)_2$ **1a** (—— ——), $[CuL_2](NO_3)_2$ **1b** (- -) and $[CuL_2(H_2O)](NO_3)_2 \cdot H_2O$ **2** (———).

energy of the red complex is also compatible with the increased involvement of the copper orbitals with the in-plane ligands due to electronic or steric reasons. The electronic spectra of **1a** and **1b** are very similar to that of **1** consisting of a broad structureless band in the visible region suggesting retention of square planar geometry in both of them. The only difference is that the band positions are shifted towards lower energy.

The magnetic moments of all the complexes are around 1.7 μ_B, indicating the presence of one unpaired electron in all of them.

Infrared spectra

IR spectroscopy in the region 1700–1800 cm^{-1} where a weak combination band of the ν_1 symmetric stretching and the doubly degenerate in-plane bending mode of NO_3^- ion in a metallic complex appear was used by several groups of researchers to determine the coordination mode of the NO_3^- ion [17–20]. It is believed that an ionic nitrate group gives rise to one relatively strong and very sharp peak at *ca.* 1750 cm^{-1} while coordinated nitrate groups give two peaks with the bidentate coordination mode giving a wider separation (20–66 cm^{-1}) of these two peaks than the unidentate coordination mode (5–26 cm^{-1}). X-ray single crystals analyses of **1** and **2** show that the NO_3^- ions are free in both of them. Therefore, a single relatively strong peak is expected at *ca.* 1750 cm^{-1}. The IR spectra in nujol mull however, show two additional peaks in this region. It is very difficult to assign whether those peaks correspond to i) the splitting of the combination band or ii) to the appearance of some other combination bands or iii) to the intermolecular or intramolecular correlation coupling of the nitrate groups. However, considering the uncoordinated mode of the NO_3^- ion only the peak near 1730 cm^{-1} is considered here as the combination band. The IR spectra of **1a** and **1b** in this region are very similar to complex **2**; thus the NO_3^- ions in both of them are considered as uncoordinated. The IR spectra of **1a** and **1b** differ appreciably in the regions of 3300–3100, 3000–2800, 1400–1350, 1330–1100 and 1000–430 cm^{-1} where the vibrations of $\nu(NH_2)$, $\nu(CH_2)$, $\rho w(CH_2)$, $\tau(NH_2)$ + $\rho w(NH_2)$ + $\tau(CH_2)$, and $\rho w(NH_2)$ + ν(M–N) appear. In our earlier studies it was observed that the isomers which differ only in the conformations of the diamine chelate rings usually show such differences [21, 22].

Conclusion

The single crystal X-ray analysis, IR and electronic spectra of the complexes reveal that the red complex (**1**) retains its square planar geometry on deaquation. The deaquated species on further heating undergoes thermochromic phase transition due to conformational isomerism. The blue isomer (**2**), on the other hand, is square pyramidal, having an additional coordination from one of the water molecules. It starts to decompose immediately after deaquation. Thus the characterisation and thermal studies of the deaquated species (from **2**) was not possible.

(Received 10 December 1997; accepted 3 March 1998)

Abstract—A vanadium(V) dimer [{$VO_2(py)_2$}$_2$(μ–C_2O_4)] **1**, has been isolated from a solution of [VO(sal–Phe)(H_2O)] **2** (sal–Phe = N–salicylidene–L–phenylalaninate) in H_2O/pyridine. Its crystal and molecular structure has been determined by X-ray diffraction analysis, the oxalate acting as a symmetrical bis(chelating) bridge. Possible mechanisms for the formation of oxalate are briefly discussed. © 1998 Elsevier Science Ltd. All rights reserved

Complexes of metal ions with N–salicylideneamino acids serve as model systems for pyridoxal-potentiated enzymes [1] and several studies [2–9] have focused on vanadium in this context.

Several unusual reactions have been recently reported involving such systems. One case involves the reaction of VO^{2+} with salicylaldehyde, D, L-asparagine (D,L-Asn) and pyridine, first forming [VO(sal–D,L–Asn)(py)(H_2O)]; ageing with di-oxygen produced coumarine–3–carboxamide [10]. Other coumarine–3–carboxamides are produced starting with salicylaldehyde derivatives [11]. These reactions cannot be simply explained by mechanisms described for pyridoxal model systems [12]. Another interesting reaction occurred from solutions of [VO(sal–L–Trp)(H_2O)] (L–Trp = L–tryptophan) in H_2O/pyridine. Brown crystals of $(Hpy^+)_4(L^+)_2[V_{10}O_{28}{}^{6-}]$ (py = pyridine, $L^+ = C_{14}H_{13}N_2$, product of the condensation of the tryptophan side group with pyridine), have been isolated after 4 weeks and characterized by X-ray crystallography [13]. The formation of L^+ can be explained assuming a mechanism similar to that for model systems of pyridoxal-potentiated enzymes [12], which involves the release of the side group of the amino acid [13].

The present paper describes the synthesis and characterization (by X-ray crystallography and IR) of the vanadium(V) dimer [{$VO_2(py)_2$}$_2$(μ–C_2O_4)] **1** containing a bridging bis(chelating) oxalato ligand. Part of this work has been communicated [14]. Rather similar dinuclear complexes are known with crystal and molecular structures determined by X-ray diffraction, *e.g.*[$Ni(NO_2)(py)_3$–μ–(ox)–$Ni(NO_2)(py)_3$].2py [15] **3** (py = pyridine, ox = oxalate), [$Ru(NO_2)(py)_4$–μ–(ox)–$Ru(py)_4$].(BF_4) [16] **4**, [{Cu(terpy)(H_2O)}$_2$(ox)].[{Cu(terpy)}$_2$(ox)].(ClO_4).2H_2O] [17] (terpy = 2,2′:6′,2″–terpyridine), [Cu(bipy)(H_2O)–μ–(ox)–Cu(bipy)(H_2O)]$^{2+}$.[Cu(bipy)(ox)](NO_3^-)$_2$ [18]. (bipy = 2,2′–bipyridyl). Many other dinuclear complexes with the oxalate ion functioning as a bridging bis(chelating) ligand were characterized by X-ray diffraction [19–30]; most are dimeric compounds of Ni(II) or Cu(II) with interesting magnetic properties. A similar bis-bidentate bridging oxalate has been proposed for several other complexes mainly by consideration of the infrared spectra (*e.g.* [31–33]). These include the dinuclear vanadium(IV) complexes (Ct)$_2$[$V_2O_2Cl_4$(ox)(H_2O)$_2$].2H_2O (Ct = $(CH_3)_4N$), $(C_2H_5)_4N$) [33]. There are, of course, several vanadium complexes [34] with

*Author to whom correspondence should be addressed.

the oxalate acting as a bidentate ligand, including several compounds characterized by single crystal X-ray diffraction [21, 35, 36, 37]. All these, from **3** onwards, required oxalate ion for their synthesis, in contrast to **1**, which involves the unexpected formation of oxalate.

EXPERIMENTAL

Reagents and apparatus

[VO(sal–Phe)(H_2O)] **2** (sal–Phe = N–salicylidene–L–phenylalaninate) was prepared as described earlier [6, 38]. This (0.25 g, 0.71 mmol) was dissolved in the minimum amount of pyridine ($\approx$1.5 ml), and $\approx$0.2 ml of water were added. The mixture was kept at $\approx$4°C in a small tube with a polyethylene stopper. After a week the brown solution became yellow and after $\approx$3 months yellow crystals of **1** were separated. No recrystallization was needed. The compound is slightly sensitive to moisture, but can be kept in its mother liquor for several months. The FTIR spectrum of **1** was recorded with the solid dispersed in KBr disk using a Perkin-Elmer 1720 spectrometer.

The reaction was repeated twice and is reproducible; in these two distinct batches **1** was isolated and characterized by FTIR and/or determination of cell constants.

X-ray crystal structure determination of complex **1**

Crystal data. $V_2O_4(C_2O_4)(C_5H_4N)_2$, $M_r = 285.1$, monoclinic, space group $P2_1/c$, $a = 6.267(1)$, $b = 19.432(3)$, $c = 10.626(1)$ Å, $\beta = 103.13(1)°$, $V = 1260.2(3)$ Å^3, $Z = 4$, $F(000) = 580$, $D_c = 1.50$ g cm^{-3}, μ(Mo–K_α) = 7.94 cm^{-1}. Crystal dimensions 0.37 × 0.20 × 0.18 mm.

Data collection. X-ray measurements were made at room temperature with a Siemens P4 diffractometer and graphite monochromatized Mo–K_α radiation ($\lambda = 0.71073$ Å). Cell dimensions were determined from the measured θ-values for 40 intense reflections with $8.9 < \theta < 24.8°$. 4475 reflections were scanned in the range $1 < \theta < 30°$ by the ω–2θ scan mode, and of these 3635 were independent ($R_{int} = 0.025$). Examination of three standard reflections, monitored after 97 scans, showed no sign of crystal deterioration. Data were corrected for Lorentz and polarization effects, and also for absorption effects using an empirical method based on azimuthal scan data.

Structure determination and refinement. The structure was solved by direct methods and subsequent Fourier differences and refined by full-matrix least-squares using anisotropic thermal parameters for non-hydrogen atoms. The hydrogen atoms were located from a differential Fourier synthesis and placed in idealised positions (C–H = 0.96 Å) riding on their respective bonded atoms. The final refinement was carried out with a weighting scheme of $w = [1/\sigma^2(F_0) + 0.0004F^2_0]$ and converged to $R(F) = 0.043$ and $R_w(F) = 0.043$ for 2274 reflections with $F_0 > 4\sigma(F_0)$ and 163 refined parameters. The largest negative and positive peaks in the final difference map were 0.31 and -0.27 e Å^{-3} and were located near the vanadium atoms. All calculations were performed on an Silicon Graphics Iris Indigo XS24 computer using the SHELXTL-IRIS program package [39].

Additional material is available from the Cambridge Crystallographic Centre: it comprises hydrogen atom co-ordinates, atomic thermal motion parameters, remaining bond lengths and angles and a list of observed and calculated structure factors.

RESULTS AND DISCUSSION

The solid dimer **1** was isolated from H_2O/pyridine solutions. Although pyridine and bipyridyl may stabilise oxovanadium(IV) complexes [4, 6, 9, 34, 40], the formation of a vanadium(V) compound may be explained by the slow diffusion of atmospheric dioxygen into the solution, and its reaction with oxovanadium(IV). Several examples of similar oxidations have been reported (*e.g.*[5, 6, 41]).

A molecular diagram presenting the numbering scheme is shown in Fig. 1; selected bond distances and bond angles are listed in Table 1. The crystal contains two centrosymmetrical binuclear molecules per unit cell, with the vanadium(V) ions separated by 5.787(1) Å and bridged by a bis-bidentate oxalate group. The co-ordination geometry around each vanadium atom is distorted octahedral; the equatorial positions are occupied by two vanadyl oxygen atoms [O(1) and O(2)] and two oxalate oxygen atoms [O(3)

O(3)–C(11)–C(11A)	115.9(2)	O(4A)–C(11)–C(11A)	116.5(2)

Atoms labelled with letter A are related to respective atoms by symmetry operation 1–x, 1–y, 1–z.

and O(4)] from the two different carboxylate groups, whereas the apical positions are occupied by two nitrogen atoms [N(1) and N(2)] of two pyridine ligands. The bond distances between the central atom and the vanadyl oxygen atoms are practically identical [V–O(1), 1.618(2); V–O(2), 1.616(2) Å] and are in the expected range for this type of bond. The bond lengths [V–O(3), 2.205(2); V–O(4), 2.219(2) Å] of the vanadium atom to the oxalate O-atoms, *trans* to the vanadyl bonds, are relatively long, as expected [34], and are comparable to the bond lengths to oxalato O-atoms co-ordinated *trans* to V=O bonds reported [21] for $(NH_4)_3[V^VO_2(ox)_2].2H_2O$ [2.185(2); 2.235(2) Å]. Finally, the apical bonds V–N(1) [2.133(2) Å] and V–N(2) [2.141(2) Å] are similar to the corresponding distances in $[Ni(NO_2)(py)_3$–μ–C_2O_4–$Ni(NO_2)(py)_3]$[15] **3** [2.139(5), 2.152(5)], [VO(sal–D,L–Asn)(py)(H_2O)] [2.151(4)] and [VO(sal–gly)$(py)_2$] [equatorial py: 2.144(7)] [4], slightly longer than the corresponding distances in $[Ru(NO_2)(py)_4$–μ–C_2O_4–$Ru(py)_4]$ [16] **4** [2.089(7), 2.095(7)], and somewhat shorter than V–N(bipyridine) bonds reported for $[V_4O_8(CH_3O)_4\}_2(bipy)_2]$ [2.189(1), 2.168(1) Å][41].

The oxalate ligand here has a bite of only 73.4(1)°. Normally, the dimensions of the oxalate ion are relatively insensitive to co-ordination and hence the angle subtended at a metal by a bidentate oxalate group is largely determined by the M–O distances [22]. Thus, M–O distances larger than 2.1 Å are normally accompanied by O–M–O angles smaller than 80° [22, 42, 43]. As a consequence of the value for the O(3)–V–O(4) angle, the other bond angles between adjacent equatorial positions are greater than 90° (Table 1). The angle between the two apical V–N bonds is 161.9(1)°, smaller than for **3** (177.9(2)°) where a NO_2^- and a pyridine are co-ordinated to Ni(II) in positions equivalent to the two oxo-atoms O(1) and O(2) of vanadyl. The corresponding angle in **4** is 177.8(8)°.

The bond lengths and angles of the oxalate ligand are not significantly different from those reported previously for the free oxalate ion [43] and other compounds in which such an ion acts as a bis(chelating) ligand [15, 16, 17, 22]. This anion is planar with maximum mean-plane deviation for C(11) (0.003 Å). In addition, the oxalate ion, the vanadium atoms and the vanadyl O-atoms are all in a plane, with maximum deviation for O(1) (0.027 Å).

Bond angles and distances in the pyridine moieties are normal. All are planar. The largest deviation from the plane occurs for C(1) (0.005 Å) and N(2) (0.014 Å). Pyridine rings A [N(1)–C(1)–C(2)–C(3)–C(4)–C(5)] and B [N(2)–C(6)–C(7)–C(8)–C(9)–C(10)] are at 40.7° to each other with their normals forming angles with the V–V axis of the dimer of 160.8 and 157.1°, respectively. In the molecule, there is no significant interaction between pyridine rings A and B co-ordinated to different vanadium ions, since the distance between them is 4.599 Å.

Infrared spectra.

The present bis-bidentate μ-oxalato ligand is symmetrical (within experimental error), and due to the *trans* effect of the vanadyl O-atoms the bonds O(ox)–V are relatively weak. This is probably why the IR spectra has features of both bi- and bis-bidentate oxalate. Table 2 summarizes the assignment of bands based on previous assignments for several complexes containing oxalate ligands and pyridine [15, 17, 30–32, 35, 36, 44, 45].

The formation of **1** from [VO(sal–Phe)(H_2O)] is quite surprising. It is not straightforward to explain the formation of oxalate from any known amino acid reaction activated by pyridoxal model systems. The formation of CO_2 could be explained as resulting from the decarboxylation of the amino acid [12]

It is known that with strong reducing agents reactions such as (1) may proceed:

$$2Na\ (\text{liquid}\ NH_3) + 2CO_2 \rightarrow Na_2C_2O_4 \qquad (1)$$

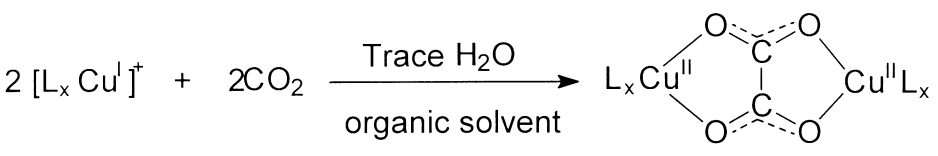
It is further known that for L_xCu^I the reductive formation of bridging $C_2O_4^{-2}$ may occur [46]:

where L_x is a terdentate ligand co-ordinating by three N-atoms.

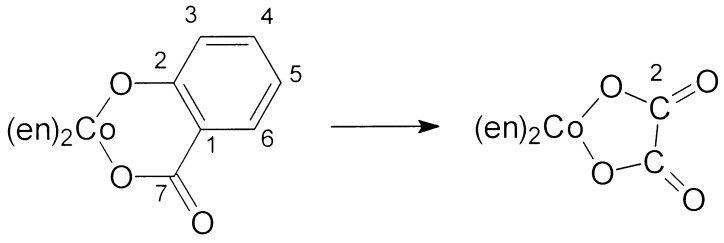
These reactions occur in reductive medium. In the present case vanadium(V) is present in the final product, perhaps suggesting that mechanisms involving steps equivalent to those corresponding to eqns (1) or (2) are not likely to explain our results. However, the initial oxidation state of vanadium is IV, so a reaction akin to (1) cannot be ruled out.

Instead of oxalate arising from reductive coupling of CO_2 formed in the decarboxylation of the amino acid, it could have formed by a mechanism involving first the oxidation of salicylaldehyde to salicylate (salct) (*e.g.* by V(V)), followed by oxidative degradation of salicylate yielding oxalate. This type of reaction has been described [47, 48] for $(-)-[Co(en)_2(salct)]^+$, which on oxidation by acid $KMnO_4$ produced $[Co(en)_2(C_2O_4)]^+$ in 100% yield (eqn (3)).

In reaction (3) there is retention of optical configuration and purity: ^{14}C-labelling at C-7 of **5** is entirely lost in the product [47, 48], while the retention of C-2 in the contraction of the 6-membered ring in **5**



(2)



5 **6** (3)

to 5-membered in **6** was ≈83% [48]. In the absence of acid the salicylato-complex reacted only very slowly [47, 48]. The reaction of **6** with acid permanganate is negligible under the conditions used for the degradation of **5**; this is in marked contrast with the behaviour of free oxalate, which very readily undergoes oxidation.

Whether the present reaction involves the formation of a [VO_2(salct)($X)_n$] complex is not clear. However oxalate is normally readily oxidised by V(V), while **1** may be kept in its mother liquor for many months without decomposition. This behaviour parallels that in eqn (3). Loss of C-7 early in the reaction and attack by an oxidising agent (O_2, V(V) or other) to produce intermediates of the type proposed by Gillard and coworkers [47, 48] could in fact explain the formation of **1** in the present system.

(Received 26 November 1997; accepted 6 March 1998)

Abstract—$Hg(CH_2SR)_2$, (R = Me (**1**), R = Ph (**2**)), prepared by reaction of $HgCl_2$ with $[Li_2(CH_2SR)_2(tmeda)_2]$, reacts with magnesium activated by mercury in boiling THF to give $[Mg(CH_2SR)_2(thf)_3]$ (R = Me (**3**), R = Ph (**4**)). **3** readily splitts off THF in vacuo to give the solvate free complex $[Mg(CH_2SMe)_2]$ (**3′**). The complexes **3′** and **4** are fully characterized by microanalysis and NMR spectroscopy (^1H, ^{13}C).

The X-ray structure analyses of **3** and **4** reveal mononuclear compounds with two symmetry independent molecules in the unit cell of **3**. In both complexes the coordination of Mg is trigonal–bipyramidal. The two apical positions are occupied by THF and the three equatorial positions by one THF and the two thiomethyl ligands. The C–Mg–C angles are slightly greater (123.9(1)–131.0(2)°) than the ideal angle for equatorial atoms in a trigonal–bipyramidal coordination. In neither case, the sulfur atoms are involved in the coordination of Mg. © 1998 Elsevier Science Ltd. All rights reserved.

Keywords: thiomethyl magnesium compounds; functionalized methyl magnesium compounds; mercury-magnesium transmetallation; crystal structures.

INTRODUCTION

The very low thermal stability ($T_{dec.} < -100°C$) and the carbenoid reactivity of Köbrich's (halogeno)-methyl lithium compounds [1] had exhibited, that a Lewis-basic heteroatom may strongly influence the reactivity and stability of functionalized methyl lithium compounds. Since then, the influence of Lewis-basic heteroatoms Y on structure, reactivity and stability of organolithium complexes of the type $LiCH_2YR_n$ (**A**) (YR_n = NR_2, PR_2, OR, SR, Cl, ...) has been investigated thoroughly [2, 3]. X-ray structure investigations reveal a wide variety of solid state structures exhibiting a coordination Y → Li in most cases [4]. The THF adducts, $[Li(CH_2YR_n)(thf)_x]$ are polymeric (YR_n = SMe [5], PPh_2 [6]), tetrameric (YR_n = NC_5H_{10} [7], NMe_2 [8]) or dimeric with a four-membered Li_2C_2 ring (YR_n = SPh [5], NPh_2 [7]). Monomeric compounds are not known at all.

Compared to the numerous lithium compounds **A**, there are far fewer examples of functionalized methyl Grignard compounds $Mg(CH_2YR_n)X$ (**B**) with Lewis-basic heteroatoms Y (YR_n = OR, SR, X) [2, 9, 10]. To date, there have been no reports of functionalized dimethyl magnesium compounds $Mg(CH_2YR_n)_2$ (**C**). Although a lot of structures of organomagnesium compounds had been described [11], those of type **B** and **C** are not known at all.

We report here the synthesis of thiomethyl magnesium compounds $[Mg(CH_2SR)_2(thf)_3]$ (R = Me (**3**), R = Ph (**4**)) and their solid state structures being the first compounds of type **C**.

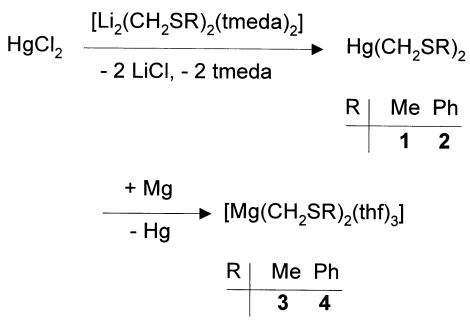
RESULTS AND DISCUSSION

The thiomethyl mercury complexes $Hg(CH_2SR)_2$ (R = Me (**1**), R = Ph (**2**)) were prepared by the reac-

* Author to whom correspondence should be addressed.

tion of $HgCl_2$ with $[Li_2(CH_2SR)_2(tmeda)_2]$ in THF, cf. Equation (1). The identities of **1** and **2** were confirmed by microanalysis and NMR spectroscopy (^1H and ^{13}C). In the case of the complex **2** these values agree with the data given in the literature [12].

The organomercury compounds **1** and **2** undergo with magnesium in boiling THF a transmetallation reaction yielding the bis(thiomethyl)magnesium complexes $[Mg(CH_2SR)_2(thf)_3]$ (R = Me (**3**), R = Ph (**4**)) that precipitate from the concentrated solutions at $-40°C$ as well shaped colorless crystals, eq. (1).



(1)

There is an induction period of several hours. Activating the magnesium with one drop of mercury, the reactions take not more than three hours (degree of conversion >90%). The transmetallation of **2** with magnesium was proved to proceed also in boiling toluene and xylene with mercury activated magnesium (degree of conversion >80%). Within eight hours no reaction was observed in boiling ether, not even with magnesium activated by mercury.

For Hg–Mg transmetallation reactions, a wide range of reactivity was described in the literature: Me_2Hg was found to react with magnesium immediately in a strong exothermic reaction [13]. On the other hand, transmetallation reactions of aryl mercury compounds take up to two weeks in THF at room temperature [14]. An activation of the Hg–Mg transmetallation with $HgCl_2$ was observed [15], but the isolation of R_2Mg in a pure state might be difficult due to the Schlenk equilibrium.

The thiomethyl magnesium complexes **3** and **4** are very sensitive against air and moisture. The (methylthio)methyl complex **3** loses the coordinated THF very easily in vacuo to give the solvate free complex $[Mg(CH_2SMe)_2]$ (**3′**). **3** and **4** are well soluble in THF and ether and insoluble in aromatic and aliphatic hydrocarbons. The identities of **3′** and **4** were confirmed by microanalysis and NMR spectroscopy (^1H and ^{13}C).

Table 1 shows the resonances of the methylene group in **3**, **4** and in related lithium complexes. Compared with their lithium analogues, the ^1H resonances of **3** and **4** are shifted downfield because of the magnesium is less electropositive. The difference $\Delta\delta(^1H) = 0.20$ ppm between **3** and **4** should be caused by the electronic effect of the phenyl substituent. As in the (phenylthio)methyl lithium compounds, there is an unusual high field shift of the methylene carbon in **4**. The coupling constants $^1J(^{13}C,^1H)$ for the CH_2 groups of all compounds in Table 1 are in the expected range exhibiting no unusual bonding relationships.

Structures of $[Mg(CH_2SMe)_2(thf)_3]$ (*3*) *and* $[Mg(CH_2SPh)_2(thf)_3]$ (*4*)

The molecular structures of complexes **3** and **4** along with the atom numbering schemes are shown in Figs 1 and 2. Selected bond lengths and angles are listed in Table 2.

The two structures consist of monomeric molecules without any unusal intermolecular interactions. The unit cell of complex **3** contains two symmetry independent molecules (**3** and **3a**); one of them (**3a**) exhibits a crystallographically imposed C_2 symmetry. Related bond lengths of **3** and **3a** differ less than 1% while related bond angles show noteable differences (up to 5–6%).

Both in **3** and in **4**, the magnesium displays a distorted trigonal–bipyramidal coordination. As usual for trigonal–bipyramidal structures [18], the more electronegative ligands (THF) occupy the apical positions. These Mg–O bonds are longer than that to the

[a]Symmetry transformations used to generate equivalent atoms: ': $-x, y, -z+1/2$.
[b]C1a–Mg1a–C1′.
[c]C1a–Mg1a–O2′.
[d]O2a–Mg1a–O2′.

equatorially bonded THF molecule (d(Mg–O_{ap}) = 2.140(4)–2.236(4) Å vs. d(Mg–O_{eq}) = 2.087(4)–2.107(2) Å).

The distortions of the coordination polyhedron around Mg are relatively small: The angles O_{ap}–Mg–O_{ap} are between 163.40(8)° and 169.6(1)° and the sum of angles in the equatorial planes is between 359.6(4)° and 360.0(2)°. The less electronegative organo ligands are more space-demanding as can be seen at the widening of the C–Mg–C angles (123.9(1)–131.0(2)°) and at the lowering of the O_{ap}–Mg–O_{eq} angles (81.4(2)–84.79(6)°).

The Mg–C bond lengths in **3** and **4** (d(Mg–C) = 2.168(6)–2.196(3) Å) are in the range for Mg–C bond lengths of other monomeric five-coordinate dialkylmagnesium compounds such as $[MgR_2(pmdta)]$ [19] (R = Me, Et; pmdta = *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine) (d(Mg–C) = 2.158(5)–2.223(9) Å).

The CH_2–S distances (d(C–S) = 1.757(3)–1.777(6) Å) are substantially shorter than the S–CH_3 distances in **3** (d(C–S) = 1.803(4)–1.811(4) Å). They are in the same range as the S–C_{Ph} distances in **4** (d(C–S) = 1.766(5) and 1.773(6) Å) in spite of the smaller covalent radii of sp^2 hybridized carbons in comparison with sp^3 hybridized ones [18]. This indicates a stabilizing influence on the carbanionoid centre of sulfur by polarization.

The complexes **3** and **4** are the first functionalized dimethylmagnesium complexes $Mg(CH_2YR_n)_2$ with a Lewis-basic heteroatomic centre Y. Unexpectedly, the sulfur is not involved in the coordination sphere of magnesium. Furthermore, for the first time a trigonal–bipyramidal coordination around magnesium was found with monodentate coligands L ($[MgR_2L_3]$). To date, monomeric five-coordinate diorganomagnesium compounds were observed only with tridentate co-

ligands ([MgR_2L_3]; R = alkyl, aryl; L_3 = pmdta, diglyme, tetraglyme) [19, 20]. With mono- and oligodentate coligands, tetrahedral complexes [MgR_2L_2] (R = alkyl, aryl; L = THF, quinuclidine; L_2 = TMEDA) [19, 21–26] and octahedral complexes [MgR_2L_4] (R = alkyl, alkynyl; L_2 = TMEDA, L_4 = crown ether) [20, 27–29] are formed.

EXPERIMENTAL

General comments

All reactions and manipulations were carried out under purified argon using standard Schlenk techniques. *n*-Hexane, *n*-pentane, TMEDA and THF-d_8 were dried with $LiAlH_4$. Toluene, xylene, THF and diethyl ether were distilled from sodium benzophenone ketyl. NMR spectra were recorded on Varian Unity 500 spectrometer using the protio impurities and ^{13}C resonances of the deuterated solvents as references for ^1H and ^{13}C NMR spectroscopy, respectively. Microanalyses (C, H, S) were obtained from the microanalytical laboratory of the Department of Chemistry. A CP9000 (Chrompack) was used for gas-chromatographic analyses. [$Li_2(CH_2SR)_2(tmeda)_2$] (R = Me, Ph) was prepared according to the literature [16, 17].

Synthesis of $Hg(CH_2SR)_2$ (*R = Me* (*1*), *R = Ph* (*2*))

To a solution of $HgCl_2$ (6.5 g, 24 mmol) in THF (50 ml), [$Li_2(CH_2SR)_2(tmeda)_2$] (R = Me, Ph) (48 mmol) in THF (50 ml) was added dropwise at −78°C. After stirring for 1 h and warming up to r.t. water (100 ml) was added. The half of the solvent was removed in vacuo and the colorless precipitate formed was filtered off, washed with water and cold methanol and dried in vacuo. Yields: **1** (5.6 g, 75%); **2** (9.7 g, 90%).

Anal. Calcd for **1**: C, 14.88; H, 3.12; S, 19.86. Found: C, 15.24; H, 3.20; S, 18.74. ^1H NMR (500 MHz, THF-d_8): δ 2.27 (s, 4H, $^2J(^{199}Hg, ^1H)$ = 104.0 Hz, CH_2), 2.15 (s, 6H, CH_3). ^{13}C NMR (125 MHz, THF-d_8): δ 43.1 (s+d, $^1J(^{199}Hg, ^{13}C)$ = 820.1 Hz, CH_2), 22.8 (s+d, $^3J(^{199}Hg, ^{13}C)$ = 137.0 Hz, CH_3).

Anal. Calcd for **2**: C, 37.62; H, 3.16; S, 14.35. Found: C, 38.13; H, 3.22; S, 14.08. ^1H NMR (500 MHz, THF-d_8): δ 2.60 (s, 4H, $^2J(^{199}Hg, ^1H)$ = 107.3 Hz, CH_2), 7.06–7.46 (m, 10H, *Ph*). ^{13}C NMR (125 MHz, THF-d_8): δ 39.2 (s+d, $^1J(^{199}Hg, ^{13}C)$ = 855.4 Hz, CH_2), 124.9 (*p*-C), 125.9 (*o*-C), 128.3 (*m*-C), 142.0 (*i*-C).

Synthesis of [$Mg(CH_2SR)_2(thf)_3$] (*R = Me* (*3*), *R = Ph* (*4*))

A mixture of $Hg(CH_2SR)_2$ (R = Me (**1**), R = Ph (**2**)) (3.4 mmol), powdered magnesium (0.75 g, 31 mmol) and mercury (about 0.1 g, 0.5 mmol) in THF (10 ml) was refluxed under vigorous stirring for about 3 h. The amalgam formed was filtered off and the solution was concentrated in vacuo up to about 5 ml. At −40°C, **3** and **4** precipitated in well shaped crystals which were filtered off, washed with hexane and dried in vacuo. Yield: **3′** (0.3 g, 60%); **4** (1.1 g, 65%). To

(Due to partial hydrolysis a small amount ot MeSPh was detected in the spectra.)

*X-ray structure determinations of **3** and **4***

Suitable single crystals of **3** ($0.4 \times 0.3 \times 0.3$ mm) and **4** ($0.8 \times 0.2 \times 0.1$ mm) were obtained from pentane/THF solution at -40°C. X-ray measurements were performed on a Stoe IPDS (**3**) and on a Stoe STADI 4 diffractometer (**4**), respectively, with $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å). The structures were solved by direct methods (SHELXS86 [30]) and refined using full-matrix least-squares procedures on F^2 (SHELXL93 [31]). Non-hydrogen atoms were refined with anisotropic displacement parameters. The hydrogen atoms were found in the Fourier list and refined isotropically, except of some in **3**, which were placed in calculated positions. Crystal data, details of data collections, structure solutions and refinements are summarized in Table 3. Complete tables of the atomic coordinates, H-atom parameters, bond distances, bond angles and anisotropic displacement parameters atoms have been deposited with the Editor as supplementary material.

(Received 16 February 1998; accepted 7 March 1998)

Abstract—Alternative routes to bis(cyclometallated) complexes have been explored. Divergent approaches involving a final multiple cyclometallation step and convergent approaches in which cyclometallated complexes of multinucleating ligands are prepared *in situ* from mononuclear cyclometallated complexes are exemplified. © 1998 Elsevier Science Ltd. All rights reserved. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: Cyclometallates; ruthenium complexes; metallosupramolecular chemistry; oligopyridines

We are interested in the synthesis and utilisation of metallodendrimers [1] and related species [2] and are currently probing ways of controlling the redox and photochemical properties of multinuclear species. One approach that seemed to be worth pursuing involved the replacement of oligopyridine-metal substructures by cyclometallated motifs involving 2-phenylpyridine (Hppy) or 6-phenyl-2,2′-bipyridine (Hpbpy) [3].

Although the fundamental chemistry of such potentially cyclometallating ligands is well-developed [3], there are remarkably few examples of complexes containing two or more such cyclometallated sites [4–13]. Two strategies for the synthesis of such compounds appear feasible: (i) preparation of a ligand with two or more of the desired metal-binding domains with subsequent multiple metallation and (ii) preparation of suitable mononuclear cyclometallated complexes bearing functionality which will allow a subsequent coupling reaction. The former approach is, formally, divergent whilst the latter is convergent. The divergent approach is a conventional one, but in view of the subtlety involved in the selective addressing of either *NN* or *CNN* bonding domains in 6-phenyl-2,2′-bipyridines [13, 14] we anticipated considerable problems in controlling a large number of parallel or consecutive cyclometallation reactions. The convergent approach is attractive in that only a single cyclometallation reaction is required, although the stability of cyclometallates under the coupling conditions was a cause for concern. However, recent reports [4, 9, 15, 16] describing coupling reactions of metal complexes encouraged us to pursue this approach. In this paper we compare the two approaches in the synthesis of a bis(cyclometallated) complex.

EXPERIMENTAL

Infrared spectra were recorded on a Mattson Genesis Fourier-transform spectrophotometers with samples in compressed KBr discs. Proton NMR spectra were recorded on Brüker WM250, AM400 or Varian Gemini 300 MHz spectrometers. All coupling constants within the aromatic systems are typical and are not explicitly reported. Time of flight (MALDI) spectra were recorded using a PerSeptive Biosystems Voyager-RP Biospectrometry Workstation. Electrochemical measurements were performed with an Eco Chemie Autolab PGSTAT 20 system using platinum bead or glassy carbon working and auxiliary electrodes with an Ag/AgCl electrode as reference. The experiments were conducted using purified acetonitrile as solvent and freshly recrystallised 0.1 M [Bu^n_4N, BF_4] or [Bu^n_4N, PF_6] as supporting electrolyte; ferrocene was added at the end of each experiment as an internal reference. 2-Oxo-2-pyridylethylpyridinium iodide [17], [$NiCl_2(PPh_3)_2$] [18] and [Ru(tpy)Cl_3] [19]

were prepared by the literature methods. Hydrated ruthenium trichloride was purchased from Oxchem.

[4-*Bromo*(3-*ammonio*-1-*oxopropyl*)*benzene*]*chloride*, **3**

N,*N*-Dimethylammonium chloride (1.20 g, 0.015 mol), paraformaldehyde (3.52 g, 0.059 mol) and 4-bromoacetophenone (2.78 g, 0.014 mol) were heated to reflux in dry ethanol (40 cm^3) containing three drops of concentrated hydrochloric acid for 4 h. After this period an additional quantity of paraformaldehyde (0.71 g, 0.012 mol) was added and the heating continued for a further 4 h. The clear yellow solution so obtained was concentrated *in vacuo* to 10 cm^3 volume and treated with acetone (120 cm^3) to give a suspension of a white solid. This suspension was cooled to −18°C for 12 h and the salt **3** collected by filtration. Yield: 2.79 g (68%). (Found: C, 45.3; H, 5.1; N, 4.8%. $C_{11}H_{15}NBrOCl$ requires: C, 45.15; H, 5.2; N, 4.8%). Mass spectrum (+ve FAB): *m*/*z*: 291/293/295 (M). IR (KBr): 2957 m, 2938 m, 2910 m, 1681 vs, 1601 s, 1476 m, 1464 m, 1411 m, 1383 m, 1297 m, 1019 m, 951 m, 823 m, 782 m cm^{-1}.

6-(4-*Bromophenyl*)-2,2′-*bipyridine*, *H***1**

A mixture of ammonium acetate (4.20 g, 55 mmol) and-2-oxo-2-(2-pyridyl)ethylpyridinium iodide (1.41 g, 4.32 mmol) were heated to reflux for 10 min. in dry ethanol (10 cm^3) under an atmosphere of dinitrogen. After this period, **3** (1.26 g, 4.32 mmol) was added and the mixture heated to reflux for a further 4.5 h. The reaction mixture was then cooled and the beige precipitate collected by filtration. Recrystallisation from ethanol gave **H1** as an off-white solid. Yield: 0.47 g (92%); m.p. 89.2°C. (Found: C, 61.9; H, 4.2; N, 8.8%. $C_{16}H_{12}N_2Br$ requires: C, 61.6; H, 3.9; N, 9.0%). Mass spectrum (+ve FAB): *m*/*z*: 310/312 (M). IR (KBr): 1582 m, 1560 m, 1430 m, 1008 m, 771 s, 745 m, 510 m cm^{-1}. ^{1}H NMR ($CDCl_3$): δ 8.70 (H, d, $H^{6'}$), 8.58 (H, d, H^3), 8.39 (H, d, $H^{3'}$), 8.02 (2H, d, H^{ortho}), 7.85 (2H dd, $H^{4'}$, H^4), 7.70 (1H, d, H^5), 7.62 (2H, d, H^{meta}), 7.32 (H, ddd, H^{5A}). ^{13}C NMR ($CDCl_3$): δ 156.1(C^6), 155.8(C^2), 155.2($C^{2'}$), 149.1 ($C^{6'}$), 138.2(C^4), 137.8 (C^{ipso}, 136.8 ($C^{4'}$), 131.8 (C^{meta}), 128.4 (C^{ortho}), 123.8 ($C^{3'}$), 123.4(C^{para}), 121.2 ($C^{5'}$), 119.9 ($C^{5/3}$), 119.6 ($C^{3/5}$).

4,4′-*Diacetylbiphenyl*, **4**

[$NiCl_2(PPh_3)_2$] (2.29 g, 3.51 mmol), zinc dust (3.44 g, 52.6 mmol) and tetraethylammonium iodide (0.90 g, 3.51 mmol) were placed in a flask fitted with a condenser. The apparatus was then purged with dinitrogen and freshly dried THF (70 cm^3) added. The reaction mixture was stirred at room temperature until the initial blue-green colour had changed to reddish-brown, after which a solution of 4-bromoacetophenone (6.9 g, 35.1 mmol) in degassed THF (30 cm^3) was rapidly added to the stirring solution. The resulting mixture was heated to 60°C for 48 h. After completion of the reaction, the mixture was filtered and the solid residues washed with dichloromethane. The filtrate and the washings were evaporated *in vacuo* and the residue purified by flash column chromatography (silica gel/CH_2Cl_2). Yield: 3.26 g (77%); M.p.: 192–193.4°C (lit. 192–193°C [20], 193.5–194°C [21]). (Found: C, 80.4; H, 6.0%. $C_{16}H_{14}O_2$ requires; C, 80.6; H, 5.9%). Mass spectrum (EI): *m*/*z*:238 (M), 223 (M-CH_3). ^{1}H NMR ($CDCl_3$): δ 7.91 (2H, d, *J* 7.8 Hz, H^3), 7.29 (2H, d, *J* 7.81 Hz, H^2), 2.60 (3H, s, CH_3). IR (KBr): 1680 s, 1606 m, 1395 m, 1363 m, 1275 s, 961 m, 819 m, 513 s cm^{-1}.

4,4′-*Bis*[3-(*N*,*N*-*dimethylammonio*)-1-*oxopropyl*]*biphenyl dichloride*, **5**

4,4′-Diacetylbiphenyl (**1**) (3.1 g, 12.9 mmol), paraformaldehyde (4.6 g, 158 mmol) and rigorously dried *N*,*N*-dimethylammonium chloride (2.3 g, 28.2 mmol) were placed in a reflux apparatus under a dinitrogen atmosphere. Freshly dried absolute ethanol (50 cm^3) and 3 drops of concentrated hydrochloric acid were added and the mixture heated at reflux for 4 h. The initially milky-white suspension changed to a straw-coloured solution over this period. An additional portion of paraformaldehyde (1.2 g, 41 mmol) was added and the mixture heated at reflux for a further two hours. Precipitation of the Mannich salt was effected after cooling of the reactant mixture (3°C) by the addition of cold (−18°C) acetone. The formation of an oil can be suppressed by a short period in an ultrasonic cleaning tank. The Mannich salt was precipitated as a white powder after standing for 12 h at −18°C. Yield (2.3 g, 42%). Mass spectrum (EI): *m*/*z*: 354 (M-2Cl). IR (KBr): 2682 m, 2464 m, 1680 s, 1604 m, 1471 m, 1395 m, 1357 m, 1230 s, 977 m, 823 m, 790 m cm^{-1}.

4,4′-*Bis*(2,2′-*bipyridin*-6-*yl*)*biphenyl*, H_2**2**

Method 1: A mixture of ammonium acetate (2.00 g, 2.6 mmol) and 2-oxo-2-(2-pyridyl)ethylpyridinium iodide (0.76 g, 2.33 mmol) was heated to reflux for 10 min. in ethanoic acid (8 cm^3) under dinitrogen. After this period, **5** (0.50 g, 1.14 mmol) was added and the mixture heated to reflux for a further 4.5 h. After this period, the suspension was cooled, and the beige precipitate collected by filtration. Recrystallisation from EtOH gave H_2**2** as an off-white solid. Yield: 0.47 g (85%); m.p. 204–205°C. (Found: C, 83.3; H 4.7; N, 12.0%. $C_{32}H_{22}N_4$ requires: C, 83.1; H, 4.8; N, 12.1%). Mass spectrum (MALDI-TOF, 1,8,9-trihydroxyanthracene matrix): *m*/*z*: 462 (M). ^{1}H NMR ($CDCl_3$): δ 8.69 (2H, d, *J* 4.53 Hz, H^{6A}), 8.63 (2H, d, *J* 7.95 Hz, H^{3B}), 8.36 (2H, d, *J* 7.74 Hz, H^{3A}), 8.10 (4H, d, *J* 8.28 Hz, H^{3C}), 7.83 (6H, m, $H^{4A,4B,5B}$), 7.38 (4H,

d, J 8.25 Hz, H^{2C}), 7.31 (2H, m, H^{5A}). IR. (KBr): 1582 m, 1561 m, 1454 m, 1427 s, 815 m, 776 s cm^{-1}.

Method 2: H**1** (0.20 g, 0.65 mmol) and the nickel reagent prepared as above from $[NiCl_2(PPh_3)_2]$ (1.51 g, 2.64 mmol), zinc dust (0.17 g, 2.64 mmol) and tetraethylammonium iodide (0.32 g) in THF under a dinitrogen atmosphere were treated as described for the preparation of **4**. After demetallation in a mixture of aqueous KCN and MeCN and filtration, extraction of the aqueous phase into dichloromethane and subsequent purification by column chromatography (silica gel, CH_2Cl_2), H_2**2** was isolated as an off-white solid in 65% yield (0.098 g). Mass spectrum: (TOF, 1,8,9-trihydroxyanthracene matrix) m/z: 462 (M). All spectroscopic and analytical data as above.

[*Ru*(*tpy*)(*CNN*-**1**), PF_6]

A mixture of [Ru(tpy)Cl_3 (0.13 g, 0.30 mmol), H**1** (0.095 g, 0.31 mmol) and *N*-ethylmorpholine (0.5 mL) was heated to reflux in water:methanol (5:1) (30 cm^3) for 2 hours. After this time the product distribution was checked by thin layer chromatography using an eluent of MeCN:KNO_3(saturated aqueous solution):H_2O, 14:2:1. After two hours, three products were detected: orange $[Ru(tpy)_2]^{2+}$ (Rf: 0.3), purple [Ru(tpy)(*CNN*-**1**), PF_6] (Rf: 0.85) and crimson [Ru(tpy)(*NN*-H**1**)Cl, PF_6] (Rf: 0.81). The crude purple mixture was treated with methanolic [NH_4, PF_6] and purified by column chromatography (silica gel with a MeCN:saturated aqueous KNO_3:H_2O; 14:2:1 mobile phase). The cyclometallated product was collected as a fast-running purple band and the complex [Ru(tpy)(*CNN*-**1**), PF_6] was isolated as a dark purple-black microcrystalline solid after the addition of [NH_4, PF_6]. Yield 0.18 g (75%). (Found: C, 47.0; H, 2.9; N, 8.8%. $RuC_{31}N_5H_{21}BrPF_6$ requires: C, 47.2; H, 2.7; N, 8.9%). Mass spectrum (FAB): m/z: 644/646 (M-PF_6); (MALDI-TOF): m/z 644/646 (M-PF_6). ^{1}H NMR (CD_3CN): δ 8.61 (2H, d, H^{3E}), 8.42 (4H, 2d, $H^{3A,3B,3D}$), 8.23 (1H, d, H^{5B}), 8.08 (2H, t, $H^{4B,4E}$), 7.85 (1H, d, H^{4A}), 7.77 (2H, t, H^{4D}), 7.72 (1H, d, H^{3C}), 7.43 (1H, d, H^{6A}), 7.39 (2H, d, H^{6D}), 7.06 (3H, t, $H^{5A,5D}$), 6.91 (1H, dd, H^{4C}), 5.81 (1H, d, H^{6C}). IR (KBr): 1135 m, 1063 m, 841 vs, 765 m cm^{-1}. UV-VIS (MeCN): λ_{max} (ϵ) 274 (36,000), 318 (46,500), 511 nm (12,300) nm.

[(*tpy*)*Ru*(μ-κ^3*CNN*:κ^3*CNN*-**2**)Ru(tpy), PF_6]$_2$

Method 1: A mixture of [Ru(tpy)Cl_3] (0.072 g, 0.16 mmol) and H_2**2** (0.039 g, 0.085 mmol) was heated to reflux in methanol:water (5:1, 15 cm^3) for 16 hours. The resulting deep purple solution was quenched with water, treated with a methanolic solution of [NH_4, PF_6] and cooled to -18°C. The deep purple cyclometallated complex which precipitated was collected by filtration and purified by preparative thin layer chromatography (silica on glass, 0.5 mm thickness, MeCN:saturated aqueous KNO_3:H_2O; 14:2:1 mobile phase). The fastest running purple band (Rf: 0.68) was the collected and isolated as the hexafluorophosphate salt [(tpy)Ru(μ-κ^3*CNN*:κ^3*CNN*-**2**)Ru(tpy), PF_6]$_2$ (75%). (Found C, 50.6; H, 3.0; N, 9.5%. $Ru_2C_{62}H_{42}N_{10}P_2F_{12}.2H_2O$ requires: C, 50.1; H, 2.99; N, 9.4%). Mass spectrum (MALDI-TOF, 1,8,9-trihydroxyanthracene matrix): 1275 (M-PF_6), 1130 (M-2PF_6). ^{1}H NMR (CD_3CN) δ: 8.59 (2H, d, $H^{3,5E}$), 8.41 (1H, d, H^{3A}), 8.37 (3H, d, $H^{3B,3D}$), 8.13 (1H, d, H^{5B}), 8.07 (1H, dd, H^{4B}), 8.01 (1H, d, H^{4E}), 7.83 (1H, m, H^{4A}), 7.73 (2H, m, H^{4D}), 7.32 (3H, 2d, $H^{6A,6D}$), 7.09 (1H, br s, H^{3C}), 7.03 (3H, m, $H^{5A,5D}$), 6.35 (1H, d, H^{4C}), 5.19 (1H, s, H^{6C}). UV-VIS (MeCN): λ_{max} (ϵ) 274 (52,000), 318 (46,500) 519 (14,800) nm.

Method 2: [$Ni(PPh_3)_2Cl_2$] (151 mg, 0.26 mmol) and PPh_3 (0.14 g, 0.53 mmol) were added to a dry, degassed stirred sample of DMF (40 cm^3). After 30 minutes, the deep blue solution was treated with zinc dust (0.017 g, 0.26 mmol) and stirring continued until a brick-red suspension had been obtained. To this suspension was added a solution of [(tpy)Ru(*CNN*-**1**), PF_6] (0.042 g, 0.054 mmol) in the minimum quantity of dry, degassed DMF. The system was then heated to reflux for 24 h, after which time, TLC analysis showed the formation of a new purple species with RF 0.68. The purple compound [(tpy)Ru(μ-κ^3*CNN*:κ^3*CNN*-**2**)Ru(tpy), PF_6]$_2$ was isolated in the same way as in Method 1. Yield: 0.026 g (71%). The compound was identical in all respects to that above.

RESULTS AND DISCUSSION

6-*Phenyl*-2,2′-*bipyridine complexes*

The ligand Hpbpy gives rise to two series of complexes: in the first series, the ligand behaves as a conventional didentate 2,2′-bipyridine and acts as an *NN* donor, whilst in the second the *ortho*-position of the phenyl ring is deprotonated to give an anionic terdentate *CNN* donor ligand (Fig. 1). We [4, 14, 22–25] and others [26–28] have studied the factors which control the adoption of a particular bonding motif and have shown that protic solvents favour the formation of the cyclometallated species [13, 14].

Although a number of ligands incorporating two

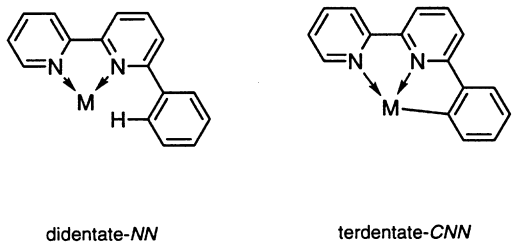

Fig. 1. Cyclometallated and non-metallated bonding modes for Hpbpy.

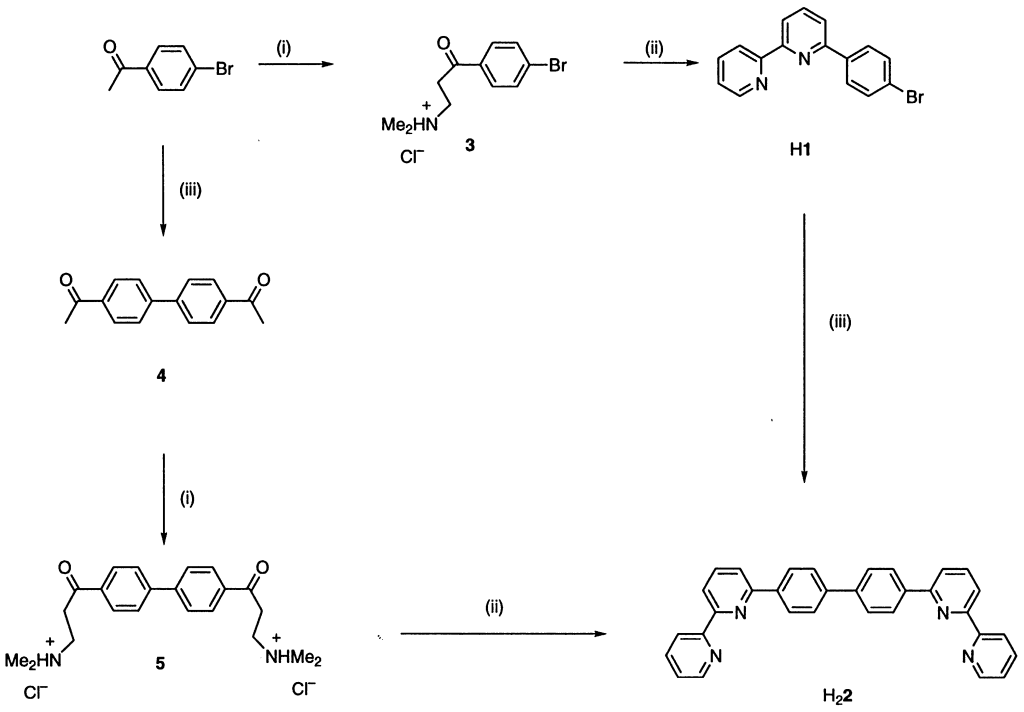
or more Hpbpy metal-binding domains have been described, their structures have not been such to allow a facile comparison of the various strategies for the formation of multiply cyclometallated complexes. Accordingly, we decided to investigate a system which would be amenable to both convergent and divergent syntheses.

Ligand synthesis

We initially prepared a functionalised Hpbpy ligand which had a reactive group which would allow dimerisation in both free and coordinated forms. We decided to adopt the nickel(0) coupling of haloarenes for the dimerisation step, a method which we [29–36] and others [37–45] have successfully used for the synthesis of oligopyridines. Accordingly, our initial step was the synthesis of a suitable 6-(4-halophenyl)-2,2′-bipyridine.

The initial target was 6-(4-bromophenyl)-2,2′-bipyridine H**1** which was prepared using the Kröhnke method [17] as shown in Scheme 1. Commercially available 4-bromoacetophenone was converted in 68% yield to the Mannich salt **3** by reaction with *N*,*N*-dimethylammonium chloride and paraformaldehyde in dry ethanol to give the salt as a white solid with a typical carbonyl absorption in its IR spectrum at 1681 cm^{-1}. Compound **3** was then reacted with the enolate precursor 2-(2-pyridyl)-2-oxoethylpyridinium iodide in the presence of ammonium acetate in ethanol to give the desired ligand in 92% yield as a cream-coloured solid. Spectroscopic and analytical data for the new ligand H**1** fully support the proposed formulation. The mass spectrum exhibited parent ions at *m*/*z* 310 and 312 with the 1:1 isotopic distribution expected of a monobromo compound and the ^{1}H NMR spectrum of a $CDCl_3$ solution of H**1** (Fig. 2a) showed nine aromatic proton environments. The ^{13}C NMR spectrum of a $CDCl_3$ solution of H**1** displayed the expected 14 resonances.

The potentially dinucleating ligand H_2**2** is formally a dimer of Hpbpy and could exhibit a range of coordination modes including mononuclear didentate *NN*, mononuclear terdentate *CNN*, dinucleating κk^2-*NN*:κ^2-*NN*, dinucleating κ^2-*NN*:κ^3-*CNN* and dinucleating κ^3-*CNN*:κ^3-*CNN* (Fig. 3). For the synthesis of H_2**2** we considered two routes. In both cases, the B ring was to be prepared in a Kröhnke synthesis, but in the first route the biphenyl unit was constructed as the first step, whilst in the second it was assembled as the last reaction step. Once again, 4-bromoacetophenone was the starting point and was converted to 4,4′-diacetylbiphenyl **4** in 77% yield using the Iyoda [40] nickel-coupling reaction. This method is more convenient than the Friedel-Crafts acetylation of biphenyl [46] or the use of $[Ni(COD)_2]$ as a reagent [21]. The conversion of **4** to the bis(Mannich) salt **5** was achieved in 42% yield by reaction with *N*,*N*-dimethylammonium chloride and paraformaldehyde in dry ethanol. Finally, H_2**2** was obtained as a pale



Scheme 1. (i) $[Me_2NH]Cl$, CH_2O, EtOH (ii) 2-oxo-2-pyridylethylpyridinium iodide, $[NH_4]OAc$ (iii) '$[Ni(PPh_3)_n]$'.

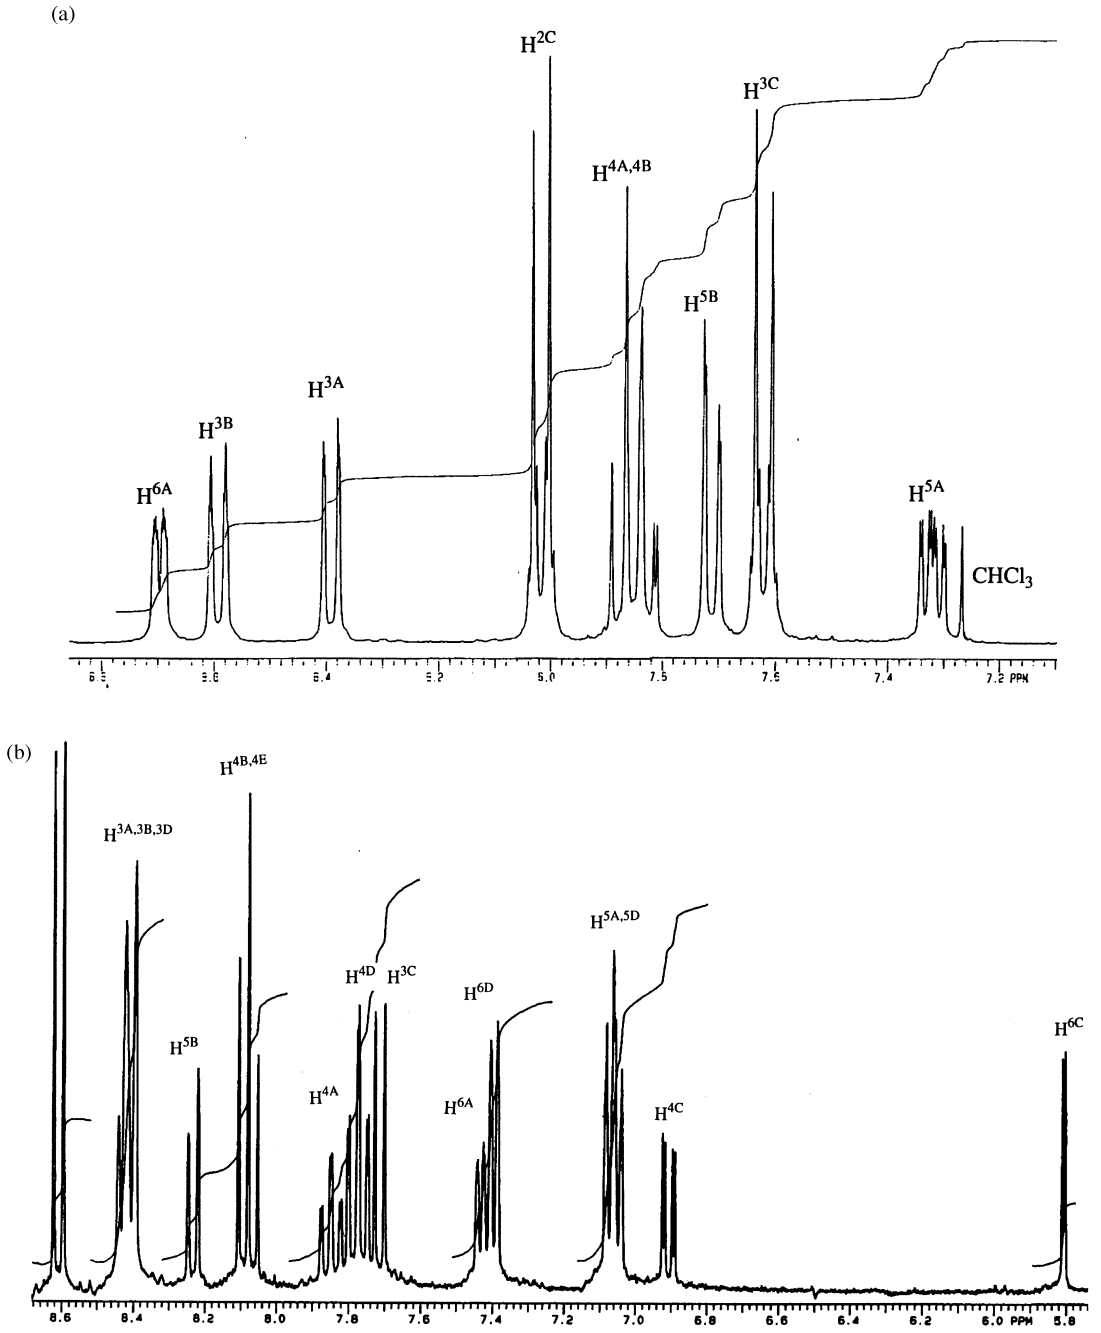


Fig. 2. 300 MHz ^{1}H NMR spectra of (a) a $CDCl_3$ solution of H**1** and (b) a CD_3CN solution of [Ru(tpy)(*CNN*-**1**), PF_6] showing the assignments.

beige solid in 85% yield after recrystallisation from EtOH, from the reaction of **5** with 2-(2-pyridyl)-2-oxoethylpyridinium iodide and ammonium acetate in acetic acid under an atmosphere of dinitrogen for 4.5 h. The mass spectrum displayed a parent ion at m/z 462 and no carbonyl absorptions were observed in the IR spectrum. The ^{1}H NMR spectrum of a $CDCl_3$ solution exhibited the expected 9 resonances in the aromatic region and was generally similar to the spectra of H**1** and Hpbpy.

The second approach to H_2**2** involved the coupling of H**1**under Iyoda conditions. The ligand H_2**2** was obtained in 65% yield and was in all respects identical to that obtained above. Comparing the efficiency of the two routes with respect to 4-bromoacetophenone, H_2**2** was obtained in 25% yield when the dimerisation

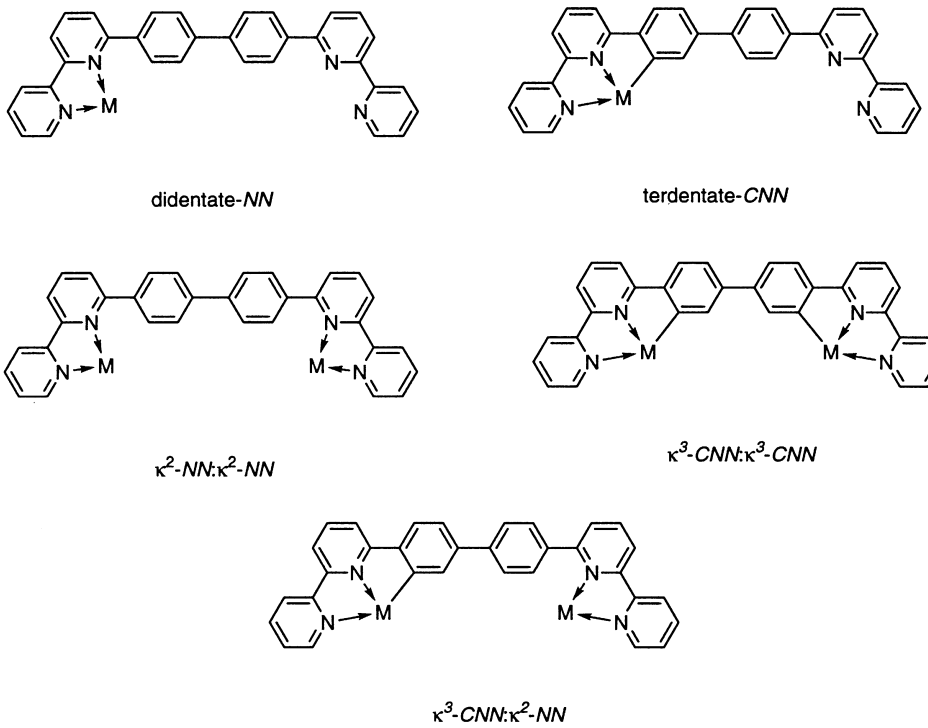

Fig. 3. Cyclometallated and non-metallated bonding modes for H_2**2**.

was made early in the synthesis and in 41% yield when the dimerisation was used as the final step. This suggests that the convergent approach will prove to be of more general utility for ligands incorporating additional metal-binding domains *and* that a convergent approach to the metal complexes might also be effective.

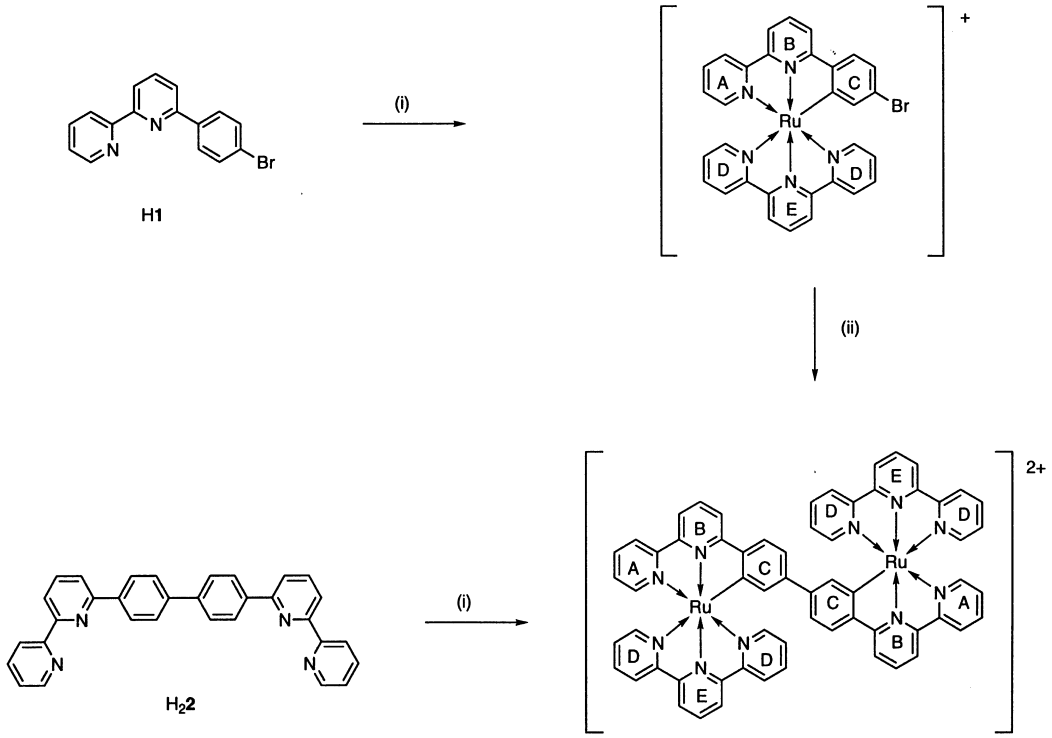
*Cyclometallation reactions of H***1** *and* H_2**2**

The mononucleating ligand H**1** can exhibit *NN* or *CNN* bonding modes. Thus, reaction with [Ru(tpy)Cl_3] in which three of the coordination sites at the metal are occupied by a non-labile chelating tpy ligand, under reductive conditions leading to ruthenium(II) compounds could give the cyclometallated species [Ru(tpy)(*CNN*-**1**)]$^+$ or the non-metallated complex cation [Ru(tpy)(*NN*-H**1**)Cl]$^+$ in which the remaining coordination site is occupied by a chloride ligand. We have shown that the formation of the cyclometallated complex is favoured by reaction under mildly basic, aqueous conditions [13, 14]. The cyclometallated complex [Ru(tpy)**1**, PF_6] was prepared from the reaction of H**1** with [Ru(tpy)Cl_3] in aqueous methanol:water containing *N*-ethylmorpholine. As the reaction progressed, the reactants dissolved to give a deep purple solution. Chromatographic purification of this dark solution followed by precipitation with ammonium hexafluorophosphate yielded [Ru(tpy)(*CNN*-**1**), PF_6] as a dark purple-black micro-crystalline solid. Small amounts of crimson [Ru(tpy)(*NN*-H**1**)Cl, PF_6] were also isolated (Scheme 2).

The time-of-flight mass spectrum of [Ru(tpy)(*CNN*-**1**), PF_6] exhibited base peaks at m/z 644 and 646 (M-PF_6). The cyclic voltammogram of an acetonitrile solution of the complex exhibits a single reversible ruthenium(II)/ruthenium(III) wave at $+0.27$ V *versus* Fc/Fc$^+$. This value is relatively high compared to that of the analogous complex [Ru(tpy)(*CNN*-pbpy), PF_6] which is observed at $+0.12$ V [14] an effect which may be ascribed to the electron-withdrawing bromine substituent destabilising the ruthenium(III) state. The electronic spectrum of the complex exhibits absorption maxima at 274, 316 and 514 nm which correlate well with those in [Ru(tpy)(*CNN*-pbpy), PF_6] (274, 317 and 512 nm).

The ^{1}H NMR spectrum of a CD_3CN solution of [Ru(tpy)(*CNN*-**1**), PF_6] is shown in Fig. 2(b). The most noticeable feature of the spectrum is the upfield-shifted doublet at δ 5.81 which is characteristic [14] of the proton adjacent to the site of cyclometallation, H^{6C}. The equivalent proton in the ^{1}H NMR spectrum of [Ru(tpy)(*CNN*-pbpy), PF_6] is observed at δ 5.69 and the down-field shift correlates well with that of δ-0.13 predicted on the basis of a *meta* bromo substituent [47].

The reaction of H_2**2** with two equivalents of [Ru(tpy)Cl_3] was investigated under a wide range of experimental conditions. In most cases, dark purple-



Scheme 2. (i) [Ru(tpy)Cl_3], *N*-ethylmorpholine, H_2O-MeOH (ii) '[$Ni(PPh_3)_n$]'.

coloured solutions were formed but chromatographic analysis indicated the formation of a large number of species. The addition of ammonium hexafluorophosphate to these solutions precipitated mixtures of salts which were shown by ^{1}H NMR spectroscopy to contain the various species indicated in Fig. 3. However, we eventually found a procedure that maximised the formation of [(tpy)Ru(μ-κ^3*CNN*:κ^3*CNN*-**2**)Ru(tpy), PF_6]$_2$. The most convenient experimental procedure is to add water to a solution of H_2**2** in methanol until the ligand begins to precipitate (about 5:1 MeOH:H_2O) and then to heat this solution with two equivalents of [Ru(tpy)Cl_3]. Chromatographic purification of the dark coloured solution yielded [(tpy)Ru(μ-κ^3*CNN*:κ^3*CNN*-**2**)Ru(tpy), PF_6]$_2$ as a purple-black solid in 75% yield. The mass spectrum of this compound exhibited intense peaks at *m*/*z* 1276 (M-PF_6) and 1130 (M-2PF_6) and the cyclic voltammogram of an acetonitrile solution exhibited a single reversible (E_a-E_c = 60 mV) ruthenium(II)/ruthenium(III) process at +0.18 V, typical of a ruthenium centre in an N_5C environment (*c.f.* +0.12 V for [Ru(tpy)(*CNN*-pbpy), PF_6]). The observation of a single process is somewhat disappointing and indicates that with the biphenylene spacer, no significant metal-metal interaction is occurring. We note that the most efficient interactions between metal centres appear to occur when the cyclometallated sites are linearly connected-*i.e.* when the cyclometallated ring replaces the central ring of the tpy to give a *CNN* donor [5, 8]. The electronic spectrum of the complex is also characteristic and exhibits absorptions at 274, 318 and 513 nm in full accord with [Ru(tpy)(*CNN*-pbpy), PF_6] (see above). The ^{1}H NMR spectrum of a CD_3CN solution of [(tpy)Ru(μ-κ^3*CNN*:κ^3*CNN*-**2**)Ru(tpy), PF_6]$_2$ is presented in the experimental section and exhibits the expected upfield shifted resonance for H^{6C} which is observed at δ 5.19.

Finally, we investigated the nickel-mediated coupling of [(tpy)Ru(*CNN*-**1**), PF_6], which may be regarded as a bromoarene which also bears a ruthenium-containing substituent. This allows us to prepare the complex [(tpy)Ru(μ-κ^3*CNN*:κ^3*CNN*-**2**)Ru(tpy), PF_6]$_2$ by an *in situ* ligand synthesis. In view of the use of soft iodide ions in the Iyoda reaction, we used an alternative procedure which has proved successful for us in the past. The nickel(0) reagent was prepared *in situ* as a red solid by the reduction of [$Ni(PPh_3)_2Cl_2$] by zinc dust in the presence of excess triphenylphosphine in dmf solution. Subsequent reaction with [(tpy-)Ru(*CNN*-**1**), PF_6] resulted in the formation of [(tpy)Ru(μ-κ^3*CNN*:κ^3*CNN*-**2**)Ru(tpy), PF_6]$_2$ in 71% yield and in all respects identical to the material obtained directly from H_2**2**.

Although the direct cyclometallation of H_2**2** gives a slightly higher yield than the coupling of [(tpy-)Ru(*CNN*-**1**), PF_6], it is instructive to consider the overall yields from 4-bromoacetophenone. The direct

cyclometallation route involves 4 steps and gives [(tpy)Ru(μ-κ^3*CNN*:κ^3*CNN*-**2**)Ru(tpy), PF_6]$_2$ in 31% overall yield, whilst the coupling of the metal complex [(tpy)Ru(*CNN*-**1**), PF_6] also involves four steps but give the bis(cyclometallate) in 33% yield. Clearly in the case of only two metal-binding domains there is no clear choice between the approaches in terms of yields. However, in species with more than two metal-binding domains, the convergent approach involving the coupling of metal complexes is expected to prove superior.

CONCLUSIONS

We have investigated a series of strategies for the synthesis of multiply cyclometallating ligands and their metal complexes. The synthesis of the free ligands is best achieved using a convergent approach in which pre-formed metal-binding domains are combined late in the reaction sequence. Bis(cyclometallates) may be obtained directly by reaction of a ligand bearing two *CNN*-metal-binding domains with a metal source or by the nickel-mediated dimerisation of a haloarene functionalised cyclometallate. Although yields in the direct bis(cyclometallation) reaction are marginally higher under optimised conditions, considerable investment of time is required to establish these optimal experimental conditions. In conclusion, we have shown that cyclometallated complexes may be coupled in nickel-mediated reactions to give multiply cyclometallated species.

Abstract—Crystal structures of the ligands $MeNH{\cdot}CO{\cdot}CH_2{\cdot}CO{\cdot}NHMe$, $MeNH{\cdot}CO{\cdot}CH_2{\cdot}CH_2{\cdot}CO{\cdot}NHMe$ and $MeNH{\cdot}CS{\cdot}CH_2{\cdot}CS{\cdot}NHMe$ have been determined by X-ray diffraction studies. The framework C–C, C–N, and C=O/C=S bond distances and the associated interbond angles are all closely similar and the packing of these molecules is dominated by intermolecular hydrogen bonding of the type N–H···O=C and, to a lesser extent, N–H···S=C. For means of comparison the bond parameters of all the structurally characterised related ligands belonging to the N,N′-disubstituted series $RNH{\cdot}C\O{\cdot}(CH_2)_n{\cdot}C\O{\cdot}NHR$ where R = alkyl; Ø=O, S and n = O, 1, 2 are listed and a general overview of the characteristics of such ligands including conformational variations is provided. Structural characterisation (X-ray diffraction) of $SnBr_4$ ($MeNH{\cdot}CO{\cdot}CH_2{\cdot}CO{\cdot}NHMe$)·$MeNH{\cdot}CO{\cdot}CH_2{\cdot}CO{\cdot}NHMe$, $SnBr_4({}^iPrNH{\cdot}CO{\cdot}CH_2{\cdot}CO{\cdot}NH{}^iPr){\cdot}2THF$ and $SnBr_4({}^iPrNH{\cdot}CS{\cdot}CH_2{\cdot}CS{\cdot}NH{}^iPr){\cdot}MeCN$ reveals bidentate chelate ligand attachment for these six coordinate mononuclear *cis*-octahedral Sn(IV) complexes. In all three structures, the NH groups are involved in intermolecular hydrogen bonding being linked either to C=O/C=S groups of adjacent molecules, or solvent molecule(s) entrapped in the lattice and/or halogen atom(s) of a neighbouring $SnBr_4$ moiety. The general range of Sn-Br distances is 2.504(3)-2.565(12) Å excluding those halogen atoms directly involved in N-H···Br-Sn interactions. These several types of intermolecular hydrogen bonding are viewed as a direct cause of ring puckering in the chelated rings approximating to a chair conformation. © 1998 Elsevier Science Ltd. Keywords: X-ray structures; octahedral Sn(IV) complexes; oxalamides; malonamides; succinamides; oxa/thia derivatives.

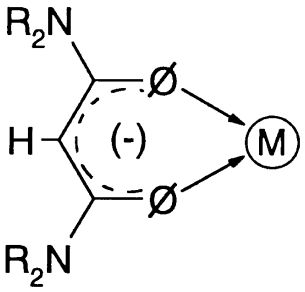
*Author to whom correspondence should be addressed.

The generic series RHN·CØ·$(CH_2)_n$·CØ·NHR [H_2L] comprising oxa (Ø═O) and thia (Ø═S) derivatives of oxalamides ($n=0$), malonamides ($n=1$) and succinamides ($n=2$) has been used extensively in metal complexation both for analytical purposes and in the development of novel p-and d-block metal compounds [1]. With both 'hard' (N, Ø═O) and 'soft' (Ø═S) donor centres available this is clearly a versatile family of ligands in terms of metal selectivity. In view of the structural diversity of these ligands e.g., the co-ordination mode(s) adopted for specific metal ion(s) and the conformational rearrangements consequent with complexation, we have undertaken a crystallographic investigation of representative members of the series. Recent studies from these laboratories have been focused on the structural classification of **neutral** H_2L-*p*-block metal complexes involving the halides of Groups 14/15 as reference Lewis acids [2]. Perhaps the main point that has emerged from our work relates to the ligand binding; of the potential donor sites, it is always the oxygen (sulphur) atoms that are involved in bonding to the metal. The trigonal (sp^2) geometry around the nitrogen atoms indicates that the formal lone pair of electrons is incorporated in 'internal' p_π-p_π bonding within the thia (oxa)-amide moiety.

Related studies by other research groups have been directed towards the coordination behaviour of these ligands, often in the anionic form and sometimes involving nitrogen coordination, with transition metal ions [3]. De-protonation of the nitrogen centres provides the amide forms HL^- and L^{2-} and typical examples of the former include: [$Pd(C_6H_{11}NH{\cdot}CS{\cdot}CS{\cdot}NC_6H_{11})_2$] [4] featuring square planar Pd^{II} with S_4 coordination and [$Pd(C_5H_9NH{\cdot}CS{\cdot}CS{\cdot}NC_5H_9)_2$] [5] with a similar metal environment. One other variation of proton-loss leading to HL^- has been noted: This is specific to malonamide ligands and features loss of a proton from the methyne backbone to provide six-membered ring formation of the type



with accompanying delocalised π-character similar to M(acac) complexation. The compound Ni(dpdtma)$_2$·2DMF [6] where dpdtma-,N,N′-diphenyldithiomalonamide mono-anion provides a typical example. Examples of L^{2-} include $Na_2[Ni(etox)_2]{\cdot}H_2O$ (H_2etox = $H_2N{\cdot}CO{\cdot}CO{\cdot}NH(CH_2)_2OH$) [7] where each ligand is bonded to the central Ni^{2+} ion through both of its deprotonated nitrogen atoms and the Cu(II) complexes $\{Cu_2[S_2C_2(NCH_2CH_2OH)_2](H_2O)_2\}SO_4$ and $[\{Cu_2[S_2C_2(NCH_2CH_2OH)_2](H_2O)(SO_4)\}(H_2O)_2$ [8] where the deprotonated amine centres of each ligand bind to separate metal ions resulting in zig-zag chain structures.

In this report we describe the crystal and molecular structures of the ligands, MeNH·CO·CH_2·CO·NHMe (L^1), MeNH·CO·CH_2·CH_2·CO·NHMe (L^4), MeNH·CS·CH_2·CS·NHMe (L^5) and the Sn(IV) derivatives $SnBr_4L^1{\cdot}L^1$ (I), $SnBr_4L^2{\cdot}2THF$ (2) and $SnBr_4L^3{\cdot}MeCN$ (3) where $L^2 = {}^iC_3H_7NH{\cdot}CO{\cdot}CH_2{\cdot}CO{\cdot}NH{}^iC_3H_7$ and $L^3 = {}^iC_3H_7NH{\cdot}CS{\cdot}CH_2{\cdot}CS{\cdot}NH{}^iC_3H_7$.

EXPERIMENTAL

Manipulations of materials were carried out using standard Schlenk techniques in conjunction with a dinitrogen-filled 'dry-box'. Solvents were stored over CaH_2-P_4O_{10} and distilled under a dinitrogen atmosphere immediately prior to use. Infrared spectra (4000-200) cm^{-1} were recorded on a Perkin Elmer 580B instrument with samples as Nujol mulls between CsI plates. The ^1H (400 MHz) nmr spectra were recorded on a Bruker ACP 400 spectrometer using CD_3CN solutions. Microanalytical data were obtained using a Leeman Labs Inc., PS 1000 sequential inductively coupled plasma (ICP) spectrometer and a CE440 elemental (C,H,N) analyser.

REAGENTS

$SnBr_4$ was obtained commercially and used directly. The oxa ligands were prepared from the corresponding acid esters via direct aminolysis with the appropriate primary amine as previously described [2]. Conversion of these oxa ligands to their corresponding thia derivatives can be carried out by direct thiation using Lawesson's reagent i.e., 2,4-bis(p-methoxyphenyl) - 2,4 - dithioxo - 1,3,2,4 - dithiaphosphetane [9, 10].

Typically for L^3: N,N′-di-isopropyl malonamide (20.0 g, 107.4 mmol) dissolved in toluene (25 cm^3) was added to a solution of Lawesson's Reagent (43.4 g, 107.4 mmol) in toluene (80 cm^3) and the mixture was heated at reflux for 3 hrs. The resulting yellow solution was cooled, and the solvent removed *in vacuo* to give a yellow solid, which was purified by column chromatography (Silica gel, 50:50 ether/acetone as elutant). Recrystallisation from acetonitrile provided yellow needle crystals of the product (14.5 g, 62%). Anal. Calcd. for $C_9H_{18}N_2S_2$:C, 49.5; H, 8.3; N, 12.8. Found: C, 49.2; H, 8.2; N, 12.7%. IR, $\bar{\nu}/cm^{-1}$ (Nujol) 3187 s (NH); 1538 m (CN), 904 m (CS); $\delta_H(CDCl_3)$ 8.83 (s, 2H, NH), 4.55–4.44 (m, 2H, CH), 4.05 (s, 2H, CH_2), 1.24, 1.21 (d, 12H, CH_3).

PREPARATION OF THE METAL COMPLEXES

(*a*) *$SnBr_4L^1{\cdot}L^1$*(1)

$SnBr_4$ (1.0 g, 2.3 mmol) in acetonitrile (20 cm^3) was added to a solution of N,N′-dimethylmalonamide (0.3 g, 2.3 mmol) and the mixture was stirred for 6 hrs at 50°C under an inert atmosphere of dinitrogen. Removal of solvent *in vacuo* provided a white powder which was washed with n-hexane (3×10 cm^3). Recrystallisation from THF/CH_2Cl_2 (50:50) provided colourless rhomboid crystals suitable for X-ray diffraction. Yield (1.09 g, 68%). Anal. Calcd. for $C_{10}H_{20}N_4O_4SnBr_4$. C, 17.2; H, 2.9; N, 8.0. Found: C, 17.4; H, 2.8; N, 8.1%. IR $\bar{\nu}/cm^{-1}$ (Nujol) 3235 m(NH), 1624 s (CO), 320 m, 280 vs (SnBr). δ_H ($CDCl_3$) 8.41 (s, 2H, NH), 3.87 (s, 2H, CH_2) 2.90 (2, 6H, CH_3).

(*b*) *$SnBr_4L^2{\cdot}2THF$* (2)

To a solution of N,N′-di-isopropylmalonamide (0.4 g, 2.2 mmol) in THF (25 cm^3) was added a solution of $SnBr_4$ (0.94 g, 2.15 mmol) in THF (25 cm^3). The mixture was maintained at 50°C and stirred under an atmosphere of argon for 6 hrs. Removal of the

X-RAY CRYSTALLOGRAPHY

Crystal Data for the 5 compounds are given in Table 1, together with refinement details. Data for (1), (2), (3) and L^5 were collected with MoKα radiation using the MARresearch Image Plate System. The crystals were positioned at 70 or 75 mm from the Image Plate. 95 frames were measured at 2° intervals with a counting time of 2 mins. Data analysis was carried out with the XDS program [11]. Data for L^4 were collected on a Stoe Stadi2 diffractometer via variable ω scan. All structures were solved using direct methods with the Shelx86 program [12].

The non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were included in geometric positions. Empirical absorption corrections were carried out on (1), (2) and (3) using DIFABS [13]. Structures (1), (2), (3) and L^5 were refined on F^2 using Shelxl [14]. Structure L^4 was refined on F^2 using Shelx76 [15].

RESULTS AND DISCUSSION

As a convenient summary the bonding modes of neutral $RNH{\cdot}C\phi{\cdot}(CH_2)_n{\cdot}C\phi{\cdot}NHR$ (H_2L) that are feasible for metal complexation are depicted in Fig. 1.

Types **A** and **B** have the ligand in a 'trans-bridging' arrangement with either **one** (type A) or **both** (Type B) of the lone pairs on ϕ (O,S) involved in bonding to a metal. In contrast types **C** and **D** feature a 'cis-chelating' arrangement whereby one (type C) or both (type D) of the lone pairs associated with ϕ are involved in ϕ: $\rightarrow$M bond formation. Further interactions involving the hydrogen atoms of the NHR groups with either (a) the residual lone pair(s) on ϕ of an adjacent molecule(s) (b) entrapped lattice solvent molecules or (c) halogen atoms of an adjacent molecule (Lewis acid) are possible and have been observed; these hydrogen bonding interactions are denoted by the dotted lines. Previous structures of metal complexes incorporating the neutral $RNH{\cdot}C\phi{\cdot}(CH_2)_n{\cdot}C\phi{\cdot}NHR$ ligands confirm bonding types A, B and C but there is a conspicuous absence of type D. As noted later, all the oxamide and thiaoxamide ligands ($n=0$) adopt the *trans-*ϕ geometry in the free form. In metal complexation of types A/B this arrangement is retained unchanged but in the case of type C internal rotation about the C–C bond must occur in order for the ligand to achieve the required *cis-*ϕ configuration. Using Fenske-Hall molecular orbital calculations, Busch et al [1] and Stufkens et al [3] show that this conformational change for dithiooxamide brings no detrimental change to the bonding/electronic structure of the ligand [the valence group orbitals LUMO/HOMO of the two forms are closely similar in energy and composition] which can function as an effective bidentate chelate σ-donor. Clearly there are no structural/conformational restrictions present in the malonamide and succinamide derivatives where the skeletonal CH_2 unit(s) allow free rotation about C–C bonds. As a general point bidentate binding (whether bridging or chelation) is the hallmark of ligand attachment to a metal centre throughout the series. However, there is one example of monodentate binding i.e., the neutral complex $CuCl(PPh_3)_2(H_2N{\cdot}CS{\cdot}CS{\cdot}NH_2)$ [16] where the dithiaoxamide ligand retains its *trans*-configuration but is bound to the tetrahedral Cu(I) via only **one** of the two available S donor atoms leaving the other in a non-coordinating role.

STRUCTURAL CHARACTERISATION OF THE LIGANDS

Structures of the three ligands L^1, L^4 and L^5 are shown in Fig. 2, Fig. 3 and Fig. 4 respectively together with the atomic notation. The structures of L^4 and L^5 both have crystallographic symmetry with L^4 containing a centre of symmetry and L^5 a two-fold axis. The structure of L^1 was obtained from the adduct $SnBr_4L^1{\cdot}L^1$ (1) and this presumably could affect its conformation. We can describe the conformation by the O═C···C═O torsion angle: in the free ligand, the angle for L^1 is $-83.2°$ compared to a value of 0.5° in the complexed molecule present in the structure of (1). The two carbonyl groups in L^1 are both hydrogen bonded to N–H groups in a chelating ligand. For L^5 the analogous S═C··· C═S angle is $-112.4°$. whereas the equivalent torsion angle in L^4 is perforce 180°.

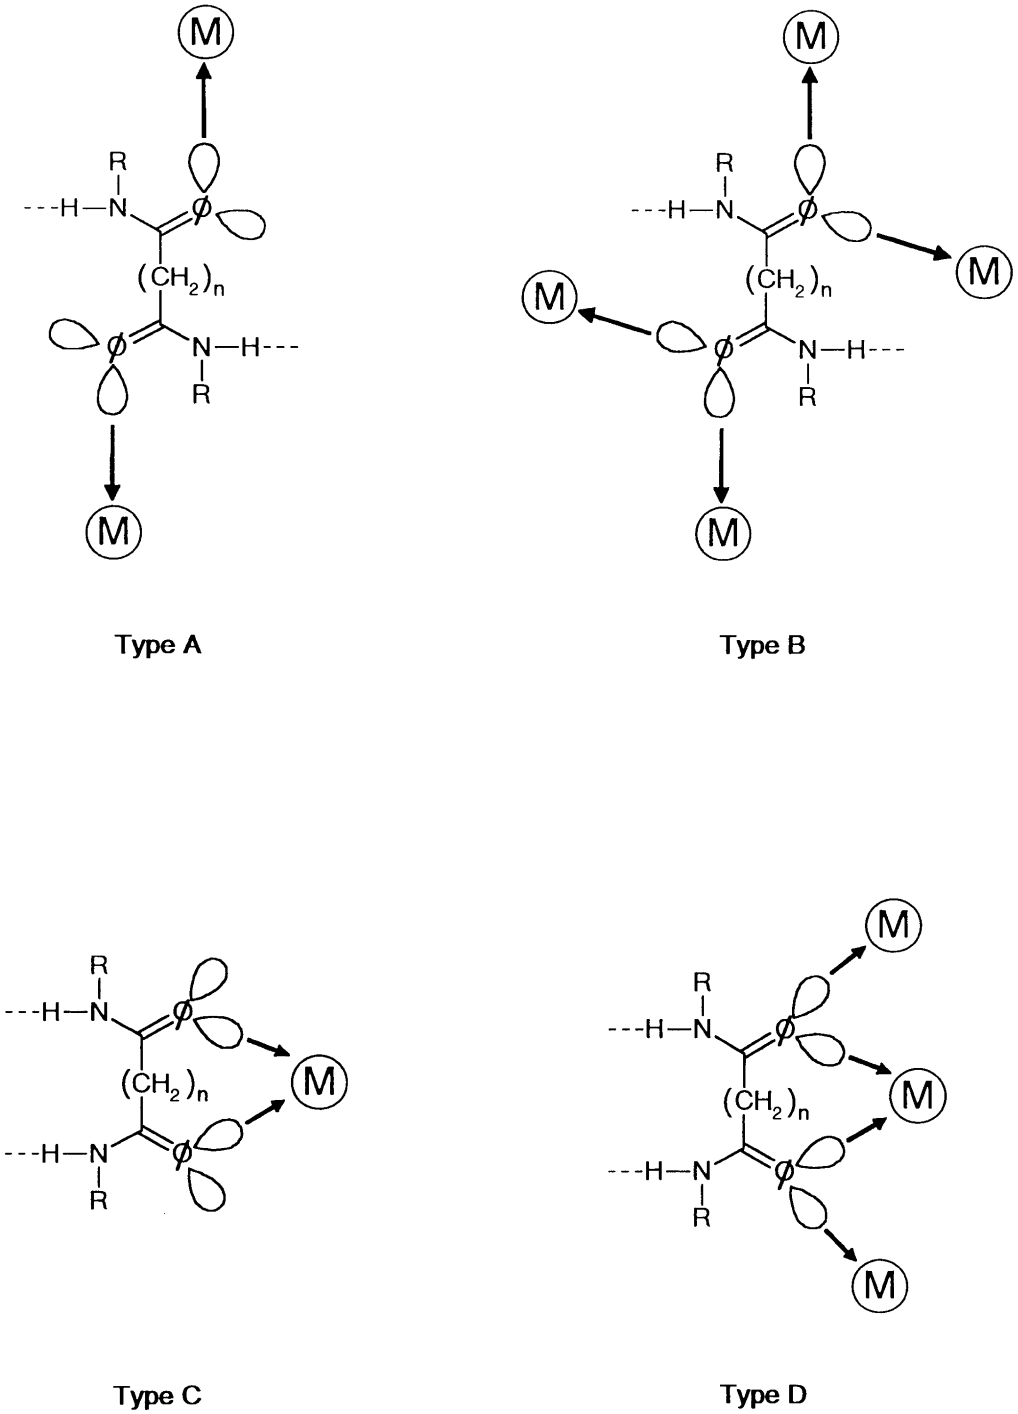

Fig. 1. Bonding modes of neutral (RNH·CØ·$(CH_2)_n$·CØ·NHR ligands.

Several features emerge for these ligands that are consistent throughout and can be summarised as follows: the angles at the central carbon atom(s) are tetrahedral; the bond arrangements and angles at each of the terminal nitrogen atoms indicate a trigonal planar (120°) disposition; the NHR groups, R=Me(L^1, L^4, L^5) are clearly rotated about the linkage C–N bonds and lie outside the O–C–N (L^1, L^4) and S–C–N (L^5) planes; the framework C–C, C–N and C–Ø bond distances and the associated interbond angles are all closely similar and can be favourably compared with those observed previously for other

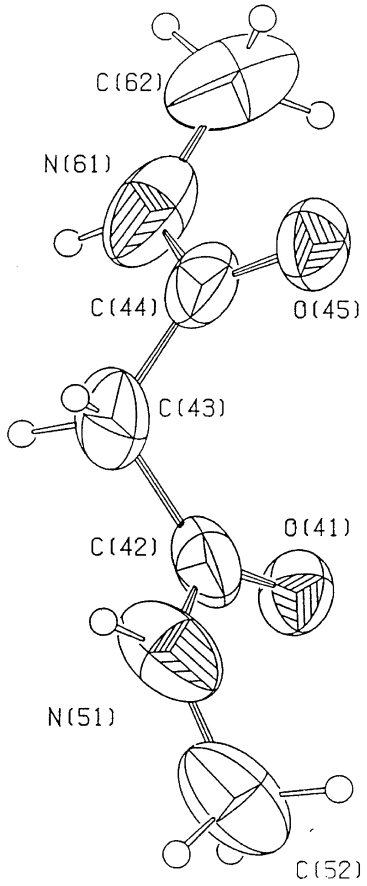

Fig. 2. The structure of L^1 as found in the structure of $SnBr_4L^1 \cdot L^1$ (1). Ellipsoids shown at 30% probability.

members of the series. For convenience a listing of the related LH_2 ligands that have been structurally characterised is included in Table 2 along with their pertinent bond dimensions.

It is clear that the $n=0$ compounds invariably have the trans conformation as do the $n=2$ compounds though there is much less evidence for this. However the $n=1$ compounds have much greater flexibility. The torsion angles in L^1 and L^5 are -83.2°, -112.4° respectively and this can be compared with values of 90.8° and -144.6° found in the analogous diamines. A recent study of the structures of disubstituted malonamides [1(d)] has established a wide range of low energy conformations. With R^1 = methyl, R^2 = phenyl, the four lowest energy conformations have O═C···C═O torsion angles of -70.4, 132.7, -158.0, 174.4 while for R^1 = methyl, R^2 = cyclohexyl, the corresponding values are 161.2, 164.4, 168.5, -71.0°. The conformational analyses are all consistent with facile reorientation of the ligand to form chelates with metal atoms.

The packing of the molecules L^4 and L^5 is dominated by intramolecular hydrogen bonding and details are listed for all structures in Table 3. L^4 forms hydrogen bonds between amide N-H and amide carbonyls on adjacent molecules N(21)···O(11) 2.84 Å. In L^5 similar bonding is found between adjacent N–H and S atoms N(21)···S(11) 3.35 Å.

STRUCTURES OF Sn(IV) COMPLEXES

Previous examples of metal complexation involving a Sn(IV) halide as reference Lewis acid include $SnBr_4(^tC_4H_9NH \cdot CO \cdot CO \cdot NH^tC_4H_9) \cdot THF$ [2(f)], (X), $SnBr_4(^nC_4H_9NH \cdot CS \cdot CS \cdot NH^n \cdot C_4H_9)$ [2(c)] (Y) and $SnBr_4$ (MeNH·CO·CH_2·CH_2·CO·NHMe). THF [2(f)] (Z). All feature type C bonding. In this present study we show that the ligand types $n=1$, Ø═0 and $n=1$, Ø═S also provide bidentate chelation with Sn(IV).

The three metal complex structures are shown in Fig. 5, Fig. 6 and Fig. 7 and include the atom notation used. The principal bond lengths and angles are listed in Table 4. In all cases the metal atom is octahedral being bonded to four bromine atoms and a bidentate ligand. It is remarkable that in all three structures the metal complex co-crystallises with other molecules [in (1) this is L^1 and in (2) and (3) these are solvent molecules] so that both amide nitrogen atoms can form intramolecular hydrogen bonds. Thus in (1),

each nitrogen on the chelating ligand forms strong hydrogen bonds to the free ligand N(21)···O(31) 2.85, N(31)···O(41) 2.75 Å. In (2) these bonds are to THF solvent molecules N(21)···O(41) 2.85, N(31)···O(51) 2.90 Å and in (3) to a solvent acetonitrile N(21)···N(100) 3.19 Å, N(21)···N(100) 3.23 Å. In addition there are short contacts with the bromine atoms that could represent hydrogen bond interactions. These are also listed in Table 3. By way of comparison the oxalamide derivative compound (X) features a highly symmetrical N–H···$O_{solvent}$ hydrogen bonding interaction whereby the **two** N–H groups of the chelated ligand are linked directly to the oxygen atom of the single solvate (THF) molecule with dimensions O·····H–N 178°, O·····H 1.90, O·····N 2.85 (3) Å. In the particular case of compound (Z) whereas one of the NH centres is involved in N–H·····$O_{solvent}$ hydrogen bonding (N–H·····O 176°, H·····O 1.75, N·····O 2.69 Å) the other is linked to a bromine atom of an adjacent molecule with dimensions Br·····H–N 172°, Br·····H 2.67 Å, Br·····N 3.56 Å. It is interesting that in all three of the present structures (1)-(3) the chelate ring around the metal is not planar and indeed takes up a chair conformation. Thus taking the plane of O(11), C(12), C(14) and O(15), the distances of Sn and C(13) from the plane are 0.48, 0.54 Å in (1), 0.38, 0.53 Å in (2) and 0.87, 0.75 Å in (3). Clearly the presence of the donating sulphur atoms in (3) has had a significant effect on the ring conformation compared to the oxygen atoms in (1) and (2). This is also demonstrated by the Sn-Br bond lengths which are perceptibly longer in (3) by *ca*. 0.07 Å than those in (1) or (2).

The general range of Sn-Br bond distances observed for the six structures (1)-(3) and (X)-(Z) is 2.504(3)-2.565(12) Å excluding those halogen atoms involved in hydrogen bonding. For the latter type a discernible lengthening is noted *e.g.*, 2.625(13) Å in compound (Y). For oxa ligand complexes, the Sn–O bond distances remain fairly constant *viz.*, (1) 2.131(6), 2.152(6), (2) 2.158(7), 2.164(8), (X) 2.180(14), (Z) 2.124(18), 2.148(20) Å; similarly the Sn-S bond distances do not vary overmuch for the thia ligand complexes *viz.*, (3) 2.568(4), 2.576(4), (Y), 2.565(28), 2.551(25) Å. The bite of the bidentate ligands, as gauged by the angle Ø-Sn-Ø, follows the series: Ø═0: $n=0$, 73.3(5)°(X); $n=1$, 83.6(2)°(1); $n=1$, 82.5(3)°(2); $n=2$, 84.0(7)°(Z) and Ø=S: $n=0$, 83.6(7)°(Y); $n=1$, 92.64(12)°(3) *e.g.*, as the size of the ligand increases there is an **increase** in bite angle with the change from $n=0\rightarrow n=1$ showing a dramatic increase of *ca.* 10° in both systems. At the same time the Br–Sn–Br angle subtended by the Br atoms positioned *trans* to the Ø atoms follows the opposite trend: Ø═0: $n=0$, 106.2(1)° (X); $n=1$, 97.89(5)° (1); $n=1$, 98.94(5)° (2); $n=2$, 99.18(14)° (Z) and Ø=S: $n=0$, 101.8(4)° (Y); $n=1$, 97.89(6)° (3).

Supplementary material

(Received 26 November 1997; accepted 7 March 1998)

Abstract—The polymeric complexes $[CuCl(pyrazinato)(H_2O)]_n$ (1) and $[Cu(N_3)(pyrazinato)(H_2O)]_n$ (2) have been synthesized and characterized by spectroscopic methods and X-ray crystallography. The overall spectral results indicate that these complexes contain tridentate pyrazinato ligands, terminal chloride or azide groups and aqua molecules. In the structure of complex (1), each copper atom, which is chelated by O(1) and N(1) atoms of the pyrazinato anions, links Cl(1) atom, O(3) atom from an aqua molecule and the second nitrogen, N(2) from a pyrazinato group of a neighbouring unit giving rise to a 1D polymeric structure. The structure of complex (2), which is very similar to 1 features five coordinate copper(II) atom, *N*, *N*,*O*-tridentate pyrazinato ligand, terminal azido ligand, aqua molecule and 1D polymeric structure. There are different types of hydrogen bonds in both complexes. The thermal decomposition of complexes (1) and (2) was investigated thermogravimetrically in nitrogen atmosphere. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: copper(II) chloride; copper(II) azide; pyrazinato complexes; crystal structure; spectra; thermal analysis.

It is now well estalished that the picolinate anion, also known as pyridine-2-carboxylate, acts as a chelating bidentate ligand [1–4], as a N,O,O′-tridentate chelating bridging ligand as found in the structure of $[Cu(picolinato)_2 \cdot 2H_2O$ [5], as a N,O,O-tridentate ligand as in $[Mn(picolinato)(N_3)(H_2O)]_n$ [6] and as a N,O,O,O′-tetradentate ligand as in the structure of $[Cu(picolinato)Cl]_n$ [7] or $[Cd(picolinato)X]_n$ (X = N_3 or NCS) [8]. Both coordinative interactions to transition metal centers and ionic interaction to alkali metals, have been observed in the crystal structures of $[NaCu(picolinato)_2(N_3)(H_2O)_2]_n$ [9] and $[MCu(picolinato)(N_3)_2]_n$ [M = Na or K] [10]. Thus, the picolinato anion is a versatile ligand that can bind metal ions in a variety of bonding modes.

Pyrazine and pyrazinic acid, also called pyrazine-2-carboxylic acid (hereafter abbreviated as H-pyz) combine the coordinating properties of the pyridine-2-carboxylic acid with the fact that the pyrazine moiety may act as a bridge and thus aid the formation of polymeric structures [11, 12]. Pyrazinic acid is therefore expected to be at least as versatile as the picolinic acid. Recently we established that pyrazinic acid serves as a N,O-chelating bidentate ligand as found in the structures of $[NaMn(pyrazinato)(X)_2(H_2O)_2]_n$ (X = N_3 or NCO) [13, 14], and as a monodentate ligand in $[Cu_2(pyrazinic\ acid)_2I_2] \cdot 3H_2O$ [15]. In the

* Author to whom correspondence should be addressed.

later complex, the two pyrazinic acid molecules in the asymmetric unit behave differently; one acid molecule acts as a neutral ligand whereas the other molecule functions as a zwitterion. We also established that the structure of KCu_2(pyrazinato)$(N_3)_4$ complex consists of a dinuclear complex anion $[Cu_2(N_3)_6]^{2-}$, potassium cations and neutral polymeric complex [Cu(pyrazinato)(N_3)] [16]. Further studies led to the isolation of dark green complexes of the general formula Cu(pyrazinato)X(H_2O), for X = Cl or N_3, the first to have been reported. The structure characterizations of these two new hydrated complexes as elucidated by spectroscopic and crystallographic methods are the subject of the present paper.

EXPERIMENTAL

Pyrazinic acid was obtained from Aldrich and other chemicals are of analytical grade quality.

Preparation of [Cu(pyrazinato)Cl$(H_2O)]_n$ *complex* (1)

Mixing of the components in aq/ethanol media yields a mixture of pale green powder and blue microcrystalline powder.

Crystals of this complex suitable for X-ray diffraction were prepared by mixing $CuCl_2 \cdot 2H_2O$ (0.68 g, 4 mmol) and pyrazinic acid (0.37 g, 3 mmol) in boiled 2:1 ethanol/water (30 cm^3) and several drops of 0.1 M sodium azide. This mixture was allowed to stand in the open air for several days to growth a small amount of green crystals along with a blue microcrystalline powder. The yield is 15%.

Anal. Found. C, 24.5; *H*, 2.2; *N*, 11.7; *Cl*, 15.1; *Cu*, 26.9. **Calcd. for $C_5H_5ClCuN_2O_3$**: *C*, 25.0; *H*, 2.1; *N*, 11.7; *Cl*, 14.9; *Cu*, 26.4 (%).

Preparation of [Cu(pyrazinato)$(N_3)(H_2O)]_n$ *complex* (2)

This complex was prepared by adding ethyl pyrazinate (0.43 g, 3 mmol) in 20 cm^3 ethanol to 10 cm^3 ethanol solution of $Cu(NO_3)_2 \cdot 3H_2O$ (0.68 g, 4 mmol) followed by dropwise addition of an aqueous solution (5 cm^3) NaN_3 (0.19 g, 3 mmol), The mixture was shaken after each addition, and then allowed to stand over several days until dark green crystals of the complex deposited together with a blue microcrystalline powder. The yield is 28%.

Anal. Found C, 24.2; *H*, 2.1; *N*, 28.0; *Cu*, 25.2. **Calcd. for $C_5H_5CuN_5O_3$:** *C*, 24.3; *H*, 2.0; *N*, 28.4; *Cu*, 25.7 (%).

Physical measurements

The procedure and instruments used for other physical measurements were as described previously [14, 16].

X-ray crystal structure analysis

A modified STOE four circle diffractometer was used for single crystal X-ray measurements. Orientation matrix and lattice parameters were obtained by least-squares refinement of the diffraction data from 45 (compound 1) and 59 (compound 2) reflections in the 2θ range 7–33°. Data were collected at 298(2) K using graphite crystal-monochromatized Mo–K_α radiation ($\lambda = 0.71069$ Å) and the ω-scan technique. The intensities were corrected for Lorentz-polarisation effects and for absorption. Crystallographic data are given in Table 1.

The structure was solved by direct methods and subsequent Fourier analysis. Anisotropic displacement parameters were applied to non-hydrogen atoms in full-matrix least-squares refinements based on F^2. The hydrogen atoms were assigned with common isotropic displacement factors and included in the final refinement cycles by use of geometrical restraints. Analytical expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated. The program DIFABS [17], and SHELXTL/PC [18] program package were used for computations. Selected bond distances and bond angles are given in Tables 2 and 3. Additional material, consisting of fractional atomic coordinates, displacement parameters, observed and calculated structure factors and complete lists of bond distances and bond angles, has been deposited with the editor.

RESULTS AND DISCUSSION

Mixing of $CuCl_2 \cdot 2H_2O$ and pyrazinic acid (1:1 molar ratio) in aq./EtOH medium afforded a pale green powder of the chloride complex, whereas addition of pyrazinic acid to $Cu(NO_3)_2 \cdot 3H_2O$ in ethanol followed by an aq. solution of NaN_3 (1:1:1 molar ratio) afforded an olive green powder of the azide complex. In both cases, however, a blue crystalline powder is co-precipitated, the amount of which can be reduced by decreasing the amount of pyrazinic acid to be less than 1:1 to copper. Single crystals of the chloride complex were prepared by mixing the components in ethanol followed by addition of several drops of 0.1 M NaN_3 aq. solution. Dark green crystals of the azide complex were isolated by mixing ethyl pyrazinate and copper(II) nitrate in ethanol followed by sodium azide, which suggests that the ethyl ester is easily hydrolyzed. Both complexes are insoluble in many non-polar solvents, e.g. benzene, CCl_4, etc., as well as polar solvents, e.g. alcohols, acetone, chloroform, etc., but they are soluble in DMSO and DMF giving non-conducting solutions.

Structures

The principle structural features of complex (1) are illustrated in Fig. 1. The pyrazinato anion chelates the

copper(II) atom via its ring nitrogen atom, N(1), and a carboxylato oxygen, O(1), to form a five membered chelate ring. The chelating ring deviates only 0.030(3) Å from planarity and the N(1)–O(1) distance is 2.613(4) Å. Each copper center is further coordinated by a chloride atom, Cl(1), and an oxygen atom, O(3), from an aqua molecule and a nitrogen atom, N(2) from a pyrazinato ligand of a neighbouring unit giving rise to a 1D chain along the *c*-axis (Fig. 2). The coordination environment of each five-coordinate copper atom is best described as a square pyramid with the oxygen atom, O(3) of the aqua molecule at its apex.

The structure determination has established the title

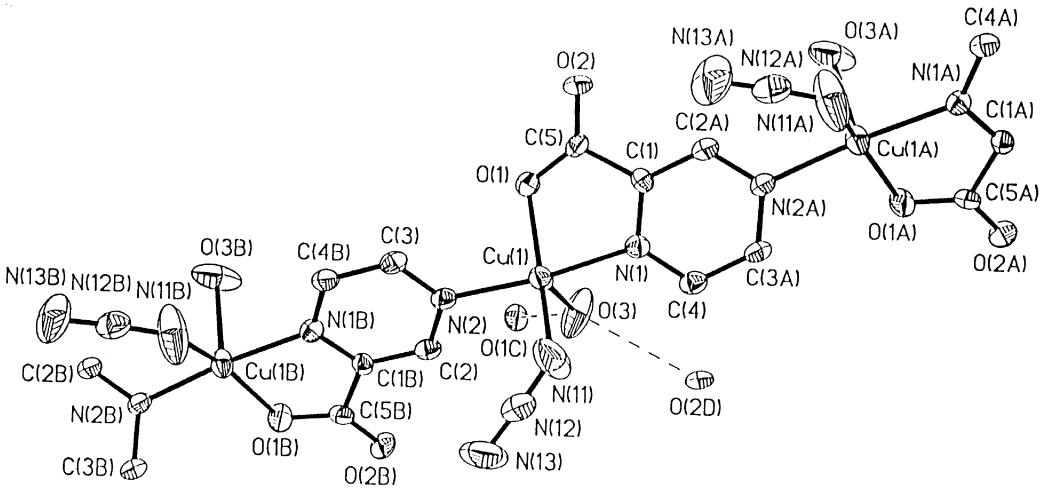

Fig. 1. Molecular geometry and atom labelling scheme of $[CuCl(pyz)(H_2O)]_n$, 1. Hydrogen atoms are omitted.

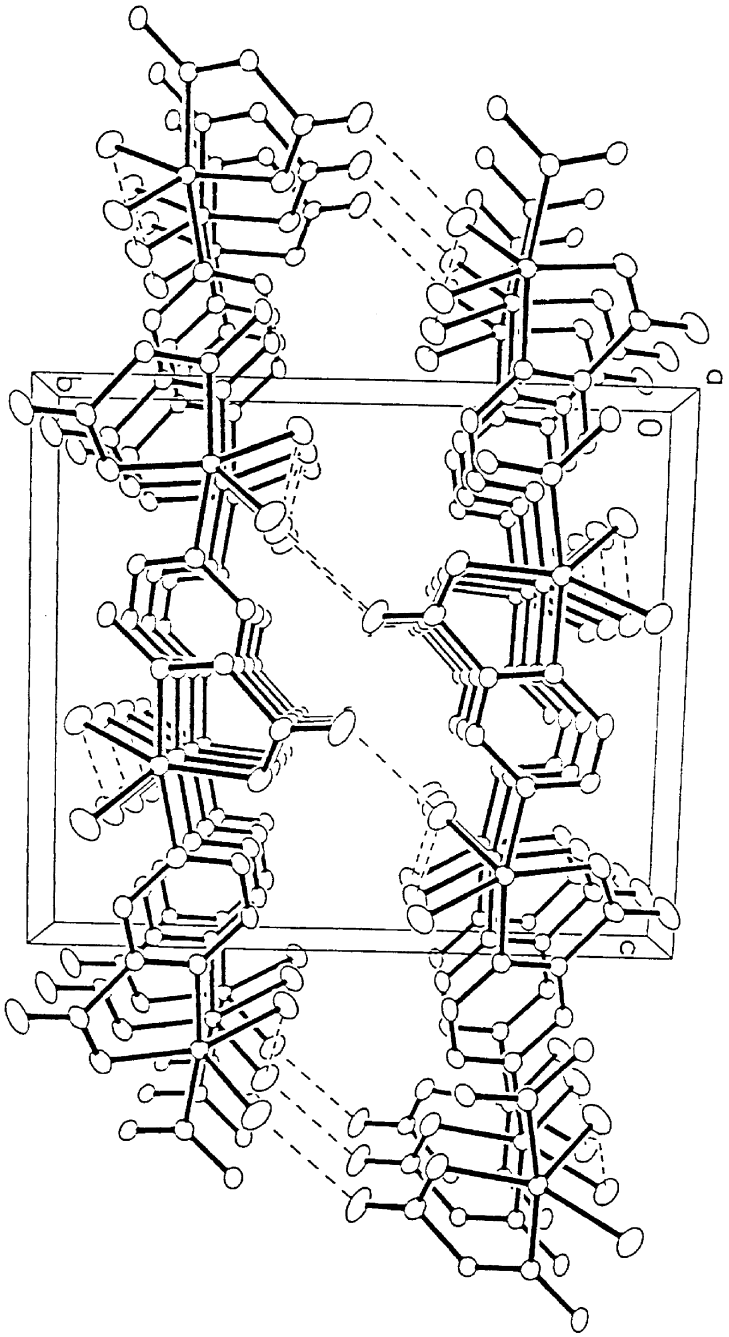

Fig. 2. Packing plot of $[CuCl(pyz)(H_2O)]_n$, 1. Viewed along the *a*-axis of the unit cell.

complex (2) as $[Cu(N_3)(pyrazinato)(H_2O)]_n$, for which Fig. 3 illustrates the principle structural features. The structure of complex (2) is very close to that of complex (1) except that a terminal azide replaces the chloride atom. The deviation of the chelating ring from planarity of 0.036(4) Å, and the N(1)–O(1) distance of 2.605(6) Å found in 2, are slightly greater, whereas the Cu–N(1) and Cu–O(1) distances of 2.009(4) and 2.605(6) Å, respectively are very close to corresponding values in (1). As in the structure of complex (1), the geometry around each copper atom in 2 attains a distorted square pyramid with O(3) at its apex forming 1D chain along the *a*-axis.

The structures 1 and 2 differ from that of the polymeric complex $[Cu(pyrazinato)(N_3)]_n$ (3) found in the structure of $KCu_2(pyrazinato)(N_3)_4$ [20]. In the later complex, also contains *O*,*N*,*N*′-tridentate chelating bridging pyrazinato anion, each copper atom is four

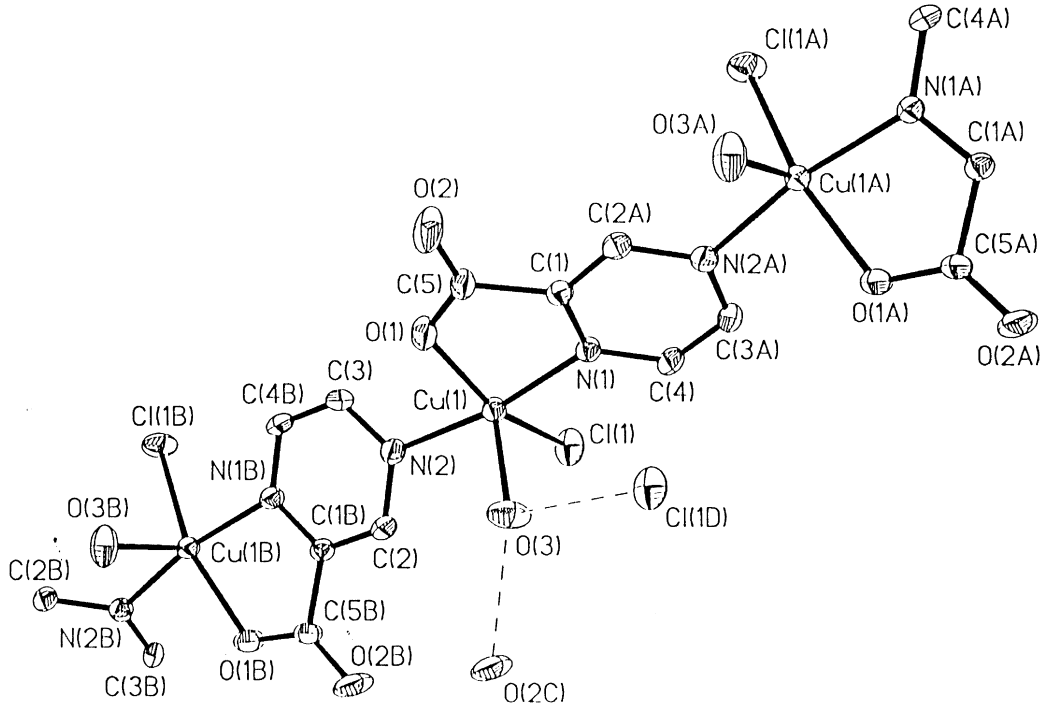

Fig. 3. Molecular geometry and atom labelling scheme of $[Cu(N_3)(pyz)(H_2O)]_n$, 2. Hydrogen atoms are omitted.

coordinated with the fourth position occupied by a nitrogen atom of a terminal azide. The Cu–N(11) distance of 1.942(7) Å in 2 is very similar to corresponding value of 1.943(5) Å found in 3. The Cu–N(1) and Cu–N(2) bond lengths are very close, whereas the Cu–O(1) distances in complexes (1) and (2) are little longer than corresponding values of 2.010(4), 2.022(4) and 1.944(5) Å, respectively, found in complex (3). The structures of both complexs 1 and 2 also differ from the structures of the monomer $[Cu(pyrazinato)_2(H_2O)_2]$, polymer $[Cu(pyrazinato)_2]_n$ and dimer $[Cu(pyrazinic\ acid)Cl_2]_2$ complexes [19, 20], where the pyrazinate ligand acts as chelating *N-O*-bidentate in the monomer and dimer complexes and as a chelating bridging *N-O-O′*-tridentate in the polymer. In accordance with the infrared spectra (see later), different kinds of hydrogen bonds exist in both structures. In 1 the interaction between chains of polyhedra occurs by hydrogen bonds only Fig. 2, whereas in 2 hydrogen bonds cause the formation of double sheets of polyhedra chains oriented parallel to the *ab*-plane, followed by stacking interaction of these double layers (Fig. 4). Details of the hydrogen-bonding geometry are given in Tables 2 and 3.

IR spectra

The IR spectra (Table 4) of complexes 1 and 2 exhibit a strong broad band around 34000 cm^{-1} due to H-bonds of the type O–H...O between H_2O molecule and oxygen atoms of the carboxylato groups. The H-bonds of the types N–H...O and O–H...N or O–H...O in free pyrazinic acid are replaced by O–H...O bonds since both nitrogen atoms of the pyrazinato ligand are involved in coordination to copper. Both complexes show a substantial decrease of the $\nu_{as}(COO^-)$ to about 1660 cm^{-1}, compared to that of free ligand (1720 cm^{-1}), and an increase of the $\nu_s(COO^-)$ to 1365 and 1343 cm^{-1} for 1 and 2, respectively. This large separation between the ν(COO) indicates the unidentate coordination of the carboxylato group to the metal atom as found for many metal complexes of carboxylic acids [21–23]. Vibrations related to the pyrazine moiety are substantially shifted to higher wave numbers when compared with those of the free ligand. Such shifts are much greater than in other complexes containing N,O-bidentate pyrazinato ligand [13]. Thus the coordination of the pyrazinato group via its two nitrogens manifests itself in a greater shift of the pyrazine vibrations as compared with those when it coordinates via one nitrogen atom only.

The IR specrum of the azide complex, 2 shows a very strong band at 2051 cm^{-1} due to $\nu_{as}(N_3)$. This value is very similar to those reported for metal azide complexes containing symmetrical azide groups [24, 25]. In support, the $\nu_s(N_3)$mode which appears as a weak band at 1295 cm^{-1}, suggests a slightly asymmetric azide. In the far IR region a medium band appeared at 392 cm^{-1}, in 2, assigned to the νCu–$N(N_3)$, and a band at 325 cm^{-1} in 1, assigned as the

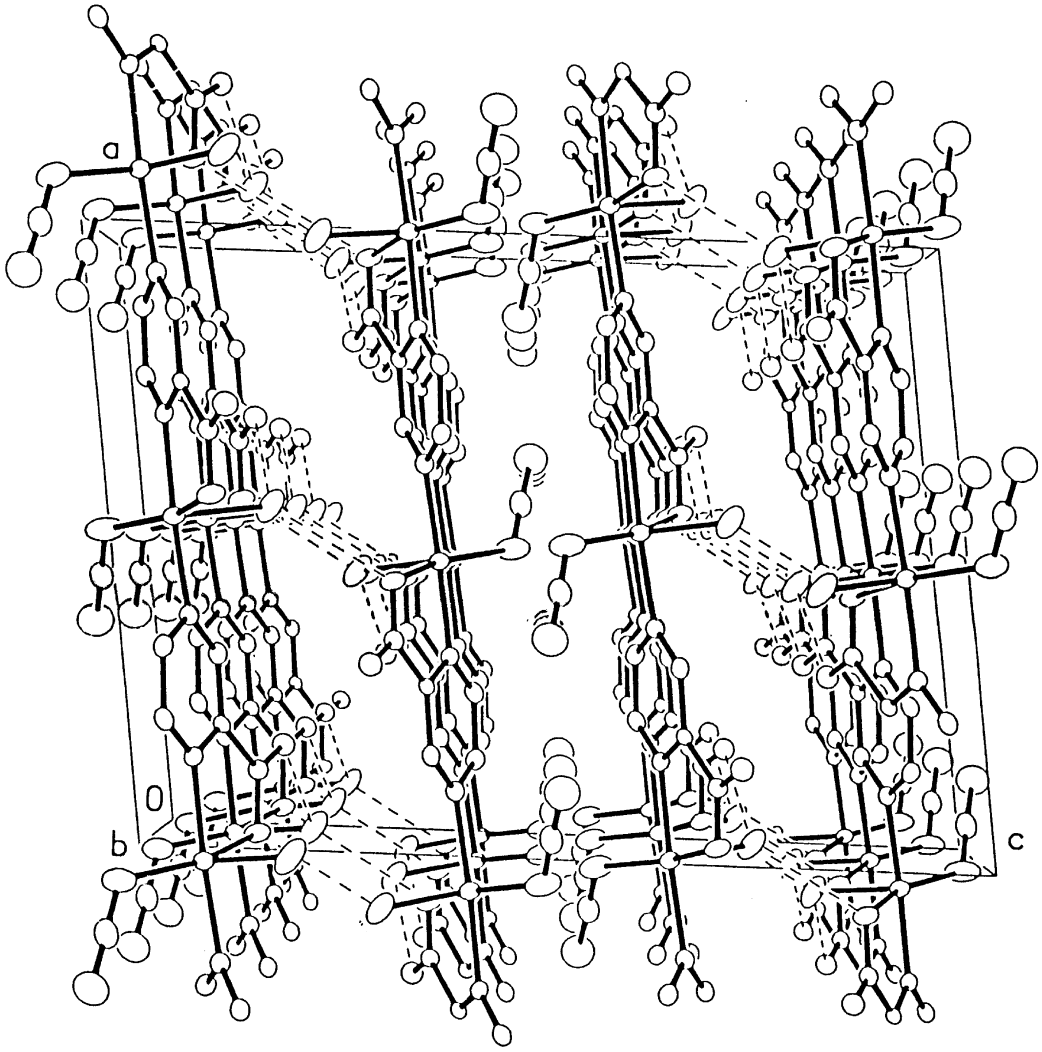

Fig. 4. Packing plot of $[Cu(N_3)(pyz)(H_2O)]_n$, 2. Viewed along the *b*-axis of the unit cell.

terminal *ν*Cu–Cl vibration, since only one band appeared in each case.

Electronic spectra

The electronic spectra (Fig. 5) of both solid complexes as mulled in Nujol exhibit the *d-d* transitions as a very broad band centered at *ca* 12680 cm^{-1}, and a broad band with a maximum around 14570 cm^{-1} for 1 and 2, respectively. The position of these bands suggests that the copper atoms are five-coordinated in both complexes [26]. In DMSO solution, the spectra show these bands at 12500 and 14265 cm^{-1}, for 1 and 2 respectively. Thus, both complexes retain their five-coordination in this solvent. Additionally, the solid state electronic spectrum of 1 shows a pronounced shoulder around 25000 cm^{-1}, whereas that of the azide complex, 2 exhibits a strong band centered around 22730 cm^{-1}. These bands are due to LMCT tran-

sitions from the chloride or azide to copper. The position of these bands indicate the influence of the azide group on the charge transfer as compared to the chloride ion. In DMSO, The N_3^-–Cu^{II} CT band is shifted to higher energy and appeared at 25125 cm^{-1}, whereas the chloride complex shows a less pronounced shoulder at the same position. Previous studies [27, 28] have shown that the electronic spectra of solid copper(II) azide complexes containing cyclic $Cu_2N_2(N_3)$ units usually exhibit a distinct absorption band in the vicinity of 17000–20000 cm^{-1}. This band was considered as due to LMCT transition bridging azides of the type $\mu-1,1$ to copper(II) [28]. The disappearance of any absorption in the range 17000–20000 cm^{-1} from the spectrum of complex 2 having only one terminal azide, confirms our previous conclusion that the existence of such a band should be taken as strong evidence of the existence of binuclear cyclic Cu_2N_2 units, and hence at least two $\mu-1,1$ azides.

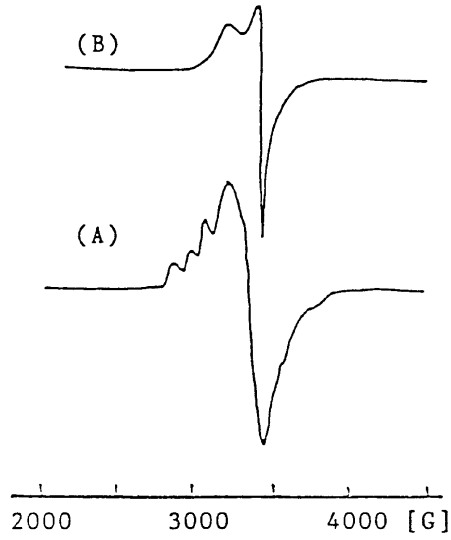

Fig. 6. EPR spectra of solid complexes: (a) [CuCl (pyrazinato)$(H_2O)]_n$, 1, (b) $[Cu(N_3)$(pyrazinato)$(H_2O)]_n$, 2.

EPR spectra

The room temperature EPR spectra of polycrystalline samples of complexes 1 and 2 are given in Fig. 6. The spectrum of the chloride complex 1, shows hyperfine coupling with the copper nucleus of the g parallel, the hyperfine constant $A_\parallel$ (average) is 102 G, and $g_\perp = 2.044$. The spectrum of the azide complex, 2, however, is a well defined typical spectrum of cop-

per(II) system of axial type with $g_{\parallel} = 2.21$ and $g_{\perp} = 2.07$. The value of G, calculated as the ratio of $(g_{\parallel}-2)/(g_{\perp}-2)$ is below 4 suggesting exchange coupling [29] between bridged copper(II) centers in complex 2. Such exchange coupling is expected because pyrazine is an excellent ligand providing exchange pathways when paramagnetic metals are involved [30, 31]. Both complexes, 1 and 2 dissolve in DMF and their spectra in this solvent display four hyperfine lines of uncoupled copper(II) ($I = 3/2$) with $A_o(Cu) = 73$ and 51 G (average), respectively.

Thermal properties

The results of the thermal decomposition of complexes 1 and 2 are represented in Fig. 7. In case of the chloride complex, (1) the residue of the decomposition was followed by measuring its IR spectrum at 200, 250, 275, 300 and 380°C. The first step of the thermal decomposition of complex 1 consists of a dehydration around 160–210°C [loss of weight (%); experimental 7.5 and theortical 7.5]. The DTA curve shows two successive endothermic peaks with maxima at 171.9 and 280°C, corresponding to a loss of weight of 5.4 and 2.13%, respectively. The IR spectrum at 200°C shows that there is some amount of water. This indicates that the dehydration process occurs at two successive stages. In the second step which starts around 275°C, the dehydrated complex starts to lose the pyrazinate and a loss of weight of 43.2% is completed around 310°C. The DTA curve shows this step as a sharp endotherm with a maximum at 304.4°C. This loss of weight does not correspond to all the pyrazinate in the complex. The IR spectrum at 300°C, shows that the residue contains about 10% of the pyrazinato ligand. This step is followed by a gradual loss of weight until *ca* 700°C, at which it reaches 75%, corresponding to a complete loss of pyr and Cl giving rise to a residue of copper metal.

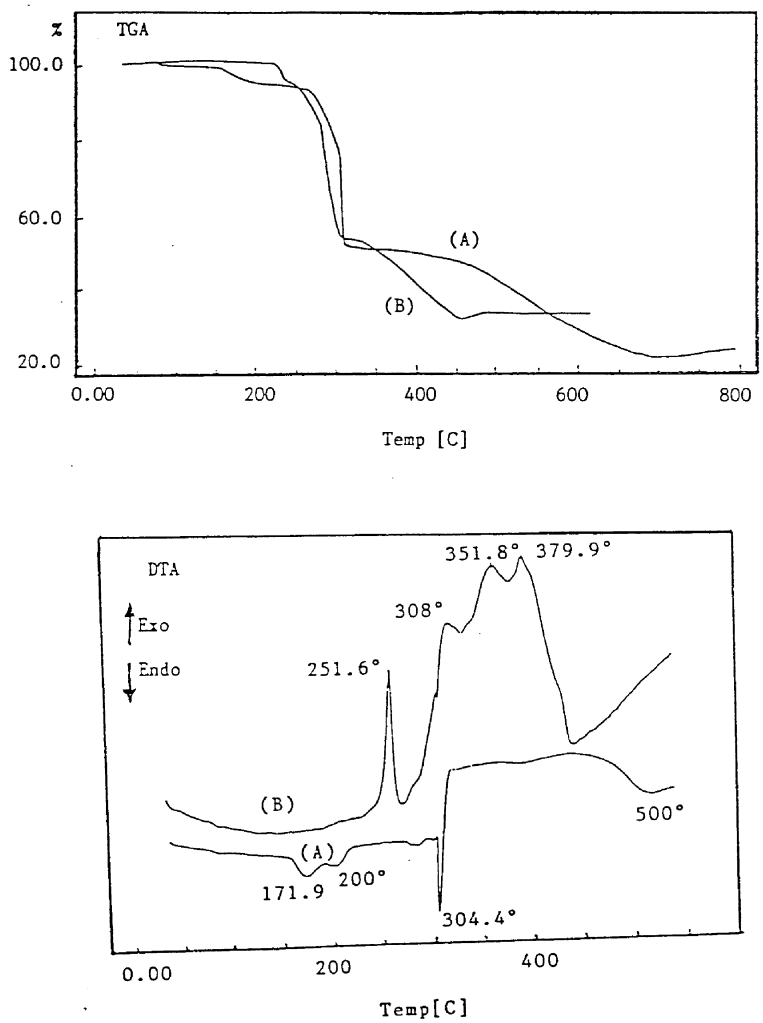

Fig. 7. Thermal decomposition of: (a) $[CuCl(pyrazinato)(H_2O)]_n$, 1, (b) $[Cu(N_3)(pyrazinato)(H_2O)]_n$, 2.

The DTA curve of the azide complex, 2 is similar to that of complex, 1, except the narrow range of temperature upon which the different decomposition steps take place. Thus the thermal decomposition which starts around 210°C is completed around 470°C. As seen from Fig. 7. complex 2 is stable until 210°C, at which the dehydration process takes place. This step is completed around 260°C with an experimental loss of weight of 6.9% (theoretical 7.2%). The DTA curve of this complex, however, does not show the endotherms which observed in case of 1, instead a smooth slight curvature is continued and ended with an exothermic peak with $T_{max} = 251.6$°C. This may suggest a smooth phase transition of the complex. The ΔH corresponds to this exotherm is 85.2 kJ/mol. The following step for the dehydrated compound does not reflect a simple one-stage process and the DTA curve shows a very broad exotherm with three peaks ($T_{max} = 308$, 351.8 and 379.9°C, respectively). The ΔH for this exotherm is 1462.2 kJ/mol. The loss of weight in the range 260–290°C is 46.1%, which represents 92% of the pyrazinate. Unfortunately we could not measure the IR spectrum of the residue in this case at different temperatures, therefore it is not clear if the pyrazinate is the only eliminated radical despite the similarity between the TG curves of 1 and 2. This stage is followed by a gradual decomposition until about 450°C, with a total weight loss of 69.9% which corresponds to a complete loss of pyz, N_2 and H_2O (theoretical = 68.8%).

(Received 8 January 1998; accepted 7 March 1998)

Abstract—The equilibria $pH^+ + qMoO_4^{2-} + rCH_3PO_3^{2-} \rightleftarrows (H^+)_p(MoO_4^{2-})_q(CH_3PO_3^{2-})_r$ have been investigated at 25.0°C in 1.000 M Na(Cl) by the combined emf-NMR method. Quantitative analysis of the emf and ^{31}P NMR data confirmed the existence of the following ternary species, denoted by (p, q, r) according to the general equilibria above: (10, 5, 2), (11, 5, 2), (11, 7, 1), (12, 7, 1), and (12, 6, 1). Least-squares calculation gave $\log \beta_{10,5,2} = 69.51 \pm 0.01$, $\log \beta_{11,5,2} = 71.07 \pm 0.08$, $\log \beta_{11,7,1} = 72.69 \pm 0.04$, $\log \beta_{12,7,1} = 76.23 \pm 0.05$, and $\log \beta_{12,6,1} = 70.31 \pm 0.05$. The formation constants of the (p, 5, 2) species of the current system and the molybdoselenite system correlate with the pK_a of the heteroatom source. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: molybdophosphonate; heteromolybdate; solution equilibria; ^{31}P NMR; methylphosphonate; formation constants.

Molybdate is known to condense in acidic aqueous solution to form polynuclear oxometalates [1]. If other ions such as AsO_4^{3-} coexists in solution, molybdate condenses together with those ions and forms various heteropolymolybdates, incorporating those ions in their metal-oxygen framework. The nature of those ions should affect the stability or formation constants of heteropolymolybdates formed. However, our knowledge on this matter is still very limited.

Some time ago we found that the formation constants of molybdoarsenates and molybdoarsonates correlate with the pK_a's of arsenate and its organic derivatives [2]. An arsonate that has greater pK_a forms more stable heteropolymolybdates. Is this correlation between pK_a's and formation constants a phenomenon observed just for a series of organic derivatives of a certain hetero-atom group? Or, is it rather a "general rule" that is applicable to different heteroatom groups?

To answer this question, we need to know the formation constants of different heteromolybdates that have the same basic structure but contain different heteroatoms. The X_2Mo_5 species is suitable for this purpose. It forms for X = P [3], As [4], S [5], and Se [6]. The formation constants of the P [7], As [8], and Se [9] species have been determined. Unfortunately, however, they were all determined in different media. The formation constants of the P species were determined in either 0.6 M Na(Cl) or 3.0 M Na(ClO_4) medium. For the Se species, 1.0 M Na(Cl) was used as a medium. The 1.0 M Na(Cl) medium was also used for the As system, but the solvent there was D_2O.

Methylphosphonoate is expected to form relatively strong P_2Mo_5 complex [3b, 10]. In addition, the equilibria of the molybdomethylphosphonate system are expected to be much simpler than that of the parent molybdophosphate system. Thus we have carried out a complete equilibrium analysis of the molybdomethylphosphonate system in aqueous 1.0 M Na(Cl) medium, and compared the formation constant of the P_2Mo_5 species with that of Se_2Mo_5.

EXPERIMENTAL

Reagents and general procedures

$Na_2MoO_4 \cdot 2H_2O$ (Wako, S) was used as received. $CH_3PO_3H_2$ (Aldrich) was recrystallized from acetone.

* Author to whom correspondence should be addressed.

NaCl (Manack, JIS Primary Standard) was dried at 300°C for 30 min before use. The Na^+ concentrations of all sample solutions were kept constant at 1.000 M by adding appropriate amounts of NaCl. The least-squares calculations were performed by using the program LAKE [7b, 11].

Emf measurements

The same apparatus as in our previous report was employed [2]. The temperature was kept constant at 25.0 ± 0.1°C throughout the experiment. Six series of titrations were performed and 452 data points were collected. The data covered the ranges $1.53 < -\log h < 7.04$, $0.00 < B/\text{mM} \leq 100$, $10.4 < C/\text{mM} \leq 19.4$, and $0.00 < B/C \leq 9.61$, where h is the concentration of the free hydrogen ion in solution. B stands for the total concentration of molybdate and C that of phosphonate.

NMR measurements

$^{31}P\{^1H\}$ NMR spectra were recorded on a Varian UNITY-plus 300 spectrometer operating at 121.46 MHz and referenced externally to 85% H_3PO_4. An inner concentric tube ($o.d. = 2.5$ mm) that contains D_2O was inserted to a sample tube ($o.d. = 5$ mm) to provide the lock signal. The spin-lattice relaxation time (T_1) of 0.1 M aqueous solution of $CH_3PO_3H_2$ was determined to be 7.9 s, and a recycle time of 52.4 s was used for all spectra recording. In total 64 spectra were recorded in the ranges $1.19 < -\log h < 7.04$, $0.00 < B/\text{mM} \leq 100$, $10.4 < C/\text{mM} \leq 19.4$, and $0.00 < B/C \leq 9.61$.

Binary systems

Since there was no former report on the binary H^+-$CH_3PO_4^{2-}$ equilibria in 1.000 M Na(Cl), several separate emf and NMR titrations were performed to determine the formation constants of this system. They covered the ranges $1.60 < -\log h < 11.00$ and $2.00 \leq C/\text{mM} \leq 20.80$. Both emf and ^{31}P NMR data did not show any sign of concentration dependence, meaning that only monomeric species existed in the ranges investigated. The system was well explained by $CH_3PO_3^{2-}$, $CH_3PO_3H^-$, and $CH_3PO_3H_2$ [(0, 0, 1), (1, 0, 1), and (2, 0, 1), respectively, in the (p, q, r) notation] with the formation constants $\log \beta_{1,0,1} = 7.18(4)$ and $\log \beta_{2,0,1} = 9.26(5)$ [12]. Least-squares calculations on the δ *vs* $-\log h$ curve gave the ^{31}P NMR chemical shifts of (0, 0, 1), (1, 0, 1), and (2, 0, 1) as 23.6(1) ppm, 27.42(2) ppm, and 33.54(9) ppm, respectively [12].

For the $H^+ - MoO_4^{2-}$ equilibria the constants reported elsewhere were used [13].

RESULTS AND DISCUSSION

The equilibria of the current system can be written in the general form

$$pH^+ + qMoO_4^{2-} + rCH_3PO_3^{2-} \leftrightarrows (H^+)_p(MoO_4^{2-})_q(CH_3PO_3^{2-})_r$$

The complex on the right-hand side will simply be referred as (p, q, r) and its formation constant $\beta_{p,q,r}$.

In Fig. 1 chemical shifts of different peaks are plotted against $-\log h$. Peak A is assigned unambiguously to the free phosphonate in solution, because it appears in the spectra even if the solution contains no molybdate.

When $B/C \leq 2.5$, both emf and NMR data clearly showed the existence of only one ternary species over a wide $-\log h$ range. Only one ternary NMR peak (peak B) was observed under such conditions irrespective of $-\log h$. Its chemical shift remained unchanged when $-\log h$ was larger than 2.4. The potentiometric $Z_{B,C}$ vs $-\log h$ curves at low B/C ratios showed plateaus over a relatively wide range of $-\log h$ [14].

Figure 2 shows the result of a series of NMR measurements in which B/C was varied and $-\log h$ was kept around 2.0. The figure implies that the q/r ratio for the ternary species that gives rise to peak B is 2.5. Although this experiment does not tell us much about the p value of this species, potentiometric data gives us a good estimate of that. The potentiometric titration curve at $B/C = 2.5$ showed a plateau at $Z_{B,C}$ somewhat higher than 1.4, indicating this species is $(H^+)_{10}(MoO_4^{2-})_5(CH_3PO_3^{2-})_2$ $(10/(5+2) = 1.43)$. In fact, the *pqr* search performed on the emf data of $B/C \leq 2.5$ and $-\log h > 2$ confirmed this speciation. All the other species tested gave unacceptably high residuals in the least-squares calculation.

However, the residuals in the least-squares analysis of the emf data showed some systematic trend in the very acidic region when we tried to explain these low-ratio data only by (10, 5, 2). This systematic deviation disappeared after the introduction of (11, 5, 2) to the system. Slight changes in chemical shift of peak B in the low -log h region also indicates protonation of (10, 5, 2) (see Fig. 1).

Figure 2 also tells us that one more ternary species of considerably higher q/r ratio forms when B/C is increased. Since peak B is now assigned unambiguously to the $(p, 5, 2)$ species, we can calculate the amount of molybdate left available for the formation of the species responsible for peak C from the NMR intensity data. Such calculations revealed that the q/r ratio of this species should be less than 8. In addition, chemical shift dependence of peak C on $-\log h$ indicated that (at least) two different species were involved, either a protonation series or a fast exchange between species that have different q and/or r. Thus we tried different pairs that have q/r ratio smaller than 8 on the NMR data. The least-squares calculations

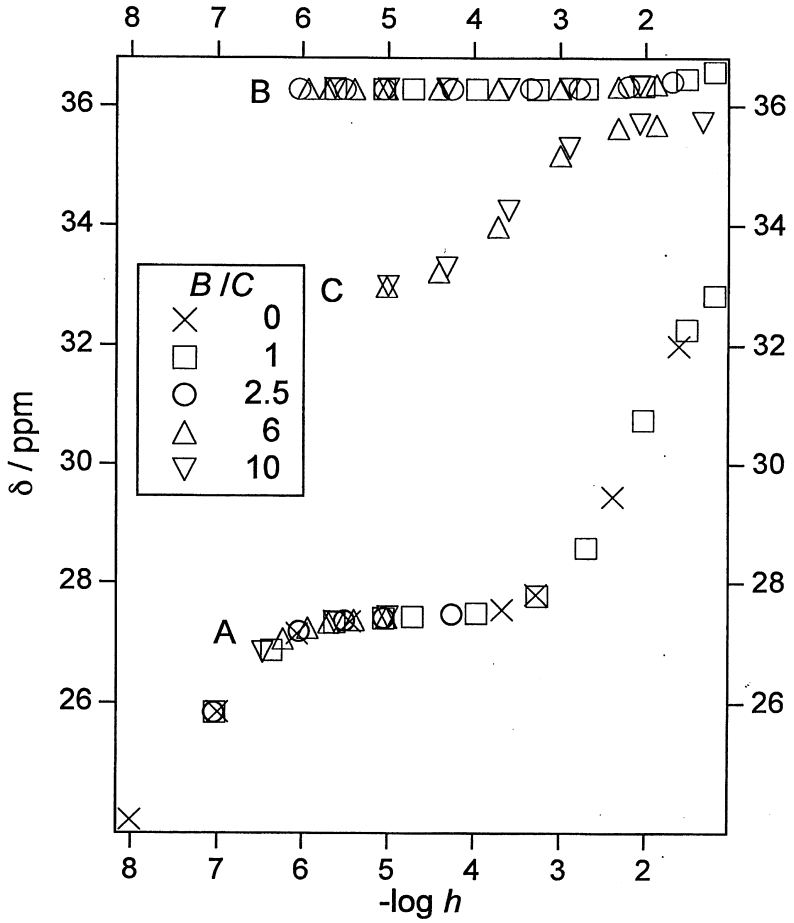

Fig. 1. ^{31}P chemical shifts, δ, as a function of $-\log h$.

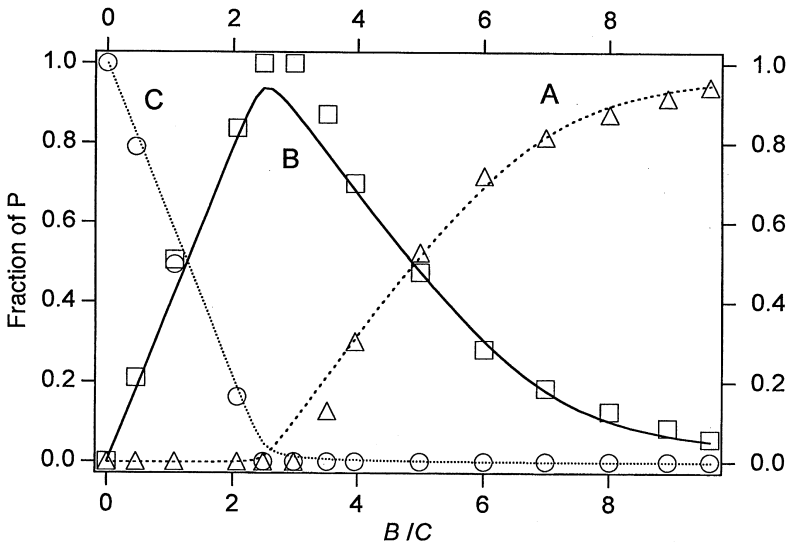

Fig. 2. Relative intensities of different peaks as a function of the B/C ratio at $-\log h \approx 2$. C was kept constant at 10.41 mM. Solid and dotted lines have been calculated by using the determined formation constants.

gave us two pairs, (10, 6, 1)/(11, 6, 1) and (11, 6, 1)/(11,7, 1), as possible candidates.

When we tried these pairs on the emf data, however, both gave unsatisfactory results. They consumed less protons than observed in very acidic region and the fit between the calculated and observed titration curves got worse in a systematic manner in the range $-\log h < 2.5$. This means species that consume more protons exist in solution. We performed several more least-squares calculations including species of greater p values into the candidates mentioned above. The combination of (11, 6, 1), (12, 6, 1), and (11, 7, 1) gave the lowest residual on the NMR intensity data. However, this model did not improve the fit on the emf data. The pK_a value calculated for (12, 6, 1) (~ 1.4) was not consistent with the observed δ vs $-\log h$ curve, either. The NMR intensity residual for the combination of (12, 6, 1), (11, 7, 1), and (12, 7, 1) was slightly larger, but the calculated pK_a of (12, 7, 1) (~ 3.5) was consistent with the δ vs $-\log h$ curve. This model also explained the emf data satisfactorily.

The results of the least-squares calculations are summarized in Table 1. The species found in the current system are the same as those found in the closely related $H^+ - MoO_4^{2-}$-$C_6H_5PO_3^{2-}$ system [7b]. Figure 3 illustrates the distribution of molybdenum and phosphorus among different species. Formation of the ternary species starts at $-\log h \approx 6$, which is a common feature of heteropolymolybdate systems that have tetrahedral heteroatoms [7–9, 11]. The diagram also tells us that (p, 7, 1) of the current system are weak, just like their phenyl analog in the $H^+ - MoO_4^{2-}$-$C_6H_5PO_3^{2-}$ system. Notable amounts of isopolymolybdates form even at such a low B/C ratio as 5.6.

The composition of (10, 5, 2) coincides with that of

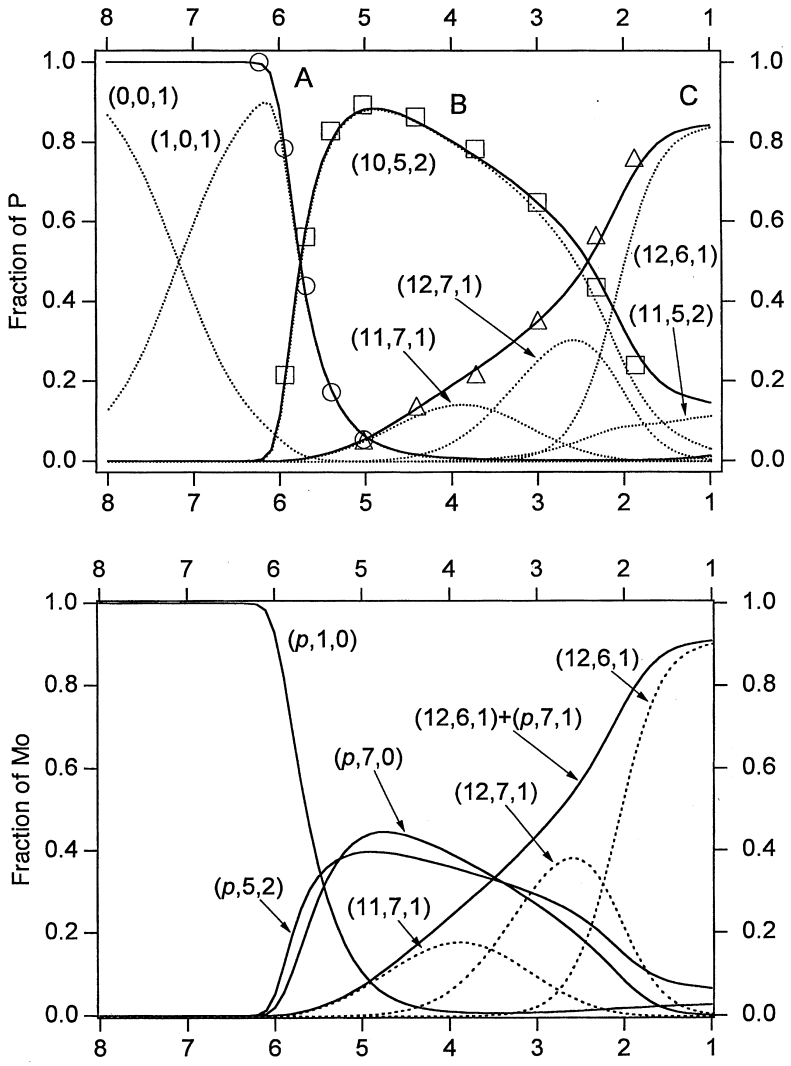

Fig. 3. Calculated distribution of molybdenum (2) and phosphorus (1) among different species at $B = 60.00$ M and $C = 10.76$ M. Observed data points are plotted together with the calculated curves for phosphorus.

Table 1. Summary of the Results

(p, q, r)	$\log \beta_{p,q,r}$*	pK_a	Peak	δ/ppm*	Proposed formula
(0, 0, 1)			A	23.6(1)	$CH_3PO_3^{2-}$
(1, 0, 1)	7.18(4)	7.18		27.42(2)	$CH_3PO_2(OH)^-$
(2, 0, 1)	9.26(5)	2.08		33.54(9)	$CH_3PO(OH)_2$
(10, 5, 2)	69.51(1)		B	36.28(1)	$[(CH_3P)_2Mo_5O_{21}]^{4-}$
(11, 5, 2)	71.07(8)	1.56		36.65(3)	$[(CH_3P)_2Mo_5O_{20}(OH)]^{3-}$
(11, 7, 1)	72.69(4)		C	32.89(1)	$[CH_3PMo_7O_{25}(OH)]^{5-}$
(12, 7, 1)	76.23(5)	3.54		35.61(2)	$[CH_3PMo_7O_{25}(OH_2)]^{4-}$
(12, 6, 1)	70.31(5)			35.73(1)	$[CH_3PMo_6O_{21}(OH_2)_6]^{2-}$

* See [12].

$[(CH_3P)_2Mo_5O_{21}]^{4-}$, whose structure is depicted in Fig. 4 [3b]. We assume this structure is maintained in solution. Single ^{31}P NMR peak observed for (10, 5, 2) is also consistent with this structure. Possible protonation sites are indicated by asterisks in the figure. Bond order calculation [15] showed that the oxygen atoms doubly shared by one Mo atom and one P atom are slightly more basic than others. Protonation of either of these sites would yield (11, 5, 2).

The observed pK_a's of the (11, 5, 2) species and the bond orders of $[(CH_3P)_2Mo_5O_{21}]^{4-}$ and $[Se_2Mo_5O_{21}]^{4-}$ are consistent with the argument above. Both anions have the same basic structure [3b], [6]. Replacing CH_3P groups in Fig. 4 with Se atoms would yield $[Se_2Mo_5O_{21}]^{4-}$. The average bond order sum of the oxygen atoms marked with asterisks is 1.7 in the $[(CH_3P)_2(Mo_5O_{21})]^{4-}$ structure. The bond order sum for the same type of oxygen atom in $[Se_2Mo_5O_{21}]^{4-}$ is 1.8. This implies that the former anion is more basic than the latter. The pK_a's of (11, 5, 2) in the current system and the $H^+ - MoO_4^{2-}$-SeO_3^{2-} system [9] are 1.56 and 1.41, respectively, and agree with the bond order difference of $[(CH_3P)_2(Mo_5O_{21})]^{4-}$ and $[Se_2Mo_5O_{21}]^{4-}$.

When we compare the formation constants of (p, 5, 2) species of the current system and those of the $H^+ - MoO_4^{2-}$-SeO_3^{2-} system, we notice another interesting thing. The formation constants for the current system is somewhat smaller than those for the latter ($\log \beta_{10,5,2} = 71.32(2)$ and $\log \beta_{11,5,2} = 72.73(4)$ for the $H^+ - MoO_4^{2-}$-SeO_3^{2-} system). Selenite ($pK_1 = 2.36$, $pK_2 = 8.28$ in aqueous 1.0 M Na(Cl) medium [9]) is more basic than methylphosphonate. Here we see the same kind of correlation that was observed for molybdoarsenates and its organic derivatives: hetero atom source that has greater p*Ka* forms more stable heteropolymolybdates.

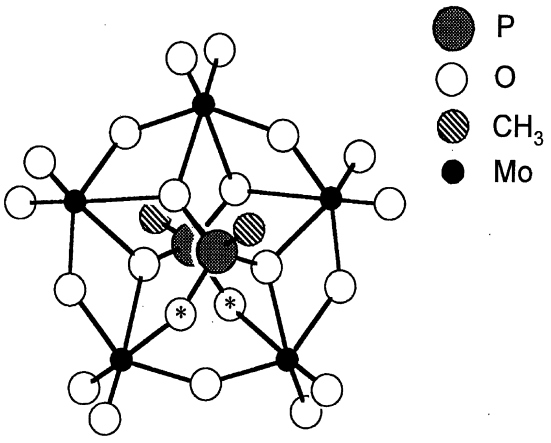

Fig. 4. Perspective view of the $[(CH_3P)_2Mo_5O_{21}]^{4-}$ structure. Possible protonation cites are indicated by *.

New dinuclear thiobenzoato complexes of molybdenum(V) containing $Mo_2O_2S_2$ core. X-ray crystal structures of $[Mo_2O_2S_2(OSCC_6H_5)_2(py)_2]$ and $[Mo_2O_2S_2(OSCC_6H_5)_2(\gamma\text{-pic})_2]\cdot 2H_2O$

(Received 17 December 1997; accepted 9 March 1998)

Abstract—The $[Mo_2O_2S_2(OSCC_6H_5)_2]$ (**1**) has been prepared either by the reaction of $[Mo_2O_3(C_5H_7O_2)_4]$ or of $[Mo_4Cl_2O_6(O_2CCH_3)_6]\cdot(CH_3CO)_2O$ with thiobenzoic acid. The product was then used to prepare two complexes of the general formula $[Mo_2O_2S_2(OSCC_6H_5)_2L_2]$ (where L = pyridine (**2**) or γ-picoline (**3**)). All complexes were characterized by elemental analyses, IR spectra and magnetic measurements. The structures of (**2**) and (**3**) were proved by X-ray structure analysis. Both complexes are dinuclear containing $Mo_2O_2S_2$ core with two Mo atoms linked by a Mo–Mo single bond. The Mo atoms are octahedrally coordinated by oxo-oxygen, two bridging sulfido-sulfurs, one pyridine (or γ-picoline)-nitrogen and thiobenzoato-sulfur and thiobenzoato-oxygen atoms.

Keywords: crystal structure; molybdenum(V) complexes; thiobenzoato complexes; dimeric structure.

Relevance of molybdenum(V) complexes containing Mo–S bonding to the molybdoenzymes is well known and extensively studied [1–4]. This is particularly true due to the suggestion that the molybdoenzymes in the oxidized forms such as xanthine oxidase and sulfite oxidase contain oxo-molybdenum cores with the molybdenum atom coordinated by two or more sulfur ligands. The usual octahedral surroundings about molybdenum atoms in such systems are commonly completed by the additional nitrogen donor ligands [5]. In addition, interest in Mo–S chemistry has also grown due to the implication of this metal in the catalytic hydrodesulfurization processes [6, 7].

In this paper we describe the synthesis and structural characterization of three new complexes containig MoS_2Mo bridging core with thiobenzoato ligands as simultaneous oxygen and sulfur donors. Two of them with additional pyridine and γ-picoline as nitrogen donor ligands. Similar dinuclear di-μ-oxo and μ-oxo-μ-sulfido molybdenum(V) complexes of the formulae $[Mo_2O_3X(OSCC_6H_5)_2]_n$ and $[Mo_2O_3X(OSCC_6H_5)_2(py)_2]$ (X = O or S) have been prepared by M. Rakowski DuBois in 1978 but their structures have never been determined by X-ray diffraction method [8]. They were prepared using molybdenum(VI) compounds, MoO_2Cl_2 and Na_2MoO_4.

EXPERIMENTAL

The starting acetylacetonato $[Mo_2O_3(acac)_4]$ [9] and acetato $[Mo_4Cl_2O_6(O_2CCH_3)_6]\cdot(CH_3CO)_2O$ [10] complexes were prepared as described earlier. Reagent grade solvents and all other chemicals were used without further purification.

The IR spectra of KBr pellets were recorded on a FTIR 1600 Fourier-transform spectrometer in the 4500–450 cm^{-1} region. Magnetic measurements were carried out at room temperature using Gouy method.

Preparation of $[Mo_2O_2S_2(OSCC_6H_5)_2]$ (1)

Procedure (*i*). A mixture of $[Mo_2O_3(acac)_4]$ (1 g, 1.57 mmol) and thiobenzoic acid (1.8 g, 13.03 mmol) in dichloromethane (10 cm^3) was heated for 2 hours.

The resulting red-brown precipitate was filtered and washed with dichloromethane and methanol. Yield: 0.5 g, 57%.

Procedure (*ii*). The same product was prepared by warming a mixture of $[Mo_4Cl_2O_6(O_2CCH_3)_6]\cdot(CH_3CO)_2O$ (0.25 g, 0.25 mmol) with thiobenzoic acid (0.35 g, 2.53 mmol) in dichloromethane (10 cm^3) for 45 min. After 2 days at room temperature red-brown product was isolated. Yield: 0.25 g, 86%. Found: C, 29.97; H, 1.58; Mo, 34.18; S, 22.16. Calc. for $C_{14}H_{10}Mo_2O_4S_4$: C, 29.90; H, 1.79; Mo, 34.12; S, 22.81%. IR (cm^{-1}): 3061w, 1592m, 1455s, 1421s, 1310m, 1230s, 1175s, 974s, 937s, 839s, 678s, 475m.

Preparation of $[Mo_2O_2S_2(OSCC_6H_5)_2(py)_2]$ (**2**)

Pyridine (1.5 cm^3) was added to a suspension of $[Mo_2O_2S_2(OSCC_6H_5)_2]$ (0.15 g, 0.27 mmol) in dichloromethane (15 cm^3) and the reaction mixture warmed up for 15 min. After three days an orange-red crystalline product was isolated. Yield: 0.05 g, 26%. Found: C, 40.12; H, 2.75; Mo, 27.06; N, 3.36; S, 17.93. Calc. for $C_{24}H_{20}Mo_2N_2O_4S_4$: C, 40.0; H, 2.80; Mo, 26.63; N, 3.89; S, 17.80%. IR (cm^{-1}): 3065m, 1595m, 1460s, 1446s, 1435s, 1309m, 1248s, 1220s, 1012m, 978s, 940s, 469m.

Preparation of $[Mo_2O_2S_2(OSCC_6H_5)_2(\gamma\text{-pic})_2]\cdot 2H_2O$ (**3**)

Analogously as above, to a suspension of $[Mo_2O_2S_2(OSCC_6H_5)_2]$ (0.15 g, 0.27 mmol) in dichloromethane (10 cm^3) γ-picoline was added and the reaction mixture warmed up for 15 min. From the resulting solution after three days an orange crystalline product was isolated. Yield: 0.05 g, 25%. Found: C, 39.29; H, 3.79; Mo, 24.67; N, 3.91; S, 16.01. Calc. for $C_{26}H_{28}Mo_2N_2O_6S_4$: C, 39.80; H, 3.60; Mo,

X-ray crystallography

Intensity data were collected at 293 K by using graphite-monochromated Mo-K_α radiation ($\lambda =$ 0.7107 Å) on a STOE updated Philips PW1100 diffractometer. Three standard reflections were monitored periodically. Intensity variations of 8.9% (**2**) and 9.9% (**3**) were observed and consequently corrected for in the data reduction. The intensities were reduced to *F*o by applying corrections for Lorentz and polarization effects. Absorption corrections were not applied.

The structures of both compounds were solved by using direct methods implemented in SIR92 programs [11] and succesive Fourier syntheses. The refinements were performed by full matrix least squares method assuming anisotropic temperature factors for all non-H atoms using SHELXL96 [12] program. All hydrogen atoms, except those belonging to the water molecules, were calculated on the geometrical ground and treated with the constrained lengths in the refinement. Hydrogen atoms of water molecules were not located. Crystal parameters, data collection details for both compounds and the results of the refinements are summarized in Table 1. Selected bond lengths and angles are listed in Table 2. Crystals of **3** were extremely fragile thus causing difficulties to manipulate with them. They cracked very easily. This is most probably the reason for relatively high reliability index for the structure of **3**. The distances and angles were calculated by SHELXL96 and PARST [13] program, the molecular and crystal structures by ORTEP-3 [14]. All calculations were performed on an IBM PC/AT compatible microcomputer (processor 80486/ 66 MHz).

Tables with complete interatomic distances and angles, positional and anisotropic thermal parameters, and observed and calculated structure factors for the two structures have been deposited with the Editor, from whom copies are available on request.

RESULTS AND DISCUSSION

The complex **1** was prepared by two alternative ways, either by the reaction of $[Mo_2O_3(C_5H_7O_2)_4]$ or of $[Mo_4Cl_2O_6(O_2CCH_3)_6]\cdot(CH_3CO)_2O$ with thiobenzoic acid. The product was stable and insoluble in all common solvents suggesting its polynuclear nature $[Mo_2O_2S_2(OSCC_6H_5)_2]_n$ rather with six than five-coordinated molybdenum atom. The complex containing five-coordinated molybdenum would be unsaturated and therefore more reactive. Its IR spectrum supports such structure: strong broad band at 839 cm^{-1} is indicative for an intermolecular metal... oxygen interaction (Mo=O···Mo=O···) the same as it has been observed for $[Mo_2O_4(OSCC_6H_5)_2]_n$ at 830 cm^{-1} [8]. Due to its insolubility we were not able to prepare

Table 2. Selected bond lengths (Å) and angles (°) for $[Mo_2O_2S_2(OSCC_6H_5)_2(py)_2]$ (**2**) and $[Mo_2O_2S_2(OSCC_6H_5)_2(\gamma\text{-pic})_2]\cdot 2H_2O$ (**3**)

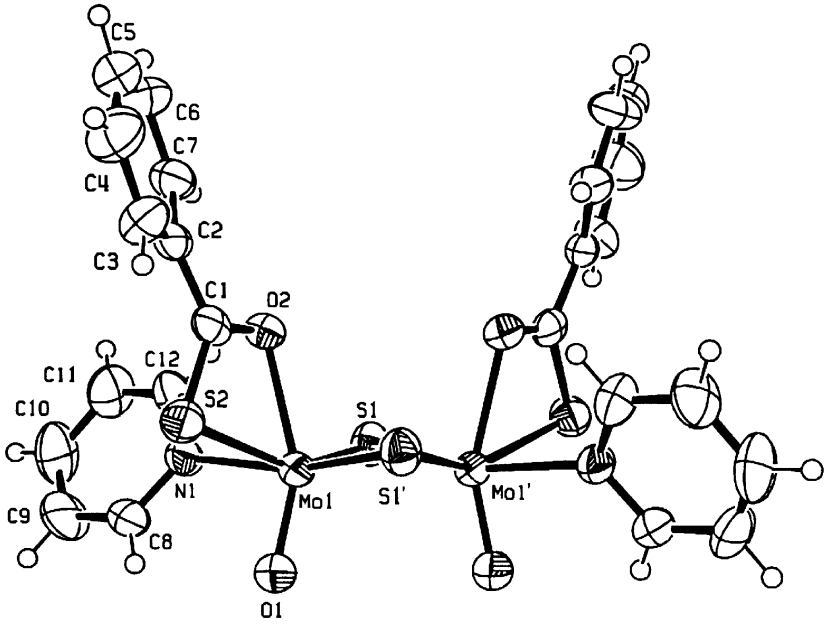
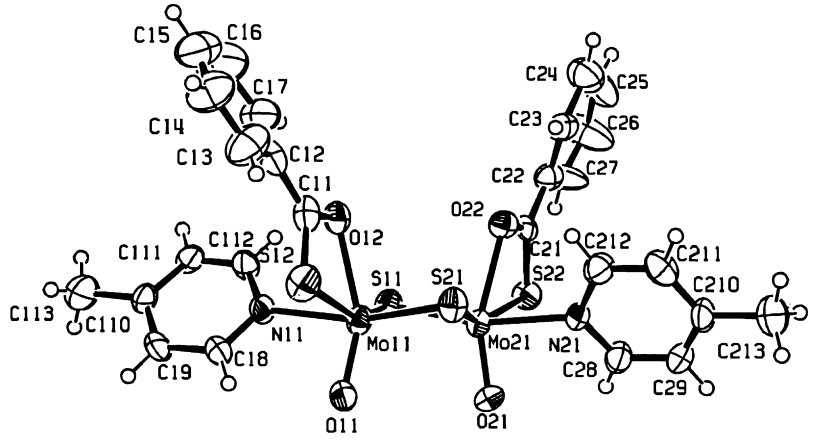
suitable crystals to prove this structure also by the X-ray diffraction method. The formation of the MoS_2Mo bridge may be explained by the apperance of H_2S produced *in situ* from the molybdenum catalyzed hydrolysis of thiobenzoic acid. The analogous observations have been made also in preparing some other molybdenum(V) complexes with thio-ligands [15–18]. The strong donor ligands such as pyridine or γ-picoline stabilized the dinuclear structures producing complexes **2** and **3**.

The structures of $[Mo_2O_2S_2(OSCC_6H_5)_2(py)_2]$ (**2**) and $[Mo_2O_2S_2(OSCC_6H_5)_2(\gamma\text{-pic})_2]\cdot 2H_2O$ (**3**) are built up of dinuclear complex molecules as shown in Fig. 1. However, while the molecular structure of the **2** has crystallographically imposed two-fold symmetry axis the structure **3** exhibits a pseudo two-fold symmetry. The octahedral coordination about each molybdenum atom within a dimer is considerably distorted with the angles ranging from 76.1(2) to 107.8(2)° in **2** and from 74.4(3) to 108.6(3)° in **3**. The distances between two Mo atoms of 2.822(1) in **2**, and 2.831(1) Å in **3** are indicative of a single Mo–Mo bond [19, 20]. The observed diamagnetism of these complexes suggests a strong metal-metal interactions. In both compounds the two molybdenum atoms are bridged *via* two sulfur atoms with average values for the $Mo–S_{br}$ bond lengths



(a)



(b)

Fig. 1. ORTEP-3 illustration of the structures of (a) $[Mo_2O_2S_2(OSCC_6H_5)_2(py)_2]$ (**2**) and (b) $[Mo_2O_2S_2(OSCC_6H_5)_2(\gamma\text{-pic})_2]\cdot 2H_2O$ (**3**) showing the atom numbering schemes and thermal ellipsoids (50%) for the atoms. The H atoms are unlabelled.

of 2.316(2) Å in **2** and of 2.315(3) Å in **3**, respectively [17, 21]. The four-membered rings of the Mo_2S_2 bridging core are not planar but folded along the lines connecting two bridging sulfur atoms: the dihedral angles between two SMoS planes are 158.35(0) and 157.2(2)° in **2** and **3**, respectively. The Mo═O bond lengths of 1.685(5), and 1.679(8) and 1.684(8) Å for **2** and **3**, respectively are normal values for such bond to the terminal oxo-oxygen atoms [22]. The Mo–S bond lengths [2.580(2) in (**2**), 2.567(3) and 2.579(3) Å in **3**] as well as the Mo–O bond lengths [2.257(4) in **2**, 2.263(8) and 2.270(7) Å in **3**] from the thiobenzoato ligands are in good agreement with the values found for such bonds in similar molybdenum(V) structures [23–25]. The molybdenum-to-thiobenzoato-oxygen bond lengths are lengthened due to the *trans* influence of the terminal oxo-oxygen atoms. The same applies to the molybdenum-to-thiobenzoato sulfur and molybdenum-to-nitrogen bonds [2.305(5) in **2**, 2.279(9) and 2.272(8) Å in **3**] owing to their *trans* positions to the bridging sulfido-sulfur atoms [26, 27]. Bond lengths and angles within thiobenzoato ligands, pyridine and γ-picoline are within expected values.

Two water molecules in **3** are hydrogen-bonded to each other having O1w...O2w distance amounting to 2.76(1) Å. Otherwise there are no any other than van der Waals interactions between the complex and water molecules.

The IR spectra of all three complexes confirm the presence of C–S group at 937 (complex **1**), 940 (**2**) and 944 cm^{-1}(**3**), as well as of the C–O group at 1445 (complex **1**), 1460 (**2**) and 1462 cm^{-1} (**3**), respectively. The strong apsorption maxima at 974 and 475 (complex **1**), 978 and 469 (**2**), 978 and 465 cm^{-1} (**3**), belong to the Mo–O (terminal) and Mo–S (bridging) stretching frequencies, respectively [8, 17, 28].

Tungsten(VI) *p–tert–*butylcalix[4]arene diolato complexes. Crystal structure and reactions of [W(*t–*butylcalix)(eg)]

Ari Lehtonen* and Reijo Sillanpää

Department of Chemistry, University of Turku, FIN-20014, Turku, Finland

(Received 23 January 1998; accepted 12 March 1998)

Abstract—Air- and moisture stable tungsten(VI) calixarene complex was prepared from $[W(eg)_3]$ (H_2eg = 1,2–ethanediol) and H_4tbcalix (*p–tert–*butylcalix[4]arene) by a ligand exchange reaction. X-ray structure of [W(tbcalix)(eg)] reveals that tungsten ion is octahedrally surrounded by six oxygen atoms. The reaction of the obtained complex with thionyl chloride or water leads to known dichloro and oxo complexes. © 1998 Elsevier Science Ltd. All rights reserved

INTRODUCTION

Calix[*n*]arenes [1] can provide a polyphenolic binding surface that resembles the surface of inorganic oxide carriers. Metalation of these compounds facilitates to study the chemistry of metal sites bonded on a polyoxo surface and calix[*n*]arenes can be treated as potential organic supports for reactive metal fragments of catalytic utility [2, 3]. Several oxo and chloro tungsten(VI) complexes with calix[4]arenes have been prepared. In the syntheses the starting chemicals are normally $WOCl_4$ or WCl_6 [4]. We have earlier used $[W(eg)_3]$ (**1**) (eg = 1,2–ethanediolato dianion) in the preparation of silica supported tungsten catalysts and also as starting material for new tungsten(VI) complexes [5, 6]. In continuation of this work, we have studied the reaction of **1** with organic polyfunctional OH-donor. The present paper describes synthesis and crystal structure of a new W(VI) calixarene complex [W(tbcalix)(eg)] (**2**) and its conversions to complexes [WO(tbcalix)] (**3**) and $[W(tbcalix)Cl_2]$ (**4**) (tbcalix = tetravalent anion of *p–tert–*butylcalix[4]arene). Complex **4** is known to be suitable starting material to the calixarene supported organotungsten complexes [3].

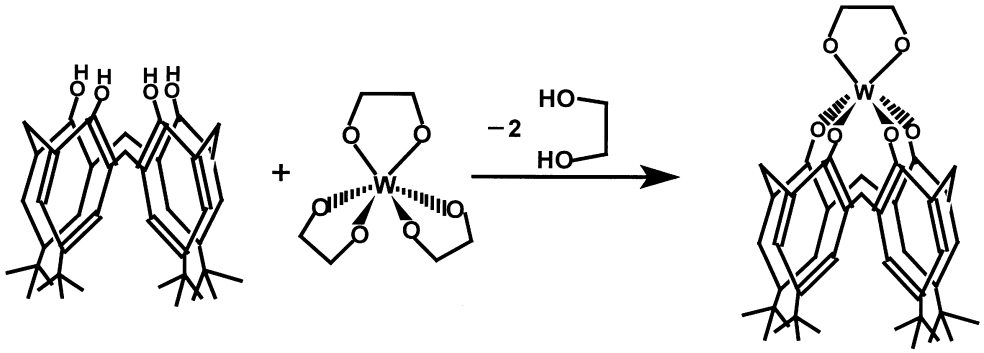
RESULTS AND DISCUSSION

Syntheses

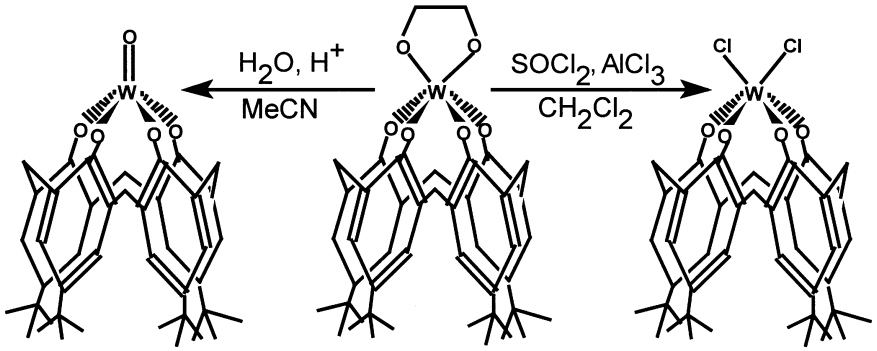
The treatment of the ethanediolato complex **1** with one equivalent of H_4tbcalix in boiling toluene produces complex **2** leads to the formation of intense red coloured solution (Scheme 1). The reaction can be run into an end by distilling out liberated H_2eg, as a toluene azeotrope. Evaporation of the volatiles and crystallisation of the orange–red residue from hexane–CH_2Cl_2 mixture gives crystalline, air-stable complex **2** as a dichloromethane solvate in high yield. Crystallisation from acetonitrile produces an acetonitrile solvate. Complex **2** is stable in moist air and does not react further with other diols to exchange the last eg ligand with a diol. The exchange of the eg ligand in $[W(diol)_2(eg)]$ can be done easily [6].

As the diolato group (eg) in **2** is not very reactive, we tried to remove it in order to get more labile complexes. Several deprotection reactions for alkoxide moiety were tested. To produce the oxo functionality complex **2** was treated with wet ethanol, which is known to hydrolyse comparable trisdiolato complexes, e.g. $[W(eg)(pin)_2]$ (pin = pinacolate dianion) [7].

Complex **2** resist hydrolysis in neutral conditions, but it can be converted to tungstenyl compound by using an acidic solution (Scheme 2). Thus reaction of **2** with aqueous hydrochloride in acetonitrile solution



Scheme 1.



Scheme 2.

leads to the formation of yellow [WO(tbcalix)] **3** in 58% yield.

Complex **2** does not react with typical halide-for-alkoxide substitution reagents ($AlCl_3$, MeCOCl), as reported for comparable cyclohexanediolato complex [8]. It also resists reaction with $SOCl_2$, although ethanediolato ligand in $[W(eg)(pin)_2]$ is easily replaced by this method [9]. However, treatment of **2** (Scheme 2) with excess of thionylchloride in the presence of $AlCl_3$ leads to the displacement of eg ligand and formation of [W(calix[4]arene)Cl_2] **4**. Vigorous reaction indicates that also some decomposition of **2** could happen, but in spite of that complex **4** was isolated in relative high yield (63%).

Crystal structure of ***2***

Complex **2** crystallises as monomeric distorted octahedral tungsten(VI) species with one dichloromethane molecule in the asymmetric unit. The refinements of the data suggest that there is one dichloromethane in the asymmetric unit, but the elemental analysis of the bulk material gives the value 1/2. The dichloromethane molecules are not inside the calixarene cavities but in the empty spaces of the unit cell. The complex unit is described in Fig. 101. The eg ligands are randomly distributed in a 1:1 ratio over W(VI) atoms of the complex **2** in the unit cell, and display two conformations with the torsion angles of 33(3) and $-29(4)^\circ$, respectively. Also two *t*–butyl groups of the calixarene ligand and the dichloromethane molecule have two orientations (a and b). In one *t*–butyl group and CH_2Cl_2 molecule the ratio for the disordered groups is 1:1, but in the other *t*–butyl group the ratios for different rotamers are 58% and 42%.

The tungsten(VI) ion is surrounded by four phenolato oxygen atoms of the calixarene ligand and by two oxygen atoms of chelating diolato ligand. Selected bond parameters are presented in Table 1. The W–O distances vary from 1.860(6) to(W–O(4)) to 1.933(5) (W–O(5)) and are typical for alcoholato and arylato tungsten(VI) complexes. Differences between aliphatic and aromatic W–OR bond distances are quite small. The W–O–C_{aryl} angles vary from 123.6(4) to 179.0(5). The largest angle is associated with the shortest W–O bond distance and *vice versa* as expected [10]. Angular variation of W–O–C_{aryl} angles is most probably caused by W(VI) ion as it modifies the calixarene conformation in order to get a less strained six coordination. This W–O–C_{aryl} angular arrangement indicates for the calixarene a conformation in which

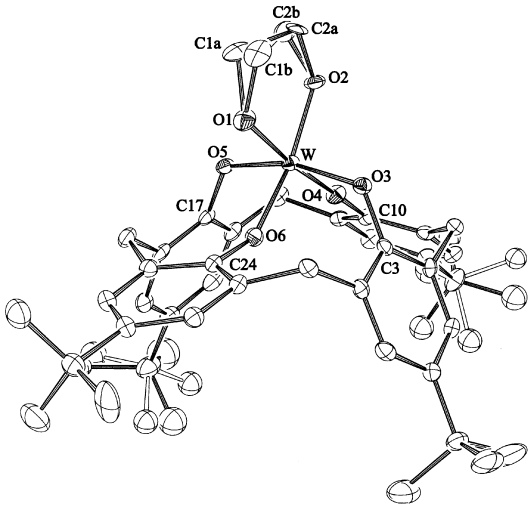


Fig. 1. ORTEP drawing of [W(tbcalix)(eg)]. Thermal ellipsoids are drawn at 20% probability. Hydrogen atoms are omitted for clarity.

the cavity adopts a half-ellipsoid shape. In this conformation the dihedral angles of the opposite phenyl groups show the values of 52.1(2) and 132.2(2)°.

CONCLUSION

Tungsten(VI) *p–tert*–butylcalix[4]arene complex [W(eg)(tbcalix)] can be prepared by the reaction of $[W(eg)_3]$ with the calixarene ligand. This new complex crystallises as monomeric species, in which the tungsten(VI) ion is surrounded by four phenolato oxygen atoms of calixarene and two alkoxide oxygen atoms of diolato ligand. The reaction of the obtained compound with $SOCl_2$–$AlCl_3$ or water leads to comparable dichloro and oxo complexes.

EXPERIMENTAL

Solvents and reagents were commercial products and used as received. Complex **1** was prepared as described earlier [6]. ^{1}H NMR spectra were measured on a JEOL GSX-400 spectrometer in $CDCl_3$. Elemental analysis were performed by a Perkin-Elmer series II analyser.

Preparation of (**2**)

p–tert–butylcalix[4]arene (320 mg, 0.50 mmol) and $[W(eg)_3]$ (180 mg, 0.50 mmol) were suspended in 50 ml of toluene. The reaction mixture was allowed to reflux overnight, upon which period the colour of the solution turned intense red. The formed H_2eg was removed by azeotropic distillation with toluene. After evaporation of the solvent *in vacuo*, the red residue was dissolved by warming in hexane–CH_2Cl_2 mixture (15 ml + 3 ml) and filtered as hot. The solution was allowed to cool and then kept at −18°C for a week. Red needles (355 mg, 80%) were separated and washed with hexane. The formula of the crystalline material was $[W(tbcalix)(eg)]\cdot 1/2CH_2Cl_2$ as was indicated by X-ray and elemental analysis. (Found: C, 60.20; H, 6.15. $C_{46}H_{56}O_6W\cdot 1/2CH_2Cl_2$ requires C, 59.97 H, 6.17%). NMR (Solvent $CDCl_3$, standard $SiMe_4$): δ_H 7.14 (s, 4 H, ArH), 6.97 (s, 4H, ArH), 5.66 (s, 8 H, CH_2O), 4.55 (d, 4 H, CH_2Ar), 3.28 (d, 4 H, CH_2Ar), 1.28 (s, 18 H, CH_3), 1.12 (s, 18 H, CH_3).

Reaction of (**2**) *with water*

Concentrated, aqueous HCl (1.0 ml) was added to the solution of complex **2** (100 mg, 0.11 mmol) in acetonitrile (20 ml). The colour of the solution changed from dark red to yellow while it was stirred for an

hour. The volatiles were evaporated and the yellow residue was extracted with 20 ml of hot toluene. Cooling the solution yielded complex **3** as yellow microcrystals containing a toluene molecule of crystallisation. The yield was 60 mg, 58%. (Found: C, 65.30; H, 6.55. $C_{51}H_{60}O_5W$ requires C, 65.40 H, 6.45%). NMR (Solvent $CDCl_3$, standard $SiMe_4$): δ_H 7.15 (m, ArH and toluene), 4.55 (d, $ArCH_2$), 3.32 (d, $ArCH_2$), 2.32 (s, CH_3 (toluene)), 1.20 (m, CH_3). The spectrum is identical to that given in reference 4.

Reaction of (**2**) *with* $SOCl_2$ *and* $AlCl_3$

Compound **2** (200 mg, 0.22 mmol) and $AlCl_3$ (30 mg, 0.22 mmol) were dissolved in dichloromethane (10 ml), then $SOCl_2$ (0.10 ml, 1.4 mmol) was quickly added to the solution. The reaction mixture was stirred about 15 min and the colour of the solution changed from orange–red to purple. After volatiles had been removed, the residue was extracted with hot hexane–CH_2Cl_2–mixture (10 + 3 ml) yielding complex **4** as red crystalline solid (125 mg, 63%). (Found: C, 58.65; H, 5.90. $C_{44}H_{52}O_4Cl_2W$ requires C, 58.75 H, 5.85%). NMR (Solvent $CDCl_3$, standard $SiMe_4$): δ_H 7.12 (m, ArH), 4.50 (d, $ArCH_2$), 3.30 (d, $ArCH_2$), 1.20 (m, CH_3). The spectrum is identical to that given in reference 4.

X-ray studies

Single-crystal data collections for **2** were performed at ambient temperature on a Rigaku AFC5S diffractometer using graphite monochromatized Mo K_α radiation ($\lambda = 0.71069$ Å). The unit cell parameters were determined by least-squares refinement of 25 carefully centered reflections. The data (8941 reflections) were collected by ω–2θ technique to a maximum 2θ value of 50°. The data were corrected for Lorentz and polarization effects, decay (−5%) and for absorption (PSI scans, $T_{min} = 0.559$ and $T_{max} = 0.718$). Data reduction and subsequent calculations were performed with *teXsan for Windows* [11].

The structures were solved by direct methods by using the *SIR*92 program [12]. Full-matrix least-squares refinements on F^2 were performed using the *SHELXL*-97 program [13]. Non-hydrogen atoms except the atoms of disordered t–butyl groups and dichloromethane group were refined with anisotropic displacement parameters and the hydrogen atoms were included in the calculations at the fixed distances from their host atoms (riding model). The hydrogen atoms of the dichloromethane molecule were not included. The refinement cycle with 67 restraints and 511 parameters gave a $R1$[a] value 0.048 for 5463 reflections ($F_o > 4\sigma(F_o)$) and a $wR2$[b] value 0.118 for all reflections (8541). The figure is plotted with *ORTEP-3 for Windows* [14].

$$^{a}R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|,$$

$$^{b}wR2 = \{\Sigma[w(F_o^2 - F_c^2)]/\Sigma[W(F_o^2)^2]\}^{1/2}$$

Crystal Data for $C_{46}H_{56}O_6W \cdot CH_2Cl_2$: $M_r = 973.68$, red needles, crystal size $0.14 \times 0.24 \times 0.26$ mm, monoclinic, space group $P2_1/c$, $a = 12.830(3)$, $b = 24.215(7)$, $c = 16.638(4)$ Å, $\beta = 109.93(2)°$, $V = 4860(2)$ Å^3, $Z = 4$, $\mu(MoK_\alpha) = 2.53$ mm^{-1}.

(Received 19 January 1998; accepted 15 March 1998)

Abstract—Chelating properties exhibited by a series of monohydroxamic acids toward copper(II) and iron(III) ions were studied by pH-metric, spectrophotometric and EPR methods. The ligands can be divided into three groups: **(i)** ligands with alkyl substituents either on the hydroxamate carbon atom (acetohydroxamic acid, Aha; propanohydroxamic acid, Pha; and hexanohydroxamic acid, Hha) or on both the carbon and nitrogen atoms (N-methyl-acetohydroxamic acid, MAha; N-isopropyl-acetohydroxamic acid, iPAha) **(ii)** ligands with aryl substituents (benzohydroxamic acid, Bha; N-phenyl-acetohydroxamic acid, PhAha; and N-phenyl-benzohydroxamic acid, PhBha); **(iii)** cyclic derivatives (the natural 2,4-dihydroxy-2H-1,4-benzoxazin-3-(4H)-on-glucoside, DIBOA-gl; and 2-hydroxypyridine-N-oxide,PYRha).

In addition to the complexes with the well-known hydroxamate type chelate(s), 1:2 species containing one or both of the coordinated ligands in hydroximato (R_C-$CONO^{2-}$) form, have been found in the copper(II)-Aha and copper(II)-Bha systems. Complex formation with iron(III) starts at a very acidic pH and in the most systems, if the ligand excess is high enough, the 1:3 species solely exists in the pH range ca. 4–8. Hydroxo complexes are generally formed above pH 8–8.5. However, in the cases of iron(III)-iPAha or -Hha, where the ligands have quite large bulky groups, the hydrolysis starts at somewhat lower pH if the metal to ligand ratios are below 1:5 and precipitation starts to form in iron(III)-DIBOA-gl system at ca. pH 5–5.5. In all systems, the stability constants were determined only for the complexes formed below hydrolytic regions. Evaluation of calculated stability constants show that they are determined by a combination of different substituent effects (electronic, resonance and steric effects). The most significant effects are due to substituents on the nitrogen atom in the hydroxamate moieties. The phenyl ring on carbon atom results in somewhat higher stabilities of the complexes. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: Cu(II)complexes; Fe(III)complexes; hydroxamic acids; EPR; pH-metry; spectrophotometry.

The hydroxamic acid group is generally present in natural compounds and for example often is the specific iron(III) chelating moiety in microbial siderophores [1–3]. Special cyclic monohydroxamic acids are synthesized by several types of plants [4, 5] first of all to inhibit plant pathogens [4], but also for metal ion uptake from soil as recently suggested [5]. Moreover, hydroxamic acids have a wide spectrum of activities in all types of biological systems [1, 6]. The relationship between the biological effects and the strong chelating ability of hydroxamic acids is in no doubt. In spite of this, equilibrium results for metal complexes formed with natural cyclic monohydroxamic acids are extremely rare [7, 8]. The main problem is the decomposition of these types of compounds in solution and precipitation occurring in presence of metal ions e.g. copper(II) [8].

Some synthetic monohydroxamic acids (first of all acetohydroxamic acid), have already been studied [9–16], as useful analytical reagents for a range of metal ions [9] and primarily as models of iron(III) binding siderophores. Stability constants determined for 1:1

iron(III)-monohydroxamate complexes showed systematic, parallel changes with the electron donor or acceptor ability of R_C and especially R_N substituents [10, 11]. The R_N and R_C substituents can also modify the cis/trans (Z/E) ratio as was found for a series of monohydroxamic acids [17, 18]. As the required conformation for the formation of a normal (O,O) chelate is cis(Z), correlation between the Z/E ratio and the stability of the chelate (both thermodynamic and kinetic) can be expected.

Very few stability constants have been published for iron(III)-monohydroxamato 1:2, 1:3 species [13, 19–21].

Due to the poor solubility of many copper(II)-monohydroxamate complexes, the equilibrium data in these cases are even fewer [16, 17].

We have performed equilibrium studies on a number of iron(III)- and a couple of copper(II)-monohydroxamate systems using pH-metric. UV-VIS spectrophotometric and EPR techniques.

EXPERIMENTAL

Chemicals

Acetohydroxamic acid (Aha), benzohydroxamic acid (Bha), 2-hydroxypyridine-*N*-oxide (PYRha) and *N*-phenyl-benzohydroxamic acid (PhBha) were pure commercially available chemicals (Aldrich or Sigma). The propanohydroxamic acid (Pha), hexanohydroxamic acid (Hha), *N*-phenyl-acetohydroxamic acid (PhAha), *N*-methyl-acetohydroxamic acid (MAha) and *N*-isopropyl-acetohydroxamic acid (iPAha) were prepared by standard procedures from the corresponding carboxylic esters and hydroxylamine [22]. The isolation of 2,4-dihydroxy-2H-1,4-benzoxazin-3-(4H)-on-glucoside (DIBOA-gl) was carried out as described previously [5]. The glucoside derivative was found to be stable in solution. The purity of the ligands and the concentrations of the ligand stock solutions were determined by Gran's method [23].

The metal ion stock solutions were prepared from $CuCl_2 \cdot 2H_2O$ and $FeCl_3 \cdot 6H_2O$ (Reanal). To prevent hydrolysis of the metal ion, the iron(III) stock solution contained HCl in known concentration ($\sim 0.1\,mol/dm^3$). Concentrations of the metal ion stock solutions were determined gravimetrically via precipitation of the quinolin-8-olate. $CuSO_4 \cdot 5H_2O$ was used to prepare $Cu(Bha)_2$ and $Cu(PhBha)_2$.

Potentiometric and spectroscopic studies

The pH-metric and spectrophotometric measurements were carried out at an ionic strength of $0.2\,mol/dm^3$ (KCl). Carbonate-free KOH solutions of known concentrations (ca. $0.2\,mol/dm^3$) were used as titrant.

The pH-metric titrations were performed throughout the approximate pH range 2.0–10.0, or below precipitation, on samples of 5.00 or $10.00\,cm^3$. The ligand concentration was varied in the range $6 \cdot 10^{-3} - 3 \cdot 10^{-3}\,mol/dm^3$. The metal-ligand ratios were 1:1–1:10. Measurements were made with samples at four or five different ratios. As a result of the very poor solubility of the $Cu(Bha)_2$ complex in water, the stability constants for copper(II)-Bha complexes were determined in mixed solvents: (water-methanol, water-DMSO 50–50%(m/m)). For comparison, the copper(II)-Aha was also studied in these mixed solvents. The analytical concentrations and ratios were the same as for the other systems in aqueous solutions. The pH-metric measurements were carried out with a Radiometer pHM 84 instrument equipped with CMAWL/5 Russel combined electrode. The titrant was added from an ABU 13 autoburette. The electrode system was calibrated by the method of Irving et al [24]. so that the pH-meter readings could be converted into hydrogen ion concentration. The calibration and measurements in mixed solvents were performed by a known method [25].

The UV-visible measurements for the iron(III)-monohydroxamate systems were carried out in two sets. Individual samples were prepared in the first series, in which the $0.2\,mol/dm^3$ KCl was replaced by HCl in some part or completely. The pH values, varying in the range 0.7–1.3, were calculated from HCl contents. In the second set, titrations were made with samples containing the iron(III) ion in $5 \cdot 10^{-4}\,mol/dm^3$. The metal ion to ligand ratios were 1:5 and 1:10, the pH was varied in the range 1.7–8.5 (-9.0) and spectra were recorded at 10–15 different pH values. A HP 8453 spectrophotometer was used to record the spectra in the region 300–600 nm. The spectra for the copper(II)-DIBOA-gl system were collected in the region 200–600 nm at a $5 \cdot 10^{-4}\,mol/dm^3$ copper(II)-concentration and a metal to ligand ratio of 1:4.

Both the pH-metric and spectrophotometric results were used to find the stoichiometry of the species and to calculate the stability constants. Calculations were not performed for the pH-regions where the experimental findings showed the possibility of hydrolysis (continuous decrease of the pH or formation of precipitate). The calculations were made with the PSEQUAD computer program [26] using literature data for the iron(III) hydroxo complexes [27]. Volumes of titrant were fitted in the case of pH-metric data and absorbance values of spectrophotometric titration curves. Accepted fittings were below 1.10^{-2} in the former cases and below ca. 2.10^{-2} in the latter ones.

X-band EPR spectra (9.15 GHz) were recorded at 140 K with varying pH and ligand to metal molar ratios, using a Varian E-9 spectrometer. As usual, a few drops of DMSO was used to ensure good glass formation in frozen solutions. DPPH was used as a standard field marker.

Syntheses of Cu(Bha)$_2$ and Cu(PhBha)$_2$ for EPR measurements

The Cu(II) complexes of Bha and PhBha acids were prepared by adding $1 \cdot 10^{-3}$ moles of ligand to 25 cm^3 of an aqueous solution containing $5 \cdot 10^{-4}$ mole of $CuSO_4 \cdot 5H_2O$ and adjusting the pH to 5–6. Precipitates were immediately obtained which, after filtration, washing with water and then with EtOH and drying under a nitrogen stream, exhibited analytical data consistent with the formula $Cu(A)_2$, where A is the monoanionic form of the ligand. *Anal.*[Cu(Bha)$_2$]: Calcd.: for $CuC_{14}H_{12}N_2O_4$: C, 50.07; H, 3.60; N, 8.34; Found: C, 50.4; H, 3.7; N, 8.2%; Residue from TG analysis (CuO): Calcd.: 23.69; Found: 23.5% [Cu(PhBha)$_2$]: Calcd.: for $CuC_{26}H_{20}N_2O_4$ C, 63.99; H, 4.13; N, 5.74; Found: C, 64.0; H, 4.3; N, 5.7%. Residue from TG analysis (CuO): Calcd.: 16.29; Found: 16.0%. Microanalyses (C, H, and N) were performed using a Perkin-Elmer 240B elemental analyser. Thermogravimetric data were obtained with a Perkin-Elmer TGS-2 apparatus in a nitrogen atmosphere.

RESULTS AND DISCUSSION

Acidity of the ligands

These ligands (formulas shown in Scheme 1) can each release one proton in the measurable pH-range. The pK_{HA} values measured by pH-metry are listed in Table 1. Due to the measurable decomposition of PhBha in solution during the pH-metric titration period, Table 1 does not contain a value for this ligand. The values in Table 1 are consistent with hydroxamic acid acidity in general and they are also in good agreement with the related literature data [10, 11, 13–16, 20]. Evaluation of the effects of C- and N-substituents on the acidity of the hydroxamic acid group leads to the conclusion that the pK_{HA} increases slightly in the series Aha < Pha < HhA and is significantly lower for Bha. This is probably due to the increased electron donating effect of alkyl chain in the above series and electron withdrawing effect of the phenyl moiety in Bha. The differences in the electronic effects result in more definite changes in the acidity of secondary hydroxamic acids. As expected, there is a significant increase in the acidity of the hydroxamic acid moiety if the C–N bond is involved in a delocalised ring-system [12, 13]. The OH in the 'hydroxamic acid like' PYRha is the most acidic.

The pK_{HA} values determined in 50–50% (m/m) methanol-water or DMSO-water solvent mixtures for Bha and Aha are 9.32(1), 9.64(1) as well as 9.93(1), 10.57(1), respectively. The study of solvent effects was beyond the scope of this work.

Copper(II) complexes

Precipitation which occurs quite frequently in copper(II)-hydroxamic acid systems was found in some of our systems too. It occurs at pH ca. 2.5 in the aqueous solution of copper(II)-Bha. The precipitate, known as Cu(Bha)$_2$ both from former work [9] and from the synthetic results of this work, starts to dissolve at ca. pH 9 consuming two equivalents of base up to pH ~ 11. The precipitate is also formed in mixed solvents, at pH ca. 4–5 and 6–7 in MeOH-H_2O and DMSO-H_2O, respectively. We could not calculate any stability constant in aqueous solution but values could be calculated for $[CuA]^+$ and $[CuA_2]$ in mixed solvents, as can be seen in Table 2. Due to the slow decomposition of PhBha in solution (see former section) stability constants for copper(II)-PhBha have not been calculated. In the case of Aha, if the copper(II):Aha ratio is at least 1:4, precipitation occurs at ca. or above pH 9. The model involving $[CuA]^+$, $[CuA_2]$ and $[CuA_2H_{-1}]^-$ yields the best fit of the experimental results. The calculated data are in good agreement with those formerly published for $[CuA]^+$ and $[CuA_2]$ [20]. Representative concentration distribution curves are shown in Fig. 1. As model data, the stability constants for copper(II)-Aha complexes formed in mixed solvents were also determined. Precipitation occured at pH 5–5.5 in the copper(II)-DIBOA-gl system even at the highest ligand excess. Below this pH, the formation of $[CuA]^+$ and $[CuAH_{-1}]$ was found. The calculated stability constants for these species and also for $[CuA]^+$ and $[CuA_2]$ complexes formed in copper(II)-PYRha system are also shown in Table 2.

For copper(II) complexes, EPR measurements were also carried out to obtain information about the complexes formed with Aha, Bha or with models without NH proton (PYRha and PhBha). In the case of Bha the complexes formed following dissolution of the precipitate, Cu(Bha)$_2$ were studied. As representative example, X-band EPR spectra recorded for copper(II)-Aha system at different pH values, at 140 K are shown in Fig. 2. The parameters calculated from the EPR spectra are summarized in Table 3.

Based on the pH-metric and EPR results the following conclusions can be done: Varying pH and metal-to-ligand molar ratios, a number of species were detected in the copper(II)-Aha system. Their distinctive EPR parameters as well as their formation ranges provide information on the complexation behaviour in this system. Based on the sequence of EPR spectra (see Fig. 2) mononuclear species taking part in the complex formation equilibria can be identified. Complexation starts at pH somewhat below 3, with the formation of the mono-chelated complex ($[CuA]^+$) containing the ligand in the monoanionic form. This species is in equilibrium with aqua ion up to pH ca. 4–5, depending on molar ratios. The increase of ligand excess allows the detection of the corresponding bis-chelated species, $[CuA_2]$. (The relating EPR parameters are in good agreement with those for other bis-hydroxamato species [28]). This species is a single component in the system from pH 5 to 9.5 if the ligand-to-metal molar ratio is 10:1 (see Fig. 2). Concentration distribution curves in Fig. 1 show the

dominance of the $[CuA_2]$ also at lower ligand-to-metal molar ratio (4:1). Additional complexes were detected in copper(II)-Aha system by EPR at high pH. In two of these species, the change in the $g_\parallel$ and $A_\parallel$ parameters suggests the stronger coordination of the ligands (see *f* and *g* spectra in Fig. 2). It is in accord with further stepwise deprotonation processes of the ligand molecules. As a consequence, the bis-hydroxamato(1-) complex, $[CuA_2]$ is transformed into the bis-hydroximato(-2) species, $[CuA_2H_{-2}]^{2-}$ yielding $[CuA_2H_{-1}]^-$ as the intermediate species with mixed hydroximato-hydroxamato coordination (the most probable bonding modes are shown in Scheme 2). Hydrolysis starts at higher pH values to yield mixed hydroxo species (the change in $g_\parallel$ and $A_\parallel$ values support this), presumably a monohydroxo derivative, where only one ligand molecule, in the hydroximate(2-) form, is bound to the metal species (spectrum *h* in Fig. 2). In this pH region the decrease in linewidth of EPR signals was found what is also supportive of a diminished number of nitrogen atoms in metal coordination. As it is known, pH-metry can not differentiate between deprotonated and mixed hydroxo species. Taking into account the quite low ligand

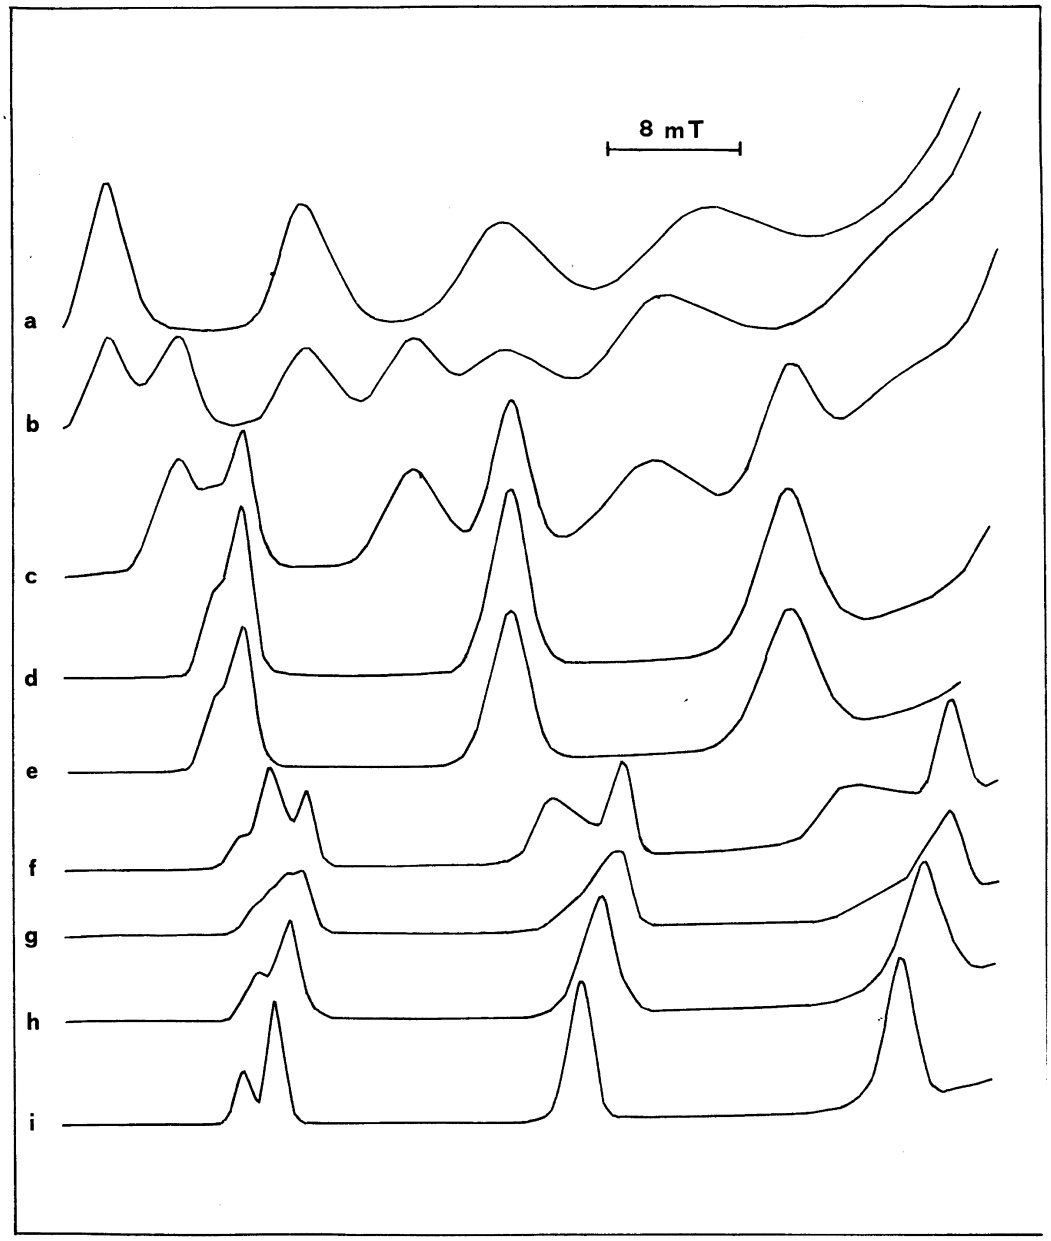

Fig. 2. X-band EPR spectra recorded at 140 K on aqueous solutions of copper(II)-Aha at a ligand-to-metal molar ratio of 10:1 with varying pH: (a) 2.70; (b) 3.35; (c) 4.55; (d) 6.80; (e) 9.55; (f) 11.10; (g) 12.30; (h) 13.35; $C_{Cu} = 5 \cdot 10^{-3}$ mol/dm^3.

excess, the $[CuA_2H_{-1}]^-$ in Fig. 1 represents in that case most probably a mixture of deprotonated and mixed hydroxo species.

The interaction between Cu(II) and Bha in aqueous solution leads to the precipitation of an insoluble complex at pH values as low as 2.5. The compound, after the purification procedure described in the experimental section, satisfactorily analysed as $[Cu(Bha)_2]$, as found previously with the VO^{2+} ion [29], indicating the presence of two benzohydroxamate(1-) anions bound to the metal. A complex with analogous composition was obtained in a former paper [9]. The solid compound completely redissolves in aqueous solution at pH values as high as 11. (As it was stated above, exactly two equivalents of base was necessary to do this.) The redissolution allows the identification of a single species which has EPR parameters quite comparable with those of $[CuA_2H_{-2}]^{2-}$ formed with Aha. However, in case of Aha this species is formed at somewhat higher pH. This result, may supports the suggestion that the second deprotonation process for the Bha is more favoured than in the case of the Aha. The same trend was previously found with the VO(IV) ion [29]. A further indication of the rather high stab-

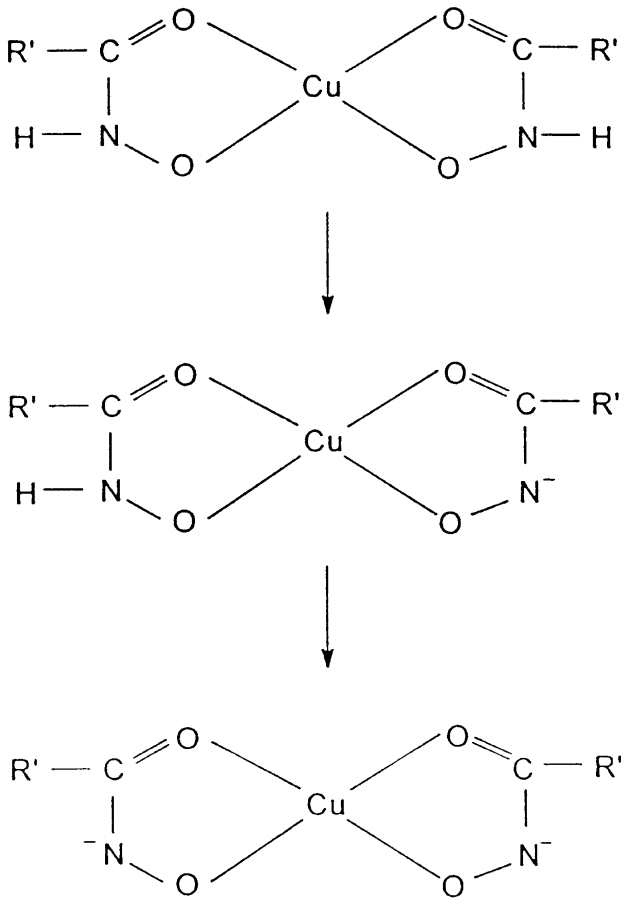

Scheme 2.

ility of the complex $[CuA_2H_{-2}]^{2-}$ formed by Bha is the absence of any hydrolytic processes, at least up to pH 13.

As the EPR results show, the behaviour of PYRha and PhBha, which do not contain dissociable protons on their nitrogen atoms, is remarkably different from that of simple hydroxamic acid molecules. With the hydroxamic-like ligand PYRha, the complexation starts with formation of a species analogous to [CuA], which is favoured to a larger extent if the ligand excess is lowered to 1:1. As for Aha and Bha, the complexation process is associated with a single proton dissociation. The bis-chelated complex, $[CuA_2]$ is formed with increasing ligand to metal ratio, with maximum formation being detected over the pH range 7–10. A solid compound also separates from solution in this case. It can not be satisfactorily characterized by analytical data, most likely because of some ligand decomposition reaction which occurs during the purification procedure. However, its redissolution, with increasing amount of base, yields EPR spectra characteristic only for a mixed hydroxo species and then the tetrahydroxocuprate(II) ion, demonstrating that no more acidic protons are available on the ligand. The different chelating mode of the PYRha, as compared to Aha and Bha, is reflected also by different parameters relating to the mixed hydroxo species formed with Aha or Bha and PYRha.

The solid compound may also be dissolved in MeOH or 1,4-dioxane, where spectral parameters similar to those measured for $[CuA_2]$ in aqueous solution are observed. Also, some effects due to solvent coordination are evident in these systems. Actually, the higher $A_{\parallel}$ value measured in dioxane suggests a more pronounced tetragonal elongation at the metal site, as a consequence of weaker axial binding of solvent molecules.

The ligand PhBha is sparingly soluble in water. However, a solid complex with formula $[Cu(PhBha)_2]$ may be obtained on stirring aqueous Cu^{2+} solutions in the presence of the undissolved ligand at pH ca. 5. The solid compound may be dissolved in MeOH or 1,4-dioxane. In the latter solvent, an equilibrium mixture of $[CuA]^+$ and $[CuA_2]$ can be observed by EPR. Complete transformation of $[CuA]^+$ into $[CuA_2]$ is achieved by adding an excess of ligand indicating their nature of mono- and bis-chelated species respectively. Again, the comparison of the EPR parameters measured for $[CuA_2]$ in MeOH indicates that a stronger axial interaction occurs with this solvent.

Iron(III) complexes

It is general that hydroxamic acids, compared to their pK_{HA} values, form very stable iron(III) complexes. Consequently, the determination of the formation constants is impossible only by pH-metry. Fortunately, the iron(III)hydroxamate interaction is characterized by a charge transfer absorption band. Each added hydroxamate group results in a characteristic change both in λ_{max} and the absorption intensities [13]. The 1:1 complexes have spectra with λ_{max} of ca. 510 nm ($E^{\circ} \sim 1000\ mol^{-1}cm^{-1}$), the 1:2 ones display λ_{max} of ca. 470 nm ($E^{\circ} \sim 1800\ mol^{-1}cm^{-1}$) and the 1:3 complexes show λ_{max} of 420–430 nm ($E^{\circ} \sim 2500$–$2700\ mol^{-1}cm^{-1}$).

Based on this possibility, pH-metric studies were complemented with uv-visible spectrophotometric measurements. The pH-metric titrations were performed above pH 2. Precipitation occurred with Pyrha at already pH 2 and with DIBOA-glucoside at pH ca. 5. In the former case the iron(III)-PYRha complex(es) can be assumed to precipitate whereas most probably, hydrolysis of the metal ion occurs in the latter case.

In the case of spectrophotometry two sets of measurements were made. In the first set, the iron(III)-ligand ratio was maintained at the same value in the different samples and the pH was changed by replacing the KCl electrolyte by HCl partly or completely. From the spectra, those recorded for iron(III)-Hha are shown, as representative examples, in Fig. 3. As can be seen in Fig. 3a, only one type of iron(III)-Hha complex exists in measurable concentration in the pH-range 0.7–1.3. Its amount increases with increasing pH. The λ_{max} value (ca. 510 nm) is characteristic of the 1:1 species. (A minimal shift in λ_{max} at pH ~ 1.3 towards a lower wavelength stars in the case of iron(III)-iPAha indicating the appearance of some 1:2 species already under these conditions.)

In the second set of spectrophotometric measurements, titrations were performed. Figures 3b shows some of the spectra recorded at different pH values for iron(III)-Hha system. The Figure shows significant shifts in λ_{max} values and increase in absorbances as well as two well-defined isosbestic points each; at λ_{max} ca. 530 nm at lower pH and at λ_{max} ca. 470 nm at higher pH. This supports the formation of three species in the pH-ranges shown in Figure 3b.

Using all the spectrophotometric and pH-metric experimental results we calculated the formation constants for the different species formed in the systems below hydrolytic regions (in the most systems up to ca. pH 8.5). The results are summarized in Table 4. Representative concentration distribution curves for complexes formed in iron(III)-iPAha system in the pH range 1–7 are shown on Fig. 4.

Taking into account the differences in conditions, the stability constants formerly determined for iron(III)-Aha, -MAha, -Bha and -PhAha (in the cases of latter two ligands only for 1:1 species) are in good agreement with our data [10, 13, 16, 20, 21]. The ligands involved in these studies differ in many respects. Some of them are primary hydroxamic acids containing alkyl or aryl R_C substituents, others also have R_N substituents and there are cyclic derivatives too. The above differences sometimes result in significant differnces of pK_{HA} values (Table 1). The correlation between the basicity of hydroxamate moieties and the stability of their metal complexes can be evalu-

ated e.g. by the adequate competition reactions. From these, the values relating to the reaction $M + HA \rightleftharpoons MA + H$ are shown in Table 5. Table 5 also contains the data for the copper(II) complexes. (The higher value for the above equilibrium, means more favoured complex formation.) From the data in Table 5, it can be concluded that the superposition of many substituent effects can modify the stability of chelates formed with copper(II) and iron(III). As the data in Table 5 shows, the position of the substituent in the molecule seems to be one of the main effects, as was found formerly also by Crumbliss [10–13]. This dominance originates from the more significant effect of R_N on delocalisation of the lone electron pair of N into the C–N bond (see below). As is evident, delocalisation of the N atom lone pair inreases the electron density on the carbonyl oxygen thus increasing the

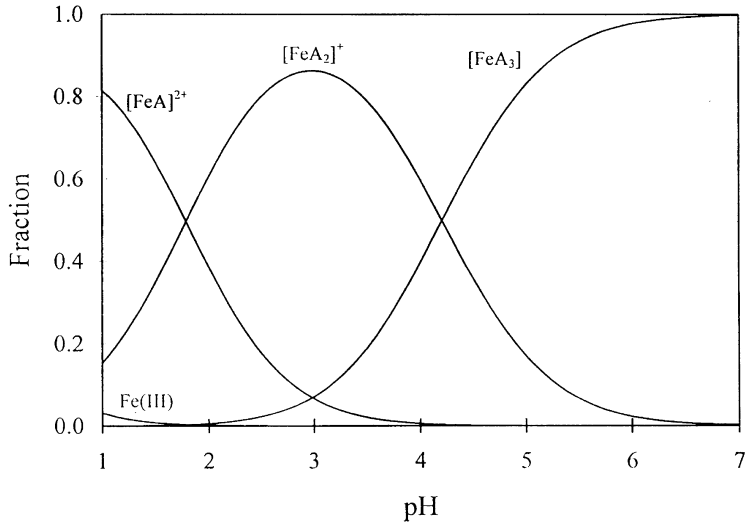

Fig. 4. Concentration distribution curves for the complexes formed in Fe(III)-iPAha system $C_{Fe(III)} = 1.5 \cdot 10^{-3}$ mol/dm^3; $C_{iPAha} = 6 \cdot 10^{-3}$ mol/dm^3.

stability of the metal chelate. The correlation of the data is very good in the case of iron(III) 1:1 complexes formed with Aha, Pha, Hha. However, if we try to calculate the adequate constants for their 1:2 and 1:3 species ($MA + HA \rightleftharpoons MA_2 + H$ and $MA_2 + HA \rightleftharpoons MA_3 + H$ reactions) we do not find such a good correlation what is most probably due to steric effects. This assumption is supported by the experimental finding that the quite bulky R_C substituent in the Hha caused precipitation in the iron(III)-Hha system at

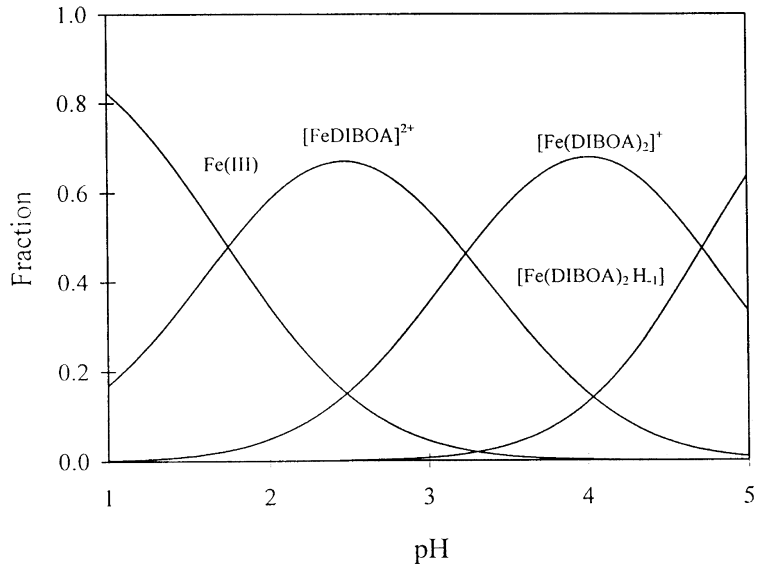

Fig. 5.

around neutral pH if the ligand excess was not larger than 1:5. The steric hindrance of the iso-propyl substituent may exceed its electron donating effect resulting in the lower stability of the iron(III) 1:1 complex formed with iPAha compared to that with MAha.

Superposition of different effects cause that electron withdrawing effect of the phenyl ring (being in the R_C position) doesn't appear in the stability of the complexes. (E.g. it can be assumed that the presence of π-electrons results in the more favoured charge distribution in the chelates)

When proton dependent equilibria involving HA are expessed (Table 5) the data show that the pyridine-oxide derivative forms the most stable Cu(II) complex, while less stable complexes are formed with the natural monohydroxamate DIBOA-gl. However, even in this latter case, the formation of iron(III) DIBOA-gl complex starts below pH 1 as can be seen in Fig. 5. The fact that the iron(III)-DIBOA-gl complex(es) can be formed under acidic conditions (pH ca. 2) existing in the rhizosphere (root-soil surface), supports the recent findings, that DIBOA (together with some other monohydroxamic acids synthesized by grasses) can play a role in iron(III) uptake from the soil [5].

(Received 13 January 1998; accepted 15 March 1998)

Abstract—Complexes of formula $[M_2(D\text{-}Pen^-)_2Cl_2]$, where M = Pd or Pt and D-Pen$^-$ = D-penicillaminate were synthesized and characterized by the usual spectroscopic methods. Red crystals suitable for X-ray study were obtained, after several days, from the mixture of K_2PdCl_4/D-Penicillamine solutions. The crystals were identified as $[Pd_3(Pen^{2-})_3].7/8KCl.19/8H_2O$. The structure shows four chemically but not crystallographically equivalent trinuclear clusters in the cell. Three D-penicillamine molecules act as divalent anions in tridentate fashion between three palladium atoms forming neutral units. Each S atom bridges two palladium atoms inside the molecular units. Potassium and chloride ions are curiously distributed along the crystallographic units contributing, together with the water molecules, to the stability of the crystal. The capacity of the penicillamine to act as tridentate ligand can be related to the capacity to capture toxic metals. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: Pd trinuclear clusters; D-penicillamine complexes; tridentate D-penicillamine complex; crystal structure Pd cluster; S bridging pencillamine ligands.

INTRODUCTION

Penicillamine is an active molecule related to natural amino acids that has been used in the treatment of Wilson's disease and other cases of metal toxicity [1, 2]. In contrast to the protein-forming amino acids which are present in the L form, the natural form is D-penicillamine, the L and DL forms being both toxic and non-active. Due to the presence of a sulfur atom in the thiolate group, penicillamine is also a good ligand to coordinate soft metals such as Pb, Hg, Pd or Pt. This possibility of binding led to the administration of D-penicillamine together with platinum antitumor drugs, to reduce their nephrotoxicity [3]. However, the interest of D-penicillamine as a ligand can be extended to its several possibilities of coordination. The molecule of penicillamine, together with its zwitterionic form, with the three functional groups ($-NH_2$, $-S^-$ and COO^-), is shown in Scheme 1. This molecule usually forms bidentate complexes by coordination of N and S atoms [4, 5] but the formation of monodentate (S) [6, 7], tridentate (N,O,S) or tetradentate (N,O,O,S) complexes [8, 9] cannot be ruled out. The sulfur, nitrogen or oxygen atoms can also act as a bridge between two or more metallic atoms.

The complex $[Pd(DL\text{-}Pen)Cl]_2$ was synthesized and characterized by IR spectroscopy by McAuliffe [10]. Later Srinivasan et al. [11] synthesized the complex $[Pt(DL\text{-}Pen)Cl]_2$ and studied both Pd(II) and Pt(II) dimer complexes using other techniques such as XPS. A dimer structure with two chlorides acting as bridges and bidentate coordination (N,S) for the DL-penicillamine was assigned in both cases. No crystal structure has been described for Pd(II) or Pt(II) penicillamine derivatives. Although several complexes

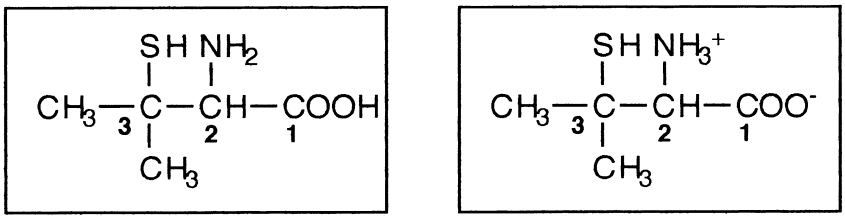

Scheme 1

of other metals such as Co, Pb, Cd and Cr showing anionic penicillamine tridentate coordinated (N,S,O) [8, 12, 13] have been characterized, no complexes of Pd(II) and Pt(II) with the tricoordinated ligand are known. We have synthesized and characterized compounds of Pd(II) and Pt(II) with D-penicillamine of formula $[M(D\text{-}Pen)Cl]_2$ and a tripalladium cluster with composition $Pd_3(D\text{-}Pen)_3.(KCl)_{7/8}.(H_2O)_{19/8}$, the crystal structure of which was solved. This is the first Pd(II) compound described in which the trimer unit shows the double anionic tridentate D-penicillamine acting as bridge between two Pd atoms via the S atom and via NH_2 and COO^- groups simultaneously.

MATERIALS AND METHODS

The complexes were prepared using $K_2[PdCl_4]$ and $K_2[PtCl_4]$ from Johnson Matthey and D-penicillamine from Fluka.

Elemental analyses were carried out on a Carlo Erba 1500 microanalyzer at the Serveis Científico-Tècnics at the University of Barcelona. Monocrystal chlorine and potassium analysis were carried out by ESCA. The infrared spectra were recorded in solid state (KBr pellets) on an FT-IR Nicolet 5DZ spectrometer in the 4000–400 cm^{-1} range and on an FT-IR Bomem DA-3 spectrometer in the 400–150 cm^{-1} range. $^1H\{^{13}C\}$ and $^{13}C\{^1H\}$ NMR spectra were obtained on a Bruker 250 spectrometer using DMSO as solvent. Chemical shifts were measured relative to TMS.

Suitable crystals for X-ray diffraction experiments were mounted on an Enraf-Nonius CAD4 four-circle diffractometer. Unit cell parameters were determined from 25 reflections and refined by least-squares method. Intensity data were collected using graphite monochromated MoK_α radiation. The unit cell was checked trying to find (unsuccessfully) higher metric symmetry by means of the facility included in the program package [14]. The chirality of penicillamine left P1 as the only possible choice for the space group.

Palladium and sulfur atoms were located by direct methods; other atoms were identified in successive different syntheses. Interstitial peaks were assigned to chloride and potassium ions or water molecules according to their intensity and their environment, some of them with partial occupancy and were used to define the formula $[Pd_3(Pen^{2-})_3].7/8KCl.19/8H_2O$. The formula was also checked by chemical analysis.

The structure was refined by full-matrix least-squares on F^2. Palladium and sulfur atoms were refined anisotropically, as were full occupancy chlorine and potassium atoms; all others were refined isotropically. Distances and angles within the penicillaminate anion (except those involving the sulfur atom) were constrained to be equal for the twelve units applying the SAME instruction of the program SHELX-93 [15]. Hydrogen atoms were introduced at ideal positions with an isotropic thermal parameter 1.2 times that of their parent atoms.

The program package SHELXTL Plus [14] was used for the structure solution and for the drawings. The program SHELX-93 [15] was used for structure refinement. A summary of crystal data and data collection is given in Table 1.

Syntheses of the complexes

(*a*) $[Pd_2(D\text{-}Pen^-)_2Cl_2]$ (***1***). A solution of 1 mmol of $K_2[PdCl_4]$ in 10 mL of water was mixed with another solution of 1 mmol of D-penicillamine in 10 mL of water at room temperature. An orange solid was immediately obtained from the final solution. The pH of this solution was then 1.1. The solution was stirred for 1 h at 40°C and the pH rose to 5.1. The orange solid was filtered from a red solution, washed in distilled water and dried overnight over silica gel. Found: C, 20.82; N, 4.81; H, 3.76; S, 10.89; Cl, 12.17. $Pd_2C_{10}H_{20}N_2S_2Cl_2O_4$ requires: C, 20.70; N, 4.83; H, 3.47; S, 11.05; Cl, 12.22. Red crystals suitable for X-ray diffraction were obtained from the solution, pH = 5.1. The crystals correspond to $[Pd_3(Pen^{2-})_3].7/8KCl.19/8H_2O$ (**2**). Found: C, 20.51; N, 4.66; H, 3.92; S, 10.94; Cl, 3.47; K, 3.91; $Pd_3C_{15}H_{31.75}N_3S_3Cl_{0.88}K_{0.88}O_{8.38}$ requires: C, 20.72; N, 4.83; H, 3.65; S, 11.05; Cl, 3.60; K, 3.96. The same crystals were repeatedly collected from the red solution, pH = 5.07, in further syntheses.

(*b*) $[Pt_2(D\text{-}Pen^-)_2Cl_2]$ (***3***). A solution of 1 mmol of $K_2[PtCl_4]$ in 10 mL of water was mixed with another solution of 1 mmol of D-penicillamine in 10 mL of water at room temperature. The solution was stirred for 2 h at 40°C and for 24 h at room temperature and

a reddish orange solution with a yellow precipitate was obtained. The solid was filtered, washed in distilled water and dried overnight over silica gel. Found: C, 14.84; N, 3.45; H, 2.97; S, 7.83; Cl, 7.95. $Pt_2C_{10}H_{20}N_2S_2Cl_2O_4$ requires: C, 14.80; N, 3.45; H, 3.24; S, 7.90; Cl, 8.74. All efforts to obtain crystals suitable for study by X-ray were unsuccessful. Only twinned needles were isolated.

RESULTS AND DISCUSSION

IR Spectra

The FT-IR data of the D-penicillamine and the Pd(II) and Pt(II) compounds are shown in Table 2. The most important bands in the spectrum of the D-penicillamine are assigned to $\nu_{st}(NH_3^+)$ at 3174–2967 cm^{-1}, $\nu_{as}(COO^-)$ at 1595 cm^{-1} corresponding to the zwitterionic form of amino acids. Consequently, the ν(C═O) at 1700 cm^{-1} of the protonated carboxylic group is absent. The frequencies corresponding to $\delta_d(NH_3^+)$ (aa-I) and $\delta_{sym}(NH_3^+)$ (aa-II) appear, respectively, at 1618 cm^{-1} and 1526 cm^{-1}. The bands at 2609 and 2513 cm^{-1} assigned to ν(S–H) in the D-penicillamine disappear in the spectra of the three compounds, indicating the coordination of the S atom to the metal. The shift of $\nu_{as}(NH_3^+)$ toward higher frequencies in the spectra of the complexes, typical for coordination of NH_2 [10], and the changes in the bands related with $\delta(NH_3^+)$ confirm the coordination through the nitrogen atom [16].

The presence in the spectra of (**1**) and (**3**) of bands at frequencies higher than 1700 cm^{-1}, assigned to the free carboxylic group, indicates no coordination by the oxygen atom [5]. The spectrum of (**2**) is quite different. No band corresponding to free carboxylic group was observed, while a wide band between 1632 and 1594 cm^{-1} includes ν(C═O) from the coordinated carboxylic group and $\delta(NH_2)$. The new bands at 395 cm^{-1} for the $[Pd_2(D\text{-}Pen)_2Cl_2]$ (**1**), at 385 cm^{-1} for the $[Pt_2(D\text{-}Pen)_2Cl_2]$ (**3**), and at 397 cm^{-1} for the cluster of palladium (**2**) were assigned to ν(M–S) [17]. The bands observed in the zone about 300 cm^{-1} for both (**1**) and (**3**) were assigned to bridge ν(M–Cl). These bands are split and shifted to lower values, as corresponds to *cis* bridged chlorine atoms [10, 18]. Only in the spectrum of (**2**) was a band at 500 cm^{-1} assigned to ν(Pd–O). In this spectrum ν(Pd–N) also appear at 443 cm^{-1}. These findings are consistent with the tridentate coordination through N, S and O atoms shown by the penicillamine in (**2**). In this case, the penicillamine has lost two protons, while in complexes (**1**) and (**3**) the coordination is only bidentate through N and S atoms, acting as a mononegative anion.

^1H and ^{13}C NMR study

The complex $[Pt_2(D\text{-}Pen)_2Cl_2]$ (**3**) presents low solubility in DMSO and other solvents and it was impossible to register its ^1H, ^{13}C and ^{195}Pt NMR spectra. The palladium complex $[Pd_2(D\text{-}Pen)_2Cl_2]$ (**1**), is quite soluble in DMSO but several species were formed in solution, probably due to the coordination of DMSO to palladium atom which replaces the penicillamine molecule and breaks the dimer to give monomer complexes. The ^1H and ^{13}C NMR spectra are very complicated and it is difficult to assign the signals corresponding to several species co-existing in equilibrium. Attempts to isolate and identify the differents species chromatographically using solvents such as chloroform or DMF were unsuccessful, because a mixture of several species was always obtained. Both orange crystals and yellow crystals were isolated from an eluted fraction, but unfortunately, they were not suitable for X-ray study.

In Table 3, the chemical shifts (ppm) corresponding to the ^1H and ^{13}C NMR spectra of D-penicillamine and the compound $[Pd_3(Pen^{2-})_3]$ (**2**) are shown. The

Table 3. ^1H and ^{13}C NMR shifts (ppm) of D-penicillamine and $[Pd_3(Pen^{2-})_3]$*

^1H NMR Compound	NH_2	CH(2)	CH_3

				25.74

*in DMSO

shift observed for the methyl groups in the complex is consistent with the coordination by the S atom. Likewise, the signal assigned to NH_2 proton in free penicillamine shifts upfield due to the coordination of the NH_2 group to the palladium atom. In the spectrum of the complex, two signals appear for each type of proton. It is possible that new species are formed in solution due to the opening of the ring in the cluster as observed for other penicillamine compounds [19].

In the ^{13}C spectrum of $[Pd_3(Pen^{2-})_3]$ (**2**), a significant shift in the signal assigned to C═O can be observed. It is consistent with the coordination of Pd(II) by O atoms. Changes in C(3) signals are also due to the coordination of the metal atom to S. The signal assigned to CH(2) also shifts downfield as a consequence of the coordination of palladium to the NH_2 group.

X-ray study

Crystal parameters for the complex (**2**), $[Pd_3(Pen^{2-})_3].7/8KCl.19/8H_2O$ and a summary of the data-collection and refinement process are given in Table 1. Tables 4 and 5 contain a selection of bond distances and angles with their e.s.d.'s. The complete list of bond distances and angles and final atomic coordinates as well as anisotropic thermal parameters and the listing of observed and calculated structure factors are included as supplementary material.

The structure is built of trimeric [Pd_3(penicillaminate)$_3$] units plus potassium ions, chloride ions and water molecules in interstitial positions. There are four crystallographically independent but chemically equivalent trimeric clusters in the unit cell. In Fig. 1 one of the units is represented. The other three are included as supplementary material.

The palladium atoms in each trimer define an isosceles triangle (Table 6). Each pair of metal atoms in the trimer is bridged by a penicillaminate anion, which is linked via its amino group to one palladium atom, via its carboxylate group to the other and via the sulfur atom to both. Two chelate rings, one five-membered and the other six-membered are defined in this way.

The environment of the metal atoms deviates appreciably from ideal square planar (Table 7), especially the angle inside the six-membered chelate ring (O–Pd–S(O)). The twelve Pd–N and the twelve Pd–O distances are similar, whereas Pd–S distances are slightly shorter (in average) for the O-chelated sulphur than for the N-chelated.

In all cases, the metal atom slightly (below 0.1 Å) deviated from the average NOS_2 plane away from the centre of the triangle. Only two other structures with Pd_3S_3 triangles have been published [20, 21], but the molecule bearing the sulfur atoms in these cases does not doubly chelate the palladium atoms, so the Pd-Pd distances are considerably longer.

The conformation of the bonds in the organic ligand is severely constrained by the formation of the chelate rings. In all cases, O1 is gauche respect to C3 and the nitrogen atoms (the ranges for the corresponding torsion angles are: O1–C1–C2–N, 59,9···83,3° and O1–C1–C2–C3, −42,0···−66,7°). The sulfur atom is gauche respect to the nitrogen atom and Cl (torsional angle ranges: C1–C2–C3–S, 75,4···81,0° and N–C2–C3–S, −41,8···−49,2°).

Crystal packing, showing the distribution of potassium and chloride ions between the cluster units, is depicted in Fig. 2.

Although several complexes containing tridentate penicillamine have been reported, this is the first palladium compound in which the penicillamine bridges three atoms in a cluster. Appleton, on the basis of NMR studies, proposed a tridentate coordination for a penicillamine molecule acting as bridge between two

platinum atoms [19]. The type of coordination proposed for the penicillamine was identical to that found in $[Pd_3(Pen^{2-})_3]$ (**2**) but the complex was a dimer in which each Pt coordination was completed with two amine ligands. In other metal complexes reported [22–24], the penicillamine does not act as a tridentate ligand but the S atom bridges two or three metallic atoms other than Pd or Pt. The methionine molecule has also shown its capacity to act as a tridentate ligand and to bridge metallic atoms, but through the N atom [25]. Finally, structures have been reported in which cysteine acts as a tridentate ligand but to date there is no report of this forming part of a cluster [26].

The synthesis of a tridentate penicillamine complex of a heavy metal offers interesting possibilities. The capacity of penicillamine to act as a tridentate ligand can be related to its capacity to capture toxic metals. Müller et al. [9]. have studied the decrease of toxicity of Cr(VI) in animals when penicillamine was administered. In this case the Cr(VI) was reduced to Cr(III) and a tridentate Cr(III)-penicillamine complex was formed.

A hydroxo-and phenoxo-bridged dinuclear Nickel(II) Complex: structure and characterization

Yilma Gultneh,* A. Raza Khan, Bijan Ahvazi and Ray J. Butcher

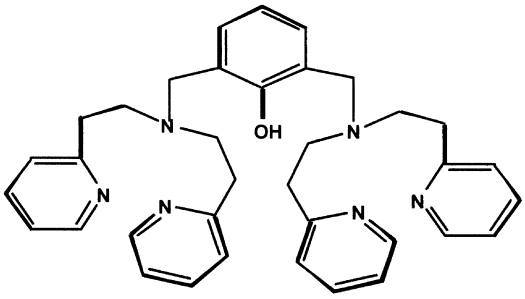
Contribution from the Department of Chemistry, Howard University, 525 College St. NW, Washington, DC 20059, U.S.A.

(Received 25 August 1997; accepted 16 March 1998)

Abstract—The structure and properties of the dinuclear complex $[Ni(II)_2(\mu\text{-LO})(\mu\text{-OH})](ClO_4)_2 \cdot 2CH_3CN$(**1**) (LOH = 2,6-bis((bis (2-(2-pyridyl)ethyl)amino)methyl)phenol is reported. The structure of the cation $[Ni(II)_2(\mu\text{-LO})(\mu\text{-OH})]^{2+}$ shows two doubly bridged, square pyramidal Ni(II) ions. The electronic absorption spectrum showed maxima at 204, 264, 300, 362, 607 and 820 nm. Cyclic voltammetry in dry acetonitrile showed irreversible reduction peaks at −1.25 V and −1.45 V (vs. Ag/AgCl) assigned to the stepwise reduction to the Ni(II)Ni(I) and the $Ni(I)_2$ state and also irreversible oxidation waves at +0.13 V and +0.87 V (vs. Ag/AgCl) assigned to the stepwise oxidation to the Ni(II)Ni(III) and the $Ni(III)_2$ state. The room temperature magnetic moment, corrected for diamagnetism, is 2.67 BM indicating an antiferromagnetic coupling of the two Ni(II) ions. © 1998 Elsevier Science Ltd. All rights reserved

The interest in the structures and reactions of transition metal complexes is, in part, as small molecule models for the active sites of metalloenzymes. Nickel is found at the catalytic active sites of several redox [1, 2] and hydryoltic [3] enzymes. In synthetic nickel complex catalysts [4] for redox reactions of organic substrates [5], nickel oxidation states range from +1 to +4, while in the redox enzymes nickel ions are cycled between the formal oxidation states of +3 and +1 [6, 7]. Bacterial and plant urease contain two nickel ions per catalytic subunit [8]. However, it has not been settled whether the Ni(II) ions are magnetically coupled [9, 10] since a recent magnetic saturation study of jack bean and *Klebsiella aerogenes* urease by Day *et al* [11] has been interpreted as showing no evidence for magnetic coupling. The mechanism of the catalysis of hydrolysis of urea by urease is thought to involve a two-Ni(II) center wherein urea coordinates to one Ni(II) ion inducing greater susceptibility to nucleophilic attack by the OH^- that is coordinated to the other Ni(II) ion in the binuclear active site [12]. This is similar to the widely accepted mechanism for catalysis by dinuclear Zn(II) hydrolytic enzymes [13]. Recently, Yamaguchi *et al* [14]. have reported a carboxylate (or bicarbonate)-bridged dinuclear Ni(II) model complex that catalyzes the ethanolysis of urea to ethyl carbamate.

X-ray absorption spectroscopy [15] of urease shows 5 or 6-coordinate tetragonal Ni(II) [16] with histidyl-imidazole donors and the UV-visible absorption spectrum is similar to those of some octahedral dinuclear Ni(II)model complexes [17]. EXAFS data indicate Ni–N and Ni–O distances of about 2.03 Å and a Ni–Ni distance of about 3.3 Å [18].



LOH

Dinuclear Ni(II) complexes with phenol and polyimidazole ligand donor sets have been reported [19] as

*Author to whom correspondence should be addressed.

models for the active site of urease. The dinucleating ligand, LOH has been used in the syntheses of phenoxo bridged dinuclear complexes of Mn(II) [20], Fe(II) [21] and Cu(II) [22] with exogenous bridging by acetate, methoxide, halide or azide groups.

Here we are reporting the synthesis, structure, electrochemistry, spectral, and magnetic properties of the dinuclear Ni(II) complex of LO^-.

EXPERIMENTAL

Reagents and solvent purification

Reagent grade dry solvents were used without further purification for synthetic and purification procedures. Dimethylsulfoxide was refluxed over and distilled from P_4O_{10} and redistilled from anhydrous $CaCl_2$. Diethyl ether was refluxed and distilled under nitrogen from Na/benzophenone. Acetonitrile was refluxed and distilled from P_4O_{10}. Commercial anhydrous $(n\text{-}Bu)_4NClO_4$ was recrystallized from ethyl acetate/hexane (1:2, v/v).

Synthesis of the ligand LOH

The ligand, LOH, was made and purified according to the literature method [22].

Synthesis of the complex $[Ni(II)_2(\mu\text{-LO})(\mu\text{-OH})](Clo_4)_2.\ 2CH_3CN$ (1) [23]

To a stirred methanol solution (50 mL) of $Ni(ClO_4)_2.6H_2O$ (3.66 g, 10 mmole) and 5 mL dimethoxypropane was added, dropwise, a methanol solution (30 mL) of the ligand (2.78 g, 5 mmole) and triethylamine (0.55 g, 5.5 mmole). The green solution formed was refluxed slowly overnight. A green powdery precipitate was formed which was filtered, washed with ether and dried in air (yield 2.73 g, 55%). Crystals suitable for crystallography were obtained by recrystallization from an acetonitrile solution layered with dry ether. Green crystals formed over three days, which were isolated, washed with ether, and dried in air. Elemental analysis: Calculated for $C_{40}H_{46}\ Cl_2N_8\ Ni_2\ O_{10}$ C: 47.20%, H: 4.42%; N: 9.28%; Found: C: 46.45%; H: 4.52%; N 9.80%.

pH-metric titrations

Potentiometric titrations of the ligand and **1** were done using Fisher accumet model 50 pH/ion conductivity meter and Fisher combination glass electrodes. Typically, 0.18 mmole of the complex (or ligand) was dissolved in 25 mL of water/DMF (3:5, v/v) mixture that had been purged of dissolved CO_2 by bubbling with nitrogen gas. A standard aqueous solution of $HClO_4$ (5.1 mL of 0.10 M) was added and stirred for about 10 minutes under a nitrogen atmosphere and followed by potentiometric back-titration against a standard aqueous solution of NaOH (0.10 M).

Cyclic voltammetry

Cyclic voltammetry was carried out with a BAS CV-27 voltammograph at 25°C. The sample solution was 1.0 mM in **1** and 0.10 M in the supporting electrolyte, $(n\text{-}Bu)_4NClO_4$. (degassed by bubbling dry N_2 gas for 10 min). Glassy carbon working electrode, Ag/AgCl reference, and Pt auxiliary electrodes supplied by Bioanalytical Systems Inc. were used in the electrochemical measurements. Experiments were run at 100 mV/s scan rate.

Magnetism

Room temperature magnetic susceptibility measurements were done on powdered samples of **1** with a Johnson-Matthey magnetic susceptibility balance and calculations included correction for diamagnetic effects of the ligand.

Rates of catalysis of the hydrolysis of bis(p-nitrophenyl)phosphate (BNPP)

In a typical experiment, 3.0 mL of 0.1 M buffer solution of THAM, adjusted to the desired pH by adding $HClO_4$ solution and made to be 0.1 M $NaClO_4$, was transferred to a quartz cuvette and the solution was thermostated at 75°C. To this was added 0.15 mL of 50.0 mM solution of the substrate BNPP and 0.15 mL of 4.81 mM solution of 1, both in 1:1 DMF/water mixture. UV-Visible absorption scans were taken every 5 minutes for 3 hours.

X-ray structure determination and refinement

A bright green crystal of the title compound having approximate dimensions of $0.43 \times 0.33 \times 0.25$ mm was mounted on a glass fiber using quick setting epoxy cement. All measurements were made on a Siemens P4S diffactometer with graphite monochromated Mo Kα radiation. Cell constants and an orientation matrix for data collection were obtained by standard methods [24] and corresponded to a monoclinic cell. Systematic absences intensity statistics based on the collected data set indicated the space group P2/n. Crystal data and structure refinement data are summarized in Table 1. Data were collected by standard techniques [25]. Of the 3745 reflections collected, 3400 were unique. The structure was solved by direct methods [26] and refined by full matrix least-swuares methods (based on F^2) as implemented in the SHELXTL system [27] of computer programs. Hydrogen atoms were included in structure factor calculations in their idealized positions and considered to ride on the atoms to which

they were attached. In the lattice, there are two disordered CH_3CN molecules. The occupancy factors of these carbon atoms were constrained to sum to 1.0. The refinement converged with R_1 [28] = 6.80% for the 2242 reflections for which $I > 2\sigma(I)$.

RESULTS AND DISCUSSION

Dinucleating ligands, with the general structure of LOH presenting a potentially bridging phenoxy oxygen and two N_3 chelating donor sets per molecule with imidazolyl, pyrazolyl, pyridyl, phenolate, and benzimidazolyl donor groups (or their ring substituted derivatives), have been widely utilized in the syntheses of dinuclear complexes of copper [29], manganese [30], cobalt [31], iron [32], and zinc [31]. The donor properties of pyridyl groups approximate those of histidylimidazole in urease and in several Zn(II) hydrolytic enzymes [33, 34].

Structure of the complex $[Ni(II)_2(\mu\text{-LO})(\mu\text{-OH})](ClO_4)_2.2CH_3CN$ (1)

Tables 1 and Table 2 show the crystal data and atomic coordinates of **1** respectively. Table 3 summarizes selected bond lengths and angles. The ORTEP drawing of the cation $[Ni_2(\mu\text{-LO})(\mu\text{-OH})]^{2+}$ is shown in Fig. 1.

The structure of the cation of **1** consists of a discrete dinuclear complex in which two Ni(II) ions are each coordinated in a nearly square pyramidal geometry, to two pyridyl and an amine nitrogen, and to the bridging phenoxide oxygen of the chelating ligand and a bridging exogenous hydroxide. The apical positions taken by pyridyl groups are on opposite faces of the two square bases. There is a crystallographic C_2 axis passing through the phenoxy and hydroxide oxygens of the planar Ni_2O_2 unit. The $Ni–N_{amine}$ bond lengths are about 0.1 Å longer than the $Ni–N_{pyridyl}$ lengths attributable to the π-bonding potential of the pyridyl group. The intramolecular $Ni\cdots Ni$ distance, 3.174(1) Å, is significantly shorter than those in doubly acetate-bridged complexes (3.40 to 3.62 Å) [14, 19, 35] attributed to the larger bite of carboxylate bridges but longer than those in diphenoxy- and acetate triply bridged complex of a macrocyclic ligand (3.043 Å) [36]. It is in the range (3.10–3.20 Å) observed in the doubly phenoxy-bridged Ni(II) complexes [37]. Each nickel ion is displaced towards the apical pyridyl nitrogen, by 0.313(5) Å also evidenced by the greater than 90° N_{apical}–Ni–N and N_{apical}–Ni–O angles. The analogous hydroxide-[22] and methoxide-bridged [38] Cu(II) complexes of LOH also show a planar Cu_2O_2 geometry with the Cu (II) ion similarly displaced toward the apical N. The basal and apical $Ni–N_{pyridyl}$ bond lengths are similar, whereas in the Cu(II) analog, Jahn-Teller lengthening of the $N–N_{apical}$ bond is observed [22].

Table 2. Atomic coordinates [$\times 10^4$] and equivalent isotropic displacement parameters [$Å^2 \times 10^3$] for 1. U(eq) is defined as one third of the trace of the orthogonalized U_{ij} tensor

Electronic absorption spectrum

The electronic absorption spectrum of **1** in acetonitrile solution in the region 300 to 1100 nm shows maxima at (λ_{max}, nm (ϵ, $M^{-1}-cm^{-1}$)) 306 (3.78×10^3), 362 (1.21×10^3), 607 (128.9) and 820 (29.0). Four absorption bands (with a fifth band in the near IR region) have been observed for square pyramid, high spin Ni(II) complexes [24, 36] whereas octahedral Ni(II) complexes of ligands analogous to LOH [22, 35] show three weak absorption peaks expected for octahedral d^8 Ni(II) ions [39]. The native jack bean urease exhibits three week d-d bands at 407, 645 and 1060 nm consistent with an octahedral coordination [40] but also additional peaks at 630, 820 and 910 nm [17].

Nanda *et al* [36]. have reported the conversion of octahedral complexes to square pyramidal Ni(II) complexes which then show absorption peaks at 600 and 630 nm. This is in agreement with the observation of the broad absorption peak at 607 nm in the spectrum of 1. Addition of one equivalent aqueous $HClO_4$ to an acetonitrile solution of **1**, decreases the absorbances at 364 and 607 nm to very low values, while subsequent neutralization with aqueous NaOH reverses the reaction and restores the absorption. This process is observed for several such cycles. The addition of acid protonates the bridging hydroxide with subsequent coordination of water molecules to give an octahedral complex with far lower absorbances (Fig. 2).

$$[Ni_2LO(\mu-OH)]^{2+}+2H_2O\underset{OH^-}{\overset{H_3O^+}{\rightleftharpoons}}[Ni_2(LO)(OH_2)_4]^{3+}$$

Equilibrium shifts between square planar and octahedral coordinations on adding strong acid and strong base are known [41] in Ni(II) complexes of cyclic amines.

pH-metric titrations

Fig. 3 shows the superimposed pH-metric titration curves of acidified DMF/H_2O (5/3, v/v) solutions of the ligand and that of the ligand plus $Ni(ClO_4)_2.6H_2O$ (in 1:2 mole ratio). Three equivalents of aqueous $HClO_4$ were added each to, (a) a solution of the ligand and, (b) a solution of the ligand plus 2× mmoles of $Ni(ClO_4)_2.6H_2O$. On back-titration of each solution with standard aqueous NaOH, the titration of the solution of the ligand plus metal ion required one more equivalent of the base and showed one more end

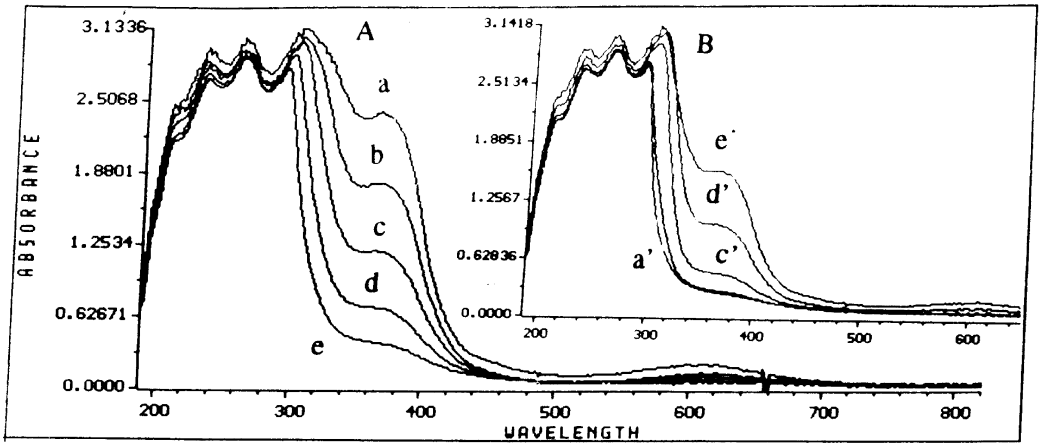

Fig. 2. A. Changes in the UV- Visible absorption spectrum, in the 190–650 nm region, of a 2.34 M acetonitrile solution of complex **1**, on stepwise addition of aqueous $HClO_4$ solution (0.1 M). Number of equivalents of acid added: **a**. 0.; **b**. 1; **c**.2; **d**. 3; **e**. 4. **B**. Reversal of the changes in the spectra in **A** on addition of aqueous NaOH solution (0.1 M) on the acidified solution in A. Number of equivalents of base added: **a′**. 0; **b′**. 1; **c′**.2; **d′**.3; **e′**.4. (Note: the absorbances of the starting solution (spectrum '**a**') and that of the final solution (spectrum '**e′**') are the same when dilution effects are factored).

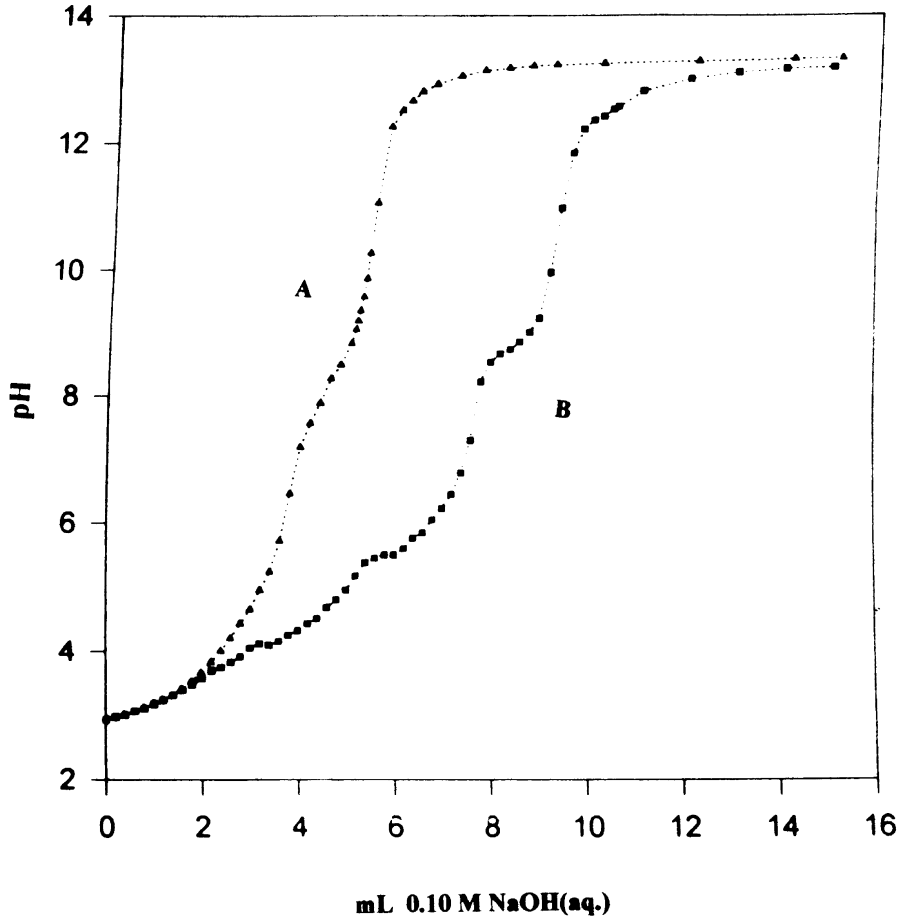

Fig. 3. Potentiometric titration curve for the back titration, vs. a 0.10 M aqueous NaOH solution, of 0.18 mmole of the ligand (**A**) and 0.18 mmole of the ligand plus 2X moles of $Ni(ClO_4)_2$ (B) each dissolved in 25 mL DMF/water (5:3, v/v) mixture that has been acidified by addition of 0.51 mmole (5.1 mL of a 0.10 M) aqueous $HClO_4$.

point (curve b) than the titration of the solution of the ligand alone (curve a). This additional end point is due to the titration of one Ni-coordinated water molecule (pKa $\approx$8.5) forming the bridging OH. This is also confirmed by the increase, during the titration, of the absorbances at 362 nm and 607 nm when the titration is followed spectrophotometrically.

Catalysis of hydrolysis

We studied the rate of the catalysis of the hydrolysis of a diester, bis(p-nitrophenyl)-phosphate (BNPP) in water/DMF (1:1, v/v) solution in buffers with pH ranging from 6 to 10. A plot of the rate constant (Kobs.) vs pH (Fig. 4) showed a sigmoid curve with an inflection point at a pH close to the pK_a of the Ni-coordinated water($\approx$8.5) consistent with the accepted mechanism that the metal-coordinated hydroxide is the effective nucleophile.

Magnetism

The room temperature magnetic moment of **1**, corrected for diamagnetic effects of the ligands and anions, is 2.67 BM per Ni(II) ion. For high spin square pyramidal Ni(II) complexes [42], this value indicates antiferromagnetic coupling between the bridged Ni(II) ions. This value is close to the value reported (2.68 BM) [24] for a doubly phenoxy bridged Ni(II) complexes similar to **1** in bridging angles and Ni $\cdots$ Ni distance.

The size of the Ni(II) magnetic exchange coupling constants (-J) of doubly oxy-bridged Cu(II) and Ni(II) tetragonal macrocyclic complexes show a linear correlation with the size of the bridging M-μ-O-M angle and the M $\cdots$ M distance (M = Cu(II) or Ni(II)) [43]. Antiferromagnetic interactions decrease with decreasing M-μ-O-M angle and crossover at 97.5° to ferromagnetic interactions [44]. The observed magnetic moment and antiferromagnetic interactions in **1** (average Ni-μ-O-Ni angle = 105.5°) are consistent with this correlation.

Cyclic voltammetry

The cyclic voltammetry of **1** in dimethylsulfoxide solution is shown in Fig. 5. Four distinct irreversible

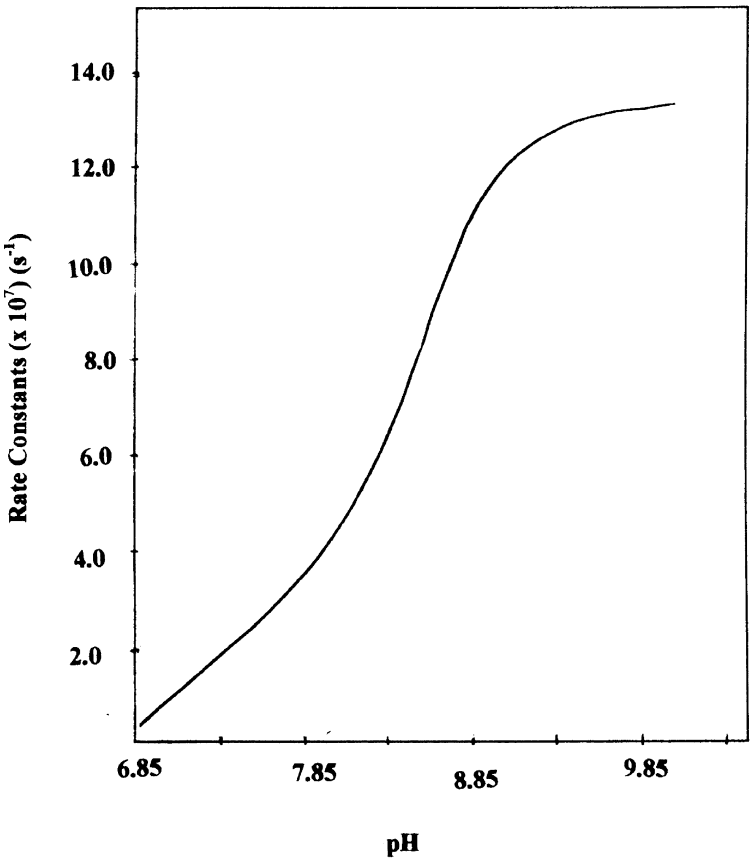

Fig. 4. K_{obs} vs. pH in the hydrolysis of BNPP (0.15 mL of 50 mM solution) in the presence of complex **1** (0.15 mL of 4.81 mM solution) in 3.0 mL of 0.1 solution of tris(hydroxymethyl)aminomethane buffer that was also made 0.01 M in $NaClO_4$ to maintain constant ionic strength.

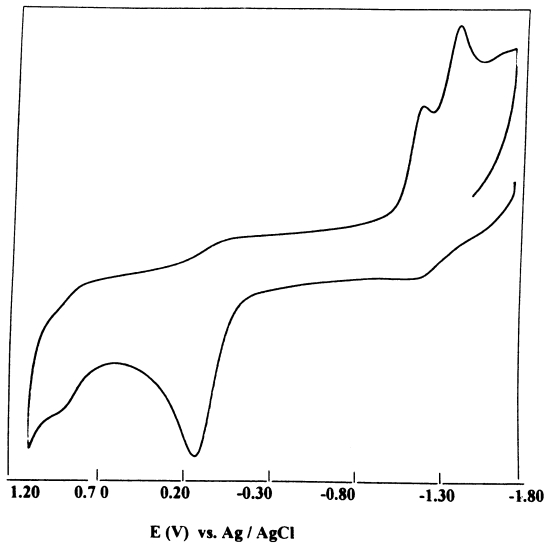

Fig. 5. Cyclic voltammogram of a 1.0 mM solution of complex **1** in dry DMSO using glassy carbon working electrode, Ag/AgCl reference electrode and Pt. auxillary electrode with $(t\text{-}Bu)_4NaClO_4$ (0.1 M) as a supporting electrolyte (scan rate = 100 mV/s.

peaks, two cathodic and two anodic, are observable. The cathodic waves at $E_p = -1.25$ V and -0001.45 V (vs Ag/AgCl) are assigned to the stepwise one-electron reductions of $Ni(II)_2$ to Ni(II),Ni(I), and to Ni(I),Ni(I) states respectively while the two anodic peaks at $E_p = +0.15$ V and $+0.87$ V (vs. Ag/AgCl) are assigned to the irreversible stepwise one-electron oxidations of **1** to Ni(II),Ni(III) and to $Ni(III)_2$ states respectively. By comparison, in the reported cyclic voltammetry (in dimethylsulfoxide) of the dinuclear square pyramidal Ni(II) complex of a tetraaminodiphenol macrocyclic ligand with aliphatic amine nitrogens and phenolate oxygen bridging, successive reversible one-electron processes are observed with potential peaks (vs SCE) of -1.32 V and -01.65 V (reductions) [45] and $+0.98$ and $+1.08$ V (oxidations). Both the reduction oxidation potentials of the corresponding processes are lower in **1** showing the easier accessibility of the various oxidation states. This result could be attributed to the greater flexibility of the ligand. Coordination geometry rearrangement, which often accompanies oxidation state changes in metal complexes, may be more difficult in the constrained cyclic ligand compared with the open chain structure of the ligand LOH. Other dinuclear octahedral Ni(II) complexes of macrocyclic ligands containing unsaturated and saturated amine and phenolic oxygen donor sets show reduction potentials in the range of -1.6 to -1.9 V (vs. SCE) [28]. The lower reduction potentials exhibited by **1** are also expected since the soft base pyridyl nitrogen donor, with its π -bonding ability, stabilizes the lower oxidation states better.

CONCLUSION

We have reported a new phenoxy and hydroxy doubly-bridged dinuclear Ni(II) complex in which each nickel is square pyramidally coordinated. The cyclic voltammetric studies in dimethylsulfoxide demonstrate that the complex can be reduced electrochemically to the Ni(II),Ni(I) state, the $Ni(I)_2$ state and oxidized to the Ni(II),Ni(III) and the $Ni(III)_2$ states at more moderate potentials than is observed for other Ni(II) dinuclear complexes of macrocylic ligands. The observed room temperature magnetic moment indicates antiferromagnetic coupling between the Ni(II) ions, which is consistent with the known correlation between the Ni-μ-O-Ni bridging angle and the sign of the magnetic coupling constant J in Ni(II) (and Cu(II) dinuclear) complexes. The electronic absorption spectral features are similar to those observed in other five coordinate square pyramidal Ni(II) complexes.

Comparison of divalent dimethoxyethane-solvated thulium and samarium diiodides in hexamethylphosphoramide and pyridine: Isolation of the cations $\{[TmI_2(HMPA)_4][I](pyridine)_5\}$ and $\{[TmI(HMPA)_4(pyridine)][I]_2\}$ and a single crystal containing both linear and bent dimethoxyethane-solvated SmI_2

William J. Evans*, Randy N. R. Broomhall-Dillard and Joseph W. Ziller

(Received 8 December 1997; accepted 16 March 1998)

Abstract—The highly reducing nature of $TmI_2(DME)_3$ is shown by comparison with SmI_2 in its reactions in hexamethylphosphoramide (HMPA) and pyridine. Addition of 4 equiv. of HMPA to green $TmI_2(DME)_3$ in dimethoxyethane (DME) forms pale yellow solids which dissolve in pyridine and can be isolated as $TmI_3(HMPA)_4$, **1**. Recrystallization of **1** from pyridine yields $\{[TmI_2(HMPA)_4][I](pyridine)_5\}$, **2**, or $\{[TmI(HMPA)_4(pyridine)][I]_2\}$, **3**, depending upon conditions. Both **2** and **3** crystallize with distorted octahedral geometries around thulium. Addition of HMPA to TmI_3 in DME also forms **1**. $TmI_2(DME)_2$, formed by the loss of DME from $TmI_2(DME)_3$ under vacuum, reacts with pyridine to form intensely colored materials, which have magnetic moments consistent with the presence of Tm(III). In comparison, $SmI_2(THF)_2$ dissolves in a mixture of pyridine and DME and can be recrystallized as divalent $SmI_2(DME)_3$, **4**. **4** crystallizes with both linear and bent I-Sm-I arrangements in the same crystal. In the former case a hexagonal bipyramidal coordination geometry is present and in the latter a dodecahedral geometry is observed. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: thulium; samarium; iodide; divalent; trivalent.

Divalent lanthanide chemistry traditionally has been limited to the three elements, Eu, Yb, and Sm, which have the most accessible +2 oxidation states [1]. Samarium is the most strongly reducing of these metals and $SmI_2(THF)_x$ is widely used in organic chemistry as a one-electron reducing agent [2]. However, recently the synthesis and X-ray crystal structure of the first molecular complex of Tm(II), $TmI_2(DME)_3$ (DME=$MeOCH_2CH_2OMe$) was reported [3]. The Tm(III)/Tm(II) reduction potential, cited in the literature as −2.3 V vs. NHE [4], suggests that $TmI_2(DME)_3$ should be highly reactive. We report here some comparisons of the behavior of thulium diiodide and samarium diiodide in strongly coordinating polar solvents commonly used with the samarium reagent. The isolation of two different forms of cationic solvated trivalent thulium iodide complexes is reported as well as a single crystal of $SmI_2(DME)_3$ containing both linear and bent I-Sm-I units.

EXPERIMENTAL

General procedures

The chemistry described below was performed under nitrogen with rigorous exclusion of air and

* Author to whom correspondence should be addressed..

water using standard Schlenk, vacuum line and glove box techniques. $TmI_2(DME)_2$ was prepared from TmI_3 and Tm metal following the procedure for the preparation of $TmI_2(DME)_3$ [5]. Removal of solvent from the initially obtained solution of $TmI_2(DME)_3$ without subsequent recrystallization gives $TmI_2(DME)_2$. (Anal. Calcd. for $C_8H_{20}O_4I_2Tm$: C, 15.8; H, 3.3; O, 11.6, I, 41.6, Tm, 27.7. Found: C, 15.00; H, 3.21; I, 39.75; Tm, 26.85.) $SmI_2(THF)_2$ was prepared as described previously [5]. Dimethoxyethane (Acros) was pre-dried over molecular sieves and distilled from NaK before use. Pyridine and hexamethylphosphoramide (Acros) were dried over molecular sieves, distilled, and degassed before use. NMR spectrometry and magnetic susceptibility measurements were recorded on either General Electric GN500 or QE300 or Bruker DRX400 spectrometers following the Evans' method [6]. Infrared spectra were obtained on a Perkin Elmer 1600 FTIR. Elemental analyses were done by Analytische Laboratorien, D-51779 Lindlar, Germany, or by complexometric titration [7].

Synthesis and spectroscopic characterization

Reactions of $TmI_2(DME)_2$ with HMPA. In a glove box, addition of HMPA (0.95 g, 5.31 mmol) to a green DME solution of $TmI_2(DME)_2$ (0.80 g, 1.33 mmol) caused immediate formation of a deep brown solution. Within 2 h, the color faded to pale yellow with the formation of a pale yellow precipitate which was separated by centrifugation. The pale yellow precipitate was dissolved in pyridine to form a clear, pale yellow solution. Evaporation of the solvent by rotary evaporation gave pale yellow $TmI_3(HMPA)_4$, **1** (1.073 g, 60% based on $TmI_2(DME)_2$). IR (KBr): 2916s, 2815s, 1752w, 1484s, 1451s, 1307s, 1191s, 1124s, 1067s, 990s, 797w, 756s, 711w, 649w, 478s cm^{-1}. Anal. Calcd for $C_{24}H_{72}I_3N_{12}O_4P_4Tm$: C, 22.76; H, 5.73; I, 30.06; N, 13.27; P, 9.78; Tm, 13.34. Found: C, 23.01; H, 5.70; I, 30.30; N, 13.25; P, 9.64; Tm, 13.60. Magnetic susceptibility (293 K, pyridine) $\chi_M = 2.42 \times 10^{-2}$; $\mu_{eff} = 7.5\ \mu_B$. Recrystallization of **1** in pyridine at $-38^\circ C$ yielded pale yellow crystals of $\{[TmI_2(HMPA)_4][I](pyridine)_5\}$, **2**.

The reaction of $TmI_2(DME)_2$ (0.200 g, 0.332 mmol) with a smaller amount of HMPA (0.119 g, 0.664 mmol) in DME immediately formed a brown solution whose color faded slowly over 12 hours to green with the formation of a pale yellow precipitate. The pale yellow precipitate was separated by centrifugation, dissolved in pyridine, and dried by rotary evaporation to pale yellow **1** (0.175 g, 0.138 mmol, 40%). Recrystallization at $-38^\circ C$ of these pale yellow solids in pyridine yielded crystals of $\{[TmI(HMPA)_4(pyridine)][I]_2\}$, **3**, in one case, and crystals of **2** when the procedure was repeated several times.

The reaction of $TmI_2(DME)_2$ (0.150 g, 0.249 mmol) with HMPA (0.268 g, 1.49 mmol) in DME and the reaction of $TmI_2(DME)_2$ (0.150 g, 0.249 mmol) with neat HMPA (5 mL) also gave pale yellow solids which dissolved in pyridine and could be recrystallized as $\{[TmI_2(HMPA)_4][I](pyridine)_5\}$, **2**.

Reactions of TmI_3 with HMPA In a glovebox, HMPA (0.098 g, 0.546 mmol; 0.196 g, 1.09 mmol; and 0.293 g, 1.64 mmol in three separate reactions) was added to grey TmI_3 (0.150 g, 0.273 mmol for each reaction) in DME and the mixture was stirred for 5 h. The pale yellow solution was separated by centrifugation from the precipitate and was dried by rotary evaporation to a yellow/brown oil containing excess HMPA (0.064 g, 0.102 g, or 0.164 g, respectively). The pale yellow precipitate was dissolved in pyridine to form a clear, pale yellow solution which was dried by rotary evaporation to a pale yellow solid, **1**, (0.134 g, 0.106 mmol, 40%; 0.230 g, 0.182 mmol, 65%; or 0.250 g, 0.197 mmol, 70% respectively). Recrystallization of **1** in each case yielded $\{[TmI_2(HMPA)_4][I](pyridine)_5\}$, **2**, by unit cell determination.

Reactions of $TmI_2(DME)_2$ with pyridine. In a glovebox, pyridine (0.197 g, 2.488 mmol) was added to a green solution of $TmI_2(DME)_2$ (0.300 g, 0.498 mmol) in DME (10 mL) at ambient temperature producing a deep green brown solution instantly. After stirring for 4–5 hours, a red/purple precipitate and a pale orange solution were present. The precipitate was separated from the solution by centrifugation. The pale orange solution was dried on a rotary evaporator to an oily dark orange solid (0.141 g), which darkened overnight to a deep blue color. IR (KBr): 3025m, 2919s, 1631w, 1596s, 1525w, 1484w, 1437s, 1261w, 1214w, 1091m, 1038s, 1002w, 854w, 802m, 750m, 697s, 626m cm^{-1}. Metal content: Tm, 23.9%. Magnetic susceptibility (293 K, pyridine) $\chi_M = 2.29 \times 10^{-2}$; $\mu_{eff} = 7.3\ \mu_B$. The red/purple precipitate was dried on a rotary evaporator (0.164 g). IR (KBr): 3031w, 2938m, 1547m, 1577w, 1458m, 1370w, 1280m, 1213w, 1190w, 1086m, 1028s, 975w, 860s, 747m, 631w cm^{-1}. Metal content: Tm, 24.5%. Magnetic susceptibility (293 K, pyridine) $\chi_M = 2.07 \times 10^{-2}$; $\mu_{eff} = 7.0\ \mu_B$.

$TmI_2(DME)_2$ (0.300 g, 0.498 mmol) was dissolved in pyridine (approximately 10 mL) instantly producing a very dark blue solution. The intense blue solution was stirred overnight and dried on a rotary evaporator yielding a thick oily, black solid (0.345 g). IR (KBr): 3049m, 2928s, 1601s, 1488m, 1441s, 1220m, 1149w, 1098w, 1067m, 1039s, 1006s, 963s, 808w, 755m, 700s, 624m cm^{-1}. Metal content: Tm, 22.7%. Magnetic susceptibility (293 K, pyridine) $\chi_M = 2.12 \times 10^{-2}$; $\mu_{eff} = 7.1\ \mu_B$.

Reactions of $SmI_2(THF)_2$ with pyridine. In a glovebox, pyridine (0.144 g, 1.823 mmol) was added to a mixture of deep blue $SmI_2(THF)_2$ (0.200 g, 0.365 mmol) in DME (approximately 10 mL) at ambient temperature. The solution immediately turned black and was stirred for 4–5 hours. The dark purple solids remaining after this time were separated from the solution by centrifugation and were extracted

three times with 10 mL of DME. The combined DME solutions were dried on a rotary evaporator yielding deep purple/black solids (0.212 g). ^{1}H NMR (THF-d_8): 7.90 (br. s, 2H), 6.96 (t, 1H), 6.54 (d, 2H), 3.42 (s, 10H), 3.25 (s, 14H) d. IR (KBr): 2931s, 1640w, 1461s, 1367w, 1284w, 1261w, 1190w, 1120m, 1091m, 1026s, 850s, 803m, 756w, 697w cm^{-1}. Metal Content: Sm, 21.3%. Magnetic susceptibility (293 K, THF) $\chi_M = 3.64 \times 10^{-3}$; $\mu_{eff} = 2.9\,\mu_B$. Recrystallization of the purple/black solids in DME at -38°C yielded red/purple crystals of $SmI_2(DME)_3$, **4**.

X-ray structure determinations

$\{[TmI_2(HMPA)_4][I](pyridine)_5\}$, ***2***. A pale yellow crystal of approximate dimensions $0.13 \times 0.16 \times 0.24$ mm was immersed in Paratone-D oil under nitrogen and then manipulated in air onto a glass fiber and transferred to the nitrogen stream of a Syntex P4 diffractometer. The determination of Laue symmetry, crystal class, unit cell parameters and the crystal's orientation matrix were carried out according to standard procedures [8]. Intensity data were collected at 163 K using a $2\theta/\omega$ scan technique with Mo Kα radiation.

The raw data were processed with a local version of CARESS [9] which employs a modified version of the Lehman-Larsen algorithm to obtain intensities and standard deviations from the measured 96-step peak profiles. Subsequent calculations were carried out using the SHELXTL program [10]. All 1745 data were corrected for absorption and for Lorentz and polarization effects and were placed on an approximately absolute scale. The diffraction symmetry was 4/m with the systematic extinction *hkl* for $h+k+l=2n+1$. It was later determined that the noncentrosymmetric tetragonal space group $I\bar{4}[S_4^2;\text{No.82}]$ was correct.

The structure was solved by direct methods and refined on F^2 by full-matrix least-squares techniques. The analytical scattering factors for neutral atoms were used throughout the analysis [11]. The molecule is located on a site of $\bar{4}$ symmetry. There are five molecules of pyridine present per formula unit. One pyridine molecule is in a general position and one is located on a $\bar{4}$ site. The pyridine located on the $\bar{4}$ site is disordered. Three atoms defined as carbon with SOF = 0.51388 were included to account for the disorder. Hydrogen atoms (except those on the disordered pyridine) were included using a riding model. At convergence, w$R2 = 0.0590$ and GOF = 1.058 for 175 variables refined against all 1736 unique data ($R1 = 0.0276$ for those 1539 data with $F > 4.0\sigma(F)$). The absolute structure was determined by refinement of the Flack parameter [12].

$\{[TmI(HMPA)_4(pyridine)][I]_2\}$, ***3***. A pale yellow crystal of approximate dimensions $0.10 \times 0.21 \times 0.23$ mm was handled at 158 K on a Syntex P4 diffractometer solved and as described for **2**. All 7030 data were corrected for absorption and for Lorentz and polarization effects and were placed on an approximately absolute scale. The diffraction symmetry was 2/m with the systematic extinction *hkl* for $h+k=2n+1$ and *h0l* for $l=2n+1$. The two possible monoclinic space groups are Cc and C2/c. It was later determined that the centrosymmetric space group C2/c was correct.

The structure was solved and refined as described for **2**. Atoms N(4), N(5), N(6), C(7), C(9), C(10, C(11), and C(12) are disordered. Each of these atoms was included with two components which were assigned site-occupancy-factors of 0.5. There appears to be a pyridine solvent molecule present which is disordered. It was not possible to model the disordered solvent and it was not included in the refinement or in the calculation of density, absorption coefficient, etc. Hydrogen atoms were not included in the refinement. At convergence, w$R2 = 0.1772$ and GOF = 1.115 for 190 variables refined against all 6757 unique data. (As a comparison for refinement on *F*, $R1 = 0.0572$ for those 5298 data with $F > 4.0\sigma(F)$)

$SmI_2(DME)_3$, ***4***. A red/purple crystal of approximate dimensions $0.10 \times 0.20 \times 0.23$ mm was handled at 163 K on a Siemens P4 rotating-anode diffractometer, solved, and refined as described for **2**. All 5059 data were corrected for absorption and for Lorentz and polarization effects and were placed on an approximately absolute scale. The diffraction symmetry was 2/m with systematic absences *hkl* for $h+k=2n+1$ and *h0l* for $l=2n+1$. The two possible monoclinic space groups are Cc and C2/c. It was determined that the centrosymmetric space group C2/c was correct.

There are two independent molecules of the formula unit present. One molecule is located on a two-fold rotation axis while the other is located on an inversion center ($Z=8$). Molecule 1 has a SmI_2 unit which is bent (I-Sm-I = 157.65(2)$^\circ$), while the SmI_2 unit in molecule 2 is linear due to the crystallographic inversion center. There is no indication that the SmI_2 unit in molecule 2 is disordered which might result in the observed linear arrangement. The dimethoxyethane ligands on molecule 2 are disordered. All twelve carbon atoms associated with this molecule were included with site-occupancy-factors = 0.50. The three unique oxygen atoms were assigned occupancy factors of 1.0. Hydrogen atoms were included using a riding model. At convergence, w$R2 = 0.0698$ and GOF = 1.055 for 246 variables refined against all 4950 unique data. (As a comparison for refinement on *F*, $R1 = 0.0309$ for those 3915 data with $F > 4.0\sigma(F)$.)

Further evidence for this linear SmI_2 arrangement is that the same pattern is observed when the structure is refined in the noncentrosymmetric space group Cc. In the space group Cc there are three independent molecules ($Z=8$). Two of the molecules are located on two-fold rotation axes while the third is in a general position. The I-Sm-I angles of the molecules on the two-fold axes are 157.50(12)$^\circ$ and 157.82(13)$^\circ$. The I-

Sm-I angle for the molecule in the general position is 179.86(8)°. There is no disorder observed, however, the light atoms could not be refined anisotropically. It is concluded that the SmI_2 units adopt different (bent and linear) arrangements and that refinement of the structure in the centrosymmetric space group C2/c is preferred.

RESULTS

Hexamethylphosphoramide (HMPA) reactions

HMPA is a strongly coordinating ligand which displaces THF from blue $SmI_2(THF)_x$ to form divalent black-purple $SmI_2(HMPA)_4$ and displaces the iodide ligands in yellow $YbI_2(THF)_x$ to form dark yellow $[Yb(HMPA)_4(THF)_2]I_2$ [13]. Similar behavior was investigated with $TmI_2(DME)_3$ and its bis(dimethoxyethane) derivative $TmI_2(DME)_2$, which is isolated when solutions of $TmI_2(DME)_3$ are dried on a rotary evaporator.

The intense green color of $TmI_2(DME)_3$ in DME immediately changes to brown upon addition of HMPA. This color fades within 2 to 12 hours to a pale yellow color characteristic of Tm(III) and the precipitation of pale yellow $TmI_3(HMPA)_4$, **1**, is observed. Complex **1** can also be obtained from the reaction of TmI_3 with HMPA in DME. Although insoluble in DME and HMPA, **1** dissolves in pyridine to form a pale yellow solution from which crystals of $\{[TmI_2(HMPA)_4][I](pyridine)_5\}$, **2** (Figure 1), or $\{[TmI(HMPA)_4(pyridine)][I]_2\}$, **3** (Figure 2), can be obtained. Even though crystals of **2** and **3** readily desolvate, structural data were obtainable on each. **2** can also be obtained from the reaction of TmI_3 with HMPA in pyridine.

The isolation of the two different forms of solvated thulium iodides **2** and **3** is consistent with previously studied HMPA/lanthanide chemistry. For example, both $YbCl_3(HMPA)_4$ and $\{[Yb(H_2O)_5(HMPA)_2]Cl_3(H_2O)(HMPA)\}$ can be isolated from reactions of $YbCl_3$ with HMPA in THF depending on crystallization conditions [13]. As a strongly solvating ligand, it is also not uncommon for HMPA to displace anionic ligands from the coordination sphere of the metal. Examples include $[Yb(HMPA)_4(THF)_2][I]_2$ [14], $[\{Yb(HMPA)_3\}_2(\mu\text{-}SPh)_3][SPh]$ [15], and $\{[Yb(H_2O)_5(HMPA)_2]Cl_3(H_2O)(HMPA)\}$ [13].

In both **2** and **3**, the geometry around thulium is distorted octahedral. In **2**, the two iodide ligands are trans and in **3**, the iodide is trans to pyridine. The Tm-I distances in **2** and **3** are 3.0452(6) and 3.0057(14) Å, and, as expected, are shorter than the Tm-I average distances (3.16(2) Å) in divalent $TmI_2(DME)_3$ [3]. The difference is consistent with the difference in effective ionic radii of six coordinate Tm(III) (0.88 Å) and seven coordinate Tm(II) (1.09 Å) [17]. The Tm-I distances in **2** and **3** are also consistent with other trivalent lanthanide iodide and thulium chloride distances in the literature after the appropriate differences in radii are considered [17–19]. Hence, no significant elongation of the Tm-I bonds is observed in

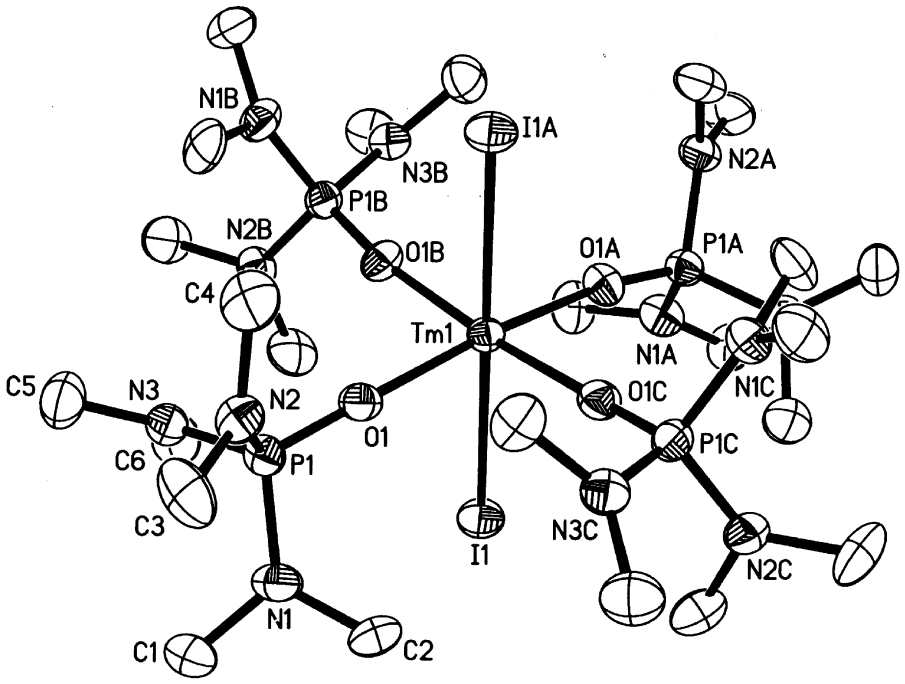

Fig. 1. Thermal ellipsoid plot of $\{[TmI_2(HMPA)_4][I](pyridine)_5\}$, **2**, drawn at the 50% probability level with pyridine omitted for clarity.

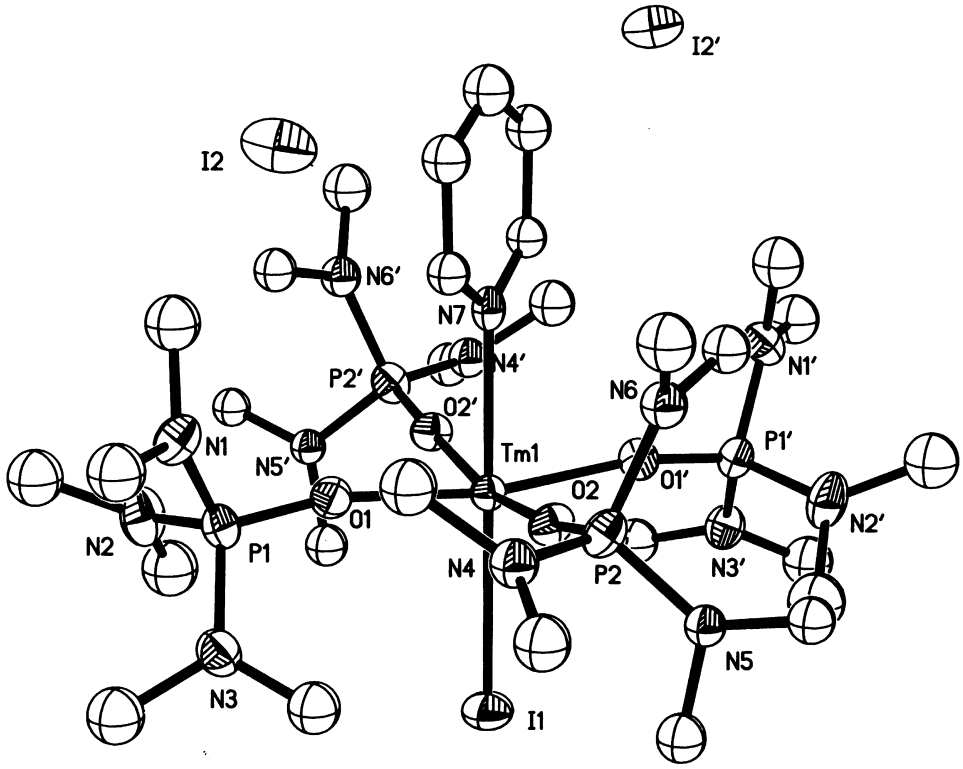

Fig. 2. Thermal ellipsoid plot of $\{[TmI(HMPA)_4(pyridine)][I]_2\}$, **3**, drawn at the 50% probability level.

the presence of the strongly coordinating HMPA [13, 14], as was observed in divalent $SmI_2(HMPA)_4$ [13].

The Tm(III)-O(HMPA) distances vary between 2.189(4) Å and 2.208(5) Å in **2** and **3**. These are significantly shorter than the 2.353(3) and 2.315(3) Å Tm(III)-O(THF) distances of in trivalent $(C_8H_8)Tm[PhC(NSiMe_3)_2](THF)$ [20] and $Tm[P(SiMe_3)_2]_3(THF)_2$ [21] respectively. The short Tm(III)-O(HMPA) distances are consistent with the analogous distances in $DyCl_3(HMPA)_3$ [22].

Pyridine reactions

The addition of pyridine to DME solutions of $TmI_2(DME)_3$ produces intensely colored compounds: a red/purple precipitate and a solution which yielded a deep blue oil. Addition of $TmI_2(DME)_2$ to pure pyridine generated a black oil. Although these intense colors are often characteristic of divalent lanthanides, in this case magnetic moments of these materials were found to be 7.0–7.1 μ_B and are consistent with the presence of Tm(III) [23].

In contrast, addition of pyridine to $SmI_2(THF)_2$ in DME gives divalent products. Deep blue/purple solids can be isolated which have a magnetic moment of 2.9 μ_B consistent with Sm(II) [23]. Recrystallization of this material in DME yields red/purple crystals of $SmI_2(DME)_3$, **4**, which have not incorporated any of the pyridine.

Complex **4** crystallizes with two different eight coordinate molecular geometries (Figs 3 and 4) and two very different I-Sm-I angles within the same unit cell. In each of the independent molecules in the unit cell, the samarium center is surrounded by two iodide and three chelating DME ligands, but the arrangements of the ligands differ. In the asymmetric molecule **4A**, the I-Sm-I angle is bent, 157.65(2)°, and the eight ligands form a distorted dodecahedron, Fig. 5. In the symmetric molecule **4B**, the I-Sm-I angle is linear at 180°, and a distorted hexagonal bipyramidal coordination environment surrounds samarium, Fig. 6. Although, in previously characterized SmI_2 complexes an extensive range of I-Sm-I angles have been observed, in no case have both bent and linear I-Sm-I units been found in the same crystal. Previously reported I-Sm-I angles include: 87.75(1)–173.04(2)° for $[SmI_2(NCCMe_3)_2]_n$ [24], 92.0(1)° for cis-$SmI_2[(O(CH_2CH_2OMe)_2]_2$ [25], 84.0(1)–175.7(1)° for $[Sm(\mu\text{-}I)(N\text{-}MeIm)_3]_2$ [26], 178.1(1)° for $SmI_2(DME)_2(THF)$ [27] and $SmI_2(DME)(THF)_3$ [27], and 180.0° for the complexes trans-$SmI_2[(O(CH_2CH_2OMe)_2]_2$ [24] and $[SmI_2(OPMePh_2)_4]I$ [28].

The Sm-I distances in **4** are similar: 3.2897(4) Å for the linear I-Sm-I molecule and 3.3091(5) Å for the bent compound. These distances are also similar to the analogous lengths in eight coordinate cis- and trans-$SmI_2[(O(CH_2CH_2OMe)_2]_2$, 3.333(1) [25] and 3.265(1) Å [24], respectively, except that the difference

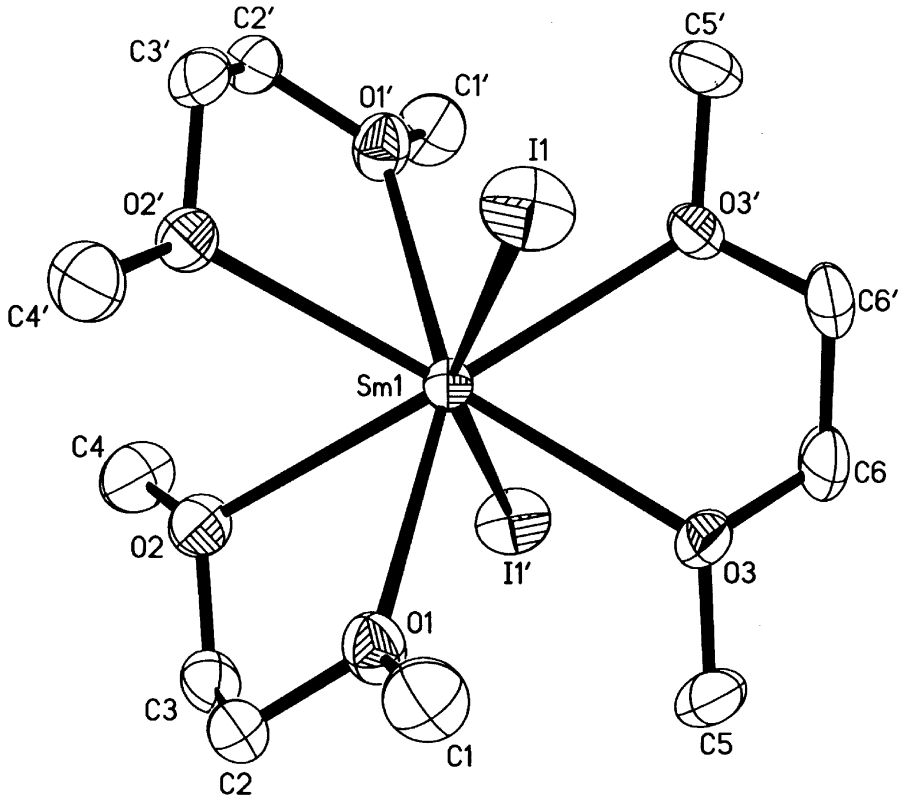

Fig. 3. Thermal ellipsoid plot of the bent I-Sm-I molecule of $SmI_2(DME)_3$, **4A**, drawn at the 50% probability level.

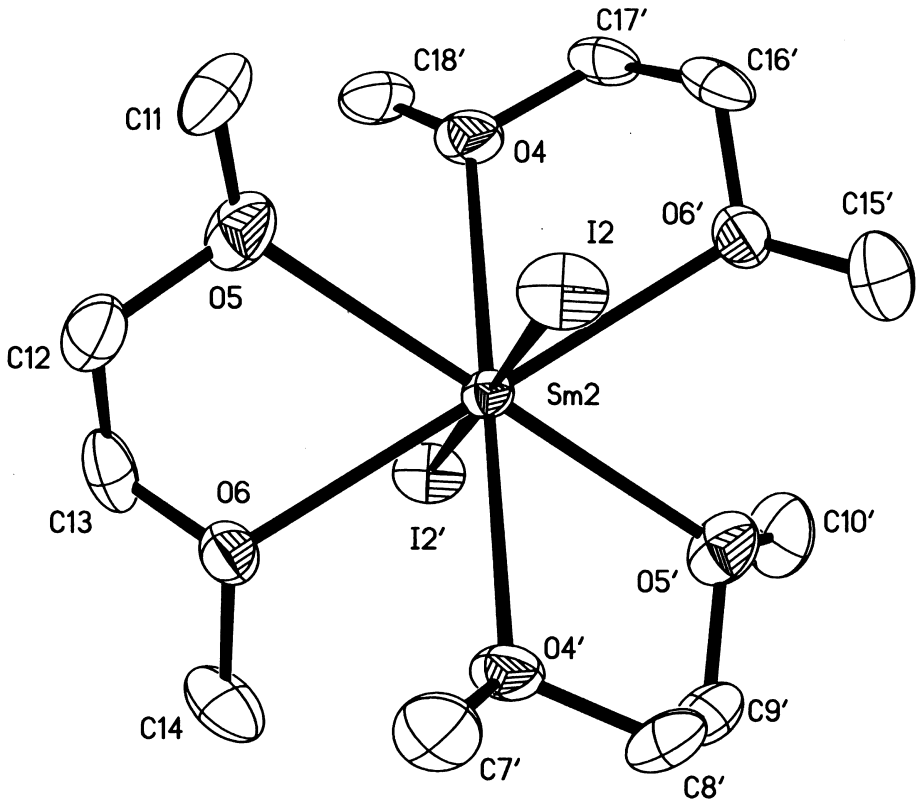

Fig. 4. Thermal ellipsoid plot of the linear I-Sm-I molecule of $SmI_2(DME)_3$, **4B**, drawn at the 50% probability level.

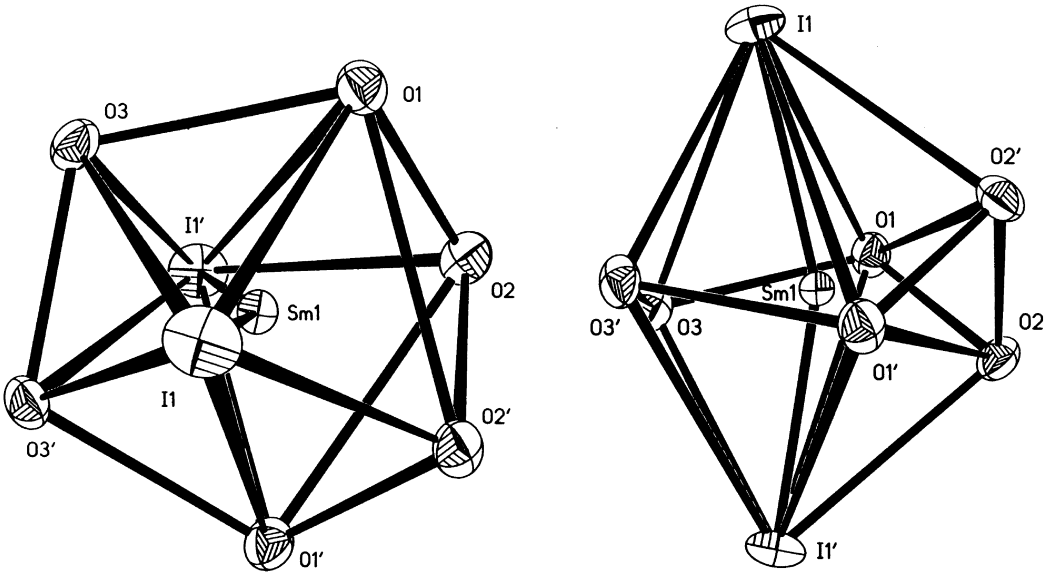

Fig. 5. Top and side views of the distorted dodecahedron of donor atoms surrounding samarium in the bent I-Sm-I form of $SmI_2(DME)_3$, **4A**.

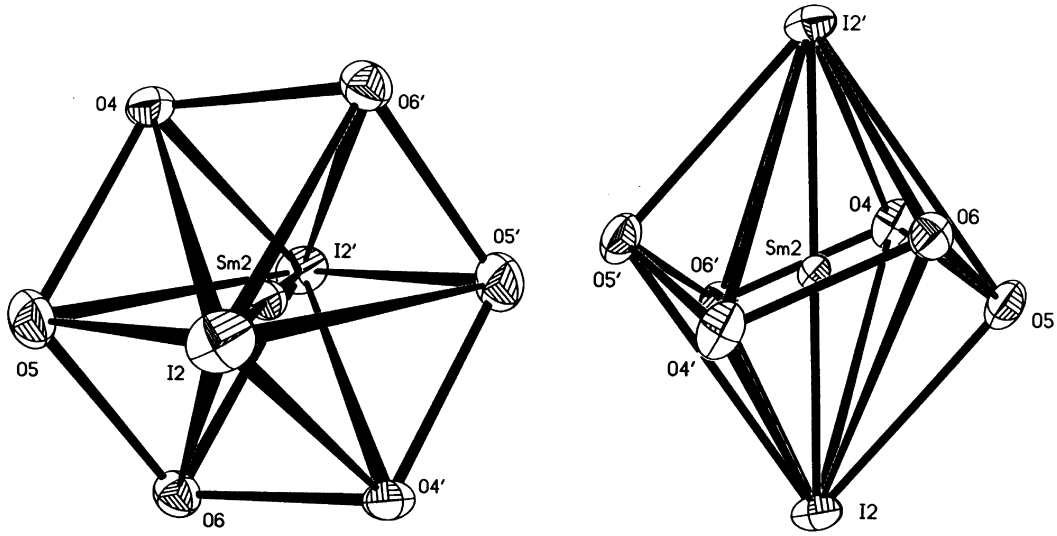

Fig. 6. Top and side views of the distorted hexagonal bipyramid of donor atoms surrounding samarium in the linear I-Sm-I form of $SmI_2(DME)_3$, **4B**.

between cis and trans is smaller in **4**. The Sm-I distances of **4** are longer than the distances found in the seven coordinate complexes $SmI_2(DME)_2(THF)$ [27] (3.246(1) Å) and $SmI_2(DME)(THF)_3$ [27] (3.231(1) and 3.235(1) Å) as expected for a higher coordinate structure. However, the six coordinate $SmI_2(HMPA)_4$ [13] complex has longer Sm-I bonds of length 3.390(2) Å.

The average Sm-O distance of 2.68(3) Å in **4** is not significantly longer than the average Sm-O(DME) distances of 2.62(2) and 2.641(5) Å in the seven coordinate complexes $SmI_2(DME)_2(THF)$ [27] and $SmI_2(DME)(THF)_3$ [27] respectively. Nor does this value differ from the Sm-O(diglyme) distances of 2.68(2) and 2.70(2) Å in the eight coordinate complexes cis- and trans-$SmI_2[(O(CH_2CH_2OMe)_2]_2$ [24, 25], respectively.

DISCUSSION

The strong reduction potential of Tm(II) is evident when thulium diiodide is placed in HMPA and compared to samarium diiodide. The strongly solvating

HMPA can be added to SmI_2 to increase the reduction potential of this reagent and make the divalent samarium ion a more potent reducing agent for added substrates [29]. In contrast, the intense green color characteristic of $TmI_2(DME)_3$ is immediately discharged upon the addition of HMPA and Tm(III) products form without an added substrate. Isolation of the trivalent complex $TmI_3(HMPA)_4$, **1**, indicates that ligand redistribution occurs in addition to the redox chemistry. These results are consistent with the large reduction potential expected for Tm(II) and indicate that the coordination environment of this ion

Symmetry transformations used to generate equivalent atoms: a) $-x,y,-z+1/2$; b) $-x-1/2,-y+1/2,-z$

needs to be adjusted to *lower* its reduction potential if it is to be a viable one electron reagent.

Addition of pyridine to divalent $TmI_2(DME)_3$ also demonstrates the strong reducing power of Tm(II) when compared to samarium. Trivalent thulium products are produced upon the addition of pyridine to $TmI_2(DME)_3$, whereas divalent Sm(II) can be recovered from solutions of $SmI_2(THF)_x$ and pyridine in DME. Remarkably in the case of samarium, the crystalline form isolated from DME is pyridine free: $SmI_2(DME)_3$, **4**. Complex **4** has another interesting feature: both cis and trans arrangements of the I-Sm-I unit are observed in the same crystal. Although SmI_2 has previously been found to form cis- and trans-isomers of eight coordinate $SmI_2[(O(CH_2CH_2OMe)_2]_2$ [24, 25], these were obtained from different systems of crystallization. The isolation of two different structures in the same crystal under the same conditions shows that the two structural types are very close in energy. Previously, this phenomenon had been observed in $[Cr(NH_2CH_2CH_2NH_2)_3][Ni(CN)_5]$ $(1.5H_2O)$, which contains both trigonal bipyramidal and square pyramidal geometries in the same crystal [30]. The formation of two different eight coordinate geometries in the same crystal is consistent with the similarity of the energies of eight coordinate geometries [31]. However, it has not been established that linear and bent ligand-lanthanide-ligand geometries are so similar in energy. This is an area of considerable theoretical interest [32–36].

CONCLUSION

The formation of Tm(III) products directly upon addition of HMPA or pyridine to $TmI_2(DME)_3$ emphasizes how much more reducing thulium diiodide is compared to $SmI_2(THF)_2$ which remains divalent in the presence of these strong donor ligands. These results show that the strong reduction potential of Tm(II) needs to be moderated with donor ligands to allow substrate reductions to be carried out.

Abstract—Complexes formed between D-glucoheptonate, D-galactonate, D-gulonate and D-ribonate, and several metal ions were obtained in the solid state. Specifically: D-glucoheptonates, $Be(C_7H_{13}O_8)_2 \cdot 1/2H_2O$, $Mn(C_7H_{13}O_8)_2 \cdot 2H_2O$, $Co(C_7H_{13}O_8)_2 \cdot 2H_2O$, $Ni(C_7H_{13}O_8)_2 \cdot 2H_2O$, $Cu(C_7H_{13}O_8)_2 \cdot 2H_2O$, $Pb(C_7H_{13}O_8)_2$; D-galactonates, $Mn(C_6H_{11}O_7)_2 \cdot 2H_2O$, $Co(C_6H_{11}O_7)_2 \cdot 3H_2O$, $Ni(C_6H_{11}O_7)_2 \cdot 3H_2O$, $Cu(C_6H_{11}O_7)_2$, $Pb(C_6H_{11}O_7)_2$; D-gulonates, $Co(C_6H_{11}O_7)_2 \cdot H_2O$, $Ni(C_6H_{11}O_7)_2 \cdot 2H_2O$, $Cu(C_6H_{11}O_7)_2 \cdot 2H_2O$; D-ribonates, $Mn(C_5H_9O_6)_2$, $Co(C_5H_9O_6)_2 \cdot 2H_2O$, $Ni(C_5H_9O_6)_2 \cdot 2H_2O$, $Cu(C_5H_9O_6)_2.2H_2O$ and $Pb(C_5H_9O_6)_2$ have been isolated. These metal sugar salts were characterized by elemental analysis, thermogravimetric analysis, magnetic susceptibility measurements, FT–IR, diffuse reflectance and EPR spectroscopies. © 1998 Elsevier Science Ltd. Keywords: D-aldonic acids; metal sugar complexes; divalent metal ions.

INTRODUCTION

Solid complexes formed between the metal ions beryllium (II), manganese (II), cobalt (II), nickel (II), copper (II) and lead (II), and ligands of biological interest, such as D-glucoheptonic acid (I), D-galactonic acid (II), D-gulonic acid (III) and D-ribonic acid (IV) (Fig. 1), were isolated. This work is part of our program on the coordination chemistry of sugar acids [1–8]. In previous papers, studies were carried out on equilibrium reactions in aqueous solution and in the solid state for metal complexes of both D-gluconolactone and D-lactobionic acid [1, 2]. The importance of studying the interaction between carbohydrates and transition metal ions is related to the use of this type of ligands as sequestering agents for metal ions present in biological media [9, 10]. The present work complements previous information afforded with metal ions cobalt (II), nickel (II) and copper (II), and the ligands I, II, III and IV in solution studies [2, 4, 8]. Interactions of the above-mentioned D-aldonic acids with beryllium (II), manganese (II) and lead (II) are given as additional information.

The studies in the solid state were performed by elemental, thermogravimetric and susceptibility analyses, and by FT–IR, diffuse reflectance and EPR spectroscopies.

These studies represent a contribution to future crystallographic analyses, which are complicated by the difficulties in obtaining X-ray quality crystals of complexes containing carbohydrates with non-blocked hydroxyl groups.

EXPERIMENTAL

Reagents

D-glucoheptono-γ-lactone, D-galactono-γ-lactone, D-gulono-γ-lactone and D-ribono-γ-lactone were purchased from Sigma. Their purities were checked by elemental analysis, chromatography and potentiometric titrations. The metal carbonates or oxides used were: $Co(CO_3)\cdot xH_2O$ (Aldrich), $2NiCO_3\cdot 3Ni(OH)_2\cdot 4H_2O$ (Aldrich), $CuCO_3\cdot Cu(OH)_2$ (Aldrich), $MnCO_3$ (BDH), $BeCO_3\cdot 5H_2O$ (BDH) and $PbCO_3$ (Aldrich).

Synthesis of complexes in the solid state

The complexes were prepared following the procedures described previously [11]. Briefly, the metal ion was added to a previously refluxed (1 h) solution of the lactone, in order to promote the opening of the sugar ring affording the aldonic acid. This mixture was boiled for 2 hrs. The metal–lactone ratio was 1:2. Ethanol was added to the clear solution and a solid phase was obtained. The precipitate was separated by filtration and recrystallized four times from a mixture of ethanol–water (4:1). Finally, the product was washed with ethanol, dried under vacuum over phosphorus pentoxide at room temperature and again dried for 2 hrs. at 80°C under vacuum over phosphorus pentoxide.

The purity of the obtained complexes was checked by elemental analysis.

Analysis of the solid complexes

Microanalyses of C and H were performed using a Fisons 1108 CHNS microanalyser. The nickel (II) percentages in its complexes was determined by complexometric titration with EDTA and zinc nitrate solutions employing eriochrome black T as an indicator [12]. The content of beryllium was calculated from the thermogravimetrical residue. The metal percentage in the other complexes were determined by atomic absorption using a Metrolab 250 AA atomic absorption spectrophotometer. Thermogravimetric curves were obtained in an atmosphere of pure air using a Shimadzu TGA-50 H, with a heating speed of $20^{\circ}C\,min^{-1}$, equipped with a Nicolet model 550 IR gas analyzer and Fisons model Thermolab mass detector. DSC data were obtained on a Shimadzu DSC-50 differential scanning calorimeter, using a heating speed of $10^{\circ}C\,min^{-1}$. The diffuse reflectance spectra were obtained with a Cary-5E refractometer provided with a praying mantis module. IR spectra were performed on a FT–IR Nicolet 20 SX8 spectrophotometer. Susceptibility magnetic measurements were carried out on Manics DSM-8 instrument in the 80–290 K temperature range. X-band ($\sim$9.2 GHz) EPR spectra were recorded as the first derivative of absorption at 77 and 298 K, on a Bruker ESP 300E EPR spectrometer with 100 kHz field modulation. The microwave frequency was generated with a Bruker 04 ER and measured with a Racal–Dana frequencymeter. The magnetic field was measured with a Bruker NMR-probe gaussmeter.

RESULTS AND DISCUSSION

Elemental Analysis

The analytical results for the synthesized complexes are reported in Table 1. All the complexes present a 1:2 metal–ligand ratio and were obtained either in

Table 1. Analytical data and colors for D-aldonic complexes

anhydrous or solvated form. It was not possible to prepare pure Be(II) D-ribonate because it was contaminated with the starting material ($BeCO_3$). This fact would be due to low acidity of the ribonic acid which makes it less reactive towards the carbonate.

Thermogravimetric curves

As was already reported [1, 2, 6], the thermogravimetric curves of this type of complexes present two steps: dehydration (between 100–200°C) and pyrolytic processes (above 200°C). Figure 2 shows two typical thermal decompositions for both hydrated and anhydrous complexes, respectively. Thermoanalytical data are in good agreement with the elemental analysis. The temperature of water loss and the sharp peak on the DSC diagram may indicate that these molecules are coordinated to the metal. The pyrolitic process took place in two, three or four steps. The pyrolitic products identified by IR spectra were: water, carbon monoxide and carbon dioxide. The pyrolitic residues at 400–800°C were determined to be oxides or mixture of carbonates and oxides of the corresponding metal ion. Thermoanalytical data are given in supplementary material.

Reflectance spectra

As an example, Fig. 3 shows reflectance spectra for different complexes of cobalt (II), copper (II) and nickel (II). The bands of the recorded spectra are shown in Table 2 (A and B). In this table both the calculated and experimental frequency ratios according to the DQ/B values are presented [14]. The band of the spectra of cobalt (II) complexes were these expected for the electronic transition of a d^7 metal ion in an octahedral arrangement [15](a)[16](b). The spectra of the nickel (II) complexes also show three absorption bands and the relationship between the first two bands (1.7) suggests octahedral geometries for these complexes [15](b)[16](a). In all cases, the second bands were found to split into two signals. This fact can be attributed either to interactions with the nearest electronic level ^1Eg or to spin–orbit coupling. The copper (II) complexes showed spectra with a single wide band with maxima in the range 799–

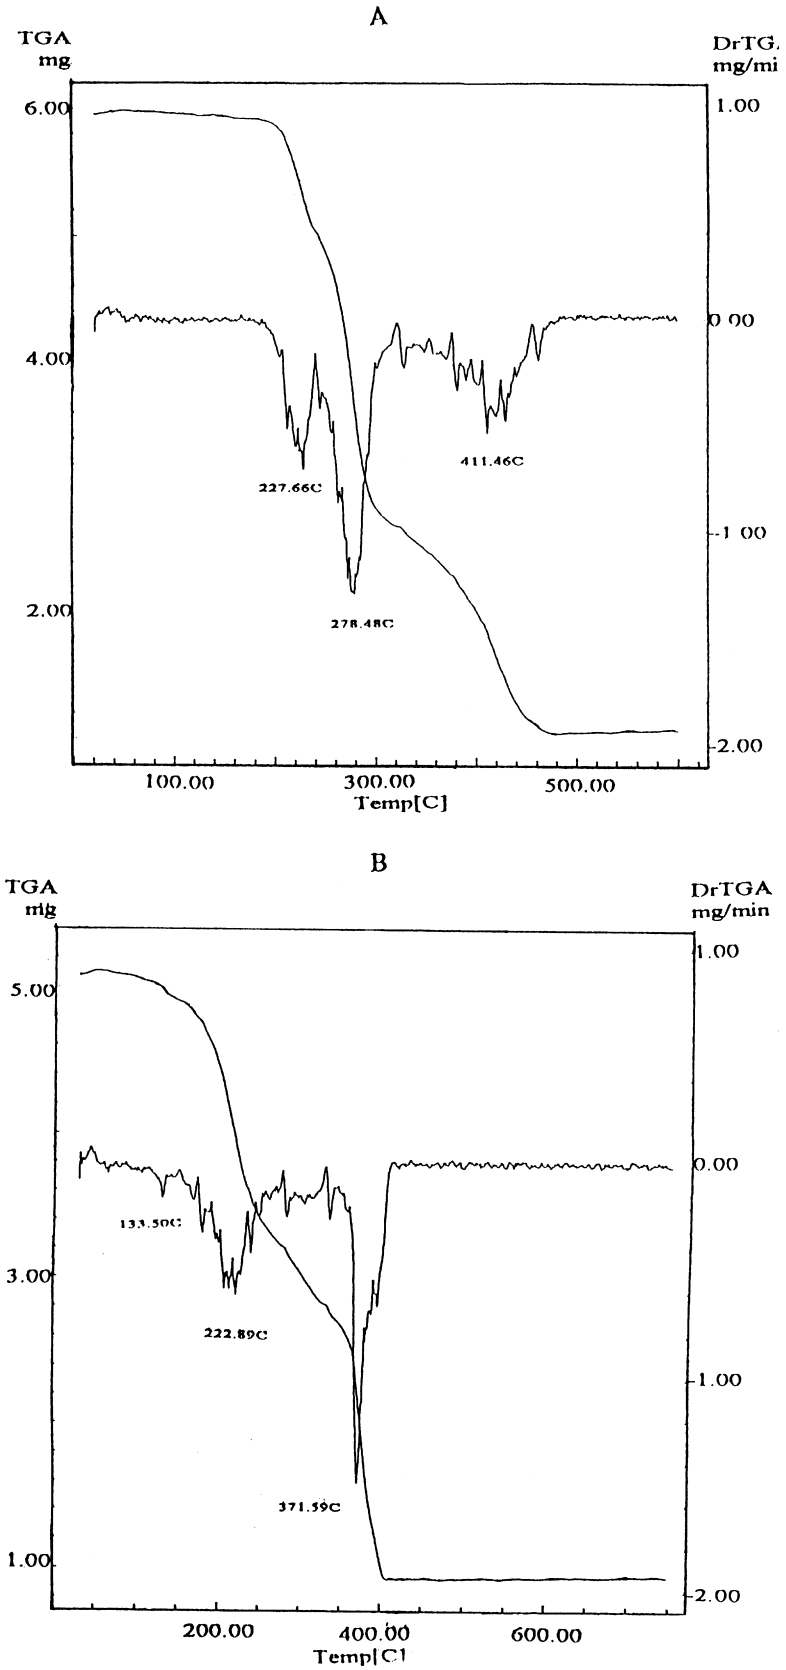

Fig. 2. Thermogravimetric curves for (a) Cu (II) D-galactonate (initial mass: 5.973 mg); (b) Co (II) D-gulonate (initial mass: 5.093 mg).

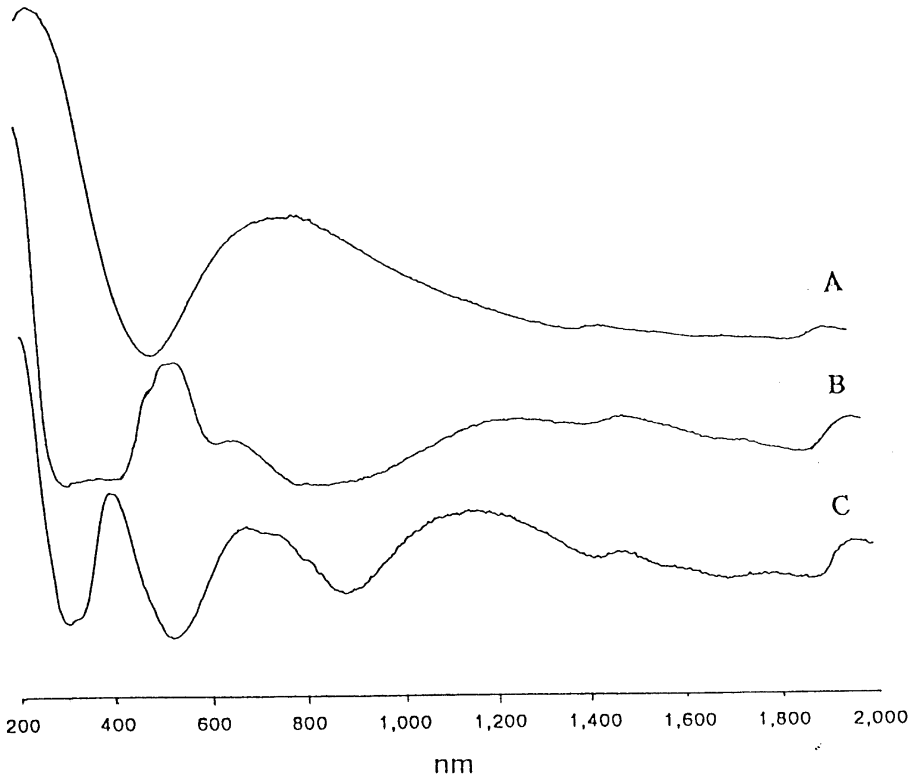

Fig. 3. Reflectance spectra for (a) Cu (II) D-gulonate; (b) Co (II) D-galactonate; (c) Ni (II) D-glucoheptonate.

814 nm. The frequencies of these maxima are coincident with the value of the crystal field splitting and correspond to the electronic transitions $^2T_2g \leftarrow ^2Eg$. According to these results tetragonal distortion of octahedral arrangements was proposed for these complexes [15](c)[16](c).

IR spectra

The IR spectra of the solid complexes were carried out between 4000–400 cm^{-1} and the interpretation was based on a comparison with both the corresponding sugar acids and structurally related compounds.

The wide bands at 3500–3100 cm^{-1} in the spectra of the free ligands were assigned to strongly hydrogen-bonded OH groups. The interaction between the hydroxyl groups of the aldonolactones and the metals produces broadening, but not shifting, of the sugar OH stretching vibrations. The carbonyl stretching bond in the spectra of the studied lactones appeared at 1700–1800 cm^{-1}. In the spectra of the complexes, this band disappeared and two new bands were detected at about 1600 and 1400 cm^{-1}. The latter were assigned to the antisymmetric and symmetric frequencies of stretching carboxyl groups, respectively [17]. The difference in frequency between these two bands allowed us to infer the coordination mode of the metal center towards the carboxylate groups. Most of the complexes under study showed values which were equal to, or higher than, 200 cm^{-1}, always related to a monodentate coordination [18]. Lead (II) D-glucoheptonate and cobalt (II), nickel (II) and copper (II) D-galactonate presented values in the range 160–200 cm^{-1}, which were in agreement with an additional hydrogen-bonded coordination between the carbonyl oxygen and protons of the carbonate chain [18]. Lead (II) D-ribonate complex spectrum showed a splitting of the signals corresponding to symmetric and antisymmetric stretching, suggesting that the metal ion is not located in a symmetric environment. In the spectral region of 1400–1100 cm^{-1}, shifting and broadening for the CH_2, OH and COH bending modes were observed in the presence of the metal ions, and were attributed to the metal–OH interaction in the complexation. Both the sugar C–O stretching vibrations (1100–940 cm^{-1}) and the deformation modes of the lactone ring skeletal (900–500 cm^{-1}) showed major changes upon metal ion chelation. Selected infrared absorption frequencies for complexes and aldonolactones are given in supplementary material.

( )According to Ref. [14].

Magnetic susceptibility measurements

Table 3 shows the magnetic data for the studied complexes. In all cases the Curie–Weiss law was verified: $\chi_M = C/(T-\theta)$, where χ_M is the corrected molar susceptibility, C is the Curie Constant, T is the absolute temperature and θ is the Weiss Constant. Copper (II) and nickel (II) D-galactonates, and manganese (II) D-glucoheptonate showed ferromagnetic interactions while the rest of the isolated compounds displayed an antiferromagnetic coupling. The values of the effective magnetic moment (μ_{eff}) for all the complexes studied suggest that the metal ions are in an octahedral high spin environment. The plots of χ_M *vs.* T (not shown) for both cobalt (II) and copper (II) D-ribonates present a significant deviation of the linearity at values lower than 170 and 150 K respectively.

EPR measurements

Cu(II) D-aldonic acids complexes. The polycrystalline samples exhibit rhombic EPR spectra with EPR parameters (g factors and hyperfine splitting constants A) summarized in Table 4. The spectra recorded at 77 K are very similar to those at room temperature, indicating no significant change in the coordination geometry (Fig. 4).

Table 3. Magnetic moments for complexes

Complex	Temperature (K)	θ (K)	μ_{eff} (BM)

Cu (II) D-glucoheptonate	85–290	−18.4	1.99
Mn (II) D-galactonate	140–290	−8.48	5.60
Co (II) D-galactonate	100–290	−10.31	5.14
Ni (II) D-galactonate	81–280	0.47	3.27
Cu (II) D-galactonate	90–290	2.18	1.75
Co (II) D-gulonate	99–290	−12.25	4.92
Ni (II) D-gulonate	90–290	−9.83	3.37
Cu (II) D-gulonate	130–290	−14.0	2.04
Mn (II) D-ribonate	101–290	−0.33	5.81
Co (II) D-ribonate	170–290	−11.9	5.22
Ni (II) D-ribonate	122–290	−4.98	3.34
Cu (II) D-ribonate	150–290	−24.58	1.95

Table 4. Room temperature (or 77 K) EPR parameters for copper (II) complexes

Compound	gz ($g_\parallel$)	$A_\parallel$ (G)	gx, gy ($g_\perp$)
Cu (II) D-gluconate	2.36	135	2.05, 2.02
Cu (II) D-lactobionate	2.34	143	2.05
Cu (II) D-gulonate	2.34	143	2.05
Cu (II) D-glucoheptonate	2.34	143	2.05

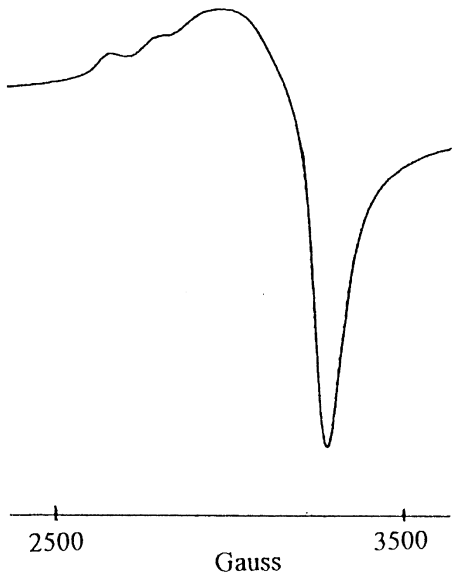

Fig. 4. EPR spectra for Cu (II)-D-gulonate (77 K).

The EPR spectral patterns and parameters observed for the Cu(II) D-gluconate, Cu(II) D-lactobionate [1], Cu(II) D-gulonate and Cu(II) D-glucoheptonate were typical for molecules of pseudo-axial symmetry, having $gz > gx \approx gy > 2$; generally showing a hyperfine structure due to the nuclear spin ($I = 3/2$) at the $g_\parallel$ region and were indicative for a predominantly dx^2–dy^2 ground state with small mixing of a dz^2 contribution [19, 20]. The rhombic signal was probably a consequence of the bulkiness of the carbohydrate moiety as well as its tendency to form intermolecular hydrogen bonds [21]. For Cu(II) D-galactonate a rhombic signal centered at $\approx$3135 G was observed. In this case the coordination sphere of the copper center was less distorted than for the other complexes and the different anisotropic components of g were not resolved.

CONCLUSION

All isolated complexes presented a 1:2 metal–ligand stoichiometry, with different hydration degrees. Both the presence or absence of water in the compounds was confirmed by thermogravimetric analyses. The water molecules would be coordinated to the metal center. The infrared spectra suggest that the carboxylic groups of sugars are involved in the chelation. The structural data obtained from magnetic measurements would indicate that the metal ions in manganese (II), cobalt (II), nickel (II) and copper (II) complexes are in an octahedral environment. For cobalt (II), nickel (II) and copper (II) complexes was confirmed an octahedral geometry by diffuse reflectance spectra. In the case of the copper (II) complexes, the EPR measurements confirm also octahedral environment. The molecular flexibility of the studied sugar acids would enable on octahedral coordination mode.

(Received 20 October 1997; accepted 12 March 1998)

Abstract—Kinetics of the oxidative dehydrogenation of the tris(2-aminomethylpyridine)cobalt(III) complex, $[Co(pic)_3]^{3+}$, have been studied following spectrophotometrically the appearance of blue species under nitrogen atmosphere. The mechanism involves a deprotonation step, in a pre-equilibrium, generating an intermediate which is susceptible to an oxidation by either the complex itself or the perchlorate ion. The equilibrium constant ($K_{OH} = 27.2 \pm 0.2\ M^{-1}$) and the rate constant ($k_{el} = 0.41 \pm 0.001\ M^{-1}s^{-1}$) were obtained by two distinct and independent treatments as well as different sets of experiments. © 1998 Elsevier Science Ltd. Keywords: oxidative dehydrogenation; cobalt(II)/(III); 2-aminomethylpyridine; kinetics; ligand reactivity; catalysis.

INTRODUCTION

Several reactions involving the oxidative dehydrogenation of coordinated amines to imines have been reported for macrocyclic amines [1, 3], diamines [4–10], aminopyridines [11–15] and primary amines [16, 17]. These reactions exemplify a determining role of transition metal ions in the reactivity of organic substrates which present also an important catalytic and biological interest.

The process has been investigated in a variety of ruthenium, iron and nickel complexes containing amine ligands that undergo oxidative dehydrogenations, yielding the corresponding imine complexes. Little has been focused for cobalt complexes, except for the α-amino acidato ones in the studies of the oxidative deamination process [18–22]. α-imino-acids are postulated as the intermediate of the reaction, since the first step of the process is the dehydrogenation of the amino group. The blue color of basic anaerobic Co(II) solutions with 2-aminomethylpyridine (pic) and 2-dipicolylamine (dpa) has once been attributed to a deprotonation of the ligand [23], although Huchital and Debesis referred to the formation of a triply-bridged binuclear species in which the two metal centers were linked by one μ-hydroxo and two μ-amido bridges [24].

Martell and coworkers [25, 26] have also reported a ligand-centered oxidative dehydrogenation in some cobalt-macrocyclic aminopyridine complexes that meet a certain steric requirement and a stabilization of the C=N bond by conjugation with an aromatic ring, although the irreversible metal-centered autooxidation is the most common decomposition reaction of cobalt dioxygen complexes. The mechanism, as well as the identity of the blue species, are therefore still controversial and not completely understood.

To have a better understanding of these systems, we carried out a detailed kinetic study of the metal-activated dehydrogenation reaction on the $[Co(pic)_3]^{3+}$ complex in basic aqueous solutions.

EXPERIMENTAL

The *fac*-$[Co(pic)_3]Cl_3.3H_2O$ complex was synthesized from *trans*-$[CoCl(py)_4]Cl.6H_2O$ and 2-aminomethylpyridine (Aldrich) following the method previously described [27]. Anal. calcd. for *fac*-$[Co(pic)_3]Cl_3.3H_2O$; C, 39.8, N, 15.5, H, 5.6, Co, 10.8. Found: C, 39.7, N, 15.4, H, 5.5, Co, 10.8.

Lithium perchlorate was prepared and purified as described previously [28].

All other chemicals were reagent grade and used as supplied.

The electronic spectra in the visible and near-UV region were recorded on a Cary 14 or a model 8451-A Hewlett–Packard diode-array spectrophotometer at 293.0 K.

Reaction rate measurements

Spectra or optical densities at the maximum absorptivity wavelength of the blue species were recorded at appropriate time intervals after the rapid mixing of deaerated aqueous solutions of *fac*-$[Co(pic)_3]^{3+}$ and OH^-.

All the kinetic experiments were carried out at 293.0 ± 0.2 K under continuous N_2 bubbling, in triplicate, under pseudo nth order conditions in the presence of a high excess of the reactants over the cobalt complex. The ionic strength was maintained at 0.10 M (NaCl). The observed rate constants, k_{obs}, were obtained from linear regression of the dependence of $\ln(A_\infty - A_t)$ or $1/(A_\infty - A_t)$ versus time.

RESULTS AND DISCUSSION

Solutions of the *fac*-$[Co(pic)_3]^{3+}$ complex are stable in neutral or slightly acidic medium and present a pale yellow color with absorption bands at 464 ($\epsilon = 119\ M^{-1}\,cm^{-1}$) and 341 nm ($\epsilon = 128\ M^{-1}\,cm^{-1}$) ascribed to the $^1A_1 \rightarrow {}^1T_1$ and $^1A_1 \rightarrow {}^1T_2$ ligand field transitions, respectively.

In basic solutions, a deep blue color (formal molar absorbance ca. $6.0 \times 10^3\ M^{-1}\,cm^{-1}$) appears gradually with a maximum at 590 nm, as can be seen in Fig. 1(a). The same color change has also been reported for *mer*-$[Co(pic)_3]^{3+}$ or $[Co(XX)(pic)_2]^{3+}$ (XX = CO_3^{2-}, $C_2O_4^{2-}$, en or bpy) yielding a remarkable similar spectra with approximately the same molar absorbance [29, 30]. Traces of oxygen, as well as the interruption of N_2 bubbling during kinetic determinations, result in the appearance of a shoulder at 654 nm (Figure 1b). The blue species decays rapidly in the atmosphere with oxygen, resulting in a brown yellow solution.

In anaerobic basic solutions, the kinetics of the blue species formation exhibited a second order behavior for at least two half-lives, as can be seen in Fig. 2(a). The plots of the reciprocal of $(A_\infty - A_t)$ versus $[OH^-]$ are linear and the k_{obs} values are obtained from the angular coefficients, Fig. 2b and 2c. The dependence of the observed rate constants on the OH^- ion concentrations, both from NaOH solutions or Na_3PO_4/Na_2HPO_4 buffers is presented in Fig. 3.

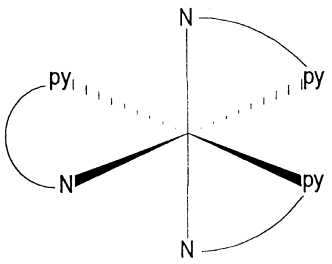
Using ClO_4^- ion as an oxidant, or even keeping the ionic strength with a $LiClO_4$ solution, the reaction is typically pseudo first order for at least three half lives as follows:

$$dP/(P_\infty - P_t) = k_{obs}.dt$$

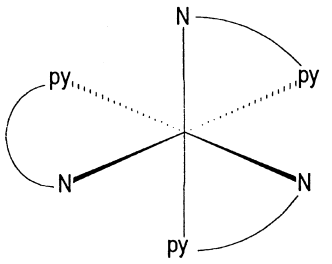
Figure 4(a) presents the plots of $\ln(A_\infty - A_t)$ versus time at different OH^- ion concentrations at a constant ClO_4^- ion concentration in a high excess, and Fig. 4(b) shows similar plots at several ClO_4^- concentrations keeping a high excess of OH^- ion concentration as well. Table 1 displays the k_{obs} values obtained from these plots.

The kinetic behavior is characteristic of an induced electron transfer process, where the perchlorate ion or the complex itself is acting as the oxidizing agent, assisted by OH^- ions [14], leading to an oxidative dehydrogenation of the ligand coordinated to the complex, as represented in Scheme 1.

Similar to the oxidative dehydrogenation process



mer



fac

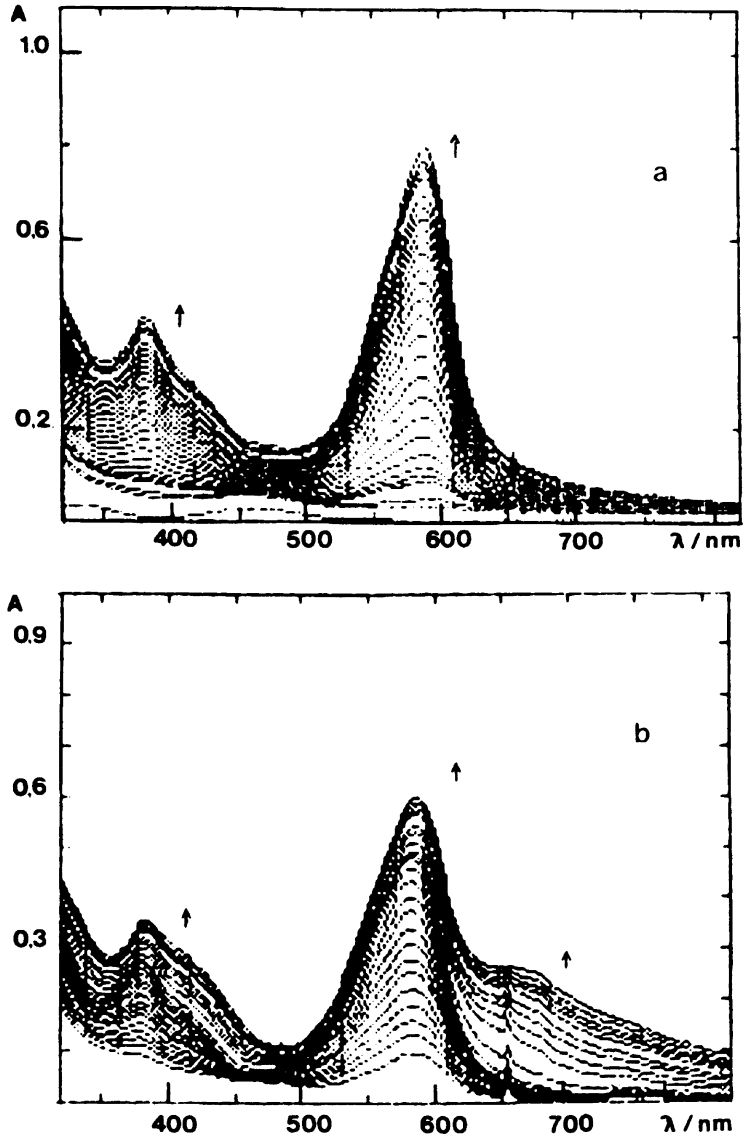


fig. 1. Spectral variation after the mixture of the $[Co(pic)_3]^{3+}$ 2.01×10^{-4} M solution and the OH^- 4.86×10^{-3} M solution at 293.0 K and $I=0.10$ M ($LiClO_4$). (a) under continuous N_2 bubbling. (b) without continuous N_2 bubbling.

of the 2-aminomethylpyridine ligand coordinated to a cyanoferrate compound [31], the first step involved is a rapid reversible deprotonation of the coordinated ligand followed to the oxidation by ClO_4^- or $[Co(pic)_3]^{3+}$. This process does not need a previous electron transfer step, as in the Fe(II) system, since the cobalt already presents the high oxidation state as Co(III) species.

According to the mechanism,

$$k_{obs}=\frac{k_{el}K_{OH}[OH^-][Ox]}{1+K_{OH}[OH^-]} \qquad (1)$$

The k_{el} and K_{OH} values were obtained independently, using two distinct treatments from independent sets of experiments at different conditions as described as follow.

For experiments carried out with a high excess of OH^- and ClO_4^-, in which the latter acts as an oxidant, two sets of measurements are made.

In the first one, keeping the OH^- concentration constant, the expression (1) can be rewritten as a function of reciprocal of the ClO_4^- concentration.

$$\frac{1}{k_{obs}}=\left[\frac{1}{k_{el}}+\frac{1}{k_{el}K_{OH}[OH^-]}\right]\cdot\frac{1}{[Ox]} \qquad (2)$$

Figure 5 presents the plots of $1/k_{obs}$ versus $1/[ClO_4^-]$, which are straight lines that intercept the origin. From the angular coefficient of each plot, called $\mathbf{b_1}$ from now

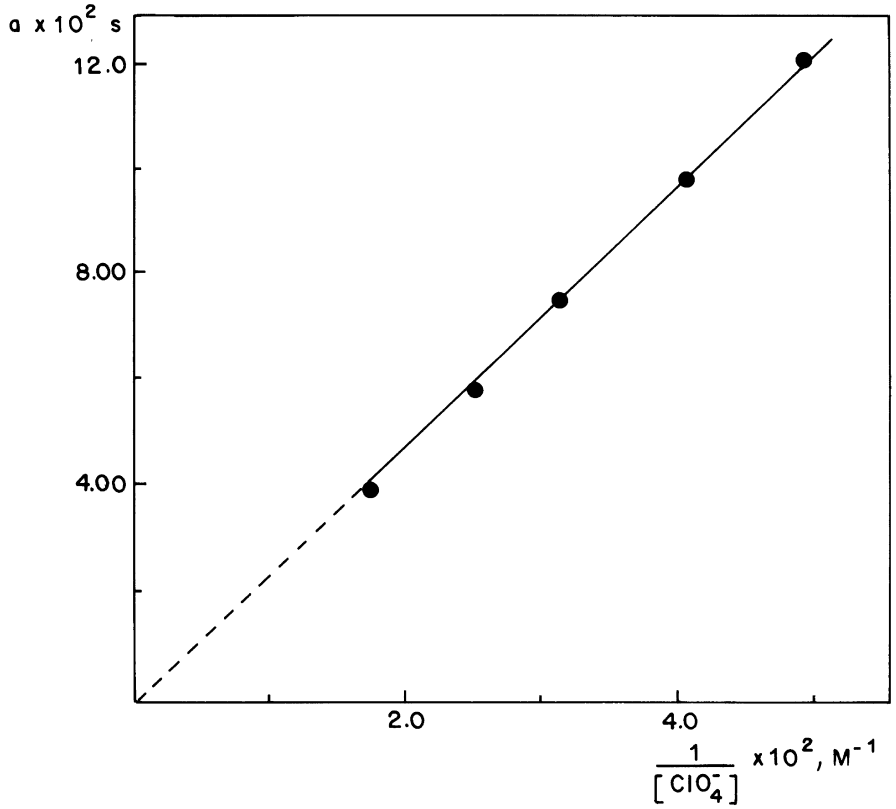

Fig. 8. Plots of **a** versus $1/[ClO_4^-][[Co(pic)_3]^{3+}] = 2.01 \times 10^{-4}$ M, $I = 0.10$ (NaCl), $T = 293.0$ K.

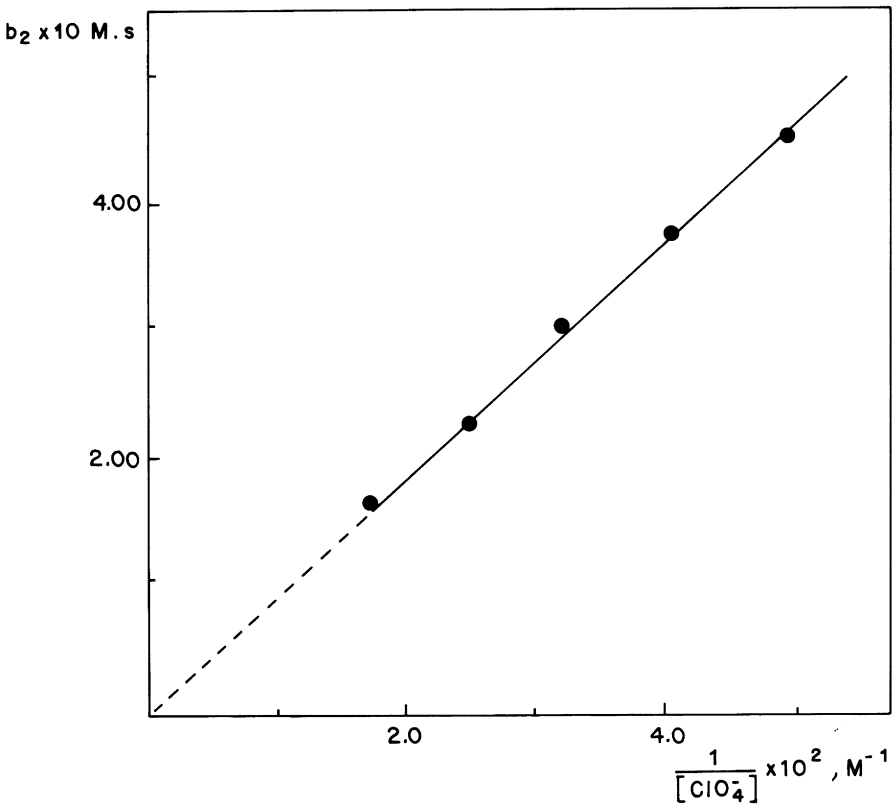

Fig. 9. Plots of $\mathbf{b_2}$ versus $1/[ClO_4^-][[Co(pic)_3]^{3+}] = 2.01 \times 10^{-4}$M, $I = 0.10$ (NaCl), $T = 293.0$ K.

on, versus the reciprocal of the $[OH^-]$ concentration, Fig. 6, the k_{el} and K_{OH} values of $0.40\,M^{-1}s^{-1}$ and $27.4\,M^{-1}$, respectively, are obtained.

In the second one, keeping the ClO_4^- concentration constant, the expression (1) can be rewritten as follows:

$$\frac{1}{k_{obs}}=\frac{1}{k_{el}[OH^-]}+\left[\frac{1}{k_{el}K_{OH}[Ox]}\right].\frac{1}{[OH^-]} \qquad (3)$$

The dependence is plotted in Fig. 7 and each plots of $1/k_{obs}$ versus $1/[OH^-]$ leads to a corresponding linear coefficient, represented as **a**, and an angular coefficient, $\mathbf{b_2}$. The plots of **a** and $\mathbf{b_2}$ versus the reciprocal of the oxidant concentration, respectively Figs 8 and 9, give the k_{el} and K_{OH} values of $0.41\,M^{-1}s^{-1}$ and $27.0\,M^{-1}$, respectively. The consistency of the mechanism and rate law are proved by k_{el} and K_{OH} values independently obtained from the two distinct treatments. They are also in complete agreement with those values obtained from an independent set of experiments, using $LiClO_4$ to control the ionic strength. In this case, the approach is the same of the above described condition and the k_{el} and K_{OH} values, obtained from expression (3), are $0.44\,M^{-1}s^{-1}$ and $24.5\,M^{-1}$.

In the absence of the perchlorate ion, as described initially, Fig. 2(a–c), the $[Co(pic)_3]^{3+}$ complex itself acts as an oxidant, and the blue species formation process follows the pseudo second order kinetic.

$$dP/(P_\infty - P)^2 = k_{obs}.dt$$

where k_{obs} is:

$$k_{obs}=\frac{k_{el}K_{OH}[OH^-]}{(1+K_{OH}[OH^-])^2} \qquad (4)$$

The plot of k_{obs} versus $[OH^-]$, from Fig. 3, is a straight line and its angular coefficients, $10.1\,M^{-2}s^{-1}$, is in accord with the $k_{el}K_{OH}$ product obtained from the treatments previously described. This treatment considered, at first rough approximation, the $K_{OH}[OH^-]$ term negligible and much lower than 1.

The autoconsistency of the results and the reproducibility of the independent constant values evaluated from different treatments, mainly from the first two sets which do not require any approximation, led to the validity of the mechanism proposed in Scheme 1, which is able to account quantitatively for the rate determining steps involved in the overall reaction.

(Received 12 December 1997; accepted 16 March 1998)

Abstract—The reaction between the alkyne, N-(5-Benzyloxy-2-pentynyl)phthalimide and decaborane (14) in the presence of dimethyl sulfide resulted in the isolation of 1-$C_6H_4(CO)_2NCH_2$-2-$C_6H_5CH_2OCH_2CH_2$-1, 2-$C_2B_{10}H_{10}$ **(5)**, 1-methylphthalimido-2-ethylbenzyl ether-*o*-carborane, in moderate yield. Compound **5** was characterized by single crystal X-ray diffraction study. Compound **5** crystallizes in the $P\bar{1}$ space group, a = 10.5328 (5) Å, b = 11.9209 (6) Å, c = 10.3451 (3) Å, $\alpha = 110.492$ (3)°, $\beta = 102.868$ (3)°, $\gamma = 87.279$ (2)°, Z = 2, $D_{calc} = 1.226$ g/cm^3, $R = 0.0491$ for 3521 reflections with $F > 4.0\sigma$. Deprotection of the ether linkage of **5** results in the formation of 1-$C_6H_4(CO)_2NCH_2$-2-$HOCH_2CH_2$-1, 2-$C_2B_{10}H_{10}$ **(6)**, 1-methylphthalimido-2-ethylalcohol-*o*-carborane. The transformation is accomplished by hydrogenation of **(5)** over a Pd/C catalyst and resulted in the efficient conversion of **(5)** into **(6)** (83% yield). Experimental details and analytical data leading to the identification of the reported compounds is provided. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: carborane; synthesis; amino; alcohol; reactivity; crystallography.

INTRODUCTION

The recent report by Hawthorne and coworkers and that of Kahl and Kasar regarding the high-yield synthesis of polyhedral carborane amino acids are significant steps in the field of boron neutron capture therapy [1–3]. There is definitely a need for the synthesis and characterization of a wide variety of these compounds if progress is to be made in this field. Our approach relies in the introduction of a protected amine and a protected alcohol into the carborane cage, using the well established synthetic route for the preparation of substituted *ortho*-carboranes, relying on the reaction of an alkyne with decaborane (14) [4–10].

The scope of the presented work is the synthesis of compounds that might be suitable for use in boron neutron capture therapy (BNCT). Although in recent years there is an apparent acceptance of this technique as a viable option for the treatment of certain tumors, specifically malignant melanoma and glioblastoma multiforme, there are too few compounds that are sufficiently selective to perform this task. The two compounds currently under clinical trials, $Na_2B_{12}H_{11}SH$ (BSH) and boronophenylalanine (BPA) exhibit a tumor to normal brain ratio of 1.69:1 and 3:1 respectively [11, 12]. Another problem is the low solubility of these compounds at physiological pH, this is especially true for BPA. Therefore, synthetic methodology for the synthesis of bifunctional carboranes is highly desirable.

The introduction of bifunctional alkynes into the decaborane (14) framework to produce heterobifunctional *o*-carboranes is not unprecedented in the literature [4–10, 13, 14]. This methodology is simple and efficient. The main obstacle is choosing the appropriate bifunctional alkyne needed to perform the reaction. Our objective was to find the appropriate alkyne containing a protected amine and a protected alcohol precursor that could be reacted with decaborane (14). Given the fact that this type of compound is not commercially available, one of the tasks for this study

* Author to whom correspondence should be addressed. Fax: 001 505 646 2649.

was the synthesis of such a compound. We chose $C_6H_4(CO)_2NCH_2C{\equiv}CCH_2CH_2OC_6H_5$ as our precursor, since it contained a protected amine and a protected alcohol. In this communication we describe the synthesis of this alkyne from its precursors and its subsequent transformation to the heterobifunctional *ortho*-carborane. The synthesis of this carborane could open the door for the preparation of other bifunctional carboranes needed for BNCT. The key to successful BNCT is the delivery of ^{10}B-containing compounds to the malignant tumor cell selectively. The necessary tumor/normal tissue and tumor/blood ratios must be at least two [15, 16].

Common strategies used to achieve the above indicated objective include the attachment of boron containing residues to existing compounds known to accumulate in tumor tissues [17] and to a variety of recognition elements, such as amino acids [18, 19], peptides [15], antibodies [20], nucleosides [21–24], liposomes [25] and other regulatory biomolecules [26]. The most commonly used boron containing residues are carborane clusters, such as *ortho*-carborane and derivatives. These clusters have the advantage over monoboronated compounds, since they contain up to ten boron atoms and naturally abundant ^{10}B may be used [27]. Also these clusters are stable at physiological pH. The main task is the design and combination of the boron clusters with the recognition elements or derivative thereof. This communication intends to address this strategy.

EXPERIMENTAL

All manipulations were carried out using standard high vacuum or inert atmosphere techniques, when warranted, as described by Shriver [28].

Materials

3-butynyl-1-ol, benzyl bromide, sodium hydride, tetrahydrofuran, dimethylformamide, paraformaldehyde, n-butyllithium (2.0 M in cyclohexane), magnesium sulfate, chloroform, acetonitrile, methanol, ethanol, potassium phthalimide, hexanes, silica gel, acetone-d_6, CD_3CN and $CDCl_3$ were purchased form Aldrich. All solvents were dried prior to use. Decaborane (14) was obtained from Strem Chemicals.

Physical measurements

The 128.4 MHz boron-11 and 400.0 MHz proton spectra were obtained on a Varian Unity-400 Fourier transform spectrometer. All boron-11 chemical shifts were referenced to $BF_3{\cdot}O(C_2H_5)_2 = 0.0$ ppm with a negative sign indicating an upfield shift. Proton NMR at 200 MHz and carbon-13 NMR at 50.0 MHz were obtained on Varian Gemini-200 Fourier transform spectrometer. Proton chemical shifts and carbon-13 chemical shifts were referenced to TMS = 0.00 ppm with positive values indicating downfield shifts. Infrared spectra were recorded on a Perkin-Elmer 337 grating infrared spectrophotometer and on Perkin Elmer 1720 Fourier transform spectrophotometer. Low resolution mass spectrometry data was obtained in a HP GC/MS system, model 5995.

X-ray crystallography

X-ray intensity data were collected on a Rigaku R-AXIS IIc area detector employing graphite-monochromated Mo-Kα radiation ($\lambda = 0.71069$ Å) at a temperature of 223 K for compound **5**. Indexing was performed from a series of 1° oscillations with exposures of 8 minutes per frame. A hemisphere of data was collected using 6° oscillations with exposures of 4 minutes per frame. The crystal to detector distance was 82 mm. Oscillation images were processed using bioteX [29], producing a listing of unaveraged F^2 and $\sigma(F^2)$ values which were then passed to the teXsan [30] program package for further processing and structure solution on a Silicon Graphics Indigo R4000 computer. A total of 9100 reflections were measured over the ranges: $5.18 \leqslant 2\theta \leqslant 50.70°$, $-12 \leqslant h \leqslant 12$, $-14 \leqslant k \leqslant 12$, $-12 \leqslant l \leqslant 12$, yielding 3949 unique reflections ($R_{int} = 0.0176$). Other relevant crystallographic data are given in Table 1. The intensity data were corrected for Lorentz and polarization effects but not for absorption.

The structure was solved by direct methods (SIR92) [31]. The refinement was full-matrix least squares based on F^2 using SHELXL-93 [32]. All reflections were used during refinement (F^2's that were experimentally negative were replaced by $F^2 = 0$). The weighting scheme was $w = 1/[\sigma^2(F_o^2) + 0.0586P^2 + 0.3395P]$ where $P = (F_o^2 + 2F_c^2)/3$.

Non-hydrogen atoms were refined anisotropically; cage hydrogens were refined isotropically; all other hydrogen atoms were refined using a 'riding' model which the positions of the hydrogen atoms were re-idealized before each least squares cycle by applying the coordinate shifts of the atom to which each hydrogen atom is attached. Refinement converged to $R_1 = 0.0491$ and $wR_2 = 0.1215$ for 3521 reflections for which $F > 4\sigma(F)$ and $R_1 = 0.0556$, $wR_2 = 0.1270$ and GOF = 1.070 for all 3949 unique, non-zero reflections and 348 variables. The maximum Δ/σ in the final cycle of least squares was 0.000 and the two most prominent peaks in the final Fourier were +0.191 and −0.176 e/Å^3.

Selected bond distances and angles are given in Table 2 and Table 3 respectively. Final atomic positions for non Hydrogen atoms and their isotropic parameters, Hydrogen atom coordinates and displacement parameters, non-hydrogen atom thermal parameters, full listing of interatomic distances and bond angles are available as supplementary material.

Synthesis of $HC{\equiv}CCH_2CH_2OCH_2C_6H_5$ (**1**)

In a 250 cm^3 round bottom flask were placed 7.0 g (0.10 mol) of 3-butyn-1-ol and 100 cm^3 of anhydrous THF. To the resulting suspension, 2.8 g (0.11 mol) of sodium hydride were added slowly. After gas evolution had ceased, 19.0 g (0.11 mol) of benzyl bromide were added to the solution and stirred at room temperature overnight. After 12 hrs, a voluminous precipitate had formed. The precipitate was filtered and the solvent removed by rotary evaporation. The resulting residue was distilled under reduced pressure, resulting in the isolation of a colorless oil which was identified as benzyl-3-butynyl ether (12.3 g, 0.077 mol, 77% yield, bp 66–68°C/0.6 mm Hg). ^{1}H NMR: ($CDCl_3$), 1.98 (1H, t, $J=2.64$ Hz), 2.47 (2H, d of t, $J_{AB}=2.64$ Hz, $J_{AX}=6.96$ Hz), 3.58 (2H, t, $J=6.96$ Hz), 4.54 (2H, s), 7.32 (5H, m), ^{13}C NMR: ($CDCl_3$), 19.66 (CH_2), 67.90 (CH_2O), 69.21 (OCH_2), 72.71 (≡C), 81.04 (HC≡), 127.47 (C_6H_5), 128.19 (C_6H_5), 137.82 (C_6H_5), IR (cm^{-1}): 3296 (s), 3028 (m), 2868 (s), 2220 (w), 1720 (m), 1496 (m), 1456 (m), 1364 (m), 1275 (w), 1204 (w), 1100 (s), 1028 (m), 795 (w), 740 (m), 700 (m), 648 (m). MS (EI): *m*/*z* relative intensity 159 (M^+-H, 100), 107 (M^+-$HC{\equiv}CCH_2CH_2$, 9.1), 83 (M^+-C_6H_5, 22.7).

Synthesis of $HOCH_2C{\equiv}CCH_2CH_2OCH_2C_6H_5$ (**2**)

To a solution containing 9.6 g (0.060 mol) of benzyl-3-butynyl ether in 90 cm^3 of dry THF kept at −20°C, 31 cm^3 (0.061 mol) of a 2.0 M solution n-BuLi in cyclohexane were added slowly. The mixture was allowed to warm to room temperature and stirred for one hour. To this solution, 2.0 g (0.066 mol) of paraformaldehyde were added and stirring of the resulting solution was continued for an additional 2 hrs. The THF was removed by rotary evaporation and to the resulting residue, 25 cm^3 of distilled water were added. This solution was extracted with three 20 cm^3 of anhydrous ether. The ethereal solution was dried over $MgSO_4$. The ether was then removed by rotary evaporation. The resulting oil was distilled and a colorless oil (8.2 g, 0.043 mol, 72% yield, bp 130–132°C/0.5 mm Hg) was obtained and identified as 5-benzylox-2-pentyn-1-ol. ^{1}H NMR: ($CDCl_3$), 2.31 (1H, t, $J=5.94$ Hz), 2.52 (2H, m), 3.57 (2H, t, $J=6.88$ Hz), 4.20 (2H, m), 4.54 (2H, s), 7.33 (5H, m). ^{13}C NMR: ($CDCl_3$), 19.84 (CH_2), 50.86 ($HOCH_2$), 67.90 (CH_2O), 72.69 (OCH_2), 79.34 (C≡), 82.61 (C≡), 127.27 (C_6H_5), 128.20 (C_6H_5), 137.66 (C_6H_5). IR (cm^{-1}): 3444 (s, br), 2872 (s), 2240 (m), 1716 (m), 1680 (sh), 1480 (w), 1456 (m), 1310 (m), 1272 (m), 1096 (m), 975 (m), 750 (m), 700 (m). MS (EI): *m*/*z* relative intensity 189 (M^+-H, 3.6), 159 (M^+-$HOCH_2$, 3.6), 121 (M^+-$HOCH_2C{\equiv}CCH_2$, 92.6), 113 (M^+-C_6H_5, 7.1), 107 (M^+-$HOCH_2C{\equiv}CCH_2CH_2$, 3.6), 83 (M^+-$OCH_2C_6H_5$, 3.6).

Synthesis of $BrCH_2C{\equiv}CCH_2CH_2OCH_2C_6H_5$ (**3**)

In a 250 cm^3 round bottom flask were placed 7.0 g (0.037 mol) of $HOCH_2C{\equiv}CCH_2CH_2OCH_2C_6H_5$ and 10.0 g (0.046 mol) of $(CH_3)_2NCHBr_2$, which was prepared according to the literature procedure [33]. To this mixture, 100 cm^3 of dry acetonitrile was added

and the resulting solution was heated to reflux for 2 hrs. The acetonitrile was removed *in vacuo* and the resulting residue extracted with ether. After evaporation of the ether from the solution, the extract was separated on a silica gel column chromatography using a 2:1 mixture of hexanes/methylene chloride. The resulting oil obtained was identified as benzyl-5-bromo-2-pentynyl ether. (8.0 g, 0.031 mol, 85% yield). ^{1}H NMR ($CDCl_3$), 2.56 (2H, m), 3.58 (2H, t, $J=6.88$ HZ), 3.91 (2H, t, $J=2.24$ Hz), 4.55 (2H, s), 7.34 (5H, m). ^{13}C NMR ($CDCl_3$), 15.03 ($BrCH_2$), 20.13 (CH_2), 67.61 (CH_2O), 72.71 (OCH_2), 77.37 (C≡), 84.49 (C≡), 127.43 (C_6H_5), 128.16 (C_6H_5), 137.68 (C_6H_5). IR (cm^{-1}): 3028 (m), 2868 (s), 2236 (m), 1720, 1648 (w), 1496 (w), 1456 (s), 1364 (s), 1212 (s), 1100 (s), 740 (s), 700 (s), 608 (s). MS (EI, ^{81}Br) m/z relative intensity 255 ($M^+ + H$, 5.3), 254 (M^+, 4.1), 252 (M-2^+, 1.2), 173 (M^+-Br, 35.8), 159 (M^+-$BrCH_2$, 2.6), 147 (M^+-$BrCH_2C$, 3.0), 143 (M-2^+-$HOCH_2C_6H_5$, 100), 121 (M^+-$BrCH_2C{\equiv}CCH_2$, 4.7), 108 (M^+-$BrCH_2C{\equiv}CCH_2CH_2$, 2.1), 77 (M^+-$BrCH_2C{\equiv}CCH_2CH_2O$, 15.9).

Synthesis of $C_6H_4(CO)_2NCH_2C{\equiv}CCH_2CH_2OCH_2C_6H_5$ (**4**).

A solution consisting of 2.53 g (0.010 mol) of $BrCH_2C{\equiv}CCH_2CH_2OCH_2C_6H_5$ dissolved in 15 cm^3 of DMF was added to 2.04 g (0.011 mol) of potassium phthalimide and stirred at room temperature overnight. After that time, 50 cm^3 of distilled water was added to the solution and the mixture extracted with three 20 cm^3 portions of chloroform. This solution was dried over $MgSO_4$ and the chloroform stripped off *in vacuo*. The residue was dissolved in a minimal amount of methylene chloride and separated via silica gel column chromatography. This resulted in the isolation of a viscous oil which was identified as N-(5-benzyloxy-2-pentynyl)phthalimide (3.05 g, 0.0096 mol, 96% yield). ^{1}H NMR: ($CD_3C(O)CD_3$), 2.45 (2H, m), 3.53 (2H, t, $J=7.12$ Hz), 4.41 (2H, t, $J=2.24$ Hz), 4.50 (2H, s), 7.30 (5H, m), 7.86 (4H, m). ^{13}C NMR: ($CD_3C(O)CD_3$), 20.08 (CH_2), 27.36 (CH_2), 68.50 (CH_2O), 72.67 (OCH_2), 75.44 (C≡), 80.54 (C≡), 123.65 (C_6H_5), 127.86 (C_6H_5), 128.67 (C_6H_5), 132.57 (C_6H_5), 134.86 (C_6H_5), 139.23 (C_6H_5), 167.22 (C═O). IR (cm^{-1}): 3020 (m), 2872 (m), 2245 (w), 1772 (s), 1716 (s), 1650 (m), 1550 (w), 1520 (w), 1420 (m), 1392 (m), 1320 (m), 1116 (s), 944 (m), 724 (s), 628 (m), 532 (m). MS (EI), m/z relative intensity 320 ($M^+ + H$, 5.9), 212 (M^+-$OCH_2C_6H_5$, 3.0), 198 (M^+-$CH_2OCH_2C_6H_5$, 5.3), 173 (M^+-$C_6H_4(CO)_2N$, 8.3), 172 (M^+-$CH_2CH_2OCH_2C_6H_5$, 21.6), 160 (M^+-$C{\equiv}CCH_2CH_2OCH_2C_6H_5$, 42.4), 159 ($M^+$-$C_6H_4(CO)_2NCH_2$, 83.2), 131 ($M^+$-CO and $HC{\equiv}CCH_2CH_2OCH_2C_6H_5$, 3.5), 104 ($M^+$-CO and $NCH_2C{\equiv}CCH_2CH_2OCH_2C_6H_5$, 15.1), ($M^+$-91($M^+$-$C_6H_4(CO)_2NCH_2C{\equiv}CCH_2CH_2$, 100), 77 ($M^+$-$C_6H_4(CO)_2NCH_2C{\equiv}CCH_2CH_2OCH_2$, 12.8).

Synthesis of 1-$C_6H_4(CO)_2NCH_2$-2-$C_6H_5CH_2OCH_2CH_2$-1, 2-$C_2B_{10}H_{10}$ (**5**)

In a 100 cm^3 round bottom flask, 0.400 g (0.0033 mol) of decaborane (14) and 0.60 cm^3 (0.008 mol) of dimethyl sulfide were dissolved in 35.0 cm^3 of dry benzene. The solution was stirred to reflux for 4 hrs. After allowing the solution to cool to room temperature, 1.03 g (0.0033 mol) of N-(5-benzyloxy-2-pentynyl)phthalimide were added quickly and stirred at room temperature for 10 min., to ensure complete dissolution of the alkyne. The resulting solution was then heated to reflux for 10 hrs. The benzene was removed *in vacuo* and to the resulting solid, 2.5 cm^3 of methanol were added and stirred at room temperature for 4 hrs. The suspension was filtered, resulting in a white solid which was washed with three portions of 5.0 cm^3 of cold ethanol. The white solid was dissolved in a 1:1 mixture of CH_3CN/CH_2Cl_2 and recrystallized from this solution, resulting in the isolation of 1-methylphthalimido-2-ethylbenzyl ether-*o*-carborane (0.70 g, 50% yield, mp 1175–177°C). The identity of this compound was confirmed by a single crystal X-ray diffraction study. ^{1}H NMR: ($CD_3C(O)CD_3$), 3.04 (2H, t, $J=5.86$ Hz), 3.77 (2H, t, $J=5.86$ Hz), 4.56 (2H, s), 4.57 (2H, s), 7.35 (5H, m), 7.89 (4H, m). ^{13}C NMR ($CD_3C(O)CD_3$), 35.68 (CH_2), 40.49 (CH_2), 68.79 (CH_2O), 73.26 (OCH_2), 78.16 (carborane C), 80.89 (carborane C), 124.20 (C_6H_5), 128.16 (C_6H_5), 128.76 (C_6H_5), 131.95 (C_6H_5), 135.30 (C_6H_5), 138.36 (C_6H_5), 167.36 (C═O). ^{11}B NMR: ($CD_3C(O)CD_3$), −0.48 (2B), −5.49 (8B). The coupling constants for this compound could not be reliably determined due to coincidental overlap of signals. IR (cm^{-1}): 2996 (m), 2888 (m), 2580 (s), 1776 (s), 1724 (s), 1612 (w), 1484 (m), 1468 (w), 1456 (w), 1420 (m), 1400 (s), 1364 (s), 1288 (m), 1136 (m), 1104 (s), 1080 (s), 1036 (m), 960 (m), 864 (w), 848 (w), 824 (w), 792 (w), 752 (m), 716 (s), 700 (m), 646 (w), 608 (w), 528 (m). MS (EI), m/z relative intensity 439 (M^+, 6.5), 348 (M^+-$CH_2C_6H_5$, 7.6), 332 (M^+-$OCH_2C_6H_5$, 42.7), 303 (M^+-H and $CH_2CH_2OCH_2C_6H_5$, 7.8), 160 (M^+-$C_2B_{10}H_{10}CH_2CH_2OC_6H_5$, 14.4), 107 ($M^+$-$C_6H_4(CO)_2NCH_2C_2B_{10}H_{10}CH_2CH_2$, 39.7), 91 ($M^+$-$C_6H_4(CO)_2NCH_2C_2B_{10}H_{10}CH_2CH_2O$, 100), 77 ($M^+$-$C_6H_4(CO)_2NCH_2C_2B_{10}H_{10}CH_2CH_2OCH_2$, 15.9).

Synthesis of 1-$C_6H_4(CO)_2NCH_2$-2-$HOCH_2CH_2$-1, 2-$C_2B_{10}H_{10}$ (**6**)

In a 5.0 cm^3 round bottom flask, 0.045 g (0.10 mmol) of 1-methylphthalimido-2-ethylbenzyl ether-*o*-carborane were placed and 0.50 cm^3 of $CHCl_3$ added. To the resulting solution, 0.50 cm^3 of ethanol and 30 mg of Pd/C were added. The flask was then attached to a three-way vacuum stopcock, the contents frozen and degassed. A balloon filled with H_2 gas was then attached to the three-way vacuum stopcock and opened to fill the flask with an atmosphere

of hydrogen. The solution was then stirred at room temperature overnight. The solution was then filtered to remove the catalyst and the solvent was removed *in vacuo*. The resulting residue was dissolved in CH_2Cl_2 and purified via column chromatography (packed with silica gel). The elutant used was a 2% CH_3OH mixture in CH_2Cl_2. This resulted in the isolation of 29 mg of a white solid, which was identified as 1-methylphthalimido-2-ethylalcohol-*o*-carborane (0.029 g, 0.083 mmol, 83% yield, mp 137–139°C). ^{1}H NMR: (CD_3CN), 2.83 (2H, t, $J = 6.50$ Hz), 3.10 (1H, t, $J = 5.20$ Hz), 3.75 (2H, m, $J_{AB} = 6.50$ Hz, $J_{AX} = 5.20$ Hz), 4.47 (2H, s), 7.86 (4H, m). ^{13}C NMR: (CD_3CN), 38.24 (CH_2), 41.18 (CH_2), 61.15 (CH_2O), 78.89 (carborane C), 81.53 (carborane C), 124.65 (C_6H_5), 132.52 (C_6H_5), 135.90 (C_6H_5), 168.55 (C═O). ^{11}B NMR: (CD_3CN), 0.89 (1B, $J_{BH} = 129$ Hz), −0.89 (1B, $J_{BH} = 129$ Hz), −4.76 (4B, the coupling constant for this peak could not be reliably be calculated due to coincidental overlap of signals), −5.44 (4B, $J_{BH} = 128$ Hz). IR (cm^{-1}): 3536 (s), 3444 (br), 2956 (w) 2596 (s), 1776 (m), 1716 (s), 1488 (m), 1420 (m), 1400 (s), 1360 (m), 1140 (w), 1088 (w), 1054 (w), 960 (w), 716 (m), 532 (w). MS (EI), *m*/*z* relative intensity, 349 (M^+, 87.8), 348 (M^+-H, 41.1), 331 (M^+-H_2O, 87.6), 130 (M^+-$HOCH_2CH_2C_2B_{10}H_{10}$, H_2 and CO, 100).

RESULTS AND DISCUSSION

In order to prepare the desired precursor, it was necessary to first synthesize the corresponding alkyne needed for the reaction with decaborane (14). This procedure was a multistep synthesis starting from 3-butyn-1-ol, which is the commercially available alkyne needed for the synthesis of the desired alkyne. The synthesis of **1** was accomplished by adapting the reported literature procedure [33]. The isolation of benzyl-3-butynyl ether in significant yield (77%) allowed for the continuation of the proposed synthetic scheme, shown in Fig. 1. The identity of this compound was determined by ^{1}H and ^{13}C NMR, mass spectrometry, as well as IR spectroscopy. The nature of **1**, an air stable colorless oil, allowed for the easy handling of this compound. The ^{1}H NMR data shows an interesting pattern of resonances. The proton assigned to the terminal hydrogen of the alkyne appears at δ 1.98 ppm, as a triplet. Obviously there is coupling between this proton and the CH_2 group next to the β-carbon of the alkyne, even though they are separated by four bonds. This is confirmed by the splitting of resonances arising from the CH_2 group of protons bonded directly to the alkylinic carbon, these protons show a resonance at δ 2.47 ppm, as a doublet of triplets. The coupling constant of the doublets is 2.64 Hz, which corresponds to the coupling constant obtained for the triplet at δ 1.98 ppm. Furthermore, the downfield triplet at δ 3.58 ppm, assigned to the CH_2 group bonded to that CH_2 group and to the $OCH_2C_6H_5$ group, exhibits a coupling constant of 6.96 Hz, matching that of the triplets of the resonance at δ 2.47 ppm. The benzylic hydrogens appear as a singlet at 4.54 ppm, typical of benzylic protons. The IR spectra also shows the typical peaks, especially the C≡C triple bond stretch, which is found at 2220 cm^{-1}, also typical for this class of compounds. The ^{13}C NMR consists of eight resonances, at the typical shifts for the type of functional groups present in compound **1**.

The next step in the synthesis of the alkyne precursor is the preparation of the amino end of the molecule. Care had to be taken in choosing an appropriate procedure that would carry the protected alcoholic part of the alkyne intact. For this reason, the reaction of **1** with n-BuLi, followed by the addition of paraformaldehyde was chosen. The method is simple and does not result in deprotection of the benzylic group to form the corresponding alcohol. Compound **2** was isolated in reasonable yield (72%), as a colorless air stable oil. The identification of this compound was not as straightforward as that of **1**. The presence of multiplets at δ 2.52 ppm and δ 4.20 ppm, each due to two set of protons, prevents an analysis based on coupling constants as that performed for **1**. Nonetheless, the peak as δ 2.31 ppm, is due to the OH group and the resonance at δ 3.57 ppm is due to the CH_2O group. The other two resonances, δ 2.52 and δ 4.20 ppm respectively are assigned to the CH_2 groups bonded to the C≡C bond. The downfield resonance is that of the CH_2 group bonded to the OH and the other one corresponds to the other CH_2 group. The fact that the obtained coupling constants are similar in value, resulted in the observed multiplets for these resonances. The benzylic protons were assigned to the resonance at δ 4.54 ppm, again typical for these type of protons. The ^{13}C NMR showed nine resonances, which is the expected number of resonances for compound **2**. The IR spectra was more informative, the presence of a broad peak at 3440 cm^{-1}, typical of a OH group, coupled with a resonance at 2240 cm^{-1} assignable to the C≡C triple bond, indicated the formation of **2**. Based on this information, the fact that the benzylic group was left intact, as indicated by the ^{1}H and ^{13}C NMR data, the task of continuing toward the formation of the alkyne precursor could be continued.

Compound **3** was prepared by the reaction of **2** with $(CH_3)_2NCHBr_2$. This procedure resulted in the bromination of the CH_2 group carrying the alcohol, while keeping the protected alcohol on the other side of the alkyne unaffected. The isolated yield (85%) of the colorless oil, which was purified by column chromatography was high enough to allow the continuation of the synthetic strategy proposed. The ^{1}H and ^{13}C NMR data agrees with the formulation of compound **3**. The IR spectra also showed the presence of the C≡C triple bond, which is of paramount importance for the synthesis of the sought carborane. The mildness of the bromination method and the ease of synthesis of **3** in high yield is an attractive feature of

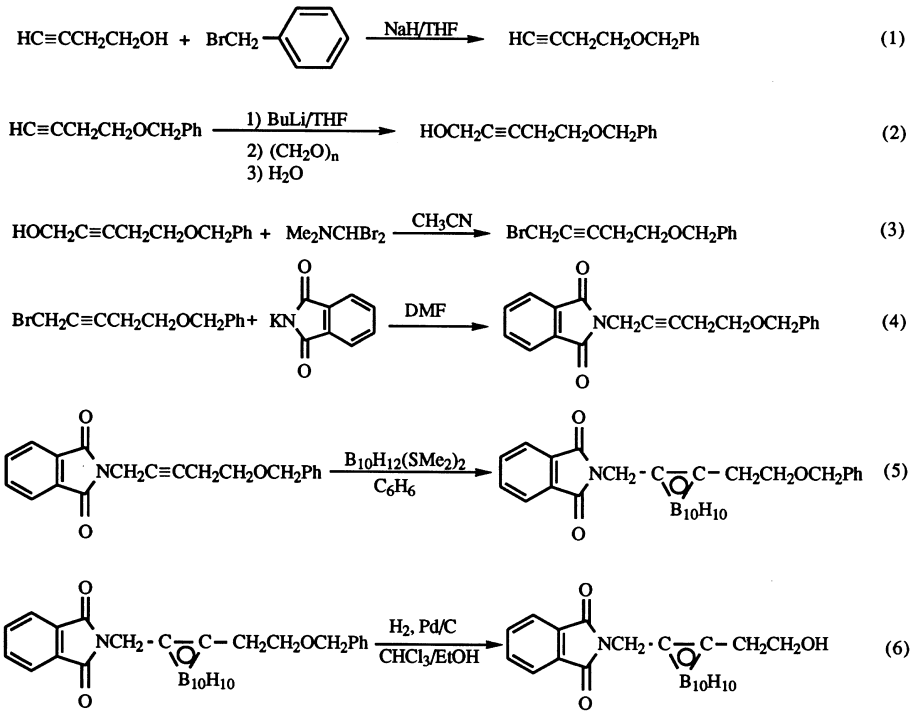

Fig. 1. Reaction sequence leading to the synthesis of heterodisubstituted *ortho*-carboranes.

this synthetic strategy. Compound **3** is the immediate precursor to the protected amino alcohol alkyne sought for the preparation of carborane **5**.

The preparation of compound **4** was accomplished by using Gabriel's reagent, potassium phthalimide, this allowed for the convenient preparation of the protected amine in high yield (96%). Compound **4** was isolated as a viscous oil. The ^{1}H NMR showed a multiplet at δ 2.45 ppm, assignable to CH_2 protons bonded to the β-carbon of the alkyne, a triplet at δ 3.53 ppm, corresponding to the NCH_2 group, a triplet at δ 4.41 ppm, due to the CH_2O group, a singlet at δ 4.50 ppm, for the benzylic protons of the protected alcohol, an two different sets of aromatic multiplets at δ 7.30 and δ 7.84 ppm, respectively, due to the $OCH_2C_6H_5$ and $C_6H_4(CO)_2N$ groups. The ^{13}C NMR of **4** should consist of thirteen peaks, which were observed. The C=O resonance was found at δ 167.22 ppm, typical for an amide group. The IR spectra of **4** also indicated its identity. The weak resonance at 2245 cm^{-1} coupled with the strong carbonyl stretch at 1716 cm^{-1} clearly indicated that compound **4** was formed. The high yield of this reaction indicates that this is a convenient method to prepare the desired precursor. The next step is simply the reaction of decaborane (14) in the presence of dimethyl sulfide with **4**, in order to produce the sought compound.

The identities of compounds **1** through **4** were further confirmed by mass spectrometric experiments and the synthesis and characterization of compound **5**. The single crystal X-ray structure determination of **5** is ample evidence of the identity of every intermediate leading to its formation.

The identity of **5** is supported by the ^{1}H, ^{11}B, and ^{13}C NMR data, as well as the IR spectra, mass spectrometry and the single crystal X-ray diffraction study of this compound. An ORTEP diagram for this compound is shown in Fig. 2.

The ^{1}H NMR data shows the expected peaks for a compound of this type. The triplet at δ 3.04 ppm is due to the CH_2 group of the ethylene unit in the carborane, which is coupled to the CH_2 group of the ether moiety and the CH_2 group of the phthalimide unit. The triplet at δ 3.77 ppm is due to the other CH_2 of the ethylene group in this carborane. The coupling constants were found to be identical for these protons, indicating that they are neighbors. The singlets at δ 4.56 and δ 4.57 ppm respectively are the result of the protons in the CH_2 group linked to the oxygen atom of the ether unit and the CH_2 group in the phthalimide unit. The expected multiplets, consisting of 4 protons and 5 protons respectively, are due to the benzene groups present in this molecule. The ^{13}C NMR data shows the expected thirteen peaks. The presence of the carbonyl resonance at δ 167.36 ppm clearly indicates that the alkyne incorporated into the cage. This fact coupled to the resonances are δ 78.16 and δ 80.89 ppm, assignable to the carborane carbons showed that the expected product was indeed synthesized.

The IR data for **5** further supports the identity of this compound. Peaks at 2558 cm^{-1}, typical of B–H

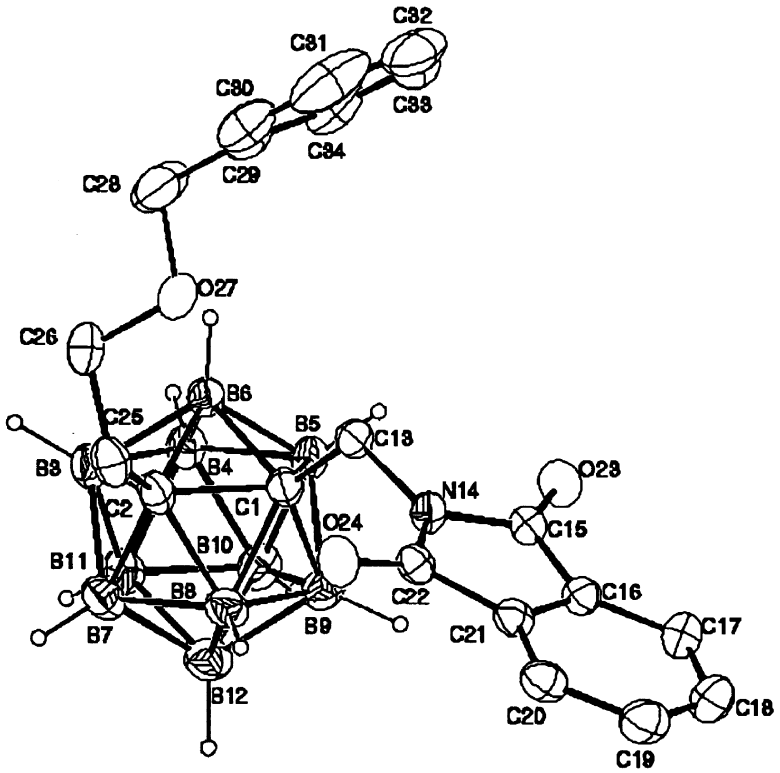

Fig. 2. ORTEP drawing of 1-$C_6H_4(CO)_2NCH_2$-2-$C_6H_5CH_2OCH_2CH_2$-1, 2-$C_2B_{10}H_{10}$ (5) with 30% probability thermal ellipsoids.

stretches, coupled with peaks at 1776 and 1724 cm^{-1} respectively, due to the carbonyl groups of the phthalimide unit are indicative of the incorporation of the alkyne into the decaborane (14) framework.

The single X-ray data shows the expected bond distances for a compound of this type. The boron-boron distances are within the expected range, 1.765 to 1.787 Å, typical of these type of compounds. The carbon-carbon in the cage and the boron-carbon distances are also typical, 1.684 to 1.732 Å. This clearly indicates that the steric effects imposed by the substituent groups are minimal, since in systems like 1-diphenylphosphino-2-methyl-1, 2-dicarba-*closo*-dodecaborane (12) [34], 1-diphenylphosphino-2-phenyl-1, 2-dicarba-*closo*-dodecaborane (12) [35], 1-phenyl-2-(*tert*-butyldimethylsilyl)-1, 2-dicarba-*closo*-dodecaborane (12) [36], 1-phenyl-2-trimethylsilyl-1, 2-dicarba-*closo*-dodecaborane (12) [37], 1-diisopropylphosphino-2-methyl-1, 2-dicarba-*closo*-dodecaborane (12) [38], 1, 2-Bis(diisopropylphosphino)-1, 2-dicarba-*closo*-dodecaborane (12) [38], 2-bromo-1-phenyl-1, 2-dicarba-*closo*-dodecaborane (12) [39], 1-diisopropylphosphino-2-phenyl-1, 2-dicarba-*closo*-dodecaborane (12) [40], and 1-phenyl-2-methyl-1, 2-dicarba-*closo*-dodecaborane (12) [41] the carbon-carbon bond length is significantly lengthened due to the steric constraints placed by the exopolyhedral groups in the cage. The values obtained in these compounds for the carbon-carbon bond length range from a minimum of 1.692 (8) Å for 2-bromo-1-phenyl-1, 2-dicarba-*closo*-dodecaborane (12) [39], which could be argued to be the less sterically demanding of these compounds and therefore closer in electronic structure to that of **5** to a maximum of 1.769 (4) Å in 1-diisopropylphosphino-2-phenyl-1, 2-dicarba-*closo*-dodecaborane (12) [40], which would be more sterically demanding and dissimilar to the electronic structure of **5**. The argument used for the lengthening of the carbon-carbon bond in these compounds is the partial overlap of tangentially oriented p orbitals of the cluster carbon with orbitals having the appropriate symmetry in the exopolyhedral group. When the overlap is between a sp^3 hybridized carbon and the cluster carbon, no significant effect should be observed, as is the case in compound **5**.

The relative importance of the characterization of **5** lies in the fact that a viable precursor to an amino acid containing carborane has been isolated. The exploration of its chemistry could potentially lead to the synthesis of such a compound, which could prove useful in BNCT.

The identity of compound **6** is based on the ^1H, ^{11}B, ^{13}C NMR, IR spectral and mass spectrometric data obtained. The ^1H NMR consists of two triplets at δ 2.83 and δ 3.10 ppm of relative intensities two and one respectively. The first triplet is due to the CH_2 group

bonded directly to the cluster carbon. Its coupling constant of 6.50 Hz, which corresponds to one of the coupling constants found in the resonance at δ 3.75 ppm, allows for the identification of these protons, as well as those at δ 3.75 ppm, which is a triplet of doublets. The coupling constant of the doublets is 5.20 Hz, which corresponds to the coupling constant found for the resonance at δ 3.10 ppm, assigned to the alcoholic proton. The singlet at δ 4.47 ppm is due to the CH_2 group in the phthalimide unit. The downfield multiplet of area four is due to the phenyl group in the compound. The ^{13}C NMR shows a total of nine peaks, which the number of resonances expected for compound **6**.

The IR spectral data shows the expected OH stretch at 3444 cm^{-1}, as well as the expected BH and C=O stretches in the normal regions.

The ^{11}B NMR data, as mentioned earlier consists of four peaks, of relative intensities 1:1:4:4. The signals observed are not the expected pattern of signals for a compound of this type, but similarly heterodisubstituted compounds had shown the same type of pattern in the ^{11}B NMR spectra [42, 43]. The coincidental overlap of resonances in the ^{11}B NMR time scale is not unprecedented, a relevant example for the observation of this type of pattern in the ^{11}B NMR spectrum is 1-phenyl-2-methyl-1, 2-dicarba-*closo*-dodecaborane (12) [41], which is also a bifunctionally substituted *ortho*-carborane.

With the isolation of compound **6**, the goal of preparing an amino acid *ortho*-carborane derivative is in principle possible. Unfortunately, all attempts to isolate this compound have proven unsuccessful at this time. Although there is some evidence that upon deprotection of the phthalimide group and oxidation of the alcohol, a compound that could possibly be the amino acid carborane is formed, its isolation has not been possible. The conditions upon which the deprotection is being carried out might be too harsh and unwanted side reactions could be taking place. We are continuing to investigate alternate routes for the preparation of the amino acid carborane and the results from this effort will be reported in the future.

Supporting information available—Tables of bond lengths and angles, atomic coordinates and thermal parameters (10 pages) are available. Order information is available on any current masthead page.

(Received 30 January 1998; accepted 23 March 1998)

Abstract—In absolute methanol medium, eight new 1:1 metal complexes of general formula $M^{II}X_2L{\cdot}nH_2O$ have been isolated (L = 1,3–dimethyllumazine (DLM) or 1,3,6,7–tetramethyllumazine (DLMD); M = Cu, Cd, Hg, Pd and Pt; X = Cl^- or NO_3^-). The experimental techniques used for their structural characterization were thermal (TG and DSC) and spectral methods (IR, ^{13}C and ^1H–NMR and EPR) and magnetic measurements (77–290 K). Single-crystal X-ray diffraction studies have been performed on the complexes $[CuCl_2(DLMD)(H_2O)]{\cdot}H_2O$ (**1**), $[HgCl_2(DLMD)]$ (**2**) and $[HgCl(NO_3)(DLMD)]$ (**3**). In all the complexes, the lumazine-derived ligands seem to be coordinated in bidentate form through the N5 and O4 atoms. The complex **1** shows a monomeric five-coordinated structure in which the coordination polyhedron can be best described as a trigonal bipyramid. The equatorial plane is occupied by two chlorine atoms (Cu–Cl 2.268 and 2.261 Å) and an oxygen O(4) from the organic ligand (Cu–O(4) 2.294 Å), whereas the apical positions were designed by a coordinated water molecule and the N(5) atom of the bidentate pteridine ligand (Cu–O(1W) 1.950 Å and Cu–N(5) 2.038 Å). The crystal structure is conformed by an extense hydrogen bonds scheme in which the non-coordinated water molecule plays an important role. In the compound **2**, the pteridine ligand interacts only weakly with the Hg(II) ion (Hg–O(4) 2.772 Å and Hg–N(5) 2.675 Å); the structure must be described as an adduct between the $HgCl_2$ and the organic ligand in which the molecules of metallic salt retain their identity (Hg–Cl 2.284 and 2.288 Å). These units are weakly paired through long interactions of each metal centre with chloride ions of a neighbour molecule (Hg···Cl 3.664 Å). The mixed complex **3** displays a polymeric structure in which the nitrate groups act as bridging bifurcate ligands between two Hg(II) ions through only one of their three oxygen atoms. The coordination polyhedron around the Hg(II) ion must be described as a trigonal bipyramid in which the metal is surrounded by the O(4), O(1N) and O(1N′) atoms in the equatorial plane at distances of 2.551, 2.563 and 2.618 Å, respectively. In the axial positions, a terminal chloride ligand (Hg–Cl(1) 2.307 Å) and the N(5) atom of pteridine ligand (Hg–N(5) 2.208 Å) can be found.

The biological importance of lumazines and pterines has been extensively pointed out. Their capability to undergo electron-transfer reactions through their potentially metal-chelating α–carbonylpyrazine moiety [1, 2] have promoted their use as model to determine the reactivity metal sites in several enzymes [3–13]. Also, they have been used as a basic skeleton to construct extended hydrogen bonded systems to explain the cooperative interaction between electron transfer and proton transfer in hydrogen-bonded charge-transfer systems [14–16].

There are a few structurally characterized compounds in which these organic compounds act as ligand [17–27]. In this way, and following our research program focused to the structural characterization of metal complexes with lumazine (pteridin–(1*H*,3*H*)–2,4–dione) methylated derivatives, we have already published the molecular and crystal structure of several complexes $[ML_2(H_2O)_2]X_2{\cdot}nH_2O$ [28–31] (X = nitrate or perchlorate) containing both 1,3–dimethyllumazine and 1,3,6,7–tetramethyllumazine, hereafter denoted as DLM and DLMD. In this paper, we now report the study of eight new $MLX_2{\cdot}nH_2O$ complexes, where M = Cu(II), Cd(II), Hg(II), Pd(II) and Pt(II), L = DLM and DLMD, and X = chloride or nitrate.

EXPERIMENTAL SECTION

Synthesis

The pteridine-derived ligands were prepared from glyoxal (for DLM) or dimethylglyoxal (for DLMD) and 5,6–diamino–1,3–dimethyluracil, as described elsewhere [28].

The synthesis of the complexes was carried out as follows:

$Cu(NO_3)_2(DLM){\cdot}3H_2O$ and $CuCl_2(DLMD){\cdot}2H_2O$. 1 mmol of pteridine ligand dissolved in hot MeOH (*ca.* 50 ml and 50°C) was reacted, slowly with stirring, with 1 mmol of the corresponding copper salt dissolved in the minimum amount of methanol. The resulting solution was allowed to stand at room temperature. By evaporation over several days, the crystalline green solids were isolated.

$Cd(NO_3)_2(DLM){\cdot}2H_2O$. To a hot aqueous solution of DML (*ca.* 50 ml, 50°C and 0.5 mmol), 1 mmol of cadmium nitrate was added under continuous stirring. On evaporating the resulting solution at room temperature, a yellow solid complex was isolated.

$HgCl_2(DLM)$ and $HgCl_2(DLMD)$. On heating at 40–50°C, 1 mmol of pteridine ligand was dissolved in MeOH. This solution was mixed and stirred with another containing 1 mmol of mercury(II) chloride in the minimum amount of MeOH. After standing a few days, the solid complexes were isolated.

$HgCl(NO_3)(DLMD)$. A hot solution (50°C, 50 ml, MeOH/H_2O 1:1) containing 1 mmol of DLMD ligand was treated with 1 mmol of mercury(II) nitrate dissolved in the minimum volume of water. On adding the metallic salt, the solution, initially orange and clear, became opaque and yellow. To remove the turbidity, 5 ml of concentrated hydrochloric acid (25%) was added drop by drop until the solution was clear. On cooling to room temperature, orange crystals of the complex were obtained.

$PdCl_2(DLM)$ and $PtCl_2(DLM)$. 1 mmol of DLM ligand dissolved in hot MeOH (*ca.* 50 ml and 50°C) was reacted, slowly with stirring, with 1 mmol of either Na_2PdCl_4 or K_2PtCl_4 dissolved in the minimum amount of methanol. In both cases, the resulting solution was allowed to stand at room temperature and after a few minutes, a brown solid appeared.

All the solids were filtered off, washed with ethanol and diethylether and air dried. The analytical data, color, conductivity values ($mho{\cdot}cm^2{\cdot}mol^{-1}$) were as follows: $Cu(NO_3)_2(DLM){\cdot}3H_2O$ (green, 105), found 22.6%C, 3.5%H, 20.0%N, 13.2%H_2O, calcd. 22.2%C, 3.3%H, 19.4%N, 12.5%H_2O; $CuCl_2(DLMD){\cdot}2H_2O$ (green, 43), found 30.5%C, 4.2%H, 14.2%N, 9.8%H_2O, calcd. 30.7%C, 4.1%H, 14.3%N, 9.2%H_2O; $Cd(NO_3)_2(DLM){\cdot}2H_2O$ (yellow, 86), found 20.5%C, 2.5%H, 18.0%N, 7.8%H_2O, calcd. 20.7%C, 2.6%H, 18.1%N, 7.7%H_2O; $HgCl_2(DLM)$ (orange, 14), found 20.7%C, 1.8%H, 12.3%N, calcd. 20.7%C, 1.7%H, 12.1%N; $HgCl_2(DLMD)$ (yellow, 11), found 24.2%C, 2.4%H, 11.3%N, calcd. 24.2%C, 2.5%H, 11.4%N; $HgCl(NO_3)(DLMD)$ (orange, 85), found 22.9%C, 2.4%H, 13.7%N, calcd. 23.2%C, 2.3%H, 13.5%N; $PdCl_2(DLM)$ (brown, 58), found 26.6%C, 2.2%H, 15.2%N, calcd. 26.0%C, 2.2%H, 15.2%N; $PtCl_2(DLM)$ (brown, 13), found 21.2%C, 1.9%H, 12.4%N, calcd. 21.0%C, 1.8%H, 12.2%N.

Crystallographic studies

The structures were solved using a Siemens P4 diffractometer with MoKα radiation ($\lambda = 0.71073$ Å). Data were semiempirically corrected by absorption (ψ scans). Other crystal data and structure refinement details are given in Table 1. Non-H atoms were located in successive ΔF maps and refined anisotropically by full-matrix least-squares on F^2; hydrogens from the ligand were idealized whereas those of water molecules were refined with fixed O–H (0.86 Å) and H–H (1.40 Å) distances. The isotropic displacement coefficient for H-atoms was taken as 1.2 times the isotropic displacement parameter of the parent atom.

All calculations and drawings have been performed using the Siemens SHELXTL PLUS system.

Apparatus

Microanalyses of C, H and N were performed in a Fisons EA1108 apparatus; the water content of the complexes were determined from the TG plot. Conductivity measurements have been carried out using 10^{-3} M freshly prepared dimethylformamide solu-

tions on a Hanna HI8820 instrument. TG and DSC studies were carried out under pure air on a Mettler TA-3000 system (TG-50 thermobalance and DSC-20 differential scanning calorimeter), using *ca.* 5 mg of sample and a 10°C·min^{-1} heating rate. Infrared spectra were measured on a Perkin-Elmer FT-IR 1760-X (KBr pellets, 4000–400 cm^{-1}) and Perkin-Elmer 983-G spectrophotometer (polyethylene pellets, 600–180 cm^{-1}). The electron paramagnetic resonance spectra were obtained in the X-band at room temperature on a Bruker ESP 300E apparatus, with a microwave frequency of 9.79 GHz and a modulation frequency of 100 kHz. Magnetic measurements were carried out on a Manics DSM-8 system between 77 and 290 K.

RESULTS AND DISCUSSION

Crystallographic studies

The molecular structure of the complex $[CuCl_2(DLMD)(H_2O)]\cdot H_2O$ is shown in Fig. 1. The metal ion is surrounded by a pteridine ligand, in bidentate form through N(5) and O(4) atoms, two chloride and a water molecule, the other water molecule being linked to the first by hydrogen bonding.

Bond distances and angles around the metal ion are listed in Table 2. A detailed analysis indicates that the N(5)–O(4) edge substended by the bidentate pteridine ligand is perpendicular (89.9°) to the Cl(1)–Cl(2) edge, which shows that the coordination polyhedron may be described as a distorted trigonal bipyramid [32], whose equatorial plane is formed by the atoms O(4), Cl(1) and Cl(2), the N(5) and O(1W) being in the apical positions. The ratio between apical and equatorial bond lengths is 0.88, which indicates that the TBP is flattened. This fact does not satisfy the electron pair repulsion model since, following this theory, the ligands in equatorial positions must be less repelled than those in apical positions, resulting in an elongation of the coordination polyhedron. The explanation may be found if we consider that the molecules which fit the VSEPR model usually contain relatively simple M–L bonds and ligands with low π-bonding capability (type α) [32]. Therefore, in the

Equivalent positions: (a) 1/2−x,y+1/2,1/2−z; (b) 1/2−x,y−1/2,1/2−z

present complex, the presence of a more complicated type of metal–ligand bonding may be suspected (type β complexes), this assumption being in according with the π–bonding capability through the N5 atom found in the methylated derivatives of lumazine by means of semiempirical methods [33]. Also, the geometry of the coordination polyhedron has been quantified in terms of trigonal bipyramid (TBP) and tetragonal pyramid (TP)limits as indicated by Galy, the dihedral angles of the polyhedron being defined following Muetterties

and Guggenberger [34, 35]. The results point out that the polyhedron can be best described as a trigonal bipyramid because it only displays 15% TP (85% TBP). The three equatorial donor atoms and the metal ion are virtually coplanar, the latter being 0.042 Å displaced from this plane. The mean values of the three angles over Cu atom towards O(1W) and towards N(5) atoms are 91(1)° and 87(6)°, respectively; the O(1W)–Cu–N(5) angle is 170.0°.

The metallic atom and the DLMD ligand are practically coplanar (deviation 0.005 Å). The organic ligand is also planar, the atoms more deviated from the mean plane being C(2) (endo 0.043 Å) and C(1) (exo 0.102 Å). The chelate and pteridine mean planes are angled by 179.0°. The metal–ligand distances are in the range cited in the bibliography for analogous compounds [17–31].

The values of bond lengths and angles in the DLMD ligand for the three compounds are very similar showing, as also reported elsewhere [14, 26, 28–31], a great electronic delocalization. The C4═O4 bond (*ca.* 1.23 Å) is a little longer than the C2═O2 (*ca.* 1.20 Å) as consequence of the O4-coordination.

In Fig. 2, a view of the unit cell of the copper compound together with some geometrical features of the hydrogen bonds are shown. There is a hydrogen bond O(1W)–H···O(2W) (x,y,z) which links the non-coordinated water molecule with the complex moiety. The coordinated water molecule also establishes an intermolecular hydrogen bond with a neighbour chlorine atom O(1W)–H···Cl(2) (1/2−x,y−1/2,z). The crystallization water also acts as donor in other two intermolecular hydrogen bonds, with the atoms O(2) (x,1/2−y,z−1/2) and Cl(1) (x−1/2,y,−z−1/2). The hydrogen bonding pattern can be described as a tridimensional network in which each molecule is attached to three other ones, the non-coordinated water molecule playing a fundamental role.

The structure of two-paired molecules of [$HgCl_2$(DLMD)] is shown in Fig. 3. In this compound, the interactions between the organic ligands and metal ions take place in the usual way for the lumazine-derived ligands, this is through N(5) and O(4) atoms, but these interactions (Hg–N(5) 2.675 Å, Hg–O(4) 2.772 Å) are weaker (see Table 2) if compared with the Hg–Cl distances (2.284 and 2.288 Å). These Hg–Cl lengths are slightly longer than those found in the solid $HgCl_2$ (2.25 Å) [36]. The Cl(1)–Hg–Cl(2) angle, 166.66°, is near to exact lineality (180°) found in $HgCl_2$. Therefore, this compound could be an addition compound between DLMD and mercury(II) chloride, in which practically none of them have lost their identity. The structural features of this compound are very similar to those reported for the dichloro–(octachloro– 1,10–phenantroline–N,N′) mercury(II), in which there also are very long Hg–N bonds (2.269(3) and 2.586(3) Å), and *quasi*-linear $HgCl_2$ moieties (∠ Cl–Hg–Cl 162.19(6)°) [37].

The metal is distanced 1.193 Å from the pteridine plane; the direction Cl(1)–Cl(2) defines an angle with

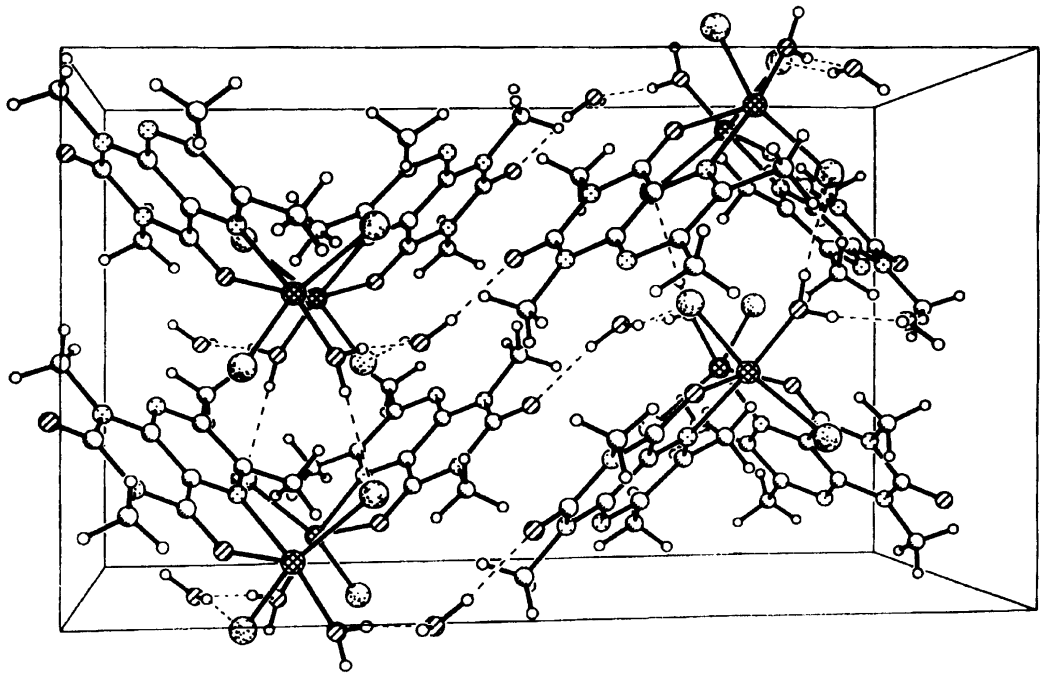

Fig. 2. A view along the *a* axis of the unit cell of [$CuCl_2$(DLMD)(H_2O)]·H_2O. Hydrogen bonds are as follow (A···B: d(A···B),Å, ∠(A–H···B),°): O(1W)···O(2W): 2.648(5), 171; O(1W)···Cl(2)(1/2−x,y−1/2,z): 3.175(4), 164; O(2W)···O(2)(x,1/2−y,z−1/2): 2.844(5), 172; O(2W)···Cl(1)(x−1/2,y,−z−1/2): 3.198(4), 167.

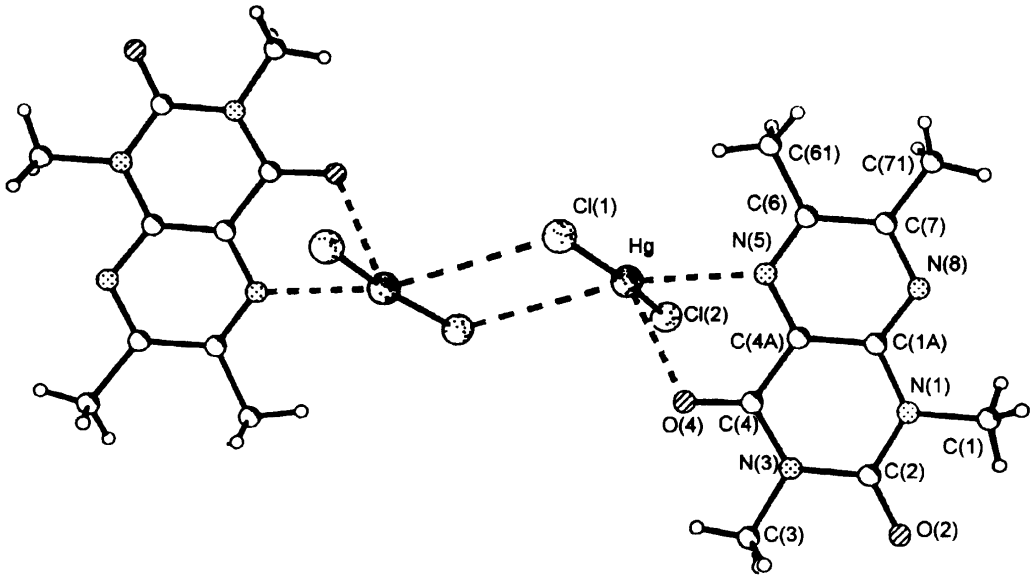

Fig. 3. A view of two-paired molecules of $[HgCl_2(DLMD)]$, showing the atom numbering.

this plane of 37.9°. As in previous copper complex, the pteridine ligand is planar, the atoms more deviated being O(2) (exo 0.129 Å) and C(2) (endo 0.052 Å).

In addition to the above-described bonds, the molecular units are paired (see Fig. 3) through very long-distance interactions Hg···Cl(2) (2 − x, − y,1 − z; 3.664 Å). The planes defined by two $HgCl_2$ units are roughly perpendicular to the *b* axis. The mean plane of the pteridine is parallel to [0 3 1] direction and the Cl(1)–Cl(2) segment of each unit is practically aligned (12.3°) with the *c* axis.

The molecular unit of $[HgCl(NO_3)(DLMD)]$ is shown in Fig. 4 and the bond distances and angles around the metal ion are given in Table 2. Although apparently it seems to be closely related with the above described mercury complex, it is really very distinct from the structural point of view. In this compound, there are Hg–O(4) (2.551 Å) and Hg–N(5) (2.208 Å)

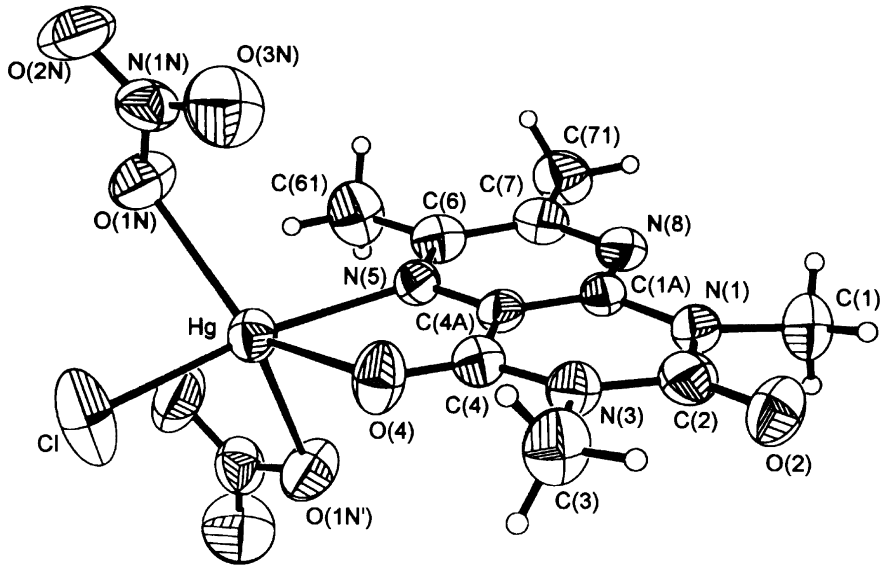

Fig. 4. Molecular structure of the monomeric unit of $[HgCl(NO_3)(DLMD)]$ with the numbering scheme (ellipsoids at 50% probability).

bonds significantly shorter and stronger than those found in the previous mercury complex. In addition, there are a terminal Hg–Cl bond (2.307 Å) and two Hg–O bonds with nitrate-bridging groups (Hg–O(1N) 2.563 Å, Hg–O(1N′) 2.618 Å). The metal ion is five-coordinated and the coordination polyhedron can be described as a distorted trigonal bipyramid, but in this case the geometry is a little nearer to TBP than in the above-described copper complex because it has 87% TBP [34]. The equatorial plane is designed by O(4), O(1N) and O(1N′) atoms and the axial positions are occupied by Cl and N(5) atoms. In this polyhedron, the angle defined by N(5)–O(4) and O(1N)–O(1N′) is 93.4°. The mean angles over the Hg towards Cl and towards N(5) — this is over and under the equatorial plane — are 96 and 84°, respectively, the metal being 0.221 Å over the equatorial plane. The axial Cl–Hg–N(5) angle is 168.8°. As in the previous described copper complex, the trigonal bipyramid is also flattened, the axial bonds being *ca.* 12% shorter than those in equatorial positions. The coordination mode of the nitrate is similar to the one found in the chloro–pyridyl–mercury(II) nitrate, but in this compound the interaction between O–nitrate bifurcate bridges and Hg atoms is significantly weaker (Hg–O 2.9 Å) [38].

The DLMD skeleton is practically planar, the greatest deviated atoms being N(3) (endo 0.056 Å) and C(1) (exo 0.229 Å). The metal ion is distanced by 0.359 Å from this mean plane.

In the Fig. 5, a portion of the polymeric chain is shown. The nitrate anion acts as bridging ligand between two metal centres but only through one of their oxygen atoms, thus making a zig-zag chain which follows the *b* direction with the pteridine planes parallel to the [5 0 4] direction. The polymeric chains are linked to each others through Van der Waals' interactions.

Conductivity and thermal studies

Conductivity values of complexes $CuCl_2(DLMD)\cdot 2H_2O$, $HgCl_2(DLM)$, $HgCl_2(DLMD)$ and $PtCl_2(DLM)$, obtained in DMF solutions, clearly indicate their non-electrolyte character. The other Pd(II), Cd(II) and Hg(II) compounds show conductivity values corresponding to 1:1 electrolytes, but, it is possible that some degree of solvolisis exists, since, as it has been shown from X-ray diffraction and far-infrared spectra, in all cases, the anions are coordinated to the metal ion. Otherwise, the $Cu(NO_3)_2(DLM)\cdot 3H_2O$ has 1:2 electrolyte molar conductivity, corroborating the presence of free nitrate groups [39].

The main features of thermal studies (TG and DSC) were as follows. In $Cu(NO_3)_2(DLM)\cdot 3H_2O$ and $CuCl_2(DLMD)\cdot 2H_2O$, DSC curves show two different endothermic effects assignable to the loss of both crystallization and coordination water molecules. The DSC peak temperatures were 95 and 120°C for the first one and 75 and 149°C, for the second one. These endothermic effects were followed by a third at around 180°C, without weight loss, assignable to the melting of the anhidrous compounds. For the $Cd(NO_3)_2(DLM)\cdot 2H_2O$, the presence of only one endothermic peak for the loss of the water may suggest that both molecules are structurally equivalent.

Infrared and NMR spectra

The infrared spectra of these complexes are very similar, which indicates that the coordination of pteridine ligands takes place in the same way. Also, the spectral data are very similar to those reported elsewhere for other complexes with DLM and DLMD ligands [28–31]. Two bands, one slightly over

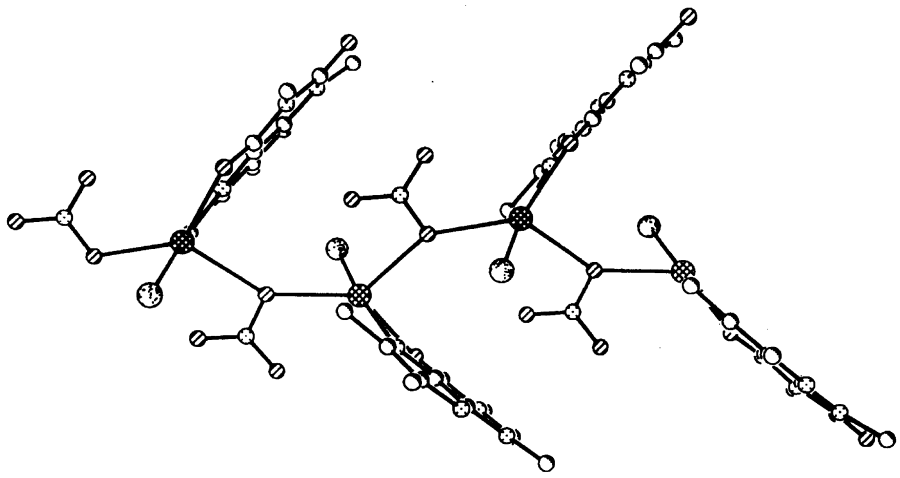

Fig. 5. View, along [5 0 4] direction, of the zig-zag polymeric structure of $[HgCl(NO_3)(DLMD)]$.

1700 cm^{-1} (1705–1728) and another from 1635 to 1660 cm^{-1} may be assigned to a combination of the stretching vibrations of both exocyclic carbonyl groups, the first, weaker, being mainly due to ν(C2═O) whereas the second must be assigned to ν(C4═O). In all cases, these bands appear shifted to lower wavenumber with respect to their position in the IR spectrum of free ligands (*ca.* 1725 and 1685 cm^{-1}, respectively), but, as it may be expected due to the involvement of O4 atom in the coordination, this displacement is stronger in the second band than in the first one. Other vibration modes related to potential donor atoms may be assigned as follows: ν(C═N) (1558–1596 cm^{-1}), ν(C═C)+ν(C–N) (two bands at 1445–1475 and 1270–1305 cm^{-1}). These bands also appear shifted to higher wavelengths with respect to their position in the IR spectrum of the free ligands [28–31]. In the IR spectra of the nitrate-containing complexes, a band corresponding to ν(N–O) of the nitrate group [40] appears at 1385 cm^{-1}; however, in the $Cu(NO_3)_2(DLM)\cdot 3H_2O$ spectrum, this band is very strong and sharp, which may indicate the presence of free nitrate, whereas in the Cd(II) and Hg(II) complexes, this band is broadened due to the behavior of the nitrate anion as ligand [40]. In the far-infrared region, chloro-complexes display bands assignable to ν(M–Cl) mode at the following wavenumbers (cm^{-1}): $CuCl_2(DLMD)\cdot 2H_2O$, 300; $HgCl_2(DLM)$, 343; $HgCl_2(DLMD)$, 367; $HgCl(NO_3)(DLMD)$, 355; $PdCl_2(DLM)$, 348 and 366; $PtCl_2(DLM)$, 321. In all cases, this bands must be attributed to terminal M–Cl bonds and, in the two latter compounds, both M–Cl bonds must be in *cis* position [41].

Within experimental error, ^1H and ^{13}C–NMR spectra of Cd(II), Hg(II), Pd(II), and Pt(II) complexes (DMSO–d_6 solution) display signals at the same values of chemical shift than the free ligands [30]. This fact may be justified taking into account that, on coordinating to the metal, the π electronic density in the ligand remains practically unaffected, although an alternative explanation based on the existence of solvolysis processes in both DMF and DMSO solutions, as suggested by conductivity values, cannot be rejected.

EPR spectra and magnetic measurements

The complex $Cu(NO_3)_2(DLM)\cdot 3H_2O$ displays an axial EPR powder spectrum (Figure 6a) with $g_\perp = 2.04$ and $g_\parallel = 2.40$ and is in accordance with the existence around the Cu(II) ion of a square-plane based geometry with the tetragonal axes aligned [42, 43]. The values of magnetic susceptibility have been fitted to the Curie–Weiss' law ($1/\chi_M = (T-\theta)/C$) (Figure 7a) with the following parameters: r = 0.9929, C = 0.220(6) cgsu·K·mol^{-1} and $\theta = -86(9)$ K. The high value of the latter parameter and the positive slope of the χT *versus* T plot may be indicative of the existence of a strong antiferromagnetic coupling between metallic centres, which could justify the low value found for the effective magnetic moment (1.2 ± 0.1 BM) if compared with the one expected in mononuclear magnetically diluted Cu(II) compounds (1.7–2.2 BM) [44]. This permits us to suggest the existence of any interaction between metal centres, although, in order to corroborate this fact, both the knowledge of structure and the magnetic behaviour up to 4 K would be needed. The value of the effective magnetic moment (1.98 ± 0.01 BM) and the fit of the magnetic susceptibility values of the $[CuCl_2(DLMD)(H_2O)]\cdot H_2O$ at different temperatures (Fig-

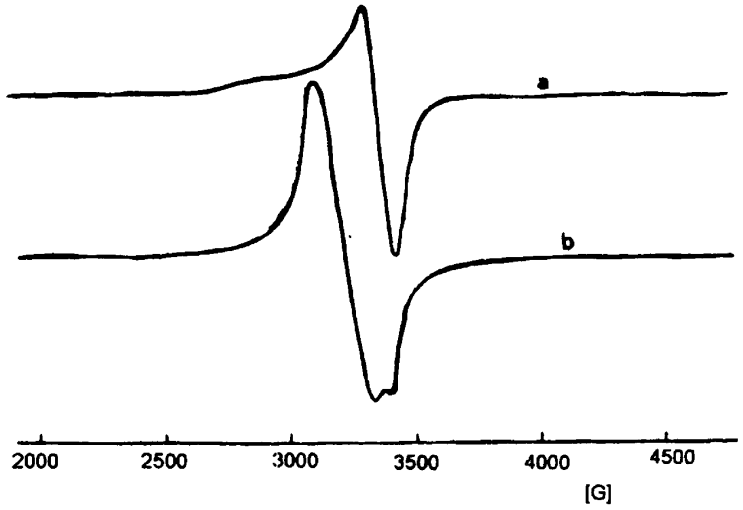

Fig. 6. EPR powder spectra of (a) $Cu(NO_3)_2(DLM)\cdot 3H_2O$ and (b) $[CuCl_2(DLMD)(H_2O)]\cdot H_2O$.

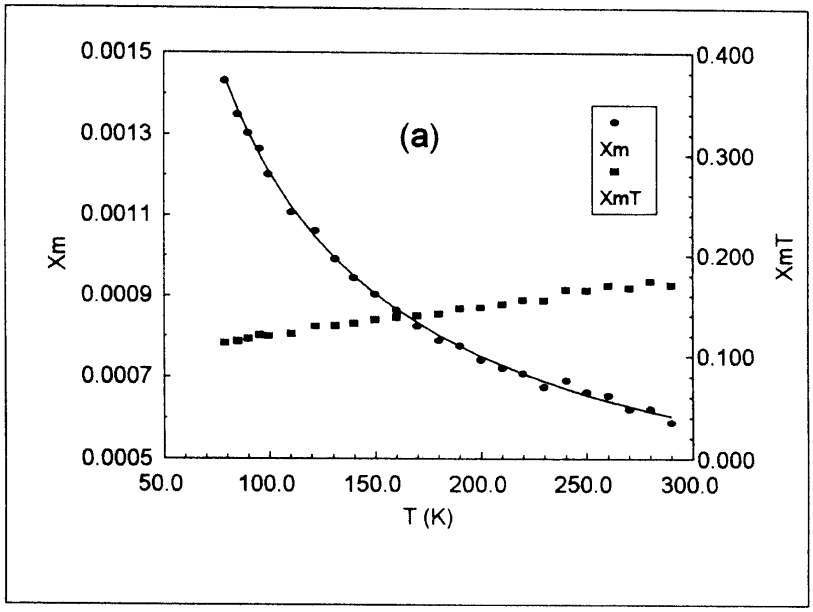
ure 7b) to the Curie–Weiss' law ($C = 0.425(5)$ cgsu·K·mol^{-1}, $\theta = 12(3)$ K, $r = 0.9987$) clearly corroborate the existence of monomeric magnetically diluted units [44], as it has been shown from X-ray diffraction studies. Also, the EPR spectrum (Figure 6b) — axial, $g_{\perp} = 2.05$ and $g_{\parallel}$ not observed — may be explained on the basis of the existence of a trigonal bipyramid [43].

CONCLUSIONS

About the structure of the complexes which have not been studied by X-ray diffraction, the following suggestions could be made. The spectral and thermal data of $Cu(NO_3)_2(DLM)\cdot 3H_2O$ complex allow us to propose a structure based in roughly square-planar $[Cu(DLM)(H_2O)_2]^{2+}$ cations, free nitrate anions and



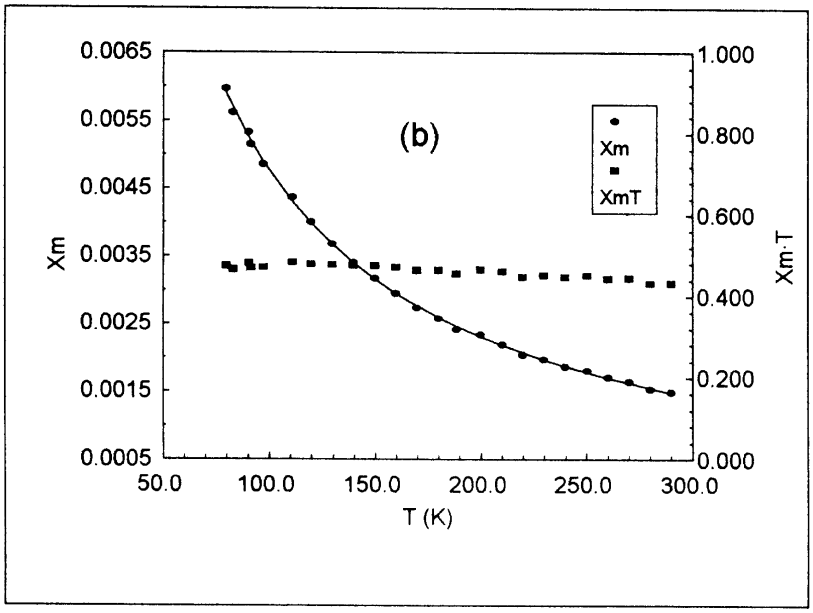


Fig. 7. Magnetic susceptibility values at different temperatures of (a) $Cu(NO_3)_2(DLM)\cdot 3H_2O$ and (b) $[CuCl_2(DLMD)(H_2O)]\cdot H_2O$.

one water molecule only linked by hydrogen bonds, which justifies the existence of two types of water molecules and the possibility of antiferromagnetic interactions between the square-planar Cu(II) units. For the $Cd(NO_3)_2(DLM)\cdot 2H_2O$ complex, an eight-coordinate structure designed by bidentate O,O′–nitrate and N5,O4–DLM ligands and two water molecules may be proposed; this structure is very related with the one reported for the $[Cd(NO_3)_2(DLMD)_2]$ complex [30]. The structure of the $HgCl_2(DLM)$ may be very similar to that found for its analogous DLMD compound. Finally, the two Pd(II) and Pt(II) studied complexes seem to be a *cis*–MCl_2(N5,O4–DLM) structure.

Supplementary material—For each reported structure, a list of structure factors and tables with atomic coordinates and isotropic thermal parameters for non-H atoms, bond, lengths and angles, anisotropic temperature factors for non-H atoms, hydrogen atom coordinates, equations of planes and dihedral angles (40 pages) are available.

Abstract—A series of seven-coordinate tungsten(II) nitrile complexes of the type $[WCl(SnCl_3)(CO)_3(NCR)_2]$(**1**–**4**), R=Me, Et, *n*-Bu, Ph, has been synthesized. These new complexes have been characterized by IR, NMR and UV-vis spectroscopy. In addition single-crystal X-ray diffraction was used to structurally characterize $[WCl(SnCl_3)(CO)_3(NCMe)_2]$(**1**). The most prominent feature of complex **1** is the facility by which acetonitrile and carbonyl ligands can be replaced by other ligands. Complexes were isolated in which CO and acetonitrile ligands were substituted by alkyne ligands. The alkyne tungsten(II) complexes **5**–**8** formed were structurally characterized by IR and NMR spectroscopy. The complex **1** has been found to be an active catalyst for the polymerization of phenylacetylene. The structures and mechanisms of the formation of various new types of complexes and their role in the catalytic process are discussed. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: tungsten; tin; crystal structure; nitrile complexes; alkyne complexes; polymerization of phenylacetylene.

A number of seven-coordinated compounds with a tungsten-tin or a molybdenum-tin bond have been prepared by reaction of tungsten- and molybdenum-substituted carbonyls, $[M(CO)_4L_2]$ (2L = 2,2′-bipyridyl, 2,5-dithiahexane, 1,2-bis(diphenylphosphino)ethane, RN=CHCH=NR, R = *i*-Pr, *n*-Bu or Cy, two molecules of acetonitrile) and tin tetrahalides or organometallic halides, R_nSnCl_{4-n}, R=Me, Bu, Ph [1–10]. Among them acetonitrile compounds are especially interesting as useful starting materials in which the labile acetonitrile groups can be easily replaced by other ligands [10–17]. This can be the basis for synthetic procedures, including the preparation of alkene and alkyne derivatives as well as a model of a catalytic centre. In the reaction of $[WCl(SnCl_3)(CO)_3(NCMe)_2]$(**1**) with norbornadiene two acetonitrile ligands are replaced by one molecule of norbornadiene and $[WCl(SnCl_3)(CO)_3(\eta^4\text{-NBD})]$ is formed [17]. In this paper we present results concerning the reactivity of complex **1** towards alkynes. Complexes were isolated in which CO and acetonitrile ligands were replaced by alkyne ligands. The complex **1** has been found to be an active catalyst for the polymerization of phenylacetylene.

The unknown coordination geometry of acetonitrile compound **1** together with the fact that compounds of this class have been used for synthetic purpose on several occasions [10–17], make it an interesting problem for X-ray structure analysis.

EXPERIMENTAL

All operations were carried out in an inert atmosphere using standard Schlenk techniques. All solvents and liquid reagents were dried and distilled over CaH_2. IR spectra (KBr pellets) were recorded on an FT-IR Model-400 Nicolet instrument and Far-IR spectra (500–50 cm^{-1}) were recorded with a Brücker IFSv instrument in Nujol mull on a polyethylene film. ^1H and $^{13}C\{^1H\}$ NMR spectra were run using a Bruker AMX-300 spectrometer. UV-visible absorption spectra were recorded on a Hewlett–Packard 8452A spectrophotometer. The analysis of the catalytic reaction products was performed on a Hewlett–Packard GC-MS system and by ^1H NMR spectroscopy.

Synthesis of $[WCl(SnCl_3)(CO)_3(NCMe)_2]$(**1**)

To $[W(CO)_4(NCMe)_2]$ [18] (1.8 g, 4.7 mmol) dissolved in CH_2Cl_2 (50 cm^3) with continuous stirring

* Author to whom correspondence should be addressed.

under a stream of nitrogen, was added a stoichiometric amount of $SnCl_4$ (0.56 cm^3, 4.7 mmol) by means of a syringe. The mixture was stirred for 6 hours, during which time the yellow solution gradually changed to an orange colour, while the ν(CO) frequency of $[W(CO)_4(NCMe)_2]$ disappeared. After the completion of the reaction, the solution was separated from some insoluble blue powder by filtration and evaporated to dryness. The crystallization from CH_2Cl_2/heptane produced the analytically pure dark orange crystalline complex **1** (Table 1).

Preparation of $[WCl(SnCl_3)(CO)_3(NCR)_2]$, **2** (R=$C_2H_5$); **3** (R=$C_3H_7$); **4** (R=$C_6H_5$).

1 was dissolved in an appropriate nitrile and the solution was stirred for 60 min. Filtration, followed by removal of the solvent *in vacuo*, gave a residue coloured from orange **2** to red **4**, which was recrystallized from CH_2Cl_2-heptane giving a pure crystalline bis(nitrile) complex **2**-**4** (Table 1).

Reaction of **1** *with PhC≡CPh*

To a solution of **1** (0.2 g, 0.33 mmol) in 15 cm^3 of CH_2Cl_2 was added PhC≡CPh (0.12 g, 0.66 mmol) in 5 cm^3 of CH_2Cl_2. The mixture was stirred for two hours, after which time the full conversion of **1** was observed by IR. Evaporation of the solvent followed by washing with heptane produced a mixture of compounds identified by IR and NMR studies as $[WCl_2(CO)(NCMe)(PhC{\equiv}CPh)_2]$ **5**, and $[WCl_2(NCMe)_2(PhC{\equiv}CPh)_2]$ **6** (Table 2). Crystallization of the above greenish-yellow solid from CH_2Cl_2/heptane always produced mixture of the compounds **5** and **6**, but with different molar ratios depending on reaction time. Beside **5** and **6**, a side products were formed. One was identified by IR: ν(CO) 2069 (vw), 1939 (vs) and ^{13}C NMR: δ 202.47 (1 CO), 196.54 (4 CO) ppm as $[W(CO)_5SnCl_2]$ and other was separated by filtration as white, insoluble in CH_2Cl_2 solid of $SnCl_2$.

Reaction of **1** *with phenylacetylene* (*PA*)

A slight excess of PA (0.125 cm^3, 1.18 mmol) was syringed into a stirred CH_2Cl_2 solution (15 cm^3) of **1** (0.2 g, 0.33 mmol) at room temperature. Immediately the solution became dark orange. Stirring for 2 hours followed by the evaporation of the solvent under low pressure gave an orange solid, which was washed out with a small portion of heptane and dried *in vacuo* to give a greenish yellow mixture of compounds containing mainly $[WCl_2(CO)(NCMe)(PhC{\equiv}CH)_2]$ **7** and $[WCl_2(NCMe)_2(PhC{\equiv}CH)_2]$ **8** as was shown by ^1H and $^{13}C\{^1H\}$ NMR spectra (Table 2). The heptane extract contained organic products: 1,2,4-triphenylbenzene (41%), 1,3,5-triphenylbenzene (39%), different isomers of diphenylbutadienes (19%), and a dimer of PA detected by MS as 1*H*-indene-1-(phenylmethylene) (1%).

Procedures for testing catalytic activity and characterization of organic products

Polymerization experiments were carried out in a reaction mixture composed of toluene or CH_2Cl_2 as solvent, *ortho*-xylene (the internal chromatographic standard), phenylacetylene (PA)(1 mol dm^{-3}), and complex **1**(PA/W 100). The reaction mixture was stirred by a magnetic stirrer at room temperature in a 50 cm^3 glass reactor provided with a septum through which liquid reactants were introduced and removed by a syringe. The gas-samples were removed with a syringe and injected into the PORA PLOT-Q 15 m column of the chromatograph fitted with a flame ionization detector. The conversion of PA, monitored by chromatography, was not higher than 10% after 24 h reaction. For the analysis of PA reaction products, reactions were continued for 24 h and then methanol was added. The polymer (PPA) was collected, washed with methanol, dried and weighed. The polymerization yield (%) is defined by comparing the polymer weight to the weight of the PA used and 24 h reaction catalyzed by **1** was about 7%. The polymer was analysed by ^1H NMR, IR spectroscopy and gel-permeation chromatography. Molecular weights of the PPA were measured using $CHCl_3$ solutions, a refractive index monitor and a Plgel 10 m MIXED-B column. The value recorded ($M_w = 5 \times 10^3$) is the weight of polystyrene that would exhibit the chromatogram observed.

The filtrate obtained after the precipitation of the polymers was evaporated to dryness and the CH_2Cl_2 solution of the residue was investigated by GC-MS (HP5 25 m column). Analysis showed 1,2,4-triphenylbenzene (45%), 1,3,5-triphenylbenzene (34%), different isomers of diphenylbutadienes (16%), and a dimer of PA detected by MS as 1*H*-indene-1-(phenylmethylene) (5%).

^1H NMR spectra of the polymers were recorded in a $CDCl_3$ solution at 300 MHz. The microstructural details of the polymers were deduced from the ^1H NMR integrals [19] as mainly *trans*.

Crystallography

Crystal data for **1**. $C_7H_6Cl_4N_2O_3SnW$, $M = 610.48$, monoclinic, space group $P2_1/m$, $a = 6.803(1)$, $b = 13.669(3)$, $c = 8.640(2)$ Å, $\beta = 102.68(3)^\circ$, $U = 783.9(3)$ $Å^3$, $Z = 2$, $D_c = 2.586$ g cm^{-3}, $F(000) = 556$, μ(Mo-Kα) = 96.04 cm^{-1}. The dark orange crystals of **1** were grown from a CH_2Cl_2/toluene/heptane solution. The crystals were stable enough when handled in an inert atmosphere or coated with a light hydrocarbon oil to protect them from the atmosphere. Crystallographic data were

obtained for a crystal approximately $0.10 \times 0.10 \times 0.15$ mm using a KM4 κ-axis computer-controlled [20] four-circle diffractometer operating in the ω-2θ scan mode. All measurements were made using graphite-monochromated Mo Kα radiation ($\lambda = 0.71069$ Å) at 293 (3) K. The accurate cell dimensions and the crystal orientation matrix were determined by a least-squares refinement of the setting angles of 30 carefully centred reflections in the range $20.6^\circ < 2\theta < 37.3^\circ$. A total of 2114 unique reflections were measured, of which 1995 (137 variables) with $I \geq 4\sigma(I)$ in the range 5 to 70° were used to solve and refine the structure in the monoclinic space group $P2_1/m$. A surprisingly high R value ($R_1 = 0.0791$, $wR_2 = 0.1981$) was obtained after first refinement. A difference synthesis at this stage revealed two regions of significant electron density (11.2, 8.0, e/Å^3) located at approximately 0.5 Å from both sides of W(1), Sn(1) and Cl(1) atoms. During refinement the molecule was found to be disordered between three adjacent positions with occupancy factor 0.76, 0.12 and 0.12 for W(1), Sn(1), Cl(1). Further refinement of this three site model gave a final R_1 value of 0.0560 ($wR_2 = 0.1546$). The largest peak in the final difference map was 2.86 e/Å^3. Goodness-of-fit was 1.130. The structure was given a weighting scheme in the form $w = 1/[\sigma^2(F_0^2) + (0.0278P)^2 + 0.0000P]$, where $P = (F_0^2 + 2F_c^2)/3$.

The structure was solved by the heavy-atom method with the SHELXS-86 program [21] and refined by a full-matrix least-squares method, using the SHELXL-93 program [22]. Neutral atomic scattering factors were taken from the SHELXL-93 program [22]. The positions of C-bonded H atoms were calculated assuming typical stereochemistry and three atoms were refined with fixed positions at 0.96 Å from the C atoms to which they were bonded.

The remaining dimensions, positional parameters and equivalent isotropic thermal parameters and anisotropic thermal parameters are deposited in supplementary material.

RESULTS AND DISCUSSION

In 1995 we reported [23] that a photochemical reaction of $W(CO)_6$ with $SnCl_4$ led to the formation of an orange crystalline air-sensitive complex. This was structurally identified by single-crystal X-ray crystallography as the first example of a dinuclear halogenocarbonyl complex of tungsten(II) with a W–Sn bond. When this product is dissolved in toluene and acetonitrile added, an equimolecular mixture of $[WCl(SnCl_3)(CO)_3(NCMe)_2]$(**1**) and $[WCl_2(CO)_3(NCMe)_2]$ is formed immediately [24]. Recrystallization of the mixture from CH_2Cl_2/toluene/heptane produces quite stable orange crystals of **1** while considerable less stable $[WCl_2(CO)_3(NCMe)_2]$ decomposes with loss of carbon monoxide and formation of deep blue, insoluble solid in methylene chloride, most probably the chloro-bridged dimer.

Another method which proved useful in obtaining the compound **1** was the oxidative-addition reaction of $[W(CO)_4(NCMe_2]$ with $SnCl_4$ in dichloromethane. Baker and Bury briefly mentioned the formation of mixture of compounds containing **1** by reaction of $[W(CO)_3(NCMe)_3]$ with $SnCl_4$ in acetonitrile, but without synthetic and spectroscopic details for **1** [10].

The compounds **2**–**4** containing nitriles with a longer carbon chain, were prepared in the reaction of **1** with an appropriate nitrile at room temperature. The compounds **1**–**4** are very soluble in nitriles and in acetone, less soluble in chlorinated solvents (CH_2Cl_2, $CHCl_3$) but insoluble in hydrocarbon solvents. They are air-sensitive in solution but in the solid state it can be stored under nitrogen for a month without decomposition.

Structure of **1**

The molecule $[WCl(SnCl_3)(CO)_3(NCMe)_2]$(**1**), is shown in Fig. 1 together with the atomic numering scheme Selected interatomic bond distances and angles are presented in Table 3.

The environment of the tungsten atom is an almost ideal capped octahedron with the tin atom occupying the unique capping position above an octahedral face defined by the bridging chlorine and two crystallographically equivalent carbonyl groups. The octahedral face that is capped by the $SnCl_3$ group is distorted to allow a close approach of the tin atom. The angles subtended at the tungsten atom by the three atoms determining the capped face are in the range 107.7(8)–108.2(4)°; compared with the opposite face, determined by C(2), N(1) and N(1)^i, where the angles are in the range 80.0(7)–93.3(5)°. Thus, there is a distortion of octahedral symmetry in order to accommodate the tin atom.

In addition one may notice that the molecule of **1** is remarkable in its symmetry. The crystallographic plane of symmetry extends through W, Sn, Cl(1) and

Symmetry elements represented by i: x, 0.5-y, z.

Cl(2). In such an arrangement two acetonitrile ligands are crystallographically equivalent and effectively *cis* with N(1)–W–N(1)^{i} angle 80.0(7)° and the W–N distances identical (2.18(1) Å). Two CO groups in the capped face are mutually *cis* with C(1)–W–C(1)^{i} angle 107.7(8)° and the same W–C distance 2.00(1) Å. The angles between carbonyl groups in the capped and uncapped face are smaller with 76.6(6)° for C(2)–W–C(1) angle.

The W–N–C angle is 178(1)° to evidence that the nitrile ligand is coordinated in an almost linear manner. The C–N lengths of 1.13(2) Å are not significant but are shorter than C–N distance of 1.155 Å observed in free CH_3CN [25]. Comparison of bond length for **1** and tungsten(0) complex, reveals that the W–N distance is shorter in **1**, being 2.18(1) Å *vs.* 2.21 Å(av) in $[W(CO)_3(NCMe)_3]$ [26], while the tungsten-carbonyls distances in **1** are about 0.07 Å longer, being 2.00 Å (av) *vs.* 1.93 Å (av) in tungsten(0) complex. This correlates qualitatively with the expected lower electron density and π-donor ability of the tungsten in the higher oxidation state.

The tungsten atom is seven-coordinate and tin atom is five-coordinate, with one chlorine atom occupying a bridging position between the two metal atoms. The tungsten-tin bond is short at 2.710(1) Å compared to the sum of the relevant covalent radii of 2.97 Å [27, 28]. The W–Sn distances of 2.759(3) [4], 2.731(1) [18], 2.711(1) [29] and 2.737(1) [29] Å have been observed previously. In view of the established π-acceptor properties of the $[SnCl_3]^-$ group it seems probable that the bond does possess some double-bond character [30]. The tin to bridging chlorine distance is 2.840(5) Å, being considerably longer than the other tin-chlorine distances, which are average 2.34 Å, indicates that this bond is much weaker than a tin-chlorine single bond. The tungsten to bridging chlorine distance is 2.511(5) Å and indicates that the bridging chlorine forms a stronger bond with the tungsten while the Sn–Cl bond is weakened. The angle of 60.5(1)° subtended at the chlorine by the tungsten-tin bond agrees with the value 59.9(2)° for bridging chlorine in $[WCl(MeSnCl_2)(CO)_3(C_4H_{10}S_2)]$ [4], 60.5(1)° in $[MoCl(SnCl_3)(CO)_3(C_4H_{10}S_2)](CH_2Cl_2)$ [6] and 61.6(1)° in $[MoCl(MeSnCl_2)(CO)_3(C_{10}H_8N_2)]$ [3]. The form of the tungsten atom coordination in **1** is indeed very similar to the monocapped octahedral geometries observed earlier in W–Sn or Mo–Sn compounds [3, 4, 6]. A common feature of those structures is the presence of a tin atom in the unique capping position and a chlorine atom bridging the W–Sn or Mo–Sn bond.

The tin atom in **1** is five-coordinate with a geometry that is best described as trigonal bipyramidal with the two chlorine atoms occupying the axial sites. The $WSnCl_2$ unit is nearly planar with the tin atom only 0.605(3) Å out of the W–Cl(1)–Cl(2) plane. The Cl(1)–Sn–Cl(3) and Cl(1)–Sn–Cl(3)^{i} angles are identical (89.5(1)°) as are the W–Sn–Cl(3) and W–Sn–Cl(3)^{i} angles (120.4(1)°). However, the Cl(1)–Sn–Cl(2) angle is 168.4(2)°, and the Cl(1)–Sn–W angle is much smaller than 90°, at 53.7(1)°; so the trigonal bipyramid is significantly distorted.

Similar capped octahedral geometry with two crystallographically equivalent nitrile and carbonyl groups seen in **1** has been detected for $[WI_2(CO)_3(NCR)_2]$, R=Me, Et [31]. However, those complexes contain a carbonyl ligand in the unique capping position and two mutually *trans* iodine ligands.

The molecular structure of the recently investigated $[WCl(SnCl_3)(CO)_3(\eta^4\text{-NBD})]$ [17] is best described as a capped trigonal prism with the tin atom lying above a square face formed by the chlorine atom and three carbonyl groups. Unlike the situation in other W–Sn compounds in $[WCl(SnCl_3)(CO)_3(\eta^4\text{-NBD})]$ the chlorine attached to the tungsten does not bridge the W–

Sn bond. The W–Cl bond length is much shorter at 2.454(2) Å and W–Sn distance longer at 2.764(1) Å than in other W–Sn or Mo–Sn compounds [3, 4, 6].

Spectroscopic studies of nitrile compounds **1**–**4**

The carbonyl region of the infrared spectra of the compounds **1**–**4** in KBr are almost identical in showing three carbonyl bands (Table 1). The infrared spectrum of compound **1** shows three carbonyl bands at ν(CO) 2030vs, 1935s(sh) and 1903vs cm^{-1} and is similar to that for the analogous molybdenum-tin complex obtained first time by Baker and Bury, (ν(CO) 2026s, 1939s and 1912vs cm^{-1} [10]) but qualitatively different from that reported by Baker and Bury for the tungsten compound (ν(CO) 2017, 1978 and 1934 cm^{-1} [10]). As noted by Baker and Bury their tungsten complex was extremely unstable to exposure to air and could not be isolated in a pure state. This is marked contrast to the quite good stability of the complex obtained by us. However, IR spectra of **1** in a dichloromethane solution shows more than three bands in the carbonyl stretching region: 2040 (s), 2020 (s), 1970 (m) and 1930 (vs) cm^{-1}. The spectral differences correspond to different coordination geometries, and in a dichloromethane solution distinct isomers of **1** may co-exist, as was proposed previously by Kummer and Graham [1]. In the ν(C≡N) region of the IR spectra for **1** two bands are observed. One is the ν(C≡N) band and the other a combination band resulting from the symmetrical CH_3 deformation and the C–C stretch which borrows its intensity from the ν(C≡N) [25]. For the compound **1** those bands are at 2320 and 2292 cm^{-1}, these are at higher frequencies than the ν(C≡N) band in the free acetonitrile observed at 2268 cm^{-1} [25]. The intensity ratio of the ν(C≡N) band to that of the combination band was found to differ greatly between *cis* and *trans* isomers [25]. Two sharp bands of comparable intensities in the ν(C≡N) region of **1** are consistent with *cis* acetonitrile ligands [25]. The ν(C≡N) frequencies of coordinated propionitrile and butyronitrile in **2** and **3** were observed as one band at 2292 cm^{-1}. The lower frequency region of the infrared spectrum is dominated by the principal absorptions at 344, 325 cm^{-1}, which can be regarded as ν_s and ν_{as} (Sn–Cl) vibration. This is in good agreement with increased frequencies of these bands upon coordination to metal or other ligand. Tin-halide frequencies of $[SnCl_3]^-$ ion were observed in, for example, $^1Et_4N[SnCl_3]$ at 295 (A_1) and 253 cm^{-1} (E) [32].

The similarity of the IR spectra in a solid state of the series of nitrile compounds obtained by us, shows that the most probable solid state structure for those compounds is the same as that of **1** (Fig. 1).

The ^1H and ^{13}C NMR spectra of the nitrile compounds **1**–**4** are very similar and are consistent with the solid-state structure of **1** (Fig. 1). The spectrum shows one carbonyl resonance from three equivalent CO groups and a single signal from each carbon of the two nitriles (Table 1).

The electronic spectrum of **1** is quite similar to those of the starting tungsten (II) compound [23] and shows one strong band at 250 nm with a shoulder at 290 nm which, because of its high intensity and its position is assigned to CT transition π^*(CO)←dπ(W). There is also another band at 398 nm. Because of its relatively low intensity it is assigned to a ligand-field transition.

Reaction of **1** *with alkynes*

When the reaction of **1** with two molecular equivalents of PhC≡CPh at room temperature in CH_2Cl_2 was monitored by IR, the substitution of the CO ligands by an alkyne can be observed. The ν(CO) bands for **1** decrease, while this of the alkyne complex at 2101 (s) appears. The ^1H, ^{13}C NMR and IR spectral data for the reaction product indicate that it is a mixture of two alkyne compounds (Table 2). One compound, with acetonitrile *trans* to CO ligand, two *cis* PhC≡CPh ligands and two *cis* anionic ligands (Cl^-) in the coordination sphere, can be formulated as $[WCl_2(CO)(NCMe)(PhC{\equiv}CPh)_2]$ **5**, which probably has a structure similar to that observed by Baker *et al.* for $[WI_2(CO)(MeCN)(MeC{\equiv}CMe)_2]$ [33]. The other alkyne compound does not contain CO in coordination sphere and can be formulated as $[WCl_2(NCMe)_2(PhC{\equiv}CPh)_2]$ **6**. Both compounds dimerize in solution, first with a loss of carbon monoxide and second with a loss of acetonitrile molecule to give probably the chloride-bridged dimer $[W(\mu\text{-}Cl)Cl(NCMe)(PhC{\equiv}CPh)_2]_2$. The dimeric compound is less soluble than monomeric and could not be characterized by ^{13}C NMR spectroscopy in solution. A similar dimerization process was observed by Baker *et al.* in their molybdenum(II) and tungsten(II) diiodide alkyne complexes [33, 34]. In ^{13}C NMR spectra of the reaction products two sets of carbon signals of coordinated PhC≡CPh for **5** and **6** are observed. However, after prolonged reaction time (24 h) ν(CO) band characteristic of alkyne complex **5** disappears and in the residue obtained after evaporation of solvent only compound **6** was identified by NMR. ^{13}C NMR spectra of **5** and **6** revealed acetylenic carbon resonances in the range from 196–167 ppm, as is typical for three-electron-donor alkynes. The white precipitate which appeared as the side product during the reaction of **1** with alkynes was identified as $SnCl_2$, what suggests that the $SnCl_3^-$ ligand undergoes hydrolysis to $SnCl_2$ and Cl^- in the presence of an alkyne.

In the reaction of **1** with two molecular equivalents of phenylacetylene, a mixture of alkyne complexes is formed. The monomeric compound $[WCl_2(CO)(MeCN)(PhC{\equiv}CH)_2]$ **7**, with a solitary CO ligand was identified as the main product by IR and NMR spectroscopy. The other alkyne complex does not contain CO and most probably can be formulated as

$[WCl_2(NCMe)_2(PhC{\equiv}CH)_2]$ **8** (Table 2). However, complexes **7** and **8** are not the only reaction products because several other proton signals of coordinated PA in the region 11–14 ppm appeared in the reaction of PA with **1**. Also several lower intensity carbon signals of coordinated PA were observed in ^{13}C NMR spectra.

Catalytic activity of **1**. The starting point of the present investigation was to examine the scope of our earlier finding [35, 36, 37] that the formation of tungsten(II) might be an important event in the creation by Lewis acids (Group 14 tetrachlorides) of the catalytic activity of tungsten(0) compounds. To be precise, polymerization of PA occurs at room temperature in CH_2Cl_2 containing tungsten(II) compound **1**. Treatment of the resultant deep-red solution with a large amount of methanol produced, quantitatively, poly(phenylacetylene) (PPA) as a fine dark-orange powder with a number-average molecular weight (M_w) of 5×10^3, determined by GPC. The polymers produced were soluble in CH_2Cl_2, $CHCl_3$ and toluene. IR and ^1H NMR spectroscopy was used to establish the stereochemistry in PPA as mainly *trans* [19].

However, the catalytic coupling of alkynes in the presence of **1** yields at least two types of product, namely polymers with conjugated polyenic structures and cyclic oligomers, especially the aromatic cyclotrimers 1,2,4- and 1,3,5-triphenylbenzene. Minor amounts of other oligomers arise, mainly linear diphenylbutadienes, which contain, for example, hydrogen derived from the solvent and also a dimer of PA detected by MS as 1*H*-indene-1-(phenylmethylene).

The intermediates formed in mechanisms most frequently suggested for the catalytic polymerization and cyclotrimerization of alkynes are alkylidene complexes [38] and metallacyclic species [39]. The catalytically active species are, as yet, rather poorly characterized. Our results provide direct information only as regards to the first step and strongly suggest that the loss of three labile two-electron-donor ligands (CO or CH_3CN), and coordination of two alkyne molecules as three-electron-donor ligands, is common to all the reactions studied. In the reactions of **1** with alkynes that we investigated, the tungsten complexes that could be isolated contained a *cis* arrangement of the two alkyne ligands. We were unable to isolate any intermediates beyond the first bis(alkyne) complexes and their decomposition product: 1*H*-indene-1-(phenylmethylene). The formation of dimers, cyclotrimers and linear conjugated polyenic polymers involves oxidative coupling and formation of a series of metalacyclic species [39]. The metallacycle formed with four molecules of alkyne can then rearrange to an alkylidene ligand, as was observed by Yeh *et al.*[40]. The mechanism of PA polymerization induced by tungsten(II) complex is therefore seen to involve a series of stepwise *cis* insertions of coordinated PA into a C–W bond giving a metallacycloheptatriene complex. A further PA *cis* insertion then occurs to give an alkylidene complex initiating the increase of the polymer chain.

(Received 6 January 1998; accepted 25 March 1998)

Abstract—The preparation of a pentadentate binucleating ligand 2,6-bis[(N-methyl piperazin-1-yl)methyl]-4-cyano phenol (HL) is described together with the corresponding acetato bridged Cu(II) complex $[Cu_2L(CH_3COO)_2]ClO_4$. Both the ligand and the complex were characterized by elemental analysis and spectral studies. The electro-chemical behavior of the complex is discussed in detail. A Crystal structure analysis shows that the ligand is pentadentate donating two nitrogens as well as a bridging oxygen to each copper. Two acetates bridge the coppers through axial and apical positions to yield square-pyramidal coppers with a distorted square base. Perchlorates occupy interstitial positions. The structure is held in three-dimensional space by electrostatic attractions and Vander Waals forces. © 1998 Published by Elsevier Science Ltd. All rights reserved

Keywords: binucleating ligand; copper complex; crystal structure; electrochemical.

INTRODUCTION

As a part of a wide study of structure, magnetism and redox relation of binuclear Cu(II) complexes [1–5], we have synthesized a binucleating ligand HL by the Mannish reaction of a para substituted phenol, formaldehyde and N-methyl piperazine [6, 7]. Molecular models showed that simultaneous coordination of the phenol oxygen and the four piperazine nitrogen atoms to the two copper(II) ions in the presence of exogenous bridging ligands would be difficult in view of the sterically controlled ligand conformation. In attempting to insert exogenous X groups, particularly those having two or more coordinating atoms, we have come across an unusual and unexpected product. In the case of X = acetate, a triply bridged (μ-phenoxo) bis (μ-acetato) complex $[Cu_2(CH_3COO)_2]ClO_4$ was obtained. This observation is in contrast with similar studies with other binucleating ligands in which mono (μ-acetato) copper (II) derivatives are obtained. Interestingly, similar bis(μ-acetato) bridged complexes of Cu(II) [8], Fe(III) [9] and Mn(III) [10] have been reported with other ligands; the bridging unit found in these structures have been proposed by Anderson *et al* [11]. to be a thermodynamically favored core structure. In this paper, we describe the synthesis, structure, spectral and electrochemical properties of bis(μ-acetato) and (μ-phenoxo) bridged binuclear copper complex $[Cu_2(CH_3COO)_2]\ ClO_4$.

EXPERIMENTAL

Synthesis of the ligand

The ligand 2,6-bis[(N-methyl piperazin-1-yl)methyl]-4-cyano phenol (HL) was prepared by a slight modification of the reported procedure [7].

4-cyanophenol (0.05 mol) in ethanol (75 ml) was mixed with excess (0.12 mol) N-methyl piperazine and stirred on with slow addition of 35% formaldehyde (12.5 ml, 0.125 mol). The solution was refluxed for 24

*Author to whom correspondence should be addressed.

hours with further addition of 2.5 ml formaldehyde at intervals of 8 hrs. The alcohol was evaporated under vacuum and the resulting oil, washed with saturated aqueous solution of sodium carbonate, was extracted with benzene. After evaporation of benzene, brown crystals were obtained which were recrystallised from light petroleum.

^{1}H NMR: $CDCl_3$ δppm 7.1 (m) aromatic H, 3.5 (s) benzylic CH_2, 2.6 (s) N-CH_2, 2.25 (s) N-CH_3; IR: νCH_2, 2800–3000 cm^{-1}, νOH, 3400 (b) cm^{-1}, ν-aromatic CH_2 1600 cm^{-1}, νCN 2220 cm^{-1}. Found C, 66.4; H, 8.2; N, 20.1. $C_{19}H_{29}N_5O$ requires C, 66.4; H, 8.5; N, 20.4.

Synthesis of the complex

Copper(II) acetate monohydrate (0.99 g, 0.005 mol) was dissolved in warm aqueous ethanol (100 ml). Addition of the ethanolic solution of the ligand HL(0.88, 0.0025 mol) and of sodium perchlorate (1.756 g, 0.0125 mol) to the above solution led to the formation of a dark green solution, which on slow evaporation gave blue diamond-shaped crystals in 75% yield. Anal. Calculated for $C_{23}H_{28}N_5O_9ClCu_2$: C, 40.2; H, 4.9; N, 10.1; Found C, 39.5; H, 4.8; N, 9.5.

Physical measurements

IR spectrum was recorded on a Perkin Elmer IR 598 instrument (KBr pellet) in the 4000–200 cm^{-1} spectral range. Proton NMR spectrum was recorded using $CDCl_3$ on a JEOL FX-400 FT-NMR spectrometer. The electronic spectrum of the complex was recorded with a Hitachi-320 UV-Visible double beam spectrophotometer. C, H and N were analyzed with Hetueuas C-H-N rapid analyser. Electrochemical measurements were carried out with a PAR model 175 Universal programmer.

X-ray structure determination

Blue diamond-shaped crystals, suitable for X-ray diffraction were obtained by slow evaporation of an alcoholic solution. A crystal of dimensions $0.18 \times 0.24 \times 0.32$ mm was used for data collection using an Enraf-Nonius CAD-4 diffractometer with graphite-monochromatised Mo-Kα radiation in the 2θ range 2°–47°. Two sets of three control reflections were measured at specified intervals to monitor orientation and decay. The data were corrected for Lorentz polarization factors. Absorption corrections were applied using the psi-scan method [12].

The structure was solved by direct methods using Multan 82 [13] with magic integers. Hydrogen positions were generated using stereochemical constrains and were given isotropic thermal parameters based on the heavy atom to which they are connected. A mixed-mode block-diagonal refinement, in which the non-hydrogens were refined anisotropically, keeping hydrogens fixed resulted in convergence at an R of 0.040 (Rw = 0.042) for 3203 observed reflections. A weighting scheme with Dunitz Seiler [14] factor was used in the refinement. The scattering factors for copper, chlorine, oxygen, nitrogen and carbon were from Volume IV of the international Tables for Crystallography [15] while the scattering factors for hydrogen were from Stewart *et al.*[16]. All the computations were carried out using the SDP package available for the PDP-11/73 system [17]. The relevant crystallographic data are given in Table 1.

RESULT AND DISCUSSIONS

The complex $[Cu_2L(CH_3COO)_2]ClO_4$ was obtained by the reaction of copper(II) acetate and the ligand in a 2:1 molecular ratio with subsequent addition of sodium perchlorate in ethanol. The I.R. spectrum of the complex exhibits a symmetrical band at 1095 cm^{-1} indicating the presence of uncoordinated perchlorate ion; strong bands at 1606 cm^{-1} and 1420 cm^{-1} are due to ν(-COO). The expected absorbance for νCu-N and νCu-O are found at 480 and 280 cm^{-1} respectively [18]. The band at 2220 cm^{-1} is indicative of the presence of the -CN group. The electronic spectrum of the complex shows two bands at 635 nm ($\epsilon = 260$) and 420 nm ($\epsilon = 657$) which are assigned to the d-d transitions and to the phenolato to Cu(II) charge-transfer band respectively [19]. The third band at 346 nm ($\epsilon = 878$) is assigned to acetate LMCT [20].

The redox behviour of the binucleating complex is given in Fig. 1; the large ΔEp value shows that the complex is not a truly reversible system. The value of cathodic current is larger than the value of the anodic current, indicating that the complex undergoes a chemical change after reduction. In addition to the oxidation peak at 0.62 V, we observed another small oxidation peak at -0.04 V. After the first cycle, the shape of the reduction peak is altered and a small reduction peak is observed at -0.52 V, apart from the main reduction peak at -1.25 V. Thus after the first complete cycle, the system shows two redox couples, the reduction at -1.25 V corresponding to the oxidation wave at -0.62 V and the reduction at -0.52 V corresponding to the oxidation peak at -0.04 V. The second redox couple may be due to a new species generated after the reduction of the original complex. As can be seen from the figure, the shape of the cyclicvoltammogram during the continuous scan shows that the peak current of the original complex decreases with increase in the peak current of the generated species.

A number of important observations follow from our cyclicvoltametric studies. The coulometric analysis of reduction process indicates that two electron per mole are transferred suggesting the formation of two Cu(II) ions and it occurs in a single step electron transfer process. The huge difference between Epc and

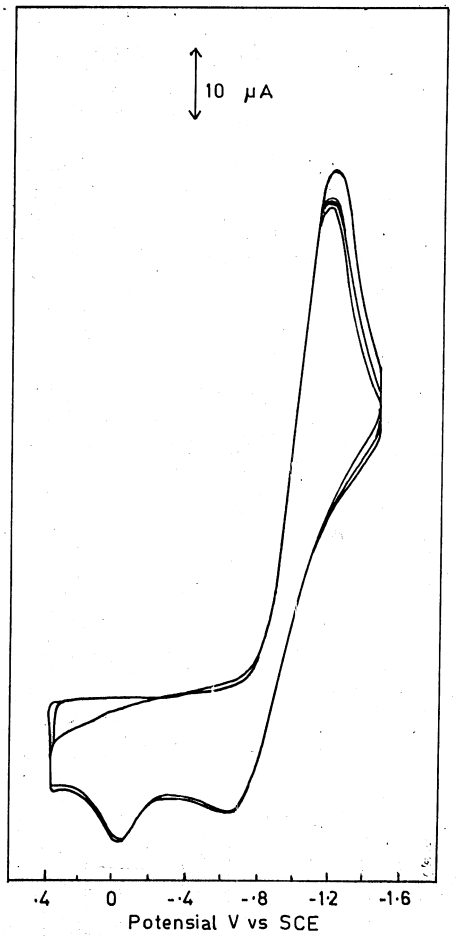

Fig. 1. Cyclic voltammogram of the copper complex.

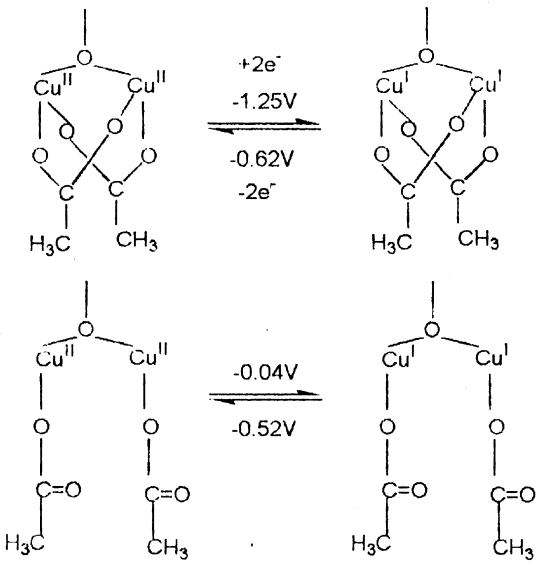
Epa suggests that the system is quasireversible and a chemical change is occurring with electron transfer resulting most probably from a structural reorganization of the copper coordination sphere. The presence of the new redox couple can be attributed to the formation of a new complex, which may contain only endogenous bridging unit, by the first reduction of the original complex. Our results are in confirmity with the earlier reports of stereochemical changes [21] and the observation of the ligand loss [22–24] induced by the electron transfer in related complexes. We speculate that the reduction of the complex can be described by Scheme 1.



Crystal and molecular structure of the complex

Bond lengths and bond angles, along with estimated standard deviations are shown in Table 2. The quoted deviations are underestimates because of the use of block-diagonal least-squares methods.

Figure 2 shows the ORTEP [25] view of the molecule, along with the numbering scheme. The triply bridged cationic complex and perchlorate anions occur as DL-diasteromeric pairs, related by the centre of inversion of the space group by $P2_1/c$. The pentadentate ligand connects both the coppers through the phenoxy bridge and donates three coordination sites to each of the copper atoms. Two acetates bridge both

the coppers, through -O-C-O- bridge, and provide coordination sites to the square base and apexes. The resulting square pyramidal geometry around Cu1 and Cu2 exhibits angular distortions caused by the ring constraints. The distances Cu-O [1.990(5) Å, 1.914(6) Å and 1.974(5) Å and 1.912(7) Å in Cu1 and Cu2 polyhedra respectively] and distances Cu-N [2.091 (6) Å, 1.993(6) Å in Cu1 and 2.074(8) and 2.005(7) Å in Cu2 polyhedra] lie in the range reported for such values in other Cu(II) square-pyramidal complexes [26–34]. The distribution of Cu-O values follows the expected pattern, and shows that the oxygens of the acetates bind more strongly. Within experimental errors, Cu1-O1 and Cu2-O1 distances are equal, which is in line with a number of observations reported before [35]. The bonds Cu–N trans to Cu–O1 are elongated. The differences between Cu–O(av) to Cu–N(av) is 0.094 Å; part of this difference obviously arises due to differences in the atomic radii of oxygen and nitrogen ($\sim$0.05 Å), while the remainder can be attributed to steric constraints. The distortion in the basal squares are reflected in the trans angles, which are 157.3(2)° and 163.3(2)° for Cu(1) polyhedron and 153.6 (3)° and 161.0(3)° for Cu(2) polyhedron; the cis angles have a span of 25.2° [73.6(3)° to 98.8(2)°] and 24.5 [73.8(3)° to 98.3(2)° in Cu(1) and Cu(2) polyhedra respectively] showing that tetrahedral like deviations from planarity result from steric interferences. The pendants offer constraining five-membered rings that result in a contraction of the N–Cu–N angles i.e. 73.6(3)° and 73.8(3)° in Cu(1) and Cu(2) polyhedra. As a result, angles O1–Cu1–O2 and O1–Cu2–O5 open up to 98.8(2) and 98.3(2) respectively. The apical O4–Cu1 and O3–Cu2 distances are 2.184(6) Å and 2.160 (7) Å and lie in the short range, showing that the metal-oxygen (apical) interactions are strong in this complex. Literature values range from 2.114(6) Å [32] to 2.414(6) Å [31]. Longer distances than this denote weak interactions.

Atoms Cu1 and Cu2 are displaced by 0.259(1) Å and $-0.325(1)$ Å from the planes O1N1O2N2(A) [maximum deviation of any of the constituent atom, m = 0.082(7) Å] and O1N3N4O5(B) [m = 0.072(7) Å] towards the apical oxygens O(4) and O(3); O(4) lies 2.419(6) Å above plane A and O(3) lies 2.480(6)Å below plane B respectively. The five membered rings in the structure have envelope conformation. Atom Cu(1) is displaced by 1.373(1) Å and 1.401(1) Å from the planes defined by N1N2C1C2 (C) [m = 0.013(9) Å] and N1N2C3C4(D) [m = 0.009(9) Å] respectively. Similarly, atom Cu2 is displaced by $-1.441(1)$ and $-1.330(1)$ Å from planes defined by N3N4C14C15(E)

[m = 0.008(12) Å] and N3N4C16C17(F) [m = 0.001(12) Å] respectively. The six membered rings connected through the phenolic oxygen O1, N2C6C7Cu1C5O1 and N4C7C8Cu2C13O1 occur as boats flattened at one end. Atoms C(5) and O(1) deviate by 0.523(8) Å and 0.340(5) Å from the plane Cu1N2C6C7(G) [m = 0.024(7) Å, while atoms C13 and O1 deviate by −0.583(9) Å and −0.450(5) Å from the plane Cu2N4C7C8(H) [m = 0.009(8) Å]. Two more six-membered rings formed by the triple-bridge occur as envelopes. O1 displaced by −0.897(5) Å and 0.967(5) Å.

(Received 13 February 1998; accepted 25 March 1998)

Abstract—The reaction of $[Ru_3(CO)_{12}]$ with dicyclohexylphosphine (Cy_2PH) in refluxing toluene leads to the metal clusters $[Ru_3(CO)_7(\mu\text{-}H)(\mu\text{-}PCy_2)_3]$ (**1**) and $[Ru_3(CO)_6(\mu\text{-}H)(\mu\text{-}PCy_2)_3(Cy_2PH)]$ (**2**). Complexes **1** and **2** react with carbon monoxide under elevated pressure to give the novel 52-electron cluster $[Ru_3(CO)_9(\mu\text{-}H)(\mu\text{-}PCy_2)_3]$ (**3**), which could be isolated as a solid and characterized spectroscopically. The molecular structure of **1** has been determined by means of a single-crystal X-ray structure analysis. © 1998 Published by Elsevier Science Ltd. All rights reserved

Keywords: ruthenium; carbonyl; phosphido-bridged; electron-rich clusters; crystal structure.

A rich and fascinating chemistry of phosphido-bridged metal complexes and clusters has been developed over the past two decades [1]. The class of electron-rich clusters, i.e., molecules having similar structural features, like electron-precise compounds, but possessing more electrons and expanded metal frameworks, has now received more attention [2]. As part of a study of the chemistry of transition metal complexes containing bulky phosphido groups, we recently described the synthesis and X-ray crystal structure of the electron-rich cluster $[Ru_3(CO)_6(\mu\text{-}Cl)_3(\mu\text{-}PBu^t_2)(Bu^t_2PH)]$ (50 cluster valence electrons, c.v.e.) [3]. Herein, we report the reaction of $[Ru_3(CO)_{12}]$ with the secondary phosphine Cy_2PH (Cy = cyclohexyl) leading to the complexes $[Ru_3(CO)_7(\mu\text{-}H)(\mu\text{-}PCy_2)_3]$ (**1**) and $[Ru_3(CO)_6(\mu\text{-}H)(\mu\text{-}PCy_2)_3(Cy_2PH)]$ (**2**). The crystal and molecular structure of compound **1** is presented and the reactions of **1** and **2** with carbon monoxide have been investigated, affording the 52-electron cluster $[Ru_3(CO)_9(\mu\text{-}H)(\mu\text{-}PCy_2)_3]$ (**3**). A preliminary X-ray crystal structure investigation of **3** gives a satisfactory explanation to describe **3** in the solid as an electron-rich cluster containing three expanded metal–metal bonds.

RESULTS AND DISCUSSION

Treatment of $[Ru_3(CO)_{12}]$ with the phosphine Cy_2PH in refluxing toluene for 2 h resulted in a reaction with a colour change from orange to brown. Cooling to room temperature, removal of the solvent and recrystallization from dichloromethane/hexane afforded orange microcrystals in good yield which could be identified by elemental analysis and spectroscopic means as the metal cluster $[Ru_3(CO)_7(\mu\text{-}H)(\mu\text{-}PCy_2)_3]$ (**1**). A second fraction of orange crystals could be obtained by fractional crystallization and identified as a substitution product of **1**, namely $[Ru_3(CO)_6(\mu\text{-}H)(\mu\text{-}PCy_2)_3(Cy_2PH)]$ (**2**) (Scheme 1). The molecular structure of complex **1** has been established by X-ray crystallography (*vide infra*). This compound was recently prepared by two other groups and characterized spectroscopically [4, 5].

The infrared spectrum of **1** contains ν(CO) absorption bands in the region characteristic of terminal carbonyl ligands. The ^{1}H NMR spectrum of this compound (C_6D_6) shows, besides signals corresponding to

[1] Dedicated to Dr. Bernhard Walther on the occasion of his 60th birthday.

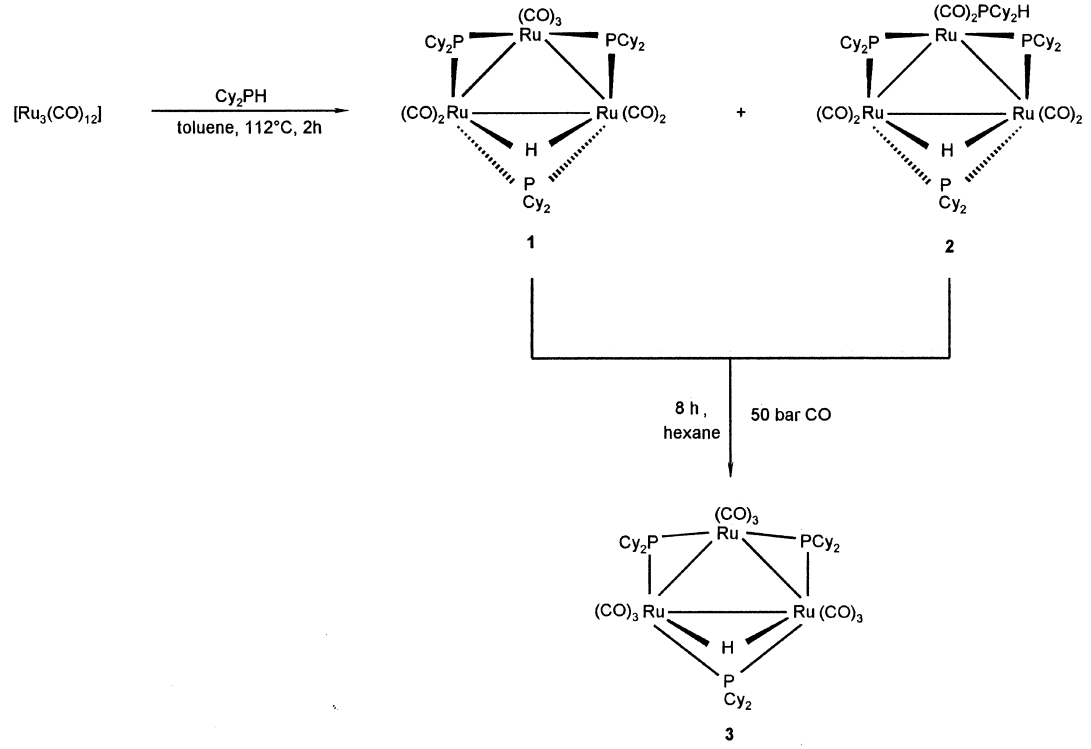

Scheme 1

the protons of the cyclohexyl groups, a resonance in the metal hydride region at δ −17.97 (dt, $^2J_{PH}$ = 19.4 Hz, $^2J_{PH}$ = 14.6 Hz). The splitting pattern is indicative of two chemically equivalent phosphorus nuclei and a third phosphorus, which couple with one hydride ligand. This is additionally confirmed by the $^{31}P\{^1H\}$ NMR spectrum, which exhibits signals corresponding to a typical AB_2 spin system at δ 207.06 (ν_A) and 203.69 (ν_B) with $^2J_{AB}$ = 80.6 Hz. These observations are in disagreement with the NMR data found for the homologue $[Os_3(CO)_7(\mu\text{-H})(\mu\text{-PCy}_2)_3]$ (**4**) [6]. For the latter, the $^{31}P\{^1H\}$ NMR spectrum at room temperature shows only a singlet at δ 112.75 (C_6D_6), indicating that the three phosphido ligands are equivalent in solution. Additionally, this fact is affirmed by the proton NMR spectrum, which shows only a simple quartet for the hydride indicating that this ligand is fluxional and is equivalent to all three phosphido groups. On the contrary, the molecular structure of **4** in the solid differs from that in solution [6]. Unfortunately, variable-temperature $^{31}P\{^1H\}$NMR studies of complex **1** (toluene-d_8, −80 to +80°C) revealed no significant changes in the spectra, therefore there is no indication of a fluxional behaviour of the molecular structure of the latter in solution in the examined temperature range.

The infrared spectrum of **2** exhibits ν(CO) absorption bands in the region characteristic of terminal CO groups. The proton NMR spectrum of complex **2** contains, besides signals corresponding to cyclohexyl protons, a complex multiplet centered at δ −17.32 which can be assigned to a hydride ligand in a similar chemical environment like the hydride in compound **1**. The $^{31}P\{^1H\}$ NMR spectrum of **2**, recorded at room temperature, is of higher order. It contains two sets of peaks centered at δ 204.88 and 181.52, respectively, corresponding to the phosphido bridges across metal–metal bonds. Furthermore, a set of peaks at δ 11.92 can be assigned to a terminal bound Cy_2PH ligand (calculated coupling constants see Section 2, Experimental).

*Reactions of **1** and **2** with carbon monoxide*

Inspired by the investigations of Haines and coworkers, including the reactions of $[Ru_3(CO)_7(\mu_3\text{-PPh})(\mu\text{-PPh}_2)_2]$ with carbon monoxide [7], we became interested in similar reactions of compounds **1** and **2**. Bubbling a stream of carbon monoxide through a solution of the corresponding complex resulted in a slight colour change from orange to yellow. Monitoring by means of $^{31}P\{^1H\}$ NMR spectroscopy showed that the reaction seemed not to be complete under these conditions. The reaction can be completed by using a pressure of 50 bar CO in an autoclave for 5 h. Evaporation of the solvent and crystallization from dichloromethane/hexane afforded an orange

crystalline product which could be identified by elemental analysis and spectroscopic means as a compound with the formula $[Ru_3(CO)_9(\mu\text{-}H)(\mu\text{-}PCy_2)_3]$ (**3**) (Scheme 1). Both species (**1** as well as **2**) gave complex **3** in the same manner, therefore, we assume that **2** reacts with CO in a first step to afford **1**, which then yields compound **3** by additional treatment with carbon monoxide.

The infrared spectrum of **3** shows ν(CO) absorption bands in the region characteristic of terminal carbonyl ligands. The ^{1}H NMR spectrum of this compound (C_6D_6) exhibits, besides the signals corresponding to the cyclohexyl protons, a hydride resonance centered at δ −10.24 (t, $^2J_{PH}$ = 21.0 Hz). Only one coupling to the phosphorus nuclei could be found, the second is assumed to be very small. The $^{31}P\{^1H\}$ NMR data of compound **3** are in accordance with the structural formulation shown in Scheme 1. The spectrum recorded in C_6D_6 at room temperature contains two signals centered at δ 90.66 (d) and 48.88 (t) with a coupling $^2J_{PP}$ = 54.3 Hz. Normally, such chemical shift values indicate phosphido bridges across two metal centers without a metal–metal bond [8]. Therefore, these ambiguous NMR data complicate the description of **3** as an 'opened' framework with only one metal–metal interaction. A preliminary crystal structure investigation of **3** (*vide infra*) confirms that three elongated metal–metal bonds are involved in the structure and supports the formulation of **3** as an electron-rich species containing 52 cluster valence electrons. Moreover, recent investigations on phosphido-bridged 50-electron derivatives with expanded metal–metal bonds generally showed considerable shifts of the ^{31}P resonances of the phosphido ligands towards lower frequencies [2, 9]. The same tendency is observed during the transformation of **1** into **3**.

The molecular structure of $[Ru_3(CO)_7(\mu\text{-}H)(\mu\text{-}PCy_2)_3]$ (***1***)

Compound **1** crystallizes from dichloromethane in the triclinic space group $P\bar{1}$ with two molecules in the unit cell. The molecular structure of **1** is shown in Fig. 1, selected bond lengths and angles are summarized in Table 1.

Compound **1** consists of a triangular metal core, while each Ru–Ru edge is supported by a μ-PCy_2 group. Additionally, the Ru(1)–Ru(2) bond is bridged by a hydride ligand, therefore a shortening of this bond is observed, caused by the doubly-bridged nature [Ru(1)–Ru(3), 3.013(1); Ru(2)–Ru(3), 3.034(1) vs. Ru(1)–Ru(2), 2.808(1) Å]. The hydride ligand in **1** has been found during the refinement by difference fourier analysis [Ru(1)–H, 1.78; Ru(2)–H, 1.71 Å; angle Ru(1)–H–Ru(2), 107.3°]. The metal–metal distances agree well with those found in the closely related $[Ru_3(CO)_7(\mu\text{-}H)(\mu\text{-}PPh_2)_3]$ [10, 11] and the mixed bridging species $[Ru_3(CO)_7(\mu-H)(\mu-PBu^t_2)(\mu-PCy_2)_2]$ [12]. Moreover, the same bonding characteristics were observed in the osmium analogue $[Os_3(CO)_7(\mu\text{-}H)(\mu\text{-}PCy_2)_3]$ (**4**) with Os(1)–Os(3), 3.022(1); Os(2)–Os(3), 3.059(1) vs. Os(1)–Os(2), 2.817(1) Å [6]. However, in the light of the found NMR data at room temperature for the latter (*vide supra*), the structure of **4** in the solid seems to differ from that in solution. The found NMR data in solution of **1** agree better with the structure in the solid, i.e., there is no indication of a fluxional behaviour of the hydride under these conditions.

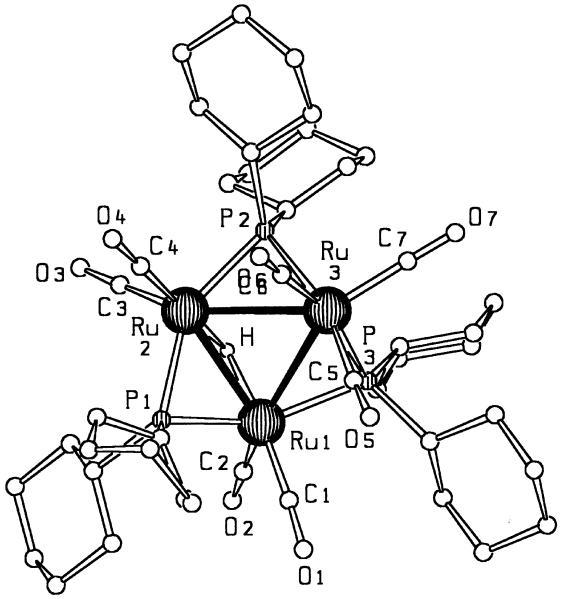

Fig. 1. The molecular structure of $[Ru_3(CO)_7(\mu\text{-}H)(\mu\text{-}PCy_2)_3]$ (**1**).

As in **4**, one of the phosphido bridges [P(1)] in **1** is bent below the plane of the three ruthenium atoms, while the other two μ-PCy_2 ligands are situated above the triangular plane. Neglecting the metal–metal bonds, each ruthenium in **1** has a roughly square–pyramidal coordination sphere. The average of the Ru–P distances falls within normal limits [av. d(Ru–P) = 2.377(1) Å] and are comparable to those found in other phosphido-bridged ruthenium clusters.

Preliminary X-ray investigations of ***2*** *and* ***3***

Despite intense efforts, only a very small crystal size of compounds **2** and **3** could be obtained, therefore, merely preliminary crystal structure data can be discussed here. The compound **2** crystallizes from dichloromethane/hexane in the monoclinic space group $P2_1/n$ (a = 10.396, b = 26.223, c = 22.371 Å; β = 91.9°; V = 6095 Å^3) with four molecules in the unit cell. The structural arrangement of **2** is closely related to that of the parent cluster **1** with a carbonyl from the ruthenium atom unbridged by the hydride ligand, having been replaced by the Cy_2PH. As in **1**, two longer Ru–Ru distances have been determined

Table 1. Selected bond lengths (Å) and bond angles (°) for **1**.

[Ru(1)–Ru(2), 3.00; Ru(1)–Ru(3), 2.98 Å], while the third was found to be shorter [Ru(2)–Ru(3), 2.82 Å]. The presence of a hydride in **2** is clearly indicated by the proton NMR spectrum (*vide supra*) and, in analogy to **1**, we assume for this ligand a bridging position across the shortest Ru–Ru bond [Ru(2)–Ru(3)].

Moreover, the composition of **2** is closely related to that of $[Ru_3(CO)_6(\mu\text{-H})(\mu\text{-PPh}_2)_3(Ph_2PH)]$ (**5**) [11]. In the molecular structure of the latter, no hydride ligand has been found during the X-ray study and its position is assumed to be bridging the shortest Ru–Ru edge [2.793(1) Å]. The most remarkable difference is that in **2** the secondary phosphine is bonded to the ruthenium atom, which is unbridged by the hydride ligand, while in **5** the phosphine is bonded to one ruthenium bridged by the hydride. We assume that the position of the phosphine in **2** is favoured by sterical reasons, since the two phosphido ligands unbridged by the hydride lie below the triruthenium plane, whereas the phosphine is situated above the triangle.

Crystals of **3** suitable for X-ray diffraction studies were grown from a dichloromethane/hexane mixture. The compound crystallizes in the monoclinic space group $P2_1/n$ ($a = 12.080$, $b = 17.215$, $c = 23.388$ Å; $\beta = 90.4°$; $V = 4864$ Å^3) with four molecules in the unit cell. The preliminary crystal structure analysis confirms the trinuclear structure of **3**. In the light of the discussion of **3** either as an 'opened' trimetal core or an electron-rich 52-electron cluster with three metal–metal bonds, the Ru–Ru distances are of interest. On the basis of the 18-electron rule, the trimetal cluster **3** (52 c.v.e.) would be expected to exhibit a triangle with only one direct Ru–Ru bond. However, in **3** the metal–metal distances are roughly equivalent and a global expansion is found [Ru(1)–Ru(3), 3.18; Ru(1)–Ru(2), 3.19; Ru(2)–Ru(3), 3.16 Å]. These values are in accordance with 'elongated' metal–metal interactions and a description of **3** as an electron-rich cluster seems to be reasonable. The three very similar Ru–Ru bond lengths refer to a hydride ligand in a μ_3-coordination. However, this would be in disagreement with the found NMR data for **3** in solution (*vide supra*). Therefore, a better structure refinement would be desirable. In comparison with the molecular structure of **1**, the most remarkable feature of **3** is that the three phosphorus atoms lie essentially in the triruthenium plane. This fact is rarely found for complexes containing three bridging phosphido ligands, for instance for the 50-electron clusters $[Ru_3(CO)_6(\mu_3\text{-}\eta^2\text{-PPhpy})(\mu\text{-PPh}_2)_3]$ [1] and $[Ru_3(CO)_6(\mu_3\text{-H})\{\mu_3\text{-}\eta^2\text{-P(Ph)C}_6H_4\}]$ [13]. It seems that it could be a characteristic for such electron-rich triruthenium species only.

EXPERIMENTAL

General considerations

All manipulations were performed under oxygen-free argon, using conventional Schlenk techniques. Solvents were dried over molecular sieves or sodium/benzophenone ketyl and were distilled under argon

prior to use. Starting materials were either commercially available or were prepared according to literature procedures. IR spectra were obtained using a Mattson 5000 instrument. ^1H NMR and $^{31}P\{^1H\}$ NMR spectra were recorded on the spectrometer Gemini 200 (^1H at 199.975 MHz, referenced to Me_4Si; ^{31}P NMR at 80.950 MHz, referenced to 85% H_3PO_4 aq). The mass spectra were obtained on a Hitachi Perkin Elmer RMU 6, Nermag R30-10 instrument. The elemental analyses were performed by the Analytisches Laboratorium des Pharmazeutischen Institutes der Martin-Luther-Universität Halle–Wittenberg.

Synthesis of $[Ru_3(CO)_7(\mu\text{-}H)(\mu\text{-}PCy_2)_3]$ (***1***) *and* $[Ru_3(CO)_6(\mu\text{-}H)(\mu\text{-}PCy_2)_3(Cy_2PH)]$ (***2***)

A mixture of $[Ru_3(CO)_{12}]$ (300 mg, 0.47 mmol) and Cy_2PH (372 mg, 1.88 mmol) was heated in toluene (40 cm^3) under reflux for 2 h. After cooling to room temperature and removal of the solvent, the residue was dissolved in a minimum of dichloromethane and hexane (10 cm^3) was added. After standing at $-30°C$ for two days, compound **1** crystallized as orange microcrystals. Yield: 319 mg **1** (62%). Filtration and further standing for two days at $-30°C$ afforded compound **2** as orange crystals. Yield: 82 mg (15%), based on $[Ru_3(CO)_{12}]$.

*Analytical data for **1***. Found: C, 47.0, H, 5.9, P, 8.8; Calc. for $C_{43}H_{67}O_7P_3Ru_3$; C, 47.2, H, 6.2, P, 8.5%. IR (KBr pellet, cm^{-1}): ν(CO): 2042(m), 1996(vs), 1975(m), 1940(s). ^1H NMR (C_6D_6): δ 2.57–1.08 (m, 66H, C_6H_{11}), −17.97 (dt, 1H, $^2J_{PH} = 19.4$ Hz, $^2J_{PH} = 14.6$ Hz, μ-H).

$^{31}P\{^1H\}$ NMR (C_6D_6): AB_2 pattern, δ 207.06 (m, P_A), 203.69 (m, P_B), $^2J_{PP} = 80.6$ Hz. Mass spectrum: $m/z = 1094$ $[M]^+$.

*Analytical data for **2***. Found: C, 50.9, H, 6.8, P, 9.8; Calc. for $C_{54}H_{90}O_6P_4Ru_3$; C, 51.4, H, 7.2, P, 9.8%. IR (KBr pellet, cm^{-1}): ν(CO): 2040(m), 1992(s), 1972(vs), 1944(vs), 1906(s), 1876(sh). ^1H NMR (C_6D_6): δ (dt, br, $J_{PH} = 329.4$ Hz), δ 2.59–0.80 (m, 88H, C_6H_{11}), −17.32 (m, 1H, μ-H). $^{31}P\{^1H\}$ NMR (C_6D_6): δ 204.88 (m, $^2J_{P3P2/P4} = 26.3$ Hz, $^3J_{P1P3} = 2.2$ Hz, μ-P3), 181.52 (m, $^2J_{P3P2/P4} = 26.3$ Hz, $^2J_{P1P2/P4} = 101.3$ Hz, μ-P2/P4), 11.92 (m, $^2J_{P1P2/P4} = 101.3$ Hz, $^3J_{P1P3} = 2.2$ Hz, Cy_2PH).

*Reaction of **1** with carbon monoxide*

Compound **1** (110 mg, 0.10 mmol) was dissolved in a mixture of dichloromethane (5 cm^3) and hexane (30 cm^3) and the solution transferred into a glass tube containing a magnetic stir bar and placed into a 200 ml steel autoclave. The solution was pressurized with 50 bar CO and stirred at room temperature for 5 h. After venting, the resulting yellow solution was evaporated to dryness. The residue was crystallized from dichloromethane/hexane at $-30°C$ to give **3** as orange microcrystals. Yield: 115 mg (nearly quantitative).

The reaction of **2** with carbon monoxide under pressure was carried out in the same manner as described before with similar results.

*Analytical data for **3***. Found: C, 47.1, H, 5.8, P, 7.7; Calc. for $C_{45}H_{67}O_9P_3Ru_3$; C, 46.9, H, 5.9, P, 8.1%. IR (KBr pellet, cm^{-1}): ν(CO):2042(s), 2007(vs), 1990(s), 1972(vs), 1936(s), 1885(sh). ^1H NMR (C_6D_6): δ 2.67–0.82 (m, 66H, C_6H_{11}), −10.24 (dt, 1H, μ-H). $^{31}P\{^1H\}$ NMR (C_6D_6): δ 90.66 (d, $^2J_{PP} = 54.3$ Hz, μ-PCy_2), 48.88 (t, $^2J_{PP} = 56.0$ Hz). Mass spectrum: m/z: 1150 $[M]^+$.

*X-ray crystal structure determination of **1***

Crystal data, data collection and refinement parameters are summarized in Table 2. Crystals of **1** suitable for X-ray diffraction studies were grown by crystallization from dichloromethane/hexane. For

data collection the diffractometer Stoe–IPDS was used. The structure was solved by direct methods and refined on F^2 (program systems: SHELXS-86, SHELXL-93 [14]). It should be mentioned, that one cyclohexyl ring on P(1) is disordered. Full details of the structure determination of **1** has been deposited at the Fachinformationszentrum Karlsruhe, Gesellschaft für wissenschaftlich-technische Information mbH, D-76344 Eggenstein–Leopoldshafen, Germany, from where this material may be ordered on quoting the full literature citation and the reference number CSD 408426 (**1**).

CONCLUSION

The complexes $[Ru_3(CO)_7(\mu\text{-H})(\mu\text{-PCy}_2)_3]$ (**1**) and $[Ru_3(CO)_6(\mu\text{-H})(\mu\text{-PCy}_2)_3(Cy_2PH)]$ (**2**) were prepared and the X-ray crystal structure of **1** has been determined. Both compounds react in solution with carbon monoxide to yield the novel triruthenium cluster $[Ru_3(CO)_9(\mu\text{-H})(\mu\text{-PCy}_2)_3]$ (**3**). Because of unsufficient crystal qualities, only preliminary X-ray crystal structure data of compounds **2** and **3** could be obtained. These investigations showed that the three intermetallic distances in **3** are short enough to be considered as metal–metal bonds. Therefore, complex **3** exhibits, at present, the first electron-rich trimetal cluster containing 52 cluster valence electrons.

(Received 8 October 1997; accepted 27 March 1998)

Abstract—Nickel(II) complexes of the hexadentate $N_2S_2O_2$ donor ligands, 1,3-di(*o*-salicylaldiminophenylthio)propane (H_2DSALPTP) and 1,2-di(*o*-salicylaldiminophenylthio)xylene (H_2DSALPTX) have been synthesised and characterised. H_2DSALPTP reacted with $NiCl_2.6H_2O$ or $Ni(ClO_4)_2.6H_2O$ in presence of ammonia to give the complex [Ni(DSALPTP)] (**1**). H_2DSALPTX reacted smoothly with $Ni(ClO_4)_2$ to yield the corresponding complex [Ni(DSALPTX)] (**2**). The ligand did not react with $NiCl_2$ in the absence of ammonia but in its presence produced the complex (**2**). The molecular and crystal structure of [Ni(DSAL PTX)] exhibits a very unusual deployment of the six donor sites of the ligand. It crystallises in the orthorhombic system with space group $P2_12_12_1$. In dichloromethane solution both the complexes are found to exhibit Ni(II)/Ni(III) redox couples in their cyclic voltammograms at room temperature with $E_{1/2}$ values 0.87 and 0.78 V (vs. Ag/AgCl).

Keywords: hexadentate NSO-donors; Ni(II) complexes; X-ray and molecular structure; electrochemical studies.

Hexacoordinating flexidentate ligands with ONS donor sites in strategic positions of the donor framework are not commonly encountered in coordination chemistry and our group has explored some of them previously [1, 2]. Disclosure of the fact that nickel is an essential constituent of several hydrogenases [3] and that nickel sites are believed to have a distorted octahedral arrangement consisting of 2 or 3 sulphur atoms and the rest nitrogen and/or oxygen atoms [4, 5] prompted us to undertake the study of nickel complexes of the ligands which have $N_2S_2O_2$ donor sites. Nickel bound to sulphur and nitrogen/oxygen is also present in carbon monoxide dehydrogenases [6]. The catalytic properties of hydrogenase arise from the remarkably low oxidation potential for the nickel(II)/nickel(III) redox couple [3b,7]. In this paper we report the synthesis, characterisation and cyclic voltammetric studies of the nickel(II) complexes of two $N_2S_2O_2$ donor ligands. The molecular structure of [Ni(DSALPTX)] is also reported and it reveals a very large distortion of the coordination environment around the nickel(II) acceptor centre from the perfect octahedron.

EXPERIMENTAL

Synthesis of the ligands

They were prepared by methods described earlier [1].

* Author to whom correspondence should be addressed.

Synthesis of the complexes

[Ni(DSALPTP)](**1**): A solution of $NiCl_2.6H_2O$ (0.24 g, 1 mmol) or $Ni(ClO_4)_2.6H_2O$ (0.33 g, 1 mmol) in methanol (20 cm^3) was added to a stirring solution of the ligand (0.49 g, 1 mmol) in chloroform (20 cm^3) and the mixture was stirred for 1 h. A few drops of 6(N) NH_3 was then added to the mixture. The mixture was further stirred for 48 h. Red precipitate separated out which was recrystallised from methanol (yields: 75%).

[Ni(DSALPTX)] (**2**): This complex was prepared by the same procedure as above by taking $NiCl_2.6H_2O$ (0.24 g, 1 mmol) as the starting metal salt and H_2DSALPTX (0.56 g, 1 mmol) as the ligand, with a few drops of 6(N) NH_3. The complex was recrystallised from methanol with an yield of about 70%. $Ni(ClO_4)_2.6H_2O$ readily reacts with the ligand in the same ratio in absence of NH_3 to give the same orange-red product. It was recrystallised from methanol (yield 75%).

Physical measurements

Physical measurements were done as reported in our earlier communications [1, 2]. Electrochemical data were collected with a BAS CV-27 and a BAS model X-Y recorder at 298 K. The electrodes used were flat platinum disc working electrode, Pt wire auxiliary electrode and a Ag/AgCl reference electrode.

Crystal structure determination of [*Ni*(*DSALPTX*)] (***2***)

X-ray data were collected in Enraf-Nonius-CAD-4 diffractometer for a crystal mounted on top of a glass fibre. The unit cell parameters were determined from a least-square refinement of 17 high angle reflections. The three intensity controlled reflections (-3 1-2, 3-1-2, -4-3-4) checked every hour, showed no significant variations ($\pm 0.5\%$). The intensities were corrected for Lorentz-polarisation effects and an empirical absorption correction was also made [8]. A total of 3250 unique reflections measured contained 3118 with $F_o \geqslant 4\sigma(F_o)$. The structure was solved by direct methods using the program, SHELXS-86 [9] which revealed the positions of all the non-hydrogen atoms. The program SHELXL-93 [10] was used to refine the structure. Refinement on F using anisotropic displacement parameters for all non-hydrogen atoms was performed. Positions of 11 hydrogen atoms were located from the difference Fourier map. The other 14 residual hydrogen atoms were placed in their calculated positions with a temperature factor 1.2 times the U_{eq}. of the parent atom to which it is attached. Coordinates of the 11 hydrogen atoms and their isotropic temperature factors were refined. Figure 1 shows thermal ellipsoid of the molecule, excluding the hydrogen atoms for the clarity of the figure. The final full matrix least-square refinement coverged at R to 0.053. Crystallographic data and additional details regarding data collected and refinement are given in Table 1.

Structure description

The compound [Ni(DSALPTX)] crystallises in the $P2_12_12_1$ space group with four molecules in general position. The ligand binds the Ni(II) acceptor centre in a distorted octahedral pattern. The square base of the octahedron is defined by the O(A), S(B), S(A) and O(B) atoms with two nitrogen N(A) and N(B) in the two apical positions. Selected bond lengths and bond angles are given in Table 2 and a few selected torsion angles are listed in Table 3. The two phenolate oxygen and thioether sulphur donors occupy cis-positions of the distorted square plane defined by O(A)–O(B)–S(A) and S(B) with the Ni(II) ion centrally placed on it with a mean deviation of −0.012(2)A. The bite

angles involving the two sulphur atoms S(A) and S(B) generates highly distorted seven membered ring Ni–S(B)–C(4B)–C(3B)–C(3A)–C(4A)–S(A). Each bite angle corresponding to a pair of nitrogen and oxygen donors attached to the Ni(II) centre is found to form two six membered rings (Ni–O–C(17)–C(12)–C(11)–N) and the N–S donor pairs to create two five membered chelate rings (Ni–S–C(5)–C(10)–N). The bite angle corresponding to the pair S(A)–Ni–S(B), O(A)–Ni–O(B) are 96.99(5)° and 96.7(2)° respectively and for the other other pair O(A)–Ni–S(B) and O(B)–Ni–S(A) are 81.97(13)° and 84.90(14)° respectively. The severe distortion of the coordination octahedron being clearly manifested in the values of the angles at the metal centre generated by the six donor points. The observed bond distances (vide Table 2) fall well within the range found in most of the distorted octahedral Ni(II) complexes accommodating thioether sulphur coordination [11]. The large distortion of the coordination octahedron is probably arising due to the unusual orientation of the donor sites of the ligand which is very difficult to anticipate and is a clear indication of the flexidentate nature of the ligand.

No hydrogen bonding or any intermolecular short contacts are observed in the lattice. The molecules are packed in the lattice by intermolecular van der Waals forces. Each five-membered and six-membered chelate ring formed with the Ni(II) ion is also attached with a benzene ring and the dihedral angles of each chelate ring with its corresponding benzene ring lie in the range of 6–16°.

RESULTS AND DISCUSSION

The complexes synthesised and characterised during the present investigation are [Ni(DSALPTP)] (**1**) and [Ni(DSALPTX)] (**2**) in which both the ligands function as dibasic hexadentate donors. The ligand H_2DSALPTP did not react at all with either $NiCl_2$ or $Ni(ClO_4)_2$ in the absence of ammonia, but H_2DSALPTX is found to react with $Ni(ClO_4)_2$ in absence of NH_3 to produce a yellowish-green compound. On recrystallisation from methanol it yielded the orange-red compound (**2**). However, H_2DSALPTX does not react with $NiCl_2$ without the presence of ammonia. When, however, the ligand is reacted with $Ni(ClO_4)_2$ in presence of ammonia, a different compound separated out which was identified as $[Ni(DAPTX)(NH_3)](ClO_4)_2$, H_2DAPTX being the diamine dithioether ligand 1,2-di(*o*-aminophenylthio)xylene whose Pd(II), Ni(II) and Cu(II) compounds were reported earlier [12, 13]. It is quite probable that base hydrolysis of the Schiff base generated the ligand *in situ* which then coordinated to the Ni(II) ion. Single crystals for X-ray diffraction

were grown from methanol-ether solution. Two compounds were identified in the crop of crystals. One was the complex (2) and the other one was the Ni(II)-salicylaldehyde complex. This indicates that partial hydrolysis of the imine moiety occurred leading to the rupture of the Schiff base ligand to produce salicylaldehyde, which led to the formation of the Ni(II) salicylaldehyde complex.

Infrared, electronic spectra, magnetic moment and conductance

In the IR spectra of the complex [Ni(DSALPTP)](**1**) and [Ni(DSALPTX)](**2**) the ν(O–H) band of the corresponding ligands observed at 3500 and 3400 cm^{-1} respectively are absent due to the coordination of the deprotonated phenolic –OH to the Ni(II) acceptor centre. The ν(C=N) bands of the ligands observed at 1610 and 1600 cm^{-1} respectively are red shifted by 5–10 cm^{-1} in the spectra of the complexes (**1**) and (**2**) pointing to the involvement of the azomethine nitrogen in coordination. In the complexes (**1**) and (**2**), bonding from the thioether sulphur is indicated by the 50–35 cm^{-1} red shift of the ν(–S–CH_2) mode of the ligands observed as split bands at 700 and 650 cm^{-1} for H_2DSALPTP and at 660 and 640 cm^{-1} for H_2DSALPTX. Bands observed below 400 cm^{-1} (Table 4) (which are absent in the spectra of the ligand) are attributed to Ni–S linkage. These observations are in complete agreement with X-ray crystallographic data. The electronic spectral data supports the octahedral stereochemistry of the complexes (vide Table 4). [Ni(DSAL PTP)] and [Ni(DSAL PTX)] both exhibit bands in the 17,000 cm^{-1} region. The expected lower energy band could not be detected as it is out of the range of the scanning instrument. The third *d-d* band expected in the higher energy region could not be identified due to the presence of intense charge-transfer bands in the UV region. Both the complexes exhibit normal room temperature magnetic moment values of 2.95–3.25 B.M. and both behave as non electrolytes in nitromethane solution. The findings corroborate that both the phenolic-OH are deprotonated during complexation, the ligands coordinating as their dianions DSALPTP^{-2} and DSAL PTX^{-2}.

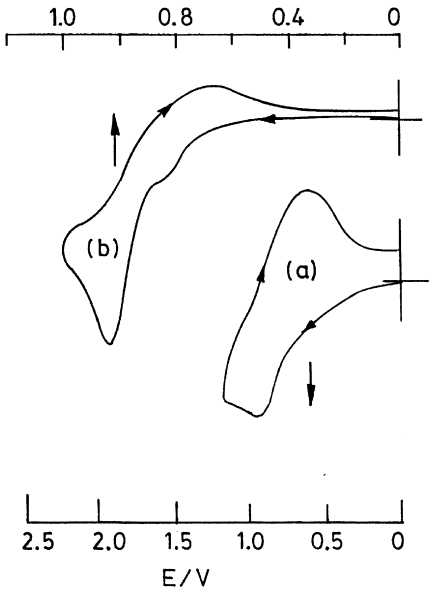

Fig. 2. Cyclic voltammograms of solutions of (a) [Ni(DSALPTP)] (scan rate 200 mvs^{-1}) and (b) [Ni(DSALPTX)](scan rate 50 mvs^{-1}) in dichloromethane using platinum electrode and NEt_4ClO_4 as supporting electrolyte.

Electrochemical studies

Cyclic voltammograms of [Ni(DSALPTP)] and [Ni(DSALPTX)] are shown in Fig. 2 with peak potentials listed in Table 5. Ni(II)-Ni(III) oxidation potential data in the case of thioether complexes generally lie in the range, 0.3–0.8 V [14]. The redox behaviour of the complexes have been examined in dichloromethane solution. The cyclic voltammogram of [Ni(DSALPTP)] exhibits a quasi-reversible Ni(II)/Ni(III) redox couple centered at 0.87 V vs. Ag/AgCl and that of [Ni(DSALPTX)] displays a reversible couple at 0.78 V. Therefore the $E_{1/2}$ values of these complexes lie at the higher end of the thioether contaning Ni(II) species indicating that Ni(II) is fairly stabilised in both the complexes. The ligand

Table 5. Electrochemical data[a]

Complex	$E_{1/2}$ (V)	ΔE_p (mV)[c]
[Ni(DSAL PTP)] (**1**)	0.87	300
[Ni(DSAL PTX)] (**2**)	0.78	120

[a] In CH_2Cl_2 (0.1 M TEAP) at a platinum electrode with an Ag/AgCl reference electrode.
[b] From cyclic voltammetry at a scan rate of 200 mVs^{-1}.
[c] Peak-to-peak separation.

H_2DSALPTP offers comparatively better stabilisation of the Ni(II) state towards oxidation. No cathodic responses was observed for both the complexes up to −1.5 V.

CONCLUSION

This work illustrates the coordination behaviour of two interesting hexadentate NSO donor ligands towards Ni(II). Structure of [Ni(DSALPTX)] exhibits the very unusual deployment of the six donor points of the ligand H_2DSALPTX while coordinating to the Ni(II) acceptor centre. Only single crystal X-ray diffraction study could establish such unusual orientation of the donor sites.

Synthesis, characterisation, electrochemical studies and catecholase activity of a new series of binuclear copper(II) complexes

S. Parimala, K. N. Gita and M. Kandaswamy*

Department of Inorganic Chemistry, University of Madras, Guindy campus, Madras, 600 025, India

(Received 17 February 1998; accepted 13 April 1998)

Abstract—New binucleating ligands L (L-, N′-R-bis(methyl-N-(2-pyridinyl)ketoacetamide) where R = ethylene, 1,3-propylene, o-phenylene were prepared by the condensation of 2 equivalents of methyl-N-(2-pyridinyl) ketoacetamide with the diamines. The binuclear copper(II) complexes of the type $[Cu_2L]X_4$ where

$$X = ClO_4^-$$

and $[Cu_2LX_2]X_2$ where $X = Cl^-$ and Br^- were synthesised by refluxing the ligand with 2 equivalents of Cu(II) salts. Conductivity studies showed a 1:4 electrolyte for perchlorate complexes and a 1:2 electrolyte for chloro and bromo complexes. Room temperature magnetic studies gave moment for the complexes in the range 1.08 to 1.45 B.M which are less than 1.73 B.M for d^9 system. This shows that there is antiferromagnetic coupling between the two copper centers. ESR spectra of the complexes show a broad band which is centered at 3300G and the g values obtained were in the range 2.09–2.14. Electrochemical studies show a quasireversible two electron reduction occuring at the negative potential in the range −0.25 to −0.70 V. The initial rate constant for the oxidation of catechol to o-quinone by the complexes are in the range 1.504×10^{-1} to 3.83×10^{-1} min^{-1}.

Keywords: binucleating ligands; Binuclear Cu(II) complexes; Electrochemical studies; Catecholase activity.

Binuclear copper(II) complexes have attracted immense attention with the onset of the studies of metalloproteins [1–8]. Proteins and enzymes have binuclear metallocites in which the metals are essential for the biological activity [9, 10]. The enzymes like hemocyanin [11], tyrosinase [12] etc, have binuclear copper centers in their active sites. Though these proteins have binuclear copper centers, the functions of the centers vary. For example hemocyanin acts as oxygen carriers, tyrosinase acts as phenolic oxidases. Therefore the properties of the binuclear centers are defined by the geometry, the coordination sites, the bridging ligands between the centers, etc. With the aim of understanding the properties of the metalloproteins, many binucleating ligands and their copper(II) complexes have been synthesised and studied [13, 14].

With the continuation of our studies [15, 16], in this paper, we report the synthesis, characterisation, magnetic and electrochemical studies of new series of binuclear copper(II) complexes. The ability of the complexes to oxidise catechol to o-quinone is also studied.

EXPERIMENTAL

All the reagents and solvents used in this study were commercially obtained. o-phenylenediamine and 2-aminopyridine were used as received. Ethylacetoacetate, ethylenediamine and 1,3-propylenediamine were distilled once before use. Catechol was used after recrystallisation. Copper(II)perchlorate hexahydrate

* Author to whom correspondence should be addressed. Fax: 2352494; E-mail-mkands@unimad.ernet.in

was prepared by treating copper(II)carbonate with an excess of concentrated perchloric acid. All the samples were thoroughly dried prior to elemental analysis, which were performed by Regional Sophisticated Instrumentation Centre, Indian Institute of Technology, Madras.

UV-Visible spectra were recorded using Hitachi 320 model double beam spectrophotometer. Proton NMR spectra were obtained using a Varian XL 300 spectrometer. IR spectra were recorded on a Shimadzu IR 408 spectrometer. Room temperature solid state magnetic susceptibility data were obtained from Guoy balance using $Hg[Co(SCN)_4]$ as the calibrant. Diamagnetic corrections were obtained using Pascal's constants [17]. Conductivity measurements were made using Elico digital conductivity bridge model CM-88 using freshly prepared solutions of the complexes in acetonitrile. Electrochemical measurements were performed at room temperature in DMF using PAR model 173 potentiostat/galvanostat, 175 universal programmer, 176 current follower and 179 coulometer. The cyclic voltammogram were recorded using Perkin Elmer Hitachi model 057 X-Y recorder. A three electrode cell assembly was used in which the working electrode, as well as the counter electrode were platinum and a saturated calomel electrode (SCE) was the reference. Tetrabutylammoniumperchlorate (0.1 M) was used as supporting electrolyte. The concentration of the complexes were 10^{-3}–10^{-4} M. The solutions were deoxygenated by purging nitrogen. Kinetic studies were conducted using Hitachi model 320 double beam spectrophotometer. The catalytic oxidation of catechol to o-quinone by the complexes were studied in a 10^{-4} M DMF solutions. The reaction was followed spectrophotometrically by choosing the strongest absorption band of o-quinone at 390 nm and monitoring the increase in the absorbance at this wavelength as a function of time. A plot of $\log(A_\infty/A_\infty - A_t)$ (where A = Absorbance) Vs time was made for each complex and the rate constant for the catalytic oxidation were calculated.

Ligand synthesis

Methyl-N-(2-pyridinyl)ketoacetamide [18] (*PC*). The compound was prepared by boiling 0.11 mol, 15 ml of ethylacetoacetate with 0.1 mol, 9.4 g of 2-aminopyridine for two minutes. The above mixture was cooled to 0°C, filtered and recrystallised from warm 95% ethanol (Yield:85%). M.p:112°C (lit. 113–114°C).

N,N′-R-bis(methyl-N-(2-pyridinyl)ketoacetamide) (R = ethylene,1,3-propylene, o-phenylene)

The compounds N,N′-R-bis(methyl-N-(2-pyridinyl)ketoacetamide) R = ethylene, 1,3-propylene, o-phenylene) were prepared by dissolving 0.02 mol, 3.56 g of (PC) in minimum amount of ethanol and adding 0.01 mol of the corresponding diamines (ethylenediamine, 1,3-propylenediamine, o-phenylenediamine) and refluxed for one hour. The above solution was cooled and the product obtained was filtered and dried.

N,N′-ethylenebis(methyl-N-(2-pyridinyl) ketoacetamide) (L^1)

Yellow coloured compound (Yield: 95%); M.p:214°C; ^{1}H NMR (DMSO,δ) 1.8 (s, $-CH_3$), 2.7 (s, $-CH_2$ between two imine groups), 4.2 (s, $-CH_2$ between ketone and imine groups), 6.5–8.5 (m, aromatic), 9.1 (s, NH). Mass spectrum, major mass (m/e (relative intensity)): 380 (3.2)P, 287 (2), 259 (3), 204 (4), 176 (4), 162 (12), 97 (34), 83 (28), 78 (7), 68 (12), 57 (100), 42 (10).

N,N′-1,3-propylenebis(methyl-N-(2-pyridinyl) ketoacetamide) (L^2)

Yellow coloured compound (Yield: 80%); M.p: 213°C;^{1}H NMR (DMSO, δ): 1.8 (s, $-CH_3$), 3.1 (s, $-CH_2$ between two imine groups), 4.5 (s, $-CH_2$ between ketone and imine groups), 6.5–7.9 (m, aromatic), 9.1 (s, NH). Mass spectrum, major mass (m/e (relative intensity)): 394 (2)P, 379 (3.2), 261 (2), 218 (3), 162 (8), 121 (10), 97 (40), 83 (40), 68 (8), 57 (100), 42 (9).

N,N′-o-phenylenebis(methyl-N-(2-pyridinyl) ketoacetamide) (L^3)

Yellow coloured compound (Yield: 82%); M.p: 123°C; ^{1}H NMR (DMSO, δ): 1.3 (s, $-CH_3$), 3.6 (s, $-CH_2$ between ketone and imine groups), 8.2–7.4 (m, aromatic). Mass spectrum, major mass (m/e (relative intensity)): 413 (0.05)P, 336 (0.09), 294 (0.14), 176 (2), 162 (2), 135 (3), 121 (6), 93 (2), 253 (1).

Synthesis of metal complexes

Copper(II)perchlorate complexes. $[Cu_2(L)](ClO_4)_4$ were prepared by adding 0.002 mol, 0.74 g of $Cu(ClO_4)_4.6H_2O$ to a hot ethanolic suspension of the ligands (0.001 mol) and refluxing the solution for two hours. The above solution was filtered, the filtrate was cooled and the green coloured crystals obtained were filtered and dried in vacuum.

$[Cu_2(L^1)](ClO_4)_4{\cdot}4H_2O$

Elemental analysis: Calculated for $C_{20}H_{24}O_{18}N_6Cu_2Cl_4$:Theor: C, 26.54; H, 2.65; N, 8.66; Cu, 13.12. Found: C, 26.23; H, 2.45; N, 8.42; Cu, 13.07.

$[Cu_2(L^2)](ClO_4)_4{\cdot}4H_2O$

Elemental analysis: Calculated for $C_{21}H_{26}O_{18}N_6Cu_2Cl_4$: Theor:C, 27.45; H, 2.83; N, 8.55; Cu, 12.93. Found: C, 27.18; H, 2.54; N, 8.49; Cu, 11.89.

$[Cu_2(L^3)](ClO_4)_4{\cdot}4H_2O$

Elemental analysis: Calculated for $C_{24}H_{24}O_{18}N_6Cu_2Cl_4$: Theor: C, 30.17; H, 2.72; N, 8.25; Cu, 12.48. Found: C, 30.08; H, 2.57; N, 8.19; Cu, 12.35.

Copper(II)chloride complexes

$[Cu_2(L)Cl_2]Cl_2$ were prepared by adding 0.002 mol, 0.35 g of $CuCl_2$ to a hot ethanolic suspension of 0.001 mol of the ligand and refluxing for two hours. The resulting solution was filtered and the filtrate was cooled to obtain a brown coloured complex, filtered and dried in vacuum.

$[Cu_2(L^1)Cl_2]Cl_2{\cdot}2H_2O$

Elemental Analysis: Calculated for $C_{20}H_{24}O_2N_6Cu_2Cl_4$: Theor:C, 38.50; H, 4.05; N, 12.45; Cu, 18.50. Found: C, 37.80; H, 4.10; N, 12.40; Cu, 18.35.

$[Cu_2(L^2)Cl_2]Cl_2{\cdot}2H_2O$

$[Cu_2(L^3)Cl_2]Cl_2{\cdot}2H_2O$

Elemental analysis: Calculated for $C_{24}H_{24}O_2N_6Cu_2Cl_4$: Theor:C, 45.30; H, 4.30; N, 11.85; Cu, 18.03. Found: C, 45.15; H, 4.28; N, 11.81; Cu, 18.01.

Copper(II)bromide complexes

$[Cu_2(L)Br_2]Br_2$ complexes was prepared by refluxing an ethanolic suspension of the ligand (0.001 mol) with 0.002 mol, 0.442 g of $CuBr_2.2H_2O$ for two hours. The resulting solution was filtered, the filtrate was cooled and the brown coloured complex obtained was filtered and dried in vacuum.

$[Cu_2(L^3)Br_2]Br_2{\cdot}2H_2O$

Elemental analysis: Calculated for $C_{24}H_{24}O_2N_6Cu_2Br_4$: Theor:C, 40.18; H, 3.62; N, 9.58; Cu, 11.5. Found: C, 40.05; H, 3.46; N. 9.69; Cu, 11.43.

RESULTS AND DISCUSSION

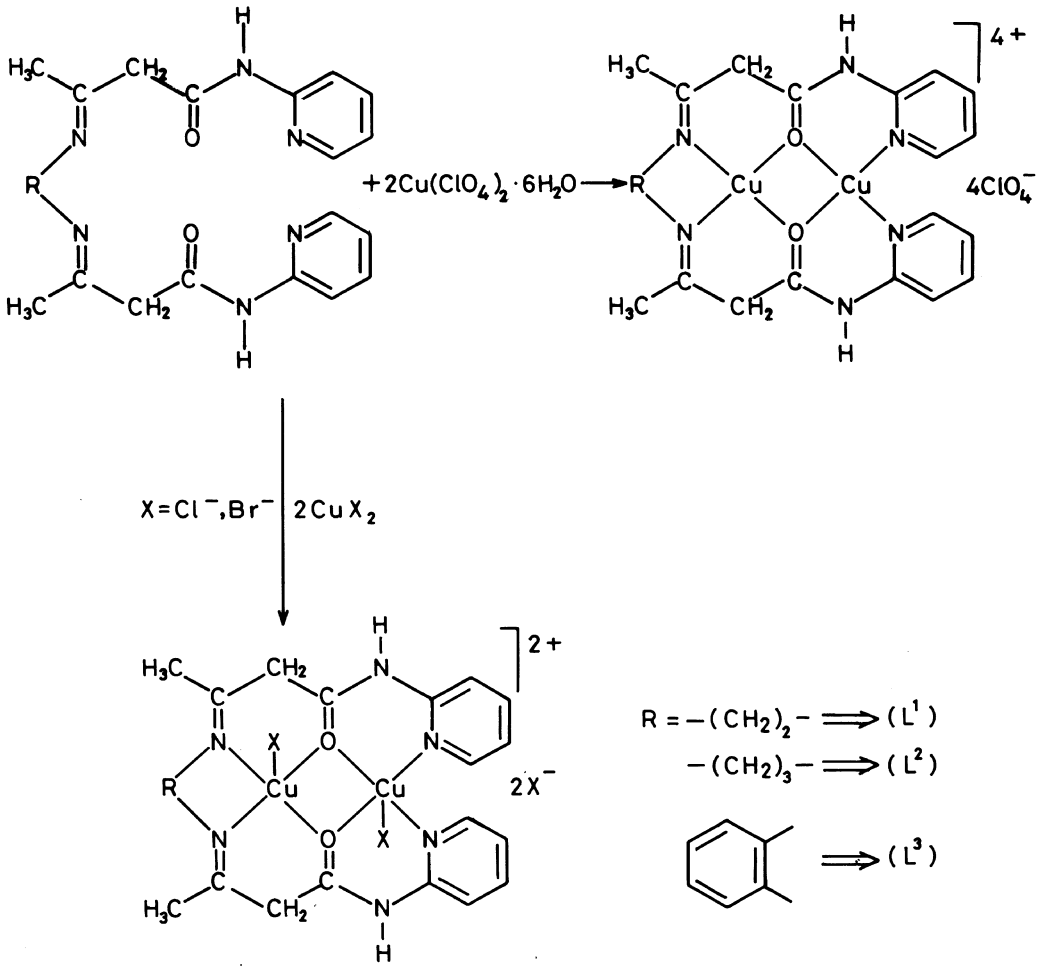
The ligand Methyl-N-(2-pyridinyl) ketoacetamide was prepared by the condensation of ethylacetoacetate and 2-aminopyridine [18]. The IR spectrum of the compound showed υ(N–H) at 3250 cm^{-1} and υ(C═O) frequencies at 1725 cm^{-1} corresponding to the keto group and 1670 cm^{-1} corresponding to the amido carbonyl group [18, 19]. The binucleating ligands were prepared by the condensation of one mole of diamine and two moles of methyl-N-(2-pyridinyl)ketoacetamide.

IR spectra of the ligands showed a peak in the range 3245–3255 cm^{-1} which corresponds to υ(N–H) vibrations, a peak at 1660–1680 cm^{-1} which corresponds to υ(amido carbonyl group) and a peak at 1620–1640 cm^{-1} which corresponds to υ(C═N). The precursor compound and the ligand have common peaks at 3200 and 1670 cm^{-1}. This is due to υ(N–H) and amido carbonyl vibrations. The 1725 cm^{-1} peak present in the precursor compound, which corresponds to the keto group, is not present in the ligands. In the ligands there is an additional peak at 1620 cm^{-1} corresponding to the C═N frequency. This indicates that a complete Schiff base condensation has taken place in the reaction.

Synthesis of copper complexes are shown in scheme 1. The copper complexes showed υ(C═O) in the range 1640–1660 cm^{-1}, υ(N–H) in the range 3250–3350 cm^{-1}, υ(C═N) in the range 1620–1630 cm^{-1}, $\upsilon(ClO_4)$ in the range 1100–1110 cm^{-1} and $\upsilon(H_2O)$ in the range 3480–3550 cm^{-1}. The IR spectral data of the ligands and the complexes are given in Table 1.

Electronic spectra

The data of electronic spectra of the complexes are given in Table 2. These complexes show peaks in the visible as well as in the UV region. A broad band was observed for all the complexes in the visible region of 800–500 nm which are assigned to the d–d transitions of the metal ions. A ligand to metal charge transfer band was observed in the range 310–380 nm. The chloro and bromo complexes show d–d band at longer wavelengths than the perchlorate complexes. This



Scheme 1.

may be due to the distortion of geometry upon coordination of chloride or bromide to copper ions.

Conductance measurements

The equivalent conductance of the perchlorate complexes were carried out in acetonitrile and the values were found to be in the range 391–481 ohm $^{-1}$ cm^2 mol^{-1} suggesting that the complexes belong to 1:4 electrolytes [20]. This indicates that the perchlorate is not coordinated to the metal in solution. Equivalent conductance of chloride complexes carried out in acetonitrile were found in the range 180–209.1 ohm $^{-1}$ cm^2 mol^{-1} suggesting that the chloride complexes belong to 1:2 electrolytes. Two chloride ions are outside the coordination sphere and the other two chloride ions are in the axial positions of the Cu(II) centers. The same effect was observed for bromo complex with the equivalent conductance 170.1 ohm$^-$ cm^2 mo1^{-1}. The equivalent conductance data are listed in Table 2.

Magnetic studies

The magnetic susceptibility studies measured at room temperature (298 K) are substantially lower than the spin only value of 1.73 B.M, which may be due to the presence of antiferromagnetic coupling. Room temperature susceptibilities gave μ_{eff} values in the range 1.02–1.13 B.M for the complexes $[Cu_2(L^1)](ClO_4)_4$ and $[Cu_2(L^1)Cl_2]Cl_2$. The reason for such an observation is due to the quenching of the

unpaired spin of the metal ion by the unpaired spin on the adjacent Cu(II) ion, coupled by superexchange interaction (Cu–O–Cu). Similar results were observed for the $[Cu_2(L^2)](ClO_4)_4$ and $[Cu_2(L^2)Cl_2]Cl_2$ in the range 1.02–1.15 B.M and for $[Cu_2(L^3)Br_2]Br_2$ with $\mu_{eff} = 1.04$ B.M. The magnetic moment are listed in Table 3.

Table 3. ESR spectral data and Magnetic moment values

Complex	g	μ_{eff} B.M
$[Cu_2(L^1)](ClO_4)_4$	2.09	1.13
$[Cu_2(L^2)](ClO_4)_4$	2.09	1.15
$[Cu_2(L^3)](ClO_4)_4$	2.10	1.03
$[Cu_2(L^1)Cl_2]Cl_2$	2.14	1.02
$[Cu_2(L^2)Cl_2]Cl_2$	2.11	1.03
$[Cu_2(L^3)Br_2]Br_2$	2.13	1.04

ESR spectra

The ESR spectra of the complexes (at 298 K) were obtained in the X band region. The absorption signal for the complexes consist of a broad band centered at 3300 G with a width of 1000 G. The g values were calculated using the equation $h\upsilon = g\beta H$. The hyperfine splitting of copper nucleus was not observed due to the broad signal. The g values are listed in Table 3 and the ESR spectra are shown in Fig. 1.

Electrochemical measurements

The redox behaviour of the complexes have been studied in the negative potential region. The electrochemical data are summarised in the Table 4 and the cyclic voltammogram of some of the complexes are reproduced in the Fig. 2. The cyclic voltammogram exhibit a quasireversible redox wave at negative potential. The quasireversibility is confirmed by the shift in

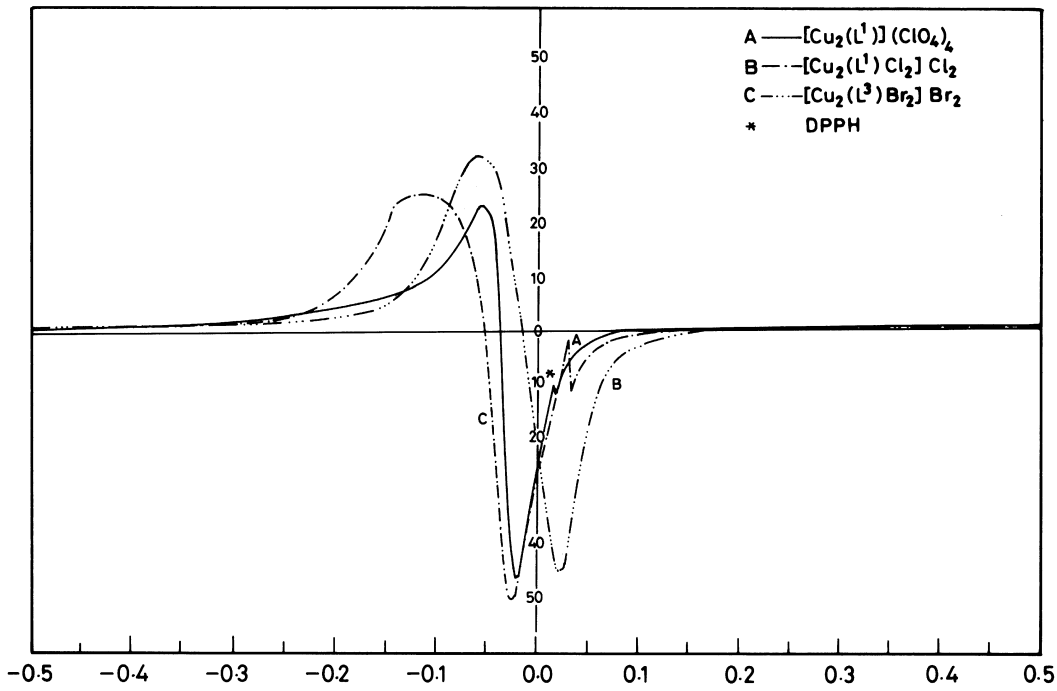

Fig. 1. ESR Spectrum of Dicopper(II) complexes.

Table 4. Cyclic voltammetric data of the complexes

Complex	Scan rates mV/sec	Ep_cV	Ep_aV	ΔEp mV	$E_{1/2}V$

	200	−1.04	−0.44	600	

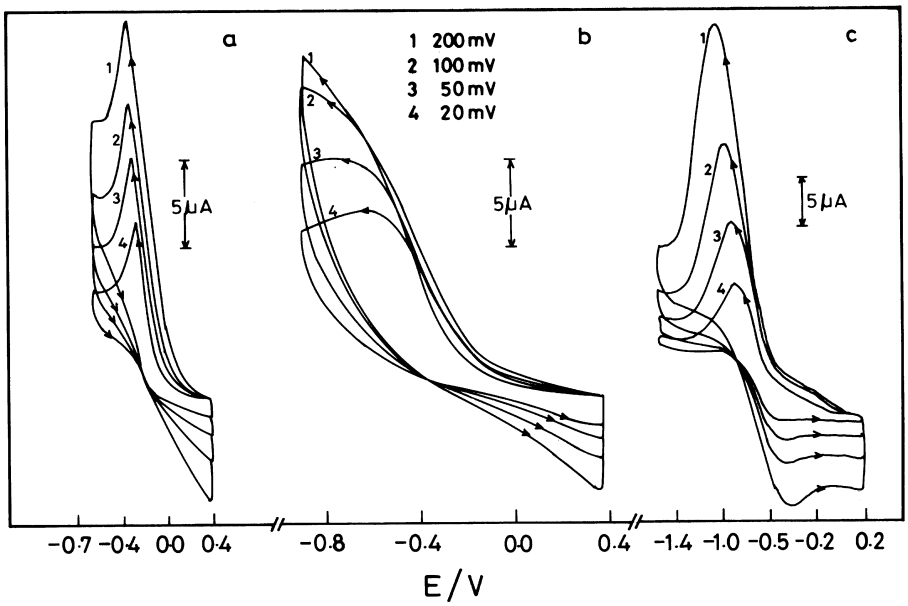

Fig. 2. Cyclic voltammogram of the complexes. a. $[Cu_2(L^1)](ClO_4)_4$; b. $[Cu_2(L^2)](ClO_4)_4$; c. $[Cu_2(L^3)](ClO_4)_4$.

the Ep values and an increase in the ΔEp value with increasing scan rate. The coulometric experiments confirm that the redox couple is associated with two electron transfer process. The electron transfer process of the complexes can be explained by the following scheme.

$$[Cu(II)Cu(II)L]^{n+} + e^- \rightleftharpoons [Cu_2L]^{(n-1)+} + e^- \rightleftharpoons [Cu_2L]^{(n-2)+}$$

This type of reduction process is in agreement with the earlier reports made by Lintvedt [21] *et al.* and E. L. Urbach [22, 23] *et al.* The reduction potentials of the metal centers are influenced by the chelate ring size. The $E_{1/2}$ value for the six membered chelate ring i.e propylenediamine complex is −0.50 V. The $E_{1/2}$ value for the five membered chelate ring i.e. ethylenediamine complex is −0.25 V. The decrease in the $E_{1/2}$ value for the complex $[Cu_2(L^1)](ClO_4)_4$ is due to the distortion in the geometry of the complex as a result of decrease in the chelate ring size [24]. Increased distortion in the coordination geometry around the metal center favours easy electrochemical reduction. The $E_{1/2}$ value for the complex $[Cu_2(L^3)](ClO_4)_4$ is −0.70 V which is higher than the complexes $[Cu_2(L^1)](ClO_4)_4$ and $[Cu_2(L^2)](ClO_4)_4$. This may be due to the presence of o-phenylene moiety, which makes the complex more planar.

Kinetic studies of oxidation of catechol

The Kinetics of oxidation of catechol were determined by the method of initial rates by monitoring the growth of the 390 nm band of the product o-quinone. A linear relationship for initial rate and the complex concentration is obtained for complexes, meaning a first order dependence on the catalytic concentration for the systems. The plot of $\log(A_\infty/A_\infty - A_t)$ Vs time for the catecholase activity of the complexes are shown in Fig. 3 and the rate constant values are reported in Table 5. The perchlorato and the chloro complexes have lower activities than the bromo complexes. This may be attributed to the bromide ligand to be more susceptible for catechol substitution than the chloro or aquo (perchlorato counter ion complexes) ligands. The rate constant for the oxidation of catechol to o-quinone by the complex of ligand L^1 and ligand L^3 are nearly equal and are lower than the complex of ligand L^2. The high value for the complex $[Cu_2(L^2)Br_2]Br_2$ is due to the fact that the complex of ligand L^2 is more planar than the other two ligand (L^1 and L^3) complexes and a planar structure favours easy oxidation [25]. The planarity enhances coordination of one molecule of catechol to two copper ions which increases the rate of oxidation of catechol. It is also observed that the rate constant of the catecholase activity of the binuclear Cu(II) complexes

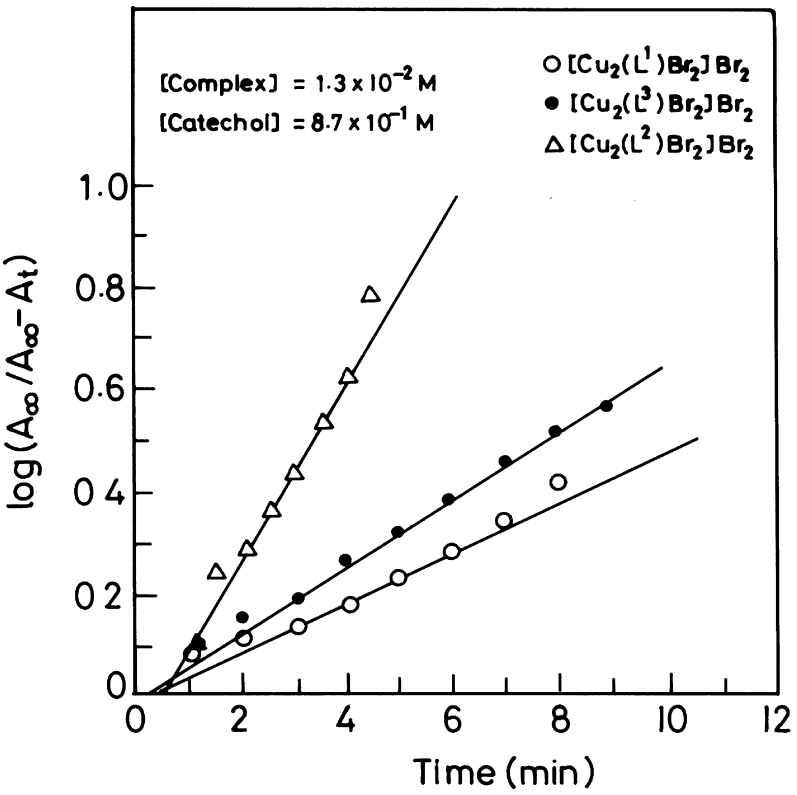

Fig. 3. Oxidation of catechol by Dicopper(II) complexes.

Table 5. Rate constant values for the oxidation of catechol by the complexes

Complexes	Rate constant hr^{-1}
$[Cu_2(L^1)Br_2]Br_2$	9.00
$[Cu_2(L^2)Br_2]Br_2$	23.04

(Received 16 January 1998; accepted 13 April 1998)

Abstract—Reaction of $[MoXX'(CO)_3(NCMe)_2]$ with RC_2R' in CH_2Cl_2 at room temperature gave the bis (alkyne) complexes $[MoXX'(CO)(NCMe)(\eta^2\text{-}RC_2R')_2]$ (X = X′ = I, R = R′ = Me; X = X′ = Br, R = R′ = Me, Ph; X′ = I, X = Cl, Br, R = R′ = Me, Ph) (**1**→**7**) in high yield. The molecular structures of $[MoI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me, Ph) have been determined by X-ray crystallography. The two structures are very similar, with the two alkyne ligands *cis*- and parallel to each other and *trans*- to the two iodo ligands. The carbon monoxide and acetonitrile ligands occupy the two axial sites. Treatment of $[MoI_2(CO)(NCMe)(\eta^2\text{-}RC_2Ph)_2]$ with an equimolar amount of L⌒L {for R = Ph, L⌒L = 5,6-Me_2-1,10-phen, $Ph_2P(CH_2)_2PPh_2$; for R = Me, L⌒L = 2,2′-bipy, $Ph_2P(CH_2)_nPPh_2$, $n = 1, 3, 4$} yielded the mono(alkyne) complexes $[MoI_2(CO)(L⌒L)(\eta^2\text{-}RC_2Ph)]$ (**8**→**13**), which for L⌒L = 5,6-Me_2-1,10-phen, R = Ph (**8**) was crystallogaphically characterised. The geometry around the molybdenum centre is essentially octahedral, with the phenanthroline ligand *trans*- to a carbonyl and an iodide ligand, with the alkyne and other iodide group in the axial sites. Reaction of $[MoI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Ph)_2]$ with two equivalents of NaS_2CNMe_2 in CH_2Cl_2 gave $[Mo(CO)(S_2CNMe_2)_2(\eta^2\text{-}MeC_2Ph)]$ (**14**). © 1998 Elsevier Science Ltd. All rights reserved

Keywords: halocarbonyl alkyne complex; molybdenum(II); crystal structures.

Alkyne ligands have orthogonal p_π-orbitals which enables them to have variable electron-donor interactions to a transition-metal centre. This can range from two to four electrons depending upon which complex is being considered [1]. Both experimental studies [2,3] and theoretical calculations [4–7] support this variable electron donor ability of alkynes. A wide range of alkyne complexes of molybdenum(II) and tungsten(II) have been reported [8,9], and the majority of these have alkyne ligands which donate four electrons to the metal.

In 1988 [10], we described the reactions of $[MI_2(CO)_3(NCMe)_2]$ (M = Mo or W) with two equivalents of RC_2R' to yield $[MI_2(CO)(NCMe)(\eta^2\text{-}RC_2R')_2]$ (M = Mo, W, R = R′ = Ph, R = Me, R′ = Ph; M = W, R = R′ = Me, CH_2Cl, *p*-tol, R = Ph, R′ = CH_2OH) and the dimeric molybdenum complex $[\{Mo(\mu\text{-}I)I(CO)(\eta^2\text{-}MeC_2Me)_2\}_2]$. The molecular structures of $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me and Ph) were crystallographically determined [10]. At the time we considered the molybdenum complexes were much less stable than their tungsten analogues; in particular it was found difficult to isolate [10] the bis(but-2-yne) complex $[MoI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$, which dimerised to give $[\{Mo(\mu\text{-}I)I(CO)(\eta^2\text{-}MeC_2Me)_2\}_2]$. One example of the different reactivity pattern of the two metals has also been previously observed [11], namely the reaction of $[MI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ with one equivalent

* Author to whom correspondence should be addressed.

of PPh_3 which gave $[MoI_2(CO)(PPh_3)(\eta^2\text{-}PhC_2Ph)_2]$ or a mixture of products for M = W, namely $[WI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$, $[WI_2(CO)(PPh_3)(\eta^2\text{-}PhC_2Ph)_2]$ and $[WI_2(CO)(PPh_3)_2(\eta^2\text{-}PhC_2Ph)]$.

We have reinvestigated the reactions of $[MoXX'(CO)_3(NCMe)_2]$ with alkynes to give $[MoXX'(CO)(NCMe)(\eta^2\text{-}RC_2R')_2]$, and in this paper describe their reactivity with both neutral and anionic donor ligands. The molecular structures of the complexes $[MoI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me and Ph) and $[MoI_2(CO)(5,6\text{-}Me_2\text{-}1,10\text{-phen})(\eta^2\text{-}PhC_2Ph)]$ are also described.

EXPERIMENTAL

All reactions described in this paper were carried out under a dry dinitrogen atmosphere using vacuum/Schlenk line techniques. The starting materials, $[MoXX'(CO)_3(NCMe)_2]$ (X = X′ = I [12], Br [13]; X = Cl, X′ = I [14]; X = Br, X′ = I [15]) and $[MoI_2(CO)(NCMe)(\eta^2\text{-}RC_2Ph)_2]$ (R = Me, Ph) [10] were prepared by the published methods. The solvents diethyl ether and dichloromethane were dried and distilled before use. All chemicals used in this research were purchased from commercial sources.

Elemental analyses (C, H and N) were determined using a Carlo Erba Elemental Analyser MOD 1108 (using helium as a carrier gas). Infrared spectra were recorded as thin $CHCl_3$ films between NaCl plates on a Perkin-Elmer 1600 series FTIR spectrophotometer. ^1H and ^{13}C (referenced to $SiMe_4$) and ^{31}P (referenced to 85% H_3PO_4) NMR spectra were recorded on a Bruker AC 250 NMR spectrometer.

Preparations

$[MoI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2].\frac{1}{2}CH_2Cl_2$ **1**

To a solution of $[MoI_2(CO)_3(NCMe)_2]$ (1.0 g, 1.9 mmol) dissolved in CH_2Cl_2 (30 cm^3) in a foil covered Schlenk tube at room temperature was added but-2-yne (0.6 g, 7.8 mmol) and the reaction was stirred for 1 hr. The resulting red solution was filtered, and the solvent removed *in vacuo* giving a red crystalline solid of $[MoI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2].\frac{1}{2}CH_2Cl_2$ **1**. This was recrystallised by cooling a CH_2Cl_2 solution of the complex to −17°C to yield single crystals suitable for X-ray crystallography of **1** as a $\frac{1}{2}$MeOH solvate, which must have arisen as a result of a small amount of MeOH remaining in the degassing unit before degassing the CH_2Cl_2 used in this reaction. Yield 0.9 g, 90%.

Similar reactions of $[MoXX'(CO)_3(NCMe)_2]$ (X = X′ = Br, I, X = Br, Cl, X′ = I) with two equivalents of diphenylacetylene or 4 equivalents of but-2-yne in CH_2Cl_2 gave the products $[MoXX'(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (X = X′ = Br, I; X = Br, Cl, X′ = I; R = Me, Ph) **2**→**7**.

$[MoI_2(CO)(5,6\text{-}Me_2\text{-}1,10\text{-}phen)(\eta^2\text{-}PhC_2Ph)]$ **8**

To a solution of $[MoI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ (0.2 g, 0.258 mmol) dissolved in CH_2Cl_2 (20 cm^3) with continuous stirring at room temperature was added, 5,6-Me_2-1,10-phen (0.054 g, 0.258 mmol) and the reaction mixture stirred for 24 hrs. The product was then washed with hexane (20 cm^3) and diethyl ether (30 cm^3) to give the dark orange complex $[MoI_2(CO)(5,6\text{-}Me_2\text{-phen})(\eta^2\text{-}PhC_2Ph)]$ (**8**) (yield = 0.17 g, 93%). Suitable crystals as their $CDCl_3$ solvate for X-ray analysis were grown from $CDCl_3$ at 298 K in an NMR tube over 7 days.

In a similar reaction of $[MoI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ with an equimolar amount of $Ph_2P(CH_2)_2PPh_2$ gave $[MoI_2(CO)\{Ph_2P(CH_2)_2PPh_2\}(\eta^2\text{-}PhC_2Ph)]$ (**9**).

$[MoI_2(CO)\{Ph_2P(CH_2)PPh_2\}(\eta^2\text{-}MeC_2Ph)]$ **11**

To a solution of $[MoI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Ph)_2]$ (0.3 g, 0.461 mmol), dissolved in degassed CH_2Cl_2 (20 cm^3), with continuous stirring under a stream of dry dinitrogen, was added $Ph_2P(CH_2)PPh_2$ (0.177 g, 0.461 mmol), and the mixture stirred for 24 hrs. Filtration over Celite and removal of the solvent *in vacuo* gave the dark red crystalline complex $[MoI_2(CO)\{Ph_2P(CH_2)PPh_2\}(\eta^2\text{-}MeC_2Ph)]$ (**11**) (Yield = 0.37 g, 91%), which was then washed with hexane (30 cm^3) and diethylether (20 cm^3).

In a similar fashion, reactions of $[MoI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Ph)_2]$ with an equimolar amount 2,2′-bipy or $Ph_2P(CH_2)_nPPh_2$ ($n = 3, 4$) in CH_2Cl_2 gave the complexes $[MoI_2(CO)(2,2'\text{-bipy})(\eta^2\text{-}MeC_2Ph)]$ (**10**) and $[MoI_2(CO)\{Ph_2P(CH_2)_nPPh_2\}(\eta^2\text{-}MeC_2Ph)]$ (**12**) ($n = 3$) and (**13**) ($n = 4$).

$[Mo(CO)(S_2CNMe_2)_2(\eta^2\text{-}MeC_2Ph)]$ **14**

To a solution of $[MoI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Ph)_2]$ (0.2 g, 0.31 mmol) dissolved in CH_2Cl_2 (20 cm^3) at room temperature was added $Na[S_2CNMe_2]$ (0.08 g, 0.61 mmol) and the reaction mixture stirred for 24 hrs. The resulting solution was filtered, and the solvent removed *in vacuo* giving a purple powder, which was washed with hexane (30 cm^3) and diethyl ether (20 cm^3) to give $[Mo(CO)(S_2CNMe_2)_2(\eta^2\text{-}MeC_2Ph)]$ (**14**). Yield = 0.10 g, 83%.

X-ray crystallography

Crystals of complexes, **1**, $[MoI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$, and **8** were grown as described in the experimental section. Crystal data for the three structures are given in Table 1, together with refinement details. Bond lengths and angles for the metal coordination spheres of **1**, $[MoI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ and **8** are given in Table 2. Data were collected with MoKα

radiation using the MAR Research Image Plate System. The crystals were positioned at 75 mm from the Image Plate. 95 frames were measured at 2° intervals with a counting time of 2 mins. Data analysis was carried out with the XDS program [16]. All three structures were solved using direct methods with the Shelx86 program [17]. The non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were included in geometric positions and given thermal parameters equivalent to 1.2 times those of the atom to which they were attached. In all three structures, disordered solvent molecules were located. In (**1**), a solvent methanol was given 50% occupancy, in $[MoI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ a solvent dichloromethane was given 25% occupancy and in (**8**) a solvent trichloromethane was given 50% occupancy. Empirical absorption corrections were applied [18]. The structures were then refined using Shelxl [19]. All calculations were carried out on a Silicon Graphics R4000 Workstation at the University of Reading.

RESULTS AND DISCUSSION

$[MXX'(CO)(NCMe)(\eta^2\text{-}RC_2R')_2]$ complexes

The starting materials for this research, namely $[MoXX'(CO)_3(NCMe)_2]$ (X=X′=I [12], Br [13]; X=Cl, X′=I [14]; X=Br, X′=I [15]) were prepared as described previously [12–15] by reacting the zero-valent complex *fac*-$[Mo(CO)_3(NCMe)_3]$ (prepared *in situ*) with an equimolar amount of XX′. Reaction of $[MoXX'(CO)_3(NCMe)_2]$ with two equivalents of RC_2R' in CH_2Cl_2 at room temperature gives the bis(alkyne) complexes $[MoXX'(CO)(NCMe)(\eta^2\text{-}RC_2R')_2]$ (X=X′=I, R=R′=Me; X=X′=Br, R=R′=Me, Ph; X=Br, X′=I, R=R′=Me, Ph; X=Cl, X′=I,

R = Me, Ph) (**1**→**7**) in good yield. Complexes **1**→**7** have been characterised by elemental analysis (C, H and N) (Table 3), IR (Table 4) and ^{1}H NMR spectroscopy (Table 5). Repeated elemental analysis results and ^{1}H NMR spectroscopy confirmed complexes **1**, **2**, **6** and **7** contained various amounts of CH_2Cl_2 as a solvate in the crystal lattice. Complexes **1**→**7**, although less stable than related tungsten complexes [10, 20, 21], can be stored in the solid state under dinitrogen for several days in the absence of light. Complexes **1**→**7** are soluble in polar chlorinated solvents such as CH_2Cl_2, $CHCl_3$, but very much less soluble in diethyl ether and hydrocarbon solvents.

The IR spectra for complexes **1**→**7**, all show single carbonyl bands which are as expected at lower wavenumber for the but-2-yne complexes compared to the diphenylacetylene analogues. All the complexes **1**→**7** have alkyne stretching bands at considerably lower wavenumber compared to the uncoordinated alkyne.

The complex $[MoI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ was prepared as previously described [10]. Single crystals suitable for X-ray analysis of

[a] Spectra were recorded in $CHCl_3$ as thin films between NaCl plates.
s = strong, *m* = medium, *w* = weak.

$[MoI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me, Ph) were grown by cooling a CH_2Cl_2 solution of the complexes to $-17^\circ C$ for 24 hrs. The single crystal chosen for X-ray analysis of complex **1** contained a $\frac{1}{2}$MeOH solvate in the crystal lattice which probably arose from small quantities of MeOH in the degassing unit containing CH_2Cl_2. This is surprising, but complex **1** has been prepared a number of times and from elemental analysis results and ^1H NMR spectroscopy is always confirmed as a $\frac{1}{2}CH_2Cl_2$ solvate. It must be that the suitable single crystal of **1** chosen for X-ray analysis as a $\frac{1}{2}$MeOH solvate is not representative of the bulk sample of complex **1**. The structures of **1** and $[MoI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ are shown in Figs 1 and 2 together with the atomic numbering schemes. The geometry of the coordination spheres for both complexes are listed in Table 2. Both structures are isomorphous with their tungsten analogues [10] and contain equivalent coordination spheres with the molybdenum atoms bonded to two iodide atoms, one carbonyl group, one acetonitrile group and two alkyne ligands. The geometry of the coordination spheres can best be considered as six-coordinate with the alkyne ligands each occupying one coordination site. The two

* Spectra recorded in $CDCl_3$ (+25°C) and referenced to $SiMe_4$: *s* = singlet, *br* = broad, *d* = doublet, *m* = multiplet.

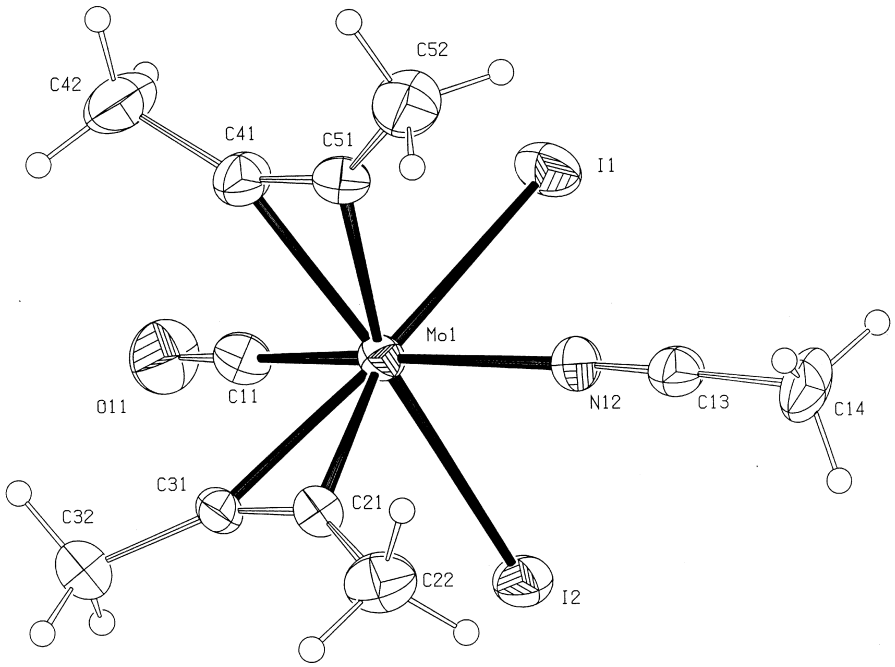

Fig. 1. Crystal structure of $[MoI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ (**1**) showing the atom numbering scheme. Ellipsoids shown at 30% probability.

iodine atoms are mutually *cis* and each is *trans* to an alkyne group. The carbonyl group is *trans* to the acetonitrile group.

There is some small difference in geometry between these two molybdenum complexes and their tungsten analogues reflecting the larger size of the molybdenum atom. Thus the Mo–I bond lengths are 2.905 (2), 2.924 (2) in (**1**) and 2.914 (3), 2.946 (3) Å in $[MoI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$ compared to W–I distances of 2.843–2.862 Å in the tungsten analogues. Similar differences are found in the Mo–N distances and to a lesser extent in the Mo–C distances.

The ^{1}H NMR spectra of complexes **1**→**7** conforms with the structures shown in Figs 1 and 2. The ^{13}C

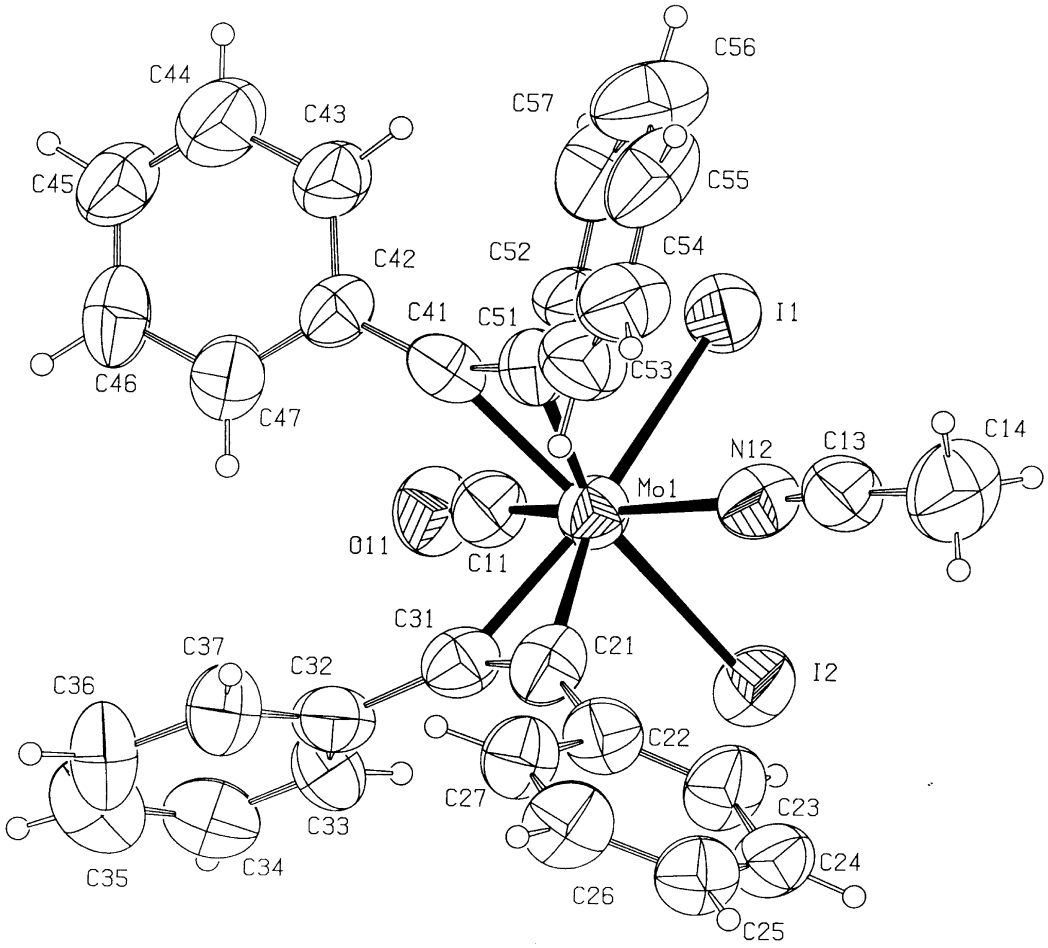

Fig. 2. Crystal structure of $[MoI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$, showing the atom numbering scheme. Ellipsoids shown at 50% probability.

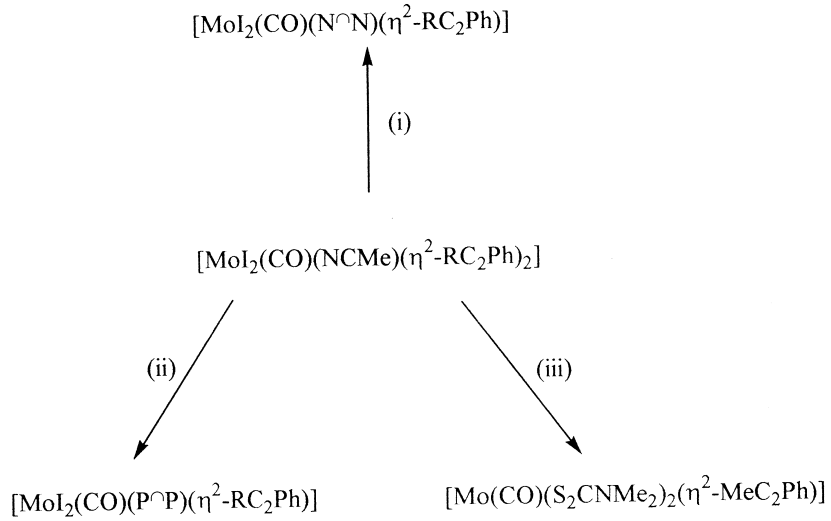
NMR spectrum of complex **1** has alkyne contact carbon resonances at $\delta = 168.0$ and 159.0 ppm, which conforms with the two alkyne ligands donating a total of six-electrons to the molybdenum [1], which enables the complex to obey the effective atomic number rule.

It should be noted that we reported the mono(acetonitrile) complex $[MoI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ (**1**) 'could not be isolated in a pure state' [10]. When reinvestigating this reaction we found that reaction of $[MoI_2(CO)_3(NCMe)_2]$ with excess but-2-yne gave high yields of pure complex **1**. As we have previously observed complex **1** reacts in CH_2Cl_2 at room temperature (17 hrs) to afford the dimeric complex $[\{Mo(\mu\text{-}I)I(CO)(\eta^2\text{-}MeC_2Me)_2\}_2]$. The ease of dimerisation of complexes **1** and **2** was investigated by IR spectroscopy. The room temperature reactions of $[MoX_2(CO)_3(NCMe)_2]$ (X = I, Br) with four equivalents of but-2-yne in $CHCl_3$ were followed by IR spectroscopy. Complete dimerisation of the initially formed bis(alkyne) complexes $[MoX_2(CO)(NCMe)(\eta^2\text{-}MeC_2Me)_2]$ to $[\{Mo(\mu\text{-}X)X(CO)(\eta^2\text{-}MeC_2Me)_2\}_2]$ {for X = I, $\upsilon(CO) = 2020$ and 1966 cm^{-1}; for X = Br, $\upsilon(CO) = 2023$ and 1987 cm^{-1}} were observed after 2 hrs (for **1**) and 1 hr (for **2**) respectively. This might be explained by the smaller size of the bromide ligands enabling more rapid formation of the dimeric complex. It should be noted that Davidson and Vasapollo [22] described the reactions of RC_2R (R = Me, Et, Ph) with $[\{W(\mu\text{-}Br)Br(CO)_4\}_2]$ to give the bromide-bridged dimers $[\{W(\mu\text{-}Br)Br(CO)(\eta^2\text{-}RC_2R)_2\}_2]$, which were fully characterised, and are analogous to the dimers, $[\{Mo(\mu\text{-}X)X(CO)(\eta^2\text{-}MeC_2Me)_2\}_2]$ (X = Br, I) described in this paper. The spectroscopic properties of the $[\{Mo(\mu\text{-}X)X(CO)(\eta^2\text{-}MeC_2Me)_2\}_2]$ (X = Br, I) and $[\{W(\mu\text{-}Br)Br(CO)(\eta^2\text{-}RC_2R)_2\}_2]$ (R = Me, Et, Ph) [22] complexes are very similar.

$[MoI_2(CO)(L^{\frown}L)(\eta^2\text{-}RC_2Ph)]$ *complexes*

The reactions of $[MoI_2(CO)(NCMe)(\eta^2\text{-}RC_2Ph)_2]$ with neutral and anionic ligands described in this



Scheme 1

All reactions were carried out in CH_2Cl_2.

(i) R = Ph, N⌒N = 5,6-Me_2-1,10-phen; R = Me, N⌒N = 2,2′-bipy;
(ii) R = Ph, P⌒P = $Ph_2P(CH_2)_2PPh_2$; R = Me, P⌒P = $Ph_2P(CH_2)_nPPh_2$, n = 1, 3, 4;
(iii) R = Me; 2Na[S_2CNMe_2].

paper are given in Scheme 1. Equimolar quantities of $[MoI_2(CO)(NCMe)(\eta^2\text{-}RC_2Ph)_2]$ and L⌒L in CH_2Cl_2 react at room temperature to give the neutral mono (alkyne) complexes $[MoI_2(CO)(L⌒L)(\eta^2\text{-}RC_2Ph)]$ {R = Ph, L⌒L = 5,6-Me_2-1,10-phen; $Ph_2P(CH_2)_2PPh_2$, R = Me, L⌒L = 2,2′-bipy, $Ph_2P(CH_2)_nPPh_2$ (n = 1, 3, 4)} (**8**→**13**) in high yield. All complexes **8**→**13** have been characterised as shown in Tables 3→5. Complexes **8**→**13** are generally more stable, but less soluble that their bis(alkyne) precursors **1**→**7**.

It is interesting to note [23] that reaction of the analogous tungsten complexes $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me, Ph) react with an equimolar amount of N⌒N (N⌒N = 2,2′-bipy, 1,10-phen) to afford the cationic bis(alkyne) complexes [WI(CO)(N⌒N)(η^2-$RC_2R)_2$]I, which was crystallographically characterised for N⌒N = 2,2′-bipy, R = Me, as its $[BPh_4]^-$ salt. It is well known that low valent molybdenum organometallic complexes are much more labile than their analogous tungsten compounds. This probably accounts for the greater lability of the alkyne ligand bonded to molybdenum. However, reaction of $[WI_2(CO)(NCMe)(\eta^2\text{-}RC_2R)_2]$ (R = Me, Ph) with an equimolar quantity of $Ph_2P(CH_2)_nPPh_2$ (n = 1→6) in CH_2Cl_2 at room temperature yields the mono(alkyne) complexes $[WI_2(CO)\{Ph_2P(CH_2)_nPPh_2\}(\eta^2\text{-}RC_2R)]$ [11], ie. analogous to the molybdenum reactions. The infra red spectra of **8**→**13** all show a single carbonyl band between 1947 and 1977 cm^{-1}. Alkyne stretching bands are also observed at considerably lower wavenumber compared to the free alkyne.

Single crystals of $[MoI_2(CO)$(5,6-Me_2-1,10-phen)(η^2-$PhC_2Ph)]$ (**8**) have been grown from a concentrated $CDCl_3$ solution of **8** in an NMR tube for one week. The molecular structure of $[MoI_2(CO)$(5,6-Me_2-1,10-phen)(η^2-$PhC_2Ph)]$ (**8**) is shown in Fig. 3 together with the atomic numbering scheme and can also best be described as a distorted octahedron in which the PhC_2Ph ligand occupies one site which is *trans*- to an iodide. The second iodide is *trans*- to a nitrogen atom of the phenanthroline ligand, while the carbonyl group is *trans* to the other nitrogen atom. There is half a molecule of $CDCl_3$ per unit formula of **8** in the crystal lattice since suitable single crystals for X-ray analysis were grown from $CDCl_3$. Complex **8**, prepared in CH_2Cl_2 does not have a molecule of solvent as shown by elemental analysis (C, H and N) Table 3 and ^{1}H NMR spectroscopy Table 5. It is interesting that the two Mo–I bond lengths are considerably shorter than in **1** and $[MoI_2(CO)(NCMe)(\eta^2\text{-}PhC_2Ph)_2]$[2.834 (2), 2.868 (2) Å] but presumably this is due to a decrease in strain as the angle subtended at the metal by the two iodides is 90.1° compared to 83.5 (1), 84.2 (1)° in (**1**) and $[MoI_2(CO)(NCMe)(\eta^2PhC_2Ph)_2]$ respectively.

The ^{1}H NMR data (Table 5) for complexes **8**→**13** comply with the formulation of the complexes. Since we have previously described [11] the synthesis and structure of the but-2-yne complex $[WI_2(CO)\{Ph_2P(CH_2)PPh_2\}(\eta^2\text{-}MeC_2Me)]$, we tried to grow single crystals of complexes **9**, **12** and **13**. Suitable single crystals of $[MoI_2(CO)\{Ph_2P(CH_2)_2PPh_2\}(\eta^2$-$PhC_2Ph)]$ (**9**) were grown and subjected to X-ray analysis. The data collected were poor, however the

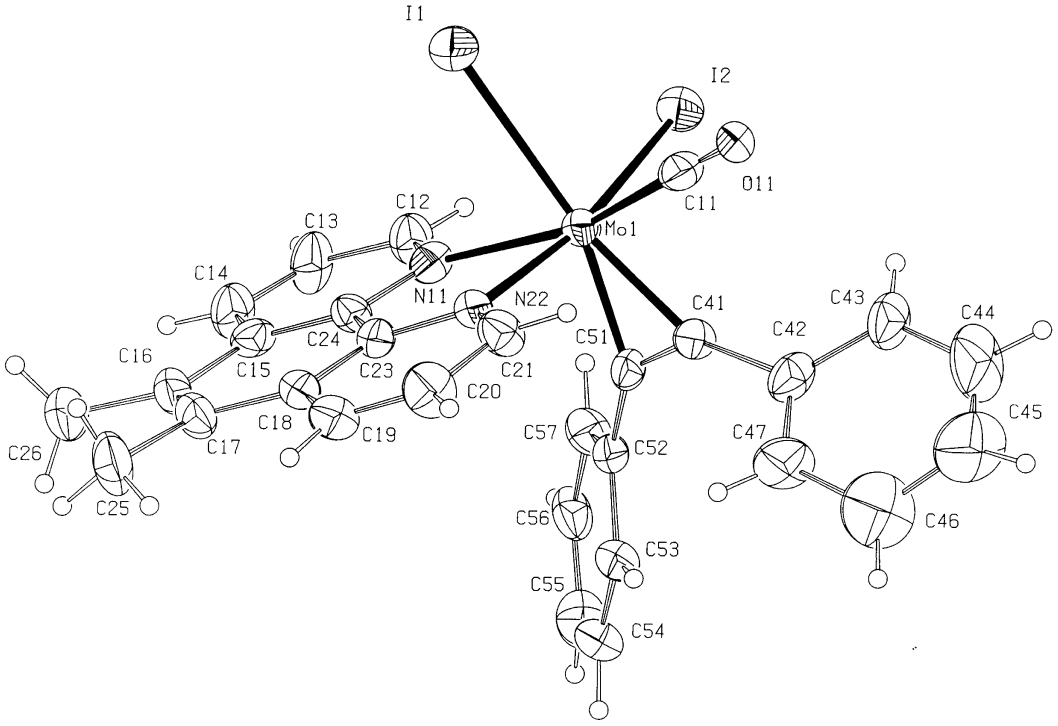


Fig. 3. Crystal structure of $[MoI_2(CO)(5,6\text{-}Me_2\text{-}1,10\text{-phen})(\eta^2\text{-}PhC_2Ph)]$ (**8**), showing the atom numbering scheme. Ellipsoids shown at 30% probability.

basic coordination geometry for the structure is shown in Fig. 4 and is discussed in a footnote[1].

$[Mo(CO)(S_2CNMe_2)_2(\eta^2\text{-}MeC_2Ph)]$ (14) *complex*

Treatment of $[MoI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Ph)_2]$ with two equivalents of NaS_2CNMe_2 in CH_2Cl_2 at room temperature gives the mono(alkyne) complex $[Mo(CO)(S_2CNMe)_2(\eta^2\text{-}MeC_2Ph)]$ (**14**). Complex **14** has been fully characterised in the normal manner (see Tables 3→5). The bis(dithiocarbamate) complex $[Mo(CO)(S_2CNMe_2)_2(\eta^2\text{-}MeC_2Ph)]$ is closely related to the previously reported complexes $[Mo(CO)(S_2CNEt_2)_2(\eta^2\text{-}RC_2R')]$ (R = R′ = H, Ph of CO_2Me; R = H, R′ = Me or Ph; R = Me, R′ = Ph) [24,25], $[Mo(CO)(S_2P^iPr_2)_2(\eta^2\text{-}HC_2H)]$ [26,27] $[W(CO)(S_2CNEt_2)_2(\eta^2\text{-}RC_2R')]$ (R = R′ = H, Me, Et or Ph; R = H, P′ = Ph) [28,29] $[Mo(CO))(S_2CNR_2)(\eta^2\text{-}C_8H_{12})]$ (M = Mo W; R = Me or Ph) [30] and $[W(CO)(L^{\frown}L')_2(\eta^2\text{-}RC_2R')]$ (R = R′ = Me, $L^{\frown}L' = S_2CNMe_2$ or $2\text{-}SC_5H_4N$; R = Ph, R′ = Me, $L^{\frown}L' = S_2CNMe_2$ or S_2PMe_2; R = R′ = Ph, $L^{\frown}L' = S_2PMe_2$) [31]. Since the spectral properties of **14** are similar to the crystallographically characterised complex $[W(CO)(S_2CNEt_2)_2(\eta^2\text{-}HC_2H)]$ [28], the structure of **14** is likely to be similar as shown in Fig. 5.

[1]Data for (**9**), $[MoI_2(CO)\{Ph_2P(CH_2)_2PPh_2\}(\eta^2\text{-}PhC_2Ph)]$, $C_{41}H_{38}I_2MoP_2$, $M = 958.4$, $a = 11.333$ (9), $b = 23.70$ (2), $C = 14.990$ (12) Å, $\beta = 107.50$ (1), $U = 3839$ Å^3, monoclinic, spacegroup $P2_1/c$, $Z = 4$. The crystals gave a highly disordered diffraction pattern, and while the structure was determined, it is of insufficient quality to be reported here in detail. The molybdenum atom occupies an octahedral environment being bonded to two phosphorus atoms *trans* to iodide and the carbonyl group, and a diphenylalkyne *trans* to the second iodide group. The arrangement of ligands is thus different from that observed in $[WI_2(CO)\{Ph_2P(CH_2)PPh_2\}(\eta^2\text{-}MeC_2Me)]$ [11] where the alkyne is *trans* to one of the phosphorus atoms and the iodide groups are *trans* to the remaining phosphorus atom and the carbonyl group.

CONCLUSIONS

Although the bis(alkyne) complexes of molybdenum(II) $[MoXX'(CO)(NCMe)(\eta^2\text{-}RC_2R')_2]$ are less stable than their tungsten analogues, they can be isolated and their chemistry studied. Many of the reactions of the molybdenum and tungsten bis(alkyne) complexes $[MXX'(CO)(NCMe)(\eta^2\text{-}RC_2R')_2]$ are very similar, however their reactions with bidentate nitrogen donors are quite different. For example, the reaction of $[MI_2(CO)(NCMe)(\eta^2\text{-}MeC_2Ph)_2]$ with 2,2′-bipy gives the cationic bis(alkyne) tungsten complex $[WI(CO)(2,2'\text{-bipy})(\eta^2\text{-}MeC_2Ph)_2]I$ [23] and the

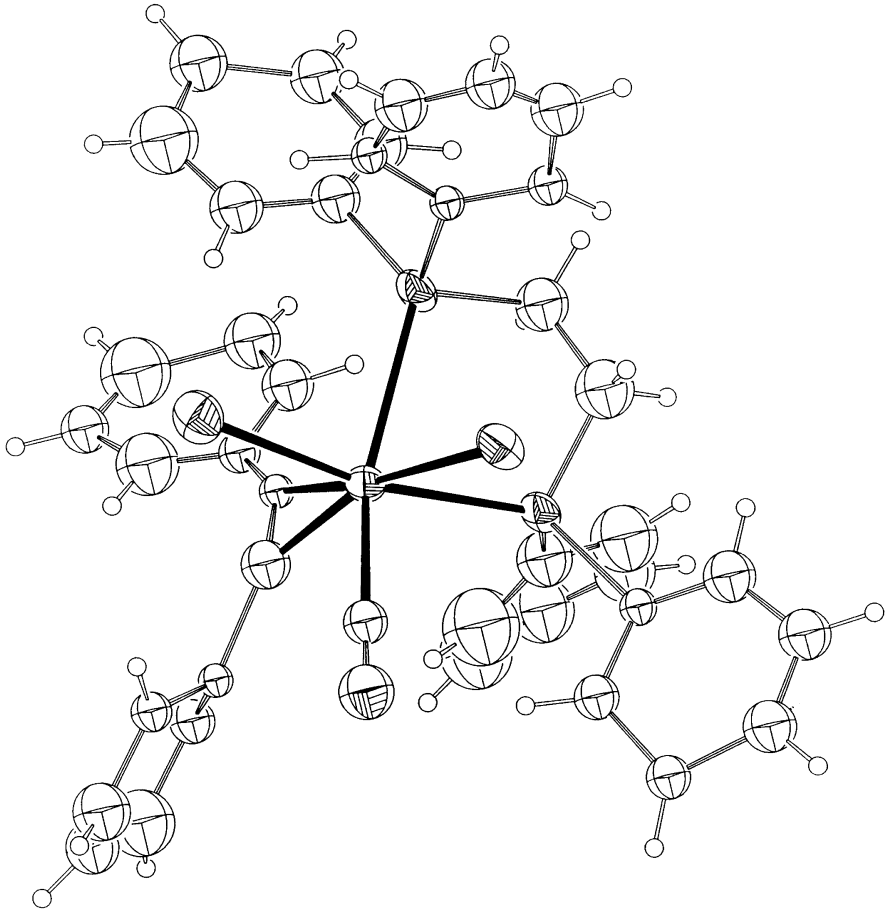

Fig. 4. Ortep picture of $[MoI_2(CO)\{Ph_2P(CH_2)_2PPh_2\}(\eta^2\text{-}PhC_2Ph)]$ (**9**). Ellipsoids shown at 30% probability.

Photoassisted reduction of thionyl chloride by neodymium, europium, thulium and lutetium diphthalocyanines

Ngudiankama Nensala and Tebello Nyokong*

Department of Chemistry, Rhodes University, Grahamstown, 6140, South Africa

(Received 11 February 1998; accepted 7 April 1998)

Abstract—Diphthalocyanine complexes of Nd^{III}, Eu^{III}, Tm^{III} and Lu^{III} ($[Pc(-2)Nd^{III}Pc(-2)]^-$, $[Pc(-2)Eu^{III}Pc(-2)]^-$, $[Pc(-2)Tm^{III}Pc(-2)]^-$ and $[Pc(-2)Lu^{III}Pc(-2)]^-$, respectively), undergo one or two-electron oxidation in the presence of thionyl chloride. The oxidation products depend on the concentration of the thionyl chloride. At low concentrations of $SOCl_2$ ($<10^{-4}$ mol dm^{-3}) one-electron oxidation occurs only upon photolysis, giving the neutral lanthanide diphthalocyanine, $Pc(-2)LnPc(-1)$, complexes. The $Pc(-2)LnPc(-1)$ species undergo one-electron photooxidation to the $[Pc(-1)LnPc(-1)]^+$ in dichloromethane and in the presence of $SOCl_2$. At large concentrations of $SOCl_2$ ($>10^{-2}$ mol dm^{-3}), two electron oxidation of the $[Pc(-2)LnPc(-2)]^-$ species directly to $[Pc(-1)LnPc(-1)]^+$ occurs. © 1998 Elsevier Science Ltd. Keywords: thionyl chloride; diphthalocyanine; photolysis; lanthanide.

Batteries based on lithium–thionyl chloride (Li–$SOCl_2$) chemistry are receiving increasing attention due to their high current density. Research into the reduction mechanism of $SOCl_2$ is thus of current interest [1–3]. It is generally accepted that the cell reaction involves the formation of sulphur, sulphur dioxide and lithium chloride by eq. (1).

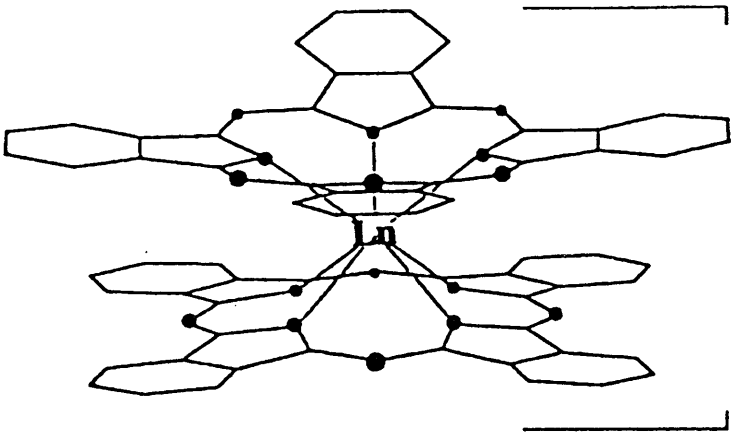
$$SOCl_2 + 4LI \rightarrow S + SO_2 + LiCl \quad (1)$$

The formation of sulphur and sulphur dioxide as final products has been confirmed by electrochemical and spectroscopic methods [2]. Intermediate species such as SO and S_2O have been reported [2, 3]. The $SOCl_2$ reduction mechanism is sometimes complicated by the reaction between $SOCl_2$ and the electrolytes [4]. Possible aggregation of $SOCl_2$ may also further complicate the mechanism for its reduction.

The Li/$SOCl_2$ battery can, however, be explosive. Explosions during storage or exposure to the environment of a partly discharged cell have been attributed to unstable intermediates from the $SOCl_2$ reduction [5]. Another disadvantage of the Li/$SOCl_2$ battery is the polarization of the Li anode associated with the prolonged storage of the batteries. It has been suggested that this polarization is caused by a passive film of LiCl formed on the lithium anode. The LiCl film also adds to the complication of the reduction mechanism of $SOCl_2$.

It has been shown that the modification of the carbon cathode of the Li/$SOCl_2$ battery with metallophthalocyanines (MPc(−2), Pc(−2) = phthalocyanine dianion) complexes improves the cell voltage and the lifetime of the battery [6]. The MPc complexes also prevent passivation of the electrode by LiCl. Studies have shown that CoPc and FePc complexes show catalytic activity towards the reduction of $SOCl_2$ [6]. Lanthanide diphthalocyanine (Pc_2Ln) complexes have been extensively studied for their possible applications in visual display devices [7–10]. There has not been much attention paid to the possible use of Pc_2Ln complexes as electrocatalysts. Studies on the photochemical properties of the Pc_2Ln complexes and on the use of these complexes as photocatalysts are limited [11, 12]. We report in this work on the photocatalytic behaviour of the neodymium^{III}, europium^{III}, thulium^{III} and lutetium^{III} diphthalocyanine complexes (**1**) towards the reduction of $SOCl_2$. Redox processes are centred at the phthalocyanine rings in Pc_2Ln complexes. The cationic and

* Email: CHTN@warthog.ru.ac.za.



1

anionic species of Pc_2Ln complexes are generally described in terms of their colour. The electronic spectra of the blue, $[Pc(-2)LnPc(-2)]^-$; the green, $Pc(-2)LnPc(-1)$; and the orange/red, $[Pc(-1)LnPc(-1)]^+$complexes have been reported [8, 11, 13–15]. Electronic spectra thus provide a reliable method for assessing the redox state changes following interaction between lanthanide diphthalocyanine complexes and $SOCl_2$. It is expected that photolysis of the Pc_2Ln species in the visible region populates the $^3\pi\pi^*$ states as was observed for the tin(IV) diphthalocyanine species [16]. Our studies on the catalytic reactions of the Pc_2Ln complexes towards the reduction of SO_2 and pentachlorophenol have shown that following photoexcitation, the $[Pc(-2)LnPc(-2)]^-$ species transfers one electron to the species being catalysed, with the reversible formation of its one-electron oxidation product, the $Pc(-2)LnPc(-1)$ species. So far, attempts to photochemically induce one-electron oxidation of $Pc(-2)LnPc(-1)$ to the $[Pc(-1)LnPc(-1)]^+$ species have been unsuccessful. We show in this work that the $[Pc(-1)LnPc(-1)]^+$ species is formed in the presence of $SOCl_2$.

EXPERIMENTAL

Materials

The blue forms of neodymium, europium, thulium and lutetium diphthalocyanines ($[Pc(-2)Nd^{III}Pc(-2)]^-$, $[Pc(-2)Eu^{III}Pc(-2)]^-$, $[Pc(-2)Tm^{III}Pc(-2)]^-$ and $[Pc(-2)Lu^{III}Pc(-2)]^-$) were synthesized by reported procedures [8, 17], by mixing 1 mole the appropriate lanthanide acetate with 9 moles of 1,2 dicyanobenzene and heating the mixture in a crucible (with a lid) at 200°C for 3 hours. The $[Pc(-2)Ln^{III}Pc(-2)]^-$ complexes were purified as described before [8], by extraction of the complex with dimethylformamide (DMF), followed by chromatography on a silica column. Only fractions with a ratio of Soret to Q bands of less than 1.4 were retained. The samples gave satisfactory IR (KBr discs, Perkin Elmer Spectrum 2000 IR Spectrophotometer) and UV/vis spectra (Cary 1E Spectrophotometer). The cyclic voltammograms (Bio Analytical Services CV-50W Voltammetric Analyser) obtained for the $[Pc(-2)Ln^{III}Pc(-2)]^-$ complexes were similar to those reported in the literature [18]. The green forms of the lanthanide diphthalocyanine complexes, $(Pc(-2)Ln^{III}Pc(-1))$ were obtained on dissolving the blue forms in neat dichloromethane. These complexes gave reported electronic absorption spectra and cyclic voltammetry [14]. Extinction coefficients [11, 19, 20] for $Pc(-2)Lu^{III}Pc(-1)$, $Pc(-2)Nd^{III}Pc(-1)$, $Pc(-2)Tm^{III}Pc(-1)$ and $Pc(-2)Eu^{III}Pc(-1)$ of $\epsilon = 2\times10^5$, 2×10^5, 1.9×10^5 and 1.8×10^5 $1\,mol^{-1}\,cm^{-1}$, respectively, were used in estimating the concentration of these species in solution. All solvents were freshly distilled before use.

Photochemical methods

Solutions to be photolysed were contained in a 1 cm pathlength UV/vis cell fitted with a stopper. Solutions of the blue, $[Pc(-2)Ln^{III}Pc(-2)]^-$, complex dissolved in acetonitrile or a mixture of acetonitrile and dimethylformamide (DMF) were degassed, then known amounts of thionyl chloride in the same solvent (or solvent mixture) were added to the cell and the solution deoxygenated. The electronic absorption spectra were recorded (Cary 1E spectrophotometer) before photolysis and periodically during the photolysis with a 50 W tungsten lamp. For some experiments photolysis was carried in the visible region, and this was achieved by using a 590 nm filter to exclude the UV radiation. The reported quantum yields were determined using unfiltered radiation. The

$Pc(-2)Ln^{III}Pc(-1)$ species were photolysed in the presence of $SOCl_2$ as described for the blue $[Pc(-2)Ln^{III}Pc(-2)]^-$ species. Concentrations of the lanthanide diphthalocyanine complexes were in the range 1×10^{-6} to 1×10^{-5} mol dm^{-3}, whereas concentrations of thionyl chloride were varied from 1×10^{-6} to 0.1 mol dm^{-3}, depending on the type of experiment. The light intensity was determined at 545 nm, using Reinecke's salt actinometry [21], to be 1.1×10^{-8} einstein sec^{-1}.

RESULTS AND DISCUSSION

Interaction of $[Pc(-2)LnPc(-2)]^-$ species with $SOCl_2$

The interaction of the lanthanide diphthalocyanine complexes with $SOCl_2$ was concentration dependent. At concentrations of $SOCl_2$ less than 10^{-4} mol dm^{-3} for lanthanide diphthalocyanine concentrations of the order of 10^{-6} mol dm^{-3}, no noticeable reaction between $SOCl_2$ and the $[Pc(-2)LnPc(-2)]^-$ was observed. At these low concentrations, photolysis of the solution containing $[Pc(-2)LnPc(-2)]^-$ and $SOCl_2$ resulted in significant spectral changes. When solutions containing 4×10^{-5} mol dm^{-3} of $SOCl_2$ and 1×10^{-6} mol dm^{-3} $[Pc(-2)EuPc(-2)]^-$ in acetonitrile were photolysed with unfiltered radiation from the a tungsten lamp, spectral changes shown in Fig. 1 were observed. These spectral changes were also observed when DMF or a mixture of DMF and acetonitrile were employed as solvents. Spectral changes shown in Fig. 1 were also observed for $[Pc(-2)NdPc(-2)]^-$, $[Pc(-2)TmPc(-2)]^-$ and $[Pc(-2)LuPc(-2)]^-$. Figure 1(a) shows the spectra of $[Pc(-2)EuPc(-2)]^-$ before the addition of $SOCl_2$. This spectra is typical of the blue $[Pc(-2)LnPc(-2)]^-$ species and shows a relatively intense absorption band at 623 nm and a weaker band at 667 nm. The spectra observed on addition of $SOCl_2$, prior to photolysis, was similar to the spectra shown in Fig. 1(a). There was no shift in the Q band spectra. Shifting in the spectra of the MPc complexes on addition of $SOCl_2$ has been attributed to the formation of an adduct between $SOCl_2$ and the MPc species [3]. When the solution containing $SOCl_2$ and the $[Pc(-2)EuPc(-2)]^-$ was photolysed, the 623 nm band decreased in intensity and the low energy band increased in intensity, Fig. 1. The new spectra was formed with a clear isosbestic point at 593 nm showing that only two species are involved. The colour of the solution changed from blue to green. The spectra at the end of photolysis, Fig. 1(b), is typical of the spectra of the $Pc(-2)LnPc(-1)$ species [21], with a charac-

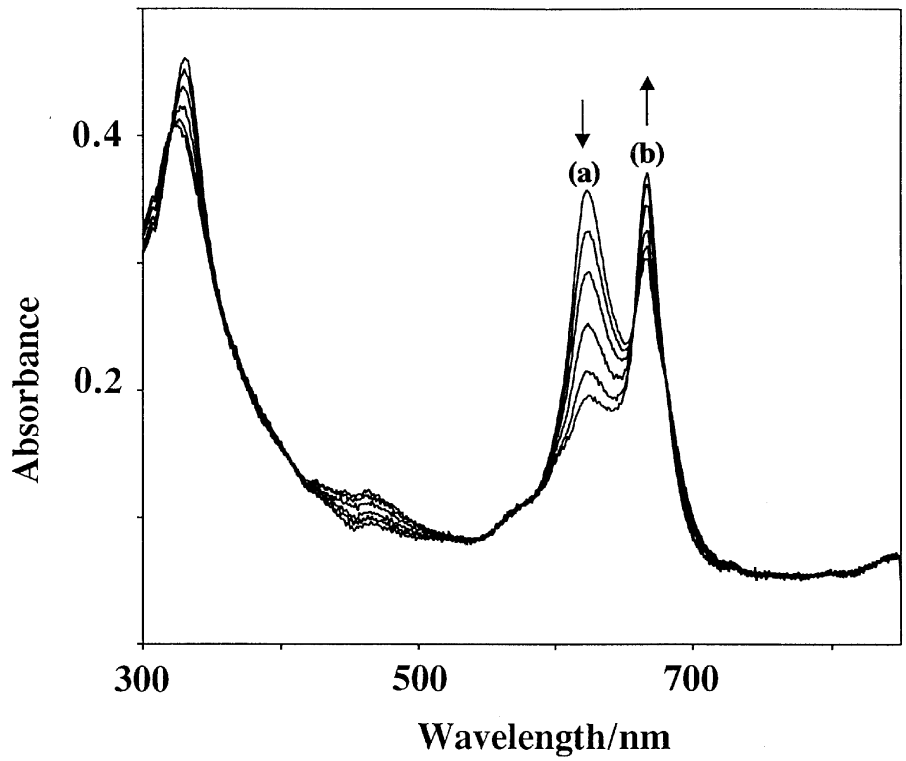


Fig. 1. Absorption spectral changes observed during the photolysis of acetonitrile solutions of 1×10^{-6} mol dm^{-3} of $[Pc(-2)EuPc(-2)]^-$ in the presence of 4×10^{-5} mol dm^{-3} $SOCl_2$, using unfiltered radiation from the tungsten lamp. a) spectra of $[Pc(-2)EuPc(-2)]^-$ before addition of $SOCl_2$ and b) spectra after 20 minutes of photolysis.

teristic weak band near 460 nm associated with electronic transition into the semi−occupied molecular orbital (SOMO) of the phthalocyanine ring. Similarly, photolysis of the $[Pc(-2)NdPc(-2)]^-$, $[Pc(-2)TmPc(-2)]^-$ and $[Pc(-2)LuPc(-2)]^-$ species in the presence of $SOCl_2$ gave spectra due to the corresponding green $[Pc(-2)NdPc(-1)$, $Pc(-2)TmPc(-1)$ and $Pc(-2)LuPc(-1)$, respectively. The $[Pc(-2)NdPc(-2)]^-$, $[Pc(-2)TmPc(-2)]^-$ and $[Pc(-2)LuPc(-2)]^-$ species were found to have low solubility in acetonitrile, thus the photochemical reactions of these complexes were carried out in DMF or a mixture of DMF and acetonitrile. The oxidation of the $[Pc(-2)LnPc(-2)]^-$ species was reversible since the green species could be reduced back to the starting blue complexes by chemical reductants such as sodium borohydride. Spectral changes shown in Fig. 1 were observed even when the UV light was excluded by using a 590 nm filter. Without photolysis, no changes in the spectra were observed at these low concentrations of $SOCl_2$.

We examined the possibility of the photodecomposition of $SOCl_2$ under our conditions. At low concentrations of $SOCl_2$ ($<3\times10^{-4}$ mol dm^{-3}), the spectra consists of a single absorption band near 220 nm in acetonitrile. The observation of a single absorption band at 220 nm confirmed that $SOCl_2$ was not aggregated at these low concentrations. Since concentrations lower than 1×10^{-4} mol dm^{-3} were employed for the photolysis studies Fig. 1 we assume that $SOCl_2$ is not aggregated under our conditions. Photolysis of 4×10^{-5} mol dm^{-3} of $SOCl_2$, in the absence of the lanthanide diphthalocyanine complexes, and using unfiltered radiation resulted in no changes in the absorption spectra of $SOCl_2$, hence suggesting that $SOCl_2$ does not photodecompose under these conditions. Also, we observed no spectral changes when we photolysed the $[Pc(-2)LnPc(-2)]^-$ species in acetonitrile, in the absence of $SOCl_2$. No noticeable spectral changes were observed, without photolysis, for the solutions containing $SOCl_2$ and $[Pc(-2)LnPc(-2)]^-$ at the concentrations used in Fig. 1.

It has been shown before that $SOCl_2$ rapidly (within seconds) oxidizes cobalt^{I} tetraneopentoxyphthalocyanine ($[Co^{I}TnPc(-2)]^-$) by a two-electron transfer process to form the $[Co^{III}TnPc(-2)]^+$ species [3]. Whereas the two-electron oxidation of $Co^{II}TnPc(-2)$ by $SOCl_2$ occurred relatively, more slowly with the formation of a $[Co^{III}TnPc(-1)]^{2+}$ species [3]. One-electron oxidation of the $[Co^{III}TnPc(-2)]^+$ to $[Co^{III}TnPc(-1)]^{2+}$ by $SOCl_2$ occurred very slowly. As mentioned above, oxidation of the $[Pc(-2)LnPc(-2)]^-$ species by $SOCl_2$ was concentration dependent. When concentrations of $SOCl_2$ greater than 1×10^{-4} mol dm^{-3} were employed for $[Pc(-2)LnPc(-2)]^-$ concentrations in the range 1×10^{-6} to 1×10^{-5} mol dm^{-3}, oxidation of the later occurred immediately without photolysis. As the concentration of the $SOCl_2$ decreased, the extent of the oxidation of the $[Pc(-2)LnPc(-2)]^-$ decreased and at very low concentrations of $SOCl_2$ ($<1\times10^{-4}$ mol dm^{-3}), no noticeable oxidation of $[Pc(-2)LnPc(-2)]^-$ was observed spectroscopically, without photolysis of the solution. The actual concentration of $SOCl_2$ needed for oxidation of the $[Pc(-2)LnPc(-2)]^-$ species without need for photolysis depended on the central lanthanide metal ion. The ease of oxidation of lanthanide diphthalocyanine species increase across the series [18]. Thus, $[Pc(-2)LuPc(-2)]^-$ is more readily oxidized, followed by $[Pc(-2)TmPc(-2)]^-$, then $[Pc(-2)EuPc(-2)]^-$, with $[Pc(-2)NdPc(-2)]^-$ being the least readily oxidized. Considering the same concentrations of the lanthanide diphthalocyanine species, the $[Pc(-2)LuPc(-2)]^-$ species requires lower concentration of the $SOCl_2$ species to initiate one-electron oxidation (without photolysis) to the green, $Pc(-2)LnPc(-1)$, complex than the rest of the blue $[Pc(-2)LnPc(-2)]^-$ species.

As shown by equation. 1, SO_2 and S are the expected final products for the four electron reduction of $SOCl_2$. Since only one electron was transferred to $SOCl_2$ from the $[Pc(-2)LnPc(-2)]^-$ species, it is unlikely that S or SO_2 are formed during the photolysis reactions shown in Fig. 1. Spectra due to the $SOCl_2$ species is located in the ultraviolet region and hence it is masked by the Soret band absorption of the $[Pc(-2)LnPc(-2)]^-$ species, hence it was not possible to monitor changes in the spectra of $SOCl_2$ during photolysis. The species formed by the one-electron transfer reaction occurring between $SOCl_2$ and the $[Pc(-2)LnPc(-2)]^-$ species is most likely the reactive intermediate, SOCl, eq. (2):

$$SOCl_2 + e^- \rightarrow SOCl^{\cdot} + Cl^- \qquad (2)$$

The $SOCl^{\cdot}$ radical is not good for the safe operation of the $Li/SOCl_2$ battery since the radical is known to dimerize and decompose into hazardous intermediates [22]. In the presence of metallophthalocyanine complexes, the $SOCl^{\cdot}$ radical can undergo a further one-electron reduction, leading to safer reduction products. Attempts to photoinduce the transfer of the second electron from the green, $Pc(-2)LnPc(-1)$ species formed following the photolysis of solutions containing $SOCl_2$ and $[Pc(-2)LnPc(-2)]^-$ in acetonitrile or DMF, at low concentrations of $SOCl_2$, were unsuccessful. There was no spectroscopic evidence for the formation of the red, $[Pc(-1)LnPc(-1)]^+$, species expected to be formed by one-electron oxidation of $Pc(-2)LnPc(-1)$. As will be discussed below, one-electron oxidation of the green $Pc(-2)LnPc(-1)$ species to the red $[Pc(-1)LnPc(-1)]^+$ occurred in dichloromethane on photolysis in the presence of low concentrations of $SOCl_2$.

Kinetic data for the photolysis of $[Pc(-2)LnPc(-2)]^-$ species in the presence of $SOCl_2$ were collected by keeping the concentration of the former constant at 1×10^{-6} mol dm^{-3} and varying the con-

centration of the latter, then photolysing the solution. Since concentrations of the $SOCl_2$ were larger than those of the lanthanide diphthalocyanines by a factor of at least 20, pseudo first order conditions were assumed. The formation of the Pc(−2)LnPc(−1) species was followed by monitoring the absorption spectra at 667 nm. Plots of $\ln(A_\infty - A_t)$ versus time were linear for at least 80% completion, confirming a first order dependence of the photocatalytic reaction on the lanthanide diphthalocyanine complexes. A_t and A_∞, represent the absorbances at time t and infinity, respectively. The slopes of the plots of $\ln(A_\infty - A_t)$ ver-

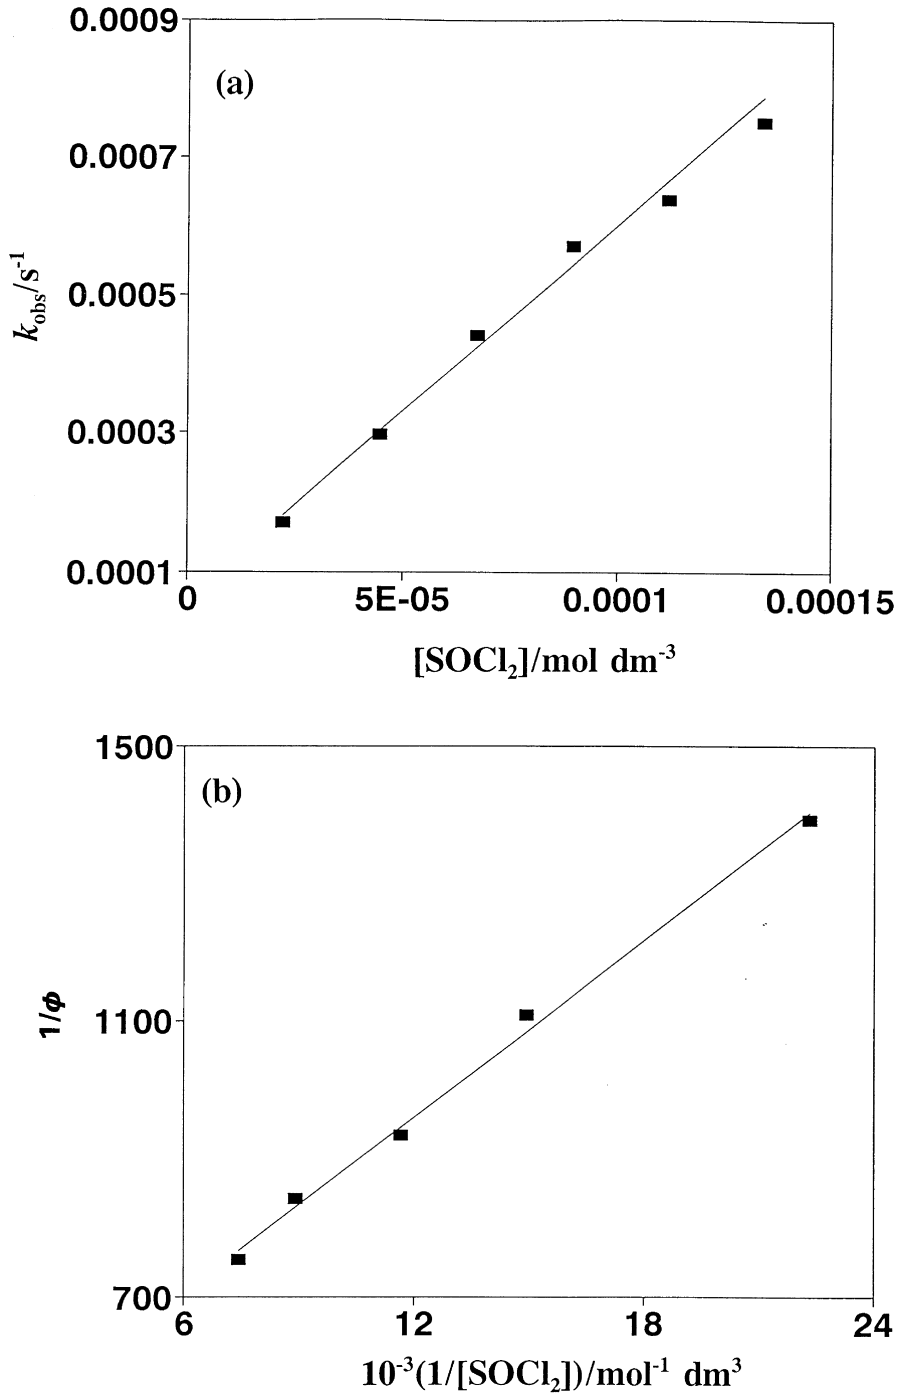

Fig. 2. a) Plots of k_{obs} (s^{-1}) versus $[SOCl_2]$ and b) plots of $1/\phi$ versus $1/[SOCl_2]$ for the photooxidation of 1×10^{-6} mol dm^{-3} $[Pc(-2)EuPc(-2)]^-$ in the presence $SOCl_2$.

sus time gave the observed rate constant, k_{obs}, and plots of k_{obs} versus the concentration of $SOCl_2$ were linear as shown if Fig. 2(a) for the $[Pc(-2)EuPc(-2)]^-$ species, confirming a first order dependence of the reaction on $SOCl_2$. As has been discussed before[11] and in comparison with Pc_2Sn^{IV} [16], it is expected that the triplet states of the lanthanide diphthalocyanine species are populated by photolysis of these complexes in the visible region. The $^3\pi\pi^*$ states may then be quenched by the reaction with $SOCl_2$, eqs. (3–4):

$$[Pc(-2)\,Ln\,Pc(-2)]^- \xrightarrow{h\nu} *[Pc(-2)LnPc(-2)]^- \quad (3)$$

$$*[Pc(-2)LnPc(-2)]^- + SOCl_2 \rightarrow SOCl^{\cdot} + Cl^- + Pc(-1)LnPc(-2) \quad (4)$$

The inverse of the quantum yields for the reaction between $SOCl_2$ and the $*[Pc(-2)LnPc(-2)]^-$ species were plotted versus the inverse of $SOCl_2$ concentration, Fig. 2(b) for $[Pc(-2)EuPc(-2)]^-$, giving linear Stern–Volmer plots and hence showing that $SOCl_2$ is a quencher for the photoexcited $*[Pc(-2)LnPc(-2)]^-$ species. The quantum yields were of the order of 10^{-4} to 10^{-3}. The relative quantum yields for the quenching of $*[Pc(-2)LnPc(-2)]^-$ with $SOCl_2$ are of the same order of magnitude as the quantum yields reported for the quenching of these species by pentachlorophenol and SO_2 [11].

Interaction of the Pc(−2)LnPc(−1) species with $SOCl_2$

When $[Pc(-2)LnPc(-2)]^-$ was dissolved in dichloromethane, the $Pc(-2)LnPc(-1)$ species was formed instantly. Electron transfer from the photoexcited $Pc(-2)LnPc(-2)H$ to CH_2Cl_2 has been observed before [12]. It was thus important to determine the role of the solvent in the photolysis studies involving the $Pc(-2)LnPc(-1)$ species. When solutions of $Pc(-2)LnPc(-1)$ in CH_2Cl_2 were photolysed in the absence of $SOCl_2$, no significant spectral changes were observed, hence showing that CH_2Cl_2 does not act as a quencher of the photoexcited $*[Pc(-2)LnPc(-1)]$ species. The interaction between $Pc(-2)LnPc(-1)$ and $SOCl_2$ was also concentration dependent, with no significant spectral changes observed without photolysis for concentrations of $SOCl_2$ of the order of $10^{-5}\,mol\,dm^{-3}$, for

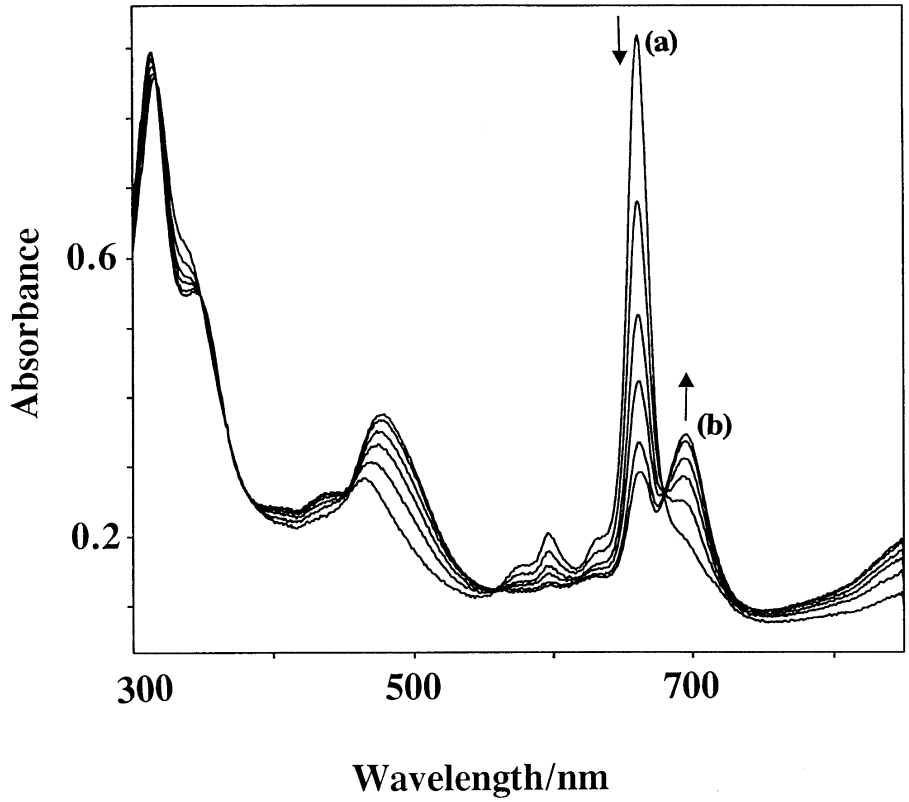

Fig. 3. Absorption spectral changes observed during the photolysis of CH_2Cl_2 solutions of $Pc(-2)TmPc(-1)$ in the presence of $2\times10^{-5}\,mol\,dm^{-3}$ $SOCl_2$, using unfiltered radiation from the tungsten lamp. a) spectra of $Pc(-2)TmPc(-1)$ before addition of $SOCl_2$ and b) spectra after 30 minutes of photolysis.

Pc(−2)LnPc(−1) concentrations ranging from 1×10^{-6} to 1×10^{-5} mol dm^{-3}.

Photolysis of a solution containing Pc(−2)LnPc(−1) and 2×10^{-5} mol dm^{-3} $SOCl_2$ in CH_2Cl_2 resulted in the spectral changes shown in Fig. 3. There was a decrease in the intensity of the Q band at 622 nm and a formation of a new weaker band at lower energies, 696 nm. The band near 464 nm due to the transition into the SOMO shifted to 475 nm. The new spectra was formed with clear isosbestic points at 346, 375, 557 and 681 nm. The solution turned from green to red. The spectral changes and the corresponding colour changes are typical of the formation of the $[Pc(-1)LnPc(-1)]^+$ species [8, 23].

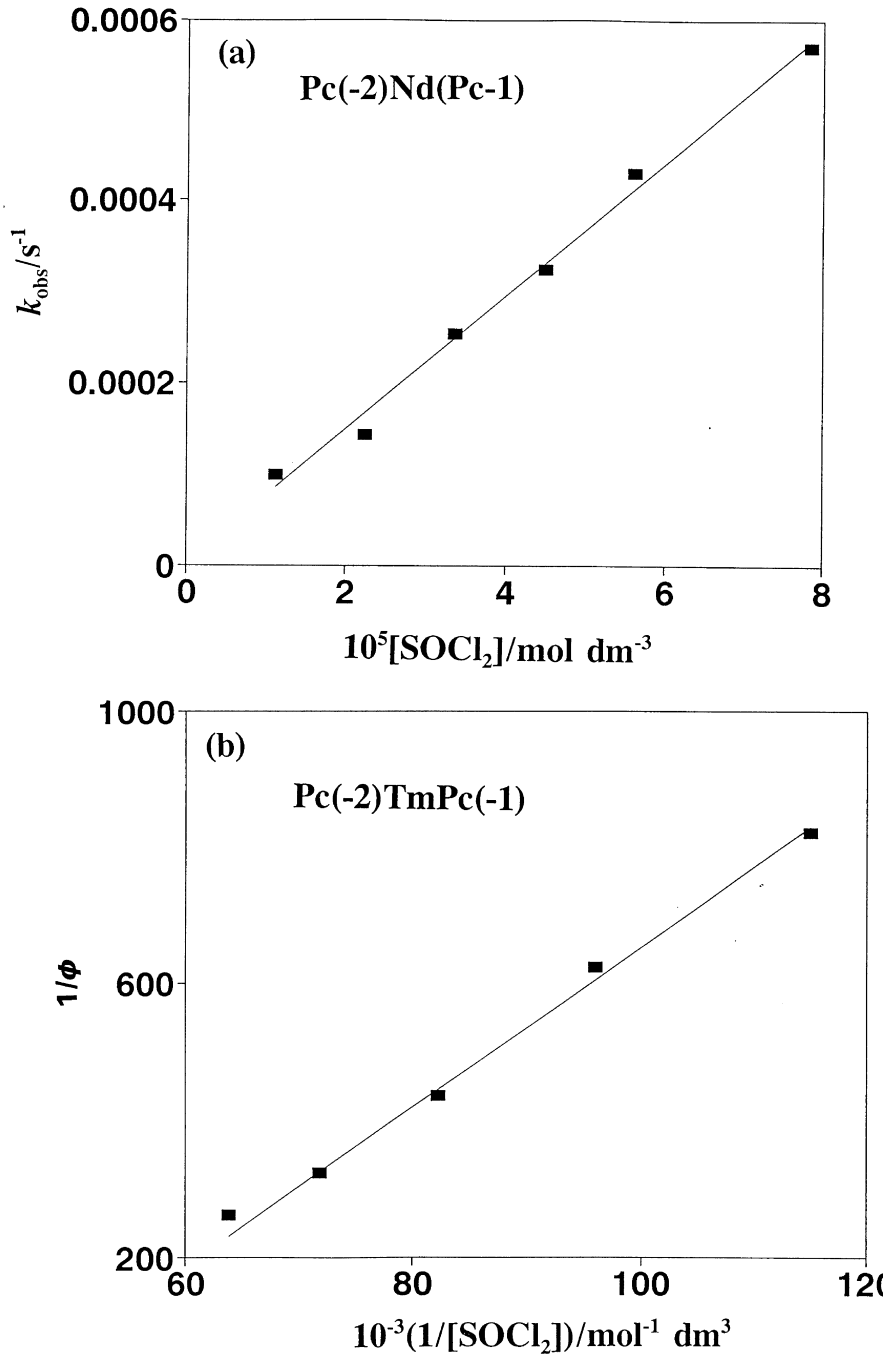

Fig. 4. a) Plots of k_{obs} (s^{-1}) versus $[SOCl_2]$ and b) plots of $1/\phi$ versus $1/[SOCl_2]$ for the photooxidation of [Pc(−2)NdPc(−1)] (a) and Pc(−2)TmPc(−1) (b) in the presence $SOCl_2$.

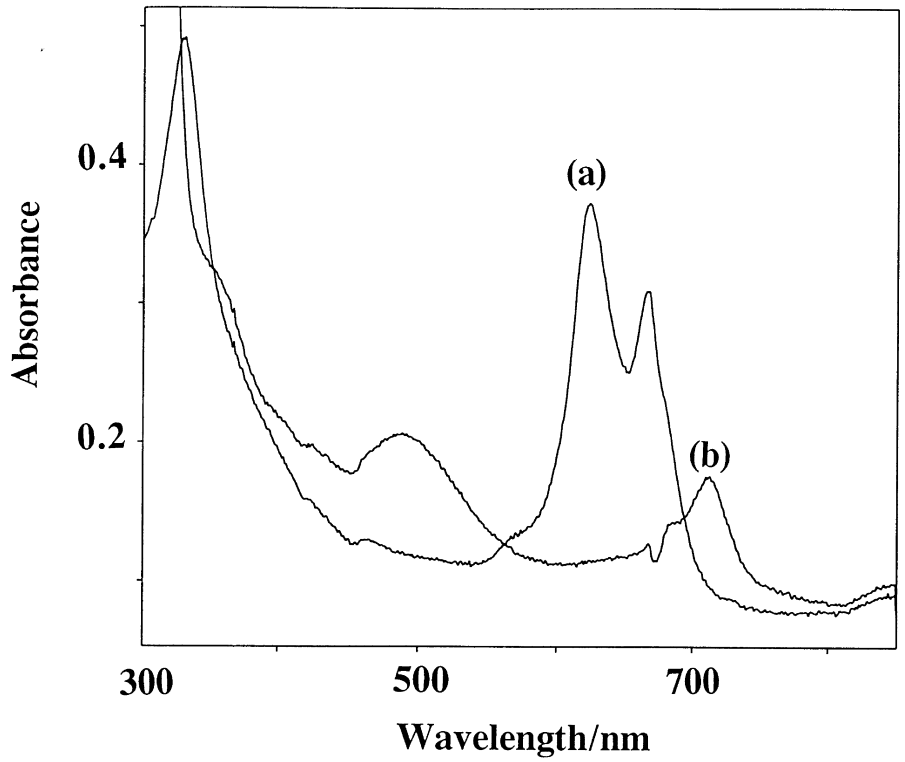

Fig. 5. Absorption spectral changes observed when a large concentration ($\sim 10^{-2}$ mol dm^{-3}) of $SOCl_2$ was added to the acetonitrile solution of 1×10^{-6} mol dm^{-3} of $[Pc(-2)EuPc(-2)]^{-3}$. a) spectra of $[Pc(-2)EuPc(-2)]^{-}$ before addition of $SOCl_2$ and b) spectra after addition of $SOCl_2$.

The formation of the $[Pc(-1)LnPc(-1)]^{+}$ species was reversible. At concentrations larger than 10^{-4} mol dm^{-3}, oxidation of the $Pc(-2)LnPc(-1)$ species to $[Pc(-2)LnPc(-2)]^{+}$ occurred by $SOCl_2$ without the need for photolysis.

The one-electron oxidation of $Pc(-2)LnPc(-1)$ suggests that the reduction of $SOCl_2$ under these circumstances again involves the formation of the same species (SOCl) as was formed by the photolysis of $[Pc(-2)LnPc(-2)]^{-}$ in the presence of thionyl chloride. We thus suggest that eqs. (5–6) are applicable for the photolysis of $Pc(-2)LnPc(-1)$ in the presence of $SOCl_2$.

$$Pc(-1)\,LnPc(-2) \xrightarrow{h\nu} *[Pc(-1)LnPc(-2)] \quad (5)$$

$$*[Pc(-1)\,LnPc(-2)] + SOCl_2 \quad (6)$$

$$\rightarrow SOCl^{\cdot}Cl^{-} + [Pc(-1)LnPc(-1)]^{+}$$

We collected the kinetic data for the photolysis of $Pc(-2)LnPc(-1)$ in the presence of $SOCl_2$ as described above for $[Pc(-2)LnPc(-2)]^{-}$. The disappearance of the $Pc(-2)LnPc(-1)$ species was followed by monitoring its Q band absorption spectra. Plots of the logarithm of absorbance versus time were linear confirming a first order dependence of the photocatalytic reaction on the $Pc(-2)LnPc(-1)$ complexes. Plots of k_{obs} versus the concentration of $SOCl_2$ were linear as shown in Fig. 4(a) for the $Pc(-2)NdPc(-1)$ species, confirming a first order dependence of the reaction on $SOCl_2$. Plots of the inverse of the quantum yields versus the inverse of the concentration of $SOCl_2$ for the reaction between $SOCl_2$ and the $*[Pc(-2)LnPc(-1)]$ species gave linear Stern–Volmer plots, Fig. 4(b) for the $Pc(-2)TmPc(-1)$, again showing that $SOCl_2$ is a quencher for this reaction. Quantum yield values were of the order of 10^{-3} for the Lu^{III} and Tm^{III} complexes and of the order of 10^{-4} for the Nd^{III} and Eu^{III} complexes.

A direct two-electron reduction of $SOCl_2$ in the presence of lanthanide diphthalocyanine complexes was observed when large concentrations ($>10^{-2}$ mol dm^{-3}) of $SOCl_2$ were added to solutions of the blue $[Pc(-2)LnPc(-2)]^{-}$ species. There was no need for photolysis. The solution went directly from blue to red, hence confirming the formation of the $[Pc(-2)LnPc(-1)]^{+}$, species, Fig. 5. The two electron reduction was reversible in that the red species could be reduced in a stepwise manner to the green, $Pc(-2)LnPc(-1)$, and finally to the blue, $[Pc(-2)LnPc(-1)]^{-}$; in the presence of chemical reductants. The most likely product formed by the two electron reduction of $SOCl_2$ is the SO species [3].

In conclusion we have shown in this work that photolysis enhances oxidation of the Pc(−2)LnPc(−1) or $[Pc(-2)LnPc(-2)]^-$ species by $SOCl_2$. At low concentrations of $SOCl_2$, oxidation occurs by one-electron transfer only, probably generating the reactive $SOCl^{\cdot}$ intermediate in the presence of light. At high concentrations of $SOCl_2$, it is possible for one or two-electron reductions of this species to occur, most likely producing $SOCl^-$ or SO, respectively, without photolysis. The one-electron reduction of $SOCl_2$ in the presence of the photoexcited lanthanide diphthalocyanine species, may be useful in the elucidation of the mechanism for reduction of $SOCl_2$ by MPc complexes.

(Received 23 January 1998; accepted 16 March 1998)

Abstract—Reaction of the iodo-bridged tungsten dimer $[(PhN)W(CO)_2I_2]_2$ with 2 equiv of $LiOCH_3$ produced new dimers of the type $[(PhN)W(CO)_2I(OCH_3)]_2$. The intermediate iodo-bridged dimer $[(PhN)W(CO)_2(\mu\text{-}I)(OCH_3)]_2$ (**5**) reacted with PMe_3, $P(OMe)_3$ or $NH_2C_6H_2Me_3$ to yield mononuclear derivatives of the type $(PhN)W(CO)I(OCH_3)L_2$ [for **10**: L = PMe_3, for **11**: $P(OMe)_3$] or $(PhN)W(CO)_2I(OCH_3)(NH_2C_6H_2Me_3)$ (**9**). In solution, **5** slowly isomerized to $[(PhN)W(CO)_2I(\mu\text{-}OCH_3)]_2$ (**6**), for which an X-ray crystal structure confirmed the presence of bridging methoxide ligands. Further reaction of **6** with excess $LiOCH_3$ resulted in substitution of methoxide for the remaining iodides of **6** to produce $[(PhN)W(CO)_2(OCH_3)_2]_2$ (**7**) in low yield. © 1998 Elsevier Science Ltd. Keywords: metal imido; iodo-bridged dimer; ligand substitution; metal-metal interaction; binuclear complex.

INTRODUCTION

Despite the high level of interest in transition metal imido complexes [1], examples containing π-acceptor ligands such as CO, alkenes, alkynes and isocyanides still remain relatively rare. The conflicting requirements of an electrophilic metal center that can accept electrons from the strongly donating NR^{2-} ligand and high lying filled metal *d* orbitals for back donation into the π^* levels of the acceptor ligands restrict such complexes to a d^2 electron configuration. Because competition for the available *d* electrons limits the strength of the backbonding interaction, imido complexes can generally support only a single π-acid ligand [2–6], although a few examples contain two [7].

We recently reported the preparation of the tungsten imido dimer $[(PhN)W(CO)_2I_2]_2$ (**1**) by oxidation of the zwitterion $(CO)_5WNPhNPhC(OMe)Ph$ with one equiv of I_2 [8]. The iodide bridges of **1** can be readily replaced by two-electron donor ligands to yield the series of mononuclear complexes $(PhN)W(CO)_2I_2L$ [L = CH_3CN, THF, NEt_3 or C_5H_5N; for **2**: $C_6H_2(CH_3)_3NH_2$] [9]. When **1** is treated with the more strongly nucleophilic PMe_3 or $P(OMe)_3$, a second equivalent of L replaces one of the carbonyls to produce $(PhN)W(CO)I_2L_2$ [for **3**: L = PMe_3; for **4**: $P(OMe)_3$] [8b]. Although the iodide bridges are broken in the reactions, no further displacement of iodide occurs.

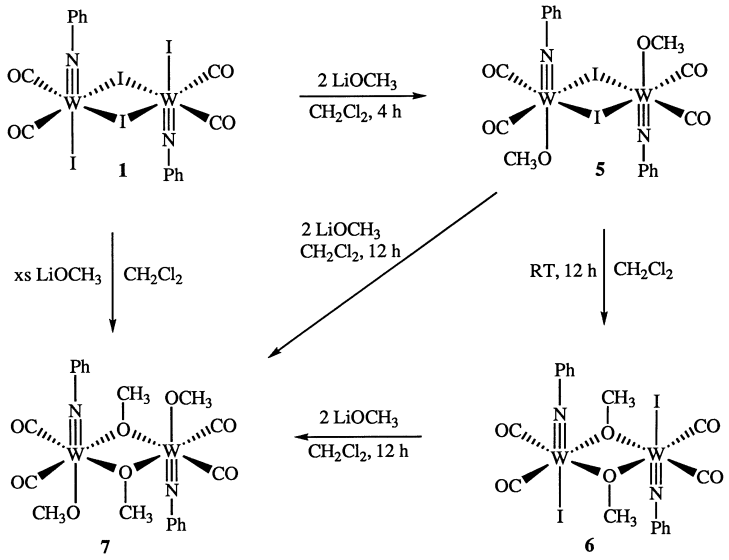
We now report the reactions of dimer **1** with the harder nucleophile CH_3O^-. In contrast to the previously reported chemistry with neutral two-electron donors, methoxide displaces iodide to yield new dimeric complexes in which the alkoxide ligands occupy terminal or bridging positions. These complexes contain strongly donating imido and alkoxide ligands at the same metal center as π-acid carbonyls. The interplay of these ligands can be seen in the structure and bonding of the alkoxide-bridged dimer $[(PhN)W(CO)_2I(\mu\text{-}OCH_3)]_2$ (**6**).

RESULTS AND DISCUSSION

Reaction of $[(PhN)W(CO)_2I_2]_2$ (**1**) *with* $LiOCH_3$ *and* $NaOCH_3$

Treatment of dimer **1** with 2 equiv $LiOCH_3$ in CH_2Cl_2 resulted in the substitution of methoxide for two of the iodide ligands over the course of 4 hr (Scheme 1). The initial major product could not be isolated but was assigned as iodo-bridged dimer **5** on the basis of its spectral data and the products of subsequent reactions. Most significant is the single $-OCH_3$ signal at 3.53 ppm in the ^1H NMR spectrum of **5**, indicative

* Author to whom correspondence should be addressed.



Scheme 1.

of equivalent methoxy ligands. Comparison of the chemical shift of the methoxy groups in **5** with the lower field signals in the isomeric dimer **6** (*vide infra*) allowed the assignment of terminal $-OCH_3$ groups in **5** [10, 11].

After the reaction mixtures had stirred for 6 hr, the characteristic IR bands for the carbonyl ligands of dimer **1** at 2069 and 2009 cm^{-1} had completely given way to new signals at 2055 and 1984 cm^{-1}. The ^1H NMR spectra showed the reaction mixtures to contain small amounts of **5** and a new major product whose only $-OCH_3$ signal at 4.71 ppm indicated the presence of equivalent bridging methoxy groups [11]. Conversion of dimer **5** to the new product was complete within 12 hr. Identification of the new product as dimer **6** was confirmed by X-ray crystallography (*vide infra*).

Dimer **1** was also treated with 4–10 equiv of $LiOCH_3$ in CH_2Cl_2, in attempt to induce further substitutions of iodide by methoxide. Increasing the amount of $LiOCH_3$ led to mixtures of **6** and a new dimeric complex which has been identified as **7** (Scheme 1). Dimer **7** could also be obtained by treating isolated **6** with 2 equiv of $LiOCH_3$ in CH_2Cl_2. Although addition of 2 equiv of $LiOCH_3$ to **5** also generates **7**, the time scale of the reaction is consistent with initial rearrangement of **5** to **6**, followed by formation of **7**. Complete conversion of all four original iodide ligands of **1** to methoxide ligands was indicated by the ^1H NMR spectrum of **7**, in which signals of equal intensity at 3.46 and 4.60 ppm established the presence of both terminal and bridging methoxy groups.

The sequence of reactions in Scheme 1 suggests that the facile substitution reactions in this system are conversions of the terminal iodide ligands to terminal methoxy groups. This process converts complex **1** to **5**. Cleavage of the iodo bridges in **5** then produces mononuclear complexes that can either revert to **5** or recombine through bridging methoxy groups to yield **6**. Although complexes with one iodide and one methoxide bridge could also be generated in this process, they have not been unambiguously identified in the reaction mixtures. Once the conversion of **5** to **6** regenerates terminal iodide ligands, excess $LiOCH_3$ can convert **6** to **7** via substitution. The isomerization of **5** to **6** and the reluctance of **6** and **7** to undergo bridge cleavage reactions (*vide infra*) are indicative of greater stability of methoxide bridges in this system as compared with bridging iodide ligands.

In an attempt to increase the selectivity in substitution reactions of dimer **1**, the source of methoxide was changed to $NaOCH_3$. Although NaOR/ROH systems have been used for substitution of halide ligands by OR groups [12], reaction of **1** with $NaOCH_3$ in CH_3OH did not yield the expected products. Instead, as the reaction of **1** with 2 eq $NaOCH_3$ in CH_3OH was monitored by IR spectroscopy, the CO bands for dimer **1** disappeared within 4 h, and the only new CO band at 1929 cm^{-1} belonged to a species that could not be identified. Following removal of the solvent under vacuum, no identifiable products could be isolated. Similarly disappointing results were obtained in CH_2Cl_2 and C_6H_6. These reaction mixtures exhibited a new IR stretch at 1742 cm^{-1}, suggesting the presence of a bridging CO ligand and a new bridging OCH_3 signal (4.17 ppm) in the ^1H NMR spectrum but the complexity of the reaction mixtures and the lability of the species involved prevented characterization of the products.

Crystal structure of dimer **6**

A crystal structure of compound **6** was obtained as described in the Experimental Section. The crystal

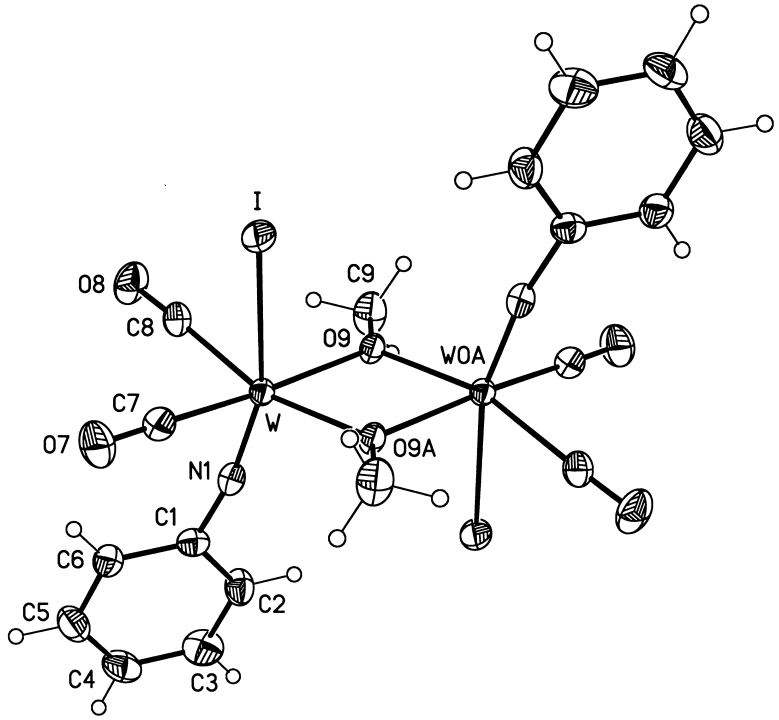


Fig. 1. Thermal ellipsoids diagram of $[(PhN)W(CO)_2(I)(\mu\text{-}OCH_3)]_2$ (**6**) showing the crystallographic numbering scheme. Ellipsoids are drawn at the 40% probability level.

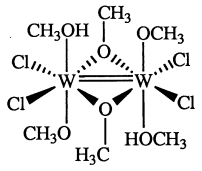
structure of **6** confirmed the presence of bridging methoxide ligands as assigned from spectroscopic data. A thermal ellipsoids diagram appears in Fig. 1 and selected structural data are collected in Table 1. The $(CO)_2W(NPh)$ moiety of **6** bears a strong resemblance to the analogous fragment in the iodo-bridged dimer **1** [8b], in that the three ligands maintain nearly 90° bond angles to one another. In both complexes the terminal iodide ligands are distorted toward the carbonyls [for **6**: C7–W–I = 79.0(2)°; for **1** the analogous angle is 81.4(4)]. The more strongly donating nature of the bridging $-OCH_3$ groups in **6** can be seen in the more strongly bent imido ligand [for **6**: C1–N1–W = 168.7(4)°; for **1** the analogous angle is 177.0(8)]. The W–CO bond lengths are also slightly shorter in **6**, consistent with stronger backbonding to the carbonyl ligands. This analysis is supported by the lowered CO stretching frequencies in the IR spectrum of **6** as compared to **1** [**6**: 2055, 1984 cm^{-1} vs. **1**: 2069, 2009 cm^{-1}].

Table 1. Selected distances [Å] and angles [°] for $[(PhN)W(CO)_2I(\mu\text{-}OCH_3)]_2$ (**6**)

W–N1	1.764(4)
W–C8	2.039(5)
W–C7	2.042(5)
W–O9	2.093(3)
W–I	2.8308(4)
O7–C7	1.133(7)
C8–O8	1.131(6)
O9–C9	1.423(6)
W–W	3.393(1)
N1–W–C8	88.7(2)
N1–W–C7	87.8(2)
N1–W–O9	103.9(2)
O9A–W–O9	71.7(1)
C7–W–I	79.0(2)
C9–O9–W	123.8(3)
C1–N1–W	168.7(4)
W–O9–WOA	108.3(2)

The structure of the center W_2O_2 core of **6** provides an interesting contrast to the analogous fragment in $W_2Cl_4(OCH_3)_4(CH_3OH)_2$ (**8**), which also contains W(IV) centers bridged by methoxy groups [11a]. The W–N multiple bonding in the linear imido ligands of **6** provides electron density at the metal that obviates the need for metal-metal bonding. In the case of **8**, the W–W distance of 2.481(1) Å is indicative of a metal-metal double bond. However, the W–W distance of 3.393(1) Å in **6** is a nonbonding metal-metal distance [13]. This difference in the metal-metal interaction is reflected in the remainder of the W_2O_2 core. In W=W doubly-bonded **8**, the short metal-metal distance forces the W–O–W bond angles to narrow to 75.2(2)°. In contrast, because there is no metal-metal bond in **6**, the W_2O_2 ring distorts to relieve repulsion between the metal centers [14]. The W–O–W bond angles in **6** have

expanded to 108.3(2)° (instead of 90°) while the O–W–O angles are compressed to 71.7(1)°. In fact, the bond angles in **6** closely resemble those in the Nb(V)–Nb(V) alkoxide-bridged dimer $Nb_2(OMe)_{10}$ [O–Nb–O = 70.1(3)°; Nb–O–Nb = 109.9(3)] [15], for which no metal-metal bonding is possible.



8

Electronic structure calculations on dimer **6**

The differences in metal-metal interaction between the two W(IV)–W(IV) methoxy-bridged dimers **6** and **8** led us to perform Extended Hückel calculations [16] on **6** for comparison to published calculations on **8** [11a]. The atomic coordinates of **6** were taken from the crystal structure described above and the HOMO is depicted in Fig. 2. The HOMO and the occupied orbital immediately below (HOMO-1) are similar in character, both being primarily devoted to back-bonding from metal *d* orbitals to the carbonyl ligands. The availability of these high lying filled metal *d* orbitals for backbonding is a consequence of the strong π-donation from the imido ligands. Although the *d* orbitals are in phase in the HOMO, the overlap between them is minimal as both are distorted toward the carbonyl carbons. This lack of interaction is reflected in the structure of **6**, where the W(IV) centers maintain a nonbonding distance. This situation can be contrasted to the metal-metal interaction in **8** [11a], where the HOMO ($11b_u$) is primarily comprised of the π-bonding combination of d_{xz} orbitals and the HOMO-1 ($10a_g$) contains a major contribution from the σ-bonding combination of the d_{z2} orbitals. Thus, in **8**, the two highest occupied orbitals form the metal-metal double bond. The difference is attributable to the fact that **6** bears the strongly donating imido ligands as well as four π-acid carbonyls.

Reactions of dimers **5** and **6** *with* $NH_2C_6H_2Me_3$, PMe_3 *and* $P(OMe)_3$

Mixtures of methoxide-substituted dimers **5** and **6** were generated by the reaction of dimer **1** with 2 equiv of $LiOCH_3$. After 3–4 h, when the concentration of terminal methoxide **5** was at its maximum, mesityl amine ($NH_2C_6H_2Me_3$) was added to the reaction mixtures. Dimer **5** was converted to the monomeric amine complex $(PhN)W(CO)_2I(OCH_3)(NH_2C_6H_2Me_3)$ (**9**)

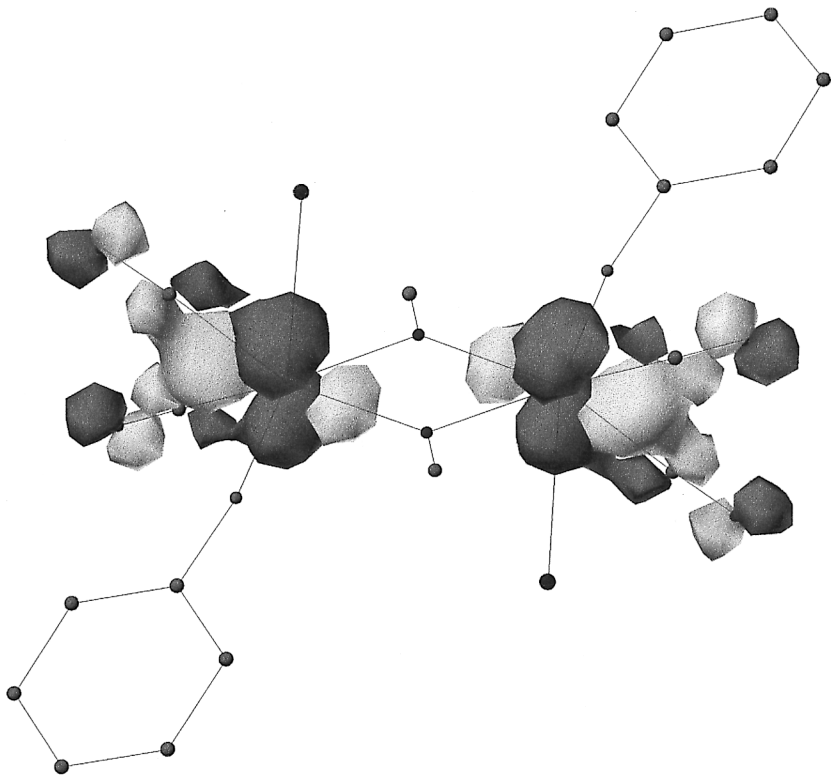


Fig. 2. HOMO of **6**. Orbital surfaces are taken from EHT calculations as described in text and plotted with an isosurface value of 0.055. The orientation of the molecule is as in Figure 1 but the hydrogens are omitted for clarity.

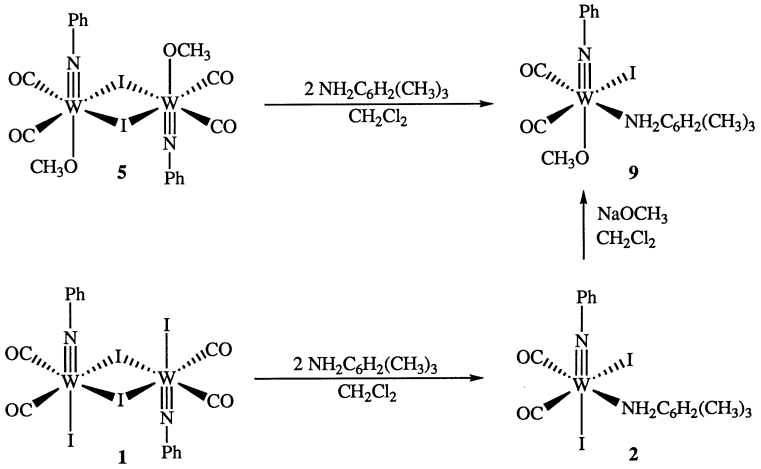
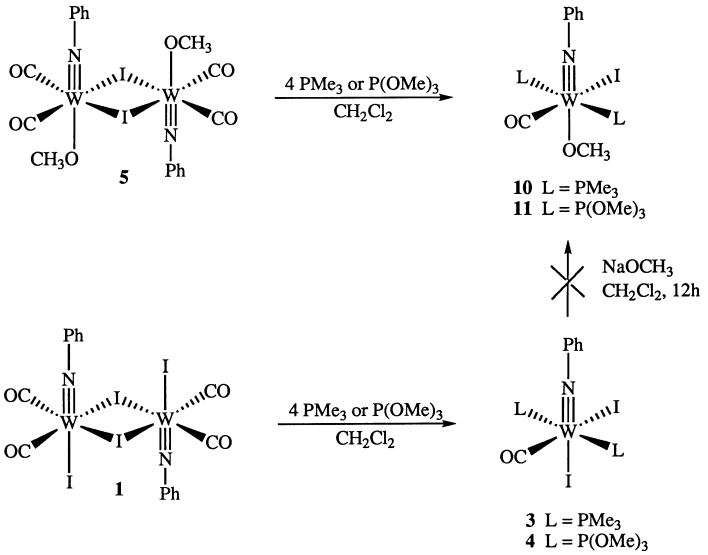
while **6** remained untouched (Scheme 2). The lack of reactivity between **6** and mesityl amine was confirmed in a control experiment in which pure **6** was treated with 4 equiv of $NH_2C_6H_2Me_3$ in CH_2Cl_2 overnight. Complex **9** was also independently synthesized by reacting the known amine complex $(PhN)W(CO)_2I_2(NH_2C_6H_2Me_3)$ (**2**) [8a] with 1 equiv of $NaOCH_3$ in CH_2Cl_2 overnight.

Mixtures of **5** and **6** were generated as described above for reaction with PMe_3. When the concentration of **5** had reached its maximum, 4 equiv of PMe_3 were added to the solution to yield $(PhN)W(CO)I(OCH_3)(PMe_3)_2$ (**10**) (Scheme 3). In contrast to the reaction with mesityl amine, both isomeric dimers **5** and **6** reacted with the more nucleophilic PMe_3. This observation was corroborated by treatment of pure **6** with excess PMe_3, resulting in the formation of **10**. Although the initial product of cleavage of the ligand bridges was most likely the unobserved monophosphine complex $(PhN)W(CO)_2I(OCH_3)(PMe_3)$, the final product **10** was the result of a second substitution in which a carbonyl was replaced by PMe_3. Similar chemistry was observed in the reaction of dimer **1** with PMe_3, in which two equivalents of phosphine were incorporated into the final monomeric product $(PhN)W(CO)I_2(PMe_3)_2$ (**3**) [8b]. Although mesityl amine derivative **9** could be prepared from the corresponding diiodide **2**, efforts to synthesize **10** independently from **3** and $NaOCH_3$ were not successful.

The products of dimers **5** and **6** with other potential ligands were highly dependent on the nucleophilicity



Scheme 2.



Scheme 3.

and base strength of the reacting species. As shown in Scheme 3, reaction of dimer **5** with $P(OMe)_3$ gave a similar result to the PMe_3 reaction. The isolated product, $(PhN)W(CO)I(OCH_3)[P(OMe)_3]_2$ (**11**), also bore a single carbonyl due to a second substitution involving $P(OMe)_3$. As was the case with PMe_3, dimer **6** also reacts with $P(OMe)_3$ to yield **11**. Reactions of similar mixtures of **5** and **6** with CH_3CN, $C_5H_{10}NH_2$, NEt_3 and *p*-$TolNMe_2$ were also attempted. In the cases of CH_3CN and *p*-$TolNMe_2$, complex **5** decomposed to unidentifiable material while **6** remained in the mixture as unreacted starting material. When $C_5H_{10}NH_2$ and NEt_3 served as nucleophiles, no inorganic products could be identified but the amine salts $[C_5H_{10}NH_3]I$, and $[HNEt_3]I$ could be isolated from the reaction mixtures.

CONCLUSION

Reaction of dimer **1** with $LiOCH_3$ demonstrates that substitution for the terminal iodide ligands is a facile process. The resulting iodo-bridged dimer **5** can then undergo further reactions with PMe_3, $P(OMe)_3$ or $NH_2C_6H_2Me_3$ to yield mononuclear derivatives. Rearrangement of iodo-bridged **5** to its methoxide-bridged isomer **6** produces a binuclear complex that is less prone to bridge-cleavage reactions, although the phosphorus nucleophiles PMe_3 and $P(OMe)_3$ do react with **6** to yield mononuclear complexes. X-ray crystallography of **6** confirms its structural assignment and establishes the lack of a metal-metal bonding interaction. Although related alkoxide-bridged binuclear W(IV) complexes are metal-metal doubly bonded, the strongly π-donating nature of the imido ligands and the backbonding to the carbonyl ligands of **6** prevent strong metal-metal interaction.

EXPERIMENTAL

General considerations

Standard inert atmosphere techniques were used throughout. Hexane and methylene chloride were distilled from CaH_2. Diethyl ether and THF were distilled from Na/Ph_2CO. NMR solvents were degassed by three freeze-pump-thaw cycles and stored over 3 Å molecular sieves in a dry box. All reagents were purchased in reagent grade and used without further purification. ^1H, ^{13}C and ^{31}P NMR spectra were recorded on Gemini-300 or VXR-300 NMR spectrometers. IR spectra were recorded on a Perkin-Elmer 1600 spectrometer. High resolution mass spectrometry was performed by the University of Florida analytical service. Elemental analyses were performed by Robertson Microlit Laboratories, Madison, NJ. Column chromatography was performed at 20°C on neutral alumina (Brockmann Activity 1). Dimer **1** was synthesized as previously reported [8].

$[(PhN)W(CO)_2(\mu\text{-}I)(OCH_3)]_2$ (**5**)

Dimer **1** (165 mg, 0.141 mmol) and $LiOCH_3$ (10.7 mg, 0.282 mmol) were dissolved in 10 mL of CH_2Cl_2 and stirred at room temperature for 3 h, during which a white solid formed. After the IR spectrum of the solution showed disappearance of the CO bands from dimer **1** and appearance of the CO bands for dimer **5**, the solid was filtered out, and the solvent was removed under vacuum. The ^1H NMR of this crude product showed a mixture of dimers **5** and **6**, which converted to **6** upon standing at room temperature in $CDCl_3$. The lability of **5** precluded its purification. IR (CH_2Cl_2): ν_{CO} 2048, 1983 cm^{-1}. ^1H NMR ($CDCl_3$): δ 7.36, 7.24 (m, 10H, Ph), 3.53 (s, 6H, OCH_3).

$[(PhN)W(CO)_2I(\mu\text{-}OCH_3)]_2$ (**6**)

Dimer **1** (75.0 mg, 0.064 mmol) and $LiOCH_3$ (4.86 mg, 0.128 mmol) were loaded into a Schlenk flask in the dry box. CH_2Cl_2 (5 mL) was added to dissolve the mixture and then the solution was stirred at room temperature in the dry box for 14 h. During this time, white solid formed in the red solution. The solvent was removed under vacuum. The residue was then dissolved in a very small amount of CH_2Cl_2 and transferred to a neutral alumina column. Elution with ether yielded complex **6** (48.0 mg, 76.6%). IR (CH_2Cl_2): ν_{CO} 2055, 1984 cm^{-1}. ^1H NMR ($CDCl_3$): δ 7.48 (d, $J=7$ Hz, 4H, Ph), 7.33 (m, 6H, Ph), 4.71 (s, 6H, μ-OCH_3). ^{13}C NMR ($CDCl_3$): δ 215.2 (W–CO), 153.1, 129.1, 128.6, 127.1 (Ph), 75.4 (μ-OCH_3). HRMS (FAB): calcd 949.8168 $(M–CO)^+$, found 949.8175.

$[(PhN)W(CO)_2(OCH_3)_2]_2$ (**7**)

A Schlenk flask was charged with dimer **6** (32 mg, 0.033 mmol) and $LiOCH_3$ (5 mg, 0.132 mmol). CH_2Cl_2 (5 mL) was then added to dissolve the mixture. The solution was stirred 3 h while the color of the solution changed to orange red and white solid precipitated out. The solid was removed by filtration through Celite and the solvent was removed under vacuum. The residue was recrystallized in CH_2Cl_2/hexane to yield dimer **7** (16 mg, 61.7%). IR (CH_2Cl_2): ν_{CO} 2052, 1964 cm^{-1}. ^1H NMR ($CDCl_3$): δ 7.14 (t, $J=8$ Hz, 4H, Ph), 6.75 (t, $J=7$ Hz, 2H, Ph), 6.68 (d, $J=7$ Hz, 4H, Ph), 4.60 (s, 6H, μ-OCH_3), 3.46 (s, 6H, OCH_3). ^{13}C NMR ($CDCl_3$): δ 218.2 (W–CO), 154.1, 128.8, 128.5, 127.6 (Ph), 75.4 (W-μ-OCH_3), 50.7 (W–OCH_3). The lability of the complex precluded obtaining an elemental analysis.

$(PhN)WI(CO)_2(NH_2C_6H_2Me_3)(OCH_3)$ (**9**)

Dimer **1** (63 mg, 0.054 mmol) and $LiOCH_3$ (4.08 mg, 0.108 mmol) were dissolved in 8 mL of CH_2Cl_2. The solution was stirred 3 h, during which white solid pre-

cipitated and the CO stretches in the IR spectrum of **1** were replaced by new CO bands at 2050 and 1984 cm^{-1}. The solution was filtered through Celite, 15.1 μL (0.108 mmol) of $NH_2C_6H_2Me_3$ was added, and the solution was stirred for another 4 h. The solvent was removed under vacuum and the residue was washed with hexane to yield a red powder. The ^1H NMR spectrum showed the product to be a mixture of complexes **9** and **6** (ratio of **9:6** = 9:1, based on ^1H NMR integration). The isolated yield of the mixture was 34 mg or 44.5% yield of **9**. IR (CH_2Cl_2): ν_{CO} 2072, 1986 cm^{-1}. ^1H NMR ($CDCl_3$): δ 7.50, 7.41 (m, 3H, Ph), 7.31 (t, 2H, Ph), 6.82 (s, 2H, C_6H_2), 6.47, 5.63 (d, 2H, NH_2), 2.46 (s, 6H, $C_6H_2Me_3$), 2.29 (s, 3H, $C_6H_2Me_3$), 2.17 (s, 3H, OCH_3). ^{13}C NMR ($CDCl_3$): δ 209.0, 207.1 (W–CO), 152.7, 139.3, 135.4, 129.7, 129.2, 129.1, 127.1 124.9 (Ph, C_6H_2), 20.5, 18.9, 18.1. HRMS (FAB): calcd 624.0107, found 624.0110.

(PhN)WI(CO)(PMe$_3$)$_2$(OCH$_3$) (**10**)

Dimer **1** (92.0 mg, 0.079 mmol) and $LiOCH_3$ (5.96 mg, 0.158 mmol) were loaded into a Schlenk flask in a dry box and 6 mL of CH_2Cl_2 was added to dissolve the mixture. The solution was stirred for 3 h during which white solid (LiI) precipitated out. Hexane (3 mL) was added to the solution and the solid was filtered out. A 1.0 M solution of PMe_3 in THF (0.316 mL, 0.316 mmol) was added and the solution was stirred 1 h while the color changed to dark red. The solvent was removed under vacuum and the residue was recrystallized with hexane/CH_2Cl_2 to yield pure **10** as a red solid (34.0 mg, 35.1%). IR (CH_2Cl_2): ν_{CO} 1951 cm^{-1}. ^1H NMR ($CDCl_3$): δ 7.40, 7.30, 7.23 (m, 5H, Ph), 3.86 (s, 3H, OCH_3), 1.97 (d, 18H, PMe_3). ^{13}C NMR ($CDCl_3$): δ 233.6 (W–CO), 154.3, 129.2, 127.0, 123.6 (Ph), 68.1 (OCH_3), 18.4 [d, $P(CH_3)_3$]. ^{31}P NMR ($CDCl_3$): δ −39.0 (J_{WP} = 281.6 Hz). Anal. Calcd for $C_{14}H_{26}O_2NIP_2W$: C, 27.43; H, 4.28; N, 2.29. Found: C, 27.32; H, 4.30; N, 2.20.

(PhN)WI(CO)[P(OMe)$_3$]$_2$(OCH$_3$) (**11**)

Dimer **1** (65 mg, 0.056 mmol) and $LiOCH_3$ (4.2 mg, 0.111 mmol) were dissolved in 8 mL of CH_2Cl_2 and the solution was stirred 3 h while a white solid precipitated out and the IR stretches of **1** were replaced by CO bands at 2058 and 1984 cm^{-1}. The solution was filtered through Celite and $P(OMe)_3$ (13.2 μL, 0.111 mmol) was added. After stirring at room temperature for 15 h, the solution had become dark red. The solvent was removed under vacuum and the residue was recrystallized with CH_2Cl_2/hexane to yield **11** as a red solid (28.0 mg, 38.8%). IR (CH_2Cl_2): ν_{CO} 1974 cm^{-1}. ^1H NMR ($CDCl_3$): δ 7.37, 7.29, 7.16 (m, 5H, Ph), 3.80 [dd, 18H, $P(OCH_3)_3$], 3.70 (s, 3H, OMe). ^{13}C NMR (CD_2Cl_2): δ 234.4 (W–CO), 154.5, 129.0, 127.7, 124.5 (Ph), 55.1 (W–OCH_3), 54.2 ($P\{OCH_3\}_3$). ^{31}P NMR ($CDCl_3$): δ 109.7. Anal. Calcd for $C_{14}H_{26}O_4NIP_2W$: C, 26.07; H, 4.06; N, 2.17. Found: C, 25.85; H, 4.16; N, 2.47.

X-ray structure determination for [(PhN)W(CO)$_2$I(μ-OCH$_3$)]$_2$ (**6**)

Data were collected at 173 K on a Siemens SMART PLATFORM equipped with a CCD area detector and a graphite monochromator utilizing MoKα radiation (λ = 0.71073 Å). Cell parameters were refined using 3901 reflections. A hemisphere of data (1381 frames) was collected using the ω-scan method (0.3° frame width). The first 50 frames were remeasured at the end of data collection to monitor instrument and crystal stability (maximum correction on I was <1%). Empirical (psi scan) absorption corrections were applied based on the entire data set.

Crystal data

$C_{18}H_{16}I_2N_2O_6W_2$, M = 977.83, triclinic, space group $P\bar{1}$, a = 6.6853(5), b = 9.5201(6), c = 10.3551(7) Å, α = 97.960(1), β = 107.413(1), γ = 92.328(1)°, V = 620.44(7) Å^3 at 173(2) K, Z = 1, D_c = 2.617 Mg/m^3, μ = 11.784 mm^{-1}, $F(000)$ = 440.

Data collection and processing

Crystal size 0.19 × 0.17 × 0.11 mm, θ range 2.09–27.48°, index ranges $-9 \leqslant h \leqslant 7$, $-12 \leqslant k \leqslant 12$, $-14 \leqslant l \leqslant 13$, transmission 0.219–0.405, 4290 measured reflections, 2731 unique data, R(int) = 0.0199.

The structure was solved by the direct methods in *SHELXTL5* [17], and refined using full-matrix least squares. Each dimer is located on a center of inversion, thus the asymmetric unit contains a half dimer. The non-H atoms were treated anisotropically, whereas the hydrogen atoms were calculated in ideal positions and were riding on their respective carbon atoms. A total of 137 parameters were refined in the final cycle of refinement using 2584 reflections with $I > 2\sigma(I)$ to yield $R_1 = \Sigma(\|F_o| - |F_c\|)/\Sigma|F_o\| = 2.76\%$ and $wR_2 = [\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]]^{1/2} = 7.27\%$, respectively. Refinement was done using F^2. Extinction coefficient 0.0087(6), final difference map between 1.752 and −1.278 e•Å^{-3}, goodness-of-fit = 1.047 on F^2.

Atomic coordinates, complete bond lengths and angles, and displacement parameters have been deposited as supplementary material at the Cambridge Crystallographic Data Center.

(Received 19 January 1998; accepted 18 March 1998)

Abstract—Yellow to red–brown copper(I) complexes of the type CuXL for X = Cl, Br,I, CN, SCN and N_3 and $CuXL_2$ for X − NO_3 and ClO_4, where L = 4-benzoylpyridine, have been synthesized and characterized. All complexes exhibit MLCT bands in the visible region and the neutral complexes gave non-conducting solutions in DMF. The IR and Raman spectral data suggest monodentate 4-Bzpy, bridging halides or pseudohalides, *bidentate* nitrate and perchlorate in the respective complexes in the solid state. The structure of the 1:1 chloride complex, as determined by X-ray crystallography, features a discrete centrosymmetric [CuCl(4-benzoylpyidine)]$_2$ molecule with a Cu···Cu distance of 2.953 Å. Each copper atom in the dimeric molecule is trigonally planar coordinated by two μ-chlorine atoms and the nitrogen atom of 4-benzoylpyridine. All the isolated complexes display emission spectra in the solid state at room temperature. The neutral halide or pseudohalide complexes show one emission band with λ_{max}^{em} in the range 586–642 nm which is independent of the excitation wavelength and is related to MLCT or XLCT excited state. The 1:2 nitrate and perchlorate complexes exhibit their λ_{max}^{em} around 468–504 nm. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: copper(I) complexes; 4-benzoylpyridine; crystal structure; vibration spectra; luminescence spectra.

Copper(I) usually forms four-coordinate tetrahedral complexes [1], compounds with lower coordination numbers are known but are less common [2]. Structural evidence has been reported for some trigonal planner three-coordinate copper(I) complexes, e.g., $[Cu(C_6H_7N)_3]^+$ [3], $[Cu(CN)_3]^-$ [4] and $[Cu(CN)_2]^-$ [5]. On the other hand, copper(I) halides form complexes with unidentate nitrogen donor ligands which display a variety of stoichiometries, structures [6] and emission characteristics [7] in the solid state. In some instances, CuX–ligand clusters of the same stoichiometry (1:1:1) exist in more than one crystaline format.

For example, $[CuI(py)]_4$ is a cube, whereas $[CuI(py)]_n$ is a pleated sheet polymer [8]. Similarly, $[CuI(CH_3CN)]_n$, a pleated sheet and $[CuI(CH_3CN)]_4$-dibenzo-18-crown-6, a distorted cubic structure with second sphere interactions between crown ether and acetonitrile methyl hydrogens, are both of stoichiometry Cu:I:CH_3CN of 1:1:1 [9]. These families of structures are of particular interest because the emission behaviour of the solid state material varies with structure. Thus, $[CuI(py)]_n$ displays broad band emission at room temperature and shows no shift of λ_{max} at cooling, whereas $[CuI(py)]_4$ displays two emission maxima corresponding to differing excitation maxima [10].

Recently, we isolated and characterized two types of copper(I) complexes of 2-benzoylpyridine; red to dark brown CuXL type complexes, for X = Cl, Br, I, CN, SCN and N_3, and orange yellow $(CuX)_2L$ complexes for X = Cl and Br and structurally characterized those of the first type for X = Br, I and CN [11]. In all

* Author to whom correspondence should be addressed.

complexes of the first type, 2-benzoylpyridine behaves as a bidentate ligand and all of them display no emission when excited in the UV region at room temperature. Both complexes of the second type contain *monodentate* 2-benzoylpyridine ligand, as inferred from their IR spectra and display visible emission when excited in the UV region at room temperature. Further work led to the isolation of copper(I) complexes of 4-benzoylpyridine (hereafter abbreviated as 4-Bzpy). These complexes exhibit solid state emission at room temperature. We have now performed an X-ray structure determination of the title complex for which suitable crystals are available.

EXPERIMENTAL

4-Benzoylpyridine was obtained from Aldrich company and the other chemicals were of analytical grade quality.

Preparation of the complexes:

1. CuCl(4-Bzpy) and $CuX(4\text{-Bzpy})_2$ complexes, X = NO_3 and ClO_4. These complexes were prepared by mixing the corresponding copper(II) salt (4 mmol) dissolved in water with an ethanolic solution of 4-Bzpy ligand (10 mmol) and the subsequent addition of excess L(+)-ascorbic acid. The mixture was boiled for several minutes and allowed to stand over several hours to produce the complexes.
2. CuX(Bzpy), X = Br, I, CN, SCN and N_3. These complexes were prepared by one of the following general procedures.

(i) An aqueous solution of $Cu(NO_3)_2.3H_{22}O$ (4 mmol) was mixed with KX or NaX, followed by the addition of L(+)-ascorbic acid. An ethanolic solution of the benzoylpyridine ligand (10 mmol) was then added and the mixture stirred for ca. 15 minutes. The final mixture was allowed to stand over several houres or days until a crystalline product separated.

(ii) A boiled ethanolic solution of benzoylpyridine (10 mmol) was mixed with $Cu(NO_3)_2{\cdot}3H_2O$ (4 mmol) in ethanol and the subsequent addition of L(+)-ascorbic acid resulted in a clear yellow to orange solution. To this solution, an aqueous solution of KX was added dropwise, the mixture was boiled for several minutes and allowed to stand over several hours to produce the complex.

Crystals of the yellow copper(I) chloride complex suitable for X-ray structure analysis were prepared by the procedure given under (i), except that ethanol was used as the medium and a very slow evaporation of the solvent was used.

Elemental analysis results of the isolated complexes are given in Table 1.

Physical measurements

The IR absorption spectra of solid samples were measured as KBr pellets using a Bruker IFS-25 model FT–IR spectrophotometer. Raman spectra were obtained using a Perkin–Elmer System 2000 NIR FT–

Raman spectrometer. The laser power was ca. 200 mW. Electronic spectra of complexes were measured as solids mulled in Nujol using a varian cary-5 double beam spectrophotometer. The experimental procedures and instruments used for other measurements are as described previously [12].

X-ray structure analysis of dimeric CuCl(4-benzoylpyridine) complex (1)

Intensity data were collected at 294 K on a MSC/Rigaku RAXIS IIc imaging plate system, with a rotating-anode X-ray source (Mo–Kα radiation, $\lambda = 0.71073$ Å) [13] and corrected for absorption using the ABSCOR program [14]. Information concerning crystallographic data and structure refinement are summarized in Table 4.

The structure was solved by Patterson superposition and Fourier methods. All non-hydrogen atoms were subjected to anisotropic refinement. The aromatic hydrogen atoms were generated geometrically (C–H fixed at 0.96 Å), allowed to ride on their respective carbon atoms and included in structure-factor calculations with assigned isotropic thermal parameters.

All computations were performed on a DEC Micro VAX-II computer with the SHELXTL-PLUS system [15, 16]. Analytical expressions of neutral atom scattering factors, incorporating the real and imaginary components of anomalous dispersion, were employed [17]. Least-squares refinement converged to the *R* indices and other parameters, as listed in Table 4. Selected bond distances and angles are listed in Table 5. Positional parameters, anisotropic thermal parameters, hydrogen atom coordinates, a full list of bond lengths and angles and observed and calculated structure factors have been deposited with the editor as supplementary material; copies are available on request.

RESULTS AND DISCUSSION

The reaction between copper(I) salts and 4-Bzpy afforded the complexes given in Table 1. 4-Benzoylpyridine, therefore behaves differently from ethyl isonicotinate which affords copper(I) halide complexes of the type CuL_nX, where $n = 1$ and 2, and complexes of the type $[CuL_n]X$, where $n = 2$, 3 and 4 for $X = NO_3$ and ClO_4 [18]. All the isolated complexes are colored and sufficiently stable against air-oxidation when well-dried. In acetone and DMF, the neutral complexes gave non-conducting solutions, whereas the nitrate and perchlorate complexes behave as 1:1 electrolytes [19] with molar conductivities in the range 125–140 $\Omega^{-1}\,cm^{-2}\,mol^{-1}$ in acetone. Thus, the last two complexes may be formulated as $[CuL_2]X$, possessing ionic structures in acetone.

IR and Raman spectra

The IR and Raman spectra (Table 2) of free 4-Bzpy and its copper(I) complexes are similar except the systematic shifts of the vibration bands related to the pyridine moiety as expected for N-ligating pyridine ligands [20]. The carbonyl stretching vibrations appear almost at the same positions in complexes as well as in free 4-Bzpy. In the far IR region, 200–400 cm^{-1}, no bands could be attributable to terminal νCu–Cl or νCu–Br, suggesting bridging halide atoms whose copper–halogen absorption bands are expected below 200 cm^{-1} [21]. For 1:1:1 Cu: bridging halide: monodentate ligand, there are several possible structures including dimer, cubane, stepped cubane, stair and split stair [7].

As seen from Table 3, the ν_2 vibration mode of the perchlorate group in $Cu(4\text{-Bzpy})_2ClO_4$ is split into three peaks at 1148, 1110, 1048 cm^{-1} (IR) and 1160, 1049, 1025 cm^{-1} (Raman). For the ν_3 mode, at least two peaks are observed in the IR spectrum, but only one peak in the Raman. These results are consistent with a *bidentate* perchlorate group [21]. The spectral results of the nitrate 1:2 complex are consistent with a *bidentate* nitrato group [21]. A distorted tetrahedral structure is therefore assigned for the monomeric perchlorato and nitrato complexes.

The 1:1 azide complex shows a very strong band at 2030 cm^{-1} (IR) and a weak line at 2070 cm^{-1} (Raman) associated with the $\nu_{as}(N_3)$mode. In the 1350–1250 cm^{-1} region, we would not assign any absorption band related to the $\nu_s(N_3)$mode due to the absorption bands of the ligand and, therefore, the IR spectra could not tell us whether the azide group is symmetric or asymmetric in this complex. For symmetric azide groups, the $\nu_s(N_3)$mode is expected to be IR inactive but Raman active. The Raman spectrum of the azide complex shows a medium to strong band at 1336 cm^{-1}, suggesting symmetric azide. As symmetric azide groups of the type μ-1,3 bridging in the complex $[Cu(Ph_3P)_2(N_3)]_2$ exhibit a $\nu_{as}N_3$ band at 2053 cm^{-1} [22], we may assign bridging azides of the type μ-1,1,3 in this complex since azido ligands of this type usually absorb around 2040–2020 cm^{-1} [23, 24]. For the 1:1 thiocyanato complex, a single νCN band is observed above 2100 cm^{-1}, a result which is suggestive of bridging thiocyanato groups [25]. The anionic complex, $[Cu(SCN)_2]^-$, which contains two independent thiocyanato groups; a terminal and a μ-N,S,S shows two νCN bands at 2105 and 2085 cm^{-1}. The later band is related to the terminal N-thiocyanate, whereas the former is due to the second group [12]. We may assign μ-N,S,S bridging thiocyanate in the 1:1 complex. The results given for the 1:1 cyano complex with such higher νCN bands compared with those for terminal cyanides [2075–2095 cm^{-1}.] [26], or the bridging –CN– group [2100–2105 cm^{-1}.] [27], suggest a structure similar to that of $CuCN{\cdot}NH_3$ [28], in which the cyano group acts as a *tridentate* ligand.

Structure of the 1:1 *copper(I) chloride complex*

The structure determination has shown the title complex as $[CuCl(4\text{-benzoylpyridine})]_2$ (Figures 1 and 2), another example of a metal–halide monodentate ligand with hetero atoms of the stoichiometry CuClL, to be structurally characterized. This dinuclear complex is disposed about a crystallographic inversion center with a planar Cu_2Cl_2 rhombohedral core of alternating copper and chlorine atoms. The Cu–Cl distance of 2.291(2) and 2.323(2) Å are shorter than those usually observed for $[CuClL]_n$ polymeric pleated sheets where each copper has three chlorine neighbours [av. 2.410 Å] [29–31]. The Cu–N bond length is a little shorter than that found (2.035(4) Å) in $[CuI(2\text{-benzoylpyridine})]_2$ [11], but very close to the corresponding value of 1.995(7) Å found in [CuClL], where L is isonicotinic acid [32].

The structure of the title complex with a trigonal planar geometry about each copper atom is one of the rare examples of copper(I) chloride complexes of nitrogen donor ligands of such stoichiometry having three coordinate copper atoms. Three coordinate copper(I) complexes are known for $[CuL_3]^+$, L is 2-picoline [3], $[CuXL_2]$, for X = Cl or I [33] and $[CuIL]_2$ for L = 2,6-dimethylpyridine [31], in all of these examples, the steric hinderance of the methyl group(s) in the pyridine ring is the reason for such coordination number 3 and not the usual tetrahedral geometry. In case of complex (1), however, there is no such steric hindrance. The existence of a bulk group, such as a benzoyl in position 4 in the pyridine ring is responsible for the formation of a dimer complex with three coordinate copper, rather than polymeric pleated structure with four coordinate copper atoms. This explains why we could not isolate copper(I) halide complexes of this ligand with ligand content higher than 1:1:1. The Cu···Cu separation of 2.953 Å in the present structure is comparable with the corresponding value found (2.995(3) Å) in the structure of $[CuCl(2,4\text{-dimethylpyridine})_2]_2$ [34], but shorter than that found (3.145(3) Å) in the structure of $[CuCl(2\text{-Picoline})_2]$ [34].

Electronic absorbtion spectra

The electronic absorption spectra of the solid complexes mulled in Nujol (Table 6 and Fig. 3) exhibit a strong absorption band in the visible region due to charge transfer transitions from Cu (I) d^{10} to the empty π^* orbital on the pyridine ligand. The MLCT bands is dependent on the nature of the counter ion, as found for other copper(I) complexes [35]. That the position of the MLCT bands appear at lower energies in the case of the red–brown 1:1 azide and thiocyanate complexes reflects the influence of these anions on the MLCT. These ligands enhance the MLCT transitions, particularly the azide one.

Emission spectra

Table 6 and Figs 4–6 summarize the results of the emission and excitation spectra of the isolated copper(I) complexes in the solid state at room temperature. The following points are observed. (1) The emission spectra of the 1:1 halide and pseudohalide complexes exhibit a single slightly asymmetric band in the range 586–642 nm, whereas the 1:2 nitrate and perchlorate complexes show their emission bands in the range 468–504 nm with more than one maxima. (2) The emissions, as well as the excitation spectra of the nitrate and perchlorate complexes, could not be distinguished from each other. (3) The luminescence

(b) Emission maxima (excitation wavelength at λ_{max}^{ex}).
(c) Excitation maxima (monetored at λ_{max}^{em}).

spectra of these solid complexes proved independent of the excitation wavelength at room temperature. (4) It is also observed that the λ_{max}^{em} changes from 642 for the chloride to 631 nm for the iodide complex, i.e., the emission maxima is shifted to a lower energy on going from the iodide complex to the chloride. (5) The 1:1 bromide complex shows its λ_{max}^{em} at 600 nm and its excitation spectrum differs a little from the other halide complexes.

Extensive studies of the emission spectra of a series of $[CuI(py\text{–}X)]_4$ complexes, both in solid state and in solutions at room temperature and at 77 K, have been undertaken [36–38]. These complexes display two emission maxima; a low energy (LE) band (620–698 nm) and a high energy (HE) band (430–540 nm). The LE band was observed for complexes with Cu–Cu distances less than the summed Cu(I) Van der Waals radii (2.8 Å) and considered as a property of the Cu_4X_4 core and involves extensive interactions between the copper(I) centers owing to the σ bonding nature of the LUMO for these clusters with short metal–metal distances [39]. The HE band, which was

also observed for $[CuXpy]_n$, was attributed to metal-to-ligand charge transfer (MLCT) or halide-to-ligand charge transfer (XLCT) [40]. In order to assign the emission spectra of the present complexes, the following points have to be considered. (1) The structure of the chloride complex, as shown by crystal structure analysis is a dimer and not a cubic tetramer. (2) The Cu–Cu distance of 2.953 Å in the chloride complex exceed the 2.8 Å value required for emission due to the Cu–Cu interactions as observed in complexes having the Cu_4X_4 core. (3) Point 4, given above, is consistent with what has been observed previously [41] that the emission bands for the chloride clusters occur at lower energy than the HE bands of the respective iodide clusters. Thus, the emitting state in the present copper(I) halides or pseudohalide complexes of 4-benzoylpyridine would be triplet MLCT or XLCT excited states. That the position of the emission λ_{max} for the present complexes appear at lower energies (586–642 nm) compared with those of $[CuI(py)]_n$ or the HE bands of $[CuI(py)]_4$ is due to the fact that the HE band energies are quite sensitive to substituents on the pyridine: electron withdrawing substituents shift these to lower values [41, 42]. X-ray powder diffraction has shown the bromide complex to be different from the chloride or iodide, this may explain the difference in their emission and excitation spectra.

The 1:2 nitrate and perchlorate complexes display their emission spectra in the range 468–504 nm with more than one emission maxima, which differs from the range where the halide complexes emit. This may support the assignments of the emission of the halide complexes as arising from MLCT and XLCT excited states. In the case of the 1:2 complexes, the emission may arise from the MLCT states, There is, however, another possibility for their emission. It was found that when aromatic ligands are packed in parallel planes separated by 3.225–3.279 Å, it results in emission spectra of the ligand alone [42]. As a solution of 4-benzoylpyridine in ethanol displays emission spectra at room temperature with λ_{max}^{em} at 453 nm and a pronounced shoulder around 492 nm, the emission spectra of the nitrate and perchloratye complexes may arise from ligand interactions alone and from MLCT interactions between Cu(I) and 4-benzoylpyridine.

(Received 26 November 1997; accepted 18 March 1998)

Abstract—σ_N-Coordinated compounds $[PtCl_3(4\text{-}X\text{-}C_6H_4NO)]^- K^+$ have been prepared and studied by ^{13}C NMR spectroscopy and by variable temperature ^1H NMR spectroscopy. It is shown that the anomalous behaviour of the NO group on the ^{13}C chemical shifts is modified by coordination but where X = $N(CH_3)_2$ or OCH_3 the free energy barriers to rotation of the NO group determined by ^1H NMR studies are closely similar to those of the free ligands. Restricted rotation of the $N(CH_3)_2$ group was also studied in $[PtCl_3(2\text{-}CH_3\text{-}4\text{-}N(CH_3)_2\text{-}C_6H_3NO)]^- K^+$. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: nitrobenzenes; Pt complexes; restricted N=O rotation; $^1H/^{13}C$ NMR shifts.

Some years ago [1] we demonstrated from ^{13}C NMR studies that the nitroso group in *para*-substituted nitrosobenzenes behaves in a manner different from all other functional groups (twenty eight in number at that time and now thirty four) in that the chemical shift for *C*-NO was *always* found to be upfield of that in the unsubstituted nitrosobenzene. Such behaviour is, of course, found for all *para*-π-electron donor groups in conjunction with any functional group Z in the 1-position, but when the *para*-substituent is a π-electron acceptor group the shift of the Cl carbon rises above the value for the unsubstituted reference compound C_6H_5Z. Following upon a suggestion made by Topsom [2], we tentatively ascribed this behaviour to the very strong π-electron accepting character of the nitroso group the effect of which is to produce the extreme conditions under which *para*-π-electron acceptor groups such as NO_2 and CN act as π-electron donors. In collaboration with Topsom [3], molecular orbital calculations were carried out both by the semi-empirical CNDO/2 method and at the STO-3G level. These showed that the observed, unexpected, upfield chemical shifts of *C*–NO in substituted nitrosobenzenes are not a function of unusual electron distribution in these molecules in so far as this can be measured using these theoretical tools. In view of the wide variety of coordination compounds that can be formed by substituted nitrosobenzenes [4] it was of interest to see whether this anomalous property of the NO group persists on coordination to metals. We have recently demonstrated [5] that the anomalous effect is modified but not completely removed on σ_N coordination of *para*-substituted nitrosobenzenes to palladium dichloride in contrast to the complete removal of the effect when *para*-substituted nitrosobenzenes are π-coordinated to molybdenum [6].

We had previously observed that $[PtCl_3(C_6H_5NO)]^- K^+$ displays a downfield shift [7] of the *C*–NO signal compared with free ligand in contrast to all other known examples of nitrosobenzene coordination compounds where an upfield shift is observed.

Our earlier studies [8] of the energy barrier to free rotation of the nitroso group in $4\text{-}X\text{-}C_6H_4NO$, where X = NRR′, suggested their extension to the corresponding $PtCl_3$-complexes in order to investigate whether σ_N coordination to the metal has any effect on the energy barrier to rotation of the nitroso group with respect to the aromatic ring.

EXPERIMENTAL

Measurements of the natural abundance, broad band proton-decoupled ^{13}C NMR spectra were made using a Bruker DRX 400 spectrometer equipped with a standard B-VT-1000 variable-temperature unit for

^{13}C and ^{1}H NMR measurements, the solvent being $(CD_3)_2CO$.

IR measurements were made for the platinum complexes on a Nicolet Magna FT-IR spectrometer equipped with a CsI beamsplitter operating in the range 4000–200 cm^{-1} using CsI discs.

Preparation of nitroso compounds

(a) 4-*Substituted nitrosobenzenes*. With the exception of the nitrosoanilines these were prepared from the corresponding aniline by catalytic oxidation using Porta's method [9]. The nitrosoanilines were prepared by direct nitrosation of the corresponding aniline [5].

(b) *Complexes of substituted nitrosobenzenes with* $PtCl_3^-$. The method of Mansuy [10] as previously used by us [7] was adapted in the following manner. K_2PtCl_4 (1 g, 2.4 mmol) was dissolved in 20 cm^3 water. To this solution was added a solution of the nitrosoarene (2.4 mmol) in 10 cm^3 acetone. The mixture was stirred at room temperature for 30 h, the acetone removed by rotary film evaporation, the remaining solution filtered and the filtrate evaporated to dryness. The residue was then dissolved in acetone; after concentration of the solution addition of ether resulted in precipitation of the complex. This was then recrystallized from acetone/ether. In every case the complex did not melt below 260°C. Microanalytical data are given in Table 1, ^{13}C NMR data in Table 2 and ^{1}H NMR data in Table 3. In addition to the complexes $[PtCl_3(4\text{-}X\text{-}C_6H_4NO)]^-K^+$, the complex $[PtCl_3$ $(2\text{-}CH_3\text{-}4\text{-}N(CH_3)_2\text{-}C_6H_3NO)]^-$ K^+ was also prepared.

Variable temperature NMR studies

^{1}H NMR spectra of hexadeuteroacetone solutions of the complexes $[PtCl_3(4\text{-}X\text{-}C_6H_4NO)]^-$ K^+, [X = $(CH_3)_2N$ and OCH_3] were recorded in the temperature ranges −20°C to 50°C and −90°C to 30°C respectively in order to determine whether hindering of the rotation of the coordinated NO group was occurring. In addition to this the complex of 2-methyl-4-dimethylaminonitrosobenzene with $PtCl_3^-$ was investigated over the temperature range −90°C to 30°C.

DISCUSSION OF RESULTS

Our interpretation of the ^{13}C NMR data follows that given by Lynch [11] whose relationship is

$$S(\underline{C}-NO) = a + bSCS_{para}(PhX)$$

where S(*C*-NO) is the chemical shift of the carbon attached to the NO group and $SCS_{para}(PhX)$ is the substituent chemical shift in the *para* position of the monosubstituted phenyl compound [12]. Our earlier studies showed that for *para*-substituted nitrosobenzenes b is approx. 0.25 for π-electron donor substituents X and approx. −0.5 for π-electron acceptor substituents X.

The data given in Table 2, are used together with other published data [1, 5, 12] to obtain values for the Lynch parameter b for the coordination compounds $[PtCl_3(4\text{-}X\text{-}C_6H_4NO)]^-$ K^+. The C–1 chemical shift occurs downfield of X = H for three of the four π-electron acceptor groups X, whereas when X is a π-electron donor group the C–1 shifts occur upfield. This is parallelled [5] in the case of the σ_N-coordinated compounds $[PdCl_2$ $(4\text{-}X\text{-}C_6H_4NO)_2]$, where we concluded that there is some modification of the high electron demand of the NO group following σ_N coordination. In these two cases of σ_N coordination, as for $4\text{-}X\text{-}C_6H_4\text{-}NO$, the standard plot is bilinear and the effect upon the b values is far more marked than that noted for $4\text{-}X\text{-}C_6H_4\text{-}NO_2$ (see Table 4) which Bromilow *et al.* [13] found to be the most marked case of such behaviour in *para*-disubstituted benzene derivatives. We therefore conclude that the electron demand exerted by the σ_N coordinated NO group is much greater than that for the nitro group though less than that for the free NO group. This is in marked contrast to the results obtained when substituted nitrosobenzenes are π-bonded to molybdenum(VI) [6] for which the plot is linear [5] with a slope b = 0.70. The

structural changes in the NO group are much greater when π-coordination occurs as evidenced by the extension of the NO bond to lengths approaching those of a single bond in contrast to the examples of σ_N coordination where the NO bond length increases by very small amounts [14]. Further preparative and ^{13}C NMR studies of both σ_N and π-coordinated compounds of 4-X-C_6H_4–NO are required in order to substantiate these suggestions.

We conclude that the NO group reduces the sensitivity at *C*-NO to electron density changes in *para*-substituted nitrosobenzenes to a much greater extent than is operative for any other functional group, in particular the isoelectronic pairs –CH═CH_2, –CH═O and the pairs –N═N–R and –CH═N–R (analogous to the isoelectronic pairs –N═NH and –CH═NH) and the –NO_2 group which is a strong π-electron acceptor.

The variable temperature proton NMR studies were initiated in order to discover whether the large barriers to free rotation in 4-nitrosoanilines [10, 15–17] and in nitrosoanisole [18] were significantly altered on σ_N coordination. There appears to have been only one previous example of evidence for the hindering of rotation of the NO about the CN bond in a coordinated compound of 4-dimethylamino-nitrosobenzene [19] and in this case no calculation of the free energy barrier to rotation was made.

^1H NMR spectra of the complex where X = $N(CH_3)_2$ were recorded in the temperature range 50 to −30°C. At the lowest temperature the spectrum indicated that the –N═O rotation was arrested as four aromatic hydrogen shifts were detected (Table 3). The pairs of *ortho*- and *meta*-hydrogen signals broadened and coalesced on warming as a result of the increasing rate of –N═O rotation. From the coalescences of the *ortho* signals (at 303 K) and the *meta* signals (at 278 K), rate constants for the rotation process were calculated to be 2422 s^{-1} and 240 s^{-1} respectively. These values gave activation free energies $\Delta G^{\ddagger}$ (303 K) = 54.6 kJ mol^{-1} and $\Delta G^{\ddagger}$ (278 K) = 55.3 kJ mol^{-1} (Table 5) which are of similar magnitude to that of the nitrosoligand itself [8].

Table 5. Free energies of activation for C–NO rotation in 4-X-nitrosobenzene and in coordination to $PtCl_3^-$

X	Free ligand	Coordination compound
	$\Delta G^{\ddagger}$/kJ mol^{-1}	$\Delta G^{\ddagger}$/kJ mol^{-1}
$(CH_3)_2N$	53.6 (298 K)[16]	54.6(303 K)(H 2,6)
		55.3(278 K)(H 3,5)
CH_3O	41.0 (298 K)[16]	39.7(223 K)(H 2,6)
		41.3(213 K)(H 3,5)

^1H NMR spectra of the complex X = OCH_3 showed similar changes to the 4-$N(CH_3)_2$ complex but these occurred in a much lower temperature range, 30 to −90°C. The –N═O rotation process became slow on the NMR timescale at temperatures below −70°C and clear distinction between the four ring hydrogen environments was obtained at −90°C (Table 3). The spectral changes in the range −80 to 20°C are depicted in Fig. 1. Rate data for the –N═O rotation process were derived from the band coalescences of the *ortho* hydrogen signals (223 K) and *meta* hydrogen signals (213 K). These data provided activation free energies, $\Delta G^{\ddagger}$, of 39.7 kJ mol^{-1} (223 K) and 41.3 kJ mol^{-1} (213 K). The former magnitude is considered somewhat more reliable. Both values are very similar to the value of $\Delta G^{\ddagger}$ (298 K) for the free ligand of 41.0 ± 0.3 kJ mol^{-1} [18].

$[PtCl_3(2\text{-}CH_3\text{-}4\text{-}N(CH_3)_2\text{-}C_6H_3NO)]^-\ K^+$

^1H NMR spectra of this complex recorded in the range −90 to 50°C showed no significant changes in the aromatic region, only the $N(CH_3)_2$ signal changing from a doublet (at temperatures ⩽ −40°C) to a singlet (at temperatures ⩾ −30°C) with coalescence at −35°C (238 K). The spectra indicate the existence in solution of a single rotameric species. The low δ value (2.14) of the 2-methyl group is characteristic of the group lying in the strong shielding zone of the aniso-

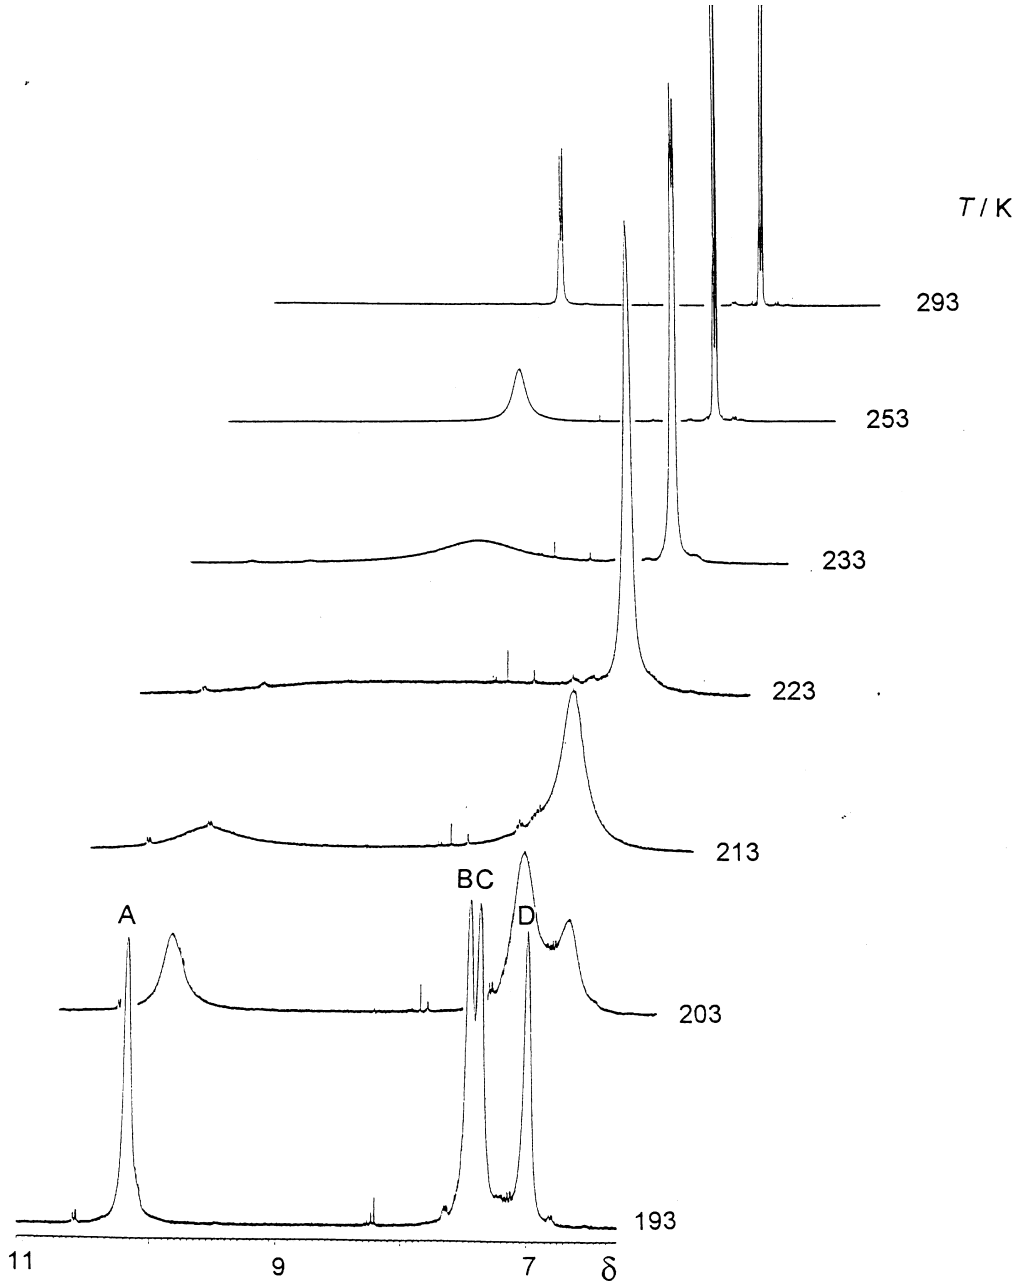

Fig. 1. Variable temperature ^1H NMR spectra of $[PtCl_3\ (4\text{-}CH_3OC_6H_4NO)]^-\ K^+$ in deuteroacetone showing the effects of the restricted rotation (see Table 3 for signal labelling).

tropic –N=O group, namely *cis* to this group [8, 18]. The structure of the complex is thus as indicated in Table 3. The NMR spectra are therefore insensitive to the –N=O rotation process, and the changes of the dimethylamino signal are attributed to restricted rotation of this group relative to the aromatic ring. Measurements of the dimethylamino bandshapes both at coalescence (238 K) and slightly above coalescence (243 K) and use of the appropriate analytical expressions [20] for the rate constants at these two temperatures gave energy data ($\Delta G^{\ddagger}$ of 50.8 and 50.9 kJ mol^{-1} respectively. These values are slightly lower than those obtained [8] for methylamino rotation in *p*-nitroso-N-methylaniline where $\Delta G^{\ddagger}$ (298 K) = 57.4 kJ mol^{-1} (major → minor rotamer). The relatively large activation free energies reflect the considerable contribution of the quinonoid forms to the overall structures of these free and coordinated ligand species with strong π-electron donors in the 4-position.

[a]This work.

The close correspondence of the $\Delta G^{\ddagger}$ values for the coordination compound and the free ligand is shown in Table 5. We conclude that the values can be regarded as equal within experimental error. Applying the same treatment for deriving $\Delta G^{\ddagger}$ to the rhodium complex [19] RhCl[cod][4-$(CH_3)_2N$–C_6H_4–NO] yields a value of 53 kJ mol^{-1}. The data suggest that σ_N coordination of C-nitroso groups to transition metals has virtually no effect on the barriers to rotation of the –N═O group relative to the aromatic ring. More precisely, any change in electronic nature of the C–N bond attaching the nitroso group to the ring must affect the near co-planar ground state and orthogonal transition state structures of the complexes equally. This is a somewhat surprising result as the electronic effects of coordination are considerable, viz the paramagnetic shielding, $\Delta\delta$, of the 6-position hydrogen, H_A, is 0.8 to 1.0 for $X = N(CH_3)_2$ or OCH_3.

The effects of σ_O and π_{NO} coordination of nitroso groups [4] might be expected to affect the rotational characteristics of the group more extensively, but this has yet to be explored.

In Table 6 the values of the wave numbers of the NO stretching mode in the complexes are compared with those of the corresponding ligand. The value of ν_{NO} falls on coordination within the range 7–23 cm^{-1}. This is characteristic of σ_N coordination and is associated with a small lengthening of the NO bond when coordination occurs [14].

CONCLUSIONS

Our results imply that the structural and electronic properties of the NO group are only slightly changed on σ_N coordination to metals implying that the π-electrons of the –N═O bond must be only slightly influenced by this coordination. Any significant reduction in π-character would have led to an appreciable lowering of the energy barrier by virtue of the smaller contribution of the quinonoid form of structure. A recent paper by Witanowski *et al.* [24] has demonstrated the remarkable deficit of electronic charge in the rings of nitrosoaromatic compounds due to the strong electron withdrawing effect of the nitroso group. This supports our case for the nitroso group being uniquely strong in its electron withdrawing power and for its anomalous effects on 4-substituents as evidenced by the C-1 substituent chemical shifts.

(Received 14 October 1997; accepted 30 March 1998)

Abstract—Interactions of the complex bis(diethyl–diselenocarbamato)copper(II), ($Cu(dsc)_2$) with some copper(II) salts in solution have been studied by EPR and electronic spectroscopy. The complex interacts with copper salts (CuX_2, X = Cl, Br, NO_3) to produce EPR silent dimers of the type [(dsc)CuX_2Cu(dsc)] which are formed in equilibrium with mixed-ligand Cu(dsc)X complexes. The same dimers are found to be formed in the course of the exchange reaction between the zinc diselenocarbamate and copper chloride. The electronic spectrum of the bis-chelate has a characteristic absorption band at 20,200 cm^{-1} (ϵ = 11,800 m^{-1} dm^3 cm^{-1}) whereas the dimers are characterized by a band at 22,600 cm^{-1} (ϵ = 23,800 m^{-1} dm^3 cm^{-1}). This property of complex could be used in analytical practice for increasing sensitivity of photometric estimations. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: EPR; UV-vis; bis(diselenocarbamato)copper(II); mixed-ligand complexes; dimeric structure.

INTRODUCTION

In the last decades complexes of dialkyl–diselenocarbamates have been shown to be useful in several different areas of science and technology. They, for example, are used as: analytical reagents [1–4], photo stabilizer [5], antioxidant additives to hydrocarbons like polymers [5, 6] or motor oil [7], metal deactivators [8], pesticides and fungicides [9, 10], floatation agents [11], precursors e.g. in preparation of solar cell materials [12–22]. In some applications they exhibit better properties than the corresponding sulfur-containing complexes, e.g. the dialkyl–dithiocarbamates or dithiophosphates. However, the inherent problems in the synthesis of the ligands makes them a less popular choice of reagent unless there is a major advantage or the element selenium must be used for some technological reason. The literature on their properties and reactivity is generally quite limited but their use as precursor for selenium containing materials had led to an increased interest in recent years [14–22].

In this paper we describe some of our results obtained by EPR and electronic spectral studies on the interaction of bis(diethyl–diselenocarbamato) copper(II) ($Cu(dsc)_2$) with CuX_2 (X = Cl, Br, NO_3). In the previous work from our laboratory interesting intermolecular interactions were observed for the related bis(dithiocarbamato)copper(II) complex ($Cu(dtc)_2$) [23–28] and the possibility of such effects for the selenium analogue has been investigated in the present work.

EXPERIMENTAL

Starting materials

The complex [$Zn(Et_2$–$dsc)_2$] was obtained by the reaction of $Et_2NH + CSe_2$ in the presence of zinc sulfate as previously described [29]. All other chemicals

* Author to whom correspondence should be addressed. E-mail: ndyepr@bgearn.acad.bg.

and solvents were of reagent grade and used as obtained.

The copper complex [$Cu(Et_2–dsc)_2$] was obtained by exchanging the zinc ion of $Zn(Et_2–dsc)_2$ with Cu^{2+} as previously described [30]. [$Zn(dsc)_2$] (0.2 g) dissolved in 10 ml $CHCl_3$ was shaken with $CuSO_4 \cdot 5H_2O$ (4 g) in water (40 ml). The chloroform layer was separated, evaporated and the black product was recrystallized from acetone/chloroform. The purity of the product obtained was checked by its electronic spectrum ($\epsilon = 11{,}800\,m^{-1}\,dm^3\,cm^{-1}$ at $\lambda = 20{,}200\,cm^{-1}$) [30–32] as well as by its elemental analysis: For $C_{10} \cdot H_{20} \cdot N_2Se_4$ calculated (found) Cu calc. 11.6 (11.4); C 21.9 (22.1); H 3.6 (2.4), N 5.1 (5.3). The same product was not obtained when $CuCl_2$ was used instead of $CuSO_4$ (*vide infra*).

The EPR spectra were taken at 315 K on an X-band, portable, model PS100.X, spectrometer produced by ADANI (Minsk), using 100 kHz magnetic field modulation. A full description of this spectrometer has been given in an earlier publication [33]. The electronic spectra were recorded on a SPECORD UV-Vis (Carl Zeiss, Jena) spectrophotometer.

RESULTS AND DISCUSSIONS

Peculiarities noted in synthesis of Cu(dsc)$_2$

In the course of attempting the synthesis of $Cu(dsc)_2$ using the exchanged reaction eq. (1)

$$Zn(dsc)_2 + Cu^{2+} \rightarrow Cu(dsc)_2 + Zn^{2+} \qquad (1)$$

significant differences were found in the product obtained by the use of $CuSO_4$ [30] from that with $CuCl_2$. The sulphate salt gave a 100% yield of Cu $(Et_2–dsc)_2$ characterized by an absorption maximum at 20,200 cm^{-1} (Fig. 1(a)) and a strong EPR spectrum (Fig. 2) stable with the time. The material obtained when $CuCl_2$ was used instead of $CuSO_4$ showed an absorption maximum at 22,600 cm^{-1} with a shoulder at 20,200 cm^{-1} (Fig. 1(b)). In addition the EPR spectrum was very weak as compared to those recorded with the same quantity of the substance produced in the first case. The crystals were slightly soluble in benzene and this solution gave an intensive EPR signal and an absorption maximum at 20,200 cm^{-1}. The remaining main portion was $CHCl_3$ soluble with an absorption band at 22,600 cm^{-1}, but the solution was EPR silent. Two possibilities were considered that the insoluble material was the product of a redox reaction or a dimeric complex of the type (dsc)$CuCl_2$Cu(dsc) with strongly antiferromagnetically coupled copper ions. The former assumption was rejected because the EPR spectrum of $Cu(dsc)_2$ did not change over the period of study (5 months). Therefore, assuming the formation of a dimeric form, we have observed by gradual addition to its $CHCl_3$ solution of known amounts of $Zn(dsc)_2CHCl_3$ solution a stoichiometric formation of the same product as obtained by the use of $CuSO_4$. This fact we consider as evidence for the formation of dimeric (dsc)$CuCl_2$Cu(dsc) complex. A similar chloride bridged dimeric mixed-ligand complex of copper(II) dithiocarbamate (dtc)$CuCl_2$Cu(dtc) was recently observed as a product of $Cu(dtc)_2$ photolysis in $CHCl_3$ [34].

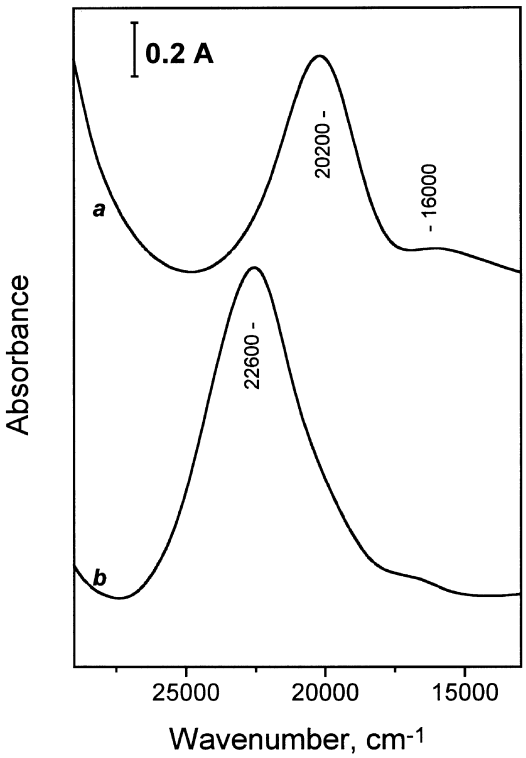

Fig. 1. (a) Electronic spectrum recorded of the sample obtained when $Zn(dsc)_2$ is exchanged with $CuSO_4$. This is the spectrum typical for $Cu(dsc)_2$ complex; (b) Electronic spectrum recorded of the sample obtained when $Zn(dsc)_2$ is exchanged with $CuCl_2$. This is the spectrum typical for the dimer (dsc)CuZ_2Cu(dsc).

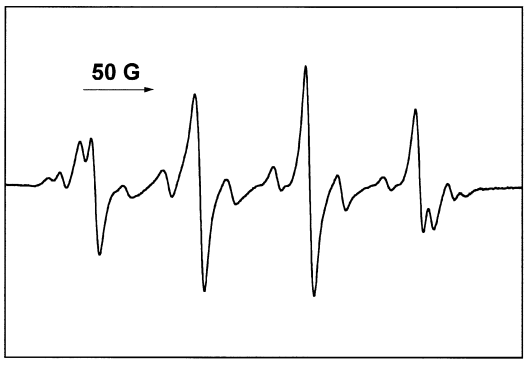

Fig. 2. Typical room temperature EPR spectrum of $Cu(dsc)_2$ complex dissolved in organic solvents.

EPR spectra of Cu(dsc)$_2$ complex

The structure of the isotropic EPR spectrum of Cu(dsc)$_2$ (Fig. 1) dissolved in solvent in which specific interactions are not expected (e.g. in benzene, toluene, $CHCl_3$, acetone, DMFA) was as has been described in the literature [35–38]. The spectrum (Fig. 2) consists of four hyperfine lines due to the interaction of the unpaired electron with ^{63,65}Cu (nuclear spin $I = 3/2$). Furthermore, since the natural abundance of ^{77}Se ($I = 1/2$) is 7.5%, approximately 30% of the Cu(dsc)$_2$ molecules will contain one ^{77}Se atom from which shf splitting is expected. The remaining 70% of Cu(dsc)$_2$ will not exhibit ^{77}Se shf splitting. Therefore, the EPR spectrum, Fig. 2, is a superimposition of the two spectra from the two different molecules — one consisting of only four Cu hf lines and other in which each of the Cu hf lines is split into two superhypefine lines because the nuclear spin of ^{77}Se. The EPR parameters typical of Cu(dsc)$_2$ in benzene, toluene, $CHCl_3$, acetone or DMFA are given in Table 1. It is worthy of note that the value of $g_o = 2.02 \pm 0.002$ is the lowest known to date and suggests an extremely covalent character for the Cu–Se bonds. In pyridine solution Cu(dsc)$_2$ forms an adduct with axial coordination of pyridine molecules(s) along the z-axis of the complex. The EPR parameters of this adduct (obtained at 324 K by Cu(dsc)$_2$ dissolved in pure pyridine) are also given in Table 1. These results are in excellent agreement with our previous studies and show that upon axial adduct formation g_o increases while A_o decreases [28, 39]. This fact was attributed to the decreased covalent character of the Cu–Se bonds and a rhombic deformation in the chromophore $CuSe_4$ result of the axial adduct formation [28, 39].

Interaction of Cu(dsc)$_2$ with some copper(II) salts

EPR studies. In Fig. 3 are shown several EPR spectra obtained upon mixing DMFA solutions of Cu(dsc)$_2$ and Cu(NO$_3$)$_2$. As seen from this figure increasing of the molar ratio Cu(dsc)$_2$/Cu(NO$_3$)$_2$ is accompanied by the appearance of new EPR spectrum due to mixed-ligand complex [Cu(dsc)$^+$·Solv...NO$_3$]. For this mixed-ligand complex shfs from the NO_3 anion can not be expected because ^{16}O has a nuclear spin $I = 0$ the ion is unlikely to interact directly with copper and to lie in the second coordination sphere [24, 25]. The EPR parameters of this spectrum are given in Table 1.

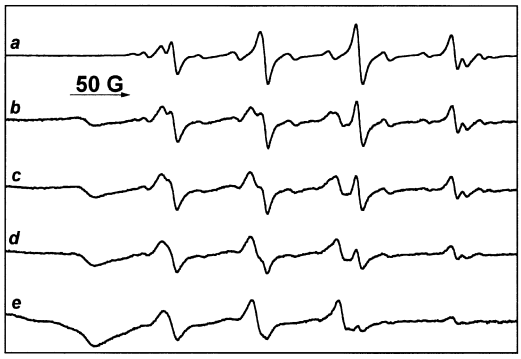

Fig. 3. Several room temperature EPR spectra taken after mixing of Cu(dsc)$_2$ with Cu(NO$_3$)$_2$. The ratio Cu(dsc)$_2$/Cu(NO$_3$)$_2$ is: (a) 1:0; (b) 3:2; (c) 1:1; (d) 3:4; (e) 1:2. Solution DMFA.

On mixing Cu(dsc)$_2$ (dissolved in $CHCl_3$ or in acetone) with CuX_2 (X = Cl, Br, dissolved in EtOH or i-PrOH or acetone) EPR spectra of the Cu(dsc)Cl mixed-ligand complex are recorded (Fig. 4). These complexes may be identified unambiguously by the shfs due to ^{35,37}Cl nuclear spin ($I = 3/2$) and therefore four shf lines should be recorded. The EPR parameters of this mixed-ligand spectra are given in Table 1. In pyridine however EPR spectrum of only Cu (dsc)Cl complex is observed. When $CuBr_2$ was used it

Table 1. EPR parameters of the parent and mixed-ligand complexes obtained by the interactions of Cu(dsc)$_2$ with Cu(II) salts

Complex	Solvent	$g_o \pm 0.002$	$^{Cu}A_o \pm 1$ G	$^{Se}A_o \pm 1$ G	$^{Cl}A_o \pm 0.5$ G

	EtOH	2.067	80	40	–

[a]Can not be estimated due to overlapping of the lines.

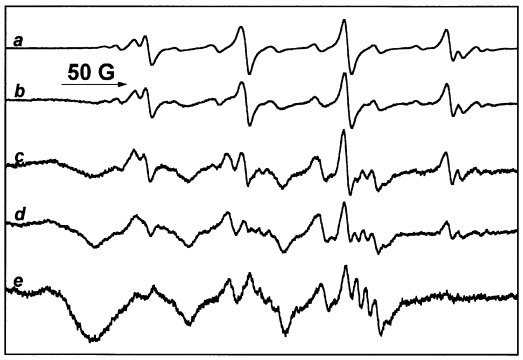

Fig. 4. Several room temperature EPR spectra taken after mixing of $Cu(dsc)_2$ with $CuCl_2$. The ratio $Cu(dsc)_2/CuCl_2$ is: (a) 1:0; (b) 3:1; (c) 1:1; (d) 2:3; (e). 1:2. Solution DMFA.

was impossible to record any EPR spectrum of mixed-ligand complexes. Only a progressive gradual decrease of the intensity of $Cu(dsc)_2$ was observed.

When DMFA is used as a solvent EPR spectra of two mixed-ligand complexes are recorded (Fig. 4)—that of Cu(dsc)Cl characterized by its shf splitting form one $^{35,37}Cl$ nucleus and another with EPR parameters fully consistent with those of $Cu(dsc)^+ \cdot Solv_2$. In order to record the mixed-ligand CuCl(dsc) complexes the instrument amplification was increased 100 fold times.

The general conclusion is that when a solution of $Cu(dsc)_2$ in an organic solvents ($CHCl_3$, DMFA, acetone or pyridine) reacts with solutions of CuX_2 (X = Cl, Br, NO_3, dissolved in C_2H_5OH, i-C_3H_7OH, DMFA), and pyridine mixed-ligand complexes are obtained. The above qualitative observations however show that the equilibrium position for the reaction leads to a predominance of the dimer.

$$Cu(dsc)_2 + CuX_2 \Leftrightarrow (dsc)CuX_2Cu(dsc) \overset{Solv}{\Leftrightarrow}$$

$$2Cu(dsc)_2 \cdot X \cdot solv \overset{Solv}{\Leftrightarrow} 2[Cu(dsc) \cdot Solv_2]^+ ... X^-.$$

$$(X = Cl, Br, NO_3) \qquad (2)$$

The extent of reaction is affected by the anions in the order $NO_3^- < Cl^- < Br^-$ and the EPR silent dimeric (dsc)$CuBr_2$Cu(dsc) complex is formed in contrast with $Cu(dtc)_2$ complexes where at room temperature the equilibrium eq. (2) is shifted to the right [24–28] hence the above result is specific for $Cu(dsc)_2$.

Inspecting the EPR parameters of the mixed-ligand complexes given in Table 1 it is clear that g_o increases whereas A_o decreases with the increasing of the donor properties of the solvents; which follows the order: i-PrOH < acetone < EtOH < pyridine [24, 25, 39]. On the other hand the Se shf splitting, which is due to only 15% of the mixed-ligand copper(II) complexes (*vide supra*) is 40 G when EtOH is used and increases to 50 G in the case of DMFA. This effect may be explained by considering the coordinating properties of the solvents and *trans*-effects of NO_3 group. In the presence of DMFA the Cu complex is solvated by two molecules of the solvent and NO_3^- group is in the second coordination sphere [24, 25, 27]. Thus dsc ligand may be shifted into more close contact with copper and Se shf splitting will increase. In contrast to this observation when EtOH is used as a solvent NO_3 group is in the first coordination sphere and from electrostatic point of view it may be expected that repulsion between the ligands which take place will increase the distance Cu–Se and it will reflect to decrease of the Se shf splitting.

Electronic spectral studies. When to solutions of $Cu(dsc)_2$ in different organic solvents ($CHCl_3$, DMFA, acetone, pyridine) CuX_2 (X = Cl, Br, NO_3) dissolved in C_2H_5OH, i–C_3H_7OH, DMFA or pyridine was added hypsochromic and hyperchromic shift was observed (Fig. 5). The new band at 22,600 cm^{-1} is the same as those reported above for the dimeric (dsc)CuX_2Cu(dsc) (X = Cl, Br) complexes. On the other hand it is clear from Fig. 5 that the doubling (ε = 23,800) of the intensity of the band at 22,600 cm^{-1} takes place compared to that at 20,200 cm^{-1}. The isosbestic point at 21,000 cm^{-1} clearly supports the reaction scheme as is proposed in

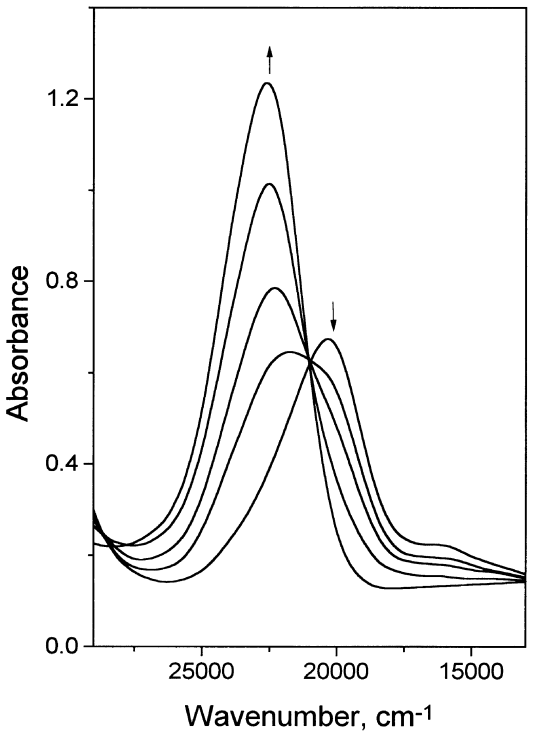

Fig. 5. Several electronic spectra taken after mixing of $Cu(dsc)_2$ (in $CHCl_3$) with $CuCl_2$ (in EtOH). The gradual hypsochromic and hyperchromic shift of the initial absorption maxima of 5.5×10^{-5} M/l $Cu(dsc)_2$ at 20,200 cm^{-1} to 22,600 cm^{-1} with isosbestic point at 21,000 cm^{-1} is observed when the ratio $Cu(dsc)_2/CuCl_2$ is changed from 1:0 to 2:1.

eq. (2). This property of the dimer may be used in the analytical work for increasing sensitivity of photometric estimations of the $Cu(dsc)_2$ complex.

(Received 15 December 1997; accepted 31 March 1998)

Abstract—Two series of trinuclear iron(III) carboxylate complexes with long alkyl chains, $[Fe_3O(O_2CR)_6L_3]NO_3$ where $L=H_2O$ or py (pyridine), were prepared. Powder X-ray diffraction patterns of each series suggested that the aqua series has a double-layer structure and the pyridine series has a single-layer structure. The single crystal X-ray structure determination of $[Fe_3O(O_2CC_{13}H_{27})_6(py)_3]NO_3$ revealed that the compound forms a single-layer structure with the interlamellar orientation of alkyl chains being arranged alternately to those of adjacent layers. © 1998 Elsevier Science Ltd. Keywords: trinuclear iron complex; long alkyl chain carboxylate complex.

INTRODUCTION

Complexes with long-alkyl chains prefer to construct layer structures, in which the metallic lamellae are layered apart from each interposing alkyl-chain layer, showing a long interlayer distance. The distance can easily be controlled by changing the carbon number of the alkyl chain in the starting materials. Such characteristics of the long-alkyl chain complexes are useful to investigate how the structure can modulate the intermolecular interactions.

In a previous study, we reported the preparation and the mixed-valence states of a series of mixed-valence Fe_3O complexes with long alkyl chain fatty acid, $[Fe_3O(O_2CC_nH_{2n+1})_6(py)_3]$ ($n=13$, 15, 17) [1]. In their ^{57}Fe Mössbauer spectra, a temperature-dependent mixed-valence state was observed for each complex; two quadrupole-split doublets ascribed to a high-spin Fe^{II} and a high-spin Fe^{III} were observed with an area ratio of $\sim$1:2 at low temperature, whereas only one quadrupole-split doublet ascribed to an intermediate valence state between Fe^{II} and Fe^{III} was observed at room temperature. The result was interpreted in terms of the rate of intramolecular electron transfer in the Fe_3O system, *i.e.*, the rate is slower than the time-scale of ^{57}Fe Mössbauer spectroscopy at lower temperature, while it goes quicker and

* Author to whom correspondence should be addressed.

exceeds the ^{57}Fe Mössbauer time scale at room temperature. This result has indicated that the valence-detrapping process in the Fe_3O type complexes is not always related to the dynamics of the solvate molecules of the crystal [1], although a close relation between the valence-detrapping and the dynamics of solvate molecules has been found for an acetate series, $[Fe_3O(O_2CCH_3)_6L_3]S$ (S is the solvate molecule) [2].

In the recent studies of mixed-valence Fe_3O complexes, the structural studies have become more important for studying the mixed-valence properties [3, 4]. However, no crystal structure analysis of the mixed-valence complexes with long alkyl chains has been done because of the difficulties of preparation of a single crystal suitable for structure determination. The available structural information is only that these complexes have a single-layer structure because the reflection lines of their powder X-ray diffraction patterns appeared with an equal interval in the small 2θ angle region and with a monotonously decreasing intensity [1].

In the previous studies, some fully oxidized Fe_3O–aqua complexes with long alkyl chains, $[Fe_3O(O_2CC_nH_{2n+1})_6(H_2O)_3]NO_3$ ($n=14$, 15, 17), were prepared and their IR and electronic spectra were reported [5]. However, the crystal structure of the Fe_3O-type complexes with long alkyl chains is, so far, still unknown regardless of whether they are mixed-valent or fully oxidized. Therefore, the crystal structure determination of the Fe_3O-type complexes with long alkyl chains will be very important for adding new information to the crystallographic data base. The crystal structure of the fully oxidized Fe_3O complex is expected to give some insight into the crystal structure of the mixed-valence Fe_3O complexes. In the present paper, the layer-structure of two series of fully-oxidized Fe_3O complexes, $[Fe_3O(O_2CC_nH_{2n+1})_6L_3]NO_3$ ($L=H_2O$, $n=11$, 13, 15, 17; L = py, $n=13$, 15, 17) and the crystal structure of the myristate–pyridine complex, $[Fe_3O(O_2CC_{13}H_{27})_6(py)_3]NO_3$, will be reported.

EXPERIMENTAL

Preparation of $[Fe_3O(O_2CC_nH_{2n+1})_6(H_2O)_3]NO_3$ (n = 11, 13, 15, 17)

Palmitate ($n=15$) and stearate ($n=17$) complexes were prepared according to the previously reported method [5](a), and laurate ($n=11$) and myristate ($n=13$) complexes were prepared according to the method for palmitate and stearate complexes by using lauric acid or myristic acid instead of stearic acid and palmitic acid. One portion of finely powdered $Fe(NO_3)_3{\cdot}9H_2O$ was added to the diethyl ether solution of triple the molar quantity of the corresponding acid by stirring, the mixture then being refluxed in a flask fitted with a reflux condenser. Pale orange precipitates, insoluble in diethyl ether, were filtered off. They were washed with diethyl ether, then dried in air. Found: C, 58.45; H, 9.99; N, 0.81. Calc. for $n=11$, $C_{72}H_{144}NO_{19}Fe_3$: C, 57.83; H, 9.71; N, 0.94%. Found: C, 61.49; H, 10.64; N, 0.70. Calc. for $n=13$, $C_{84}H_{168}NO_{19}Fe_3$: C, 60.64; H, 10.18; N, 0.84%. Found: C, 63.17; H, 11.02; N, 0.75. Calc. for $n=15$, $C_{96}H_{192}NO_{19}Fe_3$: C, 62.94; H, 10.56; N, 0.76%. Found: C, 64.98; H, 11.12; N, 0.70. Calc. for $n=17$, $C_{108}H_{216}NO_{19}Fe_3$: C, 64.85; H, 10.88; N, 0.70%.

Preparation of $[Fe_3O(O_2CC_nH_{2n+1})_6(py)_3]NO_3$ (n = 13, 15, 17)

The pyridine complexes were prepared by recrystallizing the aqua complexes from a pyridine–ethanol (1:1) mixture. The stearate and palmitate complexes were obtained as yellow–green powder, while the myristate complex was obtained as dark-green well-grown rectangular crystals suitable for X-ray crystal structure analysis when the solution was cooled. The laurate complex ($n=11$) was not obtained by this method. Found: C, 64.18; H, 10.01; N, 2.87. Calc. for $n=13$, $C_{99}H_{177}N_4O_{16}Fe_3$: C, 64.38; H, 9.66; N, 3.03%. Found: C, 66.29; H, 10.32; N, 2.54. Calc. for $n=15$, $C_{111}H_{201}N_4O_{16}Fe_3$: C, 66.15; H, 10.05; N, 2.78%. Found: C, 67.68; H, 10.63; N, 2.39. Calc. for $n=17$, $C_{123}H_{225}N_4O_{16}Fe_3$: C, 67.65; H, 10.38; N, 2.57%.

Powder X-ray diffraction measurement

Powder X-ray diffraction patterns were measured by using Cu–$K\alpha$ (40 kV, 20 mA) radiation on a Rigaku RAD-C system.

X-Ray structure determination

The data were collected on an Enraf Nonius CAD-4 diffractometer by using graphite-monochromated Mo–$K\alpha$ (0.71069 Å) radiation at 296 K. The structures were solved by using a direct method SIR88 [6] and refined by full-matrix least-squares. All calculations were carried out with MolEN computer software [7] on a Micro VAX 3400.

A crystal of $[Fe_3O(O_2CC_{13}H_{27})_6(py)_3]NO_3$ with dimensions $0.3\times0.3\times0.3\,mm^3$ cut out from one of the large crystals was mounted on a glass fiber in random orientation by using epoxy cement. Cell parameters and an orientation matrix for data collection were obtained from least-squares refinement by using the setting angles of 14 reflections in the range $9^\circ\leqslant\theta\leqslant11^\circ$. Three reflections (1,8,9;$\bar{6}$,3,11; $\bar{6}$,0,$1\bar{4}$) were remeasured every 120 minutes to monitor instrument and crystal stability and showed 3.1% variation in intensity. The intensities were corrected for Lorentz-polarization effects, and empirical absorption correction based on a series of ψ scans was applied. The minimum and maximum correction factors were 0.982 and 0.999, respectively. The structure was

refined with anisotropic thermal parameters for all atoms in the cation. Four intense peaks found in the difference Fourier map were regarded as the nitrate anion and refined isotropically with nonfixed positional parameters and thermal parameters. No hydrogen atoms were found in the final differential Fourier map. Crystal data for $[Fe_3O(O_2CC_{13}H_{27})_6(py)_3]NO_3$ are summarized in Table 1. The selected bond distances (Å) and bond angles (deg) are summarized in Table 2 and Table 3, respectively.

RESULTS AND DISCUSSION

X-Ray diffraction patterns of $[Fe_3O(O_2CC_nH_{2n+1})_6(H_2O)_3]NO_3$ ($n=11$, 13, 15, 17) and $[Fe_3O(O_2CC_nH_{2n+1})_6(py)_3]NO_3$ ($n=13$, 15, 17) are shown in Fig. 1 and Fig. 2, respectively. One of the most remarkable features of them is that the reflection lines appear with an equal interval in the small 2θ angle region, suggesting a layer structure for both series. But their intensity variation is different from each other; in the aqua complexes the intensity of reflections decreases alternately whereas, in the pyridine complexes, it decreases monotonously with increasing 2θ. The second reflection of the myristate–pyridine complex at $\sim 8^\circ$ shows an irregularly high intensity because a weak reflection, which is observed separately for the cases of palmitate and stearate complexes, may be superimposed. The estimated interlayer distances are plotted in Fig. 3, together with the interlayer distances of the mixed-valence series [1]. The interlayer distance of each series increases linearly with increase of the number of carbon atoms in the alkyl chain, suggesting that each series has the same structure in which the only difference is the length of the alkyl chains, respectively. The pyridine series of the fully-oxidized complexes has a slightly longer interlayer distances than the mixed-valence pyridine series and the slope of the straight lines of both series are very close to each other. The differences of the interlayer distance between $n=11$ and $n=13$, $n=13$ and $n=15$, and $n=15$ and $n=17$ are 3.79, 4.15, and 3.71 Å, respectively, for the aqua complexes. These values are more than the length of two methylene groups $-(CH_2)_2-$, ca. 2.5 Å and less than twice the length of $-(CH_2)_2-$, ca 5.0 Å. This indicates that the aqua complexes have a double-layer structure with an interlamellar orientation of alkyl chains being of a head-to-head configuration, as shown in Fig. 4(a). On the other hand, the differences in the interlayer distance between $n=13$ and $n=15$, and $n=15$ and $n=17$ are 2.40, and 2.51 Å, respectively, which are almost equal to the length of two methylene groups. This indicates that the pyridine complexes have a single-layer structure with an interlamellar orientation of mutually inserted alkyl chains, as shown in Fig. 4(b). The monotonous decrease of the reflection intensity also supports this structure.

An ORTEP [8] drawing of the central part of $[Fe_3O(O_2CC_{13}H_{27})_6(py)_3]^+$ cation is shown in Fig. 5. The Fe_3O cations are located on sites of C_2 symmetry. The two-fold axis passes through O–Fe1–N1–C53 atoms, thus two iron atoms are related by the imposed symmetry and the Fe_3O triangle is planar. The nitrate anion located near the Fe_3O core should be disordered at least in two positions related to the C_2 axis. The position of the nitrate anion could not be precisely determined, probably because of further disordering. The Fe–(μ_3-O) distances of 1.908(7) Å and 1.898(4) Å are consistent with the typical value for Fe(III) [9] in $[Fe_3O(O_2CR)_6L_3]^+$ [10]. Two of the three coordinated

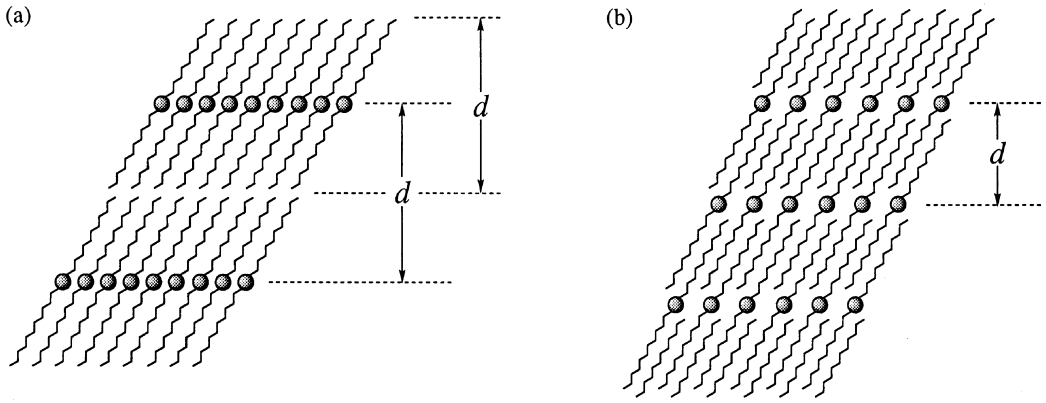

Fig. 4. Schematic representation of layer structures; (a) double-layer structure, (b) single-layer structure.

pyridine rings (N2, C54–C58) related to the C_2 axis are approximately parallel to the Fe_3 plane, whereas one pyridine ring (N1, C51–C53) is tilted by 51.3(2)° with respect to the Fe_3O plane. The Fe_3O plane is also tilted by 25.43(3)° with respect to the *ab* plane.

In Fig. 6, an ORTEP drawing of the whole cation structure is presented. The structure shows the presence of three inequivalent alkyl chains named A chain (C2–C14), B chain (C16–C28), and C chain (C31–C42). The directions of the three chains lying on the same side of the Fe_3O plane are approximately parallel to one another. As listed in Table 4, the A and B chains are regarded to have all-*trans* configuration within the torsion angle of 5°. However, a *gauche* conformation is seen at the bond between α and β carbon atoms of the C chain with the torsion angle of −63.56°. The bond between β and γ carbon is also significantly deformed from a *trans* conformation with the torsion angle of −164.82°. This indicates that the C chain must introduce a *gauche* conformation and a slightly deformed *trans* conformation to be accommodated in the same direction as the A, B chains.

A stereo view of the unit cell is shown in Fig. 7. As frequently seen in a number of long alkyl chain compounds, the myristate complex was found to form a single layer structure with interlamellar orientation of mutually inserted alkyl chains. The interlayer distance is found to be $c/2 = 22.30$ Å, which agrees with the estimated value, according to the Bragg condition, of 22.51 Å. Since the directions of the alkyl chains lying on the opposite side of the Fe_3O plane are different from each other, the inclination of the alkyl chains varies alternately as the alkyl chains are oriented in a zigzag along the *c*

axis. They are tilted by $\sim 20^\circ$ with respect to the *c* axis. The fundamental structure of the palmitate and the stearate complexes is probably the same as that of the myristate complex. On the other hand, it is difficult to conclude whether the crystal structure of the mixed-valence pyridine series is similar to that of the fully-oxidized pyridine series or not, because the *intra*lamellar packing arrangement and the conformation of the alkyl chains are unknown in the mixed-valence series, although their powder X-ray diffraction patterns are very similar to those of the fully-oxidized pyridine series.

Department of Chemistry, University of Newcastle upon Tyne, Newcastle upon Tyne, NE1 7RU, U.K.

(Received 30 January 1998; accepted 30 March 1998)

Abstract—The presence of three adjacent bulky groups in 1,2,3,5-*tetrakis*(diphenyl-thiophosphino)benzene leads to structural distortion and hindered rotation about P–C bonds with concomitant inequivalence of P_1 and P_3 in the solution-state ^{31}P n.m.r. spectrum at low temperatures. The crystal structure shows that in the solid there are substantial deviations [up to 71 pm] from planarity of the central C_6P_4 skeleton, although the aromaticity appears to be retained. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: poly-*tertiary*-phosphinesulfide; hindered rotation; ^{31}P n.m.r.; X-ray diffraction; aromaticity; molecular distortion.

In earlier preparative and n.m.r. spectroscopic studies [1, 2] of the *polykis*(diphenylphosphino)benzenes, $(Ph_2P)_nC_6H_{6-n}$($n=1$ to 4), we have attributed the patterns of their ^{31}P chemical shifts and vicinal ^{31}P–^{31}P coupling constants to steric interference of adjacent diphenylphosphino groups which leads to specific phosphorus electron lone-pair orientations, although in no case was rotation about any bond between the phosphorus and carbon atoms of the central skeleton found to be slow on an n.m.r. time-scale.

In connection with studies of derivatives of these species in which there is even greater potential for internal steric hindrance we now report that the low temperature proton-decoupled ^{31}P n.m.r. spectrum at 202 MHz of 1,2,3,5-*tetrakis*-(diphenylthio-phosphino)benzene, 1,2,3,5-$\{Ph_2P(S)\}_4C_6H_2$, **1**, shows P_1 and P_3 to be inequivalent with a chemical shift separation of 3.5 ppm at 198 K [Fig. 1]. At higher temperatures the resonances of P_1 and P_3 exhibited characteristic coalescence behaviour, and above 270 K a normal A_2MX spectrum [i.e. P_1 equivalent to P_3] was obtained [Fig. 1] with $^3J(P_1–P_2)=10.9$ Hz, $^4J(P_1–P_5)<1$ Hz and $^5J(P_2–P_5)=4.9$ Hz. Spectra at intermediate temperatures showed that the P_5 signal remained sharp [$v_{1/2}<3$ Hz] throughout, and from the coalescence of the P_1/P_3 resonances [$\Delta v=716$ Hz] a value of 39 kJmol^{-1} for the free energy of activation at 214 K was obtained. At the lowest attainable temperatures the P_1, P_2, and P_3 resonances still had widths in excess of 100 Hz, presumably owing to slow internal molecular motions, and therefore only the high temperature averaged values could be obtained for $^3J(P_1–P_2)$, $^3J(P_2–P_3)$ and $^4J(P_1–P_5)$, $^4J(P_3–P_5)$. In view of the large line widths at the lower temperatures no attempt was made to calculate an entropy of activation.

Consideration of a physical molecular model of **1** indicates that it is likely that this free energy of activation refers to concerted ["geared"] rotations about the phosphorus-carbon bonds linking P_1, P_2, and P_3 to the central C_6 skeleton. In principle, the observed inequivalence of P_1 and P_3 could be due to restricted rotation about any one of these bonds, and since the middle diphenylthiophosphino moiety will be the most sterically crowded its preferential adoption of any conformation with the sulfur atom at different distances from P_1 and P_3 could lead to the observed effect. The model shows that in practice the crowding is likely to be so great that the motions of all three adjacent diphenylthiophosphino moieties will be correlated and that the conformations adopted by P_1 and P_3 should be different, thus potentially enhancing their inequivalence. It is striking that between 296 and 198 K $\delta(^{31}P)$ for P_2, the most hindered phosphorus

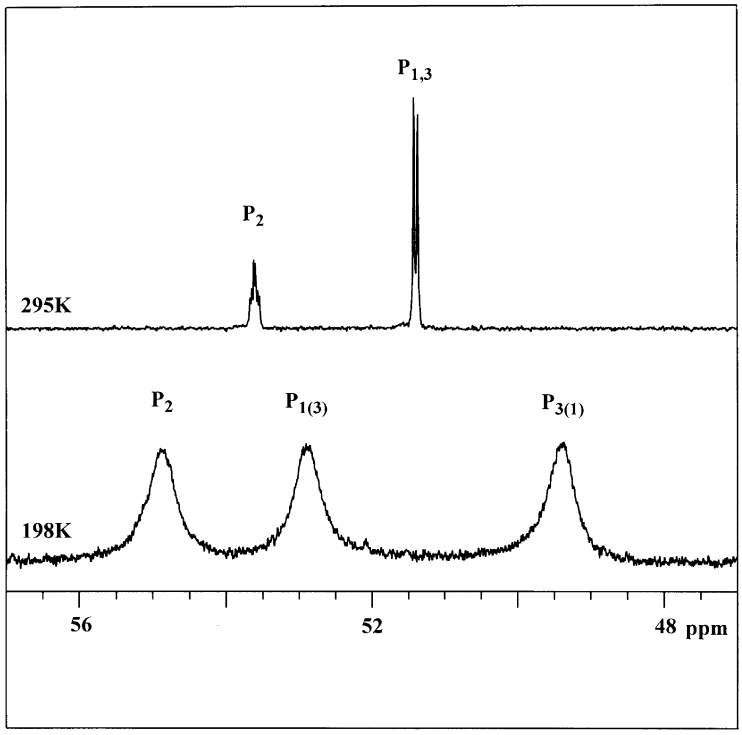

Fig. 1. Part of the proton-decoupled ^{31}P n.m.r. spectra at 202.4 MHz of 1,2,3,5-*tetrakis*-. (diphenylthiophosphino)benzene at 295 and 198 K.

atom, increases by 1.4 ppm, whereas that for P_5 is essentially unchanged and the mean chemical shift for P_1, P_3 decreases by only 0.25 ppm.

The above conclusions regarding steric compression were confirmed by a single crystal X-ray diffraction study which gave the solid state molecular structure of **1** represented in Fig. 2. Selected bond lengths and interbond angles are in Table 1. The unit cell contains four molecules of the tetrathiophosphine and a total of approximately three molecules of disordered dichloromethane. There are no significant intermolecular contacts and so the overall conformation adopted must be dominated by intramolecular constraints. Fig. 3 summarises the key features of the central C_6P_4 skeleton in which there are considerable distortions from an idealised geometry. The substituted benzene ring is not exactly planar with the largest deviations [6 pm] from the mean C_6 plane of individual carbon atoms substantially exceeding those found in hexaiodobenzene [3] but being less than those [up to 11 pm] in *hexakis*(trimethylsilyl)benzene [4]. The steric compression near C_2 leads to the C_1–C_2 and C_2–C_3 bonds of the ring being some 3–4 pm longer than those in benzene [5], triphenylphosphinesulfide [6], and indeed the phenyl groups of **1** itself, and this is compensated by a slight shortening of the C_4–C_5 and C_5–C_6 bonds. The C_1–P_1, C_2–P_2, and C_3–P_3 bonds are also elongated compared with C_5–P_5 in **1** and the P–C bond in triphenylphosphinesulfide [6].

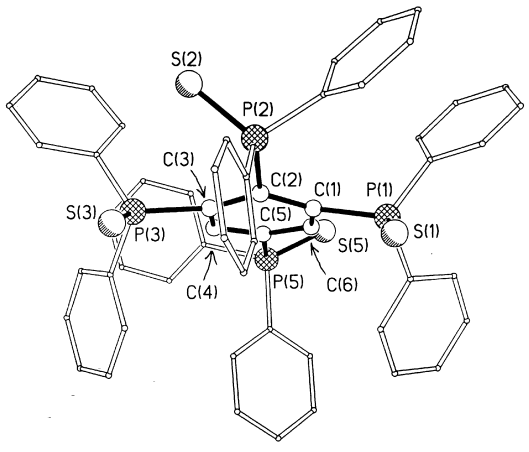

Fig. 2. Molecular structure of 1,2,3,5-*tetrakis* (diphenylthiophosphino)benzene determined by single crystal X-ray diffraction and viewed from somewhat below the central C_6 mean plane.

In this structure P_1 and P_3 are forced away from P_2, the $P_1C_1C_2$ and $P_3C_3C_2$ interbond angles being enlarged to 129°, and the $P_1C_1C_6$ and $P_3C_3C_4$ interbond angles correspondingly reduced to 111°. Most strikingly, P_1 and P_3 are on the opposite side to P_2 of the mean C_6 plane with deviations of up to 71 pm, so that the P_1-C_1-C_2-P_2 dihedral angle exceeds 36°.

Although this amount of distortion is exceeded in *hexakis*(trimethylsilyl)benzene [4] in which all six substituents are very large, and in other highly hindered substituted benzenes such as *hexakis*(trimethylgermyl)benzene [7] and the 1,3,5-*tris*-(dialkylamino)-2,4,6-trinitrobenzenes [8], we are unaware of any other example in which the presence of only three adjacent bulky substituents on a benzene or other aromatic ring leads to so great an effect. In hexaiodobenzene [3] no iodine atom deviates by more than 5 pm from the carbon plane and all I-C-C-I dihedral angles are less than 5°, while in *hexakis*(trimethylsilyl)benzene [4] the corresponding Si-C-C-Si dihedral angles have an average value of 61°.

It is not clear to what extent the distortion from planarity of the benzene ring in *hexakis*(trimethylsilyl)benzene [4] perturbs its aromaticity, but the chemistry is unusual [4]. In the proton n.m.r. spectrum of **1** H_4 and H_6 were found to resonate at δ 7.6 [high temperature average] which is in the range expected for protons attached to an aromatic carbon ring, implying that the electronic ring current is intact. It was not possible to identify the corresponding resonances in the ^{13}C spectrum which extended from 125 to 155 p.p.m.; however, it should be noted that carbon shieldings are generally less satisfactory as criteria of aromaticity. The pattern of C–C bond lengths in the central carbon ring of **1** indicates that the π-electron density is somewhat greater near C_5 than C_2. Our results therefore suggest that approximate planarity of the ring itself, even when the extra-cyclic bonds are seriously displaced from ideal positions, is sufficient for the retention of aromaticity in carbocyclic molecules. It is likely that the synthesis of **1** was possible only because the diphenylphosphino substituents were attached to the central carbon ring prior to their

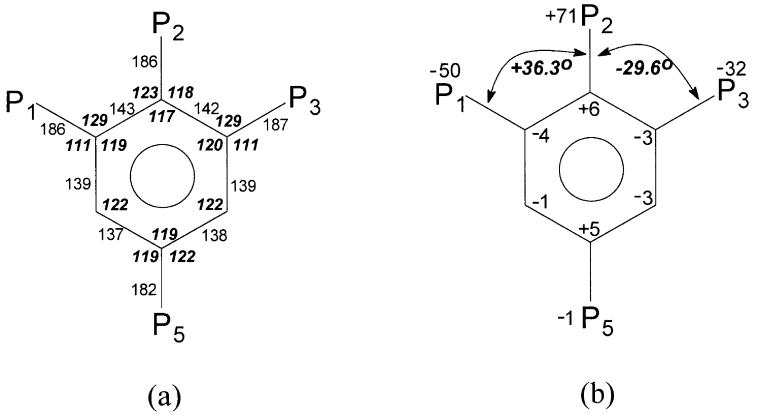

Fig. 3. Geometry of the central C_6P_4 skeleton of 1,2,3,5-*tetrakis*(diphenylthio-phosphino)benzene. (a) Bond lengths in pm in normal type, interbond angles in degrees in **bold italic** type. (b) Atomic deviations in pm above (+) or below (−) the mean central C_6 plane in normal type, dihedral angles in degrees in **bold italic** type.

steric demands being increased by the reaction with elemental sulfur. There is a clear parallel here with the synthesis of *hexakis*(trimethylsilyl)benzene from *hexakis*(dimethylsilyl)benzene by the conversion of Me_2SiH into the more bulky Me_3Si groups [4]. Prolonged reaction of elemental selenium with 1,2,3,5-*tetrakis*(diphenylphosphino)benzene did not progress beyond the formation of 1,3,5-*tris*(diphenylselenophosphino)-2-diphenylphosphinobenzene, presumably because the greater size of selenium compared with sulfur prevented its addition to the more crowded P_2.

EXPERIMENTAL

Preparation

1,2,3,5-*tetrakis*(diphenylthiophosphino)benzene, **1**, was made by the reaction between 1,2,3,5-*tetrakis*(diphenylphosphino)benzene and four equivalents of elemental sulfur in dichloromethane at room temperature for three weeks. It was recrystallized from a 1:1 mixture of dichloromethane and diethylether as yellow crystals suitable for X-ray diffraction. These lost solvent of crystallization under vacuum at 160° to give a pale yellow powder m.p. 267–270°. Found C 68.8, H 4.49, P13.1%; $C_{54}H_{42}P_4S_4$ requires C68.6, H4.47, P 12.9%.

N.m.r. Spectroscopy

^1H, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ n.m.r spectra were measured at 500.15, 125.7 and 200.2 MHz respectively on a JEOL Lambda 500 spectrometer on solutions of **1** in CD_2Cl_2. Chemical shifts are to high frequency of Me_4Si, Me_4Si, and external 85% H_3PO_4 respectively. Spectral assignments were confirmed by 2D proton COSY, ROESY [9] and $^1H\{^{31}P\}$ decoupling experiments.

X-ray diffraction

Crystal data for **1**. $0.75(CH_2Cl_2)$: $C_{54}H_{42}P_4S_4 \cdot 0.75(CH_2Cl_2)$, M = 1006.7, monoclinic, space group $P2_1/n$, $a = 1235.6(3)$, $b = 1.885.1(4)$, $c = 2315.3(6)$ pm, $\beta = 103.57(4)°$, $V = 5.242(2)$ nm^3, $Z = 4$, $D_c = 1.276$ g cm^{-3}, $\mu = 0.415$ mm^{-1} (Mo–Kα radiation $\lambda = 71.073$ pm), $F(000) = 2086$, $T = 160$ K, crystal size $0.53 \times 0.42 \times 0.34$ mm. Measurements were made on a Stoe-Siemens four-circle diffractometer. Cell parameters were refined from 2θ values (20–24°) of 20 reflections measured at $\pm\omega$; intensities were measured with ω/θ scans and on-line profile-fitting [10]. Absorption corrections were based on azimuthal scan measurements for selected sets of symmetry-equivalent reflections [11]. 9286 reflections were collected ($2\theta_{max} = 50°$, maximum indices 14, 22, 27), giving 9250 unique data ($R_{int} = 0.0776$ for a few high-angle reflections only).

The structure was solved by direct methods and refined [11] by full-matrix least-squares on F^2 values, with weighting $w^{-1} = \sigma^2(F_o^2) + (0.092P)^2 + 9.8265P$, where $P = (F_o^2 + 2F_c^2)/3$.. Anisotropic displacement parameters were refined; isotropic hydrogen atoms were constrained with a riding model. Extinction effects were negligible. The structure was found to contain disordered solvent. Satisfactory refinement was achieved with one molecule of CH_2Cl_2 disordered over three orientations on one general position, and half a molecule of CH_2Cl_2 distributed equally over two sites around an inversion centre, giving a total of three molecules per unit cell; only Cl atoms were anisotropic, H atoms were not included, and geometrical restraints were applied.

At convergence, $wR = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2} = 0.1810$ for all data, conventional $R = 0.0608$ on F values of 7140 reflections having $F_o^2 > 2\sigma(F_o^2)$, goodness of fit = 1.044 for all F^2 values and 617 refined parameters. A final difference synthesis showed a few peaks of height up to 1464 e nm^{-3} in the disordered solvent regions, but no other significant features.

Supplementary material

Additional material submitted comprises a complete list of fractional coordinates, H-atom coordinates, displacement parameters, bond lengths, interbond angles, and structure factors.

(Received 2 February 1998; accepted 6 April 1998)

Abstract—A novel, monomeric triphenylphosphine silver(I) complex $[Ag(Htsa)(PPh_3)_3]$ ($H_2tsa = o\text{-}HS(C_6H_4)CO_2H$) was synthesized from three different ligand-exchange reactions, as **3** without any solvate or as **3a** with CH_2Cl_2 solvate, in good yield. The complex **3** can be interconverted with the previously obtained, two antimicrobially-active silver(I) thiosalicylates; one was the oligomeric, water-soluble complex $\{Na[Ag(tsa)] \cdot H_2O\}_n$, **1** ($n = 21$–$27$) and the other the polymeric, water-insoluble complex $[Ag(Htsa)]_n$, **2**. The analogous gold(I) complex $[Au(Htsa)(PPh_3)]$, **4**, was also isolated. The complexes **3**, **3a** and **4** were characterized with complete elemental analyses, TG/DTA, FT-IR and multinuclear NMR (^1H, ^{13}C, ^{31}P and ^{109}Ag) spectroscopies. The crystal structures of **3** and **4** were determined with single-crystal X-ray diffraction. The monomeric structure for **3** and the dimeric structure via hydrogen bonds of the carboxylic acid for **4** in the solid state were found.

1. INTRODUCTION

In the medicinally or pharmaceutically active compounds of silver(I) and gold(I), most of the complexes formed with thiol and nitrogen-containing heterocyclic ligands are harder to crystallize and are believed to be polymeric [1–43]. In general, tertiary phosphine ligands have been usually employed in order to obtain crystalline compounds [23–35, 41, 42], although several crystalline thiolatogold(I) complexes without tertiary phosphines such as $[Au(SR)_2]^{n-}$ (HSR = mercapto-group compound) have been recently found [17–22, 39]. Probably, a recent development of monomeric Au^I compounds composed of both thiol and tertiary phosphine ligands stems from a discovery of auranofin ((2,3,4,6-tetra-*O*-acetyl-β-1-thio-D-glucopyranosato-*S*)(triethylphosphine)gold(I)) [6–10, 14–16], which has been used in chemotherapy as an effective antiarthritic agent and also as a realized medicine of oral-administration, although its mechanism or mode of action is unclarified as yet [6–10]. On the other hand, for non-crystalline, polymeric metal–thiolate and metal–imidazolate compounds, only a few structural studies have been performed by synchrotron X-ray studies containing EXAFS, XANES, WAXS and DAS [11, 12] and by Rietveld analysis using powder X-ray diffraction data [44, 45].

Very recently, we have prepared a monomeric imidazolatotris(triphenylphosphine) silver(I) complex $[Ag(imd)(PPh_3)_3]$ (Himd = imidazole) [41] by a reaction of PPh_3 ligands in CH_2Cl_2 with a polymeric complex $[Ag(imd)]_n$ which has shown wide spectra of excellent antibacterial and antifungal activities [42]. This monomeric complex was neither obtained from reactions of precursors $[AgCl(PPh_3)_3]$ and $[AgCl(PPh_3)_2]_2$ with a free Himd ligand in the presence of NaOH nor of $[AgCl(PPh_3)_2]_2$ with sodium salt of

imidazolate. On the contrary, the corresponding Au^{I} complex [Au(imd)(PPh_3)] was obtained from a reaction of the precursor [AuCl(PPh_3)] with the Himd ligand in the presence of NaOH.

Also, two types of thiosalicylatosilver(I) complexes have been recently found [38]; one was an oligomeric, water-soluble and yellow complex $\{Na[Ag(tsa)]\cdot H_2O\}_n$, **1** ($n = 21$–$27$; $H_2tsa = o$-$HS(C_6H_4)CO_2H$) and the other a polymeric, water-insoluble and orange complex $[Ag(Htsa)]_n$, **2**, both of which have displayed effective antimicrobial activities against selected bacteria, yeast and molds. The present work has been aimed at (i) preparing a monomeric form of the thiosalicylatosilver(I) complex, e.g. [Ag(Htsa)(PPh_3)$_3$], **3**, through ligand-exchange reactions of polymeric complex **2** or of some precursor silver(I) complexes such as [AgCl(PPh_3)$_3$] and [AgCl(PPh_3)$_2$]$_2$, (ii) applying the same concept to gold(I) chemistry to obtain the thiosalicylatogold(I) complex, e.g. [Au(Htsa)(PPh_3)], **4**, (iii) providing X-ray crystal structures of **3** and **4** in the solid state and (iv) clarifying the behavior in solution of **3** and **4**. The X-ray crystal structures of several (arenethiolato)metal complexes have been determined such as [Au(Htsa)(PCy_3)] (PCy_3 = tricyclohexylphosphine) [26], [Cu($SC_6H_4NMe_2$-2)]$_3$, [Cu(S-1-$C_{10}H_6NMe_2$-8)]$_9$, [Cu$_3$(S-1-$C_{10}H_6NMe_2$-8)$_2$(C≡C^{t}Bu)]$_2$ [46], [Cu$_8${$SC_6H_3(CH_2NMe_2)_2$-2,6}$_3$Br$_5$] [47], [Mg{S(C_6H_4-2-CH_2NMe_2)}$_2$]$_2$ [48] and [Li{SC_6H_4((R)-CH(Me)NMe_2)-2}]$_6$ and [Li{$SC_6H_3(CH_2NMe_2)_2$-2,6}]$_6$ [49].

Herein we report the full details of the synthesis and characterization of the complexes [Ag(Htsa)(PPh_3)$_3$], **3**, in 37% yield and [Ag(Htsa)(PPh_3)$_3$]·CH_2Cl_2, **3a**, in 52% yield both as colorless needle crystals, and [Au(Htsa)(PPh_3)], **4**, in 72% yield as pale yellow prism crystals. The X-ray crystal structures of **3** and **4** were determined by single-crystal X-ray diffraction. Also reported are the compositional characterization of **3**, **3a** and **4** by full elemental analyses, FT-IR, thermoglavimetric and differential thermal analyses (TG/DTA) and their structural characterization in solution by ^{1}H, ^{13}C and ^{31}P NMR spectroscopies, and additionally by solution ^{109}Ag NMR spectroscopy for **3**.

2. EXPERIMENTAL

2.1. *Materials*

All chemicals were reagent grade and were used as received: thiosalicylic acid (H_2tsa; *o*-mercaptobenzoic acid), $AgNO_3$, Na[$AuCl_4$]·$2H_2O$, $(C_6H_5)_3P$, NaOH, ethanol, acetone, diethyl ether, dichloromethane (all from Wako); $CDCl_3$, DMSO-d_6 (Aldrich); CD_2Cl_2 (Isotec). Several precursor complexes such as [AgCl(PPh_3)$_3$] [50], [AgCl(PPh_3)$_2$]$_2$ [51] and [AuCl(PPh_3)] [52–54] were prepared according to the literature, respectively. Polymeric, water-insoluble and orange complex $[Ag(Htsa)]_n$, **2**, was prepared as previously described [38].

2.2. *Instrumentation/analytical procedures*

Elemental analyses on samples dried overnight at room temperature under 10^{-3}–10^{-4} Torr were carried out by Mikroanalytisches Labor Pascher (Remagen, Germany). Infrared spectra were obtained on a JASCO FT-IR 300 spectrometer as KBr disks at room temperature. Thermogravimetric (TG) and differential thermal analyses (DTA) were acquired using a Rigaku TG 8101D and TAS 300 data-processing system. TG/DTA measurements were run under air with a temperature ramp of 1°C/min between 20 and 500°C.

^{1}H NMR (399.65 MHz), ^{13}C NMR (100.4 MHz) and ^{31}P NMR (161.70 MHz) spectra were recorded at 22°C in 5 mm o.d. tubes on a JEOL JNM-EX 400 FT-NMR spectrometer with a JEOL EX-400 NMR data-processing system. ^{1}H and ^{13}C{^{1}H} NMR spectra of the complexes were measured in $CDCl_3$ with reference to an internal standard of tetramethylsilane (TMS). Chemical shifts are reported on the δ scale and resonances downfield of TMS (δ 0) are recorded as positive. ^{31}P{^{1}H} NMR spectra of the complexes were measured in $CDCl_3$ with reference to an external standard of 25% H_3PO_4 in H_2O in a sealed capillary. Chemical shifts are reported as negative for resonances upfield of H_3PO_4 (δ 0). The ^{31}P{^{1}H} NMR spectra at −90°C were measured in CD_2Cl_2 with an external standard of 25% H_3PO_4 by a substitution method.

The two-dimensional ^{1}H–^{13}C COSY NMR spectra and both two-dimensional NMR spectra of ^{1}H–^{13}C HMBC (heteronuclear multiple bond correlation) method by a correlation $^3J_{C-H}$ between ^{1}H and ^{13}C atoms separated by three bonds and ^{1}H–^{13}C HMQC (heteronuclear multiple quantum coherence) by a correlation between ^{1}H and ^{13}C which are directly spin–spin coupled, were measured in $CDCl_3$ solution, all spectra referenced to an internal TMS in 5 mm o.d. tubes using a JEOL JNM-EX 400 NMR spectrometer and JEOL EX-400 NMR data-processing system or using a VARIAN UNITY 500 FT-NMR spectrometer. Pulse sequences and spectral parameters for the HMBC and HMQC methods are reported elsewhere [55].

^{109}Ag NMR (18.45 MHz) spectra were recorded at 22°C in 10 mm o.d. tubes on a JEOL JNM-EX 400 FT-NMR spectrometer equipped with a JEOL NM-40T10L low-frequency tunable probe. The ^{109}Ag NMR spectra of the complexes were measured in $CDCl_3$ with reference to an external standard of saturated $AgNO_3$–D_2O solution by a substitution method. Chemical shifts are reported on the δ scale with resonances downfield of $AgNO_3$ (δ 0) as positive. Spectral parameters for ^{109}Ag NMR include: pulse width of

13.2 μs, acquisition time of 0.39 s, recycle time of 1.39 s and sweep width of 21,008 Hz.

2.3. *Preparation of the complexes*

[Ag(Htsa)(PPh_3)$_3$], **3**: From a reaction of [AgCl(PPh_3)$_2$]$_2$ with H_2tsa in the presence of NaOH. To 0.600 g (0.449 mmol) [AgCl(PPh_3)$_2$]$_2$ dissolved in 40 ml dichloromethane was added a clear yellow solution of 0.140 g (0.908 mmol) of H_2tsa and 0.036 g (0.900 mmol) of NaOH in 50 ml ethanol. The yellow–white suspension obtained was stirred for 30 min and filtered through a folded filter paper (Whatman No. 5). The clear filtrate was concentrated at 60°C to a volume of *ca*. 70 ml by rotary evaporation, followed by standing for a few days in a refrigerator at 5°C. Colorless needle crystals formed were collected on a membrane filter (JG 0.2 μm), washed with water (100 ml × 2), then with ethanol (100 ml × 2) and finally with 100 ml diethyl ether, and dried *in vacuo* for 2 h. Yield: 0.35 g (37.4%) of light- and thermally-stable, colorless needle crystals, which were soluble in chloroform and dichloromethane, sparingly soluble in DMSO, acetone and acetonitrile, but insoluble in water, ethanol and diethyl ether.

Found: H, 4.81; C, 70.00. Calc. for $H_{50}C_{61}O_2P_3SAg$ or [Ag(Htsa)(PPh_3)$_3$]: H, 4.81; C, 69.92. TG/DTA: no weight loss observed below 150°C; decomposition started around 150°C with an endothermic peak at 170°C. IR (KBr disk): *v* 1701vs, 1583m, 1479s, 1433vs, 1327m, 1309m, 1271m, 1217m, 1184w, 1157m, 1093m, 1026m, 997m, 742vs, 694vs, 515s, cm^{-1}. ^{1}H and ^{13}C NMR in $CDCl_3$ are shown in Table 3.

[Ag(Htsa)(PPh_3)$_3$]·CH_2Cl_2, **3a**: From a reaction of [AgCl(PPh_3)$_3$] with H_2tsa in the presence of NaOH. To 2.79 g (3.00 mmol) [AgCl(PPh_3)$_3$] dissolved in 60 ml dichloromethane was added a clear yellow solution of 0.463 g (3.00 mmol) of H_2tsa and 0.120 g (3.00 mmol) of NaOH in 180 ml ethanol. The yellow–white suspension obtained was stirred for 30 min and filtered through a folded filter paper (Whatman No. 5). The clear filtrate was concentrated at 60°C to a volume of *ca*. 200 ml by rotary evaporation, followed by standing for a few days in a refrigerator at 5°C. Colorless needle crystals formed were collected on a membrane filter (JG 0.2 μm), washed with water (100 ml × 2), then with ethanol (100 ml × 2) and finally with 100 ml diethyl ether and dried *in vacuo* for 2 h. Yield: 1.75 g (51.5%) of colorless needle crystals, which were soluble in chloroform and dichloromethane, sparingly soluble in DMSO, acetone and acetonitrile, but insoluble in water, ethanol and diethyl ether.

Found: H, 4.74; C, 65.91; O, 2.66; P, 8.10; S, 2.63; Cl, 5.75; Ag, 9.68; total 99.47%. Calc. for $H_{52}C_{62}O_2P_3SCl_2Ag$ or [Ag(Htsa)(PPh_3)$_3$]·CH_2Cl_2: H, 4.63; C, 65.74; O, 2.82; P, 8.20; S, 2.83; Cl, 6.26; Ag, 9.52. TG/DTA: weight loss of 6.82% observed below 117°C with an endothermic point at 110°C. Calc. for [Ag(Htsa)(PPh_3)$_3$]·$x$$CH_2Cl_2$, 7.50% ($x$ = 1); decomposition gradually started around 150°C. IR (KBr disk): *v* 1703vs, 1583m, 1479s, 1433vs, 1327m, 1309m, 1273m, 1221w, 1182w, 1157w, 1092s, 1026m, 999m, 742vs, 694vs, 513vs cm^{-1}. ^{1}H and ^{13}C NMR in $CDCl_3$ are shown in Table 3. ^{31}P NMR ($CDCl_3$): δ 4.55 (PPh_3). ^{109}Ag NMR ($CDCl_3$): δ 1196.

3a: From a reaction of polymer [Ag(Htsa)]$_n$ with PPh_3. To a yellow suspension of 0.522 g (2.00 mmol) of powder-solid [Ag(Htsa)]$_n$ in 40 ml ethanol was added a clear colorless solution of 1.57 g (6.00 mmol) of triphenylphosphine in 120 ml dichloromethane. Stirring continued for 3 h. During the initial 15 min-stirring, the solution became clear yellow. The clear filtrate obtained by passing through a folded filter paper (Whatman No. 2) was slowly evaporated at room temperature. A crude compound of pale yellow plate crystals formed within a few days was collected on a membrane filter (JG 0.2 μm), washed with ethanol (100 ml × 2) and then with diethyl ether (100 ml × 2) and dried *in vacuo* for 2 h. The yield of this crude product was 1.64 g.

To the crude product redissolved in 40 ml dichloromethane was added 40 ml ethanol, followed by filtering through a filter paper (Whatman No. 2) and the filtrate was slowly evaporated by standing for a few days at room temperature. Colorless needle crystals formed here were collected on a membrane filter (JG 0.2 μm), washed twice each with 100 ml ethanol and 100 ml diethyl ether and dried *in vacuo* for 2 h. Yield: 0.95 g (42.1%).

Found: H, 4.59; C, 65.94. Calc. for $H_{52}C_{62}O_2P_3SCl_2Ag$ or [Ag(Htsa)(PPh_3)$_3$]·CH_2Cl_2: H, 4.63; C, 65.74. TG/DTA: weight loss of 7.24% observed below 125°C with an endothermic peak at 104°C; Calc. for [Ag(Htsa)(PPh_3)$_3$]·$x$$CH_2Cl_2$, 7.50% ($x$ = 1); decomposition started around 150°C with an endothermic peak at 170°C. IR (KBr disk): *v* 1704vs, 1584m, 1478s, 1433vs, 1327w, 1308w, 1272m, 1222w, 1182w, 1157m, 1092s, 1027m, 998m, 742vs, 694vs, 512vs, cm^{-1}. ^{1}H and ^{13}C NMR in $CDCl_3$ are shown in Table 3. ^{31}P NMR ($CDCl_3$): δ 4.57 (PPh_3).

[Au(Htsa)(PPh_3)], **4**: This compound was prepared by a modification of the literature method [26], using 0.247 g (0.500 mmol) of [AuCl(PPh_3)], 0.077 g (0.500 mmol) of H_2tsa in 50 ml ethanol and 1 ml (0.500 mmol) of 0.5 M NaOH aqueous solution. Yield: 0.22 g (72.0%) of pale yellow cubic crystals with melting point 154–156°C, which were soluble in acetone, chloroform and benzene, sparingly soluble in ethanol, but insoluble in water and diethyl ether. This compound was light- and thermally-stable.

Found: H, 3.31; C, 48.92; O, 5.47; P, 5.19; S, 5.09; Au, 31.40; total 99.38%. Calc. for $H_{20}C_{25}O_2PSAu$ or [Au(Htsa)(PPh_3)]: H, 3.29; C, 49.03; O, 5.22; P, 5.06; S, 5.23; Au, 32.16. TG/DTA: negligible weight loss (0.3%) observed below 150°C with an endothermic peak at 163°C; decomposition began at 270°C. IR (KBr disk): *v* 1682vs, 1585m, 1477m, 1464m, 1433s, 1406m, 1309s, 1265m, 1248m, 1099s, 1053m, 1036m, 997w, 958w, 754s, 694s, 538s, 507s, 496s cm^{-1}. ^{1}H and

^{13}C NMR in $CDCl_3$ are shown in Table 3. ^{31}P NMR ($CDCl_3$) δ 37.56 (PPh_3).

2.4. *X-ray structural analysis*

Crystals of complex **3** were obtained as colorless needles from a solution of the solvent mixture, dichloromethane–ethanol, and those of **4** as pale yellow cubes from a solution of dichloromethane–acetone. During a few days' standing at room temperature, crystals of sufficient quality suitable for single-crystal X-ray diffraction studies were grown.

Each single-crystal of **3** and **4** was mounted on glass fiber and transferred to a Rigaku AFC5S diffractometer. Cell contents and orientation matrix of **3** and **4** were obtained from the least-squares refinement of 25 and 23 reflections, respectively. The reflection data were collected using ω–2θ scan with graphite-monochromated Mo–Kα radiation at room temperature. The intensities of three standard reflections which were measured after every 150 reflections remained constant throughout the data collection. The data were corrected for Lorentz and polarization effects and empirical absorption corrections based on PSI scan were applied to the data. For the overall averaged transmission curve, the transmission factors of **3** and **4** were in the range of 0.93–1.00 and 0.23–1.00, respectively. The structures were solved by direct methods followed by subsequent difference Fourier calculation and refined by a full-matrix least-squares procedure using TEXSAN package [56]. For **3**, all atoms except hydrogen and carbon were refined anisotropically. Carbon and hydrogen atoms were refined isotropically. For **4**, all atoms except hydrogen were refined anisotropically and hydrogen atoms isotropically.

Crystal data, data collection and refinement for **3** and **4** are summarized in Table 1.

3. RESULTS AND DISCUSSION

3.1. *Molecular formula and compositional characterization*

The composition and molecular formula of **3** which consists of one silver(I) atom, one coordinating $Htsa^-$ ligand and three PPh_3 ligands without any solvated molecules, those of **3a** with one solvated CH_2Cl_2 molecule and those of **4** composed of one gold(I) atom, one $Htsa^-$ ligand and one PPh_3 ligand without any solvated molecules are based on elemental analyses (in particular for **3a** and **4**, all elements including oxygen, 99.47 and 99.38% totals are observed; see Section 2), TG/DTA and single-crystal X-ray analyses described later.

As to the solvation by one CH_2Cl_2 molecule in **3a**, in the absence of any other sources of chlorine, the Cl analysis (calc. 6.26, found 5.75%) reflects the presence of solvated CH_2Cl_2. The additional evidence for the presence of solvated CH_2Cl_2 is provided by a proton signal at 5.27 ppm observed in ^1H NMR spectra and by a carbon signal at 53.42 ppm in ^{13}C NMR spectra. TG/DTA analyses of two independent samples prepared from different starting materials also confirm the presence of one solvated CH_2Cl_2 as the observed weight loss 6.82 and 7.24% (calc. 7.50%) with an endothermic peak at 110 and 104°C, respectively.

The solid FT-IR spectra (Fig. 1) of complexes **3** and **4** show a disappearance of the S–H stretching band around 2560 cm^{-1} due to the SH group in the free H_2tsa ligand, suggesting the metal–S bond formation. Also shown is that the carbonyl stretching bands around 1700 cm^{-1} are unchanged after complexation, compared with that of the free H_2tsa ligand, suggesting that the carboxyl group remains protonated and does not coordinate to the central metal ions. Many small bands observed in 3000–2500 cm^{-1} region are also attributed to the presence of a protonated carboxylic group as usually observed. Thus, the IR spectra of all complexes **3**, **3a** and **4** show that the coordination by the $Htsa^-$ ligand to metal centers is only through the sulfur atom in the mercapto group.

No coordination of the carboxyl oxygen atoms to the metal is also supported by the X-ray analysis described later. It has been also clarified by ESCA measurements of the two thiosalicylatosilver(I) complexes **1** and **2** that even the deprotonated carboxyl group does not participate in the coordination to the silver(I) atom [38].

3.2. *Synthetic reactions and ligand replacement*

The conceptually straightforward, synthetic reactions of thiosalicylatotris(triphenylphosphine)silver(I), which has been herein isolated as **3** without any solvate and/or as **3a** with CH_2Cl_2 solvate, are outlined in equations (1)–(3) (Scheme 1). On the other hand, the synthesis of thiosalicylato(triphenylphosphine)gold(I) obtained as **4** is shown in equation (6).

The reactions in equations (2) and (6) exhibit a simple ligand replacement of the coordinated Cl^- ligand with free H_2tsa without change in the coordination number of the starting silver(I) and gold(I) atoms. In the reaction shown in equation (1), the dimeric silver(I) structure with bridged Cl^- ligands is transformed to the monomeric structure by their ligand exchange with free H_2tsa, where the coordination number of silver(I) remains unchanged. In the reaction in equation (3), the polymeric structure with bridged sulfur atoms is changed to the monomeric structure accompanied with a change in the coordination number of the silver(I) atom from 2 to 4.

From the synthetic reactions in equations (1)–(3), the ease of ligand replacement, i.e. the relative ordering of ligand replacement, is suggested for the formation of the silver(I) complexes $[AgL(PPh_3)_n]_m$ from the starting complexes $[AgL]_x$ (L = N, S donor atoms) and $[AgCl(PPh_3)_n]_m$ to be: Ag–P $\gg$ Ag–S > Ag–Cl

$R = \Sigma[|F_o| - |F_c|]/\Sigma|F_o|$, $R_w = [\Sigma(\omega\,[|F_o| - |F_c|]^2/\Sigma\omega(|F_o|)^2]^{1/2}$, with $\omega = 4F_o^2/[\sigma^2(F_o^2)]$.

and, from equation (6), that for the gold(I) complexes is also suggested to be: Au–P ≫ Au–S > Au–Cl. On the other hand, the synthetic reactions of the recently found, metal(I) complexes containing nitrogen-containing heterocycles such as imidazole and triazoles have indicated that the relative ordering for silver(I) follows Ag–P ≫ Ag–Cl > Ag–N ≫ Ag–O, while that for gold(I) follows: Au–P ≫ Au–N > Au–Cl ≫ Au–O [41–43]. Thus, we can deduce the relative ligand replacement for the silver(I) complexes as Ag–P ≫ Ag–S > Ag–Cl > Ag–N ≫ Ag–O, while that for the gold(I) complexes, i.e, as Au–P ≫ Au–S > Au–N > Au–Cl ≫ Au–O. This information allows us to know if target molecules by medicinally or pharmaceutically active compounds of silver(I) and gold(I) are proteins containing enzymes as N,O,S-donors or nucleic acids as N,O-donors of biological ligands. In fact, the wide spectra of excellent antibacterial and antifungal activities found in the [Ag(imd)]$_n$ (Him-d = imidazole) has been attributed to proteins containing a sulfur donor atom as the potential target molecule for inhibition of growth of the test organisms, but not to nucleic acids without a sulfur donor [41, 42].

The proton attached to the carboxyl group in the present complexes **3** and **4** could not be exchanged with an alkali metal ion such as sodium ion; i.e. neither "Na[Ag(tsa)(PPh_3)$_3$]" nor "Na[Au(tsa)(PPh_3)]" can be derived by the reactions of aqueous NaOH with **3**, **3a** or **4**, respectively. We found, or rather, that the reactions of **3** and **3a** with aqueous NaOH resulted in reproducing the water-soluble, oligomeric species, {Na[Ag(tsa)]}$_n$ **1** by a loss of the PPh_3 ligands. Since the polymeric compound **2** can be converted to the oligomer **1** by its reaction with aqueous NaOH and **1** can also be transformed to **2** by its reaction with aqueous HCl [38], there exists an interconversion relationship between **3** and **2** via the oligomer **1** as a mediator as shown in equations (3)–(5) (Scheme 1).

3.3. *Molecular and crystal structures of* **3** *and* **4**

The molecular structures of **3** and **4** were determined with single-crystal X-ray diffraction analysis and are shown in Figs 2 and 3, respectively. Their selected distances and angles are listed in Table 2.

The silver atom of **3** is coordinated with three phosphorus atoms of the PPh_3 ligands and the sulfur atom of the Htsa$^-$ ligand to form a tetrahedral geometry.

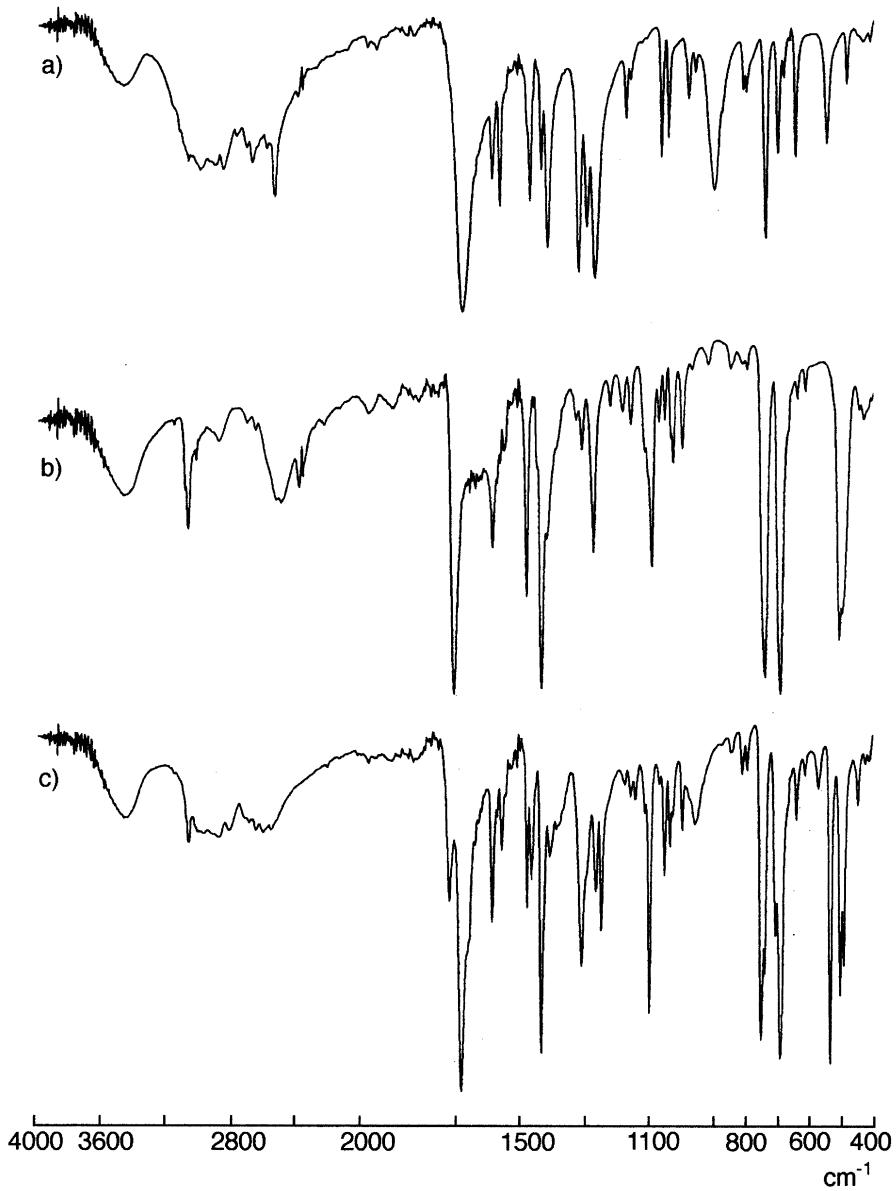

Fig. 1. Solid FT-IR spectra measured in KBr disks in the 4000–400 cm^{-1} region of (a) free H_2tsa ligand, of (b) [Ag(Htsa)$(PPh_3)_3$], **3**, and of (c) [Au(Htsa)(PPh_3)], **4**.

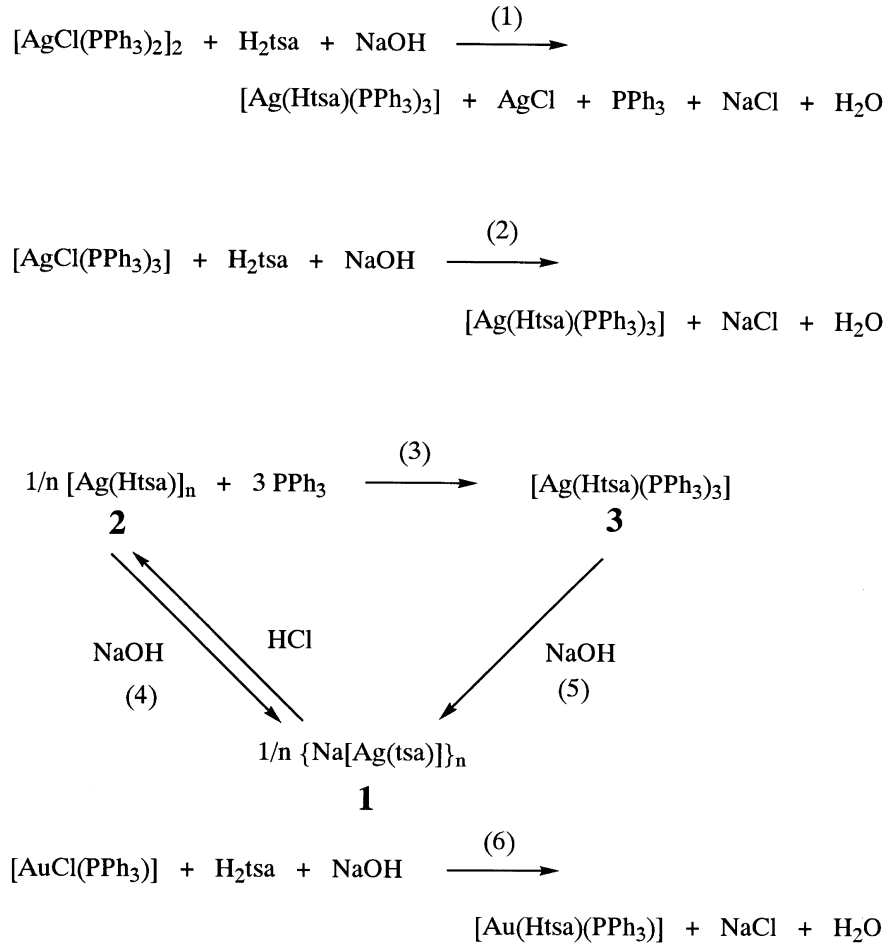
As found in Table 2, the angles around the silver atom deviate from the ideal value of 109.5°. One S–Ag–P angle is smaller and two of them are greater than 109.5°. All P–Ag–P angles are greater than 109.5°. The geometries around the silver atoms of the starting materials [$AgCl(PPh_3)_3$] and [$AgCl(PPh_3)_2]_2$ are also tetrahedral [50, 51]. Three structures of the silver(I) complexes can be compared with each other. The distances and angles of **3** are similar to those of [$AgCl(PPh_3)_3$], except longer Ag–S bond vs Ag–Cl bond, rather than those of [$AgCl(PPh_3)_2]_2$. The dihedral angle between the planes of the carboxyl group (A; O1, O2, C61) and the $Htsa^-$ (B; S1, C55, C56, C57, C58, C59, C60) is 176°, showing the $SC_6H_4CO_2H$ moiety of **3** planar. The dihedral angles between the plane C (Ag–S–C56) and the A or the B are 139° and 43°, respectively. The distances between the silver and oxygen atoms are 6.70 (Ag–O1), 6.84 (Ag–O1′) and 5.10 (Ag–O2) Å. These angles and distances indicate that the carboxyl group is directed away from the silver atom. From the intermolecular oxygen distances, no intermolecular hydrogen bond between the carboxyl groups of the $Htsa^-$ is observed for **3**. Thus, the complex **3** is monomeric.

The gold atom in **4** is placed in the linear geometry defined by the phosphorus atom of the PPh_3 ligand and the sulfur atom of the $Htsa^-$. The P–Au–S angle of **4** is smaller (173.0(1)°) than that of the recently



Scheme 1. Reaction schemes.

reported, related complex [Au(Htsa)(PCy_3)] (PCy_3 = tricylcohexylphosphine) (176.8°) [26]. The Au–S and the Au–P distances of 4 ((2.292(4), 2.260(3) Å) are slightly shorter than those of [Au(Htsa)(PCy_3)] (2.313(1), 2.271(1) Å) and they are equal within experimental errors to the distances of other gold(I) complexes with a PPh_3 ligand, [Au(2-tu)(PPh_3)] (2-Htu = 2-thiouracil) (Au–S 2.296(2) A; Au–P 2.300(2) Å) [30]. This picture may be attributed to the difference in cone-angles of the phosphine ligands. The dihedral angles of the carboxyl group (D; O2, O3, C4) and the $Htsa^-$ (E; S1, C5, C6, C7, C8, C9, C10) is 142°, indicating some delocalization of π-electron density occurs between the SC_6H_4 and CO_2H moieties. The dihedral angles of the planes of F (Au–S1–C10) and the D or the E are 48° and 138°, respectively. The Au–O3 distance of **4** is 3.21 Å, which is much shorter than that of [Au(Htsa)(PCy_3)] [26]. These angles and distances show that the carboxyl group is not directed away from the gold atom as seen in [Au(Htsa)(PCy_3)] (5.10 and 6.35 Å). The distance of O2–$O3^i$ of the $Htsa^-$ is 2.56(1) Å (a symmetry operation i; $-x$, $1-y$, $-z$), revealing that an intermolecular hydrogen bond is formed in **4**. This is contrasted with the structure of **3**. In **4**, two [Au(Htsa)(PPh_3)] units are centrosymmetrically associated via the carboxylic moieties to form a dimeric unit. This picture has also been shown in [Au(Htsa)(PCy_3)] [26].

3.4. *Solution NMR* (^{1}H, ^{13}C, ^{31}P *and* ^{109}Ag) *characterization*

The ^{31}P NMR spectra measured in $CDCl_3$ at 22°C show a single peak due to the coordinating PPh_3 ligands at 4.79 ppm for **3** [Fig. 4(a)], at 4.55–4.57 ppm for **3a** and at 37.56 ppm for **4** [Fig. 4(c)], while at −5.33 ppm for the free PPh_3 ligand. It is obvious that the coordination of the phosphorus donor atom to the metal center significantly influences the phosphorus resonance and the ^{31}P chemical shift also reflects a difference between silver(I) and gold(I) as the metal center.

On the other hand, the ^{31}P NMR [Fig. 4(b)] at

−90°C measured in CD_2Cl_2 of **3** showed two signals with equal intensity at 4.90 and 3.26 ppm, each with splittings, which are attributed to a coupling of ^{31}P with ^{109}Ag ($I = 1/2$) or ^{107}Ag ($I = 1/2$) nucleus as previously observed in [Ag(imd)(PPh_3)$_3$] [42], [AgCl(PPh_3)$_3$] [57], [Ag(dppe)$_2$]NO_3 (dppe = 1,2-bis(diphenylphosphino)ethane) [58], [Ag(pz)(PPh_3)$_3$] (Hpz = pyrazole) [59] and [Ag(triz)(PPh_3)$_2$]$_n$ (Htriz = 1,2,3- or 1,2,4-triazole) [43]. The coupling constants $^1J(^{109}Ag–^{31}P)$ and $^1J(^{107}Ag–^{31}P)$ were estimated as 285 and 266 Hz, respectively, and the chemical shift was as δ (^{31}P) = 4.08 ppm. These data are consistent with those of four-coordinate, tetrahedral complexes included in the above related complexes in solution [57–60].

The ^{31}P NMR spectrum of **3** at −90°C consisting of only two major peaks is in contrast to those of the related silver(I)–N bonding complexes such as [Ag(imd)(PPh_3)$_3$] [42], [Ag(pz)(PPh_3)$_3$] [59] and [Ag(triz)(PPh_3)$_2$]$_n$ [43], all of which have furthermore exhibited additional several signals due to various degrees of association in addition to dissociation of PPh_3 and perhaps also of the nitrogen-donor ligands, i.e. due to the dynamic exchange very rapidly in the NMR timescale. These results reveal that the four-coordinate geometry of **3** is kept in solution and the complex **3** is also present only as a monomeric species in solution. Thus, we conclude that the behavior of **3** in solution is unusually static.

^{109}Ag NMR spectra in $CDCl_3$ measured at 22°C exhibit only one resonance at 1196 ppm for **3a**, also suggesting that only a single species is present in solution, because of the monomeric structure of **3** kept in solution. The chemical shift is assignable to a four-coordinate silver(I) complex with sulfur and phosphorus donor atoms. This resonance is compared with those of the two-coordinate silver(I) complexes formed only by the bridged sulfur atom, previously measured at room temperature in D_2O; at 855.6 ppm for **1** [38] and at 868.7 ppm for {Na[Ag(Htma)] · 0.5H_2O)}$_n$ [36] (H_3tma = thiomalic acid; $HO_2CCH(SH)CH_2CO_2H$). Also, this chemical shift is compared with those of the averaged single peak due to the rapid, dynamic exchange among unequivalent ^{109}Ag species present in $CDCl_3$ solution at room temperature; at 1186 ppm for [Ag(imd)(PPh_3)$_3$] [42] and at 994 ppm for [Ag(1,2,3-triz)(PPh_3)$_2$]$_n$ and at 925 ppm for [Ag(1,2,4-triz)(PPh_3)$_2$]$_n$ [43].

In ^{1}H and ^{13}C NMR spectra measured in $CDCl_3$ at 22°C of the complexes **3**, **3a** and **4**, four proton and seven carbon resonances of the coordinating Htsa$^-$ ligand were completely assigned using several two-dimensional NMR (^{1}H–^{13}C COSY, ^{1}H–^{13}C HMBC and ^{1}H–^{13}C HMQC) methods and their chemical shifts are shown in Table 3.

4. CONCLUSIONS

In conclusion, the novel complex [Ag(Htsa)(PPh_3)$_3$], **3**, as a monomeric form of the oligomeric or polymeric silver(I) thiosalicylates **1** or **2** showing effective antimicrobial activities, has been isolated in good yield and also as its CH_2Cl_2 solvate, **3a**. These

H_2tsa : thiosalicylic acid

[a]Both ^{1}H and ^{13}C NMR spectra of **3**, **3a** and **4** were measured in $CDCl_3$ at 22°C with reference to an internal TMS and those of free ligand H_2tsa measured in DMSO-d_6. The assignment of the chemical shifts was based on the 2D-NMR (COSY, HMBC and HMQC) methods.

[b]These signals were overlapped with the PPh_3 multiplet signals.

complexes, **3** and **3a**, have been derived from three different ligand-exchange reactions. The interconversion relationship among three thiosalicylatosilver(I) complexes, **1**, **2** and **3** was clarified. The corresponding gold(I) analog, [Au(Htsa)(PPh_3)], **4**, was also isolated. From a synthetic viewpoint, the relative ordering of ligand replacement in the silver(I) complexes was found to be: Ag–P ≫ Ag–S > Ag–Cl > Ag–N, while that in the gold(I) complexes followed Au–P ≫ Au–S > Au–N > Au–Cl. The crystal structures of **3** and **4** were determined with single-crystal X-ray diffraction, suggesting the monomeric structure of **3** and the dimeric structure of **4** in the solid state. All complexes obtained have been fully characterized with complete elemental analyses, TG/DTA, FT-IR and multinuclear (^{1}H, ^{13}C, ^{31}P and ^{109}Ag) NMR spectroscopies. In particular, it was found that the monomeric, 4-coordinate geometry of **3** was kept in solution.

(Received 2 December 1997; accepted 6 April 1998)

Abstract—The reaction of $[M_2Cl_2(\mu\text{-}Cl)_2(PR_3)_2]$ (M = Pd or Pt; $PR_3 = PEt_3$, PBu_3, PMe_2Ph, $PMePh_2$) with lithium amidinate or sodium triazenide gave binuclear complexes containing amidinato- or triazenido-bridges, $[M_2Cl_2(\mu\text{-}ArNENAr)_2(PR_3)_2]$ (E = CH, CMe or N). These complexes were characterized by elemental analysis and NMR (^1H, ^{31}P or ^{195}Pt) data. The structures of two complexes, $[Pd_2Cl_2\{\mu\text{-}PhNC(Me)NPh\}_2(PMe_2Ph)_2]$ (**10**) and $[Pt_2Cl_2(\mu\text{-}PhNNNPh)_2(PEt_3)_2]$ (**11**) were established by single crystal X-ray structural analyses. The ^{195}Pt NMR data show coupling between two metal centers in the *cis* triazenido-bridged complex. The corresponding amidinate bridged complex does not show coupling. The role of the bridging ligand in mediating interaction between the metal centers is probed through Extended Huckel Theory (EHT) calculations. It is suggested that M–M interactions are primarily affected by the bridging ligands. © 1998 Elsevier Science Ltd. All rights reserved.

INTRODUCTION

Recently we have synthesised and characterised a series of binuclear palladium and platinum complexes [1–5] of the type $[M_2X_2(\mu\text{-}Y)_2L_2)]$ (I and II). In particular, molecules with anionic bidentate three-atom bridging ligands showed unusual properties. For example, complexes containing bridging carboxylate [2] and triazenido [3] groups exhibited unusually strong M–M interactions with a formal bond order of zero, whereas such interactions were vanishingly small for the corresponding acetamidinato [4]- and 2- hydroxypyridinato [5]-bridged complexes. This has motivated us to initiate a systematic study on palladium and platinum complexes with anionic three-atom ligands. Amidines are one of the members of this class of ligands. They are known to stabilize metal-metal bonds [6]. Amidines coordinate either in the neutral form (via amine-N or imine-N atom) or as the amidinate ion [7, 8]. Electronic and steric properties of an amidine ligand can be modified by varying the organic substituents on the nitrogen atoms and the central carbon atom. For example, formamidinate ligands are known to favour unusual structural features in metal complexes [9, 10].

(where M = Pd or Pt; X = halide, alkyl or aryl groups, Y = anionic one-atom bridging ligand such as halide, SR etc., two-atom bridging ligand such as pyrazolate ion or three-atom bridging ligands such as AcO, $RNNNR^-$, $RNCR'NR^-$, etc.)

Herein we report, as part of our ongoing investigation, synthesis and characterisation of palladium

and platinum complexes with amidinate ligands. For comparison, X-ray structure and ^{195}Pt NMR data for a triazenido-bridged platinum complex, $[Pt_2Cl_2(\mu\text{-}PhNNNPh)_2(PEt_3)_2]$ (**11**) are also included.

RESULTS AND DISCUSSION

Amidinato-bridged binuclear palladium and platinum complexes, $[M_2Cl_2(\mu\text{-}ArN{=}CH{-}NAr)_2\ (PR_3)_2]$ (M = Pd or Pt; Ar = tol, $MeOC_6H_4$) can readily be obtained by the reaction of $[M_2Cl_2(\mu\text{-}Cl)_2(PR_3)_2]$ (M = Pd or Pt; $PR_3 = PEt_3$, PBu_3, PMe_2Ph or $PMePh_2$) with the lithium salt of formamidine in 1:2 molar ratio. The treatment of $[M_2Cl_2(\mu\text{-}Cl)_2(PR_3)_2]$ with formamidines affords mononuclear complexes containing neutral formamidine. These complexes are yellow to orange coloured crystalline solids, soluble in common organic solvents.

The $^{31}P\{^1H\}$ NMR spectra (Table 1) of these complexes exhibited a single resonance for tertiary phosphines indicating the formation of only one isomeric form exclusively. The magnitude of ^1J(Pt–P) for the $[Pt_2Cl_2\{\mu\text{-}tolNCHNtol\}_2(PMe_2Ph)_2]$ is comparable to the corresponding acetamidinato- and triazenido-bridged [3, 4] platinum complexes. The ^{1}H NMR spectra of these complexes showed two singlets of equal integration each for methyl and methoxy protons of aryl groups attached to the nitrogen atoms. One can be assigned to the NAr group *trans* to the phosphine and other *trans* to the terminal chloride. The sym *trans* configuration is further substantiated by the presence of one NCHN resonance for the formamidinate group, however in the platinum complex two closely spaced singlets were observed. The complexes containing PMe_2Ph ligands displayed two doublets due to $J(^{31}P\text{–}^1H)$ couplings for methyl protons indicating non-equivalence of the methyl groups. The ^{195}Pt NMR spectrum of $[Pt_2Cl_2\{\mu\text{-}tolNC(H)Ntol\})_2(PMe_2Ph)_2)]$ exhibited a doublet at δ-3245 ppm with $^1J(^{195}Pt\text{–}^{31}P)$ 3555 Hz. The ^{195}Pt NMR spectrum of $[Pt_2Cl_2(\mu\text{-}PhNNNPh)_2(PEt_3)_2]$ (11) showed a doublet at δ-3194 ppm with $^1J(^{195}Pt\text{–}^{31}P)$ 3542 Hz (Fig. 1). Unlike the amidinato bridged complex **10**, the spectrum of **11** also showed ^nJ(Pt–Pt) coupling of 1535 Hz in the ^{195}Pt

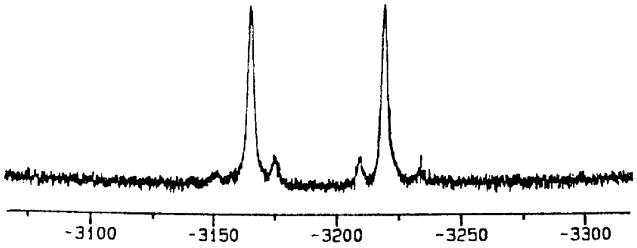

Fig. 1. $^{195}Pt\{^{1}H\}$NMR spectrum of $[Pt_2Cl_2(\mu\text{-PhNNNPh})_2(PEt_3)_2]$ in $CDC1_3$.

NMR spectrum indicating significant platinum platinum interaction as reported earlier by us [3].

A few reactions of formamidinato-bridged palladium complexes were also investigated. The complex $[Pd_2Cl_2\{\mu\text{-tolNCHNtol}\}_2(PBu_3)_2]$ on treatment with an ethereal solution of HCl afforded a mononuclear complex, $[PdCl_2(tolN{=}CH{-}NHtol)(PBu_3)]$ (δ ^{31}P 26.1 ppm) formed by protonation of the bridging ligand eq. (1). A similar species (δ ^{31}P 26.1 ppm) was formed when $[Pd_2Cl_2(\mu\text{-Cl})_2(PBu_3)_2]$ was treated with di-p-tolylformamidine. It is interesting to note that the triazenido-bridged complexes react reversibly with HCl [3]. Addition of triphenylphosphine to a $CDCl_3$ solution of $[Pd_2Cl_2\{\mu\text{-tolNCHNtol}\}_2(PBu_3)_2]$ has no effect on its ^{31}P NMR spectra indicating non-lability of the formamidinato-bridges with neutral donor ligands.

$$[Pd_2Cl_2\{\mu-tolNC(H)Ntol\}_2(PBu_3)_2]+2HCl \rightarrow 2[PdCl_2\{tolNHC(H)Ntol\}(PBu_3)]\ldots. \quad (1)$$

The molecular structures of acetamidinato- and triazenido-bridged complexes, $[Pd_2Cl_2\{\mu\text{-PhNC(Me)NPh}\}_2(PMe_2Ph)_2]$ (**10**) and $[Pt_2Cl_2(\mu\text{-PhNNNPh})_2(PEt_3)_2]$ (**11**) were established by X-ray diffraction. The structures of **10** and **11** comprise of four molecules per unit cell separated by normal van der Waals distances. Molecular structures together with the crystallographic numbering scheme are shown in ORTEP drawings (Figs 2 and 3). Each molecule consists of two distorted square planar metal (Pd or Pt) atoms bridged together by [PhNC(Me)NPh]$^-$ or $[PhNNNPh]^-$ groups. The bridging ligands in both molecules are *cis* with respect to each other, whereas the ancillary ligands Cl and PR_3 are *trans* related.

In **10** the C–N bond distances [N(1A)–C(11A), N(1B)–C(11A), N(1C)–C(11B), N(1D)–C(11B) [av. 1.326 Å] are intermediate between the typical C–N (1.48 Å) and C=N (1.24 Å) covalent bond distances, indicating π-electron delocalozation in the NCN skeleton. This is further substantiated by the sum of inter bond angles around carbon (359.9°) and nitrogen (av. 359.7(5)°) atoms of the NCN skeleton. The NCN bite angles [121.7(6), 122.6(6)°] and bite distances [(N(1A)–N(1B) 2.321 Å and N(1C)–N(1D) 2.324 Å] are of the same magnitude as reported for other bridging amidinato-bridged complexes [11–13]. There are distinctly two types of Pd–N distances (Table 2). One with chloride *trans* to nitrogen is shorter than the other one where phosphine is *trans* to nitrogen, owing to the stronger *trans* influence of the phosphine. The two Pd–N distances lie in the range 1.86 and 2.15 Å reported in several palladium complexes [6, 11, 14–16]. The two Pd–P and Pd–Cl distances are essentially identical and compare well with the reported values [17, 18]. The Pd–Pd separation [2.914(2) Å] is shorter than the $[Pd_2(\mu\text{-NHCPhNH})_2(\eta^3\text{-}C_3H_5)_2]$ [3.218(1) Å], however it is comparable to $[Pt_2(\mu\text{-PhNCHNPh})_2(\eta^2\text{-PhNCHNPh})_2]$(2.918(9) Å) [13]. The two palladium atoms lie within the distances reported for binuclear complexes containing anionic three-atom bridging ligands (Table 3) [19–25].

The complex **11** has two platinum atoms at a separation of 2.9302(8) Å (Table 4). This distance is comparable with other binuclear complexes containing anionic three atom bridging ligands (Table 3). The two N–N bonds are nearly equivalent and the N–N–N angle is 116.6(6)° indicating pronounced π-electron deloclization [20]. The Pt–N bond distance *trans* to the phosphine ligand is longer than the Pt–N bond *trans* to the chloride. The bridging PhNNNPh ligands are *cis* with respect to each other. Unlike complex **10**, complex **11** has a crystallographically imposed C_2 symmetry.

The face to face juxtaposition of two square planar d^8 metal centres is expected to result in antibonding interactions between the metal centres on the basis of qualitative molecular orbital theory. However, the frequent occurrence of short contacts in such units has caused much debate [26] regarding the possible ways by which these metal–metal interactions could become favorable. Recent work in this area has suggested several factors which make the metal–metal interaction in these systems less antibonding [27]. In the present work, it was possible to observe Pt–Pt coupling in the ^{195}Pt NMR spectra of the triazenido-bridged complexes, whereas in the corresponding acetamidinato-bridged platinum derivatives no coupling between the metal centres could be observed. The metal–metal distance in the complex **10** should be comparable to that of complex **11** since M–M distances are primarily controlled by the ligand [28]. It is

Spy = SC_5H_4N (2-mercaptopyridinate ion).

possible that the ligand controls, not only the distance but the interaction between the two metal centres in a significant fashion. In order to probe the role of the ligand in mediating metal–metal interactions, we have carried out Extended Huckel Theory (EHT) calculations on model systems. Our results suggest that in addition to the factors identified earlier, the nature of bridging ligands and their relative disposition (Scheme 1) in the metal complex could play a significant role in determining the metal–metal interactions.

Calculations were carried out using the program CACAO [29], on model complexes constructed using the crystallographic coordinates for the heavy atoms wherever available. In other cases, models were constructed based on observed metal-ligand geometries of related d^8 complexes. The reduced overlap population (ROP) computed by EHT, gives a measure of the relative interaction between the metal centres in various complexes studied. Being fully aware of the limitations of EHT to reliably quantify interaction energies, we merely interpret trends in the computed ROP as done by Aullon and Alvarez [30]. The computed ROPs along with the M–M distances and the nature of the bridge are given in Table 5 together with the ROP computed in the absence of the bridging ligand. In general the bridging ligand has greater influence on metal–metal interactions in these systems compared to the ancillary ligands Cl and PH_3. While

Bridging ligands: NNN═HNNNH; OAc = $OC(CH_3)O$; NCN═HNC(H)NH.

the σ donor and $\pi-$ acceptor capabilities of the ligand, PH_3 (with no d orbitals on the P) would be different from that of PPh_3, we expect the trends would be similar even if PPh_3 were to be used in the calculations. The bridging ligand reduces the observed ROP except in the case of triazenide ligand where the ROP is increased marginally. It is also important to note that the relative orientation of the supporting ligands Cl and PH_3, do not change the ROP to a significant degree. However, the *cis* or *trans* nature of the bridging ligand changes the ROP between the metal centres by approximately 0.01 units which is 20% of the computed ROP. This suggests that the metal–metal interaction is significantly affected by the nature and relative orientation of the bridging ligand.

The ROP in these three cases are not very different. However, it is important to note the relative changes the ligands bring about in the computed ROP. For the amidinato complex and the acetato complex, the ROP is decreased by 36% and 19% respectively on adding the bridging ligands. In the case of amidinato complex, the reduction in the ROP is even greater (55%) when the bridging ligands are *trans*. A significant change is observed in the case of the triazenido complex where a small increase (1%) in the computed ROP is observed. To understand how the amidinato complex enhances the antibonding interaction between the metal centres, and the triazenido ligand decreases the antibonding interaction, a fragment molecular orbital analysis was carried out. The results of this analysis suggest that the bridging ligand primarily interacts through its non bonding σ donor orbitals and the empty π^* orbitals. Apart from donation of electrons to the empty metal orbitals, the σ orbitals interact with the metal–metal σ (*cis* or *trans* geometry) and π (*trans* geometry only) orbitals. The empty π^* orbitals on the other hand have the appropriate symmetry to interact with the metal–metal δ type orbitals. The former interaction results in the interaction of the filled shells and reduces the ROP and the latter is responsible for a marginal increase in ROP. In the trans geometry, there is a greater reduction in the M–M ROP due to destabilisation of the π type M–M bonding orbitals. The metal–metal interaction is significantly decreased on adding the amidinato bridging ligands, because of the larger overlap of the the nonbonding electrons in the ligand with the filled metal–metal σ orbital. In addition, the amidinato ligand is a poor π acceptor because the π^* levels lie much higher in energy and have smaller contributions on the interacting atoms compared to the π acceptor orbitals of the triazenido ligand. On the other hand the triazenido ligand has suitable π^* orbitals of low energy which stabilize the M–M δ bond. As a result the triazenido ligand increases the M–M ROP, albeit, to a small extent.

Our results are in complete agreement with a recent study carried out on the interaction between d^8 metal centres stacked in a face to face fashion by Aullon and Alvarez [28]. While the nature of bridging ligands has not been addressed, the effect of π acidic ligands in modulating the ROP of the interacting metal centres has been studied. They have noted an increase in the ROP with increase in the number of π acid-ligands surrounding the metal atom. Where structures are available, the corresponding M–M distances observed in such complexes are also smaller. The X-ray crystallographic database analysis done by them demonstrates the generality of the phenomenon. Similarly, π donor ligands were shown to increase the antibonding effect between the metal atoms.

On the basis of the results obtained above, it is clear how the nature and relative disposition of the bridge determines whether one observes Pt–Pt coupling in the ^{195}Pt NMR. There are two three-atom bridged complexes for which Pt–Pt coupling have been observed and one, the amidinato-bridged complex where there is no Pt–Pt coupling. In the case of the amidinato complex some of us had studied earlier [4], the geometry of the bridging ligands are *trans* and no Pt–Pt coupling was observed. This is readily explained by the large reduction in ROP (55%) with amidinato ligands in the *trans* geometry. In cases where the bridging ligands are *cis* to each other, the reduction in ROP is less, especially in the case of triazenido- and acetato-bridged complexes. Hence it is possible to observe the Pt–Pt coupling in the ^{195}Pt NMR spectra of the latter systems.

EXPERIMENTAL

Formamidines (ArN=CH–NHAr); Ar = 4-MeC_6H_4 (tol), 4-$MeOC_6H_4$) [31] and $[M_2Cl_2(\mu\text{-}Cl)_2(PR_3)_2]$ (M = Pd or Pt) [32] and $[Pt_2Cl_2(\mu\text{-}PhNNNPh)_2(PEt_3)_2]$[3] were prepared according to the literature methods. All the reactions were carried out in dried and distilled analytical grade solvents under a nitrogen atmosphere. The ^{1}H, $^{31}P\{^1H\}$ and $^{195}Pt\ \{^1H\}$ NMR spectra were recorded on a Bruker DPX-300 spectrometer in freshly prepared $CDCl_3$ solutions. Chemical shifts are referred to internal chloroform peak (δ $CHCl_3$ 7.26 ppm) for ^{1}H, external 85% H_3PO_4 for ^{31}P and external Na_2PtCl_6 solution in D_2O for ^{195}Pt. Elemental analyses were carried out by the Analytical Chemistry Division of this research centre.

Preparation of $[PtCl_2\{tolNCH\text{-}NHtol\}(PBu_3)]$

To a dichloromethane (10 cm^3) solution of $[Pt_2Cl_2(\mu\text{-}Cl)_2(PBu_3)_2]$ (119 mg, 0.127 mmol) was added a dichloromethane (5 cm^3) solution of N,N′-di-p-tolylformamidine (64 mg, 0.284 mmol) and the reaction mixture was stirred for 1 h at room temperature. The solvent was stripped off in vacuo and the residue was recrystallised from hexane as a pale yellow colored solid (70 mg, 40% yield).

dtfH = tolN = CH–NHtol; dtf = $[tolNC(H)Ntol]^-$; bpmpf = $[MeOC_6H_4NC(H)NC_6H_4OMe]^-$ dpa = $[PhNC(Me)NPh]^-$; dpt = $[PhNNNPh]^-$.

Preparation of $[Pd_2Cl_2\{\mu\text{-}tolNC(H)Ntol\}_2(PMe_2Ph)_2]$

To a lithioformamidinate suspension, prepared by neutralizing a THF solution of N,N′-di-p-tolylformamidine (98 mg, 0.436 mmol) with a hexane solution of n-butyllithium (0.45 N, 1 cm^3, 0.45 mmol), solid $[Pd_2Cl_2(\mu\text{-Cl})_2(PMe_2Ph)_2]$ (128 mg, 0.203 mmol) was added. The resulting solution was stirred for two days at room temperature under a nitrogen atmosphere. The solvents were removed in vacuo and the residue was extracted with benzene ($3 \times 3\ cm^3$) and filtered. The filterate was concentrated *in vacuo* and the residue was recrystallised from benzene-hexane mixture in 58% (119 mg) yield as an orange crystalline solid. Similarly all other complexes were prepared. Pertinent data are given in Table 6.

Reaction between $[Pd_2Cl_2\{\mu\text{-}tolNC(H)Ntol\}_2(PBu_3)_2]$ *and* PPh_3

To a $CDCl_3$ solution of $[Pd_2Cl_2\{\mu\text{-tolNC(H)Ntol}\}_2(PBu_3)_2]$ (24.5 mg, 0.022 mmol) in a 5 mm NMR tube was added solid triphenylphosphine (11.5 mg, 0.044 mmol). The resulting solution was studied by ^{31}P NMR spectroscopy.

Reaction between $[Pd_2Cl_2\{\mu\text{-}tolNC(H)Ntol\}_2(PBu_3)_2]$ *and HCl*

To a dichloromethane (5 cm^3) solution of $[Pd_2Cl_2\{\mu\text{-tolNC(H)Ntol}\}_2(PBu_3)_2]$ (26.7 mg, 0.024 mmol) was added an ethereal solution of HCl (0.02 cm^3, 2.44 N, 0.048 mmol). After stirring for 30 min, the solvent was stripped off and the residue was dissolved in $CDCl_3$. The resulting solution was studied by ^{31}P NMR spectroscopy.

Crystallography

All measurements for $[Pd_2Cl_2\{\mu\text{-PhNC(Me)NPh}\}_2(PMe_2Ph)_2]$ (**10**) were made at $20 \pm 2°C$ on a Rigaku AFC 6S diffractometer using graphite monochromated Mo–Kα radiation ($\lambda = 0.71073$ Å). The crystallographic data together with data collection and structure refinement details are given in Table 7. The numbering scheme employed is shown in Fig. 2 drawn with the ORTEP program [33]. All the data were corrected for Lorentz and polarization effects. The structure was solved by a combination of the Patterson method and direct methods [34] and refined by full-matrix least-squares on F^2. Neutral atom scattering factors were taken from Cromer and Waber [35]. Anamolous dispersion effects were included in F_{calc} [36]. The values of $\Delta f'$ and $\Delta f''$ were those of Cromer [37]. All calculations were performed using the TEXSAN [38] crystallographic software package of the Molecular Structure Corporation.

The crystal data for the complex $[Pt_2Cl_2\{\mu\text{-PhNNNPh}\}_2(PEt_3)_2]$ (**11**) were collected on an Enraf Nonius CAD-4 with monochromated MoKα. Three check reflections were measured for every 100 reflections; these showed no decay in intensity during the period of data collection. The structure was solved by Patterson and full matrix least squares refinement on F_o using SHELX -76 [39]. The refinement was carried out first with isotropic thermal parameters and subsequently with anisotropic thermal parameters for all non-hydrogen atoms. The scattering factors for Pt were taken from International tables for X-ray crystallography [35] and the absorption corrections were made using Psi data [40].

(Received 16 February 1998; accepted 17 April 1998)

Abstract—The following complexes have been prepared: $[Ru(bipy)_2(pic)][PF_6]$ (bipy = 2,2′-bipyridine; Hpic = picolinic acid); [Ru(terpy)(dipic)] (terpy = 2,2′:6′,2″-terpyridine; H_2dipic = dipicolinic acid); $[Ru(bipy)_2(Hbig)][PF_6]_2$ (Hbig = biguanide); and $[Ru(bipy)_2(apps)][PF_6]$ [where Happs is the *p*-tolylsulfonamide of 2-(2-aminophenyl)-pyridine]. The latter three have been characterised by X-ray crystallography and are all mononuclear pseudo-octachedral complexes. Electrochemical studies reveal the relationship between the potential of the metal-based Ru(II)/Ru(III) couple, with the potential values being clearly related to the σ-donor or π-acceptor capabilities of the ligands. The energies of the lowest-energy m.l.c.t. maxima in the electronic spectra also correlate with ligand properties. $[Ru(bipy)_2(Hbig)][PF_6]_2$, which has a dissociable proton on the biguanide ligand, undergoes deprotonation in strongly basic conditions ($pK_a = 12.3 \pm 0.2$), which results in a red-shift of the m.l.c.t. transition consistent with weakening of the ligand field due to the increased π-donor capability of the deprotonated ligand. © 1998 Elsevier Science Ltd. Keywords: ruthenium complexes; electrochemistry; crystal structures.

INTRODUCTION

We [1–3] and others [4, 5] have been interested in studying the properties of ruthenium complexes with a variety of ligand donor sets. One impetus for this is the particularly clear correlations which can be observed between electrochemical properties and ligand donor set [1, 4]. Another is the widespread use of redox-active ruthenium fragments as components of polynuclear complexes linked by conjugated bridging ligands, in which inter-valence charge transfer is studied as a model for electron transport in molecular wires [6]. The kinetic stability of ruthenium in several different oxidation states (particularly +2 and +3), the often reversible nature of the +2/+3 couple, and the relative ease with which mixed-ligand complexes can be prepared by controllable stepwise methods, all make ruthenium complexes particularly attractive targets of study.

We describe here the syntheses and the electrochemical and electronic spectroscopic properties of four mononuclear complexes of ruthenium(II) with mixed donor sets. These complexes are $[Ru(bipy)_2(pic)][PF_6]$ (bipy = 2,2′-bipyridine; Hpic = pyridine-2-carboxylic acid, also known as picolinic acid); [Ru(terpy)(dipic)] (terpy = 2,2′:6′,2″-terpyridine; H_2dipic = pyridine-2,6-dicarboxylic acid, also known as dipicolinic acid); $[Ru(bipy)_2(Hbig)][PF_6]_2$ (Hbig = biguanide); and $[Ru(bipy)_2(apps)][PF_6]$ [where Happs is the *p*-tolylsulfonamide of 2-(2-aminophenyl) pyridine]. The ligands are shown below; the latter three complexes have been crystallographically characterised. The complexes $[Ru(bipy)_2(pic)][PF_6]$ [7, 8] and [Ru(terpy)(dipic)] [9] were both reported very recently while this work was in progress but have not been directly compared.

EXPERIMENTAL

General details

$[Ru(bipy)_2Cl_2]\cdot 2H_2O$ [10], $[Ru(terpy)Cl_3]$ [11], biguanide [12], Happs [13] and $[Ru(bipy)_2(pic)][PF_6]$ [7, 8] were prepared according to the published procedures. Dipicolinic acid was obtained from Aldrich and used as received. Instrumentation used for routine spectroscopic and electrochemical analyses has been described in earlier papers [1, 2].

Preparations

[*Ru*(*terpy*)(*dipic*)]. A mixture of dipicolinic acid (15.2 mg, 0.09 mmol) and Na_2CO_3 (20 mg, 0.18 mmol) was dissolved in water and heated to reflux. [Ru(terpy)Cl_3] (40 mg, 0.09 mmol) was then added and the mixture heated to reflux for a further 5 hours, during which time a purple solid precipitated and the supernatant solution became green. The solid was filtered off, washed with water, and air-dried to give [Ru(terpy)(dipic)] in 65% yield. X-ray quality crystals were grown by diffusion of diethyl ether vapour into a saturated solution of the complex in dmf. Found: C, 49.0; H, 3.5; N, 10.4%. Required for $C_{22}H_{14}N_4O_4Ru\cdot H_2O$: C, 49.3; H, 3.4; N, 10.5%. The complex is not sufficiently volatile to give a good mass spectrum.

$[Ru(bipy)_2(Hbig)][PF_6]_2$. A mixture of $[Ru(bipy)_2Cl_2]\cdot 2H_2O$ (0.130 g, 0.25 mmol) and Hbig (0.029 g, 0.29 mml) in dry ethanol (15 cm^3) was heated to reflux under N_2 for 4 hours to give a purple solution. After cooling, aqueous KPF_6 was added and the mixture was concentrated *in vacuo* until a purple precipitate appeared. This was collected by filtration and dried to give $[Ru(bipy)_2(Hbig)][PF_6]_2$ in 80% yield. Recystallisation from MeCN/ether afforded X-ray quality crystals. Found: C, 33.8; H, 3.0; N, 16.5%. Required for $C_{22}H_{23}F_{12}N_9P_2Ru\cdot MeCN$: C, 34.1; H, 3.1; N, 16.6%. Electrospray MS: *m*/*z* 513 [50%, $\{Ru(bipy)_2(big)\}^+$]. ^{1}H NMR (300 MHz, CD_3CN): δ 8.92 (2 H, d, *J* 5.5), 8.43 (2 H, d, *J* 7.9), 8.34 (2 H, d, *J* 7.9), 8.08 (2 H, td, *J* 7.9, 1.5), 7.83 (2 H, td, *J* 7.9, 1.5), 7.66 (4 H, m), 7.17 (2 H, ddd, *J* 7.5, 5.7, 1.3 Hz), 5.64 (*ca.* 1 H, br s, NH), 5.02 (*ca.* 2 H, br s, NH).

$[Ru(bipy)_2(apps)][PF_6]$. A solution of $[Ru(bipy)_2(H_2O)_2]^{2+}$ (0.16 mmol) was generated by reaction of $[Ru(bipy)_2Cl_2]\cdot 2H_2O$ (84 mg, 0.16 mmol) with $AgNO_3$ (2 equiv.) in $EtOH/H_2O$ (1:1, 30 cm^3) at reflux for 1 hour, followed by removal of the AgCl by filtration. To this was added Happs (50 mg, 0.16 mmol) and the mixture was refluxed with stirring for a further 1 h. Addition of aqueous KPF_6 precipitated a solid which was collected by filtration and dried. The crude product was purified by chromatography on silica with $MeCN/H_2O$/saturated aqueous KNO_3 (14:2:1) as eluent. The main deep red/purple band was collected, the solution concentrated *in vacuo*, and the product precipitated by addition of aqueous KPF_6. Filtration and drying *in vacuo* afforded pure $[Ru(bipy)_2(apps)][PF_6]$ in 70% yield. Recrystallisation from CH_2CI_2/hexane afforded X-ray quality crystals. Found: C, 49.0; H, 3.4; N, 8.3%. Required for $C_{38}H_{31}F_6N_6O_2PRuS\cdot CH_2Cl_2$: C, 48.5; H, 3.4; N, 8.7%. FAB MS: *m*/*z* 737 [80%, $\{Ru(bipy)_2(apps)\}^+$].

X-ray crystallography

Suitable crystals were quickly transferred from the mother liquor to a stream of cold N_2 at -100°C on a Siemens SMART diffractometer fitted with a CCD-type area detector. In all cases data were collected at -100°C to a 2θ limit of 55° using graphite-monochromatised Mo–Kα radiation. A detailed experi-

mental description of the methods used for data collection and integration using the SMART system has been published [14]. Table 1 contains a summary of the crystal parameters, data collection and refinement. Empirical absorption corrections were applied to the datasets using SADABS [15]. The structures were solved by conventional heavy-atom or direct methods and refined by the full-matrix least-squares method on all F^2 data using the SHELXTL 5.03 package on a Silicon Graphics Indy computer [16]. Non-hydrogen atoms were refined with anisotropic thermal parameters; hydrogen atoms were included in calculated positions and refined with isotropic thermal parameters riding on those of the parent atom. The structural determinations of $[Ru(bipy)_2(Hbig)][PF_6]_2 \cdot MeCN$ and $[Ru(bipy)_2(apps)][PF_6] \cdot CH_2Cl_2$ were straightforward and presented no particular problems; the only point to note is that in $[Ru(bipy)_2(Hbig)][PF_6]_2 \cdot MeCN$ the asymmetric unit contains two crystallographically independent molecules of the complex and two molecules of MeCN.

Crystals of $[Ru(terpy)(dipic)] \cdot H_2O \cdot Et_2O$ were very thin plates (those used had a thickness of 0.02 mm) and therefore diffracted rather weakly. Only data to a 2θ limit of 50° was used in the final refinement, as no significant diffracted intensity was observed between 50° and 55°, and inclusion of the higher-angle data only increased the R indices with no concomitant improvement in the precision of the structure. The molecule lies on a C_2 axis which passes through C(24), N(21), Ru(1), N(31) and C(34); there are therefore 16 complete molecules in the *F*ddd unit cell which has 32 general positions. Each asymmetric unit contained one half of the complex molecule, one half of a water molecule (the oxygen atom also being on a special position), and a badly disordered solvent molecule around the intersection of two C_2 axes. This could only be modelled by putting carbon atoms at the sites of maximum electron density and allowing the site occupancies to refine. The result was approximately 2.5 atoms, which we assume corresponds to half a disordered ether molecule in the asymmetric unit *per* half complex molecule and half solvent molecule, i.e. $[Ru(terpy)(dipic)] \cdot H_2O \cdot Et_2O$. Hydrogen atoms were not included in the refinement for the disordered solvent molecule.

RESULTS AND DISCUSSION

Synthesis of and crystal structure of [*Ru*(*terpy*)(*dipic*)]

Preparation and purification of this complex was straightforward and it was isolated cleanly in good yield. It is only very sparingly soluble in dmf and dmso, and insoluble in other solvents, so a good mass spectrum could not be obtained. Attempts to obtain NMR spectra were likewise unsuccessful, due to a

combination of poor solubility and the ease with which it oxidises in solution to the paramagnetic Ru(III) state (see below). However the elemental analysis and crystal structure (below) provide unambiguous characterisation.

[Ru(terpy)(dipic)] (Fig. 1, Table 2) has the expected pseudo-octahedral structure, with a *trans*-N_4O_2 donor set. The terpy ligand shows the usual pattern of Ru–N bond lengths, with a short bond to the central atom [Ru(1)–N(21), 1.964(5) Å] and longer ones to the terminal two atoms [Ru(1)–N(11)/N(11A), 2.060(5) Å], which arise from the steric limitations of the terpyridyl ligand [17]. The dipicolinate ligand behaves similarly for the same steric reasons, with the two Ru–O bonds being significantly longer than the four Ru–N bonds, and the localisation of single and double C–O bond character being apparent in the two carboxylate fragments [7, 8]. The presence of two anionic σ-donor ligands on the same axis *trans* to one another has not resulted in any significant lengthening of the Ru–O bonds compared to those complexes with N_5O donor sets where a carboxylate donor is *trans* to a pyridyl ring, as in $[Ru(bipy)_2(pic)][PF_6]$ [8] and $[Ru(bpy\text{-}CO_2)_2]$ (where bpy-CO_2H is 2,2′-bipyridine-6-carboxylic acid) [7]. The non-coordinated oxygen atom O(36) is hydrogen-bonded to the lattice water molecule, with the non-bonded O(36)···O(water) separation being 2.91 Å, typical of O–H···O hydrogen-bonding.

Synthesis and crystal structure of $[Ru(bipy)_2(Hbig)][PF_6]_2$

Although complexes of first-row transition metal ions with biguanide have been known for a long time [18–24], there are no reports of any complexes with ruthenium. As a bidentate ligand with two unsaturated (formally sp^2-hybridised) N-donors there is an obvious similarity with other diimines such as 2,2′-bipyridine (bipy). A notable property of biguanide is that it can coordinate in either the neutral form (Hbig) or in the deprotonated form $[big]^-$ with a delocalised structure reminiscent of the acetylacetonate anion [18], and crystal structures of both types of complex are known.

Reaction of $[Ru(bipy)_2Cl_2]$ with Hbig in refluxing ethanol, followed by precipitation of the complex as its hexafluorophosphate salt and recrystallisation, afforded in high yield a material whose elemental analysis was consistent with the formulation $[Ru(bipy)_2(Hbig)][PF_6]_2$. This implies that the biguanide ligand is neutral, rather than coordinating in the anionic deprotonated form which would have given $[Ru(bipy)_2(big)][PF_6]$ with only one hexafluorophosphate anion and a substantially different elemental analysis. The ES mass spectrum confirmed the presence of the expected complex cation, and the structure was finally confirmed by X-ray crystallography (Figure 2, Table 2).

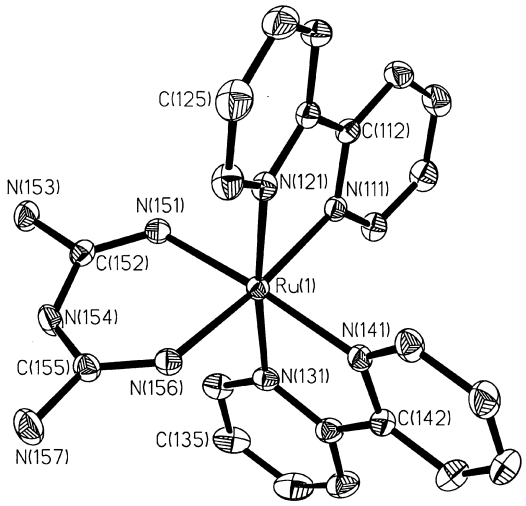

Fig. 2. Crystal structure of the cation of [Ru(bipy)$_2$(Hbig)][PF_6]$_2$.

The asymmetric unit contains two independent [Ru(bipy)$_2$(Hbig)][PF_6]$_2$·MeCN groups. Figure 2 shows one of the independent complex cations; the structure of the alternate one is very similar. It has the expected octahedral structure with unremarkable bond lengths and angles in the coordination sphere. There is no sign of any significant *trans* effect, as the Ru–N(pyridyl) bonds *trans* to the biguanide donor atoms are very similar to the other two. The Ru–N(biguanide) distances are consistent with the N atoms being sp^2-hybridised. Two geometric features of the coordinated biguanide ligands are worth a comment. Firstly, the angle at the central N atom, C(155)–N(154)–C(152), is 129.0(2)° [129.1(3)° at N(254) in the independent complex dication]. This is consistent with the ligand being in the neutral Hbig form, with steric repulsion between the two bulky arms attached to the central N atom resulting in the C–N–C angles being considerably "opened out"; [20, 21] when the ligand is deprotonated, the increased delocalisation throughout the chelate ring results in these C–N–C angles being much closer to the ideal 120° [20, 22, 24]. Secondly, the Ru atom is not quite in the same plane as the (near-planar) biguanide ligand; the angle between the mean plane of the five ligand atoms in the chelate ring [N(151), C(152), N(154), C(155), N(156)] and the RuN_2 coordination plane [Ru(1), N(151), N(156)] is 6.9° in the cation depicted (9.2° for the independent complex dication). This is again a common, but not consistent, feature of biguanide complexes [20, 21].

The solution ^{1}H NMR spectrum showed the presence of the expected 8 aromatic proton environments (relative intensity 2 H each) for the bipyridyl ligands, which are equivalent but within which the two pyridyl rings are inequivalent. Two broad singlets at 5.02 and 5.65 ppm we assign to NH protons, but the integrals are rather low, presumably due to exchange with pro-

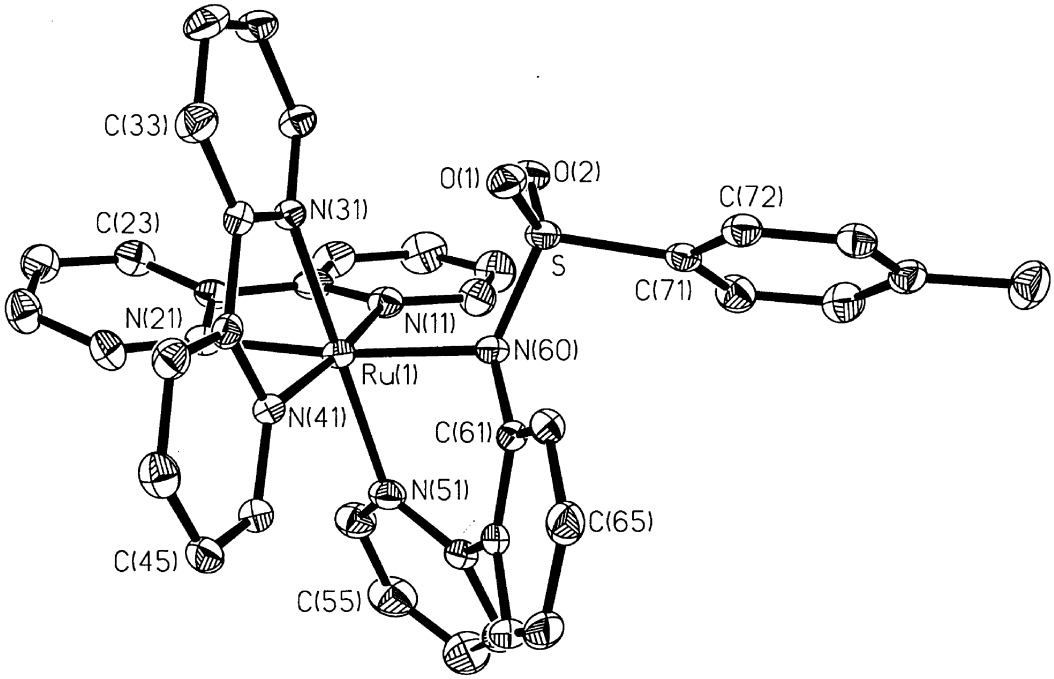

Fig. 3. Crystal structure of the cation of $[Ru(bipy)_2(apps)][PF_6]$.

tons in the moisture that is present in the solvent. We would expect three different NH proton environments on the basis of the crystal structure, so we assume that the most acidic proton (the central NH) is in fast exchange with the H_2O protons and the signal for this is therefore invisible.

Synthesis and crystal structure of $[Ru(bipy)_2(apps)][PF_6]$.

We recently reported the synthesis of Happs, a bidenatate chelating ligand with one pyridyl and one sulfonamide donor, and the crystal structures of some of its complexes [13]. The new complex $[Ru(bipy)_2(apps)][PF_6]$, with five pyridyl ligands and one anionic sulfonamide ligand, was simply prepared by reaction of Happs with the labile complex $[Ru(bipy)_2(H_2O)]^{2+}$; we found that this gave a cleaner product than that obtained from the reaction of Happs directly with $[Ru(bipy)_2Cl_2]$. The elemental analysis and FAB mass spectrum confirmed the formulation of the complex. The ^1H NMR spectrum in MeCN gave the correct ratio of integrals for the aromatic and aliphatic (methyl) protons, but the 28 inequivalent aromatic protons occurred in an overlapping mass between 6.5 amd 8.5 ppm which could not be individually assigned.

The crystal structure (Figure 3, Table 2) shows that the usual octahedral structure has been adopted despite the bulky and sterically hindering nature of the *p*-tolyl-sulfonamide fragment. There is an interaction between O(1) of the sulfonamide group and one of the pyridyl rings, with a distance of 3.11 Å between O(1) and the mean plane of this pyridyl ring. This appears to lengthen the Ru–N bonds to the apps ligand, as Ru–N(51) is the longest of the Ru–N(pyridyl) bonds at 2.099(3) Å, and the Ru–N(sulfonamide) distance [2.141(3) Å] is even longer. This contrasts with the four-coordinate, relatively unhindered, complexes of the same ligand with Cu(II), Co(II) and Pd(II) in which the metal-N(sulfonamide) bonds were shorter than, or about the same length as, the metal-N (pyridyl) bonds [13].

Electrochemical properties of $[Ru(bipy)_2(pic)][PF_6]$ *and* $[Ru(terpy)(dipic)]$

Cyclic voltammetry in dmf showed that $[Ru(bipy)_2(pic)][PF_6]$ has a reversible one-electron wave at $+0.40$ V *vs.* the ferrocene/ferrocenium couple (Fc/Fc^+), corresponding to a metal-centred Ru(II)/Ru(III) couple, and two reversible one-electron waves at -1.87 and -2.12 V *vs.* Fc/Fc^+, corresponding to ligand-centred processes (electrochemical data are collected in Table 3). By "reversible" is meant that the waves were symmetric (equal cathodic and anodic peak currents), with peak-peak separations in the

Table 3. Electronic spectral and electrochemical data for the complexes. The maxima of the lowest-energy m.l.c.t. transitions are in bold type

Complex	λ_{max} (nm) [$10^{-3}\epsilon$ ($dm^3\ mol^{-1}\ cm^{-1}$)]	Cyclic voltammetric data [$E_{1/2}$ V *vs.* Fc/Fc^+]	
$[Ru(bipy)_2(pic)][PF_6]$	**495** (**14**), 455 (sh), 369 (13), 295 (78)[a]	+0.40	−1.87, −2.12[a]
[Ru(terpy)(dipic)]	660 (sh), 595 (sh), **532** (**8.3**), 393 (10.6), 323 (27), 279 (24)[a]	+0.12	−2.01[a]

region of 60–100 mV, at a range of scan rates. These results agree well with recently reported values of +0.88, −1.43 and −1.68 V *vs.* SCE in acetonitrile [7].

The Ru(II)/Ru(III) couple of $[Ru(bipy)_3][PF_6]_2$ under the same conditions is +0.89 V *vs.* Fc/Fc^+, so replacement of a neutral pyridyl ligand by an anionic carboxylate therefore stabilises the Ru(III) state by 490 mV. This may be compared with the 860 mV stabilisation of the Ru(III) state which occurs on replacing a pyridyl residue of $[Ru(bipy)_3]^{2+}$ with a phenolate group in $[Ru(bipy)_2(no)][PF_6]$ [Hno is 2-(2-hydroxyphenyl)pyridine], which also has a N_5O donor set containing one anionic oxygen donor [1]. The comparison of $[Ru(bipy)_2(pic)]^+$ with $[Ru(bipy)_2(no)]^+$ allows us to cancel out the electrostatic part of the stabilisation of the Ru(III) state which arises just as a consequence of reducing the overall charge on the complex from +2 to +1, which will be common to both complexes. The fact that a phenolate donor results in a cathodic shift of the Ru(II)/Ru(III) couple which is 370 mV larger than that caused by the carboxylate donor is an indication of the different σ-donor/π-acceptor properties of the two groups. Clearly carboxylate is a poorer net electron donor than phenolate, because of the partial delocalisation of the negative charge within the carboxylate group onto the non-coordinated oxygen atom. The potentials of the two one-electron bipy-based reductions may be compared with $[Ru(bipy)_3]^{2+}$, whose first two reductions occur at −1.72 and −1.92 V *vs.* Fc/Fc^+. The more negative potentials required to reduce the bipy ligands of $[Ru(bipy)_2(pic)]^+$ reflect the smaller positive charge on the complex.

Cyclic voltammetry of [Ru(terpy)(dipic)] in dmf revealed reversible one-electron waves centred at +0.12 V and −2.01 V *vs.* Fc/Fc^+. The first of these corresponds to the Ru(II)/Ru(III) couple, which has undergone an additional cathodic shift of 280 mV compared to $[Ru(bipy)_2(pic)][PF_6]$ (which in turn was cathodically shifted by 490 mV from $[Ru(bipy)_3]^{2+}$). The couple at −2.01 V *vs.* Fc/Fc^+ we assign to reduction of the terpy ligand; a reduction of the doubly negatively-charged dipicolinate ligand was not observed.

The relationship between Ru(II)/Ru(III) redox potential and donor set in the series $[Ru(bipy)_3]^{2+}$, $[Ru(bipy)_2(pic)]^+$ and [Ru(terpy)(dipic)] (with N_6, N_5O and *trans*-N_4O_2 donor sets respectively) is clearly not linear: the second substitution of pyridyl by carboxylate has a much smaller effect than the first substitution. In [Ru(terpy)(dipic)] the two carboxylates are *trans* to one another, and each will repel the other electrostatically, reducing their ability to donate electron density to the metal centre compared to the carboxylate donor of $[Ru(bipy)_2(pic)]^+$ which is *trans* to an electron-withdrawing pyridyl group (although this is not really detectable in the crystal structures, as described above). Further support for this comes from the observation that in $[Ru(bpy\text{-}CO_2)_2]$, with a *cis*-N_4O_2 donor set, the shift in the potential of the Ru(II)/Ru(III) couple is almost exactly double that found for $[Ru(bipy)_2(pic)][PF_6]$, since in this case both carboxylate donors are *trans* to pyridyl groups [7].

Electrochemical properties of $[Ru(bipy)_2(hbig)][PF_6]$ *and* $[Ru(bipy)_2(apps)][PF_6]$

Cyclic voltammetry of $[Ru(bipy)_2(Hbig)][PF_6]_2$ in MeCN using a glassy carbon working electrode gave a single reversible wave at +0.21 V *vs.* Fc/Fc^+. We ascribe this to the Ru(II)/Ru(III) couple. Replacing one bipy ligand by Hbig therefore results in stabilisation of the Ru(III) state by 680 mV, indicating that the metal centre of $[Ru(bipy)_2(Hbig)][PF_6]_2$ is much more electron rich than that of $[Ru(bipy)_3]^{2+}$ because of the poorer π-acceptor capability of Hbig compared to the highly delocalised bipy. At high negative potentials only poorly-defined irreversible processes could be observed which were not examined further. Use of a Pt working electrode instead of glassy carbon resulted in a very asymmetric wave for the Ru(II)/Ru(III) couple because of absorption of the oxidised species onto the electrode surface.

Cyclic voltammetry of $[Ru(bipy)_2(apps)][PF_6]$ at a

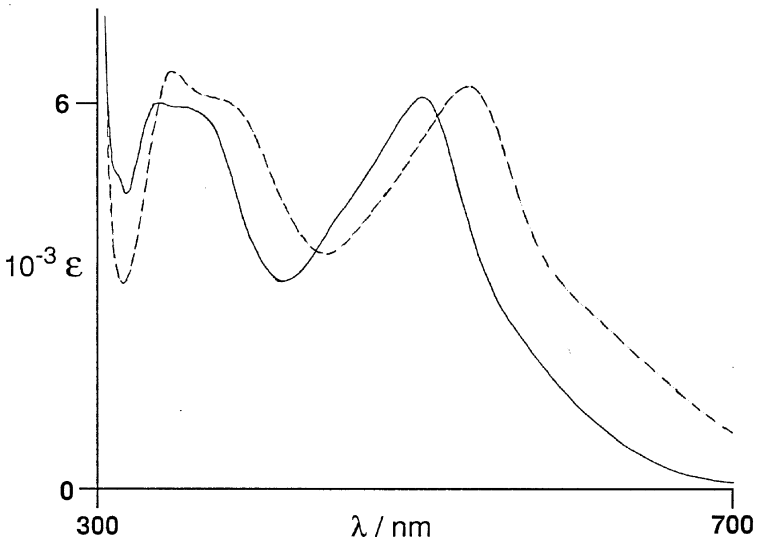

Fig. 4. Electronic spectra of $[Ru(bipy)_2(Hbig)]^{2+}$ in water at pH 7 (solid line), and $[Ru(bipy)_2(big)]^{+}$ in water at pH 13 (dotted line).

Pt-bead electrode in MeCN gave reversible waves centred at +0.20 V and −1.91 V *vs.* Fc/Fc^+, assignable to Ru(II)/Ru(III) and bipy-centred couples respectively. The stabilisation of the Ru(III) state by 690 mV compared to $[Ru(bipy)_3]^{2+}$ arises because apps is both a better σ-donor than bipy because of its negative charge, and a poorer electron-acceptor because it contains only one pyridyl ring. Interestingly, the Ru(II)/Ru(III) couple of $[Ru(bipy)_2(apps)][PF_6]$ is 200 mV more cathodic than that of $[Ru(bipy)_2(pic)][PF_6]$, indicating that the anionic sulfonamide group is a better net electron donor to ruthenium than the anionic carboxylate group, possibly because nitrogen is less electronegative than oxygen and therefore more polarisable.

Electronic spectra of the complexes and pH titration of $[Ru(bipy)_2(Hbig)][PF_6]_2$

The electronic spectra of the complexes are summarised in Table 3. In all cases the lowest-energy feature, in the visible region, may be ascribed to the $Ru[d(\pi)]\rightarrow L(\pi^*)$ m.l.c.t. process, where L = bipy or terpy as appropriate. The red-shift of these compared to the same transition in $[Ru(bipy)_3][PF_6]_2$ (*ca.* 450 nm) [25] arises because of the weakening of the ligand field by replacement of a strong-field pyridyl donors by weaker-field carboxylate, sulfonamide or biguanide ligands, which raises the $d(\pi)$ levels. The incremental weakening of the ligand field on addition of one and then two carboxylates to the donor set is apparent in the shift of the m.l.c.t. maximum from 450 to 495 and then 534 nm in the series $[Ru(bipy)_3][PF_6]_2$, $[Ru(bipy)_2(pic)][PF_6]$ and [Ru(terpy)(dipic)]. All of the complexes have one or two near-UV transitions in the 300–400 nm range, and the usual intense ligand-centred transitions in the higher-energy UV region.

A pH titration of the electronic spectrum of $[Ru(bipy)_2(Hbig)][PF_6]_2$ was effected by dissolving it in aqueous 0.1 M KCI acidified to pH 1, and slowly raising the pH to 13 by addition of very small portions of solid KOH. In the pH range 1 to 11 the spectrum was invariant, but in the pH range 11–13 the spectrum changes significantly, which we ascribe to deprotonation of the central NH group of the coordinated Hbig ligand to give $[Ru^{II}(bipy)_2(big)]^+$, since $[Ru(bipy)_3]^{2+}$ undergoes no such pH-induced spectral change. The pair of transitions at 340 and 360 nm become red-shifted to 348 and 384 nm, and the lowest-energy MLCT band at 504 nm is likewise red-shifted to 533 nm (Figure 4). A graph of λ_{max}(MLCT) *vs.* pH (Figure 5) indicates that the pK value is 12.3 (±0.2), and the same pK value could be obtained from plotting other spectral parameters (*e.g.* absorbance at 400 nm) as a function of pH. The red-shift of the m.l.c.t. transitions indicates that on deprotonation the metal $d(\pi)$ orbitals are raised, *i.e.* $[big]^-$ is a weaker-field ligand than Hbig; that the bipy-based orbitals are not significantly perturbed is shown by the fact that the two intense UV transitions are hardly affected by deprotonation of the complex. Deprotonation of Hbig to $[big]^-$ results in formation of a negatively-charged, delocalised "acac-like" ligand [19] which is expected to be a better π-donor than neutral Hbig, consistent with the above observation.

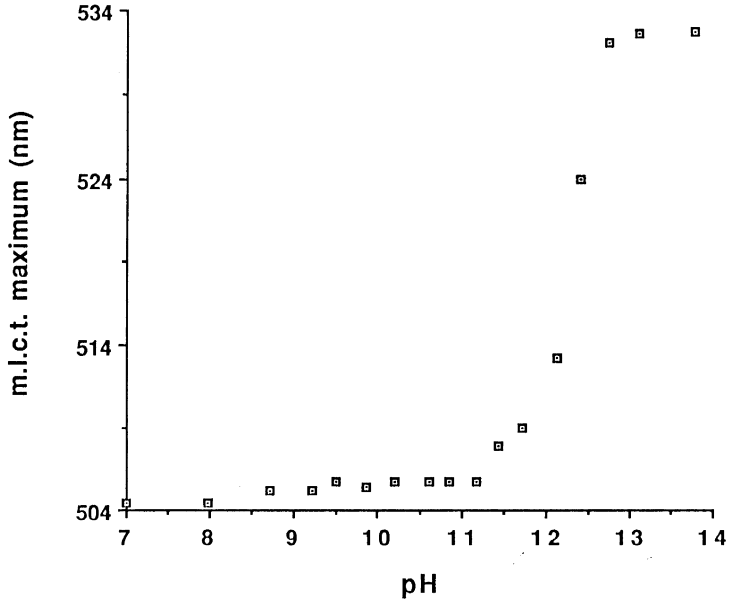

Fig. 5. Wavelength of the m.l.c.t. maximum of $[Ru(bipy)_2(Hbig)]^{2+}$ as a function of pH.

Spontaneous and base-catalyzed nitrito to nitro linkage isomerization of *trans*-$[Co(NH_3)_4(NH_2CH_3)ONO]^{2+}$ complex

Fernando Bozoglián, Marcelo Queirolo and Beatriz Sienra*

Química Inorgánica, Facultad de Quimica, C.C. 1157, Montevideo, Uruguay

(Received 8 November 1997; accepted 8 April 1998)

Abstract—The nitrito ion *trans*-$[Co(NH_3)_4(NH_2CH_3)ONO]^{2+}$ rearranges to its nitro form *trans*-$[Co(NH_3)_4(NH_2CH_3)NO_2]^{2+}$ in aqueous base according to the rate law $k_{obs}=k_s+k_{bc}[OH^-]$. At $\mu=1.0$ M, 25°C $k_s=1.01\times10^{-4}$ s^{-1}; $\Delta H_s^*=98$ kJ mol^{-1}; $\Delta S_s^*=7$ JK^{-1}; $k_{bc}=3.3\times10^{-2}$ $M^{-1}s^{-1}$; $\Delta H_{bc}^*=121$ kJ mol^{-1}; $\Delta S_{bc}^*=132$ JK^{-1} mol^{-1}. The base-catalyzed isomerization proceeds enterely *via* an intramolecular conjugate-base mechanism. The reaction is fully retentive and *trans*-$[Co(NH_3)_4(NH_2CH_3)NO_2]^{2+}$ is the only species that could be detected by ^{1}H nmr after the reaction was completed. The results are discussed in the light of the reaction mechanisms proposed so far and in relation to the normal substitution chemistry of pentaamminecobalt(III) complexes. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: nitrito ion; nitro linkage isomerization; pentaamminecobalt(III) complexes.

The nitrito ligand shows an ambident character [1]: coordination to a metal center can be achieved by either its O or N atoms in Co(III) complexes. The O-bound nitrito complexes isomerize spontaneously and stereoretentively [2] to the more stable N-bound nitro complexes, both in the solid state [3, 4] and in solution [5–10]. This reaction [11] is confirmed to be an intramolecular process [3, 6] for which a seven-coordinated [1, 3, 7] or a six-coordinated π bonded species [8] has been proposed as reaction intermediate. Despite the extensive investigations in this field, little attention has been paid to the kinetics aspects of this reaction in basic solution. In fact, the existence of a base-catalyzed path (eqn (1)) for the rearrangement has been recognized some years ago [12–14], but only one nitrito complex of Co(III) has been subjected to kinetic measurements: $[Co(NH_3)_5ONO]^{2+}$.

$$[Co(NH_3)_5ONO]^{2+} \xrightarrow{OH^-} [Co(NH_3)_5NO_2]^{2+} \quad (1)$$

We have been studying the base hydrolysis of *trans*-$[Co(NH_3)_4(NH_2CH_3)X]^{(3-n)+}$ in the presence of excess of NO_2^-, which lead to the production of some $[Co(NH_3)_4(NH_2CH_3)ONO]^{2+}$ and $[Co(NH_3)_4(NH_2CH_3)NO_2]^{2+}$ along with $[Co(NH_3)_4(NH_2CH_3)OH_2]^{3+}$ and so, became interested in the nitrito-to-nitro linkage isomerization reaction. In the present study, the spontaneous and base-catalyzed isomerization for the *trans*-$[Co(NH_3)_4(NH_2CH_3)ONO]^{2+}$ ion was followed, in order to determine the influence of methylation on the isomerization rate. Furthermore, the availability of a nitrito complex of *trans* configuration makes it possible to determine the stereochemical course of the isomerization reaction. Since the present linkage isomerization is an intramolecular process in which no Co(III)-ligand bonds are ruptured, it is likely that configuration is retained during the process.

EXPERIMENTAL

Spectrophotometric measurements were made on a Spectronic 3000 diode array spectrophotometer. Cation exchange experiments were performed with a Dowex 50 W × 2 (Na^+ form, 200–400 mesh) resin. A Varian XL-100 spectrometer was used for the ^{1}H nmr spectra.

Materials

trans-$[Co(NH_3)_4(NH_2CH_3)ONO]^{2+}$ and *trans*-$[Co(NH_3)_4(NH_2CH_3)NO_2]^{2+}$ were prepared as

* Author to whom correspondence should be addressed.

described in the literature [15], and their authenticy were checked by their UV-VIS (in aqueous solution) and ^{1}H nmr (in deuterated dimethylsulfoxide *vs* tetramethylsilane as internal reference) spectra. Ion-exchange chromatography and ^{1}H nmr spectroscopy were used to establish the absence of trace impurities, particularly *trans*-$[Co(NH_3)_4(NH_2CH_3)OH_2]^{3+}$ [15]. The isomeric purity of the complexes was confirmed by this last technique [15]. Freshly prepared (or stored at $-18°C$ for less than a week) nitrito complex was used for the experiments, since it isomerizes even in the solid state.

All other reagents and solvents used were of analytical grade.

Reaction stoichiometry and product analyses

The absorption spectrum of *trans*-$[Co(NH_3)_4(NH_2CH_3)ONO]^{2+}$ in water and in aqueous NaOH changed with time and displayed isosbestic points at 295,6 (ϵ 469) and 367 nm (ϵ 284). These agree with those expected for *trans*-$[Co(NH_3)_4(NH_2CH_3)NO_2]^{2+}$ as the only product. Furthermore, the final (10 $t_{1/2}$) absorption spectra were identical with that of the authentic nitro complex (Fig. 1). The absence of any significant base hydrolysis of *trans*-$[Co(NH_3)_4(NH_2CH_3)ONO]^{2+}$ to give $[Co(NH_3)_4(NH_2CH_3)OH_2]^{3+}$was confirmed as follows. A sample of the nitrito complex (0.5 g) was dissolved in 0.10 M NaOH ($\mu = 1.0$, $NaClO_4$) and allowed to react for 10 $t_{1/2}$ (35 min). The reaction was quenched to pH 2 with $HClO_4$ and the solution was sorbed on and eluted from Dowex resin with 0.2 M $NaClO_4$. No $[Co(NH_3)_4(NH_2CH_3)OH_2]^{3+}$ complex was detected. The absence of *trans-cis* rearrangement during the isomerization reaction of *trans*-$[Co(NH_3)_4(NH_2CH_3)ONO]^{2+}$ ion was confirmed by ^{1}H nmr. The chloride salt (0.15 mg) was dissolved in a D_2O/NaOD (0.5 ml, 0.01M) solution, and its spectrum recorded. After the reaction was completed, the final spectrum was recorded. Tetramethylsilane (tms) was used as internal reference.

Kinetic studies

The reactions were followed spectrophotometrically, with the reaction cell thermostated ($\pm 0.1°C$) by a thermoelectric cuvette holder (Peltier effect). After preliminary spectral searching experiments to characterize the reaction and identify the most suitable wavelength, the progress of the isomerization was monitored at 327 nm. Solutions containing NaOH and $NaClO_4$ were brought to the reaction temperature in the thermostated cell com-

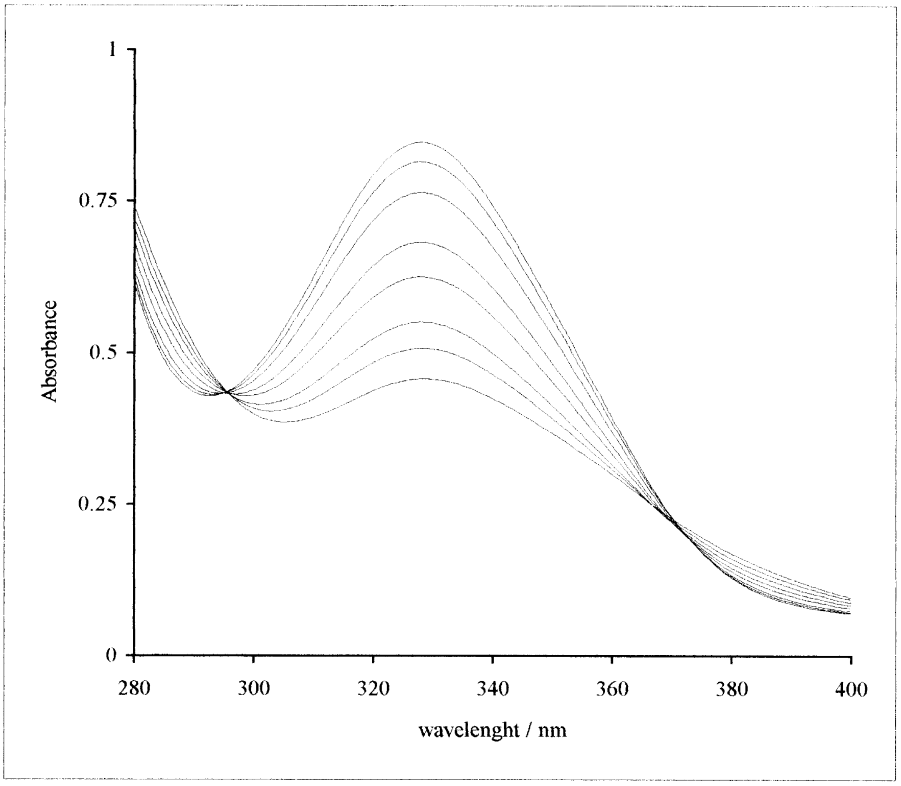

Fig. 1. Change in the absorption spectrum of *trans*-$[Co(NH_3)_4(NH_2CH_3)ONO]^{2+}$ in aqueous NaOH solution, accompanied by its isomerization to the nitro complex.

partment and the reaction was iniciated by adding 40 μL of a solution (2.5×10^{-2} M) of the complex which was rapidly mixed with the cuvette stirrers. Base concentrations between 0.0025 and 0.1 M were employed, at unit ionic strength adjusted with sodium perchlorate. Plots of $\ln(A_t\text{-}A_\infty)$ *vs.* time were linear to completion of reaction. Rate constants for the base-catalyzed isomerization were determined by the usual least-squares analysis of absorbance data. Activation entalphy and entropy were determined from plots of ln(k/T) *vs.* 1/T. The spontaneous isomerization of *trans*-$[Co(NH_3)_4(NH_2CH_3)ONO]^{2+}$ complex was studied in aqueous solution at unit ionic strength adjusted with sodium perchlorate. The same procedure outlined above was followed.

RESULTS AND DISCUSSION

The observed rate constants, k_{obs}, for the base-catalyzed isomerization of *trans*-$[Co(NH_3)_4(NH_2CH_3)ONO]^{2+}$ ion studied at base strengths between 0.0025 and 0.1 M, at 25°C obey (Fig. 2) the relationship

$$k_{obs} = k_{s3} + k_{bc}[OH^-] \quad (2)$$

and least-square analysis yielded the two independent rate constants k_s(spontaneous) $= 1.01 \times 10^{-4}\,s^{-1}$ and k_{bc}(base-catalyzed) $= 3.3 \times 10^{-2}\ M^{-1}s^{-1}$. The temperature dependence of k_{bc} is shown in Table 1.

The linkage isomerization reaction was also followed in aqueous solution at ionic strength 1M($NaClO_4$). The isomerization rate, k_s, at 25°C, obtained

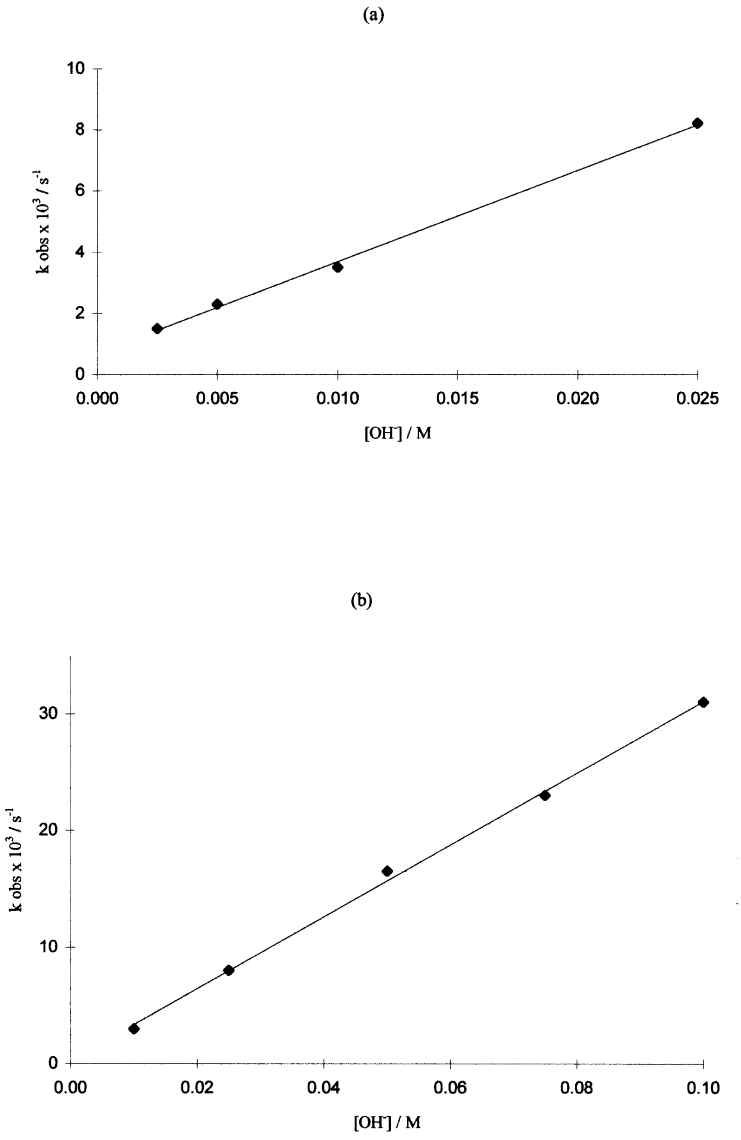

Fig. 2. Base-dependence of the linkage isomerization rate of $[Co(NH_3)_4(NH_2CH_3)ONO]Cl_2$ in (a) 0.0025–0.01M NaOH, $\mu = 1.0$ ($NaClO_4$); (b) 0.01–0.1 M NaOH, $\mu = 1.0$ ($NaClO_4$), at 25°C.

Table 1. Temperature dependence of the rate constant for the base-catalyzed linkage isomerization of *trans*-$[Co(NH_3)_4(NH_2CH_3)ONO]^{2+}$ ion[a]

T(°C)	10.0	16.8	25.0	30.3	40.0
$k_{bc}(s^{-1}\,M^{-1})$	1.5×10^{-3}	6.7×10^{-3}	3.3×10^{-2}	6.3×10^{-2}	2.4×10^{-1}

[a] Complex concentration 5×10^{-4} M, base concentration 0.05M and ionic strength 1.0 M ($NaClO_4$).

in this independent way agrees, within experimental error, with the value obtained from the application of eqn (2) to the data in basic solution. Table 2 shows the temperature dependence of k_s.

Rate constants and activation parameters for the spontaneous and base-catalyzed isomerization of *trans*-$[Co(NH_3)_4(NH_2CH_3)ONO]^{2+}$ ion are collected in Table 3 together with the corresponding data for the $[Co(NH_3)_5ONO]^{2+}$ ion. Literature data for the acid and base-catalyzed hydrolysis of some acidoamminecobalt(III) complexes are also included for comparison.

For both the spontaneous and base-catalyzed paths, the rates of isomerization of *trans*-$[Co(NH_3)_4(NH_2CH_3)ONO]^{2+}$ complex are greater than the corresponding rates for the $[Co(NH_3)_5ONO]^{2+}$ ion. In the substitution chemistry of pentaamminecobalt(III) complexes, there is also a modest rate enhancement of both, aquation and base hydrolysis, when one NH_3 is substituted by a NH_2CH_3 ligand (*trans* position), as shown in Table 3 [16–19]. This acceleration has been attributed to inductive effect of the methyl substituent [19]. The same interpretation holds for the reaction under study since it is conceivable that the methyl

group influences the stretching of the Co–O bond, donating negative charge to the cobalt. The present results are therefore compatible with the assumption that the isomerization is an intramolecular process which is facilitated in the *trans*-$[Co(NH_3)_4(NH_2CH_3)ONO]^{2+}$ complex when compared with the $[Co(NH_3)_5ONO]^{2+}$ ion.

The ratios k_{OH}/k_{aq} are $5.4\times10^5\,M^{-1}$, $4.4\times10^5\,M^{-1}$ for *trans*-$[Co(NH_3)_4(NH_2CH_3)X]^{2+}$ ions, where $X=Cl^-$, Br^- and NO_3^- respectively and comparable ratios are observed for the corresponding pentaammines complexes ($3.8\times10^5\,M^{-1}$, $5.5\times10^5\,M^{-1}$ and $3.8\times10^5\,M^{-1}$) [19]. The isomerization reaction does not follow this pattern; the ratio k_{bc}/k_s is $3.3\times10^2\,M^{-1}$ for *trans*-$[Co(NH_3)_4(NH_2CH_3)ONO]^{2+}$ ion and $0.86\times10^2\,M^{-1}$ for $[Co(NH_3)_5ONO]^{2+}$ complex, *i.e.*, it differs significantly.

Moreover, the greater reactivity towards base hydrolysis of *trans*-$[Co(NH_3)_4(NH_2CH_3)X]^{2+}$ ions when compared with the parent pentaammines lies in the lower ΔH^* values, while the faster base-catalyzed isomerization reaction of *trans*-$[Co(NH_3)_4(NH_2CH_3)ONO]^{2+}$ ion compared with that of $[Co(NH_3)_5ONO]^{2+}$ complex is originated in a greater ΔS^* for the former. For example ΔH^*_{OH} of the $[Co(NH_3)_5ONO_2]^{2+}$ complex is 27 kJ mol^{-1} higher than for the *trans*-$[Co(NH_3)_4(NH_2CH_3)ONO_2]^{2+}$ ion whereas ΔH^*_{bc} for the pentammine complex is 11 kJ mol^{-1} lower. Similar observations can be made for the variations in ΔS^*_{OH} and ΔS^*_{bc}.

Differences to normal substitution chemistry are also apparent in the stereochemistry of the linkage isomerization reaction. The hydrolysis of $[CoA_5L]^{n+}$ complexes, which yield $[CoA_5OH_2]^{m+}$, often proceeds with stereochemical change. This is particularly true of base-catalyzed hydrolysis. For example, the base hydrolysis of *trans*-$[Co(NH_3)_4(NH_2CH_3)X]^{2+}$ ions yield 11, 13 and 17% of *cis*-$[Co(NH_3)_4(NH_2CH_3)OH_2]^{3+}$ complex, where $X=Cl^-$, Br^- and NO_3^- respectively [19]. This is not the situation with the reaction under study. The ^1H nmr spectrum of *trans*-$[Co(NH_3)_4(NH_2CH_3)ONO]Cl_2$ in D_2O/NaOD solution only showed the methyl ^1H resonance, due to complete exchange of amine protons [16] (chemical shift = 2.04 ppm relative to tms). After the reaction was completed the spectrum showed the methyl ^1H signal at 2.2 ppm. The presence of only one methyl resonance proves that the reaction proceeds under complete (>98%) stereochemical retention of configuration [15]. This result is consistent with synchronous bond breaking (Co–O) and bond making (Co–N) and with nitrito ion remaining bonded to cobalt throughout the rearrangement.

However, inspection of Table 3 also shows that for the spontaneous reactions ΔH^* values are essentially the same, whether or not the reactions are aquations or isomerizations. Furthermore the ΔS^* values for the nitrate complexes aquations are very similar to those for the isomerization reaction. This behaviour may be originated in the fact that for the nitrato and the nirito complexes the reactions, aquations or isomerizations respectively, involve Co–O bonds.

The activation parameters for the k_s and k_{bc} pathways differ substantially, indicating obvious mechanistic differences. For the base-catalyzed path, a conjugate base (CB) deprotonation preequilibrium has been proposed [12]. Support for this mechanism derives from the large positive ΔV^* [12] and ΔS^* values found for the isomerization reaction of $[Co(NH_3)_5ONO]^{2+}$ ion.

$$[Co(NH_3)_5ONO]^{2+} + OH^- \xrightleftharpoons{K} [Co(NH_3)_4(NH_2)ONO]^+ + H_2O,\ \Delta S^o_{CB}$$

$$[Co(NH_3)_4(NH_2)ONO]^+ \xrightarrow{k_2} [Co(NH_3)_4(NH_2)NO_2]^+,\ \Delta S^*_2$$

$$[Co(NH_3)_4(NH_2)NO_2]^+ + H_2O \xrightarrow{fast} [Co(NH_3)_5NO_2]^{2+} + OH^-$$

Since k_{bc} is a composite quantity ($=K\,k_2$) the corresponding activation parameters listed in Table 3 can not be readily rationalized. However a positive value of ΔS^*_{bc} ($=\Delta S^o_{CB}+\Delta S^*_2$) is predicted for this mechanism, the first step of which is closely similar to known "neutralization" reactions in the literature [20], because of the considerable charge neutralization. The second step is expected to have a ΔS^*_2 near zero, as the one found for the spontaneous pathway. The conclusion is that k_s and k_{bc} isomerization processes are mechanistically similar after account is taken of the base preequilibrium step.

Ruthenium substituted Keggin type polyoxomolybdates: synthesis, characterization and use as bifunctional catalysts for the epoxidation of alkenes by molecular oxygen

Ronny Neumann* and Mazal Dahan

Casali Institute of Applied Chemistry, Graduate School of Applied Science, The Hebrew University of Jerusalem, Jerusalem, Israel, 91904

(Received 24 February 1998; accepted 14 April 1998)

Abstract—The ruthenium substituted polyoxomolybdate of the Keggin structure, $Q_4PRu^{III}(H_2O)Mo_{11}O_{39}$ ($Q = n\text{-}Bu_4N$), has been synthesized and characterized. The IR spectra show that this compound is isostructural with the known manganese and cobalt analogs. The cyclic voltammogram showed similar redox potentials and the UV–vis spectra showed similar energies for the *d–d* transitions compared to the corresponding tungstate, $Q_4PRu^{III}(H_2O)W_{11}O_{39}$. The catalytic activity of the molybdate *versus* tungstate in reactions with molecular oxygen was, however, significantly different. IR and ^{31}P NMR evidence indicated that treatment of $Q_4PRu^{III}(H_2O)Mo_{11}O_{39}$ with oxygen showed no structural changes whereas, for $Q_4PRu^{III}(H_2O)W_{11}O39$, a clear change was observed. This finding probably explains the lack of catalytic activity for the latter in the co-oxidation of cumene and 1-octene to cumyl alcohol and 1-octene oxide. For the molybdenum compound, this reaction took place by a kinetic balance of ruthenium metal-catalyzed autooxidation of cumene to cumene hydroperoxide and the molybdenum catalyzed oxygen transfer from cumene hydroperoxide to 1-octene to yield the products. High catalyst loading led to reaction inhibition whereas low loading and excess cumene led to increased autooxidation. © 1998 Elsevier Science Ltd. All rights reserved

INTRODUCTION

Transition metal substituted polyoxometalates have, over the last decade, attracted considerable interest as oxidatively stable catalysts for oxidation of hydrocarbons [1]. Transition metal substituted polyoxometalates can be defined as having a transition metal octahedrally or tetragonally coordinated by a lacunary polyoxometalate. The lacunary polyoxometalate may also be viewed as integrating 'hard' donor oxide ions with adjacent d^0 addenda atoms (Mo^{VI} and/or W^{VI}) providing acceptor orbitals. The interaction of a substituted transition metal with the addenda should be a function of the reduction potential of the heteropolyoxometalate, especially for a second-row transition metal such as ruthenium which has extended *d*-orbitals. Despite the known difference in the redox properties of polyoxotungstates *versus* polyoxomolybdates, the transition metal polyoxomolybdates and their catalytic properties have been only scarcely investigated. A typical transition metal substituted Keggin structure with the transition metal in a polyhedral representation is presented in Fig. 1. Numerable oxidation reactions for these structures and some others have been reported for polyoxotungstates containing chromium [2], manganese [3], iron [4], cobalt [5], nickel [6], niobium [7], rhodium [8] and ruthenium [9] active centers, using a variety of oxidants such as iodosobenzene, *t*-butylhydroperoxide, periodate, amine-oxides, hydrogen peroxide and oxygen. One current interest of our research group is the utilization of oxygen in catalytic transformations involving ruthenium substituted polyoxometalates [9]. In this context, we describe in this paper the synthesis and characterization of ruthenium substituted polyoxomolybdates of the Keggin structure and their use as bifunctional catalysts for the aerobic

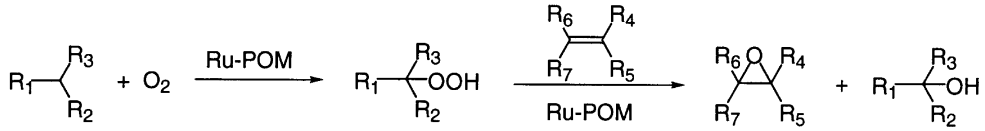
epoxidation of alkenes using alkanes as the source of electron donors [10]. In the past, there have been several reports on the combined use of two metals for such reactions in the intramolecular (cyclohexene) [11] and intermolecular mode [12]. The scheme for epoxidation is summarized in Scheme 1. First, there is an autooxidation of alkanes, for example, cumene presumably catalyzed at the ruthenium site to intermediate hydroperoxides. Instead of the usual metal catalyzed decomposition of the hydroperoxide, there occurs heterolytic oxygen transfer (epoxidation) from the intermediate hydroperoxide catalyzed at a molybdenum site to the alkene yielding epoxide and alcohol as co-product.

RESULTS AND DISCUSSION

Synthesis and characterization

As has been pointed out in the past, the relative instability of Keggin type lacunary polyoxomolybdates prevents the preparation of such transition metal substituted polyoxomolybdates in water [13]. Instead however, they may be prepared in non-aqueous solvents such as acetonitrile using quaternary ammonium cations, as has been described for $Q_4HPMMo_{11}O_{39}$ where $M = Co^{II}$, Mn^{II} and Cu^{II} and $Q = (n\text{-}Bu_4N)$ [13]. We have now adapted the non-aqueous procedure for the preparation of $Q_4PRu^{III}(L)Mo_{11}O_{39}$ for $L = H_2O$ and $(CH_3)_2SO$. The synthesis and purification of the lacunary species, $Q_4H_3PMo_{11}O_{39}$, was carried out as published [13]. The lacunary species was then reacted both with an equivalent amount of solid $RuCl_3 \times H_2O$ or $Ru^{II}(DMSO)_4Cl_2$ to yield $Q_4PRu^{III}(H_2O)Mo_{11}O_{39}$, **1**, and $Q_4PRu^{III}(DMSO)Mo_{11}O_{39}$ [14], **2**, respectively, which were purified by recrystallization. The labile ligand on the ruthenium atom in **1** is rather arbitrarily given as being water although it could well be acetonitrile or a mixture of both (see analysis of IR spectrum below). The IR spectra of the two ruthenium substituted polyoxomolybdates are shown in Fig. 2, along with the spectrum of $Q_4PRu^{III}(H_2O)W_{11}O_{39}$, **3** [15], for com-



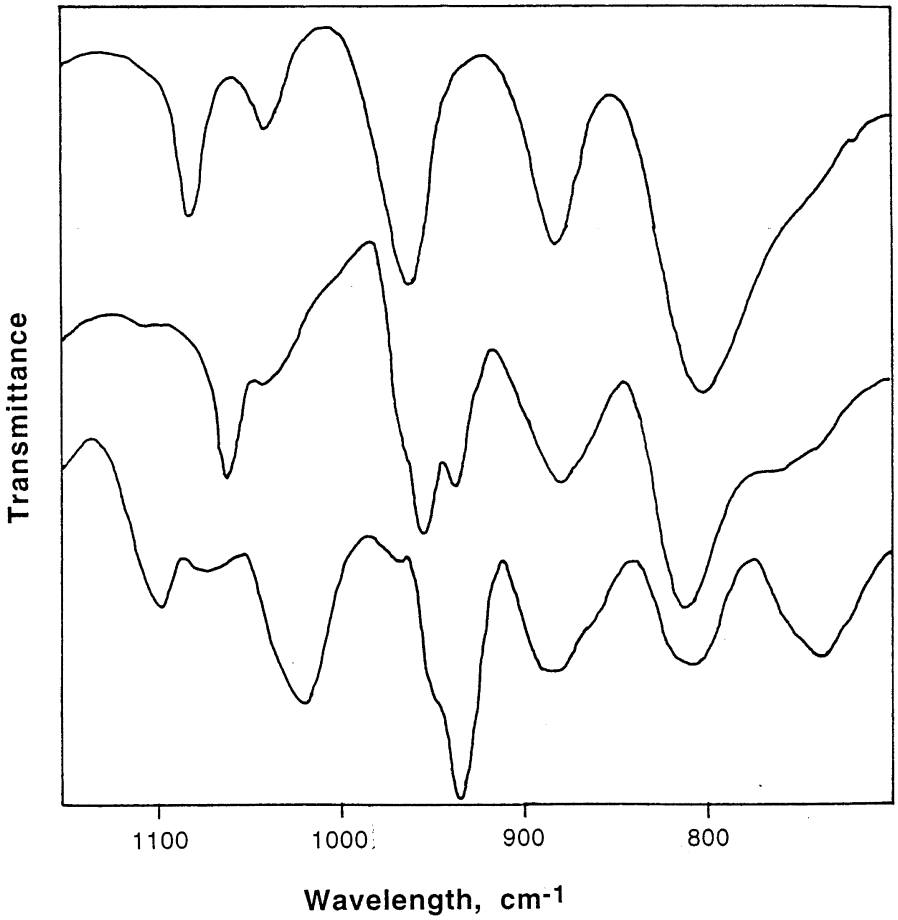


Fig. 2. IR spectra of ruthenium substituted polyoxometalates. Top: $Q_4PRu^{III}(H_2O)W_{11}O_{39}$ 1080, 1036 cm^{-1} P–O; 961 cm^{-1} W–O_t; 881 cm^{-1} W–O_c–W; 802 cm^{-1} W–O_e–W. Middle: $Q_4PRu^{III}(H_2O)Mo_{11}O_{39}$ 1061, 1038 cm^{-1} P–O; 952, 936 cm^{-1} Mo–O_t; 878 cm^{-1} Mo–O_c–Mo; 813 cm^{-1} Mo–O_e–Mo. Bottom: $Q_4PRu^{III}(DMSO)Mo_{11}O_{39}$ 1098, 1021 cm^{-1} P–O; 933 cm^{-1} Mo–O_t; 884 cm^{-1} Mo–O_c–Mo; 806 cm^{-1} Mo–O_e–Mo; 737 cm^{-1}.

parison. The spectra (not shown) measured for $Q_4HPMMo_{11}O_{39}$ (M = Co^{II} and Mn^{II})[13] were practically identical to that of $Q_4PRu^{III}(H_2O)Mo_{11}O_{39}$. The IR peaks attributable to stretching vibrations at corner shared bridges, M–O_c–M, and edge shared bridges, M–O_e–M, were similar for all three compounds. The peaks attributable to P–O vibrations were all split due to the reduction in symmetry from T_d in the parent Keggin structure to a C_s symmetry found in the transition metal substituted analog [16]. The large split observed in $Q_4PRu^{III}(L)Mo_{11}O_{39}$ with DMSO as ligand indicates a large displacement of the ruthenium cation from the heteroatom with the strongly coordinating DMSO. For the less coordinating water or acetonitrile ligands, a much smaller split is observed. Thus, there is a smaller displacement and a more compact structure is postulated [16]. For compounds **2** and **3**, there were single peaks attributable to the terminal M–O_t moiety. However, for $Q_4PM(H_2O)Mo_{11}O_{39}$ (M = Co, Mn and Ru) two peaks at 952 and 936 cm^{-1} were observed. We have no certain explanation for this phenomenon but hypothesize that it may be connected to the labile ligand at the ruthenium atom with compounds with different ligands yielding different peaks [17].

$Q_4PRu^{III}(DMSO)Mo_{11}O_{39}$ proved to be catalytically inactive due to the non-lability of the DMSO ligand [15]. Thus, further characterization was limited to the catalytically active $Q_4PRu^{III}(H_2O)Mo_{11}O_{39}$. The ^{31}P NMR spectrum in acetonitrile showed a single very broad peak at -105 ppm ($\Delta\nu_{1/2} = 1200$ Hz) which indicated a pure paramagnetic compound. The UV–vis spectrum [Fig. 3(a)] shows the expected charge transfer peak at $\lambda = 240$ nm, $\epsilon = 7 \times 10^4$ M^{-1} cm^{-1} with relatively intense *d–d* transitions at 410 and 576 nm ($\epsilon = 10000$ and 3000 M^{-1} cm^{-1} respectively). These *d–d* absorptions are slightly shifted (10–25 nm) relative to the reported spectrum of the tungsten analog [15]. The cyclic voltammetry measurement in CH_3CN (Fig. 4) showed two reversible waves assigned by literature precedence of other ruthenium subtituted polyoxometalates [15] to Ru(III)/Ru(II) at -0.11 V and

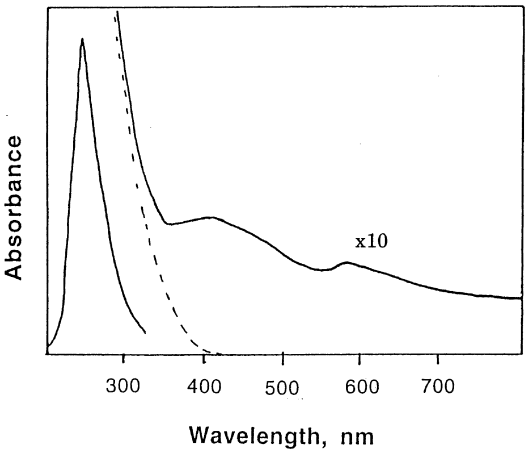

Fig. 3. UV–vis spectrum of $Q_4PRu^{III}(H_2O)Mo_{11}O_{39}$ in acetonitrile. (a) ——— without treatment. (b) - - - after bubbling O_2 for 12 h.

Ru(IV)/Ru(III) at 0.08 V. These reduction potentials are only marginally lower compared to those reported for the tungsten compound at neutral pH. No Ru(V)/Ru(IV) transition was observed due to solvent interference. In the past [15] it had been concluded that the low spin configuration of the ruthenium atom allows partial π-delocalization into vacant $p\pi^*$ orbitals of oxygen atoms bridging ruthenium and the addenda atoms. Inasmuch as it is well known that polyoxomolybdates, *e.g.*, $PMo_{12}O_{40}^{3-}$, are significantly stronger oxidants than their analogous polyoxotungstates *e.g.*, $PW_{12}O_{40}^{3-}$ and show significant bathochromic shifts [18], a more significant effect on both the ruthenium redox chemistry and electronic spectrum was expected [15], however, only slight differences were observed. It would appear that there is little π-delocalization between the ruthenium cation and the neighboring addenda atoms, which has little effect on the properties at the ruthenium center. Despite these observations, the $Q_4PRu^{III}(H_2O)Mo_{11}O_{39}$ compound showed different (a) reactivity to molecular oxygen and (b) catalytic activity and selectivity compared to the $Q_4PRu^{III}(H_2O)W_{11}O_{39}$ analog, as will be shown below.

Reaction of $Q_4PRu^{III}(H_2O)M_{11}O_{39}$ *with molecular oxygen*

Since we were interested in the catalytic co-oxidation of two substrates with molecular oxygen as presented in Scheme 1, the reaction of $Q_4PRu^{III}(H_2O)M_{11}O_{39}$ with molecular oxygen was examined by FTIR, UV–vis and ^{31}P NMR. Reaction of the molybdenum compound, 0.01 M $Q_4PRu^{III}(H_2O)Mo_{11}O_{39}$ in acetonitrile with 1 atm molecular oxygen for 8 h at 60°C yielded only the disappearance of the peak at 936 cm^{-1} in the IR spectrum (Fig. 5) and *no* formation

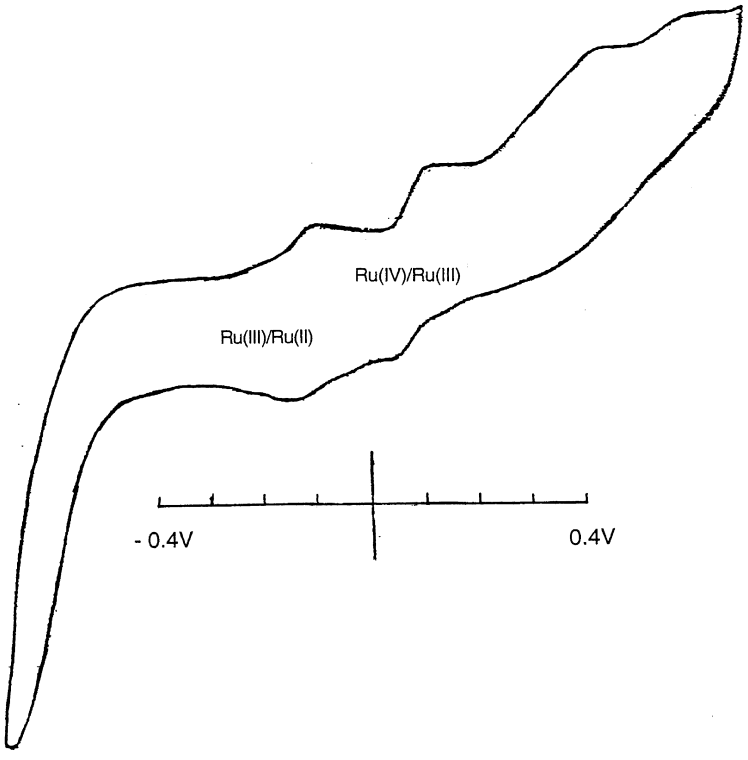

Fig. 4. Cyclic voltammogram of $Q_4PRu^{III}(H_2O)Mo_{11}O_{39}$.

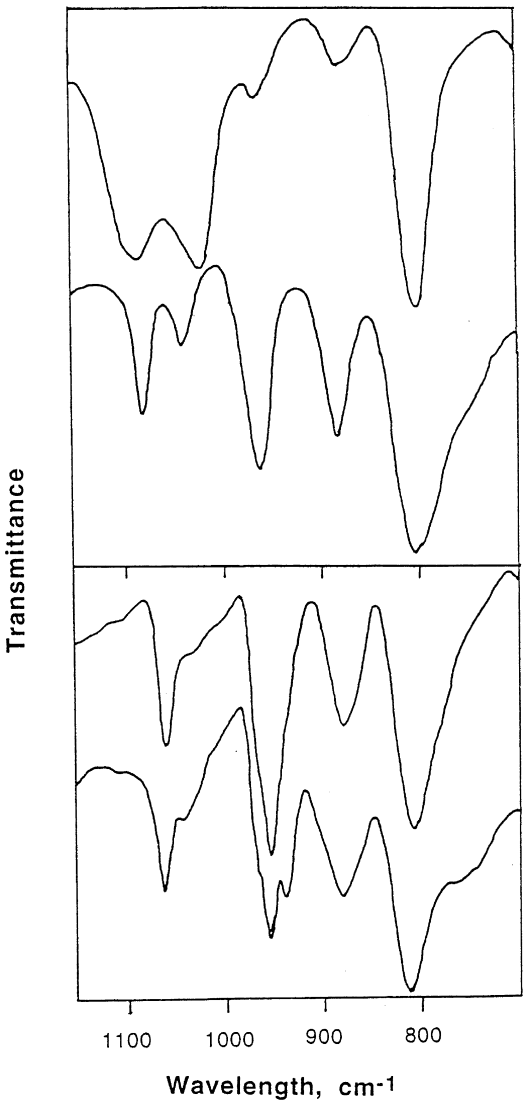

Fig. 5. IR spectrum of $Q_4PRu^{III}M_{11}O_{39}$ before and after treatment with O_2. Upper box: $Q_4PRu^{III}W_{11}O_{39}$ (top: before treatment with O_2, bottom: after treatment with O_2). Lower box: $Q_4PRu^{III}Mo_{11}O_{39}$ (top: before treatment with O_2, bottom: after treatment with O_2).

of a new absorption peak. An identical experiment replacing dioxygen with dinitrogen yielded the same change in the IR spectrum. A further UV–vis experiment (0.1 mM in acetonitrile, 1 atm O_2, 8 h, 60°C) with both the molybdenum and tungsten compounds showed the disappearance of the peaks in the visible region [Fig. 3(b)]. Our explanation of these results is that the bubbling of dioxygen or dinitrogen through a solution of $Q_4PRu^{III}(H_2O)Mo_{11}O_{39}$ in an apolar solvent only leads to the removal of the labile ligand [19]. This removal of the labile ligand manifests itself in the absence of peaks in the visible spectrum as has been reported also for the $ZnWRu(ZnW_9O_{34})_2^{12-}$ compound [9]. For the $Q_4PRu^{III}(H_2O)Mo_{11}O_{39}$ compound, there was also a change in the IR *i.e.*, the disappearance of the peak at 936 cm^{-1}. As stated above, we have postulated that the split peaks at 952 and 936 cm^{-2} were due to the presence of a labile ligand at the ruthenium atom. Removal of the ligand leads due a single peak indicative of only Mo–O_t stretching vibrations; importantly the Keggin structure is retained. Another indication of the absence of a significant structural change was obtained by ^{31}P NMR. The original broad peak at −105 ppm was unchanged after treatment with oxygen.

By contrast, in the case of the tungsten compound, $Q_4PRu^{III}(H_2O)W_{11}O_{39}$, after treatment with oxygen, there appeared in the IR spectrum a new distinct peak at 1019 cm^{-1} whilst the other peaks remained unchanged (Fig. 5). However, in this case, application of dinitrogen instead of dioxygen yielded only the original spectrum. The change in the IR spectrum of the tungsten analog, $Q_4PRu^{III}(H_2O)W_{11}O_{39}$, would seem to indicate some structural change in the polyoxometalate. There was also a clear change in the ^{31}P NMR spectrum. The original compound has a very broad peak at −70 ppm [15] whereas, after treatment, a new, narrower peak at 268 ppm ($\Delta\nu_{1/2}$ = 120 Hz) is formed. In addition, to the change in the IR and ^{31}P NMR spectra, heating of $Q_4PRu^{III}(H_2O)W_{11}O_{39}$ was also coupled with the formation of a black precipitate which was insoluble in a wide range of polar and apolar solvents. We have no certain explanation of which change has occurred, but the formation of a dimeric μ-oxo bridged species followed by precipitation of RuO_2 is a very distinct possibility [20]. Unfortunately, our hypothesis concerning the identity of the new ruthenium tungstate could not be verified due to our inability to obtain single crystals of sufficient quality. This speculation is also supported by the catalytic inertness of the tungsten compound *versus* the active molybdate (see below) [10]. Another puzzling point to explain concerns the reasoning behind the different reactivity of the molybdate and tungstate with molecular oxygen. The IR spectra of the original compounds (see above) indicate that the ruthenium is more tightly bound in the molybdate *versus* tungstate, as borne out by the smaller split in the vibrations atttributed to the P–O stretch. In the one case where a dimeric compound with a Ru^{IV}–O–Ru^{IV} bridge has been isolated [20], the bridge is placed over rather than in the lacunary position. It is possible but of course not certain that the more labile structure *vis a vis* the ruthenium position in the tungsten *versus* molybdenum compound may lead to a more facile formation of the bridged compound and ruthenium removal from the lacunary site of the tungstate.

Catalytic oxidation

In our previous communication, we reported that in a reaction according to Scheme 1 (1 M cumene, 1 M 1-octene, 1 mM $Q_4PRu^{III}(H_2O)M_{11}O_{39}$ (M = Mo, W)

in CH_3CN 1 atm O_2, 80°C, 24 h), the tungstate showed essentially no reactivity, whereas the molybdate, ~100 turnovers, gave ~1:1 ratio of 1-octene oxide/cumyl alcohol and only traces of acetophenone [10]. For the tungstate compound, the formation of an inert compound is postulated as mentioned and discussed above. For the molybdenum compound, there was a clear balance in the rate of formation of the intermediate cumene hydroperoxide and the oxygen transfer reaction from the intermediate to the alkene. An induction period of three to four hours was typically observed for these reactions. The ratio of cumene/1-octene (Fig. 6) was a critical parameter for determining the activity and selectivity in the $Q_4PRu^{III}(H_2O)Mo_{11}O_{39}$ catalyzed reaction. As the amount of cumene was increased, the turnover frequency to cumene hydroperoxide decomposition products (acetophenone and cumyl alcohol in excess of the amount of 1-octene oxide formed) increased significantly, whereas the amount of 1-octene oxide formed, (~100 turnovers) remained more or less constant. This shows that increased amounts of cumene had no positive effect on the rate of epoxide formation in the oxygen transfer reaction but, rather simply, was 'wasted' in the formation of decomposition products. The effect of $Q_4PRu^{III}(H_2O)Mo_{11}O_{39}$/substrate ratio on the conversions and selectivities is presented in Fig. 7 (ratio cumene/1-octene = 1). Here, one may observe that high catalyst loading *inhibited* the reaction. At $Q_4PRu^{III}(H_2O)Mo_{11}O_{39}$/substrate ratios up to 1/1500, there was an excellent selectivity to 1-octene oxide. As the solution became more dilute in catalyst and the $Q_4PRu^{III}(H_2O)Mo_{11}O_{39}$/substrate ratios decreased, there was a loss of activity in parallel with loss of selectivity for formation of the epoxide.

The results of the catalytic reaction are most easily explained via a combination of the classical [21] low valent metal (Ru^{III}) catalyzed autooxidation mechanism together with the heterolytic oxygen transfer mechanism at the high valent metal (Mo^{VI}), see

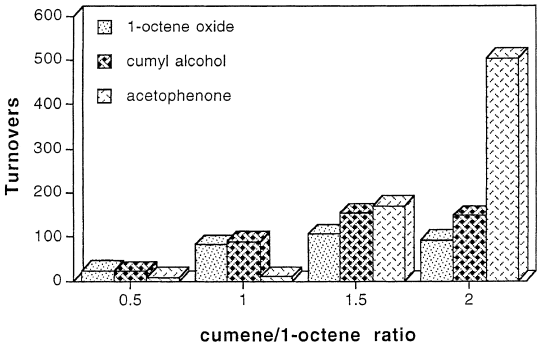

Fig. 6. Catalytic activity of $Q_4PRu^{III}(H_2O)Mo_{11}O_{39}$ as a function of the amount of cumene and 1-octene. Reaction conditions: 0.5–2.0 mmol cumene, 1 mmol 1-octene, 1 μmol $Q_4PRu^{III}(H_2O)Mo_{11}O_{39}$, 1 mL acetonitrile, 1 atm O_2, 80°C, 24 h.

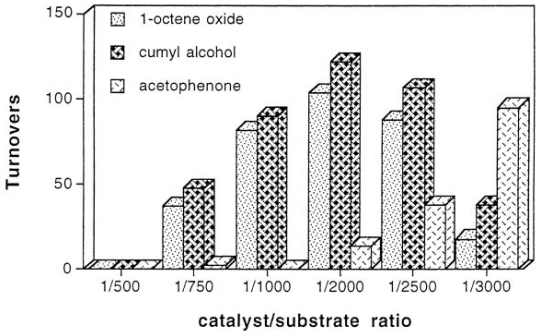

Fig. 7. The effect of the amount of $Q_4PRu^{III}(H_2O)Mo_{11}O_{39}$ on activity and selectivity. Reaction conditions: 1 mmol cumene, 1 mmol 1-octene, 0.33–2 μmol $Q_4PRu^{III}(H_2O)Mo_{11}O_{39}$, 1 mL acetonitrile, 1 atm O_2, 80°C, 24 h.

Scheme 2 [22]. First, the catalyst (Ru) initiates a chain reaction for the formation of cumene hydroperoxide. The intermediate alkyl hydroperoxo or peroxo species react with the molybdenum based polyoxometalate ligand to form an active Mo–O–O-alkyl species which transfers oxygen to the alkene to form epoxide and alcohol. When the catalyst loading is high the intermediate cumene peroxide is shunted by the catalyst from the propagation (autooxidation) reaction, leading to low turnover numbers and apparent reaction inhibition. Such phenomena have been observed in the past for transition metal substituted polyoxometalate catalyzed reactions [23]. When the amount of cumene is too high or the amount of catalyst is too low, the propagation of the cumene peroxide and hydroperoxide, independent of the catalyst, becomes the major reaction pathway. This then leads to excess autoxidation products, especially acetophenone via decomposition of the cumyl oxo radical [24].

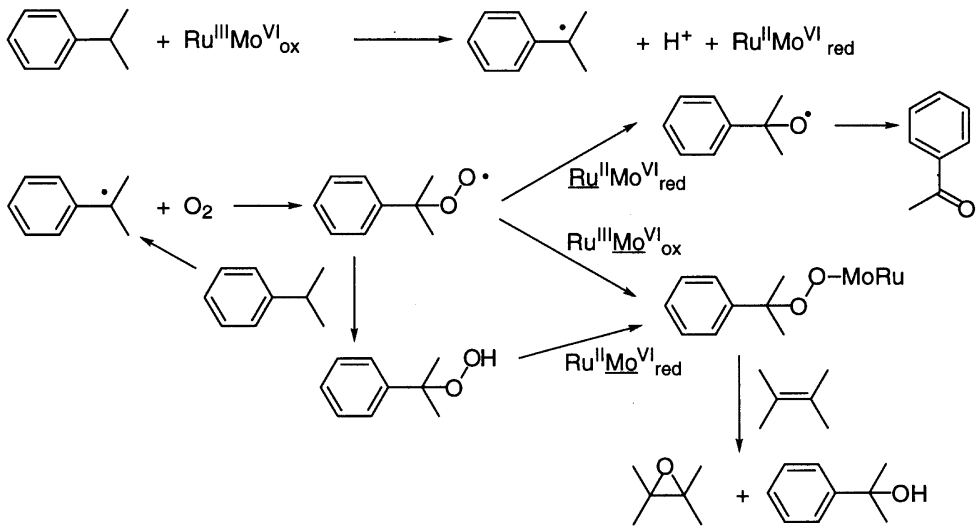
CONCLUSION

A ruthenium substituted polyoxomolybdate, $Q_4PRu^{III}(H_2O)Mo_{11}O_{39}$, of the Keggin structure has been prepared and characterized. The compound is an effective bifunctional catalyst for the co-oxidation of cumene and 1-octene, in contrast to the analogous tungsten compound which undergoes, in the presence of molecular oxygen, an apparent structural change to an inert form.

EXPERIMENTAL PART

Materials and polyoxometalate synthesis

Organic substrates of highest available purity (Aldrich and Fluka) were purified prior to use by passing the compound over a neutral alumina column. The known polyoxometalates, $n-(C_4H_9)_4N]_4PRu^{III}(H_2O)W_{11}O_{39}^{15}$ and $[n\text{-}(C_4H_9)_4N]_4HPM(H_2O)Mo_{11}O_{39}$,



M = Mn (II), and Co(II) were prepared by the published literature procedures. Similarly, $[n\text{-}(C_4H_9)_4N]_4PRu^{III}(H_2O)Mo_{11}O_{39}$ was prepared by dissolving 0.30 mmol (800 mg) $[n-(C_4H_9)_4N]_4H_3PMo_{11}O_{39}$ [13] in 15 mL acetonitrile to form a light green solution followed by addition of 0.31 mmol (65 mg) solid $RuCl_3 \times H_2O$. After stirring for two hours under argon at room temperature, a few drops of water were added, air was passed through the solution for one hour and the solvent was evaporated. It may be noted that the insertion reaction failed when an aqueous solution of $RuCl_3 \times H_2O$ was used. The dark green ruthenium substituted polyoxomolybdate, $[n\text{-}(C_4H_9)_4N]_4PRu^{III}(H_2O)Mo_{11}O_{39}$ was recrystallized from 3 mL acetonitrile, yield 78%. Carbon, hydrogen, nitrogen and phosphorous were determined by microanalysis, ruthenium as RuO_2 and molybdenum as the 8-hydroxy quinolate were determined gravimetrically after decomposition with 1 M NaOH. Analysis: found (calculated) C 28.12 (27.46); H 5.57 (5.26); N 2.35 (2.00); P 1.00 (1.11); Ru 3.3 (3.61); Mo 36.93 (37.70). ^{31}P NMR -105 ppm ($\Delta\nu_{1/2} = 1500$ Hz). IR 1061, 1038, 952, 936, 878, 813 cm^{-1}

In an analogous procedure, $[n\text{-}(C_4H_9)_4N]_4PRu^{III}(DMSO)Mo_{11}O_{39}$ was prepared by reacting 0.30 mmol (800 mg) $[n\text{-}(C_4H_9)_4N]_4H_3PMo_{11}O_{39}$ in 15 mL with 0.31 mmol (130 mg) solid $Ru^{II}(DMSO)_4Cl_2$ [25]. After removal of the solvent overnight under vacuum, the product was recrystallized from 3 mL acetonitrile, yield 48%. Analysis: found (calculated) C 28.58 (27.72); H 5.65 (5.29); N 2.55 (1.96); P 1.00 (1.08); Ru 3.3 (3.53); Mo 38.45 (36.91). IR 1098, 1021, 933, 884, 806, 737 cm^{-1}.

Instruments and polyoxometalate characterization

UV–vis spectra were measured using a diode array spectrometer (HP 8452) using 1 cm quartz cuvettes. Solutions, 20 μM, were prepared by dissolving $Q_4PRu^{III}(L)Mo_{11}O_{39}$ ($Q = n\text{-}(C_4H_9)_4N$, $L = H_2O$, DMSO) in acetonitrile. IR spectra were measured on a Nicolet 510 M FTIR instrument. Spectra were measured neat by placing a few drops of the polyoxometalate dissolved in acetonitrile on a KBr plate. The acetonitrile was evaporated off and the spectra were measured. ^{31}P NMR spectra were measured using a Bruker DRX-400 instrument at 161.976 MHz with 85% D_3PO_4 as external standard. Approximately 10 mM solutions were prepared in 80% CH_3CN, 20% $CDCl_3$. A cyclic voltammogram of 5 mM $Q_4PRu^{III}(H_20)Mo_{11}O_{39}$ was measured using a BAS-1 instrument in a 0.1 M solution of $n\text{-}(C_4H_9)_4NBF_4$ in acetonitrile using a glassy-carbon working electrode, an $Ag/AgNO_3$ reference electrode and a platinum auxiliary electrode; scan rate 300 mV/sec. Potentials were referenced to the ferrocene/ferrocenium couple (-0.22 V).

Epoxidation of alkenes

The epoxidation of alkenes were carried out in $\sim$13 mL pressure tubes (Ace Glass). In a typical procedure, 1.0 mmol 1-octene, 1.0 mmol cumene and 1.0 μmol $[n\text{-}(C_4H_9)_4N]_4PRu^{III}(H_2O)Mo_{11}O_{39}$, dissolved in 1 mL acetonitrile, were placed in the glass tube with a teflon stirrer. Dioxygen, >99% purity, was introduced to the reaction at 80°C and 1 atm dioxygen after a series of three pump–thaw operations. The tubes were immersed in a temperature controlled oil bath equipped with a magnetic stirrer. Samples of the reaction mixture were taken at the desired time intervals and directly injected into a gas chromatograph (HP 5890, FID detector, He carrier gas) fitted with a capillary methyl silicone bonded phase column (RTX 1, length 15 m, ID 0.32 mm, coating thickness 0.25 μm).

Acknowledgements—This research was supported by the Israel Science Foundation founded by the Israel Academy of Science and Humanities. Professor Michael T. Pope of Georgetown University is kindly thanked for his sample of $Q_4PRu^{III}(H_2O)W_{11}O_{39}$.

Abstract—One dinuclear $[Mn_2(hfac)_4(\mu\text{-pyz})(H_2O)_2]2H_2O$ (**1**) and three mononuclear complexes $[Mn(hfac)_2(pym)(H_2O)]$ (2), $[Mn(hfac)_2(pydz)_2]$ (3), and $[Mn(hfac)_2(mpydz)_2]$ (**4**) (Hhfac = 1,1,1,5,5,5-hexafluoropentane-2,4-dione, pyz = pyrazine, pym = pyrimidine, pydz = pyridazine, and mpydz = 3-methylpyridazine) have been synthesized and their crystal structures and cryomagnetic properties have been investigated. Complex **1** has a centrosymmetric dinuclear structure with two adjacent manganese atoms linked by a pyz ligand. The geometry about each manganese atom is distorted octahedral with NO_5 coordination sphere. The structure of complex **2** is a mononuclear manganese complex with a distorted octahedral geometry of NO_5 coordination sphere. The crystal structures of complexes **3** and **4** consist of mononuclear manganese complex with the *cis*-N_2O_4 six-coordination sphere. The temperature dependence of magnetic data for **1** revealed a dinuclear spin ($S_1 = S_2 = 5/2$) weak antiferromagnetic exchange interaction with $J = -0.47\,cm^{-1}$. Complexes **2**–**4** play a cryomagnetic behaviour followed the Curie–Weiss law. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: crystal structure; magnetic properties; manganese complexes; binuclear complexes; diazine complexes.

INTRODUCTION

The coordination chemistry of manganese has achieved remarkable progress in the past decade due to the increased recognition of this metal's role in the biological system involved in the oxygen-evolving complexes of photosystem II of green plants [1, 2] and catalases [1, 3, 4].

A number of manganese-containing, non-haem catalases have, in recent years, been isolated and characterized [3, 4]. This important class of metalloprotein catalyses the disproportionation of hydrogen peroxide to dioxygen and water very efficiently. Recently, some studies have been achieved in the preparation of a number of functional, non-haem catalase mimics of the model manganese complexes [5, 6].

As part of our continuing studies into the magneto-structural correlation of manganese(II) complexes with 2,2′-dipyrimidine (bpym) [7], very recently, we have prepared three complexes of bis(2,4-pentanedionate)manganese(II) with diazine ligands and these complexes exhibited high catalytic activity for H_2O_2 disproportionation [8]. Heterocyclic diazines, such as pyrazine, pyrimidine and pyridazine, are known to be an excellent bidentate ligand when coordinated to metal ions [9]. In our laboratory, we have continually prepared four new bis(1,1,1,5,5,5-hexafluoropentane-2,4-dionate)manganese(II) complexes with diazines: $[Mn_2(hfac)_4(\mu\text{-pyz})(H_2O)_2]2H_2O$ (**1**), $[Mn(hfac)_2(pym)(H_2O)]$ (**2**), $[Mn(hfac)_2(pydz)_2]$ (**3**) and $[Mn(hfac)_2(mpydz)_2]$ (**4**) (pyz = pyrazine, pym =

pyrimidine, pydz = pyridazine, and mpydz = 3-methylpyridazine) (Scheme 1). Here, we reported on the synthesis, X-ray crystal structure and cryomagnetic properties.

EXPERIMENTAL

2.1. *Preparation of compounds*

Bis(1,1,1,5,5,5-hexafluoropentane-2,4-dionate)manganese(II) dihydrate, $Mn(hfac)_2 \cdot 2H_2O$, was prepared from the metal acetate by the literature procedures [10]. Pyrazine (pyz), pyrimidine (pym), pyridazine (pydz) and 3-methylpyridazine (mpydz) were purchased from a commercial source (Aldrich Chemical Co.) and used without further purification.

$[Mn_2(hfac)_4(\mu\text{-pyz})(H_2O)_2]2H_2O$ (**1**), $[Mn(hfac)_2(pym)(H_2O)]$ (**2**), $[Mn(hfac)_2(pydz)_2]$ (**3**) and $[Mn(hfac)_2(mpydz)_2]$ (**4**) were synthesized by mixing the absolute ethanol solutions of an equimolar quantity of the complex $Mn(hfac)_2 2H_2O$ and the diazines. The solutions were allowed to stand for a few days, orange–yellow crystals of **1** (75% yield), light-yellow crystals of **2** (85% yield), **3** (75% yield) and **4** (80% yield) were filtered off, air dried and characterized initially by elemental analysis and then by single-crystal X-ray diffractional analysis. Physical measurements

IR spectra were recorded on a Bio-Rad FTS40-FTIR spectrophotometer as KBr pellets in the 4000–400 cm^{-1} region. X-band EPR spectra at 25°C for the complexes in powder were recorded on a Bruker ESC-106 spectrometer. Temperature dependence of magnetic susceptibilities of the polycrystalline samples were measured between 4 and 300 K at field 1 T, using a Quantum Design Model MPMS computer-controlled SQUID magnetometer. Corrections for the diamagnetism of the complexes were estimated from Pascal's constants [11].

Crystal structure determination

Crystallographic data for complexes **1**–**4** were collected on an Enraf–Nonius CAD-4 diffractometer with graphite-monochromatized Mo–K_α radiation ($\lambda = 0.7107$ Å) at 25°C. Crystallographic parameters and pertinent refinement results are summarized in Tables 1 and 2. The structures were solved by the heavy-atom method using a Patterson map and refined by a full-matrix least-squares method based on *F*, using the NRCVAX software package [12]; the function minimized was $\Sigma w(|F_o| - |F_c|)^2$ with $w = 1/\sigma^2(F_o)$ and unit weights were used. All non-hydrogen atoms were readily located and refined with anisotropic thermal parameters.

RESULTS AND DISCUSSION

3.1. *Crystal structures of complexes **1**–**4***

Perspective views with the atomic numbering of complexes **1, 2, 3**, and **4** are shown in Figs 1–4, respectively. The selected bond distances and angles relevant to manganese coordination spheres are given in Tables 3–6.

Complex **1** has a centrosymmetric dinuclear structure and two adjacent manganese atoms, 5.968(4) Å apart, are linked by a pyz bridging ligand. This intermetallic separation is expected for a weak intramolecular antiferromagnetic exchange interaction between two Mn(II) atoms. The geometry about each manganese atom is distorted octahedral with NO_5 coordination sphere. The axial positions are filled with the nitrogen atom of the bridging pyz ligand and the oxygen atom [O(5)] of the water molecule, while the four equatorial positions are occupied by four oxygens [O(4),O(2),O(3),O(4)] from the bidentate hfac ligands. It is notable that F(10), F(11) and F(12) of the CF_3 group of the hfac ligand are rotationally disordered about the C(11)–C(12) bond.

The average Mn–O [2.115 Å] bond distances of Mn–O(1), Mn–O(2), Mn–O(3) and Mn–O(4) are somewhat shorter than those of Mn–O(5) [2.172(7) Å] and Mn–N [2.332(8) Å] Table 2. The bond angles of N–Mn–O(1) [91.46(25)°] and N–Mn–O(4) [95.2(3)°] are larger than those of N–Mn–O(2) [89.63(25)°] and N–Mn–O(3) [89.71(25)°]. Furthermore, the resultant bond angle of the axial N–Mn–O(5) [172.6(3)°] deviated from 180°.

The structure of **2** is a mononuclear manganese(II) complex with a distorted octahedral geometry of NO_5 coordination sphere. The manganese coordination sphere consists of two chelating hfac ligands, one monodentate pym ligand and one water molecule. The axial positions are occupied by nitrogen [N(1)] of the pym and oxygen [O(5)] of the water molecule, and the four equatorial positions are occupied by oxygen atoms from the bidentate hfac ligands that form a tetragonal plane. The in-plane equatorial average Mn–O bond distances of 2.139 Å are somewhat shorter than the axial Mn–O(5) [2.214(3) Å] and Mn–N(5) [2.285(3) Å] bond distances.

The crystal structure of **3** consists of the neutral $[Mn(hfac)_2(pydz)_2]$ units. The complex has an approxi-

Table 6. Selected bond distances (Å) and angles (°) for **4**

Mn–N(1)	2.233(7)	Mn–N(3)	2.247(7)
Mn–O(1)	2.145(3)	Mn–O(2)	2.177(6)
Mn–O(3)	2.137(5)	Mn–O(4)	2.174(5)
N(1)–Mn–O(2)	166.33(24)	N(3)–Mn–O(4)	167.14(23)
O(1)–Mn–O(3)	170.38(52)	O(1)–Mn–O(2)	80.97(21)
O(3)–Mn–O(4)	81.58(21)	N(1)–Mn–O(3)	102.3(3)
N(3)–Mn–O(1)	98.60(25)	N(1)–Mn–O(4)	86.04(24)
N(3)–Mn–N(1)	87.13(24)	N(3)–Mn–O(3)	86.77(24)
O(1)–Mn–O(1)	85.90(25)	N(1)–Mn–N(3)	91.1(3)
Mn–N(1)–N(2)	109.4(5)	Mn–N(1)–C(1)	130.9(6)
Mn–N(3)–N(4)	110.4(5)	Mn–N(3)–C(6)	128.9(6)

mate C_2 axis of symmetry. The coordination geometry of Mn belongs to the six-coordination type by virtue of two bidentate hfac and two pydz ligands, in which two pydz ligands are of *cis* arrangement. The three oxygens [O(2),O(3),O(4)] from the hfac and one nitrogen [N(1)] from the pydz ligand are approximately coplanar and the atoms of nitrogen [N(3)] of pydz and oxygen [O(2)] lie on an axial perpendicular to this plane. The bond distances of Mn–O(2) [2.188(4) Å] and Mn–O(4) [2.195(4) Å] show longer lengths than those of Mn–O(1) [2.130(4) Å] and Mn–O(3) [2.118(4) Å]. Both of the Mn–O(2) and Mn–O(4) bonds are *trans* to the two pydz basic ligands, are lengthened compared with the others of Mn–O(1) and Mn–O(3) bonds due to a *trans* effect of the pydz ligands. The bond angles of O(1)–Mn–O(3) [175.65(17)°] are somewhat larger than those of O(2)–Mn–N(3) [171.78(17)°] and O(4)–Mn–N(1) [168.74(17)°]. Furthermore, The bond angles of Mn–N(1)–N(2) [121.8(4)°], Mn–N(1)–C(11) [122.1(4)°], Mn–N(3)–N(4) [122.0(4)°] and Mn–N(3)–C(15) [122.5(4)°] are similar and normal [13].

The crystal structure of **4** is also a mononuclear manganese(II) complex. The coordination geometry of Mn also belongs to the N_2O_4 distorted octahedral type, being similar to that of Mn in complex **3**. The two pydz molecules are coordinated by the less hindered 1-nitrogen atoms [N(1) and N(3)]. Mn–O(2) [2.177(6) Å] and Mn–O(4) [2.174(5) Å] bonds show longer lengths than Mn–O(4) [2.145(5) Å] and Mn–O(3) [2.137(5) Å] as well as in complex **3**, these elongations are also due to a *trans* effect of the mpydz ligands. The bond angles of Mn–N(1)–N(2) [109.4(5)°] and Mn–N(3)–N(4) [110.4(5)°] are smaller than those of Mn–N(1)–C(1) [130.9(6)°] and Mn–N(3)–C(6) [128.9(6)°]. These different angles are probably due to the substantial steric interactions between the methyl groups of mpydz and the trifluoromethyl groups of hfac ligands. The resultant bond angles of O(2)–Mn–N(1) and O(4)–Mn–N(3) are 166.33(24)° and 167.14(23)°, respectively. Comparison of the Mn–N(1) and Mn–N(3) bond distances for **4** and **3** give 2.233(7) *vs.* 2.270(7) Å and 2.247(7) *vs.* 2.258(5) Å. This may result from the rather higher basicity of the mpydz than the pydz ligand.

EPR spectra and cryomagnetic properties

The powder X-band EPR spectra (9.80 GHz) at 300 K of complexes **1** and **2** display *ca* 0.062 and 0.095 T, respectively, symmetric broad resonance absorptions with the same g value of 2.02. Whereas, at 300 K, the EPR spectra, without discernible hyperfine structure of ^{55}Mn, for **3** and **4** are observed with resonances at g: 5.4 (w), 3.18 (w), 2.03 (s) and 1.42 (w) for **3**; 6.7 (w), 2.70 (w), 1.96 (s) and 1.47 (w) for **4**. These data thus indicate that, in complexes **3** and **4**, and even in complexes **1** and **2**, there exist weak magnetic interactions or zero-field splitting interactions (D). Although the low temperature EPR spectrum for the present complexes has not been determined, in our case however, for octahedral high-spin Mn(II), due to its smaller Jahn–Teller effect, in general, the values of D for the present species are of the order of $10^{-2}\,cm^{-1}$ [14, 15].

The cryomagnetic behavior of complex **1** represented by the plots of molar magnetic susceptibility, χ_m and $\chi_m T$ *vs.* T is depicted in Fig. 5. At 300 K, $\chi_m T = 8.15\,cm^3\,K mol^{-1}$, a value somewhat smaller than expected for two uncoupled manganese(II) ions; $\chi_m T$ slowly decreases upon cooling and reaches a value of $7.34\,cm^3\,K mol^{-1}$ at 4 K. Such a behavior is characteristic of a weak antiferromagnetic interaction between two high-spin manganese(II) ions. We have attempted to reproduce theoretically the experimental magnetic data of dinuclear complex **1** by use of the temperature-dependent magnetic susceptibility expression eq. (1) [16],

$$\chi_m = (2Ng^2\mu_B/kT)(A/B), \qquad (1)$$

based on the isotropic Heisenberg model ($H = -2JS_1S_2$), without intermolecular interaction and the Mn(II) single-ion zero-field considerations, coupling for $S_1 = S_2 = 5/2$, where $A = x^{28} + 5x^{24} + 14x^{18} + 30x^{10} + 55$, $B = x^{30} + 3x^{28} + 5x^{24} + 7x^{18} + 9x^{10} +$

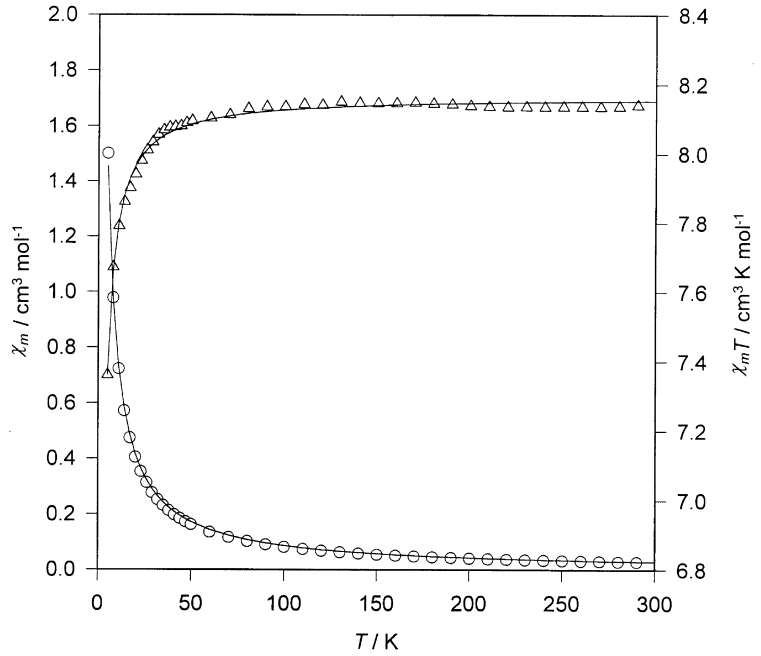

Fig. 5. Plots of χ_m (○) and $\chi_m T$ (△) *vs.* T for $[Mn_2(hfac)_4(pyz)(H_2O)_2]2H_2O$ **1**. The solid line is the fit provided by equation (1) (see text).

11 and $x = \exp(-J/kT)$; the other symbols have their usual meanings. The temperature-independent paramagnetics for Mn(II) are assumed to be zero. Values of $-0.47\,cm^{-1}$ and 2.02 were obtained for J and g, respectively. The best data fits, as shown in Fig. 5 (the solid lines), display that a satisfactory match to the experimental data is achieved. Consequently, the weak antiferromagnetic coupling J for **1** most likely accounts for the longer metal–metal separation (5.97 Å) through the bridged pyrazine ligand.

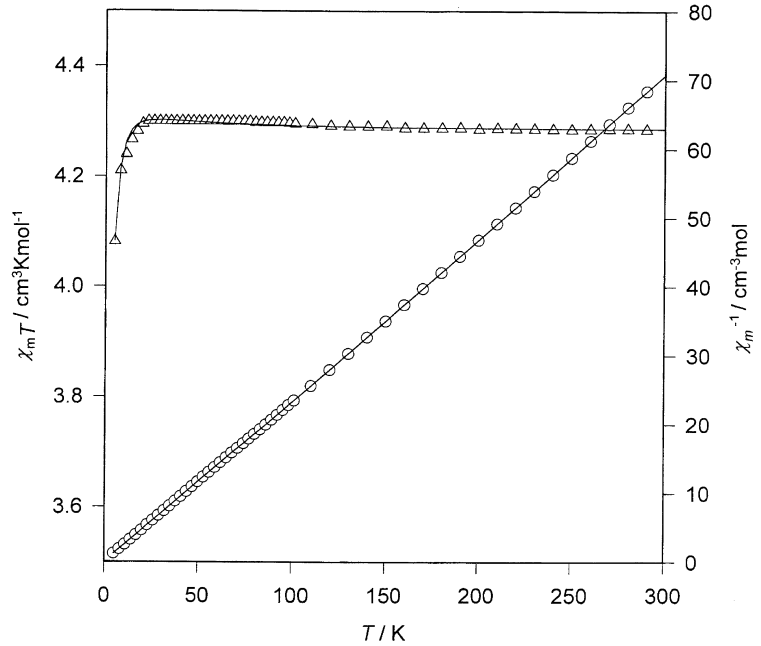

Fig. 6. Plots of χ_m^{-1} (○) and $\chi_m T$ (△) *vs.* T for $[Mn(hfac)_2(pydz)_2]$ **3**. The solid line is the fit provided by equation (2) (see text).

Magnetic susceptibility measurements for mononuclear complexes **2**–**4** were made on powder samples in the temperature range 4–300 K. The values of $\chi_m T$ at 300 K are in the range 4.30–4.38 $cm^3 Kmol^{-1}$ and are close to the spin-only value (4.377 $cm^3 Kmol^{-1}$) of the high-spin Mn(II) ion. The χ_m^{-1} and $\chi_m T$ *vs.* T plots for **2**–**4** show a typical behavior for the paramagnetic species which obey the Curie–Weiss law. The presentative plots of χ_m^{-1} and $\chi_m T$ *vs.* T for complex **3**, as shown in Fig. 6 and the $\chi_m T$ values decrease as the temperature below *ca* 15 K. The drop in $\chi_m T$ below 15 K may be the result of an intermolecular antiferromagnetic interaction or zero-field splitting (D) of the spin multiples [14–16]. Since the inverse susceptibility plots are linear as a function of temperature for complexes **2**–**4**, the Curie–Weiss law eq. (2), without zero-field splitting consideration, was used in the preliminary fits of the data.

$$\chi_m = Ng^2\mu_B S(S+1)/3k(T-\theta) \qquad (2)$$

The solid lines in Fig. 6 for complex **3** are the fit of the data to the susceptibility eq. (2), using the parameters $g=2.01$, and $\theta=-1.05$ K. Similarly, the cryomagnetic properties of **2** and **4** are also well reproduced by eq. (2). The best-fitting magnetic parameters are $g=2.0$ with $\theta=-1.25$ K for **2** and $g=2.02$ with $\theta=-1.45$ K for **4**. The molecular field exchange constant, J', may be calculated from $\theta=zJ'S(S+1)/3k$ [17] and z is the number of the nearest neighbours. The values obtained for zJ' in this manner are -0.25, -0.30 and $-0.34\,cm^{-1}$ for **2**, **3** and **4**, respectively. These zJ' values indicate the existence of very weak intermolecular antiferromagnetic interactions in complexes **2**–**4**.

Copper(II) and zinc(II) complexes of N,N-bis(benzimidazole-2-ylmethyl)-amine. Synthesis, formation constants and the crystal structure of $[ZnLCl]_2$]. MeOH. Catalytic activity of the complexes in the hydrolysis of the phosphotriester 2,4-dinitrophenyl diethyl phosphate

Robert W. Hay,* Thomas Clifford and Philip Lightfoot

School of Chemistry, University of St Andrews, St Andrews, KY16 9ST, U.K.

(Received 24 February 1998; accepted 17 April 1998)

Abstract—The copper(II) and zinc(II) complexes of N,N-bis(benzimidazole-2-ylmethyl)amine (L) have been prepared and the crystal structure of $[ZnLCl_2]$. MeOH determined. The complex is five-coordinate with a distorted square pyramidal geometry on zinc. Two pyridine nitrogen donors from the imidazole groups, the secondary amino group and one chloride act as in-plane donors with the axial site occupied by chloride. The zinc(II) lies some 0.65 Å above the basal plane. The stepwise protonation constants of the ligand have been obtained, $\log K_{11} = 5.638(3)$ and $\log K_{12} = 10.12(1)$ and the stability constants ($\log \beta_{1mh}$) for the copper(II) and zinc(II) complexes determined using 50% MeOH–H_2O as solvent. The hydroxoaqua complexes $[ML(OH)(OH_2)]^+$ show only slight catalytic activity in the hydrolysis of the phosphotriester 2,4-dinitrophenyl diethyl phosphate. © 1998 Elsevier Science Ltd. Keywords: benzimidazole ligand; crystal structure; copper(II); zinc(II); catalytic activity; phosphotriester.

Currently there is considerable interest in the use of benzimidazole complexes to model the active site of a variety of metalloenzymes such as carbonic anhydrase and carboxypeptidase. Ligands incorporating benzimidazole are useful in the preparation of model complexes as they relate to the biologically important imidazole group found in histidine [1]. Fenton and coworkers [1–3] have previously described the complexing properties of the two ligands bis(benzimidazole-2ylmethyl)amine ($1 = L$) and bis(benzimidazole-y2ylmethyl)methylamine ($2 = L'$) towards the first row transition metals Mn(II) and Fe(III).

The benzimidazole complex (3) has been found to be active in the transesterification of 2-hydroxypropyl-4-nitrophenyl phosphate ($hpnp = 4$) [4] which has been used as a model for RNA [5]. The complex (3) was shown to be much more active towards phosphodiesters than the catalysts (5) and (6) which form inactive dihydroxo-bridged dimers as the concentration is increased. It has been suggested that the steric bulk of the benzene rings in (3) prevents the formation of the dihydroxo-bridged dimer but allows the formation of the monohydroxo-bridged complex (7) which is catalytically active.

In the present paper we describe the characterisation of the copper(II) and zinc(II) complexes of ($1 = L$) and the crystal structure of $[ZnLCl_2]$MeOH. Formation constants for the copper(II) and zinc(II) complexes have been determined and their potential as catalysts for the hydrolysis of the phosphotriester 2,4-dinitrophenyl diethyl phosphate (8) assessed.

EXPERIMENTAL

Synthesis

N,N-bis(benzimidazole-2-ylmethyl)amine.3HCl (*L.3HCl*). The ligand was prepared essentially as described by Berend and Stephen [6]. Iminodiacetic acid (108.1 g, 1 mol) and *o*-phenylenediamine (108 g, 1.2 mol) were refluxed in 6 mol dm^{-3} hydrochloric acid for 72 hours. On cooling a blue powder formed which was filtered off, washed with acetone and recrystallised from 40–60 (v/v) water-acetone (yield 62 g, 16%).

N,N-bis(benzimidazole-2-ylmethyl)amine hydrate (*L.H_2O*). The hydrochloride salt prepared above (5.72 g, 14.8 mmol) was dissolved in water (100 cm^3) and sodium hydrogen carbonate (3.73 g, 44.5 mmol) added in portions to give a pale lilac precipitate. The precipitate was filtered off then refluxed with methanol containing active charcoal for 2 hr and filtered hot. Pale mauve needles crystallised on standing and were filtered off and dried (yield 3.95 g, 81%). Found: C, 65.0; H, 6.05; N, 23.8. Calc. for $C_{16}H_{17}N_5O$: C, 65.1; H, 5.8; N, 23.7%. IR 3433 (*v* OH), 3224, 3206 (*v* imidNH), 3052 (*sec* NH). ^{13}C NMR 157, 141.3, 126, 118, 50 ppm.

N,N-bis(benzimidazole-2-ylmethyl)amine dihydrochloride (*L.2HCl*). The amine (2.71 g, 9.2 mmol) was dissolved in hot methanol (50 cm^3) and conc. HCl added dropwise. The white precipitate which formed was immediately filtered off, washed with ethanol then ether and dried in *vacuo* (yield 2.51 g, 78%). Found: C, 54.9; H, 4.8; N, 20.0. Calc. for $C_{16}H_{17}N_5Cl_2$: C, 54.9; H, 4.9; N, 20.0%. Titration studies confirmed

that the halide salt is diprotonated and not triprotonated. The dihydrobromide salt was prepared in a similar manner using conc. HBr. Found: C, 43.8; H, 4.3; N, 15.9. Calc. for $C_{16}H_{17}N_5Br_2$: C, 43.9; H, 3.9; N, 15.95%.

[*CuLCl*$_2$].*MeOH*. The ligand (0.5 g, 1.8 mmol) in methanol (50 cm^3) was added to a hot solution of copper(II) chloride dihydrate (0.5 g, 1.8 mmol) in methanol (20 cm^3) to give a blue-green solution. On standing the blue complex crystallised and was filtered off, washed with ethanol and dried in *vacuo*. Found: C, 46.1; H, 4.2; N, 16.3. Calc. for $C_{17}H_{19}N_5OCuCl_2$: C, 46.4; H, 4.9; N, 15.7%. IR ν OH 3373(br) cm^{-1}. The complex has λ_{max} 684 nm in water ($\epsilon = 97$) with $\Lambda_M = 221$ S cm^2 mol^{-1} in aqueous solution.

[*ZnLCl*$_2$].*EtOH*. The ligand (2.5 g, 8.5 mmol) in ethanol (50 cm^3) was added rapidly to a hot solution of zinc(II) chloride (1.23 g, 4.2 mmol) in ethanol (20 cm^3). On standing colourless plates formed which were filtered off, washed with ethanol and dried in *vacuo*. Found: C, 47.0; H, 4.4; N, 15.2. Calc. for $C_{18}H_{22}N_5OZnCl_2$: C, 47.0; H, 4.6; N, 15.2%. IR ν OH 3370 cm^{-1}. The complex has $\Lambda_M = 213$ S cm^2 mol^{-1} in aqueous solution. Colourless crystals suitable for X-ray diffraction were grown by vapour diffusion of diethyl ether into a solution of the complex in methanol-water.

Crystal data

$C_{17}H_{19}N_5ZnCl_2O$, $M = 445.66$, primitive orthorhombic $a = 14.642(1)$, $b = 18.357(2)$, $c = 13.962(4)$ Å, $U = 3752.8(9)$ Å^3 (by least square refinement on diffractometer angles for 25 automatically centred reflections in the range $32.17 < 2\theta < 34.77^\circ$, $\lambda = 0.71069$ Å, space group Pbca (No. 61), $Z = 8$, $D_c = 1.577$ g cm^{-3}, $F(000) = 1824$. Pale block crystal approximate crystal dimensions $0.50 \times 0.40 \times 0.30$ mm, μ(Mo–K$_\alpha$) = 16.10 cm^{-1}.

Data collection and processing

Rigaku AFC7S diffractometer, ω-2θ scan type with ω scan width $= (1.47 + 0.35\tan\theta)^\circ$, ω scan width 16.00° min^{-1} (up to 4 scans), graphite monochromated MoK$_\alpha$ radiation, 3724 reflections measured (max $2\theta = 50^\circ$), 3718 unique ($R_{int} = 0.74$). No decay correction or absorption correction was required. Corrections were made for Lorentz and polarisation effects.

Structure analysis and refinement

Direct methods were employed [7] and expanded using Fourier techniques [8]. Non-hydrogen atoms were refined anisotropically, hydrogens were included but not refined. The final cycle of full matrix least squares refinement was based on 2245 observed reflections ($I > 3.00\sigma(I)$) and 235 variable parameters and converged with agreement factors of $R = 0.036$ and $R_w = 0.034$. The goodness-of-fit was 2.17. The maximum and minimum peaks on the final difference Fourier map correspond to 0.45 and -0.41 e$^-$ Å^{-3} respectively. The secondary nitrogen atom N1 was initially refined anisotropically, but after finding large anisotropy perpendicular to the plane of the complex at this position, the model was replaced by one with the nitrogen occupying two positions (designated N1 and N6). All calculations were carried out using the TEXSAN [9] crystallographic software package of the Molecular Structure Corporation.

Potentiometric titrations

Potentiometric measurements and the computation of the protonation and stability constants were carried out by procedures which have been described in detail [10]. Solutions were made up with 50 weight percent aqueous methanol and the ionic strength was adjusted to 0.1 mol dm^{-3} with KNO_3. The concentrations of the components in the titrations are summarised in Table 1. The potentiometric results were processed using SUPERQUAD [11] and the stability constants are expressed in the form β_{1mh}. The glass electrode was calibrated and checked for linearity with borax and potassium hydrogen phthalate buffers in aqueous solution. Checks for the presence of carbonate were made using a Gran plot and the determination of K_w for the solvent system. Although a correction was not made to compensate for the methanol-water liquid junction potential a correction of 0.1236 pH units can be substracted from the measured pH readings as suggested by Bates *et al*. [12] to enable a comparison to be made with measurements in aqueous solution.

Kinetic studies

Hydrolysis of the phosphotriester 2,4-dinitrophenyl diethyl phosphate in the presence of the metal complexes was monitored using the absorption increase at 360 nm due to the release of the 2,4-dinitrophenolate ion. Measurements were made at 25°C using a Perkin Elmer Lambda 14 spectrophotometer. Solutions were buffered at the required pH using MES (pH 5.0–6.0), HEPES (6.5–7.5) and TAPS (8.0–9.0) buffers (0.05 mol dm^{-3}). The ionic strength was adjusted to 0.1 mol dm^{-3} with KNO_3. To prevent the formation of insoluble copper hydroxo complexes the ligand was present in a three fold excess over the metal ion.

RESULTS AND DISCUSSION

The crystal structure of $[ZnLCl_2].MeOH$

An ORTEP view of the complex is shown in Fig. 1 with the atomic numbering scheme. Selected bond lengths and angles are summarised in Table 2. The coordination sphere around the zinc is made up of the two pyridine nitrogens of the imidazole rings, the secondary amino group and two chlorides which form a distorted square pyramid with a chloride in the axial site. The benzimidazole nitrogen-zinc bond distances are 2.079(3) and 2.078(3) Å. Average zinc-imidazole bond distances are 2.02–2.08 Å in six coordination [13]. The zinc–N(1) bond distance to the secondary nitrogen donor is 2.300(5) Å which compares well with the average value of 2.27 Å observed for *sec*-NH donors in five-coordinate zinc(II) complexes [13]. The benzimidazole donors and one chloride form the base of the pyramid and the zinc atom lies approximately 0.65 Å above this plane. Five coordinate zinc complexes are frequently found with tetradentate nitrogen macrocycles. In these complexes the basal plane is occupied by the four nitrogen donors with the apical position occupied by pyridine or chloride [13]. The displacement of the zinc atom from the basal plane ranges from 0.31 to 0.71 Å. The mean Zn–L apical distance increases with the covalent radius of the ligand atom in the sequence 2.082 Å (oxygen donor) < 2.158 Å (nitrogen donor) < 2.31 Å (chloride). The zinc-apical chlorine bond distance in the present complex is 2.316 Å. The structure also contains one molecule of methanol which is hydrogen bonded to an imidazole nitrogen (N–5). It was found that there were two conformations at the secondary amino nitrogen (N–1). Two positions were refined, N(1) and N(6)

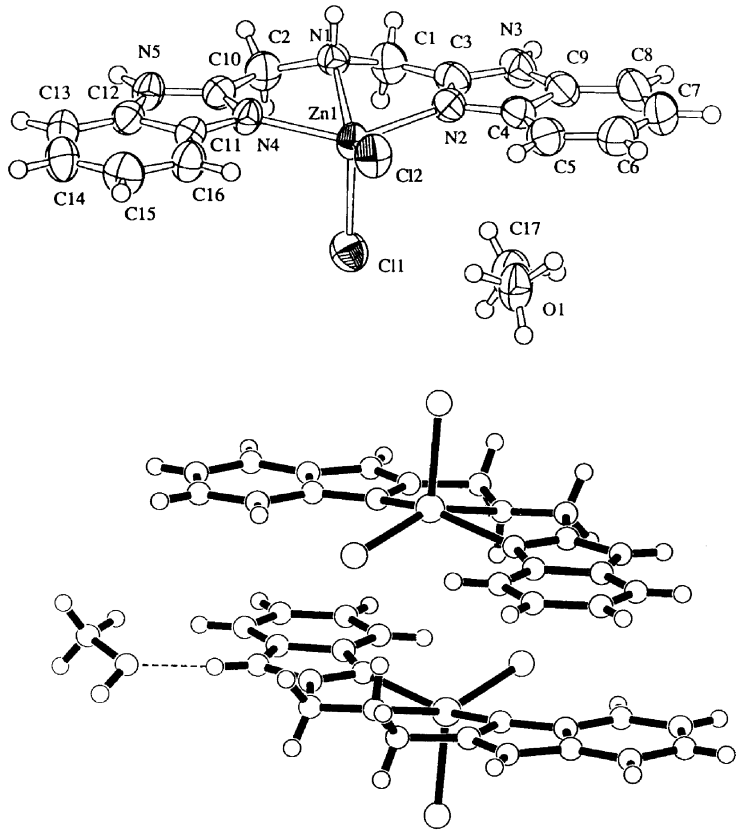

Fig. 1. ORTEP diagram and atomic numbering scheme for the complex $[ZnLCl_2]$.MeOH. The packing diagram is also shown.

Table 2. Selected bond lengths (Å) and bond angles (°) for $[ZnLCl_2].MeOH$

Zn(1)–N(1)	2.300(5)	N(1)–Zn(1)–N(2)	72.6(2)
Zn(1)–N(2)	2.079(3)	N(1)–Zn(1)–N(4)	73.1(2)
Zn(1)–N(4)	2.078(3)	N(4)–Zn(1)–N(2)	143.5(1)
Zn(1)–Cl(1)	2.316(1)	N(1)–Zn(1)–Cl(2)	144.1(2)
Zn(1)–Cl(2)	2.304(7)	N(1)–Zn(1)–Cl(1)	109.4(2)
O(1)–N(5)	2.827(4)	Cl(1)–Zn(1)–Cl(2)	106.51(5)

with a total occupancy equal to one. Refined occupancies were 0.68 and 0.32 corresponding to *trans* and *cis* configurations with respect to the axial chloride. The imidazole ligand is remarkably planar. A plane described by the two benzene rings indicates a deviation of only 0.02 Å with the zinc atom sitting approximately 0.4 Å above the plane. The structure of $[ZnLCl_2]$ is analogous to that of $[CuLCl_2]$ which has recently been described [4].

Potentiometry

The titration curve for the ligand dihydrobromide is shown in Fig. 2. A sharp inflection point occurs after addition of two equivalents of base. The ratio B/L is the number of moles of base added per mole of the ligand. The log β values obtained are summarised in Table 3 and give a pK of 4.48(1) for loss of the first proton and 5.638(2) for the second. The low pK values indicate that the protonation sites are the imidazole nitrogens rather than the secondary amino group. A secondary amine would be expected to have a much higher pK. For example, the pK for the dibenzylamine cation is 8.08 in 50% ethanol [14]. Protonation of the pyridine nitrogen of imidazole is probably favoured as this minimises electrostatic repulsion in the dication LH_2^{2+}.

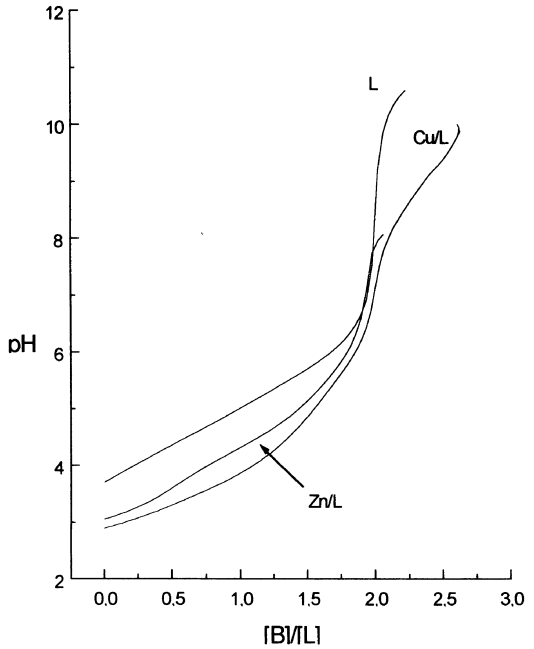

Fig. 2. Titration curves for the ligand alone and in the presence of copper(II) and zinc(II). The experimental conditions are listed in Table 1.

The titrations in the presence of copper(II) show an inflection point after addition of two equivalents of base indicating the formation of mono complexes. The potentiometric results obtained at a three to one ligand to metal ratio can be rationalised in terms of the equilibria summarised in Table 3. At high pH the important complexes are the hydroxo complexes (11–1 and 11–2). Using the β values listed the following pK values can be calculated for the equilibria:

$$[CuL(OH_2)_2]^{2+} \rightleftarrows [CuL(OH)(OH_2)]^{+} + H^{+}\,;\, pK = 7.31(7)$$

$$[CuL(OH)(OH_2)]^{+} \rightleftarrows [CuL(OH)_2] + H^{+}\,;\, pK = 9.10(5)$$

The speciation curve, Fig. 3 indicates that the species CuL^{2+} disappears prior to the formation of $[CuL(OH)]^{+}$, and that the major species in solution is the bis-complex $[CuL_2]^{2+}$. As a result it seems probable that the monohydroxo complex is formed by hydroxide ion displacement of a benzimidazole ligand rather than by deprotonation of a coordinated water molecule.

Titration curves in the presence of zinc(II) were rather similar to those observed with copper(II) except that precipitates formed above pH 7. The stability constants obtained are summarised in Table 3. The monohydroxo complex forms in the pH range where precipitation begins and as a result the stability constant for the 11–1 species and the calculated pK of the zinc bound water (8.29 ± 0.06) can only be regarded as estimates.

Kinetic studies

A number of hydroxoaqua complexes such as $[Cu(dpa)(OH)(OH_2)]^{+}$ (dpa = 2,2′-dipyridylamine) have been found to be very effective catalysts for the hydrolysis of phosphotriesters [15]. For this reason we studied the effect of the copper(II) and zinc(II) complexes on the hydrolysis of 2,4-dinitrophenyl

Table 3. Protonation constants and stability constants for the copper(II) and zinc(II) complexes of N,N-bis(benzimidazole-2ylmethyl)amine

Protonation constants (ligand = L, errors as σ)		
$\log \beta_{HL}$	$H^+ + L = HL^+$	5.638 ± 0.003

$\log \beta_{ZnL}$	$Zn^{2+} + L = ZnL^{2+}$	5.96 ± 0.02
$\log \beta_{ZnL2}$	$Zn^{2+} + 2L = ZnL_2^{2+}$	8.97 ± 0.08
$\log \beta_{ZnLOH}$	$Zn^{2+} + OH^- + L = ZnL(OH)^+$	-2.33 ± 0.06

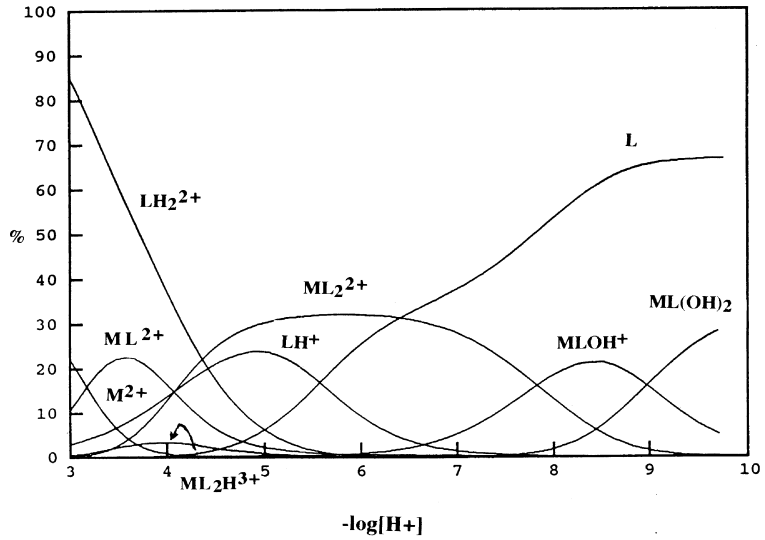

Fig. 3. Speciation curves for the copper(II) complexes.

diethyl phosphate. Hydrolysis of this ester to give diethyl phosphate can be readily monitored spectrophotometrically at 360 nm due to the release of 2,4-dinitrophenoxide. The complexes exhibit only small catalytic effects. The pH dependence of the catalysis with the copper(II) complex was consistent with the monohydroxo complex being the active catalytic species. Studies with zinc were limited due to the insolubility of the monohydroxo zinc complex. These complexes do not act as effective catalysts for the hydrolysis of phosphotriesters.

(Received 2 February 1998; accepted 7 April 1998)

Abstract—Treatment of copper(I) with 3-chloro-6-(3,5-dimethylpyrazol-l-yl)pyridazine (MeppdCl) in dichloromethane yields firstly red crystals of $[Cu(MeppdCl)_2]BF_4$ and secondly blue crystals of $[Cu(MeppdCl)_2Cl]BF_4 \cdot 0.5(C_2H_5)_2O$. The provenance of the chloride anion is uncertain; it may be attributed to either copper(I) activation of dichloromethane or minor impurities arising during MeppdCl synthesis. In the copper(I) cation, two MeppdCl molecules, which are N-donor bidentate chelating ligands, generate a squashed tetrahedral coordination geometry [Cu...N = 2.000(3)-2.052(3) Å] with an open side [N–Cu–N = 140.1(1)°]—effectively a trigonal bipyramid with a missing equatorial ligand. In the copper(II) cation, a trigonal biypramidal arrangement is formed by two MeppdCl ligands, which straddle equatorial [Cu...N = 2.066(4), 2.151(4) Å] and axial [Cu...N = 1.976(4), 1.979(4) Å] sites and an equatorially located chlorine atom [Cu...Cl = 2.292(1) Å]. Viewing the two coordination geometries as trigonal bipyramidal, the orientation of the MeppdCl molecules reverses on oxidation, the pyrazole nitrogens moving from equatorial to axial sites [N–Cu–N increases from 98.9(1)° to 168.5(2)°] and the pyridazine nitrogens vice versa [N–Cu–N decreases from 140.1(1)° to 110.8(2)°].

The copper(I) complex is the most severely distorted, structurally characterised, $[Cu(diimine)_2]^+$ complex. A novel method of parameterising the stereochemistry of $[Cu(diimine)_2]^+$ complexes is proposed; four readily calculated parameters are used to assess the extent of distortion of the molecule from D_{2d} symmetry. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: copper(I); copper(II); chelating diimines; stereochemistry; chloride abstraction.

Although the coordination chemistry of symmetrical chelating diimines [e.g., 2,2-bipyridine (bipy), 1,10-phenanthroline (phen) and 2,9-dimethyl-l,10-phenanthroline (dmp)] with copper(I) and copper(II) has been extensively studied [1–10], there are few data on complexes with unsymmetrical diimines [11]. 3-Chloro-6-(pyrazol-l-yl)pyridazine (ppdCl) and 3-chloro-6-(3,5-dimethylpyrazol-l-yl)pyridazine (MeppdCl) provide examples of such ligands (Scheme 1) [12]. Following our work in which we compared the coordination chemistry of the mixed ligand complexes copper(II)-ppdCl or MeppdCl-cnge and copper(II)-bipy-cnge (cnge = 2-cyanoguanidine) [12, 13], we have initiated a study of copper(I)-ppdCl or MeppdCl complexes. In this paper, we described the synthesis, isolation and structural characterisation of $[Cu(MeppdCl)_2Cl]BF_4$, **1**, and its oxidation product, $[Cu(MeppdCl)_2Cl]BF_4 \cdot 0.5(C_2H_5)_2O$ (**2**).

Complex **1** adopts the tetrahedral structure typical of $[Cu(diimine)_2]^+$ cations [1–7] and complex **2** the trigonal bipyramidal structure typical of $[Cu(diimine)_2Cl]^+$ cations [8, 9, 10]. The former is, however, the most severely distorted $[Cu(diimine)_2]^+$ coordination geometry determined thus far. Although stereochemical descriptions for these cations already exist [1, 2], we propose an alternative approach in which readily calculated parameters are used to

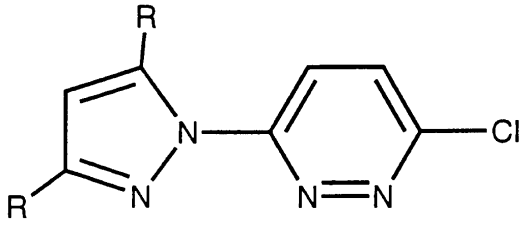

Scheme 1. Pyrazolylpyridazines. R = H; 3-chloro-6-(pyrazol-1-yl)pyridazine (ppdCl), R = Me; 3-chloro-6-(3,5-dimethyl-pyrazol-1-yl)pyridazine (MeppdCl).

assess the relative orientation of the two diimine ligands.

The process by which complex **2** is generated is uncertain; it may be attributed to either activation of the solvent, CH_2Cl_2, by the copper(I) complex or to adventitious oxidation in the presence of chloride impurity. Dichloromethane activation is well established, particularly with conversion of square planar d^8 to octahedral d^6 metal centres (e.g., $Ir^I \rightarrow Ir^{III}$ [14] and $Rh^I \rightarrow Rh^{III}$ [15]). More recently [16], it has been observed for the conversion of the tetrahedral d^{10} Ni^O centre in $[Ni(dmp)_2]$ (dmp = 2,9-dimethyl-1,10-phenanthroline), an isoelectronic analogue of $[Cu(MeppdCl)_2]^+$, to the square pyramidal d^8 metal centre in $[\{Ni(dmp)Cl\}_2(\mu\text{–}Cl)_2]$.

EXPERIMENTAL

Preparation of 3-*chloro*-6-(3,5-*dimethylpyrazol-l-yl*) *pyridazine* (*MeppdCl*)

3,5-Dimethylpyrazole (Aldrich Chemical Co., 4.005 g, 0.0417 mol) was dissolved in dry tetrahydrofuran (100 cm^3) and small pieces of clean potassium metal (1.629 g, 0.0417 mol) added with stirring under nitrogen to yield a white precipitate. An exit needle was fitted to the reaction vessel to permit hydrogen release. Upon complete reaction (12 hours), a solution of 3,6-dichloropyridazine (Aldrich Chemical Co., 9.289 g, 0.0624 mol) in dry tetrahydrofuran (50 cm^3) was added with stirring to yield a red/brown solution which was refluxed for 4 hours. After cooling, the resulting red/brown suspension was added to ice-cold deionised water (250 cm^3) to yield a white precipitate which was filtered under suction, washed with ice-cold deionised water and dried under vacuum over P_4O_{10} to give MeppdCl as a white powder. Yield, 6.00 g (69%), m.p. 104–106°C. Analysis: found (calculated for $C_9H_9ClN_4$) {RMM = 208.7}; C 52.00 (51.80), H 4.40 (4.35), N 26.75 (26.85). ^{1}H NMR ($CDCl_3$) (δ(ppm), J (Hz)); 8.16 (*d*, J 9.30, 1 H), 7.56 (*d*, J 9.21, 1 H), 6.06 (*s*, 1 H), 2.72 (*s*, 3 H), 2.29 (*s*, 3H). IR (KBr disc) (ν/cm^{-1}) 3054 m, 1576s, 1543 m, 1425s, 1364 m, 1270 w, 1141 m, 1066 m, 1008 w, 972 m, 854 m, 792 m, 744 m, 591 w, 529 w, 511 m. EI mass spectrum (*m*/*e*, relative intensity): 208 $\{[M]^+, [(C_5H_7N_2)(C_4H_2ClN_2)]^+$, 100%}, 191 $\{[(C_4H_4N_2)(C_4H_2ClN_2)]^+$, 31%}, 180 $\{[(C_5H_7N_2)(C_4H_2Cl)]^+$, 18%}, 173 $\{[(C_5H_7N_2)(C_4H_2N_2)]^+$, 20%}, 95 $\{[(C_5H_7N_2)]^+$, 68%}. Although the elemental analytical data are consistent with a pure sample and there is no evidence for impurities in the ^{1}H-nmr and mass spectra, the synthetic route could give KCl or hydrochloride impurity which could lead.to small quantities of **2** following adventitious oxidation of **1**. Such impurities are invisible to ^{1}H-nmr and E.I.-M.S. methods and chloride analysis was unsuccessful. An attempt to identify KCl by X-ray powder diffraction methods also failed; the experiment, a relatively insensitive technique which needs >2 mole % for detection, neither confirmed nor refuted the presence of KCl.

Preparation of $[Cu(MeppdCl)_2]BF_4$ (**1**) *and* $[Cu(MeppdCl)_2Cl]BF_4 \cdot 0.5(C_2H_5)_2O$ (**2**)

Dichloromethane (50 cm^3) was added under nitrogen to a mixture of tetrakis(acetonitrile)copper(I) tetrafluoroborate (0.151 g, 0.48 mmol) and MeppdCl (0.10 g, 0.48 mmol). After stirring for 16 hours a pale red and solid was recovered from a red solution by canula filtration. The product (0.104 g, 0.18 mmol; 75%) was identified as $[Cu(MeppdCl)_2]BF_4$ from elemental analytical data obtained in the University of Nottingham Chemistry Department by Mr. T. J. Spencer. Analysis: found (calc. for $C_{18}H_{18}BCl_2CuF_4N_8$): C, 37.85 (38.10); H, 3.35 (3.20); N, 19.30 (19.75). Infrared spectra {ν/cm^{-1}; 3050 w, 1580 s, 1535 w, 1428 s, 1375 m, 1085–1035 s br, 831 m, 799 m, 740 w}, obtained on a Perkin Elmer PE983G spectrometer as KBr pressed pellets, confirmed the presence of MeppdCl ligand and BF_4^- anion.

Tiny red crystals of **1** were obtained by vapour phase diffusion of Et_2O into the mother liquor. Although too small for data collection using a four circle diffractometer, they diffracted sufficiently well for study with an area detector. On prolonged standing, a limited number of small blue crystals appeared. X-ray diffraction experiments with an area detector showed them to be the copper(II) complex, $[Cu(MeppdCl)_2Cl]BF_4 \cdot 0.5(C_2H_5)_2O$ (**2**).

X-ray crystallography

Selected crystals of **1** were mounted in Lindemann glass capillary tubes for preliminary study. Oscillation and Weissenberg photographs revealed approximate cell dimensions (a = 10.10, b = 20.50, c = 11.05 Å, β = 100°) and space group $P2_1/n$. Diffraction data for **1** and **2** were collected for more than one hemisphere at 150 K using an Enraf Nonius FAST TV area detector situated at the window of a rotating anode generator with a molybdenum anode [17]. The data sets for both compounds were extremely weak owing to the small size of the crystals. They were corrected for Lorentz

and polarisation effects as well as absorption (DIFABS) [18]. Crystal data, together with details of both diffraction experiments, are listed in Table 1.

The structures were solved by direct methods (SIR92) [19]. The majority of the hydrogen atoms were located from difference Fourier syntheses (CRYSTALS) [20] Those which could not be found were placed (d(C...H) = 1.00 Å; $U_{iso} = 0.05$ Å^2) except for the ether hydrogens in **2** which were omitted. In **2**, both the anions and solvent molecules exhibit disorder. The anion was modelled by two full occupancy and four half occupancy fluorines based on a common boron. The solvent molecule was modelled by half occupancy atoms (equivalent to one Et_2O molecule per two cations) lying in channels at $\pm 1/4, \pm 1/4$, 0. Both structures were refined by full-matrix least squares method on F^2 using all positive data, with anisotropic displacement parameters for non-hydrogen atoms, except those of the ether molecules in **2** which, together with the located hydrogen atoms, were allocated isotropic displacement parameters (CRYSTALS) [20]. The final cycle of refinement, with two-parameter Chebychev weighting schemes [parameters 93.8, 96.4, for **1**; parameters 15.2, 14.3 for **2**] gave conventional R indices of 0.0450 and 0.0574 for **1** and **2**, respectively. Full details of the structure solutions are given in Table 1. Selected interatomic distances and angles are collected in Table 2 and structure diagrams, generated using the CAMERON suite of programs [21], are shown in Figs. 1–3. The numbering sequences for the two MeppdCl ligands differ solely in starting at 101 and 201; in the text, they are designated by the notation 1xx and 2xx, respectively.

RESULTS AND DISCUSSION

Crystal and molecular structure of $[Cu(MeppdCl)_2]BF_4$ (**1**)

The structure of **1** comprises $[Cu(MeppdCl)_2]^+$ cations and BF_4^- anions. Although the tetrahedral copper(I) coordination sphere of the cation is structurally similar to those in other $[Cu(diimine)_2]^+$ (diimine = phen, dmp, 2,2′-bipy, 3,3′-dimethyl-2,2′-bipyridine and 3,3′5,5′-tetramethyl-2,2′-bipyridine) cations [1–7], it is much more severely distorted (Fig. 1). The bidentate ligands are not orthogonal as their normals subtend a dihedral angle of 52.8°. Furthermore, they are not planar but have internal dihedral angles of

14.6° (ligand 1xx; Fig. 1) and 20.8° (ligand 2xx; Fig. 1) between their pyridazine and pyrazole rings. These distortions result in a 'squashed tetrahedral' geometry, reminiscent of the entatic state of type 1 copper proteins [22]. The small bite angles of the ligands dictate one large (~140°), two medium (~130°) and one small (~100°) interligand angle (Table 2). The two bidentate ligands are arranged such that the pyridazine nitrogens are marginally closer to the copper atom than the pyrazole nitrogens (Table 2). The BF_4^- anion exhibits no disorder.

Crystal and molecular structure of $[Cu(MeppdCl)_2Cl]BF_4 \cdot 0.5(C_2H_5)_2O$ (**2**)

The structure of **2** comprises $[Cu(MeppdCl)_2Cl]^+$ cations, BF_4^- anions and ether solvent molecules. The five co-ordinate copper(II) coordination sphere in **2** is shown in Fig. 2. The bidentate MeppdCl ligands straddle equatorial and axial sites. The third equatorial site is occupied by a relatively weakly bound chlorine atom [Cu...Cl 2.292(1) Å]. Although the normals to the least squares through the two diimines subtend a dihedral angle of 70.7°, they are both effectively perpendicular to the copper(II) equatorial plane (dihedral angles, 90.0, 88.2°). The stronger binding of the axial sites is confirmed by the axially located pyrazole nitrogens being much closer to the copper atom than the equatorially located pyridazine nitrogens (Table 2). The bidentate ligands are somewhat more planar than in **1**, with dihedral angles of only 11.3° (ligand 1xx; Fig. 2) and 11.5° (ligand 2xx; Fig. 2) between their pyridazine and pyrazole rings.

The BF_4^- anion is disordered over two equally occupied sites. Two fluorines (F11, F12) are common, the other four (F131, F132, F141, F142), which are coplanar and orthogonal to F11 and F12, form two pairs related by a rotation of ~45°. The boron atom has an elongated thermal ellipsoid to accommodate this disorder. Somewhat disordered solvent molecules (equivalent to one Et_2O molecule per two cations) lie in channels, centered at $\pm 1/4$, $\pm 1/4$, 0, which run parallel to the *c* axis (Fig. 3).

The molecular geometry of $Cu(MeppdCl)_2]^+$ is typical of those of [Cu(diimine)X]$^+$ (diimine = 2,2′-bipyridine or phenanthroline, X = Cl^-, I^-, CN^-, N_3^-, NCS^-, $NCSe^-$, $CH_3CO_2^-$, HCO_2^-) cations [8, 9, 10], for which the structural pathways of $[Cu(phen)_2Cl]^+$ [8] and $[Cu(bipy)_2Cl]^+$ [9] have been discussed in detail. Using the notation of Addison *et al.*[23], the copper(II) co-ordination geometry is best described as square based pyramidal distorted trigonal bipyramidal [τ = (168.5–130.8)/60} = 0.63].

Comparison of the structures of the two cations

A significant relationship exists between the two cations. The copper(I) cation can be considered to be based on a trigonal bipyramidal arrangement with a missing equatorial ligand; the pyridazine nitrogens [Cu...N = 2.000(3), 2.009(3) Å] occupy the pseudo-axial positions [angle NCuN = 140.1 (1)°] and the more remote pyrazole nitrogens [Cu...N = 2.049(3), 2.052(3) Å] the pseudo-equatorial positions [angle NCuN = 98.9(1)°] (Fig. 1). Other than the presence of the equatorial chlorine atom in the copper(II) cation, the only difference is the inversion of the ligands, the pyrazole nitrogens [Cu...N = 1.976(4), 1.979(4) Å]

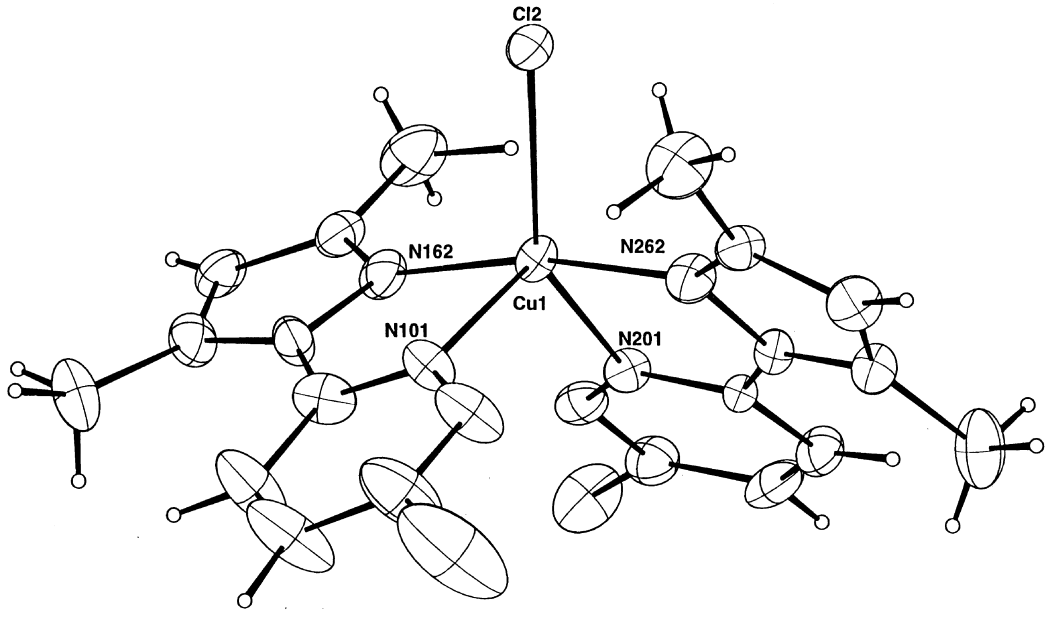

Fig. 2. Molecular structure and numbering scheme for $[Cu(MeppdCl)_2Cl]^+$

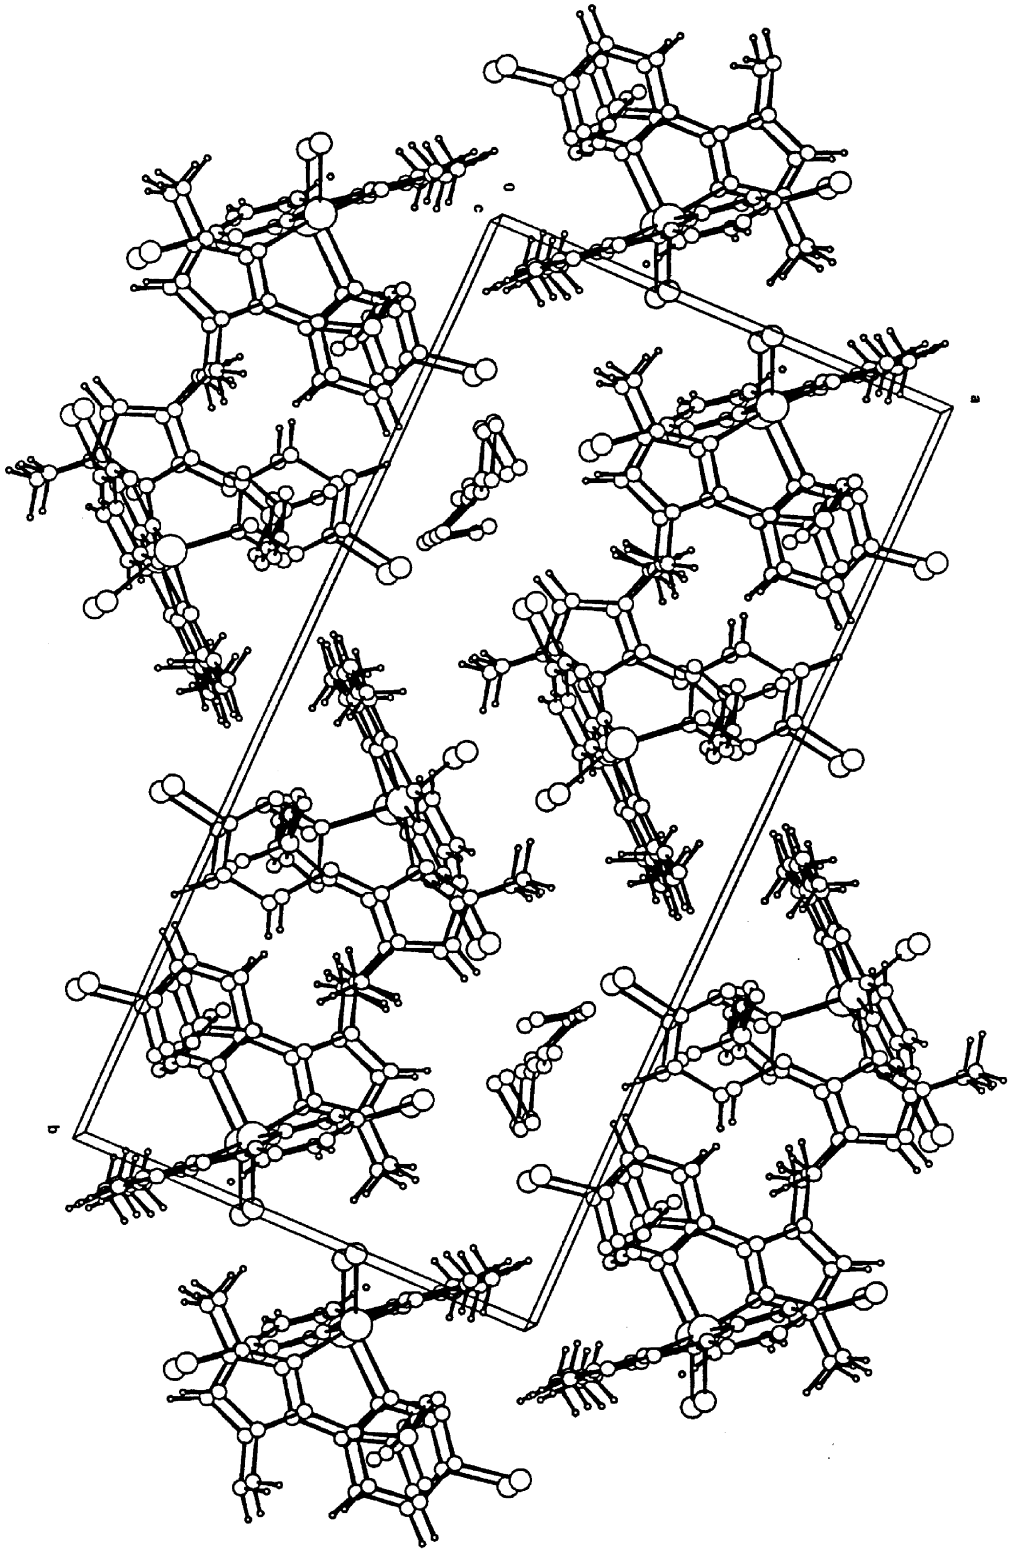

Fig. 3. Packing diagram for $[Cu(MeppdCl)_2Cl]BF_4 \cdot 0.5(C_2H_5)_2O$ showing the channels, centred on ($\pm 1/4$. $\pm 1/4$, 0), containing the ether solvent molecules.

occupying the axial positions [NCuN = 168.5(2)°] and the more remote pyridazine nitrogens [Cu...N = 2.066(4), 2.151(4) Å] the equatorial positions [NCuN = 110.8(2)°] (Fig. 2). The copper(II) cation is analogous to the only other structurally characterised bis(MeppdCl) copper(II) cation, $[Cu(MeppdCl)_2(cnge)]^{2+}$ (cnge = 2-cyanoguanidine) [13], in which the diimine ligands adopt an identical arrangement, the pyrazole nitrogens [Cu...N = 1.965(5), 1.965(5) Å] occupying the axial positions [angle NCuN = 169.5(2)°] and the more remote pyridazine nitrogens [Cu...N = 2.052(5), 2.070(5) Å] the equatorial positions [angle NCuN = 119.2(2)°].

The geometry of the copper(I) cation has an open face giving ready access to the metal centre. This may responsible for the activation of the dichloromethane molecule and the chlorine abstraction process which would result in the generation of **2**.

Stereochemistry of bis(diimine)copper(I) complexes

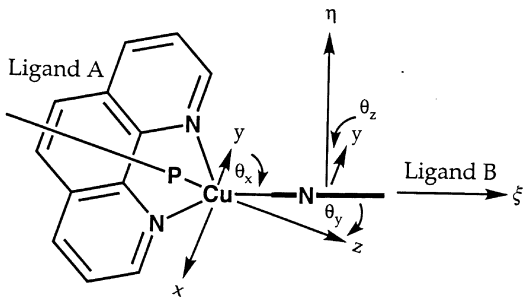
Bis(diimine)copper(I) complexes adopt diverse stereochemistries. The majority exhibit little symmetry containing two crystallographically independent diimines. A small number, $[Cu(bipy)_2]ClO_4$ [1], $[Cu(phen)_2]CuBr_2$ [3], $[Cu(dmp)_2]NO_3$ [4] and $[Cu(dmp)_2]BF_4$ toluene [5], are, however, located on 2-fold axes of symmetry which pass through the copper ion thus crystallographically relating the two diimines. Finally, in one example, $[Cu(phen)_2]ClO_4$ [3], the cation is located on a 2-fold axis, which not only passes through the copper ion but also bisects both of the crystallographically independent diimines.

Several authors have devised models to describe the stereochemistry of these cations. They range from the consideration of the dihedral angle between the two ligands [1] to the application of complex vector algebra techniques to the determination of the three angles, θ_x, θ_y and θ_z, which refer to the orientation of the N, Cu, N, triangle in ligand A relative to that of the corresponding triangle in ligand B (Scheme 2) [2]. We wish to propose an alternative method of describing the stereochemistry of $[Cu(diimine)_2]^+$ cations, which is more realistic than the simple consideration of the dihedral angle but which is more readily assessed quantitatively than by the application of complex vector algebra techniques.

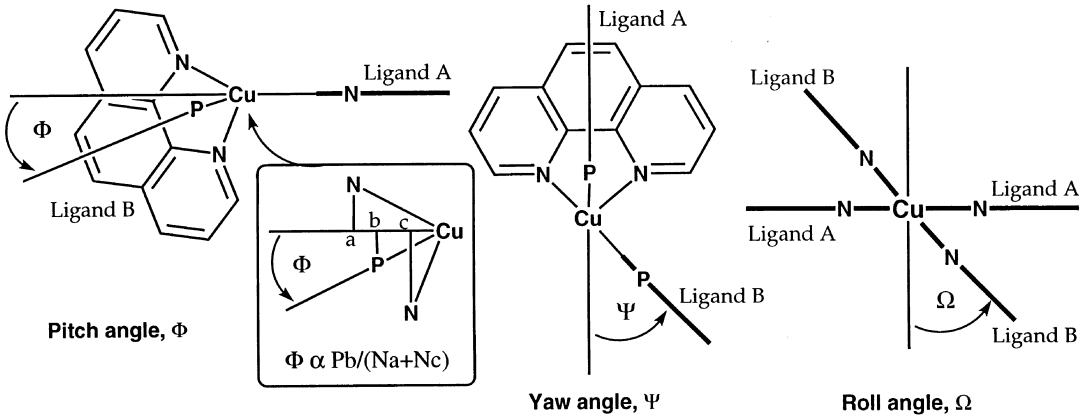
The orientation of the plane of diimine ligand B with respect to that of diimine ligand A is described by three angles, named, by analogy with spacecraft manoeuvres, the pitch, roll and yaw angles. These three angles, Φ, Ω and Ψ are shown and defined in Scheme 3. They are comparable with θ_x, θ_z and θ_y, as defined by Dobson et al. (Scheme 2) [2]. Difficult to calculate precisely, they can be assessed semi-quantitatively in terms of four readily calculated parameters:

1. τ-the twist parameter-the sum of the perpendicular distances of the nitrogen atoms of ligand B from the plane of ligand A [(Na + Nc): observed range 2.69–2.04 Å],
2. η-the tilt parameter–the ratio of the perpendicular distance of point P [the mid-point of the intraligand N...N vector (Scheme 3)] of ligand A from the plane containing ligand B to the sum of the perpendicular distances of the nitrogen atoms of ligand A from the plane containing ligand B [Pb/(Na + Nc): observed range 0.00–0.23].
3. δ-the bisector parameter–the angle between the lines bisecting the two N–Cu–N angles (ie the lines which radiate from the copper atom and pass through points P) [observed range 180–155°],
4. ε-the dihedral parameter–the angle at the intersection of the perpendiculars to the planes of the two diimine ligands [observed range 90–50°].

The twist parameter, τ, is a measure of the roll angle, Ω, and the tilt parameter, η, is a measure of the pitch angle, Φ. The effect of roll on Φ is allowed for by calculating the ratio, Pb/(Na + Nc), rather than the absolute length, Pb. The bisector parameter δ is a combination of the pitch and yaw angles, Φ and Ψ,



Scheme 2. Definition of the three angles, θ_x, θ_y, and θ_z, which refer to the orientation of the N, Cu, N triangle in ligand A relative to that of the corresponding N, Cu, N triangle in Ligand B [2]. x, y and z are orthonormal vectors chosen such that ligand A is in the xz plane with z as the bisector of the NCuN angle; ξ and η are unit vectors defined to lie along the bisector of the NCuN angle of ligand B and perpendicular to ligand B, respectively. θ_x is the angle between ξ and y, θ_y between ξ and x, θ_z between η and y.



Scheme 3. Definition of the pitch, yaw and roll angles relating the orientation of ligand B with respect to ligand A.

and the dihedral parameter, ϵ, although affected by pitch, yaw and roll, is primarily a measure of the roll angle, Φ.

For $[Cu(diimine)_2]^+$ cations with D_{2d} symmetry (Cu...N = 2.05 Å, NCuN = 82°) the parameters would be $\tau = 2.69$ Å, $\eta = 0.00$, $\delta = 180°$ and $\epsilon = 90°$. For symmetrical diimines (diimine = 2,2′-bipy, phen or their substituted derivatives), maximum observed distortion values are $\tau = 2.05$ Å $[Cu(phen)_2]ClO_4$ [3], $\eta = 0.19$ $[Cu(phen)_2]CuBr_2$ [3], $\delta = 160.4°$ $[Cu(dmp)_2]BF_4 \cdot CH_2Cl_2$ [5] and $\epsilon = 49.7°$ $[Cu(phen)_2]ClO_4$ [3]. Even greater distortion is observed, however, for the unsymmetrical diimine (MeppdCl) in $[Cu(MeppdCl)_2]BF_4$ with $\tau = 2.04$ Å, $\eta = 0.23$, $\delta = 155.8°$ and $\epsilon = 52.8°$. Full details for a representative selection of $[Cu(diimine)_2]^+$ cations are given in Table 3.

The cation with symmetry closest to D_{2d}, $[Cu(dmp)_2]BF_4$ toluene [5] [Fig. 4(a); Table 3], is located on a 2-fold axis. Surprisingly, the other complexes located on 2-fold axes are less symmetrical. In fact, that for which the 2-fold axis also bisects the diimine ligands, $[Cu(phen)_2]ClO_4$ [3], has a very large twist distortion [Fig. 4(b)] as indicated by the small dihedral angle (Table 3).

Trends in the parameters collated in Table 3 can be discerned by comparison with data calculated for molecules with distortions restricted to one of the three angles, pitch, roll and yaw. The bisector parameter is dependent on both pitch and yaw angles. To ascertain the relative significance of these two angles on bisector parameter, tilt parameters are plotted as a function of bisector parameters in Fig. 5 together with the calculated variation of the tilt parameter assuming increasing pitch angle only (AB, Fig. 5). Increasing the yaw angle has no effect on the tilt parameter (AC, Fig. 5). For the majority of the complexes, the variation in bisector parameter can be attributed to a change in the pitch angle, as exemplified by $[Cu(dmp)_2]Br \cdot H_2O$ [Fig. 4(c)] [2]. The exception is $[Cu(dmp)_2]BF_4 \cdot CH_2Cl_2$ [5] which exhibits a

Each cation is shown such that the plane of the upper ligand is parallel to the plane of the paper.

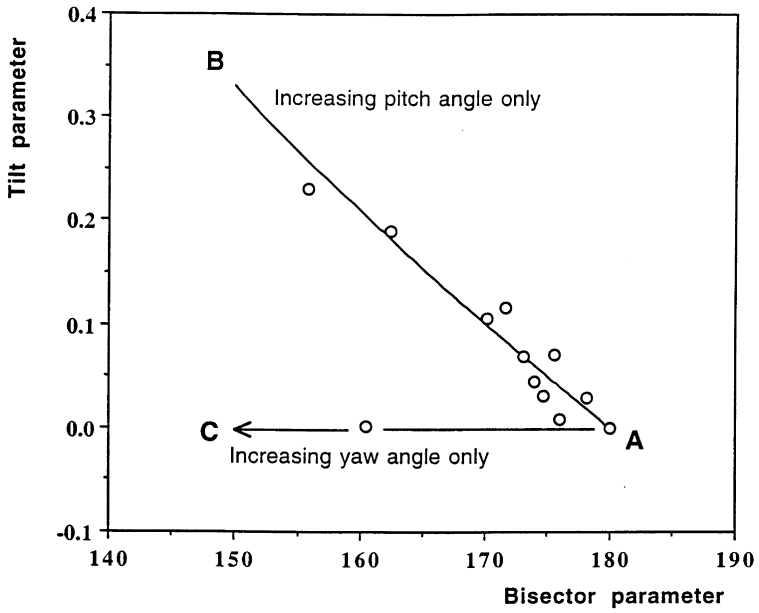

Fig. 5. Variation of tilt parameters with bisector parameters.

large yaw angle, but virtually no pitch distortion [Fig. 4(d)].

The dihedral parameter is dependent on all three angles. To ascertain their relative significance, dihedral parameters are plotted as a function of twist parameters in Fig. 6 together with the calculated variation of the dihedral parameter assuming increasing roll angle only (DE, Fig. 6). Increasing either yaw and/or pitch angle only has no effect on the dihedral parameter (DF, Fig. 6). All complexes exhibit some degree of roll. For the majority, the variation in dihedral parameter reflects solely a change in the roll angle, Ω, the maximum being observed for $[Cu(phen)_2]ClO_4$ [Fig. 4(b)] [3] and $[Cu(MeppdCl)_2]BF_4$ [Fig. 4(e)]. Of the cations which deviate significantly from curve DE (Fig. 6), $[Cu(dmp)_2]BF_4 \cdot CH_2Cl_2$ [5] [Fig. 4(d)] and

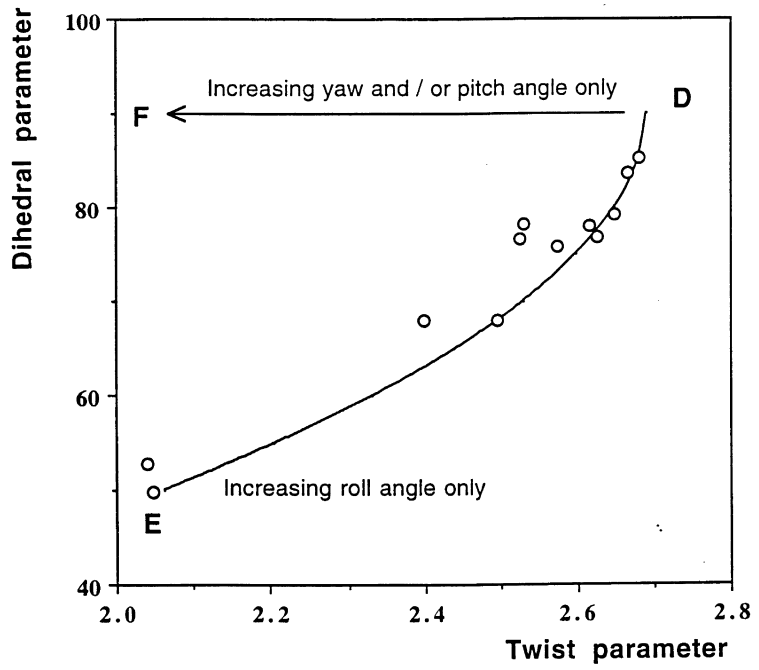

Fig. 6. Variation of dihedral parameters with twist parameters.

$[Cu(bipy)_2]ClO_4$ [1] [Fig. 4(f)] exhibit yaw and pitch distortions, respectively.

In summary, distortion of the pitch and roll angles, Φ and Ω, is dominant. Few complexes exhibit distortion of yaw angle, Ψ. The relative significance of yaw and pitch angle increase can be extricated from a consideration of tilt and bisector parameters (Fig. 5) while the significance of increasing roll angle relative to yaw and/or pitch angle increase can be assessed from a consideration of dihedral and twist parameters (Fig. 6).

CONCLUSION

Unsymmetrical diimines form $[Cu(diimine)_2]^+$ and $[Cu(diimine)_2X]^+$ cationic complexes structurally similar to their symmetrical analogues. For the copper(I) complex, however, the extent of distortion from the predicted tetrahedral geometry is much greater for the unsymmetrical diimine. The distortion, the relative orientations of the planes of the two diimine ligands, can be described, by analogy with spacecraft manoeuvres, the pitch, roll and yaw angles. The majority of structurally characterised $[Cu(diimine)_2]^+$ cations exhibit either pitch or roll distortion or some combination of both. Those few complexes which do exhibit yaw distortion do so without pitch or roll distortion. $[Cu(MeppdCl)_2]^+$ exhibits severe pitch, yaw and roll distortion.

Syntheses and characterization of four novel monooxovanadium(v) hydrazone complexes with hydroxamate or alkoxide ligand

Shan Gao, Zhi-Qiang Weng and Shi-Xiong Liu*

Dept. of Chem., Fuzhou University, Fuzhou 350002, P. R. China

(Received 3 December 1997; accepted 6 April 1998)

Abstract—Four novel monooxovanadium(V) hydrazone complexes, $[VOL^1(Hshi)]$ (**1**), $[VOL^1(bz)]$ (**2**), $[VOL^2(bz)]\cdot CH_2Cl_2$ (**3**), and $[VOL^2(OCH_3)(CH_3OH)]\cdot CH_3OH$ (**4**) (H_2L^1 = salicylaldehyde benzoylhydrazone, H_2L^2 = o-vanillin benzoylhydrazone, H_2shi = salicylhydroxamic acid, Hbz = benzohydroxamic acid), were prepared and characterized by IR, Raman, UV, ^{1}H NMR spectra, cyclic voltammetry measurements and X-ray diffraction. The geometry around the vanadium atoms is a distorted VO(ONO)(OO) octahedron in complexes **1**, **2** and **3**, while the geometry is a distorted VO(ONO)(O)(O) octahedron in **4**. The V═O bond distance is 1.574(4), 1.593(5), 1.594(4) and 1.577(4) Å for complexes **1**, **2**, **3** and **4**, respectively. In complexes **1**, **2** and **3**, the O, N, O atoms of a tridentate hydrazone ligand and one oxime oxygen atom of a bidentate hydroxamate ligand are coordinated to the vanadium(V) atom, forming an equatorial plane. In complexes **1**, **2** and **3**, the axial position *trans* to the oxo group is occupied by the carbonyl oxygen atom of the hydroxamate ligand, but not by the oxime oxygen atom. The bond distances in the equatorial plane in the title complexes follow the order: alkoxide oxygen < phenoxide oxygen, oxime oxygen < enolic oxygen < imine nitrogen. The complexes **1**, **2** and **3** represent the first structural examples of vanadium complexes containing both hydrazone and hydroxamate ligands. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: monoxovanadium(V) complexes; hydrazone complexes; hydroxamate complexes; crystal structures; spectroscopic properties.

Knowledge of the biological role of vanadium as a trace element has considerably increased over the past decade [1, 2]. A vanadium enzyme has been described which exhibits histidine-nitrogen coordination to vanadium [3]. The active sites of some biological enzymes include the hydroxamic acids [4]. Many small biomolecules such as hydroxy- or mercaptocarboxylates, amino acids, hydroxamates, hydrazones, phosphates, phosphonates, catechol derivatives, etc. are able to bind this element rather strongly in both the +4 and +5 oxidation states [5–15].

However, only a few structures of the simplest vanadium complexes with hydroxamate ligands have been studied [5, 16–18]. Up to now, only a few oxovanadium hydrazone complexes have been reported. These hydrazone complexes are only limited to dioxovanadium(V) complexes with VO_2(ONO) coordination [8, 19–21], and to monooxovanadium(V) complexes with square pyramidal VO(ONO)(O) coordination [10, 22–27] and octahedral (VO(ONO)(O)(O) [28] or VO(ONO)(ON) [9, 15] coordination.

The relationships between structure, spectroscopy, and reactivity must be elucidated in order to understand fully the role of vanadium in biological systems. We have undertaken the syntheses and characterization of some vanadium compounds containing tridentate ligand with VO(ONO)(ON) or VO(ONO)(OO) coordination [15, 29]. Herein we report four monooxovanadium(V) hydrazone complexes with the hydroxamate or alkoxide ligand, $[VOL^1(Hshi)]$ (**1**), $[VOL^1(bz)]$ (**2**), $[VOL^2(bz)]\cdot CH_2Cl_2$ (**3**), and $[VOL^2(OCH_3)(CH_3OH)]\cdot CH_3OH$ (**4**) (H_2L^1 = salicylaldehyde benzoylhydrazone, H_2L^2 = o-vanillin benzoylhydrazone, H_2shi = salicylhydroxamic acid, Hbz = benzohydroxamic acid). To the best of our knowledge, the complexes **1**, **2**, and **3** are the first examples of vanadium hydrazone complexes with VO(ONO)(OO) coordination.

EXPERIMENTAL

Materials

The materials $VO(acac)_2$ (acac = acetylacetonate), Hbz and H_2shi, were synthesized according to references [30, 31], respectively. The ligand H_2L^1 was prepared by condensing salicylaldehyde with equimolor benzoylhydrazine in ethanol. The ligand H_2L^2 was synthesized by condensing o-vanillin with equimolor benzoylhydrazine in ethanol. Analytically pure dichloromethane was distilled over calcium hydride before use. All other analytical grade chemicals and solvents were purchased commercially and used without further purification.

Synthesis of $[VOL^1$ *(Hshi)]* (*1*)

$[VO(acac)_2]$ (0.263 g, 1.00 mmol) dissolved in 10 cm^3 methanol was added dropwise to a methanol solution containing 0.240 g (1.00 mmol) of H_2L^1 with stirring, and then the mixture was heated at reflux with stirring for 1 h and cooled to room temperature. 10 cm^3 of mixed solution of methanol and salicylhydroxamic acid (1 mmol) was slowly added to the above red-black solution. The reaction mixture was stirred for 30 min. and filtered. Then deep red solid was dissolved in the dichloromethane and filtered. The deep red crystals of the complex **1** were obtained by slow diffusion of hexane into the filtrate for several days and collected under vacuum over P_4O_{10}.

Synthesis of $[VOL^1(bz)]$ (*2*)

The synthesis of complex $[VOL^1(bz)]$ (**2**) was analogous to that of complex **1**, only except that salicylhydroxamic acid was replaced by benzohydroxamic acid. The deep red crystals of the complex **2** were formed upon slow evaporation of the filtrate for several days and collected under vacuum over P_4O_{10}.

Synthesis of $[VO(L^2)(bz)]\cdot CH_2Cl_2$ (*3*)

A 15 cm^3 CH_3OH solution of $VO(acac)_2$ (0.263 g, 1.00 mmol) was added dropwise to a 15 cm^3 CH_3OH solution of H_2L^2 (1.00 mmol). The mixture was refluxed with stirring for 1.5 h, cooled to room temperature. A 10 cm^3 solution of benzohydroxamic acid (1.00 mmol) in CH_3OH was added to the above dark red solution. The mixture was stirred for 30 min. and filtered. The red brown solid was dried under vacuum over P_4O_{10} for 2 days, dissolved in the dichloromethane and filtered. The deep red crystals of the complex **3** were isolated by slow diffusion of hexane into the above filtrate for several days and collected under vacuum over P_4O_{10}.

Synthesis of $[VO(L^2)(OCH_3)(CH_3OH)]\cdot CH_3OH$ (*4*)

To H_2L^2 (1.00 mmol) dissolved in 15 cm^3 CH_3OH was added $VO(acac)_2$ (0.263 g, 1.00 mmol) in 15 cm^3 CH_3OH. The mixture was refluxed with stirring for 1 h, cooled to room temperature and filtered. The deep red crystals of the complex **4** were obtained by slow evaporation of the deep red filtrate at room temperature in a few days, and then collected under vacuum over P_4O_{10}.

Physical measurements

IR spectra and Raman spectra were measured on a Nicolet Magna 750 Fourier transform IR spectrometer and a Nicolet Raman 910 Fourier transform laser-Raman spectrometer, respectively. UV-vis spectra were obtained on a Perkin-Elmer lambda 9 UV/vis/near-IR spectrometer in CH_2Cl_2 solution and in the 300–1000 mm range. ^{1}H NMR spectra were collected on a Varian FT-80A spectrometer in $CDCl_3$, using TMS as internal standard. Electrochemical measurements were undertaken on a BAS 100 A electrochemical analyzer on CH_2Cl_2 solution (1 mM complex, 0.1 M $(Et_4N)ClO_4$). A three-electrode system was composed of a platinum working electrode, a platinum wire auxiliary electrode, and a Ag/AgCl reference electrode.

X-ray structure determination

X-ray diffraction data were recorded on a Rigaku AFC5R diffractometer with graphite-monochromated Mo–K_α radiation ($\lambda = 0.71069$ Å), the scan mode being ω-2θ. Cell dimensions were refined using 25 reflections in the ranges $20 < 2\theta < 30^\circ$. The diffraction data were corrected for Lorentz effect and polarization effect for the title complexes. The crystallographic data are given in Table 1.

The structures were solved by direct methods and refined by a full-matrix least-squares procedure. All non-hydrogen atoms were refined with anisotropic thermal parameters. All hydrogen atoms were located by difference Fourier map or HYDROGEN program and added to the structure factor calculation, but their positions were not refined.

RESULT AND DISCUSSION

Spectroscopic studies

Table 2 summarizes the IR and Raman spectra data of the free ligands and the title complexes. A strong and broad band near 3138 ~ 3057 cm^{-1} is observed in IR spectra of the free ligands and assigned to the ν(OH) absorption with hydrogen bond [32, 33], but disappeared in the four title complexes. The bands at 3234 cm^{-1} in **1** and at 3158 cm^{-1} in **4** are due to the

Ar–OH absorption in **1** and the coordinated CH_3–OH absorption in **4**, respectively. The medium strong bands at 966–980 cm^{-1} (IR) and at 960–979 cm^{-1} (Raman) in these title complexes are attributed to the typical V═O stretching frequencies, falling within the range of 950–990 cm^{-1} reported for six-coordinated oxovanadium(V) complexes [9, 15–17, 29]. The very strong stretching vibrations of ν (C═N) and ν(C═O) are displaced to lower frequency [27, 33], and the strong ν(C–O) (phenolato oxygen) and the middle ν(N–H) absorption bands in the title complexes display a shift to higher frequency with respect to the free ligands [15, 27, 33]. The new medium bands at 1255–1279 cm^{-1} (IR) and at 1251–1278 cm^{-1} (Raman) may be due to the enolic ν(C–O) absorption [25, 29]. It shows that the hydrazone ligands in the title complexes are in a dianionic form of the type ($^-$O∼N∼O$^-$) and the two hydroxamate ligands are in a monoanionic form of the type (O∼O$^-$). The stretching vibrations of the V–O bond and the V–N bond have been observed at 499–355 cm^{-1} (far-IR), and 500–356 cm^{-1} (Raman) [25].

The ^{1}H NMR spectra data of the free ligands and the title complexes are also shown in Table 2. As expected, O–H and N–H resonances of the free hydrazone ligand are absent in the title complexes. Broad NH–OH resonances (δ 8.77 and 8.90 ppm) of free salicylhydroxamic acid and benzohydroxamic acid change into a singlet (δ = 8.98, 8.96 and 8.93 ppm in **1**, **2** and **3**, respectively) [33], indicating the coordination through their deprotonation of the hydroxyl group in the hydroxamate ligand. In complex **1**, the peak at δ 10.86 ppm is assigned to O–H resonance bonding to aromatic ring of the salicylhydroximate ligand. In complex **3**, the peak at 5.30 ppm is assigned to CH_2 resonance to a dichlormethane molecule. In complex **4**, the peaks at 5.31 ppm and 3.44–3.94 ppm are assigned to H and –CH_3 resonances of the bonded methanol molecule. These are agreement with the results of their single crystal analysis.

The LMCT transition (λ = 454, 448, 537 and 492 nm for **1**, **2**, **3** and **4**, respectively) is considered as a charge transfer from a p-orbital on the lone-pair of phenolato or oximate oxygen to the empty d-orbital of vanadium atom. In contrast to other oxovanadium(V) hydrazone complexes with 8-quinolinol co-ligand [29, 34], the absorption peaks of the visible region in the title complexes are obviously moved to the UV region. The other strong bands (λ = 338, 335, 352 and 365 nm in **1**, **2**, **3** and **4**, respectively) are generally attributed to the intraligand absorption peaks [34]. The other LMCT band observed in the UV region (365 nm in **4**, 352 nm in **3**) is due to alkoxo/enolic oxygen bound to vanadium(V) [34].

As illustrated in Fig. 1, there is a quasi-reversible redox behavior corresponding to V^V/V^{IV} couple in

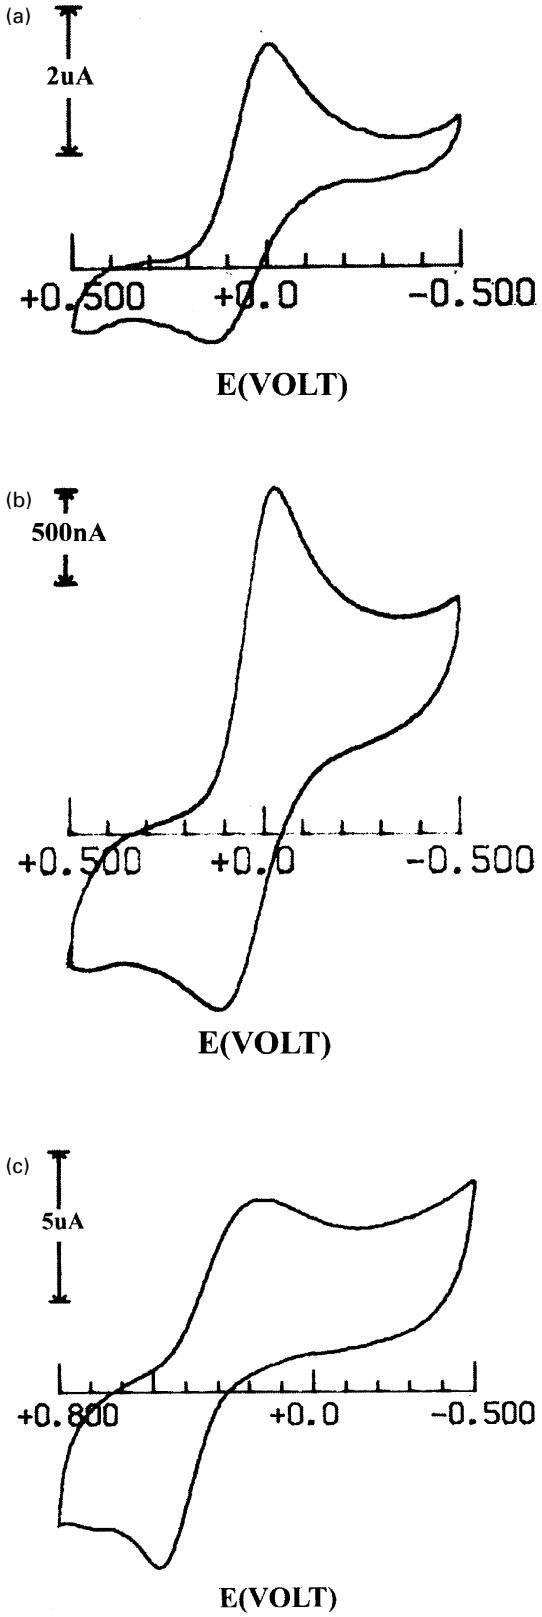

Fig. 1. Cyclic voltammogram of the title complexes **2**, **3** and **4** in dichloromethane (a) complex **2** (b) complex **3** (c) complex **4**

dichloromethane solution in the title complexes. Their redox potentials in complexes **1**, **2**, **3** and **4** are at $E_{1/2}=0.131$ V, 0.060 V, 0.030 V and 0.338 V with respect to Ag/AgCl, respectively. The peak-to-peak separations ($\triangle E_p$ of coupled peaks D/E) are 94 mV (**1**) and 90 mV (**2**) at a rate of 200 mV s^{-1}. The $E_{1/2}$ value of the complex **1** is smaller of 71 mV than that of the complex **2** due to the difference between the bidentate hydroximate ligands. It is noteworthy that the potentials of the VO^{3+}-VO^{2+} couple in the complexes **3** and **4** are significantly more positive than those observed for some VO^{3+} complexes [34], indicating that the complexes **3** and **4** are relatively unstable.

Description of the structures of complexes $[VOL^1(Hshi)]$ (*1*), $[VOL^1(bz)]$ (*2*) *and* $[VOL^2(bz)]\cdot CH_2Cl_2$ (*3*)

The selected bond lengths and angles in complexes **1**, **2** and **3** are listed in Table 3, Table 4 and Table 5, respectively. The molecular structures of complexes **1**, **2** and **3** are shown in Fig. 2, Fig. 3 and Fig. 4.

There are seven common structural features in the complexes **1**, **2** and **3**.

(a) The coordination sphere around the vanadium atoms is a distorted octahedral configuration with $[V^VO(ONO)(OO)]$ type. However, most of vanadium atoms in the known vanadium hydrazone complexes have a square pyramidal $[V^VO(ONO)(O)]$ coordination [10, 22–27], only one complex has octahedral $[V^VO(ONO)(O)(O)]$ coordination [28] and two complexes have $[V^VO(ONO)(ON)]$ coordination [9, 15]. The title complexes **1**, **2** and **3** represent the first structural characterization of any vanadium hydrazone complex with VO(ONO)(OO) coordination.

(b) The equatorial plane is formed by the O, N, O atoms of the fully deprotonated tridentate hydrazone ligand (L) and an oxime oxygen atom of the hydroxamate ligand. The vanadium atom is 0.271 Å, 0.279 Å and 0.271 Å out the equatorial plane and toward the oxo oxygen atom in the complexes **1**, **2** and **3**, respectively.

(c) The atom lying *trans* to the oxo oxygen atom (O_o) is the carbonyl oxygen atom (O_c.) of the hydroximate ligand, but not the oxime oxygen of the same ligand. It may be related to the structural *trans* effect and the delocalized conjugated system between the V=O unit and the related group in hydroxamic acids. The *trans* angle O_o–V–O_c. is 171.4(2)°, 172.8(2)° and 170.5(2)° in complexes **1**, **2** and **3**, respectively. The vanadyl bond of V=O is 1.574(4), 1.593(5) and 1.594(4) Å in complexes **1 2** and **3**, respectively. The vanadyl bond length in complex **1** is at the shortest limit of normal V=O bond lengths, although it is within the range (1.57–1.61 Å) found in VO^{3+} complexes [15–18, 22–28]. In complex **2**, the V=O bond length and V–O(3)(carbonyl) are 1.593(5) and 2.201(5) Å,

which are longer than the corresponding bond distances of the complex **1**. It may be related to the difference between hydroxamate ligands in these two complexes.

(d) The four V–O or V–N bond distances in the equatorial plane follow the order: alkoxide oxygen < phenoxide oxygen, oxime oxygen < enolic oxygen < imine nitrogen. The bond length of V(1)–O(2) (enolic oxygen) in complex **1** is ~0.1 Å longer than that of the V(1)–O(1) (phenolate) and V(1)–O(4) (oxime) in the equatorial plane. It can been explained that the phenolate and oxime oxygen atoms have a high basicity and ensure significant back bonding of their O→V bond as revealed by the bond length data.

(e) The V–N bond distance is 2.090(4), 2.056(5) and 2.073(5) Å in complexes **1**, **2** and **3**, respectively, which lie in the range (2.05–2.12 Å) reported in the VO^{3+} hydrazone complexes [9, 10, 15, 22–28]. The V–N bond length (2.090(4) Å) in complex **1** is slightly shorter than the corresponding one (2.119(6) Å) in complex [VOL^1(OCH$_3$)(CH$_3$OH)]

[28]. It means that the presence of hydroxamate ligand in complex **1** results in the difference of V–N bond lengths between these two complexes.

(f) The hydrazone ligand in all four title complexes, except the methanol group in complexes **3** and **4**, constitute a good plane with mean derivation of 0.032, 0.019, 0.010 and 0.073 Å in complexes **1**, **2**, **3** and **4**, owing to the existence of delocalized π bond in hydrazone ligand.

(g) The N–N bond distance in salicylhydroxamate or benzohydroxamate ligand is 1.404(5), 1.405(7), 1.379(6) and 1.388(5) Å in complexes **1**, **2**, **3** and **4**, respectively, which agree well with the N–N bond distances (1.38–1.41 Å) observed in the known VO^{3+} hydrazone complexes [9, 10, 15, 22–28].

The first four common structural features mentioned above have also been observed in the two vanadium hydroxamate complexes reported by our group [29].

For the first time the salicylhydroxamate ligand $(Hshi)^{-1}$ is coordinated to oxovanadium(V) in a monoanion form of the type (O ~ O^-) in complex **1**. In all known VO^{3+} salicylhydroxamate complexes, the salicylhydroxamate ligand is a dianion [5] or trianion [17]. It is interesting to note that there is no intramolecular hydrogen bond between the oxygen atom of the pendant phenol and the hydroxamate nitrogen in complex **1**, although this kind of the hydrogen bond has been found in complex [VO(HSHED)(shi)] [5]. In complex **1**, there are two kinds of intermolecular hydrogen bonds between the pendant O(5)–H group in the hydroxamate ligand and the nitrogen atom N(2a) in the hydrazone ligand of a neighbouring molecule and between vanadyl oxygen atom O(6) and N(3b)–H group in the hydroxamate ligand of another neighbouring molecule, as given in Table 3.

In complex **2**, the bond length of V(1)–O(4) is 1.855(4) Å, somewhat shorter than the average observed in the complex $VOCl(bz)_2$ (1.902 Å) [16].

In complex **1**, the five-membered chelate ring of O(2), C(8), N(2), N(1), V(1) and the six-membered chelate ring of O(1), C(1), C(6), C(7), N(1), V(1) for-

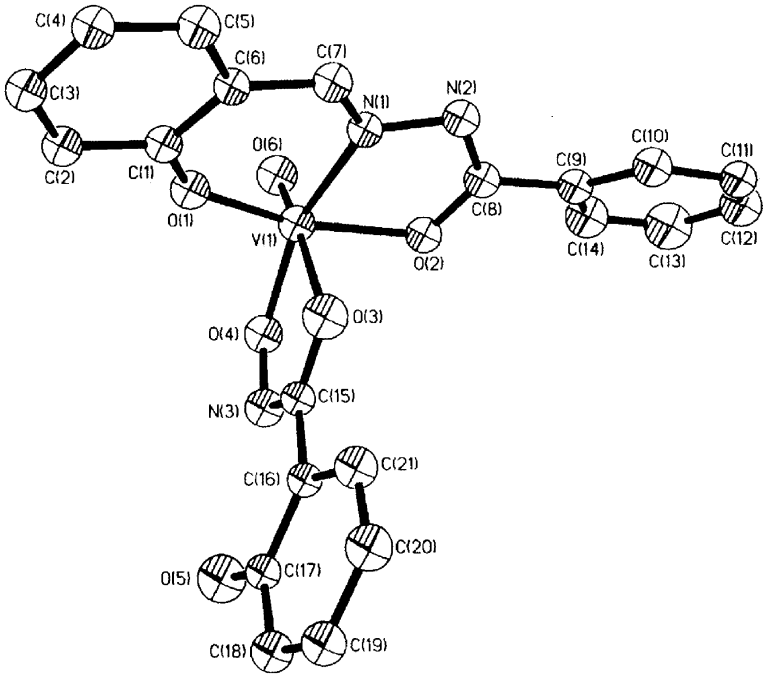

Fig. 2. Molecular structure of complex **1** showing the atom numbering and 30% probability displacement ellipsoids

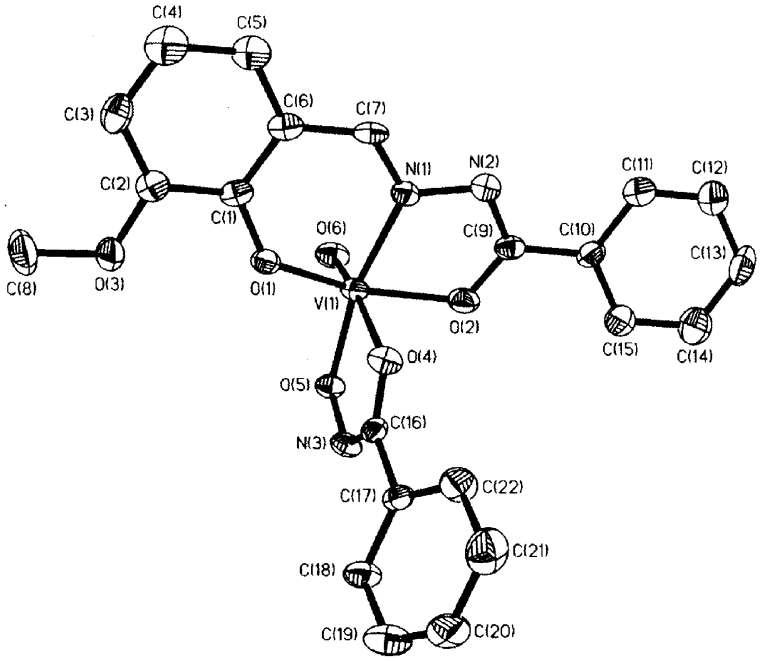

Fig. 4. Molecular structure of complex **3** showing the atom numbering and 30% probability displacement ellipsoids

med by the tridendate hydrazone ligand are planar with mean deviations of 0.040 Å and 0.057 Å, respectively. However, in complex **2** the five-membered chelate ring is a good plane with a mean deviation of 0.006 Å, but the six-membered chelate ring is not planar. The dihedral angle of two benzene rings of the hydrazone ligand is 21.2° in **1** and 9.2° in **2**. The dihedral angle between the hydroxamate ligand and the tridentate hydrazone ligand is 85.4° in **1** and 82.4° in **2**. In complex **3**, the atoms V(1), N(1), N(2), C(9), O(2) constitute an excellent plane with a mean deviation of 0.005 Å and the atoms V(1), O(4), C(16), N(3), O(5) also constitute a good plane with a mean deviation of 0.028 Å.

As illustrated in Table 5 and Fig. 5, two [VO(L)(bz)] units related by a center of symmetry in complex **3** are joined by the two intermolecular hydrogen bonds N(3)–H(24) ... O(3a) and N(3a)–H(24a) ... O(3) (symmetry code: a, -x, -y, -z).

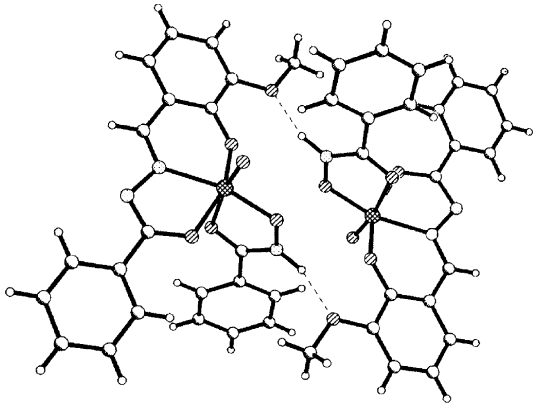

Fig. 5. Packing diagram of complex **3** showing H-bonding as broken lines

Description of the structure of complex [VOL^2 (OCH_3)(CH_3OH)] CH_3OH (4)

The selected bond lengths and angles for complex **4** are listed in Table 6. As shown in Fig. 6, the complex **4**, $VOL^2(OCH_3)(CH_3OH)]CH_3OH$, has a distorted octahedral VO^{3+} species with VO(ONO)(O)(O) type. The atoms O(1), O(2), N(1) from the dinegative tridentate hydrazone ligand and atom O(4) from a methoxide ion define a basal plane with small mean deviation (0.019 Å). The vanadium atom deviates by 0.324 Å from the equatorial plane towards the oxo oxygen atom. The oxo oxygen atom O(6) and the oxygen atom O(5) of the methanol molecule occupy the apical positions with a *trans* angle of 173.89(1)°, the bond distances of the vanadyl V═O(6) and the V(1)–O(5) (methanol) are 1.577(4) Å and 2.346(4) Å, respectively, due to the structural *trans* effect. The structural *trans* effect in the complexes with VO(ONO)(O)(O) type, such as in complex 4 and VO(sal-L-ala) (OCH_3)(CH_3OH) [35], is stronger than that in the ones with VO(ONO)(OO) type.

The vanadyl V═O distance (1.577(4) Å) in complex [$VOL^2(OCH_3)(CH_3OH)$] CH_3OH is shorter than that in complex [VOL^2(bz)]·CH_2Cl_2, but is in the accept-

(Received 11 February 1998; accepted 2 April 1998)

Abstract—The preparation and the characterization of the (isothiocyanato)(α,α,α,α-tetrakis(*o*-pivalamidophenyl)porphinato)iron(III) complex is described. The synthesis procedure utilizes the crown ether 18-C-6 to solubilize potassium thiocyanate. ^{1}H NMR and EPR data of the isolated product are in accordance with a high-spin ($S=5/2$) ferric porphyrin species. The X-ray molecular structure confirms the above deductions. The iron atom is pentacoordinated by the four nitrogen atoms of the pyrrole rings of the porphyrin and the nitrogen atom of the NCS^- group. It lies at 0.504 Å out of the porphinato plane and 0.462 Å out of the four nitrogen plane. The Fe–N(NCS) bond length is 1.956(5) Å and the Fe–N–C(NCS) bond angle is 176.1(5)°. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: porphyrin; iron(III) complex; isothiocyanate complex; high-spin Fe(III); molecular structure.

INTRODUCTION

The interest in iron porphyrins stems not only from the diverse biological roles of the iron porphyrin moiety found in proteins, cytochromes, peroxidases, etc. but also from the array of physical properties observed for the coordinated Fe(II) and Fe(III).

In most cases, when weak crystal field ligands such as halides or pseudohalides are bound to an iron(III) of a metalloporphyrin or a hemoprotein, the resulting porphyrinate is high spin and five coordinate. Nevertheless, many examples of six coordinate high-spin heme-like species exist, i.e. (2-MeHIm)[Fe(F)$_2$(TPP)] [1]. In some special circumstances the ferric ion may be in the spin "crossover" region and show thermal spin-equilibrium. Thus, in the case of the azide ligand, Scheidt *et al.* [2], confirmed the high spin ($S=5/2$)⇔low spin ($S=1/2$) equilibrium of the bisazide Fe(III) porphyrin species; [Fe(N$_3$)$_2$(TpivPP)]$^-$. Korszun and Moffat [3] have determined the structure of the isothiocyanato-liganded hemoglobin which shows a spin equilibrium between the high-spin NCS^- pentacoordinate heme and the "(NCS)MetHb proximal histidine" low spin six coordinate methemoglobine.

The isothiocyanate ferric porphyrinate was mentioned in the literature for decades [4] as a high-spin ($S=5/2$) pentacoordinate derivative. However, a complete characterization of such species has not been previously reported.

It is the aim of this work to synthesize and spectroscopically and structurally characterize the isothiocyanate Fe(III) picket fence porphyrin complex.

We also report in this paper the use of crown ethers to solubilize the inorganic potassium thiocyanate salt in organic solvents typically used with iron porphyrinates.

The use of the picket fence porphyrin for the characterization of this ferric porphyrinate was directly related to the fact that ionic not very bulky ligands as it is shown by X-ray molecular structures [5], are in

all cases bound to the iron by the pocket side of the protected porphyrin. Consequently, these complexes are remarkably stable.

RESULTS AND DISCUSSION

The reported synthesis for halide and pseudohalide Fe(III) porphyrin species make use of organic-soluble iron porphyrinates and typically water-soluble inorganic salts [6] (KCl, KBr, NaN_3, etc.) or aqueous acids (CH_3COOH [7], HNO_3 [8], etc.). In our case, the (isothiocyanato)(α,α,α,α-tetrakis(*o*-pivalamidophenyl)porphinato)iron(III) complex has been prepared by using only one organic phase. The 18-C-6 crown ether was used to solubilize the potassium thiocyanate in chlorobenzene solution[1]. Our synthetic strategy has the advantage of avoiding the use of a mixture of an organic and an aqueous solution and obtaining the anionic reagent in high concentration.

Figure 1 represents the electronic spectrum of the [Fe(NCS)(TpivPP)] species recorded in chlorobenzene. The spectrum belongs to the hyper class [9]. The Soret and the β bands values (respectively, 417 and 513 nm) are quite identical to those of other pentacoordinate Fe(III) high-spin *meso*-porphyrin species [10].

The EPR spectra carried out at 77 K show similar features in solution and in solid state. Both spectra are axially symmetric; $g\perp = 5.8$ and $g_{\parallel} = 1.98$ for the frozen chlorobenzene solution and $g\perp = 5.7$ for the powder (crushed single crystals). These results provide unequivocal evidence that either in solid state or in solution the [Fe(NCS)(TpivPP)] complex is high-spin ($S = 5/2$).

A proton NMR spectrum of [Fe(NCS)(TpivPP)] in $CDCl_3$, recorded at room temperature, supports the latter conclusion. Thus, the pyrrole proton resonance at 75.7 ppm (line with ≈ 365 Hz) is in the range 100–70 ppm, a downfield region characteristic of high-spin iron(III) tetraarylporphyrin complexes [11]. The *ortho*-phenyl protons of the macrocycle are not observed. Strong dipolar interactions should be the cause of the important broadening. *Meta*-phenyl protons are highly anisotropic giving rise to two singlets at 11.5 and 14.4 ppm.

The IR spectrum of [Fe(NCS)(TpivPP)] shows that the value of the stretching frequency ν(CN) which is 2015 cm^{-1}, is a clear evidence that NCS^- is N-bonded to the iron (an isothiocyanate) [12].

The molecular structure of the [Fe(NCS)(TpivPP)] complex is illustrated in Fig. 2. The NCS^- ligand lies, as expected, in the axial position inside the cavity formed by the pivalamide arms of the picket fence porphyrin. The iron atom is five coordinated and the resulting polyhedron is a slightly deformed square pyramid with the nitrogen atom of the NCS^- group in the axial position. Selected bond distances and angles for this complex are given in Table 1. Other distances and angles, fractional coordinates and thermal parameters have been deposited as supplementary data with the editor.

The bond parameters for the coordination environment of the Fe(III) in this compound and for a selec-

tion of some other Fe(III) metalloporphyrins are given in Table 2. A brief description of the molecular structure of the otherwise analogous [Fe(NCS)(TPP)] complex was mentioned by Bloom and Hoard [13]. The values of the Fe–Np distances of the TpivPP and TPP derivatives are, respectively, 2.055(2) and 2.065 Å. These values are a clear indication that these species are high-spin [14]. In order to accommodate the high-spin iron(III) atom, the porphinato cores undergo a significant radial expansion. This is very well illustrated by the long Fe–P_C and Fe–P_N distances shown by [Fe(NCS)(TpivPP)] and [Fe(NCS)(TPP)].

Table 2. Porphinato core parameters (Å) for selected Fe(III) porphyrin complexes

Complex	Fe–Np	Fe–X_L	Fe–P_C	Fe–P_N	δ[a]	Spin (S)	Refs.
[Fe(NCS)(PivPP)]	2.055 (2)	Fe–N_L[b]: 1.956 (5)	0.504	0.462	0.042	5/2	this work
[Fe(NCS)(TPP)]	2.065	Fe–N_L[b]: 1.957	0.550	0.485	0.065	5/2	[13]
[Fe(NCS)(Py)(OEP)]	2.048 (4)	Fe–N_L[b]: 2.031 (2)	0.240[c]	0.180[c]	—	5/2	[15]
[Fe(NCS)(Py)(TPP)]	1.988 (9)	Fe–N_L[b]: 1.942 (4)	0.050[c]	0.050[c]	—	1/2	[15]

[a]δ = the doming.
[b]Fe–N_L = Fe–N(NCS) distance.
[c]Displacement toward the isothiocyanate ligand.

The corresponding values are, respectively, 0.504 and 0.462 Å for the former complex and 0.55 and 0.485 Å for the latter. For both [Fe(NCS)(Porph)] derivatives, the Fe–N(NCS) distances have the same values; 1.956(5) Å for the picket fence porphyrin product and 1.957 Å for the tetraphenylporphyrin moiety.

As expected for an N-bonded thiocyanate to an iron atom, the Fe–NCS group, is found to be essentially linear for all NCS^- derivatives shown in Table 2 (except the ambiguous [Fe(NCS)(Py)(TPP)] [15] case). Both isothiocyanate TpivPP and OEP derivatives exhibit rather identical values for the Fe–N–C(NCS) angle [respectively, 176.1 (5)° and 176.0 (2)°]. These two derivatives present very close N–C–S angle values with 178.6° (6) for the picket fence complex and 179.6° (2) for the OEP six coordinate species.

The porphyrinato core in [Fe(NCS)(TpivPP) is decidedly non-planar as can be seen from an inspection of Fig. 3. The pattern of the atom displacements in the porphinato core correspond closely to those

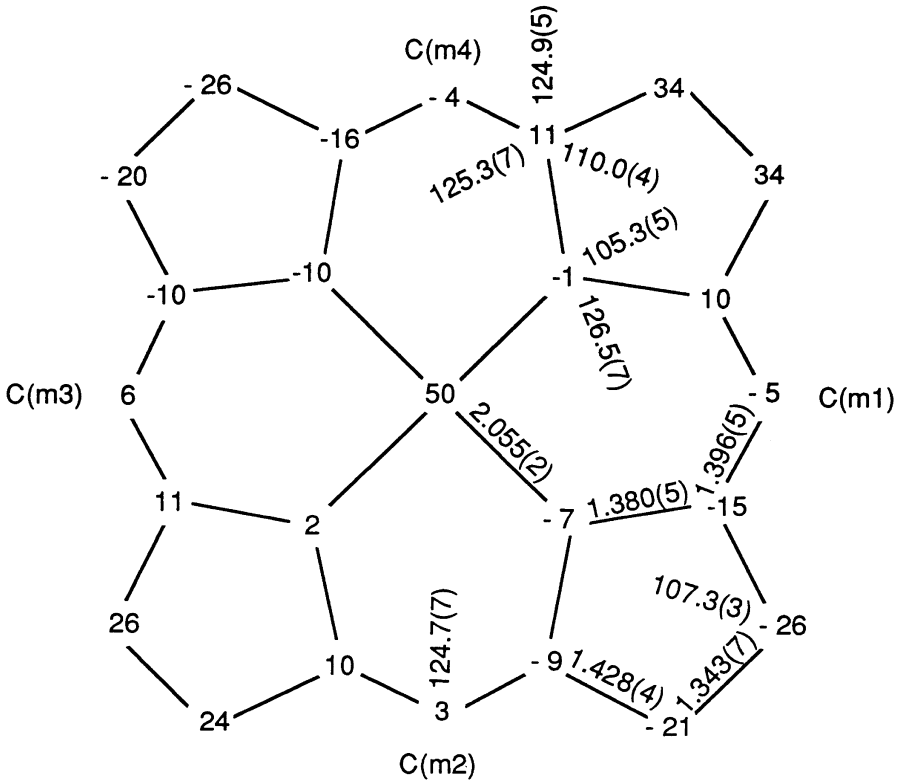

Fig. 3. Formal diagram of the porphinato core in the [Fe(NCS)(TpivPP)] molecule displaying the displacement, in units of 0.01 Å, from mean plane of the porphinato core. Also displayed on the diagram is the average value of each type of bond distance and angle in the porphinato core.

required by exact D_{2d} symmetry, often simply called S_4-ruffling. Least squares planes calculations indicate a small doming of the porphyrin (0.042 Å).

EXPERIMENTAL

The complex [Fe(SO_3CF_3)(H_2O)(TpivPP)] was prepared as described previously [16]. The 18-C-6 crown ether was recrystallized in toluene, dried under vacuum overnight and stored under argon. Toluene and hexanes were distilled from their sodium–benzophenone solution under a nitrogen atmosphere. Chlorobenzene was purified by washing with sulfuric acid and then distilled over P_2O_5.

UV-VIS spectra were recorded on a Perkin-Elmer Lambda 19 spectrometer, Fourier-transform IR data on a Bio-Rad FT S4000 spectrometer and EPR spectra were obtained at 77 K on a Varian E-line spectrometer operating at X-band frequency.

^{1}H NMR data were obtained on a Nicolet NT300 spectrometer operating at 300.063 MHz.

Preparation of the [Fe(NCS)(TpivPP)] compound

The (isothiocyanato)(α,α,α,α-tetrakis(*o*-pivalamidophenyl)porphinato)iron(III) complex was prepared by reacting [Fe(SO_3CF_3)(H_2O)(TpivPP)] (0.016 mmol) with KSCN (0.32 mmol) and 18-crown-6 (0.16 mmol) in 20 ml of C_6H_5Cl. The resulting red brownish solution was then filtered and an X-ray quality crystals were prepared by slow diffusion of hexanes into C_6H_5Cl. The crystalline material was washed with several portions of water and then with hexanes.

UV-VIS [C_6H_5Cl, λ_{max} in nm, ($\log\varepsilon$)]: 417 (4.99); 513 (4.21); 586 sh (3.63); 655 (3.54) IR (KBr, cm^{-1}): ν(CN): 2015. EPR (C_6H_5Cl, 77 K): $g\perp = 5.8$; $g_\parallel = 1.98$. ^{1}H NMR (300 MHz, $CDCl_3$): H(pyrr): 75.7 ppm; H(*meta*-Ph): 11.5, 14.4; H(*para*-Ph): 8.0 ppm.

Determination of crystal and molecular structure

Crystal data. $C_{65}H_{64}N_9O_4SFe$, $M = 1123.2$, monoclinic, space group $P2_1/n$, $a = 13.237(3)$ Å, $b = 18.272(4)$ Å, $c = 23.678$ Å, $\beta = 94.910(10)^\circ$, $V = 5706.0$ Å^3, $D_c = 1.31$ g·cm^{-3}, $Z = 4$, $F(000) = 2724$, $\lambda = 0.71073$ Å, μ(Mo–Kα) = 35.3 cm^{-1}.

Data collection and processing. A dark single crystal of approximate size $0.6 \times 0.3 \times 0.3$ mm^3 was examined on an Enraf-Nonius FAST area detector diffractometer at 127 K. All measurements were performed with graphite-monochromated Mo–Kα radiation. Data collection and reduction were defined as before [17]. Intensity data were corrected for absorption effects using a modified version of the absorption correction program DIFABS[2].

A total of 10020 unique reflections was collected and 6791 having $I > 2\sigma(I)$ [merging R(int) = 0.132].

Structure analysis and refinement. The structure was solved in the centrosymmetric space group $P2_1/n$ using the direct methods program SHELXS-86 [20]. All non-hydrogen atoms were refined anisotropically and all hydrogen atoms were idealized with the standard SHELXL-93 [21] idealization method. The final cycles of refinement based on F^2 of 733 variables converged to the final $R_1 = 0.079$ and $wR_2 = 0.167$[3] for reflections with $I > 2\sigma(I)$. The final difference Fourier map had the largest peak at 0.76 eÅ^{-3}.

Acknowledgements—We gratefully acknowledge professor W. R. Scheidt of the University of Notre Dame (Indiana, U.S.A.) for the use of the Enraf Nonius area detector FAST diffractometer. We also acknowledge M. K. Ellison from the University of Notre Dame (Indiana, U.S.A.) for her kind help in recording the EPR spectra.

(Received 11 February 1998; accepted 2 April 1998)

Abstract—The preparations and X-band EPR spectra are reported of a series of manganese(II) complexes with N,N′-butylenebis(imidazole) (=BBI) of the types $Mn(BBI)_2X_2$ (X = Cl, Br, NO_3, NCS) and $[Mn(BBI)_3]X_2$ (X = ClO_4, I). An X-ray crystallographic study on $Mn(BBI)_2Cl_2$ (**1**) shows that each Mn atom is coordinated to four imidazole nitrogen atoms and two chloride ions in a *trans*-octahedral arrangement and that the BBI ligands link the Mn centres into sheets of contiguous 44-membered rings. X-Ray studies on $[Mn(BBI)_3](ClO_4)_2$, and on analogous compounds containing combinations of ClO_4^-/PF_6^- or ClO_4^-/AsF_6^- as counter anions, reveal the formation of a family of interpenetrating network structures with anion-dependent cavity sizes. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: X-ray structures; polymeric complexes; manganese complexes; bis(imidazole).

There is appreciable interest in the development of new zeolites, and related materials (zeotypes), with redox active metals incorporated into their frameworks [1]. As recently summarised by Janiak [2], a promising line of development in this field is the formation of zeotypes based on polymers comprising metal-organic ligand coordination arrays. Providing one can overcome the potential problem of matrix instability under the operating conditions required for effective catalysis or separation process activity, such materials offer a number of advantages. These include, *inter alia*: (a) a wide variation in the incorporated metal ions and their consequent redox activity and (b) an enhanced potential for alteration in the sizes, shapes and natures of the cavities and channels, by selective changes in the design of the organic ligands and the coordination geometries available to the metal ions which link them.

Various approaches based on the self-assembly principle, using extended reach ligands, have been adopted for the formation of discrete molecular "boxes" [3] or polymeric networks containing cavities and/or channels [4]. In practice, the aim of creating materials genuinely capable of taking up guest molecules in a controllable and useful fashion can be vitiated by a number of factors. Energy minimisation of the crystal lattice frequently results in arrays in which any "cavities" are essentially self-filled by the surrounding matrix. The cavities may also be occupied by counter ions and/or solvent molecules, though solvent inclusion may not preclude zeotype utility if the matrix is sufficiently robust to permit solvent removal followed by its replacement by other substrates without major structural reorganisation.

Another serious obstacle to the formation of "box" arrays containing cavities of useful size is the formation of interpenetrating lattices either by interweaving of adjacent sheets (polycatenances and polyrotaxanes) [5] or multiple interpenetrating 3-D lattices [6]. Elucidation of the factors leading to avoidance of such interweaving or interpenetration, and

*Authors to whom correspondence should be addressed.

consequent formation of new materials combining metal centres potentially capable of redox action and also genuinely useful large cavities, is an intriguing challenge.

To exemplify this problem, one may compare the structures of three recently reported arrays of contiguous rhomboidal "boxes" based on octahedrally coordinated metal centres. In $[Mn(BBI)_3](BF_4)_2$ (**2**), where BBI = N,N′-butylenebis(imidazole) **I**, rhomboid lattice interpenetration occurs [7], but in [Mn(N,N′-*p*-phenylenedimethylenebis(4-methylpyridin-2-one)$_3$]$(ClO_4)_2$, formed by **II** [8], and in [Ni(N,N′-1,2-ethylenebis(pyridin-2-thione)$_3$]$(ClO_4)_2$, formed by **III** [9], there is no such interpenetration. We are currently attempting to investigate the factors influencing the onset of lattice penetration in compounds of this type and we report here the results of a study of the anion dependence of the structures of the manganese(II) complexes formed by **I**.

EXPERIMENTAL

Preparation of compounds

N,N′-butylenebis(imidazole). This was prepared as described previously [10].

Metal complexes of N,N′-butylenebis(imidazole)

Elemental analyses were by the Microanalytical Laboratory, Imperial College.

$[Mn(BBI)_2Cl_2 \cdot H_2O$.

Dropwise addition of $MnCl_2 \cdot 4H_2O$ (0.05 mmol) in methanol (4 cm^3) to a solution of BBI (0.1 mmol) in a mixture of acetonitrile (4 cm^3) and methanol (1 cm^3) gave a colourless microcrystalline solid which was collected by filtration, washed with acetonitrile and methanol and dried over P_2O_5. Yield 62%. Found: C, 45.8; H, 5.3; N, 20.6; Calc. for $C_{20}H_{28}N_8Cl_2Mn \cdot H_2O$: C, 45.8; H, 5.8; N, 21.4%. The same compound was obtained (in 76% yield) when $MnCl_2 \cdot 4H_2O$ and BBI were reacted in 1:4 mole ratio in methanol.

Single crystals for the X-ray studies were obtained by slow diffusion (15 days in the refrigerator) of a methanolic solution of $MnCl_2 \cdot 4H_2O$ (0.05 mmol in 8 cm^3) into a DMF solution of BBI (0.1 mmol in 10 cm^3).

$Mn(BBI)_2Br_2 \cdot MeOH$.

A solution of $MnBr_2 \cdot 4H_2O$ (0.2 mmol) in methanol (3 cm^3) was added to a methanolic solution of BBI (0.8 mmol in 3 cm^3). Upon standing, an off-white microcrystalline powder separated in 72% yield. Found: C, 39.8; H, 5.1; N, 17.7; Calc. for $C_{20}H_{28}N_8Br_2Mn \cdot MeOH$: C, 40.2; H, 5.1; N, 17.9%.

$Mn(BBI)_2(NO_3)_2$.

A solution of $Mn(NO_3)_2 \cdot 6H_2O$ (0.05 mmol) in a mixture of methanol (1 cm^3) and acetonitrile (3 cm^3) was slowly added to a solution of BBI (0.1 mmol) also dissolved in methanol (1 cm^3) and acetonitrile (4 cm^3). Upon standing overnight, a pale tan microcrystalline powder separated in 68% yield. Found: C, 42.8; H, 4.9; N, 24.5; Calc. for $C_{20}H_{28}N_{10}MnO_6$: C, 42.9; H, 5.0; N, 25.0%. The same compound was obtained (but in 48% yield) when $Mn(NO_3)_2 \cdot 6H_2O$ and BBI were reacted in 1:4 mole ratio in methanol.

$Mn(BBI)_2(NCS)_2.0.5EtOH$.

This white complex precipitated immediately on mixing ethanol solutions of BBI (0.72 mmol in 1 cm^3) and manganese(II) thiocyanate (0.36 mmol in 5 cm^3). Yield 67%. Found: C, 47.6; H, 4.7; N, 24.1; Calc. for $C_{22}H_{28}N_{10}MnS_2 \cdot 0.5EtOH$: C, 48.1; H, 5.4; N, 24.4%. IR: ν(CN) 2053 cm^{-1}.

$Mn(BBI)_3(ClO_4)_2$, (**3**).

A solution of $Mn(ClO_4)_2 \cdot 6H_2O$ (0.033 mmol) in acetonitrile (3 cm^3) was added to a solution of BBI (0.1 mmol) also dissolved in methanol (1 cm^3) and acetonitrile (4 cm^3). Colourless crystals formed overnight. Yield 50%. Found: C, 43.9; H, 5.0; N, 20.1; Calc. for $C_{30}H_{42}N_{12}Cl_2MnO_8$: C, 43.7; H, 5.1; N, 20.4%.

$Mn(BBI)_3I_2 \cdot 2H_2O$.

This off-white complex precipitated immediately on mixing ethanolic solutions of MnI_2 (0.2 mmol in 2.5 cm^3) and BBI (0.8 mmol in 3 cm^3). Yield 61%. Found: C, 39.6; H, 5.0; N, 18.6; Calc. for $C_{30}H_{42}N_{12}I_2Mn \cdot 2H_2O$: C, 39.4; H, 5.1; N, 18.4%.

Reactions of BBI with mixtures of MnX_2 (X = ClO_4, PF_6, AsF_6)

The general procedure was to mix a solution of $Mn(ClO_4)_2 \cdot 6H_2O$ (0.033 mmol) in acetonitrile (4 cm^3) with one of either NH_4PF_6 (0.133 mmol) or $KAsF_6$ (0.066 mmol) respectively in methanol (2 cm^3) and then to add the resulting solution to one of BBI (0.1 mmol) in a mixture of acetonitrile (3 cm^3) and methanol (1 cm^3). The colourless crystals which formed overnight were characterised by X-ray diffraction methods.

Spectroscopy

EPR spectra were measured at room temperature on a Varian E12 X-band (*ca.* 9.5 Ghz) spectrometer using powdered samples.

Crystallography

Data for $Mn(BBI)_2Cl_2$ (**1**), $Mn(BBI)_3(ClO_4)_2$ (**3**) and the compounds $Mn(BBI)_3XY$ containing the anion combinations ClO_4^-/PF_6^- or ClO_4^-/AsF_6^- **4–6**, were collected on a Siemens P4 diffractometer using either Cu–Kα or Mo–Kα radiation and ω-scans. The data were corrected for Lorentz and polarisation effects and, for compounds **1** and **3**, for absorption by ψ scans. All five structures were solved by direct methods and the major occupancy non-hydrogen atoms were refined anisotropically on F^2, using the SHELXTL suite of programs [11]. The absolute structure was determined for compounds **3–6** by refinement of the Flack parameter. In the case of **3** the Flack parameter indicated a racemic twinned crystal. A summary of the crystal data, structure solution and refinement parameters is given in Table 1.

Compounds **3–6** comprise a framework containing two distinct sites for counter anions. In compound **3** both sites are occupied by perchlorate ions but the anion in one of the sites is crystallographically disordered within that site. Compounds **4–6** contain mixed counter ion systems, the constituents of which were found from the difference maps, and their relative occupancies were refined. Compound **4** contains one fully occupied ClO_4^- ion on one site and the other site refined as $0.5ClO_4^-/0.5PF_6^-$; **5** contains $0.7ClO_4^-/0.3AsF_6^-$ on one site and $0.8ClO_4^-/0.2AsF_6^-$ on the other; **6** contains one fully-occupied PF_6^- ion on one site and $0.7ClO_4^-/0.3PF_6^-$ on the other.

Selected bond lengths and angles for compounds **1** are given in Table 2 and those for **3–6** are listed in Table 3.

RESULTS AND DISCUSSION

The stoichiometries of the products formed from the reaction of **I** with the salts of manganese(II), MnX_2, depend on the anion X. For X = Cl, Br, NO_3, or NCS the complexes are of the type $Mn(BBI)_2X_2$, even when an excess of BBI was used in the reaction mixture. On the other hand, with iodide or with non- or poorly-coordinating anions such as BF_4^- [7] or ClO_4^- complexes with a 3:1 BBI:Mn stoichiometry are formed.

The effect changing the anion has on the metal ion coordination geometry is clearly seen from the X-band EPR spectra of the solid compounds. The spectra of the complexes of type $Mn(BBI)_3X_2$ (X = BF_4, ClO_4 or I) are virtually identical and comprise a single sharp band at $g_{eff} = 2.00$, indicating a symmetry very close to O_h about the metal ion. In contrast, the spectra of the 2:1 complexes, $Mn(BBI)_2X_2$, are typical of Mn(II) in a *trans*-MnL_4X_2 coordination environment, where L represents a heterocyclic nitrogen-donor ligand [12] (Fig. 1).

The chloride, bromide, and nitrate all show the characteristic complex spectra, with bands well away from the $g_{eff} = 2.00$ region (*ca.* 0.34 Tesla for the operating frequency employed), arising from the zero-field splitting terms in the spin Hamiltonian for high-spin d^5 in ligand fields of lower than cubic symmetry [12]. The spectra show that the axial asymmetry increases markedly in the order X = NO_3 < Cl < Br. The zero-field splitting for $Mn(BBI)_2(NCS)_2$ is, however, much less as the main band is still at $g_{eff} = 2.00$ but this has additional, weaker components at lower field, as in e.g. Mn(4-methylpyridine)$_4$(NCS)$_2$ [12], pointing to a much smaller distortion of the ligand field at the Mn centre. This is in accord with the observation of ν(CN) at 2053 cm^{-1}, indicating coordination of the anion via nitrogen and the consequent presence of a slightly distorted MnN_6 coordination geometry.

Although these observations provide good evidence for the main coordination geometry about the metal centres in these compounds, it is the long-range structure that is of particular interest in the present context. As we were able to obtain crystals of the chloride, **1**, we have determined its structure by X-ray methods.

Structure of $Mn(BBI)_2Cl_2$ (**1**)

The X-ray results show that in the structure of **1** each Mn centre is coordinated to four nitrogen atoms, one from each of four different BBI ligands, and two chloride ions in a *trans*-octahedral arrangement (Fig. 2). Distortions from octahedral geometry are small, with *cis*-angles ranging from 88.9(1) to 91.1(1)°. The *trans*-angles are all 180° as the Mn atom is positioned on a crystallographic inversion centre. The Mn–N bonds, 2.249(3) and 2.270(3) Å, are the same as those observed in $[Mn(BBI)_3](BF_4)_2$, **2**, [7] and the Mn–Cl distance of 2.579(1) Å is unexceptional. The planes of the pairs of coordinated imidazole rings are steeply inclined, by 59 and 85° respectively, to the equatorial coordination plane.

The BBI ligand has an extended geometry with a near planar, all *anti*, N–$(CH_2)_4$–N backbone, the planes of the imidazole rings both being steeply inclined (58 and 71°) to that of the backbone. The rotations of each imidazole ring are in opposite senses so that, unlike the co-planar conformation observed for these rings in **2**, here they are inclined by *ca.* 60° to each other.

Each BBI ligand links adjacent, symmetry equivalent Mn centres in the crystal to form a contiguous two-dimensional network (Fig. 3). Each macrocyclic component of this network has a pseudo-rhombic shape with opposite arms having either a concave or convex relationship to each other—this is a con-

sequence of the non-coplanarity of the two imidazole ring systems within each bridge. The edges of the rhomb (Mn ... Mn) are 14.02 Å, with inter-edge angles of 82.8 and 97.2°. The trans-annular separations between the centres of opposite aliphatic linkages are 12.1 and 16.4 Å, reflecting a very open ring conformation.

In network structures comprising open-ring systems the sheets are sometimes aligned in register, thus creating "nanotubes" which are filled either by counter ions or by solvent molecules [13]. Alternatively the sheets can interweave and become self-filling via polycatenation [5, 14]. In **1** the voids are filled via partial interpenetration of successive (ABCABC) stacked, slightly corrugated sheets—shown schematically in Fig. 4. This packing is remarkably efficient, the separation between adjacent planes of Mn atoms being only 2.88 Å. Indeed, one of the imidazole rings [that containing N(12)] of each BBI ligand within one sheet interpenetrates and π-stacks with its C_i related neighbour in the next (mean interplanar separation 3.27 Å, centroid-centroid distance 3.67 Å). There is also evidence for secondary edge-to-face C–H ... π interactions between the C(4) hydrogen atom of the imidazole rings in one sheet and the N(12) imidazole rings in the next (C ... π 3.01 Å, C–H ... π angle 163°).

Structures of $Mn(BBI)_3X_2$

The next logical step in the progression from the above two-dimensional array to a three-dimensional network is the replacement of the two chloride atoms by the imidazole rings of an additional pair of BBI ligands. As we have shown in a preliminary communication for **2** [7], the resulting charged species not only formed a contiguous three-dimensional network but also, because of the size of the voids created, satisfied the "self-filling" preference via interlinked interpenetration. The two BF_4^- anions were located in the cusp of two interpenetrating rhombohedra.

We speculated that such a system would have the potential to adjust its dimensions so as to accommodate different anions of varying size and/or shape. The number of variable parameters to achieve this is limited, namely the effective ligand length and the distortions from octahedral geometry at the metal centres. To this end we have investigated the structural changes induced by replacement of the BF_4^- anions by perchlorate ions and also by varying proportions of ClO_4^-/PF_6^- or ClO_4^-/AsF_6^- combinations. The products for which we were successful in obtaining crystalline samples of appropriate quality for X-ray studies are listed in Table 1.

A notable feature of all of these new products is that, although they crystallise in the rhombohedral system with unit cell dimensions similar to, but larger than, those for $[Mn(BBI)_3](BF_4)_2$, **2**, they no longer possess inversion symmetry, all being polar.

Analyses of their structures show them to be virtually identical to that of **2** (Fig. 5), the interpenetrating three-dimensional $\{Mn(BBI)_3\}_n$ network being retained with the new anions trapped within the cusp formed between the interpenetrating rhomboids (Fig. 6). On progressing from the tetrafluoroborate to the somewhat larger [15] perchlorate ion as counter ion the structure changes from being centrosymmetric to polar, thereby destroying the inversion symmetry of the BBI ligand [16]. Overall, the gross structure is unchanged.

Anion competition experiments with the combinations ClO_4^-/PF_6^- and ClO_4^-/AsF_6^- resulted in the formation of polar, mixed anion, inclusion materials each of which retains the same basic structure (Fig. 7).

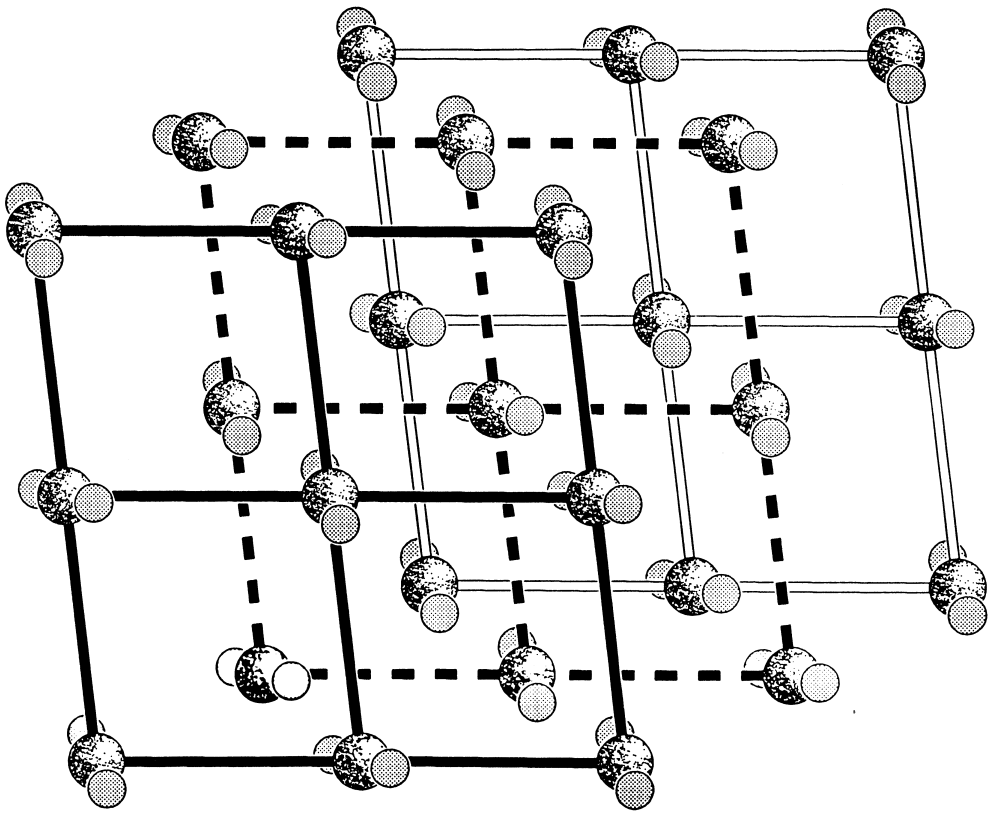

Fig. 4. Schematic representation of the stacking of polymeric sheets in the structure of **1**.

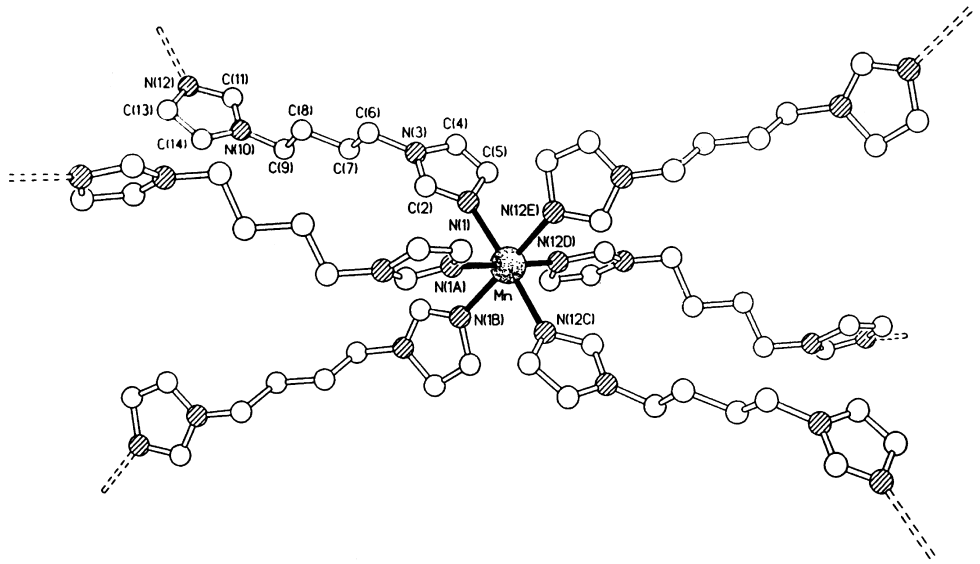

Fig. 5. The Mn coordination environment in the structures of **3**–**6**.

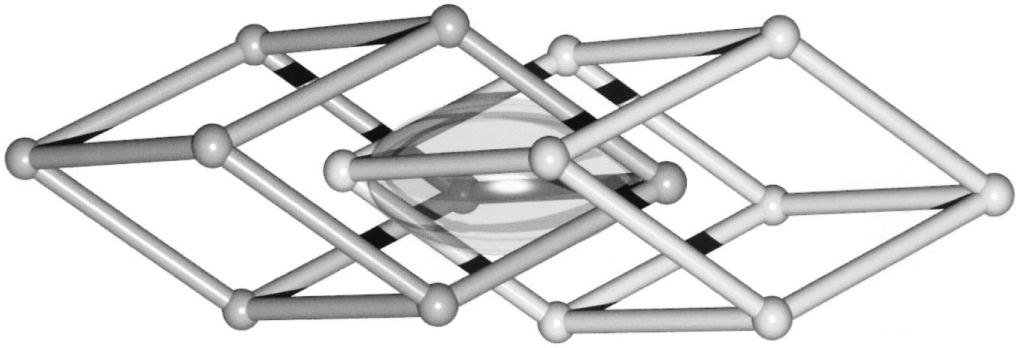

Fig. 6. The domain between the intersecting cuboids where the anions are located in **3**–**6**.

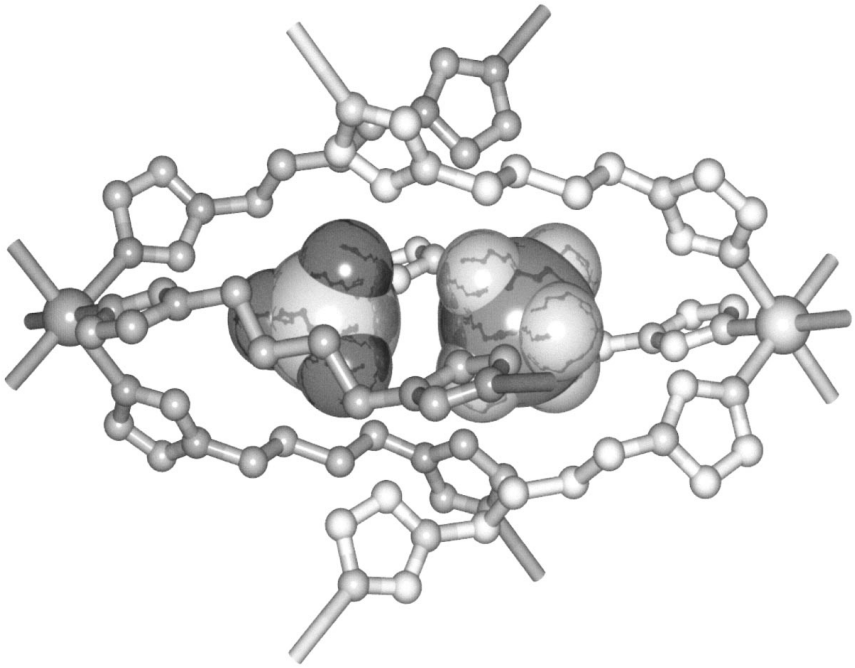

Fig. 7. The location of the ClO^-_4/PF^-_6 anions in the structure of **4**.

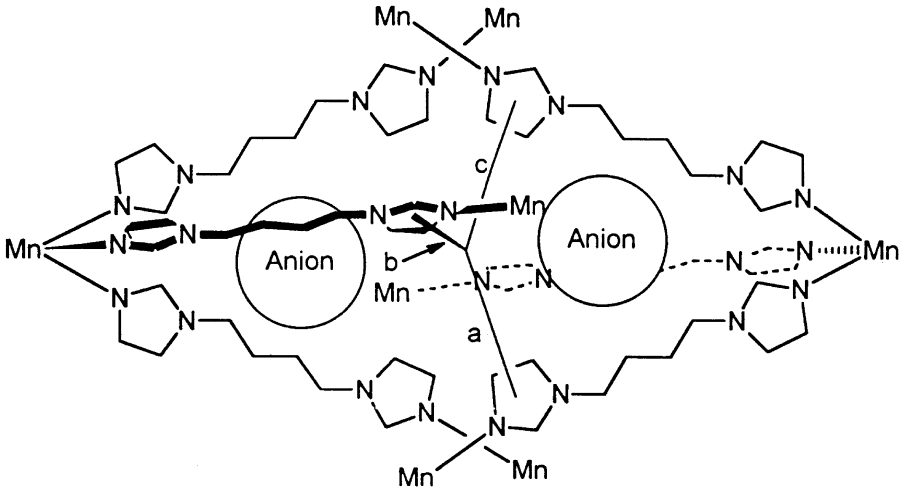

Fig. 8. Schematic representation of Figure 7 indicating the equatorial radii of the ellipsoidal cavity.

On increasing the mean encapsulated anion volume requirements, the internuclear Mn ... Mn separation within the cage decreases from 17.78 Å for **2** to 17.68 Å for **6**, whilst the maximum radii, taken from the centre of the Mn–Mn vector to the centroids of the imidazole rings about the "equator" of the cage (b in the schematic view shown in Fig. 8), increase from 5.33 to 5.45 Å. Thus with these essentially spherical anions there is a measure of "spare" capacity along the longest dimension (Mn ... Mn) of the cage which is relaxed to accommodate the change in anion. The other notable feature of this series of anion encapsulating structures is an increase in the unit cell volume, and hence those of the associated rhomboids, from 2925 $Å^3$ in **2** to 3027 $Å^3$ in **6**. There is therefore a slight expansion of the same basic lattice to accommodate the change in anions.

A thermal study of several lanthanide triflates

Naohisa Yanagihara,* Shin Nakamura and Masayoshi Nakayama

Department of Materials Science and Engineering, Teikyo University, 1-1 Toyosatodai, Utsunomiya, 320, Japan

(Received 6 March 1998; accepted 8 April 1998)

Abstract—Five lanthanide triflates, $Ln(TfO)_3 \cdot nH_2O$, where $TfO^- = CF_3SO_3^-$, $Ln = La^{3+}$, Nd^{3+}, Sm^{3+}, Gd^{3+} and Yb^{3+}, and $n = 9$ and 13, have been prepared and the thermal decomposition processes of these triflates up to 600°C were characterized by means of TG, DTA, XRD. The thermal studies have shown almost all the lanthanide triflates prepared in this study to exist as a stable nonahydrate. During the stepwise dehydration processes, it was found that mono-, di-, tri-, penta-, and heptahydrates were formed. Decompositions were found to be exothermic, and calcinations of these triflates at 600°C resulted in the formation of the corresponding LnF_3. Crystal systems of the trifluorides thus obtained were hexagonal for La, Nd and Sm trifluorides, whereas those of Gd and Yb were found to be orthorhombic. The volatile decomposition products at 600°C were identified by MS, and it was revealed that the over all reaction scheme for the thermal decomposition proceeds as follows: $Ln(OTf)_3 \rightarrow LnF_3 + 3SO_2 + CO_2 + CF_3OCF_3$. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: lanthanide triflates; thermal process; stable nonahydrate.

INTRODUCTION

Trifluoromethanesulfonic acid, commonly known as triflic acid (TfOH), was first reported in 1954 by Haszeldine and Kidd [1]. Since then, there has been a rapid growth in the chemistry of triflate and its derivatives, and a great variety of metal complexes containing the coordinated trifluoromethanesulfonate (triflate) have been synthesized [2–4]. Interest in these compounds as a potential use in both inorganic and organic synthons stems from specific properties of the triflate anion, e.g., the low basicity and the poor coordinating ability [5]. A recent striking example in this area is the use of lanthanide triflates as Lewis acid catalysts in organic synthesis [7]. Until now, however, it appears that most of the interest in the derivatives has centered on the chemistry involving transition metals, and that little attention has been paid to the lanthanide triflates. Moreover, a survey of the literature revealed only a few studies [7–10] on the thermal decomposition of lanthanide compounds.

Recently, we reported a study on the thermal decomposition of lanthanum triflate [11]. In our continuing investigations, we report, here, the results obtained in studies of the thermal decomposition of several other lanthanide triflates.

EXPERIMENT

Preparation of lanthanide triflates

Trifluoromethanesulfonic acid (TfOH) was used as received. Lanthanide oxides were of 99.5% pure (Wako Pure Chemical, Japan). Prior to use the oxides were freshly ignited at 800°C in quartz crucibles. On the basis of reports in the literature [12, 13], an excess of the corresponding sesquioxide was added to a 50% aqueous solution of TfOH, and the mixture was boiled and filtered to remove the unreacted oxide. The water was then removed from the filtrate under reduced pressure until the hydrate was formed. The hydrates were dried in a rotary vacuum evaporator at 80°C for 1 h. The drying was not prolonged in order to maintain the same dehydration conditions, and the triflates thus obtained were used for the thermal analysis studies. The IR spectra of the hydrated triflates that were used initially were prepared as KBr disks and recorded with the aid of a Shimadzu FTIR 4300.

The lanthanide content and the water content of the each starting triflates were determined by titration

with a standard EDTA solution and TGA experiments, respectively. Found: La, 18.5. Calc for $[(LaC_3F_9S_3O_9)\cdot 9H_2O]$: La, 18.6%. Found: Nd, 19.1. Calc for $[(NdC_3F_9S_3O_9)\cdot 9H_2O]$: Nd, 19.0%. Found: Sm, 19.9. Calc for $[(SmC_3F_9S_3O_9)\cdot 9H_2O]$: Sm, 19.8%. Found: Gd, 20.8. Calc for $[(GdC_3F_9S_3O_9)\cdot 9H_2O]$: Gd, 20.5%. Found: Yb, 20.5. Calc for $[(YbC_3F_9S_3O_9)\cdot 13H_2O]$: Yb, 20.3%.

Thermal analysis

TG and DTA curves were obtained on heating up to 600°C, using a Shimadzu DT-40. The heating rate was 5°C min^{-1} in a static atmosphere of air. A small portion (*ca.* 15–20 mg) of sample was used for the TG, and the highly sintered α-Al_2O_3 was the thermally inert reference material used for the DTA.

Using copper(II) sulfate pentahydrate as an external standard, a computational integration of the endothermic area on the DTA curves of each Ln triflate was applied to estimate roughly an enthalpy change for the process encountered throughout the dehydrations.

Analysis of solid and gaseous products obtained by the calcination

The calcined solid was fused with NaOH, and dissolved in a minimum of 6 m HCl, diluted, and the lanthanide content was determined by titration with a standard EDTA solution [14]. The oxygen content in the calcined product was not determined. Found: La, 71.0. Calc for LaF_3: La, 70.9%. Found: Nd, 71.4. Calc for NdF_3: Nd, 71.7%. Found: Sm, 72.1. Calc for SmF_3: Sm, 72.5%. Found: Gd, 73.0. Calc for GdF_3: Gd, 73.4%. Found: Yb, 74.8. Calc for YbF_3: Yb, 75.2%.

Powder diffractograms of the calcination products were obtained by means of a Shimadzu XD-610 with a source of Cu Kα radiation. For identification purposes, diffraction patterns [(I/I_0) vs d spacing (Å)] of the products were matched with the relevant data on JCPDS cards.

Mass spectra (MS) of a gas phase decomposition products were obtained with a JEOL A V505W in the electron impact positive ion mode.

RESULTS AND DISCUSSION

Dehydration and decomposition processes

While Fig. 1 shows the simultaneous DTA and TG curves for La triflate as a typical example of the thermal analysis of lanthanide triflates, DTA curves for all the triflates studied are shown in Fig. 2. For convenience, each weight loss (WL) steps monitored on the TG curve is designated in Roman Numerals, and the corresponding peak temperature on the DTA curve is denoted as T_{1max}, T_{2max}, and so on. In addition, the superscript s in the peak temperature means that the peak is poor or a shoulder. The reaction temperatures along with the WL obtained from both TG and DTA curves are summarized in Table 1.

TG studies revealed that the decomposition of triflates occurred in two main stages. The first stage involved a stepwise dehydration to the anhydrous state, followed by the decomposition of the triflates to stable final products. As shown in Table 1, the observed WL values that were found in both dehydration and decomposition processes are in good agreement with the calculated values. In conjunction with the TG curves, it is obvious that the multiplicity of the endothermic peaks corresponds to each dehydration step, and the exothermic peaks correspond to the decomposition (see Fig. 2). Rather complex peaks observed in the decomposition temperature region may be explained by the postulate that the decomposition process also occurs step by step.

The triflates began to lose water of hydration from 42–64°C giving two or three clearly defined steps prior to reaching the anhydrous state. The corresponding to the anhydrous state, beginning around 190–220°C were not quite horizontal, and suggests that a slow decomposition occurs. Finally, more rapid decompositions at 360–410°C resulted in a sharp weight loss to a continuous horizontal plateau. After the complete decompositions, however, some of the TG curves tend to increase and the weight increases, which suggests a probable slow oxidation of the final product. These oxidations are anticipated from reexaminations, in which when the same experiments were carried out in a dynamic atmosphere of N_2, the resulting final plateaus on the TG curves remained quite horizontal until a temperature reached 600°C.

As shown in Table 1, the number of hydrated water molecules in almost all starting triflates were found to be 9, except for Yb triflates. These stoichiometries of the hydrated water molecules are consistent with the results of X-ray structural studies of the hydrates of lanthanide triflates, $[Ln(H_2O)_9][TOf]_3$; (Ln = La, Nd, Gd, Ho and Lu) [15, 16] and with those analogous compounds such as $Tb(H_2O)_9(BrO_3)_3$ [17] and non-aquasamarium(III) bromide-1,4-dioxane adduct, e.g., $Sm(H_2O)_9\cdot Br_3(C_4H_8O_2)_2$ [18]. In the present study, although the number of hydration molecules varies in each triflate, it is of interest to note that all the triflates lose the 6 hydrated water molecules at the first dehydration step, which corresponds to the strongest endothermic peak in the DTA curves. On the basis of the IR measurements of the starting hydrated Ln triflates, it was suggested [9] that there exist two types of distinct water molecules in the triflates. The IR bands, attributed to the OH stretching frequency, which appeared around 3690 and 3650 cm^{-1} may be due to very weakly held water while the broad OH band around 3450 cm^{-1} may be due to more strongly hydrogen-bonded water in the complexes. Therefore, it is reasonable to conclude that the aforementioned 6

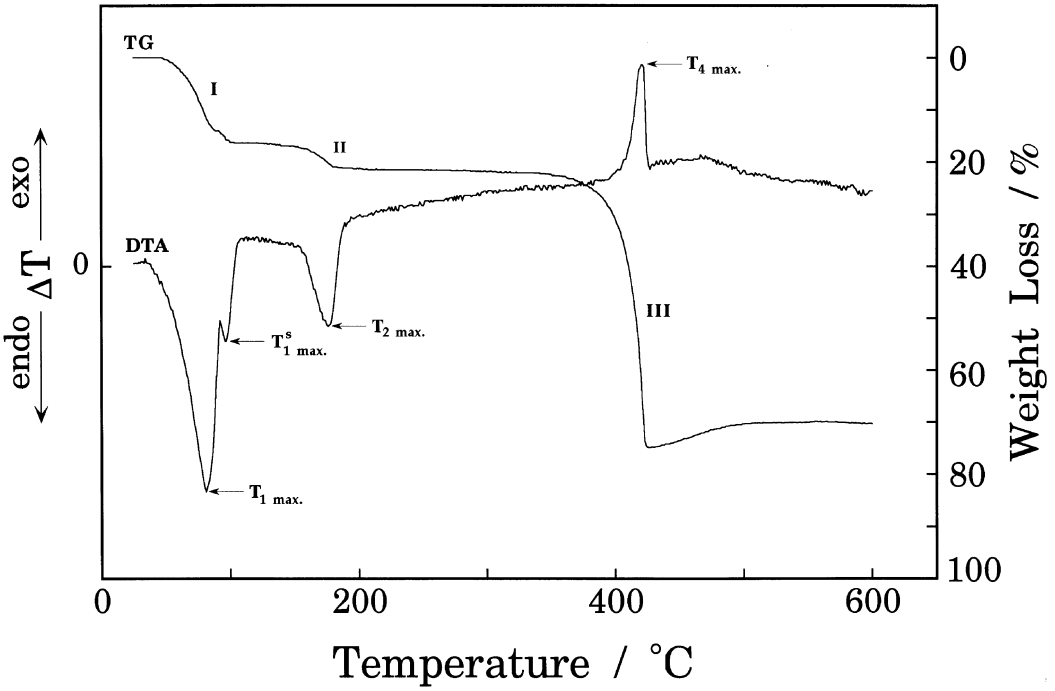

Fig. 1. TG and DTA curves for lanthanum triflate.

water molecules which were liberated at relatively low temperature regions are those that are not strongly bonded to the salts.

In the subsequent series of the stepwise dehydration processes, a variety of hydrated intermediates were formed (see Table 1). However, the most stable hydrate formed as an intermediate was the dihydrated species for the La, Pr, Nd, and Sm triflates. Mono and trihydrates were found to be stable for Gd and Yb triflates, respectively. The observations of the series of intermediates also confirm that there exist different types bonded water molecules in the lanthanide triflate, and they play a special role in the coordination of the ligands with the lanthanide metal. Similar findings were reported by Rillings *et al.* [9], during the thermal study of the lanthanide salts. They reported that Pr, Sm and Er trifluoroacetates show mono-, sesqui- and dihydrate intermediates while the corresponding pentafluoropropionates show sesqui- and dihydrate intermediates during their dehydrations.

In addition, the roughly estimated enthalpy values [$\Delta H_{\text{dehyd.}}$ (kJ mol^{-1})] for the total dehydration process of each Ln triflate are: 123 (La); 125 (Nd); 131 (Sm); 135 (Gd) and 125 (Yb). These values are within the range characteristic of dehydration processes [10].

In Table 1, it is also worth noting that the initial temperature of the dehydration process increases as the atomic number of the lanthanide increases thus reflecting the lanthanide contraction and decreasing base strength of the elements. In contrast to this tendency, however, the decomposition behavior of the triflates is somewhat more complicated. It appears that the initial decomposition temperature tends to decrease gradually with an increase in atomic number of the lanthanide.

Solid decomposition products

In an effort to confirm the products remaining after decomposition at 600°C in a static atmosphere of air, the products were subjected to an XRD study. In order to identify the solid products, the relevant JCPDS cards were employed. The JCPDS cards used for the verification were 32–483, 9–416, 12–792, 12–788 and 34–102 for the trifluorides of La, Nd, Sm, Gd and Yb, respectively. In a typical result, the XRD data of the La and Yb samples are compared with the reference data of LaF_3 and YbF_3, respectively, in Table 2. As shown in Table 2, it is clear that both the XRD data match very well, and this is the case for the rest of the triflates. Furthermore, since no peaks corresponding to lanthanide oxyfluorides were found on the XRD profiles, it is reasonably safe to conclude that all the lanthanide triflates prepared in this study are converted almost completely to the corresponding trifluorides at 600°C. This conclusion is also substantiated by the quantitative analysis of the each trifluoride (see Experimental section).

When the calcinations of the triflates were carried out at higher than 700°C, almost all of them decomposed gradually to a mixture of oxyfluoride and oxide, and finally at 1000°C, they were all converted into the Ln_2O_3. These observations are consistent with the

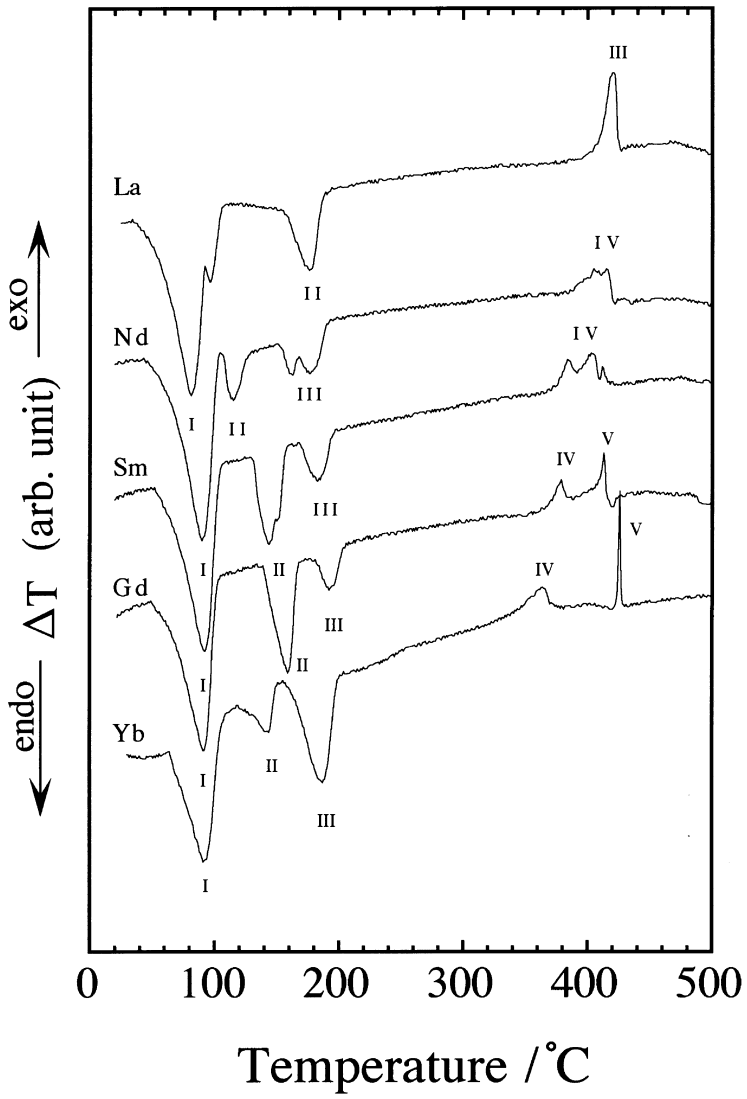

Fig. 2. DTA curves for lanthanide triflates (see text for roman numerals).

results reported by Rillings *et al.* [9]. During a study of the thermal decomposition of several lanthanide perfluoroacetates, they found that LnF_3 and LnOF (Ln = Pr, Sm and Er) are formed around 450°C and 700°C upon the decomposition of the corresponding trifluoroacetates and pentafluoroacetates. In addition, they reported that the decomposition of the fluoride to oxyfluoride is a hydrolysis reaction. Thus, there is a little chance of the formation of LnOF under the experimental conditions of this study.

On the other hand, based on the JCPDS cards, the trifluorides of La, Nd and Sm are hexagonal, whereas GdF_3 and YbF_3 are found to be orthorhombic and isostructural with YF_3. It was reported [19–21] that the trifluorides of the rare earths of La to Nd and those of Sm to Lu are thought to occur in the hexagonal form and the orthorhombic form, as stable forms at atmospheric temperature, respectively. These results are consistent with our observations, except for the crystal system of the SmF_3. It is known [19, 22] that samarium trifluoride is dimorphic occurring as a high-temperature phase (β-SmF_3, hexagonal) and low-temperature phase (α-SmF_3, orthorhombic), and the latter is substantially more stable than the former. Thus, it is noteworthy that the β-SmF_3 can be easily obtained upon the thermal decomposition of the corresponding Sm triflate.

Volatile decomposition products and overall reaction

When the triflates were pyrolyzed at a slightly higher temperature at the end of the decomposition, it was found that volatile products are evolved. The

[a]Calculated as LnF_3.

MS analysis of the gases showed that three peaks at m/z 44, 64 and 85 with relatively high intensity are present in the spectra (see Fig. 3). The first two peaks are easily assigned to be molecular ion peaks of CO_2 and SO_2, respectively, and each of them has isotopic peaks at m/z 45 and 66. The peak at m/z 85 can be considered as a fragment ion peak that was generated as a result of the cleavage from the molecular ion, $[CF_3OCF_3]^{\bullet +}$, which is probably unstable and easily decomposes during the ionization process in the MS analyzer. And the $[CF_3]^+$ peak at m/z 69 arises subsequently from the $[CF_3O]^+$. Thus, the probable pathway of the fragmentation can be rationalized as:

$$[CF_3OCF_3]^{\bullet +} \xrightarrow{-CF_3^{\bullet}}$$

$$[CF_3O]^+ (m/z\,85) \xrightarrow{-O^{\bullet}} [CF_3]^+ (m/z\,69)$$

Consequently, the present studies revealed that the general thermal decomposition reaction for the lanthanide triflates proceed according to an overall reaction scheme as follows:

$$Ln(CF_3SO_3)_3 \rightarrow LnF_3 + 3SO_2 + CO_2 + CF_3OCF_3$$

This reaction mechanism is different from those that have been proposed by Rillings *et al.* [9] and others [7, 23]. They studied the thermal decomposition of Pr and Sm trifluoroacetates in the temperature range from 275 to 300°C. In this study, on the basis of IR analysis, they suggested that trifluoroacetic anhydride exists as an intermediate during the decomposition in the first stage, in the next stage the anhydride decomposes to trifluoroacetyl fluoride, carbonyl difluoride and carbon monoxide. Accordingly, they reported the pyrolysis of the trifluoroacetates to proceed as:

$$2Ln(CF_3CO_2)_3 \rightarrow 2LnF_3 + 3CF_3COF + 3CO_2 + 3CO$$

The main difference in the thermal decomposition of the trifluoroacetacs and triflates can be found in the gaseous products; i.e., CF_3COF and CF_3OCF_3. Although it is difficult to compare both mechanisms since the gases formed during pyrolysis are usually very complicated, the difference between the mechanisms and the major gaseous products might be attributable to the counter anion in these compounds, and also to the temperatures at which decomposition occurs.

Constitutional isomers and stereoisomers of lanthanum(III) complexes of the dimethyl-substituted six-nitrogen-donor ligand $C_{24}H_{30}N_6$ and crystal structure of $[La(C_{24}H_{30}N_6)(NCS)_3(H_2O)]\cdot 0.5H_2O$

(Received 21 November 1997; accepted 2 April 1998)

Abstract—Complexes of La(III) with the macrocyclic ligand $C_{24}H_{30}N_6$, in which each di-imine side chain carries a $-CH_3$ substituent, were synthesized by the metal-templated cyclic Schiff-base condensation of 2,6-diacetylpyridine with (R)-, (S)- and (R,S)-1,2-diaminopropane. The complexes were obtained as mixtures of constitutional isomers and stereoisomers, which were identified by ^1H NMR spectra and separated by fractional crystallization. The molecular structure of the 10-coordinate complex $[La(C_{24}H_{30}N_6)(NCS)_3(H_2O)]\cdot 0.5H_2O$ was established by X-ray crystallography. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: lanthanum(III); complexes; diaminopropane; diacetylpyridine.

Complexes containing a lanthanide(III) ion bound into the six-nitrogen-donor macrocyclic cavity schematically illustrated in Fig. 1 have potential bio-medical applications. Specifically, the luminescent complexes of europium(III) can serve as markers in cell analysis and immmunology, provided they contain functional groups for covalent linking to bio-substrates [1–5]. The complexes of gadolinium(III), which have high relaxivity [6], could be useful as contrast enhancers for *in vivo* magnetic resonance imaging, if their tolerance were enhanced by appropriate functional groups incorporated into the macrocyclic ligand. Thus, functionalization of the macrocycle is a prerequisite for these bio-medical applications, and lanthanide(III) complexes with two peripheral hydroxo or primary amino groups have been synthesized by the metal-templated cyclic Schiff-base condensation of 2,6-diacetylpyridine with carbon-substituted 1,2-diaminoethanes [2–5]. In these functionalized complexes, the lanthanide-macrocycle entities retained the chemical and spectroscopic properties characteristic of the non-functionalized analogues and the peripheral functional groups retained their typical reactivities. For example, the Eu(III) complex of a diamino-macrocycle reacted with thiophosgene to give the corresponding di-isothiocyanate, and this in turn reacted with the primary amino groups (lysine residues) of avidin to produce a highly luminescent conjugate which exhibited the usual avidin-biotin affinity [2, 5].

The preceding considerations focus attention on this class of disubstituted macrocyclic complexes and their isomeric forms. For each complex, two constitutional isomers are possible, with the substituents attached to the 5,14 or 5,15 positions of the macrocycle cavity (see Fig. 1 for numbering scheme). In addition, the carbon atom to which the substituent

* Author to whom correspondence should be addressed.

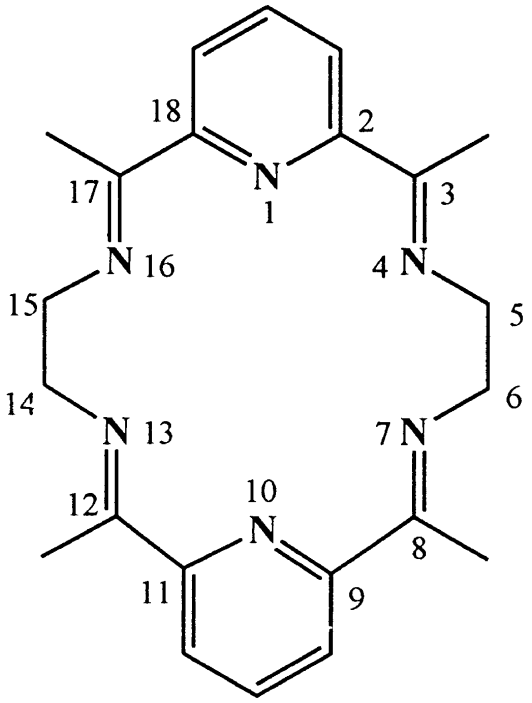

Fig. 1. Schematic formula of the six-nitrogen-donor macrocycle cavity with conventional numbering scheme.

is attached is a stereocenter and each constitutional isomer can exist as stereoisomers, the (R,R) and (S,S) enantiomer pair and the (R,S) *meso* form [7, 8]. Three questions then arise: (1) Are constitutional isomers formed in the Ln(III)-templated macrocycle synthesis and, if so, are they distinguishable? (2) Can synthetic conditions provide some degree of isomer selectivity? (3) Can isomers be separated and identified structurally? In an effort to answer these questions, a study was carried out using as model the simplest member of this series—the macrocyclic complex with two $-CH_3$ substituents on the di-imine side chains, $=N-CH_2-CH(CH_3)-N=$. Lanthanum(III) was selected as the metal center to permit the use of nuclear magnetic resonance spectrometry as a diagnostic tool without the complication of internal paramagnetic shifts; La(III) acetate was used as template in the syntheses because preliminary screening had shown it to produce high yields of complexes with desirable solubilities.

EXPERIMENTAL

Materials and procedures

Lanthanum(III) acetate hydrate, 2,6-diacetylpyridine, (R)- and (S)-1,2-diaminopropane dihydrochloride, 1,3-diphenyl-propane-1,3-dione (dibenzoylmethane, HDBM), and deuterated solvents (all from Aldrich) were used as received. (R,S)-1,2-Diaminopropane (Aldrich) was dried over solid KOH, distilled, and stored over 3A Molecular Sieves. The sodium salt of HDBM was prepared by reaction of the diketone with sodium ethoxide (1:1 mole ratio) in anhydrous ethanol at 0°C, followed by precipitation with diethyl ether and recrystallization from ethanol/diethyl ether. Micronalyses (C, H, N) were performed by Atlantic Microlabs, Atlanta, GA; all compounds had correct analyses corresponding to the given formulas.

NMR spectra were obtained with a GE QE-300 spectrometer at ambient temperature (24–26°C). Chemical shifts (as δ for ^{1}H spectra) are reported in ppm; coupling constants, *J*, are given in Hz. Proton spectra were referenced to TMS (0.00 ppm) or to the residual proton signal of the solvent ($CDCl_3$ 7.26 ppm; deuterated dimethylsulfoxide, DMSO-d_6 2.49); carbon spectra were referenced to the solvent signal ($CDCl_3$ 77.00 ppm; DMSO-d_6 39.50 ppm).

Infrared spectra were obtained on a Perkin-Elmer Model 1600 FT instrument (4000–500 cm^{-1}). Samples were examined as KBr pellets as well as mulls in hexachloro-butadiene/NaCl disks (4000–1800 and 1500–1300 cm^{-1}) and Nujol/KBr disks (1800–1500 and 1300–400 cm^{-1}); no difference was observed between the two sets of spectra. Absorption frequencies are reported in cm^{-1}; abbreviations: s = strong, m = medium, w = weak, br = broad, v = very; an asterisk indicates an absorption only partly resolved from an adjacent stronger peak.

Thermograms were obtained with a Perkin-Elmer TGS4 system, with helium flow of 40 cm^3/min.

La(III) complexes of the dimethyl-macrocyclic ligand $L = 2C_{24}H_{30}N_6$

Only general procedures are given here. Reactions were carried out on a scale of one-to-two millimoles for reagents, and 150–200 cm^3 for solvents. Details are available from L. M. Vallarino upon request.

Complexes from metal-templated Schiff-base condensation

{LaL} triacetate from (R,S)-1,2-diaminopropane. La(III) acetate hexahydrate, 2,6-diacetylpyridine and (R,S)-1,2-diaminopropane (1:2:2 mole ratio) were dissolved in methanol at room temperature. The subsequent procedure varied as follows. The mixture was: (1) refluxed for 6 h in methanol (65°C) or ethanol (78°C), (2) kept at 40°C for 3 days, (3) kept at room temperature (24–26°C) for 5 days, (4) kept at 4°C for 10 days. (Optimum reaction times were determined in pilot experiments by withdrawing aliquots of the reaction mixture at regular intervals, isolating the product, and measuring yields.) At the end of each reaction period, the solution was taken to dryness under reduced pressure without heating and the resulting yellow-brown gummy solid was bulk-purified by

washing it with diethyl ether, dissolving it in chloroform, stirring with charcoal, filtering, and diluting the filtered solution with diethyl ether at 0°C.

The purified bulk product, {LaL}$(CH_3COO)_3 \cdot nH_2O$ with $n = 4.0$–6.5, was obtained as small colourless crystals, very soluble in water and polar organic solvents, insoluble in diethyl ether and hydrocarbons. Thermogravimetric analyses showed a gradual loss of water in the 35–105°C range; dried samples rapidly rehydrated when exposed to moist air. The complexes decomposed above 170°C. *IR absorptions* (cm^{-1}) and selected assignments: 3400 vs, br, ν(OH), water; 3093 vw, 2977 w, 2932 w, 1640 s, ν(C═N), imine; 1588 s, ν(C═N), pyridine; 1540 vs, $\nu_{asym.}$(COO); 1429 vs, $\nu_{sym.}$(COO); 1380 m*, 1278 vvw, 1251 s, 1198 s, 1153–1150 m, 1002 m, 966 vw, 928 w, 817 m, 745 m-w, 667 m-s, δ(COO); 619 w, 568 w. The latter four peaks were overlaid on the broad absorption centered at *ca* 600 cm^{-1} (librational mode of lattice water). The ^1H *NMR spectra* of the bulk products in $CDCl_3$ showed three distinct set of signals, diagnostic of the macrocycle structure and assigned to three isomers provisionally designated as A, B, and C (for structural assignment, see Discussion). Total yields and isomer ratios (calculated from the intensities of the $-CH_3$ side-chain signals and reproducible within *ca*. 5%): (1) 78 or 65°C, 6 hr: 80% (A:B:C = 55:25:20); (2) 40°C, 3 days: 50% (A:B:C = 20:10:70); (3) 24–26°C, 5 days: 45% (A:B:C = 15:5:80); (4) 4°C, 10 days: no product.

{*LaL*} *acetate-chlorides from* (*R*)- *and* (*S*)-1,2-*diaminopropane*. The diamine precursors were obtained from their dihydrochlorides by reaction with KOH (1:1 mole ratio) in methanol at 0°C. The solutions were dried over 3A Molecular Sieves, filtered, and used directly for the macrocycle syntheses. Two sets of reactions were carried out, following the procedure outlined in Section 1.1 for the (R,S)- analog: (1) 65°C, 6 hr and (2) 24–26°C, 5 days. The products, {LaL}-$(CH_3COO)_{3-x}Cl_x \cdot nH_2O$, with $x = 0.2$–1.0 and $n = 3.0$–6.5, were very similar to those from the R,S-diamine in their general properties, including IR spectra. The NMR spectra of products obtained at the same temperature from the (R)- and (S)-diamine were indistinguishable and showed the presence of two isomers, identical to those designated as A and B in the products from the R,S-diamine. Total yields and isomer ratios: (1) 65°C, 6 hr: A:B = 55:45; (2) 24–26°C, 5 days: A:B = 75:25.

Separation of the isomers. Fractional crystallization of the bulk products from methanol/diethyl ether gave the following yield of single isomers relative to bulk product: C, 15–25%: A, 5–10%; B from (S)-diamine, $< 5\%$. The B isomer from the (R)-diamine was not obtained pure. The ^1H *NMR spectra* and ^{13}C *spectra* of the isomers are given in Tables 1 and 2.

Complexes from anion metathesis

The precursors were {LaL} triacetate or diacetate chloride complexes of known isomer composition. From these, the acetate diperchlorate and the tri-isothiocyanate were obtained by treatment with an excess of $NaClO_4$ and NaNCS, respectively, in methanol solution. The trichloride was obtained by treatment with an excess of hydrogen chloride in methanol-diethyl ether at °C. The (DBM) hydroxide chloride was obtained by treatment with NaDBM (1:1 mole ratio) in chloroform. For all these complexes, fractional crystallization of isomer mixtures failed to yield single isomers.

$\{LaL\}Cl_3 \cdot 4H_2O$. Colourless microcrystals, less soluble in polar solvents than the corresponding triacetate and diacetate chloride. *IR absorptions* (cm^{-1}) and selected assignments: 3400 vs, br, ν(OH), water; 3072 vw, 2970 w, 2928 w, 2919 w, 1637 s, ν(C═N), imine; 1587 s, ν(C═N), pyridine; 1442 m, 1372 s, 1278 vvw, 1247 m-s, 1196 s, 1147 m, 997 m, 966 vw, 928 w, 806 m, 745 m, 620 w, 568 w (the latter four peaks overlaid on the broad H_2O absorption at *ca*. 600 cm^{-1}).

$\{LaL\}(CH_3COO)(ClO_4)_2 \cdot 3.5H_2O$. Colorless microcrystals, with solubility similar to the diacetate chloride. The *IR spectrum* was similar to that of the diacetate chloride, except for the lower relative intensity of the carboxylate absorptions in the 1500–1380 cm^{-1} region and the additional presence of the absorptions of ionic perchlorate (ν_3 1109 vs, br; ν_4 625 s).

$\{LaL\}(DBM)(OH)Cl \cdot 5H_2O$. Almond-colored crystals, with solubility similar to that of the triacetate. *IR absorptions* (cm^{-1}) and selected assignments: 3400 vs, br, ν(OH), water; 3040 vw, 2966 vw, 2931 vw, 1637 m-s, ν(C═N), imine; 1599 vs, ν(C═N), pyridine; 1550 vs, 1519 s, 1478 m, 1455 m, 1384 vs, ν(C–C), ν(C–O) of DBM; 1308 vw, 1249 m, 1196 m-w, 1155 vw, 1067 vw, 997 w, 814 w, 750 m, 727 m, 700–500 numerous weak and poorly resolved absorptions. ^1H *NMR spectrum* ($CDCl_3/CD_3OD$, v/v = 90/10; ppm vs. TMS) of the A-DBM isomer from the S-diamine: CH_3 side-chain: 1.01 d (6H) d, J 6.9, coupling to CH of macrocycle; CH_3 macrocycle: 2.54 s (6H), 2.68 s (6H); CH_2: AB spin pattern (total 4H), J 15.0, νH_A 3.94 and νH_B 4.16 (both components of H_B signal showed ill-resolved splitting, J *ca*. 2, coupling to CH of macrocycle); CH of macrocycle: 4.41–4.47 m (2H); CH of DBM: 6.68 s (1H); phenyl: 7.10–7.40 m (10H); pyridine: AMX spin pattern (total 6H), νH_A 8.14, νH_M 8.25, νH_X 8.34; $J_{AX} = J_{MX}$ 7.8, J_{AM} *ca*. 0.6.

$\{LaL\}(NCS)_3 \cdot nH_2O$ (n = 0–2.0). Colourless prisms or needles, moderately soluble in DMSO and dimethylformamide, very sparingly soluble in methanol, insoluble in other common solvents and water. When the precursors were the single-isomers C or B from (S)-diamine, crystals suitable for X-ray analysis were obtained. *IR absorptions* of [{LaL}$(NCS)_3(H_2O)] \cdot 0.5H_2O$, B isomer from (S)-diamine: 3400 m-w, br, ν(OH), water; 3085 vw, 2970 w, 2928 w, 2826 vvw, 2060–2031 vvs, ν(C≡N), coordinated NCS^-; 1641–1626 vs, ν(C═N), imine; 1588 vs, ν(C═N), pyridine; 1449 m, 1371 s, 1328 vvw, 1312 w, 1278 vvw, 1249 s, 1194 s, 1154 m-w, 1128 m, 1068

[a]Chemical shifts in ppm vs. TMS; coupling constants in Hz; small variations in chemical shifts were observed for samples with different concentrations and/or different water contents. All signal integrations were consistent with assignments. Spectra of the (R,R)/(S,S)-5,15 complexes were obtained from enriched isomer mixtures. Abbreviations: s = singlet, d = doublet, dd = doublet of doublets, t = triplet, m = multiplet, br = broad.

[b]In $CDCl_3$.

[c]In DMSO-d_6.

[d]Coupling to vicinal CH.

[e]In some samples, the signal is a doublet (J = 0.6–1.5, long-range coupling to H_B of CH_2).

[f]Some samples show two equal intensity, closely spaced signals (12H total), with the signal at higher field split into a doublet (J = 0.6–1.0, long-range coupling to H_B of CH_2 group).

[g]Long-range coupling to H_B of CH_2.

[h]Chemical shifts and coupling constant calculated from AB spin pattern.

[i]Broad signals with ill-resolved splittings.

[j]Each component of the H_A signal is further split into a doublet (J = 2.1, coupling to vicinal CH).

[k]Both components of the H_B signal are broad and show splitting consistent to coupling to the vicinal CH (J = *ca.* 3.8) and to the higher-field CH_3 of macrocycle (J = 0.9–1.3).

[l]Both components of the H_A signal are broad, with ill-defined splittings.

[m]Each component of the H_A signal is further split into a doublet (J = 2.1, coupling to vicinal CH).

[n]Pattern consistent with a quartet of doublets of doublets (J = 6.8, 3.8, 2.1, coupling to vicinal CH, and to H_A and H_B of CH_2,, respectively).

[o]Chemical shifts and coupling constants calculated from A_2B pattern where A = β-H and B = γ-H of pyridine moiety.

[p]Central peaks merged to give an apparent triplet.

[q]Pattern could not be identified.

Attempted {LaL}-Eu(III) transmetallation

{LaL} triacetate and Eu(III) acetate hexa-hydrate (1:1 mole ratio) were heated at reflux in methanol for 6 hr. Work up of the mixture gave only unreacted starting materials.

X-ray measurements and structure determination

Crystal data for $[La(C_{24}H_{30}N_6)(NCS)_3(H_2O)]\cdot 0.5H_2O$, Mr = 742.7 triclinic, space group $P\bar{1}$, a = 8.666(3), b = 11.980(3), c = 16.889(4) Å, α = 78.36(3), β = 95.98(4), γ = 110.13(2); V = 1611.3(8) Å^3, Z = 2, Dx = 1.54 Mg m^{-3}, λ = (Mo-Kα) = 0.71069 Å, μ(Mo-Kα) = 15.6 cm^{-1}, $F(000)$ = 750, T = 293 K.

A prismatic white trasparent crystal of dimensions 0.20 × 0.22 × 0.38 mm was centered on a four-circle Philips PW1100 (Febo System) [9] diffractometer operating in $\theta/2\theta$ scan mode with graphite-monochromated (Mo-Kα) radiation λ = 0.71069 Å), following standard procedures. There were no significant fluctuations of intensities other than those expected from Poisson statistics. The intensity data were corrected for Lorentz-Polarization effects and for absorption, as described by North *et al* [10]. No correction was made for extinction.

The structure was solved by heavy atoms methods [11]. Refinement was carried out by full-matrix least-squares; the function minimized was $\Sigma w(Fo^2\text{-}Fc^2)^2$, with weighting scheme $w = 1/[\sigma^2(Fo^2) + (0.0475P)^2 + 5.26P]$, where $P = \max(Fo^2 + 2Fc^2)/3$. All non-hydrogen atoms were refined with anisotropic thermal parameters, except for the clathrated water molecule that was refined isotropically. The H-atoms were located from difference Fourier maps and refined isotropically, except for those belonging to the methyl groups which were placed in calculated positions with fixed, isotropic thermal parameters (1.2 $\mathbf{U}_{equiv}$ of the parent carbon atom). For a total of 416 parameters, $wR' = [\Sigma w(Fo^2\text{-}Fc^2)^2/\Sigma w(Fo^2)^2]^{1/2} = 12.45$, $S = 1.098$, and conventional $R = 0.047$, based on the F values of 4937 reflections having $Fo^2 \geq 3\sigma(Fo^2)$. Structure refinement and final geometrical calculations were carried out with SHELXL-93 [12] and PARST [13] programs, drawings were produced using *ORTEP II* [14]. Selected geometric parameters are reported in Table 3.

Lists of structure factors, H-atom coordinates and anisotropic thermal parameters have been deposited

RESULTS AND DISCUSSION

Synthesis and characterization of the complexes

Complexes of La(III) acetate containing the macrocyclic ligand $L = C_{24}H_{30}N_6$, in which a methyl group is attached to each of the di-imine side chains, $=N–CH(CH_3)–CH_2–N=$, were synthesized using (R,S)- as well as (R)- and (S)-diaminopropane as precursors. The complex obtained from the (R,S)-diamine had formula $\{LaL\}(CH_3COO)_3\cdot nH_2O$. with $n = 3.0–6.5$, whereas the products obtained from the R- and S-diamines (formed *in situ* by neutralization of the respective hydrochlorides) were isolated as hydrated species with non-integer acetate/chloride ratios, e.g. $\{LaL\}(CH_3COO)_{2.5}Cl_{0.5}.\ 4H_2O$, from which the corresponding triacetates and diacetate-chlorides were isolated by fractional crystallization. All complexes were colourless, crystalline solids, very soluble in water and polar organic solvents, insoluble in diethyl ether and hydrocarbons. The hydrated solids lost water completely when heated between 45 and 110°C, but dry samples rehydrated rapidly when exposed to the atmosphere; the complexes began to decompose at 170°C. In this thermal behavior, as in their other general properties, the La(III) complexes of the dimethyl-substituted macrocycles resembled very closely those of the corresponding non-substituted analogues [15–19]. In particular, the La-macrocycle moieties were resistant to decomposition by hydrogen chloride; they did not undergo metal release in the presence of competing ligands such as β-diketonates or metal exchange in the presence of competing metal ions such as Eu(III). The acetate counter-ion ligands, however, were labile; complexes of formula $\{LaL\}Cl_3\cdot nH_2O$ with $n = 4–6$, $\{LaL\}(CH_3COO)_2(ClO_4)\cdot 3.5H_2O$, and $\{LaL\}(NCS)_3\cdot nH_2O$, where $n = 0–2$, were obtained from the triacetate or acetate chlorides by anion metathesis.

The infrared spectra of all complexes showed identical patterns for the $\{LaL\}$ moieties, with the charac-

teristic absorptions arising from the C=N stretching modes of the imine and pyridine at 1640–1637 and 1588–1584 cm^{-1}, respectively. The absorptions of the counterion-ligands appeared in their usual ranges and were structurally informative. The tri-isothiocyanates had very strong, slighly split absorptions at 2060–2030 cm^{-1}, consistent with the presence of N-coordinated SCN^- ligands in slightly different environments. The triacetate and acetate chloride complexes had two strong carboxylate absorptions at *ca.* 1540 and 1430 cm^{-1}. For each complex, these absorptions were identical to those of the non-substituted europium(III) analogues, $[Eu(CH_3COO)_2(C_{22}H_{26}N_6)](CH_3COO)\cdot 9H_2O$ [17] and $[Eu(CH_3COO)_2(C_{22}H_{26}N_6)]Cl\cdot 4H_2O$ [16], suggesting similar structures with two acetates acting as bidentate chelating ligands on opposite sides of the La-macrocycle moiety, and either an ionic acetate or an ionic chloride balancing the residual +1 charge of the coordination entity. A somewhat similar structure can be assigned to the acetate diperchlorate complex, which in addition to the carboxylate absorptions showed the absorptions characteristic of ionic ClO_4^- at 1109 cm^{-1} and 625 cm^{-1}. In all these complexes, the frequency separation between the absorptions of the antisymmetric and symmetric carboxylate stretching modes, $\Delta\nu = ca.$ 110 cm^{-1}, was consistent with the suggested formulation [20, 21].

The proton and carbon-13 nuclear magnetic resonance spectra of the bulk products obtained from the (R)-, (S)- and (R,S)-diamines clearly showed the presence of non-interconvertible isomers: two (provisionally designated as A and B) in the products from the (R)- and (S)-diamines and three (A and B, plus a new species designated as C) in the product from the (R,S)-diamine. A very minor quantity of a fourth isomer (less than 3% of the total) was present in some samples of the bulk-product from the (R,S)-diamine. Repeated fractional crystallization of the bulk products from methanol/diethyl ether, using ^1H NMR spectra to monitor the composition of each fraction, gave minute quantities of pure A, B, and C. Their ^1H NMR spectra, discussed in a following section, suggested the following isomer identifications: A = (R,R)/(S,S)-5,14, B = (R,R)/(S,S)-5,15 and C = (R,S)-5,15, where the numbers identify the carbon atoms of the di-imine side chains to which the CH_3 substituents are attached (Fig. 1). When single-isomer triacetates or acetate chlorides were used to prepare the tri-isothiocyanates by anion metathesis, well formed crystals of $[La(NCS)_3$(S,S-5,15-dimethyl-macrocycle)] and $[La(NCS)_3(H_2O)$(R,S-5,15-dimethyl-macrocycle)] were obtained. The crystal structure of the former has been reported [8], that of the latter is discussed in the following section; both confirmed the formulation suggested by ^1H NMR spectra.

Crystal structure of $[La(C_{24}H_{30}N_6)(NCS)_3(H_2O)]\cdot 0.5H_2O$. An ORTEP view of the molecule with the atom numbering scheme is shown in Fig. 2. The complex is identified as the *meso* (R,S)-5,15 (S-5, R-15 or R-5, S-15) isomer. The La(III) ion is 10-coordinate, being linked to the six N atoms of the macrocyclic ligand, to the N atoms of three isothiocyanates on one side of the macrocycle, and to a water molecule on the opposite side. This uncommon mode of coordination for the three NCS^- ions, which in other complexes of this type are usually located two on one side of the macrocycle and one on the opposite side (see for example the (S,S)-5,15-[LaL$(NCS)_3$] [8] and the two forms of the non-substituted analog $[Eu(NCS)_3(C_{22}H_{26}N_6)]$) [22], is favored by the conformation of the {LaL} moiety. In the (R,S)-5,15 complex the torsion angles of the di-imine side chains, =N–CH_2–CH(CH_3)–N=, are very different from those of the previously reported (S,S)-5,15 isomer: N(5)–C(11)–C(12)–N(6) is -59.9(7)° v.s. 59(2)° and N(8)–C(23)–C(25)–N(9) is 57.7(7)° v.s. -72(2)°. These torsion angles determine a rather flat structure for the {LaL} moiety, with the two -CH_3 substituents at the 5 and 15 positions in the same hemisphere and with nearly parallel orientations, thus allowing sufficient space for the coordination of one molecule of water in the same hemisphere and of the three NCS^- ions in the other. The structure of the (R,S)-5,15 {LaL} moiety shows a total puckering amplitude of 0.493(6) Å for the six N atoms of the macrocycle and an interplanar angle of 14.4(1)° between the two pyridine-containing sections. In contrast, the six-nitrogen ring of the (S,S)-5,15 isomer has an approximate 'chair' conformation, with a total puckering amplitude of 0.84(1) Å and an interplanar angle of 38.3(3)° between the two pyridine-containing sections. A side view of the complex is shown in Fig. 3, together with that of the 9-coordinate (S,S)-5,15 isomer for comparison [8].

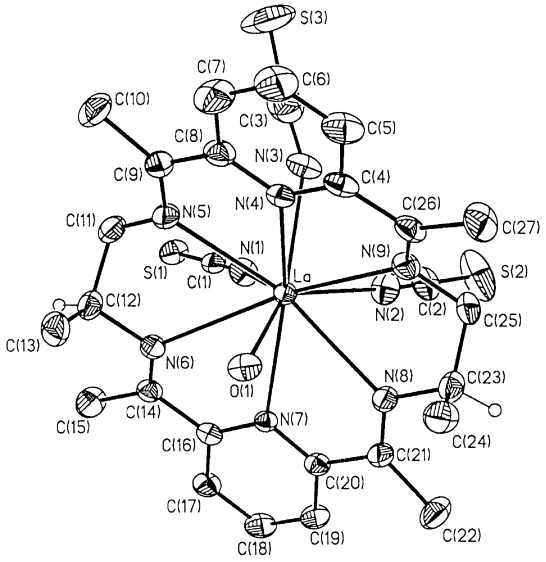

Fig. 2. ORTEP drawing of the $[La(C_{24}H_{30}N_6)(NCS)_3(H_2O)]$ molecule containing the (R,S)-5,15-dimethyl-substituted macrocyclic ligand.

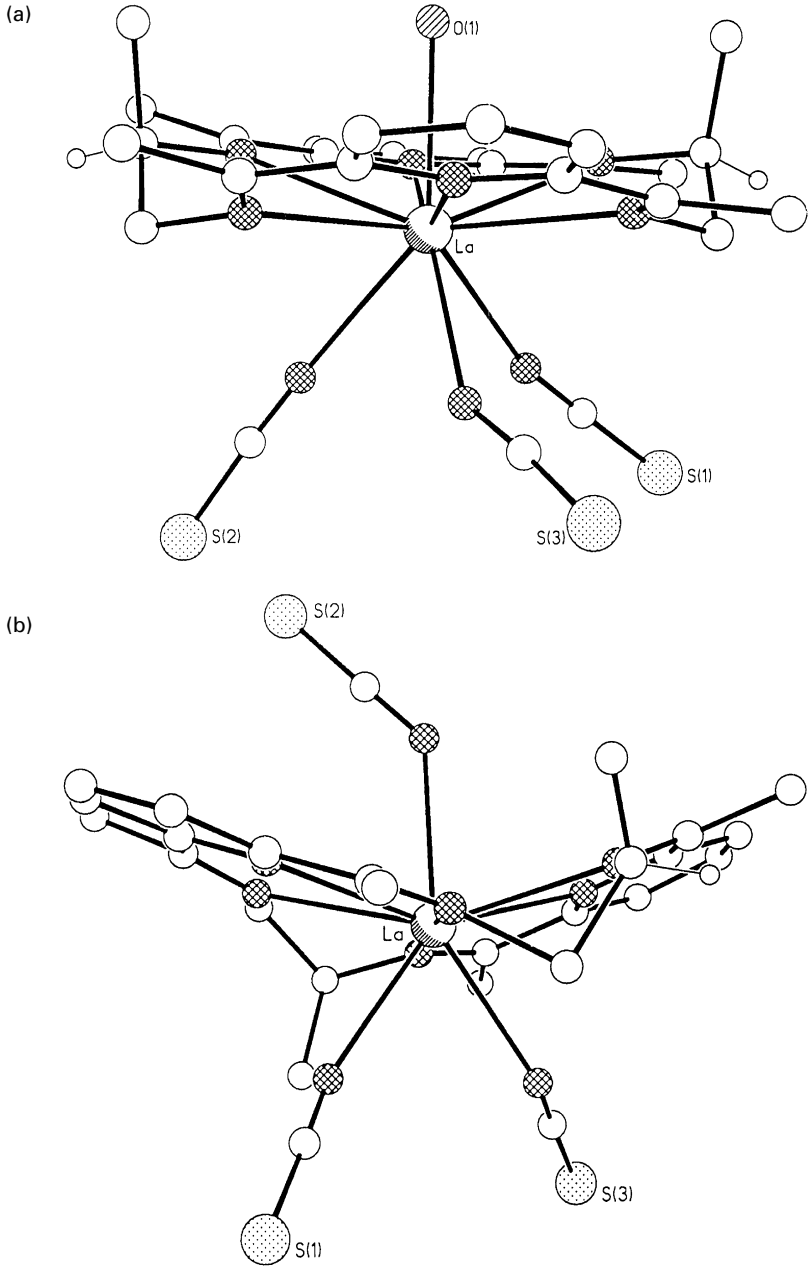

Fig. 3. Side view of the two isomeric complexes: (a) [La{(R,S)-5,15-($C_{24}H_{30}N_6$)}$(NCS)_3(H_2O)$] and (b) [La{(S,S)-5,15-($C_{24}H_{30}N_6$)}$(NCS)_3$].

In the (R,S)-5,15 isomer, the non-bonded interatomic distances C(13)···O(1)*w* 3.725(8) Å and C(24)····O(1)*w* 3.641(8) Å between the coordinated water molecule and the $-CH_3$ substituents show a rather symmetric arrangement promoted by the particular conformation of the ligand. The La-N(pyridine) bond distances are greater than in the (S,S)-5,15 isomer: 2.787(4) vs. 2.72(1) Å and 2.819(6) vs. 2.75(1); also the La-N(imine) bond distances cover a broader range, 2.730(5)–2.851(5), v.s. 2.67(1)–2.74(1) Å in the (S,S)-5,15 isomer. The La-(NCS) bond distances, which vary from 2.557(6) to 2.645(7) Å, are again greater than those observed for the (S,S)-5,15 isomer (2.55(2) to 2.58(2) Å). The longer bond lengths for the coordinated N-ligands are consistent with the increase in coordination number from 9 in the (S,S)-5,15 isomer to 10 in the (R,S)-5,15 analog, and could also be indicative of a weaking of the La-ligand bonds.

NMR spectra. Representative proton and carbon-13 NMR spectra of the isomeric complexes are reported in Tabs. 1–2. A summary discussion of the proton spectra follows.

CH_3 side-chain. In each isomer the CH_3 groups attached the $=N–CH_2–CH(CH_3)–N=$ side chains gave rise to a single signal in the 1.1–1.3 ppm region (doublet, $J = 6.6$–6.9 Hz, coupling to vicinal CH group). The signals of the isomers were well separated, and their integrated intensities were used to determine the isomer ratios of mixtures.

CH_3 acetate. In the triacetates and acetate chlorides, the acetate CH_3 gave a single sharp signal at 1.6–1.7 ppm, showing the coordinated and ionic acetates present in the triacetates to be in fast equilibrium on the NMR time-scale. The integrated intensity of the acetate signal, relative to the signals of the macrocycle, was in agreement with the stoichiometry of the sample as determined by microanalysis.

CH_3 macrocycle. The signals of the CH_3 groups originally belonging to the diacetylpyridine precursor occurred in the 2.4–2.7 ppm region. The spectra of the (R,R)/(S,S)-5,14 enantiomer pair showed either a single signal or two closely spaced, equal intensity signals, with that at lower-field split by long range coupling ($J = 1.2$–1.5 Hz) to the lower-field proton (H_B) of the neighboring CH_2 group. The (R,R)/(S,S)-5-15 enantiomers showed two well separated, equal intensity signals, and the (R,S)-5,15 isomer had two closely spaced equal intensity signals, with that at higher field slightly broadened and sometimes split into a doublet ($J = ca.$ 1 Hz) by long-range coupling to H_B of the CH_2 group.

CH. In the spectra of the (R,S)-5,15 isomer and of the (R,R)/(S,S)-5,14 enantiomer pair, the proton of the CH group appeared as a multiplet centered at about 4.5 ppm. For the (R,S)-5,15 isomer, the multiplet pattern was well defined and consistent with coupling to the vicinal CH_3 'side-chain' ($J = 6.8$ Hz) and to the two non-equivalent protons of the vicinal CH_2 group ($J = 3.8$ Hz to H_B and 2.1 Hz to H_A). In the (R,R)/(S,S)-5,15 enantiomers, the CH proton appeared as a doublet ($J = 6.9$ Hz, coupling to CH_3 side-chain).

CH_2. In the spectra of the (R,S)-5,15 isomer and of the (R,R)/(S,S)-5,14 enantiomers, the non equivalent protons of the CH_2 group gave rise to an AB spin pattern in the 3.9–4.2 ppm region, with geminal coupling $J = 12$–14 Hz. For the (R,S)-5,15 triacetate, each component of the lower-field B subspectrum was further split by coupling to the vicinal CH ($J = 3.8$ Hz), whereas each component of the A subspectrum was severely broadened with ill-defined splitting. The spectra of the (R,R)/(S,S)-5,15 diacetate chlorides showed instead a single sharp signal at 4.04 ppm.

Pyridine. The protons of the pyridine moieties gave signals in the 8.0–8.5 ppm region. For the (R,R)/(S-S)-5,14 enantiomers, in which the two pyridine moieties are identical and non-symmetrical, the diacetate chloride produced a single A_2B spin pattern, whereas the triacetate gave two well separated doublets for the two β-H and a partly overlapping doublet of doublets for the γ-H. In contrast, both the (R,R)/(S-S)-5,15 enantiomers and the (R,S)-5,15 isomer, in which the pyridine moieties are symmetrical and different from one another, produced two equal intensity A_2B patterns. The pyridine sections of the spectra, which were well resolved for the acetates and acetate chlorides in chloroform solutions, correlated univocally with the isomer structure established by X-ray crystallography.

CONCLUSIONS

The results of this work, taken in conjunction with the previously reported structure of the (S,S)-5,15 $[LaL(NCS)_3]$ complex [8], answer some of the questions raised in the introduction. First, when La(III) acetate was used as template in the synthesis of dimethyl-substituted macrocycles, constitutional isomers were indeed formed and could be distinguished on the basis of their different ^{1}H NMR spectra. The (R,R)/(S,S) enantiomers of the same constitutional isomer, however, had identical NMR spectra. Second, the temperature at which the synthesis was carried out provided a remarkable degree of isomer selectivity: at room temperature, products obtained from the (R)- or (S)-diamine were greatly enriched in the respective 5,14 isomers, whereas products obtained from the (R,S)-diamine consisted primarily of the (R,S)-5,15 *meso* isomer. A rather surprising aspect of this selectivity is the virtually complete absence of a (R,S)-5,14 isomer in products obtained from the (R,S)-diamine at any temperature. It can be noted that in each of the more abundant isomers the side-chain $-CH_3$ groups are in the same hemisphere relative to the macrocycle, but no rationalization for this preference can be suggested at this time. Third, constitutional isomers with somewhat different solubilities could be separated, although in minimal yields, by NMR-monitored fractional crystallization. The molecular structures of two single-isomers, the 9-coordinate $[La(NCS)_3\{$(S,S)-5,15-dimethyl-macrocycle$\}]$ [8] and the 10-coordinate $[La(NCS)_3(H_2O)\{$(R,S-5,15-dimethyl-macrocycle$\}]$ (this work), were established by X-ray crystallography and the La-macrocycle moieties were found to have different conformations in the two complexes. In the (R,S)-5,15 isomer, with the $–CH_3$ substituents in the same hemisphere, the La-macrocycle is nearly flat, whereas in the (S,S)-5,15 isomer, with the two $–CH_3$ substituents in opposite hemispheres, the La-macrocycle is puckered and appreciably folded at the flexible $–CH–CH_2–$ side chains. These conformational changes also account for the different coordination numbers of the two isomers. Finally, this work has shown that there is an unambiguous correlation between isomer structure and certain features of the proton NMR spectra; this correlation may prove very useful in the identification of similar disubstituted macrocyclic systems for which crystallographic evidence can not be obtained.

(Received 8 January 1998; accepted 7 April 1998)

Abstract—Hydrolysis of (6,5), (6,7) and (6,8)-spirophosphoranes containing the six-membered ring P($OCH_2CMe_2CH_2O$) has been studied; in all the cases the six-membered phosphorinane ring is retained during the first stage of hydrolysis. The X-ray structure of one such product, ($OCH_2CMe_2CH_2O$) P(O)(2,2′–O–C_6H_4–C_6H_4OH) which exhibits intermolecular H-bonding, has been determined. © 1998 Elsevier Science Ltd. Keywords: spirophosphorane; phosphorinane; hydrolysis; hydrogen bonding; X-ray structure.

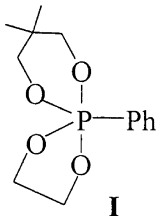
While investigating the acid hydrolysis of the cyclic (5,6)-spirophosphorane **I**, McGall and McClelland have noted the formation of several products (**II**–**IV**) [1]. The cyclic ester **IV** with the five membered ring



I

was observed under mild acidic conditions whereas the phosphorinane **V** was not detectable at all. In a somewhat contrasting way, Gallucci and Holmes isolated the phosphorinane **1** in an attempted synthesis of the cyclic (5,6)-spirophosphorane **VI** [2, 3].

In our efforts to obtain penta- and hexa-coordinated cyclic phosphoranes with six and higher membered rings, in addition to the expected products, we encountered hydrolysis products—the phosphate esters on several occasions [4–6]. In particular, during the synthesis of hexacoordinated spirophosphoranes with an oxinate substituent, quite often we ended up

isolating the hydrolyzed products. We believe that a knowledge of these reactions is useful in ascertaining the hydrolytic stability of phosphoranes of different ring sizes; besides, the residual -OH functionalities in these phosphates can be connected to other reactive substrates. In this paper we report the directed synthesis of **1**–**5**; the X-ray structure of **3** featuring intermolecular H-bonding is also described.

EXPERIMENTAL

Chemicals were procured from Aldrich or from local manufacturers; they were purified when required. Solvents were purified according to standard procedures [7]. NMR spectra were recorded on a Bruker 200 MHz spectrometer. Chemical shifts ($CDCl_3$, ppm) are measured against tetramethylsilane (^1H, ^{13}C) or ext. 85% H_3PO_4. IR spectra were recorded on a Perkin-Elmer 1310 spectrophotometer. Elemental analysis was performed on a Perkin-Elmer 240C CHN analyzer.

The compound $(OCH_2CMe_2CH_2O)(PhO)P(9,10–O_2C_{14}H_8)$ (**VI**) was prepared according to the procedure of Ramirez *et al.*[3]; synthesis/ identification of compounds $(OCH_2CMe_2CH_2O)P(9,10–O_2C_{14}H_8)(OC_9H_6N)$ (**6**), $(OCH_2CMe_2CH_2O)P(1,2–O_2C_6H_4)(OC_9H_6N)$ (**7**), $(OCH_2CMe_2CH_2O)P(2,2'–OC_6H_4–C_6H_4O)(OC_9H_6N)$ (**8**), $(OCH_2CMe_2CH_2O)P[(OC_6H_3–4–Cl)_2CH_2]$ (OC_9H_6N) (**9**), $(OCH_2CMe_2CH_2O)P(2,2'–OC_{10}H_6–C_{10}H_6O)(OC_9H_6N)$ (**10**) has been described in detail elsewhere [5].

(*a*) *Preparation of the phosphate esters* $(OCH_2CMe_2CH_2O)P(O)(9,10–OC_{14}H_8OH)$ (**1**) *and* $[(HOCH_2CMe_2CH_2O)P(O)(9,10–OC_{14}H_8OH)(O)]^-[HOC_9H_6NH]^+ 1/2H_2O$ (**11**)

Compound **VI** (1.00 g, 2.3 mmol) was dissolved in a mixture of chloroform (1 cm^3) and ether (3 cm^3) and kept in open air till all the solvent evaporated. The residue was crystallized from dichloromethane-*n*-heptane to obtain **1**. Yield: 0.55 g (67%). M.p. 162°C [lit. m.p. 162–164°C] [2]. IR: 3185 cm^{-1} (ν(OH)). ^1H NMR: δ 1.00 (*s*, 3H, CH_3), 1.35 (*s*, 3H, CH_3), 4.05 (*dd*, $J \approx 14$, 25 Hz, OCH_2(A)), 4.50 (*d*, $J \approx 140$ Hz, 2H, OCH_2(X)), 7.50–8.70 (*m*, 8H, *H*(Ar)), 9–50 (*br*, 1H, O*H*). ^{31}P NMR: −10.2.

The same compound (**1**) was observed [^1H, ^{31}P] when **6** (1.0 g) was dissolved in chloroform (5 cm^3) and kept aside for 2 days in open air. Although the product was pure by ^{31}P NMR, it could not be obtained free of 8-hydroxy quinoline. Upon washing this product with hot water, the doubly hydrolyzed product **11** (which could be recrystallized from CH_2Cl_2-*n*-heptane (1:1)) was obtained. Yield of **11**: 0.4 g. M.p. 162°C. ^1H NMR: δ 0.74 (*s*, 6H, CH_3), 3.23 (*s*, 2H, $HOCH_2$), 3.80 (*d*, $^3J = 20.0$ Hz, 2H, P–O–CH_2), 4.45 (*br*, variable, OH_2?)). 7.30–8.80 (*m*, 14H, *H*(Ar)). ^{31}P NMR: −0.6. Anal. calcd. for $C_{28}H_{28}NO_7P$. $1/2H_2O$: C, 63.39; H, 5.47; N, 2.64. Found: C, 63.47; H, 5.45; N, 2.85.

(*b*) *Preparation of the phosphate ester* $(OCH_2CMe_2CH_2O)P(OC_6H_4OH)$ (**2**)

(i) To a mixture of the cyclic phosphite $(OCH_2CMe_2CH_2O)P(OC_9H_6N)$ (**12**) [5] (1.33 g, 4.79 mmol), and catechol (0.53 g, 4.79 mmol) in dry ether (40 cm^3) maintained at −60°C was added $ClN(i\text{-}Pr)_2$ (0.65 g, 4.79 mmol), in ether (30 cm^3) over a period of 15 min with continuous stirring. The mixture was gradually brought to 30°C, stirred overnight and filtered. The precipitate was given a quick water wash (2×5 cm^3) and dried *in vacuo*. The product was crystallized from dichloromethane-*n*-heptane (2:1) to afford **2**. Yield 0.7 g (57%). M.p. 142°C. IR (KBr): 3202 cm^{-1}(ν(OH)). ^1H NMR: δ 0.96 (*s*, 3H, CH_3), 1.35 (*s*, 3H, CH_3), 4.04 (*dd*, 2H, OCH_2(A)), 4.36 (*d*, 2H, OCH_2(X)), 6.80–7.20 (*m*, 4H, *H*(Ar)), 7.79 (*s*, 1H, O*H*). ^{13}C NMR: 20.16, 21.69 (2 CH_3), 32.28 (*d*, ^3J(P–C) = 6.2 Hz), 78.84 (*d*, ^2J(P–C) = 6.8 Hz), 119.35, 120.65, 120.88 (^3J(P–C) = 3.9 Hz), 126.61, 138.16 (^2J(P–C) = 8.5 Hz), 147.59. ^{31}P NMR: −11.93. Anal. calcd. for $C_{11}H_{15}O_5P$: C, 51.17; H, 5.86. Found: C, 51.74; H, 6.17.

(ii) When the reaction of $(1,2\text{-}C_6H_4O_2)P(OC_9H_6N)$ [5] (1.17 g, 4.12 mmol) with 2,2-dimethyl-1,3-propanediol (0.43 g, 4.12 mmol) and $ClN(i\text{-}Pr)_2$ (0.52 g,

4.12 mmol) was conducted, the same product **2** [^{1}H, ^{31}P] was observed.

(iii) Reaction of 5.34 mmol each of ($OCH_2CMe_2CH_2O$)P(O)Cl, catechol and triethylamine in toluene at room temperature, and washing the obtained solid with water, afforded **2** (0.88 g, 64%) which was recrystallized from CH_2Cl_2-toluene [m.p.; ^{1}H NMR].

(*c*) *Preparation of the phosphate ester* ($OCH_2CMe_2CH_2O$)P(2,2′–OC_6H_4–C_6H_4OH) (**3**)

Following the same procedure as in *b*(*i*), the precipitate obtained by treating **12** (2.33 g, 8.42 mmol), 2,2′-biphenol (1.57 g, 8.42 mmol) and ClN(*i*-pr)$_2$ (1.14 g, 8.42 mmol) was washed quickly with water and dried *in vacuo*. The residue was crystallized from CH_2Cl_2-n-heptane (3:1). Yield 1.1 g (39%), M.p. 182°C. IR: 3292 cm^{-1}(*v*(OH)). ^{1}H NMR: δ 0.40 (*s*, 3H, C*H*$_3$), 1.10 (*s*, 3H, C*H*$_3$), 3.35–3.62 (*m*, 4H, OC*H*$_2$), 5.4 (*br*, 1H, O*H*), 6.81–7.65 (*m*, 8H, *H*(Ar)). ^{31}P NMR: −15.1. Anal. calcd. for $C_{17}H_{19}O_5P$: C, 61.08; H, 5.69. Found: C, 61.00; H, 5.55.

(*d*) *Preparation of the phosphate ester* ($OCH_2CMe_2CH_2O$) P(OC_6H_3(Cl)–CH_2–OC_6H_3(Cl)–OH) (**4**)

(i) Following the same procedure as in **b**(i), the precipitate obtained using 3.73 mmol each of **12**, 2,2′-methylene-bis-(4-chlorophenol) and ClN(*i*-pr)$_2$ was dissolved in dichloromethane and left in open air to obtain **4**. Yield: 0.3 g (19%). M.p. 175°C. IR: 3350, 3295 cm^{-1} (*v*(OH)). ^{1}H NMR (DMSO + $CDCl_3$): δ 0.52 (*s*, 3H, C*H*$_3$), 1.03 (*s*, 3H, C*H*$_3$), 3.50–3.80 (*m*, 4H, OC*H*$_2$), 4.35 (*s*, 2H, C*H*$_2$Ar), 6.56–7.28 (*m*, 6H, *H*(Ar)). ^{31}P NMR: −14.4. Anal. calcd. for $C_{18}H_{19}Cl_2O_5P$:C, 51.81; H, 4.56. Found: C, 51.80; H,4.81.

(ii) When compound **8** (0.5 g, 1.28 mmol) was dissolved in acetone (3 cm^3) and left in open air a solid was obtained which was washed with ether to remove 8-hydroxyquinoline. The residue was pure **3** [M.p. IR]. Yield: 0.2 g (47%).

(*e*) *Preparation of the phosphate ester* ($OCH_2CMe_2CH_2O$) P(O){$OC_{10}H_6$–CH_2–$C_{10}H_6$OH} (**5**)

The procedure was essentially the same as in **b**(i) using toluene as the solvent and 2.95 mmol each of **12** and bis-(2-hydroxy-1-naphthyl) methane. The reaction mixture showed peaks at −124.5, −69.8 −14.7 and −14.2 ppm in the ^{31}P NMR spectrum. The product was recrystallized from toluene to afford pure **5**. Yield: 0.31 g, 23%. M.p. 128–134°C. IR: 3287 cm^{-1}(*v*(OH)). ^{1}H NMR: δ 0.73, 1.26 (2s, 6H, C*H*$_3$), 2.38, 3.80–4.20 (*m*, 4H, OC*H*$_2$), 4.94 (*s*, 2H, Ar-C*H*$_2$-Ar), 6.95 (*s*, 1H, O*H*), 7.0–8.2 (*m*, 12H, *H*(Ar)). An unassigned peak at 2.38 ppm was also observed. ^{13}C NMR: 20.05, 21.64 (2s, *C*H$_3$), 23.58 (*C*H$_2$), 32.09 (*C*H$_2$, ^3J (P–C) = 5.5 Hz), 78.42 (O*C*H$_2$, ^2J (P–C) = 5.5 Hz), 117.73–152.20 (many lines, *C* (Ar)). ^{31}P NMR: −14.0 ppm. Anal. calcd. for $C_{26}H_{25}O_5P$: C, 69.99; H, 5.88. Found: C, 69.64; H, 5.62.

(*f*) *Reaction of* **12** *with pinacol*/ClN(*i*-Pr)$_2$

Using the same procedure as in *b*(*i*), the residue upon evaporating the filtrate (^{31}P NMR: -57.45, −55.46, −42.50, −13.76, −5.58, 11.85; the intensities of the peaks varied with time as well as the batch) and keeping in air over a prolonged period of time ($\approx$10 days) exhibited ^{1}H NMR signals at 1.00 (CH_2-C*Me*$_2$), and 4.00 (d, ^3J = 12 Hz, OC*H*$_2$P) ppm in addition to the signals for 8-hydroxyquinoline and pinacol. Peaks corresponding to ≡P($OCH_2CMe_2CH_2OH$) were not observed and ^{31}P NMR showed peaks at −5.6 (90%) and 11.85 (10%) ppm.

X-ray Structure Determination of **3**

Data were collected at −120°C on a Stoe-Siemens-AED-diffractometer with monochromated MoKα radiation (λ = 0.71073 Å). Data were collected from a oil-coated rapidly cooled crystal [8] with a profile-fitted method [9]. The structure was solved by direct methods [10]. All non-hydrogen atoms were refined anisotropically [11]. For the hydrogen atoms bonded to carbon the riding model was used. The hydrogen atom bonded to oxygen was localized in a difference electron density map and refined freely. An extinction correction was applied. The structure was refined against F^2 with a weighting scheme of $w^{-1} = \sigma^2(F_o^2) + (0.0323P)^2 + 0.8659P$ with $P = (F_o^2 + 2F_c^2)/3$. The R values are defined as $R1 = S\|F_o| - |F_c\|/\Sigma|F_o|$ and $wR2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma wF_o^4]^{0.5}$. Crystal data for **3**: $C_{17}H_{19}O_5P$, M_r = 334.29, monoclinic, space group Cc, a = 15.372(1), b = 9.725(1), c = 10.678(1) Å, β = 97.23(1)°, V = 1583.6(2) Å^3, Z = 4, ρ(calcd) = 1.402 Mg/m^3, μ = 0.197 mm^{-1}, F(000) = 704, crystal size (mm) 0.3 × 0.3 × 0.4, 2810 reflections in the range of $8° < 2\theta < 50°$ collected, 2805 unique reflections (R_{int} = 0.003), 2803 reflections and 2 restraints used for the refinement of 215 parameter, S = 1.028, R1 = 0.028 for $I > 2\sigma(I)$, wR2 = 0.068 for all data, absolute structure parameter −0.01(8) [12], extinction coeffient 0.0039(5), maximum/minimum residual density 0.172/–0.183 eÅ^{-3}.

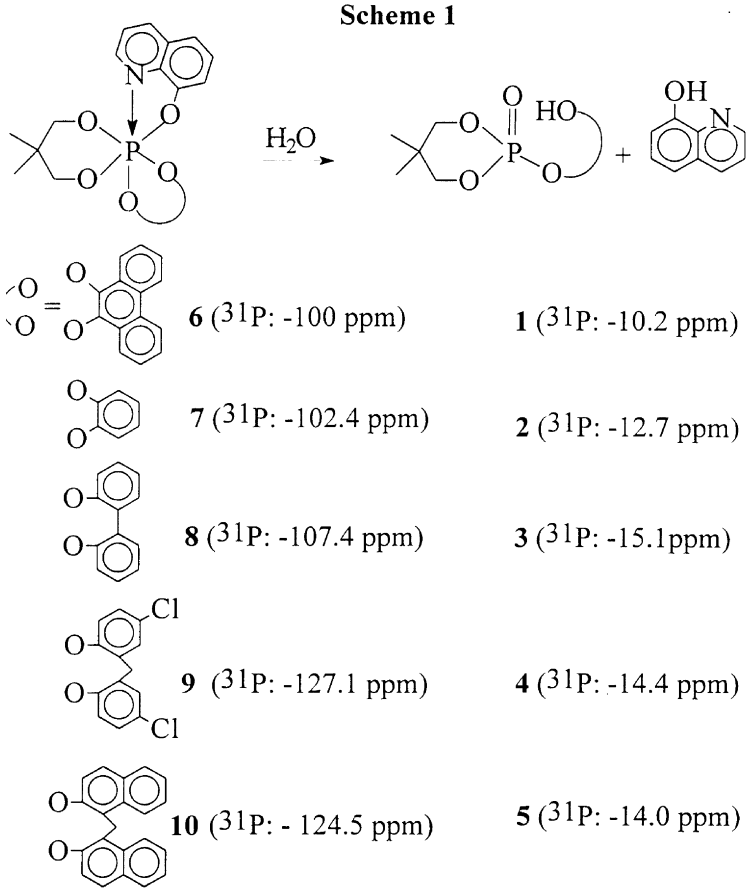
Further details on the crystal structure analysis are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, U. K. by quoting the full journal citation.

RESULTS AND DISCUSSION

Synthesis and Spectroscopy

Compound **1** (δ_p −10.02) is readily isolated in a pure state by the hydrolysis of Ramirez's compound

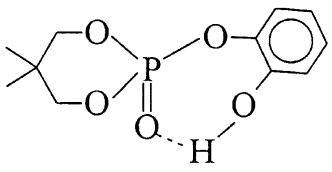
Scheme 1



VI [3] in open air. It is also the only phosphorus product observed in the hydrolysis of our hexacoordinated phosphorane **7** (see Scheme 1 for structure) [5]; however compound **1** could not be obtained free of the 8-hydroxy quinoline this way. The synthetic route leading to **1**–**5** *via* the oxinate compounds is illustrated in Scheme 1; the hexacoordinated compounds themselves have been prepared by the oxidative addition of a quinone or diol/N-chlorodiisopropylamine to a cyclic phosphite as described earlier [5]. The intermediates **6** and **8** have been structurally characterized by us previously [5]; others (**7**, **9** & **10**) have been identified by ^{31}P NMR spectroscopy.

That compounds **1** and **3** result from the hydrolysis of the hexacoordinated phosphoranes is shown by isolation followed by hydrolysis of **6** (or **VI**) and **8**. Compound **2** has also been independently synthesized by treating $(OCH_2CMe_2CH_2O)P(O)Cl$ with equimolar quantities of catechol and triethylamine.

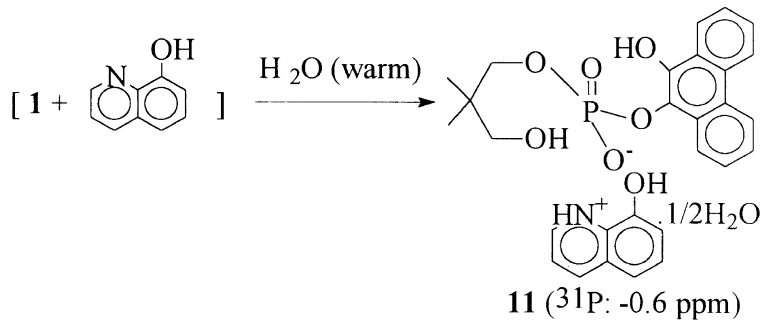
The δ(P) values for **1**–**5** are in the range expected for tetracoordinated phosphate esters; in the ^{1}H NMR the OCH_2 protons show an AX (**1** and **2**) or AB (**3**–**5**) pattern with coupling to phosphorus [^{3}J(P–O–C–H)] and two separate signals for the CH_3 protons of the neopentyl glycolate residue, thus clearly showing that the six-membered phosphorinane ring is retained in these compounds. The similarity in the spectra of **1** and **2** suggests that **2** also has intramolecular H-bonding (structure **VII**) analogous to that observed by Gallucci and Holmes for **1** [2]; on a similar note it may be expected that compounds **3** and **5** exhibit intermolecular H-bonding similar to that in **4** (see below) [13].



VII

In the hydrolysis of **6**, when the initial product mixture was washed with hot water to remove 8-hydroxy quinoline, further hydrolysis leading to the cleavage of the six-membered ring occurred to give a crystalline product (Scheme 2). On the basis of ^{1}H and ^{31}P NMR as well as elemental analysis, structure **11** is assigned to this compound. It can be noted that in

Scheme 2



11 (^{31}P: -0.6 ppm)

this compound both the five and six-membered rings are cleaved (*cf* structure **III**). We have also tried to analyze the hydrolysis products from the reaction of $(OCH_2CMe_2CH_2O)P(OC_9H_6N)$ (**12**) with an aliphatic diol like pinacol. Although there are several hydrolysis products in the reaction mixture as shown by ^{31}P NMR, there is at least one of these in which the six-membered ring is retained (see experimental). Thus this result is different from the acid hydrolysis of **I** studied by McGall and McClelland [1].

In summary, the first stage of the hydrolysis of spirophosphoranes containing a 1,3,2-dioxaphosphorinane ring occurs by retaining this six-membered ring. Such a feature contrasts with the acid hydrolysis of the (5,6)-spirophosphorane **I** in which a product with the phosphorinane ring intact was not observed.

X-ray Structure of **3**

Compound **3** crystallizes in the space group *Cc*. The molecular structure of **3** along with atom labeling scheme is depicted in Fig. 1. The phosphorus atom is coordinated tetrahedrally with the O=P–O angles larger and the O–P–O angles smaller than the ideal tetrahedral angle as expected. All bond lengths are in typical ranges. The 1,3,2-dioxaphosphorinane ring adopts a chair conformation, which is quite typical for six membered rings perpendicular to oxo groups [2]. The most important feature in the structure is perhaps the presence of *intermolecular* hydrogen bonding involving the OH group of the 2,2′-biphenoxy group [O(5)–H(5O), 0.86(4) Å; O(5) . . . O(1A), 2.702(2) Å; H(5O) . . . O(1A), 1.85(4) Å; O(5)–

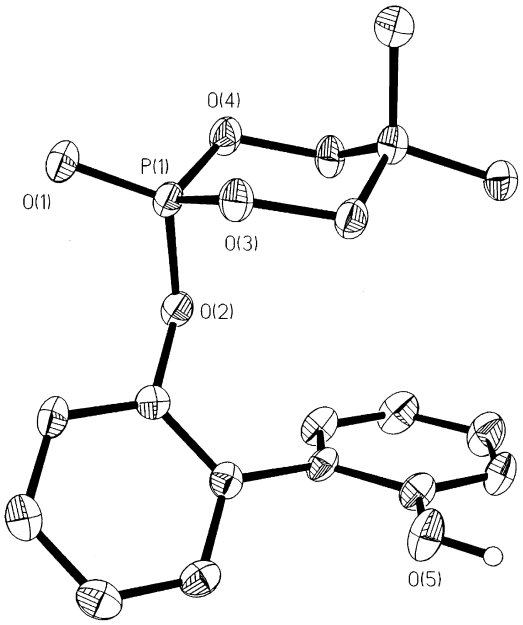


Fig. 1. Crystal structure of **3**, selected bond lengths [Å] and angles [°]: P(1)–O(1) 1.459(2), P(1)–O(3) 1.556(2), P(1)–O(4) 1.559(2), P(1)–O(2) 1.583(2), O(1)–P(1)–O(3) 111.97(9), O(1)–P(1)–O(4) 113.45(9), O(3)–P(1)–O(4) 107.15(8), O(1)–P(1)–O(2) 115.18(8), O(3)–P(1)–O(2) 106.92(8), O(4)–P(1)–O(2) 101.32(8).

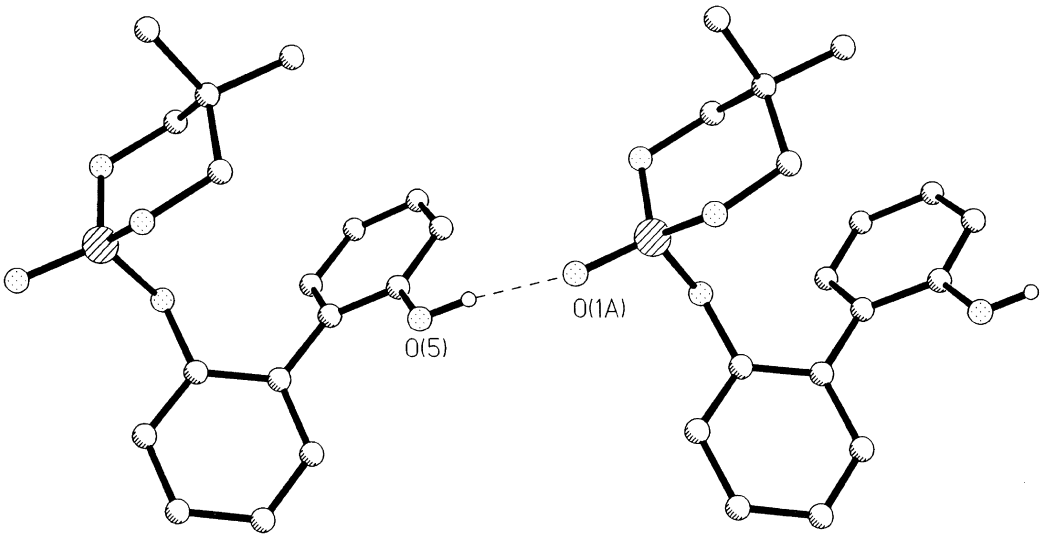

Fig. 2. Hydrogen bonding pattern in **3**: O(5)–H(5O), 0.86(4) Å; O(5) . . . O(1A), 2.702(2) Å; H(5O) . . . O(1A), 1.85(4) Å; O(5)–H(5O) . . . . O(1A), 169(3)°.

H(5O) . . . O(1A), 169(3)°] leading to chains in the crystal (Fig. 2). This pattern is different from the *intramolecular* hydrogen bonding observed in Holmes' compound **1** [2, 14]. Such a difference arises because in **3** the –OH group is too far from the P=O in the molecule.

(Received 10 December 1997; accepted 7 April 1998)

Abstract—The extraction of the alkaline-earth metal ions by 25,27-dicarboxymethyl-26,28-dimethoxy-5,11,17,23-tetra-*tert*-butylcalix[4]arene (L^IH_2) and 25,27-dicarboxymethyl-26,28-dimethoxyethoxy-5,11,17,23-tetra-*tert*-butylcalix[4]arene ($L^{II}H_2$) in 1,2-dichloroethane is shown to be pH dependent. The analysis of the extraction equilibrium results indicates that the extraction process takes place via the formation of $ML_2^IH_2$ ($M^{2+} = Ca^{2+}$, Sr^{2+} and Ba^{2+}), $ML_2^{II}H_2$ ($M^{2+} = Ca^{2+}$ and Sr^{2+}) and ML^{II} ($M^{2+} = Ba^{2+}$) complexes. Both ligands show a high selectivity for calcium. The existence of the ML_2H_2 complexes is supported by ^{1}H-NMR and FAB^+ experiments on the corresponding Ca^{2+} complexes. ^{1}H-NMR investigations show that the calcium ion is located outside the calixarene cavity. Competitive extraction of Mg, Ca, Sr and Ba suggests the formation of mixed complexes. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: calix[4]arene-dicarboxylic; liquid–liquid extraction; alkaline-earth; complex; selectivity.

INTRODUCTION

In previous studies [1] on the extraction properties of the dicarboxycalix[4]arene derivatives (L^IH_2 and $L^{II}H_2$) (Fig. 1) we have shown that the extraction of the alkali ions occurs in a relatively acidic pH range with a high selectivity for sodium.

It was shown that mono and dinuclear complexes of formula MLH and M_2L can be formed. The location of an alkali ion in the calix[4]arene moiety was confirmed by ^{1}H-NMR spectrometry [2].

Rare earth extractions [3] were also investigated with a dicarboxymethyl–dimethoxycalix[4]arene (L^IH_2). It was shown in particular that the extraction takes place via the formation of mixed alkali-rare earth complexes.

In this paper we present some results on the extraction of alkaline-earth by dicarboxymethyl–dimethoxycalix[4]arene (L^IH_2) and the more rigid dicarboxymethyl–dimethoxyethoxycalix[4]arene ($L^{II}H_2$) in the cone conformation. Alkaline-earth dicarboxylic systems are of particular interest because of the equality of ion charge (+2) and the number of acidic protons in the extractant molecule.

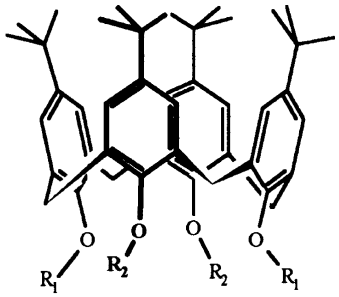

Fig. 1. The studied calixarenes in this work: (I) $R_1 = CH_3$, $R_2 = CH_2COOH$: 25,27-dicarboxymethyl-26,28-dimethoxy-5,11,17,23-tetra-*tert*-butylcalix[4]arene (L^IH_2). (II) $R_1 = CH_2CH_2OCH_3$, $R_2 = CH_2COOH$: 25,27-dicarboxymethyl-26,28-dimethoxyethoxy-5,11,17,23-tetra-*tert*-butylcalix[4]arene ($L^{II}H_2$).

MATERIALS AND EXPERIMENTAL

Materials

The dicarboxylated compounds 25,27-dicarboxymethyl-26,28-dimethoxy-5,11,17,23-tetra-*tert*-butylcalix[4]arene ($L^{I}H_2$), and 25,27-dicarboxymethyl-26,28-dimethoxyethoxy-5,11,17,23-tetra-*tert*-butylcalix[4]arene ($L^{II}H_2$) were prepared according to the literature [4–6].

1,2-Dichloroethane (SDS) was washed by pre-equilibration with water in order to remove the stabilizer. The organic solutions were freshly prepared by dissolving a weighted amount of the ligand in the 1,2-dichloroethane. Commercially available $MgCl_2 \cdot 6H_2O$ (Prolabo), $CaCl_2 \cdot 6H_2O$, $SrCl_2 \cdot 6H_2O$ and $BaCl_2 \cdot 2H_2O$ (Merck) were used as received and stock solutions were prepared by dissolving the salts in deionized water.

Extraction procedure

Liquid–liquid extraction experiments were carried out by stirring equal volumes of aqueous and organic phases (90 mL) for 20 min. This time was found to be sufficient to reach equilibrium. The temperature was kept at $25.0 \pm 0.1^{\circ}C$ during the experiments. The pH was adjusted by adding small volumes of the cesium hydroxide (0.2 M). The cesium hydroxide was chosen, because this metal is not extracted by the ligands [7]. The metal organic concentrations were determined by sampling the organic phase (2 mL) which were then stripped with 0.1 M hydrochloric acid (10 mL). In this way quantitative transfers of the alkaline-earth ions from the organic to the acidic water phase were obtained. The aqueous phase was analyzed by using a Perkin-Elmer (2380) Atomic Absorption instrument with an air-acetylene flame or by Varian-Liberty 220 ICP/AES.

FAB^+ and ^1H-NMR experiments

FAB^+ spectra were obtained on a VG-Analytical ZAB HF apparatus. ^1H-NMR spectra were recorded on a Bruker SY200 spectrometer (200 MHz, $CDCl_3$).

Free ligand $L^{II}H_2$. 7.17 and 6.57 ppm (2s, 8H, Ar*H*); 4.75 ppm (s, 4H, OCH_2COOH); 4.42 ppm (d, 4H, $J_{H-H} = 13$ Hz, $ArCH_AH_BAr$); 3.97 ppm (m, 4H, $ArOCH_2CH_2OCH_3$); 3.75 ppm (m, 4H, $ArOCH_2CH_2OCH_3$); 3.46 ppm (s, 6H, OCH_3); 3.24 ppm (d, 4H, $J_{H-H} = 13$ Hz, $ArCH_AH_BAr$); 1.34 ppm (s, 18H, C_4H_9); 0.83 ppm (s, 18H, C_4H_9).

$CaL_2^{II}H_2$ complex. 7.17 ppm (s, 4H, Ar*H*); 7.13 and 7.11 ppm (2s, 8H, Ar*H*); 6.57 ppm (s, 4H, Ar*H*); 4.74 ppm (s, 4H, OCH_2COOH); 4.42 ppm (d, 4H, $J_{H-H} = 13$ Hz, $ArCH_{A1}H_{B1}Ar$); 4.36 ppm (d, 4H, $J_{H-H} = 13$ Hz, $ArCH_{A2}H_{B2}Ar$); 4.33 ppm (m, 4H, $ArOCH_2CH_2OCH_2$); 3.96 ppm (m, 8H, $ArOCH_2CH_2OCH_3$); 3.81 ppm (s, 6H, OCH_3); 3.75 ppm (m, 4H, $ArOCH_2CH_2OCH_3$); 3.45 ppm (s, 6H, OCH_3); 3.41 ppm (d, 4H, $J_{H-H} = 13$ Hz, $ArCH_{A2}H_{B2}Ar$); 3.24 ppm (d, 4H, $J_{H-H} = 13$ Hz, $ArCH_{A1}H_{B1}Ar$); 1.34 ppm (s, 18H, C_4H_9); 1.15 ppm (s, 18H, C_4H_9); 1.13 ppm (s, 18H, C_4H_9); 0.83 ppm (s, 18H, C_4H_9).

RESULTS AND DISCUSSION

Single metal extractions

The extraction of an alkaline-earth ion by a calixarene dicarboxylic derivative ($L^{I}H_2$ or $L^{II}H_2$) is analyzed by plotting experimentally $r_M = [M]_{org}/L_o$ as a function of pH for three different concentrations (L_o) of extractant (Fig. 2).

The aqueous metal ion concentration $[M^{2+}]_{aq}$ is considered as constant and equal to the initial metal concentration (0.16 M) within the experimental conditions.

The experimental results confirm that the extraction takes place via an ion exchange process. In some cases the r_M plots exhibit a plateau value $r_{M\,max}$ which is independent of L_o, suggesting that the $r_{M\,max}$ value corresponds to the metal ion/ligand stoichiometry of the extracted species. The plateau for $r_M = 0.5$ observed in the $Ca/L^{I}H_2$ and $Ba/L^{I}H_2$, systems suggests the formation of a 1:2 ion/ligand complex. The $Sr/L^{I}H_2$ system appears to be more complicated because of the occurrence of a solubility limit which induces a decrease of the plateau value with increase of the extractant concentration. It was observed that magnesium is not extracted. $L^{I}H_2$ extracts preferentially calcium according to the selectivity order:

$$Ca \gg Sr > Ba >>> Mg$$

The extraction of alkaline-earth by $L^{II}H_2$ is generally accompanied by the occurrence of a precipitation which hides the observation of a plateau. The experimental $r_M = f(pH)$ plots with $L^{II}H_2$ show that the extraction takes place at a higher pH range than for $L^{I}H_2$. Moreover, in contrast with $L^{I}H_2$ the $r_{Ba} = f(pH)$ plots suggest the existence of a complex 1:1 metal/ligand stoichiometry.

A quantitative analysis of the $r_M = f(pH)$ curves was made on the basis of the following assumptions:

—a single equilibrium is involved in the extraction process,
—a single metal ion is involved in the extracted species.

If a complex with 1:2 metal/ligand stoichiometry is formed, the corresponding equilibrium can be written:

$$M_{aq}^{2+} + 2/m(LH_2)_{m\,org} \rightleftharpoons ML_2H_{2org} + 2H_{aq}^{+}$$

(equilibrium 1)

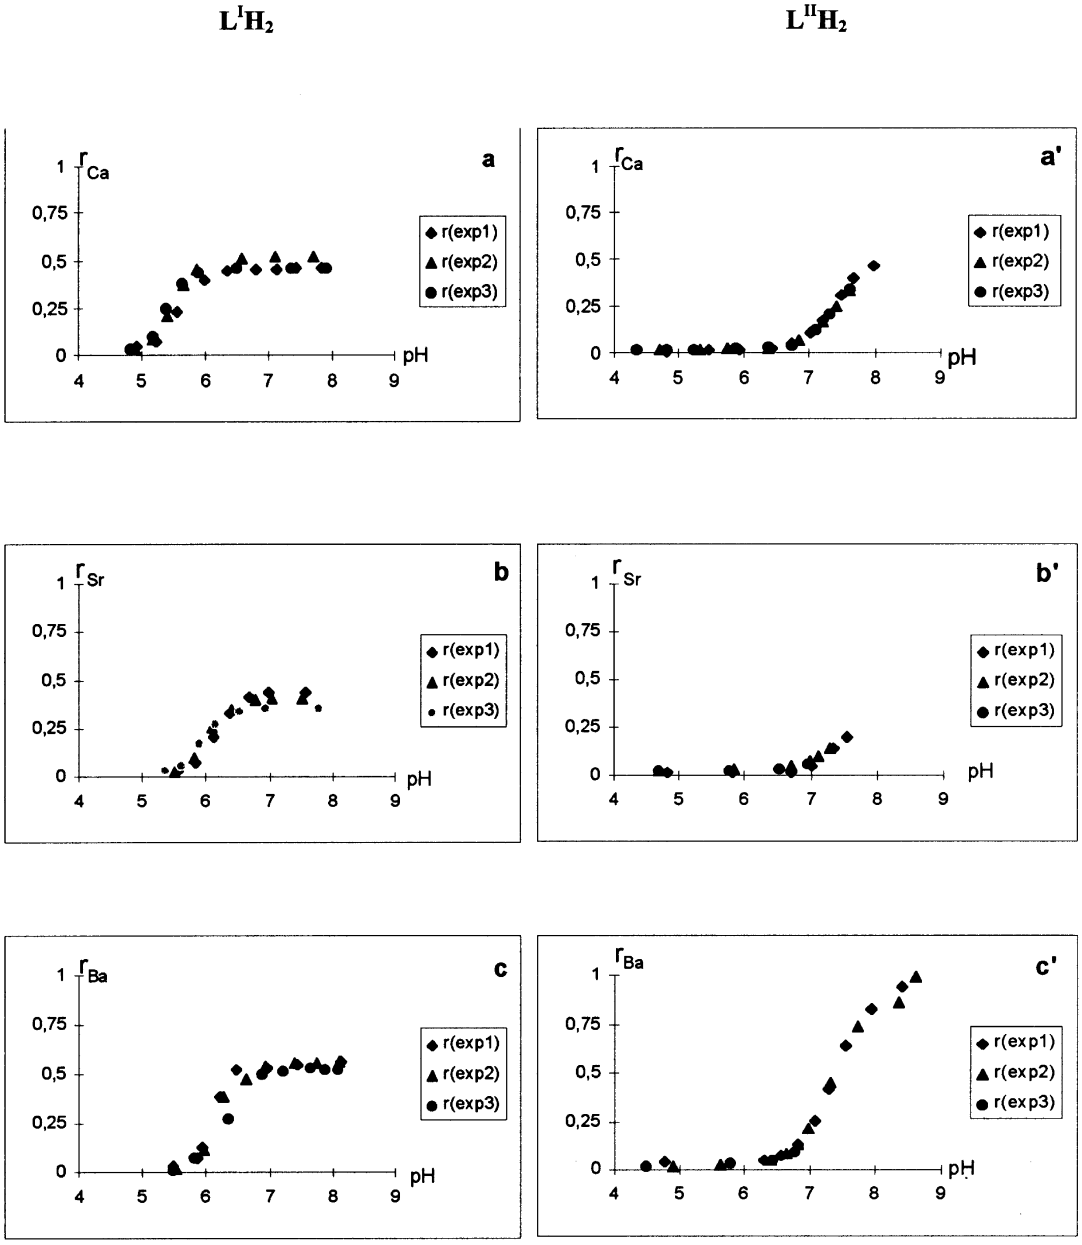

Fig. 2. Extraction of alkaline-earth by $L^{I}H_2$ (a, b, c) and $L^{II}H_2$ (a′, b′ c′) in 1,2-dichloroethane at 298 K, $r_M = f(pH)$ plots. Experimental conditions: aqueous initial concentration 0.16 M; ligand concentration: L_o: ◆ 5×10^{-4} M: r(exp1); ▲ 1×10^{-3} M: r(exp2); ● 2×10^{-3} M: r(exp3) a, a′: Ca; b, b′: Sr; and c, c′: Ba.

where m is the degree of association of the free ligand.

The conditional equilibrium constant is defined as:

$$K_{12m} = \frac{[ML_2H_2]_{org}[H^+]^2_{aq}}{[LH_2]^{2/m}_{m\,org}[M^{2+}]_{aq}} \quad (1)$$

where $[ML_2H_2]_{org} = [M]_{org}$.

Hence the $r_M = f(pH)$ curve can be drawn by introducing an equilibrium constant defined as

$$K'_{12m} = K_{12m}[M^{2+}]_{aq} = \frac{[M]_{org}[H^+]^2_{aq}}{[LH_2]^{2/m}_{m\,org}} = \frac{[M]_{org}[H^+]^2_{aq}}{1/m[L_o - 2M_{org}]^{2/m}}$$

Using the same general assumptions (single equilibrium, monometallic complex) the formation of a 1:1 metal–ligand complex is described by the equilibrium:

$$M^{2+}_{aq} + 1/m(LH_2)_{m\,org} \rightleftharpoons ML_{org} + 2H^{+}_{aq}$$

(equilibrium 2)

$$K_{11m} = \frac{[ML]_{org}[H^+]^2_{aq}}{[LH_2]^{1/m}_{m\,org}[M^{2+}]_{aq}} \qquad (2)$$

with $[ML]_{org} = [M]_{org}$.

The quantity

$$K'_{11m} = K_{11m}[M^{2+}]_{aq} = \{[M]_{org}[H^+]_{aq}{}^2\}/\{(1/m)[L_o - M_{org}]^{1/m}\}$$

can be considered as an equilibrium constant.

By setting the appropriate mass balance equations, the computed $r_M = f(pH)$ functions were drawn with arbitrary values of K' and for $m = 1$ (monomer) and $m = 2$ (dimer) (Fig. 3). It is shown that the approach should be able in principle to show whether the ligand is monomeric or dimeric.

The model is tested with $m = 1$ and $m = 2$ by introducing appropriate K values and fitting the calculated curves and the experimental plots [Fig. 4(a, b)]. It is confirmed [Fig. 4(a)] that the extraction of alkaline earth by L^IH_2 takes place via the formation of complexes of formula $ML_2{}^IH_2$ according to equilibrium 1. The formation of BaL^{II} complex according to equilibrium 2 is also confirmed [Fig. 4(b)].

In addition, it was shown that the 1:2 ion/ligand stoichiometry is highly probable for the extracted species formed in the $M/L^{II}H_2$ systems (M = Ca, Sr) [Fig. 4(b)].

So it is seen that the experimental data provide information on the number of ligand molecules involved in the extraction of a given alkaline-earth. However the data do not provide a confirmation on the monomeric or dimeric nature of the free extractant.

^{1}H-NMR and FAB$^+$ investigations

To confirm the $ML_2{}^{II}H_2$ species with $M = Ca^{2+}$, we run an extraction from water to 1,2-dichloroethane at pH 7.4.

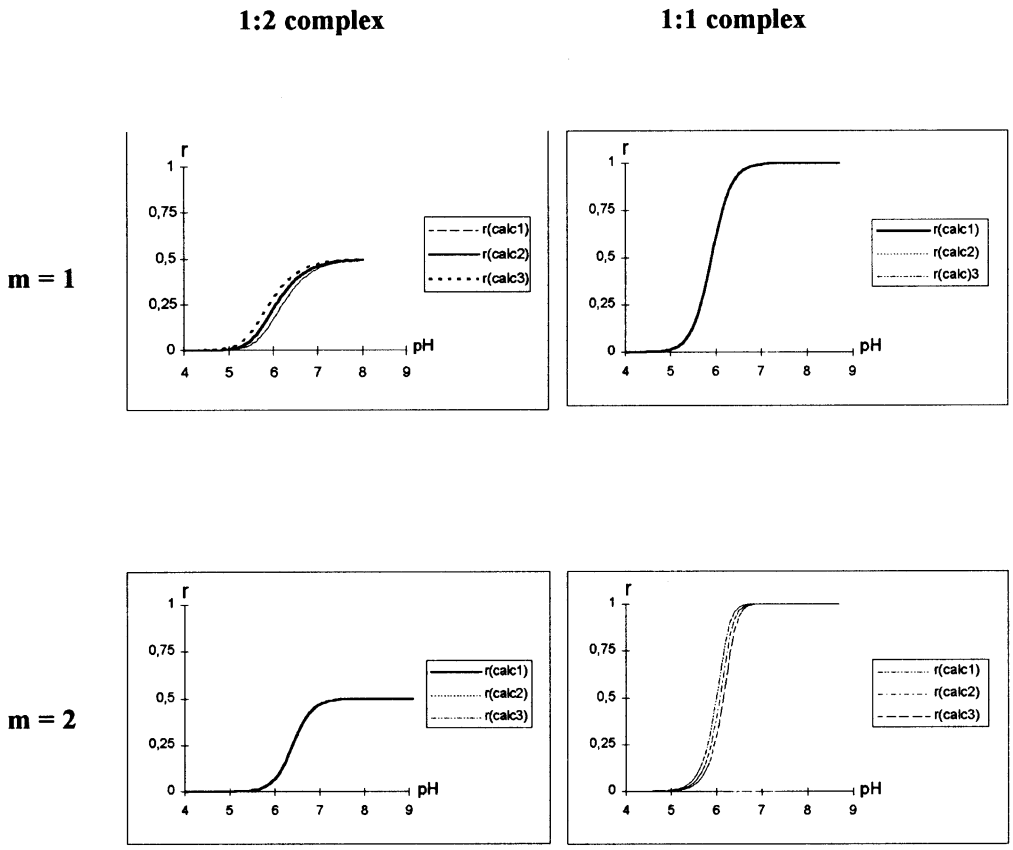

Fig. 3. Calculated curves $r_M = f(pH)$, using the experimental conditions given in the caption of Fig. 2: L_o: 5×10^{-4} M: r(calc1); 1×10^{-3} M: r(calc2); 2×10^{-3} M: r(calc3). The following arbitrary values for the equilibrium constants are used: $m = 1$, $K_{12} = (5.00 \pm 0.03) \times 10^{-9}$ and $K_{11} = (1.00 \pm 0.02) \times 10^{-11}$. $m = 2$, $K_{12} = (1.05 \pm 0.05) \times 10^{-12}$ and $K_{11} = (1.00 \pm 0.02) \times 10^{-13}$.

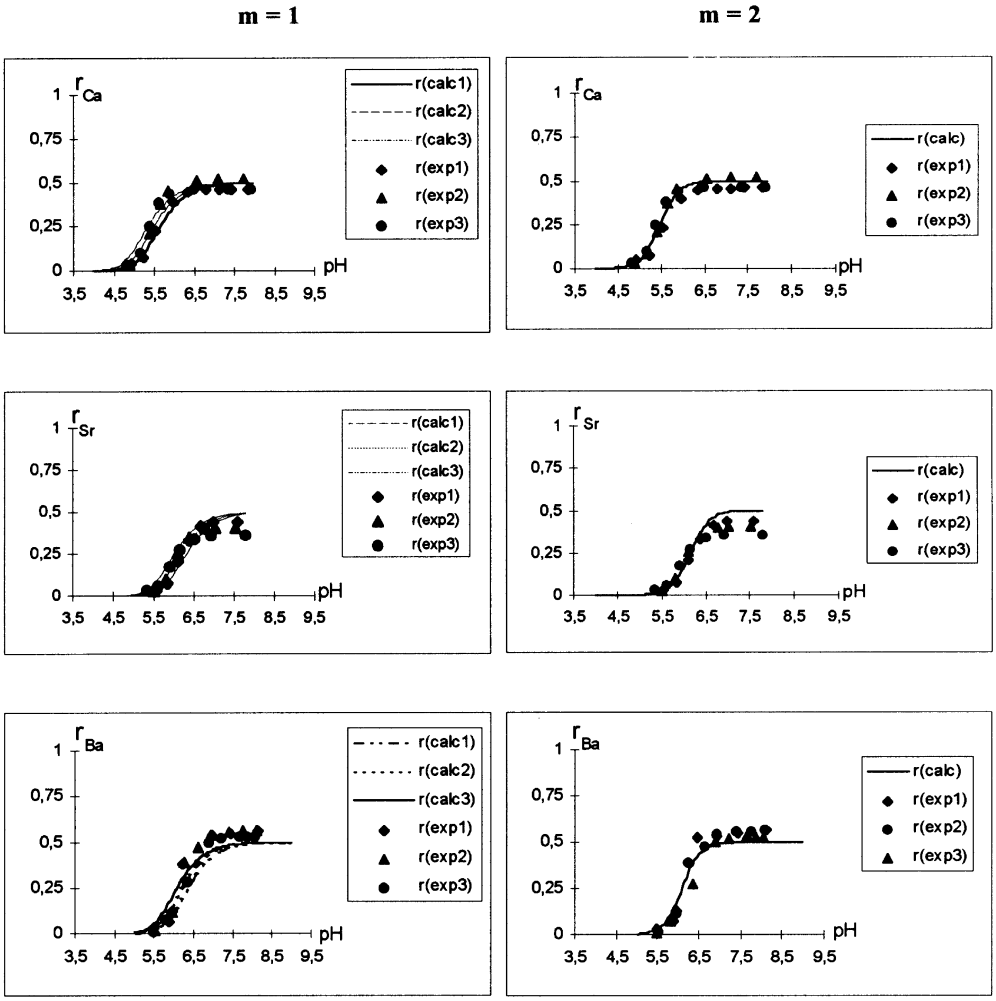

Fig. 4. Fitting of the $r_M = f(\text{pH})$ data according to equilibrium 1 and 2 (see caption of Figs. 2–3 for the definition of $r(\text{expi})$ and $r(\text{calci})$ $(i = 1, 2, 3)$). (a): $L^{I}H_2$. $m = 1$, $K_{12}(\text{Ca}) = (6.5 \pm 0.03) \times 10^{-8}$, $K_{12}(\text{Sr}) = (3.00 \pm 0.30) \times 10^{-9}$ and $K_{12}(\text{Ba}) = (2.20 \pm 0.07) \times 10^{-9}$. $m = 2$, $K_{12}(\text{Ca}) = (7.00 \pm 0.80) \times 10^{-11}$, $K_{12}(\text{Sr}) = (3.15 \pm 0.35) \times 10^{-12}$ and $K_{12}(\text{Ba}) = (4.00 \pm 0.70) \times 10^{-12}$.

Then the solvent was evaporated to dryness and the solid was investigated with FAB^+ and ^{1}H-NMR techniques. Figure 5 shows the FAB^+ spectrum of the solid giving a m/z peak at 1838.36 (calculated for $(C_{54}H_{72}O_{10})_2Ca^{2+}K^+$-$2H^+$ 1838.02, K^+ is coming from the matrix). The solid was dissolved in $CDCl_3$ and the ^{1}H-NMR spectrum is shown in Fig. 6 with the spectrum of the free ligand. The spectrum [Fig. 6(b)] was interpreted considering the formation of a 1:2 (metal/ligand) complex, the spectrum of the free ligand [Fig. 6(a)] being recovered by the formation of an *exo*-complex. Similar 1:2 (metal/ligand) *exo*-complexes had already been observed with alkali metal cations and related calixcrown compounds [8].

Competitive extraction

Competitive extractions involving the four alkaline-earth and one of the two LH_2 extractants were investigated.

With the $L^{II}H_2$ extractant it was observed that the extraction is accompanied by a precipitation for pH > 7. A simultaneous extraction of Mg, Ca, Sr and Ba by $L^{I}H_2$ takes place according to the order:

$$\text{Ca} > \text{Ba} > \text{Sr} >> \text{Mg}$$

(Mg was not detected in the organic phase).

In addition, plateau values for r_M were observed for Ca (r_{Ca} # 0.5), Sr (r_{Sr} # 0.07) and Ba (r_{Ba} # 0.19) (Fig. 7). Such a behavior cannot be explained by assuming the existence of extracted species formed in the single ion metal systems.

The experimental plots $r_M = f(\text{pH})$ for Ca^{2+}, Sr^{2+} and Ba^{2+} suggest the existence of coupled extractions via the formation of mixed extracted species.

This can be understood if one considers that the charge of a given alkaline-earth cation cannot be neutralized by two carboxylate functions which belong to the same calixarene molecule. This observations is

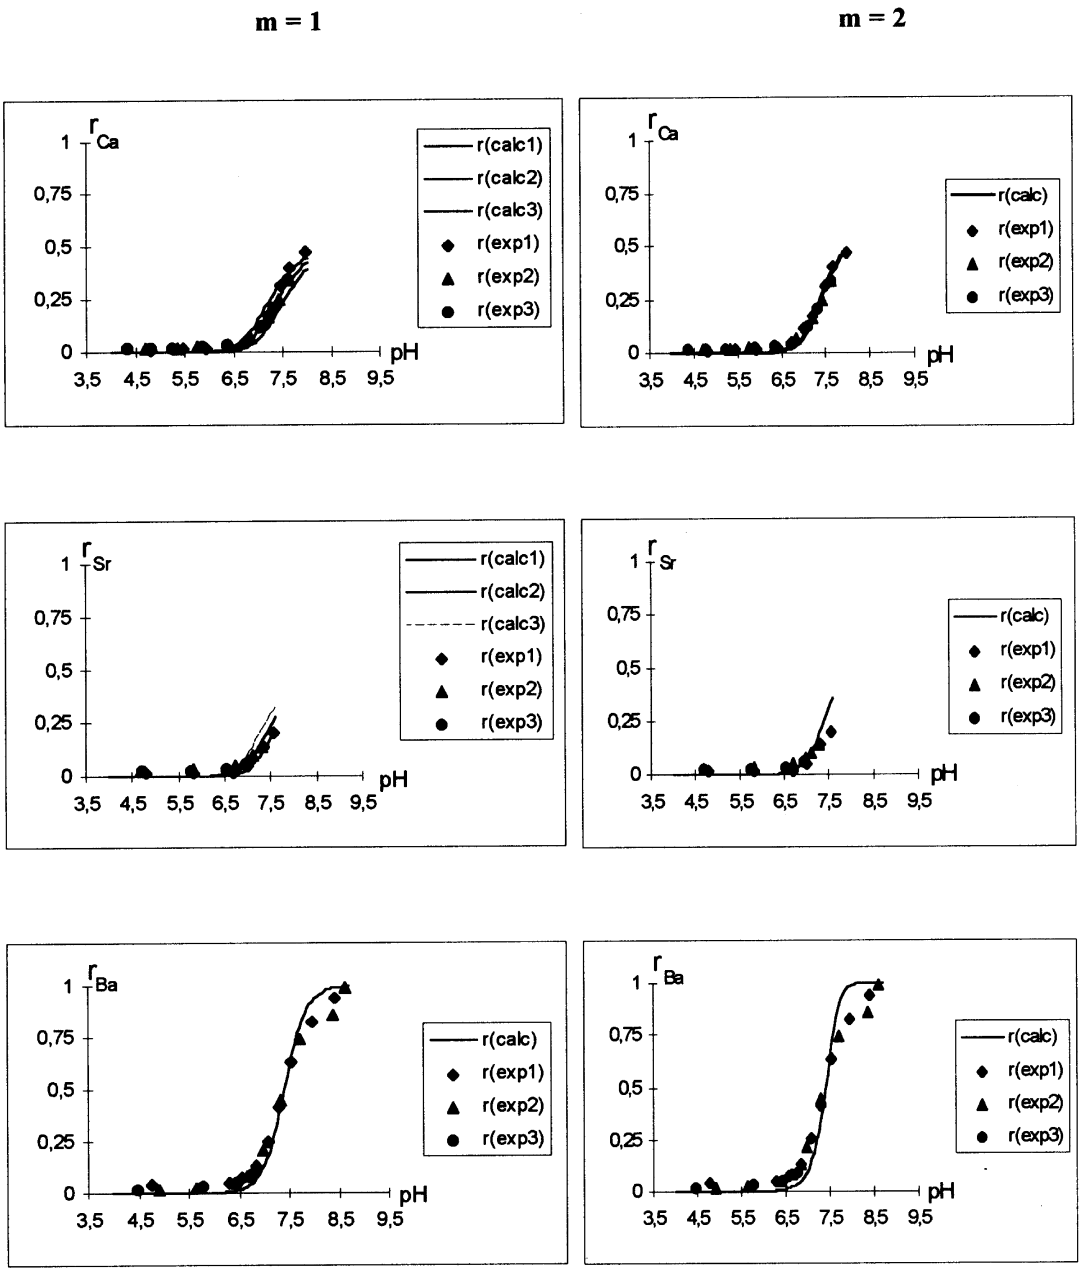

Fig. 4(b): $L^{II}H_2$. $m = 1$, $K_{12}(Ca) = (1.00 \pm 0.03) \times 10^{-11}$, $K_{12}(Sr) = (5.45 \pm 0.30) \times 10^{-12}$ and $K_{11}(Ba) = (2.20 \pm 0.07) \times 10^{-14}$ mol l^{-1}. $m = 2$, $K_{12}(Ca) = (1.05 \pm 0.02) \times 10^{-14}$, $K_{12}(Sr) = (1.00 \pm 0.08) \times 10^{-14}$ and $K_{11}(Ba) = (1.50 \pm 0.20) \times 10^{-16}$ mol l^{-1}.

also valid for the $ML_2{}^{II}H_2$ species which exist in the single metal systems.

CONCLUSION

The liquid–liquid extraction of calcium, strontium and barium by dicarboxylic calix[4]arene derivatives takes place via a proton–cation exchange process and is accompanied by the formation of metallic complexes having the 1:2 ion–ligand stoichiometry in most cases.

It was shown by ^{1}H-NMR that these complexes have an "*exo*" structure. It was also shown that the competitive extraction of calcium, strontium and barium cannot be considered as the superimposition of individual extractions. The experimental feature is

Abstract—Reaction of the intermediate $[Pd_2(\mu\text{-dppm})_2]^{2+}$ which was prepared from $[Pd_2(\mu\text{-dppm})_2X_2]$ (X = Cl, Br and I) and $AgClO_4$ in ethanol with 2-vinylpyridine (vpy) afforded dinuclear Pd(I) dppm complex $[Pd_2(\mu\text{-dppm})_2(vpy)Cl]$ (**1**). When the intermediate $[Pd_2(\mu\text{-dppm})_2]^{2+}$ was allowed to stand for a few days, tetranuclear Pd dppm complex $[Pd_4(\mu\text{-dppm})_4(\mu\text{-X})_2](ClO_4)_2$ (X = Cl (**2**), Br (**3**) and I (**4**)) was systematically formed. The structure for **1** and **2** were crystallographically determined. On complex **1** two Pd atoms are doubly bridged by two dppm ligands to form an eight-membered $Pd_2P_4C_2$ framework in a twist-chair conformation. Each Pd atoms is also coordinated by the Cl atom and the N atom of vpy in unsymmetrical side-by-side mode. The Pd–Pd distance is 2.597(2) Å and the torsion angle between two Pd_2P_2 plane is 43.2°. On the other hand four Pd atoms on **2** are bridged by four dppm ligands to form a rectangular Pd_4 core, which is composed of the shorter Pd–Pd separations (2.590(1) Å) and the close Pd···Pd separations (3.818(2) Å). The later Pd···Pd separation is also bridged by the Cl atom. The Pd–P distance (2.351(1) Å) bridging the close Pd···Pd separation is rather longer than that (2.238(2) Å) bridging the shorter Pd–Pd separation. © 1998 Elsevier Science Ltd. Keywords: palladium complexes; dinuclear complexes; tetranuclear complexes; crystal structures; bidentate phosphine ligands; nitrogen donor ligands.

Bidentate phosphine ligands such as bis(diphenylphosphino)methane (dppm) and 2-(diphenylphosphino)pyridine (Ph_2Ppy) are useful bridging ligands to form homo- and heteronuclear Pd(I) complexes with a close metal-metal distance. There has been considerable interests in synthesis, structure and reaction of dinuclear Pt(I) and Pd(I) complexes [1–3], since these dinuclear complexes can provide unique properties for an unusual coordination mode of small molecules, their activation and catalytic transformation. Three typical coordination modes of (a) $[Pd_2(\mu\text{-dppm})_2L_2]$ (side-by-side) [4–9], (b) $[Pd_2(\mu\text{-X})(\mu\text{-dppm})_2L_2]$ (A-frame) [10–18] and (c) $[Pd_2(\mu\text{-dppm})_2L_4]$ (face-to-face) [19, 20] have been known in dinuclear Pd(I) complexes. It has been reported that dinuclear Pd(I) dppm complexes in a side-by-side mode react with small molecules such as CO, SO_2, RCN, $CR{=}{=}CR_2$ to afford those in A-frame mode via a insertion reaction into a Pd–Pd bond [14, 17, 21, 22]. Although crystal structures of several trinuclear [23–26] and tetranuclear Pd complexes [27–30] bridged by dppm ligands has been investigated, investigations to polynuclear Pd dppm complexes are relatively few and their structure, property and reactivity are not fully researched [2].

We have so far interested in the reactivity of the intermediate $[Pd_2(\mu\text{-dppm})_2]^{2+}$ which was prepared from $[Pd_2(\mu\text{-dppm})_2X_2]$ and $AgClO_4$ in alcohol (Scheme) [31, 32]. It has been reported that reaction of

the intermediate $[Pd_2(\mu\text{-dppm})_2]^{2+}$ with 4-mercaptopyridine (pySH) as a S-donor ligand afforded the dinuclear Pd(I) complex $[Pd_2(\mu\text{-dppm})_2(HpyS)_2](ClO_4)_2$ [31]. In this study, the reaction of the intermediate $[Pd_2(\mu\text{-dppm})_2]^{2+}$ with 2-vinylpyridine (vpy) as a N donor ligand was furthermore attempted and dinuclear Pd(I) complex $[Pd_2(\mu\text{-dppm})_2(vpy)Cl]$ (1) was obtained. It was found that tetranuclear Pd complex $[Pd_4(\mu\text{-dppm})_4(\mu\text{-X})_2](ClO_4)_2$ (X = Cl(**2**), Br(**3**) and I(**4**)) were systematically constructed by the standing of the intermediate $[Pd_2(\mu\text{-dppm})_2]^{2+}$ in ethanol. The structure for **1** and **2** were determined by a single crystal X-ray structure analysis.

EXPERIMENTAL

General

Dinuclear Pd(I) dppm complex $[Pd_2(\mu\text{-dppm})_2X_2]$ (X = Cl, Br and I) were prepared according to the literature [22]. Bis(diphenylphosphino)methane (dppm), 2-vinyl-pyridine (vpy) and $AgClO_4$ were purchased from Aldrich and used without further purification. All organic solvents were dried by general procedures and distilled before use. All operations were carried out using standard Schlenk techniques under Ar. IR spectra were measured with a JASCO 8000 FT IR spectrometer, using a CsI pellet. ^{1}H NMR and ^{31}P NMR spectra were obtained with a JEOL GSX 270 FT NMR spectrometer at 23°C. Deuterium solvents were available from Merck and were dried by molecular sieves before use. Tetramethylsilane and 85% H_3PO_4 in D_2O were used as a reference, respectively.

Synthesis of $[Pd_2(\mu\text{-dppm})_2(vpy)Cl]ClO_4$ (**1**)

$[Pd_2(\mu\text{-dppm})_2Cl_2]$ (21.0 mg, 0.02 mmol) and $AgClO_4$ (9.0 mg, 0.04 mmol) were mixed in ethanol (10 ml) for 3 hours. The reddish brown suspension was filtered. The vpy ligand (1.0 ml) was then added to the filtrate. After stirring for 2 hours, the orange suspension was filtered and the filtrate was sealed in a 5 mm diameter glass tube. The orange solution was allowed to stand for 1 week at an ambient temperature and the yellow crystals were collected. Yield. 17 mg (32%). Found: C, 55.83; H, 3.99; N, 1.09. Calc. for $Pd_2P_4C_{57}NCl_2O_4H_{51}$: C, 56.04 H, 4.21; N, 1.15. IR (CsI, cm^{-1}): 1435(ν_{P-C}). ^{1}H NMR ($CDCl_3$): δ {7.92 and 7.40} (40 H, *br m*, Ph) and 4.39 (4 H, *br s*, CH_2) for dppm, 8.69 (1 H, *br s*, 2-H), 7.71 (1 H, *br s*, 4-H), 7.10 (1 H, *br s*, 5-H), 6.87 (1 H, *br s*, 3-H), 6.73 (1 H, *br s*, CH=), 6.40 (1 H, *br d*, $=CH_2$) and 5.80 (1 H, *br d*, $-CH_2$) for vpy. ^{31}P NMR (ethanol): −1.28. UV-VIS (nm ($\epsilon(M^{-1}cm^{-1})$), ethanol): 332 (1.7×10^4), 395 (7×10^3).

Synthesis of $[Pd_4(\mu\text{-dppm})_4(\mu\text{-Cl})_2](ClO_4)_2$ (**2**)

$[Pd_2(\mu-dppm)_2Cl_2]$ (21.0 mg, 0.02 mmol) and $AgClO_4$ (9.0 mg, 0.04 mmol) were mixed in ethanol

(10 ml) for 3 hours. The reddish brown suspension was filtered and the filtrate was sealed in a 5 mm diameter glass tube. The reddish brown solution was allowed to stand at an ambient temperature for 3 days and the red prism crystals were collected. Yields. 15 mg (69%). Found: C, 53.21; H, 3.65. Calc. for $Pd_4Cl_4P_8O_8C_{100}H_{88}$: C, 53.79; H, 3.97. IR (CsI, cm^{-1}): 1437 (ν_{P-C}), 1098 (ν_{ClO4}). ^1H NMR ($CDCl_3$): δ {7.98, 7.51 and 7.45} (80 H, m, Ph), 4.41 (8 H, tt, CH_2). ^{31}P NMR (ethanol): -4.91. UV-VIS (nm ($\epsilon(M^{-1}cm^{-1})$), THF): 358 (1.0×10^4), 431 (8.7×10^3), 512 (8.7×10^3). XPS (eV): 342.9 ($3d_{3/2}$), 337.5 ($3d_{5/2}$).

Synthesis of $[Pd_4(\mu\text{-dppm})_4(\mu\text{-X})_2](ClO_4)_2$ (X = Br(**3**) *and* I(**4**))

In a similar manner as **2**, red brick crystals of **3** or red needle crystals of **4** were obtained using $[Pd_2(\mu\text{-dppm})_2Br_2]$ (45.6 mg, 4.0×10^{-5} mol) or $[Pd_2(\mu\text{-dppm})_2I_2]$ (49.5 mg, 0.04 mmol) and $AgClO_4$ (18.0 mg, 0.08 mmol) in ethanol (10 ml). **3**: Yields. 17 mg (40%). Found: C, 51.25; H, 3.58. Calc. for $Pd_4Br_2P_8C_{100}H_{88}Cl_2O_8$: C, 51.73; H, 3.82. IR (CsI, cm^{-1}): 1437 (ν_{P-C}), 1096 (ν_{ClO4}). ^1H NMR ($CDCl_3$): δ {7.97, 7.52 and 7.46} (80 H, *m*, Ph), 4.28 (8 H, *t*, CH_2). ^{31}P NMR (ethanol): -4.96. UV-VIS (nm ($\epsilon(M^{-1}cm^{-1})$), THF): 356 (8.3×10^3), 435 (7.8×10^3), 515(7.5×10^3). **4**: Yields. 11 mg (37%). Found: C, 49.37; H, 3.49. Calc. for $Pd_4I_2P_8C_{100}H_{88}Cl_2O_8$: C, 49.71; H, 3.67. IR (CsI, cm^{-1}): 1435 (ν_{P-C}), 1096 (ν_{ClO4}). ^1H NMR ($CDCl_3$): δ {7.97, 7.48 and 7.46} (80 H, *m*, Ph), 4.39 (8 H, *br s*, CH_2). ^{31}P NMR (ethanol, 23°C): -4.91. UV-VIS (nm ($\epsilon(M^{-1}cm^{-1})$), THF): 342 (1.3×10^4), 444 (9.9×10^3), 512 (7.6×10^3).

Data collection, structure solution and refinements for **1** and **2**

A suitable crystal for **1** or **2** was attached to the end of a glass fiber and were mounted on a Rigaku AFC-5R diffractometer with a graphite mono-chromated Mo Kα radiation ($\lambda = 0.71069$ Å). The detailed measurement conditions and crystal data are summarized in Table 1. The intensity data were collected at 23°C using the ω scan technique for **1** and ω-2θ scan technique for **2**. The reflection data of 5721 and 11222 reflections were collected. On **1** the intensities of three representative reflections which were measured after every 150 reflections remained constant through data collection, indicative of crystal and electronic stability. No decay correction was applied. On the other hand the intensities of three representative reflections on **2** which were measured after every 150 reflections declined by 8.1%. A linear correction factor was applied to the data to account for this phenomena. The linear absorption coefficient for Mo

[a] $R = \|\|F_0|-F_c\|/|F_0|$.
[b] $R_w = [(w(|F_0|-|F_c|)^2/w|F_0|^2)]^{1/2}$, $w = 4F_0^2/\sigma^2(F_0)^2$.

Kα is 9.1 and 10.5 cm^{-1} for **1** and **2**, respectively. Azimuthal scans of several reflections indicated no need for an absorption correction. The data were corrected for Lorentz and polarization effects.

The structures were solved by a direct method (MITHRIL) [33]. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included but not refined. The final cycle of the full-matrix least squares refinement was based on 2579 and 7704 observed reflections ($I > 3\sigma(I)$), and 618 and 559 variable parameters for **1** and **2**, respectively. Reliability factors are defined as $R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o|$ and $R_w = [\Sigma w \ (|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$, where $w = 4F_o^2/\sigma(F_o^2)$. The final R and R_w values were 0.048 and 0.046 for **1**, and 0.035 and 0.041 for **2**, respectively. The maximum and minimum peaks on the final difference Fourier map corresponded to 0.50 and $-0.50\,e\text{Å}^{-3}$ for **1**, and 1.01 and $-0.45\,e\text{Å}^{-3}$ for **2**, respectively. Atomic scattering factors and anomalous dispersion terms were taken from the International Tables for X-ray Crystallography, Vol. IV [34]. All calculations were performed using the program TEXSAN crystallographic software package [35].

RESULTS AND DISCUSSION

Crystal structure of $[Pd_2(\mu\text{-dppm})_2(vpy)Cl]ClO_4$ (**1**)

According to the Scheme, reaction of the intermediate $[Pd_2(\mu\text{-dppm})_2]^{2+}$ with 2-vinylpyridine (vpy) gave the dinuclear Pd(I) complex $[Pd_2(\mu\text{-dppm})_2(vpy)Cl](ClO_4)$ (**1**). Crystal structure of **1** is shown in Fig. 1, together with the atomic labeling scheme. Selected bond distances and bond angles are listed in Table 2. The two Pd atoms are doubly bridged by two dppm ligands to form an eight-membered $Pd_2P_4C_2$ ring framework in a twist-chair conformation: The P(1)–Pd(1)–P(4) and P(2)–Pd(2)–P(3) angles are 176.2(2) and 171.6(2)°, respectively. Each Pd atoms is furthermore coordinated by the Cl atom and the N atom of the vpy ligand, providing an unsymmetrical side-by-side mode. The Cl(1)–Pd(1)–Pd(2)–N(1) axis is almost linear. The Pd(2)–Pd(1)–Cl(1) and Pd(1)–Pd(2)–N(1) angle are 176.9(1) and 179.4(4)°, respectively, which are slightly larger than those (169.1(3), 173(1)°) of other dinuclear Pd(I) dppm complexes [4, 8].

The average Pd–P distance of 2.291(3) Å is within those (2.274(2)–2.302(2) Å) of other dinuclear Pd(I) dppm complexes in a side-by-side mode [4–9, 36], whereas the distance is rather shorter than those (2.307(2)–2.358(4) Å) in a A-frame mode [10–18]. The Pd(1)–Cl(1) distance of 2.381(5) Å is similar to those in other dinuclear Pd(I) dppm complexes [7, 8].

The Pd(1)–Pd(2) distance of 2.597(2) Å is rather shorter than that (2.75Å) in Pd metal and those (2.594(2)–2.699(5) Å) of other dinuclear Pd(I) dppm complexes with Pd–Pd bond [4–9], indicative of a direct Pd–Pd bond. It has been theoretically reported on dinuclear Pd(I) dppm complexes that the twist

Table 2. Selected bond distance (Å) and bond angles (°) of **1**

Pd(1)–Pd(2)	2.597(2)	Pd(1)–Cl(1)	2.381(5)
Pd(1)–P(1)	2.309(5)	Pd(1)–P(3)	2.308(5)
Pd(2)–P(2)	2.312(5)	Pd(2)–P(4)	2.285(5)
Pd(2)–N(1)	2.16(1)		
Pd(2)–Pd(1)–Cl(1)	176.9(1)	Pd(2)–Pd(1)–P(1)	88.8(1)
Pd(2)–Pd(1)–P(3)	87.7(1)	P(1)–Pd(1)–Cl(1)	93.2(2)
P(3)–Pd(1)–Cl(1)	90.2(2)	P(1)–Pd(1)–P(3)	176.2(2)
Pd(1)–Pd(2)–P(2)	87.5(1)	Pd(1)–Pd(2)–P(4)	85.1(1)
Pd(1)–Pd(2)–N(1)	179.4(4)	P(2)–Pd(2)–P(4)	171.6(2)
P(2)–Pd(2)–N(1)	91.9(4)	P(4)–Pd(2)–N(1)	95.5(4)
P(1)–C(1)–P(2)	107(1)	P(3)–C(2)–P(4)	104.8(8)

along the Pd–Pd axis is due to anti-bonding interactions of filled metal *d* orbitals which are minimized when the torsion angle equals 45° [4, 5]. The twisted conformation allows the ligands to span a shorter metal-metal bond. The crystallographic data for **1** reveal that the torsion angle between the plane defined by {P(1), Pd(1), P(3) and Pd(2)} and {P(2), Pd(2), P(4) and Pd(2)} is 43.2° and the Pd–Pd distance is 2.597(2) Å. The torsion angle is more close to 45° and the Pd–Pd distance is correspondingly more short, compared with other dinuclear Pd(I) dppm complexes {[Pd_2(μ-dppm)$_2$$Br_2$] (39°, 2.699(5) Å) [9], [Pd_2(μ-dppm)$_2$($SnCl_3$)Cl] (41.3°, 2.644(2) Å) [6], [Pd_2(μ-dppm)$_2$($OCOF_3$)$_2$] (44.5°, 2.594(2) Å) [4], [Pd_2(μ-dppm)$_2$(C_6Cl_5)$_2$] (44.98°, 2.6704(21) Å) [8], [Pd_2(μ-dmpm)$_2$$Br_2$] (50.5°, 2.603(1) Å)[5]}. This facts illustrate that the smaller deviation from 45° leads to the shortening of Pd–Pd distance.

Crystal structure of [Pd_4(μ-dppm)$_4$(μ-Cl)$_2$](ClO_4)$_2$

When the intermediate [Pd_2(μ-dppm)$_2$]$^{2+}$ was allowed to stand in ethanol according to the Scheme, tetranuclear Pd complex [Pd_4(μ-dppm)$_4$(μ-X)$_2$](ClO_4)$_2$ (X = Cl(**2**), Br(**3**) and I(**4**)) was systematically formed. This facts indicate that if no other suitable ligands (or higher affinity solvents and counter anion) were present in solution, tetranuclear Pd complex [Pd_4(μ-dppm)$_4$(μ-X)$_2$](ClO_4)$_2$ was constructed from [Pd_2(μ-dppm)$_2$]$^{2+}$ and dissolving halogen anions. It has been reported that the similar complex [Pd_4(μ-dppm)$_4$(μ-Cl)$_2$]Y_2 (Y = BF_4 and PF_6) was obtained from reaction of [Pd_2(μ-dppm)$_2$$Cl_2$] with copper or gold complexes [27]. Crystal structure of **2** was shown in Fig. 2, together with the atomic labeling scheme. Selected bond distances and bond angles are listed in Table 3. Complex **2** has the center of inversion at the midpoint of Pd(1)···P(1′). Four Pd atoms are bridged by four dppm ligands to form the rectangular Pd_4 core, which consists of the shorter Pd–Pd separations and the close Pd···Pd separations. The close Pd···Pd separations are moreover bridged by the Cl atom, which is situated 1.45 Å from the mean Pd_4 plane. All the Pd atoms are coplanar. The similar Pd_4 core has been known in [Pd_4(μ-dppm)$_4$(μ-Cl)$_2$](BF_4)$_2$• (CH_3)$_2$CO [27, 28] and [Pd_4(μ-dppm)$_4$(μ-Cl)$_2$](ClO_4)$_2$•bpe [29].

The shorter Pd(1)–Pd(2) distance of 2.590(1) Å is rather shorter than that (2.75 Å) in Pd metal and those (2.53–2.77 Å) of other dinuclear Pd(I) complexes [2,

Table 3. Selected bond distances and bond angles for **2**

Pd(1)–Pd(2)	2.590(1)	Pd(1)···Pd(2′)	3.818(2)
Pd(1)–Cl(1)	2.427(2)	Pd(2)–Cl(1)	2.414(2)
Pd(1)–P(1)	2.237(2)	Pd(1)–P(3)	2.331(1)
Pd(2)–P(2)	2.240(2)	Pd(2)–P(4)	2.372(2)
P(1)–C(49)	1.814(4)	P(2)–C(49)	1.848(4)
P(3)–C(50)	1.828(4)	P(4)–C(50)	1.833(4)
P(1)–Pd(1)–P(3)	100.14(6)	P(3)–Pd(1)–Cl(1)	91.33(5)
Pd(2)–Pd(1)–Cl(1)	88.70(5)	Pd(2)–Pd(1)–P(1)	82.23(5)
P(2)–Pd(2)–P(4)	110.64(6)	P(4)–Pd(2)–Cl(1′)	90.77(6)
Pd(1)–Pd(2)–Cl(1′)	76.16(5)	Pd(1)–Pd(2)–P(2)	82.44(5)
Pd(1)–Cl(1)–Pd(2′)	104.14(6)	P(1)–C(49)–P(2)	105.2(2)
P(3)–C(50)–P(4′)	121.6(2)		

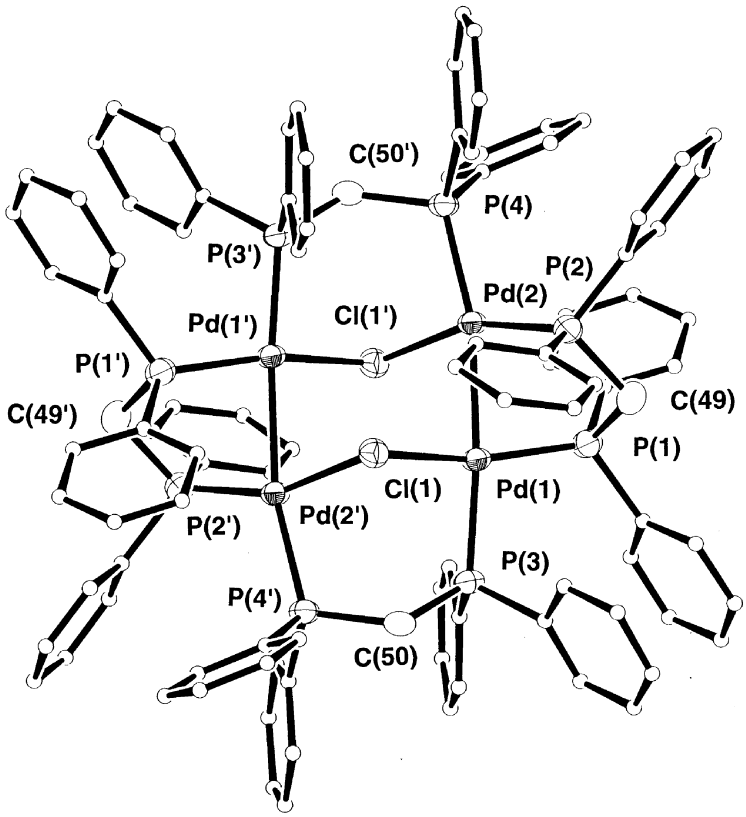

Fig. 2. Molecular structure of $[Pd_4(\mu\text{-dppm})_4(\mu\text{-Cl})_2]^{2+}$ (**2**) and the atomic labeling scheme. Only Pd(1), Pd(2), P(1), P(2), P(3), Pd(4), Cl(1), C(49), C(50), Pd(1′), Pd(2′), P(1′), P(2′), P(3′), P(4′), Cl(1′), C(49′) and C(50′) in the coordination sphere are labeled.

4, 5, 37], indicative of a direct Pd–Pd bond. On the other hand the close Pd(1)···Pd(2′) separation of 3.818(2) Å are longer than that in Pd metal, no indicative of a direct Pd–Pd bond. The shorter Pd–Pd distance is shorter than those (2.594(2)–3.332(1) Å) of other tetranuclear Pd complexes with the rectangular Pd_4 core [27–43]. The close Pd···Pd separation is longer than those (2.831(1)–3.742(2) Å) [27–43]. Consequently the Pd_4 core is rather rectangular.

The average Pd–P distance of 2.295(2) Å is within those (2.220(5)–2.353(7) Å) of dinuclear [4, 5, 37], trinuclear [24–26] and tetranuclear Pd complexes [27–30] bridged by dppm ligands. It is interesting that the Pd–P distance of 2.351(1) Å bridging the close Pd···Pd separation is very longer than that (2.238(2) Å) bridging the shorter Pd–Pd bond. The difference is considered due to both steric and electronic factors arising from the *trans* influence of the Pd–Pd bond and the bulk of the phenyl substituents. The average Pd–Cl of 2.420(2) Å is close to those (2.406(5)–2.430(1) Å) in other tetranuclear Pd complexes [27, 30, 39]. The Pd(1)–Cl(1)–Pd(2′) of 104.14(6)° is rather larger than those (78.1(1)° [30] and 93.15(3)° [39]) in other tetranuclear Pd complexes.

SUPPLEMENTARY MATERIALS

Complete listings of the atomic coordinates, bond distances, bond angles, hydrogen atomic coordinates, anisotropic thermal parameters, and a listing of observed and calculated structure factors for **1** and **2** are available from the Cambridge Crystallographic Data Centre and the author.

Self-assembled one-dimensional zigzag structure of mercury(II) complex with sulphur rich ligand 4,5-ethylenedithio-1,3-dithiole-2-thione

Qing-Hua Wang, De-Liang Long and Jin-Shun Huang*

State Key Laboratory of Structural Chemistry, Fujian Institute of Research on the Structure of Matter, Chinese Academy of Sciences, Fuzhou, Fujian, 350002, P. R. China

(Received 28 January 1998; accepted 20 March 1998)

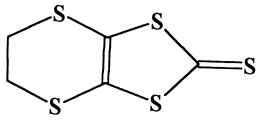
Abstract—Mercury(II) complex of 4,5-ethylenedithio-1,3-dithiole-2-thione ($C_5H_4S_5$), $[Hg_2(C_5H_4S_5)_2Cl_4]_n$, was synthesized and characterized crystallographically. It possesses the one-dimensional polymeric structure composed of centrosymmetric quasi-isolated binuclear subunits. The mercury atoms in zigzag arrangement achieve five-coordination in a distorted trigonal bipyramidal geometry by bonding to two bridging Cl, a terminal Cl, a thione S and a thioether S atom of $C_5H_4S_5$. The S ... S contacts of 3.568(3) Å between two nearby chains generate a two-dimensional network. Through S ... S interactions of 3.583(3) Å between the two-dimensional layers, a three-dimensional supramolecular network is formed. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: crystal structure; mercury; supramolecule; S ... S contact

INTRODUCTION

Supramolecular chemistry has developed rapidly in the past ten years. Intermolecular interactions such as hydrogen bonding [1], S ... S contacts [2, 3] and π-π stackings [4] are efficient organizing forces in supramolecular architecture and the design of new solid state materials for a number of applications [5]. Molecular conductors derived from organic donor molecules such as tetrathiafulvalene (TTF), bis(ethylenedithio)tetrathiafulvalene (BEDT-TTF), and 4,5-dimercapto-1,3-dithio-2-thione (dmit) are of these kinds of solid state materials. These ligands contain plentiful sulphur atoms and when they are combined with suitable metal ions to form certain structure, molecular metals and superconductors may be produced via intermolecular S ... S interaction [3, 6, 7].

The sulphur rich compound 4,5-ethylenedithio-1,3-dithiole-2-thione ($C_5H_4S_5$) is a derivative of dmit. It is well known as an electron donor and has available sites to coordinate to metal ions. The particular affinity of sulphur for mercury has been known for a long time. Recently, we used $C_5H_4S_5$ and $HgCl_2$ as starting materials and obtained a new compound, $[Hg_2(C_5H_4S_5)_2Cl_4]_n$. It has a unique polymeric chain structure and through S ... S contacts it forms a three-dimensional network.



$C_5H_4S_5$

EXPERIMENTAL

Synthesis

The reagent $C_5H_4S_5$ was prepared according to literature [8]. A solution of $C_5H_4S_5$ (0.12 g, 0.5 mmol) in 3 ml CH_2Cl_2 was added to the solution of $HgCl_2$

* Author to whom correspondence should be addressed. e-mail: hjs@ms.fjirsm.ac.cn

(0.14 g, 0.5 mmol) in 20 ml acetonitrile with stirring at room temperature. A red precipitate was formed immediately. Then the mixture was heated with stirring until the precipitate was redissolved. The solution was rapidly filtered and cooled slowly in air. After two hours, fine red plate crystals of $[Hg_2(C_5H_4S_5)_2Cl_4]_n$ **1** were formed. Yield 0.11 g. Chemical analyses are consistent with the formula. IR (KBr pellet): ν/cm^{-1} 1508m, 1443s, 1400m, 1383w, 1238w, 1011s, 968m, 918m, 878m, 814w, 733w, 696w, 459m.

X-RAY CRYSTALLOGRAPHY

Crystal data for **1**: $C_5H_4Cl_2HgS_5$, $F_w = 495.90$, triclinic, space group $P\bar{1}$, $a = 8.373(3)$, $b = 8.509(3)$, $c = 9.800(7)$ Å, $\alpha = 102.71(4)$, $\beta = 100.67(4)$, $\gamma = 118.07(3)^\circ$, $v = 566.2(6)$ Å3, $z = 2$, μ(Mo-$K\alpha$) = 14.91 cm^{-1}. A single crystal with approximate dimensions $0.25 \times 0.12 \times 0.12$ mm^3 was mounted on a glass fibber in a random orientation. The determination of unit cell and the data collection were performed with Mo-$K\alpha$ radiation ($\lambda = 0.71073$ Å) on an Enraf-Nonius CAD4 diffractometer equipped with a graphite monochromator. A total of 2470 independent reflections were collected in the range of $2 < 2\theta < 54.0$ ($0 < h < 10$, $-10 < k < 10$, $-12 < l < 12$) by using an ω-2θ scan mode at room temperature, of which 1918 reflections with $I > 3.0\sigma(I)$ were used in the succeeding structure solution and refinement. Intensities were corrected for *L*p factors and empirical absorption based on Ψ scan technique with transmittance in the range from 0.440 to 0.999. The structure was solved using direct method. Hg, two Cl and a S atoms were located from the *E*-map. Other non-hydrogen atoms were derived from the successive difference Fourier syntheses. The hydrogen atoms were located theoretically and refined on riding mode ($d_{C\text{-}H} = 0.95$ Å). The final full-matrix least-squares refinement converged with unweighted and weighted agreement factors $R = \Sigma(|F_o| - |F_c|)/\Sigma|F_o| = 0.030$ and $Rw = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2} = 0.036$, $w = 1/[\sigma^2(F_o) + (0.020\,F_o)^2 + 1.0]$. $S = 1.19$, $(\Delta/\sigma)_{max} = 0.000$. The highest peak on the final difference Fourier map has a height of 1.33 $e \cdot Å^{-3}$, which is located at a position 1.0 Å away from Hg atom. All calculations were performed on a COMPAQ PC 486 computer using MOLEN program package [9].

RESULTS AND DISCUSSION

The selected bond distances and bond angles are shown in Table 1. The ORTEP drawing and labelling scheme of the complex are shown in Fig. 1. The mercury achieves effective five-coordination in a trigonal bipyramidal geometry which is composed of Cl(1), Cl(2) and S(1) on the equatorial plane and Cl(1^i), S(4^{ii}) on axis (symmetry code i: $-x, -y, -z$; ii: $-x, -y, 1-z$). The bond angles around Hg atoms, S(1)–Hg–Cl(2), S(1)–Hg–Cl(1) and Cl(1)–Hg–Cl(2) sum to 355.13° indicating that the mercury atom is quasi coplanar with the equatorial plane. In fact the mercury atom is displaced by 0.3 Å from the equatorial plane toward Cl(1^i). The bond angle S(4^{ii})–Hg–Cl(1^i) is 169.80(7)° showing some distortion from ideal trigonal bipyramidal geometry. Similar five-coordination geometry of mercury is also found in the structure of $Hg(L)Cl_2$ (L = Tetrahydrothiophen [10], Dehydrodithizone [11] and Etheyl N,N-dimethylthiocarbamate [12]). Each mercury is bonded to two types of sulphur atoms: one is the thiocarbonyl sulphur S(1), the other is the thioether sulphur S(4^{ii}). The Hg–S(1) bond distance of 2.454(2) Å is within the expected Hg–S bond distances, whereas the Hg–S(4^{ii}) separation of 3.271(2) Å can be taken as a weak coordination. These data demonstrate that the thiocarbonyl sulphur atom (C=S) more strongly coordinates to the metal ion than the ether type sulphur atom (–S–) [13]. All of the atoms of $C_5H_4S_5$ in the complex except for C(4) are in a conjugated plane with a deviation less than 0.04 Å. The C(4) is deviated from the conjugated plane by 0.75 Å.

Two $HgCl_2$ units are bounded together through two chlorine bridges and form a centrosymmetric Hg(μ–Cl)$_2$Hg ring. The Hg–Hg^i distance of 3.936(1) Å is much longer than the sum of 2.94 Å of the covalent radii of the two Hg atoms indicating that there exists no Hg–Hg bond. The distance between Hg and the two bridge chlorine atom is not equal. The bond lengths Hg–Cl(1), Hg–Cl(1^i) are 2.564(2) and 2.791(2) Å, respectively. The distance between Hg and the terminal chlorine Cl(2) is 2.381(1) Å and it is much shorter than Hg–Cl(1). This proves that the connection of bridging chlorine Cl(1) to Hg is weaker than terminal chlorine Cl(2) to Hg. A survey of the literature indicate that most Hg–Cl bond distances are in the range 2.28–2.33 Å, irrespective of the coordination number at mercury, and that larger Hg–Cl bond distance are always found in compounds where the chlorine atoms are bridging, or hydrogen bonded, or weakly bonded in polymeric structures [12].

As shown in Fig. 1, the subunits $Hg_2(C_5H_4S_5)_2Cl_4$ through weak coordination of Hg–S(4) form a one-dimensional infinite chain, $[Hg_2(C_5H_4S_5)_2Cl_4]_n$. A zigzag arrangement of metal atoms could be considered if the whole polymer is viewed. The molecular packing diagram viewed down the *c* axis is shown in Fig. 2. The S ... S contacts of 3.568(3) Å between two nearby chains along *c* axis is shorter than the sum of 3.70 Å of the van der Waals radii of the two S atoms and result in the formation of two-dimensional layers. The shortest S ... S distance between two nearby two-dimensional layers is 3.583(3) Å and also fall in the range of van der Waals interaction. Thus, this complex come forth a supramolecule with a three-dimensional structure assembled by S ... S contacts. Since the average S ... S contact distance of highly conductive compound of TTF, BEDT-TTF and their derivatives are

about 3.50 Å, [3, 13] the distance of 3.568(3) Å and 3.583(3) Å here is an example of strong S ... S contact. In $Hg(SC_6H_{11})_2$ [14], which also has a polymeric chain structure, the inter-chain S ... S distances are all larger than 8 Å, so it is a pure one-dimensional chain structure. $[Ag(C_5H_4S_5)NO_3]_\infty$ [13] with the inter-chain S ... S distance of 3.41 Å is a supramolecule of two-dimensional structure. However, the shortest S ... S distance of 3.84 Å between the two-dimensional layers of this complex shows no inter-layer S ... S contacts.

The 'side-by-side' or 'up-down' arrangement of $C_5H_4S_5$ with short S ... S distances indicates an efficient intermolecular π-π orbital interaction, which forms a broadened energy band over the whole lattice [3]. The S ... S contact is one of the most important factors by which the sulphur-rich compound exhibit high con-

ductivity. It is known that the stronger the S ... S contact, the more effective the increase in the conductivity. When the temperature is decreased or the pressure increased, the S ... S distance is shorter than in ambient conditions and accordingly the conductivity is increased [15]. A conductivity measurement is still undertaken with the title compound.

(Received 9 January 1998; accepted 27 March 1998)

Abstract—The thermal analysis of the complexes $[Ni(phen)_3][PdCl_4]\cdot 3H_2O$ and $[Ni(bipy)_3][PdCl_4]\cdot 2\frac{1}{2}H_2O$ revealed, after the elimination of the molecules of water, the reciprocal migration of the ligands between the coordination spheres of the two metal ions. This solid-state reaction leads to mixtures of two neutral complexes: $Ni(AA)_2Cl_2$ and $Pd(AA)Cl_2$ (AA = phenanthroline or bipyridine). In both cases, the migration was found to be exothermic. The bis-chelated nickel complexes, $Ni(AA)_2Cl_2$, were extracted in ethanol and separated from $Pd(AA)Cl_2$. Subsequent addition of an hydrochloric acid solution of $ZnCl_2$ to the ethanol solution containing $Ni(phen)_2Cl_2$ led to the formation of $[Ni(phen)_2(H_2O)_2][ZnCl_4]\cdot H_2O$ which was studied by X-ray diffraction methods. The Ni–N bond distances vary from 2.078(3) to 2.089(4) Å, while the *cis* Ni–O distances are 2.057(3) and 2.073(3) Å. The crystal structure of $Ni(bipy)_2Cl_2\cdot 2H_2O\cdot\frac{1}{2}CH_3CN$ was also determined. The compound is the *cis* isomer, with the Ni atom located on a 2-fold axis. The Ni–N bonds distances are 2.084(3) and 2.094(2) Å, while the Ni–Cl bonds distances are 2.428(1) Å. The compound crystallizes with two water molecules situated in the lattice and $\frac{1}{2}$ molecule of acetonitrile located on a 2-fold axis. The two crystals are stabilized by hydrogen bonds involving the water molecules. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: nickel complexes; palladium complexes; 2,2′-bipyridine; 1,10-phenanthroline; irreversible thermochromism

INTRODUCTION

In a series of papers we have reported on the thermochromic behavior of some ionic coordination compounds, where the cation is a tris-chelate complex with aromatic diamine ligands, while the anion is a tetrahalocomplex [1–4]. The general formula is $[M(AA)_3][M'X_4]$, with M(II) = Co(II), Ni(II), M′ = Cu(II), Zn(II), Pd(II), AA = 2,2′-bipyridine, 1,10-phenanthroline, 4,7-diphenyl-1,10-phenanthroline, $X^- = Cl^-$, Br^-. The irreversible thermochromism [5] in these complexes is due to the reciprocal migration, in the solid-state, of one molecule of the aromatic neutral ligand from the tris-chelated cationic sphere towards the anionic one, accompanied by a transfer of a pair of X^- ligands in the reverse direction:

$$[M(AA)_3][M'X_4](s) \rightarrow M(AA)_2X_2(s) + M'(AA)X_2(s)$$

Similar migrational processes have been studied especially when M = M′ (Pt(II), Pd(II) and Ni(II)) [6–8]. These reactions can be considered as isomerization

* Author to whom correspondence should be addressed.
[1] Alternative corresponding author.

reactions and have important preparative significance, e.g.:

$$[Pd(en)_2][PdCl_4](s) \rightarrow 2Pd(en)Cl_2(s)$$

The migration of ligands between the coordination spheres of the two metallic centers is clearly indicated by thermal effects (DTA or DSC analyses) without any mass loss, or by electronic spectroscopy, which allows the characterization of the different chromophores. The latter technique is particularly useful for complexes of Co(II or III), Ni(II) and Cu(II), since their *d–d* spectra are very sensitive towards modifications of the coordination sphere. For the complexes $[M(AA)_3][M'X_4]$ mentioned above [1–4], the transition temperatures were in the range 200–315°C. In one case, the process was found to be reversible [4]. The final products can usually be separated, because of their different solubilities in adequate solvents.

Such solid state rearrangements can be useful for the synthesis of complexes possessing interesting magnetic properties. For example, the spin-crossover complex $Fe(phen)_2(NCS)_2$ has been obtained by heating the parent compound $[Fe(phen)_3]_2[Fe(NCS)_4](NCS)_2$ [9].

New examples of solid-state reaction involving ligand migration between different coordination spheres are presented in this paper. This work is focused on the $[Ni(bipy)_3][PdCl_4]\cdot 2\frac{1}{2}H_2O$ system. The crystal structures of two complexes, $[Ni(phen)_2(H_2O)_2][ZnCl_4]\cdot H_2O$ and $[Ni(bipy)_2Cl_2]\cdot 2H_2O\cdot \frac{1}{2}CH_3CN$ were determined. These compounds were obtained through solid-state migration from the parent compounds $[Ni(phen)_3][PdCl_4]\cdot 3H_2O$ and $[Ni(bipy)_3][PdCl_4]\cdot 2\frac{1}{2}H_2O$, respectively.

EXPERIMENTAL

Synthesis

The chemicals were purchased from Aldrich and all manipulations were performed using materials as received. $[Ni(phen)_3][PdCl_4]\cdot 3H_2O$ (**1**) was synthesized as already reported [2].

$[Ni(phen)_2(H_2O)_2][ZnCl_4]\cdot H_2O$ (**2**): By heating **1** (1 mmol) at 230°C, the color changed from pink–beige to green, and a mixture containing $Ni(phen)_2Cl_2$ and $Pd(phen)Cl_2$ was obtained. The nickel compound, $Ni(phen)_2Cl_2$, was extracted from the mixture with 25 mL ethanol and filtered from the insoluble palladium complex. A 3 mL solution of concentrated hydrochloric acid (12 M) containing 1 mmol of $ZnCl_2$ was added to the green ethanolic solution of $Ni(phen)_2Cl_2$. Lilac crystals of $[Ni(phen)_2(H_2O)_2][ZnCl_4]\cdot H_2O$, adequate for crystal structure determination, appeared within a few days. Yield: 63%. IR data (KBr, cm^{-1}): 3420br, 1630m, 1590m, 1520s 1430vs, 1345w, 1230w, 1145m, 1110m, 1050w, 870m, 850s, 725vs, 645w, 600w, 500w, 430w.

$[Ni(bipy)_3][PdCl_4]\cdot 2\frac{1}{2}H_2O$ (**3**) was prepared as follows: An ethanolic solution (10 mL) containing 1 mmol of $[Ni(bipy)_3]Cl_2$ (prepared as already reported [10]) was mixed with 10 mL aqueous solution containing 1 mmol $PdCl_2$ and 4 mL HCl 12 M (HCl was added in order to achieve the formation of $[PdCl_4]^{2-}$ anions). The reaction was carried out at 0°C. The resulting precipitate was filtered off, washed with cold ethanol and dried in a desiccator. Yield: 87%. $[Ni(bipy)_3][PdCl_4]\cdot 2\frac{1}{2}H_2O$: pink–beige; IR data (KBr, cm^{-1}): 3497m, 3101m, 3055m, 1630w, 1598s, 1569w, 1491m, 1470m, 1449vs, 1312m, 1246w, 1156m, 1103w, 1061w, 1043w, 1019m, 902w, 811w, 766vs, 735m, 651w, 632w, 417w. Analysis: calc.: 43.91% C, 3.56% H, 10.24% N; found: 44.1% C, 3.3% H, 10.6% N.

Compound **3** was heated to 200°C and the resulting mixture was treated as described above. $Ni(bipy)_2Cl_2$ was obtained by separation from the palladium complex, $Pd(bipy)Cl_2$, as for the phenanthroline complex. The evaporation of the corresponding ethanolic solutions gave blue–green microcrystals. Yield: 72%. Crystals suitable for crystallographic studies were obtained by recrystallization from acetonitrile: $Ni(bipy)_2Cl_2\cdot 2H_2O\cdot \frac{1}{2}CH_3CN$ (**4**): IR data (KBr, cm^{-1}): 3160br, 2105m 1610s, 1600s, 1580m, 1570m, 1495m, 1475s, 1445vs, 1315s, 1250m, 1225w, 1170w, 1150s, 1105m, 1060w, 1040w, 1020s, 815w, 770vs, 730s, 650m, 630m, 420w.

The two palladium compounds were identified by elemental analysis, after separation from the nickel complexes as described above. Analysis: $Pd(phen)Cl_2$: calc.: 40.31% C, 2.26% H, 7.83% N; found: 40.2% C, 2.3% H, 7.2% N. $Pd(bipy)Cl_2$: calc.: 36.01% C, 2.42% H, 8.40% N; found: 35.9% C, 2.3% H, 8.6% N.

The final degradation products of compound **3** obtained at a temperature greater than 520°C was a mixture of Pd and NiO which were identified from their powder diffraction patterns [11].

Physical measurements

The IR spectra (KBr pellets) were measured on a BIO-RAD FTS 135 spectrometer. UV-VIS spectra (diffuse reflectance technique) were recorded with a VSU2 spectrophotometer. The thermal analysis (TG, DTG and DTA) were performed in air with a Q-1500D (MOM Budapest) instrument and the DSC curves were obtained on a DuPont 2000 instrument. The heating rate was 10°/min. X-Ray powder diffraction data were measured on a Philips PW 1140 diffractometer, using Ni filtered CuKα radiation.

Crystal structure determinations

The crystals were selected after examination under a polarizing microscope for homogeneity. The unit cell parameters were obtained by least-squares refinement of the angles 2θ (14–25°C), ω and χ for 26 and 44 well-centered reflections. The data collections were made at room temperature on a Siemens P4

diffractometer with graphite-monochromatized MoKα radiation using the XSCANS program. The $\omega-2\theta$ scan technique was used and three standard reflections were measured after every 97 reflections. The coordinates of the heavy atoms were determined from direct methods and the positions of all the other non-hydrogen atoms were found by the usual Fourier methods. The refinement of the structures was done by full-matrix least-squares analysis. The H atoms of the phenanthroline and the dipyridyl ligands were fixed at their calculated positions (riding model) with $U_{iso}=0.08$ Å^2. Those of the aqua ligands and of the lattice molecules of water were located on the Fourier difference map and were refined isotropically. Crystal **4** was found to contain molecules of CH_3CN located on the two-fold axis. The N and methyl C atoms were found to be disordered. Therefore the C–C and C–N distances are not precise. The best results were obtained assuming a site occupancy of CH_3CN of 0.5. The TG curve confirmed this result. The H atoms of CH_3CN were neglected because of the disorder. For crystal **4**, the largest residual peaks were found around the CH_3CN molecule. The calculations were done on a SHELXTL system [12]. The crystallographic data and other pertinent information are summarized in Table 1.

RESULTS AND DISCUSSION

The solid-state migration of the ligands between the coordination spheres of two different metal ions, $[M(AA)_3]^{2+}$ and $[M'X_4]^{2-}$, seems to be general, at least for systems where the anion is a tetrahalocomplex. New examples of such solid-state migrational processes are reported in this work. The molecular and crystal structures of the two compounds, $[Ni(phen)_2(H_2O)_2][ZnCl_4]\cdot H_2O$ and $Ni(bipy)_2Cl_2\cdot 2H_2O\cdot \frac{1}{2}CH_3CN$, obtained through the interchange of the ligands between the coordination spheres of the two different metallic centers, were determined. This solid-state reaction could be an alternative method for the synthesis of some bis-chelated complexes. This rearrangement is particularly important, since such complexes are relatively unstable in aqueous solutions, where they usually disproportionate to the more stable tris-chelated species and, probably, the hexaaqua metal(II) complexes [13].

The solid-state reaction of the complex $[Ni(phen)_3][PdCl_4]\cdot 3H_2O$ (**1**) will first be discussed. When the pink–beige compound **1** was heated to about 230°C, a green mixture of $Ni(phen)_2Cl_2$ and $Pd(phen)Cl_2$ was formed. One phenanthroline molecule from the cation $[Ni(phen)_3]^{2+}$ was caught in the solid state by the palladium complexed ion. The greater stability of the Pd(II) chelate is probably an important factor in this reaction. The two compounds $Ni(phen)_2Cl_2$ and $Pd(phen)Cl_2$ were separated by dissolving the mixture in ethanol.

The insoluble complex $Pd(phen)Cl_2$ was filtered out and identified by elemental analysis. An aqueous solution of $[ZnCl_4]^{2-}$ was added to the $Ni(phen)_2Cl_2$ ethanol solution. The resulting product $[Ni(phen)_2(H_2O)_2][ZnCl_4]\cdot H_2O$ (**2**) was characterized by crystallographic methods.

The thermal analysis of the pink–beige compound (**1**) has shown that the endothermic elimination of the three lattice molecules of water takes place in the region 70–106°C. No other mass change is observed on the TG curve up to 357°C, where the loss of the phenanthroline molecules starts. The migration of the phenanthroline molecule and of the two chloride ions takes place in the range 195–230°C, during an exothermic process. The heat of the transformation ΔH is -67 kJ/mol. The green color of the resulting mixture is due to the superposition of the spectra of two chromophores, $Ni(phen)_2Cl_2$ (blue–green) and $Pd(phen)Cl_2$ (yellow) [2].

The crystal structure of $[Ni(phen)_2(H_2O)_2][ZnCl_4]\cdot H_2O$ (**2**) consists of discrete *cis*-$[Ni(phen)_2(H_2O)_2]^{2+}$ cations, tetrahedral $[ZnCl_4]^{2-}$ anions and lattice molecules of water. A labeled diagram is shown in Fig. 1. The selected bond distances and angles are listed in Table 2. The coordination sphere of the nickel atom is a distorted octahedron, the aqua ligands being disposed in *cis* positions to each other. The Ni–N distances [ave. 2.083(4) Å] are identical to the average value found in the tris-chelated cation, $[Ni(phen)_3]^{2+}$ [2.090(5) Å [14] and 2.091(8) Å [15]]. As expected, the N–Ni–N chelate angles [80.2(1) and 80.6(1)°] are significantly smaller than the other *cis* angles which vary between 88.1(1) and 96.3(1)°. The *trans* angles are in the range 171.5(1)–174.1(1)°. The Ni–O (H_2O) bonds are 2.057(3) and 2.073(3) Å. The external angles with the phenanthroline ligands, Ni–N–C [ave. 129.5(3)°] are much larger than the Ni–N–C chelate angles [ave. 112.3(3)°].

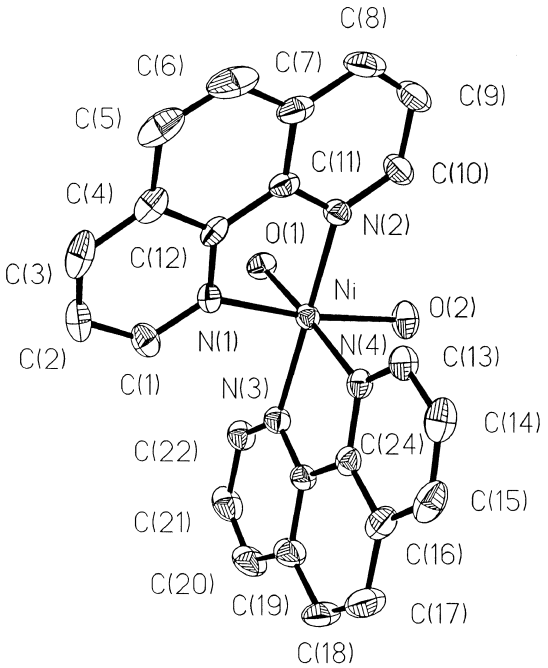

Fig. 1. Labeled diagram of the cation $[Ni(phen)_2(H_2O)_2]^{2+}$ in **2**.

The $[ZnCl_4]^{2-}$ anions exhibit the characteristic features already reported in the literature [16]. The Zn–Cl bond distances vary between 2.242(2) and 2.293(1) Å and the angles are close to the tetrahedral value [105.1(1)–112.2(1)°].

The complex salt crystallizes with a molecule of water. The complexed ions and the lattice water molecules are held together by an extensive three-dimensional hydrogen-bond network. The aqua ligands are hydrogen-bonded to the lattice water molecules with distances of O(1)···O(3) = 2.713 Å and the angle Ni–O(1)···O(3) is 121.6°. The aqua ligands are also hydrogen-bonded to the chloride ligands with distances O(1)···Cl(1) = 3.102 Å [angle Ni–O(1)···Cl(1) = 105.7°] and O(2)···Cl(2) = 3.163 Å [angle Ni–O(2)···Cl(2) = 124.0°]. The distance O(2)···Cl(1) is also short (3.174 Å) but the angle is not favorable [Ni–O(2)···Cl(1) = 165.8°]. Furthermore, the lattice molecule of water is hydrogen-bonded to two different Cl(3) atoms with distances O(3)···Cl(3) = 3.178 and 3.192 Å, and angle Cl(3)···O(3)···Cl(3′) = 122.3°. Face-to-face stacking interactions between the phenanthroline aromatic rings of the cationic entities (Figure 2) play also an important stabilization role in the packing energy of the crystal.

The diffuse reflectance spectrum of **2**, measured in the range 380–1100 nm, exhibits the characteristic features of a pseudo-octahedral $[Ni(II)N_4O_2]$ chromophore. Two of the three expected *d–d* bands are observed at 920 and 580 nm, and are assigned to the transitions $^3A_2 \rightarrow {}^3T_2$ and $^3A_2 \rightarrow {}^3T_1(F)$, respectively (assuming the *O* point group for the Ni(II) chromophore). The electronic spectrum of the nickel chromophore of the solid mixture obtained after the migration process is identical to the one reported for $Ni(phen)_2Cl_2$ [13].

The solid state rearrangement of the tris-bipyridine complex $[Ni(bipy)_3][PdCl_4]\cdot 2\frac{1}{2}H_2O$ (**3**) is quite similar to the phenanthroline complex. The TG, DTG and DTA curves are shown in Fig. 3. The DSC curve of the compound was also measured. A first decomposition step due to the loss of the water molecules was observed below 120°C. Between 120 and about 220°C, the TG curve showed no weight loss, while the DTA curve exhibited an exothermal peak centered around 190°C, assigned to the migration of the ligands:

$$[Ni(bipy)_3][PdCl_4](s) \xrightarrow{190^\circ C} Ni(bipy)_2Cl_2(s) + Pd(bipy)Cl_2(s)$$

The migration of the bipyridine molecule and of the two chloride ions occurred in the range 160–220°C, during an exothermic process, the total heat of the transformation being $\Delta H = -35$ kJ/mol. This value is significantly lower than the one observed for the phenanthroline compound discussed above (-67 kJ/mol). It is noteworthy to point out that in the case of the tetrachlorozincate complexes,

$[Ni(AA)_3][ZnCl_4]$, the migration of the ligands was found to be endothermic [17].

Heating $[Ni(bipy)_3][PdCl_4]\cdot 2{\cdot}5H_2O$ (**3**) close to 200°C caused an irreversible thermochromic change from the initial pink–beige to a green color. The green mixture was treated with ethanol in order to separate the two compounds. $Ni(bipy)_2Cl_2$ is soluble, while $Pd(bipy)Cl_2$ is very insoluble in this solvent, and the latter was characterized by elemental chemical analysis.

The green color is due to the superposition of the electronic spectra of two chromophores (as seen in Fig. 4): $Ni(bipy)_2Cl_2$ (blue–green) and $Pd(bipy)Cl_2$ (yellow). The color changes accompanying the ligand interchanges merely reflect the modifications of the coordination spheres of the metal ions, that is, the nature of the chromophores. The visible spectra recorded before and after the migration reflect the features of the two nickel(II) chromophores, $[NiN_6]$ and $[NiN_4Cl_2]$. The electronic spectrum of the pure nickel compound obtained after the migration process exhibits the characteristic bands [13] at 1010 and 610 nm, which are assigned to the transitions $^3A_2\rightarrow{}^3T_2$ and $^3A_2\rightarrow{}^3T_1(F)$, respectively (assuming again the *O* point group). It is identical to the one reported for $Ni(bipy)_2Cl_2$ [13].

The nickel compound was recrystallized in acetonitrile and its crystal structure was determined by X-ray diffraction methods. A labeled diagram of $Ni(bipy)_2Cl_2\cdot 2H_2O\cdot\frac{1}{2}CH_3CN$ (**4**) is shown in Fig. 5. The coordination sphere around Ni atoms is octahedral with the two chloro ligands located in *cis* positions to each other. The metal atom is situated in special position on a two-fold axis. The bond distances and angles are listed in Table 2. The Ni–Cl bond distances are 2.428(1) Å, and the Ni–N bonds are 2.084(3) and 2.094(2) Å. The latter values compare well with those [2.088(2) Å] observed in a $[Ni(bipy)_3]^{2+}$ complex [18]. The N–Ni–N chelated angles are smaller [78.5(1)°] than the *cis* angles [89.6(1)–95.9(1)°] around the Ni atom, as expected. The *trans* angles are 172.1(1) and 173.1(1)°. The external angles with the bipyridine ligands, Ni–N–C [ave. 126.5(2)°] are larger than the Ni–N–C chelate angles [ave. 115.2(2)°], but the differ-

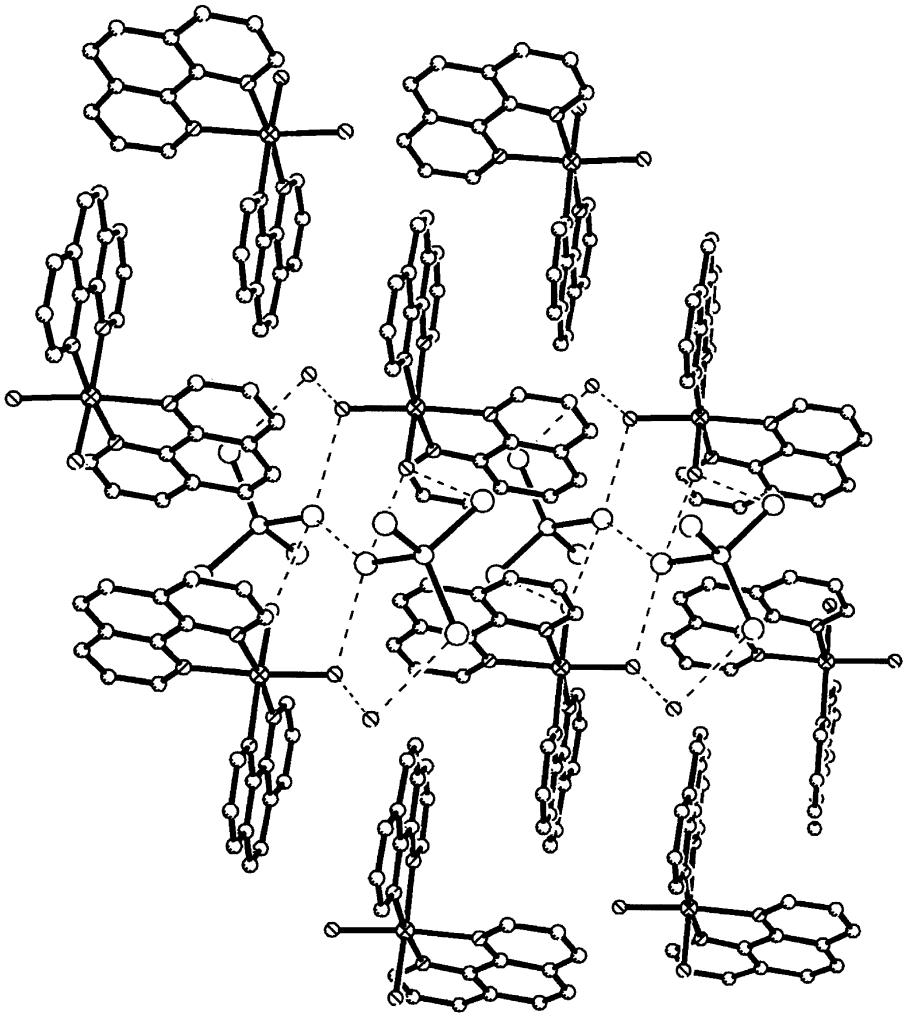

Fig. 2. Packing diagram of the molecules in the crystal $[Ni(phen)_2(H_2O)_2][ZnCl_4]\cdot H_2O$ (**2**).

ence is smaller than the one observed in the phenanthroline compound **2** described above. The average N–C distance is 1.345(4) Å, while the aromatic C–C bonds have an average value of 1.380(5) Å. The C(5)–C(6) bond is 1.476(4) Å. The *ortho* aromatic internal angles around C(1), C(5), C(6) and C(10) are slightly larger [ave. 122.0(3)°] than the other internal aromatic angles [ave. 119.1(4)°]. The internal angles around the C atoms in the chelate rings are 115.4(2) and 115.6(3)°, while the external angles C(4)–C(5)–C(6) and C(5)–C(6)–C(7) are 123.0(2) and 123.1(3)°, respectively.

The compound crystallized with two molecules of water (general position) and $\frac{1}{2}$ molecule of CH_3CN, located on a two-fold axis. The methyl group and the N atom of the CH_3CN molecules are disordered on the two sides of the central C atom. Therefore the distances in the CH_3CN molecules are not precise.

The molecules are held together by hydrogen bonding around the lattice molecules of water. Each water molecule is hydrogen bonded to two chloro ligands, with Ow···Cl distances of 3.235 and 3.238 Å and an angle Cl···Ow···Cl = 120.0°. The acetonitrile molecules are not involved in the hydrogen bonding system, but contribute to the packing energy. Stacking interactions between the dipyridyl aromatic rings play also an important stabilization role in the packing energy of the crystal.

The IR spectrum of the green mixture obtained after the ligand interchange is simply the sum of the corresponding spectra of $Ni(bipy)_2Cl_2$ and $Pd(bipy)Cl_2$. For comparison, the solvent free compound $Ni(bipy)_2Cl_2$ was obtained by heating **4** at 160°C (according to its thermal analysis) and by the controlled thermal decomposition of $[Ni(bipy)_3]Cl_2\cdot 7H_2O$ [19]. The two corresponding spectra were identical. Furthermore, all the characteristic frequencies of $Ni(bipy)_2Cl_2$ were identified in the IR spectrum of the green mixture.

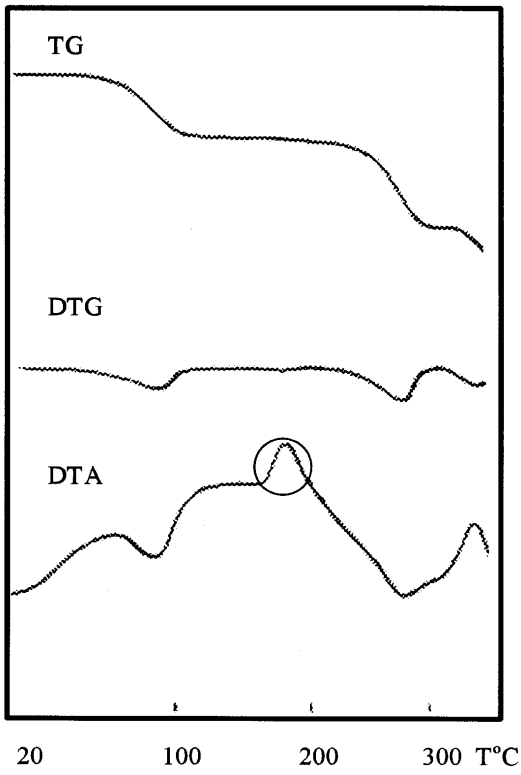

Fig. 3. Thermal analysis curves (TG, DTG, DTA) for $[Ni(bipy)_3][PdCl_4]\cdot 2\frac{1}{2}H_2O$ (**3**).

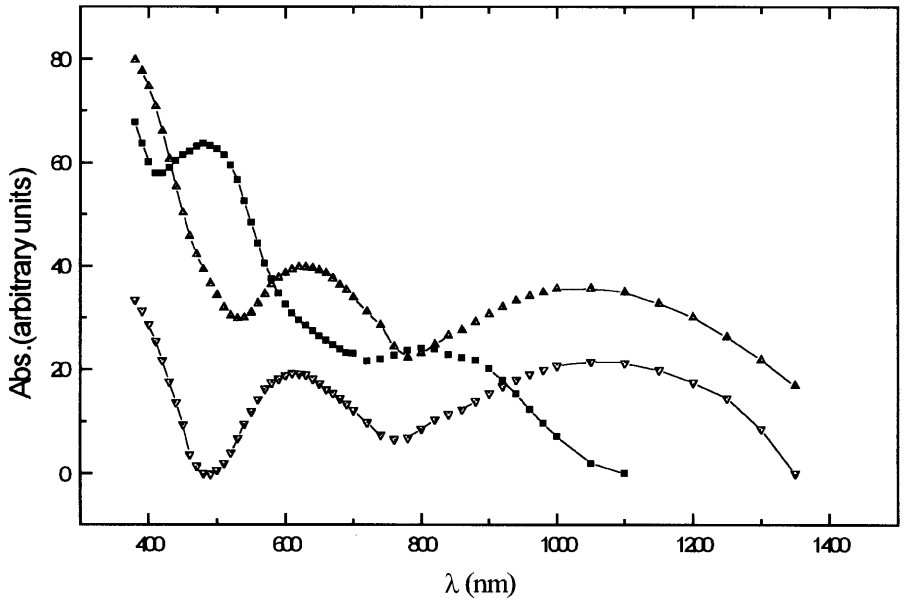

Fig. 4. Diffuse reflectance spectra for: $[Ni(bipy)_3][PdCl_4]\cdot 2\frac{1}{2}H_2O$ (■), $[Ni(bipy)_2Cl_2]+[Pd(bipy)Cl_2]$ (▲) and $[Ni(bipy)_2Cl_2]$ (▼) (after the elimination of the molecules of solvent).

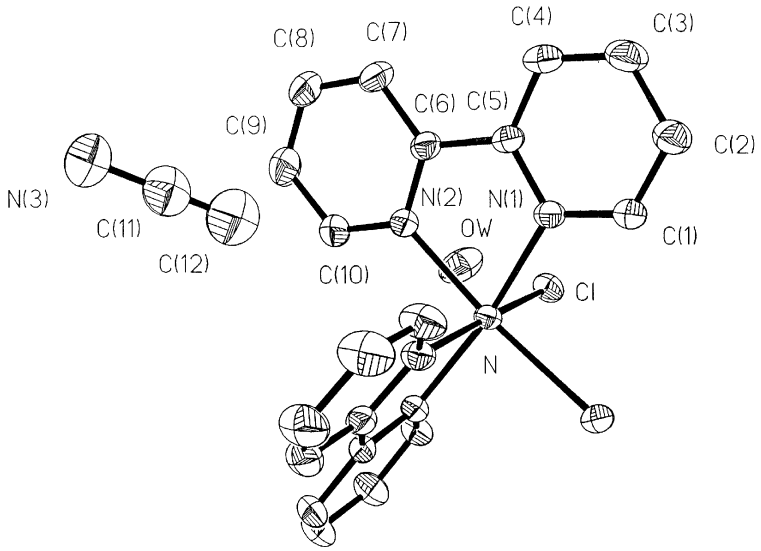

Fig. 5. Labeled diagram of $Ni(bipy)_2Cl_2{\cdot}2H_2O{\cdot}\frac{1}{2}CH_3CN$ (**4**).

According to the TG curve of the compound $[Ni(bipy)_3][PdCl_4]{\cdot}2\frac{1}{2}H_2O$ (**3**), the loss of the organic ligands starts at 220°C:

$$Ni(bipy)_2Cl_2(s) + Pd(bipy)Cl_2(s) \xrightarrow{220\text{–}280^\circ C} \{Ni(bipy)_{2.56}PdCl_4\} \times (s) + 0.44bipy(g)$$

$$\{Ni(bipy)_{2.56}PdCl_4\}(s) \xrightarrow{280\text{–}370^\circ C} \{Ni(bipy)_{2.34}PdCl_4\}(s) + 0.22bipy(g)$$

$$\{Ni(bipy)_{2.34}PdCl_4\}(s) \xrightarrow{370\text{–}520^\circ C} \{Ni(bipy)PdCl_4\}(s) + 1.34bipy(g)$$

$$\{Ni(bipy)PdCl_4\}(s) \xrightarrow{520\text{–}840^\circ C} NiO(s) + Pd(s) + bipy(g) + 2Cl_2(g)$$

The final products of the complete oxidative degradation of compound **3** are Pd and NiO. They were identified from their powder X-ray patterns [11].

The loss of bipyridine in the compound $Ni(bipy)_2Cl_2{\cdot}2H_2O{\cdot}\frac{1}{2}CH_3CN$ (**4**) starts around 160°C. Its thermal decomposition is as follows:

$$[Ni(bipy)_2Cl_2]{\cdot}2H_2O{\cdot}\tfrac{1}{2}CH_3CN(s) \xrightarrow{20\text{–}160^\circ C} Ni(bipy)_2Cl_2(s) + 2H_2O + \tfrac{1}{2}CH_3CN$$

$$Ni(bipy)_2Cl_2(s) \xrightarrow{160\text{–}320^\circ C} Ni(bipy)_{1.33}Cl_2(s) + 0.67bipy(g)$$

The degradation process seems to follow the decomposition pathway of the reported compound $[Ni(bipy)_3]Cl_2{\cdot}7H_2O$ [19] (after the loss of the first bipy molecule), namely:

$$[Ni(bipy)_3]Cl_2{\cdot}7H_2O(s) \xrightarrow{20\text{–}120^\circ C} [Ni(bipy)_3]Cl_2(s) + 7H_2O(g)$$

$$[Ni(bipy)_3]Cl_2(s) \xrightarrow{120\text{–}250^\circ C} Ni(bipy)_2Cl_2(s) + bipy(g)$$

$$Ni(bipy)_2Cl_2(s) \xrightarrow{250\text{–}325^\circ C} Ni(bipy)_{1.33}Cl_2(s) + 0.67bipy(g)$$

The temperatures are slightly different, probably caused by different heating rates. The following stages of the decomposition are identical for both compounds and consist in a multistep oxidation process, leading finally to NiO at about 700°C.

The examples presented in this work fall in the category of irreversible thermochromism [5], the color changes being caused by major structural modifications.

(Received 11 February 1998; accepted 27 March 1998)

Abstract—Diferrocenylphosphine (PFc_2Ph) reacts with Ag(TfO) or $[Ag(TfO)(PR_3)]$ (TfO = trifluoromethanesulfonate) to afford the three-coordinate complexes $[Ag(TfO)(PFc_2Ph)_2]$ or $[Ag(TfO)(PFc_2Ph)(PR_3)]$ ($PR_3 = PPh_2Me$, PPh_3), respectively. The complex $[Ag(TfO)(PFc_2Ph)_2]$ further reacts with bidentate ligands, such as bis(diphenylthiophosphoryl)methane (dptpm) or $S_2CNEt_2^-$ leading to the cationic, $[Ag(PFc_2Ph)_2(dptpm)]TfO$, or neutral, $[Ag(S_2CNEt_2)(PFc_2Ph)_2]$, four-coordinate complexes. The reaction with 1,10-phenanthroline (phen) gives to the four-coordinate $[Ag(TfO)(PFc_2Ph)(phen)]$. © 1998 Elsevier Science Ltd. All rights reserved. © 1998 Elsevier Science Ltd. Keywords: Silver; Ferrocene; Diferrocenylphenylphosphine

The study of the coordination chemistry of ferrocenylphosphines, such as the diphosphine 1,1′-bis(diphenylphosphino)ferrocene, has attracted a great deal of interest because the resultant complexes often find applications in homogeneous catalysis, in organic synthesis, manipulation of materials and production of fine chemicals [1, 2]. However, diferrocenylphenylphosphine (PFc_2Ph), although synthesised more than three decades ago, by interaction of ferrocene with dichlorophenylphosphine in the presence of anhydrous aluminium chloride [3], has scarcely been studied. Only very few complexes, such as $[M(CO)_5(PFc_2Ph)]$ (M = Mo or W), $[CoMe(DH)_2(PFc_2Ph)]$ (DH = dimethylglioximate), $[Ni(acac)_2(PFc_2Ph)]$ [4] or the gold derivative $[AuCl(PFc_2Ph)]$ [5], have been reported, but no silver derivative has been described so far.

Here we report on the synthesis of mononuclear three- or four coordinate silver(I) complexes that contain one or two diferrocenylphenylphosphine ligands.

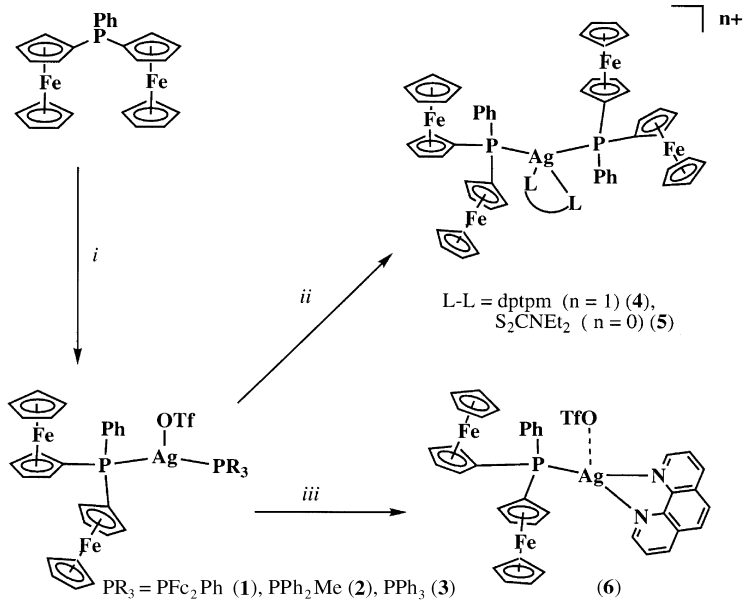
RESULTS AND DISCUSSION

The reaction of Ag(TfO) (TfO = trifluoromethanesulfonate) with diferrocenylphenylphosphine (PFc_2Ph) in diethyl ether, in a 1:2 molar ratio, gives a suspension from which $[Ag(TfO)(PFc_2Ph)_2]$ **1** can be isolated (Scheme 1). Other mononuclear complexes with two different phosphines, $[Ag(TfO)(PFc_2Ph)(PR_3)]$ ($PR_3 = PPh_2Me$ **2**, PPh_3 **3**), can be prepared by reaction of $[Ag(TfO)(PR_3)]$ with the ferrocenylphosphine in dichloromethane. Complexes **1**–**3** are yellow solids, air- and moisture stable. They behave as 1:1 electrolytes in acetone solution, which confirms an ionic nature, $[Ag(PFc_2Ph)(PR_3)]TfO$, in solution. In the IR spectra, the trifluoromethanesulfonate group gives rise to strong absorptions at 1625 (br) [$\nu(SO_3)$], 1225 [$\nu_{sym}(CF_3)$] and 1559 [$\nu_{as}(CF_3)$] cm^{-1}.

In the positive-ion liquid secondary ion mass spectra (LSIMS) the cation peaks $[Ag(PFc_2Ph)(PR_3)]^+$ appear at m/z 1063 (**1**, 50) and 847 (**3**, 57%). Additionally, other fragments in the spectrum of **3** correspond to $[Ag(PPh_3)_2]^+$ (633, 85) and $[Ag(PFc_2Ph)_2]^+$ (1063, 25%).



Scheme 1. (i) 1/2 Ag(TfO) or [Ag(TfO)(PR_3)], (ii) **1** + P(S)$Ph_2CH_2PPh_2$(S) or NaS_2CNEt_2, (iii) **1** + phen.

The ^{1}H NMR spectra of complexes **1**–**3** show the four different protons of the P(C_5H_4) rings as four multiplets or as a broad multiplet and the equivalent protons of the C_5H_5 rings as a singlet (see Table 1). In the spectrum of complex **3** the resonances due to complex **1** are also present. In the $^{31}P\{^1H\}$ NMR spectrum of **1**, $CDCl_3$ at -55°C, two doublets are observed as a consequence of chemically equivalent phosphorus atoms coupled to ^{107}Ag and ^{109}Ag nuclei. Complexes **2** and **3** present an AB system, both coupled to the two silver nuclei (Table 1). In the spectrum of **3** the resonances due to complex **1** and $[Ag(PPh_3)_2]^+$ [two doublets at δ -3.2, J(AgP) 604.3, 524.0 Hz] are also observed, indicating the existence of a ligand exchange equilibrium of **3** and the corresponding homoleptic species, although complex **3** is predominant. In complex **2** only signals of very low intensity at δ -2 ($[Ag(PFc_2Ph)_2]^+$) and -4 ($[Ag(PPh_2Me)_2]^+$) are present.

The structure of complex **1** was confirmed by X-ray diffraction analysis. The molecule is shown in Fig. 1, with selected bond lengths and angles in Table 2. The trifluoromethanesulfonate is coordinated by one oxygen to the silver atom. The silver presents a somewhat distorted trigonal-planar coordination, probably due to the steric requirements of the phosphines, with angles P(2)–Ag–P(1) of 135.20(6), O(1)–Ag–P(1) of 104.6(2) and O(1)–Ag–P(2) of 120.2(2)°. The silver atom lies only 0.01 Å out of the plane of the two phosphorus and oxygen atoms. The Ag–P distances [2.450(2) and 2.445(2) Å] are similar to those found in other tri-coordinate silver complexes $[Ag(dppf)(PPh_3)]ClO_4$ [dppf = 1,1′-bis(diphenylphosphino)ferrocene] [6] which range from 2.424(1) to 2.480(1) Å and slightly longer than those found in $[Ag_2(PPh_3)_2(SPPh_2CHPPh_2CHCO_2Me)]ClO_4$, 2.372(3) and 2.404(3) Å [7]. The Ag–O bond length of 2.345(7) Å is smaller than in the preceding dinuclear compound, 2.488(7) Å [7], but longer than in $[Ag(NO_3)(4\text{-}NO_2C_5H_4NO)_2]$, 2.364(3) and 2.318(3) Å [8]. The cyclopentadienyl rings are as expected parallel and planar. The rings are staggered by 13, 18 and 13° for Fe(2), Fe(3) and Fe(4), respectively, but by 29° for Fe(1), around the Cp · · · Cp axis (Cp = centre of cyclopentadienyl ring) defined by the torsion angles C–Cp–Cp–C. The Fe–Cp distances are in the range 1.639(3)–1.650(3) Å.

We have studied the reactivity of complex **1** with bidentate ligands such as bis(diphenylthiophosphoryl)methane (dptpm), $S_2CNEt_2^-$ (from NaS_2CNEt_2) or 1,10-phenanthroline (phen). Treatment of equimolecular amounts of **1** with the first two ligands affords the four-coordinate cationic or neutral complexes, $[Ag(PFc_2Ph)_2(dptpm)]TfO$ (**4**) and $[Ag(S_2CNEt_2)(PFc_2Ph)_2]$ (**5**). They are air- and moisture stable yellow solids. The IR spectrum of **4** shows bands at 1258 (s, br), 1224 (s) and 1157 (s) cm^{-1}, from the TfO anion, and the ν(P=S) vibration appears at 557 (m) cm^{-1}. A band at 1515 (m) cm^{-1} in the IR spectrum of **5** is attributable to ν(C=N) of the dithiocarbamate ligand. In the LSIMS spectra the molecular peak does not appear, but the peaks assigned to the fragments $[Ag(PFc_2Ph)(L\text{-}L)]^+$ at m/z 1035 (**1**, 50) and 847 (**3**, 57%) are present. Complex **4** is an 1:1 electrolyte in acetone solution, but **5** behaves as nonconductor in solution.

The ^{1}H NMR spectra of complexes **4** and **5** show the expected four resonances for the P(C_5H_4) protons

and a singlet for the C_5H_5 rings (Table 1). The CH_2 groups of **4** appears as a triplet at 4.57 ppm [*J*(PH), 14.3 Hz] and ethyl groups of **5** are present as a quartet (CH_2, 4.07 ppm, *J*(HH) 6.96 Hz) and a triplet (CH_3, 1.37 ppm). The $^{31}P\{^1H\}$ NMR spectrum of **4**, $(CD_3)_2CO$ at $-85°C$, shows a singlet for the two phosphorus of the diphosphine and two doublets for the phosphorus of the ferrocenylphosphine coupled with the ^{107}Ag and ^{109}Ag nuclei. In complex **5** only the resonance due to the phosphorus coupled to the silver nuclei (two doublets) is observed.

The crystal structure of complex **5** has been established by X-ray diffraction. The compound crystallises as a chloroform solvate. The molecule is shown in Fig. 2, with selected bond lengths and angles in Table 3. The silver atom is coordinated to two phosphines and one chelating dithiocarbamate ligand and has a distorted tetrahedral geometry. The distortion arises from the restricted bite of the dithiocarbamate, S(1)–Ag–S(2) 67.40(6)°, whereas the other angles are wider than ideal, P(2)–Ag–S(2) 131.73(7) or P(1)–Ag–S(1) 126.87(7)°. The dihedral angle between the planes Ag–P(1)–P(2) and Ag–S(1)–S(2) is 66°. The cyclopentadienyl rings of Fe(1), Fe(2), Fe(3) and Fe(4) are staggered by 10, 2, 19 and 15°, respectively, around the Cp · · · Cp axis. The Ag–P distances are 2.500(2) and 2.528(2) Å, similar to those in $[Ag\{(PPh_2)_2C_2B_{10}H_{10}\}(dptpm)]ClO_4$, 2.526(2) and 2.532(2) Å [9], or in other four-coordinate complexes, such as $[Ag(dppe)_2]^+$ [10]. However the two different Ag–S distances, 2.605(2) and 2.739(2) Å, are longer than in $[Ag\{(PPh_2)_2C_2B_{10}H_{10}\}(dptpm)]ClO_4$, 2.540(2) and 2.588(2) Å [9].

Complex **1** reacts with equimolecular amounts of 1,10-phenanthroline in a different way; substitution of one ferrocenylphosphine is now observed to give [Ag(TfO)(PFc_2Ph)(phen)] (**6**). Complex **6** is an air- and moisture stable light orange solid. It behaves as an 1:1 electrolyte in acetone solution, which indicates the dissociation of the trifluoromethanesulfonate ligand to give the ions $[Ag(PFc_2Ph)(phen)]^+$ TfO^-. In the LSIMS spectrum the cation peak $[Ag(PFc_2Ph)(phen)]^+$ appears at *m*/*z* 765 as the most intense one.

The ^1H NMR spectrum of **6** shows the expected resonances of the ferrocenylphosphine (Table 1) and four multiplets at 7.44, 7.94, 8.56 and 9.32 ppm due to the eight protons of the phenanthroline. The phosphorus atom appears as a broad doublet ($CDCl_3$, $-55°C$), due to the coupling with the silver nuclei, in the $^{31}P\{^1H\}$ NMR spectrum.

The molecule of complex **6** is shown in Fig. 3 with selected bond lengths and angles in Table 4. The silver atom presents a distorted tetrahedral geometry, lying 0.39 Å out of the plane formed by the two nitrogen and phosphorus atoms in the direction of the triflate oxygen O(1), with Ag–O(1) 2.626(3) Å. The interplanar angle between AgN(1)N(2) and AgPO(1) is 88°. The restricted "bite" of the phenanthroline, N(1)–Ag–N(2) 72.12(10)°, represents one major deviation from ideal geometry. The Ag–P bond, 2.3445(12) Å, is shorter than in complex **1** or in other three-coordinate derivatives, such as $[Ag(dppf)(PPh_3)]ClO_4$, 2.424(1) to 2.480(1) Å [6], or $[Ag\{(PPh_2)_2C_2B_9H_{10}\}(PPh_3)]$, 2.3974(10) to 2.4942(10) Å [11], reflecting the correspondingly weak Ag coordination to N and O atoms in **6**. The phenanthroline is asymmetrically coordinated through two different Ag–N bonds of 2.289(3) and 2.351(3) Å which are of the same order as those found in other phenanthroline complexes, such as $[Ag\{(PPh_2)_2C_2B_{10}H_{10}\}(phen)]ClO_4$ [9] or [Ag(dppf)(phen)]ClO_4 [6]. The shorter Ag–N distance is associated with the widest angle, P–Ag–N(1) 142.11(7)°. The ferrocene systems display twists of 7 and 17° for Fe(1) and Fe(2), respectively.

EXPERIMENTAL

General

Infrared spectra were recorded in the range 4000–200 cm^{-1} on a Perkin-Elmer 883 spectrophotometer

using Nujol mulls between polyethylene sheets. Conductivities were measured in *ca.* 5×10^{-4} mol dm^{-3} solutions with a Philips 9509 conductimeter. C and H analyses were carried out with a Perkin-Elmer 2400 microanalyser. Mass spectra were recorded on a VG autospec, with the LSIMS technique, using nitrobenzyl alcohol as matrix. NMR spectra were recorded on a Varian Unity 300 spectrometer and a Bruker ARX 300 spectrometer in $CDCl_3$ or $(CD_3)_2CO$. Chemical shifts are cited relative to $SiMe_4$ (^{1}H, external) and 85% H_3PO_4 (^{31}P, external). The starting complexes [Ag(TfO)(PR_3)] ($PR_3 = PPh_2Me$, PPh_3) where prepared by reaction of equimolar amounts of Ag(TfO) and the ligand PR_3 in dichloromethane.

[c] $S=[\Sigma\{w(F_o^2-F_c^2)^2\}/(n-p)]^{0.5}$, where n is the number of data and p the number of parameters.

$[Ag(TfO)(PFc_2Ph)_2]$ (**1**)

To a suspension of PFc_2Ph [3] (0.096 g, 0.2 mmol) in diethyl ether (20 cm^3) was added Ag(TfO) (0.021 g, 0.1 mmol). The mixture was stirred for 1 h and then filtered. The product was dissolved in dichloromethane (20 cm^3) and the solution was concentrated to *ca.* 5 cm^3. Addition of diethyl ether (15 cm^3) gave complex **1** as a yellow solid. Yield 79%, Λ_M 121 Ω^{-1} cm^2 mol^{-1} (Found: C, 52.05; H, 3.5; S, 3.0. Calc. for $C_{53}H_{46}AgF_3Fe_4O_3P_2S$: C, 52.5; H, 3.7; S, 2.6%).

$[Ag(TfO)(PFc_2Ph)(PR_3)]$ ($PR_3=PPh_2Me$ (**2**), PPh_3 (**3**))

To a solution of PFc_2Ph (0.048 g, 0.1 mmol) in dichloromethane (25 cm^3) was added $[Ag(TfO)(PR_3)]$ (0.046 g, $PR_3=PPh_2Me$; 0.052, $PR_3=PPh_3$; 0.1 mmol) and the mixture was stirred for 1 h. The solution was concentrated to *ca.* 5 cm^3 and addition of hexane (15 cm^3) gave complex **2** and **3** as a yellow solids. Complex **2**: Yield 65%, Λ_M 106 Ω^{-1} cm^2 mol^{-1} (Found: C, 52.05; H, 3.95; S, 3.4. Calc. for $C_{40}H_{36}AgF_3Fe_2O_3P_2S$: C, 52.35; H, 3.85; S, 3.4%). Complex **3**: Yield 86%, Λ_M 111 Ω^{-1} cm^2 mol^{-1} (Found: C, 54.1; H, 3.85; S, 3.05. Calc. for $C_{45}H_{38}AgF_3Fe_2O_3P_2S$: C, 54.25; H, 3.85; S, 3.2%).

$[Ag(PFc_2Ph)_2(dptpm)]TfO$ (**4**)

To a solution of complex **1** (0.121 g, 0.1 mmol) in dichloromethane (20 cm^3) was added $P(S)Ph_2CH_2PPh_2(S)$ [12] (0.045 g, 0.1 mmol) and the mixture was stirred for 1 h. The solution was concentrated to *ca.* 5 cm^3 and addition of diethyl ether (15 cm^3) gave complex **4** as a yellow solid. Yield 60%, Λ_M 140 Ω^{-1} cm^2 mol^{-1} (Found: C, 56.25; H, 4.15; S, 6.3. Calc. for $C_{78}H_{68}AgF_3Fe_4O_3P_4S_3$: C, 56.35; H, 4.1; S, 5.8%).

$[Ag(S_2CNEt_2)(PFc_2Ph)_2]$ (**5**)

To a dichloromethane solution (20 cm^3) of complex **1** (0.121 g, 0.1 mmol) was added NaS_2CNEt_2 (0.023 g,

0.1 mmol). The mixture was stirred for 4 h and then filtered off to remove the sodium trifluoromethanesulfonate. The solvent was evaporated under vacuum to *ca.* 5 cm^3; addition of diethyl ether (15 cm^3) afforded complexes **5** as a yellow solid. Yield 68% (Found: C, 55.9; H, 4.3; N, 1.15; S, 5.1. Calc. for $C_{57}H_{56}AgFe_4NP_2S_2$: C, 56.45; H, 4.65; N, 1.15; S, 5.2%).

[*Ag*(*TfO*)(*PFc*$_2$Ph)(phen)] (**6**)

To a dichloromethane solution (20 cm^3) of complex **1** (0.121 g, 0.1 mmol) was added 1,10-phenanthroline (0.018 g, 0.1 mmol). The mixture was stirred for 1 h and then the solution was concentrated under vacuum to *ca.* 5 cm^3; addition of diethyl ether (15 cm^3) afforded complexes **6** as a light orange solid. Yield 75%, Λ_M 140 $\Omega^{-1}\,cm^2\,mol^{-1}$ (Found: C, 51.9; H, 3.45; N, 3.05; S, 3.75. Calc. for $C_{39}H_{31}AgF_3Fe_2N_2O_3PS$: C, 52.6; H, 3.4; N, 3.05; S, 3.5%).

Crystal Structure Determinations

The crystals were mounted in inert oil on glass fibres and transferred to the cold gas stream of a Siemens R3 (**1**) or P4 (**5**) or a STOE Stadi4 (**6**) diffractometers equipped with an LT-2 low temperature attachment. Data were collected using monochromated MoKα radiation ($\lambda = 0.71073$ Å). Scan type ω (**1**,**5**) or ω/θ (**6**). Cell constants were refined from setting angles (**1**,**5**) or $\pm\omega$ angles of *ca.* 60 reflections in the range 2θ 10–25°. Absorption corrections were applied on the basis of Ψ-scans (**1**,**6**). Structures were solved by the heavy-atom method and refined on F^2 using the program SHELXL-93 [13]. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included using a riding model. A system of restraints to light-atom displacement-factor components was used. Special refinement details for **1**: The high displacement parameters of O(1) may indicate some disorder (flexibility of coordination geometry at silver). Crystal data are given in Table 5.

(Received 26 February 1998; accepted 7 April 1998)

Abstract—Compound CpMo(η^3-C_3H_5)$_2$, **3**, has been synthesized from $CpMoCl_4$ and four equivalents of allylmagnesium bromide. While the compound is stable in donor solvents at room temperature, warming in refluxing MeCN induces the formation of 1,5-hexadiene by a metal-mediated allyl-allyl coupling process. Treatment of **3** with Bu^{t}NC at room temperature affords CpMo(η^3-C_3H_5)(Bu^{t}NC)$_2$, **4**. A similar reduction with presumed allyl radical loss occurs for [CpMo(η^3-C_3H_5)(η^4-C_4H_6)]$^+$, [**1c**]$^+$, to afford [CpMo(η^4-C_4H_6)(Bu^{t}NC)$_2$]$^+$, **5**. Treatment of [**1c**]$^+$ with methyllithium affords two products, the major one (**1c**) corresponding to the one-electron reduction pathway and the minor one (CpMo(η^3-C_3H_5)(η^3-C_3H_4-1-Et), **6**, ca. 4%) corresponding to nucleophilic addition. Protonation of the **1c**:**6** mixture affords a 2:1 mixture of *cis* and *trans* 2-pentene, in addition to propene. The room temperature $Cp_2Fe^+PF_6^-$ oxidation of **3** in MeCN induces the immediate release of 1,5-hexadiene. The oxidation of **3** in Bu^{t}NC gives complexes [CpMo(CNBu^t)$_3$(η^2−CH_2═$CHCH_2CH_2CH$═CH_2)]$^+PF_6^-$ (**7**, major) and [CpMo(CNBu^t)$_4$]$^+PF_6^-$ (**8**, minor). Finally, the oxidation of **3** in the presence of butadiene, followed by treatment with CD_3CN, affords a mixture of [CpMo(η^3:η^3−$C_3H_4CH_2CH_2C_3H_4$)(CD_3CN)]$^+PF_6^-$, **9**, and [CpMo(η^4−C_4H_6)(CD_3CN)$_2$]$^+PF_6^-$, **10**. Thermal decomposition of this mixture affords butadiene and 1,5-cyclooctadiene. © 1998 Elsevier Science Ltd. All rights reserved

INTRODUCTION

We have recently reported the preparation and properties of a molybdenum complex that contains a cyclopentadienyl, a butadiene, and an allyl ligand in four different isomeric forms and in two redox-related oxidation states, namely [CpMo(η-C_3H_5)(η-C_4H_6)]n+ (n=0, **1a**–**c**; 1, [**1a**–**d**]$^+$), see Scheme 1 [2]. In these isomers, the allyl ligand can adopt either a *prone* (**a** or **d**) or a *supine* (**b** or **c**) configuration, while the butadiene ligand adopts either a *supine* (*s-cis*) (**a** or **b**) or an *s-trans* (**c** or **d**) configuration. While the isomerization rates are slow in the Mo(II) manifold, allowing the isolation of each of the three isomers, they are rapid in the Mo(III) manifold, thus only the most stable isomer [**1b**]$^+$ has been isolated in crystalline form as a PF_6^- salt.

We have subsequently reported on the reactivity of the coordinated ligands in the isomers **1a**–**c** and in the

Scheme 1.

bis(diene) derivative $[CpMo(\eta\text{-}supine\text{-}C_4H_6)(\eta\text{-}s\text{-}trans\text{-}C_4H_6)]^+$, **2**, which is obtained by protonation of **1a** in the presence of butadiene. While the *s-cis*-coordinated butadiene ligand is resistant to any kind of attack, the *s-trans*-coordinated butadiene can be attacked by either electrophilic or nucleophilic reagents depending on the electron richness of the system: electrophilic attack by protons has been observed for the neutral compound **1c** [3], while nucleophilic attack occurs for the cationic complex **2** [4]. The allyl ligand has only been found to engage in electrophilic addition for any of the three isomers of **1** [3].

The reactivity of organic ligands coordinated to Mo(III) has not been the subject of extensive investigations. Compounds with either diene of allyl ligands on Mo(III) are known, e.g. $CpMoCl_2(\eta\text{-}C_4H_6)$ [5] and $CpMo(\eta\text{-}C_3H_5)_2$ [6, 7], in addition to the complexes $[\mathbf{1a}\text{–}\mathbf{d}]^+$ recently reported by us. However, there is apparently no report on the reactivity of the coordinated π ligands in these or other related compounds. In fact, compound $CpMo(\eta\text{-}C_3H_5)_2$, **3**, has been described as "depressively unreactive" [8]. A study of the reactivity of the allyl and diene ligands on Mo(III) is of interest for several reasons. First, it is interesting to examine the effect of the metal oxidation state on the reactivity of the ligands. Second, it is conceivable that a stoichiometric or electron-transfer-catalytic (ETC) [9, 10] oxidation of the more accessible Mo(II) precursors could allow the development of new stoichiometric or catalytic transformations that involve the coordinated ligands. In this report, we describe our exploratory investigations of the reactivity of the isoelectronic Mo(III) compounds **3** and $[\mathbf{1b}]^+$ under a variety of conditions. We show that these complexes, under suitable conditions, are attacked by nucleophiles and electrophiles, undergo Mo–C bond breaking and C–C bond forming reactions, and engage in oxidative and reductive redox processes. A new and improved synthesis of compound **3** is also presented.

RESULTS

(*a*) *New synthesis of* $CpMo(C_3H_4)_2$

The reaction of $CpMoCl_4$ with 4 equivalents of allylmagnesium bromide involves chloride/allyl metathesis and metal reduction, to provide a single-step synthesis of $CpMo(\eta\text{-}C_3H_5)_2$ (see eq. (1). The unoptimized yield is moderate (44%). Nevertheless, considering that $CpMoCl_4$ can be easily prepared in a single, nearly quantitative step from commercially available $[CpMo(CO)_3]_2$ [11], this procedure represents an improvement over the previously reported 3-step synthesis from $MoCl_4(THF)_2$ via $Mo(\eta^3\text{-}C_3H_4)_4$ and $MoCl(\eta^3\text{-}C_3H_4)_3$ [6, 7]. The precursor $MoCl_4(THF)_2$ must also be prepared in two steps from commercially available $MoCl_5$ [12].

$$CpMoCl_4 + 4CH_2{=}CHCH_2MgBr \rightarrow \underset{\mathbf{3}}{CpMo(\eta\text{-}C_3H_5)_2} \quad (1)$$

Compound **3** has previously been characterized by X-ray crystallography, magnetic susceptibility, and cryoscopic molecular weight determination [6]. An EPR spectrum was not reported. We have recently observed that allyldiene complexes such as $[\mathbf{1}]^+$, isoelectronic with **3**, exhibit sharp EPR absorptions with observable coupling to the diene and allyl protons [2]. Comparative studies have shown that the *supine* allyl ligand in $[\mathbf{1b}]^+$ gives measurable coupling to the *syn* H atoms but not to the *anti* H atoms or to the central H atom, whereas no coupling can be observed with either type of H atom for the *prone* allyl ligand in $[\mathbf{1a}]^+$ [2, 4]. The spectrum of compound **3**, shown in Fig. 1, consists of a pentet of pentets, indicating coupling with all the H atoms of the terminal allyl positions. This suggests that the configuration of **3** in solution is identical with that previously determined in the solid state, with both allyl ligands adopting a *supine* configuration. By comparison with our previous EPR studies, the stronger coupling of 6.6 G is assigned to the *syn* H atoms and the weaker one of 3.3 G to the *anti* H atoms.

(*b*) *Reaction of* $CpMo(\eta\text{-}C_3H_5)_2$ *with nucleophiles*

Compound **3** is stable in donor solvents, including MeCN at room temperature. Warming a MeCN solution to the reflux temperature caused the complete decomposition of the complex and the formation of 1,5-hexadiene and propene in a ca: 2:1 ratio as the major products (>80% by ^{1}H NMR integration).

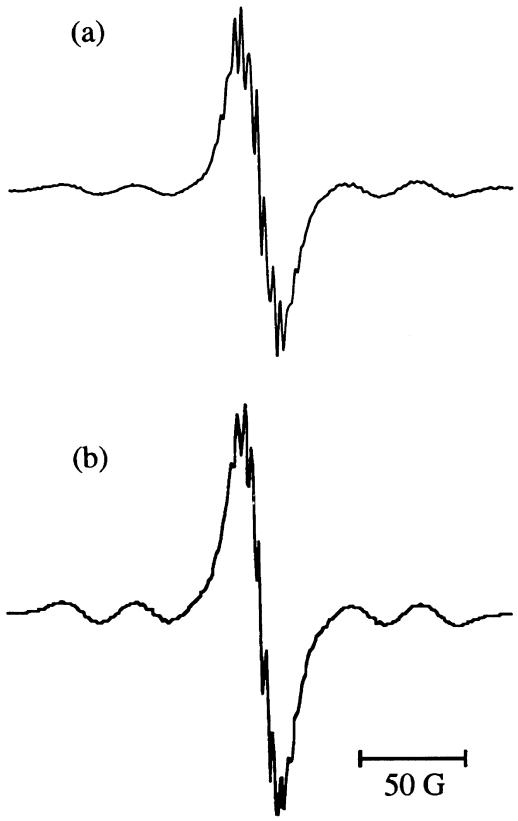

Fig. 1. Experimental (top) and simulated (bottom) EPR spectrum for compound **1** (solvent = THF, T = −100°C).

Neither does **3** react with a large excess of butadiene at room temperature. However, treatment in neat Bu^tNC leads to the smooth formation of the diamagnetic compound $CpMo(\eta\text{-}C_3H_5)(CNBu^t)_2$, **4**, see eq. (2).

$$CpMo(\eta-C_3H_5)_2 + Bu^tNC(\text{excess}) \rightarrow \underset{\mathbf{4}}{CpMo(\eta-C_3H_5)(CNBu^t)_2} \quad (2)$$

The reaction is relatively slow, starting material being still present after several hours at room temperature. NMR spectroscopy shows the initial selective formation of **4**. Prolonged exposure to the Bu^tNC solvent, however, results in the formation of a new diamagnetic material that shows only resonances for the Cp ligand and for the *tert*-Bu group, thus indicating decomposition of **4** with loss of the residual allyl ligand. This by-product is different from $[CpMo(CNBu^t)_4]^+$ (*vide infra*) and was not further characterized. Its formation did not permit the isolation of compound **4** in an analytically pure form. The identity of **4**, however, is established by ^1H NMR. The allyl proton chemical shifts and coupling pattern are consistent with a *supine* coordination mode. In particular, the indiscernible geminal coupling between *syn* and *anti* protons is a clear indication of the *supine* conformation of the allyl ligand [2, 13–15].

(*c*) *Reaction of* $[CpMo(\eta\text{-}C_3H_5)(\eta\text{-}C_4H_6)]^+$ *with nucleophiles*

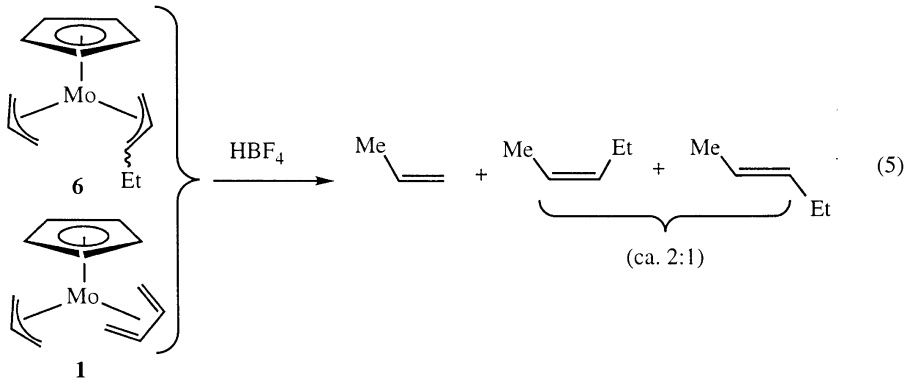
The reaction between complex $[\mathbf{1b}]^+$ and Bu^tNC follows the same path observed for compound **3**, namely reduction with formal expulsion of an allyl radical, see eq. (3). Compound **5** has previously been obtained by HBF_4 protonation of **1a** in the presence of Bu^tNC and fully characterized [3]. As established above for compound **3**, no reaction is observed between $[\mathbf{1b}]^+$ and MeCN or butadiene under mild conditions.

$$[CpMo(\eta-C_3H_5)(\eta-C_4H_6)]^+ + Bu^tNC(\text{excess}) \rightarrow \underset{\mathbf{5}}{[CpMo(\eta-C_4H_6)(CNBu^t)_2]^+} \quad (3)$$

The existence of bisallyl Mo(III) complexes such as **3**, and the established nucleophilic attack by carbanions on Mo(II)-coordinated diene ligands to afford allyl complexes, made us wonder whether the same reactivity could be observed for the Mo(III)-coordinated diene ligand. Indeed, reaction of $[\mathbf{1b}]^+$ with methyllithium in THF generates a new EPR-active complex which is formulated as $CpMo(\eta\text{-}C_3H_5)(\eta\text{-}C_3H_4Et)$, **6**. This nucleophilic addition process, however, corresponds to a minor reaction pathway (4% according to the intensity of the double-integrated EPR signal). The main product of the reaction, compound **1** [2], derives from a single electron transfer process (see eq. (4)). As expected from the previously reported investigation of the reduction of $[\mathbf{1b}]^+$ [2], the kinetically controlled reduction product is $CpMo(\textit{supine}\text{-}\eta\text{-}C_3H_5)(\textit{supine}\text{-}\eta\text{-}C_4H_6)$, **1b**, followed by the slow isomerization to the thermodynamically favored $CpMo(\textit{prone}\text{-}\eta\text{-}C_3H_5)(\textit{supine}\text{-}\eta\text{-}C_4H_6)$, **1a**.

$$[CpMo(\eta-C_3H_5)(\eta-C_4H_6)]^+ + MeLi \rightarrow \underset{\mathbf{1}}{CpMo(\eta-C_3H_5)(\eta-C_4H_6)} + \underset{\mathbf{6}}{CpMo(\eta-C_3H_5)(\eta-C_3H_4Et)} \quad (4)$$

The nature of the paramagnetic product as **6** is supported by the results of a protonation study of the **1**/**6** mixture in C_6D_6 with HBF_4Et_2O. The ^1H-NMR of the organic phase shows the formation of *cis*- and *trans*-2-pentene in a relative 2:1 ratio, in addition to propene, see eq. (5). There is no observable formation of 1-pentene from this reaction. The formation of propene by protonation of **1** has previously been studied in detail [3].



(5)

(*d*) *Oxidation of* $CpMo(\eta\text{-}C_3H_5)_2$

While compound **3** is stable in acetone and MeCN at room temperature, oxidation with Cp_2Fe^+ in either solvent induces an immediate allyl-allyl coupling and release of free 1,5-hexadiene (see eq. (6). The fate of the [$CpMo^+$] fragment is unknown but probably leads to paramagnetic products, since no resonances attributable to the Cp ligand are observed in the ^1H NMR spectrum.

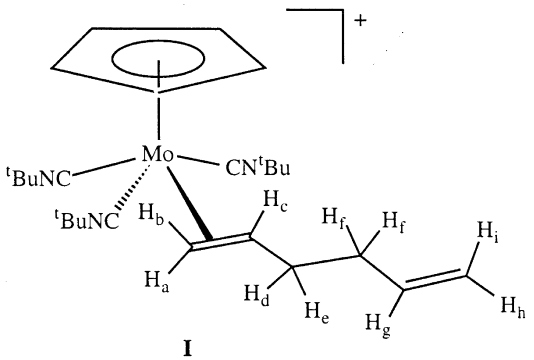
$$CpMo(\eta-C_3H_5)_2 + Cp_2Fe^+PF_6^- \rightarrow CH_2{=}CHCH_2CH_2CH{=}CH_2 \quad (6)$$

When the oxidation reaction is carried out in the presence of Bu^tNC as a trapping agent, two products are observed in a ca. 2:1 ratio (eq. (7). The predominant product is $[CpMo(CNBu^t)_3(\eta^2-CH_2{=}CHCH_2CH_2CH{=}CH_2)]^+PF_6^-$, **7**. This compound could not be obtained as a pure crystalline material because the minor product, compound $[CpMo(CNBu^t)_4]^+PF_6^-$, **8**, crystallizes preferentially. The latter compound has previously been obtained by a different synthetic method [16]. The NMR properties show the equivalence of the four Bu^tNC ligands as expected for the ubiquitous four-legged piano stool geometry, while the three IR bands observed in the CN stretching region are consistent with the expected C_{4v} local symmetry (A_1+B_1+E).

$$CpMo(\eta-C_3H_5)_2 + Cp_2Fe^+PF_6^- + Bu^tNC(\text{excess}) \rightarrow [CpMo(CNBu^t)_3(\eta^2-CH_2{=}CHCH_2CH_2CH{=}CH_2)]^+PF_6^- \quad \mathbf{7}$$

$$+ [CpMo(CNBu^t)_4]^+PF_6^- \quad \mathbf{8} \quad (7)$$

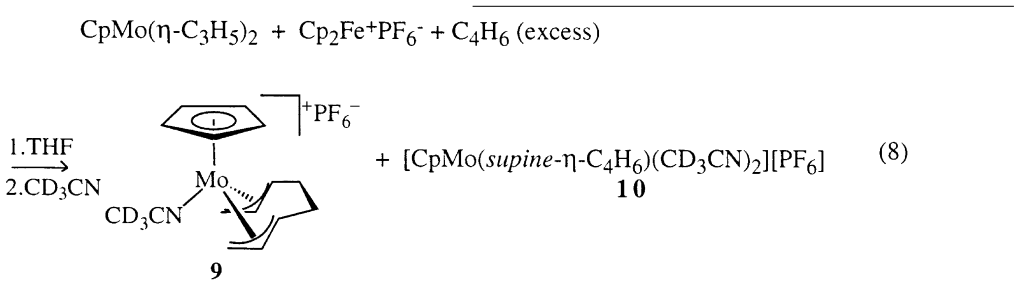
The identification of compound **7** rests on the ^1H and ^{13}C NMR properties. Unlike **8**, which has four equivalent *tert*-butyl isocyanide ligands, complex **7** has three inequivalent isocyanide ligands because of the low symmetry. All 10 protons of the coordinated 1,5-hexadiene ligand are visible in the ^1H NMR spectrum. The proton nomenclature is as shown in **I**. All assignments have been confirmed by selective homonuclear decoupling experiments, which also assisted in the determination of the coupling constants. The proton resonances of the dangling vinyl group show typical chemical shifts and coupling pattern. The coordinated vinyl group, on the other hand, exhibits resonances at higher field. The methylene protons adjacent to the coordinated vinyl group (H_d and H_e) show distinct resonances, while the other methylene protons (H_f) are chemically equivalent (2.30 ppm). Echoing the proton NMR data, the ^{13}C NMR spectrum also shows the inequivalence of the three isocyanide ligands. While the coordinated carbon resonances are significantly different, both the methyl and the tertiary carbon atoms of the three *tert*-butyl groups give common resonances, indicating the insensitivity of these nuclei to the immediate chemical environment of the metal center.



I

The oxidation of **1** has also been carried out in the presence of butadiene. In this case, a 2.5:1 mixture of the bisallyl Mo(IV) complex $[CpMo(\eta^3{:}\eta^3\text{-}C_3H_4CH_2CH_2C_3H_4)(CD_3CN)]^+PF_6^-]$, **9**, and the butadiene Mo(II) complex $[CpMo(\textit{supine-}\eta\text{-}C_4H_6)(CD_3CN)_2]^+PF_6^-]$, **10**, forms after treating the reaction residue in CD_3CN, see eq. (8). Both complexes have previously been obtained by protonation of **1c** in the presence of butadiene [3]. As reported previously, compound **9** is indefinitely stable in CD_3CN at room temperature. A thermal study at 100°C in CD_3CN in a sealed NMR tube, however, revealed its decomposition to yield

cyclooctadiene in 70% spectroscopic yield. Free butadiene is also observed, presumably deriving from the thermal decomposition of **10**.



DISCUSSION

(*a*) *Nucleophilic attack to* Mo(III) *vs.* Mo(II)

From our previous studies, we have established that the neutral Mo(II) system $CpMo(\eta\text{-}C_3H_4)(\eta\text{-}C_4H_6)$, in either of its three stable isomeric forms (**1a**–**c**), is not susceptible to nucleophilic attack [3]. However, the cationic Mo(II) complex $[CpMo(supine\text{-}\eta\text{-}C_4H_6)(s\text{-}trans\text{-}\eta\text{-}C_4H_6)]^+$, **2**, can be attacked by nucleophiles either at the metal (with substitution of the *s-trans*-butadiene ligand) or at the *s-trans*-butadiene *endo* terminal carbon atom (with formation of an allyl derivative) [4]. For these reasons, we reasoned that a nucleophilic attack to either the metal, the butadiene ligand or the allyl ligand in the Mo(III) complexes **3** and $[\mathbf{1b}]^+$ might occur under the influence of the higher formal oxidation state, especially for the cationic system. As mentioned in the Introduction, no studies of the reactivity of Mo(III)-coordinated allyl and butadiene ligands appear to have been reported.

The results obtained show that the dominant pathway is metal reduction. The tendency of the metal to reach an 18-electron configuration, especially in the presence of π-acidic ligands, is sufficiently high to force the elimination of allyl radicals. This pathway is observed for both **3** and $[\mathbf{1b}]^+$ in their reaction with Bu^tNC. It is remarkable that, for complex $[\mathbf{1b}]^+$, the observed reaction pathway is more favorable than either substitution of the neutral diene ligand or insertion of the diene into the Mo(III)-allyl bond. Weaker neutral 2-electron donor such as MeCN do not react. The reaction of the cationic substrate with methyllithium does indeed lead to the addition product **6** (eq. (4)), but the main product is the neutral derivative **1b** obtained from the single electron transfer pathway. This result, nevertheless, indicates an increased reactivity of the coordinated ligands on going from Mo(II) to Mo(III). For the Mo(II) complexes of the types investigated by us, a nucleophilic attack takes place (only in the cationic systems) at the *s-trans* butadiene ligand but never at the *s-cis* butadiene or at the allyl ligands. For the Mo(III) cationic complex reported here, we have seen for the first time a nucleophilic addition to the *s-cis* butadiene ligand.

The nature of the products obtained by protonating **6** (see section (c) below) indicate that this compound is a mixture of isomers with *syn* and *anti* ethylallyl ligand (2:1 in favor of the *anti* isomer). This mixture is probably formed by direct nucleophilic addition to the *s-cis* butadiene ligand to afford the *anti* allyl product, followed by partial isomerization. An alternative pathway to the *syn* product involving an initial isomerization to $[\mathbf{1c}]^+$, followed by nucleophilic attack at the *s-trans* diene ligand can be excluded because, according to our previous studies [2], the thermodynamics and kinetics for the isomer interconversion reaction would not allow the formation of a significant amount of the *s-trans* isomer during the short time scale of the methylation process.

(*b*) *Allyl-allyl coupling in* Mo(III) *and* Mo(IV)

Processes of allyl-allyl coupling in transition metal complexes are relevant as elementary steps of catalytic dimerization and oligometization of diene ligands [17]. The metal-assisted coupling of allyl ligands to afford 1,5-hexadiene products is a widely known reaction [17–19]. Previous reports for molybdenum complexes include the interaction of a "violet solution", presumably containing $(\eta^6\text{-}C_6H_6)Mo(\eta^3\text{-}C_3H_5)(\mu\text{-}Cl)_2AlClEt$, with propene to ultimately afford a 2,4-hexadiene complex via formation of an intermediate containing coordinated 1,5-hexadiene [20]. The proposed bis(allyl) Mo(IV) intermediate, i.e.$[(\eta^6\text{-}C_6H_6)Mo(\eta^3\text{-}C_3H_5)_2(C_3H_7)]^+$, however, was not directly observed. More recently, the reaction of the metal-metal bonded $Mo_2(\mu\text{-}\eta\text{-}C_3H_5)_2(\eta\text{-}C_3H_5)_2$ complex with CO was shown to produce $Mo(CO)_6$ and 1,5-hexadiene, via an isolable $Mo(CO)_4(\eta^4\text{-}1,5\text{-hexadiene})$ intermediate [21]. The corresponding reaction of $Mo(\eta^3\text{-}C_3H_5)_2(PMe_3)_3$ with CO yields $Mo(CO)_2(PMe_3)_4$ and 1,5-hexadiene [22].

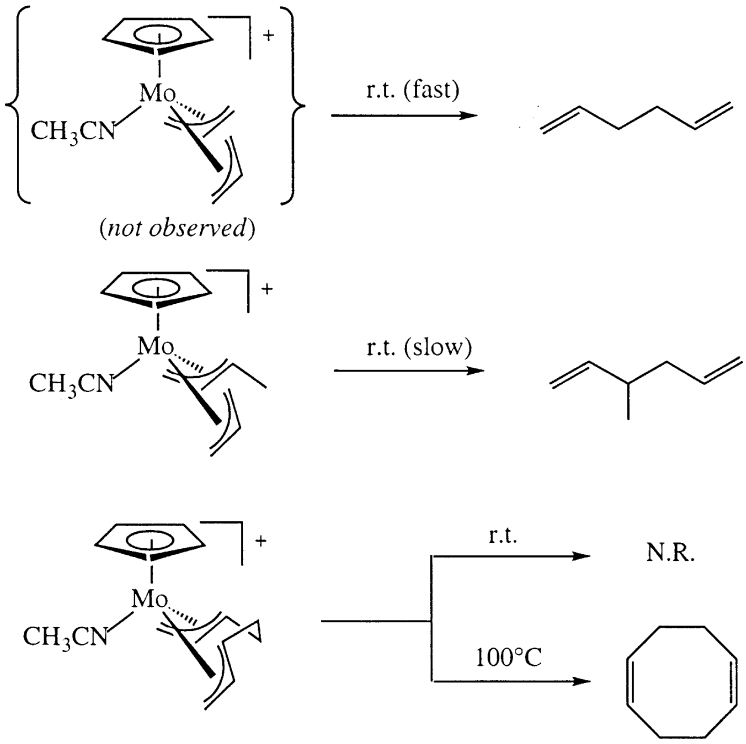
No allyl-allyl coupling process has been described for Mo(III) complexes. A spontaneous coupling has

been reported to occur upon ligand addition to the Cr(III) complex $CpCr(\eta^3\text{-}C_3H_5)_2$ [23], while the corresponding Mo complex **3** does not undergo a similar process under mild conditions [6–8], in accord with the expected greater stability of the heavier metal in the higher oxidation state. In fact, while σ-donor ligands do not react with **3**, π acidic ligands induce a reductive process with loss of an allyl radical, rather than an allyl-allyl coupling, as discussed in the previous section. When compound **3** is heated in the σ-donor solvent MeCN, however, the allyl-allyl coupling becomes possible, paralleling the reactivity of the chromium analogue.

It may be questioned whether the formation of 1,5-hexadiene during the thermal decomposition of **3** in MeCN derives from a truly metal-assisted allyl-allyl coupling or from the coupling of free allyl radicals in solution after elimination of the latter from the coordination sphere. We have not been able to find previous studies of the allyl radical reactivity in the presence of MeCN. We note, however, that the H-allyl bond is stronger than the $H\text{–}CH_2CN$ bond (89 ± 1 and 82.3 kcal/mol, respectively) [24]. This suggests that the allyl radical should preferentially abstract a H atom from the large excess of MeCN and generate propene. The ^1H NMR monitoring of the decomposition reaction shows the predominant formation of the coupling product (1,5-hexadiene:propene = ca. 2:1), in agreement with the proposed direct allyl-allyl coupling. A thermal allyl radical elimination, however, may be competing and be responsible for the formation of propene.

Even more rapid (instantaneous at room temperature) is the elimination of 1,5-hexadiene upon oxidation of **3**. No formation of propene is observed under these conditions. A hypothetical $[CpMo(\eta\text{-}C_3H_5)_2(S)]^+$ intermediate probably forms first, but its lifetime must be very short because it was not spectroscopically observed neither in acetone nor in MeCN. It is interesting to compare this rapid C–C coupling process with our previous findings in bisallyl Mo(IV) chemistry (Scheme 2). Complex $[CpMo(\eta\text{-}C_3H_5)(\eta\text{-}C_3H_4Me)(MeCN)]^+$, which is generated by HBF_4 protonation of **1c** in MeCN, is sufficiently stable to be observed in solution at room temperature but slowly decomposes by the same C–C coupling process in a regioselective manner to afford 3-methyl-1,5-hexadiene [3]. Complex **9**, on the other hand, is perfectly stable in MeCN at room temperature, whereas it eliminates cyclooctadiene upon warming to 100°C. This elimination is also regioselective: no significant amount of the possible alternative coupling products (1,2-divinylcyclobutane and 4-vinylcyclohexene) is spectroscopically observed.

It is to be emphasized that we have no detailed information on the structure of the Mo(IV) bis-allyl materials, thus the mechanism of regiocontrol is open to speculation. Mo(IV) half-sandwich derivatives adopt pseudo-octahedral geometries with one (axial) ligand trans to the Cp and four (pseudo-equatorial)



Scheme 2.

ligands slightly deviating from the perpendicular plane away from the bulkier Cp ligand [25–29]. The X-ray structure of an isoelectronic $CpMo(CO)Br_2(\eta^3$-C_3H_4-2-Me) has pseudo-equatorial Br and CO ligands, whereas the allyl ligand formally occupies one pseudo-equatorial and the pseudo-axial positions [30]. On the basis of the above information, we presume that the structures of the bisally Mo(IV) derivatives are as drawn in Scheme 2.

A product of allyl-allyl coupling containing a coordinated 1,5-hexadiene is sufficiently stable and can be observed spectroscopically when the oxidation of **3** is carried out in Bu^tNC (compound **7**). Interestingly, the 1,5-hexadiene ligand remains coordinated in a η^2 (monodentate) fashion to the metal center, rather than as a η^2:η^2 (chelating) ligand or being eliminated from the coordination sphere under the large excess of Bu^tNC which is present. No spectroscopic evidence was obtained for the intermediacy of a chelating hexadiene complex, which is presumed to form as shown in Scheme 3. The coordination mode is probably dictated by the electronic requirements of the metal and the balance between σ-donation and π back-donation, a situation which is commonplace in the chemistry of carbonyl complexes. Strain in the chelated intermediate may also be responsible for the observed outcome of the reaction.

When the oxidation of **3** is carried out in the presence of excess butadiene, a similar coupling mechanism presumably takes place (Scheme 4), leading to the formation of a mixture of **9** and **10** after treatment with CD_3CN. The formation of these two products can be understood on the basis of our previous studies: coordination of two butadiene ligands in the *s-trans* mode leads to C–C coupling; coordination of one *s-trans* and one *s-cis* ligands leads to the stable **2**; finally, coordination of two *s-cis* ligands does not occur [3]. Complex **2** is known to exchange the *s-trans* butadiene ligand upon dissolution in acetonitrile [3].

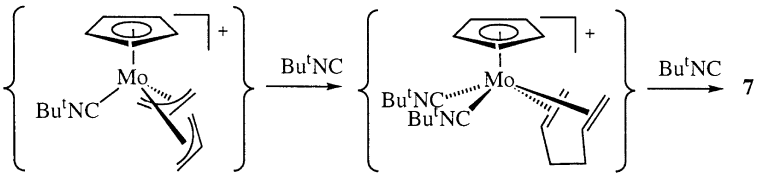
(*c*) *Electrophilic reactivity of* Mo(III)-*bonded allyl ligands*

The protonation of the allyl ligands in compound **6** to generate 2-pentene isomers (eq. (5)) demonstrates that Mo(III)-coordinated allyl ligands are sufficiently electron-rich to be subjected to electrophilic attack by protons. The absence of any 1-pentene among the reaction products shows that the proton attacks regioselectively the unsubstituted terminal allyl position, in agreement with the electron-releasing effect of the alkyl substituent. This result is identical to what we have observed for the protonation of *syn*-1-ethylallyl in the Mo(II) complex $CpMo(\eta^4$-$C_4H_6)(\eta^3$-*syn*-C_3H_4-1-Et) [4]. In that case, only *trans*-2-pentene was obtained from the *syn*-ethylallyl ligand. Therefore, the results of the protonation of **6** indicates that this is a mixture of *syn*- and *anti*-ethylallyl isomers, with a prevalence for the *anti* isomer. This, in turn, indicates that the alkylation of the *s-cis-supine* butadiene ligand is followed by partial (either for thermodynamic or kinetic reasons) isomerization of the resulting *anti*-allyl ligand to the *syn* isomer (see Scheme 5).

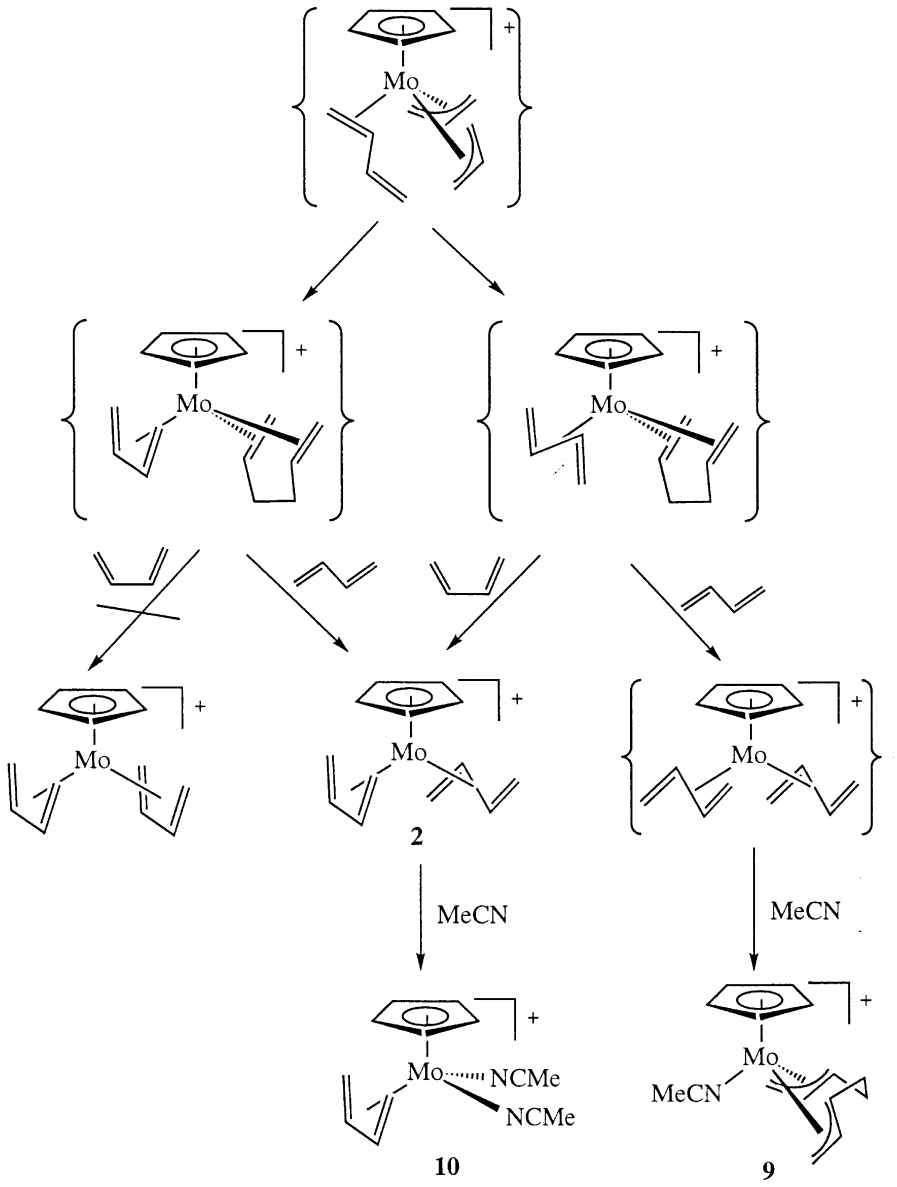
CONCLUSIONS

The reactivity of allyl and diene ligands coordinated to paramagnetic Mo(III) centers has been explored for the first time. A variety of transformations have been established, including electrophilic addition to the allyl ligand, nucleophilic addition to the butadiene ligand, allyl-allyl coupling, metal reduction by single-electron transfer or via allyl radical elimination, and metal oxidation. A few pathways have been compared with those in analogous complexes of Cr(III), Mo(II) and Mo(IV). The observed patterns can be summarized as follows:

1. While allyl-allyl coupling occurs spontaneously at room temperature in $CpCr(\eta^3$-$C_3H_5)_2$ [23], it takes place only at higher temperatures for the Mo(III) compound **3**.
2. The σ-donor/π-acceptor Bu^tNC ligand induces reduction of both **3** and $[\mathbf{1b}]^+$ at room temperature, with loss of an allyl radical and formation of 18-electron Mo(II) products.
3. The stronger σ-donor ligand LiMe induces a one-electron reduction process on $[\mathbf{1b}]^+$, to produce the parent complex **1b**.
4. While nucleophilic addition of Me^- to a *s-cis*-coordinated butadiene ligand is not observed for the Mo(II) complexes **1a**, **1b** and **2**, it does occur for the Mo(III) complex $[\mathbf{1b}]^+$, although it does not compete effectively with the preferred reduction pathway.



Scheme 3.



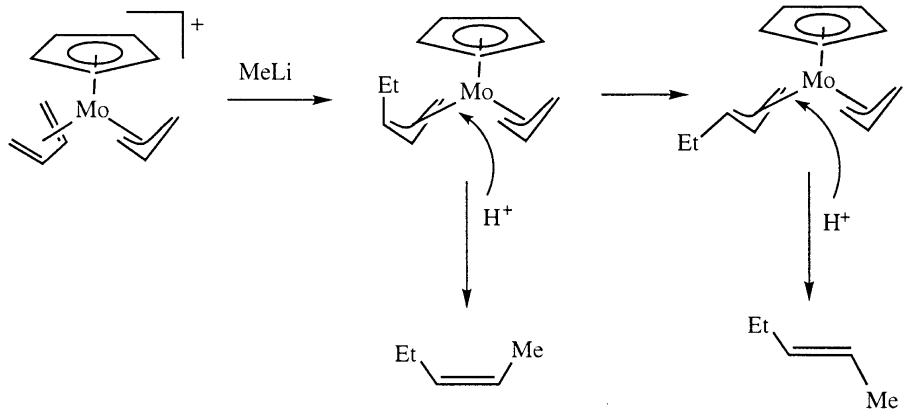
Scheme 4.

5. Protonation of the Mo(III)-bonded allyl ligands in **6** by strong acids parallels the protonation of allylmolybdenum(II) complexes, with the generation of olefins. The protonation of 1-ethylallyl occurs regioselectively to generate 2-pentenes.
6. The allyl-allyl coupling reaction is greatly accelerated by oxidation to Mo(IV). The rate of this coupling process is greatly affected by the substitution at the allyl carbons. Regioselectivity is observed for substituted allyl ligands, with the η^3:η^3-1,1′-$C_3H_4CH_2CH_2C_3H_4$ ligand giving rise to cyclooctadiene as the sole coupling product.

EXPERIMENTAL PROCEDURE

General Procedures

All operations were carried out by standard Schlenk-line techniques under a dinitrogen atmosphere. Solvents were dried by conventional methods (THF and Et_2O on Na/benzophenone, toluene and heptane on Na, CH_2Cl_2 on P_4O_{10}) and distilled directly from the drying agent under dinitrogen. All routine NMR experiments were carried out on a Bruker AM400 or WF 200 spectrometers. The ^1H and ^{13}C NMR data of



Scheme 5.

all compounds are given in Table 1. Other spectrometers used were as follows: EPR, Bruker ER200; IR, Perkin-Elmer FTIR 1600; MS, VG 7070E. Elemental analyses were performed by Atlantic Microlab, Inc. or the analytical service at the LSEO, Dijon. Compounds $CpMoCl_4$ [11] and [**1b**][PF_6] [2] were prepared according to the literature.

Preparation of $CpMo(\eta\text{-}C_3H_5)_2$, **3**

To a diethyl ether solution of allylmagnesium chloride (66 mL, 1 M, 66 mmol) was added 60 mL of THF at $-78^{\circ}C$. Solid $CpMoCl_4$ (4.5 g, 14.9 mmol) was added to the solution over 15 min, causing the precipitation of a yellow solid. The suspension was stirred for 1 h at $-78^{\circ}C$ and then an additional hour at $0^{\circ}C$. All solvent was evacuated and the solid was dried overnight under vacuum. The product was extracted with heptane (2×100 mL), each washing being stirred for 1 h to ensure maximum extraction. The combined filtered extracts were evaporated to dryness under reduced pressure. The residue was redissolved in 150 mL of heptane, leaving a small amount of undissolved grey solid which was filtered off. The solvent was removed again by evaporation and the residue

Table 1. ^{1}H-NMR data

(a) C_6D_6; (b) acetonitrile-d_3.

was recrystallized from heptane at $-80^{\circ}C$, yielding a violet microcrystalline solid which was dried under vacuum for 2 h (yield 1.6 g, 44%). Anal. Calcd for $C_{11}H_{15}Mo$: C, 54.32; H, 6.17. Found: C, 54.05; H, 6.04. The solid has a dichroic behavior. Powder and small crystals appear violet to reflected light but orange to transmitted light. Larger crystals are orange as previously reported [6]. The solid is extremely air sensitive, turning immediately black upon exposure to the laboratory atmosphere. EPR (THF, $-100^{\circ}C$): $g = 2.032$, $a_{Mo} = 33$ G, $a_{4H} = 6.6$ G, $a_{4H} = 3.3$ G. EPR (THF or benzene, room temperature): broad singlet at $g = 2.028$ with Mo satellites, $a_{Mo} = 33$ G.

Reaction of 3 *with* tert-*butyl isocyanide. Formation of* CpMo(*supine*-η-C_3H_5)($CNBu^t$)$_2$, **4**

Compound **1** (10 mg, 41 μmol) was placed in a NMR tube together with 250 μL of Bu^tNC. Standing at room temperature overnight yielded a maroon solution. The excess of *tert*-butyl isocyanide was removed under reduced pressure and 0.5 mL of C_6D_6 was added. The ^1H NMR spectrum showed the formation of compound **4**, while the EPR spectrum indicated the presence of the unreacted starting complex **3**. The separation of these two complexes was not successful. When the experiment was repeated with longer standing in Bu^tNC, decomposition of **4** occurred to generate another species with the Cp resonance at δ 5.36 in C_6D_6 and another resonance at δ 1.30, assigned to Bu^t groups. No allyl resonances are observed for this species.

Reaction of [1b][PF_6] *with* tert-*butyl isocyanide. Formation of* [CpMo(*supine*-η-C_4H_6)($CNBu^t$)$_2$][PF_6], **5**

Compound [**1b**][PF_6] (10 mg, 25 μmol) was mixed with Bu^tNC (100 μL, 0.885 mmol) in a NMR tube. Upon heating to $60^{\circ}C$ for 10 min, a yellow solution was formed, accompanied by a black precipitate. The solution was centrifuged and the supernatant was transferred into another NMR tube via cannula. After removal of excess tert-butylisocyanide under reduced pressure, a yellow oil was obtained. A ^1H NMR spectrum in $CDCl_3$ showed resonances at δ 5.56 (*m*, 2H), 5.10 (*s*, 5H), 2.32 (*d*, 2H), 1.45 (*s*, 18H), 1.00 (*d*, 2H), which are attributed to the cation of **5** by comparison with the literature [3], in addition to two unidentified species with the Cp resonances at δ 5.03 and 4.96. Integration showed a 61:16:23 ratio of the three products. No EPR active species were detected.

Reaction of [1b][PF_6] *with MeLi. Formation of* CpMo(η-C_3H_5)(η-C_4H_6), **1**, and CpMo(η-C_3H_5)(η-C_3H_4Et), **6**

Compound [**1b**][PF_6] (60 mg, 0.15 mmol) was suspended in 20 mL of THF. MeLi (107 μL, 1.4 M in Et_2O, 0.15 mmol) was added by syringe, causing the formation of a red solution. After stirring at room temperature for 1 h, all solvent was removed by evaporation under reduced pressure and the residue was extracted with 20 mL of heptane. After filtration, the solution was evaporated to dryness under reduced pressure, giving a red solid (yield 25 mg). The ^1H NMR spectrum in C_6D_6 showed resonances of Cp at δ 4.10 and 4.27 in a ca. 4:1 ratio, which are attributed to CpMo(*supine*-η-C_3H_5)(*supine*-η-C_4H_6) (**1b**) and CpMo(*prone*-η-C_3H_5)(*supine*-η-C_4H_6) (**1a**), respectively, by comparison with the literature [2]. Continued monitoring of this solution showed the slow conversion of **1b** to **1a** according to the previous report [2]. An EPR study of the C_6D_6 solution showed an unresolved multiplet resonance at $g = 2.033$, $a_{Mo} = 33$ G, which is assigned to compound **6**. Double integration of the EPR resonance against that of the starting material gives a 4% yield of the paramagnetic species.

Protonation of the mixture of CpMo(η-C_3H_5)(η-C_4H_6) (**1a** and **1b**) *and* CpMo(η-C_3H_5)(η-C_3H_4Et), **6**

The mixture of complex **1** and **6** obtained by the procedure described in the previous section (10 mg) was dissolved in 0.5 mL of C_6D_6 in an NMR tube. $HBF_4 \cdot Et_2O$ (10 μL, excess) was added, causing the immediate formation of a grey precipitate. The supernatant was transferred into another NMR tube by vacuum condensation. The ^1H NMR spectrum showed the formation of both *cis*-2-pentene and *trans*-2-pentene with a ratio of ca. 2:1, in addition to the signals of propene. The products were identified by analysis of the olefinic proton resonances, in comparison with those reported in the literature [31]. The other aliphatic resonances overlap extensively. ^1H NMR of *cis*-2-pentene (δ, C_6D_6): 5.37 (m), 1.95 (m), 1.55 (m), 1.08 (overlap with large Et_2O resonance). ^1H NMR of *trans*-2-pentene (δ, C_6D_6): 5.47 (*m*, 2H), 1.95 (*m*), 1.55 (*m*), 1.08 (overlap with large Et_2O resonance). ^1H NMR of propene (δ, C_6D_6): 5.70 (*m*, 1H), 4.99 (*dm*, 1H), 4.93 (*dm*, 1H), 1.53 (overlap). No other resonances that could be attributed to a vinyl group (e.g. of 1-pentene) could be observed.

Reactions of **3** *with ferrocenium hexafluorophosphate*

1. In acetone-d^6. Compound **3** (10 mg; 42 μmol) and $Cp_2Fe^+PF^-{}_6$ (14 mg; 42 μmol) were mixed in an NMR tube, to which 0.5 mL of CD_3COCD_3 was added. The formation of 1,5-hexadiene (δ 5.79, *m*, 2H; 4.95, *m*, 4H; 2.07, *m*, 4H) and ferrocene (δ 4.15, s) were detected by ^1H NMR. No significant amount of other species was found by ^1H NMR.
2. In acetonitrile-d^3. CpMo(*supine*-η-C_3H_5)$_2$ (5 mg, 21 μmol) and $Cp_2Fe^+PF_6^-$ (7 mg, 21 μmol) were placed in an NMR tube, to which 0.5 mL of CD_3CN was added. The ^1H NMR spectrum of the

resulting solution showed the formation of 1,5-hexadiene (δ 5.83, *m*, 2H; 4.97, *m*, 4H; 2.13, *m*, 4H) and ferrocene (δ 4.15, s) in a ca. 1:1 ratio. No significant amount of other species was detected by ^{1}H NMR, while the EPR spectrum showed several resonances with no discernible coupling pattern.

Reaction of **3** *with ferrocenium hexafluorophosphate in* tert-*butyl isocyanide. Formation of* [CpMo(CNBu^t)$_3$(η^2-CH$_2$=CHCH$_2$CH$_2$CH=CH$_2$)][PF$_6$], **7**, *and* [CpMo(CNBu^t)$_4$][PF$_6$], **8**

1. NMR tube reaction. Compound **3** (12 mg; 49 μmol) and $Cp_2Fe^+PF_6^-$ (17 mg; 51 μmol) were placed in an NMR tube, to which 100 μL of Bu^{t}NC was added by syringe. The mixture was vigorously shaken for 15 min. C_6D_6 (0.5 mL) was then added, yielding a yellow solution. Two species with Cp signals at δ 4.85 (complex **7**) and 5.03 (complex **8**) in a ca. 2:1 ratio were observed by ^{1}H NMR.
2. Isolation of compound **8**. Compound **3** (200 mg; 0.82 mmol) and $Cp_2Fe^+PF_6^-$ (272 mg; 0.82 mmol) were mixed in a Schlenk tube, to which 2 mL of Bu^{t}NC was added. The mixture was stirred at room temperature for 0.5 h, giving a yellow suspension. The excess Bu^{t}NC was completely removed by evaporation under reduced. Benzene (10 mL) was added to the yellow residue, and the resulting suspension was stirred for 1 h. The supernatant was decanted and the yellow solid was recrystallized from THF (5 mL) at -80°C, to yield a bright yellow crystalline solid which was recovered by filtration and dried under vacuum for 0.5 h (yield 85 mg, 15%). *Anal.* Calcd for $C_{25}H_{41}N_4MoPF_6 \cdot 0.75C_4H_8O$: C, 48.56; H, 6.84. Found: C, 48.31; H, 6.80. The THF of solvation was observed in the ^{1}H NMR spectrum in the correct integrated intensity. IR (Nujol, cm^{-1}): 2162 m, 2096 s, 2050 s, 841 s (PF6). Low resolution mass spectrum (FAB$^+$): m/z 495 [CpMo(CNBu^t)$_4$]$^+$, 100%.

Reaction of **3** *with ferrocenium hexafluorophosphate in THF/butadiene. Formation of* [CpMo(η^3:η^3-C$_3$H$_4$CH$_2$CH$_2$C$_3$H$_4$)(CD$_3$CN)PF$_6$], **9** *and* [CpMo(*supine*-η-C$_4$H$_6$)(CD$_3$CN)$_2$][PF$_6$], **10**

Complex **3** (ca. 10 mg) and 14 mg of $Cp_2Fe^+PF_6^-$ were placed in a Schlenk flask. Butadiene (ca. 5 mL) was condensed at -196°C. After stirring for 0.5 h at -78°C, THF (5 mL) was added and the mixture was stirred at room temperature for an additional 0.5 h. All volatiles were removed under reduced pressure and heptane (10 mL) was added to the residue. An orange-red extract containing ferrocene, as shown by ^{1}H NMR, was filtered off. The residue was dried under vacuum and then redissolved in 0.5 mL of CD$_3$CN. A ^{1}H NMR spectrum showed the formation of two major products in a 2.5:1 ratio. These have been identified as the cations of **9** and **10**, respectively, by comparison with the NMR spectra reported in the literature [3]. These two main products are accompanied by several additional Cp containing by-products, whose overall integrated intensity is $<30\%$ of the total.

Thermal treatment of compound **9** *in* CD$_3$CN

The NMR tube containing the CD$_3$CN solution of **9** and **10** obtained as described in the previous section was flame-sealed. The solution was heated to 100°C for 1 h and monitored by ^{1}H NMR spectroscopy. The formation of octa-1,5-diene [δ 5.53 (*br*, 4H), 2.33 (*br*, 8H)] was observed in 75% spectroscopic yield relative to the initial amount of **9**. Resonances attributable to free butadiene were also observed. No resonances attributable to Cp containing Mo products were observed.

Thermal treatment of complex **3** *in* CD$_3$CN

Complex **3** (15 mg) was placed in an NMR tube with 0.5 mL of CD$_3$CN. The tube was flame-sealed and heated to 100°C in an oil bath for 1 h. A ^{1}H NMR spectrum showed the formation of hexa-1,5-diene (CH$_2$=CH–C*H*$_2$C*H*$_2$–CH=CH$_2$ resonance at δ 2.14) and propene (CH$_2$=CH–C*H*$_3$ resonance at δ 1.70, doublet with $J = 6.1$ Hz) in a ca. 2:1 ratio, plus small amounts ($<20\%$) of other unidentified species, the major component of which shows a C*H*$_3$ resonance at δ 1.46 (*d*, $J = 5.1$ Hz).

(Received 16 February 1998; accepted 8 April 1998)

Abstract—The reactions of [2-(pyridin-2′-yl)phenyl]mercury(II) acetate with 2-formyl-benzene-(Hbtsc), 2-formyl-(2-hydroxybenzene)-(H_2stsc) and 2-formyl-(4-methoxybenzene)-(Hmbtsc) thiosemicarbazones in ethanol in 1:1 ratio at room temperature formed [Hg($C_6H_4C_5H_4N$)L] (L = btsc, **1**; Hstsc, **2**; mbtsc, **3**). The derivative [Hg($C_6H_4C_5H_4N$)L] **2** crystallises in the triclinic space group P/1 (n. 2), $Z=2$, $R=0.0353$ and $V=906.8(3)$Å^3. Mercury is bonded strongly only to sulphur atom of thiosemicarbazonate anion [Hg–S, 2,357(2)Å] and Hg...N(3) distance of 3.126(6)Å, slightly less than the sum of the van der Waal's radii (3.28 Å) shows a weak interaction. The pyridyl nitrogen binds strongly to Hg [Hg–N(4), 2.575(6)Å] with a short C(9)HgN(4) bite angle of 74.6(2)°, but Hg retains near linearity in C_{Ph}HgS bond angle [177.8(2)°]. ^{1}H and ^{199}Hg NMR spectra in $CDCl_3$ solution reveal two isomers (A and B) for each of **1–3** and probably also a third isomer (C) for **2**. The similarity of ^{1}H and ^{199}Hg data of B isomers (minor for **1** and **3**; major for **2**) clearly support that thiosemicarbazones are unidentate S-donors as established for crystallized B isomer of **2** (major) by X-ray study, with pyridyl nitrogen of 2-pyridylphenyl coordinating to Hg. The A isomers (major for **1** and **3**; minor for **2**) have presumably N^3,S-coordinated thiosemicarbazonates with weak Hg–N(pyridyl) interaction and the Hg atom formally tetracoordinated. © 1998 Elsevier Science Ltd. Keywords: Mercury Complexes; Arylmercury Complexes; Thiosemicarbazone Complexes; Crystal Structure.

The cleavage of one or more C–M bonds (M=Al, Ga, In, Tl, Pb or Sn) using acids such as dithiophosphorus acids [$X_2P(S)SH$, X = R, OR, R = Et, Ph, etc.] or trifluoroacetic acid leads to the protodemetallation reactions forming the corresponding dithiophosphinates, dithiophosphates or trifluoroacetates and the hydrocarbons [1–6]. Such cleavage reactions have recently generated acute interest in the activation of C–Hg bonds and their subsequent cleavage to generate parent hydrocarbons and inorganic mercury(II) [7–9] on the pattern of protodemercuriation of organomercury(II) substrates by organomercury lyase enzymes which are believed to form enzyme-substrate intermediates (via cysteine SH groups) [10, 11].

The coordination chemistry of particularly, transition metals with heterocyclic thiones or thiosemicarbazones containing active –N(H)–C(S)– chromophore has been widely explored [12, 13], the corresponding interaction of such organic substrates with organomercury(II) salts, a potential area of interest, has been scarcely investigated [12, 14–16]. As a part of our interest to study the cleavage of C–M bonds (protodemetallation reactions [6, 11]) and activation of such bonds by coordination with organic substrates containing –N(H)–C(S)– chromophores, recently deprotonation reactions of 2-thiouracil with

phenylmercury(II) and pyridinephenyl-mercury(II) [15, 16] and of cyclopentanonethiosemicarbazone with methylmercury(II) [14] have been described.

In this paper, we report the results of deprotonation reactions of 2-formyl-benzene- (hereafter Hbtsc), 2-formyl-(2-hydroxybenzene)-(hereafter H_2stsc) and 2-formyl-(4-methoxybenzene)-(hereafter Hmbtsc) thiosemicarbazones (Scheme 1) with [2-(pyridin-2′-yl)phenyl]mercury(II) acetate in ethanol.

EXPERIMENTAL

General materials and instrumentation

Thiosemicarbazide (Merck, Muchen), benzaldehyde (Probus, Barcelona), salicylaldehyde (Merck, Munchen) and p-methoxybenzaldehyde (Ega-Chemie, Steinheim) were used as received.[2-(pyridin-2′-yl)phenyl]mercury(II) acetate was prepared by mercuration of 2-pyridylbenzene using mercury(II) acetate by a reported method [17]. The ligands were prepared by the literature methods [18].

The elemental analyses for C, H and N were obtained with a Carlo Erba 1108 microanalyser. The melting points were determined with a Gallenkamp electrically heated apparatus. The infrared spectra were recorded in KBr pellets (4000–400 cm^{-1}) or nujol mull in polythene sheets (500–100 cm^{-1}) on a Bruker IFS 66V spectrometer. The NMR spectra were recorded in $CDCl_3$ or $(CD_3)_2SO$ using a Bruker AMX 300 spectrometer at 300.14 MHz frequency (^1H) with TMS as the internal reference or a Bruker AMX 500 spectrometer at 89.51 MHz probe frequency (^{199}Hg) with neat Me_2Hg as external reference.

Syntheses

$$[Hg(C_6H_4C_5H_4N)(btsc)] \quad \textbf{(1)}$$

To a stirred solution of the ligand, Hbtsc (0.130 g, 0.73 mmol) in ethanol (25 ml) was added the solution of [2-(pyridin-2′-yl)phenyl]mercury(II) acetate (0.300 g, 0.73 mmol) in the same solvent (40 ml). The contents were stirred for 4 h and the light green solid was filtered, washed with EtOH and dried *in vacuo*; m.p. 138–42 (d) °C, yield, 52% (found, C, 42.39, H, 2.61, N, 10.03; required for $C_{19}H_{16}N_4SHg$, C, 42.78, H, 3.00, N, 10.51). It is partially soluble in $CHCl_3$, CH_2Cl_2, soluble in DMSO, DMF, and poorly soluble in EtOH and MeOH. It decomposes slowly in $CHCl_3$, and rapidly in DMSO or DMF.

$$[Hg(C_6H_4C_5H_4N)(Hstsc)] \quad \textbf{(2)}$$

To a solution of the ligand, H_2stsc (0.142 g, 0.73 mmol) in 30 ml of ethanol was added the solution of [2-(pyridin-2′-yl)phenyl]mercury(II) acetate (0.300 g, 0.73 mmol) in 20 ml of ethanol and the contents were stirred for 20 h. The light yellow solid was filtered, washed with ethanol and dried *in vacuo*; m.p. 165–70 (d) °C, yield, 73% (found, C, 41.04, H, 3.04, N, 10.15; required for $C_{19}H_{16}HgN_4OS$, C, 41.53, H, 2.91, N, 10.20).

It is partially soluble in $CHCl_3$, CH_2Cl_2, ethanol, methanol but soluble in DMSO and DMF. The decomposition behaviour in solution is similar to that of **1**.

$$[Hg(C_6H_4C_5H_4N)(mbtsc)] \quad \textbf{(3)}$$

To a stirred solution of the ligand, Hmbtsc (0.252 g, 1.20 mmol) in ethanol (20 ml) was added the solution of [2-(pyridin-2′-yl)phenyl]mercury(II) acetate (0.500 g, 1.20 mmol) in ethanol (20 ml). The contents were stirred for 30 h and the light green solid was filtered, washed with ethanol and dried *in vacuo*; m.p. 130–35°C (d), yield, 65% (found, C, 41.01, H, 3.13, N, 9.56; required for $C_{20}H_{18}N_4OSHg$, C, 42.63, H, 3.20, N, 9.95). It is partially soluble in $CHCl_3$, CH_2Cl_2, poorly soluble in ethanol and methanol and soluble in DMSO, where decomposes rapidly and more slowly in $CHCl_3$.

Crystallography

The light yellow crystals of **2** were grown from a mixture of $CH_2Cl_2/CHCl_3/CH_3OH$ and its ^1H NMR spectrum was identical with that of the major isomer labelled B (vide infra). A prismatic crystal of dimensions 0.1 × 0.30 × 0.40 mm was mounted in an ENRAF-NONIUS MACH3 automatic diffractometer [19]. Unit cell dimensions along with other crystal, data collection and refinement data are listed in Table 1. Data were collected at 293 K using a ω scan technique. Intensities of reflections were corrected for

$$R = N^3 - N^2(H) - C^1(S) - N^1H_2.$$

Lorentz and polarization effects [20]. Empirical absorption corrections were applied as reported [21].

The structure was solved using direct methods [22] which revealed the positions of all non-hydrogen atoms and refined on F^2 by full matrix least-squares procedure using anisotropic parameters for all non-hydrogen atoms [23]. The hydrogen atoms were included in the model on geometrically calculated positions (C–H = 0.93–0.96 Å).

Atomic scattering factors were taken from International Tables for X-ray Crystallography [24], while molecular graphics were done using ZORTEP and SCHAKAL [25].

RESULTS AND DISCUSSION

The aryl thiosemicarbazones (Scheme 1) deprotonate the most acidic hydrazinic (–NH–) proton on reaction with [2-(pyridin-2′-yl)phenyl]mercury(II) acetate in ethanol at room temperature forming [2-(pyridin-2′-yl)phenyl]mercury(II) thiosemicarbazonates, [Hg(PyPh)L] **(1–3)** where L represents deprotonated thiosemicarbazone and these are characterised with the help of analytical data, infrared and NMR spectroscopy and compound **2** using single crystal X-ray crystallography. The compounds are light green (**1** and **3**) and light yellow (**2**), stable in solid phase, have partial solubility in general organic solvents and finally decomposes rapidily in DMSO or DMF, but slowly in other solvents.

The crystal and molecular structure of [*Hg*($C_6H_4C_5H_4N$)(Hstsc]

Figure 1 shows the SCHAKAL drawing of [Hg($C_6H_4C_5H_4N$)(Hstsc] (**2**) and the atom numbering scheme used; selected bond distances and angles are listed in Table 2.

The crystal structure consists of discrete molecular units of **2** and there are no close intermolecular contacts in the lattice (Fig. 2). The geometry about Hg center is distorted T-shaped with thiosemicarbazonate anion, Hstsc$^-$, coordinating essentially via S atom leading to a nearly linear C(9)–Hg–S bond angle [C(9)–Hg–S, 177.7(2)°] and Hg–N(Py) bond [bite C(9)–Hg–N(4) = 74.6(2)°] is distorted from being at expected 90° angle for undistorted T-shaped molecule [26]. The C(9)HgS angle in **2** is higher than in methyl-(cyclopentanonethiosemicarbazonate)mercury(II) [**4**, C–Hg–S, 167,7°] [14] and the difference is attributed to N^3,S-chelation in **4** [Hg–N(3), 2.537(8), Hg–S = 2.380(3) Å] [14] and unidentate S-bonding [Hg–S, 2.357(2) Å] in **2** with very weak Hg...N(3) interaction

[Hg–N(3), 3.126(6) Å], only sligtly less than the sum of the van der Waals radii (3.28 Å) [27]. Hg–S distances are comparable in two cases, though as anticipated it is shorter in **2** than in **4**.

Table 3 shows the angles between various planes and it can be seen that the plane III of thiosemicarbazonate moiety (except N(1)) is at an angle of 76.3° with plane II containing pyridylphenyl moiety chelated to Hg. Further, phenyl and pyridyl rings are not coplanar (13.4°) as nearly are plane II and the coordination plane I (5.9°). Non-planarity of pyridyl and phenyl rings has been observed in related compounds $[\{Hg(C_6H_4C_5H_4N)_2\}_2(tuc)]$ (H_2tuc = 2-thiouracil) [16], $[Hg(C_6H_4C_5H_4N)_2]$ [17], $[Hg(C_6H_4C_5H_4N)(OAc)]$ [28] and $[Hg(C_6H_4C_5H_4N)(Cl)]$ [29].

The unidentate S-bonding by $Hstsc^-$ anion is probably influenced by Hg–N(Py) intramolecular coordination and this bond length [Hg–N(4), 2.576(6) Å] is indeed comparable with Hg–N(3) distance in N^3,S-chelation in **4**. The lack of similar N(3)–Hg coordination in **2** could be the effect of strong intramolecuar O–H...N(3) hydrogen bonding [O...N(3), 2.647(7) Å; the sum of van der Waals radii, 3.05 Å [30]; N(3)...H(O) = 1.867 Å, O–H, 0.78 Å], which weakens Hg–N(3) interaction considerably [Hg...N(3), 3.126(6) Å]. This hydrogen bond is of the same order as in the free H_2stsc ligand [N(3)...O = 2.664(3) Å, N(3)...H(O) = 1.96(3) Å [31]]. Further, the conformational change of $Hstsc^-$ moiety from E configuration (free H_2stsc) to Z-configuration (Scheme 2) as in complex **2** is necessitated by both weak Hg...N(3) interaction and relatively strong O...N(3) interaction.

The deprotonation of N(2) proton of H_2stsc and subsequent coordination to Hg via essentially S atom, affects significantly the bond distances: C(1)–S = 1.782(7), C(1)–N(1) = 1.352(8); C(1)–N(2) = 1.288(9) Å [free H_2stsc, C(1)–S = 1.689(4), C(1)–N(1) = 1.317(4), C(1)–N(2) = 1.346(4) Å] [31]. The lengthening of C(1)–S is higher in **2** than in $R_2Sn(stsc)$ [C(1)–S, 1.724–1.733 Å, R = Me, Ph, stsc is a dianion coordinating via O, N(3) and S donor atoms] [32] in agreement with strong Hg–S interaction.

The deprotonated thiosemicarbazones coordinate to a metal in the usual N^3,S-coordination mode [13, 14, 33], though one example of N(2), S-mode is also known [34]. The thiosemicarbazones with R groups containing 2-hydroxy benzene, pyridyl or similar other groups may coordinate also via additional donor atoms [13, 32, 35]. The unidentante S bonding by deprotonated $Hstsc^-$ in **2** represents an unusual coordination mode for main group and transition metals thiosemicarbazonate complexes, the only other

example being S-coordination in Ph_3SnL by a related deprotonated 2-acetyl-(2-hydroxybenzene) thiosemicarbazonate $[(2\text{-}HOC_6H_4)\text{–}C(CH_3)=N^3\text{–}N^2=C(NH_2)S^-]$ where steric bulk of Ph_3Sn moiety prevents N^3,S-coordination and the ligand retains E-configuration in the complex [36].

Table 4 gives a comparative data for some important bond lengths/angles of Hg-bonded 2-pyridylphenyl moiety. It is significant to observe that more electronegative donor atoms positioned trans to $Hg\text{–}C_{Ph}$ bond seems to shorten it (and probable deactivates the breaking of this bond) and *vice versa*. Thus, order of Hg–C bond activation appears to be: C > S > Cl > O (**5** > **6**, **2** > **7** > **8**) and consequently the study of Hg–S interactions gain significance. Hg–N(pyridyl) intramolecular coordination varies in more complicated manner. Despite the steric bulkiness of $Hstsc^-$ moiety, **2** shows the strongest Hg–N bond and this is attributed to more positional flexibility of $Hstsc^-$ with the result that the plane III makes an angle of 76.3° with plane II as discussed earlier. The CHgN bite angles are similar in **2**, **6**, and **7**, shortest in **5** and largest in **8**. The $C_{Ph}HgD$ bond angles (D=C, O, Cl, S) are similar in **2**, **7** and **8**, but shortest in **6**, imposed

Table 4. Selected bond lengths (Å) and bond angles (°) of related Hg-2-pyridylphenyl derivatives

probably by bridging requirements of 2-thiouracilate dianion (tuc^{2-}).

IR studies

The three complexes show IR bands due to the $Hg(C_6H_4C_5H_4N)$ fragment in practically the same position showing that in all the three the N atom of the pyridine ring is coordinated to the Hg as the X-ray study indicates it to be in **2**. Bands of this fragment around 1600 cm^{-1} difficult the analysis of the N(3)-coordination in **1** and **3**. As in other systems [32, 34] the S-coordination shifts to lower wavenumbers or induces an intensity decrease in ν(C=S) bands compared with the free ligand.

The slight shift to 3445, 3280 in **2** of the $\nu(NH_2)$ bands of the free ligand (3446, 3321 cm^{-1}) is common to the other complexes showing that the NH_2 group is not coordinated to Hg.

NMR studies

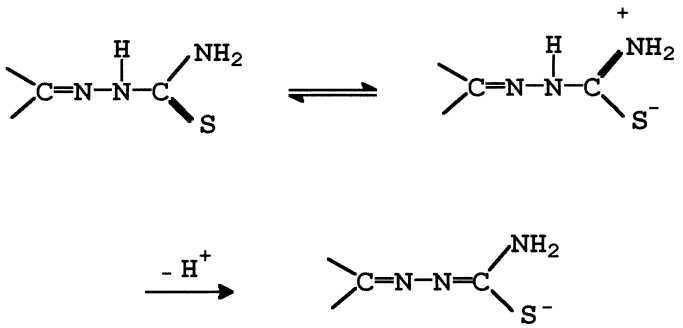
Transformation of the spectrum for the ligands under complexation is as usually: i) Spectrum of compounds **1–3** do not contain the signals due to the hydrazinic -N^2H- proton due to the deprotonation of arylthiosemicarbazones, ii) thioamidic protons [-$C(S)N^1H_2$] of the free thiosemicarbazones which show two signals at low-field (6.29–8.12 ppm) shift to the high (5.07–5.94 ppm) and merge to only one signal probably due to the reduction in the double bond character in C^1-N^1 after deprotonation of -N^2H- group (Scheme 3) and to disappearance of $N^3...H_2N^1$ hydrogen bonding when free thiosemicarbazones transform to Z-configuration in their complexes (Scheme 2). The aryl rings protons all show high-field shift and the resolution of most multiplets into clear signals is apparent.

A most interesting feature of these compounds is the existence of isomers labelled A and B. For **1** and **3**, isomers A are in major proportion (*ca* 70%, B, 30%), while for **2**, B isomer is major (*ca*. 90%; A, *ca*. 10%) (proportions were calculated from the integrals of $C^{11}H$, N^1H_2 or OH protons). Separated signals were identified for all except A isomer of **2**, for which only N^1H_2, C^2H and OH signals could be identified and others obscured by the major isomer B; however, for **1** and **3**, signals for A and B were clearly visible. Based on X-ray analysis of isomer B of **2** [being in higher proportion (90%), crystallised preferentially and for isomers **1** and **3** repeated efforts failed to give crystals] as well as similarity of ^{1}H and ^{199}Hg NMR (*vide infra*) data, similar structure for isomers of **1** and **3** is proposed. For A isomers of **1–3** ^{199}Hg NMR reveals clearly a different chemical enviroment about Hg center and N^3,S-chelation by thiosemciarbazonates is proposed as increasing coordination number in Hg generally decreases Hg chemical shift [37] (*vide infra*).

The ^{199}Hg NMR data of the compounds **1–3** is given in Table 5 and Fig. 3. Each compound showed two peaks differing in percentage, and for **2** second peak could be seen only when massive scans were taken. All the three compounds have one common isomer (B) at *ca.* $\delta -868$ ppm and it shows the similar chemical enviroment about Hg atom in these isomers. Since, the X-ray structure of **2** has established S-bonded thiosemicarbazonate ($Hstsc^-$), it can be argued that all the three compounds have one common S-bonded isomer, in addition to Hg–N(Py) and Hg–C_{Ph} bonds.

The major isomers (A) of **1** and **3** show δHg values at -715 and -709 ppm respectively indicating chemical enviroments about Hg in these isomers different from those in the isomers described above. It is known in case of Hg NMR spectroscopy that the increasing coordination number generally lowers the chemical shift [37] and that it is suggested that Hg in these isomers (A) have higher coordination number and thiosemicarbazonates are probably chelating via N^3,S-donor atoms, a usual mode of bonding of deprotonated thiosemicarbazones [13, 14]. The N^3,S-chelation by thiosemicarbazonates might affect Hg...N(Py) interaction by weakening it and it is confirmed by upfield shift in diagnostic $C^{11}H$ proton of 2-pyridylphenyl moiety of these major isomers (A) of **1** and **3**.

Minor isomer of 2 appears at -783 ppm, a different position from A isomers of **1** and **3**. Anomalous position for the signal of 2 may be due to $Hstsc^-$ which exhibits additional chelating possibilities respect to



Scheme 3.

[b] Major isomer.
[c] Minor isomer.
[d] $\delta OH = 11.26s$ ppm for B isomer and 12.00 ppm for A isomer.
[e] Assignement was not possible due to the very low percentage of this isomer together with the overlaping with the signals for the major isomer.
[f] $CDCl_3$ solvent.
[g] $(CD_3)_2SO$ solvent.

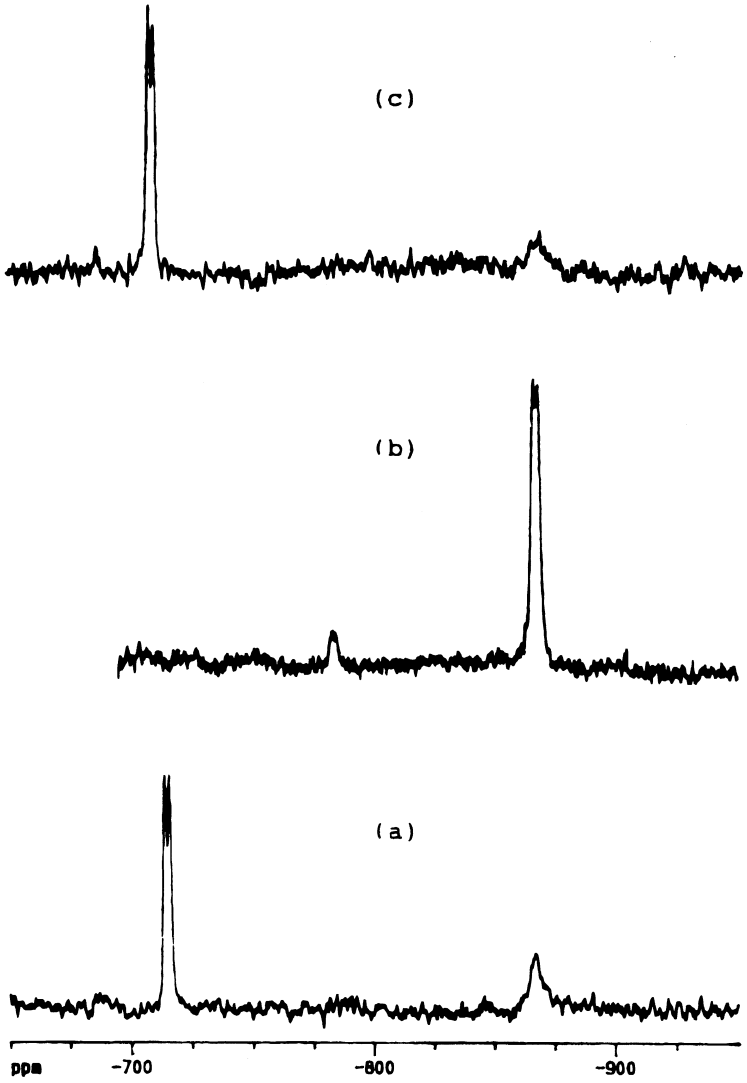

Fig. 3. The ^{199}Hg NMR spectra of (*a*) [Hg($C_6H_5C_5H_4N$)(btsc)] **1**, (*b*) [Hg($C_6H_5C_5H_4N$)(Hstsc)] **2** and (*c*) [Hg($C_6H_5C_5H_4N$)(mbtsc)] **3**.

btsc$^-$ and mbtsc$^-$ through phenolic O atom. This could originate a third isomer (C) with Hg coordinated to C^9, N^4, N^3 and O (previous proton transference, for example, from the OH group to N^2) and minor isomers (A) and (C) in a fast interchange are conceivable. Although the (C) isomer of 2 must be expected to have less importance than (A) (if both the mercury-sulphur affinity and the relationship between the chelating ring size and the stability are considered), its presence introduces an oxygen atom in the coordiantion sphere of the metal increasing the shielding [37].

Among the B isomers of compounds **1–3**, the $^3J_{Hg\text{-}H}$ coupling was observed in **2** only and that too after massive scans and the value is lower than $^3J_{Hg\text{-}H}$ value show by the major isomers (A) of **1** and **3**. It shows that the electron density on phenyl bonded to Hg is higher in the latter cases as compared to that in the former case. It can occur by both weakening of Hg...N(Py) interaction and/or by chelation of thiosemicarbazonates.

(Received 11 February 1998; accepted 20 April 1998)

Abstract—In the course of our efforts to synthesize rhenium(V) complexes for potential use in nuclear medicine, tridentate dithiolate ligands were combined with (dialkylamine) ethylene thiols [HS–$(CH_2)_2$–NR'_2] (R′ = alkyl, alkoxy) to form amine group bearing mixed-ligand complexes [ReO(SNS)(S)]. The reaction of HS–CH_2–CH_2–N–(CH_2–CH_2–N(C_2H_5)$_2$)CH_2–CH_2–SH (*N*,*N*-bis(2-mercaptoethyl)-*N*′,*N*′-diethylethylenediamine, **2**, as a tris-chelating ligand and 1,4-dioxa-8-azaspiro-*N*-2-mercaptoethylene-[4,5]-decane, **3**, with the neutral Re(V) complex [$ReOCl_3(PPh_3)_2$], **1**, yields, in addition to the expected square-pyramidal "**3**+**1**" compound (1,4-dioxa-8-azaspiro-*N*-2-thiolatoethylene-[4,5]-decane)*N*,*N*-bis(2-mercaptoethyl)(*N*′,*N*′-di-ethyl-ethylenediamine) oxorhenium(V), **4**, the new five-coordinated complex [1,4-dioxa-8-azaspiro-*N*-2-mercaptoethylene-[4,5]-decane(triphenylphosphinato)dioxorhenium(V)], **5**. Being the only product in the absence of the tridentate component, **5** has a trigonal–bipyramidal structure, where the coordination sphere is formed by two oxo groups in an uncommon *cis*-arrangement, S and N from the aminothiolate and by the phosphorus atom from the phosphine group originating from the precursor molecule. The structure was verified by mass, ^{1}H NMR, IR spectroscopy as well as by XRD. In addition, extended x-ray absorption spectroscopy (EXAFS) was applied to both the precursor and the resulting compound **5** to compare the complex structures in the solid and the soluted state. Experiments with ^{18}O labelled water added to the reaction mixture led to ^{18}O in the dioxo core, showing that water is the origin of the additional oxo group. © 1998 Elsevier Science Ltd. Keywords: rhenium(V) mixed ligand complexes; *cis*-dioxo; trigonal–bipyramidal; X-ray structure; XANES; EXAFS

INTRODUCTION

There is great interest in the chemistry of technetium and rhenium [1] because of the high significance that the radioactive nuclides ^{99m}Tc and ^{186}Re/^{188}Re have in nuclear medicine. Our special attention is focused on the so-called "3+1" mixed-ligand complexes, a class of compounds useful for the design of new radiotracer molecules [2, 3], where the MO^{3+} core is coordinated by both a tridentate and a monodentate ligand.

We were particularly interested in "3+1" com-

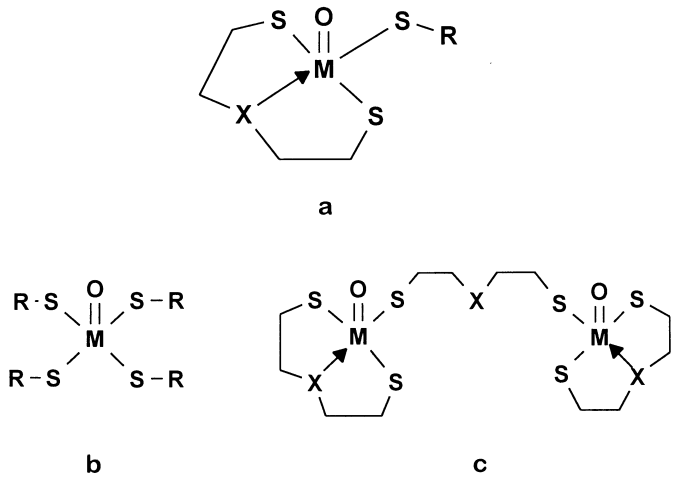

Fig. 1. A selection of known oxometal(V) complexes as the results of ligand exchange reactions on oxometal(V) precursors.

plexes in which dialkylaminothiolates are the monodentate ligands, since some of the "3+1" complexes are of interest with respect to brain imaging agents [4, 5] and play an important role in the search for neuroreceptor–affine complexes.

The involvement of two competing ligands in the formation of the mixed-ligand complexes gives rise to various species (Figure 1). Depending on the stoichiometric ratios of the ligands, not only the desired "3+1" compound (a) but also complexes of only the monodentate ligands having a formal S_4 coordination (b) [6] and dinuclear complexes (c) containing only the tridentate ligand may be formed [7, 8].

In order to optimize the reaction conditions for the preparation of such a complex **4** (Figure 2) by ligand exchange reactions, we studied the reaction of $[ReOCl_3(PPh_3)_2]$ (**1**) with the tridentate ligand [HS–$(CH_2)_2$–N(CH_2–CH_2NEt_2)–$(CH_2)_2$–SH] (**2**) [9, 10] and dialkylaminothiolates such as **3** Fig. 2. When the tridentate ligand was used as the minor compound versus one to one ratios of the dialkylaminothiolate and the metal precursor in reaction mixtures in order to avoid the formation of dinuclear bridged complex products, two compounds were obtained. One consists of the expected "3+1"-product **4** while the other is a hitherto unknown type of a *cis*-dioxorhenium(V) complex, **5**.

Here we describe the formation and structural characterization of these new compounds. Structure investigations in solution using EXAFS were performed in addition.

RESULTS AND DISCUSSION

Starting from *trans*-monooxotrichlorobis-(triphenylphosphine)rhenium(V) $[ReOCl_3(PPh_3)_2]$ (**1**) as a rhenium(V) precursor [11] with a mixture of **2** [SNS] and **3** [S(N)], the reactants **1**, **2** and **3** were used in various stoichiometric amounts (1:1:2, 1:0.5:1 or 1:1:1). In all cases the expected "3+1" mixed-ligand complex **4** was formed and a second neutral rhenium(V) complex **5** was observed with an excess of **3** over **1** and **2** or with the tridentate ligand as a minor compound Fig. 2. **5** became the major product and could be isolated as a dark red, stable, crystalline solid in a 49 percent yield (Figure 2, route b) when **2** was omitted in the reaction mixture. A base such as sodium acetate or triethyl amine in the reaction mixture seems to be essential for the formation of **4** and **5**. No formation of **5** and less yields for **4** are observed after refluxing in methanol for one hour [12] without addition of the described bases. **5** was also formed in oxygen free solvents such as dichloromethane or acetonitrile (Figure 3).

Complexes **4** and **5** are readily soluble in organic solvents. Elemental analysis shows that **4**, as expected, contains both the tridentate ligand **2** and the monodentate ligand **3,** while complex **5** contains ligand **3** and one triphenylphosphane.

^{1}H *NMR spectroscopy*

^{1}H NMR studies of **4** show signals with chemical shifts identical to those found for the O-methylene-bound protons of ligand **3** as well as the typical signal pattern of the two ethyl groups bound to the ethylene diamine fragment. All this verifies the presence of the tris chelating ligand **2** in the complex. In order to identify the other protons of the coordinated ligand **2**, NOESY spectra of a similar compound [9] bearing **2** were used for comparison.

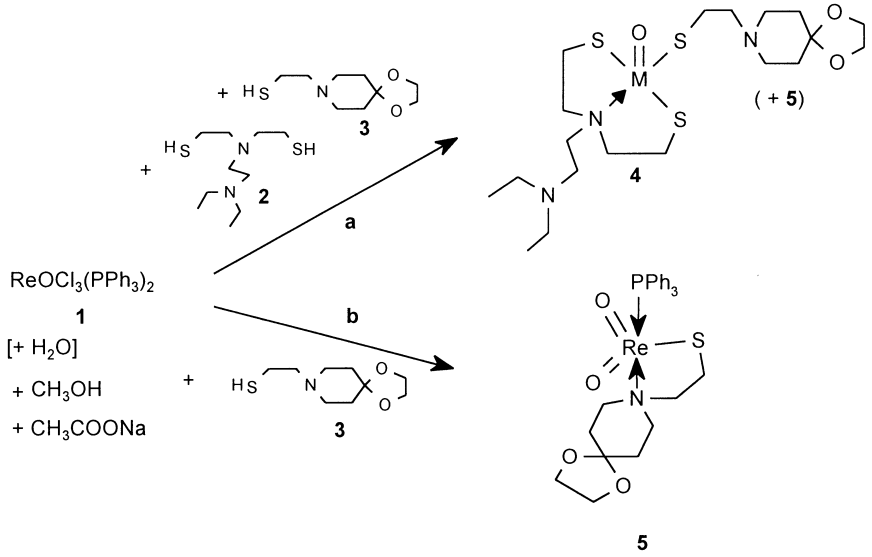

Fig. 2. Reaction scheme of the formation of the mono-oxo rhenium(V) complex **4** and the *cis*-dioxo rhenium(V) complex **5**.

^{1}HNMR investigations of **5** confirm the formulation, showing a signal pattern typical of phosphorus bound to arylic protons and a defined multiplet signal of four O-methylene bound protons in the expected range. Due to the bound nitrogen of the ring system of **3** in case of **5**, the symmetry of the O-methylene protons is disturbed and shows the splitting of the signal pattern as expected. The measured intensities of the arylic/aliphatic signals yield a 1:1 ratio corresponding to **3**/PPh_3.

IR spectroscopy

The IR spectrum of **5** did not show the intensive signal at $\nu = 945\,cm^{-1}$ for Re═O as observed for **4**. Two intense bands shifted to shorter wave numbers at $\nu = 836$ and $907\,cm^{-1}$ were detected. These values are typical of the *cis*-O═Re═O group as recorded for postulated [13] or established [14] *cis*-dioxorhenium(V) coordinated complexes.

Unlike **4**, **5** needs the attack of an oxygen donor on **1** for its formation. We assume that traces of water are the source of the second oxygen in the *cis*-dioxo arrangement of **5**. To prove this assumption, [^{18}O] water was added to the reaction mixture. As described in literature [15] the increased mass of the (^{18}O)-oxygen in the molecule should effect a noticeable shift of the obtained O═Re═O signals to shorter wave numbers. The resulting **5** shows a modified IR spectrum [Fig. 4(a)], where the oxo-rhenium stretches were shifted to $\eta = 798\,cm^{-1}$ and $\eta = 856\,cm^{-1}$ and the exactly identical fingerprint range clearly revealed the formation of an [^{18}O]-containing compound **5**. The found shifts are in a comparable range to IR data of (^{18}O)–CO vs (^{16}O)–CO [15] studies.

X-ray crystal structure

Crystals of **5** suitable for X-ray diffraction studies were obtained by recrystallization from ether/*n*-heptane. The structure determination clearly reveals the formation of a trigonal bipyramid. As already anticipated from IR data, the O-donors are arranged in a *cis* configuration and form a plane with the S-atom. The phosphorus and nitrogen donors compose the apices of the trigonal P–Re–N bipyramid. The small distortion of the ideal 180° P–Re–N angle is caused by the S-donor in the trigonal plane. In contrast to a *trans*-dioxo configuration, the O–Re–O angle is decreased to 135°. Due to the O_x–Re–S angles of about 112° and to P,N donors being perpendicular to the trigonal plane, a distorted trigonal bipyramid is formed. The parameter τ, introduced to classify five coordinated complexes to square–pyramidal ($\tau = 0$) or trigonal–bipyramidal geometry ($\tau = 1$) [16], was determined as 0.64. Discrepancies concerning the ideal trigonal bipyramid can be explained by the O_3–Re–O_4 angle of oxygen coordination in the equatorial plane. In accordance with theory, the bond length found for the dioxo core increases to 1.73 Å, compared with 1.65 Å for the mono-oxo core (Re═O, **4**) [10]. The bond lengths of the other donors show no significant differences between structures [10] such as **4** and **5** (Table 1).

The occurrence of a dioxo core shows a remarkable parallel to *trans*-dioxorhenium(V) compounds containing [P, N, Cl] or [P, I] chelating systems [14, 17]. We assume that this phenomenon results from the tendency of the metal core to become neutral. The *cis*-dioxo configuration of **5** is obviously influenced by the steric effects of the ligand **3**. The C_2 distance of

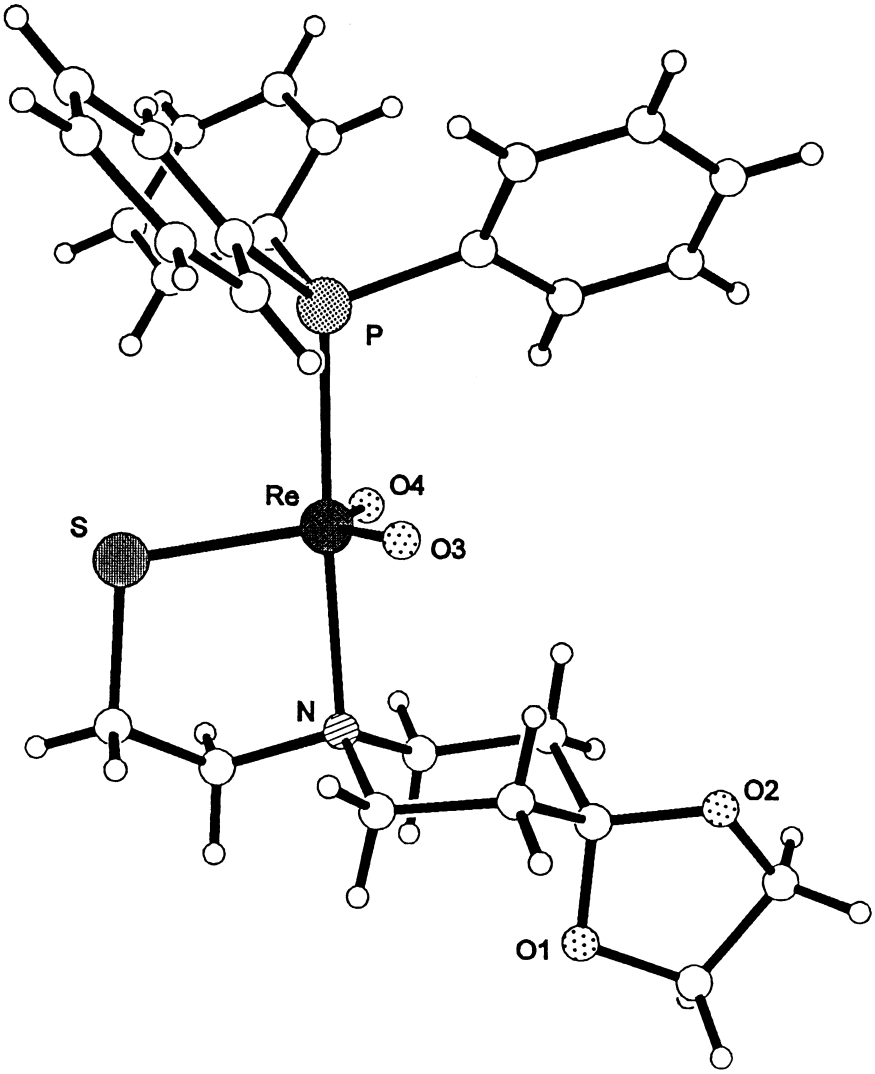

Fig. 3. X-ray crystallographic structure of **5**.

both the nitrogen and sulphur donors affects the arrangement out of the trigonal equatorial plane. This is caused by the intramolecular tension in **5** in opposition to the coordination mode in the base plane of a square pyramidal complex such as **4**. That fact excludes the *trans*-configuration of the dioxo core.

XANES/EXAFS measurements

To better understand the changes in the atomic environment of the central atom associated with the formation of the *cis*-dioxo compound, investigations of the rhenium coordination sphere at the precursor state and the final *cis*-dioxo complex state appeared to be helpful. Therefore, EXAFS measurements were applied to deliver atomic radial distributions of the ligand atoms around the rhenium central atom. EXAFS investigations made it possible to trace the structural relationships in the reaction mixture by considering the neighbourhood closest to rhenium in the solid (suspended) precursor state as well as in the soluted *cis*-dioxo compound state, which are both present in the reaction mixture. A comparison of the clarified crystal structure of **5** with its rhenium coordination sphere in a non-crystalline state was of special interest from a nuclear medical point of view.

XANES data

A strong white line as typical of measurements at the rhenium L_{III} absorption edge [16] was observed for both complexes under investigation. The absorption edge position of complex **1** was determined to be 10533 eV, that of complex **5** was 10535 eV. The differ-

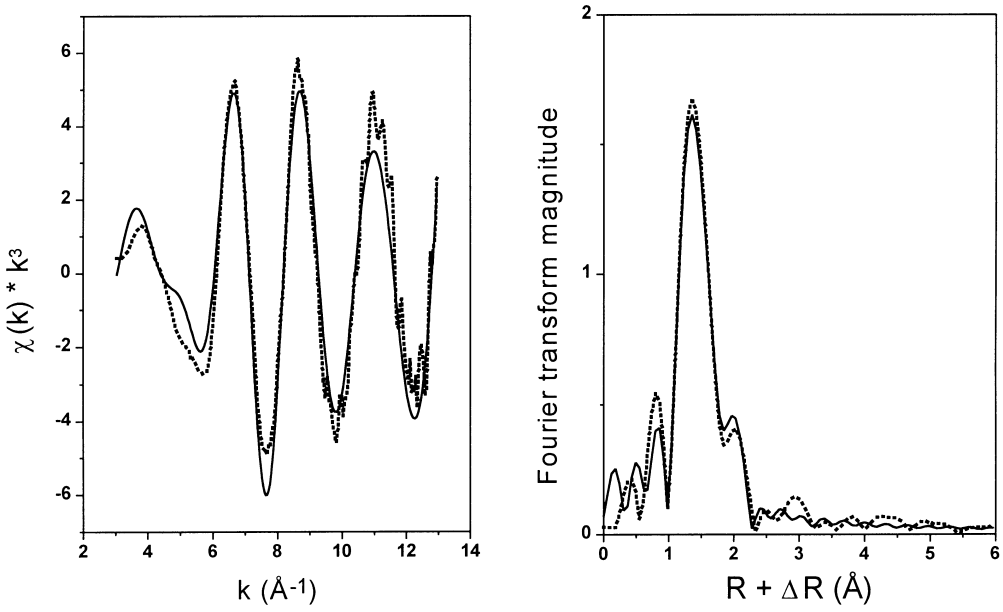
ence in the absorption edge position suggests different electron densities at both complex central atoms.

EXAFS data of ***1***

The Fourier transform of the complex **1** EXAFS data consists of two coordination shells which are well resolved. Figure 5(a) and (b) show the EXAFS data, their Fourier transforms and the corresponding fit data of complex **1**.

The peak at 1.4 Å in the Fourier transform (not corrected for scattering phase-shift) is thought to represent the short-bound oxygen atom, the large peak at 1.9 Å is probably generated by the mixed chlorine/phosphorus coordination shell. Taking this model as a default to fit the data, the EXAFS fit data shown in Table 2 were obtained.

A short-bound oxygen atom is detected at a distance of 1.70 Å as is typical of a rhenium central atom with a formal oxidation state of +5. The second coordination shell was fitted with a backscattering function of the atomic number 16 as the mean number of phosphorus (atomic number 15) and chlorine (atomic number 17), since EXAFS functions for the latter are not expected to be resolvable. As the fit result for this shell, five P/Cl atoms at a mean distance of 2.41 Å were found. The Debye–Weller factor of 0.005 Å^2 suggests a distribution of the backscattering atoms over a distance range within the coordination shell. On the one hand, this may be due to the difference in distance between the chlorine and the phosphorus atoms, on the other, the relatively high coordination number of five may also lead to increased Debye–Weller terms. As described elsewhere [20], the precursor complex **1** may occur in various forms of the general constitution $ReOCl_3(PPh_3)_2$. These conformation isomers are mainly characterized by differences in the PPh_3 ligand conformation and crystal packing patterns (monoclinic and triclinic), which lead to changes in the rhenium–ligand distances. The rhenium–oxygen bond distances as elucidated by XRD analysis are 1.66 Å for one monoclinic (A) and one triclinic isomer (B) and 1.73 Å for the other triclinic monomer (C). EXAFS analysis of the precursor showed a rhenium–oxygen distance of 1.70 Å, which is regarded as a mean value of various isomers, including the triclinic isomer C and one or both other isomers. The EXAFS value of the bond distance of the P/Cl coordination shell also seems to represent a mean value of various isomers, since the mean value of this shell as shown



6. (a) EXAFS data of complex **5**. (b) Fourier transform corresponding to (a).

by XRD analysis was 2.45, 2.40 and 2.44 Å for isomers A, B and C. Hence, an unambiguous assignment of the analyzed isomers is not possible, although the existence of the triclinic isomer C can be assumed. However, the constitutional identity of the precursor could be proven by EXAFS.

EXAFS data of ***5***

Complex **5** exhibits a significantly different radial distribution function around the rhenium central atom. Figure 6(a) and (b) show the EXAFS data and their Fourier transform of complex **5**. Dotted lines represent the experimental data, solid lines the best fit.

A strong Fourier transform amplitude is detected at 1.3 Å (not corrected for scattering phase-shift) suggesting a remarkably changed first coordination shell with respect to the rhenium precursor. A second peak occurs at 2.1 Å, obviously caused by the second coordination shell. Taking the complex structure as elucidated by XRD analysis as a default to fit the data, the results presented in Table 3 were obtained.

A substantial increase in the coordination number of the oxygen shell as well as an increase in its mean bond distance to rhenium were observed. This strongly suggests the existence of a dioxo rhenium core. The bond distance is in excellent agreement with the value determined by XRD analysis of the crystalline complex. Considering the second coordination shell, two sulphur backscatterers were used to fit the data and gave results of two backscattering atoms with a mean distance of 2.33 Å. It is noteworthy that the Debye–Weller factor of this coordination shell is increased, probably caused by two distant backscatterers which were fitted within one coordination shell. These two atoms are thought to be a sulphur atom at a distance of around 2.27 Å and a phosphorus backscatterer located at around 2.40 Å. The detected bond length seems likely to represent the mean distance between these two atoms. The results obtained are in good agreement with the values determined by XRD analysis of the complex. However, there is a discrepancy in view of the comparison of the crystal and the solution structure. The nitrogen atom located at 2.28 Å as determined in crystal is not detectable. Attempts to include it in the EXAFS fit gave unreasonable results and thus failed. This problem is obviously caused by the strong dominance of the phosphorus/sulphur shell contribution in the complex EXAFS. The relatively weak backscattering contribution of the amine nitrogen atom at the expected

Table 3. EXAFS fit results for complex **5**

Shell	N	R^a (Å)	σ^2 (Å^2)

a Distance to the rhenium central atom.

distance of 2.28 Å is therefore not believed to be resolvable. Similar phenomena were observed on other systems [21, 22]. However, it can be stated that the unexpected complex as determined in XRD analysis is also existent in solution and seems therefore to represent a relatively stable coordination.

CONCLUSIONS

The described ligand exchange reaction procedure resulted in **4** and the new complex species **5** with the remarkable configuration of the O-donor atoms and an unexpected bidentate coordination of one mercaptoethylene amine derivative. ^{1}H NMR, FAB/CI mass spectroscopy investigations and the elemental analysis suggest a 1:1:1 ratio of **3**, a triphenylphosphane and a dioxo metal core. The *cis*-arrangement of the dioxo core could be proved by IR investigations. The completely trigonal–bipyramidal structure was elucidated by XRD measurements. The origin of the second short-bound oxygen proved to be water present in the reaction mixture, as shown by ^{18}O labelling studies. Even at 1:1 to 1:3 ratios of the reactants **1**/**3** no formation of further compounds analogous to that shown in Fig. 1 was observed.

Five-fold coordinated compounds of trigonal–bipyramidal O-coordination [23], S, or bis-alkyl coordination [24] and *cis*-configuration of the oxo groups have previously been described mainly for rhenium(VII) compounds. For the oxidation state of +5, however, only the *trans*-configuration has been published, with the exceptions of one P,P,I *cis*-dioxo complex characterized [14] by XRD, as well as two complexes containing bipyridyl compounds and a *cis*-dioxo structure characterized by IR data [13].

XRD and EXAFS studies of **5** showed that the coordination of the *cis*-dioxo compound is nearly identical in the solid and in the soluted state.

The formation of the *cis*-dioxo complex is not specific to the applied amine thiol **3**. Products containing other amino alkyl thiols which were obtained further show almost the same UV-spectra and was characterized by XRD in one special case (part of a further publication).

Regarding the "3+1" approach it has to be remarked the reactants should be used strictly in a 1:1:1 ratio in cases of such potentially bidentate ligands. A compensation of the higher reactivity of the tris chelating unit by the use of an excess of the "monodentate" co-ligand **3** is impossible.

EXPERIMENTAL SECTION

Materials and instrumentation

Elemental analyses were performed on a LECO CHNS-932 elemental analyser. Infrared spectra (KBr pellets, in $CHCl_3$) were measured on a Specord M80 or on a Perkin Elmer FT-IR Spectrum 2000. Proton NMR investigations were carried out on a Varian Inova-400 device (solvent $CDCl_3$). Mass spectrometry was done using a Finnigan MAT 95 mass spectrometer. Column chromatography was done using Silica gel 60 (0.04–0.063 mm) from Merck.

Preparation of ligands and the precursor

The *trans*-mono-oxotrichlorobis(triphenylphosphine)rhenium(V) was prepared starting from perrhenate as described in the literature [11].

To prepare the ligands *N*,*N*-bis(2-mercaptoethyl)-*N*′,*N*′-diethylethylenediamine **2** and 1,4-dioxa-8-aza-spiro-*N*-2-mercaptoethylene-[**4**,**5**]-decane **3**, a published procedure was applied [25].

*Preparation of compounds **4** and **5***

The precursor **1** (166.0 mg, 0.2 mmol) was suspended in 20 ml of methanolic sodium acetate solution (0.15 N) by gentle stirring. The ligand **2** (17.9 mg, 0.1 mmol) and the co-ligand **3** (40.7 mg, 0.2 mmol) were dissolved in dichloromethane/methanol and added as a mixture. The resulting suspension was heated at 70°C for 30 min and a change of colour from yellowish green to greenish brown was observed. The reaction mixture was diluted with 10 ml of dichloromethane, washed twice with 10 ml of water and the organic phase was extracted with 10 ml of 0.1 N hydrochloric acid. A dark red organic phase (**5**) and a dark green aqueous phase ("3+1" product **4**) were obtained. The organic portion was dried over sodium sulphate, filtered, reduced in volume by evaporation and purified by chromatography over silica gel 60 with trichloromethane as the liquid phase. The eluate was evaporated to dryness and the precipitate dissolved in diethyl ether. After adding a mixture of ether/n-heptane (1:1), dark red, analytically pure crystals were obtained by slow evaporation of the solvents. Yield: 67 mg (*ca.* 49%, referred to **1**); m.p. 172–174°C. - IR(KBr): $\nu = 836$; 907 cm^{-1} (O═Re═O). Mass spectrum: (FAB pos.) *m*/*z* 681(32)/683(78) $[M]^+$; 682(62)/684(100) $[M+H]^+$; ^{1}H NMR($CDCl_3$): δ 3.943 [m, 4H, O–CH_2–CH_2–O (3)], δ 3.366 [m, 2H, N–CH_2–CH_2–S (3)], δ 2.700 [m, 2H, S–CH_2–CH_2 (3)], δ 2.660; 2.345 [2m, 4H, N–CH_2–CH_2 (3)], δ 1.696; 1.528 [2m, 4H, C–CH_2–CH_2 (3)].

A quantity of dichloromethane was added to the dark green aqueous phase and the pH was increased to 10 by adding a small volume of sodium hydroxide in order to re-extract compound **4**. The organic portion was dried over sodium sulphate, filtered and reduced in volume by evaporation. Compound **4** was purified by chromatography as described above and eluted by using a mixture of dichloromethane/methanol (19:1). The solvent mixture was removed by allowing to stand overnight and crude green crystals were obtained. Yield: 40 mg (*ca.* 62%, referred to **2**); m.p. 134–136°C. IR(KBr): $\nu = 945$ cm^{-1}

(Re═O). Mass spectrum: (CI neg.) m/z 637(58)/639(100) $[M]^+$. ^1H NMR ($CDCl_3$): δ 3.953 [s, 4H, O–CH_2–CH_2–O (**3**)], δ 2.721 [m, 4H, N–CH_2–CH_2 (*3*)], δ 1.805 [t, 4H, N–CH_2–CH_2–C (**3**)], δ 3.872 [t, 2H, N–CH_2–CH_2–NEt_2 (**2**)], δ 3.626; 3.584; 3.292; 2.971 [m, 8H, N–CH_2–CH_2–S (**2**)], δ 2.860 [t, 2H, N–CH_2–CH_2–NEt_2 (**2**)], δ 2.602 [m, 2H, S–CH_2–CH_2–N (**2**)], δ 2.566 [q, 4H, N–CH_2–CH_3 (**2**)], δ 1.061 [t, 6H, N–CH_2–CH_3 (**2**)].

Preparation of the [^{18}O]*-bearing complex* ***5***

The precursor **1** (166.0 mg, 0.20 mmol) was suspended in a mixture of 1 ml of [^{18}O] water and 5 ml dried methanol which contained water-free sodium acetate (0.15 N). After addition of **3** (47.8 mg, 0.24 mmol) dissolved in 0.5 ml of dried methanol the reaction mixture was stirred and refluxed for 30 min. The dark reddish solution obtained was reduced in volume by evaporation to give a final volume of approximately 2 ml. The solution was applied to a silica gel column and purified by eluting with chloroform. The dark reddish chloroformic solution obtained was used for IR measurements.

X-ray crystal structure analysis of ***5***

The structure was determined using a single crystal, obtained by slow evaporation of an ether/*n*-heptane solution of **5**. $C_{27}H_{31}N_1O_4P_1S_1Re_1$ ($M = 682.79$). The intensity data for compound **5** were collected on a ENRAF-NONIUS CAD4 diffractometer. The reflections were performed by the ω–2θ scan method, using graphite monochromated CuK_α radiation ($\lambda = 1.5418$ Å) at $T = 296(2)$ K. Triclinic space group P-1 (No. 2), $a = 9.323(3)$ Å, $b = 15.438(3)$ Å, $c = 20.671(3)$ Å, $\alpha = 103.18(3)^\circ$, $\beta = 100.39(3)^\circ$, $\gamma = 105.39(3)^\circ$, $V = 2699.6(11)$ Å^3, $Z = 4$, $D_c = 1.677$ g cm^{-3}, $\mu = 10.355$ mm^{-1}. The number of totally measured reflections was 11077, of which 9947 were considered to be significant and were used for the structure determination. The refinement procedure was carried out by full-matrix least-squares, where the minimized function was $\omega(|F_0| - |F_c|)^2$. Refinement converged at $R = 0.0514$ and $R_w = 0.1521$.

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited at the Cambridge Crystallographic Data Center. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. (fax: +44-1223-336-033; e-mail: teched@chemcrys.cam.ac.uk) (CCDC-No. 100471).

EXAFS measurements of ***1*** *and* ***5***

Rhenium L_{III} edge data were collected in transmission mode using ionization chambers at beamline X1.1 of the HASYLAB synchrotron, Hamburg, Germany. To monochromatize the synchrotron beam, a monochromator system consisting of a Si(211) double-crystal monochromator was used. The DORIS III storage ring was operated at 3 GeV at ring currents between 40 and 70 mA during measurements. Higher harmonics were rejected by detuning the monochromator crystals to 50% of the incident beam intensity. A rhenium(V) complex served as a reference for energy calibration of the monochromator. Three scans were used per sample on average. A check for anomalies was carried out after each scan. Data were energy-calibrated using the first derivative method, where the first inflected point in the reference derivative was set to 10535 eV. Sample absorption edge positions were determined by derivatizing the sample spectra and detecting the first inflected points. Data processing and analysis were performed using the program package EXAFSPAK [26]. The experimental data were analyzed by being fitted with theoretical EXAFS functions generated by the FEFF6.01a program [27]. Since phosphorus, sulphur and chlorine produce very similar backscattering functions, mixed-atom coordination shells consisting of these atoms were fitted with EXAFS functions for sulphur backscatterers. To fit the data, coordination numbers were at first kept constant. When constant values for DE_0 and distances were obtained, coordination numbers were allowed to float.

(Received 19 January 1998; accepted 20 April 1998)

Abstract—The previously unknown heteropolytungstate $(Me_4N)_{10}[Fe_4(OH)_4(PW_{10}O_{37})_2]\cdot 15H_2O$ has been prepared by the reaction of Δ–$Na_8HPW_9O_{34}$ and $FeCl_3$ in aqueous solution, and characterized by elemental analysis, infrared spectrum as well as X-ray single crystal structure determination. Four bridging hydroxo groups link with four Fe^{III} ions, forming an eight-member ring; and this $Fe_4(OH)_4$ aggregation is sandwiched by two bi-vacant Keggin type heteropolyanion fragments. The bridging hydroxo groups are divided into two classes: one is the hydroxo groups linking two $PW_{10}Fe_2$ half moieties, the other is the hydroxo group linking two FeO_6 octahedra in each half moiety. The location of the bridging hydroxo groups is identified by the bond valence sum (BVS) calculations for various oxygen atoms. © 1998 Elsevier Science Ltd. All rights reserved.

Keywords: heteropolytungstate; synthesis; crystal structure; bridging hydroxo group; ferric compound; Keggin heteropolyanion dimer

In recent years there has been a growing interest in the heteropolymetalates, especially in the transition metal di- and tri-substituted Keggin or Dawson type heteropolytungstates. These substituted series can serve as ideal model compounds in the domains of magnetic chemistry study, and are also regarded as a class of potential magnetic materials [1, 2]. Finke *et al.* reported the rational syntheses and characterization of a series of di-valence transition metal trisubstituted Keggin and Dawson type heteropolytungstate dimers in 1987 [3]. These substituted heteropolytungstates contain an oxo-bridged tetranuclear transition metal cluster sandwiched by two trivacant heteropolyanion fragments. In the view of magnetic chemistry, the large and robust framework of heteropolyanions may block intermolecular magnetic interaction, therefore they are favourable models to understand the magneto-structural correlation for encapsulated magnetic clusters. During the past decade, the syntheses of this series of heteropolytungstates have been successively reported, and their magnetic investigations show ferro- or antiferro-magnetic interactions in the oxo-bridged magnetic clusters [4, 5].

In order to expand this study from di-valence transition metals to tri-valence transition metals, we attempt to synthesize an Fe^{III} or Cr^{III} tri-substituted Keggin type heteropolyanion dimer using a similar method described by Finke *et al.* Many efforts failed, however we have separated some light brown single crystals from the resultant mixtures. The X-ray structure determination reveals that this crystalline heteropolytungstate has an unexpected hydroxo-bridged dimeric structure. There are two sets of Fe^{III} ions, related by a central symmetry, which are symetrically

* Author to whom correspondence should be addressed.

placed in two Keggin type $PW_{10}Fe_2$ half moieties. Two kinds of bridge hydroxo groups that linked two Fe^{III} ions are found: one is the bridge hydroxo group in each $PW_{10}Fe_2$ half moiety, the other is the bridge hydroxo group in two $PW_{10}FE_2$ half moieties. To our knowledge, the bridging hydroxo group within the framework of heteropolyanion has not been previously reported. Here we report the synthesis, infrared spectrum and X-ray crystal structure of the title compound.

EXPERIMENTAL

Materials

Analytical grade $Na_2WO_4{\cdot}2H_2O$, $FeCl_3{\cdot}6H_2O$, Me_4NBr, H_3PO_4 (85%) and glacial acetic acid were used without further purification. The tri-vacant tungstophosphate, Δ–$Na_8HPW_9O_{34}{\cdot}19H_2O$ was prepared according to the procedure described by Finke *et al.* and identified by infrared spectrum [3].

Analytical methods and apparatus

The elemental analysis for C, H and N were performed on a Perkin-Elmer 240C Analyzer. The amounts of other elements were obtained on a Jarrell-Ash Division Atomscan 2000 ICP analyzer. Infrared spectrum was recorded on a Nicolet 5DX FTIR spectrophotometer using KBr pellet. The number of H_2O was identified by a LCT-2 Thermogravimetric Analyzer.

Synthesis

The title heteropolytungstate was synthesized by addition of (5.5 g 2.0 mmol) tri-vacant tungstophosphate Δ–$Na_8HPW_9O_{34}$ to a 10 ml aqueous solution of $FeCl_3{\cdot}6H_2O$ (1.1 g, 4.0 mmol) with vigorous stirring, yielding a homogeneous orange–red solution. The solution was stirred for 12 h, and then a 10 ml Me_4NBr (1.0 g, 6.5 mmol) aqueous solution was added carefully and kept stratified with the solution. As Me_4NBr diffused slowly into the orange–red solution, a mixture containing small light brown crystals and unknown pale yellow powdery compounds was precipitated out after two weeks, the yield being 20%. The crystals were selected for elemental analysis, infrared spectrum analysis and X-ray crystal structure determination. Elemental analysis for $(Me_4N)_{10}[Fe_4(OH)_4(PW_{10}O_{37})_2]{\cdot}5H_2O$ calculated (found): C, 7.72% (7.61); H, 2.49% (2.33); N, 2.25% (2.20); Fe, 3.59% (3.63); P, 0.99% (1.01); W, 59.05% (58.87); H_2O, 4.34% (4.41). IR (ν/cm^{-1}): 3476sb, 3033m, 2959w, 1634m, 1488s, 1450w, 1419w, 1059s, 956s, 881s, 775sb, 516m.

Crystal structure determination

A single crystal ($0.30 \times 0.15 \times 0.15$ mm) of title compound was sealed in a Lindeman glass capillary and aligned on an Enraf-Nonius CAD-4 diffractometer equipped with graphite-monochromotatic Mo–Kα radiation ($\lambda = 0.71073$ Å). Unit cell parameters were determined on the basis of 25 reflections in the range $12 < \theta < 16^\circ$. The intensity data were collected by ω–2θ scan technique in the 2θ range 0–46°. During data collection, the intensities of three standard reflections were monitored every hour and showed no significant variation. The intensity data were corrected for Lorentz-polarization effects and empirical absorption. Details of the crystal data, intensity collection and refinement are listed in Table 1.

The crystal structure was solved by direct methods and refined by full-matrix least squares techniques using anisotropic temperature factors for non-hydrogen atoms. Hydrogen atoms were placed on the related atoms and refined in the riding mode with fixed thermal parameters. 7032 reflections with $I > 3\sigma(I)$ were used in the refinement of 601 parameters, and the refinement converged at

Table 1. Summary of crystal and intensity collection data

Empirical formula	$C_{40}H_{154}Fe_4N_{10}O_{93}P_2W_{20}$
Formula weight	6225.75
Crystal system	Monoclinic
Space group	$P2_1/C$
a(Å)	13.228(5)
b(Å)	35.634(3)
c(Å)	15.226(2)
β(°)	94.20(0)
V(Å^3)	7157.6
Z	2
D_c (g/cm^3)	2.888
F(000)	5576
Radiation	Mo–K_α ($\lambda = 0.71073$ Å)
μ(cm^{-1})	168.534
Temperature (K)	293
Scan width	$0.5 + 0.350 \tan\theta$
$(h,k,l)_{min}$, $(h,k,l)_{max}$	(−14,0,0), (14,39,16)
Number of reflections collected	10597
Number of unique reflections	9954
Observed reflections, $I > 3\sigma(I)$	7032
Function minimized	$\Sigma W(\|F_o\| - \|F_c\|)^2$
Variable refined	601
R	0.036
R_w	0.049
Maximum shift in final cycle	0.03
Largest peak in final difference map (e/Å^3)	1.95

$R = 0.036$ and $R_w = 0.049$. All calculations were performed on a Micro VAX II computer using SDP/VAX PLUS programs.

RESULTS AND DISCUSSION
