
POLYHEDRON

The International Journal for Inorganic and Organometallic Chemistry

Founding Editor
Sir Geoffrey Wilkinson

Executive Editors
G. Christou
C. E. Housecroft

PERGAMON

POLYHEDRON

Aims and Scope

Polyhedron will publish original, fundamental, experimental and theoretical work of the highest quality in the major areas of inorganic and organometallic chemistry. These areas include synthetic and reaction chemistry, kinetics and mechanisms of reaction, bioinorganic chemistry, photochemistry and the use of metal and organometallic compounds in stoichiometric and catalytic synthesis of organic compounds. Papers concerned solely with stability constants determined by potentiometric titration data unsupported by other e.g. spectroscopic techniques will not be acceptable nor will solvent extraction data unless supported by other data of interest to inorganic chemists.

Back Issues: Back issues of all previously published volumes are available direct from Elsevier Science offices (Oxford and New York). Complete volumes and single issues can be purchased for 1991–1997. Earlier issues are available in high quality photo-duplicated copies as complete volumes only. Back volumes on microfilm are available from UMI, 300 North Zeeb Road, Ann Arbor, MI 48106, U.S.A.

Copyright © 1998 Elsevier Science. All rights reserved
This journal and the individual contributions contained in it are protected by the copyright of Elsevier Science, and the following terms and conditions apply to their use:

Photocopying. Single photocopies of single articles may be made for personal use as allowed by national copyright laws. Permission of the publisher and payment of a fee is required for all other photocopying, including multiple or systematic copying, copying for advertising or promotional purposes, resale, and all forms of document delivery. Special rates are available for educational institutions that wish to make photocopies for non-profit educational classroom use.

In the U.S.A., users may clear permissions and make payment through the Copyright Clearance Center Inc., 222 Rosewood Drive, Danvers, MA 01923, U.S.A. In the U.K., users may clear permissions and make payment through the Copyright Licensing Agency Rapid Clearance Service (CLARCS), 90 Tottenham Court Road, London W1P 9HE, U.K. In other countries where a local copyright clearance centre exists, please contact it for information on required permissions and payments.

Derivative Works. Subscribers may reproduce tables of contents or prepare lists of articles including abstracts for internal circulation within their institutions. Permission of the publishers is required for resale or distribution outside the institution. Permission of the publisher is required for all other derivative works, including compilations and translations.

Electronic Storage. Permission of the publisher is required to store electronically any material contained in this journal, including any article or part of an article. Contact the publisher at the address indicated.

Except as outlined above, no part of this publication may be reproduced, stored in a retrieval system or transmitted in any form or by any means, electronic, mechanical, photocopying, recording or otherwise, without prior written permission of the publisher.

Disclaimer. No responsibility is assumed by the Publisher for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions or ideas contained in the material herein.

Although all advertising material is expected to conform to ethical standards, inclusion in this publication does not constitute a guarantee or endorsement of the quality or value of such product or of the claims made of it by its manufacturer.

♾™ The paper in this publication meets the minimum requirements of American National Standard for Information Sciences—Permanence of Paper for Printed Library Materials, ANSI Z39.48-1984.

The Item-fee Code for this publication is: 0277–5387/98 $19.00 + 0.00

ContentsDirect, the ***free*** e-mail alerting service, delivers the table of contents for this journal directly to your PC, prior to publication. The quickest way to register for **ContentsDirect** is via the Internet at: **http://www.elsevier.nl/locate/ContentsDirect.** If you don't have access to the Internet you can register for this service by sending an e-mail message to cdsubs@ elsevier.co.uk— specifying the title of the publication you wish to register for.

Publisher's Note

As from January 1998, *Polyhedron* will no longer publish a "Communications" section. Instead, a new periodical, *Inorganic Chemistry Communications*, is being launched and distributed to all *Polyhedron* subscribers.

The change has been dictated by several factors, one of which is the obvious need for a specialized periodical covering the swift publication of hot research results. The project has received sustained support from scientists, and will be managed in coordination and parallel with other Elsevier inorganic chemistry journals.

Another reason for the launch of *Inorganic Chemistry Communications* is the imperative need to publish communications within 8–10 weeks. The exercise has proved to be very difficult when regular articles and rapid papers are combined within the same cover. The separate publication of both sections will technically help to achieve the targeted publication times.

Finally, it should be mentioned that communications and regular articles do not serve exactly the same purpose. Communications aim to function as an efficient early notice board on current research whereas articles constitute the essential detailed validation of the findings. By binding the two sections under separate covers, readers will clearly obtain what they expect to find in these volumes.

From January 1998, all submissions to the "Communications" section of *Polyhedron* will be channelled to *Inorganic Chemistry Communications*. Authors will be informed of this change and offered the choice of publishing their paper in *Inorganic Chemistry Communications*, withdrawing it, or having it published as a regular article in *Polyhedron*. It is important to note that the circulation of *Inorganic Chemistry Communications* is also being extended to subscribers of *Inorganica Chimica Acta*, *Polyhedron* and the *Journal of Organometallic Chemistry*, thus these papers will reach an audience that far surpasses the initial expectations of the authors.

Publisher's Note

As from January 1998, *Polyhedron* will no longer publish a "Communications" section. Instead, a new periodical, *Inorganic Chemistry Communications*, is being launched and distributed to all *Polyhedron* subscribers.

The change has been dictated by several factors, one of which is the obvious need for a specialized periodical covering the swift publication of hot research results. The project has received sustained support from scientists, and will be managed in coordination and parallel with other Elsevier inorganic chemistry journals.

Another reason for the launch of *Inorganic Chemistry Communications* is the imperative need to publish communications within 8–10 weeks. The exercise has proved to be very difficult when regular articles and rapid papers are combined within the same cover. The separate publication of both sections will technically help to achieve the targeted publication times.

Finally, it should be mentioned that communications and regular articles do not serve exactly the same purpose. Communications aim to function as an efficient early notice board on current research whereas articles constitute the essential detailed validation of the findings. By binding the two sections under separate covers, readers will clearly obtain what they expect to find in these volumes.

From January 1998, all submissions to the "Communications" section of *Polyhedron* will be channelled to *Inorganic Chemistry Communications*. Authors will be informed of this change and offered the choice of publishing their paper in *Inorganic Chemistry Communications*, withdrawing it, or having it published as a regular article in *Polyhedron*. It is important to note that the circulation of *Inorganic Chemistry Communications* is also being extended to subscribers of *Inorganica Chimica Acta*, *Polyhedron* and the *Journal of Organometallic Chemistry*, thus these papers will reach an audience that far surpasses the initial expectations of the authors.

(Received 21 May 1997; accepted 3 July 1997)

Abstract—Treatment of titanium tetrachloride with a range of organothiols affords adducts of the formula $TiCl_4(HSR)_2$ in 77–89% yields. Reaction of titanium tetrachloride with organic sulfides gives sulfide adducts of the formula $TiCl_4(SR_2)_2$ in 87–98% yields. These complexes are volatile and monomeric with cis-organosulfur ligands. Treatment of titanium tetrachloride with methyl disulfide affords the adduct $(TiCl_4)_2(CH_3SSCH_3)$ in 98% yield, which adopts a dinuclear structure with a Ti_2Cl_8 core and a bridging disulfide ligand. The crystal structures of $TiCl_4(C_4H_8S)_2$ and $(TiCl_4)_2(CH_3SSCH_3)$ were determined. The relevance of these observations to the chemical vapor deposition of titanium disulfide and trisulfide films is discussed. © 1997 Elsevier Science Ltd

Keywords: titanium disulfide; titanium trisulfide; titanium tetrachloride; chemical vapor deposition.

Titanium disulfide is one of the desirable cathode materials for lithium batteries [1]. Titanium disulfide films have also been used as a solid lubricant due to weak Van der Waals interactions between adjacent layers in the lattice [2]. The majority of Chemical Vapor Deposition (CVD) routes to titanium disulfide films are based on the reaction between titanium tetrachloride and hydrogen sulfide, organic sulfides, or disulfides [3–5]. Schleich [4] has recently disclosed that the CVD reaction between titanium tetrachloride and di-tert-butyl disulfide affords titanium trisulfide films at temperatures between 200–260°C, mixtures of titanium trisulfide and titanium disulfide films between 260–400°C, and titanium disulfide films above 400°C. In contrast, di-tert-butyl sulfide reacted with titanium tetrachloride at $\geqslant$260°C to give titanium disulfide films. Recently we reported a new atmospheric pressure CVD process for titanium disulfide films, which relies upon the reaction of titanium tetrachloride with organothiols at temperatures $\geqslant$200°C, and affords highly pure, crystallographically oriented, stoichiometric, adhesive coatings [6]. We subsequently disclosed that complexes of the formula $TiCl_4(HSR)_2$ (R = alkyl) constitute the first single-source precursors for the CVD of titanium disulfide films [7]. Significant aspects of the processes based upon organothiols include a large drop in the minimum deposition temperature for titanium disulfide film deposition ($\geqslant$200°C versus $\geqslant$400°C for hydrogen sulfide) and the fact that no carbon or chlorine impurities were detected in the films.

The differences observed between the use of organothiols, organosulfides, and organodisulfides in the deposition of titanium disulfide films raise the possibility that there are corresponding variations in the reactions between titanium tetrachloride and the respective sulfur sources. Since there is very little known about the reactivity of titanium tetrachloride toward organosulfur compounds [8–11], we have initiated an investigation of the solution coordination chemistry of titanium tetrachloride with sulfur

donors. Herein we describe the reaction of titanium tetrachloride with several sulfides and disulfides and also report the crystal structures of two complexes.

EXPERIMENTAL

General considerations

All manipulations were performed under an inert atmosphere using either glovebox or Schlenk line techniques. Hexane was distilled from sodium. Chloroform-*d* and dichloromethane-d_2 was dried over activated 4 Å molecular sieves. Titanium tetrachloride and the organosulfur compounds were used as received from Aldrich Chemical Co.

^{1}H NMR and ^{13}C{^{1}H} NMR spectra were obtained at 300 or 75 MHz in chloroform-*d* or dichloromethane-d_2. Infrared spectra were obtained using Nujol as the medium. Elemental analyses were performed by Midwest Microlab, Indianapolis, IN. Melting points were obtained on a Haake-Buchler HBI digital melting point apparatus and are uncorrected.

Preparation of $TiCl_4(HSC_6H_{11})_2$ (**1**)

A 200-cm^3 Schlenk flask was charged with titanium tetrachloride (2.00 cm^3, 18.2 mmol), dichloromethane (30 cm^3), and a stir bar and was fitted with a septum. The solution was cooled to 0°C, and cyclohexylthiol (4.46 cm^3, 36.48 mmol) was added by syringe to afford a clear, deep yellow solution. The solution was allowed to reach ambient temperature and was stirred for 2 h. The volatiles were pumped off and the resultant yellow solid was extracted with hexane (100 cm^3) and filter through a 2 cm pad of Celite to afford a clear, yellow solution. This solution was kept at −20°C, to afford needle shaped yellow crystals of **1**. The supernatant was removed by cannulation and the crystals were vacuum dried (5.96 g, 84% based upon titanium tetrachloride): m.p. 78°C (dec with sublimation); IR (Nujol, cm^{-1}) 2492 (m, S—H stretch), 1340 (w), 1263 (w), 1210 (w), 1022 (w), 995 (m), 886 (w), 875 (w), 809 (w), 755 (s, broad), 727 (s), 667 (w); ^{1}H NMR ($CDCl_3$, 23°C, δ) 3.11 (m, C*H*SH), 2.33 (s, S—*H*), 2.06 (m, CH_2), 1.74 (m, CH_2), 1.60 (m, CH_2), 1.35 (m, CH_2); ^{13}C{^{1}H} NMR ($CDCl_3$, 23°C, ppm) 42.60 (s, *C*HSH), 36.68 (s, 2 *C*H_2), 26.09 (s, 2 *C*H_2), 25.16 (s, *C*H_2). Found: C, 33.82; H, 5.68. Calc. for $C_{12}H_{24}Cl_4S_2Ti$: C, 34.14; H, 5.73%.

Preparation of $TiCl_4(HSC_5H_9)_2$ (**2**)

A 100-cm^3 Schlenk flask was charged with cyclopentylthiol (0.20 cm^3, 1.83 mmol), hexane (15 cm^3), a stir bar and was fitted with a rubber septum. This solution was cooled to 0°C, and titanium tetrachloride (0.1 cm^3, 0.91 mmol) was added *via* a syringe to give a clear, deep yellow solution. This solution was allowed to reach ambient temperature and stirred for 2 h. The solution was placed at −20°C for 6 h to afford yellow crystals of **2**. The solvent was transferred and the crystals were vacuum dried to afford **2** (0.28 g, 78% based upon titanium tetrachloride): m.p. 60°C (dec. with sublimation); IR (Nujol, cm^{-1}) 2520 (m, S—H), 2505 (m, S—H), 1310 (s), 1261 (s), 1236 (m), 1158 (w), 1089 (w), 1020 (m), 794 (s), 715 (s); ^{1}H NMR ($CDCl_3$, 23°C, δ) 3.53 (m, C*H*SH), 2.95 (s, S*H*), 2.09 (s, CH_2), 1.72 (s, CH_2), 1.57 (s, CH_2); ^{13}C{^{1}H} NMR ($CDCl_3$, 23°C, ppm) 44.52 (s, *C*HSH), 36.25 (s, 2CH_2), 24.57 (s, 2*C*H_2). Found: C, 30.26; H, 4.99. Calc. for $C_{10}H_{20}Cl_4S_2Ti$: C, 30.48; H, 5.12%.

Preparation of $TiCl_4(C_4H_8(SH)_2)$ (**3**)

A 100-cm^3 Schlenk flask was charged with 2,3-butanedithiol (0.86 cm^3, 6.9 mmol), dichloromethane (10 cm^3), and a stir bar and was fitted with a rubber septum. This solution was cooled to 0°C, and titanium tetrachloride (0.75 cm^3, 6.90 mmol) was added *via* a syringe to give a yellow solution. The solution was allowed to reach ambient temperature and was stirred for 3 h. This solution was filtered through a 2 cm pad of Celite to give a clear, yellow solution. Hexane (75 cm^3) was carefully layered on the dichloromethane layer. The system was allowed to equilibrate for 24 h. The solvent was decanted by cannula and the crystals were vacuum dried to afford **3** as yellow rods (1.87 g, 87% based on titanium tetrachloride): m.p. 98°C (dec); IR (Nujol, cm^{-1}) 2724 (w), 2678 (w), 2518 (s, S—H), 1443 (s), 1381 (s), 1325 (m), 1294 (w), 1257 (w), 1236 (w), 1221 (w), 1144 (m), 1092 (m), 1061 (w), 1051 (w), 1040 (w), 994 (w), 983 (w), 968 (w), 958 (w), 865 (s), 828 (w), 766 (w), 715 (w), 679 (w), 642 (w); ^{1}H NMR ($CDCl_3$, 23°C, δ) 3.95 (m, C*H*), 3.72 (broad s, S—H), 3.59 (m, C*H*), 3.55 (broad s, S—*H*), 1.67 (d, J = 5.7 Hz, CH_3), 1.58 (d, J = 6.9 Hz, CH_3); ^{13}C{^{1}H} ($CDCl_3$, 23°C, ppm) 52.10 (broad s, *C*H), 49.38 (broad s, *C*H), 22.68 (s, *C*H_3), 18.43 (s, *C*H_3). Found: C, 15.46; H, 3.24. Calc. for $C_4H_{10}Cl_4S_2Ti$: C, 15.40; H, 3.23%.

Preparation of $TiCl_4(HSCH_2CH_2CH_3)_2$

A 5-mm NMR tube was charged with titanium tetrachloride (0.010 cm^3, 0.090 mmol) and chloroform-*d* (0.70 cm^3) and was fitted with a rubber septum. *n*-Propylthiol (0.020 cm^3, 0.20 mmol) was added into the NMR tube by syringe to afford a bright yellow solution of $TiCl_4(HSCH_2CH_2CH_3)_2$: ^{1}H NMR ($CDCl_3$, 23°C, δ) 3.15 (broad s, S—*H*), 2.97 (t, CH_2CH$_2$CH$_3$, J = 6.9 Hz), 1.78 (sextet, CH$_2$CH_2CH$_3$, J = 7.2 Hz), 1.04 (t, CH$_2$CH$_2$CH_3, J = 7.5 Hz); ^{13}C{^{1}H} NMR ($CDCl_3$, 23°C, ppm) 34.23 (s, *C*H$_2$CH$_2$CH$_3$), 25.09 (s, CH$_2$*C*H$_2$CH$_3$), 12.98 (s, CH$_2$CH$_2$*C*H$_3$).

Preparation of $TiCl_4(HSCH(CH_3)_2)_2$

In a fashion similar to $TiCl_4(HSCH_2CH_2CH_3)_2$, titanium tetrachloride (0.010 cm^3, 0.090 mmol) and isopropylthiol (0.020 cm^3, 0.20 mmol) were reacted to afford a bright yellow solution of $TiCl_4(HSCH(CH_3)_2)_2$ in chloroform-*d* (0.70 cm^3): ^1H NMR ($CDCl_3$, 23°C, δ) 3.29 (m, *H*SCH$(CH_3)_2$), 2.12 (broad s, HSC*H*$(CH_3)_2$), 1.35 (d, $J = 6.6$ Hz, HSCH$(CH_3)_2$); $^{13}C\{^1H\}$ NMR ($CDCl_3$, 23°C, ppm) 33.16 (s, HS*C*H$(CH_3)_2$), 26.92 (s, HSCH$(CH_3)_2$).

Preparation of $TiCl_4(SC_4H_8)_2$ (**4**)

A 100-cm^3 Schlenk flask was charged with titanium tetrachloride (0.10 cm^3, 0.91 mmol), hexane (30 cm^3), a stir bar and was fitted with a rubber septum. The contents were cooled to 0°C and tetrahydrothiophene (0.16 cm^3, 1.8 mmol) was added by syringe to afford an orange solution. This solution was stirred for 1.5 h and the volatiles were pumped off to afford **4** as an orange solid (0.29 g, 87% based on titanium tetrachloride): m.p. 132°C (with sublimation); IR (Nujol, cm^{-1}) 1438 (s), 1424 (m), 1405 (w), 1304 (m), 1252 (s), 1204 (w), 1128 (m), 1090 (broad, w), 1066 (m), 1013 (s), 955 (m), 879 (w), 869 (w), 798 (s), 659 (m); ^1H NMR ($CDCl_3$, 23°C, δ) 3.35 (t, $J = 6.0$ Hz, SC*H*$_2$), 2.13 (m, SCH$_2$C*H*$_2$); $^{13}C\{^1H\}$ NMR ($CDCl_3$, 23°C, ppm) 39.90 (s, S*C*H$_2$), 29.81 (s, SCH$_2$*C*H$_2$). Found: C, 24.95; H, 4.28. Calc. for $C_8H_{16}Cl_4S_2Ti$: C, 26.25; H, 4.41%.

Preparation of $TiCl_4(SC_5H_{10})_2$ (**5**)

In a fashion similar to the preparation of **1**, titanium tetrachloride (0.10 cm^3, 0.91 mmol) and pentamethylene sulfide (0.19 cm^3, 1.8 mmol) were reacted to afford **5** as an orange solid (0.35 g, 97% based on titanium tetrachloride): m.p. 127°C (with sublimation); IR (Nujol, cm^{-1}) 1453 (s), 1435 (s), 1420 (s), 1367 (w), 1352 (m), 1346 (m), 1336 (m), 1300 (m), 1266 (m), 1258 (m), 1231 (m), 1210 (m), 1202 (m), 1143 (w), 1095 (m), 1064 (m), 1013 (m), 966 (s), 961 (s), 894 (s), 838 (w), 828 (w), 813 (m), 739 (w), 719 (w), 678 (w), 645 (w), 636 (m); ^1H NMR ($CDCl_3$, 23°C, δ) 3.11 (t, $J = 6.0$ Hz, SC*H*$_2$), 1.92 (m, C*H*$_2$), 1.62 (m, C*H*$_2$); $^{13}C\{^1H\}$ NMR ($CDCl_3$, 23°C, ppm) 37.97 (s, S*C*H$_2$), 27.02 (s, *C*H$_2$), 25.42 (s, C*H*$_2$). Found: C, 30.41; H, 5.13. Calc. for $C_{10}H_{20}Cl_4S_2Ti$: C, 30.48; H, 5.12%.

Preparation of $TiCl_4((CH_3)_2S)_2$ (**6**)

In a fashion similar to the preparation of **1**, titanium tetrachloride (3.0 cm^3, 27.4 mmol) and dimethyl sulfide (4.02 cm^3, 54.7 mmol) were reacted to afford **6** as an orange solid (8.41 g, 98% based on titanium tetrachloride): m.p. 79–82°C; IR (Nujol, cm^{-1}) 1597 (w), 1426 (s), 1422 (s), 1411 (m), 1366 (w), 1325 (w), 1303 (w), 1258 (m), 1104 (w), 1095 (w), 1089 (w), 1066 (w), 1062 (w), 1028 (m), 1019 (m), 978 (w), 970 (w), 922 (w), 916 (w), 796 (m); ^1H NMR ($CDCl_3$ 23°C, δ) 2.54 (s, C*H*$_3$); $^{13}C\{^1H\}$ NMR ($CDCl_3$, 23°C, ppm) 25.00 (s, *C*H$_3$). Found: C, 15.17; H, 3.75. Calc. for $C_4H_{12}Cl_4S_2Ti$: C, 15.30; H, 3.85%.

Preparation of $(TiCl_4)_2(CH_3SSCH_3)$ (**7**)

A 250-cm^3 Schlenk flask was charged with titanium tetrachloride (3.0 cm^3, 27.4 mmol), hexane (60 cm^3), and a stir bar and was fitted with a rubber septum. The contents were cooled to 0°C and dimethyl disulfide (4.93 cm^3, 54.7 mmol) was added *via* a syringe to afford an orange solution. This solution was stirred for 1.5 h and the volatiles were pumped off to afford **7** as a yellow-brown solid (6.34 g, 98% based on titanium tetrachloride): m.p. 63–64°C (dec. with sublimation); IR (Nujol, cm^{-1}) 1605 (w), 1446 (s), 1408 (w), 1365 (w), 1257 (w), 1084 (w), 1075 (w), 1058 (w), 1022 (w), 799 (m); ^1H NMR ($CDCl_3$, 23°C, δ) 2.56 (s, C*H*$_3$); $^{13}C\{^1H\}$ NMR ($CDCl_3$, 23°C, ppm) 23.20 (s, *C*H$_3$). Found: C, 5.12; H, 1.27. Calc. for $C_2H_6Cl_8S_2Ti_2$: C, 5.07; H, 1.28%.

Crystal structure determinations of **4** *and* **7**

Crystals of **4** and **7** were grown by sublimation. Suitable crystals were selected and mounted in nitrogen-flushed, thin-walled capillary tubes. The unit-cell parameters were obtained by the least-squares refinement of the angular settings of 25 reflections ($20° \leqslant 2\theta \leqslant 25°$). The systematic absences in the diffraction data for **4** are consistent with the space groups *Pnma* and $Pn2_1a$; for **7**, $P\bar{1}$ and $P1$. *E*-statistics suggested the centrosymmetric alternative for **4** and the non-centrosymmetric space group for **7**. The space group assignments were verified subsequently through further refinement. The η parameter refined to 0.87(7), indicating that the absolute structure has been determined for **7**.

Structure **4** was solved by direct methods while **7** was solved with a sharpened Patterson map. Both structures were completed by subsequent difference Fourier syntheses and were refined by full-matrix least-squares procedures. The tetrahydrothiophene carbon atoms of **4** were initially refined anisotropically, however, this led to unacceptable bond distances caused by the averaging of the positions of unique atoms with reflections on the mirror plane. Thus, the tetrahydrothiophene carbon atoms were refined isotropically with a restrained refinable bond distance. All other non-hydrogen atoms were refined with anisotropic displacement coefficients. Hydrogen atoms were treated as idealized contributions. All software and sources of the scattering factors are contained in either the SHELXTL (5.1) or the SHELXTL

PLUS (4.2) program libraries (G. Sheldrick, Siemens XRD, Madison, WI).

RESULTS

Organothiol adducts

Stable, easily isolated adducts were obtained upon treatment of titanium tetrachloride with two equivalents of cyclohexylthiol, cyclopentylthiol, or 2,3-butanedithiol in hexane at ambient temperature. Workup afforded spectroscopically pure yellow solids of $TiCl_4(C_6H_{11}SH)_2$ (**1**, 77%), $TiCl_4(C_5H_9SH)_2$ (**2**, 89%), and $TiCl_4(C_4H_8(SH)_2)$ (**3**, 87%), respectively (eq. (1)). Sublimation of these crude products (60°C, 0.1 mmHg) yielded analytically pure, moisture-sensitive yellow crystals of **1–3**. Complexes **1–3** were fully characterized by spectroscopic and analytical techniques. The X-ray crystal structure of **1** has been previously published [7]. Compound **3** exists as a 1 : 1 mixture containing syn- and anti-2,3-butanedithiol ligands. The mixture is evident in the NMR spectra, which reveal resonances for two similar 2,3-butanedithiol ligands. The infrared spectra showed sharp S—H stretches (**1**, $\nu_{SH} = 2492$ cm^{-1}; **2** $\nu_{SH} = 2520$, 2505 cm^{-1}; **3**, $\nu_{SH} = 2518$ cm^{-1}), at values slightly lower than the neat thiols, (e.g., cyclohexylthiol, 2557 cm^{-1}). We propose that the lower S—H stretches in **1–3** are due to S—H···X (X = S or Cl) hydrogen bonding [12].

$$TiCl_4 + 2\,RSH \xrightarrow{\text{hexane, 23 °C}} TiCl_4(HSR)_2 \quad (1)$$

1, R = cyclohexyl
2, R = cyclopentyl
3, 2 RSH = 2,3-butanedithiol

Reaction of titanium tetrachloride with low-boiling organothiols, such as 1-propanethiol (b.p. 67°C) and 2-propanethiol (b.p. 57°C), afforded adducts of the formula $TiCl_4(RSH)_2$. However, these adducts were exceptionally difficult to handle, due to their high volatility (estimated vapor pressures $\geqslant 10$ mmHg at 22°C). Use of hexane as solvent gave isolation difficulties, since evaporation of the solvent also led to loss of the desired complexes. It was found that the isopropylthiol and propanethiol adducts could be prepared by mixing titanium tetrachloride with 2 equivalents of the thiol at ambient temperature. Using this procedure, relatively pure samples were obtained, which were characterized by ^{1}H and $^{13}C\{^1H\}$ NMR spectroscopy. Despite the absence of a solvent, we were unable to purify $TiCl_4(n\text{PrSH})_2$ or $TiCl_4(i\text{PrSH})_2$ on the small scales (*ca.* 2 mmol) that were used. It is likely that the adducts readily dissociate to titanium tetrachloride and the respective thiols. The adducts were not explored further, since they posed no advantage over the more easily manipulated complexes **1–3**.

Organosulfides

Treatment of titanium tetrachloride with two equivalents of tetrahydrothiophene, pentamethylene sulfide, or dimethyl sulfide in hexane at ambient temperature, followed by evaporation of the solvent afforded spectroscopically pure orange solids of $TiCl_4(C_4H_8S)_2$ (**4**, 87%), $TiCl_4(C_5H_{10}S)_2$ (**5**, 97%), and $TiCl_4(C_2H_6S)_2$ (**6**, 98%), respectively (eq. (2)). Sublimation of these crude products (25–50°C, 0.1 mmHg) yielded analytically pure, moisture-sensitive orange crystals of **4–6**. Complexes **4–6** were fully characterized by spectroscopic and analytical techniques. The ^{1}H and $^{13}C\{^1H\}$ NMR spectra of **4–6** were particularly diagnostic of the adduct structures and showed downfield shifts relative to the free ligands. For example, **6** revealed resonances at δ 2.54 in the ^{1}H NMR spectrum and 25.00 ppm in the $^{13}C\{^1H\}$ NMR spectrum. The analogous values for free dimethyl sulfide were δ 2.04 and 17.81 ppm. The vapor pressures of **4–6** were estimated to be *ca.* 1–2 mmHg at 22°C, as determined by differential pressure measurements. Again, these vapor pressures may reflect equilibrium dissociation of the complex to thiol and titanium tetrachloride. These values are similar to that of **1**, which we have previously reported to be a single-source precursor to titanium disulfide films [7]. Complexes **4–6** have been previously reported, and our physical data generally agree with those of previous workers [9–11].

$$TiCl_4 + 2\,R_2S \xrightarrow{\text{hexane, 23 °C}} TiCl_4(R_2S)_2 \quad (2)$$

4, $R_2 = (CH_2)_4$
5, $R_2 = (CH_2)_5$
6, $R_2 = 2\,CH_3$

Organodisulfides

Treatment of titanium tetrachloride with dimethyl disulfide ($\geqslant 0.5$ equiv.) under conditions used to prepare **1–6** afforded $(TiCl_4)_2(CH_3SSCH_3)$ (**7**, 98%) as a yellow-brown powder upon workup (eq. (3)). NMR analysis of **7** revealed intact methyl groups with downfield shifts (^{1}H NMR δ 2.56, $^{13}C\{^1H\}$ NMR 23.20 ppm), relative to free methyl disulfide (^{1}H NMR δ 2.38, $^{13}C\{^1H\}$ NMR 21.94 ppm), which suggested an adduct structure. The microanalysis results for **7** were incompatible with a structure analogous to **1–6**, but rather implied a formulation with a 2 : 1 ratio between titanium tetrachloride and methyl disulfide. The molecular geometry of **7** was established by an X-ray structure determination (*vide infra*). Complex **7** was easily sublimed and possessed a vapor pressure similar

to **1–6**. Treatment of titanium tetrachloride with isopropyl disulfide or tert-butyl disulfide under conditions used to prepare **7** afforded complicated mixtures that we are still studying.

Crystal structures of **4** *and* **7**

The crystal structures of **4** and **7** were determined in order to establish their nuclearities and molecular geometries. X-ray data were collected under the conditions summarized in Table 1. Bond lengths and bond angles are provided in Tables 2 and 3. Perspective views of **4** and **7** are shown in Figs 1 and 2.

Complex **4** crystallized as a distorted octahedral monomer with cis-tetrahydrothiophene ligands. The tetrahydrothiophene ligands were disordered; the disorder was treated as described in the experimental section. The titanium–chlorine bonds that were trans to sulfur atoms (Ti—Cl(1) 2.232(8) Å, Ti—Cl(3) 2.233(8) Å) were *ca.* 0.05 Å shorter than the chlorines that were mutually trans (Ti—Cl(2,2A) 2.280(4) Å). The shorter bond lengths of the titanium-chlorine bonds that are trans to sulfur can be understood by the weaker trans influence of sulfur, relative to chloride. The titanium–sulfur bond lengths were 2.626(7) Å (Ti—S(1)) and 2.625(7) Å (Ti—S(2)). The cis-chlorine–titanium–chlorine angles ranged from 97.0–98.9° (av. = 97.5°), while the chlorine–titanium–sulfur angles ranged from 81.1–90.1° (av. = 83.9°). The trans chlorine–titanium–chlorine angle (Cl(2)—Ti—Cl(2A)) was 158.0(2)°, which is a considerable deviation from the idealized 180° angle. The chlorine–titanium–sulfur angles were 171.3(3)° (Cl(1)—Ti—S(2)) and 171.0(3)° (Cl(3)—Ti—S(1)). The slightly extended angles associated with cis chlorine–titanium–chlorine can be attributed to steric crowding about the titanium center caused by the shorter titanium–chlorine bonds, relative to the titanium–sulfur bonds. Such distortions were compensated by chlorine–titanium–sulfur angles that were slightly less than 90°. The disorder in the tetrahydrothiophene ligands, while successfully modeled, led to large uncertainties in the bond lengths associated with the ligands.

Complex **7** crystallized as a Ti_2Cl_8 unit with each sulfur of the dimethyl disulfide ligand bonded to a titanium atom. There were three distinct types of titanium–chlorine bonds present in **7**. The bridging chlorides (Cl(1), Cl(2)) were symmetrically bonded and showed titanium–chlorine bond lengths ranging from 2.450–2.482 Å (av. = 2.464 Å). The equatorial chlorides (Cl(3), Cl(4), Cl(6), Cl(7)) (all trans to bridging chlorides) exhibited titanium–chlorine bond lengths of 2.187–2.200 Å (av. = 2.194 Å). These bonds are *ca.* 0.09 Å shorter than the titanium–chlorine bond in **4** that is trans to a terminal chloride. The shorter equatorial titanium–chlorine bonds in **7** are the result of a diminished trans influence of a bridging chloride, relative to a terminal chloride. The third type of titanium–chlorine bond was represented by the chlorines trans to the sulfurs. These bond lengths were 2.190(3) Å (Ti(1)—Cl(5)) and 2.184(3) Å (Ti(2)—Cl(8)), and were not significantly different than the equatorial titanium–chlorine bond lengths. The geometry about each titanium exhibited substantial deviations from idealized octahedral geometry. The cis chlorine–titanium–chlorine angles ranged from 87.4–102.6°, with an average value of 95.1°. The angles associated with the bridging chlorides (Cl(1)—Ti(1)—Cl(2) 79.0(1)°, Cl(1)—Ti(2)—Cl(2) 78.8(1)°) were constrained to be considerably less than an idealized 90° by the Ti_2Cl_2 ring. The trans chlorine–titanium–chlorine angles ranged from 159.7–164.6° (av. = 161.8°). The data for the dimethyl disulfide ligand in **7** merit discussion. The sulfur–sulfur bond length was 2.052(3) Å, while the sulfur–carbon bond lengths were 1.784(5) Å (S(1)—C(1)) and 1.801(6) Å (S(2)—C(2)). The angles associated with the dimethyl disulfide ligand illustrate the geometrical distortions that are required to bind this ligand to the Ti_2Cl_8 moiety. The sulfurs were bent in toward the center of the Ti_2Cl_2 core. In addition, each sulfur was bent out of the plane containing Ti(1), Cl(5), Ti(2), and Cl(8) (i.e., S(1)—Ti(1)—Cl(1) 72.6(1)°, S(1)—Ti(1)—Cl(2) 86.2(1)°, S(1)—Ti(1)—Cl(3) 79.5(1)°, S(1)—Ti(1)—Cl(4) 91.8(1)°; S(2)—Ti(2)—Cl(1) 84.6(1)°, S(2)—Ti(2)—Cl(2) 73.1(1)°, S(2)—Ti(2)—Cl(6)

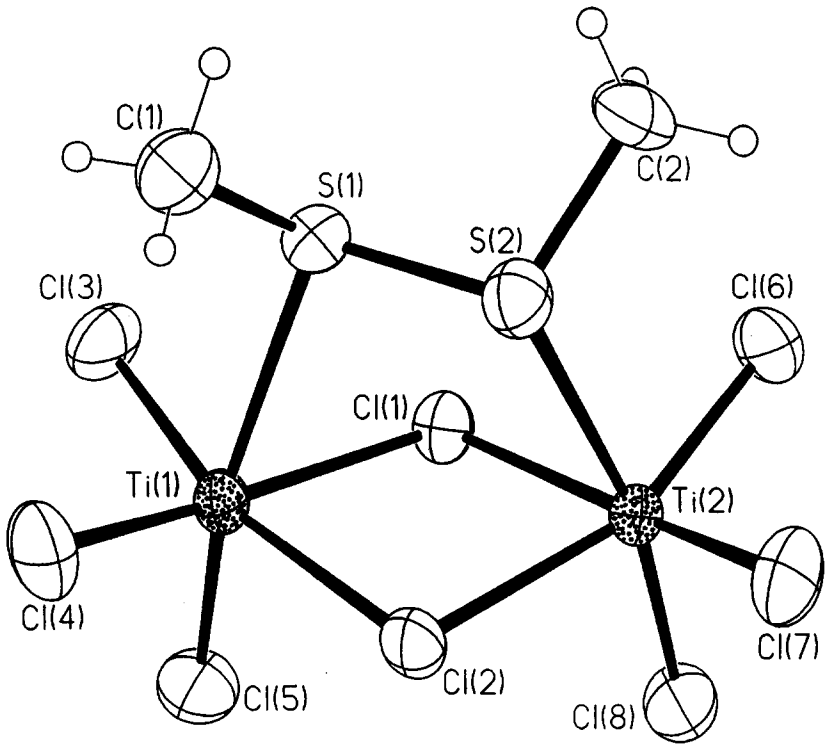

Fig. 2. Perspective view of **7** drawn with 35% probability ellipsoids.

91.0(1)°, S(2)—Ti(2)—Cl(7) 79.5(1)°). In effect, the dimethyl disulfide ligand is bonded to the Ti_2Cl_8 fragment with an approximate C_2 axis that runs through the center of the S(1)—S(2) bond and the center of the Ti_2Cl_2 ring, although such symmetry is not crystallographically imposed. The sum of the angles about each sulfur (S(1) 315.4°, S(2) 317.7°) is slightly less than that expected for pyramidal, trisubstituted sulfur with one lone pair (*ca* 328.5°).

Solution structures

We sought to determine if the solid state structures established for **4** and **7** persisted in solution. It is possible that these structures happen to be the most crystalline phases, and that different structures could be present in solution. Accordingly, variable temperature ^1H NMR spectra were recorded for **6** and **7**. With **6** in dichloromethane-d_2 the methyl singlet was

invariant at δ 2.51 between +20 and −80°C. At −80°C, a trace of dimethyl sulfide (δ 2.06, *ca.* 10% of total integration) was present. With **7** in dichloromethane-d_2, the methyl signal in the ^{1}H NMR spectrum moved steadily downfield from δ 2.52 at +20°C to δ 3.00 at −80°C. Between +20°C and −60°C, there was only one methyl singlet present. However, below −70°C a second minor methyl singlet appeared. At −80°C, the major species was at δ 3.00, the minor species appeared at δ 2.89, and the ratio between the two was 87 : 13. Free methyl disulfide (^{1}H NMR δ 2.38 at +20°C) was not observed at any temperature.

DISCUSSION

The motivation for the present study was to characterize complexes that might be involved in chemical vapor deposition processes. Furthermore, such compounds might serve as single-source precursors to titanium disulfide films. With thiols and sulfides, adducts are formed that are monomeric in the solid state by X-ray crystallography. The static chemical shift of the methyl groups in **6** suggests that there are not major changes in the coordination sphere of **6** in solution between +20 and −80°C. We propose that **6** is monomeric and 6-coordinate in solution, with a structure similar to that observed in the solid state. Based upon the easy formation of **1–6**, it is very likely that adducts of the formula $TiCl_4(HSR)_2$ and $TiCl_4(R_2S)_2$ form in the gas phase, at least in equilibrium with titanium tetrachloride and the organosulfur compounds, and are present in a CVD reaction employing titanium tetrachloride and these sulfur compounds.

Complexes **4** and **5** did not serve as single-source precursors to films under CVD conditions, while **6** and **7** gave titanium disulfide films at reactor temperatures between 400–600°C [10]. We suggest that the failure of **4** and **5** to function as precursors to titanium disulfide films can be attributed to kinetically slow β-hydrogen cleavage from the cyclic sulfur ligands due to the strained nature of such a transition state, relative to an acyclic sulfur ligand. We have previously noted that the atmospheric pressure CVD reaction of titanium tetrachloride with dimethyl sulfide or dimethyl disulfide fails to afford titanium disulfide films under conditions where tert-butythiol gives excellent coatings [6]. The presence of preformed titanium–sulfur bonds in **6** and **7** must provide a kinetically viable path for titanium disulfide film formation, while a similar path is inefficient in the two-component atmospheric pressure CVD process.

Adduct **7** adopts a very different structure than is found in **1–6**. The dinuclear structure appears to form because the disulfide ligand cannot bind strongly to the small titanium center in a bidentate fashion. Instead, the methyl disulfide coordinates to two faces of a Ti_2Cl_8 unit, leading to a bridging methyl disulfide ligand. The large chemical shift change observed upon cooling **7** from +20 to −80°C raises the possibility that there is a major change that is occurring in the coordination sphere in this temperature range. While the data do not require a change in structure, a possible structure change would be a rapid equilibrium between dinuclear **7** and a monomeric titanium tetrachloride adduct with an η^2-dimethyl disulfide ligand. Accordingly, **7** may simply be the most crystalline complex and may not be the major species in dichloromethane solution. Freezing point depression molecular weight measurements on **7** in cyclohexane and benzene designed to probe this point were inconclusive due to preciptation near the freezing points of these solvents.

Complex **7** functions as a single-source precursor to titanium disulfide films at reactor temperatures of 400–600°C [13]. Schleich has reported that the two-component CVD reaction of titanium tetrachloride with di-butyl disulfide affords titanium trisulfide films between 260–400°C, and titanium disulfide films above 400°C [4]. By contrast, di-tert-butyl sulfide gave titanium disulfide films above 260°C. It was proposed that di-butyl disulfide acts as a disulfido ion synthon, which leads to the sulfur-rich titanium phase as a kinetic product at low deposition temperatures. Our present data do not allow us to comment on Schleich's work in any detail. However, our results demonstrate that the interaction of organic sulfides and organic disulfides with titanium tetrachloride leads to different structure types. The formation of dinuclear adducts of organic disulfides may be a factor that leads to sulfur-rich phases at low temperatures. This could be a significant observation, given the current interest in the "design" of precursors to desired phases. We are continuing to explore the coordination chemistry of titanium tetrachloride with organosulfur compounds in the context of chemical vapor deposition and will report further studies in the near future.

(Received 27 May 1997; accepted 23 June 1997)

Abstract—A series of cobalt(II) complexes of general formula $[CoX_2L^2]$ (X = Cl, Br, I, NO_3, ClO_4, NCS; $L^2 = Ph_2PCH_2Si(CH_3)_2CH_2PPh_2$) have been synthesised and characterised by electronic and infrared spectroscopy and by magnetic moment studies. The bidentate phosphine ligand is an analogue of 1,3-bis(diphenylphosphino)propane (dppp). X-ray analysis of the $[CoBr_2L^2]$ complex proves tetrahedral geometry at the metal centre with the bidentate phosphine exhibiting a bite angle of 101.54(6)°. A range of evidence supports the existence of tetrahedral geometry about the metal in all the complexes in both the solid state and solution. Electronic spectroscopy is diagnostic for the tetrahedral d^7 metal ion in each case, with the ν_2 and ν_3 transitions clearly visible. Calculations of D_q and B', the RACAH parameter, have been performed for each complex; the relative magnitudes of B' indicate that the metal-phosphorus bonds are of increased covalency in comparison with Co(dppp) analogues. Magnetic moment studies show values of μ_B in the range 4.4–4.9 B.M., as expected for tetrahedral cobalt(II). IR studies show that the nitrate and perchlorate ions in the respective complexes are bound in monodentate fashion, while the $[Co(NCS)_2(L^2)]$ complex exhibits N-bonded thiocyanate groups. © 1997 Elsevier Science Ltd

Keywords: cobalt II; bidentate phosphine; X-ray structure; spectroscopic studies.

Tertiary phosphine ligands form an extensive part of the known co-ordination chemistry of the transition metals [1]. Bidentate phosphine ligands comprise an integral part of this chemistry, with the ligand 1,2-bis(diphenylphosphino)ethane (dppe) perhaps the most widely studied. The bidentates offer greater stability than their monodentate equivalents, and influence control over the stereochemistry, co-ordination number and stoichiometry of their complexes [2]. There is interest [3] in observing the effects that varying the length of the backbone in $R_2P(CH_2)_nPR_2$ ligands has upon the stereochemistry of metal complexes. Transition metal complexes of the tertiary phosphines are also of interest as homogeneous catalysts; the nature of the complex can influence selectivity, reactivity and stability [4].

The incorporation of silicon into the backbone of phosphine ligands was first carried out in 1962 [5]. Alyea and co-workers [6] subsequently reported the preparation of the novel ligand 2,2-dimethyl-2-sila-1,3-bis(diphenylphosphino)propane, $Ph_2PCH_2Si(CH_3)_2CH_2PPh_2$, subsequently denoted L^2. This ligand is a cousin of the more renowned 1,3-bis(diphenylphosphino)propane (dppp), but the presence of the dimethylsilyl backbone confers several advantages over the dppp analogue: L^2 is highly soluble in organic solvents, and the dimethylsilyl group provides a sensitive NMR probe. The crystal structure of $[Ni(NO_3)_2L^2]$ was reported in 1987 [7]. The complex provided a rare example of *allogons*, where both square planar and tetrahedral forms occur for the same complex; the square planar form was structurally characterised.

Cobalt(II) combines with diphosphines in 1:1, 1:2 and, rarely, 1:1.5 stoichiometry [1]. Studies again revolve around dppe-type ligands, with pseudo-tetrahedral geometries reported for $[Co(dppm)X_2]$ [8] and $[Co(dppe)X_2]$ [9] (X = Cl, Br, I). Complexes with dppp, the analogue of L^2, are also known; the pseudo-

tetrahedral [Co(dppp)(SPh)$_2$] [10] is a rare example of a crystallographically characterised four co-ordinate cobalt(II)-dppp complex. Complexes of general formula [Co(dppp)$_{1.5}$X$_2$] (X = CN, NCS) have also been reported [11]. These latter compounds were thought to exhibit a dimeric structure in which one of the dppp groups acted as a bidentate bridging ligand between the two cobalt centres.

The scope of the research reported here was to synthesise a range of complexes of general formula [CoX$_2$L^2] and investigate their co-ordination properties by structural, magnetic and spectroscopic (electronic, infrared) studies. Characterisation of these species would afford a direct comparison between L^2 and dppp complexes of cobalt(II) and also provide some insight into the different bonding properties of the two ligands. A further objective was to use spectroscopic techniques to determine the mode of co-ordination of the nitrate, perchlorate and thiocyanate ligands in the respective complexes.

EXPERIMENTAL

General comments

Ligand L^2 was prepared according to the literature method [6]. All complexes were prepared and handled under a nitrogen atmosphere using standard Schlenk techniques. The solvents used were reagent grade and were dried and distilled immediately prior to use. Elemental analyses were performed by M.H.W. Laboratories, Phoenix, Az. UV–vis spectra were recorded on CsI plates as Nujol mulls on a Cary-14 UV-visible spectrophotometer. Infrared spectra were recorded on a Perkin–Elmer 180 double beam spectrometer. Magnetic moment measurements were performed by the Evans method[12] on a Varian EM 360 NMR spectrometer.

X-ray crystallography

Diffraction-quality crystals of (**1**) were obtained by slow evaporation of a dichloromethane solution of the complex. The crystallographic data are summarised in Table 1. X-ray measurements were made on an Enraf–Nonius CAD4 diffractometer equipped with graphite-monochromated Mo-K_α radiation. Data were collected in the range $4 \leqslant 2\theta \leqslant 55°$ and corrected for Lorentz, polarisation and absorption effects. The structure was solved using the heavy-atom method and the NRCVAX [13] program system. Final refinement was performed with SHELXL-93 [14] using all F^2 data, with all non-H atoms allowed anisotropic motion and hydrogen atoms allowed for as riding atoms.

ligand were added together and stirred for 1 h. The resultant green precipitate was filtered, washed with ethanol and dry ether and dried *in vacuo* overnight. Yield 62%. Anal. Calcd for $C_{30}H_{30}CoN_2P_2S_2Si$: C, 57.05; H, 4.79; N, 4.43. Found: C, 57.21; H, 4.93; N, 4.50.

RESULTS AND DISCUSSION

Crystal structure of $[CoBr_2(Ph_2PCH_2Si(CH_3)_2CH_2PPh_2)]$ (**1**)

An ORTEP [16] view of the molecule appears in Fig. 1, and selected bond lengths and angles are given in Table 2. The metal centre is tetrahedral, bound to two bromine atoms [Co(1)—Br(1) 2.360(1), Co—Br(2) 2.347(1) Å] and the two phosphorus donor sites on the bidentate ligand. The Co—P distances [Co(1)—P(1) 2.344(2), Co(1)—P(2) 2.364(2) Å] compare closely with values noted in the two structurally characterised four co-ordinate Co-dppp complexes ($[CpCo(dppp)(SPh)]PF_6$ [17] Co—P 2.225, $[Co(dppp)(SPh)_2]$ [10] Co—P 2.346 Å). Angles around the metal centre range from 101.54(6) [P(1)—Co(1)—P(2)] to 117.54(4)° [Br(1)—Co(1)—B(2)]. The six membered chelate ring comprising Co(1), P(1), C(1), Si(1), C(2), P(2) adopts a chair conformation; it is noteworthy that the equivalent chelate ring in $[Ni(NO_3)_2L^2]$ [7] adopts a boat conformation. This difference is presumably due to the square planar metal centre in the nickel analogue. The chelate bite angle in (**1**) is 101.54(6)° [P(1)—Co(1)—P(2)]; this compares to much lower values observed in the dppp complexes, the enhanced value reflecting the incorporation of the larger silicon

atom into the ligand backbone. The C—Si—C angles in complex (**1**) range from 105.1(3) [C(2)—Si(1)—C(3)] to 114.0(3)° (C(2)—Si(1)—C(4)), with the C(1)—Si(1)—C(2) backbone at 111.0(3)°.

Electronic spectra

The electronic spectra of tetrahedral complexes of cobalt(II) show three electronic transitions from the $^4A_2$ ground state. ν_1 ($^4A_2 \rightarrow {}^4T_2$) occurs in the range 3000–5000 cm^{-1} and is rarely observed. ν_2 [$^4A_2 \rightarrow {}^4T_1(F)$] is usually a broad band which appears in the near IR region, while ν_3 [$^4A_2 \rightarrow {}^4T_1(P)$] is broad and intense, with noticeable fine structure. Unfortunately the broadness of these latter two bands renders their assignment somewhat arbitrary. However, electronic spectroscopy can be used to ascertain metal geometry: the structures of $[CoX_2(L)]$ (X = Cl, Br and L = dppe, dppp) and $[Co(dppe)_2I]I$ were identified as tetrahedral and pentaco-ordinate, respectively, on the basis of their electronic spectra [18a].

The electronic spectroscopic data for the cobalt(II) complexes are presented in Table 3. The solid state and solution UV–vis spectra are very similar: the spectra in the visible range for $CoCl_2L^2$ appear in Fig. 2. Bands corresponding to the ν_2 transition appear in the near-IR region; they are typically broad, with a degree of splitting observed. Dynamic Jahn–Teller effects in the excited states are almost certainly responsible for the energy spread. The bands arising from ν_3 appear in the range 13,000–20,000 cm^{-1}. The assignment of ν_2 and ν_3 allows calculation of ligand field strength Dq and the RACAH parameter B; for example, the chloride complex has average values of $\nu_2 = 7775$ cm^{-1} and $\nu_3 = 16{,}310$ cm^{-1}. These values are calculated using the method reported by Drago [18b]. B is a measure of electron–electron repulsion and has a lower value in complexes as compared with the free ion: it is hence denoted B′. Values for Dq and B′ also appear in Table 3.

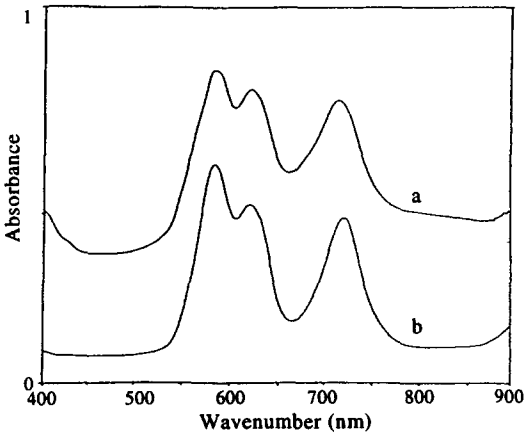

Fig. 2. UV–vis spectra of $[CoCl_2L^2]$: (a) solid state, (b) dichloromethane solution. The absorbance (*y*-axis) scale has arbitrary units.

On the basis of the Dq values calculated for the cobalt(II) complexes here, it is possible to assign the spectrochemical series as $I^- < Br^- < Cl^- \leqslant ClO_4^- < NO_3^- \leqslant NCS^-$. This is consistent with previously reported complexes [19,20]. Calculation of Dq for $[CoX_2(dppp)]$ (X = Cl, Br, I) using data given in Ref. [18a] resulted in slightly lower values than in the analogous L^2 systems here. Thus L^2 shows a slightly greater ligand field strength and a different bonding ability than dppp. It is also possible to determine that the thiocyanate ligands in $[Co(NCS)_2L^2]$ are N-bonded to the metal centre; if the ligand was S-bonded it would appear between Br^- and Cl^- in the spectrochemical series. B′ values for all the complexes are 60–73% of the free ion values, reflecting an appreciable orbital overlap. The intensities of the bands in the

electronic spectra are due in large part to molecular orbital mixing i.e. covalency [9]. The extinction coefficients of the L^2 complexes are higher than those of analogous dppp systems, again reflecting increased covalency. Lower values of the RACAH parameter B′ for $[CoCl_2L^2]$ and $[CoI_2L^2]$ compared to their dppp analogues also suggests increased covalency in the Co—P bonds in the L^2 complexes.

Magnetic moment studies

Magnetic moments for the complexes were measured by the Evans method [12] and were corrected for ligand diamagnetism and temperature-independent paramagnetism (T.I.P.). The values, which appear in Table 4, fall in the range 4.4–4.9 μ_B and are similar to those for other pseudotetrahedral cobalt(II)–phosphine complexes [21]. The values are slightly higher for complexes of L^2 than the dppp analogues (μ_B = 4.43 (Cl), 4.47 (Br), 4.56 (I) B.M.], indicative of more regular tetrahedral geometry around the metal; this is a reflection of the larger chelate ring available in L^2. The data are also consistent with the $S = 3/2$ ground state with a significant orbital contribution to the magnetic moment (μ_{eff} = 3.87 B.M. (spin only)]. The magnetic moment order ($I^- > Br^- > Cl^- \geqslant NO_3^- > ClO_4^- > NCS^-$) is concurrent with the order established by Cotton [19] and Nicolini [22] for tetrahedral $[CoX_2(L)_2]$ (L = amine) complexes.

Infrared spectra

All the complexes display characteristic ligand bands [23]. The halide complexes each show characteristic Co–X stretching frequencies, with ν(Co—Cl) 320, ν(Co—Br) 270, ν(Co—I) 224 cm^{-1}. The presence of these bands is indicative of terminal Co-halide bonds [24]. Co—P stretches are assigned in the region 210–250 cm^{-1} and, although weak, their appearance is consistent with tetrahedral geometry. For the complex $[Co(NCS)_2L^2]$ the infrared spectrum confirms the presence of N-bonded thiocyanate; Bailey *et al.* [25] established IR patterns in M–NCS, M–SCN and M–NCS–M′ systems and concluded that for S-bonded thiocyanate, the characteristic IR stretch appeared at 2130–2160 cm^{-1}. The band at 2050 cm^{-1} in the complex here is concurrent with the N-bonded form. Signals at 790 [ν(CS)] and 485 [δ(NCS)] cm^{-1} provide additional confirmation.

[d] $\mu \pm 0.1$ B.M.

Electronic spectroscopy and magnetic moment studies point to a tetrahedral geometry for $[Co(NO_3)_2L^2]$, with each nitrate ligand bound in monodentate fashion. The extent of splitting of the ν_3 band is often used to determine mono- or bidentate co-ordination of nitrate ions, with a separation of > 150 cm^{-1} implying a bidentate mode, and a corresponding value < 150 cm^{-1} pointing towards monodenticity. In this case bands at 1380 and 1280 cm^{-1} (ν_3) have a separation of 100 cm^{-1}: other bands at 1005 (ν_1), 830 (ν_2) and 750, 720 (ν_4) are consistent with monodentate NO_3^- groups. The previously-reported [7] $Ni(NO_3)_2$ complex of L^2 also shows monodentate nitrate, with a ν_3 splitting of 85 cm^{-1}.

The perchlorate complex $[Co(ClO_4)_2L^2]$ shows a split in the fundamental ν_3 (1100, 1030) and ν_4 (640, 605 cm^{-1}) modes, suggesting monodentate ClO_4^- of C_{3v} symmetry. Observation of bands for ν_2 (920) and ν_6 (440 cm^{-1}) verifies the monodentate nature of the perchlorate [26]. Tetrahedral perchlorate usually has four modes of vibration with only ν_3 and ν_4 IR active. However, monodentate co-ordination lowers the symmetry to C_{3v} and the extra modes thus appear.

CONCLUSIONS

The novel ditertiary phosphine ligand L^2, an analogue of dppp, readily forms 1:1 complexes with cobalt(II) salts (anions = Cl^-, Br^-, I^-, NO_3^-, ClO_4^-, NCS^-). The electronic and infrared spectroscopic and magnetic moment data indicate that Co^{II} has tetrahedral geometry in both the solid state and solution. The IR evidence shows that the nitrate and perchlorate anions are monodentate and that the thiocyanate group is N-bonded. The electronic spectral and magnetic data suggest that the Co—P bonds in

Scheme 1.

the L^2 complexes are of increased covalent character than those in corresponding dppp analogues, and that the L^2 ligand chelates better to the tetrahedral sites. Verification of the metal geometry and these deductions was obtained by the X-ray structural determination of the $[CoBr_2L^2]$ complex, in which the bidentate L^2 phosphine ligand exhibits a bite of 101.54(6)°.

(Received 21 April 1997; accepted 23 June 1997)

Abstract—A series of metal complexes M[HB(4-Brpz)$_3$]$_2$ [HB(4-Brpz)$_3$ = hydridotris(4-bromo-1*H*-pyrazol-1-yl)borate and M = Mn, Fe, Co, Ni, Cu, Zn, Cd, Pb] were obtained from reaction of K[HB(4-Brpz)$_3$] and the appropriate metal salt in aqueous solution. These air-stable complexes are sparingly soluble in most common solvents; they have been investigated through elemental analysis, conductivity measurements, IR, UV–vis and, in the case of diamagnetic compounds, ^{1}H and ^{13}C NMR spectroscopy. The X-ray crystal structure of cadmium(II)bis[hydridotris(4-bromo-1*H*-pyrazol-1-yl)borate] has been resolved. Six-coordinate cadmium is present in a slightly distorted octahedron with the axes not linear [angles 176.8(3), 177.2(3) and 178.7(3)°]. The 'bite' of the ligand, i.e. N—Cd—N angle, lies in the range 81.6(2)–84.1(3)° (weighted average 82.4(4)°). The Cd—N distances vary from 2.298(8) to 2.329(8) Å (weighted average 2.317(5) Å). The geometry around the B atom is tetrahedral. The N—B—N angles range from 105.8(8) to 110.5(7)° (weighted average 108.5(7)°); the B—N bond distances vary from 1.53(2) to 1.62(1) Å (weighted average 1.58(1) Å). We report and discuss also the ^{113}Cd NMR solution data of several cadmium poly(pyrazol-1-yl)borates). © 1997 Elsevier Science Ltd

Keywords: pyrazolyl borates; group 12 and 14 complexes; cadmium; ^{113}Cd NMR; X-ray; boron.

Poly(pyrazol-1-yl)borates are a versatile class of uninegative nitrogen-donor ligands [1], which form several stable coordination compounds with transition and main-group metal ions [2]. These stable and flexible polydentate ligands are ideally suited for the synthesis of monomeric derivatives in which the coordination sphere about the metal atom can be carefully controlled. Several metal derivatives containing poly(pyrazol-1-yl)borates have been found to be excellent model compounds in the interpretation of the spectroscopic features of biological systems [3].

We have recently reported on the interaction between M^{II} transition metal ions and two anionic tridentate chelating donors, namely hydridotris(4-methylpyrazol-1-yl)borate {HB(4-Mepz)$_3$} and tetrakis(4-methylpyrazol-1-yl)borate {B(4-Mepz)$_4$} [4]. These ligands incorporate respectively three and four pyrazole rings with a methyl substituent in the 4-position which can display its electronic effect on the donor strength without any additional steric influence on the metal site, as has been observed in the case of 3- and 3,5-substituted poly(pyrazolyl)borates, currently employed by other researchers.

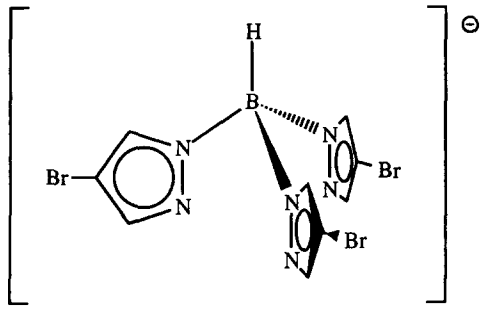

Fig. 1. Ligand used in this work.

It seemed interesting to replace an electron releasing group such as a methyl with an electron withdrawing one such as Br, to investigate the consequent net electronic effect on the chelating ability of the resulting ligand.

The present account details the synthesis and analytical and spectroscopic characterization of the anionic hydridotris(4-bromopyrazol-1-yl)borates {$HB(4\text{-}Brpz)_3$} (Fig. 1) and of its derivatives with first-row transition and post-transition M^{2+} metal ions.

We also report the X-ray crystal structure and the ^{113}Cd solution NMR characterization of the cadmium derivative $Cd[HB(4\text{-}Brpz)_3]_2$ together with a detailed comparison of the structural features of analogous cadmium compounds.

Comparison is made with the ^{113}Cd solution NMR data of several poly(pyrazolyl)borate cadmium complexes [4,5]. In fact the ^{113}Cd NMR spectroscopy, based on the fact that cadmium has two important NMR active isotopes with spins = 1/2, has been used as a 'spin spy' in the study of the properties of proteins containing zinc and other spectroscopically silent metals [6]. In the last few years Reger *et al.* have investigated the synthesis and ^{113}Cd NMR characterization of several $Cd[HB(Pz)_3]_2$ [7], $[HB(Pz)_3]CdL$ [8] and $[HB(Pz)_3]CdR$ [9] (where $HB(Pz)_3$ stands for tris (pyrazolyl)borates in general and L = N_3-, N_2-, O_2- and S_2-donors, and R = alkyl and aryl groups), containing CdN_6, CdN_5, CdN_4, CdN_3O_2, CdN_3S_2 and CdN_3C central cores. The present ^{113}Cd NMR investigation would be a further support of the actual knowledge of the rules governing ^{113}Cd NMR chemical shift in solution of this kind of complexes.

RESULTS AND DISCUSSION

Synthesis of the derivatives

Derivatives **1–8** were synthesized in a water solution by the metathetic reaction of $K[HB(4\text{-}Brpz)_3]$ with the appropriate metal salt in the ratio 2 : 1, as indicated in the following equation:

$$MX_2 + 2K[HB(4\text{-}Brpz)_3] \xrightarrow{H_2O} M[HB(4\text{-}Brpz)_3]_2 + 2KX \quad (1)$$

1–8

M = Mn, Co, Ni, Zn, Cd or Pb, X = Cl
M = Fe or Cu, $X_2 = SO_4$

All the complexes were isolated as micro crystalline air-stable solids. Analytical data or derivatives **1–8** are summarized in Table 1. Some of them are high-melt-

[a] $[HB(4\text{-}Brpz)_3]$ is hydridotris(4-bromopyrazol-1-yl)borate $C_9H_7BN_6$.
[b] Calculated values in parentheses.
[c] Decomposes without melting.

ing solids whereas some others gradually decompose on heating without melting. They are insoluble in water, alcohols and hydrocarbons, and moderately soluble in chlorinated solvents, DMSO, aromatic hydrocarbons and acetone, in which they are not electrolytes.

IR data

Selected infrared data of the spectra of derivatives **1–8** in the solid (Nujol mull) state, are shown in Table 2.

In all the compounds **1–8** a medium absorption in the range 2460–2480 cm^{-1}, due to ν(B—H) stretching, has been detected. This band is generally shifted to higher frequencies with respect to that of the potassium ligand salt K[HB(4-Brpz)$_3$], and appears as a single neat peak, whereas in the derivatives of {HB(4-Mepz)$_3$} it was always split into two components [4].

Besides the expected weak absorptions over 3000 cm^{-1}, assignable to heterocyclic ν(C—H) stretching, we have found the bands due to 'breathing' of the pyrazole rings at unusually high frequencies, in the range 1650–1700 cm^{-1}; the same bands in the case of {HB(pz)$_3$} and {HB(4-Mepz)$_3$} derivatives were found in the range 1550–1600 cm^{-1} [1,4]. This fact could be explained by a stronger polarization on the pseudo-double C—C and C—N pz bonds in M[HB(4-Brpz)$_3$]$_2$, caused by the presence of an electron withdrawing group such as Br in 4-position. The bands assignable to ν(B—N) vibrations are probably hidden under the typical strong absorptions of Nujol.

In the far-IR region two main groups of absorptions, likely due to various bending modes of vibration of the ligand skeleton, have been detected: the first

between 480 and 400 cm^{-1} and the second between 300 and 200 cm^{-1}. Finally the medium or strong absorptions at *ca* 380–330 cm^{-1} could be tentatively assigned to ν(N—M) stretching frequencies modes [10].

UV–vis data

The UV–vis spectra of the potassium ligand salt and of derivatives **1–8** have been carried out in chloroform solution and the absorption maxima with their extinction coefficients are reported in Table 3.

In all cases the extinction coefficient of the band at 240 nm is approximately twice of that found for K[HB(4-Brpz)$_3$], in agreement with the 2 : 1 ligand to metal ratio found by elemental analyses (Table 1).

In all the spectra a broad and intense absorption was detected at *ca* 240 nm, which is due to the pyrazolyc intraligand transition [4,11]. This band is similar to that found in the spectra of {HB(4-Mepz)$_3$} derivatives [4], thus indicating that substitution of an electron releasing group (Me) with an electron withdrawing one (Br) doesn't give rise to appreciable electronic changes on the relative energy levels of HOMO and LUMO in pz chromophores of the ligand.

It is worth noting that the derivatives **1–8** are less soluble in chlorinated solvents with respect to analogues {HB(4-Mepz)$_3$} derivatives, and none of the expected *d–d* transition bands were detected at the concentration employed. Consequently a comparison of the crystal field stabilization energies between {HB(4-Brpz)$_3$}, {HB(4-Mepz)$_3$} [4] and {HBpz$_3$} [11] derivatives is impossible.

In the spectra of Fe, Co and Cu complexes, two additional bands at 270–290 and 310–340 nm were observed, which should be attributed to 'metal to ligands charge transfer' (MLCT) transitions, based on their relatively high extinction coefficient [11]. The MLCT absorption (ε = 11620) found at 336 nm in the spectrum of Fe[HB(4-Brpz)$_3$]$_2$ is particularly intense.

NMR data

The ^{1}H and ^{13}C NMR spectra have been performed in the case of diamagnetic zinc, cadmium and lead derivatives and the data are reported in Table 4. The choice of the deuterated solvent employed was dictated by the solubility of the derivatives, K[HB(4-Brpz)$_3$] being sufficiently soluble only in protic solvents such as water and methanol, whereas Zn[HB(4-Brpz)$_3$]$_2$ only in deuterated DMSO.

The presence of only one set of signals in both proton and carbon NMR spectra, over the temperature range 220–300 K indicates equivalence of the three pz rings and, as expected, the presence of ligands acting as tridentate not only in the solid state (see crystallographic section) but probably also in solution.

The 3- and 5-H resonances are downfield shifted upon coordination, those of Cd[HB(4-Brpz)$_3$]$_2$ being more deshielded with respect to those of Zn[HB(4-Brpz)$_3$]$_2$, in accordance with a likely stronger donation of the ligand in the former compound, and also with that observed in the other Zn and Cd poly(pyrazolyl)borates derivatives previously synthesized [4,5].

The C(3) and C(5) nuclei absorb at approximately the same frequencies observed in Zn[HB(4-Mepz)$_3$]$_2$ and Cd[HB(4-Mepz)$_3$]$_2$ [4], whereas C(4) resonance

has been found in the range 93–96 ppm, upfield shifted of *ca* 20 ppm with respect to C(4) in {HB(4-Mepz)$_3$} analogues [4], due to the different electronic features of the 4-substituents Br and Me.

The X-ray crystal structure of Cd[HB(4-Brpz)$_3$]$_2$

The crystal structure of the title compound consists of discrete molecules. The representation of the molecule along the *b* axis with the numbering scheme drawn with the program ORTEP [12] is given in Fig. 2.

The molecule shows a virtual C_{3i} symmetry although it exhibits no real crystallographic symmetry and all atoms occupy general positions.

Since the differences among chemically equivalent interatomic distances or angles have only relative meaning, their average values are given in Table 5, whereas selected bond distances and angles in the coordination sphere are listed in Table 6.

The packing of the molecules in the crystal is ensured by intermolecular short approaches: Br(3)···C(5D) *i* 3.74(1) Å, where *i* means $1+x$, y, z; N(1E)···Br(1) *ii* 3.46(1), C(5C)···Br(5) *ii* 3.72(1), C(3E)···Br(1) *ii* 3.59(1), C(4E)···Br(1) *ii* 3.54(1), C(5E)···Br(1) *ii* 3.50 (1), Br(2)···C(4F) *ii* 3.58(1), Br(2)···C(5F) *ii* 3.56(1), Br(4)···C(4B) *ii* 3.70(1), Br(4)···C(5B) *ii* 3.47(1) Å, where *ii* means $3/2-x$, $1/2+y$, $1/2-z$.

[a] All values were calculated according to A. Domenicano, A. Vaciago and C. A. Coulson, *Acta Cryst.*, 1975, **B31**, 221.
[b] *cis* intraligand.
[c] *cis* interligand.
[d] *trans* interligand.

The structure of Cd[HB(4-Brpz)$_3$]$_2$ is a distorted octahedron where the Cd—N distances vary from 2.298(8) to 2.329(8) Å with a weighted average of 2.317(5) Å, slightly shorter than the values found in other similar complexes given in Table 7. The crystal data, data collection and refinement of the structure are reported in Table 8.

The chelate rings restrain the intraligand N—Cd—N bond angles in the range 81.6(2)–84.1(3)°, with a weighted average 82.4(4)°, whereas the *cis* interligand N—Cd—N bond angles range from 95.2(3)

[a] **A** is $Cd[HB(3,5\text{-}Me_2pz)_3]_2$.
[b] **B** is $Cd[B(3\text{-}Mepz)_4]_2$.
[c] **C** is $Cd[B(pz)_4]_2$.
[d] **D** is $Cd[HB(pz)_3]_2$.
[e] **E** is $Cd[HB(3\text{-}phpz)_3]_2$.
[f] **F** is $[B(pz)_4]Cd[HB(3\text{-}phpz)_3]$.
[g] **G** is $Cd[HB(4\text{-}Brpz)_3]_2$.

to 100.6(3)°, with weighted average 97.6(9)°. These angles are comparable with the corresponding angles 82.7(1) and 97.3(1)° found in $Cd[HB(3,5\text{-}Me_2pz)_3]_2$ [7b]. The *trans* interligand N—Cd—N bond angles are in the range 176.8(3)–178.7(3)°, with a weighted average 177.6(6)°. The weighted average intraligand N···N non-bonding distances for the donor atoms is 3.05(1) Å whereas the weighted average interligand N···N is 3.48(2) Å.

The planarity of the six pyrazole rings was derived from the least-squares planes. The probability that the ring is non-planar turned out to be: $P > 99\%$ for N(1B)—C(5B), N(1C)—C(5C), N(1D)—C(5D) and N(1F)—C(5F); $P = 26.5\%$ for N(1A)—C(5A) and $P = 98.7\%$ for N(1E)—C(5E). Maximum out of plane displacement (Å): C(5B) −0.029(9), C(3C) 0.025(11), C(5D) 0.024(10), C(5E) 0.016(11) and C(3F) −0.029(11). In the pyrzole rings, the rules about the pattern of values for the angles [13] apply: Cd—N(2)—C(3) > Cd—N(2)—N(1) (weighted average 134.6(8) > 118.5(7)°), N(2)—N(1)—C(5) > N(1)—N(2)—C(3) (weighted average 111.7(3) > 106.1(4)°), N(2)—C(3)—C(4) > C(4)—C(5)—N(1) (weighted average 109.5(4) > 104.3(3)°). A similar trend was observed in $[HB(pz)_3Cu(PPh_3)]$ [14] and in $Zn[HB(4\text{-}Mepz)_3]_2$ [4].

The geometry around the B atom is tetrahedral. The B—N bond distances vary from 1.53(2) to 1.62(1)

Å with weighted average 1.58(1) Å, longer than the values found in $Zn[HB(pz)_3]_2$, 1.541(3) [15] and in $Zn[HB(4\text{-}Mepz)_3]_2$, 1.547(6) Å [4]. The angles N—B—N range from 105.8(8) to 110.5(7)° with weighted average 108.5(7)°, comparable with the values found in $Zn[HB(pz)_3]_2$ 108.9(5)° [15] and in $Zn[HB(4\text{-}Mepz)_3]_2$ 108.7(7)° [4]. The B(1)···Cd and B(2)···Cd distances are 3.37(1) and 3.43(1) Å (weighted average 3.40(3) Å); the B(1)···Cd···B(2) angle is 177.8(3)°.

It is also of interest to compare the structural data of the coordination environment of the metal of $Zn[HB(pz)_3]_2$ (M—N_{av} 2.15 Å, N—M—N_{av} 85.6°) [15], $Zn[HB(3,5\text{-}Me_2pz)_3]_2$ (M—N_{av} 2.17 Å, N—M—N_{av} 86.4°) [16] and $Zn[HB(4\text{-}Mepz)_3]_2$ (M—N_{av} 2.14 Å, N—M—N_{av} 85.5°) [4] with those of homoleptic $Cd[HB(pz)_3]_2$ (M—N_{av} 2.33 Å, N—M—N_{av} 81.8°) [7d], $Cd[HB(3,5\text{-}Me_2pz)_3]_2$ (M—N_{av} 2.35 Å, N—M—N_{av} 82.7°) [7b] and our $Cd[HB(4\text{-}Brpz)_3]_2$ (M—N_{av} 2.32 Å, N—M—N_{av} 82.4°). All the structures are six-coordinate, but there is an average M—N bond distance increase of 0.18 Å together with an average N—M—N bond angle decrease of 3.53°, on going from zinc to cadmium derivatives, caused by the larger cadmium atom size, compared to that of the zinc atom [17].

The steric demand of the ligands determine the stability of complexes, in ligand competition and exchange [18]. It is interesting to calculate effective cone angles of ligands from the crystallographic structural data. For the $\{HB(4\text{-}Brpz)_3\}$ ligands, the cone vertex was centered on the cadmium atom and the middle of the Cd—N vectors was assumed to be the cone axes. The angle between the cone axes and the vector which touches the van der Waals radii of the hydrogen atoms closest to Cd (r = 1.17 Å) is: 100.5° for H(3A), 100.2° for H(3B) and 100.9° for H(3C) for one ligand and: 100.0° for H(3D), 98.6° for H(3E) and 100.0° for H(3F) for the other ligand. These angles correspond to a total average value θ: 201.0 and 199.1°, respectively. These angles are narrower than the corresponding angles 212.2° found in the complex $[HB(pz)_3Cu(PPh_3)]$ [14] and 208.0 and 212.0° found in $Zn[HB(4\text{-}Mepz)_3]_2$ [4]. The difference is attributable to the longer Cd—N bond distance 2.317(5) Å as compared with the corresponding Cu—N 2.076(6) [14] or Zn—N 2.135(15) Å [4] bond distances.

^{113}Cd *NMR data*

The ^{113}Cd NMR chemical shifts of various bis(polypyrazolyl)borate cadmium derivatives [4,5] have been recorded in $CDCl_3$ and acetone-d_6 solutions, at concentrations ranging from 0.5 to 1.0 mM, and are given in Table 9.

We have thought to employ both deuterated chloroform and acetone in order to compare the effects of the chemical shift caused by a non-polar solvent and a polar one, respectively. All the absorptions fall in

$Cd[HB(pz)_3]_2$	196.4	198.3	[7b]
$Cd[HB(4\text{-}Mepz)_3]_2$	193.6	195.9	[4]
$Cd[HB(4\text{-}Brpz)_3]_2$	187.6	193.8	This work

the range typical for six-coordinate species [7,8,9] and, apart from a general increase in shielding (*ca* 2–6 ppm), which could be ascribed to a secondary effect such as dipolar interactions between solvent molecules and the B—H fragment in tris or with the free lone pair of N donor atom of the fourth pyrazole in tetrakis, the choice of acetone as solvent does not produce any other relevant effect on ^{113}Cd chemical shift for coordinatively saturated CdN_6 complexes.

The value of $Cd[B(4\text{-}Mepz)_4]_2$ (218.3 ppm) can be compared to those of $Cd[B(pz)_4]_2$ (221.1 ppm) [7b] and of $Cd[B(3\text{-}Mepz)_4]_2$ (202.5 ppm) [7b], the only other tetrakis cadmium derivatives till now known. It seems that the Me group in 4- and mainly in 3-position of the pyrazole rings produces a shielding with respect to the unsubstitute tetrakis:

$$\{B(3\text{-}Mepz)_4\} > \{B(4\text{-}Mepz)_4\} > \{B(pz)_4\}$$

In the case of tris(pyrazolyl)borate cadmium derivatives more ^{113}Cd data are available [7,8,9]. The following trend of shielding power for Tris (pyrazolyl)borate donors is found:

$$\{HB(4\text{-}Brpz)_3\} > \{HB(4\text{-}Mepz)_3\} > \{HB(pz)_3\}$$
$$> \{HB(3\text{-}Mepz)_3\} > \{HB(3,5\text{-}Me_2pz)_3\}$$

It is interesting to note that the chemical shift of cadmium complexes of $\{HB(4\text{-}Brpz)_3\}$, $\{HB(4\text{-}Mepz)_3\}$ and $\{HB(pz)_3\}$ ligands cannot be related to pK_a of the pyrazole moiety [19]. If we compare the ^{113}Cd NMR data of our derivatives with those reported in literature for analogous compounds it can be noted that in the case of derivatives containing donors having relatively small or no substituents in pz rings, a decrease in Cd—N_{av} bond distance is accompanied by an increase in shielding.

It has been argued by Reger [7d] that the ^{113}Cd shielding effect depends upon the coordination number and the geometry, primarily the Cd—N distances. In order to vary the M—N bond lengths it has been recently demonstrated [7,8,9] that the steric hindrance in 3-position plays a relevant role, while other electronic effects can also be introduced by changing the 5-position of the rings and/or going from a tris (pyrazolyl)borate to a tetrakis one.

With regard to ^{119}Sn NMR spectroscopy, the trends observed are easier to explain [20], whereas in the case of ^{113}Cd, at this stage of the research it is not clear why our ligand $\{HB(4\text{-}Brpz)_3\}$ is able to generate a higher shielding of Cd nucleus with respect to $\{HB(pz)_3\}$ and to $\{HB(4\text{-}Mepz)_3\}$, which differ by a H and a Me in 4-position, respectively. Additional X-ray structural data are necessary to further investigate the effect of substitution in 4-position upon ^{113}Cd NMR chemical shifts here discussed, and several studies are ongoing in our laboratory regarding this point on mixed donor atom combinations and also in presence of 4-substituted neutral bis- and tris (pyrazolyl)methanes [21], which are isoelectronic analogues of the anionic poly(pyrazolyl)borate donors.

EXPERIMENTAL

General laboratory equipment

Concentration was always carried out *in vacuo* (water aspirator). The samples were dried *in vacuo* till constant weight (20°C, *ca* 0.1 Torr). Carbon, hydrogen, and nitrogen analyses were carried out on a Fisons Instruments EA 1108 CHNS-O, while molecular weight determinations were performed by a Knauer membrane osmometer. Infrared spectra were recorded from 4000 to 250 cm^{-1} on a Perkin–Elmer 2000 System Series FTIR instrument. The electronic spectra were recorded in chloroform solution with an HP 8452A Diode Array Spectrophotometer. ^{1}H-, ^{13}C- and ^{113}Cd-NMR spectra were recorded on a Varian VXR-300 spectrometer operating at room temperature (299.94 MHz for ^{1}H, 75.05 MHz for ^{13}C and 66.55 MHz for ^{113}Cd). Some spectra were also recorded on a Varian Gemini-200 (200 MHz for ^{1}H, 50 MHz for ^{13}C). The chemical shift is reported in ppm from Me_4Si (^{1}H and ^{13}C, calibration from internal deuterium solvent lock) and $CdClO_4$ (^{113}Cd) values. The conductivity of the acetone solutions was measured with a Crison CDTM 522 conductimeter at room temperature.

Synthesis

Potassium[hydridotris(4-bromo-1H-pyrazol-1-yl)borato], *K[HB(4-Brpz)$_3$]*. A mixture of 4-Br-pyrazole (20 g, 0.136 mol) and KBH_4 (1.83 g, 0.034 mol) was heated gradually. Melting with a slight evolution of hydrogen occurred at *ca* 90°C. The mixture was finally heated at 170°C until the volution of 3 equiv. of hydrogen per KBH_4. The mixture was cooled to room temperature and xylene was added with vigorous stirring. The xylene solution was separated by filtration. This treatment was repeated several times to remove unreacted 4-Br-pyrazole. The remaining solid was washed with hexane–petroleum ether (1 : 1 *v/v*) to give a white crystalline solid, which was identified as K[HB(4-Brpz)$_3$] by elemental and spectral analyses. M.p.: 287–

289°C. Elemental analyses calcd for $C_9H_7BBr_3KN_6$: C, 22:1; H, 1.4; N, 17.2; found: C, 22.2; H, 1.5; N, 16.9.

Bis[hydridotris(4-bromo-1H-pyrazol-1-yl)borate] metal (II), **1–9**. These compounds were prepared by adding an aqueous solution (*ca* 50 cm^3) of 1 mmol of the appropriate metal salt to an aqueous solution (*ca* 50 cm^3) of potassium hydridotris(4-bromo-1*H*-pyrazol-1-yl)borate in a 1:2 molar ratio. The compounds **1–8** precipitated immediately: the complexes were filtered off, washed with diethyl ether, and dried *in vacuo*.

X-ray analysis

Suitable crystals of the complex $Cd[HB(4\text{-}Brpz)_3]_2$ were obtained by crystallization from dichloromethane/acetonitrile. A crystal of dimensions $0.24 \times 0.28 \times 0.98$ mm was used for data collection. Accurate unit-cell parameters were determined from a least-squares fit for 25 reflections measured on the Enraf–Nonius CAD4 diffractometer with graphite-monochromated Cu-K_α radiation of the Centro Grandi Strumenti dell'Università, Pavia, Italy.

The intensities of 6761 independent reflections in a complete quarter of the reflection sphere were collected by the $\omega/2\theta$ scan technique within the angular range $4 < 2\theta < 70°$. A total 4234 reflections having $I > 3\sigma(I)$ were regarded as observed and used in the structure analysis. The data were corrected for Lorentz-polarization effects and for absorption according to North *et al.* [22] with minimum and maximum absorption factors of 0.7150 and 0.9997. An approximate absolute scale factor and a mean thermal parameter of 6.54 $Å^2$ were determined by Wilson's method [23]. Crystal data, intensities data collection parameters and structure refinement results are summarized in Table 8.

Structure determination and refinement

The structure was solved by Patterson and Fourier methods. The positional parameters of the cadmium atom derived from the three-dimensional Patterson map and the isotropic thermal parameter, were refined in three cycles of least-squares refinement. A subsequent three dimensional difference Fourier synthesis revealed all the remaining non-hydrogen atoms. The full-matrix least-squares method refined the positional and first isotropic and later anisotropic thermal parameters. The positions of hydrogen atoms were calculated from the geometry of the compound and checked in a final difference Fourier map and not refined but included in the calculations in fixed positions, with the same isotropic thermal parameters of their bonded atoms.

The final R was 0.047 for the observed reflections. At all stages of the analysis the observed reflections were given unit weight, since the use of weights obtained from counting statistics did not lead to better results. The average shift/esd ratio in the final refinement cycle was 0.02 both in the positional and in the thermal parameters of the non-hydrogen atoms. The final difference Fourier map showed maximum and minimum $\Delta\rho$ values 0.674 and -0.349 e $Å^{-3}$.

All calculations were carried out with the Enraf–Nonius SDP crystallographic computing package [24] and with local programs.

Supplementary material—Tables of atomic positional parameters of non-hydrogen atoms and hydrogen atoms, table of anisotropic thermal parameters, tables of bond distances and bond angles involving non-hydrogen atoms and hydrogen atoms, table of planarity of molecular regions and a listing of observed and calculated structure factors (total of 40 pages).

(Received 1 November 1996; accepted 16 June 1997)

Abstract—Influence of nickel oxide loading (5; 10; 20 wt% Ni) and temperature of heat treatment (400, 700, 1100°C) on the structure, texture and reducibility of coprecipitated $NiO–Al_2O_3$ catalyst was investigated. X-ray diffraction (XRD), diffuse reflectance spectroscopy (DRS), low temperature nitrogen adsorption (LTNA) and hydrogen reduction confirmed significant changes in physico-chemical properties as the function of mentioned variables. The results showed that the interactions in coprecipitated $NiO–Al_2O_3$ system are intensive even at 400°C. At 700°C the observed interactions are accompanied by considerable changes in surface area, reducibility and the coordination of Ni(II), while at 1100°C treatment intensive structural and textural changes were registered. © 1997 Elsevier Science Ltd

Keywords: structure; Ni^{II} coordination; texture; reducibility; coprecipitation; nickel–alumina catalyst.

The behavior of $NiO–Al_2O_3$ catalysts is strongly dependent on the preparation method, as well as on pretreatment conditions. Different methods of $NiO–Al_2O_3$ system preparation include precipitation of Ni ions on Al_2O_3 support [1,2], coprecipitation of Ni and Al ions on Al_2O_3 [3], coprecipitation of Ni and Al ions [4,5,6], impregnation of appropriate form of alumina [4,7,8–10] by different Ni-precursor solutions; bulk fusion of nickel and aluminum salts [2], mechanical powder mixing [2] etc. The complete procedure of catalyst synthesis includes different subsequent steps of drying, dehydration, activation (calcination/reduction) and passivation. It has been shown that each step in this preparation sequence affects the performance of the obtained catalysts [7,9]. For nickel–alumina catalyst, obtained by wet impregnation with nitrate solution, Bartholomew and Farrauto [7] have shown that the calcination temperature, temperature and heating rate during reduction step, hydrogen space velocity during reduction, nickel loading and passivation procedures affect the surface area and the fraction of the reduced nickel. We do believe that these observations could be generalized for the other catalysts, prepared by different methods.

Catalyst component interactions, influenced by each of the steps in complex catalyst preparation procedure, have an additional affect on catalyst activity and selectivity. Tauster *et al.* [11] were first to report about these phenomena in the TiO_2 supported catalyst. They observed that hydrogen and carbon monoxide chemisorption on reduced transient metal oxides, deposited on titania support, decrease with the increase of reduction temperature. The phenomenon was explained by formation of metal–metal bonding between transient metal and either titanium atoms, or titanium cations, resulting in $TiPt_3$-type compounds on the catalyst surface. This type of interaction was later on signified as strong metal support interactions (SMSI). Metal support interactions were not studied in $NiO–Al_2O_3$ systems for quite a long time, perhaps since alumina is not a reducible oxide. However, Huang *et al.* [12] have revealed that in the system $NiO–Al_2O_3$ some kind of metal-support interactions apparently are present. In these systems SMSI are promoted by formation of nickel spinel $NiAl_2O_4$. A small amount of metallic nickel on $Ni^{2+}/NiAl_2O_4/Al_2O_3$ catalyst surface, detectable only by ESCA,

* Author to whom correspondence should be addressed.

does not adsorb hydrogen. Namely, some species of mobile $/Al_xO_y/_n$ aggregates, formed during the thermal disproportiation of $NiAl_2O_4$, prevent or hinder hydrogen adsorption. The surface of metallic nickel is partially covered by $/Al_xO_y/_n$ species. It has to be mentioned that the hydrogen adsorption on the catalyst surface is increased after catalyst pretreatment by CO and O_2, similar to the behavior of the transient metals supported on titania.

The considerable influence of the variety of subtle structural differences on catalyst properties could be an explanation why the supported nickel catalyzes such different processes, as steam reforming [13,14], methanation [9,15], oxidation [16–20], hydrogenolysis [21] and enantioselective processes [22].

The investigations on the effect of catalyst preparation procedure on structural, textural and other physico-chemical properties of the $NiO–Al_2O_3$ as catalyst precursor for different processes were performed. The results on the $NiO–Al_2O_3$ catalyst precursors prepared by coprecipitation method are presented in the paper. The following papers will consider the catalyst prepared by impregnation and mechanical powder mixing.

EXPERIMENTAL

Catalyst preparation

Catalyst precursors were coprecipitated from nitrate solution by NaOH (20 wt% solution, pH = 9.5, ambient temperature). The Ni/Al ratio in initial nitrate solutions was varied in order to obtain different Ni loading. The precipitates, matured for 24 hrs, were vacuum filtered and subsequently washed until free of nitrate. The air dried samples (105°C, 48 h) were ground in an agate mortar and the powders obtained were air dried again (105°C, 6 h). The nickel loading obtained in the dried samples was 5.1, 9.93 and 19.96 wt%, respectively. The samples were thermally treated at 400, 700 and 1100°C in a static air atmosphere for 6 h.

Sample characterization

Wet chemical analysis. The amount of nickel in the oxide form was determined by acidic extraction of nickel from the sample, followed by dimethylglyoxime precipitation [23,24].

Total surface area. The surface area was determined by dynamic low temperature nitrogen adsorption in helium as a carrier (Perkin–Elmer Shell, Sorptometer Model 212 D). The data were interpreted using the BET equation and an effective N_2 cross-sectional area of 16.2 nm^2.

Porosity. The total porosity (Q) was calculated from apparent (γ) and true (d) densities, $Q(\%) = (1-\gamma/d)\,100$, determined pycnometrically using mercury and benzene vapors as working fluids [25].

Pore size distribution. Pore size distribution was determined by mercury porosimetry (Carlo Erba, Series 1500), pressure range up to 1500 bars.

X-ray diffraction. Phase composition was determined by X-ray diffraction (XRD) (Philips PW 1050 diffractometer with Ni filter and Cu radiation). The average crystallite size (D) was calculated by Scherrer method (X-ray line broadening, $D = K\lambda/\beta\cos\theta$) with NaCl as an internal standard. The half-maximum line width (β) for NiO (111), NiO (200) and NiO (220) planes were applied. The constant K was approximated as 0.95 as previously published [18].

Diffuse reflectance spectroscopy. Diffuse reflectance spectra were registered in the range 10,000–45,000 cm^{-1} at room temperature. (Carl Zeiss Jena, SPM-2). The Kubelka–Munk function $F(R) = (1-R_\infty)^2/2R_\infty$ was applied in data interpretation.

Reducibility. The reducibility of the samples were analyzed by dynamic DSC method (Du Pont 1050) in dry hydrogen flow 25 cm^3/min, in the temperature range 20–450°C at heating rate 10°C/min.

Nomenclature of the samples

The following unified C–W–T nomenclature of the catalyst samples was used in the paper: C-designate the coprecipitation preparation method; *W*—nickel loading in wt%, *T*—temperature of the heat treatment (as example C-5-400 is sample prepared by coprecipitation, containing 5 wt% of Ni, thermally treated at 400°C).

RESULTS AND DISCUSSION

X-ray phase and crystallite size analysis

The phase composition of the coprecipitated samples is illustrated by the XRD patterns in Fig. 1. The broadened Bragg peaks observed for the samples heated at 400°C indicate the small particle sizes of crystalline phases. The presence of γ–Al_2O_3 is confirmed in all samples. Akimov *et al.* [26] claimed, based on phase composition and magnetic properties of similar materials prepared by coprecipitation using ammonia, that spinel formation is possible at temperatures as low as 400°C. Based on our results it is difficult to say anything about $NiAl_2O_4$ formation, since in the broadened XRD patterns, the signals of nickel spinel and γ–Al_2O_3, having very similar crystal lattices, overlapped. The color of the samples are bright gray, characteristic of a mixture of diluted nickel and alumina oxides. The d-spacing of the γ–Al_2O_3 was increased related to the ASTM data; for C-5-400 sample the experimental and reference ASTM values are as follows: 2.392/2.39 (311); 1.977/1.977 (400) and 1.406/1.395 (440). The increase of the d-spacing could be explained by NiO–γ-Al_2O_3 solid solution formation. Since the increase of d-spacing is not

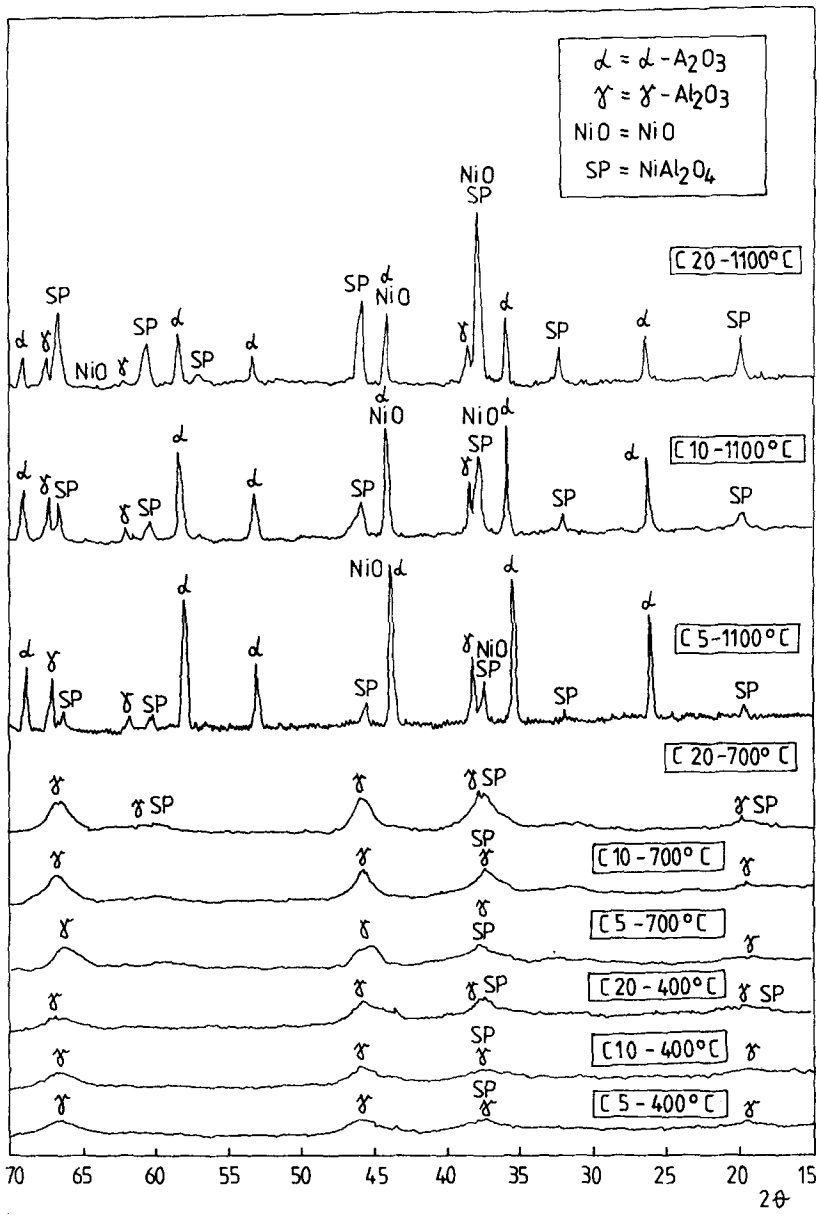

Fig. 1. XRD patterns of the coprecipitated samples.

linearly proportional to the NiO content, the effect of $NiAl_2O_4$ formation, its crystallinity and/or clustering of dopant ions within structures, i.e. regions of high or low concentrations, should be additionally considered. It could be concluded that in the coprecipitated $NiO–Al_2O_3$ system treated at 400°C, with up to 20 wt% of Ni, the components form a solid solution of $NiO–NiAl_2O_4$-γ-Al_2O_3.

The diffraction patterns of the samples treated at 700°C are similar to those obtained at lower temperature, the sharpening of the Bragg peaks indicating some higher crystallinity in the system. The increased d-spacing of the γ–Al_2O_3 in comparison to the ASTM data is also observed; for C-5-400 sample values are: 2.392/2.39 (311); 2.019/1.977 (400) and 1.413/1.395 (440). These results also suggest the formation of a solid solution NiO-$NiAl_2O_4$-γ-Al_2O_3 with previously mentioned additional effects.

In all samples treated at 1100°C, the diffraction lines for the following phases: NiO, $NiAl_2O_4$ γ- and α-Al_2O_3 were identified. The presence of γ-Al_2O_3 in the samples treated at so high temperatures suggests that the nickel oxide hinders the crystallization and phase transformations of alumina. However, since there is overlapping of main XRD signals of the presence phases, as illustrated in Table 1, the calculation of NiO crystallite size was not reliable.

For semi-quantitative estimation of $NiAl_2O_4$, for-

Table 1. XRD data of the nickel and aluminum compounds

Compound	2θ (°)	d (Å)	I/I (%)	*hkl*	ASTM
$NiAl_2O_4$	37.04	2.427	100	311	10-339
NiO	37.31	2.410	91	111	4-0835
η-Al_2O_3	37.47	2.400	60	311	4-0875
γ-Al_2O_3	37.63	2.390	80	311	10-425

α-Al_2O_3	43.39	2.013	65	113	10-173

med during the thermal treatment of the samples, the (440) plane ($2\theta = 65.69°$) is most suitable [27], showing the increase of spinel quantity by increased initial NiO content and treatment temperature (Fig. 1).

Reflectance spectra analysis

In Table 2 the reflection spectral bands of the samples depending on nickel content and temperature of heat treatment are presented.

Based on the data of energies of optical transitions cited in reference [28], the following points could be outlined:

(i) In all the samples a nickel spinel like phase is formed. The characteristic bands in the region of $^3T_1 \rightarrow {}^3T_1$ (*P*) at 16,000 cm^{-1} and $^3T_1 \rightarrow {}^1E$ at 13,350 cm^{-1} are present in the samples treated at 400 and 700°C.

(ii) The fact that the more intense band for the purely octahedral nickel is at 27,000 cm^{-1} [29] and for the tetrahedral nickel is at 16,000–17,000 cm^{-1} [30] suggests that the tetrahedral Ni^{II} is dominant in the spinel like phases, increasing with the nickel oxide content in the samples. Namely, the intensity ratio of the most intense octahedral band (27,000 cm^{-1}) and the most intense tetrahedral bands (16,000–17,000 cm^{-1}) indicate the distribution of the Ni^{II} ions among tetrahedral and octahedral sites.[31] Figure 2 shows the increased tetrahedral Ni^{II} content in the samples treated at 1100°C.

(iii) For the sample C-20-1100 a strong absorption is present above 30,000 cm^{-1}. Absorption in this region emerge if small amounts of free NiO [28] are present. The other two samples (C-5-1100 and C-10-1100) showed a weaker absorption band in the same region (Fig. 2), which is in accordance with the XRD results (Fig. 1).

(iv) The degree of occupancy of tetrahedral/octahedral sites, *i.e.* the degree of spinel inversion, depends on temperature of heat treatment. The intensity of the octahedral band, at 27,000 cm^{-1} in the sample treated at 1100°C is more pronounced than in the sample treated at 700°C (Fig. 3).

In the case of full inversion, Ni^{II} cations occupy the octahedral positions and the formula of inverse spinel can be written as $Al(NiAl)O_4$. Namely, in the spinel structure the oxygen ions are in a face-centered cubic lattice. The unit cell contains 32 oxygen ions, 64 tetrahedral holes, and 32 octahedral holes. In normal spinel, AB_2O_4, $8A^{2+}$ cations occupy 8 tetrahedral positions and $16B^{3+}$ cations 16 octahedral positions. In

inverse spinel $8B^{3+}$ cations occupy 8 tetrahedral positions, and $8B^{3+}$ and $8A^{2+}$ cations 16(8+8) octahedral positions [32].

Textural properties

Textural properties of the coprecipitated catalysts are presented in Table 3. The surface area of the catalyst is decreasing with the increased initial nickel oxide content in the samples and temperature of heat treatment.

It is interesting to note that the porosity of samples reach the maximal value at 700°C, when the surface area is about a half of the surface area of the respective samples treated at 400°C. That means that at the temperature as low as 700°C the surface area of the catalyst is not determined by sintering, but by polymorphic transformations of alumina and its interaction with nickel oxide. The surface area of the samples treated at 1100°C is about 40 times less than the surface area of the samples treated at 400°C. This dramatic drop of surface area is caused by sintering, followed by chemical interaction between NiO and Al_2O_3, i.e. by $NiAl_2O_4$ spinel formation, and alumina phase transformation to the stable α–Al_2O_3 form. The pore size distribution of some samples seems to be bimodal, but in these samples the main pore volume contribute to *ca* 80% of the total porosity. These dominant pores are characterized by lower radius values in the case of samples treated at 400°C and 700°C, and in samples treated at 1100°C with the higher radius values. The data of average pore radius r (Table 3), are calculated as $r = 2Q/\gamma S = 2V/S$, where Q is porosity; γ—apparent density; V—pore volume and S—surface area of the samples [33]. The average pore radii of the samples treated at 400 and 700°C are closer to the lower dominant pore radius, and in the samples treated at 1100°C to the higher dominant pore radius, experimentally determined by Hg-porosimeter.

Reducibility

According to the phase composition of the samples and reflectance spectra of Ni^{II}, the catalysts consists of nickel oxide partially dissolved in alumina and poorly ordered spinel. The ordering of the $NiAl_2O_4$ structure is improved when the temperature of heat treatment was raised. It is known that the coprecipitated catalysts are difficult to reduce, because of the high distribution of nickel oxide in alumina and therefore a good opportunity for interaction [34], as confirmed also by the present results. There are differences in reducibility between free nickel oxide and alumina supported nickel oxide even at higher nickel oxide loading because alumina dissolves in NiO, so NiO could not be considered as a free and independent component of the system [35]. Even the reduction of unsupported nickel oxide is rather difficult, demanding an induction period up to reduction temperature of 400°C [36]. However, kinetic studies of NiO reduction were carried out even at significantly lower temperatures, e.g. Frety *et al.* [37] studied the reducibility of NiO at 240°C.

The DSC curves of the synthesized catalyst samples in hydrogen flow are shown in Fig. 4. The exothermal effects of NiO reduction are registered in all catalyst samples, being shifted to significantly higher temperatures compared to the data obtained for similar systems by means of DTA (195–210°C) [38].

The reduction temperature of the samples with 5 and 10 wt% of nickel is higher at 700 than at 400°C pretreatment temperature. Such behavior is expected because of stronger interaction of NiO and Al_2O_3 and more intensive spinel formation of higher temperature. For the sample with 20 wt% of nickel the inverse trend is observed, indicating the presence of small amount of free NiO in the catalyst. This assumption is supported by the high spinel and proportionally low alumina content, visible from the XRD data, Fig. 1. The reduction temperature of all the samples treated at 1100°C is lower compared to those pretreated at

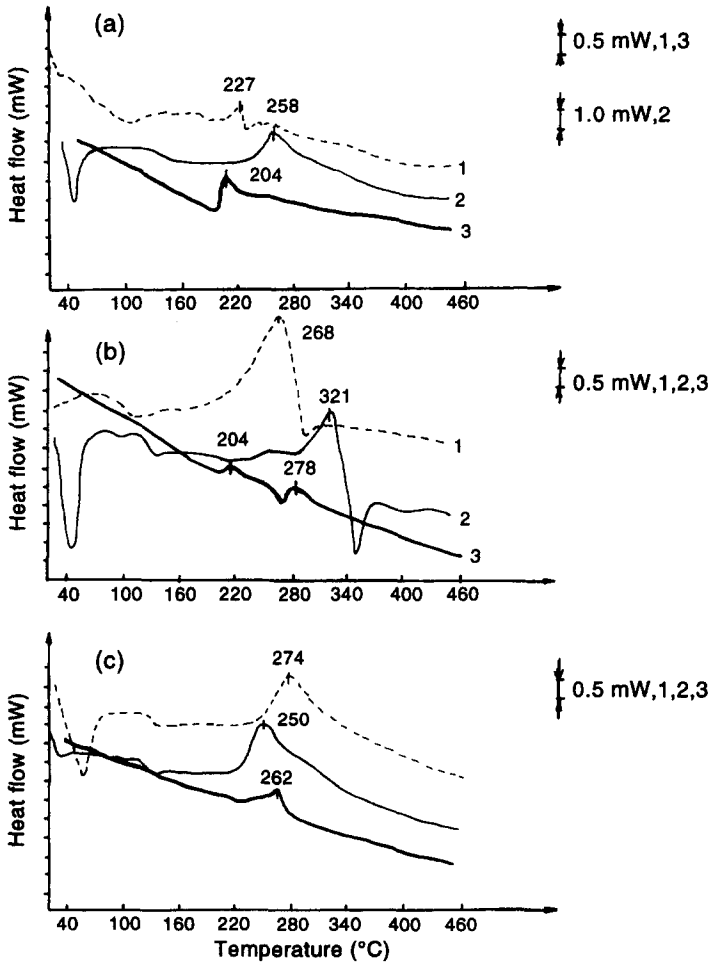

Fig. 4. DSC curves of coprecipitated NiO–Al_2O_3 samples, in hydrogen flow (20–25 cm^3/min) (a) 5; (b) 10; and (c) 20 wt% of nickel in the samples; pretreatment of samples at 400 (1); 700 (2); and 1100°C (3) in air.

lower temperatures, which could be explained by the presence of the small fraction of nickel oxide segregated during the spinel formation at high temperature [35]. The previous result is in accordance with the results of Chespokova *et al.* [38] who claim that the reducibility of NiO in binary and ternary systems is not determined by NiO content and chemical composition of nickel oxide containing phases, but by the inhomogeneity of the system.

CONCLUSIONS

It has been shown that in the $NiO–Al_2O_3$ coprecipitated catalysts metastable mixed oxides are formed. During the heat treatment of the catalysts, the strength and the degree of NiO and Al_2O_3 interaction is changing, depending on the treatment temperature. That is manifested by phase segregation, chemical interactions and polymorphic transformations of alumina support. Nickel oxide hinder the crystallization and phase transformations of alumina. Formation of surface spinel, $NiAl_2O_4$, was registered in all samples. The cation distribution is affected by the nickel content and the temperature of heat treatment. Both the nickel loading and the temperature of the heat pretreatment are the factors influencing the reducibility of the nickel in the catalyst. It seems, however, that the nickel loading, after reaching a critical temperature become the more significant factor in the formation of the tetrahedral coordinated nickel, Ni^{II}.

The surface area of the samples is regularly increasing with alumina content of the catalyst. The strong changes of textural properties of the coprecipitated $NiO–Al_2O_3$ catalyst at 700°C are caused by chemical interaction of catalyst components and by polymorphic transformation of alumina. The dramatic decrease of surface area at 1100°C is caused by intensive $NiAl_2O_4$ and α-Al_2O_3 formation and by sintering of oxide particles.

(Received 7 May 1997; accepted 11 June 1997)

Abstract—The bridged double tetrahedral clusters $[RPhC_2MCo(CO)_5(\eta^5\text{-}C_5H_4)]_2[C(O)CH_2CH_2C(O)]$ (**1a** M = Mo, R = Ph; **1b** Mo, *p*-MeC_6H_4; **1c** Mo, *m*-$MeOC_6H_4$; **1d** W, Ph), $[Ph_2C_2MCo(CO)_5(\eta^5\text{-}C_5H_4)]_2[p\text{-}C(O)C_6H_4C(O)\text{-}p]$ (**2a** M = Mo; **2b** W) and $[Ph_2C_2MCo(CO)_5(\eta^5\text{-}C_5H_4)]_2[o\text{-}CH_2C_6H_4CH_2\text{-}o]$ (**4**) were synthesized from single tetrahedral clusters $RPhC_2Co_2(CO)_6$ and corresponding bridging intermediate reagents $[NaM(CO)_3(\eta^5\text{-}C_5H_4)]_2Z$ (Z = $C(O)CH_2CH_2C(O)$, *p*-$C(O)C_6H_4C(O)$-*p*, *o*-$CH_2C_6H_4CH_2$-*o*), whereas those clusters $[FeMCoS(CO)_8(\eta^5\text{-}C_5H_4)]_2[p\text{-}C(O)C_6H_4C(O)\text{-}p]$ (**3a** M = Mo; **3b** W), $[FeMCoS(CO)_8(\eta^5\text{-}C_5H_4)]_2[o\text{-}CH_2C_6H_4CH_2\text{-}o]$ (**5**) and $[FeMoCoS(CO)_8(\eta^5\text{-}C_5H_4)]_2[Me_2SiOSiMe_2]$ (**6**) were prepared by reactions of a single tetrahedral cluster $FeCo_2(CO)_9(\mu_3\text{-}S)$ with bridging intermediate reagents $[NaM(CO)_3(\eta^5\text{-}C_5H_4)]_2Z$ (Z = *p*-$C(O)C_6H_4C(O)$-*p*, *o*-$CH_2C_6H_4CH_2$-*o*) or $[LiMo(CO)_3(\eta^5\text{-}C_5H_4)]_2$ $[Me_2SiOSiMe_2]$, respectively. Further reactions of **3a–b** with reducing agent $NaBH_4$ gave corresponding bridged double clusters $[FeMCoS(CO)_8(\eta^5\text{-}C_5H_4)]_2[p\text{-}CH(OH)C_6H_4CH(OH)\text{-}p]$ (**8a** M = Mo; **8b** W), whereas **1a** reacted with $NaBH_4$ afforded $[Ph_2C_2MoCo(CO)_5(\eta^5\text{-}C_5H_4)]_2[CH(OH)CH_2CH_2CH(OH)]$ (**7**), which could be converted to its ether cluster derivative $[Ph_2C_2MoCo(CO)_5(\eta^5\text{-}C_5H_4)]_2[\alpha\text{-}CHCH_2CH_2CH\text{-}\alpha]$ (**9**). All the new clusters **1–9** have been characterized by elemental analysis, IR and ^1H NMR spectroscopy, whereas new terephthaloylbis(cyclopentadienylsodium) used to prepare intermediate reagents $[NaM(CO)_3(\eta^5\text{-}C_5H_4)]_2[p\text{-}C(O)C_6H_4C(O)\text{-}p]$ has been isolated and characterized by IR and ^1H NMR spectroscopy. © 1997 Elsevier Science Ltd

Keywords: double $CoMC_2$ (M = Mo, W) clusters; double FeMCoS clusters; bridging biscyclopentadienyl ligands; synthesis; characterization.

Since the mid-1970s transition metal cluster chemistry has enjoyed tremendous growth, largely due to the potential applications of transition metal cluster complexes in catalysis, as well as the novelty and diversity of their structures and reactions [1–5]. However, there are so far very few transition metal double cluster complexes containing bridging biscyclopentadienyl ligands [6] although numerous such dinuclear complexes have been well-documented in the literature [7–9].

In connection with our project aimed to develop the synthetic methodology for clusters [6,10–12], we initiated investigations on the isolobal displacement reactions of a series of isolobal reagents containing bridging biscyclopentadienyl ligands with tetrahedral Co_2C_2 and $FeCo_2S$ clusters, and on the functional transformation reactions of some isolobal displacement products, through which corresponding novel transition metal double cluster complexes were successfully synthesized. Herein we report the results concerning this study.

RESULTS AND DISCUSSION

We recently reported [6] the reaction of bridging biscyclopentadienyl transition metal reagents $[NaM(CO)_3(\eta^5\text{-}C_5H_4)]_2[C(O)CH_2CH_2C(O)]$ (M = Mo, W) with a tetrahedral cluster $FeCo_2(CO)_9$

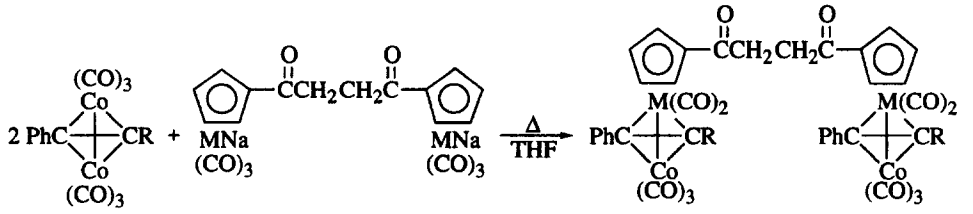
(μ_3-S). This is actually a new type of isolobal displacement reaction [13,14], which involves the double displacement of two d^9ML_3 isolobal fragments in two molecules of $FeCo_2(CO)_9(\mu_3\text{-}S)$ by two d^5ML_5 fragments derived from the bridging reagent. In order to show the generality of this new double isolobal displacement mode in the synthesis of bridged double cluster complexes, we carried out a series of reactions between various tetrahedral clusters and bridging bis[cyclopentadienyltricarbonylmolybdenum (or tungsten) sodium]. We found that the bridging biscyclopentadienyl intermediate reagents $[NaM(CO)_3(\eta^5\text{-}C_5H_4)]_2[C(O)CH_2CH_2C(O)]$ (M = Mo, W) prepared from 1,4-succinoyl bis(cyclopentadienylsodium) and $M(CO)_6$ reacted *in situ* with tetrahedral Co_2C_2 clusters in THF at reflux to give a series of double isolobal displacement products **1a–d,** as shown in Scheme 1.

Reagents $[NaM(CO)_3(\eta^5\text{-}C_5H_4)]_2[p\text{-}C(O)C_6H_4C(O)\text{-}p]$ (M = Mo, W) prepared from $M(CO)_6$ and terephthaloylbis(cyclopentadienylsodium) could also react *in situ* with cluster $Ph_2C_2Co_2(CO)_6$ or $FeCo_2(CO)_9(\mu_3\text{-}S)$ in THF at reflux to afford the bridged double clusters **2a–b** and **3a–b**. The terephthaloylbis(cyclopentadienylsodium) was prepared by reaction of sodium cyclopentadienide with dimethylterephthalate and isolated as a slightly air-sensitive and quite moisture-sensitive, yellow solid. The reactions mentioned above are shown in Scheme 2.

Other bridged double clusters could be similarly prepared by this type of double isolobal displacement reaction. For example, clusters **4** and **5** might be obtained by the reaction of $[NaMo(CO)_3(\eta^5\text{-}C_5H_4)]_2[o\text{-}CH_2C_6H_4CH_2\text{-}o]$ prepared from $Mo(CO)_6$ and $[Na(\eta^5\text{-}C_5H_4)]_2[o\text{-}CH_2C_6H_4CH_2\text{-}o]$ with $Ph_2C_2Co_2(CO)_2$ or $FeCo_2(CO)_9(\mu_3\text{-}S)$, whereas cluster **6** was prepared by reaction of $[LiMo(CO)_3(\eta^5\text{-}C_5H_4)]_2[Me_2SiOSiMe_2]$ derived from $M(CO)_6$ and $[Li(\eta^5\text{-}C_5H_4)]_2[Me_2SiOSiMe_2]$, with $FeCo_2(CO)_9(\mu_3\text{-}S)$, as shown in Scheme 3.

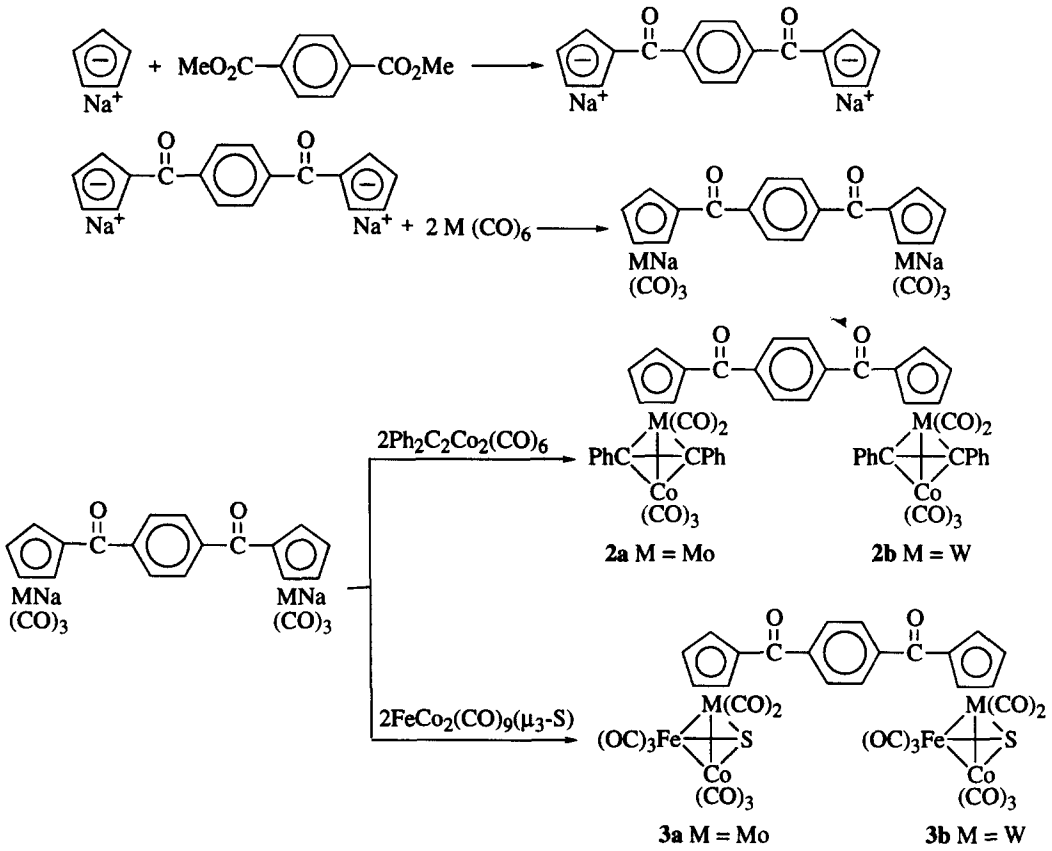
Interestingly, clusters **1a** and **3a–b** could be reduced under the action of $NaBH_4$ to give dihydroxyl double clusters **7** and **8a–b,** whereas **7** might be further converted to corresponding ether double cluster **9** by elimination of one molecule of water intramolecularly in the presence of Et_3OBF_4, as shown in Scheme 4.

The bridged double clusters **1–9** are all new and have been fully characterized by elemental analysis. IR and ^1H NMR spectroscopy. For example, the IR spectra for those double $MCoC_2$ clusters **1, 2, 4, 7** and **9** have four terminal carbonyl absorption bands at 2057–1926 cm^{-1}, whereas those for the double FeCoMS clusters **3, 5, 6** and **8** contain six to seven terminal carbonyl absorption bands in the range 2082–1852 cm^{-1}. The latter clusters, compared to the former, have more IR bands for the terminal carbonyls, which is obviously due to the more terminal carbonyls present in the latters' molecules. Additionally, the IR spectra of the clusters containing 1,4-succinoyl biscyclopentadienyl and *p*-bis(cyclopentadienylcarbonyl) benzene bridges, namely **1–3,** all have a medium absorption band at 1680–1647 cm^{-1}, characteristic of the ketonic groups, whereas those of the clusters with 1,4-biscyclopentadienyl-1,4-dihydroxylbutylene- and *p*-bis(cyclopentadienylhydroxylmethyl)benzene bridges, i.e. **7** and **8,** contain a broad band centered at about 3420 cm^{-1}, diagnostic of the hydroxyl groups. The ^1H NMR spectra of clusters **1–9** show the presence of their corresponding organic groups. For example, for the two substituted cyclopentadienyl rings the ^1H NMR spectra of clusters **4, 5** and **7** show one multiplet at about 4.9–5.6 ppm, whereas those of clusters **1–3, 6, 8** and **9** exhibit two sets of peaks at about 5.1–6.5 ppm. For clusters **1–3,** the downfield set of the peak has been assigned to H^2 and H^5, and the upfield assigned to H^3 and H^4, whereas for clusters **6, 8** and **9** the assignment of those protons is opposite. This is because the substituents on cyclopentadienyl rings for the formers, in contrast to those for the latters, are electron-withdrawing. In addition, the ^1H NMR spectra of **8a–b** have one broad peak centered at about 2.5 and 2.4 ppm, assigned to their hydroxyl groups. However, those two peaks disappeared when determining their ^1H NMR spectra in D_2O, due to D/H exchange. Finally, it should be pointed out that the terephthaloylbis(cyclopentadienylsodium) used in the synthesis, for example, of **2a–b** is new and has been



1a R = Ph M = Mo
1b R = p-MeC_6H_4 M = Mo
1c R = m-$MeOC_6H_4$ M = Mo
1d R = Ph M = W

Scheme 1.



Scheme 2.

characterized by IR and ^{1}H NMR spectroscopy. The IR spectrum shows its ketonic carbonyl absorption band at 1636 cm^{-1}, and its ^{1}H NMR spectrum exhibits corresponding resonances for C_5H_4 and C_6H_4 groups, as well as two triplets in equal intensity assigned to four α-protons and four β-protons of THF. The terephthaloylbis(cyclopentadienylsodium), therefore, exists in a THF solvated form and could be best formulated as $C_{18}H_{12}O_2Na_2 \cdot C_4H_8O$ in terms of the integral value of corresponding signals.

EXPERIMENTAL

All reactions were carried out under prepurified tank nitrogen using standard Schlenk techniques. THF and diglyme were distilled from sodium-benzophenone ketyl under nitrogen. Column chromatography and TLC were carried out by using silica gel of 300–400 mesh and silica gel G (10–40 μm), respectively. $Mo(CO)_6$ and $W(CO)_6$ were purchased from Strem Chemicals Inc. $[NaC_5H_4C(O)CH_2]_2$ [9], o-$[NaC_5H_4CH_2]_2C_6H_4$/THF solution [15], $C_5H_5Si(Me_2)OSi(Me_2)C_5H_5$ [16], Et_3OBF_4 [17], $FeCo_2(CO)_9(\mu_3\text{-}S)$ [18], $Ph_2C_2Co_2(CO)_6$ [19], $Ph(p\text{-}MeC_6H_4)C_2Co_2(CO)_6$ [20], $Ph(m\text{-}MeOC_6H_4)C_2Co_2(CO)_6$ [20] were prepared according to literature methods. IR spectra were recorded on a NICOLET FT-IR 5DX infrared spectrometer; ^{1}H NMR spectra were recorded on a JEOL FX 90Q NMR spectrometer. C/H analyses and melting points were determined on a 240 C analyzer and a Yanaco micromelting point apparatus MP-500.

Preparation of **1a**

A 100 cm^3 three-necked flask fitted with a magnetic stir-bar, a rubber septum, and a reflux condenser topped with a nitrogen inlet tube was charged with 528 mg (2.0 mmol) of $Mo(CO)_6$, 258 mg (1.0 mmol) of $[NaC_5H_4C(O)CH_2]_2$ and 20 cm^3 of THF. The mixture was refluxed for 20 h. Upon cooling to room temperature, 928 mg (2.0 mmol) of $Ph_2C_2Co_2(CO)_6$ was added and the mixture stirred at reflux for 7 h. Solvent was removed under reduced pressure and the residue was extracted with CH_2Cl_2. The extracts were subjected to TLC using 2:1 CH_2Cl_2/petroleum ether as eluent. Several tiny bands with a major band developed. From the major band 285 mg (25%) of **1a** was obtained as a brown-yellow solid. M.p. 81–83°C. Found: C, 54.23; H, 3.13. Calc. for $C_{52}H_{32}Co_2Mo_2O_{12}$: C, 53.91; H, 2.78%. IR (KBr disk): $\nu_{C\equiv O}$, 2057 (s), 2009 (vs), 1983 (vs), 1942 (s); $\nu_{C=O}$ 1680

(m) cm^{-1}. ^1H NMR ($CDCl_3$, δ, ppm): 2.59 (s, 4H, CH_2CH_2), 5.46 (t, 4H, $2H^3$, $2H^4$), 5.88 (t, 4H, $2H^2$, $2H^5$), 7.31 (s, 20H, $4C_6H_5$).

Preparation of **1b**

The same procedure as that for **1a** was followed, but 956 mg (2.0 mmol) of Ph (p-MeC_6H_4)$C_2Co_2(CO)_6$ was used instead of $Ph_2C_2(CO)_6$ to give 185 mg (16%) of **1b** as a brown–yellow solid. M.p. 88–90°C. Found: C, 54.16; H, 3.17. Calc. for $C_{54}H_{36}Co_2Mo_2O_{12}$: C, 54.66; H, 3.06%. IR (KBr disk): $\nu_{C\equiv O}$, 2057 (s), 2008 (vs), 1983 (vs), 1942 (s); $\nu_{C=O}$ 1672 (m) cm^{-1}. ^1H NMR ($CDCl_3$, δ, ppm): 2.36 (s, 6H, $2CH_3$), 2.62 (s, 4H, CH_2CH_2), 5.54 (t, 4H, $2H^3$, $2H^4$), 5.94 (t, 4H, $2H^2$, $2H^5$), 7.08–7.64 (m, 18H, $2C_6H_5$, $2C_6H_4$).

Preparation of **1c**

The same procedure as that for **1a** was followed, but 988 mg (2.0 mmol) of Ph (*m*-MeO-C_6H_4)$C_2Co_2(CO)_6$ was used instead of $Ph_2C_2Co_2(CO)_6$ to give 130 mg (11%) of **1c** as a brown–yellow solid. M.p. 100–102°C. Found: C, 53.78; H, 3.08. Calc. for $C_{54}H_{36}Co_2Mo_2O_{14}$: C, 53.22; H, 2.98%. IR (KBr disk): $\nu_{C\equiv O}$, 2057 (s), 2008 (vs), 1983 (vs), 1942 (s); $\nu_{C=O}$ 1672 (m) cm^{-1}. ^1H NMR ($CDCl_3$, δ, ppm): 2.54 (s, 4H, CH_2CH_2), 3.76 (s, 6H, $2CH_3O$), 5.50 (t, 4H, $2H^3$, $2H^4$), 5.90 (t, 4H, $2H^2$, $2H^5$), 6.70–7.08 (m, 8H, $2C_6H_4$), 7.34 (s, 10H, $2C_6H_5$).

Preparation of **1d**

The 100 cm^3 flask described above was charged with 704 mg (2.0 mmol) of $W(CO)_6$, 258 mg (1.0 mmol) of $[NaC_5H_4C(O)CH_2]_2$ and 20 cm^3 of diglyme. The mixture was refluxed for 6 h. After removing diglyme 928 mg (2.0 mmol) of $Ph_2C_2Co_2(CO)_6$ and 20 cm^3 of THF was added and the mixture stirred at reflux for 7 h. The same workup as that for **1a** gave 345 mg (26%) of **1d** as a brown–yellow solid. M.p. 85–87°C. Found: C, 48.62; H, 2.52. Calc. for $C_{52}H_{32}Co_2O_{12}W_2$: C, 48.81; H, 2.42%. IR (KBr disk): $\nu_{C\equiv O}$, 2049 (s), 2008 (vs), 1983 (vs), 1934 (s); $\nu_{C=O}$ 1680 (m) cm^{-1}. ^1H NMR ($CDCl_3$, δ, ppm): 2.61 (s, 4H, CH_2CH_2), 5.61 (t, 4H, $2H^3$, $2H^4$), 5.89 (t, 4H, $2H^2$, $2H^5$), 7.31 (s, 20H, $4C_6H_5$).

Preparation of terephthaloylbis(cyclopentadienylsodium)

The 100 cm^3 flask described above was charged with 1.15 g (50 mmol) of sodium sand and 60 cm^3 of THF. The mixture was stirred and cooled by an ice-bath. To this suspension was slowly added 5.5 cm^3 (60 mmol) of freshly cracked cyclopentadiene and the mixture continued to be stirred at room temperature for 3 h. To this resulting pink solution of sodium cyclopentadienide was added 4.85 g (25 mmol) of dimethyl terephthalate and the mixture refluxed for 25 h. Solvent was removed at reduced pressure. The residue was carefully washed under nitrogen with 3×50 cm^3 of absolute ethyl ether and dried *in vacuo* to give 6.732 g (71%) of 1:1 THF solvated terephthaloylbis (cyclopentadienylsodium) p-$[NaC_5H_4C(O)]_2C_6H_4 \cdot$ THF as a yellow solid. M.p. 190°C (dec). IR (KBr disk): $\nu_{C=O}$, 1636 (s) cm^{-1}. ^1H NMR ($CDCl_3$, δ, ppm): 1.81 (t, $J = 6.5$ Hz, 4H, CH_2CH_2 of THF), 3.69 (t, $J = 6.5$ Hz, 4H, CH_2OCH_2 of THF), 6.28, 6.78 (br. s, 8H, $2C_5H_4$), 7.62 (s, 4H, C_6H_4).

Preparation of **2a**

The 100 cm^3 flask was charged with 700 mg (2.0 mmol) of p-$[NaC_5H_4C(O)]_2C_6H_4 \cdot$THF, 1.056 g (4.0 mmol) of $Mo(CO)_6$ and 30 cm^3 of THF. The mixture was refluxed for 15 h. Upon cooling to room temperature 1.856 g (4.0 mmol) of $Ph_2C_2Co_2(CO)_6$ was added and the mixture was refluxed for 7 h. Solvent was removed and the residue was subjected to TLC using 2:1 CH_2Cl_2/petroleum ether as eluent. Several tiny bands with a major band developed. The major yellow–brown band was collected to give 152 mg (8%) of **2a** as a red solid. M.p. 175–177°C. Found: C, 56.63; H, 2.69. Calc. for $C_{56}H_{32}Co_2Mo_2O_{12}$: C, 55.74; H, 2.67%. IR (KBr disk): $\nu_{C\equiv O}$, 2057 (s), 2008 (vs), 1983 (vs), 1950 (s); $\nu_{C=O}$ 1647 (m) cm^{-1}. ^1H NMR ($CDCl_3$, δ, ppm): 5.44 (br. s, 4H, $2H^3$, $2H^4$), 5.92 (br. s, 4H, $2H^2$, $2H^5$), 7.25 (s, 20H, $4C_6H_5$), 7.64–7.88 (m, 4H, C_6H_4).

Preparation of **2b**

The 100 cm^3 flask was charged with 352 mg (1.0 mmol) of p-$[NaC_5H_4C(O)]_2C_6H_4 \cdot$THF, 700 mg (2.0 mmol) of $W(CO)_6$ and 30 cm^3 of diglyme. The mixture was refluxed for 6 h. After removing diglyme under reduced pressure 928 mg (2.0 mmol) of $Ph_2C_2Co_2(CO)_6$ and 30 cm^3 of THF were added. The mixture was stirred at reflux for an additional 7 h. Solvent was removed at reduced pressure. The residue was extracted with CH_2Cl_2. The extracts were subjected to TLC using 2:1 CH_2Cl_2/petroleum ether as eluent. Several tiny bands with a major band developed. From the major band was obtained 142 mg (12%) of **2b** as a red solid. M.p. 163–165°C. Found: C, 48.59; H, 2.68. Calc. for $C_{56}H_{32}Co_2O_{12}W_2$: C, 48.66; H, 2.33%. IR (KBr disk): $\nu_{C\equiv O}$, 2049 (s), 2008 (vs), 1975 (vs), 1950 (s); $\nu_{C=O}$ 1655 (m) cm^{-1}. ^1H NMR ($CDCl_3$, δ, ppm): 5.52 (br. s, 4H, $2H^3$, $2H^4$), 6.00 (br. s, 4H, $2H^2$, $2H^5$), 7.29 (s, 20H, $4C_6H_5$), 7.78 (s, 4H, C_6H_4).

Preparation of **3a**

The 100 cm^3 flask was charged with 312 mg (1.0 mmol) of p-$[NaC_5H_4C(O)]_2C_6H_4 \cdot$THF, 528 mg (2.0

mmol) of $Mo(CO)_6$ and 30 cm^3 of THF. The mixture was refluxed for 15 h. Upon cooling to room temperature 932 mg (2.0 mmol) of $FeCo_2(CO)_9(\mu_3\text{-}S)$ was added and the mixture was stirred for 30 min at reflux. Solvent was removed under reduced pressure. The residue was extracted with CH_2Cl_2. The extracts were subjected to column chromatography. Several tiny bands with a major band developed using petroleum ether, 2 : 1 CH_2Cl_2/petroleum and CH_2Cl_2 as eluents successively. The major brown band was eluted with CH_2Cl_2 to give 150 mg (16%) of **3a** as a black powder. M.p. 125–127°C. Found: C, 34.33; H, 1.61. Calc. for $C_{34}H_{12}Co_2Fe_2Mo_2O_{18}S_2$: C, 34.20; H, 1.01%. IR (KBr disk): $\nu_{C\equiv O}$, 2082 (s), 2032 (vs), 2008 (vs), 1975 (s), 1934 (m), 1901 (m), 1852 (m); $\nu_{C=O}$ 1647 (m) cm^{-1}. ^1H NMR ($CDCl_3$, δ, ppm): 5.60–5.92 (m, 4H, $2H^3$, $2H^4$), 6.00–6.24 (m, 4H, $2H^2$, $2H^5$), 7.96 (br. s, 4H, C_6H_4).

Preparation of **3b**

The flask described above was charged with 352 mg (1.0 mmol) of p-$[NaC_5H_4C(O)]_2C_6H_4 \cdot THF$, 700 mg (2.0 mmol) of $W(CO)_6$ and 30 cm^3 of diglyme. The mixture was refluxed for 6 h. After removal of diglyme under reduced pressure 932 mg (2.0 mmol) of $FeCo_2(CO)_9(\mu_3\text{-}S)$ and 30 cm^3 of THF were added and the mixture was stirred at reflux for 30 min. Solvent was removed under reduced pressure. The residue was extracted with CH_2Cl_2. The extracts were first subjected to short column chromatography using 1 : 2 acetone/petroleum ether as eluent. From the major band 180 mg (16%) of **3b** was obtained as a black powder. M.p. 98–100°C. Found: C, 29.42; H, 0.57. Calc. for $C_{34}H_{12}Co_2Fe_2O_{18}S_2W_2$: C, 29.81; H, 0.88%. IR (KBr disk): $\nu_{C\equiv O}$, 2082 (s), 2032 (vs), 2008 (vs), 1983 (s), 1942 (m), 1909 (m), 1860 (m); $\nu_{C=O}$ 1647 (m) cm^{-1}. ^1H NMR ($CDCl_3$, δ, ppm): 5.92–6.18 (m, 4H, $2H^3$, $2H^4$), 6.20–6.42 (m, 4H, $2H^2$, $2H^5$), 7.91–8.18 (m, 4H, C_6H_4).

Preparation of **4**

The flask described above was charged with 660 mg (2.5 mmol) of $Mo(CO)_6$, 4.4 cm^3 (1.23 mmol) of o-$(NaC_5H_4CH_2)_2C_6H_4$/THF solution and 20 cm^3 of THF. The mixture was refluxed for 20 h. Upon cooling to room temperature 1.16 g (2.5 mmol) of $Ph_2C_2Co_2(CO)_6$ was added and the mixture was stirred for 30 min and at reflux for an additional 5 h. Solvent was removed under reduced pressure. The residue was extracted with CH_2Cl_2. The extracts were subjected to TLC using 1 : 5 CH_2Cl_2/petroleum ether as eluent. Several tiny bands with a major band developed. From the major band 300 mg (20%) of **4** was obtained as a brown–yellow solid. M.p. 75–77°C. Found: C, 57.28; H, 3.12. Calc. for $C_{56}H_{36}Co_2Mo_2O_{10}$: C, 57.07; H, 3.08%. IR (KBr disk): $\nu_{C\equiv O}$, 2049 (s), 1991 (vs), 1975 (vs), 1926 (s) cm^{-1}. ^1H NMR ($CDCl_3$, δ, ppm): 3.32 (s, 4H, $2CH_2$), 4.98–5.34 (m, 8H, $2C_5H_4$), 6.82–7.54 (m, 24H, C_6H_4, $4C_6H_5$).

Preparation of **5**

The flask was charged with 528 mg (2.0 mmol) of $Mo(CO)_6$, 3.6 cm^3 (1.0 mmol) of o-$(NaC_5H_4CH_2)_2C_6H_4$/THF solution and 20 cm^3 of THF. The mixture was refluxed for 20 h. Upon cooling to room temperature 916 mg (2.0 mmol) of $FeCo_2(CO)_9(\mu_3\text{-}S)$ was added and the mixture stirred at reflux for an additional 1 h. The same workup as that for **4** gave 160 mg (14%) of **5** as a black solid. M.p. 135–137°C. Found: C, 35.08; H, 1.34. Calc. for $C_{34}H_{16}Co_2Fe_2Mo_2O_{16}S_2$: C, 35.02; H, 1.38%. IR (KBr disk): $\nu_{C\equiv O}$, 2073 (s), 2036 (s), 2016 (vs), 2004 (vs), 1975 (s), 1948 (m), 1876 (m) cm^{-1}. ^1H NMR ($CDCl_3$, δ, ppm): 3.90 (s, 4H, $2CH_2$), 5.20–5.60 (m, 8H, $2C_5H_4$), 7.52 (s, 4H, C_6H_4).

Preparation of **6**

The flask was charged with 262 mg (1.0 mmol) of $C_5H_5Si(Me_2)OSi(Me_2)C_5H_5$ and 15 cm^3 of diglyme, and then 1.4 cm^3 (2.0 mmol) of n-BuLi/hexane solution was dropped into the flask under −50°C. The mixture was stirred for 0.5 h at room temperature. Then, 528 mg (2.0 mmol) of $Mo(CO)_6$ was added and the mixture stirred at reflux for 6 h. After removing diglyme under reduced pressure 20 cm^3 of THF and 916 mg (2.0 mmol) of $FeCo_2(CO)_9(\mu_3\text{-}S)$ were added and the mixture was refluxed for an additional 1 h. The same workup as that for **4** gave 230 mg (19%) of **6** as a brown oil. Found: C, 30.05; H, 2.05. Calc. for $C_{30}H_{20}Co_2Fe_2Mo_2O_{17}S_2Si_2$: C, 30.17; H, 1.69%. IR (KBr disk): $\nu_{C\equiv O}$, 2073 (s), 2035 (s), 2000 (vs), 1965 (vs), 1925 (s), 1893 (s) cm^{-1}. ^1H NMR ($CDCl_3$, δ, ppm): 0.32, 0.40 [s, s, 12H, J = 3.6 Hz, $2Si(CH_3)_2$], 5.36 (t, 4H, $2H^2$, $2H^5$), 5.56 (t, 4H, $2H^3$, $2H^4$).

Preparation of **7**

The 50 cm^3 flask was charged with 100 mg (0.086 mmol) of **1a**, 13 mg (0.34 mmol) of $NaBH_4$ and 5 cm^3 of MeOH. The mixture was stirred for 1 h at room temperature. The residue was extracted with CH_2Cl_2. The extracts were subjected to TLC using CH_2Cl_2 as eluent. Several tiny bands with a major band developed. From the major band was obtained 30 mg (30%) of **7** as a brown–yellow solid. M.p. 95–97°C. Found: C, 53.69; H, 3.09. Calc. for $C_{52}H_{36}Co_2Mo_2O_{12}$: C, 53.72; H, 3.12. IR (KBr disk): $\nu_{C\equiv O}$, 2049 (s), 2008 (vs), 1975 (vs), 1934 (s); ν_{OH} 3427 (m) cm^{-1}. ^1H NMR ($CDCl_3$, δ, ppm): 1.52–1.80 (m, 4H, CH_2CH_2), 1.96–2.28 (m, 2H, 2OH), 3.96–4.28 (m, 2H, 2CH), 5.08–5.48 (m, 8H, $2C_5H_4$), 7.00–7.74 (m, 20H, $4C_6H_5$).

Preparation of **8a**

The 50 cm^3 flask was charged with 100 mg (0.083 mmol) of **3a,** 11 mg (0.29 mmol) of $NaBH_4$ and 4 cm^3 of MeOH. The mixture was stirred at room temperature for 10 min. Solvent was removed under reduced pressure. The residue was extracted with CH_2Cl_2. The extracts were subjected to TLC using CH_2Cl_2 as eluent. From the major band was obtained 37 mg (37%) of **8a** as a black solid. M.p. 122–124°C. Found: C, 34.25; H, 2.09. Calc. for $C_{34}H_{16}Co_2Fe_2Mo_2O_{18}S_2$: C, 34.09; H, 1.35. IR (KBr disk): $\nu_{C\equiv O}$, 2073 (s), 2034 (s), 2024 (vs), 1998 (vs), 1975 (s), 1877 (m), ν_{OH} 3400 (m) cm^{-1}. ^1H NMR ($CDCl_3$, δ, ppm): 2.52 (br. s, 2H, 2OH), 5.16 (br. s, 4H, $2H^2$, $2H^5$), 5.28 (br. s, 2H, 2CH), 5.40–5.60 (m, 4H, $2H^3$, $2H^4$), 7.28 (s, 4H, C_6H_4).

Preparation of **8b**

The same procedure as that for **8a** was followed, but 150 mg (0.109 mmol) of **3b,** 16 mg (0.42 mmol) of $NaBH_4$ and 6 cm^3 of MeOH was used instead of those for **8a** to give 60 mg (40%) of **8b** as a black solid. M.p. 136–138°C. Found: C, 29.79; H, 1.40. Calc. for $C_{34}H_{16}Co_2Fe_2O_{18}S_2W_2$: C, 29.72; H, 1.17. IR (KBr disk): $\nu_{C\equiv O}$, 2073 (s), 2032 (vs), 2010 (vs), 1991 (vs), 1976 (s), 1893 (m), ν_{OH} 3420 (m) cm^{-1}. ^1H NMR ($CDCl_3$, δ, ppm): 2.40 (br. s, 2H, 2OH), 5.16 (br. s, 4H, $2H^2$, $2H^5$), 5.40 (br. s, 2H, 2CH), 5.48–5.68 (m, 4H, $2H^3$, $2H^4$), 7.32 (s, 4H, C_6H_4).

Preparation of **9**

The 50 cm^3 flask was charged with 75 mg (0.065 mmol) of **7,** 85 mg (0.45 mmol) of Et_3OBF_4 and 4 cm^3 of CH_2Cl_2. The mixture was refluxed for 10 min. Solvent was removed under reduced pressure. The residue was extracted with CH_2Cl_2. The extracts were subjected to TLC using 1 : 1 CH_2Cl_2/petroleum ether as eluent. From the major band was obtained 37 mg (51%) of **9** as a brown–yellow solid. M.p. 75–77°C. Found: C, 54.65; H, 2.85. Calc. for $C_{52}H_{34}Co_2Mo_2O_{11}$: C, 54.57; H, 2.99%. IR (KBr disk): $\nu_{C\equiv O}$, 2049 (s), 2008 (vs), 1983 (vs), 1934 (s) cm^{-1}. ^1H NMR ($CDCl_3$, δ, ppm): 1.60–2.40 (m, 4H, CH_2CH_2), 4.28–4.80 (m, 2H, CHCH), 5.22 (t, 4H, $2H^2$, $2H^5$), 5.32–5.52 (m, 4H, $2H^3$, $2H^4$), 7.32 (s, 20H, $4C_6H_5$).

(Received 22 April 1997; accepted 11 June 1997)

Abstract—The title complex was synthesized by the reaction of 1,4,7,10,13,16-hexaazacyclooctadecane (abbreviated as hexacyclen) with erbium(III) trifloromethanesulfonate in 1:1 (molar ratio) in acetonitrile under nitrogen. The crystal structure determination shows that the complex is dinuclear with two erbium ions bridged by two hydroxide ions. Each of the two metal ions is coordinated similarly by the two bridging hydroxide groups and six nitrogen atoms of a hexacyclen molecule, giving a coordination number eight and a slightly distorted dodecahedron geometry. The four trifloromethanesulfonate ions are not included in the coordination of the metal ions. © 1997 Elsevier Science Ltd

Keywords: erbium; 1,4,7,10,13,16-hexaazacyclooctadecane; crystal structure; lanthanide complex.

As the nitrogen analogue of 18-crown-6, the macrocycle 1,4,7,10,13,16-hexaazacyclooctadecane (abbreviated as hexacyclen) has been studied extensively for the stereochemistry of its complexes with transition metal ions like Co^{3+} and Ni^{2+} arising from the coordination of the ligand [1] as well as its great ability to form 1:1 or 1:2 complexes with many different metal ions [1–5]. But up to now, only six metal complexes [6–11] with M/L = 1:1 for Co^{3+}, Cr^{3+}, Hg^{2+}, UO_2^{2+} and two [4,5] with 2:1 for Pd^{2+} have been structurally determined by single-crystal X-ray diffraction methods. The structural information of these complexes indicated that the geometry of the six nitrogen atoms of the ligand around a central ion seems based on two factors: the favor coordination geometry of the metal ion and the radius of the metal ion. This is somewhat different from the results obtained from the molecular mechanics calculation [10].

We are interested in the coordination chemistry of lanthanide complexes with aza-crown and have determined the crystal and molecular structures of [La(Me-cyclen)(OSO_2CF_3)(OH_2)(NCMe)] [12], [Nd(Me-cyclen)(NCMe)(OSO_2CF_3)$_3$] [13], and [Er(cyclen)(NCMe)(OSO_2CF_3)$_3$] [14]. As a further investigation, we synthesized and structurally characterized the title complex.

EXPERIMENTAL

Preparation

Anhydrous $Er(CF_3SO_3)_3$ [15] and hexacyclen [16] was synthesized using the literature procedures. Acetonitrile was distilled from P_2O_5 immediately before use.

The title complex was synthesized by the addition of 0.52 mmol (0.38 g) of $Er(CF_3SO_3)_3$ to a solution of 0.59 mmol (0.15 g) of hexacyclen in 12 cm^3 of acetonitrile under N_2. A light pink solid appeared after

heating the resulting suspension to reflux for 2 h. Then a small amount of acetonitrile was added gradually to the system until the solid dissolved. The solution was kept in a desiccator with P_2O_5 at room temperature. Light pink prism crystals suitable for X-ray determination were obtained after 2 weeks. IR (KBr): 3297 m, 1621 w, 1091 w, 575 w cm^{-1}. Anal. Calcd for $Er_2C_{28}H_{12}O_{14}S_4F_{12}$: C, 22.69; H, 4.22; N, 11.35. Found: C, 22.56; H, 4.02; N, 11.36%.

X-ray structure determination

A crystal with approximate dimensions $0.24 \times 0.34 \times 0.36$ mm was quickly mounted in a glass capillary. Diffraction measurements were performed on a Siemens P4 diffractometer with Mo-K_α radiation ($\lambda = 0.71073$ Å) and a graphite monochromator. A total of 8156 ($R_{int} = 2.02\%$) independent reflections were collected by ω scanning technique in the range $2.0 \leqslant 2\theta \leqslant 50.0°$ with scan speed 6.00°/min in ω. Three standard reflections were monitored every 97 reflections. Intensity data were corrected by the ψ-scan technique. The structure was solved by direct methods using Siemens SHELXTL P4/PC software and refined by full-matrix least-squares techniques using 6168 reflections with $F > 4.0\ \sigma(F)$ and refining 649 parameters. The hydrogen atoms, except the two on the bridging O atoms, were added in calculated positions and their positions refined isotropically. All non-hydrogen atoms were refined anisotropically. The final values for R, wR and GOF for observed data are given in Table 1 and for all data.

RESULTS AND DISCUSSION

Figure 1 shows the view of the molecular structure of the title complex. The complex is dinuclear with two erbium ions bridged by two hydroxide ions. Each of the two metal ions is coordinated by the two bridging OH^- ions and six nitrogen atoms of a ligand, giving a coordination number eight. The coordination geometries of the two erbium ions are similar and can be described as slightly distorted dodecahedrons (Fig. 2). The four $CF_3SO_3^-$ ions are not involved in the coordination of the metal ions. The examination of the distances between N(hexacyclen) and O($CF_3SO_3^-$), which are near or longer than 3.0 Å, reveals that there is no strong H-bond interaction between the $CF_3SO_3^-$ ions and the hexacyclen molecules. They interact with the complex species [(hexacyclen)Er(μ-OH)$_2$Er(hexacyclen)]$^{4+}$ through electrostatic forces and keep the molecule neutral (see Fig. 3).

Selected bond lengths and angles of the title complex are listed in Table 2. The coordination of the two erbium ions are similar though they are different crystallographically. The Er—O bond lengths average 2.264 Å with the Er(1)···Er(2) distance 3.802 Å. The two metal ions and the two bridging oxygen atoms form a planar four membered-ring with the mean deviation 0.0314 Å. This result agrees with those in complex species [Yb(paphy)$(H_2O)_3(\mu$-OH)]$_2^{4+}$ [17] and [Y(μ-OH)$(H_2O)_2$(Phen)$_2]_2^{4+}$ [18], where the M—O(μ-OH^-) bond distances averaged 2.225(3) and 2.20(1) Å for Y^{3+} and Yb^{3+}, and the separation of the two metal ions was 3.651(2) and 3.608(1) Å for Y^{3+} and Yb^{3+}. The Er—N bond lengths of the title complex range from 2.522(3) to 2.609(2) Å [average 2.552(3) Å] for Er(1) and from 2.504(3) to 2.588(2) Å [average 2.541(3) Å] for Er(2), indicating a slight difference on conformation of the two hexacyclen. Comparing with its cyclen analogue: [Er(cyclen)(NCMe)$(OSO_2)_3$] [14], where the Er—N bond lengths are between 2.460(5) and 2.51(1) Å with the mean value 2.48(2) Å, and Er—O($OSO_2CF_3^-$) bond lengths averaged 2.32(2) Å, we find that the title complex has longer Er—N distances and shorter Er—O distances.

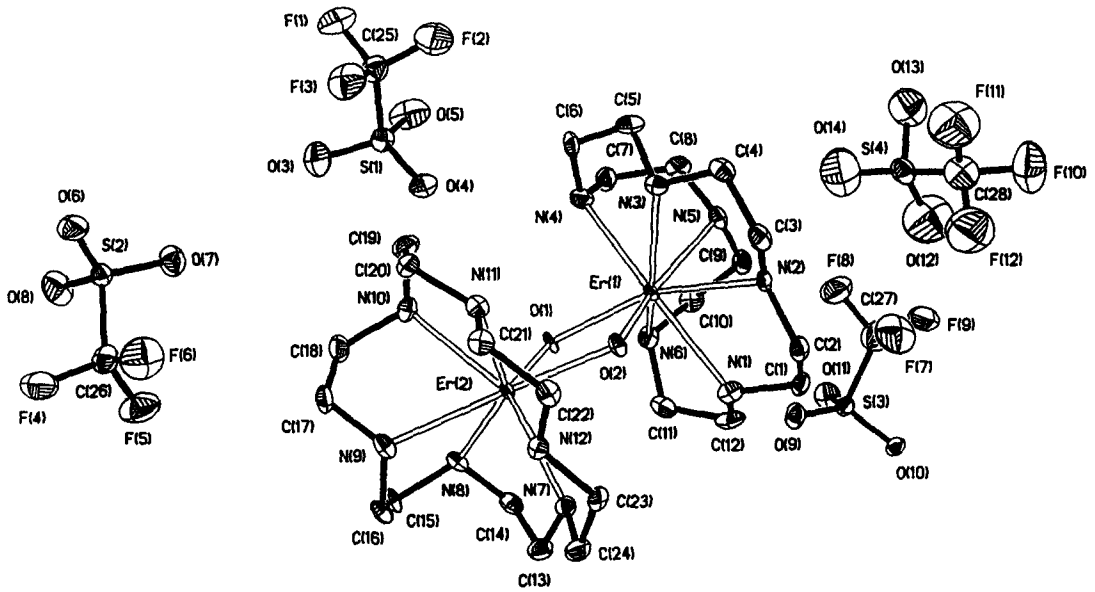

Fig. 1. ORTEP drawing of [(hexacyclen)Er(μ-OH)$_2$Er(hexacyclen)](CF$_3$SO$_3$)$_4$ with 50% probability ellipsoids.

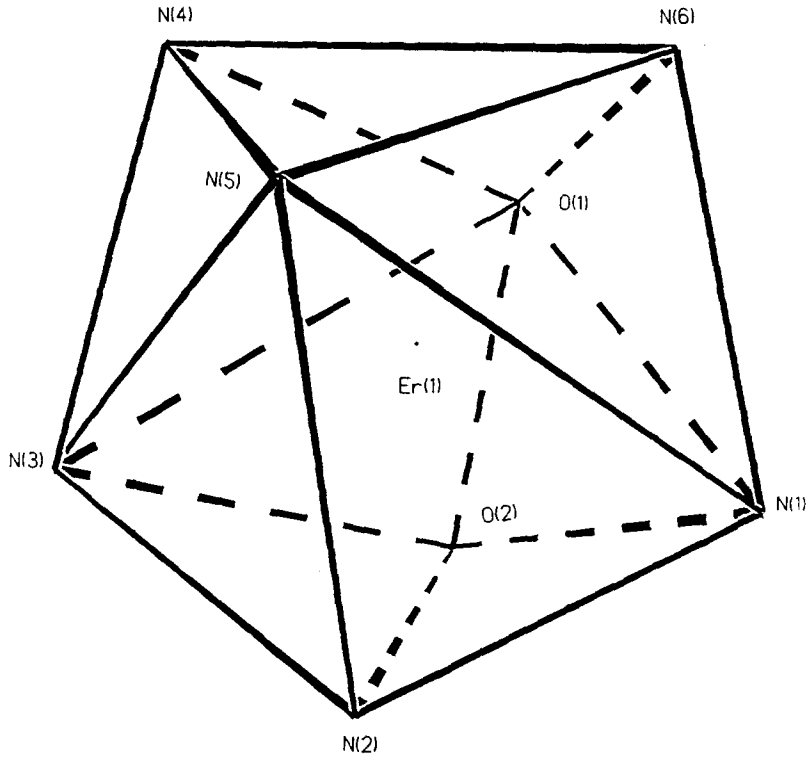

Fig. 2. Coordination polyhedron of Er^{3+} [Er(1) shown].

We owe this to the stronger coordination ability of hydroxide ions than that of trifloromethanesulfonate ions and the limited deformation ability of a hexacyclen molecule. The C—C bond lengths are normal, ranging from 1.463(4) to 1.535(3) Å. The C—N bond lengths vary from 1.443(4) to 1.533(3) Å, which agree with those in the complex species $[UO_2(hexacyclen)]^{2+}$ (1.41 ~ 1.56 Å) [11], *fac*-$[Co(hexacyclen)]^{3+}$ (1.48 ~ 1.51 Å) [8] and $[H_4(hexacyclen)]^{4+}$ (1.49 ~ 1.52 Å) [19], but apparently longer than those in neutral hexacyclen (1.45 ~ 1.47 Å) [18]. This indicates that the C—N bonds are weakened by the formation of N—M (M = positive ions) dative bonds.

The title complex contrasts markedly with its pre-

viously reported analogues in two ways: first, in the geometry of the ligand arranged around metal ions, and secondly, in the presence of the bridging hydroxide groups. In the previously reported 1 : 1 complexes of hexacyclen, the six nitrogen atoms were arranged in octahedral symmetries for smaller metal ions like Co^{3+} and Cr^{3+} (where the M—N bond lengths are about 2.0 Å) [6–9], in a distorted trigonal prism for a medium ion Hg^{2+}(Hg—N, ~2.5 Å) [10] and in a hexagonal plane for a larger ion UO^{2+}(U—N, ~2.7 Å) [11]. Furthermore, a series of lanthanide complexes with the oxygen analogue of hexacyclen, 18-crown-6, have been structurally characterized with the ligand folding around the metal ions and the other species such as anions (Cl^- and NO_3^-) and solvent molecules (H_2O) coordinating to the metal ions from 'above' and

'below' the crown ether [20]. But completely different from the structures mentioned above, the title complex is eight coordinated with each of the two metal ions siting between a hexacyclen ligand and the two bridging hydroxide ions. Thus, the structure of the title complex is rather unusual. The presence of the bridging coordinated hydroxide ions is another feature of the complex. Although the presence of the complex species 'Ln(OH)-hexacyclen' in aqueous solution has been predicted by W. Szczepaniak *et al.* in 1988 [3], no structural information for such a species has been reported until now. And it is of interest to note that the title complex can form in an anhydrous system and the ligand can stabilize the complex. In a similar synthesis, we have obtained a monoaquo–lanthanum complex: [La(Me-cyclen)(NCMe)(OH_2)(OSO_2CF_3)$_3$] [12], where a water molecule is included in the coordination sphere and the lanthanum ion does not hydrolyze.

New solid state routes to lithium transition metal oxides *via* reactions with lithium oxide

Marco D. Aguas, Graham C. Coombe and Ivan P. Parkin*

Department of Chemistry, Christopher Ingold Laboratory, University College London, 20 Gordon Street, London, WC1H OAJ.

(Received 14 April 1997; accepted 11 June 1997)

Abstract—Thermolysis of a mixture of lithium oxide and transition metal halides MX_n (M = Ti, Zr, Hf, V, Nb, Ta, Mo, W, Fe, Mn) at 800°C for 2–12 h produces crystalline lithium transition metal oxides Li_2MO_3 (M = Ti, Zr, Hf, Mn), Li_3MO_4 (M = V, Nb, Ta), Li_2MnO_3 $Li_2Fe_3O_4$ and Li_2MO_4 (M = Mo, W). For M = Cr, Co, Ni, Cu and Zn the reaction produces the metal oxides Cr_2O_3, NiO, CuO, ZnO and Co_3O_4. The metal oxides and lithium metal oxides were characterised by X-ray powder diffraction. SEM/EDAX, FT-IR and magnetic moment measurements. © 1997 Elsevier Science Ltd

Keywords: lithium oxide; solid state metathesis.

Transition metal oxides have a wide variety of structural types and an extensive range of properties from dielectric insulators to superconductors [1]. Commercially, lithium transition metal oxides have been used as solid breeder materials for nuclear reactors (Li_2ZrO_3) [2], non linear optical materials ($LiNbO_3$) [3] and corrosion inhibitors ($LiCrO_2$) [4,5].

Transition metal oxides can be made by heating the metal nitrate or carbonate in air [6]. Other routes include hydrothermal synthesis, molecular precursor, sol–gel and self propagating high temperature synthesis for bulk materials; CVD and MBE routes for coatings [7]. These materials are probably the most important class of ceramics both for industrial usage and for academic interest. Lithium transition metal oxides are typically made by reaction of metal carbonates or the action of Li_2O on metal oxide at 1200°C.

Solid state metathesis (SSM) reactions have been used to prepare a wide range of metal nitrides, phosphides, arsenides, stibides, oxides, sulfides and selenides [8]. In these reactions a metal halide is reacted with a group Ia or IIa pnictide or chalcogenide Eq (1). The coproduced halide provides for up to 90% of the reaction enthalpy and insures a rapid exothermic reaction.

$$Na_3E + MCl_3 \rightarrow 3NaCl + ME \quad (1)$$

In a previous paper [9] we reported on the synthesis of metal oxides from reactions of lithium oxide and anhydrous metal halides in sealed glass ampoules under vacuum. In all cases metal oxides and lithium chloride were produced except for Nb and Ta where $LiNbO_3$ and $LiTaO_3$ were obtained. In this paper we detail the effect of carrying out SSM reactions in air and with different stoichiometries.

EXPERIMENTAL

All preparations were conducted in a Saffron scientific glove box under a nitrogen atmosphere. Thermal studies were obtained in open ceramic crucibles in a Lenton Thermal Designs tube furnace. Metal chlorides and lithium oxide were purchased from Aldrich Chemical Co and used as supplied. X-ray powder diffraction was obtained using a Siemens D5000 diffractometer using germanium monochromated Cu-$K_{\alpha 1}$ radiation (λ = 1.54056 Å). Patterns were indexed using the TREOR program. SEM and EDAX analysis were obtained on a Jeol JSM 820 instrument using Quantex 6.2 with quantum detector Kevex delta 4. FT-IR spectra were obtained as pressed KBr pellets on a Nicholet 205; magnetic moment measurements were obtained on a Johnson Matthey balance.

[a] Observed XRD parameters were obtained to +/− 0.01 Å. The *a*, *b*, and *c* cell constants are given in order except for cubic cells where only one parameter is quoted and for hexagonal cells where the last number is the *c* constant. ^{R} = Rhombohedral, ^{T} = Tetragonal, ^{H} = Hexagonal.

Lithium transition metal oxide preparation (M = Ti, Zr, Hf, V, Nb, Ta, Mn, Fe)

Metal chlorides and lithium oxide (100–200 mg, 33–66 mmol) were combined such that the stoichiometric ratio of lithium to chloride was 1 : 1 (see Table 1). The reactants were ground together in a pestle and mortar and then sealed in an ampoule under nitrogen. The reaction mixture was opened in air and immediately placed in an open ceramic crucible at 300°C. The crucible was heated to 800°C for 12 h before allowing to cool to room temperature (*ca* 2 h). The product was triturated with water (2×50 cm^3) acetone (2×20 cm^3) and air dried. Products were analysed by power X-ray diffraction (Table 1). FT-IR, magnetic moment measurement and SEM/EDAX. Typical yields were in the range of 75–95%. Variation in reaction temperature (500 and 800°C) times (2 and 48 h) and reaction stoichiometries were explored for selected samples.

[Note the 1 : 1 stoichiometries of lithium to halide utilised above could not give rise to some of the phases and idealised equations (1–11) outlined below, too much lithium is required. In this case it is probable that some of the starting metal halide is evaporated during the course of the reaction. In a number of reactions excess over the 1 : 1 lithium to halide stoichiometry was tried, this gave the same lithium metal oxide product in a higher yield, this is commented upon below]

Caution. Metal halides and lithium oxide/metal halide reaction mixtures can undergo extremely exothermic reactions when heated and can produce a thermal flash. Reactions should be conducted in a fume cupboard behind a glass safety screen.

RESULTS AND DISCUSSION

Characterisation

Reaction of ground powders of Li_2O and anhydrous transition metal halides at 800°C for 12 h produces crystalline lithium transition metal oxides in good yield (*ca* 80%), Eqs (2)–(11).

$$TiCl_3 + 5/2Li_2O + 1/2O_2 \rightarrow Li_2TiO_3 + 3LiCl \quad (2)$$

$$MCl_4 + 3Li_2O \rightarrow Li_2MO_3 + 4LiCl \quad (M = Zr, Hf) \quad (3)$$

$$VCl_3 + 3Li_2O \rightarrow Li_3VO_4 + 3LiCl \quad (4)$$

$$MCl_5 + 4Li_2O \rightarrow Li_3MO_4 + 5LiCl \quad (M = Nb, Ta) \quad (5)$$

$$2CrCl_3 + 3Li_2O \rightarrow Cr_2O_3 + 6LiCl \quad (6)$$

$$MCl_4 + 3Li_2O \rightarrow Li_2MO_4 + 4LiCl \quad (M = Mo, W) \quad (7)$$

$$3FeCl_2 + 4Li_2O \rightarrow Li_2Fe_3O_4 + 6LiCl \quad (8)$$

$$MnCl_2 + 2Li_2O + 1/2O_2 \rightarrow Li_2MnO_3 + 2LiCl \quad (9)$$

$$3CoCl_2 + 3Li_2O + 1/2O_2 \rightarrow Co_3O_4 + 6LiCl \quad (10)$$

$$MCl_2 + Li_2O \rightarrow MO + 2LiCl \quad (M = Ni, Cu, Zn) \quad (11)$$

The products from the reactions were often fused coloured masses. Trituration with water and acetone removed the co-produced lithium chloride. The powders were characterised by X-ray powder diffraction

(Table 1). FT-IR, magnetic moment measurements, SEM and EDAX.

The SEM profile of the triturated powders revealed a variety of morphologies dependent on the sample from micron size crystallites with sharp angles and faces through to porous materials with a rounded structure. EDAX showed only the presence of transition metal, oxygen and some chlorine in the untriturated powders commensurate with the formation of lithium metal oxide and some lithium chloride (lithium is below the EDAX detection threshold). On trituration the EDAX peak for chloride disappeared leaving only peaks for metal and oxygen in the expected ratios.

The FT-IR spectra of the triturated lithium transition metal oxides and metal oxides were identical to authentic samples and typically showed a broad band centred at 650–450 cm^{-1} corresponding to a metal oxygen stretch. In no cases were other bands such as an O—H stretch observed. The magnetic moments (Table 1) of the paramagnetic materials were consistent with calculated spin only values.

The X-ray powder diffraction data for the lithium transition metal oxides and the metal oxides are summarised in Table 1. In general after a reaction time of 12 h at 800°C a crystalline material was formed, crystallite sizes varied from *ca* 300–1000 Å as assessed from the Scherrer equation [10]. In virtually all the reactions after trituration a single phase was identified by X-ray powder diffraction [11].

Scope of the reaction

Reaction of lithium oxides and anhydrous transition metal halides in air at 800°C for 2 h produces either metal oxide or lithium metal oxide. For early transition metals, lithium metal oxides were formed whilst for the latter transition metals no lithium incorporation was observed and metal oxides were produced. In the cases where metal oxides were produced, the metal was not oxidised in the reaction except for cobalt where Co_3O_4 was produced. In the cobalt case the oxidation is promoted by oxygen in the air because in sealed ampoule reactions CoO is produced. Reaction of the anhydrous chlorides of group IVa and Va with Li_2O at 800°C for 12 h produces only a single phase of material Li_2MO_3 (Fig. 1) and Li_3MO_4 respectively. In both cases the transition metal is in its maximum oxidation state. For the reactions of $TiCl_3$ and VCl_3 the metal has been oxidised in air. In comparable sealed ampoule reactions at 550°C the transition metal is not oxidised and little or no lithium incorporation is observed (except for $LiNbO_3$ and $LiTaO_3$) [9]. Reactions involving Mn and Fe chlorides with Li_2O in air show both oxidation of the metal and lithium incorporation. The reaction of $MoCl_5$ or $MoCl_3$ with Li_2O at 700°C produced Li_2MoO_4 (Fig. 2). Reducing the reaction temperature to 600°C produce a mixed phase of material in the case of $MoCl_3$; Li_2MoO_4 and Li_4MoO_5. The lithium incorporation in the lithium metal oxide could be increased by using more Li_2O.

Reaction pathway

The pathway followed in these reactions is difficult to determine. It could be a direct solid state metathesis reaction between Li_2O and metal halide. Alternatively the metal halide could decompose on heating in air to form a metal oxide that could then combine with the lithium oxide at the elevated temperatures to form lithium metal oxide. A number of reactions were followed to try and determine the reaction pathway.

Reaction of finely divided metal oxide and lithium oxide did not produce crystalline lithium metal oxide at 800°C after 8 h (M = Ti, Nb). Heating a mixture of LiCl with metal oxides or metal halides under similar conditions did not produce lithium metal oxides. Competitive reactions were investigated by reaction of a mixture of MCl_n and $M'O_x$ with Li_2O. This produced only $LiMO_p$ and no $LiM'O_p$. This indicates that the metathesis pathway is probably favoured.

Reducing the reaction time to 2 h for the reaction of Li_2O and MCl_n and lowering the temperature to 500°C did, in general, produce the same phases of material as the higher temperature reactions however the products were notably less crystalline.

It should be noted that in the majority of the reactions the amount of lithium oxide added was adjusted to remove all the lithium as lithium chloride. In the reactions carried out in a sealed ampoule no metal halide can escape during the course of the reaction and the degree of lithium incorporation is low or non existent. In the reactions carried out in air the metal halides which in some cases are relatively volatile can be partly lost from the reaction or evaporated (in the case of reactions that proceed with a thermal flash). This would mean that an excess of lithium oxide is available for combination and allows for the formation of lithium metal oxides. Indeed the most volatile metal halides studied ($NbCl_5$, $TaCl_5$) showed the greatest degree of lithium incorporation in the product.

Reaction of excess lithium oxide over the stoichiometric 1 : 1 lithium to chloride ratio was also studied. Once the preferred formula of the product had been determined from the stoichiometric reactions outlined above, excess lithium oxide was used in the reaction. These reactions proved to give a single phase of the required material in slightly higher isolated yields than the stoichiometric reactions. This observation supports the idea that some metal halide is lost by evaporation in the stoichiometric reactions. Notably no new or lithium rich phases were observed on increasing the amount of lithium oxide in the reaction, just improved yields.

The temperatures employed in this new route to lithium transition metal oxides are up to 500°C lower

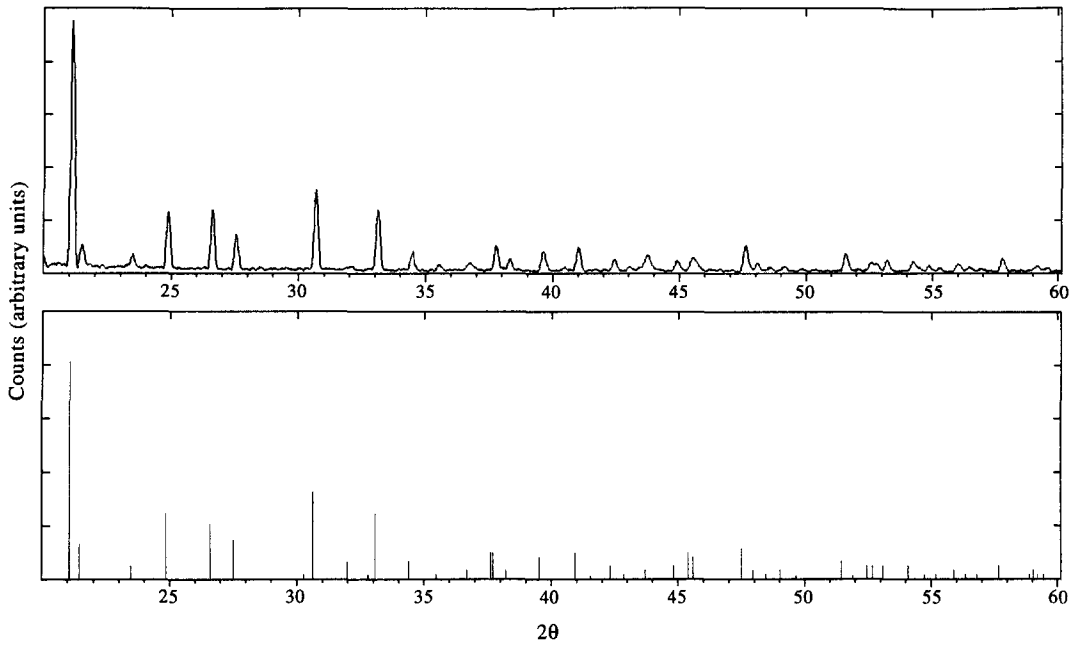

Fig. 1. Upper trace; pattern obtained from reaction of Li_2O and $HfCl_4$ in air at 800°C. Lower trace; stick pattern for Li_2HfO_3.

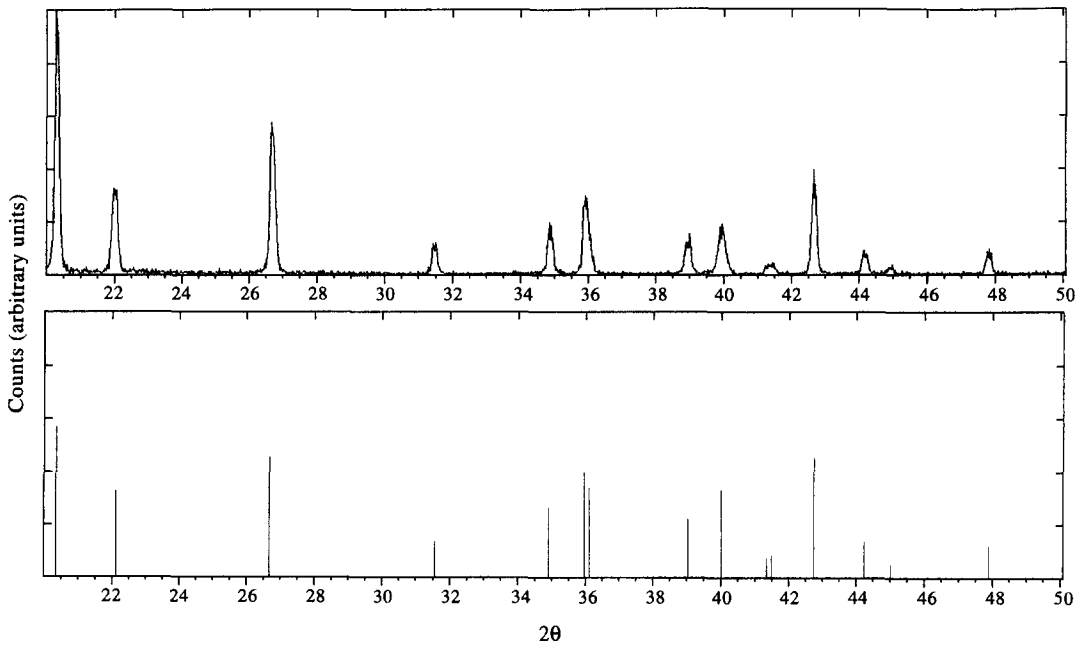

Fig. 2. Upper trace; pattern obtained from reaction of Li_2O and $MoCl_3$ in air at 800°C. Lower trace; stick pattern for Li_2MoO_4.

than conventional preparations from the oxides. The procedure is also relatively straightforward and does not involve the use of multiple heating and grinding stages or long annealing periods used in traditional methods. Compared to hydrothermal routes this method does not involve any prior wet chemistry stage. The new method is easy to duplicate, involves inexpensive apparatus and can be achieved without pelletising the reagents. The lower temperature and shorter times in these reactions is attributable to the ease in which the solid state diffusion barrier is overcome as the starting metal chlorides melt or partly decompose during the reaction, further the coproduced lithium halide provides a flux for the reactants.

The reaction may be proceeding *via* a solid state metatheses reaction. It should be noted that no unusual or novel phases of lithium metal oxides have been achieved using this route. It would be desirable to produce highly oxidised phases such as $Li_xNi_{1-x}O$ via this method, however all attempts to date have been unsuccessful.

CONCLUSIONS

Reaction of lithium oxide with anhydrous metal halides in air at 800°C provides a straightforward relatively high yield route to lithium metal oxides. The phases isolated are significantly different to sealed ampoule reactions of lithium oxide and anhydrous metal halides where metal oxides were produced. It is likely that the reaction occurs via solid state metathesis. The new reaction to form lithium metal oxides is at significantly lower furnace temperature than conventional methods possibly because a flux of lithium chloride is coproduced in the reaction.

Abstract—A new vanadium(V) complex, diammonium (nitrilotriacetato)dioxovanadate(V) $(NH_4)_2$ [VO_2NTA], has been synthesized. The structure of the complex has been studied by solution and solid-state NMR spectroscopies as well as single crystal X-ray crystallography. It is confirmed from NMR studies that the octahedral geometry is retained in both solution and solid-state of the complex. The chemical exchange between glycinate rings *cis* to and *trans* to V=O bond in the complex has been observed in the solution ^{13}C NMR spectra at elevated temperatures. Large ^{51}V chemical shift anisotropy ($\Delta\delta_{aniso} = -800$ ppm) and quadrupole coupling ($e^2qQ/h = 8.80$ MHz) were observed in ^{51}V spectra of the solid complex. Distortion of octahedron also results in an increase of the electric field gradient at a V nucleus. The NMR spectra are discussed on the basis of the crystal structure. © 1997 Elsevier Science Ltd

Keywords: X-ray; NMR; nitrilotriacetate; vanadium(V) complex; dioxovanadate(V) complex; ^{51}V NMR.

With the recent discoveries of the first two naturally occurring vanadium-containing enzymes, the bromoperoxidase and nitrogenase, the coordination chemistry and reactivity of vanadium is receiving renewed attention [1]. Of the various ligands, many carboxylates are known to form anhydrides with vanadate in solution, if they have additional hydroxyl or amine groups available for chelation. Oxalate [2–4] gives the simple mono- and *bis*-oxalato octahedral complexes, presumably with *cis*-VO_2 species. Aminopolycarboxylate such as ethylenediaminetetraacetate (EDTA) also forms similar octahedral complex having *cis*-VO_2 species [5–8]. However, 2-hydroxycarboxylates such as lactate and glycerate etc., form a variety of derivatives, including simple esters and chelates having trigonal bipyramidal coordination, and two binuclear complexes with mixed coordination [3,9,10].

Not many crystal structures of the vanadium(V) complexes are known yet. The vanadium(V) complexes of oxalate [11,12] and EDTA [13,14], in which the anion has irregular octahedral geometry with two double-bonded oxygen atoms, are known to have a *cis*-VO_2 core from the X-ray diffraction studies.

In recent years, solid-state ^{51}V NMR spectroscopy has emerged as a powerful tool for studying the local environment of vanadium in vanadia based catalysts [15], metavanadates [16,17] and vanadium complexes [8]. However, the resulting ^{51}V magic-angle-spinning (MAS) spectra are not simple due to the simultaneous line-broadening effects arising from quadrupole and chemical shift anisotropy. The ^{51}V nucleus (spin $I = 7/2$, natural abundance 99.76%) has an electric quadrupole moment which interacts with the gradient of the intramolecular electric field. This interaction produces the so called quadrupole effects of the first and second order in ^{51}V NMR spectra [18]. The analysis of these effects allows one to measure the quadrupolar coupling constant, e^2qQ/h, and asymmetry parameter, η_Q. These parameters directly characterize the gradient of the electric field which is created at the ^{51}V nucleus by the surrounding atoms and thus can be related to distortions of the symmetry of the local environment of the V atom. As found recently, the principal components of the chemical shift tensor δ_1, δ_2 and δ_3 are also very sensitive to the type of local environment of ^{51}V nucleus [19].

In this paper we have prepared a new vanadium(V) complex, diammonium (nitrilotriacetato)dioxovanadate(V), and its structure has been studied by the

solution (^{1}H, ^{13}C and ^{51}V) and solid-state (^{13}C and ^{51}V) NMR spectroscopies, for the purpose of studying the interactions of vanadium(V) with amino-polycarboxylate ligand. Also the NMR spectra were discussed on the basis of the X-ray structure of the complex.

EXPERIMENTAL

Materials

All reagent grade chemicals were used without further purification. Ammonium metavanadate (NH_4VO_3), nitrilotriacetic acid (H_3NTA), 25% ammonia water and D_2O were purchased from Aldrich Chemical Company.

Synthesis of the vanadium(V) complex

The reaction of NH_4VO_3 (0.02 mole, 2.34 g) with H_3NTA (0.02 mole, 3.82 g) and 25% ammonia water (0.02 mole, 1.3 cm^3) in 100 cm^3 of water produced a yellow solution, which was filtered after being stirred for 3 h. The solution was concentrated by passing a stream of dry air at room temperature for 2 days. The pale yellow crystals were formed and then filtered. The complex was recrystallized from water. The yield was 1.95 g (63.1%). The single crystals were obtained by evaporating slowly the aqueous solution of the complex. Chemical formula of the complex is $VN_3O_8C_6H_{14}$ on the basis of elemental analyses. Analytical data; calculated (%): C 23.46, H 4.59, N 13.68, found (%): C 23.34, H 4.68, N 13.83.

X-ray measurements

Preliminary experimentation and data collection for the X-ray crystal structure determination were performed on an Enraf–Nonius CAD4/Turbo diffractometer using Mo-K_α radiation ($\lambda = 0.71069$ Å). A small single crystal, $0.5 \times 0.5 \times 0.5$ mm, was cut from a larger one and glued to a glass fiber with an epoxy resin. Twenty-five reflections in diverse reciprocal space were centered by an automatic search program and used to obtain cell parameters. After the preliminary cell was confirmed, high-angle data ($2\theta > 20°$) were collected and 25 of these reflections were centered and used to obtain more accurate cell parameters. Unit cell parameters and the systematic absences indicated the monoclinic space group $P2_1/n$ (No. 14) [20] with $Z = 4$. Data were collected on this improved unit cell at ambient temperature up to $2\theta = 50°$. Data reduction including the corrections for Lorentz-polarization, decay and absorption were performed. The crystal structure was solved and refined with full-matrix least-squares by using MolEN, the Enraf–Nonius structure determination package, resulting in R_1 and R_w indices of 0.049 and 0.076, respectively, without hydrogen atoms. Other details of crystallographic data are summarized in Table 1. The selected bond distances and angles are tabulated in Table 2. The structure model was drawn using ORTEP, Oak Ridge Thermal Ellipsoid Plot Program [21].

Solution and solid-state NMR measurements

^{13}C and ^{51}V NMR spectra of samples in D_2O were recorded on a JEOL GSX-400 NMR spectrometer at 100.5 and 105 MHz, respectively, at 298 K. The solution ^{13}C spectra were measured with broad-band ^{1}H decoupling. ^{13}C spectra of solid samples (*ca* 0.2 g) were recorded on a Bruker MSL-300 spectrometer (75.47 MHz) with cross-polarization/magic-angle-spinning (CP/MAS) technique at ambient temperature. A spectral width of 29,411 Hz and an accumulation of 200 transients with an acquisition time of 0.85 s were used. The contact time was 2 ms and the delay between each scan was 5 s. Spinning (MAS and off-MAS) and static ^{51}V spectra of the powder samples were recorded at room temperature on a Bruker MSL-400 and an ASX-200 spectrometer at 105.25 and 52.64 MHz, respectively. The angle in the off-MAS measurements was chosen so that the intensities of the spinning sidebands caused by the satellite transitions were negligible. The spinning axis used in off-MAS was inclined at 53.9 and 53.7° to the magnetic field for MSL-400 and ASX-200, respectively. The spin rates for spinning spectra were between 8 and 12 kHz. The ordinary single pulse sequence with phase alternation was used

with and without ^1H high-power decoupling during signal acquisition. ^1H high-power decoupling had negligible effect on the line shape. ^1H decoupling power was 56 kW for both MSL-400 and ASX-200 spectrometers. Typical accumulation numbers were 800 for MAS and 1200 for static and off-MAS by MSL-400, and 2400 for MAS and off-MAS by ASX-200. The $\pi/2$ pulse width for solution was set at 6.0 μs. The pulth length used was 1.0 μs and the repetition time was 1.0 s. Recovery time after the pulse transmission was set at 5 μ s at 105.25 MHz. The detailed measuring conditions are described elsewhere [26]. ^{13}C and ^{51}V chemical shifts are referred to external TMS and $VOCl_3$, respectively.

Analysis of solid-state ^{51}V NMR spectra

The line shape of the spectra and the intensity of spinning side band (SSB) were analyzed using our own software written in Fortran and working on an NEC PC9801 series personal computer. The powder averaging procedure incorporates the two-dimensional interpolation and partitioning all directions presented by Alderman *et al.* [22] The intensity of SSB in MAS spectra produced by chemical shift anisotropy was calculated using the formula derived by Herzfeld and Berger [23]. Chemical shift anisotropy was estimated from the SSB intensity using a least squares fitting [24], in which the procedure was based on Fenzke *et al.* [25] The detailed procedure is described elsewhere [26].

RESULTS AND DISCUSSION

It is reported from the kinetic study that the VO_{2+}ion formed a 1:1 complex with NTA ($K_{VO_2NTA} = 10^{13.8}$ at 25°C) [27]. Nitrilotriacetate, containing a nitrogen and three oxygens, is considered to react with VO_{2+}ion as a tetradentate ligand. The synthesized vanadium-NTA complex is soluble in water and stable at room temperature. Its synthesis is readily accomplished in good yield (63.1%). Large single crystals were easily grown by slow evaporation of the aqueous solution and showed no evidence of twinning and other defects.

X-ray crystal structure

The solid-state structure of the complex is remarkably simple with four discrete $(NH_4)_2[VO_2NTA]$ units in a unit cell. There is no particular interaction between adjacent complexes in the unit cell and the geometry around the vanadium (V) ion appears to be distorted octahedron as shown in Fig. 1.

The anion $[VO_2NTA]^{2-}$ has a slightly irregular octahedral geometry in which two oxo ligands are *cis* to each other as shown in oxalate [11,12] and EDTA [13,14] complexes. These two oxygens have short V—O bonds (1.653 and 1.613 Å) which indicate strong multiple bond character. The O—V—O angle [107.1 (2)°] in the VO_2 moiety is larger than 90° that is the standard octahedral value. The small difference (0.040 Å) of V=O bonds observed in the unconstrained complex might be due to interactions with the

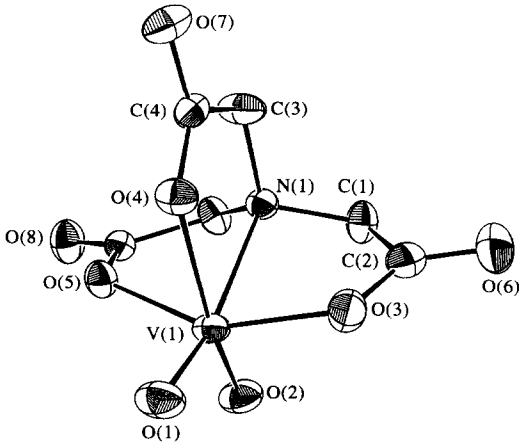

Fig. 1. ORTEP of $[VO_2NTA]^{2-}$ anion.

asymmetric environments. The average V=O bond length (1.633 Å) in the complex is shorter (1.648 Å) than that found in EDTA complex [14].

The remaining four coordination sites of vanadium atom are occupied by a nitrogen atom and three oxygen atoms of the NTA ligand, giving three five-membered glycinato rings in the complex. Three oxygen atoms of the NTA ligand in the complex fall into two groups depending on whether or not they are *trans* to a V=O bond. The *trans* V—O (glycinate) bond (2.225 Å) is significantly longer than the other bonds (1.980 and 1.995 Å), showing a good illustration of the structural *trans* effect. This lengthening (by an average 0.237 Å) and weakening of V—O bond which is *trans* to the oxo ligands can also be found in the crystal structure of vanadium(V)–oxalate complexes (by 0.23 Å) [11]. This weakening of the σ bond strength is reflected throughout the rest of the anion. The stronger of the inner C—O bonds are adjacent to the weaker of the V—O bonds. It is assumed that the hydrogen bonding to the vanadyl oxygen atoms occurs in the complex, also giving unsymmetric V=O bond lengths. The longer of the non-equivalent V=O bonds is the one which has the stronger hydrogen bonding to it.

The bond length of V—N is shorter in NTA complex (2.246 Å) than in EDTA complex (2.359 and 2.366 Å) [14], indicating stronger bond in NTA complex. A short V—N bond would give some reduction of strain within the glycinato rings in the complex. Since a difference of ~0.04 Å in V—O and V—N distance is predicted from consideration of the covalent radii of oxygen and nitrogen [13], the V—N bond is much stronger than the V—O(4) bond in the complex. It appears that the difference (0.021 Å) between the bond distances to nitrogen and carboxylate oxygen which is *trans* to V=O in the NTA complex is indicative of a low affinity of the VO_2^+ ion for carboxylate oxygen relative to amino nitrogen. Minor variations in length of the C=O bonds can also be attributed to hydrogen bonding with ammonium ions. The oxygens of C=O groups are the atoms most influenced by the environment of the anion.

Solution NMR spectroscopy

In the ^{13}C NMR spectrum of the complex in D_2O as shown in Fig. 2, there are two sets of glycinate group signals at room temperature: one set (65.03 and 179.72 ppm) is assigned to the glycinate *trans* to V=O and the other set (66.64 and 181.25 ppm) is assigned to the glycinate to *cis* to V=O. The assignment of ^{13}C peaks was based on the relative intensities of peaks and the chemical shifts in EDTA complex [8]. This indicates that the fast exchange between two types of the glycinate groups does not occur on NMR time scale at room temperature. But at elevated temperature the carboxylate group *trans* to the V=O bond will be easily broken and the chemical exchange between the glycinate groups *trans* to and *cis* to the V=O bond will occur faster, giving one set of glycinate signals, as shown in Fig. 3. Below the coalescence temperature (T_c) of 300 K, two sets of signals are observed in ^{13}C NMR spectrum. But at higher temperature the exchange rate increases and, thus, two sets of signals coalesce to give a set of signals. The process for the exchange might be a one-ended dissociation equilibration of the coordinated ligand, accompanied by a rotation and reclosure of the glycinate group. This phenomenon is also observed in the ^{13}C NMR spectrum of the $[VO_2\ (oxalate)_2]^{3-}$ anion [4], in which the exchange between two types of carboxylate groups *trans* and *cis* to V=O occurs at elevated temperature.

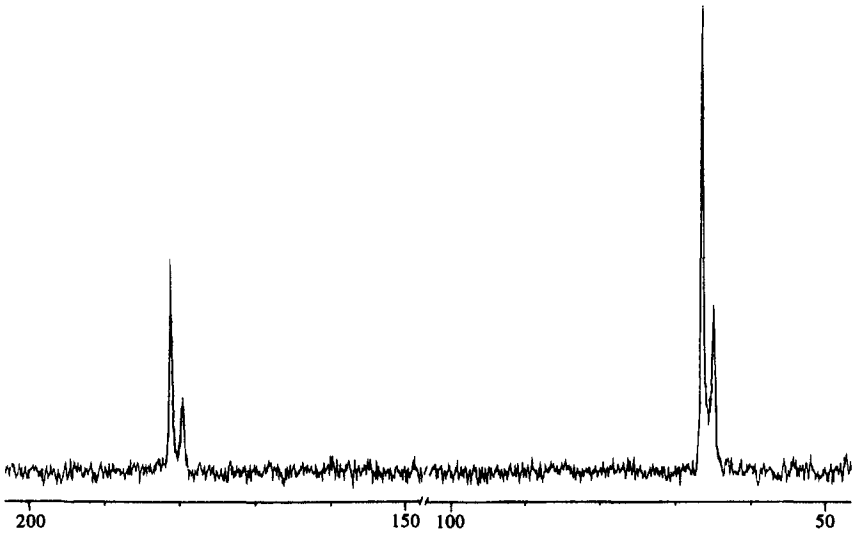

Fig. 2. ^{13}C NMR spectrum of $(NH_4)_2[VO_2NTA]$ in D_2O at ambient temperature.

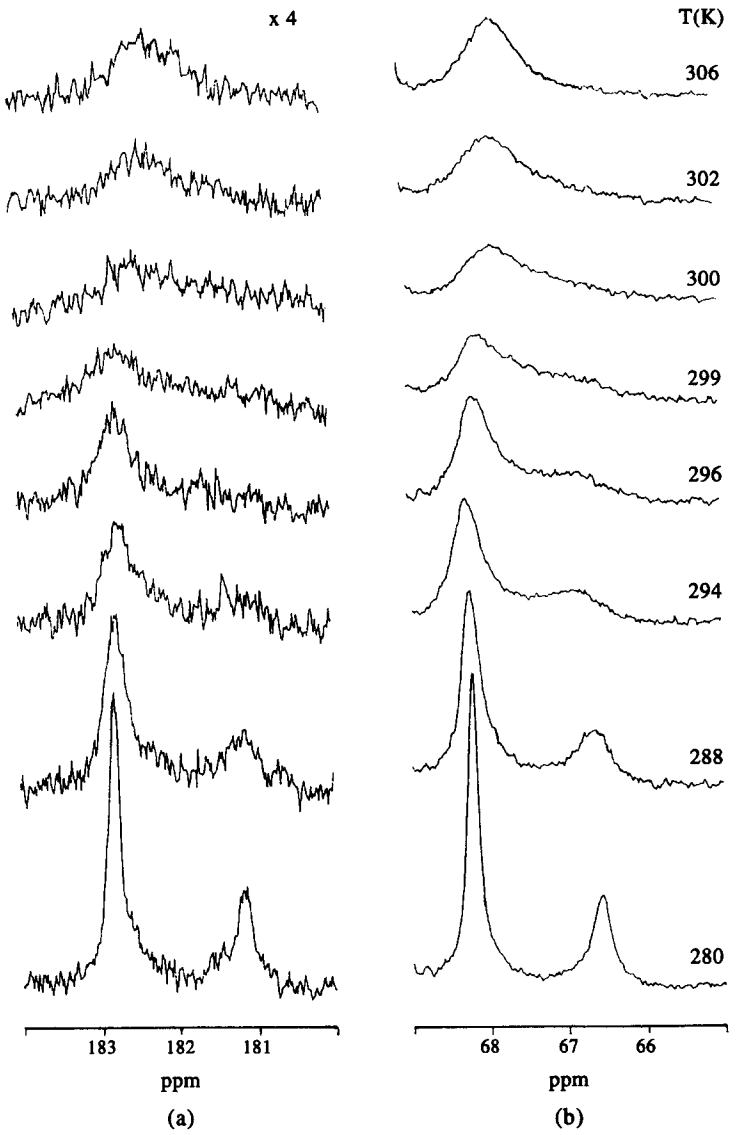

Fig. 3. (a) Methylene and (b) carboxylate regions of ^{13}C NMR spectrum of $(NH_4)_2[VO_2NTA]$ in D_2O at various temperatures.

The complex shows the ^{51}V peak at -504.3 ppm which falls in the range of octahedral coordination around vanadium atom [28]. The half-width (430 Hz) of ^{51}V peak is smaller than that (1000 Hz) of EDTA complex [8], due to increase of symmetry in the structure of NTA complex.

Solid-state NMR spectroscopy

The CP/MAS ^{13}C spectrum of the powder $(NH_4)_2[VO_2NTA]$ is shown in Fig. 4. There is only one CH_2 signal at 66.20 ppm, but two COO signals at 180.02 and 178.14 ppm indicating inequivalence of two COO groups. The broad line width of the CH_2 signal might be produced by residual dipolar coupling with the nearby ^{14}N, which disables the observation of the inequivalency of CH_2 groups. This result indicates that the chemical exchange between the two types of glycinate groups does not occur in the solid-state complex. These are consistent with X-ray diffraction results.

MAS ^{51}V spectrum of the powder $(NH_4)_2[VO_2NTA]$ is shown in Fig. 5(a). A large number of spinning sidebands are observed over a frequency range wider than 1.0 MHz. These sidebands originate mainly from the satellite transitions broadened by the first-order quadrupole interaction. Several stronger signals in the central position might be originated from the central transition. The large shielding anisotropy at high magnetic field (9.4 T) causes the MAS spectrum to be broken up into centerbands and an extensive set of the spinning side bands, which are spaced by integer multiples of the spinning frequency. We cannot separate the central transition from the satellite transitions due to the severe overlapping. Thus, we measured off-MAS ^{51}V spectrum, as shown

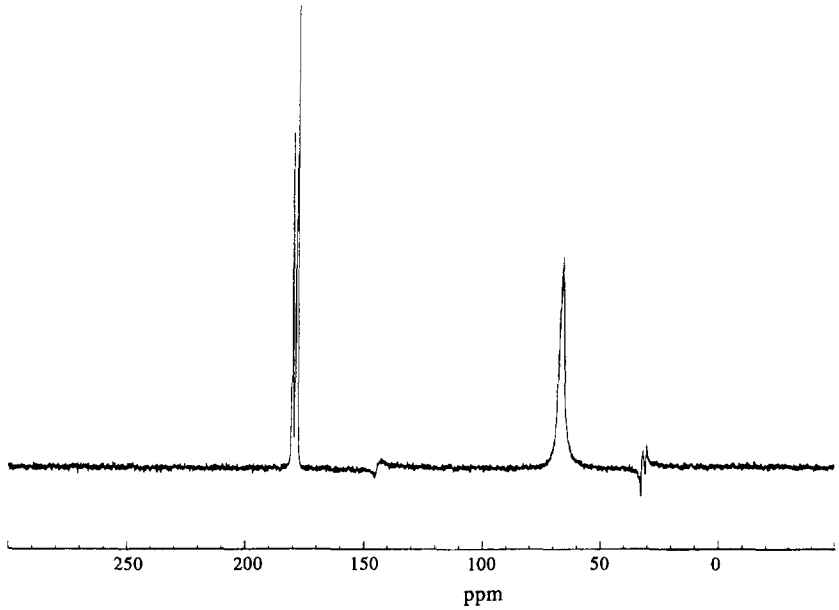

Fig. 4. CP/MAS ^{13}C NMR spectrum of the powder $(NH_4)_2[VO_2NTA]$.

in Fig. 5(b) to obtain only the signals from the central transitions [16]. These signals are ascribed to the central transition. The first-order quadrupole interaction does not work on the central transition ($+1/2 \leftrightarrow 1/2$), and therefore, the chemical shift anisotropy and the second-order quadrupole interaction influence the line shape and the chemical shift of ^{51}V signal. We analyzed the SSB intensities and line shapes of the off-MAS spectrum to obtain chemical shift anisotropy and the quadrupole coupling data, summarized in Table 3.

We have also measured the ^{51}V spectrum for a static sample as shown in Fig. 6. Static spectrum signals from the satellite transitions are not clearly observed and the line shape of the central transition is governed dominantly by chemical shift anisotropy. We have simulated the static spectrum to check and confirm

$\delta_{solution}$ (ppm)	-504.3 ± 0.1

[a] Definitions of parameters are the same as in Ref. [26]. Reanalysis resulted in slightly different values from Ref. [26] for some parameters.

validity of the parameters obtained from analysis of the off-MAS spectrum. We obtained the large chemical shift anisotropy ($\Delta\delta_{aniso} = -800$ ppm) for ^{51}V atom. The components of the ^{51}V chemical shift tensor are very sensitive to the type of atoms in the first coordination sphere of the V atom. The isotropic chemical shift δ_{iso} of the powder complex, having five oxygens and a nitrogen is -507.0 ppm which is very close to the value obtained from solution measurement. The peak of the solid-state ^{51}V is essentially unshifted in frequency from the solution value except by outer-sphere interactions. The values of eulerian angles (α_C, β_C and γ_C) indicate that the principal axes of chemical shift tensor and quadrupole interaction tensor are almost the same.

Vanadium in a distorted octahedral environment gives spectra with the nearly axial symmetry of the chemical shift tensor (i.e. $\delta_1 \sim \delta_2 \neq \delta_3$), which reflects similar deshielding environments for both nitrogen and oxygen donor atoms. The stronger the distortion from a regular octahedron, the larger the value of $\Delta\delta$ is. Thus, for the vanadium complex, the anisotropy of the ^{51}V chemical shift is much more sensitive to the character of the local arrangement of donor atoms around the V atom, than the isotropic chemical shift δ_{iso} is. Distortion of the octahedron also results in an increase of the electric field gradient at the V nucleus, giving a large quadrupolar coupling constant (8.80 MHz). It seems to expect a correlation between $\Delta\delta$ and the quadrupolar coupling constant, e^2qQ/h, and the asymmetry parameter η_Q for metavanadates [15]. From the proximity of the ^{51}V chemical shifts in solution and solid-state complex, we speculate that the geometry in the solid-state might be retained in the solution. The static ^{51}V spectrum of a single crystal is shown in Fig. 7. Two distinguishable signals appeared, indicating two magnetically inequivalent but chemically identical vanadium sites. These sites are generated by the 2_1 symmetry operator within the unit cell [20].

Simple adducts of samarium and ytterbium diiodide: synthesis and molecular structures of $LnI_2(3,5\text{-lutidine})_4$ (Ln = Sm, Yb) and $YbI_2(4\text{-t-butylpyridine})_4$

Graham H. Maunder and Andrea Sella*

Christopher Ingold Laboratories, University College London, 20 Gordon Street, London WC1H 0AJ, U.K.

(Received 22 April 1997; accepted 9 June 1997)

Abstract—Reaction of LnI_2 (Ln = Sm, Yb) with substituted pyridines in THF gives good yields of the highly coloured complexes $[LnI_2(py)_4]$. The structures of complexes $[LnI_2(3,5\text{-lutidine})_4]$ (Sm, Yb) and $[YbI_2(4\text{-t-butylpyridine})_4]$ have been determined by X-ray crystallography and show simple octahedral coordination about the metal centre with *trans*-iodide ligands. © 1997 Elsevier Science Ltd

Keywords: lanthanide; crystal structure; pyridine; iodide; samarium; ytterbium.

The divalent iodides of ytterbium and samarium are increasingly used as one-electron reducing agents in organic synthesis in reactions which often have remarkably high stereoselectivity [1]. Indeed solutions of samarium iodide in THF have been available commercially for several years but are conveniently prepared by direct reaction of an excess of metal with diiodoethane [2]. From an inorganic point of view the iodides are among the most convenient starting materials for the exploration of the divalent state of these elements [3]. It came as something of a surprise to us to realize that the simple coordination chemistry of the iodides themselves remains essentially unexplored. Recent work by Yamanuchi has shown that the reducing power of the SmI_2 greatly increased upon addition of hexamethylphosphoramide, and that in some cases the chemoselectivity of the reactions are sometimes significantly altered [1]. Hou and Wakatsuki have recently reported the crystal structures of HMPA adducts of samarium and ytterbium and have suggested that the behaviour of HMPA may be unique [4]. In this note we report on our studies of the addition of pyridines to solutions of LnI_2 (Ln = Sm, Yb) and on the crystal structures of the 3,5-dimethylpyridine adducts of each.

RESULTS AND DISCUSSION

During one attempt to displace the coordinated THF from $[Tp^3\text{-}t\text{-Bu-5-MeSmI(THF)}_2]$ [5], a large excess of 3,5-lutidine (3,5-Me_2py) was added to a solution of this complex in toluene. Slow diffusion of 30/40 petrol into this solution gave black crystals (**1a**). IR spectroscopy of this product showed that it no longer contained a pyrazolylborate ligand. The ^{1}H NMR spectrum simply showed peaks due to the pyridine shifted slightly from their normal positions by the paramagnetic samarium centre.

The complex $[SmI_2(3,5\text{-}Me_2py)_4]$, **1a**, could also be prepared directly by reaction of SmI_2 in THF with an excess of 3,5-lutidine, and precipitates as black crystals upon diffusion of 30/40 petrol into this solution or by slow evaporation of THF.

$$SmI_2 + 4(3,5\text{-}Me_2py) \rightarrow [SmI_2(3,5\text{-}Me_2py)_4]$$

1a is very slightly soluble in benzene or toluene and gave broad ^{1}H NMR spectra. The corresponding ytterbium compound, $[YbI_2(3,5\text{-}Me_2py)_4]$ **2a**, was prepared similarly. The insolubility of **2a** precluded the recording of solution spectra. The ^{13}C CPMAS NMR spectrum however was sharp, consistent with the presence of the diamagnetic f^{14} ytterbium(II) ion. Attempts to prepare the corresponding complexes with pyridine gave deeply coloured, air-sensitive crys-

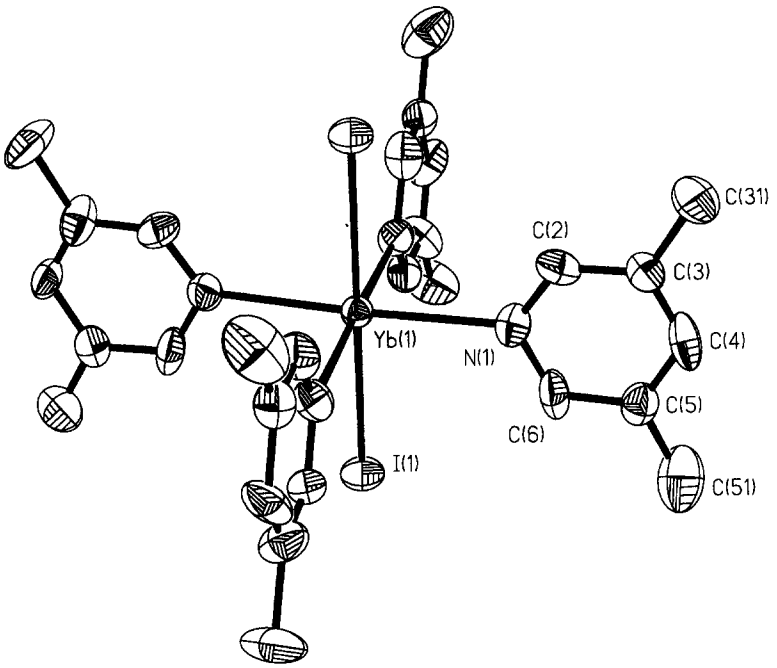

Fig. 1. ORTEP view of $YbI_2(C_7H_9N)_4$, **2a** (50% probability ellipsoids, H atoms are omitted for clarity).

talline solids which degraded rapidly when removed from the mother liquor, as a result of which consistent NMR spectra and elemental analyses were not obtained. In order to increase the solubility of the complex in non-polar solvents without however altering the steric demand of the pyridine, complexes were prepared with 4-*t*-butylpyridine. Addition of 4-*t*-butylpyridine to a solution of ytterbium diiodide in THF gave a dark purple solution from which crystals of **2b** were obtained upon addition of low boiling petroleum spirit. The elemental analyses of this complex was consistent with a stoichiometry of $[YbI_2(t\text{-}BuC_5H_4N)_5]$. Crystal structure determinations were therefore undertaken to compare the two coordination environments. The structures of **1a, 2a,** and **2b** were determined and to our surprise all three were found to be remarkably similar and will be discussed together.

Crystallographic studies

Crystals of **1a** and **2a** were obtained by slow diffusion of pentane into a tetrahydrofuran solution of the diiodide saturated with 3,5-lutidine yielding isomorphous crystals in the space group $I\bar{4}$. Each molecule has crystallographically imposed D_{4h} symmetry. The molecular structure of **2a** is shown in Fig. 1. The metal lies on the $\bar{4}$ site at the origin with the iodide ligands lying on the fourfold axis, and the plane of the pyridine ligands lying aligned parallel to that axis. **2b** crystallized from a similar mixture of solvents containing *t*-butylpyridine, in the space group $C2/c$. Thus only half the molecule is crystallographically unique. The data set collected for **1a** was of substantially lower quality than that of **2a** and only the heavy atoms could be refined anisotropically. For **2b** some unresolved disorder of the *t*-butyl groups somewhat reduces the reliability of the structure. The metal iodide distances are **1a** 3.221(1) Å (Ln = Sm), **2a** 3.132(1) Å and **2b** 3.120(2) Å (Ln = Yb), the differences being consistent with the contraction in ionic radius across the lanthanide series. For **1a** the distance is less than that in the six-coordinate compound $SmI_2(HMPA)_4$, 3.390(2) Å [4], as expected due to the rather large HMPA ligands. Furthermore the distance of **1a** is slightly shorter than for the two seven-coordinate complexes recently reported by Evans, $SmI_2(THF)(DME)_2$ [3.246(1) Å] and $[SmI_2(THF)_3(DME)]$, 3.233(1) Å [6], due to the reduced coordination number. A trivalent phosphine oxide complex $[Sm(OPMePh_2)_4I_2]I$ crystallized by Sen shows much shorter distances due to the smaller ion 3.077(1) Å [7]. For **2a** and **2b** the metal iodide distances are somewhat longer than in $YbI_2(THF)_4$ [3.103(1) Å] [8] suggesting the steric demand of the rigid pyridine groups to be intermediate between that of HMPA and the flexible THF group.

The metal nitrogen distances follow a similar pattern, **1a** 2.708(10) (Ln = Sm), **2a** 2.586(3) and **2b** 2.56(2) Å (Ln = Yb). Although few samarium pyridine complexes have been isolated, octahedral coordination has been found for the majority of tetrakis–pyridine divalent ytterbium derivatives, including borohydrides, thiolates, selenolates, which have been crystallographically characterized and show similar Yb—N bond distances $[Yb(BH_4)_2(C_5H_5N)_4]$ {av. 2.573(5)} [9], $[Yb(SePh)_2(C_5H_5N)_4]$ {av. 2.532(6) Å} [10], $[Yb(SPh)_2(C_5H_5N)_4]$ {av. 2.549(9) Å} [11].

Intriguingly the tellurolate analogue is seven-coordinate $[Yb(TePh)_2(C_5H_5N)_5]$, Yb—N = 2.61(1) Å [10]. Other divalent ytterbium complexes with pyridine ligands also exhibit similar Yb—N distances: $[Yb(C_5H_5N)_5(CH_3CN)_2]^{2+}$ 2.50(5) Å [12], $[Yb(\eta\text{-}C_5Me_5)_2(C_5H_5N)_2]$ 2.565(3) Å [13] $[(\eta^8\text{-}C_8H_8)Yb(C_5H_5N)_3]$ (av.) 2.58(2) Å [14].

DISCUSSION

All three compounds adopt a structural motif which is quite common and a range of six-coordinate compounds have been reported previously: $[Ti(C_5H_5N)_2I_2]I$ [15], [Co(3,5-dimethylpyridine)$_2I_2$] [16], $[Cu(C_5H_5N)_2I_2]$ [17], $[Ni(C_5H_5N)_2I_2]$ [18], $[Cd(C_5H_5N)_2I_2]$ [19], and [Sr(3,5-dimethylpyridine)$_2I_2$] [20]. The observation of six rather than seven coordination in the crystal structure of **2b** as had been expected from the elemental analysis suggests that a crystal unrepresentative of bulk of the material may have been chosen. Nevertheless, the observation of six-coordinate complexes for both **1** and **2,** as for the other lanthanide(II) iodides, regardless of ionic radius, goes some way towards accounting for the stereoselectivities observed for divalent lanthanide reagents. Although the reactivity of the divalent lanthanides is the result of one-electron transfer, the possibility of substrates binding to a stereochemically rigid six-coordinate metal coordination sphere should not be discounted.

The remarkable colour changes which occur upon coordination of pyridine are intriguing. Ytterbium diiodide is canary yellow both in THF solution and in the solid state with absorptions at 390, 342 and 307 nm which have been attributed previously to electronic transitions from the 4*f* and 5*d* orbitals and are very intense by virtue of being fully allowed [21]. The colour is virtually unaltered by substitution by other anionic ligands such as borohydride [22] or a single pyrazolylborate ligand [23]. Although the structure of these complexes is not known in solution it is reasonable to conclude that such ligands do not alter the energy of the *d*-orbitals significantly. In contrast, the recently prepared hydrocarbyl, alkoxide and amide complexes tend to be red, although the absorption spectra have not been reported, this may well arise from perturbation of the *d* levels by these strongly electron releasing groups. For all such compounds, addition of pyridine results in the appearance of a deep red/purple colour* which has been attributed by Brennan to metal to ligand charge transfer transitions. In the case of **1a** there is a strong absorption at 450 nm with a shoulder at 660 nm while in **2a** the corresponding bands are at 367 and 573 nm respectively, the shifts being consistent with the changes in reduction potential of the metal itself.

* $Yb(OR)_2(pyr)_n$ has been reported to be green.

EXPERIMENTAL

All preparations and manipulations were carried out using dry box techniques in an atmosphere of dinitrogen [24]. Oxygen-free nitrogen was purified by passage over columns containing 3 Å molecular sieves and MnO [25]. All solvents were pre-dried over 5 Å molecular sieves or sodium wire and distilled under nitrogen from appropriate drying agents {Na (toluene), K (benzene, tetrahydrofuran), Na/K alloy (petroleum ether b.p. 40–60°C, pentane, diethyl ether), CaH_2 (CH_2Cl_2)} before use. Pyridines were dried and distilled from calcium hydride before use. Ytterbium iodide was prepared from ytterbium metal (Aldrich) and ammonium iodide in liquid ammonia [26]. Samarium iodide was prepared from samarium metal and diiodoethane in THF [13].

Infrared spectra were recorded as KBr pellets or in $CDCl_3$ solution on a Nicolet 205 FTIR spectrometer. ^1H and ^{13}C spectra in solution were recorded on Varian XL-200 and VXR-400 spectrometers at 200 and 400 and 100.6 MHz, respectively. Spectra were calibrated using residual proton (^1H) and solvent resonances (^{13}C) respectively and chemical shifts are reported relative to tetramethylsilane. Elemental microanalyses were determined by Mr Alan Stones of the UCL Analytical Services.

Preparation of $[SmI_2(3,5\text{-}Me_2py)_4]$

$SmI_2 \cdot 1.65THF$ (0.098 g, 0.187 mmol) was dissolved in THF (5 cm^3) and 3,5-dimethylpyridine (3,5-Me_2py; *ca* 0.6 g, 5.6 mmol) was added dropwise to give a dark green solution. This was layered with 30/40 petrol (10 cm^3) and, after equilibration, black block-like crystals were deposited. Following removal of solvent, the product was washed with 30/40 petrol (3×2 cm^3) to leave 0.116 g (0.139 mmol, 74%) of $[SmI_2(3,5\text{-}Me_2py)_4]$.

Solid state CPMAS ^{13}C NMR: δ 147, 114 (aromatic C); 13 (Me); (all resonances were broad, *ca* 1000 Hz). UV–vis (KBr): 450 nm; 660 nm (br sh). Analysis (%) calc. for $SmC_{28}H_{36}N_4I_2$: C, 40.38; H, 4.36; N, 6.73. Found: C, 40.22; H, 4.44; N, 6.90.

Preparation of $[YbI_2(3,5\text{-}Me_2py)_4]$

$YbI_2 \cdot 1.7THF$ (0.162 g, 0.295 mmol) was dissolved in THF (5 cm^3). 3,5-Dimethylpyridine (*ca* 0.5 g, 4.7 mmol) was added dropwise giving an immediate colour change from pale yellow to dark red. The solution was layered with 30/40 petrol (10 cm^3) and left to equilibrate for several days. Large black block-like crystals were formed, which were washed with 30/40 petrol (3×2 ml). Yield: 0.164 g (0.192 mmol, 65%).

Analysis (%) calc. for $YbC_{28}H_{36}N_4I_2$: C, 39.31; H, 4.24; N, 6.55; I, 29.67. Found: C, 39.15; H, 4.33; N, 6.84; I, 29.25. Solid state CPMAS ^{13}C NMR: δ 149.1, 137.8, 133.8 (aromatic C); 20.3 (Me). UV–vis (KBr): 367 nm; 573 nm.

Preparation of $SmI_2(py)_n$

$SmI_2 \cdot 1.65THF$ (0.200 g, 0.382 mmol) was dissolved in THF (20 cm^3) and pyridine (*ca* 0.60 g, 7.6 mmol) was added drop-wise, giving an immediate colour change from dark blue to dark green. The solution was layered with 30/40 petrol (20 cm^3) and left to equilibrate for several days. Large black crystals were formed which desolvated rapidly upon removing the solvent and washing with 30/40 petrol (3 × 2 ml). Yield: *ca* 0.25 g.

Preparation of $YbI_2(py)_n$

YbI_2 (0.400 g, 0.897 mmol) was dissolved in THF (20 cm^3) and Yb metal removed by vacuum filtration. Pyridine (py; *ca* 1.0 g, 13 mmol) was then added dropwise, giving an immediate colour change from pale yellow to dark red. The solution was layered with 30/40 petrol (20 cm^3) and left to equilibrate for several days. Large black crystals were formed which desolvated and turned dark brown/red on the surface upon removing the solvent and washing with 30/40 petrol (3 × 2 cm^3). Yield: 0.49 g.

Analysis (%) calc. for $YbC_{17}H_{17}N_{3.4}I_2$ ($YbI_2(py)_{3.4}$): C, 29.35; H, 2.46; N, 6.84. Found: C, 29.31; H, 2.56; N, 6.86.

Preparation of $[SmI_2(4\text{-}Bu^tpy)_4]$

$SmI_2 \cdot 1.65THF$ (0.212 g, 0.405 mmol) was dissolved in THF (5 cm^3) and *tert*-butylpyridine (*ca* 1.0 g, 7.4 mmol) was added. The dark green solution was layered with 30/40 petrol (10 cm^3) and, after equilibration, large black blocks were deposited which were washed with 30/40 petrol (3 × 2 cm^3). The surface of the crystals became opaque on standing. Yield: 0.225 g (0.238 mmol, 59%).

^1H NMR (C_6D_6): δ 4.36 (s, $w_{1/2}$ = 50 Hz, 8H, 2,6-H py); 2.90 (s, $w_{1/2}$ = 21 Hz, 8H, 3,5-H py); −0.27 (s, 36H, CMe_3). ^{13}C NMR (C_6D_6): δ 225.3 (d, $w_{1/2}$ = 16 Hz, 2-C py); 175.0 (s, 4-C py); 103.5 (d, 3-C py); 33.9 (q, CMe_3 py); 28.2 (s, CMe_3 py). UV–vis (toluene): 381 nm (ε = 700); 443 nm (ε = 700); 642 nm (ε = 500). Analysis (%) calc. for $SmC_{36}H_{52}N_4I_2$: C, 45.76; H, 5.55; N, 5.93. Found: C, 44.13; H, 5.28; N, 5.99.

Preparation of $[YbI_2(4\text{-}Bu^tpy)_4]$

YbI_2 (0.168 g, 0.385 mmol) was dissolved in THF (5 cm^3) and Yb metal removed by vacuum filtration. *tert*-Butylpyridine (*ca* 0.5 g, 3.7 mmol) was added dropwise, causing an immediate colour change from pale yellow to dark red. The solution was layered with 30/40 petrol (10 cm^3) and left to equilibrate for several days. Black crystals were formed which were washed with 30/40 petrol (3 × 2 cm^3) and dried under dynamic vacuum. Yield: 0.210 g (0.217 mmol, 56%). ^1H NMR (C_6D_6): δ 9.73 (s, $w_{1/2}$ = 17 Hz, 8H, 2,6-H py); 6.68 (s, $w_{1/2}$ = 14 Hz, 8H, 3,5-H py); 0.79 (s, 36H, CMe_3). ^{13}C NMR (C_6D_6): δ 161.3 (s, 4-C py); 151.2 (d, 2-C py); 121.1 (d, 3-C py); 34.5 (s, CMe_3 py); 30.0 (q, CMe py). UV–vis (toluene): 359 nm (ε = 800); 410 nm (ε = 800); 480 nm (ε = 700). Analysis (%) calc. for $YbC_{36}H_{52}N_4I_2$: C, 44.68; H, 5.42; N, 5.79. Found: C, 50.31; H, 5.92; N, 6.51.

X-ray crystallography

Data collection and processing for 1*a*, 2*a*, *and* 2*b*. All data were collected on a Nicolet R3mV four-circle diffractometer using graphite-monochromated Mo-K_α (λ = 0.71073 Å) radiation. Crystals were mounted in Lindemann glass capillaries in a nitrogen filled glovebox. Data were corrected for Lorenz polarization effects, and for absorption by a semi-empirical method based on ψ-scan data. The intensity of three check reflections measured every 97 reflections showed no decay over the course of the data collection.

Structure solution and refinement for 1*a*, 2*a*, *and* 2*b*. Crystallographic calculations were carried out with the SHELXTL PLUS suite of programmes on a MicroVAX II computer. The structures were solved by Patterson or Direct methods and developed by alternating cycles of full-matrix least squares refinement and difference Fourier techniques. For **2a**, all non-hydrogen atoms were refined anisotropically and hydrogen atoms were placed in calculated positions with one overall, refined, [U_{iso} = 0.08(2) Å^2]. For **1a**, the quality of the data set did not allow anisotropic refinement of any atom other than the samarium and iodine. Hydrogen atoms were placed in calculated positions as for **2a**. For **2b**, the *t*-butyl groups were found to be disordered and were therefore refined as

two sets of interpenetrating groups with the methyl to central carbon distance set to 1.55 ± 0.001 Å and the Me–Me distance set at 2.50 ± 0.01 Å. The occupancies of the pairs of groups were refined independently. Atomic coordinates, bond lengths and angles, and displacement parameters have been deposited with the Cambridge Crystallographic Data Centre (CCDC). See Information for Authors, Issue No. 1.

(Received 11 April 1997; accepted 9 June 1997)

Abstract—Complexes of $M(hfac)_2 \cdot Ln$ [M = Sr, n = 1, L = tetraglyme, db24c8; n = 2, L = bpy, phen; M = Ba, n = 1, L = tetraglyme, db24c8] have been prepared by *in situ* reactions of MX_2 (X = OH, OAc) with Hhfac in the presence of the ancillary ligands in aqueous ethanol in high yields and characterized by ^1H NMR, IR, mass spectrometry and elemental analysis. A molecular structure of the complex $Sr(hfac)_2 \cdot (bpy)_2$ has been determined by X-ray single crystal analysis. © 1997 Elsevier Science Ltd

Keywords: strontium; barium; MOCVD; β-diketones; bipyridine.

There has been considerable interest recently in the chemistry of alkaline–earth metal β-diketonates, mostly because of their potential application as MOCVD precursors in the epitaxy of metal oxide thin films [1–6]. It is found that fluorocarbon-based β-diketonates are among the best performing precursors in terms of their stability and volatility [7–9]. Coordination of the appropriate ancillary ligands due to the β-diketonates could increase their volatility [10–13]. The free ancillary ligands applied so far are mostly polyethers. Here, we hope to report two nitrogen donor ligands coordinated complexes $Sr(hfac)_2(bpy)_2$ and $Sr(hfac)_2(phen)_2$ (hfac = 1,1,1,5,5,5-hexafluoropentane-2,4-dinato; bpy = 2,2′-bipyridine-N,N′, phen = 1,10-phenanthroline-N^1,N^{10}).

Syntheses of the complexes $M(hfac)_2Ln$ were usually performed under anaerobic conditions. We [15] found that the preparation could be easily carried out in aqueous ethanol solution with the metallic hydroxides or acetates as the starting material. Whilst our work was proceeding, Malandrino *et al.* [4] reported a similar one-step procedure for $M(hfac)_2 \cdot$ tetraglyme (M = Ca, Sr, Ba). In this paper, we hope to present the detailed procedures of our preparation. Apart from the two nitrogen donor ligand coordinated adducts mentioned above, several polyether coordinated complexes $M(hfac)_2$(polyether) [M = Sr, Ba; polyether = tetraglyme, dibenzo-24-crown-8 (db24c8)] have also been prepared.

All complexes obtained have been characterized by ^1H NMR, IR, mass spectrometry and elemental analysis. $Sr(hfac)_2(bpy)_2$ has also been characterized by single crystal structure analysis.

EXPERIMENTAL

All reagents used were of commercial quality. Elemental analyses were performed on a Perkin–Elmer 240 elemental analysis instrument. ^1H NMR spectra were recorded on a Bruker AM-500 and JEOL PMX-60SI spectrometer with TMS as internal standard. IR spectra were obtained as KBr pellets on 5DX FT-2 spectrometer. Mass spectra were obtained on

a VG ZAB-HS GC-MS spectrometer. Melting and boiling points are given without correction.

Preparation of Sr(hfac)$_2$ · tetraglyme

Hhfac (0.833 g, 4.0 mmol) was added dropwise to a stirred solution of $Sr(OH)_2 \cdot 8H_2O$ (0.532 g, 2.0 mmol) or $Sr(OAc)_2$ (0.411 g, 2.0 mmol) in aqueous ethanol solution (20 cm^3, 35% *aq.* EtOH) in 5 min. After stirring for 10 min, tetraglyme (0.444 g, 2.0 mmol) in ethanol (4 ml) was added dropwise. Stirring was continued for 20 min. The product as white powder was isolated by filtration dried *in vacuo* at 60°C for 3 h. The complex sublimed readily at 140–145°C/0.03 mmHg. Yield: 1.32 g (91.1%), mp: 137–139°C. Anal. Calc. for $C_{20}H_{24}O_9F_{12}Sr$: C, 33.18; H, 3.34. Found: C, 33.19; H, 3.34%. The ^{1}H NMR and IR data are in good agreement with those reported [6].

Preparation of Ba(hfac)$_2$ · tetraglyme

Prepared as described for Sr(hfac)$_2$ · tetraglyme from Hhfac (0.833 g, 4 mmol), $Ba(OH)_2 \cdot 8H_2O$ (0.631 g, 2.0 mmol) or $Ba(OAc)_2$ (0.511 g, 2.0 mmol) and *aq.* EtOH. Yield: 1.42 g (91.7%), m.p.: 147–150°C. The complex sublimed readily at 140–145°C/0.03 mm Hg. Anal. Calc. for $C_{20}H_{24}O_9F_{12}Ba$: C, 31.04; H, 3.13. Found: C, 31.37; H, 3.14%. The ^{1}H NMR and IR data are in good agreement with those reported [16].

Preparation of Sr(hfac)$_2$ · (bpy)$_2$

Hhfac (0.833 g, 4.0 mmol) was added dropwise, with stirring to a solution of $Sr(OH)_2 \cdot 8H_2O$ (0.532 g, 2.0 mmol) in aqueous ethanol solution (20 cm^3, 35% *aq.* EtOH). After stirring for 10 min, a solution of bpy (0.624 g, 4.0 mmol) in water (10 cm^3) was added. The resulting heavy turbid solution was filtered. The product obtained was recrystallized with ethanol and dried *in vacuo* at 60°C for 3 h. Yield: 1.50 g (92.1%). The complex sublimed at 165–170°C/0.10 mm Hg. Melting point: 179–181°C. Anal. Calc. for $C_{30}H_{18}N_{14}F_{12}O_4Sr$: C, 44.24; H, 2.23; N, 6.88. Found: C, 44.20; H, 2.14; N, 7.19%. IR data: 3400 (m), 3100 (w), 1691 (vs), 1605 (m), 1532 (m), 1484 (m), 1435 (m), 1320 (m), 1260 (s), 1139 (vs), 1084 (m), 1005 (m), 800 (m), 757 (m), 660 (m), 576 (m), 539 (m), 490 (w), 430 (w) cm^{-1}. ^{1}H NMR: 8.71 (d, 4H J = 4.3 Hz), 7.95 (t, 4H, J = 7.0 Hz), 7.45 (dd, 4H, J = 4.97, 7.03 Hz), 8.45 (d, 4H, J = 7.02), 5.66 (s, 2H) ppm. MS data: 295 (6.7%), 419 (3.4%), 107 (100%), 147 (15.6%), 157 (15.3%), 195 (22.9%), 451 (1.5%), 623 (1.3%), 815 (0.2%).

Preparation of Sr(hfac)$_2$ · (phen)$_2$

Prepared as described for Sr(hfac)$_2$ · (bpy)$_2$ from Hhfac (0.833 g, 4.0 mmol), $Sr(OH)_2 \cdot 8H_2O$ (0.532 g, 2.0 mmol) and phen (0.720 g, 4.0 mmol). The adduct was purified by recrystallization from ethanol. Yield: 1.54 g (89.3%). M.p. 269–271°C. Anal. Calc. for $C_{34}H_{18}N_{14}F_{12}O_4Sr$: C, 47.35; H, 2.10; N, 6.50. Found: C, 47.15; H, 2.13; N, 6.46%. IR data: 3400 (m), 1671 (vs), 1526 (s), 1423 (m), 1345 (w), 1260 (s), 1193 (s), 1139 (vs), 1084 (m), 45 (m), 860 (m), 848 (m), 836 (m), 794 (m), 733 (m), 666 (s), 582 (m), 527 (w). ^{1}H NMR: 9.20 (d, 2H, J = 4.3), 7.8 (dd, 2H, J = 8.33, 4.73), 8.53 (d, 2H, J = 8.39), 7.99 (s, 1H), 5.64 (s, 1H). MS data: 655 (6%), 475 (9.6%), 287 (12.5%), 217 (55.1%), 181 (67.4), 109 (32.8%), 91 (100%).

Preparation of Sr(hfac)$_2$ · db24c8

Prepared as described for Sr(hfac)$_2$ · (bpy)$_2$ from Hhfac (0.833 g, 4.0 mmol), $Sr(OH)_2 \cdot 8H_2O$ (0.532 g, 2.0 mmol) and dibenzo-24-crown-8 (0.897 g, 2.0 mmol in 10 ml ethanol). The adducts was recrystallized from ethanol. Yield: 1.67 g (87.9%). M.p.: 246–247°C. Anal. Calc. for $C_{34}H_{34}F_{12}O_{12}Sr$: C, 42.96; H, 361. Found: C, 42.72; H, 3.53. IR data: 2984 (w), 1669 (s), 1554 (s), 1527 (s), 1449 (m), 1461 (w), 1308 (w), 1259 (vs), 1204 (s), 1138 (vs), 1089 (m), 1050 (m), 947 (w), 788 (w), 775 (w), 662 (m), 575 (m) cm^{-1}. ^{1}H NMR: 6.83–7.13 (s, 8H), 5.67 (s, 2H), 3.73–4.33 (m, 16H). MS data: 743 (11.8%), 448 (32%), 208 (2.8%).

Synthesis of Ba(hfac)$_2$ · db24c8

Prepared as described for Sr(hfac)$_2$ · (bpy)$_2$ from Hhfac (0.833 g, 4.0 mmol), $Ba(OH)_2 \cdot 8H_2O$ (0.631 g, 2.0 mmol) and db24c8 (0.897 g, 2.0 mmol in 10 cm^3 ethanol). The adduct was recrystallized from ethanol. Yield: 1.80 g (90.0%). M.p. 246–247°C. Anal. Calc. for $C_{34}H_{34}F_{12}O_{12}Ba$: C, 40.82, H, 3.43. Found: C, 40-.06, H, 3.23. IR data: 2937 (w), 2894 (s), 1712 (m), 1669 (s), 1543 (s), 1499 (s), 1461 (m), 1253 (vs), 1198 (vs), 1133 (vs), 1045 (m), 947 (m), 783 (m), 755 (w), 662 (m) cm^{-1}. ^{1}H NMR: 6.83–7.16 (s, 8H), 5.6 (s, 2H), 3.84–4.5 (m, 16H). MS data: 792 (5.2%), 5.85 (0.2%), 448 (31.1%), 345 (2.1%).

X-ray determination of Sr(hfac)$_2$ · (bpy)$_2$

The crystal was obtained from ethanol. Crystallographic data are summarized in Table 1. The structure was solved by the direct methods using MITHRIL [17] and subsequent Fourier techniques. Hydrogens were added geometrically (before the final amendment). All calculations were performed using TEXSAN [18]. ORTEPII [9] was used to produce the figures and CAD-4 software [20] was used for data collection and cell refinement.

RESULTS AND DISCUSSION

Reactions of Hhfac with both $M(OAc)_2$ and $M(OH)_72$ (M = Sr and Ba) in the presence of the

stoichiometric free ancillary ligands proceeded very smoothly in *aq.* ethanol. Complexes $M(hfac)_2 \cdot Ln$ (M = Sr, $n = 1$, L = tetraglyme, db24c8; $n = 2$, L = bpy, phen; M = Ba, $n = 1$, L = tetraglyme, db24c8) were isolated in nearly quantitative yields. As both the metallic salts and the ligands used were fairly soluble in *aq.* ethanol and the adducts formed were nearly insoluble, separation and purification procedures were simple. Intermediate $Sr(hfac)_2 \cdot nH_2O$ was also isolated and characterized by IR spectroscopy. Interaction of $Sr(hfac)_2 \cdot nH_2O$ with tetraglyme yielded the expected adduct $Sr(hfac)_2 \cdot$ tetraglyme. $Sr(hfac)_2 \cdot (bpy)_2$ could be sublimed easily. It is obvious that the adduct is much more volatile than $Sr(hfac)_2$ itself, although it is a little less volatile than $Sr(hfac)_2 \cdot$ tetraglyme. $Sr(hfac)_2 \cdot (bpy)_2$ could be a potential MO precursor for MOCVD application. Attempts to sublime the complex $Sr(hfac)_2 \cdot (phen)_2$ (over 175°C/0.1 mmHg) resulted in the dissociation of the adduct. The free ancillary ligand phen was collected on the cool-finger of the sublimator instead of the adduct.

All the products obtained gave satisfactory elemental analysis results. They have also been characterized by IR, ^{1}H NMR and mass spectroscopy respectively. The spectroscopic data of the compounds $Sr(hfac)_2 \cdot$ tetraglyme and $Ba(hfac)_2 \cdot$ tetraglyme are in very good agreement with those previously reported. The chemical shift of the protons on hfac in compound $Sr(hfac)_2 \cdot (bpy)_2$ moves ~0.2 ppm further upfield than those of the tetraglyme adduct. This demonstrates good electron donating nature of the nitrogens on bpy. A similar phenomenon was observed for the phen adduct. ^{1}H NMR data for $Sr(hfac)_2 \cdot$ db24c8 and $Ba(hfac)_2 \cdot$ db24c8 were similar to those of $Ba(hfac)_2 \cdot$ 18c6 [13]. In MS spectra, only fragments were observed for all the compounds obtained. For the complex $Sr(hfac)_2 \cdot (phen)_2$, clear fragments for

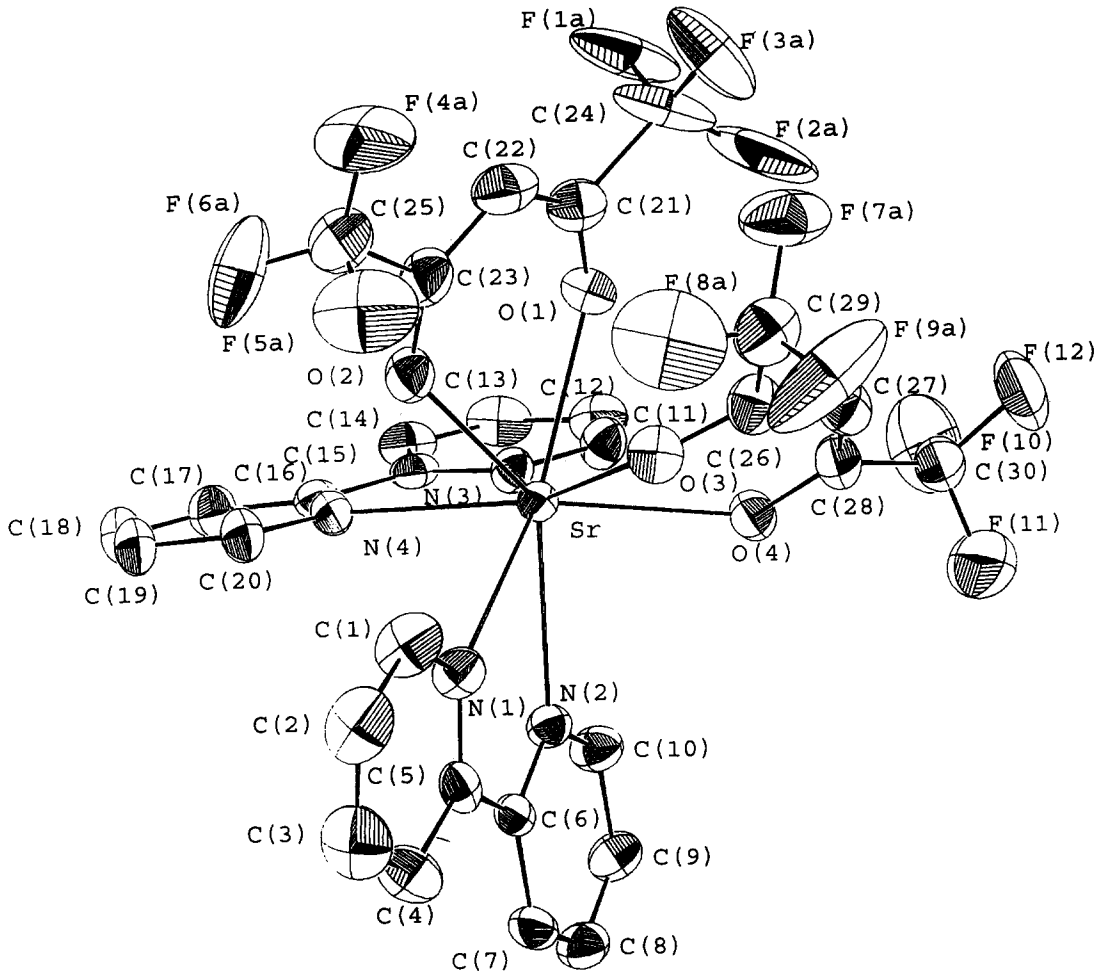

Fig. 1. Molecular structure of $Sr(hfac)_2 \cdot (bpy)_2$ showing the atom numbering scheme. Hydrogen atoms are omitted for clarity.

$Sr(hfac)(phen)_2$ (655, 6.0%) and $Sr(hfac)(phen)$ (475, 9.6%) were observed. It is quite interesting to note that peaks of $bpy+H^+$ (15.3%) and $phen+H^+$ (67.4%) are even more abundant then the free bpy (not observed) and phen (2.2%). For $Sr(hfac)_2 \cdot$ db24c8, the peak of $Sr(hfac) \cdot$ db24c8 (743, 11.8%) is visible. In IR spectra, the stretch vibration absorptions for the carbonyl groups of all compounds locate at almost the same region (about 1670 cm^{-1}).

The molecular structure of $Sr(hfac)_2 \cdot (bpy)_2$ is shown in Fig. 1 with selected bond lengths and angles listed in Table 2. In the structure, the center Sr atom is eight coordinated with two hfac moieties on one side and the two bpy ligands on the other. The location of the two hfacs and the two bpys could be described as *cis*. This is different from those in $Sr(Ph_2acac)_2 \cdot$ (tetraglyme) [21] and the analogous barium complexes $Ba(hfac)_2 \cdot$ (tetraglyme) [12,22] and $Ba(thd)_2 \cdot$ (tetraglyme) [3], where the two hfac moieties are positioned on either side of the polyether plane. The coordination geometry around the Sr center is better described as square antiprism. The Sr—O bond distances in $Sr(hfac)_2 \cdot (bpy)_2$ range from 2.529 (5) to 2.559 (5) Å (average 2.540 (5) Å) which are exactly the same as those in $Sr(Ph_2acac)_2 \cdot$ (tetraglyme) [2.500 (6)–2.564 (6), average 2540 (6)]. This implies a similar Sr—O bond strength between the compounds. The Sr—N bond lengths range from 2.703 (6) to 2.733 (5) Å, with an average 2.717 (6) Å. The much longer Sr—N bond distances compared to those of Sr—O in the compound, means that bonding between Sr and N is much weaker than that between Sr and O. The average bond angle of O—Sr—O in hfac is 69.7 (2)°, about 1° larger than those in $Sr(Ph_2acac)_2 \cdot$ (tetraglyme) [average 68.5 (2)°]. This could be attributed to the less steric hindrance of the bpy ligands. The dihedral angle between the two bpy planes is 85.25°. The obtuse angle (144.08°) between the two hfac planes, O(1)—C(21)—C(22)—C(23)—O(2) plane and O(3)—C(26)—C(27)—

(Received 9 April 1997; accepted 9 June 1997)

Abstract—The mixed-metal complex of copper(II) and magnesium(II) ions with glutamate has been firstly synthesized by self-assembling, and characterized by elemental analyses, IR spectra and electronic spectra. The structure of the complex has been determined by single-crystal X-ray diffraction. The $[CuMg(L\text{-}glu)_2(H_2O)_3]\cdot 2H_2O$ (L-glu = L-glutamate) complex has a one-dimensional polymeric structure, in which Cu^{II} and Mg^{II} ions are bridged by glutamate. Each Cu atom exhibits distorted square pyramidal five-coordination, with two glutamate ions acting as a bidentate ligand through the amino N and the α-carboxylate O atoms in trans positions in the equatorial plane, forming two glycine-like rings, and with a water molecule in apical position. Each Mg atom is coordinated in a slightly distorted octahedral geometry by two γ-carboxylate O atoms from two glutamate ions and by four water molecules. The average Cu—O, Cu—N and Mg—O distances are 2.048(2), 1.979(3) and 2.084(2) Å, respectively. The coordination patterns of glutamate ion in different glutamate Cu^{II} complexes are also discussed. © 1997 Elsevier Science Ltd

Keywords: copper(II); magnesium(II); L-glutamate; structure.

Metal–glutamate complexes and their adducts with amine have been extensively investigated both in solution [1,2] and in solid state [3–6]. It is generally considered that chelation of the amino and α-carboxylate groups occurs readily, and much of the study of metal binding has been devoted to attempts to deduce whether the side chain carboxylate (γ-carboxylate) is also coordinated to the metal ion [1]. X-ray diffraction analysis has shown that the coordination patterns of glutamate in different glutamate Cu^{II} complexes are much different [3,5], in which the γ-carboxylates are coordinated or uncoordinated to the metal ions, forming polymeric or mononuclear complexes.

Although metal–glutamate chemistry has a very long history, all of the studies were only focused on the coordination behavior of monometallic salts with glutamate, the mixed-metal complexes, to our knowledge, have not been reported. The design and synthesis of polynuclear mixed-metal complexes have attracted much current attention. These compounds have been studied as metal enzyme models [7], as supramolecular devices [8], as magnetic materials [9], and as possible precursors production of high temperature superconductor [10]. Glutamate has three binding sites for metal ions [1], the amino N atom is bound to transitional metal ions first, while the α- and γ-carboxylate O atoms are bound to alkaline earth metal ions first. So mixed-metal complexes may be formed by self-assembling of glutamate with different metal ions. In this paper, we firstly report the synthesis and spectroscopic and structural investigations on the mixed-metal complex of copper and magnesium ions with L-glutamate. X-ray diffraction analysis shows that L-glutamate can be bound to Cu^{II} and Mg^{II} ions to form a polymeric compound in an extended-chain

configuration, in which the glycinate and γ-carboxylate groups are coordinated selectively to Cu^{II} and Mg^{II} ions, respectively.

EXPERIMENTAL

All the reagents were commercially available and used without further purification. Carbon, nitrogen and hydrogen contents were determined using a Perkin–Elmer elemental analyser. The IR spectra were recorded in the 4000–400 cm^{-1} region using KBr pellets and a Nicolet 5DX spectrometer. A Shimadzu UV-240 spectrophotometer was used to obtain the electronic absorption spectra. Thermal analyses (TG and DTA) were performed on a Beijing PcT-2 thermobalance. The heating rate was 10°C min^{-1}.

Preparation of the complex

A mixed water solution (10 cm^3) of $CuCl_2 \cdot 2H_2O$ (0.341 g, 2 mmol) and $MgCl_2 \cdot 6H_2O$ (0.407 g, 2 mmol) was added to a water solution (10 cm^3) of glutamic acid (0.588 g, 4 mmol). The resulting solution was adjusted to pH ≈ 6 by very slow addition of 0.5 mol dm^{-3} aqueous NaOH. The mixture was stirred at room temperature for 24 h, then was evaporated to 10 cm^{-3} under heating. The blue precipitate was filtered, washed with water/alcohol (1 : 2) several times, and dried in a desiccator over P_4O_{10} for 3 days. Yield 70% (Found: C, 28.2; H, 4.3; N, 6.6. Calc. for $C_{10}H_{20}N_2O_{11}CuMg$: C, 27.8; H, 4.6; N, 6.5%).

Single crystals of the complex were obtained by dissolving the powdery solid complex in water, and leaving the solution in acetonitrile. After about 7 days, blue prismatic crystals suitable for X-ray analysis formed from the solution.

Crystallography

Crystal data. $C_{10}H_{24}N_2O_{13}CuMg$, $M = 467.96$, orthorhombic, space group $C222_1$, $a = 10.260(2)$, $b = 16.262(2)$, $c = 11.609(1)$ Å, $U = 1979.8(5)$ $Å^3$, $F(000) = 1052$, $Z = 8$, $D_C = 1.692$ g cm^{-3}, λ(Mo-K_α) = 0.71073 Å, $\mu = 1.213$ mm^{-1}.

Data collection. X-ray diffraction intensities were collected at 296 K from crystals of dimensions 0.58 × 0.42 × 0.20 mm on an R3M/E four circle X-ray diffractometer with graphite-monochromatized Mo-K_α radiation, by using the $\theta/2\theta$ scan technique. Negligible change in the intensities of three standards monitored during the data collection indicated no crystal decomposition. Some 2268 independent reflections were collected in the range $2.33 \leqslant \theta \leqslant 25.99°$ (h from 0 to 12, k from −1 to 20, l from −14 to 14). Of these, 1953 reflections with $I > 2\sigma$ (I) were used in the structure determination and refinement, $R_{int} = 0.0304$ after absorption correction (maximum and minimum transmission factors = 0.9421 and 0.7362). The intensities were corrected for Lorentz-polarization effects, and for empirical absorption.

Structure solution and refinement. The structure was solved using the Patterson heavy-atom method which revealed the positions of the Cu and Mg atoms. The remaining atoms were located in subsequent difference-Fourier synthesis and refined by full-matrix least-squares methods with anisotropic thermal factors. All the hydrogen atoms (except the hydrogen atoms of uncoordinated water molecules) were revealed by the difference-Fourier synthesis and refined with isotropic thermal factors. All calculations were performed by using the SHELXTL system of computer programs [11]. The final cycle of full-matrix least-squares refinement (F) was based on 1953 reflections [$I > 2\sigma$ (I)] and 183 variable parameters and converged with R and R' values of 0.0289 and 0.0327, respectively. The weighting scheme was $w = 1/[2\sigma^2(F_o)^2 + 0.0541P]$, where $P = [\max.(F_o^2, 0) + 2F_c^2]/3$. The maximum and minimum peaks on the final difference-Fourier map corresponded to 0.424 and −0.284 e $Å^{-3}$. Selected bond lengths and angles are listed in Table 1.

RESULTS AND DISCUSSION

Spectroscopic results

IR spectra. The results of the IR spectra show that the asymmetric and symmetric absorptions of the carboxylate groups shift from 1583 and 1421 cm^{-1} in the free glutamic acid ligand to 1546 and 1405 cm^{-1} in the complex, indicating that the carboxylate groups are coordinated to the metal ions [12]. The disappearance of the $\nu(NH_3^+)$ absorption of 3050 cm^{-1} in the free L-glutamic acid and the appearance of two absorptions of 3261 and 3332 cm^{-1} assigned to N—H stretching modes in the complex suggest the amino N atom is also coordinated to the metal ion [12]. Owing to the presence of extensive hydrogen bonding, it's difficult to distinguish between the bidentate coordination and the monodentate coordination of the carboxylate groups [13].

Thermal analyses. The ligand decomposes at 231°C, and continuous weight loss is detected up to 620°C, at this temperature the ligand decomposes completely. The thermal analytical result of $[CuMg(L\text{-glu})_2(H_2O)_3] \cdot 2H_2O$ shows that the two uncoordinated water molecules are lost below 100°C, while the three coordinated water molecules are lost in the 150 ~ 170°C temperature range. After the loss of water molecules, the complex decomposes exothermically at 331°C. After this other exothermic peaks and continuous weight loss are detected up to 800°C.

From the above thermal analytical results it can be found that the thermal decomposition temperature of the ligand (231°C) is much lower than that of the

complex (331°C), indicating that the complex is more thermally stable than the ligand.

Electronic spectra. The electronic spectra of the complex was recorded at room temperature, and the maximum at 16023 cm^{-1}, is assigned to *d–d* transition. This data is similar to those of other square-pyramidal copper(II) complexes [13], indicating the coordination geometry of the Cu atom in the complex is a square pyramid. This result is consistent with that of X-ray diffraction analysis. The *d–d* band maximum in $[CuMg(L\text{-}glu)_2(H_2O)_3]\cdot 2H_2O$ with CuN_2O_3 chromophore, at lower energy than those of the $[Cu(L\text{-}glu)(o\text{-}phen)H_2O]\cdot 3H_2O$ (16530 cm^{-1}) and $[Cu(L\text{-}asp)(bpy)H_2O]\cdot 3H_2O$ (16390 cm^{-1}) complexes [5] with CuN_3O_2 chromophore, indicates that the crystal field stabilization energy in the former is smaller than those of the latter.

Description of the structure

Figure 1 shows the molecular structure of $[CuMg(L\text{-}glu)_2(H_2O)_3]\cdot 2H_2O$. Figure 2 illustrates the molecular packing arrangement in the unit cell. For the sake of comparison, a summary of structural parameters for the known L-glutamate Cu^{II} complexes is presented in Table 2.

The structure is made up of one-dimensional polymeric chains by self-assembling of Cu^{II} and Mg^{II} ions with L-glutamate, in which copper and magnesium ions are bridged by L-glutamate. The uncoordinated water molecules provide crystalline stability through a network of hydrogen-bonding interactions. Each Cu atom exhibits distorted square pyramidal five-coordination, with two glutamate ions acting as a bidentate ligand through the amino N and the α-carboxylate O atoms in *trans* positions in the equatorial plane, forming two five-membered glycine-like rings, and with a water molecule in apical position. This coordination pattern of L-glutamate has not been found in other Cu^{II}–glutamate complexes. Each Mg atom is coordinated in a slightly distorted octahedral geometry by two γ-carboxylate O atoms from two L-glutamate ions and by four water molecules. The Cu—N distance is 1.979(3) Å, which is the shortest in all the square pyramidal Cu^{II}–glutamate complexes (see Table 2). The Cu—O distances lie in the range 1.950(2)–

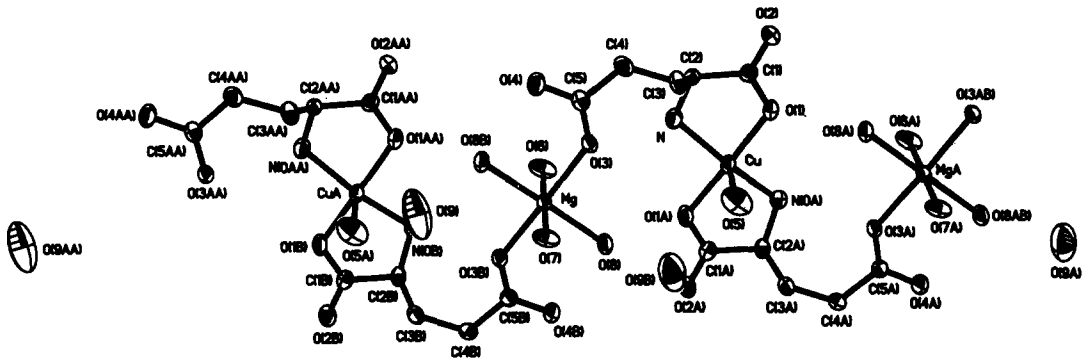

Fig. 1. The molecular structure of $[CuMg\ (L\text{-}glu)_2\ (H_2O)_3]\cdot 2H_2O$.

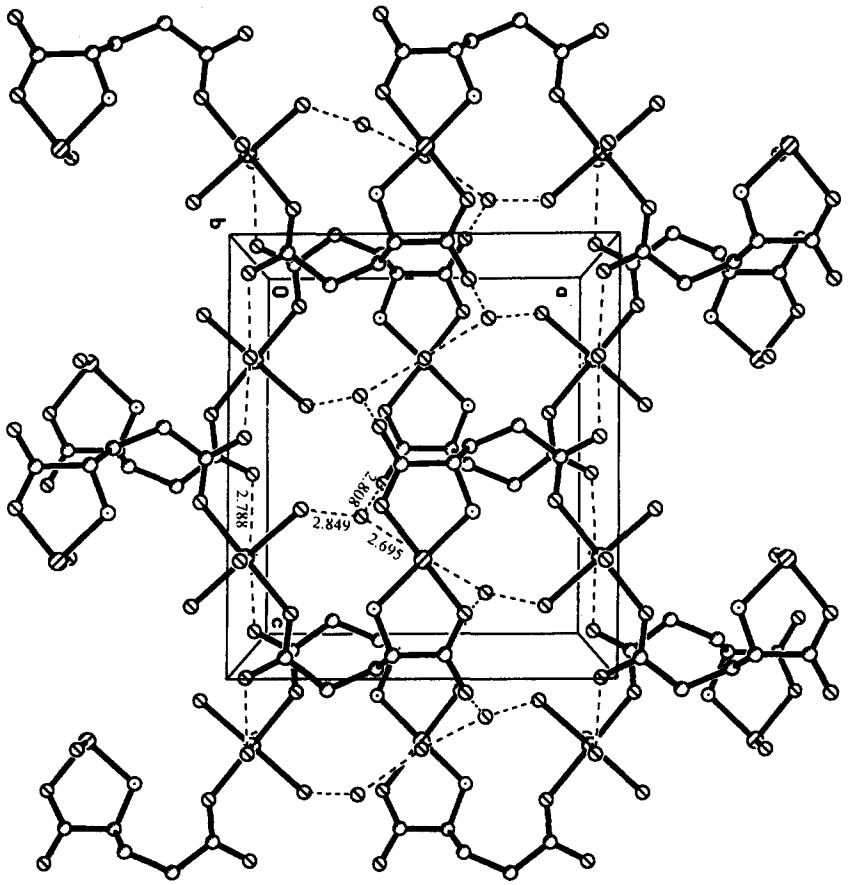

Fig. 2. The molecular packing arrangement in the unit cell. Hydrogen bonds are shown as dashed lines.

2.243(3) Å and averaged 2.048(2) Å. The rather longer Cu—O apical bond length of 2.243(3) Å is consistent with the values found in other Cu^{II}–glutamate complexes (Table 2). The six Mg-O distances lie in the range 2.066(3)–2.093(2) Å and averaged 2.084(2) Å.

It is interesting to make a comparison of the coordination patterns of L-glutamate in different Cu^{II}–glutamate complexes listed in Table 2. In [Cu(L-glu)(*o*-phen)$(H_2O)]\cdot 3H_2O$ complexes [5], L-glutamate acts as a simple bidentate ligand, giving rise to mononuclear complex. In [Cu(L-glu) (im)] [5] and [Cu(L-glu)(bpy)] [5] complexes, the L-glutamate binds one Cu^{II} ion through the glycinate ring and bridges a second Cu^{II} ion through the γ-carboxylate O atoms, forming one-dimensional polymeric chain structural complexes. In $[CuMg(L\text{-}glu)_2\ (H_2O)_3]\cdot 2H_2O$ complex, the L-glutamate bridges another different metal ion (Mg^{II}) through the γ-carboxylate O atom to form a mixed-metal complex. In [Cu(L-glu) $(H_2O)]\cdot H_2O$ complex, a third Cu^{II} ion is bridged through the α-carboxylate O atom, forming a two-dimensional polymeric network structural complex [3]. From the above comparison it can be found that the γ-carboxylate group of glutamate can be coor-

(Received 5 March 1997; accepted 9 June 1997)

Abstract—The title complex was prepared by the reaction of bis(acetylacetonato)oxovanadium(IV) benzoylhydrazine and 8-quinolinol in methanol and characterized by IR, Raman, UV spectra and cyclic voltammetry measurements. The vanadium atom has a distorted octahedral VO(ONO)(ON) coordination with a normal V=O bond [1.580(4)Å]. Two oxygen atoms and one nitrogen atom of the tridentate hydrazone ligand, and one oxygen atom of 8-quinolinol ligand are coordinated to a vanadium(V) atom, forming an equatorial plane, the axial positions being occupied by an oxo oxygen atom and a nitrogen atom of the 8-quinolinol ligand, respectively. The title complex is the first example of a six-coordinated VO^{3+} complex with acetylacetone benzoylhydrazone ligand. © 1997 Elsevier Science Ltd

Keywords: monooxovanadium complex; hydrazone complex; crystal structure; spectral properties.

There has been considerable interest in coordination chemistry and biochemistry of vanadium due to the discovery of haloperoxidases (V-PO) [1–3] and nitrogenase [4] in the past ten years. For example, the vanadium-dependent bromoperoxidase (V-BrPO) [5–7] not only catalyze the oxidation of halides by hydrogen peroxide and form a halogenated organic substrates, but also have some potential antifungal, antibacterial and antitumour properties [8]. EXAFS measurements on the enzyme containing vanadium(V) suggest that the catalytically active centre contains a mononuclear oxovanadium(V) coordinated by six oxygen/nitrogen atoms, and that neither a metal sulfide cluster nor a vanadoporphyrin is an appropriate description of the active site. Therefore it is more important to intensively study the relationship of the syntheses, structures and biological effects of the vanadium complexes.

In contrast to the common monooxovanadium(IV)(VO^{2+}) and dioxovanadium(V)(VO_2^+) compounds, little is known about the structures of VO^{3+} complexes [9,10]. On the other hand, most of hydrazone ligands are coordinated to the metal centre through their oxygen/nitrogen atoms and are similar to the coordination environments of the biological system. So far only a few kinds of the VO^{3+} compounds with hydrazone ligands are synthesized, in which the hydrazone ligands are only formed by the condensing hydrazine with salicylaldehyde [9,11,12] or benzoylacetone [9,10,13,14]. Here we describe the synthesis, structure and spectroscopic characterization of a novel VO^{3+} complex, VO(L)(hquin), where L and hquin are acetylacetone benzoylhydrazone and 8-quinolinol, respectively.

EXPERIMENTAL

Materials and measurements

The materials $VO(acac)_2$ (acac = acetylacetonate) was synthesized according to the literature [15]. Analytically pure dichloromethane was distilled over calcium hydride before use. All other analytical grade chemicals and solvents were purchased commercially and used without further purification.

IR spectra were recorded on a Nicolet Magna 750 Fourier transform IR spectrometer by use of KBr discs in the 400–4000 cm^{-1} range. Raman spectra were measured using a Nicolet Raman 910 Fourier transform laser Raman spectrometer in the 200–4000

* Author to whom correspondence should be addressed.

cm^{-1} range. UV–vis spectra were obtained on a Perkin–Elmer lambda 9 UV–vis–IR spectrometer in CH_2Cl_2 solution and in the 300–800 nm range. Cyclic voltammetry was performed on a BAS 100A electrochemical analyzer. A three-electrode system was employed with a platinum-head as the working electrode, an Ag/AgCl reference electrode and a platinum-wire auxiliary electrode, CH_2Cl_2 being the solvent, $(Et_4N)ClO_4$ (0.1 M) being the supporting electrolyte.

Synthesis of VO(L)(hquin)

Benzoylhydrazine (0.116 g, 1 mmol) dissolved in 15 cm^3 of methanol and was added dropwise to a methanol solution containing 0.263 (1 mmol) of $VO(acac)_2$ with stirring, and then the mixture was refluxed with stirring for 2 h. 10 cm^3 of mixed solution of methanol and 8-quinolinol was added to the above red–black solution. The reaction mixture was stirred for 30 min and filtered off. The red–black crystals of the title complex were formed upon slow evaporation of the filtrate for several days and collected under vacuum over P_4O_{10}.

X-ray structure determination

X-ray diffraction on a crystal with dimensions $0.35 \times 0.35 \times 0.20$ mm was obtained on a Rigaku AFC5R diffractometer with graphite-monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å). Cell dimensions were refined using 25 reflections in the range $20 < 2\theta < 30°$. The reflection data were collected with ω–2θ mode in the range $2\theta < 50.1°$. The data were corrected for Lorentz effect, polarization effect and DIFABS correction.

The structure was solved by direct methods and refined by a full-matrix least-squares procedure. All non-hydrogen atoms were refined with anisotropic thermal parameters. All hydrogen atoms were located by combination of the difference Fourier map and HYDROGEN program and added to the structure factor calculation, but their positions were not refined. The final R and R_w values were 0.056 and 0.071, respectively. The maximum residual electron density peak in the final difference Fourier map was 417 e/nm^3 with no chemically significant features. The crystallographic data and the selected bond distances and angles are listed in Table 1 and 2, respectively.

RESULTS AND DISCUSSION

Spectroscopic studies

The N—H and C=O absorptions of free tridentate L, and the O—H absorption of free Hhquin in the IR and Raman spectra are absent in the spectra of the title complex, showing that the tridentate ligand is in dinegative form of the type ($^-O\sim N\sim O^-$) [10] and the 8-quinolinol ligand is in monoanion form of the type ($^-O\sim N$). The strong absorption bands at 1603, 1453 cm^{-1} in the IR spectrum and at 1602, 1450 cm^{-1} in the Raman are related to the stretching vibration of unsaturated C=C and C=N linkage [16], and the C=N stretching vibration is displaced to a lower frequency [17,18]. The medium bands at 1319, 1267 cm^{-1} in IR and at 1321, 1263 cm^{-1} in Raman are attributed to the C—O (phenolic oxygen and alkoxidic oxygen) stretching frequencies, respectively [16], which display the shifts to higher frequency owing to the V—O bonds [10,17,18]. The IR band and Raman band due to ν(V=O) stretching vibration are observed at 955 cm^{-1} (m.s.) and 956 cm^{-1} (w.), respectively. This is within the usually observed range (950–990 cm^{-1}) for six-coordinate oxovanadium(V) complexes [9,10]. The stretching vibrations of bonds V—O and V—N have been observed at 497 cm^{-1}, 363 cm^{-1} (far-IR) and 500 cm^{-1}, 368 cm^{-1} (Raman).

The transition ($\lambda = 548$ nm) is considered as a charge transfer from a p_π orbital on the phenolato oxygen long-pair to the empty 3d-orbitals of vanadium atom. The other strong band ($\lambda = 331$ nm) is generally attributed to the alkoxo or the phenolate bound vanadium(V) species. It is consistent with the two LMCT transition ranges of 320–380 and 475–550 nm reported in some d^0 oxovanadium(V) complexes [9,17].

There is a quasi-reversible redox behavior corresponding to a V^V/V^{IV} couple in dichloromethane solution, as shown in Fig. 1. Its redox potential is at $E_{1/2} = -0.287$ V, which was calculated from the average of anodic $E_{pa} = -0.245$ V and cathodic $E_{pc} = -0.330$ V *vs* Ag/AgCl. The peak-to-peak separation (ΔE_p of coupled peaks D/E) is 85 mV at a rate of 200 mV s^{-1}, suggesting that the electrode process is an one-electron transformation [9,17]. Consequently,

the redox process may be expressed by the following equation:

$$[V^{V}O(L)(ON)] + e^{-} \rightleftarrows [V^{IV}O(L)(ON)]^{-}$$

Crystal structure studies

The molecular structure of the title complex is illustrated in Fig. 2. The vanadium atom is coordinated by four oxygen atoms and two nitrogen atoms to form a distorted octahedral O_4N_2 configuration, O(1), O(2) and N(1) from a fully deprotonated tridentate L; atoms O(3) and N(2) from a hquin, and atom O(4) from the vanadyl oxygen atom. The equatorial plane is defined by the atoms O(1), O(2), N(1) and O(3) with the mean deviation of 0.004 Å, vanadium atom is 0.312 Å out the plane and toward the oxo oxygen atom O(4). In most of the VO^{3+} complexes with hydrazone, vanadium atom has a square pyramidal coordination; only two six-coordinated VO^{3+} complexes are known [9,11]. To our knowledge, the title complex is the first example of a six-coordinated VO^{3+} complex with an acetylacetone benzoylhydrazone ligand.

The five-membered chelate ring of O(2), C(6), N(2), N(1) and V(1) is a good plane with a small mean derivation (0.003 Å), but the six-membered chelate

ring of O(1), C(2), C(3), C(4), N(1) and V(1) is non-planar.

The V(1)=O(4) distance of 1.580(4) Å is within the normal values in the structures of VO^{3+} complexes [9–14,19,20]. The bonds V(1)—O(1), V(1)—O(2), V(1)—O(3) and V(1)—N(1) in the equatorial plane are 1.873(4), 1.912(4), 1.842(4) and 2.051(4) Å, respectively. The bond length of V(1)—O(3) (phenolate) is significantly shorter than that of V(1)—O(1) and V(1)—O(2) in the fragment including V atom and tridentate ligand. The bond distance of V(1)—N(3) (2.333(5) Å) is relatively longer due to structural *trans* effect [21].

Supplementary material—Tables of the atomic coordinates, thermal parameters, non-essential bond distances and angles and positional parameters of hydrogen atoms are available from author S.-X. Liu.

Acknowledgements—The authors wish to thank Associate Professor Yu Zheng for the IR and Raman measurements and her valuable discussion.

(Received 20 February 1997; accepted 9 June 1997)

Abstract—A number of mixed-metal complexes of Cu^{II} and Pb^{II} containing 2-dimethylaminoethanol (HL) is reported. The compounds were identified and characterized by chemical analyses and IR investigations. The crystal structure of $[CuPbCl_2L_2]_n \cdot n/2H_2O$ and $[CuPbI_2L_2]_2$ were determined by X-ray crystallographic analysis. The metal complex motif of both compounds is a centrosymmetric tetranuclear dimer with square pyramidal coordination geometry around the Cu atom and highly distorted octahedral coordination to the Pb atom. The Cu and Pb atoms are bridged by alkoxide oxygens from L to form a $Pb_2Cu_2O_4$ core which displays a flattened chair conformation. In the chloride complex tetranuclear units are connected successively *via* μ-chloro bridging between two Pb sites forming polymeric chains. In the iodide complex the I atom bonded to the Pb atom bridges to Cu and Pb atoms of adjacent complex molecules to produce a layer parallel to the *bc* plane. © 1997 Elsevier Science Ltd

Keywords: mixed-metal complexes; crystal structure; coordination polymers.

The interest in mixed-metal complexes may be attributed to increased recognition of the importance of polynuclear centres in biological catalytic processes and the potential application of expected metal–metal interactions to synthetic systems possessing useful magnetic and electrochemical properties [1,2]. From a chemical point of view a major task is to achieve systems to keep the two metal ions not too distant from each other at the scale of the whole lattice. Many mixed-metal complexes have been synthesized to date as complexes of binucleating or polynucleating macrocycles through the design of appropriate macrocyclic ligands [1, 3]. A different approach can be the use of bridging ligands to bind two metal ions [4, 5]. Our previous work in the field of synthesis of coordination compounds from metal powders or metal oxides [6] prompted us to design a procedure for the synthesis of mixed-metal complexes. Our strategy consists of reacting a copper powder with lead salt in non-aqueous solution of 2-dimethylaminoethanol (HL):

$$Cu + PbX_2 + 2HL + 1/2O_2 \xrightarrow{Solv} CuPbX_2L_2 + H_2O$$

X–Cl, Br, I, SCN; Solv–dmf, dmso, CH_3CN, CH_3OH

The synthesis of metal complexes from metal powders is the fascinating and promising approach to provide complexes of unusual stoichiometry and

* Author to whom correspondence should be addressed.

structure [7–9]. We have used aminoalcohol to bridge unlike metal atoms, namely copper and lead, due to the attractive feature of these ligands to form polynuclear oxygen-bridged metal complexes [10–12]. The halide anion is also an effecting bridging ligand, which imposes few steric constraints upon the coordination geometry.

The merit of the procedure is one-pot synthesis under mild reaction conditions and short reaction time, good yield and its versatility. We can prepare predictable mixed-metal complexes by reacting different metal powders and metal salts in solutions of different aminoalcohols or other complexing agents. Here we describe the preparation and X-ray structure of $[CuPbCl_2L_2]_n \cdot n/2H_2O$ (**1**) and $[CuPbI_2L_2]_2$ (**2**).

EXPERIMENTAL

All chemicals were commercial products of reagent grade, used without further purification, all experiments were carried out in air. As is clear from Table 1, in the studied systems several types of complexes formed mainly depending on the ratio of initial reagents and the nature of solvent. Mixed-metal complexes $[CuPbI_2L_2dmso]_2 \cdot 2dmso$ and $[CuPbBr_2L_2dmso]_2$ have been crystallographically characterized and reported previously [13,14]. All the complexes were prepared by similar procedures as those for above mentioned complexes [13,14] and a typical procedure for **1** is given below.

Copper powder (0.63 g, 0.01 mol), $PbCl_2$ (2.78 g, 0.01 mol), dmso (15 cm^3) and 2-dimethylaminoethanol (2.0 cm^3, 0.02 mol) were heated to 60°C and stirred until total dissolution of Cu and $PbCl_2$ was observed (30–35 min). The resulting clear solution was allowed to stand at room temperature for 12 h after which blue crystals **1** separated from the solution. They were filtered, washed with dry isopropanol and finally dried *in vacuo* at room temperature; yield 4.29 g (81.2%).

All the compounds obtained are green or blue crystalline substances which are insoluble in water and sparingly soluble in common organic solvents. Elemental analyses were performed by the Institute of

Crystal structure determination

Crystallographic measurements were made at 20°C using an Enraf–Nonius CAD-4 diffractometer operating in the $\omega/2\theta$ scan mode. The accurate unit cell parameters and the orientation matrix for data collection were obtained from least-squares refinement of the setting angles of 24 reflections in the range $13 < \theta < 15°$. The crystallographic data are summarized in Table 2. Correction for the Lorentz and polarization effects as well as an empirical absorption correction using DIFABS [20] for **1** and an analytical correction by the Gaussian method [21] for **2** [A*(min, max) = 2.57, 3.24] were applied.

The structures were solved by direct (**1**) and Patterson (**2**) methods followed by subsequent difference Fourier routines and refined by full matrix least squares on *F*. Anisotropic thermal parameters were assigned and refined for all non-hydrogen atoms in case of **2** and only for Pb, Cu and Cl atoms for **1**. All the hydrogen atoms in the structures were included in calculated positions, but not refined. Each hydrogen atom was assigned an isotropic thermal parameter of 1.25; 1.5 times that of attached C atom for CH_2 and CH_3 groups, respectively, (**1**) and fixed $B_{iso} = 5$ Å^2 (**2**). 'Solvent' in the structure **1** was modelled as oxygen of water molecule with population 0.5, hydrogen atoms were not included for the solvent molecule. The convergences were reached at the agreement factors listed in Table 2.

Selected bond distances and angles are given in Tables 3 and 4. Atomic coordinates, anisotropic displacement parameters, observed and calculated structure factors, the list of interatomic distances, bond angles and torsion angles are given in the supplementary material.

RESULTS AND DISCUSSION

In the IR spectra of the compound $CuPb(SCN)_2L_2$ only the very strong ν(CN) vibrations of the thiocyanate groups (2110 and 2060 cm^{-1}) coordinated in bridging mode and *via* the nitrogen atom can be identified easily [15]. The rather strong bands corresponding to $\nu(SO) = 1000$ and weak one corresponding to $\delta(H_2O) = 1620$ cm^{-1} vibrations of the coordinated dmso and water molecules of crys-

to higher energy, the strong bands at 1270 and 1100 cm^{-1} are not observed and the intensive band near 900 cm^{-1} appears.

Complex **1** is a centrosymmetric dimer composed of two $CuPbCl_2L_2$ units linked by alkoxobridges of L groups (Fig. 1). The Pb atom is six-coordinate, being surrounded by three oxygen atoms, O(1), O(2) and O(1) $\{1-x, 1-y, 1-z\}$ from the three L groups and three chloride atoms, Cl(1), Cl(1) $\{2-x, 1-y, 1-z\}$ and Cl(2) $\{1-x, 1-y, 1-z\}$ with substantial departure from an ideal octahedral geometry. The coordination geometry around the Cu atom is distorted square pyramidal. The basal plane consists of two oxygen, O(1), O(2) and two nitrogen atoms, N(1) and N(2) from the two L groups while the axial coordination site is occupied by Cl(2) atom. The Cu and Pb atoms are bridged by an alkoxide oxygen O(2) from L resulting in Cu-Pb separation of 3.463(4) Å with Cu—O(2)—Pb angle 107.0(1.2)°. The alkoxide oxygen O(1) forms a bridge between three metal centres linking Cu and Pb to a centrosymmetric Pb′ $\{1-x, 1-y, 1-z\}$, resulting in Pb—Pb′ and Cu—Pb′ distances of 3.840(2) and 3.557(4) Å, respectively, with Cu—O(1)—Pb′ angle of 108.4(6)°. The Cu and Pb′ atoms are asymmetrically bridged by μ-Cl(2) atom. $Pb_2Cu_2O_4$ core displays a flattened chair conformation with the $PbCuO_2$ planes each folded by 70(1)° with respect to the strictly planar Pb_2O_2 plane.

The basic complex motifs are further extended through μ-Cl(1) bridging between two Pb sites to form doubly-bridged chains running along the *a* axis at $b = ca$ 0 and 0.5 (Fig. 1). These chains are considerably flattened staircase polymers with an angle between adjacent Pb_2O_2 and Pb_2Cl_2 planes of 32.6(2)°. The chains are in turn crosslinked *via* hydrogen bonds to the included water molecules (Fig. 2). The oxygen atom O(3) forms hydrogen bonds with Cl(2) and Cl(2)′ $\{-x, 1-y, -z\}$ atoms with distances of 3.25 and 3.21 Å, respectively, and O(3)···Cl(2)···O(3)′ $\{-x, 1-y, -z\}$ angle of 151(2)°.

The overall structure of complex **2** with square pyramidal coordination geometry around the Cu atom

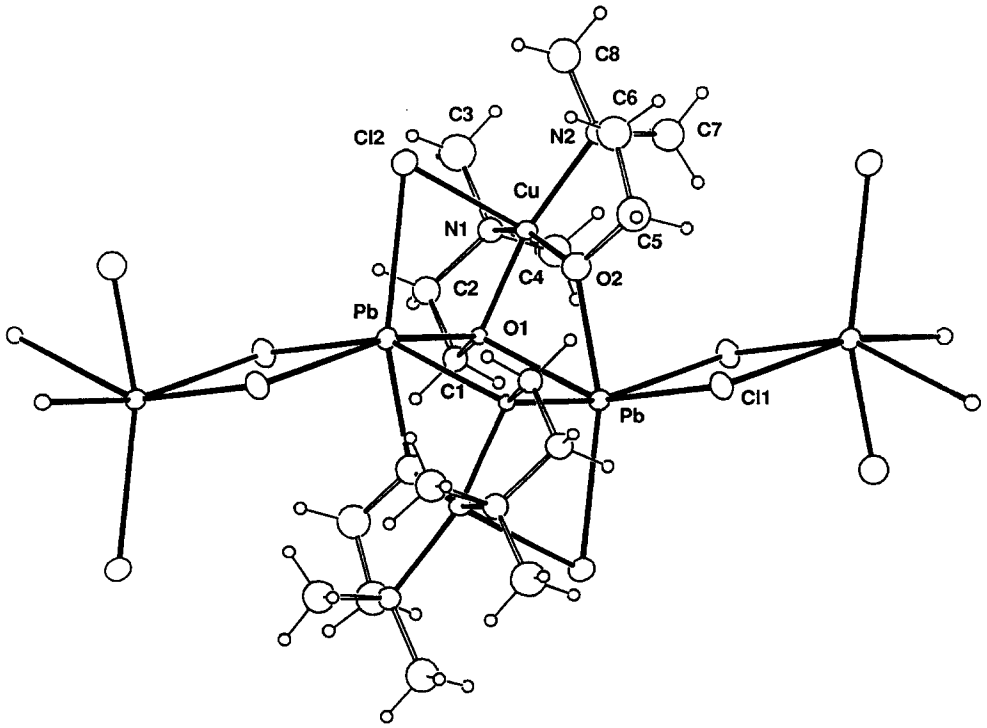

Fig. 1. Fragment of the polymeric chain present in the crystal structure of **1**.

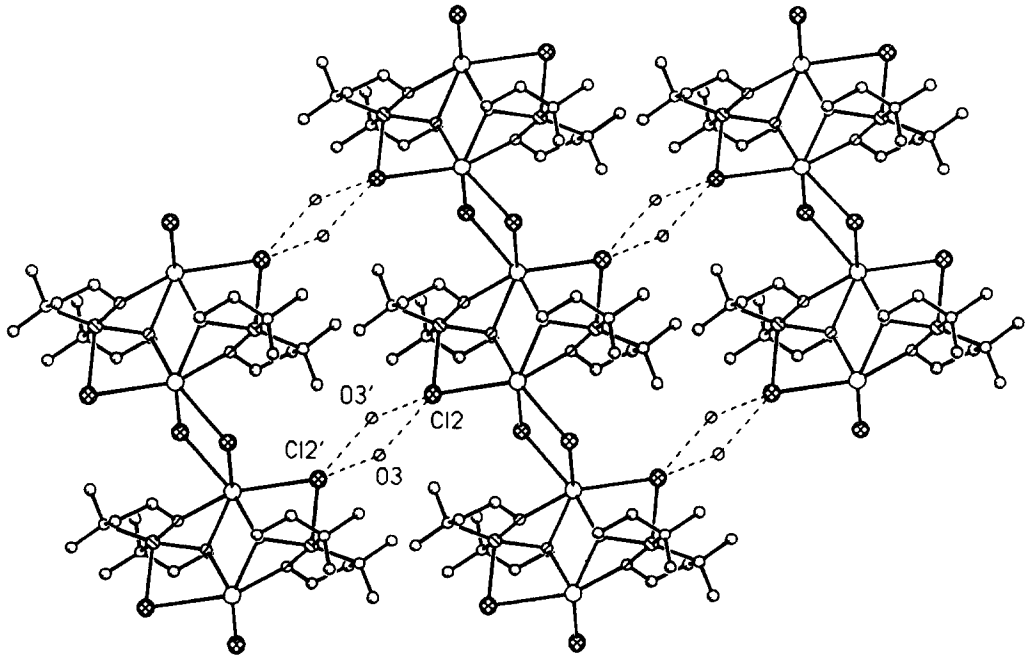

Fig. 2. Plan-view of part of the polymeric chains linked *via* hydrogen bonding to included water molecules in the crystal structure of **1** (hydrogen atoms are omitted for clarity, the additional interactions are shown as dashes).

and highly deformed octahedral coordination of the Pb atom resembles that of the compound **1** (Fig. 3). The copper and lead metal centres are bridged by alkoxide oxygens from L groups resulting in Cu—Pb, Cu—Pb′ $\{1-x, -y, -z\}$ separations of 3.343(1) and 3.753(1) Å, respectively with 103.5(2)° Cu—O(1)—Pb and 112.8(3)° Cu—O(2)—Pb′ angles. The I(1) atom bound to Pb bridges to Cu $\{x, -0.5-y, 0.5+z\}$ and Pb $\{1-x, -0.5+y, 0.5-z\}$ atoms of adjacent complex molecule (3.649(1), 3.5326(8) Å, respectively) to form a layer parallel to the *bc* plane (Fig. 4).

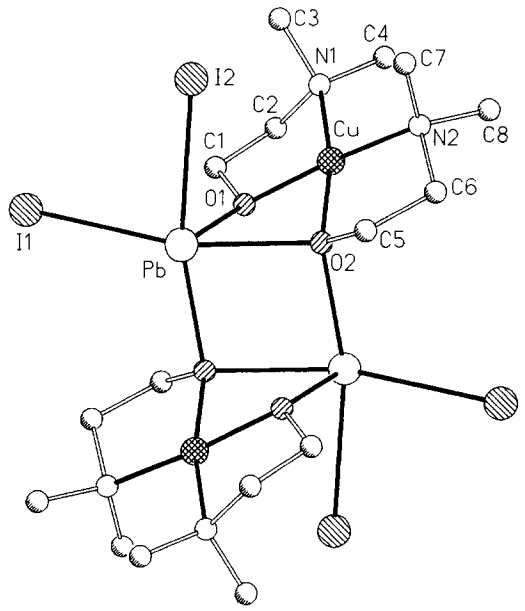

Fig. 3. The molecular structure of **2** (hydrogen atoms are omitted for clarity).

The 2-dimethylaminoethoxo groups in both compounds are structurally normal [22] [d(O—C) *ca* 1.42(1)–1.45(5), d(C—C) *ca* 1.47(2)–1.52(2), d(C—N) *ca* 1.48(2)–1.53(5), d[(N–C(terminal)] *ca* 1.43(2)–1.52(5) Å] and are coordinated to copper *via* oxygen and nitrogen atoms, forming five-membered puckered rings with the *gauche* configuration [the torsion N—C—C—O angles are *ca* 47(4)–53(1)°]. The oxygen atoms of the L groups are in μ- and μ_3-bridging positions.

From comparison of the structures of **1, 2** and ones reported previously [13,14] we can suppose that $Cu_2Pb_2L_4$ unit should be sufficiently rigid to retain the structural similarity in these complexes, and the compounds from Table 1 of composition $CuPbX_2L_2$ should contain the tetranuclear complexes with similar structures, with the $Pb_2Cu_2O_4$ core and the bridging halide or SCN groups.

Acknowledgements—X-ray data were collected and one of the structures was solved in part at the IUCr/ACA Summer Course in Crystallography, Pittsburgh, 1996. We thank the IUCr for financial support for O. Yu. V. to attend the Course.

(Received 29 April 1997; accepted 3 June 1997)

Abstract—The protonation constants of **L1** [7,11-bis(carboxymethyl)-1,4-dioxa-7,11-diazacyclotridecane] and the stability constants of complexes formed by this ligand with the alkaline-earth metal ions, the divalent first-row transition metal ions, Cd^{2+}, and Pb^{2+} were determined by potentiometric methods, at 25°C and ionic strength 0.10 M in tetramethylammonium nitrate. In general, the stability constant values for the complexes studied are lower than expected for a potential six-co-ordinate ligand with an N_2O_4 co-ordination sphere. The complexes of **L1** with metal ions, forming mainly electrostatic interactions (the alkaline–earth metal ions, Mn^{2+} and Pb^{2+}), have a sharp decrease of stability when compared with the corresponding complexes of 12-membered ligands, **L3** and **L4** [7,10-bis(carboxymethyl)-1,4-dioxa-7,10-diazacyclodecane and 4,10-bis(carboxymethyl)-1,7-dioxa-4,10-diazacyclododecane, respectively]. However, the Cu^{2+} and Ni^{2+} complexes of **L1** and **L4** have about the same values of stability constants. Hence, the 13-membered ligand is more selective for the divalent first-row transition metal ions than the 12-membered ones are. To explain these results we suggest that probably all the donor atoms of the ligands (**L1, L3** and **L4**) are involved on the co-ordination to the metal ions when mainly electrostatic interactions take place (also to the Co^{2+}, as spectroscopic measurements have revealed) but the distances and principally the orientation of the lone-pairs of electrons of **L1** are not in the better position for the co-ordination. Based on electronic and EPR spectroscopic measurements in solution and in magnetic moments of the complexes some explanations about the peculiarities of the Ni^{2+} and Cu^{2+} complexes of **L1** and **L4** were proposed. The Ni^{2+} complexes of both ligands exhibit tetragonally distorted octahedral geometry, but this metal ion seems to fit better in the cage formed by **L1** than that of **L4,** as indicated by the values of stability constants. Both ligands should adopt different arrangements around the metal ion, the distortion from the octahedron being more important for **[NiL4]** reflecting the loss in terms of crystal field stabilisation energy. However, the Cu^{2+} forms with **L1** a square pyramidal pentaco-ordinate complex while **L4** prefers a distorted octahedral arrangement. © 1997 Elsevier Science Ltd

Keywords: macrocycle; bis(carboxymethyl)-dioxa-diazacyclotridecane; stability constants; protonation constants; EPR copper complexes; Co^{2+}, Ni^{2+} and Cu^{2+} complexes.

The increase in size of the cavity of macrocycles carrying pendant N-methyl carboxylate arms, from 12- to 15-membered rings, causes a sharp decrease in stability of the metal complexes when the metal ion forms mainly electrostatic interactions, such as the alkaline–earth ions, Mn^{2+} or Pb^{2+} [1–4]. However, for the first-row transition divalent metal ions involved mainly in covalent interactions upon complexation, the situation is completely different; the increase of the number of atoms on the ring of the macrocycle does not significantly affect the stability of the complexes, specifically those of Co^{2+}, Ni^{2+} and Cu^{2+} [1–4]. Nevertheless, data in the literature are scarce to draw general conclusions. Only one series is completely studied, that of the N-tetracarboxymethylate

* Author to whom correspondence should be addressed.

tetraazamacrocylces, DOTA, TRITA and TETA [1,2] (*cf* Scheme 1) where the above conclusions were verified. The series of the N-tricarboxymethylate oxatriaza-macrocycles was undertaken [5–7], but data for the 13- and 14-membered ligands are not yet completely published. Another series of N-tricarboxymethyl tetraazamacrocycles containing a pyridine in the ring was also studied and the results published only for the 12-membered [3] and a 14-membered [8] ligands.

It is known that for the parent amines, the increase of the macrocyclic ring size may lead to an increase of the stability constants. For instance, for the tetraazamacrocycles, the peak in stability constants for the Ni^{2+} and Cu^{2+} complexes occurs for cyclam, the 14-membered ring [9,10]. The explanations are fully discussed [9,10].

Therefore, in order to have a complete knowledge of the effect of the increase of the ring size of these macrocycles results for the 13-membered ligands are

needed but not available owing to difficulties of their synthesis. The yield of the cyclization step for the 13-membered ligands is low, using the procedures developed for the 12- and 14-membered compounds, and the last step, of introduction of the N-carboxymethyl groups, leads to mixtures hard to work up.

We decided to undertake the synthesis of the 13-membered N-carboxymethyl dioxadiaza macrocycle, **L1**, because two 12-membered compounds of this series were studied before, **L3** and **L4**. Although we knew that the stability constants of the complexes involving these ligands were relatively low [6], the preparation of **L1** was not hard and has made possible the comparison of the behaviour of the complexes of this ligand with the corresponding 12-membered ones and also the study of the effect of the replacement of two nitrogen by two oxygen atoms of the ring to compare with the tetraaza series, DOTA and TRITA.

The parent amine, **L2** (1,4-dioxa-7,11-diazacyclotridecane), has been previously synthesised [11–13] and its protonation and stability constants with some first-row transition divalent metal ions have been published [11,12]. **L1** has been obtained by Ewin and Hill [13] and the stability constants of its complexes with the alkaline–earth metal ions determined. However, the results are so different from ours that we decided to repeat the determinations for all of them and extend the study to the complexes of all the divalent first-row transition metal ions, and also Cd^{2+} and Pb^{2+}.

Note that completely deprotonated forms of the ligands are charged species but for simplicity the charges will generally be omitted in the text.

EXPERIMENTAL

Reagents

The commercial chemicals were of reagent grade and used without further purification. 1,2-Propanediamine (99%), 2,2′-ethylenedioxybis(ethanol) (98%), anhydrous disodium phosphate (99%) and mercury, p.a. were obtained from Merck, sodium hydride (20% in paraffin oil) and sodium lumps (99.5%) from Riedel, anhydrous sodium sulfate (99%) from Pronalab, chloroacetic acid and Amberlite IR-120 ion exchange resin standard grade in the Na^+ form (which was treated with 1.0 mol dm^{-3} hydrochloric acid before use) from BDH, and K_2H_2EDTA (dipotassium 1,2-diaminoethane-N,N,N′,N′-tetraacetate) from Fluka. N,N′-di-*p*-toluenesulfonyl-1,2-propanediamine and di-*p*-toluene-sulfonyl-2,2′-ethylenedioxybis(ethanol) were prepared as described before [14–16]. The organic solvents were purified by standard methods [17].

Synthesis and characterisation of the ligands

L2 was synthesised by the cyclization procedure of Richman and Atkins [18] with small modifications. In a typical experiment a solution of disodium salt of N,N′-di-*p*-toluenesulfonyl-1,2-propanediamine was prepared by the slow addition of sodium hydride (3 g), as a suspension in oil, in dry dimethylformamide (dmf) (62 cm^3) to a solution of N,N′-di-*p*-toluenesulfonyl-1,2-propanediamine (0.05 mol; 19.12 g) in dry dmf (250 cm^3), at room temperature and under nitrogen. After the evolution of hydrogen ceased the temperature of the solution was increased to 110–120°C and di-*p*-toluenesulfonyl-2,2′-ethylenedioxybis(ethanol) (0.05 mol; 22.91 g) in dmf (250 cm^3) was added, dropwise, under nitrogen over 5 h. The temperature and stirring was continued for another 3 h and left overnight at room temperature. Then the mixture was filtered off, the volume of the filtrate reduced by vacuum distillation and slowly poured into crushed ice. The white precipitate of the ditosylated cyclic amine (tosyl ≡ *p*-toluenesulfonyl) formed was filtered and washed several times with warm water (200 cm^3 at 75°C), then a solution of sodium hydroxide 2M (200 cm^3 at 75°C), finally with cold water several times and then recrystallized from toluene/n-hexane. Yield: 4.22 g (17%); m.p. 195–197°C; ^{1}H NMR ($CDCl_3$, TMS): δ 7.69 (d, 4H, tosyl groups), 7.32 (d, 4H, tosyl groups), 3.67 (t, 4H, —OCH_2—), 3.58 (s, 4H, —OCH_2CH_2O—), 3.22 (m, 8H, —NCH_2—), 2.43 (s, 6H, —CH_3) and 2.18 (q, 2H, —CH_2C$H_2$$CH_2$—) p.p.m.

The tosyl groups were removed under reductive alkaline conditions with a sodium amalgam in buffered methanol solution [6,19]. A mixture of the cyclic tritosylamine (2.02 mmol, 1.00 g), anhydrous disodium phosphate (17.5 mmol, 2.48 g) and 2% sodium amalgam (48 g) in dry methanol (20 cm^3) was stirred rapidly and heated to reflux for about 20 h, under nitrogen. After cooling to room temperature, the mercury was decanted from the slurry and the solution filtered off. The filtrate was concentrated almost to dryness, water was added (25 cm^3) and extracted four times with chloroform (25 cm^3). The organic layers were combined and dried over anhydrous sodium sulfate. The mixture was filtered off and the solvent removed *in vacuo* to obtain **L2** as a pale yellow oil. The oil was dissolved in chloroform (5 cm^3), 5 M hydrochloric acid (20 cm^3) was added slowly and then the solvent was removed. A white powder was formed when ethanol was added, corresponding to **L2**·2HCl. Yield: 0.265 g (≈50%); m.p. 220–222°C. ^{1}H NMR (D_2O, DSS; pD 4.08): δ 3.74 (t, 4H, —OCH_2—), 3.62 (s, 4H, —OCH_2CH_2O—), 3.27–3.21 (m, 8H, —NCH_2—), 2.08 (q, 2H, —CH_2C$H_2$$CH_2$—) p.p.m. ^{13}C NMR ($D_2O$, dioxane; pD 4.08): δ 69.76, 64.63, 45.16, 42.68, 21.26 p.p.m. Found: C, 37.88; H, 8.28; N, 9.58. Calc. for $C_9H_{22}N_2O_2Cl_2$1.25H_2O: C, 38.09; H, 8.64; N, 9.88%. (The microanalysis data were provided by the 'Laboratório de Análises Químicas', IST, Lisbon.)

The N-carboxymethylated ligand (**L1**) was synthesised by condensation of the parent dihydrochloridrated amine, **L2**·2HCl (1.92 mmol; 0.5 g)

with sodium chloroacetate (obtained by addition of 3 M NaOH solution to a concentrated aqueous chloroacetic acid, 4.02 mmol, 1.34 cm^3, at 5°C), in aqueous basic solution. The temperature was increased slowly during the reaction to a maximum of 65°C and the pH was kept below 10.5, by slow addition of 3 M NaOH. When the pH no longer changed, the reaction was considered completed (40 days); then the mixture was cooled and the pH adjusted to ≈ 1 with 5 M hydrochloric acid. Upon withdrawal of part of the solvent *in vacuo*, a precipitate of NaCl was formed and filtered off. The desired product was purified by chromatography using a cationic resin in the H^+ form (column 20.0 × 2.0 cm). The flow rate was kept at 1.0 $cm^3\ min^{-1}$. After washing with water (250 cm^3), the final product was eluted with a solution of 0.5 M ammonia. The pure product was isolated from the column fractions 15–21 (each fraction of 15 cm^3). The fractions were collected, the solvent evaporated and the white solid obtained was washed with ethanol and acetone. Yield: 55%; m.p. 151–153°C (decomp.); ^1H NMR (D_2O, DSS, pD = 5.03): δ 3.85 (t, 4H, —OCH_2—); 3.71 (s, 4H, —NC$H_2CO_2^-$); 3.63 (s, 4H, —OCH_2CH_2O—); 3.47 (t, 4H, —NCH_2—); 3.36 (t, 4H, —NCH_2—); 2.26 (q, 2H, —$CH_2CH_2CH_2$—) p.p.m. ^{13}C NMR (D_2O, dioxane; pD = 5.03): δ 169.77; 69.91; 64.66; 57.39; 53.66; 51.90; 18.33 p.p.m. Found: C, 39.52; H, 6.81; N, 10.93%. Calc. for $C_{13}H_{24}N_2O_6.1.2HNO_3.H_2O$ (after addition of HNO_3 to the product obtained by chromatography): C, 39.24; H, 6.84; N, 11.27%. The amount of HNO_3 in the final product was confirmed by titration with a standard solution of NaOH.

Potentiometric measurements

Reagents and solutions. Metal ion solutions were prepared at about 0.010 and 0.100 M from the nitrate salts of the metals, of analytical grade, with demineralized water (obtained by a Millipore/Milli-Q system) and were standardised by titration with K_2H_2EDTA. Carbonate-free solutions of the titrant, $(CH_3)_4NOH$, were prepared as described earlier [8]. Solutions were discarded when the percentage of carbonate was about 0.5% of the total amount of base.

Equipment and work conditions. The equipment used was described earlier [8]. All the experiments were monitored by computer. The temperature was kept at 25.0 ± 0.1°C; atmospheric CO_2 was excluded from the cell by passing purified N_2 across the top of the experimental solution. The ionic strength of the solutions was kept at 0.10 M with $(CH_3)_4NNO_3$.

Measurements. The hydrogen ion concentration, $[H^+]$, was determined by the measurement of the emf of the cell, $E = E'^0 + Q \log [H^+] + E_j$. E'^0 and Q were obtained by previous calibration, titrating a standard solution of known hydrogen-ion concentration at the same ionic strength, using the values of the acid range. The term pH is defined as $-\log [H^+]$. The liquid-junction potential, $E_j = j_H[H^+] + j_{OH}[OH^-]$, whose constants j_H and j_{OH} were determined by an acid/base titration of concentrated solutions [20], was found to be negligible in the experimental conditions used. The value of $K_W = ([H^+][OH^-])$, was determined from data obtained in the alkaline range of the calibration, considering E'^0 and Q valid for the entire pH range, and found equal to $10^{-13.77}\ M^2$.

The potentiometric equilibrium measurements were performed on 20 cm^3 of ligand solutions $\cong 2.50 \times 10^{-3}$ M, diluted to a final volume of 30 cm^3, first in the absence of metal ions and then in the presence of each metal ion for which the $C_M : C_L$ ratios were 1:1, 1:2 and in some cases 2:1. The emf values were taken after additions of 0.025 or 0.050 cm^3 increments of standard 0.0974 M $(CH_3)_4NOH$ solution, and after stabilisation in this direction, equilibrium was then approached from the other direction by adding standard 0.100 M nitric acid solution.

Stabilisation of the systems studied. The formation of complexes of **L1** with all the metal ions studied in this work was fairly rapid, as verified by the fast stabilisation of the emf of the solutions and potentiometric titrations could be performed by an automated technique. For the Co^{2+} and Ni^{2+} complexes (the slowest cases) the equilibrium was verified by a backtitration with a HNO_3 solution as titrant.

Calculation of equilibrium constants. Protonation constants:

$$K_i^H = \frac{[H_iL]}{[H_{i-1}L][H]}$$

were calculated by fitting the potentiometric data obtained for the free ligand to the SUPERQUAD program [21]. Stability constants of the various species formed in solution were obtained from the experimental data corresponding to the titration of solutions of different ratios of the ligand and metal ions, also with the aid of the SUPERQUAD program. The results were obtained in the form of overall stability constants or $\beta_{M_mH_hL_l}$ values:

$$\beta_{M_mH_hL_l} = \frac{[M_mH_hL_l]}{[M]^m[L]^l[H]^h}$$

Only mononuclear species, ML, MHL, $MH_{-1}L$ (being $\beta_{MH_{-1}L} = \beta_{MLOH} \times K_W$) were found. Differences, in log units, between the values β_{MHL} (or $\beta_{MH_{-1}L}$) and β_{ML} provide the stepwise protonation reaction constants. The errors quoted are the standard deviations of the overall stability constants given directly by the program. In the case of the stepwise constants the standard deviations were determined by the normal propagation rules and do not represent the total experimental errors. The protonation constants were obtained from ≈ 200 experimental points (6 titration curves) and stability constants for each metal ion from 75 to 150 experimental points (2–6 titration curves).

Spectroscopic studies

^{1}H NMR spectra were recorded with a Varian Unity 300 spectrometer at probe temperature. Solutions of the ligand for the measurements ($\approx$0.01 M) were made up in D_2O and the pD was adjusted by addition of DCl or CO_2-free KOD with a Crison 2001 instrument fitted with a combined Ingold microelectrode. The $-\log[D^+]$ was measured directly in the NMR tube, after the calibration of the microelectrode with buffered aqueous solutions. The final pD was calculated from pD = pH + 0.40 [22]. Sodium 3-(trimethylsilyl)-d_4-propionate (DSS) was used as an internal reference. ^{13}C NMR spectra were recorded with the same spectrometer and dioxane was used as internal reference. The metal complexes, for the determination of the magnetic moments, were prepared in H_2O by addition of the metal ion, in the form of nitrate salts, to an equivalent amount of the ligand and enough KOH to obtain the final pH, and after evaporation of water were taken in D_2O. Magnetic moments of the complexes were determined by the Evans method in solution [23] at room temperature.

Electronic spectra were performed with an electronic spectrophotometer, Perkin–Elmer, model Lambda 9 for UV–vis–near-IR, using aqueous solutions of the complexes prepared as indicated in the last paragraph, in 1 cm cells. The temperature of the solutions was kept at 25.0 $\pm$ 0.1°C using a thermostat Grant W6. The spectra were recorded in the range 250–1350 nm.

EPR spectra were recorded with a Bruker ESP 380 spectrometer equipped with a continuous-flow cryostat for liquid nitrogen, operating at X-band. The spectra of the Cu^{2+} complexes ($1.1–1.3 \times 10^{-3}$ M in 1.0 M $NaClO_4$) were recorded at 100 K. The computer simulation of the EPR spectrum of the complex was carried out with a program for a microcomputer [24].

RESULTS AND DISCUSSION

Synthesis

L2 has been synthesised by Hill *et al.* and Hancock *et al.* [11–13]. Rasshofer *et al.* have prepared the precursor **L2·2Ts** but it is not clear from the publication if the removal of the tosyl groups was tried [25]. **L1** was only synthesised before by Ewin and Hill [13]. However, the technique for the removal of the tosyl groups used by the last authors, and giving 89% yield, could not be reproduced neither by us nor by Hancock *et al.* [11,12]. These authors described an alternative method in basic conditions (sodium in isoamyl alcohol) which did not lead to the expected result in our case. Indeed, the critical step of the synthesis of **L2** is the withdrawal of the tosyl groups, because in acid conditions the breaking of ether linkage of the macrocyclic ring is faster than removal of the tosyl groups, so that at long reaction times there is a total degradation of the free amine formed, although some tosylated amine remains. The protonation of the oxygen atom seems to be the first step in the acid dissociation of the ether linkage, therefore intramolecular hydrogen bonds involving the ether oxygen atom do not favour this step [26]. We have preferred to remove the tosyl groups under reductive alkaline conditions by sodium amalgam in a buffered methanol as described earlier [6,19]. Even in these conditions our yield was only of about 50%.

Protonation

Table 1 summarises the protonation constants (K_i^H, in log units) for the ligand studied in the present work and also for some other ligands with the same number and type of donor atoms, for comparison. Also Table 1 refers to the only value of the protonation constant reported in the literature for **L1**. This ligand has four basic centres for which we could determine three protonation constants by potentiometric measurements. The last one is very low to be obtained by this technique. The ligand presents a high value for the first protonation constant and a fairly high value for the second one, which correspond to the protonation of the two nitrogen atoms of the ring. The other two constants correspond to the protonation of the two carboxylate groups and are low when compared with the value of acetic acid ($\log K = 4.8$) or, even, of that of some other polyacetatepolyaza macrocyclic ligands, such as DOTA [1]. These values can be explained by the presence of the positive charge of the nitrogen atoms already protonated and probably also by the simultaneous disruption of the hydrogen bonds in which these carboxylate groups are involved. The protonation of the two amines of the ring occurs before the protonation of the carboxylate ones, in spite of the short distance between the two charged nitrogen and the possible electrostatic repulsions between them. The same happens with **L3** and **L4**, although in **L4** the two nitrogen atoms are in opposite position in the macrocyclic ring, and in **L3** the distances between the two ammonium ions are shorter leading to the decrease of the second protonation constant of this ligand ($\log K_2 = 4.84$) [6]. So the second constant of **L1** has an intermediate value between that of **L3** and **L4**.

The 12 to 14-membered tetraaza macrocycles usually have two high values of protonation constants, corresponding to the protonation of two nitrogen atoms in opposite positions, two values of about 4 for the protonation of the carboxylate groups bound to non-protonated nitrogens, and finally protonation constants of about 2 or less corresponding to the protonation of the remaining carboxylate groups and nitrogen atoms of the ring [1]. This means that the repulsions within the macrocycle are strong enough and the protonation of a nitrogen contiguous to another already protonated only occurs at very low pH

Table 1. Protonation ($\log K_i^H$) constants of **L1** and similar ligands (**L2, L3, L4** and **EDDA**) for comparison. ($T = 25.0°C$; $I = 0.10$ M in $(Me)_4NNO_3$)

values. This is not observed with the dioxadiaza macrocycles where the second nitrogen atom to be protonated is adjacent and consequently the charge concentration must be lower and the mobility of the macrocycle more important, making the protonation behaviour of this kind of macrocycles more similar to that of linear ligands [27], as shown in Table 1 for **L1** and EDDA (1,2-diaminoethane-N,N′-diacetic acid).

Complexation

The stability constants of **L1** with the alkaline–earth and divalent first-row transition metal ions are collected in Table 2, together with the constants for the complexes formed with some related ligands with the same metal ions taken from the literature. Only mononuclear species (1:1, metal to ligand ratio) were found for the complexes of **L1**. In most cases only ML and hydroxocomplexes (MLOH) species are formed, but protonated species (MHL) were also detected for the Fe^{2+}, Zn^{2+}, Cd^{2+} and Pb^{2+} systems. However, the hydroxocomplexes are always formed at high pH values ($\geqslant 10.3$). We have checked the possibility of formation of other species such as other protonated, MH_iL ($i \geqslant 2$) or dinuclear, but they do not seem to be formed under our conditions. The constants for the alkaline–earth metal ion complexes were determined before [13] but the difference from ours is very great, higher for the Mg^{2+} complex and lower for the others. Ewin and Hill [13] have made their measurements in a different medium ($NaClO_4$) but this does not explain the discrepancies as the ligand forms no complexes with Na^+. They determined the constants by a thermometric titrimetric method, $\log K_{ML}$, ΔH and ΔS being calculated simultaneously. We have before detected the same type of disagreement in other values from the same publication [13] for the complexes of other ligand [28] (higher stability constant for the Mg^{2+} complex and smaller ones for the other alkaline–earth metal ions) and we have also checked that the different media did not justify the discrepancies found.

The examination of Table 2 and Fig. 1 leads to the following conclusions: (1) The values of the stability constants of **L1** are lower than expected for a potential hexadentate ligand, specially for the complexes of the alkaline–earth metal ions, as shown when data of this ligand are compared with those of 12-membered macrocycles such as **L3** and **L4**, or even with linear hexadentate ligands with the same set of donor atoms [27,29]. (2) However, when stability constants of **L1** are compared with those of EDDA, a linear ligand with two amines and two carboxylate groups, it is possible to infer that the oxygen atoms of the ring of **L1** are involved on the co-ordination to the metal ions (at least one of them). (3) **L1** is more selective for the complexation of the divalent first-row transition metal ions than are the 12-membered ligands. (4) When the size of the ring of those N-acetate macrocyclic ligands increases from 12- to 13-membered, there is a significant fall in the values of the stability constants of the complexes formed mainly by electrostatic interactions, such as those of alkaline–earth metal ions, Mn^{2+} and Fe^{2+}. However, the stability of the Ni^{2+} and the Cu^{2+} complexes seems indifferent to the increase of the size of the cavity and the Zn^{2+} and Cd^{2+} complexes have an intermediate behaviour. The Co^{2+} and Pb^{2+} complexes are apparently anomalous, although the last complex behaves in the expected manner if compared with **L3**. (Note that **L1** and **L4** have the same overall basicity, but **L3** has a lower value (*cf* Table 1), so to have identical conditions concerning competition between protons and metal ions for the ligand, we shall compare the ability of our ligand to form complexes predominantly with that of **L4**.)

The same behaviour was found for the tetraazamacrocyclic ligand series, DOTA and TRITA (see Fig. 1). In spite of the stability constants of the complexes formed by those ligands being much higher than those studied in this work, the differences arising from the increase of the cavity (from 12 to 13-membered) are similar to those found in the present work. The determination of ΔH and ΔS of the complexes of

[e] Value with less precision due to precipitation.

DOTA and TRITA [2] have revealed that for the complexes mainly formed by electrostatic interactions the difference is essentially due to the enthalpic variations, although a decrease in the entropic variations was also observed. The decrease of the values of ΔH with the increase of the size of the ring is probably due to the increase in the distances between the metal ions and the donor atoms and also a less favourable orientation of the lone-pair electrons of the donor atoms. However, the metal ions forming more covalent bonds, which are more strict for specific co-ordination geometries (Fe^{2+} to Zn^{2+}), probably select the donor atoms of the ligand in better position for the preferred geometry, some of them should not be used on the co-ordination [2].

An analogous explanation may also be advanced for the behaviour of the **L1** and **L4** complexes. Hence, probably all the donor atoms of both ligands are involved on the co-ordination to metal ions forming mainly electrostatic interactions but the distances and/or the orientation of the lone-pairs of electrons of the nitrogen and oxygen atoms of the ring of **L1** were not in the best position for the co-ordination to the metal ions. For the Cu^{2+} and Ni^{2+} ions, whose complexes have identical stability with both ligands, and the ligands have the right number of donor atoms to form six co-ordinate complexes, a different explanation is needed. To have more insight about the co-ordination sphere of the Co^{2+}, Ni^{2+} and Cu^{2+} complexes some spectroscopic measurements were performed.

Spectroscopic measurements

Spectroscopic UV–vis–near-IR data for Co^{2+}, Ni^{2+} and Cu^{2+} complexes of **L1** and **L4** and EPR parameters for the Cu^{2+} complexes of **L1, L2** and **L4**, in water solution, were collected in Tables 3 and 4.

The electronic spectrum of the [Co**L1**] exhibits a shoulder located at 304 nm, which is probably a charge transfer band, a multiple structured band in the visible region with shoulders at higher and lower energies and a large near-IR band at 1226 nm with a shoulder at 946 nm (*cf* Table 3). All the bands have very low intensities, which slightly increase between pH values

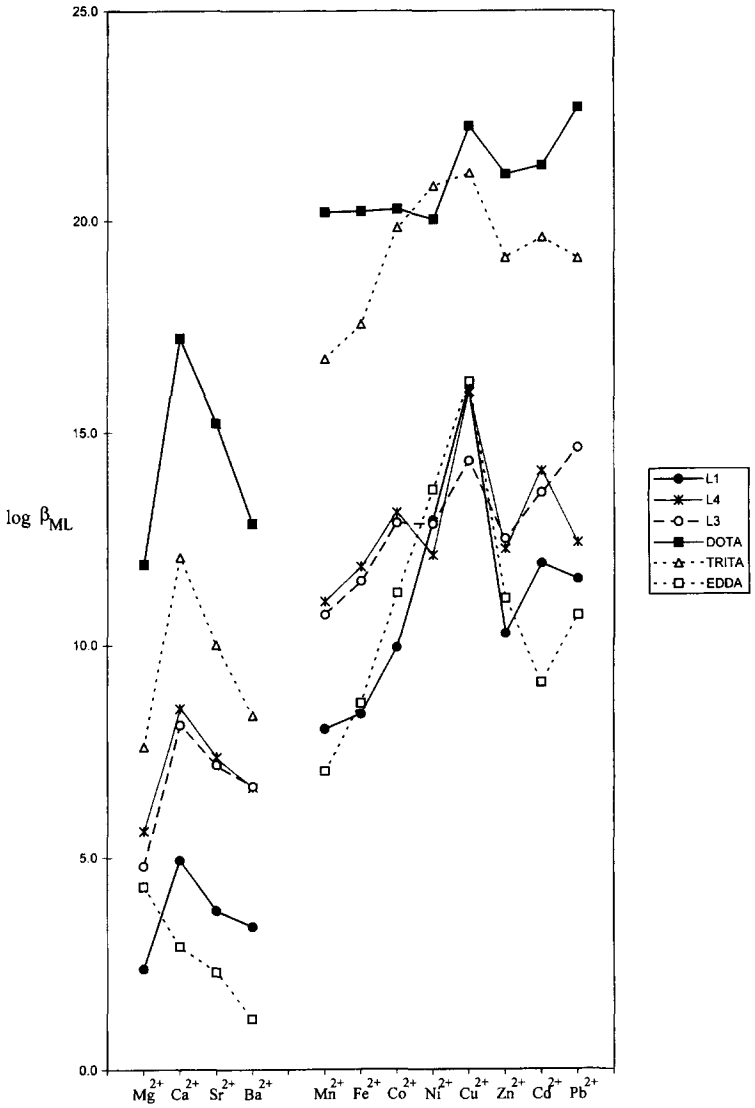

Fig. 1. Variation of the stability constants (log K_{ML}) of the metal complexes of **L1** (●), **L3** (○), **L4** (*), DOTA (■), TRITA (△) and EDDA (□) with the atomic number of the metal ion.

2.8 to about 7. This spectrum, together with the value of the magnetic moment, point to a six co-ordinate symmetry of a high-spin species [30–32]. It is known that six co-ordinate chromophores have in general low absorptions since all transitions are forbidden and magnetic susceptibility values between 5.0 and 5.4 BM [30]. Carlin [33] indicates lower values (4.7–5.2 BM). At high pH values (>9) two new bands appear (at 647 and 592 nm) and the band at about 900 nm moves to higher energy. Decreasing the pH the spectrum acquires the original form but loses intensity. Until pH values of about 8 are reached, the complex does not undergo degradation with time. The complex of the 12-membered ligand, [Co**L4**], exhibits a similar electronic spectrum but with less intense bands and a magnetic moment of 4.93 BM. Thus, in this case there is no ambiguity in its characterisation as a high-spin distorted octahedral complex. At high pH (>9) the spectrum presents new bands at 646 and 596 nm. These additional bands, appearing in both **L1** and **L4** Co^{2+} complexes, are probably related to the formation of hydroxocomplexes and subsequent degradation by dimeric species.

The electronic spectrum of the blue solution of [Ni**L1**] exhibits three main bands at 969, 575 and 356 nm, several shoulders and a small band at 798 nm (*cf* Table 3). This spectrum and the value of the magnetic momentum (3.21 BM) are characteristic of a tetragonally distorted octahedral symmetry. The ratio between the near-IR and the visible bands is 1.68, also characteristic of tetragonal nickel(II) [31]. The spectrum of a d^8 complex with octahedral symmetry shows three bands of low intensities corresponding to the three spin allowed transitions and the reduction of symmetry to a tetragonal leads to additional d-orbital splittings or band broadening [31–35]. The

electronic spectrum of the green [Ni**L4**] exhibits six broad but well defined bands at 1249, 1082, 928, 625, 388 and 296 nm with several shoulders, similar to that of five co-ordinate high spin derivatives [31,32,35–39]. The magnetic moment (3.42 BM) also falls in the range normally observed for high-spin five co-ordinate Ni^{2+} species [31,32,35,40]. However, the molar absorptivity of all the bands are too low for a square pyramidal or a trigonal bipyramidal symmetry and probably the most probable geometry of this complex is also a tetragonally distorted octahedral one.

The turquoise [Cu**L1**] exhibits a broad band in the visible region with two shoulders at lower energies, due to the copper *d–d* transitions, and an intense band in the ultraviolet region. The copper(II) complex of **L2** is blue showing an electronic spectrum similar to that of **L1** but shifted to lower energies and having more intense bands. The Cu^{2+} complex of **L4** is also blue but exhibits an electronic spectrum with two broad bands in the visible/near IR region and an intense band in the UV region (*cf* Table 3). The EPR spectra of the three Cu^{2+} complexes are shown in Fig. 2. All of them exhibit three well resolved lines of the four expected at low field, due to the interaction of the unpaired electron spin with the copper nucleus, and no superhyperfine splitting due to the coupling with the four nitrogen atoms of the macrocycle. The fourth copper line is completely overlapped by the high field part of the spectra. The simulation of the spectra [24] led to three different principal values of g, indicating that the Cu^{2+} ion in these complexes is in a rhombically-distorted ligand field. The hyperfine coupling constants and g values are compiled in Table 4.

Though electronic and EPR spectra of Cu^{2+} complexes are not specially good indicators of geometry [41], the comparison of spectra of complexes of the same series, such as those compiled in Table 4, allows some conclusions. The EPR spectra of the Cu^{2+} complexes of **L1**, **L2** and **L4** show $g_z > (g_x + g_y)/2$ and the lowest $g > 2.04$, typical of rhombic symmetry of the copper(II) ion with elongation of the axial bonds and a $d_{x^2-y^2}$ ground state. Elongated rhombic–octahedral, rhombic square-coplanar or distorted square-based

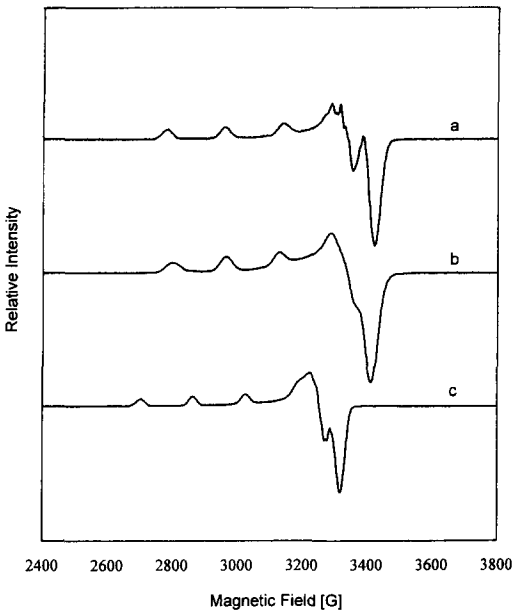

Fig. 2. EPR X-band spectra of the Cu^{2+} complexes of (a) **L1**, (b) **L2** and (c) **L4**, in 1.0 mol dm^{-3} $NaClO_4$, recorded at 100 K, microwave power of 2.4 mW, modulation amplitude of 1 mT. The frequency (ν) was of 9.61, 9.62 and 9.41 GHz for *a*, *b* and *c*, respectively.

pyramidal stereochemistries would be consistent with these data. Consequently it is possible to exclude a trigonal–bipyramidal geometry or a tetragonal structure involving compression of axial bonds [42,43].

The g values and hyperfine constants (A_i) may be related to the electronic transitions by the usual factors derived from the ligand field theory [44–46]. The strength of the axial donor and the displacement of the copper from the donor atoms plane. The g values increase and the A_z value decrease as the planar ligand field becomes weaker, or as the axial ligand field becomes stronger and this is accompanied by a red-shift of the *d–d* absorption bands in the electronic spectra [45–48]. This sequence, in principle, parallels the degree of distortion from a square-planar arrangement to a square pyramidal geometry, and then to an octahedral or tetragonal symmetry.

Data of Table 4 show that [Cu**L4**] and $[CuEDTA]^{2-}$ [49,50] have similar EPR parameters and analogous electronic spectra. It is known by X-ray diffraction analysis that $[CuEDTA]^{2-}$ [32,51] and [Cu**L4**] [52] exhibit octahedral structures. In the last complex the Cu^{2+} is in a very distorted octahedral environment, with the macrocycle in a folded conformation, the two nitrogen atoms and the two oxygen of the acetate groups forming the equatorial plane and the two oxygen atoms of the ring in axial positions (the O_{axial}—Cu—O_{axial} angle being 147.7°). However, [Cu**L1**] which presents lower g values, higher A_z and a blue-shift of the electronic spectra when compared with the $[CuEDTA]^{2-}$ or [Cu**L4**] spectra, can be considered penta co-ordinate with a square-pyramidal arrangement. This means that in this case one of the oxygen atoms (either from the macrocycle or from one of the acetate groups), is not co-ordinated to the copper ion or is located at a longer distance. The Cu^{2+} complex of **L2** showing a slight decrease of g values and a slight increase of A_z compared with those of [Cu**L4**] or $[CuEDTA]^{2-}$, probably is also penta-coordinate, but with a different coordination sphere. Probably the donor atoms of the macrocycle form the equatorial plane and one perchlorate ion occupies an axial position in a square pyramid, and so its data do not fit well in the analysed series.

CONCLUSION

The complexes of **L1** with metal ions forming mainly electrostatic interactions (the alkaline–earth metal ions, Mn^{2+} and Pb^{2+}) and also Co^{2+}, show a sharp decrease of stability when compared with the corresponding complexes of 12-membered ligands, **L3** and **L4**. However, the Cu^{2+} and Ni^{2+} complexes of **L1** and **L4** have about the same values of stability constants. To explain these results we propose that all the ligand donor atoms (**L1, L3** and **L4**) are involved in the co-ordination to metal ions which form mainly electrostatic interactions (and also to Co^{2+}, as spectroscopic measurements have revealed) but the distances, and specially the orientation of the lone-pairs of electrons, are not in the best position for the co-ordination to **L1**. Also for the Ni^{2+} complexes, all the donor atoms of the ligands are involved in the co-ordination to the metal, as shown by electronic spectroscopy in solution and the value of the magnetic moments of [Ni**L1**] and [Ni**L4**], both complexes exhibiting tetragonally distorted octahedral geometry. Therefore it seems that Ni^{2+} probably fits better in the cage formed by **L1** than that of **L4**, as indicated by the values of stability constants, both ligands probably adopting different arrangements around the metal ion. Additionally, the structure adopted by [Ni**L4**] would be similar to that of the Cu^{2+} one, for which the crystal X-ray structure [52] and preliminary molecular mechanics studies [53] have revealed a significant distortion (the O_{axial}—Cu—O_{axial} angle being about 150°, far from the 180° predicted for the octahedron) and so the loss in terms of crystal field stabilisation energy (CFSE) is very important (as the octahedral Ni^{2+} complexes are more favoured in CFSE than the other first row transition metal ions). The more plastic Cu^{2+} ion would adjust better to the different arrangement of the ligands and so with **L1** forms a pentacoordinate complex, while **L4** prefers an octahedral arrangement.

As mentioned earlier [6] the Ni^{2+} complex of **L4** presents a lower stability constant than the Co^{2+} one and therefore the complexes of the divalent first-row transition metal ions with **L4** do not obey the Irving–Williams series. This was tentatively interpreted [6] speculating a possible pentacoordination of the Ni^{2+} complex of **L4**, which is not favoured in terms of

CFSE [6,54]. However, this hypothesis was not proved in the present work. The Cu^{2+} complex of **L1** presents a slightly higher value of stability constant than that of **L4** because the copper ion is more stable (by crystal field stabilisation energy) when pentacoordinated (square-pyramidal or trigonal bipyramidal) [54] and the structure adopted by the complex of **L1** points to a square pyramidal one.

Preparation and characterization of different two types of di-μ-oxo dimanganese(IV) complexes with tetradentate Schiff bases

Hitoshi Torayama, Tamao Nishide, Hideyuki Asada, Manabu Fujiwara and Takayuki Matsushita*

Department of Materials Chemistry, Faculty of Science and Technology, Ryukoku University, Seta, Otsu 520-21, Japan

(Received 22 April 1997; accepted 3 June 1997)

Abstract—Novel di-μ-oxo dimanganese(IV) complexes with a series of tetradentate Schiff base ligands have been prepared and characterized by spectroscopy, magnetic susceptibility, electrochemical measurements and X-ray crystallography. The di-μ-oxo dimanganese(IV) complexes, $[Mn^{IV}(\mu\text{-salophen})(\mu\text{-O})]$, **1** (salophen H_2 = *N*,*N*′-disalicylidene-1,2-diaminobenzene), $[Mn(\mu\text{-salen})(\mu\text{-O})]_2$, **2** (salen$H_2$ = *N*,*N*′-disalicylidene-1,2-diaminoethane), $[Mn(salen)(\mu\text{-O})]_2$, **3**, $[Mn(salipn)(\mu\text{-O})]_2$, **4** (salipn$H_2$ = *N*,*N*′-disalicylidene-1,2-diaminopropane) and $[Mn(salbn)(\mu\text{-O})]_2$, **5** (salbn$H_2$ = *N*,*N*′-disalicylidene-1,4-diaminobutane), have been found to be obtained by the reaction of the tetradentate Schiff base ligands and potassium permanganate ($KMnO_4$) in MeCN with stirring at room temperature. X-ray analysis revealed that these complexes are classified by two different types of di-μ-oxo manganese(IV) complexes in the coordination features of the ligands: one of them (**1** and **2**) has a structure in which salophen or salen ligands are coordinated to two manganese ions as a bridging bidentate ligand, whereas the other (**3, 4** and **5**) has a structure in which salen, salipn or salbn ligands are coordinated to each manganese ion as a tetradentate ligand. These types were characterized from their IR spectra around 650 cm^{-1}, UV–vis spectra and electrochemical properties. © 1997 Elsevier Science Ltd

Keywords: Photosystem II; oxygen-evolving center; di-μ-oxo dimanganese(IV) complexes; tetradentate Schiff base ligand; crystal structure.

Manganese plays an important role in biological redox systems, which is exemplified by the oxygen-evolving center of Photosystem II (PSII OEC) in green plants. The current understanding is that there are four manganese atoms per OEC, although their precise arrangement has not been determined unambiguously. EXAFS spectra of the OEC indicate that the catalytic site in the system consists of an oxo-manganese tetramer with two short Mn–Mn (2.7 Å) and two somewhat longer Mn–Mn (3.3 Å) distances [1–3]. During the water oxidation cycle these are of the (II), (III), and (IV) valence states. In order to understand its function, a number of oxomanganese cluster with various nuclearity, ligation, and number and type of oxo-bridges, have been prepared and studied [4–10]. In particular, there have been many reports on the preparation of structurally characterized di-μ-oxo dimanganese complexes, since the close Mn–Mn distance of OEC (2.7 Å) implies a strong interaction between the manganese atoms of the substructure consistent with a di-μ-oxo dimanganese core. All of the common stable higher oxidation states (i.e. III,III; III,IV; IV,IV) of manganese have been achieved in the di-μ-oxo dimanganese complexes. So far, the most of di-μ-oxo dimanganese(IV) complexes [11–22], such as $[Mn^{IV}(salpn)(\mu\text{-O})]_2$, **6** (salpn$H_2$ = *N*,*N*′-disalicylidene-1,3-diaminopropane) [11–13], have been prepared by the reaction of mononuclear manganese(II) or manganese(III) complexes with dioxygen, hydrogen peroxide, or other oxidants.

Recently, we have reported on the properties and molecular structures of di-μ-oxo dimanganese(IV) complexes, $[Mn^{IV}(\mu\text{-salophen})(\mu\text{-O})]_2$, **1** (salophen$H_2$ = *N*,*N*′-disalicylidene-1,2-diaminobenzene), $[Mn^{IV}(salbn)(\mu\text{-O})]_2$, **5** (salbn$H_2$ = *N*,*N*′-disalicylidene-1,4-diaminobutane) and $[Mn^{IV}(N\text{-R-X-sal})_2(\mu\text{-O})]_2$ (*N*-R-X-salH = *N*-alkyl-substituted-salicyli-

deneamine) obtained by the reaction of $KMnO_4$ with these ligands in MeCN [23,24]. In this paper, we describe the preparation and the detailed properties of different two types of novel dinuclear manganese(IV) complexes with a di-μ-oxo structure.

EXPERIMENTAL

Preparation of tetradentate Schiff base ligands

The tetradentate Schiff base ligands used in this work, *N,N'*-disalicylidene-1,2-diaminobenzene (salophenH_2), *N,N'*-disalicylidene-1,2-diaminoethane (salenH_2), *N,N'*-disalicylidene-1,2-diaminopropane (salipnH_2), and *N,N'*-disalicylidene-1,4-diaminobutane (salbnH_2) were obtained by the condensation of salicylaldehyde and appropriate diamines in methanol. The products were recrystallized from methanol and dried *in vacuo*.

Preparation of di-μ-oxo dimanganese complexes

$[Mn^{IV}(\mu\text{-}salophen)(\mu\text{-O})]_2$, **1**. The manganese(IV) complex, $[Mn^{IV}(\mu\text{-salophen})(\mu\text{-O})]_2$, **1,** was prepared by the reaction of salophenH_2 (0.27 g, 1.0 mmol) and $KMnO_4$ (0.16 g, 1.0 mmol) in MeCN (400 cm^3) with stirring at room temperature. The solution color changed from purple to brown and was allowed to stand in the dark at room temperature. Two weeks later the resulting brownish black crystals were collected on a glass filter (yield 51%). IR spectrum on KBr pellets (cm^{-1}): 1608(vs), 1586(m), 1534(s), 1464(m), 1444(s), 1318(m), 1190(m), 1150(m), 755(m), 641(s), 632(m).

$[Mn^{IV}(\mu\text{-}salen)(\mu\text{-O})]_2$, **2** *and* $[Mn^{IV}(salen)(\mu\text{-O})]_2$, **3**. The reaction of salenH_2 and $KMnO_4$ yielded two types of di-μ-oxo dimanganese(IV) complexes. The manganese(IV) complex, $[Mn^{IV}(\mu\text{-salen})(\mu\text{-O})]_2$, **2** and $[Mn^{IV}(salen)(\mu\text{-O})]_2$, **3** were prepared by the reaction of salenH_2 (1.08 g, 4.0 mmol) and $KMnO_4$ (0.64 g, 2.0 mmol) in MeCN (200 cm^3) with stirring at room temperature. The solution color changed from purple to brown red and 24 h after a mixture of **2** and **3** precipitated as brown solids was collected on a glass filter and dried *in vacuo*. They were extracted with dichloromethane (CH_2Cl_2) (250 cm^3), and **3** was obtained with manganese oxide as the brown residue. The extract was reprecipitated by the addition of MeCN and the resulting brownish red micro crystals, **2,** were collected on a glass filter and dried *in vacuo*. They were recrystallized from CH_2Cl_2 and MeCN (yield 0.45 g, 30%). In addition, **3** was found to be obtainable preferentially by the reaction of the Schiff base (0.56 g, 2.0 mmol) and $KMnO_4$ (0.32 g, 2.0 mmol) in a mixed solvent of MeCN and H_2O (4 : 1) (200 cm^3) with stirring at room temperature. The solution color changed from purple to brown and was allowed to stand in the dark at room temperature. Two weeks later the resulting brownish black crystals, **3,** were collected on a glass filter (yield 70%). IR spectrum on KBr pellets (cm^{-1}) : complex **2** ; 1627(vs), 1600(s), 1543(m), 1468(m), 1449(s), 1298(s), 753(m), 634(s), 453(m). Complex **3**; 3435(m), 1632(vs), 1600(s), 1540(s), 1447(s), 1339(m), 1297(s), 757(m), 658(m), 648(m), 627(m), 604(s), 460(m).

$[Mn^{IV}(salipn)(\mu\text{-O})]_2$, **4**. The manganese(IV) complex, $[Mn^{IV}(salipn)(\mu\text{-O})]_2$, **4,** was prepared by the reaction of the Schiff base (0.56 g, 2.0 mmol) and $KMnO_4$ (0.32 g, 2.0 mmol) in MeCN (200 cm^3) with stirring at room temperature. The solution color changed from purple to brown and was allowed to stand in the dark place at room temperature. Two weeks later the resulting brownish black crystals were collected on a glass filter (yield 75%). A single crystal of **4** was obtained by recrystallization from methanol. This complex is considered to be one of isomers of $[Mn^{IV}(salipn)(\mu\text{-O})]_2$, because the salipn ligand has an asymmetric carbon atom on the bridging propylene group. Single crystals of $\mathbf{4}\cdot 2CH_3OH$ have been used for X-ray crystallographic characterization. IR spectrum on KBr pellets (cm^{-1}): 1628(vs), 1600(s), 1540(m), 1445(s), 1336(m), 1299(s), 760(m), 663(m), 638(m), 609(s), 454(m).

$[Mn^{IV}(salbn)(\mu\text{-O})]_2$, **5**. The manganese(IV) complex, $[Mn^{IV}(salbn)(\mu\text{-O})]_2$, **5,** was prepared by the reaction of salbnH_2 (0.59 g, 2.0 mmol) and $KMnO_4$ (0.32 g, 2.0 mmol) in MeCN (400 cm^3) with stirring at room temperature. The solution color changed from purple to brown and was allowed to stand in the dark at room temperature. After one week the resulting brownish black crystals were collected on a glass filter (yield 76%). IR spectrum on KBr pellets (cm^{-1}): 2955(m), 2925(m), 1622(vs), 1598(s), 1542(s), 1470(m), 1444(s), 1333(m), 1308(s), 1149(m), 756(s), 738(m), 650(m), 631(s), 619(s), 603(m).

Elemental analyses data for all of the complexes are given in Table 1.

Physical measurements

Elemental analyses were made on Yanaco Model CHN-CORDER MT-5. UV–vis and IR spectra were recorded on a Shimadzu Model UV-3100 spectrophotometer and Shimadzu Model IR-470 infrared spectrophotometer, respectively. Electrochemical studies were performed under argon, using a BAS Model CV-27 voltammograph equipped with a Graphtec Model WX 2400 XY recorder and a standard three-electrode assembly (glassy carbon working, Pt wire auxiliary, and Ag/AgCl MeCN 0.1 M *n*-Bu_4NClO_4, TBAP, reference electrode) with 0.1 M TBAP (*n*-Bu_4NClO_4) as the supporting electrolyte. All the redox potentials were corrected to the saturated calomel electrode (SCE). Magnetic susceptibility measurements were carried out by the Gouy method at room temperature. The temperature dependency of the magnetic susceptibilities was obtained by the Faraday method from 5 to 290 K, using a Tamagawa Faraday method magnetic balance.

Table 1. Elemental analyses of the complexes

Complex	Formula	Analyses[a] C (%)	H (%)	N (%)	Mn (%)
1·2MeCN	$Mn_2C_{44}H_{34}N_6O_6$	62.2 (62.0)	4.10 (4.02)	9.86 (9.86)	12.5 (12.9)
2·2MeCN	$Mn_2C_{36}H_{34}N_6O_6$	56.6 (57.2)	4.50 (4.53)	10.9 (11.1)	14.9 (14.5)

[a] Required values in parentheses.

X-ray crystallography

Single crystals of **1**·2MeCN, **2**·2MeCN and **5**·2MeCN were obtained by one-step reaction of the Schiff bases and $KMnO_4$. On the other hand, single crystals **4**·2CH_3OH were obtained by recrystallization from CH_3OH. A crystal was mounted in a glass capillary and coated with silicone oil. All the data were collected on a Rigaku AFC7R four circle automated diffractometer with graphite monochromated Mo-K_α radiation ($\lambda = 0.71069$ Å) at room temperature. Unit-cell parameters were obtained from a least squares fit of 25 reflections, $8.0 < 2\theta < 15.9°$ for **1**·2MeCN, $6.5 < 2\theta < 21.8°$ for **2**·2MeCN, $8.0 < 2\theta < 14.6°$ for **4**·2CH_3OH and $8.2 < 2\theta < 15.3°$ for **5**·2MeCN. Three standard reflections were measured every 150 reflections; they showed no systematic decay throughout data collection. The data were corrected for Lorentz and polarization effects. All the calculations were carried out using the TEXSAN [25] crystallographic software package. The structure of **1**·2MeCN was solved using direct methods (MITHRIL84) [26] and expanded using Fourier techniques (DIRDIF) [27]. The structure of **2**·2MeCN was solved using heavy-atom Patterson methods (SAP191) [28] and expanded using Fourier techniques. The structures of **4**·2CH_3OH and **5**·2MeCN were solved using direct methods (SHELX86) [29] and expanded using Fourier techniques. These structures were refined by the full-matrix least-squares technique with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were introduced in calculated positions but not refined. Crystallographic data are summarized in Table 2.

Reagents

The reagents (salicylaldehyde and diamines) were obtained commercially and used without further purification. $KMnO_4$ was of the reagent grade (99.5%). MeCN was purified by distillation over P_4O_{10} twice and then distilled further before use. Other solvents were purified by usual method.

RESULTS AND DISCUSSION

Reactions of $KMnO_4$ with tetradentate Schiff base ligands

In acidic or basic aqueous solutions, a permanganate ion acts as a powerful oxidizing agent: its standard electrode potential being +1.51 or +0.50 V, respectively. We have found that $KMnO_4$ is soluble in dry acetonitrile (MeCN) and the solution is stable for about 24 h. The redox potential of $KMnO_4$ in MeCN was found to be −1.10 V (*vs* SCE), which can be assigned to the redox couple of $Mn^{VII}O_4^- \leftrightarrow Mn^{VI}O_4^{2-}$. This means that MnO_4^- is not so powerful oxidant in MeCN.

Figure 1 shows the absorption spectral changes of a MeCN solution of $KMnO_4$ caused by the addition of a MeCN solution of salbnH_2 in different molar ratios measured at room temperature. The intensity of characteristic absorption bands at 525, 545 and 570 nm for MnO_4^- ion decreased with addition of the salbnH_2 solution. The final absorption spectrum observed after 12 h exhibits a new broad absorption band around 500 nm, which can be assigned to LMCT transitions for Mn—O bonds of a di-μ-oxo dimanganese(IV) complex.

The dinuclear manganese(IV) complexes with a di-μ-oxo structure were prepared by the reaction of a series of tetradentate Schiff base ligands and $KMnO_4$ in MeCN with stirring at room temperature. This synthetic method has the advantage that high-valent manganese complexes can be obtained as crystals in 50–70% yields depending on the ligands by one-step reaction, in which MnO_4^- may be reduced with a part of the ligands.

Molecular structures of di-μ-oxo dimanganese complexes

From the X-ray crystallography, the complexes obtained by the reaction of $KMnO_4$ with tetradentate Schiff base ligands are found to be classified into two different types of di-μ-oxo dimanganese(IV) complex: one of them, **1** and **2**, is a bridging ligand, and the other, **4**, **5** and $[Mn^{IV}(salpn)(\mu\text{-}O)]_2$, **6**, is a dimer type.

Although X-ray structural analysis of **3** has not yet been successful, the results of other physico-chemical measurements indicate that **3** belongs to the dimer type of di-μ-oxo manganese(IV) complex.

Bridging ligand type

The di-μ-oxo dimanganese(IV) complexes, [Mn^{IV}(μ-salophen)(μ-O)]$_2$, **1**, and [Mn^{IV}(μ-salen)(μ-O)]$_2$, **2**, adopt the unusual structure in which two tetradentate Schiff base ligands bridge two manganese atoms. The ORTEP plots of **1** and **2** are shown in Figs 2 and 3 and these selected bond distances and angles are listed in Tables 3 and 4, respectively. These structures consist of two Mn^{IV} centers bridged by two oxygen atoms to yield a planar Mn_2O_2 core. In the structures of **1** and **2** two salophen or salen ligands bridge two manganese atoms with a planar Mn_2O_2 core and bond *via* one phenolic oxygen atom and

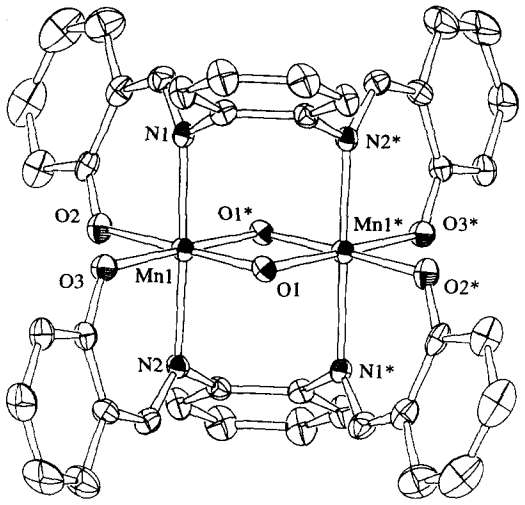

Fig. 2. Molecular structure of $[Mn^{IV}(\mu\text{-salophen})(\mu\text{-O})]_2$, **1**.

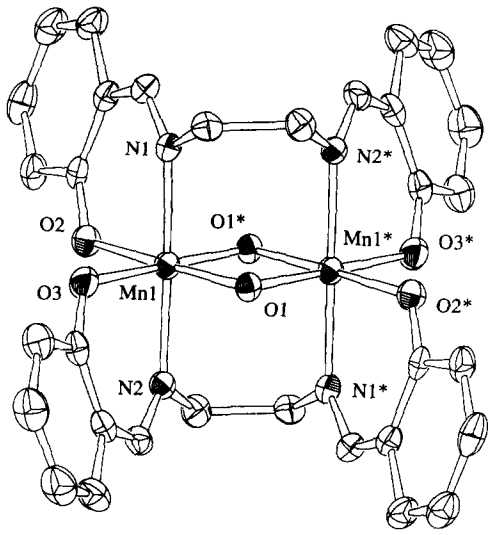

Fig. 3. Molecular structure of $[Mn^{IV}(\mu\text{-salen})(\mu\text{-O})]_2$, **2**.

one imine nitrogen atom to each manganese atom to complete the roughly octahedral coordination environment. The Mn–Mn separations of 2.718 (2) Å for **1** and 2.706 (2) Å for **2** are shorter than those reported for the $[Mn^{IV}(salpn)(\mu\text{-O})]_2$, **6** [2.728 (1) or 2.731 (2) Å] [12,13], and this may be caused by the existence of μ-salophen or μ-salen as a bridging ligand. As a stronger ligating atom, phenolic oxygen atoms of the ligands are oriented in the plane with the Mn_2O_2 core, and as a weaker ligating atom, imine nitrogen atoms are located to *cis* positions of the Mn_2O_2 core. The Mn—O (phenolate oxygen) and Mn—N (imine nitrogen) bond distances of **1** and **2** are almost regular: Mn—O, 1.934 (3) and 1.923 (4) Å for **1**, and 1.916 (4) and 1.926 (4) Å for **2**; Mn—N, 2.024 (5) and 2.015 (4) Å for **1**, and 2.002 (4) and 2.014 (4) Å for **2**.

As for complexes **1** and **2**, N—Mn—O angles formed by phenolic oxygen and imine nitrogen ligating atoms of these ligands and the manganese atom are close to a right angle [88.7 (2), 88.5 (2), 90.7 (2) and 90.2 (2)° for **1** and 90.4 (2), 90.6 (2), 88.3 (2) and 89.6 (2)° for **2**] and N—Mn—N angles are close to 180° [177.1 (2) for **1** and 177.7 (2)° for **2**]. Thus, there are few distortions around the manganese ions of **1** and **2**.

Recently, the bridging ligand type of the di-μ-oxo dimanganese(IV) complex, $[Mn^{IV}(\mu\text{-dbsalen})(\mu\text{-O})]_2$ ($dbsalenH_2$ = *N,N'*-di-3,5-dibromo-salicylidene-1,2-diaminoetane), has been prepared from the reaction of $dbsalenH_2$ and $Mn(ClO_4)_2 \cdot 6H_2O$ in air [30]. Its structure is very similar to those of the present complexes, with the Mn–Mn distance being 2.688 (1) Å.

Dimer type

The ORTEP plots of the dimer type of di-μ-oxo dimanganese(IV) complexes $[Mn^{IV}(salipn)(\mu\text{-O})]_2$, **4**, and $[Mn^{IV}(salbn)(\mu\text{-O})]_2$, **5**, are shown in Figs 4 and 5 and these selected bond distances and angles are listed in Tables 5 and 6, respectively. These structures

consist of two Mn^{IV} centers bridged by two oxygen atoms to yield a planar Mn_2O_2 core with a Mn–Mn separation of 2.733 (3) Å for **4** and 2.729 (1) Å for **5**. In the structures of **4** and **5**, the salipn or salbn ligand bonds *via* two phenolic oxygen atoms and two imine nitrogen atoms around each manganese atom to complete a roughly octahedral coordination environment similar to **6**. These complexes have one phenolic oxygen atom and one imine nitrogen atom at *trans* and *cis* positions to a bridging oxo group of Mn_2O_2 unit. A distinct lengthening of the Mn—O (phenolate oxygen) and Mn—N (imine nitrogen) bond distances *trans* to the Mn—O (oxo) bonds is observed: Mn—O, 1.931 (6) (*trans*) and 1.907 (7) (*cis*) Å for **4** and 1.940 (2) (*trans*) and 1.910 (3) (*cis*) Å for **5**; Mn—N, 2.056 (8) (*trans*) and 1.975 (8) (*cis*) Å for **4** and 2.069 (3) (*trans*) and 2.008 (3) (*cis*) Å for **5**. As the length of bridging diamines of the Schiff base ligands becomes short to the turn of 1,4-diaminobutane (salbn), 1,3-diaminopropane (salpn) and 1,2-diaminopropane (salipn), the bond angles of these complexes at around manganese ions N(1)—Mn—N(2), O(2)—Mn—N(2) and O(3)—Mn—N(1) deviate gradually from a right angle or 180°; N(1)—Mn—N(2), 86.0 (1) for **5**, 84.7 (2) for **6** and 78.6 (4)° for **4**; O(2)—Mn—N(2), 171.8 (1) for **5**, 169.7 (1) for **6** and 166.4 (4)° for **4**; O(3)—Mn—N(1), 90.2 (1) for **5**, 95.5 (1) for **6** [13] and 100.1 (3)° for **4**. On the other hand, the other bond angles of these complexes, O(2)—Mn—N(1), O(3)—Mn—N(2) and O(2)—Mn—O(3), are almost constant and close to a right angle.

Structural distortions of the dimer type complexes **4**, **5** and **6** are significant compared with the ligand bridging type complexes. The Schiff base ligands, salipn, salbn and salpn in the dimer type complexes should coordinate to the central manganese ion by

adjusting their configurations due to the rigidity of the Mn_2O_2 unit; in fact the angularity distortion of the plane constituted by Mn_2O_2 unit was not observed by changes in the type of these Schiff base ligands (Table 7).

The different coordination feature of the Schiff base ligands between the bridging ligand and the dimer types may arise mainly from the difference in their flexibility. However, there is possibility that two types of complexes are formed in solution, because the Schiff base ligands salenH_2 and salipnH_2 having the same length of bridging diamine group [i.e. 1,2-diaminoethane (salen) and 1,2-diaminopropane (salipn)] take different coordination feature.

IR spectra

It has been reported that IR spectra of the di-μ-oxo dimanganese(IV) complexes exhibit sharp absorption bands characteristic for a $\{Mn_2O_2\}$ core in the region 600–700 cm^{-1}, which can be assigned to stretching vibrations of Mn—O (oxo) bonds [31]. Figure 6 shows the IR spectra of the bridging ligand type complexes,

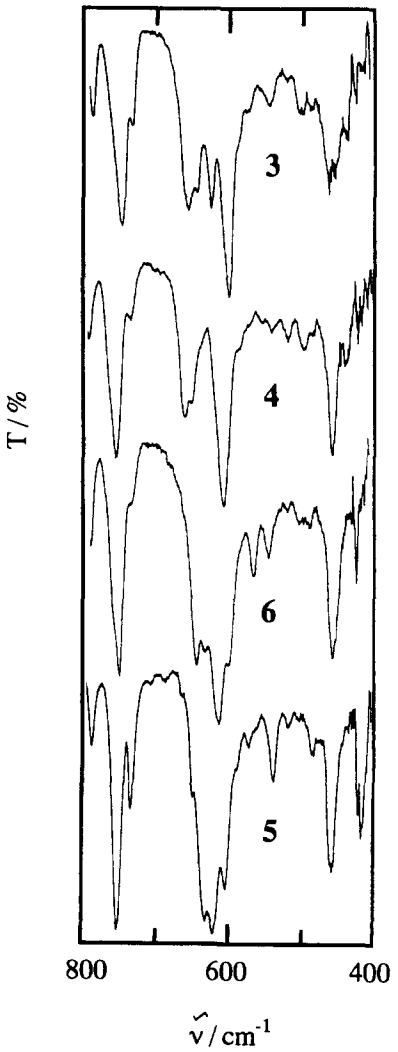

Fig. 7. IR spectra of the dimer type di-μ-oxo dimanganese(IV) complexes **3**–**6**.

1 and **2**, in this region which exhibit two intense bands at 641 and 632 cm^{-1} for **1** and at 642 and 634 cm^{-1} for **2**. On the other hand, the IR spectra of the dimer type complexes, **3**, **4**, **5** and **6**, exhibit a combination of three or four intense bands, 658, 648, 627 and 604 cm^{-1} for **3**, 660, 638 and 609 cm^{-1} for **4**, 650, 631, 619 and 603 cm^{-1} for **5**, and 648, 636, 618 and 604 cm^{-1} for **6**, as shown in Fig. 7. A clearly different spectral pattern is seen between the bridging ligand and dimer type complexes, nevertheless complexes **2** and **3** possess the same salen ligand. Such a difference may have arisen from the difference in the symmetry around the central manganese atoms: as shown in the structural determination of these complexes, the two *trans* positions of Mn—O (oxo) bonds in the bridging ligand type complexes are occupied by the phenolic oxygen atoms, whereas the corresponding *trans* positions in the dimer type complexes are occupied by the phenolic oxygen and imine nitrogen atoms. Moreover, different spectral features of these complexes are seen at around 1300 cm^{-1}, which can be assigned to the stretching vibrations due to the phenolic C—O bond. In this region, the spectra of the bridging ligand type (**1** and **2**) exhibit one intense band at 1318 cm^{-1} for **1** and at 1298 cm^{-1} for **2**, whereas those of the dimer type, (**3**, **4**, **5** and **6**) exhibit a medium intensity band additional to an intense band at 1339 and 1297 cm^{-1} for **3**, at 1336 and 1299 cm^{-1} for **4**, at 1333 and 1308 cm^{-1} for **5**, and at 1340 and 1298 cm^{-1} for **6**. This may arise from the fact that two phenolic oxygen atoms in these complexes are located each at *trans* and *cis* positions to the bridging oxo group of the Mn_2O_2 unit. These results indicate that both types can be distinguished by the IR spectra.

Electronic spectra

Figure 8 shows the electronic absorption spectra of the complexes, **1**, **2**, **4** and **5** in CH_2Cl_2. A general spectral feature exhibits two absorption bands around 410 and 480 nm with moderate intensity in the visible region and two or three absorption bands around 245, 270 and 360 nm with high intensity in the near- and ultra-violet region. All the numerical data are listed in Table 8. The former absorption bands can be assigned to the ligand to metal charge-transfer transitions from oxygen atoms of the oxo groups to manganese atoms, and the latter bands mainly to the transitions in the ligands themselves.

Although these absorption bands could not be assigned correctly, a clear difference in the UV spectra between the bridging ligand and dimer types of the di-

[c] $E_{ap} - E_{cp}$.

μ-oxo dimanganese(IV) complexes is seen in Fig. 8: the spectra of the former type exhibit an additional absorption peak around 270 nm, which is lacked in the spectra of the latter type. These absorption spectral differences may be caused by the difference in hybridization of the ligand π orbital systems and manganese $d\pi$ orbitals. As mentioned in the above IR spectra, two coordinating types of the tetradentate Schiff base ligands are also found to be discriminative from the UV spectra.

Electrochemistry

Cyclic voltammograms (CV) of the di-μ-oxo dimanganese(IV) complexes **1–5** were measured in dimethyl sulfoxide (DMSO) over the potential range from +1.00 to −1.70 V. In a DMSO solution, all the complexes exhibit a pair of quasi-reversible reduction and oxidation (see Fig. 9 and Table 8). The reduction waves of **1** and **2** (−0.24 and −0.36 V *vs* SCE, respectively) are observed at slightly positive potentials com-

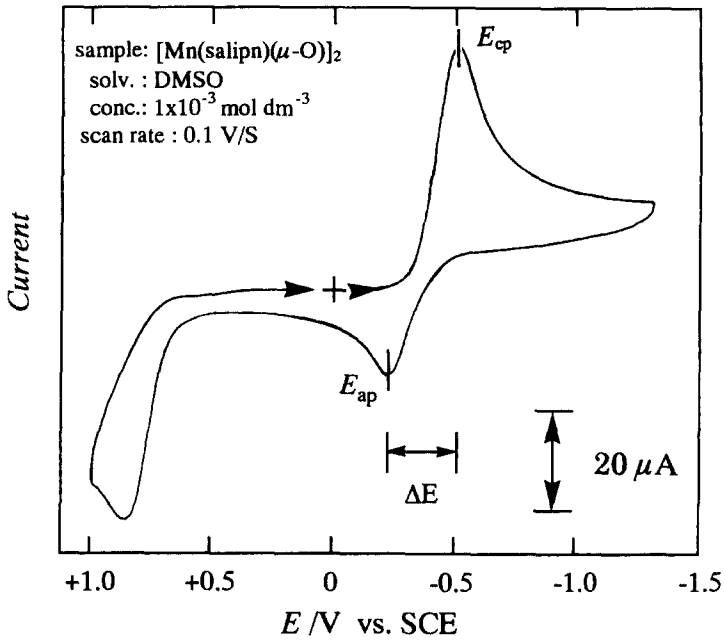

Fig. 9. Cyclic voltammogram (CV) of **4** in DMSO.

pared with those for **3**, **4** and **5** (−0.47, −0.51 and −0.46 V *vs* SCE, respectively). Controlled potential reduction of **5** in DMSO at −0.60 V showed that the reduction of the complex undergoes *via* a 2-electron electrode process, which means that $[Mn^{IV}O_2Mn^{IV}]^0$ is reduced to $[Mn^{III}O_2Mn^{III}]^{2-}$.

Magnetic properties

The magnetic susceptibilities were measured for complexes **1**, **2** and **5** in the temperature range 5–290 K and for the complexes **3** and **4** in the range 77–290 K by the Faraday method. The temperature-dependent effective magnetic moments for **1**, **2** and **5** per dimeric unit at 5, 77 and 290 K are calculated as follows: 0.86, 1.68 and 3.09 μ_B for **1**, 0.45, 1.29 and 2.98 μ_B for **2** and 0.75, 1.37 and 2.96 μ_B for **5**, respectively. And those for **3** and **4** per dimeric unit at 77 and 290 K are calculated as follows: 1.31 and 2.77 μ_B for **3** and 0.91 and 2.58 μ_B for **4**, respectively. These values indicate that an intramolecular antiferromagnetic interaction between the two manganese(IV) ions (d^3) exists in these complexes. The magnetic data obtained for **2** and **5** (Figs 10 and 11) were fitted by employing an expression derived from an isotropic spin-exchange Hamiltonian $H = -2JS_1 \cdot S_2$ ($S_1 = S_2 = 3/2$) and the Van Vleck equation. The magnetic data obtained for **1**, **3** and **4** (Figs 12 and 13) were fitted by the same method as the above, although these were used somewhat roughly approximation. The curve fitting leads to values of $J = -80$ cm^{-1}, $g = 1.78$, TIP $= 1.0 \times 10^{-3}$ and $P = 0.7\%$ for **2** and $J = -78$ cm^{-1}, $g = 1.71$, TIP $= 1.25 \times 10^{-3}$ and $P = 2.2\%$ for **5**, where TIP is the temperature-independent paramagnetism and P is the mole per cent of paramagnetic impurities assumed to be a mononuclear manganese(III) complex. The J values (g value) for **1**, **3** and **4** were −80 (1.85), −95 (1.71) and −88 cm^{-1} (1.87), respectively. These J values are comparable with those observed for the di-μ-oxo dimanganese(IV) having an ancillary ligand with both of O and N donating atoms, i.e. complex **6** [$J = -82$ cm^{-1} ($g = 1.79$)] [12] and $[Mn^{IV}(pic)_2(O)]_2$ [$J = -87$ cm^{-1} ($g = 1.83$)] (pic denotes a monoanion of picolinic acid) [14], and slightly lower than those ($J \approx -125$ cm^{-1}) for the di-μ-oxo dimanganese(IV) complexes having an ancillary ligand with all N donating atoms [15–17].

The temperature-dependent magnetic behavior for **1** is peculiar and will require further study: it did not fit and deviated at lower temperatures from the calculated values by applying the above mentioned equations. It can be ruled out that more paramagnetic impurities were included in the complex **1**, because the repeated measurements for it obtained from the different batch preparations also gave almost the same results. Figure 14 shows intermolecular close π–π stacking between the phenylene rings of *o*-phenylenediamine groups of salophen ligands of **1**, which are placed to form a parallel plane with separation by 3.40 Å (plane to plane distance). This distance is enough for π–π interaction between the phenylene rings [32–34]. Therefore, the temperature-dependent magnetic behavior for **1** may be caused by existence of intermolecular ferromagnetic interaction *via* the phenylene rings of *o*-phenylenediamine groups of salophen ligands. In this work, further experiments have not been carried out.

CONCLUSION

Two different types of di-μ-oxo dimanganese(IV) complex have been found to be obtained by the one step reaction of $KMnO_4$ with tetradentate Schiff base ligands in MeCN. The bridging ligand type of di-μ-oxo dimanganese(IV) complexes, **1** and **2**, adopts the unusual structure in which two tetradentate Schiff base ligands bridge two manganese atoms. In contrast, the dimer type, **3**, **4** and **5**, has a structure in which salen, salipn or salbn ligands are coordinated to each manganese ion as a tetradentate ligand. In addition,

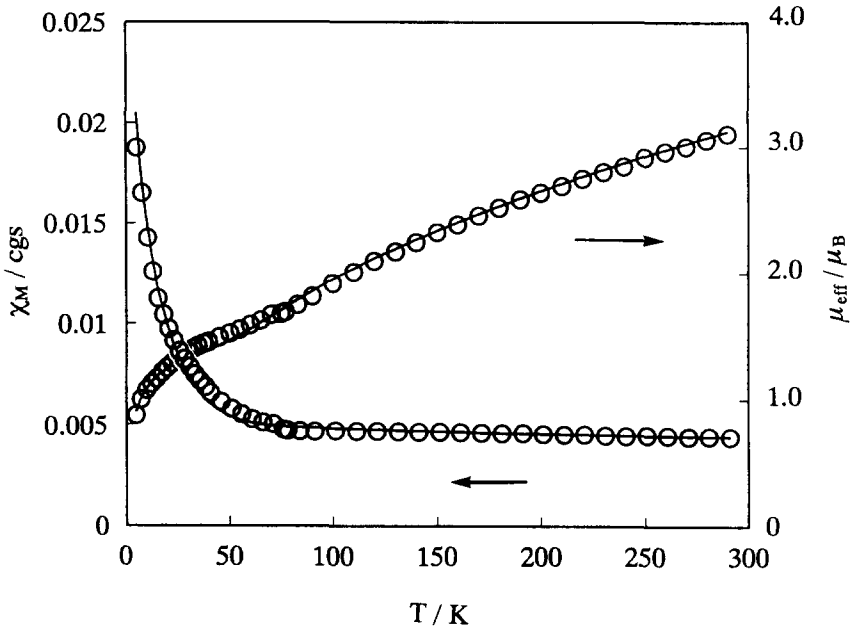

Fig. 12. Plots of molar susceptibility (left scale) and effective magnetic moment (right scale) per dimer *vs* temperature of a polycrystalline sample of complex **1**. Solid lines represent best fits of the data using the parameters described in the text.

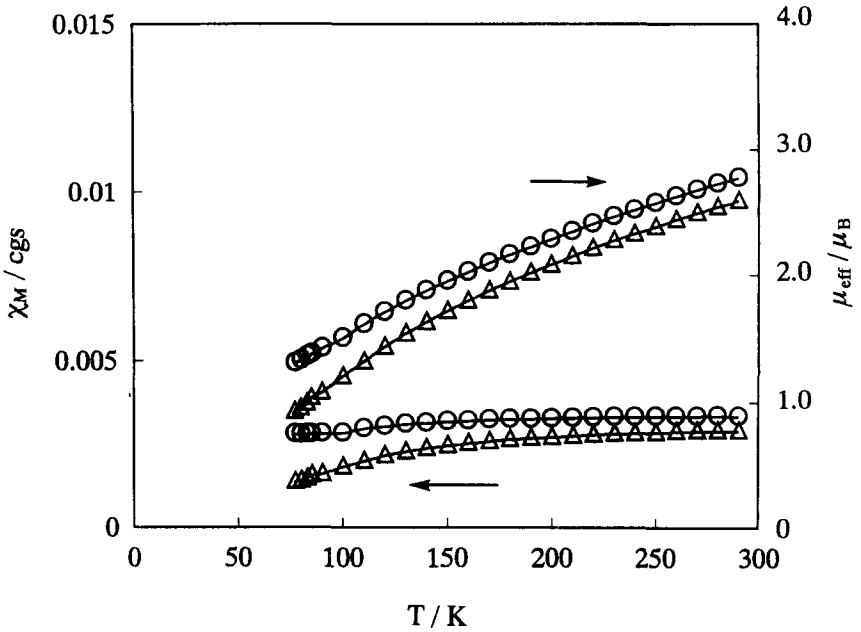

Fig. 13. Plots of molar susceptibility (left scale) and effective magnetic moment (right scale) per dimer *vs* temperature of polycrystalline samples of complexes **3** (○) and **4** (△).

these two types of di-μ-oxo dimanganese(IV) complexes, **2** and **3**, have been also obtained by the oxygenation of Mn^{II}(salen) with molecular oxygen, depending upon the organic solvents used [35]. Two such coordinating types of the Schiff base ligands are also found to be discriminative from the IR and UV spectra. The temperature-dependent effective magnetic moments of these complexes, with the exception of $[Mn^{IV}(\mu\text{-salophen})(\mu\text{-O})]_2$, **1**, indicate that an intramolecular antiferromagnetic interaction between the two manganese(IV) ions (d^3) exists in these complexes. A curious temperature-dependent mag-

(Received 21 April 1997; accepted 2 June 1997)

Abstract—The chloroborane, $ClB(C_6F_5)_2$, has been investigated as a useful synthon for the preparation of a series of amino(pentafluorophenyl)boranes. The compounds $[(Me_3Si)_2NB(C_6F_5)_2]$, **1**, $[(Me_3Si)(H)NB(C_6F_5)_2]$, **2**, and $[HN\{B(C_6F_5)_2\}_2]$, **3**, have been synthesised and **1** has been characterised by X-ray crystallography.
© 1997 Elsevier Science Ltd

Keywords: aminoborane; Lewis acid; X-ray crystallography; ^{11}B NMR spectroscopy; N—B π-bonding; pentafluorophenyl.

The nature of the bonding in aminoborane compounds has been subjected to numerous investigations as these species are analogues of asymmetrically substituted alkenes [1]. In particular, numerous attempts to quantify the extent of N—B π-bonding in these compounds *via* ^1H, ^{11}B and ^{13}C NMR spectroscopic measurements [2] and X-ray diffraction studies have been reported [3]. Pentafluorophenyl rings have been utilised as a means of introducing strongly electron withdrawing groups into Lewis acids and hence increasing the electrophilicity of the acceptor atom [4]. Metal imido complexes may be readily prepared by the reaction of H_2NR, $HN(SiMe_3)R$ or $RN(SiMe_3)_2$, R = alkyl or aryl, with suitable transition metal complexes [5] and we hoped that these aminoboranes would behave in an analogous manner. Most complexes containing the M=NR unit display little reactivity associated with the imido moiety and we hoped to activate this functionality by synthesising $L_nM{=}NBR_2$ complexes from aminoborane compounds possessing the highly electrophilic $\{B(C_6F_5)_2\}$ unit. Herein we report the synthesis of a series of aminoboranes from the precursor $ClB(C_6F_5)_2$ and a preliminary exploration of their reactivities.

RESULTS AND DISCUSSION

The reaction of equimolar amounts of $MN(SiMe_3)_2$, M = Na or K, and $ClB(C_6F_5)_2$ in toluene leads smoothly to the formation of a white solid characterised as $[(Me_3Si)_2NB(C_6F_5)_2]$, **1**. Cooling a concentrated pentane solution of the aminoborane produces large colourless crystals which were studied by X-ray crystallography. The molecular structure of **1** is shown in Fig. 1 and selected bond lengths and angles are given in Table 1. The analytical and spectroscopic data of compound **1** are unexceptional and are reported in Table 2.

The N—B bond length of 1.400(3) Å is at the shorter end of the range observed for N—B bonds in similar environments reflecting the strong electron

withdrawing capacity of the pentafluorophenyl rings; compare with 1.433(6) Å in $[^tBu(Me_3Si)NBPh_2]$, 1.430(3) Å in $[HN(BPh_2)_2]$, 1.435(3) Å in $[(Me)N(BPh_2)_2]$ and 1.439(3) Å in $[HN\{B(2,4,6\text{-trimethylphenyl})_2\}_2]$ [6]. The Si, N and B atoms in compound **1** are coplanar indicating some degree of delocalised π-bonding (Fig. 2). The bulkiness of the pentafluorophenyl rings preclude them from participating fully in this type of bonding and they adopt an orientation which strikes a compromise between maximum π-bonding and minimum steric repulsions, one in which the rings are separated by an interplanar angle of 89.1°. The interplanar angle, α, between the C_2B and NSi_2 planes is 34.0°. The closely related compound, $[^tBu(Me_3Si)NBPh_2]$, mentioned above [6], was synthesised in a similar fashion from the reaction of Ph_2BBr and $LiN^tBu(SiMe_3)$ and displays little structural variation from compound **1**. The molecule $[(F_3C)_2BNMe_2]$ has also been structurally characterised by electron diffraction and exhibits a B—N bond length of 1.425(18) Å [7]. The CF_3 group has similar σ acceptor properties to those of the C_6F_5 moiety but whilst the latter species is also able to function as a π donor the former is not.

In an attempt to prepare the mono(trimethylsilyl) analogue of **1**, $ClB(C_6F_5)_2$ was reacted with one equivalent of $HN(SiMe_3)_2$ in toluene. After heating at 70°C for 1.5 h, under slightly reduced pressure, the solvent was removed *in vacuo* and the product extracted with hexane. Concentration and cooling of this colourless solution to −78°C results in the formation of a white solid identified as having the empirical formula $[(Me_3Si)(H)NB(C_6F_5)_2]$. Characterising data for the compound is given in Table 2. The ^{11}B NMR spectrum of this compound in C_6D_6 reveals two signals in the ratio of approximately 4 : 1 (δ 38.2 ppm, **2**, and δ −2.8 ppm, **2′**, respectively). The minor signal is typical of a four co-ordinate boron environment indicating that in solution about 20% of the aminoborane exists as a dimer, **2′** (Fig. 3).This phenomenon has been frequently observed for $R_2NBR'_2$ compounds and, when R and R′ are alkyl or aryl substituents, the extent of dimerisation appears to be mainly dependent on the steric demands of the R groups [1,8]. No dimer formation is observed for compound **1** presumably due to increased steric crowding around the nitrogen centre in the *bis*(trimethylsilyl) derivative. If the nitrogen lone pair is involved in π bonding to silicon in both **1** and **2** then the presence of a single $SiMe_3$ substituent in **2** should, on purely electronic grounds, encourage dimerisation in the (*mono*)trimethylsilylated species.

Harsher reaction conditions (70°C in octane for 7 h) are required to synthesise $[HN\{B(C_6F_5)_2\}_2]$, **3**, from the reaction between $HN(SiMe_3)_2$ and 2 equiv. of $ClB(C_6F_5)_2$. Under the same conditions the reaction of equimolar amounts of $HN(SiMe_3)_2$ and $ClB(C_6F_5)_2$

[f] CD_2Cl_2.

also produces compound **3** but in slightly reduced yield. The aminoborane may be purified by crystallisation although unfortunately the crystals obtained were unsuitable for X-ray diffraction. The spectroscopic properties of compound **3** are unexceptional and described in Table 2. The molecular ion peak was not observed by mass spectroscopy although a peak was visible at 360 amu corresponding to $\{HNB(C_6F_5)_2\}$ presumably formed by loss of $\{B(C_6F_5)_2\}$ from the parent ion. Evidently decomposition occurs resulting in the observation of further peaks assignable to $B(C_6F_5)_3$ and $H_3N\cdot B(C_6F_5)_3$. The spectroscopic data of compound **3** is consistent with the structure described in Fig. 4.

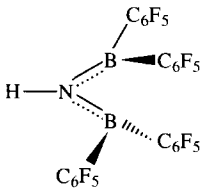

Fig. 4. Structural representation of compound **3**.

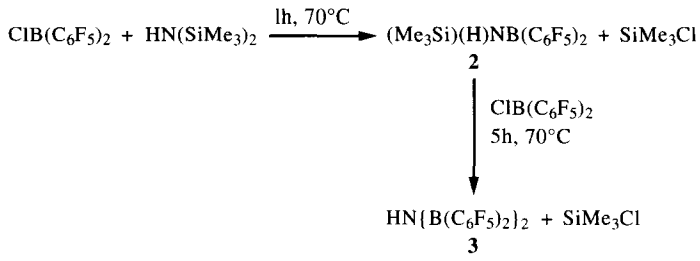
It is clear that the reaction of $ClB(C_6F_5)_2$ with $HN(SiMe_3)_2$ proceeds *via* elimination of $SiMe_3Cl$ in a stepwise fashion such that, after a reaction time of 1.5 h, compound **2** and one mole of $SiMe_3Cl$ has formed [9]. If the reaction is continued further, a second equivalent of $SiMe_3Cl$ is produced with concomitant for-



Stepwise formation of compound **3** from $ClB(C_6F_5)_2$ and $HN(SiMe_3)_2$.

mation of aminoborane **3**, eq. (1). Attempts to monitor the reaction *via in situ* ^{11}B and ^{1}H NMR spectroscopies in a sealed NMR tube were hindered by the observation that under such conditions the reaction reaches an equilibrium mixture of $SiMe_3Cl$, $ClB(C_6F_5)_2$, $HN(SiMe_3)_2$ and compound **2** and that the ^{11}B NMR spectroscopic resonances for $ClB(C_6F_5)_2$ and compound **2** are coincident. From integration of the ^{1}H NMR spectroscopic signals assigned to the $SiMe_3$ groups it appears that equilibrium is reached when approximately 80% of $HN(SiMe_3)_2$ has reacted to form compound **2**; the absence of a broad signal attributable to the amine proton in compound **3** indicates that **3** is formed from **2** only after complete consumption of $HN(SiMe_3)_2$.

Reactivity of compounds **1** *and* **2**

Compounds **1** and **2** were originally synthesised so as to obtain amines substituted with highly electrophilic $\{B(C_6F_5)_2\}$ units which would hopefully react with transition metal complexes to generate metal imido species with the general formula $L_xM{=}NB(C_6F_5)_2$. To date only one compound containing the $M{=}NBR_2$ moiety has been prepared; *cis,cis,trans*-$[W\{NB(mes)_2\}_2Cl_2(PMe_3)_2]$, mes = 1,3,5-trimethylphenyl, has been synthesised from the reaction of $[W(PMe_3)_4Cl_2]$ with N_3Bmes_2 and crystallography characterised [10]. However there are numerous examples of metal imido complexes which have been synthesised from the reaction of H_2NR, $RN(SiMe_3)_2$ or $HN(SiMe_3)R$, R = alkyl or aryl, with metal chlorides which is accompanied by HCl or HNR_3Cl formation [5].

To investigate the reactivity of compounds **1** and **2** we typically refluxed equimolar quantities of the aminoborane and metal chloride in CH_2Cl_2 for a few hours. None of the reactions were successful. For the complexes MCl_4, M = Zr, Hf, U, $[(\eta\text{-}^{i}PrC_5H_4)MoCl_4]$, $[(\eta\text{-}C_5Me_5)RhCl_2]_2$, $[(\eta\text{-}C_5H_5)NbCl_4]$, $[(\eta\text{-}C_5H_5)_2TiCl_2]$, $[(\eta\text{-}C_5Me_5)UCl_2]$, $[(\eta\text{-}C_5H_5)UCl_3]$ and $[UOCl_5]^-$ the starting materials could be recovered unchanged whilst reactions with $MoCl_5$ and $NbCl_5$ gave numerous uncharacterisable species. It is believed that formation of the M=NR unit proceeds *via* initial coordination of the nitrogen lone pair to the metal centre followed by elimination of either HCl or $SiMe_3Cl$. Based upon this premise the lack of reactivity of the nitrogen lone pair in aminoboranes **1** and **2** may be because it is either too sterically protected or electronically unavailable, the latter due to delocalised Si—N—B π-bonding. Attempts to generate the anion $[(SiMe_3)NB(C_6F_5)_2]^-$ by reaction of compound **1** with $^{n}Bu_4NF$ (as a THF solution containing 5% H_2O) resulted in the formation of $[^{n}Bu_4N][B(C_6F_5)_2F(OH)]$ (^{11}B NMR: 1.3 d, J_{BF} = 56 Hz) [11] whilst KF in the presence of 18-crown-6 failed to elicit any reaction. The reaction of compound **2** with $^{n}BuLi$ in pentane at $-78^{\circ}C$ resulted in the formation of a white solid however, as the reaction was gradually warmed to room temperature a small explosion occurred suggesting that LiC_6F_5, which is extremely thermally sensitive, may have been formed. Finally, to try and understand the failure of these aminoboranes to react with metal chlorides, we investigated the reaction of compound **2** with $[NMe_3 \cdot HCl]$. The formation of metal-imido species from the reaction of L_xMCl_y complexes with primary or secondary amines simultaneously generates HCl which may prevent the formation of the desired $[L_xM{=}N{-}B(C_6F_5)_2]$ species. Hydrogen chloride is observed to add across the N—B bond to form the Lewis acid adduct $(Me_3Si)NH_2 \cdot ClB(C_6F_5)_2$.

EXPERIMENTAL

Fourier-transform ^{1}H and ^{11}B NMR spectra were recorded on a Bruker AM 300 spectrometer at 300 and 96 MHz, respectively, ^{13}C NMR spectra were recorded on a Bruker AM 300 spectrometer at 75.5 MHz or Varian Unity plus 500 spectrometer at 125 MHz, ^{19}F NMR spectra were recorded similarly at 470 MHz: ^{1}H and ^{13}C shifts are reported with respect to δ 0 for $SiMe_4$, ^{11}B with respect to δ 0 for $BF_3 \cdot OEt_2$, ^{19}F with respect to δ 0 for $CFCl_3$; all downfield shifts are positive. Infrared spectra were recorded on either Mattson 'Polaris' Fourier–transform, Perkin–Elmer FT 1710 spectrophotometer, or Perkin–Elmer 457 grating spectrometers. Mass spectra were obtained on a Varian MSS instrument in this department or by Dr Ballantyne at the SERC facility at the University of Swansea on a Varian E 109 instrument. Microanalyses were obtained from the microanalytical department of this department.

All reactions were carried out under nitrogen using standard Schlenk techniques. Solvents were dried over suitable reagents and freshly distilled under N_2 before use. The compounds $[KN(SiMe_3)_2]$, $[NaN(SiMe_3)_2]$, $HN(SiMe_3)_2$, KF and 18-crown-6 were used as received (Aldrich), $^nBu_4NF$ was obtained as a THF solution (5% H_2O) (Aldrich) and used without further purification whilst $ClB(C_6F_5)_2$ [4c] was prepared as previously described.

Preparations

$[(Me_3Si)_2NB(C_6F_5)_2]$, **1**. $ClB(C_6F_5)_2$ (760 mg, 2.00 mmol) was dissolved in petroleum ether (b.p. 30–40°C) and slowly added at room temperature to a toluene solution of $NaN(SiMe_3)_2$ (370 mg, 2.02 mmol). The mixture was allowed to stir for 30 min and then pumped to dryness. The title compound was extracted from the residue using pentane leaving behind KCl as a white solid. Concentration of this solution and cooling to 5°C resulted in the formation of large colourless block shaped crystals of $[(Me_3Si)_2NB(C_6F_5)_2]$ (952 mg, 94% yield). Compound **1** sublimes at 75°C.

$[(Me_3Si)(H)NB(C_6F_5)_2]$, **2**. $ClB(C_6F_5)_2$ (760 mg, 2.00 mmol) was dissolved in toluene (30 cm^3) in a Rotaflo ampoule and $HN(SiMe_3)_2$ (0.42 cm^3, 2.00 mmol) added. The ampoule was sealed under slightly reduced pressure and heated at 70°C for 1.5 h. The solvent was removed *in vacuo* to leave a white solid. The product was extracted into pentane and the solution concentrated and cooled to −80°C. A white solid precipitated and, after removal of the supernatant liquid and drying *in vacuo*, $[(Me_3Si)(H)NB(C_6F_5)_2]$ was isolated (682 mg, 79% yield).

$[HN\{B(C_6F_5)_2\}_2]$, **3**. $ClB(C_6F_5)_2$ (760 mg, 2.00 mmol) was dissolved in octane (50 cm^3) in a Rotaflo ampoule and $HN(SiMe_3)_2$ (0.21 cm^3, 1.00 mmol) was added. The ampoule was closed and heated at 70°C for 7 h with regular removal of Me_3SiCl under reduced pressure. The solvent was removed *in vacuo* and the residual solid washed with hexanes. The product was extracted into toluene and the filtrate was concentrated and cooled to −80°C to give small white crystals of $[HN\{B(C_6F_5)_2\}_2]$ (282 mg, 40% yield).

Reaction of $[(Me_3Si)_2NB(C_6F_5)_2]$, **1**, *with* KF *and* 18-*crown*-6. $[(Me_3Si)_2NB(C_6F_5)_2]$ (134 mg, 0.265 mmol) was dissolved in toluene and slowly added to a toluene suspension of KF (30 mg, 0.52 mmol) and 18-crown-6 ether (70 mg, 0.265 mmol). The mixture was stirred at room temperature for 3.5 h and then the solvent removed *in vacuo*. Extraction with petroleum ether (b.p. 30°C–40°C) led to the recovery of unreacted aminoborane.

Reaction of $[(Me_3Si)_2NB(C_6F_5)_2]$, **1**, *with* $^nBu_4NF$. $[(Me_3Si)_2NB(C_6F_5)_2]$ (234 mg, 0.463 mmol) was dissolved in THF and a 1.0 M THF solution of $^nBu_4NF$ (0.47 ml, 0.47 mmol) was slowly added. The colourless solution was stirred at room temperature for 2 h. Solvent was removed *in vacuo* and the residue extracted into with petroleum ether (b.p. 30–40°C) to give the isolation of a white, non boron-containing solid: NMR (CD_2Cl_2, 298 K) ^1H (300 MHz) δ 3.5 (s); the residual solid is tentatively characterised as $[^nBu_4N][B(C_6F_5)_2F(OH)]$. ^{11}NMR ($CD_2Cl_2$, 298 K); ^{11}B (96 MHz) δ 1.3 (d, $J_{BF} = 56$ Hz).

Reaction of $[(Me_3Si)_2NB(C_6F_5)_2]$, **1**, *or* $[(Me_3Si)(H)NB(C_6F_5)_2]$, **2**, *with the metal chlorides*. MCl_4, M = Zr, Hf, U, $[(\eta\text{-}^iPrC_5H_4)MoCl_4]$, $[(\eta\text{-}C_5Me_5)RhCl_2]_2$, $[(\eta\text{-}C_5H_5)NBCl_4]$, $[(\eta\text{-}C_5H_5)_2TiCl_2]$, $[(\eta\text{-}C_5Me_5)UCl_2]$, $[(\eta\text{-}C_5H_5)UCl_3]$, $[UOCl_5]^-$, $MoCl_5$ *and* $NbCl_5$. Typically equimolar quantities of the aminoborane and metal chloride were refluxed in CH_2Cl_2 for a few hours. The reactions between $MoCl_5$ or $NbCl_5$ and compound **2** produced several products which could not be characterised. From all other reactions the starting reagents could be recovered unchanged.

Crystal structure determination of compound **1**

Experimental. Crystals of compound **1** were grown from pentane solutions at 278 K and dried *in vacuo*. A crystal was immersed in highly viscous perfluoropolyether to exclude oxygen and prevent solvent loss. It was then mounted on a glass fibre and plunged in a cold stream (150 K) nitrogen stream.

Crystal data. Compound **1**, $C_{18}H_{18}BF_{10}NSi_2$, $M = 505.31$ g mol^{-1}, monoclinic, $a = 11.054(4)$ Å, $b = 11.228(4)$ Å, $c = 18.619(3)$ Å, $\alpha = 105.77(2)°$, $V = 2224(1)$ Å^3, space group $P2_1/c$, $Z = 4$, $D_x = 1.51$ g cm^{-3}, $\mu = 23.12$ cm^{-1}, transparent prism, crystal dimensions $0.48 \times 0.51 \times 0.64$ mm^3.

Data collection and processing. The data for compound **1** was collected at 150 K on an Enraf-Nonius MACH3 diffractometer, ω–2θ scan mode with the ω scan width $= 0.66 + 0.25 \tan\theta$, ω scan speed 1.4–10.1° min^{-1}, graphite-monochromated Cu-K_α radiation ($\lambda = 1.5418$ Å). 4424 reflections were measured ($2 < \theta < 70°$, 0, h; 0, k; −1, l), 3978 unique (merging $R = 0.055$), giving 3844 with $I > 3\sigma(I)$. Neither significant crystal decay nor movement was noted.

Structure solution and refinement. The crystal structure was solved by direct methods and refined by the full-matrix least-squares method with all non-hydrogen atoms in anisotropic approximation (289 variables, observations/variables = 13.3). All hydrogen atoms were located in the difference Fourier maps and included in the final refinement with fixed positional and thermal parameters. Chebyshev weighting scheme [12] with parameters 31.90, 2.84 and 17.60 was applied. Corrections for Lorentz and polarisation effects but not for absorption were applied. Final R and R' values are 0.049 and 0.053. Minimum and maximum peaks in the final difference synthesis are −0.37 and 0.46 e Å^{-3}. All crystallographic calculations were carried out using the CRYSTALS program package on PC/AT −486 [13]. Neutral atom

scattering factors were taken from the usual sources [14]. Additional material is available from the Cambridge Crystallographic Data Centre.

CONCLUSION

The aminoboranes $[(Me_3Si)_2NB(C_6F_5)_2]$, **1**, $[(Me_3Si)(H)NB(C_6F_5)_2]$, **2**, and $[HN\{B(C_6F_5)_2\}_2]$, **3**, have been prepared and characterised. Compounds **1** and **2** fail to produce metal imido complexes when reacted with a variety of metal chloride complexes. This lack of reactivity may be caused by steric shielding of the nitrogen lone pair or reduced basicity due to strong Si_x—N—B π-bonding, $x = 2$ for compound **1**, 1 for compound **2**.

(Received 11 April 1997; accepted 2 June 1997)

Abstract—The rate of substitution by ethylenediamine, of Cl^-, in the substrates $[Pd(R_2N(CH_2)_2NR_2)Cl_2]$ and of 2,2′-bipyridine (bpy), in the complexes $[Pd(bpy)(R_2N(CH_2)_2NR_2)](ClO_4)_2$ (R = H, methyl, ethyl or phenyl) have been studied, at 25°C, respectively in dimethylformamide and in water. In both processes the rate of reaction depends on the nature of the substituent R at nitrogen. While the kinetic data for neutral complexes can be accounted for simply in terms of electronic and steric properties of the ligands, the trend of the kinetic constants seem to be related to the capacity of the various complexes to form hydrogen bonding with water.

Keywords: palladium(II) complexes; kinetics; ligand replacement; 2,2′-bipyridine; N-substituted ethylenediamine.

Dependence of the rate of reaction on electron density of the central metal is one of the essential features of the substitution reactions at square planar complexes [1]. In these processes, usually associative in character, decreasing electron density on the metal favours, in fact, the attack of the nucleophile, easing the formation of the activated complex so leading to increase in the rate of reaction. The capability of a ligand to exert its electron withdrawing or electron donating properties on the central metal, is therefore reflected on the rate of substitution of one of the coordinated ligands [2]. For a series of homologous complexes, differing only by the nature of the substituents at one of the ligands, the rate of displacement of a given ligand by a given nucleophile can be taken as a direct indication of the electron donating ability of the substituent.

In this investigation we have synthesised a series (Table 1) of neutral and dicationic palladium(II) complexes of the type $[Pd(RR'N(CH_2)_2NR''R''')Cl_2]$ and $[Pd(bpy)(RR'N(CH_2)_2NR''R''')](ClO_4)_2$ (bpy = 2,2′-bipyridyl; R = H, methyl, ethyl or phenyl) differing each other only be the nature of the substituents at the nitrogen atoms of ethylenediamine. Furthermore we have studied the rate of substitution of chloride, by ethylenediamine (en), in the neutral complexes, in dimethylformamide at 25°C, and the rate of substitution of bipy, by en, in the cationic complexes, in water at the same temperature. The kinetic parameters should give information on the electron donating properties of the substituents at ethylenediamine and, if charge is transmitted through the metal to the ancillary ligands, on the electron density of the coordinated ligands. This is particularly useful in the case of the cationic complexes since $[Pd(bpy)(H_2N(CH_2)_2NH_2)]^{2+}$ is known to interact [3] with DNA by intercalation. Variation of the rate of reaction in these complexes could give indications of the variations of electron density on bipyridine rings, useful to correlate the interactions of the various complexes with DNA.

EXPERIMENTAL

The chloro complexes $[Pd(RR'N(CH_2)_2NR''R''')Cl_2]$ were prepared following the procedure reported in the literature [4]. To this end, $K_2[PdCl_4]$ was heated with the appropriate substituted ethylenediamine in the presence of HCl. Experimental conditions such

as pH and reaction time were found to be strongly dependent on the particular ligand.

The complexes $[Pd(bpy)(RR'N(CH_2)_2NR''R''')](ClO_4)_2$ were prepared by treating the respective chlorocomplexes with silver perchorate in a ratio 1 : 2 in acetone and adding, after filtering off the formed silver chloride, to the resulting solution the stoichiometric amount of 2,2′-bipyridyl. The formed complexes, crystallized from acetone/methanol mixtures, were characterized by elemental analysis and NMR [5]. Ethylenediamine was distilled over potassium hydroxide pellets; N,N′-dimethylformamide was distilled over calcium sulfate and stored over molecular sieves. Other chemicals were of reagent grade.

The rates of reaction were followed either spectrophotometrically or conductometrically; a Perkin–Elmer Lambda 5 spectrophotometer and a Radiometer CDM3 conductivity bridge connected to a computer were used respectively. In all cases a large excess of ethylenediamine was used to provide pseudo-first-order conditions and to force the reaction to completion. Pseudo-first order rate constants k_{obsd} were obtained from non-linear least squares fit of the experimental spectrophotometric data to $A_t = A_\infty + (A_0 - A_\infty)\exp(-k_{obsd}t)$, where A_0, A_∞ and k_{obsd} were the parameters to be optimized (A_0 = absorbance after mixing of the reagents, A_∞ = absorbance at completion of reaction). An analogous equation using conductivity instead of absorbance was used to fit the experimental conductivity data. In both cases the k_{obsd} values were reproducible to better than ±5%. The k_{obsd} values are listed in Table 2.

RESULTS AND DISCUSSION

Chloro complexes

The complexes $[Pd(RR'N(CH_2)_2NR''R''')Cl_2]$ react with ethylenediamine according to the reaction:

$$[Pd(RR'N(CH_2)_2NR''R''')Cl_2] + en \rightarrow [Pd(RR'N(CH_2)_2NR''R''')(en)]^{2+} + 2Cl^- \quad (1)$$

The kinetic course of this reaction in dimethylformamide has been followed by monitoring the increase in time of the conductivity. A 1 : 2 electrolyte is in fact formed starting from neutral reagents. Under pseudo-first-order conditions with respect to the complex the observed rate law is:

$$k_{obs} = k_2[en] \quad (2)$$

Ethylenediamine is a bidentate ligand, however the circumstance that the conductivity increase occurs in only one step, shows that ring closure is fast and the monitored kinetic process refers to the replacement of the first chloride coordinated to palladium. The absence of a k_1 term in the rate law indicates that the substitution process occurs essentially by direct attack of the nucleophile en on palladium. The k_2 values (Table 3) are dependent on the nature of the substituents at nitrogen of ethylenediamine and the extreme values of the series vary by over 500 times. In terms of reactivity the substrates can be divided into three sets (Fig. 1) (i) a first set of complexes, where ethylenediamine is partially substituted at nitrogen by aryl groups, which exhibit the highest reactivity; (ii) a second set of less reactive complexes including those substrates where ethylenediamine is partially replaced at nitrogen by alkyl groups, and finally (iii) a third set of substances, where ethylenediamine is totally substituted at nitrogen by alkyl groups, which shows the largest inertness toward substitution by en.

The presence of a substituent at a ligand coordinated to the central atom, even in a peripheral position, can influence to large extent the rate of substitution [2,6].

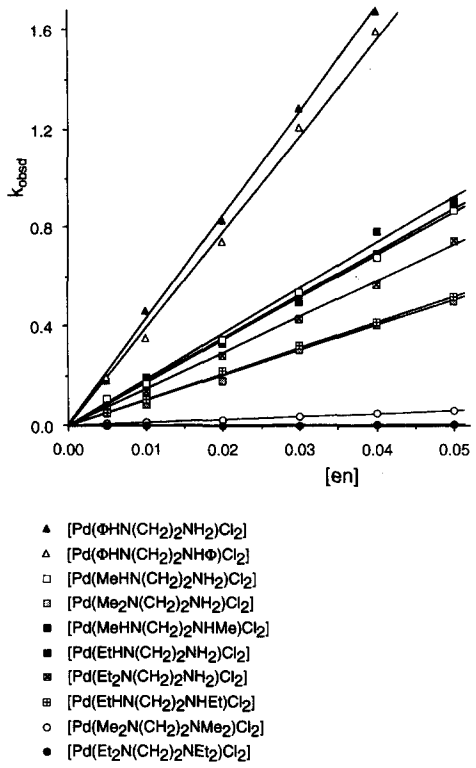

Fig. 1. Plot of k_{obs} against ethylenediamine concentration for reaction (1) in dimethylformamide at 25°C.

In the case of the complexes here studied only the aryl substituents are able to exert their strong electron withdrawing capacity on the reaction centre favouring the attack of ethylenediamine so leading to an increase in reaction rate with respect to the complexes with unsubstituted ethylenediamine. By contrast, the electrondonating properties of the alkyl substituents are not transmitted to palladium and the presence of one or two methyl or ethyl groups does not alter significantly the reactivity of this series of complexes. The drop in reaction rate of the tetraalkylsubstituted complexes, therefore, is not interpretable in terms of electronic effects but rather in terms of steric hindrance created by the presence of alkyl groups below and above the reaction centre. Steric hindrance plays a role also in the case of N-arylsubstituted ethylenediamine. The rate constant for reaction of $[Pd(H\Phi N(CH_2)_2N\Phi H)Cl_2]$, in fact, is not higher than that of the homologous monophenylsubstituted complex, as expected on the basis of the number of electron withdrawing substituents; the more effective shielding of the reaction centre by a second bulky phenyl in the first substrate can account for the relative reactivity of these to complexes.

Cationic complexes

All the complexes $[Pd(bpy)(R,R'N(CH_2)_2NR'', R''')](ClO_4)_2$ are very stable in aqueous solution in

which they behave as 1:2 electrolytes; the conductivity values in water, for 5×10^{-4} mol dm^{-3} solutions of the substrates, range in fact from 130 to 160 μS [7] and do not change in time. In addition the linear dependence of absorbance on concentration, in the range used for the experiments (2×10^{-5}–2×10^{-4} mol dm^{-3}), rules out self-association of the complexes. The absence of spectral variations in the UV spectra of the substances, on alkalinization of the solutions with OH^-, excludes also the presence of solvolytic equilibria with formation of aquospecies easily deprotonable by addition of base. The complexes react with ethylenediamine in water according to the reaction:

$$[Pd(bpy)(RR'N(CH_2)_2NR''R''')]^{2+} + en \rightarrow [Pd(RR'N(CH_2)_2NR''R''')(en)]^{2+} + bpy \quad (3)$$

The reaction is associated to large spectral variations in the UV–vis region (Fig. 2) and the reaction course can be easily monitored following the decrease in absorbance of the coordinated bipy ligand or the increase in absorbance of free bipyridine formed. Only one step of reaction can be observed and therefore ring closure of the bidentate ligand is fast. The term k'_2 in the rate law

$$k_{obs} = k'_2[en] \quad (4)$$

is, so, to refer to the replacement of the first nitrogen atom of bipyridine. The linear relation between k_{obs} and nucleophile concentration, also at very high values of (en), shows that the process is pH independent.

The k_2 values, reported in Table 4, show as well as for the analogous dichloro compounds, dependence on the nature of the substituents at nitrogen of ethylenediamine. However, the trend of the k_2 values for the two series of complexes are very different and for the cationic complexes the dependence of the rate constants on the nature of the group R,R'N-$(CH_2)_2$-NR''R''', is not straightforward. In fact, in contrast with the expected decrease in reactivity as a result of electron donor or steric properties of alkyl groups, the k_2 values increase on going from the complex with unsubstituted ethylenediamine to the complexes with alkylated ethylenediamine.

[a] Value from ref. [8].

A possible explanation for the observed trend of k_2 values may lie in the nature of the solvent, i.e. water. It is well known that in substrates containing bipyridine the hydrogen atoms of groups coordinated to platinum(II) an palladium(II) are acidic [10]. For instance the pH of a 6×10^{-3} mol dm^{-3} solution of $[Pd(bpy)(H_2O)_2]^{2+}$, at $I = 0.1$ mol dm^{-3}, is 2.8 [10]. In the present studies deprotonation of amino groups

is conceivable and as a matter of fact a stable monoprotonated adduct of $[Pt(bpy)(H_2N(CH_2)_2NH_2)]I_2$ [11] has been reported. Therefore, in the cationic complexes here studied, strong hydrogen bonds between the acidic hydrogen atoms of the amino groups of en and the oxygen atom of water are expected to be present; thus complexes with a larger number of hydrogen atoms bound to nitrogen should be more stabilized by interaction with water. The passage from ground state to transition state, where both the interaction of palladium with the lone pair of a fifth ligand and the contemporary bond weakening with nitrogen atoms of bpy should reduce the acidity of the amino groups, leading to substantial desolvation. Therefore, the observed decrease in reactivity along the series of complexes, could be correlated to an increasing degree of desolvation on forming the activated complex. Accordingly the complex with unsubstituted ethylenediamine is the most inert one. The lower reactivity of the complexes $[Pd(bpy)(R,R'N(CH_2)_2NH_2]^{2+}$, where two alkyl groups are bound to the same nitrogen atom, may be simply due to steric reasons owing to the shielding of the reaction centre by these groups.

In conclusion, in both series of complexes electronic effects due to the presence of substituents at nitrogen of en play a minor role, while, in some cases, steric effects become dominant; the electron density on bipyridine rings should be almost unchanged along the series of cationic complexes.

(Received 8 April 1997; accepted 2 June 1997)

Abstract—The synthesis and characterization of novel indium(III) complexes with pyridine-thiosemicarbazone ligands are reported as well as ligand exchange reactions on the products. 2,6-Diacetylpyridine-bis(thiosemicarbazone), $C_5H_3N(C_3N_3SH_6)_2$ ($H_2DAPTSC$), and 2-acetylpyridine-thiosemicarbazone, $C_5H_4N(C_3N_3SH_6)$ (HAPTSC), were reacted with indium(III) halides and indium(III) nitrate, respectively, to give $[InX_2(HDAPTSC)]$, $\{O[In(HDAPTSC)(OH)]_2\}$, $[InX_2(APTSC)(MeOH)]$ and $[In(APTSC)_2]PF_6$. © 1997 Elsevier Science Ltd

Keywords: indium complexes; thiosemicarbazones; nitrogen donor liquids; mixed ligand complexes; X-ray structure.

Heterocyclic thiosemicarbazones, as well as their metal complexes, are currently under discussion because of their biological activity [1–8]. They are of interest due to their antibacterial [3], antineoplastic [4], antimalarial [5], and antivirial behaviour [6]. Relationship has been found between chelate formation in the complexes and *in vivo* activity [9–12]. This makes structural studies on complexes with tri-, tetra- and pentadentate thiosemicarbazone ligands interesting. Although there exists a number of studies dealing with complex formation properties of thiosemicarbazones [8,13], comparatively few structural reports are published. They deal with iron(II) [14], cobalt(III) [15], nickel(II) [16,17], copper(II) [17–19], palladium(II) [20], zinc(II) [21], tin(II) [22], tin(IV)

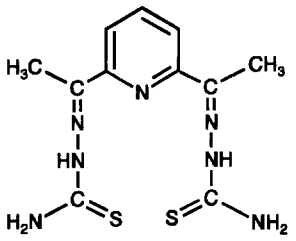
[23] and bismuth(III) [24]. Indium complexes with this type of ligand have not yet been reported.

As part of our systematic studies on indium complexes with tri- and pentadentate ligands, we prepared novel In^{III} compounds by reaction of InX_3 (X = Cl, Br) with the potentially pentadentate thiosemicarbazone 2,6-diacetylpyridine-bis(thiosemicarbazone) (H_2DAPTSC) and its tridentate analogue 2-acetylpyridine-thiosemicarbazone (HAPTSC). Here we report the synthesis and characterization of $[InX_2(HDAPTSC)]$, $\{O[In(HDAPTSC))(OH)]_2\}$, $[InX_2(APTSC)(MeOH)]$ (X = Cl, Br) and $[In(APTSC)_2]^+(Y)^-$ (Y = BPh_4^-, BF_4^-, $F_3CSO_3^-$, PF_6^-) complexes and of the mixed-chelate complexes [In-



H_2DAPTSC

$Cl(APTSC)(mnt)]^-$, $[InCl(APTSC)(Et_2dtc)]$ (mnt^{2-} = 1,2-dicyanoethene-1,2-dithiolate, Et_2dtc^- = diethyldithiocarbamate). The complexes $[InCl_2(HDAPTSC)]\cdot 2$ DMSO, $\{O[In(HDAPTSC)(OH)]_2\}\cdot 5$ MeOH, $[InCl_2(APTSC)(MeOH)]$, $[In(APTSC)_2]PF_6$ and $(H_2APTSC)[InCl(APTSC)(mnt)]\cdot 0.5\ H_2O$ have been characterized crystallographically.

EXPERIMENTAL

General considerations

Routine infrared spectra were recorded as KBr discs on a Bruker IFS 25. Mass spectra were recorded on a MAT TSQ-70 spectrometer (Finnigan). For the FAB measurements xenon was used as primary beam gas. The ion gun was operated at 8 kV and 100 μA (probe temperature 30°C); nitrobenzylalcohol was used as matrix. ^1H and ^{13}C NMR spectra were recorded on a Bruker DRX250 spectrometer in acetone-d_6 or dmso-d_6.

Elemental analyses for carbon, hydrogen, nitrogen, sulfur and chlorine were carried out by the Analytical Service Department of the University of Tübingen.

$InCl_3$ and $InBr_3$ were purchased from Fluka and Strem Chemicals, respectively. The thiosemicarbazones H_2DAPTSC, HAPTSC and HAPTSC $\cdot$HCl have been prepared according to previously published procedures [25,26]. Na_2mnt has been synthesized from NaCN and CS_2 following the route of Bähr and Schleitzer [27]. $NaEt_2dtc\cdot 3H_2O$, KPF_6, $NH_4(F_3CSO_3)$, $NaBF_4$ and $Na(BPh_4)$ were purchased from Merck. The chemicals were used without further purification. All operations were carried out in normal laboratory equipment under a normal atmosphere. Standard procedures have been used to dry solvents.

Syntheses

Dichloro[2,6 - *diacetylpyridine - bis*(*thiosemicarbazonato*)]*indium*(*III*), $[InCl_2(HDAPTSC)]$. H_2DAPTSC (77 mg, 0.25 mmol) was placed into a flask along with 50 cm^3 of methanol. The ligand nearly dissolved upon heating. $InCl_3$ (55 mg, 0.25 mmol) in 5 cm^3 of methanol was slowly added to the hot mixture. A clear yellow solution was formed immediately. After a few minutes a pale yellow solid began to precipitate. The reaction was completed after 30 min and after cooling to room temperature the nearly insoluble solid was isolated by filtration and washed with hot water and methanol (yield 70%). Anal. Calcd for $C_{11}H_{14}N_7S_2Cl_2In$: C, 26.74; H, 2.86; N, 19.84; S, 12.98; Cl, 14.35%; Found: C, 25.95; H, 2.65; N, 19.79; S, 12.88; Cl, 14.00%. IR: ν(NH) 3610(br), 3410(br), 3292(br), 3134 cm^{-1}, ν(C=N) 1609 cm^{-1}. FAB^+ MS: m/z = 422 ($[In(DAPTSC)]^+$).

Dibromo - [2,6 - *diacetylpyridine - bis*(*thiosemicarbazonato*)]*indium*(*III*), $[InBr_2(HDAPTSC)]$. The complex was prepared according to the procedure for the chloro analogue starting from $InBr_3$ and H_2DAPTSC. Yellow powder (yield 85%). Anal. Calcd for $C_{11}H_{14}N_7S_2Br_2In$: C, 22.66; H, 2.42; N, 16.82; S, 11.00%. Found: C, 22.92; H, 2.31; N, 17.08; S, 10.87%. IR: ν(NH) 3470m (br), 3320 (br), 3215m (br), 3149m cm^{-1}, ν(C=N) 1599 cm^{-1}. FAB^+ MS: m/z = 502/504 ($[InBr(HDAPTSC)]^+$), 422 ($[In(DAPTSC)]^+$).

μ_2 - *oxo* - *bis*{[2,6 - *diacetylpyridine - bis*(*thiosemicarbazonato*)](*hydroxo*)*indium*(*III*)}, $\{O[In(HDAPTSC)(OH)]_2\}$. H_2DAPTSC (77 mg, 0.25 mmol) was dissolved in about 50 cm^3 of hot methanol and $In(NO_3)_3\cdot 5\ H_2O$ in 5 cm^3 of methanol was slowly added. The mixture was heated under reflux for about 30 min. The colour of the reaction mixture turned to red-brown. The volume was reduced to about 20 cm^3 and stored overnight at ambient temperature. During this time pale yellow cubes deposited which were collected and washed with cold methanol. (Yield 65%). Anal. Calcd for $C_{22}H_{30}N_{14}S_4O_3In$: C, 29.48; H, 3.37; N, 21.87; S, 14.31%. Found: C, 30.01; H, 3.60; N, 21.78; S, 14.50%. IR: ν(NH, OH) 3450, 3310, 3245, 3144 cm^{-1}, ν(C=N) 1612 cm^{-1}. FAB^+ MS: m/z = 422 ($[In(DAPTSC)]^+$).

(2 - *Acetylpyridine - thiosemicarbazonato*)*dichloro*(*methanol*)*indium*(*III*), $[InCl_2(APTSC)(MeOH)]$. HAPTSC (48.5 mg, 0.25 mmol) was dissolved in 25 cm^3 of methanol and $InCl_3$ (55 mg, 0.25 mmol) in 5

cm^3 of methanol was slowly dropped into the solution. After heating on reflux for 30 min, the hot solvent was reduced to about 10 cm^3 and the mixture was placed in a refrigerator. Overnight yellow crystals deposited (yield 70%). Anal. Calcd for $C_9H_{13}N_4SOCl_2In$: C, 26.30; H, 3.19; N, 13.63; S, 7.80; Cl, 17.25%. Found: C, 25.79; H, 3.27; N, 13.59; S, 7.75; Cl, 17.01%. IR: ν(NH, OH) 3422, 3309, 3184, 3062 cm^{-1}, ν(C=N) 1601 cm^{-1}. FAB^+ MS: $m/z = 308$ ($[In(APTSC)]^+$), 343 ($[InCl(APTSC)]^+$), 378 ($[InCl_2(APTSC)]^+$). ^{1}H-NMR (dmso-d_6, 293 K): pyridine δ 8.93–7.91 (m, 4H); NH_2 δ 7.61 (s, 2H); CH_3(APTSC) δ 2.70 (s, 3H); CH_3 (methanol) δ 2.57 (s, 3H). ^{13}C-NMR (dmso-d_6, 293 K): C=S δ 175.3; C=N δ 148.6; pyridine δ 146.7, 146.3, 142.3, 126.1, 124.1; CH_3(APTSC) δ 13.8; CH_3 (methanol) δ 12.3.

(2 - *Acetylpyridin - thiosemicarbazonato)dibromo (methanol)indium(III)*, [$InBr_2$(APTSC)(MeOH)]. The complex was prepared following the procedure outlined for the chloro analogue. Yellow crystals (yield 65%). Anal. Calcd for $C_9H_{13}N_4SOBr_2In$: C, 21.62; H, 2.62; N, 11.21; S, 6.41%. Found: C, 21.91; H, 2.77; N, 11.35; S, 6.55%. IR: ν(NH) 3452, 3425, 3313, 3164 cm^{-1}, ν(C=N) 1593 cm^{-1}. FAB^+ MS: $m/z = 469$ ($[InBr_2(APTSC)]^+$), 387/389 ($[InBr(APTSC)^+$), 308 ($[In(APTSC)]^+$).

Bis(2 - *acetylpyridine - thiosemicarbazonato) indium(III) hexafluorophosphate*, [In(APTSC)$_2$]PF_6. $In(NO_3)_3 \cdot 5\ H_2O$ (98 mg, 0.25 mmol) was dissolved in 20 cm^3 of methanol, mixed with HAPTSC (122 mg, 0.625 mmol) in 20 cm^3 of methanol and heated under reflux for 30 min. After addition of NH_4PF_6 (50 mg, 0.3 mmol) yellow needles precipitated from the reaction mixture. More product could be obtained by reducing the solvent to half of its volume. Yellow crystals (yield 68%). Anal. Calcd for $C_{16}H_{18}N_8S_2PF_6In$: C, 29.74; H, 2.81; N, 17.34; S, 9.92%. Found: C, 29.72; H, 2.79; N, 16.98; S, 9.94%. IR: ν(NH) 3359, 3230, 3166 cm^{-1}, ν(C=N) 1602, 1579 cm^{-1}, ν(PF) 847 cm^{-1}. FAB^+ MS: $m/z = 501$ ($[In(APTSC)_2]^+$). ^{1}H NMR (acetone-d_6, 293 K): pyridine δ 8.33–7.37 (m, 4H); NH_2 δ 8.24 (s, 2H); CH_3 δ 2.09 (s, 3H). ^{13}C NMR (acetone-d_6, 293 K): C=S δ 175.8; C=N δ 148.9; pyridine δ 147.4, 146.8, 142.5, 127.2, 124.4; CH_3 δ 14.2.

Bis(2 - *acetylpyridine - thiosemicarbazonato) indium(III) tetraphenylborate*, [In(APTSC)$_2$]BPh_4. The compound was prepared following the route described for the PF_6^- salt from $In(NO_3)_3 \cdot 5\ H_2O$ (391 mg, 1 mmol), HAPTSC (485 mg, 2.5 mmol) and $Na(BPh_4)$ (342 mg, 1 mmol). Recrystallization from acetone/methanol gave yellow blocks (yield 80%). Anal. Calcd for $C_{40}H_{38}N_8S_2BIn$: C, 58.55; H, 4.67; N, 13.66; S, 7.82%. Found: C, 58.71; H, 4.39; N, 13.70; S, 7.85%. IR: ν(NH) 3405, 3281, 3167 cm^{-1}, ν(C=N) 1595 cm^{-1}. FAB^+ MS: $m/z = 501$ ($[In(APTSC)_2]^+$). ^{1}H NMR (acetone-d_6 293 K): aromatic protons δ 8.83–7.89 (m, 28H); NH_2 δ 8.63 (s 4H); CH_3 δ 2.42 (s, 6H). ^{13}C NMR (dmso-d_6, 293 K): C=S δ 178.4; C=N δ 147.4; pyridine δ 143.9, 142.7, 138.9, 124.8, 124.4; phenyl δ 143.3, 136.4, 126.2, 122.4; CH_3 δ 14.2.

Bis(2 - *acetylpyridine - thiosemicarbazonato) indium(III) tetrafluoroborate*, [In(APTSC)$_2$]BF_4. The compound was prepared from $In(NO_3)_3 \cdot 5\ H_2O$ (391 mg, 1 mmol), HAPTSC (485 mg, 2.5 mmol) and $NaBF_4$ (110 mg, 1 mmol) according to the procedure reported for the PF_6^- salt. No precipitate was formed spontaneously. The solution was halved in volume, placed in a refrigerator at 5°C and overnight yellow crystals of [In(APTSC)$_2$]BF_4 deposited which were isolated by filtration and recrystallized from boiling methanol. Yellow plates (yield 70%). Anal. Calcd for $C_{16}H_{18}N_8S_2BF_4In$: C, 32.68; H, 3.09; N, 19.05; S, 10.90%. Found: C, 33.01; H, 3.13; N, 19.01; S, 10.12%. IR: ν(NH) 3624, 3410, 3322, 3166 cm^{-1}, ν(C=N) 1599 cm^{-1}, ν(BF) 1082 cm^{-1}. FAB^+ MS: $m/z = 501$ ($[In(APTSC)_2]^+$). ^{1}H NMR (acetone-d_6, 293 K): pyridine δ 8.19–7.22 (m, 4H); NH_2 8.11 (s, 2H); CH_3 δ 1.95 (s, 3H). ^{13}C NMR (acetone-d_6 293 K): C=S δ 175.6; C=N δ 149.7; pyridine δ 148.1, 147.6, 143.3, 128.0, 125.2; CH_3 δ 15.0.

Bis(2 - *acetylpyridine - thiosemicarbazonato) indium(III) trifluormethylsulfonate*, [In(APTSC)$_2$](F_3CSO_3). The compound was prepared from $In(NO_3)_3 \cdot 5\ H_2O$ (391 mg, 1 mmol), HAPTSC (485 mg, 2.5 mmol) and $NH_4(F_3CSO_3)$ (167 mg, 1 mmol) as described for the tetrafluoroborate salt. Yellow crystals (yield 60%). Anal. Calcd for $C_{17}H_{18}N_8S_3O_3F_3In$: C, 31.39; H, 2.79; N, 17.23; S, 14.79%. Found: C, 31.18; H, 2.87; N, 16.92; S, 15.00%. IR: ν(NH) 3359, 3229, 3165 cm^{-1}, ν(C=N) 1601 cm^{-1}. FAB^+ MS: $m/z = 501$ ($[In(APTSC)_2]^+$). ^{1}H NMR (dmso-d_6, 293 K): pyridine δ 8.81–7.84 (m, 4H); NH_2 δ 8.59 (s, 2H); CH_3 δ 2.42 (s, 3H). ^{13}C NMR (dmso-d_6 293 K): C=S δ 178.7; C=N δ 148.2; pyridine δ 147.4, 143.4, 140.0, 124.9, 123.4; CH_3 (APTSC) δ 11.9.

(2 - *Acetylpyridine - thiosemicarbazonato)chloro (diethyldithiocarbamoto)indium(III)*, [InCl(APTSC) (Et_2dtc)]. [$InCl_2$(APTSC)(MeOH)] (103 mg, 0.25 mmol) was dissolved in 25 cm^3 of hot methanol and allowed to cool to room temperature. Na(Et_2dtc) $\cdot 3\ H_2O$ (37 mg, 0.25 mmol) in 5 cm^3 of methanol was slowly added under stirring to the cold solution. The mixture was stirred for another 30 min. Tiny yellow crystals formed upon slow evaporation of the solvent. Recrystallization from methanol gave yellow needles (yield 60%). Larger crystals could be obtained from slow diffusion of *n*-hexane into a CH_2Cl_2 solution of the complex. Anal. Calcd for $C_{13}H_{19}N_5S_3ClIn$: C, 31.75; H, 3.89; N, 14.24; S, 19.56; Cl, 7.21%. Found: C, 31.92; H, 3.80; N, 14.17; S, 20.01; Cl, 7.20. IR: ν(NH) 3420, 3350, 3270 cm^{-1}, ν(C=N) (APTSC) 1605 cm^{-1}. FAB^+MS: $m/z = 308$ ($[In(APTSC)]^+$), 343 ($[InCl(APTSC)]^+$), 456 ($[In(APTSC)(Et_2dtc))]^+$).

(2 - *Acetylpyridiniumthiosemicarbazone*)(2 - *acetylpyridine - thiosemicarbazonato)chloro*(1,2 - *dicyanoethene*-1,2-*dithiolato)indium(III)*, (H_2APTSC)[InCl (APTSC)(mnt)]. [$InCl_2$(APTSC)(MeOH)] (103 mg,

0.25 mmol) was dissolved in 25 cm^3 of hot methanol and allowed to cool to room temperature. Na_2mnt (46.5 mg, 0.25 mmol) in 10 cm^3 methanol was added dropwise. The clear solution was stirred at room temperature for 1 h and placed in a refrigerator. Overnight, a yellow precipitate was formed which was filtered off. The product was extracted with hot methanol leaving a small amount of an insoluble solid. The solvent was reduced to a volume of about 5 cm^3. Yellow plates of $(H_2APTSC)[InCl(APTSC)(mnt)]$ were formed upon standing overnight at ambient temperature (yield 25%). Anal. Calcd for $C_{20}H_{20}N_{10}S_4ClIn$: 35.38; H, 2.97; N, 20.63; S, 18.89; Cl, 5.22%. Found: C, 35.29; H, 2.80; N, 20.51; S, 18.88; Cl, 5.70%. IR: ν(NH) 3433, 3293, 3105 cm^{-1}, $\nu(C{\equiv}N)$ 2205 cm^{-1}, $\nu(C{=}N)$ 1617 cm^{-1}, $\nu(C{=}C)$ 1555 cm^{-1}, FAB^+ MS: $m/z = 308$ ($[In(APTSC)]^+$), 343 ($[InCl(APTSC)]^+$), 448 ($[In(APTSC)(mnt)]^+$). FAB^-MS: $m/z = 448$ ($[In(APTSC)(mnt)]^-$), 483 ($[InCl(APTSC)(mnt)]^-$). The compound was too insoluble to get NMR spectra of reasonable quality.

X-ray crystallography

$[InCl_2(HDAPTSC)] \cdot 2$ DMSO, $\{O[In(HDAPTSC)(OH)]_2\} \cdot 5$ MeOH, $[InCl_2(APTSC)(MeOH)]$, $[In(APTSC)_2]PF_6$ and $(H_2APTSC)[InCl(APTSC)(mnt)] \cdot 0.5\ H_2O$ were studied in detail by X-ray structure determinations. The structure determination on $[InCl(APTSC)(Et_2dtc)]$ could not be finished due to decomposition of the crystals during the measurement. Nevertheless, the obtained data allowed to derive the structure of the complex molecule. Therefore, the measurement will be briefly described (monoclinic, space group $P2_1/c$, $a = 18.527$, $b = 7.926$, $c = 13.314$ Å; $\beta = 103.13°$; $Z = 4$; 1937 reflections, 1496 unique reflections; 118 parameters, anisotropic refinement for In, Cl, S; $R_1 = 0.049$, $wR_2 = 0.129$). Crystal data and refinement parameters for the other X-ray measurements are summarized in Table 1. All measurements have been done on automated single-crystal CAD4 diffractometers (Enraf–Nonius) using Mo-K_α and Cu-K_α radiation, respectively, at 203(2)K. Absorption corrections (ψ scans) were applied when appropriate. Standard procedures have been used for data reduction (CAD4 software, HELENA/PLATON [28]), structure solution (SHELXS-86 [29]) and refinement (SHELXL-93 [30]). Anisotropic thermal parameters have been used in the refinement for all non-hydrogen atoms.

Single crystals of $[InCl_2(HDAPTSC)] \cdot 2$ DMSO were obtained by dissolving the only sparingly soluble compound in boiling DMSO, filtration of the hot solution and slow cooling (about 10°/h). The crystals contain two molecules of the solvent DMSO per complex molecule. One of the solvent molecules is disordered which has been considered in the calculation by refining two positions for the atom S(42) with an occupancy of 50 per cent. The hydrogen positions have been derived from the final Fourier map and refined.

Single crystals of $\{O[In(HDAPTSC)(OH)]_2\} \cdot 5$ MeOH have been obtained directly from the reaction mixture. The solvent molecules are highly disordered by occupying 'tube-like' vacancies which are formed by the staggered arrangement of the almost planar complex dimers. Therefore, only the atoms of the complex molecule have been refined anisotropically and the C and O atoms of the solvent which have 50% occupancy are considered with isotropic thermal parameters. The obtained model was checked by comparison with that obtained with the program SQUEEZE [28] which allows detection and evaluation of highly disordered solvent areas in crystal structure calculations. Approximately 70 e^- have been detected for our example and an 'artificial correction' by removing the disordered solvent molecules by SQUEEZE would lead to a final R_1 value of 0.056. The hydrogen atoms have been calculated for idealized positions and treated in the refinement with the 'riding model' option of SHELXL-93 [30]. The H atoms of the solvent molecules have been omitted.

Single crystals of $[InCl_2(APTSC)(MeOH)]$ of X-ray quality were obtained by slow cooling of a hot methanol solution of the complex. The hydrogen atoms H(12A), H(12B) and H(20) which might be important for the discussion of the structure have been derived from the Fourier map and refined. All other hydrogen atoms have been calculated for idealized positions using the 'riding model' option of SHELXL-93 [30].

Single crystals of $[In(APTSC)_2]PF_6$ were obtained by recrystallization from hot methanol. All hydrogen positions have been derived from the final Fourier map and refined.

Single crystals of $(H_2APTSC)[InCl(APTSC)(mnt)] \cdot 0.5\ H_2O$ were grown by slow evaporation of a methanol/water (5/1 v/v) solution of the compound. Hydrogen positions have been calculated and refined using the 'riding model' option except those on the nitrogen atoms which are of relevance for the discussion of the structure. They have been derived from the final Fourier map and refined freely. The H atoms of the solvent water have been omitted.

RESULTS AND DISCUSSION

The reaction of indium(III) chloride or indium(III) bromide with 2,6-diacetylpyridinebis(thiosemicarbazone) yields seven coordinate complexes according to eq. (1). The complexes are airstable. They are sparingly soluble in the most common solvents. Considerable amounts are only soluble in hot DMSO. Thus, single-crystals for an X-ray analysis could be

$$InX_3 + H_2DAPTSC \xrightarrow{MeOH} \text{[In(DAPTSC)X]} + HX \qquad \text{equ. (1)}$$

obtained, however, their solubility was too low for NMR measurements. FAB mass spectra could be measured by mixing a hot saturated DMSO solution of the complexes with nitrobenzylalcohol immediately before the measurement. No evidence was found for the molecular ion. However, peaks due to the $[In(HDAPTSC)]^+$ fragment could be observed at $m/z = 422$ (about 20% B) in the spectra of both complexes. The IR spectra of the complexes suggest an only single deprotonation. This is confirmed by an X-ray structural study on $[InCl_2(HDAPTSC)]$. The compound crystallizes in monomeric units together with two equivalents of the solvent dimethylsulfoxide. An ORTEP [31] representation of the complex molecule is given in Fig. 1. Selected bond lengths and angles are summarized in Table 2. The coordination polyhedron of indium can be discussed as a distorted pentagonal bipyramid with the chloro ligands occupying the axial positions [Cl(1)—In—Cl(2) angle: 166.02(5)°]. The pentadentate thiosemicarbazone forms the equatorial coordination sphere. The atoms of this ligand and In are coplanar within 0.579(6) Å. Different bond lengths in the chelate rings confirm that the ligand is only deprotonated at N(10). Consequently, S(13) possesses 'thiolate character' and the S(13)–C(11) distance is longer by 0.063 Å than the distance S(20)—C(18). The bond lengths inside the 5-membered chelate rings support the conclusion drawn: the N(10)—C(11) and In—S(13) distances are shorter than the corresponding values in the protonated part of the molecule. The detection of H(17) in the final Fourier map confirms the conclusions of this discussion.

The same bonding situation is expected for $[InBr_2(HDAPTSC)]$. The IR spectrum is similar to that of the chloro analogue: ν(NH) frequencies can be detected at 3470, 3320, 3215 and 3149 cm^{-1}. Fragments due to $[InBr(HDAPTSC)]^+$ and $[In(HDAPTSC)]^+$ could be assigned in the FAB^+ mass spectrum of the compound at $m/z = 502/504$ ($^{79,81}Br$ isotopic pattern) and $m/z = 422$.

Despite the general reaction pattern of $H_2DAPTSC$ with indium(III) halides [eq. (1)] the reaction with $In(NO_3)_3 \cdot 5\ H_2O$ gives a μ-oxo-bridged dimer with angle deprotonated thiosemicarbazonato and terminal hydroxo ligands. The formation of an oxo-bridge is unexpected and can be understood by the absence of halide ligands. The dimeric unit is stable and does not undergo further hydrolysis when treated with water. An ORTEP [31] representation of the dimeric complex is given in Fig 2. Corresponding bond lengths and angles are summarized in Table 3. The μ-oxo ligand resides on a two-fold crystallographic axis. Despite the situation in the μ-oxo-

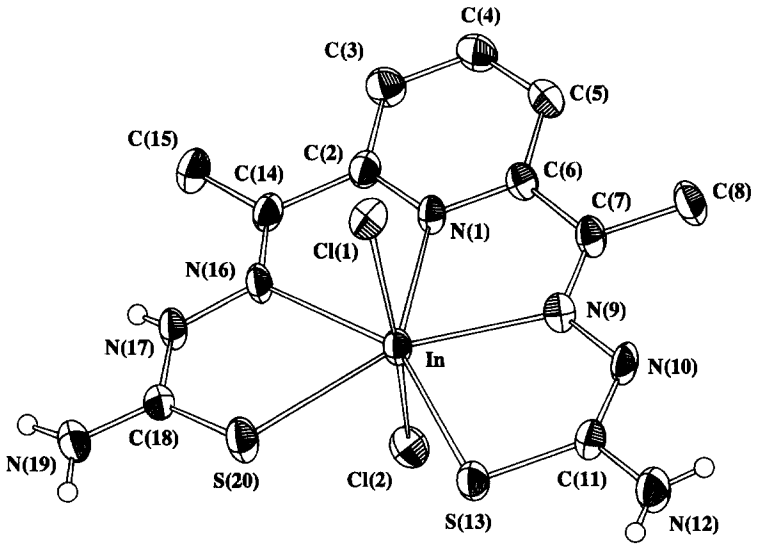

Fig. 1. ORTEP representation [31] of $[InCl_2(HDAPTSC)]$. Thermal ellipsoids represent 50% probability. H atoms at the carbon atoms have been omitted for clarity.

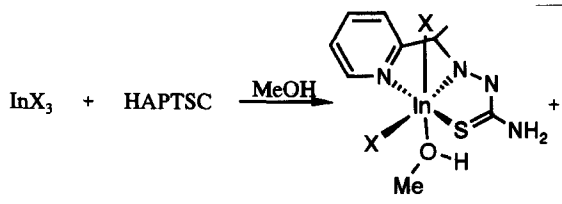
bridged dimer $\{O[In(acetato\text{-}O)_2L]\}$ (L = 1,4,7-triazacyclononane-N,N′,N″) [32], where the oxo bridge is bent with an angle of 142°, the In—O(1)—In′ angle in $\{O[In(HDAPTSC)(OH)]_2\}$ is 179.8(5)°. The In—O bond lengths in the bridge are shorter by 0.1 Å than those to the terminal hydroxy groups. With this, they come close to the In—O distances in the solid state structure of In_2O_3 [33]. The chelating ligand is singly deprotonated as in $[InCl_2(HDAPTSC)]$. This has been checked by IR and mass spectra. A unequivocal verification by X-ray structural results cannot be given, since we were not able to locate all hydrogen atoms in the final Fourier map. However, the bond length differences in the sulfur-containing chelate rings suggest deprotonation of N(10).

tonation of the ligand is realized without addition of base. To obtain pure $[InBr_2(APTSC)(MeOH)]$ it is necessary to start from HAPTSC instead of from HAPTSC · HCl. The use of the hydrochloride works well with $InCl_3$, but causes halide exchange on the bromo complex and considerable amounts of $[InCl_2(APTSC)(MeOH)]$ are formed.

$[InCl_2(APTSC)(MeOH)]$ and its bromo analogue are yellow solids which are soluble in $CHCl_3$, CH_2Cl_2 and methanol. They are insoluble in hydrocarbons. The compounds are indefinitely stable in air as solids as well as in solution. The infrared spectral results obtained agree with the coordination of a deprotonated thiosemicarbazonato ligand. FAB^+ spectra show peaks at $m/z = 308$ which can easily be assigned



equ. (2)

The potentially tridentate ligand HAPTSC reacts with $InCl_3$ and $InBr_3$ in methanol under formation of six-coordinate species of the composition $[InX_2(APTSC)(MeOH)]$ according to eq. (2). Deprotonation of the ligand is realized without addition of base. To obtain pure $[InBr_2(APTSC)(MeOH)]$ it is necessary to start from HAPTSC instead of from HAPTSC · HCl. The use of the hydrochloride works well with $InCl_3$, but causes halide exchange on the bromo complex and considerable amounts of $[InCl_2(APTSC)(MeOH)]$ are formed.

$[InCl_2(APTSC)(MeOH)]$ and its bromo analogue are yellow solids which are soluble in $CHCl_3$, CH_2Cl_2 and methanol. They are insoluble in hydrocarbons. The compounds are indefinitely stable in air as solids as well as in solution. The infrared spectral results obtained agree with the coordination of a deprotonated thiosemicarbazonato ligand. FAB^+ spectra show peaks at $m/z = 308$ which can easily be assigned as $[In(APTSC)]^+$. Additionally, signals of less intensity due to the molecular ion and $[InX(APTSC)]^+$ can be observed. ^1H and ^{13}C NMR spectra confirm the formation of the product.

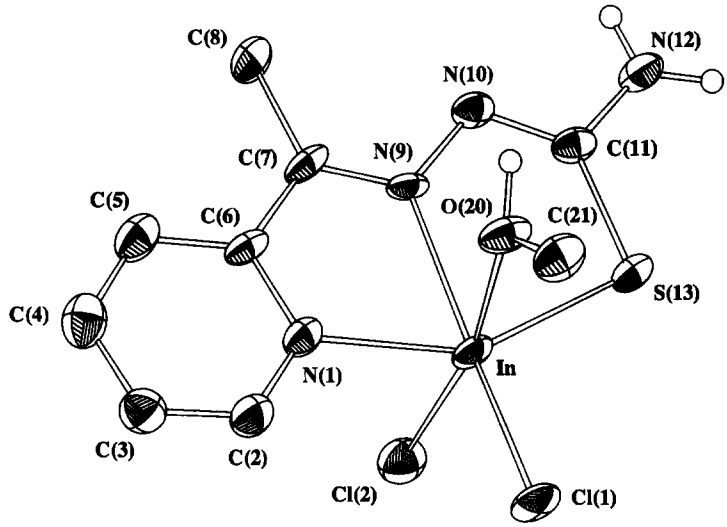


Fig. 3. ORTEP representation [31] of $[InCl_2(APTSC)(MeOH)]$ with thermal ellipsoids of 50% probability. H atoms at the carbon atoms have been omitted for clarity.

A crystal structure determination has been performed for $[InCl_2(APTSC)(MeOH)]$. The compound crystallizes as monomeric neutral molecules in an orthorhombic unit cell. Fig. 3 contains an ORTEP representation of the molecule. Selected bond lengths and angles are summarized in Table 4. The coordination polyhedron can best be described as a distorted octahedron. Deviations from the idealized symmetry result from the restricted bite angle of the tridentate ligand [N(1)—In—S(13): 150.9(2)°]. The chloro ligands are in *cis* arrangement and the In—Cl(1) bond length is shorter by 0.053 Å compared with the In—Cl(2) distance. The bonding situation in the In—N(9)—N(10)—C(11)—S(13) chelate ring is very similar to that in the 'deprotonated half' of $[InCl_2(HDAPTSC)]$ showing relatively short N(10)—C(11) [1.331(1) Å] and long C(11)—S(13) [1.744(7) Å] distances. The thiosemicarbazonato ligand is coplanar with In and Cl(1) within 0.541(3) Å. The methanol ligand is coordinated without deprotonation.

As a side-product of the reactions of $InCl_3$ or $InBr_3$ with HAPTSC, the cationic bis-chelate $[In(APTSC)_2]^+$ can be detected (e.g. by mass spectrometry). Small amounts of this complex can be isolated when excess HAPTSC is used. Reasonable amounts of $[In(APTSC)_2]^+$ can be prepared from $In(NO_3)_3 \cdot 5\ H_2O$ and HAPTSC. The bis-chelate can be precipitated with anions like PF_6^-, BF_4^-, $CF_3SO_3^-$ or BPh_4^-. A crystal structure determination has been done with $[In(APTSC)_2]PF_6$. The structure consists of discrete complex cations and PF_6^- anions. An ORTEP plot of $[In(APTSC)_2]^+$ is shown in Fig. 4. The corresponding bond lengths and angles are contained in

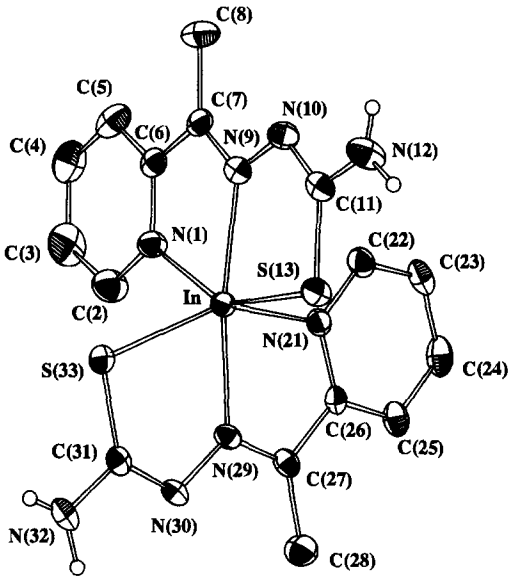

Fig. 4. ORTEP representation [31] of the cation $[In(APTSC)_2]^+$. Thermal ellipsoids represent 50% probability. H atoms at the carbon atoms have been omitted for clarity.

Table 5. The metal is six-coordinate with approximately planar tridentate ligands. While the bond distances and angles inside the thiosemicarbazone moiety are almost equal for both ligands, slightly different bond lengths have been observed for the In—S and In—N bonds. Similar differences have been found for a cationic cobalt(III) complex $[Co(L4M)_2]BF_4$ (L4M = 2-acetyl-^{4}N-methylthiosemicarbazonate) [15]. This is result is restricted to the solid state structure of the complex and should be assigned to crystal packing effects. ^{1}H and ^{13}C NMR spectra confirm equivalence for the two coordinated ligands in solution.

$[InCl_2(APTSC)(MeOH)]$ has been proved to be a good starting material for further ligand exchange reactions. This has been checked with bidentate sulfur-containing ligands. The reaction with sodium diethyldithiocarbamate, $NaEt_2dtc$, at room temperature yields the six-coordinate complex $[InCl(APTSC)(Et_2dtc)]$ (Fig. 5). The compound can be isolated as pale-yellow needles which are airstable and readily soluble in chloroform or dichloromethane. The FAB^+ mass spectrum shows an intense peak (80% B) at $m/z = 455$ which corresponds to a fragment of the composition $[In(ATPSC)(Et_2dtc)]^+$. The structure of the complex is confirmed by the IR and NMR results as well as by an X-ray structure determination. Since the data collection was interrupted after about 2000 reflections due to crystal decomposition, only In, Cl and S atoms could be refined anisotropically. Therefore, this crystal structure shall not be discussed in full detail. Nevertheless, main structural features could be derived and are contained in Fig. 5. The remaining chloro ligand is positioned *trans* to a sulfur atom of the dithiocarbamate and the coordination geometry of the metal significantly deviates from an idealized octahedron as a consequence of the bite angles of the chelating ligands (selected bond angles: N(1)—In—N(9) 72.1(5)°, N(1)—In—Cl 87.9(3)°, N(1)—In—S(13) 149.8(3)°,

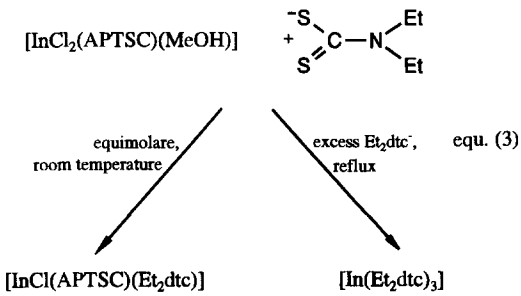
When excess of $NaEt_2$dtc is used, the ligand exchange does not stop at the mixed ligand complex stage but yields the well known tris-chelate [In(Et_2dtc)$_3$] according to eq. (3). Similar



results have been found earlier for indium(III) complexes with 2-acetylpyridineoxime where the reaction with dithiocarbamates gives the [In(R_2dtc)$_3$] chelates in high yields [34].

A similar tendency can be discussed for the reaction of [$InCl_2$(APTSC)(MeOH)] with disodium 1,2-dicyanoethene -1,2-dithiolate, Na_2mnt, where in a first stage a ligand exchange 2 Cl^- *vs* mnt^{2-} takes place. Parallely, $APTSC^-$ is removed from the metal and the anion $[InCl(mnt)_2]^{2-}$ is formed. This complex can be detected mass spectrometrically using the negative ionization FAB technique. It can be isolated after addition of (Ph_4As)Cl to the methanolic reaction mixture. Formation of the tris-chelate $[In(mnt)_3]^{3-}$ could not be detected when Na_2mnt and [$InCl_2$(APTSC)(MeOH)] were reacted stoichiometrically. Without addition of a bulky cation $[InCl(mnt)_2]^{2-}$ remains in solution and upon slow evaporation of the solvent yellow crystals of (H_2APTSC)[InCl(APTSC)(mnt)] deposit. Considerable amounts of $[InCl(mnt)_2]^{2-}$ can be obtained from the oily residue after complete evaporation of the solvent and extraction with acetonic tetrabutylammonium or tetraphenylarsonium chloride solutions.

In the yellow crystals which precipitate directly from the mother liquor, the mixed ligand anion $[InCl(APTSC)(mnt)]^-$ crystallizes as H_2APTSC^+ salt together with a half molecule of solvent water. This composition has been confirmed by spectroscopic methods and X-ray crystallography. The thiosemicarbazonate coordinates in the same way as discussed above, as monoanionic, tridentate ligand. Figure 6 gives an ORTEP [31] representation of the ion pair. Selected bond lengths and angles are summarized in Table 6. The bonding situation inside the $APTSC^-$ skeleton of the complex anion is the same as found in [$InCl_2$(APTSC)(MeOH)] or $[In(APTSC)_2]^+$ with a relatively short N(10)—C(11) [1.325(9) Å] and a relatively long C(11)—S(13) [1.729(7) Å] distance suggesting an extended π-system inside the chelate ring. This contrasts the bonding mode in the H_2APTSC^+ counterion where an almost isolated C—S double bond can be found between C(41) and S(43) [1.675(7) Å] and the N(40)—C(41) distance of 1.371(8) Å has single bond character. Weak hydrogen bonds can be discussed between the chloro ligand and H(31) (distance: 2.402 Å) and H(42B) (2.565 Å) of the cation and H(12A) (2.688 Å) of the complex anion. These weak interactions between the ion pair might be responsible for the stereochemistry of the H_2APTSC^+ cation which prefers hydrogen bonds to the complex anion rather than an intramolecular hydrogen bridge between H(40) and S(43) which has been found for the related thiosemicarbazone 2'-[1-(2-pyridyl) ethylidene] - 3 - azabicyclo[3.2.2]nonane - 3 - carbthiohydrazide [34]. With this, the bonding situation of the cation in (H_2APTSC)[InCl(APTSC)(mnt)] compares with that in ($H_2APTSC)^+Cl^-$, the structure of which has been reported previously [26].

CONCLUSIONS

Indium(III) complexes with tri- and pentadentate thiosemicarbazones can be easily prepared from either indium(III) halides or $In(NO_3)_3 \cdot 5\ H_2O$. Halide ligands remain in the coordination sphere of the metal, whereas the reactions from indium nitrate yields cationic bis-chelates with tridentate ligands and neutral μ-oxobridged hydroxo species when pentadentate bis(thiosemicarbazones) are used. The symmetrical, pentadentate bis(thiosemicarbazone) H_2DAPTSC

undergoes only a single deprotonation during the complex formation.

[InX_2(APTSC)(MeOH)] complexes are suitable starting materials for the synthesis of mixed-ligand indium(III) compounds when powerful chelating ligands as dialkyldithiocarbamates or maleonitrildithiolate are used. One halide and the methanol ligand are replaced when mild conditions are applied. Additional ligand exchange including the tridentate thiosemicarbazonate occurs when excess of the sulfur donor ligand and longer refluxing periods are applied.

The new compounds represent a novel class of indium(III) complexes which may possess interesting biological properties. Cell toxicity studies are presently under progress.

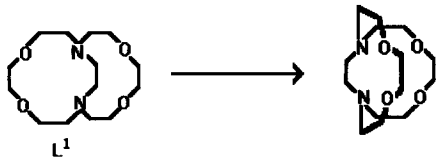
Abstract—The protonation of 1,4,7,10-tetraazabicyclododecane (L^2), 4,7-dioxa 1,10,13,16-tetraazabicyclo[8.8.2]eicosane (L^3) and 1,4,7,10,13,16-hexaazabicyclo[8.8.2]eicosane (L^7) was studied by potentiometric methods at 18°C and ionic strength of 0.1 ($NaClO_4$) in aqueous medium. In all instances, two buffer regions have been observed. The logarithms of the protonation constants were equal to 10.55, 9.50, 3.00 for L^2, 10.80, 9.95, 8.60, 3.30 for L^3 and 10.25, 9.00, 7.80, 5.70, 2.80, 1.20 for L^7. The stability constants for copper(II) complexes were determined. The methods of synthesis of cryptands L^3, L^7 are presented. © 1997 Elsevier Science Ltd

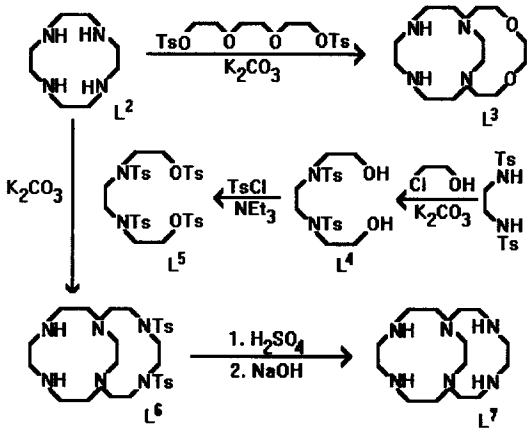
Keywords: cyclene; cryptands; protonation constants; copper complexes; stability constants; absorption spectra.

It is known that cryptands containing nitrogen atoms have three-dimensional macrocycles, the cavities of which can accommodate suitable cations [1–3] or anions [4]. These complexes are approximately ellipsoidal, the 'meridians' of which contain various heteroatoms.

In terms of the complexing ability of cryptands, the structures with hemispherical cavities are of interest. This situation occurs when one of the chains connecting the polar nitrogen atoms is considerably shorter than the others. The well-known representative of this class cryptands is 4,7,13,16-tetraoxa-1,10-diazabicyclo[8.8.2]eicosane (L^1), X-ray data [5] for which confirm a clamlike construction. The polyether links rotate with respect to the $>N(CH2)_2N<$ fragment and selectively bind alkaline–earth ions and there is a correlation between the angle of opening and stability of the corresponding cryptates [6,7]

In this work, we consider the complexing ability of structural analogues of L^1 containing links with donor nitrogen atoms instead of polyether chains. The synthesis of two new cryptands, 4,7-dioxa-1,10,13,16-tetraazabicyclo[8.8.2]eicosane (L^3) and 1,4,7,10,13,16-hexaazabicyclo[8.8.2]eicosane (L^7), that can be considered as bicyclic derivatives of cyclene, 1,4,7,10-tetraazabicyclododecane (L^2), is described. The latter relates to the class of cyclic tetraamines and forms stable complexes with copper(II) ions [8,9]. The scheme for the synthesis of cryptands and intermediates is shown in Scheme 1.





Scheme 1.

Alkylation of the cyclene by triethyleneglycol ditosylate in dry DMF, in the presence of K_2CO_3, leads to the formation of L^3. In analogous conditions, L^6 was prepared by a condensation of L^2 with N,N′-bis(2-hydroxyethyl)ethylenediamine tetratosylate L^5. After removing the tosyl fragments, the bicyclic hexaamine L^7 was obtained. The reagent L^5, required for this synthesis, was obtained from the initial ditosylate in two steps.

EXPERIMENTAL

1,4,7,10-tetraazacyclododecane (cyclene) (L^2) (Aldrich) was used as received.

Measurements

The control of the reaction course and purity of compounds synthesized was determined by TLC methods on Silufol UV-254 plates, the eluent was ethanol–acetonitrile–aqueous ammonia, 10:3:5. ^{1}H NMR spectra of $CDCl_3$ solutions of the compounds were recorded on a Bruker AM-250 spectrometer. Electronic spectra of the copper complex solutions were obtained on a Perkin–Elmer Lambda 9 spectrophotometer. Mass spectra were measured on a Varian MAT CH-112 spectrometer.

Protonation constants for the ligands and stability constants for the copper complexes were determined by pH-potentiometric titration methods at the temperature $T = 18°C$ and ionic strength $\mu = 0.1$ ($NaClO_4$). Titrant was 0.1 M $HClO_4$ aqueous solution. Measurements were performed on a OP0211/1 laboratory digital pH-meter (Radelkis, Budapest, Hungary).

Preparation of 4,7-*dioxa*-1,10,13,16-*tetraazabicyclo*[8.8.2]*eicosane* (L^3)

Ethyleneglycol ditosylate, 4.12 g (0.009 mole) dissolved in 50 cm^3 of DMF was slowly added to 80 m^3 of dry DMF containing 1,4,7,10-tetraazacyclododecane (L^2) (1.72 g, 0.01 mole) and 3.2 g of freshly prepared K_2CO_3, and the mixture was stood for 3 h 100°C. The reaction mixture was cooled, filtered and evaporated under reduced pressure. The oil-like residue was extracted by hot hexane, the solvent was removed by distillation, and the resulting light-yellow product was crystallized from pentane. Yield 0.84 g (32.8%), M.p. 109–111°C, ^{1}H NMR, 250 MHz (δ, ppm relative to TMS): 2.47–2.78 (22H, m, CH_2N, NH), 3.54–3.80 (8H, m, CH_2O). Found: C, 59.01; H, 10.43; N, 19.61. Calc. for $C_{14}H_{30}N_4O_2$: C, 58.74; H, 10.49; N, 19.58%.

Preparation of 1,4,7,10,13,16-*hexaazabicyclo*[8.8.2]*eicosane* (L^7)

5.92 g of compound L^5 was dissolved in 50 cm^3 of 96% H_2SO_4, heated to 110–115°C and stirred for 20 h. To a cooled reaction mixture, 200 cm^3 of ether was slowly added. The precipitate was filtered, dissolved in a minimal amount of water that saturated with granular KOH or NaOH. The resulting oil-like product was isolated by extraction with hot benzene. Yield 1.65 g (58%). ^{1}H NMR, 250 MHz (δ, ppm relative to TMS): 2.11–2.16 (4H, s, NH), 2.59–2.71 (28H, m, CH_2N). Found: C, 59.48; H, 11.43; N, 29.61. Calc. for $C_{14}H_{32}N_6$: C, 59.15; H, 11.27; N, 29.58%.

RESULTS AND DISCUSSION

The isolated cryptands are soluble in water and are strong bases. Their titration curves against perchloric acid consist of two buffer regions. Before a jump of pH, 3 and 4 equiv. of the acid are expended for a titration of L^3 and L^7, respectively. From the titration data, the formation curves were obtained as the functions of $n = f(pH)$, where n is average number of attached protons. Then the protonation constants (K_n) (the inverse values of acid dissociation constants) were calculated using established equations [10]. For comparison, the protonation constants for cyclene were determined under similar conditions and the values for the first two protonation constants are in good agreement with the literature data (Table 1). The log K_3 value is somewhat increased, but has the same order of magnitude as the log K_n value for synthesized cryptands corresponding to the last buffer region. These data correspond well with the accepted scheme for protonation of macrocyclic polyamines [11], according to which, the first proton is attached to one of the secondary amino groups, and the second forms a hydrogen bond, bridging between adjoining nitrogen atoms. Two such possibilities exist for cyclene and hexaamine L^7 and one for tetraamine L^3. In the presence of copper(II) ions, the titration curve of L^2 is in the acid region when 2 equiv. of acid are already added, while the copper complex of the cryptand L^3 is protonated easily on the first step. Competition between protons and the copper(II) ion for cryptand L^3 occurs in the range K_2–K_3 and is expressed by an equation:

$$Cu^{2+} + LH_3^{3+} \leftrightarrow CuLH^{3+} + 2H^+$$

The stability constant for the complex, $K_s = [CuLH^{3+}]/[Cu^{2+}][LH^+]$, can be calculated by a graphical method used for two basic ligands [13]. Comparing the values of the stability constants of complexes with L^2 and L^3 and taking into account the nearness of their spectral parameters in region of *d–d* transitions (Table 2), it can be supposed that both in cyclene and cryptand L^3 the copper(II) ions possess closed environments.

The resulting value of log $K = 19.8$, and a considerable hypsochromic shift for the band ($\lambda_{max} = 641$ nm) of *d–d* transition in electronic absorption spectrum allow us to propose that the nitrogen atoms of

(Received 10 March 1997; accepted 20 May 1997)

Abstract—Tin K-edge EXAFS show that low concentrations of tin in compounds of composition $Fe_{3-x}Sn_xO_4$ ($x < 0.3$) adopt the octahedral, as opposed to tetrahedral, sites of the inverse spinel structure. X-ray photoelectron spectroscopy shows that incorporation of tin is accompanied by the partial reduction of Fe^{3+} to Fe^{2+}.
© 1997 Elsevier Science Ltd

Keywords: tin-doped magnetite; doped ion oxides.

The iron oxide of composition Fe_3O_4 which is called magnetite adopts the inverse spinel structure in which Fe^{3+} occupies the tetrahedral sites whilst the octahedral sites are occupied by both Fe^{3+} and Fe^{2+}.

Iron–titanium oxides of composition $Fe_{3-x}Ti_xO_4$ have attracted interest because of their magnetic properties and the time–temperature-dependent phase transformations which they undergo [1]. Some initial studies of tin-doped Fe_3O_4 of composition $Fe_{3-x}Sn_xO_4$ described [2,3] the materials as ferrimagnets with the same inverse spinel structure as that observed in $Fe_{3-x}Ti_xO_4$. We have recently [4] prepared materials of composition $Fe_{3-x}Sn_xO_4$ ($x = 0.1$ and 0.2) by solid state reactions in sealed tubes. X-ray powder diffraction and ^{57}Fe- and ^{119}Sn-Mössbauer spectroscopy showed [4] the Curie temperature to be lower than that of Fe_3O_4 and related $Fe_{3-x}Ti_xO_4$ compounds. However, we were unable to identify whether tin in the Fe_3O_4 structure was located on the octahedral or tetrahedral sites of the spinel-related structure. We therefore report here on our study of the location of tin in $Fe_{3-x}Sn_xO_4$ and on the mechanism of charge balance.

EXPERIMENTAL

Compounds of composition $Fe_{3-x}Sn_xO_4$ ($x < 0.3$) were prepared by heating stoichiometric quantities of powdered tin (IV) oxide, iron (III) oxide and metallic iron in sealed evacuated quartz ampoules at 900°C for 48 h and allowing the products to cool in the furnace.

Tin K-edge EXAFS measurements were performed at the Synchrotron Radiation Source at Daresbury Laboratory U.K. with an average current of 200 mA at 2 GeV. The data were collected in transmission geometry on Station 9.2 (5T wiggler) with 50% higher harmonic rejection. All data were recorded at 298 K. The raw data were background-subtracted using the Daresbury programme EXBACK and fitted using the non-linear least squares minimisation programme EXCURV92 which calculates the theoretical EXAFS function using the fast curved wave theory.

X-ray photoelectron spectra were recorded with a triple channeltron CLAM 2 analyser using Al-Kα radiation under an operating vacuum better than 1×10^{-8} m bar and a constant analyser transmission energy of 20 eV. The powdered samples were pressed on double sided adhesive conductive carbon tape. All binding energies were corrected to the C ls signal which was set at 284.6 eV.

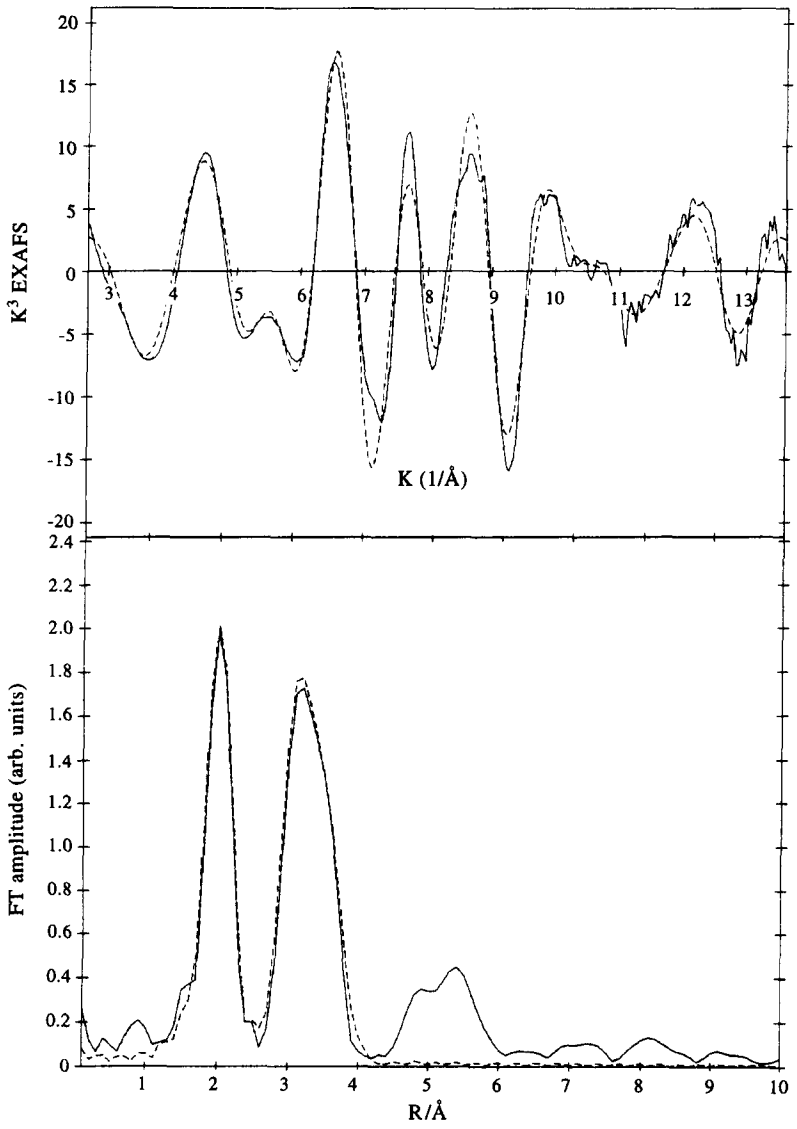

Fig. 1. Tin K-edge EXAFS and Fourier Transform recorded from $Fe_{2.9}Sn_{0.1}O_4$.

RESULTS AND DISCUSSION

X-ray powder diffraction showed the products to be monophasic. The compositions were confirmed by edx analysis. The tin K-edge EXAFS and its Fourier Transform recorded from the compound of composition $Fe_{2.9}Sn_{0.1}O_4$ are shown in Fig. 1. The data are collected in Table 1.

Table 1. Best fit parameters to tin K-edge EXAFS showing coordination around tin in $Fe_{2.9}Sn_{0.1}O_4$

Atom type	R (Å)	$2\sigma^2$ (Å^2)
6O	2.04(1)	0.007
6 Fe	3.07(1)	0.014
6 Fe	3.49(1)	0.016

The results show the tin to be coordinated by six oxygen atoms at 2.037 Å. The results demonstrate that the tin atoms in tin-doped Fe_3O_4 adopt the octahedral, as opposed to tetrahedral, sites in the inverse spinel structure. The tin-oxygen distance compares well with that observed in tin dioxide of 2.041 Å (as also determined here by tin K-edge EXAFS) which is consistent with data recorded by X-ray diffraction [5].

The Fe 2*p* X-ray photoelectron spectrum and the Fe $2p_{3/2}$ binding energy of 710.9 eV recorded from Fe_3O_4 (Fig. 2, Table 2) were similar to data reported in the literature [6,7]. The peaks in the Fe 2*p* X-ray photoelectron spectra recorded from $Fe_{2.9}Sn_{0.1}O_4$ and $Fe_{2.8}Sn_{0.2}O_4$ (Fig. 2) were broader than those observed in the spectrum recorded from Fe_3O_4 and the maxima of the Fe $2p_{3/2}$ envelopes were shifted to the lower energies of 710.4 eV and 710.0 eV respectively. A peak at 715.4 eV, which corresponds to the binding energy

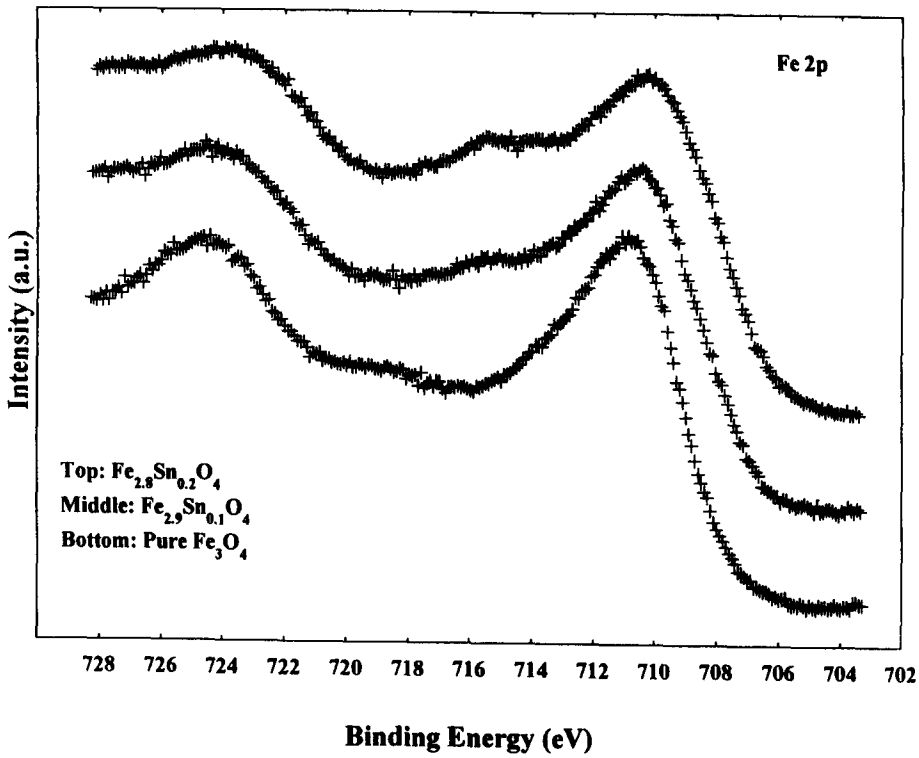

Fig. 2. Fe 2*p* X-ray photoelectron spectra recorded from Fe_3O_4, $Fe_{2.9}Sn_{0.1}O_4$ and $Fe_{2.8}Sn_{0.2}O_4$.

$Fe_{2.9}Sn_{0.1}O_4$	709.2	43	Fe^{2+}
	710.7	57	Fe^{3+}
$Fe_{2.8}Sn_{0.2}O_4$	709.1	66	Fe^{2+}
	710.7	34	Fe^{3+}

[a]The relative intensity of the Fe^{2+} contribution includes the satellite contribution at the 714.0 eV.

of the Sn $2p_{3/2}$ core level, was also visible in both spectra. The Fe 2*p* spectrum recorded from $Fe_{2.8}Sn_{0.2}O_4$ suggested an additional structure at 714.0 eV which we associate with the presence of a Fe^{2+} satellite. The shifts to lower binding energy of the Fe $2p_{3/2}$ level, the increase in broadening of the Fe 2*p* peaks and the development of satellite structure are all indicative [7,8] of increasing Fe^{2+} content as increasing amounts of tin are incorporated within the Fe_3O_4 structure. This is more clearly demonstrated in Fig. 3 which shows the deconvolution of the Fe $2p_{3/2}$ peak. The single component in the Fe $2p_{3/2}$ peak of Fe_3O_4 at 710.9 eV is characteristic of Fe^{3+} and, although Fe_3O_4 contains both Fe^{2+} and Fe^{3+}, the

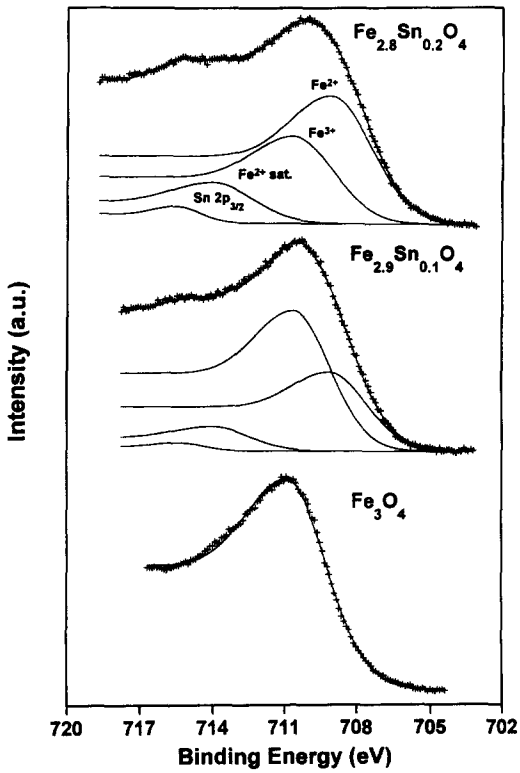

Fig. 3. Deconvolution of the Fe $2p_{3/2}$ X-ray photoelectron spectra recorded from Fe_3O_4, $Fe_{2.9}Sn_{0.1}O_4$ and $Fe_{2.8}Sn_{0.2}O_4$.

surface is usually oxidised such that only the Fe^{3+} contribution is observed in the X-ray photoelectron spectrum [9,10]. In contrast the Fe $2p_{3/2}$ peak in the spectra recorded from $Fe_{2.9}Sn_{0.1}O_4$ and $Fe_{2.8}Sn_{0.3}O_4$ were deconvoluted to four peaks. The peaks at 710.7 eV and 715.4 eV correspond to Fe^{3+} and the Sn $2p_{3/2}$ level respectively whilst the peak at 709.2 eV, together with the satellite at 714.0 eV, are characteristic [7,8] of Fe^{2+}.

The developing presence of Fe^{2+} as tin is incorporated within Fe_3O_4 was endorsed by the Fe 3*p* spectra (Fig. 4) which, with increasing tin content in the oxide, broaden and shift to lower energies. Deconvolution of the Fe 3*p* spectra showed a contribution at 56.2 eV characteristic [7] of Fe^{3+} together with a peak in the tin-containing materials at 54.3 eV characteristic [7] of Fe^{2+} which increased in intensity as the tin content increased (Table 3). The relative intensities obtained from the fit of the Fe 3*p* spectra agree well with those obtained from the fit of the Fe 2*p* spectra. The possible enrichment of the surface layers by either iron or tin was investigated using methods previously described [11,12] and by constructing calibration curves using standard compounds. The results gave no unequivocal evidence for the enrichment of the surface layers by either tin or iron.

Table 3. Fe 3*p* binding energy values obtained from the compounds Fe_3O_4, $Fe_{2.9}Sn_{0.1}O_4$ and $Fe_{2.8}Sn_{0.2}O_4$

Compound	BE (eV)	I_{rel} (%)	Assignment
Fe_3O_4	56.2	100	Fe^{3+}
$Fe_{2.9}Sn_{0.1}O_4$	54.3	47	Fe^{2+}
	56.2	53	Fe^{3+}
$Fe_{2.8}Sn_{0.2}O_4$	54.3	62	Fe^{2+}
	56.2	38	Fe^{3+}

Taken together the results show that the replacement of Fe^{3+} by Sn^{4+} in Fe_3O_4 is achieved by substitution on the octahedral sites of the inverse spinel structure and is accompanied by the partial reduction of Fe^{3+} to Fe^{2+}. It would seem that the lowering of the Curie temperature [4] of low tin-content tin-doped Fe_3O_4 as compared to that of Fe_3O_4 may therefore be associated with tin occupying the octahedral sites.

Acknowledgements—We thank the EPSRC for the award of a studentship (SS) and the provision of beamtime at Daresbury laboratory.

(Received 21 January 1997; accepted 20 May 1997)

Abstract—Manganese(II) complexes of the amino acids L-leucine, glycine, L-valine, L-glutamine, L-threonine, L-tryptophan, L-phenylalanine, L-methionine, L-aspartic acid and L-glutamic acid have been prepared. The complexes have metal : acid ratios of 1 : 2. Spectroscopic, magnetic and physical data for the complexes are presented. All of the manganese complexes catalytically disproportionate hydrogen peroxide in the presence of imidazole. © 1997 Elsevier Science Ltd

Keywords: manganese(II) complexes; amino acid complexes.

Recently, a number of manganese containing non-haem catalases have been isolated and characterised [1–3], and these enzymes catalytically disproportionate hydrogen peroxide, a reaction which is important for cell detoxification. Evidence has accumulated that the active site of the pseudo-catalase isolated from *Lactobacillus plantrum* comprises two manganese ions per protein subunit [3], and currently intense efforts are being made to design and synthesise manganoenzyme mimetic complexes [4–12].

In this laboratory, previous efforts in this area have focused on the preparation, structural characterization and catalytic testing of manganese(II) carboxylates [13–18]. Herein we detail the preparation and properties of manganese(II) complexes of the amino acids L-leucine (L-leuH), glycine (glyH), L-valine (L-valH), L-glutamine (L-glnH), L-threonine (L-thrH), L-tryptophan (L-trpH), L-phenylalanine (L-pheH), L-methionine (L-metH), L-aspartic acid (L-aspH_2) and L-glutamic acid (L-gluH_2). The ability of the complexes to catalytically disproportionate hydrogen peroxide is also discussed.

RESULTS AND DISCUSSION

The complexes were synthesised using modifications of the methods previously published for the preparation of manganese(II) complexes of glycine, L-tryptophan and L-aspartic acid [19]. Synthetic routes to the manganese(II) amino acid derivatives are summarized in Scheme 1 (for complexes **1**–**8**) and Scheme 2 (for complexes **9** and **10**). The physical, analytical and IR spectral data for the complexes are given in Table 1. On the basis of microanalytical data the compounds were formulated as [Mn(L-leu)$_2$] (**1**), [Mn(gly)$_2$] (**2**), [Mn(L-val)$_2$]·1.5H_2O (**3**), [Mn(L-gln)$_2$] (**4**), [Mn(L-thr)$_2$]·H_2O (**5**), [Mn(L-phe)$_2$]·0.5 H_2O (**6**), [Mn(L-trp)$_2$]·H_2O (**7**), [Mn(L-met)$_2$]·

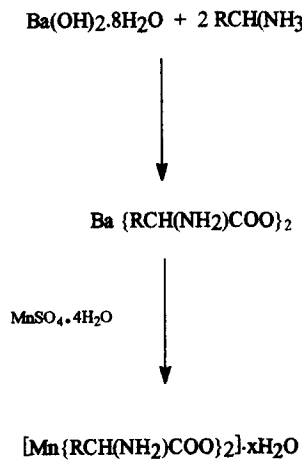

Scheme 2.

$0.5H_2O$ (**8**), $[Mn(L\text{-}aspH)_2]\cdot 3H_2O$ (**9**) and $[Mn(L\text{-}gluH)_2]\cdot 4H_2O$ (**10**), respectively.

The IR spectra of the complexes were compared with those of the free amino acids and a number of differences were noted. The characteristic bands for the amino acids and the important IR spectral bands that provide evidence for the structures of the complexes are listed in Table 2. The IR spectra of the amino acids contain broad, strong $—NH_3^+$ stretching bands in the region 3100 cm^{-1} which were replaced by several sharp bands (some of which were to higher frequencies) in the spectra of the manganese(II) complexes. Such changes are known to signify deprotonation and coordination of the $—NH_2$ groups [20]. Combination and overtone bands in the 2100 cm^{-1} region characteristic of $—NH_3^+$ groups were absent from the spectra of the complexes. Furthermore, the spectra of all of the complexes contained bands characteristic of species containing coordinated NH_2 functions [20]. In addition there were differences in the positions of the $\nu_{asym}(OCO)$ and $\nu_{sym}(OCO)$ stretching vibrations of the free acids and the complexes consistent with the coordination of the carboxyl groups (Table 2). The $\Delta(OCO)$ values for the complexes are all greater than the $\Delta(OCO)$ values found for the free amino acids (Table 2). Such increase in the value of $\Delta(OCO)$ values is indicative of monodentate coordination of the amino acidato carboxyl function [21].

Thus, from the IR data, one can deduce that the monovalent anions of the amino acids are coordinated to the metal as bidentate N,O-ligands (Fig. 1) [22]. With the exception of **5** and **8** the IR spectra of the complexes appear to posses only one Mn—N band (Table 2) which may suggest a *trans* coordination of the amino acid ligands [Fig. 1(a)] [21]. The spectra of **5** and **8** on the other hand each exhibit two possible Mn—N bands (Table 2) and thus it is possible that in these complexes the ligands are bound to the metals in a *cis*-configuration [Fig. 1(b)] [21].

The magnetic moment values for **1–10** (μ_{eff} = 5.6–6.0 B.M per Mn) are in the range expected for normal manganese(II) complexes, i.e. those lacking Mn—Mn interactions [23]. Whereas complexes **1, 6, 8–10** were found to be water soluble the others were insoluble in all common solvents suggesting that they may be polymeric in the solid state. All attempts to crystallise the soluble complexes from water were unsuccessful. Furthermore, the use of buffered solutions yielded either precipitated manganese dioxide (from basic solution) or crystals of the free amino acids (from acidic solution).

We have recently described the synthesis and structures of a series of manganese(II) carboxylate complexes, and demonstrated their ability to catalyse the disproportionation of H_2O_2 [13–18,24]. The reactivity of the present complexes as catalysts for peroxide disproportionation was investigated in the presence of the base imidazole. All of the amino acid complexes were found to be ineffective for the disproportionation of hydrogen peroxide in the absence of the added base. In the presence of added imidazole the complexes vigorously catalysed the breakdown of the peroxide. The results of these reactions are summarised in Tables 3 and 4. Examination of Table 4 shows that over the first minute of reaction complex **10** appears to be the most efficient catalyst with 2362 molecules of peroxide being disproportionated by one molecule of the complex. Complex **5** appears to be the least efficient catalyst over the first minute with one molecule of the compound knocking down 1302 molecules of the peroxide. It should be noted that the imidazole by itself causes only a very slight disproportionation of peroxide (Table 3). Such an enhancement in the rate of peroxide disproportionation in the presence of added base was also found to be the case for the manganese(II) carboxylate complexes previously synthesised in this laboratory [24]. Furthermore, similar effects have been reported previously by other workers [8,9,12,25]. It is significant that heterocyclic bases are known to be present in the vicinity of the active sites of manganoenzymes [26].

With the exception of $[Mn(\eta^1\eta^1\text{-nda})(phen)_2]\cdot EtOH\cdot H_2O$[15] ($ndaH_2$ = *cis*-5-norbornene-*endo*-2,3-dicarboxylic acid, and phen = 1,10-phenanthroline), the amino acid complexes **3, 4, 6, 7, 8** and **10** appear to be more efficient catalysts than the manganese(II) carboxylate complexes previously published by our group [13,14,16–18]. Furthermore, the performance of complexes **3, 4, 6, 7, 8** and **10** as catalysts for the disproportionation reaction appear to be superior to that of most of the binuclear manganese catalase mimetic complexes reported thus far.

EXPERIMENTAL

The amino acids were purchased from commercial sources and used without further purification. IR spectra (KBr discs) were recorded in the region 4000–400 cm^{-1} on a Nicolet Impact 400DST/IR spectrophotometer. Room temperature magnetic sus-

Fig. 1. Possible binding modes of the amino acid ligands in the bis(amino acid)manganese(II) complexes: (a) *trans*-configuration, (b) *cis*-configuration.

ceptibility measurements were made using a Johnson Matthey Magnetic Susceptibility Balance ($\mu_{eff} \pm 0.2$ B.M.) and $Hg[Co(SCN)_4]$ was used as a reference standard. Elemental analyses were carried out by the Microanalytical Laboratory, University College Cork, Ireland. The complexes were prepared using the methods described below.

Method 1

$LiOH \cdot H_2O$ (5.50 mmol) was dissolved in ethanol (70 cm^3) and any undissolved material was removed by gravimetric filtration. The amino acid (5.90 mmol) was then added to the filtrate and the solution was refluxed for 1.5 h. To the solution was added $Mn(NO_3)_2 \cdot 4H_2O$ (2.70 mmol) and refluxing was continued for a further 1.5 h. The resulting suspension was cooled to room temperature and the solid product was filtered off, washed with ethanol and air-dried at *ca* 25°C.

Method 2

To a solution of $Ba(OH)_2 \cdot 8H_2O$ (8.0 mmol) in water (90 cm^3) was added the amino acid (16 mmol) and the solution was stirred at room temperature for 2 h. The resulting solution was filtered and the supernatant was evaporated to *ca* 20 cm^3. To the supernatant was added ethanol (10 cm^3) to give a white suspension of the barium salt of the respective amino

acid and this was concentrated to dryness. The solid was washed with ethanol and air-dried at *ca* 25°C.

To a solution of the amino acid barium salt (8 mmol) in water (60 cm^3) was added a solution of $MnSO_4 \cdot H_2O$ (8 mmol) in water (20 cm^3) and the resulting suspension was stirred, at room temperature, for 2 h. The solid was filtered off and the supernatant was evaporated to *ca* 25 cm^3. To the supernatant was added ethanol (10 cm^3) to give a suspension and this was concentrated to dryness, yielding a solid. The solid was washed with ethanol and air-dried at *ca* 25°C for several days.

Hydrogen peroxide disproportionation studies

To a solid sample (*ca* 10 mg) of the manganese complex was added aqueous H_2O_2 (35% w/w, 5 cm^3, 57 mmol). The mixture was stirred and thermostated at 25°C, and the evolved O_2 was measured volumetrically (volume $\pm$ 0.10 cm^3). In cases where imidazole (50 mg) was added this was introduced into the reaction vessel before the addition of H_2O_2.

Abstract—The values of the first formation constant are reported for some substituted bis(1,10-phenanthroline)Cu^{I} complexes in dimethylsulfoxide. The formation constant increases along the series 5 Cl phen < phen < 5,6 diCH_3 phen < 3,4,7,8 tetraCH_3 phen. A lineal correlation is found between formation constant or acidity constant of the substituted phenanthroline with the vibration frequency of the Cu—N bond. © 1997 Elsevier Science Ltd

Keywords: cuprous complexes; 1,10 phenanthroline; formation constant.

Some years ago we reported that the substituents on the coordinated ligand affects the rate of oxidation of the corresponding bis-(1,10-phenanthroline) copper(I) complexes.

The changes in the oxidation rates are attributed to the electronic effect of the substituents. Therefore, the methyl groups increases the oxidation rate whereas the chlorine group decreases the rate of the reaction in such a way that these effects can be correlated with the basicity of the complexing agent by using the Hammett linear free energy relationship [1].

The stepwise instability constants of bis(1,10-phenanthroline)Cu^{I} complex in dimethysulfoxide (DMSO) are so small, $-\log K_1 = 5.56$ and $-\log K_2 = 5.44$, at 23°C that the optical data can be used to obtain the first instability constant ($-\log K_1^* = 5.53$) omitting the second dissociation step [2]. Only the partial formation constants of bis(2,9-Dimethyl-1,10-phenanthroline)Cu^{I} complex has been reported in aqueous solution [3].

EXPERIMENTAL

Dimethylsulfoxide was purified and dried by standard methods and stored in a deoxigenated, dried, N_2 atmosphere. The purified DMSO contained H_2O of concentration in 10^{-2}–10^{-3} mol dm^3 range as found by using Karl–Fischer reagent. The substituted phenanthrolines were obtained from Aldrich Chem Co. All the cuprous complexes were prepared in an inert atmosphere by the technique described by Schilt and Taylor [4].

A Unicam SP8000 Spectrophotometer with a thermostatted cell compartment and quartz cell (1.0 cm) was used to measure the optical density at 23°C.

RESULTS AND DISCUSSION

Spectrophotometric determination

The dissociation of the substituted bis(1,10-phenanthroline)copper^{I} complex, $Cuph_2$, in solution may be represented by the following equations:

$$Cuph_2 \overset{K_1}{\rightleftharpoons} Cuph + ph \quad (1)$$

$$Cuph \overset{K_2}{\rightleftharpoons} Cu + ph \quad (2)$$

Where the solvent and the charge on the particles are omitted. Considering that K_2 value is very small it is possible to use the optical density data of the

Table 1. First formation constant of substituted bis-(1,10-phenanthroline)Cu^{I} complexes in dimethylsulfoxide at 23°C

	ε ($mol^{-1}\,dm^3\,cm^{-1}$)	λ nm	$10^6\,K_1^*$ ($mol\,dm^{-3}$)	$\log \beta_1^*$	ν(Cu—N)[a] (cm^{-1})
$Cu(5Clphen)_2^+$	6786	451	5.24	5.28	280
$Cu(1,10\text{-phen})_2^+$	7200[b]	445	2.95	5.53	288
$Cu(5,6DiMe\text{-phen})_2^+$	7636	450	1.25	5.9	301
$Cu(3,4,7,8\,tetraMephen))_2^+$	9056	436	0.66	6.18	306

[a] Asymmetric copper–nitrogen stretching vibrations reported in Ref. [5].
[b] Ref. [8].

$Cuph_2$ complex to calculate a K_1^* value omitting the second dissociation (2). Then $K_1 \sim K_1^*$.

$$K_1^* = \frac{[Cuph][ph]}{[Cuph_2]} \tag{3}$$

The analytical concentration of copper $[Cu]_A$, and substituted 1,10-phenanthroline, $[ph]_A$, are represented by eqs (4) and (5)

$$[Cu]_A = [Cuph_2] + [Cuph] \tag{4}$$

$$[ph]_A = [ph] + [Cuph] + 2[Cuph_2] \tag{5}$$

The equilibrium concentration necessary to calculate K_1^* with eq. (3) can be evaluated by using eqs 4, 5, 6 and 7.

$$\varepsilon_{Cuph2}[Cuph_2] = O.D. \tag{6}$$

$$[Cuph] = [ph] = [Cuph_2]_A - [Cuph_2] \tag{7}$$

Where ε_{Cuph_2} corresponds to the molar absorptivity of the $Cuph_2$ complex at λ (wavelength) in the visible spectral range and O.D. corresponds to the optical density.

Table 1 gives the average value of the first dissociation constant K_1^* (formation constant $\log \beta_1^* = -\log K_1^*$) at 23°C in dimethylsulfoxide of substituted bis(1,10-phenanthroline) cuprous complexes and its maximum molar absorptivity at λ.

Let us consider the dissolution process of a solid phase of the $Cuph_2ClO_{4(s)}$ complex, in a solvent S in several steps.

$$Cuph_2ClO_{4(S)} \xrightarrow{S} [S]Cuph_2ClO_4 \tag{8}$$

$$[S]Cuph_2ClO_4 \rightarrow [S]Cuph_2^+ + [S]ClO_4^- \tag{9}$$

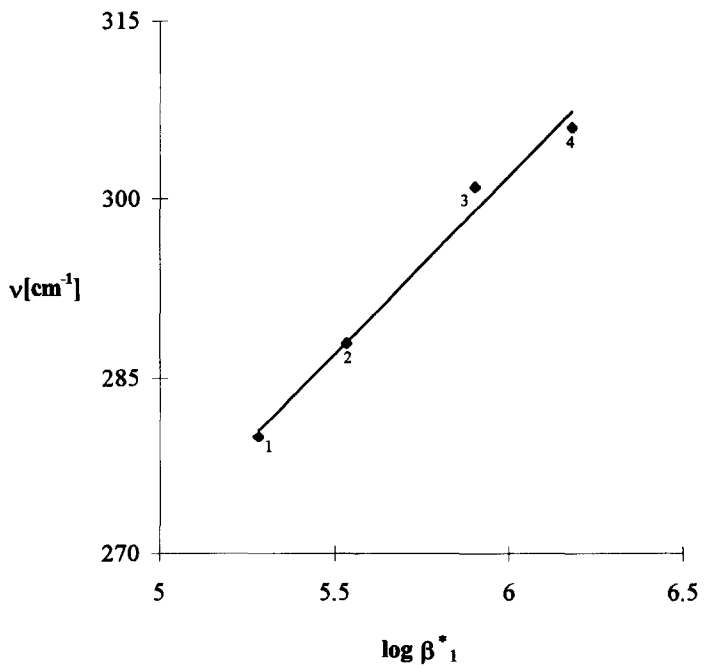

Fig. 1. Dependence of IR vibration frequency of the Cu—N bond on the log of the first formation constant β_1^* of the cuprous complexes obtained from substituted 1,10-phenanthroline. (1): 5 Cl phen; (2): phen; (3): 5,6 dimethylphen; (4): 3,4,7,8 tetramethylphen.

$$[S]Cuph_2^+ \overset{K_1}{\rightleftharpoons} [S]Cuph(S)^+ + [S]ph \qquad (10)$$

Where [S] corresponds to a solvent with a weak interaction with a neutral particle or with an ion, (S) correspond to a coordinated solvent molecule with the cuprous ion.

Reactions 8 and 9 correspond to a simple dissolution process but reaction 10 is concerned with a breaking Cu—N bond process and the formation of the Cu—S bond.

The strength of the Cu—N bond in the solid phase is related to the vibration frequency that changes to a ν' value owing to the solvation process of $Cuph_2^+$ ion complex in the solution. In a series of cuprous complexes obtained from a family of complexing agents like the substituted phenanthroline it is possible to assume similar perturbation value. We should expect therefore that for a greater Cu—N bond strength, related with ν, the dissociation constant to form $Cuph(S)^+$ ion complex should be smaller. It should be possible to find a correlation between ν and the dissociation constant if the free energy variation of reaction 10 is the greater one.

Figure 1 shows that there is a roughly lineal relationship between the I.R. vibration frequency of the Cu—N bond [5] and log β_1^*. A similar linear plot is found between ν and the acidity constants of the substituted, 1,10-phenanthroline [6] but the ν frequency of the cuprous complexes related to 4,7 dimethyl and 5-methyl phenanthroline, 282 and 284 cm^{-1}, respectively, does not follow this trend because they have lower frequencies than with the unsubstituted phenanthroline (288 cm^{-1}).

A more elegant approach can be designed with a Born–Haber cycle, but there is no available gas-phase reaction values to carry out the calculation.

Bond distance is the other magnitude that it is possible to obtain from the crystallographic data in the solid phase. In spite of the Cu—N distance in bis-(1,10-phenanthroline)Cu^I complex has been reported, 2.045 Å [7], our attempts to form X-ray quality crystals of the cuprous complexes with substituted phenanthrolines failed.

Synthesis and characterization of some unique heterocyclic derivatives containing aluminium(III) atoms in different coordination states—4. Reaction of bis(β-diketonato) aluminium(III)-di-μ-isopropoxo-di-isopropoxo aluminium(III) with 8-hydroxyquinoline

Anita Dhammani, Rakesh Bohra* and Ram C. Mehrotra

Department of Chemistry, University of Rajasthan, Jaipur 302004, India

(Received 5 March 1997; accepted 14 May 1997)

Abstract—Reactions of bis(β-diketonato)aluminium(III)-di-μ-isoproxo-di-isopropoxo aluminium(III), $[(CH_3COCHCOR)_2Al(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$ with 8-hydroxyquinoline, C_9H_6NOH in 1 : 1 and 1 : 2 molar ratios, have resulted in the synthesis of $[(CH_3COCHCOR)_2Al(\mu\text{-}OPr^i)_2Al(ONC_9H_6)(OPr^i)]$ and $[(CH_3COCHCOR)_2Al(\mu\text{-}OPr^i)_2Al(ONC_9H_6)_2]$, respectively. These are soluble in a variety of organic solvents (e.g. benzene, chloroform and dimethylsulfoxide), except $[(CH_3COCHCOCH_3)_2Al(\mu\text{-}OPr^i)_2Al(ONC_9H_6)_2]$ and $[(CH_3COCHCOOC_2H_5)_2Al(\mu\text{-}OPr^i)_2Al(ONC_9H_6)_2]$, which are insoluble in benzene but soluble in chloroform and dimethylsulfoxide. These derivatives show dinuclear behaviour in chloroform. Plausible structures have been proposed on the basis of elemental analyses, molecular weight measurements, IR and NMR (^1H, ^{13}C and ^{27}Al) spectral studies. ^{27}Al NMR spectra show the presence of six and four/five coordinated aluminium sites.

Keywords: heterocyclic derivatives; bis(β-diketonato)aluminium(III)-di-μ-isopropoxo-di-isopropoxo aluminium(III); aluminium(III)isopropoxide; 8-hydroxyquinoline; ^{27}Al NMR spectra; coordination states.

8-Hydroxyquinoline behaves as a strong bidentate chelating ligand with aluminium(III) [1–3] in its compounds.

In continuation with our interest in the reactivity of $[(CH_3COCHCOR)_2Al(\mu\text{-}OPr^i)_2\ Al(OPr^i)_2]$ derivatives with various ligands containing hard [4,5] or/and soft [6] donor atoms, the present work deals with the reaction of $[(CH_3COCHCOR)_2Al(\mu\text{-}OPr^i)_2Al(OPr^i)_2]$ with C_9H_6NOH in 1 : 1 and 1 : 2 molar ratios.

RESULTS AND DISCUSSIONS

The reactions of $[Al(CH_3COCHCOR)(OPr^i)_2]_2$ with 8-hydroxyquinoline in 1 : 1 and 1 : 2 molar ratios in refluxing benzene, can be represented by the following equation:

$$[Al(CH_3COCHCOR)(OPr^i)_2]_2 + xC_9H_6NOH \xrightarrow[\text{Reflux}]{\text{Benzene}}$$

$$[(CH_3COCHCOR)_2Al(\mu\text{-}OPr^i)_2$$

$$Al(ONC_9H_6)_x(OPr^i)_{2-x}] + xPr^iOH\uparrow$$

($x = 1$ or 2 and R = $-CH_3$, $-C_6H_5$ and $-OC_2H_5$)

These reactions are facile and pushed to completion by fractionating out azeotropically the liberated isopropanol which was estimated. The analytical data of these complexes support the stoichiometry assigned to these compounds. All these derivatives are hygroscopic, bright yellow solids, soluble in a variety of organic solvents (e.g. benzene, chloroform and dimethylsulfoxide), except $[(CH_3COCHCOCH_3)_2 Al(\mu\text{-}OPr^i)_2\ Al(ONC_9H_6)_2]$ and $[(CH_3COCHCOOC_2$

* Author to whom correspondence should be addressed.

$H_5)_2Al(\mu\text{-}OPr^i)_2$ $Al(ONC_9H_6)_2]$, which are insoluble in benzene but soluble in chloroform and dimethylsulfoxide. These derivatives show dinuclear behaviour in chloroform and can be recrystallised unchanged from dichloromethane and n-hexane mixture.

IR spectra

The tentative assignments of some of the important bands have been made and are recorded in Table 1.

The broad stretching vibration at $\sim 3242\ cm^{-1}$ due to —O—H group of the free 8-hydroxyquinoline ligand was found to be absent in all these derivatives, suggesting the formation of Al—O bond with the 8-hydroxyquinolinate moiety. The single peak observed at $1586\ cm^{-1}$ in the free 8-hydroxquinoline due to ν(C=C)/ν(C=N) vibrations is found to split into two sharp peaks in the regions 1600–1605 and 1565–1598 cm^{-1} in all these derivatives, probably as a result of augmentation [2] of the ν(C=N) which was previously hidden in the ring C=C vibration. This appears to suggest that the lone pair on nitrogen is also involved in the formation of a coordinate bond with aluminium(III), leading to a reduction in the double bond character of the C=N bond and appearance of two sharp peaks as compared to the free ligand. Thus it may be assumed that the 8-hydroxyquinolinate moiety, in all these complexes is behaving as a bidentate chelating ligand.

The shifting of ν(C···O) of β-diketonate moiety towards lower wave numbers (at 1530–1540 cm^{-1}) as compared to the free ligand and the presence of a strong band at 1500–1505 cm^{-1} due to C···C stretching vibrations, appear to indicate bidentate quasi-aromatic nature of β-diketonate moiety [7].

The C—O stretching vibrations of the bridging isopropoxy groups were observed in region 1000–1009 cm^{-1}. The weak absorption at 750–759 cm^{-1} may be ascribed [8] to Al—O—Al stretching vibrations. Bands in the lower region 700–450 cm^{-1} may be arising [8] due to Al—O and Al—N stretching vibrations.

^{1}H *NMR spectra*

Characteristic chemical shifts of these derivatives are given in Table 2. The signal due to hydroxy proton of the free 8-hydroxyquinoline (QOH) ligand at δ 8.45 ppm (Table 2) is found to be absent in all these complexes, indicating the formation of Al—O bond by deprotonation of the 8-hydroxquinoline ligand.

The signal due to CH(2) ring proton at δ 8.30 ppm in the spectra of 8-hydroxyquinoline undergoes an upfield shift at δ 8.18–8.30 ppm in these complexes, suggesting coordination of nitrogen to aluminium. The doublet at δ 8.92 ppm in the spectra of free QOH ligand undergoes an upfield shift at δ 8.64–8.81 ppm.

The methyl and methine signals of the bridging isopropoxy group present in the derivative, $[(CH_3CO\text{-}CHCOR)_2Al(\mu\text{-}OPr^i)_2Al(ONC_9H_6)_2]$ appear at δ 1.18–1.21 and δ 4.05–4.09 ppm, respectively. In the case of $[(CH_3COCHCOR)_2Al(\mu\text{-}OPr^i)_2Al(ONC_9H_6)(OPr^i)]$ the methine protons of the terminal and the bridging isopropoxy groups were observed at δ 3.53–4.02 and δ 4.02–4.51 ppm, respectively, while the corresponding methyl protons appeared in the region δ 1.18–1.21 ppm (Table 2).

The methyl and methine signals of the β-diketonate moiety appear at δ 1.88–2.15 and δ 4.92–6.30 ppm, respectively, in all these complexes. The methylene protons of the ethylacetylacetate moiety appeared in the range δ 3.92–3.98 ppm and the aromatic protons of the benzoylacetone moiety are observed in the region δ 6.93–7.69 ppm.

^{13}C *NMR spectra*

The ^{13}C NMR chemical shifts of these compounds and the free QOH ligand were recorded in chloroform at ambient temperature (Table 3).

In all these complexes, both the C(8) and C(9) carbons of the 8-hydroxyquinoline moiety are slightly shifted as compared to the corresponding signals present in the free QOH ligand. The other aromatic carbons of the QOH and benzoylacetone moieties were observed in the range δ 110.40–138.99 ppm.

Methyl carbons of the terminal and bridging isopropoxy groups are observed at δ 24.92–25.13 and δ 25.52–26.02 ppm, respectively. While the methine carbons of the terminal and bridging isopropoxy groups are observed at δ 59.70–63.66 and δ 63.71–64.74 ppm, respectively. In the case of $[(CH_3CO\text{-}CHCOR)_2Al(\mu\text{-}OPr^i)_2Al(ONC_9H_6)_2]$, only a single peak at δ 25.34–26.00 and δ 63.55–65.01 ppm, corresponding to the methyl and methine carbons of the bridging isopropoxy groups have been observed.

The carbonyl carbons of the β-diketonate moiety appear at δ 183.62–193.40 ppm, while that of ester group, at δ 170.58–174.60 ppm. The methyl and methine carbons of the β-diketonate moiety have been observed at δ 24.24–27.36 and δ 85.22–100.71 ppm, respectively. The methyl and methylene carbons of $—OCH_2CH_3$ group of the ethylacetylacetate moiety are observed at δ 14.30–14.41 and δ 60.79–60.81 ppm, respectively.

^{27}Al *NMR spectra*

The ^{27}Al NMR spectrum of $[(CH_3COCHCO\ CH_3)_2Al(\mu\text{-}OPr^i)_2Al(ONC_9H_6)(OPr^i)]$ at 23.79 MHz in benzene (25°C) exhibits an unresolved signal at δ 0.79 ppm. No further resolution of this signal could be observed even after varying the temperature.

Since the chemical shift value depends on the field strength, ^{27}Al NMR spectra of some of these representative derivatives have been recorded at 78.16 MHz in toluene (Table 4). The ^{27}Al NMR spectra of $[(CH_3COCHCOR)_2Al(\mu\text{-}OPr^i)_2Al(ONC_9H_6)(OPr^i)]$

Table 1. IR spectral data (cm^{-1}) of $[(CH_3COCHCOR)_2Al(\mu\text{-}OPr^i)_2Al(ONC_9H_6)(OPr^i)]$ and $[(CH_3COCHCOR)_2Al(\mu\text{-}OPr^i)_2Al(ONC_9H_6)_2]$

4	$[(CH_3COCHCOC_6H_5)_2Al(\mu\text{-}OPr^i)_2Al(ONC_9H_6)_2]$	+2.724	Hexa-coordinated
		+12.732	Penta-coordinated
		+21.055	Tetra-coordinated

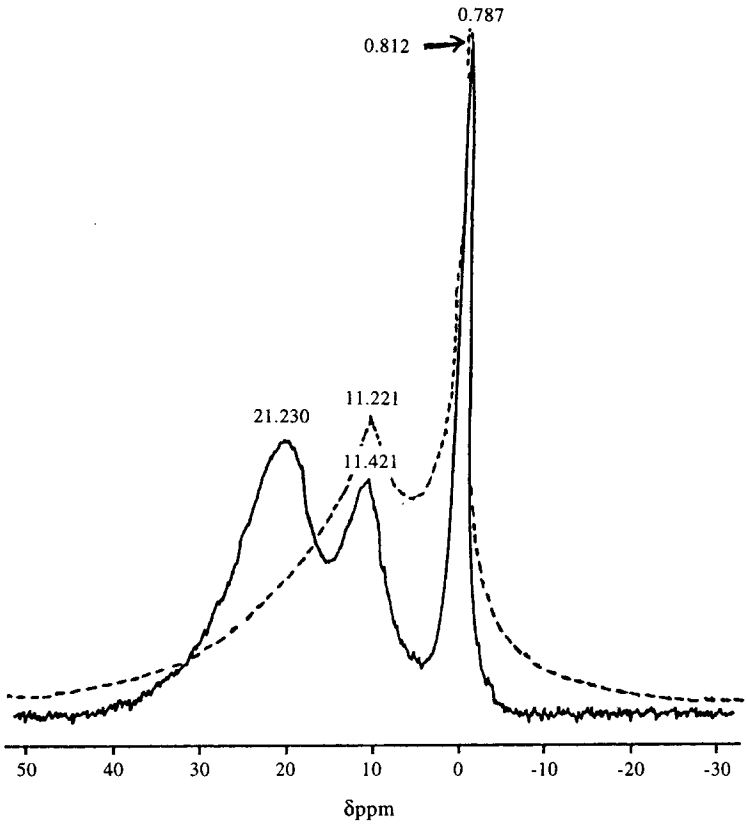

Fig. 1. ^{27}Al NMR spectra of $[(CH_3COCHCOCH_3)_2Al(\mu\text{-}OPr^i)_2Al(ONC_9H_6)(OPr^i)]$ (dotted line); $[(CH_3COCHCOCH_3)_2Al(\mu\text{-}OPr^i)_2Al(ONC_9H_6)_2]$ (dark line).

(R = —CH_3 and —C_6H_5) at 78.16 MHz exhibit two signals in the ranges at δ +0.812 to +2.724 and δ +11.221 to +12.683 ppm corresponding to six- and five-coordinated aluminium(III) atoms.

It is interesting to point out here that the ^{27}Al NMR spectra of $[(CH_3COCHCOR)_2Al(\mu\text{-}OPr^i)_2Al(ONC_9H_6)_2]$ (R = —CH_3 and —C_6H_5) at 78.16 MHz exhibit three signals in the ranges δ +0.787 to +2.724, δ +11.421 to +12.732 and δ +21.230 to +21.055 ppm, corresponding to six-, five- and four-coordinated aluminium(III) atoms.

The ^{27}Al NMR spectra of the two representative derivatives, $[(CH_3COCHCOCH_3)_2Al(\mu\text{-}OPr^i)_2Al(ONC_9H_6)(OPr^i)]$ and $[(CH_3COCHCOCH_3)_2Al(\mu\text{-}OPr^i)_2Al(ONC_9H_6)_2]$ have been shown in Fig. 1.

Although the actual structures can be established only after X-ray analysis, yet the available physicochemical data suggest that following unique structure for $[(CH_3COCHCOR)_2Al(\mu\text{-}OPr^i)_2Al(ONC_9H_6)(OPr^i)]$ derivatives, in which coordination around aluminium(III) atoms is six and five (Fig. 2).

Although, a number of references are available in

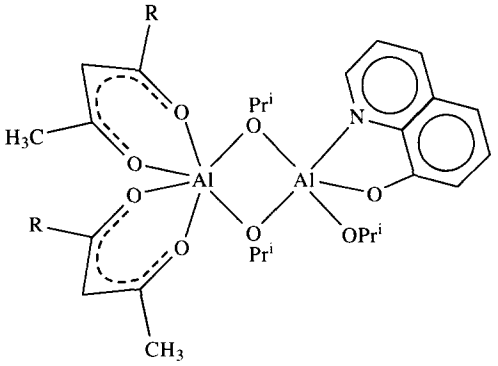

Fig. 2. Structure of $[(CH_3COCHCOR)_2Al(\mu\text{-}OPr^i)_2Al(ONC_9H_6)(OPr^i)]$ (R = —CH_3, —C_6H_5 and —OC_2H_5).

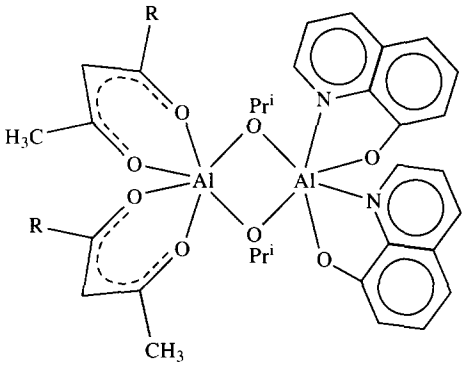

Fig. 3. Expected structure of $[(CH_3COCHCOR)_2Al\ (\mu\text{-}OPr^i)_2\ Al(ONC_9H_6)_2]$ (R = —CH_3, —C_6H_5 and —OC_2H_5).

the literature dealing with comparatively less stable penta-coordination around aluminium(III) atom, yet the above derivative, of the type $[(CH_3CO\text{-}CHCOR)_2Al(\mu\text{-}OPr^i)_2Al(ONC_9H_6)(OPr^i)]$ appears to be unique containing both hexa- and penta-coordination around aluminium(III) atoms, similar to that reported [9] for the anion, $[Al_3(OCH_2\ CH_2O)_5(OCH_2CH_2OH)_2]^{-3}$.

The structure of the corresponding 1 : 2 derivatives of the type $[(CH_3COCHCOR)_2Al(\mu\text{-}OPr^i)_2Al\ (ONC_9H_6)_2]$ is also unique. From the available physico-chemical data, excluding ^{27}Al NMR spectral studies, one would expect structure containing two hexa-coordinated aluminium(III) atoms (Fig. 3).

If the above structure is assumed for these derivatives then the ^{27}Al NMR spectra should exhibit two close peaks in octahedral range corresponding to two octahedrally coordinated aluminium(III) atoms. However, the presence of three ^{27}Al NMR signals corresponding to hexa-, penta- and tetra-coordinated aluminium(III) atoms may suggest an equilibrium of the following type (Fig. 4). This equilibrium is obviously not observed in the ^1H and ^{13}C NMR spectra of these derivatives due to differences in the timescales of these and the ^{27}Al NMR experiments carried out during the course of these investigations.

The above structures can be explained by steric hindrance around aluminium(III) atom due to the presence of two QOH moiety, which do not permit the coordination of both the nitrogen atoms simultaneously, thus resulting in the unusual five-coordination around aluminium(III), rather than stable six-coordination. In view of these interesting inferences, efforts were made to record the X-ray crystal structures of the different derivatives, but unfortunately substained efforts to obtain good quality crystals have not been successful.

EXPERIMENTAL

All the solvents used during the present investigation were of reagent grade and were made anhydrous by standard methods. Aluminium isopropoxide was prepared as described by Mehrotra [10]. Benzoylacetone, acetylacetone and ethylacetylacetate were distilled before use, while 8-hydroxyquinoline was purified by crystallization from diethylether. Isopropanol was estimated [11] by oxidation with normal $K_2Cr_2O_7$ solution in 12.5% H_2SO_4. Isopropoxy groups in the products were estimated by hydrolysing them and collecting the liberated isopropanol azeotropically with benzene. Aluminium was estimated gravimetrically as the oxinate.

Infrared spectra were recorded as Nujol mulls on a Perkin–Elmer 577 spectrophotometer in the range 4000–200 cm^{-1}. ^1H NMR spectra were recorded on a Jeol FX 90Q spectrometer in $CDCl_3$ using TMS as an internal reference. ^{13}C NMR spectral studies have been carried out in chloroform at 22.49 MHz using D_2O locks. ^{27}Al NMR spectral studies have been carried out in benzene/chloroform on a Jeol FX 90Q MHz at 23.79 MHz, using aluminium nitrate as standard reference. Some ^{27}Al NMR spectra were recorded on a varian 300 MHz at 78.16 MHz in toluene. Molecular weight measurements were carried out on a Knauer Vapour Pressure Osmometer in chloroform at 45°C temperature.

$[Al(CH_3COCHCOR)(OPr^i)_2]_2$ was prepared as reported earlier [4–6,12]. All the present mixed ligand aluminium(III) complexes were synthesized by a similar route and hence, synthesis of only one representative compound is described below.

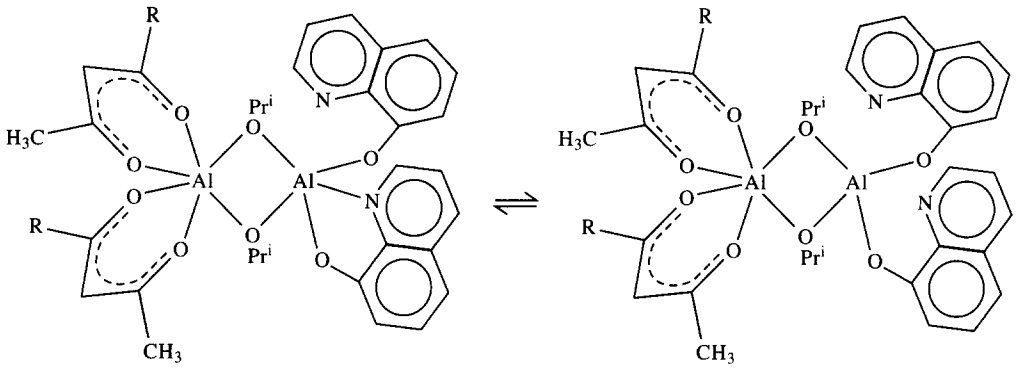

Fig. 4. Interconversion between penta- and tetra-coordination states of aluminium.

[a] Compound numbers as in Table 1.

Reaction of $[Al(CH_3COCHCOCH_3)(OPr^i)_2]_2$ *with* C_9H_6NOH *in* 1 : 1 *molar ratio: synthesis of* $[(CH_3COCHCOCH_3)_2Al(\mu\text{-}OPr^i)_2Al(ONC_9H_6)(OPr^i)]$

8-Hydroxyquinoline (1.39 g, 9.58 mmol) was added in benzene solution (~70 ml) of $[Al(CH_3COCHCOR)(OPr^i)_2]_2$ (4.68 g, 9.58 mmol) and was refluxed on a fractionating column for about 3 h. The isopropanol in the reaction was fractionated out azeotropically with benzene. Progress as well as the completion of the reaction was checked by the estimation of isopropanol in azeotrope by oxidimetric method [11]. The product was found to be soluble in benzene. After stripping off the solvent under reduced pressure, a bright yellow coloured solid was obtained in good yield, which was purified by recrystallization from a mixture of dichloromethane and *n*-hexane.

Details of synthesis of other derivatives and the analytical data have been summarized in Table 5.

Acknowledgement—One of us (A.D.) thanks the C.S.I.R., New Delhi for the award of Senior Research Fellowship and R.S.I.C., Bombay for obtaining ^{27}Al NMR spectral data of some of the samples.

Redox chemistry of copper acetate binuclear complexes in acetic acid–methanol mixture as solvent

I. Toledo, M. Arancibia, C. Andrade and I. Crivelli*

Facultad de Ciencias, Universidad de Chile, Casilla 653, Santiago, Chile

(Received 17 February 1997; accepted 14 May 1997)

Abstract—The redox chemistry of the photochemically generated bioinorganic model $(CH_3COO)_2Cu^{II}Cu^{I}(OOCCH_3)_2$ and the parent species $(CH_3COO)_2Cu^{II}Cu^{II}(OOCCH_3)_2$ (complex **I**) are reported. The purpose is to achieve a more complete physicochemical characterization of the acetate binuclear copper complex and consequently a closer evaluation of its behaviour as a model of type III Cu sites in cuproproteins. Complex I may be sequentially reduced (broad not resolved peaks around −0.2 and −0.4 V) and reoxidized (peaks at 0.16 and 0.36 V), but in competition with a thermal disproportionation to Cu^{II} and Cu^0. Controlled potential electrolysis (CPE) at −0.4 V measures quantitatively the overall reduction process including disproportionation and involves four electrons per mole of initial complex **I**. Structural changes seem to play a role in the oxidation–reduction processes as suggested by $ip/\sqrt{v}$ *vs* v studies (Nicholson and Shain's criteria), and they make the processes irreversible. The mixed-valence Cu^{II}–Cu^{I} species could not be produced by CPE at any voltage before the second reduction peak; however, its electrochemical generation by pulses at −0.4 V render direct experimental evidence that the reduction process is sequential. The voltammograms of the Cu^{II}–Cu^{I} species generated photochemically are more complicated: the reduction and oxidation peaks are centered at −0.2 and 0.0 V, respectively. The species Cu^{II}–Cu^{II} originated from the oxidation of this mixed valence complex, called as complex **II**, shows similarities and differences with complex **I**. The results are discussed in relation to the structure stability and to the copper interactions in the binuclear species considered as models for the copper protein centers. © 1997 Elsevier Science Ltd

Keywords: copper binuclear; copper mixed-valence; copper acetate; copper electrochemistry; copper proteins model; copper redox chemistry.

The absorption spectra of the prototype dimeric copper species $(CH_3COO)_2Cu^{II}Cu^{II}(OOCCH_3)_2$ and the interaction between the copper centers in it have been studied for several years [1], however, only recently have the magnetic properties of the copper acetate bridged pyrazine dimer been properly understood and the observed 'dimer band' assigned as a *z*-polarized A_{1g}–A_{2g} acetate ligand-to-metal charge transfer [2].

Recently, we reported [3] an electron transfer study in the mixed-valence $(CH_3COO)_2Cu^{II}Cu^{I}(OOCCH_3)_2$, species |MV|, generated by UV irradiation of the Cu^{II}–Cu^{II} precursor species in acetic acid-methanol mixtures. The Cu^{II}–Cu^{II} species shows antiferromagnetic coupling [2] and the MV species shows a weak interaction between the metallic centers (class II in the Robin and Day classification [4]). The results also indicate that the symmetry of the Cu^{II} and Cu^{I} sites is similar. Otherwise, the MV complex has some characteristics in common with type III copper observed in copper oxidases in the MV state [3]. It appears interesting to determine the feasibility of generating the MV species electrochemically, since this fact thermodynamically means that the overall redox process Cu^{II}–$Cu^{II} \rightarrow Cu^{I}$–$Cu^{I}$ proceeds through sequential one electron steps and also from the kinetic point of view this fact means a certain stability of the electrochemically generated Cu^{II}–Cu^{I} (and Cu^{I}–Cu^{I}) complex [5].

The thermodynamic stability of the MV species may be appreciated from the peak-to-peak separation, ΔE_p, on a cyclic voltammogram for the sequential reduction of binuclear Cu^{II}–Cu^{II} to binuclear Cu^{I}–Cu^{I}. In the absence of major structural changes, i.e.,

* Author to whom correspondence should be addressed.

changes in coordination number, bond making and breaking, and severe changes in coordination geometry associated with the redox process, ΔE_p reflects the interaction between the metal centers, the magnetic superexchange effects between them, and the electron delocalization in the MV state [6a,b]. A combination of factors, including structural changes, will determine if the overall two-electron reduction of the binuclear Cu^{II} species will consist of a simultaneous two- electron or two one-electron steps, at the same or different potential [7]. Considering the system as a bioinorganic model, it seems also important to know were the redox changes take place (positive or negative potentials).

In this paper we report studies of the redox behaviour of both the Cu^{II}–Cu^{II} and the mixed-valence species photochemically generated in order to achieve a more complete physicochemical characterization of the acetate binuclear copper complex and consequently a closer evaluation of its behaviour as a model of type III—Cu sites.

EXPERIMENTAL

Materials

$(CH_3COO)_2Cu \cdot H_2O$ p.a. Merck was used without further purification. Glacial acetic acid (AcOH) 100% p.a. Merck and methanol (MeOH) (Merck–Uvasol spectroscopic grade) were used directly. Solutions of the cupric acetate dimer $(CH_3COO)_4Cu_2$ were prepared by dissolving $(CH_3COO)_2Cu \cdot H_2O$ in 95/5% (vol./vol.) MeOH/AcOH mixtures to obtain solutions approximately 6×10^{-3} mol dm^{-3} in copper(II). Tetrabutylammonium tetrafluoroborate ($TBABF_4$) was purchased from Aldrich Chemical Co. The violet mixed-valence compound (MV) was generated *in situ* as indicated in reference [3]. Argon or N_2 gas was used to provide an inert atmosphere.

Electrochemistry

The controlled-potential electrolysis (CPE) and cyclic voltammetry (CV) measurements were recorded with a PAR 173 potentiostat-galvanostat coupled to a PAR 176 current-detection module. For the cyclic voltammetry experiments, a PAR 175 universal programmer was also used. A Watanabe WX 4301 X-Y recorder was used for i versus V plots. A three-electrode system, with SCE as reference, was used for both CPE and CV experiments. In the last case, a platinum wire was used as working electrode and a platinum coil as auxiliary electrode. For the CPE measurements, a platinum mesh and coiled platinum wire were used as working and auxiliary electrodes, respectively. ($TBABF_4$) 0.1 M was used as supporting electrolyte. The concentration of the complex under study was 1.5×10^{-3} M.

RESULTS

Electrochemistry of $(CH_3COO)_2Cu^{II}Cu^{II}(OOCCH_3)_2$ *(complex* **I**)

The cyclic voltammogram of the $(CH_3COO)_2Cu^{II}Cu^{II}(OOCCH_3)_2$ solution is shown in Fig. 1. It shows two broad reduction peaks, one from +0.2 to −0.2 (A) V and a second one centered at −0.4 (B) V. Two oxidation peaks appear at −0.16 (C) and 0.36 (D) V by reversing the potential sweep after the reduction processes have occurred. Figs 2 and 3 shows the relationship between the oxidation and reduction reactions, i.e. between (A) and (D), and (B) and (C), (E) peaks. The sharp peak around 0 V provides evidence for a metal (Cu^0) deposit on the Pt electrode surface and the small shoulder around 0.2 V, observed in the CV of the Cu^{II} salts, evidences the presence of Cu^{II} ions in solution. Both species Cu^0 and Cu^{II} ions result from a disproportionation process. The disproportionation does not take place at potentials below −0.4 V (Figs 2 and 3) although there is a dependence on the scan speed (Fig. 5) indicating the presence of a kinetic factor. Figure 4 and Fig. 5 show the CV study of the redox processes as a function of the scan speed. Analysis of the *ip vs* $\sqrt{v}$ data shows that the processes are diffusion controlled (not shown). Figures 6 and 7 show the Nicholson and Shain diagrams [8].

CPE at −0.4 V results in an uncoloured solution after the overall passage of four electrons per mole of complex and Cu^0 deposition on the platinum working electrode is verified.

Electrochemical generation of $(CH_3COO)_2Cu^{II}Cu^{I}(OOCCH_3)_2$

The mixed-valence species could not be generated by CPE at any voltage in the range of the first

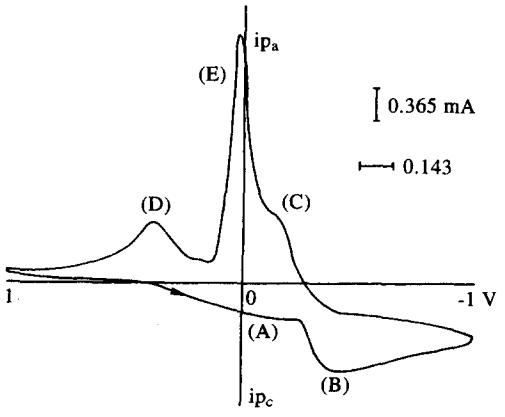

Fig. 1. Cyclic voltammogram of a 1.5×10^{-3} M degassed solution of cupric acetate dimer inn 0.1 M $TBABF_4$ 95/5% (vol/vol) MeOH/AcOH mixture as solvent. Scan rate 200 mV/s^{-1}. Saturated calomel electrode as reference; platinum wire and platinum coil as working and auxiliary electrodes, respectively.

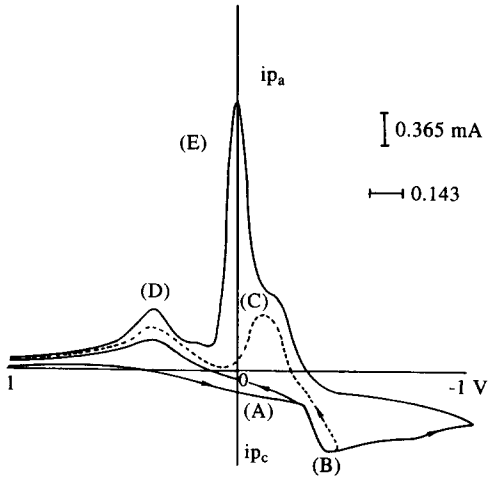

Fig. 2. Relationship between the reduction (A) and oxidation (D) peaks in the cyclic voltammogram of a 1.5×10^{-3} M degassed solution of cupric acetate dimer in 0.1 M $TBABF_4$ 95/5% (vol/vol) MeOH/AcOH mixture as solvent. Same conditions as Fig. 1. Peak (E) is related to Cu^0 deposit on the working electrode.

reduction zone, but when short pulses of current were applied at −0.4 V the original green solution turns to a blue–violet color, presumably the mixed-valence species. The concentration of the generated blue–violet species may be increased only to a maximum value since after several pulses (4–6) the blue–violet color began to decrease.

Due to the low concentration of the blue–violet species, the differential spectra did not allow the determination of the visible and near IR band maxima that are characteristic of the MV species [3]. If oxygen diffuses into the solution the violet colour changes to the original green of the Cu^{II}–Cu^{II} dimeric complex.

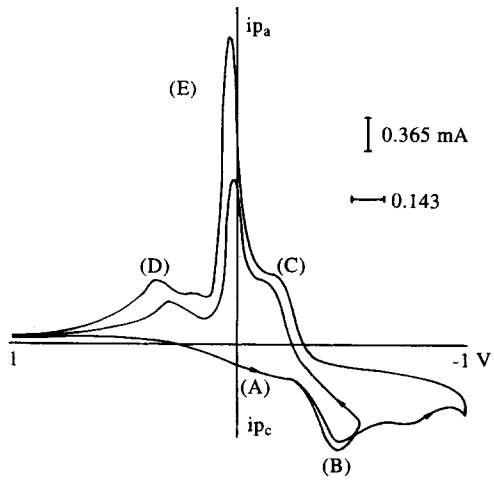

Fig. 3. Same as Fig. 2, but for (B) and (C), (E) peaks.

Electrochemistry study of the MV complex generated photochemically

Figure 8 shows the CV of the MV species starting from a small negative potential toward reduction and oxidation and Fig. 9 from a small positive potential also toward reduction and oxidation. The reduction processes (approximately at −0.1 and −0.3 V) are diffusion controlled as indicated from the ip *vs* $\sqrt{v}$ function (not shown). The analysis of the $ip/\sqrt{v}$ *vs* v study starting from the oxidized species, i.e. from +1 V, is shown in Fig. 10 which is similar to Fig. 6a.

DISCUSSION

The electrochemical results for the $(CH_3COO)_2Cu^{II}Cu^{II}(OOCCH_3)_2$ complex in AcOH/MeOH mixture (Figs 1, 2 and 3) show that it is sequentially reduced to the $(CH_3COO)_2Cu^{I}Cu^{I}(OOCCH_3)_2$ species which may be reoxidized, also sequentially, but in competition with the thermal disproportionation to Cu^0 (s) and Cu^{II} ions. In fact, this may be seen in Fig. 2 from a comparison of the extended range and dotted voltammograms and from Fig. 6a in which the dependence of $ip/\sqrt{v}$ *vs* v indicates that the reduction process at −0.4 V is followed by an irreversible catalytic reaction, i.e.

$$Cu^{II}\text{–}Cu^{II} + 2e \leftrightarrow Cu^{I}\text{–}Cu^{I} \quad (1)$$

$$Cu^{I}\text{–}Cu^{I} \rightarrow Cu^0 + Cu^{II} \quad (2)$$

The CPE at −0.4 V is a quantitative measure of the overall reduction process including the disproportionation reaction, since it involves four electrons per mole of initial binuclear Cu(II) complex. If the CV scan range is reduced from (+1.0, −1.0) V to (+1.0, −0.4) V (Fig. 3 and Fig. 5) and depending on the scan rate, the dismutation process may not be detected during the electrode process. Consequently, the $ip/\sqrt{v}$ *vs* v plot (Fig. 6b) is different and in light of the ip_a/ip_c *vs* v dependence (Fig. 6c), it shows that the reduction process is in this case followed by an irreversible reaction. Since the Cu^{I}–Cu^{I} species may be sequentially oxidized, as may be seen in the voltammograms, this irreversible reaction should not be associated with a destructive process of the species. Furthermore, taking in account that a comparison of the solid X-ray data for Cu^{II} acetate [9a] and Cu^{I} acetate [9b] suggests only a small axial distortion expected for Cu^{I} as compared to Cu^{II} sites, it is possible that this irreversible process may be associated with a structural change. Similarly, the electrochemical irreversibility of the first couple (Fig. 2) may also be associated with a structural change. In this case, the Nicholson and Shain criteria for two reduction processes (A and B) coupled with a 'chemical reaction' [8b], indicate that Fig. 6b is in agreement with the R–R case, that is two sequential one-electron reduction processes both of which are reversible.

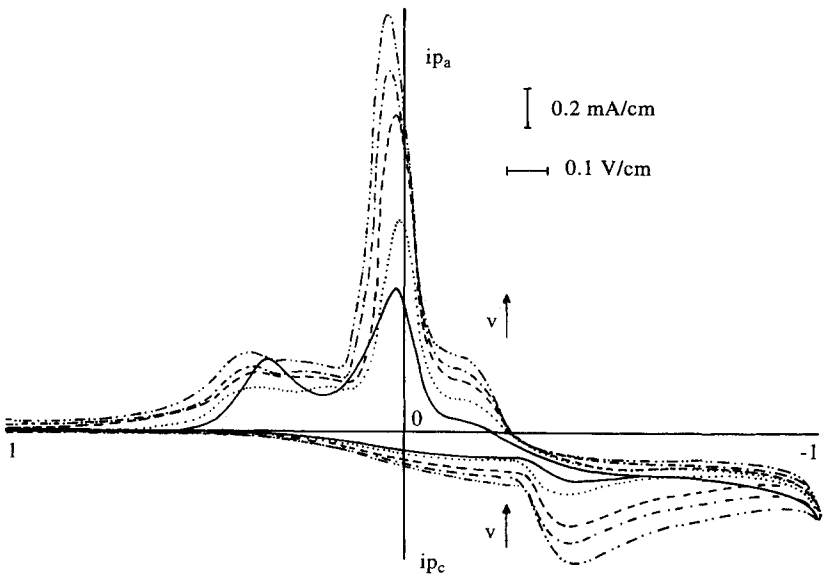

Fig. 4. Cyclic voltammogram of a 1.5×10^{-3} M degassed solution of cupric acetate dimer in 0.1 M $TBABF_4$ 95/5% (vol/vol) MeOH/AcOH solvent mixture as a function of the scan rate: scan range +1 to −1 V. v: 10(–), 25(...), 50(– – –), 75(– · – · –), 100(– · · – · ·) m Vs^{-1}. Same conditions as Fig. 1.

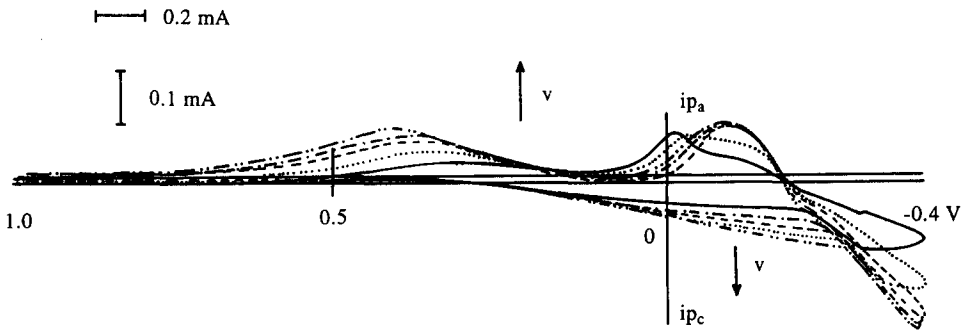

Fig. 5. Same as Fig. 4 but in restricted potential range +1 to −0.4 V. v: 10(–), 25(...), 50(– – –), 75(– · – · –), 100(– · · – · ·).

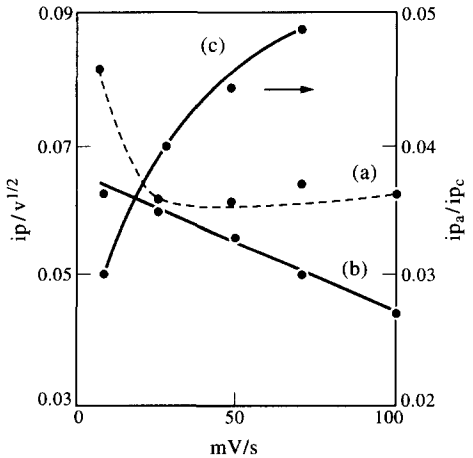

Fig. 6. Plot of the current function $ip/\sqrt{v}$ as a function of the scan rate for the electrode process at −0.4 V (a) extended range (see Fig. 3 (a), (b)) restricted range (see Fig. 3 (b), (c)) *ipa/ipc vs v* restricted range.

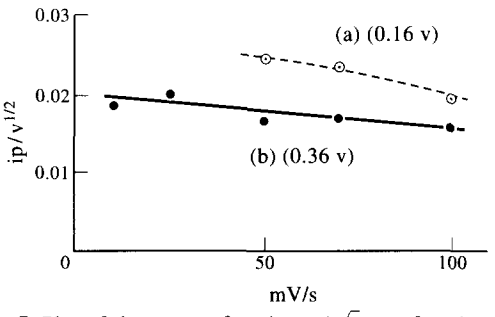

Fig. 7. Plot of the current function $ip/\sqrt{v}$ as a function of the scan rate for the electrode process at −0.16 V and +0.36 V in restricted range (see Fig. 3).

Unfortunately, the presence of the competitive disproportionation process, after the second reduction and before the first oxidation peaks, complicates the results and prevents us from analyzing the four peak behaviour (two red., two oxid.) as a whole for the R–R case. Nevertheless, the diagrams of Fig. 7, for each

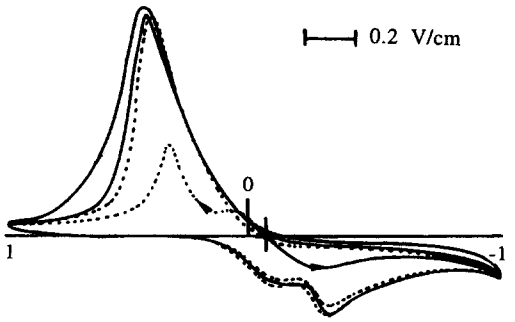

Fig. 8. Cyclic voltammogram of a 1.5×10^{-3} M degassed solution of $(CH_3COO)_2Cu^{II}Cu^{I}(OOCCH_3)_2(MV)$ species generated *in situ* as indicated in ref. [3], in 0.1 M $TBABF_4$ 95/5% (vol/vol) MeOH/AcOH mixture as solvent, starting from a small negative potential toward reduction and oxidation.

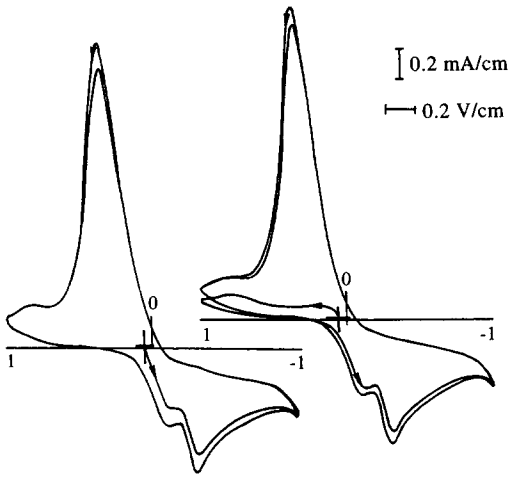

Fig. 9. Same as Fig. 8 but starting from a small positive potential.

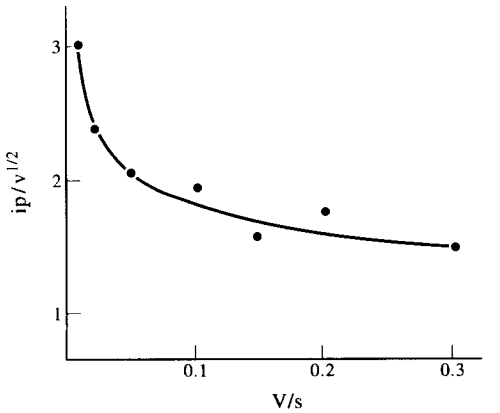

Fig. 10. Plot of the current function $ip/\sqrt{v}$ as a function of the scan rate for the electrode process at -0.30 V for the Cu^{II}–Cu^{II} species (complex **II**) generated from the MV species solution of Fig. 8.

process at -0.16 and 0.36 V in the oxidation direction, show that both processes are preceded by an irreversible reaction. These irreversible reactions may be considered as structural changes since they are congruent with the structural framework requirements of the Cu^{II} and Cu^{I} sites and with the change observed in the reduction direction.

Direct experimental evidence that the reduction process of the Cu^{II}–Cu^{II} complex is a sequential electrode reduction, and not a simultaneous two-electron reaction, is given by the fact that the mixed-valence complex may be generated at -0.4 V as indicated in the experimental section. It may be suggested that, the MV species can be generated by short pulses and not by CPE, due to the fact that after being produced by the pulse, the MV species diffuses away from the electrode surface, so when the next pulse is applied the Cu^{II}–Cu^{II} species is preferentially reduced. However, after several pulses the concentration distribution of both species, (MV and Cu^{II}–Cu^{II}) around the electrode becomes similar and the probability of reduction of the MV increases; therefore, the next pulse may reduce both species allowing the MV species to be formed only in a small amount. It must be mentioned that, although the MV species is involved in a disproportionation equilibrium in which *Kc* may be estimated to be on the order of 10^3 at room temperature [10], we think this equilibrium is not a factor in the decrease of the MV concentration after several pulses.

Therefore, the electrochemical behaviour of the $(CH_3COO)_2Cu^{II}Cu^{II}(OOCCH_3)_2$ complex may be summarized as:

$$Cu^{II}\text{–}Cu^{II} + 1e \leftrightarrow Cu^{II}\text{–}Cu^{I} \quad -0.2\,V \qquad (3)$$

$$2\,Cu^{II}\text{–}Cu^{I} \leftrightarrow Cu^{II}\text{–}Cu^{II} + Cu^{I}\text{–}Cu^{I} \qquad (4)$$

$$Cu^{II}\text{–}Cu^{I} \rightarrow [Cu^{II}\text{–}Cu^{I}]\ (d) \qquad (5)$$

$$[Cu^{II}\text{–}Cu^{I}](d) + 1e \leftrightarrow Cu^{I}\text{-}Cu^{I} \quad -0.4\,V \qquad (6)$$

$$Cu^{I}\text{–}Cu^{I} \rightarrow [Cu^{I}\text{–}Cu^{I}]\ (d) \qquad (7)$$

$$Cu^{I}\text{–}Cu^{I} \rightarrow Cu^{0} + Cu^{II} \qquad (8)$$

(d) = structural change

which indicates that the global electrochemical reduction process appears as irreversible, in which the structural changes play an important role. In relation with the electrochemical behaviour of the MV complex generated photochemically, the analysis of the cyclic voltammograms is more complex. The reduction peak is broad and centered at ~ 0.2 V (Fig. 8). When the potential sweep is reversed after reduction, a large and broad oxidation peak appears around 0.4 V. In a second cycle two overlapping reduction peaks are observed at -0.1 and -0.3 V, respectively, associated with the reduction of the Cu^{II}–Cu^{II} species just generated (complex **II**).

Otherwise, Figs 8 and 9 show that the voltammograms are highly dependent on the starting

voltage and it may be seen also that the oxidation potential of the MV complex seems to be around 0 V. The broad and large oxidation peak envelopes the 0.2 V peak associated with the Cu(II) ions and the peak related to the Cu^0 metal deposit on the platinum electrode surface. In fact, when the $ip/\sqrt{v}$ *vs* v dependence on the scan speed is studied starting from the completely oxidized species (complex **II**) i.e., starting from +1 V, the Nicholson and Shain criteria indicate that the electrochemical process at the second reduction peak is similar to the reduction process in the parent, non-irradiated Cu^{II}–Cu^{II} complex (complex **I**) (Fig. 6a and Fig. 10). This similarity shows that the overall process is also similar (i.e., reduction followed by a disproportionation process), generating a Cu^0 deposit and Cu^{II} ions in solution. Although complex **II** (Cu^{II}–Cu^{II} species obtained by electrochemical oxidation of the MV species generated photochemically) exhibits an overall behavior similar to that of the Cu^{II}–Cu^{II} species studied in the first part of this paper (complex **I**), some differences are apparent. In fact, although the overlapping makes it difficult to know the real value of the reduction potentials, they appear different: complex **II** shows less negative values and more resolved peaks than complex **I**. In addition, the disproportionation reaction seems competitive at higher rates for complex **II** than for complex **I** (Figs 6a and 10). It is possible to speculate that these differences may be related to a more appropriate structural framework toward reduction in complex **II** and to a greater interaction between the coppers derived from a shorter Cu–Cu distance; both facts may be associated with the structure of the complex **II** precursor species and with the observation that the structural changes have measurable kinetic rate evidenced by the Nicholson and Shain diagrams.

In summary, the results of this work reveal:

(a) A violet mixed-valence species Cu^{II}–Cu^{I} may be generated electrochemically from the Cu^{II}–Cu^{II} complex. The species is thermodynamically and kinetically stable in the absence of oxygen, at least for 4 h. Oxygen oxidizes the MV species to the original green Cu^{II}–Cu^{II} complex. Considering that the mixed-valence species may be a good bioinorganic model for copper type III in multicopper oxidases, as shown in refs [3] and [11], it is particularly interesting that a similar species may be generated from the binuclear Cu^{II}–Cu^{II} complex which can be sequentially reduced.

(b) Nicholson and Shain criteria indicate that there are 'thermal reactions' coupled to the electrochemical processes making the overall process irreversible. The coupled thermal process related to the Cu^{II}–Cu^{II} → Cu^{I}–Cu^{II} → Cu^{I}–Cu^{I} redox reactions are considered to be structural distortions according to the different symmetry sites preferred for Cu^{II} and Cu^{I} centers. It is very important to note that these results are in agreement with the fact that a comparison of the solid state X-ray data for Cu^{II} acetate and Cu^{I} acetate suggests only a small axial distortion expected for the Cu(I) site as compared to Cu^{II} and with the similarity of the symmetry of both metal sites signalled for the UV–vis–NIR spectroscopic studies of ref. [3].

(c) Associated with the Cu^{I}–Cu^{I} species there is also a disproportionation process which is kinetically in competition with the electrochemical reoxidation. This irreversible reaction may be seen from the Nicholson and Shain criteria applied to the extended range voltammogram and also from the Cu^0 deposition on the platinum working electrode in the electrolysis experiments.

(d) The mixed-valence species generated photochemically may be reduced to Cu^{I}–Cu^{I} and oxidized to Cu^{II}–Cu^{II} at less negative and less positive potentials, respectively, in comparison with the species generated electrochemically. Furthermore, the Cu^{II}–Cu^{II} (complex **II**) species resulting from the oxidation of the MV species photochemically generated shows a less negative reduction potential with better resolved peaks, and the resulting Cu^{I}–Cu^{I} species disproportionates to Cu^0 and Cu^{II} ions at a faster rate than the Cu^{I}–Cu^{I} species resulting from reduction of complex **I**.

Although the structural factors may not be the only ones, it is possible to suggest that a shorter Cu–Cu distance in the MV generated photochemically is responsible for the different electrochemical behaviour of this MV complex and species derived from it.

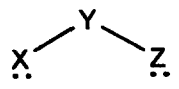
(Received 10 March 1997; accepted 12 May 1997)

Abstract—The reactions of Lihpp with vanadium(II) chloride, chromium(II) chloride and tetrakis(trifluoroacetato)dimolybdenum produce the dinuclear tetrabridged compounds $V_2(hpp)_4$, **1**, $Cr_2(hpp)_4$, **2**, and $Mo_2(hpp)_4$, **3**. Compound **1** crystallizes as red blocks in the space group $P\bar{1}$ with unit cell dimensions, $a = 8.489(2)$, $b = 9.709(2)$, $c = 9.835(2)$ Å, $\alpha = 89.98(3)$, $\beta = 73.04(3)$ and $\gamma = 79.29(3)°$. This compound contains the shortest known vanadium to vanadium bond, 1.932(1) Å. Compound **2** crystallizes as orange blocks in the space group $P\bar{1}$ with unit cell dimensions, $a = 8.488(2)$, $b = 9.687(2)$, $c = 9.747(2)$ Å, $\alpha = 90.89(3)$, $\beta = 100.86(3)$ and $\gamma = 106.42(3)°$. This compound contains a 'supershort' chromium to chromium bond, 1.8517(7) Å. Compound **3** crystallizes as red blocks in the space group $P\bar{1}$ with unit cell dimensions, $a = 8.455(2)$, $b = 9.702(2)$, $c = 10.094(2)$, $\alpha = 88.84(3)$, $\beta = 72.01(3)$ and $\gamma = 79.89(3)°$ and has a short molybdenum to molybdenum bond distance of 2.067(1). Both **2** and **3** have M—M bonds distances shorter than most analogous compounds containing nitrogen donor atom bridges. The basicity of Hhpp is also evidenced by the formation of the cation $[H_2hpp]^+$ upon reaction with trifluoroacetic acid and acetic acid. $[H_2hpp][O_2CCF_3]$, **4**, crystallizes as colorless needles in the space group $P2_1/c$ with cell dimensions, $a = 7.431(2)$, $b = 13.243(2)$, $c = 11.741(2)$, $\beta = 96.50(3)°$. $[H_2hpp][O_2CCH_3]$, **5**, crystallizes as colorless needles in the space group $P2_1/n$ with cell dimensions, $a = 7.888(2)$, $b = 11.182(2)$, $c = 11.902(2)$, $\beta = 91.91(3)°$. © 1997 Elsevier Science Ltd

Keywords: metal–metal bond; divanadium; dichromium; dimolybdenum; supershort; bridging ligand.

The usefulness of bridging ligands of the general type **I** for stabilizing multiply bonded (as well as singly bonded) dimetal units, M_2^{n+}, has been long recognized [1]. Some of the first [e.g., $Mo_2(O_2CCH_3)_4$] although not the first (i.e., $Re_2Cl_8^{2-}$) multiply bonded M_2 complexes to be recognized have the carboxylate anion as the bridging ligand.



I

Scheme 1.

More recently, it was recognized that the amidinate anions, especially the formamidinate anions, [PhN-C(H)NPh]$^-$ and [(*p*-tol)NC(H)N(*p*-tol)]$^-$ are especially useful. Indeed, at present, there is a greater variety of M_2^{n+} units stabilized by these ligands than by any others [1]. However, even more recently, it has been found that the formamidinates have a major problem, in that they are cleaved under certain reaction conditions into ArN and ArNC fragments [2]. Thus, products containing these fragments rather than the intact ArNC(H)NAr$^-$ ligand are obtained.

These disappointing (although interesting) results posed the challenge of finding, if possible, a ligand having the essential desirable features of the amidinato anions (especially their high basicity) while at

* Author to whom correspondence should be addressed.

the same time showing promise of displaying greater resistance to cleavage. Bicyclic systems in which the likelihood of the two nitrogen atoms being separated naturally came to mind. The 1,8-naphthyridine type, **II,** is not exactly suitable since it is neutral, whereas an anionic system is preferable. Another, and more attractive candidate is the 7-azaindole anion, **III**. In fact this has been looked into before [3], and it was recognized that this has two disadvantages. The major one is that the preferred N—M bond directions diverge thus biasing this ligand against short M—M distances, and the minor one in that there tends to be orientational disorder of the ligands because of the steric similarity of the 5- and 6-membered rings.

The bicyclic system **IV,** or something similar, then came to mind but this has the practical disadvantages that it is neither commercially available nor simple to prepare. However, the similar compound, **V,** 1,3,4,6,7,8-hexahydro-2H-pyrimido[1,2-a]pyrimidine, which is conveniently represented by Hhpp is available commercially at a reasonable price.

Some minds do tend to run in the same channels and we were anticipated in the use of the hpp^- ligand by Bear *et al.* [4], who recently reported the first $M_2(hpp)_4$ species, $Ru_2(hpp)_4Cl_2$. However, our interest in finding the most robust possible $RNC(\dot{R})NR^-$ type ligand for purposes of our own was whetted further by Bear's success and we have undertaken a broad exploration of the capabilities of the hpp^- for promoting the stability of M_2^{n+} units.

We chose to begin with Mo_2^{4+}, Cr_2^{4+}, and V_2^{4+} because (a) Mo_2^{4+} offers the largest group of M_2L_4 species with which to make comparisons, (b) Cr_2^{4+} forms the shortest known metal–metal bonds, and (c) V_2^{4+} has so far been obtained only twice, in the compounds $V_2(DtolF)_4$ [5] and $V_2(DCyF)_4$ [5] and it was considered desirable to enlarge the group. We report here the preparation and characterization of the three compounds $Mo_2(hpp)_4$, $Cr_2(hpp)_4$ and $V_2(hpp)_4$ as well as two compounds, $[H_2hpp][CF_3CO_2]$ and $[H_2hpp][CH_3CO_2]$ that turned up unexpectedly.

EXPERIMENTAL

$VCl_3(THF)_3$ [7] and $Mo_2(O_2CCF_3)_4$ [8] were prepared according to literature procedures. Hhpp was obtained from Aldrich Co. and further purified by vacuum sublimation. Li[hpp] was prepared *in situ* at room temperature by deprotonation of Hhpp with one equivalent of MeLi. All other reagents, including 1.0 M MeLi in THF/cumene and 1.0 M $NaHBEt_3$ in toluene, were obtained from commercial sources and used without further purification. All solvents were freshly distilled from sodium/potassium benzophenone. All manipulations were carried out in either an argon atmosphere dry box, or in dry nitrogen using standard Schlenk techniques. ^{1}H-NMR studies were performed on a Varian XL-200 spectrometer; IR spectra were recorded on a Perkin–Elmer 16PC FT-IR spectrophotometer as KBr pellets. UV–vis spectra were recorded on a Cary-17D spectrometer.

Preparation of $V_2(hpp)_4$, **1**

$VCl_3(THF)_3$ (0.75 g, 2.0 mmole) was reduced by one equivalent of $NaHBEt_3$ in 25 cm^3 THF at $-78°C$ resulting in a deep purple solution. A cold ($-78°C$) solution of Li[hpp] (4.0 mmole) in 15 cm^3 THF was then added and the solution was allowed to warm to room temperature while stirred. An additional 30 min of stirring resulted in a brown solution. The solvent was removed under vacuum, and the dried brown powder was extracted with 30 cm^3 warm toluene, and the extract was filtered through Celite®. The toluene was then removed under vacuum allowing isolation of a brown powder in 62% yield. Crystallization by slow diffusion of a layer of hexanes into a toluene

Scheme 3.

solution of **1** yielded orange/brown, block-shaped crystals in a few days.

^{1}H NMR (C_6D_6, 25°C) $\delta = 2.016$ (quin), 3.063 (trip), 3.160 (trip). UV–vis (THF): λ_{max} [nm] = 280. IR (KBr, cm^{-1}): 2932, 2856, 1636, 1522, 1441, 1380, 1319, 1262, 1197, 1023, 802.

Preparation of $Cr_2(hpp)_4$, **2**

A solution of Li[hpp] (4.0 mmole) in 10 cm^3 THF cooled in a dry ice/ethanol bath was transferred via cannula into a grey 10 cm^3 THF suspension containing 0.2 g (1.63 mmole) of anhydrous $CrCl_2$ at −78°C. The reaction mixture turned brown immediately, but gradually became yellow. The reaction was allowed to warm to room temperature, and a yellow-orange solid that precipitated was collected on a frit and dried *in vacuo* to yield 0.46 g (0.7 mmole); 43%. Crystals were grown from an orange solution in benzene layered with hexanes at room temperature.

^{1}H NMR (C_6D_6, ppm): 2.0 (quin, CH_2), 3.0 (t, CH_2), 3.32 (t, CH_2). UV–vis (benzene): λ_{max} (nm) = 430. IR (KBr, cm^{-1}): 2933, 2843, 1617, 1560, 1525, 1447, 1385, 1316, 1197, 1082, 804.

Preparation of $Mo_2(hpp)_4$, **3**

A solution of Li[hpp] (1.0 mmole) prepared in 5 cm^3 toluene was added to a yellow solution of $Mo_2(O_2CCF_3)_4$ (0.155 g, 0.24 mmole) in 10 cm^3 toluene. The resulting dark red solution was stirred for 45 min, filtered into a Schlenk tube, and layered with hexanes. Red crystals of **3** were observed within 1 day. The crystalline yield was 22% but more of **3** could be obtained by reduction of the mother liquor.

^{1}H NMR (C_6D_6, ppm): 1.95 (quin, CH_2), 2.95 (t, CH_2), 3.61 (t, CH_2). UV–vis (THF): λ_{max} (nm) = 460, 365, 335. IR (KBr, cm^{-1}): 2962, 2869, 1636, 1420, 1262, 1098, 1045, 804.

Preparation of $[H_2hpp][O_2CCF_3]$, **4**

Hhpp (0.28 g, 2.0 mmole) was dissolved in 10 cm^3 toluene. Upon addition of 2 mmole trifluoroacetic acid, a white solid, **4**, precipitated. The toluene was removed *in vacuo*. **4** was isolated in nearly quantitative yield and recrystallized by the cooling of a saturated solution in acetone.

^{1}H NMR (D_2O, ppm): 1.74 (quin, CH_2), 3.02 (t, CH_2), 3.08 (t, CH_2). IR (KBr, cm^{-1}): 1684, 1653, 1559, 1420, 1325, 1199, 1122, 799, 720.

Preparation of $[H_2hpp][O_2CCH_3]$, **5**

Hhpp (0.14 g, 1.0 mmole) was dissolved in 5 cm^3 toluene. Upon addition of 1 mmole acetic acid, a white solid, **5**, precipitated. The toluene was removed *in vacuo*. **5** was isolated in nearly quantitative yield and recrystallized by the cooling of a saturated solution in acetone.

^{1}H NMR (D_2O, ppm): 1.71 (s, CH_3), 1.73 (quin, CH_2), 3.02 (t, CH_2), 3.09 (t, CH_2). IR (KBr, cm^{-1}): 2976, 1656, 1569, 1412, 1322, 1293, 1262, 1207, 1068, 1020, 925, 832, 709, 461.

Crystallographic studies

In each case, a crystal was mounted on the tip of a quartz fiber and cooled to −60°C under a nitrogen stream on the diffractometer. All data were collected on a Nonius FAST area-detector system. Unit cell dimensions were obtained for each by indexing between 153 and 250 strong reflections in 2θ ranges of approximately 10.4–41.6°. Axial lengths and Laue symmetry were confirmed from axial images. Details of the use of the FAST in our laboratory have been described elsewhere [9]. These highly redundant data sets were corrected for Lorentz and polarization effects. The absorption correction, only done on **2**, was based on fitting a function to the empirical transmission surface as sampled by multiple equivalent measurements [10].

In each case the structure was solved either by direct methods or a Patterson map and refined using the SHELXTL programs [11]. All non-hydrogen atoms were refined with anisotropic displacement parameters. The amine hydrogen atoms in **4** and **5** were found in the difference map and refined with light restrictions; all other hydrogen atoms in the five complexes were placed in calculated positions and refined constrained to their parent atoms.

Crystallographic parameters are summarized in Tables 1, 2 and 3.

RESULTS AND DISCUSSION

The synthesis of **1**, by the low temperature addition of Li[hpp] in THF to vanadium (II) chloride in THF, followed a previously reported procedure [5] with few variations. The product was separated from LiCl by extraction of the dried reaction mixture with toluene and filtration through Celite®.

The analogous chromium complex, **2**, was readily prepared by the addition of Li[hpp] in THF to a suspension of cold anhydrous chromium(II) chloride in THF. The LiCl stayed in solution while the desired product precipitated. ^{1}H NMR of the yellow powder and of the orange powder isolated from the benzene extract gave identical spectra. $Cr_2(hpp)_4$ is diamagnetic (by NMR). The THF and benzene solutions are extremely air and moisture sensitive and turn green upon exposure. The powder of **2** is also very sensitive, and the crystals are stable for only a couple of minutes in air. The reflux of $Cr(CO)_6$ and Hhpp in a high boiling solvent can also be used to prepare **2**, but the reaction is more difficult to control.

The synthesis of **3** was quite straightforward once

the appropriate molybdenum source was used. The addition of Li[hpp] in toluene to $Mo_2(O_2CCF_3)_4$ in toluene resulted in a red solution of **3**. The red solution was filtered through Celite® to remove the LiO_2CCF_3.

Two of the three metal complexes, $V_2(hpp)_4$ and $Mo_2(hpp)_4$, are crystallographically isotypic but the packing of the molecules in $Cr_2(hpp)_4$ does not conform to the same pattern. It is possible to choose a unit cell for $Cr_2(hpp)_4$ that more closely resembles those for the other two compounds, but then the frac-

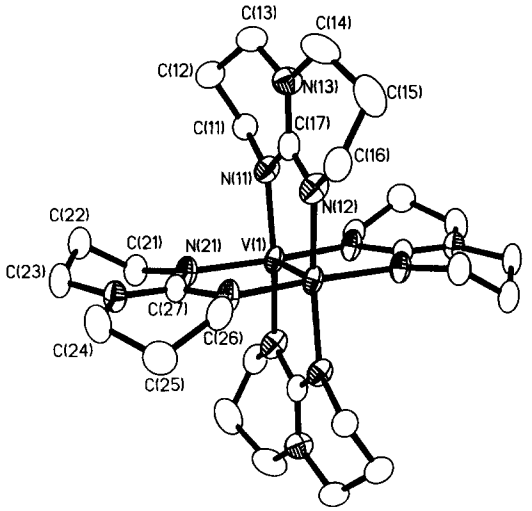

Fig. 1. Molecular Structure of $V_2(hpp)_4$, **1**, with ellipsoids at the 50% probability level. Hydrogen atoms have been omitted for clarity.

tional coordinates of the atoms do not correspond. It is surprising that this occurs, but it does not mean anything from a chemical point of view. Because each $M_2(hpp)_4$ molecule lies on an inversion center and the M—M—N—C—N rings are essentially planar (no atom deviates by more than 0.005 Å), each molecule has an eclipsed conformation. Figures 1 and 2 show views of two of the molecules. The three structures are all so similar that this should suffice for all.

In all three metal complexes the M—M bond lengths are remarkably short. $V_2(hpp)_4$ contains the shortest V—V bond known (1.932 (1) Å). Two other vanadium paddlewheel complexes exist: $V_2(DTolF)_4$ [5] (1.978 (2) Å); $V_2(CyNC(H)NCy)_4$ [6] (1.968 (2) Å). The M—M bonds in $Cr_2(hpp)_4$ and $Mo_2(hpp)_4$ are not the shortest known, but they are shorter than those in most similar complexes containing nitrogen-donor atom bridges. The Cr—Cr bond distance in $Cr_2(hpp)_4$ is shorter than in the two known formamidinato complexes [6,12] and the triazenato complex [13], but not as short as that in Cr_2(dimethybenzamidinate)$_4$ [14] (1.843 Å). The corresponding molybdenum analogs [13,15,16] all contain longer Mo—Mo bonds than in $Mo_2(hpp)_4$.

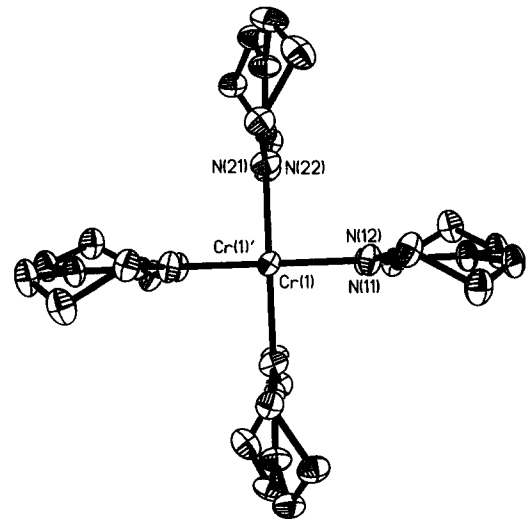

Fig. 2. Molecular Structure of $Cr_2(hpp)_4$, **2**, along the metal-to-metal bond axis. Hydrogen atoms have been omitted for clarity.

The hpp ligands are all puckered. The average C_{17}—N distance is 1.35(2) Å, which is consistent with partial double bond character in these bonds. The C_{17} and three nitrogen atoms can be regarded as sp^2 hybridized with some of their electrons occupying $p\pi$ molecular orbitals. This leads to planarity, or near planarity, in the central part of the ligand, but the two sets of three CH_2 groups need not, and do not, all lie in this plane. In each of the $M_2(hpp)_4$ compounds the conformation of each ligand is such that in one ring the central CH_2 group deviates in one direction and in the other ring the corresponding CH_2 group deviates in the opposite direction.

In all three of our $M_2(hpp)_4$ molecules we found that the puckered ligand rings were well ordered. This is in contrast to the disorder found by Bear *et al.* in their $Ru_2(hpp)_4Cl_2$ compound. We were pleased to see that the problem of refining disordered ligands need not arise in all cases.

While the high basicity of the hpp^- anion is one of its attractive features, the Hhpp molecule itself also has high basicity. This follows from the fact that it is a derivative of the extremely basic prototype guanidine, $(H_2N)_2C{=}NH$. Hhpp is therefore easily protonated to form the H_2hpp^+ ion, and this happens whenever it is used in an acid medium [17]. Having encountered this behavior several times by accident, we decided to prepare two such compounds deliberately and determine the structure of the H_2hpp^+ ion.

Turning now to the conformation of the H_2hpp^+ cation in compounds **4** and **5**, we note that these too are puckered, but in such a way, as shown in Fig. 3, that the two most deviant atoms, one in each ring, go in the same direction out of the mean plane. There is some disorder at C_{12} in **5** and at both C_{12} and C_{15} in **4**.

In conclusion, it can be said that the work reported here as well as that of Bear *et al.* on $Ru_2(hpp)_4Cl_2$ shows that the hpp^- ligand has the same general character as the amidinato anions and hence the same capacity to stabilize dimetal units in paddle wheel molecules. In view of the more connected internal structure of the hpp-ligand it is reasonable to expect it to be more robust and resistant to the fragmentation processes that have so often frustrated attempts to employ the amidinato ligands in conjunction with very highly reactive M_2^{n+} such as Nb_2^{4+} and Ta_2^{4+}.

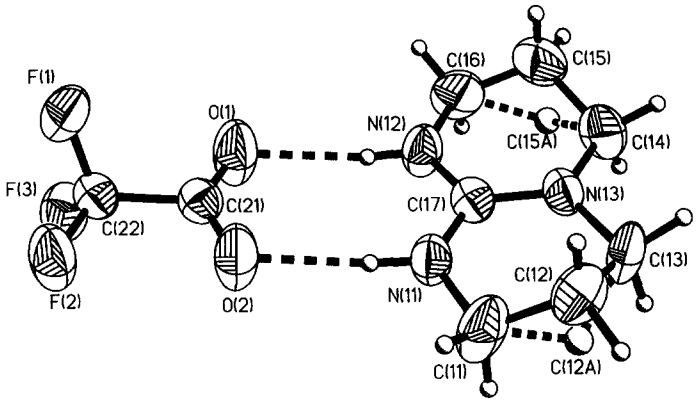

Fig. 3. Molecular Structure of $[H_2hpp][CF_3CO_2]$, **4,** with ellipsoids at the 50% probability level. C(12) and C(15) are disordered over two positions.

(Received 25 February 1997; accepted 12 May 1997)

Abstract—Six secondary aziridines (Az) bearing unsaturated vinylic or allylic groups on one of the carbon atoms of the ring have been reacted with palladium compounds. Complexes of general formula $PdCl_2(Az)_2$ have been isolated and spectroscopically characterized for fully substituted aziridines. The crystal structure of the complex of allylaziridine has been determined, showing the *trans*-arrangement of the ligands around the palladium center. © 1997 Elsevier Science Ltd

Keywords: complex; palladium; aziridine; allyl; vinyl; X-ray structure.

Hybrid ligands exhibiting two different coordination sites have been widely studied and have found numerous applications in coordination chemistry and in homogeneous catalysis, as proved by the industrial SHOP process of oligomerization of ethylene to linear α-olefins [1]. We continue to be interested in the chemistry of hybrid ligands containing one nitrogen site and either phosphorus or carbon–carbon double bond as second coordination site. The first case is illustrated by synthesis of transition-metal complexes of cyclic aminophosphonites arising from the P—N bond cleavage of bicyclic phosphoranes [2] and their applications in homogeneous hydroformylation, oligomerization and teleomerization of alkenes and dienes. The second series of hybrid ligands is confined to secondary aziridines (abbreviated Az) bearing an unsaturated substituent on one of the carbon atoms of the ring. We have recently described the synthesis of rhodium complexes with 2,2-dimethyl-3-phenyl-3-allylaziridine **1**. The X-ray crystal structure of the carbonyl complex Rh(CO)(Az)Cl (Az = **1**) has proved that **1** is simultaneously bound to the metal by the double bond of the allyl substituent and by the nitrogen atom in a chelating mode [3]. This species is active for the hydroformylation of styrene and is recovered unchanged after reaction. The complex is very stable and the double bond of the allyl group is not activated by coordination to rhodium. Then, it should be interesting to change the metal in order to make the double bond reactive and to transform the starting aziridine. Thus, we have devoted the present paper to a study of the reactions between some palladium complexes with the unsaturated aziridines described in Scheme 1.

The literature concerning the reactions between palladium and aziridines is limited and can be divided in two groups: aziridine as a ligand or stoichiometric reagent in palladium complexes or as a substrate in reactions catalysed by palladium compounds. Since the pioneering work of Jackson *et al.* [4] on the synthesis of $PdCl_2(Az)_2$ (Az = ethylenimine), Porta *et al.* [5] have synthesized aziridine ligands by reacting the complex $PdCl_2(coe)_2$ (coe = cyclooctene) with phenyl

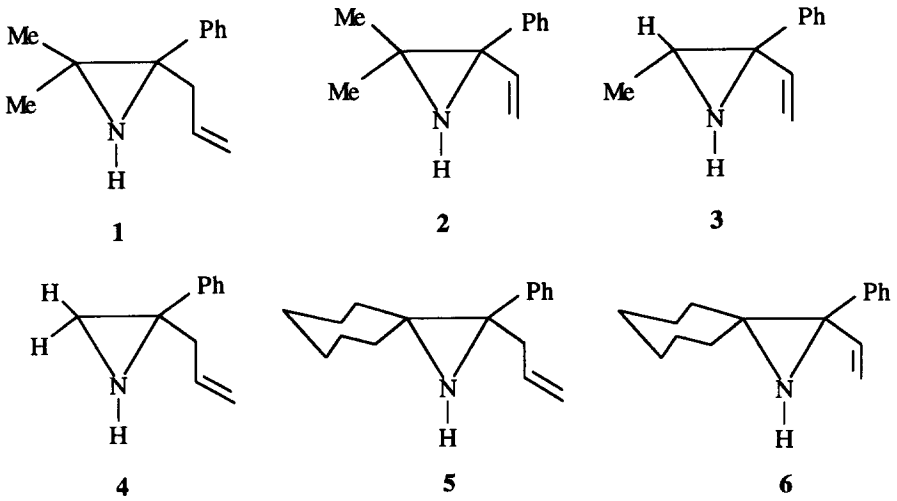

Scheme 1.

azide and have obtained a *trans*-$PdCl_2(Az)_2$ species. Bertani *et al.* [6] proved the formation of carbene complexes from ethylenimine and isocyanide palladium complexes. Tanner [7] described the use of chelating bis-aziridines in palladium complexes and their use in various catalytic reactions. Very recently, Beck *et al.* [8] studied the chelating behavior of L-aziridine-2-carboxylate with various transition metals. Most of the catalytic reactions described in the literature are devoted to the ring expansion of the aziridine by insertion in the C—N bond of either carbon monoxide [9], heteroallenes [10], or C—C double bond [11] giving rise to four and five-membered heterocycles. Other reactions are represented by isomerization [12], formation of unsaturated amines by aziridine ring opening [13] and catalytic hydrogenation [14].

RESULTS AND DISCUSSION

The allyl and vinylaziridines **1–4** have already been described and were prepared according to the published methods [15]. The hitherto unknown spiro aziridines **5** and **6** have been synthesised by the action of respectively allyl and vinyl magnesium bromide on cyclohexyl-2-spiro-3-phenyl azirine [16] following the method described by Chaabouni *et al.* [15] and have been fully characterized.

Reaction of aziridines **1–6** does not give any defined product with Pd(dibenzylideneacetone)$_2$, $Pd(PPh_3)_4$, $PdCl_2$ or $PdCl_2(PPh_3)_2$. Two equivalents of **1–6** react with 1 equiv. of $PdCl_2(PhCN)_2$ or $PdCl_2$(cod), but only the tetrasubstituted compounds **1**, **2**, **5** and **6** give a well defined complex of formula $PdCl_2(Az)_2$ in good yields (Scheme 2).

The non-fully substituted aziridines **3** and **4** are not stable enough in the presence of the palladium salt. Indeed, the aziridine **3** gives the corresponding complex **9**, but in only moderate yield (55%), while the aziridine **4** undergoes decomposition and polymerization under the reaction conditions. Therefore, the degree of substitution of the starting aziridine strongly influences its coordinating properties.

The infrared NH stretching band of aziridine in the complexes $PdCl_2(Az)_2$ are slightly shifted towards low frequencies as expected for a coordinated NH group (Table 1). On the contrary, the C=C stretching bands are practically unchanged, in accordance with a free double bond.

NMR spectra of the complexes are described in the Experimental section and the discussion will be focused on complex **7** with the aziridine **1**. The main feature of the ^1H NMR spectrum is a significant deshielding of most of the peaks, compared to those of the corresponding free aziridine. Simultaneously, the protons of the methyl groups give rise to two singlets of unequal intensity. All the signals in the $^{13}C\{^1H\}$ NMR spectrum, but those of the methylene group of the allylic substituent are split. Such a splitting may originate from several reasons. First, both aziridine ligands are not strictly symmetrical around palladium. However, in this case, the magnitude of the splitting would be much smaller than that observed, particularly for the most shielded methyl group ($\Delta\delta$ = 0.08 ppm for aziridine **1**). A second possibility is the presence of both *cis*- and *trans*-isomers, but that would give rise to two distinct peaks for the NH signal. Finally, the existence of two asymmetric centres for the aziridine ligands in the complex can induce the formation of a mixture of two diastereomeric complexes (R,R) and (R,S). This last hypothesis has been confirmed for complex **7** $PdCl_2(Az)_2$ with Az = **1** by means of an X-ray crystal structure analysis. Single crystals of **7** were grown by slow evaporation of 0.5 g of the complex dissolved in a hot mixture of 25% THF/75% petroleum ether *v/v* and contained 5% THF. The diastereomeric species isolated in the crystalline form has the (R,R) configuration. The structure consists of two slightly different molecules ligated by hydrogen bonds between hydrogen atom of the

NH groups of **1** in the molecule **A** and chlorine atoms of the other molecule **B**, as shown in Table 2 and Fig. 1. The N(A)···Cl(B) and N(B)···Cl(A) distances (3.36 Å) between two adjacent molecules indicate the existence of weak hydrogen bonding, ensuring the crystalline cohesion.

Figure 2 shows a perspective view of one molecule of complex **7** and clearly indicates that the aziridine ligands are bound to palladium in a monodentate mode, by their nitrogen atom and that they are located in *trans* position. This structure is very close of that observed by Hassner *et al.* [17] for a *trans*-$PdCl_2$(2-*p*-tolyl-azirine)$_2$. Some selected distances and bond angles are gathered in Table 3.

The coordination polyhedron around palladium is roughly square planar, as proved by Cl—Pd—N angles ranging from 88.0(1) to 92.6(1)° and a mean value of N—Pd—N equal to 169.7° and of Cl—Pd—Cl to 176°. The mean Pd—Cl (2.305 Å) and Pd—N bonds (2.034 Å) fall in the range generally observed [18], 2.326(43) Å and 2.04(36) Å, respectively. The projection of the molecule clearly demonstrates that the absolute configuration of C(1) and C(14) atoms is (R*,R*).

The bond lengths inside the aziridine ring (C(1)—N = 1.498 Å; C(2)—N = 1.495 Å; C(1)—C(2) = 1.501 Å) are very similar to those observed in Rh(Az)(CO)Cl (C(1)—N = C(2)—N = 1.499 Å; C(1)—C(2) = 1.498 Å). In contrast, the C=C bond length of the allylic substituent (C(19)—C(20) = 1.256 Å) is shorter than in the rhodium complex in which the double bond is coordinated (1.388 Å), and close to the value generally found for a free C=C double bond (1.299 Å) [18].

The chemistry of such complexes has been detailed for the allylaziridine complex, with the main objective being to synthesize a complex in which both nitrogen atom and C=C double bond are bound to the palladium in a chelating or bridging mode. Such a π-coordinated double bond might be activated and manifest enhanced reactivity. The reaction of only one equivalent of aziridine per PdL_2Cl_2 [L_2 = cod, $(PhCN)_2$] might give the expected Pd[κ^2-

N,C=C)Az]Cl_2 species, but actually gives only an equimolar mixture of the starting material and the disubstituted complex $PdAz_2Cl_2$. Another possibility lies in the methatetical exchange of chloro ligands of the pre-formed $Pd(Az)_2Cl_2$ by non-coordinating anions, like tetrafluoroborate or hexafluorophosphate by means of the silver or thallium salt, giving rise to a cationic complex **12** (Scheme 3).

A third way going through the preliminary formation of a cationic complex and further addition of

Estimated standard deviations in the least significant digit are given in parentheses.

aziridine does not work either. Finally, addition of triphenylphosphine on the $Pd(Az)_2Cl_2$ species with various PPh_3/Pd ratios only induces the substitution of the aziridine ligand by the phosphorus ligand without any formation of mixed complexes containing both types of ligand. Only $Pd(PPh_3)_2Cl_2$ is detected in the reaction mixture beside the starting complex. This observation is in agreement with the fact that neither $Pd(PPh_3)_4$ nor $Pd(PPh_3)_2Cl_2$ reacts with aziridine. Such behavior is very similar to that observed with cyclic aminophosphonite ligands, for which rhodium complexes always exhibit bidentate κ^2-P, N chelation, whereas palladium prefers the monodentate κ^1-P mode in most of the characterized complexes [2].

EXPERIMENTAL

All manipulations were performed under argon atmosphere. All solvents were dried by standard methods and distilled before use. The starting allyl and vinylaziridines **1–4**, palladium complexes $PdCl_2(PhCN)_2$ and $PdCl_2(cod)$ were prepared according to literature methods [15,16].

Spectroscopic measurements were performed with the following equipment. IR: Perkin–Elmer 597 and FT-IR 1725 X (Nujol mull or film between KBr plates or in solution). NMR: Bruker AC 200 (^1H, 200.13 MHz; ^{13}C, 50.32 MHz, TMS as external standard; ^{31}P, 81.01 MHz, H_3PO_4 85% in D_2O as external/internal standard, in a coaxial capillary tube).

Elemental analyses were obtained from the Service d'Analyse du Laboratoire de Chimie de Coordination du CNRS in Toulouse and the Service Central d'Analyse du CNRS in Solaize.

Syntheses of new aziridines **5** *and* **6**

The cyclohexyl-2-spiro-3-phenyl-3-allyl aziridine **5** was prepared by the action of 30 mmol of magnesium allyl bromide in THF with 15 mmol of cyclohexyl-2-spiro-3-phenyl azirine according to the method described by the literature [15]. The crude was distilled *in vacuo* leading to **5** with 85% yield. Anal. $C_{16}H_{21}N$

Syntheses of palladium complexes **7–11**

The dichlorobis(2,2-dimethyl-3-phenyl-3-allyl-aziridine)$_2$palladium(II) **7** was prepared by dropwise addition of a solution of 385 mg of aziridine **1** (2.06 mmol) in CH_2Cl_2 (5 cm^3) to a solution of 500 mg of $PdCl_2(PhCN)_2$ (1.03 mmol)] in the same solvent (10 cm^3). After stirring for 15 min and having removed 75% of the solvent *in vacuo*, the addition of 5 cm^3 of petroleum ether caused the immediate precipitation of a yellow solid. The precipitate was filtered off, washed with petroleum ether and crystallised from a mixture of 50% ether and 50% petroleum ether leading to 540 mg (95% yield) of complex **7**. The same complex **7** was also obtained from $PdCl_2$(cod): a solution of 419 mg of **1** (2.24 mmol)] in toluene (15 cm^3) was added dropwise to a solution of 320 mg of $PdCl_2$(cod) (1.12 mmol)] in the same solvent (5 cm^3). The colour turned yellow. After 4 h of stirring, the solution was evacuated to dryness and the crude was then dissolved in 5 cm^3 of hexane and maintained for a night in the freezer. A precipitate appeared which was filtered off, leading to 605 mg (97% yield) of **7**. Anal. $C_{26}H_{34}N_2PdCl_2$ (551.30) Calc.: C, 56.59; H, 6.21; N, 5.1 Found: C, 56.88; H, 6.33; N, 5.9. Measurement of intensity data

Instrument: Enraf–Nonius CAD4	Scan speed: 1.10–8.24°/min
Radiation: Mo-Kα	($\lambda = 0.71073$ Å) graphite monochromated
Max 2θ 47°	(h 0.21 k 0.27 l −26.26)
Detector window	Height 4.0 nm
Standard	Intensity 3 refl. every 2 h
Width 4.0 mm	Orientation 3 refl. every 400 data refl.
Scan mode ω–2θ	Take-off angle 4.0°
Scan range $(0.80+0.35\tan\theta)°$	No. of refl. collected 7817

procedure: Reduction to F_O^2 and $\sigma(F_O^2)$, corrections for backgrounds, attenuator and LP in the usual manner [19]. No significant standards variation (±0.9%). Empirical absorption corrections [20] ($T_{min} = 0.9621$, $T_{max} = 0.9998$). All measured reflections were unique and used. No. of observed data [$F_O^2 > 2\sigma(F_O^2)$]: 5818.

Structure solution and refinement use direct methods using SHELXS-86 [21]. Full-matrix least-squares refinement using SHELXL-93 [22]. Two independent molecules in the asymmetric unit and one solvent molecule (i.e. THF, O atom in special position refined with an occupancy factor of 0.10 and 2 C atoms with an occupancy factor of 0.20). All non-H atoms anisotropic, except those of phenyl rings and of solvent molecule which were refined isotropically. H atoms bonded to C atoms were introduced in calculations in idealized geometry [d(C—H) = 0.97 Å]. H atoms bonded to N atoms were allowed to vary. All hydrogen thermal parameters were isotropic and kept fixed in final refinement cycles. Scattering factors were taken from 'International Tables for X-ray Crystallography' [23]. Refinement on F_O^2 for all reflections (7817). Weighted R-factors wR and goodnesses of fit S are based on F_O^2, conventional R-factors R are based on F_O, with F_O set to zero for negative F_O^2. Last refinement cycle: wR(all) = 0.1009, R(all) = 0.0632, wR(obs) = 0.0866, R(obs) = 0.0364 with 5818 obs. reflections > $4\sigma(F_O)$, 461 variable parameters, $w = [\sigma^2(F_O^2) + (0.0457\ P)^2 + 40.5368\ P]^{-1}$ where $P = (F_O^2 + 2F_O^2)/3$, S(all) = 1.026, S(obs) = 1.031, max. shift/esd = 0.056, mean shift/esd = 0.002, max. and min. residual peaks of 0.502 and 0.519 e/Å^3.

(Received 24 January 1997; accepted 12 May 1997)

Abstract—A positive-ion Fast Atom Bombardment (FAB) study was performed to determine the structure of samarium(III) triiodine complex (**I**). Collision Induced Dissociation (CID) and High Resolution Mass Spectrometry were used to establish the fragmentation pattern of the $C_{24}H_{72}O_4N_{12}P_4I_3Sm$ compound. The structure of (**I**) was confirmed by X-ray analysis. © 1997 Elsevier Science Ltd

Keywords: samarium complex; mass spectrometry; fast atom bombardment; collision induced dissociation; α,β-unsaturated ketones.

Samarium diiodide, a unique one-electron transfer reagent first introduced by Kagan and coworkers [1] has become the focus of growing interest in organic chemistry [2], mainly because in some processes [3] the reactions can be strongly accelerated with the addition of hexamethyl phosphoramide (HMPA) ligand $[(CH_3)_2N]_3PO$. As a part of our research program, we studied the behavior of SmI_2/HMPA system in the reductive coupling of α,β-unsaturated ketones. At the end point of the named reaction, we were able to isolate two crystalline coordination compounds as by-products highly sensitive to moisture; both ionic solids were non volatile compounds to give the conventional mass spectra, however one of them, using Fast Atom Bombardment technique (FAB) afforded an excellent spectrum. In this contribution the structure of the compound (**I**) is suggested based on the use of collisional induced dissociation (CID) [4,5] and high resolution mass spectrometry. The structure of **I** was finally confirmed by the X-ray diffraction study [6].

RESULTS AND DISCUSSION

The main fragmentation pathway of $[Sm(HMPA)_4I_2]I$ (**I**) has been investigated with the aid of high resolution data, the highest peak observed (a) at *m/z* 1122 is proposed for this process (Scheme 1) and Figs 1–2, where the CID spectra is represented. The elemental composition for (a) was found to be $C_{24}H_{72}O_4N_{12}P_4I_2Sm$ (Table 1) (1122.2037 observed) which suggests that the I^- ion was lost from the molecular ion (*m/z* 1249); the M—I^- fragmentation is supported by the *m/z* 127 (I^-) fragment observed in negative ion (FAB) mass spectra of compound (**I**) and also because the elemental analysis of the named complex $[C_{24}H_{72}O_4N_{12}P_4I_2]^+I^-$ affords 30.66% of Iodine (found) and 30.50% (calc.). Other primary fragmentations observed in the mass spectra of (**I**) are due to the loss of HMPA ligands yielding the species (b) at *m/z* 943 $C_{18}H_{54}O_3N_9P_3I_2Sm$ (943.0867), (c) at *m/z* 764 $C_{12}H_{36}O_2N_6P_2I_2Sm$ (763.9619) and (d) at *m/z* 585 $C_6H_{18}ON_3PI_2Sm$ (584.8469), this last peak gives (e) for expulsion of I^- radical with *m/z* 458 $C_6H_{18}ON_3$ PISm (457.9421). A secondary fragmentation of ion

(c) gives the (f), (g) and (h) fragments. The elemental composition $C_{12}H_{36}O_2N_6P_2ISm$ (637.0623) for (f), $C_{11}H_{33}O_2N_6P_2ISm$ (622.0388) for (g) and $C_8H_{24}O_2N_4P_2I_2Sm$ (675.8683) for (h) are in agreement with the proposed pattern shown in scheme 1. The structure of samarium complex (**I**) determined by X-ray diffraction and shown in Figs. 3 and 4 agrees with the mass spectrometry study reported here.

EXPERIMENTAL

The FAB mass spectra were obtained with a Jeol SX 102 Double-Focusing mass spectrometer with reverse geometry using a 6 Kv Xenon Beam (10 mA); *m*-Nitrobenzyl alcohol was used as matrix for recording the mass spectra, the samples were dissolved in acetone. The FAB desorbed ions were accelerated to 10 KeV. The range of the mass measurement was set so as to cover at least two standard peaks which encompassed the sample peak. The mass calibration was carried out by interpolation of two signals observed in the spectrum of polyethyleneglycol 1500 (1207.7261 and 1251.7524). The mass resolution and scanning speed used were 10,000 and 120 s/decade, respectively. The accurate mass was given as the mean value of the masses observed 5–10 scans of mass spectra and determined from mass centroids of $[M+H]^+$ peaks. Elemental compositions for the accurate mass were calculated within an error of 10 ppm by using the program installed in the above system. The CID spectra were recorded with the same instrument using the constant B/E linked scan-technique. The Helium pressure in the first field-free region collision cell was adjusted until the main beam signal was reduced 50%. Each B/E scan spectrum reported here is the average of 5–10 scans. The general procedure used for the reductive coupling reaction was reported previously [7,8]. The two sensitive samarium complexes $[Sm(HMPA)_4I_2]I$ (**I**) and $[Sm(HMPA)_3(H_2O)]I_3$ [8],

(Received 3 December 1996; accepted 12 May 1997)

Abstract—A variety of α-dicarbonylbis(aroylhydrazone) H_2L (**1**) ligands were synthesized and used to synthesize complexes formulated as $NiL \cdot nH_2O$, $Zn_2L_2 \cdot nH_2O$, CuL, $CoL \cdot nH_2O$ and $Na[CoL(NO_2)_2]$, where L refers to the dinegative anion of α-dicarbonylbis(aroylhydrazone) ligand. These complexes were investigated by elemental analyses, IR and UV–vis spectra and, for zinc(II), $Na[CoL(NO_2)_2]$ and the anhydrous NiL complexes, ^1H NMR spectra were measured in order to elucidate their structures. Other octahedral complexes such as $Ni(H_2L)_2(OAc)_2$ and $Co(HL)_3 \cdot nH_2O$ were isolated and characterized. Different modes of coordination were assigned to the ligand **1** and its anions in the isolated complexes; dinegative tetradentate, mononegative bidentate and neutral bidentate. © 1997 Elsevier Science Ltd

Keywords: Schiff bases; nickel(II) complexes; zinc(II) complexes; copper(II) complexes; cobalt(II) complexes; cobalt(III) complexes; α-dicarbonylbis(aroylhydrazone).

It has long been known that condensation of α-dicarbonyl compounds with aroylhydrazines affords the corresponding α-dicarbonylbis(aroylhydrazone) [1,2] compounds, H_2L (**1**). Due to the ability of these compounds to form coloured products with various metal ions, they have been used as analytical reagents [3–7].

Most of the information about the reactivity of α-dicarbonylbis(aroylhydrazone), (**1**), focused on their reactions with different oxidizing agents such as potassium ferricyanide [8], silver oxide [9], iodine [10], a mixture of mercuric oxide and iodine [9,10] and nickel peroxide [11]. The products of these reactions were found to vary considerably with the nature of the oxidizing agents [8–11].

Compounds **1** provide potentially tetradentate ligands with NNOO donor atoms which can form stable chelates with metal ions. In fact, the first metal complex of this type of ligands was [diacetylbis(benzoylhydrazone)(-2)]nickel(II) (**2**: $R = R' = CH_3$, $R'' = C_6H_5$; $M = Ni^{2+}$) [12] where it has been shown that the central nickel ion is in a distorted square–planar arrangement with the coordination of the two oxygen atoms in *cis*-configuration [13]. The following study was undertaken in order to shed the light on the chelating properties of α-dicarbonylbis(aroylhydrazone) compounds.

EXPERIMENTAL

Preparation of compounds

Organic ligands. Aroylhydrazones were generally prepared by the reaction of α-dicarbonyl compounds (glyoxal, phenylglyoxal, phenylmethylglyoxal, diacetyl, benzil) with two equimolar amounts of aroylhydrazine in an ethanol–water mixture (2 : 1). A few drops of conc. HCl or HOAc were added and the reaction mixture was refluxed for *ca* 30 min. The product was filtered and washed with ethanol-water mixture (1 : 1) and air dried (yield : 60–80%).

Metal complexes

Nickel(II) complexes. NiL : a hot suspension of α-dicarbonylbis(aroylhydrazone) (20 mmol) and KOH (20 mmol) in MeOH (30 cm^3) was treated with a hot solution of $Ni(OAc)_2 \cdot 4H_2O$ (10 mmol/20 cm^3 of MeOH). The reaction mixture was refluxed with stirring for 2 h. The precipitate was collected by filtration, recrystallized from chloroform or benzene and then dried *in vacuo* (yield : 60–75%). Crystallization of the pale green complex, $NiL \cdot 4H_2O$ derived from glyoxalbis(benzoylhydrazone) afforded the anhydrous form. With benzilbis(benzoylhydrazone), a grey–green precipitate insoluble in MeOH was obtained. Also, a dark green precipitate was obtained when the reaction was performed in DMSO. This was recrystallized from benzene.

$Ni(H_2L)_2(OAc)_2$ {$H_2L \equiv$ **1**: R = R′ = R″ = C_6H_5}. This complex was prepared by treating a hot solution of 10 mmol of benzilbis(benzoylhydrazone), dissolved in DMSO (20 cm^3) with a hot solution of $Ni(OAc)_2 \cdot 4H_2O$ (10 mmol) in MeOH (20 cm^3) and the reaction mixture was then refluxed for 1 h. The isolated pale yellow complex was crystallized from benzene–methanol solution (yield : 50% ; m.p. 70°C).

Copper(II) complexes. $CuL \cdot nH_2O$ (n = 0, 1/2, 1): these complexes were prepared in a similar manner to that described above for NiL complexes (yield : 40–60%) using excess NaOAc. In case of glyoxalbis(benzoylhydrazone), 2 equiv. of KOH were added instead of NaOAc.

$Cu(H_2L)_2X_2$ {$H_2L \equiv$ **1**: R = R′ = H, R″ = C_6H_5, p-$CH_3 \cdot C_6H_4$; X = OAc^-, Cl^-}. A hot methanolic solution of 10 mmol of $CuCl_2$ or $Cu(OAc)_2 \cdot 2H_2O$ and excess NaOAc was added dropwise to a hot suspension of glyoxalbis(aroylhydrazone) (20 mmol) in MeOH (20 cm^3). The reaction mixture was then refluxed with constant stirring for 4 h, after which the corresponding dichloro or diacetato complex was filtered off, washed with boiling methanol and dried *in vacuo*.

Zinc(II) complexes. $ZnL \cdot nH_2O$: these were prepared following procedures similar to those described for the corresponding NiL complexes. Shiny yellow complexes were isolated when solutions were reduced to small volumes (yield : 40–60%).

Cobalt(II) complexes. $CoL \cdot nH_2O$: an ethanolic solution of $CoCl_2 \cdot 6H_2O$ or $Co(OAc)_2 \cdot 4H_2O$ (10 mmol) was added to a hot suspension of 10 mmol of α-dicarbonylbis(aroylhydrazone) and KOH (20 mmol). The reaction mixture was refluxed for 30 min and volume was reduced by evaporation. The isolated brick-red complex was recrystallized from chloroform and dried *in vacuo* over P_4O_{10} (yield : 70–80%).

Cobalt(III) complexes. $Na[CoL(NO_2)_2] \cdot nH_2O$ (n = 0, 1/2, 1) : a hot ethanolic (40 cm^3) suspension of 20 mmol of the α-dicarbonylbis(aroylhydrazone) was treated dropwise with a hot solution of $Na_3[Co(NO_2)_6]$ (20 mmol), dissolved in H_2O (10 cm^3). The resulting solution which turned red was filtered while hot and evaporated to a small volume. The crude precipitate which was separated upon standing at room temperature was filtered off and recrystallized from absolute ethanol (yield : 40–50%). In case of benzilbis(benzoylhydrazone), crystallization of the crude product from chloroform afforded two complexes ; $Na[CoL(NO_2)_2]$ as an insoluble compound and $Co(HL)_3 \cdot 3H_2O$. The latter was obtained by evaporating the filtrate till crystallization.

Physical measurements

The IR spectra were recorded with a Perkin–Elmer 1430 ratio recording infrared spectrophotometer. Solid samples were examined between KBr plates. UV–vis spectra of the complexes were obtained with a Perkin–Elmer Lambda 4B spectrophotometer using 2 mm and/or 10 mm quartz cells. ^1H NMR spectra were recorded with a Varian 90 MHz spectrometer using TMS as an internal reference. The metal contents in the synthesized complexes were determined by the standard literature methods. The elemental analyses were performed at the Micro analytical Laboratory at Kuwait University, Kuwait and at Darmstadt University, Germany.

RESULTS AND DISCUSSION

Synthesis of the complexes

The reaction of α-dicarbonylbis(aroylhydrazone) (**1** ≡ H_2L) with $Ni(OAc)_2$ in presence of potassium hydroxide in methanol resulted in the formation of green neutral mono ligand complexes, NiL where L refers to the dinegative anion (**2**: R = R′ = CH_3, R″ = C_6H_5, *p*-$CH_3 \cdot C_6H_4$, *p*-$Cl \cdot C_6H_4$; R = CH_3, R′ = R″ = C_6H_5). With glyoxalbis(benzoylhydrazone) (**1**: R = R′ = H, R″ = C_6H_5), the isolated complex, $NiL \cdot 4H_2O$ undergoes dehydration to produce the anhydrous red species. In DMSO and MeOH, the reaction of $Ni(OAc)_2$ with benzilbis(benzoylhydrazone) (**1**: R = R′ = R″ = C_6H_5)

yielded dark and grey green complexes, respectively of stoichiometric composition NiL. The former complex has the same characteristic features as those reported for the above monomeric species, whereas the grey green complex was found to be insoluble in most common organic solvents; a property which may suggest a polymeric structure. When the reaction was conducted in DMSO–MeOH mixture (1 : 1), a yellow compound of the formula $Ni(H_2L)_2(OAc)_2$ was obtained.

In methanol the reaction of copper(II) acetate or chloride with α-dicarbonylbis(aroylhydrazone) in presence of excess NaOAc gave complexes of the general formula $CuL \cdot nH_2O$ ($n = 0$, 1/2, 1). The glyoxal derivatives were only isolated when KOH was used instead of NaOAc, however when the latter was used in excess $Cu(H_2L)_2(OAc)_2$ complexes were obtained. Similarly the corresponding $Cu(H_2L)_2Cl_2$ were isolated when the reactions were carried out using $CuCl_2 \cdot 2H_2O$ and in absence of a base.

Hydrated zinc(II) and cobalt(II) complexes of the general formula $ML \cdot nH_2O$ were isolated from reactions of **1** with zinc(II) or cobalt(II) acetate in presence of KOH. Also, reaction of **1** with $Na_3[Co(NO_2)_6]$ in aqueous ethanol afforded $Na[Co^{III}L(NO_2)_2]$ complexes. With benzilbis(benzoylhydrazone), besides the expected dinitro compound, the tris complex $Co(HL)_3 \cdot 3H_2O$ was isolated.

The purity of the synthesized complexes were checked by elemental analyses (Table 1).

IR spectra

α-Dicarbonylbis(aroylhydrazone) compounds and their complexes are similar to those of aroylhydrazones derived from monocarbonyl compounds, both can exist in the keto or enol forms depending on the pH of solution [14–17]. The ligands under investigation, **1** display different modes of chelation with divalent metal ions [12,18–22].

The infrared spectra of ligands **1** exhibit absorption bands characteristic for aroylhydrazone residue, CONH—N=C [17,23,24]. The IR data are listed in Table 2. In general the complexes $ML \cdot nH_2O$ and $Na[CoL(NO_2)_2]$ lack absorption bands due to ν(N—H), amide I ν(C=O) and amide II; instead they display a very intense band at 1600–1580 cm^{-1}, attributable to ν(C=N—N=C). This finding clearly indicates the deprotonation of the two amide residues and may suggest the coordination of the hydrazone ligand *via* the two azomethine nitrogens and the two ionized enolic oxygens in a fashion similar to that described by structure **2**.

The IR spectra of the complexes $M(H_2L)_2X_2$ (M = Ni, X = OAc, R = R′ = C_6H_5, R″ = C_6H_5; M = Cu, X = Cl, OAc, R = R′ = H, R″ = C_6H_5; *p*-$CH_3 \cdot C_6H_4$) show ν(N—H), amide I ν(C=O) and amide II bands at almost the same positions as those found in their parent free ligands, indicating that the two carbonyl groups remain uncoordinated. The lower frequency shift observed for the ν(C=N) stret-

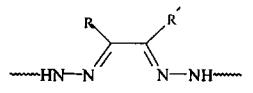
ching vibration confirms the NN bidentate nature of the hydrazone molecule; chelation mode **3**.

The N-bonded nature for NO_2^- in $Na[CoL(NO)_2]$ was confirmed by the presence of strong absorption bands in the 1430–1420 and 1320–1300 cm^{-1} regions, attributed to $\nu_a(NO_2)$ and $\nu_s(NO_2)$ stretching vibrations, respectively [25]. The presence of a single band for each type of vibration is in agreement with the *trans* geometry [26] expected in these complexes (**4**).

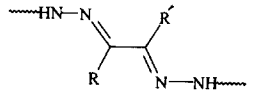
The IR spectrum of tris[benzilbis(benzoylhydrazonato)(-1)]cobalt(III) trihydrate, $Co(HL)_3 \cdot 3H_2O$ displayed a series of bands at 3230, 1671 and 1525 cm^{-1} due to ν(N—H), amide I ν(C=O) and amide II, respectively; same positions as those observed in the parent organic ligand (Table 2). Also, the spectrum exhibits a new intense band at 1575 cm^{-1} attributable to ν(C=N—N=C) of the deprotonated ligand. These results clearly indicate that the hydrazone molecule is acting as a mononegative NO bidentate where half of the ligand is uncoordinated and exists in the keto form and the second half is binding to Co^{III} through the azomethine nitrogen and the enolic group. Thus, the following mode of chelation can be proposed for $Co(HL)_3 \cdot 3H_2O$ complex.

^{1}H *NMR spectra*

The ^{1}H NMR spectral data for diacetyl- and methylphenylglyoxalbis(benzoylhydrazone) molecules and their diamagnetic zinc(II), nickel(II) ($ML \cdot nH_2O$) and cobalt(III) ($Na[CoL(NO_2)_2]$) complexes are summarized in Table 3. The spectrum of **1** (R = R′ = CH_3, R″ = C_6H_5) shows two equivalent signals at 10.60 and 2.32 ppm due to N—H and the two equivalent CH_3 protons, respectively and two multiplets centered at 7.77 and 7.46 ppm attributable to the two aromatic protons. The spectrum of methylphenylglyoxalbis(benzoylhydrazone) (**1**: R = CH_3, R′ = R″ = C_6H_5) gave the resonances expected for the two phenyl groups, also it displays two proton signals for each methyl (2.13 and 2.33 ppm) and the N—H protons (11.03 and 10.67 ppm). These signals can be rationalized by considering the following two isomers: rotomeric species **6** and **7** in solutions.

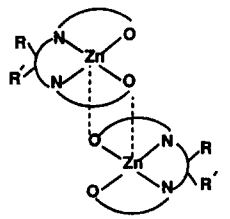


[6]

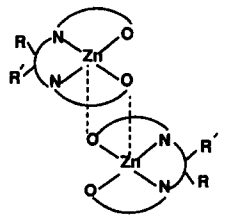


[7]

The complexes $ML \cdot nH_2O$ (M = Zn^{II}, Ni^{II}) and $Na[CoL(NO_2)_2]$ derived from the diacetyl and methylphenylglyoxal display spectra comparable to those of their parents, except the lack of the N—H signals. The ^{1}H NMR signals of the aromatic and methyl groups in $ML \cdot nH_2O$ complexes show clear upfield shifts relative to those observed in the free ligands. This may result from the increased electron densities; delocalization of the two negative charges all over the highly conjugated bis-hydrazone residues as well as the back donation from the occupied metal ion orbitals to the unoccupied π^* ligand orbitals (M → L). In [methylphenylglyoxalbis(benzoylhydrazonato)(-2)]zinc(II) complex, the CH_3 protons appear as a doublet at 1.37 and 1.43 ppm. The nonequivalency of the two methyl groups can be interpreted by assuming the existence of the two dimeric structures **8** and **9**, where the methyl and phenyl groups are oriented differently with respect to the plane formed by Zn^{2+} ions and the two oxygen bridges. For [diacetylbis(benzoylhydrazonato)(-2)]zinc(II) complex, all the CH_3 protons are equivalent and hence only one dimeric isomer would be predicted.

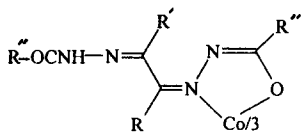


[8]



[9]

The ^{1}H NMR spectra of cobalt(III) complexes, $Na[CoL(NO_2)_2]$ derived from diacetyl- and methylphenylglyoxalbis(benzoylhydrazone) exhibit the methyl and aromatic protons at low fields; only σ-interaction is taking place in these complexes.



[5]

Electronic spectra

tra of the $ZnL \cdot nH_2O$ complexes exhibit a series of bands at *ca* 300 and 400 nm, due to π–π^* transitions in the highly conjugated dinegative anion, L^{2-}. The bands at *ca* 450 nm are most probably due to MLCT transitions.

The band maxima detected at 430–470 nm in the CuL chelates are quite similar to those found in square planar CuN_2O_2 complexes, and most probably due to LMCT transitions [27]. Moreover, the spectra exhibit an absorption band or a shoulder in the 500 nm region due to MLCT band. The *d*–*d* transitions which were detected as a broad band or a shoulder in the 650–730 nm region ($\varepsilon = 120\ M^{-1}\ cm^{-1}$) result from the two energetically close $^2A_{1g} \leftarrow {}^2B_{1g}$ and $^2B_{2g} \leftarrow {}^2B_{1g}$ transitions [27]. In cobalt(II) complexes, $CoL \cdot nH_2O$, the expected weak *d*–*d* transition in the octahedral environment is obscured by the intense LMCT band.

The spectra of the cobalt(III) complexes of $Na[CoL(NO_2)_2]$ (Table 4) clearly reveal the presence of three maxima in the visible region located at 465, 529, 575 nm and 464, 548, 598 nm for diacetyl and for methylphenylglyoxal derivatives, respectively. These bands can be assigned for $^1T_{2g} \leftarrow {}^1A_{1g}$, $^1A_{2g} \leftarrow {}^1A_{1g}$ and $^1E_g \leftarrow {}^1A_{1g}$ transitions, respectively as would be predicted in d^6 low-spin *trans*-octahedral species [27,28]. The splitting of the low energy band is not clearly pronounced due to the small difference in ligand field strengths between the axial NO_2^- and the planar N_2O_2 coordinating sites. The relative strong intensity of the three observed bands presumably results from the contribution of the MLCT transition. The electronic spectra for $Na[CoL(NO_2)_2]$ chelates are illustrated in Fig. 1.

The visible spectra of the nickel(II) complexes, NiL in chloroform display several bands as depicted in Fig. 1. The band located around 525 nm is most probably due to a LMCT transition. The three intense bands detected at the wavelength region 640–810 nm (Table 4) can be attributed to the different d(M) → π^*(L) transitions (MLCT) rather than *d*–*d* transitions. This assignment is based on the fact that Ni^{2+} ion is located at the center of a delocalized π-bond of three conjugated chelate rings. Thus, the extended conjugation as well as the *p*–π interaction in these complexes tend to decrease the energy difference between the unoccupied ligand π^* orbitals (LUMO) and the occupied metal *d*-orbitals (HOMO).

In conclusion, α-dicarbonylbis(aroylhydrazone) compounds provide ligands with great tendency to bind different metal ions in planar arrangements as a result of the high delocalization of dinegative charge of the anion.

Unexpected coordination behavior of dinucleating ligand: infinite zigzag chain of alternating sodium(I) and dinuclear-zinc(II) units

Masahiro Mikuriya* and Sumiko Tashima

Department of Chemistry, School of Science, Kwansei Gakuin University, Uegahara, Nishinomiya 662, Japan

(Received 21 May 1997; accepted 9 June 1997)

Abstract—A zinc(II) complex, $[Zn_4Na_2L_2(CH_3COO)_4CH_3CN]_n \cdot 2nCH_3CN \cdot 2nH_2O$ (H_3L = 2,6-bis(saliclylideneaminomethyl)-4-methylphenol), has been isolated and characterized by X-ray crystallography, which reveals a unique zigzag-chain structure consisting of dinuclear $Zn_2L(CH_3COO)_2$ units and sodium ions.
© 1997 Elsevier Science Ltd

Keywords: sodium(I); zinc(II); Schiff-base; dinucleating ligand; sodium(I)–zinc(II) complex; crystal structure.

There has been much interest in the synthesis of polynuclear metal complexes because of their structural variety and novelty. An interesting approach to design of such compounds is to assemble dinuclear metal units into polynuclear molecules. Schiff-bases as dinucleating ligands are known to give dinuclear units for *d*-block metal ions [1]. One of these dinucleating ligands, 2,6-bis(saliclylideneaminomethyl)-4-methylphenol (H_3L) which has two terminal phenoxo-oxygen atoms in addition to the central phenoxo-oxygen atom as the bridging group, has potential to form polynuclear compounds on deprotonation to L^{3-} (Fig. 1). We recently described synthesis of dinuclear (**I**) [2], tetranuclear (**II**) [3,4], and pentanuclear (**III**) [5] complexes which are formed by the use of the L^{3-} ligand (Fig. 2). In the case of the tetranuclear complexes [3,4], two dinuclear units (**I**) are associated

Primes refer to the equivalent positions ($x-1$, y, z).

to form the tetranuclear molecules (**II**) by the bridging of the terminal phenoxo-oxygen atoms of L^{3-}. In the course of this study, we have isolated a novel polynuclear complex which has a chain structure (**IV**). Although successful chain formation has been accomplished for metal carboxylate dimers [6], there appears to be no examples using dinuclear units other than metal carboxylates for one-dimensional array. Herein we report an intriguing method using the dinucleating ligand to obtain a new class of chain compound.

Treatment of H_3L (0.04 mmol) with zinc(II) acetate dihydrate (0.11 mmol) and sodium perchlorate (0.14 mmol) in acetonitrile (6.5 cm^3) containing three drops of triethylamine and two drops of *N,N*-dimethylacetamide resulted in deposition of pale yellow crystals (**1**). An X-ray crystallographic study revealed that the compound is composed of a chain of the Schiff-base ligands L^{3-}, each of which binds two zinc (II) atoms, bound to sodium ions to give a ZnZnNa-zigzag chain (Fig. 3).‡ The asymmetric unit contains two crystallographically different dinuclear zinc(II) units and sodium ions, $[Zn_4Na_2L_2(CH_3COO)_4 CH_3CN]$. Each dinucleating ligand L^{3-} is octadentate and the central phenoxo oxygen [O(2), O(9)] acts as the bridging atom binding two zinc atoms. The distances are 3.325(2) and 3.343(2) Å for Zn(1)–Zn(2) and Zn(3)–Zn(4), respectively. Two acetate ions are incorporated in each dinuclear units as two exogenous *syn–syn* bridges. Each zinc atom adopts a distorted trigonal–bipyramidal coordination geometry with Zn–O distances in the range 1.985(10)–2.037(9) Å for the equatorial bonds [Zn(1)—O(1), Zn(1)—O(2), Zn(1)—O(6); Zn(2)—O(2), Zn(2)—O(3), Zn(2)—O(5); Zn(3)—O(8), Zn(3)—O(9), Zn(3)—O(13); Zn(4)—O(9), Zn(4)—O(10), Zn(4)—O(12)] and 2.158(9)–2.175(9) and 2.068–2.090(13) Å for the axial oxygen [O(4), O(7), O(11), O(14)] and nitrogen [N(1), N(2), N(3), N(4)] atoms, respectively. The two terminal phenoxo oxygens [O(1), O(3); O(8), O(10)] of each dinucleating ligand L^{3-} act as bridging groups being further coordinated to sodium ions [Na(1),

‡ Crystallographic data: **1**; $C_{60}H_{63}N_7Na_2O_{16}Zn_4$, F.w. = 1445.67, triclinic, space group $P\bar{1}$, a = 14.533(6), b = 20.487(6), c = 12.108(7) Å, α = 100.34(2), β = 92.95(3), γ = 89.55(3)°, V = 3542(3) Å^3, Z = 2, D_m = 1.43, D_c = 1.36 g cm^{-3}, μ(Mo-K_α) = 14.46 cm^{-1}, 10,050 reflections measured ($2\theta_{max}$ = 48°), 5450 [$I \geqslant 3\sigma(I)$] used in the refinement, R = 0.065, R_w = 0.097. Intensity data were collected on an Enraf–Nonius CAD4 diffractometer using graphite-monochromated Mo-K_α radiation. All the structures were solved by the direct method and refined by the full-matrix least-squares method using a MolEN program package.

Na(2)] with one of the exogenous acetate bridges in a monatomic bridging; the intermetallic separations are Zn(1)—Na(1) 3.425(7), Zn(3)—Na(1) 3.331(7), Zn(4)—Na(2) 3.438(7), and Zn(2′)—Na(2) 3.349(7) Å. One of the most interesting findings in **1** is the combination of *syn–syn* and monatomic bridging of the acetate ions. Such an η^3 behavior is seldom observed in metal carboxylates [7]. The IR spectrum exhibits absorptions indicative of the bridging nature of the acetate groups [$\nu_{asym}(CO_2^-)$ 1591s, $\nu_{sym}(CO_2^-)$ 1434s cm^{-1}] [8]. In the asymmetric unit, an acetonitrile molecule is coordinated to one [Na(2)] of the two sodium ions. Thus the coordination geometries of the sodium ions are distorted tetrahedral and trigonal bipyramidal for Na(1) and Na(2), respectively. The Na—O distances are in the range 2.301(11)–2.434(12) Å and the Na—N [Na(2)—N(5)] distance is 2.495(23) Å. Within a crystal, the heterometal asymmetric units are united to form an infinite zigzag chain along the *a* axis. To our knowledge, this is the first example of polymeric assembling by dinucleating ligands.

The Na ions play a vital structural role in that all the terminal phenoxo groups of the dinucleating ligands interact with these ions. The present result emphasizes the importance of the use of bridging properties of the terminal groups of the dinucleating ligands as part of the design strategy for creating new polynuclear complexes.

(Received 4 August 1997; accepted 18 September 1997)

Abstract—The new ligands 2-(2-hydroxyphenyl)-4-'butyl-pyridine (HL^1), 2-(2-hydroxyphenyl)-6-methyl-pyridine (HL^2) and 2-(2-hydroxyphenyl)-6-[(2-phenyl)ethyl]pyridine (HL^3) were prepared. They are all substituted derivatives of the simple *N,O*-bidentate chelating ligand 2-(2-hydroxyphenyl)pyridine. HL^1 is solubilised derivative bearing a 'Bu substituent in a position which will not sterically interfere with metal-ion coordination; HL^2 and HL^3 contain substituents at C^6 of the pyridyl ring, adjacent to the N atom, which will therefore sterically hinder metal-ion coordination. The complexes $[PdL_2]$ (L = L^1, L^2 and L^3) were prepared and structurally characterised to determine the effects (if any) of the substituents on the structures of the metal complexes. All are four-coordinate complexes with square planar coordination geometry about the Pd(II) ion, but the sterically hindered ligands L^2 and L^3 have to adopt a different conformation from L^1 to allow planar coordination, resulting in "bowl-like" structures. $[Cu_2(L^1)_4]$ was also prepared and found to be a phenolate-bridged dinuclear complex in the solid state, both by X-ray crystallography and EPR measurements. In solution, however, it dissociates to give $[Cu(L^1)_2]$ monomeric units. Cu(II) complexes of L^2 and L^3 could not be isolated. © 1997 Elsevier Science Ltd

Keywords: copper; palladium; crystal structures.

As part of our continuing study on the synthesis and coordination chemistry of mixed-donor polydentate ligands [1–5], we describe here some derivatives of the simple bidentate ligand 2-(2-hydroxyphenyl)pyridine HL, an *N,O*-donor chelate. Remarkably little coordination chemistry of this simple ligand was described until recently, despite its appeal as a hydrolytically stable structural and electronic analogue of salicylaldimines, because it was difficult to prepare; prior to our work the sole structurally characterised complexes were $[PdL_2]$ and $[CoL_3]$ [6]. We recently developed [4] a simple, high-yield synthesis of HL and subsequently described the crystal structures, electrochemical and spectroscopic properties of a series of ruthenium (II and III) and chromium(III) complexes [4,5].

In this paper we describe the preparation of three new substituted derivatives of HL. Ligand HL^1, containing a tertiary-butyl substituent at the C^4 position of the pyridyl ring, is a soluble analogue of HL which was prepared to facilitate characterisation of those complexes of HL which were only poorly soluble. Ligands HL^2 and HL^3 contain substituents at the C^6 position of the pyridyl ring, which are intended to provide steric hindrance to square-planar or octahedral coordination. Ligands which can impose an irregular geometry on metal ions may provide the basis for selective extraction of metal ions other than Cu(II) from a mixture [7] and we were therefore interested to see the extent to which addition of bulky substituents at the C^6 positions of these ligands would result in distortions away from regular coordination geometries.

The preparations and crystal structures of the three

mononuclear Pd(II) complexes $[Pd(L^1)_2]$, $[Pd(L^2)_2]$ and $[Pd(L^3)_2]$, and the dinuclear Cu(II) complex $[Cu_2(L^1)_4]$, are described in this paper.

EXPERIMENTAL

Preparation of 2-(2-methoxyphenyl)-4-^{t}butyl-pyridine (MeL^1)

A solution containing 2-lithioanisole was prepared by adding lithium pieces (388 mg, 56 mmol) to 2-bromoanisole (6.89 g, 37 mmol) in dry ether (50 cm^3) under N_2, and stirring the mixture at room temperature for 2 h. This solution was added to a solution of 4-tert-butylpyridine (4.99 g, 37 mmol) in dry toluene (40 cm^3), and the resultant mixture was stirred at 50°C under N_2 for 48 h. The solvents were removed under reduced pressure, and the residue was dissolved in acetone (50 cm^3). A saturated solution of $KMnO_4$ in acetone (3×100 cm^3) was added to oxidise the dihydropyridine, and the MnO_2 was removed by filtration through Celite. Evaporation of the acetone afforded a brown oil which was purified by column chromatography on alumina, using CH_2Cl_2 as the eluent to give a yellow oil. Yield: 1.27 g (14%). EIMS: $m/z = 241$ (M^+), 196 (M^+—^{t}Bu), 136 (M^+—C_7H_8O). Anal. Found C, 79.1; H, 8.0; N, 6.0%. Required for $C_{16}H_{19}NO$: C, 79.3; H, 7.5; N, 6.2%. See Table 1 for ^{1}H NMR data.

Preparation of 2-(2-hydroxyphenyl)-4-^{t}butyl-pyridine (HL^1)

This was prepared by demethylation of the precursor MeL^1 (1.20 g, 5 mmol) using molten pyridinium chloride at 190°C for 1.75 h according to the published method [8]. The mixture was allowed to cool, water (50 cm^3) was added and the dark red solution was neutralised using aqueous KOH. The resulting precipitate was extracted into CH_2Cl_2 and purified further on silica using CH_2Cl_2 as the eluent to give a yellow solid. Yield: 0.50 g (45%). EIMS: $m/z = 227$ (M^+). Anal. Found C, 78.8; H, 7.1; N 5.9. Required for $C_{15}H_{17}NO$: C, 79.6; H, 7.1; N, 6.2. See Table 1 for ^{1}H NMR data.

Preparation of 2-bromo-6-methylpyridine

This preparation is based on a published method [9]. To a three necked flask fitted with a mechanical stirrer, a low temperature thermometer, and containing 45% HBr (60 cm^3), 2-amino-6-picoline (17.5 g, 0.16 mol) was carefully added. The mixture was cooled to −40°C and bromine (24 cm^3, 0.47 mol) was added dropwise with vigorous stirring. A solution of sodium nitrite (27.5 g, 0.40 mol) in water (60 cm^3) was then added dropwise to the orange perbromide, whilst maintaining the temperature below −10°C. A solution of sodium hydroxide (60 g, 1.5 mol) in water (60 cm^3) was added slowly, maintaining the temperature

below 0°C. After warming up to room temperature, the mixture was extracted with ether (2×100 cm^3) and the product purified using column chromatography on silica with CH_2Cl_2 as the eluent. Yield 18.5 g (67%). EIMS: $m/z = 171$ (M^+) (based on ^{79}Br). Anal. Found C, 42.0; H, 3.7; N, 7.7%. Required for C_6H_6NBr: C, 42.1; H, 3.5; N, 8.2%.

Preparation of 2-(2-methoxyphenyl)-6-methylpyridine (MeL^2)

To an ice-cold mixture of $Ni(dppe)Cl_2$ (0.53 g, 1 mmol) and 2-bromo-6-methylpyridine (5.68 g, 33 mmol) in dry THF (50 cm^3) under N_2, a solution of the Grignard reagent prepared from 2-bromoanisole (9.26 g, 50 mmol) and magnesium turnings (1.2 g, 50 mmol) in THF (50 cm^3) was added. The mixture was allowed to warm up slowly to room temperature, and then stirred under N_2 for 24 h. The reaction was quenched with water (50 cm^3), and the solvents were removed under reduced pressure. The remaining oil was purified by column chromatography on alumina with CH_2Cl_2/MeOH (98:2) as the eluent to give a straw-coloured oil. Yield: 4.22 g (71%). EIMS: $m/z = 199$ (M^+), 169 (M^+—OMe). Anal. Found C, 78.0; H, 6.4; N, 7.1%. Required for $C_{13}H_{13}NO$: C, 78.4; H, 6.6; N, 7.0%. See Table 1 for ^{1}H NMR data.

Preparation of 2-(2-hydroxyphenyl)-6-methylpyridine (HL^2)

This was prepared by demethylation of the precursor MeL^2 (0.82 g, 4 mmol) using molten pyridinium chloride at 190°C for 1.75 h according to the published method [8]. After allowing the mixture to cool to room temperature, water (50 cm^3) was added and the resultant dark red solution was neutralised using aqueous KOH. The resulting precipitate was extracted into CH_2Cl_2, and purified on silica using CH_2Cl_2 as the eluent to give HL^2 as a yellow solid. Yield: 0.52 g (70%). EIMS: $m/z = 185$ (M^+). Anal. Found C, 77.7; H, 5.8; N 7.4%. Required for $C_{12}H_{11}O$: C, 77.8; H, 6.0; N, 7.6%. See Table 1 for ^{1}H NMR data.

Preparation of 2-bromo-6-[(2-phenyl)ethyl]-pyridine

This preparation is based on a published method for alkylation of the methyl group of 2-bromo-6-methylpyridine [10]. A solution containing lithium diisopropylamide (LDA; 40 mmol) was prepared by mixing diisopropylamine (4.05 g, 40 mmol) and *n*-butyllithium (26.6 cm^3 of a 1.5 M solution in hexanes, 40 mmol) at −78°C under N_2 and then allowing the mixture to warm up to 0°C. The solution was cooled back to −78°C, and a solution of 2-bromo-6-methylpyridine (6.23 g, 36 mmol) in dry THF (20 cm^3, precooled to −10°C) was added and the mixture stirred at −78°C for 0.5 h. Benzyl bromide (6.84 g, 40 mmol) was added, and the mixture was allowed to warm up to room temperature and stirred for 24 h. Removal of the THF afforded a dark brown residue which was dissolved in ether and washed with aqueous NaOH. The organic layer was purified by column chromatography on flash silica using CH_2Cl_2/hexane (2:1, v/v) as the eluent, to give a pale yellow oil which slowly crystallised on standing. Yield: 6.17 g (66%). EIMS: $m/z = 261$ (M^+), 185 (M^+—C_6H_5), 171 (M^+—C_7H_8) (all based on ^{79}Br). Anal. Found C, 58.7; H, 4.7; N, 5.6%. Required for $C_{13}H_{12}NBr$: C, 59.8; H, 4.6; N, 5.4%.

Preparation of 2-(2-methoxyphenyl)-6-[(2-phenyl) ethyl]pyridine (MeL^3)

To an ice cold mixture of $Ni(dppe)Cl_2$ (0.53 g, 1 mmol) and 2-bromo-6-[(2-phenyl)ethyl]pyridine (5.0 g, 19 mmol) in dry THF (50 cm^3), a solution of the Grignard reagent prepared from 2-bromoanisole (4.30 g, 23 mmol) and magnesium turnings (0.55 g, 23 mmol) in THF (50 cm^3) was added. The mixture was allowed to warm up slowly to room temperature, and was then stirred under N_2 for 24 h. The reaction was quenched with water (50 ml), and the solvents were removed under reduced pressure. The remaining oil was purified using column chromatography on alumina with CH_2Cl_2/MeOH (98:2) as the eluent to give a straw-coloured oil. Yield: 1.27 g (23%). EIMS: $m/z = 289$ (M^+), 258 (M^+—OMe), 212 (M^+—C_6H_5). Anal. Found C, 82.6; H, 6.7; N, 4.7%. Required for $C_{20}H_{19}NO$: C, 82.8; H, 6.9; N, 4.8%. See Table 1 for ^{1}H NMR data.

Preparation of 2-(2-hydroxyphenyl)-6-[(2-phenyl) ethyl]pyridine (HL^3)

This was prepared by demethylation of the precursor MeL^3 (1.00 g, 3.5 mmol) using molten pyridinium chloride at 190°C for 1.75 h according to the published method [8]. The mixture was allowed to cool, water (50 cm^3) was added and the dark red solution was neutralised using aqueous KOH. The resulting precipitate was extracted into CH_2Cl_2 and purified further on silica using CH_2Cl_2 as the eluent to give a yellow crystalline solid. Yield: 0.56 g (59%). EIMS: $m/z = 274$ (M^+). Anal. Found, 82.6; H, 6.7; N, 4.7%. Required for $C_{19}H_{17}NO$: C, 82.8; H, 6.9; N, 4.8%. See Table 1 for ^{1}H NMR data.

Preparation of complexes with Pd(II) and Cu(II)

The complexes $[Pd(L^1)_2]$, $[Pd(L^2)_2]$ and $[Pd(L^3)_2]$, and $[Cu_2(L^1)_4]$ were all prepared by reaction of the appropriate metal acetate (1 equivalent) with the appropriate ligand (2 equivalents) in MeOH at reflux for 30 min. The typical reaction scale was 0.5 mmol

of metal and 1 mmol of ligand in 20 cm^3 of solvent. After evaporation of the solvent *in vacuo*, the residue was recrystallised from CH_2Cl_2/hexane by layering the hexane onto a concentrated solution of the crude complex in CH_2Cl_2 and slowly allowing the layers to mix. This afforded a crop of X-ray quality crystals in every case. The crude yields were near-quantitative; the yields of crystalline material were much lower (10–40%) but not optimised. FAB mass spectral data (3-nitrobenzylalcohol matrix) were as follows: $[Pd(L^1)_2]$, $m/z = 558$ (M^+); $[Pd(L^2)_2]$, $m/z = 474$ (M^+); $[Pd(L^3)_2]$, $m/z = 655$ (M^+) and 381 $\{Pd(L^3)\}$; $[Cu_2(L^1)_4]$, $m/z = 804$ $\{Cu_2(L^1)_3\}$, 579 $\{Cu_2(L^1)_2\}$, 516 $\{Cu(L^1)_2\}$ and 289 $\{Cu(L^1)\}$. Satisfactory elemental analytical data were obtained for each complex.

X-ray crystallography

Suitable crystals were coated with paraffin oil, mounted on a brass pin, and quickly transferred to the diffractometer under a stream of cold N_2. Data were collected using a Siemens SMART three-circle diffractometer with a CCD area detector (173 K, graphite-monochromatised Mo—K_α X-radiation, $\lambda = 0.71073$ Å); a full description of the general experimental method has been given elsewhere [11]. Data were collected for Lorentz/polarisation effects, and for absorption effects by an empirical method based on multiple measurements of equivalent data. Details of the crystal parameters, data collection and refinement are in Table 2, and bond lengths and angles are in Tables 3 and 4. The structures were solved by conventional direct or heavy-atom methods, and refined by the full-matrix least-squares method on all F^2 data, using the SHELX suite of programs [12] on a Silicon Graphics Indy computer. All non-hydrogen atoms were refined anisotropically; hydrogen atoms were included in calculated positions and refined with isotropic thermal parameters.

RESULTS AND DISCUSSION

Ligand syntheses

Preparation of the 2-(2-hydroxyphenyl)pyridine core of HL^2 follows the previously-published method used for HL; viz. Ni(dppe)Cl_2-catalysed coupling of the Grignard reagent 2-$MeOC_6H_4$–MgBr with a substituted 2-bromopyridine [4] (in this case 2-bromo-6-methyl-pyridine which is readily prepared from the commercially available 2-amino-6-methyl-pyridine) to give the protected MeL^2, followed by deme-

thylation of the methoxy group with molten pyridinium chloride. HL^3 was likewise prepared from the cross-coupling of 2-bromo-6-[(2-phenyl)ethyl] pyridine (readily prepared by alkylation of deprotonated 2-bromo-6-methyl-pyridine with benzyl bromide) and 2-$MeOC_6H_4$–MgBr, followed by demethylation of the methoxy group. Ligand HL^1 in contrast was prepared by this route, as the required 2-bromo-4-*tert*-butyl-pyridine is not easily available. Instead, it was prepared by the direct reaction of the lithium reagent 2-$MeOC_6H_4Li$ with 4-*tert*-butyl-pyridine to give MeL^1, followed by demethylation. This is a low-yield reaction but allows preparation of reasonable quantities of HL^1 if done on a large scale, and would doubtless also be effective as route preparing the parent ligand HL. The identities of all three new ligands were confirmed by mass spectrometry and ^1H NMR spectroscopy, as well as the crystal structures of their complexes.

Syntheses and structures of $[Pd(L^1)_2]$, $[Pd(L^2)_2]$ *and* $[Pd(L^3)_2]$

We were interested in the Pd(II) complexes of these ligands to see if the various ligand substituents were capable of imposing a distorted coordination geometry on a metal ion that has a very pronounced stereoelectronic preference for regular square-planar geometry. Reaction of each ligand with 0.5 equivalents of palladium(II) acetate afforded neutral, CH_2Cl_2-soluble complexes for which analytical data in each case indicated a 1 : 2 metal : ligand ratio. All three of these were crystallographically characterised and the structures are in Figs 1, 2 and 3.

$[Pd(L^1)_2]$ (Fig. 1) is mononuclear and centrosymmetric, and the coordination geometry is a near-perfect square plane with a *trans* N_2O_2 donor set and unremarkable bond lengths. The ligands each have an angle of 35° between the pyridyl and phenolate rings, and the ligands are disposed such that the phenyl rings are directed towards opposite faces of the PdN_2O_2 plane for steric reasons. This structure is similar to that of $[PdL_2]$ [6]. This arrangement of ligands could not tolerate the addition of bulky substituents to the pyridyl C^6 position, as these substituents would be directed towards the phenyl ring of the alternate ligand, one on each side of the PdN_2O_2 plane.

The structure of $[Pd(L^2)_2]$ (Fig. 2) shows how the ligand conformation has changed to alleviate unfavourable steric effects involving the methyl groups, whilst still allowing the metal centre to retain a regular square-planar geometry. The ligands are

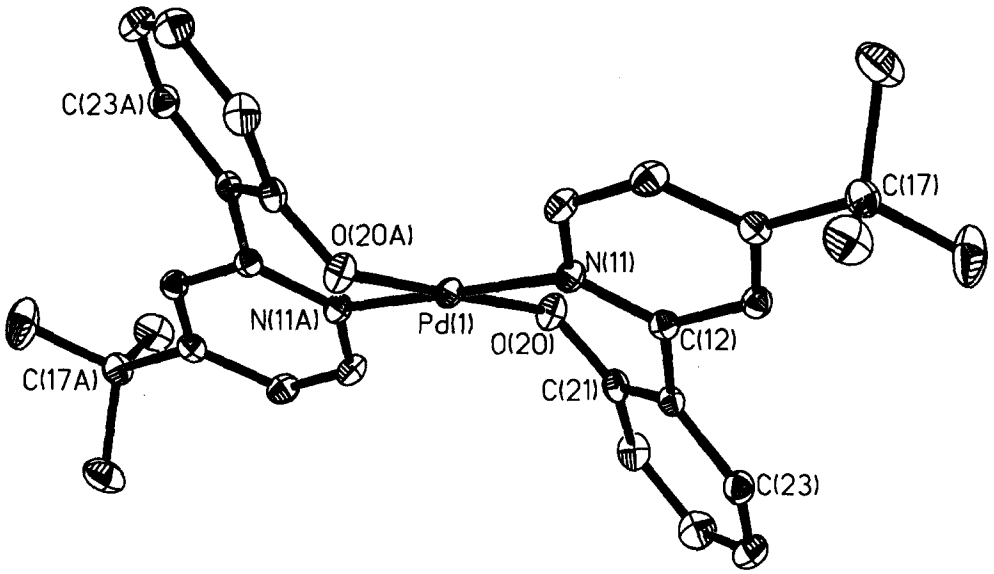

Fig. 1. Crystal structure of $[Pd(L^1)_2]$ (thermal ellipsoids at 40% probability level).

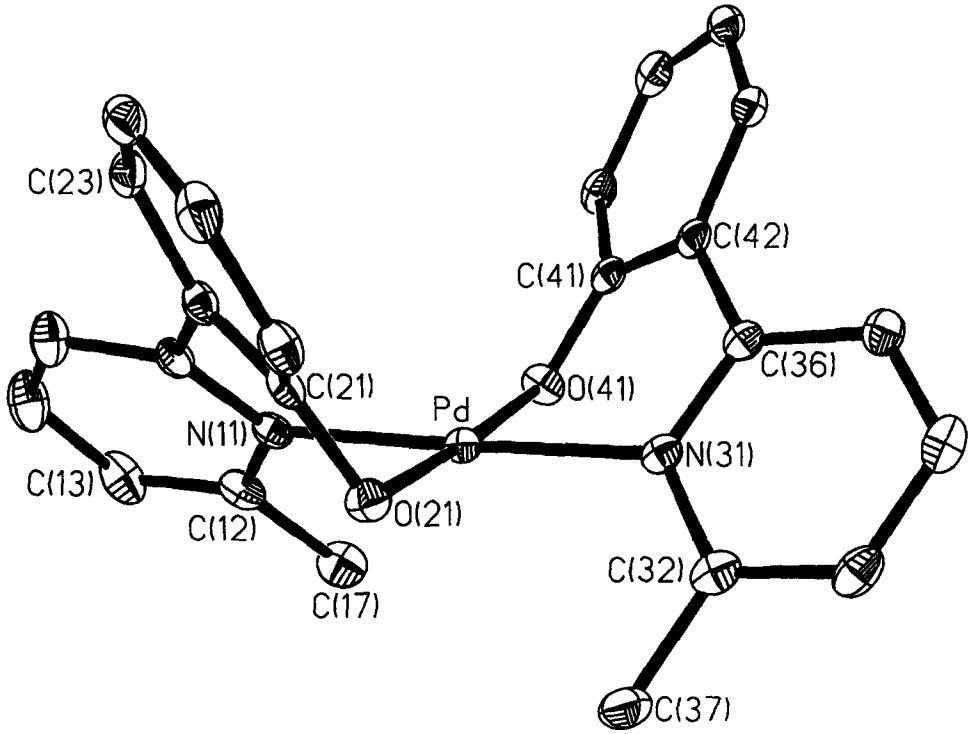

Fig. 2. Crystal structure of $[Pd(L^2)_2]$ (thermal ellipsoids at 40% probability level).

now disposed such that both phenyl rings are directed towards the same face of the *trans*-PdN_2O_2 plane, with both methyl groups directed to the opposite face. The dihedral angles between the mean planes of the aromatic rings within each ligand are 39.6° between rings 1 and 2, and 33.5° between rings 3 and 4, where the ring number is given by the first digit of the crystallographic atom numbering scheme [e.g., ring N(21) to C(26) is ring 2]. All of the metal-ligand bond distances are fractionally longer in $[Pd(L^2)_2]$ than in $[Pd(L^1)_2]$, by about 0.01 Å, which is about five standard deviations and therefore just significant.

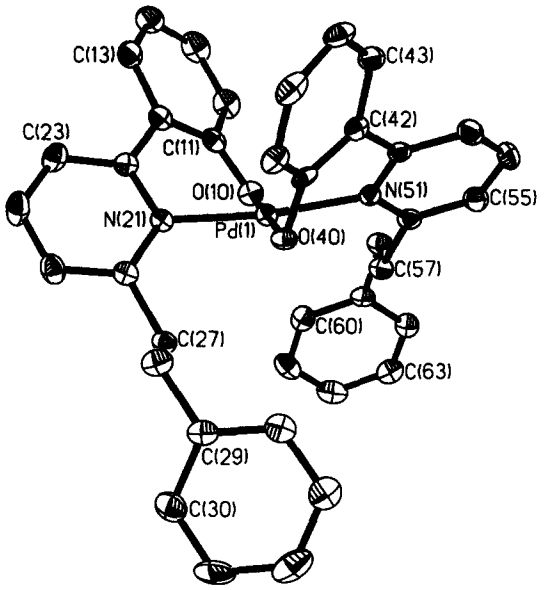

Fig. 3. Crystal structure of $[Pd(L^3)_2]$ (thermal ellipsoids at 40% probability level).

In $[Pd(L^3)_2]$ (Fig. 3) the same type of behaviour is observed. The two CH_2CH_2Ph substituents pendant from the C^6 position of the pyridyl rings are directed to one face of the *trans*-PdN_2O_2 plane, and the two phenyl rings lie on the other side. The disposition of the pyridine/phenol fragments of each ligand are very similar to that observed in $[Pd(L^2)_2]$, which allows relief of all unfavourable steric effects whilst maintaining the planar geometry about the metal centre. The dihedral angles between the mean planes of the aromatic rings within each ligand are 34.8° between rings 1 and 2, and 37.0° between rings 3 and 4. The Pd—O and Pd—N bond lengths are not significantly different from those of $[Pd(L^2)_2]$.

An interesting feature of the latter two structures is that the non-planar conformation of the ligands results in the formation of cavities enclosed by ligand fragments on either face of the metal coordination plane. In both $[Pd(L^2)_2]$ and $[Pd(L^3)_2]$ the two phenyl groups form the base of a bowl-like cavity on one face of the complex. Addition of more substituents to the C^4 positions of the phenyl rings, which should be synthetically straightforward, could extend the bowl and form a "calixarene-like" cavity which could protect/enclose guest species such as solvent molecules or axial ligands. On the other face of the complex, the CH_2CH_2Ph substituents of $[Pd(L^3)_2]$ perform the same function, forming a protective cavity around the space directly "under" the metal centre to which an axial ligand would coordinate. By attachment of suitable "upwardly-directed" substituents at the phenyl C^4 positions, and/or "downwardly-directed" substituents to the pyridyl C^6 position, complexes may be formed which can bind a guest molecule within the protective cavity adjacent to a (coordinatively unsaturated) metal centre, with interesting implications for catalysis. Investigations along these lines are in progress. We note, however, that our original aim of preventing the adoption of a regular square planar geometry about the metal centre was unsuccessful because of the flexibility of the ligands.

Syntheses and structure of $[Cu_2(L^1)_4]$

The Cu(II) complex $[CuL_2]$ was described earlier by Ganis *et al.* but not characterised except by elemental analysis [6]. In view of the tendency of phenolate-containing ligands to form phenolate-bridged dimeric complexes with Cu(II) [3], we were interested to re-investigate $[CuL_2]$. However crystallographic (and spectroscopic) characterisation of $[CuL_2]$ was prevented by its poor solubility, so we instead prepared the Cu(II) complex of the more soluble ligand HL^1. A material analysing as $Cu(L^1)_2$ was easily prepared, and gave X-ray quality crystals from CH_2Cl_2/hexane.

The crystal structure (Figs 4 and 5) shows this complex to be in fact the phenolate-bridged dimer $[Cu_2(L^1)_4]$. The complex is centrosymmetric. Each Cu(II) ion is in an irregular 5-coordinate N_2O_3 geometry, arising from two bidentate ligands $[L^1]^-$ and an additional (bridging) phenolate from a ligand associated with the other metal. The geometry is approximately square-pyramidal, with the basal plane containing N(21), O(10), O(40) and N(51) within each $Cu(L^1)_2$ monomeric unit. The metal atom is situated 0.219 Å out of the mean plane of these four donor atoms, displaced towards to the two oxygen donors. The axial site is used for the bridging interaction to O(40A) associated with the other metal centre. The

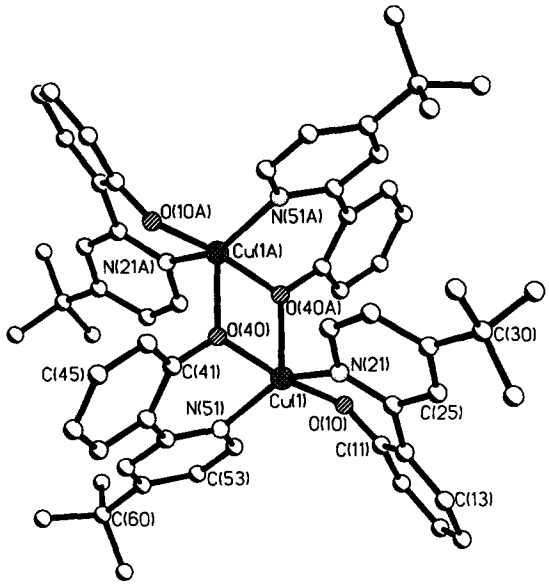

Fig. 4. Crystal structure of $[Cu_2(L^1)_4]$.

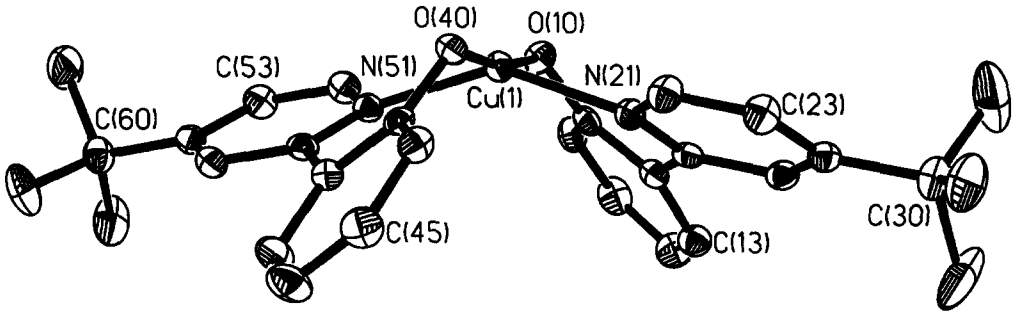

Fig. 5. Crystal structure of the monomer unit of $[Cu_2(L^1)_4]$ (thermal ellipsoids at 40% probability level).

axial metal–ligand bond distance at 2.193(2) Å is significantly longer than the four equatorial ones due to the expected Jahn–Teller distortion. As usual, there is a substantial twist between the mean planes of the pyridyl and phenolate rings within each ligand because of the steric constraints of the six-membered chelate rings: the dihedral angles are 28.8° between rings 1 and 2, and 29.5° between rings 4 and 5. The Cu···Cu separation is 3.215 Å.

EPR spectroscopic studies on this complex gave some interesting information on its solution structure (Fig. 6). A room-temperature spectrum of the powdered microcrystalline material is poorly resolved [Fig. 6(a)], but has the appropriate number of features for a triplet species [2] including a half-field transition at 1580 G ($g = 4.44$), which confirms the presence of the dimer that was apparent from the crystal structure. Figures 6(b) and 6(c) show the spectra of $[Cu_2(L^1)_4]$ dissolved in CH_2Cl_2/thf (2:1, v/v) at room temperature and at 77 K respectively. These spectra in contrast are entirely characteristic of isolated, mononuclear Cu(II) centres with a basically planar structure and the unpaired electron in the $d(x^2-y^2)$ orbital. The axial bridging interactions of $[Cu_2(L^1)_4]$ therefore break in solution to give mononuclear $[Cu(L^1)_2]$ fragments. The spectral parameters are as follows: room temperature; $g_{iso} = 2.114$, $A_{iso} = 70$ G: 77 K; $g_{\parallel} = 2.257$, $g_{\perp} = 2.046$, $A_{\parallel} = 171$ G. Also apparent in the room temperature spectrum is superhyperfine coupling to the N atoms, which can be seen clearly on the highest-field component of the signal and is also just apparent on the adjacent component. Differentiation of the signal [Fig. 6(d)] shows this superhyperfine coupling much more clearly, and a 1:2:3:2:1 quintet is apparent with $A_N = 13$ G, consistent with coupling to two equivalent nitrogen atoms, which is what we would expect in the $[Cu(L^1)_2]$ monomer assuming a high-symmetry (probably planar) structure.

The 77 K frozen glass spectrum showed no evidence for the half-field signal that would be expected if the dimeric structure were retained in solution [2,3]. It is

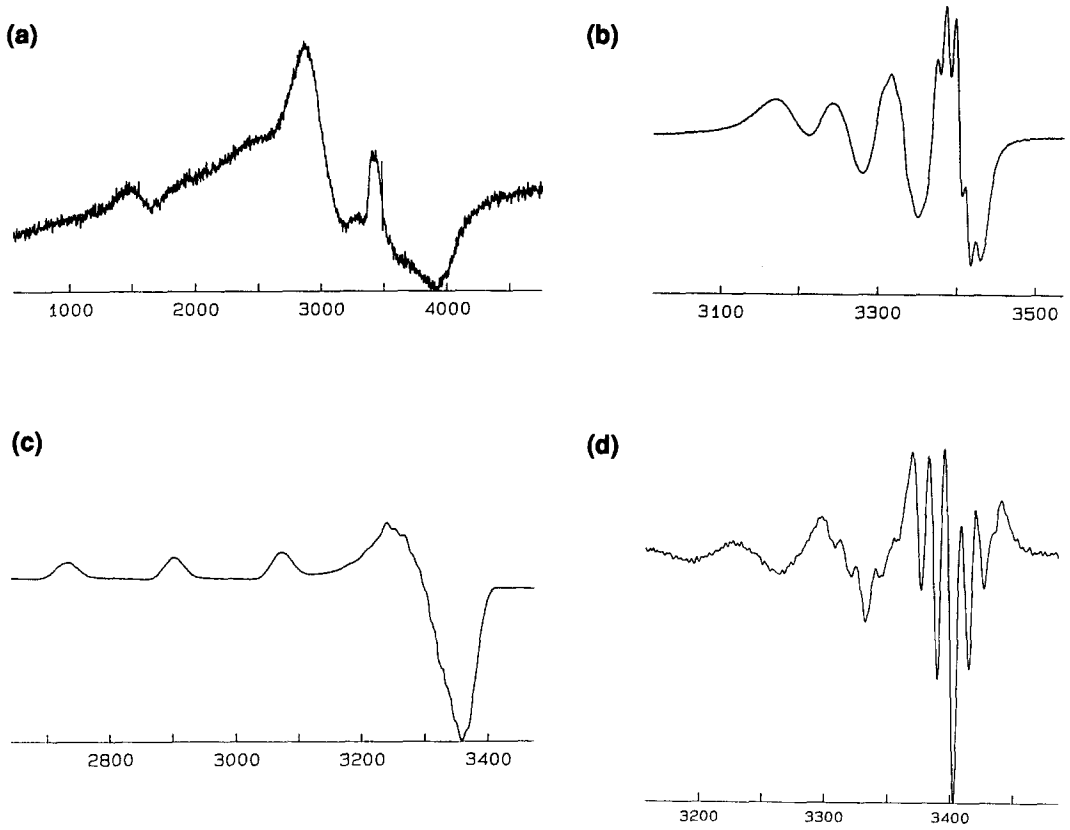

Fig. 6. X-band EPR spectra of $[Cu_2(L^1)_4]$: (a) microcrystalline powdered solid at room temperature; (b) CH_2Cl_2/thf solution at room temperature; (c) CH_2Cl_2/thf frozen glass at 77 K; (d) derivative of (b) emphasising the superhyperfine nitrogen coupling (1 : 2 : 3 : 2 : 1 quintet). Units on the x-axes are Gauss in every case.

perhaps surprising that the dimer is cleaved so easily. In a related dimeric Cu(II) complex with much weaker phenolate bridges [Cu—O(axial) $\approx$ 2.4 Å] the dimeric structure was largely retained in CH_2Cl_2/dmf solution, and addition of pyridine was required to break up the dimer. In this case, however, there was crystallographic evidence for aromatic π-stacking between the aromatic ligands of two near-planar monomeric units, and it may be that this aided association in solution. In $[Cu_2(L^1)_4]$ by contrast there is no evidence for strong inter-component π-stacking interactions, and the dimer dissociates more readily despite the stronger Cu—O(axial) bonds.

Attempts to prepare Cu(II) complexes with the more sterically hindering ligands HL^2 and HL^3 were unsuccessful. Although reaction of the ligand with $Cu(OAc)_2 \cdot 2H_2O$ in methanol immediately afforded a dark green solution similar in colour to solutions of $[Cu_2(L^1)_4]$, these decomposed on concentration and recrystallisation. It appears that the addition of bulky substituents at the pyridyl C^6 position is sufficient to destabilise the planar Cu(II) complexes even though planar Pd(II) complexes could be prepared with the same ligands.

Acknowledgements—We thank the EPSRC and Zeneca Specialities for a CASE award (to CAO) and the EPSRC for grants to purchase the EPR spectrometer and the diffractometer.

Platinum(II) thiosalicylate and related complexes as ligands towards mercury(II) halides; X-ray crystal structure of the tetrametallic complex $\{[Pt(SC_6H_4CO_2)(PPh_3)_2] \cdot HgI_2\}_2$

Louise J. McCaffrey, William Henderson* and Brian K. Nicholson

Department of Chemistry, University of Waikato, Private Bag 3105, Hamilton, New Zealand

(Received 3 June 1997; accepted 8 August 1997)

Abstract—The platinum(II) thiosalicylate complex $[Pt(SC_6H_4CO_2)(PPh_3)_2]$ **1a** reacts with HgI_2 to form a tetrametallic complex comprising an $IHg(\mu\text{-}I)_2HgI$ central core with the thiolate sulphur of **1a** coordinated to each mercury centre, completing a distorted tetrahedral coordination environment. Overall, the structural features of the complex, determined by an X-ray diffraction study, are similar to the parent thiosalicylate complex **1a**, but with an increased fold angle (59° compared to 46°) of the thiosalicylate ligand relative to the platinum coordination plane. Reactions of related five-membered ring thiolate complexes $[Pt(SCHRCO_2)(PPh_3)_2]$ (R=H or Me) and of **1a** with a range of metal cations were investigated using ^{31}P NMR spectroscopy. Changes in the $^1J(PtP)$ coupling constants are discussed in terms of coordination to the various metal halide moieties. Reactions of the organomercury(II) thiosalicylate complex Thiomersal ($EtHgSC_6H_4CO_2Na$) with *cis*-$[PtCl_2(PPh_3)_2]$, or *cis*-$[MCl_2(dppe)]$ (M=Ni or Pd) leads to complete transfer of the thiosalicylate ligand from the mercury, and isolation of the previously reported thiosalicylate complexes $[Pt(SC_6H_4CO_2)(PPh_3)_2]$ and $[M(SC_6H_4CO_2)(dppe)]$ (M=Ni, Pd) in high yields. © 1997 Elsevier Science Ltd

Keywords: platinum; mercury; thiolate; thiosalicylate; crystal structure.

Thiosalicylic acid **I** is an interesting heterodifunctional ligand capable of coordinating to both hard and soft metal centres in a variety of bonding modes [1]. In a recent paper [2] we reported the syntheses of a range of platinum(II) **1**, palladium(II) **2** and nickel(II) **3** metallacyclic complexes containing thiosalicylate dianions, together with some related complexes **4** derived from thioglycollic and 2-mercaptopropionic acids. X-ray crystal structure determinations on the platinum and nickel thiosalicylate derivatives $[Pt(SC_6H_4CO_2)(PPh_3)_2]$ **1a** and $[Ni(SC_6H_4CO_2)(dppp)]$ **3a** [dppp = 1,3-bis(diphenylphosphino)propane] revealed different bonding arrangements of the thiosalicylate ligand towards the two metal ions. These differences were tentatively ascribed to the effects of metals of different sizes coordinated by a relatively inflexible ligand. Metal thiolate complexes are well known to possess ligand properties towards other metal centres [3] and we have previously shown that the five-membered ring thiolate complex **5** coordinates to mercury(II) halides to form tetrametallic complexes consisting of an $XHg(\mu\text{-}X)_2HgX$ core, with each mercury atom ligated by the sulphur atom of a platinum–thiolate complex, i.e. **6a** [4]. The bis(thiosalicylato) mercury(II) complex $[Hg(tsalH)_2]$ (containing S-bonded thiosalicylate monoanions) is known to be able to complex other metal ions, such as Zn^{2+}, Cd^{2+} and Pb^{2+} [5]. Metal–thiosalicylate complexes are known to display a range of coordination geometries [1] and thus it was of interest to investigate whether coordination of the sulphur

atom of **1a** would influence the geometry of the platinum–thiosalicylate moiety.

In this contribution we report that the platinum–thiosalicylate complex **1a,** together with the related cyclic thiolate complexes **4,** have analogous ligand properties towards mercury(II) halides. We also report that the thiosalicylate ligand is completely transferred from the organomercury complex $EtHgSC_6H_4CO_2Na$ to platinum(II), palladium(II) and nickel(II) centres.

RESULTS AND DISCUSSION

Synthesis and X-ray crystal structure

Reactions of the platinum(II) cyclic thiolate complexes **1a, 4a** and **4b** with excess solid $HgBr_2$ or HgI_2 were carried out in dichloromethane solution. Addition of the mercury salt followed by shaking typically resulted in a lightening of the solution (for $HgBr_2$), or little change (for HgI_2), though when smaller quantities of the mercury salt were used, dissolution was observed. In general, crystalline products **6b–6e** were obtained by slow diffusion of diethyl ether into the solution (after removal of excess HgX_2). However, the mercaptopropionate–HgI_2 complex did not crystallise well, though it was analytically pure. The attempted synthesis of a comparable HgI_2 complex of the cyclo-octa-1,5-diene (COD) complex $[Pt(SC_6H_4CO_2)(COD)]$ led only to the crystallisation of the pure platinum starting complex, as shown by elemental microanalytical data.

In order to unambiguously confirm the structure of one derivative (which was considered important given

the known structural complexity of the coordination chemistry of mercury(II) halides with neutral donor ligands [6]) a single-crystal X-ray diffraction study was carried out on the HgI_2 complex **6b**. Since excess mercury halide was used, and complexes of the type $LHgX_2$ are known to commonly have dimeric structures [6] it is likely that the range of related HgX_2 (X=Cl, Br, I) complexes **6** have similar structures.

The structure of **6b** comprises a centrosymmetric dimer with a near-rectangular $Hg_2(\mu\text{-}I)_2$ core. The Hg is further coordinated to a terminal I ligand and to the S atom of a $[Pt(SC_6H_4CO_2)(PPh_3)_2]$ molecule. It is related to a range of other $[L(I)Hg(\mu\text{-}I)]_2$ dimers, and three structures have been reported where L is a sulphur donor ligand [7]. Additionally we have previously reported the structure of the related $HgBr_2$ adduct **6a** [4].

The coordination about the Hg atom is distorted tetrahedral, with angles subtended at Hg ranging from 87° to 125°. The iodo-bridge is strongly unsymmetrical with Hg—I distances of 2.7139(5) and 3.2870(5) Å; both of these are longer than the bond to the terminal iodo ligand [2.6667(5) Å]. The large iodo bridge results in an essentially rectangular motif, with I—Hg—I and Hg—I—Hg angles of 87.76(1) and 92.24(1)° respectively. These features are in accord with those in other examples [7].

The attachment of the sulphur atom to the Hg atom has only a small effect on the geometry of the platinum-complex part of the molecule, in comparison with the free species **1a**. The Pt(1)—S(1)—C(7) angle in the mercury adduct is 99.2(2)°, from 103.8(2)° in **1a**, but the Pt—S and S—C distances show negligible change. There is an apparent change in the Pt—O(1)—C(1) angle from 135.8(4) to 126.0(3)°, with a decrease in the Pt—O(1) distance from 2.109(3) to 2.076(3) Å in the adduct, but the significance of this must remain tentative in view of the suspicion that the parameters involving O(1) may be unreliable in the free complex [2]. The S—Pt—O(1) angle and the P(1)—Pt—P(2) angles show no chemically significant differences on attachment to the mercury atom.

The coordination about the platinum atom is essentially planar, with a small twist defined by the dihedral angle of 8.2° between the P(1)—Pt—P(2) and S(1)—Pt—O(1) planes. The CO_2 group of the thios-

alicylate ligand is twisted so that O(1) and O(2) are displaced by ca 0.3 Å from the plane of the rest of the ligand. Somewhat unexpectedly, it was found that the thiosalicylate ligand plane of **1a** was inclined at an angle of 46° to the platinum coordination plane. This feature is maintained in the mercury adduct **6b,** with the corresponding angle increased to 59°. This is not an essential requirement to accommodate the Hg atom at the S, since the corresponding $HgBr_2$ adduct **6a** forms by coordination from the S atom in a complex in which the chelating ligand lies essentially within the coordination plane.

NMR spectroscopy and electrospray mass spectrometry

Reactivity of the platinum–thiolate complexes towards mercury(II) halides, and other metal centres, can be conveniently monitored using ^{31}P NMR spectroscopy; chemical shift and coupling constant data are summarised in Table 2. For example, after addition of an excess of solid HgI_2, $HgBr_2$ or $HgCl_2$ to a $CDCl_3$ solution of **1a,** the ^{31}P-$\{^1H\}$ NMR spectra showed overall similar features to the starting complex (*viz* an AB spin system with ^{195}Pt satellites), but with the chemical shifts of all triphenylphosphines shifted to lower δ by about 3–4 ppm; no ^{199}Hg-^{31}P coupling could be ascertained in any of the complexes. The $^1J(PtP)$ coupling constant for the PPh_3 ligand *trans* to the thiolate increases from 2884 Hz in **1a** to 3073, 3112, 3156 Hz on addition of HgI_2, $HgBr_2$ or $HgCl_2$ respectively. These are similar to those observed previously [4] and are consistent with the reduction in the *trans* influence of the thiolate ligand upon coordination to mercury(II). There is a concomitant decrease in the magnitude of $^1J(PtP)$ for the phosphine *trans* to the carboxylate upon coordination of the sulphur atom. The decreasing electron-withdrawing nature in the series $HgCl_2 > HgBr_2 > HgI_2$ influences the strength of interaction; the more electrophilic $HgCl_2$ effects a greater interaction with the Pt—S group, strengthening the *trans* Pt—P bond, increasing its coupling constant. Correspondingly, the $^1J(PtP)$ coupling constant for the phosphine *trans* to oxygen (i.e. *cis* to the thiolate) decreases from the starting complex (3899 Hz) to the $HgBr_2$ complex (3842 Hz), and even further for the $HgCl_2$ complex (3808 Hz).

The trends in $^1J(PtP)$ values are also extended further to the HgI_2 complexes of **1a, 4a** and **4b**. It is interesting for this series of complexes to compare the magnitude of change in $^1J(PtP)$ values for both triphenylphosphines, upon complex formation with HgI_2. Upon addition of HgI_2 to **1a,** the value of $^1J(PtP)$ for the phosphine *trans* to thiolate increases by 182 Hz, while that for the phosphine *trans* to carboxylate decreases by 88 Hz. For **4a** and **4b** upon addition of HgI_2, the $^1J(PtP)$ values for the phosphines *trans* to thiolate increase by 278 and 304 Hz respectively, while the values of $^1J(PtP)$ for the phosphines *trans* to carboxylate decrease by 151 and 159 Hz respectively. Thus, the changes upon coordination for **4a** and **4b** are almost twice those for **1a,** suggesting a much stronger interaction of the HgI_2 moiety with complexes **4**. This

Table 2. A comparison of ^{31}P NMR spectroscopic data, recorded in $CDCl_3$ solution, for the platinum–thiolate complexes[a] and their HgX_2 adducts, isolated by crystallisation, or generated *in situ*[b]

[a] NMR spectroscopic properties for the starting thiolate complexes **1** and **4** are from Ref. [2].

[b] Data are also included for other metal centres where little or no interaction is considered to occur, evidenced by no change in the ^{31}P chemical shifts or coupling constants. Experiments were carried out by dissolving the platinum complex in $CDCl_3$, adding the solid metal salt (where appropriate), briefly shaking, and then recording the ^{31}P NMR spectrum.

[c] Addition of $ZnBr_2$ produced a mixture of products, including *cis*-$[PtBr_2(PPh_3)_2]$.

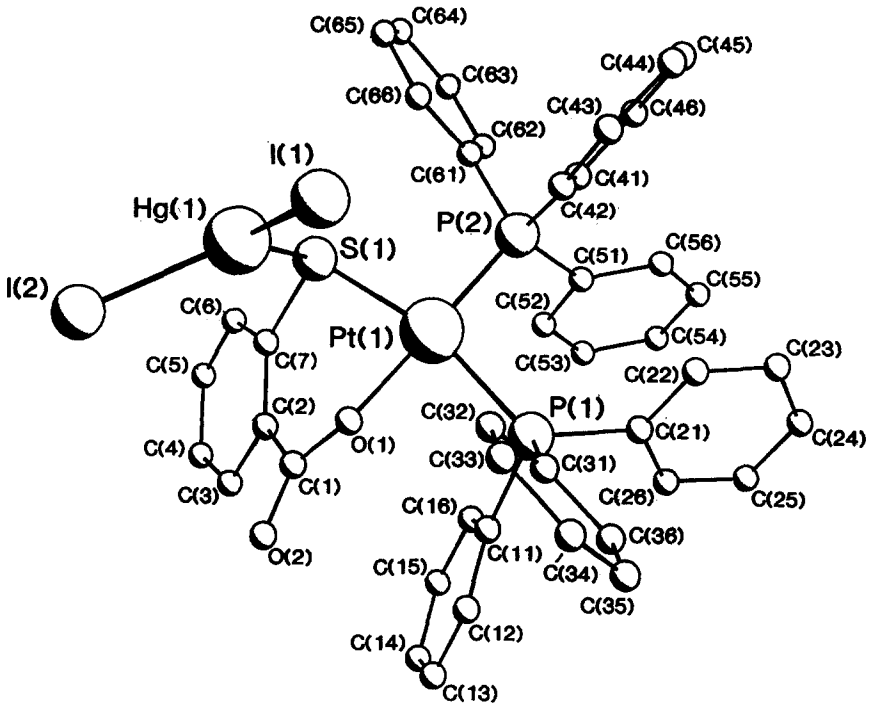

Fig. 1. Molecular structure of the unique half of complex **6b** showing the atom numbering scheme.

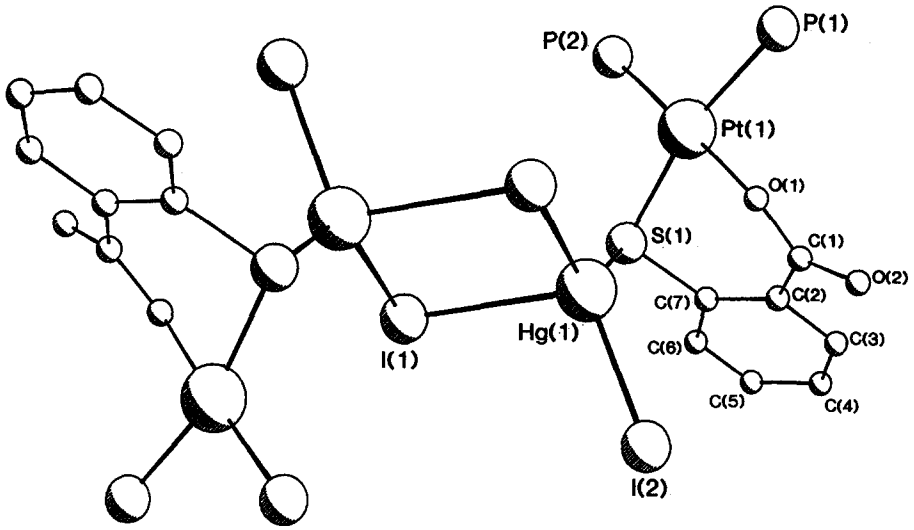

Fig. 2. Diagram showing the central core unit of complex **6b**; all hydrogen and triphenylphosphine carbon atoms have been omitted for clarity.

is not unexpected, since the *ortho*-phenyl hydrogen of the thiosalicylate group is likely to experience a steric interaction with a metal centre coordinated to the sulphur atom.

It is worth noting that a small amount of *cis*-$[PtCl_2(PPh_3)_2]$ is formed as a by-product along with **6f** in the reaction of **1a** with $HgCl_2$, identified by ^{31}P NMR spectroscopy. Upon allowing the solution to stand overnight with excess $HgCl_2$, no additional *cis*-$[PtCl_2(PPh_3)_2]$ was formed. No $[PtBr_2(PPh_3)_2]$ or

$[PtI_2(PPh_3)_2]$ complexes were detected by NMR in the reactions with $HgBr_2$ or HgI_2, presumably due to the less electrophilic nature of these metal centres.

Reaction of **1a** with $Hg(SCN)_2$ produces a rather complex mixture of products, identified by ^{31}P NMR, possibly in part as a result of thiocyanate transfer from mercury to platinum. Similarly, a mixture of products was observed with added $ZnBr_2$, though *cis*-$[PtBr_2(PPh_3)_2]$ could be identified from its ^{31}P-$\{^1H\}$ NMR spectrum. There appeared to be no interaction between **1a** and either $CdCl_2$, CdI_2 or $PdCl_2$, by ^{31}P NMR spectroscopy.

Electrospray mass spectrometry (ESMS) has also been evaluated as a potential technique for characterisation of the complexes formed between the cyclic platinum–thiolate complexes and mercury(II) ions, particularly in light of the NMR results described above. One of the principal attractions of the ESMS technique is that it allows the direct analysis of species in solution [8]. We have previously used ESMS to characterise the neutral thiosalicylate complexes **1–3** [2]. However, when crystals of the HgI_2 adduct **6b** were analysed in MeCN—H_2O solution, no Pt—Hg adducts could be observed. Instead, the spectrum indicated that the complex had completely dissociated, with the starting complex $[\mathbf{1a}+H]^+$ being the base peak at *m/z* 872, as observed for the pure complex **1a**. Identical results were observed for the complex **6d**. Complexes of mercury(II) halides with thioether ligands would be expected to relatively labile in solution [6], although a thiolate-bridged structure might be expected to be less labile.

Addition of a small quantity of NaCl to the ESMS solution of **6b** in MeCN—H_2O solution yielded the species HgI_3^- (*m/z* 583), HgI_2Cl^- (*m/z* 491) and $HgICl_2^-$ (*m/z* 399) in the negative ion ESMS spectrum; no adducts of the parent thiosalicylate complex **1a** with mercury species were detected.

Thiosalicylate transfer reactions with Thiomersal ($EtHgSC_6H_4CO_2Na$)

Following the successful reactions between the platinum–thiosalicylate complex **1a** and HgX_2, we wished to investigate whether the organomercury complex Thiomersal (Merthiolate, sodium ethylmercurithiosalicylate), which contains a monodentate thiosalicylate ligand, could be used as a ligand towards platinum(II) centres. This was considered as a possible alternative route to other types of platinum–mercury thiosalicylate-bridged complexes. Thiomersal is of interest since it has biological activity and has been used as an antiseptic [9].

The reaction of *cis*-$[PtCl_2(PPh_3)_2]$ with one mole equivalent of Thiomersal in hot methanol yields the platinum–thiosalicylate complex **1a** *via* a thiolate-transfer reaction, eqn (1). In this case, the thiolate ligand is completely transferred from mercury(II) to platinum(II), and thus EtHgCl and NaCl are the presumed byproducts, though no attempt was made to confirm these;

$$cis\text{-}[PtCl_2(PPh_3)_2] + EtHgSC_6H_4CO_2Na \rightarrow [Pt(SC_6H_4CO_2)(PPh_3)_2] \quad \mathbf{1a}$$

Eq. 1 $(+EtHgCl+NaCl)$

Analogous reactions also proceeded readily when $[PdCl_2(dppe)]$ [dppe = 1,2-bis(diphenylphosphino) ethane] or $[NiCl_2(dppe)]$ were reacted with Thiomersal, also in methanolic solution, giving the previously reported [2] thiosalicyate complexes $[M(SC_6H_4CO_2)(dppe)]$ (M=Ni, Pd). In methanol solvent, there is a vary rapid colour change to that of the product. However, the reaction of *cis*-$[PtCl_2(PPh_3)_2]$ with Thiomersal can be slowed down by carrying it out in $CDCl_3$, so that the course of the reaction can be followed by ^{31}P NMR spectroscopy. The reaction proceeds smoothly, with consumption of the starting *cis*-$[PtCl_2(PPh_3)_2]$ complex with a concomitant increase in intensity of resonances due to the thiosalicylate product **1a**. Only one very minor additional peak was present, and since $^1J(PtP)$ data could not be discerned, it is not possible to comment upon the identity of this species. Any possible intermediates formed in the reaction, such as **7**, containing Pt—S—Hg thiosalicylate-bridged species clearly do not reach significant concentrations under these conditions.

In a separate experiment, the reaction was monitored by positive-ion ESMS. An equimolar mixture of *cis*-$[PtCl_2(PPh_3)_2]$ and Thiomersal was analysed several minutes after mixing in 1 : 1 MeCN—H_2O. The spectrum showed the platinum–thiosalicylate complex $[\mathbf{1a}+H]^+$ at *m/z* 872 as the predominant ion together with a small ion at *m/z* 894, assigned as the sodium adduct $[\mathbf{1a}+Na]^+$; this ion is not unexpected, since Thiomersal is a sodium carboxylate salt. Addition of alkali metal salts to pure samples of **1a** also yielded $[M+cation]^+$ ions in the ESMS spectra [2]. The ion $[(\mathbf{1a})_2+H]^+$ was also observed at *m/z* 1744, as observed previously for **1a** [2]. A very weak ion at around *m/z* 1100 can be tentatively assigned as the species $[(Ph_3P)_2Pt(SC_6H_4CO_2)+EtHg]^+$. This complex, for which **7** is a likely structure, is a plausible intermediate in the thiosalicylate transfer reaction. However, an isotope pattern could not be obtained for this ion, and so its assignment remains tentative. The ESMS results therefore parallel the NMR results by showing no significant intermediates. The absence of the ions $[PtCl(PPh_3)_2]^+$ and $[PtCl(MeCN)(PPh_3)_2]^+$ which are observed for *cis*-$[PtCl_2(PPh_3)_2]$ in MeCN—H_2O solutions also confirms the rapid conversion of *cis*-$[PtCl_2(PPh_3)_2]$ into **1a** [10]. No platinum-containing intermediates were observed when the *cis*-$[PtCl_2(PPh_3)_2]$/Thiomersal reaction mixture was analysed in negative-ion mode.

Thiolate transfer reactions have been documented in the literature, generally transferring the thiolate

ligand from a harder metal centre to a softer one, which provides a driving force for the reaction [11]. Despite the very strong affinity of mercury for thiolate ("mercaptan") ligands, it is evident that the formation of the chelating thiosalicylate complexes, possibly assisted by precipitation of NaCl, is the major driving force in this exchange reaction. The tendency for mercury(II) thiolate complexes to adopt low coordination numbers, in many cases typified by linear two-coordination, is also likely to bear a major influence [12].

EXPERIMENTAL

General experimental procedures have been described previously [2]. All complexes described in this work are air-stable, and reactions were carried out without regard for the exclusion of air. Diethyl ether and petroleum spirits (bp 40–60°C) were LR grade, while dichloromethane was distilled from CaH_2 prior to use. Standardless EDAX analyses were obtained on a Hitachi S4000 scanning electron microscope.

The following compounds were used as supplied from BDH: red mercury(II) iodide, mercury(II) bromide, mercury(II) chloride, cadmium iodide, cadmium chloride and zinc bromide. The complexes $[Pt(SC_6H_4CO_2)(PPh_3)_2]$ **1a**, $[Pt(SCH_2CO_2)(PPh_3)_2]$ **4a** and $[Pt(SCHMeCO_2)(PPh_3)_2]$ **4b** were prepared as described previously [2]. $[PdCl_2(dppe)]$ was prepared by ligand substitution of the COD ligand of $[PdCl_2(COD)]$ [13] with 1 mole equivalent of dppe in CH_2Cl_2. $[NiCl_2(dppe)]$ was prepared by the literature procedure [14].

Synthesis of the thiolate-bridged platinum–mercury complexes **6**. *General method*

To a solution of the platinum complex (ca 100 mg) in dichloromethane (ca 2 cm^3) was added an excess of the solid mercury(II) halide, and the mixture briefly shaken. After allowing the excess mercury salt to settle, the supernatant was removed by a Pasteur pipette and transferred to a glass vial. Vapour diffusion of diethyl ether into the solution yielded a crystalline or microcrystalline product in most cases, which was dried *in vacuo* for 24 h.

$\{[Pt(SC_6H_4CO_2)(PPh_3)_2]\cdot HgI_2\}_2$

The platinum complex **1a**. 0.33MeOH (82 mg, 0.093 mmol) and HgI_2 (190 mg, 0.418 mmol) gave bright yellow crystals of **6b** (122 mg, 99%), m.p. 198–203°C (decomp.). Despite several attempts, satisfactory elemental analytical data could not be obtained for this compound. Found: C, 35.9; H, 2.1; N, 0.0. $C_{43}H_{34}O_2P_2PtSHgI_2$ requires C, 38.9; H, 2.6; N, 0.0%.

The presence of Pt, Hg and I were confirmed using EDAX analysis.

$\{[Pt(SCH_2CO_2)(PPh)_2]\cdot HgI_2\}_2$

The platinum complex **4a** (75 mg, 0.093 mmol) and HgI_2 (170 mg, 0.374 mmol) gave light yellow microcrystals of **6c** (94 mg, 80%), m.p. 207–209°C (decomp.). Found: C, 36.4; H, 2.4; N, 0.0. $C_{38}H_{32}O_2P_2PtSHgI_2$ requires C, 36.1; H, 2.6; N, 0.0%.

$\{[Pt(SCHMeCO_2)(PPh_3)_2]\cdot HgI_2\}_2$

The platinum complex **4b** (79 mg, 0.096 mmol) and HgI_2 (224 mg, 0.493 mmol) gave a pale yellow solid of **6d** (59 mg, 48%), m.p. 204–208°C (decomp.). Found: C, 36.8; H, 2.4; N, 0.0. $C_{39}H_{34}O_2P_2PtSHgI_2$ requires C, 36.6; H, 2.7; N, 0.0%.

Attempted synthesis of $\{[Pt(SC_6H_4CO_2)COD]\cdot HgI_2\}_2$

The platinum complex $[Pt(SC_6H_4CO_2)(COD)]$ and excess HgI_2 gave bright yellow crystals, which were found to be the unreacted platinum complex, by elemental analysis: Found: C, 39.6; H, 3.4. $C_{15}H_{16}O_2PtS$ requires C, 39.6; H, 3.5%.

Thiolate exchange reaction between cis-$[PtCl_2(PPh_3)_2]$ *and* $EtHgSC_6H_4CO_2Na$

A suspension of *cis*-$[PtCl_2(PPh_3)_2]$ (391 mg, 0.495 mmol) and Thiomersal (200 mg, 0.494 mmol) in methanol (25 cm^3) was refluxed for 2 h; the mixture turned bright yellow over the course of several minutes. Water (50 cm^3) was added, and the resulting yellow precipitate filtered, washed with water and diethyl ether, and dried *in vacuo*. Yield 378 mg (88%). The product was identified as **1a** by ^{31}P-$\{^1H\}$ NMR spectroscopy.

Thiolate exchange reaction between $[PdCl_2(dppe)]$ *and* $EtHgSC_6H_4CO_2Na$

A suspension of $[PdCl_2(dppe)]$ (109 mg, 0.189 mmol) and Thiomersal (77 mg, 0.189 mmol) was refluxed in methanol (20 cm^3) for 20 min, to give an orange suspension. Water (60 cm^3) was added, the product filtered, washed with water (10 cm^3) and ether (10 cm^3) and dried under vacuum to give 88 mg (71%) of **2a**, identified by ^{31}P-$\{^1H\}$ NMR spectroscopy.

Thiolate exchange reaction between $[NiCl_2(dppe)]$ *and* $EtHgSC_6H_4CO_2Na$

A suspension of $[NiCl_2(dppe)]$ (77 mg, 0.146 mmol) and Thiomersal (59 mg, 0.146 mmol) was refluxed in

methanol (10 cm^3) for 30 min, to give a red-orange solution/suspension. Water (50 cm^3) was added, the product filtered, washed with water (10 cm^3) and ether (10 cm^3) and dried under vacuum to give 60 mg (68%) of [Ni($SC_6H_4CO_2$)(dppe)], identified by ^{31}P-{^1H} NMR spectroscopy.

Crystal structure determination of {[$Pt(SC_6H_4CO_2)(PPh_3)_2$]·HgI_2}$_2$ **6b**.

Bright yellow crystals of **6b** were obtained from the slow diffusion of ether into a CH_2Cl_2 solution. The unit cell dimensions and intensity data were obtained on a Siemens SMART diffractometer. The data collection nominally covered over a hemisphere of reciprocal space, by a combination of three sets of exposures; each set had a different ϕ angle for the crystal and each exposure 0.3° in ω. The crystal to detector distance was 5.0 cm. The data set was corrected empirically for absorption using SADABS [15].

Crystal data and refinement for **6b**

$C_{43}H_{34}HgI_2O_2P_2PtS$. 0.5 $(C_2H_5)_2O$, M_r 1363.24, triclinic, space group $P\bar{1}$, $a = 12.4725(2)$, $b = 12.6573(2)$, $c = 14.9196(1)$ Å, $\alpha = 79.420(1)$, $\beta = 70.357(1)$, $\gamma = 82.106(1)°$, U 2173.27(5) $Å^3$. $D_{calc} = 2.083$ g cm^{-3}, $Z = 2$, $F(000)$ 1278, μ(Mo–K_α) = 8.323 mm^{-1}. Crystal size 0.52 × 0.32 × 0.24 mm. A total of 21,943 reflections were collected at 203(2) K in the range $1.5° < \theta < 28.2°$, corresponding to 9691 unique data ($R_{int} = 0.0368$), $T_{max,min}$ 0.2633, 0.1342.

The structure was solved by automatic interpretation of a Patterson map and developed routinely. In a penultimate difference map an Et_2O of crystallisation, disordered across an inversion centre, was revealed. In the final cycles of least-squares refinement based on F^2 against all data, all non-hydrogen atoms were treated anisotropically and hydrogen atoms (other than those of the disordered solvent) were included in their calculated positions. The refinement converged with $R_1 = 0.0387$ [for 6817 data with $I > 2\sigma(I)$], $R_1 = 0.0437$, $wR_2 = 0.1033$, GoF 1.079 (all data). The largest features in a final difference map were +2.707/−3.634 e $Å^{-3}$ adjacent to heavy metal atoms. The SHELX-96 package [16] was used for all calculations.

Complete lists of atomic coordinates, bond parameters and tables of thermal parameters and hydrogen atom coordinates have been deposited at the Cambridge Crystallographic Data Centre (CCDC), and are available from the authors on request.

Acknowledgements—The University of Waikato and the New Zealand Lottery Grants Board are acknowledged for financial support of this work. We thank Assoc. Prof. C. E. F. Rickard and Dr L. J. Baker (University of Auckland) for collection of the X-ray data set, and Johnson-Matthey plc for a generous loan of platinum metal salts. Alf Harris (Waikato Microscope Unit) is thanked for EDAX measurements.

(Received 19 November 1996; accepted 1 August 1997)

Abstract—The title complex has been prepared by the reaction of $[Co(Hdmg)_2(NH_3)_2]Cl$ with $CuCl_2$ in HCl solution (where Hdmg = dimethylglyoxime monoanion) and its crystal structure has been determined by X-ray diffraction. The Co(III) and Cu(II) atoms lie on different two-fold axes. The coordination geometries around the Co(III) and Cu(II) atoms are octahedral and distorted trigonal bipyramidal, respectively. The Hdmg chelates Co(III) and bridges to the Cu(II) atoms to form a polyheteronuclear helical structure along the *c* axis. Based on the structure the IR spectrum of the complex is discussed. © 1997 Elsevier Science Ltd

Keywords: polynuclear complex; dimethylglyoximato complex; Co(III)–Cu(II) complex; crystal structure; helical structure.

Dimethylglyoxime normally behaves as a monoanionic chelate ligand (Hdmg) to form mononuclear complexes. The loss of both protons is unusual but is known—as in multinuclear bridging complexes, several such structures have been reported [1,2]. In each complex, the doubly deprotonated dimethylglyoxime chelates a metal atom, with both terminal oxime O atoms coordinating to adjacent metal atoms to form the multinuclear structure. During preparation of complexes bridged by dimethylglyoxime we have obtained a novel complex, in which the dimethylglyoxime behaves as a monoanionic chelate ligand and bridges to the adjacent metal atom, through the oxime O atom to form a novel polyheteronuclear helical structure.

EXPERIMENTAL

Synthesis

0.588 g (2 mmol) of $CoCl_2 \cdot 6H_2O$ and 0.464 g (4 mmol) of H_2dmg were dissolved in 20 cm^3 of a hot 95% ethanol solution, and 1.0 cm^3 of NH_4OH solution was added producing a yellow precipitate. Following the addition of 0.5 cm^3 of H_2O_2 solution to the solution the precipitate changes colour to dark yellow. After stirring for 0.5 h and standing overnight, the precipitate of $[Co(Hdmg)_2(NH_3)_2]Cl$ was filtered and washed with ethanol and ether.

0.100 g (0.28 mmol) of $[Co(Hdmg)_2(NH_3)_2]Cl$ and 0.038 g (0.28 mmol) of $CuCl_2$ were dissolved in a dilute HCl solution (pH = 1) at room temperature. After stirring 10 min and standing for two weeks, dark-red single crystals were obtained.

Elemental analysis

C, H and N were analyzed using a Carlo Erba 1160 Elemental Analyzer. Found: C 9.7, H 2.6, N 11.4; Calc. for $C_8H_{20}O_4N_6Cl_3CoCu$: C 9.8, H 2.6, N 11.4%.

Infrared spectra

The IR spectra were recorded with a Perkin-Elmer 683 spectrophotometer (4000–400 cm^{-1}) on a powdered sample spread on a KBr plate and a Nicolet FTIR 170sx spectrophotometer (500–100 cm^{-1}) employing CsI pellets.

Crystal structure determination

Diffraction intensity data were collected on a Nonius-CAD4 diffractometer with graphite-monochromatized Mo–K_α radiation.

Up to 2θ value of 52° a total of 1933 independent reflections was collected, of which 844 observed reflections [$I > 3\sigma(I)$] were used for structure refinement. Lp correction and empirical absorption correction were applied.

The structure was solved by Patterson methods followed by Fourier syntheses. The structure refinement was carried out by full-matrix least-squares. H atoms were located in a difference Fourier map. Anisotropic refinement including all the non-H atoms converged to agreement factors $R = 0.052$ and $Rw = 0.058$, where $w = 1/\sigma^2(F)$. Atomic scattering factors were taken from *International Tables for X-ray Crystallography* [3]. All calculations were performed on a Micro Vax-II 3100 computer using TEXSAN software package [4].

Crystal data. $C_8H_{20}O_4N_6Cl_3CoCu$, $Mr = 492.7$, orthorhombic, $C222_1$, $a = 11.828(2)$, $b = 12.787(2)$, $c = 11.275(4)$ Å, $V = 1705.3(8)$ Å^3, $Z = 4$, $D_x = 1.92$ g cm^{-3}, F(000) = 996, μ(Mo–K_α) = 2.80 mm^{-1}, No. of variables = 107, $(\Delta/\sigma)_{max} = 0.01$, $(\Delta\rho)_{max} = 0.68$ e Å^{-3}.

RESULTS AND DISCUSSION

Crystal structure

The molecular structure of the title complex is illustrated in Fig. 1 with the numbering system. The selected bond distances and angles are presented in Table 1. In the crystal the Co(III) and Cu(II) atoms lie on different two-fold axes. The Hdmg ligands, related to each other by a two-fold axis, chelate to a Co(III) atom with an average Co–N distance of 1.903 Å. Two NH_3 molecules, lying on the two-fold axis, coordinate to the Co(III) atom with Co–N distances of 1.983 and 1.961 Å, respectively to complete an octahedral coordination around the Co(III) atom. Coordination distances between Co(III) and N atoms agree well with those in diammine-bis(dimethylglyoximato) cobalt(III) perchlorate and fluoroborate [5]. Each Hdmg ligand is coplanar with the Co(III) atom, but the dihedral angle of 7° between the least-squares planes of the Hdmg ligands shows an umbrella-like configuration around the Co(III) atom as reported previously [1]. The remarkable structural feature of the present complex is that each dimethylglyoxime loses only one oxime proton from the oxime O atom which coordinates to the adjacent Cu(II) atom to form a helical polyheteronuclear molecule along the *c* axis as illustrated in Fig. 2. It is interesting that the oxime O atom which has not lost its H atom does not coordinate to the Cu(II) atom and the H-bonding between Hdmg ligands, which is always found in *trans*-bis(dimethylglyoximato) complexes, does not exist in the present structure. The coordination geometry around the pentacoordinated Cu(II) atom is distorted trigonal bipyramidal. One Cl(1) atom, lying on a two-fold axis, and two oxime O atoms [O(1) and O(1)a], related by the two-fold axis, form the equatorial plane with a Cu(II) atom, while two Cl(2) atoms related by a two-fold axis occupy the apical sites. Both the Cl(2)—Cu—Cl(2)a bond angle of 161.04(5)° and Cl(1)—Cu—Cl(2) bond angle of 99.48(5)° indicate distortion of the trigonal bipyramid. The Cu–Cl(1) distance of 2.191(2) Å in the equatorial plane is slightly shorter than the Cu–Cl(2) distance of 2.236(2) Å in the apical direction. The Cu–O(1) distance of 2.298(5) Å is in agreement with 2.301(3) Å found in a dimer complex $[Cu(Hdmg)_2]_2$ [6]. The coordinated NH_3 molecules [N(4)] fill in the hole of the helical structure. The distance of 3.072 Å suggests the H-bonding between N(4) and Cl(2) atoms, which is considered to be the factor stabilizing the helical structure and to be the reason resulting in distortion of the trigonal bipyramid around the Cu(II) atom.

Infrared spectrum

The stretching vibrations of NH_3 are observed at 3225 and 3167 cm^{-1}, which is significantly lower than that found in the free NH_3 molecule and agrees well with that in $[Co(III)(NH_3)_6]Cl_3$ [7]; this frequency shift is considered to be due to coordination of the NH_3 molecule and H-bonding between Cl(2) and N(4) atoms. Rutherfold *et al.* assigned the band at 510 cm^{-1} to ν[Co—H(Hdmg)] for [Co(Hdmg)$_2$(py)Cl] based on isotopic labeling with ^{15}N [8], therefore the band at 509 cm^{-1} observed in the title complex is reasonably assigned to ν[Co—N(Hdmg)]. The bands at 463 and 440 cm^{-1} are assigned to ν(Co—NH_3), which are in agreement with that reported for other ammine cobalt(III) complexes [7]. The band at 302 cm^{-1} is assigned to ν(Cu—Cl), which is higher than the 268 cm^{-1} found in the trigonal bipyramidal structure of $[CuCl_5]^{3-}$ [9]. The band at 350 cm^{-1} is tentatively assigned to ν(Cu—O), which is consistent with the value of 340–360 cm^{-1} reported for ν(M—O) in nitrato complexes [10].

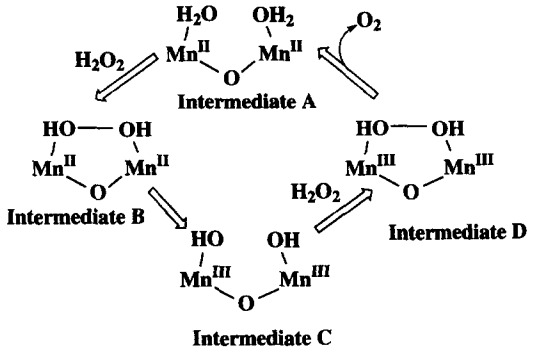
(Received 27 May 1997; accepted 29 July 1997)

Abstract—The structures and ESR spectral properties of binuclear manganese(II) compounds which functionally mimic the bacterial dimanganese catalase enzyme have been developed. These compounds are formulated as $[(L^1)Mn_2X_2]Y$(X=Cl, Br, CH_3COO, C_6H_5COO, $(C_6H_5)_2HCCOO$; Y=ClO_4, PF_6), $[(L^2)Mn_2X_3]$ (X=Cl, Br), and $[(L^2)Mn_2(benzoate)_2$ (NCS)], where $H(L^1)$=2,6-bis[bis(2-pyridylmethyl)aminomethyl]-4-methyl-phenol and $H(L^2)$=2,6-bis[N-(2-dimethylamino)ethyl]iminomethyl]-4-methyl-phenol. An X-ray diffraction structure determination of $[(L^1)Mn_2Cl_2(CH_3OH)_2]PF_6$ confirmed the anticipated N_6O septadentate coordination of the (L^1)-ligand, binuclear manganese(II) complex with μ-phenoxide, and two halogenide ions and two methanol molecules. In the crystal of $[(L^2)Mn_2Cl_3]CH_3CN$, there exists tetranuclear manganese(II) complex having center of symmetry. The terminal and central manganese(II) ions are bridged by phenoxide oxygen and a chloride ion (Mn···Mn = 3.440(1) Å), and two central atoms are bridged by two chloride ions with Mn···Mn distance of 3.804(1) Å. In acetonitrile solution, catalase-like function of the manganese(II) compounds with $H(L^1)$-ligand are found to be highly dependent the anions coordinating the Mn(II) ion; the activity of the X=Cl complex is much higher than those of the acetate and benzoate. On the other hand, the activity of $[(L^2)Mn_2Cl_3]$ is slightly lower than that of the $[(L^2)Mn_2(benzoate)_2(NCS)]$, where two manganese ions are bridged by benzoate anion. The Mn(II/III) complex of $H(L^1)$, $[(L^1)Mn_2(CH_3COO)_2]^{2+}$ exhibits much higher activity than that of the corresponding Mn(II/III) complex, $[(L^1)Mn_2(CH_3COO)_2]^+$. In dimethylformamide(dmf) solutions, an induction period (at least 30 minutes) is necessary before vigorous evolution of oxygen gas occurs for both the Mn(II) complexes with (L^1) and (L^2), however, some binuclear Mn_2(II/III) and Mn_2(III/III) complexes exhibited high catalase-like function in dmf. The latter fact may give a reasonable explanation for the fact that the manganese cluster in S_2-state of the Photosystem II shows a high catalase-like function instead of the negligible action in the S_1-state. Based on these facts, it is concluded that the most important factor to control the catalase-like function of binuclear Mn(II) complex should be the oxidizable nature of the Mn(II) ion to a higher oxidation state, and the unusual behavior in dmf solution was accounted for on the assumption that dmf molecule may contribute to the activation of peroxide ion through interaction with an Mn(II)-peroxide adduct, leading to oxidation of the Mn(II) ion. © 1997 Elsevier Science Ltd

Keywords: catalase-like-function; binuclear Mn(II) complex; crystal structure; μ-phenoxide bridge; solvent effect; dimethylformamide.

Some bacterial catalases found in *thermophilic* [1] or *lactaterich* [2] possess a rare dimanganese active site, in contrast to more widely distributed monoheme cofactor of iron catalase. Catalysis appears to involve both Mn ions that are located within 3.6 Å to one another [3]. Spectroscopic studies of the dimanganese catalase have revealed a picture implicating two of the four accessible oxidation states, a "reduced Mn_2(II/III) state" and "oxidized Mn_2(III/III)" in the catalase mechanism (see Scheme I) [4,5]. In 1982, Nishida and co-workers reported that some binuclear

* Author to whom correspondence should be addressed.



Scheme I.

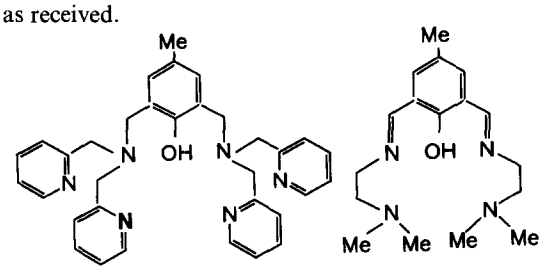
manganese(III) complexes with μ-alkoxo bridge exhibit high catalase-like function instead of the negligible activity of the corresponding monomeric compounds [6]. Thus, the process assumed in Scheme I is consistent with Nishida's results, however, formation of an Mn(II) state from the Mn(III) state by the hydrogen peroxide (from Intermediate D to Intermediate A) is not confirmed in these model systems. Interestingly, it is well known that manganese cluster in the Photosystem II also exhibits a catalase-like function [7,8]. It vigorously disproportionates the added hydrogen peroxide in the dark following the formation of the S_2-state by a single flash [9]. These facts suggest that study on the catalase-like function of the dimeric manganese compounds should be very important in elucidating the function of manganese ions in the enzymes [10].

Very recently, Okawa *et al.* [11] investigated the catalase-like function of the binuclear Mn(II) complex, $[(L^2)Mn_2(benzoate)_2(NCS)]$ (for (L^2), see the figure below) in dmf(dimethylformamide) solution, and observed the formation of Mn(IV)=O species in the solution, and proposed that this Mn(IV)=O species is an active species for catalase-like function of the compound. However, we cannot detect the formation of an Mn(IV)=O species in the acetonitrile solution of the complex even at lower temperature (−20°C). Probably, this may be due to unstability of the Mn(IV)-species in acetonitrile solution or alternatively may indicate that formation of an Mn(IV)=O species is not related with the catalase-like function of the compound, because both manganese(II) compounds with (L^2)-ligand, $[(L^2)Mn_2Cl_3]$ and $[(L^2)Mn_2(benzoate)_2(NCS)]$, exhibit high catalase-like function in acetonitrile solution. In this study we have investigated the catalase-functions of several binuclear manganese(II) complexes with (L^1) and (L^2) in order to clarify the origin of the different behavior in the acetonitrile and dmf solvents, especially the role of dmf molecule for decomposition of hydrogen peroxide by the manganese(II) compounds.

EXPERIMENTAL

Materials

The manganese compounds, $[(L^1)Mn_2X_2]Y_2$ (X=Cl, Br, CH_3COO, C_6H_5COO, Y=ClO_4, PF_6), $[(L^2)Mn_2X_3]$(X=Cl, Br), and $[(L^2)Mn_2X_2]Y$ (X=CH_3COO, C_6H_5COO; Y=NCS, ClO_4) were prepared according to the published methods [12–14], chemical structures of $H(L^1)$ and (L^2) being illustrated below. Hydrogen peroxide (30% in aqueous solution) was titrated by the use of Titanium sulfate [15]. All other chemicals are obtained commercially and used as received.



$H(L^1)$ $H(L^2)$

Crystal structure determination. The crystals of the compounds $[(L^1)Mn_2Cl_2(CH_3OH)_2]PF_6$ and $[(L^2)Mn_2Cl_3]CH_3CN$ were grown from a reaction mixture, and the single crystals of the compounds were mounted on a Rigaku AFC-5 four-circle diffractometer at Keio University for data collection. The crystal data are listed in Table 1. X-ray diffraction intensities were measured using Mo Kα radiation on a Rigaku four-circle diffractometer AFC-5 at Keio University. Absorption was corrected by a numerical method. Structure analysis was carried out using CRYSTAN-GM software version 6.3 on a SUN PARK10 workstation at Keio University [16]. The structures were solved by Direct methods, and refined by full-matrix least-squares. A full report of the experimental and refinement procedure, and the atomic coordinates are available as Supplementary data.

Catalase-like function. All reactions were performed at 25°C in a 10 cm^3 reactor containing a stirring bar under air. The flask containing a manganese complex (10 m mole) solution (5 cm^3) was closed with a rubber septum. Hydrogen peroxide solution (1 cm^3, commercial 30% aqueous solution was diluted to 1 M solution by solvent) was injected through the septum with a syringe. The reactor was connected to a graduated burette filled with water and dioxygen evolved was measured at an appropriate time by volumetry. In the case of MnO_2 as a catalyst, ca. 16 cm^3 of dioxygen evolved under our experimental conditions.

Physical measurements

x-band ESR spectra were obtained with a JEOL ESR apparatus model RE-2X spectrometer at 77 K.

Absorption spectra were measured with a Shimadzu Spectrophotometer model UV-2200 at 298 K.

RESULTS AND DISCUSSION

Crystallography

Two compounds, $[(L^1)Mn_2X_2(CH_3OH)_2]PF_6$ (X=Cl and X=Br) are isostructural. An ORTEP view of $[(L^1)Mn_2Cl_2(CH_3OH)_2]^+$ is shown in Figure 1, and the selected bond distances and angles are listed in Table 2. The solid state structure consists of discrete dimanganese(II) complex solution cation, and hexafluorophosphate anion. The binuclear manganese complex has a chemical twofold axis passing through C(42) and O(12) atoms, and two Mn coordination spheres are rotated relative to the bridging O—Mn bonds. Two manganese atoms within the complex exhibit a similar coordination number and geometries, and are six-coordinate and have an N_3O_2Cl distorted octahedral geometry. Two pyridine moieties and a tertiary amine from one-half of the heptadentate ligand (L^1) are coordinated to Mn1, and an analogous set of three nitrogen from the remaining half of the ligand are coordinated to Mn2. Two manganese atoms are bridged by the (L^1) phenoxy functional group, O(12). The coordinated methanol molecules form hydrogen bonds with the coordinated chloride ions to make a weak bridge. The average Mn1-N(pyridine) and Mn2-N(pyridine) distances are 2.272(7) and 2.265(7) Å, while the Mn1-N(amine) and Mn2-N(amine) distances are longer at 2.321(6) and 2.326(6) Å, respectively. The μ-phenoxo O12 atom forms a symmetrical bridge between Mn1 and Mn2 with observed distance of 2.169(5) and 2.170(5) Å, respectively. The Mn1—Mn2 separation of 3.923(2) Å and Mn1—O12—Mn2 angle of 129.3(3)° are different from those observed in related binuclear complexes containing another bridging group such as carboxylate [17]. The Mn1—O13 and Mn2—O14 methanol bonds are 2.210(7) and 2.237(6) Å are in good agreement with those observed in analogous compounds [5].

Table 2. Selected geometric data (Å, °) of $[(L^1)Mn_2Cl_2(CH_3OH)_2]PF_6$

Mn1—Mn2	3.923(2)	Mn2—Cl4	2.452(3)
Mn1—Cl3	2.427(3)	Mn2—O12	2.170(5)
Mn1—O12	2.169(5)	Mn2—O14	2.237(6)
Mn1—O13	2.210(7)	Mn2—N18	2.326(6)
Mn1—N15	2.321(6)	Mn2—N19	2.292(7)
Mn1—N16	2.302(7)	Mn2—N20	2.237(7)
Mn1—N17	2.241(7)	O13···Cl4	3.076(7)
Mn1—O12—Mn2	129.3(3)	O14···Cl3	3.058(6)

The ORTEP drawing of $[(L^2)Mn_2Cl_3]$ is shown in Figure 2, and the selected bond distances and angles are listed in Table 3. In the solid state, there is a tetranuclear manganese unit possessing a inversion center; the tetranuclear Mn_4 unit is a zig-zag chain, rather than a closed cluster. Mn1 is six-coordinate, having an N_2OCl_3 distorted octahedral geometry. The Mn(1) and Mn(1′) atoms are bridged by Cl(4) and Cl(4′) atoms with Mn—Cl distances 2.511(1) and 2.584(1) Å. Mn2 is five-coordinate with N_2OCl_2 coordination sphere, where basal plane is consisted of O(6), Cl(3), N(10), and N(9); Cl(5) being at the apical position of tetragonal pyramid. The Mn(1) and Mn(2) atoms are bridged by the ligand phenoxy oxygen atom O(6) and chloride ion Cl(3). The μ-phenoxo O(6) atom forms a symmetrical bridge between Mn(1) and Mn(2) with observed distances of 2.131(2) and

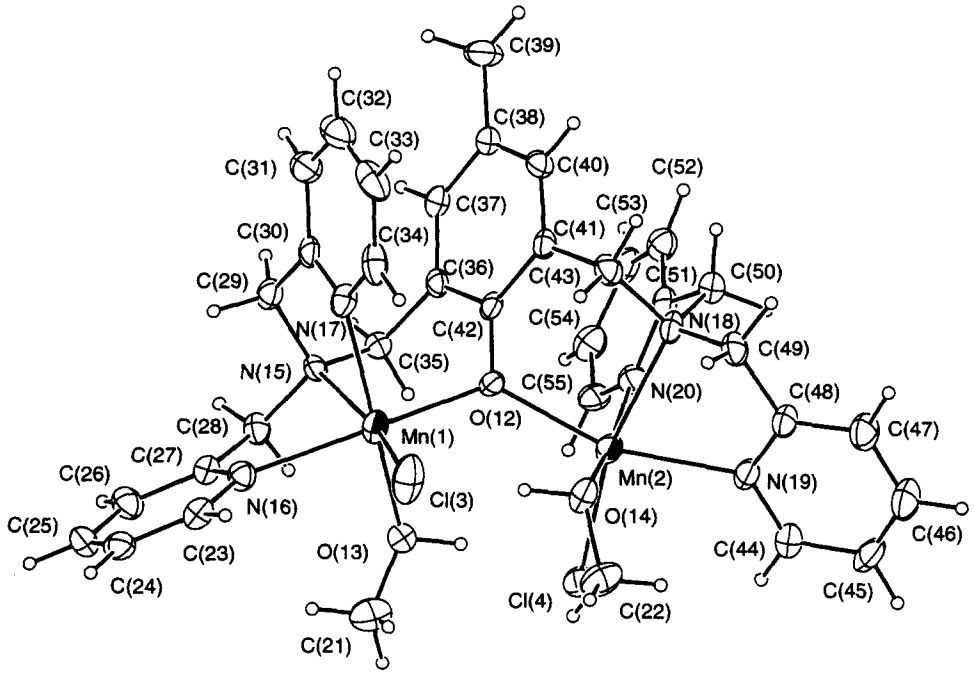

Fig. 1. ORTEP drawing of $[(L^1)Mn_2Cl_2(CH_3OH)_2]^+$.

2.095(2) Å, respectively. The Mn(1)···Mn(2) separation of 3.440(1) Å and Mn(1)—O(6)—Mn(2) angle 109.0(1)°.

Catalase-like function: in acetonitrile solution. The time course of O_2 evolution by the manganese(II) compounds are illustrated in Figure 3. As shown in Figure 3, the activity of $[(L^1)Mn_2Cl_2(CH_3OH)_2]^+$ in acetonitrile is much higher than those of the corresponding acetate and benzoate derivatives. When an acetonitrile solution of hydrogen peroxide was added to an acetonitrile solution of the X=Cl or Br compound, the colorless solution turned to dark brown immediately (see Figure 4), and the drastic change was also observed in the ESR spectra (see also Figure 5). In the ESR spectrum of the brown solution, a "16-line ESR signal" [18] is observed, indicating that a binuclear Mn_2(III/IV) species may exist in the solution. Little change was observed in the ESR spectra of the acetate compound upon the addition of hydrogen peroxide (data not shown). These are implying that the oxidation of Mn(II) ion by hydrogen peroxide is closely related with the appearance of catalase-like function of the (L^1)-compounds.

Interestingly, no remarkable change in ESR and absorption spectral features was observed for the $[(L^2)Mn_2Cl_3]$ and $[(L^2)Mn_2(benzoate)_2(NCS)]$ complexes upon addition of hydrogen peroxide, despite their high activity for catalase-like function (see Figure 3). It should be noted here that the present results are quite different from that reported by Okawa *et al.*, who reported the formation of an Mn(IV)=O species in the dmf solution of the $[(L^2)Mn_2(benzoate)_2(NCS)]$ [11]. This may be due to unstability of an Mn(III) state of the (L^2)-complex in acetonitrile solution.

(B) To 5 ml of the A-solution was added 1 ml H_2O_2-solution (acetonitrile, 0.5 mol dm^{-3} solution), and measured immediately after addition. (C) Measured at 15 minutes after addition of H_2O_2.

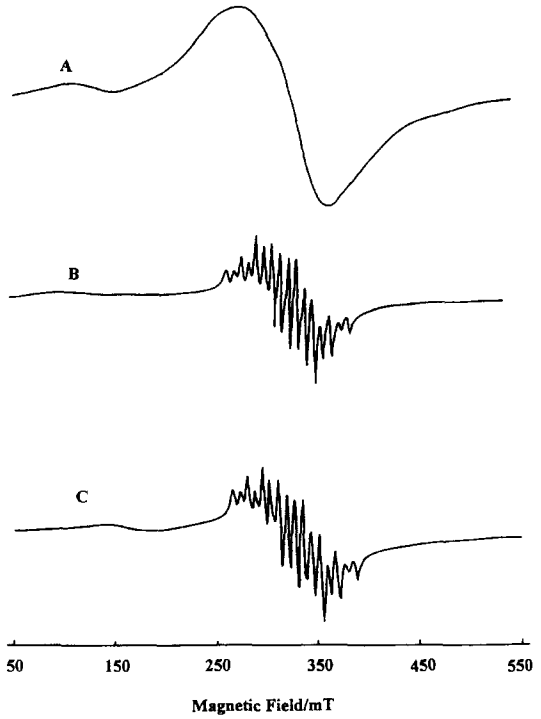

Fig. 5. ESR spectra (in acetonitrile, X-band, 77 K). (A) $[(L^1)Mn_2Cl_2(CH_3OH)_2]PF_6$. (B) Solution C in Figure 4. (C) $[(L^1)Mn_2(acetate)_2](PF_6)_2$ and H_2O_2 (measured at 15 minutes after addition of H_2O_2; experimental conditions are the same as those described for the corresponding $[(L^1)Mn_2Cl_2(CH_3OH)_2]PF_6$ complex).

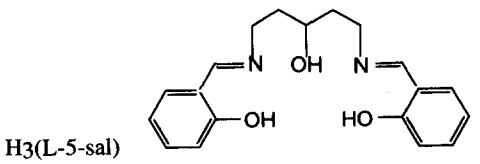
The first dinuclear manganese complex to be reported that catalytically disproportionates H_2O_2 was that of Nishida and co-workers in 1982 [6]. This functional model contained two manganese(III) ions bridged by alkoxy group; in this paper they proposed the importance of coordination of a peroxide ion to two manganese(III) ions, forming a $(\mu\text{-}\eta^1:\eta^1)$-coordination mode (see the Intermediate D in Scheme I). This situation may make two-electron transfer between peroxide ion and manganese ions to be more facile. This consideration has been applied to several other systems; for example, Dismukes *et al.* explained the high catalase-like activity of manganese(II) complex with N,N,N′,N′-tetrakis(2-methylene-benzimidazolyl)-1,3-diaminopropane-2 on this consideration [4,5]. As shown in the present study, it is general that the binuclear manganese(II) complexes are active for decomposition of hydrogen peroxide in acetonitrile solutions. In the case of $[(L^1)Mn_2Cl_2(CH_3OH)_2]^+$, Mn···Mn distance is nearly 4 Å, indicating that Mn···Mn distance in this complex may be flexible in the solution, leading to facile formation of a peroxide adduct with $\mu\text{-}\eta^1:\eta^1$-coordination mode (see Intermediate B in Scheme I). The formation of a peroxide adduct with $(\mu\text{-}\eta^1:\eta^1)$-coordination mode may be less favorable for the acetate-bridged compound, because the acetate is chelated to manganese ions. This will explain the lower activities of the acetate and benzoate compounds, as shown in Figure 3. The high activity observed for the $[(L^2)Mn_2(benzoate)_2(NCS)]$ complex seems to be noteworthy, because in this complex benzoate is chelated to two manganese(II) ions, similar to that in the (L^1)-complex. The geometrical environment around the two manganese(II) ions in this complex are not identical (one, six-coordinate, and another one, five-coordinate), and this situation is very similar to that of the chloride-derivative $[(L^2)Mn_2Cl_3]$; the latter complex also contains a five-coordinate Mn(II) species. These are indicating that facile coordinating of peroxide ion to a manganese(II) ion, in this case five-coordinate Mn(II) ion, is closely related with high catalase-like function of the compound.

It should be noted that the bis(μ-acetato)Mn(II/III) binuclear complex with (L^1) [17] exhibits much higher catalase-like function than that of the μ-acetato Mn_2(II/II) complex (see trace (D) in Figure 7) [12]. This is demonstrating that the presence of an Mn(III) state induces high activity for decomposition of hydrogen peroxide. Above discussion may give a reasonable elucidation for the fact that high catalase-like function is observed in the S_2-state of the Photosystem II instead of the negligible effect observed in the S_1-state. Above discussion may be consistent with the fact that several binuclear manganese(III) complexes always show high catalase-like function, as observed at first by Nishida *et al.* [6], and also by the complex with H_3(L-5-sal) [19] (see the trace (E) in Figure 7) shown below:



H3(L-5-sal)

Catalase-like function in dmf solution. As shown in Figure 6, the induction time (at least 30 minutes) is necessary before vigorous evolution (indicated by an arrow in Figure 6, trace A) of oxygen occurs in the dmf and dimethylacetamide solutions containing $[(L^1)Mn_2Cl_2(CH_3OH)_2]^+$ (see traces A and B) and also in the solution of $[(L^2)Mn_2(benzoato)_2(NCS)]$ [11]. These are quite different from those observed in the acetonitrile solutions. In the cases of the dmf solution, it seems likely that dmf molecules coordinate to a metal ion (see Scheme II (A)), and this may prevent the approach of hydrogen peroxide to a metal

Scheme II

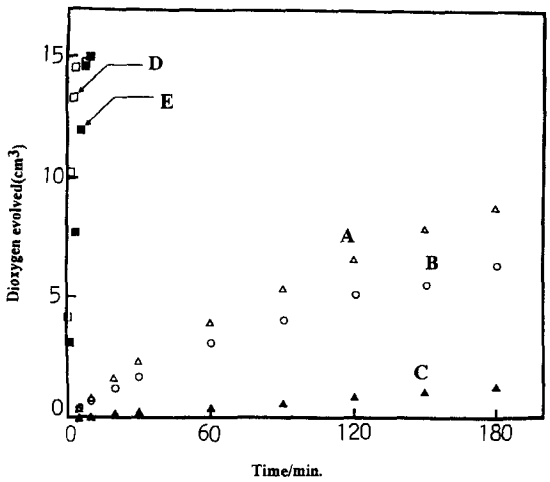

Fig. 7. Dioxygen evolution catalyzed by manganese compounds. (A) $[(L^1)Mn_2(acetate)_2]ClO_4$ in dimethylformamide. (B) $[(L^1)Mn_2(acetate)_2]ClO_4$ in dimethylacetamide. (C) $[(L^1)Mn_2(acetate)_2]ClO_4$ in dimethylsulfoxide. (D) $[(L^1)Mn_2(acetate)_2](PF_6)_2$ in acetonitrile. (E) $[Mn_2(L\text{-}5\text{-}sal)(acetate)(CH_3OH)]ClO_4$ in acetonitrile.

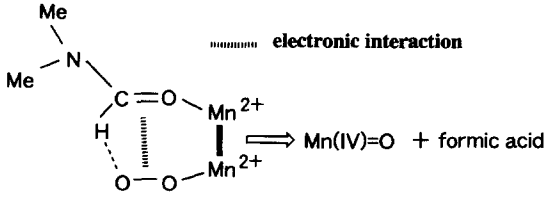
ion, leading to the lower activity of the compounds for decomposition of hydrogen peroxide. These may explain the presence of induction period before oxygen evolution as described above.

Upon the addition of hydrogen peroxide in the dmf solution of the Mn(II) compounds, formation of mono(dmf)-mono(peroxide) species (see Scheme II (B)) and (μ-η^1 : η^1) peroxide adduct (Intermediate B in Scheme I) may increase gradually. Formation of the intermediate B may lead to the same results as described for the acetonitrile solution, however, this may be inconsistent with the fact that an Mn(IV)=O formation is detected only in the dmf solution of $[(L^2)Mn_2(benzoate)_2(NCS)]$. Very recently, we have observed that dmf (and also dimethylacetoamide) molecule can activate peroxide ion in the presence of nickel(II) or cobalt(II)-acetylacetonate compounds through the intermediate formation of cis-mono(dmf)mono(peroxide)nickel(II) species [20], and this has been explained in the same manner to that proposed for activation of dioxygen molecule in the presence of an aliphatic aldehyde and nickel(II)-acetylacetonate [21]. Above discussion may be rationalized because dmf molecule is very similar to aldehydes on the structural and electronical points of view. We already reported that the peroxide ion in the intermediate (B) in Scheme II exhibits high electrophilicity, tending to bind with an organic moiety through electronic interaction [22]. Thus, it seems quite reasonable to assume that activation of peroxide ion in the mono(dmf)-mono(peroxide) Mn(II) species occurs through electronic interaction between them (see the figure below), and this will promote heterolytic cleavage of the peroxide adduct, leading to formation of an Mn(II)—O(atomic) and OH^- [23]; the former species may be alternatively written as an Mn(IV)=O. The sudden evolution of oxygen gas after the induction time in dmf solutions observed in both the (L^1)- and (L^2)-compounds should be elucidated in terms of the discussion that formation of an Mn(IV)=O species promoted by dmf molecule is a trigger for decomposition of hydrogen peroxide in these systems. Our model can well explain the reason why Mn(IV)=O species is detected only in the dmf solution, and may give a reasonable elucidation for formation of formic acid in the dmf solution containing a binuclear copper complex [24].



Based on the discussion described above, it should be recommended that dmf molecule should not be used as a solvent when oxygen or peroxide ion plays an important role in the reaction, and the results reported in this solvent hitherto must be re-evaluated.

(Received 2 July 1997; accepted 28 July 1997)

Abstract—The coordination of silver(I) acetate with 2,2′:6′,2″-terpyridine (tpy) and 6,6″-diphenyl-2,2′:6′,2″-terpyridine (dptpy) has been investigated. In contrast to the behaviour with copper(I), no dinuclear double-helical species have been unambiguously isolated although there is evidence that double-helical $[Ag_2L_2]^{2+}$ complexes exist in weakly-coordinating solvents. In the case of 2,2′:6′,2″-terpyridine, a species containing a square-planar $[Ag(tpy)(MeCN)]^+$ caton has been isolated and structurally characterised whilst with 6,6″-diphenyl-2,2′:6′,2″-terpyridine a related but very distorted $[Ag(dptpy)(MeCN)]^+$ species has been structurally characterised. © 1997 Elsevier Science Ltd

Keywords: silver(I) complexes; oligopyridines; supramolecular chemistry; helicates; crystal structures; 2,2′:6′,2″-terpyridine.

We have long been interested in understanding the interplay between metal ions and ligands that controls the assembly of metallosupramolecules [1,2]. In particular, we have tried fully to comprehend the factors leading to the self-assembly of helical systems involving oligopyridines [3]. As a prototype system it has been demonstrated that simple 2,2′:6′,2″-terpyridines give rise to double-helical $[Cu_2L_2]^{2+}$ complexes upon reaction with copper(I) [4–6]. Recently, we have extended these studies to the control of the right-handed or left-handed chirality of the helix by the use of chiral oligopyridines [6–8] and have shown that enantiomerically pure chiral 2,2′:6′,2″-terpyridines lead to enantiomeric excesses of the *P* or *M* double helicates upon reaction with copper(I) [6]. The enantiomeric excesses observed were modest (75%) and we considered a number of approaches to improve them. We adopted three principal strategies: (i) variation of the metal ion (ii) increasing the number of donor atoms and (iii) increasing the amount of chiral information contained within the chiral ligand. In this paper we consider strategy (i) and report the behaviour of 2,2′:6′,2″-terpyridine (tpy) and 6,6″-diphenyl-2,2′:6′,2″-terpyridine (dptpy) with silver(I).

EXPERIMENTAL

Infra-red spectra were recorded in compressed KBr discs on Perkin-Elmer 983 or Philips PU9624 Fourier-transform spectrophotometers, electronic spectra on a PU8730 spectrophotometer and ^1H NMR spectra on Bruker WM-250 or AM-400 spectrometers. Fast

atom bombardment (FAB) spectra were recorded on a Kratos MS-50 spectrometer; the sample was loaded using acetonitrile as solvent, and 3-nitrobenzyl alcohol as supporting matrix, 2,6-Bis(3-dimethylamino-1-oxopropyl)pyridine dichloride and *N*-(2-phenyl-2-oxoethyl)pyridinium iodide were prepared by the literature methods [9].

N-(2-phenyl-2-oxoethyl)pyridinium iodide

A mixture of iodine (25.38 g, 0.1 mol) and dry pyridine (100 cm^3) was warmed until the iodine had dissolved, after which acetophenone (12.0 g, 0.1 mol) was added and the mixture heated to reflux for 6 h. The reaction mixture was then cooled, the solid product filtered off, and recrystallised from ethanol to give cream crystals of *N*-(2-phenyl-2-oxoethyl)pyridinium iodide (16.3 g, 50%). Mp. 190–192°C. IR 3049 w, 2875 w, 2828 m, 1697 s, 1578 w, 1468 s, 1385 w, 1352 w, 1213 m, 1058 w, 997 m, 755 m, and 688 m cm^{-1}. MS (+ve FAB): *m/z* 199 {M-I}. Found: C. 47.8, H, 3.7; N, 4.3. Calc. for $C_{13}H_{12}INO$: C, 48.0; H, 3.7; N, 4.3%.

6,6″-Diphenyl-2,2′:6′,2″-terpyridine, dptpy

A mixture of ammonium acetate (2.8 g, 0.04 mol) and *N*-(2-phenyl-2-oxoethyl)pyridinium iodide (1.1 g, 3.4 mmol) were dissolved in methanol (20 cm^3) and the solution brought to reflux. 2,6-Bis(3-dimethylamino-l-oxopropyl)pyridine dichloride (0.5 g, 1.4 mmol) was added and the mixture refluxed for 12 h after which it was cooled and the resultant grey solid filtered off. Recrystallisation from ethanol gave dptpy as a pale cream solid (0.43 g, 80%). Mp. 206–206.5°C. IR 1567 s, 1431 m, 1268 w, 1076 w, 805 m, 762 s, and 695 m cm^{-1}. MS (+ve FAB): *m/z* 386 {M}. Found: C, 84.1; H, 5.0; N, 10.9. Calc. for $C_{27}H_{19}N_3$: C, 83.9; H, 5.0; N, 11.0%. ^1H NMR ($CDCl_3$): δ 7.42–7.60 (6H, m, H^m, H^p), 7.81 (2H, dd, *J* 0.9, 7.8 Hz, H^5), 7.95 (2H, t, *J* 7.8 Hz, H^4), 8.02 (1H, t, *J* 7.8 Hz, $H^{4'}$), 8.20 (4H, m, H^o), 8.63 (2H, dd, *J* 0.9, 7.8 Hz, H^3), 8.71 (2H, dd, *J* 7.8 Hz, $H^{3'}$).

$[Ag_2(tpy)_2][PF_6]_2$

A solution of tpy (0.030 g, 0.13 mmol) and Ag(OAc) (0.022 g, 0.13 mmol) was heated under reflux in methanol (5 cm^3) for 3 h. The pale yellow solution was filtered through cotton wool and then treated with excess methanolic $[NH_4][PF_6]$ to yield a white precipitate of $\{Ag(tpy)(PF_6)\}$ which filtered off and dried under reduced pressure (0.048 g, 77%). IR: 1591 m, 1580 m, 1563 m, 1479 w, 1471 w, 1449 m, 1423 m, 1401 w, 1312 w, 1287 w, 1248 w, 1188 w, 1168 w, 1104 w, 1095 w, 1076 w, 1041 w, 1025 w, 1005 w, 844 vs, 773 s, 762 s, 653 w, 630 w, and 559 s cm^{-1}. MS (+ve FAB): *m/z* 827 $\{Ag_2(tpy)_2(PF_6)\}$, 573 $\{Ag(tpy)_2\}$, 448 $\{Ag_2(tpy)\}$, 340 $\{Ag(tpy)\}$. Found: C, 37.0; H, 2.4; N, 8.8. Calc. for $C_{17}H_{14}AgF_6N_4P$: C, 37.0; H, 2.3; N, 8.6%.

$[Ag_2(tpy)_2][BF_4]_2$

This compound was prepared in a similar manner to $[Ag_2(tpy)_2][PF_6]_2$ but using $[NH_4][BF_4]$ to precipitate the product which was obtained as a white precipitate (0.044 g, 80%). IR: 1582 m, 1563 s, 1455 m, 1423 s, 1084 vs, 762 cm^{-1}. MS (+ve FAB): *m/z* 770 $\{Ag_2(tpy)_2(BF_4)\}$, 573 $\{Ag(tpy)_2\}$, 448 $\{Ag_2(tpy)\}$, 340 $\{Ag(tpy)\}$. Found: C, 42.2; H, 2.8; N, 9.6%. Calc. for $[Ag_2(tpy)_2][BF_4]_2$: C, 42.1; (H, 2.6; N, 9.8%).

$[Ag_2(tpy)_2(MeCN)_2][PF_6]_2$

Recrystallisation of $[Ag_2(tpy)_2][PF_6]_2$ from acetonitrile by the diffusion of diethyl ether vapour into the solution afforded colourless crystals of the salt $[Ag_2(tpy)_2(MeCN)_2][PF_6]_2$. IR: 1592 m, 1580 m, 1563 m, 1478 w, 1450 m, 1423 m, 1401 w, 1385 w, 1312 w, 1249 w, 1188 w, 1168 w, 1104 w, 1077 w, 1012 w, 845 vs, 796 m, 773 s, 653 m, 630 w, and 558 s cm^{-1}. MS (+ve FAB): *m/z* 827 $\{Ag_2(tpy)_2(PF_6)\}$, 573 $\{Ag(tpy)_2\}$, 340 $\{Ag(tpy)\}$. Found: C, 38.3; H, 2.8; N, 10.4. Calc. for $C_{34}H_{28}Ag_2F_{12}N_8P_2 \cdot 0.5\ H_2O$: C, 38.1; H, 2.8; N, 10.4%.

$[Ag(dptpy)][BF_4]$

A solution of $[Ag(MeCN)_4][BF_4]$ (0.2 g, 0.56 mmol) and dptpy (0.22 g, 0.56 mmol) were stirred in methanol (15 cm^3) for 3 h, after which period the pale yellow precipitate was filtered off and dried. IR: 3086 w, 1590 m, 1465 m, 1444 s, 1283 w, 1242 m, 1186 w, 1055 s, 809 s, 763 s, 705 m, and 655 w cm^{-1}. MS (+ve FAB): *m/z* 1074 $\{Ag_2(dptpy)_2(BF_4)\}$, 986 $\{Ag_2(dptpy)_2\}$, 879 $\{Ag(dptpy)_2\}$, 600 $\{Ag_2(dptpy)\}$, 492 $\{Ag(dptpy)\}$. Found: C, 55.9; H, 3.3; N, 7.25. Calc. For $C_{54}H_{38}N_6Ag_2B_2F_8$: C, 55.5; (H, 3.25; N, 7.75%). Recrystallisation from acetonitrile by the diffusion of diethyl ether vapour into the solution gave colourless crystals of $[Ag(dptpy)(MeCN)][BF_4]$.

X-ray crystallography of $[Ag_2(tpy)_2(MeCN)_2][PF_6]_2$ **(1)** *and* $[Ag(dptpy)(MeCN)][BF_4]$ **(2)**

Crystallographic measurements were made on a Rigaku AFC7 (**2**) or a Stoe four circle diffractometer (**1**) using Mo–K_α radiation ($\lambda = 0.71073$ Å) by standard procedures. The data were corrected for Lorrentz and polarization effects and also for absorption (semi-empirical). The structures were solved by direct methods (SHELXTL-PLUS for **1**) [10] and refined on F^2 by full-matrix least-squares (SHELXL93) [11]. The non-hydrogen atoms were refined anisotropically and

hydrogen atoms were included in calculated positions (riding model). Final wR (on F^2) and R (on F) were 0.0687 and 0.2007 or 481 parameters and all 4224 data for **1** and 0.1102 and 0.1485 for 381 parameters and all 2378 data for **2**. The corresponding R values for data with $I > 2\sigma(I)$ were 0.0547 and 0.1603 for **1** and 0.0554 and 0.1158 for **2**. Sources of atomic scattering factors are as in Ref. [10]. The diagrams were drawn with ORTEP3 [12]. The crystal data and data collection and structure refinement parameters are summarized in Table 1. Selected bond lengths and angles for the two structures are presented in Table 2. Final atom coordinates, displacement coefficients, and a full list of bond lengths and angles have been deposited with the Editor as supplementary material.

RESULTS AND DISCUSSION

Silver(I)-2,2′ : 6′,2″-terpyridine complexes

Although tpy usually functions as a chelating terdentate ligand this bonding mode is not possible with metal ions which have a tendency towards four-coordinate tetrahedral coordination. In these circumstances, it is possible to anticipate double-helical structures in which two quasi-four-coordinate metal centres are coupled by a bridging nitrogen of the central pyridine ring (Scheme 1). Such structures are formed with copper(I) [4–6] although we were always aware of the possibility of reaction with a good donor to give a square-planar species in which the tpy behaved in the expected terdentate manner (Scheme 1). Other low-charged metal ions with no electronically imposed preference for a particular geometry such as silver(I) were expected to behave in a similar manner to copper(I) as we have shown in the case of 2,2′ : 6′,2″-quaterpyridine ligands [13,14].

Although a number of reports of silver(I)–2,2′ : 6′,2″-terpyridine complexes have appeared [15–20], structural data is sparse [19,20] and no evidence for a dinuclear double-helical species has been presented. Of most relevance is a compound of stoichiometry $Ag_4(MeCN)(tpy)_5(ClO_4)_4$ isolated from a 1 : 1 reaction of tpy with silver(I) perchlorate which contains a helical, but not double helical,

$[Ag_3(tpy)_4]^{3+}$ unit in which two of the tpy ligands are bridging [19].

Ligand synthesis

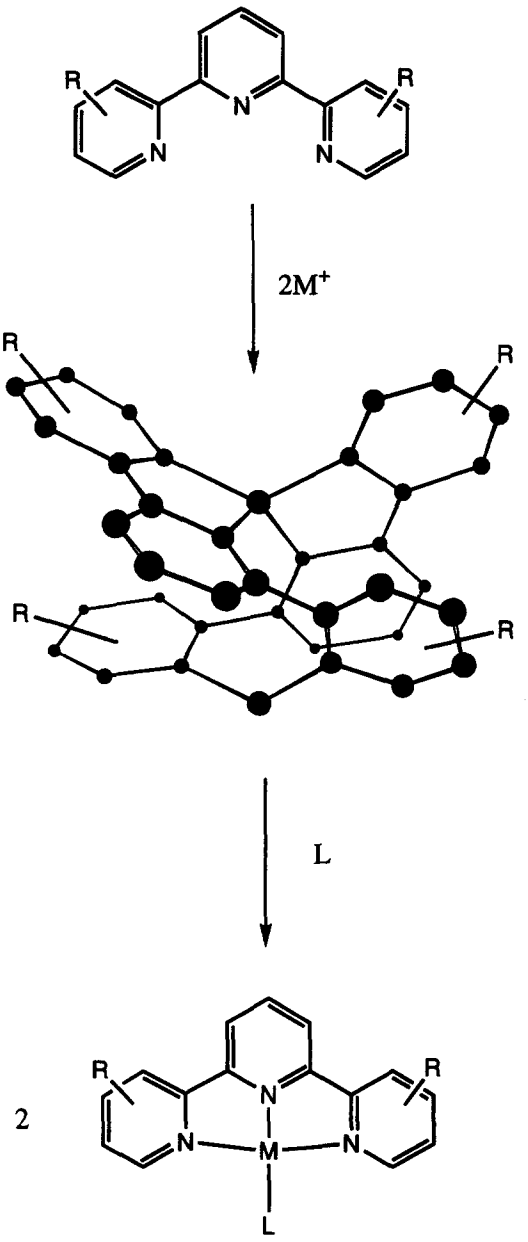
We have previously shown that copper(I) complexes with 2,2′:6′,2″-terpyridines were stabilised by the introduction of sterically demanding substituents into the 6- and 6″-positions [5]. Accordingly, we have made parallel studies with tpy itself and with 6,6″-diphenyl-2,2′:6′,2″-terpyridine (dptpy) prepared by a Kröhnke type synthesis (Scheme 2). The key step involves the reaction of the bis(Mannich) salt of 2,6-diacetylpyridine with an acetophenone enolate equivalent in the presence of an excess of ammonium acetate. The new ligand was obtained in 80% yield as a pale buff solid. Characterisation data for dptpy are presented in the experimental section.

Coordination behaviour of silver(I) with tpy and dptpy

The reaction of one equivalent of silver acetate with one equivalent of tpy in methanol gave a colourless solution from which colourless microcrystalline solids were obtained upon the addition of $[NH_4][PF_6]$ or $[NH_4][BF_4]$. An analogous colourless solid was obtained from the reaction of $[Ag(MeCN)_4][BF_4]$ with dptpy in methanol. Microanalysis of these solids indicated a formulation $\{AgLX\}$ (L = tpy or tptpy; X = BF_4 or PF_6) to be appropriate. In no case, was evidence found for a coordinated solvent molecule. Assuming that the weakly coordinating anions are not directly coordinated to the metal centre, a mononuclear formulation of these materials would imply a three-coordinate silver(I) centre. Whilst three-coordinate silver(I) is relatively common, it is not likely to occur with the T-shaped donor set of the chelating tpy or dptpy ligands. Accordingly, we wish to propose that these initially formed materials are double-helical $[Ag_2L_2]^{2+}$ species with bridging tpy or dptpy ligands analogous to the previously reported copper(I) species.

Support for this proposal comes from the observation of intense peaks with the correct isotopomer distributions for $\{Ag_2L_2X\}^+$. In order to further elucidate the structures of these complexes we have made repeated attempts to obtain X-ray quality crystals from weakly coordinating solvents such as acetone, but have had no success to date. The materials obtained from acetonitrile solution will be discussed later.

Solutions of the complexes $\{Ag(tpy)X\}$ (X = BF_4 or PF_6) in any given solvent were identical, but showed a considerable solvent dependence (Table 3). All spectra were fully assigned by COSY methods and a representative example in CD_3SOCD_3 solution is presented in Fig. 1. The spectra in CD_3COCD_3 were broadened and varied with time. All of these data



Scheme 1.

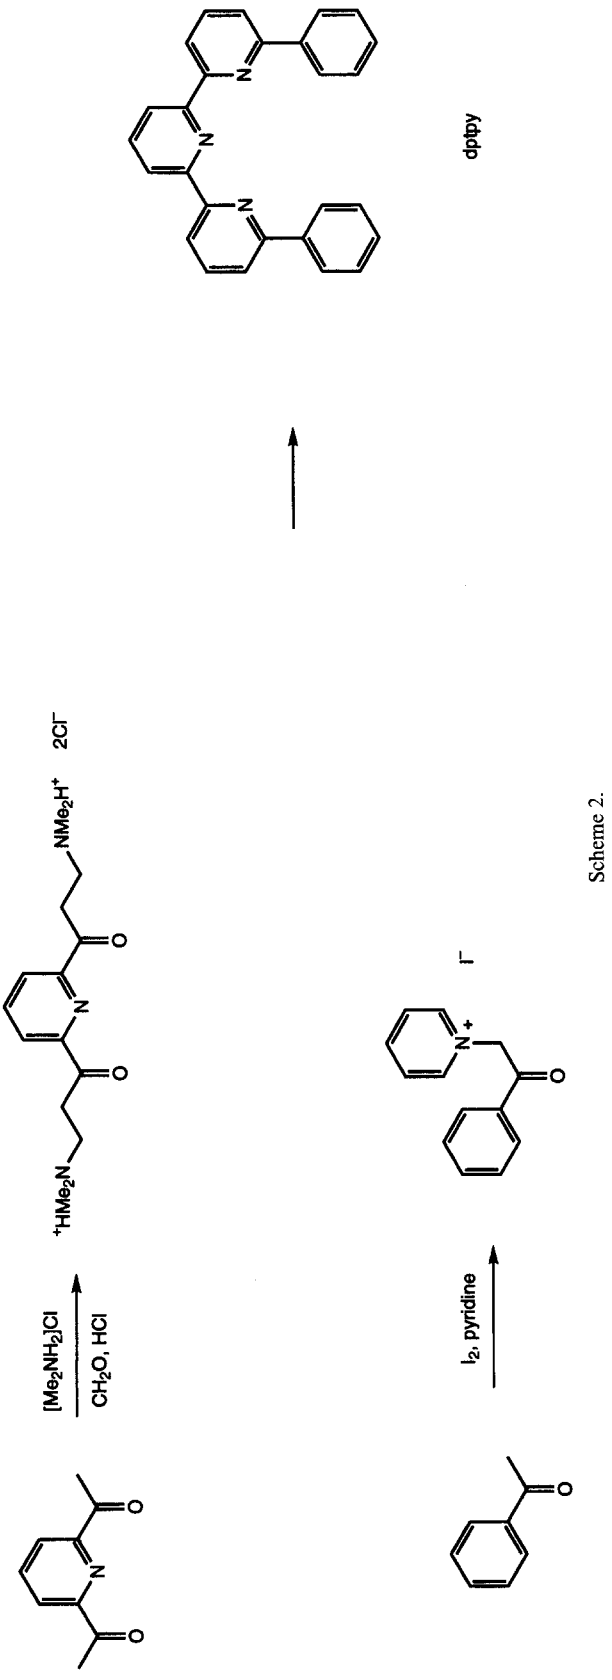
are compatible with an initially formed double-helical species reacting with solvent to give a mononuclear $[Ag(tpy)(S)]^+$ solvent species. We had hoped that the introduction of the phenyl substituents in the dptpy ligand would result in the formation of more stable double-helical species. However, a similar pattern of solvent dependence was observed. This is in contrast to the behaviour of copper(I) with dptpy which gives double-helical dinuclear $[Cu_2(dptpy)_2]^{2+}$ species which are soluble in a range of solvents. There are sufficient similarities between the spectra of acetone solutions of the copper(I) and silver(I) complexes of dptpy (Fig. 2) to propose that similar solution species are present in each case. In conclusion, we suggest that both tpy and dptpy react with silver(I) salts to give double-helical dinuclear species, but that these compounds are substantially less stable with respect to solvation and the formation of mononuclear complexes than the copper(I) analogues.

In the course of numerous attempts to obtain X-ray quality crystals of these materials we noted that the solids obtained from acetonitrile solutions consistently had a stoichiometry {Ag(tpy)(MeCN)X} or {Ag(dptpy)(MeCN)X} and also observed that these materials exhibited identical ^1H NMR spectra to solutions of the original compounds to CD_3CN. X-ray quality crystals of the acetonitrile solvates with both ligands have been obtained and show interesting differences.

X-ray structure of $[\{Ag(tpy)(MeCN)\}_2][PF_6]_2$

The X-ray structural analysis of this complex revealed a number of interesting features. First of all, the expected square-planar $[Ag(tpy)(MeCN)]^+$ unit was present. However, a dinuclear $[\{Ag(tpy)(MeCN)\}_2]^{2+}$ cation is present with a short silver–silver contact of 3.1698(12) Å (Fig. 3). This short contact is a common feature of silver complexes containing planar macrocyclic units [21] and is also found in disilver double-helicates [13,14]. Interestingly, the $[Ag(tpy)(MeCN)]^+$ cation is also present in the lattice of $Ag_4(MeCN)(tpy)_5(ClO_4)_4$ [19], but in this case, although short Ag···Ag contacts are present within the trinuclear $Ag_3(tpy)_4$ unit, no short contacts to the $[Ag(tpy)(MeCN)]^+$ cation are observed, which shows 4.728 Å and 5.332 Å distances to the closest silver atoms of two trinuclear units. The $[Ag(tpy)(MeCN)]^+$ cation within our structure exhibits significantly longer silver–nitrogen interactions with the acetonitrile ligands (2.211(9), 2.222(8) Å) and the central ring of the tpy (2.392(6), 2.377(6) Å) than in $Ag_4(MeCN)(tpy)_5(ClO_4)_4$, which presumably represents the increased electron density at silver as a result of the silver–silver interaction. The cations are very close to square-planar about each silver centre, with the sum of angles about the two independent silver atoms totalling 358.5 and 360.1°. Within the dinuclear unit, the N_4Ag planes are twisted about the Ag···Ag axis to give a 137.27° angle between the two acetonitrile ligands (Figure 4a). The acetonitrile ligands are significantly non-linear. The consequence of the short silver–silver contact and the twisting of the two AgN_4 planes is a near perfect stacking between terminal rings of the two tpy ligands within the dinuclear unit. The individual tpy units are not exactly planar and exhibit dihedral angles between the terminal rings and the central ring in the range 11.7–18.5°.

However, the dinuclear units are further arranged in stacks within the lattice giving a zig-zag chain of alternating short (3.1698(12) Å) and long (5.223 Å)



Scheme 2.

contacts (Figure 4b). Finally, these stacks are arranged in the crystal lattice with channels containing the hexafluorophosphate counterions lying between them (Figure 4c). There are no cation–anion interactions below 3.0 Å and no short Ag···F contacts below 4.0 Å

X-ray structures of [Ag(dptpy)(MeCN)][BF_4] · MeCN

The solid state structure of this complex differs significantly from that of the analogue with a tpy ligand. The gross structural feature of an approximately square-planar cation is retained, with the sum of angles about the silver totalling 363° (Fig. 5). There are no short silver–silver contacts and the closest contact between adjacent silver atoms is 5.656 Å. This distance is too great to allow any stacking between the aromatic rings of the ligands. The distortion from a square-planar arrangement is quite marked with the donors lying up to 0.36 Å from the least squares plane describing Ag(1), N(1), N(21), N(31) and N(41). The overall effect is to place both of the phenyl substituents above this plane and to bend the acetonitrile ligand below it. In effect, the two phenyl groups create a pocket for the acetonitrile ligand (Fig. 6). The additional steric interactions between the phenyl substituents and the acetonitrile lead to significant changes in the coordination around the silver. The bonds between the silver and the terminal pyridine rings are

considerably longer, and the bonds to the acetonitrile and the central pyridine ring shorter, than those in the $[Ag(tpy)(MeCN)]^+$ cation.

CONCLUSIONS

We have found some evidence for the formation of dinuclear (presumably double-helical) complexes between silver(I) and 2,2′ : 6′,2″-terpyridines in weakly coordinating solvents. However, we have also shown that under conditions in which the corresponding copper(I) double helicates are stable (acetonitrile solution), the silver complexes are solvolysed to give mononuclear species. In the light of these observations, we have decided that our original strategy (i) for increasing enantiomeric excesses of helicates involving chiral ligands is flawed and we will concentrate upon strategies (ii) and (iii).

(Received 14 April 1997; accepted 24 July 1997)

Abstract—Complexes of copper(II) octanoate, nonanoate and decanoate with 2-aminoethanol (ethanolamine) have been synthesized and characterized. The crystal structure of $Cu(O_2CC_8H_{17})_2(NH_2C_2H_4OH)_2$ consists of mononuclear units with pairs of amino nitrogen atoms and deprotonated nonanoato oxygen atoms forming a square coordination plane around the central copper. The hydroxyl oxygen atoms from the 2-aminoethanol ligands are positioned axially with respect to the coordination plane. Results of screening for fungicidal activity against the wood-rotting fungus *Trametes versicolor* (L. ex Fr.) Pilat show that the complexes totally inhibit fungal growth at a concentration of 1.0×10^{-3} mol/l but only partially at a concentration of 5.0×10^{-4} mol/l.

Keywords: copper(II) carboxylates; 2-aminoethanol; octanoate; nonanoate; decanoate.

A large number of copper(II) carboxylates and their complexes, especially with nitrogen donor ligands, have been studied extensively and the results published in several monographs and reviews [1–7]. Our interest in copper(II) complexes of saturated carboxylic acids originates from their use as wood preservatives [8–10]. Copper(II) carboxylates of higher fatty acids are not soluble in water, though they are soluble in aqueous ammonia or other amine solutions. The aim of our work was to synthesize and characterize some complexes of copper(II) carboxylates with 2-aminoethanol and to examine their fungicidal activity.

EXPERIMENTAL

Preparation of the complexes

The starting copper(II) octanoate, nonanoate and decanoate species were synthesized as described earlier [11]. To make the 2-aminoethanol adducts, 2.00 g of the copper complex (2.86 mmol of octanoate, 2.65 mmol of nonanoate or 2.46 mmol of decanoate) was dissolved in 30 cm^3 of boiling acetone (40 cm^3 for the decanoate species) with stirring and 2-aminoethanol added (0.69 cm^3, 0.64 cm^3 or 0.59 cm^3 which is 11.4, 10.6 or 9.9 mmol, respectively) to give 4:1 amine:carboxylate molar ratios in each case. Subsequent cooling resulted in the precipitation of blue solids.

These products were recrystallized from hot acetonitrile with yields in the range 78–87%.

Blue platy needles of $Cu(O_2CC_8H_{17})_2(NH_2C_2H_4OH)_2$ suitable for X-ray crystallographic analysis were obtained by dissolving 0.06 g of the compound in 20 cm^3 of acetonitrile, heating to boiling, filtering and slowly cooling to room temperature.

Physical measurements

Vibrational spectra in the region 4000–220 cm^{-1} were obtained using a Perkin-Elmer FT-IR 1720 X spectrophotometer using Nujol and poly(chlorotrifluoroethylene) oil suspension techniques. Room-temperature magnetic susceptibility measurements of powdered samples were performed with a Sherwood Scientific MSB-1 balance using $HgCo(NCS)_4$ as a calibrant. EPR spectra of the powders were recorded on a Bruker ESP-300 X-band spectrometer at room temperature and at 150 K.

Elemental analysis

$Cu(O_2CC_7H_{15})_2(NH_2C_2H_4OH)_2$; found (calc.): Cu 13.2 (13.5), C 49.8 (50.9), H 9.5 (9.3), N 6.0 (5.9)%. $Cu(O_2CC_8H_{17})_2(NH_2C_2H_4OH)_2$; Cu 12.4 (12.7), C 53.1 (52.8), H 9.6 (9.6), N 5.9 (5.6)%. $Cu(O_2CC_9H_{19})_2(NH_2C_2H_4OH)_2$; Cu 12.0 (12.0), C 53.7 (54.6), H 10.3 (9.9), N 5.4 (5.3)%.

Crystal data for bis(2-aminoethanol)di(nonanoato) copper(II)

$C_{22}H_{48}N_2O_6Cu$, $M = 500.2$, monoclinic, space group $P2_1/c$, $a = 18.015(2)$, $b = 4.908(1)$, $c = 15.898(3)$ Å, $\beta = 102.25(1)°$, $V = 1373.7(4)$ Å^3, $Z = 2$ (the molecule has crystallographic C_i symmetry), $D_c = 1.209$ g cm^{-3}, $\mu(Cu\text{–}K_\alpha) = 14.1$ cm^{-1}, $F(000) = 542$. A blue platy needle of dimensions $0.50 \times 0.20 \times 0.03$ mm was used. Data were measured on a Siemens P4/PC diffractometer with Cu–K_α radiation (graphite monochromator) using ω-scans. 2172 independent reflections were measured ($2\theta \leqslant 124°$) of which 1921 had $|F_0| > 4\sigma(|F_0|)$ and were considered to be observed. The data were corrected for Lorentz and polarization factors, but not for absorption. The structure was solved by direct methods and all the non-hydrogen atoms were refined anisotropically. The amino and hydroxyl hydrogen atoms were located from a ΔF map and refined isotropically subject to a distance constraint (0.90 Å). The positions of the remaining hydrogen atoms were idealized, assigned isotropic thermal parameters, $U(H) = 1.2U_{eq}(C)$ [$U(H) = 1.5U_{eq}(C\text{–}Me)$], and allowed to ride on their parent atoms. Refinement was by full-matrix least-squares based on F^2 to give $R_1 = 0.051$, $wR_2 = 0.140$ for the observed data and 155 parameters. The maximum and minimum residual electron densities in the final ΔF map were 0.54 and -0.70 eÅ^{-3} respectively. The mean and maximum shift/error ratios in the final refinement cycle were 0.000 and 0.000 respectively. Computations were carried out using the SHELXTL PC program system [12]. Additional material available from the Cambridge Crystallographic Data Center comprises H-atom coordinates, thermal parameters and remaining bond lengths and angles.

Screening of the compounds for fungicidal activity

0.1 cm^3 of solutions of the studied compounds in dimethyl sulfoxide (DMSO) were added to 10 cm^3 of sterilized cooling potato dextrose agar (PDA, Difco). Final concentrations of the tested substances in the growth medium were 1.0×10^{-3}, 5.0×10^{-4}, 2.5×10^{-4} and 1×10^{-4} mol/l. The solidified growth medium was inoculated by approximately 0.5 cm^2 pieces of mycelium of wood-decay fungus *Trametes versicolor* (L. ex Fr.) Pilat (ZIM, L053) [13]. Nine tubes with the inoculated medium were used for each substance. The tubes were then put into the growth chamber at 25°C. The fungal growth was estimated visually and compared with growth on the control medium without chemicals and on PDA containing 1 vol% of DMSO.

RESULTS AND DISCUSSION

Crystal and molecular structure of $Cu(O_2CC_8H_{17})_2(NH_2C_2H_4OH)_2$

The X-ray analysis of the product of the reaction between copper(II) nonanoate and 2-aminoethanol in acetone reveals the formation of a C_i symmetric square planar copper complex (Fig. 1). Selected bond lengths and angles are presented in Table 1. The nonanoic acid coordinates via the deprotonated oxygen atom [Cu—O(1) 2.009(2) Å] whilst the 2-aminoethanol is bound via the amino nitrogen atom [Cu—N(10) 1.999(3) Å]; the *cis* angles at copper are 89.8(1) [N(10)—Cu—O(1′)] and 90.3(1)° [N(10)—Cu—O(1)]. The 2-aminoethanol ligands have a *gauche* geometry about the C—C bond, being folded such that the terminal hydroxyl oxygen atoms are positioned axially with respect to the coordination plane, thereby filling the vacant octahedral sites at copper [Cu···O(13) 2.477(2) Å]. The O···Cu vector is inclined by ca 78° to the coordination plane. Examples of 2-aminoethanol behaving as a "bidentate" ligand to copper in this fashion are rare. Indeed, there is only one prior example of a crystal structure where an analogous octahedral geometry is observed [14], but this structure is of poor accuracy.

This secondary coordination results in the hydroxyl hydrogen atoms of the 2-aminoethanol ligands being directed towards the carbonyl oxygen atoms of the nonanoic acid moieties (the aliphatic chains of which

have a near planar, extended all *anti* geometry), forming pairs of strong, intramolecular O—H · · · O hydrogen bonds [O · · · O 2.61, H · · · O 1.72 Å; O—H · · · O 169°].

Adjacent complexes are linked via pairs of N—H · · · O hydrogen bonds between one of the amino N—H hydrogen atoms in one molecule and the hydroxyl oxygen atom of the 2-aminoethanol ligand of a lattice translated counterpart [N · · · O 2.99, H · · · O 2.10 Å; N—H · · · O 167°] (Fig. 1). This pat-

tern of hydrogen bonding results in the aliphatic residues being aligned parallel to each other to form a sheet-like array. Adjacent sheets are oriented such that these aliphatic chains interleave head-to-tail to form a close-packed array, as shown in Fig. 2. The overall superstructure is thus dominated by alternating hydrophobic and hydrophillic regions.

Magnetic and spectroscopic data

The effective magnetic moments of the 2-aminoethanol adducts (Table 2) lie above the spin-only value of 1.73 BM, in the range between 1.92–1.97 BM, and are consistent with the presence of one unpaired electron in a mononuclear copper(II) complex [15]. These results were confirmed by EPR measurements of powder samples at room temperature and at 150 K (Table 2). The spectra are typical for axial symmetry and indicate a $d_{x^2-y^2}$ ground state ($g_\parallel > g_\perp > 2.0$) [15]. The value of $G = (g_\parallel - 2)/(g_\perp - 2)$ equals approximately 4.5 for all three compounds and signifies low exchange coupling [16].

IR spectra of all three copper(II) carboxylates are very similar, being noticeably different only in the region between 1350 and 1000 cm^{-1}, where the CH_2 "wagging" of long hydrocarbon chains exhibit a series of sharp regularly spaced bands. It is known that complexity of the spectra in this region increases with increasing chain length [17,18]. Between 3630 and 3150 cm^{-1} four bands were observed in each case, resulting from 2-aminoethanol O—H and N—H stretches. The shift of the N—H stretches toward lower wave numbers, compared to those of primary amines in the gas phase or in dilute solutions, can be explained by hydrogen bonding [19–21]. The band at 1600 cm^{-1}, present in the spectra of all three compounds, was assigned to the NH_2 asymmetric deformation and the bands at 1071 and 1032 cm^{-1} to the NH_2 symmetric deformation mode. Bands due to vibrations in the aliphatic chains of the carboxylato ligands are at the expected wavelengths, as assigned by Strommen and coworkers [18]. The broad and strong $\nu_{as}(COO)$ band is located at 1556–1560 cm^{-1} and the split band, tentatively assigned to the symmetric carboxylate stretch, $\nu_s(COO)$, occurs at 1408–1412 cm^{-1}. The separation, Δ, between these two bands is only 144–152 cm^{-1}, which is unexpectedly small for unidentate carboxylate ligands. It is even smaller than the difference of 171–177 cm^{-1} observed for the bridging bidentate carboxylate arrangement in copper(II) octanoate, nonanoate and decanoate [11]. The small magnitude

[a] Fungicidal activity was estimated with fungal growth retardation, labelled by the following visually determined marks: 1, normal growth, no retardation; 2, slightly visible signs of retardation; 3, significant retardation; 4, retardation is very strong; 5, no fungal growth.

[b] Concentration of dimethyl sulfoxide in the growth medium was in all cases the same i.e. 1% by volume.

ND = Not determined.

of this separation in these 2-aminoethanol complexes can be attributed to strong intramolecular hydrogen bonding between the carbonyl oxygen atoms of the carboxylic acid ligands and hydroxyl hydrogen atoms of the 2-aminoethanol units (as already shown, the O···O distance in the nonanoato complex is only 2.61 Å). In the nickel complex $Ni(O_2CCH_3)_2(H_2O)_4$, which contains monodentate acetates, the low Δ value of 107 cm^{-1} has been attributed to hydrogen bonding of the uncoordinated carboxylate oxygen atom compensating for the asymmetry produced by the monodentate coordination [22].

The magnetic and spectroscopic data are very similar for all three complexes, strongly supporting our conclusion that they are of the same type as the structurally characterized bis(2-aminoethanol)di(nonanoato)copper(II) species.

Fungicidal activity

Results of screening for fungicidal activity against the wood-rotting fungus *Trametes versicolor* (L. ex Fr.) Pilat are presented in Table 3. The 2-aminoethanol complexes totally inhibit fungal growth at a concentration of 1.0×10^{-3} mol/l but only partially at a concentration of 5.0×10^{-4} mol/l. Fungicidal activity slightly increases with the chain length. The fungicidity of the complexes at 1.0×10^{-4} mol/l as well as the activity of 2-aminoethanol itself could not be determined due to the slight fungitoxic effect of the DMSO solvent, which masks any possible biological activity of other substances at low concentrations.

In order to evaluate the influence of 2-aminoethanol on the fungicidal activity of the studied complexes, a comparison with the activity of copper(II) octanoate, nonanoate and decanoate was performed. At the same Cu(II) concentration of 5.0×10^{-4} mol/l [concentration of binuclear $Cu_2(O_2CR)_4$ is 2.5×10^{-4} mol/l and 5.0×10^{-4} mol/l of mononuclear $Cu(O_2CR)_2(NH_2C_2H_4OH)_2$], the 2-aminoethanol complexes exhibit weaker fungicidal activity. It is well known that fungi require nitrogen for their growth [23] and we believe that the enhanced nitrogen content in the growth medium, originating from 2-aminoethanol, increases the activity of *Trametes versicolor* and its growth rate.

Indeed, Ruddick and Xie [24] showed that enrichment of nitrogen in ammoniacal-copper preservative treated wood enhances wood decay by brown rot fungi, e.g. *Postia placenta* and *Gloeophyllum trabeum*. In contrast to our results, they did not observe utilization of enhanced nitrogen by the white rot fungus *Trametes versicolor*. However, it has to be taken into account that Ruddick and Xie made their experiments with the preserved wood, whilst we were using a much more simple system—that of a solution of the preservatives in PDA growth medium.

(Received 15 May 1997; accepted 21 July 1997)

Abstract—The reaction of the heterobimetallic phosphido- and hydrido-bridged complexes $Cp_2TaH(\mu\text{-}H)(\mu\text{-}PMe_2)M'(CO)_4$ (M′ = Cr, Mo, W) (**1–3**) with phosphines (L = PPh_2Me, PMe_2Ph) or diphosphines (L = dmpm, dmpe) leads to $Cp_2Ta(H)_2(\mu\text{-}PMe_2)M'(CO)_4(L)$ (**1a, 1b, c, d–3b, c, d**) with L regiospecifically coordinated to M′. Except for L = PPh_2Me, the reaction is stereospecific, since a cis arrangement (with respect to the PMe_2 bridge) on the M′ site is obtained. The new compounds $Cp_2Ta(H)_2(\mu\text{-}PMe_2)M'(CO)_4(Me_2P(CH_2)_2PMe_2)$ (M′ = Mo, W) are able to bind $[Cr(CO)_5]$ fragments affording the linear trinuclear chain compounds $Cp_2Ta(H)_2(\mu\text{-}PMe_2)M'(CO)_4(Me_2P(CH_2)_2PMe_2)(Cr(CO)_5)$ (**4, 5**). All new complexes have been fully characterized by NMR and IR spectroscopy, and by their elemental analyses. © 1997 Elsevier Science Ltd

Keywords: tantalum; phosphines; diphosphines; dibridged complexes; polynuclear species.

Considerable interest has focused on the synthesis and chemistry of binuclear complexes containing two different transition metals. In particular, the chemistry of heterometallic compounds stabilized by bridging phosphido groups continues to attract great interest [1–8]. In the course of our works on these systems we have recently described new synthetic routes to μ-PR_2 μ-CO [9–12] and μ-PR_2 μ-H [13,14] dibridged complexes involving group 5 metallophosphines as precursors. These metallophosphines are easily synthesized starting from chlorophosphines and d^2 monohydrido complexes $Cp_2M(H)(L)$ [15–19] or d^0 three hydrido complexes Cp_2MH_3 [13,20,21].

Addition reactions between μ-phosphido μ-carbonyl complexes and phosphines or isonitriles have been studied [10,11]. Described herein is the reactivity of μ-phosphido, μ-hydrido dibridged complexes toward Lewis bases. A synthetic route to linear heterotrinuclear complexes is also presented.

EXPERIMENTAL

All reactions were carried out under an argon atmosphere with use of standard Schlenk techniques. The solvents and eluents were dried and distilled under argon from sodium and benzophenone immediately before use. $Cp_2TaH(\mu\text{-}H)(\mu\text{-}PMe_2)M'(CO)_4$ (M′ = Cr, Mo, W) (**1–3**) were synthesised as previously described [13,14]. $Cr(CO)_5(THF)$ was prepared according to literature procedures [22]. PPh_2Me, PMe_2Ph, dmpm and dmpe (Strem) have been used as received.

Elemental analyses (C, H) were performed by the "Service Central d'Analyse du CNRS" (Gif-sur-Yvette, France). Infrared spectra were recorded on a Nicolet 205 IR-FT. ^1H and ^{31}P NMR spectra were recorded on a Bruker AC 200 spectrometer; chemical shifts are given in ppm relative to Me_4Si (^1H) or (external) H_3PO_4 (^{31}P).

Synthesis of $Cp_2Ta(H)_2(\mu\text{-}PMe_2)M'(CO)_4(L)$ (M' = Cr, Mo, W; L = *phosphine, diphosphine*)

To a THF solution (40 mL) of $Cp_2Ta(H)(\mu\text{-}H)(\mu\text{-}PMe_2)M'(CO)_4$ (0.5 mmol) was added one equivalent of the Lewis base L. The reaction mixture was heated at 45°C for 2 h. The solvent was removed, and the product was washed with 3 × 20 mL of pentane and dried under vacuum. The analytical samples were obtained by recrystallization from acetone as yellow solids. Yields 75–80%.

Synthesis of $Cp_2Ta(H_2)(\mu\text{-}PMe_2)M'(CO)_4(dmpe)Cr(CO)_5$ (M' = Mo, W)

To a THF solution (30 mL) of $Cp_2Ta(H)_2(\mu\text{-}PMe_2)M'(CO)_4(dmpe)$ (0.5 mmol) was added one equivalent of $Cr(CO)_5(THF)$. The reaction mixture was stirred for 20 min at room temperature (the reaction was monitored by IR spectroscopy). The solvent was removed, and the product was washed with 3 × 20 mL of pentane and dried under vacuum affording an orange product. The analytical samples were obtained by recrystallization from acetone—yields 65–70%.

$Cp_2Ta(H_2)(\mu\text{-}PMe_2)Mo(CO)_4(dmpe)(Cr(CO)_5)$ (**4**). ^1H NMR (CD_3COCD_3) δ 5.54 (s, Cp), 1.64 (d, J = 5.1 Hz, Me), 1.63 (d, J = 7.8 Hz, Me), 1.54 (d, J = 6.0 Hz, Me), 0.40 (d, $J_{P\text{-}H}$ = 56 Hz, H), 2.07–2.30 (m, CH_2). ^{31}P $\{^1H\}$ NMR (CD_3COCD_3) δ −103.7 (d, J = 25 Hz, μ-PMe_2), 0.8 (t, J = 25 Hz, Mo-PMe_2), 21.2 (d, J = 25 Hz, PMe_2-Cr). IR (THF): ν(CO) 2060 (m), 1999 (m), 1936 (vs), 1891 (s), 1877 (s), 1847 (s) cm^{-1}. Found: C, 35.52; H, 3.87. Calc. for $C_{27}H_{34}CrMoO_9P_3Ta$: C, 35.08; H, 3.71%.

$Cp_2Ta(H_2)(\mu\text{-}PMe_2)W(CO)_4(dmpe)(Cr(CO)_5)$ (**5**). ^1H NMR (CD_3COCD_3) δ 5.56 (s, Cp), 1.79 (d, J = 5.0 Hz, Me), 1.67 (d, J = 6.8 Hz, Me), 1.63 (d, J = 7.8 Hz, Me), 0.66 (d, $J_{P\text{-}H}$ = 56 Hz, H), 2.03–2.36 (m, CH_2). ^{31}P $\{^1H\}$ NMR (CD_3COCD_3) δ −126.8 (d, J = 25 Hz, $J_{P\text{-}W}$ = 176 Hz, μ-PMe_2), 14.2 (t, J = 25 Hz, W-PMe_2), 21.0 (d, J = 25 Hz, PMe_2-Cr). IR (THF): ν(CO) 2060 (m), 1994 (m), 1935 (vs), 1883 (s), 1868 (s), 1842 (s) cm^{-1}. Found: C, 32.29; H, 3.59. Calc. for $C_{27}H_{34}CrO_9P_3TaW$: C, 32.04; H, 3.39%.

RESULTS AND DISCUSSION

Synthesis of dibridged complexes **1–3**

The trihydride Cp_2TaH_3 easily reacts with PMe_2Cl in toluene at room temperature affording the phosphine salt $[Cp_2Ta(H_2)(PMe_2H)]^+Cl^-$ which is deprotonated in aqueous KOH. The resulting metallophosphine $Cp_2Ta(H)(PMe_2H)$ is able to bind metal tetracarbonyl fragments $M'(CO)_4L_2$ (M' = Cr; L_2 = NBD—M' = Mo, W; L = piperidine) leading to the μ-phosphido μ-hydrido dibridged complexes **1–3** (Scheme 1) [13,14].

"Open" structures (**1a, 1b,c,d–3b,c,d**)

The dibridged μ-phosphido μ-hydrido complexes $Cp_2TaH(\mu\text{-}H)(\mu\text{-}PMe_2)M'(CO)_4$ (M' = Cr, Mo, W) (**1–3**) react at 45°C for 2 h with phosphines or diphosphines L (L = PMe_2Ph, PPh_2Me, $Me_2P(CH_2)PMe_2$ (dmpm) or $Me_2P(CH_2)_2PMe_2$ (dmpe)), in THF solution, leading to "open" structures $Cp_2Ta(H)(\mu\text{-}PMe_2)M'(CO)_4(L)$ (**1a, 1b,c,d–3b,c,d**) (Scheme 2). Experimental details and spectroscopic data for all complexes are given in the Experimental section.

The addition of L is regiospecific and can lead to cis or trans arrangements at the M' site. Bonding of phosphines or diphosphines to M' rather than to the tantalum site is clearly evidenced by the hydride resonance signal which appears as a single doublet (2H) in the range 0.30–0.70 ppm. When opposed to PPh_2Me complex **1** leads to a mixture of cis and trans "open" structures **1a** with a slight excess of the cis isomers (70%). In contrast, stereospecific addition in the cis position is observed with PMe_2Ph, dmpm and dmpe, whatever the nature of M'. It is worth noting that no addition reaction occurs with the bulky PPh_3. These results illustrate the dependence of the coordination site on the bulk of incoming ligands [23,24] and are in accordance with our previous studies concerning the dibridged μ-PR_2 μ-CO complexes [10,11].

Complexes **1b,c,d–3b,c,d** show four ν(CO) stretching vibrations indicating the cis position of the two phosphorus atoms around the M' metal. The ^1H NMR data are able to provide information on the selectivity of the addition at the M' site but cannot show whether a cis or a trans configuration arrangement is formed. However, for **1a**, a decisive con-

figurationnal assignment is available from ^{31}P NMR chemical shifts since a trans configuration involves a systematic deshielding of the two phosphorus resonances ($\Delta\delta \approx 20$ ppm for **1a**) [25,26]. The ^{31}P NMR spectra reveals dramatic effects upon the breaking of the hydrido bridge: the μ-PMe_2 ^{31}P resonance is shifted upfield ($\Delta\delta \approx -120$ to -140 ppm) with respect to the parent complexes **1–3**, indicating the large increase of the Ta-PMe_2-M′ angle [27]. With dmpm or dmpe, the ^{31}P NMR data confirm the presence of a dangling phosphorus atom since two distinct resonances are observed: a downfield doublet assigned to the metal-bonded phosphorus atom, and a more shielded signal for the uncoordinated PMe_2 group whose chemical shift is very close to that of the free phosphine.

Linear trinuclear chain compounds (**4,5**)

Treatment of complexes $Cp_2Ta(H)_2(\mu\text{-}PMe_2)M'(CO)_4$(dmpe) (M′ = Mo, W) (**2c, 3c**) with $Cr(CO)_5$(THF), at room temperature, afford the expected trinuclear chain compounds **4** and **5** (Scheme 3). Structures of **4** and **5** are established from their spectra. In particular, the ^{31}P NMR data are very informative: the doublet resonance of the terminal PMe_2 is shifted downfield upon coordination of the fragment $[Cr(CO)_5]$ ($\Delta\delta \approx 65$ ppm).

An unexpected behaviour is observed with dmpm derivatives (**2d, 3d**) since no trimetallic structure is formed when opposed to $Cr(CO)_5$(THF). Both steric and electronic considerations can be advanced to account for the lack of reactivity of these complexes. A critical distance between the two phosphorus coordination sites should be required for minimizing the severe steric hindrance of the two metal carbonyl entities. In addition, as previously reported by Angelici *et al.* [28,29] monocomplexation by a Lewis acid organometallic fragment on a bidentate phosphine could greatly affect the basicity of the pendant phosphorus atom.

In conclusion, addition of Lewis bases to μ-phosphido μ-hydrido dibridged complexes (**1, 2, 3**) is regiospecific on the metal M′ and leads to a cis arrangement with respect to the phosphido bridge—except for the bulky PPh_2Me. The free phosphorus of the "open" structure $Cp_2Ta(H)_2(\mu\text{-}PMe_2)M'(CO)_4$(dmpe) (M′ = Mo, W) (**2c, 3c**) binds the metal carbonyl fragment $[Cr(CO)_5]$ to form new linear trimetallic complexes.

(Received 27 February 1997; accepted 21 July 1997)

Abstract—Treatment of *cis*-[Pt(L-*S,O*)$_2$] in $CDCl_3$ solution, directly in an NMR tube with concentrated mineral acid HX and/or HY (X = Cl^-, Y = Br^-), leads to the reversible protonation of the co-ordinated ligand of these complexes across the aqueous-organic phase boundary; these processes have been followed by means of ^{195}Pt and ^{1}H NMR. Treatment with HCl yields a mixture of *cis*- and *trans*-[Pt(HL-*S*)$_2$Cl$_2$] species, in addition to the partially-ring-opened [Pt(L^n-*S,O*)(HL^n-*S*)Cl] complex in solution, the *cis*-[Pt(HL-*S*)$_2$Cl$_2$] complex predominating in solution at steady-state. These species are rapidly and reversibly converted back to only the *cis*-[Pt(L-*S,O*)$_2$] complex on washing of the $CDCl_3$ solution with aqueous ammonia. Similar observations pertain to protonation by HBr, yielding the corresponding bromo complexes; treatment of *cis*-[Pt(L-*S,O*)$_2$] in $CDCl_3$ with a mixture of HCl and HBr, leads to the formation of mixed-halide species of *cis*- and *trans*-[Pt(HL-*S*)$_2$XY] in addition to the [Pt(HL-*S*)$_2$X$_2$] and [Pt(HL-*S*)$_2$Y$_2$] as well as the partially-ring-opened [Pt(L^n-*S,O*)(HL^n-*S*)X/Y] complexes in solution, which revert to *cis*-[Pt(L-*S,O*)$_2$] on treatment with aqueous base. These observations clearly have important consequences in the use of *N*-acyl-*N'N'*-dialkylthioureas for the solvent extraction of the platinum metals. © 1997 Elsevier Science Ltd

Keywords: *N*-benzoyl-*N'*,*N'*-dialkylthiourea; platinum(II) complexes; ^{195}Pt NMR; isomerism; protonation.

The ligands *N*-acyl-*N'*-alkyl- (**H$_2$L**) and *N*-acyl-*N'*,*N'*-dialkylthioureas (**HL**) have attracted attention in view of their selective co-ordination particularly of the 'softer' 2nd and 3rd row transition metals. In this context the pioneering work of Beyer *et al.* should be mentioned, in view of the use of *N*-acylthiourea ligands for the solvent extraction of transition metal ions [1]. The selective co-ordination of these ligands to the platinum group metals (PGMs) is particularly noteworthy as this allows for the efficient extraction and pre-concentration of the PGMs [2], as well as the analytical separation of traces of these metals by chromatographic means, notably HPTLC [3].

We have become interested in targeted ligand design incorporating the *N*-acylthiourea functional group as central motif, exploiting the ease of synthesis of these types of molecules to prepare a variety of new ligands with potential applications in the extractive metallurgy of the platinum metals. Consequently we have studied the deceptively simple co-ordination of ligands of type (**H$_2$L**) and (**HL**) to Pt(II), finding the binding of **H$_2$L** to be controlled by an intramolecular H-bond, resulting in essentially monodentate co-ordination of the ligand through the S-atom, yielding mixtures of *cis*- and *trans*-[Pt(H$_2$L-*S*)$_2$Cl$_2$] complexes [4]. By contrast, ligands of type **HL** react with $PtCl_4^{2-}$ in a neutral aqueous solution to form predominantly *cis*-[Pt(L-*S,O*)$_2$] complexes [5]. Recent studies by Sadler *et al.* on the co-ordination of L-methionine to $PtCl_4^{2-}$, have shown an interesting example of the reversible interconversion of bidentate *N,S* to monodentate *S* co-ordination of L-methionine to Pt(II), depending on the solution pH [6]. This work, as well as the negative effects of the presence of mineral acids which we observed on the attempted chromatographic separation of the platinum metals using *N*-acyl-*N'*,*N'*-dialkylthioureas as selective ligands, have prompted us to undertake an investigation of the effect of protonation of the *S,O*-bound *N*-benzoyl-*N'*,*N'*-dial-

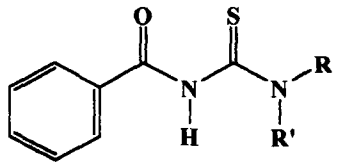
H_2L



HL

kylthiourea ligand in complexes such as *cis*-[Pt(L-*S*,*O*)$_2$], with a view to establishing the nature of the resulting species in solution.

We show here that protonation of the co-ordinated ligand in *cis*-[Pt(L-*S*,*O*)$_2$] complexes in chloroform solution, with HCl or HBr, leads to the reversible opening of the 6-membered *S*-*O* chelate ring, with concomitant co-ordination of the Cl^- and/or Br^- ion to the Pt(II) atom, resulting in the *O*-donor atom of the **HL** ligand being pendant. In this contribution, we shall focus on the platinum complexes with the ligands *N*-benzoyl-*N'*,*N'*-di(*n*-butyl)thiourea (**HL**^{1}), *N*-(4Br-phenyl)-*N'*,*N'*-di(*n*-butyl)thiourea (**HL**^{2}), and *N*-(4NO_2-phenyl)-*N'*,*N'*-di(*n*-butyl)thiourea (**HL**^{3}) only.

EXPERIMENTAL

Preparation of ligands and cis-[Pt(L^1-*S*,*O*)$_2$] *complexes*

All ligands (**HL**^{1})–(**HL**^{3}) were prepared as previously described [5], and were satisfactorily characterized by means of C, H and N elemental analysis, and mass spectroscopy, as well as ^{1}H and ^{13}C NMR spectroscopy. The neutral complexes *cis*-[Pt(L^1-*S*,*O*)$_2$] (**I**), *cis*-[Pt(L^2-*S*,*O*)$_2$] (**II**) and *cis*-[Pt(L^3-*S*,*O*)$_2$] (**III**) were also prepared and characterized as previously described [5,7].

Preparation of bis(N-benzoyl-N'-propylthiourea)dichloroplatinum(II)

This complex was prepared and fully characterized as described previously, $C_{22}H_{28}Cl_2N_4O_2PtS_2$ requires C, 37.19; H, 3.97; N, 7.88%; Found C, 37.16; H, 4.0; N, 7.90% [4].

Preparation of bis(N-benzoyl-N'-propylthiourea)dibromoplatinum(II)

This complex was prepared by the same procedure as the corresponding *dichloro* complex, except that the $PtCl_4^{2-}$ was converted *in situ* to the corresponding $PtBr_4^{2-}$ by treatment with excess NaBr and 0.1 M HBr, prior to ligand addition. The complex was recrystallized from a chloroform–ethanol mixture, resulting in orange crystals in *ca* 75% yield, which are clearly a mixture of the *cis*- and *trans*-[Pt(H_2L-*S*)$_2$$Br_2$] complexes, as shown by the two distinct melting points at 162–164 and 174–178°C. (This isomerization is confirmed by the NMR spectra shown in Table 1 below.) $C_{22}H_{28}Br_2N_4O_2PtS_2$ requires C, 33.05; H, 3.53; N, 7.01%; Found C, 33.3; H, 3.53; N, 6.95%.

NMR spectroscopy

^{1}H and ^{195}Pt NMR spectra were recorded in 5 mm tubes in $CDCl_3$ solution, using a Varian UNITY-400 spectrometer operating at 400 and 85.8 MHz respectively (^{1}H, spectra at 25°C and ^{195}Pt at 30°C). The ^{195}Pt NMR spectra were recorded using 100 kHz spectral widths with 20 μs pulses ($\sim$90°) with 0.5 s pulse delay, since the T_1 of the ^{195}Pt nucleus was $<$0.1 s; between 2048 and 16,000 pulses gave excellent spectra for typical concentrations of the complex between 40–80 mg ml^{-1}. All ^{195}Pt shifts are quoted relative to external H_2PtCl_6 (500 mg ml^{-1} in 30% v/v D_2O/1 M HCl) at 30°C and are estimated to be accurate to $\pm$4 ppm.

Protonation experiments

Aliquots of 100 μL concentrated mineral acid (HX; X = Cl^-, Br^-) were directly added to the NMR tube containing 0.6 mL pale yellow solutions of *cis*-[Pt(L''-*S*,*O*)$_2$] complex in $CDCl_3$. After vigorous shaking the phases were allowed to separate, which was complete after *ca* 5 min; where necessary, the distinctly darker yellow/orange organic phase was filtered through microfibre glass-wool, resulting in a clear solution, prior to NMR spectroscopy. After spectral acquisition, the mineral acid was removed, the $CDCl_3$ solution washed with water and/or ammonia solution, filtered and followed by re-acquisition of the spectrum.

RESULTS AND DISCUSSION

The ^{195}Pt spectra of the uncharged complexes *cis*-[Pt(L''-*S*,*O*)$_2$], **I**–**III** in $CDCl_3$ solution, show only a single, relatively sharp, resonance at $\delta(^{195}Pt) = -2727$, -2719 and -2688 ppm respectively. The corresponding ^{1}H NMR spectra are all

consistent with only a single unprotonated complex species in solution, as confirmed by the *absence* of the characteristic amido N–H resonance in the 10–12 ppm range; the full, detailed ^{1}H assignments are trivial and will not be given here.

Addition of 100 μL *conc.* HCl directly to the NMR tube containing **I** in $CDCl_3$ as described in the experimental section, yields a ^{1}H spectrum (acquired within 10 min of adding the HCl) showing the presence of at least three species, characterized by N–H resonances at 10.79 (6.6%), 11.14 (83.7%) and 11.27 (9.6%) ppm (relative intensities given in parentheses). These N–H resonances clearly indicate the protonation of the coordinated ligands by some HCl partitioned into the $CDCl_3$ phase. The corresponding ^{195}Pt spectrum of this solution (obtained within an acquisition time of *ca* 3 h) consists of only two ^{195}Pt resonances at $\delta = -3034$ (rel. int. 22%) and −3218 ppm (78%). After 4 h, the corresponding ^{1}H spectrum also shows only two resonances at 10.79 (10%) and 11.14 (90%) ppm, while the ^{195}Pt spectrum of this solution remains essentially unchanged. Thus the transient appearance of the ^{1}H resonance at 11.27 ppm, suggests a time dependent process in solution, which appears only to reach a steady-state after several hours.

The time dependence of these processes are well illustrated by the ^{1}H NMR spectra acquired as a function of time as a solution of **I** in $CDCl_3$ which has been treated with 50% *diluted* HCl (1+1, *conc.* HCl+water, v/v) as shown in Fig. 1(a). These spectra show the initial appearance of only two N–H resonances at 11.27 and 11.14 ppm, both of which slowly grow in intensity at differing relative rates over a 5 h period. Some 3.5 h after the addition of the 50% HCl, a new peak at 10.79 ppm appears in the spectrum, growing in intensity. Removal of the 50% HCl after *ca* 5 h and substitution by 100 μL *conc.* HCl, followed by spectral acquisition in the same way as before, leads to ^{1}H spectra as illustrated in Fig. 1(b). Evidently the resonance at 11.27 ppm disappears relatively rapidly, while the peaks at 11.14 and 10.79 ppm continue to grow in intensity reaching steady-state after *ca* 10 h; the ^{1}H spectral acquisition was arbitrarily terminated after *ca* 11 h. The ^{195}Pt NMR spectrum of this solution acquired immediately after this time shows only two resonances at $\delta(^{195}Pt) = -3034$ and −3218 ppm corresponding exactly to the case described above, in which *conc.* HCl was used from the start. After *ca* 24 h re-acquisition of both ^{1}H and ^{195}Pt NMR spectra confirm that only these two complex species exist in solution at steady-state.

In general, the appearance of the ^{195}Pt and ^{1}H NMR spectra for **II** and **III** obtained after addition of the *conc.* HCl show similar trends as illustrated for **I**, although the actual time-resonance intensity dependencies are somewhat different for each case. Significantly by sampling the ^{195}Pt NMR spectrum at the appropriate times after treatment with *conc.* HCl, it becomes possible to detect at least *four* species in solution, as illustrated for the protonation of **III**, for which we obtain a ^{195}Pt spectrum consisting of four peaks at −2688 (9%), −2938 (53%), −3029 (3%) and −3213 (33%) ppm, 4 h after addition of HCl to the NMR tube. After 24 h standing, followed by re-acquisition of the ^{195}Pt spectrum for the same solution the resulting spectrum shows resonances only at −2938 (30%), −3029 (2%) and −3213 (68%) ppm, the peak at −2688 ppm, corresponding to the starting *cis*-[Pt(L^{3}-*S*,*O*)$_2$] having disappeared; after 48 h the ^{195}Pt spectrum at steady state shows the same peaks at −2938 (17%), −3029 (9%) and −3213 (74%) ppm respectively with different relative intensities, Fig. 2. Evidently the species with $\delta(^{195}Pt) = -2938$ ppm is slowly converting into the species at −3029 and −3213 ppm. Similar observations can be made for the complexes **I** and **II**, where the ^{195}Pt resonance at

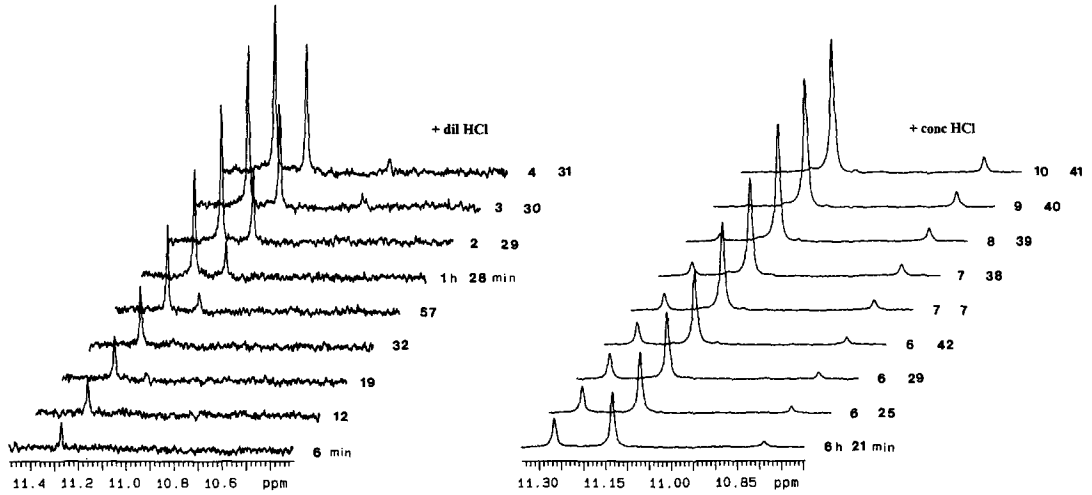

Fig. 1. (a) Partial ^{1}H NMR spectra of *cis*-[Pt(L^1-*S*,*O*)$_2$] in $CDCl_3$ acquired as a function of time after addition of dilute HCl (50% v/v *conc.* HCl+H_2O (acid addition at $t = 0$ min)). (b) solution (a) to which *conc.* HCl has been added after *ca* 6 h 4 min after removal of dilute HCl.

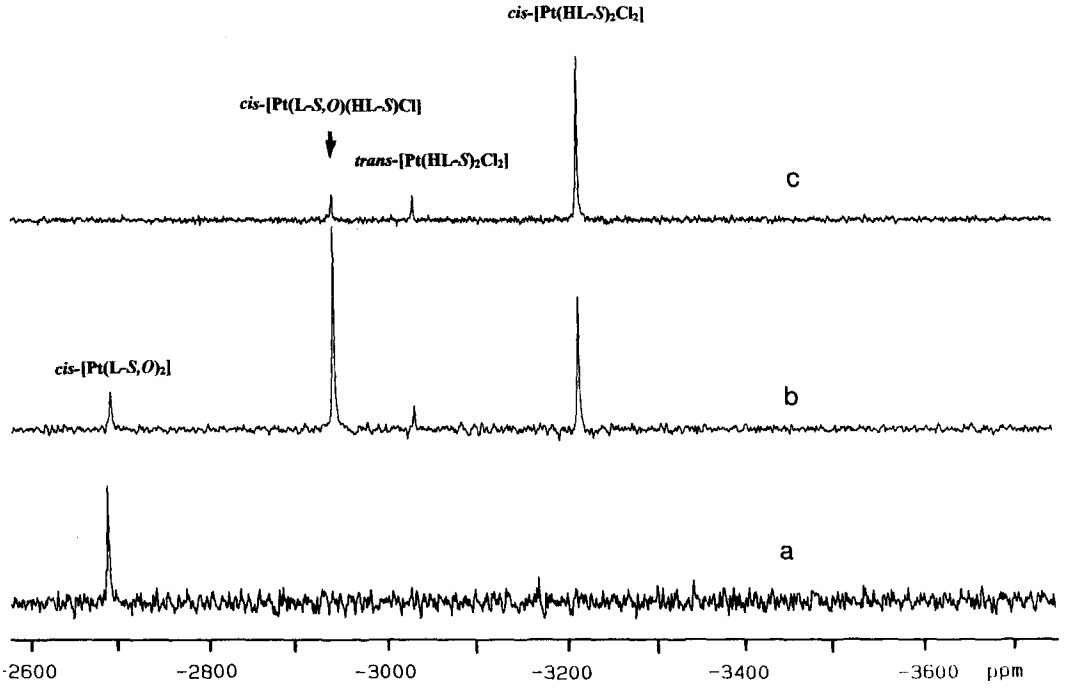

Fig. 2. ^{195}Pt NMR spectrum of (a) *cis*-[Pt(L^3-*S*,*O*)$_2$] in $CDCl_3$ after an acquisition time *ca* 30 min. (b) solution (a) to which *conc.* HCl has been added after *ca* 4 h acquisition time; (c) solution (b) after 48 h standing at room temperature followed by re-acquisition.

−2938 ppm for **III**, corresponds to similar peaks at −2968 and −2959 ppm for complexes **I** and **II**, respectively.

Removal of the excess mineral acid directly from the NMR tube containing the $CDCl_3$ solutions of complexes **I, II** and **III**, followed by *in situ* washing of the $CDCl_3$ phase with a small volume of 5 M ammonia, results in ^{195}Pt and ^{1}H spectra which are identical to those of the pure uncharged *cis*-[Pt(L^n-*S*,*O*)$_2$] complexes, there being no spectroscopic evidence for any other complex species in solution. It is significant to note that the ^{1}H spectra recorded immediately after washing with the ammonia solution are indistinguishable from those of the pure *cis*-[Pt(L^n-

$S,O)_2$] complexes, *within the time needed to record the* ^{1}H *spectrum* (*ca* 10 min). Evidently the effect of deprotonation of the various complex species in solution is qualitatively much more rapidly reversible, relative to the much slower changes induced by protonation with concentrated or diluted HCl.

Consideration of the ^{195}Pt and ^{1}H NMR spectra obtained by addition of HCl to $CDCl_3$ solutions of **I–III,** together with the well known sensitivity of the ^{195}Pt chemical shifts to changes in the co-ordination sphere of the metal [8], suggest that protonation of the bound ligand in the presence of co-ordinating Cl^- anions, leads to ring opening of the *S,O*-chelate such that the *N*-acyl-*N'N'*-dialkylthiourea ligand remains bound to Pt through the S-atom only. The O-atom of the ligand is thus displaced from the co-ordination sphere of the Pt(II) atom, the amido moiety of the S-atom bound ligand becoming pendant. Convincing support for this assignment is obtained from the ^{195}Pt spectrum of an *authentic* mixture of *cis-* and *trans*-bis(*N*-benzoyl-*N'*-propylthioureato)dichloroplatinum(II) in $CDCl_3$, which shows only ^{195}Pt resonances at -3219 and -3040 ppm respectively. The resonance at -3219 ppm has been shown to be due to the *cis*-bis(*N*-benzoyl-*N'*-propylthioureato)dichloroplatinum(II) complex, which has been characterized by means of x-ray crystallography [4]. Hence in the case of the protonation of **I–III** with HCl, we assign the resonances at *ca* -3220 ppm to the *cis*-[Pt(HL^n-*S*)$_2$Cl$_2$] complexes, while the smaller peaks which develop over time at *ca* -3030 ppm correspond to the *trans* isomers, which result from the isomerization of the *cis* species. Moreover, these assignments are consistent with the generally observed trend that, for complexes of type [PtA_2X_2], the *cis* isomer is usually more shielded by typically 200–500 ppm for X = Cl^-, depending on the nature of the donor atom of the ligand A [8]. Our assignment of the ^{195}Pt peak at *ca* -3029 ppm (corresponding to the 10.79 ppm ^{1}H peak, which is ultimately present in all concentrated acid treated solutions of **I–III**), to the *trans*-[Pt(HL^n-*S*)$_2$Cl$_2$] isomer, is also consistent with the work of Castan *et al.* who reported similar ^{195}Pt shift trends for simple *cis*/*trans*-[PtL_2X_2] complexes in DMSO-d_6 solution (where L = unsubstituted monodentate, S-atom bound thiourea and X = Cl^- and Br^-) [9].

Treatment of solutions of **I–III** in $CDCl_3$ with *conc.* HBr gives rise to quite different ^{195}Pt spectra, as may be anticipated by replacement of the co-ordinated Cl^- ion by a Br^- ion. This is illustrated for the case of **I,** for which a ^{195}Pt NMR spectrum consisting of only two resonances at -3609 (29%) and -3630 (71%) ppm, is obtained at steady-state, after treatment with HBr. The corresponding ^{1}H spectrum shows only two species with N–H resonances at 10.48 (28%) and 10.72 (72%) ppm respectively. Re-acquisition of the ^{195}Pt NMR spectrum after keeping the solution at room temperature for 24 h results in an identical spectrum; a careful search for any other ^{195}Pt resonances both ± 2500 ppm upfield and downfield of these shifts shows no additional resonances. Very similar ^{195}Pt spectra are obtained for complexes **II** and **III,** for which the corresponding ^{195}Pt peaks occur at -3606, -3624, and -3605, -3626 ppm respectively. These resonances are thus assigned to the *trans*-[Pt(HL^n-*S*)$_2$Br$_2$] and *cis*-[Pt(HL^n-*S*)$_2$Br$_2$] complexes respectively, where the much smaller shift differences between the bromo as compared with the chloro complexes is consistent with the generally observed trends for related complexes [8]. Final confirmation of these assignments is obtained from the comparison of the chemical shifts of an authentic mixture of *trans-* and *cis*-[Pt(H_2L-*S*)$_2$Br$_2$] (H_2L = *N*-benzoyl-*N'*-propylthiourea) in $CDCl_3$. The ^{195}Pt NMR spectrum of this mixture shows resonances at -3678 and -3697 ppm (Table 1), in which the resonance at a slightly higher field is assigned to the *cis* complex; the corresponding amido N–H resonances for *cis*-[Pt(H_2L-*S*)$_2$Br$_2$] appear at 11.49 and that for the *trans* complex at 11.31 ppm in the ^{1}H NMR spectrum respectively [10].

Removal of the excess HBr from the NMR tube containing complexes **I–III,** followed by washing of the $CDCl_3$ solution with 5 M aqueous ammonia solution, results again in single resonance ^{195}Pt NMR spectra, identical to those of the pure complexes **I–III.** These observations convincingly demonstrate the reversible, *S,O*-chelate ring opening on protonation of the amido-N atom of the co-ordinated ligand, with concomitant halide ion co-ordination to Pt(II).

Very interesting ^{195}Pt spectra are obtained when solutions of *cis*-[Pt(L^n-*S,O*)$_2$] are treated with mixtures of *conc.* HCl and HBr. As may be reasonably expected, if the above assignments are correct, it should be possible to observe in solution under appropriate conditions, the mixed-halide complexes of type [Pt(HL^n-*S*)$_2$XY], in addition to species such as [Pt(HL^n-*S*)$_2$X$_2$] and [Pt(HL^n-*S*)$_2$Y$_2$] (where X = Cl^-; Y = Br^-). This expectation is confirmed as shown in Fig. 3, for the complex **II** in $CDCl_3$ treated with 100 μL of a mixture of *conc.* HCl + HBr (0.7 + 0.3 v/v); the resulting ^{195}Pt spectrum consists of nine well defined resonances in the -2700 to -3700 ppm range. Apart from the residual peak at -2719 ppm, which is clearly due to a small amount of unchanged **II,** six of the remaining eight resonances may consistently be assigned to the four possible mononuclear, *cis-* and *trans*-dichloro- and dibromo-complexes, together with the two possible *cis-* and *trans*-[Pt(HL^2-*S*)$_2$XY] mixed-halide complexes (Table 1). The relative proportions of HCl to HBr in the acid mixture used in these experiments, determine the distribution of complex species as obtained in the ^{195}Pt spectra, so that if HBr is present in excess, the resulting spectrum resembles that obtained with pure HBr only. This is understandable in terms of the greater binding affinity of the Br^- ion to the Pt(II) atom with respect to that of the Cl^- anion. In general the ^{1}H NMR spectra are consistent with these assignments, although these become rather complicated due to extensive peak

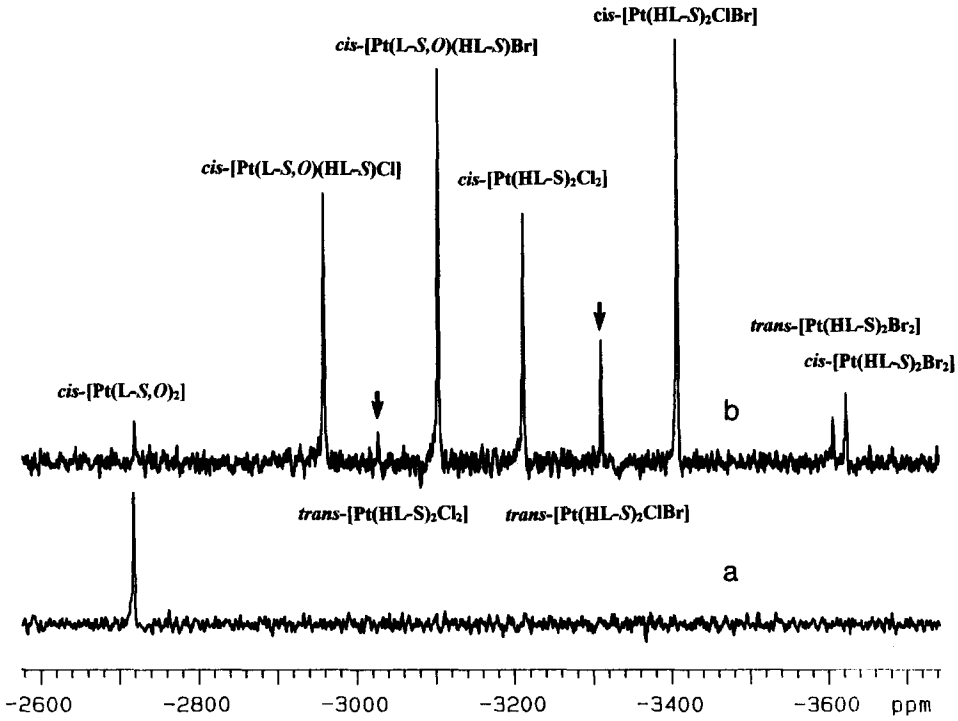

Fig. 3. ^{195}Pt NMR spectrum of (a) a fresh solution of *cis*-[Pt(L^2-*S*,*O*)$_2$] in $CDCl_3$; (b) after addition of a mixture of *conc* HCl + HBr (see text) followed by a 12 h spectral acquisition time.

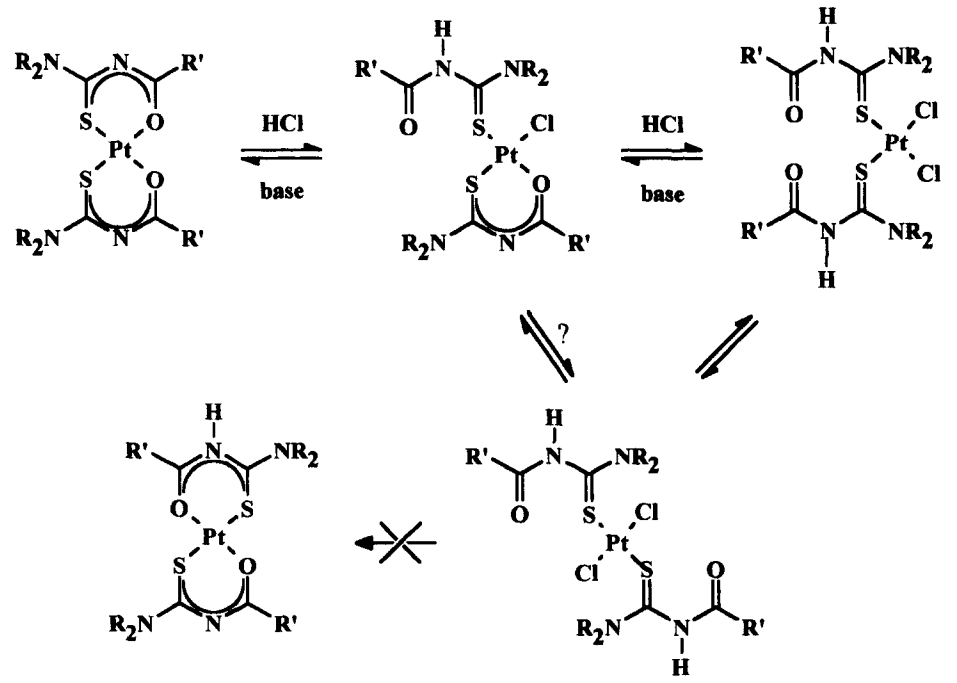

Fig. 4. Schematic representation of the effects of addition of *conc.* HCl to solutions of *cis*-[Pt(L^n-*S*,*O*)$_2$] complexes (n = 1-3) in $CDCl_3$.

overlap. Remarkably, on washing the mixed-acid treated solution of **II** in $CDCl_3$ with 5 M ammonia solution, one again obtains only the simple single line ^{195}Pt spectrum (−2719 ppm) of the parent *cis*-[Pt(L^2-*S*,*O*)$_2$] complex. Similar spectra are obtained for complexes **I** and **III**.

Finally, the two ^{195}Pt resonances at −2959 and −3104 ppm in the spectrum of **II** treated with the mixture of HCl and HBr, shown in Fig. 3(b) are assigned to the partially-ring-opened complex *cis*-[Pt(L^2-*S*,*O*)[HL^2-*S*)Cl] and *cis*-[Pt(L^2-*S*,*O*)(HL^2-*S*)Br] respectively. The ^{195}Pt peak at −2959 ppm (assigned to *cis*-[Pt(L^2-*S*,*O*)(HL^2-*S*)Cl]) corresponds to similar ^{195}Pt resonances in the range −2938 to −2968 ppm, which appear in the spectra of $CDCl_3$ solutions on treatment of **I–III** with only HCl, as described above. In the case of the HCl treated solutions of **I–III**, these ^{195}Pt resonances show a more marked time dependence, and correspond to the species giving rise to a peak at *ca* 11.27 ppm in the ^{1}H spectrum shortly after the addition of HCl to the fresh solutions of **I–III**, (Fig. 1(a)). In any event, the ^{195}Pt resonances in the −2938 to −2968 ppm range are assigned to the partially-ring-opened *cis*-[Pt(L″-*S*,*O*)(HL″-*S*)Cl] complexes. Evidently these *cis*-[Pt(L″-*S*,*O*)(HL″-*S*)Cl] complexes are relatively reactive, since in the presence of excess *conc.* HCl, this species eventually disappears fairly rapidly from the spectrum, it clearly becoming protonated to yield the *cis*-[Pt(HL″-*S*)$_2$Cl$_2$] complex, which in turn, isomerizes slowly to the *trans* isomer. Table 1 summarizes the full ^{195}Pt assignments for all complexes in this study.

There are two interesting aspects of the chemistry of this system, (i) the apparently rapid chelate ring closure of the *S*,*O*-chelate ring following de-protonation of the *S*-atom co-ordinated ligand and (ii) the fact that no evidence for the formation of a *trans*-[Pt(L″-*S*,*O*)$_2$] complex could be found despite several attempts to do so.

In respect to the first-mentioned observation, it is clear that de-protonation of a pendant *S*-atom co-ordinated ligand results in the carbonyl donor atom of the amido moiety becoming substantially more nucleophilic toward the Pt(II) atom, presumably as a result of the conversion of the carbonyl to a more highly charged O^- tautomeric form. The more nucleophilic pendant O^- donor atom of the co-ordinated ligand is likely to be held in a sterically favourable position within the co-ordination sphere of the Pt(II) atom, resulting in rapid closure of the *S*,*O*-chelate ring followed by concomitant expulsion of the halide ion from the co-ordination sphere of the metal ion. We envisage a concerted process taking place *via* a 5-co-ordinate trigonal–bipyramidal transition state, consistent with the generally observed associative nature of substitution reactions in square planar d^8 metals ions. As regards the second point, and particularly in view of our recent characterization of the first example of *trans*-bis(*N*,*N*-di-*n*-butyl-*N*′-naphthoylthioureato)platinum(II) [11], it is indeed interesting and somewhat surprising that no *trans*-[Pt(L″-*S*,*O*)$_2$] complex appears to be formed for the *N*-benzoyl substituted ligands studied in this work. This despite the demonstrated existence of *trans*-[Pt(HL″-*S*)$_2$XY], *trans*-[Pt(HL″-*S*)$_2$X$_2$] and *trans*-[Pt(HL″-*S*)$_2$Y$_2$] complexes (X = Cl^-; Y = Br^-) in solution prior to washing the $CDCl_3$ solution with ammonia; it is not unreasonable to expect ring closure to yield at least some *trans*-[Pt(L″-*S*,*O*)$_2$] complex. Evidently de-protonation of the ligand results in any *trans S*-co-ordinated species undergoing rapid isomerism during, or prior to, the *S*,*O*-chelate ring closure within the time scale of the NMR spectroscopic experiment, so yielding exclusively the thermodynamically favoured *cis*-[Pt(L″-*S*,*O*)$_2$] complexes. It is tempting to speculate that for the case of *trans*-bis(*N*,*N*-di-*n*-butyl-*N*′-naphthoylthioureato)platinum(II) [11], the steric demands of the *N*-naphthoyl moiety may play a role, particularly in view of a postulated 5-co-ordinate transition state, in which steric crowding may well lead to some *trans*-[Pt(L-*S*,*O*)$_2$] being formed. Finally the possibility of a photochemically induced *cis*/*trans* isomerism of the [Pt(L-*S*,*O*)$_2$] species cannot be ruled out at this stage, in view of experimental evidence for such isomerization in related systems [12]. Studies aimed at elucidating these questions are underway.

In conclusion, it is clear from this multinuclear NMR study, that treatment of complexes **I–III** in $CDCl_3$ with aqueous HCl results in reversible protonation with concomitant halide ion co-ordination across the phase boundary, the extent of which, and the rates of formation of the various species in the $CDCl_3$ solution, depends on the *effective* HCl concentration in the $CDCl_3$ phase. In view of the two phase nature of these protonation experiments, as well as the variable ^{1}H and ^{195}Pt spectral acquisition times, it is not meaningful to quantitatively estimate relative rates for the observed species formation on protonation; nevertheless our study shows qualitatively that the relative rates of protonation induced halide ion co-ordination of complexes **I–III** in $CDCl_3$ are substantially slower than the de-protonation induced *S*,*O*-chelate formation in these Pt(II) complexes. Moreover, subsequent washing of previously acid treated solutions of **I–III** with 5 M ammonia, results in the formation of exclusively the *cis*-[Pt(L″-*S*,*O*)$_2$] complexes. This implies that relatively rapid isomerization of any *trans*-[Pt(HL″-*S*)$_2$Cl$_2$] must occur on de-protonation and/or ring closure. These observations are summarized in a diagram for the addition of *conc.* HCl to solutions of *cis*-[Pt(L″-*S*,*O*)$_2$] in Fig. 4.

Such processes clearly have profound synthetic and mechanistic implications in the practical utilization of these ligands for the potential solvent extraction [2], and/or chromatographic separations [3] of the PGMs.

Correlation of ^{95}Mo NMR chemical shifts, electronic absorption bands, and solvent donor numbers for some dimeric $Mo_2(O_2CR)_4L_2$ solvent adducts

Elmer C. Alyea* and José Campo

Department of Chemistry and Biochemistry, University of Guelph, Guelph, Ontario, Canada N1G 2W1

(Received 2 June 1997; accepted 15 July 1997)

Abstract—The ^{95}Mo NMR chemical shifts are reported for two series of solvent adducts of the dimeric molybdenum(II) complexes $Mo_2(O_2CR)_4L_2$ (R = CF_3, Bu^t; L = solvent). The large deshielding effect (over 450 ppm for the R = CF_3 series as the solvent changes from chloroform to hexamethylphosphoramide) correlates well with the donor number of the solvent. The lowest energy electronic absorption band corresponding to the δ–δ^* transition also moves to longer wavelength with the more strongly coordinating solvents, which is consistent with weakening of the Mo≡Mo quadruple bond and the dominance of the ΔE parameter in the paramagnetic term which controls the magnitude of $\delta(^{95}Mo)$. © 1997 Elsevier Science Ltd

Keywords: tetrakis-μ-carboxylatomolybdenum(II) complexes; correlations of ^{95}Mo NMR and visible spectral data; donor numbers.

The structural diversity and chemical reactivity of dinuclear complexes with strong multiple metal-to-metal bonds have attracted attention for many years [1]. Interest has focused on the nature of the metal–metal bond, synthetic strategies for producing the dinuclear units, and their potential catalytic activity for carbonylation and hydrogenation reactions [1,2].

Development of the chemistry of compounds containing the $[Mo_2]^{4+}$ core has often involved carboxylate ligands, as reflected by recent papers [3]. Extensive attention has been paid these dinuclear tetracarboxylate complexes containing $\sigma^2\pi^4\sigma^2$ Mo—Mo quadruple bonds because of their interesting structural and spectroscopic properties. However, few characterization studies of such species by ^{95}Mo NMR spectroscopy are known.

Previous ^{95}Mo NMR studies have shown that increased bond order in multiple bonded dimolybdenum species causes greatly deshielded chemical shifts, with the $\delta(^{95}Mo)$ values of ca 4000 ppm for the quadruply bonded $Mo_2(O_2CR)_4$ complexes [4] representing the lowest shielding reported for any molybdenum compound [5]. In contrast, the normal range for mononuclear Mo(II) species is between +70 and −2100 ppm [4b,6], though some nitrosyl species of the type $[Mo\{HB(Me_2pz)_3\}(NO)X_2]$ extend the range to nearly +2300 ppm [7]. Other quadruply bonded dinuclear compounds with phosphorus and halide ligands show $\delta(^{95}Mo)$ values which are several hundred ppm upfield (i.e. more shielded) compared to the carboxylates [5]. The earlier preliminary observations [4] that more polar solvents caused the molybdenum nucleus to be deshielded [e.g. by 325 ppm for $Mo_2(O_2CCF_3)_4$ in pyridine compared to $CDCl_3$] suggested that $\delta(^{95}Mo)$ values could serve as a very sensitive probe of the interaction of the dinuclear unit with weakly bound ligands. In this paper we have documented the influence of a range of different solvents on the ^{95}Mo NMR chemical shift for two tetrakis-μ-carboxylatodimolybdenum(II) complexes. The two derivatives, with R = CF_3 or Bu^t-substituents, were chosen because of the difference in electronegativity of the substituents, their stability and (especially, to reduce spectral accumulation times) their solubility. Correlations were examined between

$\delta(^{95}Mo)$ values, donor numbers (DN) of the solvents, and the lowest energy electronic absorption band (λ_{max}).

EXPERIMENTAL

$[Mo_2(O_2CR)_4]$ (R = CF_3, *t*-Bu) were isolated by procedures described in the literature [8]. Dried and degassed solvents were used and the reactions were carried out under a dry oxygen-free dinitrogen atmosphere. Two new dinuclear carboxylates were prepared as follows.

$[Mo_2(O_2CC_6H_4N(CH_3)_2\text{-}p)_4]\cdot H_2O$

$Mo(CO)_6$ (2 g) and $p\text{-}HO_2CC_6H_4N(CH_3)_2$ (2.5 g) were mixed and diglyme (35 cm^3) was added. The mixture was stirred at reflux temperature for 3.5 h, during which a yellow–green precipitate formed. After cooling to room temperature, the solid was collected by filtration and washed with diethylether. The green solid was dried *in vacuo* at 70°C for 4 h. Found: C, 49.09; H, 4.56; N, 6.06. Calc.: C, 49.87; H, 4.88; N, 6.46. IR (in KBr): ν_{asym}, 1570 cm^{-1}, ν_{sym}, 1468 cm^{-1}. UV-vis (solid state): 310, 360 (sh), 800 nm. ^1H NMR ($CDCl_3$): 3.06 s; 6.66 d, 7.97 d (J = 9 Hz).

$[Mo_2(O_2CC_6H_4CF_3\text{-}p)_4]$

$Mo(CO)_6$ (0.66 g) and $HO_2CC_6H_4CF_3$ (0.95 g) were mixed and dichlorobenzene (30 cm^3) was added. After stirring the solution at reflux temperature for 2 h, the yellow–orange precipitate that had formed was collected at room temperature by filtration. The product was washed with diethylether and dried *in vacuo*. Found: C, 40.08; H, 1.86. Calc.: C, 40.52; H, 1.70. IR (in KBr): ν_{asym} (CO_2), 1502 cm^{-1}, ν_{asym} (CO_2), 1408 cm^{-1}. UV–vis (solid state): 275, 340 (sh), 385 (sh), 470, 770 nm. ^1H NMR ($CDCl_3$): 7.76 d, 8.23 d (*J* = 8 Hz).

The ^{95}Mo NMR spectra were acquired on a Varian Unity-400 spectrometer operating at 26.06 MHz in the FT mode at ambient temperature. Chemical shifts are relative to external aqueous 2M Na_2MoO_4 (at pH 11). Samples were freshly prepared just prior to ^{95}Mo NMR analysis. Typically, $[Mo_2(O_2CR)_4]$ (0.75 mmol) was dissolved in the appropriate solvent (2.5 cm^3) in a 10 mm NMR tube under a dinitrogen atmosphere. The UV–vis spectra were recorded in the 200–900 nm region for solutions of 10^{-3} M or less concentration in 1 cm silica cuvettes. Linear regression analyses were performed using Microcal Origin 4.1 with the confidence level being set at 0.99 in obtaining correlation coefficients.

RESULTS AND DISCUSSION

Tetrakis-μ-carboxylatodimolybdenum(II) compounds are well known to form $Mo_2(O_2CR)_4L_2$ complexes with Lewis bases [1,9]. Spectroscopic and structural data indicate that two main isomers are possible (Fig. 1); several other less symmetrical isomers than those depicted are also possible at least for phosphine ligands [9]. The common axial diadducts, type *a*, consist of four carboxylate groups bridging the Mo_2^{4+} unit, while the L donor ligands occupy the axial positions with a variable coordinating strength. The other main isomer, type *b*, has two monodentate and two bridging carboxylate groups, with the L donor ligands occupying an equatorial position on each molybdenum atom. In the present study involving donor solvents of variable coordinating strength, as reflected by their donor number, the $Mo_2(O_2CR)_4L_2$ (R = CF_3, Bu^t) diadducts are all expected to be type *a*, as already established by X-ray structural determinations for L = diethylene glycol dimethyl ether and pyridine [1,9]. However, two ^{95}Mo resonances were observed for the R = CF_3, L = N,N-dimethylacetamide (DMA) derivative, and thus we suggest the presence of an equatorial isomer (type *b*) also in that case. Whilst the two ^{95}Mo signals are separated by 73 ppm, it is noteworthy that neither IR nor UV–vis spectroscopy could be expected to definitively identify the existence of both isomers. The sensitivity of the ^{95}Mo chemical shift to the molybdenum environment results in $\delta(^{95}Mo)$ changing from 3920 to 4333 ppm as the solvent changes from nitrobenzene to hexamethylphosphoramide (HMPA), respectively, for the R = CF_3 series. At the same time, the electronic absorption band in the visible region (λ_{max}) increases from 421 nm to 501 ppm for the same solvents. Table 1 summarizes the $\delta(^{95}Mo)$ and λ_{max} values for 14 solvents for the R = CF_3 series and six solvents for the R = Bu^t series, listed according to the increasing magnitude of the solvent donor number (DN).

The paramagnetic shielding term which dominates in the Ramsey expression [eqn (1)] for quadrupolar nuclei such as ^{95}Mo (I = 5/2, natural abundance

15.7%) can be expressed in a simplified form [eqn (2)] which is useful

$$\delta = \delta_{dia} + \delta_{para} \quad (1)$$

$$\delta_{para} = K\Delta E^{-1} < r^{-3} >_{4d} k^2 \quad (2)$$

for comparisons of complexes of the same symmetry. The spectrochemical parameter, ΔE, which is the HOMO–LUMO gap for paramagnetic circulations in the magnetic field corresponds to the ligand field splitting, the *d–d* excitations being magnetic dipole allowed. It is acknowledged that a summation over two or more ΔE terms may be required for low symmetries, but regardless, large excitation energies (such as normally due to strong ligand σ-bonding in mononuclear complexes) will lead to shielding. The radial term, $\langle r^{-3} \rangle_{4d}$, which is the inverse cube of the valence *d*-electron radius, and the covalency factor, k^2, which reflects the amount of covalent bonding, together constitute a nephelauxetic dependency for δ_{para}. Its magnitude will be low, giving greater shielding, the farther the paramagnetic circulation is from the resonant nucleus. Either the spectrochemical or nephelauxetic components of the δ_{para} expression can be dominant, as well documented [5,10].

As noted by previous works, the $\delta(^{95}Mo)$ values for the $Mo_2(O_2CR)_4L_2$ complexes constitute the most deshielded ones known [4,5]. Such high frequencies for these quadruply bonded species must be related to the existence of small ΔE excitation energies and considerable charge asymmetry in the valence shell (which would also explain the significant line broadening that occurs, as discussed below). The larger deshielding that occurs for the R = CF_3 complexes relative to the R = Bu^t complexes (ca 400 ppm) can be attributed to the large increase in acid strength of the carboxylic acid with the electronegative substituent. In other words, the weakly basic $CF_3CO_2^-$ anion induces smaller ΔE splittings, as indicated by the larger λ values (Table 1). Surprisingly, X-ray crystallography does not detect any influence on the interaction between the Mo atoms since the quadruple bond is identical (2.090(4) Å) for the free R = CF_3 derivative and the R = Bu^t complex [2.088(1) Å]. This constancy of the Mo≡Mo bond distance is an established feature in $Mo_2(O_2CR)_4$ complexes [1].

In the diadducts, the Mo atoms might be expected to be more shielded as the solvent ligands become more strongly coordinated, since greater σ donor ability increases ΔE in mononuclear complexes. However, the $\delta(^{95}Mo)$ values move to higher frequency in both series of diadducts as the donor number (DN) of the solvents increases. As a measure of the basicity or donor ability of a solvent, DN is defined [11] as the negative enthalpy of reaction of a base with the Lewis acid antimony pentachloride, i.e.

$$B + SbCl_5 \rightarrow B \rightarrow SbCl_5\,;\, DN \equiv -\Delta H, \quad (3)$$

Good linear correlations between $\delta(^{95}Mo)$ and DN are observed for both series ($r = 0.94$ for R = CF_3, with the plot shown in Fig. 2; $r = 0.95$ for R = Bu^t). Similarly, the lowest energy electronic absorption moves to longer wavelength, though the correlation of either $\delta(^{95}Mo)$ or DN and λ_{max} is only moderately good [e.g., $r = 0.86$ between $\delta(^{95}Mo)$ and λ_{max} for the R = CF_3 series]. The correlation coefficient becomes 0.90 if point 12 is not included, for the plot shown in Fig. 3. Coordination of solvents of better donor ability apparently induces a reduction in the orbital overlap between the molybdenum atoms, resulting in a smaller ΔE (or a further splitting of energy levels). Com-

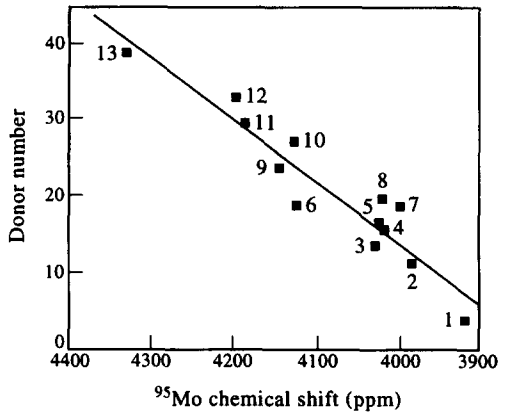

Fig. 2. The correlation of donor number and ^{95}Mo chemical shift (in ppm) for the $Mo_2(O_2CCF_3)_4L_2$ series.

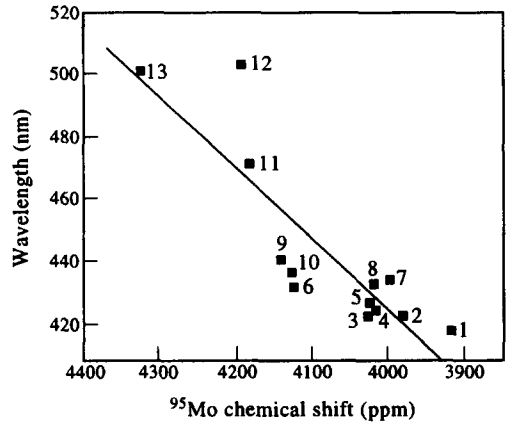

Fig. 3. The correlation of wavelength and ^{95}Mo chemical shift (in ppm) for the $Mo_2(O_2CCF_3)_4L_2$ series.

mensurate with these observations, the Mo≡Mo quadruple bond might be expected to increase in length within the diadducts as the solvent DN increases, but X-ray structural data are not yet available to verify this prediction. Further confirmation of the longer bond being expected for diaxial solvent coordination comes from the observation [12] of Raman Mo≡Mo stretching frequencies at 367 cm^{-1} for $Mo_2(O_2CCF_3)_4(py)_2$ vs 397 cm^{-1} for $Mo_2(O_2CCF_3)_4$, and at 363 cm^{-1} for $Mo_2(O_2CCH_3)_4(py)_2$, vs 404 cm^{-1} for $Mo_2(O_2CCH_3)_4$.

The linewidths observed for the ^{95}Mo spectral bands are significantly larger than those reported for complexes of higher symmetry, ranging from 180 to 1000 Hz for the R = CF_3 series (Table 1). Undoubtedly, the lower symmetry of these diaxial adducts leads to asymmetry in the electric field gradient, a primary factor in line broadening. Other factors such as solvent viscosity and correlation time may also be contributing to the observed large line widths. Nevertheless we note that the lowest linewidths, 180 Hz for the R = CF_3 series diadduct with DMSO, occurs for a viscous solvent (2.00 cp for DMSO). The strong DMSO coordination, and resultant expected short Mo—O (DMSO) bond, must lead to a higher charge symmetry in the Mo valence shell. The influence of correlation time in enlarging the line width can be seen as the coordinating ligand becomes larger (e.g. benzonitrile vs acetonitrile, and the R = Bu^t complexes vs the R = CF_3 ones).

The electronic spectra of tetrakis-μ-alkylcarboxylato-dimolybdenum complexes are well documented in the literature [1]. In general, representative bands occur near 230 nm ($\varepsilon \sim 4000$), 300 nm ($\varepsilon \sim 8000$) and 430 nm ($\varepsilon \sim 60\ cm^{-1}\ M^{-1}$). The origin of the weak, lowest energy band has been the subject of considerable controversy [1,13,14]. However, Martin *et al.* [15] and others later concluded that the lowest energy electronic excitation for such tetrakis (μ-carboxylate) complexes was an electric-dipole-allowed transition and thus should be the $\delta \rightarrow \delta^*$ transition. Much recent literature for the entire d^4–d^4 $M_2(O_2CR)_4$ (M = Cr, Mo, W) series concurs with this assignment [1,3]. Under a D_{4h} symmetry for these dimeric compounds, this characteristic $\delta \rightarrow \delta^*$ transition is denoted as ($^1A_{1g} \rightarrow {}^1A_{2u}$).

In both series of complexes (Table 1), the longest wavelength visible absorption band moves to longer wavelengths with better coordinating solvents. An earlier study of the axially coordinated adducts of $Mo_2(O_2CC_6H_5)_4$ noted only a very qualitative relationship between solvent donor character and the magnitude of the spectral shift [16]. The correlation in our case between λ_{max} and donor number is only moderately good ($r = 0.89$ for the R = CF_3 series) but nevertheless the trend is consistent with the observation that solvents with greater donor ability induce smaller $\delta \rightarrow \delta^*$ transitions which lead to larger δ_{para} values in the simplified Ramsay expression [eqn (2)], and thus more deshielded $\delta(^{95}Mo)$ values. A correlation between $\delta(^{95}Mo)$ and ΔE, as given by observed visible absorption bands, has already been noted for both Mo^0 and Mo^{VI} complexes [17]. Very recently, confirmation of the correlation was affirmed for both dimeric Mo^V complexes and mononuclear $Mo(CO)_4L_2$ complexes [18]. The same trend in the present Mo^{II} dimers suggest that although other factors cannot necessarily be assumed to be constant for the series under study, the ΔE term is nevertheless the dominant one affecting the δ_{para} magnitude. Our attempt to extend the $\delta(^{95}Mo)$ and ΔE correlation to new $Mo_2(O_2CR)_4$ species (R = $C_6H_4N(CH_3)_2$-*p* and R = $C_6H_4CF_3$-*p*) having very low wavelength absorptions was not successful; the low solubility of these two complexes precluded the observation of a ^{95}Mo NMR resonance, even after overnight accumulations at elevated temperatures.

(Received 5 September 1996; accepted 10 July 1997)

Abstract—Four novel oxamide type ligands have been obtained by reaction of "half units" **1–4** and oxalyl chloride. They were used to prepare corresponding related binuclear Cu^{II} and Ni^{II} complexes. The products obtained were characterized by elemental analysis, MS, IR and NMR spectra and X-ray single crystal analysis.

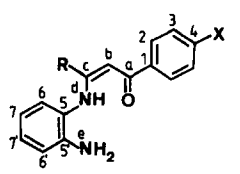
Keywords: binuclear complexes; nickel and copper complexes; Schiff base; synthesis; NMR spectra; X-ray crystal structure.

There is increasing interest in binuclear complexes, which contain ligand structures capable of holding two metal centres in close proximity. These polymetallic systems are attractive as synthetic models of metallo biomolecules. Among the known polynucleating ligands, particular attention has recently been paid to oxalic acid derivatives due to their wide range of possibilities [1]. Our work described herein has concentrated on developing new binuclear complexes from more easily prepared tridentate precursors such as condensation products of the carbonyl function with only one amino group of a diamine ("half-units") **1–4**. The monocondensation products have received increasing attention due to interesting structural properties of their metal chelates [2] and also due to their application as intermediates in the synthesis of unsymmetrical multidentate Schiff base ligands [3] or heterocyclic compounds [4]. Recently Costes *et al.* have described the syntheses and characterization of new oxamido bridging Schiff bases from a monocondensation product and diethyl oxalate [5].

Experimental

Materials and physical measurements

All materials were reagent grade and were used without further purification, except for solvents which were dried by standard methods. The starting benzoylacetaldehyde, p-nitrobenzoylacetaldehyde and 3-ethoxyvinylidene-2,4-pentanedione were prepared by literature procedures [12, 13]. Compound **1** was prepared following a modified procedure of Cutler *et al.*



1: R = CH_3; X = H

2: R = H; X = H

3: R = H; X = NO_2

[6b]. All melting points are uncorrected. IR spectra were measured as KBr discs using a Specord M-50 (Carl Zeiss Jena) spectrometer over the range 200–4000 cm^{-1}, ^1H and ^{13}C NMR spectra were taken on a Bruker AMX-500 NMR spectrometer in $CDCl_3$ with TMS as an internal standard. Mass spectra were recorded on a LKB 2091 mass spectrometer at 15 and 75 eV ionization potentials.

X-ray structure analysis

$C_{34}H_{26}N_4O_4Cu_2$, Mr = 681.7, monoclinic $P2_1/c$, $a = 6.5137(4)$, $b = 8.0053(6)$, $c = 27.182(2)$ Å, $\beta = 90.382(4)°$, $V = 1417.3$ Å^3, $Z = 2$, $D_x = 1.6$ g cm^{-3}, $\lambda = 1.5418$ Å. A crystal with approximate dimensions $0.05 \times 0.10 \times 0.40$ mm was used for data collection on an Enraf-Nonius CAD-4 diffractometer with graphite-monochromated Cu K_α radiation and ω-2θ scan. A total of 2662 unique reflections was measured within the range $-7 \leq h \leq 0$, $0 \leq k \leq 9$, $-31 \leq l \leq 31$. Of these reflections 1910 were above the significance level of 2.5 s(I). The range of $(\sin\theta)/\lambda$ was 0.037–0.609 Å^{-1} ($2.3 < \theta < 69.8°$). Two reference reflections (200 and 012) were measured hourly and showed no decrease during the 42 h collecting time. Unit cell parameters were refined by a least-squares fitting procedure using 23 reflections with $39.9 < \theta < 44.8°$. Data were corrected for Lorentz and polarization factors. Absorption correction was performed with the program ABSCAL [15] using Ψ-scans of the 200 reflection, with coefficients in the range 1.02–1.74.

The structure was solved both by the PATT option of SHELXS 86 [16] and PATTY option of DIRDIF 94 [17] programs system. Initial positions of hydrogen atoms were calculated. Full-matrix least-squares refinement on F, anisotropic for the non-hydrogen atoms and isotropic for hydrogen atoms, restraining the latter in such a way that the distance to their carrier remained constant at approximately 1.0 Å, converged to $R = 0.056$, $R_w = 0.054$, $(\Delta/\sigma)_{max} = 0.32$, $S = 0.854$). A weighting scheme $w = [3.0 + 0.1*(\sigma(F_o))^2 + 0.001/(\sigma(F_o))]^{-1}$ was used. The secondary isotropic extinction coefficient [18] refined to Ext = 0.009(2). A final difference Fourier map revealed a residual electron density between −0.8 and 0.5 e Å^{-3}. Scattering factors were taken from Cromer and Mann [19]. The anomalous scattering of Cu was taken into account. All calculations were performed with XTAL [20], unless stated otherwise.

Preparation of the compounds.

Preparation of 1-*phenyl*-3-[*N*-(2′-*aminophenyl*)*amino*]-2-*propen*-1-*one* (**2**). Compound (**2**) was synthesized in a manner similar to the procedure described in the literature [7]. Benzoylacetaldehyde (5 g, 0.34 mol) was dissolved in methanol (30 cm^3) and added with stirring to a solution of 1,2-diaminobenzene (3.6 g, 0.34 mol) in methanol (15 cm^3) at room temperature. The separated solid was filtered off and recrystallized from *n*-propanol to give a yellow solid **2** (2.53 g, yield 31.2%). M.p. 158–160°C. Found: C, 75.2, H: 5.4; N: 11.5. Calc. for $C_{15}H_{14}N_2O$: C, 75.6; H, 5.9; N, 11.8%. MS[(*m*/*z*) ab.%]: 238 (M^+), 50; 219 (M^+–18), 15; 119 ($H_2NC_6H_4NH^+$), 100; 105 ($C_6H_5CO^+$), 30. IR(KBr): 3376br w, 3328w, 1640s, 1620s, 1600 m, 1580m, 1544m cm^{-1}. δ_H ($CDCl_3$) 12.49, [1H, *br d*, $J(H^dH^c)$ 11.5 Hz, N*H*^{d}], 6.81–8.40 [10H, *m*, C*H*$_{phen}$ + C*H*^{c}], 6.04 [1H, *d*, $J(H^bH^c)$ 7.5 Hz, C*H*^{b}], 4.25 [2H, *br s*, N*H*^{e}]. δ_C($CDCl_3$) 191.18 [C^a], 147.27 [C^c], 137.17 and 139.25 [C^1 and C$^{5'}$], 132.15, 131.50, 128.47, 127.53, 127.27 and 125.25 [C^2, C^3, C^4, C^5, C^7 and C$^{7'}$], 119.91 [C^6], 117.72 [C$^{6'}$], 95.47 [C^b].

Preparation of 1-(4′-*nitrophenyl*)-3-[*N*-(2′-*aminophenyl*)*amino*]-2-*propen*-1-*one*(**3**). The compound **3** was prepared from the reaction of stoichiometric amounts of p-nitrobenzoylacetaldehyde (5 g, 0.026 mol) and 1,2-diaminobenzene (1.9 g, 0.026 mol), as described in the literature [7]. Yield 3.35 g (54%). M.p. 171° (Lit. [7] 170–171°C). MS [(*m*/*z*) ab.%]: 238 (M^+), 45; 265 (M^+–18), 21; 150 ($NO_2C_6H_4CO^+$), 37; 119 ($H_2NC_6H_4NH^+$), 100; 104 ($C_6H_4CO^+$), 26. Preparation of 1,16-*di*(4′-*nitrophenyl*)-5,6:11,12-*dibenzo*-4,7,10,13-*tetgraazaheksadeca*-2,14-*diene*-1,8,9,16-*tetraone* (**7**). Compound **7** was prepared from monocondensation product **3** (2.0 g, 0.007 mol), oxalyl chloride (0.44 g, 0.004 mol) and triethylamine (0.71 g, 0.007 mol) by a similar method to that described for **5** to give 5.09 g (41%) yellow solid. M.p.: 248°C. Found: C, 58.6; H, 3.6;N, 12.8. Calc. for $C_{32}H_{24}N_6O_8$: C, 61.9; H, 3.9; N, 13.5%. IR (KBr): 3270 s, 1750 s, 1630 s, 1580 m. Compound **7** is insoluble in most common organic solvents.

Preparation of 3,16-*diacetyl*-6,7:12,13-*dibenzo*-5,8,11,14-*tetraazaoctadeca*-2,9,10,17-*tetraone* (**8**). Compound **8** was obtained from monocondensation product **4** (2.0 g, 0.009 mol), oxalyl chloride (0.57 g, 0.005 mol) and triethylamine (0.91 g, 0.009 mol) by a similar method to that described for **5** to give 1.24 g (59%) of a light yellow solid. M.p. 267°C (decomp.). Found: C, 68.4; H, 5.8; N, 12.4. Calc. for $C_{26}H_{26}N_4O_4$: C, 68.1; H, 5.7; N, 12.2%. IR (KBr): 3100s 1680s, 1676s, 1624s, 1585s cm^{-1}. δ_H ($CDCl_3$) 12.73 [2H, *br*, *d*, J(H^{c}H^b) 12.5 Hz, N*H*^{c}], 9.43 [2 H, s, N*H*^{d}], 8.11 [2 H, *d*, J(H^{b}H^c) 12.5 Hz, C*H*^{b}], 7.73–7.71 [2 H, *m*, C*H*$^{2,2'}_{phen}$], 7.42–7.39 [4 H, *m*, C*H*$^{3,3'}_{phen}$], 2.53 and 2.37 [6 H, *s*, 6H, *s*, C*H*^{e}], 2.18 [12 H, *s*, C*H*^{a}].

General preparation of the complexes (**9–16**)

A solution of 0.01 mol of nickel(II) acetate tetrahydrate or solution of 0.01 mol of copper acetate monohydrate in DMF (20 cm^3) was added to a suspension of 0.01 mol of the corresponding ligand **5–8** in DMF (50 cm^3). The reaction mixture was heated under reflux for 1 h with stirring. After cooling a brown crystalline product was filtered off, washed with hot water and dried *in vacuo* for several hours. Average yield: 95–98%.

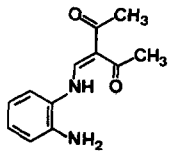
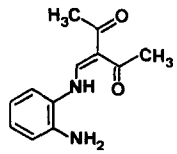
RESULTS AND DISCUSSION

The monocondensation products **1–4** are readily obtained by reactions of equimolar amounts of 1,2-diaminobenzene and 1,3-dicarbonyl compounds such as benzoylacetone, benzoylacetaldehyde, p-nitrobenzoylacetaldehyde and 3-ethoxyvinylidene-2,4-pentanedione. Synthesis of compounds **1** and **3** was described earlier [6, 7], but in the case of compound **3** only elemental analyses were reported [7]. The "half units" **2–4** were characterized by IR, mass, ^1H and ^{13}C NMR spectroscopy. On the basis of our spectral investigations we have found that compounds **2**, **3** and **4** exist as enaminone tautomers rather than as imine-enol or iminone [8]. In the IR spectra a group of strong bands resulting from C=O, C=N, and C=C stretching vibrations are present in the *ca.* 1640–1540 cm^{-1} region. The MS data were suitable for structure proof of "half units" type compounds **2** and **3**. The mass spectra give the peak of low abundance corresponding to the molecular ion. For the compounds **2** and **3** the intense peak at 105 *m/z* (**2**) or 104 *m/z* (**3**) confirms the fact that the condensation takes place on the carbonyl of the formyl group. For compounds **2**, **3** and **4** in the ^1H NMR spectra the low-field proton signal appears as a one proton doublet with coupling constant *J ca.* 11.5–12.5 Hz. This large value of the coupling constant is typical for *trans* coupling in H—C=N—H systems [9]. On the basis of detailed analysis of NMR spectra (three singlets of methyl groups) it was possible to assume that the compound **4** may exist at room temperature as a mixture of two rotamers **A** and **B**.



A



B

We have found that only in the case of the reaction of monocondensates **1–4** with oxalyl chloride, when the molar ratio of reagents was 2:1, could binucledating ligands **5–8** of the oxamido type be obtained. No such products have been isolated from the related reactions involving diethyl oxalate. The reactions leading to compounds **5–8** were carried out in the presence of triethylamine at room temperature according to the modified procedure of Amerago and Willette [10]. These oxamido ligands were characterised by elemental analyses and spectral methods, but ^1H and ^{13}C NMR spectra of ligand **7** and ^{13}C NMR spectra of ligands **5** and **8** could not be obtained by reason of their low solubility. Attempts to use mass spectra were unsuccessful because of decomposition of the compounds **5–8**. The IR spectra of the four ligands are very similar. In the case of compounds **6** and **8** we have observed the same effect of coupling H—C=N—H protons (as in the case of monocondensates **2–4**) and possibility of two rotamers of ligand **8**.

Binuclear complexes of Cu^{II} and Ni^{II} (**9–12**) with Schiff bases have been prepared by the reactions of ligands **5–8** with copper(II) acetate or nickel(II) acetate. These were characterised by combination of microanalyses and IR spectroscopy. ^1H and ^{13}C NMR spectra of the complexes of Ni^{II} (**8**, **11**, **13** and **15**) could not be obtained because of poor solubility. IR spectra of these complexes in comparison with the IR spectra of the ligands have shown the difference in the amine and carbonyl regions. In the IR spectra of complexes **9–16** no absorption is observed in the 3500–3000 cm^{-1} in accord with deprotonation of all NH enamine and amide groups upon complexation. The strong absorption at *ca.* 1750–1605 cm^{-1} assigned to the uncomplexed carbonyl groups, for coordinated ones is observed at *ca.* 1632–1604 cm^{-1} in accordance with earlier observations of similar complexes [11].

Structural studies

The X-ray crystal structure of the binuclear complex Cu^{II} (**10**) was determined. Figure 1 shows an

ORTEP [14] plot of the title compound and the atom numbering scheme. Tables 1 and 2 list selected bond distances and angles for non-hydrogen atoms. The compound consists of discrete binuclear centrosymmetric $C_{34}H_{26}N_4O_4Cu_2$ units. There are two Cu atoms and four phenyl rings in each unit related by a symmetry centre. Each copper atom is surrounded by two nitrogen and two oxygen atoms. The oxygen and nitrogen ligands are *cis* coordinated to the metal. The whole molecule, including phenyl rings, is nearly planar. The dihedral angles between planes of phenyl rings formed by atoms C(12)—C(17), C(5)—C(10) and the least-squares plane of the main ring of the molecule (defined by C(1)—C(6), N(1), N(2), O(1), O(2) are 8.6(2) and 4.3(1)°, respectively. The Cu atoms are shifted from the least-squares plane of the molecule by 0.055(2) ≤ Å.

The Cu—Cu distance within the same molecule is 5.254 (8) Å, while the shortest intermolecular Cu—Cu distance is 5.66(5) Å. Within phenyl rings the bond lengths and angles are in good agreement with the corresponding values found in the literature.

From the molecular packing it is observed that no intermolecular contacts in this structure for different

(Received 11 March 1997; accepted 9 July 1997)

Abstract—The title complex, $[NiL](ClO_4)_2$ was synthesized by the reaction of nickel(II) perchlorate and the new macrocycle ligand, 1,4,7,10-tetrakis(2-pyridylmethyl)-1,4,7,10-tetraazacyclododecane (L) in ethanol solution. The crystal and molecular structure of this complex has been determined by single-crystal X-ray diffraction. The complex consists of $[NiL]^{2+}$ cation and two perchlorate anions. Within the $[NiL]^{2+}$ cation, the potential octadentate ligand is using its 4 nitrogen atoms of the macrocycle and 2 pyridine nitrogens to coordinate with the central nickel(II), while the other two pyridine nitrogens remained uncoordinated. The central nickel(II) ion is in a distorted-octahedral coordination environment and in high-spin state. © 1997 Elsevier Science Ltd

Keywords: nickel(II) complex; crystal structure; synthesis; 1,4,7,10-tetrakis(2-pyridylmethyl)-1,4,7,10-tetraazacyclododecane.

The coordination properties toward metal ions of macrocycles bearing pendant donor groups from the macrocycle skeleton have recently attracted much interest, mainly as the study of such systems may provide a basis for a better understanding of the metal environment in some metalloenzymes and metalloproteins [1,2]. Recently some reports have indicated that functionalized macrocycles containing pendant arms can form stable complexes with transition metals and exhibit functional properties. These types of macrocycles can bond to metals ion forming 1 : 1 or 1 : 2 molar ratio complex [2–5].

We report herein the functionalization of 1,4,7,10-tetraazacyclododecane (cyclen) with four pyridine groups connected to the macrocycle through methylene chains. This potential octadentate ligand, 1,4,7,10-tetrakis(2-pyridylmethyl)-1,4,7,10-tetraazacyclododecane (L), can form binuclear complexes with large metal ions (e.g. lanthanide ions) and mononuclear complexes with smaller metal ions (e.g., copper(II) and nickel(II) ions). In this paper, we describe the synthesis and characterization of the new ligand L and the crystal and molecular structure of its Ni(II) complex.

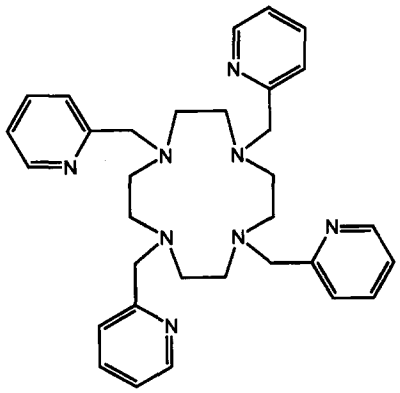
EXPERIMENTAL

Materials

1,4,7,10-tetraazacyclododecane (cyclen) was prepared according to the literature method [6]. 2-(Chloromethyl)pyridine hydrochloride was obtained from Aldrich Co. Inc. and used without further purification. Other chemicals were of analytical grade.



L

All the solvents were purified by standard procedures prior to use.

Physical measurements

IR spectra were recorded on a FT-IR 5DX (Nicolet) spectrophotometer using KBr discs. Proton NMR spectra were recorded on a Bruker AC-P 200 spectrometer (200 MHz, at 25°C, in $CDCl_3$ solution, with tetramethylsilane as the internal reference). EI-mass spectra (MS) were measured on a VG ZAB-HS instrument. Electronic absorption spectra were obtained by using a Shimadzu UV-240 spectrophotometer. Elemental analysis was performed on a P-E 240C analyzer. Magnetic susceptibility was measured on a Faraday balance at room temperature and the calibration was made with Mohr's salt. Effective magnetic moment was calculated by the equation $\mu_{eff} = 2.828(X_m T)^{1/2}$, where X_m is the magnetic susceptibility corrected for diamagnetism of the constituting atoms using Pascal's constants.

Synthesis of 1,4,7,10-*tetrakis*(2-*pyridylmethyl*)-1,4,7,10-*tetraazacyclododecane* (*L*)

To a solution of 1,4,7,10-tetraazacyclododecane (0.5 g, 2.9 mmol) in dichloromethane (30 cm^3) was added a solution of NaOH (0.93 g, 23.2 mmol) in water (25 cm^3). This two-phase mixture was stirred for *ca.* 30 min. Then, a solution of 2-(chloromethyl)pyridine hydrochloride (2.0 g, 12.6 mmol) in dichloromethane (15 cm^3) was added dropwise to the mixture over a period of *ca.* 1 h. The stirring was continued at *ca.* 30°C for one day and the organic layer was then separated. The aqueous layer was extracted with chloroform (5×50 cm^3), and the combined organic layers were evaporated to give a residue which was purified by column chromatography on silica gel (eluent: CH_2Cl_2 : Acetone = 98 : 2 ~ 10). The final product was obtained by recrystallization from $C_2H_5OH \sim (C_2H_5)_2O$ as colourless needles. Yield 1.24 g (80%), m.p. 159–161°C. EI-MS (*m*/*z* peak): 536 (Mr = 536.72). ^1H NMR (200 MHz, $CDCl_3$) δ 2.61 (broad peak, 16H, CH_2—CH_2), 3.37 (broad peak, 8H, N—CH_2—Py), 6.94 (t, 4H, Py), 7.09 (d, 4H, Py), 7.37 (t, 4H, Py), 7.58 (t, 4H, Py). Calc. for $C_{32}H_{40}N_8$: C, 71.61; H, 7.51; N, 20.88. Found: C, 71.52; H, 7.24; N, 20.77%. IR (KBr pellet, cm^{-1}): 2813 (C—H), 1631, 1592 (Py ring), 1095 (C—N). UV-vis (in CH_3OH) [λ_{max} nm (ε: 1 mol cm^{-1})]: 204 (2.13×10^4), 260 (0.94×10^4).

Preparation of [NiL] $(ClO_4)_2$

The violet single crystal of the title complex suitable for X-ray analysis was obtained by mixing a 1 : 1 molar ratio of $Ni(ClO_4)_2 \cdot 6H_2O$ (40 mg, 0.11 mmol) and L (60 mg, 0.11 mmol) in ethanol solution (10 cm^3) under reflux for *ca* 30 min. The reaction mixture was filtered and the beautiful violet crystal was obtained from the slow evaporation of the solvent. Yield: 44 mg (50%). IR (KBr pellet): 3483, 3070, 2870, 2013, 1608, 1571, 1593, 1475, 1436, 1352, 1308, 1090 (broad and strong), 1015, 968, 772, 622 cm^{-1}. Calc. for $C_{32}H_{40}N_8Cl_2O_8Ni$: C, 48.39; H, 5.08; N, 14.11. Found: C, 48.60; H, 5.32; N, 13.82%.

Warning! The perchlorate compounds are potentially explosive and should be handled carefully.

Crystallographic studies

A crystal (approximately $0.2 \times 0.3 \times 0.4$ mm) of complex [NiL] $\cdot (ClO_4)_2$ was mounted on an Enraf-Nonius CAD-4 diffractometer equipped with a graphite crystal monochromator situated in the incident beam for data collection. The determination of unit cell and the data collection were performed with Mo-K_α radiation ($\lambda = 0.71073$ Å). Unit cell dimensions were obtained by least-square refinements using 25 reflections in the range of $9.91° < \theta < 12.24°$. The intensities of reflections were measured at the $\omega/2\theta$ scan mode in the range of $2° < \theta < 23°$ at room temperature. A total of 4230 independent reflections were collected, in which 2396 reflections with $I \geqslant 3\sigma(I)$ were considered to be observed and used in the succeeding refinement. The structure was solved by SHELXS-86 method. Ni atom was located from an *E*-map. The other non-hydrogen atoms were determined with successive differential Fourier synthesis. The positions of hydrogen atoms were treated theoretically as riding on their relative atoms and refined isotropically. The final refinement by full matrix least-squares method with anisotropic thermal parameters for non-hydrogen atoms was converged with unweighted and weighted (unit weights for all observed reflections) agreement factors of 0.066 and 0.078. The highest peak on the final difference Fourier map had a height of 0.76 $eÅ^3$.

All the calculations were performed on a PDP11/44 computer, using SDP-PLUS, SHELXS-86 and

RESULTS AND DISCUSSION

Synthesis of ligand and preparation of the complex

The synthesis of L can be carried out easily in water-dichloromethane two-phase solution by the reaction of cyclen with an excessive amount of 2-(chloromethyl)pyridine hydrochloride, and then extracted by chloroform and further purified by column chromatography and recrystallization from ethanol/ether in high yield. All the analytical data are in good agreement with the theoretical requirements of the ligand.

The complex was prepared by the reaction of hydrated nickel perchlorate and L in 1 : 1 molar ratio in ethanol solution in good yield. The violet crystalline compound is soluble in water and DMF, and is slightly soluble in ethanol and methanol.

General characterization of the complex

The ligand L shows strong IR bands at 1631 and 1592 cm^{-1} attributable to ν(py ring) stretching vibrations. There are two vibration bands in the IR spectrum of the complex assigning to the vibrations coordinated ($\sim$1608 and $\sim$1575 cm^{-1}). In addition, strong peaks of the vibrations of free perchlorate at $\sim$1090 and $\sim$622 cm^{-1} appeared in the IR spectrum of the complex.

The effective magnetic moment of the Ni^{II} complex is determined to be 3.12 B.M. (at room temperature), which indicates that the complex is octahedral and the central nickel(II) atom is in high spin state in nature [7]. Electronic spectrum of the complex in methanol solution shows strong absorption bands at 208 nm ($\varepsilon = 2.48 \times 10^4$ l mol^{-1} cm^{-1}) and 260 nm ($\varepsilon = 1.66 \times 10^4$ l mol^{-1} cm^{-1}), which can be assigned to the intra-ligand transitions. The spectra of the pseudo-octahedral nickel(II) complexes retain the simple form found in O_h symmetry showing validity of average environment rule [8]. The UV-vis spectra of nickel(II) complex in DMF solution gave three bands at 11364, 18315 and 26455 cm^{-1}, which corresponds to the transitions $^3A_{2g} \rightarrow {}^3T_{2g}(F)$, $^3T_{1g}(F)$ and $^3T_{1g}(P)$, respectively. The value of B (711.5 cm^{-1}), the Racah parameter, was calculated using the diagonal sum rule [8]. The calculated value of $\beta = B_{complex}/B_{free\,ion} = 0.691$ shows strong covalent bonding of nickel in the complex.

Crystal and molecular structure

The labelling scheme of the $[NiL]^{2+}$ cation is shown in Fig. 1 and the selected bond lengths and angles are presented in Table 2.

The structure consists of a discrete monomeric $[NiL]^{2+}$ cation and two uncoordinated perchlorate anions. The nickel(II) centre is six-coordinated [with N(1), N(2), N(3), N(4), N(11) and N(13)] and adopts a distorted-octahedral geometry. Only two of the four pyridine donor pendants in nonadjacent-positions interacting with the central nickel(II) and the other two pendant pyridines remaining uncoordinated. The four amine nitrogens span two contiguous faces of the distorted octahedron about the nickel atom, and the pyridine nitrogens occupy the remaining pair of *cis* positions in the coordination polyhedron.

The main deviations from the idealized geometry, possibly imposed by geometric requirements of the ligand, are due to (1) incomplete folding of the 12-membered macrocycle ring, revealed by the 105.3(3)° N(1)—Ni(1)—N(3) angle, larger than the expected 90° angle for the idealized geometry and (2) the inability of the nitrogen atoms of the macrocycle bearing pendant groups to reach *trans* positions in the coordination sphere. As a consequence of the latter constraint, the N(2)—Ni(1)—N(4) angle [153.7(3)°] is smaller than the expected 180° for the octahedral coordination geometry and all donor atoms of the macrocycle are forced to lie on one side of the nickel atom.

The macrocycle takes a *trans-I* configuration in which all the lone pairs in the four basal nitrogens are

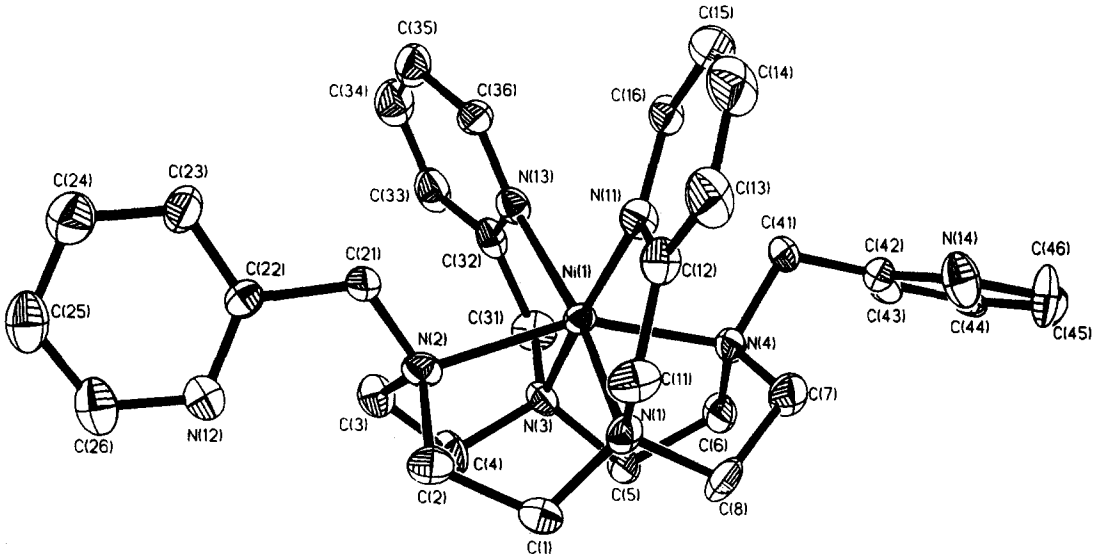

Fig. 1.

oriented to the same side of the macrocycle plane [9]. The macrocyclic ring folds to coordinate to the metal ion, thereby relieving steric strain within the macrocycle and minimizing repulsion among the coordinated pyridine groups.

The averaged Ni—N distances of the six Ni—N bonds are 2.166(8) Å, being typical Ni—N distance for the high spin nickel(II) in octahedral environment. This is in agreement with the effective magnetic moment of the complex. The bond distances of Ni(1)—N(1) and Ni(1)—N(3) are slightly shorter than those of Ni(1)—N(2) and Ni(1)—N(4), indicating weaker coordination of the macrocycle nitrogens connected to the uncoordinated methylpyridines than those connected to the coordinated methylpyridines, possibly for relieving steric strain within the macrocycle and minimizing repulsion among the coordinated pyridylmethyl groups. All sets of distances are in the ranges of values found for nickel complexes formed by other macrocycles [1,10].

The nickel atom is constrained to lie on the least-squares plane, defined by the atoms N(1), N(3), N(11), N(13) but is high above the mean plane formed by the four basal macrocycle nitrogens N(1), N(2), N(3) and N(4) by *ca* 0.9 Å, which in turn lie in pairs at 0.39 Å on opposite sides of that plane. While in the nickel(II) complex of Me_4-12aneN$_4$ [11], the nickel (II) ion extruded from the four basal macrocycle plane only by 0.29 Å. This great difference may arise from the fact that the nickel atom rises out of the basal plane to accept the strong coordination of the pendant pyridines in our complex.

(Received 9 June 1997; accepted 7 July 1997)

Abstract—The reaction of Na_2dmise (dmise = 2-selenoxo-1,3-dithiole-4,5-dithiolate) with [AuClL] in 1:2 molar ratio affords $[Au_2(dmise)L_2]$ (L = PR_3 or CH_2PPh_3) but in 1:1 ratio in the presence of (NBu_4) Br gives $(NBu_4)[Au(dmise)L]$. The PPh_2Me dinuclear derivative further reacts with $[Au(OClO_3)(PPh_2Me)]$ to give $[Au_3(dmise)(PPh_2Me_3)_3]ClO_4$. The reaction with $[Au_2(P\text{-}P)Cl_2]$ renders $[Au_2(P\text{-}P)(dmise)]_n$ with different nuclearity depending on the diphosphine used (P-P = dppe, $n = 1$; dppm, $n = 2$). Anionic derivatives $(PPN)_2[Au_2(dmise)(C_6F_5)_2]$ and $(PPN)[Au(dmise)_2]$ are obtained by reaction with the corresponding halo-anionic gold complexes. © 1997 Elsevier Science Ltd

Keywords: gold; dithiolate; dmise; phosphine; ylide.

The ligands dmit (2-thioxo-1,3-dithiole-4,5-dithiolate), dmise (2-selenoxo-1,3-dithiole-4,5-dithiolate) and analogues have been shown a considerable interest as versatile building blocks of conducting materials [1–6]. Since several examples of $M(dmit)_2$ salts with intramolecular S···S interactions *via* terminal thioxo group have been found [7], a selenoxo group is expected to increase these terminal contacts owing to the more diffuse and spatially extended orbitals of selenium compared with sulphur. Few studies on dmise ligand have been reported to date, in particular $[M(dmise)_2]^{n-}$ (M = Ni, Pd n = 1–2) [5,8] derivatives and only two of them have shown a metallic behaviour [1,9].

In this paper we report a study of co-ordination properties of dmise ligand with gold derivatives leading to complexes in which the dmise is acting as bidentate chelate {$(NBu_4)[Au(dmise)L]$ and $(PPN)[Au(dmise)_2]$} among others with novel coordination modes as bridge μ_2 {$[Au_2(dmise)L_2]$ (L = phosphine), $[Au_2(dmise)(L\text{-}L)]_n$ (L-L = dppm, dppe) or $(PPN)_2[Au_2(dmise)(C_6F_5)_2]$} and μ_3 {$[Au_3(dmise)L_3]ClO_4$}.

EXPERIMENTAL

General procedures

Infrared spectra were recorded on a Perkin Elmer 883 spectrophotometer, over the range 4000–200 cm^{-1}, by using Nujol mulls between polyethylene sheets, ^1H and ^{31}P NMR spectra on a Varian UNITY 300 in $CDCl_3$ solutions; chemical shifts are quoted relative to $SiMe_4$ (^1H) and H_3PO_4 (external ^{31}P). The C, H, N and S analyses were performed with a Perkin Elmer 2400 microanalyser. Conductivities were measured in acetone with a Philips PW 9509 apparatus. Mass spectra were recorded on a VG Autospec, by liquid secondary ion mass spectrometry (LSIMS + or −) using nitrobenzylalcohol as matrix. The yields C, H, N and S analyses and $^{31}P\{^1H\}$ and some ^1H NMR data are listed in Table 1.

Starting materials

4,5-Bis(benzoylthio)-1,3-dithiole-2-selenone [1,8(c)] $[AuCl(PR_3)]$ [15], $[AuCl(CH_2PR_3)]$ [16], $Q[Au(C_6F_5)X]$ [15], $[Au_2(\mu\text{-dppm})Cl_2]$ [17] and $[Au_2(\mu\text{-dppe})Cl_2]$ [17] were obtained according to the literature procedures.

[a] At −60°C: 17.6 (s) and 19.3 (s).

Preparation of $[Au_2(dmise)(L)_2]$ [L = PPh_3 (**1**), P(p-$C_6H_4OMe)_3$ (**2**), PPh_2Me (**3**), PMe_3 (**4**), CH_2PPh_3 (**5**)].

Sodium metal (9 mg, 0.4 mmol) and 4,5-bis(benzoylthio)-1,3-dithiole-2-selenone (68 mg, 0.15 mmol) were dissolved under nitrogen atmosphere in methanol (20 cm^3) to give a dark red solution of Na_2dmise, to which was added $AuCl(PPh_3)$ (148 mg, 0.3 mmol), $AuCl(P(p\text{-}C_6H_4OMe)_3)$ (175 mg, 0.3 mmol), $AuCl(PPh_2Me)$ (129 mg, 0.3 mmol), $AuCl(PMe_3)$ (93 mg, 0.3 mmol) or $AuCl(CH_2PPh_3)$ (152 mg, 0.3 mmol). Immediately different colour solid complexes (**1–5**) precipitated: dark yellow (**1, 4**), brown (**2, 3**) and orange (**5**), which were collected by filtration, washed with methanol and dried *in vacuo*.

Preparation of $[Au_3(dmise)(PPh_2Me)_3]ClO_4$ (**6**)

To a dichloromethane solution of $[AuCl(PPh_2Me)]$ (43 mg, 0.1 mmol) was added $AgClO_4$ (20 mg, 0.1 mmol). After stirring for 1 h the suspension was filtered through 1 cm of Celite, $[Au_2(dmise)(PPh_2Me)_2]$ (104 mg, 0.1 mmol) was added to the resulting solution. After stirring for 3 h the solution was concentrated by evaporation and the addition of diethyl ether led to precipitation of a dark garnet solid which was filtered off and dried *in vacuo*.

Preparation of $[Au_2(dmise)(L\text{-}L)]_n$ [$n = 1$, L-L = dppe (**7**), $n = 2$, L-L = dppm (**8**)]

To a methanolic solution (20 cm^3) with sodium metal and 4,5-bis(benzoylthio)-1,3-dithiole-2-selenone (68 mg, 0.15 mmol) under dinitrogen, was added $[Au_2(\mu\text{-dppe})Cl_2]$ (129 mg, 0.15 mmol) or $[Au_2(\mu\text{-dppm})Cl_2]$ (127 mg, 0.15 mmol). The solutions turn brown. After 1 h of stirring, the solutions were concentrated to dryness. Addition of acetone (20 cm^3) gave white solids corresponding to NaCl, which were filtered through 1 cm of Celite. Partial evaporation of the resulting solutions and addition of diethyl ether led to the precipitation of light brown solids which were filtered off and dried *in vacuo*.

Preparation of $NBu_4[Au(dmise)L]$ [L = PPh_3 (**9**), PPh_2Me (**10**)]

4,5-Bis-(benzoylthio)-1,3-dithiole-2-selenone (68 mg, 0.15 mmol) was dissolved under nitrogen atmosphere in a methanol (20 cm^3) solution containing sodium metal (9 mg, 0.4 mmol). A dichloromethane (5 cm^3) solution of $AuCl(PPh_3)$ (75 mg, 0.15 mmol) or $AuCl(PPh_2Me)$ (64 mg, 0.15 mmol) was added followed by a dichloromethane (5 cm^3) solution of NBu_4Br (48 mg, 0.15 mmol) with stirring. The solu-

tions turned red. After stirring for 12 h the solutions were evaporated to remove all the solvent, and acetone (15 cm^3) was added affording a white solid corresponding to NaCl, which was filtered off. The solutions were concentrated to 5 cm^3. Addition of diethyl ether precipitated garnet solid, which was filtered off.

Preparation of $(PPN)_2[Au_2(dmise)(C_6F_5)_2]$ **(11)**

Sodium metal (9 mg, 0.4 mmol) and 4,5-bis(benzoylthio)-1,3-dithiole-2-selenone (68 mg, 0.15 mmol) were dissolved under nitrogen atmosphere in methanol (20 cm^3) to give a dark red solution, to which was added PPN[Au(C_6F_5)Cl] (222 mg, 0.3 mmol). Immediately pink solid precipitated, which was collected by filtration, washed with methanol and dried *in vacuo*.

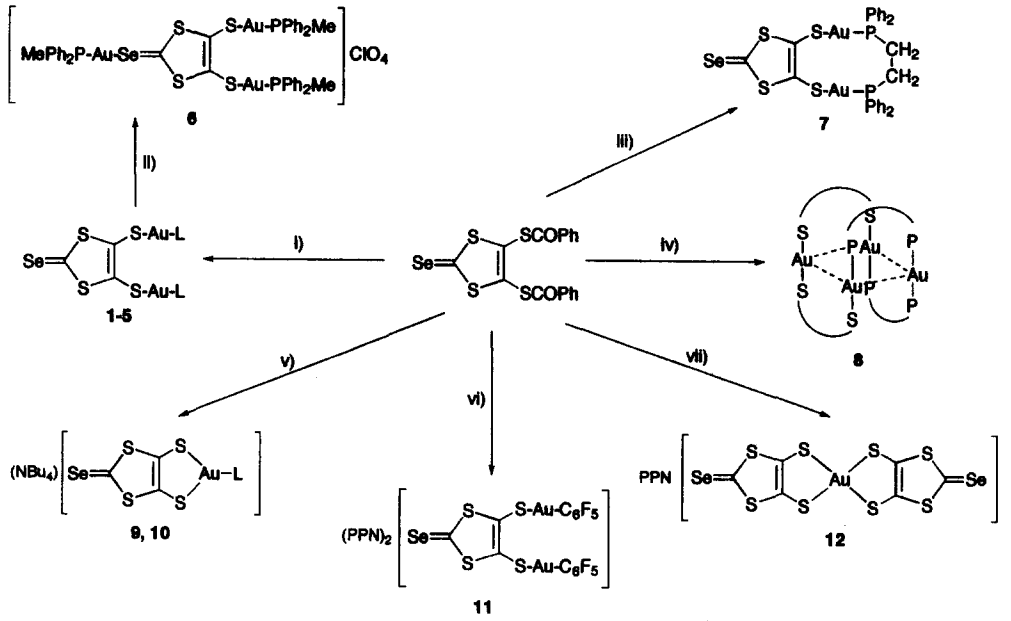
Preparation of PPN[Au(dmise)$_2$] **(12)**

Sodium metal (9 mg, 0.4 mmol) and 4,5-bis(benzoylthio)-1,3-dithiole-2-selenone (90 mg, 0.2 mmol) were dissolved under nitrogen atmosphere in methanol (20 cm^3) to give a dark red solution, to which was added PPN[$AuBr_4$] (105 mg, 0.1 mmol). A garnet solid precipitated which was collected by filtration, washed with methanol and dried *in vacuo*.

RESULTS AND DISCUSSION

The synthesis of complexes with dmit and analogues ligands with other calcogen atoms reported to date have been carried out starting from the COPh protected derivatives. In our case, the reaction of methanolic solutions of dmise$(COPh)_2$ in the presence of sodium to give Na_2dmise with chlorogold(I) complexes [AuClL] (L = phosphine or ylide) in 1 : 2 molar ratio, leads to dinuclear compounds where the dmise ligand acts as a bridge between the metallic centres, in a similar way to those reported by us for dmit derivatives [10] (See Scheme 1, i).

Complexes with the general formula [Au_2(dmise)L_2] (L = PPh_3 **1**, $P(p\text{-}C_6H_4OMe)_3$ **2**, PPh_2Me **3**, PMe_3 **4**, CH_2PPh_3 **5**) can be isolated as air- and moisture-stable solids at room temperature. Their spectroscopic properties are in agreement with its formulation: one singlet in $^{31}P\{^1H\}$ NMR very close to the values observed in the analogues of dmit, since the selenoxo group is too far to affect these signals. Their IR spectra show a band at *ca* 950 cm^{-1} due to ν(C=Se) vibration [11] and a band at 580 cm^{-1} assignable to ν(Au—C_{ylide}) [12]. The mass spectra (LSIMS+) show the parent peak M^+ at m/z (%): 1161 (15) **1**, 1341 (9) **2**, 1037 (15) **3**, 789 (20) **4**, with the expected isotopic distribution which in this case are illustrative because of the presence of six isotopes of selenium. As occurred for the dmit derivatives there



I) 2 [AuClL], II) [$AuOClO_3PPh_2Me$], III) [$Au_2(\mu$-dppe)Cl_2] IV) [$Au_2(\mu$-dppm)Cl_2], V) [AuClL] + NBu_4Br, VI) 2 PPN[Au(C_6F_5)Cl], VII) 1/2 PPN[$AuBr_4$]

Scheme 1.

are signals due to $[M+AuL]^+$ ion at *m/z* (%): 1620 (10) **1**, 1890 (6) **2**, 1434 (5) **3**, 1062 (30) **4**. The corresponding trinuclear complex in the case of L = PPh_2Me **6** can be achieved by a reaction of the dinuclear one **2** and a fresh solution of [Au($OClO_3$)(PPh_2Me)] (ii). Its ^1H NMR spectrum shows a doublet at 2.11 ppm [$^2J_{H-P} = 10.2$ Hz] and the $^{13}P\{^1H\}$ NMR at room temperature shows a broad signal, which is resolved in two singlets of relative intensity 2 : 1 at −60°C. This complex shows conductivity in acetone solution (5×10^{-4} M) characteristic of a 1 : 1 electrolyte [13] and the mass spectrum shows the parent ion at *m/z* (%) 1899 (16). According to the data for **1–6** complexes, we can postulate similar structures to those reported for dmit ligand, with the dmise ligand acting as μ_2 and μ_3 bridge.

Similar reaction with bisphosphine gold complexes (iii and iv) give different results depending on the phosphine. So, when dppe (1,2-bis(diphenylphosphine)ethane) is used, complex [Au_2(dmise)(dppe)] **7** can be isolated, but with dppm (1,2-bis(diphenylphosphine) methane) [Au_2(dmise)(dppm)]$_2$ **8** is obtained instead. The $^{31}P\{^1H\}$ NMR for **7** consists on a singlet centred at 32.7 ppm in accordance with the proposed formulation and complex **8** shows an AA′XX′ system: $\delta_A = 37.7$ ppm, $\delta_X = 24.1$ ppm, $^2J_{AA'} = 81$ Hz, $^2J_{AX} = {}^2J_{A'X} = 46.4$ Hz. These data are very close to those reported to the dmit derivatives pointing out similar structures for dmit and dmise compounds [10,14] (see Scheme 1).

When the reaction i with [AuClL] is made in 1 : 1 molar ratio and after addition of NBu_4Br (v) anionic NBu_4[Au(dmise)L] (L = PPh_3 **9**, PPh_2Me **10**) are obtained. Complexes **9** and **10** behave as 1 : 1 electrolytes in acetone solution in accordance with their formulation. Their $^{31}P\{^1H\}$ NMR spectra show singlets displaced down field with respect to the dinuclear compounds **1** and **3** (Table 1) and in a similar δ to those reported for the corresponding tricoordinated dmit complexes [10].

Other anionic gold dmise complexes can be obtained starting from anionic halo gold derivatives such as PPN[Au(C_6F_5)Cl] and PPN[$AuBr_4$] and reacting with a solution of Na_2dmise in 1 : 2 and 2 : 1 molar ratio, respectively (vi and vii). The corresponding complexes (PPN)$_2$[Au_2(dmise)(C_6F_5)$_2$] **11** and (PPN)[Au(dmise)$_2$] **12** are isolated as pink and garnet coloured solids and only **11** is soluble enough in acetone showing a Λ_M value characteristic of 2 : 1 electrolyte. The ^{19}F NMR spectrum of **11** shows three signals: −115.1 (m, F_o), −163.4 (t, F_p), −164.5 (m, F_m) in accordance with two equivalents C_6F_5 groups. Both complexes show in the mass spectra (LSIMS−) signals corresponding to the parent anion [**11**−2PPN]$^-$, [**11**−PPN]$^-$, [**12**−PPN]$^-$ at *m/z* (%): 972 (10), 1510 (4) and 684 (8) respectively. It is noteworthy that the mass spectra of complex **11** shows other ion-molecule association as [**11**+Au(C_6F_5)−2PPN]$^-$ and [**11**+Au(C_6F_5)−PPN]$^-$ at *m/z* (%): 1336 (6) and 1874 (4).

The reactivity of zirconium acetylacetonate with phenols

William J. Evans,* Mohammad A. Ansari and Joseph W. Ziller

Department of Chemistry, University of California, Irvine, CA 92697-2025, U.S.A.

(Received 2 June 1997; accepted 7 July 1997)

Abstract—Although zirconium acetylacetonate, $Zr[CH_3C(O)CHC(O)CH_3]_4$, **1**, does not react with phenol, 4-methylphenol, or 2,6-dimethylphenol at reflux temperature in toluene or THF, it does react with *p*-nitrophenol in THF at room temperature to form $(acac)_3Zr(OC_6H_4NO_2\text{-}4)$, **2**, in 70% yield. **1** also reacts with 1,4-dihydroxybenzene to form bimetallic $[(acac)_3Zr]_2(\mu OC_6H_4O\text{-}4)$, **3**, in 90% yield. **2** crystallizes from THF to form a capped trigonal prismatic geometry around zirconium with the aryloxide ligand in the capping position. **3** crystallizes from THF/C_6H_6 to form a structure similar to that of **2** except that the aryloxide ligand occupies a trigonal prismatic vertex in the square face which is capped. © 1997 Elsevier Science Ltd

Keywords: zirconium; aryloxide; acetylacetonate; bimetallic.

Metal alkoxide and aryloxide complexes are desirable precursors for the preparation of metal-containing ceramics since they can be decomposed at a relatively low temperature with the formation of volatile organic byproducts which are not incorporated in the final product [1]. Although an extensive alkoxide and aryloxide chemistry has been developed for many of the early transition metals and the *f* elements [2], the chemistry of zirconium complexes is less extensive despite the fact that zirconium is an important component in a variety of practical ceramic devices [3]. The number of fully characterized zirconium inorganic aryloxide complexes is particularly small [4].

In efforts to extend the range of known zirconium aryloxide complexes and to examine the utility of zirconium acetylacetonate, $Zr(acac)_4$, **1** [acac = $CH_3C(O)CHC(O)CH_3$], as a precursor, we have examined the reactivity of **1** with various phenols. Zirconium acetylacetonate is an attractive starting material since it is a relatively inexpensive, alkane and arene soluble, water-free compound which has ligands which stabilize by chelation. In addition, the acetylacetonate ligands have the potential to bridge to form polyzirconium complexes, a class of compounds for which there are not many examples [5]. Although zirconium acetylacetonate does not readily react with simple phenols, we have found that by increasing the acidity of the phenol fully characterizable zirconium aryloxide acetylacetonate derivatives can be obtained from **1**.

EXPERIMENTAL

The chemistry described below was performed under nitrogen with rigorous exclusion of air and water using Schlenk, vacuum line, and glovebox techniques. Solvents were purified as previously described [6]. NMR spectra were recorded on a General Electric QE 300 spectrometer at 25°C. Elemental analyses were determined on a Carlo Erba EA 108 intrument or performed by Analytische Laboratorien, Gummersbach, Germany. 2,6-Dimethylphenol, 4-methylphenol, and 4-nitrophenol were obtained from Aldrich and sublimed before use. $Zr(acac)_4$ was obtained from Aldrich.

Synthesis of $Zr(acac)_3(OC_6H_4NO_2\text{-}4)$, **2**

In the glovebox, colorless $Zr(acac)_4$ (487 mg, 1.0 mmol) was added to 4-nitrophenol (140 mg, 1.0 mmol) in 10 cm^3 of THF and stirred for 2 days. Removal of solvent by rotary evaporation gave a yellow powder which was washed with hexanes and recrystallized from THF/benzene to form **2** (385 mg, 73%). The complex is only slightly soluble in toluene. Anal. calcd for $C_{21}H_{25}NO_9Zr$: C, 47.89; H, 4.78; N, 2.65; Zr, 17.32. Found: C, 47.68; H, 4.63; N, 2.65; Zr, 17.55. IR (Nujol): 1580 s, 1560 m, 1525 s, 1495 s, 1420 w, 1385 w, 1360 s, 1315 s, 1295 m, 1160 w, 1122 m, 1030 m, 1025 m, 944 w, 875 s, 862 w, 665 w cm^{-1}. ^1H NMR (C_6D_6):

8.10 (d, 2H, $C_6H_4NO_2$), 6.80 (d, 2H, $C_6H_4NO_2$), 5.24 (s, 3H, $CH_3COCHCOCH_3$), 1.68 (18 H, CH_3CO $CHCOCH_3$). ^{13}C NMR (C_6D_6): 190.8 (CH_3CO $CHCOCH_3$), 126.0 ($C_6H_4NO_2$), 119.6, ($C_6H_4NO_2$), 104.3 ($CH_3COCHCOCH_3$), 26.7 ($CH_3COCHCO$ CH_3).

X-ray data collection, structure determination, and refinement for $(acac)_3Zr(OC_6H_4NO_2\text{-}4)$, **2**

A pale yellow crystal of approximate dimensions $0.15 \times 0.30 \times 0.30$ mm was mounted on a glass fiber and transferred to a Siemens P4 rotating anode diffractometer. The determination of Laue symmetry, crystal class, unit cell parameters, and the crystal's orientation matrix were carried out according to standard procedures [7]. Intensity data were collected at 158 K using a $2\theta/\omega$ scan technique with Mo-$K\alpha$ radiation. The raw data were processed with a local version of CARESS [8] which employs a modified version of the Lehman–Larsen algorithm to obtain intensities and standard deviations from the measured 96-step peak profiles. Subsequent calculations were carried out using the SHELXL program [9]. All 2933 data were corrected for Lorentz and polarization effects and were placed on an approximately absolute scale. The diffraction symmetry was *mmm* and the systematic absences are consistent with the noncentrosymmetric space group $P2_12_12_1$. The analytical scattering factors for neutral atoms were used throughout the analysis [10]. The structure was solved by direct methods and refined on F^2 by full matrix least-squares techniques. Hydrogen atoms were included using a riding model. At convergence, $wR2 = 0.0770$ and GOF = 1.104 for 296 variables refined against all 2993 unique data [as a comparison for refinement on F, $R1 = 0.0279$ for those 2650 data with $F > 4.0\sigma(F)$]. The absolute structure was assigned by refinement of the Flack parameter [11]. Details are in Table 1.

Synthesis of $[(acac)_3Zr]_2(OC_6H_4O\text{-}4)$, **3**

In the glovebox, addition of a solution of 1,4-$(HO)_2C_6H_4$ (55 mg, 0.5 mmol) in 5 cm^3 of THF to a solution of $Zr(acac)_4$ (487 mg, 1.0 mmol) in 10 mL of THF causes an immediate color change from colorless to yellow. After stirring overnight the product was isolated as a light yellow powder by centrifugation and washing with hexanes (410 mg, 90%). The complex is only slightly soluble in toluene and THF and was crystallized from hot toluene. Anal. calcd for $C_{36}H_{46}O_{14}Zr_2$: C, 48.84; H, 5.24; Zr, 20.60. Found: C, 49.03; H, 5.07; Zr, 20.40. IR (Nujol): 1580 m, 1530 s, 1495 m, 1360 w, 1280 m, 1240 s, 1020 s, 935 m, 850 m, 832 m, 810 w, 775 w, 760 w, 665 m cm^{-1}. ^1H NMR (C_6D_6): 6.98 (s, 4H, C_6H_4), 5.28 (s, 6H, CH_3CO-$CHCOCH_3$), 1.74 (36 H, $CH_3COCHCOCH_3$).

X-ray data collection, structure determination, and refinement for $[(acac)_3Zr]_2(\mu\text{-}OC_6H_4O\text{-}4)$, **3**

A colorless crystal of approximate dimensions $0.34 \times 0.40 \times 0.47$ mm was mounted on a glass fiber and transferred to the Siemens P4 diffractometer and handled as described above for **2**. There were no systematic absences nor any diffraction symmetry other than the Friedel condition. The centrosymmetric triclinic space group $P\bar{1}$ was assigned and later determined to be correct. The structure was solved as described for **2**. Hydrogen atoms were located from a series of difference-Fourier maps and refined isotropically. The molecule is located about an inversion center. There is one molecule of benzene solvent present per formula unit. At convergence, $wR2 = 0.0548$ and GOF = 1.055 for 366 variables refined against all 2790 unique data [as a comparison for refinement on F, $R1 = 0.0219$ for those 2537 data with $F > 4.0\sigma(F)$].

RESULTS AND DISCUSSION

The complex $(acac)_3Zr(OC_6H_4NO_2\text{-}4)$, **2**

$Zr(acac)_4$, **1**, reacts with 1 equiv. of $HOC_6H_4NO_2$-4 ($pK_a = 7.16$) in THF according to equation 1 to give the pale yellow complex, **2**

$$\underset{\mathbf{1}}{Zr(acac)_4} + HOC_6H_4NO_2\text{-}4 \xrightarrow{THF} \underset{\mathbf{2}}{(acac)_3Zr(OC_6H_4NO_2\text{-}4)} + Hacac. \quad (1)$$

Attempts to use $Zr(acac)_4$ as a precursor to aryloxide derivatives of phenol ($pK_a = 10$), 4-methylphenol ($pK_a = 10.26$), and 2,6-dimethylphenol ($pK_a = 10.65$) were unsuccessful in both refluxing THF and toluene. This reactivity is consistent with the pK_a of acetylacetone which is 9.0.

The ^1H NMR spectrum of **2** indicated the presence of a single type of $CH_3COCHCOCH_3$ ligand with chemical shifts only slightly different from the starting material and a 3:1 acac:aryloxide ratio. Complex **2** crystallizes readily from THF/benzene at ambient temperature in >70% yield and an X-ray diffraction study was carried out to definitively characterize it as the neutral monometallic complex $(acac)_3Zr(OC_6H_4NO_2\text{-}4)$, Fig. 1.

Complex **2** contains a heptacoordinate zirconium center attached to three bidentate acetylacetonate ligands and a nitrophenoxide ligand through the phenolic oxygen. The closest examples to **2** in the literature are the mixed ligand complexes $Zr(acac)_3Cl$ [12] and $Zr(acac)_3NO_3$ [13]. Important bond lengths and distances are given in Table 2.

The coordination geometry around zirconium in complex **2**, Fig. 2, is best described as a distorted square-face-capped trigonal prism with the O(7) nitrophenoxide oxygen in the capping position. The

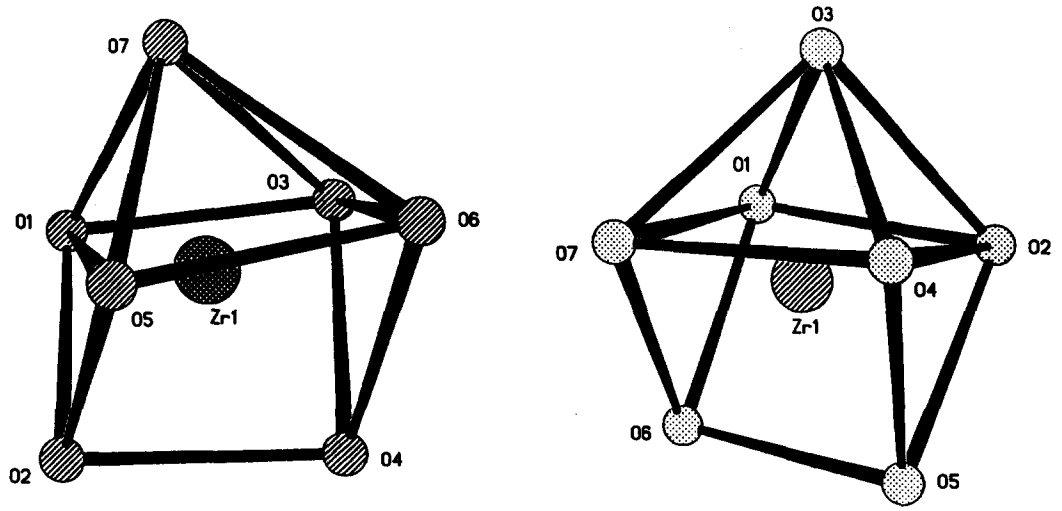

Fig. 2. Capped trigonal prismatic coordination spheres of zirconium in $(acac)_3Zr(OC_6H_4NO_2\text{-}4)$, **2**, left, and $[(acac)_3Zr]_2(\mu\text{-}OC_6H_4O\text{-}4)$, **3**, right.

the unequal 131.35(11)° O(7)—Zr—(O2) and 153.92(11)° O(7)—Zr—O(4) angles which would be equivalent in an idealized capped trigonal prism. The oxygen atoms comprising the three square faces of the prism are coplanar to within 0.12 Å for O(1,2,3,4), 0.15 Å for O(2,4,5,6), and 0.30 Å for O(1,3,5,6). The zirconium atom lies 0.03 Å below this latter plane and is 0.41 Å from the centroid of the oxygen atoms. The four O(7)—Zr—O(1,3,5,6) angles involving the capping O(7) position and the square face which it caps fall in the narrow range of 79.66(12) to 83.50(11)°. The O—Zr—O bite angles for the acetylacetonate ligands vary from only 75.14(11) to 77.84(10)°. The analogous angles in $Zr(acac)_4$ are 75.1(1) and 74.6(1)°.

The Zr—O(acac) distances involving the oxygens in the trigonal prism have a narrow 2.106(3) to 2.195(3) Å range and the 2.15(3) Å average Zr—O(acac) distance can be compared with the 2.188(6) and 2.141(4) Å averages in eight coordinate $Zr(acac)_4$ [14] and $Zr(acac)_3NO_3$ [13], respectively. The 2.045(3) Å Zr—O(nitrophenoxide) length is the shortest Zr—O distance in the structure and is similar to the 2.030(6) and 2.047(7) Å lengths reported for $Zr(OC_6H_3Bu^t_2\text{-}2,6)_2(=NPh)$ (4-pyrrolidinopyridine)$_2$ [4h]. The nitro group is too distant from the metal center of any neighboring molecule to have an interaction.

The complex $[(acac)_3Zr]_2(\mu\text{-}OC_6H_4O\text{-}4)$, **3**

Since the reaction of $Zr(acac)_4$ with $HOC_6H_4NO_2\text{-}4$ did not lead to a bridged structure through either the acetylacetonate or the nitrophenoxide ligands, reactions with a precursor more likely to form bridged structures, $HOC_6H_4OH\text{-}4$, were examined. The reaction of 2 equiv. of $Zr(acac)_4$ with 1 equiv. of $HOC_6H_4OH\text{-}4$ in THF formed **3** as a yellow powder in 80% yield according to reaction (2)

$$\underset{\mathbf{1}}{2Zr(acac)_4} + HOC_6H_4OH\text{-}4 \xrightarrow{THF} \underset{\mathbf{3}}{[Zr(acac)_3]_2(\mu\text{-}OC_6H_4O\text{-}4)} + 2Hacac \quad (2)$$

The ^1H NMR spectrum of **3** indicated the presence of both aryloxide and acetylacetonate ligands in a 1:6 ratio, but it was not structurally definitive. X-ray diffraction revealed the existence of a bimetallic complex as shown in Fig. 3.

Complex **3** crystallizes as a centrosymmetric dimer. Like **2**, it has seven coordinate zirconium centers which have distorted square-face-capped trigonal prismatic geometries, Fig. 2. In this case, however, oxygen donor atom, O(7), of the aryloxide ligand is in a prismatic rather than a capping position. As shown in Table 2, the metrical parameters in the two complexes are similar despite the different location of the aryloxide ligand. Since there are no O—Zr—O angles greater than 161°, again a capped-octahedral structure is ruled out. The four O(3)—Zr—O(1,2,4,7) angles fall in a narrow 75.78(7)–82.97(7)° range and the three planes of four oxygen atoms are coplanar to 0.09 Å (1,2,5,6), 0.12 Å (4,5,6,7) and 0.07 Å (1,2,4,7). The zirconium lies 0.43 Å below the O(1,2,4,7) plane and is 0.44 Å from the centroid of the oxygen atoms. The capped trigonal prism is somewhat more regular than in **2**. For example, the 143.32(7)° O(3)—Zr—O(5) and 141.54(7)° O(3)—Zr—O(6) angles involving the capping oxygen are quite similar. The Zr—O(acac) distances average 2.16(4) Å with a 2.142(2)–2.198(2) Å range similar to that in **2**. The acetylacetonate oxygen in the unique capping position, O(3), has the longest Zr—O distance, but it is

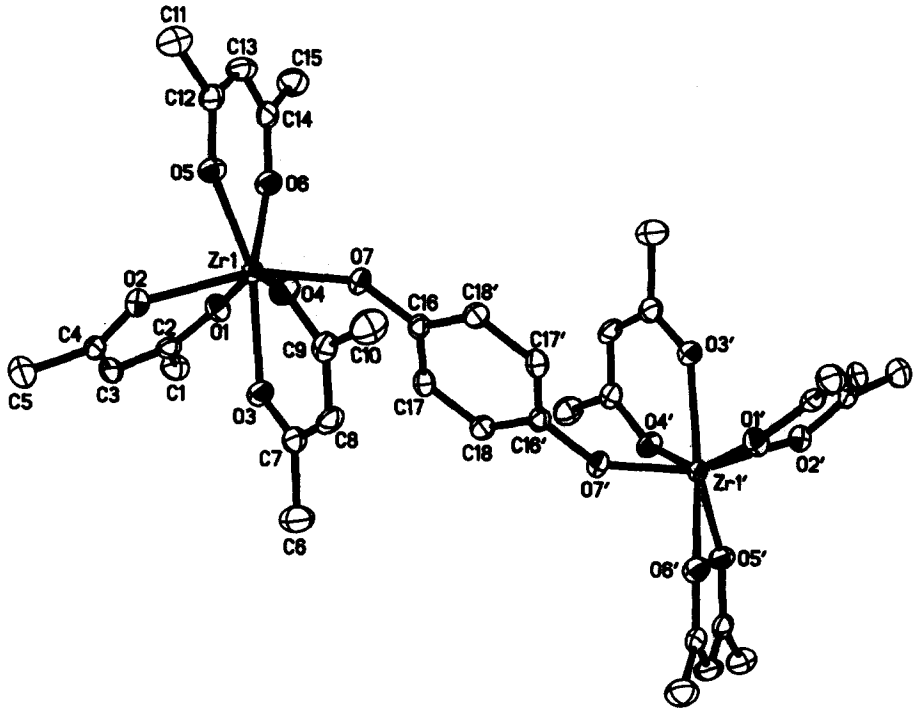

Fig. 3. Structure of $[(acac)_3Zr]_2(\mu\text{-}OC_6H_4O\text{-}4)$, **3**. The thermal ellipsoid plot is shown at the 50% probability level.

not unusually long. Neither does this acetylacetonate have an unusual O—Zr—O bite angle: the 74.87(7)–77.85(7)° range for all of the acac ligands is normal. The 1.977(2) Å Zr—O(aryloxide) length, Zr—O(7), is the shortest Zr—O distance as in **2**.

CONCLUSIONS

The reactivity of zirconium acetylacetonate with phenols can be correlated with the acidity of the phenol. Phenols with $pK_a < 9.0$ substitute one acetylacetonate ligand and readily form $Zr(acac)_3(OAr)$ complexes. 1,4-Dihydroxybenzene provides a method to generate bimetallic aryloxide acetylacetonate zirconium complexes.

Abstract—The products obtained by reacting the title selenium donors, **1** and **2**, with molecular dibromine, both in 1 : 1 and 1 : 2 **1**(**2**)/Br_2 molar ratios in CH_2Cl_2 solution, are described. Depending on the molar ratio of the reagents, **1** gives two different products having stoichiometries **1** · Br_2 (**I**) and $C_8H_{14}Br_8N_2S_2Se$ (**II**). Compound **II**, characterised by X-ray diffraction on a single crystal, is an ionic compound having formula $(C_4H_7BrNS)_2[SeBr_6]$. Thus, the reaction occurs through C=Se bond breaking and formation of the *N*-methyl-2-bromothiazolidinium cation and oxidation of the selenium atom to a hexabromo selenate(2-) anion. In the corresponding reaction with **2**, the same compound of stoichiometry **2** · Br_2 (**III**) is obtained in both molar ratios. The X-ray diffractometric analysis on a single crystal of **III** shows that it is a hypervalent Se-compound, $C_8H_7Br_2NSSe$, bearing the Br—Se—Br linear group. FT-IR and FT-Raman spectra are in accordance with structural results for **II** and **III** and help to characterise **I**. © 1997 Elsevier Science Ltd

Keywords: *N*-methylthiazolidine-2(3H)-selone; *N*-methylbenzothiazole-2(3H)-selone; hypervalent selenium compounds with bromine; hexabromoselenate(2-); X-ray structures.

We are extensively investigating the donor/acceptor reactions between heterocycles containing the thionic and selonic groups and dihalogens or interhalogens. We have found that, besides the donor/acceptor adducts, a large variety of products can be obtained and that X-ray crystal structure determination plays a crucial role in their characterisation. As an example of the above, Scheme 1 summarizes the case of the reaction of the donors *N*-methyl-1,3-thiazolidine-2(3H)-selone (**1**) and *N*-methylbenzothiazole-2(3H)-selone (**2**) with the acceptors I_2 and IBr [1]. An analogous variety of products has also been found with other selenium donors [2–8]. As a development of our research in this field, we here report the results obtained by reacting **1** and **2** with molecular dibromine in CH_2Cl_2 solution (also collected in Scheme 1). Whatever the reagent molar ratio, **2** gives the hypervalent compound $C_8H_7Br_2NSSe$ (**III**), which bears the Br—Se—Br linear group. **1** gives the hypervalent compound $C_4H_7Br_2NSSe$ (**I**) when the reaction is carried out in 1 : 1 **1**/Br_2 molar ratio while by using the 1 : 2 or lower reagent molar ratios, ionic compound $2[C_4H_7BrNS]^+ [SeBr_6]^{2-}$ (**II**) is obtained.

EXPERIMENTAL

Materials

N-methyl-1,3-thiazolidine-2(3H)-selone (**1**) was synthesized according to the procedure report in [9]. *N*-methylbenzothiazole-2(3H)-selone (**2**) and dibro-

mine were purchased from Aldrich and used without further purification.

N-methyl-1,3-thiazolidine-2-ylium dibromo selenanide (**I**). This compound was obtained as yellow-orange microcrystals by evaporating a dichloromethane solution of *N*-methyl-1,3-thiazolidine-2(3H)-selone (**1**) (0.05 g, 2.8×10^{-4} moles) and bromine (2.8×10^{-4} moles) in air at room temperature (yield 94%). m.p. 115–117°C; Found (Calc. for $C_4H_7Br_2NSSe$): C, 14.38 (14.13); H, 2.09 (2.08); N, 4.18 (4.12); S, 9.46 (9.43)%.

N-methyl-2-bromothiazolidinium hexabromoselenate(2-) (**II**). **II** was obtained as yellow-orange crystals by evaporating a dichloromethane solution of *N*-methyl-1,3-thiazolidine-2(3H)-selone (**1**) (0.05 g, 2.8×10^{-4} moles) and bromine (5.6×10^{-4} moles) in air at room temperature. m.p. 129–135°C; Found (Calc. for $C_8H_{14}Br_8N_2S_2Se$): C, 10.32 (10.44); H, 1.43 (1.53); N, 2.97 (3.04); S, 6.75 (6.97); Se, 8.60 (8.58)%. After ascertaining the stoichiometry, subsequent preparations were repeated using bromine amounts corresponding to 1:2.5 molar ratio (yield 60%).

N-methylbenzothiazole-2-ylium dibromo selenanide (**III**). This compound was quantitatively obtained as red-black crystals by evaporating a dichloromethane solution of *N*-methylbenzothiazole-2(3H)-selone (**2**) (0.05 g, 2.2×10^{-4} moles) and bromine (2.2×10^{-4} moles) in air at room temperature. m.p. 219–220°C; Found (Calc. for $C_8H_7Br_2NSSe$): C, 24.50 (24.77); H, 1.91 (1.82); N, 3.55 (3.61); S, 8.05 (8.26)%. The same compound was obtained using double the amount of dibromine.

FT-Raman and FT-IR spectra

The FT Raman spectra were recorded by means of a Bruker FRS 100 Fourier Transform Raman Spectrometer, operating with a diode-pumped Nd:YAG exciting laser emitting at a 1064 nm wavelength and having a power impinging on the sample tunable up to 350 mW. The detection of the signal was made with an Indium-Gallium-Arsenide detector operating at room temperature; all spectra were recorded at a 4 cm^{-1} resolution, down to about a Raman shift of 50 cm^{-1}. The solid samples were packed into a suitable cell and fitted into the compartment designed to use a 180° scattering geometry. No sample decomposition was observed during the experiments. The infrared spectra were recorded by means of a Bruker IFS66 Fourier Transform Infrared Spectrometer on polyethylene pellets in the 500–80 cm^{-1} range.

X-ray crystal structure determination

Details of the data collection and refinement of the structures are reported in Table 1 [10]. Crystals of compounds **II** and **III** were mounted on a glass fiber in a random orientation. Preliminary examination and data collection were performed with graphite monochromatized Mo-K_α radiation (0.71073 Å) on an Enraf-Nonius CAD4 computer controlled kappa axis diffractometer. Cell constants and an orientation matrix for data collection were obtained from least-squares refinement, using the setting angles of 25 reflections. The data were collected at room temperature using a variable scan rate (2 to 20° min in omega). Three representative reflections were measured every hour to check the stability of the crystals under X-ray exposure; these measurements revealed a decay of the scattering power of the crystal which amounts to about 8 and 7% (on F_o) for **II** and **III**, respectively. Lorentz, polarization and a linear correction for decay were applied to the intensities. An empirical absorption correction, performed as described in [11], was also applied to the data. Both structures were solved using direct methods (MULTAN) and difference Fourier syntheses, and were refined in full-matrix least-squares, the function minimized being $\Sigma w(|F_o| - |F_c|)^2$. All the hydrogen atoms were seen in a difference map and introduced in the structure model at idealized positions (C—H 0.95 Å) and not refined. Scattering factors were taken from Cromer and Waber [12]. Anomalous dispersion effects were included in F_c; the values for $\delta f'$ and $\delta f''$ were those of Cromer [13]. All calculations were performed on an 80486/33 computer using Personal SDP software [14]. Selected interatomic distances and angles are shown in Table 2.

RESULTS AND DISCUSSION

As summarized in Scheme 1, the variety of products, obtained by reacting *N*-methyl-1,3-thiazolidine-2(3H)-selone (**1**) and *N*-methylbenzothiazole-2(3H)-selone (**2**) with molecular diiodine and iodinebromine in CH_2Cl_2 solution, is further increased by using the molecular dibromine as acceptor. In fact, while with a 1:1 reagent molar ratio, both **1** and **2** yield compounds having $\mathbf{1} \cdot Br_2$ (**I**) and $\mathbf{2} \cdot Br_2$ (**III**) stoichiometry, with a 1:2 reagent molar ratio, the isolated products are very different. **2** gives the same compound **III**, and **1** produces the ionic compound **II**. **I** and **III** are hypervalent selenium compounds, bearing the Br—Se—Br linear group (see later) and **II** is the unusual compound *N*-methyl-2-bromothiazolidinium hexabromoselenate(2-), in which the C=Se double bond of **1** has been broken [15] with oxidation of the selenium atom to $[SeBr_6]^{2-}$ and formation of $[C_4H_7BrNS]^+$ cations. **I**, **III** and the $[C_4H_7BrNS]^+$ cation may be regarded as adducts of the nucleophilic carbene ligands thiazolin-2-ylidene (C_4H_7NS) and benzothiazol-2-ylidene (C_8H_7NS) with the acceptors $SeBr_2$ (**I** and **III**) and Br^+ (**II**).

Crystal structure of N-methyl-2-bromothiazolidinium hexabromoselenate(2-) (**II**)

A projection of the crystal structure of **II**, seen almost along [010] is shown in Fig. 1. The unit cell

contains eight $C_4H_7BrNS^+$ cations in general position and four $SeBr_6^{2-}$ anions located on crystallographic two-fold axes. The $C_4H_7BrNS^+$ cations are essentially planar; their geometry can be compared with that of the *N*-methyl-1,3-thiazolidine-2(3H)-selone molecule in the adducts with I_2 or IBr [1]. The effects on bond distances and angles of the pentaatomic ring, due to replacement of a Se atom with a bromine atom and also to the presence of a delocalized positive charge are not appreciable, because of the high e.s.d.s observed in all these compounds. However, a regular trend in the shortenings of the S—C(1) and N(1)—C(1) bond distances can be seen as well as in the opening of the S—C(1)—N(1) angle on increasing the positive charge on the ring passing from **I** · I_2 to **1** · IBr [1] and to the $C_4H_7BrNS^+$ cation. The higher value of the N—C—N angle in 1,3-dimesitylimidazolinium chloride with respect to that observed in 1,3-dimesitylimidazolin-2-ylidene has been recently pointed out by Arduengo *et al.* [16] as one of the noteworthy differences in the pentaatomic ring structure between the two compounds. For the stabilization of **I** (hypervalent Se-compound) and of the cation in **II** (formally an adduct of the thiazolin-2-ylidene with Br^+) it is evident that the delocalization of the positive charge on the whole pentaatomic ring, as occurs for **III**, is not necessary. Also for the dications bearing the —Se—Se— bridge, recently reported by us [8], the delocalization of the positive charge on the whole ring is not strictly necessary to their stability, as proved by the isolation of such dications starting from 1,3-dimethyl-4-imidazoline-2-selone and 1,3-dimethylimidazolidine-2-selone.

The $SeBr_6^{2-}$ anion does not have the distorted octa-

Symmetry code: $a = -x, y, 1/2-z$.

hedral geometry expected for AX_6E molecules on the basis of the VSEPR theory [17] the bond angles are very close to the ideal values of 90 and 180°, and only a slight asymmetry can be appreciated in the Se—Br distances, ranging from 2.532(2) to 2.616(2) Å, probably due to packing effects. Their average value (2.570 Å) is very close to that observed in K_2SeBr_6 [2.575(2) Å] [18]. These features, also common to other isoelectronic anions such as TeX_6^{2-} and $SbBr_6^{3-}$, have been explained assuming that on increasing the size of the central atom the lone pair is drawn inwards toward the core and spread around it, and consequently the bond pairs move further from the central nucleus [17]. In fact the Se—Br distances are considerably longer than the sum of the covalent radii (*ca.* 2.31 Å).

Crystal structure of N-methylbenzothiazole-2-ylium dibromo selenanide (**III**)

The crystal packing of compound **III** is shown in Fig. 2. The content of the unit cell consists of four pairs of $C_8H_7Br_2NSSe$ molecules and two dichloromethane molecules, the latter being disordered about crystallographic inversion centers. Each $C_8H_7Br_2NSSe$ molecule contains an almost linear Br—Se—Br moi-

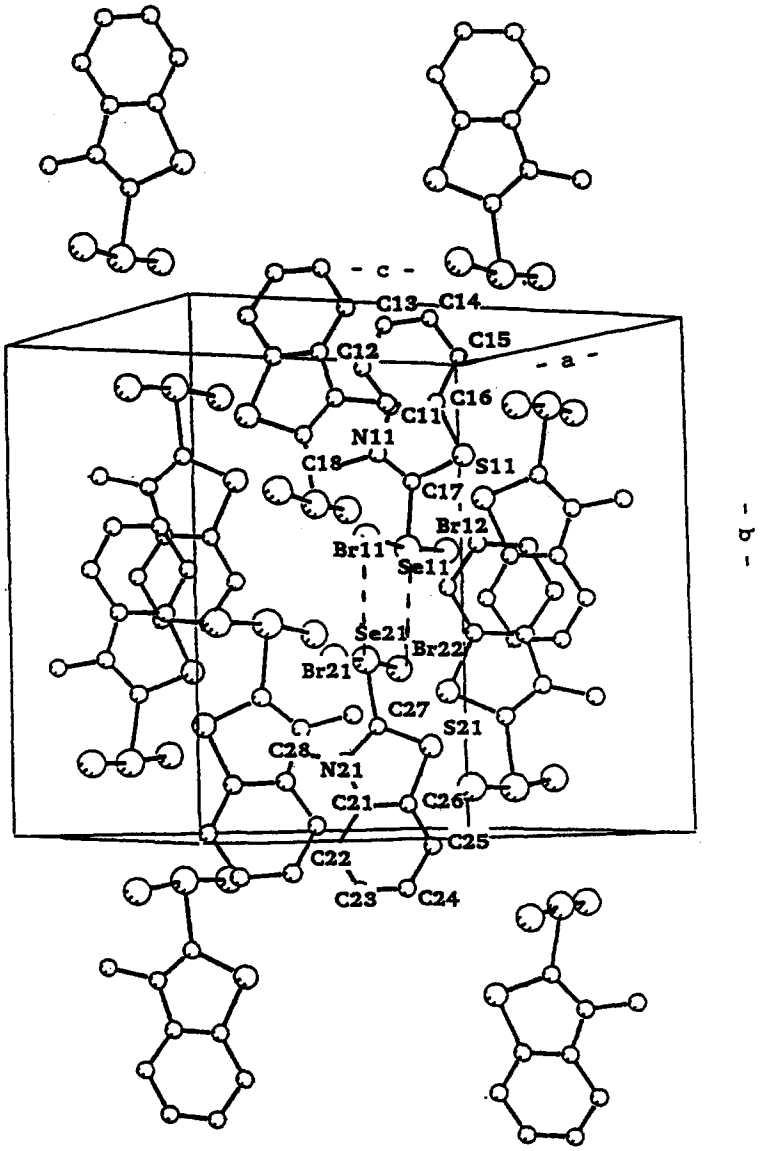

Fig. 2. Crystal packing of **III**.

ety [Br—Se—Br angles are 173.6(1) and 175.1(1)°, respectively], which is roughly perpendicular to the plane of the benzothiazole molecule [the Br—Se—C—S torsion angles are 102.4(6) and 92.0(6)° for the two molecules, respectively]. Within the pentaatomic ring, the S(11)—C(17)—N(11) and S(21)—C(27)—N(21) angles [average value of the two independent molecules is 113.6(7) Å] are somewhat closed compared with the derivatives of **1** (**1**·I_2 and **1**·IBr) [1] and with the $C_4H_7BrNS^+$ cation, according to shorter C(11)—C(16) and C(21)—C(26) bonds [average value 1.354(14) Å] relative to C(2)—C(3) values, 1.546(11), 1.522(18) and 1.449 (15) Å in **II**, **1**·IBr [1] and **1**·I_2 [1] respectively. The two independent molecules interact to form a dimeric unit through the Se and Br interactions (the Se(11)···Br(22) and Se(21)···Br(11) contacts are 3.492(2) and 3.503(2) Å respectively). In spite of being about 1 Å longer than the distances corresponding to Se—Br bonds (average value 2.564 Å), these secondary interactions are significantly shorter than the sum of the van der Waals radii of Se and Br, and allow the charge density on the Se atom to be further delocalized. In this way, the T-shape arrangement about the Se atoms could be considered almost square planar.

FT-IR and FT-Raman spectra of **II** are reported in Fig. 3. The simpleness of the Raman spectrum of **II** agrees well with a high symmetry of the octahedral structure of the $[SeBr_6]^{2-}$ ion in accordance with X-ray results. The Raman bands at 168 (ν_1) [19], 152 (ν_2) and 93 (ν_5) cm^{-1} agree well with the values reported for the $[SeBr_6]^{2-}$ and $[TeBr_6]^{2-}$ ions in O_h symmetry [20]. The IR spectrum contains an intense absorption

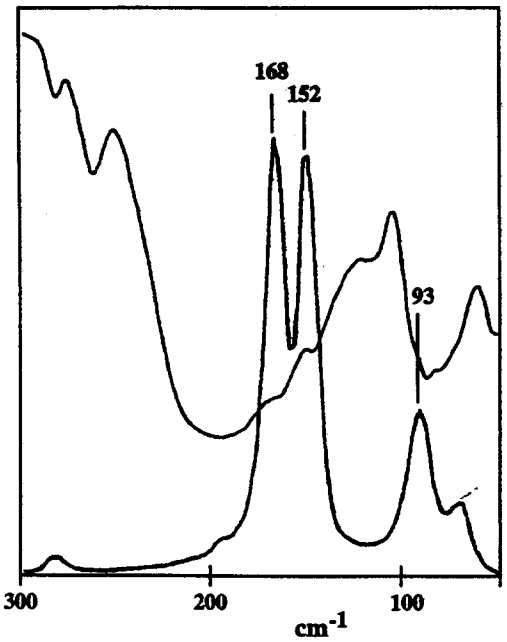

Fig. 3. FT-IR and FT-Raman spectra of II.

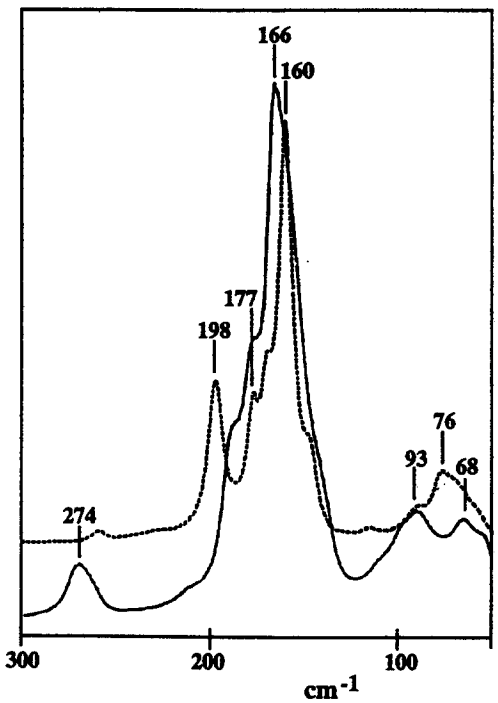

Fig. 4. Superimposed FT-Raman spectra of I (full line) and III (dotted line).

centred at 199 (ν_3) cm^{-1} and extending from 140 to 240 cm^{-1} with shoulders at 149 and 167 cm^{-1}, close to the Raman values.

The superimposed FT-Raman spectra of **I** and **III** are reported in Fig. 4; the similarity of the spectra indicates that **I**, like **III**, is a compound bearing the Br—Se—Br group. They show the most intense peak, which is attributable to the symmetric stretching of the Br—Se—Br group, at 166 and 160 cm^{-1} for **I** and **III** respectively. According to selection rules, the antisymmetric stretching vibration and the deforming of the Br—Se—Br group appear with high intensity in the infrared spectrum of **I** (not reported here) and fall at 184 (broad band) and 149 cm^{-1} respectively. At these frequencies, shoulders appear in its Raman spectrum. For **III**, the infrared spectrum shows an unresolved band envelops centred at about 170 cm^{-1} (ranging from 140 to 210 cm^{-1}), so that the frequencies of the antisymmetric stretching vibration and of the deforming cannot be assigned; however, the medium-weak peak at 198 cm^{-1} and the shoulder at about 150 cm^{-1}, present in the Raman spectrum of **III** (see Fig. 4), could be attributed to the antisymmetric stretching vibration and the deforming respectively, on the basis of the similarity with **I**.

(Received 22 March 1997; accepted 3 July 1997)

Abstract—The complex $[Ru(4,4'\text{-}Me_2bpy)_2(PPh_3)(H_2O)](ClO_4)_2$ has been synthesized and characterized by elemental analysis, spectroscopic and electrochemical methods. $E_{1/2}$ *vs* pH studies are consistent with one-electron, one-proton transfer; at higher pH the potentials become pH independent. The catalytic activity of the complex has been investigated at pH 6.5 in the homogeneous electrooxidation of benzylic compounds. The reactivity was found to decrease in the order 1-phenylethanol ≫ phthalic alcohol > benzyl alcohol > 4-methylbenzyl alcohol > ethylbenzene > toluene. Carbon paste electrode (CPE) containing the complex has shown catalytic activity in oxidations of alcohols. Benzyl alcohol oxidation by CPE is first order on substrate concentration and for low concentrations is controlled by the diffusion rate of the substrate from solution.

Keywords: ruthenium aquacomplex; electrocatalysis; electrooxidation; carbon paste electrode; alcohols; benzylic compounds.

The chemistry of ruthenium-aqua/ruthenium-oxo complexes system has received much attention due, in part, to the potential applications of these complexes as oxidation catalysts [1–14]. The chemistry and use as oxidants of oxo ruthenium complexes containing polypyridyl and tertiary phosphine ligands have been recently studied [5,12].

Electrocatalysis with chemically modified electrode surfaces has been a research topic of large interest [15,16]. Electrooxidations of alcohols using modified electrodes by polypyrrole films containing ruthenium complexes have been reported recently [17–19]. Carbon paste electrodes into which mediators have been admixed have also been used as electrocatalysts [20,21].

We report here the synthesis of $[Ru(4,4'\text{-}Me_2bpy)_2(PPh_3)(H_2O)](ClO_4)_2$ (**1**) ($4,4'\text{-}Me_2bpy$ = 4,4′-dimethyl-2,2′-bipyridine). We have studied the electrochemical and spectrochemical properties of (**1**) in solution and we describe its use in oxidation of benzylic compounds. The oxo-aqua ligands provide for rapid proton transfer concomitant with electron transfer permitting the accessibility of several oxidation states *via* gain or loss of protons. The interest in phosphine-ruthenium(IV)-oxo complex lies in its ability to act as a two-electron, two-proton redox agent which is selective due to the electronic, steric and hydrophobic versatility of the phosphine ligand [5]. In addition, the complex was admixed with carbon powder and mineral oil to form the modified carbon paste electrode. In the Ru^{IV} state, the electrode electrocatalyzes the oxidation of alcohols.

EXPERIMENTAL

Materials

Water was distilled twice from alkaline potassium permanganate. $RuCl_3 \cdot 3H_2O$, 4,4′-dimethyl-2,2′-bipyridine, PPh_3 and mineral oil were obtained from Aldrich Chemical Co. Carbon powder was purchased

from Bioanalytical Systems (CF-1010). 4-methylbenzyl alcohol [22(a)], 1-phenylethanol [22(b)] and phthalic alcohol [22(b)] were prepared according to literature procedures. All other reagents and solvents were of reagent quality and were used without further purification.

Measurements

UV-vis spectra were obtained in quartz cells by using a 8452A Hewlett-Packard spectrophotometer. Electrochemical experiments were carried out with a PAR model 273A Potentiostat/Galvanostat. Cyclic voltammetric experiments were conducted in a one-compartment cell using glassy carbon, carbon paste or platinum working electrodes, a platinum wire auxiliary electrode and a saturated calomel reference electrode (SCE). The $E_{1/2}$ values for reversible couples were calculated from half the difference between E_p values for the cathodic and anodic waves. The bulky electrolyses experiments were performed in a two-compartment cylindrical cell, at 25 ± 1°C, using a platinum gauze working electrode, a platinum plate auxiliary electrode and a SCE. The electrolyses were performed at a fixed applied potential of +0.90 V which is sufficient to generate the $Ru^{IV}{=}O^{2+}$ oxidant from the corresponding $Ru^{II}{-}OH_2^{2+}$ complex. The products of the electrolyses were extracted with diethyl ether and identified by conventional methods. The pH values of aqueous solutions were buffered at an ionic strength of 0.20 mol l^{-1} by HNO_3 and $NaNO_3$ (pH 1.0–2.6), potassium hydrogen phthalate, HNO_3 and $NaNO_3$ (pH 3.1–3.8), potassium hydrogen phthalate, NaOH and $NaNO_3$ (pH 4.4–5.2), Na_2HPO_4 and NaH_2PO_4 (pH 5.6–8.0), $Na_2B_4O_7 \cdot 10\ H_2O$ and $NaNO_3$ (pH 8.8) and $Na_2B_4O_7 \cdot 10\ H_2O$ and NaOH (pH 10.1). ^1H NMR spectra were obtained with a Brucker AC-80 spectrometer. GL chromatograms were recorded with Intralab 300 gas chromatograph. IR spectra were registered on a 1600 FT Perkin-Elmer spectrophotometer. Mass spectra were obtained with a Hewlett-Packard Gas Chromatograph/MS System 5988A.

Syntheses of the complex

$[Ru(4,4'\text{-}Me_2bpy)_2(PPh_3)(H_2O)](ClO_4)_2$ [23] (**1**) as well its precursors *cis*-$[Ru(4,4'\text{-}Me_2bpy)_2Cl_2] \cdot 2H_2O$ [24] (**2**) and $[Ru(4,4'\text{-}Me_2bpy)_2(PPh_3)Cl](PF_6)_2$ [23,25] (**3**) were prepared by procedures described for related complexes. The preparation of (**1**) was performed in a mixture of 3:2 ethanol:water; the reaction for (**2**) was conducted in ethylene glycol, and for (**3**), in 4:1 ethanol:water. Yield of (**1**) in the last step: 86%. Found: C, 53.5; H, 4.2; N, 5.4. Calc. for $C_{42}H_{41}N_4Cl_2O_9PRu$: C, 53.2; H, 4.4; N, 5.9%.

Carbon paste electrodes

Carbon paste electrodes containing 60:40% by weight of carbon powder and mineral oil were used for cyclic voltammetric studies. The modified electrodes contained 88:12% by weight of paste and complex. The carbon paste holder was constructed of a thick walled Teflon tube with 0.3 cm i.d. A copper sleeve equipped with a copper wire plunger was mounted at the top of the Teflon tube. By rotating the sleeve, the plunger could be made to extrude a used paste layer which was sliced off to form a fresh paste surface.

RESULTS AND DISCUSSION

Spectroscopic and redox properties of $[Ru(4,4'\text{-}Me_2bpy)_2(PPh_3)H_2O)](ClO_4)_2$ *in solution*

Figure 1 shows the absorption spectrum of the complex $[Ru(4,4'\text{-}Me_2bpy)_2(PPh_3)(H_2O)]^{2+}$ (**1**) in aqueous solution. Table 1 shows spectroscopic and redox data for the synthesized complexes. The bands in the UV region are assignable to ligands $\pi \rightarrow \pi^*$ excitations; the bands in the visible region can be attributed to metal to ligands transitions. When an aqueous solution of (**1**) is submitted to a potential of +0.90 V one can observe the disappearance of the band at 432 nm, since the species $Ru^{IV}{=}O^{2+}$ is practically transparent in the visible region; the same

[e] pH 6.5 in 8:2 aqueous phosphate buffer (μ = 0.2 mol l^{-1}): tert-butyl alcohol.

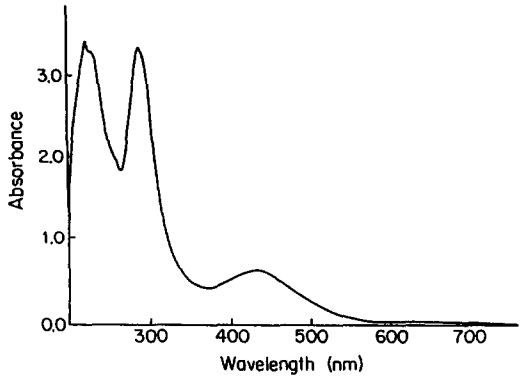

Fig. 1. UV-vis spectrum of 1.0×10^{-4} mol l^{-1} $[Ru(4,4'\text{-}Me_2bpy)_2(PPh_3)(H_2O)]^{2+}$ in 8:2 phosphate buffer solution (μ = 0.20 mol l^{-1}): tert-butyl alcohol, pH 6.5.

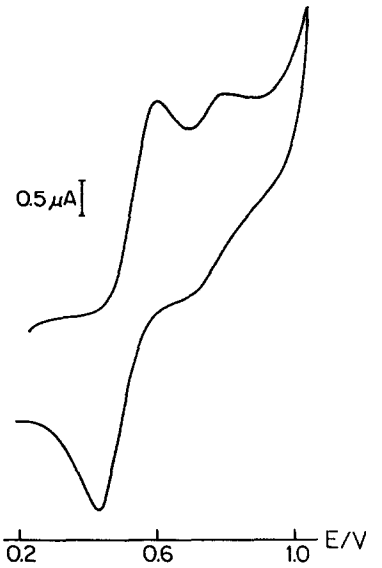

Fig. 2. Cyclic voltammogram of 1.0×10^{-3} mol l^{-1} $[Ru(4,4'\text{-}Me_2bpy)_2(PPh_3)(H_2O)]^{2+}$ in 8:2 phosphate buffer solution (μ = 0.20 mol l^{-1}): tert-butyl alcohol, pH 6.5; glassy carbon working electrode (diameter 3 mm); v = 10 mV s^{-1}.

observation occurs when (**1**) is oxidized stoichiometrically by Ce^{4+}. When the oxidized solution is reduced electrochemically at +0.1 V, the band at 432 nm is regenerated but a low broad band at 650 nm appears. This band can be due to the formation of Ru^{III}—O—Ru^{III} dimer [26] (eq. (1)) which is formed as consequence of rapid coproportionation reaction (eq. (2)).

$$2[(4,4'\text{-}Me_2bpy)_2(PPh_3)Ru^{III}\text{—}OH]^{2+} \leftrightarrows [\{(4,4'\text{-}Me_2bpy)_2(PPh_3)Ru^{III}\}_2O]^{4+} \quad (1)$$

$$[(4,4'\text{-}Me_2bpy)_2(PPh_3)Ru^{III}\text{—}OH_2]^{2+} + [(4,4'\text{-}Me_2bpy)_2(PPh)Ru^{IV}O]^{2+} \rightarrow 2[(4,4'\text{-}Me_2bpy)_2(PPh)Ru\text{—}OH]^{2+} \quad (2)$$

Cyclic voltammogram of (**1**) in aqueous solution (Fig. 2) shows two reversible redox waves corresponding to the $Ru^{III/II}$ and $Ru^{IV/III}$ couples, according to Scheme 1:

$$(4,4'\text{-}Me_2bpy)_2(PPh_3)Ru^{II}\text{—}OH_2^{2+} \underset{+e,+H^+}{\overset{-e,-H^+}{\rightleftarrows}} (4,4'\text{-}Me_2bpy)_2(PPh_3)Ru^{III}\text{—}OH^{2+} \underset{+e,+H^+}{\overset{-e,-H^+}{\rightleftarrows}} (4,4'\text{-}Me_2bpy)_2(PPh_3)Ru^{IV}{=}O^{2+}$$

Scheme 1.

The observed potentials in methylene chloride are higher than those obtained in aqueous solution. The separation between the two couples (320 mV) is larger than in water (220 mV). This behavior can be due to a very slow deprotonation kinetic of the first oxidized species.

The potentials for the $Ru^{III/II}$ couple vary with the pH of the solution, resulting in the $E_{1/2}$ *vs* pH variations shown in Fig. 3. Within the 7.8 > pH > 2.0 region, the potentials form a straight line, with slope (−0.064) very close to Nernstian prediction of −0.059 V/pH unit, indicative of one-electron oxidation accompanied by the dissociation of one proton (first step in Scheme 1). At pH > 7.8, the potentials become pH independent indicating that, in this region, $[Ru^{II}(4,4'\text{-}Me_2bpy)_2(PPh)(OH)]^+$ is the dominant species, and the couple becomes

$$(4,4'\text{-}Me_2bpy)_2(PPh_3)Ru^{II}\text{—}OH^+ \underset{+e}{\overset{-e}{\rightleftarrows}} (4,4'\text{-}Me_2bpy)_2(PPh_3)Ru^{III}\text{—}OH^{2+}$$

The $Ru^{IV/III}$ couple is not well-behaved in the studied pH range.

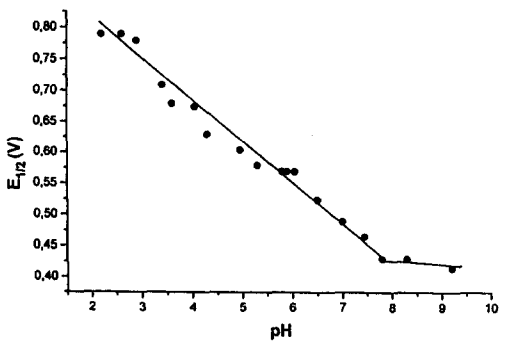

Fig. 3. Plot of $E_{1/2}$ *vs* pH for the $Ru^{III/II}$ redox couple of $[Ru(4,4'\text{-}Me_2bpy)_2(PPh_3)(H_2O)]^{2+}$; glassy carbon working electrode.

Electrocatalytic oxidations of benzylic compounds in homogeneous solution

In the presence of excess of benzyl alcohol (25 times), the cyclic voltammogram of (**1**) shows a great enhancement of the oxidation current peaks and a decreasing of the reduction peaks upon potential scan reversal (Fig. 4). This is indicative of catalytic activity.

Table 2 shows the results obtained in electrooxidations of benzyl alcohol, 4-methylbenzyl alcohol, 1-phenylethanol, phthalic alcohol, ethylbenzene and toluene. The efficiency of current by time unit relationship can give a reactivity order for the electrooxidations: 1-phenylethanol ≫ phthalic alcohol > benzyl alcohol > 4-methylbenzyl alcohol > ethylbenzene > toluene. The proposed mechanism for oxidations using ruthenium oxo complexes suggests the formation, in the transition state, of an electron-deficient carbon [27]. A substituting group can decrease the reaction activation energy, inducing a delocalization of the positive charge by hyperconjugation, inductive or resonance effects. In this way, the secondary 1-phenylethanol is the more reactive due to the methyl group bound to the benzylic carbon. The primary benzylic diol, phthalic alcohol, is more reactive than the benzylic monoalcohols as expected. Benzyl alcohol has unexpected higher reactivity than 4-methylbenzyl alcohol; although the difference in reactivity between 4-methylbenzyl alcohol and benzyl alcohol was not pronounced, higher reactivity was expected for the former due to the presence of the methyl group; we have observed that 4-methoxylbenzyl alcohol is more reactive than benzyl alcohol when $Ru(trpy)(bpy)O^{2+}$ (trpy = 2,2′:6′,2″-terpyridine) was used [7]: methoxyl group is a strong π donor and methyl group is a weak σ donor. Ethylbenzene is more reactive than toluene, due to the methyl group in the α position relative to the benzylic carbon, which contributes to the positive charge delocalization by hyperconjugation or inductive effect.

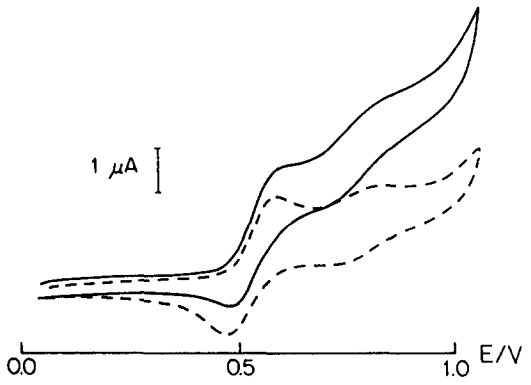

Fig. 4. Cyclic voltammograms at glassy carbon electrode (diameter 3 mm) of 1.0×10^{-3} mol l^{-1} $[Ru(4,4'\text{-}Me_2bpy)_2(PPh_3)(H_2O)]^{2+}$ in 8:2 phosphate buffer solution ($\mu = 0.20$ mol l^{-1}): tert-butyl alcohol, pH 6.5 in absence (---) and presence (——) of 25×10^{-3} mol l^{-1} benzyl alcohol.

It is worth noting the importance of the results from the point of view of synthesis: benzyl alcohol, 4-methylbenzyl alcohol yield the corresponding aldehydes exclusively (electrooxidations using $Ru(trpy)(bpy)(OH_2)^{2+}$ yielded carboxylic acids [7,28]), in the case of 4-methylbenzyl alcohol it should be noted that the methyl group was not oxidized as occurs when $Ru(trpy)(bpy)(OH_2)^{2+}$ was used [28]. In the oxidation of phthalic alcohol similar yields of phthalic aldehyde and phthalide were obtained, the latter being obtained from the formation of a hemiketal intermediate. The oxidation of toluene to benzaldehyde is another result to be noted; using $Ru(trpy)(bpy)(OH_2)^{2+}$ the product was benzoic acid [28]. The oxidation of ethylbenzene yielding acetophenone is very interesting, because alkylaromatics are mostly oxidized to benzoic acids [29]. These results demonstrate that the phosphine-ruthenium(IV)-oxo complex is a mild oxidant, which is advantageous since more powerful oxidants usually cause undesirable side reactions.

Electrocatalysis of alcohols with carbon paste electrode containing complex (**1**) (*CPE*)

The cyclic voltammogram of CPE in 8 : 2 phosphate buffer: tert-butyl alcohol, pH 6.5 shows only the reversible wave for the Ru^{IV}/Ru^{III} couple at +0.75 V while the redox wave for the Ru^{III}/Ru^{II} couple observed in solution is kinetically hindered in the carbon paste.

The cyclic voltammetric behavior of CPG in pH 6.8 phosphate buffer in the presence of benzyl alcohol, phthalic alcohol and cyclohexanol shows pronounced enhancement of the anodic currents corresponding to Ru^{IV}/Ru^{III} couple. There were no reduction peaks upon reversal scan direction, which are typical for electrocatalytic processes. The recorded oxidation peak decreased upon potential cycling between 0.0 and +1.0 V. Therefore, each quantitative experiment was performed at a new surface, freshly extruded from the holder. The peak height reproducibility at a fresh carbon paste electrode was 5% (standard deviation of 5 independent measurements). The observed reactivity order is benzyl alcohol > phthalic alcohol > cyclohexanol. The higher reactivity of the primary benzylic alcohol related to the secondary one was also observed in homogeneous catalysis by using $Ru(trpy)(bpy)(H_2O)^{2+}$ [7,8]. The high reactivity of benzyl alcohol can be due to its higher permeability into the active surface of the carbon paste electrode. For quantitative evaluation of the electrocatalysis surface, the dependence of the peak height on the benzyl alcohol bulky concentration and on the potential scan rate were studied. The respective results are presented in Figs 5 and 6. The peak height was linearly dependent (Fig. 5) (correlation coefficient 0.986) with plot intercept close to zero, on the concentration of benzyl alcohol indicating that the electrocatalysis is first-order in this benzyl alcohol concentration range. The dependence of the peak height on the square root of the potential scan rate (Fig. 6) was studied in pH 6.8 phosphate buffer solution for five different concentrations of benzyl alcohol in the range of v from 10 mV s^{-1} to 200 mV s^{-1}; the straight lines have a correlation coefficient close to 1.0 and for concentrations of 15, 25 and 35 mmol l^{-1} have plot intercept very close to zero. One can say that, for low concentrations, the behavior is characteristic for surface electrocatalysis with a catalyst confined to the electrode surface under diffusion rate control of the substrate from solution.

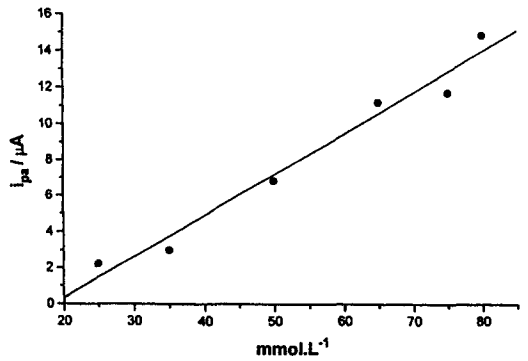

Fig. 5. Plot of the oxidation peak currents of CPE in pH 6.8 phosphate buffer solution (μ = 0.20 mol l^{-1}) against benzyl alcohol concentration.

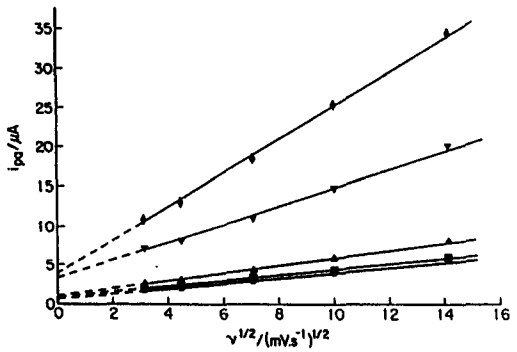

Fig. 6. Plot of the oxidation peak currents of CPE in pH 6.8 phosphate buffer solution (μ = 0.20 mol l^{-1}) against square root of the potential scan rate for different benzyl alcohol concentrations: (●) 15 mmol l^{-1}; (■) 25 mmol l^{-1}; (▲) 35 mmol l^{-1}; (▼) 50 mmol l^{-1}; (◆) 65 mmol l^{-1}.

One can conclude that $[Ru(4,4'\text{-}Me_2bpy)_2(PPh_3)(H_2O)]^{2+}$ is useful in selective oxidations of benzylic compounds and that the preparation of the carbon paste electrode is simple and straightforward and the characteristic of the mediator is fully preserved upon transfer from solution to the immobilized state.

The synthesis and characterization of copper(II) complexes of a novel binucleating tetraoxime ligand

Serdar Karaböcek[a]* and Nevin Karaböcek[b]

Departments of [a]Chemistry and [b]Science Education, Karadeniz Technical University, Trabzon, Turkey

(Received 23 April 1977; accepted 2 July 1997)

Abstract—6,6′-Methylenebis-[1,11-di(hydroximino)2,3:9,10-dibenzo-4,8-dioxaundecane], (H_4L) **4** was prepared by the reaction of 6,6′-methylenebis-(5′-on-3′,4′-benzo-2′-oxapentyl)-1,11-dion-2,3:9,10-dibenzo-4,8-dioxaundecane, **3** with hydroxylamine hydrochloride. Di- and tetranuclear copper(I) and (II) complexes with a bistetradentate ligand, (LH_4) have been prepared and identified by a combination of elemental analysis, ^{13}C, ^1H-NMR, mass spectra, magnetic moments, IR, UV/Vis, and ESR spectral studies. A geometric optimization of the synthesized ligand **4** was made by the method of molecular mechanics (MM2) in order to establish a stable conformation. The total energy for these conformations are calculated to be 10.94 and 9.49 kcal/mol.

Keywords: tetraoxime; bistetradentate ligand; dinuclear; tetranuclear.

In recent years, binucleating macrocyclic or acyclic compounds have been extensively studied since these structural units are thought to be involved in a variety of biochemical and industrial processes [1–3]. The study of the exchange interaction between metal centers through extended bridges has been one of the most active research fields in magnetism [4–6]. The fundamental understanding of the factors that govern the magnetic properties, the design of new materials which can fulfil specific tasks and the biological relevance of the exchange-coupled polynuclear systems are at the origin of the increasing interest in this phenomenon.

Many reports are available for the preparation and properties of model copper complexes which mimic copper-containing metalloproteins such as hemocyanine and tyrosinase. Two noticeable properties of copper proteins are an intense absorption band [7–9] near 600 nm and relatively high copper(II)/copper(I) reduction potentials [8–10]. Particular attention was focused on their correlation with the active site of metalloenzymes and metalloproteins containing dinuclear metallocenters in order to elucidate the factors that determine the reversible binding and activation of O_2 in various natural oxygen transport systems and mono- and dioxygenases and to mimic their activity [7–9]. A number of dinuclear complexes containing linear ligand systems have been prepared and examined for oxygen uptake [10–12]. Such metal complexes have been prepared by using an acyclic ligand containing a bi-coordination site which can link one metal ion in the inner N_2O_2 [13–16].

In the present study, a binucleating tetraoxime ligand was prepared. This ligating system provide an additional active site besides conferring on the copper(II) ion within a square-planar N_2O_2 environment (Fig. 1).

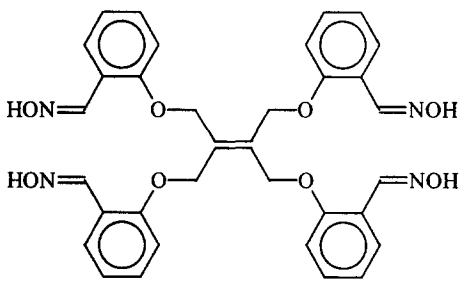

Fig. 1. Proposed structure of the ligand (**4**).

EXPERIMENTAL

Tetrabromomethylethylene **2**, was prepared by a reported procedure [17]. ^{1}H-NMR spectra were recorded on a Bruker 200-MHz spectrometer. Mass spectra [FAB(positive)-MS] were measured on a VG AutoSpec provided by GV Analytical Instruments. C, H, N were analyzed microanalytically on a Hewlett Packard 85 CHN analyzer. Copper was estimated spectrophotometrically on a Hitachi 180-80 atomic absorption spectrometer. Electronic spectra were obtained on a ATI Unicam UV2 Model UV-Vis spectrophotometer. ESR measurements were made with a Varian model 109C E-line X-band spectrometer fitted with a quartz Dewar for measurements at liquid nitrogen temperature, IR spectra were recorded on a Matson 1000 Model FTIR spectrophotometer as KBr pellets. Room temperature magnetic susceptibility measurements were done on a PAR model 155 vibrating sample magnetometer. TLC was done on Merck Kieselgel 60-HF_{254} precoated aluminium plates. Conformational analysis was made by using the Allinger's MM2 method.

6,6′-*methylenebis*-(5′-*on*-3′,4′-*benzo*-2′-*oxapentyl*)-1,11-*dione*-2,3:9,10-*dibenzo*-4,8-*dioxaundecane*, (3)

Freshly prepared potassium 2-formylphenolate 6.4 g (40 mmol) and tetrabromomethylethylene **2**, (4 g, 10 mmol) were refluxed for 4 h in dimethylformamide (DMF) (50 cm^3). The solution was then poured onto ice-water (200 cm^3) and the solid product filtered off and recrystallised from acetone with decolourising charcoal. The compound **3**, m.p. 160°C, was isolated in 72% yield; IR (KBr disc.)/cm^{-1} 1690 (C=O) and 1234 (C—O); ^{1}H-NMR($CDCl_3$)/ppm δ: 10.20 (s, 4H, CHO), 6.80–7.95 (m, 16H, aryl) and 5.10 (s, 8H, OCH_2) MS (ei.) m/z = 564. Found: C, 73.8; H, 5.2. Calc. for $C_{34}H_{28}O_8$: C, 73.7; H, 5.0%.

6,6′-*methylenebis*-[1,11-*di*(*hydroximino*)2,3:9,10-*dibenzo*-4,8-*dioxaundecane*], (4)

A solution of tetraldehyde **3**, (5.54 g, 10 mmol) and hydroxylamine hydrochloride (5.5 g, 80 mmol) in pyridine (100 cm^3) was stirred at room temperature for 48 h. The mixture was then poured into ice-cold water (300 cm^3). The resulting precipitate was collected, washed successively with ice-cold water and diethyl ether, and dried *in vacuo* over P_2O_5. Recrystallization from a mixture of DMSO and MeOH (7:1) gave **4** as a colourless microcrystalline solid in 85% yield; m.p. 208–210°C; IR, (KBr disc)/cm^{-1} 1600 (C=N), 3200 (=N—O—H) and 1230 (C—O); ^{1}H-NMR ($CDCl_3$)/ppm δ: 12.15 (s, 4H, =N—OH) 9.80 (s, 4H, N=CH), 6.95–8.15 (m, 16H, aryl) and 5.45 (s, 8H, OCH_2) MS (FAB-positive) m/z = 624. Found: C, 66.3; H, 5.3; N, 9.1. Calc. for $C_{34}H_{32}N_4O_8$: C, 66.4; H, 5.2; N, 9.1%.

Preparation of $[Cu_2(LH_2)(ClO_4)_2 \cdot (H_2O)_2]$, (5)

A solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (2 mmol, 741 mg) in dried acetone was added to the ligand (1 mmol, 624 mg) suspended in 30 cm^3 of acetone, and the mixture was refluxed with stirring for 12 h. A green-brown product was filtered off, washed with acetone and Et_2O and dried over P_4O_{10}. Found: C, 41.3; H, 3.5; N, 5.6; Cu, 13.0. Calc. for $C_{34}H_{34}N_4O_{18}Cl_2Cu_2$: C, 41.5; H, 3.5; N, 5.7; Cu, 12.9%.

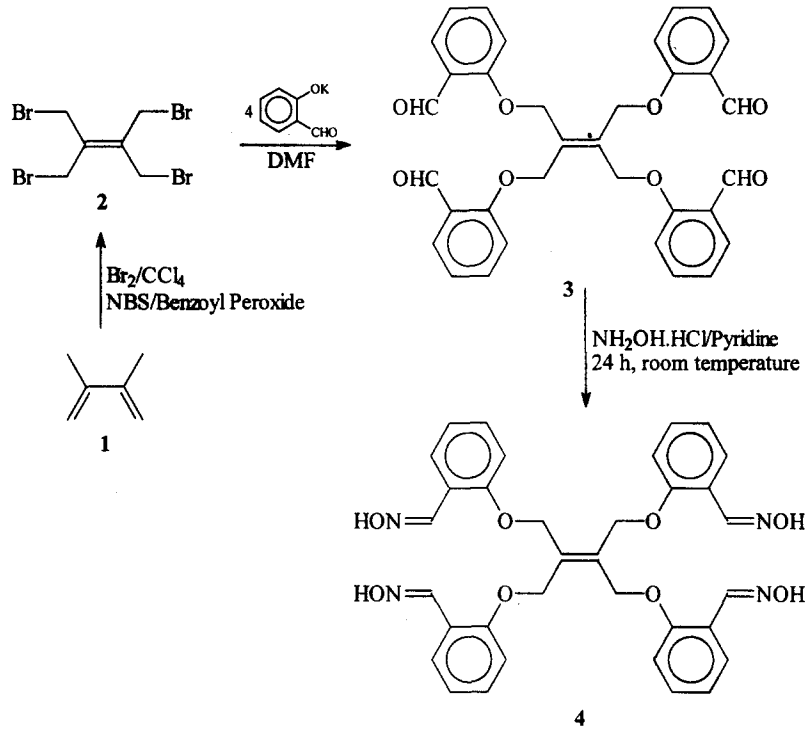
Preparation of $[Cu_4(L)(ClO_4)_2(H_2O)_2L'_2] \cdot (ClO_4)_2$, (6)

L′:1,10-*phenanthroline*

Dinuclear copper complex (0.5 mmol, 490 mg) was mixed with triethylamine (1 mmol) by stirring for 0.5 h and then the solution in acetone (30 cm^3) was added to a 20 cm^3 solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (1 mmol, 370 mg) and then subsequently to a solution of 1,10-phenanthroline (1 mmol, 180 mg) in 10 cm^3 acetone, and the mixture was refluxed for 8 h. The blue product was filtered off, washed with EtOH and Et_2O and dried over P_4O_{10}. Moreover, oxidation of the tetranuclear copper(I) complex in DMF with H_2O_2 gave the copper(II) complexes of tetraoxime. Found: C, 41.8; H, 3.0; N, 6.6; Cu, 15.3. Calc. for $C_{44}H_{48}N_8O_{26}Cl_4Cu_4$: C, 41.8, 2.9; N, 6.7; Cu, 15.2%.

RESULTS AND DISCUSSION

6,6′-Methylenebis-[1,11-di(hydroximino)2,3:9,10-dibenzo-4,8-dioxaundecane], (**4**) was prepared by the reaction of 6,6′-methylenebis-(5′-on-3′,4′-benzo-2′-oxapentyl)-1,11-dione-2,3:9,10-dibenzo-4,8-dioxaundecane (**3**), with hydroxylamine hydrochloride (Scheme 1). The structures of the tetraoxime (**4**), and tetraaldehyde (**3**), which is a precursor of the tetraoxime, were identified by a combination of elemental analysis, ^{1}H-NMR, IR and mass spectroscopy and their conformational analysis were made by molecular mechanics (MM2). The mass (FAB-positive) of (**4**) exhibits a strong parent ion at m/z 625 $[M+1]^+$, which indicates formation of the 13-membered acyclic bis-dioxime (**4**). ^{1}H-NMR spectrum of this compound in DMSO-d_6 clearly demonstrates the presence of a four =N—OH environment. The singlets at δ = 9.80 and 12.15 at ppm correspond to the =N—OH and N=CH proton resonances, respectively. In 12.15 ppm, the singlet disappears on deuterium exchange. In addition to 10.20 at ppm band, a singlet belonging to tetraldehyde protons of (**3**) disappears after the added reaction of hydroxylamine. A singlet chemical shift for the hydroximino protons indicates that oxime groups are in the tetraoxime [18–20] (**4**). In the IR spectrum of (**4**), the O—H stretching vibration is observed at 3200 cm^{-1}. The azomethine (C=N) stretching vibration is located at 1600 cm^{-1}. The



Scheme 1.

strong sharp band at 1230 cm^{-1} doublet was due to the N—O and C—O stretching vibrations [20].

A geometric optimization of the synthesized ligand, (**4**) was made by the method of molecular mechanics [21] (MM2) in order to establish a stable conformation and the data were compared with the experimental observations. The data for the two most stable conformations are listed in Table 1. These two conformations are given in Fig. 2. The total energy for one of these conformations is calculated to be 10.94 kcal/mol (Fig. 2(A)) and that of the other is 9.49 kcal/mol (Fig. 2(B)). Analysis of total energies for both of the conformations has shown that the energies are primarily due to especially the angle bending and van der Waals interactions (Table 1). All of the data obtained from the spectral and molecular mechanics (MM2) studies support the structural properties of the ligand.

X-Band ESR studies of copper(II) complexes were obtained in DMSO. The spectra reveal the presence of less than four components. The broadening of the $g_\perp$ line and splitting is due to the overlap of $g_\parallel$ and $g_\perp$ components, further indicating a lowered site simetry [22–24]. The $g_\parallel$ is 2.23 as observed in dinuclear complexes (Table 2). A clear five-line pattern emerges on the $g_\parallel$ component with ≈ 14.5 G. Thus, the ESR data supports the binding of the tetradentate ligand with two N and two O donor sites to the copper(II) ion, providing a square planar geometry, the other axial sites being occupied by chlorate anion and water molecule [25]. Figure 3 shows the ESR spectra of the $[Cu_2(LH_2)(ClO_4)_2 \cdot (H_2O)_2]$ complex in frozen DMSO. The value of the coupling constant evaluated from the peaks is *ca.* 118 G. This value is nearly half of that found for the present mononuclear complexes (Table 2). This situation could arise when four equivalent copper(II) ions are coupled *via* an exchange inter-

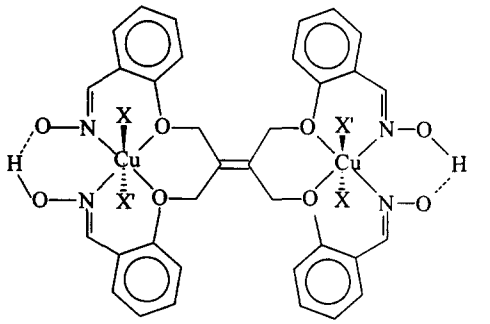
[a] All spectra were taken in DMSO.

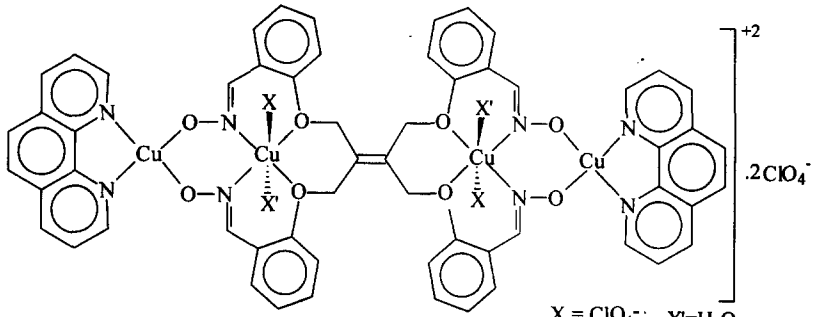
action, in a tetranuclear complex. The room temperature solid state magnetic moment data of the copper(II) complexes are listed in Table 2. Dinuclear copper(II) complex showed normal magnetic moment. The tetranuclear complex shows μ_{eff} value of 1.46 B.M., indicating an exchange coupled tetrameric complex, a structure also supported by ESR study [13, 22, 33].

The ligand was dissolved in DMF and shows characteristic UV-Vis spectra of the oxime group. The absorption bands are given in Table 2. The electronic spectra of all complexes measured in DMF showed intense absorptions around 400 nm which are assigned to charge-transfer transition from the $p\pi$ orbitals of the donor atoms to the d orbitals of the metal (Table 2). In the dinuclear-copper(II) complex, d–d transition base observed at 628 nm. The energy of the d–d transition suggests a distorted octahedral copper(II) complex [26].

Infrared spectra of complexes **5** and **6** have been compared with that of similar structures in order to establish the coordination modes of the oxime ligand



(5)



(6)

Fig. 3. Proposed structures of copper(II) complexes (**5**) dinuclear, (**6**) tetranuclear.

in complexes **5** and **6**. The more relevant OH, C=N and N—O absorption bands are listed in Table 3. In general, the complexes exhibited very similar IR features. This is indirect evidence that the complexes are of similar structures. In the IR spectra of these complexes (OH) stretching vibrations have disappeared and there is no distinct shift in (C=N) stretches after complex formation. The absence of O—H stretching vibrations for the free ligand indicates the formation of a hydrogen bridge between tetraoxime oxygen atoms [27].

IR data confirms the binding of the copper(II) by O and N donor groups of the present ligand and supports the tentative structure of the complexes (Fig. 1). The sharp intensity bands in the 1600 cm^{-1} region of **4** were assigned to C=N stretching vibrations. The

Table 3. Observed frequencies and proposed mode of assignments for the ligand and the complexes

Compound	(O—H)	(C=N)	(N—O)	(C—N)	(ClO_4)	(Cu—N)	(Cu—O)	(O—H···O)
Tetraoxime, H_4L (**4**)	3184	1600	1230	1491	—	—	—	
$[Cu_2(LH_2)(ClO_4)_2 \cdot (H_2O)_2]$ (**5**)	3446br	1598	1225	1495	1103 1006 621	438	375	1684

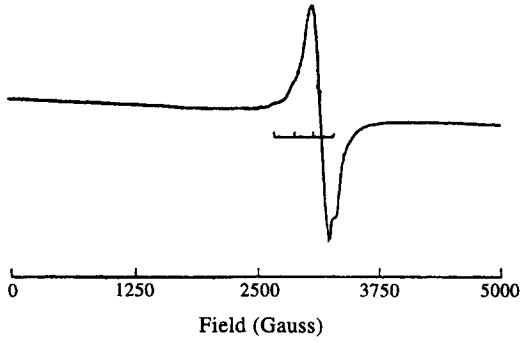

Fig. 4. ESR spectra of frozen DMSO solution of $[Cu_2(LH_2)(ClO_4)_2 \cdot (H_2O)_2]$.

N—O stretching vibrations for the complex shift to upfield suggesting that the oxime groups are nitrogen coordinated.

As a conclusion, in the complex **5**, both copper atoms are in a slightly distorted octahedral environment formed by the two oxime-nitrogen atoms and two phenolate-oxygen atoms from the tetraoxime ligand. Moreover, one perchlorate anion and one water molecule are arranged in axial positions. The small distortion from planar toward tetrahedral stereochemistry around the copper atoms of these four donor sets of atoms within tetraoxime ligand is characterized by a twisting angle as calculated by molecular mechanics (MM2) minimization. In complex **6**, four copper-containing fragments, Cu_2L and $Cu_2(Phen)_2$ are joined through the 1,10-phenantroline-nitrogen atoms to form a tetrameric compound. Since the ligand is a very symmetrical molecule, shifts in IR absorption bands are very slight. However, in compound **5**, the bands belonging to OH groups at 3184 cm^{-1} disappear, and a band at 1684 cm^{-1} belonging to O···H—O appears upon complexation, whereas in compound **6**, the O···H—O band at 1684 cm^{-1} disappears. The results are all in good agreement with the proposed structures for the obtained complexes. Moreover, all of the data obtained from the spectral studies support the structural properties of the complexes (Fig. 4).

Syntheses, solubilities and oxygen absorption properties of new cobalt(II) Schiff-base complexes

Sangsook Park, V. K. Mathur,* and Roy P. Planalp*

Departments of Chemical Engineering and Chemistry, University of New Hampshire, Durham, New Hampshire, 03824, U.S.A.

(Received 25 November 1996; accepted 30 June 1997)

Abstract—The syntheses, solubilities and oxygen absorption properties of cobalt(II) complexes of *N,N'*-bis(salicylidene)-2,2'-dimethyl-1,3-propanediimine ligand derivatives, termed CoSaldmpr, are reported. These are homologs of the well-known *N,N'*-bis(salicylidene)ethylenediiminocobalt(II) (CoSalen) complexes, in which a 2,2-dimethyl-1,3-propanediimino bridging group replaces the ethylenediimino bridging group of CoSalen. Solubility data and limited oxygen-carrying properties of the complexes in 1-methyl-2-pyrrolidinone (NMP) solution, either alone or in the presence of 2-cyanopyridine (2 M) as an axial base, are reported. Oxygen transport of the solutions is tested with a flow system and a thermal swing process with O_2 absorption conditions of 37°C and desorption conditions of 100–180°C. The two CoSaldmpr complexes that are tested have higher solubilities and oxygen affinities than the CoSalen homologs. In NMP solution with 2 M 2-cyanopyridine axial base, loading of Co(3-methoxy-Saldmpr), measured in (g O_2/g solution) remains about 35% higher than Co(3-methoxy-Salen) for at least four absorption/desorption cycles. © 1997 Elsevier Science Ltd

Keywords: cobalt(II) Schiff-base complexes; oxygen complexes; oxygen carriers; oxygen separation; thermal swing absorption.

Synthetic dioxygen carriers [1] have attracted much attention since the initial reports concerning the cobalt Schiff-base complex *N,N'*-bis(salicylidene)ethylenediiminocobalt(II) (CoSalen) [2]. Numerous reports of systems for the separation of oxygen from air using complexes of the cobalt bis(salicylidene) family have appeared. Among these are solution-phase [3], solid-phase [4] and liquid-membrane systems [5]. The need for methods for separation of oxygen which are less energy-intensive than the cryogenic process of distillation of liquid air is clear. The use of a thermal swing process in which oxygen carriers which absorb oxygen from air at ambient temperature, followed by desorption at elevated temperature, may provide oxygen-enriched combustion air to a furnace [6]. This application would be energy-efficient in that waste heat from the furnace may be used to accomplish the desorption of oxygen. The key problem with these systems has been the stability of the complexes to oxidative degradation over repeated oxygen separation cycles at room temperature and above [7]. An additional practical requirement of the solution-phase and liquid-membrane systems is high solubility of the carriers in polar organic solvents, which will maximize the amount of oxygen carried per mass of solution or area of membrane.

This paper describes our studies of effect of carrier structure on solubility, oxygen affinity and stability. We have previously described the development of a thermal swing absorption oxygen carrying system which can be run continuously for many cycles that uses known Co^{II} Schiff-base oxygen carriers [8]. Previous studies have indicated that addition of electron-donating groups such as alkoxy to carriers can increase oxygen affinity, with some quantitative affinity data available [2(c)]. Further, steric effects in the immediate environment about cobalt [9] can be expected to increase stability of the carriers through preventing μ-peroxo dimer formation, but in only one study have hindered-bridge salicylidene (diimino) carriers been prepared and quantitatively tested for oxy-

* Authors to whom correspondence should be addressed.

gen absorption [10]. To increase oxygen carrier performance, we pursued the strategies of addition of steric hindrance and electron-donating groups, and of increasing carrier solubility. We report the preparation of new carriers employing the Schiff-base ligand *N,N'*-bis(salicylidene)-2,2'-dimethyl-1,3-propanediimine [11] (Saldmpr, Chart 1) in place of ethylenediiminosalicylidene (Salen), and the addition of alkoxy groups to the salicylidene phenyl rings of Saldmpr. The solubility in 1-methyl-2-pyrrolidinone (NMP) and the stability to several cycles of oxygen absorption and desorption of Saldmpr carriers relative to Salen carriers is reported.

EXPERIMENTAL

General

All operations were conducted using Schlenk technique [12]. Chemicals were purchased from Aldrich, except for 3-ethoxysalicylaldehyde which was purchased from Pfaltz and Bauer. Salicylaldehyde was vacuum distilled. The CoSalen ligand and complex derivatives were prepared as previously reported [13]. Proton NMR spectra were measured on a Bruker 360 MHz NMR spectrometer. Mass spectra were measured on a Hewlett Packard 5890 GC/MS spectrometer. Elemental analyses were carried out by the University of New Hampshire Instrumentation Center using a Perkin-Elmer Series II 2400 analyzer.

Oxygen absorption and desorption measurements

The measurement system, as previously described [8], is shown in Fig. 1. Air (A) was passed through a needle valve and a calibrated Hastings mass-flow meter (B) to establish and measure the air flow rate. The air was bubbled through the reactor (D) where absorption and desorption take place. Each absorption/desorption cycle requires about 1.5 h. The effluent of the reactor was passed through an Infrared Industries IR-2200 Oxygen Analyzer (E) and then exhausted into a hood. A bypass line (C) around the reactor allowed for calibration and check of the analyzer. The reactor consists of an outer metal jacket around a glass reaction vessel fitted with a rubber stopper through which the gas inlet, gas outlet, thermometer and thermocouple were passed. The reactor was alternately cooled in each absorption cycle and heated in each desorption cycle. The gas inlet consisted of a glass line with a fritted glass termination attached to promote contact of the gas with the liquid.

The data from the oxygen analyzer, mass flow meter, and thermocouple were collected using an IBM PC/XT with the labtech/Notebook data acquisition system. The amount of oxygen absorbed and desorbed was calculated by integrating the product of the oxygen concentration and flow rate over the cycle.

N,N' - Bis(salicylidene) - 2,2 - dimethyl - 1,3 - propane - diimine

This is a modification of [11]. 2,2-Dimethyl-1,3-propanediamine (2.4 cm^3, 20 mmol) was added to a boiling solution of salicylaldehyde (4.3 cm^3, 40 mmol) in 50 cm^3 of ethanol, causing a color change from colorless to yellow. About one-third of the solvent was removed under reduced pressure, initiating the formation of yellow crystals. When crystal formation ended, the product was filtered and dried *in vacuo* (5.2 g, 83%). Mp: 96–97.5°C. Found: C, 73.51; H, 7.04; N, 8.96. Calc. for $C_{19}H_{22}N_2O_2$: C, 73.55; H, 7.10; N, 9.03%. ^1H NMR ($CDCl_3$, 25°C): δ 1.05 (s, 3 H, CH_3), 3.47 (s, 2 H,—CH_2), 6.84–7.52 (m, 4 H, C_6H_4), 8.32 (s, 1 H, C*H*), 11.26 (s, 1 H, O*H*). MS (EI, 70 eV): 310 amu (M^+).

N,N' - Bis(salicylidene) - 2,2 - dimethyl - 1,3 - propane - diiminocobalt(II) hemihydrate (6)

A mixture of bis(salicylidene)ethylenediimine (5.15 g, 16.6 mmol), sodium acetate (0.050 g, 0.61 mmol), 1.07 M NaOH (31.0 cm^3, 33.2 mmol), distilled water (30 cm^3) and ethanol (60 cm^3) was warmed to 70°C to dissolve the ligand. Aqueous cobalt chloride (3.95 g in 20 cm^3 H_2O, 16.6 mmol) at 50°C was added to the solution. The brown powder (5.4 g, 89% yield) was separated by filtration and dried at 110°C under reduced pressure for 3 h. Mp: 312–315°C (dec). Found: C, 60.72; H, 5.38; N, 7.48. Calc. for $C_{19}H_{20}N_2O_2Co \cdot 0.5\ H_2O$: C, 60.64; H, 5.62; N, 7.44%. MS (EI, 70 eV): 367 amu (M^+).

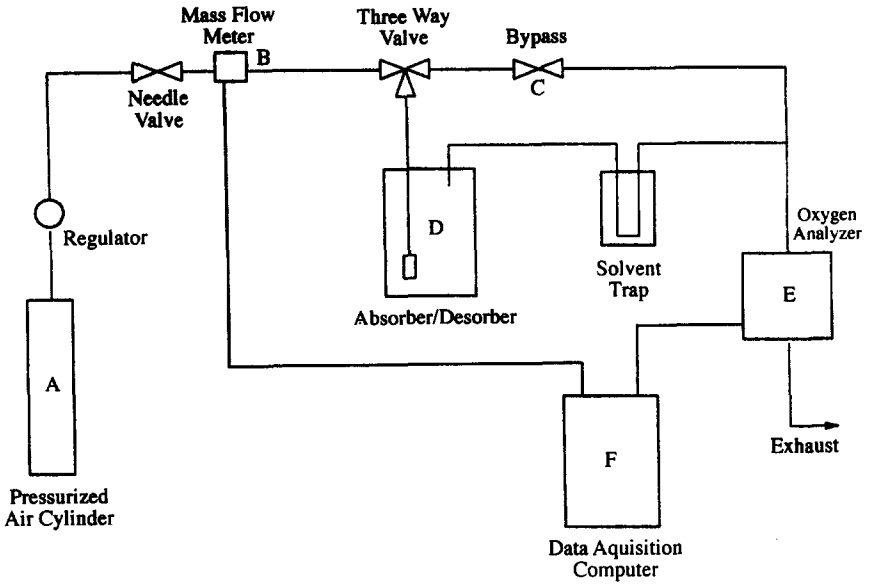

Fig. 1. Oxygen Absorption and Desorption Measurement System.

N,N' - Bis(3 - methoxysalicylidene) - 2,2 - dimethyl - 1,3 - propanediimine

2,2-Dimethyl-1,3-propanediamine (1.4 cm^3, 12 mmol) was added to a boiling solution of 3-methoxysalicylaldehyde (3.5 g, 23 mmol) in 30 cm^3, of ethanol, causing a color change from colorless to yellow. About one-third of the ethanol was removed under reduced pressure, leading to formation of a yellow precipitate. The precipitate was separated by filtration, dried under reduced pressure, and recrystallized from toluene/hexane (30 cm^3: 20 cm^3) at −5°C, giving yellow crystals (3.2 g, 75%). Mp: 113–114°C. Found: C, 68.10; H, 7.19; N, 7.44. Calc. for $C_{21}H_{26}N_2O_4$: C, 68.11; H, 7.03; N, 7.57%. ^1H NMR ($CDCl_3$, 25°C): δ 1.06 (s, 3 H, CH_3), 3.48 (s, 2 H, —CH_2), 3.89 (s, 3 H, OCH_3), 6.76–6.92 (m, 3 H, C_6H_3), 8.34 (s, 1 H, C*H*), 10.68 (s, 1 H, O*H*). MS (EI, 70 eV): 370 amu (M^+).

N,N' - Bis(3 - ethoxysalicylidene) - 2,2 - dimethyl - 1,3 - propanediimine

2,2-Dimethyl-1,3-propanediamine (3.6 cm^3, 30 mmol) was added to a boiling solution of 3-methoxy salicylaldehyde (10.0 g, 60.2 mmol) in 50 cm^3 of ethanol, causing a color change from colorless to yellow. The solution volume was reduced to 15 cm^3 giving a yellow precipitate which was separated by filtration, dried under reduced pressure, and recrystallized from toluene/hexane (1:1 75 v/v) to give yellow crystals (7.8 g, 65%). Mp: 96–98°C. Found: C, 69.22; H, 7.68; N, 6.95. Calc. for $C_{23}H_{30}N_2O_4$: C, 69.35; H, 7.54; N, 7.04%. ^1H NMR ($CDCl_3$, 25°C): δ 1.05 (s, 3 H, CH_3), 1.48–1.50 (t, 3 H, CH_3), 3.47 (s, 2 H, —CH_2), 4.07–4.13 (q, 2 H, OCH_2), 6.75–6.91 (m, 3 H, C_6H_3), 8.30 (s, 1 H, C*H*), 10.79 (s, H, O*H*), MS (EI, 70 eV): 398 amu (M^+).

N,N' - Bis(3 - methoxysalicylidene) - 2,2 - dimethyl - 1,3 - propanediiminocobalt(II) (**7**)

This complex was prepared as for **6** using 3.0 g (8.0 mmol) of the corresponding Schiff base, 15 cm^3 of aqueous sodium hydroxide (1.07 M, 16 mmol), 0.026 g (0.31 mmol) of sodium acetate, 15 cm^3 water, 30 cm^3 ethanol, and 2.0 g (8.0 mmol) cobalt chloride (solution in 10 cm^3 H_2O). A brown powder was obtained (2.9 g, 85% yield). Mp: 299°C (dec). Found: C, 58.46; H, 5.74; N, 6.52. Calc. for $C_{21}H_{24}N_2O_4Co$: C, 59.02; H, 5.62; N, 6.56%. MS (EI, 70 eV): 427 amu (M^+).

N,N' - Bis(3 - ethoxysalicylidene) - 2,2 - dimethyl - 1,3 - propanediiminocobalt(II) hemihydrate (**8**)

This complex was prepared as for **6** using 7.76 g (19.5 mmol) of the corresponding Schiff base, 35.5 cm^3 of aqueous sodium hydroxide (1.07 M, 39.0 mmol), 0.059 g (0.72 mmol) of sodium acetate, 40 cm^3 water, 80 cm^3 ethanol, and 4.64 g (19.5 mmol) cobalt chloride (solution in 30 cm^3 H_2O). A brown powder was obtained (7.1 g, 80%). Mp: 252°C (dec). Found: C, 59.98; H, 6.21; N, 6.01. Calc. for $C_{23}H_{28}N_2O_4Co \cdot 0.5\ H_2O$: C, 59.48; H, 6.29; N, 6.03%. MS (EI, 70 eV): 455 amu (M^+).

N,N′-Bis(4-methoxysalicylidene)-2,2-dimethyl-1,3-propanediimine

2,2-Dimethyl-1,3-propanediamine (4.4 cm^3, 35 mmol) was added to a boiling solution of 4-methoxysalicylaldehyde (10.7 g, 70.4 mmol) in 40 cm^3 of ethanol, causing a color change from colorless to yellow. About 30 cm^3 of solvent was removed under reduced pressure, initiating the formation of yellow crystals. When crystal formation ended, the product was filtered, dried *in vacuo*, and recrystallized from toluene/hexane (2/3 v/v) giving yellow crystals (8.5 g, 65%). Mp: 96–99°C. Found: C, 67.46: H, 7.10; N, 7.47. Calc. for $C_{21}H_{26}N_2O_4$: C, 68.11; H, 7.02; N, 7.57%. ^1H NMR ($CDCl_3$, 25°C): δ 1.05 (s, 3 H, CH_3), 3.39 (s, 2 H, —CH_2), 3.79 (s, 3 H, OCH_3), 6.36–6.45 (m, 3 H, C_6H_3), 8.34 (s, 1 H, C*H*), 13.20 (s, 1 H, O*H*). MS (EI, 70 eV): 370 amu (M^+).

N,N′-Bis(4-methoxysalicylidene)-2,2-dimethyl-1,3-propanediiminocobalt(II) hemihydrate (**9**)

This complex was prepared as for **6** using 7.85 g (21.2 mmol) of the corresponding Schiff base, 38.5 cm^3 of aqueous sodium hydroxide (1.07 M, 42.4 mmol), 0.064 g (0.78 mmol) of sodium acetate, 40 cm^3 water, 100 cm^3 ethanol, and 5.05 g (21.2 mmol) cobalt chloride (solution in 30 cm^3 H_2O). A brown powder was obtained (7.97 g, 88%). Mp: 180–190°C (dec). Found: C, 58.10; H, 5.84; N, 6.58. Calc. for $C_{21}H_{24}N_2O_4Co \cdot 0.5\ H_2O$: C, 57.80; H, 5.77; N, 6.42%. MS (EI, 70 eV): 427 amu (M^+).

N,N′-Bis(4,6-dimethoxysalicylidene)-2,2-dimethyl-1,3-propanediimine

2,2-Dimethyl-1,3-propanediamine (2.6 cm^3, 11 mmol) was added to a boiling solution of 4,6-dimethoxysalicylaldehyde (8.0 g, 22 mmol) in 50 cm^3 of ethanol, causing a color change from colorless to yellow. After 30 min, all volatile material was removed under reduced pressure and the resulting solid was washed by stirring in hexane (85 cm^3) for 12 h. The resulting yellow powder (2.9 g, 62%) was dried under reduced pressure. Mp: 116–118°C. Found: C, 64.59; H, 7.44; N, 6.54. Calc. for $C_{23}H_{30}N_2O_6$: C, 64.19; H, 6.98; N, 6.51%. ^1H NMR ($CDCl_3$, 25°C): δ 1.06 (s, 3 H, CH_3), 3.34 (s, 2 H, —CH_2), 3.75 (s, 3 H, OCH_3), 3.76 (s, 3 H, OCH_3), 5.64–5.91 (m, 2 H, C_6H_2), 8.34 (s, 1 H, C*H*), 10.23 (s, 1 H, O*H*). MS (EI, 70 eV): 430 amu (M^+).

N,N′-Bis(4,6-dimethoxysalicylidene)-2,2-dimethyl-1,3-propanediiminocobalt(II) hemihydrate (**10**)

This complex was prepared as for **6** using 5.88 g (13.6 mmol) of the corresponding Schiff base, 25.0 cm^3 of aqueous sodium hydroxide (1.07 M, 27.2 mmol), 0.041 g (0.50 mmol) of sodium acetate, 75 cm^3 water, 45 cm^3 ethanol, and 3.24 g (13.6 mmol) cobalt chloride (solution in 20 cm^3 H_2O). A brown powder was obtained (5.50 g, 83%). Mp: 282°C (dec). Found: C, 55.53; H, 5.76; N, 5.34. Calc. for $C_{23}H_{28}N_2O_6Co \cdot 0.5\ H_2O$: C, 55.65 H, 5.89; N, 5.64%. MS (EI, 70 eV): 487 amu (M^+).

RESULTS AND DISCUSSION

Synthesis and characterization

The cobalt(II) Schiff-base complexes (see Chart 1) were prepared by known synthetic methods in a two-step process. Schiff-base ligands were prepared in the first step by condensing salicylaldehyde with a diamine. In aqueous ethanol, these were then reacted with cobalt(II) chloride in presence of a trace of sodium acetate (forming cobalt(II) acetato complexes which are more soluble in alcohol than cobalt chloro compounds) and 2 molar equivalents of aqueous sodium hydroxide. All compounds were characterized by elemental analysis, melting point, and mass spectroscopy. Ligands were also characterized by ^1H NMR spectroscopy.

Solution formulations

Solubility of carrier or carrier–axial base complex is an important parameter in the total oxygen capacity of solutions because more concentrated carrier solutions will have higher capacity, as long as degradation is not induced or accelerated by higher carrier concentrations. Solubilities of the complexes in NMP are given in Table 1. These data indicate that metal complex solubilities increase with the number of alkoxy groups substituted on the phenyl ring of the ligands and with length of the alkoxy group chain. Further, a Saldmpr complex has greater solubility than the

Table 1. Solubilities of cobalt Schiff-Base complexes in 1-methyl-2-pyrrolidinone solvent at 25°C

Complex	Solubility (M)

4,6-$(MeO)_2$CoSaldmpr	0.35

corresponding Salen complex, as expected due to the addition of methyl groups to the diimino bridging group. Recently, complexes of Saldmpr with metals, including, In^{III} and Re^{V}, have been reported [14].

Oxygen-carrying properties

Results of oxygen capacity studies of solutions of carriers **1**, **2**, **6**, and **7** are reported in Table 2. An additional five cycles of absorption and desorption were conducted 24 h after the data in Table 2 were obtained. There is no sign of carrier degradation, as judged by use of GC/MS to monitor the gas stream exiting the carrier solution for CO_2 and H_2O. Preliminary results indicate some loss of O_2 binding and formation of CO_2 after 20 cycles. The average carrier loading gives an indication of the carrier affinity for oxygen. At this point we are only describing this affinity empirically, as we do not have mechanistic oxygen complexation information, such as whether the oxygen binding species is a 2 : 1 or 1 : 1 complex of carrier to dioxygen [2(c)]. The presence of 2-cyanopyridine axial base clearly increases oxygen affinity, as seen from the affinity data for solutions of CoSalen and 3-MeOCoSalen. This may be ascribed to the electron-donating nature of the base which strengthens the cobalt-dioxygen interaction.

The 3-methoxy ring-substitution of the CoSaldmpr carrier leads to a greater than twofold increase in carrier loading. Surprisingly, under these conditions, 3-methoxy ring substitution of Cosalen has no effect on loading. Clearly, further oxygen absorption tests, including those of **8–10**, may clarify the substitution effects and the structure effects on oxygen affinity and determine the extent of influence of the 2,2-dimethyl-1,3-propanediimino bridging group on the stability of the carriers. Additionally, the amount of oxygen absorbed by the solutions as a function of oxygen partial pressure will provide an indication of the

(Received 17 April 1997; accepted 27 June 1997)

Abstract—Reaction of VCl_3 with 2-mercapto-3-pyridinol (H_2mpp) in the presence of CH_3ONa yields $(VO(Hmpp)_2 \cdot CH_3CN$ (**1**). The coordination geometry around the vanadium is square pyramidal, with a V=O double bond of 1.602(6) Å and average V—S and V—O distances of 2.392 and 1.943 Å, respectively. The mpp ligands behave as the thione tautomer with the N atoms prontonated rather than the thiol alternative form. The intermolecular hydrogen bonding interactions between the protonated N atoms and the terminal O or the coordinated O atoms of mpp ligands result in an infinite two-dimensional network of $VO(Hmpp)_2$. Complex (**1**) has been characterized by infrared, and EPR spectroscopic studies. © 1997 Elsevier Science Ltd

Keywords: 2-mercapto-3-pyridinol; oxovanadium complex; thione; hydrogen bonding; network.

Vanadium thiolate chemistry has drawn our attention for several reasons. Some of the impetus has derived from the relevance of this area to industrial petroleum refining. Certain crude oils contain large amounts of soluble vanadyl (VO^{2+}) impurities categorized into two types according to their ligands [1], the vanadyl petroporphyrins, which have been well studied and characterized [2]; and the vanadyl non-porphyrins whose ligand environment is thought to contain S, N, and/or O donor atoms [3]. These vanadyl impurities result in formation of insoluble vanadium sulfide deposits which poison the catalyst (e.g. Mo/Co/S on alumina) during hydrodesulfurization (HDS) [4–8]. This has stimulated interest both in the identification of the crude oil impurities and in the mechanism of their subsequent conversion to vanadium sulfide. Further motivation has come from the recently discovered roles of vanadium in biological systems [9], including the vanadium nitrogenase [10], in which the vanadium is bounded to S and probably also to O and or N atoms simultaneously. In addition, another driving force for our investigation of vanadium thiolate chemistry is our current interest in construction of transition-metal cluster complexes from simple thiolate containing building blocks [11].

Over the last few years, we have engaged in developing the thiolate chemistry of vanadium, concentrating on a ligand system with mixed sulfur and oxygen donors at 1,2-positions. Vanadium complexes with ligands that provide S and O donors simultaneously are not so well explored as compared to independent oxo-vanadium or thio-vanadium complexes. Oxovanadium(IV) mercaptocarboxylate has been investigated in aqueous solution [12], while bis(2-mercaptopyridine N-oxide) oxovanadium(IV) has recently been structurally characterized [13]. Our efforts along these lines with the ligand 2-mercaptophenolate (mp^{2-}, $C_6H_4OS^{2-}$) afforded already the trinuclear complex $[V_3(mp)_6]^-$ [14], and the dimeric complexes $[V(mp)_3NaLL']_2^{2-}$ (L, L′ = solvent) [15] and $[\{V(mp)_3\}_2Na]^{3-}$ [16]. In related works, Klich [17] reported a series of mononuclear vanadium(IV) complexes $[VO(mp)_2]^{2-}$, $[V(mp)_3]^{2-}$

and $[V(mmp)_3]^{2-}$ (H_2mmp = 2-mercapto-4-methylphenol). We now set out to further explore the chemistry of vanadium with the ligand 2-mercapto-3-pyridinol (H_2mpp, C_5H_5NOS) and obtain a product which is simultaneously self-assembled via coordinate- and hydrogen-bond formation.

Molecular self-assembly through hydrogen bonding has become a hot topic in crystal engineering recently [18]. In particular, the aggregation of transition-metal containing building blocks based on hydrogen bonding interaction is very important, because the incorporation of transition-metal ions into such systems introduces magnetic, optical and conductive properties characteristic of these ions into materials with potential for nonlinear optical, conducting and ferromagnetic properties [18,19]. We report herein the synthesis and crystal structure of $[VO(Hmpp)_2]\cdot CH_3CN$ (1), a novel self-assembly network of bis(2-mercapto-3-pyridinol)oxovanadium(IV) based on hydrogen bonding interactions, together with the IR and EPR spectroscopic data.

EXPERIMENTAL

All operations were carried out under an atmosphere of dinitrogen using conventional Schlenk techniques. All solvents were dried over molecular sieves and degassed before use. VCl_3 (Aldrich) and 2-mercapto-3-pyridinol (H_2mpp) (Aldrich) were used as received.

Infrared spectra were obtained as KBr pellet on a Bio-Rad FTS-40 spectrophotometer over the range 4000–200 cm^{-1}. Magnetic moment was measured at room temperature (298 K) on a model CF-1 superconducting extracting sample magnetometer at the magnetic field of 5.0 T with the powder sample kept in a capsule. EPR spectra were recorded on a Bruker ER-420 spectrometer at the X-Band frequency. Elemental analyses were carried out by the Analytical Chemistry Group of this Institute.

Synthesis of $[VO(Hmpp)_2]\cdot CH_3CN$ (1)

The mixture of H_2mpp (0.53 g, 4.2 mmol) and CH_3ONa (0.30 g, 5.6 mmol) in 20 cm^3 of EtOH was added to a stirred solution of VCl_3 (0.22 g, 1.4 mmol) in EtOH (15 cm^3). The reacting solution rapidly turned red–purple then converted to red–brown. After 2 h of stirring, the resultant solution was filtered and the filtrate stored at 4°C for several days to give the dark-purple microcrystalline product which was collected by filtration and dried *in vacuo*. Recrystallization from $EtOH/CH_3CN$ (1:1) gave (1) as prismatic crystals, yield 0.13 g (26%, based on VCl_3). The same procedure in the presence of Et_4NCl ($Et_4NCl:VCl_3$ ratio of 2:1) afforded the same products. Anal. Calcd for $C_{12}H_{11}N_3O_3S_2V$ (%): C, 40.00; H, 3.08; N, 11.66; S, 18.13; V, 14.14. IR (KBr): 3187(m), 3014(m), 2984(m), 2869(m), 2613(w), 2100(w), 1594(s), 1576(m), 1503(s), 1447(s), 1338(m), 1291(s), 1192(s), 1161(w), 1129(s), 1104(w), 1050(s), 937(s), 854(s), 787(s), 720(m), 698(s), 620(s), 575(w), 448(m), 390(s), 349(m) cm^{-1}.

Crystal data, structure determination and refinement

Crystallographic data for (1) are summarized in Table 1. Diffraction data were collected on an Enraf-Nonius CAD 4 diffractometer with Mo-$K\alpha$ radiation (λ = 0.71073 Å) and graphite monochromator using ω–2θ scan mode. The intensities of three standard reflections were measured every 120 min, indicating a total loss in intensity of 3.0%. The reflections were corrected for anisotropic decay and Lorentz-polarization effects. Intensity of equivalent reflections were averaged (R_{int} = 3.5%). The structure was solved by direct methods on a COMPAQ PL4/50 computer with the MolEN/PC program package [20] and refined by full matrix least-squares procedures with anisotropic thermal parameters for all the non-hydrogen atoms. The hydrogen atoms were visible in a difference Fourier map phased on the non-hydrogen atoms. The two hydrogen atoms [H(1A) and H(2A)] attached to the N atoms of the Hmpp ligands were

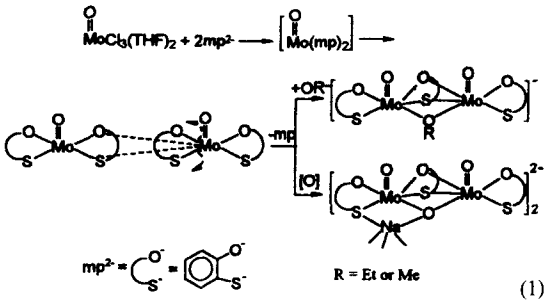
located from the difference Fourier synthesis and the remaining ones were placed in an ideal position with C—H = 0.95 Å. All hydrogen atoms were added to the structure factor calculations but not refined.

RESULTS AND DISCUSSION

Synthesis

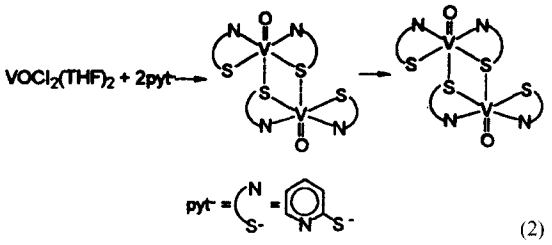
Our work with the H_2mpp ligand was an extension to earlier studies [14,15] employing H_2mp. The latter ligand had been shown to react with VCl_3 in alchol to yield purple solutions containing the $[V(mp)_3]^{2-}$ fragments, which further coordinate to the metal ions present in the solution to form polynuclear complexes such as $[V_3(mp)_6]^-$ and $[V(mp)_3NaLL']_2^{2-}$ (L, L′ = solvent). We decide to investigate similar reaction with H_2mpp, which possesses the same ring size and donors as H_2mp. Initial reaction was employed with a mixture comprising VCl_3, H_2mpp, CH_3ONa and Et_4NCl in a 1:3:6:2 molar ratio in EtOH, but this was fruitless. Consequently, we adjusted the reaction stoichiometry in a VCl_3:H_2mpp:CH_3ONa ratio of 1:3:4 in the presence or absence of Et_4NCl. No likely species corresponding to $[V(mp)_3]^{2-}$ was obtained, except the oxovanadium(IV) complex (**1**). The source of the terminal oxygen is most probably adventitious O-containing impurities (H_2O or O_2) in the solvents of N_2 atmosphere.

As an offshoot of our interest in transition-metal 1,2-bidentate thiolates as building blocks and their construction into cluster complexes, we have previously reported [11] that oxometal complexes $M(O)L_2$ (L = bidentate sulfur-containing ligand) can function as building blocks. For example, in the reaction of $MoOCl_3(THF)_2$ with mp^{2-} [21], the building block $Mo(O)(mp)_2$ was presumably formed, two of which then condensed with the elimination of one ligand to give complex $[\{MoO(mp)\}_2(\mu\text{-mp})(\mu\text{-OR})]^-$ (R = Me [21a] or Et [21b]) or $[\{MoO(mp)\}_2(\mu\text{-mp})(\mu\text{-O})Na(EtOH)_2]_2^{2-}$ [21b, c] as shown in eqn (1).



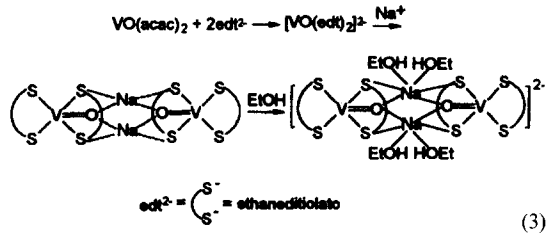
(1)

For the recently documented complex $V_2O_2(pyt)_4$ (Hpyt = pyridine-2-thiolate) [22,23], the moiety $VO(pyt)_2$ can be visualized as the building block, two of which bridged through the sulfur donor atoms to form the binuclear complex [eqn (2)]. Dissociation of this complex to mononuclear $VO(pyt)_2$ species in solution has been shown by EPR studies [23].

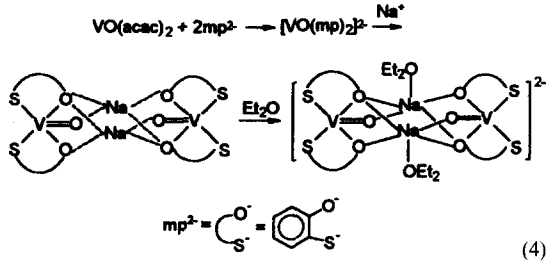


(2)

The anions $[VO(edt)_2]^{2-}$ [24] (edt^{2-} = ethane-1,2-dithiolato) and $[VO(mp)_2]^{2-}$ [17] have been known to further coordinate to the Na^+ ions present in the solutions to form dimeric complexes as depicted in the eqns (3) and (4), respectively.



(3)



(4)

In this regards, the $VO(Hmpp)_2$ moiety has attracted our interest as a potential building block of which the reactivity is still under investigation.

Structure description

The acetonitrile solvent molecule is well separated from the metal and will not be further discussed. The structure of $VO(Hmpp)_2$ is shown in Fig. 1. Selected bond lengths and bond angles are given in Table 2 in which C(11), C(12) and N(3) represent the acetonitrile solvent molecule.

The geometry of $VO(Hmpp)_2$ can be described as a square pyramid in which the V atom is coordinated to a terminal O atom and two Hmpp ligands through the O and S atoms in the basal positions, each forming

two five-membered chelate rings V–O–C–C–S in a *cis* configuration. The whole molecule thus exhibits *pseudo-*C_s symmetry with the σ plane passing through the apical V—O(3) bond and bisecting the O(1)···O(2) and S(1)···S(2) vectors. The same *cis* configuration is found in other oxovanadium(IV) complexes [13,17,25] with an O_2S_2 donor set in the basal plane. Structural features of (1) are compared in Table 3 with related oxovanadium complexes possessing O_2S_2, N_2S_2, S_4 and N_2O_2 donor sets.

The vanadium atom is displaced 0.636 Å towards the oxo ligand above the O_2S_2 least-squares plane [the maximum deviation from which is 0.013 Å for O(1)]. This value is almost identical to the corresponding displacement in $VO(mpo)_2$ (0.642 Å) and $[VO(mp)_2]^{2-}$ (0.638 Å), but is longer by 0.03 Å than that in VO(tsalen) (tsalen = N,N′-ethylene-bis(thiosalicylideneaminato), 0.608 Å) and shorter by 0.03 Å than that in $[VO(edt)_2]^{2-}$ (0.668 Å) (see Table 3). This difference is probably subject to the change of flexibility of the ligands [13b]. The former three complexes display similar values of this distance due to

Table 3. Comparison of structural parameters of (1) and related compounds (Å)

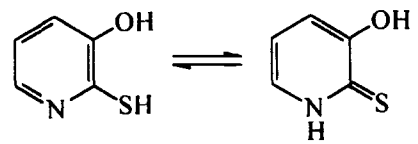
Complex	Donor set	V=O	Distance of V to basal place	V—O (basal plane)	V—S (basal plane)	Ref.
$VO(Hmpp)_2$	$(OS)_2$	1.602(6)	0.636	1.943(5)	2.392(3)	This work
$VO(mpo)_2$[a]	$(OS)_2$	1.593(3)	0.642	1.956(3)	2.374(2)	[13]
$[VO(mp)_2]^{2-}$[a]	$(OS)_2$	1.611(5)	0.638	1.959(4)	2.365(2)	[17]
$VO[SSi(OBu^n)_3]_2$	$(OS)_2$	1.642(13)		2.106(13)	2.333(6)	[25]
VO(tsalen)[a]	(N_2S_2)	1.598(6)	0.608		2.346(3)	[26]
$[VO(edt)_2]^{2-}$[a]	$(SS)_2$	1.625(2)	0.668		2.378(1)	[27]
VO(salphen)[a]	(O_2N_2)	1.589(3)		1.927(2)		[28]

[a] mpo = 2-mercaptopyridine N-oxido, $C_5H_4NOS^-$; mp = 2-mercaptophenolato, $C_6H_4OS^{2-}$; tsalen = N,N′-ethylene-bis(thiosalicylideneaminato); edt = ethane-1,2-dithiolato; salphen = N,N′-disalicylidene-*o*-phenylenediaminato.

the similar flexibility of the ligands mpp, mpo and mp. In VO(tsalen), the less rigidity of the ligand (as compared to mpp, mpo and mp) provides a more flattened pyramid, while the anion $[VO(edt)_2]^{2-}$, with a more flexible aliphatic dithiolate gives rise to a more pronounced pyramid geometry. The V—O(3) bond is tilted slightly relative to the normal to the basal plane, with which it makes an angle of 3.6°. The V—O(3) bond length of 1.602(6) Å is close to the average distance of 1.598 Å found by Mayer [29] for a substantial number of oxovanadium(IV) complexes, consistent with the presence of a V=O double bond. It is likewise within the reported range of the related complexes (1.589–1.642 Å, Table 3). The V—S bonds in the basal plane average to 2.392 Å, which is slightly longer than that in $VO[(SSi(OC_4H_9)_3]_2$ (av. 2.333 Å) and is comparable to those in other related oxovanadium(IV) complexes (Table 3). This value is also comparable to the average V—S distances observed in the *tris*-chelated vanadium(IV) complexes $[V(mmp)_3]^{2-}$ (av. 2.363 Å, mmp = 2-mercapto-4-methylphenolato) [17], $[V(mp)_3NaLL']_2^{2-}$ (av. 2.369 Å) [15] and $[\{V(mp)_3\}_2Na]^{3-}$ (av. 2.367 Å) [16]. The basal V—O bonds averaging 1.943 Å are somewhat shorter than those in $VO[SSi(OC_4H_9)_3]_2$ (av. 2.106 Å), but close to those in other complexes containing similar donor sets (Table 3).

The organic ligands are essentially coplanar, respectively, with maximum deviations observed for C(4) (0.020 Å) and C(6) (0.022 Å), respectively. The two five-membered chelate rings V–O–C–C–S are folded about the O–S vector, showing an envelope configuration. The ligand planes bend toward the apical O and make angles of 15.9(5)° and 13.9(4)° with the O(1)—V—S(1) and O—(2)—V—S(2) planes, respectively (Fig. 1). This folding of the ligand planes has also been observed in $VO(mpo)_2$ [13] and $[VO(mp)_2]^{2-}$ [17]. The mean chelate V—O—C angle of 120.8° suggests that the O donor atoms are sp^2 hybridized, while the mean value of the V—S—C angles of 93.9° shows the bonding orbitals of the S donor atoms are predominantly of *p* character.

It has been shown that the N-heteroaromatic mercapto ligand exists in two tautomeric forms (thiol or thione) and has been established that the thione form is the predominant one [23,30–33]. Again, as was the case for the free ligand 2-mercaptopyridine (Hpyt) [23] and 2-mercaptopyridine N-oxide (Hmpo) [33], the H_2mpp molecule exists as a tautomeric equilibrium between the thiol (A) and thione (B) forms shown.



A B

The C—S bond lengths in (1), averaging to 1.699(1) Å, are significantly shorter than the normal covalent distance (1.81 Å) [34] for a single bond and considerably shorter than the C—S bonds values of aryl thiolates observed in the bdt (benzenedithiolate, av. 1.76 Å), tdt (toluene-3, 4-dithiolate, av. 1.79 Å) or mp (av. 1.75 Å) ligated complexes that contain delocalization of $p\pi$-electrons in the chelate rings [11]. In fact, the rather short C—S distances approach the C=S distance in thiourea [35] [1.720(9) Å] and its derivatives [1.67(2)–1.73(1) Å] [36]. Similar results have been found in the mpo ligated complexes (C—S average to 1.71 Å), in which the C—S bonds show double bond character due to the predominant thione contribution of the mpo ligand [11,37]. In this regard, the mpp ligands should exist in the thione tautomer (B) instead of the thiol alternative form (A) in complex (1). Further support for this conclusion comes from the facts as follows: (i) for all pyridine derivatives, the C—N—C angle in the rings is sensitive to the protonation (or nonprotonation) of the N atom, protonated (or nonprotonated) N atoms possess angles larger (or smaller) than 120°, respectively [23,32,38]. In this case, the C—N—C angles of the

mpp ligands are 124.9(8) and 124.6(9)°, respectively, consistent with the protonated form (B). (ii) The hydrogen atoms attached to the N atoms can be located in a difference Fourier map phased on the nonhydrogen atoms. (iii) The six-membered pyridinyl rings show varied C—C bond lengths expected for the thione form (B) rather than equivalent ones expected for the thiol form (A) which is aromatic.

The X-ray analysis of (1) shows that the intermolecular contacts of N(2)···O(3′) (2.843 Å) and N(1)···O(2″) (2.950 Å) are in the normal hydrogen-bonding interaction range for N—H···O [39] (Symmetry code: $' = x-1,\ y,\ z$; $'' = x-1/2,\ y-1/2,\ -z-1/2$). The crystal packing is mainly determined by a network of these two hydrogen bonds (Fig. 2).

As can be seen from Fig. 2, the parallel $VO(Hmpp)_2$ moieties related by the symmetry operation $(x-1, y, z)$ are linked to each other *via* N(2)—H(2A)···O(3′) hydrogen bonds to form staircase-like tapes. Further cross-linking between adjacent tapes related by the operation $(x-1/2,\ y-1/2,\ -z-1/2)$ *via* N(1)—H(1A)···O(2″) hydrogen bonds result in a novel infinite two-dimensional network along the *ac* plane (Fig. 3).

Spectroscopic studies

The IR spectrum (KBr pellet) of (**1**) shows strong V=O stretching at 937 cm^{-1}. The relatively low value at the lower end in the range 935–1035 cm^{-1} as reported for a large set of oxovanadium complexes [40] is consistent with the rather long V=O bond (1.602 Å as compared to 1.56–1.60 Å for most square pyramid vanadyl(IV) complexes) [17,24]. It is almost identical to that in $[VO(mp)_2]^{2-}$ (940 cm^{-1}) [17], but is substantially lower than those in VO(salphen) (984 cm^{-1}) [28], $VO(mpo)_2$ (984 cm^{-1}) [13b] and VO(t-salen) (975 cm^{-1}) [26], but slightly higher than that in $[VO(edt)_2]^{2-}$ (930 cm^{-1} for the Me_4N^+ cation and 909 cm^{-1} for the Ph_4P^+ cation) [24], in accord with the trends in V=O bond lengths (Table 3). The characteristic metal-ligand absorptions at 448 [ν(V—O)], 390 [$\nu(V—S)_{as}$] and 349 [$\nu(V—S)_s$] cm^{-1} agree well with those reported for $VO(mpo)_2$ [13b]. The doublet appeared at 1129 and 1104 cm^{-1} is assigned to the C—S stretch, consistent with the double bond character [30,31,33a,37]. Only one absorption at 3187 cm^{-1} is assignable to the ν (N—H) stretch [31], indicating that there are hydrogen bonding interactions concerning all N—H groups of $VO(Hmpp)_2$ moieties.

The room temperature magnetic moment of 1.69 μ_B of solid (1) is consistent with the spin-only value of 1.73 μ_B expected for a vanadium(IV) complex (d^1, $S = 1/2$).

The powder EPR spectra of (1) both at room temperature and at 77 K show only one broad signal with g_0 values of 1.978 and 1.980, respectively. In DMF solution at room temperature, the EPR spectrum displays the characteristic eight-line pattern of vanadium (^{51}V, $I = 7/2$) (see Fig. 4a), with isotropic g_0 and hyperfine coupling parameter A_0 values of 1.981 and 81.0×10^{-4} cm^{-1}, respectively (Table 4). The spectrum recorded for the frozen solution at 77 K is more informative (Fig. 4b). The corresponding g and A values are given in Table 4, together with EPR data for complexes with related donor sets.

The anisotropic g and A values of (**1**) are typical for square-pyramidal oxovanadium(IV) complexes having the unpaired electron largely in a d_{xy} orbital (for the ligands along x and y) [17,44,45]. As can be

[c] Small rhombicity in $g_{x,y}$.

[d] 1 : 1 $CHCl_2$/DMF solvent.

seen in Table IV, such complexes exhibit $A_z > A_{x,y}$ and $g_z < g_{x,y}$.

CONCLUSIONS

Complex (1) has confirmed that 2-mercapto-3-pyridinol can coordinate to metal ions in its thione form. In particular, the thione form Hmpp ligand in (1) fulfils its bifunctional role by generating a network of transition-metal building block by a combination of coordinate- and hydrogen-bond formation. This work provides a new direction in the designed synthesis of supramolecular system containing transition-metal ions.

Supplementary material

List of observed and calculated structure factors, fractional atomic coordinates and anisotropic thermal parameters for non-hydrogen atoms, and hydrogen atoms parameters as well as complete bond distances and angles are available from the authors upon request.

(Received 4 March 1997; accepted 27 June 1997)

Abstract—Reaction of Cs[6-*arachno*-SB_9H_{12}] with $[RhCl(CO)(PPh_3)_2]$ yields the known complex [8-CO-8,8-$(Ph_3P)_2$-8,7-*nido*-$RhSB_9H_{10}$], **1**. In contrast, treatment of the same thiaborane with $[RhCl(CO)(PPh_3)]_2$ affords a number of 12-vertex dirhodathiaboranes of the type [2,3-$(CO)_2$-$\mu_{2,3}$-CO-2,3-$(PPh_3)_2$-7-X-2,3,1-*closo*-$Rh_2SB_9H_8$] in modest yields. For X = H, **3a**, and X = Cl, **4**, single crystal X-ray diffraction studies are reported; crystals of **3a** contain the compound with X = OH, **3b**, in approximately 28% occupancy. © 1997 Elsevier Science Ltd

Keywords: borane; thiaborane; rhodium; phosphine; carbonyl; crystal structure.

Among the heteroatomic derivatives of the binary boranes, by far the most extensively studied are the carbaboranes [1] and their metal complexes [2]. Recently, however, the chemistry of other polyhedral hetero(metalla)boranes has seen greater development [3], in which arguably the most common non-carbon heteroatom has been sulfur. As a result a range of sulfur-containing heteroborane polyhedra is now known which encompasses diverse examples of intermediate- and larger-sized heterothiaboranes [4], metallathiaboranes [5] and metalladithiaboranes [6], and even 'macropolyhedral' dithiaboranes [7].

As part of our continuing synthetic and structural studies [8,9], of these and other larger metallaheteroboranes, we have investigated the reaction of Cs[6-*arachno*-SB_9H_{12}] with the complexes $[RhCl(CO)(PPh_3)_2]$ and $[RhCl(CO)(PPh_3)]_2$, and have obtained from the latter an unexpected series of dimetallic thiaborane-containing products.

EXPERIMENTAL

Synthesis and characterization

All reactions were carried out under an atmosphere of dry, oxygen-free dinitrogen using standard Schlenk line techniques, with some subsequent manipulation in air. Solvents were freshly distilled from appropriate drying agents and degassed immediately prior to use. Preparative thin-layer chromatography employed Kieselgel 60 F_{254} plates (Merck), pre-washed in the appropriate solvents. NMR spectra were recorded from $CDCl_3$ solutions at 298 K. The starting materials Cs[6-*arachno*-SB_9H_{12}] [10], $[RhCl(CO)_2]_2$ [11] and $[RhCl(CO)(PPh_3)_2]$ [12] were prepared as described.

Reaction of Cs[6-*arachno*-SB_9H_{12}] *with* $[RhCl(CO)(PPh_3)_2]$. *Preparation of* [8-CO-8,8-$(Ph_3P)_2$-8,7-*nido*-$RhSB_9H_{10}$], **1**

To a frozen (77 K) solution of $[RhCl(CO)(PPh_3)_2]$ (130 mg, 0.19 mmol) in CH_2Cl_2 (15 cm^3) was added solid Cs[6-*arachno*-SB_9H_{12}] (55 mg, 0.20 mmol). The mixture was allowed to warm to room temperature with stirring, and consumption of the starting Rh

complex was monitored by IR spectroscopy. After ca 18 h, the reaction mixture was evaporated at reduced pressure. The only thiaborane-containing product (identified by $^{31}P-\{^1H\}$ and $^{11}B-\{^1H\}$ NMR and infrared spectroscopy) was the known [13] compound [8-CO-8,8-$(Ph_3P)_2$-8,7-*nido*-$RhSB_9H_{10}$], **1**.

Reaction of $Cs[6\text{-}arachno\text{-}SB_9H_{12}]$ *with* $[RhCl(CO)(PPh_3)]_2$

Preparation of compounds **2–4**. $[RhCl(CO)(PPh_3)]_2$ [14] was formed *in situ* from $[RhCl(CO)_2]_2$ (100 mg, 0.257 mmol) and PPh_3 (134 mg, 0.511 mmol) in benzene (10 cm^3). This solution of $[RhCl(CO)(PPh_3)]_2$ was frozen to 77 K and solid $Cs[6\text{-}arachno\text{-}SB_9H_{12}]$ (141 mg, 0.514 mmol) added; the mixture was allowed to warm to room temperature and stirred for ca 3 h. During the course of the reaction gas evolution was apparent; the yellow solution became more intensely orange and an apparently yellow solid was deposited. The mixture was filtered and the orange filtrate evaporated at reduced pressure to yield an orange–brown solid. (Infrared spectroscopic analysis of the solid removed by filtration showed a broad absorption in the B—H stretching region, suggesting that this solid is largely residual $Cs[SB_9H_{12}]$ or its decomposition products, in addition to CsCl.)

The orange—brown residue was dissolved in a small amount (ca 5 cm^3) of CH_2Cl_2 and applied to chromatographic plates; repeated preparative thin layer chromatography (CH_2Cl_2/*i*-hexane, 3:2) gave bands as follows:

1. Brown: R_f 0.6, (very small amount, < 1 mg). IR (CH_2Cl_2): ν_{max}(BH) 2528 (m, br); ν_{max}(CO) 2027 (s, br), 1868 (vw, br) cm^{-1} (compound **2** was not further pursued).
2. Orange: R_f 0.5, (37 mg) (compounds **3a, 3b** and **3c**).
3. Red: R_f 0.4, (33 mg) (compound **4**).

Bands 2 and 3 yielded three identifiable metallathiaboranes, namely compounds **3a** and **3b,** and compound **4** respectively, which were characterised as described in the two following sections.

Characterisation of $[2,3\text{-}(CO)_2\text{-}\mu_{2,3}\text{-}CO\text{-}2,3\text{-}(PPh_3)_2\text{-}2,3,1\text{-}closo\text{-}Rh_2SB_9H_9]$ **3a** *and partial characterisation of* $[2,3\text{-}(CO)_2\text{-}\mu_{2,3}\text{-}CO\text{-}7\text{-}OH\text{-}2,3\text{-}(PPh_3)_2\text{-}2,3,1\text{-}closo\text{-}Rh_2SB_9H_8]$ **3b**

Band 2, upon repeated crystallisation (slow mutual diffusion of *i*-hexane and a CH_2Cl_2 solution at −30°C), afforded mainly red–orange *rods* which were very unstable with respect to solvent loss upon removal from the mother liquor; seven red–orange *crystals*, and a larger number of yellow *blocks* were also obtained. A single-crystal X-ray diffraction study (*vide infra*) of one of the second kind of red–orange crystals identified this as primarily $[cis\text{-}2,3\text{-}(CO)_2\text{-}\mu_{2,3}\text{-}CO\text{-}2,3\text{-}(PPh_3)_2\text{-}2,3,1\text{-}closo\text{-}Rh_2SB_9H_9]$, **3a,** and a fraction as the 7-OH derivative **3b**. The yellow crystals, **3c,** are as yet unidentified. However, there is very close similarity in the infrared and ^{31}P NMR spectra of all three crystal types obtained from band 2, and this strongly suggests them simply to be polymorphs of **3a**. (Moreover, microanalytical data are also consistent with compound **3b** being present in only small amounts overall.) Taking the bulk of band 2, therefore, to be of formulation $[(CO)_3(PPh_3)_2Rh_2SB_9H_9]$: combined yield (as crystals) of band 2: 27 mg, 0.030 mmol, 5.8% based on {Rh}.

Anal. Found: C, 49.40; H, 4.09 %. Calcd for $C_{39}H_{39}B_9O_3P_2Rh_2S$: C, 49.16; H, 4.13%. IR (CH_2Cl_2): ν_{max}(BH) 2529 (m, br); ν_{max}(CO) 2031 (s), 1863 (m, br) cm^{-1}. Cluster NMR data for **3a,** in the order $\delta(^{11}B)$ [$\delta(^1H)$] relative ^{11}B integral: +10.3 [+3.5] 1B, +6.2(br) [+3.0 (2H), +2.7 (2H), +2.6 (1H)] 5B, −3.2 [+2.4] 2B, −32.9 [+1.0] 1B. In addition: $\delta(^1H)$ +7.20 to +7.41 (m, C_6H_5); $\delta(^{31}P)$ +23.2 [d, $^1J(^{31}P\text{-}^{103}Rh)$ ca 110 Hz]. We tentatively assign an additional broad ^{11}B singlet resonance, at $\delta(^{11}B)$ ca +19, to the 7-OH substituted position in **3b**; other ^{11}B resonances due to **3b** appear to coincide with those of **3a,** as do the ^{31}P resonances of the two species.

Characterisation of $[2,3\text{-}(CO)_2\text{-}\mu_{2,3}\text{-}CO\text{-}7\text{-}Cl\text{-}2,3\text{-}(PPh_3)_2\text{-}2,3,1\text{-}closo\text{-}Rh_2SB_9H_8]$ **4**

The compound **4,** obtained as band 3 above, was fully characterised spectroscopically (*vide infra*) and was unambiguously identified as $[cis\text{-}2,3\text{-}(CO)_2\text{-}\mu_{2,3}\text{-}CO\text{-}7\text{-}Cl\text{-}2,3\text{-}(PPh_3)_2\text{-}2,3,1\text{-}closo\text{-}Rh_2SB_9H_8]$, by the single crystal X-ray diffraction study reported later. Yield (as crystals): 29 mg, 0.029 mmol, 5.7% based on {Rh}.

Anal. Found: C, 44.30; H, 3.11%. Calcd for $C_{39}H_{38}B_9ClO_3P_2Rh_2S$: C, 47.45; 3.88%. IR ($CH_2Cl_2$):

	X
3a	H
3b	OH
4	Cl

ν_{max}(BH) 2535 (m, br); ν_{max}(CO) 2064 (s), 1880 (m, br) cm^{-1}. Cluster NMR data for **4**, in the order $\delta(^{11}B)$ [$\delta(^{1}H)$] relative ^{11}B integral: +23.9 [−] 1B [B(7)], +11.2 [+4.44] 2B, +6.2 [+4.27] 2B, +0.9 [+2.48] 2B, −3.5 [+2.80] 2B, −35.6 [+0.61] 1B. In addition: $\delta(^{1}H)$ +7.26 to +7.48 (m, C_6H_5); $\delta(^{31}P)$ +22.6 [d, br, $^{1}J(^{31}P\text{-}^{103}Rh)$ ca 88 Hz].

Crystallisation of compound **4** (slow mutual diffusion of *i*-hexane and a concentrated CH_2Cl_2 solution at −30°C) afforded several well-formed dark red *blocks*, one of which was the subject of analysis by a single crystal X-ray diffraction experiment, as described below.

Crystallographic studies

Crystal data, and details of data collection and structure refinement, for compounds **3a/b** and **4** are listed in Table 1. Reflection data were measured at 293(2) K on an Enraf-Nonius CAD4 automatic four-circle diffractometer operating in the ω–2θ scan mode using graphite-monochromated Mo-K_α X-radiation, $\bar{\lambda} = 0.71073$ Å. Cell parameters and orientation matrices were determined from the setting angles of 25 accurately-measured reflections. Both data sets were corrected [15] for Lorentz and polarisation effects and, following isotropic convergence, benefited from an empirical absorption correction [16]. During data collection, some slight crystal decay (ca 2% for **3a/b**; ca 4% for **4**) was revealed by monitoring the intensity of two standard reflections measured after every 500 data; the data sets were corrected [15] to allow for this. In the latter stages of refinement, data were weighted according to $w^{-1} = [\sigma^2(F_o^2) + g_1^2P^2 + g_2P]$ where $P = (F_o^2 + 2F_c^2)/3$. Fractional atomic co-ordinates, full lists of bond distances and interbond angles and anisotropic thermal parameters have been deposited as supplementary data. Molecular geometry figures were drawn using SHELXTL-PC [17].

[2,3-$(CO)_2$-$\mu_{2,3}$-CO-2,3-$(PPh_3)_2$-7-X-2,3,1-*closo*-$Rh_2SB_9H_8$] (X = H/OH), **3a/b**. An irregular red–orange *block* of approximate dimensions 0.5 × 0.3 × 0.2 mm was selected for data collection.

[a] for **3a** only (i.e., ignores partial OH substituent)

The positions of the two rhodia were obtained by direct methods (*SHELXS*-86 [18]), whilst the B, C, O, P and S atoms were located in subsequent difference Fourier maps (*SHELXL*-93 [19]). Although most of the cage H atoms could also be located by this method, they would not subsequently satisfactorily refine with independent positions and so were set riding in idealised positions 1.10 Å from the corresponding B atom with isotropic thermal parameters equal to 1.2 times the equivalent isotropic thermal parameter of the parent B atom. The six phenyl rings were constrained to be planar, rigid hexagons (C—C 1.39 Å), with the attached H atoms in calculated positions (C—H 0.93 Å) and having isotropic thermal parameters equal to 1.2 times the equivalent isotropic thermal parameter of the corresponding C atom. This model (with all nine B atoms bearing only terminal H atoms) was refined towards isotropic convergence, at which point it became clear that a substantial residual electron density peak (ca 2 $eÅ^{-3}$) was located ca 1.3 Å from B(7). This was assigned as a (partial) terminal hydroxyl substituent on the basis of a reasonable B—X distance; both the OH group and the terminal H atom attached to B(7) were included with (refining) complementary occupancy. The O—H distance was constrained at 0.82 Å, and the B(7)—O—H angle was constrained to be tetrahedral, with free rotation about the B—O bond allowed such that the H atom was located at the position of maximum electron density (determined *via* structure factor calculation [19]). The H atom bound to B(7) was not further positionally refined once the partial OH group had been included in the model. At convergence the hydroxyl group had 0.28(2) fractional occupancy; no further attempt to model the disorder was deemed necessary. Refinement throughout was on F^2 using full-matrix least-squares methods (*SHELXL*-93), converging without difficulty and with no significant residual electron density. The Flack absolute structure parameter × was calculated to be 0.01(4), confirming the absolute configuration to be that chosen [20].

[2,3-$(CO)_2$-$\mu_{2,3}$-CO-7-Cl-2,3-$(PPh_3)_2$-2,3,1-*closo*-$Rh_2SB_9H_8$], **4**. A well-formed dark red *block* of approximate dimensions 0.45 × 0.25 × 0.15 mm was chosen for data collection. The positions of the two rhodium atoms were determined by inspection of the Patterson synthesis (*SHELX*-76 [21]); those of the B, C, O, P, S, Cl and cage H atoms were obtained by difference Fourier syntheses (*SHELXL*-93 [19]). The Cl atom was identified as such by comparison of its peak height in a difference map to that of a well-defined C atom, and is justified by its successful refinement, the reasonable B—Cl distance, and its chemical sense. The structure was refined by full-matrix least-squares on F^2 using *SHELXL*-93. Phenyl rings were treated as in **3a/b** above. Cage H atoms were successfully allowed positional refinement, and were assigned a common isotropic thermal parameter, $U_H = 0.062(4)$ $Å^2$ at convergence. All non-H atoms were permitted anisotropic refinement following the absorption correction. The model very readily converged and there are no significant residual peaks in the final difference Fourier map.

DISCUSSION

The reaction of [RhCl(CO)$(PPh_3)_2$] with Cs[6-*arachno*-SB_9H_{12}] in dichloromethane affords the known [13] eleven-vertex *tris*(ligand)-rhodathiaborane [8-CO-8,8-$(Ph_3P)_2$-8,7-*nido*-$RhSB_9H_{10}$], **1**, whose identity was established by ^{31}P-{^1H} and ^{11}B-{^1H} NMR and infrared spectroscopy. This complex was previously prepared by the addition of CO to [8,8-$(Ph_3P)_2$-8,7-*nido*-$RhSB_9H_{10}$] in benzene.

In contrast, the reaction between the dimer [RhCl(CO)(PPh_3)]$_2$ and the same thiaborane is far less straightforward. The Rh reagent [14] was prepared *in situ* from [RhCl$(CO)_2$]$_2$ and one molar equivalent (per Rh) of PPh_3, and the solid thiaborane salt added directly to this solution. During the reaction, considerable effervescence was noted: the stoichiometry of the products is consistent with evolution of H_2. Preparative thin layer chromatography of the filtered and concentrated reaction mixture revealed three distinct bands (see Experimental).

The first of these bands, designated compound **2**, was recovered in only very small quantity, readily decomposed and ultimately defied detailed characterisation. Nevertheless, given the identities of the other products, and the detection of (probable) terminal- and bridging-CO infrared bands in addition to BH stretching vibrations, we reasonably propose that **2** is related to the more well-defined compounds **3a**, **3b** and **4** below.

The second 'band' obtained by chromatography in fact consists of *at least* two compounds which proved too similar to be separated by this technique: repeated fractional crystallisation afforded three types of crystal which we believe (on the basis of ^{31}P-{^1H} NMR and infrared spectroscopy and microanalytical data) to be polymorphs containing largely a single compound. A single-crystal X-ray diffraction study (see below) showed one of these crystals to consist largely of [2,3-$(CO)_2$-$\mu_{2,3}$-CO-2,3-$(PPh_3)_2$-2,3,1-*closo*-$Rh_2SB_9H_9$], **3a**: this crystal was found to contain in addition the 7-hydroxyl analogue, **3b** in fractional occupancy (ca 28%). The two other crystal forms were never of adequate quality for a full X-ray diffraction structure determination.* [Formation of **3b**, pre-

* On a single occasion we succeeded in determining tentative unit cell parameters for a crystal of the form designated **3c** during a diffractometer random peak search: the cell volume so obtained was consistent with **3c** being *at least* related to **3a** and **3b** (primitive monoclinic, $Z = 4$, $U \approx 4300$ $Å^2$). In this context, we note also the possibility that there may exist an isomer of **3a** in which the Rh-bound triphenylphosphine (and terminal carbonyl) ligands are mutually *transoid*.

sumably from **3a**, conceivably occurs by reaction with silica (and/or atmospheric H_2O/O_2) during work-up.] The third band isolated by chromatography was solely the 7-Cl-substituted relative of compounds **3a** and **3b**, that is, [2,3-$(CO)_2$-$\mu_{2,3}$-CO-2,3-$(PPh_3)_2$-7-Cl-2,3,1-*closo*-$Rh_2SB_9H_8$], **4**, which was also studied by a single-crystal X-ray diffraction analysis, as discussed later. ^{11}B, ^1H and ^{31}P NMR spectra for **3a** and **4** are consistent with their crystallographically-determined structures. Six resonances occur in their ^{11}B-{^1H} NMR spectra in respective ratios (high → low frequency) of 1:2:2:1:2:1. Each of these signals becomes a doublet upon retention of proton coupling, save for the highest frequency resonance in the spectrum of **4** which is, therefore, assigned to the chloro-substituted vertex B(7). For both **3a** and **4**, the ^{31}P-{^1H} NMR spectra consist of a single ^{103}Rh-coupled doublet, as expected. Surprisingly, microanalytical results from crystals of **4** always differed significantly from expected values: we are unable fully to account for this (poor combustion may be suggested), given that microanalysis of the closely-related species **3** apparently gives good agreement with calculated figures.

X-ray diffraction studies of single crystals of compounds **3a** and **4**, to which the above spectroscopic studies are complementary, provided unequivocal identification of these species. Figure 1 shows a perspective view of **4**, whilst in Fig. 2 a view of the 'central' cluster and Rh environments in **3a** is presented. Selected interatomic distances and interbond angles for **3a/b** and **4** are listed in Table 2.

Compounds **3a** (and **3b**) and **4** are based on a distorted icosahedral 2,3,1-*closo*-Rh_2SB_9 cluster with approximate C_s molecular symmetry (ignoring the orientations of the pendant phenyl groups), fully consistent with their ^{11}B NMR spectra. In both clusters, a sulfur and two rhodium atoms are mutually adjacent at a triangular face. The unique boron atom, B(7), which is bound to both rhodia, has undergone substitution in **3b** and in **4**, whereby the *exo*-terminal H atom present in the unsubstituted parent **3a** has been replaced by -OH and -Cl substituents respectively. The B(7)—X distances determined here [B(7)—O in

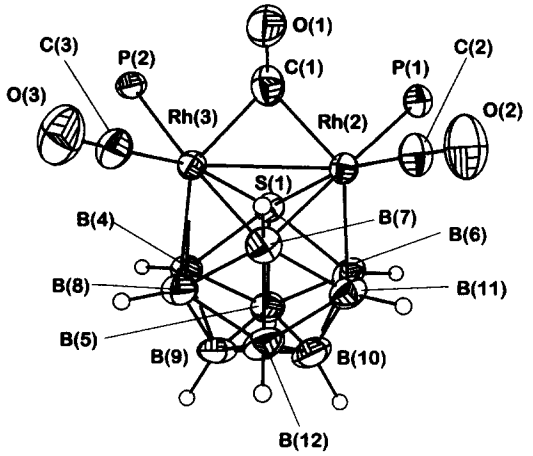

Fig. 2. View of the central Rh_2SB_9 cluster and the rhodium co-ordination environments in **3a**, drawn with the same conventions as in Fig. 1. The phenyl rings C(1*ni*) and C(2*ni*) (n = 1–3; i = 1–6, numbered cyclically) are bound to P(1) and P(2) respectively. Compound **3b**, which has a terminal hydroxyl substituent [O—H(70)] rather than an H atom bound to B(7), is present in 28(2)% occupancy in the crystal of **3a**.

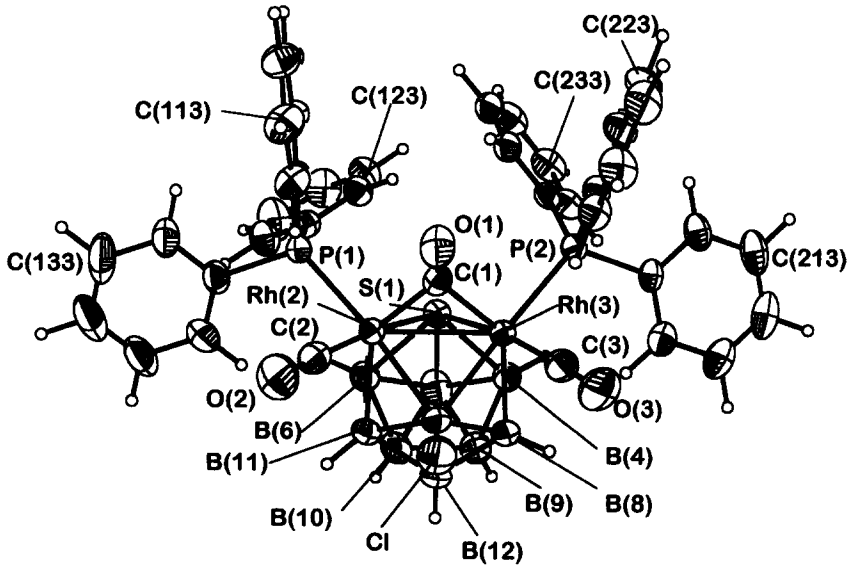

Fig. 1. Perspective view of **4** showing 50% probability ellipsoids. H atoms have artificial radii for clarity. H atoms bear the same numerical label as the heavy atom to which they are bound; phenyl rings are numbered cyclically.

[a] X = O.

[b] X = Cl.

Cluster B—B distance ranges: **3a/b**, 1.735(11) to 1.885(12)Å; **4**, 1.742(5) to 1.883(5)Å

Other cluster acute angles: B—B—B ranges: **3a/b**, 57.0(5)–65.2(5)°; **4**, 57.0(2)–65.0(2)°.

Rh—B—B ranges: **3a/b**, 64.9(4)–69.2(4)°; **4**, 64.9(2)–69.1(2)°.

S—B—B ranges: **3a/b**, 59.4(4)–65.6(4)°; **4**, 59.7(2)–65.8(2)°.

3b is 1.31(3) Å; B(7)—Cl in **4** is 1.837(4) Å] are well within the expected [22] ranges for bonds to such atoms attached to borane polyhedra (ca 1.23–1.63 Å for B—OR; ca 1.73–1.92 Å for B—Cl). Compound **3b** constitutes one of the few examples of an (albeit partially) structurally-characterised borane derivative bearing a terminal hydroxy group, rather than the relatively common alkoxy substituent. Previously reported B—OH distances are in the range 1.35(1)–1.628(19) Å; the relative shortness of the B—OH separation determined here for **3b** is *perhaps* an artefact of the crystallographic disorder.

The remainder of the thiaborane polyhedral fragment is substantially regular, and the ranges of Rh—B [**3a/b**: 2.256(7)–2.330(8) Å; **4**: 2.263(4)–2.336(4) Å], S—B [**3a/b**: 1.981(9)–2.096(9) Å; **4**: 1.996(4)–2.108(4) Å] and B—B [**3a/b**: 1.735(11)–1.885(12) Å; **4**: 1.742(5)–1.883(5) Å] distances are typical of such

metallaheteroboranes. There are, nevertheless, some significant deviations from ideal mirror symmetry within both clusters. This is evidenced by, for example, the environment of S(1): this atom is somewhat asymmetrically disposed with respect to a notional molecular mirror plane so that in **4** S(1) is 2.4187(11) Å from Rh(2), but 2.452(3) Å from the chemically equivalent Rh(3); a similar situation exists in **3a/b**.

Each rhodium vertex has a co-ordination environment resembling a distorted octahedron in which a conical $\{(CO)(\mu\text{-}CO)(PPh_3)Rh\}$ fragment is η^5-bonded to the $RhSB_3$ 'ligating face' of a $\{nido\text{-}RhSB_9\}$ polyhedron. The two terminal CO ligands, and likewise the two triphenylphosphine groups, are mutually *cisoid* in both **3a/b** and **4**; the Rh—Rh connectivity is (essentially) symmetrically bridged by one further carbonyl ligand in both cases. The rhodium-to-phosphorus bonding in both structures is unremarkable; and similarly the terminal CO functions are bound to Rh in a typical fashion and are essentially linear at carbon. The Rh(2)—Rh(3) internuclear distance is 2.7409(10) in **3a/b** and 2.749(2) Å in **4**; these are comparable to the length of the same vector in related compounds: For example, in **5** (see Table 3 below), the Rh—Rh separation is 2.6307(9) Å [23], whereas in **6** the unbridged (and perhaps, therefore, less restricted) Rh—Rh connectivity is longer, at 2.778(1) Å [24]. A steric contribution to this distance arising from the presence (and proximity) of bulky, mutually *cis* PPh_3 groups, might also be invoked in the present compounds. Both terminal CO ligands lie approximately *trans* to the cluster sulfur vertex in **3a/b** and in **4**. This is most likely a consequence of the greater basicity of the phosphines than of the carbonyl ligands, and we note that in the compound [8-CO-8-(dppm)-8,7-*nido*-$RhSB_9H_{10}$] [dppm = *bis*-(diphenylphosphino)methane], the CO ligand again is found to lie *trans* to sulfur [9]. (See refs [23–30].)

One possible consequence of this rather large metal vertex separation in **3a/b** and **4** is relatively long distances to the bridging carbonyl moiety. This is particularly so in compound **4** where C(1) is distant 2.111(3) Å from Rh(2) and 2.117(3) Å from Rh(3); the equivalent parameters in **3a/b** are 2.072(8) Å and 2.066(7) Å, respectively. The longer Rh—C(1) distances in **4** result in relatively poor overlap between Rh *d* hybrid orbitals and carbonyl σ- and π-type orbitals, so that in **4** C(1)—O(1) [1.145(3) Å] is relatively short for a μ-CO function, compared to the same separation, 1.178(8) Å, in **3a/b**. To our knowledge, the only other examples of a $\{M\cdots M\}$-bridging carbonyl function in comparable clusters are the isomeric pair of dicobalt compounds $[(CO)_5Co_2B_{10}H_8(SEt_2)_2]$ **15** and **16** [31]. In these, the much shorter intermetal separation (ca 2.49 Å) and the presence of first-row metal centres combine to afford much better orbital

overlap to the bridging carbonyl ligand, with bridging C—O distances (ca 1.18 Å) much closer to that found in **3a/b**.

Twelve-vertex complexes of formulation {2,3,1-*closo*-M_2SB_9} are not without precedent (*cf* Table 3), and the observation of B(7) substitution by a nucleophile is a common feature. The conversion of **7** to **8** has been demonstrated [25] by treatment of the former with I_2 at 250°C, in contrast to our (tentative) observation of the facile conversion of **3a** to **3b** during work-up under ambient laboratory conditions. In general, however, both substituted and non-substituted species have previously been isolated from the same reaction mixtures, and the two above observations tend to suggest that the *closo*-12-vertex Rh_2SB_9 polyhedron may be formed *prior to* B(7) substitution.

The anionic 1-carba- relative (**12**) [28] of **7** and (tentatively) the 1-selena- analogue (**13**) [29] of **7** have also been reported, although in the latter compound relative positions of vertices were not established; compound(s) **14**, 1-phenyl-1-phospha- relative(s) of compound **6** have also been identified [30]. An isomer of compound **7**, in which the cluster was proposed to have a 2,4,1-Co_2SB_9 architecture, has also been described [32]. We have formed **3** and **4** in a mild reaction at ambient conditions, whereas such compounds have previously been reported largely from reactions at elevated temperature or under 'metal vapour synthesis' conditions. Moreover, we note that the present compounds are, to our knowledge, the first examples of such dirhodathiaboranes where both metal vertices are formally in the +2 oxidation state. {The Rh(2)—C(1)—Rh(3) angles [82.9(3)° in **3a/b** and 81.11(11)° in **4**] and the μ-(CO) stretching frequencies (ca 1863 and 1880 cm^{-1}, respectively) identify the bridging carbonyl ligands as (CO) rather than $(CO)^{2-}$ [33].} Clearly the two unpaired electrons from the two isolated, formally Rh(II) fragments must in these compounds be paired in the cluster *molecular* orbital scheme: the easy observation of NMR spectra is consistent with diamagnetism.

We had anticipated that the reaction which led to the formation of compounds **2–4** might yield the species [8-CO-8-PPh_3-8,7-*nido*-$RhSB_9H_{10}$], an analogue of the 'non-Wadian' compound [8,8-$(PPh_3)_2$-8,7-*nido*-$RhSB_9H_{10}$] [23]. A novel Rh co-ordination environment (involving the phosphine-bound phenyl groups) has been proposed [8] to account for the failure of the latter rhodathiaborane to adopt the predicted [34] *closo* cluster geometry. However, if one PPh_3 ligand in the latter complex is replaced by CO the possibility of such co-ordination is severely limited, and the above (hypothetical) [*nido*-$(CO)(PPh_3)RhSB_9H_{10}$] complex would be required to 'close up'. It appears that such a scenario may be compromised by the need to accommodate an 'additional' (formerly bridging) H atom within the closed cluster, and the intermediate reacts by 'scavenging' a further metal vertex and appropriate ligands, with the ultimate result that the observed *closo*-12-vertex products are formed. In related systems where this 'additional' H atom has, in effect, been removed either by deprotonation [35], or by formal replacement of a $\{BH_2\}$ vertex by $\{B—PR_3\}$ [13], a *closo*-11-vertex {1,2-$RhSB_9$} cluster is obtained as expected. Perhaps surprisingly, we have thus far been unable significantly to alter the yields of compounds **3** and **4** by adjustment of reactant stoichiometry or reaction conditions.

As has already been noted, and Table 3 further suggests, compounds of this kind appear rather susceptible to nucleophilic substitution at that cluster boron atom [B(7)] which is adjacent to both metal vertices. There is considerable current interest [36] in the formation of *B*-substituted heteroboranes for a number of purposes. The ease of formation of compounds such as **3** and **4** leads us to consider them as candidates for further boron atom functionalisation: this work will be the subject of future contributions.

Institut für Anorganische Chemie der Martin-Luther-Universität Halle-Wittenberg, Kurt-Mothes-Str. 2, D-06120 Halle (Saale), Germany

(Received 30 April 1997; accepted 25 June, 1997)

Abstract—$Bu_3SnCH_2PPh_2$, prepared by reaction of Bu_3SnCH_2I with $NaPPh_2$ in liquid ammonia and by reaction of Bu_3SnCl with $LiCH_2PPh_2$/tmeda, reacts with BuLi in hexane as solvent in the presence of a small amount of THF to give $[\{Li(CH_2PPh_2)(thf)\}_\infty]$ (**4**). An X-ray structure analysis revealed that the (*P,P*-diphenylphosphino)methyl ligands are arranged in a μ_3-1:$2\kappa^2C$:$3\kappa P$ fashion. Thus, compound **4** exhibits a polymeric ladder-like structure in which six-membered $Li_2C_2P_2$ rings with a chair conformation and planar four-membered Li_2C_2 rings are arranged alternately. The interplanar angle between the Li_2C_2 rings and the planar Li_2C_2 units belonging to the neighbored six-membered rings amounts to 145.0(4)°. The Li—C bonds within the six-membered rings are shorter than those within the four-membered rings [2.21(1) *vs* 2.39(1) Å]. The distorted tetrahedral donor set of Li is made up by one phosphorus, one oxygen (tetrahydrofuran) and two methylene carbon atoms. © 1997 Elsevier Science Ltd

Keywords: phosphinomethyl lithium; functionalized methyl lithium compounds; tin–lithium transmetallation; crystal structure.

Structures of functionalized methyl lithium compounds of the type $LiCH_2YR_n$ with Lewis-basic heteroatoms Y are strongly dependent (i) on the nature of the heteroatom Y, (ii) on the type of the substituents R (alkyl, aryl) and (iii) on co-ligands which might be present. To date there have been found two common structural types: $[Li_2(CH_2SPh)_2(tmeda)_2]$ (**1a**) [1], $[Li_2(CH_2PMe_2)_2(tmeda)_2]$ (**2a**) [2], $[Li_2(CH_2PPhMe)_2(tmeda)_2]$ (**2b**) [2], $[Li_2(CH_2PPhMe)_2(sparteine)_2]$ (**2c**) [2], and $[Li_2(CH_2PPh_2)_2(tmeda)_2]$ (**2d**) [3] crystallize as dimers with six-membered rings $[Li_2C_2Y_2]$ in which the heteroatom Y is coordinated to lithium (type **A**). $[Li_2(CH_2SMe)_2(tmeda)_2]$ (**1b**) [1], $[Li_2(CH_2SPh)_2(thf)_4]$ (**1c**) [4], and $[Li_2(CH_2NPh_2)_2(thf)_3]$ (**3a**) [5] are dimeric complexes with four-membered rings $[Li_2C_2]$ in which the heteroatom is not coordinated to lithium (type **B**). $[\{Li(CH_2SMe)(thf)\}_\infty]$ (**1d**) [4] is the only example where the six-membered $Li_2C_2Y_2$ and the four-membered Li_2C_2 rings are arranged alternately giving a polymeric ladder-like structure. Furthermore, there is one example of a tetrameric structure, namely $[Li_4(CH_2NC_5H_{10})_4(thf)_2]$ (**3b**) [5].

Comparing **1a** with **1c** and **1b** with **1d**, it can be seen that the structures are strongly influenced by co-ligands. As far as structures of (phosphino)methyl lithium complexes are concerned, there have been reported only those with chelating N,N donors as co-ligands (**2a–d**). Thus, we were interested to synthesize the (*P,P*-diphenylphosphino)methyl lithium tetrahydrofuran adduct and to determine its structure. Of special interest is a comparison of the title compound with the special features observed in the structure of the corresponding amino derivative **3a** having a three

coordinated lithium and an approximately planar environment of nitrogen [5].

RESULTS AND DISCUSSION

$Bu_3SnCH_2PPh_2$(Bu = *n*Bu) was prepared (i) by reaction of Bu_3SnCH_2I with $NaPPh_2$ in liquid ammonia and (ii) by reaction of Bu_3SnCl with $LiCH_2PPh_2$/tmeda, *cf.* Scheme 1.

The identity of $Bu_3SnCH_2PPh_2$ was established by microanalysis, NMR (^1H, ^{13}C, ^{31}P, ^{119}Sn) and mass spectroscopy. $Bu_3SnCH_2PPh_2$ react with BuLi in hexane as solvent in the presence of a small amount (*ca* 4 vol-%) of THF to give $[\{Li(CH_2PPh_2)(thf)\}_\infty]$ (**4**) as pale yellow precipitate [eq. (2)]. Without being added THF, the transmetallation reaction proceeds, too, but $LiCH_2PPh_2$ remains in solution.

Complex **4** is very sensitive to air and moisture. It is highly soluble in THF, sparingly soluble in ether and benzene and unsoluble in aliphatic hydrocarbons. **4** starts to decompose at 150°C and its identity was established by NMR spectroscopy. The methylene carbon and hydrogen atoms resonate at relatively high field [$\delta(^{13}C) = 2.0$ ppm, $\delta(^1H) = -0.39$ ppm] and exhibit typical coupling to phosphorus [$^1J(^{31}P,^{13}C) = 46.2$ Hz, $^2J(^{31}P,^1H) = 3.5$ Hz]. These values are the same as those of the TMEDA adduct **2d** [$\delta(^{13}C) = 2.2$ ppm, $\delta(^1H) = -0.37$ ppm, $^1J(^{31}P,^{13}C) = 46.2$ Hz, $^2J(^{31}P,^1H) = 3.4$ Hz] [3b]. The ^{31}P chemical shift amounts to 8.1 ppm. The corresponding value for **2d** is −1.9 ppm [3b].

The recrystallization of **4** from pentane/THF affords crystals suitable for X-ray investigations. A drawing of the solid state structure of complex **4** giving the atom numbering scheme is shown in Fig. 1. Selected bond lengths and bond angles are listed in Table 1. Compound **4** exhibits a polymeric structure in which six-membered $Li_2C_2P_2$ rings and planar four-membered Li_2C_2 rings are arranged alternately. Thus, the coordination of the organo ligands has to be designated as μ_3-(*P*,*P*-diphenylphosphino)methyl-$1{:}2\kappa^2C{:}3\kappa P$. The midpoints of the four- and six-membered rings are crystallographically imposed inversion centers. $[\{Li(CH_2SMe)(thf)\}_\infty]$ (**1d**) exhibits an analogous structure [4].

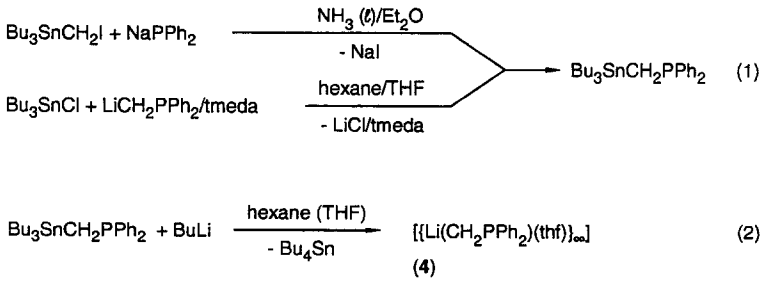
The Li—C distances in the six-membered $Li_2C_2P_2$ rings [Li(1)—C(1) 2.21(1) Å] are a little bit longer than those in the dimeric TMEDA complexes **2** [2.12(1)–2.174(4) Å], see Table 2. The distances between neighbored lithium and phosphorus [Li(1)—P(1′) 2.70(1) Å] correspond to those in the TMEDA adduct **2d** [2.686(5) Å] and in the other complexes **2a–2c** (*cf.* Table 2). In $[\{Li[o,o'\text{-}(Me_2PCH_2)_2C_6H_3]\}_2]$, a *P*-functionalized phenyllithium complex with a five membered Li—C—C—C—P ring, the Li—P distances range from 2.513(4) to 2.668(3)° [6].

As in the complexes **2a–2d,** the P—CH_2 distance [P(1)—C(1) 1.774(7) Å] is substantially shorter than the P—C_{Ph} distances [P(1)—C(2) 1.856(6) Å, P(1)—C(8) 1.861(6) Å] in spite of the smaller covalent radii of sp^2 hybridized carbons in comparison with sp^3 hybridized ones [7]. It seems likely that this in part arises from a stabilizing influence of phosphorus by polarization.

The torsion angles (absolute values) of the six-membered ring [P(1)—C(1)—Li(1)—P(1′) 54.58(5)°, C(1)—Li(1)—P(1′)—C(1′) 63.34(6)°, Li(1)—C(1)—P(1)—Li(1′) 57.63(5)°] indicate some deviations from the 'ideal' chair conformation (60°). A chair conformation was found in the dimeric TMEDA adducts **2a** and **2d,** whereas the phenylmethyl derivatives **2b** and **2c** exhibit six-membered rings with a boat conformation. The 'through space' Li(1)···P(1) distance within the six-membered rings of **4** amounts to 3.10(1) Å indicating a more compact ring structure than those of all other derivatives **2a–d** (3.16–3.45 Å), see Table 2.

The six-membered rings $Li_2C_2P_2$ are connected *via* Li—C bonds that form four-membered rings Li_2C_2. These Li—C bonds [Li(1)—C(1′) 2.39(1) Å] are much longer than those within the $Li_2C_2P_2$ rings [Li(1)—C(1) 2.21(1) Å]. They are also longer than those in other organo lithium compounds with Li_2C_2 rings (average: 2.29 Å for sp^3-hybridized carbon atoms [8]). The torsion angles P(1)—C(1)—Li(1)—C(1′) 177.6(5)° and P(1′)—Li(1)—C(1)—Li(1′) 123.0(6)° reveal that two of the four phosphorus atoms which are neighbored to the four-membered Li_2C_2 rings are lying in the planes of these rings.

The interplanar angle between the planar Li_2C_2 rings and the planar Li_2C_2 units that are parts of the neighboring six-membered rings amounts to 145.0(4)°. Thus, a ladder-like structure is obtained. The comparison with the corresponding angle in **1c** (114.7°) [4] reveals that the 'ladder' of structure **4** is more flat than those of **1c**.



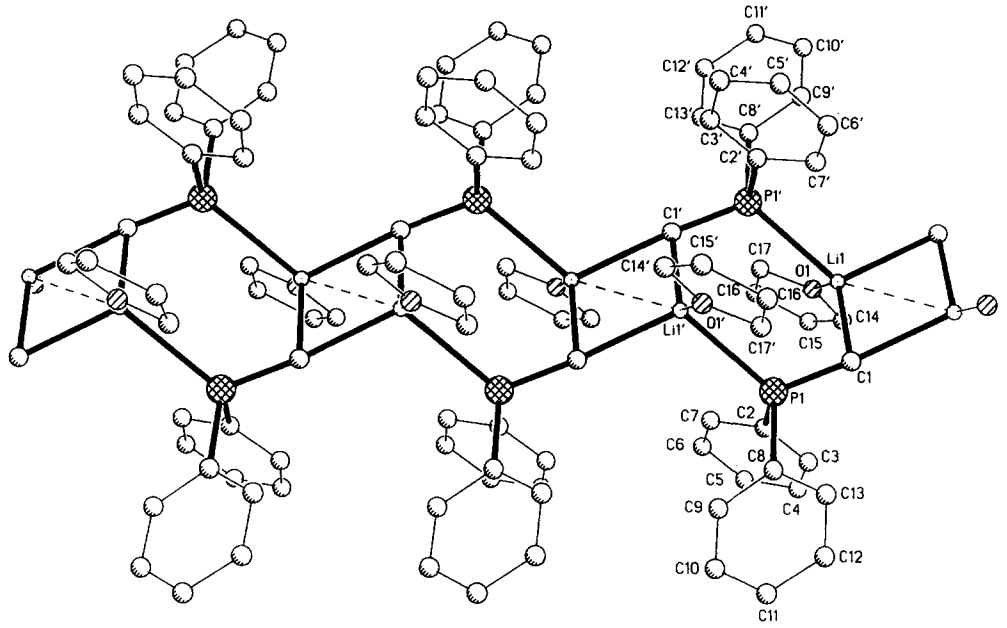


Fig. 1. Drawing of the structure of $[\{Li(CH_2PPh_2)(thf)\}_\infty]$ (**4**). Hydrogen atoms are omitted for clarity.

[b] 'Through space' distance.

The coordination sphere of lithium is completed by tetrahydrofuran. Thus, the coordination of Li is distorted tetrahedrally provided the Li(1)···P(1) contacts are not considered.

In a marked contrast to **4**, the benzyl substituted complex $[Li(CHPhPPh_2 \times (OEt_2)_2]$ adopts a monomeric solid state structure [9] demonstrating the great variability of structures of $LiCH_2PPh_2$ in dependence not only on co-ligands but also on substituents of the methylene carbon.

In the same way as for **4**, (*P,P*-phenylmethylphosphino)methyl lithium, $LiCH_2PPhMe$, could be prepared in 50% yield from the reaction of Bu_3SnCH_2PPhMe with BuLi in *n*-hexane as solvent. To date such transmetallation reactions have been used to prepare other compounds $LiCH_2YR_n$ with nitrogen ($YR_n = NR_2$) [5,10,11,12] oxygen ($YR_n = OR$) [10,13] and sulfur ($YR_n = SR$) [4,10] as Lewis-basic heteroatoms Y but not with phosphorus. The phosphinomethyl lithium compounds are obtained with a high purity free of N,N chelating ligands *via* this transmetallation reaction that seems to be superior to the metallation of methylphosphines with BuLi/tmeda [2,3,14,15] or 'BuLi [16,17,18,19]

where dimetallation might occur [14,18] and the separation from the starting phosphine might be difficult [17].

EXPERIMENTAL

General comments

All reactions and manipulations were carried out under purified argon using standard Schlenk techniques. *n*-Hexane, *n*-pentane and THF-d_8 were dried with $LiAlH_4$. THF and diethyl ether were distilled from sodium benzophenone ketyl. NMR spectra were recorded on Varian Gemini 300 or Varian Unity 500 NMR spectrometers using the protio impurities and the ^{13}C resonances of the deuterated solvents as references for ^1H and ^{13}C NMR spectroscopy, respectively. The chemical shift $\delta(^7Li)$ is reported relative to a solution of LiCl in THF-d_8 (external). Microanalyses (C, H) were obtained from the microanalytical laboratory of the Department of Chemistry.

Synthesis of $Bu_3SnCH_2PPh_2$

(*i*). To $NaPPh_2$ (0.1 mol) in liquid ammonia (300 cm^3) and diethyl ether (50 cm^3) [prepared from PPh_3 (26.2 g, 0.1 mol) and Na (4.6 g, 0.2 mol) [20]], Bu_3SnCH_2I [21] (43.1 g, 0.1 mol) in diethyl ether (50 cm^3) was added dropwise at −50°C. After evaporating ammonia and removing the solvents *in vacuo* 300–400 cm^3 diethyl ether were added. The precipitate (NaI) was filtered off, the solvents were distilled off *in vacuo* and the residue was fractionated (b.p. 165–174°C at 0.01 torr). Yield 21.3 g (45%).

(*ii*). To $LiCH_2PPh_2$/tmeda (0.25 mol) in hexane (250 cm^3) [prepared by metallation of PPh_2Me (50.0 g, 0.25 mol) with BuLi/tmeda (0.25 mol, 1.6 M in hexane) [14, 22]] Bu_3SnCl (80.6 g, 0.25 mol) in THF (200 cm^3) was added dropwise at 0°C. After stirring for 2 h at room temperature, water (250 cm^3) was added at 0°C. The reaction mixture was neutralized with an aqueous solution of NH_4Cl. The separated aqueous layer was washed twice with ether and the combined organic layers were dried (Na_2SO_4). The solvents were distilled off and the residue was fractionated (b.p. 170–180°C at 0.01 torr). Yield 71.0 g (60%). Anal. Calcd: C, 61.42; H, 8.03. Found: C, 62.08; H, 7.90. ^1H NMR (500 MHz, $CDCl_3$): δ 0.8 (t, 6H, $CH_3CH_2CH_2CH_2$), 1.40–1.46 (m, 6H, $CH_3CH_2CH_2CH_2CH_2$), 1.31 (se, 6H, $CH_3CH_2CH_2CH_2$), 0.93 (t, 9H, $CH_3CH_2CH_2CH_2$), 1.49 (s, 2H, CH_2P), 7.52 (m, 4H, *o*-H), 7.28–7.38 (m, 6H, *m*, *p*-H). ^{13}C NMR (125 MHz, $CDCl_3$): δ 9.91 [dd, $^1J(^{119}Sn,C)$ = 325.1 Hz, $^3J(P,C)$ = 4.0 Hz, $CH_3CH_2CH_2CH_2$], 28.9 [d, $^2J(^{119}Sn,C)$ = 20.0 Hz, $CH_3CH_2CH_2CH_2$], 27.2 [d, $^3J(^{119}Sn,C)$ = 58.8 Hz, $CH_3CH_2CH_2CH_2$], 13.6 (s, $CH_3CH_2CH_2CH_2$), 5.2 [dd, $^1J(^{119}Sn,C)$ = 209.4 Hz, $^1J(P,C)$ = 33.8 Hz, CH_2P], 142.5 [dd, $^3J(^{119}Sn,C)$ = 23.8 Hz, $^1J(P,C)$ = 14.9 Hz, *i*-C], 132.2 [d, $^2J(P,C)$ = 19.0 Hz, *o*-C], 128.08 (s, *m*-C), 128.13 (s, *p*-C). ^{31}P NMR (32 MHz, $CDCl_3$): δ −17.6 [s+d, $^2J(^{119}Sn,P)$ = 76.0 Hz]. ^{119}Sn NMR (30 MHz, $CDCl_3$): δ −10.2 [d, $^2J(^{119}Sn, P)$ = 77.2 Hz]. MS (70 eV, EI): *m/e* 434 (12%, $Bu_2SnCH_2PPh_2+H$), 377 (4%, $BuSnCH_2PPh_2+H$), 321 (75%, $SnCH_2PPh_2+2H$), 255 (11%, BuSnPh+H), 197 (49%, SnPh), 177 (20%, BuSn), 121 (100%, CH_2PPh-H), 120 (17%, Sn), 77 (13%, Ph).

Synthesis of $[\{Li(CH_2PPh_2)(thf)\}_\infty]$ (**4**)

To $Bu_3SnCH_2PPh_2$ (20.0 g, 42 mmol) in hexane (100 cm^3) and THF (4 cm^3) a solution of BuLi in hexane (50 mmol, 1.5 M) was added dropwise at 0°C. After stirring for 30 min at room temperature the precipitate was filtered off, washed with hexane (2 × 30 cm^3) and dried *in vacuo*. Yield 10.8 g (92%). ^1H NMR (200 MHz, THF-d_8): δ −0.39 [d, 2H, CH_2; $^2J(P,H)$ = 3.5 Hz], 6.83–6.95 (m, 2H, *p*-H), 6.96–7.04 (m, 4H, *m*-H), 7.41–7.49 (m, 4H, *o*-H). ^{13}C NMR (50 MHz, THF-d_8): δ 2.0 [d, CH_2; $^1J(P,C)$ = 46.2 Hz], 125.0 (s, *p*-C), 127.1 [d, *m*-C, $^3J(P,C)$ = 4.6 Hz], 132.3

[d, *o*-C, ^2J(P,C) = 17.0 Hz], 155.3 [d, *i*-C, ^1J(P,C) = 23.9 Hz]. ^{31}P NMR (81 MHz, THF-d_8): δ 8.13 (s). ^{7}Li NMR (194 MHz, THF-d_8): δ 0.52 (s). (Due to partial hydrolysis a small amount of PPh_2Me was detected in the spectra.)

X-ray structure determination of **4**

A suitable single crystal ($0.24 \times 0.16 \times 0.08$ mm^3) was obtained from pentane/THF solution at -35°C. X-ray measurement was performed on a Stoe STADI 4 diffractometer with Mo-K_α radiation ($\lambda = 0.71073$ Å, graphite monochromator) at 210(2) K. Due to the very weak diffracting power of the small crystal used data were collected only up to $2\theta = 40.0$°. The structure was solved by direct methods with SHELXS86 [23] and refined using full-matrix least-squares procedures on F^2 (SHELXL93) [24]. Non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were geometrically positioned with fixed isotropic displacement parameters being 1.2 times the values of the equivalent isotropic displacement parameters of the carrying carbon atoms. Crystal data, details of data collection, structure solution and refinement are summarized in Table 3. Complete tables of the atomic coordinates, H atom parameters, bond distances, bond angles and anisotropic thermal parameters have been deposited with the Editor as supplementary material.

(Received 7 April 1997; accepted 23 June 1997)

Abstract—The electrochemical study of heteropolyanions $\alpha[P_2W_{18-x}Mo_zV_yO_{62}]^{n-}$ $(x = y+z; n = 6+y)$ have been performed in various acidic media. The analysis of the voltammograms of monosubstituted compounds is described and the reduction sites are identified. These observations are extended to the polysubstituted compounds. The electrochemical results are correlated with an ESR study performed at room temperature: the ESR spectra indicate that the unpaired electron is localised around Mo or V atoms in the monosubstituted compounds. In the other compounds, ESR spectra show that electron delocalization occurs when the paramagnetic Mo^{V} ion is surrounded by other Mo^{VI} ions. The number of atoms of Mo or V substituted and their position are discussed versus their redox properties. © 1997 Elsevier Science Ltd

Keywords: molybdotungstophosphates; vanadotungstophosphates; Dawson structure; cyclic voltammetry; ESR; electrochemistry.

The very high number of papers reporting on the heteropolyanions (HPa) is certainly due, on the one hand, to the interesting properties that these compounds exhibit in heterogeneous and homogeneous catalysis [1–3], but also, on the other hand, to the fact that their synthesis is quite recent [4–9]. Concerning their catalytic activities, the position, the nature and the number of substituted atoms can play a very important part. Indeed, according to compounds used in a reaction, several questions appear: which is the determining step in the reaction and what is the function of substituted atoms of Mo or V in the catalytic properties? What is the importance of the localisation or the delocalisation of the electron in one electron reduced species?

Many works on this last subject have been described [10–15], in particular for the Keggin structure. ESR studies show that the single electron added on the monosubstituted compounds is trapped in the site occupied by the substituted metals Mo or V [12–13]. Moreover, Nadjo and co-workers have studied various aspects of their electrochemical properties [16–21]. From this point of view, we amplify here our knowledge on a new series of molybdo and vanadotungstophosphate $\alpha[P_2W_{18-x}Mo_zV_yO_{62}]^{n-}$ $(x = y+z; n = 6+y)$ with the Dawson structure. The synthesis of this series of compounds with a good purity is recent and only few electrochemical studies are related [4,9]. For clarity, we have represented in Fig. 1 the idealized structure for $\alpha[P_2W_{18}O_{62}]^{6-}$ and its substitution derivatives. The structures have three edges shared MO_6 octahedra in polar position and 12 shared MO_6 octahedra in equatorial position (M = W, Mo or V). The grey MO_6 group contains a central Mo atom substituted whereas the black MO_6 groups enclose a central V atom.

We attempted in this work to correlate the structure of the mixed heteropolyanion compounds with their redox properties. We report in this paper the elec-

trochemical behavior of a series of molybdo-vanadotungstophosphate compounds $\alpha[P_2W_{18-x}Mo_zV_yO_{62}]^{n-}$ $(x = y+z; n = 6+y)$ in acidic solution. The influence of pH is described. An ESR study on the one- and two-electron-reduced compounds is also reported. The number of atoms of Mo or V substituted and their position are discussed versus their redox properties.

EXPERIMENTAL

Solution

Heteropoly-compounds were prepared by R. Contant laboratory [4,5,7]. Pure water was used throughout. It was obtained by de-ionisation and subsequent passing through a Millipore Q water purification set. The chloridic acid was used by dilution of a commercial solution (Prolabo, Titrinorm).

UV-visible

UV-vis spectroscopic measurements were conducted with a Perkin–Elmer spectrophotometer (1 or 2 mm cells were used).

ESR measurements

All the measurements were performed at room temperature using a 2000 Bruker ESR spectrometer equipped with an NMR gaussmeter and a 5340 A Hewlett-Packard frequency counter.

Electrochemical measurements

Cyclic voltammograms were obtained with a homemade potentiostat equipped with EGG Model 175 pilot. Data were recorded on a X-Y Sefram TGM 164. The cell used has a single compartment with a standard three-electrode configuration. The reference electrode consisted of a saturated calomel electrode (SCE) for aqueous media The counter electrode was a platinum wire. The working electrode was a glassy carbon (GC) disc (Carbone Lorraine). For each new electrode, the polishing procedure, using diamond paste (DP Diamond-Struers) of decreasing grain size, was as follows: 15 min polishing with a grain size of 6 μm, then 15 min with 3 μm grain size and finally, 30 min with 1 μm grain size. Before each experiment, the electrode was polished to a mirror finish according to

this procedure. The solutions were degassed with argon U and kept under this gas during the experiments. In HCl 2.2 N, two electrochemical studies have been carried out in the same solutions containing HPa. A first electrochemical analysis is performed on the solution recently prepared. These solutions have been kept out of light for one month. The cyclic voltammetry after one month carried out on these solutions presented a similar pattern which proves a surprising stability of these compounds at pH < 1.

We note that the peak potential E_p may be affected by uncompensated solution resistance. In our experimental conditions (cell, HCl 2.2 N, 20 mV/s), the uncompensated resistance has been estimated by the interrupt method [22(a)]: $R < 30\ \Omega$. In fact, with the peak intensity I_p measured, the iR drop is very weak and it has no influence on the value of peak potential (for instance, when $I_p = 20\ \mu A$ and $R = 30\ \Omega$, the iR drop is less than 1 mV).

Preparation of one-electron reduced species

Experimental conditions given in Table 3 have been carried out, in particular for $\alpha[P_2W_{18-x}Mo_xO_{62}]^{7-}$ with $x = 2$, 3 and 4, in order to obtain an efficient separation from the bielectronic wave to two monoelectronic waves, also allowing the preparation of one-electron-reduced species. For $\alpha[P_2W_{14}Mo_4O_{62}]^{6-}$, the voltammogram in these conditions (Table 3) shows a shoulder for the first monoelectronic wave and the value of imposed potential for electrolysis has been chosen on the voltammogram right at the start of the first reduction.

Electrochemical behaviour of $\alpha[P_2W_{18-x}Mo_xO_{62}]^{6-}$ *with* $x = 2$ *to* 6 *in* HCl 2.2 N

The voltammogram in HCl 2.2 N of $\alpha[P_2W_{16}Mo_2O_{62}]^{6-}$ shows two reduction peaks close to each other at $E_{p_1} \approx 0.230$ V (small shoulder) and $E_p = 0.155$ (Table 2, Fig. 4 presents only the cyclic voltammetry of these HPa described here in HCl 1 N and 6 N for more clarity). These two processes present the pattern of the reversible system when the potential scan rate changes between 10 and 200 mV/s. UV-visible spectroscopy is characterized by two absorption bands at 204 nm and 290 nm (shoulder). The exhaustive electrolysis of the solution at constant potential on the second wave ($E_i = 0.05$ V/SCE) confirms a two-electron reduction (Table 2) corresponding to two closely separated one-electron steps described in cyclic voltammetry: the initial yellow solution leads to a blue solution characteristic of the reduced form.

In the same conditions, the voltammogram of $\alpha[P_2W_{15}Mo_3O_{62}]^{6-}$ shows a reversible two-electron step at $E_{p_1} = 0.220$ V followed by a reversible one-electron step at $E_{p_2} = -0.06$ V (Table 2, the peak ratio for these two processes is equal to 1). The exhaustive electrolysis at constant potential on the second wave ($E_i = -0.100$ V) gives three electrons per mole: the final blue solution is characterised by two new bands in UV-visible spectroscopy at 550 and 740 nm. This coulometry result confirms that overall processes include apparently direct three electron transfer, two electron transfer in the first wave followed by a monoelectronic reduction in the second wave (we note that the exhaustive coulometry carried out in HCl 0.1 N on the first wave gave $n_{app} = 2$, see below in the pH influence section).

Likewise, for $\alpha[P_2W_{14}Mo_4O_{62}]^{6-}$ and $\alpha[P_2W_{13}Mo_5O_{62}]^{6-}$, the voltammograms present the pattern of a reversible system and the electrochemical results are in Table 2. Finally, the voltammogram obtained with $\alpha[P_2W_{12}Mo_6O_{62}]^{6-}$ has three reversible bielectronic steps at $E_{p_1} = 0.520$ V, $E_{p_2} = -0.020$ V and $E_{p_3} = -0.115$ V (for each process, the peak ratio is equal to 1). The exhaustive electrolysis performed on the first wave ($E_i = 0.20$ V) confirm two-electron reduction: the UV-visible spectrum of the final intense blue solution shows two absorption bands at 540 and 720 nm. From the comparison of the peak current of the first reduction versus the others shows that the second and the third waves are also bielectronic.

RESULTS AND DISCUSSION

Electrochemical behaviour

The monosubstituted compounds. Among the Dawson anions described here, the electrochemical behaviour of the monosubstituted molybdo-tungstophosphate is chosen as a representative example. Figure 2 shows a typical voltammogram at 20 mV/s of $\alpha_2[P_2W_{17}MoO_{62}]^{6-}$ in HCl 2.2 N at GC disc electrode. It is characterised by a reduction peak at 0.21 V followed by several reduction processes at negative potentials. The reduction processes are reversible whatever the HCl concentration (2.2 N to 0.1 N). The first reduction peak current I_p is proportional to the square root of the potential scan rate restricted from 0.02 V/s to 0.1 V/s and to the heteropolyanion concentration ($10^{-4}\ M \leqslant C \leqslant 10^{-3}\ M$). Under stationary conditions at a RDE, the diffusion current of the first reduction obeys the Levich law [22(b)] as for a diffusion-controlled process: The current I_D is linearly related to the square root of the rotation speed. UV-visible spectrum before electrolysis is characterised by two absorption bands at 204 nm and 295 nm (shoulder). Exhaustive electrolysis at constant potential $E_i = 0.0$ V confirms a monoelectronic reduction (the initial yellow solution leads to a blue solution after bulk electrolysis). The ESR spectrum of the resulting blue solution recorded at room temperature shows a signal at $g = 1.93$ corresponding to Mo^V ion (see below, Table 3 and Fig. 3). The UV-visible spectrum recorded after electrolysis shows two new bands at 492 nm and 735 nm. The oxidation of this blue

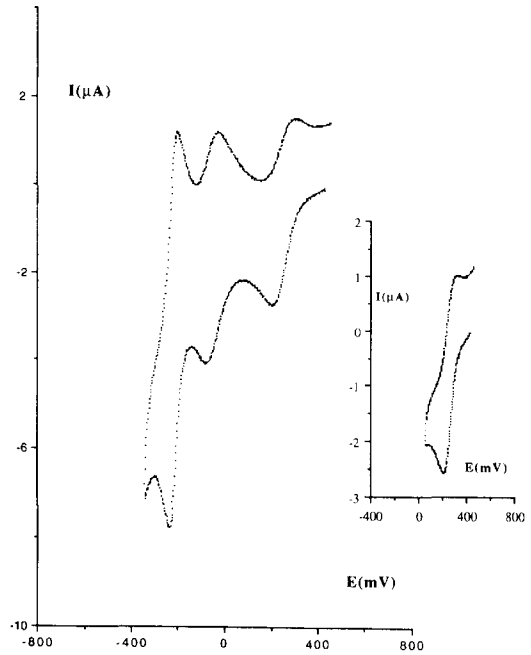

Fig. 2. Cyclic voltammetry of $\alpha_2[P_2W_{17}MoO_{62}]^{6-}$ $C \sim 10^{-3}$ M in HCl 2.2 N at a GC electrode (3 mm), scan rate 20 mV/s, potential in V *vs* SCE.

solution gives the initial species. All these results clearly correspond to a first monoelectronic reduction with a diffusion-controlled process without chemical complication. In comparison with the peak potentials of $\alpha[P_2W_{18}O_{62}]^{6-}$ in the same media, we can ascribe this first reduction peak to the monoelectronic reduction of molybdenum in the Dawson structure: the peak potential of the first reduction wave appears at $E_{p_1} = 0.00$ V for $\alpha[P_2W_{18}O_{62}]^{6-}$ and at $E_{p_1} = 0.21$ V for $\alpha_2[P_2W_{17}MoO_{62}]^{6-}$ (Table 1). The other reduction processes can be assigned to the reduction of the tungsten in the same structure. We deduce the same behaviour for the monovanado and the monomolybdotungstophosphates: the first reduction peak is more positive for these compounds than for $\alpha[P_2W_{18}O_{62}]^{6-}$. Table 1 summarizes the electrochemical results obtained for overall molybdo and vanado tungstophosphates in HCl 2.2 N.

Moreover, for the monosubstituted compounds, we observe that, on one hand, for two isomers α_1 and α_2, the substituted atoms on the belt of the structure (α_1) are more easily reduced than the substituted atoms on the cap of the structure (α_2), and, on the other hand, the first reduction peak potential of mono-

(10^{-3} M > C > 10^{-4} M) in HCl 2.2 N at GC electrode (ϕ = 3 mm)/SCE, v = 20 mV/s; n_{app} = integer value of apparent electron numbers calculated versus the first peak intensity of $\alpha_2[P_2W_{17}MoO_{62}]^{6-}$ (normalized *vs* the HPa concentration).

In bold: reduction ascribed to the Mo atoms; in italics: reduction assigned to the V atoms. Sh = shoulder.

vanadotungstophosphate is more positive than the first peak potential of monomolybdotungstophosphates (Table 1).

The generalization of this analysis for the monosubstituted compounds studied here ($\alpha_2[P_2W_{17}MoO_{62}]^{6-}$, $\alpha_1[P_2W_{17}MoO_{62}]^{6-}$, $\alpha_2[P_2W_{17}VO_{62}]^{7-}$ and $\alpha_2[P_2W_{17}VO_{62}]^{7-}$) shows that:

—For a same position, α_1 or α_2 respectively, the V atom is easier to reduce than Mo atom.

—For a same metal substituted, Mo or V, the metal in equatorial position α_1 is more easily reduced than the metal in polar position α_2.

If we take into account these observations and the location of the peak potential, the voltammogram of $\alpha[P_2W_{15}VMo_2O_{62}]^{7-}$ in the same conditions shows a first monoelectronic peak reduction at 0.48 V corresponding to the V atom followed by a bielectronic peak reduction at 0.145 V assigned to the Mo atoms (see Table 2). For this last compound, all V and Mo atoms are on the cap of the Dawson structure. The comparison of peak potentials emphasizes again that the V atom is easier to reduce than the Mo atom in this structure.

The polysubstituted compounds. According to this statement, the first redox processes of molybdo tungstophosphate described here in HCl should be ascribed to the reduction of molybdenum atoms in the structure. We attempted to extend this analysis to polysubstituted compounds. Table 2 summarizes the electrochemical results of the molybdotungstophosphate $\alpha[P_2W_{18-x}Mo_zV_yO_{62}]^{n-}$ ($x = y+z$; $n = 6+y$) with $z > 1$ in HCl 2.2 N. The electrochemical behaviour of these compounds is described in the Experimental section.

Among this electrochemical characterization, the apparent electron number of the first reduction steps seems consistent with the number of Mo atoms substituted: for $\alpha[P_2W_{16}Mo_2O_{62}]^{6-}$ a bielectronic wave, for $\alpha[P_2W_{15}Mo_3O_{62}]^{6-}$, a bielectronic wave followed by a monoelectronic reduction and finally, three two-electron steps for $\alpha[P_2W_{12}Mo_6O_{62}]^{6-}$. Moreover, the analysis of the redox potential versus $\alpha[P_2W_{18}O_{62}]^{6-}$ appears without ambiguity for the bisubstituted compound: the first peak potential $E_{p_1} = 250$ mV and $E_{p_2} = 155$ mV for $\alpha[P_2W_{16}Mo_2O_{62}]^{6-}$ are more positive than for $\alpha[P_2W_{18}O_{62}]^{6-}$ with $E_{p_1} = 0$ V. Unfortunately, the location of peak potential in comparison with the peak potentials of $\alpha[P_2W_{18}O_{62}]^{6-}$ in the same media doesn't allow us to confirm this hypothesis when the number of Mo substituted is above 3 (see Table 2): the peak potential becomes more negative than for $\alpha[P_2W_{18}O_{62}]^{6-}$.

ESR

In order to determine if the electron in the reduced species is localised on the molybdenum or vanadium site, we have carried out an ESR study at room temperature. The ESR parameters of molybdo tungstophosphate reduced obtained in HCl are listed in Table 3. We have chosen to report in Fig. 3 the representative example ESR spectra of reduced molybdo and vanado tungstophosphate in HCl at room temperature.

Molybdotungstophosphates. For the one-electron reduced monomolybdo-tungsto-phosphate, the ESR spectra carried out in HCl 1 N at room temperature show a typical characteristic of Mo^V ion: a strong central line due to the 75% abundant ^{96}Mo isotope ($I = 0$) while the weak line arises from the hyperfine coupling with the ^{97}Mo and ^{95}Mo isotope ($I = 1/2$). We cannot distinguish on the spectrum these two isotopes alone because, they have almost the same nuclear magnetic moment [12]. The behaviour illustrated by Fig. 3 clearly establishes that an unpaired electron is localised around the Mo atom at room temperature. These results seem to be in fair agreement with our electrochemical analysis (the first mono-

electronic reduction is ascribed to the Mo atom) and so, with the results of Sanchez *et al.* for the mono-substituted polyanions with the Keggin structure [12,14], who concluded that the unpaired electron is trapped on a single Mo atom.

For the other reduced $\alpha[P_2W_{18-x}Mo_xO_{62}]^{7-}$ compounds ($1 < x < 5$, Table 3), the ESR spectra showed the same behaviour with a weak variation of the g_{iso} parameter. In fact, these spectra are characterised by a large strong central line due to the ^{96}Mo isotope without hyperfine coupling. The two-electron-reduced substituted compounds from two to six Mo substituted atoms exhibit no ESR signal as expected.

The broadening of the ESR spectra indicates that electron delocalization occurs when the paramagnetic Mo^{V} ion is surrounded by other Mo^{VI} ions [12,14]. This is due to electron hopping between metal sites. Such behaviour is typical of class II mixed valence compounds [23]. The analysis of the ΔHpp values for the one reduced $\alpha[P_2W_{18-x}Mo_xO_{62}]^{7-}$ ($O < x < 4$) compound substituted in polar corner-shared site shows clearly a linear variation of the line width ΔHpp versus the substitution number of molybdenum atoms. We first note that the ΔHpp value is of 30 G for $\alpha_2[P_2W_{17}MoO_{62}]^{7-}$ which corresponds to a localised electron around the Mo site. Then, we obtained 75 G for $\alpha[P_2W_{16}Mo_2O_{62}]^{7-}$, and 110 G for $\alpha[P_2W_{15}Mo_3O_{62}]^{7-}$. Moreover, the spectra of

$\alpha[P_2W_{15}Mo_3O_{62}]^{9-}$ and $\alpha_2[P_2W_{16}MoO_{62}]^{7-}$ have identical characteristics with a $\Delta Hpp = 30$ G by contrast with $\alpha[P_2W_{15}Mo_3O_{62}]^{7-}$ and $\alpha[P_2W_{15}Mo_3O_{62}]^{9-}$ (see Table 3). So, the increase of the line width versus the substitution number of molybdenum atoms may indicate an intramolecular electron transfer (hopping) at this temperature between the neighbouring Mo atoms: as expected, the one-electron reduced bi- and tri-molybdotungstophosphate are mixed valence compounds. These observations are consistent with the work of Kozik *et al.* [11,24].

For the three-reduced trimolybdotungstophosphate, if we consider the ΔHpp value, we can suggest that the three Mo sites are occupied by the three electrons with the same spin density repartition respectively, in which two electrons are paired and one electron is unpaired. Indeed, the ΔHpp value of 30 G recall the one-electron-reduced monosubstituted molybdotungstophosphate corresponding to an unpaired electron localised around the Mo atom. Investigations of the spectra at low temperature of the reduced $\alpha[P_2W_{15}Mo_3O_{62}]^{9-}$ must be carried out to validate this last interpretation.

So, we obtain for $\alpha[P_2W_{14}Mo_4O_{62}]^{7-}$ a ΔHpp intermediate value. We can suggest in a first approximation, that the added electron is delocalized over the four sites of molybdenum, including one equatorial corner-shared Mo site and three polar corner-shared Mo sites. The fact that the added electron remains favourably in the belt of the Dawson structure could generate a repartition of spin density different between the Mo in a polar site and the Mo in an equatorial site. This leads to the decrease of the ΔHpp parameter versus the ΔHpp of the $[P_2W_{15}Mo_3O_{62}]^{7-}$.

The spectroscopic results for $\alpha[P_2W_{16}Mo_2O_{62}]^{7-}$ and $\alpha[P_2W_{15}Mo_3O_{62}]^{7-}$ have shown that the two added electrons are delocalized over Mo atoms only. Indeed, the electron cannot be delocalized on the neighbouring tungsten atoms because the tungsten orbitals are higher in energy than the molybdenum orbitals [12]. From our spectroscopic results, a hopping of an unpaired electron between Mo^{V} and Mo^{VI} ion can be expected. This phenomenon is characterised by the variation of line width ΔHpp. An electron hopping between two sites can be thermally activated through the vibrations of the molecular compound. The thermal activation energy, however, is quite difficult to measure. It was already stressed that this value of thermal activation energy could be deduced from a careful analysis of the temperature dependence of the ESR line width [12,14]. The work on this interesting point of view is in progress.

Vanadomolybdotungstophosphate. The ESR spectra of $\alpha[P_2W_{15}Mo_2VO_{62}]^{8-}$ in HCl 1 N are given in Fig. 3. The room temperature spectrum shows the expected hyperfine interaction with the $^{51}V^{IV}$ nucleus (99.75%, $I = 7/2$). The g and ΔHpp parameters are listed in Table 3. This behaviour is characteristic of an unpaired electron localised around a vanadium atom. This result seems to be in agreement with the ESR study carried out on $\alpha[P_2W_{18-y}V_yO_{62}]^{(7+y)-}$ $(0 < y < 4)$ by Halmaker *et al.* [25]. But here, it seems that the energy barrier between the occupied orbital by the unpaired electron (around the vanadium site) and the Mo orbitals is high enough and doesn't allow, at room temperature, the delocalization of this single electron on the neighbouring sites of molybdenum. The peak potential analysis of $\alpha[P_2W_{15}Mo_2VO_{62}]^{7-}$, in comparison with the monosubstituted vanado and molybdotungstophosphate, leads to a similar conclusion: the first monoelectronic wave can be assigned to the reduction of the vanadium atom while the second bielectronic wave less positive is ascribed to the reduction of two molybdenum atoms (Table 1). A particular effect must be considered here: the electrochemistry of $\alpha[P_2W_{16}Mo_2O_{62}]^{6-}$ in HCl 2.2 N shows two closely one-electron steps (practically a bielectronic wave) with a shoulder whereas for $\alpha[P_2W_{15}Mo_2VO_{62}]^{7-}$ in the same conditions, the bielectronic wave corresponding to the Mo reduction is broad with a $\Delta E_p = 30$ mV. The comparison of NMR spectra of $\alpha[P_2W_{17}O_{62}]^{10-}$ and $\alpha[P_2W_{17}VO_{62}]^{7-}$ carried out by Kozik *et al.* [24] has shown that the two cap W's adjacent to the V and the two belt W's adjacent to the V in $\alpha[P_2W_{17}VO_{62}]^{7-}$ are perturbed: their lines are missing in the $\alpha[P_2W_{17}VO_{62}]^{7-}$ spectrum. The same trend was encountered in our electrochemical study except that the two cap atoms adjacent are the molybdenum atoms. The substitution of W by V on the top of the structure changes the redox properties of the molybdenum. The location of catholic peak potential of reduction of molybdenum seems less positive for the $\alpha[P_2W_{15}Mo_2VO_{62}]^{7-}$ compound than for the bisubstituted compound $\alpha[P_2W_{16}Mo_2O_{62}]^{6-}$.

Both electrochemical and spectroscopic results show clearly that the first redox processes correspond to the reduction of vanadium and/or of molybdenum in the Dawson structure. These conclusions are consistent with the spectroscopic results already described on similar compounds having Dawson or Keggin structure. Thus, the redox and acidic properties of these compounds in water are largely affected by the nature and the number of the substituted atom.

Influence of pH on the redox properties

As a general rule, the increasing pH modifies the redox properties of the HPa (Heteropolyanions) studied here. For the monosubstituted species α_1, $\alpha_2[P_2W_{17}MoO_{62}]^{6-}$ and α_1, $\alpha_2[P_2W_{17}VO_{62}]^{6-}$, the HCl concentration variation from 0.1 N to 2.2 N leads to the increase of the half-wave potential $E_{1/2}$ (defined by $E_{1/2} = E_p + \Delta E_p/2$). The general pattern of the voltammogram remains unchanged.

The bi- and tri-molybdotungstophosphate. The main electrochemical study in the function of pH has been carried out on $\alpha[P_2W_{16}Mo_2O_{62}]^{6-}$ and $\alpha[P_2W_{15}Mo_3O_{62}]^{6-}$ because all the substituted atoms

are on the cap of the structure allowing a better comparison (see Fig. 1). In this case, we observe a particular phenomenon. The present study is restricted to the first two waves. Figure 4(A) and (B) summarize the evolution of the cyclic voltammetric pattern observed in HPa solution with the hydrochloric concentration varying from 1 N to 6 N. The potential location of these first waves obtained in our experiments are gathered in Table 4.

$\alpha[P_2W_{16}Mo_2O_{62}]^{6-}$. The voltammogram of $\alpha[P_2W_{16}Mo_2O_{62}]^{6-}$ in HCl 0.1 M (not represented here) is characterized by two monoelectronic steps. At this pH value, the first wave is a shoulder of the second wave ($E_{p_1} = 170$ mV; $E_{p_2} = 40$ mV). Controlled-potential coulometry experiments carried out on the second wave gave a blue solution and an n_{app} value of 2. As expected for such diamagnetic compounds, no ESR signal was observed at room temperature. These results confirm two successive monoelectronic steps in this media. Then, with increasing HCl concentration, all the waves are displaced in the positive direction. From 0.1 N to 2.2 N, the second wave moves more quickly than the first wave. At 2.2 N, the first wave becomes a small shoulder. In 4 N hydrochloric acid, the voltammogram shows a reversible two-electron wave. At this HCl concentration, the two first waves are practically merged for a potential sweep rate of 20 mV/s. Now, this new wave is more higher than the monoelectronic wave and the $\Delta E_p = 100$ mV. In gradually more acid concentration, the composite first wave grows and the ΔE_p value decreases. The reduction peak potential becomes less negative. At 6 N HCl, the composite wave is broad with a $\Delta E_p = 70$ mV (Fig. 4(A)). When the HCl concentration is more than 6 N, the voltammogram is characterised by a very weak peak current. For instance, in HCl 7 N and with the same HPa concentration, the peak current decreases to 80% of that in HCl 6 N, but the voltammogram is basically similar. The weak stability of HPa in this strong acid media doesn't allow our study to go further.

$\alpha[P_2W_{16}Mo_3O_{62}]^{6-}$. We observe the same evolution for $\alpha[P_2W_{16}Mo_3O_{62}]^{6-}$. In this case, we obtain already a two-electron wave in HCl 1 N with a $\Delta E_p = 90$ mV

(10^{-3} M > C > 10^{-4} M) in different concentrations of HCl on a GC electrode (ϕ = 3 mm)/SCE, v = 20 mV/s. Sh: shoulder; the peak potentials are given without considering the liquid junction potential. For $\alpha[P_2W_{18}O_{62}]^{6-}$ [18].

at a potential sweep rate of 20 mV/s (Fig. 4(B)): here, the two monoelectronic waves are already merged. Indeed, controlled potential coulometry carried out in these conditions on this wave gave a blue solution and an $n_{app} = 2$. No ESR signal was observed at room temperature on this blue solution. From HCl 1 N to HCl 4.5 N, the first wave grows higher and higher. The wave width characterised by the ΔE_p value decreases. The reduction peak potential becomes less negative. At HCl 4.5 N, this composite wave is broad with ΔE_p = 50 mV at 20 mV/s. At HCl 6 N, the ΔE_p value is equal to 35 mV, showing the characteristics of a bielectronic wave.

In contrast, decreasing the HCl concentration to 0.1 N leads to the beginning of separation into two waves: the voltammogram exhibits a small shoulder. We noted that the peak potential locations are slightly more positive for $\alpha[P_2W_{15}Mo_3O_{62}]^{6-}$ than for $\alpha[P_2W_{16}Mo_2O_{62}]^{6-}$. The main trends upon varying the hydrochloric acid for $\alpha[P_2W_{15}Mo_3O_{62}]^{6-}$ are summarized in Fig. 4(B).

Some general features emerge from the changing of cyclic voltammetric waves of $\alpha[P_2W_{15}Mo_3O_{62}]^{6-}$ and $\alpha[P_2W_{16}Mo_2O_{62}]^{6-}$. It must be emphasized that the electrochemical behaviour is strongly affected by the viscosity of the media. Therefore, the change of viscosity from acidic medium to another modifies the liquid junction potential. The variation of liquid junction affects the location of peak potential. In contrast, the anodic to cathodic peak separation remains constant throughout. In order to determinate this influence on peak potential location, we have calculated, as a first approximation, its value using the Henderson equation [27] for the electrolyte junction HCl/KCl with a saturated calomel electrode (3.5 M KCl). The mobility of H^+, K^+ and Cl^- in water are taken from literature [27]. We have considered here the variation of junction potential ΔE_j when the acid concentration goes from 0.1 N to 6 N. In this case, the value ΔE_j = 25 mV: the junction potential goes from +3 mV to −22 mV. This value shows that (i) increasing acid concentration decreases the junction potential slowly. This weak value of the junction potential obtained in the calculation with the Henderson equation can be explained by the fact that, on the one hand, the same anion Cl^- is included in the two media of the junction, HCl/KCl, and, on the other hand, the K^+ mobility is almost identical to Cl^- mobility. (ii) The working electrode appeared more negative than it really was.

A similar study with $\alpha[P_2W_{18}O_{62}]^{6-}$ in different acidic media showed the same trend [18]. The observed peak potentials in increasing acid media should be more positive than those obtained. So, the variation of the peak potential obtained in our experiments with $\alpha[P_2W_{18-x}Mo_xO_{62}]^{6-}$ seems consistent with the pH variation. For more accurate determinations, complementary experimental work is obviously needed to explain completely the quantitative variation observed. Nevertheless, the shift of some reduction peak in water allows a qualitative approach. Then, we can suggest that the evolution of the voltammetric pattern for this HPa seems to be dominated largely by acid-base properties of the reduced species. If we consider the following discussion is restricted mainly to the mechanism of formation of two electron waves, we can affirm that the bielectronic process of $\alpha[P_2W_{15}Mo_3O_{62}]^{6-}$ appears for weaker HCl concentrations than for $\alpha[P_2W_{16}Mo_2O_{62}]^{6-}$. The main point is that in water solutions the second wave of this HPa shifts to positive potential more quickly than the first wave with the increasing acid concentration (first wave remaining almost unchanged). Among our

experiments, complete merging of the waves is obtained in less acidic medium for $\alpha[P_2W_{15}Mo_3O_{62}]^{6-}$ than for $\alpha[P_2W_{16}Mo_2O_{62}]^{6-}$, which could indicate a more basic two-reduction trisubstituted species. This trend was already encountered in the case of $\alpha[P_2W_{18}O_{62}]^{6-}$ and $PW_{12}O_{40}^{5-}$ for stronger HCl concentrations [18]. Table 4 gives the results already published by Nadjo and co-workers. For the same HCl concentration, the ΔE_p value is smaller for $\alpha[P_2W_{15}Mo_3O_{62}]^{6-}$ than for $\alpha[P_2W_{16}Mo_2O_{62}]^{6-}$ and for $\alpha[P_2W_{18}O_{62}]^{6-}$. From experiments in HCl, it appears that the basicity of the reduced form of HPa follows the sequence $\alpha[P_2W_{15}Mo_3O_{62}]^{6-} > \alpha[P_2W_{16}Mo_2O_{62}]^{6-} > \alpha[P_2W_{18}O_{62}]^{6-}$. From this basicity scale, the molybdenum atom in the structure seems to have an important part. NMR and ESR studies [24–26,28,29] (see previously) on these reduced compounds have shown that the electrons are delocalised on the molybdenum site. If we take into account the spectroscopic results concerning the reduced species, it seems that the basic strength increases with the Mo substitution in the Dawson structure. Concerning the mechanism, these results in water solution can be explained with a qualitative approach, on the basis of the protonation of the reduced species. This statement is analogous to the reduction of an aromatic compound [30]: cascade of electron transfer and protonation sequence. An analogue phenomenon with this HPa in acidic medium can be considered: a reaction mechanism in which the electron transfer is followed by a protonation leading to an apparently two-electron transfer. In our experiments, the merged wave is linked to the pH and to the basicity properties of the reduced forms. In this case, the mechanism proposed is coherent at strong acidic media.

(Received 24 April 1997; accepted 20 June 1997)

Abstract—The title complexes $[Ag_2(dbpp)_2](BF_4)_2$ (**1**) and $[Ag_2(dbpe)(H_2O)_2](BF_4)_2$ (**2**), obtained as unexpected by-products while using $AgBF_4$ to eliminate Cl^- from rhodium complexes, were isolated and characterised by single-crystal X-ray diffraction. **1** was also prepared directly. The Ag atoms are bridged by two (**1**) or one (**2**) diphosphine ligands and have a linear P, P or P, H_2O coordination. According to the $^{31}P\{^1H\}$ spectra, the cation of **1** retains this structure in solution. Weak Ag···F interactions with anions (in **2** 'supported' by OH···F hydrogen bonds) form two additional interaction bridges in **1** or link the Ag atoms in a *catena*-fashion in **2** and complement the Ag^I coordination to a trigonal–bipyramidal arrangement (with one equatorial site void). © 1997 Elsevier Science Ltd

Keywords: crystal structure; phosphines; secondary coordination; silver(I) complex; water coordination.

Diphosphines $R_2P(CH_2)_nPR_2$ (L) have a well-known ability to form relatively stable $M[P(CH_2)_nP]_2M$ ring frameworks which show interesting reactivity and catalytic properties [1]. The silver(I) ion, readily bonding with phosphines and prone for linear coordination, seems particularly suited to form such structures. Indeed, a variety of complexes with the $[Ag_2L_2]^{2+}$ core was prepared from diphosphines with $n = 1$, bis-diphenylphosphinomethane (dppm) and bis-dimethylphosphinomethane (dmpm) [1–6]. In the crystals of the compounds, counterions such as nitrate [1,2], acetate [3], hexafluoro-2,5-pentanedionate [4] and bromide [5] coordinate silver atoms at equatorial sites (sometimes giving rise to cores of higher nuclearity), while a poorer nucleophile PF_6^- only forms weak electrostatic Ag···F interactions [6]. Similar systems with $n > 1$ are studied much less, in spite of the fact that the stability of the $[Ag_2L_2]^{2+}$ ring increases with n, following the trend of the corresponding complexes with diamines [7] and due probably to the increase of nucleophilicity on the phosphorus atoms and the simultaneous decrease of the steric strain in the metallacycle. On the other hand, the stability of chelating coordination of diphosphines increases in the same succession, so that while dppm forms only di- or polynuclear complexes, bis(diphenylphosphino)-ethane (dppe) and -propane (dppp) yield mononuclear ones as well [7]. It is noteworthy that the only two complexes with $n = 2$ (L = dppe and bis(dimethylphosphino)ethane) characterised crystallographically [8], both present a peculiar $[Ag_2L_4]^{2+}$ core with two diphosphines bridging and two others chelating. For $n = 3$ only one X-ray structure, of $Ag_2(dppp)_2(NO_3)_2$, has been reported so far [9], while a series of stable $[Ag_2L_2]^{2+}$ ring cations, obtained by the reaction of $AgClO_4$ with L = dppm, dppe, and dppp in DMSO, has been characterised by NMR spectroscopy [7].

The present study was initiated by an accidental synthesis of a novel silver diphosphine complex $[Ag_2(dbpp)_2](BF_4)_2 \cdot 2CH_2Cl_2$ (**1**, dbpp = $Bu^t_2P(CH_2)_3PBu^t_2$) in the course of our work [10] aimed at the preparation of (diphosphine)rhodium complexes. Silver(I) salts are commonly used to remove halide ions from a transition metal atom, thus creating vacant coordination sites for the introduction of new

ligands; earlier we used this procedure [10] to convert $[Rh_2Cl_2(C_2H_4)_4]$ into $[Rh_2Cl_2(dialkene)_2]$, then to $[Rh(dialkene)_2]^+$, prior to reaction with diphosphines L to form $[RhL(C_7H_8)]BF_4$. complexes. When we used dbpp in the above mentioned sequence of reactions, **1** was isolated, obviously due to the tendency of silver(I) to remain in solution and to carry through in the purification stages of the reaction.

Subsequently we synthesised **1** directly, from $AgBF_4$ and dbpp in a diethylether/dichloromethane solvent. An attempt to prepare a corresponding complex with $Bu^t_2P(CH_2)_2PBu^t_2$ (dbpe) by following the same route yielded instead a complex $[Ag_2(dbpe)(H_2O)_2](BF_4)_2$ (**2**) with a *single* diphosphine bridge. Herein we report the syntheses and structures of **1** and **2**.

RESULTS AND DISCUSSION

The synthesis of **1** proves that a range of complexes may be obtained directly from the treatment of silver (I) tetrafluoroborate with alkyl diphosphines L in the same way as for aryl diphosphines [1,4]. **1** is colourless, as expected for a silver(I) complex containing an alkylphosphine and a BF_4^- counterion, and is unusually light-, air- and moisture-stable. It can be exposed to the atmosphere without deterioration, and produces light- and air-stable solutions in polar solvents, including chloroform and THF. This stability against reduction to silver(0) was also demonstrated by cyclic voltammetry (1.0 V with respect to Ag/Ag^+).

Since the free bis(di-*tert*-butylphosphino)propane itself is both air- and light-sensitive, **1** may be useful in synthesis as a means of introducing this diphosphine into other complexes, *viz.*

$$2[M]\text{-}Cl + [Ag_2L_2]^{2+} \rightarrow 2[ML]^+ + 2AgCl.$$

We tried to transfer the diphosphine to $[MoCp(CO)_3Cl]$ and $[Mn(CO)_5Cl]$ in this way, to form respectively $[MoCp(CO)_2L_2]^+$ and $[Mn(CO)_5L_2]^+$. The attempts were unsuccessful under a variety of temperature and solution conditions, **1** being very robust and inactive. This is another indication of particular stability of a 12-membered $Ag(XCH_2CH_2CH_2X)_2Ag$ metallacycle towards dissociation, observed earlier for diamine (X = N) and dppp (X = P) bridging ligands (see above).

In the crystal structure of **1** (Fig. 1, Table 1) the asymmetric unit comprises half of the bis(diphosphine)disilver cation (located at an inversion centre), a tetrafluoroborate anion and a disordered CH_2Cl_2 molecule. The silver atom has, in the first instance, a linear coordination with two phosphorus atoms. The Ag···Ag distance of 5.260(2) Å is substantially longer than in the analogous complexes with $n = 1$ (3.04–3.20 Å) [1–6] but surprisingly less than in those with $n = 2$ (5.95–6.25 Å) [8], probably because the trimethylene chain in **1** acquires a compact trans-planar conformation [with the torsion angles around the C(1)—C(2) and C(2)—C(3) of 177.6(3) and 177.8(3)°], while no such favourable conformation is possible for an even-membered chain. It is well known that in Ag_2L_2 cores with $n = 1$ the metal–metal distance is relatively constant (indeed it is similar for

different metals, irrespectively of whether any direct metal–metal bonding is present or not, the peculiarity largely responsible for the catalytic properties of such complexes) [1] and anions, whether coordinated or weakly interacting with silver, are situated on the outer side of the dimetallic core. On the contrary, in **1** the F(1) atom of the anion is in a pseudo-bridging position between the silver atoms, with the distances Ag···F(1) 3.218(4) and Ag′···F(1) 3.795(4)Å; the former can be regarded as a weak electrostatic interaction and the latter as a mere intermolecular contact. The Ag—F distances for coordinated BF_4^- are usually much longer than the sum of ionic radii (2.31 Å) [11], reflecting poor nucleophilic properties of this ligand, e.g. 2.82 Å in $(Ph_3P)_3AgBF_4$ [12], although this distance decreases to 2.47–2.49 Å in the presence of π-acceptor η-ligands [13]. A similar contact with PF_6^- anion (Ag···F 2.99 Å) exists in $[Ag_2(dmpm)_2](PF_6)_2$ (**3**) [6]. Nevertheless, this interaction causes a noticeable distortion of the linear coordination of the silver atoms (PAgP angle of 169.5(4)° in **1**, cf. 174.3° in **3**), the latter bending towards the centre of the cation. In $[Ag_2(dppp)_2](NO_3)_2$ (**4**) the nitrato anion has a similar pseudo-bridging function [10] (Ag···O 2.58 and 2.98 Å), reducing the Ag···Ag distance to 4.661 Å and the PAgP angle to 152.2°. The Ag—P bond distances of 2.406(1) Å in **1** exceed appreciably those in **3** [2.384(3) Å] wherein the silver coordination is the closest to purely linear but the substituents at the phosphorus atoms are less bulky. In other silver diphosphine complexes the Ag—P distances range from 2.41 to 2.46 Å.

The $^{31}P\{^1H\}$ NMR spectrum indicates that the cation of **1** retains its structure in solution. the ^{107}Ag–^{31}P coupling constant of 467 Hz is typical for two-coordinate silver bonded to phosphorus [1] and close to the estimated value of 452 Hz, based solely on *s*-orbital contributions to the coupling [14]. The data also agrees with that for silver monophosphine complexes [15], in which the Ag—P coupling constant tends to increase with the decrease of the Ag—P distance and with the increase of both the P—Ag—P angle and the nucleophilicity of the 'coordinating cation'. However, the lack of complementary ^{31}P NMR and crystallographic data for disilver-bis(diphosphine) ring systems makes any comparisons qualitative rather than quantitative.

The formation of **2** was the result of moisture contamination from an unknown source, probably due to an adventitious hydration of the $AgBF_4$ salt used, although a commercial sample was opened and handed in a dry-box, and Schlenk tube techniques were used throughout the synthesis and crystallisation. Complex **2** could not be synthesised intentionally by introducing controlled amounts of water into the $AgBF_4$/dbpe reaction, although many attempts were made.

The crystal structure of **2** contains $[(H_2O)Ag(dbpe)Ag(OH_2)]^{2+}$ cations with a crystallographic C_i symmetry and a trans-planar conformation of the dbpe bridge (Fig. 2, Table 2). Similar bridging function of dppe in disilver complexes is common [7,16], but to the best of our knowledge, **2** is the first complex containing a di-coordinated silver(I) atom with both phosphorus and oxygen ligands bonded simultaneously. The Ag—P distance in **2** is by 0.06 Å shorter than in **1**, reflecting the lower *trans*-influence of the aqua-ligand. The distorted linear coordination of the silver atoms within the cation is completed to a trigonal–bipyramidal arrangement (with one equatorial site vacant) by secondary interactions with two fluorine atoms of different tetrafluoroborate anions, related *via* a crystallographic glide plane *n*. Both anions are simultaneously engaged (by other fluorine atoms) in hydrogen bonds with the aqua-ligand. Such 'supported' secondary $[BF_4\cdots M]$ interactions have been observed earlier in Cu^{II} complexes [17], but not in linear Ag^I ones.

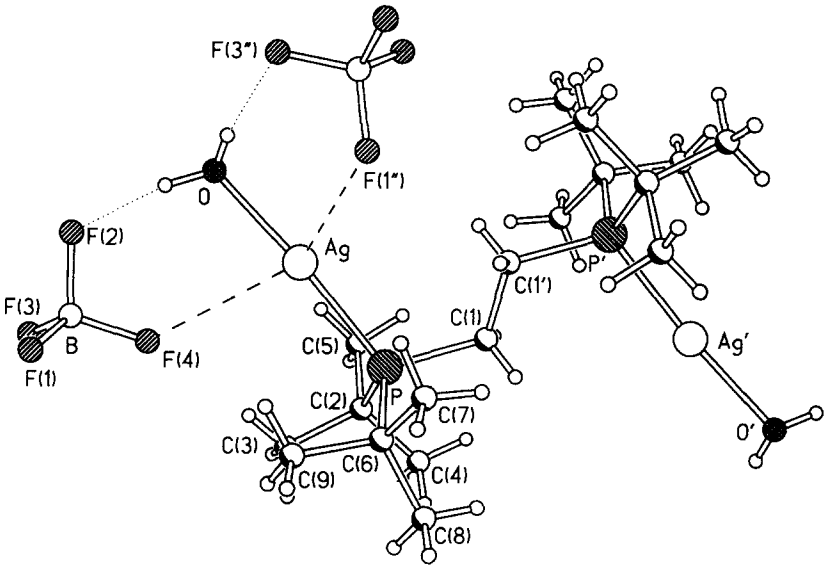

Fig. 2. X-ray molecular structure of **2**, showing the additional coordination of one silver atom, supported by hydrogen bonds. Primed atoms are symmetrically related via the inversion centre, double-primed *via* the *n* glide plane.

EXPERIMENTAL

Silver(I) tetrafluoroborate was purchased from Aldrich Chemicals and used without further purification. The diphosphines were synthesised and purified by published methods [18]. Solvents were purified by standard procedures, stored under nitrogen and used under a nitrogen atmosphere. ^1H (400 MHz), $^{31}P\{^1H\}$ (161 MHz) and $^{13}C\{^1H\}$ (100 MHz) NMR spectra were recorded using a Varian 400 spectrometer, spectra being obtained in $CDCl_3$ solution. Chemical shifts are given relative to [$SiMe_4$] (external reference for ^1H and ^{13}C, measurements) and 85% aqueous H_3PO_4 (external reference for ^{31}P measurements). Carbon, hydrogen and nitrogen analyses were performed using a CE 440 elemental analyser. Cyclic voltammetry was undertaken in cyanomethane and dichloromethane solutions (ca 10^{-3} mol dm^{-3}) using a Bioanalytical System (type CV-1B) potential wave generator with a Ag/Ag^+ couple as a reference electrode and tetrabutylammonium tetrafluoroborate as the supporting electrolyte. Mass spectra were recorded using a VG analytical 707E spectrometer. Fast atom bombardment using xenon was used on the complexes in a nitrobenzylalcohol matrix.

Isolation of $[Ag_2\{Bu^t_2P(CH_2)_3PBu^t_2\}_2](BF_4)_2 \cdot 2CH_2Cl_2$, **1**

$[Rh(C_2H_4)_2Cl]_2$ (0.7 g, 1.78 mmol) was stirred in suspension in CH_2Cl_2 (30 cm^3) and cooled in an ice-bath. A solution of norbornadiene (0.79 g, 8.6 mmol) in CH_2Cl_2 (15 cm^3) was added to the slurry, causing the mixture to turn deep red–brown and evolve ethene. After 30 min, addition of excess $AgBF_4$ (1.00 g, 5.14 mmol) produced a colourless solid (AgCl) suspended in a deep red solution of $[Rh(C_7H_8)_2](BF_4)$. After a further 45 min stirring at room temperature, the solution was filtered and dbpp (0.43 g, 1.28 mmol) in CH_2Cl_2 (6 cm^3) added slowly over 10 min. An immediate colour change from red to orange was accompanied by precipitation of [Rh(dbpp)(C_7H_8)](BF_4), which was recrystallised from a THF/pentane mixture. Found: C, 50.51; H, 8.24. $C_{26}H_{50}BF_4P_2Rh$ requires C, 50.83; H, 8.20%. M.s. (FAB+ve ion): m/z 527.4 (M^+, 12.7%). Full spectroscopic characterisation will be reported elsewhere.

The mother liquor, on reduction to small volume and cooling to −20°, yielded a small number of colourless crystals of **1**, suitable for X-ray crystallography.

Isolation of $[Ag_2\{Bu^t_2P(CH_2)_2PBu^t_2\}(H_2O)_2](BF_4)_2$, **2**

The method described above was used to synthesise $[Rh\{Bu^t_2P(CH_2)_2PBu^t_2\}(C_7H_8)](BF_4)$ (to be reported elsewhere), except that dbpe (0.41 g, 1.28 mmol) was used in place of dbpp. The mother liquor, following the removal of the precipitated rhodium complex, when reduced in volume and cooled to −20°, yielded colourless, light-sensitive crystals of **2**, suitable for an X-ray crystallography, but insufficient in quantity for spectroscopic and other studies. Subsequent attempts to synthesise the same complex from $AgBF_4$ and the diphosphine failed. The ^{31}P NMR spectra of reaction solutions indicated the presence of several products in solution, none of which could be assigned with confidence.

Direct synthesis of **1**

Dbpp (0.42 g, 1.27 mmol) was dissolved in diethyl-ether (4 cm^3) and the solution added by cannular to a stirred suspension of $AgBF_4$ (0.25 g, 1.27 mmol) in dichloromethane (200 cm^3). The mixture was then stirred in the dark for 2 h. At the end of this period, the beige silver salt had reacted and a solution formed. The solvent volume was reduced *in vacuo* to *ca* 50 cm^3 the solution filtered, and the volume further reduced to *ca* 15 cm^3. Slow addition of hexane caused the precipitation of colourless crystals of **1**, which were removed by filtration. Cooling the filtrate to −15°C produced a second crop of crystals, shown to be identical to the first crop by spectroscopic methods. Yield: 0.50 g (75%). Found: C, 39.27; H, 7.33. $C_{40}H_{88}Ag_2B_2Cl_4F_8P_4$ requires C, 39.30; H, 7.26%. NMR ($CDCl_3$): ^1H; δ 5.30 (s), 1.88 (br m, 4H, PCH_2), 1.27 (t, 36H, $J_{P\text{-}H}$ 7.2 Hz), 1.18 (s, 2H, PCH_2CH_2): $^{13}C\{^1H\}$; δ 53.43 (s, CH_2Cl_2), 29.83 (s, PC-CH_3), 31.41 (m, P*C*-CH_3), 33.84 (m, PCH_2), 22.05 (m, PCH_2CH_2); ^{31}P δ 57.83 ppm [d, $J(^{107}Ag\text{-}P)$ 467 Hz, $J(^{109}Ag\text{-}P)$ 539 Hz]. FAB Mass Spectrum (nitrobenzyl alcohol matrix): −ve ion *m/z* [100%, BF_4^-]; +ve ion *m/z* 821.4 [3%, $(M—Bu^t)^+$], 439.3 [100%, $^{107}Ag(dbpe)^+$], 565.2 [20%, $(^{107}Ag_2C_{16}H_{36}P_4)^+$], 57.0 [52%, $(C_4H_9)^+$].

Crystal structure determination

X-ray single crystal diffraction experiment for **1** was performed on a Rigaku AFC6S 4-circle diffractometer (ω scan mode with Lehmann–Larsen profile analysis), for **2** on a Siemens SMART 3-circle diffractometer with a CCD area detector, both at $T = 150$ K (Cryostream open-flow N_2 gas cooling device), using graphite-monochromated Mo–K_α radiation, $\bar{\lambda} = 0.71073$ Å. The structures were solved by direct methods and refined by full-matrix least squares (non-H atoms with anisotropic displacement parameters, H atoms in **1**

(Received 7 May 1997; accepted 9 June 1997)

Abstract—The crystal structures of the bis(terpyridyl)-metal(II) complexes $[Co(L^1)_2][PF_6]_2 \cdot 2.5MeCN$, $[Co(L^2)_2][PF_6]_2 \cdot 3dmf$, $[Cu(L^2)_2][PF_6]_2 \cdot MeCN$, $[Zn(L^1)_2][PF_6]_2 \cdot 2.5MeCN$, and $[Zn(L^2)_2][NO_3]_2 \cdot 3dmf$ are reported, where L^1 is 4′-(3,4-dihydroxyphenyl)-2,2′:6′,2″-terpyridine and L^2 is 4′-(3,4-dimethoxyphenyl)-2,2′:6′,2″-terpyridine. The two Co^{II} complexes and the Cu^{II} complex all show elongation along one axis in addition to the normal tetragonal compression imposed by terpyridyl chelates; this is ascribed to the Jahn–Teller effect, in the case of the Co^{II} complexes arising from the presence of a significant proportion of the low-spin state being present at the temperature used for the structural determination (173 K). The Zn^{II} complexes are the first structurally characterised bis(terpyridyl)-Zn^{II} compounds. These do not show the elongation along one axis that was apparent in the Co^{II} and Cu^{II} structures. The relatively small bite angles for the terpyridyl chelates (ca. 150°, compared to ca. 160° for the first three complexes), results in a greater distortion away from regular octahedral geometry, reflecting the absence of stereoelectronic requirements for Zn^{II} compared to Co^{II} and Co^{II}. © 1997 Elsevier Science Ltd

Keywords: terpyridyl; complexes; crystal structures.

We describe in this paper a series of crystal structures of complexes of Co^{II}, Cu^{II} and Zn^{II} with the two substituted terpyridine ligands 4′-(3,4-dihydroxyphenyl)-2,2′:6′,2″-terpyridine (L^1) and 4′-(3,4-dimethoxyphenyl)-2,2′:6′,2″-terpyridine (L^2). These complexes are: $[Co(L^1)_2][PF_6]_2 \cdot 2.5MeCN$; $[Co(L^2)_2][PF_6]_2 \cdot 3dmf$; $[Cu(L^2)_2][PF_6]_2 \cdot MeCN$; $[Zn(L^1)_2][PF_6]_2 \cdot 2.5MeCN$; and $[Zn(L^2)_2][NO_3]_2 \cdot 3dmf$. We have previously prepared ruthenium(II) complexes of L^1 and L^2, and used L^1 as a bridging ligand for the preparation of polynuclear complexes in which the terpyridyl site was coordinated to a ruthenium(II) core and the pendant deprotonated catechol site was coordinated to a variety of other metals [1]. We were interested to see if complexes of these ligands with first-row transition metals would also form oligonuclear species in the same way, and have found generally that simple mononuclear complexes with an $\{M(terpy)_2\}^{+}$-type core result.

Despite the large number of crystal structures of first-row transition metal complexes containing terpyridine ligands, the majority of these are of the type $[M(terpy)L_n]^{m+}$ with one terpyridine ligand and usually two or three monodentate ligands completing the coordination sphere. Crystal structures of homoleptic complexes of terpyridine and its substituted derivatives are relatively rare for first-row metals, especially considering the vast number of such ligands that are known, and a search (January 1997) of the Cambridge Structural Database found just 17 examples, all of which are confined to the later elements (Cr–Cu). Complexes of Co^{II} are the commonest (six examples) [2] because of the interest in the spin-crossover properties of $[Co(terpy)_2]^{2+}$ derivatives, which are sensitive to small changes in the crystalline lattice such as type of counter-ion and degree of solvation. There are also crystal structures of homoleptic bis-terpyridyl com-

[b] Sample for analysis recrystallised from MeCN/ether.

plexes of Co^{III} (one example) [3], Cr^{III} (one example) [4], Mn^{II} (one example) [5], Fe^{II} (two examples) [6], Ni^{II} (three examples) [7], and Cu^{II} (three examples) [8]. Surprisingly, there are no crystal structures of $[Zn(terpy)_2]^{2+}$ or its substituted derivatives, and the two Zn^{II} structures reported here are therefore the first of their type.

EXPERIMENTAL

Ligands L^1 and L^2 were prepared as described previously [1]. Complexes were prepared by adding a solution of the appropriate ligand (0.4 mmol) in H_2O/MeOH (1 : 2, 30 cm^3) to a solution of the appropriate metal salt (sulphate, chloride or nitrate) (0.2 mmol) in water (5 cm^3). After stirring for 1 h, excess aqueous KPF_6 was added to precipitate the complexes which were filtered off and dried *in vacuo*. Recrystallisation by diffusion of ether vapour into concentrated MeCN or dmf solutions of the complexes afforded X-ray quality crystals in all cases except $[Zn(L^2)_2][PF_6]_2$, which was therefore converted to its nitrate salt by anion metathesis; recrystallisation of $[Zn(L^2)_2][NO_3]_2$ from dmf/ether then afforded X-ray quality crystals. All complexes gave elemental analyses and fast-atom bombardment mass spectra in accord with their formulations (Table 1).

Crystals for X-ray analysis were mounted on glass fibres on a Siemens SMART diffractometer. A detailed description of the methods used for establishing unit cell parameters, and collecting, integrating and merging the data, has been published elsewhere [9]. Details of crystal parameters, data collection and refinement are summarised in Table 2. The structures were solved by conventional direct methods and refined by the full-matrix least-squares method on all F^2 data with the SHELXTL 5.03 package using a Silicon Graphics Indy computer. All non-hydrogen atoms were refined anisotropically; hydrogen atoms were included in calculated positions and refined with isotropic thermal parameters.

In $[Co(L^1)_2][PF_6]_2 \cdot 2.5MeCN$ the half molecule of MeCN is disordered over an inversion centre; the other two MeCN molecules are well defined. One of the peripheral hydroxyl groups is disordered between the C^3 and C^5 sites of the phenyl ring, appearing as O(47) [attached to C(43); 0.78 site occupancy] and O(49) [attached to C(45); 0.22 site occupancy]. Only the major component is shown in Fig. 1. $[Zn(L^1)_2][PF_6]_2 \cdot 2.5MeCN$ has very similar unit cell

[a] Structure was refined on F_o^2 using all data; the value of R_1 is given for comparison with refinements based on F_o with a threshold of $F \geq 4\sigma(F)$.
[b] $wR_2 = [\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma w(F_o^2)^2]^{1/2}$ where $w^{-1} = [\sigma^2(F_o^2) + (aP)^2 + bP]$ and $P = [\max(F_o^2, 0) + 2F_c^2]/3$.

parameters, the same disordered half-solvent molecule over an inversion centre, and the same disorder in the position of one of the hydroxyl groups between the C^3 and C^5 positions of the phenyl ring (site occupancies 0.76 and 0.24).

In $[Co(L^2)_2][PF_6]_2 \cdot 3dmf$ the complex cation, one of the anions, and all three solvent molecules are well ordered; the other hexafluorophosphate ion is disordered over two orientations such that the P(1), F(13) and F(15) are in fixed positions but the other four F atoms have two possible sites. The two components were successfully separated. The structure determinations of $[Cu(L^2)_2][PF_6]_2 \cdot MeCN$ and $[Zn(L^2)_2](NO_3)_2 \cdot 3dmf$ presented no problems of disorder.

RESULTS AND DISCUSSION

Cobalt complexes

The structure of the cation of $[Co(L^1)_2][PF_6]_2 \cdot 2.5MeCN$ is in Fig. 1; that of $[Co(L^2)_2][PF_6]_2 \cdot 3dmf$ is similar and not shown (the numbering scheme for the pyridyl rings is the same). Selected bond lengths and angles are in Table 3. The two structures have several features which are of significance. In both cases the Co—N bond lengths to the central rings of the terpyridine ligands [N(21) and N(61), 1.87–1.94 Å] are the shortest, which is a common steric consequence of the inability of the terminal pyridyl rings to bend around enough to achieve ideal octahedral coordination geometry at the metal centre [10]. Apart from this, the Co—N bond lengths to the terminal two pyridyl rings of one ligand [N(11) and N(31), ca. 2.15 Å] are markedly longer than the Co—N distances to the terminal pyridyl rings of the other ligand [N(51) and N(71), 1.99–2.05 Å]. Thus the N(11)—Co—N(31) axis is elongated with respect to the N(51)—Co—N(71) axis in each case, which is reflected in the separations between the *trans* pairs of pyridine ligands: in $[Co(L^2)_2][PF_6]_2$ for example, the N(11)···N(31) separation is 4.22 Å whereas the N(51)···N(71) separation is 3.94 Å, and the N(21)···N(61) separation—which would be expected to be the shortest—is 3.79 Å.

The geometry of $[Co(terpy)_2]^{2+}$ and its derivatives is sensitive to the spin-state of the Co^{II} centre, which is in turn sensitive to subtle lattice forces and therefore depends on the nature of the counter-ion and presence or absence of lattice solvent molecules. There is a clear relationship between the spin-state of the complex and the Co—N bond lengths [2]. Principally, the central Co—N bonds lengthen from ca. 1.9 Å to ca. 2.1 Å as the complex changes from predominantly low-spin to predominantly high-spin. The change in the terminal Co—N bond distances is less marked but still in the same sense, with the bonds lengthening by about 0.07 Å between predominantly low-spin and predominantly high-spin complexes [2]. In both $[Co(L^1)_2][PF_6]_2 \cdot 2.5MeCN$ and $[Co(L^2)_2][PF_6]_2 \cdot 3dmf$ therefore the values of the central Co—N bond lengths (values 1.904 and 1.942 Å for the former; 1.922 and 1.866 Å

N(31)—Co—N(11)	156.41(11)	N(11)—Co(1)—N(31)	157.66(10)

for the latter) are indicative of predominantly low-spin behaviour; the shortest previously-reported Co—N (central) distance was 1.88 Å in $[Co(terpy)_2]Br_2 \cdot [FS]3H_2O$, whose magnetic moment (2.9 BM) indicates a majority of low-spin character.

In a low-spin d^7 configuration and octahedral geometry, Jahn–Teller distortion would be expected, which could manifest itself either as a lengthening along the z-axis [as is common in Cu^{II}], or a lengthening along the x and y axes (i.e. relative compression along the z-axis). Since the steric limitations of terpyridyl chelates mean that all bis-terpyridyl complexes are necessarily compressed along one axis, then additional Jahn–Teller distortion is unnecessary. If we call the shortest axis (containing the two central pyridyl donors) the z-axis, their greater proximity to the metal ion means that the $d(z^2)$ orbital is necessarily higher in energy than $d(x^2-y^2)$, which would lift the orbital degeneracy of the low-spin d^7 configuration; thus the Jahn–Teller distortion matches the distortion imposed naturally by the ligand. This appears to be the situation in all bis(terpyridyl)-Co^{II} complexes structurally characterised so far, with the two Co—N(terminal) axes being more or less equivalent, resulting in a roughly square xy plane. These two new complexes, however, have a marked tetragonal elongation along one Co—N(terminal) axis in addition to the compression along the Co—N(central) axis, as mentioned above. If this elongation is arising from a Jahn–Teller effect then it is the first example of this type of structural distortion observed for bis(terpyridyl)-Co^{II} complexes, and may reflect the fact that the Co^{II} ions in both structures are predominantly low-spin [cf. the Co—N(central) bond lengths] so that Jahn–Teller effects are particularly apparent. This may arise from the low temperature used for the structural determinations (173 K). Unfortunately both sets of crystals lose solvent rapidly when removed from the mother liquor, which will result in a major change in the crystalline environment and will therefore perturb the spin state of the Co^{II} ions. It is not therefore possible to relate magnetic susceptibility measurements to the crystal structures.

The pendant substituted phenyl rings are in each case twisted away from coplanarity with the adjacent terpyridyl unit. In biphenyl-type groups, the competition between electronic effects (greater delocalisation can occur in a coplanar configuration) and steric effects (a dihedral twist between the two rings minimises steric interference between the H^2 and $H^{2'}$ protons of a biphenyl unit) typically results in a dihedral twist of 30–40° in the gas phase, although in the solid state this is subject to influence from crystal packing effects [11]. In $[Co(L^1)_2][PF_6]_2 \cdot 2.5MeCN$ the dihedral angles are 23.6° and 26.9°, involving phenyl rings C(41)—C(46) and C(81)—C(86) respectively, which is not much smaller than the typical values. In $[Co(L^2)_2][PF_6]_2 \cdot 3dmf$, however, the twists are much smaller at 8.1° and 6.4° respectively.

The peripheral hydroxyl groups of In $[Co(L^1)_2][PF_6]_2 \cdot 2.5MeCN$ are involved in hydrogen-bonding interactions with lattice solvent molecules and counter-ions. The OH group of O(47) is involved in a O—H···N hydrogen-bond to N(123) of a lattice MeCN, with the non-bonded O···N separation being 2.68 Å; likewise the O—H···F interaction involving O(48) and F(24) has a non-bonded O···F separation of 2.88 Å, and the O—H···N interaction involving O(87) and N(231) (of acetonitrile) has a non-bonded O···F separation of 2.67 Å. All of these separations are consistent with reasonably strong hydrogen-bonds [12]. In $[Co(L^2)_2][PF_6]_2 \cdot 3dmf$ in contrast there are no such strong hydrogen-bonds in the lattice.

Copper complex

The structure of the complex cation of $[Cu(L^2)_2][PF_6]_2 \cdot MeCN$ is shown in Fig. 2; selected bond lengths and angles are in Table 4. As we would expect, the Cu—N bonds to the central pyridyl ring of each ligand [N(21) and N(61); Cu—N distances 1.936 and 1.996 Å respectively] are the shortest for the steric reasons described above. It is comparison of the other two axes which is of more interest, and it is clear from Table 4 that the terminal rings of one ligand

N(71)—Cu—N(11)	88.70(8)		
N(51)—Cu—N(11)	102.38(8)		
N(31)—Cu—N(11)	158.58(8)		

[N(51) and N(71); Cu—N distances 2.334 and 2.261 Å respectively] are much further from the metal than are those of the other ligand [N(11) and N(31); Cu—N distances 2.102 and 2.085 Å respectively]. This is reflected in a smaller bite angle for the more remote ligand (151.9° instead of 158.6°). There is therefore a very clear Jahn–Teller elongation along the N(51)—Cu—N(71) axis in addition to the compression along the N(2)—Cu—N(61) axis. This is entirely typical of six-coordinate Cu^{II} complexes and is similar to the distortions observed in the cobalt(II) complexes above. In these respects this structure is similar to those of other bis(terpyridyl)-Cu^{II} complexes [8]. The dihedral angles between the central pyridyl and pendant phenyl rings are 8.1° and 20.2° [at pyridyl rings N(21)–C(26) and N(61)–C(66) respectively].

Zinc complexes

As far as we know there are—surprisingly—no published crystal structures of bis(terpyridyl)-zinc(II) complexes; although $[Zn(terpy)_2]^{2+}$ complexes have been prepared, the crystal structures are confined to 1 : 1 complexes such as $[Zn(terpy)Cl_2]$. The structural parameters of the complex cations of $[Zn(L^1)_2][PF_6]_2 \cdot 2.5MeCN$ and $[Zn(L^2)_2](NO_3)_2 \cdot 3dmf$ are summarised in Table 5. Pictures are not given due to the similarity of these structures to those of the Co^{II} and Cu^{II} complexes already depicted; the numbering scheme is the same as that used for the other structures, with N(21) and N(61) [or N(121) and N(161)] being the central pyridyl rings of each ligand. There are several points to notice. Firstly, the Zn—pyridyl dis-

tances are on average longer than the Co—pyridyl distances, and are also rather longer than those four Cu—N distances which do not suffer from additional Jahn–Teller elongation. This is a natural consequence of the increased occupancy of the antibonding $d(z^2)$ and $d(x^2-y^2)$ orbitals. Secondly, we see again the usual compression of the two Zn—N(central) bonds (2.074 and 2.105 Å) compared to the four Zn—N(terminal) bonds (2.16–2.23 Å). Thirdly, there is no obvious elongation along one of the Zn—N(terminal) axes. The average Zn—N distances in these directions (Table 5) differ by less than two standard deviations and are therefore equivalent within the limits of accuracy of the structure determination. This is in marked contrast to the two Co^{II} structures and the Cu^{II} structure, which all show evidence for elongation along one axis due to the Jahn–Teller effect and/or hydrogen-bonding interactions within the lattice. Fourthly, the absence of any stereoelectronic requirements for regular octahedral or tetragonal geometry is reflected in the bite angles of the coordinated terpyridyl fragments, which are all ca. 150° in the Zn^{II} complexes compared to 156–162° for the Co^{II} and Cu^{II} complexes [with the single exception of the ligand in the Cu^{II} complex which has an unusually low bite angle due to the Jahn–Teller elongation].

In $[Zn(L^1)_2][PF_6]_2 \cdot 2.5MeCN$ the dihedral angles between the pendant phenyl rings and the pyridyl rings to which they are attached are 27.6° and 25.3°; in $[Zn(L^2)_2](NO_3)_2 \cdot 3dmf$ these values are 2.5° and 19.1° respectively. This is the same pattern that was observed for the Co^{II} complexes, with the phenyl rings of L^1 more twisted away from the terpyridyl group than the phenyl rings of L^2. It is not possible to separate the different contributions to this that may arise from intermolecular (crystal packing, hydrogen-bonding) and intramolecular (electronic delocalisation) effects.

As with its isostructural Co^{II} analogue, $[Zn(L^1)_2][PF_6]_2 \cdot 2.5MeCN$ has hydrogen-bonding interactions in the lattice between the hydroxyl groups as donors, and solvent molecules or anions as acceptors. The most significant of these are O–H···N interactions between O(47)/N(132) (non-bonded O···N distance 2.71 Å) and between O(87)/N(113) (non-bonded O···N distance 2.80 Å).

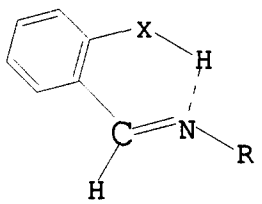
(Received 5 March 1997; accepted 29 May 1997)

Abstract—Transition metal complexes (M = Cu, Ni, Co, Pd, Zn and Cd) containing azomethinic ligands have been synthesized by conventional chemical methods and by direct electrochemical dissolution of the sacrificial metal anode. The resulting complexes were characterized by elemental analysis, IR and EPR-spectra and magnetochemical data. The influence of the type of metal, the peculiarities of the ligand structure and the methods of synthesis of metal chelates on their physico-chemical properties and structure are examined. © 1997 Elsevier Science Ltd

Keywords: electrochemical synthesis; heteroazomethinic ligands; transition metals.

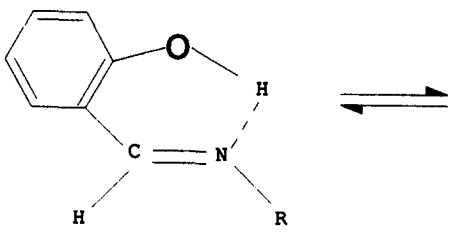
Transition metal complexes with azomethinic ligand systems have been intensively studied in the last 30 years. The main research results have been reported in a series of articles and reviews [1–11]. The following azomethinic ligands, **I**,



I

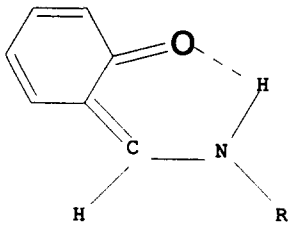
where:
X = NTs, O, S, Se, Ts; Ts = $-SO_2C_6H_4CH_3$-*p*
R = H, Alk, Ar, Het (heteroatoms), OH, $(CH_2)_nOH$ (n = 2,3); NR^1R^2, R^1 = H, R^2 = Alk, Ar;
$R^1 = R^2$ = Alk, Ar

present the peculiarity of produce different types of metal complexes starting from the same ligand [6,8,10] as a consequence of the presence of an inner-molecular hydrogen bond, of the tautomeric equilibrium between the keto–enol (thion–thiol) and imino–amine forms, and of the molecular spatial configuration, **I** and **III**.



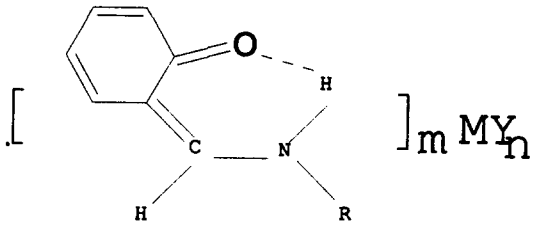
II

* Author to whom correspondence should be addressed.

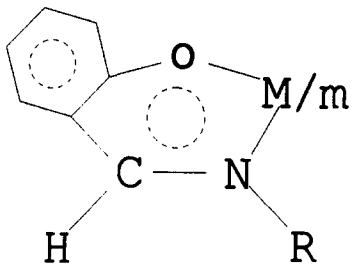


III

These structures [7,9,10] lead to the formation of two types of coordination compounds **IV** or **V**; the type **IV** are adducts (molecular complexes) with a conserved ligand system and **V** are chelates with a deprotonated azomethinic molecule having inner-chelate bonds [9,10]. The possibility of obtaining an adduct or a chelate depends on the nature of the metal and anion as well as the synthetic conditions



IV



V

where:
Y = Hal, NO_3, NCO, NCS; n = 2–5; m = 1–3

The use of these ligands permits one to carry out a selective synthesis due to the possibilities of modifying the structural details of the ligands (e.g., control of tautomeric equilibrium, nature of donor atoms, character of aldehyde and amine fragments, the total number of atoms in the chelate rings and the number of N-atoms) [9–10].

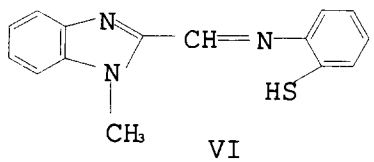
In this work transition metal complexes (M = Cu, Ni, Co, Pd, Zn and Cd) have been obtained from the Schiff bases by conventional methods and by direct electrochemical dissolution of the sacrificial metal anode (Cu, Ni) in non-aqueous solvents containing the corresponding azomethinic ligands. The main advantage of electrochemical syntheses is that the reaction takes place in one step with high yields and in a short time [12–14].

EXPERIMENTAL

Synthesis of Schiff bases

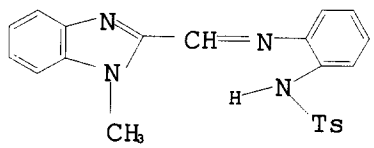
The synthesis of the Schiff bases was carried out according to an established procedure [15]. In this work we describe the synthesis of two, **VI** and **VII**; the other ones have been prepared similarly.

1-Methylbenzimidazole-2-aldehyde-2′-mercaptophenylimine. A toluene solution (50 cm^3) containing 1.25 g (0.01 mol) of *o*-aminthiophenol was added to the toluene solution (50 cm^3) containing 1.6 g (0.01 mol) of 1-methyl-2-formylbenzimidazole and was heated at full reflux. After the reaction finished the toluene was distilled off in a rotation evaporator and 50 cm^3 of boiling methanol were added to the reaction mixture. After cooling, a slightly yellow product was isolated, filtered, and recrystallized from methanol (m.p. 220°C).



VI

1-Methylbenzimidazole-2-aldehyde-2′-o-tosylaminphenylimine. The synthesis was carried out according to the above method; recrystallization was made from dioxane (m.p. 200–203°C).



VII

Ts = $-SO_2-C_6H_4-CH_3$

The data about the azomethinic ligands VI and VII are presented in Table 1.

Synthesis of transition metal complexes

Synthesis by the conventional chemical methods. The syntheses have been carried out according to ref. [16]. The ligands and their corresponding metal acetates (molar ratios 1 : 1 or 1 : 2) were dissolved in methanol (acetone in the case of Pd) and then heated in a water bath for 1 h. The solids formed were filtered, purified three times with 5 cm^3 of methanol and dried *in vacuo* 150°C.

The reaction yields were in the range 75–80%. The elemental analyses and the physico-chemical properties of the complexes are presented in Table 1.

[a] Obtained electrochemically.

Direct electrochemical synthesis of copper and nickel chelates

The complexes of Schiff bases have been obtained electrochemically. The electrosynthesis processes were carried out by anodic dissolution of metals in acetonitrile or methanol solutions of the corresponding ligands, according to the recommendations described by D. Tuck [12], M. Chakravorty *et al.* [13] and A. Sousa *et al.* [17–25] in the synthesis of similar complexes.

The cell consisted of a tall-form beaker, and the

solution phase contained the appropriate ligand (1–2 g) dissolved in acetonitrile, or in methanol containing tetrabutylammonium bromide or sodium chloride (0.1 N). The anode (sacrificial metal in each case) was supported on a platinum wire and a platinum sheet formed the cathode. All experiments were conducted at room temperature in an atmosphere of dry nitrogen, which was bubbled through the cell. The voltage was regulated to obtain an initial current of 20 mA. In each case the electrolysis was conducted for a period of 2–2.5 h, after which the anode was washed, dried and weighed in order to obtain the electrochemical efficiency. The complexes formed were filtered, washed with methanol or acetonitrile and dried in air. The experimental conditions are presented in Table 2. The yields of the final products were 85–96%.

In the case of copper complexes some of the product was occasionally formed on the surface of the anode (3 × 2 cm), which led to an increase of the voltage. To avoid this, we applied a combination of electrolysis with a simultaneous treatment by ultrasound. This stabilized the voltage because of a faster elimination of the complex formed on the anode surface [26]. The quantitative results of the study of electrosynthesis of some transition metal complexes with nitrogen-containing ligands using the combination of electrolysis and ultrasound, will be communicated later.

RESULTS AND DISCUSSION

As mentioned in the Introduction, the Schiff bases have many possibilities of modifying the structural and physico-chemical properties of their metal complexes [7,9,10]. The objective of this work is to compare the properties of metal chelates obtained in different synthetic conditions. We have obtained the complexes of Ni, Co, Zn, Cd, Pd, Cu with the ligands **VI** and **VII** by the conventional synthetic methods.

According to elemental analyses shown in Table 1, the Co, Zn, and Cd complexes of **II** have the composition $ML_2 \cdot nH_2O$ ($n = 1, 2.5$). However, the complexes of Cu, Ni and Pd with **VII** have the composition $MLAc \cdot nH_2O$ ($n = 0, 1, 2$).

Comparison of the IR-spectra (Table 3) for 1-methylbenzimidazole-2-aldehyde-2′-*o*-tosylaminphenylimine (**VII**) and the complexes 9, 11–14, 16, confirms the chelate structure of the metal complexes. Specifically, a decrease in the frequency of the azomethinic bond ν(C=N) from 1620 cm^{-1} by 27–40 cm^{-1} is observed, and the deprotonation of tosylamino group is confirmed by the disappearance of the band of the valency oscillations of the ν(NH) group in 3153 cm^{-1} in the spectra of these complexes.

It is known [27] that on coordination of the $NHSO_2$ group, a decrease of the frequencies ν_s and ν_{as} of the SO_2 group takes place between 1160 and 1353 cm^{-1}. Comparing the IR-spectra of the ligand **VII** and its chelates, we observed the shift of $\nu(SO_2)$ in the chelates, indicating the coordination of tosyl oxygens.

The ligands are tridentates, so a possibility of participation of the N-atom of heterocycle in the coordination with the metal is not excluded; it should be accompanied by the shift in the position of the absorption bands of the benzimidazole cycle in the ranges of 1630–1600 and 1580–1550 cm^{-1}. As it was observed in the IR-spectra of the obtained complexes, the absorption bands of the heterocycle have small shifts in comparison to their positions in the ligands. These shifts could not be attributed to an additional coordination [28].

The presence of water molecules in the coordination sphere is confirmed by the characteristic frequencies in the range of 3480–3300 cm^{-1}.

The elemental analysis for the metal complexes **2**–**7** (Table 1) with 1-methylbenzimidazole-2-aldehyde-2′-mercaphtophenylimine **VI** and also for the ligand **VII**, revealed the compositions $ML_2 \cdot nH_2O$ and $MLAc \cdot nH_2O$ ($n = 0$–3). The interpretation of their IR-spectra is difficult, because of the absence of both

Table 2. Experimental conditions for the electrosynthesis of metal chelates

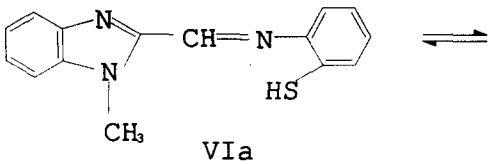
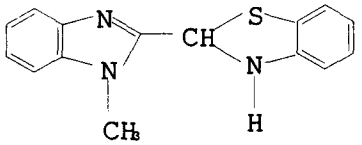
[a] To produce a current of 20 mA.

the sulphyrdril and the azomethinic absorption bands in their spectra due to the following equilibrium:



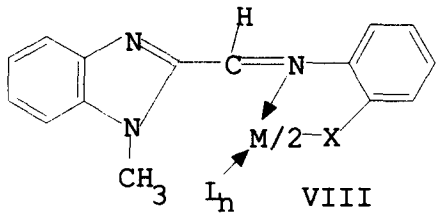
VIa



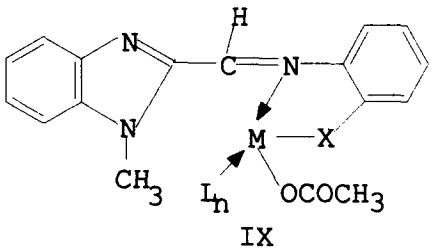
VIb

According to [29], it is possible to conclude that coordination of the ligand **VI** takes place only when it is in the azomethinic form. The frequency 1630 cm^{-1} was attributed to the ν(C=N) for the ligand **VI** with the group SCH_3 (instead of SH). In some cases (**3, 5, 6** and **7**) the acetate group is conserved.

Based on the discussed results, it is possible to assign the complexes the following formulae **VII** and **IX**:



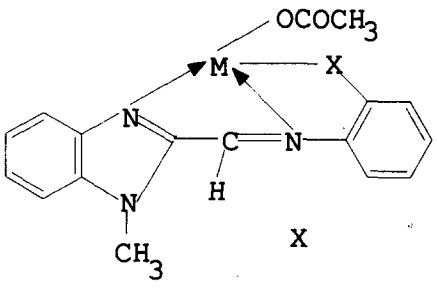
VIII



IX

L = H_2O, MeOH; n = 0–3.

The presence of 5-member chelate rings is confirmed by the agreement between our data and that reported in the reviews [9,10,27] and papers [30,31]. Also, these chelates formed initially from the ligand precursors **VI** and **VII** could contain two 5-member metal chelate rings, due to additional coordination of the nitrogen atom of benzimidazole ring to metal:

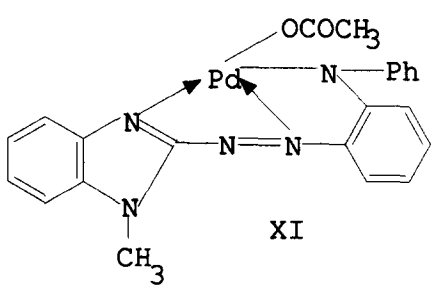


X

The existence of this type of structure has been confirmed [32] by the X-ray diffraction method for the palladium complex, **VI**.

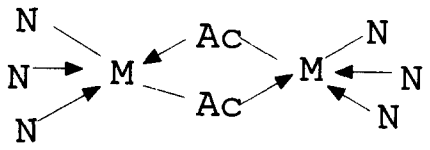
In order to obtain metal complexes with the systems **VI** and **VII** without anions, we tried to electrosynthesize the compounds starting from zero-valent copper and nickel. However, it was impossible to isolate complexes of these metals with **VI** because of the considerable decomposition of this azomethinic compound under the conditions of electrolysis. The nickel and copper complexes 15 and 16 have been isolated as a result of electrosynthesis starting from the more stable VII. According to the elemental analyses, the complexes have a composition $ML_n \cdot mH_2O$ (n = 1, 2; m = 2, 2.5).

In order to compare the physico-chemical properties and the structure of copper complexes, obtained by the conventional chemical methods, 2(LH = VI, X = S) and 9 (LH = VII, X = NTs) (Table 1), against the electrochemical procedure 15 (LH = VII, X = NTs), we have measured their EPR spectra at X-band frequency in DMF at 77 K. As seen in the EPR spectrum of complex 2, $g_{\parallel} > g_{\perp} > 2.0023$ ($g_{\parallel}$ = 2.215, $g_{\perp}$ = 2.046, $A_{\parallel}$ = 165.2 G), which indicates a $d_{x^2-y^2}$ ground state. The isotropic spectrum (298 K) of this complex has well resolved lines, which can be attributed to the interaction of electron spin with the nuclear spin of Cu^{II} (I = 3/2) A_{Cu}(iso) = 61.2 G, g(iso) = 2.102. In the case of the complexes 9 and 15, the hyperfine features at 298 and 77 K were not seen in the solution and powder spectra. The EPR spectra of these complexes measured in frozen solutions (77 K) and in polycrystalline powders showed no resolved broad ΔM = 1 ($\approx$3200 G) and weak ΔM = 2 ($\approx$1600 G) absorptions. The appearance of the ΔM = 2 signals indicates that dinuclear structures exist even in solution. This fact could be related to the presence of dinuclear structures XII sufficiently stable for this complex, in which a magnetic exchange between



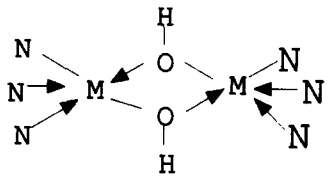
XI

copper atoms occurs probably through acetate groups:



XII

This conclusion is also confirmed by the magnetochemical data as it is shown in Table 4. The magnetic susceptibility at different temperatures also shows the presence of a weak antiferromagnetic interaction between the copper atoms. An analogous result was obtained for the chelate 15 (LH = **VII**, X = NTs, by electrosynthesis). The data from the magnetochemical studies show a small antiferromagnetic change, which, in our opinion, could be attributed to the presence of OH-groups in the dinuclear structures $(CuL)_2$ **XIII**:



XIII

It is worth mentioning that nickel chelate 16 with the ligand VII (X = NTs, by electrosynthesis) $NiL_2 \cdot 2.5H_2O$, has a weak antiferromagnetic effect between nickel atoms (Table 4). Perhaps in this case the change is carried out through the conjugated system containing an heterofragment. An additional intermolecular coordination of nitrogen atoms takes place with the formation of the coordination kernel NiN_6.

We have described above the complexes of types **VII–X,** containing 5-member metal cycles. In order to study the influence of a number of atoms in the cycle and that of the method of synthesis on the character of the obtained complexes, we have prepared the chelates on the basis of the azomethinic compounds **XIV** and **XV,** containing 6-member cycles with intermolecular hydrogen bonds, i.e., derivatives of 2-tosylaminobenzal-2′-aminobenzimidazole **XIV** and salicylal-2-aminobenzimidazole **XV**.

[a] Complexes electrochemically obtained.

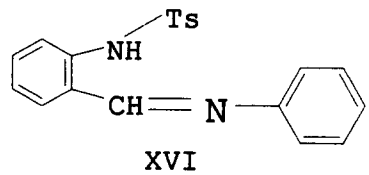
The chelate **17** $CuLAc \cdot H_2O$ was prepared (Table 1) following the conventional chemical synthesis, i.e. by the interaction between copper acetate and the ligand **XIV**, ($R = C_2H_5$.). The electrosynthesis with the ligands XIV and XV led to the formation of the chelates **18–20** (Table 1).

According to the IR spectra, the obtained complexes have structures of the chelate type. These spectra show a decrease of the frequency ν(C=N) 1630 cm^{-1} by 10–15 cm^{-1} and the disappearance of ν(N—H) at 3150 cm^{-1}. The saturation of the coordination sphere of copper is carried out at the expense of the deprotonization of *o*-tosyl-amino-(**17–19**) or *o*-hydroxo-(**20**) groups, coupled with the preservation of acetate anions (chemical method, **17**) or OH-groups (by electrosynthesis, **18, 20**). The magnetochemical study of the copper complexes **17** and **18** shows that the weak antiferromagnetic interaction takes place in these chelates, independent of the method of synthesis, chemical or electrochemical (Table 4). This fact could be connected with the formation of dimer structures stabilized at 77 K in the frozen solution, where spin–spin exchange is carried out through aceto- or OH-groups in the complexes, obtained chemically and electrochemically, respectively.

It is interesting to note that the copper complexes **18** (LH = **XIV**, $R = CH_3$) and **20** (LH = XV, R = H), obtained in the same electrochemical conditions and having the same composition $CuL \cdot nH_2O$, but different types of coordination kernels CuN_2O (LH = **XIV**) and $CuNO_2$ (LH = **XV**), have different magnetic properties. The substitution of tosylamino-group in LH = **XIV** by *o*-OH-group in LH = **XV** (R = H) leads to the formation of monomer complex **20** $CuL \cdot H_2O$ (LH = **XV**), where copper probably exists in a mixed-valent state: Cu^{I}, Cu^{II}, as it was confirmed by magnetochemical data (Table 4). The magnitude of the effective magnetic moment μ_{eff} for the complex 20 decreases (1.29 B.M.) at room temperature and does not change in the interval of 302–82 K.

The nickel chelate, 19, NiL_2 (LH = **XIV**, $R = CH_3$), obtained electrochemically, has a $\mu_{eff} = 2.75$ B.M., which is evidently related to the tetrahedral (instead of square planar) coordination environment of the metal.

In addition, we have obtained electrochemically the chelates of copper **21** and nickel **22** with the Schiff base system containing *o*-tosylamino-group, but without a heterocyclic fragment (LH = XVI):

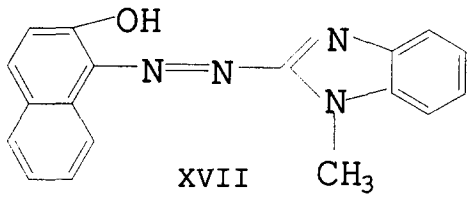


XVI

According to elemental analysis data and IR spectra (Tables 1 and 3), these compounds have the com-

position and structure which are typical [27] for metal chelates: ML_2 (LH = XVI). The EPR spectra data for the complex **21** at 77 K correspond to the data of an analogous complex obtained by the usual chemical method [28].

The electrosynthesis using a copper anode and the ligand **XVII** led to the formation of the complex ML_2, 23. The chelate structure was studied by IR spectra and magnetochemical data, $\mu_{eff} = 2.2$ B.M. at 273 K (Table 1). These results are in agreement with the data for the analogous complex obtained earlier [28] by the chemical method. It can then be concluded that the structure and the properties of these kind of complexes are independent from the method of synthesis used to obtain them.



XVII

CONCLUSIONS

The substitution of conventional chemical methods by electrochemical methods of synthesis permits us to obtain complexes of azomethinic ligands and azo-compounds which have different compositions and stereochemistry.

The main advantages of electrosynthesis are the high yields (80–96%) and the absence of anions which are frequently present in the chelates of tridentate heteroarene ligands [32]. These results are especially interesting since they show the possibility of wider application of electrosynthesis [12–14] in the modern coordination chemistry.

Abstract—The initial structural characterization of a barium–sulfur covalent interaction is reported. © 1997 Elsevier Science Ltd

Keywords: barium; thiolate; ring compound; structural characterization; dithioimidodiphosphinate.

Much effort has been focused on the topic of late Group 2 element *bis*(β-diketonate) compounds in recent years [1–3]. This is driven, to a great extent, by the potential of such species to serve as precursors for the growth of superconducting metal oxide thin films. Although β-diketonate ligands have served exceptionally as carriers for numerous metals, the large size/charge ratio for Ba^{2+} presents unique challenges for the chemist. For example, the highly sterically demanding $tmhd^-$-ligand (Htmhd: 2,2,6,6-tetramethyl-3,5-heptanedione) forms a tetrameric barium compound in the solid state [4]. In a search for possible alternates more suited to the particular difficulties of Ba^{2+}, we turned to other monoanionic bidentate ligands. Such a moiety $(SP(Ph)_2NP(Ph)_2S)^-$ has been used previously as a ligand for several transition metals [5–13] and a few main group elements including K^+ [14–15], Sn^{4+} [16], Bi^{3+} [17–19] and Te^{2+} [20].

Organometallic barium compounds have been known for over half a century [21–23]. Recently, they were joined by other classes of reagents which have been examined for use as precursors for barium-containing ceramic materials. They include barium alkoxides [24–28], -β-diketonates, [1–4,29,30] and -amides [31]. Examples of barium compounds containing less-traditional Ba—E bonds are rare. Included among them are $Ba(SiPh_3)_2$ [32], $[Ba(P(SiMe_3)_2)_2(THF)_2]_n$ [33], $Ba(P(SiME_3)_2)_2 \cdot 4$ THF [34] and $[Ba(TeSi(SiMe_3)_3)_2(pyridine)_5]$ [35]. Barium species containing Ba—S interactions have not been studied in detail. Barium is known to form complexes with dithiocarboxyllic acids [36], however, these compounds have a highly ionic character. Additionally, $Ba(SCN)_2$ [37] and examples of $R_2C{=}S \rightarrow Ba$ [38] and $R_2S \rightarrow Ba$ [39] have been characterized in the solid state. The initial characterization of a barium *bis* (thiolate) compound recently has been completed [40]. As one component of our efforts to prepare barium compounds containing Ba—S interactions, we have turned our attention to the tetraphenyldithioimidodiphosphinate ligand, $[SP(Ph)_2NP(Ph)_2S]^-$ [14]. This anion is available readily by the deprotonation of $HN(SP(Ph)_2)_2$ [41] (Eq. 1), and has the negative charge delocalized throughout the SPNPS-moiety, similar to the delocalization which occurs in β-diketonate ligands. Like β-diketonates, the

$[SP(Ph)_2NP(Ph)_2S]^-$ anion (**2**) interacts with metal centers in a chelating fashion. Barium metal reacts with $SP(Ph)_2NHP(Ph)_2S$ in the presence of gaseous NH_3 to form compound **3** (Eq. 2).

$$\underset{\mathbf{1}}{(SP(Ph)_2)_2NH} \xrightarrow[-H^+]{Base} \underset{\mathbf{2}}{[SP(Ph)_2NP(Ph)_2S]^-} \quad (1)$$

$$\mathbf{1} + Ba^\circ \xrightarrow[NH_3(g),R.T.]{THF} \underset{\mathbf{3}}{Ba[(SP(Ph)_2)_2N]_2 \cdot (THF)_n}$$

$$\xrightarrow{DME} \underset{\mathbf{4}}{Ba[(SP(Ph)_2)_2N]_2 \cdot 2\,DME} \quad (2)$$

Upon recrystallization from 1,2-dimethoxyethane (DME), the DME adduct **4** is obtained. Compounds **3** and **4** are highly soluble in organic solvents and show no sensitivity towards oxygen or water. The crystal structure of **4** has been determined by single crystal X-ray diffraction [42]. Compound **4** crystallizes as a discrete monomer in the space group Cc (Fig. 1). Both dithioimidodiphosphinato ligands interact with the metal center in a bidentate fashion resulting in the formation of two six-membered BaS_2P_2N rings with the barium atom at the *conjuncto* position. The four Ba—S interatomic distances are not equivalent, ranging from 321.07(24) pm [Ba-S(4)] to 327.0(3) pm [Ba-S(3)]. It is noteworthy that a trend is absent between the characterized derivatives of ligand **2** with *p*-block elements. For instance, non-equivalent M—S interatomic distances also are observed in the complex $Bi[(SP(Ph)_2)_2N]_3$ [18], which displays two sets of short and two sets of long Bi—S interactions. However, in the tin complex $Me_2Sn[(Sp(Ph)_2)_2N]_2$ the four Sn—S interatomic distances are equivalent [16].

The P—S interatomic distances observed for compound **4**, on average, are longer (198.5 pm compared to 194.3 pm) and the P—N interatomic distances are shorter (157.7 pm compared to 167.8 pm) when compared with the analogous data observed for compound **1** [43], indicating that the π-electrons in compound **4** are delocalized throughout the BaS_2P_2N moieties. There exists, to our knowledge, no similar parameters with which to compare Ba—S interatomic distances. Since this report is the first solid state characterization of such an interaction, comparison with ionic interactions observed in BaS (316 pm [44]) and the sum of the radii (Ba: 142 pm; S: 184 pm; sum: 326 pm) [45] is warranted [37–39]. The coordination sphere of the barium atom is completed by the oxygen atoms of two DME ligands, which form a belt around the central metal. The dihedral angle between the planes of BaS_2 units is 7.04°, while that between the planes of BaO_2 units is 5.80°. The BaS_2 to BaO_2 planes each are nearly perpendicular (range 86.28–96.86°, average of 91.62°). Thus, the overall geometry at the eight-coordinate metal center is pseudocubic. This closely approximates that observed for $[Ba(tmhd)_2 \cdot 2\ NH_3]_2$ [30], another highly symmetric molecule. The Ba—O interatomic distances observed for compound **4**, 272.4(7)–286.1(8) pm, fall within the range reported for $R_2O \rightarrow Ba$ interactions, although somewhat at the low end of the previous data, (278–282 [46], 283 [47], 281–289 [48], 286–296 [49]. The data for compound **4** are significantly longer than that found for RO^- interactions with barium (238–242 [50], 241 [46]).

The IR spectrum of **4** shows the expected differences when compared to the IR spectrum of the protonated ligand **1**. The asymmetrical P⟷N⟷P stretch is found at 1248 cm^{-1} in **4**, compared to 1217 and 1250 cm^{-1} observed for the tin complexes $Me_2Sn[(SP(Ph)_2)_2N]_2$ and $Me_3Sn[(SP(Ph)_2)N]$, respectively [16]. The protonated ligand displays a strong band at 652 cm^{-1}, which is characteristic for a P=S double bond [37]. These bands are replaced in **4** by a strong vibration at 574 cm^{-1}, attributed to delocalized P⟷S stretching.

The $^{31}P\{^1H\}$ NMR chemical shift observed for compound **4** (57.6 ppm) may be compared to that recorded for compound **1** (57.5 ppm).

In conclusion, the initial structural characterization of a barium–sulfur interaction within a ring system has been reported.

Acknowledgements—This work was supported by the Deutsch Forschungsgemeinschaft (posdoctoral fellowship to G. K.) and the US Office of Naval Research. Dr D. G. Van Derveer assisted with crystallography, Ms D. Moreno confirmed the ^{31}P NMR data and Dr H. Luten aided with the preparation of Figure 1.

Experimental Procedure

1: Synthesis according to ref. [51].

3: 7.20 g (16.0 mmol) of compound **1** was added to 1.21 g (8.8 mmol) of barium metal in 100 ml of THF. A strong stream of dry NH_3 gas was bubbled through the reaction mixture. After 30 min, the flow of NH_3 gas was stopped and the mixture was stirred overnight at ambient temperature. The majority of the elemental barium had been consumed by this time. The mixture was filtered and the THF was removed under vacuum. Compound **3** remained as a colorless crystalline material. Yield: 8.5 g (96.5% with respect to compound **1**).

4: 1 g of compound **3** was dissolved in 20 ml of hot DME. After 24 h at 5°C, compound **4** was isolated in quantitative yield. It is a molecular species in $CDCl_3$ solution; however, it thermally decomposes upon attempted sublimation at 10^{-5} mm Hg. M.p.: 150°C (decomp. 195°C); ^1H NMR (300 MHz, $CDCl_3$): δ = 3.27 (s, 12H, OCH_3), 3.40 (s, 8H, CH_2), 7.10–7.77 (m, 40H, aryl-H); IR (cm^{-1}, KBr pellet): 3053m, 2933m, 1446s, 1248s, 1117s, 715s, 751m, 715s, 696s, 603m, 574s, 513m.

BOOK REVIEW

Chemistry of Precious Metals, S.A. Cotton, Blackie Academic and Professional, London,1997. £99.00

As the author acknowledges in the Introduction, this book is the linear descendent of Cotton and Hart's "*The Heavy Transition Elements*" that was familiar to many students and lecturers over the past two decades. This book restricts its coverage to the elements Ru, Os, Rh, Ir, Pd, Pt, Ag and Au—the platinum elements. Now excluded are the early transition elements and the lanthanoids and actinoids, although the chemistry of the latter groups are discussed in the author's excellent "*Lanthanides and Actinides*" (Macmillan, Basingstoke, 1991).

What you get for your money are 374 pages discussing the chemistry of the platinum elements. The format is highly reminiscent of "*The Heavy Transition Elements*" and I personally find it a little untidy and cluttered in places (see, for example, Figure 2.88). The basic premise leads to a book that you will either love or hate—the assumption is that chemistry ultimately depends upon a knowledge of facts, and facts are what you get aplenty. Personally, I find this a valid and good approach, but fear that it will endear the book rather to the lecturer searching for a convenient source of material than to the student. This is not a book that presents general trends and explanations in a pre-packaged and easily digestible form. As an example, I am not certain that a student would come away from this book with an appreciation of the common cause for square-planar coordination geometries with gold(I), platinum(II) and iridium(III). The book is reasonably up-to-date and references provide a convenient entry into the primary and secondary literature. Of course, in rapidly developing fields, such as platinum antitumor species, the book is already somewhat behind the times.

The book consists of four chapters, one each devoted to the heavier congeners of groups 8, 9, 10 and 11 together with 33 pages of references and an index. In general, the organometallic chemistry of these elements with π-bonding ligands is not covered, although -bonded organometallics are treated. I fully appreciate and understand this choice, but I wonder how much it can be justified within the, already limited, scope of the book and its relatively high price. Factual errors are few, but in general the literature is reveiewed in an encyclopedic rather than a critical manner. There are a number of results reported which are certainly not fully and uncritically accepted.

Accepting that the devil is in the detail, there are a number of points which should be brought to the potential reader's attention. The author is rather inconsistent in the use of square brackets to denote complex species. As a typical example, on page 20 we encounter the two complexes $K_2OsO_4(OH)_2$ and $K_2[OsO_2(OH)_4]$. I would hope that future editions would remedy this deficiency, since it can prove very confusing to the student. A similar cavalier attitude exists with respect to charges—compound (a) in Figure 3.97 most certainly is not a platinum(III) complex, the dianion is. I realise that nomenclature is a dangerous topic, but I feel strongly that books such as this should adopt IUPAC nomenclature where it is appropriate or realistic. This is most certainly not the case in this text; sulfur compounds are presented throughout with the -ph- spelling, ligand names are imprecise and non-systematic (terpyridyl, bipyridyl), bidentate is used rather than didentate.

Overall, my impression of the book is favorable. It is strong in an area in which Greenwood and Earnshaw is both somewhat weak and dated. The basic material is presented with few serious factual errors, although the appearance and "feel" might have benefited from additional technical editing. I certainly will be using this book as a source of material for lecture courses. The author states in the preface that the book is probably aimed at teachers rather than students, and this is certain to be the case. I feel that this is a pity, because there is a need for students to be equipped with a certain level of raw, indigestible facts.

Finally, I feel duty bound to comment on the price of this text. At about 25 pence per page this book is expensive. With a new, and undoubtedly cheaper, edition of Cotton and Wilkinson imminent, the budgetary questions that will be raised by ever more pressed library committees will be hard to answer.

(Received 1 July 1997; accepted 18 September 1997)

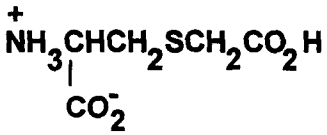
Abstract—The kinetics of the complex formation between S-carboxymethyl-L-cysteine and palladium(II) was studied by using stopped-flow technique in the acidity range from pH 1 to 4 at 25°C. The reaction rate of the formation of 1 : 1 chelate species is strongly affected by the acidity. The reaction mechanism consisting of five parallel paths which involve Pd^{2+} and $PdOH^+$, as well as LH^-, LH_2 and LH_3^+ ligand species was proposed. Fairly good agreement between the computed and experimentally determined rate constants was found. The equilibrium constants of the complex formation were determined. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: S-carboxymethyl-L-cysteine; palladium(II); stopped-flow; complex formation.

S-carboxymethyl-L-cysteine ($SCMCH_2$) belongs to a group of naturally occurring amino acid containing thioether group [1,2]. In spite of its biological importance as an intermediate in cystamine formation, $SCMCH_2$ is an effective antiseborrheic and antiacne agent and can be used as an antidote for treatment of some poisoning [1]. $SCMCH_2$ has three coordination sites and its reaction with Pd^{II} in the presence of micelles has been used as a model system in order to better understand interaction between metal ions and proteins on the surface of a biomembrane [3,4]. $SCMCH_2$ forms different complex species with metal ions such as Cu^{II}, Ni^{II} and Zn^{II} [5,6], in which the ligand chelate to the metal ion via the amino and carboxylate groups of the α-amino acid residue. The coordination of sulfur atom to the metal ion is also suggested [5,6].

Recently, the spectrophotometric method for determination of $SCMCH_2$ by using palladium(II) chloride ($PdCl_2$) have been developed [7], and the mechanism of this reaction was examined [8]. It was found that ligand attacks all $Pd(H_2O)_{4-n}Cl_n$ species ($n = 2$–4), the reaction rate being strongly dependent on Cl^- and pH.

The aim of this work was the investigation of the reaction mechanism between Pd^{2+} and $SCMCH_2$. Basically, both the free metal ion and the monohydroxy species are labile toward substitution with ligand, and different reaction pairs could be kinetically distinguished.



$SCMCH_2$ (1.99<pH<3.33)

EXPERIMENTAL

All reagents were commercial products of the highest purity available. A freshly prepared 2×10^{-3} M $SCMCH_2$ (ICN, Galenika) aqueous stock solution was used; more dilute solutions were obtained by appropriate dilution with water. The standard solution of 1×10^{-3} M Pd^{2+} was prepared as described elsewhere [9]. The acidity of the solutions were adjusted by the addition of Britton–Robinson buffer solutions. The pH of the solutions were measured by a Beckman Expandometric pH meter. The ionic

* Author to whom correspondence should be addressed.

strength was kept constant by the addition of $NaClO_4$ (I = 1.0).

The absorption spectra of the solutions were recorded on a Perkin-Elmer Lambda 5 UV–VIS spectrophotometer. For the stopped-flow experiments, the universal rapid kinetic accessory HI-TECH model SFA 12 was fitted to a spectrophotometer. The rate of the complex formation was allowed by monitoring the increase of the absorbance at 258 nm. The measurements were carried out under pseudo-first-order conditions. Values of k_{obs} were determined by fitting the experimental trace (A vs t) to the function $(A_e-A)/(A_e-A_o) = \exp(-k_{obs}t)$ (A_o and A_e are the initial and final absorbancies, respectively) by using a computer program based on the last square method. All kinetic measurements were reproducible within limits of error of $\pm 5\%$. The quoted values are the average of at least five runs under identical experimental conditions. All reported rate constants were determined at 25 ± 0.1°C.

RESULTS AND DISCUSSION

Absorption spectra and equilibra of the Pd^{II}-$SCMCH_2$ *complex*

The complex formation between Pd^{II} and $SCMCH_2$ was investigated in the pH range from 1 to 4. The absorption spectra of the solutions containing equal concentrations of Pd^{II} and $SCMCH_2$ at different acidities are shown in Fig. 1. The Pd^{II}-$SCMCH_2$ complex has the absorption maximum at 258 nm and the shoulder at 330 nm. For comparison, absorption spectra of the reacting species (Pd^{II} and $SCMCH_2$) are also given in Fig. 1.

The stoichiometry of the complex (Pd^{II}: $SCMCH_2$ = 1 : 1) was determined at different acidities (pH 1.10, 2.05 and 3.60) by continuous variation of the ratio between initial concentrations of Pd^{II} and $SCMCH_2$. Also, the absorption spectra at the constant $Pd^{II}/SCMCH_2$ ratio were followed as a function of the acidity. The absorption spectra indicated, that the metal chelate structure was not affected by the change in acidity. The slight shifts of the position and intensities of the absorption maximum are most likely due to the presence of different ionic forms of the ligand bound in the complex ($pK_{a3} = 1.99$, $pK_{a2} = 3.33$) [6]. In the acidity range close to pH 3.33 the dissociation of —COOH group in cysteine residue takes place, and most likely induces changes in absorption spectra. The extent of the changes in the absorption spectra is small and does not allow spectrophotometric determinations of equilibria constants.

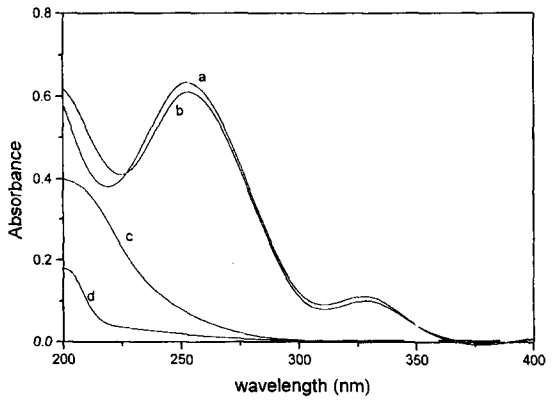


Fig. 1. Absorption spectra of solution containing equal concentrations of Pd^{II} and $SCMCH_2$ (5×10^{-5} M) at different acidities: (a) pH 1.1; (b) pH 2.3. Absorption spectra of solutions containing: (c) 5×10^{-5} M Pd^{II} at pH 1.1, and (d) 2×10^{-5} M $SCMCH_2$.

The equilibrium between the reactants and the complex is pH dependent. Under our experimental conditions, the hydrogen ion concentration is sufficiently high and its changes during the complex formation are negligible, so the equilibrium can be expressed as follows:

$$Pd_f + L_f \rightleftarrows \text{complex} \quad (1)$$

Further in the text $SCMCH_2$ should be denoted as LH_2. The pH dependent apparent formation constant (K_{app}) is defined as the total complex concentration divided by the product of concentrations of the total free Pd^{II} (Pd_f), and total free ligand (L_f):

$$K_{app} = \frac{[\text{complex}]_{tot}}{[Pd_f][L_f]} \quad (2)$$

Pd_f and L_f are given by eqns (3) and (4):

$$[L_f] = LH_3^+ + LH_2 + LH^- = \alpha[LH^-] \quad (3)$$

$$[Pd_f] = Pd^{2+} + Pd(OH)^+ = \beta[Pd^{2+}] \quad (4)$$

where $\alpha = 1 + [H^+]/K_{a2} + [H^+]^2/(K_{a2}K_{a3})$ and $\beta = 1 + K_h/[H^+]$. K_h, K_{a2} and K_{a3} are the equilibria constants of the following reactions:

$$LH_n^{(n-2)+} \overset{K_{an}}{\rightleftarrows} LH_{(n-1)}^{(n-3)+} + H^+ \quad (n = 1\text{–}3) \quad (5)$$

$$Pd^{2+} + H_2O \overset{K_h}{\rightleftarrows} Pd(OH)^+ + H^+ \quad (6)$$

α and β were calculated using the literature data: $pK_h = 2.12$ [10], $pK_{a2} = 3.33$ and $pK_{a3} = 1.91$ [6].

According to the absorption spectra of complex at different acidities, it is clear that two different complex species can be formed in the pH range from 1 to 4. The equilibrium constants are presented by eqns (7) and (8):

$$Pd^{2+} + LH_2 \overset{K''_{eq}}{\rightleftarrows} PdLH^+ + H^+ \quad (7)$$

$$Pd^{2+} + LH \overset{K'_{eq}}{\rightleftarrows} PdL + H^+ \quad (8)$$

The pH dependent apparent formation constant can be derived by appropriate manipulation of eqns (2)–(8):

Table 1. Experimental rate constant (k_{obs}) of complex formation between $SCMCH_2$ and Pd^{II} (2×10^{-5} M) as a function of the $SCMCH_2$ concentration at different acidities

$[L_f] \times 10^5$ (M)	k_{obs} (s^{-1})

$$K_{app} = \frac{K'_{eq} + \frac{K''_{eq}}{K_{a2}}[H^+]}{\alpha\beta[H^+]} \qquad (9)$$

The values of pH dependent apparent formation constant (K_{app}) were determined from kinetic measurements. Kinetics of the complex formation were investigated at different acidities ($1 < pH < 4$) under pseudo-first-order conditions (excess of ligand). Kinetic measurements in the presence of excess of Pd^{II} were not performed, because of overlapping between absorption spectra of complex and Pd^{II}. Under pseudo-first-order conditions the experimentally determined rate constant (k_{obs}) followed the simple rate expression:

$$k_{obs} = k_f[L_f] + k_r \qquad (10)$$

where k_f and k_r are the forward and reverse pH dependent rate constants, respectively. The collected values of k_{obs} as a function of L_f at constant acidity (see Table 1) indicated the presence of a measurable reverse reaction in the investigated range of acidity. The values of k_f and k_r, as well as formation constant ($K_{app} = k_f/k_r$) were determined at different pH from the plots of k_{obs} vs L_f (see Table 2). The values of K_{app} in the pH range from 2 to 4 (six points) were used to estimate K'_{eq} and K''_{eq}. The plot of $\alpha\beta[H^+]K_{app}$ vs $[H^+]$ (see eqn (9)) is shown in Fig. 2. A straight line with non-zero intercept indicated that both $[PdLH]^+$ and $[PdL]$ complex species are formed under these experimental conditions. The values of $K'_{eq} = (66 \pm 4)$ M^{-1} and $K''_{eq} = (2.7 \pm 0.1) \times 10^2$ M^{-1} were determined from the intercept and the slope, respectively.

Table 2. Forward (k_f) and reverse (k_r) rate constants as well as apparent formation constant ($K_{app} = k_f/k_r$) for the reaction between Pd^{II} and $SCMCH_2$ at different acidities

pH	k_f ($M^{-1} s^{-1}$)	k_r (s^{-1})	$K_{app} \times 10^4$ (M^{-1})

Mechanism of the complex formation

The results presented in Table 2 show significant increase of k_f with the decrease of acidity, while changes of k_r are negligible. This behaviour indicates that two different reacting species of Pd^{II} (Pd^{2+} and $PdOH^+$) are involved in the forward reaction. Also, in the pH range from 1 to 4 three acid-base forms of ligand are present. A reaction scheme which is compatible with pH dependence of k_f is given by reactions (11)–(15). Assumption was made that the reactions (5) and (6) are faster compared to the substitution by ligand, and consequently that the equilibrium between $Pd(OH)_i^{(2-i)^+}$, ($i = 0, 1$) was maintained throughout the kinetic run [10].

$$LH^- + PdOH + \underset{k_{-I}}{\overset{k_I}{\rightleftharpoons}} PdL + H_2O \quad (11)$$

$$K_{a_2} \uparrow\downarrow$$

$$LH_2 + PdOH^+ \underset{k_{-II}}{\overset{k_{II}}{\rightleftharpoons}} PdLH^+ + H_2O \quad (12)$$

$$K_h \uparrow\downarrow$$

$$LH_2 + Pd^{2+} \underset{k_{-III}}{\overset{k_{III}}{\rightleftharpoons}} PdLH^+ + H^+ \quad (13)$$

$$K_{a_3} \uparrow\downarrow$$

$$LH_3^+ + Pd^{2+} \underset{k_{-IV}}{\overset{k_{IV}}{\rightleftharpoons}} PdLH^+ + 2H^+ \quad (14)$$

$$LH_3^+ + PdOH^+ \underset{k_{-V}}{\overset{k_V}{\rightleftharpoons}} PdLH^+ + H^+ \quad (15)$$

Under our experimental conditions, the following rate low can be obtained for the proposed reaction mechanism:

$$\frac{[\text{dcomplex}]}{dt} = \frac{k_1 + k_2[H^+] + k_3[H^+]^2 + k_4[H^+]^3}{\alpha\beta[H^+]} \times \left[\frac{\alpha\beta[H^+]^2}{K'_{eq}} + L_f\left(1 + \frac{K'_{eq}K_{a2}}{K''_{eq}}\frac{1}{[H^+]}\right)\right] \times ([PdLH]_{eq} - [PdLH]) \quad (16)$$

It can be easily shown that under above mentioned experimental conditions pH dependence of k_f can be described as follows:

$$k_f = \frac{k_1 + k_2[H^+] + k_3[H^+]^2 + k_4[H^+]^3}{\alpha\beta[H^+]} \times \left(1 + \frac{K'_{eq}}{K''_{eq}}\frac{K_{a2}}{[H^+]}\right) \quad (17)$$

where $k_1 = k_I K_h$, $k_2 = k_{II}K_h/K_{a2}$, $k_3 = k_{III}/K_{a2} + k_V K_h/(K_{a2}K_{a3})$ and $k_4 = k_{IV}/(K_{a2}/K_{a3})$.

The experimentally determined pH dependence of k_f is shown by the points in Fig. 3. The best fit to eqn (17) was obtained by using k_{1-4} as a variable parameter. The agreement between experimentally determined and calculated values of k_f (see Fig. 3) was obtained for the following set of k_{1-4}: $k_1 = (20 \pm 5)$ M^{-1} s^{-1}, $k_2 = (5.81 \pm 0.18) \times 10^4$ M^{-1} s^{-1}, $k_3 = (2.12 \pm 0.07) \times 10^6$ M^{-1} s^{-1} and $k_4 = (1.19 \pm 0.06) \times 10^8$ M^{-1} s^{-1}.

It is clear that knowing values of k_1, k_2 and k_4 individual rate constants k_I, k_{II} and k_{IV} can be easily determined (see Table 3). The parameter k_3 gives the sum of contributions of path III and V. The individual rate constants k_{III} and k_V were estimated assuming that one of two rate constants is equal zero, and vice versa. The obtained values are the upper limit of individual rate constants, and they are also presented in Table 3.

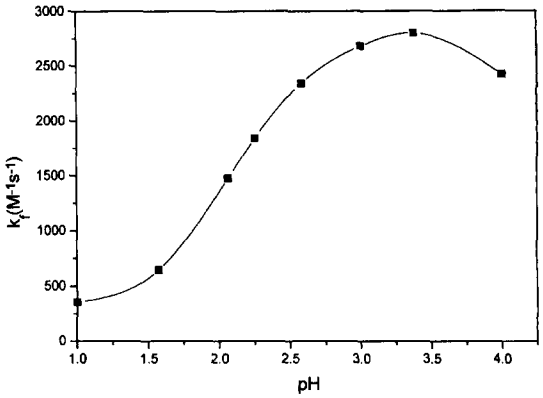

Fig. 3. pH profile of the forward rate constant (k_f) for the formation of the Pd^{II}-$SCMCH_2$ complex. The points were experimentally obtained, while the curve was calculated from eqn 17.

Table 3. Individual rate constants for different reaction paths in the Pd^{II}-$SCMCH_2$ system

Reaction path	Metal ion	Ligand	$k_{I-V} \times 10^{-2}$ (M^{-1} s^{-1})
I	$Pd(OH)^+$	LH^-	26
II	$Pd(OH)^+$	LH_2	35
III*	Pd^{2+}	LH_2	10
IV	Pd^{2+}	LH_3^+	6
V†	$Pd(OH)^+$	LH_3^+	0.09

* k_{III} was obtained by assuming that the rate of path V is negligible small.

† k_V was obtained by assuming that the rate of path III is negligible small.

The literature data suggest that an associative interchange mechanism takes place in substitution reaction of square planar hydrated Pd^{II} cation. The substitution rate is influenced by the nature of the entering ligand and a leaving ligand effect. The results presented in Table 3 show that $PdOH^+$ reacts faster with LH^- and LH_2 compared with Pd^{2+}. The enhanced reactivity of hydrolyzed species is a common feature of metal ions such as Ga^{III}, Al^{III} and Fe^{III} [11,12]. This could be explained in view of the labilising effect of OH^- on the remaining water molecules in the inner coordination sphere. From the comparison with previous results [8], it can be concluded that all ionic forms of $SCMCH_2$ react more rapidly with Pd^{2+} and $PdOH^+$ species than with $Pd(H_2O)_{4-n}Cl_n$ ($n = 1$–4), because the water can be more quickly replaced by attacking ligand than Cl^- ion.

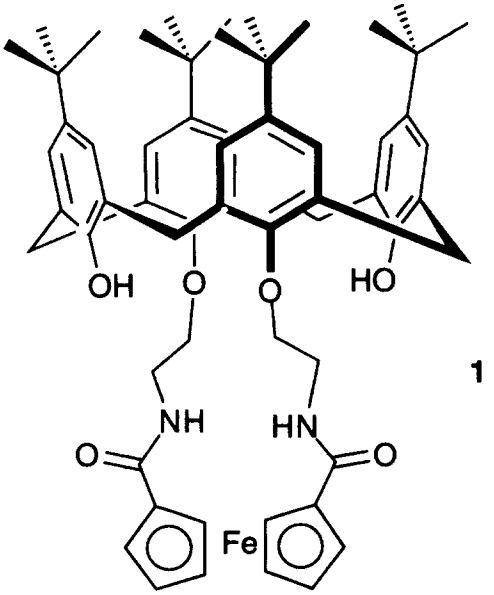
(Received 23 July 1997; accepted 16 September 1997)

Abstract—New ferrocene substituted calix[4 and 5]arenes have been prepared and the crystal structure of a lower-rim substituted bis ferrocene calix[4]arene (**7**) has been elucidated. The respective ferrocene/ferrocenium redox-couples of compounds **6** (a calix[4]arene tetra ferrocene amide) and **8** (a calix[5]arene pentaferrocene amide) are shown to be significantly cathodically perturbed in the presence of anions by up to 160 mV in the presence of dihydrogen phosphate. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: sensors; ferrocene; calixarene; anion binding; amide; electrochemistry.

Anions are ubiquitous in biological systems [1]. Many proteins contain inorganic phosphate or sulfate anions coordinated via hydrogen bonds from water, amino-acid residues or amide bonds [2]. Additionally excess phosphate pollutants in the environment cause eutrophication of rivers and inland waterways [3], whereas nitrate pollutants and their metabolites are believed to be carcinogenic [4]. There is therefore great interest in the synthesis of receptor species containing hydrogen bond donor arrays [5,6], Lewis acid centres [7] or positive charges [8,9] as sequestering agents or sensors for anions. Early work by ourselves [10–13] and others [14,15] established that amide N—H groups in acyclic synthetic receptor molecules can coordinate anions. As part of this work we demonstrated that the calix[4]arene **1**, which contains a lower-rim ferrocene amide bridge is capable of electrochemically detecting the presence of anions *via* perturbations of the ferrocene/ferrocenium redox couple [16].

As a further extension to this work we decided to synthesise a series of calixarenes containing multiple amidoferrocenyl residues at the lower rim and study these systems as potential amperometric sensors for anions.



1

RESULTS AND DISCUSSION

Syntheses

p-tert-Butycalix[4]arene tetra (acid chloride) **2**, *p-tert*-butycalix[4]arene bis (acid chloride) **3**, *p-tert*-

* Author to whom correspondence should be addressed.

butycalix[5]arene penta (acid chloride) **4** [17,18] and ferrocenemethylamine **5** [19] were synthesised *via* literature procedures. An analogous synthetic procedure was employed in the preparation of each of the new calixarene–ferrocene conjugate compounds. Typically, the calixarene acid chloride was dissolved in dry dichloromethane, a 25% excess of ferrocenemethylamine **5** and triethylamine added, and the reaction mixture stirred under nitrogen overnight, in darkness. After washing with water, drying over magnesium sulfate and removal of solvent *in vacuo*, a pale brown solid was generally produced. This was purified by column chromatography (silica support) using dichloromethane/methanol as eluent affording the *p-tert*-butycalix[4]arene tetra amidoferrocene **6** in 21% yield, the *p-tert*-butylcalix[4]arene bis amidoferrocene **7** in 29% yield and the *p-tert*-butycalix[4]arene bis amidoferrocene **8** in 16% yield (Scheme 1). The moderate yields of these reactions may be due to the incomplete reaction of the calixarene acid chlorides with ferrocenemethylamine (due to steric interactions), leading to incomplete substitution of ferrocene at the lower rim of the calixarene.

Crystallography

Diffraction quality single crystals of **7** were grown from a dichloromethane/methanol solvent mixture. The structure confirms that **7** adopts the cone conformation in the solid state (Fig. 1) with two ferrocene groups appended at the lower rim. The calixarene has usual C_2 distortion with the angles between the plane of the four methylene groups and the four phenyl rings being 44.2, 66.0, 52.9 and 70.6°, respectively. As can be seen in the figure, there is a dichloromethane molecule encapsulated within the cavity. Crystal data is given in Table 1.

Anion coordination studies: NMR titrations

^{1}H NMR titrations were carried out in dichloromethane-d_2 solutions of compounds **6, 7** and **8**. In a typical titration, 5×10^{-6} mol of receptor was dissolved in 0.5 ml dichloromethane-d_2 and equivalents of the anion added as n-$Bu_4N^+X^-$ ($X^- = Cl^-$, HSO_4^- or $H_2PO_4^-$) in dichloromethane-d_2 (0.1 mol dm^{-3}) solution. The shifts of resonances of protons involved in anion coordination were then recorded and plotted as a function of the amount of anion added. Disappointingly, in the case of **7**, no significant shifts, i.e. greater than 0.01 ppm, were observed indicating that there is little interaction between this molecule and the anionic species. Partial substitution reduces the number of amide hydrogen bond donor sites at the lower rim of **7** compared to **6** and **8**, and this may be the cause for the poor anion coordination ability of this ligand. Another possibility is that in solution, the phenolic OH groups are hydrogen bonded to the amide functionalities via either OH···O=C or HO···H—N hydrogen bonds so blocking the potential coordinating sites. This is reflected in the chemical shift of the amide resonance in the ^{1}H NMR spectrum of **7** which occurs at 8.74 ppm (i.e. it is deshielded relative to the amide protons of **6** and **8** which resonate at 7.57 and 7.42 ppm, respectively). The tetra- and penta- substituted derivatives, however, display significant downfield shifts of the amide NH proton (approximately 0.1 ppm) in the presence of anions (Figs 2 and 3). This indicates that the amide NH protons are coordinating to the added anions. Titrations with compounds **6** or **8** with chloride anions produced titration curves which could be fitted to a 1 : 1 calixarene/anion stoichiometric model. Stability constants were determined with the EQNMR computer program [20] and are shown in Table 2. Compound **6** forms a more stable complex with chloride (55 M^{-1}) than does compound **8** (15 M^{-1}). This may be due to a spacial fit effect, with chloride coordinating to the amide moieties of **6** more efficiently than to those of the calix[5]arene **8**. An adequate fit could not be obtained for the titrations of **6** and **8** against hydrogen sulfate and dihydrogen phosphate to models consistent with 1 : 1 receptor/anion stoichiometries. This may be due to the formation of complexes of other stoichiometries, or aggregation of the anions in the relatively non-polar dichloromethane solvent. Unfortunately, precipitation problems were encountered during the titration studies upon addition of higher concentrations of anions. This precluded the limiting chemical shifts of the anion complexes in these experiments from being found.

Anion coordination studies: electrochemistry

The electrochemical properties of **6, 7** and **8** were investigated using cyclic voltammetry [21] in a dichloromethane/acetonitrile (35 : 65 v/v) solvent mixture, with $(n\text{-Bu})_4NBF_4$ as the supporting electrolyte. The working electrode used was a 5 mm glassy carbon disk and the counter electrode consisted of a platinum mesh. A Ag/Ag^+ electrode was used as reference (+ 330 mV vs S.C.E.). Argon gas saturated with dichloromethane was continually bubbled through the cell to de-oxygenate the solution. It must be noted that in all cases electrochemical experimentation proved difficult with many precipitation and solubility problems encountered, as well as frequent adsorption of the oxidised species onto the electrode in the presence of anions. Each of the ligands exhibited a single quasi-reversible oxidation wave in the region 0.12 to 0.20 V (vs Ag/Ag^+) (Table 2, Fig. 4) suggesting the ferrocene moieties are behaving independently of one another and are therefore being oxidised at the same potential.

Thin layer coulometry was used to confirm that **6, 7,** and **8** are undergoing four, two and five electron oxidations, respectively. In each case, the number of electrons transferred to the compound in question was found to be approximately equal to the number of ferrocene subunits present.

iii) 6.0 $FcCH_2NH_2$, 6.0 Et_3N /CH_2Cl_2

Scheme 1.

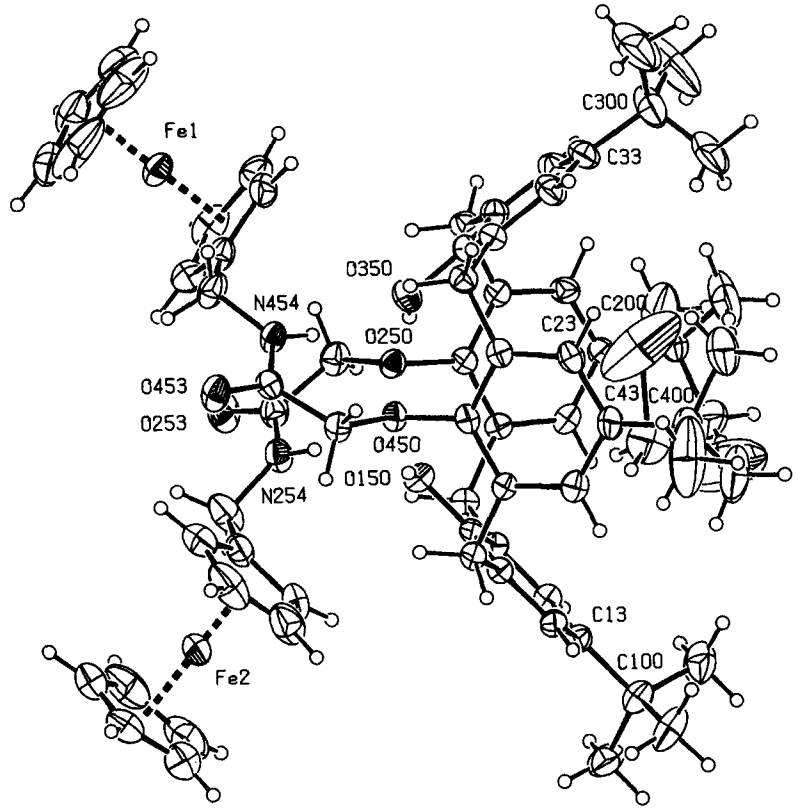

Fig. 1. The structure of **7**, with thermal ellipsoids drawn at the 30% probability level. Hydrogen atoms are included as small circles of arbitrary small radius. Intramolecular hydrogen bonds (not shown) are formed between the amide nitrogen atoms and the phenolic OH groups {N(254)···O(150) 2.98 Å, N(454)···O(350) 2.94 Å}.

Cyclic voltammograms were also recorded after progressive addition of stoichiometric equivalents of anionic guests as 0.1 M solutions of $(n\text{-}Bu_4N)H_2PO_4$, $(n\text{-}Bu_4N)HSO_4$ and $(n\text{-}Bu_4N)Cl$ in CH_2Cl_2/CH_3CN (35:65 v/v) to the electrochemical solutions of **6**, **7** and **8** (1×10^{-3} M) in CH_2Cl_2/CH_3CN (35:65 v/v), and the results are summarised in Table 3.

The addition of anions to electrochemical solutions of **6** and **8** produced cathodic shifts of the ferrocene/ferrocenium redox couple with the relative magnitudes following the order $H_2PO_4^- > Cl^- > HSO_4^-$. The most significant results were observed with compounds **6** and **8** with $H_2PO_4^-$ anions, Fig. 5. Similar results were observed with compound **1** [16].

The addition of dihydrogen phosphate anions causes a 160 mV cathodic shift in the ferrocene/ferrocenium redox couple. This large cathodic shift indicates a strong stabilisation of the oxidised forms of **6** and **8**, in the presence of dihydrogen phosphate. This may be due to dihydrogen phosphate coordination to the amide moieties of the calixarene, a consequence of suitable cavity size as defined by the pendant ferrocene amide groups. This places the anion in close proximity to the ferrocene/ferrocenium moieties, so perturbing the redox potential of these groups. No analogous result was observed with **7** (in agreement with the prior ^1H NMR titration studies).

Conclusions

In conclusion the redox-active ferroceneamide derivatised calix[4,5]arenes (**6**) and (**8**) have been shown to bind and electrochemically detect anions. The stability constants of **6** and **8** with chloride anions have been determined and found to be 55 M^{-1} and 15 M^{-1}, respectively. Compounds **6** and **8** electrochemically recognise Cl^-, HSO_4^- and $H_2PO_4^-$ anions with $H_2PO_4^-$ producing the largest shift of the ferrocene/ferrocenium redox couple (160 mV).

on a Mattson "Polaris" and Perkin Elmer "1710" Infrared Fourier Transform Spectrometers. Electrochemical experiments were conducted on a Princeton Applied Research Potentiostat/Galvanostat Model 273. Fast atom bombardment (FAB) mass spectra were carried out at the University of Wales, Swansea by the SERC/EPSRC Mass Spectrometry Service. Melting points were recorded in open capillaries on a Gallenkamp melting point apparatus and are uncorrected.

Synthesis of p-tert-butycalix[4]arenetetraferrocene-amide (**6**)

Ferrocenemethylamine (0.61 g, 2.84 mmol) was dissolved in dry CH_2Cl_2 (30 ml) and added to *p-tert*-butycalix[4]arene bis (acid chloride) (0.56 mmol). Et_3N (0.29 g, 2.87 mmol) was then added and the reaction mixture stirred under nitrogen overnight. After washing with water (4 × 25 ml), the organic layer was dried over magnesium sulfate. The solvent was then removed under reduced pressure to give a pale brown solid which was purified by column chromatography on silica gel, gradient eluting with CH_2Cl_2/MeOH (gradient elution: concentration of methanol from 0% to 5%). The product was collected, reduced *in vacuo* and then precipitated as a yellow powder from a dichloromethane/methanol solvent mixture as a yellow powder (0.2 g, 21%). ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 1.05 (s, 36H, $C(CH_3)_3$), 3.12 (d, ^2J = 12.5 Hz, 4H, $ArCH_2Ar$: H_{eq}), 4.11 (m, 8H, FcH), 4.16 (s, 20H, FcH), 4.25 (m, 8H, FcH), 4.32 (d, 8H, —$NHCH_2Fc$) and (d, 4H, $ArCH_2Ar$: H_{ax}) coincident, 4.36 (s, 8H, OCH_2), 5.31 (CH_2Cl_2), 6.72 (s, 8H, ArH), 7.57 (t, 4H, NH). ^{13}C NMR/DEPT ($CDCl_3$, 75.42 MHz) δ: 31.33 ($(CH_3)_3C$), 31.49 ($ArCH_2Ar$), 33.66 ($C(CH_3)_3$), 38.70 (—$OCH_2C(O)$—), (68.07, 68.62, 68.63, (FcH)), 74.65 ($NHCH_2Fc$), 84.93 (Fc), 125.76 (ArH), (132.72, 145.71, 152.77 (Ar)), 169.02 (C=O). Synthesis of p-tert-butylcalix[5]arenepentaferroceneamide (**8**)

Ferrocenemethylamine (0.60 g, 2.79 mmol), triethylamine (0.28 g, 2.77 mmol) and *p-tert*-butycalix[5]arene penta (acid chloride) (4.7 mmol) were dissolved in dry dichloromethane (30 ml) and the reaction mixture stirred for eighteen hours. After washing with water, the product was dried over magnesium sulfate and the solvent removed under reduced pressure to give brown/orange crystals. These were purified by column chromatography on silica gel, gradient eluting with dichloromethane/methanol. The product was collected, reduced *in vacuo*, and then precipitated as a yellow powder (0.16 g, 16%) from a dichloromethane/methanol mixture (gradient elution: concentration of methanol from 0% to 5%). ^{1}H NMR ($CDCl_3$, 300 MHz) δ: 1.02 (s, 45H, $(CH_3)_3C$), 3.31 (d, 5H, J = 14.0 Hz, $ArCH_2Ar$: H_{eq}), 4.12 (s, 10H, OCH_2), 4.17 (s, 25H, FcH), 4.24 (m, 10H, FcH), 4.26 (m, 10H, FcH), 4.27 (d, 10H, —NHCH_2), 4.47 (d, 5H, J = 14.0 Hz, $ArCH_2Ar$: H_{ax}), 6.88 (s, 10H, ArH), 7.42 (t, 5H, NH). ^{13}C NMR ($CDCl_3$, 75.42 MHz) δ: 30.02 ($ArCH_2Ar$), 31.30 ($(CH_3)_3C$), 34.05 ($(CH_3)_3C$), 38.83 (OCH_2CO), [68.14, 68.59, 68.73 (FcH)], 72.93 ($NHCH_2$), 84.93 (Fc), [126.35, 132.62, 146.11, 151.15 (Ar)], 169.01 (C=O). Microanalysis: calc. for $C_{120}H_{135}O_{10}N_5Fe_5$: C, 69.07; H, 6.52; N, 3.36 Found: C, 69.41; H, 6.75; N, 3.33. FAB MS: MH^+@2087, MNa^+@2109. Infared Data (KBr Disk): 1672 cm^{-1} (carbonyl stretch). m.p. 295°C (dec).

Crystallography

Single crystal X-ray analysis of **7** was conducted using MoKα radiation with the MARresearch Image Plate System. The crystal was positioned at 75 mm from the X-ray source. 90 frames were measured at 2° intervals with a counting time of 2 mins. Data analysis was carried out with the XDS program [22]. The structure was solved using direct methods with the Shelx86 program [23]. Apart from the substituted calixarene, there were several solvent molecules and two methanol and one dichloromethane molecules were located, though there were indications of other disordered solvent molecules. The non-hydrogen atoms were refined with anisotropic thermal parameters apart from the carbon and oxygen atoms in the solvent. All hydrogen atoms were included in calculated positions apart from those in the solvent molecules. The structure was then refined using Shelx [24], R-factors are given in Table 1. All calculations were carried out on a Silicon Graphics R4000 Workstation at the University of Reading.

Acknowledgements—We thank the EPSRC for a studentship (PAG) and the EPSRC together with the University of Reading for the provision of the image plate diffractometer.

(Received 18 June 1996; accepted 16 September 1997)

Abstract—A series of complexes of general formula $M(2\text{-}PyCO)_nX_2(H_2O)_m$ (M = Co, Cu, Zn; 2-PyCO = 2-methylpyridine-*N*-oxide, n = 1–2, X = Cl, Br, I and NO_3 and m = 0–1) has been prepared and characterised. The reactivity of these complexes with sulfur dioxide has been investigated in the solid state and in toluene slurries at room temperature. The effect of temperature on the ability of these complexes to fix SO_2 has been studied by thermogravimetrical analysis (TGA); the temperature range of study depending critically on the melting point of the initial precursors. The same technique has been used to study the reversibility of the reaction with sulfur dioxide.

The amount of sulfur dioxide fixed is dependent on the metal, the anion, the medium of the reaction and the temperature. In general, an increase in temperature results in a decrease in the reactivity of the metal precursors with SO_2 but the complexes of copper halides show that an increase in temperature favours the reaction. This is quite interesting behaviour not previously reported. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: Metals; complexes; sulfur dioxide; 2-methylpyridine-*N*-oxide; fixation; reactivity.

Sulfur dioxide is an insidious pollutant, and the main cause of acid rain. There are many methods used in industry to try to remove SO_2 from gas streams but all are relatively expensive and generate large quantities of residues. For this reason it has become necessary to search for new methods to solve the environmental problems caused by the emission of sulfur dioxide to the atmosphere. The growing magnitude of these problems, combined with the academic interest in sulfur dioxide as a ligand, due to its numerous coordination modes [1–3], has resulted in recent developments in the chemistry of SO_2 with transition metal complexes.

We have focused our attention on the reactivities of the first row transition metal complexes [4–9] with SO_2, as a means of providing a better understanding of its chemistry and to find a cheap metal-fixing precursor which could have industrial applications. As an extension of our previous paper [9a] where we have studied the reactivity of the complexes $Mn(2\text{-}PyCO)_nX_2(H_2O)_m$ with SO_2, we now report the syntheses and characterisation of mono- and bis-ligand complexes of 2-methylpyridine-*N*-oxide with cobalt, copper and zinc halides and nitrates and their reactivity with SO_2 in the solid state and in toluene slurries.

EXPERIMENTAL

Synthesis of the metal precursors

The complexes $M(2\text{-}PyCO)_nX_2(H_2O)_m$ were synthesised in absolute ethanol, using the commercial

† Dedicated to the Royal University of Santiago de Compostela in the year of its fifth century.

metal salts $CoCl_2 \cdot 6H_2O$, $CoBr_2 \cdot xH_2O$, CoI_2, $Co(NO_3)_2 \cdot 6H_2O$, $CuCl_2$, $CuBr_2$, $Cu(NO_3)_2 \cdot 3H_2O$, $ZnCl_2$, $ZnBr_2$, ZnI_2, $Zn(NO_3)_2 \cdot 6H_2O$ and the ligand 2-methylpyridine-*N*-oxide without further purification. The syntheses were performed following a method previously described [10,11] consisting of mixing the salt and the ligands in stoichiometric ratios and stirring them in ethanol at room temperature for 24 h. The isolated solids were washed with diethyl ether and dried in air. $Zn(2\text{-}PyCO)_2(NO_3)_2$ was isolated as an oil that was transformed into a powder after trituration with diethyl ether.

It must be pointed out that for most of the salts, the 1 : 2 adducts were isolated regardless of the metal : ligand ratio. $CoCl_2$ only yields the 1 : 1 adduct when it is stirred with the ligand in 1 : 2 or 1 : 4 ratios (Table 1).

Reactions with sulfur dioxide

(*i*) *Solid state at room temperature.* The SO_2-adducts were synthesised by the method previously described [9] that essentially consists of monitoring the changes in mass of a sample (0.1–0.3 g) of the complex, contained in a Rotaflo tube, when it is exposed to a sulfur dioxide stream for several days until a constant mass is achieved (ca. one week).

(*ii*) *Toluene slurries.* The method employed has been previously reported [9]. The suspension of the metal precursor in dry distilled toluene (Na, benzophenone) was saturated with sulfur dioxide until no changes in colour and/or aspect occurred (*ca.* one week). The compounds were isolated by standard Schlenk techniques and dried in a stream of argon. Full details of the synthesis have been previously described [7a].

(*iii*) *Solid state at high temperature.* The absorption of sulfur dioxide at high temperature was studied using a thermogravimetric balance CAHN Instruments TG131. The programmed scheme, already reported [9], results in an increase in temperature of the sample until its melting point is reached whilst a gas flow of 50 $cm^3\ min^{-1}$ is maintained. The uptake of SO_2 is monitored for samples (0.04–0.08 g) using a series of temperature/partial pressure programmes.

(*iv*) *High temperature SO_2 desorption.* The studies on the lability of the coordinated sulfur dioxide were performed in the same thermogravimetric balance. The sample (0.02–0.5) was heated to the melting point of the complex and maintained under a nitrogen stream for 12–24 h or alternatively heated in a Rotaflo tube to the melting point under reduced pressure for 4 h. The resultant complexes were analysed by the USC and UMIST Microanalytical Services. Infrared spectra were obtained as KBr pellets using a Bruker IFS 66 V spectrophotometer in the 2000–500 cm^{-1} range.

RESULTS AND DISCUSSION

Metal precursors

The syntheses of the metal precursors described here follows the method previously described [10,11]. All the compounds prepared are air stable but are hygroscopic, changing colour when they are stored in moist air. Some structural aspects of the compounds have been previously discussed [12–19].

Reactions with sulfur dioxide

The reactivities of the metal precursors with sulfur dioxide have been studied by methods previously described in the solid state (Tables 2 and 3) and in toluene slurries (Tables 4 and 5) at room temperature and in the solid state at high temperature [9] (Table 7). The medium and the conditions of the reaction

[a] Calculated values in parentheses.

seem to play an important role in the ability of the compounds to react with SO_2, as different adducts are obtained from the same metal precursor in the solid state at room temperature (Table 2), at high temperature (Table 7) and in toluene slurries at room temperature (Table 4).

Reactions with sulfur dioxide at room temperature

The adducts obtained from the solid state and from toluene slurries are quite different but they show some common features.

The halide derivatives of cobalt and zinc do not react with SO_2 in any of the media. Only the iodide derivatives can fix 0.25 moles of SO_2 per mole of complex in the solid state but no binding is observed in toluene slurries. This SO_2 is linked to the precursor in an irreversible manner as it is not lost upon prolonged heating at reduced pressure (Table 6). The same kind of interaction is present in the compound $Co(2\text{-}PyCO)SO_4(SO_2)_{0.25}$ that retains 0.25 moles of SO_2 when it is heated at 90°C for 4 h at reduced pressure. However, $Cu(2\text{-}PyCO)_2Cl_2(SO_2)_{0.25}(H_2O)$ loses sulfur dioxide after desorption studies. This lability and the absence in the IR spectrum of new bands associated to S—O stretches (Table 3) allow us to propose a physical rather than chemical interaction of the SO_2 present in this compound. The same kind of interaction is to be expected for the 0.25 moles of SO_2 present in the adducts $Cu(2PyCO)_2SO_4(SO_2)_{1.75}(H_2O)_3$ and $Zn(2PyCO)_2SO_4(SO_2)_{1.75}(H_2O)_2$.

For all of the nitrate derivatives it was observed that the replacement of the nitrate group by a sulfate group occurs. This sulfate group probably comes from the oxidation of one molecule of SO_2, perhaps at the expense of the reduction of the nitrate group to nitrogen oxides, in agreement with previous results [8–9]. The presence of the sulfate groups is confirmed by new IR bands in the ranges 885–870 and 642–588 cm^{-1}. Such bands are characteristic of the sulfate group acting as a bidentate chelate [20], as is expected for a sulfate group resulting from a sulfur dioxide oxidation process [2,21]. The ν(NO) and δ(NO) for the 2-methylpyridine-*N*-oxide in the new adducts were assigned in the ranges 1201–1198 and 841–830 cm^{-1}, respectively, and are not significantly different from those of the metal precursors.

Reactions with sulfur dioxide in the solid state at room temperature

Although there are many binding modes established [3] for SO_2 (η^1-S pyramidal, η^1-S planar, η^1-O, η^2-S,O bridge, ligand bound or insertion) some of them have a low probability of existence in the complexes studied here. The η^1-S pyramidal coordination mode is quite unusual in first row transition metal complexes, but very common in the adducts of second and third row transition metals [3]. The η^1-O coordination mode has not been found for transition metals [22–23]. Consequently, the η^1-S pyramidal and η^1-O binding modes are quite improbable for the first row complexes studied here.

IR spectra

Although Kubas [3] has tried to correlate the S—O stretching frequencies with the coordination mode of the sulfur dioxide in adducts of SO_2. IR spectroscopy alone is not able to establish the binding mode. A good complement to this technique is the study of the reversibility of the reaction.

All the nitrate derivatives absorb one mole of SO_2 that is oxidised to sulfate and replaces the nitrate group as was discussed. However, all of them can fix an additional quantity of sulfur dioxide (1–1.75 moles) the IR spectra show new bands in the regions 1095–1080 and 1310 cm^{-1}. These bands are not possible for the η^2-S,O and η^1-O and S-bridge binding modes; furthermore the η^1-S pyramidal coordination mode is quite improbable (see above) and insertion is not possible as there are no metal–carbon or metal–halide bonds. So the compounds can only represent either a η^1-S planar or ligand bound binding modes. IR spectroscopy does not distinguish between these coordination modes but the studies on the reversibility of the reaction allow us to discern between them.

A different binding mode seems to be present in $Cu(2\text{-}PyCO)_2Br_2(SO_2)_{0.66}$, which has an IR band at 1113 cm^{-1}. This information alone is not enough to establish the coordination mode for the SO_2 but the similarity with other well characterised compounds [24] allows us to propose a trinuclear structure with the SO_2 acting as a bridge.

Desorption studies

The desorption studies are very useful, in combination with IR spectroscopy and analogy with other well characterised complexes, to determine the possible binding mode of sulfur dioxide in SO_2-adducts. In general, only when the SO_2 presents a η^1-S pyramidal or ligand bound mode is it labile in contrast with the η^1-S planar or S-bridge coordination modes [3].

Most of the adducts link at least one part of the sulfur dioxide in a reversible way but many of them present more than one binding mode and part of the SO_2 is retained in the adduct upon an increase in temperature.

The only compound that fixes all the sulfur dioxide irreversibly is $Co(2\text{-}PyCO)_2I_2(SO_2)_{0.25}(H_2O)_2$ (Table 6). This fact indicates that the SO_2 is no simply physically absorbed or housed within cage-like structures, so the interaction should be chemical, as previously proposed. $Cu(2\text{-}PyCO)_2Cl_2(SO_2)_{0.25}(H_2O)$ loses sulfur dioxide when it is heated (Table 6). This behaviour is

in accord with the proposed physical absorption of the SO_2.

All of the sulfate derivatives, obtained from the nitrate precursors by oxidation of one mole of SO_2, fix an additional quantity of SO_2, part of it in a reversible way. $Zn(2\text{-}PyCO)_2SO_4(SO_2)_{1.75}(H_2O)_2$ seems to bind the SO_2 in many ways. This adduct loses 1.25 moles of sulfur dioxide upon an increase in temperature (see Table 6). Perhaps 0.25 moles are physically absorbed while 1 mole is labile and the IR band at 1080 cm^{-1}, seems to suggest that it is ligand bound. The irreversibility of the reaction suggests that the 0.5 moles of SO_2 that remain in the adduct is in the form of S-bridge.

The same binding modes can be proposed for $Cu(2\text{-}PyCO)_2SO_4(SO_2)_{1.75}(H_2O)_3$, which loses 1.25 moles of SO_2 when it is heated (Table 6), and the presence of an IR band at 1310 cm^{-1} is in accord with the $\nu_{as}(SO)$ for a molecule of SO_2 binding in a ligand bound mode. In the case of $Co(2\text{-}PyCO)_2SO_4(SO_2)(H_2O)_2$, a band at 1095 cm^{-1} suggests again a ligand bound mode for the coordinated sulfur dioxide.

The desorption of $Cu(2\text{-}PyCO)_2Br_2(SO_2)_{0.66}(H_2O)_3$, shows that part of the sulfur dioxide is lost, giving a compound with elemental analysis corresponding to the empirical formula $Cu(2\text{-}PyCO)_{1.5}Br_2(SO_2)_{0.5}(H_2O)_2$. This result shows that the SO_2 is partially lost and it differs from the behaviour found for other adducts of stoichiometry 1 : 0.66, that fix all the sulfur dioxide in an irreversible way [24]. The desorption studies and the IR data do not correspond with any of the binding modes previously described and it appears that more than one binding mode is present in this adduct.

Reactions with sulfur dioxide in toluene slurries

Most of the precursors lose one mole of 2-methylpyridine-*N*-oxide when they react with sulfur dioxide in toluene slurries. This fact has been previously observed by Schenk and Conway [25,26] indicating that there is a substitution of sulfur dioxide for the ligand.

Infrared spectra

All the SO_2-adducts exhibit new bands between 2000–500 cm^{-1} assignable to S—O vibrations.

The nitrate derivatives fix SO_2 replacing the nitrate group by a new sulfate ligand. The $Co(2\text{-}PyCO)SO_4(SO_2)_{0.25}$ presents a band at 1080 cm^{-1}. This IR band seems to indicate a chemical rather than a physical interaction for the 0.25 moles of SO_2.

$Cu(2\text{-}PyCO)SO_4(SO_2)_{0.5}$ has a band at 1069 cm^{-1} associated with the 0.5 moles of SO_2. The frequency of this band is in accordance with a S-bridge binding mode for the sulfur dioxide [27].

The $Zn(2\text{-}PyCO)SO_4(SO_2)$ shows a very strong band at 1250 cm^{-1}. This value, and the fact that one molecule of 2-methylpyridine-*N*-oxide is replaced, suggests a η^1-*S* planar coordination mode for the SO_2, in accordance with the results previously found by Schenk and Conway [25,26].

The comparison of the IR spectrum of $Cu(2\text{-}PyCO)_2Br_2(SO_2)(H_2O)_3$, which has a band at 1240 cm^{-1}, with the IR spectrum of $Zn(2\text{-}PyCO)SO_4(SO_2)$, shows that the sulfur dioxide is also binding in a η^1-S planar mode in this compound.

Desorption studies

Most of the metal precursors link the sulfur dioxide in an irreversible way. This clearly demonstrates that the behaviour of the precursors towards sulfur dioxide is different in the solid state and toluene slurries.

$Co(2\text{-}PyCO)SO_4(SO_2)_{0.25}$ does not lose the sulfur dioxide when it is heated and this behaviour is similar to that found for $Co(2\text{-}MePyO)_2I_2(SO_2)_{0.25}(H_2O)_2$, obtained in the solid state. So the irreversibility of the reaction indicates that the sulfur dioxide is chemically absorbed but the data are not enough to predict the binding mode.

In $Cu(2\text{-}PyCO)_2Br_2(SO_2)(H_2O)_2$ and $Cu(2\text{-}PyCO)SO_4(SO_2)_{0.5}$ the sulfur dioxide is fixed irreversibly. This behaviour reinforces the η^1-S planar and S-bridge binding modes proposed on the basis of the IR bands.

Different behaviour is shown by $Cu(2\text{-}PyCO)_2Cl_2(SO_2)_{0.66}(H_2O)_2$, that only fixes one part of the SO_2 in an irreversible way (Table 6). The band at 1281 cm^{-1} is absent from the IR spectrum of the compound obtained after desorption. This suggests that part of the sulfur dioxide is present in the ligand bound mode. These desorption studies, in conjunction with the IR spectrum indicate that the binding mode in this compound must be the same as that present in the adduct $Cu(2\text{-}PyCO)_2Br_2(SO_2)_{0.66}(H_2O)_3$, obtained from the solid state.

Reactions with sulfur dioxide at high temperature

The interaction of the precursors with sulfur dioxide at high temperature has been performed in a thermogravimetric balance TG-131 CAHN. These thermogravimetric analyses are particularly useful because it is possible to study the thermal stability of the metal precursor and the optimum temperature range over which SO_2-absorption occurs. It must be pointed out that only the nitrate and the halide derivatives of copper react with SO_2 at a temperature higher than the room temperature. All the halide derivatives of cobalt and zinc show similar behaviour and they do not react at higher temperatures (Fig. 1).

The behaviour of the chloride and bromide derivatives of copper is quite interesting. $Cu(2\text{-}PyCO)_2Cl_2$ can fix one mole of SO_2 when it is exposed to a sulfur dioxide stream in the 150–30°C temperature range for 3h 10 min (Fig. 2) but only 0.25 moles when it is maintained in contact with sulfur dioxide for one week

at room temperature. In the same way $Cu(2\text{-}PyCO)_2Br_2(H_2O)_3$ retains 0.75 moles of sulfur dioxide per mole of precursor in the 120–30°C temperature range but only 0.66 moles at room temperature. This fact is quite important as it implies that the increased temperature favours the reaction, in contrast with the behaviour observed for other metal precursor [8,9].

The nitrate derivatives of cobalt and zinc show similar behaviour. One mole of 2-methylpyridine-*N*-oxide is displaced by a mole of SO_2 which is oxidized to sulfate. This reaction occurs at the maximum temperature permitted by the melting point of the precursor and the generated adduct cannot bind more sulfur dioxide even when the temperature is decreased to 30°C (Fig. 3).

$Cu(2\text{-}PyCO)_2(NO_3)_2$ seems to be more stable towards increasing temperature as it does not lose ligand at a temperature lower than 150°C. However, the compound is unreactive towards SO_2 at a temperature higher than 120°C. Between 120–100°C, the metal precursor binds two moles of sulfur dioxide, one of which is oxidised to sulfate. The compound is saturated at the temperature of 100°C and cannot fix any more sulfur dioxide even when the temperature is decreased to 30°C (Fig. 4).

As a result of this study we can say that the copper derivatives are more thermally stable and show more ability to bind sulfur dioxide at higher temperatures than the cobalt and zinc analogues. Furthermore the reactivity of the halide derivatives of copper is favoured by an increase in temperature.

(Received 4 June 1997; accepted 10 September 1997)

Abstract—The complexes $[Ph_4As]_2[V_2O_3(NO_3)_6]$, **1** and $[Ph_4As]_2[V_2O_3Cl_4(NO_3)_2]$, **2**, crystallise from solution in the reaction of tetraphenylarsonium nitrate with $VO(NO_3)_3$ and $VOCl_3$, respectively. The compounds were characterised by their IR and Raman spectra and single crystal X-ray analysis. Compound **1** crystallises in the triclinic space group $P\bar{1}$, $a = 9.580(1)$, $b = 10.782(2)$, $c = 13.631(2)$ Å, $Z = 1$ and $R = 0.059$, whilst **2** crystallises in the monoclinic space group $P2_1/c$, $a = 10.176(1)$, $b = 17.691(2)$, $c = 13.955(2)$, $Z = 2$ and $R = 0.034$. The crystal structures show that the dianions are related, the vanadium atoms in both species possess distorted octahedral symmetry, this being achieved by one terminal and one bridging oxygen atom, one bidentate nitrate group and four other monodentate ligands. An unusual feature of **1** is the presence of both monodentate and bidentate modes of nitrate coordination whilst **2** is the first example of a mixed halonitrato species of vanadium(V) to be isolated. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: tetraphenyl-arsonium salts; monodentate; bidentate; halonitrato.

Although the aqueous chemistry of vanadium(V) has been extensively studied [1] few examples of anhydrous nitrates of vanadium(V) are known; only trinitratooxovanadium(V) [2], nitratodioxovanadium (V) [3], the acetonitrile adduct of trinitratooxovanadium(V) [4] and the tetravanadium(V) crown anion, $[V_4O_8(CH_3CO_2)_4(NO_3)]^{-1}$ [5], have been reported, the latter two examples being the only species to have been studied crystallographically.

Trinitratooxovanadium(V), a viscous yellow liquid, was the first reported anhydrous nitrate of vanadium(V) [2]. The vanadium atom is believed on the basis of spectroscopic evidence to be seven coordinate, all nitrate groups coordinating in a bidentate manner. This was followed by the isolation of its monoacetonitrile adduct by Sutton and co-workers [4] in which vanadium is coordinated by oxygen, two bidentate and one monodentate nitrates and a nitrile ligand. Examples of complexes containing both monodentate and bidentate modes of nitrate coordination are rare [4,6,7]: X-ray diffraction analysis of compound **1** has demonstrated it to be a new example of such a complex [8]. Nitratodioxovanadium(V) was reported by Panontin *et al.* [3]; the species was only poorly characterised and may not be stable at ambient temperature. Several other nitrato and mixed halonitrato species have been characterised only in solution by NMR spectroscopy [9–11]: one of these, $V_2O_3(NO_3)_4$, is a dimeric species and is thus related to the two new dianions which have now been characterised for the first time.

RESULTS AND DISCUSSION

Syntheses of $[Ph_4As]_2[V_2O_3(NO_3)_6]$ **1** *and* $[Ph_4As][V_2O_3Cl_4(NO_3)_2]$ **2**

The reaction of trinitratooxovanadium(V) with tetraphenylarsonium nitrate in acetonitrile generates the vanadium(V) compound **1**, according to eqn (1).

$$2VO(NO_3)_3 + 2Ph_4AsNO_3 \rightarrow [Ph_4As]_2[V_2O_3(NO_3)_6] + N_2O_5 \quad (1)$$
$$\downarrow$$
$$N_2O_4 + \tfrac{1}{2}O_2$$

The reaction was carried out under rigorously anhydrous conditions owing to the extreme moisture-sensitive nature of the $VO(NO_3)_3$ starting material. A colour change from yellow to orange is observed on reaction and an atmosphere of brown NO_2 gas is observed above the reaction solution (presumably derived from the decomposition of N_2O_5). When the orange solution was gradually diluted with $CFCl_3$, by vapour phase diffusion, orange plate-shaped crystals of **1** were formed.

The analogous reaction of $VOCl_3$ yields two vanadium(V) compounds, eqn (2). The reaction solution, initially dark red owing to the presence of the $VOCl_3 \cdot 2MeCN$ adduct [17], was concentrated and then diluted with $CFCl_3$ by slow vapour phase diffusion. The solution

$$3VOCl_3 + 5Ph_4AsNO_3 \rightarrow 3[Ph_4As][VO_2Cl_2] + [Ph_4As]_2[V_2O_3Cl_4(NO_3)_2] + 2NO_2Cl + NOCl + Cl_2 \quad (2)$$

gradually decolourised and block shaped crystals of two different colours were produced, the major component being yellow and the minor purple. The yellow crystals were identified as $[Ph_4As][VO_2Cl_2]$, a species first isolated by Dehnicke [14], and the purple crystals were characterised as compound **2**.

Crystal structures of compounds **1** *and* **2**

Table 1 lists selected bond lengths and angles for the anion in compound **1**. The structure of **1** comprises dimeric $[(NO_3)_3(O)VOV(O)(NO_3)_3]^{2-}$ anions possessing crystallographic C_i symmetry, see Fig. 1, and tetrahedral Ph_4As^+ cations in general positions. Each vanadium atom is six coordinate and the approximately octahedral coordination is achieved by one monodentate and two bidentate nitrate groups, one terminal and one bridging oxo ligand. The latter, O(2), is disordered with equal probability over two positions related via the inversion centre. The reason for this disorder is not clear, there being no obvious chemical basis for this behaviour. It may be an artefact of the constraints induced by crystal symmetry requirements. This disorder is probably responsible for the enhanced thermal motions of other atoms in the anion especially those in the coordination sphere of vanadium.

The small bite of the bidentate nitrate group, O(31)—V—O(32) bond angle, 57.5°, gives rise to a distorted six-fold coordination around vanadium. This characteristic of bidentate nitrate coordination has been well documented [12], and other examples of distorted octahedral coordination can be observed in $[NO^+]_2[Cr(NO_3)_5]$ [6] and $[Ph_4As]_2[Ni(NO_3)_4]$ [6]. A further characteristic of bidentate nitrate is its ability to coordinate either in a symmetrical or an unsymmetrical fashion; the latter is said to occur [12] when there is a small but real difference, 0.2–0.7 Å, between the distances of the metal atom from the two coordinated oxygens of the nitrate group: in **1** the difference between the V—O distances is 0.35 Å and is thought to arise from the strong *trans* effect exerted on the V—O(32) bond by the terminal oxygen atom O(1).

The N—O bond lengths present in both the monodentate and bidentate nitrate groups are consistent with reported literature values [12]. The terminal V—O bond length of 1.555 Å is consistent with those observed in $VO(NO_3)_3 \cdot MeCN$ [4], $[Ph_4As][VOCl_4]$ [13], and $[Ph_3PMe][VO_2Cl_2]$ [14]. The bridging V—O bond lengths, of approximately 1.8 Å, are comparable to those observed in the tetranuclear vanadium species $[Ph_4As][V_4O_8(CH_3CO_2)_4(NO_3)]$ [5] and $[n\text{-}Bu_4N][V_4O_6F(PhPO_3)_4]$ [15].

Table 2 lists selected bond lengths and angles for the anion in compound **2**. The structure consists of an ionic lattice of tetraphenylarsonium cations and binuclear vanadium anions, $[(NO_3)Cl_2(O)VOV(O)Cl_2(NO_3)]$, Fig. 2. The anions possess crystallographic symmetry C_i. As in **1** the coordination sphere of each vanadium atom is severely distorted from octahedral being coordinated by two chlorides, one terminal and one bridging oxygen atom and one bidentate nitrate group. The bite of the bidentate nitrate group, O(11)—V—O(12) bond angle, 56.7°, is similar to that in **1**. The bidentate nitrate group coordinates in an unsymmetrical fashion, the V—O(11) and V—O(12) bond lengths differing by 0.32 Å; this is attributable to the *trans* effect of atom O(1) on the V—O(12) bond. The bridging oxygen atom O(2) is disordered with equal probability over two positions related via the inversion centre.

The V—Cl bond lengths in the anion, 2.27 and 2.29 Å, are comparable with those observed in $[Ph_4As][VOCl_4]$ [13] and $[Ph_3PMe][VO_2Cl_2]$ [14]. The terminal and bridging oxygen bond lengths together with those of the bidentate nitrate group are also fully consistent with literature examples [4,5,12–15]. An interesting feature of **2** is the presence within the coordination sphere of each vanadium atom of both chloride and nitrate as ligands. Chloride, a soft base, and nitrate, a harder base, are rarely observed together as ligands on a given metal. Vanadium(V) is considered a hard acid owing to its high oxidation state, small size and high positive charge density but may be stabilised by ligands such as O, F, Cl and NO_3. To our knowledge compound **2** is the first mixed chloronitrato species of vanadium(V) and, in the wider context, represents the first mixed halonitrato species of vanadium(V) to be isolated.

Infrared and Raman spectra of **1** *and* **2**

The infrared and Raman spectral bands of these compounds in the solid state, together with proposed assignments, are listed in Tables 3 and 4. Bands arising from the tetraphenylarsonium cation have been omitted and vibrational mixing and coupling effects are not discussed. No Raman polarisation data could be collected on either compound owing to their rapid decomposition in solution in acetonitrile. The presence of one bidentate and two crystallographically inequivalent monodentate nitrate ligands in the anion $[V_2O_3(NO_3)_6]^{2-}$ increases the complexity of its vibrational spectrum and assignment of the Raman bands arising from the vibrations of the unsymmetrically bidentate nitrate ligands on the basis of polarisation and band intensity criteria [12] is not applicable here.

In the 1500–1600 cm^{-1} region the antisymmetric stretch of the monodentate nitrate ligand, $\nu_{as}(NO_2)$, is assigned at a higher wave number than the terminal N=O stretch, ν(NO), of the unsymmetrically bidentate nitrate groups in both compounds. In the 1200 to 1300 cm^{-1} region the more intense band, appearing

at 1287 cm^{-1} in the Raman effect, is assigned to $\nu_s(NO_2)$ of the monodentate ligands. The lower intensity band, appearing at 1265 cm^{-1}, is assigned to $\nu_{as}(NO_2)$ of the bidentate ligand. Not only are the bonds giving rise to the vibrations in question, shorter for the monodentate nitrate ligands, adding weight to their assignment at higher frequency but, as the stretching mode of the monodentate nitrate group in this region is symmetric, it would be expected to give rise to a band of greater intensity in the Raman effect than the antisymmetric stretch of the bidentate nitrate ligand. The Raman band at 1287 cm^{-1} is not evident in the infrared, but the infrared band at 1265 cm^{-1} is very intense, supporting its assignment as an antisymmetric stretch.

The band appearing at 1012 cm^{-1} in the Raman spectrum is assigned to $\nu(NO)$ of the monodentate nitrate group, as this band is absent from the spectra of the anion $[V_2O_3Cl_4(NO_3)_2]^{2-}$ (Table 4). The high intensity of this band is also consistent with the intensity criterion for monodentate nitrate coordination [12]. The band occurring at 962 cm^{-1} in the Raman spectrum (958 cm^{-1}, i.r.) is assigned as $\nu(V{=}O)$, consistent with a similar infrared band observed for the chloronitrato-dimer $[V_2O_3Cl_4(NO_3)_2]^{2-}$ and with reported values for species such as $[VOCl_4]^-$ [13] and $[VO_2Cl_2]^-$ [14]. The band at ca 925 cm^{-1} in the vibrational spectra of both dimers is assigned to $\nu_s(NO_2)$ of bidentate nitrate.

A variety of low intensity bands is present in the 700 to 800 cm^{-1} region of the Raman spectrum, although some of these are obscured in the infrared owing to overlap with more intense cation bands. $\delta_s(NO_2)$, $\delta_{as}(NO_2)$ and $\pi(NO_3)$ modes for both monodentate and bidentate nitrate groups are expected in this region as well as $\nu_{as}(VOV)$ [16]. With so many possibilities, no firm assignments have been attempted.

The rather broad band at 494 cm^{-1} is assigned to $\nu_s(VOV)$ [16]. This feature is probably obscured in the Raman spectrum of $[V_2O_3Cl_4(NO_3)_2]^{2-}$ (Table 4) by the more intense $\nu_s(VCl_2)$ so no direct comparison with the latter anion can be made. A very broad feature centred around 346 cm^{-1} (Raman), which appears to consist of a number of overlapping bands, and bands occurring at even lower wave numbers are attributable to vibrational modes such as V—O stretches associated with both mono- and bidentate nitrate groups and deformations of terminal V=O and bridging V—O—V bonds. Vibrational coupling of these low frequency modes will further complicate this region.

Nitrate band assignments for compound **2** (Table 4) are simplified since there is only one unsymmetrically bidentate group. The infrared band at 960 cm^{-1} is assigned to $\nu(V{=}O)$ on similar grounds to those given for compound **1**. The reason for the absence of this band from the Raman spectrum is unclear. The same observations as were made on the 700–800 cm^{-1} region for compound **1** also apply here.

The intense Raman bands at 473 and 319 cm^{-1} are assigned to $\nu_s(VCl_2)$ and $\delta(OVCl)$, respectively. Similar bands can be observed in the spectra of $[VOCl_4]^-$ [13] and $[VO_2Cl_2]^-$ [14]. The $\nu_s(VCl_2)$ band is somewhat broad and may overlap the corresponding antisymmetric mode. A further vibrational mode which may possibly contribute to the broadness of this band is $\nu_s(VOV)$, which is reported [16] to occur in the 500 cm^{-1} region (cf. the band at 494 cm^{-1} in the Raman spectrum of compound **1**). A number of weak bands is observed below 400 cm^{-1}: the comments given for similar bands of compound **1** apply here.

Nuclear magnetic resonance studies of **1** *and* **2**

Compounds **1** and **2** were studied in solution by ^{51}V NMR; rapid decomposition was observed in acetonitrile solution for both species resulting in the production of multiple resonances. In both instances, over a period of hours one resonance grows in intensity at the expense of all the others. For compound **1** the singlet finally observed occurred at −543 ppm, close to the resonance first observed by Hibbert [10], who assigned it to the monomeric vanadium(V) oxonitrato species, $[VO_2(NO_3)_2]^-$. For **2** the resonance finally observed occurred at −364 ppm close to that reported by Dehnicke [14], who assigned it to the dichlorodioxovanadate(V) anion, $[VO_2Cl_2]^-$. The stability of both compounds **1** and **2** appears to be confined to the solid state, each appearing to be the most favoured crystalline form to be generated from a complex mixture under favourable conditions.

EXPERIMENTAL

Reagents

Yellow trinitratooxovanadium(V) was prepared by the reaction of V_2O_5 with N_2O_5 using a published method [2]; the purity of the product was determined by titration with potassium manganate(VII) (for vanadium after reduction to V(IV)) and by a Kjeldahl determination for nitrogen. Trichlorooxovanadium(V) (Aldrich, 99%) was purified by distillation. Tetraphenylarsonium nitrate was produced in quantitative yield by the decomposition of $Ph_4AsCl \cdot HCl \cdot 2H_2O$ *in vacuo* at 423 K, followed by a heterogeneous reaction with excess liquid N_2O_4. Dinitrogen tetroxide (British Oxygen Co. Ltd, >99%) was purified by vapour phase distillation through molecular sieve (grade 3A, Aldrich) to reduce the water content to 0.02 wt% as determined by ^1H FT NMR spectrometry [18]. Recrystallisation of the tetraphenylarsonium nitrate from ethanol (AR grade)/ether (AR grade) then drying *in vacuo* at 423 K yielded the pure product. Acetonitrile (99%, Aldrich) was dried over molecular sieve (grade 4A), refluxed with calcium hydride and fractionated before use. Fluorotrichloromethane (99+%, Aldrich) was dried over molecular sieve (grade 3A) and distilled.

Spectroscopic measurements

Infrared spectra were recorded on a Nicolet 205 FT-IR spectrometer with samples as nujol mulls placed between AgCl windows, KBr was not used to avoid halide-nitrate exchange between window and compound. Raman spectra were recorded on a Perkin-Elmer System 2000 NIR FT-Raman spectrometer with samples contained in sealed glass capillaries under an inert nitrogen atmosphere. NMR spectra were recorded on a Bruker WM250 spectrometer at 65.79 MHz for ^{51}V; trichlorooxovanadium(V) was used as the external standard.

Preparation of $[Ph_4As]_2[V_2O_3(NO_3)_6]$ **1**

To a solution of trinitratooxovanadium(V) (0.504 g, 0.002 mol) in acetonitrile (1.502g, 0.037 mol) was added tetraphenylarsonium nitrate (0.902 g, 0.002 mol) in acetonitrile (9.598 g, 0.234 mol). An immediate colour change from yellow to orange was observed. The reaction solution was then reduced to low volume by removal of solvent *in vacuo*. Gradual addition of $CFCl_3$ by vapour phase diffusion yielded orange crystals of **1**. Yield: 0.970g (75%) (Found: C, 44.4; H, 3.1; N, 6.2. $C_{48}H_{40}As_2N_6O_{21}V_2$ Requires: C, 44.7; H, 3.1; N, 6.5%).

Preparation of $[Ph_4As]_2[V_2O_3Cl_4(NO_3)_2]$ **2**

To a solution of trichlorooxovanadium(V) (0.450 g, 0.0026 mol) in acetonitrile (2.656 g, 0.065 mol) was added tetraphenylarsonium nitrate (1.114 g, 0.0025 mol) in acetonitrile (6.056 g, 0.1475 mol). The reaction solution was then reduced in volume by removal of solvent *in vacuo*. Gradual addition of $CFCl_3$ by vapour phase diffusion yielded yellow crystals of $[Ph_4As][VO_2Cl_2]$, Yield: 0.672g (80%) (Found: C, 53.7; H, 3.7; Cl, 13.7. $C_{24}H_{20}AsCl_2O_2V$ Requires: C, 53.6; H, 3.6; Cl, 13.2%) and purple crystals of **2**. Yield 0.135g (22%) (Found: C, 49.0; H, 3.36; Cl, 11.9; N, 2.15. $C_{48}H_{40}As_2Cl_4N_2O_9$ Requires: C, 48.7; H, 3.4; Cl, 12.0; N, 2.4 %).

X-Ray crystallography—data collection and processing

Crystal data and experimental details of the samples are given in Table 5.

Compound **1**. Intensities were collected using a Rigaku AFC6S 4-circle diffractometer at 293 K using graphite monochromated Mo–K_α radiation ($\lambda = 0.71073$ Å). The crystal was sealed in a glass capillary, crystal dimensions being $0.54 \times 0.30 \times 0.13$ mm. The cell parameters were obtained from 24 reflections $13.3 < \theta < 16.0°$. The intensities of three standard reflections, monitored every 150 intensity scans remained unchanged with only statistical fluctuations, 5360 reflections of which 4551 were unique ($R_{int} = 0.017$), were measured by ω scans $2\theta \leqslant 50°$. An analytical absorption correction [19] was applied giving $T_{max} = 0.749$, $T_{min} = 0.611$, in good agreement with T_{max}: T_{min} ratio of 0.794, estimated from 108 ψ-scans of three reflections. The structure was solved by direct methods (SHELX) [20], 361 variables being refined in a full-matrix least-squares calculation against F^2 of all data employing a two term Chebyshev weighting scheme using SHELXL-93 [21]. The final $wR(F^2)$ for all data being 0.129, $R(F)$ for 2753 data

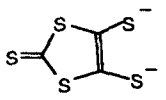
(Received 15 July 1997; accepted 5 September 1997)

Abstract—The lanthanide complexes of general formula $K_2[Ln(dmit)(phen)_2Cl_3]\cdot 6H_2O$ (Ln = La, Nd, Sm, Gd, Er, Y; $dmit^{2-}$ = 1,3-dithiole-2-thione-4, 5-dithiolate anion; phen = 1,10-phenanthroline) have been prepared and characterized by means of elemental anlaysis, IR spectra, electronic spectra and conductivity measurements. These complexes behave as insulators at 25°C as compacted pellets. On doping iodine into the complexes, they have been partially oxidized to afford $K_2[Ln(dmit)(phen)_2Cl_3]\cdot Ix$ (Ln = La, $x = 3.5$; Ln = Er, $x = 3.0$), whose electrical conductivities are raised to the range of semi-conductors. The nature of the iodine species in these solids is determined by UV–visible and resonance Raman spectroscopies. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: Lanthanide; $dmit^{2-}$; phen.

Considerable effort has been devoted to the preparation and study of conducting molecular solids and, in particular, the development of "molecular metals" and superconductors. Among the materials of interest in this connection, $[M(dmit)_2]^{n-}$ anion salts ($dmit^{2-}$ = 1,3-dithiole-2-thione-4,5-dithiolate anion, Scheme 1) have attracted much attention, because the electrical conductivities of some complexes are very high [1,2]. In particular, $TTF[Ni(dmit)_2]_2$ (TTF = tetrathiafulvalene) was reported to become a superconductor at low temperature [1]. An important goal of this research has been the understanding of the role of the intermolecular and intramolecular interactions in determining the electrical properties of this most unusual class of molecular solids.

To date, the research on the metal complexes of the $dmit^{2-}$ ligand mostly concentrated on the transition metals. One part of the research is the metal complexes with both a $dmit^{2-}$ ligand and an N_2 chelate ligand containing a pyridyl or related ring. Such complexes were reported to exhibit an intramolecular ligand-to-ligand charge transfer [3–5].



Scheme 1.

While the coordination properties and conductivities of $dmit^{2-}$ ligand with lanthanide elements have never been reported. Recently, we examined the reaction of lanthanide $dmit^{2-}$ with 1,10-phenanthroline, and the partial oxidation of the mixed-ligand complexes with iodine. In addition, we investigated the electrical conductivities of all these compounds.

EXPERIMENTAL

Reagents

The potassium salt K_2dmit is prepared following the method of Steimecke and co-workers [6]. 1,10-phenanthroline was purchased from BJCRF (China). Hydrated lanthanide chlorides were prepared by dis-

* Author to whom correspondence should be addressed.

solving the Anala R Ln_2O_3 (Ln = La, Nd, Sm, Gd, Er, Y) in 1 : 1 hydrochloric acid. All other chemicals were of A. R. grade. All reactions were carried out under inert atmosphere conditions.

Synthesis of the $K_2[Ln(dmit)(phen)_2Cl_3]\cdot 6H_2O$ *complexes (Ln = La, Nd, Sm, Gd, Er, Y)*

To the mixed methanol solution (2 cm^3) of $LnCl_3\cdot 6H_2O$ (Ln = La, Nd, Sm, Gd, Er, Y) (0.1 mmol) and 1,10-phenanthroline (0.2 mmol) was added dropwise a methanol solution of 0.1 mmol K_2dmit (1 cm^3) to give an orange precipitate of $K_2[Ln(dmit)(phen)_2Cl_3]\cdot 6H_2O$ immediately. The solid complex was collected by centrifuging, washed with methanol and dried under vacuum over P_2O_5. Yields were ca 60%. All the complexes are powdered solids and stable in air.

Iodine oxidation

Finely powdered $K_2[Ln(dmit)(phen)_2Cl_3]\cdot 6H_2O$ (Ln = La, Er) (0.05 mmol) were suspended in a hexane solution (30 cm^3) containing 0.1 mmol iodine. The solution was stirred at room temperature for 24 h to give an iodine-doped complex, which was washed with hexane (2 cm^3) several times, collected by centrifuging, and dried *in vacuo*.

Elemental analyses for $K_2[Ln(dmit)(phen)_2Cl_3]\cdot 6H_2O$ and the iodine-doped complexes are summarized in Table 1.

Chemical and physical measurements

The metal ion was determined by EDTA titration using Xylenol-orange as an indicator. Carbon, nitrogen and hydrogen were determined using an Elementar Vario EL (see Table 1). The IR spectra were recorded in the 4000–200 cm^{-1} region using KBr pellets and a 170 SX FTIR spectrometer (see Table 2). Electronic spectra were recorded on a Shimadzu UV-260 spectrophotometer in the 300–700 nm region in the DMF solution (see Table 3), and the powder electronic reflectance spectra were measured on a Shimadzu UV-240 spectrometer in the 300–700 nm region. Conductivity measurements were carried out with a DDS-11A type conductivity bridge using 10^{-3} $mol\cdot cm^{-3}$ solution in DMF at 25°C. Thermal analyses (TG and DTA) were performed on a Beijing PCD-2 thermobalance using about 10 mg powder sample and working at a heating rate of $10°C\cdot min^{-1}$ in static air. Low frequency (80–300 cm^{-1}) resonance Raman spectra were obtained using a SPEX 1403 Laser Raman spectrometer. Electrical conductivities were estimated on compressed pellets by the conventional two-probe technique [7].

RESULTS AND DISCUSSION

Composition of the complexes

Air-stable solid complexes were readily prepared by directly using hydrated lanthanide chlorides. The analytical data for the newly synthesized complexes, listed in Table 1, indicate that they had the general formula $K_2[Ln(dmit)(phen)_2Cl_3]\cdot 6H_2O$.

Solubility and molar conductance

All the complexes are very soluble in DMF and DMSO, soluble in acetonitrile, acetone and nitromethane, and sparingly soluble in methanol, ethanol, ethylacetate, chloroform, benzene, hexane and ether. The molar conductance values of the complexes measured in DMF at 25°C lie in the range of 131–143 Ω^{-1} cm^2 mol^{-1} (Table 1), indicating that all the complexes are 2 : 1 type electrolytes [8]. This indicates that all the anions in the complexes are held in the coordination sphere of Ln^{3+}.

IR Spectra

The most important IR peaks of the ligand and the complexes are reported in Table 2.

Most of the observed IR bands are due to the coordinated ligands. The most characteristic absorptions, observed between 1500 and 1400 cm^{-1}, 840 cm^{-1} and 700 cm^{-1} in the spectra of the complexes are mainly ring vibrations of the bidentate coordinated 1,10-phenanthroline [9].

On the other hand, strong bands at ca 1050 and 1030 cm^{-1} appear in the spectra of the complexes and are easily assigned to the typical ν(C⋯S) stretching frequencies of the dmit ligand [6,10,11], indicating the bidentate behavior of the dithio in all the complexes.

In all the IR spectra of the complexes, strong bands which appear near 3330 and 1650 cm^{-1} are clearly due to ν(OH) and δ(HOH), respectively. The absorptions of ν(OH) of these complexes show that the water molecules are crystallized water molecules [12]. This inference is verified by the results of the TG-DTA analysis. But, in the IR spectra of (7) and (8), no such bands could be observed.

Electronic absorption and reflectance spectra

Table 3 shows electronic absorption spectra data for the complexes. The intense absorption bands centered at 480 nm in DMF are assignable to the π–π* transition of the dmit ligand. Similar absorptions are observed in other dmit-metal complexes such as Na_2dmit (514 in methanol), $[NBu^n_4]_2[Zn(dmit)_2]$ [6] (515 in DMSO) and [Pt(dmit)(bipym)] [13] (478 in DMSO). The intense bands appearing at ca 325 nm are attributed to π–π* transition of phen. The broad bands due to charge-transfer (CT) transition from the highest-filled molecular orbital of $dmit^{2-}$ to the 4f orbitals of the metal ions center at ca 375 nm in all the complexes. The band which can be assigned to the intramolecular ligand-to-ligand charge transfer (LLCT) transition could not be observed in the visible region absorption spectra [14].

The powder electronic reflectance spectra of (1) and (5) show the bands corresponding to those observed in solution, suggesting no significant intermolecular interaction in the solid state. This may be the reason why the complexes are almost insulators ($\sigma_{25\,°C} < 10^{-12}$ S cm^{-1}).

Thermal analyses

The TG and DTA curves for the complexes (1), (5) show that the water molecules contained in the complexes are all crystallized water molecules, because the only one endothermic peak appear at ca 95°C. And the percent of water [(1) : 10.3(f), 10.9(c); (5) : 10.1(f), 10.6(c)] are consistent with the results of elemental analysis. It is also proved by experiment that the residue contain K^+ ion.

Oxidation of the complexes by iodine-doping

The complexes (1) and (5) have been doped with iodine by reacting the finely powdered complexes suspended in hexane with an excess amount of iodine. A first indication on the nature of the iodine species present in these solids and the degree of the charge transfer can be found in the powder electronic reflectance spectra: it is known that the intense absorption maximum for a chain of I_3^- ions is in the 550 nm region [15]. In our case, the oxidized K_2[La(dmit)(phen)$_2$Cl$_3$]·$I_{3.5}$ compound exhibits a very broad intense absorption at 516 nm, and the oxidized K_2[Er(dmit)(*phen*)$_2$Cl$_3$]·$I_{3.0}$ compound also exhibits a broad absorption centering at 515 nm. These observations are consistent with the presence of I_3^- species in the studied compounds.

A definitive answer to this question is given by resonance Raman spectroscopy.

Complexes (7) and (8) exhibit a Raman peak at 106 cm^{-1} which is assignable to the symmetric stretching of the I_3^- ion [16]. Thus, complexes (7) and (8) are formulated as K_2[La(dmit)(*phen*)$_2$Cl$_3$]·$[I_3]_{1.17}$ and K_2[Er(dmit)(*phen*)$_2$Cl$_3$]·$[I_3]_{1.00}$, respectively.

The complexes (7) and (8) behave as typical semiconductors. Electrical conductivities measured for the compacted pellets indicate that the conductivities of the complexes are raised by the 10^5 order on doping iodine ($\sigma_{25°C}$ are 1.7×10^{-7} and 2.1×10^{-7} S cm^{-1} for (7) and (8), respectively).

In conclusion, stable lanthanide $dmit^{2-}$ can be obtained by means of forming mixed-ligand complexes. Electronic spectra suggest the existence of small covalency between Ln—S bond. No existence of intermolecular interaction and intramolecular ligand-to-ligand charge transfer transition determine the poor conductivity of the complexes. In the case of the planar transition-metal complexes, such as $Ni(dmit)_2^{2-}$, the segregated stacking of the constituent planar units including the presence of peripheral sulfur atoms leads to highly directional intermolecular π orbital interactions and, consequently, a quasi-1D electronic system. But in these lanthanide complexes, the Ln^{3+} ion is nine-coordinated with one $dmit^{2-}$ group, two bidentate 1,10-phenanthroline and three chlorine ions. Probably, this kind of coordination geometry may preclude the close intermolecular interactions which are required for good solid state conductivity, and the partial oxidation of the complexes with iodine make the conductivities be raised by the 10^5 order.

Abstract—Quantitiative ^{31}P-NMR examination of the hydrolysis of dimethyl-H-phosphonate using ^{18}O-enriched water under base-catalysed conditions supports a mechanism involving exclusive [P—O] bond cleavage as opposed to the alternative [C—O] bond cleavage. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: dimethyl-H-phosphonate; hydrolysis; bond cleavage.

As a class of compounds, H-phosphonate mono- and diesters have been known for many years yet only relatively recently have such compounds begun to be exploited in areas such as natural product, nucleotide [1], catalysis [2] and radical chemistry [3]. Indeed, the application of H-phosphonates in the synthesis of phosphorus-containing natural products including oligonucleotides [4] sugar-phosphates [5] and phospholipids [6], has become preferred to more well-established methodologies involving phosphite or phosphate precursors.

As a result of this wide applicability, there is a need to provide a solid foundation for the basic chemistry of H-phosphonates, especially concerning some of the more important transformations such as (i) hydrolysis, (ii) [P—H] exchange, (iii) transesterification and (iv) de-alkylation. Of these, the kinetics of [P—H]/[P—D] exchange processes have been examined previously [7] and we are currently extending this early work in the development of a semi-quantitative scale of relative kinetic acidity of the [P—H] function [8]. Transesterification is important in nucleotide chemistry and has consequently been the subject of several investigations [9]. Although it is well known that methyl esters of phosphorus(V) acids are readily de-methylated by simple organo–nitrogen bases [10], we have recently extended this methodology to H-phosphonates along with the immobilisation of H-phosphonic acid esters on ion-exchange resins [11].

Reactions involving the hydrolysis of phosphate and phosphonate esters are of fundamental importance. For example, compounds containing the phospho group [$-PO(OH)_2$] have myriad medicinal applications [12] yet phosphorus acids possess poor biological transport properties; at physiological pH the acid is strongly ionised [$pK_a(1)$ values [13] are typically of the order of 1–2], which in turn inhibits passage of the compound through cell membranes. One strategy to facilitate delivery of phosphonate-based drugs involves esterification of the parent phosphorus acid to afford a pro-drug diester [14], which then has increased access to the interior of a cell. The active drug is then released, via hydrolysis, at the precise point of need [14].

RESULTS AND DISCUSSION

Mechanisms of phosphorus ester hydrolysis

The process of H-phosphonate diester hydrolysis is illustrated in Scheme 1. As a consequence of there being two ester motifs within the compound, two hydrolytic transformations are possible; primary and secondary hydrolyses.

The hydrolytic behaviour of H-phosphonate esters in aqueous acidic and basic media has been examined previously. Hydrolysis of H-phosphonate diesters to H-phosphonate monoesters (primary hydrolysis) is found to occur much more readily under basic than acidic conditions; reaction being general base and

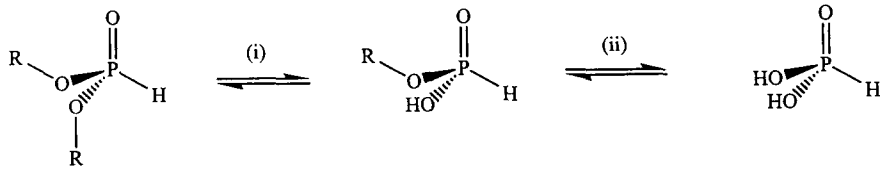


Scheme 1. The hydrolysis of dialkyl-H-phosphonate esters. (i) Primary hydrolysis. (ii) Secondary hydrolysis.

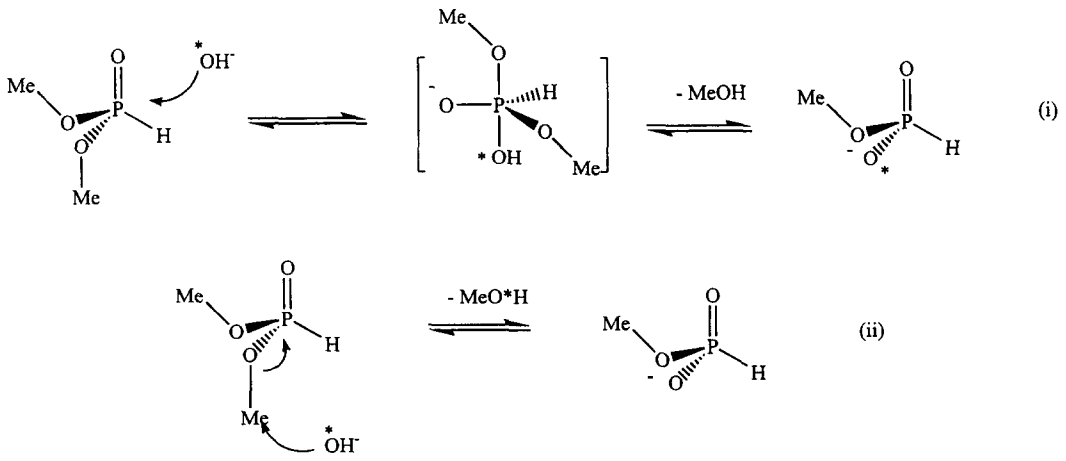
general acid catalysed, respectively [15]. In contrast, conversion of H-phosphonate monoesters to phosphorous acid (secondary hydrolysis) is more facile under acidic conditions [16]. The mechanisms of these hydrolyses have thus attracted much attention. What possibilities may be envisaged and how might we differentiate between them?

It has been suggested that H-phosphonate diesters hydrolyse both in alkali and acid with exclusive [P—O] bond fission [17]. This contrasts with the acid-catalysed hydrolysis of phosphate triesters which have been shown to proceed with both [P—O] and [C—O] bond cleavage. Evidence to support a mechanism involving [P—O] bond cleavage has been provided by Gerrard and co-workers through the hydrolysis of H-phosphonate diesters containing optically active ester functions [17]. Their work relied upon an examination of the optical purity of octan-2-ol produced during the hydrolysis of optically pure di-2-octyl-H-phosphonate, which revealed complete retention of octan-2-ol configuration, a result consistent only with exclusive [P—O] bond fission. However, since it is reasonable to suspect that steric requirements of the ester substituents should play a significant role in determining the relative rates of [P—O] and [C—O] bond cleavage in phosphorus ester hydrolysis, smaller esters such as dimethyl-H-phosphonate (DMHP) may afford different results.

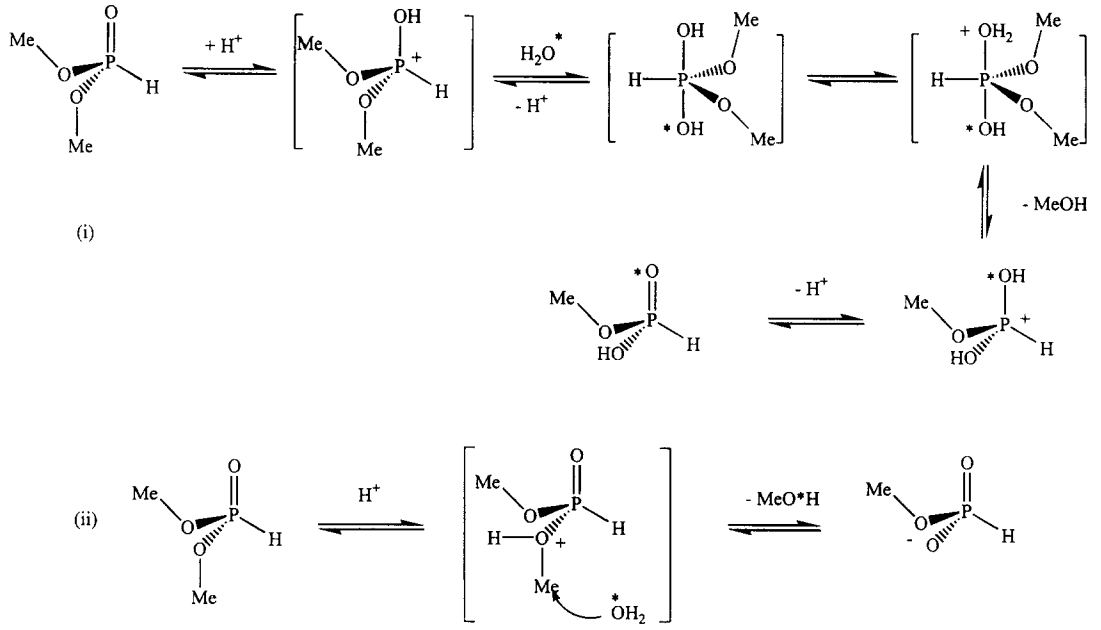
Since it is obviously not possible to exploit optical activity in DMHP hydrolysis, we selected ^{18}O-isotopic labelling in conjunction with ^{31}P-NMR spectroscopy as a technique capable of differentiating between [P—O] and [C—O] bond cleavage in DMHP hydrolysis under either basic (Scheme 2) or acidic (Scheme 3) conditions and here report our studies under the former conditions.

^{18}O-labelling and ^{31}P-NMR spectroscopy as a mechanistic tool in phosphorus chemistry

The ^{31}P nucleus is one of the most attractive nuclei for NMR analysis, due to the relatively simple spectra often produced and wide chemical shift range. Furthermore, ^{31}P chemical shifts are very sensitive to small structural changes which can be measured easily [18]. Such structural changes include the replacement of a [^{16}O-P] motif for a [^{17}O-P] or [^{18}O-P] unit [19]. An ^{17}O atom directly bonded to ^{31}P results in a marked line-broadening of the ^{31}P resonance due to quadrupolar effects of the ^{17}O nucleus (nuclear spin $I = 5/2$). However, no such line-broadening is observed when ^{18}O is directly bonded to ^{31}P due to the ^{18}O nucleus possessing nuclear spin $I = 0$, and quadrupolar relaxation is an important phenomenon only for nuclei with $I > 1/2$. There is, however, a measurable isotopic shift of the ^{31}P-NMR resonance to lower frequency (by ca 3–7 Hz depending upon the operating frequency) upon replacing phosphorus-coordinated ^{16}O for ^{18}O which has been exploited in biochemistry for the



Scheme 2. Hydrolysis of DMHP under basic conditions with (i) [P—O] and (ii) [C—O] bond cleavage.



Scheme 3. Hydrolysis of DMHP under acidic conditions with (i) [P—O] and (ii) [C—O] bond cleavage.

identification of chiral [^{16}O, ^{17}O, ^{18}O]-phosphate esters [20] and in probing enzymatic mechanisms [21].

Thus, we designed a two-step experiment to probe [P—O] vs [C—O] bond cleavage in the base-catalysed hydrolysis of DMHP based on ^{18}O-labelling:

STEP 1. Preparation of a sample of ^{18}O-labelled water, of nominally 50:50 ^{18}O:^{16}O atom purity and determination of the atom purity (^{18}O:^{16}O) of the ^{18}O-labelled water, as accurately as possible, based upon the reaction with chlorodiphenylphosphine. Determination of atom purity (and evaluation of possible error limits during such a procedure) by $^{31}P\{^1H\}$ NMR spectroscopy.

STEP 2. Perform three reactions:

(a) dimethyl H-phosphonate (1 equiv.) + $H_2{}^{18}O$ (5 equivs.) in $CDCl_3$
(b) dimethyl H-phosphonate (1 equiv.) + $H_2{}^{18}O$ (5 equivs.) + NEt_3 (1 equiv.) in $CDCl_3$
(c) dimethyl H-phosphonate (1 equiv.) + NEt_3 (1 equiv.) in $CDCl_3$.

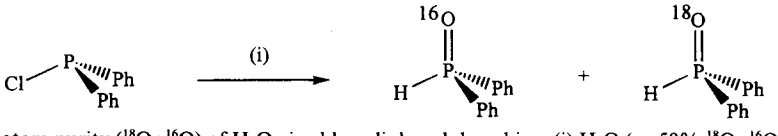
Examination of each reaction system by $^{31}P\{^1H\}$ NMR spectroscopy and determination of the extent of ^{18}O-incorporation into the products of hydrolysis and into dimethyl-H-phosphonate itself.

Preparation and assay of ^{18}O-labelled water

A sample of ^{18}O-labelled water of nominal 50:50 (^{18}O:^{16}O) isotopic composition was prepared by mixing equal quantities of ^{18}O-enriched water [^{18}O(97.9%):^{17}O(0.5%):^{16}O(1.6%)] and distilled water, under an atmosphere of dinitrogen. The atom purity (^{18}O:^{16}O) was assayed using $^{31}P\{^1H\}$ NMR spectroscopy by reaction with chlorodiphenylphosphine (Scheme 4) to afford, ^{18}O- and ^{16}O-isotopomers of diphenylphosphine oxide. The isotopomers returned ^{31}P NMR resonances separated by 3.4 Hz (operating frequency of 101.6 MHz; Fig. 1); the ^{18}O-isotopomer appearing to low frequency. Resolution of isotopomers was aided by the application of Lorentz–Gauss multiplication to the FID (LB = −1.00 Hz, GB = 10.0 %).

Di-2,6-*t*-butylpyridine was added to the reaction mixture to minimise acid-catalysed proton-exchange processes; processes which were found to cause broadening of the product signals [22]. The non-nucleophilic nature of di-2,6-*t*-butylpyridine is important since triethylamine or pyridine result in significant by-product formation.

The ratio of peak areas for the ^{18}O-P and ^{16}O-P



Scheme 4. Assay of atom purity (^{18}O:^{16}O) of H_2O via chlorodiphenylphosphine. (i) H_2O (ca 50% ^{18}O:^{16}O) (0.67 equivs), di-2,6-^{t}Bu-pyridine (0.67 equivs); $CDCl_3$. $\delta\delta_P$ (^{16}O-^{18}O) = 3.4 HZ (101 MHz).

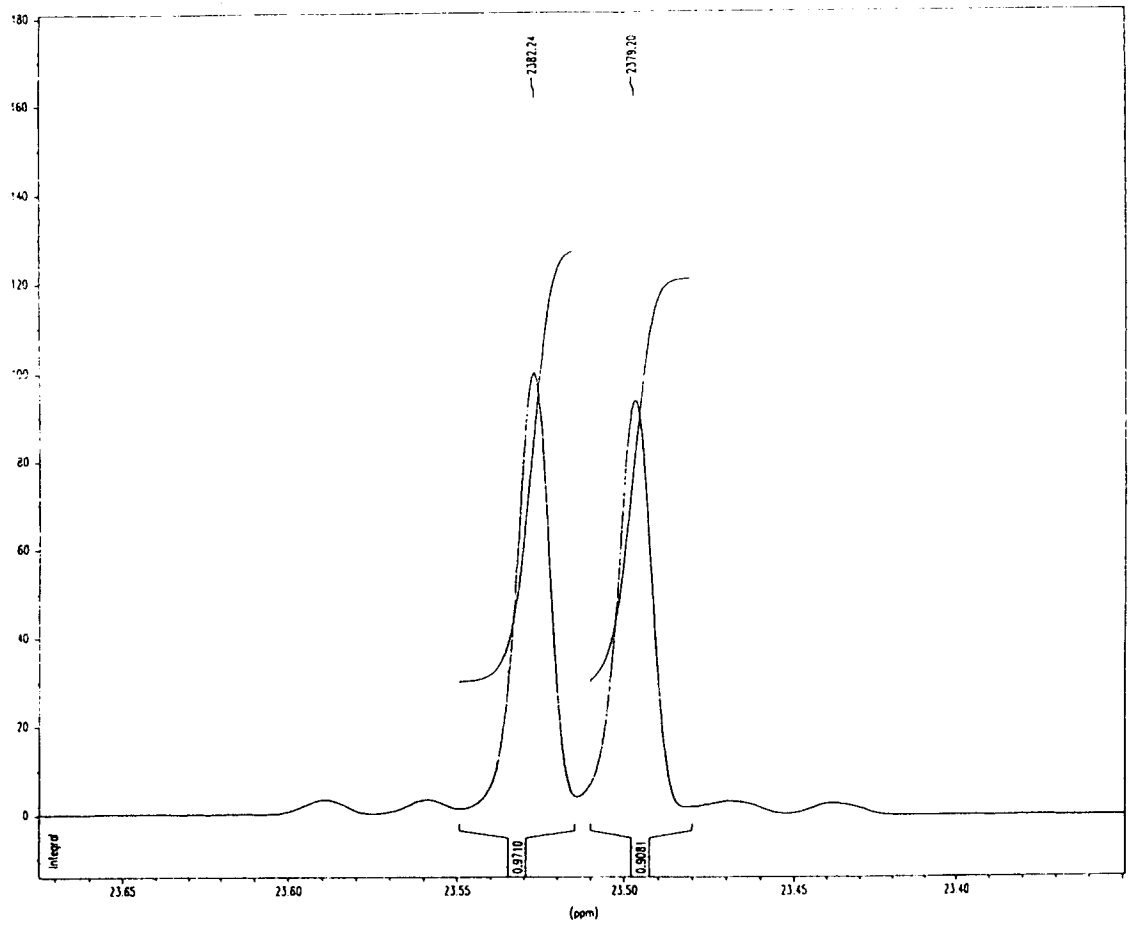


Fig. 1. ^{31}P-NMR spectroscopy of $Ph_2P(O)H$. (a) ^{16}O-P and (b) ^{18}O-P isotopomers.

isotopomers (Fig. 1) allowed the determination of the $^{18}O:{}^{16}O$ atom ratio to be 1 : 1.083; an ^{18}O-content of 48%.

The hydrolysis of DMHP with ^{18}O-enriched H_2O

Three reactions were performed concurrently, each composed of a solution of dimethyl-H-phosphonate (2.74×10^{-4} mol) in $CDCl_3$ with, respectively, the following additional components:

(a) $H_2{}^{18}O$ (48% atom purity ^{18}O, 5 equivs);
(b) $H_2{}^{18}O$ (5 equivs) and triethylamine (1 equiv.);
(c) triethylamine (1 equiv.) as a control system.

The fully proton-coupled ^{31}P NMR spectrum of each sample was collected at regular intervals. (see Experimental). Expansions of systems (a), (b) and (c) after 12 h reaction are shown in Fig. 2a–c, respectively; reaction systems (a) and (b) after 67 h reaction are illustrated in Fig. 3a, b. In each case, the doublet of septets resonance (δ_P 11.1, $^1J_{PH}$ 699 Hz, $^3J_{PH}$ 12.0 Hz) corresponds to dimethyl H-phosphonate, $(MeO)_2P(O)H$.

Comparison of the spectra in Fig. 2a–c illustrates several aspects of the hydrolysis of dimethyl H-phosphonate. Firstly, the reaction system in which only $H_2{}^{18}O$ is present (Fig. 2a) shows no evidence of hydrolysis after 12 h. The system containing both $H_2{}^{18}O$ and triethylamine (Fig. 2b) reveals hydrolysis to have occurred to an extent of ca 20%. This increased rate of hydrolysis in the presence of base is to be expected, given that hydrolysis of H-phosphonate diesters is known to be base-catalysed [15]. However, examination of Fig. 2c reveals evidence for hydrolysis even in the absence of $H_2{}^{18}O$. This suggests the presence of trace water in the system carried through presumably by the hygroscopic triethylamine; and background hydolysis involving such contamination must be considered when scrutinising data from this set of experiments. After 12 h, background hydrolysis in the system containing triethylamine only (Fig. 2c) has occurred to the extent of ca 4% and this defines the error range in the determination of ^{18}O-incorporation in our experiments. No further hydrolysis occurs in the absence of added water.

Examination of Fig. 2b reveals two hydrolysis prod-

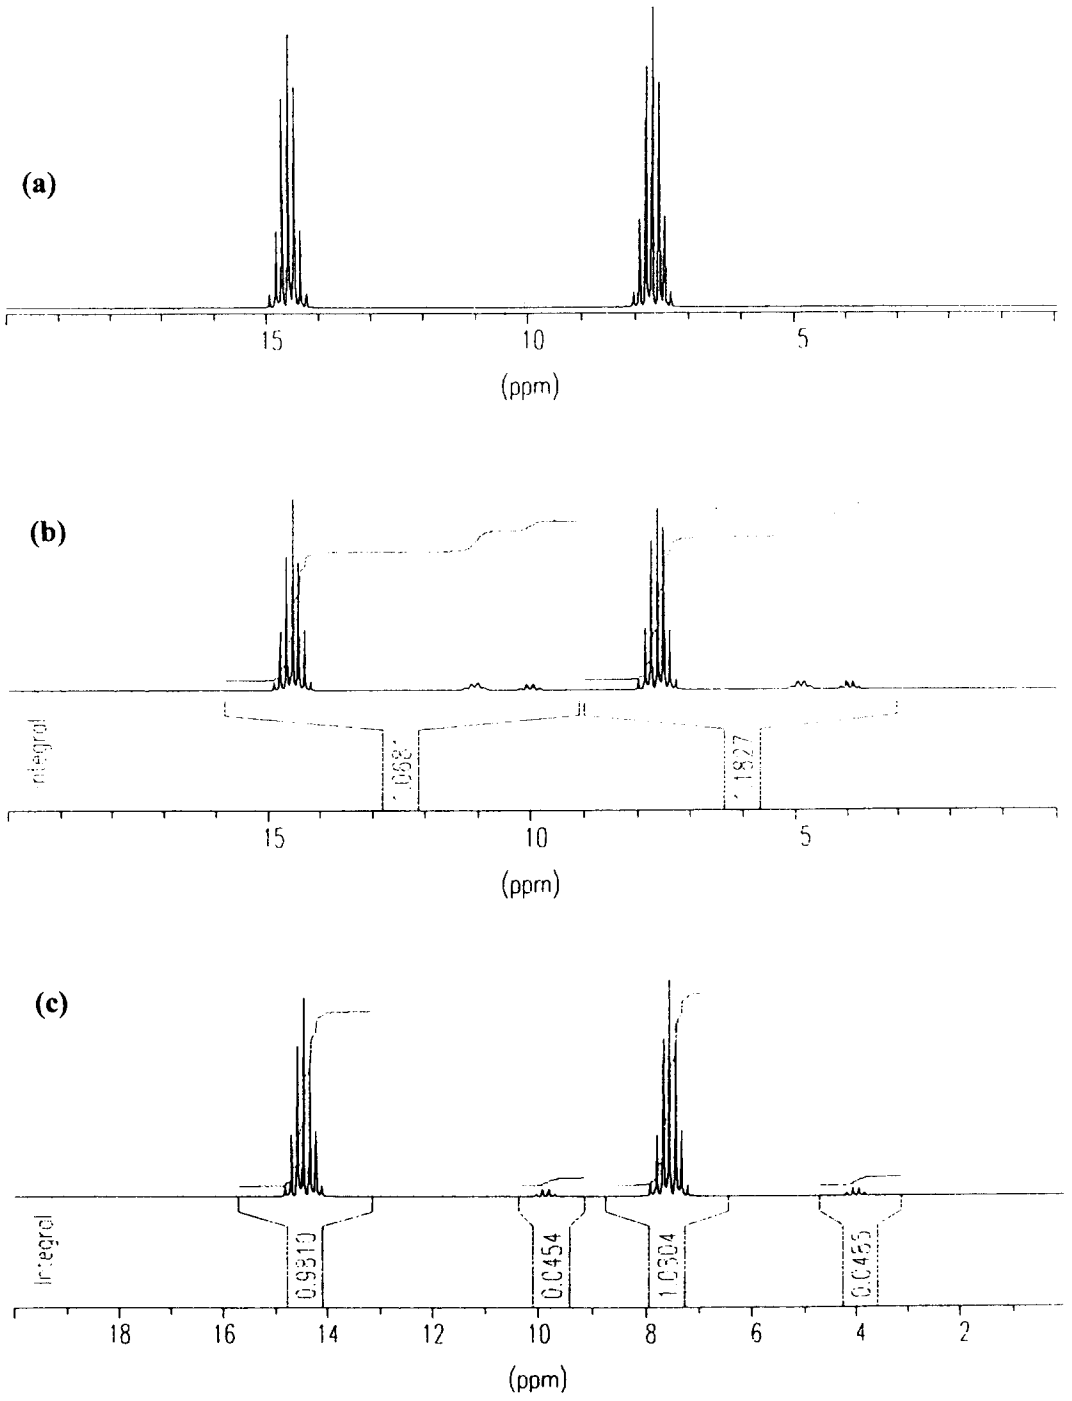

Fig. 2. ^{31}P-NMR spectra of DMHP after 12 h in the presence of (a) H_2O^*, (b) $H_2O^* + NEt_3$ and (c) NEt_3.

ucts in the ^{31}P NMR spectrum. One of the expected products, methyl-H-phosphonate, would be expected to afford a doublet of quartets in the ^{31}P NMR spectrum whilst the other logical product, phosphorus acid, should reveal itself as a doublet. However, ^{31}P-NMR reveals that both products display doublet of quartets splitting patterns. We suggest that one of these signals (expanded in Fig. 4a) may be assigned to the triethylammonium salt of methyl-H-phosphonic acid, whilst the other product may possibly be methyl-H-phosphonic acid, itself or perhaps the condensation product (MeO)HP(O)-O-P(O)H(OMe) formed by

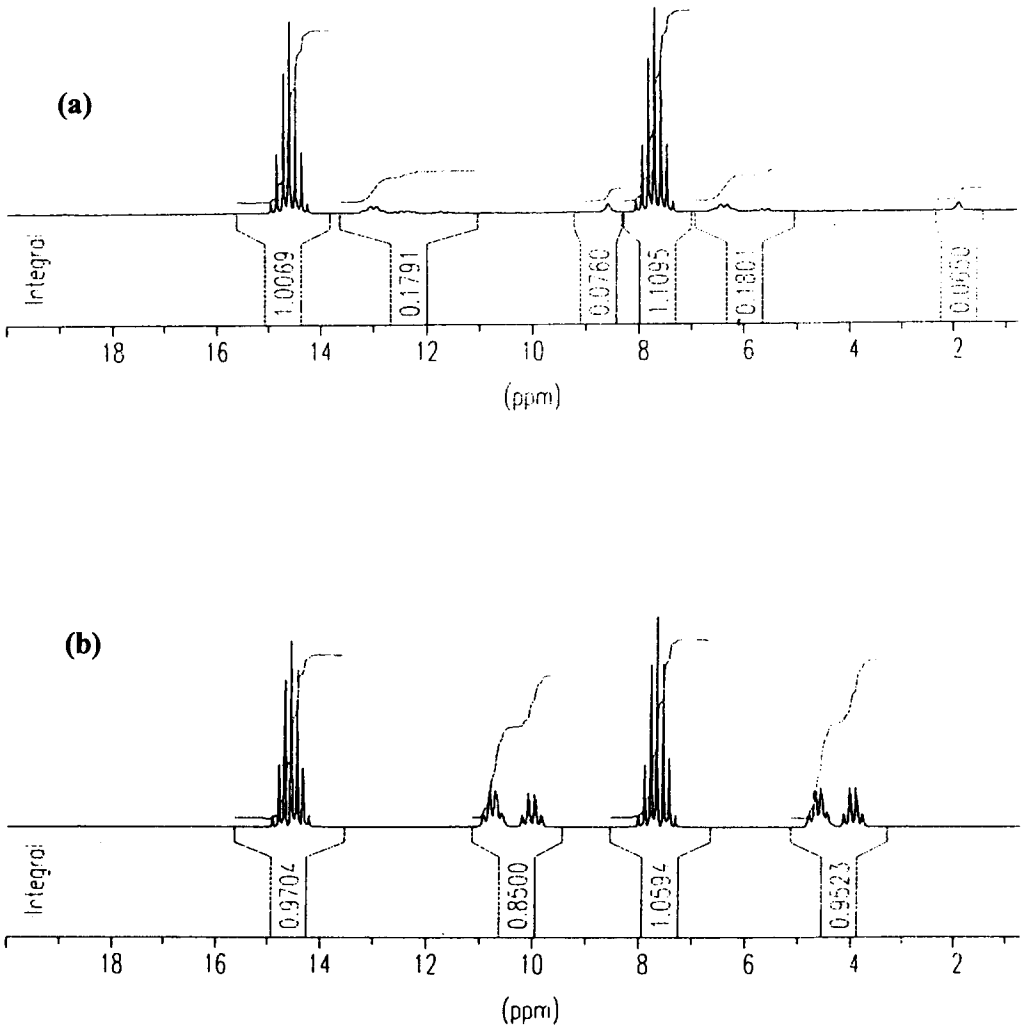

Fig. 3. ^{31}P-NMR spectra of DMHP after 67 h in the presence of (a) H_2O^* and (b) $H_2O^* + NEt_3$.

reaction of methyl-H-phosphonic acid with DMHP (Scheme 5).† The higher frequency multiplet is broader thus preventing observation of discrete ^{16}O- and ^{18}O-isotopomers; however, both isotopomers are observable in the low frequency multiplet (Fig. 4a).

After 67 h, systems (a) and (b) show further reaction (Fig. 3). The ^{31}P NMR spectrum of system (a) comprising dimethyl-H-phosphonate and $H_2{}^{18}O$ after 67 h (Fig. 3a) now reveals evidence of hydrolysis. However, inspection of the septet resonances of the DMHP shows that there is no evidence for concomitant ^{18}O-incorporation into dimethyl-H-phosphonate itself. This result seems to suggest that a mechanism of DMHP hydrolysis which proceeds as shown in Scheme 3(i) is unreasonable under the conditions here.

Further enlightening information emerges from system (b) (DMHP/$H_2{}^{18}O$/triethylamine; Fig. 3b). In this system, it is possible to observe all ^{18}O- and ^{16}O-isotopomeric resonances in the products of hydrolysis; expansions of which are shown in Fig. 4b and integrations of the peaks in the 10.2–9.8 ppm region shown in Fig. 5. In each case, zero filling to 64K points and Lorentz–Gauss multiplication was applied to the FID (LB = −0.30 Hz, GB = 40.0 %) to aid resolution of the isotopomeric peaks without distorting the shape. Integration returns an ^{18}O : ^{16}O isotopomer ratio of 44.7(5) : 55.3(5). Thus, incorporation of the ^{18}O-label during hydrolysis has occurred to the extent of 44.7(5)%. Since this experiment was performed with 48% ^{18}O-enriched water in the presence of triethylamine, which has already been shown (Fig. 2c) to result in background hydrolysis with *ca* 4% ^{16}O-incorporation, exclusive [P—O] bond cleavage during

† We are not certain of the assignements of these two species to ammonium salt and anhydride. Further experiments would be necessary to probe this in more detail. Nevertheless, it is clear that both species possess a single [MeOP] function resulting from partial hydrolysis.

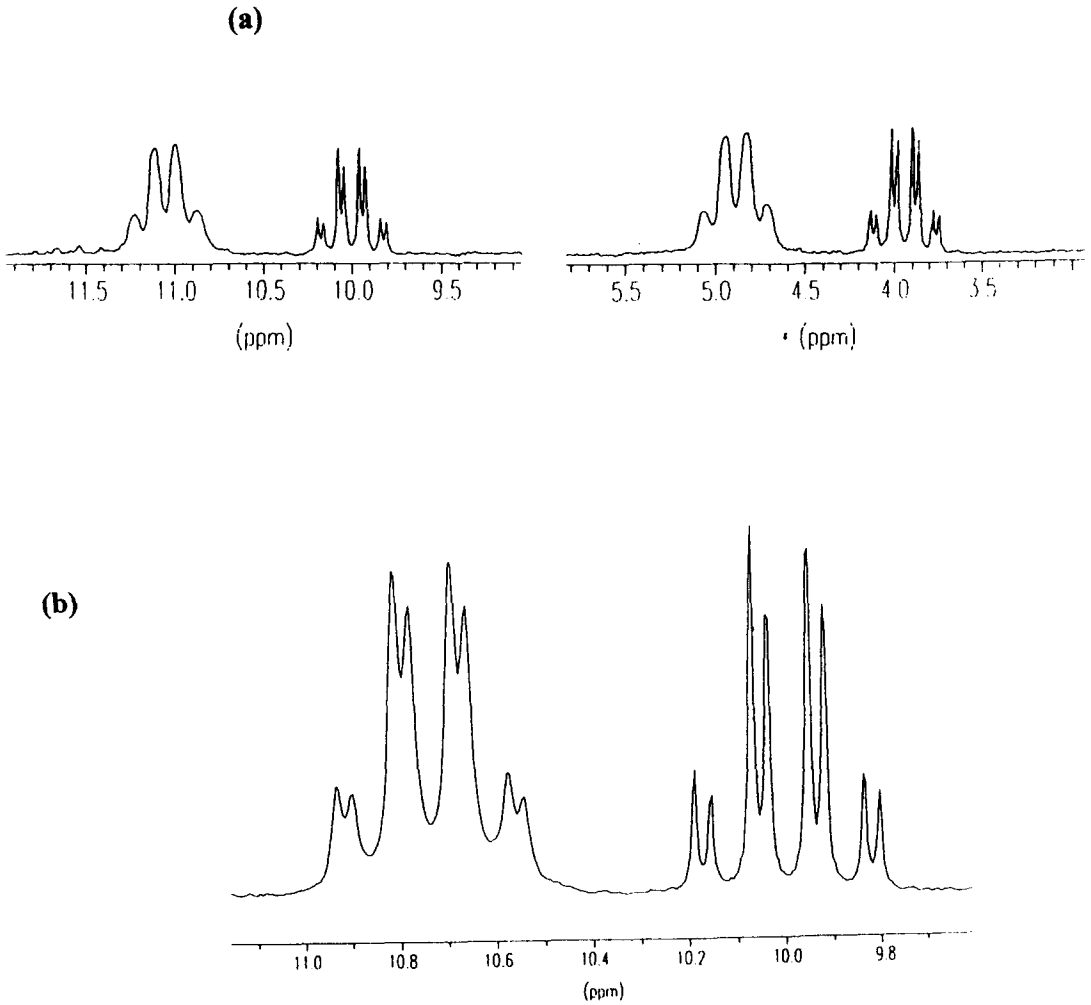

Fig. 4. (a) Expansion of selected regions Fig. 2(b). (b) Expansion of selected region of Fig. 3(b).

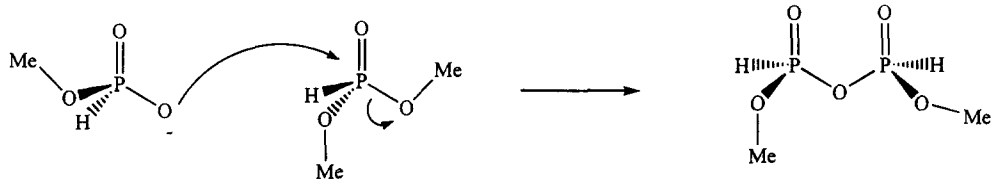

Scheme 5. Possible condensation reaction between DMHP and methyl-H-phosphonate.

hydrolysis would be expected to result in a ratio of methyl-H-phosphonic acid ^{18}O : ^{16}O isotopomers of ca 44 : 55 whereas exclusive [C—O] bond cleavage would return a ratio of 0 : 100. Consequently, within the bounds of experimental error, and allowing for trace-hydrolysis due to triethylamine, the experimental results strongly support a mechanism of base-catalysed DMHP hydrolysis which proceeds with exclusive [P—O] rather than [C—O] bond cleavage; supportive of the mechanism in Scheme 2(i).

EXPERIMENTAL

General procedures

All manipulations were performed under an atmosphere of dry dinitrogen gas using Schlenk and cannula techniques or in a dinitrogen-filled dry box, unless stated otherwise. NMR spectra were obtained on JEOL FX90Q, JEOL FX100, Bruker ARX 250 MHz and AM 400 instruments operating at 100.0

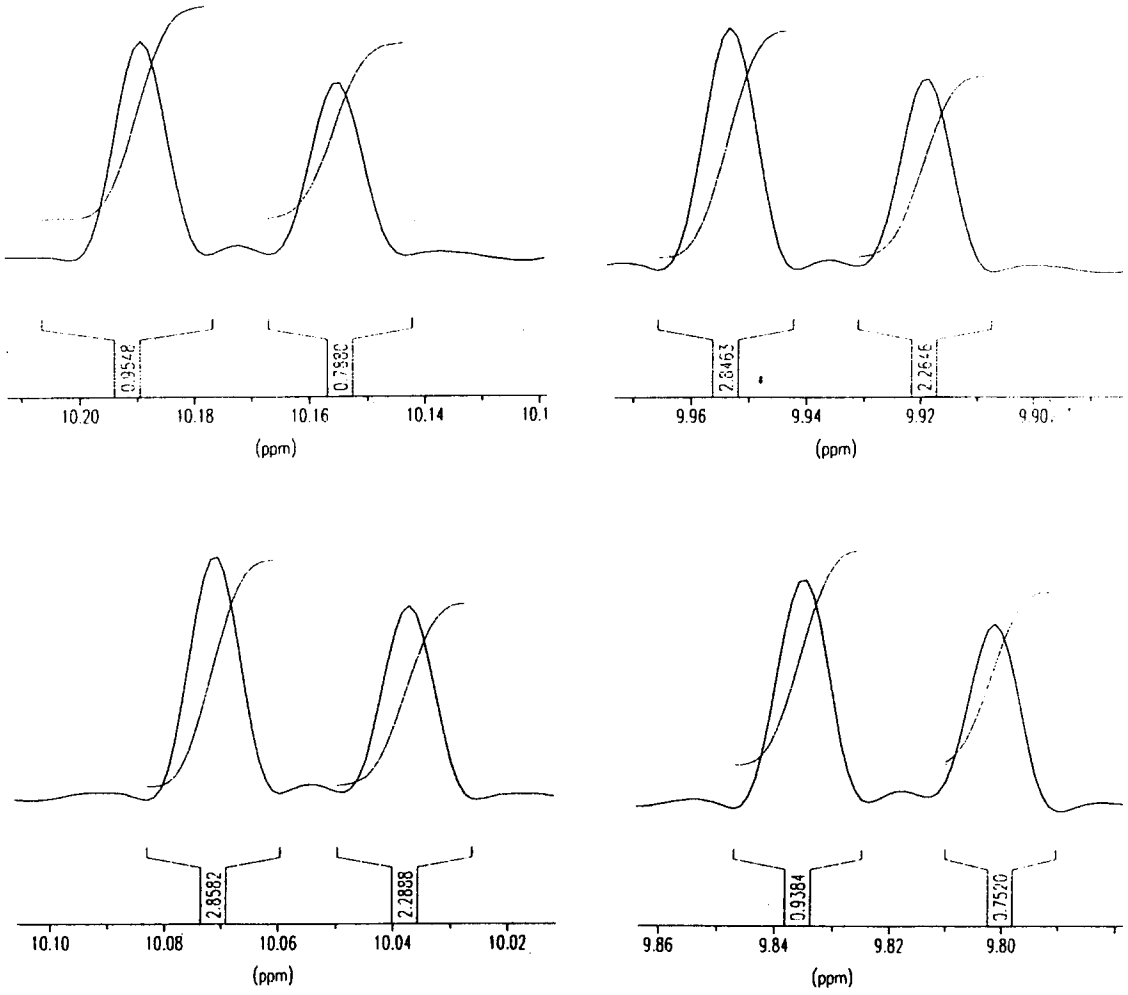

Fig. 5. Integration of expanded selected resonances of Fig. 4(b).

MHz, 250.133 MHz or 400.132 MHz for ^{1}H, 100.614 MHz or 62.895 MHz for ^{13}C and 36.2 MHz or 101.614 MHz for ^{31}P. Deuterated solvents were deoxygenated and where necessary ($CDCl_3$) dried by passage down a short column of basic (Brockman grade I) alumina before use. All spectra are reported at 298 K and referenced to 85% H_3PO_4 (^{31}P) as $\delta_P = 0$ ppm unless stated otherwise. ^{18}O-Enriched water (Euriso-Top) with a specification of $^{18}O(97.9\%):{}^{17}O(0.5\%):{}^{16}O(1.6\%)$ was purchased from MSD Isotopes and Ph_2PCl from Aldrich.

Assay of ^{18}O atom enrichment in ^{18}O-labelled water

A commercial sample of ^{18}O-enriched water $^{18}O(97.9\%):{}^{17}O(0.5\%):{}^{16}O(1.6\%)$ (50 μl, 0.056 g, 2.77 mmol) was added to distilled water (50 μl, 0.050 g, 2.78 mmol) under a dinitrogen atmosphere and sparged with dinitrogen. A sample of this mixture of $H_2{}^{18}O/H_2{}^{16}O$ isotopomers at a nominal atom ratio of ca $^{18}O:{}^{16}O$; 50:50 (1.5 μl, 9.1×10^{-5} mol) was added to a solution comprising Ph_2PCl (24 μl, 0.030 g, 0.14 mmol; 1.5 equivs), 2,6-di-*tert*-butylpyridine (20 μl, 0.017 g, 9.1×10^{-5} mol; 1.0 equiv.) and $CDCl_3$ (0.6 cm^3) in a 5 mm NMR tube. The NMR tube was closed with a push-on cap, sealed with cling-film and shaken briskly to ensure complete mixing of the components. The contents of the mixture were observed using $^{31}P\{^{1}H\}$ NMR spectroscopy. Spectra were recorded (141 scans) at 300 K on a Bruker 250 MHz spectrometer (101.268 MHz) over a spectroscopic width of 5102.04 Hz centred at 1518.83 Hz. Lorentz–Gauss multiplication was applied to the FID (LB = −1.00 Hz, GB = 10.0 %) and the resulting Fourier transformed spectrum was phased manually. Integration of the $^{18}O:{}^{16}O$ isotopomeric resonances afforded the relative quantities of each.

$\delta_P(CDCl_3)$ ppm	Assignment	% composition
23.53	$Ph_2P(O^{16})H$	52%
23.50	$Ph_2P(O^{18})H$	48%

Hydrolysis of $(MeO)_2P(O)H$ using ^{18}O-enriched water

Two reaction systems were prepared:

(1) To a solution of $(MeO)_2P(O)H$ (25 μl, 0.030 g, 2.73×10^{-4} mol) in $CDCl_3$ (0.6 cm^3) in a 5 mm NMR tube was added $H_2{}^{18}O$ (48 % atom purity ^{18}O) (23 μl, 0.026 g, 1.36 mmol) under an atmosphere of dinitrogen. The tube was sealed with a push-on cap, wrapped with cling-film and shaken briskly to afford a fully homogeneous solution. The fully proton-coupled ^{31}P NMR spectrum (101.268 MHz) was collected (2520 scans) on a Bruker 250 MHz spectrometer over a spectroscopic width of 8196.72 Hz; 16,384 data points; acquisition time 1.000 s; pulse delay 0.300 s; line-broadening 1.50 Hz. Resonances consistent with the formation of the hydrolysis products (MeO)(HO)P(O)H and $(HO)_2P(O)H$ were seen to develop over time, but the broad nature of these product resonances prevented resolution of ^{18}O : ^{16}O isotopomers. δ_P 11.14 [dsept, $^1J_{PH}$ 699.4 Hz, $^3J_{PH}$ 12.0 Hz; $(MeO)_2P(O)H$]; 9.68 [dq, br, $^1J_{PH}$ 669.4 Hz, $^3J_{PH}$ 12.0 Hz; (MeO)(HO)P(O)H]; 5.23 [d, br, $^1J_{PH}$ 674.4 Hz; $(HO)_2P(O)H$].

(2) The above procedure was repeated in the presence of NEt_3 (38 μl, 0.028 g, 2.73×10^{-4} mol) as an additional component in the reaction mixture and the mixture analysed analogously. δ_P 11.10 [dsept, $^1J_{PH}$ 698.4 Hz, $^3J_{PH}$ 12.0 Hz; $(MeO)_2P(O)H$]; 7.69 [dq, $^1J_{PH}$ 620.9 Hz, $^3J_{PH}$ 12.0 Hz; $(MeO)(H^{16}O)P(O)H$]; 6.98 {dq, $^1J_{PH}$ 613.9 Hz, $^3J_{PH}$ 12.0 Hz; $[HNEt_3]^+[(MeO)(^{16}O)P(O)H]^-$}; 7.66 [dq, $^1J_{PH}$ 620.9 Hz, $^3J_{PH}$ 12.0 Hz; $(MeO)(H^{18}O)P(O)H$]; 6.95 {dq, $^1J_{PH}$ 613.9 Hz, $^3J_{PH}$ 12.0 Hz; $[HNEt_3]^+[(MeO)(^{18}O)P(O)H]^-$}.

Copper(II) diethylenetriamine perchlorato complexes bridged through varying length dicarboxylato spacers: synthesis, characterization and EPR studies

P. S. Subramanian, Paresh C. Dave, Vinod P. Boricha and D. Srinivas*

Sophisticated Analytical Instruments Laboratory, Central Salt & Marine Chemicals Research Institute, Gijubhai Badheka Marg, Bhavnagar 364 002, India

(Received 5 June 1997; accepted 3 September 1997)

Abstract—The synthesis and spectral characterization of dinuclear copper(II) complexes of the composition [(dien)CuLCu(dien)]$(ClO_4)_2$, where dien = diethylenetriamine and L^{2-} = oxalato, malonato, succinato, phthalato, isophthalato and terephthalato, are reported. IR spectra reveal that the mode of carboxylato coordination is *anti–anti* for oxalato complexes while it adopts chelate or polymeric *syn–anti* coordination for the rest of the complexes. The stereochemistry around copper is distorted square pyramidal. Oxalato forms two types of complexes I and II. EPR for I is characterized by a rhombic g tensor with $g_3 < g_1$ and g_2 and suggest that the unpaired electron has a predominant d_{z^2} character while II and the rest of the dicarboxylato complexes are characterized by an axial g tensor ($g_\parallel > g_\perp$) suggesting the occupancy of unpaired electron in a $d_{x^2-y^2}$ orbital. Frozen solution EPR spectra at 77 K indicate that the solvent molecule coordinates with the metal ion. Magnetic exchange in these complexes is intramolecular and both conjugated and unconjugated spacer dicarboxylato ligands propagate the exchange between the metal ions. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: dinuclear Cu(II) complexes; EPR; exchange; spectroscopy.

Magnetic exchange interactions between transition metal ions bridged through multi-atomic ligands have been the subject of several investigations [1–4]. Among the bridging ligands the carboxylato group has been extensively investigated because of its occurrence in several metalloenzymes and its capability to form complexes with different metal ions in different modes of coordination, e.g. monodentate, bidentate (chelate), *syn–syn*, *syn–anti* and *anti–anti* [5–8]. Exchange in these type of complexes predominantly takes place through the superexchange mechanism via the carboxylato group and thus the mode of coordination plays a critical role on the magnitude of exchange interaction. IR spectroscopy has been proved to be a powerful tool in identifying the mode of coordination of the carboxylato ligands [5] while EPR has been used to study the intra/inter-molecular exchange interactions between the metal centers [9]. Recently, much attention has been paid by several groups of workers to understand the distance dependence of such exchange phenomenon in cases of favorable orbital overlap. Intramolecular long-range exchange coupling was observed in dinuclear Cu(II) complexes bridged through conjugated dicarboxylato ligands even for Cu···Cu separations greater than 10 Å [10–14].

We reported earlier [15] some dinuclear Cu(II) Schiff base complexes bridged through dicarboxylato ligands with varying chain lengths. Magnetic studies on those complexes have revealed the intermolecular exchange interaction as the efficient exchange pathway. In continuation to this we report here spectroscopic and EPR studies on dinuclear complexes of the composition [(dien]CuLCu(dien)]$(ClO_4)_2$, where dien = diethylenetriamine and L = dicarboxylato ligands viz. oxalato (**1**), malonato (**2**), succinato (**3**), phthalato (**4**), isophthalato (**5**) and terephthalato (**6**). Hendrickson *et al.* [16,17] and Kahn *et al.* [18] have

* Author to whom correspondence should be addressed. E-mail: general@cscsmcri.ren.nic.in

reported structural and magnetic properties of related oxalato bridged complexes, and Tsipis *et al.* [12] have reported phthalato bridged complexes. In the case of oxalato bridged complexes the exchange interaction between the dinuclear Cu(II) units is rather negligible, while in the phthalato complexes the two Cu(II) centers are coupled ferromagnetically with a singlet-triplet energy gap being 80 ± 10 cm^{-1} and $zJ' = -1.81$ cm^{-1}. In the present study the Cu $\cdots$ Cu separation is systematically varied with an interest to examine the effect of spacer units on the magnetic properties and to investigate whether the conjugated or unconjugated spacer units propagate the exchange interaction. Also the effect of mode of coordination on magnetism will be examined. Interestingly, EPR studies in polycrystalline and frozen solutions suggest that the exchange in the complexes under investigation takes place via intramolecular rather than intermolecular pathway.

EXPERIMENTAL

Synthesis

An aqueous solution of dicarboxylic acid (LH_2) (0.5 mmol, 25 ml) was added to a hot alcoholic solution (25 ml) of $Cu(CH_3COO)_2 \cdot H_2O$ (1 mmol) and the mixture was stirred for 30 min. To that was added dien (1 mmol) in 10 ml of alcohol in small fractions and stirring was continued for further 30 min while heating gently. The solution turned to bluish-violet. Then aqueous solution of $NaClO_4$ (1 mmol) was added and kept for slow evaporation. Good quality single crystals were obtained in 3–4 days. Oxalato complexes (**1**) have yielded two types of crystal (**I** and **II**). In the case of isophthalato (**5**) and terephthalato (**6**) complexes the sodium salts were used instead of their pure dicarboxylic acids. Microanalytical data: Found (calc.): Complex **1**, C, 19.3 (19.4); H, 4.2 (4.2); N, 13.7 (13.6). **2**, C, 21.0 (20.8); H, 4.6 (4.4); N, 13.1 (13.3). **3**, C, 22.3 (22.2); H, 4.9 (4.6); N, 13.0 (13.0). **4**, C, 25.3 (25.0); H, 4.5 (4.5); N, 12.3 (12.5). **5**, C, 25.3 (25.0); H, 4.6 (4.5); N, 12.8 (12.5). **6**, C, 22.5 (22.5); H, 4.6 (4.5); N, 12.9 (12.5).

CAUTION! Percholate salts can be potentially explosive during drying and grinding. So proper care should be exercised while handling such compounds. So far we have not experienced any problems during the preparation of samples.

Physical measurements

Elemental analyses of the complexes were carried out on a Perkin–Elmer PE 2400 Series II analyzer. FT–IR spectra were recorded for KBr pellets using a Biorad FTS-40 spectrophotometer. Electronic spectra in aqueous solutions were recorded on a Shimadzu UV-160 A UV-visible spectrophotometer. Cyclic voltammetric studies were carried out in aqueous solutions on a Princeton Applied Research Electrochemical system (model 273 A). Glassy carbon was used as a working electrode, Ag/AgCl was used as a reference electrode, Pt wire was used as an auxiliary electrode and 0.1 M tetraethylammonium tetrafluoroborate as a supporting electrolyte. Electron paramagnetic resonance (EPR) measurements were conducted on polycrystalline samples and frozen solutions using a Bruker ESP 300 X-band spectrometer and 100 kHz field modulation. DPPH was used as a field marker ($g = 2.0036$). Studies at liquid nitrogen temperature (77 K) were performed with a quartz inserting Dewar.

RESULTS AND DISCUSSION

All the complexes are deep bluish-violet and are soluble in several solvents. The elemental analyses data confirm the formation of dinuclear complexes. FT–IR spectra for oxalato and malonato complexes are shown in Fig. 1. Characteristic ligand bands for the complexes are observed in the finger print region. All the complexes except oxalato (**1**) showed similar spectral behavior. Selected IR data for the complexes are given in Table 1. The spectrum for oxalato differed in the positions of bands corresponding to carboxylato group. The bands for ν(NH) occurred in the range 3000–3250 cm^{-1} while ν(CH) of dien are observed in the range 2880–2970 cm^{-1}. Intense bands at 1144, 1106, 1049 and 629 cm^{-1} are attributed to perchlorato anion. While these bands were sharp and resolved, oxalato (**1**) and phthalato (**4**) complexes showed only partially resolved bands indicating two types of ClO_4^- ions, probably one being weakly coordinated and the other being free. Indeed the crystal structure of phthalato complex (**4**) reveals the weak coordination of perchlorate ion to one of the Cu(II) moieties [12]. Although two types of crystal phases (**I** and **II**) were obtained for oxalato both of them showed identical FT–IR spectra suggesting similar mode of coordination for COO^- moiety. The oxalato complexes also exhibited two partially resolved bands at 1652 and 1632, attributable to $\nu_{as}(COO^-)$ and a single band at 1462 cm^{-1} for $\nu_s(COO^-)$, while the rest of the complexes showed only a single intense band at 1603 for ν_{as} and 1405 cm^{-1} for ν_s. The two bands for oxalato indicate a difference in the strength of binding of carboxylato groups with the metal ions while the other acids (L) form a similar kind of binding. The $\Delta\nu$ ($\nu_{as} - \nu_s$) values can be used to determine the mode of coordination. These values for the present complexes (198–200 cm^{-1}) fall in the borderline for monodentate and bidentate chelation [5,19] and probably indicate that one of the oxygen atoms of the COO^- group makes a stronger coordination with the Cu(II) ion while the other participates in a relatively weaker coordination with the same or next nearest neighboring metal ion forming a one dimensional polymeric chain. In fact the crystal structures of succinato and

phthalato complexes do reveal this type of coordination [12,20]. Interestingly in the case of malonato, succinato, phthalato, isophthalato and terephthalato complexes, the carboxylato bands have shifted to a higher wave number suggesting the formation of chelate or *syn–anti* type of coordination for the carboxylato group while it adopts an *anti–anti* coordination in the oxalato complex. As the structural assignment of carboxylato complexes from IR data alone is not very reliable, a caution is made that the structures proposed are tentative.

Aqueous solutions of the complexes showed a broad band in the region 500–800 nm attributable to *d-d* transitions. In the case of oxalate this band is centered at 629 nm while the rest of the complexes showed a maximum at 614 nm (Table 1). This value falls in the range for square pyramidal geometry around copper(II) [21].

Cyclic voltammographs of the complexes in aqueous solutions showed a quasi reversible redox couple attributable to Cu(II)/Cu(I) with $E_{1/2}$ varying in a narrow range -0.45 to -0.46 V. However, the peak–peak separation (ΔE) is sensitive to the bridging ligand and varies from 59 to 96 mV in the order isophthalato > oxalato > phthalato > terephthalato > succinato > malonato and corresponds to involvement of one electron (Table 1). Probably the variation in ΔE might be associated with the changes in magnetic exchange interactions between the metal centers due to varying lengths of spacers and overlap of magnetic orbitals with the bridging ligand. These features suggest that both the copper centers have identical molecular geometries and exhibit a single redox couple.

All the complexes except oxalato (**I** and **II**) showed similar EPR spectral characteristics for their polycrystalline samples at 298 and 77 K. The spectra consist of a broad asymmetric resonance with a partially resolved parallel g feature. In spite of the fact that the two phases of the oxalato complex have shown identical IR and UV-visible spectra, their EPR are

quite different, while phase **I** showed three narrow and well resolved signals corresponding to a rhombic g tensor with $g_1 = 2.151$, $g_2 = 2.127$ and $g_3 = 2.050(3)$, phase **II** exhibited relatively broad features attributable to an axial g tensor ($g_\parallel = 2.182$ and $g_\perp = 2.086$). Representative spectra for oxalato (**I** and **II**) and malonato are depicted in Fig. 2. Hyperfine features due to copper could not be resolved due to exchange interactions. The sharp high field signals in the ESR spectra of Fig. 2 are g markers from DPPH. The spin Hamiltonian parameters listed in Table 2 indicate that oxalato I with $g_\parallel < g_\perp$ (g_1, g_2) has a d_{z^2} electronic ground state with a tetragonally compressed square pyramidal geometry while the rest of the complexes have tetragonally elongated square pyramidal geometry with the unpaired electron in $d_{x^2-y^2}$ orbital. The broad asymmetric resonance observed for the rest of the complexes is due to exchange interactions between metal ions while this is negligible for oxalato complexes as the magnetic orbitals of the metal ion and the oxalato group do not make a suitable overlap [16–18]. Terephthalato (**6**) [13] and phthalato (**5**) [12] complexes exhibit antiferro and ferromagnetic exchange interactions.

[a] Error in g values is ± 0.003.

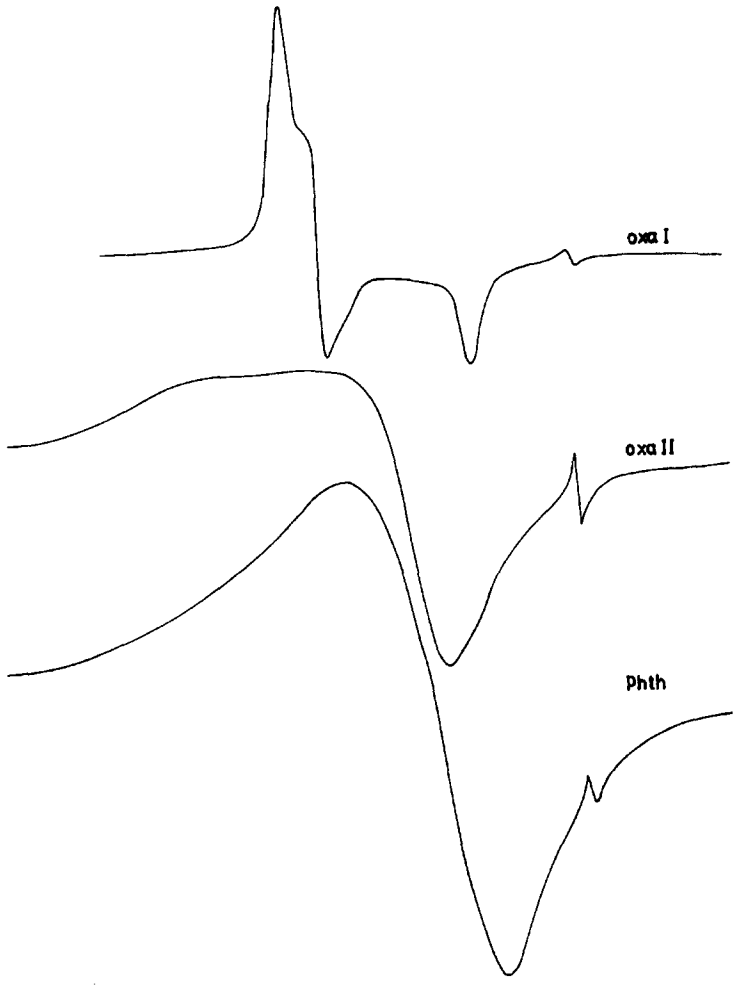

Fig. 2. X-band EPR spectra for polycrystalline samples of (a) oxalato **I**, (b) oxalato **II** and (c) phthalato at 77 K. Sharp high field signals are g markers from DPPH.

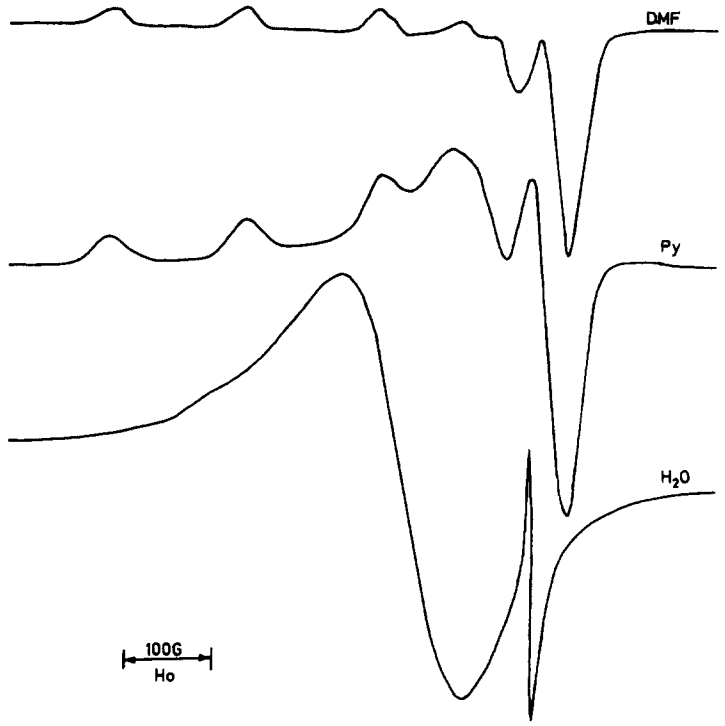

Fig. 3. X-band frozen solution EPR spectra for [(dien)Cu(malonato)Cu(dien)]$(ClO_4)_2$, **3** at 77 K.

Frozen solutions of the complexes in DMF and pyridine showed spectra characteristic of axial g and A tensors. Three of the four parallel hyperfine features due to copper are well resolved, while the fourth is overlapped by $g_\perp$ features which are partially resolved. Apart from these an extra line was observed in the highfield side which apparently coincides with the signals due to DPPH and is an "angular anomaly" due to power averaging [22]. Spectra for frozen aqueous solutions are similar that for their solid state. The spectra in different solvents for malonato are shown in Fig. 3. The spin Hamiltonian parameters (Table 3) vary with solvent and indicate the coordination of the solvent molecule with the metal ion. In the case of aqueous solutions the complexes adopt a suitable geometry so that the exchange interaction is significant. The spectroscopic and EPR investigations suggest the tentative molecular structures for the complexes as shown in Scheme 1. Identical spectra for polycrystalline samples as well as for the frozen aqueous solutions indicate that the exchange in these complexes is intramolecular rather than intermolecular. These results are consistent with the magnetic studies of Tsipis *et al.* for terephthalato and phthalato complexes [12,13]. Although the Cu···Cu separation varies due to variation length of the bridging dicarboxylato ligand, the identical spectral features for the malonato, succinato, phthalato, isophthalato and terephthalato complexes suggest that the exchange interaction in these complexes is not distant dependent and propagates through both conjugated and unconjugated bridges. The only important requirement is that the magnetic orbitals and the bridging ligand should make a proper overlap.

Table 3. EPR data for the frozen solutions of [(dien)Cu(malonato)Cu(dien)]$(ClO_4)_2$, **2** at 77 K[a]

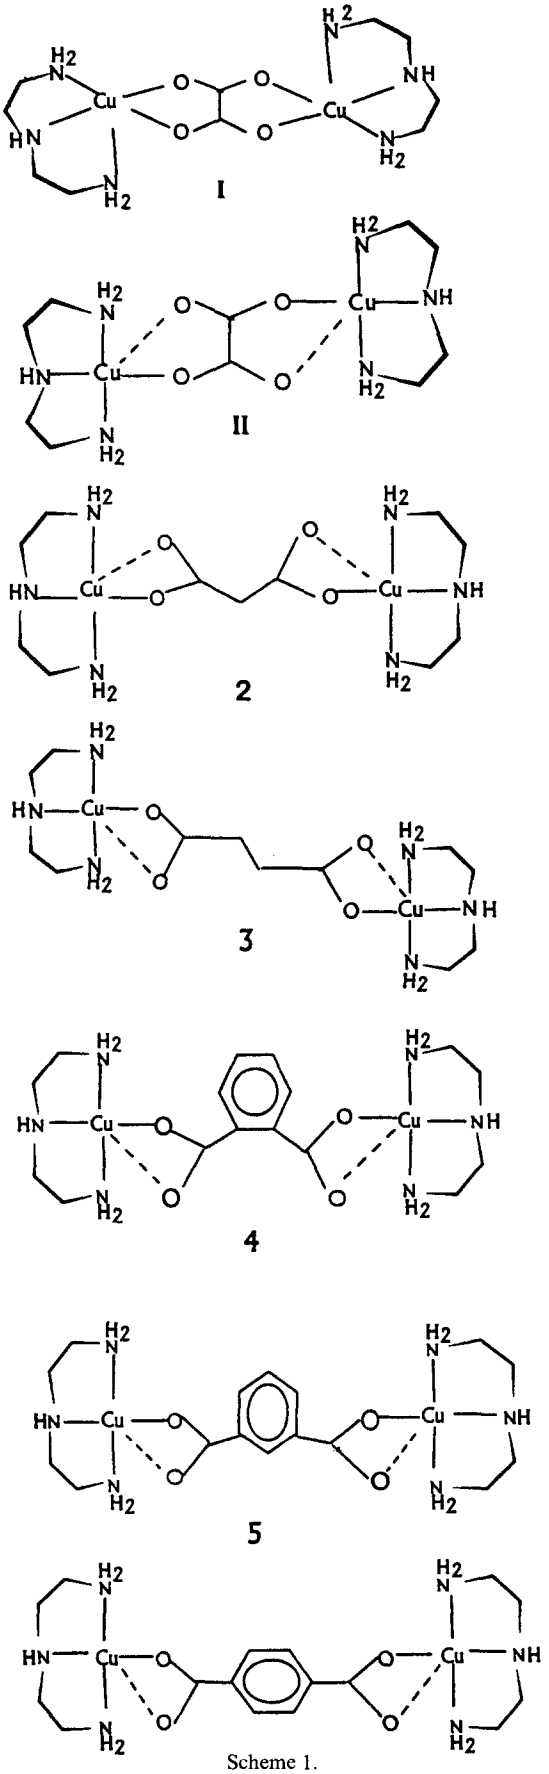
Solvent	$g_\parallel$	$g_\perp$	g_{av}	$-A_\parallel$	$-A_\perp$
Water			2.096	[b]	[b]
DMF	2.238	2.072		188.1 (177.0)	18.0
Pyridine	2.219	2.067		188.0	20.2

[a] Error in g values ± 0.003 and A values are given in units of $\times 10^{-4}$ cm^{-1}. Error in $A_\perp$ is larger as these values were estimated from the linewidth of partially resolved g perpendicular features. Values in parentheses are for ^{65}Cu isotope.

[b] Not resolved.

CONCLUSIONS

Dinuclear Cu(II) dien complexes with dicarboxylato bridges were synthesized and characterized. The Cu···Cu separation is changed by varying the length of the spacer dicarboxylato ligand. The carboxylato group adopts *anti–anti* coordination in oxalato while *syn–anti* or chelate coordination for the rest



Scheme 1.

of the complexes. The geometry around copper is distorted square pyramidal. The intramolecular exchange interaction is rather negligible for oxalato complexes while the rest show similar magnetic behavior irrespective of chain length, suggesting a significant role of the overlap between the magnetic orbitals of the metal ion and the carboxylato group to propagate the exchange between the paramagnetic centers.

Acknowledgment—The authors acknowledge Dr S. D. Gomkale, Director, C.S.M.C.R.I., Bhavnagar for constant encouragement.

(Received 10 April 1997; accepted 3 September 1997)

Abstract—Two different complexes of copper(II) propionates, $[Cu_2(C_2H_5CO_2)_4]$ (**1**) and $Na[Cu_4(C_2H_5CO_2)_9(H_2O)_3]$ (**2**) have been isolated from the reaction of $Cu(II)(NO_3)_2 3H_2O$ with propionic acid in an aqueous solution of NaOH. X-ray structural analysis revealed that complex **1** consists of a one-dimensional chain of an apical-to-basal Cu—O—Cu linkage of pairwise binuclear anhydrous cupric propionates, which agrees with results previously reported. Compound **2** consists of a cation Na^+ which interacts with six oxygen atoms of carboxylate groups, and anionic $[Cu_4(C_2H_5CO_2)_9(H_2O)_3]^-$ ion, which contains one isolated *syn–syn*-carboxylato dimeric copper(II) complex $[Cu_2(C_2H_5CO_2)_4(H_2O)_2]$, and a linear chain containing one *syn–syn*-carboxylato dimeric $[Cu_2(C_2H_5CO_2)_4]$ and its apical position linked by a carboxylate bridge with a unit of $[Cu(C_2H_5CO_2)(H_2O)]$. Cryomagnetic susceptibilities **1** and **2** have been measured over the temperature range 4–300 K. In **1**, the spins are coupled through an alternating one-dimensional antiferromagnetic interaction. In **2**, the cryomagnetic exchange interaction has been interpreted in terms of a strong antiferromagnetic interaction associated with the two paired dinuclear units of Cu(II)···Cu(II), and one mononuclear Cu(II) unit which complies with a Curie–Weiss law. © 1998 Elsevier Science Ltd. Keywords: crystal structure; magnetic property; copper complexes; polynuclear complexes; propionate complexes.

The chemistry of the copper complexes with various carboxylates has been investigated for long time. A large number of binuclear copper(II) carboxylate adducts, $[Cu(RCO_2)L]_2$, have extensively been investigated in an effort to clarify the factors influencing the magnitude of the intramolecular magnetic exchange interaction which occurs between two Cu(II) ions in these compounds [1–7]. In most $[Cu(RCO_2)_2L]_2$ complexes, two copper(II) atoms are bridged in pairs by four *syn–syn*-carboxylato groups with two additional unidentate ligand (L) occupying the apical position.

Relatively few studies have been reported on the magneto-structural corrections in the non-adduct complex of copper(II) carboxylates such as $[Cu_2(RCO_2)_4]$ [4]. Although an X-ray crystallographic structure [8] and cryomagnetic data [9] of the dimeric copper(II) propionate $[Cu_2(C_2H_5CO_2)_4]$ have been reported in the past, the precise cryomagnetic behaviour, especially with regard to the X-ray structural data for this compound has, however, been rather controversial.

The contrasting structures of dimeric adduct $[Cu_2(RCO_2)_4L_2]$, and polymeric non-adduct $[Cu_2(RCO_2)_4]$ prompted us to reinvestigate in particular the cryomagnetic behaviour of the non-adduct copper(II) propionate $[Cu_2(C_2H_5CO_2)_4]$ compound. However, in the course of our synthetic investigations of the copper(II) propionic acid system, the products of a blue-green complex $[Cu_2(C_2H_5CO_2)_4]$ (**1**) and an emerald-green species $Na[Cu_4(C_2H_5CO_2)_9(H_2O)_3]$ (**2**) are isolated from the mixted aqueous solution of $Cu(NO_3)_2 \cdot 3H_2O$, propionic acid, and NaOH depending on their isolation conditions. The preparation, structure, EPR, and cryomagnetic behaviours of these two compounds are described in this paper.

EXPERIMENTAL

Preparation of $[Cu_2(C_2H_5CO_2)_4]$ **(1)** *and* $Na[Cu_4(C_2H_5CO_2)_9(H_2O)_3]$ **(2)**

In the earliest report [9], unhydrated copper(II) propionate was prepared from excess of the diluted acid and copper carbonate and then dehydrated at 100°C over posphoric oxide. Here we modified the procedure as following: propionic acid (10 mmol) was dissolved in 50 cm^3 of water, and the resulting solution was adjusted to pH = 5.8 with ca 100 cm^3 of 0.25M NaOH. To this solution 25 cm^3 of aqueous $Cu(NO_3)_2 \cdot 3H_2O$ (60 mmol) was added under stirring. The resulting blue-green solution was allowed to stand in air at room temperature for one week and the earlier blue-green crystals of the compound **1** were filtered, after which the filtrate was concentrated (ca 3 weeks) to one third of its volume and the emerald-green crystals suitable for X-ray analysis of compound **2** were collected, washed with water, and air-dried at room temperature. Anal. Calc. (found) for $C_{12}H_{20}Cu_2O_8$ **(1)**: C, 33.40 (33.48) H, 4.60 (4.62)%. IR(cm^{-1}): 1628 (s), 1590, 1556 (s). Calc. (found) for $C_{27}H_{51}Cu_4NaO_{21}$ (2): C, 32.77 (32.56); H, 5.16 (5.21)%. IR (cm^{-1}): 1619 (s), 1592 (s), 1540.

X-ray crystallography

Intensities and lattice parameters of the blue-green crystal of **1** and the emerald-green crystal of **2** were measured at 25°C on an Enraf–Nonius CAD4 diffractometer by using monochromated Mo–K_α radiation. Crystal parameters and the selected data of collection and refinements of the complexes are summarized in Table 1. The structure was solved by heavy-atom method and subsequent difference Fourier maps, followed by full-matrix least-squares refinement based on F with the NRCVAX computer program [10]. The hydrogen atoms were placed at calculated positions with isotropic thermal parameters.

Physical measurements

Infrared spectra were recorded on a Bio-Rad FTS-40FTIR spectrophotometer as KBr pellets in the 4000–400 cm^{-1} region. X-band EPR spectra at 300 K for the complexes were recorded on a Bruker ECS-106 spectrometer. Temperature dependence of magnetic susceptibilities of the polycrystalline sample were measured between 4.2 and 300 K at a field of 1 T using a Quantum Design Model MPMS computer-controlled SQUID magnetometer. Diamagnetic corrections were made using Pascal's constants [11].

RESULTS AND DISCUSSION

Synthesis and structural characterizations of **1** *and* **2**

The reaction of $Cu(NO_3)_2 \cdot 3H_2O$ and NaOH with propionic acid in aqueous solution, on the time of

crystal growing, deposited the initial product blue-green crystal **1** from the mixed solution, and then deposited the emerald-green compound **2** after concentration of the solution.

The crystal structure of **1** is in good agreement with that previously reported [8] which shows the structure of the polymeric chain of $[Cu_2(C_2H_5CO_2)_4]$ (as shown in Fig. 1). The *syn–syn* propionate bridged Cu(II) dimer is self-assembly oxygen-bridged (apical) to the nearest dimers. This bridging arrangement gives rise to a Cu···Cu′ (apical) distance of 3.2442(3) Å, substantially longer than Cu···Cu of 2.5826(12) Å associated with the $Cu_2(C_2H_5CO_2)_4$ core. There was no doubt that the original Cu···Cu distances of 2.578(4) Å [8] are not significantly different from our refinement (2.5826(12) Å). The original Cu—O (basal) distance of 1.94 Å is shown to be somewhat shorter than the 2.0024(19) Å from our refinement, whereas the present Cu—O (apical) distance of 2.2259(19) Å is somewhat shorter at 2.28(1) Å in the original structure. The most important part of the previous determination was the geometry of their bridging propionate groups, the mean O—C—O angle (113°) was clearly quite different from our refinement value of 124.2°.

The crystal structure of **2** is shown in Fig. 2. Representative bond distances and angles are compiled in Table 2. The structure is composed of three units of formula $Na[Cu_4(C_2H_5CO_2)_9(H_2O)_3]$ (**2**); (i) the discrete hydrated binuclear $[Cu_2(C_2H_5CO_2)_4(H_2O)_2]$ (**a**), where two Cu(II) atoms are bridged by four propionate groups in *syn–syn* conformation; (ii) The bridged Cu(1)···Cu(2) distance, 2.5777(16) Å, which is close to that of **1** or to that of the well-known copper(II) acetate monhydrate dimer [12] and (iii) the polymeric chain of $[Cu_4(C_2H_5CO_2)_5(H_2O)]$ moiety, which consists of one unhydrated copper(II) propionate $[Cu_2(C_2H_5CO_2)_4]$ dimer (**b**), and its apical positions which are bridged by two additional *syn–anti*-propionate groups [O(15)—C(19)—O(16)] from the axial position of the central copper(II) [Cu $(C_2H_5CO_2)_2(H_2O)$] (**c**) moiety. In **c**, the Cu(4) atom is coordinated by one oxygen atom [O(16)] from the bridged *syn–anti*-propionate group, two oxygen atoms of O(17) and O(19) from monodentate propionate groups, one oxygen atom O(21) from an aqua ligand, and one oxygen atom O(19) from the neighbour **c** moiety, thus forming a distorted square pyramidal structure. In addition, the oxygen O(19) is self-assembling and bridged to the next Cu(4) of the neighbour **c** unit. These bridged Cu···Cu distances for Cu(1)···Cu(2), Cu(3)···Cu(3), and Cu(4)···Cu(4) in **a**, **b**, and **c** moieties are 2.5777(6), 2.6092(20), and 3.2146(20) Å, respectively.

Finally, it is noteworthy that Na^+ cation is six-coordinated with six oxygen atoms [O(2), O(9), O(13), O(15), O(18), and O(20)] of the subunits of **a**, **b**, and **c**, respectively, as shown in Fig. 2. The mean Na—O interatomic distance is 2.40 Å.

Magnetic properties

The room-temperature X-band (9.8 GHz) EPR spectra of the samples of **1** and **2** show a broad signal

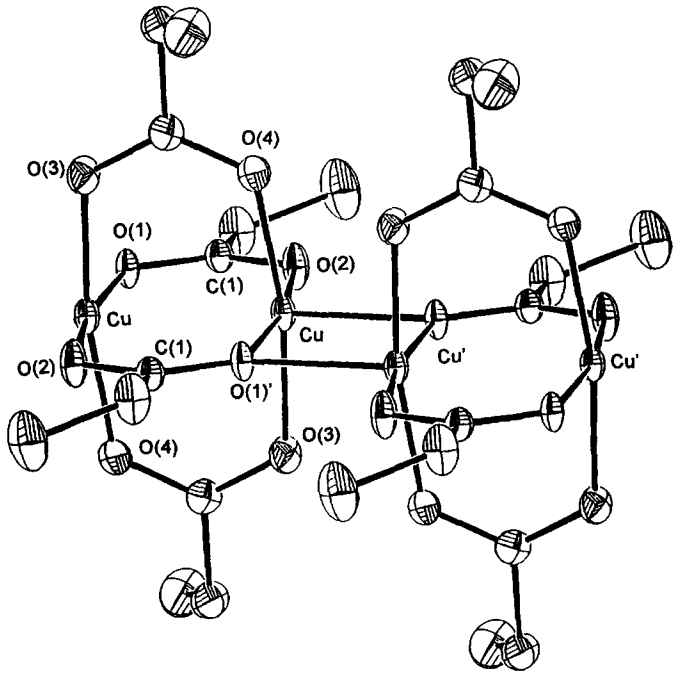

Fig. 1. ORTEP stereoview of **1** (30% probability thermal ellipsoids).

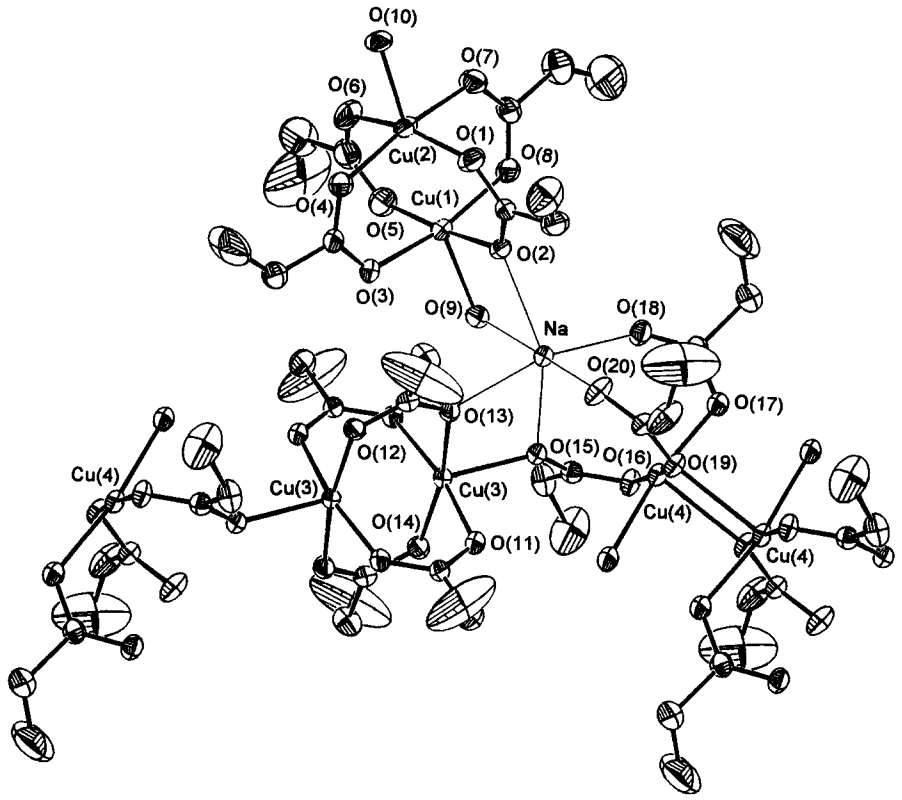

Fig. 2. ORTEP stereoview of **2** (30% probability thermal ellipsoids).

with a pronounced hump at $g = 2.07$ for **1** and 2.05 for **2** respectively. The results of the temperature dependence of magnetic measurements for $[Cu_2(C_2H_5CO_2)_4]$ **1** and $Na[Cu_4(C_2H_5CO_2)_9(H_2O)_3]$ **2** are illustrated in Figs 3 and 4, respectively.

The solid lines in Fig. 3 of compound **1** represent a best fit of data. As already mentioned in the molecular structure section, the bond distance of the two copper(II) ions Cu···Cu (basal) is shorter than that of the self-assembly oxygen-bridged Cu′···Cu′ (apical) in this polymeric chain. Thus there are two magnetic interactions present in the system. Consequently, the data were analyse by use of an analytical expression for the exchange interaction in an alternating chain of $S = 1/2$ ions developed by Hatifield [13,14] which has the following form:

$$\chi_m = Ng^2\mu_B^2[(A + B_x + C_x^2)/(1 + D_x + E_x^2 + F_x^3)] \quad (1)$$

with $x = J/kT$. The coefficients A–F are functions of the alternation parameter α defined by the Hamiltonian

$$H = -2J\sum_{i=1}^{n/2}[S_{2i}S_{2i-1} + \alpha S_{2i}S_{2i+1}] \quad (2)$$

where J and αJ are the coupling constants of Cu···Cu and Cu···Cu′ respectively. The data fit of this expression resulted (the solid lines in Fig. 3) in $J = -220$ cm^{-1}, $g = 2.07$ (from EPR) and the alternation parameter $\alpha = 0.10$. It is noteworthy that the original reported $2J$ value of 300 cm^{-1} for compound **1** [9], obtained from the simple Bleaney–Bowers equation of a two spin system with $H = 2JS_1S_2$, is smaller than that of $2J$ obtained by us.

The cryomagnetic susceptibility of compound **2** is illustrated in Fig. 4, in the form of χ_m(4Cu) and $\chi_m T$ vs T plots. Upon lowering the temperature from 300 K to about 90 K, the $\chi_m T$ value decreases from 0.86 cm^3 mol^{-1} K ($\mu_{eff} = 2.61\ \mu_B$) to a value of 0.39 cm^3 mol^{-1} K($\mu_{eff} = 1.75\ \mu_B$) indicating a strong antiferromagnetic interaction, whereas on reaching an extended plateau between 90 and 8 K, the values of $\chi_m T$ remain practically constant, and finally decreases below 8 K. In view of the crystal structure of **2**, magneto-structural correlation is complicated in the present system, nevertheless, the shorter distance between copper(II) atoms with bridging a *syn–syn* carboxylate dimer, the exchange coupling is always larger and antiferromagnetic in nature [4]. Clearly, as mentioned above in the structural analysis, this strong antiferromagnetic interaction should occur between Cu(1)···Cu(2) and Cu(3)···Cu(3). The magnetic interaction between the self-assembly oxygen-bridged Cu(4)···Cu(4) is also rather smaller in compound **1**. These become virtually diamagnetic at low temperature and Cu(4) dominates the magnetic response

of the compound **2**. Accordingly, we attempted to fit the cryomagnetic data, however, an appropriate known theoretical model is not available, and after we tested a variety of models, the only one that gave a reasonable data fit involved two different dinuclear centres and one mononuclear centre in equal proportions, with different exchange constants. The magnetic susceptibility can be described by eqn (3),

$$\chi_m = \chi_1 + (1/2)\chi_2 + \chi_3 + N\alpha \qquad (3)$$

where χ_1, χ_2, and χ_3 are the temperature-dependent magnetic susceptibilities for the units of Cu(1)···Cu(2), Cu(3)···Cu(3), and Cu(4) respectively, and $N\alpha$ is the temperature-independent susceptibility. Assuming that the Cu(4) unit conforms to the Curie–Weiss law, with Weiss constant θ as an intermolecular exchange interaction, then $\chi_3 = C/(T-\theta)$. The sum of the exchange Hamiltonian of χ_1 and χ_2 is $H = -2J_1\Sigma S_1S_2 - 2J_2\Sigma S_1S_2$ where $S_1 = S_2 = 1/2$, has the Bleaney–Bowers expression (4) [15]

$$\chi_1 + (1/2)\chi_2 = (2Ng^2\mu_B^2/kT)\{[3+\exp(-2J_1/kT)]^{-1} + 1/2[3+\exp(-2J_2/kT)]^{-1}\} \qquad (4)$$

where J_1 and J_2 are the exchange interaction constants associated with Cu(1)···Cu(2) and Cu(3)···Cu(3) units respectively. With expression (3), and letting $J_1 > J_2$ [2–4], the best fit for **2** resulted in $J_1 = -225$ cm^{-1}, $J_2 = -160$ cm^{-1}, $g = 2.0$, $C = 0.39$ cm^3 mol^{-1} K, $\theta = -0.49$ K, and $N\alpha = 60 \times 10^{-6}$ cm^3 mol^{-1}. The solid line in Fig. 4 is calculated using the parameters derived above. The constant C value of 0.39 cm^3 mol^{-1} K is close to the value of 0.38 cm^3 mol^{-1} K for the noncoupled one spin $S = 1/2$ system; and the smaller θ value of -0.49 K indicates that a weak intermolecular antiferromagnetic interaction contributes to the bulk susceptibility at low temperature.

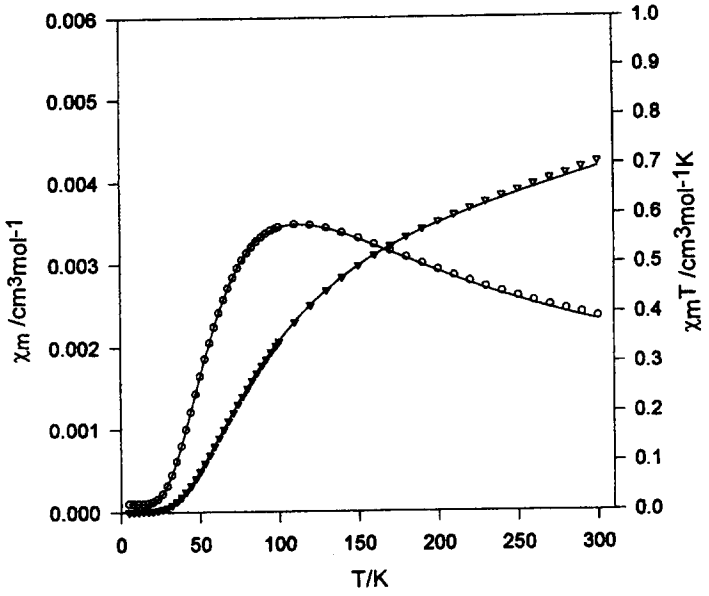

Fig. 3. Thermal variation of the molar magnetic susceptibility for **1** in the form χ_m and $\chi_m T$ vs T, the solid line is the best theoretical fit (see text).

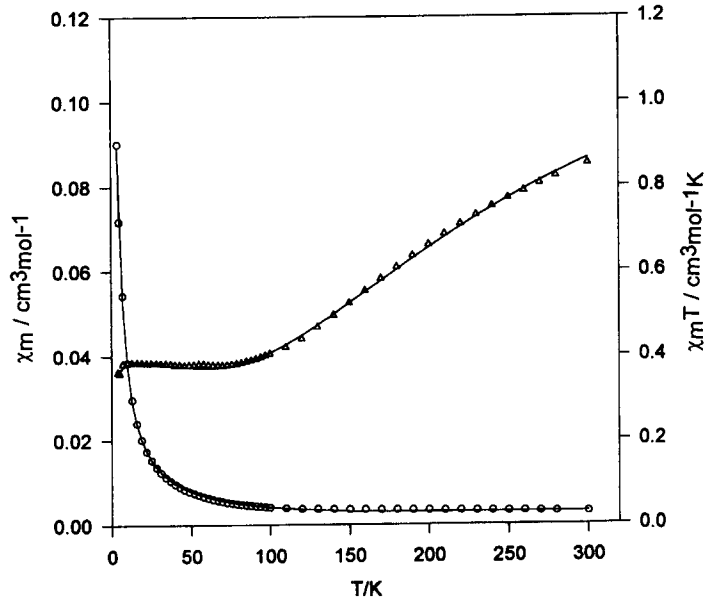

Fig. 4. Thermal variation of the molar magnetic susceptibility for **2** in the form χ_m and $\chi_m T$ vs T.

Finally, it is of interest to note that to our knowledge, compound **2** is the first example of a polymeric copper(II) compound built from a discrete copper(II) carboxylate dimer, carboxylato-bridged polymic chain, and the six-coordinated sodium cation.

SUPPLEMENTARY MATERIAL

Tables containing atom positions, anisotropic displacement parameters, hydrogen atom location, and bond lengths and angles have been deposited and are also available from the authors on request.

(Received 24 June 1997; accepted 27 August 1997)

Abstract—Treatment of $W(CO)_6$ with *N,N*-dichloro-*p*-toluenesulfonamide affords $[W(NTs)_2Cl_2]_x$ **1**, which reacts with bipy (2,2′-bipyridine) to give the adduct $W(NTs)_2Cl_2(bipy)$ **2**. The average W—N(imido), W—Cl and W—N (bipy) distances are 1.782, 2.352 and 2.284 Å, respectively. Reaction of $[W(NTs)_2Cl_2]_n$ with NaTp [Tp = hydrido(trispyrazolyl)borate] gives $TpW(NTs)_2Cl$ **4**. These tungsten(VI) tosylimido complexes undergo imido transfer reactions with tertiary phosphine to give W(IV) and the *N*-tosyl phosphinimine. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: tosylimido; complexes; tungsten(VI).

While high-valent tosylimido-metal (M=NTs) species are often implicated as the active intermediates in metal-mediated olefin aziridination [1] and aminohydroxylation [2], well-defined isolated tosylimido-metal complexes are rather uncommon [3–5]. Sheldrick and coworkers first reported the synthesis of $W(NSO_2Ph)_2Cl_2(CH_3CN)_2$ by oxidative imination of $W(CO)_6$ with *N,N*-dichlorobenzenesulfonamide [3a]. Nevertheless, the reactivity of this tungsten(VI) benzensulfonylimido complex has not been explored. In an effort to develop metal-based reagents for amination of hydrocarbons, we here report the crystal structure and reactivity of a tosylimido complex of tungsten(VI).

RESULTS AND DISCUSSION

Synthesis of bis-tosylimido tungsten(VI) complexes

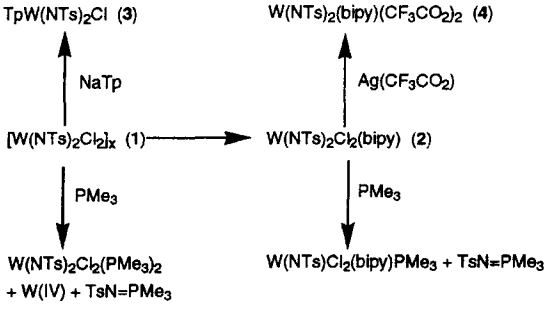
The tungsten(VI) bis-tosylimido complex $[W(NTs)_2Cl_2]_x$ **1** was prepared according to Sheldrick's procedure [3a] by oxidative imination of $W(CO)_6$ with *N,N*-dichloro-*p*-toluenesulfonamide, isolated as an air-sensitive yellow polymeric solid (eqn (1)).

$$W(CO)_6 + 2TsNCl_2 \rightarrow [W(NTs)_2Cl_2]_x + 6CO + Cl_2 \quad (1)$$

Complex **1** is insoluble in dichloromethane or toluene but readily dissolves in donor solvents such as THF and acetonitrile, in which $W(NTs)_2Cl_2(solv)_2$ are presumably formed. The IR spectrum of **1** is $\nu_{S=O}$ at 1158 cm^{-1} long with an intense band at 1098 cm^{-1}. The latter band is most likely due to $\nu_{W=N}$ which is extensively coupled with other stretching modes of the tosyl group. Polymeric **1** was found to be a good starting material for mononuclear tungsten tosylimido complexes, the syntheses of which are summarized in Scheme 1.

Adduct formation

Reactions of **1** with Lewis bases L gave adducts $W(NTs)_2Cl_2L_2$ [L = phosphines or pyridine]. Unlike



Scheme 1.

* Author to whom correspondence should be addressed.

1, these adducts are air-stable and can be recrystallized in air without decomposition. The structure of the bipy adduct $W(NTs)_2Cl_2(bipy)$ **2** has been established by X-ray crystallography. Figure 1 shows a perspective view of the molecule; selected bond lengths and angles are given in Table 2. The geometry around tungsten is octahedral with two *cis*-disposed tosylimides and two *trans*-disposed chlorides. The average W-N(imido) distance of ca 1.781 Å is comparable to that in $W(NSO_2Ph)_2Cl_2(CH_3CN)_2$ (1.78 Å) [3a] and the W(II) tosylimido analogue $[Tp'W(NTs)(CO)_2](I_3)$ [1.77(1) Å, Tp' = hydridotris(3,5-dimethylpyrazolyl) borate] [3b], indicative of the triple bond character of the W—NTs linkage. The W—N distances for these tosylimido complexes are, however, approaching the upper limit for alkylimido- and arylimido-tungsten(VI) complexes [6]. The W—N—S linkage in **2** is essentially linear (ca 171°), consistent with the *sp* hydridization for the imido nitrogen. The reactions of **1** with phosphines are complex and result in the formation of yellow adducts $W(NTs)_2Cl_2(PR_3)_2$ and reduction of W(VI) to W(IV) (see below).

Chloride substitution

Treatment of **1** with lithium alkoxides and alkyls gave intractable orange oils along with lithium chloride. There were no crystalline products isolated for the reaction of **1** with $Na(C_5H_5)$ or $Li(C_5Me_5)$. The interaction of **1** with NaTp [Tp = hydridotris (pyrazolyl)borate] yielded a yellow solid **4**, which is slightly soluble in THF and CH_2Cl_2 but readily dissolved in DMF. ^1H NMR and IR spectroscopies confirm that this yellow product contains the Tp ligand. Although X-ray quality could not be obtained, the analytical and spectroscopic data are adequate to characterize **4** as the half-sandwich compound $TpW(NTs)_2Cl$. The Tp' analogue $Tp'W(NSO_2Ph)_2Cl$ has been isolated recently by Sundermeyer and coworkers [3c]. Similarly, treatment of **1** with NaL_{OEt} (L_{OEt} = $CpCo[\{Et_2O\}_2P{=}O]_3$) gave the ether-soluble $L_{OEt}W(NTs)_2Cl$, isolated as a yellowish green powder. However the crude product was found to be contaminated with *p*-toluenesulfonamide and has not yet been obtained in a pure form.

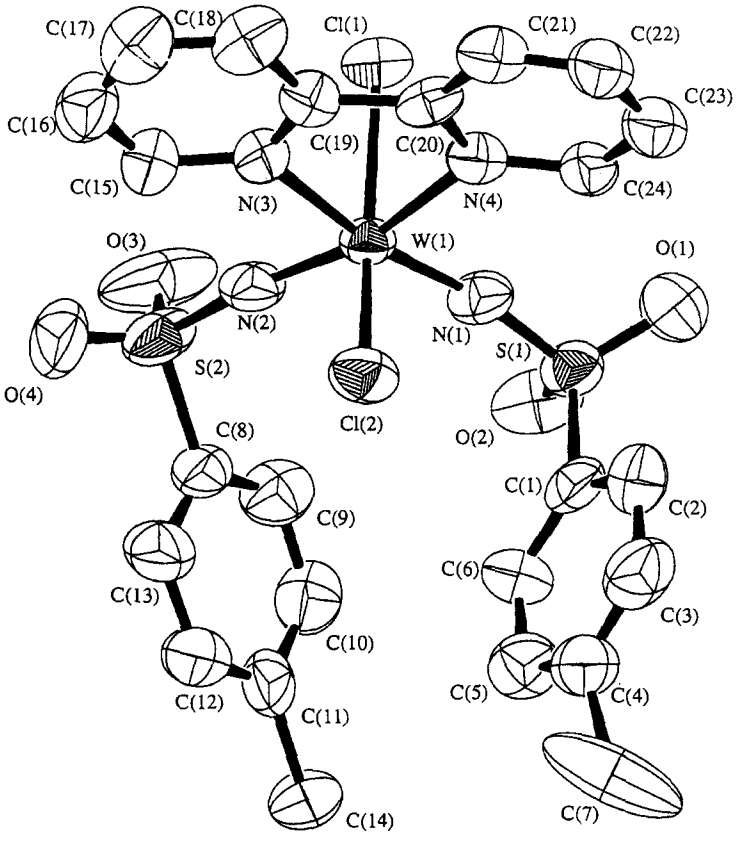


Fig. 1. Perspective view of $W(NTs)_2Cl_2(bipy)$ **2**.

Treatment of **1** with Ag(I) salts such as $AgCF_3CO_2$ and $AgCF_3SO_3$ did not lead to chloride abstraction. The chlorides in the adducts were, however, found to be more labile. For example, **2** undergoes metathesis with $AgCF_3CO_2$ slowly to give AgCl and $W(NTs)_2(bipy)(CF_3CO_2)_2$ **5**. The IR spectrum of **5** shows ν(C=O) bands at 1790, 1728 and 1674 cm^{-1}.

Reduction

No reactions between the above tungsten(VI) tosylimido complexes and olefins were observed under normal conditions. Reaction of **1** with tertiary phosphines such as PMe_3 and PMe_2Ph gave bluish green solutions, from which the *N*-tosyl phosphinimines and green oily materials were isolated along with the phosphine adducts $W(NTs)_2Cl_2(PR_3)_2$, identified by NMR spectroscopy. This suggests that imido transfer from **1** to phosphines occurred. The green oily material, presumably a reduced tungsten species, has not been characterized. Similarly treatment of **2** with PMe_3 gives $TsN{=}PMe_3$ and a green crystalline solid, which was characterized as the W(IV) imido species, $W(NTs)Cl_2(bipy)PMe_3$ (**6**), indicating that the bis-toyslimido-W(VI) complex undergoes imido transfer with phosphine to give monoimido-W(IV), as represented in eqn (2).

$$W(NTs)_2Cl_2(bipy) + 2PMe_3 \rightarrow W(NTs)Cl_2(bipy)PMe_3 + TsN{=}PMe_3 \quad (2)$$

Complex **6** is somewhat air-sensitive and decomposes in air to give a paramagnetic blue species even in the solid state.

While the W=N distance and the W—N—S(C) angle for **2** are not significantly different from those for normal W(VI) dialkylimido complexes [6], the former is apparently more reactive than the latter with respect to imido group transfer. Therefore it appears that the M=NR distance and M—N—R angle may not be a good indicator for the reactivity of imidometal complexes. On the other hand, the electronic factors, namely the electron deficiency of the imide ligand and the redox potential [7], of the imidometal complex have a profound influence on the metal-centered imido group transfer.

EXPERIMENTAL

All manipulations were carried out under nitrogen using standard Schlenck techniques. Solvents were purified, dried and distilled prior to use. Infrared spectra (Nujol) were recorded on a Perkin–Elmer 16 PC FT-IR spectrophotometer and mass spectra on a Finnigan TSQ 7000 spectrometer. ^1H NMR spectra were obtained on a Bruker ALX300 spectrometer. ^1H and ^{31}P chemical shifts (δ ppm) were reported with reference to $SiMe_4$ and H_3PO_4, respectively. Elemental analyses were performed by Medac Ltd, Brunel University, U.K.

The ligands bipy (2,2′-bipyridine) and NaTp (Tp = hydridotrispyrazolylborate) were obtained from Aldrich. The salt NaL_{OEt} (L_{OEt}=CpCo $[\{Et_2O\}_2P{=}O]_3$) was prepared according to the literature method [8].

Preparation of dichlorobis(tosylimido)tungsten(VI) (**1**)

This was prepared according to Sheldrick's procedure [3a]. To a solution $W(CO)_6$ (5.3 g, 15.06 mmol) ion CCl_4 (150 cm^3) was added dropwise a solution of *N,N*-dichloro-*p*-toluenesulfonamide (9.7 g, 40.42 mmol) in CCl_4 (70 mL) at 50–60°C. After addition, the reaction mixture was heated at reflux for 16 h. The resulting yellow solid was collected, washed with CCl_4 (3 × 20 ml) and dried *in vacuo* and is sufficiently pure for subsequent reactions (yield 8.4 g, 94%). ^1H NMR (CD_3CN): δ 2.50 (s, 6H, *p*-CH_3), 7.45 (d, J = 8 Hz, 4H, *m*-H), 7.81 (d, J = 8 Hz, 4H, *o*-H).

Preparation of 2,2′-bipyridinedichlorobis(tosylimido) tungsten(VI) (**2**)

To a suspension of **1** (0.55 g, 0.93 mmol) in CH_2Cl_2 (20 cm^3) was added 1 equiv. of bipy (0.15 g, 0.96 mmol) and the mixture was stirred at room temperature overnight. The solvent was pumped off and the residue was recrystallized from CH_2Cl_2/hexane to give orange crystals (yield 0.45 g, 65%). ^1H NMR ($CDCl_3$) δ 2.45 (s, 3H, *p*-CH_3), 7.27 (d, J = 7.8 Hz, 4H, *m*-H), 7.62 (d, J = 7.8 Hz, 4H, *o*-H), 7.67–9.72 (m, 8H, bipy). MS (FAB): m/z 750 $(M)^+$. Anal. Calc. for $[C_{24}H_{22}N_4Cl_2O_4S_2W]$: C, 38.5; H, 2.9; N, 7.5%. Found: C, 39.5; H, 3.2; N, 7.4%.

Preparation of chlorohydidotris(pyrazolyl)boratobis (tosylimido)tungsten(VI) (**3**)

To a suspension of **1** (0.5 g, 0.84 mmol) in THF (20 cm^3) was added 1 equivalent of NaTp (0.20 g, 0.85 mmol) and the mixture was stirred at room temperature overnight. The solvent was pumped off and the residue was recrystallized from THF/hexane to give a yellow crystalline solid (yield: 0.3 g, 47%). ^1H NMR ($CDCl_3$) δ 2.44 (s, 6H, *p*-CH_3), 4.62 (s, 1H, B*H*), 6.19 (t, J = 2.3 Hz, 2H, Tp), 6.39 (m, 1H, Tp), 7.24 (d, J = 7.8 Hz, 4H, *m*-H), 7.64 (d, J = 7.8 Hz, 4H, *o*-H), 7.46–7.99 (m, 6H, Tp). IR (cm^{-1}): 2538 $\nu_{B\text{-}H}$. MS (FAB): m/z 771 $(M+1)^+$, 735 $(M—Cl)^+$. Samples for analysis were recrystallised in air. Anal. Calc. for $[C_{23}H_{24}N_8BCl_8O_4S_2W \cdot H_2O]$: C, 34.9; H, 3.3; N, 14.1%. Found: C, 34.6; H, 3.1; N, 13.6%.

Reaction of **1** *with* NaL_{OEt}

To a solution of **1** (0.17 g, 0.29 mmol) in THF (20 cm^3) was added 1 equivalent of NaL_{OEt} (0.16 g, 0.29 mmol) and the mixture was stirred at room temperature overnight. The solvent was filtered and evaporated to dryness. The filtrate was recrystallized from ether/hexane to give pale yellowish green powder (yield 0.15 g). On the basis of NMR, the product was characterized as $L_{OEt}W(NTs)_2Cl$ contaminated with some *p*-toluenesulfonylamide (ca 10% by NMR). ^1H NMR ($CDCl_3$): δ 1.30 (overlapping t, 18 H, OCH_2CH_3), 2.43 (s, 6 H, *p*-CH_3), 4.21 (m, 12 H, OCH_2CH_3), 5.13 (s, 5H, C_5H_5), 7.33 (d, $J = 8.0$ Hz, 4 H, *m*-H) and 7.81 (d, $J = 8.0$ Hz, 4 H, *o*-H). $^{31}P\text{-}\{^1H\}$ NMR ($CDCl_3$): δ 116 (m). MS(FAB): 1094 $(M+1)^+$, 1059 $(M—Cl+1)^+$. Despite several attempts we have not been able to obtain analytical pure sample.

Preparation of 2,2′-bipyridinebis(tosylimido)bis (trifluoroacetato)tungsten(VI) (**5**)

To a solution of **2** (0.2 g, 0.27 mmol) in MeCN (20 cm^3) was added two equivalents of $AgCF_3CO_2$ (0.12 g, 0.53 mmol) and the mixture was stirred at room temperature overnight and filtered. The filtrate was evaporated to dryness and redissolved in THF. Addition of hexane and cooling at 0°C afforded a yellow crystalline product (Yield: 0.05 g, 25%). ^1H NMR ($CDCl_3$): δ 2.50 (s, 3H, *p*-CH_3), 2.53 (s, 3H, *p*-CH_3), 7.46 (d, $J = 7.8$ Hz, 4H, *m*-H), 7.82 (d, $J = 7.8$ Hz, 4H, *o*-H), 7.03–9.44 (m, 8H, bipy). MS (FAB): *m/z* 905 $(M+1)^+$. IR (cm^{-1}): 1790, 1728 and 1674 $\nu_{C=O}$. Samples for analysis were recrystallised in air. Anal. Calc. for $[C_{28}H_{22}N_4F_6O_8S_2W \cdot H_2O]$: C, 36.4; H, 2.6; N, 6.2%. Found: C, 36.3; H, 2.4; N, 5.8%.

Reaction of **1** *with* PMe_3

To a suspension of **1** (0.20 g, 0.34 mmol) in CH_2Cl_2 (10 cm^3) was added two equivalents of PMe_3 (0.68 mmol) and the mixture was stirred at room temperature overnight. The solvent was pumped off and the residue extracted with CH_2Cl_2. Recrystallization from CH_2Cl_2/hexane afforded a yellow solid and a green oil along with $TsN{=}PMe_3$ (δ^P 25.0). The yellow solid was identified as the phosphine adduct $W(NTs)_2Cl_2(PMe_3)_2$ by NMR spectroscopy. ^1H NMR ($CDCl_3$): δ 1.96 (d, $J = 19.8$ Hz, 18H, PMe_3), 2.33 (s, 6H, *p*-CH_3). 7.21 (d, $J = 7.8$ Hz, 4H, *m*-H), 7.73 (d, $J = 7.8$ Hz, 4H, *o*-H).

Reaction of **2** *with* PMe_3

To a solution of **2** (0.2 g, 0.27 mmol) in CH_2Cl_2 (20 cm^3) was added two equivalents of PMe_3 (0.53 mmol) and the mixture was stirred at room temperature overnight. The solvent was pumped off and the residue was recrystallized from CH_2Cl_2/hexane to give unreacted **2**, $Me_3P{=}NTs$ (δ^P 25.0), and a green solid (yield 25%). The green solid was identified as W(NTs) $Cl_2(PMe_3)$(bipy) by NMR spectroscopy and elemental analysis. ^1H NMR ($CDCl_3$): δ 1.16 (d, $J = 19.1$ Hz, 9H, PMe_3), 2.39 (s, 3H, *p*-CH_3), 7.27 (d, $J = 7.8$ Hz, 4H, *m*-H), 7.67 (d, $J = 7.8$ Hz, 4H, *o*-H), 6.72–9.46 (m, 8H, bipy). $^{31}P\text{-}\{^1H\}$ NMR ($CDCl_3$): δ 25.0 (s). Anal. Calc. for $[C_{20}H_{24}Cl_2N_3O_2PSW]$: C, 36.6; H, 3.7; N, 6.4%. Found: C, 36.0; H, 3.9; N, 6.0%.

X-ray structure determination of $W(NTs)_2Cl_2$(bipy) (**2**).

A summary of the crystal and data processing parameters for **2** is given in Table 1. Selected bond lengths and angles and final atomic coordinates are listed in Table 2. X-ray quality crystals of **2** were obtained from a saturated solution of CH_2Cl_2/hexane. Data were collected on a Rigaku AFC7R diffractometer at room temperature using graphite-monochromated Mo–K_α radiation. Intensity data were corrected for Lorentz and polarization effects. The structure was solved by Patterson method and refined by a full-matrix least-square analysis. All hydrogen atoms were refined isotropically and all other atoms were refined anisotropically. The hydrogen atoms were included as in idealized positions (C-H, 0.95 Å). List of final atomic coordinates, displacement factors and struc-

The $[Cu([9]aneN_3)(OH)(OH_2)]^+$ catalysed hydrolysis of the phosphotriester 2,4-dinitrophenyl diethyl phosphate ([9]aneN$_3$ = 1,4,7-triazacyclononane)

Robert W. Hay* and Norman Govan

School of Chemistry, University of St Andrews, St Andrews KY16 9ST, U.K.

(Received 15 July 1997; accepted 26 August 1997)

Abstract—The hydrolysis of the phosphotriester 2,4-dinitrophenyl diethyl phosphate to diethyl phosphate is catalysed by the macrocyclic complex $[Cu([9]aneN_3)(OH_2)_2]^{2+}$ ([9]aneN$_3$ = 1,4,7-triazacyclononane). The pH dependence of the hydrolysis over the pH range 6.2 to 8.7 establishes that the active catalyst is the hydroxoaqua complex. The *pK* for the equilibrium $[Cu([9]aneN_3)(OH_2)_2]^{2+} \rightleftharpoons [Cu([9]aneN_3)(OH)(OH_2)]^+ + H^+$ determined by potentiometric titration is 7.5 at 35°C and $I = 0.1$ mol dm^{-3} so that catalysis at pH values close to neutrality is observed. Hydrolysis occurs by intramolecular attack of coordinated hydroxide on the phosphate triester which is bonded via the phosphoryl oxygen to the copper centre. © 1998 Elsevier Science Ltd. Keywords: copper(II); triazacyclononane; hydrolysis; catalysis; phosphotriester.

A recent paper [1] has described the use of the complex $[Cu([9]aneN_3]^{2+}$ as a catalyst for the hydrolysis of the phosphodiester bis(4-nitrophenyl) phosphate (BNNP = 1). The complex is also active in the hydrolysis of peptides and proteins [2]. However, the mechanisms of these hydrolyses were not well defined. In the present paper we show that the complex is also a good catalyst for the hydrolysis of the water soluble phosphotriester 2,4-dinitrophenyl diethyl phosphate (**2**) and define the mechanism of the hydrolysis. X-ray crystallography has established that the complex $[Cu([9]aneN_3)Cl_2]$ [3] and the analogous bromo derivative [4] are five-coordinate with an approximate square pyramidal stereochemistry. In aqueous solution the halide ligands are displaced to give the diaqua complex. On the basis of previous studies on the activity of metal complexes on the hydrolysis of peptides [5] and phosphate esters [6] it is likely that the hydroxoaqua complex (**3**) is the active catalyst in the hydrolysis and this view is confirmed by the measurements described in this paper.

in dry DMF (350 cm^3) under an N_2 stream in a three necked flask fitted with a mechanical stirrer. The mixture was heated to 90°C in an oil bath and a solution of the ditosylate of 1,2-ethanediol [7] (32 g, 0.09 mol) in dry DMF added over a period of 45 min. Initially the solution became turbid, but on further heating at 105°C for 4 h in an oil bath, the contents of the flask turned a clear golden yellow. The solution was cooled to room temperature and the product precipitated as a white powder by slow addition of the DMF solution to water (2 dm^3) with rapid stirring. After filtration and washing with water (500 cm^3), the tosylate was recrystallised from $EtOH/H_2O$ and dried in a vacuum oven at 80°C. Yield: 38 g (74%), m.p. 220–223°C. ^1H NMR (TMS, $CDCl_3$) 2.60 (q, 12H phenyl), 3.45 (s, 12H, methyl), 2.40 (s, 9H, ethylene).

Hydrolysis of the tritosylate of 1,4,7-triazacyclononane was carried out as follows. The tritosylate (25 g) was dissolved in concentrated H_2SO_4 (120 cm^3) and the mixture heated with stirring on an oil bath at 130°C for 48 h. After cooling the solution was neutralised by the slow addition of NaOH (300 g) dissolved in water (600 cm^3). The resulting solution was cooled at 0°C overnight to allow Na_2SO_4 to crystallise. The supernatant was decanted into a continuous liquid–liquid extractor and extracted with $CHCl_3$, (200 cm^3). The $CHCl_3$ extracts were combined and the chloroform removed on a rotary evaporator. The residue obtained was dissolved in ethanol (25 cm^3) and the solution filtered from any insoluble material. The ligand trihydrochloride was precipitated by addition of concentrated HCl (10 cm^3). The solid product obtained was filtered off, washed with ethanol then diethyl ether and dried in air. Yield: 9 g. ^1H NMR (NaTMS, D_2O) 4.00 (s) with no evidence for aromatic protons.

[Cu([9]aneN$_3$)Cl$_2$]. The macrocyclic complex was prepared as follows. To a slurry of [9]aneN$_3$·3HCl (1.20 g, 5 mmol) in ethanol (15 cm^3) was added KOH (0.82 g, 15 mmol) and the mixture heated at 60°C for 20 min. After cooling the solution was filtered and added to a solution of $CuCl_2$ (0.85 g, 5 mmol) in ethanol (10 cm^3). Blue crystals formed on slow evaporation of the solvent. Found : C, 27.2; H, 6.0; N, 15.9. Calc. for $C_6H_{15}N_3CuCl_2$: C, 27.3; H, 5.7; N, 15.9%.

The ester 2,4-dinitrophenyl diethyl phosphate was prepared and purified as previously described [8].

CAUTION! The ester is a potent anticholinesterase agent and should be handled with care. Glassware was decontaminated with solutions of hypochlorite (bleach).

Physical measurements

The kinetics of hydrolysis of the phosphate triester to give diethyl phosphate were monitored spectrophotometrically at 400 nm (release of the 2,4-dinitrophenolate ion). Plots of ln $(A_\infty - A_t)$ vs time (A_∞ is the final absorbance and A_t the absorbance at time t) were linear for at least three half lives. The initial concentration of the triester employed in all the measurements was 8×10^{-5} mol dm^{-3}. Measurements were made at 35°C using an ionic strength of 0.1 mol dm^{-3} maintained using KNO_3. The kinetics were monitored using a Perkin–Elmer Lambda 5 spectrophotometer. Conductance measurements were made using 1×10^{-3} mol dm^{-3} aqueous solutions on an AGB 1000 conductivity meter and a dip-type cell with platinized electrodes. ^1H NMR spectra were determined at 300 MHz using TMS as reference in $CDCl_3$ solutions and NaTMS in D_2O solutions. Potentiometric titrations were carried out using a Radiometer Titralab system. Titrations were carried out at 35°C using KNO_3 to maintain the ionic strength at 0.1 mol dm^{-3}.

RESULTS AND DISCUSSION

Copper(II) forms a 1:1 complex with [9]aneN$_3$ ($\log K_{ML} = 16$) which is less thermodynamically stable than that of $[Cu(dien)]^{2+}$ ($\log K_{ML} = 18.0$) [9,10]. Formation constants of $[Ni([9]aneN_3)]^{2+}$ and $[Zn([9][aneN_3)]^{2+}$ ($\log K_{ML} = 16.2$ and 11.6 respectively) are substantially larger than those of $[Ni(dien)]^{2+}$ and $[Zn(dien)]^{2+}$ ($\log K_{ML} = 10.7$ and 8.9 respectively at 25°C) [10]. Normally macrocyclic copper(II) complexes form more thermodynamically stable complexes than those with analogous linear polyamines [9]. The anomalous behaviour with copper(II) has been attributed [9,10] to the steric constraints placed on copper(II) by the small triazamacrocycle. X-ray crystallography [3,4] has established that the complexes [Cu([9]aneN$_3$)X$_2$] (X = Cl, Br) have approximately square-pyramidal stereochemistry with an N_3X_2 donor set. The macrocyclic triamine is coordinated facially with N(2) and N(3) occupying equatorial sites and N(1) the apical site. The halide ligands occupy the two remaining equatorial positions.

In aqueous solution the complex [Cu([9]aneN$_3$)Cl$_2$] behaves as a 2:1 electrolyte with $\Lambda_M = 235$ S cm^2 mol^{-1} at 25°C due to displacement of the chloride ligands by water donors. In aqueous solution the complex has λ_{max} 656 nm ($\varepsilon = 47$ dm^3 mol^{-1} cm^{-1}) attri-

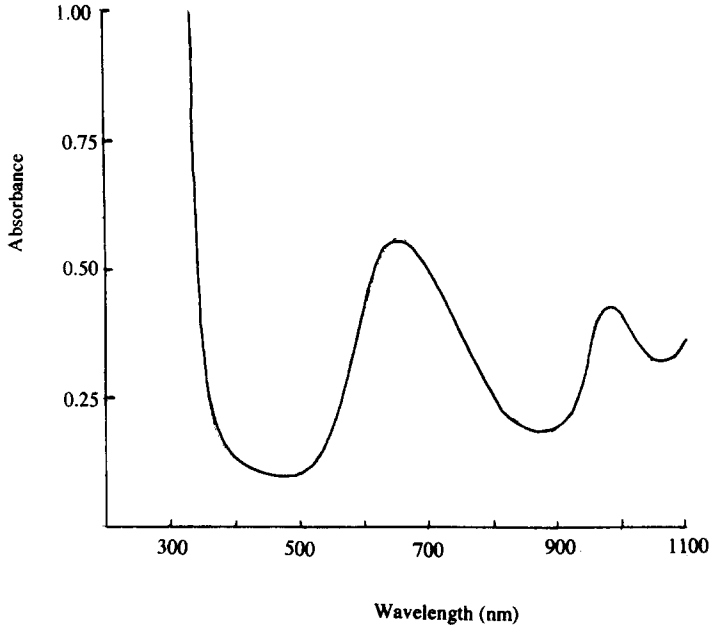

Fig. 1. The visible spectrum of $[Cu([9]aneN_3)Cl_2]$ in aqueous solution. The complex has $\varepsilon = 47$ dm^3 mol^{-1} cm^{-1} at 656 nm.

buted to the CuN_3O_2 chromophore (Fig. 1). The complex has a further band near 980 nm which is typically observed in square-pyramidal copper(II) complexes [14]. Potentiometric titration of an aqueous solution of the complex with sodium hydroxide gives a well defined end point after addition of one equivalent of base (Fig. 2), which can be attributed to the ionisation.

$$[Cu([9]aneN_3)(OH_2)_2]^{2+} \rightleftharpoons [Cu([9]aneN_3)(OH)(OH_2)]^{+} + H^{+}$$

The pK estimated from the potentiometric data is 7.5 at 35°C and $I = 0.10$ mol dm^{-3}. At pH values close to neutrality significant concentrations of the hydroxoaqua complex are present in solution. At higher pH formation of a dihydroxo-bridged dimer occurs and $[Cu[9]aneN_3)_2(OH)_2]$ has previously been characterised [15]. Formation of the dimer will be favoured by high metal complex concentrations.

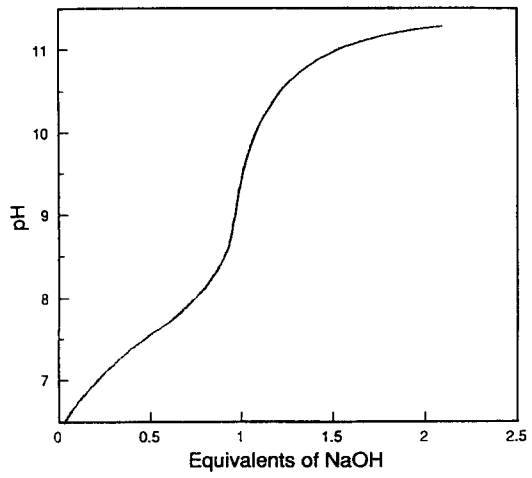

Fig. 2. Potentiometric titration of $[Cu([9]aneN_3)(OH_2)_2]^{2+}$ in aqueous solution at 35°C and $I = 0.1$ mol dm^{-3}.

Kinetic studies

In aqueous solution within the pH range 7–9 the hydrolysis of 2,4-dinitrophenyl diethyl phosphate to give diethyl phosphate and 2,4-dinitrophenoxide follows the rate expression [11]

$$k_{obs} = k_o + k_{OH}[OH^-] \quad (1)$$

where k_{obs} is the observed first order rate constant at constant pH, k_o represents the "spontaneous" water hydrolysis and k_{OH} is the second order rate constant for base hydrolysis. At 35°C and $I = 0.1$ mol dm^{-3}, $k_o = 2.26 \times 10^{-6}$ s^{-1} and $k_{OH} = 0.565$ dm^3 mol^{-1} s^{-1}. Using an activity coefficient of 0.768 calculated from the Davies' equation [12] and $pK_w = 13.712$ [13] in conjunction with eqn (1) the values of k_{obs} for the uncatalysed reaction are 2.40×10^{-6} s^{-1} at pH 7.0 and 3.69×10^{-6} s^{-1} at pH 8.

Catalysis of the reaction by $[Cu([9]aneN_3)(OH_2)_2]^{2+}$ was studied using an ester concentration of 8×10^{-5} mol dm^{-3} with the metal complex in large excess (2.5×10^{-3} mol dm^{-3}). Hydrolysis of 2,4-dinitrophenyl diethyl phosphate is subject to buffer catalysis [11] and therefore the metal complex was used as

Table 1. pH-Rate profile for the $[Cu([9]aneN_3)(OH_2)]^{2+}$ catalysed hydrolysis of 2,4-dinitrophenyl diethyl phosphate at 35°C and $I = 0.1$ mol dm^{-3}

pH	$10^4 k_{obs}$ (s^{-1})	pH	$10^4 k_{obs}$ (s^{-1})
6.20	1.98	7.53	11.90
6.51	3.02	7.85	14.90
6.67	3.86	8.13	16.68
6.93	4.34	8.38	15.82
7.21	7.62	8.71	16.10

The concentration of the metal complex was 2.5×10^{-3} mol dm^{-3} and the concentration of the phosphate ester 8×10^{-5} mol dm^{-3}. The quoted rate constants are the average values of at least three kinetic runs. The reactions were monitored by following the release of 2,4-dinitrophenoxide at 400 nm.

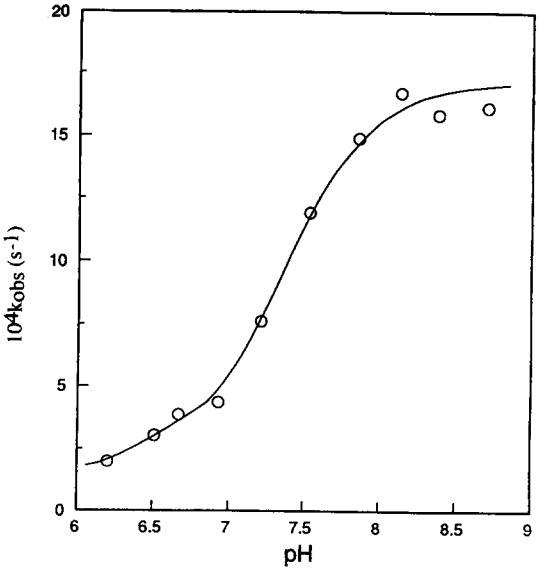

Fig. 3. pH-Rate profile for the $[Cu([9]aneN_3)(OH_2)_2]^{2+}$ catalysed hydrolysis of 2,4-dinitrophenyl diethyl phosphate at 35°C and $I = 0.1$ mol dm^{-3} (KNO_3). The total complex concentration was 2.5×10^{-3} mol dm^{-3} and the ester concentration 8×10^{-5} mol dm^{-3}.

the buffer. The pH was adjusted to the appropriate value by the dropwise addition of sodium hydroxide.

The pH-rate profile for the hydrolysis was studied over the pH range 6.20 to 8.71 (Table 1). Values of k_{obs} increase in a sigmoidal manner up to pH 8.5, Fig. 3, then begin to decline beyond pH 9.0. This behaviour is consistent with the hydroxoaqua complex being the active species in the hydrolysis. If α is the fraction of the total complex which is present as the hydroxoaqua species then values of k_{obs}/α should be constant if the hydroxoaqua complex is the active catalytic species. The results shown in Table 2 confirm that this is indeed the case. No evidence was obtained for saturation kinetics even with the metal complex in 50-fold excess over the substrate. The equilibrium constant K for the formation of the mixed ligand complex is therefore quite small.

$$[Cu([9]aneN_3)(OH_2)(OH)]^+ + O = P(OEt)_2OAr$$

$$\overset{K}{\rightleftharpoons} [Cu([9]aneN_3)(OH)(O = P(OEt)_2OAr)]^+$$

As the substitution reaction on copper(II) is rapid, formation of the mixed-ligand complex will be fast and the rate-determining step of the reaction is expected to be attack of coordinated hydroxide on the coordinated ester. However, the present results do not exclude the possibility of an intermolecular reaction involving attack of coordinated hydroxide on the free ester in solution. Recent studies [11] of the catalytic effects of a variety of bases and hydroxy complexes on the hydrolysis of 2,4-dinitrophenyl diethyl phosphate have shown that complexes such as $[Co(NH_3)_5OH]^{2+}$ lie on the Bronsted plot of $\log k_{cat}$ vs the pK_a of the conjugate acid, but that hydroxoaqua complexes such as $[Cu(tmen)(OH)(OH_2)]^+$ (tmen = *N,N,N′,N′*-tetramethylethylenediamine) are much more active than would be predicted from their pK_a. This result provides strong support for the occurrence of a cooperative type mechanism in such complexes in which attack of coordinated hydroxide occurs on the coordinated substrate which is also subject to Lewis acid catalysis by the metal ion.

Table 2. pH-Dependence as a function of α, the fraction of the metal complex ionised to the hydroxoaqua complex at 35°C and $I = 0.1$ mol dm^{-3}

pH	α	$10^4 k_{obs}$ (s^{-1})	$10^4 k_{obs}/\alpha$ (s^{-1})
6.93	0.21	4.34	20.5
7.21	0.34	7.62	22.4
7.53	0.52	11.90	22.8
7.85	0.69	14.90	21.6
8.13	0.81	16.68	20.6

α = the fraction of the total complex ionised to the hydroxoaqua complex calculated using a pK = 7.50.

One interesting feature of these reactions is that the diaqua complex also appears to exert a catalytic effect. Thus in the catalytic studies (Table 1) at pH 6.20, the value of $k_{obs} = 2 \times 10^{-4}$ s^{-1}. This pH is some 1.3 pH units lower than the pK_a of the complex. Other experiments established that free copper(II) and the ligand alone do not catalyse the reaction. At pH 6.20, k_{obs} for the uncatalysed reaction can be estimated from eqn (1) to be about 2.3×10^{-6} s^{-1} so that the rate enhancement is about 100-fold in the presence of the diaqua complex.

Experiments were also carried out to see if the reac-

$[Cu(bipy)_2(OH_2)_2]^{2+}$	7.0	1.51×10^{-4}	76.5
$[Cu([9]aneN_3(OH_2)_2]^{2+}$	7.0	3.36×10^{-4}	34.4
$[Cu(glygly\text{-}2H)(OH_2)_2]^{2+}$	8.5	5.51×10^{-5}	209.6
Control	7.0	1.55×10^{-7}	52 days

The ester concentration employed in the measurements was 8×10^{-5} mol dm^{-3} and the catalyst concentration 2.5×10^{-3} mol dm^{-3}.

tion was truly catalytic and exhibited turnover. Turnover experiments were carried out at 25°C by pH-stat methods using a complex concentration of 5×10^{-5} mol dm^{-3} and an ester concentration of 7.5×10^{-4} mol dm^{-3} (15-fold excess of the ester). The release of H^+ at pH 7.0 was monitored by the addition of 0.01 mol dm^{-3} sodium hydroxide solution. The reaction was truly catalytic in the presence of $[Cu[9]aneN_3(OH_2)_2]^{2+}$ with 2.2 turnovers h^{-1}. This contrasts with a turnover rate of 20.6 turnovers h^{-1} by the complex $[Cu(tmen)(OH_2)_2]^{2+}$ and 31.2 turnovers h^{-1} by $[Cu(dpa)(OH_2)_2]^{2+}$ (dpa = 2,2′-dipyridylamine). The latter complex is a remarkably effective catalyst for the hydrolysis of the phosphotriester.

The high catalytic activity of a variety of copper(II) hydroxoaqua complexes (Table 3) (see Scheme 1 for structures) suggests that a bifunctional type of mechanism operates. For example, in the case of $[Cu([9]aneN_3)(OH_2)]^{2+}$ the value of $k_{cat}/\alpha = 21.6$ dm^3 mol^{-1} s^{-1} is nearly 40 times greater than k_{OH} (0.58 dm^3 mol^{-1} s^{-1}) at 35°C. Since the hydroxide ion is more than 10^6 stronger as a base than $[Cu([9]aneN_3)(OH_2)_2]^{2+}$ ($pK = 7.50$) this effectively excludes the copper complex acting as a general base catalyst. Lewis acid catalysis alone involving attack by "external" hydroxide on the coordinated ester does not account for the high catalytic activity observed. The effectiveness of the purely Lewis acid mechanism can be gauged by the fact that the base hydrolysis of trimethyl phosphate in the iridium(III) complex (**4**) is only accelerated by some 400-fold [16]. The hydrolysis of 4-nitrophenyl phosphate in the cobalt(III) complex

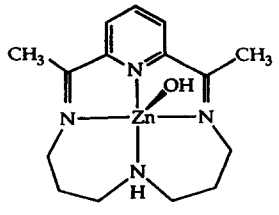
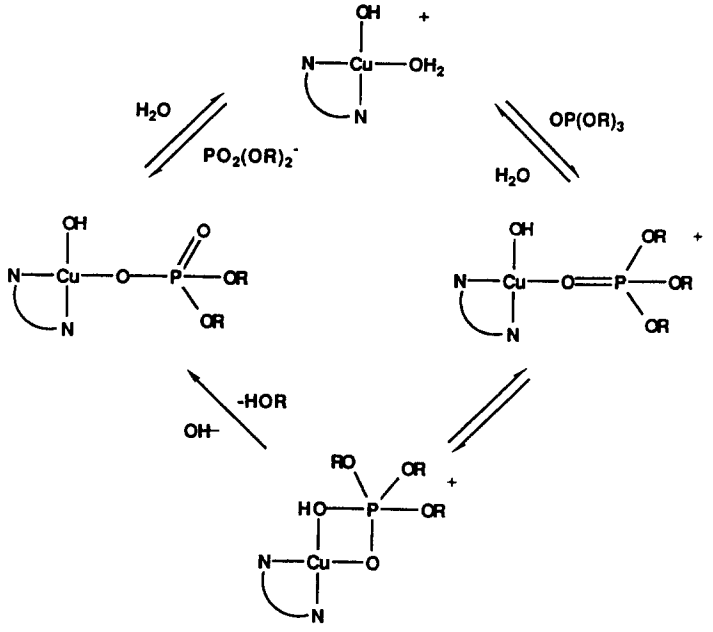
$[Cu(glygly\text{-}2H)(OH_2)]^{2+}$

Scheme 1.



(6)



Scheme 2.

(**5**) has been shown to occur by intramolecular attack of coordinated hydroxide at phosphorus to give initially a five-coordinate phosphorane, which then decays to give $[Co(en)_2PO_4]$ containing bidentate phosphate and 4-nitrophenol [17]. The present results are similar to those of Breslow *et al.* [18] on the $[Zn(CR)OH]^+$ (**6**) catalysed hydrolysis of 2,4-dinitrophenyl diphenyl phosphate and of Morrow and Trogler [19] on the $[Cu(bipy)(OH)(OH_2)]^+$ catalysed hydrolysis of 4-nitrophenyl diethyl phosphate. All these reactions appear to involve intramolecular attack of coordinated hydroxide on the metal bound ester to give a phosphorane intermediate which then decays to products (Scheme 2). Such a "push–pull" type of mechanism, in which the metal ion polarises the P=O bond by its Lewis acid effect, and also delivers a coordinated hydroxide ion in an intramolecular reaction, accounts for the efficiency of the process.

(Received 15 July 1997; accepted 20 August 1997)

Abstract—The acetonitrile ligand of *fac*-$Mo(CO)_3$(MeCN)(dppe)[dppe = bis-(1,2-diphenylphosphino)ethane] can be easily replaced by fullerene C_{60} in chlorobenzene at about 80°C to give exclusively *fac*-$Mo(CO)_3$(dppe)(η^2-C_{60}), whereas fullerene C_{60} reacted with $Mo(CO)_4$(dppe) in refluxing chlorobenzene to afford an isomeric mixture of *fac*- and *mer*-$Mo(CO)_3$(dppe)(η^2-C_{60}). These organomolybdenum C_{60} derivatives were characterized by elemental analysis and spectroscopic techniques. In addition, the η^2-C_{60} ligand in *fac*-$Mo(CO)_3$(dppe)(η^2-C_{60}) was also found to be easily displaced by MeCN, PPh_3 or pyridine to give corresponding *fac*-organomolybdenum complexes. © 1998 Elsevier Science Ltd. Keywords: fullerene C_{60}; $Mo(CO)_3$(MeCN)(dppe); $Mo(CO)_4$(dppe); ligand substitution; synthesis; characterization.

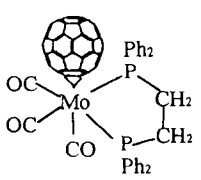
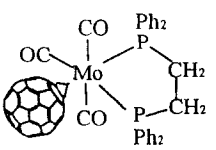
Although C_{60} derivatives of group 8 to group 10 transition metals have been extensively studied [1–8], little is known about those of group 6 metals [9–11]. So far, structurally characterized organotransition metal C_{60} derivatives may fall into two categories: (1) fullerene core directly bonded to transition metals, such as (η^2-C_{60})M(PPh_3)$_2$(M = Pd, Pt) [1], (C_{60}){Pt(PEt_3)$_2$}$_6$ [2], (η^2-C_{60})Ni(PEt_3)$_2$ [3], (η^2-C_{60})IrCl(CO)(PPh_3)$_2$ [4], (η^2-C_{60})RhH(CO)(PPh_3)$_2$ [5], (η^2-C_{60})Os_3(CO)$_{10}$(PPh_3) [6], (C_{60})Ru_2(μ-Cl)$_2$$Cp^*_2$ [7], (η^2-C_{60})Fe(CO)$_4$ [8], (C_{60})[W(CO)$_3$(dppe)]$_n$(n = 1,2) [9a], [Mo(CO)$_3$(DDH)]$_2$$C_{60}$ · 2.5C_6H_6 (DDH = diacetyldihydrazone, H_2NN = C(Me) C(Me) = NNH_2) [10]; and *fac*/*mer*-W(CO)$_3$(dppb)(η^2-C_{60}) [11]; (2) fullerene core indirectly bonded to transition metals, such as (η^2-C_{60})[S_2Fe_2(CO)$_6$] [12] and (η^2-C_{60})[*o*-$(CH_2)_2C_5H_3$-η^5]Co(η^4-C_4Ph_4) [13]. In order to further develop the organometallic chemistry of group 6 metals' fullerene derivatives, we undertook this study. Herein we report the synthesis and structural characterization of fullerene molybdenum derivatives *fac*-$Mo(CO)_3$(dppe)(η^2-C_{60}) and *fac*/*mer*-$Mo(CO)_3$(dppe)(η^2-C_{60}), as well as η^2-C_{60} substitution reactions of *fac*-$Mo(CO)_3$(dppe)(η^2-C_{60}) with MeCN, Ph_3P and pyridine.

RESULTS AND DISCUSSION

We found that an equimolar amount of C_{60} reacted with *fac*-$Mo(CO)_3$(MeCN)(dppe) in chlorobenzene at about 80°C to give 84% of the product *fac*-$Mo(CO)_3$(dppe)(η^2-C_{60}) (Scheme 1).



fac-isomer



mer-isomer

Scheme 1.

* Author to whom correspondence should be addressed.

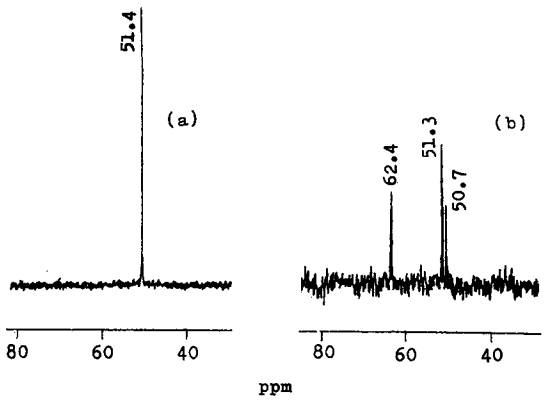


Fig. 1. (a) ^{31}P NMR spectrum of *fac*-Mo(CO)$_3$(dppe)(η^3-C$_{60}$), (b) ^{31}P NMR spectrum of *fac*- and *mer*-Mo(CO)$_3$(dppe)(η^2-C$_{60}$).

In principle, the product might exist as another isomer, i.e. *mer*-isomer or as a mixture of *fac*- and *mer*-isomers (Scheme 1). However, since its ^{31}P NMR spectrum (Fig. 1(a)) shows only one singlet at 51.4 ppm, the product should exist only as *fac*-isomer. This is because the *fac*-isomer has two P atoms in the same chemical environment and *mer*-isomer does not. The formation of only one isomer implies that the displacement of MeCN by C$_{60}$ took place completely with *fac*-configuration retention of the starting material.

The ^{1}H NMR spectrum of its ethylene group is also consistent with the *fac*-configuration of the product. It shows two kinds of resonances in an equal intensity, which were caused by two groups of hydrogen atoms: one at 2.60 ppm is on the same side of the equatorial plane (consisting of two equatorial CO, two P and two C of the ethylene group) as the C$_{60}$ cage, whereas the other at 2.40 ppm is on the opposite side of the plane as the C$_{60}$ cage. This assignment was made basically according to the electron-withdrawing effect of C$_{60}$ ligand.

In the ^{13}C NMR spectrum of the product, we observed 28 resonances in the fullerene sp^2-C area (133–152 ppm). This is actually in agreement with its Cs symmetry, although 32 peaks are theoretically expected for Cs symmetry. This is because the four carbon resonance peaks at 145.88, 142.85, 133.82 and 133.62 ppm each and have the intensity equivalent to two sp^2-C resonances [14].

In the IR spectrum of the product there are three absorption bands in the region 1880–1930 cm^{-1}, characteristic of the terminal carbonyls. The IR spectra of the product and its precursor determined in CH_2Cl_2 are shown in Fig. 2. In comparison with its precursor, the lowest ν_{CO} of the product shifts towards higher energy by about 72 cm^{-1}. Such an IR difference between them is obviously related to the stronger electron-withdrawing effect of C$_{60}$ ligand than MeCN ligand.

The UV spectrum of the product with that of free C$_{60}$ is shown in Fig. 3. As seen from Fig. 3 the first band at 280.7 nm for the product is much stronger than its second band at 350.5 nm, whereas the first band at 286.5 nm for free C$_{60}$ is smaller than its second band at 335.3 nm. This is probably due to the overlap of those two bands at around 280 nm, generated from C$_{60}$ ligand and the phenyl groups attached to P atoms in the product [15].

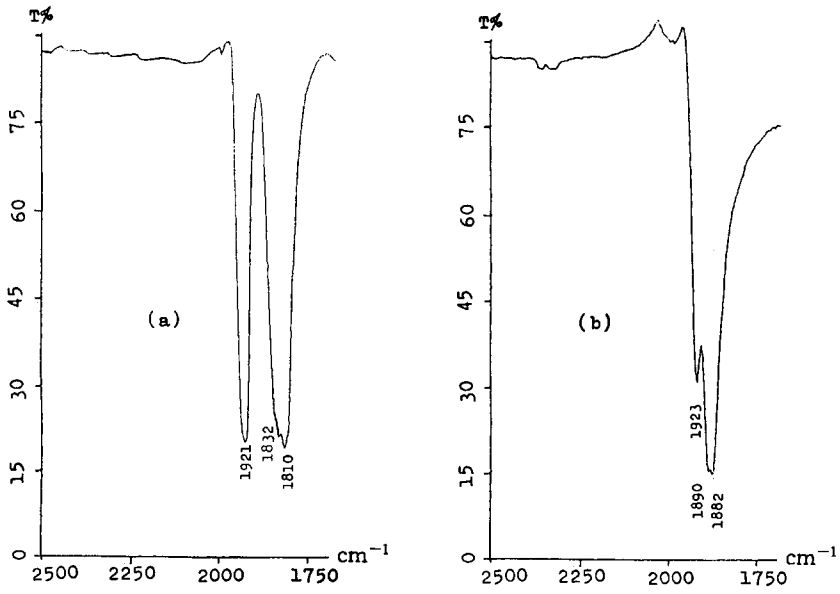

Fig. 2. (a) IR spectrum of *fac*-Mo(CO)$_3$(CH$_3$CN)(dppe), (b) IR spectrum of *fac*-Mo(CO)$_3$(dppe)(η^2-C$_{60}$).

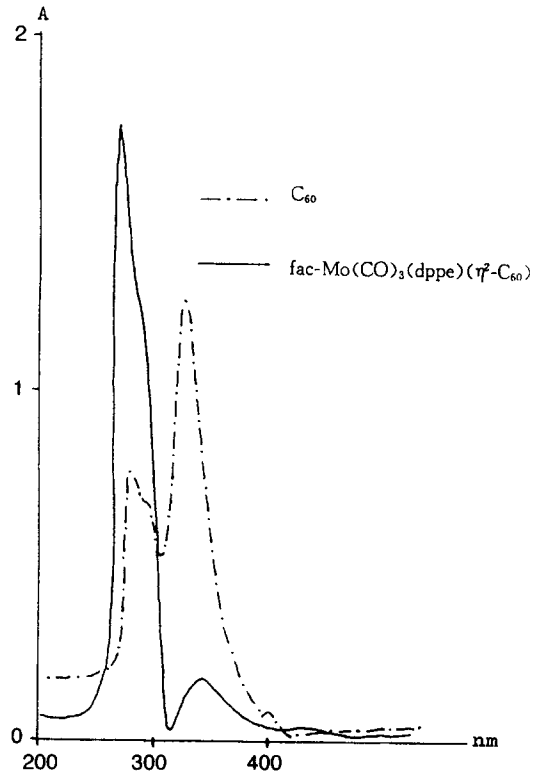

Fig. 3. UV-*vis* spectra of *fac*-Mo(CO)$_3$(dppe)(η^2-C_{60}) and C_{60} in toluene (1.85×10^{-5} M)

In addition, the C/H analysis for the product is satisfactory and its FD–MS spectrum displays a molecular ion peak at *m/z* 1296.

The product is somewhat air-sensitive, whose half-life of decomposition in CH_2Cl_2 is approximately 2.5 days. It is readily soluble in common organic solvents, for example, chlorobenzene, toluene, benzene, chloroform, dichloromethane and carbon disulphide, but it is hardly soluble in petroleum ether. Interestingly, the product *fac*-Mo(CO)$_3$(dppe)(η^2-C_{60}) can also take part in ligand displacement reactions. For example, addition of acetonitrile to a chlorobenzene solution of the product, followed by stirring the refluxing mixture for 6 h afforded 84% of *fac*-Mo(CO)$_3$(MeCN)(dppe) [16]; Similarly, the product reacted with pyridine or with PPh_3 in chlorobenzene to yield 91% of *fac*-Mo(CO)$_3$(dppe)(C_5H_5N) [17], and 85% of *fac*-Mo(CO)$_3$(PPh_3)(dppe) [17], respectively.

It is noteworthy that the thermal reaction of a slightly excessive Mo(CO)$_4$(dppe) with C_{60}, in contrast to that of Mo(CO)$_3$(MeCN)(dppe) with C_{60} mentioned above, gave a mixture of *fac*-Mo(CO)$_3$(dppe)(η^2-C_{60}) and *mer*-Mo(CO)$_3$(dppe)(η^2-C_{60}) in 43% yield. The two isomers are very close in polarity and thus could not be separated by conventional chromatography and recrystallization methods. Although the isomer mixture was claimed to be prepared by a photolytic procedure [9b], the thermal reaction procedure used here is much more convenient and produces the isomer mixture in higher yield. In addition, no detailed characterization data for the isomer mixture were given in the published paper [9b]. The ^{31}P NMR spectrum for this mixture (Fig. 1(b)) shows three signals, one at 51.3 ppm assigned to two identical P atoms of *fac*-isomer and two signals at 62.4 and 50.7 ppm in an equal intensity assigned to one P atom *cis* to C_{60} and the other P atom *trans* to C_{60} in *mer*-isomer respectively. The ^{1}H NMR spectrum for this mixture is similar to that of pure *fac*-isomer. However, the upfield broad singlet at 2.47 ppm is caused by *trans*-two hydrogens of CHCH in *fac*-isomer and two hydrogens of CH_2 attached to the *trans* P atom in *mer*-isomer, whereas the downfield singlet at 2.60 ppm is caused by *cis*- two hydrogens of CHCH in the *fac*-isomer and two hydrogens of CH_2 attached to the *cis* P atom in the *mer*-isomer due to the electron-withdrawing effect of the C_{60} ligand. While the IR spectrum of *fac*-isomer displays three terminal CO bands, that of this isomer mixture exhibits four bands within the terminal CO region. This is consistent with the observations that the number of IR active bands cannot exceed but may be less than the number of CO ligands in the complexes [18].

It follows that we have found a simple and convenient synthetic method for obtaining the single isomer *fac*-Mo(CO)$_3$(dppe)(η^2-C_{60}) in high yield. This method involves a ligand displacement reaction between C_{60} and *fac*-Mo(CO)$_3$(MeCN)(dppe) with *fac*-configuration retention of the starting material. We have also found that the thermal reaction between C_{60} and Mo(CO)$_4$(dppe) affords an isomer mixture of *fac*- and *mer*-Mo(CO)$_3$(dppe)(η^2-C_{60}) with more convenient manipulations and higher yield than the reported photolysis method [9b]. Finally, we have demonstrated that the η^2-C_{60} ligand in *fac*-Mo(CO)$_3$(dppe)(η^2-C_{60}) can also be displaced by MeCN, PPh_3 and C_5H_5N to give corresponding *fac*-organomolybdenum complexes in high yields.

EXPERIMENTAL

All reactions were carried out under a nitrogen atmosphere using standard Schlenk or vacuum-line techniques. Silica gel (10–40 μm) on TLC plates ($24 \times 16 \times 0.3$ cm) was activated for 3 h at 110°C, whereas silica gel (300–400 mesh) for column chromatography (15×2 cm) was activated for 1 h at 120°C. Toluene, THF, petroleum ether were dried and deoxygenated by distillation from sodium-/benzophenone ketyl. Chlorobenzene, MeCN and $CHCl_3$ were dried by distillation from P_2O_5. Pyridine and PPh_3 were chemical reagents used without further purification. Fullerene C_{60} was purchased from Yin-Han Fullerene High-Tech. Co. Ltd. *fac*-Mo(CO)$_3$(MeCN)(dppe) [16], dppe [19] and Mo(CO)$_4$(dppe) [20] were prepared according to the literature. The IR and UV-*vis* spectra were recorded on a Nicolet 170

SX FTIR spectrophotometer and a Shimadzu UV-240 spectrometer respectively, whereas the NMR spectra were determined on a Jeol FX qoQ or a Bruker AC-P 200 spectrometer. Elemental analysis and MS determinations were performed using a Yanaco CHN Corder MT-3 analyzer and a Zabspec spectrometer, respectively. Melting points were determined on a Yanaco MP-500 apparatus.

Reaction of fac-$Mo(CO)_3$(MeCN)(dppe) *with* C_{60} *and preparation of fac*-$Mo(CO)_3$(dppe)(η^2-C_{60})

A 100 cm^3 two-necked flask equipped with a magnetic stir-bar, a serum cap and a reflux condenser, was charged with 35 mg (0.056 mmol) of *fac*-$Mo(CO)_3$(MeCN)(dppe) and 40 cm^3 of chlorobenzene. To this solution was added 40 mg (0.056 mmol) of C_{60} in 40 cm^3 of chlorobenzene during about 2 h at room temperature. The reaction mixture was heated to about 80°C and then kept at this temperature for 6 h. After removal of the solvent under reduced pressure, the residue was purified by TLC (1:1 toluene: petroleum ether as eluent) to give 61 mg (84%) of *fac*-$Mo(CO)_3$(dppe)(η^2-C_{60}) as a dark green solid. m.p. 125–127°C. Found: C, 82.43; H, 2.21. Calc. for $C_{89}H_{24}MoO_3P_2$: C, 82.29; H, 1.85%, IR(CH_2Cl_2): $\nu_{C\equiv O}$, 1923 (s), 1890 (vs), 1882 (vs) cm^{-1}; ν_{C60} 1432 (m), 1182 (w), 588 (m), 518 (m) cm^{-1}. ^1H NMR ($CDCl_3$, TMS, 90 MHz): 2.40 (br. s, *trans*-CHCH), 2.60 (br.s, *cis*-CHCH), 7.20–7.60 (m, $4C_6H_5$) ppm. ^{31}P NMR ($CDCl_3$, H_3PO_4, 80.9 MHz): 51.4 ppm. ^{13}C NMR ($CDCl_3$, TMS, 50.3 MHz): 217.99, 210.63 (s, s, CO); 151.82, 151.59, 150.84, 150.76, 148.06, 147.94, 147.65, 147.29, 146.76, 146.59, 146.24, 146.04, 145.88 (2C), 145.18, 144.71, 144.67, 144.35, 143.47, 143.24, 142.85 (2C), 141.60, 135.70, 134.90, 134.63, 134.09, 133.82 (2C), 133.62 (2C), 133.38 (s, 28 resonances for C_{60}); 138.00, 137.39, 132.45, 132.20 (4 resonances for C_6H_5); 132.20, 130.51, 129.49, 129.30 (4 resonances for C_6H_5) ppm; 29.22, 28.14 (s, s, $2CH_2$) ppm. UV-*vis*(toluene, 1.85×10^{-5} M): λ_{max}(log ε) 280.7 (5.13), 350.5 (4.17), 433.3 (3.43), 537.7 (3.21) nm. FD–MS *m/z* (^{94}Mo, ^{31}P): 1296 (M^+).

Reaction of fac-$Mo(CO)_3$(dppe)(η^2-C_{60}) *with* MeCN *and preparation of fac*-$Mo(CO)_3$(MeCN)(dppe)

The same flask was charged with 3 mg (2.31×10^{-3} mmol) of *fac*-$Mo(CO)_3$(dppe)(η^2-C_{60}), 10 cm^3 of chlorobenzene and 10 cm^3 of MeCN. The dark green solution was refluxed for 6 h to give a light green solution. The same workup as above gave 1.20 mg (84%) of *fac*-$Mo(CO)_3$(MeCN)(dppe) as a pale yellow solid, which was identified by comparison of its m.p. and ^1H NMR spectrum with an authentic sample [16].

Reaction of fac-$Mo(CO)_3$(dppe)(η^2-C_{60}) *with pyridine and preparation fac*-$Mo(CO)_3$(dppe)(C_5H_5N)

Similarly, from 6 mg (4.62×10^{-3} mmol) of *fac*-$Mo(CO)_3$(dppe)(η^2-C_{60}), 10 cm^3 of chlorobenzene and 0.38 cm^3 of pyridine, 2.8 mg (92%) of *fac*-$Mo(CO)_3$(dppe) (C_5H_5N) as a light yellow solid was obtained and identified by comparison of its m.p. and IR spectrum with an authentic sample [17].

Reaction of fac-$Mo(CO)_3$(dppe)(η^2-C_{60}) *with* PPh_3 *and preparation of fac-Mo*$(CO)_3$(PPh_3)(dppe)

Similarly, from 6 mg (4.62×10^{-3} mmol) of *fac*-$Mo(CO)_3$(dppe)(η^2-C_{60}), 10 cm^3 of chlorobenzene and 1.3 mg (4.96×10^{-3} mmol) of PPh_3, 3.3 mg (85%) of *fac*-$Mo(CO)_3$ (dppe)PPh_3 as a light yellow solid was obtained and identified by comparison of its m.p. and IR spectrum with those of an authentic sample [17].

Reaction of $Mo(CO)_4$(dppe) *with* C_{60} *and preparation of a mixture of fac- and mer*-$Mo(CO)_3$(dppe)(η^2-C_{60})

The same flask charged with 40 mg (0.066 mmol) of $Mo(CO)_4$(dppe), 36 mg (0.05 mmol) of C_{60} and 50 cm^3 of chlorobenzene. The reaction mixture was refluxed for 12 h. Removal of the solvent gave a residue which was subjected to column chromatography using toluene as eluent. The green band was collected to give 28 mg (43%) of an isomer mixture of *fac*- and *mer*-$Mo(CO)_3$(dppe)(η^2-C_{60}) as a dark green solid. m.p. 120–128°C. Found: C, 82.30; H, 2.20. Calc. for $C_{89}H_{24}MoO_3P_2$: C, 82.29; H, 1.85% IR(CH_2Cl_2): $\nu_{C\equiv O}$, 1923 (s), 1891 (vs), 1880 (vs), 1856 (m) cm^{-1}; ν_{C60} 1429 (m), 1188 (w), 589 (m), 518 (m) cm^{-1}. ^1H NMR ($CDCl_3$, TMS, 90 MHz): 2.47 (br.s, *trans*-CHCH of *fac*-isomer and *trans*-CH_2 of *mer*-isomer, 2.60 (br.s, *cis*-CHCH of *fac*-isomer and *cis*-CH_2 of *mer*-isomer), 7.24–7.56 (m, $4C_6H_5$) ppm. ^{31}P NMR ($CDCl_3$, H_3PO_4 80.9 MHz): 62.4, 51.3, 50.7 ppm.

(Received 30 July 1997; accepted 15 August 1997)

Abstract—The kinetics of the forward and reverse steps of the process $[Pt(NNN)Cl]^+ + am \rightleftharpoons [Pt(NNN)(am)]^{2+} + Cl^-$ (NNN = 2,2′:6′,2″-terpyridine; am = one of a number of pyridines and NH_3 covering a wide range of basicity) have been studied in methanol at 25°C. Both forward and reverse reactions obey the usual two-term rate law observed in square-planar substitution. The reactivity and the ability of the chloro-complex to discriminate among the nucleophiles, as well as the sensitivity of the rate of the chloro entry upon the nature of the displaced base and the steric factors in both the forward and reverse processes are discussed in terms of intimate mechanism and compared with data for a number of different Pt^{II} systems. The equilibrium constants for the reactions have been determined from the ratio of the rate constants. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: nitrogen donors; pyridine; ammonia.

In a recent study of nucleophilicity and lability of neutral nitrogen donor bases towards planar tetracoordinate complexes and the relationships between reactivity and proton basicity, we reported kinetic and equilibrium data concerning the reversible displacement of am (am = a number of pyridines and some heterocyclic and aromatic amines) by chloride from the mono-cationic [1] $[Pt(SS)(am)Cl]^+$ and bis-cationic [2] $[Pt(SNS)(am)]^{2+}$ and [3] $[Pt(NSN)(am)]^{2+}$ complexes [SS = 1,2-bis(phenylsulfanyl) ethane; SNS = 2,6-bis(methylsulfanylmethyl)pyridine; NSN = bis(2-pyridylmethyl) sulphide] in MeOH at 25°C. The results were discussed in terms of intimate mechanism and bonding interactions in the ground and transition states.

In order to extend the experimental observations and the range of applicability of the proposed interpretation, we have now examined the system involving the tridentate aromatic nitrogen donor 2,2′:6′,2″-terpyridine (NNN) on measuring the rate of the processes

$$[Pt(NNN)Cl]^+ + am \rightarrow [Pt(NNN)am]^{2+} + Cl^- \quad (1)$$

(am = pyridines and ammonia) as well as those of the reverse reactions

$$[Pt(NNN)(am)]^{2+} + Cl^- \rightarrow [Pt(NNN)Cl]^+ + am \quad (2)$$

in methanol at 25°C. The results are herewith presented and discussed.

EXPERIMENTAL

Materials

Platinum(II) chloride, $PtCl_2$, was obtained from Acros Chimica and 2,2′:6′,2″-terpyridine from Aldrich Chimica. Pure reagent-grade CH_3SO_3Na, $AgClO_4$, $LiClO_4$ (Fluka and Aldrich) were dried over P_2O_5 in a vacuum desiccator and used without further purification. Pyridines were recrystallized or distilled before use when necessary. CH_3OH (less than 0.1% water) and dimethylformamide (dmf) were pure reagent-grade products (Baker and BDH).

Instruments

Infrared spectra (4000–500 cm^{-1}, KBr discs; 600–50 cm^{-1}, polyethylene pellets) were recorded on a Nicolet Magna FT IR 750 spectrometer. Electronic spectra and kinetic measurements were obtained on a Perkin-Elmer Lambda 16 spectrophotometer. Proton NMR spectra were taken on a Bruker AC 200 F spectrometer. Conductivity measurements were carried out with a CDM 83 Radiometer Copenhagen conductivity meter and a CDC 334 immersion cell. Elemental analysis were performed by the Microanalytical Laboratory of the University of Padua.

Preparation of complexes

$[Pt(NNN)Cl](ClO_4)$ was prepared as reported in the literature [4].

All the complexes $[Pt(NNN)(am)](ClO_4)_2$ (am = pyridine, 3-methylpyridine, 4-methylpyridine, 4-cyanopyridine, 4-aminopyridine, 4-acetylpyridine, methylisonicotinate, 2-methylpyridine, 2,4-dimethylpyridine, ammonia) were prepared as follows. $AgClO_4$ (0.207 g, 1 mmol) was added to a warm solution (20 ml, 60°C) of $[Pt(NNN)Cl](ClO_4)$ (0.563 g, 1 mmol) in dmf and the mixture was stirred in the dark for 15 min. The AgCl formed was filtered off and, after addition of methanol (10 ml) and an excess of $LiClO_4$ (0.5 g), the solution was treated with 1 mmol of am and stirred at 60–70°C for 10 min. After cooling at room temperature, the microcrystalline product precipitated was filtered off, washed with methanol, diethyl ether and dried *in vacuo*. Yield: 70–90%.

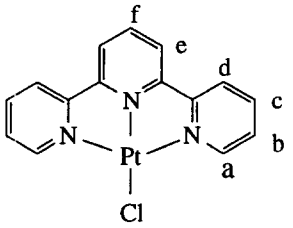
am = aniline, morpholine, methylamine, and piperidine, under the same experimental conditions, always resulted in the formation of the hydroxo species $[Pt(NNN)OH](ClO_4)$.

Analytical and some physico-chemical data for the complexes are collected in Table 1. ^1H NMR data for $[Pt(NNN)Cl](ClO_4)$ are given according to the following scheme:



Scheme 1

Kinetics

The reactions were initiated by adding a 0.015 mol dm^{-3} dmf solution (2–10 μl) of the substrate complex. $[Pt(NNN)Cl](ClO_4)$ or $[Pt(NNN)(am)](ClO_4)_2$, to a methanolic solution (3 cm^3) of the appropriate reagent, the nitrogen base or chloride ion, respectively, previously brought to the reaction temperature (25°C) in a thermostated cell in the spectrophotometer. The concentration of the entering group was always large enough to provide pseudo-first-order conditions. After preliminary repetitive scan experiments in the range 260–360 nm to search for isosbestic points and spectral changes, the kinetics were studied by measuring the changing absorbance at suitable wavelengths as a function of time. Pseudo-first-order rate constants (k_{obs}, s^{-1}) were obtained either from the gradients of plots of $\log(D_t - D_\infty)$ vs time or from a non linear least-squares fit of experimental data to $D_t = D_\infty + (D_0 - D_\infty)\exp(-k_{obs}t)$ with D_0, D_∞, and k_{obs} as the parameters to be optimized (D_0 = absorbance after mixing of reactants, D_∞ = absorbance at completion of reaction). Rate constants were accurate within 5%.

RESULTS AND DISCUSSION

Kinetics of the displacement of chloride by am from $[Pt(NNN)Cl](ClO_4)$

The spectrum of the reaction mixtures evolves in all cases with time in a first order fashion and with well maintained isosbestic points, from that of the chloro substrate $[Pt(NNN)Cl]^+$ to that of an authentic sample of the substituted products $[Pt(NNN)(am)]^{2+}$ measured under the same experimental conditions, clearly indicating that the process studied is the displacement of the coordinated chloride by the nitrogen donor base. The observed rate constants, k_{obs}, collected in Table 2, obey the two-terms rate law $k_{obs} = k_1^f + k_2^f$ [am], typical of nucleophilic substitution at planar tetra-coordinate d^8 metal complexes [5] in which the k_1^f term refers to the solvolytic pathway involving the attack of the solvent as nucleophile, and k_2^f is the second-order rate constant for the direct attack of the nucleophile (am) at the substrate. The isosbestic points characteristic of the stage, the conditions of measurements, and the values of k_2^f, are all summarized in Table 3.

The k_1^f term, obtained as intercepts of the plots of k_{obs} vs am concentrations, is small and contribute little to the observed rates except at the lowest nucleophile concentrations. It may however be observed that on using a strong base, such as piperidine, no second order contribution can be detected and the only reaction product is the inert hydroxo species $[Pt(NNN)OH]^+$. For the same reason, i.e. the dominance of the solvent pathway in the chloride substitution, the nucleophilic attack of nitrogen donors at this substrate cannot be studied in water [6].

The specific second-order rate constants k_2^f (Table 4) obey the linear free energy relationship $\log k_2^f = \alpha pK_a + \text{constant}$, with $\alpha = 0.24$ (Fig. 1), as far as the entry of the isosteric pyridine, 4-cyanopyridine, 4-methylpyridine, 4-aminopyridine, 4-acetylpyridine, methylisonicotinate, and 3-methylpyridine is concerned. Ammonia is slightly less reactive as compared to the above mentioned pyridines, and this fact may be due to small differences in the solvation of the ligands and/or to a small contribution of π interactions for the latter reagents. Values of α for a number of platinum(II) complexes,

allowing a comparison among the various substrates, are collected in Table 5, in which also the values of Δ_f [7], the usual parameter for the steric retardation observed by using 2-methyl-pyridines as nucleophiles, are reported.

Kinetics of the displacement of am by chloride from $[Pt(NNN)(am)Cl](ClO_4)_2$

When the substrates $[Pt(NNN)(am)]^{2+}$ are allowed to react with excess chloride ion, the spectral changes, again showing a first order dependence upon time, are exactly the reverse of those observed in the forward processes and with the same isosbestic points, as obviously expected for the displacement of the coordinated neutral base (am) by excess chloride ion. The reactions were studied at constant ionic strength ($I = 0.1$ mol dm^{-3}, CH_3SO_3Na). The observed rate constants, k_{obs}, collected in Table 3, obey the general relationship $k_{obs} = k_1^r + k_2^r[Cl^-]$, where k_1^r and k_2^r have the usual meaning. The k_1^r values are small as compared to $k_2^r[Cl^-]$ and almost negligible in most cases. The k_2^r values at $I = 0.1$ mol dm^{-3} are reported in Table 4 together with the corresponding values of k_2^{0r} extrapolated to zero ionic strength.

As previously found [2,3] also in this case the rate of processes between the mono-cationic platinum(II) substrate and neutral nitrogen donors is not influenced upon primary salt effect, whereas the rate of the reverse reactions between the bis-cationic species and chloride ion depends upon ionic strength. The extrapolation to zero ionic strength uses the Debye–Huckel relationship, $\log k_2^{0r} = \log k_2^r - 2\alpha Z_a Z_b I^{1/2}/(1+\beta I^{1/2})$, with $Z_a = +2$, $Z_b = -1$, $\alpha = 1.90$, and $\beta = 1.55$ (estimated from the dielectric constant of methanol at

[a] Errors on individual k_{obs} determinations are in ±5% range

25°C) [8]. As a consequence, also the equilibrium constants K depend upon ionic strength and in Table 4 are reported the values $K = k_2^f/k_2^r$ and $K^0 = k_2^f/k_2^{0r}$ determined from the ratios of the second-order rate constants for the forward and reverse reactions.

As far as the dependence of the reactivity upon the basicity of the leaving nitrogen base is concerned, the plot of $\log k_2^r$ vs pK_a (Fig. 2) leads to the linear free energy relationship $\log k_2^r = -0.53pK_a + \text{constant}$ for the complexes with the unhindered pyridine, 3-methylpyridine, 4-methylpyridine and 4-amino-pyridine. The substrates containing as leaving groups the bases with a more extended aromatic π system (4-cyano-, 4-acetylpyridine and methylisonicotinate) show the same dependence upon proton basicity, but the reactivity is slightly decreased in accordance with previous results [2,3].

The reactivity of the hindered substrates containing 2-methyl- and 2,4-dimethyl-pyridine allows to estimate a steric retardation factor $\Delta_r \approx 0.82$ (Fig. 2 and Table 5).

Ammonia is considerably more labile than expected from its basicity, reasonably for the same reasons reported above for its slightly low nucleophilicity.

On considering the second order rate constants (corrected to zero ionic strength) for the displacement, under the same experimental conditions, of chloride from $[Pt(NNN)Cl]^+$ by bromide (k_2^0 = 51.9 dm^3 mol^{-1} s^{-1}, n_{Pt}^0 = 4.18) and iodide (k_2^0 = 1941 dm^3 mol^{-1} s^{-1}, n_{Pt}^0 = 5.46) available from the literature [4], it is possible to estimate the k_2^f value for the entry of pyridine (n_{Pt}^0 = 3.19) from the n_{Pt}^0 relationship $\log k_2 = s(n_{Pt}^0) + \text{constant}$ [9]. The calculated (0.44) and experimental (0.432) values are practically the same. This nice agreement could be, to some extent, surprising on considering that (i) the nucleophilic discrimination factor has been obtained from the reactivity of two nucleophiles only and is therefore

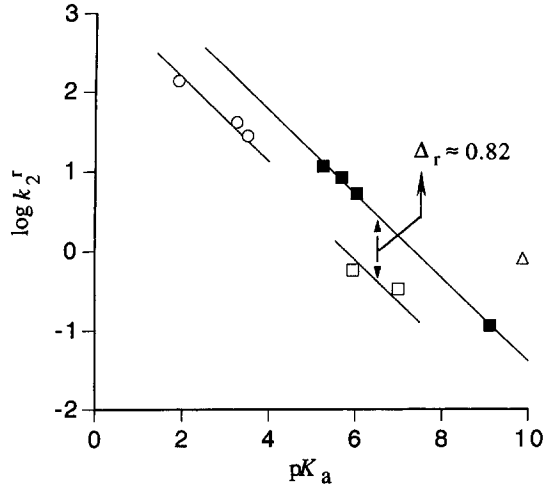

Fig. 2. $\log k_2^r$ for the reaction $[Pt(NNN)(am)]^{2+} + Cl^- \rightarrow [Pt(NNN)Cl]^+ + am$ plotted against pK_a of amH^+: ■, pyridine, 4-methylpyridine, 3-methylpyridine, 4-aminopyridine; ○, 4-acetylpyridine, methylisonicotinate, 4-cyanopyridine; □, 2-methylpyridine and 2,4-dimethylpyridine; △, ammonia.

affected by some error, (ii) the Debye–Huckel correction to zero ionic strength is approximate and (iii) the n_{Pt}^0 relationship is strictly obeyed only by neutral substrates reacting with purely σ donors. The difference in reactivity of pyridine towards the substrates $[Pt(NNN)Cl]^+$ ($k_2^f = 0.432$ dm^3 mol^{-1} s^{-1}), $[Pt(SNS)Cl]^+$ ($k_2^f = 0.0097$ dm^3 mol^{-1} s^{-1}) and $[Pt(SS)Cl_2]$ ($k_2^f = 0.283$ dm^3 mol^{-1} s^{-1}) can therefore be explained in terms of *trans*-labilizing effect and π interactions, as already reported in the study of the reactions of the same substrates with halide ions [4,10].

The parameter α_f (Table 5) is a measure of the ability of a substrate to discriminate among isosteric nitrogen donors and can be assumed to be a relative measure of its electrophilicity. This obviously implies that the intimate substitution mechanism must be the same for all the compared processes. The asynchronous substitution, characteristic of planar tetracoordinate platinum(II) complexes, offers the opportunity to describe as separated the energetic contributions of bond formation and bond rupture to the free energy of activation [11]. The relatively low discriminations among nitrogen donors (α_f, Table 5), together with the relatively high dependence of reactivity upon the basicity of the leaving nitrogen bases in the reverse processes (α_r, Table 5), strongly suggest a transition state for all these substitution in which the Pt—N bond is only partially formed in the rate determining transition state, whereas the Pt—Cl bond is practically formed to the same extent in the ground and transition states. This description is the same for all the substrates reported in Table 5.

At the same time, however, differences in electrophilicity emerge clearly on comparing the various substrates. It appears, as may be expected, that the electrophilicity increases among neutral substrates on moving from $[Pt(SS)Cl_2]$ [1] containing the aliphatic SS ligand, ($\alpha_f = 0.036$) to $[Pt(\alpha,\alpha'\text{-bipyridine})Cl_2]$ [12] ($\alpha_f = 0.06$) and [Pt(biacetylbis(N-methyl,N-phenyl)osazone)Cl_2] [13] ($\alpha_f = 0.05$), where the chelating ligands are capable of some π delocalization of negative charge during the nucleophilic attack. A further obvious increase of electrophilicity can be observed on moving from neutral to cationic species, and the presence of a very large π system in $[Pt(NNN)Cl]^+$ ($\alpha_f = 0.24$) leads to a discrimination larger than that observed with the substrate $[Pt(SNS)Cl]^+$ [2] ($\alpha_f = 0.15$).

On the contrary, the dependence of the reactivity upon the basicity of the nitrogen base in the reverse reactions (α_r, Table 5), is rather constant through all the compared substrates and may represent a limit value for platinum(II) complexes. This hypothesis requires further data to be confirmed.

The reactivity of the pyridine complex $[Pt(NNN)(py)]^{2+}$ at $I = 0$ mol dm^{-3} ($k_2^{0r} = 467$ dm^3 mol^{-1} s^{-1}) as compared with that of the mono-cationic $[Pt(SS)(py)Cl]^+$ ($k_2^{0r} = 0.078$ dm^3 mol^{-1} s^{-1}) [1] indicates that the nucleophilic attack of chloride occurs more easily at the bis-cationic than at the mono-cationic species and a comparison of the reactivity of chloride at the bis-cationic species $[Pt(NNN)(py)]^{2+}$ ($k_2^{0r} = 467$ dm^3 mol^{-1} s^{-1}) and $[Pt(SNS)(py)]^{2+}$ ($k_2^{0r} = 1.48$ dm^3 mol^{-1} s^{-1}) [2] provide a further evidence for the larger electrophilicity of the reaction centre for the former than the latter substrate.

The substrates can also be compared as far as steric retardation effects are concerned. Steric hindrance, as usually measured on using 2-methylpyridines as nucleophiles [1], is expressed by the value of $\Delta_f \approx 1.5$ [7] for the $[Pt(NNN)Cl]^+$ substrate (Fig. 1), which is comparable with the values of $\Delta_f \approx 1.6$ and 1.4 measured for the substrates $[Pt(SS)Cl_2]$ and $[Pt(SNS)Cl]^+$, respectively. It appears, therefore, that the limitation to free rotation around the Pt—N(am) bond in the trigonal bipyramidal transition state, due to the presence of two pyridine groups in the apical position, is not very different from that due to the presence of a single sulphur atom and a chloro ligand or two thioeteric sulphur atoms.

On comparing steric retardation parameters in the reverse processes, the steric factor $\Delta_r \approx 0.82$ in the present case is nearly the same as that measured for $[Pt(NSN)Cl]^+$ ($\Delta_r \approx 0.75$) [3]. In both cases two pyridine groups belonging to the chelating tridentate ligand occupy the apical positions in the trigonal bipyramidal transition states and the systems are, therefore, sterically comparable. It may be noted that the same observation was achieved on comparing the thermodynamic data concerning the relative stabilities of the corresponding halo platinum complexes. The steric retardation is slightly larger than that observed with the substrates $[Pt(SS)(am)Cl]^+$ ($\Delta_r \approx 0.6$) [1] and

Table 5. Discrimination (α) and steric hindrance (Δ) parameters for the reactions of pyridines with some platinum(II) chloro-complexes

Substrate	α_f	Δ_f	α_r	Δ_r	Ref.
[Pt(α,α'-bipyridine)Cl_2]	0.06				12
{Pt[biacetylbis(N-methyl,N-phenyl)osazone]Cl_2}	0.05				13
[Pt(SS)Cl_2]	0.036	1.6	−0.56	0.6	1
[Pt(SNS)$^+$	0.15	1.4	−0.45	0.57	2
[Pt(NSN)Cl]$^+$			−0.53	0.75	3
[Pt(NNN)Cl]$^+$	0.24	1.5	−0.53	0.82	p.w.

[Pt(SNS)(py)]$^{2+}$ ($\Delta_r \approx 0.57$) [2]. The values of Δ_r are always smaller than those of forward reactions Δ_f, as expected as a consequence of a partial compensation of steric hindrance in the ground and transition states for the nitrogen base displacement processes.

The ratio between the second-order rate constants for the forward and reverse reactions gives the corresponding equilibrium constants for the systems:

$$[Pt(NNN)Cl]^+ + am \rightleftharpoons [Pt(NNN)(am)]^{2+} + Cl^-$$

and the actual values of K and $I = 0.1$ mol dm^{-3} and K^0 at $I = 0$ mol dm^{-3} are reported in Table 4.

The plot of log K^0 versus pK_a (Fig. 3) is linear for the isosteric pyridines pyridine, 3-methylpyridine, 4-methylpyridine, and 4-aminopyridine and the free

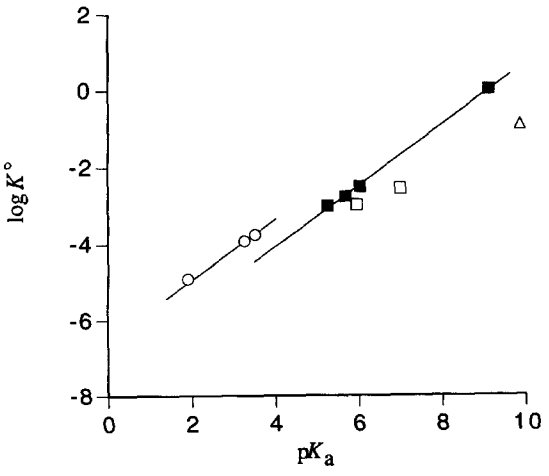

Fig. 3. log K^0 for the reaction [Pt(NNN)Cl]$^+$ + am $\rightleftharpoons$ [Pt(NNN)(am)]$^{2+}$ + Cl$^-$ plotted against pK_a of amH$^+$: ■, pyridine, 4-methylpyridine, 3-methylpyridine, 4-aminopyridine; ○, 4-acetylpyridine, methylisonicotinate, 4-cyanopyridine; □, 2-methylpyridine and 2,4-dimethylpyridine; △, ammonia.

energy relationship log $K^0 = 0.80$pK_a + constant can be derived. As expected the corresponding values for the 4-acetylpyridine, 4-cyanopyridine and methylisonicotinate is out of the line indicating an increased stability (4.3 kJ mol^{-1}), whereas the presence of hindered pyridines slightly decreases the stability.

The dependence of the stability of the complexes upon the basicity of pyridines is higher (0.80) for the presence bis-cationic substrates than that (0.58) measured with the mono-cationic substrates in the systems [Pt(SS)Cl_2] + am $\rightleftharpoons$ [Pt(SS)amCl]$^+$ + Cl$^-$. However, the values of the equilibrium constants are quite lower than those found in the previous case and this fact may reflect a larger tendency of Cl$^-$ to neutralize the positive charge in the bis-cationic than in mono-cationic substrate.

Synthesis, structure and magnetic properties of transition metal complexes of the nitroxide 2′,5′-dihydro-4′,5′,5′-trimethyl-spiro-[4,5-diazafluorene-9,2′-imidazol]-1-oxyl

Frank Hintermaier and Wolfgang Beck*

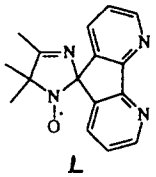
Institut für Anorganische Chemie der Universität, Meiserstr. 1, D-80333 München, Germany

(Received 4 July 1997; accepted 14 August 1997)

Abstract—With the radical 2′,5′-dihydro-4′,5′,5′-trimethyl-spiro-[4,5-diazafluorene-9,2′-imidazol]-1-oxyl L a series of transition metal complexes has been prepared: $[ML_3](SbF_6)_2 \cdot 4H_2O$ with $M^{2+} = Mn^{2+}$ (**1**), Fe^{2+} (**2**), Co^{2+} (**3**), Ni^{2+} (**4**), Zn^{2+} (**5**). Reaction of L with Cu^{2+} in methanol yielded different products depending on the counterion. In the presence of weakly coordinating anions the Cu(I) complexes $[Cu_2L_3](SbF_6)_2 \cdot H_2O$ (**6**), $[Cu_2L_3](OTf)_2 \cdot 2MeOH$ (**7**) and $[Cu_2L_3](ClO_4)_2$ (**8**) were formed. Stronger coordinating counter ions gave the complexes $CuL_2Cl_2 \cdot H_2O$ (**9**), $CuL_2Br_2 \cdot H_2O$ (**10**) and $CuL_2(NO_3)_2$ (**11**). Also the synthesis of $[Ag_2L_3](SbF_6)_2 \cdot 2H_2O$ (**12**), $Pd(L)Cl_2 \cdot H_2O$ (**13**), $Pt(L)Cl_2 \cdot H_2O$ (**14**), $Ni(L)Cl_2$ (**15a**), $Ni(L)Cl_2 \cdot 4H_2O$ (**15b**) and $[Ru(bipy)_2(L)]Cl_2 \cdot 4H_2O$ (**16**) is reported. The magnetic moments of **1–6** and **10** correspond in the range 200–300 K to those expected for noninteracting spins of the metal ion and the radicals. At low temperatures spin pairing of metal and radical spins is observed for **1–3**. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: nitroxide radicals; 3-imidazoline; transition metal complexes.

In continuation of our studies on the coordination chemistry of 3-imidazoline-1-oxyl-radicals [1,2] we report in this paper on transistion metal complexes of the radical 2′,5′-dihydro-4′,5′,5′-trimethyl-spiro-[4,5-diazafluorene-9,2′-imidazol]-1-oxyl L, which was previously reported [3].



L

Due to its diazafluorene part L is a bidentate ligand and should reveal a coordination chemistry similar to that of 1,2-diimines [5], e.g. 2,2′-bipyridyl or *o*-phenanthroline. However the bite angle of L between the two donor *N*-atoms of the 4,5-diazafluorene part is only 38° [6,7] and therefore L should be a weaker ligand than 2,2′-bipyridyl or phenanthroline (bite angle 60°). Metal complexes of 4,5-diazafluorene [7,8], 4,5-diazafluorenone [9] and *N*,*N*′-methylen-2,2′-bisimidazole [10] have been reported.

RESULTS AND DISCUSSION

Complexes $[ML_3]^{2+}$ (*M = Mn, Fe, Co, Ni, Zn*)

The metal(II) chlorides MCl_2 (Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+} and Zn^{2+}) form with L in an H_2O/CH_3OH solution complexes of the type $[ML_3]^{2+}$ (**1–5**), which can

* Author to whom all correspondence should addressed.

be isolated as tetrahydrates of hexafluoroantimonate salts, using $AgSbF_6$.

	1	2	3	4	5
M	Mn	Fe	Co	Ni	Zn

The same products were isolated when only two equivalents of L were used. In the FAB MS spectra of these compounds the ions $[ML_3(SbF_6)_2]^+$, $[ML_3(SbF_6)]^+$ and $[ML_3]^+$ were detected.

In the EPR spectra of **1–5** in methanolic solution only a triplet with slightly broadened lines of the nitroxide radical is observed at room temperature. These signals probably correspond to the dissociated nitroxide ligand while the intact complexes with small intramolecular superexchange should exhibit broad signals which may be unobservable at room temperature [4]. The EPR spectrum of the Mn complex **1** exhibits an additional sextet of the Mn^{2+} ion.

In the range 200–300 K, complexes **1, 2, 4** and **5** show magnetic moments which are close to the spin-only value for independent (noninteracting) spins of the metal ion and the nitroxide radicals (Table 1). For the cobalt complex **3** an orbital contribution has to be assumed [12]. The plots $1/\chi$ vs T obey the Curie Weiß law according to paramagnetic behaviour (Figs 1–5). At low temperature (4.2 K) a considerable decrease of the magnetic moment is found for **1–3** (Table 1) which we attribute to spin pairing of metal and radical spins.

Cu(I) and Ag(I) complexes

The reactions of L with *in situ* prepared solutions of $Cu(SbF_6)_2$ and $Cu(SO_3CF_3)_2$ (from $CuCl_2$ and $AgSbF_6$ or $AgSO_3CF_3$) or with $Cu(ClO_4)_2$ gave the complexes **6–8** in which the copper ion has the oxidation state +I. Thus a reduction of Cu(II) by methanol has occurred.

$[Cu_2L_3](SbF_6)_2 \cdot H_2O$	**6**
$[Cu_2L_3](SO_3CF_3)_2 \cdot 2$ MeOH	**7**
$[Cu_2L_3](ClO_4)_2 \cdot 3\ H_2O$	**8**

For **6** in the range 60–300 K a magnetic moment of $\mu_{eff} = 3.08\ \mu_B$ was observed which is close to that of 3.00 μ_B for Cu(I) (d^{10}) and three noninteracting radical spins ($S = 3 \cdot 1/2$).

The nitroxide reacts with $AgSbF_6$ to give the complex **9**.

$[Ag_2L_3](SbF_6)_2$ **9**

The formation of dinuclear complexes **7** and **9** is supported by FAB MS spectra in which the ions $[Cu_2L_3]^+$, $[Cu_2L_3 \cdot H_2O]^+$, $[Ag_2L_3]^+$ and $[Ag_2L_3SbF_6]^+$ could be detected. A force field calculation [13] shows that for **9** a structure with three bridging ligands, L is energetically favourable (Fig. 6).

With stronger coordinating anions during reactions of L copper(II) is not reduced and the green complexes **10–12** were obtained.

$CuL_2Cl_2 \cdot H_2O$	**10**
$CuL_2Br_2 \cdot H_2O$	**11**
$CuL_2(NO_3)_2$	**12**

The observed magnetic moment $\mu = 3.17\ \mu_B$ (Table 1) of **10** corresponds to three noninteracting spins (d^9 and two radical spins: $S = 3^1/_2$)

Complexes **10** and **11** may show a similar structure as has been reported for Cu(4,5-diazafluorene-9-one)$_2Cl_2$ [9] with hexacoordinated metal ion.

Table 1. Magnetic moments of **1–6, 10**

	S[11,12] (for independent metal and radical spins)		μ_B expected	$t\mu_B$ found	Θ (K)	Temperature (K)	μ_B found at low temperatures
1	(Mn^{2+}, high spin)	$5/2+3 \cdot 1/2$	6.64	6.37	~0	32–300	3.52(4.2 K)
2	(Fe^{2+}, high spin)	$4/2+3 \cdot 1/2$	5.75	5.77	−27	200–300	2.63(4.2 K)
3	(Co^{2+}, high spin)	$3/2+3 \cdot 1/2$	4.90	5.89	−19	190–300	2.06(4.2 K)
4	(Ni^{2+})	$1+3 \cdot 1/2$	4.12	4.25	−13	190–300	3.48(32.6 K)

Ni(II), Pd(II), Pt(II) and Ru(II) complexes

The reactions of the nitroxide L with Na_2PdCl_4, K_2PtCl_4, $NiCl_2 \cdot 6\,H_2O$ and $Ru(bipy)_2Cl_2$, respectively, gave the complexes **13–16**.

$Pd(L)Cl_2$	**13**
$Pt(L)Cl_2$	**14**
$Ni(L)Cl_2$	$Ni(L)Cl_2 \cdot 4\,H_2O$
15a	**15b**
$Ru(bipy)_2(L)]Cl_2 \cdot 4\,H_2O$	**16**

Complex **15** adds four equivalents of water on exposure to air in a reservible manner.

Ruthenium(II) complexes of diazabiarene ligands are of high interest due to their photo and redox chemistry [14]. Ruthenium(II) complexes of diazafluorene and diazafluorenenone have been previously described [7,8a].

The IR spectra of the complexes **1–16** are almost identical and differ only slightly from those of the free ligand L.

EXPERIMENTAL

The radical 2′,5′-dihydro-4′,5′,5′-trimethyl-spiro-[4,5-diazafluorene-9,2′-imidazol]-1-oxyl was prepared as described [4]. All other reagents and solvents were

purchased and used as received. The products were dried *in vacuo* (0.1 Torr) for 4–8 h. Elemental analyses: Heraeus VT. Metal analyses: AAS Perkin-Elmer 1100 B at the wave lengths Sb: 217.8 nm, Mn: 279.5 nm, Fe: 248.3 nm, Ni: 341.5 nm, Cu: 324.8 nm, Zn: 213.8 nm, and an ICP Jobin Y of JY 38 with an ICP 1500 plasmatherm generator for **6**. Dissolution with 65% HNO_3 (Merck Suprapur). EPR (X-band): Varian E-Line Spectrometer with a Varian E-101 microwave bridge. Magnetic measurements with 8–15 mg samples in the temperature range 30–300 K: Faraday-balance from the Institut für Physikalische Chemie der Universität München (Prof. Voitländer). IR: Nicolet 520 FT-IR-spectrometer in Hostaflon (2500–4000 cm^{-1}), in KBr (600–2500 cm^{-1} and sometimes in polyethylene (400–600 cm^{-1}). FAB–MS: Finnigan MAT 95 Q with Cs^+-gun in mNBA. Melting and decomposition points: Schmelzpunktsapparat Dr Tottoli from Büchi.

1. Solutions of 10.5 mg (0.0836 mmol) of $MnCl_2$ and of 57.5 mg (0.167 mmol) of $AgSbF_6$ in methanol were combined and boiled for 1 min. The solvent was removed *in vacuo* and the residue was treated with 10 ml of methanol. After separation of AgCl a methanol solution of 70.0 mg (0.252 mmol) of 2′,5′-dihydro-4′,5′,5′-trimethyl-spiro-[4,5-diazafluorene-9,2′-imidazol]-1-oxyl (L) was added. The mixture was stirred for 12 h, boiled for 1 min and evaporated to 3 ml. To this 20 ml of diethylether were added and the mixture was stirred for 2 h. The product was separated, washed with diethylether and dried *in vacuo*. Yield: 85 mg (71%) of an orange-yellow powder.

IR: ν = 2990 m, 1632 s (C4 = N), 1598 m (py), 1585 s (py), 1473 s, 1412 vs, 1384 vs, 1293 vs, 817 s, 744 s. $C_{32}H_{30}N_{10}O_8Cu$ (746.20): Calc. C, 51.51; H, 4.05; N, 18.77. Found: C, 51.56; H, 4.01; N, 18.69%.

13. A solution of 56.5 mg (0.192 mmol) of Na_2PdCl_4 in 3 ml of water and 5 ml of methanol was combined with a solution of 53.6 mg (0.192 mmol) of L in 8 ml of methanol and 4 ml of water. After 12 h the precipitate was separated, washed with 8 ml methanol: water (1 : 1) and dried *in vacuo*. Yield 87.6 mg (96.4%) of an orange powder.

IR: ν = 2978 m, 1630 s (C4 = N), 1609 s (py), 1588 m (py), 1573 s, 1464 s, 1419 vs, 1411 vs, 1382 s, 1363 m, 1252 s, 1149 s, 773 s, 751 s, 348 s, 341 s. $C_{16}H_{15}N_4OPdCl_2 \cdot H_2O$ (474.66): Calc. C, 40.49; H, 3.61; N, 11.80. Found: C, 40.09; H, 3.71; N, 11.29%.

14. A solution of 41.5 mg (0.100 mmol) of K_2PtCl_4 in 4 ml of water and 2 ml of methanol was combined with a solution of 27.9 mg (0.100 mmol) of L in 4 ml of methanol and 12 ml of water. After 3 days the precipitate was separated, washed with methanol: water (1 : 3) and dried *in vacuo*. Yield: 37 mg (66 %) of an orange powder.

IR: ν = 2982 m, 1627 vs (C4 = N), 1615 vs (py), 1571 s (py), 1463 s, 1423 vs, 1410 vs, 1382 s, 1364 m, 1148 s, 754 s. $C_{16}H_{15}N_4OPtCl_2 \cdot H_2O$ (563.33): Calc. C, 34.11; H, 3.04; N, 9.95. Found: C, 34.23; H, 3.15; N, 9.72%.

15. 39.6 mg (0.167 mmol) $NiCl_2 \cdot 6H_2O$ were dissolved in 2 ml of methanol and 8 ml of water and combined with a solution of 45.0 mg (0.161 mmol) of L in 3 ml of methanol and 12 ml of water. After 1 day the solvent was removed *in vacuo*, the residue dissolved in 5 ml of methanol and the solution overlayered with 20 ml of diethylether. After 3 days the precipitate was separated, washed with diethylether and dried for 5 h at 65°C/0.1 torr. Yield: 37 mg (55%) orange-"rosa" coloured powder (**15a**). When **15a** was allowed to stand on air, the colour changed to yellow and the tetrahydrate **15b** was formed.

IR (**15b**): ν = 2991 m, 2978 m, 2970 m, 2932 m, 1627 s (C4 = N), 1594 m (py), 1584 m (py), 1568 s, 1464 m, 1428 s, 1402 vs, 1385 s, 1163 s, 810 s, 787 s, 748 s. $C_{16}H_{15}N_4ONiCl_2$ (**15a**) (408.94): Calc. C, 46.99; H, 3.70; N, 13.70. Found: C, 46.77; H, 3.97; N, 13.44%. $C_{16}H_{15}N_4ONiCl_2 \cdot 4H_2O$ (**15b**) (481.00): Calc. C, 39.95; H, 4.82; N, 11.65. Found: C, 40.41; H, 4.77; N, 11.69%.

16. 105 mg (0.196 mmol) of $Ru(bipy)_2Cl_2$ and 60.0 mg (0.215 mmol) of L in 7 ml of ethanol were refluxed for 3 h. The solvent was removed, the residue dissolved in CH_2Cl_2 and the product was precipitated by addition of pentane, washed twice by stirring in CH_2Cl_2 for 30 min and dried. Yield: 87 mg (51%) of a bright orange powder.

IR: ν = 2960 m, 2931 s, 2860 m, 1627 s (C4 = N), 1603 s (py), 1465 s, 1445 s, 1419 vs, 770 vs. $C_{36}H_{31}N_8ORuCl_2 \cdot 4H_2O$ (835.73): Calc. C, 51.74; H, 4.70; N, 13.41. Found: C, 51.94; H, 4.51; N, 13.11%. EPR (CH_2Cl_2): g = 2.0067, a_N = 13.3.

Abstract—Some new ferrocene-functionalized amines have been synthesized and characterized. Electrochemical and potentiometric studies have been carried out in THF: H_2O (60:40 v/v) to determine protonation constants of the oxidized and "reduced" species and the oxidation potential shift between pH acid and basic. Some electrochemical studies have also been performed in CH_2Cl_2: MeOH mixtures. The change in the acidity properties after oxidation and the related redox potential shift after protonation are discussed.

Keywords: ferrocene; electroactive group; potentiometry; electrochemistry.

Ferrocene-functionalized polyamines are new receptors which have been reported to electrochemically recognize different substrates as consequence of the shift of the redox potential of the electroactive group [1–5]. Additionally we have recently shown that some of those receptors can quantitatively determine metal ions and anions in aqueous solutions [6]. It is known that amines can coordinate metal ions and, due to electrostatic forces, the oxidation potential of the redox groups is usually shifted to anodic potentials [1–7]. If the metal–ferrocenyl groups interaction is mainly electrostatic the presence of metal ions with the same charge would in principle produce the same shift of the oxidation potential. However, if the experiment is carried out in aqueous solutions different metal ions form different species in solution and therefore control of the pH can lead to selectivity in the recognition process. Working with amines the easiest coordination study is probably with protons. As a part of our interest in redox-active amines as receptors we have synthesized and studied the interaction of H^+, using potentiometric and electrochemical techniques, with some new receptors with the aim of determining (i) the effect that oxidation of the ferrocenyl groups has on the acidity of the ammonium groups and (ii) the effect that the protonation process has on the redox potential of the ferrocenyl groups.

EXPERIMENTAL

Solvents and reagents

1,2-phenylenediamine, 1,3-phenylenediamine, 1,4-phenylenediamine and ferrocenecarbaldehyde were reagent quality and were used without further purification. Tetrahydrofuran (THF) used was freshly distilled from sodium benzophenone. Carbonate-free potassium hydroxide and hydrochloric acid solutions were used in the potentiometric and electrochemical experiments. Potassium nitrate (0.1 mol dm^{-3}) was used as supporting electrolyte in water. L^3 and L^4 were synthesized following literature procedures [8].

Synthesis of L^1, L^2 and L^5

Ferrocenecarboxaldehyde (856 mg, 4 mmol) was heated with 2 mmol of the corresponding diamine in benzene. After 2 h the solvent was removed under vacuum. The red solid was dissolved in tetrahydrofuran and heated under reflux in the presence of $LiAlH_4$ (10 mmol) for 1 h. The reaction mixture was cooled and small amounts of water were added cautiously in order to eliminate the excess of reductor. The resulting mixture was filtered and the solution evaporated under vacuum. Further addition of water and dichloromethane (30×3 cm^3) produced yellow organic phases which were dried with anhydrous mag-

nesium sulphate. The compounds were recrystallized from dichloromethane-hexane solutions.

Physical measurements

NMR spectra were measured on a Bruker AC-200 FT spectrometer operating at 300 K. Chemical shifts for ^1H and ^{13}C $\{^1H\}$ spectra are referenced to TMS and $CDCl_3$, respectively. IR spectra were taken on a Perkin-Elmer 1750 spectrophotometer as KBr pellets. Electrochemical data were obtained with a programmable function generator Tacusel IMT-1, connected to a Tacusel PJT 120-1 potentiostat. The working electrode was platinum with a saturated calomel reference electrode separated from the text solution by a salt bridge containing the solvent/supporting electrolyte. The auxiliary electrode was platinum wire. Potentiometric titrations were carried out in THF: H_2O (60:40 v/v) using a reaction vessel water-thermostated at 25.0±0.1°C under nitrogen. The titrant was added by a Crison microburete 2031. The potentiometric measurements were made using a Crison 2002 pH-meter and a combined glass electrode. The titration system was automatically controlled by a PC computer using a program that monitored the e.m.f. values and the volume of titrant added. The electrode was calibrated as a hydrogen concentration proved by titration of known amounts of HCl with CO_2-free KOH solution and determining the equivalent point by Gran's method [9] which gives the standard potential E'^{O} and the ionic product of water ($K'_W = [H^+][OH^-]$). The logarithm of K'_W for the solvent used was found to be -15.1 ± 0.1 (25°C, 0.1 mol dm^{-3} tetrabutylammonium perchlorate). The computer program SUPERQUAD [10] was used to calculate the protonation and stability constants. The titration curves for each system (*ca.* 200 experimental points corresponding to at least three titration curves, pH = −log[H] range investigated 2.5–10, concentration of the ligand was *ca.* 1.2×10^{-3} mol dm^{-3}) were treated either as a single set or as separated entities without significant variations in the values of the stability constants. Finally the sets of data were merged together and treated simultaneously to give the stability constants.

RESULTS AND DISCUSSION

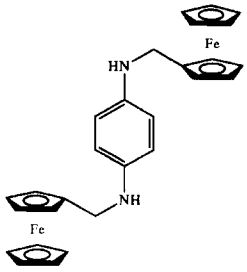
Synthesis and characterization

The reaction of ferrocenecarboxaldehyde with the diamines 1,3-, 1,4-phenylendiamine and 1,3-propylendiamine led to the corresponding Schiff base derivatives as red oils. IR spectra revealed that the condensation took place as can be observed by the strong ν(C=N) stretching vibration at about 1640 cm^{-1}. The IR also displayed for all the imine derivatives several characteristic ferrocene absorptions.

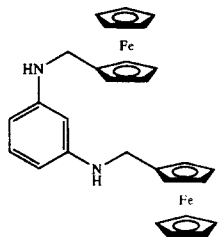
Reduction of the Schiff base derivatives with $LiAlH_4$ in tetrahydrofuran allowed isolation of the corresponding diamines L^1, L^2 and L^5. The IR showed that the imino group had been reduced by the absence of the ν(C=N) imine stretching peak. The lack after hydrogenation in the ^1H NMR of any imine protons at δ about 8.2 and the presence of characteristic CH_2 groups attached to ferrocenyl groups (δ about 3.5–3.9) also supports the proposed formulation. Similar synthetic procedures between ferrocenecarboxaldehyde and 1,2-phenylenediamine did not produce the expected Schiff-base derivatives but compounds L^3 and L^4 as we have reported [8].

Protonation behaviour

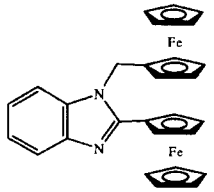
The protonation behaviour of L^1, L^2, L^3, L^4 and L^5 was studied by potentiometric titrations of acidified solutions of the amines in THF: H_2O (60:40 v/v) (0.1 mol dm^{-3} tetrabutylammonium perchlorate, 25°C). Basicity constants are gathered in Table 1. L^1, L^2 and L^3 behave as diprotic bases whereas only one protonation process was observed for the benzimidazol derivatives. As expected the diazaalkane derivative L^5 is more basic than the corresponding aryl amines L^1, L^2, L^3 and L^4, with the acidity of the first protonation constant following the order $L^2 > L^3 > L^4 > L^1 > L^5$. For the sake of comparison the basicity constants of the non-substituted 1,3- and 1,4-phenylenediamine



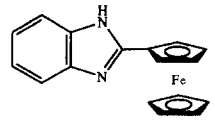
L^1



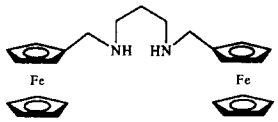
L^2



L^3



L^4



L^5

were also determined in THF : H_2O (60 : 40 v/v) mixtures, [log K ; 1,4-phenylenediamine : 5.80(1), 1.98(1) ; 1,3-phenylenediamine : 4.37(1), 1.19(2) ; for the processes, $L + H^+ \rightleftarrows LH^+$ and $LH^+ + H^+ \rightleftarrows LH_2^{+2}$, respectively]. It can be observed that the N-functionalization with ferrocenylmethyl groups reduces the basicity of the amine groups for the first protonation process but increases the basicity of the second protonation process of L^1 and L^2. Also for the sake of comparison we have determined the protonation constant for benzimidazole in THF : H_2O (60 : 40 v/v) and have obtained a value of log K = 3.09(1) for the process $L + H^+ \rightleftarrows LH^+$, indicating that the functionalization with a ferrocenyl group in the 2 position increases the basicity of the benzimidazol framework. A similar effect has been found in water when we compare the protonation constant for benzimidazole (log K = 5.47) and 2-methyl-benzimidazole (log K = 6.17) [11].

Electrochemical behaviour

Two related effects were studied electrochemically ; the possible modification of the acidity of the receptors by oxidation of the redox-active groups and the redox potential shift of the electro-active groups by addition of protons to the medium.

The receptors L^1–L^5 show an important difference with respect to the starting non-functionalized polyamines, due to the fact that L^1–L^5 are molecules whose basicity strength can be switched from "outside" by oxidation or reduction of the pendant redox-active ferrocenyl groups. That switching process between two different states containing oxidized or "reduced" ferrocenyl groups can be quantified from the study of the $E_{1/2}$–pH (half-wave potential vs pH) curves. Figure 1 shows an example of the shift of the oxidation potential of the receptor L^5. From the analysis of the $E_{1/2}$–pH curves it is possible to evaluate the protonation constants of the amines when the redox groups are oxidized. Table 2 shows the stepwise protonation constants for the oxidized L^1, L^2, L^3, L^4 and L^5 receptors obtained by fitting the $E_{1/2}$–pH curves with an equation which relates the half-wave potential with the proton concentration and the acidity constants for the "reduced" and the oxidized species [2]. As can be observed, oxidation of the ferrocenyl groups switches the acidity strength of the ammonium groups and oxidized species behave as stronger acids than the corresponding "reduced" species. Thus first protonation constants are reduced by 6 times for L^1 and by 38 times for L^4 due to the oxidation of the ferrocenyl groups. We and others have recently published that the change in the protonation constants is due mainly to electrostatic forces as a consequence of the existence of positively charged ferrocenyl groups after oxidation [12,13].

Another study on the ferrocene-functionalized

Table 1. Stepwise protonation constants (log K) of L^1, L^2, L^3, L^4 and L^5 determined in THF : H_2O (60 : 40 v/v) at 298.1 K in 0.1 mol dm^{-3} tetrabutylammonium perchlorate

Reaction	L^1	L^2	L^3	L^4	L^5
$L + H^+ \rightleftarrows HL^+$	5.59(1)[a]	3.93(1)	4.28(2)	4.80(1)	9.17(5)
$HL^+ + H^+ \rightleftarrows H_2L^{+2}$	3.69(4)	2.84(2)			7.19(3)

[a] Values in parentheses are standard deviations on the last significant figure.

Table 2. Stepwise protonation constants (log K) for the oxidized form of L^1, L^2, L^3, L^4 and L^5 determined in THF : H_2O (60 : 40 v/v) at 298.1 K in 0.1 mol dm^{-3} tetrabutylammonium perchlorate

Reaction	L^1	L^2	L^3	L^4	L^5
$^{ox}L + H^+ \rightleftharpoons {}^{ox}LH^+$	4.8(1)[a]	3.0(1)	2.78(6)	3.22(3)	7.9(1)
$^{ox}LH^+ + H^+ \rightleftharpoons {}^{ox}LH_2^{+2}$	1.8(1)	0.8(2)			5.5(1)

[a] Values in parentheses are standard deviations on the last significant figure.

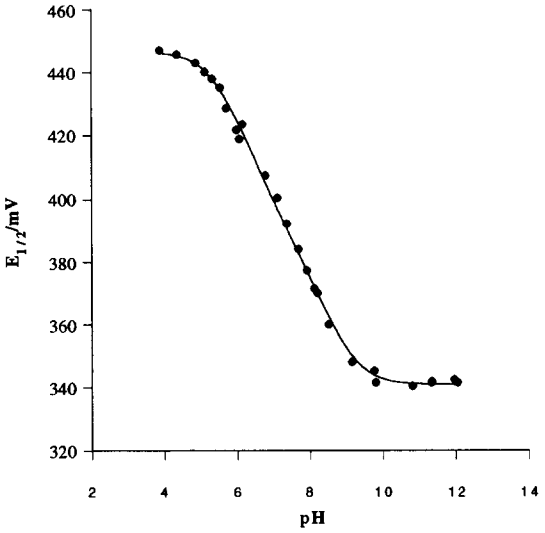


Fig. 1. Plot of the half-wave potential ($E_{1/2}$) vs pH for compound L^5.

amines is how the protonation of the amine groups affects the oxidation potential of the ferrocenyl moieties. For a fixed pH $E_{1/2}$ is a function of the acidity constants of the oxidized and "reduced" species and a steady shift is usually observed when the pH is changed. We can therefore say that the proton concentration can tune the value of the half-wave potential as can be observed for example in the $E_{1/2}$–pH curve shown in Fig. 1. On the other hand another interesting parameter is the maximum shift that can be achieved by changing the pH and can be measured as the difference between $E_{1/2}$ at basic pH and at pH = 0. That difference, ΔE, determined in THF : H_2O (60 : 40 v/v) was 79, 85, 42, 92 and 105 for molecules L^1, L^2, L^3, L^4 and L^5, respectively. We have recently shown that eqn (1) allows a prediction of the potential shift due to the coordination of H^+ in redox-functionalized polyamines as a function of the number of electrons involved in the electrochemical experiment (n); the number of redox groups (j); the distance between the protonation sites (i) and the ferrocenyl groups (r_{ji}) and the permittivity of the medium (ε) [12].

$$\Delta E = \frac{1}{jn}\left[\frac{14398}{\varepsilon}\sum_j\sum_i\frac{1}{r_{ji}} + \left(\frac{2\times10^6}{\varepsilon^2} + 1051\right)\sum_j\sum_i\frac{1}{r_{ji}^2}\right] \quad (1)$$

Distances can be calculated using molecular modeling programs such as PCMODEL [14]. The predicted ΔE values are 89, 92, 68, 165 and 93 mV, for L^1, L^2, L^3, L^4 and L^5, respectively. Although there is a good agreement between the predicted and the observed oxidation potential shift in L^1, L^2 and L^5 there is an important deviation for the benzimidazole derivatives probably due to the different nature of the protonated nitrogens.

The study of the change of $E_{1/2}$ as a function of the H^+ concentration shows for all the compounds studied in THF : H_2O (60 : 40 v/v) a steady one-wave shift, suggesting that the equilibrium is fast on the electrochemical time-scale. However the use of a different solvent may change the observed behaviour and produce a switching effect in the oxidation potential rather than a tuning process. Thus we have also studied the effect that the addition of H^+ has on the redox potential of L^1, L^2 and L^5 in dichloromethane : methanol (10 : 1) mixtures. Whereas no well defined voltammograms were observed for L^1, addition of acid (HCl, 0.1 M in dichloromethane : methanol 10 : 1) to L^2 and L^5 results in the appearance of a second wave at higher anodic potentials. After addition of two equivalents of acid the first wave disappears and only the second oxidation process is observed. The switching process is reversible and addition of KOH (KOH 0.1 M in dichloromethane : methanol 10 : 1) regenerates the first oxidation potential [8]. The ΔE between the first and the second wave is about 65 and 106 mV for L^2 and L^5, respectively. A similar behaviour has recently been observed for the benzimidazol derivatives L^3 and L^4.

(Received 24 June 1997; accepted 13 August 1997)

Abstract—Three novel gadolinium(III) co-ordination polymers containing three flexible double betaines with different numbers of methylene bridges and a rigid *tris*(ethylene) bridge between two quaternary nitrogen atoms, namely $[\{Gd(L^1)_2(H_2O)_2\}_n](ClO_4)_{3n}\cdot nH_2O$ (**1**), $[\{Gd(L^2)_2(H_2O)_2\}_n](ClO_4)_{3n}\cdot nH_2O$ (**2**) and $[\{Gd(L^3)_2(H_2O)_2\}_n](ClO_4)_{3n}\cdot 8nH_2O$ (**3**) (L^1 = *N*,*N*′-dicarboxymethyl-*N*,*N*,*N*′,*N*′-tetramethyl-1,3-propanediammonium, $^-O_2CCH_2N^+Me_2$-$(CH_2)_3$-$N^+Me_2CH_2CO_2^-$; L^2 = *N*,*N*′-dicarboxymethyl-*N*,*N*,*N*′,*N*′-tetramethyl-1,4-butanediammonium, $^-O_2CCH_2N^+Me_2$-$(CH_2)_4$-$N^+Me_2CH_2CO_2^-$; L^3 = 1,4-diazoniabicyclo[2.2.2]octane-1,4-diacetate, $^-O_2CCH_2N^+(CH_2CH_2)_3N^+CH_2CO_2^-$), have been prepared and characterized by X-ray crystallography. Each complex contains paddlewheel-like dimeric subunits in which each pair of adjacent metal atoms is bridged by four μ-carboxylato-*O*,*O*′ groups that are orientated nearly perpendicular to each other about the metal–metal axis. The dimeric subunits are extended into a polymeric chain through the linkage of each metal center to the carboxylato groups of an adjacent dimer. Such infinite chains are extended into a plane wave-like layer structure in (**1**) and (**2**), and a three-dimensional framework in (**3**) by the cross-linkage of the molecular skeletons of double betaine ligands. The formation of hydrogen bonds further leads to a three-dimensional network in (**1**). The gadolinium(III) atom in each complex is surrounded in a distorted square-antiprismatic geometry by six carboxylato oxygen atoms and two aqua ligands. The carboxylato groups in the dimeric subunits adopt the common *syn–syn* bidentate bridging and unidentate co-ordination modes in (**1**), (**2**) and (**3**). In addition, the carboxylato groups in (**1**) and (**2**) also coordinate the metal atoms in an unusual *syn–skew* μ-*O*,*O*′ bridging mode. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: gadolinium(III) perchlorate; coordination network; double betaine; dicarboxylate.

Metal co-ordination polymers of one-, two- and three-dimensional infinite frameworks have been the subject of intensive research for several decades, and major advances have been made in both their theoretical description and applications as new materials [1]. The chemistry of metal co-ordination polymers is among the most promising interfaces between synthetic chemistry and material science, as it provides a solid foundation for understanding how molecules can be organized and how functions can be achieved. Thus the structural design or modification of the framework has become a very active field in crystal engineering [2]. Our interest lies in the generation of polymeric structures in metal complexes by various double betaine ligands, each comprising two betaine moieties (betaine: $Me_3N^+CH_2CO_2^-$, IUPAC name: trimethylammonioacetate) in the same molecule and accordingly possessing pairs of anionic carboxylate groups and quaternary ammonio groups [3–6]. Recent studies have shown that variation of the double betaine ligands regarding the type of bridging unit, the flexibility of the molecular backbone and conformation preferences, as well as the metal ions employed and their counter anions, have a profound influence on the polymeric structures obtained [7–11].

† Author to whom correspondence should be addressed.

In our latest attempts to prepare lanthanide complexes of betaines [12], we have obtained co-ordination polymers of neodymium and erbium perchlorates based on two-dimensional networks by using two flexible double betaines [13]. In the present work, we report the preparation and characterization of three new gadolinium(III) dicarboxylate-like complexes containing two- and three-dimensional frameworks constructed from three flexible double betaines with different numbers of methylene units and a rigid *tris*-(ethylene) bridge between two quaternary nitrogen atoms, namely $[\{Gd(L^1)_2(H_2O)_2\}_n](ClO_4)_{3n}\cdot nH_2O$ (**1**), $[\{Gd(L^2)_2(H_2O)_2\}_n](ClO_4)_{3n}\cdot nH_2O$ (**2**) and $[\{Gd(L^3)_2(H_2O)_2\}_n](ClO_4)_{3n}\cdot 8nH_2O$ (**3**) (L^1 = *N*,*N*′-dicarboxymethyl-*N*,*N*,*N*′,*N*′-tetramethyl-1,3-propanediammonium, $^-O_2CCH_2N^+Me_2$-$(CH_2)_3$-$N^+Me_2CH_2CO_2^-$; L^2 = *N*,*N*′-dicarboxymethyl-*N*,*N*,*N*′,*N*′-tetramethyl-1,4-butanediammonium, $^-O_2CCH_2N^+Me_2$-$(CH_2)_4$-$N^+Me_2CH_2CO_2^-$; L^3 = 1,4-diazoniabicyclo[2.2.2]octane-1,4-diacetate, $^-O_2CCH_2N^+(CH_2CH_2)_3N^+CH_2CO_2^-$).

EXPERIMENTAL

Materials and measurements

The flexible double betaines L^1, L^2 and L^3 were synthesized as described previously [5(a),6]. The C, H and N microanalyses were carried out on a Perkin–Elmer 240 elemental analyser. Infrared spectra were recorded from KBr pellets in the range of 4000–400 cm^{-1} on a Perkin–Elmer 1600 FT-IR spectrometer.

Synthesis of complexes

$[\{Gd(L^1)_2(H_2O)_2\}_n](ClO_4)_{3n}\cdot nH_2O$ (**1**). Perchloric acid (2 N) was added slowly to an aqueous suspension (10 cm^3) of gadolinium oxide (Gd_2O_3 91 mg, 0.25 mmol) with stirring at about 60°C. The resulting clear solution of gadolinium(III) perchlorate (0.5 mmol) was mixed with an aqueous solution (5 cm^3) of L^1 (260 mg, 1.0 mmol). After stirring at about 60°C for a few minutes, the solution was filtered, and ethanol was diffused into the resulting solution over one week to yield colorless prismatic crystals. Found: C, 26.36; H, 5.07; N, 5.63. Calc. for $C_{22}H_{46}N_4O_{23}Cl_3Gd$: C, 26.47; H, 4.61; N, 5.61%. IR: 3449.2 (s), 2976.9 (w), 1617.9 (s), 1481.5 (m), 1435.2 (m), 1406.8 (m), 1336.5 (w), 1094.1 (s), 892.0 (w), 703.7 (w), 624.7 (m), 573.9 (w) and 481.8 (w) cm^{-1}.

$[\{Gd(L^2)_2(H_2O)_2\}_n](ClO_4)_{3n}\cdot nH_2O$ (**2**). To an aqueous solution (10 cm^3) of gadolinium(III) perchlorate (0.5 mmol) was added a solution of L^2 (274 mg, 1.0 mmol) in distilled water (5 cm^3) with stirring at about 60°C for a few minutes. After filtration, colorless block-like crystals were obtained by diffusing ethanol into the aqueous solution. Found: C, 27.63; H, 5.10; N, 5.32. Calc. for $C_{24}H_{54}N_4O_{23}Cl_3Gd$: C, 27.97; H, 5.24; N, 5.44%. IR: 3423.4 (s), 2980.5 (w), 1622.9 (s), 1483.2 (m), 1436.6 (m), 1407.5 (m), 1337.6 (w), 1138.7 (s), 1122.2 (s), 1081.5 (s), 895.1 (w), 720.5 (w), 627.3 (m), 570.4 (m) and 486.3 (w) cm^{-1}.

$[\{Gd(L^3)_2(H_2O)_2\}_n](ClO_4)_{3n}\cdot 8nH_2O$ (**3**) An aqueous solution (10 cm^3) of gadolinium(III) perchlorate (0.5 mmol) was mixed with a solution of L^3 (282 mg, 1.0 mmol) in water (5 cm^3). After stirring at about 60°C for a few minutes, a clear solution was obtained by filtration. The resulting solution was allowed to stand in air at room temperature for about a week to yield colorless prismatic crystals. Found: C, 22.31; H, 4.62; N, 5.44. Calc. for $C_{20}H_{54}N_4O_{30}Cl_3Gd$: C, 21.95; H, 4.93; N, 5.12%. IR: 3422.2 (s), 2988.9 (w), 1705.6 (m), 1644.4 (s), 1477.8 (w), 1444.4 (m), 1411.1 (m), 1322.2 (m), 1288.9 (m), 1138.9 (s), 1116.7 (s), 1088.9 (s), 905.6 (w), 877.8 (m), 850.0 (m), 682.3 (w), 627.8 (m) and 479.2 (w) cm^{-1}.

CAUTION. Metal perchlorate salts containing organic ligands are potentially explosive and should be handled with great care.

X-ray data collection and structure determination

Information concerning crystallographic data and structure refinement of the three complexes is summarized in Table 1. Raw intensities of complexes (**1**), (**2**) and (**3**) were collected at 293 K on a MSC/Rigaku RAXIS-IIC imaging plate system with a rotating anode X-ray source (Mo-K_α, λ = 0.71073 Å, 50 kV, 150 mA) [14], and corrected for absorption using the DIFABS program [15]. All calculations were performed on a PC 486 computer with the SHELXTL-PLUS program package [16]. Each crystal structure

was solved with the Patterson superposition method. The non-hydrogen atoms were refined anisotropically, except for the oxygen atoms of the slightly disordered perchlorate groups in complexes (**1**) and (**2**), which were subjected to interatomic distance restraints of Cl—O = 1.42±0.01 Å and O···O = 2.31±0.02 Å and refined isotropically. All the hydrogen atoms were generated geometrically (C—H = 0.96 Å), assigned fixed isotropic thermal parameters, and included in the structure-factor calculations. Analytical expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated [17]. Selected bond lengths and angles in Table 2. Additional information comprising atomic coordinates and thermal parameters has been deposited as Supplementary Material with the Editor.

RESULTS AND DISCUSSION

Description of structures

$[\{Gd(L^1)_2(H_2O)_2\}_n](ClO_4)_{3n}\cdot nH_2O$ (**1**). Complex (**1**) comprises a cationic polymer containing tetrakis(μ-carboxylato-*O*,*O*′)-bridged centrosymmetric dimeric subunits and discrete perchlorate anions, as well as lattice water molecules [Fig. 1(a)]. In each dimeric subunit, four carboxylato groups from respective L^1 ligands link a pair of gadolinium(III) atoms to generate a paddlewheel-like centrosymmetric [Gd_2(carboxylato-*O*,*O*′)$_4$] dimer, in both the usual *syn–syn* manner and an unusual *syn–skew* fashion. The latter mode, which is rarely encountered [18(a)], is intermediate between the *syn–syn* and *syn–anti* co-ordination modes commonly found in metal carboxylates [18(b)]. In the present complex one bridging carboxylato group coordinates the gadolinium(III) atom in an out-of-plane *skew* fashion [Gd(1)—O(5)—C(12)—C(13) 61.9°], while the other bridging carboxylato groups act in the most common *syn* mode [Gd(1)—O(4d)—C(11d)—C(10d) −178.8°, Gd(1)—O(3b)—C(11b)—C(10b) 146.7° and Gd(1)—O(6a)—C(12a)—C(13a) −159.9°]. The co-ordination sphere of each gadolinium(III) atom is completed by two unidentate carboxylato groups in the *syn* fashion [Gd(1)—O(7c)—C(22c)—C(21c) −167° and Gd(1)—O(1)—C(1)—C(2) −165.8°] and two aqua ligands in a distorted square antiprism. As shown in Fig. 1(b), one square face comprises four carboxylato oxygen atoms [O(4d), O(5), O(3b) and O(6a)] with a mean deviation of 0.043 Å from their least-square plane, whereas the other face as defined by two carboxylato oxygen atoms [O(1) and O(7c)] and two aqua oxygen atoms [O(1w) and O(2w)] has a mean deviation of 0.072 Å from their least-squares plane. The dihedral angle between the square faces is *ca.* 3.4°. The Gd—O distances lie between 2.320(4)

For clarity the Gd atoms are represented by large black circles.

and 2.526(3) Å, which are comparable to those found for other related gadolinium(III) carboxylates [19].

The molecular backbone of each of the two independent flexible double betaine ligands is extended to achieve a longer separation between its two quaternary nitrogen atoms. The conformation of the double betaine is similar to that in its hydrated form [5], but different from that in its mercury(II) adduct, in which the symmetry of the molecular backbone of L^1 has a C_2-axis at the middle methylene carbon atom [9(a)]. The Gd(1)···Gd(1a) separation is 4.418(5) Å, which is significantly larger than the average value [4.230 Å] in $[Gd_3(ClCH_2CO_2)_9(H_2O)_4]_n \cdot nH_2O$ [19]. A perspective view of complex (**1**) is shown in Fig. 1(c), where the dimeric subunits are extended into a polymeric chain running along the *b* direction. Such chains are further cross-linked by the molecular skeletons of double betaine ligands, thereby extending the structure into a wave-like layer corresponding to the plane (100). The perchlorate groups, one of which exhibits orientational disorder, are packed between the layers. The lattice water molecule O(3w) forms hydrogen bonds with aqua oxygen atom O(1w) and a symmetry-related lattice water molecule [O(3wf)] belonging to an adjacent layer [O(1w)···O(3w)···O(3wf)···O(1wf); O(1w)···O(3w) 2.736(5) Å, O(3w)···O(3wf) 2.761(5) Å], thereby leading to a three-dimensional network. A similar three-dimensional network formed by hydrogen bonding was also found in lanthanide(III) nicotinate [20].

$[\{Gd(L^2)_2(H_2O)_2\}_n](ClO_4)_{3n} \cdot nH_2O$ (**2**). The dimer in complex (**2**) is analogous to that of (**1**), being also a paddlewheel-like structure based on tetrakis(μ-carboxylato-*O*,*O*′) bridging [Fig. 2(a)]. The intra-dimeric Gd(1)···Gd(1a) separation [4.479(5) Å] and chemical environment of the gadolinium(III) atom in complex (**2**) are similar to those in (**1**), despite the fact that the two complexes crystallize in different space groups. Each gadolinium(III) atom is coordinated by six carboxylato oxygen atoms from L^2 ligands and two aqua ligands in an eight-coordination environment. The carboxylato groups of L^2 ligands in the dimeric subunits exhibit three different co-ordination modes: common bidentate bridging in the *syn–syn* configuration [Gd(1)—O(5)—C(13)—C(14) −162.6°, Gd(1a)—O(6)—C(13)—C(14) −166.2°], an unidentate mode [Gd(1)—O(1)—C(1)—C(2) 157.7°, Gd(1)—O(7)—C(19)—C(20) 157.5°], as well as an unusual *syn–skew* mode [Gd(1)—O(3c)—C(12c)—C(11c) −165.6°, Gd(1a)—O(4c)—C(12c)—C(11c) 117.9°]. The co-ordination geometry about each gadolinium(III) atom may be described as a square-antiprism with Gd—O distances in the range 2.318(5)–2.497(4) Å. One square face around the Gd(1) atom consists of oxygen atoms O(3c), O(4b), O(5) and O(6a) from different carboxylato groups with mean deviation 0.030 Å from their least-squares plane, and the other face is defined by two carboxylato oxygen atoms [O(1) and O(7)] and two aqua oxygen atoms [O(1w) and O(2w)] with a mean deviation of 0.010 Å from their least-squares plane. The dihedral angle between the square faces is *ca.* 1.6°. There are one complete and two independent "half molecules" of L^2 in the asymmetric unit of complex (**2**). Each half molecule has an inversion center located between the two middle methylene carbon atoms, being similar to that in its hydrated form [5], but different from that in its mercury(II) adduct, in which the molecular backbone of L^2 conforms to crystallographically imposed C_2 symmetry [9(a)]. A perspective view of complex (**2**) [Fig. 2(b)] shows that columns of paddlewheel-like [Gd_2(carboxylato-*O*,*O*′]$_4$ dimeric subunits stacked parallel to the *a* direction are cross-linked by the double betaine skeletons to generate a two-dimensional polymeric network corresponding to the (01$\bar{1}$) plane. The lattice water molecule O(3w) forms a hydrogen bond [O(3w)···O(1w) 2.787(5) Å] with an aqua ligand. The perchlorate groups, one of which forms an acceptor hydrogen bond [O(2w)···O(12) 2.860(5) Å] with an aqua ligand oxygen atom O(2w), occupy the inter-layer regions.

$[\{Gd(L^3)_2(H_2O)_2\}_n](ClO_4)_{3n} \cdot 8nH_2O$ (**3**). Complex (**3**) has a polymeric structure based on tetrakis(μ-carboxylato-*O*,*O*′)-bridged dimers [Fig. 3(a)] with an intra-dimeric Gd(1)···Gd(1a) distance of 4.580(4) Å, being a little longer than those in complexes (**1**) and (**2**). Each gadolinium(III) atom is coordinated by six carboxylato oxygen atoms from L^3 ligands and two aqua oxygen atoms in a square-antiprismatic geometry with Gd—O bond distances lying in the range 2.323(3)–2.469(3) Å, which are comparable to those in complexes (**1**) and (**2**). The mean deviations of the sets of oxygen atoms [O(1), O(3b), O(1w) and O(2w)] and oxygen atoms [O(5), O(7c), O(6a) and O(8d)] from their least-squares planes are 0.075 and 0.003 Å, respectively. The dihedral angle between the least-squares planes is *ca.* 2.1°. Unlike complexes (**1**) and (**2**), the carboxylato groups of L^3 ligands in complex (**3**) show two coordination modes: common *syn–syn* bridging bidentate [Gd(1)—O(5)—C(11)—C(12) −155.4°, Gd(1a)—O(6)—C(11)—C(12) −162.4°, Gd(1a)—O(7d)—C(20d)—C(19d) 146.9°, Gd(1)—O(8d)—C(20d)—C(19d) −169.3°] and unidentate [Gd(1)—O(1)—C(1)—C(2) −151.0°, Gd(1)—O(3b)—C(10b)—C(9b) −137.1°]. The two independent double betaine ligands in the asymmetric unit adopt an "S-shaped" conformation, similar to that in its hydrated form and hydrochloric acid adduct [6], but different from that in its cadmium bromide complex [21], in which the skeleton of L^3 exhibits a "C-shaped" conformation with the plane of one carboxylato group being approximately parallel to that of the other. The crystal structure of complex (**3**) is shown in Fig. 3(b), where the dimeric subunits are extended into plane wave-like layers corresponding to the (100) family of planes and further cross-linked by the double betaine skeletons to generate a three-dimensional polymeric framework. Hydrogen bonding plays an important role in consolidating this solid-state structure. The lattice water molecules form hydrogen bonds with one another [O(4w)···O(5w) 2.806(4) Å, O(6w)···O(8w)

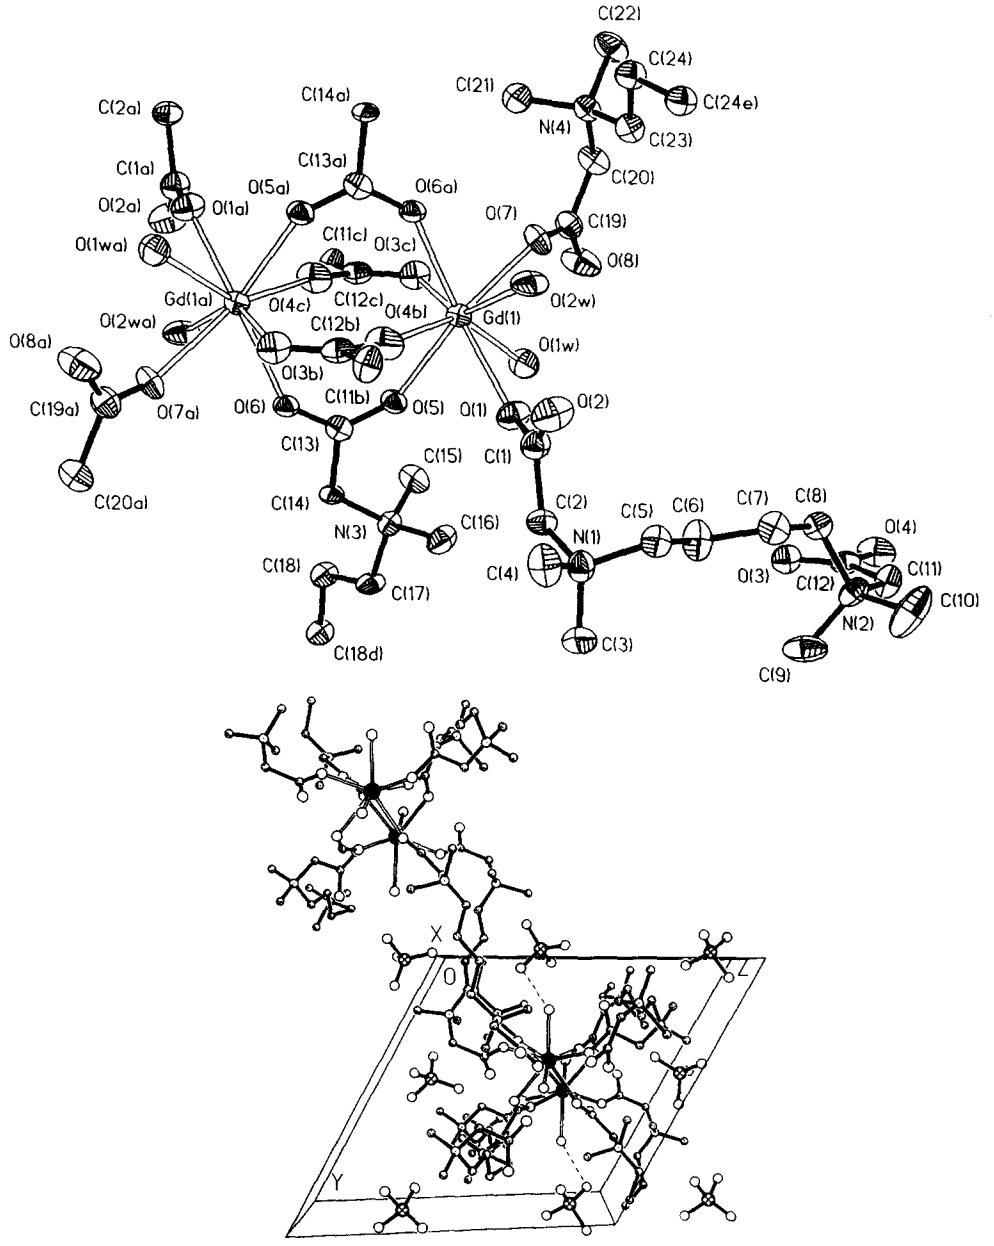

Fig. 2. (a) Structural skeleton of the asymmetric unit (35% thermal ellipsoids) of $[\{Gd(L^2)_2(H_2O)_2\}_n](ClO_4)_{3n} \cdot nH_2O$ (**2**) with atom labeling. (b) Packing drawing showing a plane wave-like layer (seen in cross section) corresponding to the $(01\bar{1})$ plane in the crystal structure of (**2**). The Gd atoms are represented by large black circles.

2.756(4) Å, O(9w)···O(10wd) 2.808(4) Å], and also donor hydrogen bonds [O(2w)···O(9w) 2.736(4) Å, O(1)···O(3w) 2.904(4) Å, O(2)···O(4w) 2.708(4) Å] with aqua ligand O(2w), co-ordinated caboxylato oxygen atom O(1), as well as unco-ordinated carboxylato oxygen atom O(2). The perchlorate groups, one of which forms an acceptor hydrogen bond [O(1w)···O(14) 2.851(4) Å] with aqua ligand O(1w), occupy the pockets and have no contact with the metal ions.

Summary

Lanthanide carboxylates have been widely studied, and most of them exhibit one- and two-dimensional polymeric structures [22]. Lanthanide co-ordination polymers with three-dimensional frameworks are very rare, although a three-dimensional lanthanide(III) nicotinate complex constructed from hydrogen bonding has been reported [20]. The present study has shown that novel lanthanide co-ordination polymers

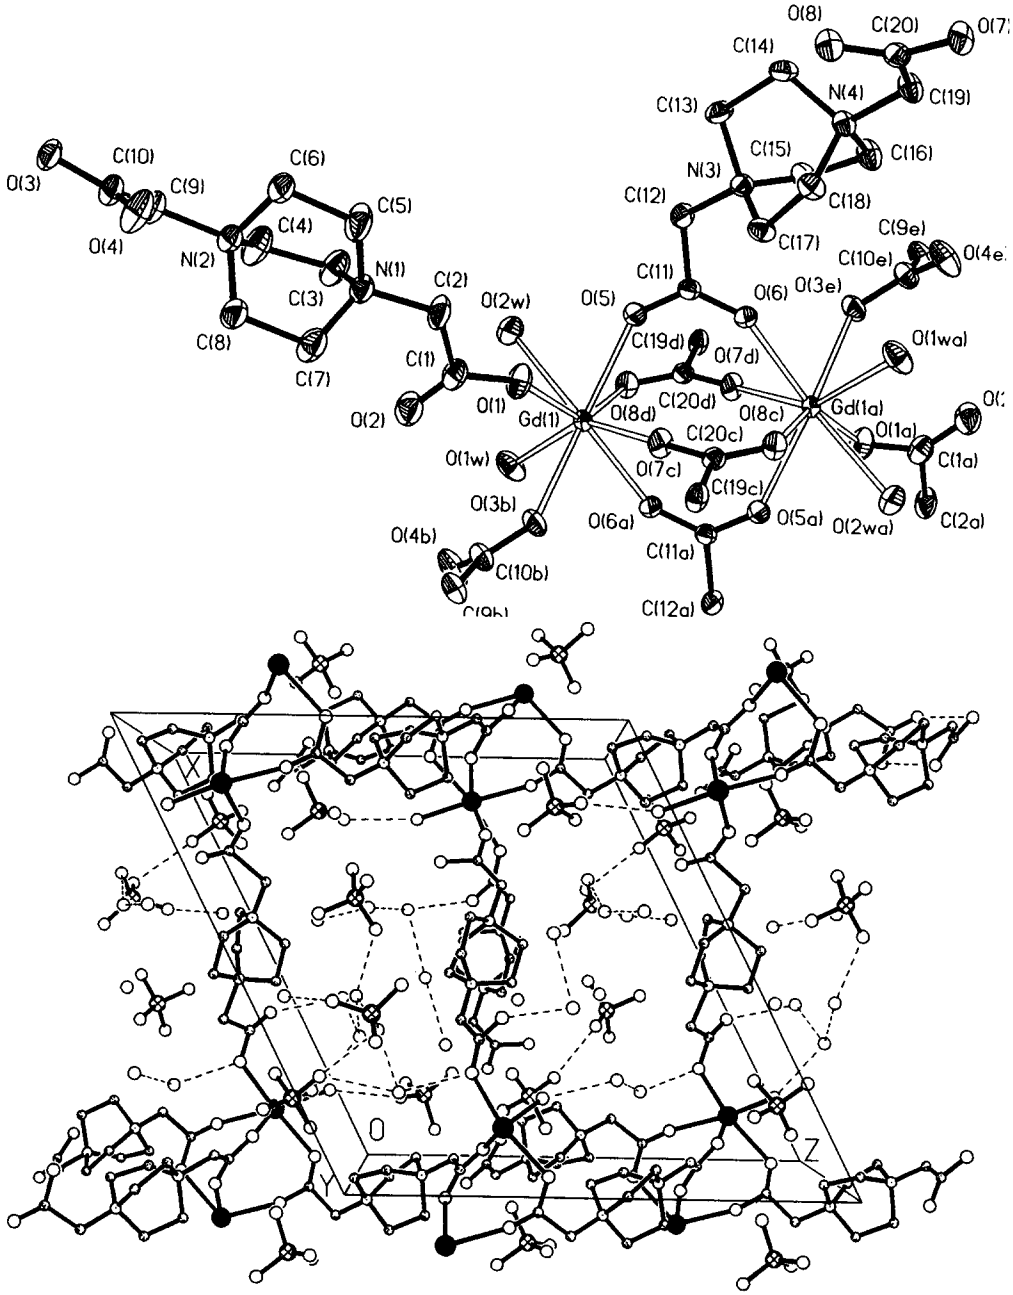

Fig. 3. (a) Structural skeleton of the asymmetric unit (35% thermal ellipsoids) of $[\{Gd(L^3)_2(H_2O)_2\}_n](ClO_4)_{3n} \cdot 8nH_2O$ (**3**) with atom labeling. (b) Packing drawing showing the three-dimensional coordination framework in the crystal structure of (**3**). The Gd atoms are represented by large black circles.

can be generated from gadolinium(III) perchlorate with flexible double betaines. The resulting three complexes in the present study are all based on the cross-linkage of paddlewheel-like tetrakis(carboxylato)-bridged dimers by the double betaine molecular backbones. Although they have the same metal-betaine ratio and nearly identical gadolinium co-ordination environments, complexes (**1**) and (**2**) have wave-like layer structures whereas (**3**) exhibits a three-dimensional framework. Variation of the bridging groups between two quaternary nitrogen atoms in three double betaines results in different crystal symmetries, co-ordination fashion of the carboxylato groups, as well as packing modes in the solid state.

Abstract—The ruthenium triphenylstibine complexes $[RuCl_2(SbPh_3)_3]$ and $[RuCl_2(SbPh_3)_4]$, and the nitrosyl complexes $[Ru(NO)Cl_3(EPh_3)_2]$ for E = Sb, As, P; $[Rh(NO)Cl_2(EPh_3)_2]$ for E = As, P, have been investigated using electrospray mass spectrometry. The mass spectrometric evidence suggests that $[RuCl_2(SbPh_3)_4]$ is formed and not $[RuCl_2(SbPh_3)_3]$ as previously reported. *In situ* derivatisation in the presence of alkali metal ions gave simple spectra for the ruthenium nitrosyl complexes but not the rhodium complexes. The crystal and molecular structure for the ruthenium complex $[Ru(NO)Cl_3(SbPh_3)_2]$ has been determined by single crystal X-ray diffraction. There is a crystallographically imposed centre of inversion and the NO and chlorides are disordered. The triphenylstibine ligands are coordinated in the *trans* configuration (Ru–Sb = 2.649(1) Å). © 1998 Elsevier Science Ltd. All rights reserved

Keywords: ruthenium; nitrosyl; rhodium; triphenylstibine; electrospray mass spectrometry X-ray structure.

The preparation, reaction, and structural chemistries of nitrosyl-organopnictide and nitrosyl organochalcogenide complexes of platinum-group metals of the form $[M(NO)X_3L_2]$ for M = Ru, Os, X = halide, L = organopnictide or organochalcogenide, and $[M(NO)X_2L_2]$ for M = Rh, Ir, X = halide, L = organopnictide have been reported by us and other workers [1–18]. The chemistry of complexes with tertiary stibine and arsine ligands is in general much less well developed compared with their phosphine analogues despite the fact that they are good donor ligands. One reason for this may be the lack of suitable analytical probes for these ligands. Tertiary phosphines are conveniently studied using ^{31}P NMR spectroscopy, but there are no readily accessible NMR active nuclei available for the arsine and stibine ligands. There have been a number of X-ray structural investigations of these complexes, but again most of the studies have been carried out on organophosphine complexes with little data available for organoarsine or organostibine complexes [15,19–28].

The versatile new soft ionisation technique available in electrospray mass spectrometry [ESMS] is well suited to studying such complexes [29–30]. The soft ionisation process used in ESMS typically results in simple patterns in which the molecular ion peak or a simple adduct is clearly evident. At low cone voltage fragmentation is usually very limited, and fragmentation can easily be investigated by raising the cone voltage.

For neutral transition metal complexes good spectra can often be obtained by *in situ* derivatisation. For example this may involve the formation of adducts in which a halide or other negative ligand has been replaced by a neutral donor ligand that is present in the solvent. Common donor ligands include acetonitrile, water, and ammonia, and replacement of a halide ion by these ligands results in the formation of adducts with a single positive charge.

Here we have investigated the reported preparation of the complex $[RuCl_2(SbPh_3)_3]$ using ESMS. In

* Author to whom correspondence should be addressed.

addition we report ESMS for the complexes $[Ru(NO)Cl_3(EPh_3)_2]$ for E = P, As, Sb, and the five coordinate rhodium analogues, $[Rh(NO)Cl_2(EPh_3)_2]$ for E = P, As. During our studies of ruthenium organostibine complexes we isolated crystals of $[Ru(NO)Cl_3(SbPh_3)_2]$. Because of the paucity of data for organostibine complexes we have determined the structure by single crystal X-ray diffraction.

EXPERIMENTAL

The complexes $[RuCl_2(SbPh_3)_3]$, $[RuCl_2(SbPh_3)_4]$, $[Ru(NO)Cl_3(PPh_3)_2]$, $[Ru(NO)Cl_3(AsPh_3)_2]$, $[Ru(NO)Cl_3(SbPh_3)_2]$, $[Rh(NO)Cl_2(PPh_3)_2]$, and $[Rh(NO)Cl_2(AsPh_3)_2]$, were prepared by literature methods [1–3,7]. Recrystallisation by the slow evaporation of a chloroform solution produced red-orange, bipyramidal crystals of $[Ru(NO)Cl_3(SbPh_3)_2]$ suitable for X-ray analysis. Spectroscopic and analytical data for the recrystallised material were as observed previously for the bulk sample [1]: IR KBr disk ν(NO) 1840 cm^{-1}; ^1H NMR (δ ppm) 7.45 3-H, m; 7.75 2-H, m. Anal: found; C, 45.77; H, 3.19%; calc. for $C_{36}H_{30}Cl_3NORuSb_2$: C, 45.83; H, 3.20%.

Electrospray mass spectra were recorded in positive-ion mode on a VG Platform II instrument, using methanol as the mobile phase. No precautions were taken to exclude oxygen from the system. The samples were introduced via a microlitre syringe and a 10 μl sample loop fitted to a Rheodyne injector, with the mobile phase being delivered to the mass spectrometer by a Spectra System P1000 LC pump, at a flow rate of 0.01 ml min^{-1}. Nitrogen was employed both as the nebulising and drying gas. Fragmentation was investigated by varying the skimmer cone voltage, typically from 10 to 80 V. Spectra were typically acquired as 10 to 12 scans, and subsequently averaged. Isotope patterns for major species were recorded, and compared with calculated patterns obtained using the Isotope simulation program [31].

The crystal data, data collection parameters, and structure refinement details are summarised in Table 1. The unit cell parameters were determined by the least square refinement of 25 accurately centred high angle reflections. The data were collected at 168 K on a Siemens R3m Four-circle X-ray diffractometer with graphite-monochromated Mo–K_α radiation (λ = 0.71073 Å) using θ-scans to a maximum angle of $2\theta = 54°$. Reflection intensities were corrected for Lorentz and polarisation effects, and crystal stability was monitored by observation of three standard reflections after every 100 reflections: no movement or decay was observed. The absorption correction was based on ψ-scans and an ellipsoidal model, and the structure was solved in the centrosymmetric space group $P\bar{1}$ using the direct methods. The structure has been modelled with the chlorides and NO disordered over all four sites using a fractional occupancy [1/4 NO + 3/4 Cl] as recommended by the crystallographic referee. The nitrogen and oxygen atoms were inserted in calculated positions using Ru—N and N—O bond lengths taken from the literature [20]. The Ru—Cl, Ru—N, and N—O bond lengths were constrained to provide an acceptable refinement. All non-hydrogen atoms except the disordered nitrogen and oxygen atoms were modelled assuming anisotropic thermal vibration. Attempts to refine the nitrogen and oxygen atoms using isotropic thermal vibration were unsuccessful, and so these atoms were modelled using fixed temperature factors. Atomic scattering factors were taken from Crommer and Mann [32] and corrected for the effects of anomalous scattering using values from Crommer and Liberman [33]. The structure was solved using the direct methods and the refinement was carried out using a full-matrix least squares refinement procedure based on F^2. The final cycle of refinement based on 3283 unique observed data [$I > 2\sigma(I)$] and 208 variables converged with an

$R = 0.0548$ and $Rw = 0.0613$, where the functions minimised are: $R = \Sigma(\|F_o\| - |F_c\|)/\Sigma(|F_o|$ and $Rw = \sqrt{[\Sigma w|F_o| - |F_c|^2)/\Sigma w|F_o|^2]}$. The data were processed and the structure solution and refinement carried out using the SHELXTL system of programs [34].

Selected atomic distances and angles are given in Table 2.

RESULTS AND DISCUSSION

Stephenson and Wilkinson (1966) [35] have reported that the reaction of hydrated ruthenium chloride with triphenylstibine at room temperature or under reflux results in the formation of the complex $[RuCl_2(SbPh_3)_3]$. Champness *et al.* (1993) have disputed the formation of $[RuCl_2(SbPh_3)_3]$ and their attempts to prepare this complex resulting in the formation of the complex $[RuCl_2(SbPh_3)_4]$ characterised by single-crystal X-ray diffraction [19]. As pointed out it is sometimes difficult to discriminate convincingly between these complexes on the basis of elemental analytical data or other spectroscopic evidence [19]. Although much structural information is provided by single-crystal X-ray studies, this does not provide information about the bulk material.

In this work the reaction of ruthenium chloride with excess triphenylstibine [6 : 1] under reflux gave a pink powder. The ESMS for this powder in the presence of a trace amount of CH_3CN contained evidence for the parent ion $[RuCl_2(SbPh_3)_4]^+$ [$M^+ = 1584$] and the adduct: $[RuCl_2(SbPh_3)_3(CH_3CN)]^+$ [$M^+ = 1273$]. A small peak assigned to the $[RuCl_2(SbPh_3)_3]^+$ ion [$M^+ = 1232$] was observed, but only a high cone voltage [> 80 V]. It is likely that this species has appeared as a result of fragmentation of the parent ion $[RuCl_2(SbPh_3)_4]^+$.

The product of the reaction of ruthenium chloride with triphenylstibine at room temperature gave a different, more complex, spectrum. The complexity of the spectrum indicated that a mixture of compounds had been produced in this reaction. There was no evidence for parent ions $[RuCl_2(SbPh_3)_3]^+$, $[RuCl_2(SbPh_3)_4]^+$, or any simple adducts of these ions. Hence our studies support those of Champness *et al.* (1993), and it seems there is some doubt over the existence of $[RuCl_2(SbPh_3)_3]$.

The nitrosyl complexes $[Ru(NO)Cl_3(EPh_3)_2]$ for E = Sb, As, P were also investigated using ESMS. None of the complexes gave simple spectra when measured in the presence of neutral donor species. Other workers have reported good ESMS for neutral metal carbonyl complexes by *in situ* derivatisation in the presence of anionic or cationic species [29–30]. For complexes containing basic carbonyl ligands, good spectra were obtained using Ag^+ ions. Non-polar, poorly basic carbonyl complexes required the presence of a nucleophile such as the methoxylate ion. This derivatisation reaction resulted in the formation of negative ion adducts of the form $[M + OMe]^-$.

In this work good spectra were obtained for ruthenium nitrosyl complexes in the presence of traces of alkali metal ions. The spectra for the complex $[Ru(NO)Cl_3(SbPh_3)_2]$ together with the isotope pattern and simulated spectra are shown in Fig. 1. Similar spectra were obtained for the triphenylphosphine and triphenylarsine complexes. The spectra suggest that simple 1 : 1 adducts are formed between the nitrosyl

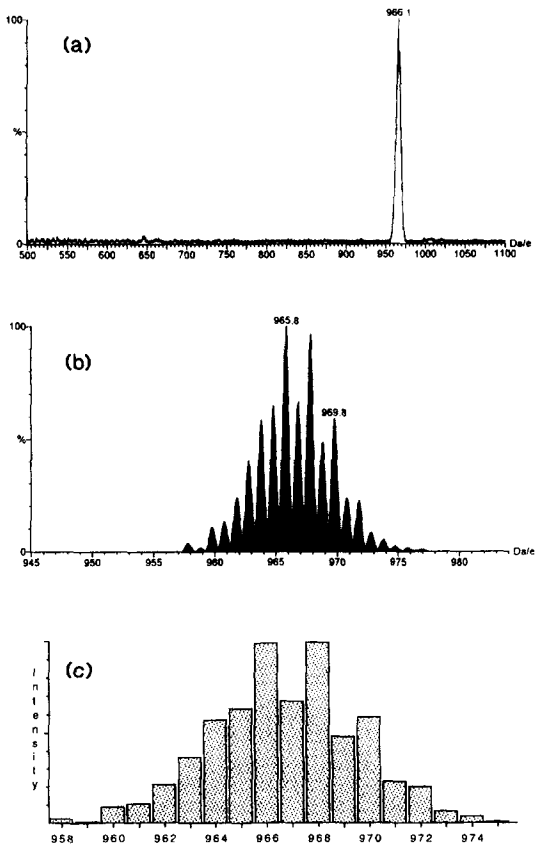

Fig. 1. Electrospray mass spectrum for [Ru(NO)$Cl_3(SbPh_3)_2] + Na^+$. (a) Mass spectrum; (b) isotope pattern for [Ru(NO)$Cl_3(SbPh_3)_2$)] + Na^+; (c) simulated mass spectrum for [Ru(NO)$Cl_3(SbPh_3)_2$)] + Na^+.

complex and the alkali metal ions. Good spectra were obtained using Li^+ Na^+ or K^+ ions, but not with Cs^+ or Rb^+. We also repeated our ESMS investigation of the complexes $[RuCl_2(SbPh_3)_3]$, and $[RuCl_2(SbPh_3)_4]$ in the presence of alkali metal ions, but were unable to obtain good spectra. Thus it seems likely that the nitrosyl oxygen is the basic centre despite the fact that the NO is bound in the linear fashion. Previous X-ray photoelectron studies have suggested that there is greater electron density on the nitrosyl ligand when it is coordinated in the bent fashion [36–42]. In view of this we also investigated some five-coordinate rhodium analogues: i.e. complexes of the form $[Rh(NO)Cl_2(EPh_3)_2]$. However, we were unable to obtain good spectra of parent ions or using any of the *in situ* derivatisation techniques described above. Previous studies have shown that the coordinated NO in these complexes is particularly labile and hence it seems likely that it is lost under the experimental conditions employed [1].

A view of the structure of $[Ru(NO)Cl_3(SbPh_3)_2]$ is shown in Fig. 2. Based on statistical analysis of the data and the recommendation of Brock and Dunitz (1994) [43] we have solved the structure in the centrosymmetric space group $P\bar{1}$, despite the fact that this imposes disorder.

The ruthenium atom lies on the origin and hence the structure has a crystallographically imposed centre of inversion and because of this, the NO and chlorides are disordered. The structure has been modelled with the chlorides and NO disordered over all four sites using a fractional occupancy of [1/4 NO + 3/4 Cl] and constrained bond lengths [see Experimental]. Crystallographically imposed disorder in NO complexes has also been reported for the related five-coordinated iridium and rhodium triphenylphosphine complexes $[Ir(NO)Cl_2(PPh_3)_2]$, and $[Rh(NO)Cl_2(PPh_3)_2]$ [4–5]. The triphenylstibine ligands in $[Ru(NO)Cl_3(SbPh_3)_2]$ are in the more common *trans* configuration as reported for other similar structures [4–5,9,12–13]. Few complexes are known in which the organopnictide or organochalcogenide ligand are coordinated in the *cis* configuration [1,15–18]. In fact the *cis* arrangement of the organopnictide ligands is only seen for complexes containing less bulky ligands such as Me_2PPh and Me_2AsPh [1,17].

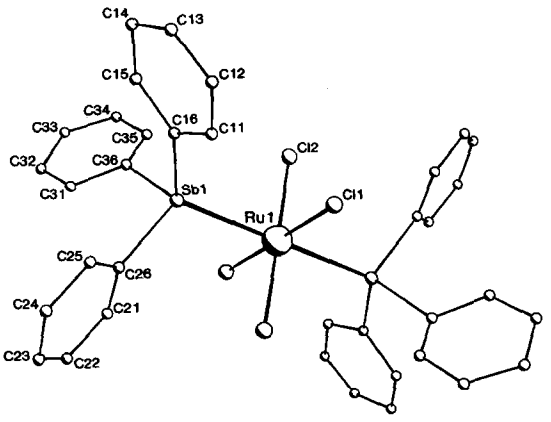

Fig. 2. Perspective view of the structure of [Ru $(NO)Cl_3(SbPh_3)_2$)]. The disorder NO has been omitted for clarity.

The structures for two analogous complexes have been reported previously: $[Ru(NO)Cl_3(PPh_3)_2]$ [12] and more recently $[Ru(NO)Cl_3(AsPh_3)_2]$ [20]. The triphenylphosphine and triphenylarsine analogues are isostructural with each other and with the related complex $[Os(NH_3)Cl_3(PPh_3)_2]$ [21]. All of these structures were solved in the space group $C2/c$. Close examination of the crystalline sample of $[Ru(NO)Cl_3(SbPh_3)_2]$ revealed that the sample contained crystals of two different morphologies: red thin plates, and red-orange bipyramids. We investigated both crystal types extensively and found no difference in unit cell parameters or any evidence for a unit cell similar to that seen for the phosphine or arsine analogues. Furthermore, there is no evidence in the spectra or analytical figures for the presence of any other compounds.

There are few reports of X-ray structural determinations of platinum group metal complexes containing organostibine ligands. Almost all of the reported complexes were carbonyl complexes [19,20–28] and the only closely comparable complexes are *mer*-$[OsBr_3(SbPh_3)_3]$ [23] and $[RuCl_2(SbPh_3)_4]$ [19]. The Ru—Sb bond length of 2.649(1) Å found in this work is at the long end of the range compared with the reported values [range 2.579(1)–2.654(2) Å]. Two of the values reported for $[OsBr_3(SbPh_3)_3$ [2.640(2), 2.644(2) Å] are a little shorter than found in this work. The third bond length reported for $[OsBr_3(SbPh_3)_3]$ [2.654(2) Å] is unusually long when compared with this work and the other reported values. This is somewhat surprising considering the osmium atom is formally in the +3 oxidation state whereas most of the other complexes are in the +2 or lower oxidation states. Interestingly the M—Sb bond lengths seen in the ruthenium (II) complex $[RuCl_2(SbPh_3)_4]$ [range 2.625(1)–2.632(1) Å] are significantly shorter than seen in either of $[OsBr_3(SbPh_3)_3]$ or in the present work, although they are similar to the other reported values. This difference may indicate a higher degree of metal-to-ligand π-back-bonding in the complex $[RuCl_2(SbPh_3)_4]$ due to the presence of the soft Ru(II) metal ion. In view of the disorder and constraints imposed upon the Ru—Cl bond lengths during refinement, comparisons with other data are unlikely to be meaningful. The C—Sb and C—C bond lengths in the ligands are similar to other reported values [9,11–13,19,21–28].

Supplementary material

Isotropic thermal parameters, atomic coordinates, a complete list of bond distances and angles, together

with observed and calculated structure factors have been deposited with the Cambridge Crystallographic Data Centre.

(Received 10 July 1997; accepted 8 August 1997)

Abstract—Complexes formed between copper(I) and 1,2-bis(diphenylphosphino)ethane (L^1) have previously been isolated as salts of the $[CuL^1_2]^+$ cation if only non-coordinating anions are present, or as $[Cu_2Cl_2L^1_3]$ if chloride is present. We describe the synthesis of $[CuL^1_2]Cl$, the stoichiometry of which is confirmed by elemental analysis, FAB mass spectroscopy and conductivity. Polar solvents (water–ethanol mixtures) lead to isolation of the latter, whereas solvents of lower polarity ($CHCl_3$, CH_2Cl_2) lead to isolation of the complexes containing coordinated chloride. Related ligands such as *cis*-1,2-bis(diphenylphosphino)ethene, 1,2-bis(diethylphosphino) ethane, 1,2-bis(dimethylphosphino)ethane and 1,2-bis(hydroxymethylphosphino)ethane, give salts $[CuL_2]Cl$. This behaviour, and that of other 1,2-bisphosphine ligands, is rationalised in terms of competition between chloride and phosphine ligands for binding sites on the metal, with the equilibrium position determined by solvent polarity, ligand structure and rigidity, and steric and electronic properties of the ligands. © 1998 Elsevier Science Ltd

Keywords: copper; phosphine.

INTRODUCTION

Copper(I) bis(diphosphine) complexes have been of interest because of their tumouricidal properties [1] and more recently, for their possible application as radiopharmaceuticals containing copper radioisotopes for medical imaging and radioisotope therapy [2,3]. Of the diphosphines tested, when complexed to copper, 1,2-bis(diphenylphosphino)ethane (L^1, see Fig. 1) produced the greatest increase in life span of rats with experimental cancers [4]. This ligand was tested in the form of the complex $[Cu_2Cl_2L^1_3]$, prepared by the reaction of CuCl with L^1 in chloroform. In contrast, reactions of CuCl with *cis*-bis(diphenylphosphino)ethene (L^2) and 1-(diethylphosphino)-2-(diphenylphospino)ethane give the salts $[CuL_2]Cl$, which were tested against tumours in this form [4,5]. Attempts to prepare the analogous complex of L^1, $[CuL^1_2]Cl$ for testing against tumours were not successful [1,5] and hence it could not be determined whether the relative tumouricidal effects of the complexes are related to their stoichiometry and charge. Progress in the application of the complexes requires understanding of the factors governing their structural and stoichiometric preferences. Here we describe the synthesis of the hitherto unreported complex $[CuL^1_2]Cl$ (**1**) and analogous complexes **2**–**5** with other 1,2-diphosphines L^2–L^5 (Fig. 1), and rationalise the equilibria between the complex types in terms of ligand electron donating power, chelate rigidity, and solvent polarity.

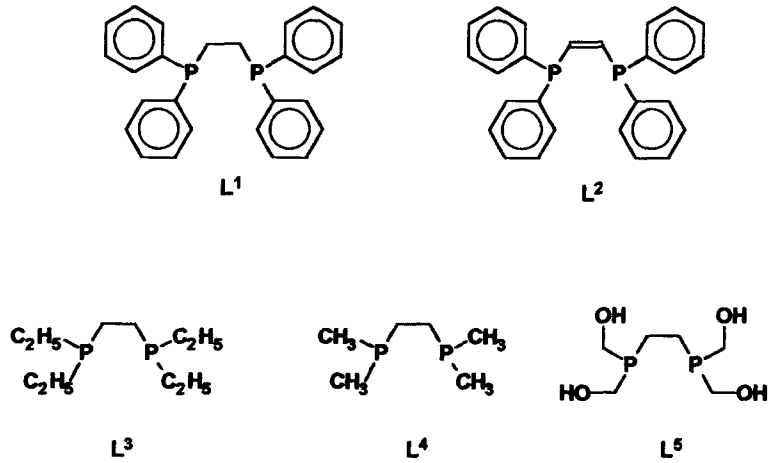

Fig. 1. Structures of ligands used in this work.

EXPERIMENTAL

All reactions were undertaken in air with anhydrous solvents unless otherwise indicated. C, H, N elemental analysis was performed by the Chemical Laboratory, University of Kent. ^{1}H NMR measurements were performed using a Jeol 270 MHz NMR spectrometer. Fast Atom Bombardment mass spectra were obtained using 3-nitrobenzyl alcohol as the matrix material at the EPSRC Mass Spectrometry Centre, Swansea, U.K. Infra-red spectra were recorded in the range 400–4000 cm^{-1} as Nujol mulls on KBr plates using a Perkin-Elmer infra-red spectrophotometer. Conductivities were measured using a Bibby MC1 conductivity meter on 1 mM solutions in anhydrous solvents, with $[Bu_4N]Cl$ solution as a calibrating standard. L^5 was prepared using published methods [6], as were the silver complexes $[AgL^1_2](NO_3)$ and $[AgL^2_2](NO_3)$ [7,8]. All chemicals were purchased from Aldrich, U.K. For thin layer chromatography (TLC), silica gel plates (Merck $60F_{254}$) and a mobile phase consisting of 0.9% saline (60%) and acetonitrile (40%) were used. The chromatograms were visualised with a UV lamp. Under these conditions the silver complexes $[AgL^1_2]^+$ and $[AgL^2_2]^+$ migrated with R_f 0.5, slightly lower than the values for their copper analogues.

Synthesis of $[Cu(L^1)_2]Cl$ (**1**) *and* $[Cu(L^2)_2]Cl$ (**2**) *from* $CuCl_2 \cdot 2H_2O$ *and diphosphines*

Typically L^1 or L^2 (52 mg, 0.13 mmol) was warmed in 2 ml of ethanol until fully dissolved. $CuCl_2 \cdot 2H_2O$ (8.5 mg, 0.05 mmol in 0.5 ml water) was added. An immediate loss of colour was observed and the resulting solution was allowed to stir at room temperature for a few minutes. The resulting white precipitate was isolated by filtration, yield 75% (L^1), 78% (L^2).

Synthesis of **1** *and* **2** *from* $[AgL^n_2](NO_3)$ (n = 1, 2) *and* $CuCl_2 \cdot 2H_2O$

The silver phosphine complex (96 mg, 0.1 mmol) was taken up in 2 ml ethanol. $CuCl_2 \cdot 2H_2O$ (1.7 mg, 0.01 mmol in 0.5 ml water) was added and the mixture stirred for 30 min. The silver chloride precipitate was removed by filtration and the filtrate analysed by thin layer chromatography.

Synthesis of $[Cu(L^3)_2]Cl$ (**3**) *and* $[Cu(L^4)_2]Cl$ (**4**)

The complexes were produced by modification of methods previously reported [5] for L^2. In brief, L^3 or L^4 (33 mg or 24 mg respectively, 0.16 mmol) was dissolved in 25 ml $CHCl_3$, and solid CuCl (8 mg, 0.08 mmol) was added. The mixture was stirred for 1 h at room temperature under a stream of nitrogen. The solvent was removed *in vacuo* to leave an oily residue. Diethyl ether was added and the compound was induced to crystallise by scratching. White crystals formed and were collected in air, yield 82% (L^3), 84%(L^4). The same complex, as identified by TLC, was obtained by using $CuCl_2 \cdot 2H_2O$ in place of CuCl.

Synthesis of $[CuL^5_2]Cl$ (**5**)

L^5 (0.075 g, 0.35 mmol) was taken up in 2 ml CH_2Cl_2. CuCl (0.017 g, 0.15 mmol) was added. The colourless solution was stirred for 1 hour at room temperature. The CH_2Cl_2 layer was extracted with 3×2 ml H_2O. The water fractions were collected and the water removed *in vacuo* to produce a colourless oil, yield 89%. ^{1}H NMR (D_2O): 4.4 (m, 16H, CH_2OH), 2.3 (m, 8H, CH_2CH_2). IR (Nujol mull): 3200–3400 (s, ν(O—H)).

RESULTS

Three approaches were employed in the synthesis of the bis(diphosphine) complexes of copper(I) chloride:

(a) reaction of CuCl with two mole-equivalents of diphosphine;
(b) reaction of $CuCl_2$ with 2.5–3 mole-equivalents of diphosphine;
(c) reaction of $CuCl_2$ with an excess of the labile silver complex of the diphosphine, $[AgL_2](NO_3)$.

All methods were successful in affording the complex salts in high yield (75–84% isolated). In method (b) the phosphine was used as a reducing agent as well as chelator, and for this reason additional phosphine was added. Method (c) was used with the more hydrophobic phosphines (L^1, L^2) in order to present the phosphine to the copper in a form that is more soluble in water or ethanol than the phosphine itself. This method also entails the phosphine acting as a reducing agent, and the reaction was accompanied by the precipitation of silver chloride which was removed by filtration. The reactions were conducted in either ethanol or water, except where literature methods were used. In all cases the complexes isolated were colourless crystalline solids (except $[CuL_2^5]Cl$ which was a colourless viscous oil) and had the stoichiometry $[CuL_2]Cl$. This formulation was consistent with elemental analysis and fast atom bombardment mass spectroscopy (Table 1). The latter all showed molecular ions corresponding to $[CuL_2]^+$ at 100% abundance. The conductivity measurements confirm that the complexes are fully ionised as 1 : 1 electrolytes in methanol solution, suggesting that chloride ion does not displace phosphine from the metal coordination sphere to a significant extent in that solvent. None of the spectroscopic techniques, however, can confirm unequivocally that the complexes exist as salts in the solid state rather than, for example, in the form $[CuCl(\eta^2\text{-}L)(\eta^1\text{-}L)]$ as found in the case where L = 2,3-bis(diphenylphosphino)maleic anhydride [3].

DISCUSSION

Previous attempts at synthesis of **1** have been unsuccessful: the $[CuL_2^1]^+$ cation has only been isolated previously in the form of salts of non-coordinating anions (trifluoroacetate, nitrate, dimesitylcuprate) [9–12]. Even weakly coordinating anions such as acetate [13] and nitrate [11] can displace one of the phosphine ligands in non-polar solvents (benzene) [13] containing an excess of L^1. The present work shows that this is primarily a solvent effect: with use of polar solvents (water/ethanol mixtures), it is not necessary to add an excess of diphosphine in order to suppress coordination of chloride ion, and chloride salt **1** can be isolated. It would now be of value to compare the anti-tumour efficacy of this complex with the other copper diphosphine complexes already examined [4], and with $[Cu_2Cl_2L_3^1]$ in particular. The conformationally rigid diphosphine L^2 does not appear to require highly polar solvents to form the corresponding chloride salt of the cationic complex: in previous reports complex **2** was isolated readily from chloroform solution [5].

The three complexes of 1,2-bis(dialkyl) phosphinoethane L^3, L^4, and L^5, (**3–5**) have not been

Table 1. Analytical and physical data

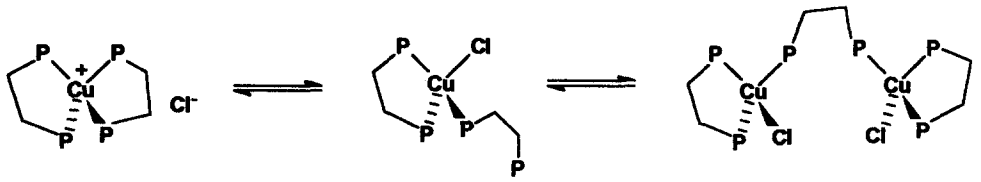

Fig. 2. Ligand exchange equilibria in copper(I) chloride complexes with 1,2-diphosphine ligands.

prepared previously, although the complex cation $[CuL^4_2]^+$ has been isolated in the solid state with a non-coordinating anion [14]. It is not necessary to use highly polar solvents to obtain the cationic complexes as chloride salts if the phosphines are alkylated rather than arylated: both L^3 and L^4 complex salts were isolated in good yield from chloroform solution. This is consistent with the earlier synthesis of $[Cu(eppe)_2]Cl$ (eppe = 1(diethylphosphino)-2-(diphenylphosphino) ethane) [8] under the same conditions.

While the results described here do not unequivocally eliminate the possibility that one or more of the complexes contain coordinated chloride ion in the solid state, they indicate that in polar solvents (e.g. methanol and, presumably, water which is of greatest relevance for the biomedical applications of these complexes) even the weakest chelator, L^1, forms a copper(I) complex that exists as 1 : 1 electrolyte with chloride as the counter ion, even in the absence of excess phosphine ligand. It appears that stronger electron donating phosphines, more rigid chelating geometries, and more polar solvents all favour displacement of chloride from the copper by phosphine groups. Thus, L^1 is a relatively weak donor and forms only non-electrolyte complexes in non-polar solvents. It displaces chloride only in polar solvents or when present in large excess, whereas the stronger (by virtue of alkyl substitution rather than aryl) and less sterically hindered donors L^3 and L^4 form 1 : 1 electrolytes in both polar and non-polar solvents and without any excess diphosphine. L^2 likewise displaces chloride more effectively than L^1, by virtue of its rigidity which entropically favours chelation. On the other hand, 2,3-bis(diphenylphosphino)maleic anhydride does not displace chloride readily: although it has a rigid chelating structure its electron donating ability is weaker than that of L^2 because of the anhydride group [3]. Upon hydrolysis of the anhydride group, however, the donor ability improves and it gives a complex analogous to that of L^2 [3].

In conclusion, by combining the experience described here with previous published work it is possible to rationalise qualitatively the coordination behaviour of the different diphosphine ligands with respect to their ability to displace chloride ion from the copper coordination sphere, as a function of the electron donating ability of the ligand, the conformational rigidity of the ligand, and the dielectric of the solvent. Chloride ion and 1,2-bis(diphosphine) ligands are thus well-matched in their affinity for the Cu^+ ion. The complex equilibria that occur, previously identified by ^{31}P NMR spectroscopy [5] in dichloromethane and dimethylacetamide solution and represented in part by Fig. 2, can be decisively controlled by relatively subtle modifications of the ligand or conditions.

(Received 25 November 1996; accepted 8 August 1997)

Abstract—The aryloxo ytterbium complex $(ArO)YbCl_2(THF)_3$ (ArO=2,6-ditertbutyl-4-methylphenoxo) has been prepared by the reaction of anhydrous $YbCl_3$ with ArONa in THF in the ratio of 1 : 1 at room temperature. The crystal structure was determined by X-ray diffraction. The molecular complex is a six-coordinate monomer. Two chlorine atoms, one oxygen atom of aryloxo and three oxygen atoms of THF coordinate to ytterbium atom to form a pseudo-octahedron. It belongs to orthorhombic crystal system, space group *Fddd*. The Yb—O(Ar) distance and the Yb—Cl distance are 2.083(5) Å and 2.555(2) Å, respectively. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: synthesis; crystal structure; aryloxide; ytterbium; dichloride.

The large growth in organolanthanide chemistry has primarily centred on the complexes stabilized by cyclopentadienyl ligands. As their precursors, cyclopentadienyl lanthanide chlorides have been extensively studied including their syntheses and reactivities. In recent years, alkoxo and aryloxo ligands have become attractive monoanionic ligands, since they will form strong bonds with lanthanides and can be easily modified in steric bulk by substitution. The syntheses and reactivities of trialkoxo- and triaryloxo-lanthanide have been developed [1–11]. Recently, some alkyl and hydride lanthanide complexes have been synthesized and structurally characterized with bulky aryloxo as auxiliary ligand and they show good catalytic activity for cyclopolymerization of diene and for the polymerization of α-olefins [12–24]. However, the syntheses and structures of mononuclear alkoxo- and aryloxo-lanthanide dichlorides have not yet been studied. The dichlorides are considered to be the precursors for further transformation. We are investigating the synthesis and molecular structure and report here the synthesis and X-ray characterization of monomeric aryloxo ytterbium dichloride.

EXPERIMENTAL

All manipulations were performed under argon using the Schlenk technique. THF was distilled from sodium benzophenone ketyl before use. Anhydrous $YbCl_3$ was prepared according to the literature [15]. ArONa was prepared from the reaction of ArOH and Na in THF. Metal and chlorine analyses were carried out using complexometric titration and the Volhard method, respectively. IR spectrum was recorded on a Nicolet-550 FTIR spectrometer as KBr pellets.

Synthesis of $(ArO)YbCl_2(THF)_3$

To a suspension of $YbCl_3$ (1.306 g, 4.67 mmol) in 20 cm^3 THF was slowly added a solution of ArONa (5.83 cm^3, 4.67 mmol) in THF at room temperature. After being stirred for 72 h, the NaCl was separated from the reaction mixture by centrifugation. The solvent was removed *in vacuo* to yield an orange-red powder (2.69 g, 85%). Found Yb, 25.8; Cl, 10.3. Calc. for $(ArO)YbCl_2(THF)_3$ Yb, 25.6; Cl, 10.5%. IR absorptions (cm^{-1}), 2957(s), 2918(w), 2873(w), 1634(s), 1434(s), 1396(m), 1362(m), 1231(m), 1151(s), 1065(m), 1027(w), 864(s), 771(s), 460(m). The powder was dissolved in THF and cooled to −5°C for crys-

tallization, the yellow crystals suitable for X-ray determination were obtained.

X-ray crystallography $(ArO)YbCl_2(THF)_3$

A yellow single crystal ($0.20 \times 0.20 \times 0.40$ mm) was sealed in a glass capillary under argon and mounted on a Rigaku AFC7R diffractometer. Intensity data were measured with ω-2θ scan type with MoK_α radiation, with $6.0 < 2\theta < 45.0°$, 8721 reflections were collected. Crystallographic data are listed in Table 1. The structure was solved by direct methods and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically. The final cycle of full-matrix least-squares refinement was based on 1635 observed reflections [$F > 4.0\sigma(F)$] and 158 variable parameters and led to final $R = 0.0285$, $Rw = 0.0351$. All the calculations was performed by the program of Siemens SHELXTL PLUS (PC Version).

RESULTS AND DISCUSSION

Synthesis of the complex $(ArO)YbCl_2(THF)_3$

The synthesis and molecular structure of monoaryloxo-(alkoxo-)lanthanide dichloride has not been reported yet, although there are a few crystal structures of alkoxo lanthanide chlorides in the literature, which were obtained as byproducts in the syntheses of trialkoxo lanthanide complexes [16,17]. We found that the monoaryloxo ytterbium dichloriden can be synthesized by use of bulky 2,6-ditertbutyl-4-methylphenoxo-(ArO-) as ligand, anhydrous $YbCl_3$ reacts with one equivalent of ArONa in THF at room temperature and gives yellow $(ArO)YbCl_2(THF)_3$ in good yields.

$$YbCl_3 + ArONa \xrightarrow{THF} (ArO)YbCl_2(THF)_3 + NaCl\downarrow$$

The title complex has good solubility in THF, and slightly soluble in aromatic solvents. This complex can be recrystallized from THF solution to give yellow crystals suitable for X-ray determination.

The complex has no melting point, decomposed at above 109°C. The IR spectrum exhibits the characteristic absorption bands for aryloxo at ca 771, 864, 1151, 1434 and 2957 cm^{-1}, for coordinated THF at 1065 cm^{-1} [18], and for Ln—O mode at near 460 cm^{-1} [19].

X-ray crystal structure

The molecular structure of the title compound is shown in Fig. 1. The important bond distances and bond angles are listed in Table 2.

The ytterbium atom is coordinated by two chlorine atoms, one oxygen atom of aryloxo and three oxygen atoms of THF, giving a six-coordinate, pseudo-octahedral complex. The geometry is related to that of the complex $CpYbCl_2(THF)_3$ [20]. The molecule lies on a two-fold axis which passes through the atoms O(3), Yb, O(1), C(1), C(4) and C(9).

It is interesting to compare the bond length values with those of other aryloxo complexes. The bond length of Yb—O(Ar) is 2.083(5) Å, subtraction of an ionic radius for six-coordinate Yb^{3+} (0.868 Å) [21] from this value gives 1.215 Å. Similar treatment of Ln—O(Ar) bond lengths for $[Yb(OC_6\text{-}H_3Ph_2\text{-}2,6)_3(THF)_2]$ [3], $Yb(OC_6H_2Bu^t_3\text{-}2,4,6)_3(THF)$ [5], $Sc(OC_6H_2Me\text{-}4\text{-}Bu^t_2\text{-}2,6)_3$ [1] gives 1.267, 1.27 and 1.30 Å, respectively. The present value is shorter than those of triaryloxo lanthanide complexes, almost certainly because of steric congestion caused by three bulky aryloxo ligands.

The bond length of Yb—Cl is 2.555(2) Å. This value is comparable with 2.52(5) Å in $YbCl_3(THF)_3$ [22] and 2.594 Å in $CpYbCl_2(THF)_3$ [20]. The Yb—O(THF) distances range from 2.292(4) Å to 2.434(5) Å and average 2.339(5) Å, and are well within the range of coordination bonds.

Synthesis and characterization of rings with the atom combination Ga/As and In/As

Anahita Dashti-Mommertz, Bert Werner and Bernhard Neumüller*†

Fachbereich Chemie der Universität, Hans-Meerwein-Straße, D-35032 Marburg, Germany

(Received 19 June 1997; accepted 6 August 1997)

Abstract—The organogallium arsenide $[Pr^i(Cl)GaAsBu^t_2]_2$ (**1**) and the organoindium arsenide $[(PhCH_2)_2InAsBu^t_2]_2$ (**2**) have been prepared by the reaction of the corresponding halides Pr^iGaCl_2 and $(PhCH_2)_2InCl$ with Bu^t_2AsLi in THF and Et_2O, respectively. **1** and **2** have been fully characterized by elemental analysis and IR, NMR, and MS techniques as well as by X-ray diffraction. According to cryoscopic molecular weight determinations in benzene, **1** and **2** are present as dimers in solution. The structures of **1** and **2** display rhombic distorted four-membered rings M_2As_2 (M = Ga, In). © 1998 Elsevier Science Ltd. All rights reserved

Keywords: gallium arsenide; indium arsenide; crystal structures.

During the last ten years the synthesis and characterization of compounds possessing the element combination group 13/group 15 has developed into one of the most exciting areas in main group chemistry. The predominant important driving force for the research in this field is the potential employment of such compounds in MOCVD processes generating layers and thin films of group 13/15 semiconductor materials [1–3]. Nitrogen and phosphorus derivatives have been studied intensively, whereas arsenic and especially antimony compounds have not been investigated in great detail [1–4].

One approach to the better understanding of this class of compounds involves basic investigations such as optimizing the synthesis and studying the structural features of the compounds which often display rings and cages.

In this paper we report the reaction of an organogallium dichloride and a diorganoindium chloride with Bu^t_2AsLi to yield species with $R(Cl)GaAsBu^t_2$ and $R_2InAsBu^t_2$. The structural features of the products have been studied in solution and the solid state. Compounds of the type $R(Cl)GaAsR'_2$ have been investigated already by Wells *et al.* who reported a dimer–trimer equilibrium in solution. A crystal structure analysis was not carried out [5].

However, not only the degree of association is of interest in this case, but also, whether Cl or As in μ_2-bridging. One should expect As as a bridging atom, nevertheless, under certain conditions the chlorine atom can occupy this position [6,7].

EXPERIMENTAL

Instruments and materials

All experiments were carried out under an atmosphere of argon. Purification and drying of the solvents were done, using standard methods [8]. Pr^iGaCl_2 [34], $(PhCH_2)_2InCl$ [10,11], and Bu^t_2AsLi [35] were prepared by literature procedures.

The ^1H and ^{13}C NMR spectra were recorded on a Bruker AC-300 spectrometer (^1H, 300.134 MHz; ^{13}C, 75.469 MHz). The standard was TMS (external) with $\delta = 0.0$ ppm. The IR spectra were obtained using a Bruker IFS-88 instrument (Nujol mulls, CsI disks for the range 4000–500 cm^{-1}; polyethylene disks for the range 500–100 cm^{-1}). For the EI mass spectra a Varian CH7a mass spectrometer (70 eV) was used. The melting points were measured with a Dr Tottoli (Büchi) melting point apparatus in sealed capillaries under argon (values not corrected). The cryoscopic measurements were performed using a Normag molecular weight determination apparatus combined with a Beckmann thermometer.

† Dedicated to Prof. Dr Manfred Weidenbruch on the occasion of his 60th birthday.

Synthesis of the compounds

Preparation of $[Pr^i(Cl)GaAsBu^t_2]_2$ (**1**). A solution of 1.81 g (9.25 mmol) of Bu^t_2AsLi in 10 ml of THF was added at −78°C to a solution of 1.70 g (9.25 mmol) of Pr^iGaCl_2 in 10 ml of THF. The green solution was stirred for 12 h until 20°C was reached. The color turned to yellow during this process. The solvent was removed under vacuum and the residue was treated with 10 ml of toluene. The suspension was filtered and the filtrate was reduced to dryness under vacuum. Recrystallization from toluene gives colorless crystals (2.69 g; 78.3%); m.p. 180°C. ^{1}H NMR (C_6D_6; ppm): 1.38 [d, 6H, CH (CH_3)$_2$], 1.39 (m, 1H, $CH(CH_3)_2$, AB_6 spin system), 1.41 [s, 18H, $C(CH_3)_3$]. ^{13}C NMR (C_6D_6; ppm): 20.2 [$CH(CH_3)_2$], 21.0 [$CH(CH_3)_2$], 32.6 [$C(CH_3)_3$], 43.8 [$C(CH_3)_3$]. Molecular weight determination (cryoscopic, benzene, $c = 0.0288$ mol/l): 703; $n = 2.1$. EI-MS: m/z (%) 190 (4) $[As(C_4H_9)_2]^+$, 179 (1) $(ClGaAs)^+$, 132 (2) $(AsC_4H_9)^+$, 105 (2) $(HGaC_3H_7)^+$, 75 (1) $(As)^+$, 69 (2) $(Ga)^+$, 57 (100) $(C_4H_9)^+$, 43 (14) $(C_3H_7)^+$. IR (cm^{-1}): 2719 w, 1198 w, 1160 vs, 1071 w, 1024 m, 977 m, 939 m, 918 m, 870 s, 845 m, 806 w, 654 vw, 522 m (νGaC), 395 m (νGaCl), 349 m (sh, νGa_2As_2), 327 m (νGa_2As_2), 266 m (br). Preparation of $[(PhCH_2)_2InAsBu^t_2]_2$ (**2**). A solution of 0.64 g (3.26 mmol) of Bu^t_2AsLi in 15 ml of Et_2O was added to a solution of 1.04 g (3.13 mmol) of $(PhCH_2)_2InCl$ in 35 ml of Et_2O at 20°C. The mixture was stirred for 18 h while a voluminous colorless solid was formed. The solvent was removed under vacuum and the residue was extracted with four portions of 25 ml of boiling toluene. The filtrate was dried under vacuum and the colorless solid was recrystallized from *n*-pentane (1.10 g, 73% calculated from $(PhCH_2)_2$ InCl; mp 210°C dec). ^{1}H NMR (C_6D_6; ppm): 1.14 [s, 18 H, $C(CH_3)_3$], 2.56 (s, 4 H, CH_2Ph), 6.82–7.06 (m, 10 H, Ph—*H*). ^{13}C NMR (C_6D_6; ppm): 26.8 (CH_2Ph), 33.4 [$C(CH_3)_3$], 40.2 [$C(CH_3)_3$], 122.9 (C^4), 127.5 ($C^{3,5}$), 128.8 ($C^{2,6}$), 146.4 (C^1). Molecular weight determination (cryoscopic, benzene, $c = 0.0255$ mol/l): 895; $n = 1.8$. EI-MS: m/z (%) 190 (5) $(InAs)^+$, 132 (2) $(AsC_4H_9)^+$, 115 (1) $(In)^+$, 91 (66) $(CH_2Ph)^+$, 57 (100) $(C_4H_9)^+$. IR (cm^{-1}): 2720 w, 1594 m, 1302 w, 1262 m, 1206 m, 1154 m, 1069 m, 1036 m, 996 w, 936 w, 895 w, 880 m, 866 m, 795 s, 747 s, 695 s, 681 m, 660 m, 621 s, 534 s, 484 w ($\nu_{as}InC_2$), 447 w ($\nu_s InC_2$), 411 w, 329 w, 284 w (νIn_2As_2), 267 vw (νIn_2As_2), 209 vw, 167 vw, 119 vw. X-ray measurements and structure determination

The crystals were covered with a high-boiling paraffin oil and mounted on the top of a glass capillary under the flow of cold gaseous nitrogen. The orientation matrix and preliminary unit cell dimensions were determined from 25 reflections on a four-circle diffractometer with graphite-monochromated Mo-K_α radiation ($\lambda = 71.073$ pm; Siemens P4). The final cell parameters were determined from 25 high-angle reflections.

The intensities were corrected for Lorentz and polarization effects (for cell parameters and collection of the intensities, see Table 1). Both structures were solved with the program SHELXTL-Plus [36] (**1**: direct methods; **2**: Patterson method) and refined against F^2 by full-matrix least-squares using SHELXTL [37] (**1**) and SHELXL-93 [38] (**2**). The positions of the hydrogen atoms for **1** were calculated for ideal positions and refined with a common displacement parameter. The hydrogen atoms for **2** have been free refined. The calculation of the bond lengths, bond angles, and U_{eq} values was performed using the program PLATON [39]. Selected bond lengths and angles are listed in Table 2.

A comparison of M—As bond lengths is compiled in Table 3.

RESULTS AND DISCUSSION

Addition of Bu^t_2AsLi to Pr^iGaCl_2 in THF at $-78°C$ gives the organogallium arsenide $[Pr^i(Cl)GaAsBu^t_2]_2$ (**1**).

$$Pr^iGaCl_2 + LiAsBu^t_2 \rightarrow \underset{\mathbf{1}}{1/2[Pr^i(Cl)GaAsBu^t_2]_2} + LiCl \quad (1)$$

In a similar metathesis reaction $(PhCH_2)_2InCl$ reacts with Bu^t_2AsLi in Et_2O at room temperature to $[(PhCH_2)_2InAsBu^t_2]_2$ (**2**).

$$(PhCH_2)_2InCl + LiAsBu^t_2 \rightarrow \underset{\mathbf{2}}{1/2[(PhCH_2)_2InAsBu^t_2]_2} + LiCl \quad (2)$$

1 and **2** are air-sensitive colorless solids and soluble in non-polar solvents like *n*-pentane or toluene. According to cryoscopic measurements, **1** and **2** both possess a dimeric character in benzene.

A solution of **1** in C_6D_6 shows the typical AB_6 spin system for the Pr^i group [6–9]. Here the multiplet for the methine proton is partly covered by the singlet of the Bu^t groups at 1.41 ppm. The signal for the methylene protons in **2** at 2.56 exhibits a distinct low field shift in comparison to $In(CH_2Ph)_3$ [10,11] (1.81 ppm), $[(PhCH_2)_2InN(H)Bu^t]_2$ [7] (transoid derivative, AB spin system: 2.08, 2.28 ppm, $^2J(HH) = 11.1$ Hz) and $[(PhCH_2)_2InPPh_2]_3$ [12] (2.26 ppm). Higher values of 2.60 and 2.72 ppm have been observed for the bromides $(PhCH_2)_2InBr$ and $[PhCH_2InBr_2(THF)_2]$ [13].

1 and **2** possess C_i-symmetry leading to only two observal M_2As_2 ring vibrations caused by the rule of mutual exclusion [14]. We assign the two bands at 349, 327 cm^{-1} (**1**) and 284, 267 cm^{-1} (**2**), respectively, to those asymmetric ring vibrations. The absorption at 395 is caused by the terminal Ga—Cl bond [15]. For the M—C vibrations in **1** and in **2** the signals at 522 (**1**), 484 ($\nu_{as}InC_2$) and 447 cm^{-1} (ν_sInC_2) have been found. Both compounds are not very stable under EI mass spectra conditions. Prominent peaks of **1** are observed for $m/z = 57$ $(C_4H_9)^+$ and $m/z = 43$ $(C_3H_7)^+$. The spectrum of **2** exhibits peaks for $(InAs)^+$ ($m/z = 190$), for $(CH_2Ph)^+$ ($m/z = 91$) and for $(C_4H_9)^+$.

Description of the structures

Figure 1 shows the centrosymmetric dimer **1** with a planar rhombic distorted Ga_2As_2 four-membered ring. The Ga—As distances of 252.0(1) and 252.9(1) pm can be compared to 251.8(1) and 253.0(1) pm in $[Ph_2GaAs(SiMe_3)_2]_2$ [16]. The dimers $[Me_2GaAsBu^t_2]_2$ and $[Bu^n_2GaAsBu^t_2]_2$ [17] possess longer bond lengths of 255 pm (average) whereas the 263.0(1) pm in $[Bu^t_2GaAs(SiMe_3)_2]_2$ can be attributed mainly to the bulk of eight large substituents. The values for the first mentioned examples are due to the exchange of the electronegative Cl atom in **1** against an organic group. For gallium centers with the coordination number (CN) three, a shortening of the Ga—As bond should be observed such as the 246.6(3) pm for Bu^t $GaAsBu^t_2$ [18] and the 245.8(1) pm in $Bu^t_2GaAs(SiPh_3)$ $[CH(SiMe_3)_2]$ [19]. The rhombic distortion of M_2E_2 rings with group 13 metals is a generally observed feature. An angle larger than 90° can be found in almost all cases at the electronegative hetero-element E. Angles of 90° for M and E have been observed for the amid $[Me_2InN(SiMe_3)_2]_2$ [20]. There exist only few examples in which the group 15 element

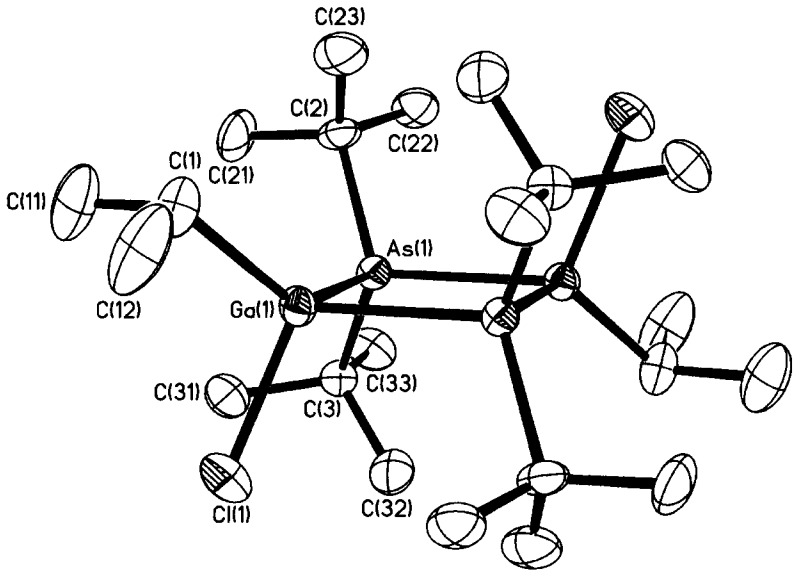

Fig. 1. Molecular structure of **1** (without H atoms). The thermal ellipsoids have a probability level of 50%.

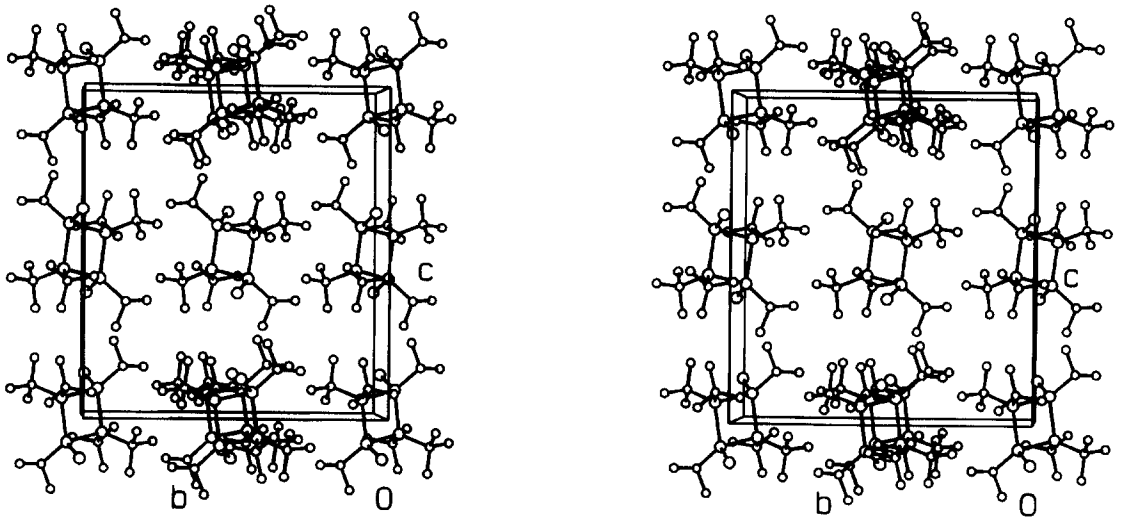

Fig. 2. Stereoscopic view of the unit cell of **1** (ORTEP) [40].

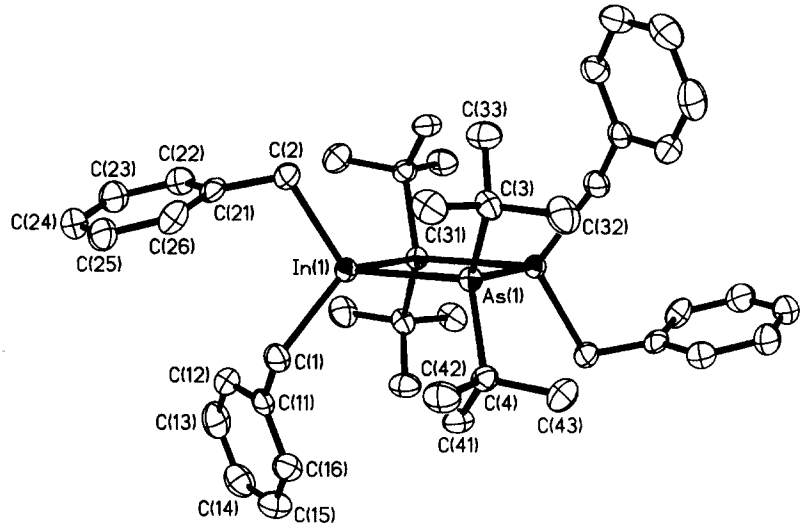

Fig. 3. Molecular structure of **2** (without H atoms).

does not occupy the μ_2-bridging position. In the case of $[Mes(Cl)InN(SiMe_3)_2]_2$ [7] this can be explained by the well-known low basicity of the $N(SiMe_3)_2$ group and in $[Bu^t(Cl)GaP(H)Mes']_2$ [Mes′ = 2,4,6-Bu^t_3 C_6H_2] [21] the bulky aryl substituent is responsible for this behavior. In both cases the Cl atoms occupy the bridging position. The Ga—Cl bond length of 223.0(2) pm is typical for a terminal Cl atom attached to a Ga center with CN four. 221.1(3) pm has been found for $[Mes^*GaCl_2(THF)]$ [22]. The shortening to 212.4(4) pm for $[Cp^*GaCl_2]_2$ [23], 215.1(2) pm for $[Bu^tGaCl_2]_2$ [24], 216 pm (average) for $[MesGaCl_2]_n$ [25] and to 218 pm (average) in $[GaCl_2(NPPh_3)]_2$ [26] are due to the two or more electronegative ligands coordinating the metal center. A low CN in combination with bulky substituents leads to Ga—Cl distances in the same range (Mes^*_2GaCl: 222.0(5) pm [22]; $Mes'GaCl_2$: 215.7(1) pm) [22,27]. The gallium atom in **1** shows no tendency to extend the coordination sphere to CN5 by intermolecular Ga···Cl contacts (Fig. 2), a characteristic behavior of Ga. Exceptions were observed if effects like intramolecular stabilization forces a higher CN, e.g. in $[2,6\text{-}(Me_2N\text{-}CH_2)_2C_6H_3Ga(N_3)_2]$ [28].

The centrosymmetric four-membered ring In_2As_2 in **2** exhibits in principle the same rhombic distortion as the Ga analogue in **1** (Fig. 3). The In—As distances of 271.21(5) and 271.64(4) pm are at the upper limit for this bond. $[Me_2InAsMe_2]_3$ [29] [265.7(3)–267.9(2) pm] and $[Ph_2InAs(SiMe_3)_3]_2$ [30] [268.2(1)–268.9(1) pm] have more typical bond lengths. A longer In—As bond of 275.2(1) pm [31] was found only in the steri-

cally crowded indium arsenide $[(Me_3CCH_2)_2InAs(SiMe_3)_2]_2$. An indicator of the sterical situation is the In—C bonds, which are relatively long [221.1(3); 223.0(3) pm] in comparison to $In(CH_2Ph)_3$ [218.6(7)–220.5(6) pm] [11] and $[(PhCH_2)_2InPPh_2]_3$ [218.5(4)–220.3(4) pm] [12].

1 possesses Ga···Ga contacts [362.7(1) pm] which are somewhat shorter than the sum of the van der Waals radii (380 pm). Recently, theoretical studies dealing with diamond shaped four-membered rings, like the ones present in **1** and **2**, verified that there is no evidence for a metal–metal bond. The contacts are rather forced by the ring geometry [32].

(Received 21 May 1997; accepted 6 August 1997)

Abstract—Spectroscopic (^{13}C NMR, UV/VIS, IR, FAB-mass) and thermal (TG, DTA) studies of dialkyl (α-anilino-*N*-benzyl)phosphonates and their palladium(II) dichloride adducts, *trans*-$Pd(L)_2Cl_2$, have been carried out to determine structural and decomposition properties of these biologically active compounds. Thermal decomposition of the complexes proceeds in two steps: dehalogenation coupled with deesterification is followed by complex pyrolysis which finally results in a mixture of Pd and P_2O_5. The main gas-phase fragmentation pathway consists of sequential losses of HCl giving rise to the mono- and bis-orthometallated species. These processes are in competition with the loss of the phosphonate ester groups. NMR and UV/VIS spectra have shown that complexes retain their integrity in chloroform, but dissociate readily in DMSO and DMF solutions, leaving free an organophosphorus ligand. The spectral and thermal properties of the complexes have been discussed with respect to their antitumor activity. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: Palladium chloride; anilinobenzylphosphonate; complex; thermal analysis; spectroscopy.

There has been continuous interest in palladium(II) halide complexes with nitrogen donor ligands since they have been found to be effective in treating various types of animal and human carcinomas [1–4]. There is general agreement that DNA is an important pharmacological target for the Pd(II), like Pt(II), compounds [5]. The ability to break Pt,Pd—X bonds seems to be the rate determining step in their reaction with DNA strands [6]. Thus, in order to prepare compounds with higher efficiency, it is important to understand dissociation properties of palladium(II) complexes and their relationship with antitumor activity. In an effort of obtaining a new class of potentially useful antitumor and antiviral agents, we have recently reported the synthesis and characterization of palladium(II) halide complexes with several dialkyl phosphonates derived from quinoline and aniline [7–9]. Most of these compounds have been found effective *in vitro* against human and tumor cell lines. In this paper we describe the decomposition behavior of diethyl and dibutyl ester of (α-anilino-*N*-benzyl) phosphonic acid and their palladium(II) dichloride adducts investigated by means of ^{13}C NMR and electronic spectra, mass spectrometric measurements carried out under FAB conditions as well as by thermal (TG and DTA) analysis accompanied by the IR spectroscopic studies.

EXPERIMENTAL

Materials

Diethyl and dibutyl (α-anilino-*N*-benzyl)phosphonates (L1 and L2) [10], prepared as previously described, were purified by repeated recrystallization from absolute ethanol. Their palladium(II) dichloride adducts, $Pd(L)_2Cl_2$ (L=L1, L2), were obtained by reaction of ligands with Na_2PdCl_4 in methanol according to published method [9]. All other reagents and solvents were of analytical grade and used without purification.

Physical measurements

^{13}C NMR spectra were recorded on a Varian 300 Gemini spectrometer in $CDCl_3$ containing TMS as an internal reference. Spectra were measured with proton broad band decoupling, attached proton test (APT) and gated decoupling techniques. Standard spectral parameters were as follows: operating frequency 75.46 MHz, sweep width 18 700 Hz, pulse width 5.0 μs, pulse delay 1.0 s, flip angle 34°, acquisition time 0.998 s, 11 K data points, digital resolution of 0.65 Hz per data point. The UV/VIS spectra were recorded on a Cary Model 17 spectrophotometer in $CHCl_3$ solution in the range of 260–600 nm. IR spectra were recorded on FT-2000 and 580 B Perkin-Elmer spectrophotometers using KBr (4000–250 cm^{-1}) and polyethylene (400–200 cm^{-1}) pellets. Mass spectrometric measurements were performed on a double-focusing reverse-geometry VG ZAB 2F instrument operating under FAB conditions by bombarding 3-nitrobenzyl alcohol sample solutions with 8 keV Xe atoms. Expected natural abundance isotope cluster patterns for various ion clusters were calculated with the Isotopic Distribution Program (IDS) contained in the FTMS 7.01 application program of the NICOS operating system using polynomial expansion, based on natural abundance of the isotopes. Thermogravimetric analyses (TG) were performed with a Cahn RG electromicrobalance in an air atmosphere at a heating rate of 4°C min^{-1} up to 800°C. Differential thermal analyses (DTA) were carried out on a Netzsch differential thermal analyser applying a heating rate of 2°C min^{-1} in a static air atmosphere. The reference substance was pure alumina. The X-ray powder diffraction patterns were taken with a Philips counter diffractometer (monochromatised Cu K_α radiation).

RESULTS AND DISCUSSION

Dialkyl (α-anilino-*N*-benzyl)phosphonates by reaction with $PdCl_4^{2-}$ form biologically active palladium dichloride adducts which have been found to possess *in vitro* cytostatic activity against human epidermoid carcinoma and murine leukemia cell lines [9]. It was found that butyl derivative is more effective than its ethyl analogue. In these square-planar complexes the two monodentate N-bonded ligands are coordinated mutually *trans* to the palladium(II) ion through the aniline nitrogen. The phosphoryl group is not involved in coordination to palladium and it is available for hydrogen bonding, which is known to have some importance in the approaching and binding of metal ions to nucleic acid constituents [11]. It has been suggested that the requirements for potential antitumor coordination compound are a pair of strongly bonded nitrogen donor ligands and a pair of moderately labile ligands such as halides [12]. Generally, it was noticed that the smaller antitumor activity show complexes containing labile ligands with the lower leaving ability. The spectroscopic and thermal studies presented for the free α-anilinobenzylphosphonates and their palladium complexes provided valuable

structural information as well as important information about stability of these compounds and the mode of their decomposition. The NMR and UV/VIS spectral analyses have shown that complexes retain their integrity in chloroform and dichloromethane solutions, but dissociate in dimethylformamide and dimethylsulphoxide. These solvents with strong complexing ability towards palladium(II) ion cleave the metal–nitrogen bond leaving free ligand molecules. ^{1}H NMR studies have shown that complexes are dissociated after 30 min [9]. This process may be stimulated by UV irradation. Therefore in this study we present only spectroscopic results obtained in a chloroform solution.

^{13}C NMR Spectra

The ^{13}C NMR chemical shifts and the carbon–phosphorus coupling constants for the organophosphorus ligands and their complexes are summarized in Table 1, according to the numbering scheme shown in Fig. 1. Spectral data of the free ligand [13] provided a basis for interpreting spectra of their palladium complexes. Broad-band decoupling, gated decoupling and APT spectra were also utilized in the spectral analysis.

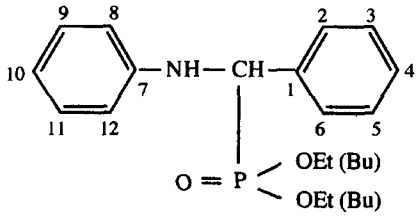

Fig. 1. Structure and numbering scheme for dialkyl (α-anilino-*N*-benzyl)phosphonates.

Signal assignment was ascertained on the basis of chemical shifts, signal intensities, spin–spin coupling constants and splitting patterns. The spectra of free ligands show that resonances of all alkyl carbons are doubled due to the non-equivalence of the two dialkyl ester groups. Two sets of separate resonances have been observed, also in their proton NMR spectra, as OR groups of the $P(O)(OR)_2$ moiety which is adjacent to a chiral center are diastereotopic [9,14]. The resonances of the alkyl carbons show also the signal splitting due to carbon–phosphorus couplings. The ^2J(POC) and ^3J(POCC) values are about 6.8 and 5.8 Hz, respectively. The benzylic PCH carbon shows one-bond PC coupling of about 150 Hz. For atomatic resonances it was observed that all *ortho* and *meta* carbons are magnetically equivalent as a consequence of the fast rotation on the timescale of NMR spectroscopy. The spectra of complexes show a great complexity due to the existence of more isomeric species with a different magnetic environment caused on one side by the presence of a new chiral center on the nitrogen atom, because of its coordination to palladium and, on the other side, by the restricted rotation around the C—N bond. Assuming that the arrangement of bonds around nitrogen approaches a tetrahedral configuration, similar to that at the adjacent asymmetric benzyl carbon atom, the simplified projection of three possible conformations of two diastereoisomers (a and b), one from each enantiomeric pair, is presented in Fig. 2. Furthermore, it could be assumed that the anilinobenzylphosphonate molecule, as a whole, is hindered in its rotation around the Pd—N coordination bond due to the proximity of the bulky phosphonate ester group. The major isomeric form, with a population of ca 70%, is most probably the less sterically hindered one. The splitting signals could be detected for almost all carbon atoms. In Table 1 only data for the major isomer obtained

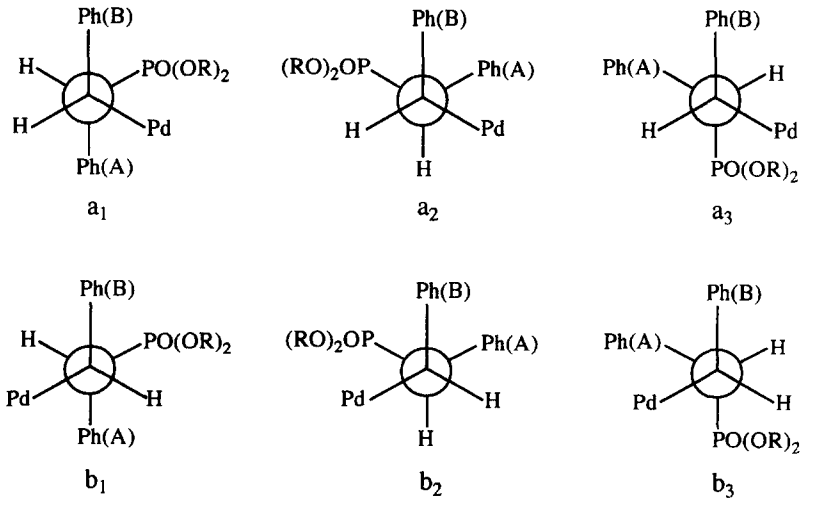

Fig. 2. Possible conformations of two diastereoisomers (a and b) of palladium(II) complexes of dialkyl (α-anilino-*N*-benzyl)phosphonates (R=Et, Bu).

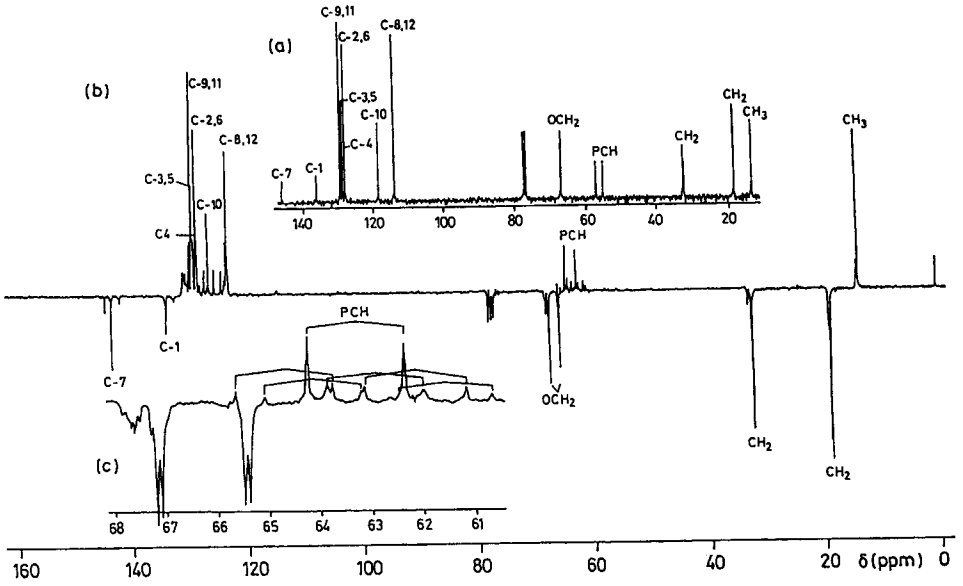

Fig. 3. ^{13}C NMR spectra of (a) L2, proton-decoupled spectrum; (b) $Pd(L2)_2Cl_2$, APT spectrum and (c) $Pd(L2)_2Cl_2$, APT spectrum showing an expansion of the doublet pattern for the PCH carbon.

from the proton decoupled spectra are given. The most pronounced shifts appear for the carbons of the PCH and $POCH_2$ groups as well as the carbons of the aniline ring which are close to the nitrogen bonded to the palladium(II) ion. In Fig. 3(c) it could be seen that the PCH carbon gives a pattern of multiplet doublets, and that one of the most intense doublets shows a downfield shift of 6.5 ppm with respect to this resonance in the free ligand. The nitrogen lone pair donation into the aniline ring is greatly reduced due to the palladium bonding, which should induce the significant chemical shift changes at the *ortho* and *para* positions [15, 16]. Thus, the moderate downfield shifts of about 9 and 8 ppm for the *ortho* carbons C-8, 12 and the *para* carbon C-10, respectively, along with an upfield shift of only 0.2–0.5 ppm for the *meta* carbons C-9 and C-11, could be observed in the spectra of complexes. The quaternary carbons C-1 and C-7 show an upfield shift of about 2.7 and 4 ppm, respectively. The coupling between phosphorus and the carbon atom C-7 ($\sim$14.6 Hz in free ligand) adjacent to nitrogen is not visible. Instead its signal is doubled in intensity. As expected, the resonances for the aromatic benzyl carbons C-2–C-6 remain almost unchanged upon complex formation.

Ultraviolet-visible spectra

The electronic absorption spectra of the free anilinobenzylphosphonate ligands in the 260–600 nm region show only one band at 292 nm (ε 10^3–10^4 M^{-1} cm^{-1}), which is in accordance with the spectra of the substituted anilino derivatives [17]. Their palladium complexes are characterized by one rather intense band at around 290 nm (ε 10^3–10^4 M^{-1} cm^{-1}) accompanied by a shoulder on the low energy side, as well as by a weaker absorption at 425 nm (ε 10^2–10^3 M^{-1} cm^{-1}). The former absorptions are predominantly originated form d–d transitions superimposed by the intraligand π–π^* transitions, while the band in the visible range is assignated to the metal-to-ligand charge-transfer transition. For the square-planar diamagnetic complexes three spin allowed d–d transitions are expected, corresponding to transitions from the three lower d-levels to the empty $d_{x^2-y^2}$ orbitals [18]. The ground state is $^1A_{1g}$ and the excited states related to these transitions are $^1A_{2g}$, $^1B_{1g}$ and ^1E_g in order of increasing energy. Strong charge-transfer or intraligand transitions may prevent the observation of these bands.

Mass spectra

The FAB mass spectra have been obtained for ligand L2 and its palladium complex. Their fragmentation pathway is very extensive and only the most abundant fragment ions are given in Table 2. The main decomposition pathway for the free ligand is the dissociation or complete loss of the phosphonate ester groups. The base peak at *m/z* 182 is formed by cleavage of the C—P bond. The further fragmentations include cleavage of the C—N and N—C bonds similarly as was observed in various benzylaniline derivatives [19, 20]. The presence of the phenyl groups could be detected by high abundance ions due to Ph^+ and Ph_2^+ at *m/z* 77 and *m/z* 154, respectively.

Table 2. Major fragments in mass spectra of L2 and $Pd(L2)_2Cl_2$[a]

[a] L = parent ligand; M = parent complex.

In the spectrum of palladium complex the molecular ion as well as the fragment ions containing palladium are identified by the presence of the characteristic clusters of isotopic peaks due to the presence of the numerous palladium isotopes. The relative abundance of these fragment ions is relatively small and the theoretical isotopic mass distributions of Pd, PdCl and $PdCl_2$ clusters were also calculated to justify their assignments. The most intense fragment ions correspond to the fragments of the free non-coordinated ligand molecule. The fragmentation pathways, including possible structures of ions containing palladium, proposed on the basis of accurate mass measurements and isotopic cluster analysis, are reported in Scheme 1. Decomposition of the complex follows two fragmentation routes: one in which the protonated molecular ion sequentially loses hydrogen chloride and the other in which this loss is in competition with the loss of the dibutyl phosphonate ester group or its fragments. Further fragmentation is considered to involve the loss of the anilinobenzylphosphonate ligand molecule or its fragments. The molecular ion is protonated, since the anilino nitrogen as well as the phosphoryl oxygen, are known to be basic and hence, prone to protonation. The most important fragmentation pathways are the loss of one or both HCl molecules, which it may be assumed give rise to both mono- and bis-ortho-metallated species. The loss of the first HCl molecule gives $[Pd(L)(L\text{–}H)Cl+H)]^+$ ion, while the loss of the second should give an ion corresponding to the dimetallated complex $Pd(L\text{–}H)_2$. The most abundant palladium containing fragment ions are monopalladated ions containing both or only one organophosphonate ligand molecule. The high stability of such metallated systems is in agreement with the reported high stability of palladium(II) 5-membered cyclometallated systems having nitrogen donor ligands [21]. It is worth noting that dialkyl anilinobenzylphosphonates as secondary benzylamino derivatives do not form cyclopalladated complexes by reaction with $PdCl_4^{2-}$. Generally, it was shown that direct activation of C—H bonds by palladium(II) chlorides to afford corresponding palladacycles, is the most feasible in the case of tertiary amines and that secondary amines are usually inert toward such activation [22, 23]. Palladium(II) acetate was found to be a much better metallating reagent than tetrachloropalladate [24, 25]. It may be assumed that metallations of the chloropalladated compounds might occur in a matrix solution by the FAB-induced condensed phase reactions.

Thermal studies

Decomposition behavior of the ligands and their palladium complexes also was investigated by thermogravimetric measurements accompanied by the infrared spectroscopic study. The results obtained

Table 3. TG and DTA data

Compound	M.p.[a] (°C)	Temp. range, TG (°C)	Dehalogenation and pyrolysis[b], T, DTA (°C)

from the TG and DTA curves are summarized in Table 3 and presented in Fig. 4 for L2 and its complex. The TG curves of the free ligands show a very sharp step between 170–240°C with a rapid weight loss of about 75%. This decomposition process could be ascribed to almost complete loss of the organic matter leaving P_2O_5 and appearing on the DTA curves as a strong exothermic effect centered at 275 and 280°C, respectively. The furthest weight loss over a broad step could be attributed to partial sublimation of P_2O_5 which takes place above 300°C [26]. Both ligands also show in a DTA curve, one endothermic effect at 55 and 105°C, respectively, which is not accompanied by the weight loss on the TG curve and corresponds approximately with the melting point values of these compounds [10].

The thermal decomposition of complexes occurs in two steps without formation of a stable intermediate. The first step between 135–280°C is attributed to the dehalogenation process overlapped with deesterification of the ligand which was confirmed by the subsequent infrared spectral study. It was shown that decomposition of the complexes started with their dehalogenation, as indicated by an intensity decrease of the Pd—Cl stretching vibration which appeared in both complexes at 332 cm^{-1}, while the loss of the alkyl ester group is accompanied by a decrease of the absorption bands arising from various modes of the P—O—Et(Bu) vibrations in the region of 1130–1035 cm^{-1} and C—C alkyl vibrations between 980–930 cm^{-1}, as well as by increasing of the ν(P=O) band at 1235 cm^{-1} [9, 27]. Furthermore, it was shown that a dehalogenation process was completed up to 300°C and that complexes were decomposed into a mixture of inorganic materials at 350–450°C. The final decomposition product as a mixture of metallic Pd and P_2O_5 was confirmed also by the X-ray diffraction analysis, as was obtained for palladium(II) halide

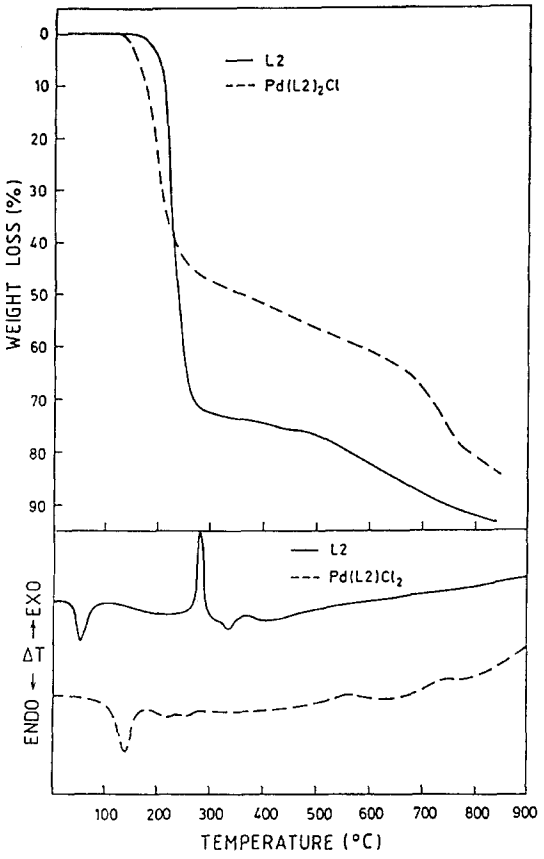

Fig. 4. TG–DTA curves for L2 and its complex $Pd(L2)_2Cl_2$.

complexes of various aminophosphonate derivatives [28]. Dehalogenation and deesterification of the complexes are accompanied by two endothermic effects in DTA curves and the first, more intense one, corresponds well with the melting point value of these compounds. This rather sharp thermal decomposition step is followed by a continuous weight loss with several unclear peaks in the DTA curves.

From the initial decomposition temperatures it could be concluded that the complex of diethyl ester is more stable than that of dibutyl ester. As the observed Pd—Cl stretching frequency is the same in both complexes indicating the similar palladium-chlorine bond strength, it may be presumed that the complex stability decreases with the length of the alkyl ester groups due to the increase of steric hindrance [29]. The observation is interesting in view of the importance of the Pd—Cl bond strength for the binding of the complexes to DNA strands, which in turn is related to their antitumor activity. The fact that ν(Pd—Cl) is not influenced by the length of the alkyl chain, indicates that other factors have a stronger influence to the complex activity. Lipophilicity of the complexes increases with increasing length of the alkyl chain and may facilitate the transport across the cellular membrane [30]. Furthermore, steric requirements of the complexes are growing in the same sequence, with the consequence of more severe damage of DNA after formation of the palladium-DNA complex. These effects are consistent with the rise in antitumor activity observed when increasing the length of the alkyl chain in palladium complexes of diethyl and dibutyl anilinobenzylphosphonates.

(Received 22 April 1997; accepted 6 August 1997)

Abstract—The crystal and molecular structure of (imidazole)(*N*-salicylidene-*β*-alaninato)copper(II), monoclinic, space group C/2c, was solved by a single crystal X-ray structure analysis and refined to $R = 0.0577$ for 1286 observed reflections. The coordination polyhedron around Cu(II) is an axially elongated square-pyramid, the basal plane being formed by the (O, N, O) atoms of the tridentate Schiff base and the N atom of imidazole. The apex of the pyramid is occupied by the terminal carboxylic atom of adjacent molecule, thereby giving rise to centrosymmetric dimers. Non-parallel aligned stacks of dimeric units are propagated in the unit cell. The powder and single-crystal EPR spectra show cooperative g factors resulting from the weak coupling between two misaligned **g** tensors from dimeric units ordered in a disturbed-ferrodistortive way. Since the N–N axes, corresponding to g_y, are oriented nearly parallel, the g–g coupling shifts only the values of g_z and g_x. A complete consistency between the angular spectroscopic EPR behaviour and the X-ray structural data was found.

Keywords: copper(II) complex; *N*-salicylidene-*β*-alaninato; tridentate Schiff base; imidazole; X-ray crystal structure; single-crystal EPR spectra.

Since the first solution studies showed that the complexes of tridentate Schiff base dianions (TSB) are key intermediates in the metabolic reaction of amino acids [2], much work has been undertaken also on studies of these complexes in solid state. A great number of structures of copper(II) complexes containing various *N*-salicylidene-aminoacidato Schiff bases and different neutral ligands (L) have been determined by X-ray crystal structure analysis [3]. An examination of the structural data of these complexes showed the possibility of a mechanism for metabolic reactions of aminoacids catalyzed by the vitamin B_6 (or salicylaldehyde)- metal system [4,5].

The great flexibility of tridentate ligands connected with the variability of π–π interactions and hydrogen bonds leads to an extraordinary richness of cooperative ordering effects in the crystal structure, which is frequently connected with different coupling patterns ranging from ferrodistortive (parallel orientation of the main axes of coordination polyhedra) to antiferrodistortive (perpendicular orientation of the main axes of coordination polyhedra) [1,6–10]. The local symmetry in plane, where the chelate and neutral ligands are bound, undergoes only slight changes. On the other hand, a rich variety of axial distortions rang-

† For Part V. see ref. 1.

* Author to whom correspondence should be addressed. E-mail: plesch@fns.uniba.sk

ing from square-planar to square-pyramidal has been found. Such structural adaptability may be one of the reasons for the diversity of interactions of these complexes with biological systems.

A valuable tool for investigations on such complexes in the non-diluted state, where *g–g* coupling between non-aligned molecules frequently modifies the **g** tensor from molecular to cooperative, is the EPR spectroscopy. The single-crystal EPR spectra in particular allow, in connection with X-ray structural data, to find the best Cartesian coordinates within the structure of these low-symmetric Cu(II) complexes, giving the qualitative measure for the character of the chemical bonding [6,9].

In (2-methylimidazole)(*N*-salicylidene-glycinato)copper(II) the square-pyramids around Cu(II) are ordered on a slightly disturbed-antiferrodistortive way, forming a zig-zag chain, where members are connected in an axial direction via the bridging carboxylate oxygen belonging to the adjacent complex unit. From the cooperative $\mathbf{g}^c$ tensor of a single crystal and the X-ray structural data, the orthorhombic molecular *g* components have been evaluated [6]. An analogical X-ray structure has been reported for (imidazole)(*N*-salicylidene-glycinato)copper(II) [10]. On the other hand (1-methylimidazole)(*N*-salicylidene-*R,S*-valinato)copper(II) forms square-planar molecules associated to dimers [1]. Two misaligned stacks related by a glide plane are propagated in the structure. The interdimeric Cu · · · Cu distance between misaligned coordination polyhedra in this case amounts to 10.52 Å, which is too large for magnetic interactions between canted **g** tensors.

Since the imidazole group is found quite frequently in biological Cu(II) systems [11], we decided to continue our studies [1,6,7] of the influence of the Schiff base ligand on the structure of adducts of the type (TSB)Cu-(imidazole and its derivatives).

The *N*-salicylidene-*β*-alaninato ligand forms two fused six-membered chelate rings around Cu(II) instead of one six- and one five-membered as in *N*-salicylidene-glycinato dianion. In this paper the X-ray structure and single-crystal EPR spectra of (imidazole)(*N*-salicylidene-*β*-alaninato)copper(II) are reported.

EXPERIMENTAL

The title complex was prepared by treatment of $[Cu_2(N\text{-salicylidene-}\beta\text{-alaninato})_2(H_2O)]\text{-}(H_2O)$ [12] with an excess of imidazole in hot diluted ethanol (3 : 1). 5.45 g of the parent complex (10 mmol) was dissolved in the solvent at 70°C. By slow cooling of the filtered reaction mixture, a light green product containing well developed single crystals was obtained. The deposited product was ether washed and air dried. Analysis for $C_{13}H_{13}CuN_3O_3$ (formula weight 322.81) : Found% (Calc. %) : C 48.52 (48.37) ; H 4.09 (4.06) ; N 13.12 (13.02).

The crystal chosen for the X-ray structure analysis was of dimensions $0.4 \times 0.2 \times 0.2$ mm. Unit cell parameters were refined by a least-squares fit of the positional angles for 15 centred reflections.

Crystal data: monoclinic, space group C2/c, $a = 19.037(7)$ Å, $b = 9.789(6)$ Å, $c = 13.701(9)$ Å, $\beta = 95.82(6)°$, $V = 2540.1(3)$ Å^3, $Z = 8$, $\mu = 1.73$ mm^{-1}, $D_m = 1.69(1)$ g cm^{-1}, $D_x = 1.688$ g cm^{-1}, Mo-K_α radiation (0.71069 Å), $T = 293$ K.

Intensity data were collected up to $2\theta = 50°$ on a Syntex $P2_1$ diffractometer using the standard θ–2θ scan technique. The data were averaged to give 2053 unique reflections, 1286 of which were observed [$I \geqslant 2\sigma(I)$]. The structure was solved by the heavy-atom method and refined on F^2 by using the SHELXL93 program package [13] and anisotropic thermal parameters for the non-H atoms. All H atoms were located from a difference Fourier map but were not refined. The final residuals were $R(F) = 0.0577$, $wR(F^2) = 0.1108$, $S = 1.056$. In the final cycle the maximal ratio shift/e.s.d. was 0.008 and maximal and minimal heights in the difference map were 0.29 and -0.35 eÅ^{-3}, respectively.

The 35 GHz powder EPR spectrum of the ground sample was measured at room temperature on a Varian E-15 spectrometer using DPPH as an internal standard.

A well shaped monocrystal of the dimensions $0.2 \times 0.07 \times 0.02$ mm was fixed on a LiF cube, placed in a resonator and the EPR spectra at room temperature and 35 GHz were measured in three orthogonal planes. The angular dependence of the spectrum was measured in 15° steps at the modulation amplitude of 10 G and a microwave power of 5 mW.

RESULTS AND DISCUSSION

The complex molecule is characterized by an axially elongated square-pyramidal Cu(II) coordination (4 + 1), with the tridentate dianionic Schiff base (TSB) and the monodentate ligand (L) occupying the basal plane of the pyramid. The selected bond distances and angles are given in Table 1. The weakly coordinating carboxylic O3 atom of an adjacent complex molecule related by a centre of symmetry at 1/2, 1/2, 0 is located on the apical site. In this way, the Cu(II) complexes are bridged to dimers in which, due to extended bridge system, the intra-dimer Cu · · · Cu spacing of 5.292(3) Å is relatively large in comparison with other dimeric Cu(TSB) complexes [1,9,10,12,14] (Fig. 1). On the other hand, the closest inter-dimer Cu · · · Cu distance between the Cu(II) centres of the ferrodistortively ordered units comes to 6.167(3) Å. The bond lengths within the basal plane are : Cu—O1 1.892(5), Cu—O2 1.948(4), Cu—N1 1.929(5), and Cu—N2 1.970(5) Å, while the apical Cu—O3′ distance is 2.590(4) Å. The four basal donor atoms are not exactly planar and show a tetrahedral type of distortion with the following displacements from the mean plane of the

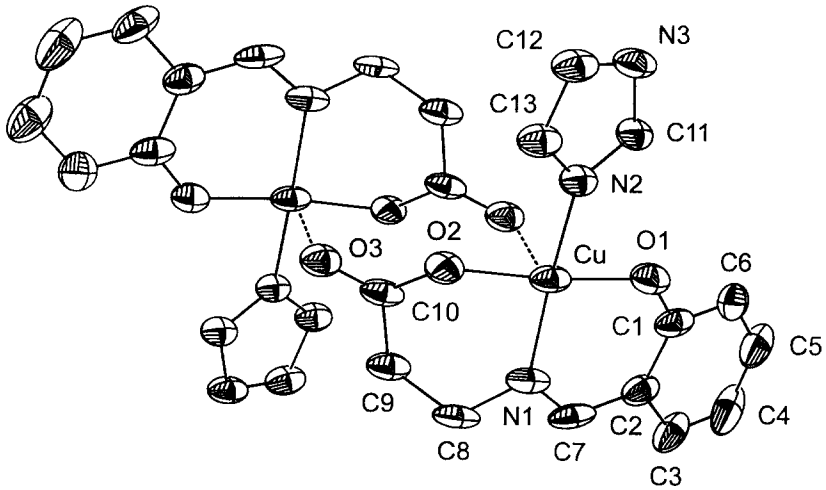

Fig. 1. A view of the binuclear complex $[Cu_2(sal\text{-}\beta\text{-}ala)_2(Im)_2]$, showing atom numbering of the reference molecule. Dashed lines represent the weak apical Cu—O′ interaction of 2.59 Å.

donor atoms: O1 0.103(5), N1 0.099(5), O2 0.102(5), N2 0.106(5) Å. The Cu atom is displaced by only 0.059(2) Å from this plane. The salicyladimine moiety is approximately planar (r.m.s. deviation 0.069 Å) but significantly folded relative to the basal coordination plane; the dihedral angle between the O_2N_2 basal plane and the mean plane of the salicyladimine moiety is 11.3(1)°. As a result, the six-membered chelate ring involving the salicyladimine part of the ligand shows considerable warping, with the endocylic torsion angles ranging from 18.6(8) to 16.4(5)°. The imidazole molecule is exactly planar (r.m.s. deviation 0.008 Å) and makes an angle of 21.5(2)° with the basal coordination plane.

The bond lengths and angles in the ligand part of the molecule are normal and well comparable with those found for related molecules [1,6,10]. The Cu—O bond length to phenolic oxygen O1 of the tridentate Schiff base is significantly shorter than the bonding to carboxylic oxygen O2, which indicates different bond

strengths. The apical Cu—O′ distance in the low-symmetry Cu(TSB)L complexes in inversely proportional to the average of bond distances in plane r_m, as well as to the experimental g values obtained from EPR. This fact shows analogy with the concept of tetragonality introduced by Hathaway [15] for complexes of tetragonal symmetry. Generally, the g_z value is most susceptible to shifts in tetragonality [15]. However, in complexes with g–g coupling between canted **g** tensors, where the experimental g_z value is hidden, the value of g_{av} can be taken as a measure of axial bond strength [1,7,8]. For example, in (1-methyl-imidazole)(*N*-salicylidene-*R*,*S*-valinato)copper(II) [1] Cu—O′ = no axial interaction, $r_m = 1.931(2)$ Å, $g_{av} = 2.097$; in the title complex Cu—O′ = 2.590(4) Å) $r_m = 1.936(4)$ Å, $g_{av} = 2.115$ and in (2-methylimidazole)(*N*-salicylidene-glycinato)copper(II) [6] Cu—O′ = 2.481(4) Å, $r_m = 1.961(5)$ Å $g_{av} = 2.126$. Similar results have been obtained by Warda [10].

The observed components $g_1 = 2.217$, $g_2 = 2.069$, $g_3 = 2.060$ of the EPR spectrum of the powdered sample (Fig. 2) give evidence that the experimental g factors result from a coupling of two magnetically non-equivalent Cu(II) complexes related by the glide plane of the monoclinic unit cell. For this case the following equations for experimental cooperative g values hold [6]:

$$g_1^c = \cos^2\gamma g_z + \sin^2\gamma(\cos^2\xi g_y + \sin^2\xi g_x),$$
$$g_2^c = \sin^2\gamma g_z + \cos^2\gamma(\cos^2\xi g_y + \sin^2\xi g_x)$$
$$g_3^c = \sin^2\xi g_y + \cos^2\xi g_x, \qquad (1)$$

where 2γ stands for the canting angle between the normal to equatorial planes of the coordination pyramids and ξ is the rotation angle around the g_z axis in this plane. From these equations the values of canting angle 2γ and molecular g parameters g_z and g_{xy} can be expressed [1,8] as a function of the well known parameter $G = (g_z - g_0)/(g_{xy} - g_0)$;

$$2\gamma = \arccos\{(g_1^c - g_2^c)(G+2)/[(g_1^c + g_2^c - 2g_0)(G-2) + 2(g_3^c - g_0)G]\},$$
$$g_z = [3g_{av}G - 2g_0(G-1)]/(G+2)$$
$$g_{xy} = [3g_{av} + g_0(G-1)]/(G+2) \approx (g_y + g_x)/2 \quad (2)$$

where $g_0 = 2.0023$.

A simple procedure, which is based on the consistency of G parameters for the complexes under investigation, has been proposed [1,8] for estimation of the anisotropy of g_{xy} components of **g** tensor with orthorhombic symmetry. For the range of $G = 4.65 \pm 0.25$, which is reasonable in our case [1,6,7,10], we obtain the following values: $g_z = 2.239 \pm 0.004$, $g_y = 2.060 \pm 0.010$, $g_x = 2.047 \pm 0.008$, $2\gamma = 40.4° \pm 3.4°$.

Looking at the mutual orientation of the magnetically non-equivalent Cu(II) coordination pyramids, we see nearly aligned N—N axes with an angle of 9.86(3)° (Fig. 3). Following to such small canting angle, the molecular $g_y \equiv g_3^c$ value corresponding to the N—N direction is observed rather exactly in the experimental EPR spectrum. On the other hand, the canting angle 2γ between the normals to the basic planes of the misaligned coordination polyhedra amounts to 40.26(3)°, which is in excellent agreement with the 2γ value calculated from EPR spectra. The ordering of the dimeric units of canted pyramids may be described as disturbed-ferrodistortive, where the closest inter-dimer Cu···Cu spacing responsible for

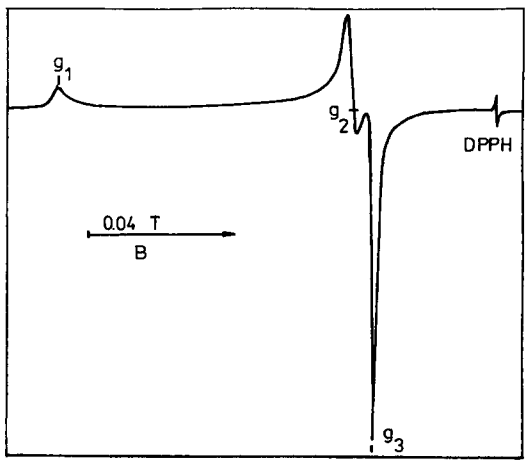

Fig. 2. The 35 GHz EPR powder spectrum of $[Cu_2(sal\text{-}\beta\text{-}ala)_2(Im)_2]$.

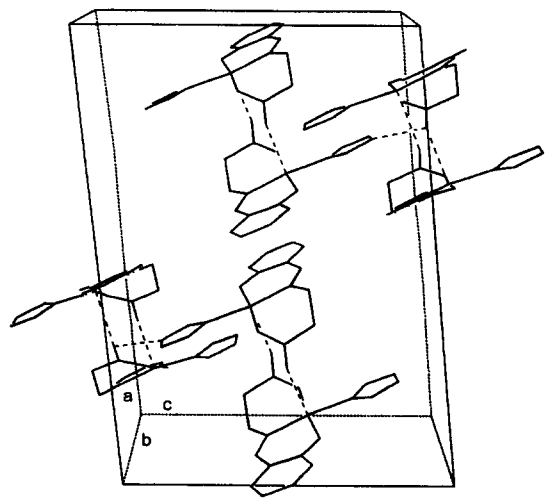

Fig. 3. View of the crystal packing of $[Cu_2(sal\text{-}\beta\text{-}ala)_2(Im)_2]$ centrosymmetric dimers propagated in the unit cell. In the disturbed-ferrodistortive ordering two stacks are related by a glide plane. The parallel orientation of aromatic parts of the ligands indicating π–π interactions is visible. The dashed lines represent the weak Cu—O′ apical interactions and the inter-dimeric hydrogen bonds.

the coupling of misaligned molecular **g** tensors is 7.359(4) Å.

Besides forming the weak apical Cu···O interaction, the carboxylate O3 atom of each complex molecule is also involved in an H bond interaction with the imidazole N3 atom (O···N = 2.748(3) Å) of a molecule related by a screw axis parallel with *b* (Fig. 3). The latter contact connects the dimers into helices going parallel to [0,1,0]. The chains are held together mainly by π–π stacking interactions between the aromatic rings of the Schiff-base ligands. All imidazole planes in the structure are lying parallel, which also contributes to the stabilisation of the crystal structure by π–π interactions.

A remarkable sharpness of all three components of the EPR powder signal suggested a single-crystal investigation. We succeeded in a quite favourable adjustment of the crystal, admitting to see all three main axes of the coupled crystal $\mathbf{g}^c$ tensor (Fig. 4). The diagonalisation of the $\mathbf{g}^2$ matrix obtained from angular measurements yields: $g_1^c = 2.219$, $g_2^c = 2.070$, $g_3^c = 2.059$, which is in excellent agreement with the results obtained from the EPR spectra of the ground sample. The extreme values g_1^c and g_3^c were observed in the plane perpendicular to the needle axis, whereas $g_2^c \equiv g_b$ was measured in both planes parallel to it. Analysing the cooperative **g** tensor in more detail, we have found a complete consistency between the angular spectroscopic EPR behaviour and the results of X-ray structural analysis. As already mentioned above, the N—N axes of two crystallographically non-equivalent complexes are tilted against the *ac** plane, perpendicular to the crystallographic *b* axis, by an angle of $\pm 4.93(3)^\circ$. Corresponding to such a small canting angle, the molecular g_y value is observed almost exactly in the *ac** plane, perpendicularly to the needle axis. On the other hand, the O—O axes of the misaligned complex molecules are strongly canted by an angle of $20.75(3)^\circ$ with respect to the crystallographic *b* axis. This canting, with regard of slight twisting, results in a canting angle $2\gamma = 40.26(3)^\circ$ between the normals to basic planes of coordination polyhedra, which correspond to g_z axes. If we neglect the slight twisting between g_y components, the g–g coupling influences only the g_z and g_x components of the misaligned molecular **g** tensors and the following equations for the experimental cooperative g values hold:

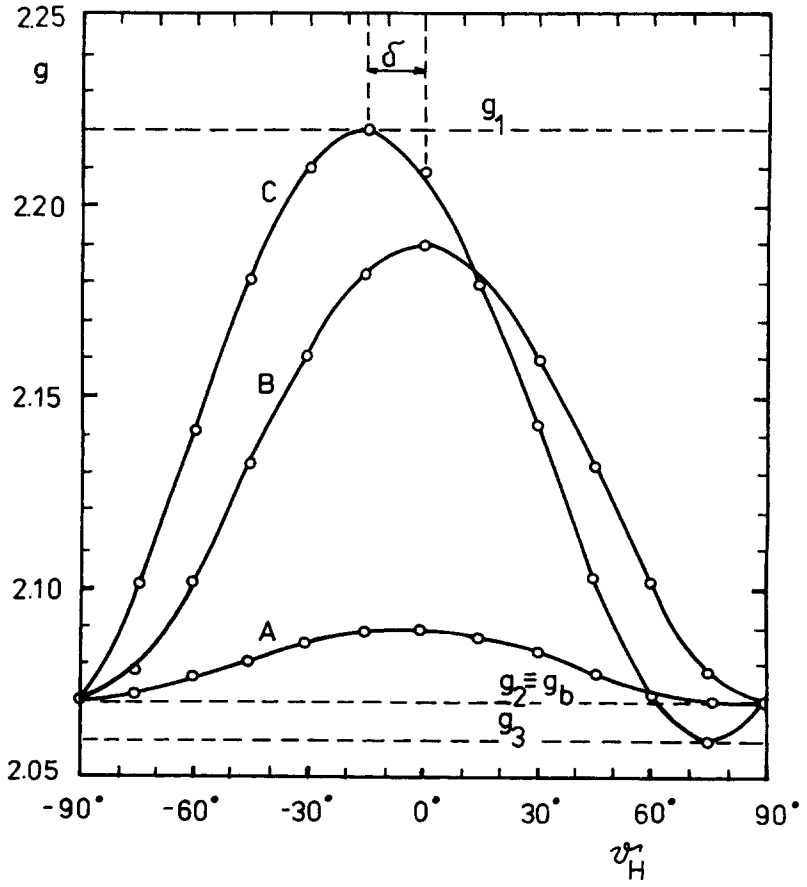

Fig. 4. Angular dependence of the single-crystal EPR spectra of $[Cu_2(sal\text{-}\beta\text{-}ala)_2(Im)_2]$ in three orthogonal planes (curves correspond to least-squares fit of the experimental results). The *C* plane, which is perpendicular to the needless axis, corresponds to (*ac**).

$$g_1^c = \cos^2 \gamma g_z + \sin^2 \gamma g_x$$

$$g_2^c = \sin^2 \gamma g_z + \cos^2 \gamma g_x \quad (3)$$

Using the angle γ obtained from X-ray structural analysis we obtain the values $g_x \equiv g_{OO} = 2.043$, $g_y \equiv g_{NN} = 2.060$, $g_z = 2.240$, which are in complete agreement with the molecular g parameters obtained from the powder EPR spectrum with a help of a simple approximation procedure [1,8], which can be used without any knowledge about the X-ray structure.

Considering the orientation of the g_1^c and g_3^c axes of the $\mathbf{g}^c$ tensor with respect to the roughly rectangular sectional area perpendicular to the crystallographic b axis, we have observed a phase shift by an angle $\delta \approx 17°$ (Fig. 4), which corresponds to the angle of 18.07(3)° between N—N and c^* axis found from X-ray structure analysis. From this finding we see that faces spread by the crystallographic b axis and a vector perpendicular to [010] running through the centres of symmetry of two adjacent misaligned dimers are preferred for the growth of crystals. Perpendicular to these faces we recognise the association of the complex units via π–π interactions between the aromatic systems of the ligands.

CONCLUSIONS

The reaction of [Cu_2(*N*-salicylidene-β-alaninato)$_2$(H_2O)]H_2O with imidazole leads to [Cu_2(*N*-salicylidene-β-alaninato)$_2$(imidazole)$_2$]. In the parent aqua-complex the dimer is realized [12] via double bridging through phenolic oxygens in basal planes (Cu—O = 1.92–2.01 Å) and the intradimeric Cu···Cu distance amounts to 3.03 Å. Due to superexchange interaction of a Cu—O—Cu type, the EPR spectra of this complex indicate [16] antiferromagnetic Cu··Cu coupling with a singlet–triplet separation being 565 cm^{-1}. In the imidazole adduct the neutral ligand is bound in-plane and the formation of dimers is achieved through weak axial Cu—O′ interaction with a length of 2.59 Å via the terminal carboxylic oxygens of the partner molecule. Due to the extended O—C—O bridge system, the intradimeric Cu···Cu spacing reaches 5.29 Å and no antiferromagnetic interaction is indicated by EPR. An analogical triatomic bridge system, however, constituting from NCS^- ambidentate ligands, is realised in [bis{(μ-isothiocyanato-N,S)(N-salicylidene-β-alaninato)}dicuprate(II)] [17] with intradimeric Cu···Cu distance of 5.77 Å.

Axial Cu—O′ interaction of different strength with the neighbouring complex molecule, which extends the square-planar coordination to (4+1), has been frequently observed in Cu(TSB)L adducts [6,10,18]. In Cu(II) complexes with tridentate Schiff bases having fused six- and five-membered chelate rings, the interaction with adjacent phenolic oxygen leads to dimers. On the other hand, zig-zag chains are formed by bonding to neighbouring terminal carboxylic oxygen. Although in the first case the intradimeric Cu···Cu spacing amounts only to 3.2–3.3 Å, no conditions for superexchange of antiferromagnetic type are given. The mutual perpendicular orientation of the bridging [Cu_2O_2'] and basal [CuN_2O_2] planes and the weak apical Cu—O′ bond, which is involved in the Cu—O′—Cu bridge do not allow an effective transfer of electron density between Cu(II) ions in dimers. In the carboxylato-bridged chains, the lowest Cu···Cu distances in the structure are in the range of 5.2–6.9 Å and they can be found between ferrodistortively ordered complex units, which are associated only by π–π interaction. The results presented here show that with tridentate *N*-salicylidene-β-alaninato Schiff base, which contains two conjugated six-membered chelate rings, the steric factors cause the formation of another type of dimers, where the Cu(II) ions are connected through triatomic O—C—O bridges from the carboxyl group of the partner molecule. The above described dimerisation and polymerisation are induced by cooperative ordering effects in solid state. Therefore, after dissolving the crystals, only monomeric complex units are present in diluted solution.

In [Cu_2(*N*-salicylidene-β-alaninato)$_2$(imidazole)$_2$] stacks of dimers, which are related by a screw axis going parallel to b, are propagated in the crystal structure. In such a way two stacks are ordered in a disturbed-ferrodistortive way. Since the interdimeric distance between misaligned coordination polyhedra amounts to 7.36 Å, weak coupling operates between canted **g** tensors and the experimental EPR spectra show cooperative character. From single-crystal EPR spectra, but also from powder EPR pattern, the orthorhombic molecular g components and the canting angle 2γ between the misaligned coordination polyhedra, which are in excellent agreement with the X-ray structure, were calculated.

(Received 20 June 1997; accepted 5 August 1997)

Abstract—The complexes $CuL_2X_2 \cdot nH_2O$ (L = *trans*-1,2-diaminocyclohexane; $n = 2$ when X is Cl and $n = 0$ when X is NO_3) have been synthesized. The complexes $[CuL_2(H_2O)_2]Cl_2$ (**1**) and $[CuL_2(NO_3)_2]$ (**2**) have been characterized by single crystal structural analyses and their thermochromism was studied in the solid state. Single crystal X-ray structure analysis of **1** and **2** shows that in both complexes copper ion possesses distorted (4+2) octahedral geometry with N_4O_2 chromophore. Complex **1** shows time-dependent reversible discontinuous thermochromism whereas, **2** shows reversible continuous thermochromism in the solid state. The discontinuous thermochromism in **1**, is due to the different ligand field strength between H_2O and Cl, and is associated with deaquation–anation reaction. The IR and electronic spectra of **2** vary with temperature, indicating reversible continuous thermochromism arising from axial interaction between semi-coordinated nitrate ions and CuN_4 plane. © 1998 Elsevier Science Ltd. Keywords: copper(II) complexes; *trans*-1,2-diaminocyclohexane; syntheses; single crystal structure; thermochromism; TG-DTA.

Thermochromism which involves the change in color of a transition metal complex under thermal excitation is a subject of interest among coordination chemists. This occurs in solids [1] as well as in liquids [2]. The solid state thermochromism can be distinguished under two headings: discontinuous thermochromism, where the color change takes place suddenly and is associated with a first order structural phase transformation, and continuous thermochromism, where the color change is due to a gradual shift and/or broadening of the visible absorption bands upon stress with an increased population of the ground state vibrational levels. Thermochromic behaviour in copper(II) complexes with *N,N*-substituted ethylenediamines has been reported [3-9]. A discontinuous thermochromism in copper(II) halide (chloride and bromide) salts and copper(II) nitrate complexes of 2,2-dimethylpropane-1,3-diamine (dmpd) are extensively studied by Willett *et al.* [10–14]. The discontinuous thermochromism of copper(II) nitrate complexes of *N,N'*-dimethylethane-1,2-diamine is known [15]. A continuous thermochromism was reported for a series of $[Cu(dmpd)_2X_2]$ (X = Cl, Br and ClO_4) complexes by Pellacani *et al.* [16]. In transition metal complexes, thermochromic phase transitions are associated with a change in coordination geometry or in the effective ligand field strength of a coordinating ligand. The solid state thermochromic complexes are very important owing to their applicability as temperature sensors [17].

1,2-Diaminocyclohexane exists in two isomeric forms: *cis*- and *trans*- forms. *Trans*-isomer is more stable than *cis*- and probably because of this it has been well studied [18–24]. In this paper we report the preparation, characterization and thermochromic properties of *trans*-1,2-diaminocyclohexane complexes of CuX_2 (X = Cl and NO_3).

EXPERIMENTAL

Materials

High-purity (99%) *trans*-1,2-diaminocyclohexane (L) was purchased from Aldrich Chemical Company Inc. and used as received. All other chemicals used were of G.R. grade (Merck or Aldrich).

Physical measurements

The thermal analysis (TG–DTA) was carried out on a Seiko TG/DTA 300 simultaneous Thermo-Gravimetric/Differential Thermal Analyzer in a dynamic atmosphere of argon (100 ml min^{-1}). The sample was heated in an Al crucible at a rate of 10°C min^{-1} with an empty Al crucible as a reference. The enthalpy change of dehydration was calculated using a Seiko DSC 200 Differential Scanning Calorimeter with indium metal as the calibrant (rate of heating 10°C min^{-1}) in a dynamic atmosphere of argon (40 ml min^{-1}). The instruments used for recording the infrared (KBr discs and Nujol mulls) and electronic spectra (Nujol mulls) were BOMEM (Hartmann and Braun, MB-Series) and HITACHI (U-3300) spectrophotometer, respectively. The magnetic susceptibility and elemental analyses were performed on an EG and G PAR 155 Vibrating Sample magnetometer and a Heraeus CHN-O-Rapid instrument, respectively. For X-ray structure determination a Siemens R3m/V diffractometer was used.

Preparation of $[CuL_2(H_2O)_2]Cl_2$ (**1**)

$CuCl_2 \cdot 2H_2O$ (1 mmol) was dissolved in ethanol (10 cm^3). *Trans*-1,2-diaminocyclohexane (2 mmol) was then added to a $CuCl_2$ solution with stirring. The resulting pink solution on slow evaporation in a desiccator yielded the desired pink crystalline complex. The crystals were separated, washed with ethanol and dried in a desiccator. Recrystallization from hot water yielded pink crystals suitable for X-ray analysis. Found: C, 35.91; H, 8.10; N, 13.97. Calc. for $C_{12}H_{32}Cl_2N_4O_2Cu$ (**1**): C, 36.09; H, 8.08; N, 14.03%. μ_{eff} = 1.81 B.M.,[a] λ_{max} (Nujol) = 562 nm.

Preparation of $[CuL_2(NO_3)_2]$ (**2**)

$Cu(NO_3)_2 \cdot 3H_2O$ (1 mmol) was dissolved in methanol (10 cm^3). *Trans*-1,2-diaminocyclohexane (2 mmol) was then added to the above solution with stirring. The resulting pink solution was kept in a desiccator. After a few days fine pink crystals were separated out, filtered, washed with ethanol and dried in a desiccator. The recrystallization was from water yielding pink crystals suitable for X-ray analysis. Found: C, 34.53; H, 6.87; N, 20.12. Calc. for $C_{12}H_{28}N_6O_6Cu$ (**2**): C, 34.62; H, 6.78; N, 20.19%. μ_{eff} = 1.83 B.M.;[a] λ_{max} (Nujol) = 526 nm.

X-ray diffraction structural study

A crystal of dimensions 0.05 × 0.15 × 0.32 mm for **1** (0.05 × 0.12 × 0.22 for **2**) was selected for indexing and intensity data collection on a Siemens SMART-CCD diffractometer equipped with a normal focus, 3 kw sealed tube X-ray source. Intensity data were collected in 2082 (1271 for **2**) frames with increasing ω (width 0.3°/frame). Unit cell dimensions were determined by a least-squares fit of 3925 (3205 for **2**) reflections with $5 < 2\theta < 50°$. Absorption correction was based on 1671 (4301 for **2**) symmetry-equivalent reflections using the SHELXTL-PC program package ($T_{min,max}$ = 0.474, 0.928 and 0.487, 0.928 for **2**). On the basis of systematic absences, statistics of intensity distribution, and successful solution and refinement of the structure, the space group was determined to $P\bar{1}$ (No. 2) (and Pb_{ca} for **2** (No. 61)). Crystallographic data are summarized in Table 1.

[a] Non-S.I. Unit employed: B.M. 9.27 × 10^{-24} Am^2.

RESULTS AND DISCUSSION

Thermal analyses and thermochromism

The simultaneous thermogravimetric/differential thermal analysis (TG-DTA) of complexes **1** and **2** are shown in Figs 1 and 2, respectively. for complex **1**, $[CuL_2(H_2O)_2]Cl_2$ the weight loss observes in the TG curve in the temperature region (65–110°C) corresponds to the liberation of two molecules of H_2O. The DTA curve shows that the dehydration proceeds endothermically. The enthalpy change for this transformation was calculated from DSC curve (ΔH = 128.69 kJ mol^{-1}). The dehydrated species **1a**, CuL_2Cl_2 is stable in desiccator and can be stored for a long time. However, the species **1a**, rehydrates on standing in a humid atmosphere. On dehydration the color of the complex changes from pink to blue-violet. This color change is due to deaquation–anation reaction and is followed by the change of strength of the coordinating ligands. Thereafter an endothermic peak appears in the range 240–275°C where the TG curve changes quite sharply due to decomposition of *bis*-complex to *mono*-species and finally to metal salt. On the other hand complex **2**, changes its color from pink to blue-violet continuously and finally starts to decompose at 300°C. The thermal stability of the *bis*-nitro complex is more than the corresponding chloro species i.e. $CuL_2(NO_3)_2 > CuL_2Cl_2$.

Structure of $[CuL_2(H_2O)_2]Cl_2$ (**1**)

Figure 3 shows an ORTEP view and atom-numbering scheme of the dication $[CuL_2(H_2O)_2]^{2+}$ together with two chlorite ions and its packing arrangement is shown in Fig. 4. Selected atomic distances and bond angles are listed in Table 2. The copper ion in the complex possesses distorted (4+2) octahedral geometry having N_4O_2 chromophore. The two oxygen atoms of weakly coordinated water molecules in the *trans* position, Cu—O = 2.590(2) Å. Two 5-membered chelate rings are arranged in such a way

Cu—N(2) = 84.8(2)°. Two 5-membered chelate rings are arranged in such a way that 6-membered cyclohexane rings are in *trans*-chair–chair conformations. The weak coordinations, Cu—O(2) = 2.620(3) Å, of the two symmetry related oxygen atoms [O(2) and O(2a)] of the NO_3^- ion complete a distorted octahedron. O(3) of the nitrate is hydrogen bonded to one of the amino nitrogen atoms N(1) of the cation: O(3)···N(1) 3.028, O(3)···H(N1) 2.155 Å; N(1)—H(N1)—(O3) 163.34°. Similar type of hydrogen bonding between NO_3^- and nitrogen atoms were reported for copper(II) nitrate complexes of ligands 1,5-diazacyclooctane [25] and *N,N'*-dimethylethane-1,2-diamine [15]. The nitrate ion is a planar one. The N—O bond distances are almost equal (average being 1.236(7) Å).

Infrared and electronic spectra

The IR spectra of the complexes $[CuL_2(H_2O)_2]Cl_2$ (**1**) and $[CuL_2(NO_3)_2]$ (**2**) were taken at three stages, i.e. at room temperature, after heating at 110 and 140°C. We have some limitation for recording the spectra at higher temperature. After heating, the sample was treated with nujol and the spectra were recorded immediately at room temperature. Therefore, we have to consider that there is no change of the sample after addition of nujol. The IR spectra of complexes **1** and **1a,** reveal that amine are chelated and almost no significant change is observed in other variation bands, except for omission of the band for H_2O, after dehydration. To determine the coordination mode of the NO_3^- ions, we measured the combination band of the ν_1 symmetric stretching which appears in the region 1700–1800 cm^{-1} in the metallic complexes [26–28]. Here the IR spectra of the complexes do not differ much. Only the combination band of the NO_3^- appearing at 1748 cm^{-1}, broadens at a higher temperature and a small change in the relative intensities of the bands is observed.

The color change from pink **1** to blue-violet **1a**

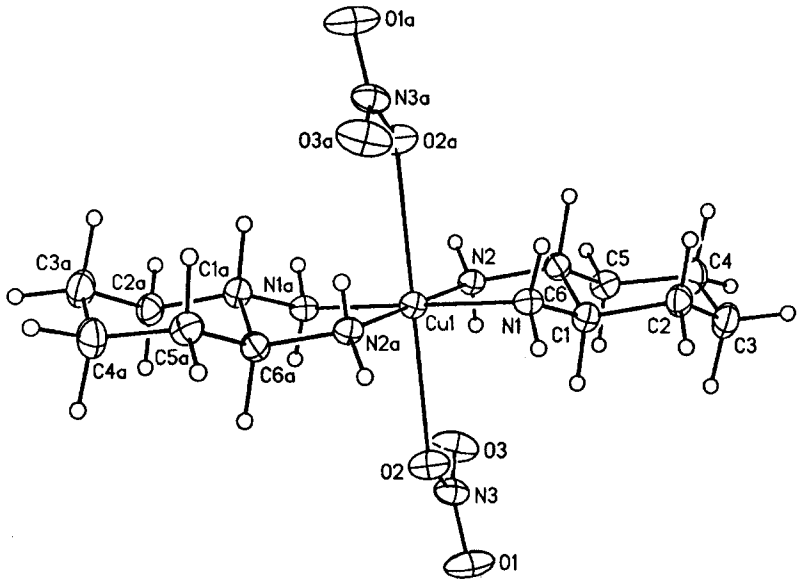

Fig. 5. ORTEP-plot of $[CuL_2(NO_3)_2]$ (**2**) with atom numbering scheme.

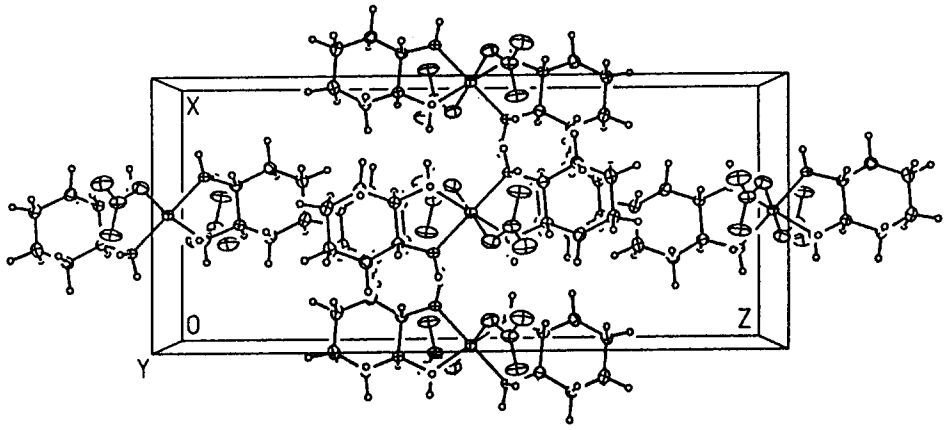

Fig. 6. Packing arrangement for $[CuL_2(NO_3)_2]$ (**2**).

associated with time dependent reversible thermochromism can be visually observed. The visible absorption spectra of the copper(II) complexes recorded at room temperature show a broad band at 562, 555 and 526 nm (Fig. 7) for **1**, **1a** and **2**, respectively. However, the absorption band becomes broader and λ_{max} is shifted to 542 nm for the species **2**, at higher temperature. Here also we have the same limitation as for the IR spectra at higher temperatures.

CONCLUSIONS

Complex **1** shows discontinuous thermochromism whereas **2** shows continuous thermochromism. In the former case the thermochromism is due to the change in ligand field strength of the coordinating H_2O and Cl. Whereas, in the latter case probably thermochromism is due to a temperature-dependent axial interaction between the anion and the CuN_4 plane, with a more square form being favored at a higher temperature [4].

(Received 17 April 1997; accepted 4 August 1997)

Abstract—$Cp_2SmCl(THF)$ reacts with 0.5 equivalent disodium salts of *trans*-(±)-*N*,*N*′-bis(salicylidene)-1,2-cyclohexanediamine give the title complex $[(\eta^5\text{-}C_5H_5)Sm(\mu\text{-}OC_{20}H_{20}N_2O)]_2(\mu\text{-}THF)(THF)_2$ (**1**). X-ray crystal determination shows that the molecule is a dimer, in which two $(\eta^5\text{-}C_5H_5)Sm(\mu\text{-}OC_{20}H_{20}N_2O)$ units are connected via a THF oxygen and two bridging oxygen atoms of Schiff base ligands. The average Sm—C distance is 2.78(7) Å, while those of Sm—O (bridging THF oxygen) and Schiff base oxygens are 2.79(3) and 2.43(4) Å, respectively. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: Schiff base ligand; dimer; crystal structure.

There is a rapidly growing interest in chiral lanthanide complexes with optically active alcohols, phenols and chiral substituted cyclopentadiene as ligands, due to their excellent catalytic properties in polymerization and asymmetric synthesis [1–11]. Jacobsen *et al.* initially utilised chiral Schiff base manganese complexes based on optically active 1,2-diamines as catalysts for epoxidation of olefins [12], and Meunier *et al.* reported the synthesis, structure and catalytic activity of chiral Schiff base complexes and transition metal complexes by using ligands derived from 1,2-cyclohexanediamine or 2,2′-diamino-1,1′-binaphthyl [13]. However, the Schiff base complex of lanthanides, synthesising in non-aqueous conditions, are rare [14]. We are interested in the synthesis and catalytic properties of chiral lanthanide Schiff base complexes and isolated the first chiral bis(cyclopentadienyl) neodymium Schiff base complex with an optically active bidentate ligand [15] and the first mono(cyclopentadienyl)lanthanide complex bearing a C_2-symmetric Schiff base ligand [16] by the reaction of $Cp_3Ln(THF)$ with racemic *trans*-(±)-*N*,*N*′-bis(salicylidene)-1,2-cyclohexanediamine (**2**) [17]. In this paper, we wish to report a novel route to synthesise the types of complex. The crystal structure of $[(\eta^5\text{-}C_5H_5)Sm(\mu\text{-}OC_{20}H_{20}N_2O)]_2(\mu\text{-}THF)(THF)_2$ (**1**) will also be discussed.

EXPERIMENTAL

All reactions were carried out under an inert atmosphere of high-purity argon on a vacuum line. Transfer and handling of the complexes were facilitated by the use of Schlenk techniques. Tetrahydrofuran was refluxed and distilled over the sodium ketyl of benzophenone immediately before use. Anhydrous $SmCl_3$ and $Cp_2SmCl(THF)$ were prepared according to the literature [18–19]. *Trans*-(±)-*N*,*N*′-bis(salicylidene)-1,2-cyclohexanediamine was prepared by the reaction of racemic *trans*-1,2-cyclohexanediamine with salicylaldehyde in the boiling toluene by azeotropic dis-

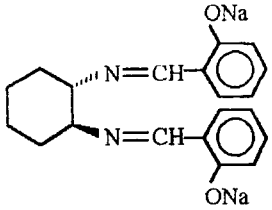
Trans-(±)-N,N'-Bis(salicylidene)-1,2-cyclohexanediamine(2)



Disodium salt of **2**

tillation of water, the structure of which has been reported elsewhere [17]. Disodium salts of **2** were prepared by the reaction of **2** with NaH in THF. The analysis for Sm was accomplished using a literature method [20] with disodium EDTA.

Synthesis of $[(\eta^5\text{-}C_5H_5)Sm(\mu\text{-}OC_{20}H_{20}N_2O)]_2$ (μ-THF) $(THF)_2$ (**1**)

To a stirring 20 cm^3 THF solution of $Cp_2SmCl(THF)$ (2.57 mmol) was added disodium salts of *trans*-(±)-*N,N'*-bis(salicylidene)-1,2-cyclohexanediamine (**2**) (1.26 mmol) in THF (15 cm^3). After stirring for 16 h at room temperature, the reaction mixture was centrifuged to remove the solid materials and then concentrated under reduced pressure to ca. 15 cm^3 and then 20 cm^3 toluene was added. The resulting mixture was cooled to ca. −18°C and pale-yellow shuttle-shaped crystals were formed several weeks later (yield 12%). Found: Sm, 22.98. Calc. for $C_{62}H_{74}N_4O_7Sm_2$: Sm, 23.35%.

X-ray crystal structure determination of **1**

Suitable crystals of the title complex were sealed under argon in thin-walled glass capillaries for X-ray structure analysis. Unit cell and intensity data were obtained using standard procedures on a Siemens P4 four-circle diffractometer. The intensities were corrected for *Lp* effect and empirical absorptions. Experimental details are given in Table 1. The Sm atom position was located by the Patterson method and other non-hydrogen atoms by Fourier-difference tech-

niques. All the positional and anisotropic thermal parameters for non-hydrogen atoms were refined by the full-matrix least-squares techniques. All hydrogen atoms were introduced in the calculated positions with a C—H bond distance of 0.96 Å. The calculations were performed on a Siemens Nixdorf PCD 4H computer with Siemens SHELXTL-Plus programs. Lists of final coordinates and thermal parameters, bond lengths and angles have been sent to the Editor as supplementary materials.

RESULTS AND DISCUSSION

It is now a general way [21] to synthesise organolanthanocene alkoxides or phenoxides by the reaction of Cp_3Ln moiety and organic acids stronger than C_5H_6 with the elimination of the latter. It is interesting to find that $Cp_3Yb(THF)$ reacts with **2** leading to the formation of $[(\eta^5\text{-}C_5H_5)Yb(\mu\text{-}OC_{20}H_{20}N_2O)]_2(\mu\text{-THF})(THF)$ (**3**) by the elimination of two C_5H_6 molecules, and which up to now, has been assigned as the only X-ray structurally determined example of mono (cyclopentadienyl)lanthanide phenoxide, by using the exchange reaction between Cp_3Ln and protic reagents. The X-ray determination of **3** indicates that two nitrogen atoms of the Schiff base can bond to the lanthanide center through their lone electron pairs. During the process of preparation of dinuclear bis(cyclopentadienyl)-samarium complex with one Schiff base as ligand, the title complex was isolated instead. We therefore postulated that the title complex may be formed as the following reaction:

$$2Cp_2SmCl(THF) + 2NaOC_{20}H_{20}N_2ONa \rightarrow [CpSm(\mu\text{-}OC_{20}H_{20}N_2O)]_2(\mu\text{-THF})(THF)_2 + 2CpNa + 2NaCl \quad (1)$$

Complex **1** is sensitive to air and moisture, but thermally stable and is only decomposed at $>226°C$. It is difficult to dissolve in aromatic solvents and only slightly soluble in THF, which may be the main reason for relative low yield. The molecular structure and atom numbering scheme of **1** is shown in Fig. 1. The selected bond lengths and bond angles are listed in Table 2. Complex **1** is a dimer composed of two $(\eta^5\text{-}C_5H_5)Sm(\mu\text{-}OC_{20}H_{20}N_2O)$ units connected via a bridging THF. Two oxygen atoms of the Schiff base ligands, and two free THF molecules are also found in the crystal. The 9-coordinated samarium atoms are each bonded to two nitrogen atoms and two oxygens of Schiff base, one Cp ring, one bridging oxygen from another Schiff base and oxygen from bridging THF to form a distorted pentagonal bipyramidal geometry with two nitrogen, two oxygens of Schiff base, one oxygen from bridging THF in pentagonal plane, while the centroid of Cp ring and bridging oxygen from

another Schiff base in the apical sites. It is interesting to find that the shadow of this complex looks like a butterfly. The Sm-bond distances range from 2.69(7)–2.86(7) Å with an average 2.78(7) Å, which is ca. 0.08 Å longer than that of **3** (2.70 Å). The Sm—O bond lengths change from 2.29(4) to 2.63(3) Å, with a specific example, Sm(2)—O(4) (2.95(3) Å), which is longer than that of Sm(1)—O(4) (2.63(3) Å), this indicates that the interaction of Sm(2) and O(4) is very weak. Why is the distance of Sm(2)—O(4) so long? This may be explained by the requirement of coordination saturation of the central atom.

However, the final *R* values and the esds for this complex are relatively higher, which is due to difficulty in obtaining fine crystals. Meanwhile many temperature factors for the complex are larger, which suggests that there might be some disorder caused by the use of a racemic ligand. Synthesis and catalytic properties of bis(cyclopentadienyl) or mono(cyclopentadienyl)lanthanide alkoxides or phenoxides with chiral C_2-symmetric chelating ligands are now under progress in this laboratory.

Tin(IV) and organotin(IV) complexes containing mono or bidentate N-donor ligands—IV.† 2-Methyl-, 2-isopropyl- and 4-methyl-imidazole derivatives: synthesis, characterization and behaviour in solution

Claudio Pettinari*, Maura Pellei, Fabio Marchetti, Carlo Santini and Michele Miliani

Dipartimento di Scienze Chimiche, Università degli Studi, via S. Agostino 1, 62032 Camerino, Macerata, Italy

(Received 5 June 1997; accepted 29 July 1997)

Abstract—The interaction between 4-methyl-, 2-methyl- and 2-isopropyl-imidazole, L^1, L^2 and L^3 respectively (L in general), and several tin(IV) and organotin(IV) acceptors in diethyl ether, acetonitrile, dichloromethane or chloroform, gives 1:1 $[(L^1)(C_6H_5)_3SnCl]\cdot 1/3H_2O$, $[(L^3)(C_6H_5)_3SnCl]$, $[(L^3)(CH_3)_3SnCl]$ and $[(L^3)(C_6H_5)_2SnCl_2]\cdot(H_2O)$, 2:1 $[(L)_2R_nSnX_{4-n}]\cdot zH_2O$ (L = L^1, R = Me, n = 1, 2 or 3, X = Cl, z = 0 or 6; L = L^1, R = Me, n = 2, X = Br or I, z = 0; L = L^1, R = Et, n = 2, X = Cl or Br, z = 0; L = L^1, R = Bu^n, n = 2 or 3, X = Cl or Br, z = 0; L = L^1, R = Ph, n = 2, X = Cl, z = 1; L = L^2, R = Me, n = 2 or 3, X = Cl, z = 0 or 1; L = L^2, R = Bu^n or Ph, n = 1, X = Cl, z = 2 or 3; L = L^3, R = Me, n = 2, z = 1) and 3:1 $(L^1)_3RSnCl_3$ (R = Bu^n or Ph) adducts. The derivative $[(L^1)_2(CH_3)_2SnCl_2]$ reacts with $AgNO_3$ and $NaBPh_4$ in ethanol and diethyl ether giving the complexes $[(L^1)_2(CH_3)_2Sn(NO_3)_2]\cdot H_2O$ and $[(L^1)_4(CH_3)_2Sn](BPh_4)_2$ respectively. The compounds were characterized by analytical and spectral data. The behavior in solution was investigated by conductivity, molecular weight determinations, ^1H, ^{119}Sn and ROESY NMR experiments. The triorganotin(IV) derivatives dissociate in chloroform and in acetone solution, the diorganotin(IV) derivatives dissociate only partly and the monoorganotin(IV) complexes probably retain the hexacoordinate configuration. The derivatives $[(L^1)_2(CH_3)_2SnX_2]$ (X = Cl or Br) react with 1,10-phenanthroline (Phen), yielding immediately the chelate adducts $[(Phen)(CH_3)_2SnX_2]$, upon complete displacement of the azole ligand, whereas the less basic 2-benzoylpyridine and the P-donors monodentate PR_3 (R = phenyl, benzyl or cyclohexyl) or bidentate $[PPh_2CH_2]_2$, are not able to displace the imidazole from the tin center. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: tin(IV) complexes; organotin(IV) complexes; imidazole.

Heavy metals such as platinum, gold, ruthenium, rhodium, iridium, palladium, rhenium, titanium and tin can be the source of biologically active derivatives and occasionally became tools in chemotherapy against different kind of tumors in humans [1]. Since 1969, following the discovery of the antitumor activity of platinum complexes [2] it was tempting to study organotin(IV) compounds as possible candidates for antitumor agents and to identify compounds containing active antitumor organotin(IV) moieties $R_nSn^{(4-n)+}$ by antileukemia screening.

In discussing structure/activity relationships for tin(IV) and organotin(IV) derivatives $[(L)_xR_nSnX_{4-n}]$ three primary factors are involved: the nature of the organic group R, of the halide or pseudohalide X, and of the donor ligand. Examination of the structural data of tin(IV) compounds containing nitrogen-donor tested for antitumor activity revealed that active tin complexes had average tin–nitrogen bond lengths >2.39 Å, whereas inactive complexes had tin–nitro-

* To whom correspondence should be addressed.
† Part III is Ref. [7].

gen bonds <2.39 Å, which implies that a predissociation of the ligand may be an important step in the mode of action of these tin complexes [3], while the coordinated ligand may favor the transport of the active species to the site of action into cells, where they are released by hydrolysis.

A consideration of the published screening data for all the tin(IV) derivatives has revealed that many diorganotin(IV) compounds exhibit higher antitumor activity than the corresponding mono-, tri- and tetraorganotin(IV) or the inorganic tin(IV) chemicals, while, within the diorganotin(IV) class, the highest activity was given by the diethyl- and diphenyl-tin derivatives [4].

Now we are trying to extend our previous reports about the interaction of 1-benzylimidazole [5] (L^4), 4-phenylimidazole [6] (L^5) and 1-methylimidazole [7] (L^6) (Fig. 1) with several R_nSnX_{4-n} acceptors to a systematic study of tin(IV) and organotin(IV) complexes of imidazole.

We report here on the synthesis, spectroscopic characterization (IR and NMR data) and behavior in solution (conductivity and molecular weight measurements) of new adducts between R_nSnX_{4-n} (R = Me, Et, Bu^n and Ph; n = 1, 2 or 3; X = Cl, Br, I, NO_3 and BPh_4) acceptors and 4-methyl- (L^1), 2-methyl- (L^2) and 2-isopropyl-imidazole (L^3) donors (Fig. 1).

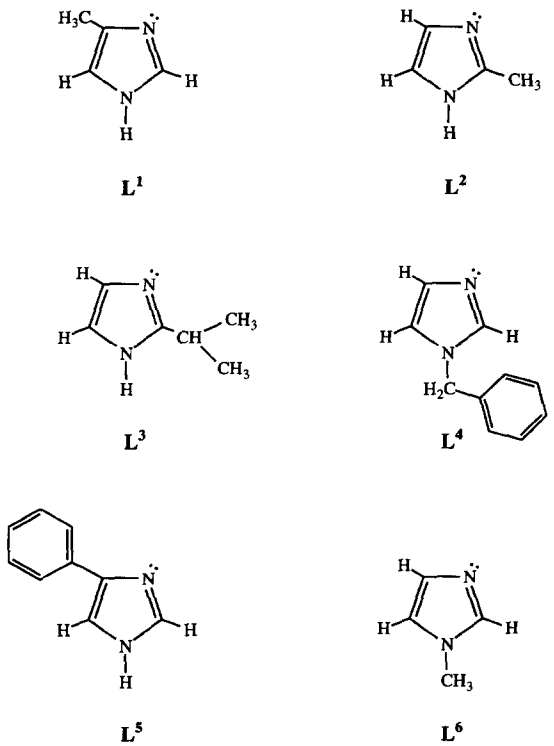

Fig. 1. Structure of the imidazole-type donors employed in the interaction with R_nSnX_{4-n} acceptors.

EXPERIMENTAL

The organotin(IV) halides were purchased from Alfa (Karlsruhe) and Aldrich (Milwaukee) and used as received. The ligands 4-methyl- (L^1), 2-methyl- (L^2) and 2-isopropyl-imidazole (L^3) were obtained from Aldrich and were crystallized from diethyl ether/petroleum ether (1 : 2).

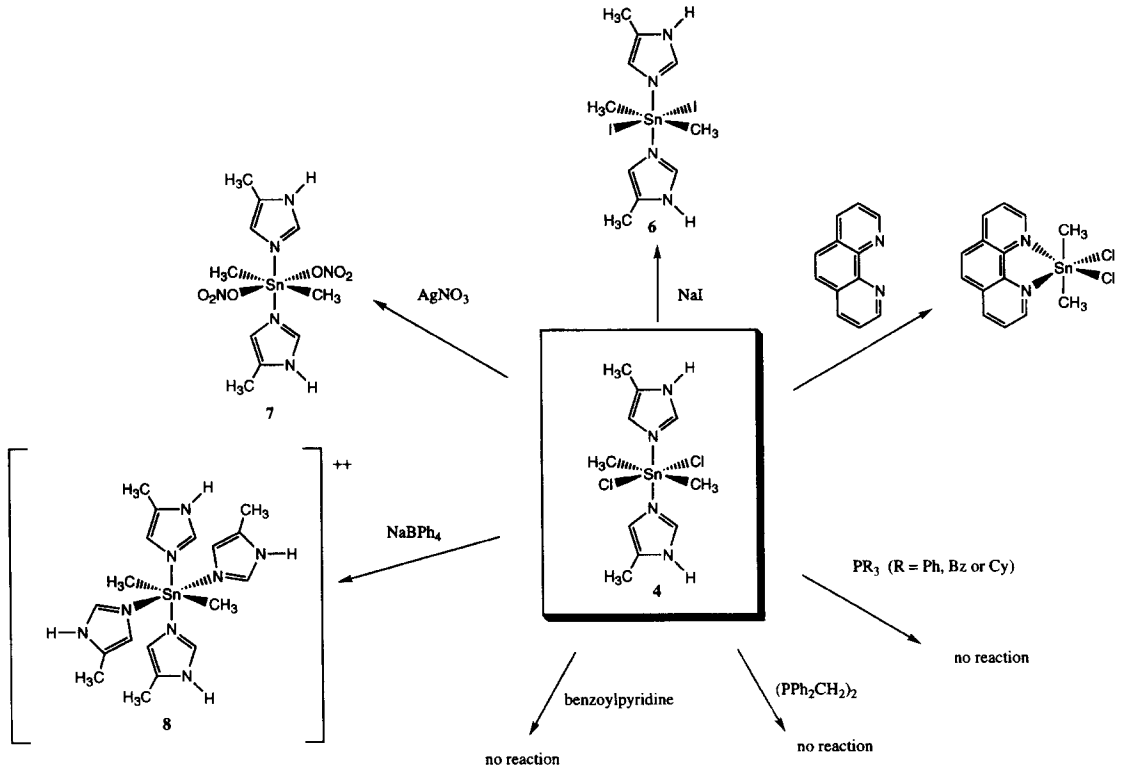
The samples for microanalysis were dried *in vacuo* to constant weight (20°C, ca 0.1 Torr). Elemental analyses (C, H, N) were performed in house with a Carlo-Erba model 1106 instrument. IR spectra were recorded from 4000 to 100 cm^{-1} with a Perkin-Elmer System 2000 FT-IR instrument. ^1H and ^{119}Sn NMR spectra were recorded on a VXR-300 Varian spectrometer operating at room temperature (300 MHz for ^1H and 111.9 MHz for ^{119}Sn). The ROESY experiment was performed in accordance with procedure reported in literature [8] on a 7 mg/ml solution of compound **8** $[(L^1)_4(CH_3)_2Sn](BPh_4)_2$ in $CDCl_3$ at 25°C: mixing time = 300 msec, acquisition time = 0.5 s, 1 K (1024) data point. Melting points were taken on an IA 8100 Electrothermal instrument. The electrical conductance of the solutions was measured with a Crison CDTM 522 conductimeter at room temperature. The osmometric measurements were carried out at 40° over a range of concentrations with a Knauer KNA0280 vapor pressure osmometer calibrated with benzil. The solvent was Baker Analyzed Spectrophotometric grade chloroform. The results were reproducible to ±2%.

Reagents

Preparation of [bis(4-methylmidazole)trimethyltin (IV)] chloro, **1**. To a stirred refrigerated (0°C) diethyl ether solution (50 cm^3) of L^1 (1.0 g, 12.2 mmol), $(CH_3)_3SnCl$ (606 mg, 3.0 mmol) was added under N_2 stream. The mixture was stored at 0°C and stirred for 1 h. The colorless residue obtained was crystallized twice from diethyl ether to yield the analytical sample **1**. Compound **3** was obtained similarly.

Preparation of [bis(4-methylmidazole)tributyltin (IV)]chloro, **2**. To a stirred refrigerated (0°C) diethyl ether solution (50 cm^3) of L^1 (1.0 g, 12.2 mmol), $(C_4H_9)_3SnCl$ (1.0 g, 3.0 mmol) was added under N_2 stream. The mixture was stored at 0°C and stirred for 12 h. The solution was stored in a freezer overnight. After addition of petroleum ether (ca 20 cm^3) an oil was formed, which was separated from the solution. The oily residue was washed with diethyl ether/petroleum ether 1 : 1 (3 × 20 cm^3) and shown to be compound **2**.

Preparation of [bis(4-methylimidazole)dimethyldichlorotin(IV)], **4**. To a stirred diethyl ether solution (100 cm^3) of L^1 (1.0 g, 12.2 mmol), $(CH_3)_2SnCl_2$ (670 mg, 3.0 mmol) was added at room temperature. A colorless precipitate was formed immediately, which was filtered off after 10 h, washed with diethyl ether



Scheme

and crystallized twice from dichloromethane and shown to be compound **4**. Compounds **5**, **9–13**, **15** and **16** were obtained similarly.

Preparation of [*bis*(4-*methylimidazole*)*dimethyldiiodotin*(*IV*)], **6**. A dry ethanol solution (100 cm^3) of compound **4** (576 mg, 1.5 mmol) was introduced into a 250 cm^3 round-bottomed flask fitted with a condenser. Sodium iodide (3.6 g, 24.0 mmol) was then added. The mixture was heated at reflux, under N_2 stream, with stirring for 10 days. It was then allowed to cool and the solvent was removed with a rotary evaporator. CH_2Cl_2 (50 cm^3) was then added, the suspension was filtered and the organic layer was dried on Na_2SO_4. It was then filtered and concentrated under reduced pressure. Petroleum ether (30 cm^3) was then added; the solution was left in the freezer for 1 day. A red-yellow precipitate was formed which was filtered off, washed with petroleum ether/Et_2O and crystallized twice from CH_2Cl_2/petroleum ether (1 : 2) to yield the analytical sample **6**.

Preparation of [*bis*(4-*methylimidazole*)*dimethyltin*(*IV*)*dinitrate*], **7**. A dry ethanol solution (100 cm^3) of compound **4** (500 mg, 1.3 mmol) was introduced into a 250 cm^3 round-bottomed flask fitted with a condenser. Silver nitrate (674 mg, 3.9 mmol) was then added. The mixture was heated at reflux, under N_2 stream, with stirring for 2 days. The pale-rose solution was then allowed to cool and the solvent was removed with a rotary evaporator. CH_2Cl_2 (50 cm^3) was added, the suspension was filtered and the organic layer was dried on Na_2SO_4. It was then filtered and concentrated under reduced pressure. Et_2O (30 cm^3) was then added. A colorless precipitate was formed which was filtered off, washed with diethyl ether and shown to be compound $(CH_3)_2Sn(NO_3)_2$. A diethyl ether solution of L^1 (250 mg, 3.0 mmol) was again added. The colorless precipitate obtained was filtered off, washed with diethyl ether and shown to be compound **7**.

Preparation of [*tetrakis*(4-*methylimidazole*)*dimethyltin*(*IV*)]*di*(*tetraphenylborate*), **8**. A dry ethanol solution (100 cm^3) of $(CH_3)_2SnCl_2$ (659 mg, 3.0 mmol) was introduced into a 250 cm^3 round-bottomed flask fitted with a condenser. $NaBPh_4$ (4.1 g, 12.0 mmol) was then added. The mixture was heated at reflux, under N_2 stream, with stirring for 1 day. It was then allowed to cool and the solvent was removed with a rotary evaporator. CH_2Cl_2 (50 cm^3) was then added, the suspension was filtered and the organic layer was dried on Na_2SO_4. It was then filtered and concentrated under reduced pressure. Et_2O (100 cm^3) and L^1 (905 mg, 12.0 mmol) were added. The mixture was stirred at room temperature for 2 h. The pale-rose solution was then concentrated under reduced pressure and *n*-hexane (30 cm^3) was added. A colorless precipitate was formed which was filtered off, washed with *n*-hexane and shown to be compound **8**.

Preparation of [*bis*(4-*methylimidazole*)*methyltrichlorotin*(*IV*)], **14**. To a stirred diethyl ether solution (100 cm^3) of L^1 (250 mg, 3.0 mmol), $(CH_3)SnCl_3$ (365 mg, 1.5 mmol) was added at room temperature. A colorless precipitate was formed immediately. It was filtered off after 2 min, washed with diethyl ether (3×15 cm^3), dried *in vacuo* to constant weight (20°C, ca 0.1 Torr) and shown to be compound **14**. If the reaction was carried out for a time longer than 2–3 min an oily product was obtained.

Preparation of [*bis*(2-*methylimidazole*)*trimethylchlorotin*(*IV*)], **17**. To a stirred refrigerated (0°C) CH_2Cl_2/CH_3CN solution (1 : 1, 50 cm^3) of L^2 (375 mg, 4.6 mmol), $(CH_3)_3SnCl$ (606 mg, 3.0 mmol) was added under N_2 stream. The colorless residue obtained was washed with diethyl ether, petroleum ether and dichloromethane, dried *in vacuo* to constant weight, and shown to be compound **17**. Compound **19** was obtained similarly.

Preparation of [*bis*(2-*methylimidazole*)*dimethyldichlorotin*(*IV*)], **18**. To a stirred CH_3CN solution (50 cm^3) of L^2 (375 mg, 4.6 mmol) was added a diethyl ether solution (50 cm^3) of $(CH_3)_2SnCl_2$ (670 mg, 3.0 mmol). The mixture was heated at reflux, under N_2 stream, with stirring for 1 day. The solution was then concentrated (20 cm^3) under reduced pressure and stored in a freezer overnight. The oily residue obtained was crystallized twice from CH_2Cl_2/CH_3CN (1 : 2) to yield the analytical sample **18**.

Preparation of [*bis*(2-*methylimidazole*)*phenyltrichlorotin*(*IV*)], **20**. To a stirred saturated diethyl ether/chloroform solution (1 : 1; 110 cm^3) of the ligand L^2 (250 mg, 3.0 mmol), $(C_6H_5)SnCl_3$ (544 mg, 1.8 mmol) was added at room temperature. A colorless precipitate was formed immediately. After 5 min the suspension was centrifuged and the residue was washed with diethyl ether to yield the analytical sample **20**.

Preparation of [(2-*isopropylimidazole*)*trimethylchlorotin*(*IV*)], **21**. To a stirred refrigerated (0°C) diethyl ether solution (50 cm^3) of L^3 (601 mg, 6.0 mmol), $(CH_3)_3SnCl$ (606 mg, 3.0 mmol) was added under N_2 stream. The mixture was stored at 0°C and stirred for 1 h. The colorless residue obtained was crystallized twice from diethyl ether to yield the analytical sample **21**. Compound **22** was obtained similarly.

Preparation of [(2-*isopropylimidazole*)*dimethyldichlorotin*(*IV*)], **23**. To a stirred diethyl ether/ dichloromethane (1 : 1) solution (100 cm^3) of L^3 (601 mg, 6.0 mmol), $(CH_3)_2SnCl_2$ (670 mg, 3.0 mmol) was added at room temperature. A colorless precipitate was formed immediately, which was filtered off after 10 h, washed with diethyl ether and crystallized twice from dichloromethane and shown to be compound **23**. Compound **24** was obtained similarly.

Preparation of [*dibromodimethyl*(1,10-*phenantroline*) *tin*(*IV*)]. To a stirred diethyl ether solution (100 cm^3) of 1,10-phenantroline (214 mg, 1.2 mmol), $[(L^1)_2(CH_3)_2SnBr_2]$ (280 mg, 0.6 mmol) was added at room temperature. The colorless precipitate became immediately pale pink; it was filtered off after 1 day, washed with diethyl ether and shown to be compound $[(Phen)(CH_3)_2SnBr_2]$. Compound $[(Phen)(CH_3)_2SnCl_2]$ was obtained similarly.

RESULTS AND DISCUSSION

Synthesis, reactivity and properties of the organotin(*IV*) *complexes*

Preparations of the organotin(IV) complexes were usually attempted with different stoichiometries in order to determine if more than one kind of derivative was afforded between the donors (L^1, L^2 and L^3) and a particular organotin(IV) acceptor. The complexes here discussed were the only ones that were isolated.

Interaction between various organotin(IV) compounds and excess L^1, L^2 or L^3 in organic solvent (diethyl ether, diethyl ether and dichloromethane, acetonitrile and dichloromethane or diethyl ether) produces the compounds **1–5, 9–24** listed in Table 1, according to eqn (1):

$$x(L) + (R_nSnX_{4-n}) \cdot zH_2O \xrightarrow{Solvent} [(L)_x(R_nSnX_{4-n})] \cdot zH_2O \quad \textbf{1–5, 9–24} \quad (1)$$

$$(L = L^1, L^2 \text{ or } L^3; R = Me, Et, Bu^n \text{ or } Ph; X = Cl \text{ or } Br; n = 1, 2 \text{ or } 3;$$

$$x = 1, 2 \text{ or } 3; z = 0, 1/3, 1, 2, 3 \text{ or } 6).$$

With the exception of compounds **3**, **21**, **22** and **24** (for which ligand-to-metal ratio of 1 : 1 was observed), and of **15** and **16** (ligand to metal ratio of 3 : 1) 2 : 1 adducts were always isolated. The first significant difference with respect to tin(IV) and organotin(IV) adducts of 1-benzyl-, 1-methyl- and 4-phenyl-imidazole is just in the obtaining of the 3 : 1 adducts **15** and **16**, likely due to the greater basicity of L^1 with respect to L^4 and L^5 or to the ability of L^1 to stabilize the tin(IV) adducts by formation of hydrogen bonds.

With the donors L^1 and L^2 2 : 1 adducts were obtained also with weak acceptors such as $(CH_3)_3SnCl$ and $(n\text{-}C_4H_9)_3SnCl$. The ligands L^1 and L^2 show the same behavior of L^5 which has been found in $[(L^5)(CH_3)_3Sn]Cl$ [6] able to saturate the coordination number equal to five upon displacement of the Cl from the coordination sphere of the tin centre and to stabilize the whole molecule involving the halide in a hydrogen bond network (Fig. 2).

With the exception of $[(L^3)_2(CH_3)_2SnCl_2] \cdot (H_2O)$ (**23**), 1 : 1 adducts were always obtained with the donor L^3, which is a more sterically hindered donor than those employed to date.

We also found that the reactions involving triorganotin(IV) chloride acceptors require a longer reac-

[a] L^1 is 4-methylimidazole; L^2 is 2-methylimidazole; L^3 is 2-isopropylimidazole.

tion time than those involving diorganotin(IV) halides, which are slower with respect to those between the donors L^1, L^2 and L^3 and monoorganotin(IV) acceptors.

The compound $[(L^1)_2(CH_3)_2SnCl_2]$ **4** is converted into the analogous diiodide complex **6** on treatment with excess sodium iodide in ethanol solution. This conversion did not occur when diethyl- (**9**), di-*n*-butyl- (**11**) and diphenyl-tin(IV) (**13**) complexes were employed as starting material: in these cases both disproportionation of the tin(IV) halide in accordance with Kocheshkov reactions [9], and breaking of the donor-acceptor σ-bond occurred.

The substitution of the Cl^- with $[NO_3]^-$ or $[BPh_4]^-$ groups when ethanol solution of $AgNO_3$ or $NaBPh_4$ were added to ethanol solution of derivative **4**, pro-

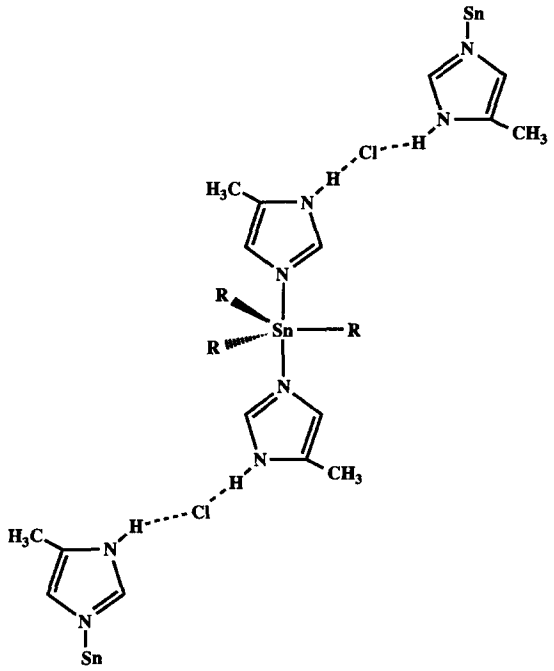

Fig. 2. Structure proposed for the 2:1 triorganotin(IV) adducts of L^1 and L^2.

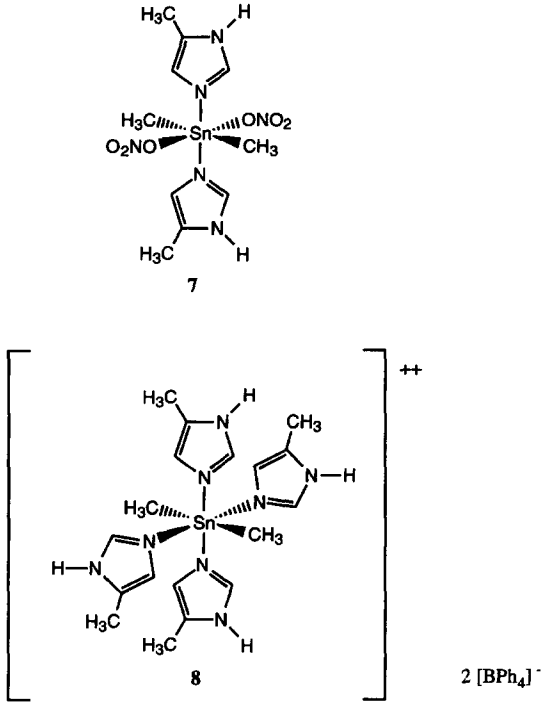

Fig. 3. Structure proposed for the adducts 7 and 8.

duced respectively the new complexes **7** and **8**, characterized by two different stoichiometries: 2:1 in the first and 4:1 in the second case. The formation of **8** gives further support [6,10] to the possibility of existence of the $[(CH_3)_2Sn]^{++}$ cation in the solid state, whereas the formation of **7** indicates the possibility of synthesis of imidazole-tin(IV) and organotin(IV) complexes containing coordinated mono- or bi-dentate nitrato groups (Fig. 3). This is a significative difference with respect to the early described organotin(IV) nitrato complexes of imidazoles, where the $[NO_3]^-$ group was always found to be ionic [10,11].

No adduct was obtained from reaction of L^2 with $(n\text{-}C_4H_9)_3SnCl$, $(C_6H_5)_3SnCl$, $(C_2H_5)_2SnCl_2$, $(n\text{-}C_4H_9)_2SnCl_2$ and $(C_6H_5)_2SnCl_2$, and of L^3 with $(n\text{-}C_4H_9)_3SnCl$, $(CH_3)_2SnCl_2$, $(C_2H_5)_2SnCl_2$, $(n\text{-}C_4H_9)_2SnCl_2$ and $(C_6H_5)SnCl_3$. These donors, which are more basic than L^4, L^5 and L^1, are also the most sterically hindered, due to the presence of a methyl (L^2) or an isopropyl (L^3) group near the coordination site. Moreover, we have found that the bond between L^2 and $(CH_3)_3SnCl$ or $(CH_3)_2SnCl_2$ and between L^3 and $(CH_3)_3SnCl$ is very weak. Compounds **17**, **18** and **21** are unstable not only in solution, but also in the solid state. When they are exposed to moisture for a long time, organotin(IV) oxides and hydroxides and/or the starting donor are often recovered. On the other hand complexes **1**–**16** are generally air-stable. Organotin(IV) oxides and/or hydroxides are also obtained upon prolonged standing of compounds **1**–**24** at 120°C. Diorgano- and triorgano-tin(IV) complexes are moderately soluble in chlorinated solvents (ca 3 mg/cm^3), acetone (*ca* 5 mg/cm^3) and DMSO (5–10 mg/cm^3) and insoluble in diethyl ether, ethanol, methanol and water. The monoorganotin(IV) adducts are generally less soluble in all the organic solvents commonly used.

The N_2-donor 1,10-phenanthroline is able to displace the 4-methylimidazole from its Me_2SnX_2 (X = Cl or Br) adducts, yielding the chelate *trans*-Me_2SnX_2(Phen) derivatives. On the other hand the 2-benzoylpyridine, which is less basic than imidazoles and Phen, in our conditions does not react with the diorganotin(IV)-4-methylimidazole derivatives. P-donors such as PPh_3, PBz_3 and $(PPh_2CH_2\text{-})_2$, more basic than benzoylpyridine, and PCy_3 more basic even than L^1 and Phen, are not able to replace the imidazole in the coordination sphere of tin(IV). This behavior is in accordance with the principle of the maximum hardness [12]. The reactivity of compound **4** is summarized in the scheme.

Several attempts to obtain crystals of adducts **1**–**24**, in suitable form for X-ray analyses, failed: in some cases amorphous powder was obtained, whereas in others one well-known hydrolysis products afforded.

IR Data

In Table 2 we report the most relevant infrared data (4000–100 cm^{-1}) for the ligands L^1, L^2 and L^3 and their tin(IV) and organotin(IV) complexes **1**–**24**. The spectra were recorded in nujol mull. By comparison with the data reported for other tin(IV) and organ-

otin(IV) adducts containing N-donor ligands [13], we suggest for adducts **1–24** the following assignments.

Ligand absorptions

In the 3200–3000 cm^{-1} region, the ligands exhibit weak bands typical of C—H stretching due to a pseudoaromatic ring, and in the region 1650–1500 cm^{-1} some more intense absorptions due to the ring breathing mode [14]. In the 2800–2600 cm^{-1} region the ligands exhibit a broad band typical of N—H stretching. In the tin(IV) and organotin(IV) adducts this band shifts in the 3400–3000 cm^{-1} region suggesting an important influence of the coordination to tin. The position and the broadening of the N—H stretching band are consistent with the presence of a hydrogen bond between the N—H moiety and the halide groups [6,15].

Sn—C stretching frequencies

In the triorganotin(IV) derivatives **1, 2** and **21** two strong or medium absorptions are observed at 555 and 546 cm^{-1}, 600 and 551 cm^{-1} and 550 and 542 cm^{-1} respectively. They are due to $\nu_{(asym)}$ and $\nu_{(sym)}$ Sn—C stretching vibrations and are consistent with an essentially trigonal pyramidal arrangement of organic groups with a marked deviation from planarity.

The appearance of only a single Sn—C bond (at 547 cm^{-1}) in the spectra of trimethyl tin(IV) complex of L^2 (**17**) and of triphenyltin(IV) complexes of L^1 (**3**) and L^3 (**22**) is taken to imply a C_{3v} symmetry of the C_3—Sn skeleton and in the first case a *trans*-pyramidal configuration of the two ligands [16].

Only a single Sn—C stretching vibration appeared in the spectra of dimethyltin(IV) complexes (**4–6** and **8**) of L^1, in accordance with a *trans*-octahedral configuration of the two alkyl groups [17]. Instead, two absorptions were observed in the spectra of the other diorganotin(IV) derivatives of L^1 (**9–13**), in the dimethyltin(IV) complex of L^2 (**18**) and in the diorganotin(IV) complexes of L^3 (**23** and **24**), in accordance with a markedly distorted *trans*-octahedral configuration of the two alkyl groups [18].

In the spectrum of derivative $[(L^1)_2(CH_3)_2Sn(NO_3)_2]\cdot H_2O$ (**7**) one broad absorption at ca 548 cm^{-1} and other less intense bands at 575, 526 and 514 cm^{-1} were found. In this case the presence of at least two markedly distorted *all-trans*-octahedral isomers is likely.

Sn—Cl stretching frequencies

In the triorganotin(IV) derivatives of L^1 (**1** and **2**) and L^2 (**17**) the tin-chloride stretching frequency is absent. On the basis of previous reports [19] on triorganotin(IV) complexes and in accordance with the X-ray crystal structure determination of [bis(4-phenylimidazole)trimethyltin(IV)]chloride [6] we have hypothesized an ionic formulation of the type $[(L)_2R_3Sn]^+[Cl]^-$. Whereas the Sn—Cl is present in the 1 : 1 triorganotin(IV) adducts of L^3, **21** and **22**.

In the di- and mono-organotin(IV) complexes the ν(Sn—Cl) are observed in the region 240–220 cm^{-1} and 330–260 cm^{-1} respectively.

Sn—N stretching frequencies

We are not able to assign the ν(Sn—N) vibrations, because they are likely hidden under some absorptions characteristic of the azole ring system [14].

Skeletal bending modes

In our alkyl complexes, the skeletal bending mode assignments are not straightforward. δ(C—Sn—C), δ(X—Sn—X), ρ(Sn—C_3), ρ(Sn—X_3) and ν(Sn—Br) fall in the region 190–120 cm^{-1} [20] and are far too close to resolve. However we are able to assign the bending of the phenyl groups in the aryltin(IV) derivatives **3, 13, 16, 20, 22** and **24** in the range 465–440 cm^{-1} respectively [21].

Other data

The nitrato complex **7** shows strong broad absorptions at 1410 and 1370 cm^{-1} due to ν_1 and ν_4 of NO_3 group. The separation of these two bands is of the same order of magnitude as that indicated for derivatives containing unidentate NO_3 [22]. In the far IR spectra this adduct exhibits also a broad absorption at ca 480 cm^{-1} due to Sn—O stretching vibration. This observation suggests that the nitrato group, upon complexation of tin(IV) by imidazole donors, remains in the coordination sphere of the metal.

Behavior in solution

The conductivity measurements (Table 3) were carried out in acetone solution for all the soluble compounds and in CH_2Cl_2 and DMSO only for selected derivatives, whereas the molecular weight determinations were performed in chloroform solution only on sufficiently soluble and stable adducts. The data show that triorganotin(IV) halide adducts **1–3, 17, 21** and **22** are not electrolytes in acetone and **1** also in CH_2Cl_2, even if they dissociate to a great extent in $CHCl_3$ solution (r = ratio between the vaporimetric molecular weight and formula weight lies in the range 0.38–0.48), in accordance with the non-ionic eqn (2) which indicates ligand loss in solution.

$$(L)_xR_3SnX \rightleftharpoons [(L)_{x-1}R_3SnX] + L \rightleftharpoons R_3SnX + xL \quad (2)$$

The diorganotin(IV) chloride and bromide adducts

[a] In Ω^{-1} cm^2 mol^{-1} at room temperature; conc. is molar concentration ($\times 10^3$).
[b] 40°C, in $CHCl_3$; r = M.W./F.W.; conc. is: mg of compound/g of $CHCl_3$.

4, **5**, **9** and **11** are non-electrolytes and presumably dissociate partly in these solvents (r is in the range 0.67–0.94). We also found that the dissociation is not very dependent on the concentration of the solutions: for example r for compound **9** is 0.80 at conc. 0.99 mg/g and 0.90 at conc. 3.45 mg/g of $CHCl_3$.

The diorganotin(IV)diiodide adduct **6** exhibits a value of conductivity in acetone typical of a 1 : 1 electrolyte: it is also strongly dissociated in $CHCl_3$ solution. On the basis of this evidence we hypothesized an ionic nature in solution of complex **6** in accordance with eqn (3):

$$[(L^1)_2(CH_3)_2SnI_2] + n(\text{solvent}) \rightleftharpoons [(L^1)_2(CH_3)_2SnI(\text{solvent})_n]^+ + [I]^- \quad (3)$$

Compounds **7**, **8**, **14**, **18**, **19** and **24** are partly ionized: a similar behavior has been previously observed for analogous organotin(IV) complexes containing imidazole-type donors [5–7].

The monoorganotin(IV) adducts **15** and **16** are not-electrolyte in acetone solution.

NMR spectroscopy

The ^{1}H NMR spectra of the donors L^1, L^2 and L^3 and of their organotin(IV) complexes **1–24** (Table 4) were recorded in $CDCl_3$ and for some derivatives in acetone or in EtOD, due to poor solubility in the former solvent. The ^{119}Sn spectra (Table 5) were carried out in $CDCl_3$ only on selected sufficiently soluble complexes.

The spectra of the triorganotin(IV) complexes **1, 2, 17** and **21** indicate a complete dissociation into the starting reagents. In fact, the Δ value (difference in chemical shift for the same type of proton in the free base and in its organotin(IV) complexes) is in the range 0.01–0.15 ppm.

Instead in the spectrum of the triphenyltin(IV) complexes **3** and **22** the signals of the ligand are displaced upfield and the Δ value is in the range (−0.15)–(−0.31) ppm. This peculiarity can be explained by considering the shielding effect exerted on CH_3, H2 and H5 protons by aromatic protons of the phenyl rings linked to tin(IV). In all these complexes the tin-proton coupling constants are of the same order of magnitude of those reported for the starting triorganotin(IV) acceptors [23].

In the spectra of the diorganotin(IV) complexes (**4–7, 9–13, 18, 23** and **24**) the signals of the ligands L^1, L^2 and L^3 are generally displaced to lower fields. The deshielding observed is attenuated at a position remote from the metal (methyl protons). The Δ observed is likely due to a σ-charge donation from the N-donor to tin(IV) acceptor and it is an evidence of the existence of the complexes in solution. However, the magnitude of the tin(IV)-proton coupling constants for all these diorganotin(IV) complexes, even if it is different from that reported in literature for the starting tetracoordinate diorganotin(IV) halides [24], is smaller with respect to that indicated for hexacoordinate undissociated organotin(IV) complexes containing N-donor ligands [25]: this suggests a partial dissociation of our complexes in chlorinate solution in accordance with the data derived from molecular weight measurements.

In the ^{1}H spectra of most of the complexes of L^1 more than one set of signals is observed for the imidazole ring protons and also for the two R groups linked to tin. None of the signals corresponds to those reported for the starting ligand and tin(IV) derivative employed [23]. It has been previously noted [26] that for $(L)_2R_2SnX_2$-type compounds *cis* and *trans* isomers are possible and also that organotin(IV) derivatives may undergo different equilibria in acetone solution. In our complexes there is also another possibility: the donor, in accordance with that previously observed in the derivatives of 4-phenylimidazole [6], may coordinate the tin atom not only by means of its N(3), but also by means of the N(1) atom. This is likely due to steric hindrance of the methyl group in the 4-position, which requires a metal/proton exchange between the two nitrogen sites [27]. At room temperature the metal/proton exchange is slow enough to allow the observation of signals due to both the organotin(IV) species in Fig. 4.

In order to confirm our hypothesis a variable temperature ^{1}H NMR experiment on a saturated solution ($CDCl_3$) of compound **4** was carried out. Some selected data are reported in Table 6. It should be noted that the magnitude of the tin-proton coupling constants becomes smaller when temperature increases; moreover the signals of the ligand upon complexation are more displaced downfield in the spectra recorded at lower temperatures. On the basis of this evidence we can hypothesize that the complex is more dissociated at high temperatures. In the spectra recorded at −45°C and at −30°C, the presence of seven different signals for the two methyl groups linked to tin is in accordance not only with the presence of isomers but also with the hypothesis of tin/proton "shuttling" between the two nitrogen sites. A similar pattern

Table 5. ^{119}Sn NMR data for some selected derivatives of L^1 and L^3

Compound	No.	Solvent	δ(^{119}Sn)
$[(L^1)_2(CH_3)_2SnCl_2]$	(**4**)	$CDCl_3$	−64.2, −117.3
$[(L^1)_2(CH_3)_2SnBr_2]$	(**5**)	$CDCl_3$	−119.2
$[(L^1)_2(C_2H_5)_2SnCl_2]$	(**9**)	$CDCl_3$	−92.2, −140.0, −184.0
$(L^1)_3(C_4H_9)SnCl_3$	(**15**)	$CDCl_3$	−285.3, −467.3, −474.0
$[(L^3)(CH_3)_3SnCl]$	(**21**)	$CDCl_3$	43.6
$[(L^3)(C_6H_5)_3SnCl]$	(**22**)	$CDCl_3$	−107.4
$[(L^3)(C_6H_5)_2SnCl_2]$	(**24**)	$CDCl_3$	[a]

[a] This compound is not very soluble in $CDCl_3$. After 30,000 cycles acquired, a broad signal likely due to oxide- or hydroxide-tin species is observed at ca 50 ppm.

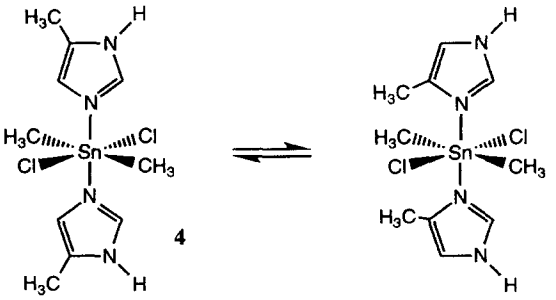

Fig. 4. Structure proposed for the 2 : 1 $(L^1)_2R_2SnX_2$ adducts: the 4-methylimidazole donor is able to coordinate by means of its N(1) or N(3) atom.

[a] In $CDCl_3$.
[b] J in Hz.
[c] Ratio of intensity in parentheses ( ).
[d] ND = Not distinguishable.

(Table 6) was also observed in the variable temperature ^{1}H NMR spectrum of **9**.

In the ^{1}H NMR spectrum of **8** two different resonances due to each CH_3, H2 and H4 or H5 of the imidazole moiety are observed upfield shifted with respect to the same resonance in the free donor ($\Delta = +0.26$ and $+0.13$, $+0.34$ and $+0.24$, and $+0.74$ and $+0.58$ respectively). This trend could be explained by considering the shielding effect exerted on CH_3, H2 and H4 or H5 by the aromatic protons of the BPh_4^- counter-ion. It has been previously reported that the existence of intermolecular and interionic contacts can be detected by Nuclear Overhauser Effects (NOEs) [28], which is the unique tool for investigating the aggregation and localization of the interacting fragments in solution. We have performed a ROESY experiment [8] on a saturated $CDCl_3$ solution of **8** at room temperature; however no cross peaks between the organometallic $(CH_3)_2(L^1)_4Sn^{++}$ moiety and BPh_4^- have been observed. In absence of crystal and molecular structure determination it is not possible to indicate if the BPh_4^- counter-ions interact, in the solid state, with the organometallic fragment.

^{119}Sn NMR signals of $[(L^1)_2R_2SnX_2]$ type compounds **4, 5** and **9** were observed in $CDCl_3$ solution (Table 5) between -64.2 and -184 ppm. The measured $\delta(^{119}Sn)$ values do not fit clearly into the reported ranges of $\delta(^{119}Sn)$ values of six-coordinate organotin(IV) compounds [23,24]. However these values are in accordance with the partial dissociation proposed on the basis of ^{1}H NMR data and molecular weight determinations. The presence of two and three signals in the spectra of derivatives **4** and **9** respectively, further supports the presence of isomers and/or of hydrolysis products. On the other hand, the ^{119}Sn chemical shift of compound **15** is typical of octahedral, pseudooctahedral or skewed trapezoidal environment [23,24]. Also on the basis of conductance values, we suggest for the 3:1 adducts **15** and **16** a non-ionic dissociation in solution such as in eqn (4):

$$(L^1)_3RSnCl_3 \rightleftharpoons (L^1)_{3-n}RSnCl_3 + nL^1 \qquad (4)$$

15, 16

(R = Bu^n, Ph)

In the absence of crystals suitable for X-ray analysis, we are not able to indicate with certainty the coordination number of tin in these compounds. In the solid state they could exist in a heptacoordinate form, but we cannot exclude the possibility of a hexacoordinate environment, with one imidazole donor out of the inner coordination sphere and hydrogen bonded to the other ligands or to the chlorides.

It has been reported [23,24] that the magnitude of the ^{119}Sn chemical shift of compounds having the same coordination number depends primarily on the electronegativity of the substituents at tin and on the geometric distortion which modify the interbond angles at tin: In our case the substitution of an R with a Cl group produces a significant upfield shift ($\delta(^{119}Sn)$ for **15**: -285.3, -467.3 and -474.0 ppm); a similar trend was previously observed in (β-diketonato)$_2$(CH_3)XSn (X = CH_3 or Cl) complexes [29].

The triorganotin(IV) derivatives **21** and **22** exhibit a single absorption at ca 43.6 and -107.4 ppm respectively, typical of four or five-coordinate central tin atom. These signals are upfield shifted with respect to those reported for the starting acceptors (Me_3SnCl: $+164.2$ ppm [30], Ph_3SnCl: -44.7 ppm) [31]. The shift is smaller than that observed in analogous 1-benzylimidazole derivatives [5].

CONCLUSIONS

The reactivity of alkyl-substituted imidazole donors towards organotin(IV) acceptors depends not only on the electronic and steric features of the groups bonded to tin, but also on the position of the alkyl substituent in the imidazole moiety and on the nature of the counter-ion: the ligand/metal ratio can range from 1:1 in $[(L^1)(C_6H_5)_3SnCl]\cdot 1/3H_2O$ to 4:1 in $[(L^1)_4(CH_3)_2Sn](BPh_4)_2$. The NMR data and molecular weight measurements indicate that the bonding interaction between L^1, L^2 and L^3 and R_nSnX_{4-n} generally increases with decreasing of n and that the donor is coordinated to tin through the nitrogen atom.

To date L^6 (1-methylimidazole) is the best imidazole-type donor investigated towards organotin(IV) acceptors: it can be deduced from the easy formation of adducts also with triorganotin(IV) acceptors and from the fairly good stability of them. The presence of a methyl substituent in the 4-position of the heterocyclic ring (L^1) seems to reduce the donating ability, with respect to the substitution in the 1-azole position (L^6), even if the pK_a of the two ligands is of the same order of magnitude [32].

On the other hand L^2 (2-methylimidazole) and L^3 (2-isopropylimidazole), which have a methyl and an isopropyl group respectively near to the coordination site, are the worst donor to date employed. Their reactions toward organotin(IV) acceptors were often unsuccessful and the few compounds obtained are not stable both in solution and in the solid state.

Combined analytical and spectral data (IR, far-IR, ^{1}H and ^{119}Sn NMR) suggest for the triorganotin(IV) adducts a bipyramid trigonal configuration, whereas a distorted octahedral or pseudooctahedral structure is likely for all the other derivatives.

Application of electrospray mass spectrometry to the characterisation of sulfonated and ferrocenyl phosphines

William Henderson* and Gregory M. Olsen

Department of Chemistry, University of Waikato, Private Bag 3105, Hamilton, New Zealand

(Received 13 May 1997; accepted 14 July 1997)

Abstract—A range of ferrocenyl-containing and sulfonated triphenylphosphines have been investigated by electrospray mass spectrometry. *In situ* formation of hydroxymethyl phosphonium salt derivatives of the ferrocenyl phosphines and *in situ* formation of silver(I) adducts of both the ferrocenyl and sulfonated phosphines provided a means of characterising such compounds. Results are discussed in terms of fragmentation and aggregation of the parent molecular ion species. Sulfonated phosphines, including their sodium adducts, were easily characterised by their negative-ion spectra. Aminoalkyl-ferrocenyl phosphines form strong $[M+H]^+$ ions in their positive-ion spectra. Ferrocenyl phosphines without amino functions give weaker $[M+H]^+$ ions and may also be complicated by the existence of $[M]^+$ ions. Less complex positive-ion mass spectra of these ferrocenyl phosphines can be observed following treatment with either a solution of $AgNO_3$ or a mixture of formaldehyde and HCl. © 1998 Elsevier Science Ltd. All rights reserved

Keywords: electrospray mass spectrometry; phosphines; ferrocene derivatives; sulfonated phosphines; water-soluble phosphines.

There is a vast literature on the chemistry of phosphines and their metal complexes [1]. Indeed, the action of some complexes, e.g. catalysts for organic synthesis, are intimately linked with the structure and characteristics of the phosphine ligand(s) coordinated [2–4]. Phosphines are important precursors for the development of such complexes and a considerable amount of data have been published on their characterisation. Recent evidence suggests that results derived from the relatively new technique of electrospray mass spectrometry (ESMS) are complementary to those obtained from other techniques such as electrochemistry or multinuclear magnetic resonance spectroscopy (NMR) [5].

In the past, mass spectrometry of either inorganic or organometallic compounds was dominated by the ionisation techniques of electron impact (EI) or fast atom bombardment (FAB). EI is largely limited to the analysis of neutral volatile species which for many reasons were also required to be thermally stable. FAB is more successful but was still disadvantaged by the relatively high degree of fragmentation, making identification of molecular ions difficult. The soft ionisation technique of electrospray (ES), which has proven particularly beneficial to biochemists for the characterisation of large organic molecules, e.g. proteins [6], has recently found favour among inorganic and organometallic chemists [5,7–12]. In general ESMS gives considerable control over the degree of fragmentation, by varying the skimmer cone voltage. In principle, the technique is applicable to any pre-existing cation, anion or neutral compound that can be modified by the addition of a suitable reagent to form an ion, providing that the ion is stable to the solution environment used in the mass spectrometer.

We recently described the ESMS analysis of a variety of hydroxymethylphosphines and their derivatives, including phosphine sulfides and phosphonium salts [12]. Results from this study identified the preferred fragmentation pathways for hydroxymethylphosphine derivatives and outlined a number of general routes for the detection of neutral phosphines, phosphine oxides and phosphine sulfides. Only weak ions are observed in the positive-ion ES mass spectra of many phosphines because they are weak

bases, however it was demonstrated that the addition of a suitable reagent (either aqueous $AgNO_3$ or a mixture of 40% formaldehyde and concentrated HCl) could aid in the formation of cations for positive-ion ESMS. In this paper we report our studies on the further development of the ESMS technique for the analysis of other important types of phosphine ligands, particularly those which contain additional functional groups, such as sulfonated aryl phosphines, and ferrocene-derived phosphines.

The water-soluble sulfonated phosphines, $Ph_2P(C_6H_4SO_3Na)$ (TPPMS) and $P(C_6H_4SO_3Na)_3$ (TPPTS) were of particular interest since the introduction of the Rhone–Poulenc water-soluble rhodium hydroformylation catalyst $HRh(CO)(TPPTS)_3$ [3,4]. We have also examined a number of ferrocenyl phosphines (structures depicted in Scheme 1), which are of interest in the development of asymmetric catalysts [13] and compounds showing anti-cancer activity [14]. Few studies describe the use of ESMS for the analysis of ferrocenes [8,9] and no extensive studies, to the best of our knowledge, have been published on the ESMS of ferrocenyl- or sulfonated aryl phosphines.

The studies by Cole and co-workers [9] and ourselves [8] illustrate the difficulties which can arise in characterising molecular ions in the ESMS of ferrocene-derived compounds. The isotope pattern for the molecular ion is often complicated by the existence of both the ferricinium ion $[M]^+$ and the protonated ion $[M+H]^+$ with variable relative intensities. Intensities depend upon both the operating conditions of ESMS and the structure of the ferrocene. This complication may be avoided if a suitable ion can be formed which is less susceptible to electrochemical oxidation. The phosphine function on the compounds under investigation may be modified quite simply to form positively-charged species [12]. Positively-charged silver complex ions can be formed by the addition of a solution of $AgNO_3$, e.g. $[M+Ag]^+$, and hydroxymethyl phosphonium salts, e.g. $[M(CH_2OH)]^+$, may be formed by the addition of a solution of formaldehyde and HCl. Colton *et al.* have previously described the use of iodomethane as an alternative ionisation agent for the analysis of tertiary phosphines by ESMS [10,11].

EXPERIMENTAL

Materials

The ferrocenyl phosphines $FcCH_2P(CH_2OH)_2$ [19] and $FcCH_2PH_2$ [20] were prepared according to literature methods. The ferrocenyl phosphine $FcCH_2PPh_2$ [21] was prepared by reaction of Ph_2PCH_2OH with $[FcCH_2NMe_3]I$, full details of which will be published in due course. Sulfonated phosphines were also prepared using literature methods [15].

Instrumentation

Electrospray mass spectra were recorded in both positive-ion and negative-ion modes on a VG Platform II single quadrupole benchtop mass spectrometer (Fisons Instruments). Samples of either the ferrocenyl phosphines or the sulfonated phosphines were dissolved in 1 : 1 v/v acetonitrile–water. The solution, typically of approximate concentration 0.1 mM, may be further treated by the addition of 1–3 drops of either a 1 : 1 mixture of 40% formaldehyde and HCl or an aqueous solution of $AgNO_3$ (0.5 g/l). The Ag^+ concentration was semi-quantitative, deemed low if one drop of $AgNO_3$ was added and high if 3 drops of $AgNO_3$ were added to a solution of the phosphine. Samples were injected directly *via* a Rheodyne injector with a 10 μl sample loop. A Spectra-System P1000 LC pump delivered the solution to the vaporisation nozzle of the electrospray ion source (60°C) at a flow rate of 0.01 $cm^3\ min^{-1}$ and nitrogen was employed as both a drying and nebulising gas. Skimmer cone voltages were varied between 20 and 90 V, in order to investigate the effects of higher cone voltages on fragmentation of the parent ions. Spectra were typically an average between 10 and 20 scans, depending upon intensity. Theoretical isotope patterns were calculated using the *Isotope* program [22] and used to aid in assignment.

$^{31}P\text{-}\{^1H\}$ NMR spectra were recorded in 1 : 1 methanol : D_2O solution on a Bruker AC300P spectrometer at 121.5 MHz with external 85% H_3PO_4 (δ 0.0) as reference.

RESULTS AND DISCUSSION

Sulfonated phosphines

TPPTS and a crude sample of TPPMS, dissolved in 50% aqueous acetonitrile, were investigated by ESMS in negative-ion mode at a low cone voltage (20 V) either in combination with formic acid or $AgNO_3$, or as a neat solution. These phosphines, in contrast to neutral triphenylphosphine, exhibited strong ions in their negative-ion ES mass spectra. ESMS data are summarised in Table 1.

The ions $[P(m\text{-}C_6H_4SO_3)_3]^{3-}$ (m/z 166.3, the base peak) and $[P(m\text{-}C_6H_4SO_3)_3Na]^{2-}$ (m/z 261, 64%) dominate the negative-ion ES mass spectrum of TPPTS, as shown in Fig. 1. A number of minor ions including $[P(m\text{-}C_6H_4SO_3)_3H]^{2-}$ (m/z 250), $[P(O)(m\text{-}C_6H_4SO_3)_3]^{3-}$ (m/z 171.7), $[P(O)(m\text{-}C_6H_4SO_3)_3Na]^{2-}$ (m/z 269) and $[P(m\text{-}C_6H_4SO_3)_3Na_2]^-$ (m/z 545) can also be identified in the spectrum. The existence of the phosphine oxide derivatives in the ES mass spectra is consistent with the known chemistry of sulfonation of arylphosphines which can commonly produce phosphine oxides [4,15]. Two signals were observed at δ +32.5 and −4.2 in the $^{31}P\{^1H\}$ NMR spectrum of TPPTS in a 1 : 1 methanol : D_2O solution, and were

Table 1. Negative-ion electrospray mass spectral data for sulfonated phosphines TPPTS and TPPMS

Compound/mixture[a]	Major ESMS ions (m/z %)[b]
TPPTS	$[P(m\text{-}C_6H_4SO_3)_3Na_2]^-$ (545, 3%); $[P(O)(m\text{-}C_6H_4SO_3)_3Na]^{2-}$ (269, 6%); $[P(m\text{-}C_6H_4SO_3)_3Na]^{2-}$ (261, 64%); $[P(m\text{-}C_6H_4SO_3)_3H]^{2-}$ (250, 12%); $[P(O)(m\text{-}C_6H_4SO_3)_3]^{3-}$ (171.7, 10%); $[P(m\text{-}C_6H_4SO_3)_3]^{3-}$ (166.3, 100%).
TPPTS + HCOOH	$[P(m\text{-}C_6H_4SO_3)_3Na_2]^-$ (545, 9%); $[P(m\text{-}C_6H_4SO_3)_3NaH]^-$ (523, 11%); $[P(m\text{-}C_6H_4SO_3)_3H_2]^-$ (501, 9%); $[P(O)(m\text{-}C_6H_4SO_3)_3Na]^{2-}$ (269, 12%); $[P(m\text{-}C_6H_4SO_3)_3Na]^{2-}$ (261, 43%); $[P(m\text{-}C_6H_4SO_3)_3(NH_4)]^{2-}$ (258.5, 30%); $[P(m\text{-}C_6H_4SO_3)_3H]^{2-}$ (250, 100%); $[P(m\text{-}C_6H_4SO_3)_3]^{3-}$ (166.3, 50%).
TPPTS + $AgNO_3$	$[P(m\text{-}C_6H_4SO_3)_3Ag]^{2-}$ (303, 29%); unknown (275, 5%); $[Ag(NO_3)_2]^-$ (231, 100%); $[P(O)(m\text{-}C_6H_4SO_3)_3]^{3-}$ (171.7, 6%); $[P(m\text{-}C_6H_4SO_3)_3]^{3-}$ (166.3, 2%).
TPPMS	$[PhP(O)(m\text{-}C_6H_4SO_3)_2Na]^-$ (459, 2%); $[PhP(m\text{-}C_6H_4SO_3)_2Na]^-$ (443, 2%); $[Ph_2P(O)(m\text{-}C_6H_4SO_3)]^-$ (357, 12%); $[P(O)(m\text{-}C_6H_4SO_3)_3Na]^{2-}$ (269, 7%); $[P(O)(m\text{-}C_6H_4SO_3)_3H]^{2-}$ (258.5, 3%); $[PhP(O)(m\text{-}C_6H_4SO_3)_2]^{2-}$ (218, 100%); $[PhP(m\text{-}C_6H_4SO_3)_2]^{2-}$ (210, 77%); $[P(O)(m\text{-}C_6H_4SO_3)_3]^{3-}$ (171.7, 29%); $[P(m\text{-}C_6H_4SO_3)_3]^{2-}$ (166.3, 3%).
TPPMS + HCOOH	$[PhP(O)(m\text{-}C_6H_4\text{-}SO_3)_2Na]^-$ (459, 3%); $[PhP(O)(m\text{-}C_6H_4SO_3)_2(NH_4)]^-$ (454, 6%); $[PhP(O)(m\text{-}C_6H_4SO_3)_2H]^-$ (437, 7%); unknown (241, 8%); $[PhP(O)(m\text{-}C_6H_4SO_3)_2]^{2-}$ (218, 100%); $[PhP(m\text{-}C_6H_4SO_3)_2]^{2-}$ (210, 3%).
TPPMS + $AgNO_3$	$[PhP(O)(m\text{-}C_6H_4SO_3)_2Ag]^{2-}$ (545, 7%); $[PhP(m\text{-}C_6H_4SO_3)_2Ag]^{2-}$ (529, 5%); $[Ag_2(NO_3)_3]^-$ (402, 2%); $[Ph_2P(O)(m\text{-}C_6H_4SO_3)]^-$ (357, 6%); $[Ag(NO_3)_2]^-$ (231, 100%); $[PhP(O)(m\text{-}C_6H_4SO_3)_2]^{2-}$ (218, 84%); $[PhP(m\text{-}C_6H_4SO_3)_2]^{2-}$ (210, 6%); $[P(O)(m\text{-}C_6H_4SO_3)_3]^{3-}$ (171.7, 20%).

[a] TPPTS = $P(m\text{-}C_6H_4SO)_3^{-3}$ and TPPMS = $PPh_2(m\text{-}C_6H_4SO_3)^-$ both as their sodium salts.
[b] m/z values quoted are for the major peak in the isotope distribution pattern.

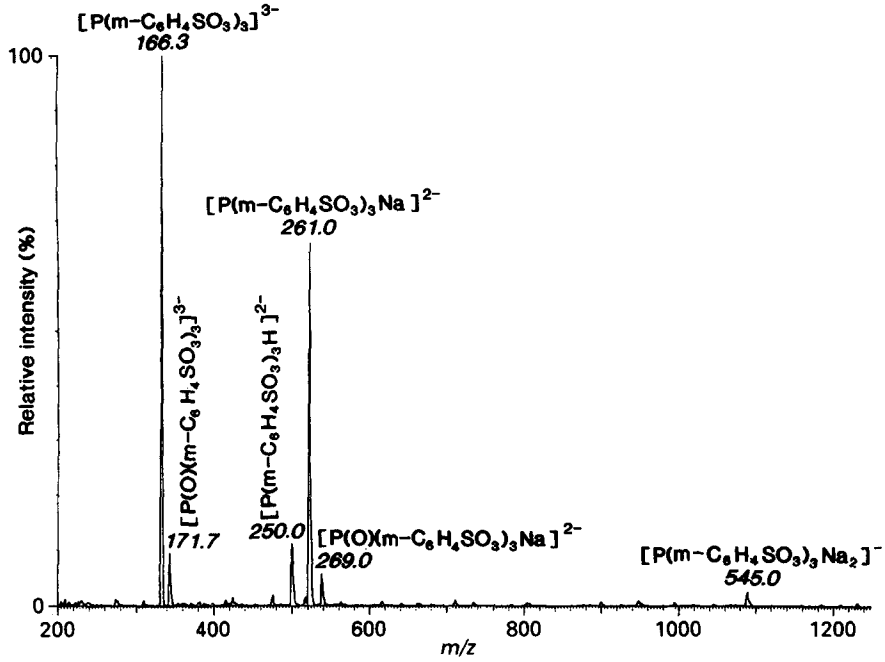

Fig. 1. Negative-ion ES mass spectrum (cone voltage 20 V) of TPPTS dissolved in 1 : 1 v/v acetonitrile–water.

assigned to the oxide of TPPTS and the free phosphine relatively. The minor protonated ions $[P(m\text{-}C_6H_4SO_3)_3NaH]^-$ (m/z 523), $[P(m\text{-}C_6H_4SO_3)_3H_2]^-$ (m/z 501) and the ammonium adduct $[P(m\text{-}C_6H_4SO_3)_3(NH_4)]^{2-}$ (m/z 258.5) were observed upon addition of formic acid to the neat solution. The ES mass spectrum was dominated by the signal at m/z 250 due to $[P(m\text{-}C_6H_4SO_3)_3H]^{2-}$. As expected, all the

sodium adducts decrease in intensity upon the addition of formic acid. The protonation pathway dominates if sufficient formic acid is added, the sodium adducts disappearing or representing only the minor ions in the ES mass spectra.

For TPPMS, $[P(O)(m\text{-}C_6H_4SO_3)_3H]^{2-}$ (*m/z* 171.7), $[Ph_2P(O)(m\text{-}C_6H_4SO_3)]^-$ (*m/z* 357), $[PhP(m\text{-}C_6H_4SO_3)_2]^{2-}$ (*m/z* 210) and the respective oxide $[PhP(O)(m\text{-}C_6H_4SO_3)_2]^{2-}$ (*m/z* 218, 100%) dominate the negative-ion ES mass spectrum. ESMS data suggests the mixture comprises the oxides of the mono-, di- and tri-sulfonated triphenyl phosphine in addition to the disubstituted phosphine $PhP(C_6H_4SO_3Na)_2$ (TPPDS). In contrast to TPPTS, the oxide peaks are highly significant ions in the negative-ion ES mass spectrum of the crude mixture of TPPMS. It seems probable that these oxides were formed as a direct result of the synthesis, as alluded to earlier, pre-existing in solution and not formed as a result of electrochemical oxidation in the ESMS. This hypothesis was later supported by data from $^{31}P\{^1H\}$ NMR using a 1 : 1 mixture of methanol and D_2O as solvent. Three signals were recorded in the chemical shift range of phosphine oxides at δ +34.4, +33.6 and +32.5 and were assigned to the mono-, di- and tri-sulfonated triphenylphosphine oxides. In addition, a single peak was recorded at δ −4.5 in the chemical shift range of free phosphines, assigned to the disulfonated analogue TPPDS. Thus, ESMS provides useful complementary information (to NMR spectroscopy) in the analysis of water-soluble sulfonated phosphines.

The major effect of adding formic acid to a solution of the crude TPPMS is the significant decrease in intensity of the ions $[P(O)(m\text{-}C_6H_4SO_3)_3]^{3-}$ (*m/z* 171.7) and $[PhP(m\text{-}C_6H_4SO_3)_2]^{2-}$ (*m/z* 210) whilst the oxide ion $[PhP(O)(m\text{-}C_6H_4SO_3)_2]^{2-}$ (*m/z* 218) maintains dominance. As indicated previously for TPPTS, the ions containing sodium decrease in intensity while the protonated ions and the ammonium adduct $[PhP(O)(m\text{-}C_6H_4SO_3)_2(NH_4)]^-$ (*m/z* 454) either appear or increase in intensity.

Addition of an aqueous solution of $AgNO_3$ to either a solution of TPPTS or TPPMS was investigated as an aid in identification. The ion $[Ag(NO_3)_2]^-$ (*m/z* 231, 100%) together with $[P(m\text{-}C_6H_4SO_3)_3Ag]^{2-}$ (*m/z* 303, 29%) represent the only ions of high intensity in the negative-ion ES mass spectrum of TPPTS. Interestingly the ion $[P(m\text{-}C_6H_4SO_3)_3Ag]^{2-}$ (*m/z* 303, 93%) increased in intensity upon the addition of formic acid to the mixture of TPPTS and $AgNO_3$.

Formic acid has been observed to aid in stripping residual Ag(I) from the surfaces inside the injector and/or capillary of the ESMS system, thus resulting in an increase in Ag(I) concentration. The ion $[Ag(NO_3)_2]^-$ (*m/z* 231, 100%) and the oxide $[PhP(O)(m\text{-}C_6H_4SO_3)_2]^{2-}$ (*m/z* 218, 84%) represent the major ions in the negative-ion ES mass spectrum of TPPMS. However, the Ag(I) complex ions $[PhP(m\text{-}C_6H_4SO_3)_2Ag]^-$ (*m/z* 529), $[PhP(O)(m\text{-}C_6H_4SO_3)_2Ag]^-$ (*m/z* 545) and $[Ag_2(NO_3)_3]^-$ (*m/z* 402) were also identified. The silver-nitrate ions observed at *m/z* 231 and *m/z* 402 were not unexpected given that comparably high concentrations of $AgNO_3$ were employed. Silver(I)-acetonitrile complexes $[Ag(CH_3CN)]^+$ (*m/z* 148) and $[Ag(CH_3CN)_2]^+$ (*m/z* 189) were the only species observed in the positive-ion ES mass spectrum following the addition of $AgNO_3$ to a solution of either TPPTS or TPPMS. Intense ions $[M+Ag]^+$ and $[2M+Ag]^+$ in the positive-ion ES mass spectra have been reported for solutions containing a neutral phosphine, e.g. PPh_3 and $AgNO_3$ [10,12]. Species such as $[\{P(m\text{-}C_6H_4SO_3)_3\}_2Ag]^{5-}$ (*m/z* 221.4) and $[\{PhP(m\text{-}C_6H_4SO_3)_2\}_2Ag]^{3-}$ (*m/z* 316.3) were not observed. For the former species, the high charge density of such an ion would likely result in association with H^+ or Ag^+, or dissociation of a phosphine ligand. For $[\{PhP(m\text{-}C_6H_4SO_3)_2\}_2Ag]^{3-}$ it is possible that the $AgNO_3$ concentration was too high.

Ferrocenyl phosphines

A number of ferrocenyl phosphines and aminoalkyl ferrocenyl phosphines **1, 2, 3** and **4** have also been studied by ESMS. Most compounds containing amino functions can be analysed easily by positive-ion ESMS; a strong $[M+H]^+$ ion is observed due to protonation of the basic nitrogen atom. Protonation can be achieved *in situ* either by interaction with water, a component of the mobile phase, or facilitated by the addition of acid. Results from the positive-ion ES mass spectral analysis of both the ferrocenyl phosphines and the amino ferrocenyl phosphines are presented in Table 2.

Nearly all the amino ferrocenyl phosphines (**3a, 3b** and **4b**) typically gave rise to a single peak due to the $[M+H]^+$ ion with the exception of PPFA (**4a**) which exhibits a strong $[M(O)+H]^+$ ion. In contrast, the corresponding phosphorus analogs are not as basic, typically giving rise to weaker $[M+H]^+$ ions. An unknown aggregate ion at *m/z* 998 and an unknown ion at *m/z* 387 both of variable percent intensity were repeatedly observed in the ES mass spectrum of BPPA. The intensity of these ions decreased over time as the spectra were being collected. Phosphine sulfide peaks of low percentage intensity were also observed in the ES mass spectra of BPPA and BPPFA. In most cases the M(S) peak cannot be discounted nor distinguished from $M(O)_2$ since the isotope patterns are very similar. However the ions of mass *m/z* 48 or *m/z* 64 higher than the $[M+Ag]^+$ ion, which were sometimes observed, are likely to be due to the phosphine derivatives $[M(O)(S)+Ag]^+$ and $[M(S)_2+Ag]^+$ respectively. The source of these species appears to be due to adventitious sulfur or sulfides in the system originating from previous solutions of metal–sulfide–thiolate clusters.

Increasing the cone voltage above 40 V can facilitate characterisation as the fragments formed provide further structural information concerning the original

[a] m/z values quoted are for the major peak in the isotope distribution pattern.

ferrocene compound. More intense $[M]^+$ ions were observed at higher cone voltages and are presumed to be due to electrochemical oxidation of Fe^{II} to Fe^{III}. Higher cone voltages also appear to facilitate oxidation of the phosphine function to form $[M(O)+H]^+$ ions. Dominant fragment ions $[M-NMe_2]^+$ and $[M(O)-NMe_2]^+$, which are stable carbonium ions (structures **6a, 6b, 7a** and **7b**), were observed at higher cone voltages, resulting from the cleavage of the CH_2—N bond in the amino ferrocenyl phosphines. This fragmentation pathway has also been reported for $FcCH_2NMe_2$ [8]. Predictably, the same stable carbonium fragment ion $[FcCH_2]^+$ **5** (*m/z* 198) was observed at higher cone voltages for those ferrocenylmethyl phosphines in which the phosphine function is separated from the cyclopentadienyl ring by a methylene unit.

Of interest was the appearance of a number of ions which were shown (by their isotope patterns) to contain silver. In particular, those ferrocenyl phosphines which contain a diphenylphosphine moiety appeared to show a strong tendency to coordinate to Ag^I. $[M+Ag]^+$ and $[2M+Ag]^+$ ions were observed for DPF, DPPF, $FcCH_2PPh_2$, PFMA and BPPFA, even though no Ag^I salts had been added to the samples prior to analysis. The existence of these ions were proposed to result from adventitious silver, a contaminant in the ESMS system. Indeed, such phenomena are not uncommon; Ag^I ions have been observed lingering in the capillary system of our ESMS instrument on previous occasions. The $[3M+Ag]^+$ ion was also observed in the positive-ion ES mass spectra of DPF and $FcCH_2PPh_2$ (20 V), consistent with a coordination number of 3 for Ag^+. In the positive-ion ES mass spectrum of DPPF only the $[M+Ag]^+$ and $[2M+Ag]^+$ ions were observed, suggesting this particular ferrocenyl phosphine has a very high affinity for Ag^I. The $[2M+Ag]^+$ complex ion is consistent with known tetrahedral four-coordinate Ag^I systems, and such an observation is supported by the knowledge that DPPF is an excellent chelating ligand and has a vast coordination chemistry which has been studied in great detail [13,16].

We have previously reported the ease with which hydroxymethyl phosphonium salts may be generated from the respective neutral phosphines, for positive-ion ES mass spectral analyses [12]. As a direct consequence of this work we wished to investigate whether similar derivatives of ferrocenyl phosphines could also be formed *in situ*. The aminoalkyl ferrocenyl phosphine derivatives were subjected to a similar regime in order to obtain comparative data. Results are presented in Table 3. The positive-ion ES mass spectra of the ferrocenyl phosphonium salt derivatives proved to be less complex when compared with the ES mass spectra obtained without the addition of formaldehyde and HCl. The hydroxymethyl phosphonium cations $[M(CH_2OH)]^+$ were the major ions in the mass spectra of $FcCH_2PPh_2$, $FcCH_2P(CH_2OH)_2$ and DPF. $FcCH_2PH_2$, a primary phosphine, underwent a significant but expected transformation to the *tris*-hydroxymethyl phosphonium salt $[FcCH_2P(CH_2OH)_3]^+$ (*m/z* 323). The reagent system, formaldehyde and HCl, is employed for the synthesis of hydroxymethyl phosphonium salts from either primary, secondary or tertiary phosphines and was originally reported by Hoffman [17]. Hemiformal adducts $[M(CH_2O)_n(CH_2OH)]^+$ ($n = 1, 2$) were also observed in these mass spectra; these are not unusual for hydroxymethylphosphine derivatives [18]. Both the hydroxymethyl phosphonium salt $[M+CH_2OH]^+$ (*m/z* 585) and the *bis*-hydroxymethyl phosphonium salt $[M+2CH_2OH]^{2+}$ (*m/z* 308) of DPPF were observed but they were only minor ions in the mass spectrum. DPPF appeared to be more susceptible to fragmentation, under these conditions the $[C_5H_5PPh_2CH_2OH]^+$ ion at (*m/z* 281) being the base peak in the mass spectrum, even at relatively low cone voltages (e.g. 20 V). The same ion was observed as the base peak in the mass spectra of BPPA and BPPFA. These three ferrocenes have one feature in common, namely a PPh_2 function on each cyclopentadienyl ring. We postulate that both these phosphine functions may become modified to form the *bis*-hydroxymethyl phosphonium salt, as observed in the mass spectrum of DPPF. However, because both these positively charged phosphorus atoms are directly attached to the cyclopentadienyl ring there is a strong possibility that the delocalised π-electron density in the ring may be disturbed due to an inductive effect. This would ultimately result in weakening the π-interaction between the Fe atom and the ring, resulting in fragmentation. It is also notable that a similar effect is not observed for either DPF or PFMA whose structures in contrast to the previous ferrocenes contain only one PPh_2 function on only one of the cyclopentadienyl rings. It seems feasible to suggest that the inductive effect is not strong enough in this system to facilitate fragmentation.

As expected, the protonated ion $[M+H]^+$ (*m/z* 428) represented the base peak in the mass spectrum of the amino ferrocenyl phosphine PFMA with added CH_2O/HCl, however the phosphonium salt $[M+CH_2OH]^+$ (*m/z* 458) was also observed. Unexpectedly, the $[M+H]^+$ ion was comparatively weak in the mass spectra of the remaining amino ferrocenyl phosphines (i.e. BPPA, PPFA and BPPFA) treated with CH_2O/HCl. A significant contribution was made by the doubly-charged ions $[M+CH_2OH+H+CH_3CN+H_2O]^{2+}$ (*m/z* 259) and $[M+CH_2OH+H]^{2+}$ (*m/z* 229.5) in the mass spectrum of PFMA, which form when both the P atom and the N atom are positively charged. A similar ion $[M+CH_2OH+H]^{2+}$ (*m/z* 328.5) was observed in the mass spectrum of BPPFA. Major fragment ions $[FcCH_2]^+$ **5** (*m/z* 198) and $[M-PPh_2]^+$ (*m/z* 370), formed in the mass spectra of the ferrocenylmethyl phosphines at higher cone voltages, were similar to those reported earlier for the same compound without the addition of CH_2O/HCl. The fragment ion $[C_5H_3(CHMe)PPh_2CH_2OH]^+$ (*m/z*

[c] m/z values quoted are for the major peak in the isotope distribution pattern.

307) was observed as the base peak in the mass spectrum of PPFA and as a major ion in the mass spectrum of BPPFA at low cone voltages. A similar ion $[C_5H_3(CH_2)PPh_2CH_2OH]^+$ (m/z 293) of low intensity was also observed in the mass spectrum of PFMA. Cleavage of the C—N bond is anticipated under these conditions to form the carbonium ion $[M-NMe_2]^+$ observed in the mass spectrum of BPPFA and PPFA at higher cone voltages and is likely to be more stable than the equivalent ion formed from BPPA or PFMA. Further fragmentation is likely to result for BPPFA to form the m/z 307 ion for reasons discussed earlier, however no explanation can be given for the existence of the same ion in the mass spectrum of PPFA. At high cone voltages cleavage of the C—P bond of the diphenylphosphino group and the cyclopentadienyl ring of the ferrocenes (**2–4**) was observed, rather than loss of a cyclopentadienyl moiety. This alternative fragmentation route becomes available at higher cone voltages and is consistent with the knowledge that such a process requires more energy than the cleavage of either a C—N bond or loss of a cyclopentadienyl moiety.

$[M+Ag]^+$ and $[2M+Ag]^+$ ions were observed in the positive-ion ES mass spectra of a number of ferrocenyl phosphines due to adventitious Ag^+ in the ESMS system. This information, in addition to supporting evidence from previous studies [10,12], suggested that the deliberate addition of Ag^I may aid in characterisation of ferrocenyl phosphines. A number of the ferrocenyl phosphines were treated with an aqueous solution of $AgNO_3$ and the positive-ion ES mass spectra recorded at a cone voltage of 20 V. Data is given in Table 4. All of the ferrocenylmethyl phosphines (**1**) showed $[3M+Ag]^+$, $[2M+Ag]^+$ and $[M+Ag]^+$ ions. Typically the $[3M+Ag]^+$ and $[2M+Ag]^+$ ions were dominant at low Ag^+ concentrations, however upon increasing the Ag^+ concentration, the $[2M+Ag]^+$ and $[M+Ag]^+$ ions become more prominent. This observation is demonstrated by comparison of the positive-ion ES mass spectra of $FcCH_2PPh_2$ with added $AgNO_3$, as depicted in Fig. 2 [(a): high Ag^+ concentration, (b): low Ag^+ concentration]. Both $[M(O)+H]^+$ and $[M]^+$ ions were observed in nearly all the mass spectra, however they were predominantly of low intensity with the exception of $FcCH_2PH_2$ and BPPA. The primary phosphine, $FcCH_2PH_2$, seemed particularly sensitive to the mild oxidising properties of Ag^+, the $[M]^+$ ion constituting the major peak in the mass spectrum at low Ag^+ concentration. For **1b** a highly characteristic aggregate ion $[M+Ag+CH_3CN]^+$ (m/z 532) was also recorded, a familiar feature of all positive-ion ES mass spectra when employing $AgNO_3$ as a reagent [13]. The major ion observed in the ES mass spectrum of BPPA at low Ag^+ concentration was the $[M+H]^+$ (m/z 612) ion, however the $[M+Ag]^+$ (m/z 718) ion dominates at higher Ag^+ concentrations. For aminoferrocenyl phosphines there appears to be competition between the protonation pathway which results in the formation of the $[M+H]^+$ ion and the complexation pathway to form either the $[M+Ag]^+$ or $[2M+Ag]^+$

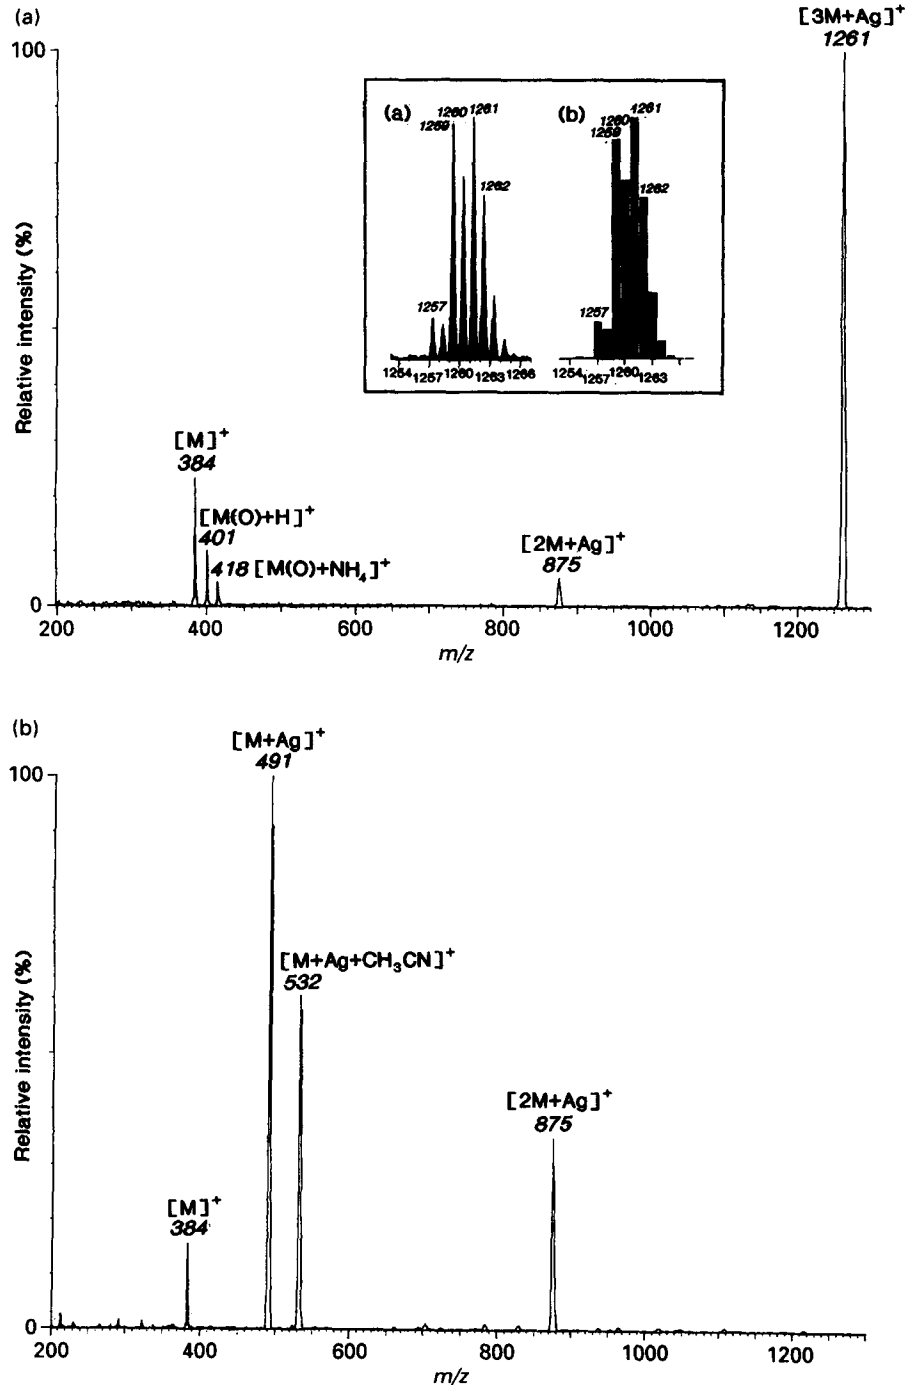

Fig. 2. Positive-ion ES mass spectra (cone voltage 20 V) of $FcCH_2PPh_2$ dissolved in 1 : 1 acetonitrile–water solution, with addition of $AgNO_3$. (a) Low concentration of Ag^+; (b) high concentration of Ag^+. M refers to $FcCH_2PPh_2$. The inset shows: (a) observed and (b) calculated isotope patterns for the $[3M+Ag]^+$ ion (*m/z* 1261).

ions. When the Ag^+ concentration is relatively low the protonation pathway appears to dominate.

CONCLUSIONS

Sulfonated phosphines may be easily characterised by negative-ion ESMS, as expected. Intense signals are observed for the singly-, doubly- and triply-charged phosphines and their oxides of TPPMS, TPPDS and TPPTS respectively. Singly- and doubly-charged sodium, protonated or ammonium adducts of the phosphines and their oxides are easily identified by analysis of the isotope patterns. Characterisation may be facilitated by the addition of formic acid or to a lesser extent, following the addition of an aqueous solution of $AgNO_3$.

A strong phosphonium ion, $[M(CH_2OH)]^+$ appears in the positive-ion mass spectra of those ferrocene phosphines that contain only one phosphine group, following the addition of formaldehyde and HCl. Amino ferrocenyl phosphines do not require such a reagent, forming strong $[M+H]^+$ ions in the positive-ion mass spectra. Fragment ions become pronounced for both the amino ferrocenyl phosphines and those ferrocenyl phosphines which contain more than one phosphine function, following the addition of formaldehyde and HCl. Silver complexes, $[3M+Ag]^+$, $[2M+Ag]^+$ and $[M+Ag]^+$, which have distinctive isotope patterns, were commonly recorded in the positive-ion ES mass spectra for the ferrocenylmethyl phosphines treated with $AgNO_3$. Both reagents therefore aid in identification and help to alleviate the difficulties associated with distinguishing between $[M]^+$ and $[M+H]^+$ ions which are common to the positive-ion ES mass spectra of ferrocenyl phosphines.

Acknowledgements—This work was supported by the University of Waikato and the Cancer Society of New Zealand. Samples of TPPTS, TPPMS and a number of ferrocenyl phosphine derivatives were kindly supplied by Professors B. H. Robinson and J. Simpson, University of Otago. We would also like to thank Mr Nick Goodwin who provided samples of $FcCH_2PPh_2$, $FcCH_2PH_2$ and $FcCH_2P(CH_2OH)_2$. We also acknowledge the New Zealand Lottery Grants Board for a grant-in-aid towards the purchase of an electrospray mass spectrometer, and Wendy Jackson for technical assistance.

(Received 16 June 1997; accepted 8 July 1997)

Abstract—This report describes several cobalt compounds that contain 2,2′-dipyridylamine (Hdpa) and its ionic forms, dpa^- and H_2dpa^+. It was carried out with the aim of structurally characterizing various coordination modes of such species. The reaction of two equivalents of Hdpa with one equivalent of $[Co(H_2O)_6](ClO_4)_2$ produces the octahedral complex $[Co(Hdpa)_2((CH_3)_2CO)_2](ClO_4)_2$. Under mild aerobic conditions, Co(II) is oxidized to Co(III) to yield the six-coordinate peroxo bridged compound $[Co_2(Hdpa)_4(\mu\text{-}O_2)(\mu\text{-}OH)](ClO_4)_3 \cdot 3$acetone (**I**), the neutral Hdpa ligand chelates to the metal and shows significant puckering of the pyridyl rings. The tetrahedral complex, $Co(Hdpa)Cl_2$ (**II**), is prepared from the reaction of anhydrous $CoCl_2$ and Hdpa; puckering of the pyridyl groups is significantly smaller than that found for **I**. The deprotonated ligand reacts with $CoCl_2$ to produce the neutral molecule, $Co(dpa)_2$ (**III**) in which the dipyridyl groups are almost planar. The reaction of Hdpa and $[Co(H_2O)_6](ClO_4)_2$ in the presence of excess HCl yields the salt, $[H_2dpa]_2[CoCl_4]$ (**IV**). The crystal structures of **I, II, III,** and **IV** are presented. In structures **I–III,** the ligands chelate to the metal atom through the nitrogen atoms of the pyridyl rings in an anti–anti configuration. The structure of **IV** is also in an anti–anti configuration with the proton residing between the two nitrogen atoms of the pyridyl rings. © 1998 Elsevier Science Ltd

Keywords: cobalt and dipyridylamine compounds; crystal structure.

2,2′-Dipyridylamine and its anion have been observed to coordinate to metal atoms in a variety of ways [1], as shown in Fig. 1. Our own interest in this type of ligand was first stimulated by the discovery of the binding mode of type **d** in the compounds $Cu_3(dpa)_4Cl_2$ [2,3], $Cu_3(dpa)_4Br_2$ [2] and $Ni_3(dpa)_4Cl_2$ [4] by Hathaway and others. It was later reported [5] that a similar trinuclear cobalt(II) compound had an unsymmetrical chain of cobalt atoms. This peculiar observation caused us to make a first report on our work [1c]. While further investigating the cobalt system, we found a type of crystal in which the trinuclear $Co_3(dpa)_4Cl_2$ unit is present along with a mononuclear species of the type $Co(H_ndpa)_2$ [6]. From the structural data on this compound, it was not clear whether this mononuclear species was the divalent cation $Co(Hdpa)_2^{2+}$ or the neutral complex $Co(dpa)_2$. We therefore undertook a structural investigation of various binding modes of 2,2′-dipyridylamine and its ions in cobalt complexes to get an overview of the structural trends.

The complexation of Hdpa to cobalt ions has been known for a long time. For example, the synthesis of $Co(Hdpa)Cl_2$ was first published in 1957 [7]. A series of such complexes which contain four- or six-coordinate Co atoms were prepared later [8]. Early studies of complexes of Hdpa and its anion also include other elements of the first transition series, namely Fe [9], Cu [10] and Ni [11]. This report describes a complex in which the cobalt atom is six-coordinate, two four-coordinate complexes, and a compound containing the H_2dpa cation. A report on various compounds that contain linear trinuclear

species of the type $Co_3(dpa)_4X_2$ has already appeared [6].

EXPERIMENTAL

Materials and methods

Except where noted, all manipulations were carried out by employing standard Schlenk techniques under an atmosphere of nitrogen. Tetrahydrofuran, toluene, diethyl ether, and hexanes were freshly distilled from Na/K benzophenone and dichloromethane was distilled from P_2O_5 prior to use. Acetone was distilled from K_2CO_3, CH_3CN was distilled from CaH_2, and methanol was distilled from magnesium turnings. Dimethyl sulfoxide was used as received. Anhydrous $CoCl_2$ was purchased from Alfa and stored in the dry box. Cobalt perchlorate hexahydrate was obtained from Aldrich Chemical Company. Hdpa was also purchased from Aldrich and sublimed prior to use. Infrared spectral data were recorded as KBr pellets on a Perkin–Elmer 16PC FT-IR spectrophotometer at 2 cm^{-1} resolution. Electronic absorption spectra were measured on a Cary 17 spectrophotometer.

Preparations

Reaction of $[Co(H_2O)_6](ClO_4)_2$ *with Hdpa.* In a small Schlenk tube, 0.187 g (1.09 mmol) of Hdpa was dissolved in 5 ml of CH_3CN. In a separate Schlenk tube, 0.181 g (0.495 mmol) of $[Co(H_2O)_6](ClO_4)_2$ was dissolved in 5 ml of CH_3CN. The two solutions were mixed to give an orange solution. Diethyl ether was added to precipitate a pale orange powder. This solid was repeatedly washed with more Et_2O and then dried under vacuum. IR (KBr, cm^{-1}): 3314 (m), 3243 (w), 3207 (w), 3141 (w), 3095 (w), 2999 (w), 2937 (w), 2320 (m), 2289 (m), 1631 (vs), 1583 (s), 1525 (m), 1472 (vs), 1434 (m), 1416 (m), 1354 (m), 1268 (w), 1237 (m), 1166 (s), 1095 (vs), 1009 (s), 930 (w), 903 (m), 881 (w), 842 (w), 792 (s), 771 (s), 751 (m), 623 (s), 534 (m), 430 (m), 422 (m). While the product is only slightly soluble in CH_3CN and acetone, it was found to be soluble in acetone containing a small amount of water. A non-deoxygenated acetone solution layered with hexanes produced orange crystals of $[Co(Hdpa)_2((CH_3)_2CO)_2](ClO_4)_2$. Also produced by this diffusion method were small black crystals of $[Co_2(Hdpa)_4(\mu\text{-}O_2)(\mu\text{-}OH)]\text{-}(ClO_4)_3 \cdot 3$acetone **(I)** arising from the oxidation of Co(II) to Co(III). We made no attempts to optimize the yields, which were roughly 80% $[Co(Hdpa)_2((CH_3)_2CO)_2](ClO_4)_2$ and 5% **I**. [CAUTION: Perchlorate complexes can potentially explode and should be handled with care!]

$Co(Hdpa)Cl_2$ **(II)**. The procedure was modified from that described by Bailar and Kirschner [7]. In a 50 ml Schlenk flask, 0.318 g (2.45 mmol) of anhydrous $CoCl_2$ was dissolved in 15 ml of CH_3CN to give a royal blue solution. In a separate Schlenk flask, 0.428

g (2.50 mmol) of Hdpa was dissolved in 10 ml of CH_3CN. The Hdpa solution was added to the stirred cobalt solution via cannula; a bright blue powder immediately precipitated. Stirring was continued for several minutes, and the supernatant liquid was seen to be colorless. The mixture was filtered and the blue powder was washed with copious amounts of CH_3CN. Yield: 0.694 g (94.3%). The solid is insoluble in most organic solvents, but readily soluble in DMSO. Blue crystals were grown from a concentrated DMSO solution layered with CH_2Cl_2 and then layered with diethyl ether. IR (KBr, cm^{-1}): 3326 (w), 3299 (w), 3249 (w), 3210 (w), 3146 (w), 3118 (vw), 3092 (vw), 3063 (vw), 1640 (vs), 1617 (w), 1592 (w), 1582 (vs), 1529 (s), 1476 (vs), 1434 (s), 1422 (m), 1236 (s), 1173 (m), 1161 (s), 1023 (m), 1018 (m), 909 (m), 764 (vs), 655 (m), 520 (m), 418 (m).

$Co(dpa)_2$ (**III**). In a 100 ml round-bottom flask, 0.963 g (5.62 mmol) of Hdpa was dissolved in 30 ml of toluene. The solution was cooled to −78°C and 4.1 ml of 1.4 M CH_3Li was added. The solution immediately turned milky white. The reaction mixture was warmed to near room temperature upon which 0.344 g (2.64 mmol) of anhydrous $CoCl_2$ was added from a solid addition tube. After several minutes of stirring, 20 ml of THF was added forming a dark red-brown solution. The reaction was stirred overnight at room temperature. Most of the product precipitated from the solution as an orange powder. It was collected by filtration, washed twice with small amounts of THF, and dried under vacuum to yield 0.700 g (66.4%) of $Co(dpa)_2$. Crystals were obtained from work-up of the filtrate. The filtrate was evaporated to dryness and the residue dissolved in 25 ml of toluene to give a deep wine-red solution. This solution was filtered through Celite and layered with 40 ml of hexanes. Red crystals (0.0395 g, 3.75%) grew after two weeks of diffusion. IR (KBr, cm^{-1}): 3051 (w), 1609 (s), 1533 (s), 1440 (vs), 1250 (m), 1241 (m), 1146 (s), 1111 (w), 1095 (w), 1045 (w), 1006 (s), 894 (m), 849 (m), 786 (m), 767 (s), 733 (m), 726 (m), 656 (w), 553 (w). UV/vis (CH_2Cl_2): λ = 390 nm; 355 nm; 342 nm.

[H_2dpa]$_2$[$CoCl_4$] (**IV**). In a 50 ml Schlenk flask, 0.343 g (2.00 mmol) of Hdpa was dissolved in 6 ml of CH_3OH. In a separate flask, 0.364 g of [$Co(H_2O)_6$](ClO_4)$_2$ was dissolved in 6 ml of CH_3OH. The pink cobalt solution was added to the stirred Hdpa. The color changed from pink to orange. The solution was concentrated to 5 ml upon which a white powder began to precipitate, presumably Hdpa. Five ml of CH_3CN were added to redissolve the powder, restoring the original orange color. Aqueous 6 M HCl, 0.7 ml, was then added which immediately formed a blue solution and a blue powder. The mixture was filtered and the clear blue filtrate was layered with 20 ml of hexanes. Small sky blue crystals grew at the solvent interface after several days. IR (KBr, cm^{-1}): 3273 (w), 3243 (w), 3211 (w), 3182 (w), 3135 (w), 3082 (w), 3054 (w), 3019 (w), 2990 (w), 1653 (s), 1601 (s), 1557 (s), 1497 (m), 1481 (m), 1452 (s), 1304 (w), 1265 (w), 1243 (m), 1157 (m), 1005 (w), 982 (w), 944 (w), 897 (m), 767 (s), 688 (w), 673 (w), 530 (m). [CAUTION: Perchlorate complexes can potentially explode and should be handled with care!]

[$Co(CH_3CN)_6$][$CoCl_3(CH_3CN)$]$_2$·CH_3CN. This compound was prepared by dissolving anhydrous $CoCl_2$ in a minimal amount of CH_3CN. The resulting royal blue solution was layered with diethyl ether to produce large rectangular, royal blue crystals. These crystals are extremely solvent sensitive and rapidly turn pink in the presence of moisture.

Structure determinations

Single crystal X-ray diffraction studies of **I, II,** and **III** were carried out at −60°C with a Nonius FAST area detector, utilizing the program MADNES [12]. X-ray diffraction data for **IV** were collected on a Nonius CAD4 diffractometer at −105°C. In structures **I** and **II,** the positions of the heavy atoms were found via direct methods from the SHELXTL package [13]. In structures **III** and **IV,** the metal atoms were located by the Patterson method. For all structures, subsequent cycles of least-squares refinement followed by difference–Fourier syntheses, revealed the positions of the remaining non-hydrogen atoms. In most cases, hydrogen atoms were located in difference–Fourier maps and then refined isotropically. Other details of data collection and refinement are given in Table 1. Selected bond distances and angles for compounds **I**–**IV** are provided in Tables 2–5, respectively. Supplementary data for **I, II, III, IV** and [$Co(CH_3CN)_6$][$CoCl_3(CH_3CN)$]$_2$·CH_3CN have been deposited with the Cambridge Crystallographic Data Centre.†

RESULTS AND DISCUSSION

[Co_2(Hdpa)$_4$(μ-O_2)(μ-OH)](ClO_4)$_3$·3acetone (**I**)

The reaction of [$Co(H_2O)_6$](ClO_4)$_2$ with two equivalents of Hdpa in CH_3CN gives an orange solution from which a pale orange solid can be obtained by the addition of Et_2O. The infrared spectrum reveals N—H absorptions at 3324, 3243, and 3207 cm^{-1}, as well as strong bands at 2320 and 2289 cm^{-1} corresponding to C≡N. This product is readily soluble in acetone containing ca 5% water and gives poorly formed crystals of [Co(Hdpa)$_2$((CH_3)$_2$CO)$_2$](ClO_4)$_2$ in which a six-coordinate divalent cobalt atom is bonded to two chelating and puckered Hdpa molecules and two acetone molecules. Its identity was established by X-ray crystallography [14], but crystallographic disorder
